used without further purification. $N_D^{20}$: 1.3873 and 1.3990.

*n-Valeric Acid.*—A guaranteed grade reagent supplied by Tokyo Oka Co., was used without further purification.

*Benzene.* — A guaranteed grade reagent supplied from Wako Junyaku Co., was dehydrated with metallic sodium and distilled under reduced pressure.

**Measurements of Adsorption.** — The adsorption of water vapor was measured at 30°C with a quartz spring balance of sensitivity of 2.4630 mg./mm. using a cathetometer graduated to 1/20 mm. The samples were out-gased at various temperatures for 6 hr. under $10^{-5}$ mmHg. The temperatures are: for sugar carbons, 300~350; for molecular sieve 5A, 250~300; for silica gel No. 28, 150~200°C. The poresize distribution was calculated from the desorption isotherm, the contact angle being assumed to be $\cos\theta=0.49$[10]. Adsorptions of monocarboxylic acids and benzene were measured with a quartz spring balance at 38±0.1°C. The adsorbents were out-gased by heating at 300~350°C and $10^{-5}$ mmHg.

**Measurement of Pore Volume.** — The total pore volume was measured by a water and mercury displacement method using a modified Juhola and Wiig's apparatus[10] shown in Fig. 1. The liquid water was introduced into a flask from an upper reservoir after the samples in the flask adsorbed such an amount of water vapor from a side tube that the adsorption equilibrium was reached. The total pore volume was calculated from the difference of volum of water and mercury displaced.

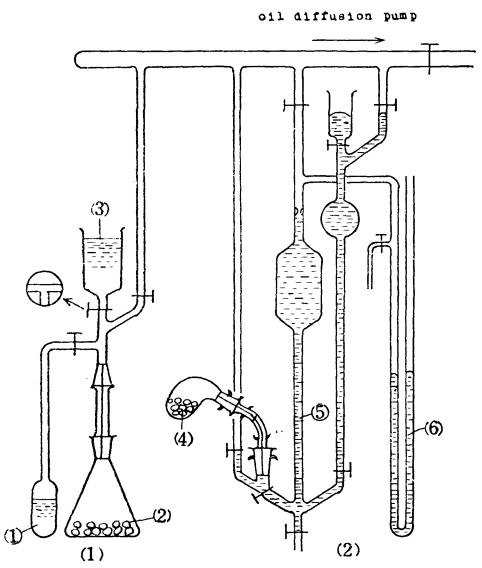

Fig. 1. Displacement volume measurement apparatus.
(1) Apparent density measurement by liquid displacement
(2) Apparent density measurement by mercury displacement
①③ Water ②④ Adsorbent
⑤ Mercury burette
⑥ Mercury manometer

**Measurement of BET Area.** — The BET surface area was obtained with a usual adsorption apparatus using nitrogen gas as an adsorbate.

**Mercury Porosimetry.**—A usual mercury porosimeter was used. In order to obtain high accuracy, the diameter of both platinum wire and dilatometer were made as small as possible. The applied pressure was measured with a gauge, and the maximum pressure reached was 1500 kg./cm². The temperature was kept at 0°C.

## Experimental Results and Discussion

**Pore Distribution.**—*$S_3$ and $S_4$.*— Plots of $dv/d\log r$ vs. $\log r$ (Å) for the samples $S_3$ and $S_4$ are shown in Fig. 2, where a tri-disperse distribution is observed. The peaks are designated as micro-, transitional and macro-pore from left to right in the figure. The shape of the transitional distribution curve is changed by modification of the carbonization or activation condition as is shown later. The distribution curves for a range 3~4 in $\log r$ are not shown as they are less than $10^{-4}$, being scaled out.

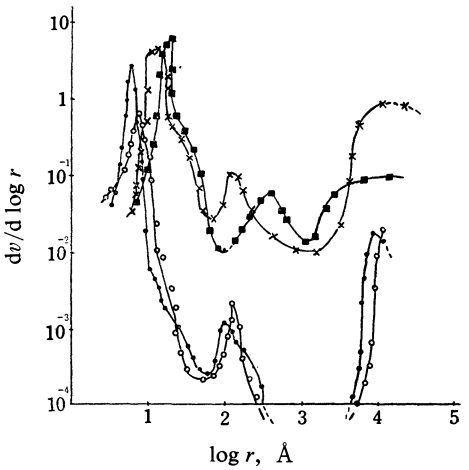

Fig. 2. Pore-size distribution in sugar carbons.
—●— $S_4$ —■— $SZ_3$
—○— $S_3$ —×— $SZ_4$

*$SZ_3$ and $SZ_4$.* — The pore-size distribution curves are also tri-disperse as a shown in Fig. 2. As is seen in Table IV, the total pore volume estimated from the results of mercury and water displacement method is in good agreement with that calculated as the total sum of the respective volumes of micro-, transitional, and macro-pores. The greater part of the surface areas of the sugar carbons ($S_3$, $S_4$, $SZ_3$ and $SZ_4$) being composed of the areas of the internal wall of the micro-pores, the number of transitional and macro-pores are too low to give any influence on the adsorption characteristics.

b) Calculated from mercury porosimetry.

*Molecular Sieve 5A.* — The micro-pore distribution curves of molecular sieve 5A were obtained by assuming $\cos\theta=1$ in Thomson's equation because of its high polarity. A di-disperse distribution curve with sharp peaks is seen in Fig. 3.

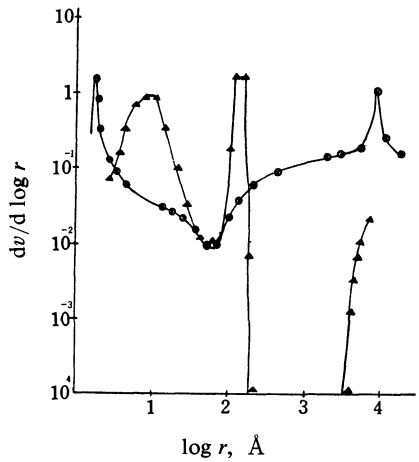

Fig. 3. Pore-size distribution in a silica gel and the molecular sievs 5A.
—▲— $SiO_2$ gel —⊗— M. S. (5A)

*Silica Gel No. 28.* — As is seen in Fig. 3, a tri-distribution curve is observed. The curve is, however, broken at a range $\log r=2\sim3$. The macro-pores are presumed to be produced by the secondary treatment, and the distribution curve is originally di-disperse. The total volumes of pores calculated from the respective peaks in the figures are shown in Table IV.

If it is assumed that the pore is a cylinder with a circular section, the total volume of the pores, $V_t$, and the inner surface area, $S$, in each peak can be calculated by the formula

$$V_t=\pi(\bar{r})^2L \qquad (5)$$

where $\bar{r}$ is an average radius of pores and $L$ the length of the cylinder. The inner surface area is related to the pore radius by the equation

$$S=2\pi\bar{r}L \qquad (6)$$

In Tables III and V, the inner wall areas calculated by the equation

$$S=2V_t/\bar{r} \qquad (7)$$

and the BET area are compared, where the coincidence is noted only in the case of the silica gel. The discrepancy seen in the tables may be ascribed to both the complexity of the pore structure and a per-sorption[13]. Another minor factor to be taken into account is the difference of densities of nitrogen in the submicro-pore and in bulk phase. The BET area is usually greater than the true area.

TABLE V. INTERNAL WALL AREA OF DISPERSE

| Sample | Surface area by $S=2V_t/\bar{r}$: Surface area of micro-P. m²/g. | Surface area of trans.-P. m²/g. | Surface area of macro-P. m²/g. | Surface area by BET m²/g. |
|---|---|---|---|---|

| $6SZ_4$ | 858 [9.0] (14.1) | 2.8 | 0.13 | 1300 |
| $S_4$ | 380 [7.5] (8.2) | 2.5 | 0.08 | 450 |
| Silica gel No. 28 | 681 [7.5] (11.0) | 16.0 | 0.08 | 720 |

a) [Å] maximum distribution radius.
b) (Å) mean radius.

The total wall area of the silica gel No. 28, $S$ (total sum of the areas of the micro-pores, transitional pores and macro-pores) is approximately 700 m./g. (Table V), and is in

13) A. Tsuruizumi, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **79**, 142 (1957),

agreement with the nitrogen BET area of 720 m./g. The areas obtained by the various fatty acids are ranged between 680 and 750 $m^2/g$. as will be shown later. These facts prove that there are only a few pores of a narrow-neck or ink-bottle type, which complicate the nature of the adsorption. The radius of the maximum distribution in the molecular sieve 5A is ca. 2Å.

### Adsorption of Organic Vapors

The adsorption isotherms of both monocarboxylic acids and benzene vapor were S-shape for all the adsorbents studied, and fit the BET equation well. The adsorption isotherms of benzene vapor on the samples $3SZ_4$ and $6SZ_4$ are shown in Fig. 4. The samples

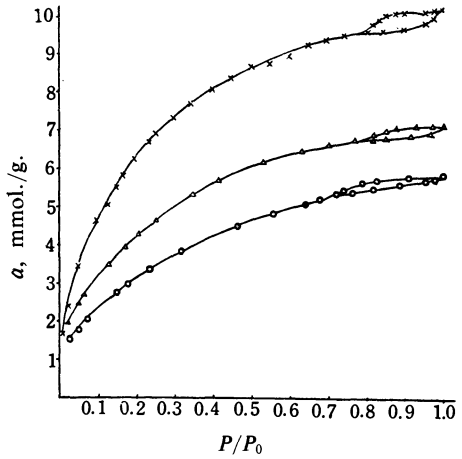

Fig. 4. Adsorption isotherm of benzene.
—×— $SZ_4$ —△— $3SZ_4$ —○— $6SZ_4$

$3SZ_4$ and $6SZ_4$ were prepared by carbonizing the sample $SZ_4$ impregnated with the nitrobenzene solution of polyvinyl chloride. The pores of the $SZ_4$ carbon were filled up to some extent, and the transitional pores were affected most sensitively. The transitional pore distribution curves for $SZ_4$, $3SZ_4$ and $6SZ_4$ obtained from the desorption isotherms of benzene vapor by using Thomson's equation are shown in Fig. 5, and the full distribution curves drawn by annexing the distribution curves estimated from the data of mercury porosimetry are shown in Fig. 6. The tri-disperse distribution is seen in the figure, and in each peak shift regularly according to the decrease in the pore volumes. The displacement of the transitional peaks are most conspicuous.

The distribution curve of the transitional pores estimated from the benzene adsorption shown in Fig. 4 was slightly higher than those obtained by the mercury porosimetry (Fig. 5).

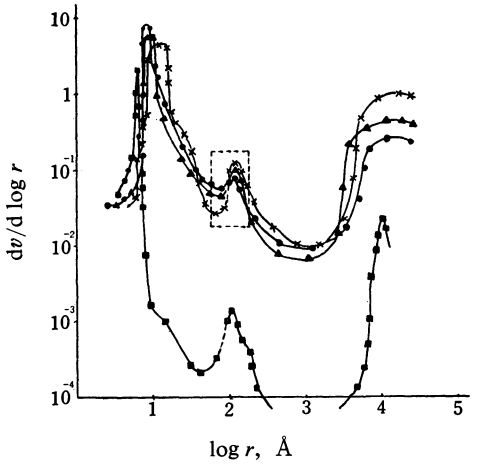

Fig. 6. Carbons pore-size distribution in sugar.
—×— $SZ_4$ —●— $6SZ_4$
—▲— $3SZ_4$ —■— $S_4$

The disagreement of the two curves may be ascribed to the errors arising from the application of Thomson's equation which is based on a number of assumptions inadequate in the

present case. Since in the mercury porosimetry no ambiguous assumptions are adduced other than the independency of the contact angle with respect to the applied pressure, the result of the porosimetry is most reliable.

A range of the distribution curve (shown by dotted lines in Figs. 5 and 6) between the micro-pore and transitional pore can not be determined precisely by the mercury porosimetry. Since the curves shown by broken lines with dots in Fig. 5 obtained by the adsorption method using benzene vapor were continuous in full range, it is quite resonable to bridge the gap between the solid line of the mercury porosimetry and the double line of the water adsorption with the dotted line as is shown in Fig. 5.

In the previous papers[11,13,14], the present author has suggested that the pore distribution of the active carbon is tri-disperse. The existence of the micro-pores of about molecular diameter size, the transitional pores (ca. 100 Å), and the macro-pores (ca. 100 $\mu$) as cracks or cavities is hereby confirmed.

Effective areas of the adsorbents, calculated from the amounts of adsorbates in a monolayer coverage (Figs. 7, 8 and 9) by using the B-point method[15] are shown in Table VI. The

sectional areas of the adsorbate molecules used for the calculation of the surface area are listed in Table VI. These were determined by the adsorption on $SZ_4$, $S_4$ and silica gel No. 28. The surface areas of sugar carbons obtained with formic and acetic acid are higher than the BET areas, while the higher acids gave lower

| *n*-Butyric acid | 31.35 | 0.9 | 717.0 | 730.0 |

a) [ ] Surface area from BET method.
b) If adsorptive section is circle from Fig. 10, its radius get 3.05Å as adsorptive sectional area is calculated 29.20Å².

values. This discrepancy can be explained as follows. The molecules of formic and acetic acid are small enough to diffuse into fine pores, and before the formation of a uniform monolayer, a capillary condensation takes place. This increases the apparent surface area. The critical temperatures of the formic and acetic acid are lower than those of the higher acids, but this is not the predominant factor for the earlier occurrence of the capillary condensation. The same situation was found in the adsorption of nitrogen gas as has been reported previously by the present author[13]. These effects of molecular size of the adsorbates on the adsorption characteristics suggest the existence of a number of pores of irregular shapes such as narrow-neck or ink-bottle on the sugar carbon surface.

BET type adsorption isotherms were observed for all the acids on $S_4$ as is shown in Fig. 8. A surface area of $S_4$ calculated by the B-point method is, however, remarkably smaller than the nitrogen BET area as is seen in Table VI, and this disagreement increased with the c-number of the acid molecule. This sieving effect of the carbon $S_4$ is presumed to be due to the special pore-distribution, a greater part of the surface being composed of the micropores of average radius less than 8.2Å. An adsorption isotherm of benzene (non-polar adsorbate) on silica gel No. 28 (polar adsorbent) obtained under the same conditions shows no hysteresis as is shown in Fig. 8, and a surface area calculated by the B-point method was identical with the nitrogen BET area as is shown in Table VI.

As is seen in the Fig. 8, the desorption curve of benzene vapor from the silica gel returns back to the original point, These facts indicate that no chemisorption takes place on the silica gel. BET type adsorption isotherms were observed for various carboxylic acids on silica gel No. 28 as is shown in Fig. 9. Values of the effective surface area of silica gel obtained by the B-point method for the series of carboxylic acids are equal to the nitrogen BET area as is seen in Table VI. These results lead us to conclude that there exist no pores of narrow-neck or ink-bottle shape on the surface of the silica gel, and the pore size is large enough to accommodate such large adsorbate molecules as the carboxylic acids.

In Fig. 9, the anomalous behavior of the adsorption of the carboxylic acids (*n*-butyric acid) on the silica gel is shown. According to a number of reports[16-23], the heat treatment in vacuo reduces the number of OH groups and changes the nature of S–O bonds. The OH groups on the silica gel were not exterminated by the usual calcination, and a greater part of the group are thought to remain in the samples of the present study. The unclosed hysteresis loop of the *n*-butyric acid is presumed to be due to the chemisorption with these residual OH groups. When the adsorption-desorption process is repeated once again from a point $P/P_0=0$, the loop returns back to the original point as is seen in Fig. 9. Clearly the second adsorption process was physical in nature, and no anomality appears in further repetitions of the process.

In Fig. 10, the filling ratio, $R=V/V_t$, is plotted against the radii of the adsorption sectional area of the adsorbate molecules, $r$, where $V_t$ is the total volume of adsorbent (Tables IV and VII) and $V$, the total volume of the adsorbate adsorbed on the adsorbent (Table VII).

TABLE VII. ADSORBED VOLUME, A, OF ADSORBATES AT $P/P_0=1.0$

| Adsorbate | Adsorbed volum, $V$ | | |
|---|---|---|---|
| | $S_4$ | $SZ_4$ | Silica gel |
| Formic acid | 0.21 | 1.06 | 0.41 |
| Acetic acid | 0.14 | 0.97 | 0.40 |
| *n*-Propionic acid | 0.06 | 0.95 | 0.39 |
| Benzene | 0.04 | 0.90 | 0.387 |
| *n*-Heptane | 0.03 | 0.86 | 0.38 |
| *n*-Butyric acid | 0.018 | 0.83 | 0.38 |
| Total pore vol., $V_t$ | 0.2126 | 1.142 | 0.4960 |

The adsorbed volume was calculated on the assumption that the density of the adsorbed liquid is the same as that in bulk. As for the *n*-heptane, the length and width of the molecule is reported to be 11.6 and 4.9Å, respectively, but the radius of the cross section, $r$, is unknown. If the values of the filling ratio of *n*-heptane are marked on the lines in Fig. 10, the three points lie on a line which meets with the abscissa at right angles. The radius can be estimated from the cut on the abscissa as 3.05Å which is proper in order of magnitude compared with the width.

The filling ratios change linearly with the radii of the adsorptive sectional area for respective adsorbents. The new term "sieving coefficient" is defined as the slope of these lines, which signifies an ability of the physical selective adsorption or the sieving effect. The sieving coefficient increases with the sharpness of the peak in the pore-size distribution curve. The coefficients for the adsorbents studied are as follows:

$S_4$ $0.947_3$, $SZ_4$ $0.155_5$, Silica gel No. 28 0.057.

The sieving coefficient would be quite a useful term to specify the adsorptive behavior of the adsorbents.

## Summary

1. The adsorption characteristics of the sugar carbon prepared by carbonization or activation and silica gel were studied in detail by the adsorption of water, benzene and fatty acid vapors, and mercury porosimetry.

The pore distribution of the active carbon was tri-disperse. The effects of the partial filling of the pores were examined. The missing link in the distribution curve between the micro-pore and transitional pore in the previous reports was replenished.

2. The narrow-neck or ink-bottle structure of the pores of sugar carbon complicated the adsorption characteristics. The pores of the silica gel were cylindrical with a uniform section.

3. In order to specify the physical selective adsorption, the new term "sieving coefficient" was defined from the relation between the pore radii and cross sections of the adsorbates.

The author expresses his gratitude to Professor I. Sano of Nagoya University for his encouragement.

# *Non-empirical Study of the π-Electronic Structure of Vinyl Chloride Molecule by Valence Bond Method*

By Shozaburo TAKEKIYO

(Received October 21, 1960)

In the year 1956, a semi-empirical consideration of conjugation in vinyl chloride molecule with molecular orbital method was performed by Goldstein[1] and recently the self-consistent field calculations of the π-electronic energy levels and the wave functions for the ground state have been carried out non-empirically by Simonetta and others[2].

On the other hand, it seems that no considerations by valence bond method have ever been made, except a semi-empirical calculation of the double bond character due to the resonance of the C–Cl bond in the molecule[3].

In this paper, the HLSP method[4] is applied to the non-empirical calculation of the π-electronic energy levels and other electronic properties of the molecule and the results are compared with those obtained by the method of LCAO self-consistent field.

## Energy Levels and Wave Functions

The skeleton of the molecule is shown in Fig. 1.

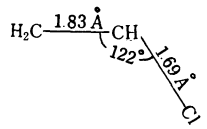

Fig. 1. Skeleton of vinyl chloride molecule.

For the carbon atoms and the chlorine atom, Slater $2p_\pi$- and $3p_\pi$-orbitals with $Z_C=3.18$, $Z_{Cl}=6.099$ have been assumed.

The approximate Hamiltonian operator $H$ employed here is

$$H=\sum_i [T(i)+U_{\text{core}}(i)]+(1/2)\sum_{\substack{i,\ j\\ i\neq j}}(e^2/r_{ij})$$

where $T(i)$ is the kinetic energy operator for electron $i$ and $U_{\text{core}}(i)$ is the potential energy operator for this electron in the field of the core.

Numerical values of integrals over atomic orbitals have been taken from Simonetta and others[2].

All the π-type resonance structures, whose corresponding bond eigenfunctions are linearly independent, and the energy values for these structures are shown in Fig. 2.

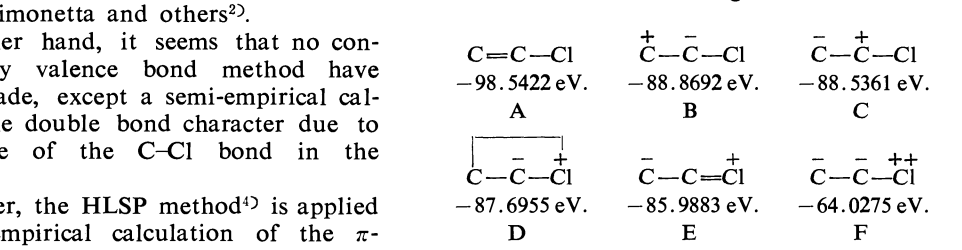

Fig. 2. Canonical structures and the energy values for the structures.

In the calculations all kinds of overlap and exchange integrals have been considered.

Wave functions for the molecule and the corresponding energy values are shown in Table I, where $\Phi_i$ is the wave function, corresponding to the energy $E_i$, and $\Psi_K$ is the normalized bond eigenfunction for structure K.

TABLE I. WAVE FUNCTIONS FOR THE MOLECULE AND THE ENERGY VALUES

### Probabilities of Resonance Structures, Charge Densities, and Bond Orders

Probability $P_K$ for structure K has been calculated by the most popular expression

$$P_K = C_K \sum_L C_L \int \Psi_K \Psi_L d\tau$$

where $C_K$ is the coefficient of bond eigenfunction $\Psi_K$ in the wave function for the ground state of the molecule and $d\tau$ is the product of the volume elements for the four π-electrons. The results are as follows:

$$P_A = 0.6846 \qquad P_B = 0.1110 \qquad P_C = 0.1198$$
$$P_D = 0.0543 \qquad P_E = 0.0300 \qquad P_F = 0.0003$$

Then π-electron density $D_i$ for atom $i$ and bond order $B_{ij}$ between atoms $i$ and $j$ have been evaluated by the following equations:

$$D_i = \sum_K P_K m_i^K$$

$$B_{ij} = \sum_K P_K (n_{ij}^K + 1)$$

where $m_i^K$ is the number of π-electrons on atom $i$ in structure K and $n_{ij}^K$ is the number of the covalent π-bonds between atoms $i$ and $j$ in structure K. These results are shown in Fig. 3.

$$\underset{1.0391}{H_2C} \overset{1.6846}{\text{——}} \underset{1.0458}{CH} \overset{1.0300}{\text{——}} \underset{1.9151}{Cl}$$

Fig. 3. π-Electron densities and bond orders.

### Discussion

The transition energy between the ground state and the first excited state is 11.41 eV. (Table I) The value, calculated by the method of LCAO self-consistent field, is

$$E_{V23} - E_N = 11.1842 \text{ eV}.^{2)}$$

The numerical difference between the two methods seems to be due to the neglect of the self-consistent procedure for the calculation of the excited state in the latter.

The formula of Pauling and others[5] has been used to evaluate the C–C and the neighboring C–Cl bond lengths from the semi-empirical values of bond radii[6]; and the results are as follows:

$$R_{C-C} = 1.358 \text{ Å} \qquad R_{C-Cl} = 1.744 \text{ Å}$$

The values, obtained by Simonetta and others, are $R_{C-C} = 1.448$ Å and $R_{C-Cl} = 1.73$ Å[2], and the experimental values are 1.38 and 1.69 Å respectively[7].

The positive charge on the chlorine atom is evaluated as $2 - 1.9151 = 0.0849$ and the interpreted value from observation is 0.06[8].

The ionic character of the molecule, calculated from the values of the probabilities, is 31.54%.

### Summary

π-electronic energy levels, probabilities of the resonance structures, π-electron densities, and the bond orders of the vinyl chloride molecule have been calculated non-empirically by the standard valence bond method, based on a complete set of the π-type resonance structures. Slater $2p_\pi$- and $3p_\pi$-orbitals have been assumed for the carbon and chlorine atoms and all the multiple exchange integrals have been considered. The calculated transition energy between the ground state and the first excited state is 11.41 eV., the ionic character is 31.54%, and the positive charge on the chlorine atom is 0.0849 (experimental value is 0.06.).

The author wishes to express his sincere thanks to Professor Kyosuke Omori, Kyushu University, for many helpful criticisms and suggestions. Thanks are also due to Professor Saburo Nagakura, the University of Tokyo, for his advice and valuable assistance.

# *Preparation of Perfluorocarboxylic Acids from Esters by Electrochemical Fluorination**

By Shunji NAGASE and Rimpei KOJIMA

(Received December 26, 1960)

Perfluorocarboxylic acids have been prepared from carboxylic acids, acid halides, acid anhydrides and acid amides, ketones, ethers etc. by electrochemical fluorination[1-4].

In a previous paper[5], it was shown that perfluorocarboxylic acids were prepared in a significant yield from alcohols which were known to give only fluorocarbons by electrochemical fluorination[1,6]. A possible mechanism of the fluorination of alcohols to perfluorocarboxylic acid fluorides was assumed to involve the first attack by fluorine on $\alpha$-carbon atom of the alcohols, and dehydrofluorination followed by exhaustive fluorination of acid fluorides formed as intermediates to perfluoro-acid fluorides.

The present paper deals with the work extended further to the fluorination of esters to obtain perfluorocarboxylic acids.

So far, there has been no detailed report on the electrochemical fluorination of simple esters. Simons[2] carried out the fluorination of butyl acetate and made decafluorobutane.

In the present series of work, ethyl, propyl and butyl acetates, ethyl, propyl and butyl propionates, and ethyl, propyl and butyl butyrates were fluorinated and trifluoroacetic, perfluoropropionic, and perfluorobutyric acids were obtained in good yields.

Again, the mechanism of dehydrofluorination at $\alpha$-carbon atom of alcohols which takes place after hydrofluorolysis of esters into carboxylic acid fluorides and alcohols, could be applied to the formation of perfluorocarboxylic acid fluorides from esters.

The perfluorocarboxylic acid fluorides formed were converted into perfluorocarboxylic acids by treatment with water. No detectable amount of partially fluorinated esters and alcohols were found in the residue in the electrolytic cell but the presence of acid fluorides and unreacted esters, etc. was confirmed.

## Experimental

**Materials.**—*Esters.*—Special or first grade commercial reagents were used after distillation through a fractionation column. Some of the esters were prepared in the usual manner in this laboratory.

*Hydrogen Fluoride.*—Hydrogen fluoride purity of 99.4% was supplied from a commercial cylinder.

**Apparatus.**—The apparatus used for this work essentially consisted of an electrolytic cell, a sodium fluoride tube, and an absorber, as described previously[5].

The electrolytic cell of 1 l. in capacity was a 10-cm. cylindrical nickel vessel provided with a copper condenser at the top to cool down vaporizing hydrogen fluoride and a drain at the bottom, and having 8 and 9 pieces of nickel plates (0.5 mm. in thickness) as anodes and cathodes, fastened together, suspended alternately from the top, and insulated from each other by Teflon pieces. The distance between the plates was 1.7 mm. and the effective surface area of the anodes and cathodes was 9.2 $dm^2$. A copper tubing was provided inside the cell to keep the optimum temperature by circulation of ice water during the reaction.

The sodium fluoride tube was an iron pipe containing sodium fluoride pellets to remove hydrogen fluoride.

The absorber used was a pair of polyethylene bottles containing 200 and 50 ml. of water.

**Procedure.**—One liter of hydrogen fluoride was introduced into the cell through the polyethylene container, and electrolysis was carried out without a sample to remove a trace of water in the hydrogen fluoride at an average of 5.2 V. for about 13 amp. hr. in nitrogen atmosphere. About 35 g. of the sample was then dissolved in this solution and electrolysis was carried out with the anodic current density of 2.5 to 3.5 amp./$dm^2$ at an average of 4.8 V., at 4~6°C for designated amp. hr. At the end, the voltage rose up to 5.2~5.3 V.

It was found that the amount of the electricity used up to this point corresponded to about 1.3 times that assumed to be required to form fluorine with discharging fluoride ion which would substitute with hydrogen in the sample and combine with it to form hydrogen fluoride.

The gaseous product generated from the cell, containing fluorocarbons, oxygen difluoride, perfluoro-acid fluorides, hydrogen, etc. was passed through

the condenser and the sodium fluoride tube, and bubbled through water in the absorber where the perfluoro-acid fluorides reacted, and converted into perfluorocarboxylic acids. In this system, the gases which are inert to water should escape as gases.

When the reaction was over, the hydrogen fluoride in the cell was distilled into the polyethylene container which was used repeatedly by adding it into the new hydrogen fluoride for the next run, but for different kinds of esters, hydrogen fluoride freshly supplied from the cylinder was used. About 50 ml. of a residue consisting mainly of hydrogen fluoride remained at the bottom of the cell and its other components were investigated further by the method described earlier[5].

The aqueous solution of the perfluorocarboxylic acids in the absorber was neutralized with sodium carbonate, filtered and the filtrate was dried. The sodium perfluorocarboxylates formed were then extracted with absolute ethanol.

Quantitative analysis of the products was made by the base line method with potassium bromide pellet infrared absorption spectrum using 11.88 $\mu$ (for sodium trifluoroacetate), 9.68 $\mu$ (for sodium perfluoropropionate), and 10.65 $\mu$ (for sodium perfluorobutyrate) as key bands. The standard sodium carboxylates were prepared from trifluoroacetic acid secured from the Eastman Kodak Co., and perfluoropropionic and perfluorobutyric acids secured from the Minnesota Mining and Manufacturing Co. by treatment with sodium carbonate.

When several runs were repeated, the electrodes were stained with a grey substance, which was removed by electropolishing in 0.5% of potassium carbonate solution.

## Results and Discussion

The effect of anodic current density on the yield was mainly examined in a similar manner as in the fluorination of alcohols. Trifluoroacetic acid was obtained from ethyl acetate and the results are shown in Table I. The yields shown were calculated on the basis that 1 mol. of ethyl acetate would give 2 mol. of sodium trifluoroacetate. The fluorination of ethanol also yielded trifluoroacetic acid, but the yield was usually less than that in the case of ester.

The calculation of current efficiencies shown was based on the amount of the electricity assumed to be required to form fluorine with a discharging fluoride ion which would substitute hydrogen in the ester and combine with it to form hydrogen fluoride. This means that the electricity to make 8 mol. of fluorine would be required for the fluorination of 1 mol. of ethyl acetate to form 2 mol. of sodium trifluoroacetate.

The results obtained from the fluorination of propyl acetate, from which trifluoroacetic and perfluoropropionic acids were obtained, are shown in Table II. The yields shown were also calculated on the basis that 1 mol. of propyl acetate would give 1 mol. of sodium trifluoroacetate and 1 mol. of sodium perfluoropropionate, which means that the acyl and the alkyl groups in the ester would give perfluorocarboxylic acids whose number of carbon atoms corresponds to those of the acyl and the alkyl group in the ester.

Table I. Fluorination of ethyl acetate

Electricity passed: 211 amp. hr.
Sample taken: 34.5 g.

| $D_A$[a] amp./dm$^2$ | Product obtained g. | Yield % | Current efficiency % |
|---|---|---|---|
| 2.5 | 45.6 | 43.4 | 34.0 |
| 2.7 | 47.2 | 44.9 | 35.2 |
| 3.0 | 52.0 | 49.5 | 38.8 |
| 3.3 | 54.2 | 51.6 | 40.5 |
| 3.5 | 54.9 | 52.3 | 41.0 |

a) $D_A$: Anodic current density.

The current efficiency was also calculated by the same method as for ethyl acetate, i. e. the electricity assumed to make 10 mol. of fluorine would be required for the fluorination of 1 mol. of propyl acetate to form 1 mol. of sodium trifluoroacetate and 1 mol. of sodium perfluoropropionate.

The results obtained from the fluorination of butyl acetate, ethyl, propyl and butyl propionates, and ethyl, propyl and butyl butyrates are shown in the Tables. All of the yields and current efficiencies shown were calculated in the same way as was mentioned above.

It was found that the yield of the perfluorocarboxylic acid obtained from the fluorination of propyl propionate or butyl butyrate was much higher than that from propyl or butyl alcohol, but the degree of cleavage which would result in the formation of perfluorocarboxylic acids consisting of a smaller number of carbon atom than that of corresponding alcohol, or acyl or alkyl group in the ester was essentially the same in alcohols and esters.

It is of interest to know which side of the ester, acyl or alkyl group, would give perfluorocarboxylic acid more easily. Comparison between the results obtained from butyl acetate and ethyl butyrate or butyl propionate and propyl butyrate indicated that perfluorobutyric acid was obtained in better yield from ethyl and propyl butyrates than from butyl acetate and butyl propionate. This showed that perfluorocarboxylic acids are formed more easily from acyl than alkyl group in the ester.

When the number of carbon atoms increased in the ester, the degree of cleavage increased, as is usually observed in electrochemical fluorination. For example, propyl acetate gave sodium trifluoroacetate and sodium perfluoropropionate in molar ratio of about 1 to 0.9, but butyl acetate gave sodium trifluoroacetate

and sodium perfluorobutyrate in molar ratio of about 1 to 0.4, which indicates that butyl radical is degradated considerably as compared with propyl radical.

In the fluorination of alcohols, the maximum yield of perfluorocarboxylic acids was obtained with anodic current density of 3.3 amp./dm², and the yield decreased sharply with higher or lower current densities, irrespective of the kind of alcohols used, but there seemed to be no such simple relationship between the anodic current density and yield for the esters within the range of the current density applied. However, the yield generally increased with increasing current density.

The presence of a small amount of unreacted ester remaining in the residue in the cell along with the acetyl fluoride and partially fluorinated carboxylic acid fluorides was confirmed. The grey precipitate consisting mainly of nickel and copper fluorides was also found in the residue.

The mechanism of the fluorination of esters to form perfluorocarboxylic acid fluorides, although this reaction obviously could and probably did follow different routes simultaneously, might involve, in the first place, hydrofluorolysis of the esters in hydrogen fluoride to form acid fluorides and alcohols as shown below. Alcohols formed in this way would be converted into acid fluorides through the mechanism of dehydrofluorination at the $\alpha$-carbon atom.

In these formulae, $R_H$ and $R_H'$ are hydrocarbon radicals, and $R_F$ and $R_F'$ are perfluorocarbon radicals. Acid fluorides $R_H$–COF and $R_H'$–COF thus formed would be fluorinated further to perfluorocarboxylic acid fluorides.

## Conclusion

1) Perfluorocarboxylic acids were obtained from esters in a good yield by electrochemical fluorination and the relationship between anodic current density and yield was examined. Generally, the yield increased with increasing anodic current density.

2) The result of electrochemical fluorination of esters was compared with that of alcohols. A better yield was obtained from the esters.

3) The presence of a larger number of carbon atoms in the acyl or alkyl group in the ester caused more degradation than those of smaller numbers.

4) The mechanism of the formation of perfluorocarboxylic acid fluorides from esters was discussed.

The authors wish to express their sincere thanks to Osaka Metal Industries Co. for supplying hydrogen fluoride.

# *Molecular Structure Investigation of Chlorotrifluoroethylene by Electron Diffraction*

By Takeshi KAWAI, Hiroshi SEKINE and Masato IGARASHI

(Received January 30, 1961)

The molecular structures of chlorine and fluorine derivatives of ethylene such as tetrachloroethylene[1-3] and tetrafluoroethylene[4,5] have been studied by electron diffraction using a sector-microphotometer or visual methods (Table I).

In order to see the carbon-halogen bond distances and the valence angles of ethylene derivative including two kinds of halogens, we investigated chlorotrifluoroethylene (Kel F monomer) by electron diffraction using the visual method and compared it with those of the related compounds.

## Experimental

The sample was prepared by Osaka Kinzoku Industrial Co.

The apparatus of electron diffraction was the same as that in the previous report[6]. In order to reduce the vapor pressure of the sample the liquid-sample reservoir was cooled by a mixture of dry ice and alcohol during the diffraction experiment. The diffraction photographs were measured by the visual method (Fig. 1).

## Analysis and Results

The radial distribution and theoretical intensity curves have been calculated by the usual method. The thermal factors were omitted for convenience in all the theoretical intensity curves except curves D′ and D″ in which the mean amplitudes listed in Table III were used. Some of the intensity curves are shown in Fig. 1 and the molecular parameters of the corresponding models are listed in Table II.

As can be seen from the first peak of the radial distribution curve (Fig. 2), it is difficult to distinguish the C=C and the three C-F bond distances separately. The mean value of them is 1.31 Å. The second peak shows that the C-Cl bond distance is 1.71 Å.

When the angles FCF and FCCl of the models are varied, the C=C and all the C-F bond distances being fixed at 1.31 Å and the C-Cl band distance at 1.71 Å, the features of the maxima or the shelves at about $q=28\sim41$ of the theoretical intensity curves change appreciably and the curves C and D, in which the two angles are equal to 115 and 114°, respectively, fit better with the observed curve

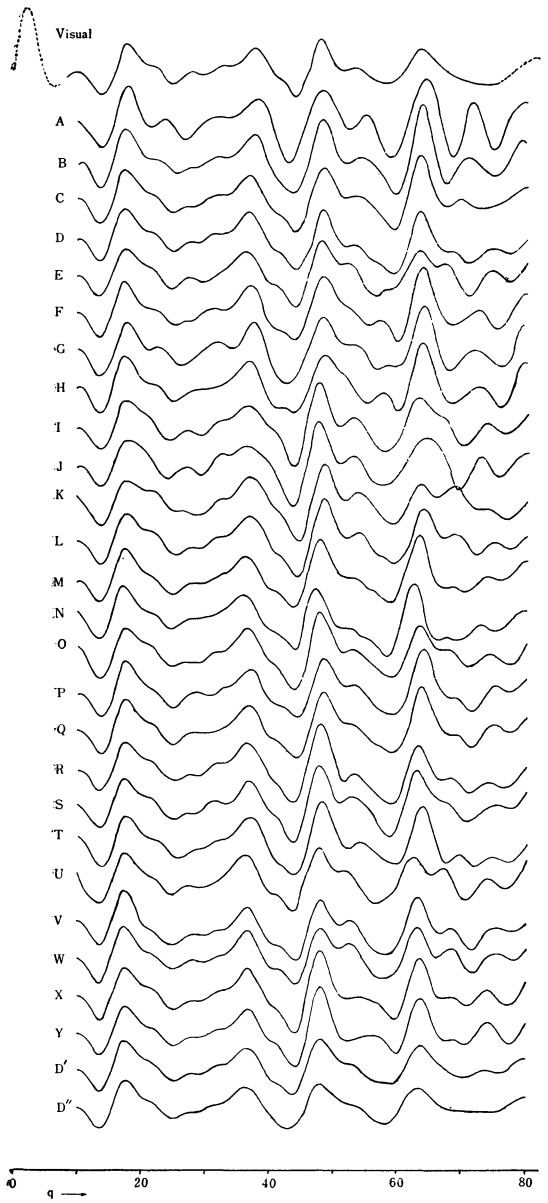
than any other curves of different bond angles.

By comparing the features and $q_{calcd}/q_{obs}$ values of the intensity curves of the models which have bond angles different from those of models C and D, the acceptable regions of the two bond angles FCF and FCCl were determined as 114±2° and the bond angle CCCl as 123±2°.

And then by comparing the intensity curves of the models in which C-Cl bond distance was varied from 1.67Å to 1.75Å, the C-Cl bond distance was determined as 1.72±0.02Å.

If either one of the C=C or the C-F bond distance is longer and the other is shorter than 1.31Å, a considerably good intensity curve is obtained by altering both the bond angles and C-Cl distance in the acceptable regions which have been described previously. But as the contribution of the C-F atomic pairs to the total intensity curve is much greater than that of C=C atomic pair, the acceptable region of C=C distance is much larger than these of C-F distances. They were 1.31±0.06Å for C=C and 1.31±0.02Å for C-F, respectively.



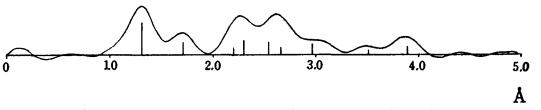


Fig. 1. Intensity curves.

Finally the theoretical intensity curves of model D including thermal factors listed in Table III are compared. They are not greatly different from that of the rigid model, but curve D' seems a little better than curve D''.

Vartical lines show the interatomic distances of model D.

Fig. 2. Radial distribution curve.

TABLE III. MEAN AMPLITUDES USED FOR THE CALCULATIONS OF INTENSITY CURVES D' AND D''

| Atomic pair | Mean amplitude, Å | |
|---|---|---|
| | Model D' | Model D'' |
| C=C | 0.04 | 0.04 |
| C-F | 0.04 | 0.05 |
| C-Cl | 0.05 | 0.05 |
| C···F | 0.06 | 0.06 |
| C···Cl | 0.06 | 0.06 |
| F···F | 0.06 | 0.09 |
| cis F···F | 0.09 | 0.09 |
| trans F···F | 0.06 | 0.11 |
| Cl···F | 0.06 | 0.09 |
| cis Cl···F | 0.09 | 0.09 |
| trans Cl···F | 0.06 | 0.11 |

When the above results are compared with those in Table I, all the parameters of the molecule are practically identical with those of Refs. 3 and 4, although the present results by visual method have broader limits of uncertainty than those of the sector-microphotometer method.

The authors wish to express their sincere gratitude to Professor Akira Kotera for his kind guidance throughout this study. They also owe much to Dr. Nobuo Yamada, The Electrical Communication Laboratory, Nippon Telegraph and Telephone Public Corporation, to whom their thanks are due.

# *Energy Distribution of Secondary Electrons from Copper-Beryllium Alloy by Positive Ions of Inert Gases. I. Electro-polished Surface*

By Toshio SUGIURA

(Received January 17, 1961)

A series of studies of electron ejection from copper-beryllium (4%) alloy by positive ions have been extended in this work. In a previous paper[1], the yields of the secondary electron emission from the variously treated copper-beryllium targets by inert gas ions and some hydrocarbons and their fragment ions were measured, and the surface composition of these alloy targets were also determined by electron diffraction analysis in order to discuss the correlation between the yields of the secondary electron emission and the surface composition of the ion targets.

The secondary electron emission by inert gas ions had been studied by Hagstrum[2-6] on the atomically clean surfaces of some transition metals. The energy distribution of the secondary electrons ejected by the Auger process obeying the assumed mechanism had been theoretically calculated by Hagstrum[7], and a good agreement had been obtained between the theory and his experimental results.

Generally, the ejection of secondary electrons from a metal surface by impact of a positive ion proceeds at the expense of the potential or kinetic energy of the incident ion. Potential ejection may take place only if the ionization potential of the incident ion exceeds twice the work function of the target metal. Kinetic ejection, on the other hand, is expected to increase with increasing ion energy, and is the dominant process for all ions with kinetic energy above a few thousand electron volts, and it also proceeds for positive ions whose ionization potential is less than twice that of the work function of the metal.

Recently, Waters[8] had intended to confirm this kinetic ejection, and had measured the kinetic energy distribution of the ejected electrons from the atomically clean surface of tungsten impacted by alkali ions.

Unfortunately, the theory of the kinetic ejection by the positive ion having low kinetic energy had not yet been clarified, but the mechanism of secondary electron emission by the impact of high speed ions had been made the analysis by Sternglass[9]. He had studied the process of secondary electron emission regarded as the component of two essentially important parts, namely the formation of secondaries inside the metal and their subsequent escape from the surface. Also he had postulated that the energy loss of the primary particle as a result of the excitation and ionization of the target materials results in the formation of internal secondary electrons, and that the secondaries formed might lose their energy by various collison processes so that only a fraction of them may be able to reach the surface of the metal with sufficient energy to escape from the surface. The assumption of Sternglass seems to be suggestive for the secondary electron emission from the practical (not atomically clean) surfaces by impact of the ions.

The main points of interest of the present work are the direct measurements of the kinetic energy distribution of the secondary electrons ejected from the practical surface usable as the first dynode of the secondary electron multiplier tube, and the confirmation of the correlation between the yield of the secondary electron emission and the energy distribution of the secondary electron emission and the energy distribution of the secondary electrons. The results reported in this paper are concerned with the energy distribution of the secondary electrons ejected from the electro-polished copper-beryllium surface by impact of the singly- and doubly-charged argon and neon ions and singly-charged herium ions, together with the influence of the kinetic energy of these incident ions.

## Experimental

In the experimentals of the electron ejection, the beam of ions which is homogeneous in constitution and kinetic energy was allowed to impinge upon a target surface. In order to measure the yield of secondary electrons ($\gamma_1$, number of electrons per incident ion) and the distribution in kinetic energy

of ejected electrons, both as functions of the ion and target and of the ion kinetic energy, the apparatus must incorporate an ion source, a mass analyzer, an arrangement of target and surrounding electron collector, and the means to vary the velocity of the ion beam while keeping it focused on the target.

**Mass Spectrometer.** — The present experiments were performed by a mass spectrometer constructed in our laboratory, and their details were already reported in the previous paper[1]. In this studies, in order to eliminate the influence of the fringing field of the analyzing magnet on the slow electrons, the magnetic shield composed of six sheets of soft iron plates of 1.0 mm. in thickness was attached to the middle part between the ion collector region and the analyzing magnet. By this shielding, the influence of the fringing field on the energy distribution of secondary electrons was considered negligible, as described below.

**Ion Target and Electron Collector.** — Since the measurements of the energy distribution of the ejected electrons were made by the retarding potential method, the target was made relatively small and placed at the center of the spherical electron collector.

The ion target and the electron collector designed for the study of energy distribution of secondary electrons are schematically shown in Figs. 1a and b. In Figs. 1a and b, T indicates the ion target box

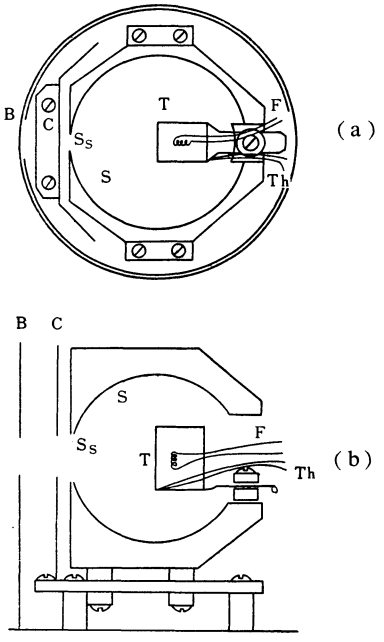

Fig. 1. Schematic top view (a) and side view (b) of the electron collector and ion target for the study of secondary electron emission by ion impact. T denotes the ion target, S the spherical electron collector, B, C and Ss the buffer, the collector and ion entrance slit, F the tungsten filament prepared for the heating of the ion target, Th the nickel-palladium thermocuple.

shaped from the copper-beryllium (4%) plate, and the front area of this box is $6\times12$ mm$^2$ and the target was mounted at the center of the spherical electron collector S by the steatite insulator. S was constructed by two pieces of the brass blocks fastened to each other and the inside of these brass blocks were spherically excavated, the diameter of this sphere is 27 mm., and the area of the ion entrance slit Ss is $10\times3$ mm$^2$. In order to minimize the tertiary electron emission by secondary electrons and the variation of the contact potential with contamination by adsorped gases, the inside surface of the electron collector was covered with evaporated gold films. C is the collector slit of $8\times2$ mm$^2$ in area and shaped from a molybudenum plate of 0.2 mm. in thickness, and B is the buffer slit of $10\times5$ mm$^2$ in area formed by a copper plate of 0.4 mm. in thickness. The tungsten filament F was prepared inside the ion target box for heating the ion target by electron bombardment, and the temperature of the ion target was measured by a nickel-palladium thermocouple Th.

By these assemblies, all ions strike only the front surface of the ion target inside the spherical electron collector, since the focusing of the mass analyzer is determined by ion beam width less than 0.3 mm. at the collector slit during the course of studies.

**Measurements of Energy Distributions of Secondary Electrons.**—Electron energy distributions were measured in this work by means of the retarding potential method. Currents $I_s$ at the electron collector were measured as a function of the voltage $V_{sT}$ supplied between the ion target and the electron collector. The net ion currents $I_i$ were measured by the ion target to which $-18$ V. was supplied against the electron collector through a battery in order to eliminate secondary electrons, and the ratio of the currents $I_s/I_i$ was obtained as a function of the retarding potential $V_{sT}$.

Typical retarding potential data for the singly-charged argon ions are shown in Fig. 2. The kinetic energy distributions of the ejected electrons $(N_0(E_k)=d(I_s/I_i)/dV_r)$ have been obtained from the retarding potential data in the following way where $V_r$ denotes the retarding potential corrected to the contact potential difference between copper-beryllium and gold against $V_{sT}$. The differences in $I_s/I_i$ for each 0.25 V. retarding potential difference was plotted vs. $V_r$. Typical energy distribution curves obtained from the data shown in Fig. 2 are shown in Fig. 3 in which the unit of $N_0(E_k)$ is electrons per ion per electron volt. A UX-54 tube was used as the primary tube of the d. c. amplifier, and the output current was recorded by two galvanometers of different sensitivities. Since a high resistance of $1\times10^{10}$ ohm was used and the measured current was less than $1\times10^{-11}$ amp. in all measurements, the inaccuracy of the retarding potential caused by the incident electrons or the primary ions is less than 0.1 V. and this causes no effective error in this study.

**Measurement of Contact Potential Difference.**— The apparatus used for the measurements of the contact potential difference is shown in Fig. 4a. The vacuum line of apparatus was all constructed

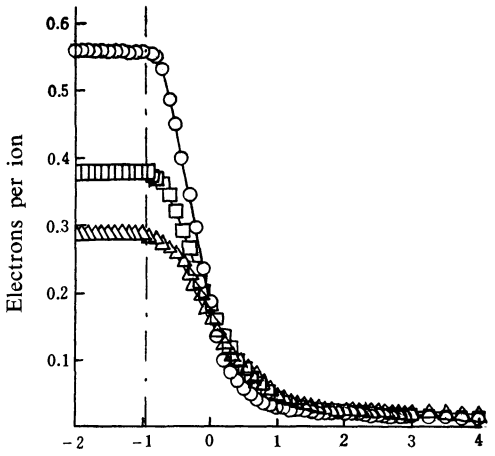

Fig. 2. Polt of ejected electron current $I_S$ in electrons per ion as a function of the retarding potential $V_{ST}$ for argon ions impinged on the electro-polished Cu-Be surface. Circule, square and triangle points denote impinged ion energy of 1240, 840 and 540 V., respectively.
The vertical line show on the electron energy scale indicates the contact potential difference between Au and electro-polished Cu-Be.

by molybdenum glass and R in Fig. 4a is the measurement tube, and these were evacuated by the Hickman type oil diffusion pump through a liquid nitrogen trap, and the vacuum during the measurements was $1\times10^{-6}$ mmHg. In Fig. 4b the electrode system is shown, the cylindrical electrode P was formed from a nickel plate of 0.2 mm. in thickness and the inside of this cylinder was covered

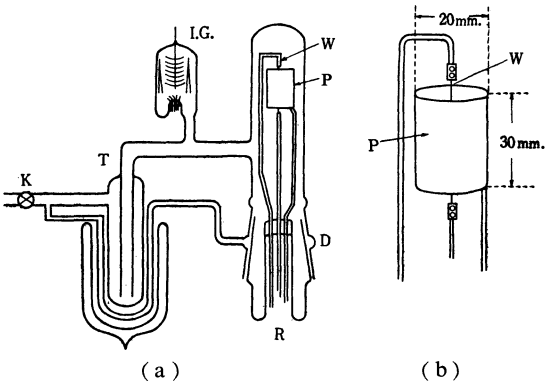

Fig. 4. Schematic diagram of the apparatus for the measurements of the contact potential difference (a). (b) show the electrode assembly. R denotes the measurement tube, P the retardation plate and the thermal electron collector, W the tungsten filament which supplying thermal electrons, I. G. the Bayard-Alpert ionization gauge, and T the liquid nitrogen trap.

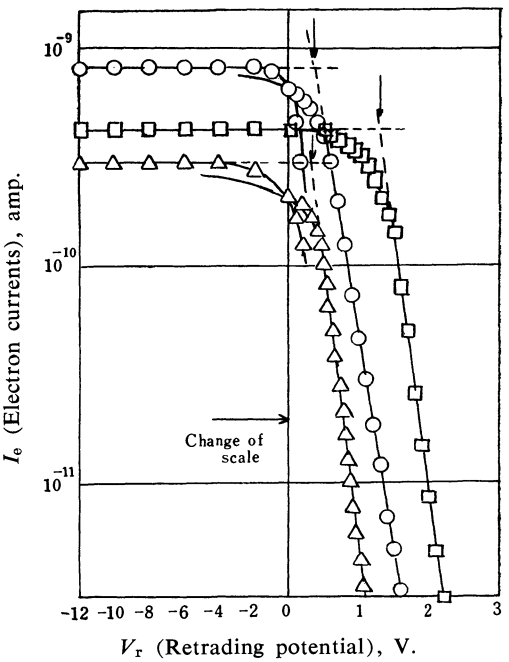

Fig. 5. Retarding potential data on thermoionic electron for the heated tungsten used to determine the contact potential difference between gold and electro-polished Cu-Be. The circle points show the Au—W system, the square points show the Cu-Be—W system, and the triangular points show the data of Hagstrum for Au—W system, in which the electron current scale is arbitrary for the Hagstrum's plot. with the evaporated gold film for the measurements of the contact potential difference between gold and tungsten, while for measurements of the contact potential difference between copper-beryllium and tungsten P was formed from a copper-beryllium plate of 0.15 mm. in thickness and was treated in the same manner as the ion target was. The tungsten filament F of 0.07 mm. in diameter was strung at the central axis of the electrode P. The electrode P and the tungsten filament F were mounted on a molybdenum rod in the measurement tube R. The geometry of the cylindrical electrode P was 20 mm. in inner diameter and 30 mm. in length. The stabilized 0.85 V. and 0.8 amp. were supplied to the filament in order to minimize the positive ion emission from the filament, the ionization of the residual gases and the photon radiation. Under these conditions, the thermal electron current of about $10^{-9}$ amp. was measured by a $\mu\mu$ ammeter. The retarding potential for the thermal electrons was applied on the center of the filament potential to the electrode P by dividing the battery potential. Typical results of the retarding potential curves for the thermal electrons emitted from the tungsten filament onto the gold plate or the copper-beryllium plate are shown in Fig. 5.

**Materials.**—The copper-beryllium ion target was shaped in a box-form after tempering and mechanical polishing with fine emery papers, and successively electro-polished in the solution which had been reported in the previous paper[1]. Spectroscopically pure argon and neon were used in the present experiments as well as in the previous sutdies, and also spectroscopically pure helium of the Teikoku Oxygen Co. was used without any further purifications. The mass spectrometric analyses of these gaseous samples revealed that the total impurities were less than 0.005% in volume.

## Results

**Contact Potential between Gold and Electro-polished Copper-Beryllium.** — Typical retarding potential data obtained from the manner described above are shown in Fig. 5. In Fig. 5, the circle points indicate the retarding potential curve between the tungsten filament and the gold surface, while the square points show the retarding potential curve between tungsten filament and the electro-polished copper-beryllium surface. The triangle points in Fig. 5 indicate the results of the tungsten~gold system measured by Hagstrum[2] in which the electron current scale was shown in an arbitarary unit. As seen in Fig. 5, the retarding potential portion had been observed to be linear from 0.5 to 1.6 V. for the tungsten ~gold system, and to be linear from 1.4 to 2.2 V. for the tungsten~copper-beryllium system, while in Hagstrum's data the linear portion is from 0.5 to 1.1 V. The point of zero field has been determined by the intersection of the extrapolated straight lines through the saturated current and retarding portions as shown by arrows in each curve in Fig. 5.

These treatments of semilog plot are strictly correct only for plane parallel geometry[10], although the present author measured by geometry of cylindrical symmetry and Hagstrum[2] had measured by spherical geometry. But the present results of the tungsten—gold system are in close agreement with Hagstrum's result, and the discrepancies between these observed values and the true values are expected to be smaller than 0.1 V. The observed value of the contact potential difference between gold and electro-polished copper-beryllium alloy is 0.95 eV., while the surface potential of the electro-polished copper-beryllium is 0.95 eV. more positive than that of gold.

**Kinetic Energy Distribution of Secondary Electrons.** — The distribution curves of the kinetic energy of the secondary electron by singly- and doubly-charged argon and neon ions and by singly-charged herium ions are shown in Figs. 3, 6, 7, 8 and 9, respectively. In these figures the results obtained for the incident ion energies of 1240, 840 and 540 V. are respectively indicated by circles, squares and triangles, and the correction of the contact potential difference between the ion target and

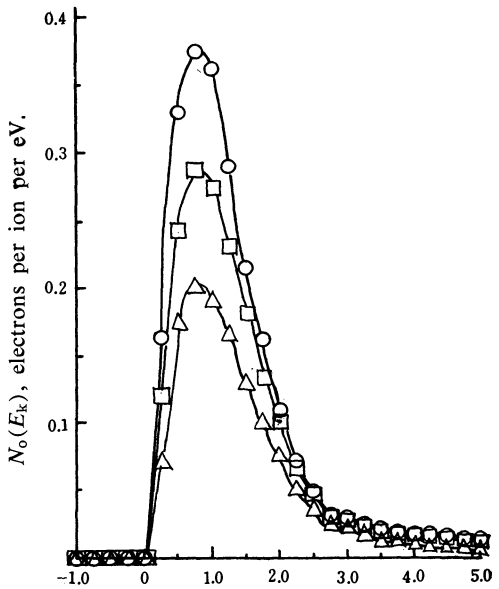

Fig. 6. Energy distributions of electron ejected from electro-polished Cu-Be by doubly-charged argon ions. Circular, square and triangular points denote the kinetic energy of incident ions of 1240, 840 and 540 V. respectively.

10) K. T. Compton and I. Langmuir, *Rev. Modern Phys.*, 3, 225 (1931).

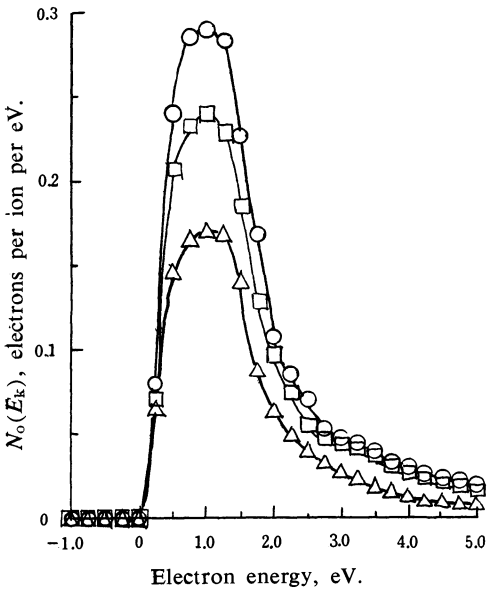

Fig. 7. Energy distributions of electron ejected from electro-polished Cu-Be by singly-charged neon ions. Circular, square and triangular points denote the kinetic energy of incident ions of 1240, 840 and 540 V. respectively.

the electron collector was made for the retarding potential $V_r$.

These curves show that the fringing field of the analyzing magnet is negligible around the electron collector. If the fringing field is effective around the electron collector, then the electrons having low kinetic energy could not reach the electron collector and the distribution curves of the electron kinetic energy would have drifted to the low energy side. This effect has been studied by Hagstrum[3]. In the present studies, the magnetic field for the mass analyzer was varied for the focusing of ions having the various masses and kinetic energies, but every distribution curve obtained in this work practically showed that $N_0(E_k) = 0$ at the zero field in the retarding potential scale and no low energy tail has been observed.

The kinetic energy distribution shown by the half widths of each distribution curve and

TABLE I. VARIATION OF THE HALF WIDTHS OF THE ENERGY DISTRIBUTION CURVES AND YIELDS OF SECONDARY ELECTRONS FORM ELECTRO-POLISHED Cu-Be SURFACE WITH ION ENERGIES OF PRIMARY INERT GAS IONS

| | Half widths of the energy distribution curves of secondary electrons in eV. | | | Yield of the secondary electrons $\gamma_1$ in electrons per ion. | | |
|---|---|---|---|---|---|---|
| Ion energy | 1240 | 840 | 540 | 1240 | 840 | 540 |
| Ion | | | | | | |
| $A^+$ | 1.00 | 1.05 | 1.20 | 0.56 | 0.38 | 0.27 |
| $A^{2+}$ | 1.30 | 1.35 | 1.40 | 0.58 | 0.43 | 0.36 |
| $Ne^+$ | 1.40 | 1.45 | 1.50 | 0.57 | 0.43 | 0.31 |
| $Ne^{2+}$ | 1.90 | 1.95 | 2.05 | 0.82 | 0.56 | 0.39 |
| $He^+$ | 2.00 | 2.05 | 2.15 | 1.35 | 0.94 | 0.68 |

the yield $\gamma_i$ of the secondary electrons are summarized in Table I.

## Discussion

**General Features of Energy Distribution Curves.**—As seen in Figs. 3, 6, 7, 8 and 9, all distribution curves have their maximum at about 1 eV. But the sharpness of each distribution curve is more similar to that of the lithium ions and the tungsten surface by Waters[8] than that of the argon ions and the tungsten surface by Hagstrum[6], both shown in Fig. 10. Although the surface in this work

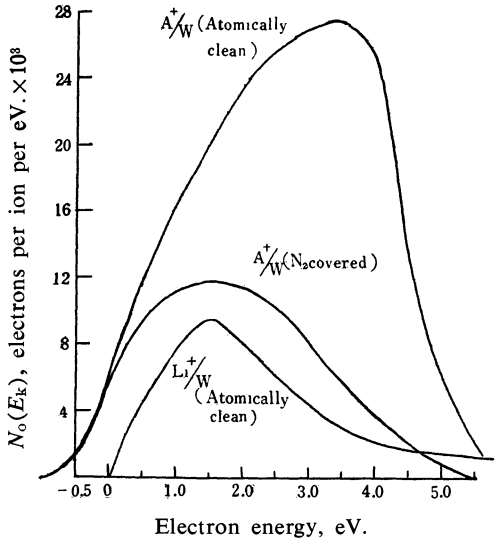

Fig. 10. Energy distributions of secondary electrons ejected by 10 eV. $A^+$ ions from atomically clean tungsten (W) and tungsten covered with the monolayer of nitrogen ($N_2$/W) given by Hagstrum[8], and the distribution curve of electron ejected by 1000 eV. $Li^+$ ions from atomically clean tungsten surface ($Li^+$) given by Waters[8].

was not atomically clean, the energy distribution curves observed in this work are not similar to that for the nitrogen covered surface of tungsten observed by Hagstrum shown in Fig. 10. The electron yields obtained in these studies are much greater than the results of Hagstrum and Waters. Since the present results were obtained from the alloy surface covered by residual gases and Hagstrum and Waters worked on the atomically clean surfaces of pure metals, the direct comparison of these data has no significant meaning, but the general features of the present distribution curves show much similarity of the kinetic ejection.

**Effect of Ion Kinetic Energy.** — As seen in Table I, the yield of the secondary electrons is clearly increased by increasing the kinetic energies of the incident ions, while the half width of the energy distribution curve of the secondary electrons is slightly decreased by increasing the ion kinetic energies. The difference between two distribution curves of different ion kinetic energies indicates the difference in the distribution of the different numbers of the secondary electrons emitted by different ion kinetic energies. In these different energy distributions, it is clearly shown that the increase in the electron yield as increasing the ion kinetic energies is mainly contributed to low energy electrons. This effect may be qualitatively explainable from the following idea similar to that of Sternglass[9]. Since the incident ions penetrate deeper as the ion kinetic energy increases, the number of secondary electrons formed in the alloy may be proportionally increased with the increase in the penetration depth. The formed secondary electrons may lose their energies in various types of collision processes, so that only a small fraction of them can reach the surface with sufficient energy to escape from the surface. But an increased number of electrons with the increase in the ion kinetic energy are formed in the deeper layer in the alloy, thus the detected secondary electrons might lose their initial energies during the passage through the layers in the alloy. The dependency of the distribution curves on the ion kinetic energy in these studies has previously been explained.

**Influence of Ion Species.**—As seen in Table I and Figs. 3, 7 and 9, the yield of the secondary electrons at any definite ion energy for the singly-charged inert gas ions is clearly increased in sequence from the argon, neon to helium ions, and this sequence has a correlation to their ionization potentials. Then, higher yield of the secondary electrons may be obtained by impact of the ion having the higher ionization potential.

As seen in Figs. 3, 7 and 9 and Table I, the energy distribution curves are broader for light ions than for heavier ions. These phenomena can not be explained by any similar explanation of the influence of the effect of the ion kinetic energy, since the ions of different masses are formed in the mass spectrometer with constant kinetic energy when the ions were accelerated by the acceleration voltage. If the penetration depth of the ions is assumed[9] to be simply dependent upon the ion kinetic energy, the penetration depth of the lighter ions is the same as that of the heavier ions. But the present results on the energy distribution clearly show the existence of the higher energy electrons in the case of lighter ions. They also indicate that the higher

energy electrons emitted by the ions have a higher ionization potential.

These phenomena indicate that the mechanism of the secondary electron ejection from the electro-polished copper-beryllium surface is not simple. The ionization potentials of argon, neon and helium are 15.76, 21.59 and 24.58 eV., respectively, and though the work function of the electro-polished copper-beryllium is not certain it may be presumed to be less than 6 eV. Then, it is considered from the present experimental conditions that the ionization potentials of the ions of the present consideration are larger then twice the work function of the alloy surface. Consequently, it remains open to discussion as to the mechanism of the potential ejection[7], but the general features of the distribution curves of the electron energies show considerable similarity to the kinetic ejection. For the reason mentioned above, it is difficult to deduce any simple conclusion on the mechanism of the electron emission by inert gas ions from the present work.

**Effect of Ionic Charges.**—From a comparison of Figs. 3 and 6 for argon ions and Figs. 7 and 8 for neon ions, the energy distribution curves by the doubly-charged ions are broader than those by the singly-charged ions, and the yield of the secondary electrons by the doubly-charged ions are greater than that by the singly-charged ions at any definite ion kinetic energy. Thus the energy distribution indicates that the doubly-charged ions ejected the higher energy electrons than the singly-charged ions do. This tendency is similar to the influence of the ion species on the yield and energy distribution of secondary electrons. The secondary ionization potential of the argon and neon ions are 43.52 and 62.57 eV., respectively, then the mechanism of the secondary electron emission from copper-beryllium may occur according to the complex mechanisms in which the secondary electron is ejected by contribution of both of the kinetic and the potential energies of the incident ions.

## Summary

The distribution curves of the kinetic energies of the secondary electrons from the electro-polished copper-beryllium surface by inert gas ions were measured by the retarding potential method together with the yield of the secondary electron emission. The contact potential difference between the ion target (electro-polished copper-beryllium) and the electron collector (gold) was also measured by the retarding potential method for the thermal electrons from tungsten, and the correction of this contact potential difference was made for the kinetic energies of secondary electrons. The main results obtained are as follows.

(1) The contact potential difference between gold and electro-polished copper-beryllium (4%) is 0.95 eV. (gold, negative).

(2) The general features of the distribution curves of secondary electrons are similar to the distribution curves of the kinetic ejection measured by Waters.

(3) The present results of the energy distribution curves of secondary electrons by the inert gas ions indicate that the yield of secondary electrons is increased by increasing the kinetic energy of the primary ions, and that this increment in the yield is mainly contributed from the secondary electrons which have lower kinetic energies than that of the secondary electrons emitted by the incident ions of low kinetic energies. These phenomena are able to be postulated qualitatively by the idea of sternglass.

(4) The total number of emitted electrons is increased with the increase in the value of the ionization potential of incident ions, and the kinetic energies of emitted electrons become greater by increasing the potential energy of incident ions. These phenomena are difficult to explain by the mechanism of the kinetic ejection, therefore the electron emission from the electro-polished copper-beryllium surface by inert gas ions may occur according to the complicated mechanism in which the potential energies of incident ions contribute to the electron emission together with their kinetic energies.

(5) In contrast with the singly-charged ions, the doubly-charged ions give rise to the broadening of the energy distribution curves. This also suggests the occurrence of the complicated ejection mechanisms.

The author wishes to acknowledge his indebtedness to Professor Shoji Shida of the Tokyo Institute of Technology, Professor Teruo Hayakawa and Professor Osamu Toyama of University of Osaka Prefecture, under whose direction and guidance this work was carried out.

The expense has been defrayed in part from a grant given by the Ministry of Education, to which the author's thanks are due.

By Reisuke SODA

(Received February 28, 1961)

It was previously reported[1] that a polymer, synthesized from *p-tert*-butyl phenol and formaldehyde, was a suitable material for coating the fiber of a dust respirator to obtain a high efficiency of filtration. This polymer showed anomalous phenomena in its benzene solution.

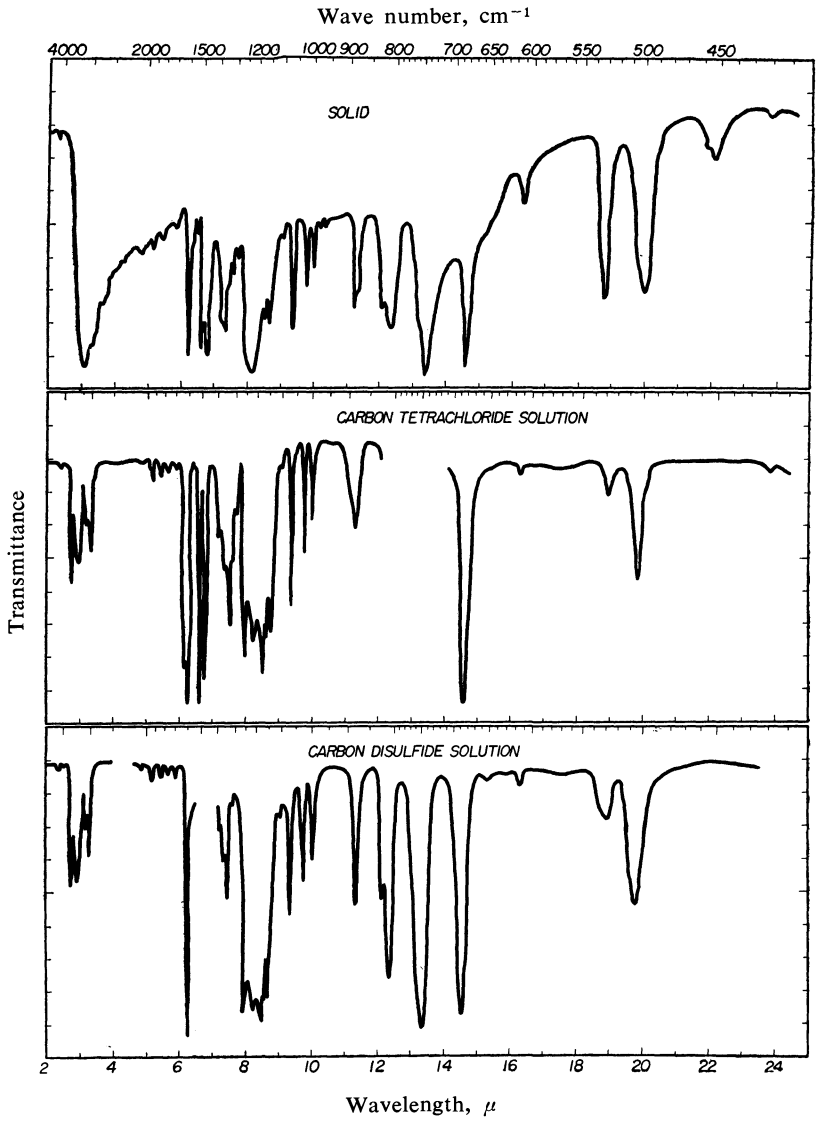

Fig. 1. Spectra of phenol in solid and solutions. Spectrum is cut off in the region of interference due to solvents. Concentration of solution is about 0.1 M in carbon tetrachloride and 0.5 M in carbon disulfide.

1) R. Soda, *Bull. Natl. Inst. Ind. Health*, No. 3, 40 (1960).

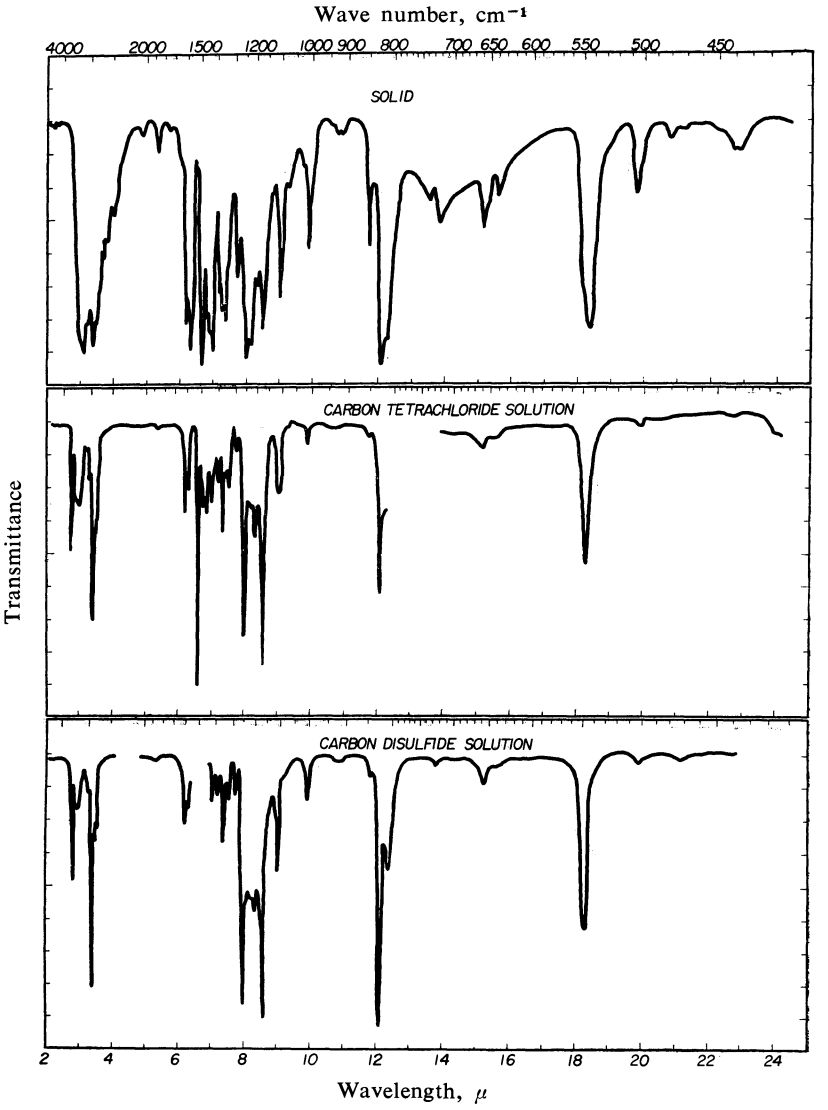

Fig. 2. Spectra of *p-tert*-butyl phenol in solid and solutions. Spectrum is cut off in the region of interference due to solvents. Concentration of solution is about 0.3 M in carbon tetrachloride and 0.4 M in carbon disulfide.

The polymer had a relatively small molecular weight and both sides of the polymer chain were *p-tert*-butyl phenol. Also the OH bonds of the polymer were bound by a very strong intramolecular hydrogen bonding and this intramolecular hydrogen bonding was made partly loose only when the polymer was dissolved in benzene. Bands of the spectrum obtained in the region of sodium chloride prism were assigned, but some ambiguity remained in these assignments.

In the present work, to eliminate the above stated doubtfulness of the assignment, the infrared absorption spectra of *p-tert*-butylphenol and the other O–H compounds were precisely measured and the observed region was extended to about 33 μ in the region of cesium bromide optics, particularly the in-plane and the out-of-plane O–H deformation vibration were investigated in more detail.

## Experimental

*p-tert*-Butyl phenol was purified by recrystallizing it from its saturated benzene solution and by vacuum distillation. α-Naphthol was recrystallized from ethyl alcohol. Phenol was purified by distillation. The solvents used were carbon tetrachloride and carbon disulfide, each being distilled once. The potassium bromide powder used for the measurement of the solid spectrum, was heated, ground to particle size of 200 to 300 mesh and dried by heating at 200°C. For the measurement of the spectrum of a solid some samples were resolidified

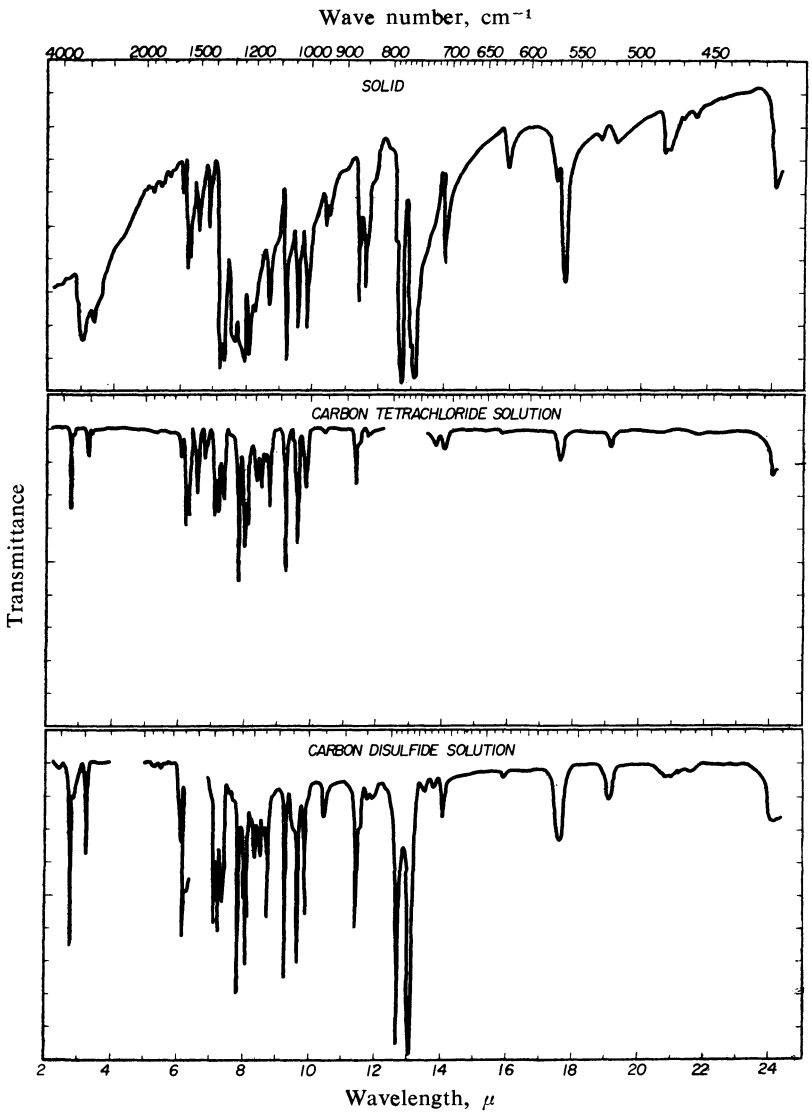

Fig. 3. Spectra of α-naphthol in solid and solutions. Spectrum is cut off in the region of interference due to solvents. Concentration of solution is about 0.05 M in carbon tetrachloride and 0.1 M in carbon disulfide.

between two rock salt plates or potassium bromide plates which were polished at both surfaces to make flat. The sample powder was sandwiched between two heated window plates and cooled moderately to make a solid film. The other spectra were obtained with potassium bromide disks.

The cell used for the solution had the thickness of 1 mm. and its window was of potassium bromide or rock salt. The infrared spectrum was observed by a Perkin-Elmer Model 137 Infracord spectrophotometer, Perkin-Elmer Model 21 spectrophotometer and Perkin-Elmer Model 221 spectrophotometer.

## Results and Discussion

The spectrum of solid of fused film between window plates was approximately the same as that of a potassium bromide pellet. It may be considered that the orientation effect does not exist in this case. Therefore the spectrum of solid obtained could be analyzed without caution of experimental condition. The spectra of phenol in the solid state, in solutions of carbon tetrachloride and of carbon disulfide are shown in Fig. 1. Those of *p-tert*-butyl phenol and of α-naphthol are illustrated in Figs. 2 and 3, respectively. The spectra of solids of these three compounds differ from those of solutions in several regions. The spectra of these compounds in solution change their features with the concentration of solution in some regions. Those changes of spectra are illustrated in Figs. 5 to 16. The spectra

of these compounds in the region of cesium bromide optics are shown in Fig. 4. No strong band which is observable at ordinary concentration is found in the region of 25 to 34 μ. Considerable changes of spectra of these compounds are observed in three regions at 3, 7 to 8 and near 18 μ when the phase and the concentration alter. The other remarkable changes are found in the regions of 6, 11 and 14 μ, but these changes are much less than those in the former regions. The changes in the regions at 6, 11 and 14 μ are observed when the solids are brought into solution but are not observed when the concentrations of solutions alter. Changes of spectral region at 18 μ of *p-tert*-butyl phenol and α-naphthol are not clear compared with that of phenol.

**Phenol.** — The spectrum of phenol has been investigated by several authors. Kuratani[2] assigned OH deformation vibrations to it and concluded that this vibration coupled with C-O stretching vibration. He reported that these vibrations gave rise to the bands at 1280 and 1195 cm$^{-1}$ respectively. Mecke and Rossmy[3] reported that these bands which occurred at 1339 and 1174 cm$^{-1}$ shifted by complete deuteration to 1294 and 915 cm$^{-1}$, respectively, and that the band at 1174 cm$^{-1}$ had a larger part of O-H deformation vibration character than the band at 1339 cm$^{-1}$.

In the present experiment, as shown in Figs. 1 and 6, the appreciable change is found in region at 1200 cm$^{-1}$ with the change of phase and concentration of solution. The change at 1300 cm$^{-1}$ region is so complex that it is not easy to make a unique assignment. The band at 1220 cm$^{-1}$ of solid spectrum shifts to 1210 cm$^{-1}$ in solution spectrum and the intensity of this band decreases when the concentration of solution is lower. In the solution, a new band appears near 1180 cm$^{-1}$ and its relative intensity to that of 1210 cm$^{-1}$ band increases at the lower concentration. The 1390 cm$^{-1}$ band of solid decreases its intensity and a strong band appears near 1340 cm$^{-1}$ in the solution. The relative intensity of the latter band to the former increases in a lower concentration of solution. Then it may be concluded that the bands 1390 and 1220 cm$^{-1}$ in solid state and the bands 1380 and 1210 cm$^{-1}$ in solution are assigned to coupled modes of C-O stretching vibration and hydrogen-bonded O-H deformation vibration. The bands at 1340 and 1180 cm$^{-1}$ may be assigned to the coupled modes of C-O stretching vibration and free O-H deformation vibration. These conclusions do not contradict the results of other papers[2-5]. These conclusions agree with what is observed in 3 μ region. In this region the stretching vibration of the O-H bond gives rise to a broad at its center at 3300 cm$^{-1}$ in solid but in solution sharp band at 3600 to 3620 cm$^{-1}$ and broad band at 3370 cm$^{-1}$ or higher. The phenol molecule will associate to a large aggregate through the hydrogen bonding in the solid state. In the solution these molecules are dispersed into monomer with free O-H bond and partly associate to build up a small polymer through O-H···O linkage. Therefore the O-H vibration of solid shows the strong hydrogen bonding character due to a larger associated molecule and that of solution shows the characters of free hydroxyl bond and partly of the weakly hydrogen-bonded bond. Other changes are observed

TABLE I. BAND POSITIONS AND ASSIGNMENT OF SPECTRUM OF PHENOL

| Band, $cm^{-1}$ | | Assignment |
|---|---|---|
| Solid | Solution | |
| | 3610 | $\nu$(O-H), free |
| | 3480 | $\nu$(O-H), bonded |
| 3360 | 3380 | $\nu$(O-H), bonded |
| 3090 | 3070 | $\nu$(C-H), aromatic |
| 3010 | 3030 | $\nu$(C-H), aromatic |
| 1605 | 1605 | Ring vibration |
| 1597 | 1597 | Ring vibration |
| 1502 | 1501 | Ring vibration |
| 1473 | 1470 | Ring vibration |
| 1389 | 1387 to 1380 | $\delta$(O-H), bonded and $\nu$(C-O)? |
| 1370 | 1355 | $\delta$(O-H), bonded and $\nu$(C-O)? |
| | 1341 | $\delta$(O-H), free and $\nu$(C-O) |
| 1337 | 1330 | Skeletal vibration |
| 1318 | 1310 | Skeletal vibration |
| 1245 | 1256 | Skeletal vibration |
| 1222 | 1211 | $\delta$(O-H), bonded and $\nu$(C-O) |
| | 1177 | $\delta$(O-H), free and $\nu$(C-O) |
| 1168 | 1166 | $\delta$(C-H) or skeletal vibration |
| 1153 | 1150 | $\delta$(C-H) or skeletal vibration |
| 1071 | 1067 | $\delta$(C-H) or skeletal vibration |
| 1024 | 1023 | $\delta$(C-H) or skeletal vibration |
| 998 | 998 | Skeletal vibration |
| 883 | 882 | Skeletal vibration |
| 822 | 824 | |
| 810 | 809 | |
| 752 | 750 | $\delta$(C-H), out-of-plane |
| 689 | 687 | $\delta$(C-H), out-of-plane |
| 663 | 656 | |
| 615 | 616 | Skeletal vibration |
| 533 | 527 | $\delta$(O-H), out-of-plane? |
| 503 | 505 | $\delta$(O-H), out-of-plane? |

near 890 and 980 $cm^{-1}$. But these changes do not clearly show its origin and are smaller than those in the above-mentioned regions. Furthermore the changes in this region are not observed with variation of concentration of solution. These changes may be explained as influence of crystal field[6]. Each band is tentatively assigned as shown in Table I. Out-of-plane O-H deformation vibration is considered to give rise to the band in lower frequency region. As shown in Fig. 4, the main intense bands arise at 530 and 500 $cm^{-1}$. These bands change their relative intensities when this substance is dissolved from a solid. The frequency shifts are slight as shown in Fig. 8. In carbon disulfide solution and in a solid form this relative absorbance ratio ($E_{530}/E_{500}$) varies as follows:

| State | Relative intensity Ratio |
|---|---|
| Solid | 1.10 |
| $CS_2$ soln. | |
| 0.9 M | 0.22 |
| 0.66 M | 0.21 |
| 0.21 M | 0.19 |
| $CCl_4$ soln. | |
| 0.49 M | 0.19 |

Then the band at 530 $cm^{-1}$ is tentatively assigned to OH out-of-plane deformation vibration of a solid and the 500 $cm^{-1}$ band to that of free O-H bond and some other vibrations. No benzene gives rise to absorption bands in these regions but with toluene a weak band arises at 521 $cm^{-1}$. Chlorobenzene, bromobenzene and iodobenzene give rise to a strong band near 450 to 460 $cm^{-1}$ and ethylbenzene at 486 $cm^{-1}$. Therefore the bands at 530 and 500 $cm^{-1}$ may be connected with the O-H out-of-plane deformation vibration and the other skeletal vibration[5].

***p-tert*-Butyl Phenol.** — The spectra of this compound as illustrated in Figs. 2, 4, 9, 10, 11 and 12, are similar to those of phenol, particulary the bands which concern the O-H vibrations. Phenol is a monosubstituted benzene derivative and *p-tert*-butyl phenol is a 1,4 disubstituted derivative. These spectra differ from each other at the bands due to some benzene ring vibrations and ring C-H vibrations. As the latter substance has further a tertiary butyl group, there appear also the bands due to the methyl group and the C·$(CH_3)_3$ group vibrations.

The change of phase and concentration causes changes of its association degree and state of molecule. This resembles that of phenol and hence O-H stretching vibration and O-H in-plane deformation vibration change their frequencies and intensities. These facts are illustrated in Figs. 9, 10 and 12. In Fig. 11, the bands at 820 and 760 $cm^{-1}$ change slightly their features with phase. The reason is still unexplained exactly but may be attributed to the crystal field effect[6]. The assignments of bands are summarized in Table II.

The spectrum of phenol in the region at 18 to 22 $\mu$ is different from that of *p-tert*-butyl phenol. It is generally accepted that in this region the band is highly sensitive to the substituent[5]. 1, 4-Dimethyl benzene gives rise to a weak band at 645 $cm^{-1}$ and a very strong band at 480 $cm^{-1}$. This strong band shifts to 432 $cm^{-1}$ in 1, 3-dimethyl benzene and to 436 $cm^{-1}$ in 1, 2-dimethyl benzene. Therefore it may be reasonable to conclude[5] that disubstituted

benzene gives rise to the band at 500 to 400 $cm^{-1}$. Solid of *p-tert*-butyl phenol absorbs at 545 $cm^{-1}$ (strong), 506 $cm^{-1}$ (medium), 482 $cm^{-1}$ (weak) and 472 $cm^{-1}$ (very weak). The band at 545 $cm^{-1}$ remains unchanged when the compound is dissolved. The band at 482 $cm^{-1}$ disappears and a new band appears at 470 $cm^{-1}$. No regularity is found among the relative intensities of bands at 545, 506, 482 and 470 $cm^{-1}$. The effect of the condition of measurement on these values is so remarkable that a quantitative argument has little meaning. Qualitatively, the bands at 506 and 480 $cm^{-1}$ of solid and those at 503 and 472 $cm^{-1}$ of solution are perhaps concerned with O-H out-of-plane deformation vibration, considering that of phenol. The other vibration may couple with this vibration. Further discussion can not be carried out now.

Other assignments are nearly the same as in the previous report[1] in the region of sodium chloride optics. These assignments are obtained with consideration of those of phenol, 1,4-disubstituted benzene and *tert*-butyl compounds.

**α-Naphthol.**—α-Naphthol is an aromatic O-H compound which has one group of three adjacent free hydrogen atoms and one group of four adjacent free hydrogen atoms. α-Naphthylamine in solid gives rise to a broad band near 3200 $cm^{-1}$ but in solution gives rise to a sharp band at 3620 $cm^{-1}$ and a weak band at 3500 $cm^{-1}$. This aspect of OH stretching vibration band is the same as those of phenol and *p-tert*-butyl phenol stated already. Regions 1400 to 1350 $cm^{-1}$, 1330 to 1250 $cm^{-1}$ and 1210 to 1160 $cm^{-1}$ vary with the change of phase. From those results it may be considered that the band due to OH deformation vibration appears near 1170 and 1330 to 1340 $cm^{-1}$ for free α-naphthol molecule. There is also some possibility of considering the coupling of OH deformation vibration with the other mode of vibration rather than with the C-O stretching vibration. Then the above-mentioned regions which show the different features with the change of phase and concentration of solution, may be concerned with the OH deformation vibration. Tentatively for free α-naphthol, the bands near 1180 and 1359 $cm^{-1}$ are assigned to those vibrations.

Out-of-plane deformation vibration of aromatic C-H bonds may give rise[4,5,7] to the bands at 760 to 740 $cm^{-1}$ and 780 to 760 $cm^{-1}$ (more generally 800 to 760 $cm^{-1}$) or 770 to 735 $cm^{-1}$ and 810 to 750 $cm^{-1}$ for α-naphthol. The other characteristic bands to the substitution may be considered to appear near 725 to 680 $cm^{-1}$, or more precisely at 740 to 710 $cm^{-1}$, (720 to 710 $cm^{-1}$), 710 to 690 and 650 $cm^{-1}$. Then the bands at 789 and 765 $cm^{-1}$ may be assigned to that mode of vibration and other characteristic bands may be attributed to those at 730, 710 and 629 $cm^{-1}$. According to the literature[5,7] the three bands at 730, 710 and 629 $cm^{-1}$ can be assigned to the in-plane deformation vibration of aromatic C-H bond.

The change of spectra in the region below 1000 $cm^{-1}$ with phase change is yet to be explained clearly. The doublet of 959 $cm^{-1}$,

7) H. Luther and H. Gunzler, *Z. Naturforsch* **10b**, 445 (1955).

the band at 867 $cm^{-1}$ and bands at 769 and 765 $cm^{-1}$ in solid are different from these in solution. The doublet bands disappear and the single band appears at 959 and 767 $cm^{-1}$, and the band 867 $cm^{-1}$ disappears completely when the solid sample is dissolved. It is not suitable to consider that these bands are attributable to the vibration mode concerned with O-H vibration because O-H vibration does not give rise to bands in these regions in general. These changes may be caused from crystal field effect[6].

TABLE III. BAND POSITIONS AND ASSIGNMENT OF SPECTRUM OF α-NAPHTHOL

| Band, $cm^{-1}$ Solid | Band, $cm^{-1}$ Solution | Assignment |
|---|---|---|
| | 3620 | ν(O-H), free |
| | 3500 | ν(O-H), bonded |
| 3240 | | ν(O-H), bonded |

| 1300 | 1297 | δ(O-H), bonded and ν(C-O)? |
| 1264 | 1276 | Skeletal vibration |
| 1253 | 1245 | Skeletal vibration |
| 1239 | 1235 | Skeletal vibration |
| | 1199 | δ(O-H), free and ν(C-O)? |
| | 1181 | δ(O-H), free and ν(C-O)? |
| 1172 | 1175 | Skeletal vibration |
| 1148 | 1145 | δ(C-H) |
| 1083 | 1082 | δ(C-H) or skeletal vibration |
| 1044 | 1040 | Skeletal vibration |
| 1015 | 1015 | δ(C-H) |
| 959 | 958 | Skeletal vibration |
| 875 | 877 | Skeletal vibration |
| 856 | 850 | δ(C-H), out-of-plane ? |
| 843 | 837 | δ(C-H), out-of-plane |
| 789 | 790 | δ(C-H), out-of-plane |
| 768 | 768 | δ(C-H), out-of-plane |
| 740 | 742 | Skeletal vibration or δ(C-H), out-of-plane |
| 731 | 725 | δ(C-H), out-of-plane |
| 712 | 710 | δ(C-H), out-of-plane |
| 628 | 629 | Skeletal vibration |
| 573 or 564 | 568 | δ(O-H), out-of-plane ? |
| 521 | 524 | δ(O-H), out-of-plane ? |
| 482 | 480 | Substituent characteristic skeletal vibration |
| 478 | 476 | Substituent characteristic skeletal vibration |
| 461 | 461 | Substituent characteristic skeletal vibration |
| 416 | 416 | Substituent characteristic skeletal vibration |

The tentative assignments are summarized in Table III. In the present experiment the concentration of solution is not altered. Therefore the assignment of the band concerned with OH vibration can not be carried out decidedly. Out-of-plane OH deformation vibration is expected to give rise to the bands in the region near 500 $cm^{-1}$ with consideration of these bands of phenol and *p-tert*-butyl phenol: But α-naphthol shows such a complex aspect in this region that a simple assignment can not be carried out at present. Perhaps bands at 530, 520 and 460 $cm^{-1}$ may be concerned with this vibration mode.

It may be accepted as true that the above three compounds give rise to the bands near 3600 $cm^{-1}$ due to OH stretching vibration, those near 1170 $cm^{-1}$ and near 1330 $cm^{-1}$ due to free OH in plane deformation vibration and those near 500 $cm^{-1}$ concerned in OH out-of-plane deformation vibration. These bands are attributed to free OH bond, but in a case of solid state or associated state, the bands at 3300 $cm^{-1}$, those at 1200 to 1230 $cm^{-1}$ and 1380 to 1430 $cm^{-1}$, and those near 500 $cm^{-1}$ may be assigned to the above mentioned vibration modes respectively. The bands in the region of 500 $cm^{-1}$ can not be decidedly assigned now but may be determined by deuteration of OH bond, considering the argument given above.

In the next paper the assignment will be made of the absorption bands of *p-tert*-butyl phenol resin and α-naphthol resin according to the result of this work.

## Summary

In connection with the work on a resin for dust respirator, the spectra of phenol, *p-tert*-butyl phenol and α-naphthol were observed in solid and in solution. Infrared absorption spectra can be explained by considering that these compounds associate by hydrogen bonding in solid form and that they hold the equilibrium between monomer and associated molecule in solution. Reasonable assignments were made to some of the bands observed. The deformation vibration of O-H (free) and stretching vibration of C-O seem to couple with each other and give rise to bands near 1340 and 1180 $cm^{-1}$ in any of these three compounds. Bands due to the out-of-plane O-H deformation vibration could not be determined but it was found that the bands in the

550～500 $cm^{-1}$ region were concerned with this vibrational mode.

The author wishes to express his hearty thanks to Assistant Professor T. Miyazawa and his collaborators at the Institute for Protein Research, Osaka University, for their kindness in permitting the use of a Perkin-Elmer Model 221 spectrophotometer. He wishes to express his thanks to Mr. M. Kawano at the Railway Technical Research Institute for the measurement of the spectrum in cesium bromide region. He also expresses his thanks to Dr. S. Koshi of this Institute for his kind supply of samples.

# *Infrared Absorption Spectra of Quartz and Some other Silica Modification*

By Reisuke SODA

(Received February 28, 1961)

Recently it was reported that the surface of a quartz particle was forced to change its structure by grinding[3-5]. Infrared absorption spectra of the quartz perticle showed that the band near 950 $cm^{-1}$ appeared as the result of grinding and disappeared when the particle was leached[1,2]. The origin of the band near 3400 $cm^{-1}$ was assumed to be the stretching vibration of O–H bond and its intensity changed depending upon the treatment of the particle. The parallel relation was observed between the intensity of 3400 $cm^{-1}$ band and that of 950 $cm^{-1}$. The intensities of the two bands increased with the degree of grinding. Another silica modification such as carplex gave rise to the 950 $cm^{-1}$ band and the intensities of both the 950 $cm^{-1}$ band and the 3400 $cm^{-1}$ band of this compound were stronger than those bands of other silica modifications. Previously the author assigned it tentatively to the deformation vibration of O–H link of silanol group at the surface layer of the particle[1]. In the present paper more evidence will be given to confirm the assignment of this band.

## Experimental

A quartz sample was prepared by grinding and in some cases by leaching the ground particle. The ground particle was fractionated by the particle size suspending it in water and separating it with centrifugal force. This procedure was reported in the other paper[1]. Ten per cent aqueous solution of sodium hydroxide was used to leach the particle. A quartz sample used was that was produced at Ishikawayama. The carplex was supplied by the Shionogi Co., Ltd. It was fine powder of particle size less than 0.5 $\mu$. The sample powder was mixed with potassium bromide in an agate mortar. The potassium bromide used was c. p. grade and pulverized in agate mortar into particle size of 200 to 300 mesh by sieving with a stainless steel sieve and dried by heating above 200°C for about one day. The mixed powder was dried by heating at about 150°C for 3 hr. and poured into the die to be pressed under 10 tons per square centimeter after evacuation for about 10 min. A shaped disk was inserted into the cell for the potassium bromide disk method.

Infrared absorption spectra were measured with Perkin-Elmer model 137 infracord spectrophotometer and Perkin-Elmer model 221 spectrophotometer.

Notations showing kinds of sample particles are as follows[1]:

Q-I-2M is the sample Ishikawayama quartz ground for 2 min., Q-I-6H that ground for 6 hr., Q-I-24H for 24 hr., O-I-100H for 100 hr. and Q-I-2M-L is the sample Ishikawayama quartz ground for 2 min. and leached with aqueous sodium hydroxide.

## Results

The spectrum of Q-I-2M gives rise to the bands at 1180, 1150 and 1070 $cm^{-1}$. These are very strong, but those at 800, 780 and 695 $cm^{-1}$ are sharp and have medium intensities. Sometimes a band near 3400 $cm^{-1}$ is observed with only a very weak intensity. The spectrum of Q-I-6H gives rise to the very weak band at 950 $cm^{-1}$ and to a weak but clear band at 3300 to 3400 cm other than those of Q-I-2M. In

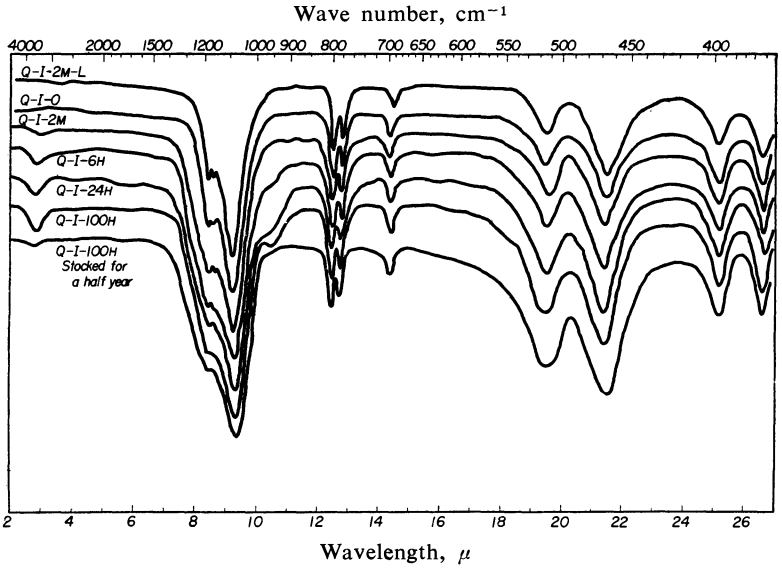

**Fig. 1.** Spectra of quartz particles prepared by various procedures. The range of particle size is 0.5~2 $\mu$ and mean size is about 1 $\mu$. Samples are Ishikawayama quartz ground by hand (Q-I-0), ground mechanically for 2 min. (Q-I-2M), for 6 hr. (Q-I-6H), for 24 hr. (Q-I-24H) and for 100 hr. (Q-I-100H). Q-I-2M-L designates Ishikawayama quartz ground for 2 min. and leached by NaOH aq.

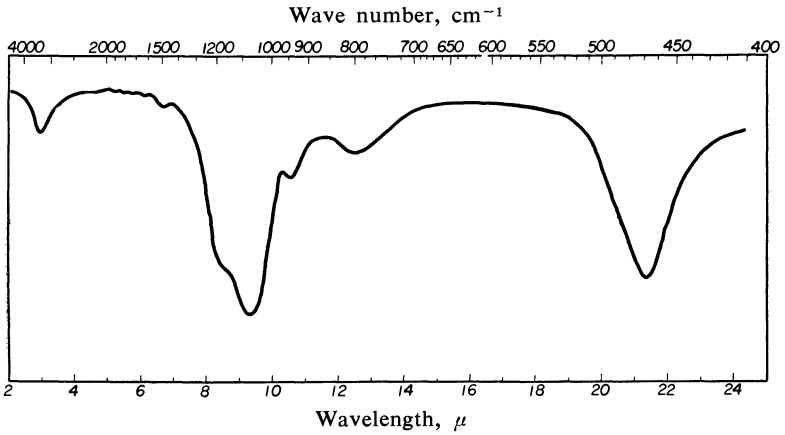

Fig. 2. Spectrum of amorphous silica "Carplex".

spectra of Q-I-24H and Q-I-100H the bands at 3300 to 3400 $cm^{-1}$ and at 950 $cm^{-1}$ are more intense than those of Q-I-6H. The intensities of those bands increase with grinding times. In the spectrum of Q-I-100H which has been kept in a desiccator for a half year, the intensities of the bands at 3400 and 950 $cm^{-1}$ decrease and sometimes the band at 950 $cm^{-1}$ is scarcely observed. The spectrum of carplex gives rise to the strongest bands at 1160 and 1090 $cm^{-1}$ and to a very weak broad band near 800 $cm^{-1}$. Besides those bands, it gives rise to a band of medium intensity at 3300 $cm^{-1}$ and to a well defined band near 950 $cm^{-1}$ as shown in Fig. 2.

The spectrum of Q-I-2M-L gives rise to no bands at 3400 and 950 $cm^{-1}$. The three bands near 1100 $cm^{-1}$ changed their aspects with their grinding times and with leaching. These band groups are sharply separated with leached quartz and lose their defined aspects with the grinding process. The band at 1070 $cm^{-1}$ is broader and first the band at 1150 $cm^{-1}$ becomes like the shoulder of 1070 $cm^{-1}$ band and finally is masked by the latter band with the increment of grinding time. The band at 1180 $cm^{-1}$ is like the shoulder of 1070 $cm^{-1}$ band also when the grinding time is longer than about 20 hr. These changes are illustrated in Fig. 1. In the region of the cesium bromide

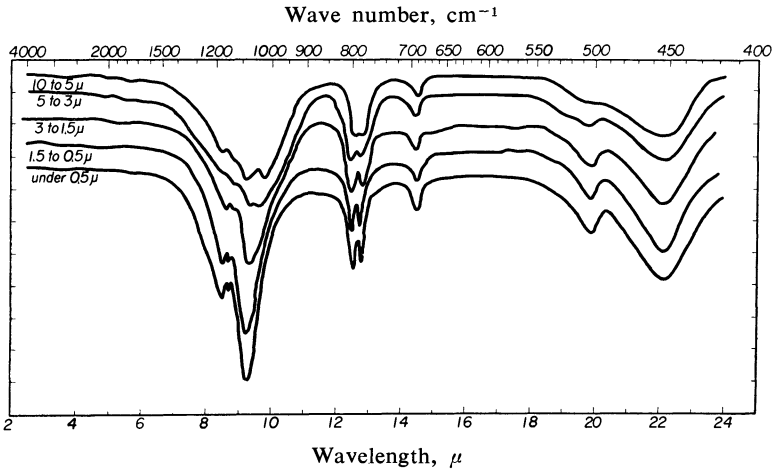

Fig. 3. Spectra of quartz in several range of particle size. Sample is Ishikawayama quartz ground for 2 min. and leached by NaOH aq.

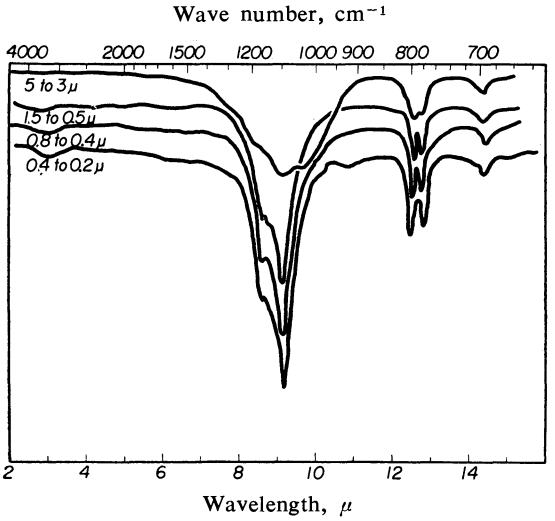

Fig. 4. Spectra of quartz in several range of particle size. Sample is Ishikawayama quartz ground for 100 hr.

optics, the spectrum of quartz powder is not influenced by the grinding times.

The spectrum of quartz powder changes its aspect with particle size in several regions. These changes are shown in Figs. 3 and 4. Figure 3 illustrates the spectra of Q-I-2M-L samples which have the particle size of the order of ten to zero microns. Figure 4 illustrates the spectra of Q-I-100H samples stocked for a half year, the particle sizes of which are from the order of 10 to that of 0.2 $\mu$. The particle size has a remarkable influence on the spectrum in the region of 8 to 9 $\mu$, and less remarkably on those in the regions of 12 and 20 $\mu$. Particularly this effect is markedly seen when the particle size is larger than 3 $\mu$. These results are summarized in Table I.

## Discussion

In general, silica modifications give rise to strong bands in the region of 1200 to 1050 $cm^{-1}$. These bands may be assigned to stretching vibration of Si-O[6,7]. The bands at 800, 780 and 694 $cm^{-1}$ of quartz are also attributed to the silica structure and are very sensitive to skeletal structure of silica. In the longer wavelength region of cesium bromide optics, the bands at 519, 470, 398 and 376 $cm^{-1}$ are attributed to the vibrations concerned with skeletal structure. Beyond those bands, the bands at 3400 and 950 $cm^{-1}$ which appear in the spectrum of carplex, Q-I-6H, Q-I-24H and Q-I-100H are not attributable to the above-mentioned structure sensitive vibrations but may be assigned mainly to hydroxyl group vibration of the silanol group[8-10]. Particle size has a very appreciable influence on the spectrum in the region of 8.5 to 9 $\mu$ and less but an effect which cannot be neglected on that in the region of 12 and 20~24 $\mu$ particularly when the particle size is larger than 3 $\mu$. These phenomena have been observed by several investigators and explained in a few ways[11]. At present the author has little interest in these explanations of the phenomena,

TABLE I. INFRARED ABSORPTION BANDS AND THEIR CHARACTERISTICS OF SILICA

| Band positions $cm^{-1}$ | Remarks |
|---|---|
| 3400 to 3300 | Band intensity: strong to weak; carplex, Q-I-100H, Q-I-24H, Q-I-6H, Q-I-2M and Q-I-2M-L. Generally assigned to O-H stretching. |
| 1180, 1150 and 1070 | Very strong band region of quartz. The sharp feature with Q-I-2M and Q-I-2M-L is lost and the broadth of 1070 $cm^{-1}$ band develops with grinding; 1150 $cm^{-1}$ band appears as shoulder of 1070 $cm^{-1}$ band with Q-I-6H and Q-I-24H, the former being covered by the latter with Q-I-100H. 1180 $cm^{-1}$ band also appears as the shoulder of 1070 $cm^{-1}$ band. Particle size influences features of these bands, and a new band occurs at 1040 $cm^{-1}$ and this shifts towards lower wave number side as the particle size is larger than 3 $\mu$. In that case, this band group is diffuse and seems to be less intense. |
| 1160 and 1090 | Very strong band with carplex. |
| Close to 950 | Intensity: medium to weak; carplex, Q-I-100H, Q-I-24H, and probably Q-I-6H. This band cannot be found out with Q-I-2M and Q-I-2M-L. |
| 800 | Broad weak band with carplex. |
| 800, 780 and 694 | Characteristic bands of quartz with medium intensity. No appreciable change in the feature is observed by grinding. Particle sizes larger than 3 $\mu$ have an influence on the aspects of bands at 800 and 780 $cm^{-1}$ but no influence on 694 $cm^{-1}$ band. |
| 520, 470, 400 and 380 | Characteristic bands of quartz. No appreciable change occurs with grinding. Particle size influences their aspects as it is larger than 3 $\mu$. |

but would like to remark on the fact that as the particle size of ground quartz is smaller the band at 950 $cm^{-1}$ is more intense and the band group in the region of 8 to 9 $\mu$ is more diffuse. This will be concerned in the considerably irregular structure different from the original quartz structure. These aspects are illustrated in Figs. 3 and 4.

From spectral change with grinding and leaching as illustrated in Fig. 1, it may be recognized that the bands at 3400 and 950 $cm^{-1}$ also change their aspects in parallel. These two characteristic bands increase their intensities with the grinding times, decrease during the stock of sample in desiccator under the reduced pressure and disappear when the particle is leached. The relative intensity of these two bands scarcely differs with the samples treated in various ways.

It is generally accepted[3-5] that quartz particle ground mechanically has a disturbed and easily soluble layer around the surface, the structure of which is different from quartz itself but not completely amorphous like silica gel. In this case it was observed by means of the BET method with argon or krypton that the surface area of particles increases with the grinding. The interior parent structure does not change its original structure during the grinding but the surface layer is gradually disturbed and the amount of disturbed layer or the thickness of this layer increases with grinding times. The leached sample decreases its surface area and it is considered that the spectrum of this sample is essentially the same as those of the original sample. The change of spectrum in the region of 8 to 9 $\mu$ is responsible for this disturbed structure on the particle surface. The more disturbed the layer is, the more diffuse bands appear in this spectral region. This will be caused by the superposition of the spectrum of the disturbed layer on the original spectrum[1]. According to the above consideration, it is concluded that the intensities of the bands at 3400 and 950 $cm^{-1}$ increase with the increment of the amount of the disturbed layer surrounding the surface of the particle. The more the surface area increases, the more the number of SiOH bonds appears. Therefore the SiOH bonds exist mainly on the particle surface, particularly in the disturbed structure. The band at 3400 $cm^{-1}$ which is assigned to the stretching vibration of OH bond will increase its intensities not only with the SiOH group but also with the absorbed water molecule. But the absorbed water molecule gives rise to the bands near 1600 $cm^{-1}$ and does not at 900 to 1000 $cm^{-1}$ generally[10]. From this consideration, the band at 950 $cm^{-1}$ may be assigned to O-H deformation vibration of silanol group.

In the lower frequency region on new band was observed by the grinding. Therefore it is inadequate to consider that the band at 950 $cm^{-1}$ be assigned to the overtone or combination tone. This argument supports indirectly above assignment of the band at 950 $cm^{-1}$ to O-H deformation vibration. From the result of spectra obtained in this work, the band at 950 $cm^{-1}$ may be reasonably assigned to the

O-H deformation vibration of silanol group on the surface of ground quartz particle.

**Summary**

Some silica modification such as carplex and ground quartz particle, gives rise to the bands near 950 $cm^{-1}$. This band has no relation with the skeletal structure of Si-O bond and can not be explained as overtone or combination tone. It is reasonable to assign this band to O-H deformation vibration of silanol group. The effect of particle size and grinding time on the spectrum of quartz was examined and it was concluded that the ground quartz particle was covered by some irregular structure on its surface, which was different from quartz structure. In this surface structure, the silanol group seems to be constructed.

The author wishes to express his thanks to Mr. A. Masuda at the University of Tokyo for the use of an infracord spectrophotometer. He wishes to express his thanks to Mr. M. Kawano at the Railway Technical Research Institute for their measurement of the spectrum in cesium bromide region. He also desires to express his hearty gratitude to Assistant Professor T. Miyazawa at the Institute for Protein Research, Osaka University for the use of a Perkin-Elmer model 221 spectrophotometer and also for valuable advice. Finally he wishes to thanks Mr. A. Hamada of this Institute for his kind supply of the dust sample to him.

# *Silanes. Vibrational Assignments and Frequency Correlations*

By George J. JANZ and Yukio MIKAWA*

(Received February 17, 1961)

Silanes have received widespread attention during the last decade and are of continuing current interest[1-4]. As part of a program in this laboratory on the vibrational spectra, molecular structure, and thermodynamic properties of this class of compounds, a review of the widely scattered results was undertaken to assess the status of our information. It became apparent in the course of this review that a need existed for a critical evaluation of the vibrational assignments, and for the interpretation of the normal frequencies on a series of simplified vibrational modes. This communication reports the results thus obtained, together with a useful table of generalized characteristic frequencies and bond distances based on this work.

## Status

Information for about one hundred silanes, widely scattered in the published literature, was reviewed relative to the subjects: frequency assignment (FA), infrared spectra (IR), Raman spectra (R) molecular structure (M), thermodynamic properties (T), normal coordinate vibrational analyses (NC) and force constants (FC). For reference and guidance, the status of knowledge is presented in summary form in Table I.

## Vibrational Spectra

Relative to the vibrations associated with the silicon atom and the surrounding four atoms attached with tetrahedral angles, all of the silanes considered can be classified into three groups based on the symmetry of molecule; $SiX_4$, $SiXY_3$ and $SiX_2Y_2$. The designation of normal vibrations, symmetry class and selection rules for each type of molecules are shown in Table II, where the symbols $\nu$, $\delta$ and $\tau$ denote stretching, deformation and twisting vibrations, respectively, and the suffixes a, e, f and b denote the class of symmetry group to which the vibration belongs. The simplified vibrational modes for each type of molecule are illustrated in Figs. 1—3. It is recognized that the exact feature of the normal mode differs from molecule to molecule depending on the masses of atoms and the force constants of the bonds, and can be calculated by the normal

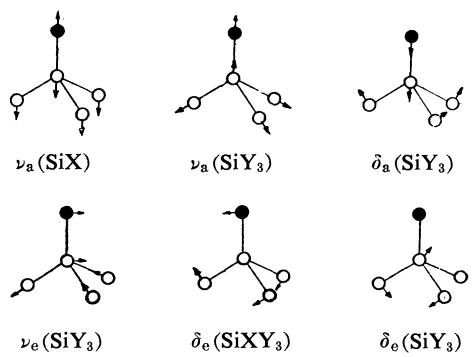
TABLE II. DESIGNATION OF NORMAL VIBRATIONS, SYMMETRY CLASS AND SELECTION RULES

| Type of molecule | Symmetry class | Designation | Activity | | Interpretation |
|---|---|---|---|---|---|
| | | | Raman | Infrared | |
| $SiX_4$ | $A_1$ | $\nu_a(SiX_4)$ | p*1 | i*3 | Symmetrical stretching |
| | E | $\delta_e(SiX_4)$ | d*2 | i | The 1st kind of deformation |
| | $F_2$ | $\nu_f(SiX_4)$ | d | a*4 | Asymmetrical stretching |
| | $F_2$ | $\delta_f(SiX_4)$ | d | a | The 2nd kind of deformation |
| $SiXY_3$ | A | $\nu_a(SiX)$ | p | a | Stretching vibration |
| | A | $\nu_a(SiY_3)$ | p | a | Symmetrical stretching |
| | A | $\delta_a(SiY_3)$ | p | a | The 2nd kind of deformation |
| | E | $\nu_e(SiY_3)$ | d | a | Asymmetrical stretching |
| | E | $\delta_e(SiY_3)$ | d | a | The 1st kind of deformation |
| | E | $\delta_e(SiXY_3)$ | d | a | Bending of SiX or wagging of $SiY_3$ |
| $SiX_2Y_2$ | $A_1$ | $\nu_a(SiX_2)$ | p | a | Symmetrical stretching |
| | $A_1$ | $\nu_a(SiY_2)$ | p | a | Symmetrical stretching |
| | $A_1$ | $\delta_a(SiX_2)$ | p | a | The 1st kind of deformation |
| | $A_1$ | $\delta_a(SiY_2)$ | p | a | The 1st kind of deformation |
| | $A_2$ | $\tau(SiX_2Y_2)$ | d | i | Twisting |
| | $B_1$ | $\nu_b(SiX_2)$ | d | a | Asymmetrical stretching |
| | $B_1$ | $\delta_b(SiX_2Y_2)$ | d | a | Rocking of $SiX_2$ or wagging of $SiY_2$ |
| | $B_2$ | $\nu_b(SiY_2)$ | d | a | Asymmetrical stretching |
| | $B_2$ | $\delta_b(SiY_2X_2)$ | d | a | Rocking of $SiY_2$ or wagging of $SiX_2$ |

*1 polarized *2 depolarized *3 inactive *4 active



coordinate treatment for the individual molecule.

$\nu_a(SiX_4)$ in $SiX_4$, $\nu_a(SiX_3)$ in $SiX_3Y$, $\nu_a(SiX_2)$ in $SiX_2Y_2$ and $\nu_a(SiX)$ in $SiXY_3$ are interpreted as symmetrical stretching vibrations of Si–X in which X atoms vibrate in phase back and forth in the direction of the bonds. $\nu_f(SiX_4)$ in $SiX_4$, $\nu_e(SiX_3)$ in $SiX_3Y$ and $\nu_b(SiX_2)$ in $SiX_2Y_2$ are interpreted as asymmetrical stretching vibrations of Si–X in which X atoms vibrate out of phase in the direction of the bonds. The deformation vibrations $\delta_e(SiX_4)$ in $SiX_4$, $\delta_e(SiX_3)$ in $SiX_3Y$ and $\delta_a(SiX_2)$ in $SiX_2Y_2$ make one group called the first kind of deformation vibrations. This kind produces the change in the angle between the two adjacent bonds. The second kind of deformation vibrations which inculdes $\delta_f(SiX_4)$ in $SiX_4$ and $\delta_a(SiX_3)$ in $SiX_3Y$ is a symmetrical deformation vibration with respect to the threefold axes. As for $\delta_e(SiXY_3)$, two alternative ways for interpretation are possible. If X is a lighter atom than Y, $\delta_e(SiXY_3)$ should be interpreted as a bending of X, whereas, in the opposite case it should be interpreted as a wagging of $Y_3$. $\delta_b(SiX_2Y_2)$ may be interpreted either as a wagging vibration in which

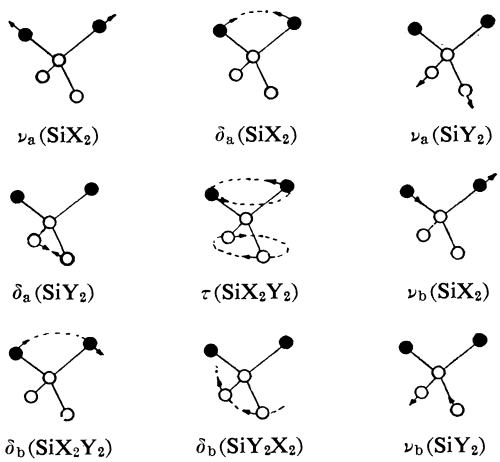

Fig. 1. Normal vibrations of $SiX_4$.

$\nu_a(SiX)$ $\nu_a(SiY_3)$ $\delta_a(SiY_3)$

$\nu_e(SiY_3)$ $\delta_e(SiXY_3)$ $\delta_e(SiY_3)$

Fig. 2. Normal vibrations of $SiXY_3$.

$\nu_a(SiX_2)$ $\delta_a(SiX_2)$ $\nu_a(SiY_2)$

$\delta_a(SiY_2)$ $\tau(SiX_2Y_2)$ $\nu_b(SiX_2)$

$\delta_b(SiX_2Y_2)$ $\delta_b(SiY_2X_2)$ $\nu_b(SiY_2)$

Fig. 3. Normal vibrations of $SiX_2Y_2$.

two X atoms swing as a unit in $SiX_2$ plane or as a rocking vibration in which two Y atoms swing back and forth parallel to the same plane. The situation is the same for $\delta_b(SiY_2X_2)$ if X is replaced by Y and vice versa. $\tau(SiX_2Y_2)$ is interpreted as a twisting vibration of $SiX_2$ in respect to $SiY_2$. This vibration depends upon the nature of the X atom as well as of the Y atom.

All of the published data are tabulated in Tables III—V in accordance with the above designations. Some values are from Raman spectra of the liquid state and some from infrared spectra of the liquid or gaseous states. In most instances, the differences in the frequencies reported with the different methods or by various investigators were not sufficiently

TABLE III. NORMAL FREQUENCIES OF $SiX_4$ TYPE MOLECULES

| $SiX_4$ | $\nu_a(SiX_4)$ | $\delta_e(SiX_4)$ | $\nu_f(SiX_4)$ | $\delta_f(SiX_4)$ |

C: calculated value

great to be of concern relative to the problem of the characteristic frequencies for the molecules. The assignments in the literature were, in large part, without ambiguity for most of the silanes in Tables III—V. Some new assignment are proposed in the light of the correlation rule developed in this work. For $Si(CH_3)_3Cl$, 188 $cm^{-1}$ should be assigned to $\delta_e(SiC_3)$ because the first kind of deformation vibration of Si–C usually appears near 200 $cm^{-1}$; and $\delta_e(SiC_3)$ should lie at a lower frequency than $\delta_a(SiC_3)$ as in the case of ethyl chlorosilanes. For $Si(CH_3)_2Cl_2$, 241 $cm^{-1}$ should be assigned to $\delta_b(SiC_2Cl_2)$, which belongs to $B_1$

TABLE V. NORMAL FREQUENCIES OF $SiX_2Y_2$ TYPE MOLECULES

| $SiX_2Y_2$ | $\nu_a(SiX_2)$ | $\nu_a(SiY_2)$ | $\delta_a(SiX_2)$ | $\delta_a(SiY_2)$ | $\nu_b(SiX_2)$ | $\nu_b(SiY_2)$ | $\delta_b(SiX_2Y_2)$ | $\delta_b(SiY_2X_2)$ | $\tau(SiX_2Y_2)$ |
|---|---|---|---|---|---|---|---|---|---|
| $SiH_2D_2$ | 2189 | 1587 | 944 | 682.5 | 2183 | 1601 | 743 | 862 | (844)[c] |

and 298 $cm^{-1}$ to $\delta_b(SiCl_2C_2)$, which belongs to $B_2$. This assignment is justified from the result of the normal coordinate treatment in which 245 $cm^{-1}$ and 304 $cm^{-1}$ were calculated[5] for $\delta_b(SiC_2Cl_2)$ and $\delta_b(SiCl_2C_2)$, respectively. For the antisymmetrical stretching vibration of Si-I in $SiCl_2I_2$ two Raman lines 418 $cm^{-1}$ and 346 $cm^{-1}$ are reported by Dewaulle[6]. 418 $cm^{-1}$ should be assigned to $\nu_b(SiI_2)$ but 436 $cm^{-1}$ is preferably assigned as a combination, $276+160=436$ $cm^{-1}$.

## Discussion of Characteristic Frequency Assignments

The survey of the normal frequencies listed in Tables III—V shows that symmetrical stretching vibrations, or $\nu_a(SiX_4)$ in $SiX_4$, $\nu_a(SiX_3)$ in $SiX_3Y$, $\nu_a(SiX_2)$ in $SiX_2Y_2$ and $\nu_a(SiX)$ in $SiXY_3$ appear in a narrow frequency range characteristic for the Si-X. In Table VI the characteristic frequencies ranges and the number of the data from which the ranges have been decided are tabulated. The generalized values of the bond lengths, similarly from this review, are listed in Table VII. More detailed inspection shows the correlation: $\nu_a(SiX_4) < \nu_a(SiX_3) < \nu_a(SiX_2) < \nu_a(SiX)$, where X represents C, O, F, Cl, Br and I. Since the Raman line due to this vibration is generally a sharp, strong, and polarized line, this frequecy may be used as a key frequency for the S-X symmetrical stretching mode.

The asymmetrical stretching vibrations: $\nu_f(SiX_4)$ in $SiX_4$, $\nu_e(SiX_3)$ in $SiX_3Y$, and $\nu_b(SiX_2)$ in $SiX_2Y_2$, also occur in a narrow range, characteristic for Si-X. These occur, without exception, in a higher frequency range than the corresponding symmetrical stretching vibrations. Since the infrared band due to this vibration is very strong, this may be used as a key band for Si-X if it lies in a region available for infrared measurements.

If the term "deformation vibration" defines the type of nomal vibration in which some of the atoms vibrate in the direction perpendicular to bands then all the other types of vibrations are included in this category. Among these, the first and the second kind of deformation vibrations may be expected as characteristic frequencies, since these fall in a rather narrow range as defined by the bonds concerned. These are included in Table VI. For Si-H or Si-D, the ranges for the first kind and the second kind of deformation vibrations overlap each other. For the rest, in most of the cases, the second kind of deformation occurs at a higher frequency range than the first kind.

The other types of vibrations such as $\delta_e(SiXY_3)$, $\delta_b(SiX_2Y_2)$ and $\tau(SiX_2Y_2)$ are generally found as broad frequency ranges so that it is difficult to assign a characteristic frequency. However, if one or more hydrogens are present, the modes: $\delta_e(SiHX_3)$, $\delta_e(SiH_3X)$, $\delta_b(SiH_2X_2)$, $\delta_b(SiX_2H_2)$ and $\tau(SiH_2X_2)$ could be characteristic, each for their own structure since the mass of the hydrogen is so very small, relative to the rest of the system.

Generally, as the mass of the atom attached to the silicon atom increases, there is a corresponding decrease in frequency for both the stretching and deformation vibrations. The effect of electronegativity on the frequency of a particular vibration is, however, striking. Thus, for example, the symmetric stretching vibrations of Si-F occcur in a higher frequency range than those of Si-C even though the atomic weight of fluorine is greater than that of carbon.

**Si-H.**—The symmetrical stretching vibration

of Si–H appears in the range 2118～2315 $cm^{-1}$. If the molecule has more than two Si–H bonds, the asymmetrical stretching vibration is also observed in the range 2142～2250 $cm^{-1}$ in addition to the symmetrical vibration. The asymmetrical mode falls, as expected, in a higher range than the symmetrical mode. The general correlation: $\nu_a(SiH_3X) < \nu_a(SiH_2X_2) < \nu_a(SiHX_3)$ is true for all of the halogenated silanes. It is striking that in the series of methyl silanes the Si–H symmetric stretching frequencies decrease appreciably as the number of methyl groups increases.

Relative to the deformation vibration, both the first and the second kinds of deformations appear in an almost identical frequency range, 903～990 $cm^{-1}$. The separation is rather small and, in most of the cases, the higher frequency is assigned to the first kind of deformation.

Since the mass of the hydrogen atom is very small compared with the others, vibrations such as $\delta_e(SiX_3H)$, $\delta_e(SiH_3X)$, $\delta_b(SiH_2X_2)$, $\delta_b(SiX_2H_2)$ and $\tau(SiH_2X_2)$ may be considered as the hydrogen bending or deformation vibrations. Although examples for these modes are very limited at present, it is apparent that these are to be found in the following ranges:

| | | |
|---|---|---|
| $\delta_e(SiX_3H)$ | 767～908 $cm^{-1}$ | (5 examples) |
| $\delta_e(SiH_3X)$ | 540～728 $cm^{-1}$ | (5 examples) |
| $\delta_b(SiH_2X_2)$ | 469～919 $cm^{-1}$ | (5 examples) |
| $\delta_b(SiX_2H_2)$ | 828～919 $cm^{-1}$ | (5 examples) |
| $\tau(SiH_2X_2)$ | 688～844 $cm^{-1}$ | (5 examples) |

**Si–D.**—Eight deuterated silanes were used in assigning the frequency range of the Si–D vibration. Although deuterium has twice the atomic weight of hydrogen, the Si–D vibration can still be regarded as that of a very light atom vibrating against an atom of infinite mass. Thus many features of this class resemble the case of Si–H.

The symmetrical stretching vibrations occur in the range of 1573～1688 $cm^{-1}$ while the asymmetrical stretching vibrations occur in the region 1597～1649 $cm^{-1}$. The higher frequencies are always assigned to the non-symmetrical vibrations. It is striking that the stretching vibration of Si–D in $SiDF_3$ has very high frequency (1688 $cm^{-1}$) compared with the stretching vibration of Si–D in the other compounds. This is the same as in the case of $SiHF_3$, where $\nu_a(SiH)$ was assigned to 2314.5 $cm^{-1}$, which seems an extraordinarily high value for the stretching vibration of Si–H.

The Si–D deformation vibrations, both the first kind and the second kind, occur in the frequency range 664～708 $cm^{-1}$, and higher frequencies are assigned to the second kind of deformation.

**Si–C.**—The Si–C symmetrical stretching vibrations occur in the frequency range of 553～764 $cm^{-1}$ while the asymmetrical stretching vibrations occur in the range of 695～805 $cm^{-1}$. The tendency of the frequency shift depending on the number of the carbon atoms attached to the silicon atom is apparent, i. e., $\nu_a(SiC_4) < \nu_a(SiC_3) < \nu_a(SiC_2) < \nu_a(SiC)$. For the asymmetrical stretching vibrations, the relation, $\nu_f(SiC_4) < \nu_e(SiC_3) < \nu_e(SiC_2)$ is also true, if a particular series, such as $Si(CH_3)_4-Si(CH_3)_3Cl-Si(CH_3)_2Cl_2$, is considered. The deformation vibrations occur in the frequency range 160～259 $cm^{-1}$ for the first kind, and 206～303 $cm^{-1}$ for the second kind. The latter appaears, without exception, in a higher frequency range than the former.

**Si–O–C.**—The Si–O symmetrical stretching vibrations in the linkage of Si–O–C occur in the frequency range of 640～808 $cm^{-1}$, while the asymmetrical stretching vibrations occur in the range of 792～851 $cm^{-1}$. The frequencies of the symmetrical stretching vibrations decrease as the number of methoxy or ethoxy groups attached to the silicon atom increases, i. e.: $\nu_a(SiO_4) < \nu_a(SiO_3) < \nu_a(SiO_2) < \nu_a(SiO)$. The asymmetric vibration frequencies are concentrated in a rather narrow range, and the correlation $\nu_f(SiO_4) < \nu_e(SiO_3) < \nu_e(SiO_2)$ is true for any series, such as: $Si(OCH_3)_4-Si(OCH_3)_3Cl-Si(OCH_3)_2Cl_2$.

Owing to the very limited data, the frequency range for the deformation vibrations can not be decided with any certainty. From the available information, it appears that the first and second kinds of deformation vibrations occur in the range 240～308 $cm^{-1}$.

**Si–Halogen.** — The Si–halogen stretching modes occur in the range of 168～1031 $cm^{-1}$. The broad frequency range is due to the large variations in atomic weights for the halogen atoms, i. e.: F=19.00 to I=126.9. As the atomic weight of the atom attached to the silicon atom increases, a corresponding decrease in the frequency of the symmetrical and asymmetrical Si–X stretching vibrations is observed. For example, in the $SiX_4$ series, the Si–X stretching frequency decreases in the order: 800～424–249～168 $cm^{-1}$, for $SiF_4$, $SiCl_4$, $SiBr_4$ and $SiI_4$ respectively. In any series of the type $SiX_4$–$SiX_3Y$–$SiX_2Y_2$–$SiXY_3$, where X is a halogen atom and Y is different or a non-halogen atom, the frequencies of the symmetrical stretching vibration, i. e., $\nu_a(SiX_4)$, $\nu_a(SiX_3)$, $\nu_a(SiX_2)$, $\nu_a(SiX)$, increase as the number of the halogen atoms attached to the silicon atom decreases. By contrast, the frequencies of the asymmetrical stretching vibrations: $\nu_f(SiX_4)$, $\nu_e(SiX_3)$ and $\nu_b(SiX_2)$ do not show this trend. It is apparent that these are limited to narrower ranges than

the symmetrical vibrations. Thus, for Si–Cl, the range of the symmetrical frequencies is 424～583 $cm^{-1}$ whereas the range of the asymmetrical is 577～610 $cm^{-1}$. It is also seen that the asymmetrical modes always occur in a higher frequency range than the corresponding symmetrical stretching modes. The first kind of deformation vibrations occurs in a definite region for each kind of halogen, e. g.: $\delta_e(SiCl_4)$ in $SiCl_4$, $\delta_e(SiCl_3)$ in $SiCl_3Y$ and $\delta_a(SiCl_2)$ in $SiCl_2Y_2$. All are in the range, 150～205 $cm^{-1}$. The second kind of deformation vibrations usually occurs in a higher frequency range than the first kind. The other deformation vibrations occur in a range so wide that to list it would be of little significance.

## Summary

The status of knowledge relative to the vibrational assignments, molecular structure, and spectral data for a series of about one hundred silanes has been surveyed and is reported in brief tabular form. A scheme of simplified vibrational modes is discussed, and used to develop the assignment of fundamentals for some fifty five silanes. Some new assignments are proposed in the light of a correlation rule which has been developed. Tables of characteristic frequencies, and the best values for bond distances, based on this work, are presented.

The authors wish to thank Fred Behnke for assitance with the compilation of the literature and the summary in Table I. This work was made possible, in part, by a grant from the National Science Foundation, Washington, D. C.

# *Syntheses and Infrared Absorption Spectra of Deuterated Polyvinyl Alcohols* $-(-CD_2-CD-)_n-$ [*1]
$OH(D)$

By Hiroyuki TADOKORO, Hiroshi NAGAI[*2], Syûzô SEKI and Isamu NITTA[*3]

(Received February 20, 1961)

We have previously reported[1] that the 1141 $cm^{-1}$ band in the infrared absorption spectra of polyvinyl alcohol (PVA) increases the intensity sensitively with crystallization (heat-treatments), and the optical density of this band is approximately in linear relationship with the degree of crystallinity determined by the methods of density and of the sorption of water vapor. We have further concluded that the 1141 $cm^{-1}$ band is a so-called "crystallization-sensitive" band. We have also made the deuteration of the OH group of PVA in order to clarify the assignment of this band[2-4], and further we have undertaken the deuteration of the main-chain of this polymer for the same purpose. In addition we have measured the infrared pleochroism of the doubly oriented PVA samples, and have shown that the experimental facts obtained so far can be explained fairly well, when we tentatively assign this band to the skeletal vibration of the planar zig-zag chain in the crystalline region[3,5,6].

On the other hand, Krimm, Liang and Sutherland[7] have reported that this band

should not be assigned to the crystalline band, but to the C–O–C stretching mode of the ether linkage produced between the molecular chains by heat-treatment. On the contrary, we have reconfirmed the linear relationship between the band intensity and the density for a number of samples subjected to heat-treatments under various conditions, by using the density-gradient tube method[6,8,9]. And furthermore we have accumulated experimental evidences for assigning this band to the crystalline band, such as comparison with the X-ray diffraction data on the formalized samples, swollen samples, etc.[6,8]

Quite recently Krimm[10] has considered the band to be a crystalline band and suggested that this band may be associated with the $\nu$(CO) mode of a portion of a chain in which an intramolecular hydrogen bond is formed between two neighboring OH groups that are on the same side of the plane of the carbon chain. On the other hand Liang and Pearson[11] have made the factor group analysis of PVA crystal based upon the symmetry of the average crystal structure deduced from X-ray analysis[12]. Then they have assigned the 1141 $cm^{-1}$ band to the symmetric skeletal stretching modes as follows:

In order to make such detailed assignments, further accumulation of the experimental data as well as the calculation of the normal modes of vibrations*4 would be necessary.

In this paper we wish to report the syntheses

and the infrared spectra of the deuterated PVA's $-(-CD_2-\underset{\underset{OH(D)}{|}}{CD}-)_n-$, and also the spectra of the intermediate products.

### Preparation of the Samples

As has already been reported, the OH group of PVA can be easily deuterated by the isotope exchange reaction with deuterium oxide, but the CH group can not be deuterated by such a simple method. Hence we have synthesized deuterated PVA's according to the following scheme:

$$CaC_2 \xrightarrow{D_2O} C_2D_2$$

$$(CH_3COO)_2O \xrightarrow{D_2O} CH_3COOD$$

$$C_2D_2 + CH_3COOD \xrightarrow{(CH_3COO)_2Zn} CD_2{=}CD{-}OCOCH_3$$

$$\xrightarrow{\text{polymerization}} -(-CD_2-\underset{\underset{OCOCH_3}{|}}{CD}-)_n-$$

$$\xrightarrow{\text{saponification}} -(-CD_2-\underset{\underset{OH}{|}}{CD}-)_n-$$

$$\xrightarrow{D_2O} -(-CD_2-\underset{\underset{OD}{|}}{CD}-)_n-$$

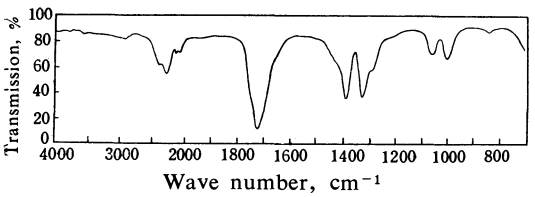

Fig. 3. Infrared spectrum of acetic acid-*d* (degree of deuteration 92%, at liquid state).

Fig. 1 shows the outline of the apparatus used for the synthesis of $\alpha, \beta, \beta$-trideuterovinyl acetate. The system can be highly evacuated by using a mercury diffusion pump and a rotary pump. The vessel B made of Telex*5 holds calcium carbide which was dried at about 580°C for about four hours under high vacuum ($10^{-4}$ mmHg or below). The container of deuterium oxide A may be rotated at the joint J, and acetylene-$d_2$ is generated by dropping deuterium oxide into B. The generated acetylene-$d_2$ is transferred to the trap $T_1$ cooled with liquid nitrogen, and then warmed up to the dry-ice temperature by exchanging the refrigerant. The same procedure was repeated at the trap $T_2$ and then acetylene-$d_2$ is transferred to the trap $T_3$ cooled with liquid nitrogen. In this way impurities and excess deuterium oxide were eliminated from acetylene-$d_2$. Then acetylene-$d_2$ is held in the gas vessel C (about 20 l.). The purity of the acetylene-$d_2$ gas was checked by measuring the infrared spectra. K is the gas cell for this purpose equipped with the windows of AgCl plates.

Acetic acid-*d* was prepared by heating the equal mole mixture of acetic anhydride and deuterium oxide at 110°C for about four hours in a sealed tube. The acetic anhydride used had been purified by distillation, standing for several days with sodium metal and subsequent distillation (b. p.:

a) The $\nu$(OH) band at about 3340 $cm^{-1}$ shows no appreciable dichroism at the absorption peak, but shows a perpendicular and parallel nature at the higher frequency and lower frequency sides, respectively. The $\nu$(OD) band at about 2470 $cm^{-1}$ also shows the same behavior.

b) The wave numbers in parentheses are for the bands associated with the residual hydrogen atoms because of the incompleteness of deuteration.

c) The band at about 1430 $cm^{-1}$ splits into 1440 and 1420 $cm^{-1}$ in the polarized spectra because of the difference of their dichroism.

ASSIGNMENTS OF PVA, PVA-*d*, PV-$d_3$A AND PV-$d_3$A-*d*

f) $\nu$: stretching, $\nu_a$: antisymmetric stretching, $\nu_s$: symmetric stretching, $\delta$: bending, $w$: wagging, $r$: rocking.

g) The notation ⊥ and ∥ in parentheses refer to the polarization with respect to the plane of the zig-zag carbon chain[5,14].

139~140°C). Acetic acid-*d* was put in the vessel D. Acetylene-$d_2$ gas, after bubbling through vessel D, was introduced into the reaction-vessel E. Then the gas mixture was caught in the vessel L cooled with liquid nitrogen. The catalyst used was zinc acetate carried on active charcoal kindly supplied by Dr. T. Omae of the Nippon Gôsei Kagaku Co., Ltd. The reaction temperature was about 200°C. The obtained vinyl-$d_3$-acetate was purified by using a concentric distillation column (Taika Kôgyô Co., Ltd., Osaka). The polymerization of vinyl-$d_3$-acetate was carried out in a sealed glass tube with $\alpha,\alpha'$-azobisisobutyronitrile catalyst at 60°C for about 24 hr.

**Infrared Spectra of the Intermediate Products.** —Fig. 2 is the infrared spectra of acetylene-$d_2$. The degree of deuteration was estimated by using the $\nu_5$ band (CH symmetric deformation, $C_2H_2$: 729.2 $cm^{-1}$, $C_2HD$: 676 $cm^{-1}$, $C_2D_2$: 538.7 $cm^{-1}$) assuming that the absorption coefficients of the above bands are equal in the spectra of $C_2H_2$, $C_2HD$ and $C_2D_2$. A spectrum of the sample of lower degree of deuteration (about 94%) was reproduced for reference. The intensity of the 676 $cm^{-1}$ band, which is absent in the spectrum of $C_2H_2$ (curve d), is very strong in the spectrum of the 94% $C_2D_2$ (curve c), but weak in the case of the 97% $C_2D_2$ (curve b). Accordingly the $\nu_5$ mode of $C_2HD$ is considered to be assigned to the 676 $cm^{-1}$ band, although this mode has been so far assigned to the 687 $cm^{-1}$ band by Stitt[13].

Fig. 3 is a spectrum of acetic acid-*d*, the degree of deuteration of which was estimated to be about 92% by using the intensity ratio of the bands of OH and OD stretching.

Fig. 4 shows the spectra of vinyl-$d_3$-acetate (broken line) and of vinyl acetate (solid line). Fig. 5 shows the spectra of polyvinyl-$d_3$-acetate (broken line) and of polyvinyl acetate (solid line). It should be noticed that the spectra of the monomer and polymer in the 1300~1100 $cm^{-1}$ region show a change similar to that of deuteration. The 1235 $cm^{-1}$ band of polyvinyl acetate and the 1212 $cm^{-1}$ band of vinyl acetate, which are considered to be assigned to the stretching mode of ester linkage, shift to the higher frequency 1245 and 1220 $cm^{-1}$, respectively. This behavior is interesting in relation to the shift of the 1141 $cm^{-1}$ band of PVA to higher frequency with deuteration as will be discussed later.

**Spectra of PVA and Deuterated PVA's.** —In Fig. 6 the polarized infrared spectra of PVA, PVA-*d*, poly-$\alpha,\beta,\beta$-trideuterovinyl alcohol (PV-$d_3$A) and poly-$\alpha,\beta,\beta$-trideuterovinyl alcohol-*d* (PV-$d_3$A-*d*) are shown. The solid and broken curves represent the spectra obtained with radiation polarized, respectively, perpendicular and parallel to the direction of elongation. The spectral data and the tentative assignments for PVA and deuterated PVA's are given in Table I. In the column of pleochroism of PVA the notations $\perp$ and $\parallel$ in parenthesis refer to the polarization with respect to the plane of the zig-zag carbon chain[5,14].

The OH stretching band at 3340 $cm^{-1}$ shifts to 2470 $cm^{-1}$ with the deuteration of the OH group, but the $CH_2$ stretching bands at about 2930 $cm^{-1}$ are not affected by this type of deuteration. By the deuteration of the CH group these bands shift to about 2200 $cm^{-1}$. Both these bands due to the OH and CH groups shift to lower frequencies, when all the hydrogen atoms are deuterated. The residual 2930 $cm^{-1}$ band is due to the incomplete deuteration of the CH group.

The 1141 $cm^{-1}$ band of PVA and the 1165 $cm^{-1}$ band of PV-$d_3$A are inferred to be due to the similar origins of absorption mechanism from the following similarities:

1) The distinguished dichroism,
2) The similar intensity,
3) The increase of the intensity with heat-treatment (Fig. 7), and

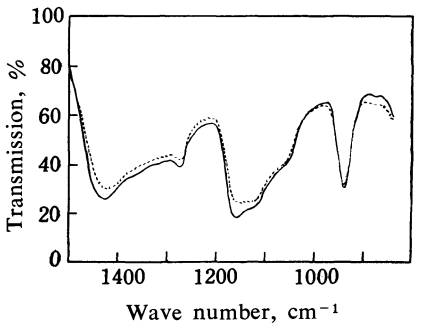

Fig. 7. Spectral change of PV-$d_3$A by heat-treatment.
---- No-treatment
—— Treated at 160°C for 20 min.

4) The small shift to higher frequencies with deuteration of the OH group. The 1141 $cm^{-1}$ band of PVA shifts to 1148 $cm^{-1}$ and the 1165 $cm^{-1}$ band of PV-$d_3$A to 1185 $cm^{-1}$ with deuteration of the OH group.

Thus the 1165 $cm^{-1}$ band of $-(-CD_2-\underset{\underset{OH}{|}}{CD}-)_n-$ is considered to be the crystalline band corresponding to the 1141 $cm^{-1}$ band of PVA.

The experimental facts we have found so far abou' the 1141 $cm^{-1}$ band are summarized as follows:

13) F. Stitt, *J. Chem. Phys.*, **8**, 56 (1940).

14) E. J. Ambrose, A. Elliott and R. B. Temple, *Proc. Roy. Soc.*, **A199**, 183 (1949).

1) The intensity increases with crystallization by heat-treatment, and shows a parallel relationship with the crystallinity determined by the density and the sorption of water vapor[1,8,9].

2) The band behaves in a parallel way with the X-ray diffraction rings due to the crystalline region, when the sample is formalized or swollen in water[6,8].

3) The band exhibits strong perpendicular dichroism in the case of an elongated sample, and distinguished pleochorism in the doubly oriented sample of PVA. The transition moment of this band is parallel to the zig-zag plane, while that of the 1093 $cm^{-1}$ band is perpendicular to the zig-zag plane[3-6]. Furthermore, we have obtained another new experimental fact as follows.

4) The shift of this band with deuteration of the CH or OH group is small. This new experimental fact also supports our tentative assignment of 1141 $cm^{-1}$ band mainly due to the stretching vibration of the extended zig-zag chain in the crystalline region. Here, of course, a considerable coupling of the vibration of the oxygen atom with the skeletal vibrations should be expected.

Next, we proceed to the interpretation of the other bands. Although we can not make any conclusive assignments of these bands merely from the present data, we may discuss here the tentative assignments of the several main bands. We have reported already that the 1430 $cm^{-1}$ band of PVA should be a superposition of $\delta(CH_2)$ and some other band related to the OH group (probably $\delta(OH)$), since the intensity of this band decreases sensitively on deuteration and there remains a sharp band which is certainly attributed to the $\delta(CH_2)$ mode. The 1383 $cm^{-1}$ band was tentatively considered to be $w(CH_2)$ or $w(CH)$, and the 1376 $cm^{-1}$ to be $\delta(CH)$. This inference was confirmed, since these bands disappear in the spectra of PV-$d_3$A-$d$.

The bands near 850 $cm^{-1}$ of PVA were considered to be skeletal or of $CH_2$ vibrations, because there was quite a little effect of deuteration. Especially the 835 $cm^{-1}$ band having the pleochroism perpendicular to the plane of zig-zag chain was assigned to $r(CH_2)$. All these bands disappear by the deuteration of the main chain. The bands near 760 $cm^{-1}$ of PV-$d_3$A and PV-$d_3$A-$d$ are supposed to be due to $r(CD_2)$ mode. But further inference about the origin of the bands may be difficult, because of the complexity which is possibly due to the strong coupling among the group vibrations.

At present we are aiming to accumulate results of further experiments such as the infrared measurements of the highly doubly oriented samples of $-(-CD_2-\underset{\underset{OH(D)}{|}}{CD}-)_n-$, the preparation of the more highly deuterated samples, and of the selectively deuterated samples, $-(-CD_2-\underset{\underset{OH(D)}{|}}{CH}-)_n-$, $-(-CH_2-\underset{\underset{OH(D)}{|}}{CD}-)_n-$, etc.

The authors wish to express their sincere thanks to Professor S. Murahashi of this Faculty, Professor T. Shimanouchi of the University of Tokyo and Dr. T. Omae of Nippon Gôsei Kagaku Co., Ltd. for helpful advice and criticism. The authors are also indebted to Mr. A. Nozaki for his cooperation in the construction of the apparatus.

# *The Study of Adsorption of Detergents at a Solution-Air Interface by Radiotracer Method. IV. The Valency and Concentration Effects of Added Electrolytes on the Adsorption of Alkyl Sulfate Ion*

By Ryohei MATUURA, Hideo KIMIZUKA and Akira MATSUBARA

(Received February 18, 1961)

The preceding study on the effect of excess electrolytes on the adsorption of dodecyl sulfate ion using the radiotracer method has confirmed directly the fact that the presence of excess electrolytes increases both the equilibrium amount and the rate of adsorption of the dodecyl sulfate ion[1], the result which was deduced by a number of authors from surface tension measurements of the solution[2]. However, in the presence of a large excess of electrolytes the rate of adsorption was too rapid to be measured accurately and also the adsorption isotherm was nearly independent of the type of added electrolytes.

We may expect to obtain further data concerning the effects of added electrolytes on the rate and the amount of adsorption of the detergent if we explore the region of the more dilute concentrations of the added electrolytes and/or the detergent. The present paper describes the results of such experiments and the discussions about them.

## Experimental and Results

The method of preparation and purification of the samples and the procedure used for the experiments have already been described[1,3]. The specific activities of the radioactive sodium dodecyl sulfate (SDS), sodium tetradecyl sulfate (STS) and sodium hexadecyl sulfate (SHS) used were ca. 10 mc. per millimole. The temperatures of the experiments were 29.5 $\pm$1.5°C.

In the study on the valency effect, the concentrations of electrolytes were all $10^{-4}$ mol./l., and those of SDS ranged from $5\times10^{-6}$ to $5\times10^{-5}$ mol./l. In the study on the effect of the excess salt the concentrations of detergents were $4\times10^{-6}$ mol./l. for SDS and $2\times10^{-6}$ mol./l. for STS and SHS and those of salt were changed from $10^{-3}$ mol./l. to 1 mol./l.

The rate of adsorption and the adsorption isotherm of dodecyl sulfate ion ($DS^-$) in the presence of electrolytes are shown in Figs. 1 and 2, respectively. In Fig. 1, $K$ represents the constant in the rate equation

$$\Gamma_t = K\sqrt{t} \qquad (1)$$

where $\Gamma_t$ denotes the amount of adsorption at time $t$[4].

As is seen from these figures, both the rate and the equilibrium amount of the adsorption of $DS^-$ increase with the increase in cationic valency of the electrolyte, while they are almost independent of the anionic valency. Table I shows the values of rate constant $K_0$ of the equation

$$K = K_0 C \qquad (2)$$

where $C$ is the concentration of SDS[4].

The value of $K_0$ in the absence of added electrolyte calculated according to the simple diffusion theory[5] is $22.8\times10^{-3}$ cm./min$^{1/2}$. It is seen from Table I that the rate constants increase in the presence of electrolyte, showing a greater increase the higher the cationic valency, but the values are less than the rate constant of the simple diffusion theory.

The effects of electrolyte concentrations on the rate constants and the equilibrium adsorptions of $DS^-$, tetradecyl sulfate ion ($TS^-$) and

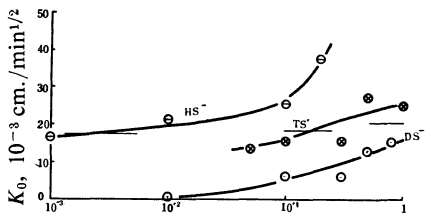

Fig. 3. Effect of salt concentration on the rate constant of adsorption of the alkyl sulfate ion. 29.5±1.5°C. Concentrations of detergents are $4\times10^{-6}$ mol./l. for SDS and $2\times10^{-6}$ mol./l. for STS and SHS. Horizontal lines indicate the values expected from the simple diffusion theory.

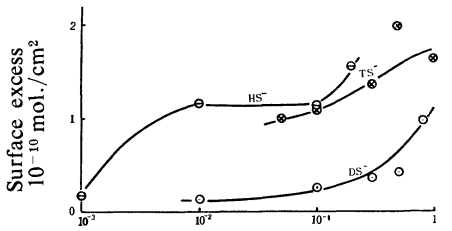

Fig. 4. Effect of salt concentration on the adsorption of the alkyl sulfate ion. 29.5±1.5°C. Concentrations of detergents are $4\times10^{-6}$ mol./l. for SDS and $2\times10^{-6}$ mol./l. for STS and SHS.

hexadecyl sulfate ion ($HS^-$) are shown in Figs. 3 and 4, respectively. These figures indicate that the presence of excess sodium chloride remarkably increases the equilibrium adsorption as well as the rate constants of the alkyl sulfate ions. It must be noted here that the rate constant does exceed the value of the simple diffusion theory when the concentration of the salt becomes great as indicated in the cases of $TS^-$ and $HS^-$. Unfortunately the diffusion coefficients of $TS^-$ and $HS^-$ in the presence of excess salt have not been known, and so we calculated the rate of adsorption by the simple diffusion theory using the diffusion coefficient in the absence of added electrolyte. But the condition described above will be held even when the diffusion coefficient in the presence of added salt is used, because it may generally be considered as less than that in the absence of salt*.

5) A. F. H. Ward and L. Tordai, *J. Chem. Phys.*, **14**, 453 (1946).

* We have measured the self-diffusion coefficient of $DS^-$ at the concentration of $4\times10^{-4}$ mol./l. in the presence (0.1 N) and absence of sodium chloride and found the values, at 25°C, to be $5.6\times10^{-6}$ and $6.5\times10^{-6}$ cm$^2$/sec., respectively. We are going to measure the corresponding values of $TS^-$ and $HS^-$, the result of which will be published in a separate paper after the work has been completed.

## Discussion

The simple diffusion theory proposed by Ward and Tordai[5] assumed that the adsorption takes place as a result of the formation of the subsurface of zero concentration, which is taken to be the region of the thickness of a few molecular diameters being situated in the immediate vicinity of the surface. The formation of a subsurface of zero concentration is explained by the fact that the surface active solute finds a position of lower potential energy in the surface than in the bulk. According to this theory, at the initial stage of the formation of the adsorbed layer, the solute molecules will diffuse from the bulk to the subsurface more slowly than they do from the subsurface to the surface, on the assumption that the equilibrium is established instantaneously between the latter two regions.

It has, however, been shown that the simple diffusion theory fails to explain quantitatively our experimental results of the adsorption of alkyl sulfate ions without added inorganic electrolytes[4], and the present result also shows that the simple diffusion theory does not hold for the adsorption of $DS^-$ in the presence of a small concentration of inorganic electrolytes, as is shown in Table I. Also the results of the experiments on the adsorption of non-electrolytes from the solution so far reported by several authors can not be explained by the simple diffusion theory[6]. All these results showed that the rate of adsorption is smaller than the value expected from the simple diffusion theory.

As the factors responsible for the delay in the rate of adsorption Blair[6] proposed an energy barrier for the adsorption of non-electrolytes and Doss[7] an electrical potential barrier for the surface active electrolytes. Some other factors, e. g., the reorientation[8] and the surface pellicle formation[9], have also been considered. Of course, these various factors taken together are responsible for the retardation of the adsorption rate of alkyl sulfate ions at the solution-air interface. It is difficult to cover the whole experimental result by any single theory. For example, let us consider Doss' theory of electrical potential barrier. According to this theory, the electrical double layer at the surface resists the adsorption of surface active ion owing to the electrical repulsion. The rate differs from the value of the diffusion theory, which may be regarded as being essentially identical with the simple diffusion theory, by a factor

$$\exp\left(-\frac{x\varepsilon\psi_0}{kT}\right) \tag{3}$$

where $x$ denotes the fraction of surface covered by the adsorbed molecules, $\varepsilon$, the elementary charge, $k$, the Boltzmann constant and $T$, the absolute temperature. $\psi_0$ is given by

$$\psi_0 = -\frac{4\pi\rho}{D}\sqrt{\frac{1000\,DkT}{4\pi N\varepsilon^2\sum_i c_i z_i^2}} \tag{4}$$

where $\rho$ is the surface charge density at monolayer adsorption, $D$, the dielectric constant of medium, $N$, the Avogadro number and $c_i$, the concentration of $i$-th ion having valency $z_i$. Eqs. 3 and 4 predict that the rate of adsorption at the given amount of adsorption depends upon the ionic strength of the solution. From Fig. 1 and Table I it may be seen that the rate of adsorption does not depend on the anionic valencies in spite of their different ionic strengths of added electrolytes, but depends essentially on the cationic valencies. These facts can not be explained by Doss' theory mentioned above. Cassie and Palmer[10] deduced from their consideration on the structure of the adsorbed film, assuming Gouy-Chapman's diffuse double layer, that the film of long chain anions will be remarkably influenced by the presence of a high valent cation, while it will be independent of the nature of the anion in solution. Our result agrees with this view and also with observation on the surface[2] or interfacial tension[11]. Of course, the electrical double layer formed at the surface will be supposed to resist the adsorption of surface active ion, but the quantitative explanation for it should be given in a somewhat different way.

As the concentration of the added electrolyte becomes larger, the rate of adsorption of alkyl sulfates becomes faster until it reaches the value predicted by the simple diffusion theory in the case of $DS^-$, while in the cases of $TS^-$ and $HS^-$ the rate constants exceed the simple diffusion values, as shown in Fig. 3. It is not easy to explain by the prevailing theories the reason why the rates of adsorption of $TS^-$ and $HS^-$ exceed the values of simple diffusion theory in the presence of a large excess of electrolyte.

Addison[12] proposed that the difference between the dynamic and the static surface tension is a measure of the driving force for the adsorption, which is introduced in his theory

explicitly as the surface activity. At equilibrium there is a concentration gradient near the surface. Since the ordinary diffusion takes place from higher to lower concentrations, the equilibrium state may be supposed to be the state at which the osmotic force due to the concentration gradient is equilibrated with an adsorptive force such as the driving force suggested by Addison.

In general, both the driving force and the activation energy may be considered to be the factors responsible for the rate of adsorption. It may be pointed out here that the difference between the amount of solute in a dynamic surface and that in an equilibrium surface is a measure of the driving force and so the equilibrium adsorption becomes a measure of the driving force at the instant of the formation of the fresh surface. Thus the higher surface active molecule may drift to the surface faster than the lower surface active one providing the activation energy remains in the constant. The change in the rate of adsorption caused by the foreign substance should, therefore, be attributed not only to the change in activation energy, but also to the change in surface activity.

By comparing Figs. 1 and 2 it is seen that the presence of polyvalent cation increases both the rate and the amount of equilibrium adsorption of $DS^-$ at a given concentration of SDS. This means that the higher rate of adsorption should be related to the larger amount of adsorption in addition to the lowering of activation energy. This is also true for the case of Figs. 3 and 4. The fact that the rate constants of $TS^-$ and $HS^-$ exceed the predicted value of the diffusion theory indicates clearly that the surface activity should be taken into account in the theory of the rate of adsorption of detergent at the solution surface.

## Summary

The adsorption of dodecyl sulfate ion in the presence of various inorganic electrolytes whose concentrations are all $10^{-4}$ mol./l. and the adsorption of alkyl sulfate ions in the presence of the excess salt were measured by using S-35 labeled alkyl sulfates.

In the presence of various electrolytes, both the rate of adsorption and the equilibrium adsorption of dodecyl sulfate ion increase with the cationic valency of added electrolyte, while they are almost independent of the anionic valency.

In the presence of the excess salt, both the rate and the equilibrium adsorption of the alkyl sulfate ions increase with the salt concentration. With increasing concentration of salt the rate of adsorption of the dodecyl sulfate ion approaches the rate of the simple diffusion theory, while that of tetradecyl- and hexadecyl sulfate ion exceeds the value predicted by the simple diffusion theory.

It was pointed out that the higher rate of adsorption is attributed to the higher surface activity of solute.

The idea of surface activity was explicitly introduced in the explanation for the adsorption process and the discussions for the theories proposed earlier were given.

# *Determination of Ortho-, Pyro- and Tripolyphosphate by the Use of a Small Column of Ion-exchange Resin*

By Shigeru OHASHI* and Shichiro TAKADA

(Received February 27, 1961)

The determination of ortho-, pyro- and tripolyphosphate in their mixture is usually carried out by paper chromatography[1] or ion-exchange chromatography[2]. In paper chromatographic determination satisfactory separation of the chain phosphates can be obtained only in acid chromatographic solvent mixtures. Therefore, care must be taken about partial hydrolysis of the condensed phosphates during a chromatographic separation. When paper chromatographic separation is performed at room temperature (15~30°C), a correction due to the hydrolysis of the condensed phosphates should be applied, depending on the temperature. When the separation is performed at a lower temperature then 5°C, the correction due to the hydrolysis is negligible, but a long time is consumed for the separation. On the other hand in the ion-exchange chromatographic determination the phosphates adsorbed by a column are successively eluted with a buffered solution of potassium chloride of pH 4~9. Therefore in the process of the elution the condensed phosphates are not hydrolyzed practically, but by the use of a column of the usual scale a long time is consumed for the separation.

The purpose of this paper is to present a rapid method for the determination of mixed ortho-, pyro- and tripolyphosphate by the use of a small column of ion-exchange resin. The continuous-gradient elution method by Jameson[2h] was applied and a paper micro-fraction collector was used.

## Experimental

The assembly of apparatus used in this investigation is shown in Fig. 1.

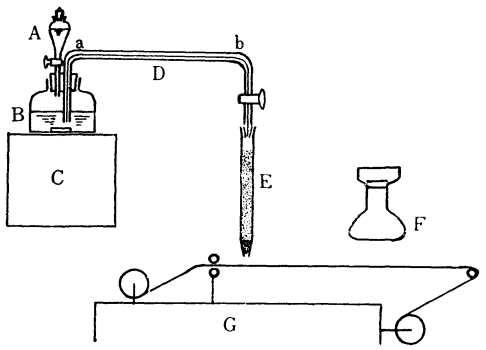

Fig. 1. Apparatus.
A : Stock bottle, B : Mixing bottle,
C : Magnetic stirrer, D : Capillary,
E : Column, F : Infrared lamp,
G : Paper micro-fraction collector.

**Ion-exchange Column.**—A coarser part of Dowex 1-X 4 (200~400 mesh) of chloride form was filled in a capillary, 2.6 mm. in diameter and 60 mm. in height.

**Phosphate Samples.**—Disodium hydrogen orthophosphate dodecahydrate, tetrasodium pyrophosphate decahydrate and pentasodium tripolyphosphate hexahydrate were used.

**Elution.** — Solutions of potassium chloride of various concentrations were buffered with sodium formate and formic acid. The concentrations of sodium formate and formic acid were kept constant (HCOONa 5.1 g./l. and 80% HCOOH 2.5 ml./l.) and the pH of the solution was regulated with aqueous ammonia. The solution of potassium chloride in a stock bottle was continuously added to a mixing bottle which contained 10 ml. of water initially. Then the solution in the mixing bottle was introduced to the ion-exchange column. The flow rate was regulated to be about 30 sec./drop.

**Fraction Collector.** — By the use of a paper micro-fraction collector[3] manufactured by Mitamura the eluted solution was collected drop by drop on a piece of filter paper and was dried immediately with an infrared lamp.

**Qualitative Observation on the Separation of Phosphates.** — After the separation the filter paper containing phosphates was sprayed with a solution which was made by mixing 5 ml. of 60% perchloric acid, 1 ml. of concentrated hydrochloric acid, and 1 g. of ammonium heptamolybdate tetrahydrate and diluting this to 100 ml. with water. The sprayed paper was dried under the infrared lamp, then placed under an ultraviolet lamp and irradiated until blue spots appeared.

**Quantitative Analysis of Phosphate Mixtures.**— The paper area containing each phosphate species was cut into small pieces and was burned to ashes in a crucible. The ash was digested with nitric acid and the acid solution was evaporated to dryness. The residue was dissolved in a diluted solution of sulfuric acid and the phosphate was determined colorimetrically according to the method of Karl-Kroupa[1c].

## Results and Discussion

Experimental results for the dependence of separation of phosphate mixtures on the elution conditions are summarized in Fig. 2 and Table I. The rectangles in Fig. 2 indicate only the positions of phosphate species in the elutions but not their concentrations. The variation of the concentration of chloride ion in the eluant is expressed by the equation,

$$x = a(1 - e^{-ft/v}) \qquad (1)$$

where $x$ (mol./l.) is the concentration of chloride ion in the mixing bottle, $a$ (mol./l.) is the concentration of chloride ion in the stock bottle, $f$ (ml./min.) is the flow rate, $v$(ml.) is the volume of solution in the mixing bottle and $t$ (min.) is the time from the start of mixing. The curves in Fig. 2 indicate the concentration of chloride ion in the eluant calculated from Eq. 1. The cross marks in Fig. 2-1 indicate the concentration of chloride ion determined experimentally.

Table I. Conditions of experiments shown in Fig. 2

| No. | Amount of phosphate μg. | | Concn. of KCl in the stock bottle M | pH of KCl soln. |
|---|---|---|---|---|
| 1 | Each | 20 | 0.75 | 5.5 |
| 2 | 〃 | 20 | 1 | 5.5 |
| 3 | 〃 | 20 | 2 | 5.5 |
| 4 | 〃 | 20 | 2 | 4.5 |
| 5 | 〃 | 20 | 3 | 4.5 |
| 6 | 〃 | 20 | 3 | 4.5 |
| 7 | 〃 | 100 | 3 | 4.5 |
| 8 | 〃 | 100 | 2 | 4.5 |
| 9 | 〃 | 300 | 2 | 4.5 |
| 10 | 〃 | 100 | 2 | 4.5 |
| 11 | Ortho<br>Pyro<br>Tripoly | 100<br>10<br>10 | 3 | 4.5 |

The capillary between a and b in Fig. 1 was shortened step by step to promote the efficiency of the elution. In the experiments of Fig. 2-1～5, 6～9 and 10～11, the capillaries of the length 41.5, 24.0 and 20.7 cm. were used, respectively.

Jameson[2h] used 0.75 M solution of potassium chloride of pH 5.5 as a stock solution to determine the compositions of strong phosphoric acids. Using a potassium chloride solution of the same concentration and pH as those used by Jameson, the authors tested the separation of the phosphate mixture. The separation of 20 μg. as phosphorus of each phosphate species is complete, but too much eluant is consumed

(Fig. 2-1). The same amounts of the phosphate mixture can be separated by the use of 1 M potassium chloride of pH 5.5 (Fig. 2-2), but in the case of 2 M potassium chloride of pH 5.5 the separation of pyro- and tripolyphosphate is incomplete (Fig. 2-3). The use of 2 or 3 M potassium chloride of pH 4.5 can separate 20 $\mu$g. as phosphorus of each phosphate species (Fig. 2-4 and 5, and 6). The separation of 100 $\mu$g. as phosphorus of each phosphate species can not be achieved by the use of 3 M potassium chloride of pH 4.5 (Fig. 2-7). On the other hand 2 M potassium chloride of pH 4.5 should be used for that purpose (Fig. 2-8 and 10). However, 2 M potassium chloride of pH 4.5 can not separate 300 $\mu$g. as phosphorus of each phosphate species (Fig. 2-9).

As shown in Fig. 2-10, 100 $\mu$g. as phosphorus of each phosphate species can be separated by letting only 79 drops of the eluant flow. Similarly 100 $\mu$g. of orthophosphate, 10 $\mu$g. of pyrophosphate and 10 $\mu$g. of tripolyphosphate, as phosphorus in all cases, can be separated satisfactorily by letting only 66 drops of the eluant flow (Fig. 2-11).

TABLE II. RESULTS OF ANALYSES OF PHOSPHATE MIXTURES

| Sample | Phosphate species | % P | | |
|---|---|---|---|---|
| | | Calcd. | Found, this method | Found, paper chromatography[1c] |
| Pure phosphate mixture | Ortho- | 50.1 | 50.4 | 50.8 |
| | Pyro- | 49.9 | 49.6 | 49.2 |
| Pure phosphate mixture | Ortho- | 66.8 | 67.5 | — |
| | Pyro- | 33.2 | 32.5 | — |
| Commercial sodium tripolyphosphate | Ortho- | — | 0.0 | 0.0 |
| | Pyro- | — | 7.6 | 7.2 |
| | Tripoly- | — | 92.4 | 92.8 |

The results of the quantitative analyses obtained by the precent procedure are shown in Table II. The first and the second sample are synthetic mixtures of pure alkali orthophosphate and pyrophosphate and the third sample is a commercial sodium tripolyphosphate. For comparison, the paper chromatographic analyses were carried out for the first and the third sample by the method of Karl-Kroupa[1c]. The data obtained by the present method were well coincident with the calculated values and the data obtained by paper chromatography.

**Summary**

The authors presented the new rapid method for the determination of ortho-, pyro- and tripolyphosphate in the mixture by the use of a small column, 2.6 mm. in diameter and 60 mm. in height, of ion-exchange resin, Dowex 1−X4 (200∼400 mesh). The continuous-gradient elution method was applied and the paper micro-fraction collector was used. For example, by the use of 2 M potassium chloride of pH 4.5 as the stock solution, 100 $\mu$g. as phosphorus of each phosphate species can be separated by letting only 79 drops of the eluant flow. The quantitative data obtained by the present method were well coincident with the calculated values or the data obtained by the paper chromatography.

# *Forschung über die katalytische Entwässerung des Isoamylalkohols. I.*

Von Akira MITSUTOMI

(Eingegangen am 26. September, 1960)

Die Gewinnung der Olefine durch Entwässerung des Isoamylalkohols geschieht entweder nach dem sogenannten „Flüssigkeits oder Gasphase-verfahren". Bei dem erst genannten Flüssigkeitsverfahren liefert Isoamylalkohol in der unter Zusatz von konzentrierter Schwefelsäure unterhalb von 100°C erfolgenden Entwässerung Amylen in 15～18%iger Ausbeute sowie Isoamyläther in ca. 27%iger Ausbeute, wie die Arbeiten von Norris und Reuter[1], und von Cramer und Cambell[2] klar zeigen. Die hier entstehenden Amylene sind zwar nach ihrem Siedepunkt, 32～42°C, als ein Gemisch aus Methyläthyläthylen und Trimethyläthylen

1) J. P. Norris und R. Reuter, *J. Am. Chem. Soc.*, **49**, 2624 (1927).
2) P. I. Cramer und J. M. Campbell, *Ind. Eng. Chem.*, **29**, 234 (1937).

anzunehmen, sie sind aber auf das Mischverhältnis, die chemischen Zusammensetzung noch nicht geprüft.

Abgesehen von der Diskontinuierlichkeit von diesem Verfahren, kann es wenn auch nur für Olefine-Herstellung als geeignet nicht angesprochen werden. Aus dem Standpunkt, für die industrielle Produktion das kontinuierlich arbeitende Gasphase-Verfahren technisch fertigzubringen, hat der Verfasser diese Forschung durchgeführt.

Ipatiew[3] berichtet für das Gasphase-Verfahren, dass man durch Zuführung des Isoamylalkohols durch das bei 540°C vorher erhitzte mit Aluminiumoxyd gefüllte Eisenrohr ein Gemisch des Isopropyläthylens (I) mit kleiner Menge Methyläthyläthylen (II) und Trimethyläthylen (III) erhält, ohne dabei aber Isoamyläther (IV) festzustellen.

Ipatiew[4] hat ferner bei der Prüfung der Isomerisation von Isopropyläthylen erkannt, dass bei Abwesenheit von Katalysatoren diese Isomerisation auch bei Erhitzung bis zu 400, 500 und 540°C immer ausbleibt, während bei Anwesenheit von Aluminiumoxyd als Katalysator bereits im Bereich von 450～535°C das Isopropyläthylen ca. 50～60% zu Trimethyläthylen isomerisiert wird. In der Genenwart von Kieselgur wird es ca. 20%.

Auch Adams, Kamm und Marvel[5] haben berichtet, dass durch Entwässerung des Isoamylalkohols bei 500～540°C unter Anwendung des Aluminiumoxyds und Bimssteins als Katalysator Isopropyläthylen mit 70～80%iger Ausbeute dargestellt werden konnte, ohne aber Trimetyläthylen bilden zu lassen.

Nach Norris und Reuter[6] bildet sich nur Isopropyläthylen, wenn Isoamylalkohol durch Aluminiumoxyd als Katalysator bei 375～400°C entwässert wird, und das wird erst nach Erhitzung bei 375～450°C in der Gegenwart von Aluminiumsulfat als Katalysator nur um 45% zu Trimethyläthylen isomerisiert, während beim Vorhandensein der Phosphorsäure als Katalysator die genannte Isomerisation des Isopropyläthylens bei 450°C absolut ausbleibt und erst bei 500°C nur um 15～29% eintritt.

Es ist zwar von Kashima[7] angegeben, dass aus *n*-Amylalkohol bei Anwendung der japanischen Säureerde als Katalysator *n*-Amylen und *n*-Amyläther dargestellt wurden. Aber von der Stellung der Doppelbindung von diesem *n*-Amylen ist keineswegs erwähnt. Fujita[8] hat unter Erhitzung des mit Aktivkohle gefüllten Kupferrohrs bei 320～340°C ein Gemisch aus Isoamylalkohol und Wasser hindurchgezogen, und ausser Isobutylen und Isopropyläthylen noch die Bildung von Isoamyläther, Isobutan, Isovaleraldehyd und Isovalersäure ermittelt.

Es muss von den oben genannten Arbeiten überhaupt gesagt werden, dass sie mit Ausnahme von Fujita die Trennung der Reaktionsprodukte und deren Ermittelung sehr ungründlich behandelten und weiterer eingehender Prüfung bedürfen.

Die Olefine, der Gegenstand der Arbeiten, die durch Entwässerung der niedrigen Alkohole gebildet werden, haben einander sehr naheliegende Siedepunkte, so dass die Trennung der einzelnen Olefinen mit grösseren Schwierigkeiten verbunden sind. Üblicherweise wird das Gemisch unter Benutzung des unterschiedlichen Löslichkeitsgrades gegenüber 60%iger Schwefelsäure getrennt. Mit solch einer Methode können die einzelnen Olefine in ihrem primären Zustande keineswegs alle voneinander getrennt werden. Solche in verhältnismässig geringer Menge vorhandenen Olefine können als reiner Verlust weder erfasst noch rein dargestellt werden.

Ferner kann als für diese Arbeiten überhaupt gemeinsamer Nachteil angeschprochen werden, dass ausgerechnet die Frage immer noch offengelassen ist, nämlich welche Typen Katalysatoren geeignet sind, um gewisse Typen Olefinen durch Entwässerung von Alkohol zu gewinnen.

Dieser Umstand kommt selbstverständlich daher, dass, wie bereits beschrieben, die Bestimmung der chemischen Zusammensetzung und des Mischverhlätnisses von den Reaktionsprodukten äusserst unbeachtet behandelt ist. Der Verfasser hat die unentbehrlichen Bedingungen bestimmt, Trimethyläthylen durch das Gasphase-Verfahren kontinuierlich herzustellen, und den Reaktionsmechanismus geklärt.

Zu diesem Zweck wurden die Hochfeindestillation, Fluoreszenz Indikator Adsorptionsanalyse, Infrarot Spektrographie sowie Gas-Chromatographie herangezogen.

### Beschreibung der Versuche

Die beiden Vorrichtungen, einmal die horizontale Type, andersmal die vertikale Type, wurden für Entwässerung von Isoamylalkohol nach dem Gasphase-Verfahren verwendet, mit aber annähernd gleichen Ergebnissen. Das Ausgangsmaterial, Isoamylalkohol, tritt tröpfenweise in gewissen Zeitabständen von dem kalibierten Behälter ins Reaktionsrohr aus. In dem Reaktionsrohr sind die in Korngrösse vereinheitlichten Katalysatoren eingepackt und von Aussern her elektrisch geheizt. Die durch Reaktion zu bildenden Olefine und weitere gasförmige Substanzen wandern über den Kühler in den Behälter ein. Dieser Behälter liegt in dem Wasserbad und bleibt unterhalb von 100°C.

Das unverwandelte Isoamylalkohol verbleiben in dem Behälter, während die Olefine mit niedrigem Siedepunkte allein durch den Kühler hinaufsteigen, in den Kühler, wo sie stark abgekühlt werden, und die Vorlage aufgesammelt werden.

Die Kondensate werden nach Feindestillation in 4 Fraktionen eingeteilt: 20～30°C, 30～33°C, 33～35°C, 35～42°C.

Die vierte Fraktion bestehen hauptsächlich aus Trimethyläthylen. Anhand deren prozentualen Ausbeute wurde das katalysatorische Vermögen beurteilt.

Als Katalysatoren wurden 15 folgende Substanzen in verschiedenen Kombinationen eingesetzt: $Al_2O_3$,

$BaSO_4$, $H_3PO_4$, $H_2SiO_3$, $ZnSO_4$, $FeSO_4$, $MgSO_4$, $ZnCl_2$, $Ca_3(PO_4)_2$, $Al_2(SO_4)_3$, $CaSO_4$, $Na_2SO_4$, $KHSO_4$, Stärke, japanische Säureerde.

Der Kakalysator wurde in geeignetem Verhältnis gemischt, mit etwas Wasser zugesetzt, angeteigt, in geeignete Korngrösse verformt, zuerst bei 60°C für 2 Std, dann bei 120°C für 1 Std erhitzt und aufgetrocknet.

## Ergebnisse

Die Versuchsergebnisse liessen folgenden Schluss ziehen: Bei dem Aluminiumoxyd als Katalysator zeigte sich die Gesammtmenge von den dritten und vierten Fraktionen nur als 5.5%, ausserdem dieselbe von den Ersten und Zweiten auch als 27%. Unter allen Umständen war Aluminiumoxyd als Katalysator für vorliegenden Versuch unbrauchbar.

Die Resultaten beim Einsatz anderer Katalysatoren sind in Tabelle I aufgezeichnet.

Die Tabelle I umfasst die beiden extremen Ausbeute, nämlich des Maximum und Minimum an der Ausbeute von der vierten Fraktion, die beim gleichen, mehr als zweimal kontinuierlich eingesetzten Mischkatalysator erhalten wurde. Die in der Tabelle I angegebenen Versuchsnummer sind identisch mit denselben in der Tabelle II. In der Tabelle II weisen sie die Beschreibung der verwendeten Reaktionsröhre auf.

Kurz gefasst, ist der Aluminiumoxyd-Katalysator für Fabrikation des Trimethyläthylens ungeeignet. Wenn daher solche Katalysatoren, die über 50%ige Ausbeute des Trimethyläthylens erzielen lassen, aus Tabelle I gesucht werden, können Mischkatalysatoren aus Kieselsäure und Phosphorsäure, aus Natriumsulfat, Eisensulfat oder Magnesiumsulfat mit jeweiligem Zusatz von japanischer Säureerde gefunden werden. Besonders beim Natriumsulfat ist durch Reaktion bei 400°C die Ausbeute von 72% an Trimethyläthylen erzielbar. Die genannte Ausbeute gilt aber nur für das erste Mal. Bei kontinuierlichen Reaktionen vermindert sich diese in einer fortwährenden Abschwächung wie 72.0→53.0→36.5→20.0%.

Auch der Mischkatalysator aus Kieselsäure und Phosphorsäure wies anfangs 55%ige Ausbeute auf, sank aber nach viermaliger kontinuierlicher Anwendung auf 5.5%ige Ausbeute ab. Bei anderen Katalysatoren blieb es fast gleich. Nach 70 bzw. 120 Std kontinuierlicher Anwendung ist das Entwässerungs- und Isomerisations-vermögen fast restlos verlorengegangen, somit sind alle für vorliegenden Versuch vollkommen ungeeignet.

Daher hat der Verfasser zwei Reaktionsröhre in Serie gestellt. In dem ersten Reaktionsrohr soll hauptsächlich die Entwässerung erfolgen, während in dem zweiten die Isomerisation gefördert wird, um die Ausbeute von Trimethyläthylen steigen zu lassen. Mit dieser Absicht wurden die Versuche unter Einsatz verschiedener Katalysatoren angestellt. Die Reaktionstemperatur betrug im ersten Reaktionsrohr 350～450°C und im zweiten 275～320°C. Auch in diesem Fall vermindert sich die Ausbeute an Trimethyläthylen mit Vermehrung der kontinuierlichen Reaktionsmale, um endlich bei dem fünften Mal bis auf 20.0% abzusinken, wie die Tabelle III klar anzeigt.

Die Versuchsergebnisse, die in Tabelle III

| 4 | 5.0 | 54.0 | 〃 | 4 | 10 | 100 | 88.9 | 56.3 |
| 5 | 3.4 | 62.5 | 〃 | 5 | 10 | 100 | 88.3 | 56.5 |

verzeichnet sind, zeigten, dass die Haltbarkeit des Vermögens arm und somit für kontinuierliche Reaktion ungeeignet ist.

Der Mischkatalysator aus Zinksulfat und japanischer Säureerde zeigte im Unterschied von den anderen in der Ausbeute von Trimethyläthylen bei der ersten Anwendung 52.5%, und die der Zweiten noch eine Höhe von 66%, also deutete auf Möglichkeit einer kontinuierlichen Anwendung an. Daher wurden 64 Male Versuche angestellt, womit endlich festgestellt wurde, dass diesser Katalysator für Entwässerung und Isomerisation des Isoamylalkohols zur hochprozentigen Gewinnung des Trimethyläthylens fabrikatorisch sehr geeignet ist. Der Auszug aus den zahlreichen Versuchsergebnissen wird zum Beispiel in Tabelle IV gegeben.

Wenn also mit dem in Tabelle V bezeichneten Reaktionsrohr Nr. 1 Isoamylalkohol 1000 ccm bei 420～450°C reagiert wird, beträgt die Ausbeute des Trimethyläthylens auch nach 10-maliger kontinuierlicher Anwendung ein- und desselben Katalysators stets über 50%, mit nur geringfügiger Nebenbildung von Isopropyläthylen und Methyläthyläthylen.

Dies liefert den Beweis dafür, dass der Zinksulfat-Katalysator zu dem Zweck des Verfassers befriedigenderweise vorzüglich ist. Dieser Umstand ist auch bei 52 Male, unter Einsatz der Reaktionsröhrenummer 2, 3, 4 und 5 klar feststellbar.

Um diejenigen Ergebnisse handelt es sich bei den Versuchen Nr. 1—5. Tabelle V zeigt eine zum Vergleich derer zusammengefasste Aufstellung.

Es sei noch hinzugefügt, dass die Ausbeute an Trimethyläthylen in solcher Versuche fast die Gleichen wie in Tabelle IV sind und somit hier fortgelassen wurden.

## Zusammenfassung

Die Methode, die hauptsächlich aus Trimethyläthylen bestehenden Olefine aus Isoamylalkohol nach dem Gasphase-Verfahren zu gewinnen, wurde ausgearbeitet. Nach der Feststellung, dass der von Ipatiew vorgeschlagene Katalysator, Aluminiumoxyd, zu diesem

Zweck ungeeignet ist, wurden verschiedene Katalysatoren, auf ihr Vermögen, Trimethyläthylen zu liefern, untersucht, mit dem Ergebnis, dass ein Gemisch des Zinksulfat es mit der japanischen Säureerde das beste Vermögen besitzt. Ihre Eignung wurde nach weiterer Forschung unter Modifizierung der Bedingungen ermittelt.

Zum Schluss sei noch davon erwähnt, dass die vorliegende Arbeit der Leitung von Herrn Professor Dr. Eiichi Funakubo an der Technischen Fakultät der Universität zu Osaka verdankt ist.

# *Forschung über die katalytische Entwässerung des Isoamylalkohols. II. Prüfung der Bedingungen für kontinuierliche Dehydratisierung bei Zinksulfat-Katalysator*

Von Akira MITSUTOMI

(Eingegangen am 26. September, 1960)

Der Verfasser hat bereits in der I. Mitteilung[1] betont, dass für kontinuierliche Fabrikation der hauptsächlich aus Trimethyläthylen bestehenden Olefinen, ausgehend von Isoamylalkohol, der Zinksulfat-Katalysator das beste Vermögen besitzt.

Um die Entwässerung und Isomerisation beim Einsatz dieses Katalysators genauer zu forschen und unter Anwendung der labormässig grösstmöglichen Apparatur die geeigneten Bedingungen für Olefin-Produktion zu ermitteln, wurden folgende Reihen Versuche gestellt.

## Beschreibung der Versuche

**Zubereitung der Katalysatoren.** — Es wurden kristallines Zinksulfat und japanische Säureerde gut vermischt, mit Zusatze von etwas Wasser genügend angeteigt, in passende Korngrösse verarbeitet, zuerst bei 60°C 2 Std, dann bei 120°C 1 Std erhitzt und abgetrocknet. Die Erhitzungsgewichtsabnahme u. s. w. stehen in Tabelle I.

Es wurden von den Katalysatoren 3 Sorten, nämlich Nr. 1, 2 und 3, wie in Tabelle II angegeben, präpariert und auf katalysatorisches Vermögen, Haltbarkeit u. s. w. geprüft.

Für Reaktionsröhre wurden die Eiserne verwendet. Die einzelnen Grössen, die Versuchsnummern, wobei die Betreffenden eingesetzt wurden, und weitere Angaben sind in Tabelle III verzeichnet.

**Versuchsmethode.** — Mittelgrosse und grosse Reaktionsröhre, deren Grössenordnung bereits in Tabelle III angegeben ist, wurden in gleicher Weise aufgestellt wie in der I. Mitteilung. Drein wurden unter Variierung der Temperaturen 1000 ccm Isoamylalkohol eingeschickt, wasserabgespaltet, isomerisiert und die Produkte, eingeteilt in 3 folgenden Fraktionen, und die Ausbeute wurde geprüft: bis 30°C, 30~35°C, 35~41°C.

Indem andererseits mit 1000 ccm Isoamylalkohol als einmaliger Einschickung ein und derselbe Katalysator kontinuierlich angewandt wurde, wurde derselbe unter Beobachtung der Änderungen von Ausbeute auf seine Haltbarkeit geprüft.

Ferner wurden unter folgendem Grundsatz Versuche angestellt: (I) Bei Versuchsreihennummer 1 bis 6 wurde unterm Einsatz der mittelgrossen Reaktionsröhre bei Einhaltung der Temperatur zu ca. 398~540°C der Katalysator Nr. 1 auf das Vermögen geprüft. (II) Bei Versuchsreihennummer 7 bis 9 wurde unterm Einsatz der Reaktionsröhr mit etwas grösserem Durchmesser bei ca. 380~451°C Reaktionstemperatur der Katalysator Nr. 1 geprüft. (III) Bei Versuchsreihennummer 10 bis 12 wurde der Katalysator Nr. 1 bei Absenkung der Reaktionstemperatur auf 320~410°C auf das Vermögen geprüft. (IV) Bei Versuchsreihennummer 16~18 wurde der Katalysator Nr. 2 und bei denen 13~15 derselbe Nr. 3 auf das Vermögen geprüft. (V) Unter dem Einsatz des labormässig zulässigen möglichstgrossen Reaktionsrohrs wurde der Katalysator Nr. 1 auf das Vermögen geprüft. Unter variierten Temperaturen wurden 96 Male Versuche angestellt. (VI) Mit gleichgrossem Reaktionsrohr wie oben wurde der Katalysator Nr. 2 geprüft. Es waren die Versuchsreihe Nr. 16~18.

## Versuchsergebnisse

Unter Einhaltung der gleichen Bedingungen mit Ausnahme der Reaktionstemperatur wurden unabhängig voneinander 290 Male Experimente durchgeführt, indem ein neuer Katalysator

jeweils eingesetzt wurde. Von den Versuchsergebnissen wurden die als typisch Erscheinenden ausgesucht und zum Vergleich auf eine Tabelle IV gebracht.

Wird die Überlegenheit durch die Fraktion von Sdp. 35~41°C, Ausbeute an Amylen und des Wiedergebungsvermögen entschieden, so lässt sich finden, dass die Reaktionstemperatur von gegen 350±30°C herum für den Zweck vorliegender Versuche die optimal Bedingung darstellt, wie die Ergebnisse bei der aus Exp. Nr. 10, 11, 12, 16, 17 und 18 bestehenden Gruppe zeigen.

Bei einer höheren Temperatur erhält man nur in seltenen Fällen gute Ausbeute, wie es bei Exp. Nr. 3 der Fall ist, aber es lässt sich nicht gut wiedergeben. Im Gegensatz hierzu ist das Wiedergebungsvermögen von den Resultaten bei Exp. Nr. 8, 9, 13, 14 und 15 ausgezeichnet gut, aber ausgerechnet die Ausbeute an Trimethyläthylen ist als verhältnismässig schlecht zu bezeichnen. Im Gegenteil davon verbessert sich die Ausbeute der Fraktion von Sdp. 30~35°C. Die dabei herschende Reaktionstemperatur von ca. 400±30°C ist als geeignet für unsere Forschung nicht anzusprechen.

Ferner, die mit dem Fortschreiten der Reaktion ununterbrochen eintretenden Destillatsmengen von Amylen und die drei,

unabhängig davon bei der fraktionierten Destillation erhaltenen Sorten von Olefinen wurden auf ein Diagramm gebracht und die mit dem Ablauf der Zeit herlaufende Bildung von Olefinen wurde beobachtet. Dann wurden zwei im Labor anwendbare grösstmögliche Reaktionsröhre wurden für längere Zeit kontinuierlich erfolgende Versuche eingesetzt. Hierbei wurden die Katalysatoren Nr. 1, 2 und 3 (Tabelle V) in Unabhängigkeit voneinander eingesetzt und die Reaktionstemperaturen wurden nur auf drei Bedingungsarten, nämlich 450±30°C, 380 ±30°C und 400±30°C, beschränkt. Und jeweils für 220, 100 und 99 Stunden wurde die Reaktion fortgesetzt. Eine Einsicht in diese Versuchsergebnisse lässt wissen, dass die Bildung von Olefinen beim Einsatz von Katalysator Nr. 3 höchst glatt erfolgt und das Dehydratisierungsvermögen des Katalysators fast nicht nachlässt. Von den gebildeten Amylenen verhält sich die vorwiegend aus Trimethyläthylen bestehende Fraktion bei Sdp. 35～40°C regelmässig und sie ist mengenmässig mehr als die zwei anderen Fraktionen.

TABLE V. DIE ZUSAMMENSETZUNG DER ZINKSULFAT-KATALYSATOREN

| Sorten der Katalysatoren | Zinksulfat, % | Japanische Säureerde, % | Zusatz |
|---|---|---|---|
| Nr. 1 | 30 | 70 | Wasser |
| Nr. 2 | 50 | 50 | Wasser |
| Nr. 3 | 30 | 70 | Ammoniak |

Es lässt sich ausserdem vermuten, dass irgendeines Verhältnis unter diesen Dreien besteht.

|---|---|---|---|
| Versuchsreihenummer | 256～290 | Katalysator | Nr. 1 |
| Dauer der kontinuierlichen Anwendung | 246 | Temperatur | 6.5～11.5°C |
| Male der kontinuierlichen Anwendung | 35 | Grosses Reaktionsrohr | (122×5.1) |

Aus der obigen Forschungsarbeit wurden folgende Folgerungen gezogen:

(I) Das Gemisch des Zinksulfates mit der japanischen Säureerde erweist sich für Gewinnung des Trimethyläthylens aus Isoamylalkohol als das beste.

(II) Die Katalysatoren mit drei folgenden Zusammensetzungen wurden in bezug auf Leistungen verglichen. Es wurde gefunden, dass der Katalysator Nr. 3 die besten Ergebnissen aufweist, und dass derselbe Nr. 1 als der nächstbeste in Frage kommt. Der Katalysator Nr. 2 ist als der schlechteste ausgefallen.

Das heisst, bei Zinksulfat ist es unnötig, viel zu verwenden. Mit 30% davon ist es ausreichend. Bei Zusatz geringer verd. Ammoniak werden die besten Ergebnisse erzielt.

(III) Die optimale Reaktionstemperatur liegt bei ca. 400°C. Bei unzweckmässig höherer Temperatur tritt Abbau des Katalysators und weitere unzweckdienliche chemische Änderung mit schlechten Ergebnissen ein.

(IV) Als Katalysator ist solcher in Kugeln mit ca. 8～10 mm Durchmesser angebracht.

(V) Nach Einpackung des Katalysators in Reaktionsrohr ist es nötig, zuerst denselben zur Aktivierung bei ca. 500°C zu erhitzen.

(VI) Die Reaktion soll unter gewöhnlichem Druck erfolgen. Eine Druckerhöhung ist unnötig.

(VII) Als das Reaktionsrohr kann ruhig gewöhnliches Eisen benutzt werden.

(VIII) Der Zinksulfat-Katalysator lässt auch nach einer ununterbrochenen Verwendung keinerlei beachtenswerte Veränderung an der Leistung feststellen. Er hat solche von anderen Katalysatoren nicht erreichbar Haltbarkeit. Es ist somit klar geworden, dass Amylen in der kontinuierlichen Arbeitsweise herstellbar ist.

(IX) Selbst in einem äusserst unglücklichen Fall wird bei dieser Arbeitsweise Isoamylalkohol nur noch um ca. 15% unverändert und immer noch zurückgewonnen. Dies kann nach Trennung von Wasser wiederum ins Reaktionsrohr eingeschickt werden.

## Zusammenfassung

Um die höchst geeigneten Bedingungen zu bestimmen, worunter aus Isoamylalkohol die hauptsächlich aus Trimethyläthylen bestehenden Olefine gewonnen werden, wurden labormässig zulässige grösste Vorrichtung herangezogen und das Zinksulfat Gemisch als Katalysatoren auf ihre Leistungen untersucht. Bei dem Mischverhältnis von 30 : 70 erwies sich das Gemisch des Zinksulfates mit der japanischen Säureerde als das Beste. Auch nach 246 stündigem ununterbrochenem Einsatz wurde noch keinerlei grössere Änderung an seiner katalysatorischen Leistung ermittelt.

Hinsichtlich des vorteilhaften Umstandes, dass die Reaktion unterm Einsatz gewöhnlichen Eisenmaterials bei normalem Druck und dem Temperaturbereich von 350±30°C erfolgt, wurde der Zinksulfat-Katalysator als höchst geeignet für Entwässerung und Isomerisation des Isoamylalkohols beurteilt.

Zum Schluss sei noch davon erwähnt, dass die vorliegende Arbeit der Leistung von Herrn Professor Dr. Eiichi Funakubo an der Technischen Fakultät der Universität zu Osaka verdankt ist.

# SHORT COMMUNICATIONS

## *On the Influence of Sodium Oxide upon the Crystal Structure of Tricalcium Silicate*

By Goro YAMAGUCHI and Hiroshi UCHIKAWA

(Received August 10, 1961)

The crystal structure of pure $3CaO \cdot SiO_2$ and the solid solution of the system $3CaO \cdot SiO_2$-$Al_2O_3$-MgO, so-called alite, had been determined[1,2]. No results, however, had been reported on the influence of $Na_2O$ upon $3CaO \cdot SiO_2$ and there existed a need for detailed investigation on this system.

In the present paper, the authors describe the results of the investigation on the formation and decomposition of the solid solution of the system $3CaO \cdot SiO_2$-$Na_2O$ and its crystal structure.

Pure $3CaO \cdot SiO_2$ was synthesized by following procedures, that is, the mixtures of alkali free guaranteed reagent of $CaCO_3$ and $SiO_2$ were heated in platinum crucible at 1500°C, then cooled rapidly, pulverized, reheated several times until no free CaO was found. Then various amount of guaranteed reagent of $Na_2CO_3$ were added to $3CaO \cdot SiO_2$ and mixed sufficiently, heated at 1450°C for 30 min. and then cooled rapidly to room temperature.

This procedure was necessary to obtain the well-crystallized $3CaO \cdot SiO_2$-$Na_2O$ solid solution. Chemical compositions, refractive indices and specific gravity of the solid solution of this system are shown in Table I.

X-Ray diffraction pattens of the characteristic peaks at 51～52°C in $2\theta$ corresponding to (220) of Jeffery's trigonal cell[1,2] of the $3CaO \cdot SiO_2$-$Na_2O$ solid solution measured by slow scanning and high resolution are shown in Fig. 1.

These characteristic peaks were triplet until $Na_2O$ content increased to 0.33% and then changed to doublet. Further increase of a $Na_2O$ content made no remarkable change of the X-ray diffraction patterns of the $3CaO \cdot SiO_2$-$Na_2O$ solid solution until 0.71%. More further addition of $Na_2CO_3$ decomposed it into $\beta$-$2CaO \cdot SiO_2$, $Na_2O \cdot CaO \cdot SiO_2$ and free CaO.

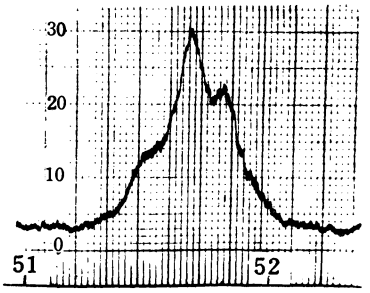

Fig. 1. X-Ray diffraction pattern of the characteristic peak of $3CaO \cdot SiO_2$-$Na_2O$ solid solution (specimen No. 6).

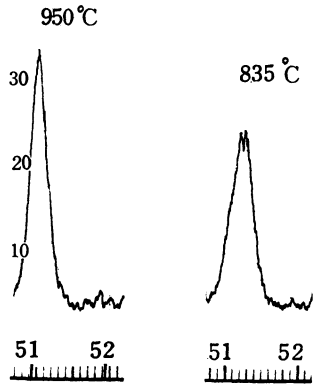

Fig. 2. High temperature X-ray diffraction patterns of the solid solution of the system $3CaO \cdot SiO_2$-$Na_2O$ (specimen No. 6).

The triplet ⇄ doublet change seemed corresponding to triclinic ⇄ monoclinic transition.

In differential thermal analysis, the low $Na_2O$ samples showed two endothermic and exothermic peaks at 900～1000°C corresponding to the reversible transitions of triclinic ⇄ monoclinic ⇄ trigonal, but the high $Na_2O$ (0.3～0.7% of $Na_2O$) samples showed one endothermic and exothermic peak of the monoclinic ⇄ trigonal transition.

In high temperature X-ray diffraction, doublet peaks of the high $Na_2O$ sample changed to singlet at about 900°C as shown in Fig. 2.

From the results of X-ray diffraction and differential thermal analysis, the high $Na_2O$ solid solution was considered to be monoclinic structure. Assuming that this solid solution have Yamaguchi and Miyabe's monoclinic cell[2] corresponding to pseudo-orthorhombic cell

| | No. 6 | 25.97 | 73.34 | 0.71 | 100.02 | 2.92 | — | 1.715±0.002 | 1.718±0.002 |

derived from Jeffery's trigonal cell[1], lattice constants were determined by precise X-ray diffraction as follows:

$a=12.262$ a. u., $b=7.053$ a. u., $c=25.086$ a. u., $\beta=90°07'$.

Calculated value of interplaner spacing from these lattice constants coinside with those obtained by the precise measurement of the diffraction peaks.

By heating for three hours at 1450°C, the monoclinic high $Na_2O$ solid solution released $Na_2O$ and changed into the triclinic low $Na_2O$ solid solution.

The gradual decomposition of $3CaO \cdot SiO_2$ into $2CaO \cdot SiO_2$ and free CaO occurred at about 1250°C was fairly accelerated in the solid solution, compared with that of pure $3CaO \cdot SiO_2$.

The rate of hydration of the solid solution was larger than that of pure $3CaO \cdot SiO_2$.

This solid solution seems significant because alite in commercial portland cement clinker contains a few amount of $Na_2O$ and effect of $Na_2O$ can not be little.

# *Zur einfachen Bestimmung im Wasser Milliardestelmenge vorhandenen Kupfers(II) durch Anreicherung mit Mikroschicht der Chelatbildungsharze**

Von Masatoshi FUJIMOTO

(Eingegangen am 2. August, 1961)

In einer vorhergehenden Mitteilung[1] wurde eine spezifische „Harztüpfelmethode[2,3]“ zum Nachweise geringer Menge Kupfers(II) mit den Kugeln eines Chelatbildungsharzes, „Dowex A-1 Chelating Resin[4],*1“, vorgeschlagen, dessen Haftgruppe, Iminodiacetat-gruppe, durch starke Chelatbildung mit Kupfer(II) am Rande der Kugeln ohne Zusatz spezifischer Reagens eine charakteristische Himmelblaufarbe liefert. Bei der vorliegenden Arbeit wurde es neu gezeigt, daß beim Durchlaufen einer Wasserprobe, die nur Spurenmenge Kupfers(II) enthalten ist, eine dünne Mikroschicht des genannten Chelatbildungsharzes eine deutliche und der Kupfer-(II)-menge entsprechende Hellgrün- bzw. Blaufarbe annimmt, welche eine eindeutige und leistungsfähige, halbquantitative Analyse der Milliardestelmenge Kupfers(II) an der Wasserprobe ermöglicht.

TABELLE I. RESULTATE DER GEGENWÄRTIGEN ULTRAMIKROSCHÄTZUNG VON KUPFER(II)-GEHALT BEI DEN VERSCHIEDENEN WASSERPROBEN

| Probewasser | | Durchlaufgeschwindigkeit ($\mu$l/Sek) | (cm/Sek) | $V_B$[c] (ml) | scheinbare Farbintensität[d] (nach 500 ml Durchlauf) | Farbton der Harzschicht | ausgeschätzter Kupfer(II)-gehalt |
|---|---|---|---|---|---|---|---|
| Probe-A | | 70 | 0.56 | $\gg$100 | − | blaßgelb | $<4\times10^{-9}$ |
| Probe-B | | 100 | 0.80 | $\simeq$200 | ++ | hell grünlich blau | $\simeq4\times10^{-8}$ |
| Probe-C | | 140 | 1.1 | $\gg$1000 | − | blaßgelb | $<4\times10^{-9}$ |
| Probe-D | | 90 | 0.72 | $\gg$1000 | − | blaßgelb | $<4\times10^{-9}$ |
| 1 | | 70 | 0.56 | $\gg$1000 | − | blaßgelb | |
| 2 | | 70 | 0.56 | >1000 | − | blaßgelb | |
| 4 | $\mu$g Cu(II)[a] | 70 | 0.56 | $\simeq$1000 | ± | blaßgelb ? | |
| 10 | pro 1 | 66 | 0.52 | $\simeq$450 | (+) | hell grünlich gelb | |
| 20 | Liter | 50 | 0.40 | $\simeq$300 | + | hell bläulich grün | |
| 40 | Probe- | 95 | 0.76 | $\simeq$200 | ++ | hell grünlich blau | |
| 100 | wassers | 100 | 0.80 | $\simeq$75 | ++ | grünlich blau | |
| 200 | | 60 | 0.48 | $\simeq$40 | +++ | intensiv grünlich blau (himmelblau) | |
| 10[b] | | 3.2 | 0.14 | $\simeq$80 | + (nach 80 ml Durchlauf) | hell grünlich gelb | |

Probe-A: durch UNIBED-Austauschersäule entionisiertes Wasser; B: mit einem Messingapparat destilliertes Wasser; C: mit Schliffglasapparat umdestilliertes Wasser; D: Trinkwasser aus Wasserleitung. a Umkristallisiertes Kupfersulfat wurde mit dem entionisierten Wasser versetzt. b Es wurde hier eine Kapillarharzschicht wie Abb. 1-c angewandt, wobei starker Einfluß der Durchlaufgeschwindigkeit auf die Färbung der Harzschicht beobachtet wurde. c Ein Volumen des Wassers, nach dessen Durchlauf erste Grünfarbe an den Harzkugeln in der Schicht sicher erkennbar wird. d −: nicht erkennbar, ±: unsicher, (+): schwach, +: sicher, ++, +++: intensiv.

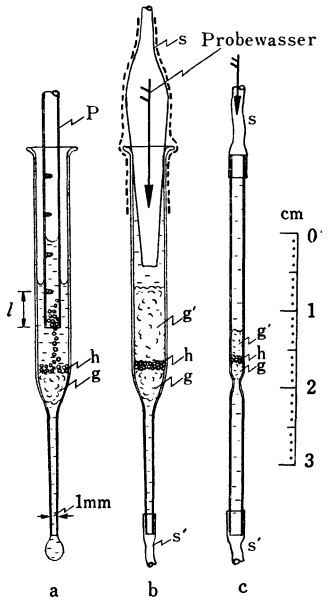

Abb. 1 Mikroharzschicht zur Anreicherung kleinster Menge der Ionen.

Man dreht ein Glasröhrchen 4 mm im Durchmesser und 3 bis 5 cm lang wie Abb. 1 aus[5], und verstöpft dieses etwa 5 mm lang mit einer Watte der feinsten Glaswolle g. Dann läßt man darauf gerade 10 $\mu$l der genannten Harzkugeln (50-100 mesh und in der Ammoniumform) mit entionisiertem Wasser zusammen mittels einer vorher je 10 $\mu$l eingeteilten Kapillarpipette P*[2] absinken.

Man packt locker andere Glaswolle g' um etwa 5-10 mm lang gerade auf diese Harzschicht h wie Abb. 1-b ein. Man steckt einen gereinigten, feinen Polyäthylenschlauch*[3] s ins Probewasser ein und läßt dieses mit Hilfe eines Aspirators durch die obenerwähnte Harzschicht h und den Schlauch s' mit mäßiger Geschwindigkeit durchfließen*[4]. Je 10 bzw. 100 ml Durchlaufen des Probewassers beobachtet man die Färbung an der Harzschicht h unter Vergrößerung mit einer Lupe. Tabelle I zeigt die einigen Beispiele über verschiedene Wasserproben ausgeführter Bestimmungen.

5) Vgl. M. Fujimoto, Dieses Bulletin, **29**, 595 (1956).

*2 Aus der einem Tropfen (etwa 0.04 ml) entionisierten Wassers entsprechenden Länge der Kapillarpipette kann man die gerade 10 $\mu$l-Gehalt entsprechende Länge ($l$) leicht bestimmen.

*3 Einen feinen Polyäthylenschlauch von beliebigem Durchmesser kann man aus einem Schlauche 1 cm im Durchmesser leicht ausdrehen, indem man diesen über einer kleinen Flamme eines Brenners bis zur anscheinenden Durchsichtigkeit gelind erhitzen läßt, und diesen etwas weichenden Schlauch langsam und stark bis zum gewünschten Durchmesser auszieht und im kalten Wasser rasch erstarren läßt.

*4 Anwendung des Wasserdrucks an Stelle des Absaugens zum Durchlaufen des Probewassers ermöglicht noch einfache Anreicherung, worüber der Verfasser zur Zeit noch eingehenden Versuch durchführt.

Die oben mit einem Chelatbildungsharze ausgeführte Ultramikroanreicherungsmethode für außerordentlich verdünnten Bestandteil sei dadurch bis zur noch niedrigen Konzentration wie Billionstel oder weniger ($<10^{-12}$) erfolgreich zu erweitern, daß man, unter genau regulierter Durchlaufgeschwindigkeit der Flüssigkeit, verschiedenartige Adsorptionsmittel, z. B., Kationen- oder Anionenaustauscher sowie anorganische Austauscher, mit empfindlichsten und spezifischen Reagenzien zusammen verwendet. Der Verfasser führt darüber eine Reihe der Untersuchungen aus, die später genau berichtet werden.

## *Experimental Evidence for the Theoretical Condensation Isotherm on Spheres Arranged in the Closest Packing*

By Izumi HIGUCHI, Yataro USHIKI and Reiko SUZUKI

(Received August 3, 1961)

One of the contentions of the capillary condensation theory is that the shape of isotherms in the range of high relative pressure is determined by the pore distribution of the sorbent. Hitherto, however, we have not known any process to control precisely the pore distribution of sorbent in its preparation. Therefore the contention seems to have no experimental evidence.

In the former report[1,2] one of us calculated three types of theoretical capillary condensation isotherms which were given by spheres of the sorbent when they were arranged linearly, or two dimensionally, or in the closest packing. A number of experimental isotherms given by corpuscular sorbents, consisting of non-porous particles, exhibited unquestionably the capillary condensation in the range of relative pressure, which was anticipated from the theory and the size of particles, arranged in the two dimensional closest packing. If we can get a corpuscular sorbent of which packing type is previously known, the theoretical condensation isotherms will be confirmed experimentally. Experimental isotherms of benzene and methanol at 0°C on the porous Vycor glass are shown in Figs. 1 and 2. The shape of sorption and desorption isotherms are very similar to what we can theoretically obtain for the corpusclar sorbent if the elementary spheres are arranged in the closest packing. Porous Vycor glass, considering from its preparation process and

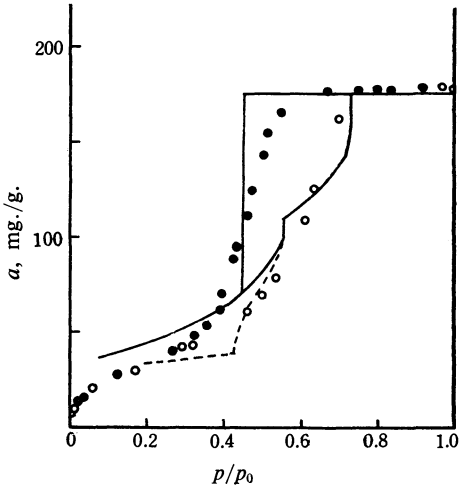

Fig. 1. Sorption isotherm of benzene at 0°C on porous Vycor glass. Circles, sorption data; solid circles, desorption data; the solid line, the theoretical condensation isotherm; the dotted line, the theoretical one, taking into account the vapor pressure correction.

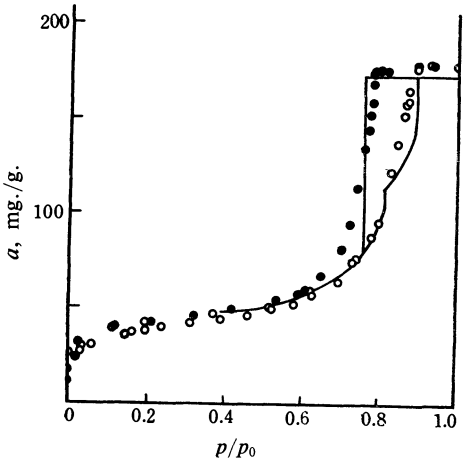

Fig. 2. Sorption isotherm of methanol on porous Vycor glass at 0°C. Circles, sorption data; solid circles, desorption data; the solid line, the theoretical condensation isotherm.

1) I. Higuchi and H. Utsugi, *J. Chem. Phys.*, **20**, 1180 (1952).
2) I. Higuchi and H. Utsugi, *Sci. Repts. Tohoku Univ. Ser. I*, **36**, 27 (1952); *J. Chem. Soc. Japan, Pure Chem. Sec. (Nippon Kagaku Zasshi)*, **73**, 395, 397 (1952).

its hardness, seems to be the most suitable sorbent which is idealized to be consisting of spherical silica particles arranged in the closest packing. The average diameter of elementary particles assumed to be spherical can be calculated from BET area, which is obtained experimentally with benzene isotherm. Then, theoretical condesation isotherms for benzene or methanol can be calculated from the $V(y)$-$y$ relation given in the previous report[2], wherein $V(y)$ denotes the condensed liquid volume per the unit volume of sorbent and $y$ is the radius of curvature of the condensed liquid surface divided by the radius of spherical particles.

The theoretical ones, exhibited by solid lines in the figures, are in good agreement with the experimental values. This is a more satisfactory agreement than expected, because the packing model used in the calculation is quite an idealized one.

From the success mentioned above, we can draw a number of important conclusions for the sorption phenomena : (1) The structure of porous Vycor glass is idealized to be consisting of almost spherical particles arranged in the closest packing. (2) Both sorption and desorption isotherms in the range of high relative pressure are due to the capillary condensation of the sorbate. (3) Kramer-McBain mechanism for the hysteresis[3] in isotherms is confirmed experimentally to be very reasonable.

Both works of Barrer et al[4]. and Kiselev et al.[5] seem to be excellent extensions from the similar standpoint for the capillary condensation theory and hysteresis mechanism. Barrer et al. calculated various theoretical condensation isotherms for a number of single pores different in their shapes and gave a reasonable formula to compute the isotherm for the contact zone between spheres. According to our precise numerical estimations, it is not adequate to calculate the condensed liquid volume between contact spheres by their scheme because the difference in volume between their model and ours is so minor as to be practically negligible. On the other hand, calculations of vapor pressure of the sorbate by our approximation using the usual Thomson equation is rather serious for the linear packing of spheres. Fortunately, however, it is not so serious, as mentioned previously[2] for the closest packing wherein true two dimensional concave meniscus is prevalent between spheres. The correction for this effect is shown by the dotted line in Fig. 1, indicating that our approximation adapted previously may not essentially influence the theory.

The authors gratefully express their appreciation to Dr. Goodman in Corning Glass Corp. and Dr. A. T. Ree for the donation of porous Vycor glass.

## *Synthesis of 4,6-Di-(D-glucopyranosyl)-deoxystreptamine*

By Sumio UMEZAWA and Yukio ITO

(Received August 9, 1961)

Recently, it has been shown that a essential group for antibiotic character of neomycin[1], kanamycin[2] and paromomycin[3] belongs to the glucosides of deoxystreptamine, however, synthesis of the allied glucosides has not been reported as yet*. In continuation of our work[2d] on kanamycin, we have synthesized 4, 6-di-(β-D-glucopyranosyl)deoxystreptamine (IV).

3) T. S. Haskell, J. C. French and Q. R. Bartz, *J. Am. Chem. Soc.*, **81**, 3483 (1959).

* It should be noted that a related compound, *O*-(β-D-2-amino-2-deoxyglucopyranosyl) derivative of *d, l-trans*-2-aminocyclohexanol was synthesized: T. Suami and S. Umezawa, This Bulletin, to be published.

Addition of excess carbobenzoxychloride in toluene to an aqueous solution of deoxystreptamine made alkaline with sodium hydroxide gave, in 48% yield, *N*, *N'*-dicarbobenzoxydeoxystreptamine (I), m. p. 233~235°C. Found: C, 62.06; H, 6.23; N, 6.55. Calcd. for $C_{22}H_{26}O_7N_2$: C, 61.38; H, 6.09; N, 6.51%.

*N*, *N'*-Dicarbobenzoxydeoxystreptamine (I) failed to react with acetobromoglucose in benzene, chloroform, dioxane or dimethylformamide, however, it has been found that the condensation proceeded in nitromethane. To a suspension of I (1.63 mmol.) in nitromethane was added acetobromoglucose (5.35 mmol.) and powdery mercuric cyanide (5.5 mmol) and the suspension was stirred for twenty-four hours at 27°C. Extraction with chloroform followed by evaporation of the solvent gave a crude product, which was recrystallized from absolute ethanol to afford, in 76% yield, *N*, *N'*-dicarbobenzoxy-4, 6-di-(tetraacetyl-D-glucosyl) deoxystreptamine (II), m. p. 253~254°C, $[\alpha]_D^{17.5}$ −9.6° (*c* 1.965, chloroform). Found: C, 54.83; H, 5.53; N, 2.85. Calcd. for $C_{50}H_{62}O_{25}N_2$: C, 55.05; H, 5.73; N, 2.57%.

Infrared spectrum: $\nu_{max}^{Nujol}$ 3480, 3340 (OH, NH); 1760 (acetyl C=O); 1700 (C=O in $OCOCH_2C_6H_5$); 1520 (CONH); 1220; 1160, 1075 (glucoside); 1035 (alicyclic secondary alcohol); 903 (β-glucoside); 733, 695 (monosubstituted benzene).

Hydrolysis of II (1.0 g.) with methanolic ammonia at room temperature followed by evaporation in vacuo and washing with ethyl acetate gave a crude product, which was recrystallized from water-dioxane-ethanol (5: 1: 10) to afford colorless needles (0.38 g.) of *N*, *N'*-dicarbobenzoxy-4,6-di-(D-glucosyl) deoxystreptamine (III), m.p. 288~290°C (decomp.), $[\alpha]_D^{17.5}$ −5.67° (*c* 1.43, pyridine). Found: C, 54.16; H, 6.06; N, 3.81. Calcd. for $C_{34}H_{46}N_2O_{17}$: C, 54.11; H, 6.14; N, 3.71%. Infrared spectrum: $\nu_{max}^{Nujol}$ 3350, 1700, 1545, 1295, 1230, 1165, 1075, 1035, 890, 735, 695 $cm^{-1}$.

Hydrogenolysis of III (0.5 g.) with palladium catalyst in water-dioxane (1:1) followed by evaporation in vacuo and washings with dioxane, ether and ethanol gave a crude product, which was recrystallized from water-ethanol to afford colorless crystals of 4,6-di-(β-D-glucosyl) deoxystreptamine (IV), $[\alpha]_D^{20}$ −4.69° (*c* 1.01, water). The product darkened and decomposed at about 190~230°C. Found: C, 43.91; H, 7.26; N, 5.37. Calcd. for $C_{18}H_{34}O_{13}N_2$: C, 44.43; H, 7.06; N, 5.76%. Infrared spectrum: $\nu_{max}^{Nujor}$ 3340, 1600 ($NH_2$), 1165, 1075, 1035, 890 $cm^{-1}$.

The positions of attachment of two D-glucoses to deoxystreptamine was substantiated by periodate oxidation of 4, 6-di-(tetraacetyl-D-glucosyl) deoxystreptamine diacetate (V), which was obtained by hydrogenolysis of II with palladium catalyst in dioxane-acetic acid -water. The compound decomposed at about 270°C (darkening at about 180°C). Found: C, 48.62; H, 6.46; N, 3.14. Calcd. for $C_{34}H_{50}N_2O_{21}\cdot 2CH_3CO_2H$: C, 48.40; H, 6.21; N, 2.97%.

Upon oxidation with sodium periodate in aqueous 50% dioxane for twenty-nine hours, V did not consume the oxidant, while, in parallel experiments, methyl α-D-glucoside and β-pentaacetyl-D-glucose consumed 1.97 and 0.1 mol. of the oxidant respectively. The glucosidic linkages in III or IV are therefore on C-4 and C-6 of deoxystreptamine.

Infrared spectra of the products (III, IV) showed absorption at 890 $cm^{-1}$ which is characteristic of β-glucosidic linkage, Moreover, a rough calculation** of the anomeric contribution (A) of the glucosidic linkages in IV gave a negative value (−13141), the presence of two β-linkages being suggested.

The structure of IV has a close resemblance to that of kanamycin, however, there is a characteristic difference regarding the configuration of anomeric carbon atoms. IV showed no antibiotic activity. The syntheses of allied compounds containing α-linkages of amino sugars are in progress.

The authors are indebted to Mr. S. Nakada for the microanalyses.

## *Effect of Impurities on the $^{81}Br$ Quadrupole Resonance in p-Dibromobenzene*

By Juro MARUHA, Jun KOIZUMI, Masahiko SUHARA and Tokuzo TONOMURA

(Received September 6, 1961)

Some investigations have been done concerning the effect of impurities on the nuclear quadrupole resonance absorption of $^{35}Cl$ in molecular crystals[1,2]. In particular Monfils

1) See for instance: J. Duchesne, "Advances in Chemical Physics", Vol. II, Ed. by I. Prigogine, Interscience Publishers, Inc., New York (1959), p. 190.
2) S. Kojima, S. Ogawa, M. Minematsu and M. Tanaka, *J. Phys. Soc. Japan*, **13**, 446 (1958).

and Grosjean derived an equation for the line height ($I$) of the absorption curve as follows[3]:

$$I = I_0 \exp(-NC) \qquad (1)$$

where $C$ is the concentration of impurity, and $N$, a "characteristic number", represents the number of resonant nuclei per impurity molecule whose resonance have been perturbed so they can no longer contribute to the central portion of the line. The main effect of impurity was considered the lattice defect due to the volume difference between the resonant atom and the substituted one[1,2]. For bromine compound, however, only one investigation has been reported. Dreyfus and Dautreppe studied the intensity of the resonance line of $^{79}Br$ in $p$-dibromobenzene[4]. The present paper contains the study of the effect of impurities on the resonance line of $^{81}Br$ in $p$-dibromobenzene.

The spectrometer used was similar one reported by Kojima[5]. The intensity of resonance line war observed with a video amplifier and an oscilloscope. The frequency of the resonace was about 224 Mc/sec. Samples are carefully purified and mixed, then sealed into glass tubes. The mixed sample in each tube was melted and crystallized slowly by standing overnight. The tube containing the mixed crystal was placed in a r-f coil of the spectrometer. All the measurements were carried out at 4±1°C, hence $p$-dibromobenzene exists in the $\alpha$-phase.

The results are shown in Fig. 1, graphically. In each case plots of log ($I/I_0$) vs. $C$ is not a single straight line but is nearly hyperbolic. If a linear relation is assumed in the small impurity region, the characteristic number is calculated according to Eq. 1, from the slope. These values are listed in Table I. The values

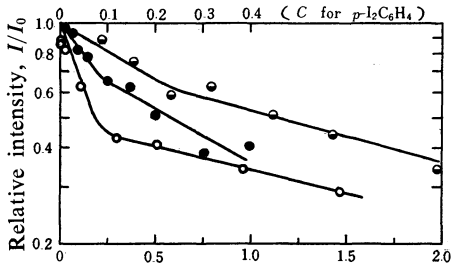

Fig. 1. Variation of relative intensities with concentration of impurities.
◒ $p$-$BrC_6H_4Cl$ ● $p$-$I_2C_6H_4$ ○ $p$-$Cl_2C_6H_4$

obtained for $p$-dichlorobenzene and $p$-diiodobenzene are not consistent with the Dreyfus and Dautreppe's values. In their experiment log ($I/I_0$) decreases linearly with $C$ over wide concentration range for the above two cases, whereas it is hyperbolic for the case of $p$-bromochlorobenzene, and they considered the latter is an exceptional case. On the contrary Kojima et al. showed in their experiment concerning the $^{35}Cl$ resonance[2] that the results are always hyperbolic, as we obtained. Thus the results of Dreyfus and Dautreppe are considered to be dubious.

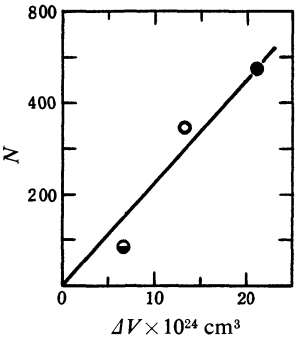

Fig. 2. Relation between characteristic number and volume difference.
● $p$-$I_2C_6H_4$ ○ $p$-$Cl_2C_6H_4$ ◒ $p$-$BrC_6H_4Cl$

TABLE I. CHARACTERISTIC NUMBER AND VOLUME DIFFERENCE

| Impurity molecule | $N$ | $\Delta V$ ($10^{-24}$ cm$^3$) | $N'$[a] |
|---|---|---|---|
| $p$-$BrC_6H_4Cl$ | 82 | − 6.63 | — |
| $p$-$Cl_2C_6H_4$ | 348 | −13.26 | 32 |
| $p$-$I_2C_6H_4$ | 475 | +21.14 | 80 |

a) Dreyfus and Dautreppe's value.

The relation between the characteristic number ($N$) and the volume difference ($\Delta V$) is shown in Fig. 2, and can be expressed by

$$N = k\Delta V \qquad (2)$$

where $k$ is $22.5 \times 10^{24}$ cm$^{-3}$. Compared with the corresponding results for chlorine compounds[6], it may also be true for the bromine compound that the main effect of impurity is attributed to the volume difference between the Br atom and the substituted one.

acids are efficiently epoxidized with hydrogen peroxide using sodium tungstate as catalyst, and Payne[2] has also established that ethyl isopropylidenecyanoacetate is converted to the corresponding epoxyamide by the use of hydrogen peroxide and sodium hydroxide.

In the present work, ethyl alkylidenecyanoacetate was epoxidized at 70~80°C in ethanol containing 30% hydrogen peroxide and sodium tungstate dihydrate. The resulting epoxyamide II reacted with alcoholic alkali at room temperature to give the compound III. Decarboxylation and rearrangment of III to α-ketoamide IV was readily accomplished by heating with a small amount of water. Further, the treatment of III and IV with dilute hydrochloric acid affored α-keto acid V in a good yield. The compounds IV and V formed the corresponding oximes. The compounds which were prepared by this process are listed in Tables I–III.

The method appears to be generally applicable in the synthesis of α-keto amide and acid.

Details of this study will be published elsewhere.

The authors wish to express their sincere thanks to Dr. Taro Hayashi and Dr. Tatsuo Takeshima for their kind advice.

## *Rhodium-Platinum Oxide as a Catalyst for the Hydrogenation of Organic Compounds. II*[1]. *Catalyst Preparation and Effects of Platinum in Rhodium-Platinum Oxide*

By Shigeo NISHIMURA

(Received September 20, 1961)

It was reported previously[1-3] that rhodium-platinum(3 : 1) oxide prepared exactly in the same way as Adams platinum oxide is easily reduced with hydrogen to the metals at the ordinary temperature and pressure and that the resulting rhodium-platinum black is an excellent catalyst retaining the nature of a pure rhodium catalyst and is substantially superior to Adams platinum and palladium catalysts both in activity and in selectivity in the hydrogenation of various organic compounds.

It has been found that the activity of rhodium-platinum(3 : 1) oxide and also that of rhodium oxide are considerably enhanced by fusing the corresponding chlorides with sodium nitrate for a shorter time at a lower temperature than as directed in the preparation of platinum oxide[4]. The rhodium-platinum(3 : 1) catalyst prepared in this way is not only more active, but also more easily dissolved in aqua regia than reported previously. This fact prompted the author to prepare a catalyst which retains the nature of a rhodium catalyst and can be completely recovered with aqua regia. Rhodium-platinum oxide of various compositions has been prepared by the improved procedure and the activity and selectivity have been studied in the hydrogenation of toluene and acetophenone in acetic acid. The results are summarized in Table I. The catalysts containing 70 to 90% of rhodium are the most active and selective. On the other hand, those containing about 30% or more of platinum dissolve on gently heating in aqua regia without leaving any insoluble residue. Thus the requirements mentioned above are satisfied to a large extent by the catalyst consisting of 70% of rhodium and 30% of platinum, which dissolves in aqua regia practically with no residue, and yet is nearly as active and as selective as rhodium-platinum(3 : 1) oxide.

Though rhodium oxide is not easily reduced with hydrogen as noted previously[2], that prepared by the improved procedure can be reduced to the metal in 3~4 hr. at 30°C or in about 1 hr. at 45~50°C in acetic acid under the atmospheric pressure of hydrogen. The resulting rhodium black, however, is unexpectedly less active than rhodium-platinum (3 : 1) oxide as shown in the hydrogenation of toluene. The proportion of hydrogenolysis in the hydrogenation of acetophenone is somewhat greater with rhodium oxide than with rhodium-platinum(3 : 1) oxide (see Table I). Thus, the platinum in rhodium-platinum oxide promotes the reduction of the oxide to the metals, makes the resulting catalyst more active and selective than the pure rhodium catalyst, and makes it possible to recover the metals with aqua regia.

TABLE I. CATALYTIC HYDROGENATION OF TOLUENE AND OF ACETOPHENONE WITH RHODIUM-PLATINUM OXIDE OF VARIOUS COMPOSITIONS[a]

| Catalyst | | Time for the reduction of oxide to metal | Hydrogenation of toluene (0.921 g.) | | Hydrogenation of acetophenone (0.601 g.) | |
|---|---|---|---|---|---|---|
| | | | Initial rate[b] | Time | $H_2$ uptake | Time |
| Rh(%) | Pt(%) | min. | ml./min. | min. | mol./mol. | min. |
| 100 | 0 | 210 | 88 | 23 | 4.08 | 30 |
| 90 | 10 | 50 | 110 | 15 | 4.03 | 20 |
| 80 | 20 | 30 | 106 | 16 | 4.02 | 22 |
| 75 | 25 | 24 | 108 | 15 | 4.02 | 20 |
| 70 | 30 | 20 | 103 | 16 | 4.02 | 20 |
| 60 | 40 | 16 | 91 | 16 | 4.05 | 24 |
| 50 | 50 | 11 | 87 | 17 | 4.08 | 36 |
| 25 | 75 | 5 | 49 | 25 | 4.15 | 50 |
| 0 | 100 | 2 | 19 | 83 | 4.65 | 75 |

a) Each hydrogenation was carried out with 50 mg. of oxide in 20 ml. of acetic acid at 30°C under the atmospheric pressure of hydrogen. The substance to be hydrogenated was added after the oxides was reduced to the metal.

b) Initial rate refers to 50 mg. of catalyst metal.

**Procedure for the Preparation of Rhodium-Platinum (7 : 3) Oxide.** — A mixture of the chlorides corresponding to 0.30 g. of rhodium and 0.13 g. of platinum in the weights of the metals is fused with 20 g. of sodium nitrate in the same way as in the preparation of platinum oxide[5]. After a violent evolution of the oxides of nitrogen has almost subsided, the temperature is raised and kept at 460~480°C for about 10 min. After cooling, the solidified mass is rinsed in distilled water. The solid is collected, washed with 100 ml. of 0.5% aqueous sodium nitrate, and then dried over calcium chloride. The yield is 0.665 g., which is quantitative on the basis of the metal content (65%) of the oxide.

The author wishes to express his sincere gratitude to Professor Yoshiyuki Urushibara for his continued encouragement.

# *Naphthalene as an Isolatable Reaction Intermediate in the Catalytic Vapor-phase Oxidation of Methylnaphthalenes to Phthalic Anhydride*

By Charles J. NORTON

(Received August 22, 1961)

Naphthalene has not been reported previously as a reaction intermediate in the heterogeneous vapor-phase oxidation of either monomethylnaphthalenes or dimethylnaphthalenes with air over vanadia catalyst at reactions which yield phthalic anhydride[1-3]. Recently, Morita tried unsuccessfully to detect naphthalene as an intermediate in the oxidation of 2-methylnaphthalene and naphthalene-1- and 2-carboxylic acid. For this reason, he concluded that naphthalene is not a reaction intermediate in the oxidation of methylnaphthalenes to phthalic anhydride[4].

The purpose of this communication is to report the discovery and isolation of naphthalene as an isolatable reaction intermediate under reaction conditions which are well known to effect its further oxidation to phthalic anhydride[1-6].

5) HC=Total recovered hydrocarbons
6) N=Naphthalene
7) $CO_2$ determined by difference
8) Largely naphthalene
9) Phthalic anhydride produced in low yield, but not determined.
10) Determined by elution chromatography; too little to confirm by auxiliary analyses.
11) Determined by elution chromatography and confirmed by melting point and infrared and ultraviolet spectrometry.
12) Determined by gas-liquid chromatographic analyses.

The experiments related below were carried out in a laboratory fluid-bed catalytic flow reactor equipped with air and liquid feed devices, and a temperature controller. The condensable reaction products were caught in a series of traps and analyzed by a combination of gravimetric, spectrometric, and chromatographic procedures. Experimental conditions a reults are summarized in Table I.

Naphthalene was first isolated in an 8.8 mol. per cent conversion in the reaction product mixture obtained from 2, 3-dimethylnaphthalene under conditions which gave a 49.0 weight per cent conversion to phthalic anhydride. This naphthalene was separated from the product mixture by means of elution chromatography with petroleum ether over alumina. The identity and purity of the reaction product were established by m. p., 80.1~80.7°C, and gas-liquid chromatographic, infrared and ultraviolet spectrometric comparisons with an authentic sample of naphthalene.

Only small amounts of naphthalene were detected by elution chromatograms in the product mixtures obtained from the oxidation of 1-methylnaphthalene under the reaction conditions for good phthalic anhydride yields. However, improved conversions of 2.18 to 4.34 mol. per cent naphthalene were obtained under milder reaction conditions, which gave low yields of phthalic anhydride (see Part B, Table I). These reaction product mixtures were distilled to obtain a 15.2 g. naphthalene cut, b. p. 214~223°C/629 mmHg, which on recrystallization from ethanol gave an infrared spectrum entirely superimposable with one of an authentic naphthalene sample.

These experimental results conclusively demonstrate that naphthalene is an isolatable reaction intermediate in the heterogeneous vapor-phase oxidation of 2, 3-dimethylnaphthalene to phthalic anhydride. Although the naphthalene conversions were too small to be confirmed under conditions favoring good phthalic anhydride production from either 1- or 2-dimethylnaphthalene, larger naphthalene conversions were demonstrated and confirmed in the oxidation of 1-methylnaphthalene at milder reaction conditions, which are less favorable for good phthalic anhydride production. Consequently, any reaction mechanism or kinetic analysis for the heterogeneous vapor-phase

oxidation of methylnaphthalenes over vanadia must consider naphthalene as an isolatable reaction intermediate which is produced in sufficient quantities to be desorbed from the catalyst and detected.

The author wishes to acknowledge the assistance of T. E. Moss in the experimental work.

## *Sudachitin, a New Flavone Pigment of Sudachi*

By Tokunaru HORIE, Mitsuo MASUMURA and F. Shigeo OKUMURA

(Received August 14, 1961)

A new flavone pigment was isolated in a 0.005% yield from the ether extract of the green fruit of *Citrus sudachi Hort ex Shirai*, one of the species of the family Rutaceae, which is produced only in Tokushima prefecture, Shikoku. The name, sudachitin is suggested for this new flavone. A better yield was obtained from the alcohol extract (0.014%) accompanying a second new flavone of m. p. 271~273°C from the mother liquor of sudachitin purifications in 0.004% yield.

Sudachitin crystallized as yellow needles from a mixture of ethyl acetate and methanol (1 : 1), 239.5~240.5°C, and its analytical values agreed with the formula $C_{18}H_{16}O_8$. When treated with metallic magnesium and hydrochloric acid, it gave typical reddish-orange color reaction for flavone pigments. It gave a greenish brown color with ferric chloride, indicating the presence of free hydroxyl groups.

The conversion of sudachitin (I) into a triacetate (II), $C_{24}H_{22}O_{11}$, m. p. 167.5~168.5°C, with acetic anhydride, and into a trimethyl ether (III), $C_{21}H_{22}O_8$, m. p. 135.5~136.5°C, with dimethyl sulfate, or into a triethyl ether (IV) $C_{24}H_{28}O_8$, m. p. 143~144°C, with diethyl sulfate, revealed the presence of three hydroxyl groups. These three derivatives gave the positive flavone color test with metallic magnesium and hydrochloric acid, but did not show a ferric chloride test. Diazomethane converted sudachitin into a dimethyl ether (V), $C_{20}H_{20}O_8$, m. p. 143~144°C, suggesting the existence of a free hydroxyl group at the 5-position of the flavone ring, at this stage, the similarity of the above two derivatives of sudachition to the nobiletin previously isolated by Robinson and coworkers[1], the structure of which has been confirmed as 3′, 4′, 5, 6, 7, 8-hexamethoxy flavone[2,3] (III), was noticed. The ultraviolet spectra of sudachitin trimethyl ether (III) and nobiletin*, and of sudachitin dimethyl ether (V) and 5-hydroxy-3′, 4′, 6, 7, 8-pentamethoxy flavone* were shown to be identical. The mixed melting point of the above two pairs also did not show any depression. From the above evidence, it is clear that the position of six substituents in sudachitin should be at 3′, 4′, 5, 6, 7 and 8

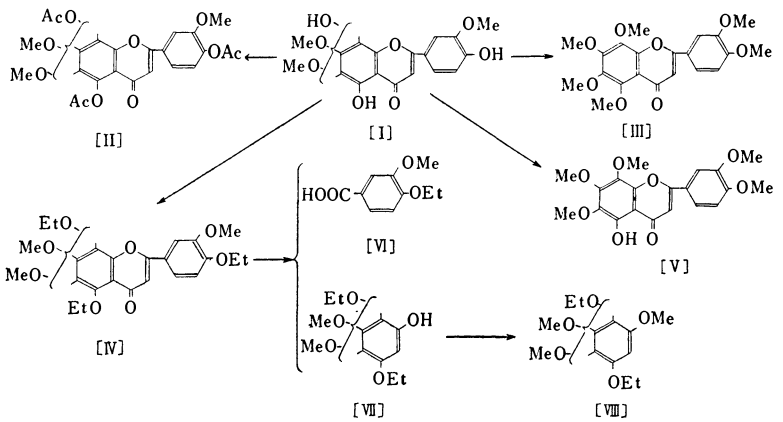

Fig. 1

1) Kwong-Fong Tseng, *J. Chem. Soc.*, **1938**, 1003; R. Robinson, Kwong-Fong Tseng, ibid., **1938**, 1004.

3) A. Tsukamoto and T. Ohtaki, ibid., **67**, 9 (1947).
* Samples of nobiletin and 5-hydroxy-3′, 4′, 6, 7, 8-pentamethoxy flavone were kindly provided by Dr. Z. Horii, University of Osaka.

positions, and one of the three free hydroxyl groups should be at the 5-position in the flavone ring.

In order to obtain furthur evidence regarding the position of the remaining two free hydroxyl groups, sudachitin triethyl ether (IV) was refluxed for 6 hr. in 10% potassium hydroxide solution. Acidificatin of the mother liquor from the ether extract of the hydrolysis mixture, gave a white precipitate in an 84% yield, which recrystallized from benzene, gave colorless needles, m. p. 193~194°C[4], (Found: C, 60.95; H, 6.23. Calcd. for $C_{10}H_{12}O_4$: C, 61.22; H, 6.16%). The mixed melting point with 4-ethoxy-3-methoxybenzoic acid[4] (VI) synthesized from vanillin was not depressed. From this fact, the position of the second free hydroxyl group was proved to be the 4'-position in the flavone ring. From the ether extract of the above mentioned hydrolysis mixture which had been saturated with carbon dioxide before ether extraction, there was obtained an oily product VII which gave a positive phenol test with ferric chloride. This was converted with dimethyl sulfate into a methyl ether, a diethoxy-trimethoxy benzene (VIII), whose analytical values agreed with the formula $C_{13}H_{20}O_5$ (Found: C, 61.04; H, 7.95. Calcd. for $C_{13}H_{20}O_5$: C, 60.92; H, 7.87%).

In the light of these findings, it was concluded that sudachitin most probably is the trihydroxy-trimethoxy flavone shown as structure I in Fig. 1.

An attempt to establish the relative positions of the hydroxyl- and methoxyl-groups on the benzene ring of VIII by direct comparison with three isomeric diethoxy-trimethoxybenzenes failed, because the amount of diethoxy-trimethoxybenzene from sudachitin was too small to purify.

The synthesis of three isomeric triethoxy-trimethoxy flavone which is only remaining way to confirm the final structure of sudachitin, is now in progress.

# *Stress Relaxation of Gels of Polyvinyl Alcohol-Glycerin-Water System*

By Kiyoshi ARAKAWA

(Received March 2, 1961)

In the previous paper[1] the results of the stress relaxation study on the gels of the polyvinyl alcohol-glycerin-water system were reported. This was taken as an example of non-electrolytic thermo-reversible gel systems of polymeric nature, and some discussions were held concerning the concentration dependence of relaxation spectrum.

The average molecular weight of the sample of polyvinyl alcohol used in the previous study was $1.1\times10^4$, which was comparatively low as a polymer. Another study on the mechanical behavior of polyvinyl alcohol-glycerin-water gels has been attempted for a polyvinyl alcohol sample of higher molecular weight in order to investigate the effect of the molecular weight difference on its mechanical behavior and to obtain further knowledge concerning the concentration dependence of relaxation spectrum.

## Experimental

**Sample.** — A commercial sample of polyvinyl alcohol was used. The amount of residual acetyl group of this powder sample was 1.0% by mole, which was determined by the titration method. The intrinsic viscosity $[\eta]_{25}$ obtained by means of a capillary viscometer of Ostwald type was 1.27 (100 cc./g.), and the viscosity average molecular weight which was calculated from the value of viscosity by Diew's formula[2] was $8.5\times10^4$.

The preparation of specimen gels was made according to the same procedure as that described in the previous paper[1] and also the mixing ratio of glycerin and water was made to be precisely the same as before. Gels of three different concentrations of polyvinyl alcohol were prepared, namely: 6.05, 7.95 and 9.07% by weight.

**Apparatus and Procedure for Measurements.** — The same relaxometer as has been used in the preceding studies[3] on the rheological properties of thermo-reversible gels was used in this experiment. The measurement of relaxation Young's modulus under a given constant strain was carried out for two hours after sudden imposition of the strain. The imposed strain was 5% for 7.95% and 9.07% gels, and 20% for 6.05% gels, respectively. The temperature was varied with about 10°C interval.

2) H. Diew, *J. Polymer Sci.*, **12**, 147 (1954).
3) K. Arakawa, This Bulletin, **32**, 1248 (1959); ibid., **33**, 1568 (1960); K. Arakawa and K. Atsumi, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*) **80**, 133 (1959).

## Results and Discussion

**Relaxation Data.** — The relaxation Young's modulus under constant compressional strain at various temperatures is plotted in the form of $(298/T)E_r$ versus log $t$, where $(298/T)$ is a reduction factor to 25°C concerning rubber-like elasticity. The results are shown in Figs. 1(a), 1(b) and 1(c) for each concentration.

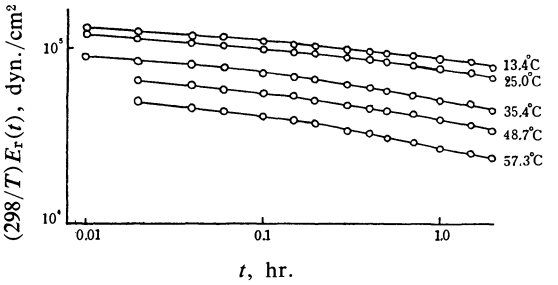

Fig. 1 (a). Reduced relaxation Young's modulus $(298/T)E_r(t)$ of 6.05% gel.

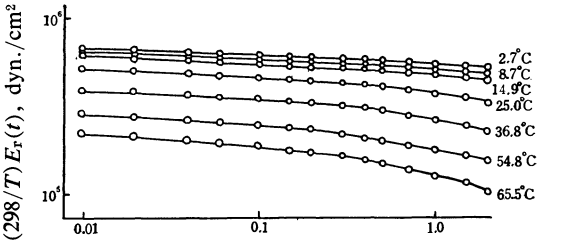

Fig. 1 (b). Reduced relaxation Young's modulus $(298/T)E_r(t)$ of 7.95% gel.

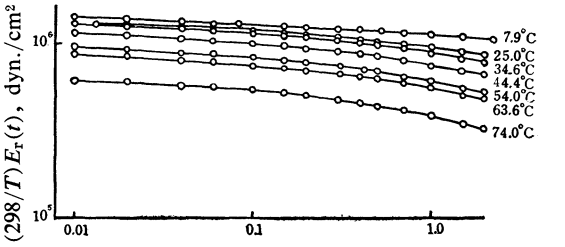

Fig. 1 (c). Reduced relaxation Young's modulus of 9.07% gel.

According to the time-temperature superposition principle[4], a master relaxation curve at 25°C for each concentration is obtained by shifting the relaxation curves at different temperatures horizontally along the $\log t$ axis. The master relaxation curves, thus obtained, are shown in Fig. 2. The coincidence of each relaxation curve by superposition is good as seen in Fig. 2.

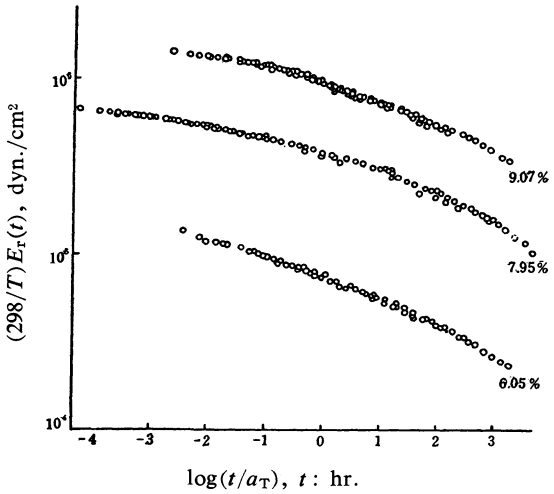

Fig. 2. Master relaxation curves at 25°C.

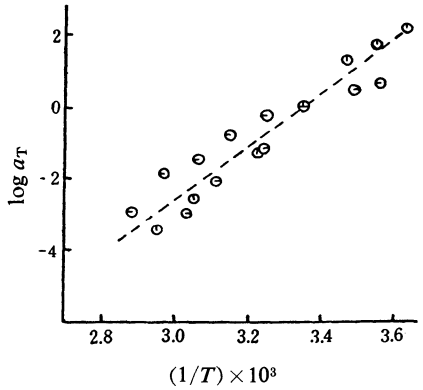

Fig. 3. $\log a_T$ versus $1/T$ relation.
⊖ 6.05%, ⏀ 7.95%, ⊖ 9.07%

The shift factors $\log a_T$ are plotted against $1/T$ in Fig. 3. This plotting shows a nearly linear relation, as in the case of the previous study[1], where the molecular weight of the polyvinyl alcohol was $1.1\times10^4$. Thus, the apparent activation energy $H_a$ calculated from the gradient of the $\log a_T$ versus $1/T$ curve is kept constant within the temperature and concentration ranges in the present study. When the apparent activation energy is constant, shift factors $a_T$ are expressed as follows,

$$a_T = A\exp(H_a/RT) \quad (1)$$

The values of $\log A$ and $H_a$ are given in Table I, together with those of molecular weight $1.1\times10^4$ in the previous paper[1].

TABLE I. VALUES OF $\log A$ AND $H_a$

| Mol. wt. of polyvinyl alcohol | $8.5\times10^4$ | $1.1\times10^4$ |
|---|---|---|
| $\log A$ | −25.7 | −43.8 |
| $H_a$ (kcal./mol.) | 35 | 60 |

The constancy of $H_a$ as well as the good coincidence of each relaxation curve by superposition is said to support the adequacy of the application of the superposition method, which exhibits the equality of the temperature dependence of all relaxation mechanisms within these ranges of temperature and concentration[5].

In order to compare the temperature dependence of shift factors in this case with the equation of the WLF form[6], the values of $\log a_T$ referred to $T_S$ are plotted against $T-T_S$ in Fig. 4, where $T_S$ is a reference temperature. The values of $\log a_T$ agree with the curve of

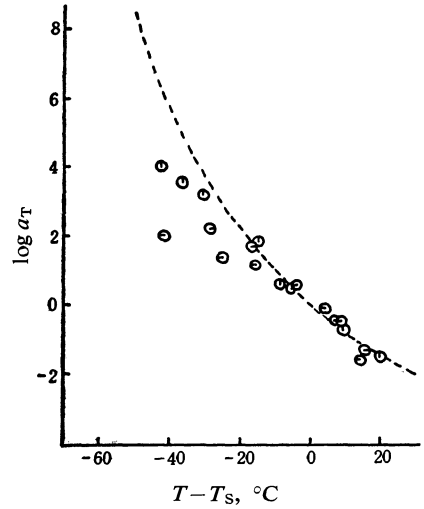

Fig. 4. $\log a_T$ versus $T-T_S$ relation.
⊖ 6.05%, ⏀ 7.95%, ⊖ 9.07%
---- Equation of WLF form, $C_1$: 8.86, $C_2$: 101.6
Values of $T_S$ 315°K for 6.05%
319°K for 7.95%
323°K for 9.07%

WLF equation within the range of $(T-T_S)=-20\sim20$°C, but outside of this range they deviate from the curve.

**Concentration Dependence of Distribution Functions of Relaxation Times.**—From the

4) A. V. Tobolsky, "Properties and Structure of Polymers", John Wiley and Sons, Inc., Publishers, New York (1960), Chapter 4, Sec. 2 and 3.

5) C. A. Dahlquist and M. R. Hatfield, *J. Colloid Sci.*, 7, 253 (1952).

6) M. L. Williams, R. F. Landel and J. D. Ferry, *J. Am. Chem. Soc.*, 77, 3701 (1955).

master curves shown in Fig. 2 distribution functions of relaxation times, $H(\log\tau)$, which are defined by Eq. 2 are obtained by Alfrey's first order approximation, Eq. 3.

$$E_r(t)=\int_0^\infty H(\log\tau)e^{-(t/\tau)}\mathrm{d}\log\tau \qquad (2)$$

$$H(\log\tau)=-2.303\left[E_r\frac{\mathrm{d}\log E_r}{\mathrm{d}\log t}\right]_{t=\tau} \qquad (3)$$

The distribution functions, thus obtained, are shown in Fig. 5. As is seen clearly, they are of typical box type character. When seen in details, there appears a fairly broad flat region in the curve for the gel of 7.95% and a peak in the curve for the gel of 9.07%. The curve for the gel of 6.05% is regarded as the one in the rubbery flow region which follows after the flat region. The distribution functions of the gels described in the previous paper[1] are shown together for comparison by dotted lines.

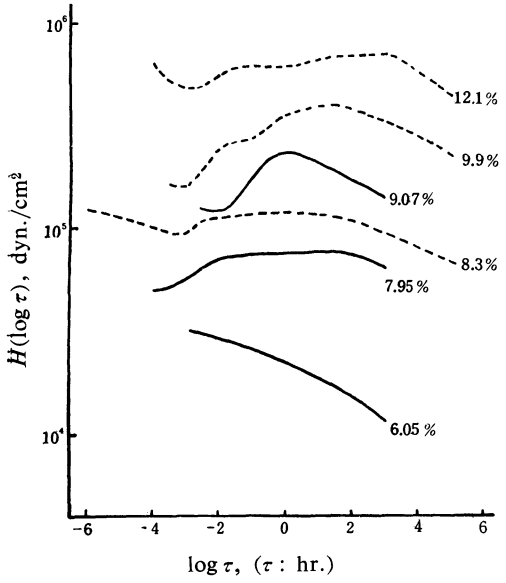

Fig. 5. Distribution functions of relaxation times.
—— Molecular weight, $8.5\times10^4$
---- Molecular weight, $1.1\times10^4$

When we see in detail the change in the shape of the curves with increase of concentration, it may certainly be said that the simple reduction rule concerning concentration which was proposed by Ferry et al.[7] and also the modified reduction rule by DeWitt et al.[8] on polymer solutions do not hold in this case, and that the circumstances are more complicated. However, when we seen all curves including dotted lines, it is found that the curves change their shapes continuously with the increase of concentration and that there is no marked difference among them in the tendency of the change in shape in spite of the fairly great difference in molecular weight.

The curve for the gel of 6.05% decreases monotonously. This corresponds to the rubbery flow region, and there appears a broad flat region in the curve of the gel of 7.95%, and the broad flat region is levelled up for the gel of 8.3%. Then there appears a peak in the flat region for the gel of 9.9%, and the peak shifts with the increase of concentration, accompanying the ascent of the curve.

Then it may be said that the difference in molecular weight has no marked effect on the distribution functions of relaxation times and that there are two or more mechanisms which behave differently with the increase of concentration.

In order to investigate the concentration dependence of distribution functions, the average values of $H(\log\tau)$ in the whole box type region, $\bar{H}$, which is regarded as the height of the idealized box type spectrum, are calculated and plotted in the form of $\log\bar{H}$ versus $\log C$, where $C$ is concentration in weight %, in Fig. 6, including those for the case of molecular weight $1.1\times10^4$. Then we see in Fig. 6 that a linear relation holds between $\log\bar{H}$ and $\log C$ as follows,

$$\log\bar{H}=\alpha+\beta\log C \qquad \alpha=0.45,\ \beta=5 \qquad (4)$$

As is shown in the equation above described, the value of $\bar{H}$ is proportional to the fifth

power of concentration. Then it is said that in the case of thermo-reversible gels there exists much more sensitive dependence of distribution functions on concentration, compared with the case of concentrated polymer solutions[7,8].

## Summary and Conclusion

A stress relaxation study was made for the gels of the polyvinyl alcohol-glycerin-water system using a chainomatic balance relaxometer, where the molecular weight of polyvinyl alcohol was $8.5\times10^4$. Relaxation Young's moduli under constant strain were measured up to two hours after sudden imposition of the strain for the gels of three different concentrations of polyvinyl alcohol: 6.05, 7.95 and 9.07% by weight. The relaxation curves at various temperatures were successfully superposed to a master relaxation curve for each concentration, and relaxation spectra were obtained from the master curves by Alfrey's approximation. The main results obtained are as follows.

1) The relaxation spectrum of the gel of the polyvinyl alcohol-glycerin-water system has a typical box type character.

2) The difference in molecular weight of polyvinyl alcohol has no marked effect on the relaxation spectrum of the gel.

3) The concentration dependence of the relaxation spectrum are fairly complicated in its details.

4) The average value of the distribution function of relaxation times in the box type region is proportional to the fifth power of concentration, rather than to the first or the second power.

# *The Infrared Absorption Spectrum of 1, 2, 4, 5-Tetrachlorobenzene in Vapor State*

By Shinnosuke SAËKI*

(Received March 4, 1961)

The molecular spectra of 1, 2, 4, 5-tetrachlorobenzene have been studied by some investigators[1]. All of these studies were, however, mainly concerned with a number of benzene derivatives to find the relation between the position of substituents in the benzene ring and C–H out-of-plane characteristic frequencies. Also 1, 2, 4, 5-tetrachlorobenzene was treated only as a member of the substituted benzenes. The assignment of the observed bands of this substance has been little discussed with the exception of its out-of-plane C–H vibration. Besides, all the spectra were taken in solid or liquid state or in solution, and the spectra taken in these states are not suitable to be used for the assignment of the bands. We measured the spectra of ordinary and deuterated 1, 2, 4, 5-tetrachlorobenzene in vapor state with the aid of a high temperature cell to make some tentative assignments of the observed infrared absorption bands.

## Experimental and Results

The measurements were carried out on ordinary and deuterated 1, 2, 4, 5-tetrachlorobenzenes, from 5000 to 2000 $cm^{-1}$ with a lithium fluoride prism, from 2000 to 700 $cm^{-1}$ with a sodium chloride prism and from 700 to 400 $cm^{-1}$ with potassium bromide prism using the Perkin-Elmer 112 infrared spectrometers. As the boiling points of these substances are considerably high, in order to observe the spectra in vapor state we used the high temperature cell which was described in a previous paper[2]. The partial pressure of each substance was not measured. The substance was simply put in the cell which has been previously heated but not evacuated, and regulated the quantity of the substance in the cell so that it might give a good spectrum.

The ordinary 1, 2, 4, 5-tetrachlorobenzene used in this experiments was extra pure grade on the market, and the deuterated one was kindly provided by Dr. Leitch in Canada.

The observed spectra of each substance are shown in Fig. 1, and the observed frequencies are shown in Table I.

## Assignment

The symmetry of this substance belongs to the point group $V_h$ as *p*-dichlorobenzene does. So it has thirteen infrared active normal vibrations of which five belong to the species $B_{1u}$ (in-plane), five to the species $B_{2u}$ (in-plane) and three to the species $B_{3u}$ (out-of-plane)*. These expected vibrational modes are listed in Table II.

Among these vibrations, the C–Cl bending vibration of each species is expected to be unobservable under the experimental conditions because of its low frequency, and some of the ring deformation frequencies might also exist beyond the experimental region. Therefore we should expect to observe from seven to ten fundamental frequencies under the experimental conditions. In the spectra nine or ten strong bands were observed for $C_6H_2Cl_4$ and eight strong bands for $C_6D_2Cl_4$. In addition to these strong bands a medium or weak band in shorter wavelength region was observed; that is, a band at 3094 $cm^{-1}$ of $C_6H_2Cl_4$ and at 2300 $cm^{-1}$ of $C_6D_2Cl_4$ which are evidently the fundamental bands of C–H and C–D stretching vibrations respectively.

Between 1500 and 1200 $cm^{-1}$ three fundamental bands, might be expected that is, the ring stretching vibrations of the species $B_{1u}$ and $B_{2u}$ and the ring in-plane deformation vibration of the species $B_{2u}$. It should be mentioned here that the third vibration, which is called a ring deformation vibration, might probably have a considerably high frequency, because the mode of this ring deformation is necessarily accompanied by a ring stretching mode. Taking into account the relative intensities of these bands and the product rule, we consider that the

* In this case, x axis was taken along the symmetry axis perpendicular to the molecular plane, and z axis along the symmetry axis combining two hydrogen atoms.

three bands at 1474, 1436 and 1319 $cm^{-1}$ of $C_6H_2Cl_4$ correspond to the three bands at 1345, 1392 and 1297 $cm^{-1}$ of $C_6D_2Cl_4$ respectively, and assigned the first pair of bands to the ring stretching vibration of species $B_{2u}$, the second to the ring stretching vibration of species $B_{1u}$ and the third to the ring in-plane deformation vibration of species $B_{2u}$.

It appeared somewhat curious that in the region between 1200 and 1000 $cm^{-1}$ we found two bands of $C_6H_2Cl_4$ at 1116 and 1060 $cm^{-1}$, but only one band of $C_6D_2Cl_4$ at 1051 $cm^{-1}$ corresponding to them. The intensities of both of the two bands of $C_6H_2Cl_4$ were too remarkable to be considered as overtone or combination bands. On closer examination of the shape of the band at 1051 $cm^{-1}$ of $C_6D_2Cl_4$, we found the two absorption maxima at 1054 and 1047 $cm^{-1}$ which were not known to be the branches of a single band or to be the peaks of two independent bands. Badger and Zumwalt[3] gave the band envelopes of several types of unsymmetrical rotator molecules. The $\rho$*1 and S values of the molecule of $C_6D_2Cl_4$ are 1.8 and $-0.7$ respectively for which the band envelope is not given in their paper. But the estimation from the different band envelopes described in their paper told us that the splitting of the two maxima would not be greater than 3 $cm^{-1}$.

Dennison[4] also showed that the diagrams of the fine structure of the band, but it was difficult to estimate the splitting of the two absorption maxima from these diagrams. If one approximates the molecule of 1, 2, 4, 5-tetrachlorobenzene by a symmetric rotator*2, the approximate value of the splitting can be found to be about 5 $cm^{-1}$ *3. Actually this splitting distance was found to be about 7 $cm^{-1}$, a little larger than the above-mentioned estimated and calculated values. But such an amount of discrepancy between the observed and calculated (or estimated) values is not enough to favor the supposition that these two absorption maxima would be caused by the two independent bands. However, we shall take this supposing at present, for it appears to explain more easily the correspondence between the absorption bands of each substance. Thus we assigned the band at 1116 and 1060 $cm^{-1}$ of $C_6H_2Cl_4$ to the C–H in-plane bending vibration of species $B_{2u}$ and to the ring deformation vibration of species $B_{1u}$ respectively, and for their corresponding bands of $C_6D_2Cl_4$ we considered that the band at 1047 $cm^{-1}$ of $C_6D_2Cl_4$ corresponds to the former band and the band at 1054 $cm^{-1}$ of $C_6D_2Cl_4$ to the latter.

In the region below 1000 $cm^{-1}$ were found four remarkable bands of each substance, that is, 880, 820, 645 and 509 $cm^{-1}$ for $C_6H_2Cl_4$, and 874, 725, 617 and 504 $cm^{-1}$ for $C_6D_2Cl_4$. Kakiuchi[5] assigned the band at 867 $cm^{-1}$ of $C_6H_2Cl_4$ to the out-of-plane C–H bending vibration. It is evident that this is the band which was observed at 880 $cm^{-1}$ in our experiments*4. But we found in the spectrum of $C_6D_2Cl_4$ a remarkable band at 874 $cm^{-1}$ which evidently corresponds to the band at 880 $cm^{-1}$. It means that the frequency shift caused by the replacement of hydrogen atoms by deuterium atoms is only 6 $cm^{-1}$. This frequency shift is too small for a vibration mainly concerned with the C–H bond. Thus we assigned the band at 820 $cm^{-1}$ to the out-of-plane C–H vibration, for its corresponding band of $C_6D_2Cl_4$ was found at 725 $cm^{-1}$, showing a great frequency shift. But the intensities of these bands appear to be too weak for the out-of-plane C–H and C–D vibrations, and we have not found a plausible explanation for this fact. As for the above-mentioned band at 880 $cm^{-1}$ (874 $cm^{-1}$ for $C_6D_2H_4$) we assigned it to the C–Cl stretching vibration of species $B_{1u}$. And to the other C–Cl stretching vibration which belongs to species $B_{2u}$, we assigned the band at 645 $cm^{-1}$ (617 $cm^{-1}$ for $C_6D_2Cl_4$). The last pair of bands which were found at 509 $cm^{-1}$ (for $C_6H_2Cl_4$) and at 504 $cm^{-1}$ (for $C_6D_2Cl_4$) were assigned to the out-of-plane deformation vibration of the ring. The assignment given above is shown in Table III.

It should be mentioned here that the assignment shown in Table III based on the assumption that the band at 1051 $cm^{-1}$ of $C_6D_2Cl_4$ is composed of two closely positioned independent bands. If not, the assignment should be quite changed as follows.

We regarded the absorption maxima at 1054 and 1047 $cm^{-1}$ observed in the spectrum of $C_6D_2Cl_4$ as the branches of one band which corresponds to the band at 1116 or at 1060 $cm^{-1}$ of $C_6H_2Cl_4$. Then one of these two bands has no corresponding band of $C_6D_2Cl_4$ except the band at 874 $cm^{-1}$. If we consider the band

3) R. M. Badger and L. R. Zumwalt, *J. Chem. Phys.*, **6**, 711 (1938).

*1 Badger and Zumwalt defined $\rho=(a-c)/b$, where $a$, $b$ and $c$ are the reciprocals of three principal moments of inertia, $I_A$, $I_B$ and $I_C$ respectively.

4) D. M. Dennison, *Rev. Mod. Phys.*, 33, 280 (1931).

*2 For this molecule three principal moments of inertia were calculated as $I_A=688\times10^{-40}$, $I_B=1752\times10^{-40}$ and $I_C=2440\times10^{-40}$. Thus the approximation by the symmetric rotator is not very bold.

*3 In this calculation we assumed that $I_B=2000\times10^{-40}$. This is the approximate mean value of the real $I_B$ and $I_C$ values.

5) Y. Kakiuchi, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **80**, 356 (1959).

*4 He used the frequencies observed by Plyler and his collaborators[2]. Those frequencies were observed in the liquid state, so it is quite natural that there are small discrepancies between their frequencies and our frequencies observed in the vapor state.

TABLE III. ASSIGNMENT I

| Species | $C_6H_2Cl_4$ | $C_6D_2Cl_4$ | Mode |
|---|---|---|---|
| $B_{1u}$ | 3094 | 2300 | C-H or C-D stretching |
| | 1436 | 1392 | Ring stretching |
| | 1060 | 1054 | Ring deformation |
| | 880 | 874 | C-Cl stretching |
| | — | — | C-Cl bending |
| $B_{2u}$ | 1474 | 1345 | Ring stretching |
| | 1319 | 1297 | Ring deformation |
| | 1116 | 1047 | C-H or C-D bending |
| | 645 | 617 | C-Cl stretching |
| | — | — | C-Cl bending |
| $B_{3u}$ | 820 | 725 | C-H or C-D bending |
| | 509 | 504 | Ring deformation |
| | — | — | C-Cl bending |

at 874 $cm^{-1}$ of $C_6D_2Cl_4$ as corresponding to the band at 1116 or at 1060 $cm^{-1}$, this great frequency shift suggests that the pair is to be assigned to the C-H (C-D) in-plane bending vibration of species $B_{2u}$. Then there are two possible assignments of the other pair (the band at 1060 or at 1116 $cm^{-1}$ of $C_6H_2Cl_4$ and the band at 1051 $cm^{-1}$ of $C_6D_2Cl_4$), that is, an assignment to the ring deformation vibration and an assignment to the C-Cl stretching vibration of species $B_{1u}$. In the case of this molecule the frequency of the ring deformation vibration of species $B_{1u}$ might be rather low, for it could occur without coupling with a stretching mode of the ring. The frequency of a C-Cl stretching vibration which is generally expected at about 700 $cm^{-1}$ might easily couple with the vibrations of other modes in this case, and its frequency might change over a wide region. From these considerations we concluded that the pair of bands in question is to be assigned to the C-Cl stretching vibration of species $B_{1u}$. Concerning the question as to which of the above-mentioned two bands at 1116 $cm^{-1}$ and at 1060 $cm^{-1}$ of $C_6H_2Cl_4$ is to be assigned to C-H in-plane bending vibration of species $B_{2u}$, we decided to assign the former band to this normal vibration from the consideration of the product rule.

As for the other fundamental bands, we assigned the pair of bands at 509 $cm^{-1}$ ($C_6H_2Cl_4$) and 504 $cm^{-1}$ ($C_6D_2Cl_4$) to the ring in-plane deformation vibration of species $B_{1u}$ and the pair of bands at 645 $cm^{-1}$ ($C_6H_2Cl_4$) and 617 $cm^{-1}$ ($C_6D_2Cl_4$) to the C-Cl stretching vibration of species $B_{2u}$. In addition to the above-mentioned change in the assignment, the correspondence of three pairs of ring stretching vibrations (in the region 1300~1500 $cm^{-1}$) is also changes from the consideration of the product rule as is shown in Table IV.

This is the second assignment which seems to us to be as plausible as the former one. This assignment is shown in Table IV.

TABLE IV. ASSIGNMENT II

| Species | $C_6H_2Cl_4$ | $C_6D_2Cl_4$ | Mode |
|---|---|---|---|
| $B_{1u}$ | 3094 | 2300 | C-H or C-D stretching |
| | 1474 | 1392 | Ring stretching |

| | — | — | Ring deformation |
| | — | — | C-Cl bending |

## Discussion

According to the product rule the theoretical value of the ratio of products of the frequencies is 1.407 for all three species ($B_{1u}$, $B_{2u}$ and $B_{3u}$) in the case of this molecule. As we could not observe all of the fundamental frequencies under our experimental conditions, it was not possible to apply the product rule to the results obtained perfectly, but it was possible to ascertain whether the ratio of products calculated from the observed frequencies alone exceeds the theoretical value or not. We carried out this calculation for every species of both of the above-mentioned assignments. The results are shown in Table V.

TABLE V. CALCULATED RATIOS OF THE PRODUCTS OF OBSERVED FREQUENCIES

| | Species | Calculated ratio | Number of observed frequency |
|---|---|---|---|
| Assignment I | $B_{1u}$ | 1.405 | 4 of 5 |
| | $B_{2u}$ | 1.242 | 4 of 5 |
| | $B_{3u}$ | 1.142 | 2 of 3 |
| Assignment II | $B_{1u}$ | 1.456 | 4 of 5 |
| | $B_{2u}$ | 1.449 | 4 of 5 |
| | $B_{3u}$ | 1.214 | 1 of 3 |

None of the calculated ratios of assignment I exceeded the theoretical value 1.407, while two of the three calculated ratios of assignment II exceed the theoretical values. From the theoretical point of view assignment I shows no contradiction. But on closer examination one will find some points of discussion. In the first place the value of the ratio for species $B_{1u}$ of assignment I is almost equal

to the theoretical value, so the ratio of the unobserved fifth frequencies must be nearly 1. As the fifth frequency is that of the C–Cl bending vibration (or skeletal vibration), this requirement will probably be fulfilled. In the second place those ratios for the species $B_{2u}$ and $B_{3u}$ of the assignment I are so small that the ratios of the last unobserved frequency of these species must be considerably great, that is, 1.144 and 1.232 for the species $B_{2u}$ and $B_{3u}$ respectively. Considering the fact that both of these values are ratios of the frequencies of C–Cl bending vibrations, they are evidently too great to attribute to the single ratios of frequencies. This appears to be an absolute defect of assignment I as well as of the above-mentioned ambiguity in the explanation of the band at 1051 $cm^{-1}$ of $C_6D_2Cl_4$.

As for assignment II, as we mentioned previously, there are two ratios exceeding the theoretical values. However, a discrepancy of a few per cent must be expected between the observed and theoretical ratios, as there are various factors which cause the deviation, such as small mechanical errors of the spectrometer, the unharmonicity of the vibrations, Fermi resonance, etc. Therefore, provided that the ratios of C–Cl bending frequencies are nearly 1, the discrepancies found for species $B_{1u}$ and $B_{2u}$ might not absolutely deny assignment II.

In the case of species $B_{3u}$, since only one of the three frequencies was observed, the application of the product rule was quite impossible. But the ratio of 1.214 obtained for the first pair of frequencies of this species seems to be perfectly plausible for the C–H (or C–D) out-of-plane bending vibration, and this assignment appears to be strongly preferable to that for species $B_{3u}$ of assignment I.

After all, although we could not find an adequate difference between two assignments shown in Table V to draw out any unambiguous conclusion, assignment II seems to us a little more plausible than the other. In order to remove this ambiguity it may be necessary to carry out the measurement of the spectra of these substances in the far infrared region or to observe the precise shape of each fundamental band or to find out the exact force constants which will allow us to calculate the normal frequencies of these molecules with sufficient accuracy.

## Summary

The infrared absorption spectra of ordinary and deuterated 1, 2, 4, 5-tetrachlorobenzenes were measured in the vapor state using the high temperature cell. For the results obtained by the measurements we proposed two possible assignments of the fundamental infrared bands, and made the discussion comparing these two tentative assignments. However, at present we have no experimental base upon which we can decide the superiority of one to the other. In order to solve this difficulty we are going to make an investigation of the spectra of these molecules in the far infrared region as well as the calculation of the exact force constants of the chlorobenzenes.

This work was done at the laboratory of Professor J. Lecomte of the Laboratoire des Recherches Physiques, Faculté des Sciences de Paris. The author acknowledges greatefully Professor Lecomte's encouragement and advice. He also wishes to thank Dr. Leitch of the National Research Council at Ottawa for kindly sending deuterated 1, 2, 4, 5-tetrachlorobenzene prepared by him.

# π Electronic Structure of Cinnamaldehyde

By Kōzō Inuzuka

(Received March 6, 1961)

In two previous papers[1,2] we studied the electronic structure of the acrolein molecule. This molecule has an intense absorption band of $(\pi, \pi^*)$ type in the region near 2000 Å, which was assigned to an intramolecular charge transfer band by Nagakura[3]. Cinnamaldehyde is regarded as a derivative of acrolein, in which a hydrogen atom is substituted by a phenyl group. From this point of view the comparison of the spectra of acrolein and cinnamaldehyde may be interesting.

The absorption spectrum of cinnamaldehyde was measured in *n*-hexane solution in the 2000~3000 Å region. Molecular orbital calculation was made for the π electronic structure of the cinnamaldehyde molecule with a view to understanding its absorption band, as there has scarcely been any theoretical work done on the electronic structure of this molecule.

## Ultraviolet Absorption Spectra

The ultraviolet absorption spectra of cinnamaldehyde and acrolein are shown in Fig. 1.

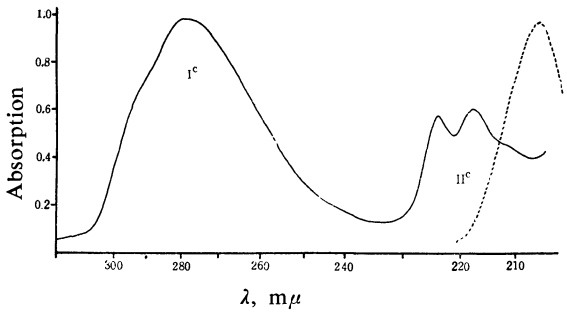

Fig. 1. Ultraviolet absorption spectra of cinnamaldehyde and acrolein.

Solid line: cinnamaldehyde in *n*-hexane
Broken line: acrolein in *n*-hexane

The spectra of these molecules were measured with a Hitachi self-recording quartz spectrophotometer of type E. P. S. The solvent was *n*-hexane carefully purified by the method of Weissberger and Proskauer[4]. It appears that the cinnamaldehyde band is displaced to the red with respect to the acrolein band, owing to the extension of conjugation within the molecule. In order to ascertain that the transition in cinnamaldehyde corresponding to the absorption in the 2000 Å region is of the $\pi-\pi^*$ type, the effect on the spectrum of changing the solvent from *n*-hexane to ethanol was also studied.

## Calculation of Energy Levels

Although the methods of Pariser and Parr[5] and others simplify the calculation of molecular energy levels in very ingenious ways, it is still not easy to apply the theory to a molecule such as cinnamaldehyde. In the present calculation the MO's of cinnamaldehyde were obtained by the simple LCAO-MO method and we took account of the interaction of electrons by including configuration interaction to some extent[6]. As the molecular dimension of cinnamaldehyde is not known, we relied on the structure inferred from the result of the electric dipole moment value by Bently et al.[7] The molecular structure is shown in Fig. 2,

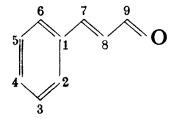

Fig. 2. Cinnamaldehyde.

but in our calculation a somewhat more simplified model was used. Actually cinnamaldehyde has not $C_{2v}$ symmetry, but the orbitals obtained in our approximation are what would be found if $C_1$-$C_7$=$C_8$-$C_9$=O was linear. Thus the cinnamaldehyde MO's may be said to resemble those with $C_{2v}$ symmetry. The MO's of cinnamaldehyde were obtained by the simple LCAO-MO method with neglect of overlap integrals. The Coulomb integral $\alpha_o$ and the resonance integral $\beta_{co}$ are expressed as

$$\alpha_o = \alpha + \delta_o\beta$$

$$\beta_{co} = \rho_{co}\beta$$

Table II. Energies and wave functions for lower excited states of cinnamaldehyde

| Symmetry | Excitation energy, eV. calcd. | Excitation energy, eV. obs. | Wave function | Oscillator strength |
|---|---|---|---|---|
| $B_2^-$ | 4.10 | | $0.946V_{46}-0.326V_{57}$ | 0.000 |
| $A_1$ | 4.11 | 4.41 | $V_{56}$ | 0.806 |
| $B_2^+$ | 5.50 | 5.53 | $0.326V_{46}+0.946V_{57}$ | 0.337 |

where $\alpha=\alpha_c$ and $\beta=\beta_{cc}$. We adopted the values of the parameters $\delta_o=1.5$ and $\rho_{co}=2^{1/2}$ as given by Baba et al.[6] Other Coulomb integrals were assumed to be equal to $\alpha$. The resonance integrals except those of the benzene ring and carbonyl group, were calculated by the approximation generally adopted

$$\beta_{rs}=(S_{rs}/S)\beta$$

were $S_{rs}$ is the overlap integral between neighboring atom r and s, and $S$ the overlap integral for benzene. In Table I the MO energies and orbitals of cinnamaldehyde are given. For the resonance integral values which are necessary for determining the energies of configurations the values given by Goodman and others[8,9]

$$\beta(B_2)=2.98\text{ eV.}$$

$$\beta(A_1)=3.30\text{ eV.}$$

were used. The configuration interaction was considered between those configurations with lower energy and belonging to the same symmetry. The matrix element of the total Hamiltonian $\mathbf{H}$ between the configurations $V_{ik}$ and $V_{jl}$ is given by

$$\int V_{ik}^*\mathbf{H}V_{jl}\,d\upsilon=2[ki|jl]-[kl|ji] \qquad (i\neq j,\ k\neq l)$$

where

$$[ij|kl]=\int\phi_i^*(1)\phi_k^*(2)(e^2/r_{12})\phi_j(1)\phi_l(2)d\upsilon$$

MO's $\phi_i$ are obtained by the simple LCAO procedure neglecting differential overlap. The integral $[ij|kl]$ can be expressed in terms of atomic orbitals as

$$[pp|qq]=\int\chi_p^*(1)\chi_q^*(2)(e^2/r_{12})\chi_p(1)\chi_q(2)d\upsilon$$

For the integrals of this type we employed Pariser and Parr's results[5]. To avoid difficult calculation only the interaction between $V_{46}$ and $V_{57}$ belonging to the same symmetry is considered. In this way the value of the matrix element

$$\int V_{46}^*\mathbf{H}V_{57}\,d\upsilon=0.449\text{ eV.}$$

is obtained. If we assume that there is approximately no interaction between $V_{56}$ and other configurations, the energy of the state represented by $V_{56}$ is calculated directly. The energies of the states resulting from the interaction of $V_{46}$ and $V_{57}$ were obtained including the

8) L. Goodman and H. Shull, *J. Chem. Phys.*, **27**, 1388 (1957).
9) E. G. McRae and L. Goodman, *J. Mol. Spectroscopy*, **2**, 464 (1958).

configuration interaction energy between them as given above. The oscillator strength, $f$, is calculated by the method described by Mulliken and Rieke[10],

$$f=1.085\times10^{11}\times\omega\sum_{r}Q_r^2 \quad (r=x, y, z)$$

where $\omega$ is the frequency of the transition in $cm^{-1}$ and $Q_r$ is the transition moment defined by

$$Q_r=\int\Psi_i^* r \Psi_j \, dv$$

$\Psi_i$ is a state wave function. The results are shown in Table II.

## Discussion

The electronic spectrum of cinnamaldehyde in *n*-hexane solution has three absorption peaks at about 280, 224 and 218 mμ (Fig. 1). Among these three peaks the one at 280 mμ is the strongest, having two weak shoulders near 293 and 300 mμ. In Fig. 3 the orbital energy level

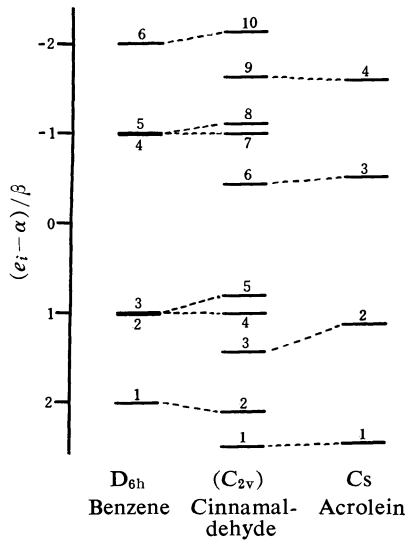

Fig. 3. Orbital energy level diagram.

diagram of cinnamaldehyde is given with those of benzene and acrolein. From this figure the occupied levels 4, 5 and the vacant levels 7, 8 of cinnamaldehyde may be assigned to the degenerate levels 2, 3 and 4, 5 of benzene. The levels 3 and 6 of cinnamaldehyde may be assigned to the levels 2 and 3 of acrolein in ground and upper states, respectively. We assigned the band at 280 mμ (4.41 eV.) to the calculated value 4.11 eV. ($A_1$), because the value of calculated oscillator strength of $A_1$ state is much greater than that of $B_2^-$ state. Therefore, the band at 280 mμ corresponds to the transition from $\phi_5$ to $\phi_6$. In our experiment no band corresponding to the calculated value 4.10 eV. ($B_2^-$) was found. The reason why we could not find the band ($B_2^-$) may be explained by the interpretation that the band ($A_1$) of cinnamaldehyde is displaced to the longer wavelength side by the greater extension of conjugation and covers the band ($B_2^-$). This interpretation conforms with the result of our calculation and with the work of Thomas et al.[11]

It should be mentioned here about the electron distribution associated with $\phi_3$, $\phi_5$ and $\phi_6$ of cinnamaldehyde. Table III shows the

Table III. Distribution of an electron in MO's $\phi_3$, $\phi_5$ and $\phi_6$

| | $\phi_3$ | $\phi_5$ | $\phi_6$ |
|---|---|---|---|
| $C_1^2$ | 0.0931 | 0.1674 | 0.0307 |
| $C_2^2$ | 0.0001 | 0.0824 | 0.0692 |
| $C_3^2$ | 0.1015 | 0.0307 | 0.0039 |
| $C_4^2$ | 0.1987 | 0.1848 | 0.0839 |
| $C_7^2$ | 0.2677 | 0.0750 | 0.2631 |
| $C_8^2$ | 0.1739 | 0.2660 | 0.1096 |
| $C_9^2$ | 0.0002 | 0.0153 | 0.2385 |
| $C_0^2$ | 0.0632 | 0.0651 | 0.1281 |

distribution of an electron occupying the MO's $\phi_3$, $\phi_5$ and $\phi_6$ in terms of squares of coefficients of atomic orbitals. It seems that the excitation of an electron from $\phi_5$ to $\phi_6$ transfers the electronic charge from the benzene ring to the acrolein group. This suggests that the transition from $\phi_5$ to $\phi_6$ corresponds to an intramolecular charge transfer band. In the region of the band II$^e$ there are two peaks at 224 and 218 mμ. Of these the 218 mμ peak is higher than the 224 mμ peak. There may arise a question as to whether or not the two main peaks constituting the band II$^e$ reveal the vibrational structure of an electronic transition, or represent two different transitions. The frequency separation between them is 1230 in *n*-hexane and 1030 $cm^{-1}$ in ethanol solutions, respectively, at room temperature. The change of 200 $cm^{-1}$ is too great. It may be reasonable to interpret the two peaks as two different transitions. The band at 224 mμ (5.53 eV.) may be assigned to the calculated excitation energy 5.56 eV. ($B_2^+$), and may correspond to the $A_{1g}$-$B_{2u}$ transition in benzene.

On the other hand, from the energy level diagram Fig. 3, we tentatively assign the band at 218 mμ (5.69 eV.) to a transition $V_{36}$ which has the lowest energy among the transitions $V_{36}$, $V_{58}$, $V_{47}$ and $V_{48}$. The transition energies for them are directly obtained from the

10) R. S. Mulliken and C. A. Rieke, *Rep. Progr. Phys.*, **8**, 231 (1941).

orbital energies in Table I, this is, $1.858\beta$, $1.932\beta$, $2.000\beta$, $2.117\beta$. Since cinnamaldehyde has in reality no $C_{2v}$ symmetry and the energies of these configurations are close to each other, the configuration interaction between them must be taken into consideration in order to ascertain the above assignment for $V_{36}$. For simplicity only the interaction is here considered between configurations of apparently the same symmetry type. Accordingly, the interaction between $V_{36}$, $V_{58}$ and $V_{47}$ is taken into consideration. The state energies for them were calculated including configration interaction. The results of the calculation are shown in Table IV. The calculated value for $V_{36}$ is

TABLE IV. EXCITATION ENERGIES FOR LOWER EXCITED STATES OF CINNAMALDEHYDE

| | $(m_i-m_j)\beta$ eV. | Including C. I. | Obs. |
|---|---|---|---|
| $V_{36}$ | 6.13 | 5.53 | 5.69 |
| $V_{58}$ | 6.38 | 6.22 | |
| $V_{47}$ | 6.60 | 7.37 | |

in good agreement with the observed value within present approximation. The calculated value 5.53 eV. for $V_{36}$ conforms rather with the band at 224 m$\mu$ (5.53 eV.), but we may tentatively assign the transition from $\phi_3$ to $\phi_6$ to the band at 218m$\mu$ within the present approximation. Since the orbitals $\phi_3$ and $\phi_6$ of cinnamaldehyde correspond to the orbitals $\phi_2$ and $\phi_3$ of acrolein in Fig. 3, it may be said that the 218 m$\mu$ band corresponds to the transition in the substituent group.

## Summary

State energies of the cinnamaldehyde molecule are calculated by the simple LCAO-MO method, including configuration interaction and assuming the $C_{2v}$ symmetry. The results of the calculation conform well with the observed absorption bands lying in the 2000~3000Å region. In cinnamaldehyde the 280 m$\mu$ band is assigned to the intramolecular charge transfer band. The $B_2^-$ band which we could not find in spectrum of cinnamaldehyde may be covered under the charge transfer band which is greatly shifted toward the red as the result of extension of conjugation. In the region of the band II$^c$ two peaks at 224 and 218 m$\mu$ represent two different transitions, respectively. The former is assigned to the $B_2^+$ type transition and the latter to the transition in the acrolein group.

The author expresses his sincere thanks to Professor Sunao Imanishi and Dr. Yoshiya Kanda for their encouragement throughout this work. He thanks also Dr. Rhōichi Shimada and Mr. Akira Sadō for their kind advice.

# *The Diamagnetic Susceptibility of Benzoate, Salicylate, Propionate, Butyrate and Succinate Ions*

By S. SRIRAMAN and S. THIRUVENGADATHAN

(Received February 9, 1961)

Magnetic susceptibilities of simple ions were evaluated by a number of workers. The importance of such a study was clearly brought out by the work of Hoare and Brindley[1], Varadachari[2] and Subramaniam[3]. In the present investigation a few alkali and alkaline earth compounds containing benzoate, salicylate, propionate, butyrate and succinate radicals have been studied in the solid state and the susceptibilities of the anions calculated assuming the previously accepted values for the cations.

## Experimental

The substances used were mostly either Merck's G. R. or B. D. H., A. R. and a few whose purity was not definite were recrystallized befor use. The salts were all found to be free from ferromagnetic impurities. Great care was taken to prevent the solids from absorbing atmospheric moisture and where this tendency existed the salts were analyzed for the moisture content by gravimetric methods and kept in vacuum desiccator before use.

Measurements of the susceptibilities of the acids

1) F. E. Hoare and G. W. Brindley, *Proc. Roy. Soc.*, **147A**, 88 (1934).
2) P. S. Varadachari, *Proc. Ind. Acad. Sci.*, **2A**, 16 (1935).
3) K. C. Subramaniam, ibid., **4A**, 404 (1936).

and their salts were made with a Curie balance. The retorsion method[4] was employed. A correction for the displaced air was applied for every bulb. For every salt and acid more than half a dozen bulbs containing different masses of the salts were examined at three field currents, viz. 4, 5 and 6 amp. Benzene (B. D. H., A. R. grade) was used as the standard and its specific susceptibility was taken as 0.702*. The susceptibilities of the salts were calculated from the usual formula.

$$\frac{\theta_S}{\theta_B} = \frac{m_S\chi_S - K_a v_S}{m_B\chi_B - K_a v_B}$$

Here $\theta_S$, $\theta_B$ and $m_S$, $m_B$ represent the deflections for and the masses of, the substance and benzene respectively; $v_S$ and $v_B$ represent the volume of the air displaced by the substance and benzene respectively. $K_a$ refers to the paramagnetic susceptibility of air at the room temperature. Its value at N. T. P. is $0.029\times10^{-6}$ (I. C. T. 6, 354, 1929) and its value at the room temperature (30°C) was found from the relation $K_a/T^2$ is constant where $K_a$ is the susceptibility of air at absolute temperature $T$°K.

## Results

The susceptibilities obtained for the acids and their salts are recorded in Table I. For the evaluation of ionic susceptibilities of the anions under investigation, Flordal and Frivold's[5] values derived from salts in dissolved

TABLE II. SUSCEPTIBILITIES OF THE CATIONS

| Ion | $Na^+$ | $K^+$ | $Ca^{2+}$ | $Sr^{2+}$ | $Ba^{2+}$ |
|---|---|---|---|---|---|
| $\chi_{ion}$ | 6.90 | 15.00 | 8.80 | 18.30 | 29.30 |

state for $Na^+$, $K^+$, $Ca^{2+}$, $Sr^{2+}$ and $Ba^{2+}$ are used and these are given in Table II for ready reference.

The susceptibilities of the anions are evaluated using Pascal's law. Also the acid values were taken to represent the value of the corresponding ion on the assumption that $H^+$ does not contribute anything[14]. The mean values obtained for the anions under study are given in Table III.

TABLE III. IONIC SUSCEPTIBILITIES

| Ion | Mean value from salts | $\chi_{ion}$ from acid | Mean |
|---|---|---|---|
| Benzoate $C_7H_5O_2^-$ | 69.11 | 71.27 | 70.19 |
| Salicylate $C_7H_5O_3^-$ | 75.17 | 73.59 | 74.38 |
| Propionate $C_3H_5O_2^-$ | 44.39 | 43.67 | 44.03 |
| Butyrate $C_4H_7O_2^-$ | 49.74 | 54.15 | 51.95 |
| Succinate $C_4H_4O_4^{2-}$ | 55.68 | 56.73 | 56.21 |

## Discussion

The general method adopted for the evaluation of the ionic susceptibilities is on the basis that the molar susceptibility of a heteropolar salt is the sum of the constituent ions. The data available on the subject show that in the case of several ions, the values given by different authors differ sometimes by large amounts. Bhatnagar and co-workers[15] and Mata Prasad and co-workers[10] have followed a statistical method in which they subtracted all the known values of the susceptibilities of anions from the molar susceptibilities of a number of salts of a cation and took the arithmetical mean of the values thus obtained as the correct value for the cation. Kido[12], Joos[16] and Ikenmeyer[17] have observed that a linear relation exists between the susceptibilities of ions of chemically related elements belonging to the same group of the periodic table and their atomic numbers. This method of evaluation of the ionic susceptibilities has been questioned by Trew[18] and Selwood[19] on the ground that it is open to theoretical objection. Mata Prasad and co-workers[10] have followed Kido's[12] suggestion. Their results show that the susceptibility values of the anions deduced from the salts of Li, Na, K etc., are distinctly different from those deduced from the salts of Ca, Sr and Ba. This difference is large in some cases and small in others. If the linear relation is assumed then the assignment of ionic value could be done by measuring the molar susceptibilities of only two salts containing the cations of the same column of the periodic table.

When two ions combine there is every likelihood of a deformation taking place in both the ions. It is quite possible that the degree of deformations in ions may be different for the different groups of cations. To what extent this will affect the susceptibility of the anions is a question which is worth considering. On the basis of Pascal's additive law[11] the $\chi$ of anions can be calculated assuming the values of alkali and alkaline earth metallic ions. In Table IV this calculation has been made with the values obtained by Mata Prasad and co-workers[10], Rao and Sriraman[20] and Venkateswarlu and Sriraman[9] for formate, acetate and oxalate ions.

The anion values given in Table IV show definitely that they do not change abruptly as we pass from one group of metallic ions to another. All the values are of the same order subject to the error in the measurements of the susceptibility of the salts.

It is interesting to compare these values for a few typical ions with the values (Table V) obtained by Prasad and others by graphical method on the basis of linearity. For four ions the values from alkali salts are larger than from alkaline earth salts, for the last two ions the change is the other way about and for the oxalate ion no change is observed. If the values of the various ions are calculated from their own measurements on the basis of additivity, such marked variations are not found. Considering the graphical method adopted, Trew[18] has definitely pointed out that the graphs do not show linearity and the points do not lie on a single straight line. Our results in the present investigation also confirm this point. The linearity may be approximately true in a very few cases as Kido[12] found but it is certainly not applicable in all cases. The large amount of literatures available on the subject and the convincing facts brought out by Trew[18] show that the additivity method

# *Refractometric Study of Some Cyano and Oxalato Complex Anions*

By Yoshio MATSUNAGA*

(Received February 20, 1961)

The molar refraction of simple salts, particularly in the dissolved state, has been studied extensively by Fajans and others; however, little attention has been paid to that of complex salts. It seemed of great interest to examine the following two effects based on this physical quantity;

(1) polarization effect; the decrease of mobility of electrons in ligands due to the field of a central metal ion, and

(2) delocalization effect; the increase of mobility of electrons by the formation of $\pi$-bonds.

The former effect is expected to contribute to the decrease of molar refraction and the latter to the increase. With this hope we studied the molar refraction of some cyano and oxalato complex salts. Because of the high polarizability and the great ability for $\pi$-bond formation of ligand, cyano complex anions of the inner orbital type were chosen to demonstrate the above-mentioned two effects. On the other hand, oxalato complex anions are of the outer orbital type and the interaction between the constituents may not be very strong.

## Experimental

**Materials.**—They were prepared by the methods described in the references cited. $K_3Cu(CN)_4$, prepared from cupric sulfate and potassium cyanide, and dried at 150°C[1]. $K_2Zn(CN)_4$, prepared from zinc sulfate and potassium cyanide, and dried at

* Present address: Cyanamid European Research Institute, Cologny, Geneva, Switzerland.

105°C[2]. $K_2Cd(CN)_4$, prepared from cadmium sulfate and potassium cyanide, and dried at 105°C[1]. $K_2Hg(CN)_4$, prepared from mercuric cyanide and potassium cyanide, and dried at 80°C[1]. $K_3Cr(CN)_6$, prepared from potassium dichromate and potassium cyanide, and dried at 100°C[3]. $K_3Mn(CN)_6$, prepared from potassium cyanide and manganese(III) phosphate[3]. $K_3Fe(CN)_6$ and $K_4Fe(CN)_6$, Dog brand guaranteed reagents supplied by Koso Chemical Co., Ltd. Tokyo. $K_3Co(CN)_6$, prepared from cobalt chloride and potassium cyanide[3]. $K_2Ni(CN)_4$, prepared from nickel sulfate and potassium cyanide, and dried at 105°C[3]. $K_3Al(C_2O_4)_3 \cdot 3H_2O$, prepared from aluminum sulfate, potassium oxalate and oxalic acid[4]. $K_3Fe(C_2O_4)_3 \cdot 3H_2O$, prepared from ferric sulfate, barium oxalate, and potassium oxalate[4]. $K_2C_2O_4 \cdot H_2O$, prepared from oxalic acid and potassium carbonate.

**Measurements.**—The refractive index $n$ of aqueous solutions was measured with a Pulfrich refractometer using the NaD line. The density $d$ of the same solution was determined with Ostwald's pycnometers of about 10 cc. Most salts involved in this study are easily soluble in water, so that a concentration higher than three per cent by weight was applied. The specific refraction $r$ of the respective solution was calculated from these data using the Lorentz-Lorenz formula,

$$r=(n^2-1)/(n^2+2)\times 1/d$$

The molar refraction $R$ of the dissolved salt was derived from this specific refraction by the application of the additivity rule,

$$R=MW[r(\text{soln.})-(100-w)\times r(\text{water})]/w$$

where $w$ is the concentration of salt and $MW$ is the molecular weight. The value $R$ was found to be independent of concentration in the measured range.

TABLE I. MOLAR REFRACTION OF COMPLEX SALTS

| | Molar refraction, cc. | | |

c The values of density were taken from Ref. 1, and those of refractive index from Ref. 7 except that for $K_3Cu(CN)_4$.
d Refractive indices were taken from Ref. 8.

## Results and Discussion

In Table I are presented our observed values of molar refraction of the complex salts in the dissolved state together with a few recorded values and also some estimated values for the crystalline salts. The molar refraction of aqueous complex anion was estimated, assuming that the contributions of cation and anion are additive. The value for aqueous $K^+$ ion was taken as 2.255 cc.[9] The molar refraction of aqueous ions is generally smaller than that of gaseous ions. For example the values: 0.20, 0.50 and 0.28 cc. were given by Fajans and Joos for gaseous $Li^+$, $Na^+$ and $Mg^{2+}$ ions, respectively[10]. On the other hand, they gave −0.42, +0.200 and −1.57 cc. for the above-mentioned ions in the dissolved state. The difference between the values in the two states can be ascribed to the polarization, or the decrease of mobility of electrons in water molecules by the electrostatic force due to the cation concerned. Great polarizing power is expected from small ions of high valency. The negative values assigned to aqueous $Li^+$ and $Mg^{2+}$ ions arise from the large polarization effect on the water molecules in the hydration sphere. However, the magnitude of this effect in hydrated ions seems to be too small and inaccurate to be discussed quantitatively. The size of complex anions is much larger than that of simple ions, therefore we may consider that the molar refraction of aqueous complex anion is approximately equal to that of gaseous complex anion.

We assume that the molar refraction of complex anions is given by the sum of the following three terms:

(1) The sum of the molar refractions of the constituents in the gaseous state. The term $A$ in Table II gives the molar refraction of the imaginary complex anion in which there is neither metal-ligand nor ligand-ligand interaction.

(2) The contribution of polarization of ligands: the term $P$ in Table II. The ligand-ligand interaction may be ignored because of the rather large size of cyanide and oxalate ions. Therefore, the magnitude of this term may be assumed to be proportional to the polarizing power of central metal ion; namely to the valency of metal ion and to the reciprocal of the square of metal-ligand distance.

(3) The contribution of delocalization of electrons by the formation of $\pi$-bonds: the term $D$ in Table II. The magnitude of this term may depend on the configuration of complex ion and the number of available electrons.

Table II. Molar refraction of complex anions

| Anion | $R$ for anion cc. | $A$, cc. (additive) | $P$, cc. (polarization) | $D$, cc. (delocalization) |
|---|---|---|---|---|
| $Cu(CN)_4^{3-}$ | 40.1 | 34.7 | − 6.4 | 11.8 |
| $Zn(CN)_4^{2-}$ | 33.3 | 34.3 | −12.8 | 11.8 |
| $Cd(CN)_4^{2-}$ | 35.4 | 36.3 | −12.8 | 11.9 |
| $Hg(CN)_4^{2-}$ | 38.6 | 36.7 | −12.8 | 14.7 |
| $Cr(CN)_6^{3-}$ | 48.8 | 50.9 | −16.5 | 15.4 |
| $Mn(CN)_6^{3-}$ | 54.3 | 50.9 | −16.5 | 20.9 |
| $Fe(CN)_6^{3-}$ | 54.4 | 50.9 | −16.5 | 21.0 |
| $Fe(CN)_6^{4-}$ | 58.2 | 51.1 | −11.0 | 19.1 |
| $Co(CN)_6^{3-}$ | 52.5 | 50.9 | −16.5 | 19.1 |
| $Ni(CN)_4^{2-}$ | 37.6 | 34.3 | − 8.7 | (12) |
| $Al(C_2O_4)_3^{3-}$ | 52.8 | 54.1 | − 1.3 | 0 |
| $Fe(C_2O_4)_3^{3-}$ | 59.7 | 54.5 | − 1.3 | 6.5 |

The molar refraction of gaseous cyanide ion was estimated to be 8.40 cc. based on the value observed for potassium cyanide in the dissolved state[11] and that of gaseous oxalate ion 18.0 cc. similarly. Pauling has given the following values for gaseous cations; $Cu^+$ 1.08, $Zn^{2+}$ 0.72, $Cd^{2+}$ 2.74, $Hg^{2+}$ 3.14 and $Al^{3+}$ 0.136 cc.[12] We assumed 0.7 cc. for $Ni^{2+}$ and $Fe^{2+}$ ions and 0.5 cc. for trivalent ions of the first transition metals. The terms $A$ given in Table II were calculated using these values. It must be noted that the values of tetrahedral complex anions are in good agreement with the observed molar refractions except in the case of $Cu(CN)_4^{3-}$ ion, However, as is shown in the following paragraph, this agreement arises from the compensation between the terms $P$ and $D$.

For the estimation of the term $P$ we must know the distance between ligand and central metal ion. Only the following values are available; Zn–CN (center) 2.61, Cd–CN 2.67 and Hg–CN 2.65 Å[13]. We may assume that the required distances are the same in the series of tetrahedral cyano complex anions including $Cu(CN)_4^{3-}$. The maximum error arising from this assumption may not be more than 10 per cent of the term $P$ or about 1 cc., as seen in Table II. The positive charge on central metal ion is mostly neutralized as a result of polarization of ligands. The magnitude of the term $D$ for the isoelectronic $Cu(CN)_4^{3-}$ and $Zn(CN)_4^{2-}$ ions may be assumed to be roughly the same. Therefore, the chief difference between the two is that of the valency of the central metal ions, and the term $P$ for $Cu(CN)_4^{3-}$ ion may be about one half of that for $Zn(CN)_4^{2-}$ ion. Consequently the difference between $(A-R)$ for $Zn(CN)_4^{2-}$ ion and that for $Cu(CN)_4^{3-}$ ion gives the magnitude of the term $P$ for the latter. The term $P$ estimated for $Zn(CN)_4^{2-}$ ion was assumed to be applicable to the other two tetrahedral complex anions. The $Cu(CN)_4^{3-}$ ion has been known to dissociate appreciably in dilute solution[14]. However, we ignored this fact in our treatment of molar refraction because rather concentrated solutions were used for our measurements.

For octahedral cyano complex anions the isoelectronic ions $Fe(CN)_6^{4-}$ and $Co(CN)_6^{3-}$ were used for the basis of discussion. We assumed again that the distance between metal ion and ligand is nearly constant in these five complex anions, therefore the term $P$ for $Fe(CN)_6^{4-}$ ion may be about two thirds of that for $Co(CN)_6^{3-}$ ion and the term $D$ for this pair may be roughly the same. The term $P$ estimated for $Co(CN)_6^{3-}$ ion was applied to the other trivalent cyano complex anions.

The contribution of polarization effect on a cyanide ion was found to be about 1.6 cc. per unit charge on central metal ion for tetrahedral anions and about 0.9 cc. per unit charge for octahedral ones. The similar polarization found in the reaction,

$$H^+ + CN^- \rightarrow \text{gaseous HCN } (6.47\,\text{cc.})^{15}$$

1.93 cc. may be compared with the above two estimations. As the mutual repulsion of cyanide ions in a complex anion must be weaker in a tetrahedral configuration than in an octahedral one, the cyanide ions in the former are closer to the central metal ion than those in the latter. Therefore, the observed order of polarization of a cyanide ion; HCN > tetrahedral complex anion > octahedral complex anion seems to be reasonable. The contribution of electron-delocalization to molar refraction was estimated to be around 3 cc. per cyanide ion for both tetrahedral and octahedral complex

anions. The term $P$ for the square planar $Ni(CN)_4^{2-}$ ion was obtained using a value of $4\times3$ cc. for its term $D$, and the polarization of a cyanide in per unit charge in this anion seems to be nearly the same as that for octahedral complex anions.

In the case of oxalato complex anions, the observed molar refraction of $Al(C_2O_4)_3^{3-}$ ion, in which the aluminum ion has no $d$-electron for $\pi$-bonding, is only slightly smaller than its term $A$ or we may say in agreement with its term $A$ within the limit of estimations. This agreement suggests that the polarization of the oxalate ions by the field of the aluminum ion is very small. The term $D$ for $Fe(C_2O_4)_3^{3-}$ ion was found to be about 6.5 cc. This value is much less than that for cyano complex anions of the inner orbital type.

TABLE III. COMPARISON BETWEEN MOLAR REFRACTION AND MOLAR VOLUME OF CYANO COMPLEX ANIONS

| Anion | Molar refraction cc. | Molar volume[a] cc. |
|---|---|---|
| $Cu(CN)_4^{3-}$ | 40.1 | 93 |
| $Zn(CN)_4^{2-}$ | 33.3 | 118 |
| $Cd(CN)_4^{2-}$ | 35.4 | 128 |
| $Hg(CN)_4^{2-}$ | 38.6 | 126 |
| $Cr(CN)_6^{3-}$ | 48.8 | 135 |
| $Mn(CN)_6^{3-}$ | 54.3 | — |
| $Fe(CN)_6^{3-}$ | 54.4 | 129 |
| $Fe(CN)_6^{4-}$ | 58.2 | 126 |
| $Co(CN)_6^{3-}$ | 52.5 | 129 |
| $Ni(CN)_4^{2-}$ | 37.6 | 98 |

a These values were taken from Ref. 1.

Recently Hieber and his collaborators have discussed the molar volumes of some complex cyano anions[16,17]. They have observed the following series of molar volumes for the isoelectronic anions with the configuration of rare gas type,

$$Zn(CN)_4^{2-} > Cu(CN)_4^{3-} > Ni(CN)_4^{4-}$$

and $$Co(CN)_6^{3-} > Fe(CN)_6^{4-} > Mn(CN)_6^{5-}$$

and concluded that the decrease of molar volume can be correlated with the increasing double bond character of metal-carbon bonds. The importance of polar structures as the determining factor was also pointed out for the molar volume of anions of non-rare gas type. Although molar refraction is a measure of size of complex anion, these two physical quantities have no simple correlation as seen in Table III. For the pairs of isoelectronic complex anions; $Cu(CN)_4^{3-}$ and $Zn(CN)_4^{2-}$, and $Fe(CN)_6^{4-}$ and $Co(CN)_6^{3-}$, the molar refractions were found in the reverse order to the molar volumes.

**Summary**

The molar refractions of ten cyano and two oxalato complex salts were measured in the dissolved state using the NaD line. The molar refractions of complex anions were assumed to be given by the sum of (1) the molar refractions of the ligands and the central metal ion in the gaseous state, (2) the polarization of the ligands due to the field of the central metal ion, and (3) the delocalization of electrons by the metal-ligand $\pi$-bonding. The estimation of each term was attempted on the assumption that the chief difference between isoelectronic anions, for example $Cu(CN)_4^{3-}$ and $Zn(CN)_4^{2-}$, is that of the valency of the central metal ions and the contribution of delocalization is roughly the same in such a pair. The polarization of a cyanide ion was found to be about 1.6 cc. per unit charge of metal ion for tetrahedral anions and about 0.9 cc. for octahedral ones. The contribution of $\pi$-bonding was estimated to be around 3 cc. per metal-ligand bond for both of the above-mentioned cyano complex anions. The small polarization and delocalization effects were observed in the case of oxalato complex anions.

The author wishes to express his hearty thanks to Professors Eiichi Minami and Shizuo Fujiwara for their interest and encouragement.

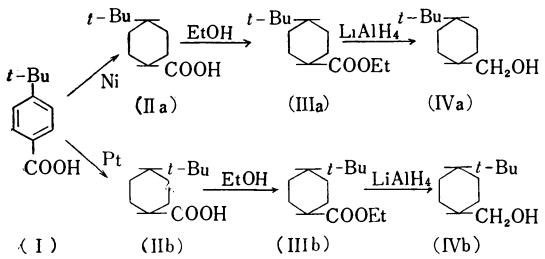
# *The Preparation of cis- and trans-4-tert-Butylcyclohexyl-1-carbinols*



By Nobuo MORI

(Received March 18, 1961)

In the course of the investigation[1] concerning the conformation of a toluenesulfoxymethyl group directly bound to a cyclohexane ring, it was found to be desirable to study *cis*- and *trans*-4-*tert*-butylcyclohexyl-1-carbinyl *p*-toluenesulfonates.

The present work relates to a process for the preparation of the hitherto unknown *cis*- and *trans*-4-*tert*-butylcyclohexyl-1-carbinols and their *p*-toluenesulfonates.

The *cis*- and *trans*-carbinols have now been prepared from 4-*tert*-butylbenzoic acid by hydrogenating them over platinum oxide in acetic acid and over Raney nickel in neutral aqueous medium, respectively. The resulting *cis*- and *trans*-4-*tert*-butylhexahydrobenzoic acids were converted into their ethyl esters which were treated with lithium aluminum hydride to give the *cis*- and *trans*-carbinols respectively, and they were converted into the *p*-toluenesulfonates. The process carried out is shown in the following scheme.

*tert*-Butylbenzoic acid (I) used as starting material was obtained by reacting dry benzene with *tert*-butyl alcohol over aluminum chloride[2], brominating the resulting *tert*-butylbenzene with bromine over iron powder[3] and treating a Grignard reagent of the 4-*tert*-butylbromobenzene with carbon dioxide according to the method[4] for the conversion of *tert*-butyl chloride into *tert*-butylacetic acid.

The hydrogenation of substituted benzene compounds in neutral medium with Raney nickel generally gives thermodynamically stable hydrogenated benzene compounds as main products and on the contrary in acetic acid with platinum oxide less stable stereoisomers. For example, the hydrogenation[1,5] of 4-methyl- or isopropylbenzoic acid over Raney nickel gives mainly the corresponding *trans*-hexahydrobenzoic acid melting at a higher temperature and over platinum oxide the corresponding cis-isomer melting at a lower temperature. The hydrogenation of the 4-isopropylbenzoic acid by either of the above methods does not proceed so readily as with the 4-methylbenzoic acid. The 4-methylbenzoic acid is completely hydrogenated with Raney nickel under an initial pressure of 90 atm. at 180~200°C in 2 hr. to give the hexahydrobenzoic acid, while the hydrogenation of the isopropylbenzoic acid[5] is effected under 150~200 atm. 200°C for 4~5 hr. On the other hand, the hydrogenation[1,5] of the methyl- and isopropylbenzoic acids with platinum oxide is completed under atmospheric pressure in 2~4.5 and 6 hr., respectively.

In the present work, the butylbenzoic acid (I) was hydrogenated in a neutral aqueous solution with Raney nickel under an initial pressure of 90 atm. 250~260°C in 5 hr., although the uptake of hydrogen was not complete and this reaction was probably accompanied by hydrogenolysis, and the *trans*-hexahydrobenzoic acid melting at 175~176°C after recrystallization was obtained in a 40% yield. On the other hand, the butylbenzoic acid (I) was not hydrogenated in acetic acid with platinum oxide within 4 hr. at 60~70°C under atmospheric pressure, but the uptake of hydrogen was very readily and completely effected under an initial pressure of 60 atm. at about 100°C in 1 hr. and the *cis*-hexahyrobenzoic acid (IIb) was obtained as scales, m. p. 115~117°C after recrystallization, in a good yield. The difficulty in hydrogenation of these 4-alkylbenzoic acids increases as the alkyl group goes from methyl to *tert*-butyl. These acids were converted into their anilides by the method without the danger of isomerization.

The above acids were converted into their ethyl esters by refluxing in ethyl alcohol with a small amount of sulfuric acid in a short

These trans- and cis-esters IIIa and IIIb were converted into the corresponding carbinols IVa and IVb by treatment with lithium aluminum hydride, according to the method[1] for the conversion of the isomeric 4-methylhexahydrobenzoic acid ethyl esters into their carbinols. It is well known that hydrogenolysis of esters with lithium aluminum hydride proceeds with complete retention of configuration while that with sodium in alcohol and over copper chromite catalyst proceeds with some isomerization. The purified *cis*-carbinol is in needles melting at 56~57°C and the trans-isomer is in needles of m. p. 25~27°C. The refractive index and the density of the *cis*-carbinol which was in a super-cooled liquid form before purification are higher than those of the super-cooled *trans*-carbinol, as shown in Table II, which also includes those of 4-methyl- and isopropyl-cyclohexyl-1-carbinols for comparison, and this fact is in accordance with the Auwers-Skita rule[7].

## Experimental

**4-*tert*-Butylbenzoic Acid (I).**—A Grignard reagent solution was prepared in the usual way by adding dropwise 4-*tert*-butyl-bromobenzene (70 g.) in dry ether (200 cc.) to magnesium strips (8 g.) covered with ether (50 cc.) while warming on steam bath and stirring. The solution was cooled to −15~−10°C in an ice-salt bath and then treated with a stream of dry carbon dioxide until the temperature rose no more. The reaction mixture was decomposed with dilute sulfuric acid and the ethereal layer was washed with aqueous sodium hydroxide solution. The aqueous layer separated was acidified with concentrated hydrochloric acid to give an acid product which melted at 163~164.4°C (lit.[2] 164°C) after one recrystallization from aqueous methanol.

***trans-tert*-Butylhexahydrobenzoic Acid (IIa).**—A solution (pH=8.0) of the butylbenzoic acid (12 g.) in 7% sodium hydroxide solution was hydrogenated in the presence of Raney nickel (6 g.) under an initial pressure of 90 atm. at 250~260°C. The reaction was stopped after 5 hr. although the uptake of hydrogen was not complete. After removal of the catalyst, the solution was acidified with concentrated hydrochloric acid and the precipitated material (10 g.) was repeatedly recrystallized from aqueous methanol to give the pure *trans*-hexahydrobenzoic acid (3 g.) as plates, m. p. 175~176°C (lit.[8] 174°C).

Found: C, 71.8; H, 10.9. Calcd. for $C_{11}H_{20}O_2$: C, 71.7; H, 10.9%.

A part of the acid was converted into an anilide by refluxing for 10 min. with one equivalent each of thionyl chloride and pyridine in dry benzene and then for 2 min. with two equivalents of aniline. Recrystallization of the anilide from aqueous ethanol readily gave fine plates, m. p. 139.5°C.

Found: N, 5.6. Calcd. for $C_{17}H_{25}ON$: N, 5.4%.

***cis-tert*-Butylhexahydrobenzoic Acid (IIb).**—A solution of the butylbenzoic acid (10 g.) in purified glacial acetic acid (60 cc.) was hydrogenated with platinum oxide (0.5 g.) under an initial pressure of 60 atm. at 90~100°C until no more hydrogen was absorbed. After removal of the catalyst and the solvent, the crystalline residue was taken up in a small volume (about 20 cc.) of petroleum ether and the undissolved parts were filtered off. The filtrate was concentrated and cooled. The separated plates were filtered off and recrystallized repeatedly from aqueous methanol to give the pure *cis*-hexahydrobenzoic acid (6 g.) as scales, m. p. 115~117°C (lit.[8] 116°C).

Found: C, 71.7; H, 10.6. Calcd. for $C_{11}H_{20}O_2$: C, 71.7; H, 10.9%.

The anilide of the cis-acid was obtained by the method used for the trans-acid as long needles from aqueous methanol and ligroin, m. p. 191°C which was depressed to 124~127°C on admixture with the trans-anilide.

Found: N, 5.6. Calcd. for $C_{17}H_{25}ON$: N, 5.4%.

8) Eliel and Acharya reported that the acids were first obtained by Stolow, but the details of preparation are not described. See E. L. Eliel and R. V. Acharya, *J. Org. Chem.*, **24**, 151 (1959).

**Ethyl *trans*-*tert*-Butylhexahydrobenzoate (IIIa).**—The trans- acid (3 g.) was refluxed in ethanol (30 cc.) with concentrated sulfuric acid (0.5 cc.) for 2 hr. After concentration of the reaction mixture, the residue was taken up in ether, washed with water, 10% sodium carbonate solution and then water, dried with sodium sulfate and concentrated. The residue was distilled under reduced pressure to give the ethyl ester (3 g.) which boiled at 125~137°C (mainly 135~136°C)/25 mmHg and had $n_D^{20}$ 1.4522. Redistillation gave the pure ester which had b. p. 146~148°C/29 mmHg, $n_D^{20}$ 1.4515 $d_4^{20}$ 0.9282 and $MR_D$ 61.70 (Calcd. 61.69).

**Ethyl *cis*-*tert*-Butylhexahydrobenzoate (IIIb).**—The cis- acid (3.5 g.) gave similarly the cis-ethyl ester (3.5 g.) which, after redistillation, had b. p. 134~137°C/28 mmHg, $n_D^{20}$ 1.4593, $d_4^{20}$ 0.9400 and $MR_D$ 61.74 (Calcd. 61.69).

***trans*-*tert*-Butylcyclohexylcarbinol (IVa).**—The trans-ester (2.5 g.) in dry ether (30 cc.) was added dropwise to a suspension of lithium aluminum hydride (1.0 g.) in dry ether (60 cc.) at 0~5°C and the reaction mixture was stirred for another hour. This mixture was then treated with a small amount of cold dilute sulfuric acid until the ether layer was clear and then filtered. The filtrate and washings of the filter cake were combined, dried with potassium carbonate and concentrated. The residue was distilled to give the carbinol (1.8 g.) as a viscous oil which had b. p. 140~140.5°C/28.5 mmHg, $n_D^{20}$ 1.4683, $d_4^{20}$ 0.9092, $MR_D$ 52.13 (Calcd. 52.32), which solidified in a refrigerator and melted at 25~27°C.

Found: C, 77.5; H, 12.9. Calcd. for $C_{11}H_{22}O$: C, 77.6; H, 13.0%.

The carbinol (1.1 g.) was treated with *p*-toluenesulfonyl chloride (1.5 g.) in dry pyridine (5 cc.) by the usual way[1] at 0~5°C and allowed to stand overnight in a refrigerator with occasional shaking. The mixture was poured into a mixture of ice and concentrated hydrochloric acid. The separated crystalline solid was filtered off and recrystallized twice from aqueous ethanol to give the *trans*-*p*-toluenesulfonate (1.4 g.) as needles, m. p. 83~84°C.

Found: C, 66.8; H, 8.6. Calcd. for $C_{18}H_{28}O_3S$: C, 66.6; H, 8.66%.

***cis*-*tert*-Butylcyclohexylcarbinol (IVb).**—A similar treatment of the cis-ester (3.0 g.) with lithium aluminum hydride (1.2 g.) gave the *cis*-carbinol (1.4 g.) as a viscous oil, b. p. 133~136°C/27 mmHg, $n_D^{20}$ 1.4781, $d_4^{20}$ 0.9243 and $MR_D$ 52.16 (Calcd. 52.32), which soon partially solidified on being allowed to stand in a refrigerator. The semi-solid mass was pressed on a porous tile and recrystallized from aqueous ethanol to give the pure *cis*-carbinol as long needles, m. p. 56~57°C.

Found: C, 78.2; H, 12.8. Calcd. for $C_{11}H_{22}O$: C, 77.6; H, 13.0%.

The pure carbinol was treated by the method used for the *trans*-carbinol with *p*-toluenesulfonyl chloride to give the *cis*-*p*-toluenesulfonate. Recrystallization from methanol gave needles, m. p. 95~95.5°C.

Found: C, 66.7; H, 8.8. Calcd. for $C_{18}H_{28}O_3S$: C, 66.6; H, 8.66%.

# *Semiconductivity and Absorption Spectrum of Perylene Single Crystal*

By Mizuka SANO and Hideo AKAMATU

(Received March 6, 1961)

Concerning the electronic conduction in organic solids, most of which are aromatic compounds, the investigation on single crystals is of special interest. For instance, it is desirable to determine the anisotropy of the electrical conductivity. If it is presumed that the conduction takes place in association with the overlapping of $\pi$-electron orbitals, the resistivity should be the lowest in such a direction where the overlapping is the largest. Mette and Pick[1] have observed such an anisotropy in the anthracene single crystal. We have found a similar anisotropy of thin evaporated films of perylene, coronene and violanthrene in which minute crystals are in alignment along the textured structure[2]. In this note, the investigation on the perylene single crystal is presented. It contributes to the above argument and suggests the correlation between the conduction level and the electronic absorption band in the molecular crystal.

Perylene, which was synthetized from naphthalene following Scholl[3], was recrystallized from the benzene solution and the gracial acetic acid solution successively, then sublimed in vacuo. However, these procedures could not

1) H. Mette and H. Pick, *Z. Phys.*, **134**, 566 (1953).

2) H. Inokuchi, H. Kuroda and H. Akamatu, This Bulletin, **34**, 749 (1961).

3) R. Scholl, *Ber.*, **43**, 2202 (1910).

eliminate a trace of reddish substance, terrylene ($C_{30}H_{16}$). Finally, the chromatographic technique with alumina was applied to its benzene solution in the dark. Subsequent sublimation yielded a faint yellow product.

Thin perfect single crystals were obtained when the sublimation procedure was carefully controlled and made to be slow. In a favorable condition, flake-like crystals were produced on the glass wall, which possessed the area of about $4\times6\,mm^2$ with the thickness of $60\sim280\,\mu$. It was proved by means of the X-ray diffraction that the surface plane of the flake-like crystal is the (001) plane.

The electrical resistivity was measured by applying the voltage perpendicularly to the (001) plane, or in parallel to the plane. Aquadag was employed as the electrodes. The voltage source was a battery of dry elements with a voltage up to 450 V. The measurement was carried out, with the aid of direct current amplifier, in vacuo ($10^{-3}$ mmHg) over a temperature range from 40 to 110°C.

No departure from Ohm's law was observed in the voltage region employed (up to $1.6\times10^3$ V./cm.). The resistivity decreased with increasing temperature and a good linear realationship was obtained between the logarithm of the resistivity ($\rho$) and the reciprocal of the temperature, (Fig. 1), which indicates the applicability of the following formula.

$$\rho=\rho_0\exp(\varepsilon/2kT)$$

where $\varepsilon$ is the energy gap.

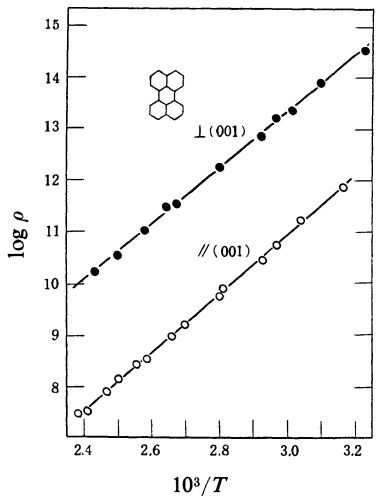

Fig. 1. The relation between resistivity and temperature for perylene single crystal.

It was found that the resistivity is isotropic in the (001) plane. But in the direction perpendicular to this plane, the resistivity is higher by a factor of $10^2$ than that in the (001) plane, (Table I).

| Absorption spectrum | | |
| the peak of the *p*-band | 2.67 | |
| the onset of the *p*-band | 2.26 | |

* after Inokuchi, Kuroda and Akamatu[2]

The absorption spectra of the perylene crystal and its solution in ethyl alcohol were recorded by the spectrophotometer (Cary model 11). The spectrum of the single crystal resembles closely that of the solution, excepting some broadening and a small shift toward the long wavelength side. In consequence, according to Clar's classification[4], the absorption bands of the crystal can be assigned to the *p*-, $\alpha$- and $\beta$-band respectively, referring to the absorption bands of the solution.

In the neighborhood of the absorption edge, it is rather difficult to decide precisely the threshold value. However, the onset of the *p*-band is found in the vicinity of 466 m$\mu$ for the solution and 550 m$\mu$ for the crystal. The value of light quantum for the latter is in agreement with the observed value of $\varepsilon$, (Table I).

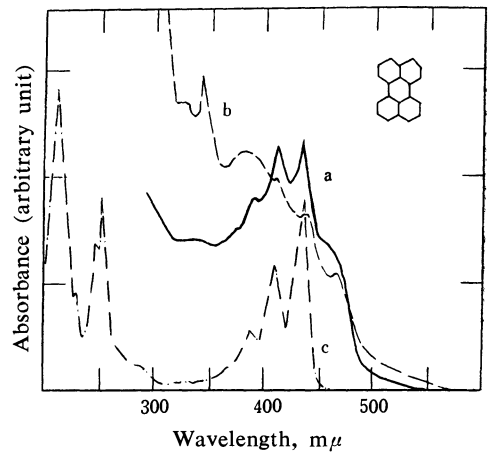

Fig. 2. Absorption spectra of perylene. (a) Single crystal, (b) Evaporated film, (c) Solution in ethyl alcohol

The anisotropy was found in regard to the conductivity, but not to the value of the energy gap. The same result has been obtained for

4) E. Clar, "Aromatische Kohlenwasserstoffe", Springer Verlag, Berlin (1952).

the evaporated film of perylene[2]. It can be concluded that the anisotropy arises due to the difference in the mobility of free carriers which is dependent on the direction of drift, but not due to the difference in the number of carriers which are in thermal equilibrium.

The direction of $\pi$-bond orbitals in each molecule extends perpendicularly from the molecular plane, and molecules are arranged in the crystal in such a way that the molecular planes are parallel with each other with a distance of 3.47 Å and nearly perpendicular to the (001) plane[5]. Therefore, the direction of the lowest resistivity is coincident with the direction of the extending of $\pi$-bond orbitals of molecules in the crystal. The maximum overlapping of the orbitals is expected to be between neighboring molecules in this direction.

If a conduction level could be assumed in the molecular crystal, the observed value of the energy gap implies that it lies in the neighborhood of the onset of the *p*-absorption band. No theory has yet explained the reason why the lowest excited state contributes to the conduction, but it is likely that the excitation of $\pi$-electrons to the lowest excited singlet state is the first process of electronic conduction in the perylene crystal.

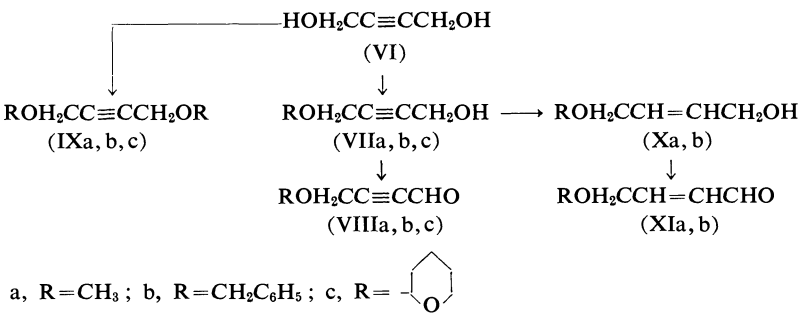
# *Syntheses of γ-Ionone Analogues. I–II.*

By Atsuaki ARAI and Iwao ICHIKIZAKI



(Received March 18, 1961)

## I. Several Asymmetric Bifunctional Dienophiles and their Diels-Alder Adducts with 2, 3-Dimethyl-1, 3-butadiene

Tetrolaldehydes or crotonaldehydes containing an adequate functional substituent in the γ-position seem to be suitable as the dienophiles for the preparation of the Diels-Alder adducts which can be used as the key intermediates for a certain synthetical project concerning γ-ionone analogues. In spite of their apparently simple structure, such compounds and their Diels-Alder adducts have hitherto scarcely been reported.

One of the present authors and his co-workers[1] synthesized the diethylacetals of γ-hydroxytetrolaldehyde (I), γ-dialkylaminotetrolaldehyde (II) and of γ-dialkylaminocrotonaldehyde (III), and then explained that all these acetals could neither give the free parent aldehydes nor behave as a dienophile, while they reported that γ-methoxycrotonaldehyde (XIa) was proved to be a dienophile. In this paper the authors wish to describe the preparation of several dienophiles in such series and the Diels-Alder reactions of them with a typical symmetric diene, 2, 3-dimethyl-1, 3-butadiene.

Five dienophiles — γ-methoxy-, γ-benzyloxy- and γ-tetrahydropyran-2-yloxytetrolaldehyde (VIIIa, VIIIb and VIIIc), γ-methoxy- and γ-benzyloxycrotonaldehyde (XIa and XIb)—were prepared successfully by the manganese dioxide oxidation of the corresponding carbinols (VIIa, VIIb, VIIc, Xa and Xb) as shown by the following scheme:

where: a, $R=CH_3$; b, $R=CH_2C_6H_5$; c, R= 

1) I. Ichikizaki, Ching-Chung Yao, Y. Fujita and Y. Hasebe, This Bulletin, **28**, 80 (1955).

4-Methoxy-2-butyn-1-ol (VIIa) was prepared in 43% yield through a partial methylation of 2-butyn-1,4-diol (VI) with dimethyl sulfate in an aqueous alkali. A modified procedure was applied for the preparation of 4-benzyloxy-2-butyn-1-ol (VIIb) by adding benzyl chloride at 110~115°C into a xylene suspension of monosodium butyndiolate prepared beforehand from a large excess of VI with sodamide in liquid ammonia. In both cases appreciable amounts of 1,4-dialkoxy-2-butynes (IXa and IXb) were isolated.

Catalytic hydrogenation of the acetylenic carbinols, VIIa and VIIb, in the presence of a palladium-calcium carbonate catalyst in ethyl acetate gave the corresponding ethylenic carbinols, Xa and Xb, in good yields.

An attempted preparation of 4-tetrahydropyran-2′-yloxy-2-butyn-1-ol (VIIc) directly from VI and dihydropyran was proved to be unsatisfactory, since it was extremely difficult to separate the pure product from the reaction mixture containing 1,4-bistetrahydropyran-2′-yloxy-2-butyne (IXc), unchanged VI besides VIIc. IXc was, therefore, prepared at first by heating VI with two moles of dihydropyran in the presence of a catalytic amount of concentrated hydrochloric acid or *p*-toluenesulfonic

acid in tetrahydrofuran, then it was similarly treated with one equivalent of VI to afford pure VIIc in a good yield. The tetrahydropyranyl ether thus prepared was fairly soluble in water and afforded the 2,4-dinitrophenylhydrazone of 5-hydroxypentanal (XII) in quantitative yield by the Brady reagent.

So far as the authors were aware, none of the acetylenic primary carbinols had ever been reported to be oxidized into the aldehydes by the technique after Attenburrow[2], however, all of the 4-alkoxy-2-butyn-1-ols (VIIa, VIIb and VIIc) and the 4-alkoxy-2-buten-1-ols (Xa and Xb) were successfully oxidized by the usual method with active manganese dioxide to yield the corresponding aldehydes (VIIIa, VIIIb, VIIIc, XIa and XIb), which were all proved to be the dienophiles of moderate activity as descrided later. Their properties and analytical data are shown in Table I and their solid derivatives are summarized in Table II.

It is worth noticing in this connection that the same oxidation technique seems not to be applicable to γ, γ-dialkoxyacetylenic carbinol, because 4,4-diethoxy-2-butyn-1-ol (XIII)[1,3] was recovered unchanged on treatment with active manganese dioxide under more vigorous conditions than that generally adopted[2,4,5].

Treatment of 4-tetrahydropyran-2′-yloxy-2-butyn-1-al (VIIIc) with the Brady reagent afforded in an excellent yield 2,4-dinitrophenylhydrazones of 5-hydroxypentanal (XII) and that of 4-hydroxy-2-butyn-1-al (I), while the latter was also obtained in a good yield by similar treatment of 4,4-diethoxy-2-butyn-1-ol (XIII). This means that VIIIc is readily hydrolyzed and quantitatively affords the above two aldehydes, namely XII and I.

The condensation between each of the aldehydes (VIIIa, VIIIb, VIIIc, XIa and XIb) and 2,3-dimethyl-1,3-butadiene under the conditions as listed in Table III essentially afforded only a sole adduct. Some chemical evidences, which will be described in the following paper, of the adducts and the ultraviolet absorption data of their semicarbazones listed in Table IV demonstrate that they all have normal structures as expected.

On the Diels-Alder reaction involving α,β-acetylenic carbonyl compound, only a few examples which have resulted in the formation of an inhomogeneous product owing to the migration of the double bonds or the partial aromaticization have been reported[6,7]. It

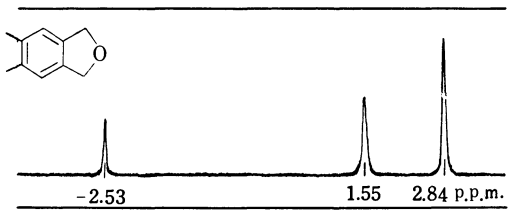
should be noted, therefore, that when the condensation between VIIIc and 2, 3-dimethyl-1, 3-butadiene was carried out at 140°C the expected adduct (XIVc) was obtained in only 24% yield and the principal product was colorless crystals, m.p. 60°C, formulated as $C_{10}H_{12}O$, which could also be obtained in 34% yield by heating XIVc with *p*-toluenesulfonic acid in tetrahydrofuran. This crystalline product has a strong menthol-like odor and becomes gradually a dark-brown resinous matter on exposure to air and light. By considering the fact that its properties and the infrared spectrum closely resemble those of phthalane[8] the authors estimated its structure as 5, 6-dimethyl-1, 3-dihydroisobenzofuran (XVII). The nuclear magnetic resonance spectrum[9] of this compound, obtained at 56.4 mc., was in complete accord with the structure XVII. The spectrum of XVII displayed three singlet peaks at −2.53, 1.55 and 2.84 p.p.m. whose area varied in a ratio of approximately 1 : 2 : 3, respectively. The resonance of −2.53 p.p.m. can be assigned to the aromatic hydrogens, while that of 2.84 p.p.m. is definitely associated with the hydrogens of methyl groups. The methylene groups linked with oxygen atom satisfactorily were accounted for by the peak of 1.55 p.p.m.



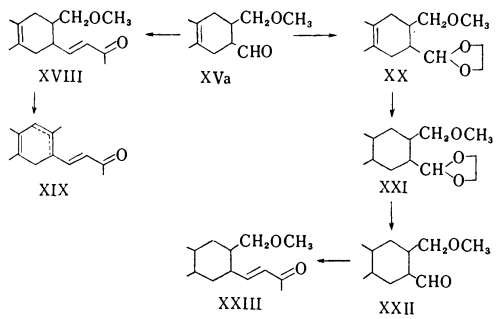


Fig. 1. NMR spectrum of 5,6-dimethyl-1,3-dihydroisobenzofuran.

## II. Synthesis of 2-Methylene-4, 5-dimethylcyclohexylmethanol and Related Compounds

In this paper the authors wish to describe the preliminary work which has been carried out in the course of study for the preparation of an analogue of γ-cyclogeraniol and related compounds by employing the Diels-Alder adducts reported in the preceding paper.

An attempt was made at first to synthesize 4-(2′-methylene-4, 5-dimethyl-4′-cyclohexenyl)-but-3-en-2-one by employing 3, 4-dimethyl-6-methoxymethyl-3-cyclohexenylmethanal (XVa) as the starting substance. Condensation of XVa with acetone in the presence of barium hydroxide afforded in 69% yield 4-(3′,4′-dimethyl-6′-methoxymethyl-3′-cyclohexenyl)-but-3-en-2-one (XVIII) which on heating with hydrogen bromide at 130°C gave a crude oil, from which a considerable amount of only one orange 2, 4 dinitrophenylhydrazone was obtained. Since the infrared spectrum of the hydrazone did not exhibit a characteristic absorption band of exocyclic methylene group, its parent aldehyde was considered to be a triply unsaturated ketone as represented by XIX which resulted from XVIII after elimination of methyl alcohol. Consequently the use of such a methoxymethyl compound as XVIII for the preparation of γ-ionone analogue was regarded as being practically unsuitable.

In order to hydrogenate a double bond in the ring of XVa a carbonyl group was once protected as the acetal. By the method of Salmi[10] XVa was converted into the corresponding ethylendioxy compound XX in 79% yield, which was hydrogenated over a palladium-charcoal catalyst in ethanol to give the saturated acetal XXI. The XXI was readily hydrolyzed, when heated under reflux in tetrahydrofuran with 2 N aqueous sulfuric acid, to yield the free aldehyde XXII which was condensed with acetone in the usual method giving 4-(4′, 5′-dimethyl-2′-methoxymethylcyclohexyl)-but-3-en-2-one (XXIII).

Since the conversion of a side methoxymethyl group into an exocyclic methylene had failed, a formyl group that is another functional group of such an adduct as XVa was investigated for the same purpose by employing 3, 4, 6-trimethyl-3-cyclohexenylmethanal (XVI) as a simple model.

In an autoclave XVI was hydrogenated in the presence of Raney nickel catalyst and anhydrous dimethylamine to afford in 80% yield *N*, *N*-dimethyl-2, 4, 5-trimethylcyclohexylmethylamine (XXV), together with an appreciable amount of 2, 4, 5-trimethylcyclohexylmethanol (XXIV). Though it is well known[11]

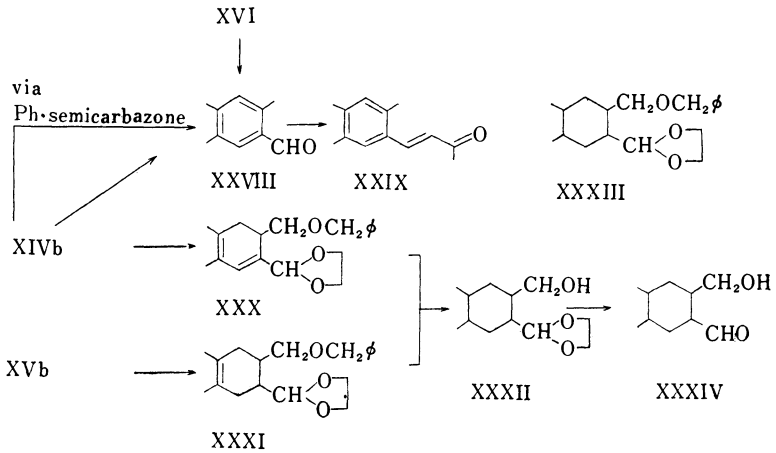
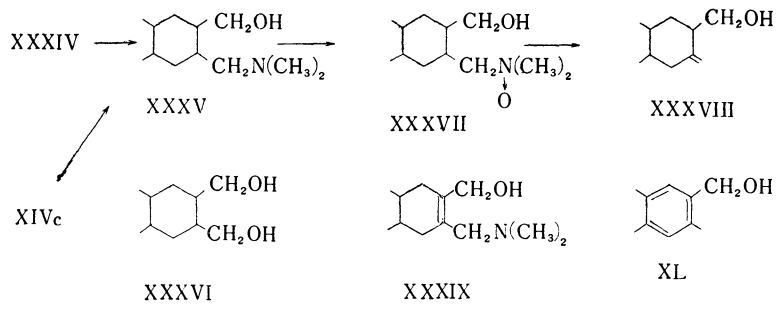
that primary and secondary amines are generally converted into tertiary amines by reductive condensation with various carbonyl compounds, no case with alicyclic aldehyde has been reported until the above preparation was completed[12].



Oxidation of the tertiary amine XXV with 30% aqueous hydrogen peroxide gave in 82% yield an amine oxide XXVI as a colorless syrup which was characterized as crystalline picrate. The amine oxide XXVI was pyrolyzed in the manner described by Cope and his co-workers[13]. The decomposition proceeded smoothly at 120 ~130°/2.5 mmHg under nitrogen, and gave in yield of 61% based on XXV, a colorless mobile liquid, $C_{10}H_{18}$, which showed b.p. 59~59.2°/16.2 mmHg, $n_D^{20}$ 1.4601 and was proved to be homogeneous by vapor phase chromatography. From the infrared absorption bands at 3077, 1648 and 885 $cm^{-1}$ indicative of exocyclic methylene group, 1-methylene-2, 4, 5-trimethylcyclohexane (XXVII) was assigned for the hydrocarbon. The above result demonstrates that the thermal decomposition of XXVI gave exclusively the expected unsaturated hydrocarbon and also provided a further example in support of the specific formation of methylene cycloalkanes previously reported by Cope and his co-investigator[14,15].



Since three of the new Diels-Alder adducts —XIVb, XIVc and XVb—have all a functional group readily convertible to a hydroxyl group, an attempt was made to prepare from them 2-methylene-4, 5-dimethylcyclohexylmethanol (XXXVIII) which can be regarded as an analogue of γ-cyclogeraniol.

In order to isolate XIVb of high purity the phenylsemicarbazone obtainable in yield of 96% from the original adduct was hydrolyzed on steam distillation in the presence of concentrated sulfuric acid and *o*-phthalic acid, whereas 2, 4, 5-trimethylbenzaldehyde (XXVIII), m. p. 43°C (lit.[16] m. p. 42°C), was obtained in 60% yield with benzyl alcohol. The compound XXVIII was also formed in 20% yield by heating XIVb under reflux in xylene with a catalytic amount of *p*-toluenesulfonic acid, and it was characterized as the semicarbazone and 2, 4-dinitrophenylhydrazone, both of which were identical with those of an authentic sample prepared by the sulfur dehydrogenation of 3, 4, 6-trimethyl-3-cyclohexenylmethanal (XVI). On condensation with acetone, the aldehyde XXVIII afforded 4-(2′, 4′, 5′-trimethylphenyl)-but-3-en-2-one (XXIX) which showed m. p. 49.5°C (semicarbazone, m. p. 223~224°C; 2, 4-dinitrophenylhydrazone, m. p. 247~249°C).

An attempted acid-catalyzed reaction of XIVb with ethylene glycol following the method of Salmi[10] gave in only 33.5% yield an acetal which was probably XXX[17], while a considerable amount of XXVIII was yielded from

17) Such migration of double bonds in the presence of acid will be discussed in the following paper, Part III.

the elimination of benzyl alcohol. However, 6-benzyloxymethyl-3,4-dimethyl-3-cyclohexenylmethanal (XVb) could be converted into the corresponding acetal XXXI in a good yield without the elimination of benzyl alcohol.

XXX as well as XXXI usually afforded XXXII on hydrogenation over a palladium-charcoal catalyst; however, they occasionally afforded an appreciable amount of 2-benzyloxymethyl-4, 5-dimethylcyclohexylmethanal ethylene acetal (XXXIII), when hydrogenated with a catalyst prepared from less active charcoal. This result suggests that the hydrogenation of double bonds proceeded more rapidly than the hydrogenolysis of the benzyloxy group. On hydrolysis with diluted aqueous sulfuric acid in tetrahydrofuran the acetal XXXII was readily converted into the hydroxy aldehyde XXXIV.

On catalytic hydrogenation with dimethylamine over Raney nickel catalyst, XXXIV afforded in 60% yield *N*, *N*-dimethyl-4, 5-dimethyl-2-hydroxymethylcyclohexylmethylamine (XXXV) and simultaneously a considerable amount of 1, 2-bishydroxymethyl-4, 5-dimethylcyclohexane (XXXVI), m. p. 113~115°C. XXXV was successively oxidized with 30% hydrogen peroxide in the usual method to the *N*-oxide XXXVII, which was decomposed at 120~130°C to exclusively yield 2-methylene-4, 5-dimethylcyclohexylmethanol (XXXVIII), b. p. 94~97°C/17.5 mmHg, $n_D^{27}$ 1.4729, as shown by its infrared absorption bands at 3058, 1642 and 884 $cm^{-1}$.

In another attempt to prepare the hydroxy amine XXXV directly from XIVc by similar reductive alkylation of dimethylamine with the aldehyde XXXIV as described above, XXXV was obtained in yield of 43.5% and it was usually contaminated with a base which was assumed from the methiodide to be the unsaturated aminoalcohol XXXIX. In this reduction a neutral compound, $C_{10}H_{14}O$, which shows m.p. 84.5°C; $\lambda_{max}^{EtOH}$ 217 mμ (ε 175), 267 (338) and 274 (322), was also isolated in 32% yield. The infrared spectrum exhibited the presence of hydroxyl group (~3360, 1038) as well as of 1, 2, 4, 5-tetra-substituted aromatic group (879 $cm^{-1}$), and clearly suggested that this compound was to be 2, 4, 5-trimethylbenzyl alcohol (XL) which had been reported elsewhere to show m. p. 168°C[18]. The NMR spectrum provided an independent confirmation of its structure. The spectrum[9] consisted of five peaks at −2.23, −2.10, 0.30, 2.25 and 2.50 p. p. m. the chemical shifts of which permit the unequivocal assignment. The two non-equivalent hydrogens on the ring are accounted for by the peaks of −2.23 and −2.10 p. p. m. The three methyl groups were found at 2.50 p. p. m. as a singlet peak, while the methylene group with hydroxyl group was found at a lower magnetic field (0.30 p. p. m.). The resonance at 2.25 p. p. m. can be assigned to the proton of hydroxyl group.

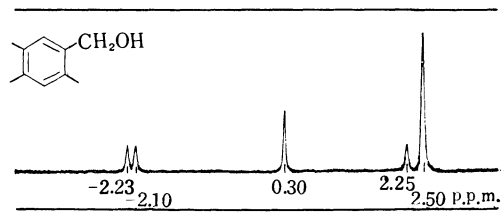

Fig. 2. NMR spectrum of 2,4,5-trimethylbenzyl alcohol.

## Experimental[19]

**4-Methoxy-2-butyn-1-ol (VIIa) and 4-Methoxy-2-buten-1-ol (Xa).**—These compounds were prepared by the method of Ichikizaki et al[1]. 4-Methoxy-2-butyn-1-ol (VIIa), b. p. 105.5~106°C/20.5 mmHg, $n_D^{20}$ 1.4595, was obtained in 43% yield. In addition to VIIa, 1, 4-dimethoxy-2-butyne (IXa), b.p. 63~65°C/20 mmHg, was obtained in 9% yield as a by-product. 4-Methoxy-2-buten-1-ol (Xa), b.p. 88~89°C/20 mmHg, $n_D^{12}$ 1.4490, was obtained by hydrogenation of VIIa with a palladium-calcium carbonate catalyst (5% Pd) in 89% yield.

18) W. J. Hickinbottom, "Chemistry of Carbon Compounds", Vol. III-A, Ed. by E. H. Rodd, Elsevier Pub. Co. (1954), p 499.

19) All melting points were determined on the Kofler block and are uncorrected. The ultraviolet spectra were determined with a Hitachi EPU-2A spectrophotometer and the infrared spectra were obtained with a Perkin-Elmer model 112, a Kōken model DS-301, and a Nippon Bunkō model IR-S recording spectrophotometers with sodium chloride optics.

**4-Benzyloxy-2-butyn-1-ol (VIIb).** — 2-Butyne-1, 4-diol (VI) (200 g.) was added portionwise to a solution of sodamide (prepared from 35 g. of sodium) in liquid ammonia (1 l.) under vigorous stirring at −45∼−50°C over a period of 10 min. After being stirred for additional 2 hr. under cooling, the reaction mixture was diluted with xylene (800 ml.) and then set aside overnight to evaporate ammonia. The residual suspension was heated gradually to 100°C under stirring to remove the remaining ammonia as completely as possible. To it benzyl chloride (200 g.) was added dropwise over a period of 30 min. under vigorous stirring at 110∼115°C and the mixture was stirred for an additional hour. After being cooled, the reaction mixture was poured into cold water (500 ml.) and the xylene layer separated was washed with 10% sulfuric acid and water and dried over sodium sulfate. Distillation gave two fractions, 198 g. (69.2%), b. p. 142∼147°C/4 mmHg and 9 g., b. p. 170∼175°C/2 mmHg. Upon redistillation the lower boiling fraction afforded pure 4-benzyloxy-2-butyn-1-ol (VIIb), b. p. 143∼146°C/2.5 mmHg, $n_D^{25}$ 1.5379.

Found: C, 73.76; H, 7.07. Calcd. for $C_{11}H_{12}O_2$: C, 74.97; H, 6.86%.

Upon redistillation the higher boiling fraction afforded pure 1, 4-dibenzyloxy-2-butyne (IXb), b. p. 169∼170°/1.5 mmHg, $n_D^{19.5}$ 1.5590.

Found: C, 81.20; H, 6.71. Calcd. for $C_{18}H_{18}O_2$: C, 81.17; H, 6.81%.

**4-Benzyloxy-2-buten-1-ol (Xb).**—A solution of 4-benzyloxy-2-butyn-1-ol (VIIb) (100 g.) in ethyl acetate (140 ml.) was hydrogenated with a palladium-barium carbonate catalyst (2.5% Pd, 1.5 g.) at 22°C until 14515 ml. of hydrogen (1.05 equiv.) had been absorbed. After removal of the catalyst and solvent the residue was distilled to afford 4-benzyloxy-2-buten-1-ol (Xb) (83 g., 82%), b. p. 125∼127.5°C/2 mmHg, $n_D^{25}$ 1.5267.

Found: C, 74.08; H, 7.88. Calcd. for $C_{11}H_{14}O_2$: C, 74.13; H, 7.92%.

**1, 4-Bistetrahydropyran-2′-yloxy-2-butyne (IXc).**—A solution of dihydropyran (18.5 g., 0.22 mol.) in tetrahydrofuran (20 ml.) was added dropwise to a solution of VI (8.6 g., 0.1 mol.) in tetrahydrofuran (20 ml.) containing 2 drops of concentrated hydrochloric acid with stirring at 60°C over a period of 30 min. and the resulting mixture was gently refluxed for additional 3 hr. After being cooled, the reaction mixture was made alkaline with a cold 5% aqueous sodium carbonate solution and extracted with three 80 ml. portions of ether. The combined extracts were washed 4 times with a saturated aqueous sodium chloride solution, dried over potassium carbonate and evaporated. Distillation of the residue under nitrogen gave the bis-ether IXc (17 g., 67%), b.p. 144∼146°C/1.0 mmHg, $n_D^{16}$ 1.4913; $\nu_{max}^{film}$ 2226 (C≡C), 1186, 1120, 1081, 1056, 1022, 973, 946, 905 and 872 cm$^{-1}$ (C-O-C-O).

Found: C, 65.66; H, 8.70. Calcd. for $C_{14}H_{22}O_4$: C, 66.11; H, 8.72%.

**4-Tetrahydropyran-2′-yloxy-2-butyn-1-ol (VIIc).**—A solution of the bis-ether IXc (25.4 g., 0.1 mol.) in tetrahydrofuran (10 ml.) was added dropwise to a solution of VI (8.6 g., 0.1 mol.) in tetrahydrofuran (30 ml.) containing 3 drops of concentrated hydrochloric acid under gentle reflux and then boiled for 3 hr. The resultant reaction mixture was worked up as described in the preceding section to leave a pale yellow oil which was distilled through a 8 cm. Vigreux column to yield VIIc (23.0 g., 68%), b. p. 122∼124°C/0.8 mmHg, $n_D^{19}$ 1.4913; $\nu_{max}^{film}$ 3470∼3450 (OH) and 2220 cm$^{-1}$ (C≡C). The characteristic absorption bands in its finger-print region were almost superimposable on those of the bis-ether IXc.

Found: C, 63.27; H, 8.46. Calcd. for $C_{11}H_{14}O_3$: C, 63.51; H, 8.29%

Upon treatment with the Brady reagent, this compound yielded 2, 4-dinitrophenylhydrazone of 5-hydroxypentanal which was crystallized from aqueous methanol and showed m. p. 115°C, undepressed on admixture with the authentic sample.

**4, 4-Diethoxy-2-butyn-1-ol (XIII).**—This compound was obtained in 57.7% by the method of Ichikizaki et al.[1], and had b.p. 118∼119°C/3 mmHg and $n_D^{26}$ 1.4335 (lit.[1] b. p. 88°C/0.5 mmHg, $n_D^{25}$ 1.4493).

The 2, 4-dinitrophenylhydrazone crystallized from 50% methanol in yellow needles, m. p. 120∼120.5°C (lit.[1] m. p. 119°C).

Found: N, 21.13. Calcd. for $C_{10}H_8O_5N_4$: N, 21.21%.

**General Procedure for Oxidation of Carbinols (VII and X) with Manganese Dioxide.**—A solution of the carbinol (5 g.) obtained above in benzene (5 ml.) was added dropwise to a suspension of manganese dioxide (50 g.) prepared by the method of Attenburrow et al.[2] in the same solvent (350 ml.) over a period of 5∼15 min. under vigorous stirring at room temperature and the resultant mixture was stirred for additional 3∼5 hr. During this period the initial temperature increased 10∼12°C. The reaction mixture was filtered and the precipitate was washed with petroleum ether. The washing was combined with the filtrate and evaporated in a nitrogen atmosphere under reduced pressure. Fractionation of the residue afforded the desired aldehydes whose properties and elemental analyses are listed in Table I. The solid derivatives prepared from these aldehydes are summarized in Table II.

**Attempted Oxidation of 4, 4-Diethoxy-2-butyn-1-ol (XIII) with Manganese Dioxide.** — XIII was treated with manganese dioxide according to the general procedure described above. Distillation afforded a trace of fore-run and unchanged starting material (76%). Although XIII was treated with a large excess of the oxidizing agent in boiling benzene for 10 hr., the unchanged starting material was recovered (78%), and the desired aldehyde could not be obtained.

**Reaction of 4-Tetrahydropyran-2′-yloxy-2-butyn-1-al (VIIIc) with the Brady Reagent.**—VIIIc was treated with the Brady reagent in the usual manner giving a mixture of two 2,4-dinitrophenylhydrazones. Recrystallization from aqueous methanol yielded 2, 4-dinitrophenylhydrazone of 4-hydroxy-2-butyn-1-al in yellow needles, m. p. 120∼120.5°C, undepressed on admixture with a sample prepared from XIII.

On addition of water the mother liquor afforded

2, 4-dinitrophenylhydrazone of 5-hydroxypentanal in orange-yellow leaflets, m. p. 115°C, undepressed on admixture with the authentic sample prepared as described below.

**5-Hydroxypentanal (XII).**—This compound was prepared in 65% yield by the method of Schniepp et al.[20] and showed b. p. 61~61.5°C/5 mmHg and $n_D^{17}$ 1.4510 (lit. b. p. 54~55°C/3 mmHg, $n_D^{25}$ 1.4514[20]; b. p. 80°C/12 mmHg, $n_D^{20}$ 1.4510[21]).

The 2, 4-dinitrophenylhydrazone crystallized from 50% methanol in orange-yellow leaflets, m. p. 115~116°C (lit. m. p. 109°C[22]; m. p. 107~109°C[23]).

Found: N, 20.19. Calcd. for $C_{11}H_{14}O_5N_4$: N, 19.85%.

**General Procedure for Diels-Alder Addition of 2, 3-Dimethyl-1, 3-butadiene to γ-Alkoxytetrolaldehydes VIII and γ-Alkoxycrotonaldehydes XI.**—A solution of freshly distilled aldehyde (1 equiv.), 2, 3-dimethyl-1, 3-butadiene (1.05 equiv.) and a trace of quinol in an appropriate solvent was taken in a 50~100 ml. glass bomb and was heated under nitrogen in an oil bath under the conditions described in Table III. After removal of the solvent the residue was distilled under reduced pressure to afford a crude product which was purified by redistillation through a short Vigreux column to give a pure adduct.

Some physical properties and sold derivatives of the adducts thus obtained are summarized in Tables III and IV.

**Phenylsemicarbazone of 2-Benzyloxymethyl-4, 5-dimethylcyclohexa-1, 4-dienylmethanal (XIVb).**—A solution of the aldehyde XIVb (4.0 g.) in ethanol (20 ml.) and phenylsemicarbazide (3.8 g.) in the same solvent (12 ml.) were refluxed for 5 min. The cooled reaction mixture was diluted with water and allowed to stand overnight at room temperature. A white precipitate which had been separated was collected and crystallized from ethanol-ethyl acetate to afford phenylsemicarbazone of XIVb (5.8 g., 96%) in needles, m. p. 179~180°C.

The elemental analysis and the ultraviolet absorption data are listed in Table IV.

**5, 6-Dimethyl-1, 3-dihydroisobenzofuran (XVII).**—*a) From 4-Tetrahydropyran-2'-yloxy-2-butyn-1-al (VIIIc) and 2, 3-Dimethyl-1, 3-butadiene.*—A solution of the aldehyde VIIIc (3.06 g.) in benzene (10 ml.) was treated with 2, 3-dimethyl-1, 3-butadiene (1.8 g.) in the presence of a trace of quinol at 140°C for 10 hr. by the general procedure described above. Distillation afforded two fractions: b. p. 90~110°/1.5 mmHg (1.5 g., 55.5%) and b. p. 133~135°C/0.55 mmHg (1.1 g., 24.1%).

The lower boiling fraction of colorless oil solidified immediately after distillation and crystallized from aqueous methanol in colorless fine plates which melted at 60°C and had a characteristic menthol-like odor. The infrared spectrum (KBr disk) showed absorption bands at 1606 (w), 1543 (m), 1495 (m), 1440 (s), 1418 (m), 1389 (s), 1320 (m), 1214 (m), 1127 (m), 1086 (m), 1028 (s), 890 (s) and 768 $cm^{-1}$ (s), and also indicated the absence of the carbonyl group.

Found: C, 80.82; H, 8.40. Calcd. for $C_{10}H_{12}O$: C, 81.04; H, 8.16%.

Upon treatment with the Brady reagent this compound yielded red 2, 4-dinitrophenylhydrazone which crystallized from ethanol-ethyl acetate in red needles, m. p. 208~209°C.

Found: C, 55.11; H, 5.62; N, 15.74. Calcd. for $C_{16}H_{16}O_5N_4$: C, 55.48; H, 5.24; N, 16.18%.

An attempt to prepare the semicarbazone of this product in the usual manner was unsuccessful.

These evidences, therefore, strongly suggest that the lower boiling product is probably 5, 6-dimethyl-1, 3-dihydroisobenzofuran (XVII).

The higher boiling fraction of a pale yellow viscous oil was an expected adduct which was proved to be identical with XIVc (Tables III and IV) by mixed melting point determination of their 2, 4-dinitrophenylhydrazones and by infrared comparison.

*b)—From 4, 5-Dimethyl-2-tetrahydropyran-2'-yloxymethylcyclohexa-1, 4-dienylmethanal (XIVc).*—A solution of the aldehyde XIVc (0.5 g.) in tetrahydrofuran (20 ml.) was heated with *p*-toluenesulfonic acid (0.1 g.) under reflux for 3 hr. After removal of the solvent the residue was taken in ether and the ethereal solution was washed with a 2% aqueous sodium carbonate solution and water, dried and evaporated. Distillation of the residue afforded an oil which boiled at 130°C (bath temperature)/15 mmHg and solidified rapidly. Recrystallization from petroleum ether yielded colorless plates which melted at 60°C and proved to be identical with XVII obtained from a) by mixed melting point determination and infrared comparison.

The compound XVII was unstable and on exposure to air or light furnished a dark-brown resinous material.

**3, 4-Dimethyl-6-methoxymethyl-3-cyclohexenylmethanal Ethylene Acetal (XX).**—A mixture of the aldehyde XVa (6.6 g.), ethylene glycol (4.0 g.), *p*-toluenesulfonic acid (20 mg.) and benzene (30 ml.) was taken in a flask provided with an azeotropic water separator and heated under reflux in an oil bath (120~130°C) until no more aqueous phase has been separated from an azeotropic distillate (for ca. 4 hr.). The solvent was removed under reduced pressure and the residual brown oil was thoroughly extracted with ether. The combined ethereal extracts were washed with a 10% aqueous sodium carbonate solution and with water, dried over sodium sulfate and evaporated under reduced pressure. Distillation of the residue afforded the acetal XX (6.5 g., 79.3%) as a colorless liquid, b. p. 105~106°C/2.0 mmHg, $n_D^{25}$ 1.4868.

Found: C, 68.90; H, 9.97. Calcd. for $C_{13}H_{22}O_3$: C, 68.99; H, 9.80%.

This compound afforded 2, 4-dinitrophenylhydrazone, m. p. 160°C, undepessed on admixture with that of XVa.

**4, 5-Dimethyl-2-methoxymethylcyclohexylmethanal Ethylene Acetal (XXI).**—The acetal XX (6.5 g.) in absolute ethanol (40 ml.) was hydrogenated in the presence of 5% palladium-on-charcoal (0.2 g.) at 100°C and a pressure of 120 kg./$cm^2$ for 2 hr.

20) L. E. Schniepp and H. H. Geller, *J. Am. Chem. Soc.*, **68**, 1646 (1946).
21) C. D. Hurd and W. H. Saunders Jr., ibid., **74**, 5326 (1952).
22) G. F. Woods and H. Sanders, ibid., **68**, 2111 (1946).
23) G. F. Woods and D. N. Kramer, ibid., **69**, 2246 (1947).

The catalyst was removed by filtration and the filtrate was evaporated under reduced pressure. Distillation of the residue yielded the saturated acetal XXI (5.0 g., 77%), b.p. 103~105°C/2.5 mmHg, $n_D^{29}$ 1.4659.

Found: C, 68.44; H, 10.48. Calcd. for $C_{13}H_{24}O_3$: C, 68.38; H, 10.59%.

The 2, 4-dinitrophenylhydrazone crystallized from ethanol in yellow plates, m. p. 129~130°C.

Found: N, 15.40. Calcd. for $C_{17}H_{24}O_5N_4$: N, 15.38%.

**4, 5-Dimethyl-2-methoxymethylcyclohexylmethanal (XXII).**—A mixture of the acetal XXI (1.8 g.), tetrahydrofuran (30 ml.) and 2 N sulfuric acid (30 ml.) was heated under reflux for 24 hr. The cooled reaction mixture was made slightly alkaline with a 10% sodium carbonate solution, concentrated under reduced pressure and then extracted with ether. The ethereal extract was washed with water, dried and evaporated. Distillation of the residue afforded the aldehyde XXII (1.0 g., 69%), b.p. 93~95°C/1.0 mmHg, $n_D^{17}$ 1.4710; $\nu_{max}^{liquid}$ 1730 $cm^{-1}$ (C=O), $\nu_{max}^{CCl_4}$ 1725.2 $cm^{-1}$ (C=O); $\lambda_{max}$ 226 mμ (ε 499), 294 (59) in 75% aqueous dioxane.

Found: C, 71.58; H, 10.67. Calcd. for $C_{11}H_{20}O_2$: C, 71.69; H, 10.94%.

The 2, 4-dinitrophenylhydrazone showed m. p. 130°C, undepressed on admixture with that of XXI.

**4-(3', 4'-Dimethyl-6'-methoxymethyl-3'-cyclohexenyl)-but-3-en-2-one (XVIII).**—The aldehyde XVa (3.6 g.) was added dropwise to a boiling solution of barium hydroxide (0.7 g.) in 90% aqueous acetone (20 ml.) and the resultant mixture was refluxed for 7.5 hr. The cooled reaction mixture was neutralized with 1 N hydrochloric acid, concentrated under reduced pressure and then extracted with ether. The dried ethereal solution was fractionated to yield the unsaturated ketone XVIII (3.0 g., 68.5%), b. p. 122~123°C/3 mmHg, $n_D^{22.5}$ 1.5000; $\nu_{max}^{liquid}$ 1680 (C=O), 1624 (C=C), 1115 (C-O-C) and 983 $cm^{-1}$ (trans-CH=CH-).

Found: C, 75.42; H, 10.10. Calcd. for $C_{14}H_{22}O_2$: C, 75.63; H, 9.97%.

The 2, 4-dinitrophenylhydrazone crystallized from ethanol in red prisms, m. p. 155~156°C.

Found: N, 14.05. Calcd. for $C_{20}H_{26}O_5N_4$: N, 13.92%.

**4-(4', 5'-Dimethyl-2'-methoxymethylcyclohexyl)-but-3-en-2-one (XXIII).**—The aldehyde XXII (1.7 g.) was added dropwise to a boiling solution of barium hydroxide (0.3 g.) in 90% aqueous acetone (10 ml.) and the resultant mixture was refluxed for 10 hr., and was then treated in the same manner as that described above to yield the ketone XXIII (1.2 g., 58%), b. p. 120~122°C/2 mmHg, $n_D^{32}$ 1.4781.

Found: C, 74.34; H, 10.65. Calcd. for $C_{14}H_{24}O_2$: C, 74.95; H, 10.78%.

The 2, 4-dinitrophenylhydrazone crystallized from ethanol in red-orange plates, m. p. 127~129°C.

Found: N, 14.06. Calcd. for $C_{20}H_{28}O_5N_4$: N, 13.85%.

**Reaction of 4-(3', 4'-Dimethyl-6'-methoxymethyl-3'-cyclohexenyl)-but-3-en-2-one (XVIII) with Hydrobromic Acid.**—A mixture of the unsaturated ketone XVIII (0.3 g.) and a constant boiling hydrobromic acid (b. p. 123°C, 12 ml.) was heated in a 50 ml. glass bomb at 130°C for 4 hr. The black tarry oil formed was poured into an ice-cooled 10% aqueous sodium carbonate solution and extracted with ether. The ethereal extract was washed, dried and evaporated. Distillation of the residue afforded a colorless oil (0.11 g.), b. p. 90~100°C/0.8 mmHg, $n_D^{24.5}$ 1.5241. This oily product gave a positive Beilstein test and a 2, 4-dinitrophenylhydrazone which contained no bromine atom and crystallized from ethanol in orange needles, m. p. 174~175°C.

Found: C, 61.15; H, 6.13. Calcd. for $C_{19}H_{22}O_4N_4$: C, 61.61; H, 5.99%.

Although the position of the double bonds on the ring could not be confirmed, the derivative obtained above was seen clearly to be 2, 4-dinitrophenylhydrazone of 4-(2', 4', 5'-trimethylcyclohexadienyl)-but-3-en-2-one, since elemental analysis was very satisfactory and the infrared spectrum exhibited no absorption band attributable to the exocyclic methylene group.

**2, 4, 5-Trimethylcyclohexylmethanol (XXIV).**—3, 4, 6-Trimethyl-3-cyclohexenylmethanal (XVI) (3.04 g.) in ethanol (30 ml.) was hydrogenated over a Raney nickel catalyst (1.5 g.) in a 100 ml. stainless-steel autoclave at 192°C and a pressure of 192 kg./cm² for 1 hr. The catalyst was removed by filtration and the filtrate was evaporated. Distillation of the residue afforded XXIV (2.9 g., 93%) as a colorless oil, b. p. 110°C/16 mmHg, $n_D^{17}$ 1.4700.

Found: C, 76.62; H, 13.02. Calcd. for $C_{10}H_{20}O$: C, 76.86; H, 12.90%.

***N*, *N*-Dimethyl-2, 4, 5-trimethylcyclohexylmethylamine (XXV).**—A mixture of XVI (7.4 g.), anhydrous dimethylamine (2.9 g.), a Raney nickel catalyst (1.2 g.) and ethanol (50 ml.) was shaken with hydrogen at 180~220°C and a pressure of 121 kg./cm² for 4 hr., after which time a pressure of 58 kg./cm² of hydrogen was absorbed. The catalyst was removed by filtration and the filtrate was evaporated under reduced pressure. Distillation of the residue afforded a crude product (7.9 g.) b. p. 100~105°C/16 mmHg, $n_D^{21}$ 1.4622~1.4658. This oil was taken up in ether and extracted with diluted hydrochloric acid. The aqueous extracts were combined, neutralized with aqueous sodium hydroxide and then extracted with ether. The dried ethereal solution was distilled under reduced pressure to yield a pure amine XXV (6.6 g., 80%), b. p. 98~99°C/15 mmHg, $n_D^{17.5}$ 1.4607.

Found: C, 78.77; H, 13.52. Calcd. for $C_{12}H_{25}N$: C, 78.61; H, 13.75%.

The methiodide crystallized from ethanol in leaflets, m. p. 262°C (decomp.).

Found: C, 48.19; H, 8.83; N, 4.18; I, 38.5. Calcd. for $C_{13}H_{28}NI$: C, 48.0; H, 8.6; N, 4.3; I, 39.0%.

The picrate was obtained as a yellow oil which could not be induced to crystallize.

The ethereal solution which had been shaken with acid was dried and then distilled under reduced pressure to yield a neutral compound (0.8 g., 10.8%), b. p. 114~116°C/17 mmHg, $n_D^{20.5}$ 1.4668. This compound was proved to be identical with

XXIV obtained above by comparison of their infrared spectra.

***N*, *N*-Dimethyl-2, 4, 5-trimethylcyclohexylmethylamine Oxide (XXVI).**—To a solution of the amine XXV (6.11 g., 1/30 mol.) in methanol (5 ml.) was added dropwise 30% aqueous hydrogen peroxide (13 g., 1/10 mol.) under vigorous stirring at 0°C and the resultant mixture was allowed to warm to room temperature. The mixture was stirred for 11.5 hr. and set aside overnight, after which time all of the reaction mixture was homogeneous. The excess of hydrogen peroxide was then decomposed with platinum foil (0.3 g.) under stirring for 35 hr. at room temperature. After removal of the platinum foil the solution was evaporated under reduced pressure (15~17 mmHg) at below 35°C to leave a syrupy residue which was taken up in absolute ethanol (10 ml.). The solution was evaporated through a 25 cm. Vigreux column under reduced pressure. This work-up was repeated 4 times to remove the last traces of water and afforded the amine oxide XXVI as a very viscous colorless liquid. The product thus obtained was used in the next preparation without further purification, since its practical purity was indicated by the determination of an amine oxide prepared in another run described below.

When an excess of picric acid in aqueous ethanol was mixed with an aqueous ethanolic solution of a crude amine oxide prepared from the amine XXV (0.46 g.) in the manner described above, there was obtained a picrate which crystallized from absolute ethanol in yellow plates, m. p. 165~166.5°C. The yield was 0.82 g. (82%).

Found: C, 50.36; H, 6.80; N, 12.69. Calcd. for $C_{18}H_{28}O_8N_4$: C, 50.46; H, 6.59; N, 13.08%.

**1-Methylene-2, 4, 5-trimethylcyclohexane(XXVII).**—The amine oxide XXVI obtained above was taken in a 100 ml. flask fitted with a 15 cm. Vigreux column and heated to 110°C, at this temperature decomposition of the amine oxide occurred. After 30 min. the distillation became slower and the bath was heated to 180°C. The pyrolysis products, which distilled mainly at 120~130°C (bath temperature), were swept with nitrogen through a trap cooled with a freezing mixture and then through a liquid nitrogen cooled trap. The products were combined and taken up in ether. The ethereal solution was washed twice with 10% hydrochloric acid and 3 times with water, dried over magnesium sulfate and then in the presence of a small amount of quinol concentrated under a 25 cm. Vigreux column at atmospheric pressure. The residue was distilled under nitrogen to yield the hydrocarbon XXVII (2.8 g., 61.0% based on XXV), b. p. 59~59.2°C/16.2 mmHg, $n_D^{20}$ 1.4601. This hydrocarbon decolorized rapidly a dilute solution of bromine in carbon tetrachloride and readily consumed potassium permanganate in acetone solution. $\nu_{max}^{liquid}$ 3077, 1648, 885 (>C=$CH_2$); 1464, 1384 (-$CH_2$- and $CH_3$) and 1770 $cm^{-1}$ (over-tone of δ CH).

Found: C, 87.12; H, 12.63. Calcd. for $C_{10}H_{18}$: C, 86.88; H, 13.12%.

The aqueous washings were combined and concentrated under reduced pressure to leave a crystalline residue, which was taken up in absolute ethanol. The solution was evaporated to dryness yielding a crude *N*, *N*-dimethylhydroxylamine hydrochloride (2.0 g., 61.5%), m. p. 103~105°C. A sample recrystallized from absolute ethanol in needles, m. p. 105~106.5°C (lit. m. p. 104.5~106.5°C[13] and m. p. 106.5~109°C[24]).

**2-Benzyloxymethyl-4, 5-dimethylcyclohexa-4, 6-(or -1, 4-) dienylmethanal Ethylene Acetal (XXX).**—A mixture of the aldehyde XIVb (47.2 g.), *p*-toluenesulfonic acid (0.05 g.), ethylene glycol (26.2 g.) and benzene (250 ml.) was taken in a flask provided with an azeotropic water separator and heated under reflux at 120°C for 4 hr. The water was drawn off from time to time. After the excess of benzene was removed under reduced pressure the residue was extracted with ether. The ethereal solution was washed with a 10% aqueous sodium carbonate solution and with water, dried over sodium sulfate and then evaporated. Distillation of the residue afforded a lower boiling fraction (5.8 g.), b. p. 52~80°C/0.001 mmHg, and an acetal XXX (18.5 g., 33.5%) as a pale yellow viscous oil, b. p. 144~148°C/0.001 mmHg, $n_D^{26}$ 1.5429.

Found: C, 75.73; H, 8.21. Calcd. for $C_{19}H_{24}O_3$: C, 75.97; H, 8.05%.

The lower boiling fraction on treatment with the Brady reagent yielded a 2, 4-dinitrophenylhydrazone. Recrystallization from ethanol-ethyl acetate gave a pure sample, m. p. 226°C, undepressed on admixture with the 2, 4-dinitrophenylhydrazone of 2, 4, 5-trimethylbenzaldehyde.

**6-Benzyloxymethyl-3, 4-dimethyl-3-cyclohexenylmethanal Ethylene Acetal (XXXI).**—A mixture of the aldehyde XVb (8.3 g.), ethylene glycol (9.0 g.), *p*-toluenesulfonic acid (0.05 g.) and benzene (40 ml.) was refluxed at 130~135°C for 4 hr. The reaction mixture was worked up in the manner described above to yield the acetal XXXI (7.2 g., 74.2%), b. p. 150~155°C/0.017 mmHg.

Found: C, 73.98; H, 8.55. Calcd. for $C_{19}H_{26}O_3$: C, 75.46; 8.67%.

**4, 5-Dimethyl-2-hydroxymethylcyclohexylmethanal Ethylene Acetal (XXXII).**—*a) From XXX.*—The acetal XXX (16.5 g.) in ethanol (40 ml.) was hydrogenated over a 5% palladium-on-charcoal catalyst (1.0 g.) in a stainless-steel autoclave at 120°C and a pressure of 120 kg./$cm^2$ for 8 hr. The catalyst was filtered off and the filtrate was evaporated. Distillation of the residue afforded a saturated acetal XXXII (3.9 g., 33%) as a viscous oil, b. p. 112~120°C/1.3 mmHg, $n_D^{25.5}$ 1.4786.

Found: C, 66.90; H, 10.62. Calcd. for $C_{12}H_{22}O_3$: C, 67.25; H, 10.35%.

The 2, 4-dinitrophenylhydrazone crystallized from methanol-light petroleum in orange-yellow leaflets, m. p. 194~196°C.

Found: N, 16.19. Calcd. for $C_{16}H_{22}O_5N_4$: N, 15.99%.

Further distillation afforded a higher boiling viscous oil (6.7 g.), which boiled at 120~125°C/0.001 mmHg and was thought probably to be 2-benzyloxymethyl-4, 5-dimethylcyclohexylmethanal ethylene acetal (XXXIII), since it afforded readily

24) A. C. Cope, N. A. LeBel, H. H. Lee and W. R. Moore, ibid., 79, 4720 (1957).

XXXII on hydrogenolysis under the same conditions as those described above.

*b) From XXXI.*—The acetal XXXI (11.4 g.) in ethanol (50 ml.) was hydrogenated over 5% palladium-on-charcoal (1.0 g.) for 5 hr. in the manner described above to yield XXXII (6.2 g., 77.5%), b. p. 131~134°C/3.0 mmHg.

The 2, 4-dinitrophenylhydrazone prepared from this liquid showed m. p. 195~196°C, undepressed on admixture with a sample obtained in a).

The 3, 5-dinitrobenzoate crystallized from benzene-petroleum ether in plates, m. p. 110~111°C.

Found: C, 55.47; H, 5.96; N, 7.01. Calcd. for $C_{19}H_{24}O_8N_2$: C, 55.87; H, 5.92; N, 6.86%.

**4,5-Dimethyl-2-hydroxymethylcyclohexylmethanal (XXXIV).**—A mixture of the acetal XXXII (3.1 g.), tetrahydrofuran (16 ml.) and 2 N sulfuric acid (16 ml.) was refluxed for 2.5 hr. The cooled reaction mixture was neutralized with a 30% aqueous sodium carbonate solution and extracted with ether. The ethereal solution was washed with a saturated sodium chloride solution, dried over sodium sulfate and then evaporated. Distillation of the residue under nitrogen afforded the hydroxyaldehyde XXXIV (1.9 g., 77.3%), which boiled at 99~105°C/2.0 mmHg and solidified rapidly. Recrystallization from methanol-light petroleum yielded colorless plates, m. p. 84°C; $\nu_{max}^{KBr}$ 3333, 1724, 1456, 1124, 1087, 1047, 971, 899 and 877 $cm^{-1}$; $\lambda_{max}$ 225 m$\mu$ ($\varepsilon$ 37.3), 294 (29.1) in 75% aqueous dioxane.

Found: C, 70.81; H, 10.62. Calcd. for $C_{10}H_{18}O_2$: C, 70.54; H, 10.66%.

The 2, 4-dinitrophenylhydrazone crystallized from methanol in orange-yellow leaflets, m. p. 194~195°C, undepressed on admixture with that of XXXII.

***N*, *N*-Dimethyl-4,5-dimethyl-2-hydroxymethylcyclohexylmethylamine (XXXV).**—*a) From XXXIV.*—A mixture of the aldehyde XXXIV (1.2 g.), anhydrous dimethylamine (0.8 g.), Raney nickel catalyst (1.2 g.) and absolute ethanol (30 ml.) was shaken with hydrogen in a 100 ml. autoclave at 180~190°C and a pressure of 118 kg./cm² for 1.6 hr. The catalyst was filtered off and the solution was evaporated to leave an oil, which was taken up in ether and extracted twice with 2 N hydrochloric acid. The aqueous extracts were combined, made alkaline with a 10% sodium hydroxide solution and then extracted with ether. The dried ethereal solution on distillation afforded the aminoalcohol XXXV (0.8 g., 57%), b. p. 100~105°C/2.0 mmHg, $n_D^{29.5}$ 1.4666.

Found: C, 71.73; H, 12.40. Calcd. for $C_{12}H_{25}ON$: C, 72.30; H, 12.64%.

The methiodide crystallized from ethanol-ethyl acetate in prisms, m. p. 221°C.

Found: C, 45.40; H, 8.33. Calcd. for $C_{13}H_{28}ONI$: C, 45.87; H, 8.28%.

The ethereal solution which had been shaken with hydrochloric acid was distilled to yield an oil (0.15 g., 12%), which boiled at 115~121°C/2.0 mmHg and solidified on being set aside for a short time. Recrystallization from light petroleum afforded colorless plates, m. p. 113~115°C.

Found: C, 69.01; H, 11.23. Calcd. for $C_{10}H_{20}O_2$: C, 69.72; H, 11.70%.

This compound is thought probably to be 1, 2-bishydroxymethyl-4, 5-dimethylcyclohexane (XXXVI), since the elemental analysis is very satisfactory and the infrared spectrum exhibits strong absorption bands of the hydroxyl group at 3310 and 1045 $cm^{-1}$ but no band attributable to an aldehyde group.

*b) From XIVc.*—A mixture of the aldehyde XIVc (2.9 g.), anhydrous dimethylamine (2.0 g.), Raney nickel (2.0 g.) and ethanol (40 ml.) was shaken with hydrogen at 200~220°C and a pressure of 197 kg./cm² for 3 hr. When the resultant reaction mixture was worked up as in the case of XXXIV, there were obtained a crude amino compound (1.2 g., 43.5%) and a neutral one (0.8 g., 31.6%).

The amino compound boiled at 80°C/0.55 mmHg, $n_D^{15}$ 1.4755, and the infrared spectrum exhibited strong absorption bands of hydroxyl group at 3370 and 1066 $cm^{-1}$ and characteristic bands attributable to the *tert*-amino group at 2838, 2800 and 2742 $cm^{-1}$.

Found: C, 72.53; H, 12.80; N, 7.10. Calcd. for $C_{12}H_{25}ON$: C, 72.30; H, 12.64; N, 7.03%.

The methiodide crystallized from methanol-ethyl acetate in leaflets, m. p. 221°C, undepressed on admixture with that of XXXV obtained in a).

From the crude methiodide, there was obtained a small amount of crystals which were slightly soluble in methanol-ethyl acetate. Recrystallization afforded a pure sample, m. p. 271~272°C.

Found: C, 46.30; H, 7.93. Calcd. for $C_{13}H_{26}ONI$: C, 46.00; H, 7.73%.

The elemental analysis indicates that the methiodide is probably that of *N*, *N*-dimethyl-4, 5-dimethyl-2-hydroxymethyl-1-cyclohexenylmethylamine (XXXIX).

The neutral product of colorless liquid obtained above boiled at 95~105°C/0.6 mmHg and solidified rapidly. Recrystallization from petroleum ether yielded 2,4, 5-trimethylbenzyl alcohol (XL) in needles, m. p. 84.5°C.

The infrared spectrum (KBr disk) exhibited strong absorption bands of hydroxyl group at 3360 and 1038 $cm^{-1}$ and other principal bands at 1621 (w), 1513 (m), 1450 (s), 1078 (s), 1009 (s), 996 (s), 899 (m), 888 (m), and 877 $cm^{-1}$ (s). $\lambda_{max}^{EtOH}$ 217 m$\mu$ ($\varepsilon$ 175), 265 (338) and 274 (322).

Found: C, 80.02; H, 9.51. Calcd. for $C_{10}H_{14}O$: C, 79.95; H, 9.39%.

***N*, *N*-Dimethyl-4, 5-dimethyl-2-hydroxymethylcyclohexylmethylamine Oxide (XXXVII).**—To a solution of the amine XXXV (0.6 g.) in methanol (3.6 ml.) was added 30% aqueous hydrogen peroxide (1.5 g.) and the resultant mixture was stirred at 30°C for 50 hr., after which time the reaction mixture gave no color with phenolphthalein. The excess of hydrogen peroxide was then decomposed with a small amount of platinum foil and the solution was worked up as in the case of XXVI to yield the amine oxide XXXVII (0.55 g., 84.6%) as a colorless glass, which was characterized as the picrate which could not be induced to crystallize. The product thus obtained was used in the next pyrolysis without further purification.

**4, 5-Dimethyl-2-methylenecyclohexylmethanol (XXXVIII).**—The amine oxide XXXVII (0.4 g.) obtained above was pyrolysed as in the case of XXVII to yield a neutral XXXVIII (0.12 g., 42%),

b. p. 94~97°C/17.5 mmHg, $n_D^{27}$ 1.4729. The infrared spectrum (liquid film) exhibited absorption bands of hydroxyl group at 3385 and 1053 $cm^{-1}$, the bands attributable to exocyclic double bond at 3058, 1642 and 884 $cm^{-1}$ and other principal bands at 1765, 1459 and 1384 $cm^{-1}$.

# *Thermodynamical Studies on Binary Systems Consisting of Polar and Non-polar Liquids. IV. Estimation of the Electrostatic Part of the Excess Enthalpy from the Observed Values aud Comparison with the Calculated Values*

By Kazuo AMAYA

(Received March 13, 1961)

In a previous paper[1], the author calculated the electrostatic part of the excess enthalpy of binary systems composed of polar and non-polar liquids according to Onsager's model. In this paper the observed values of these quantities have been derived under reasonable assumptions and are compared with the calculated values.

## The Principle of the Estimation of the Electrostatic Part of the Excess Enthalpy from the Experimental Results

In order to derive the electrostatic part of the excess enthalpy due only to the permanent dipole of the polar molecule from the experimental result of the heat of mixing, the non-electrostatic part of the excess enthalpy must be estimated under reasonable assumptions and subtracted from the experimental value, since the observed excess enthalpy contains not only the electrostatic but also the non-electrostatic part.

As a first approximation, it may be assumed that the intermolecular interaction enery of polar molecules is the sum of the non-electrostatic part of the energy due to dispersion forces and the electrostatic one due to dipoles if higher multipoles are neglected.

From this assumption the cohesive energy for 1 mol. of pure polar liquid, $\Delta U_2$, may be given by

$$\Delta U_2 = \Delta U_2^{el} + \Delta U_2^{n-el} \tag{1}$$

where $\Delta U_2^{el}$ and $\Delta U_2^{n-el}$ are the electrostatic and the non-electrostatic part of cohesive energy respectively.

Since the electrostatic intermolecular energy is absent in non-polar liquids, the cohesive energy for non-polar liquid $\Delta U_1$ is given by the non-electrostatic intermolecular energy due to dispersion forces of non-polar molecules:

$$\Delta U_1 = \Delta U_1^{n-el} \tag{2}$$

Further, if the non-electrostatic part of the energy due to dispersion forces is assumed to be the sum of the energy due to dispersion forces of the nearest neighbor pairs, then for 1 mol. of polar liquid $\Delta U_2^{n-el}$ is given by

$$\Delta U_2^{n-el} = 1/2 \cdot N_A z \omega_{22} \tag{3}$$

and similarly for 1 mol. of non-polar liquid,

$$\Delta U_1^{n-el} = 1/2 \cdot N_A z \omega_{11} \tag{4}$$

where $N_A$ is Avogadro's number, $z$ is the number of the nearest neighbors and $\omega_{22}$ and $\omega_{11}$ are the non-electrostatic part of interaction energy due to dispersion forces of the nearest neighbor pairs of polar and non-polar molecules respectively.

When 1 mol. of the solution is formed from $x_2$ mole of polar liquid and $(1-x_2)$ mol. of non-polar liquid, both liquids being composed of molecules of similar size, the total energy of the system $\Delta U_{12}$ is given by

$$\Delta U_{12} = \frac{1}{2} x_2^2 N_A z \omega_{22} + x_2(1-x_2) N_A z \omega_{12} + \frac{1}{2}(1-x_2)^2 N_A z \omega_{11} + \Delta U_{12}^{el} \tag{5}$$

where $\omega_{12}$ is the non-electrostatic part of the nearest neighbor pair interaction energy of the pair consisting of polar and non-polar molecules and $\Delta U_{12}^{el}$ is the electrostatic part of the energy due to dipoles for 1 mol. of the solution. Thus the excess energy $U^E$ is given by

$$U^E = x_2(1-x_2) N_A z \omega + \Delta U_{12}^{el} - x_2 \Delta U_2^{el} \tag{6}$$

where $\omega$ is the part of interchange energy due to dispersion forces given by

$$2\omega = 2\omega_{12} - \omega_{22} - \omega_{11} \tag{7}$$

In a similar way the electrostatic part of the excess energy due to dipole-dipole interaction as well as the non-electrostatic contribution due to dispersion forces may be expressed as a function of volume fraction $v_2$ of the polar liquid:

$$U^E = V \alpha^{n-el} v_2(1-v_2) + \Delta U_{12}^{el}(v_2) - v_2 \cdot \Delta U_2^{el} \tag{8}$$

where $V$ is the volume of 1 mol. of the solution.

TABLE I. VALUES OF $\alpha^{el}_{obs}(0)$, $\alpha^{el}_{obs}(1)$, $\Delta\alpha^{el}_{obs}$ AND $\alpha^{el}_{obs}(0)/\alpha^{el}_{obs}(1)$ FOR THE SYSTEMS IN WHICH NON-POLAR COMPONENTS ARE NON-AROMATIC

| System | $\alpha^{el}_{obs}(0)$ joul./cc. | $\alpha^{el}_{obs}(1)$ joul./cc. | $\Delta\alpha^{el}_{obs}$ joul./cc. | $\alpha^{el}_{obs}(0)/\alpha^{el}_{obs}(1)$ |
|---|---|---|---|---|
| Chlorobenzene—Cyclohexane | 12.5 | 4.9 | 7.6 | 2.54 |
| Bromobenzene—Cyclohexane | 15.7 | 6.1 | 9.6 | 2.58 |
| Benzonitrile—Cyclohexane | 65.6 | 25.0 | 40.6 | 2.62 |
| Nitrobenzene—Cyclohexane | 75 | 37 | 38 | 2.03 |
| Cyclohexanone—Cyclohexane | 54.9 | 31.8 | 23.1 | 1.73 |
| Diethylketone—Cyclohexane | 54.4 | 28.9 | 25.5 | 1.89 |
| Methylpropylketone—Cyclohexane | 56.9 | 32.5 | 24.4 | 1.75 |
| *n*-Butylchloride—Cyclohexane | 21.8 | 11.2 | 10.6 | 1.95 |
| *n*-Butylcyanide—Cyclohexane | 59.2 | 33.9 | 25.3 | 1.75 |
| Chlorocyclohexane—Methylcyclohexane | 16.0 | 9.95 | 6.0$_5$ | 1.61 |
| Bromocyclohexane—Methylcyclohexane | 17.5 | 11.3 | 6.2 | 1.55 |
| *cis*-Dichloroethylene—*trans*-Dichloroethylen | 10.4 | 5.4 | 5.0 | 1.95 |
| Pyridine—1,4-Dioxane | 4.7 | <1.9 | >2.8 | 2.24 |

It may be assumed that $\alpha^{n-el}$, the contribution of dispersion forces to the van Laar coefficient is constant over the whole concentration range, because the coefficients $\alpha$ for binary systems of non-polar liquids are nearly constant. In addition it is also assumed that there is no volume change on mixing. Then $U^E$ is equal to $H^E$:

$$U^E = H^E = V\alpha^{n-el}v_2(1-v_2) + H^{E-el} \quad (9)$$

$$U^{E-el} = H^{E-el} = U^{E-el} - \Delta U_{12}{}^{el}(v_2) - v_2 \cdot \Delta U_2{}^{el} \quad (10)$$

Further, if the electrostatic part is expressed in the form

$$H^{E-el} = V\alpha^{el}v_2(1-v_2) \quad (11)$$

then

$$H^E = V(\alpha^{n-el} + \alpha^{el})v_2(1-v_2) \quad (12)$$

where $\alpha^{el}$ is the electrostatic contribution to $\alpha$.

## The Estimation of $\alpha^{n-el}$, Non-electrostatic Part of $\alpha$

The values of $\alpha^{el}$ can be obtained if the values of $\alpha^{n-el}$ are estimated under reasonable assumptions. And for estimating the non-electrostatic part of the heat of mixing, the following procedures are employed:

**(1) The Systems of Cyclohexane—Aliphatic Polar Molecule.** — For cyclohexane—*n*-hexane system the heat of mixing per mole of cyclohexane at the extreme dilution is about 573 joul./mol.[2] corresponding to the value of 5.3 joul./cc. for $\alpha$. Since for non-polar liquid systems the values of $\alpha$ do not vary with concentration, it may be reasonable to use the above value over all the concentration range. Even for the binary systems of cyclohexane and polar aliphatic hydrocarbon derivatives, it may be permissible, as an approximation, to take the value of 5.3 joul./cc. non-electrostatic part of $\alpha$, neglecting the difference for between $CH_3$, $CH_2$ and the polar groups.

**(2) The Systems of Cyclohexane—Benzene Derivative.**—In (1) the observed values of the electrostatic part of $\alpha$ at the two extreme concentrations of $v_2=1$ and 0, $\alpha^{el}_{obs}(1)$ and $\alpha^{el}_{obs}(0)$, are obtained by subtracting the value of 5.3 joul./cc. from the observed values at the corresponding concentrations. If the ratios, $\alpha^{el}_{obs}(0)/\alpha^{el}_{obs}(1)$, are calculated, they are found to lie between 2.0 and 1.5 as shown in Table I. Accordingly, if may be permissible to approximate the corresponding ratio in the cyclohexane—toluene system to be 2. Then, by empolying the observed value of $\alpha_{obs}(0) = 24.78$ joul./cc., $\alpha_{obs}(1) = 20.81$ joul./cc. for this system, the non-electrostatic part of $\alpha$ of 17.0 joul./cc. is obtained. As an approximation, neglecting the difference between $CH_3$ group of toluene and polar groups in other benzene derivatives, it may be plausible to assume the value of 17.0 joul./cc. as the non-electrostatic part of $\alpha$ for cyclohexane—benzene derivative systems.

The ratios of $\alpha^{el}_{obs}(0)/\alpha^{el}_{obs}(1)$ for the systems in which the non-polar components are non aromatic are shown in Table I.

It is seen from the table that the values of the ratio $\alpha^{el}_{obs}(0)/\alpha^{el}_{obs}(1)$ for the aromatic polar molecules are nearly equal to about 2, but slightly larger than those for non-aromatic molecules.

**(3) The Systems of Cyclohexane—Cyclohexanone, Methylcyclohexane — Harocyclohexane and *cis*- and *trans*-Dichloroethylene Systems.**—It is assumed that the non-electrostatic part of $\alpha$ is equal to zero because of the similarity of the two components.

—— Observed ----- Calculated

For the systems in which non-polar components are aromatic such as toluene or benzene, $\alpha^{n-el}$, the non-electrostatic part of $\alpha$, is estimated as follows.

**(4) The Systems of Toluene—Aromatic Polar Molecule.**—For the systems of toluene—benzene derivatives and of benzene—pyridine, the $\alpha^{n-el}$ are assumed to be zero for their structural similarity.

**(5) The Systems of Toluene—Aliphatic Polar Molecule.** — For butylchloride — toluene, and butylcyanide—toluene systems, the values of $\alpha^{n-el}$ are estimated from the data of heat of mixing for the toluene—*n*-heptane system[3], by neglecting the differences between the polar group and $CH_3$ or $CH_2$ groups as before. For the present cases the value of $\alpha$ for *n*-heptane (1.5 joul./cc.) are assumed to be $\alpha^{n-el}$.

For the cyclohexanone-toluene system $\alpha^{n-el}$ is assumed to be 17.0 joul./cc. as before.

## Results and Discussion

The values of the electrostatic part of the van Laar coefficient $\alpha^{el}_{obs}$ were plotted against volume fraction with solid lines in Figs. 1.1—1.11.

Before comparing them with the calculated values, it will be examined whether there exist any regularity between these values and dielectric constants of the polar component or not.

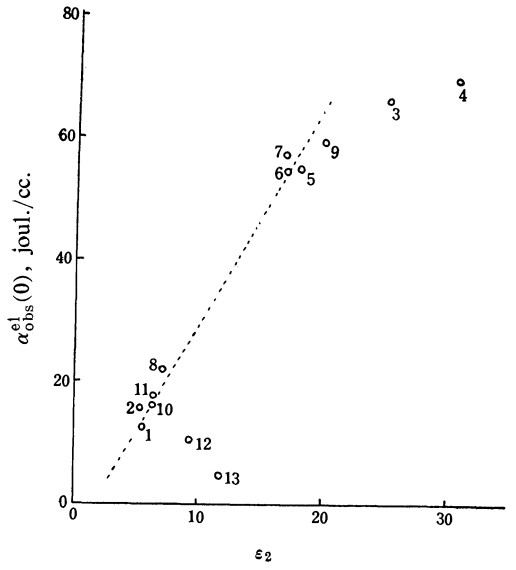

Fig. 2.

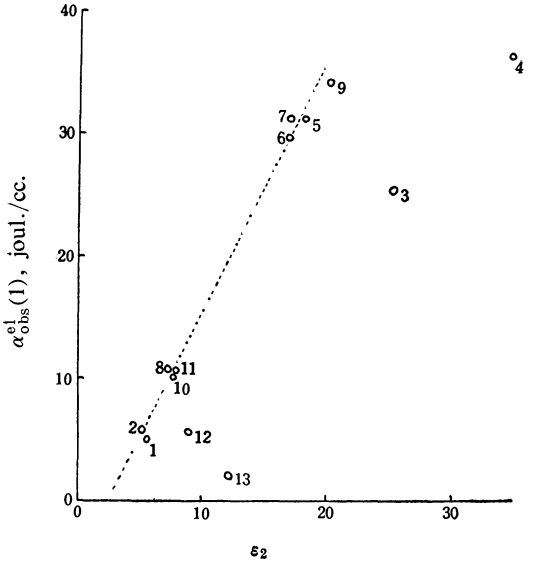

Fig. 3.

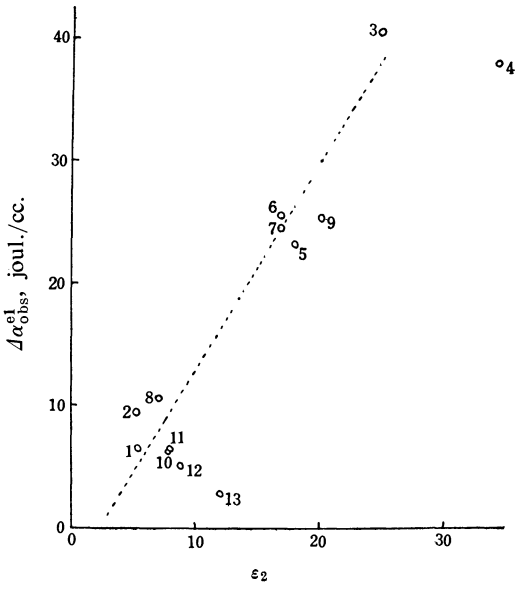

Fig. 4.

12. *cis*-Dichloroethylene—*trans*-Dichloroethylene
13. Pyridine—1,4-Dioxane

For systems in which non-polar components are non-aromatic such as cyclohexane and methyl cyclohexane etc.,. the values of $\alpha^{el}_{obs}$ at $v_2=1$ and $v_2=0$, $\alpha^{el}_{obs}(1)$ and $\alpha^{el}_{obe}(0)$ respectively, are shown in Table I.

The difference of $\alpha^{el}_{obs}(0)$ and $\alpha^{el}_{obs}(1)$, $\Delta\alpha^{el}_{obs}$, for the above systems are also shown in Table I.

The values of $\alpha^{el}_{obs}(0)$, $\alpha^{el}_{obs}(1)$ and $\Delta\alpha^{bl}_{obs}$ are plotted against the dielectric constants $\varepsilon_2$ of the polar components, in Figs. 2—4.

As is seen from the above figures, it is likely that $\alpha^{el}_{obs}(1)$, $\alpha^{el}_{obs}(0)$ and $\Delta\alpha^{el}_{obs}$ have a kind of correlation to the dielectric constants of the polar components, that is, each plot gives approximately a straight line which intersects the abscissa at about $\varepsilon_2=2$. It should be noted, however, that a slight deviation is observed for butylcyanide and nitrobenzene which have much larger dipole moments than the others. The fact that the straight line intersects the absissa at about $\varepsilon_2=2$, which is neary equal to the dielectric constant of the non-polar components shows that on mixing these non-polar liquids with liquids having a dielectric constant of about 2, which might be non-polar, the electrostatic part of the heat of mixing vanishes.

This indicates that the estimation of $\alpha^{n-el}$ mensioned above was not so inappropriate.

For *cis*-dichloroethylene—*trans*-dichloroethylene and pyridine—dioxane systems the plots

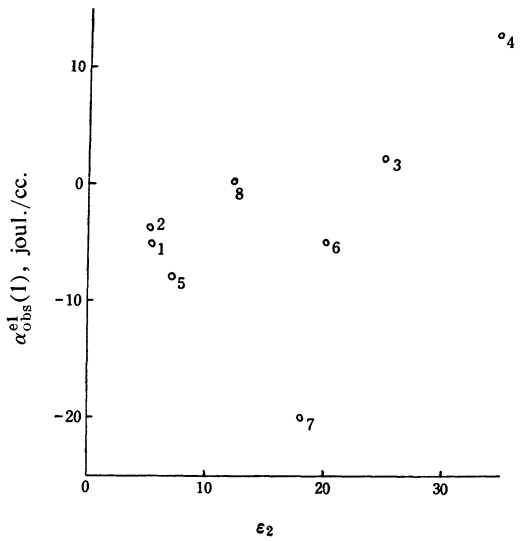

Fig. 5.

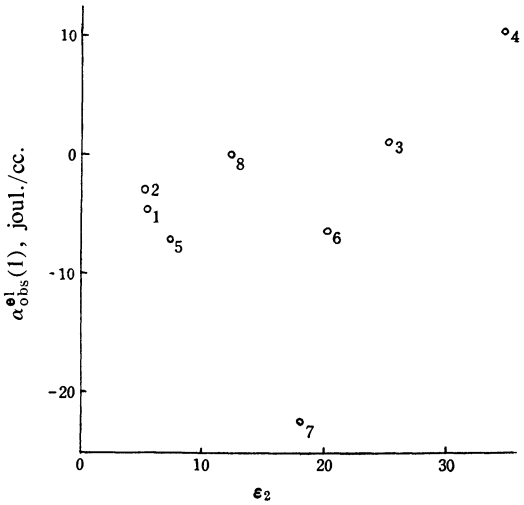

Fig. 6.

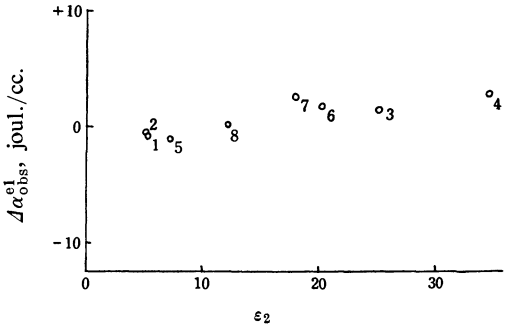

Fig. 7.

Figs. 5, 6, 7. The plots of observed values of electrostatic part of van Laar cofficients at concentrations $v_2=0$ and $v_2=1$ and their difference, $\alpha^{el}_{obs}(0)$, $\alpha^{el}_{obs}(1)$ and $\Delta\alpha^{el}_{obs}$ respectively vs. dielectric constant of polar components $\varepsilon_2$ for systems with aromatic non-polar components.

1. Chlorobenzene—Toluene
2. Bromobenzene—Toluene

6. *n*-Butylcyanide—Toluene
7. Cyclohexanone—Toluene
8. Pyridine—Benzene

of $\alpha^{el}_{obs}(1)$, $\alpha^{el}_{obs}(0)$ and $\Delta\alpha^{el}_{obs}$ versus $\varepsilon_2$ deviate largely from the other systems. This might be due to the quadrupole moment of the non-polar component molecules. These non-polar molecules behave apparently as non-polar so far as the dielectric constant is concerned, but energetically not. The contribution from the local dipoles of these molecules which is not considered here, should be introduced, in systems containing molecules with quadrupole moment. The assumption of a single point dipole is drastic for the *cis*-dichloroethylene molecule, which has two large bond dipoles at a finite distance, and this may also be one of the reasons of the deviations for the system of *cis*- and *trans*-dichloroethylenes. For the pyridine—dioxane system the deviation is much greater than the above system, and this may be attributed to the large quadrupole moments of dioxane or the special interaction between pyridine and dioxane.

For the nitrobenzene—cyclohexane system, the plot of $\alpha^{el}_{obs}$ versus $v_2$ has a peculiar shape compared with the remaining systems of this group. This may be attributed to the antiparallel orientation of nitrobenzene molecules in pure liquid and its concentrated solution, which is evidenced by the increase of the dielectric constant on application of a strong electric field[4]. This antiparallel orientation exists only at a concentration higher than about 80 mol. %, and at a lower concentration antiparallel orientation vanishes. As the antiparallel orientation of dipoles in pure liquid and concentrated solution is stable, the vanishing of the antiparallel orientation requires some energy and this contributes to make the values of $\alpha^{el}$ increase. This effect is important in a concentration higher than 80 mol. %, and in the actual system the values of $\alpha$ are rather shifted in the positive direction in this concentration range compared with the other systems.

For systems in which non-polar components are aromatic such as toluene and benzene, the values of $\alpha^{el}_{obs}(1)$ and $\alpha^{el}_{obs}(0)$ and their differences $\Delta\alpha^{el}_{obs}$ are obtained by graphical extrapolation, and are shown in Table II.

4) A. Piekara, Achelekowski, *J. Chem. Phys.*, **25**, 794 (1956).

TABLE II. VALUES OF $\alpha^{el}_{obs}(0)$, $\alpha^{el}_{obs}(1)$ AND $\Delta\alpha^{el}_{obs}$ IN joul./cc. FOR THE SYSTEMS IN WHICH NON-POLAR COMPONENTS ARE AROMATIC

| System | $\alpha^{el}_{obs}(0)$ | $\alpha^{el}_{obs}(1)$ | $\Delta\alpha^{el}_{obs}$ |
|---|---|---|---|
| Chlorobenzene—Toluene | −5.1 | −4.3 | −0.8 |
| Bromobenzene—Toluene | −3.7 | −3.1 | −0.6 |
| Benzonitrile—Toluene | 2.5 | 1.1 | 1.4 |
| Nitrobenzene—Toluene | 13.2 | 10.5 | 2.7 |
| *n*-Butylchloride—Toluene | −8.1 | −7.2 | −0.9 |
| *n*-Butylcyanide—Toluene | −4.7 | −6.5 | 1.8 |
| Cyclohexanone—Toluene | −20.0 | −22.5 | 2.5 |
| Pyridine—Benzene | 0.3 | 0 | 0.3 |

The values of $\alpha^{el}_{obs}(1)$, $\alpha^{el}_{obs}(0)$ and $\Delta\alpha^{el}_{obs} = \alpha^{el}_{obs}(0) - \alpha^{el}_{obs}(1)$ are plotted against the dielectric constant of the polar components and are shown in Figs. 5—7.

It is seen from the figures that no regulality is observed for $\alpha^{el}_{obs}(1)$ and $\alpha^{el}_{obs}(0)$ but for $\Delta\alpha^{el}_{obs}$ and they are nearly independent of the dielectric constants of the polar component. These are not on a line intersecting the abscissa at about $\varepsilon_2=2$.

Now the observed value will be compared with the calculated value. In Figs. 1.1—1.11, the values of $\alpha^{el}_{calcd}$ together with $\alpha^{el}_{obs}$ are plotted against the volume fractions of the polar component for the 21 binary systems of polar and non-polar liquids.

It is seen from the figures that for the systems in which non-polar components are non-aromatic both $\alpha^{el}_{obs}$ and $\alpha^{el}_{calcd}$ are positive and increase as the volume fraction of the polar component $v_2$ decreases. This confirms the fact that the variations of $\alpha$ with concentration are essentially due to the dipole of the polar component. However, quantitative agreements are poor for some of systems. For those in which non-polar components are aromatic, then differ in the manner of the change of $\alpha$ with concentration and sometimes even in their signs giving no qualitative agreement. This also confirms the fact that for the latter group of the systems, some kind of effect coherent to the aromaticity of the non-polar component which is not taken into consideration in the assumption of the derivation of the theory, occurs in the actual cases, and this may be the reason for the qualitative disagreement.

Further, quantitative comparison of $\alpha^{el}_{obs}$ and $\alpha^{el}_{obs}$ for the systems in which non-polar components are non-aromatic are made for the former group of the systems whose $\alpha^{el}$ may be considered to be explained principally by dipolar forces. The ratios of the calculated value to the experimental one, $\alpha^{el}_{calcd}/\alpha^{el}_{obs}$ are calculated for those systems at five values of concentration $v_2=1.00$, 0.75, 0.50, 0.25 and 0. The values of these ratios are plotted against the volume fraction in Fig. 8.

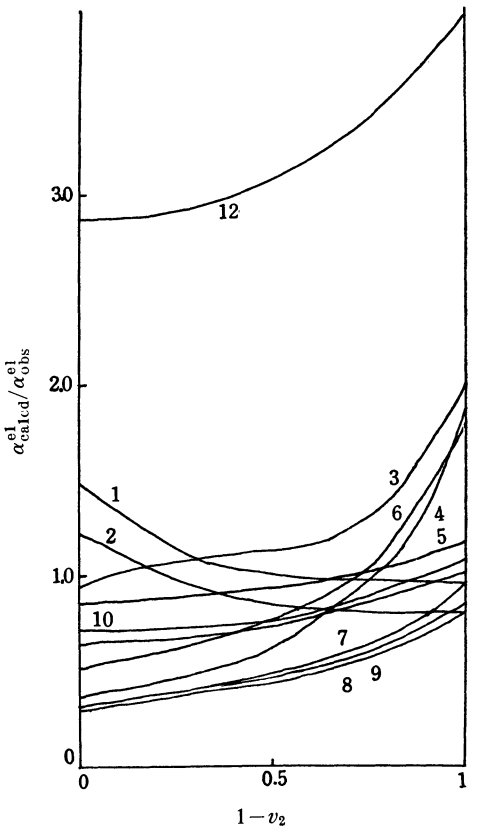

Fig. 8. Ratio $\alpha^{el}_{calcd}/\alpha^{el}_{obs}$ vs. volume fraction.

1. Chlorobenzene—Cyclohexane
2. Bromobenzene—Cyclohexane
3. Benzonitrile—Cyclohexane
4. Nitrobenzene—Cyclohexane
5. *n*-Butylchloride—Cyclohexane
6. *n*-Butylcyanide—Cyclohexane
7. Cyclohexanone—Cyclohexane
8. Diethylketone—Cyclohexane
9. Methylpropylketone—Cyclohexane
10. Chlorocyclohexane—Methylcyclohexane
11. Bromocyclohexane—Methylcyclohexane
12. *cis*-Dichloroethylene—*trans*-Dichloroethylene

It is seen from the result that most of the values of $\alpha^{el}_{calcd}/\alpha^{el}_{obs}$ are less than 2, whereas for the two systems, namely, of *cis*- and *trans*-dichloroethylene and of pyridine—dioxane, they differ considerably from the rest. Especially for the latter, it is too large to show in the figure. This indicates that the contribution due to the effect which cannot be explained merely with dipolar forces, presumably due to the quadrupole of the constituent molecules, is contained in the above two systems.

It indicates that in calculating electrostatic energy, contributions from multipoles higher than dipole such as quadrupole etc. must be taken into account for such systems.

It also indicates that for the rest of the group of the systems except the system containing the component molecules with larger dipole moments, such as nitrobenzene, benzonitrile and butylcyanide, the heats of mixing at infinite dilution of polar liquid in non-polar liquid are rather in good agreement with the theory despite of its rough assumptions. Rather good agreement obtained in a very dilute region for the systems with polar molecules of moderate magnitude of dipole moment, may be evidence that in these dilute regions, the assumptions made in the theory are not far from the actual circumstances.

Disagreement in the concentrated region may principally be due to the roughness of the theory such as the neglect of the short range interaction.

For systems containing polar molecules of large dipole moment the calculated values differ greatly from the experimental values.

This suggests that the larger the dipole moments is, the less satisfied is the condition of the assumption made in the theory in the actual circumstances.

**Summary**

The electrostatic part of the van Laar coefficients were derived from the observed value of heats of mixing and some regularity was found between these values and the dielectric constant of polar components if non-polar components are non-aromatic (group I). However, no regularity exists between them if non-polar components are aromatic (group II). These values were also compared with the calculated values. For group I, qualitative agreements were obtained and this confirms the fact that the variation of $\alpha$ with concentration is due to dipolar interaction of the polar components. The agreement is poor for systems containing a polar component with large dipole moments or for one containing a non-polar component with quadrupole moment. For group II, no qualitative agreement was obtained.

The author wishes to express his thanks to Professor Ryoichi Fujishiro of Osaka City University and to Professor Yonezo Morino of the University of Tokyo for their constant encouragement and discussions.

# *Thermodynamical Studies on Binary Systems Consisting of Polar and Non-polar Liquids. V. The Anomalies in the Binary Systems of Polar Liquid with Aromatic Non-polar Liquid*

By Kazuo AMAYA

(Received March 30, 1961)

In a previous paper it has been shown that an anomalous stabilization effect exists in those systems consisting of polar and aromatic non-polar components. To elucidate the cause of these phenomena, plausible explanations are proposed from the molecular view point.

## Experimental Evaluation of the Anomalous Stabilization Effect

As is stated above, the binary systems containing the aromatic non-polar molecule and polar molecule show anomalous behavior in the heats of mixing.

First the decrease of the van Laar coefficient $\alpha$ due to the anomalous effect which was observed in aromatic non-polar solvents but not in non-aromatic solvents, will be estimated on reasonable assumptions.

Consider an imaginary non-polar liquid which is normal in nature such as cyclohexane, and its dielectric constant is the same as that of toluene. It may be reasonable to assume that the electrostatic part of the imaginary heat of mixing of the above imaginary non-polar liquid with polar liquids, if observed, would deviate from the theoretical values calculated for systems containing toluene in a previous paper, to the same extent as that of the deviation of the experimental value from the calculated one in the corresponding systems consisting of the same polar liquid and cyclohexane, because the dielectric constant of

toluene and cyclohexane differs only slightly. Then the van Laar coefficient due to the electrostatic part of imaginary heat of mixing may be estimated according to the following expression by the use of $\alpha^{el}_{c.obs}$ and $\alpha^{el}_{c.calcd}$ for the cyclohexane-polar liquid system and the $\alpha^{el}_{t.calcd}$ for the toluene-polar liquid system.

$$\alpha^{el}_{i.obs}=\alpha^{el}_{c.obs}\cdot\alpha^{el}_{t.calcd}/\alpha^{el}_{c.calcd} \quad (1)$$

where $\alpha^{el}_{i.obs}$ is the van Laar coefficient for an imaginary binary system mentioned above. The results obtained are shown in Table I.

TABLE I. VAN LAAR COEFFICIENT DUE TO STABILIZATION ENERGY $\alpha_{stab}$ AND THE VALUES OF STABILIZATION ENERGY $\Delta E_{stab}$ IN THE SYSTEMS COMPOSED OF POLAR LIQUID AND TOLUENE

| System | $v_2$ | $\alpha^{el}_1$ joul./cc. | $\alpha_{stab}=\alpha^{el}_{obs}-\alpha^{el}_1$ joul./cc. | $\Delta E_{stab}$ joul./mol. |

| —Toluene | 0.50 | 32.34 | −55.2 | 1456 |
| | 0.25 | 41.15 | −64.6 | 1286 |
| | 0 | 46.61 | −66.6 | 0 |

These values would be the corresponding electrostatic part of the van Laar coefficient for heats of mixing of toluene and the polar liquids if toluene were normal in nature as cyclohexane is, and do not show any anomalous behavior. The difference between such apparent values and the observed values may be considered to be the contribution from the anomalous effect. The part of the contribution of the anomalous effect to the van Laar coefficient $\alpha_{stab}$ thus obtained are also shown in the same table together with the stabilization energy per mole of the solution. It is seen that $\alpha_{stab}$ is dependent on the concentration.

## The Origin of the Anomalous Stabilization Effect

**The Anisotropy of the Aromatic Non-polar Molecules.**—If an anisotropic non-polar molecule is placed in an electric field, it tends to orient its most polarizable axis to be parallel to the direction of the electric field. In a region near the polar molecule, a strong electric field is produced arouud it and hence aromatic molecules in this region would tend to orient their most polarizable axis along the direction of the electric field. Then the effective dielectric constant of this region increases somewhat more than the original macroscopic value, the extent of which depends on the anisotropy of the non-polar molecule and the magnitude of the dipole moment of the polar molecule.

The increase of the dielectric constant of the non-polar liquid makes the calculated values of the van Laar coefficient decrease as is seen from the above results that the calculated values of the electrostatic part of the van Laar coefficient $\alpha^{el}_{calcd}$ for tolune-polar liquid system is an amount of 80~90% of those for the corresponding system of cyclohexane-polar liquid. Anisotropy constants for benzene and toluene are reproduced for reference from the literature:

$$\text{for benzene}\begin{cases}\alpha_1=123.1\\ \alpha_2=123.1\\ \alpha_3=\ 63.5\end{cases}\quad\bar{\alpha}=103.2,\quad\frac{\alpha_1}{\bar{\alpha}}=1.193$$

$$\text{for toluene}\begin{cases}\alpha_1=156.4\\ \alpha_2=136.6\\ \alpha_3=\ 74.8\end{cases}\quad\bar{\alpha}=122.6,\quad\frac{\alpha_1}{\bar{\alpha}}=1.276$$

If we suppose that the non-polar molecules given above orient their most polarizable axis completely along the direction of the electric field produced by the polar molecule, the effective dielectric constant may be increased from 2.366 of toluene to about 3.

The values calculated with the values of 3

for the dielectric constant of non-polar liquid indicate the maximum contribution of this effect. In actual cases, however, the orientation of the non-polar molecule along the direction of the electric field is disturbed by thermal agitation and the effective dielectric constant may be less than 3.

The orientational effect in the solution consisting of anisotropic non-polar molecules accompanying the increase of effective dielectric constant in the region of small $x_2$ would make the values of $\alpha^{el}_{calcd}$ smaller than before.

But with this consideration alone it is impossible to make the values of $\alpha^{el}$ negative and also to explain the concentration dependence of $\alpha_{stab}$.

**The Addition Stabilizing Effect due to Orientation of Anisotropic Non-polar Molecules in an Electric Field.**—The molecules of toluene and benzene are somewhat anisotropic, and when they are placed in a strong electric field, they tend to orient their most polarizable axis in the direction of the applied electric field. In the gaseous state this effect results in the increase of polarizability, and hence somewhat stabilizes the molecules. But this effect makes little contribution as was explained above.

In the liquid state, however, molecules interact with each other, and if we are admitted to assume the orientation of these molecules increases the intermolecular interaction energy, these stabilizing effects may be explained consistently.

Anisotropic non-polar molecules near a polar molecule are in a more ordered state than those far from the polar molecule because of the strong dipolar field of the latter. It may be reasonable to assume that in a region near the dipolar molecule, anisotropic non-polar molecules stick together more or less as they do in their solid state and the degree or the extent of the orientation depends on the magnitude of the dipolar field.

Let us consider an anisotropic non-polar molecule whose polarizabilities along three principal axes x, y and z are $\alpha_x$, $\alpha_y$ and $\alpha_z$ respectively.

When this molecule is placed in an electric field $F$, then the electrostatic energy of the molecule, $E$ is expressed as

$$E=-\frac{1}{2}(\alpha_x\cos^2\theta_{\mu x}+\alpha_y\cos^2\theta_{\mu y}+\alpha_z\cos^2\theta_{\mu z})F^2 \tag{2}$$

where $\theta_{\mu x}$, $\theta_{\mu y}$ and $\theta_{\mu z}$ denote the angles between the direction of the electric field and each principal x, y and z axis respectively.

For simplicity, assuming that

$$\alpha_x=\alpha_y \tag{3}$$

the electrostatic energy $E$ is given by

$$E=-\frac{1}{2}(\alpha_z\cos^2\theta_{\mu z}+\alpha_x\sin^2\theta_{\mu z})F^2$$
$$=-\frac{1}{2}\{(\alpha_z-\alpha_x)\cos^2\theta_{\mu z}+\alpha_x\}F^2 \tag{4}$$

then

$$\overline{\cos^2\theta_{\mu z}}=\frac{2\int_{\pi/2}^{0}\int_0^{2\pi}\cos^2\theta_{\mu z}\cdot\exp\left[\frac{1}{2}\{(\alpha_z-\alpha_x)\cos^2\theta_{\mu z}+\alpha_x\}\times(F^2/kT)\right]\cdot\sin\theta_{\mu z}d\theta_{\mu z}d\varphi}{\int_{\pi/2}^{0}\int_0^{2\pi}\exp\left[\frac{1}{2}\{(\alpha_z-\alpha_x)\cos^2\theta_{\mu z}+\alpha_x\}\times(F^2/kT)\right]\cdot\sin\theta_{\mu z}d\theta_{\mu z}d\varphi}$$
$$=\frac{\int_{\pi/2}^{0}\cos^2\theta_{\mu z}\exp\left[\frac{1}{2}(\alpha_z-\alpha_x)(F^2\cos^2\theta_{\mu z}/kT)\right]\times\sin\theta_{\mu z}d\theta_{\mu z}}{\int_{\pi/2}^{0}\exp\left[\frac{1}{2}(\alpha_z-\alpha_x)F^2\cos^2\theta_{\mu z}/kT\right]\cdot\sin\theta_{\mu z}d\theta_{\mu z}} \tag{5}$$

Putting $\cos^2\theta_{\mu z}=x$, and $1/2\cdot(\alpha_z-\alpha_x)F^2/kT=a$, then the above expression becomes

$$\overline{x^2}=\frac{\int_0^1 x^2e^{ax^2}dx}{\int_0^1 e^{ax^2}dx}=\frac{\left[\frac{x}{2a}e^{ax^2}\right]_0^1}{\int_0^1 e^{ax^2}dx}-\frac{1}{2a} \tag{6}$$

As the integration in the denominater, $\int e^{ax^2}dx$ can not be expressed in a simple formula, the integrand is expanded in a power series, and is integrated, and then the following expression is obtained

$$\int e^{ax^2}dx=\int\left(1+ax^2+\frac{a^2x^4}{2!}+\frac{a^3x^6}{3!}+\cdots\right)dx$$
$$=x+\frac{a}{3}x^3+\frac{a^2x^5}{5\cdot2!}+\frac{a^3x^7}{7\cdot3!}+\cdots \tag{7}$$

For extreme cases of $a\ll1$ and $a\gg1$, the following approximate formula are obtained.

For $a\ll1$

$$\int_0^1 e^{ax^2}dx=1+\frac{a}{3}+\frac{a^2}{10}+\cdots \tag{8}$$

$$\left[\frac{x}{2a}e^{ax^2}\right]_0^1=\frac{1}{2a}+\frac{1}{2}+\frac{a}{4}+\cdots \tag{9}$$

then

$$\frac{\left[\frac{x}{2a}e^{ax^2}\right]_0^1}{\int_0^1 e^{ax^2}dx}=\left(\frac{1}{2a}+\frac{1}{2}+\frac{a}{4}+\cdots\right)\times\left(1+\frac{a}{3}+\frac{a^2}{10}+\cdots\right)^{-1}$$
$$=\frac{1}{2a}+\frac{1}{3}+\frac{7}{90}a+\cdots \tag{10}$$

Then

$$\overline{\cos^2\theta_{\mu z}}=\frac{1}{3}+\frac{7}{90}a+\cdots \tag{11}$$

For $a \gg 1$, $\overline{\cos^2\theta_{\mu z}}$ tend to unity.

For the molecule with $\alpha_z > \alpha_x = \alpha_y$, $\overline{\cos^2\theta_{\mu z}}$ tends to 1/3 as $a$ approaches to zero, and to 1 as it approaches to infinite. For the molecule $\alpha_z < \alpha_y = \alpha_y$, $\overline{\cos^2\theta_{\mu z}}$ tends to 1/3 as $a$ approaches to zero and to 0 as it approaches to infinite.

As the value of $\overline{\cos^2\theta_{\mu z}}$ varies with the order of the molecular arrangement, it may be reasonable to define an order parameter as

$$s = (\overline{\cos^2\theta_{\mu z}} - 1/3)/(1-1/3) \quad \text{for } \alpha_z > \alpha_x \quad (12)$$

and

$$s = (1/3 - \overline{\cos^2\theta_{\mu z}})/1/3 \quad \text{for } \alpha_z < \alpha_x \quad (13)$$

$s$ is proportional to $a$ for small values of $a$ and tends to approach to 1 for large values of $a$ like the Langevin function. It may reasonably be assumed that the stabilization energy due to orientation of the anisotropic non-polar molecules is proportional to $s$ and as a result it may be saturated in a strong electric field corresponding to a great value of $a$.

Now, the order of magnitude of $a$ for actual cases will be considered. For the values of $(\alpha_z - \alpha_x)$ the value $\approx 60 \times 10^{-25}$ cc. per molecule of toluene is taken, and for $F$, if the values of an electric field at a distance of 3Å from a point dipole of 1D is taken, the value of $F$ is $3.7 \times 10^4$ e. s. u., there $a$ for $T = 300°K$ becomes 0.05 for 1D, and 0.82 for 4D. For chlorobenzene $a$ is about 0.15 and for nitrobenzene this value is about 0.8.

Now, let us consider the order of magnitude of this effect. Since this effect is cooperative with respect to an aromatic non-polar molecule, it is natural that the contribution from this effect vanishes in a limit at zero concentration of aromatic non-polar component. Then it may be resonable to attribute the concentration dependent part of $\alpha_{stab}$ to this effect.

At infinite dilution of polar liquids, this stabilization energy per mole of polar liquid is from about 700 to 3200 joul.

On the other hand, heats of fusion, which may be considered to be a measure of orientational energy for benzene and toluene are about 9840 joul. and 6620 joul. per mole, respectively. As one polar molecule is surrounded by several of the nearest neighboring non-polar molecules at infinite dilution, a slight extent of ordered state in the group of molecules is possible to introduce considerable stabilization energy to their systems. Therefore, the magnitude of the above values of stabilizing energy seems to be not unreasonable as the contribution from this effect.

The stabilization energy of toluene at an infinite dilution of the polar molecule caused by 1 mol. of polar molecule is plotted against $\mu^2$ in Fig. 1.

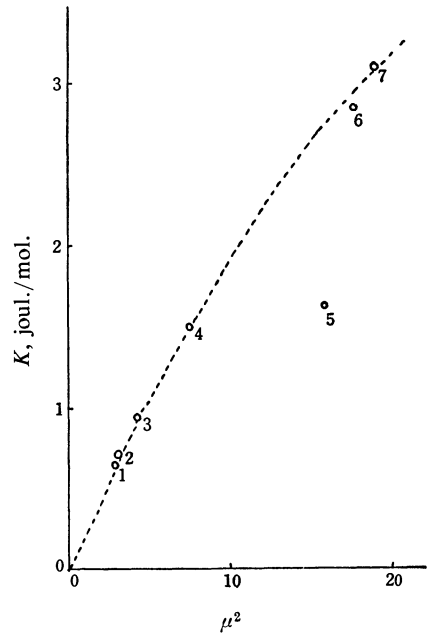

Fig. 1. Concentration dependent part of stabilization energy per mole of polar components at infinite dilution in toluene plotted against square of dipole moment of the polar molecules.

1. Chlorobenzene
2. Bromobenzene
3. *n*-Butylchloride
4. Cyclohexanone
5. *n*-Butylcyanide
6. Nitrobenzene
7. Benzonitrile

It is seen from the figure that the saturation effect is only slightly observed as the theory predicts. This fact makes the above explanation plausible. As for a concentration independent part of $\alpha_{stab}$, further investigations will be necessary.

## Summary

The anomalous stabilization energy for the systems containing polar and aromatic non-polar liquids was evaluated on reasonable assumptions. The van Laar coefficient due to this stabilizing effect was found to be dependent on the concentration. The stabilization effect corresponding to the concentration dependent part of the van Laar coefficient was explained by the cooperative orientation of aromatic non-polar molecules around the polar molecules.

# *Mass-spectrometric Study on Ionization and Dissociation of Diethyl Ether by Electron Impact*

By Ichiro KANOMATA

(Received March 28, 1961)

Since 1930 many studies on ionization and dissociation of organic molecules by electron impact have been made by means of a mass-spectrometer. The reason for using a mass-spectrometer for these kinds of studies is to obtain the information on the decomposition processes through determination of M/e values and of the appearance potentials of ions formed by electron impact.

The study on the processes of ionized decomposition by electron impact is not only fundamental for the radiation chemistry of organic compounds but also helpful for the researches on molecular structures and chemical reactions.

The author previously reported the mass-spectrometric study on ionization and dissociation of the ethyl alcohol molecule by electron impact[1,2]. The present report relates to the decomposition of the diethyl ether molecule which has one oxygen atom, and the ionization of the molecule is thought to "cause the removal" of one of the lone pair 2 p electrons of this oxygen atom as well as in the case of ethyl alcohol in the previous study.

## Experimental

The mass spectrometer[3] used for this study was a 90° sector type ($R=12$ cm.), and the appearance potentials (AP) of ions were determined by the extrapolated difference method[4]. The ionization potential of the molecule was calibrated with the ionization potential of argon (15.76 eV.) and the appearance potentials of fragment ions were determined by referring to the ionization potential of the molecule. The sample was chemically pure and was not particularly refined.

## Results

The appearance ratios of ions produced from the molecule by 75 eV. electron impact are shown in Table I. From the table it is obviously recognized that the M/e=31 ion ($CH_2OH^+$ or $CH_3O^+$) is the most abundant, and the M/e=29, 59, 45 and 74 ions are also abundant. The appearance potentials of these five species of ions obtained are tabulated in Table II.

TABLE I. APPEARANCE RATIOS

| M/e | Ion | Appearance ratio |
|---|---|---|
| 75 | Isotope peak | 0.3 |
| 74 | $(C_2H_5)_2O^+$ | 25.7 |
| 60 | $(CH_3)(C_2H_5)O^+$, isotope peak | 2.1 |
| 59 | $(CH_2)(C_2H_5)O^+$ | 46.0 |
| 46 | $C_2H_5OH^+$, isotope | 0.4 |
| 45 | $(C_2H_5)O^+$ | 31.3 |
| 44 | $C_2H_4O^+$ | $3.1_5$ |
| 43 | $C_2H_3O^+$ | $12.7_5$ |
| 42 | $C_2H_2O^+$ | 3.0 |
| 41 | $C_2HO^+$ | 6.0 |
| 31 | $CH_2OH^+$ or $CH_3O^+$ | 100.0 |
| 30 | $CH_2O^+$ | $3.1_5$ |
| 29 | $CHO^+$ or $C_2H_5^+$ | 63.5 |
| 28 | $CO^+$ or $C_2H_4^+$ | 10.2 |
| 27 | $C_2H_3^+$ | 37.1 |
| 26 | $C_2H_2^+$ | 8.0 |
| 15 | $CH_3^+$ | 14.3 |
| 14 | $CH_2^+$ | 2.7 |

TABLE II. APPEARANCE POTENTIALS (eV.)

| M/e | Ion | Appearance potential |
|---|---|---|
| 74 | $(CH_3CH_2)O^+(CH_2CH_3)$ | $9.55\pm0.02$ |
| 59 | $CH_2O^+CH_2CH_3$ | $10.80\pm0.08$ |
| 45 | $CH_3CH_2O^+$ | $13.23\pm0.04$ |
| 31 | $CH_2O^+H$ or $CH_3O^+$ | $12.3_5\pm0.1$ |
| 29 | $C_2H_5^+$ or $CHO^+$ | $14.0\pm0.2$ |

## Discussion

When a molecule $R_1R_2$ is composed of $R_1$ and $R_2$ atoms (or radicals), the appearance potential of $R_1^+$ ions is given by

$$A(R_1^+) = I(R_1R_2) + D(R_1^+ - R_2) \quad (1)$$

$$= I(R_1) + D(R_1 - R_2) \quad (2)$$

Here, $I(R)$ is the ionization potential of atom (radical) R, and $D(R_1-R_2)$ is the bond dissociation energy between $R_1$ and $R_2$. Of course, radicals or atoms produced may generally have some excitational or kinetic energy. In case the molecule consists of many atoms as organic compounds, however, the potential

1) T. Kambara and I. Kanomata, *Buturi* 4, 71 (1949).
2) T. Kambara and I. Kanomata, *Hitachi Hyoron Rombunshu*, No. 7, 15 (1949).
3) I. Kanomata, Y. Kaneko and T. Oguri, *Mass Spectroscopy*, No. 3, 12 (1954).
4) J. W. Warren, *Nature*, 165, 811 (1950).

surfaces that give the binding energies between atoms approach each other, and therefore the excess energy may be small as reported by some authors[5,6]. From this point of view the neglect of this excess energy will not be serious in the course of this discussion.

The processes of production of ions are as follows:

$$M/e=74 \quad (C_2H_5)_2O^+, \quad AP \ 9.55 \text{ eV}.$$

This ion is the parent ion and the appearance potential is the ionization potential of diethyl ether molecule. This value was obtained by Morrison[7] as 9.72 eV. by critical slope method and by Price[8] spectroscopically as 10.2 eV. These results are largely different from each other beyond their errors of measurement, though the reason can not be explained.

It must be considered what kind of electron in the molecule is concerned with its ionization. Mulliken[9] reported that the lone pair electrons of the oxygen atom in the molecules, such as water and alcohol, have the lowest ionization potential by charge transfer effect. Hence the ionization occurs at first by the removal of one of these electrons. The fact that the ionization potentials decrease in the order of H-O-H (12.76 eV.), $CH_3$-O-H (10.95 eV.), $CH_3$-O-$CH_3$ (10.5 eV.) and $C_2H_5$-O-$C_2H_5$ (9.55 eV.) can be explained by this charge transfer effect. This postulate was also used when the present author and Kambara studied the ionization and dissociation of ethyl alcohol[1,2], propyl alcohol[10,11], acetone and acetic acid[12] molecules by electron impact, and will be required to discuss the dissociation process for the production of M/e=59 ion from diethyl ether. From these facts, the ionization potential 9.55 eV. is thought to be that of the oxygen atom in the molecule.

$$M/e=59 \quad (CH_2\text{-}O\text{-}C_2H_5)^+, \quad AP \ 10.80 \text{ eV}.$$

Equation 1, in this case, leads to $A(R_{59}^+)=I(R_{74})+D(R_{59}^+-R_{15})$. Inserting the observed values, $D(R_{59}^+-R_{15})=10.80-9.55=1.25$ eV. is obtained. This dissociation energy of the ionic state should correspond to the dissociation energy of the C-C bond of the neutral molecule. The reason why the dissociation energy for such an ionized molecule is apparently low may be elucidated as follows.

If one of the lone pair electrons of the oxygen atom in the molecule is removed by ionization in accordance with Mulliken's postulate, the other electron left in the atom may have new binding activity, that is, the trivalency of the $O^+$ ion. Therefore, when the structure of M/e=59 ion is assumed as $\begin{matrix}H\\H\end{matrix}\!\!>\!C\!=\!O^+\text{-}C_2H_5$, this ion should be more stabilized, by the energy of formation of trivalent structure, than the structure of $\cdot\begin{matrix}H\\C\\H\end{matrix}\!\!\text{-}O^+\text{-}C_2H_5$ which is yielded by only removing a $CH_3$ radical from the parent ion.

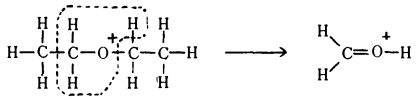
In order to estimate this stabilization energy of formation of trivalent bond, it is assumed that the dissociation energy of the C-C bond of the diethyl ether molecule is equal to that of ethane.

$$D(R_{59}-R_{15})=D(CH_3-CH_3)=80\pm6 \text{ kcal.}^{13}$$
$$=83.3\pm1 \text{ kcal.}^{14}$$
$$=3.6 \text{ eV}.$$

Then the stabilization energy becomes $3.6-1.25=2.35$ eV. $=54$ kcal./mol. Consequently, under the assumption of the additivity of bond energy, the total binding energy of trivalent bond of $O^+$ in this case is obtained as (3.26 eV. $\times2+2.35$ eV. $=8.87$ eV. $=)204$ kcal./mol., where 3.26 eV. is the value of $D$(C-O).

It may be recognized that in this ion resonance occurs as in carbon monoxide molecule, causing the stabilization near 58 kcal. of resonance energy of carbon monoxide[15].

$$M/e=45 \quad (C_2H_5\text{-}O)^+, \quad AP \ 13.23 \text{ eV}.$$



This ion is thought to be produced by the removal of a $C_2H_5$ radical from the parent ion. Therefore the relation $A(C_2H_5-O\cdot^+)=I(C_2H_5-O\cdot)+D(R_{45}-R_{29})$ exists. According to Syrkin and Dyatkina's data[16] on heat of dissociation, $D$(C-O) for diethyl ether is 75 kcal./mol. (3.26 eV.), hence from the above equation $I(C_2H_5-O^+\cdot)=10.0$ eV. is obtained. This value is somewhat greater than the ionization potential of the parent molecule (9.55 eV.). This seems to be due to the charge transfer effect which is adopted to explain the low value of the ionization potential of the parent molecule. As regards this ion, of course, the stabilization due to trivalency of $O^+$ can not take place.

M/e=31 $(CH_3\text{-}O\text{-}H)^+$, AP 12.3$_5$ eV.

The structure of this ion may be thought to be either $CH_3O^+$ or $CH_2OH^+$. Though this ion is the most abundant among those produced by 75 eV. electron impact, it can not be produced through a simple process, as the rupture of only one bond in the cases of M/e =59 and 45. Thus, in this dissociation process, rearrangement of atoms in the molecule is necessary.

The following dissociation process is energetically reasonable.

That is, it is thought that with the ionization of the oxygen atom, the rupture of bonds and the formation of O-H bond take place simultaneously. Assuming the bond energy additivity, the energy necessary for this process will be calculated as follow:

| | |
|---|---|
| ionization of oxygen atom | 9.55 eV. |
| rupture of C-C bond | 3.6 eV. |
| rupture of C-O bond | 3.26 eV. |
| rupture of C-H bond[17] | 2.9 eV. |
| formation of O-H bond | −4.8 eV. |
| formation of $>C=O^+\text{-}$ structure | −2.35 eV. |

The sum of these energies is 12.16 eV. in total and agrees well with the appearance potential obtained.

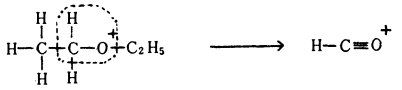
On the contrary, if this ion is assumed to have the structure of $CH_3O^+$, the energy necessary for the reaction becomes more than 16 eV. Therefore the structure of M/e =31 ion is concluded to be $H_2C=O^+\text{-}H$.

M/e=29 $C_2H_5^+$ or $CHO^+$, AP 14.0 eV.

If the M/e=29 ion is $C_2H_5^+$, Eq. 2 leads

$$A(C_2H_5^+) = I(C_2H_5) + D(C_2H_5\text{-}OC_2H_5)$$

Then $I(C_2H_5) = 14.0 - 3.26 = 10.74$ eV.



The ionization potential of $C_2H_5$ radical can be estimated from various data. For example, Bleakney gave a rather high value of 9.8 eV. from the decomposition of ethyl alcohol, and the mean value of the data given from various ionized decompositions of organic compounds is 8.75 eV.[5] Moreover, the energy for direct ionization of $C_2H_5$ radical has the rather low value of 8.60 eV.[18] Therefore, this ion should not be $C_2H_5^+$ ion, but $CHO^+$.

If it is assumed that radicals of H, $CH_3$ and $C_2H_5$ are produced in the course of the formation of $CHO^+$, the heat of reaction can be calculated from the thermochemical data as follows.

$$A(CHO^+) = \Delta H_f(CH_3) + \Delta H_f(C_2H_5) + \Delta H_f(H) + \Delta H_f(CHO^+) - \Delta H_f(C_2H_5OC_2H_5) = 14.3 \text{ eV.}$$

The calculated value agrees well with the experimental result.

From the standpoint of bond energy additivity, and the assumed reaction of

as in the case of M/e=31 ion, the energy necessary for the reaction will be calculated as follows.

| | |
|---|---|
| ionization of the molecule | 9.55 eV. |
| rupture of C-C bond | 3.6 eV. |
| rupture of C-O bond | 3.26 eV. |
| rupture of C-H bond | 2.9 eV. |
| $H\text{-}C\text{-}O^+\text{-} \rightarrow H\text{-}C\equiv O^+$ | $-2.35\times2$ eV. |

The sum of these energies is 14.6 eV. The difference between this value and the measured appearance potential is somewhat great, but this is unavoidable under such a loose assumption and rough calculation.

The total bond energy of $O^+$ ion in the case of $CHO^+$ is also calculated as in the case of M/e=59 ion. That is to say, provided that the energy of the C-O bond 3.26 eV. is conserved in one of the triple bond of $CHO^+$ ion, the total energy of $O^+$ is calculated as

$$3.26 + 2.35\times2 = 7.96 \text{ eV.} = 182 \text{ kcal./mol.}$$

This value is rather small compared with that of M/e=59 ion.

The reason why the stabilization is smaller in this case than in the case of M/e=59 ion is thought to be due to the existence of fewer resonance structures.

## Summary

A mass spectrometric study on ionization and dissociation of diethyl ether has been carried out.

The M/e=31 ion is the most abundant among the ions produced by 75 eV. electron impact and the M/e=29, 59, 45 and 74 ions are abundant in this order next to M/e=31 ion.

The appearance potential measurement of these ions leads to the following conclusion. The ions are formed by the removal of one of the lone pair electrons of the oxygen atom in the molecule.

17) C. E. Cumming and M. E. Bleakney, *Phys. Rev.*, **58** 787 (1940).
18) J. A. Hipple and D. P. Stevenson, ibid., **63**, 121 (1943).

By considering the trivalent structure of $O^+$ and by applying the bond energy additivity, which is adequate for hydrocarbons, to such an ionized dissociation process the producing processes of such ions can be satisfactorily revealed.

The stabilization energy for the formation of $\rangle C=O^+-$ structure is obtained as 54 kcal./mol. by such a calculation.

The author would like to express his deep appreciation to Professor K. Kido and Professor T. Titani for their kind guidance and to Mr. Y. Kaneko and Mr. T. Oguri for their earnest coorporation.

# *Proton Magnetic Resonance Spectra of Methylthiophenesulfonylchlorides*

By Kensuke TAKAHASHI, Yasuo MATSUKI, Yoshiteru MIYAKE and Genjiro HAZATO

(Received March 31, 1961)

In the previous communication[1], the relative magnitude of the coupling constants for the ring protons in thiophene derivatives was assumed to be $J_{23}>J_{34}>J_{25}>J_{24}$, in which the values for $J_{25}$ and $J_{24}$ could not be determined experimentally. This assumption is in accordance with the recent experimental works by Gronowitz and Hoffman[2]. In this note, the experimental results of the proton magnetic resonance spectra for the six isomers of methylthiophenesulfonylchloride are presented. Those results complement the previous communication on the substituted thiophenes. The observed values of $J_{25}$ and $J_{24}$ and some experimental coupling constants for the methyl group and the ring proton are also presented. Some qualitative results of the solvent effect on the chemical shifts of these isomers are also presented.

## Experimental

The apparatus and procedure were similar to those previously described[1], and cyclohexane was used as an internal reference. The compounds used in the present observations were synthesized by Matsuki and his collaborators. Details of the preparation of these new compounds will be given later in Journal of the Chemical Society of Japan, Ind. Chem. Sec. The boiling points and the measured conditions of the samples are given in Table I; with respect to these six isomers, 2-methyl-5-thiophenesulfonylchloride is the only one which is reported in the literature[3], as far as we know.

TABLE I

| Substituent | B. p. °C/mmHg | Measured condition wt. % Sample | $CCl_4$ | $C_6H_{12}$ |
|---|---|---|---|---|
| 2-$CH_3$, 3-$SO_2Cl$ | 91~93/3 | 77.9 | | 22.1 |
| 2-$CH_3$, 4-$SO_2Cl$ | 92~94/3 | 56.9 | 30.7 | 12.4 |

reported[1], gives the reverse effect on the chemical shift, so that all spectra here observed can be assigned easily from the standpoint of the chemical shift. In a case where the signal is split by the indirect spin-spin interaction, the shift given in Table II is that for the center of the resonance pattern, so that the difference of the values given for two ring protons in a compound (for example, in 2-methyl-3-thiophenesulfonylchloride, 234 minus 226 equals to 8 c.p.s.) does not equal the true chemical shift for those ring protons, but equals $(J^2+\delta^2)^{1/2}$. The analysis of the two-proton system was reported very early by Hahn and Maxwell[4], and later by Bannerjee, Das and Saha[5]. In this system, the spectrum consists of two

4) E. L. Hahn and D. E. Maxwell, *Phys. Rev.*, **88**, 1070 (1952).

doublets; the separation in each doublet just gives the coupling constant between two protons. The disubstituted thiophenes are also the typical model of the two-proton system in which the analysis of the spectrum can be done very easily. But sometimes, as in the case of some methylthiophenesulfonylchlorides, the spectra are somewhat complicated owing to the small interaction between the ring protons and the substituents. The magnitude of the coupling constant for the ring proton and its neighboring methyl protons, as previously reported[1], has the order of about 1.0 c.p.s.; however, the chemical shift between them is more than 170 c.p.s. at 40 Mc./sec. The chemical shifts are here so large compared with the coupling constants ($J/\delta$ <0.006) that the spectra can be analyzed by the simple method of the two-proton system. The results of the simple treatment are given in Table III.

Table III. The coupling constants ($J$) and the chemical shifts ($\delta$) of two ring protons in methylthiophenesulfonylchlorides in c. p. s. at 40 Mc./sec. Measured conditions are summarized in Table I

| Substituent | $J$ | $\delta$ |
|---|---|---|
| 2-$CH_3$, 3-$SO_2Cl$ | 5.3±0.1 | 6.6±0.1 |
| 2-$CH_3$, 4-$SO_2Cl$ | 1.5±0.1 | 29.5±0.6 |
| 2-$CH_3$, 5-$SO_2Cl$ | 4.1±0.1 | 30.6±0.1 |
| 3-$CH_3$, 2-$SO_2Cl$ | 5.2±0.1 | 26.2±0.1 |
| 3-$CH_3$, 4-$SO_2Cl$ | 3.5±0.1 | 40.2±0.3 |
| 3-$CH_3$, 5-$SO_2Cl$ | 1.8±0.1 | 7.5±0.1 |

The proton magnetic resonance spectra of the six isomers studied are reproduced in Fig. 1, in which the ring proton spectra are shown at the left-hand side and the methyl proton spectra at the right-hand side. With respect to the ring proton spectra, a and d in Fig. 1 show the typical type of two-proton system; on the other hand, the other figures in Fig. 1 show some small splittings caused by methyl protons. For 2-methyl-3-thiophenesulfonylchloride, each of the two ring proton spectra is a little asymmetric as shown in a of Fig. 1. The doublet at the low field side is somewhat broader than the doublet at the high field side. Similar broadening is observed also in the doublet at the high field side, the 4-proton spectrum in 3-methy-2-thiophenesulfonylchloride, as shown in d of Fig. 1. For 2-methyl-4-, 2-methyl-5-, 3-methyl-4- and 3-methyl-5-thiophenesulfonylchloride, as shown in b, c, e and f in Fig. 1*, the ring proton spectra consist of two doublets. The one at the low field side has a simple structure and the other doublet at the high field side shows the fine structure caused by the interaction with methyl protons. The methyl proton spectra at the higher field side show also a doublet. In these four isomers, the 2-methyl group couples to 3-proton with a coupling constant of 1.1 c. p. s. However, the 3-methyl group couples to 2-proton with the same value but does not couple to 4-proton with the same order of coupling constant. This trend was also obseved in the spectrum of 3-methyl-2-thiophenesulfonylchloride, as shown in d of Fig. 1., in which no resolved fine structure was observed. The interaction between 4-proton and the adjacent methyl group is small. But the spectra of 4-proton are somewhat broader than those of 5-proton in 2-methyl-3- and 3-methyl-2-thiophenesulfonylchloride, as shown in a and d of Fig. 1. Consequently, it can be assumed that 2-methyl or 3-methyl group couples to 4-proton with a small coupling constant but couples to 5-proton with no appreciable constant. Similar results on the long range coupling in thiophene derivatives also have been obtained by others[2f,2g,6].

The coupling constants between two ring protons in the six isomers studied are 5.3 and 5.2 c.p.s. for $J_{23}$, 4.1 c.p.s. for $J_{34}$, 3.5 c.p.s. for $J_{25}$, and, 1.5 and 1.8 c.p.s. for $J_{24}$, as shown in Table III. The previous assumption[1] that the coupling constants between the ring protons for thiophene derivatives are $J_{23} > J_{34} > J_{25} > J_{24}$, is also consistent with the present observed values. It is very interesting to note that the observed coupling constant between the two protons by way of the sulfur atom ($J_{25}$) are relatively large, as compared with the meta-coupling constants for the benzene derivatives[7]; this trend is also obtained in thiophene which was analyzed recently by several authors[2b,8,9].

Chemical shifts depend upon the nature and the concentration of the solvents, so that the observation of the solvent effects on the chemical shift in the present compounds has also been made. The measured conditions and the results are summarized in Table IV. Three typical solvents were used, cyclohexane and carbon tetrachloride as nonpolar solvents, and acetone as a polar solvent. The experiment was carried out with the definite dilute solution of the compounds in each solvent, because of the limited amount of the synthesized material

* In c, e and f in Fig. 1, some extra peaks probably due to the presence of small isomeric impurities are observed.

at hand, and a small amount of cyclohexane was used also as an internal reference. One of our aims in this experiment was to find a key for the assignment of the chemical structure by the NMR spectrum. As shown in Table IV, it is clear that, in the six compounds studied, all $\alpha$-protons are sensitive to the polarity of the solvents as compared with $\beta$-protons, notably in the case of the solution in acetone. It should be kept in mind that the self-polarizabilities given by de Heer[10] for $\alpha$- and $\beta$-carbon atoms in thiophene are qualitatively in agreement with the present results of the solvent effect.

# *Proton Magnetic Resonanace Spectra of p-Cresol*

By Ichiro YAMAGUCHI

(Received March 28, 1961)

Schaefer and Schneider[1] investigated the ring proton resonance spectra of the *p*-substituted toluene derivatives and obtained many fruitful results concerning the interaction between ring protons and solvent molecules. The present author previously reported an NMR study of several hydrogen-bonded systems[2-5]. In these reports, explanations of the NMR behavior of the ring protons were made when the protons are affected by a change in the hydrogen-bonding situation in the molecule. In the present work, the NMR spectra of *p*-cresol, which gives rather a simple spectrum for the ring protons, were measured in various solutions and the NMR behaviors of methyl, hydroxyl and ring protons were interpreted in terms of hydrogen bond formation.

2) I. Yamaguchi, This Bulletin, 34, 353 (1961).
3) I. Yamaguchi, ibid., 34, 744 (1961).
4) I. Yamaguchi, ibid., 34, 451 (1961).
5) I. Yamaguchi, to be published.

## Experimental

The NMR measurements were made with a Varian NMR spectrometer at a resonance frequency of 56.4 Mc./sec. and at a temperature of 20°C. Chemical shifts of methyl, hydroxyl and ring protons from an external reference of water proton were determined by the side band technique and the susceptibility corrections were applied. *p*-Cresol was a guaranteed grade reagent and was purified by distillation. The solvents used were benzene, chloroform, carbon tetrachloride, dioxane, acetone and pyridine. These were purified with a Podobielniak distillator. Solutions with concentrations between 0.02 and 1 mol. fractions were prepared for each solvent.

## Results and Discussion

Figure 1 shows the concentration dependence of the chemical shifts of the methyl, hydroxyl and ring protons in carbon tetrachloride solutions. The hydroxyl proton resonance curves show characteristic behavior of each solution as shown in Fig. 2. On the other hand, the methyl and ring proton resonance curves show slight dependence on the solvent. Generally, the resonance fields of the methyl and ring protons decrease on dilution. The greater part of the causes of this inclination can be ascribed to the diamagnetic anisotropy effect of aromatic rings in the solution[6]. The resonance in the ring protons shows an interesting concentration dependence: Pure cresol liquid gives a single line spectrum while it gives a spectrum with

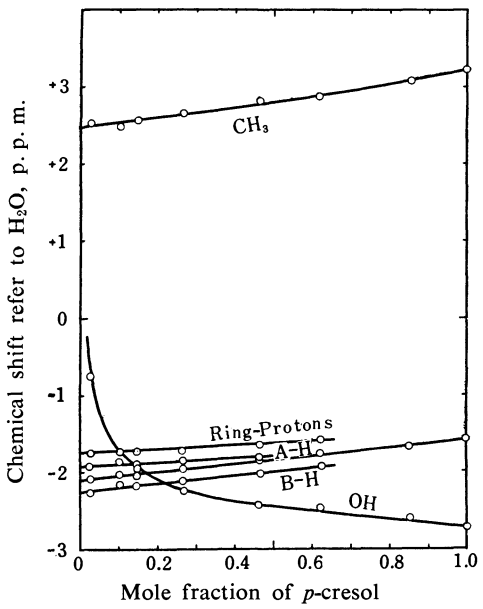

Fig. 1. Concentration dependence of chemical shift for *p*-cresol in $CCl_4$ solution.

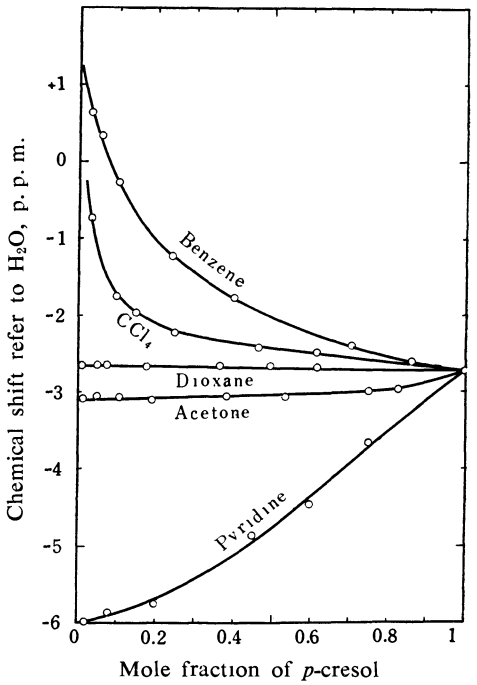

Fig. 2. Concentration dependence of OH proton chemical shift for *p*-cresol in various solutions.

a structure in dilute solution, arising from the proton pairs being chemically different from each other.

**Methyl Proton.** — The chemical shift of the methyl protons for benzene and pyridine solutions is apparently independent of the concentration because the net content of aromatic rings in the solutions is almost invariable. Those for the other solutions show the concentration dependence which is characteristic of the anisotropic effect of benzene rings of the solute in these solvents. The dilution shifts are almost the same as those for ring protons in benzene[6]* for the same solutions. The slope of the curve for the acetone solution is smaller than the others and this finding is parallel to the case of the ring protons in benzene. There seemed to be no notable effect of the hydrogen bonding on the methyl proton resonance.

**Hydroxyl Proton.** — Pure *p*-cresol gives a hydroxyl proton resonance line at slightly lower field than that in pure phenol[7]. This may be caused by the strengthening of the hydrogen bond by the hyperconjugation effect of the *p*-methyl group, although the hydrogen bond energies for the two compounds are comparable

to each other[8]. The solvent and concentration dependences of the hydroxyl proton resonance are shown in Fig. 2. The curves for benzene, chloroform and carbon tetrachloride solutions show the dissociation process of the hydrogen bond between the solute molecules on dilution. The curves for dioxane, acetone and pyridine solutions suggest new hydrogen bond forms between the solute and the solvents on dilution.

The curves for the carbon tetrachloride solution are as similar as those for phenol in carbon tetrachloride solution[9], exhibiting a representative NMR behavior of the dissociation process of a hydrogen bond system. The curve for the concentration above the concentration of about 0.3 mol. fraction is considered to correspond to the dissociation process of polymer species. In the range below about 0.05 mol. fraction the dissociation of dimer molecules is considered to be dominant. The resonance field for the benzene solution increases simply on dilution. This behavior of the curve is caused by several factors; the dissociation of the associated molecules, the ring current effect of benzene and the hydrogen bond formation with the $\pi$-electron system of the solvent molecule. The last may cause the rapid increase of the resonance field on dilution.

In dioxane and acetone solutions, the solute is considered to form a new hydrogen bond with the solvent molecules on dilution while the associated *p*-cresol molecules dissociate. The new hydrogen bonds are probably weaker ones than the intermolecular hydrogen bond of *p*-cresol. This is because the resonances at the infinite dilution are due to a more shielded proton than that in the intermolecular hydrogen bond of *p*-cresol. Pyridine, a strong proton acceptor, appeared to form a strong hydrogen bond with *p*-cresol as suggested by the curve. Pyridine seems to destroy the hydrogen-bonded association or chelation[2] of a compound by its strong proton accepting power.

**Ring Proton.**—The ring proton resonance in solutions appears at a slightly higher field than those for benzene in respectively the same solvents. This is due to the electron-releasing substituents of methyl and hydroxyl groups in *p*-cresol. *p*-Cresol liquid gives a single resonance line for the ring protons while diluted *p*-cresol with any solvent gives a spectrum with a characteristic structure of the $A_2B_2$ system[10] as shown in Fig. 1. The slope of the concentration-dependence curves for ring protons is due mainly to the anisotropic effect of the aromatic rings in the solutions. The slope of the curves for B-protons (ortho to methyl group) in chloroform, carbon tetrachloride, dioxane and acetone solutions are slightly gentler than those for benzene in respectively the same solutions[6]. This easier characteristic of the slope may be ascribed to the bulkier molecular size of *p*-cresol compared to that of benzene[11]. Therefore the B-protons can plausibly be assumed to be scarcely affected by the varying situations of the hydrogen bonding but to some effect proper to the proton in an aromatic ring. The slope for A-protons (ortho to hydroxyl group) is much easier than that for the B-protons.

If the effect of the ring current is removed for simplicity's sake from considerations of NMR behavior of the ring protons, the B-proton resonance is nearly independent of the concentration of the solutions, while the A-proton resonance is displaced to a higher field on dilution. The cause of this inclination for the A-protons may be ascribed to some changes in the following effects affected by the hydrogen bond formation; (i) the inductive and mesomeric effects of the hydroxyl group, (ii) the electrostatic field which originated from the hydroxyl bond moment, (iii) effect of magnetic anisotropy of the solvent molecule in the proximity of A-proton, (iv) preferential hydrogen bond formation between A-proton and solvent molecule, and (v) dispersion effect of solvent molecule on the A-proton. The effects (i) and (ii) have their origin in the molecule itself while (iii), (iv) and (v) come from the interaction with the solvent. Since the behavior for the A-proton is common to all solutions, the effects (iii) and (iv) are ruled out. It is difficult to consider a preferential dispersion effect on the A-proton, and the effect (v) is also ruled out. On hydrogen bond formation, the length and the polarization of the O–H bond may increase[12] and hence the electrostatic field at the A-protons originating from the bond moment may be altered. This electric field might cause the displacement of the A-proton resonance. However, the direction of the displacement is to a higher field with increasing bond moment. Therefore, the contribution of the effect (ii) should be small. For this reason, the effect (i) is considered to be dominant to cause the displacement of the resonance in A-proton. With the effect (i), this inclination for the A-protons

TABLE I. CHEMICAL SHIFTS, DILUTION SHIFT, COUPLING CONSTANT AND COALESCENT CONCENTRATION OF RING PROTON SPECTRUM IN *p*-CRESOL

| Solvent | $\delta_{ring}$ (p. p. m.) conc.=1 | $\delta_{ring}$ (p. p. m.) conc.=0 | Dilution shift (p. p. m.) $\delta_1-\delta_0$ | $\delta_{AB}$ (c./sec.) | $J_{AB}$ (c./sec.) | Coalese. conc. (mol. fraction) |
|---|---|---|---|---|---|---|
| Benzene | −1.56 | −1.46 | +0.10 | 18.6 | 8.5 | ~0.2 |
| $CHCl_3$ | 〃 | −2.03 | −0.47 | 16.6 | 〃 | ~0.6 |
| $CCl_4$ | 〃 | −2.03 | −0.47 | 15.3 | 〃 | ~0.7 |
| Dioxane | 〃 | −1.97 | −0.41 | 20.3 | 〃 | ~0.8 |
| Acetone | 〃 | −1.89 | −0.33 | 14.7 | 〃 | ~0.6 |

may be interpreted as follows: On formation of a strong intermolecular hydrogen bond between *p*-cresol molecules, the electron density on the oxygen atom should increase. This dense distribution of the negative charge is supplied from the ring, especially from the ortho-positions by inductive and mesomeric mechanisms. Thus the chemical shift of the A-proton is displaced to a lower field in the concentrated range. This qualitative explanation is plausible for the systems of hydroxyl hydrogen bond so far investigated by the present author[2,3].

Table I gives the chemical shift of the ring proton systems ($\delta_{ring}$) at the concentrations of zero and 1 mol. fractions, the dilution shift ($\delta_1-\delta_0$), the relative chemical shift and the spin coupling constant between A and B protons at infinite dilution, and the concentration where the lines of the spectrum coalesce. Figure 3 shows the position of the spectra of the ring protons schematically for the solutions investigated. The spectrum for benzene solution is displaced to a considerably high field compared to those for the other solutions. This is due to the anisotropic effect of benzene. The B-proton resonance at the infinite dilution for chloroform, carbon tetrachloride and dioxane solutions occur at about the same field in relation to one another, whereas the A-proton resonance for them occurs at fields different from one another. This fact also supports the inactiveness of the B-protons against the change in the environments. The B-proton resonance for acetone solution is the only exception: The resonance occurs at a slightly higher field than for the other solutions mentioned above. The same is observed for the ring protons of benzene in acetone solution[6]. Therefore, the preferential hydrogen bond interaction of an acetone molecule with the B-proton as suggested by Schneider and Schaefer[1] is denied in this case. This discrepancy may partly be attributed to the large dielectric constant of acetone[1].

Chemical shift refer to $H_2O$

Fig. 3. Ring proton spectra for *p*-cresol in various solutions.

In Fig. 3, the field where the resonance lines coalesce to a single line is indicated by a shaded range. It is surprising that the fields are almost the same for all solutions (about −1.74 p.p.m.) except benzene solution although the concentrations are different from one another. The coincidence of the field may have some meaning concerning the structure of the solutions or may rather be an accident. However, in this work, this phenomenon could not be well interpreted with the anisotropic effect of the aromatic rings in the solutions at the coalescent concentration. The single coalesced line in the concentrated range may suggest that only the same species of associated polymers as in pure *p*-cresol exists in this range. In benzene solution, the coalescence occurs at an exceptionally low concentration. This may be ascribed to the poor ability of the benzene molecule to disrupt the hydrogen bonds due to the geometrical similarity of the flat molecular shape of benzene and *p*-cresol.

It may be noted that the resonance fields of the methyl protons at the coalescent concentration for the four solutions are approximately +2.95 p. p. m., and this value is also nearly independent of the solvent. Accompanying the ring proton resonance data, this fact may also supply some information about the structure of the solutions.

**Summary**

The proton magnetic resonance spectra of *p*-cresol in several solutions were measured. The concentration dependence of the resonance in methyl protons suggests no remarkable effect of the hydrogen bonding on methyl protons. The resonance in the hydroxyl proton shows characteristic concentration dependences which are ascribed to the dissociation of the associated molecule in benzene, chloroform and carbon tetrachloride solutions and to the formation of new hydrogen bonds with solvent in acetone, dioxane and pyridine solutions. The ring proton resonance spectrum is a single line in concentrated range whereas it is an $A_2B_2$ type spectrum in dilute range. The splitting of the spectrum in dilute solutions is ascribed to the change in the screening of the proton ortho to the hydroxyl group affected by the change in the intermolecular hydrogen-bonding situation. The shielding of the proton ortho to the methyl group appeared to be unaffected by the same change.

# *Nuclear Magnetic Resonance in Amino-group of Aniline Derivatives*

By Ichiro YAMAGUCHI

(Received March 28, 1961)

The association of aniline molecules by their weak hydrogen bonds was suggested by several authors[1,2]. However, the association is still not well ascertained. Nuclear magnetic resonance measurements of aniline derivatives have not yet been made and are expected to give valuable information about the intermolecular hydrogen bond of these compounds and, in connection with the work on dimethyl phenols[3], about the effects of the ortho-methyl group on the proton resonance chemical shift of the amino-group. Thus this paper presents the study of the hydrogen bond of the amino-group by NMR measurements.

## Experimental

All the NMR measurements were carried out with a Varian NMR spectrometer at a radio frequency of 56.4 Mc./sec. and at a temperature of 20°C. The compounds investigated were aniline, *o*-, *m*- and *p*-toluidines and 2, 3-, 2, 4-, 2, 5-, 2, 6- and 3, 4-dimethylanilines. These were all guaranteed grade reagents and purified by distillation immediately before making solutions. The solvents used were carbon tetrachloride and acetone. These were purified with a Podobielniak fractional distillator. Solutions with concentrations of between 0.01 and 1 mol. fractions were made for all liquid aniline derivatives. 3, 4-Dimethyl aniline is solid and the concentrations of the solutions measured were up to saturated solution. The chemical shifts from water as an external reference were determined by the side band technique. Corrections for bulk diamagnetic susceptibility of the solutions were made. The values of the volume susceptibility were obtained by applying Pascal's rule and appropriate extrapolations. Their values were 0.676 for aniline, 0.70 for all toluidine isomers and 0.68 for all dimethyl aniline isomers.

## Results and Discussion

The concentration dependence of the amino proton resonance for carbon tetrachloride solutions are shown in Fig. 1a and those for acetone solutions in Fig. 1b. Pure aniline derivatives investigated give amino proton resonance at $+1.7 \sim +1.9$ p. p. m. The resonance fields are remarkably higher than those of hydroxyl proton resonance in phenols. Figure 2 shows an example of the concentration dependence of the chemical shifts for dimethyl aniline isomers. The resonance of the amino protons in carbon tetrachloride solutions was a sharp single absorption while that in acetone solutions was generally broad, especially in dilute solutions.

In Fig. 1, curves for the amino protons in various aniline derivatives investigated are observed to fall in a rather narrow field range and apparently there is no notable feature connecting the relative position of the methyl group to the amino group. This fact is remarkably in contrast with the hydroxyl proton resonance of dimethyl phenol isomers[3]. In

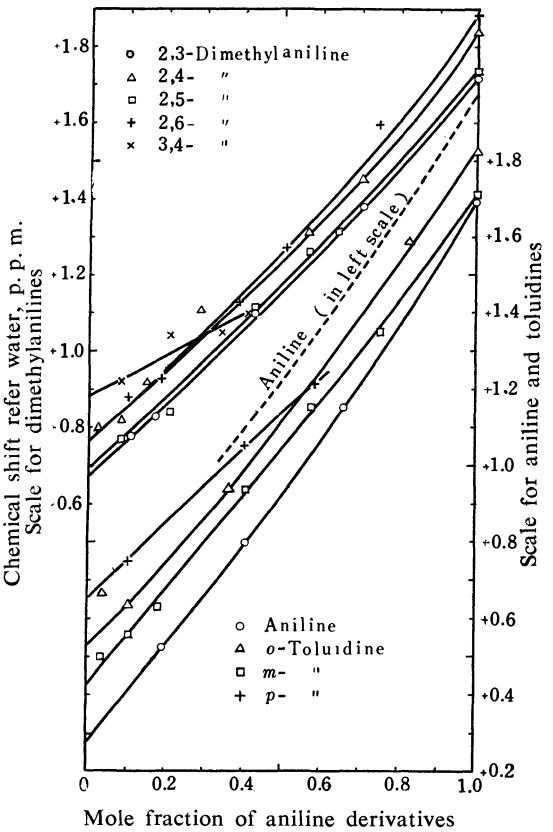

Fig. 1b. Concentration dependence of amino proton chemical shift for aniline derivatives in acetone solution.

this narrow range, the curves for dimethyl aniline isomers appear at the highest field side, those for toluidine isomers at the middle and that for aniline at the lowest side. This order seems to correspond exactly to the order of the base strength of these compounds. The cause of this arrangement of the shifts would mainly be the inductive effect of the methyl groups. In each group of the isomers, the curves for compounds with ortho- or para-methyl group appear at a higher field than those with the meta-methyl group. This result suggests that the mesomeric effect of the methyl group also has an important role to the chemical shift of the amino protons.

Dodd and Stephenson[4] showed a correlation between the basicity of amines and the NH frequency shift in the infrared absorption spectrum caused by hydrogen bond formation between amines and acetone or pyridine. Thus it seems to be natural to expect some correlations between basicity and hydrogen bond shift of proton resonance spectrum of an aniline. Several authors[5,6] pointed out that the basicity of aniline derivatives is strongly dependent on the position and the inductive and mesomeric effects of a substituent in the ring. For example, among *m*- and *p*-toluidines and aniline the base strength of *p*-toluidine is the strongest and that of aniline is the weakest, and this fact was ascribed to the inductive and mesomeric effects of the methyl group. However, the effect of an ortho-substituent on the basicity is not simple because of the additional specific ortho effect[5].

The base strengths of aniline derivatives were reported by several authors[5,7]. Although the $pK_a$ value of a compound reported in one paper is slightly different from that in another, due partly to the solvent and concentration used, the order of the magnitude of the $pK_a$ values is almost the same. The following is the increasing sequence of the $pK_a$ values of aniline derivatives: 3, 4-diMe-, *p*-Me-, 2, 4-diMe-, 3, 5-diMe-, *m*-Me-, 2, 3-diMe-anilines, aniline, 2, 5-diMe-, *o*-Me- and 2, 6-diMe-anilines. The order of the values of the chemical shift in carbon tetrachloride solutions seems to correlate approximately with that of the base strengths of the compounds although some lack of accordance between the two orders is observed. Qualitatively, the factor which

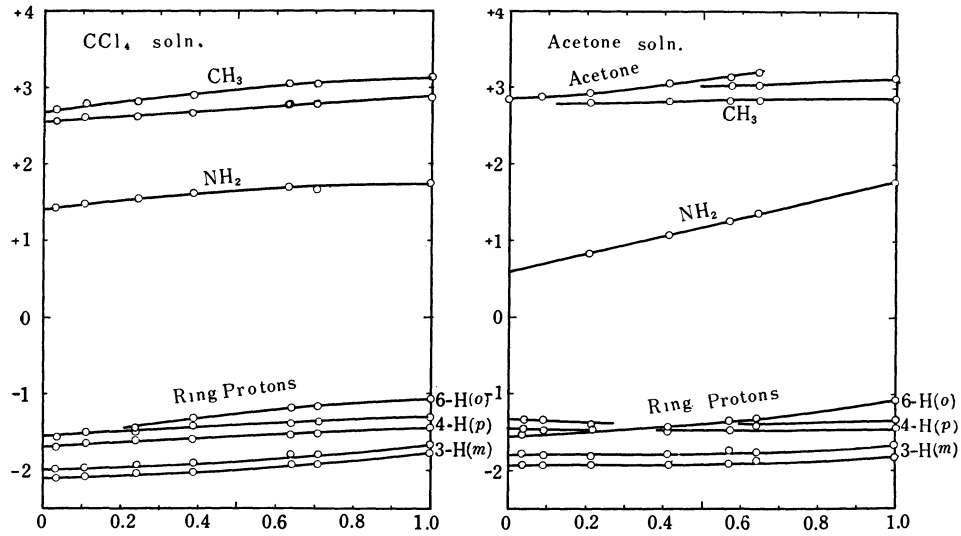

Fig. 2. Concentration dependence of chemical shift for 2,5-dimethyl aniline in carbon tetrachloride and acetone solutions.

determines the base strength of an amine is the charge density on the nitrogen atom[8] and not that on the proton in the amino group. The effective charge density on the nitrogen atom, which has lone pair electrons as well as valence electrons, may be affected in a complicated way rather by changes in the structural and chemical circumstances of the amino-group than by the electronic effect of substituents. Therefore the slight lack of accordance between the order of the proton resonance chemical shifts and that of the base strengths may be observed.

For carbon tetrachloride solutions, the slope of the concentration dependence curve for the amino protons is considerably small and is nearly the same as, but slightly smaller than, that for methyl protons in toluidine and dimethylaniline isomers. The positive slope of the curves is caused by the magnetic anisotropy effect of the aromatic rings in the solutions[9]. If the slope of the curves for methyl protons is assumed to arise merely from the anisotropic effect and if the amino protons are assumed to be affected by the same anisotropic field as that for methyl protons, the curves for the amine protons which are subtracted by the anisotropic effect can be obtained. These curves have a negative slope which might be an indication of a dissociation process of hydrogen bonds on dilution. The association of aniline molecules by intermolecular hydrogen bonds is not well ascertained, although it is, with less confidence, pointed out by several authors with physicochemical measurements[1] and infrared studies[2]. If a hydrogen bond with the same order of strength as an OH hydrogen bond exists between solute molecules, the slope would be more concentration dependent. The slopes which were observed are much smaller than those of dissociation processes of the OH hydrogen-bonded systems. This difference in the NMR behavior between the system might be partly due to the difference between the effective charge in the electronic shielding of the OH group and that of the amino group on formation of hydrogen bonds. It is unfortunate that the data available for estimation of bond energies of the N-H···N hydrogen-bonded systems as well as NMR data for amino protons are very scarce, and at the present stage, no decisive conclusion on the extent of the hydrogen bonding for aniline derivatives can be drawn from the NMR shift data. However, from the knowledge of the NMR measurements so far made with the OH hydrogen-bonded systems, it may be said that the hydrogen-bonded association of aniline derivatives occurs and the strength of it is fairly weak.

For acetone solutions, the effect of the hydrogen bond formation between the solute and the solvent is remarkable and the dilution shifts are large compared with those for carbon tetrachloride solutions. The order of the magnitude of the chemical shifts of the amino protons in acetone solutions is almost the same as that for carbon tetrachloride solutions.

A measure for the ability of the hydrogen

bond formation of a compound, $\Delta$ value*, proposed by the present author[10] is listed in Table I for the aniline derivatives investigated. The values of the chemical shift and the dilution shifts for the amino protons in carbon tetrachloride and acetone solutions are also listed in Table I. The magnitudes of the $\Delta$ value are about 1 and this value suggests the weakness in the ability of hydrogen bond formation of the compounds. This value nearly corresponds to the ability of 2,6-di-*tert*-butyl-*p*-cresol[10]. The $\Delta$ values for aniline and *m*-toluidine are large while that of 2,6-dimethyl aniline is remarkably small. With the data of the dilution shift for carbon tetrachloride solutions, the extent of the hydrogen bond formation of the aniline derivatives is clearly dependent on the existence of the ortho-methyl group.

Among the curves of the amino proton resonance for carbon tetrachloride solutions the behavior of the curves for 2,*x*-dimethyl anilines ($x=3, 4$ and 5) are peculiar as indicated by their small dilution shifts compared with that of 2,6-dimethyl aniline. The value is even smaller than that of *o*-toluidine. Considering the behavior of the curves by subtracting the anisotropic effect of the rings in the solution medium, this peculiarity apparently means that 2,*x*-dimethylanilines ($x=3, 4$ and 5) associate to a higher extent than *o*-toluidine does. However, this intrerpetation can not be accepted from the standpoint of the $\Delta$ values of these compounds. This discrepancy may possibly be caused by an additional effect of the *x*-(meta- or para-) methyl group on the amino proton resonance and this effect counterbalances the effect of the ortho-methyl group.

The ring proton spectra for dimethyl aniline isomers show slight concentration dependence. The displacement of the ortho-proton resonance line to a lower field on dilution is observed. The displacement is more remarkable for acetone solutions than for carbon tetrachloride solutions. This inclination is opposed to the behavior of the ortho-proton curves for phenol derivatives[3,11]. On association of aniline derivatives, the charge migration from the ring to the amino group would not be so much as for phenol derivatives because, possibly, the hydrogen bonding is very weak. However, the proton in the amino group is attracted by the proton-accepting group and this results the change in the electrostatic field at the ortho-proton[12]. In this way, the association would cause the displacement of the resonance field of the ortho-proton to a higher field. In acetone solutions, a weak hydrogen bond between the acetone and the ortho-proton would form and the displacement of the ortho-proton resonance to a lower field on dilution is observed as in the case of dimethyl phenols in acetone solution[3].

## Summary

Concentration dependenec of the chemical shift of amino protons in aniline derivatives in carban tetrachloride and acetone solutions were measured. The chemical shift of the amino proton in aniline derivatives is revealed to be clearly dependent on the existence of the ortho-methyl group. In carbon tetrachloride solutions, the concentration dependence of the resonance lines is slight, suggesting that the association of the solute molecules by hydrogen bonding is very weak. In acetone solutions, the dependence suggests hydrogen bond formation between solute and acetone. The base strength of aniline derivatives appeared to have no direct correlation with the

10) I. Yamaguchi, This Bulletin, 34, 451 (1961).

* $\Delta$ is defined as the difference between the chemical shift of a hydnogen-bonded proton at infinite dilution for carbon tetrachloride solution and that for an acetone solution.

magnitude of the chemical shift of amino proton in these compounds. The ring proton spectra of dimethyl aniline are slightly concentration dependent. The resonance in the ortho-protons appears to be displaced to a lower field on dilution and this tendency was ascribed to the change in the electrostatic field at the proton arising from the N–H bond moment change by hydrogen bond formation.

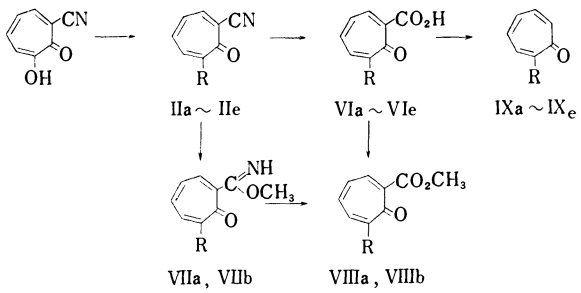
# *Synthesis and Reactions of Cyano- and Carboxytropones*

By Katsuo KIKUCHI



(Received March 20, 1961)

It has been reported that several kinds of cyanotropolones[1-4] can be obtained by the reaction of bromotropolones with cuprous cyanide or with potassium cyanide. In the case of cyanotropone, however, only the synthesis of 2-cyanotropone from 2-bromotropone and cuprous cyanide has been reported.[5]

In the present paper it is shown that several kinds of Grignard reagents react with 3-cyanotropolone (I)[1-4] to give corresponding 2-aryl- or 2-alkyl-7-cyanotropones. In this respect it is interesting to note that the cyano group of I is rather inactive to the Grignard reagents used and that the expected 3-aroyl- or 3-acyltropolones are not obtained.

The reaction of phenylmagnesium bromide and I afforded 7-cyano-2-phenyltropone (IIa) as yellow plates. Proof of the structure of IIa was obtained both by decarboxylation and by decarboxylative bromination of 2-phenyltropone-7-carboxylic acid (VIa) from IIa to yield 2-phenyltropone[6-9] and 7-bromo-2-phenyltropone[8,10], respectively.

Similarly, the reaction of I with $\alpha$- and $\beta$-naphthylmagnesium bromide each afforded 7-cyano-2-$\alpha$-naphthyltropone (IIb) as yellow needles and 7-cyano-2-$\beta$-naphthyltropone (IIc) as yellow plates. A similar reaction of I with methylmagnesium iodide afforded 7-cyano-2-methyltropone (IId) as colorless needles in rather poor yield. The treatment of I with benzylmagnesium chloride, however, resulted in the formation of 2-benzyl-7-cyanotropone (IIe) as yellow needles of m. p. 102°C and yellow prisms (III) of m. p. 145°C, with the latter predominating. The ultraviolet absorption spectra of IIa—IIe are shown in Fig. 1.

R a, $C_6H_5$; b, $\alpha$-$C_{10}H_7$; c, $\beta$-$C_{10}H_7$; d, $CH_3$; e, $C_6H_5CH_2$

III was easily reacted both with concentrated hydrochloric acid and with ethanolic hydrogen chloride to give colorless needles (IV) and colorless prisms (V), respectively. Detailed studies on the structures of III, IV and V are now under way.

The cyanotropones (IIa-IIe) obtained above were easily hydrolyzed with sulfuric acid to give corresponding tropone carboxylic acids. Thus, 2-phenyltropone-7-carboxylic acid (VIa), 2-$\alpha$-naphthyltropone-7-carboxylic acid (VIb), 2-$\beta$-naphthyltropone-7-carboxylic acid (VIc), 2-methyltropone-7-carboxylic acid (VId) and

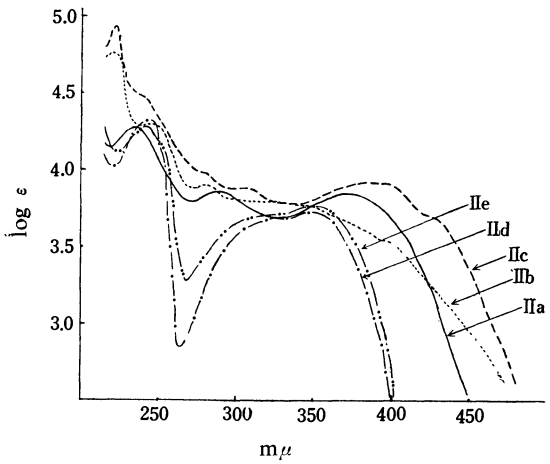

Fig. 1. Ultraviolet absorption spectra of IIa—IIe in methanol.

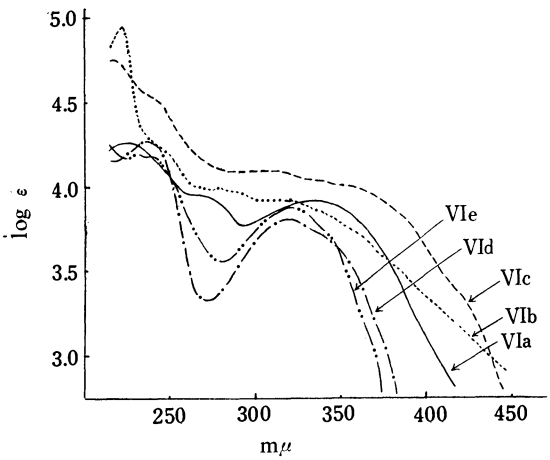

Fig. 2. Ultraviolet absorption spectra of VIa—VIc in methanol.

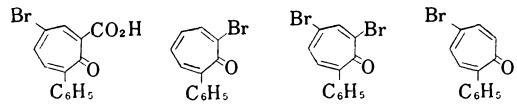
2-benzyltropone-7-carboxylic acid (VIe) were obtained. The ultraviolet absorption spectra of VIa–VIe are shown in Fig. 2.



When treated with methanolic hydrogen chloride, 7-cyano-2-phenyltropone (IIa) afforded methyl 2-phenyltropone-7-carboximidate (VIIa) as pale yellow needles, the structure of which was ascertained by the hydrolysis of VIIa with dilute hydrochloric acid to give methyl 2-phenyltropone-7-carboxylate (VIIIa). Similar treatment of 7-cyano-2-$\alpha$-naphthyltropone (IIb) afforded methyl 2-$\alpha$-naphthyltropone-7-carboximidate (VIIb) as an oil, the hydrolysis of which afforded methyl 2-$\alpha$-naphthyltropone-7-carboxylate (VIIIb).

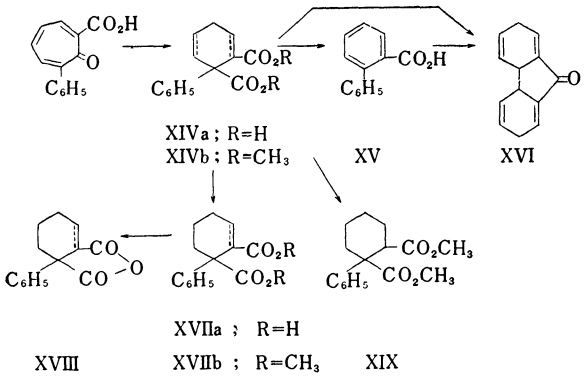
Attempted synthesis of formyltropones by Stephen's method did not succeed.

When heated to reflux in acetic anhydride, VIa, VIb and VIc were easily decarboxylated to give 2-phenyltropone (IXa), 2-$\alpha$-naphthyltropone (IXb)[11] and 2-$\beta$-naphthyltropone (IXc)[11] respectively.

The treatment of VIa with 2 mol. equivalents of bromine in acetic acid afforded an acid (X) accompanied with 7-bromo-2-phenyltropone (XI) or with 5, 7-dibromo-2-phenyltropone (XII)[12]. The structures of the latter two compounds were identified by respective admixture with authentic samples.

When heated to its decomposition points, X was submitted to decarboxylation to give yellow needles (XIII). Both X and XIII were converted by bromine in acetic acid to 5, 7-dibromo-2-phenyltropone (XII). This fact indicates that X and XIII are 5-bromo-2-phenyltropone-7-carboxylic acid and 5-bromo-2-phenyltropone, respectively.

X XI XII XIII



The action of bromine on IIb and IIc gave no satisfactory results.

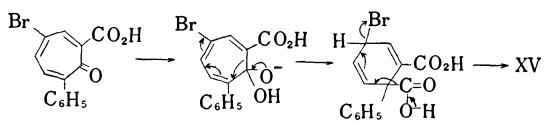
The action of alkali on 2-phenyltropone-7-carboxylic acid (VIa) was next examined. It was already reported that the action of sodium hydroxide solution on tropone-4-carboxylic acid[12] gave terephthalic acid. The behavior of VIa to alkali, however, was somewhat different. VIa, when heated with dilute sodium hydroxide solution, was easily submitted to rearrangement to form a dibasic acid XIVa of m. p. 217~218°C (decomp.), in good yield. Analysis of XIVa and its dimethyl ester XIVb are in agreement with the formulae $C_{14}H_{12}O_4$ and $C_{16}H_{16}O_4$ respectively. XIVa reduces Fehling's solution and ammoniacal silver nitrate solution. Mild oxidation of XIVa with alkaline-ammoniacal silver nitrate solution gave colorless crystals (XV) which were identified as *o*-biphenylcarboxylic acid. The treatment of XV with concentrated sulfuric acid yielded fluorenone (XVI), which was also obtained directly from XIVa by the action of the same acid under evolution of gas.

XIVa absorbed one mole of hydrogen on palladium-charcoal and on Adam's catalyst to give colorless needles (XVIIa), m. p. 223~225°C (decomp.); dimethyl ester (XVIIb) of XVIIa, m. p. 81~82°C. Analysis of XVIIa and XVIIb are in agreement with the formulae $C_{14}H_{14}O_4$ and $C_{16}H_{18}O_4$, respectively. XVVIIa, when

11) K. Kikuchi, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **77** 1439 (1956).
12) J. R. Bartels-Keith, A. W. Johnson and A. Langemann, *J. Chem. Soc.*, **1952**, 4461.

heated above its melting point, gave an anhydride (XVIII) of m. p. 125~127°C, which gave the original acid by sodium carbonate solution. The uptake of two moles of hydrogen by XIVa was difficult, but on one occasion, it was reduced on palladium-charcoal to give a small yield of colorless crystals, m. p. 160~170°C which without further purification, was converted to its dimethyl ester (XIX), m. p. 77~78°C. The analysis of XIX is in agreement with the formula $C_{16}H_{20}O_4$.

XIVa ; R=H
XIVb ; R=$CH_3$ XV XVI



XVIIa ; R=H
XVIII XVIIb ; R=$CH_3$ XIX

From these facts, it seems almost certain that XIVa is 1-phenylcyclohexadiene-1, 2-dicarboxylic acid but the exact location of double bonds in the cyclohexadiene ring is not clarified yet.

Similar treatment of 2-α-naphthyltropone-7-carboxylic acid (VIb) with dilute sodium hydroxide gave a dicarboxylic acid (XX)($C_{18}H_{14}O_4$) of m. p. 237~238°C (decomp.), which was converted to benzanthrone (XXI) with concentrated sulfuric acid. XX is considered to be 1-α-naphthylcyclohexadiene-1, 2-dicarboxylic acid formed in a manner similar to that in the case of XIVa.

The reaction of 5-bromo-2-phenyltropone-7-carboxylic acid (X) with dilute alkali, however, gave *o*-biphenylcarboxylic acid (XV). The mechanism of its formation is tentatively assumed as follows.

Recently it was reported[13] that the reaction of 4-bromo-2-phenyltropone and 4-mercapto-2-phenyltropone with alkali gave the same *o*-biphenylcarboxylic acid (XV). It seems interesting that the rearrangement of troponoid compounds is accompanied with the formation of hydroaromatic compounds or with the elimination of substituents other than in 2-(i. e. 7-) position.

## Experimental

**7-Cyano-2-phenyltropone (IIa).**—To a solution of phenylmagnesium bromide, prepared from 9.6 g. of bromobenzene, 1.7 g. of magnesium and 30 cc. of absolute ether, and subsequently diluted with 40 cc. of anhydrous tetrahydrofuran, was added 3.0 g. of powdered 3-cyanotropolone (I) during 10 min. with stirring. The resulting clear solution was stirred for 2.5 hr. at 45~55°C, decomposed with dilute sulfuric acid and extracted with chloroform. The chloroform solution was washed with water, dried and the solvent was removed by distillation. The yellow crystals thereby obtained were recrystallized from a mixture of benzene and petroleum ether to give yellow plates (IIa), m. p. 134~135°C. Yield, 2.22 g.

Found: C, 80.69; H, 3.89; N, 7.04. Calcd. for $C_{14}H_9ON$: C, 81.14; H, 4.38; N, 6.76%.

**7-Cyano-2-α-naphthyltropone (IIb).**—To a solution of α-naphthylmagnesium bromide, prepared from 2.8 g. of α-bromonaphthalene, 0.34 g. of magnesium and 5 cc. of absolute ether, was added a solution of 0.5 g. of I dissolved in dehydrated dioxane and was stirred for 7 hr. at 75~80°C. After being left overnight, the reaction mixture was decomposed with dilute sulfuric acid and extracted with chloroform. The chloroform extract was washed with water, dried and the solvent was removed. The residual oil provided 0.34 g. of IIb, m. p. 160~162°C. Recrystallization from benzene gave yellow needles, m. p. 163~164°C.

Found: C, 84.52; H, 4.18; N, 5.78. Calcd. for $C_{18}H_{11}ON$: C, 84.03; H, 4.31; N, 5.44%.

**7-Cyano-2-β-naphthyltropone (IIc).**—To a solution of β-naphthylmagnesium bromide, prepared from 2.8 g. of β-bromonaphthalene, 0.34 g. of magnesium, a small amount of iodine and 5 cc. of absolute ether, was added a solution of 0.5 g. of I dissolved in dehydrated dioxane, and the reaction mixture was treated as in the case of IIb. The residual oil provided 0.42 g. of IIc, m. p. 177~180°C. Recrystallization from dioxane gave yellow plates, m. p. 180~181°C.

Found: C, 84.51; H, 4.01; N, 5.56. Calcd. for $C_{18}H_{11}ON$: C, 84.03; H, 4.31; N, 5.44%.

**7-Cyano-2-methyltropone (IId).**—To a solution of methylmagnesium iodide, prepared from 2.56 g. of methyl iodide, 0.5 g. of magnesium and absolute ether and subsequently diluted with dehydrated tetrahydrofuran, was added 0.8 g. of powdered I with stirring. After being stirred for another 4 hr. at 45~50°C, the mixture was treated as in the case of IIa to give 0.12 g. of IId. Recrystallization from ethanol gave colorless needles, m. p. 119~120°C.

Found: C, 74.41; H, 4.66; N, 9.72. Calcd. for $C_9H_7ON$: C, 74.47; H, 4.86; N, 9.65%.

**Reaction of 3-Cyanotropolone (I) and Benzylmagnesium Chloride.**—To a solution of Grignard reagent prepared from 3.78 g. of benzyl chloride, 0.75 g. of magnesium and 15 cc. of absolute ether

and diluted with 15 cc. of dehydrated tetrahydrofuran, was added 1.5 g. of I with stirring. The mixture was stirred for another 2 hr. at 45~50°C, decomposed with dilute sulfuric acid and extracted with chloroform. The chloroform extract was washed with water, the solvent was removed under reduced pressure, and 530 mg. of yellow crystals (III) thereby obtained, were collected by filtration. Chromatographic separation of the filtrate over silica gel gave 40 mg. of III and 120 mg. of 2-benzyl-7-cyanotropone (IIe).

IIe was recrystallized from ethanol to give pale yellow prisms, m. p. 101~102°C.

Found: C, 81.16; H, 4.72; N, 6.51. Calcd. for $C_{15}H_{11}ON$: C, 81.43; H, 5.01; N, 6.33%.

III was recrystallized from ethanol to give yellow prisms, m. p. 144~145°C.

Found: C, 79.81; H, 6.22; N, 4.51. Calcd. for $C_{22}H_{19}O_2N$: C, 80.22; H, 5.81; N, 4.25%.

**Reaction of Compound (III) and Concentrated Hydrochloric Acid.**—The addition of 0.5 cc. of concentrated hydrochloric acid to 100 mg. of III at room temperature gave viscous syrup which soon solidified to colorless crystals. They were collected by filtration and recrystallized from a large amount of *n*-butanol to give colorless microneedles (IV), m. p. 225°C (decomp.).

Found: C, 76.04; H, 6.62; N, 4.24. Calcd. for $C_{22}H_{21}O_3N$: C, 76.06; H, 6.09; N, 4.03%.

**Reaction of Compound (III) and Ethanolic Hydrogen Chloride.**—The addition of 0.5 cc. of ethanol, saturated with hydrogen chloride, to 100 mg. of III at room temperature yielded a clear solution. After being left for 10 min., the solvent was removed and the crystals that were obtained were recrystallized from ethanol to give colorless prisms (V), m. p. 173~174°C.

Found: C, 76.25; H, 6.98; Calcd. for $C_{24}H_{25}O_3 \cdot N$: C, 76.77; H, 6.71%.

**2-Phenyltropone-7-carboxylic Acid (VIa).**—A mixture of 1.7 g. of IIa and 17 cc. of 75% sulfuric acid was heated at 140~150°C for one hour and the mixture was poured onto ice. The crystals that separated out were recrystallized from ethanol to give yellow plates, m. p. 107~108°C. Yield, 1.6 g.

Found: C, 74.18; H, 4.47. Calcd. for $C_{14}H_{10}O_3$: C, 74.33; H, 4.46%.

*Methyl Ester (VIIIa).*—Obtained by the reaction of VIa and ethereal diazomethane. Recrystallization from methanol gave yellow needles, m. p. 99~100°C.

Found: C, 74.88; H, 4.87. Calcd. for $C_{15}H_{12}O_3$: C, 74.99, H, 5.03%.

*p-Toluidide.*—Obtained by the usual method. Recrystallization from ethanol gave orange-yellow crystals, m. p. 121~122°C.

Found: N, 4.56. Calcd. for $C_{21}H_{17}O_2N$: N, 4.44%.

**2-α-Naphthyltropone-7-carboxylic Acid (VIb).**—Obtained by heating a mixture of 100 mg. of IIb, 1 cc. of 50% sulfuric acid and 1 cc. of glacial acetic acid at 150~160°C for one hour. Recrystallization from ethanol gave orange yellow prisms, m. p. 139~140°C. Yield, 80 mg.

Found: C, 78.01; H, 4.51. Calcd. for $C_{18}H_{12}O_3$: C, 78.25; H, 4.38%.

*Methyl Ester (VIIIb).*—Yellow prisms of m. p. 105~106°C.

Found: C, 78.17; H, 4.72. Calcd. for $C_{19}H_{14}O_3$: C, 78.60; H, 4.85%.

**2-β-Naphthyltropone-7-carboxylic Acid (VIc).**—Obtained as in the case of VIb. Recrystallization from *n*-butanol gave reddish orange microcrystals, m. p. 189~190°C.

Found: C, 78.17; H, 4.38. Calcd. for $C_{18}H_{12}O_3$: C, 78.25; H, 4.38%.

*Methyl Ester.*—Yellow plates, m. p. 81~82°C.

Found: C, 78.53; H, 5.07. Calcd. for $C_{19}H_{14}O_3$: C, 78.60; H, 4.85%.

**2-Methyltropone-7-carboxylic Acid (VId).**—Obtained as in the case of VIa. Recrystallization from ethanol gave colorless plates, m. p. 146~147°C.

Found: C, 65.75; H, 4.72. Calcd. for $C_9H_8O_3$: C, 65.85; H, 4.91%.

**2-Benzyltropone-7-carboxylic Acid (VIe).**—Obtained as in the case of VIa. Pale yellow needles of m. p. 128~129°C.

Found: C, 74.76; H, 4.75. Calcd. for $C_{15}H_{12}O_3$: C, 74.99; H, 5.03%.

**Methyl 2-Phenyltropone-7-carboximidate (VIIa).**—A mixture of 100 mg. of IIa and 2 cc. of absolute methanol was saturated with dry hydrogen chloride under ice-chilling, and the resulting clear red solution was left overnight at 0°C. Benzene and water were added successively to the solution, and the aqueous layer was neutralized cautiously with cold dilute aqueous solution of sodium carbonate. The crystals that separated out were collected by filtration, yield 70 mg. Recrystallization from ether gave pale yellow needles (VIIa) m. p. 85~86°C.

Found: N, 6.04. Calcd. for $C_{15}H_{13}O_2N$: N, 5.85%.

*Picrate.*—Reddish orange prisms, m. p. 141~142°C.

Found: N, 12.03. Calcd. for $C_{21}H_{16}O_9N_4$: N, 11.96%.

**Acid Hydrolysis of VIIa.**—A solution of 30 mg. of VIIa in 2 N hydrochloric acid was warmed on a water bath for 10 min. and cooled. The crystals that separated out were collected by filtration and recrystallized from methanol to give yellow crystals, m. p. 98~100°C. These crystals showed no depression of melting point on admixture with VIIIa.

**Methyl 2-α-Naphthyltropone-7-carboximidate (VIIb).**—Similar treatment of IIb as in the case of IIa provided VIIb as an oil which could not be solidified. This oil was subjected to acid hydrolysis with 2 N hydrochloric acid by which yellow crystals, m. p. 105~106°C were obtained. These crystals showed no depression of melting point on admixture with VIIIb.

**Decarboxylation of 2-Phenyltropone-7-carboxylic Acid (VIa).**—A solution of 50 mg. of VIa in 0.5 cc. of acetic anhydride was heated to reflux for 1.5 hr., shaken with water to decompose the acetic anhydride and extracted with benzene. The benzene extract was washed with 2 N sodium carbonate and water, dried and the solvent was evaporated. The pale yellow crystals (IXa) m. p. 82~83°C thereby obtained showed no depression of melting point on admixture with 2-phenyltropone.

**Decarboxylation of 2-α-Naphthyltropone-7-carboxylic Acid (VIb).**—Treatment of VIb similar to that in the case of VIa yielded pale yellow crystals m. p. 110°C which showed no depression of melting point on admixture with an authentic sample of 2-α-naphthyltropone (IXb).

**Decarboxylation of 2-β-Naphtyltropone-7-carboxylic Acid (VIc).**—Treatment of VIc similar to that in the case of VIa yielded pale yellow crystals of m. p. 132~134°C, undepressed on admixture with an authentic sample of 2-β-naphthyltropone (IXc).

**Bromination of VIa.**—a) To a solution of 50 mg. of VIa in 0.5 cc. of acetic acid was added 70 mg. of bromine. After standing for 5 hr. the whole was heated for 10 min. on a water bath, diluted with water and extracted with benzene. The benzene extract was washed with dilute sodium carbonate solution and the aqueous layer was acidified with dilute hydrochloric acid by which 30 mg. of 5-bromo-2-phenyltropone-7-carboxylic acid (X) was obtained as yellow needles. Recrystallization from ethanol raised the melting point to 174~175°C (decomp.).

Found: C, 55.10; H, 3.11. Calcd. for $C_{14}H_9O_3Br$: C, 55.11; H, 2.96%.

The benzene layer was washed with water, dried and the solvent was evaporated. Residual oil provided some crystals on standing which were recrystallized from cyclohexane to give pale yellow plates (XI), m. p. 78~80°C. These crystals showed no depression of melting point on admixture with 7-bromo-2-phenyltropone.

b) Similar treatment of 50 mg. of VIa with 70 mg. of bromine, except when heating was prolonged to one hour, afforded 20 mg. of X and several milligrams of pale yellow needles (XII) m. p. 131~132°C, which showed no depression of melting point on admixture with 5, 7-dibromo-2-phenyltropone.

**Decarboxylation of X.**—Acid (X), when heated to its melting point and subsequently sublimed under reduced pressure, was easily decarboxylated to give 5-bromo-2-phenyltropone (XIII). Recrystallization from ethanol gave pale yellow needles, m. p. 130~131°C.

Found: C, 59.34; H, 3.17. Calcd. for $C_{13}H_9OBr$: C, 59.79; H, 3.47%.

**Bromination of X.**—To a solution of 40 mg. of X in acetic acid was added 40 mg. of bromine and the mixture, after standing for one hour, was heated on a water bath for one hour, diluted with water and extracted with benzene. The benzene extract was washed successively with water, 2 N sodium carbonate and water, and the solvent was removed. The crystals thereby obtained were recrystallized from ethanol to give yellow needles (XII), m. p. 130~131°C, with undepressed melting point on admixture with 5, 7-dibromo-2-phenyltropone (XII).

**Bromination of XIII.**—To a solution of 30 mg. of XIII dissolved in 0.5 cc. of acetic acid was added 50 mg. of bromine and the mixture was allowed to stand for two days. The mixture was then diluted with water, extracted with benzene and the benzene solution was washed successively with water, 2 N sodium carbonate and water. The residual oil, obtained upon removal of the solvent, was heated on a water bath for 30 min. and cooled. The crystals thereby obtained were repeatedly recrystallized from ethanol to give yellow crystals (XII) m. p. 127~130°C, with undepressed melting point on admixture with 5, 7-dibromo-2-phenyltropone.

**Reaction of VIa and Alkali.**—A solution of 100 mg. of VIa dissolved in 1 cc. of 1 N sodium hydroxide was heated on a water bath for an hour, treated with active charcoal and then acidified with 2 N hydrochloric acid by which 80 mg. of 1-phenylcyclohexadiene-1, 2-dicarboxylic acid (XIVa) was obtained. Recrystallization from dilute ethanol gave colorless prisms, m. p. 216~217°C (decomp.).

Found: C, 68.60; H, 4.96. Calcd. for $C_{14}H_{12}O_4$: C, 68.84; H, 4.95%. Neutral equivalent as a dibasic acid, 122; Found. 126.

These crystals gradually reduced Fehling's solution and the ammonical silver nitrate solution.

*Dimethyl Ester (XIVb).*—Obtained by the reaction of XIVa and ethereal diazomethane. Recrystallization from methanol gave colorless prisms, m. p. 95~96°C.

Found: C, 70.41; H, 5.64. Calcd. for $C_{16}H_{16}O_4$; C, 70.57; H, 5.92%.

**Oxidation of XIVa.**—A solution of 50 mg. of XIVa dissolved in 1.5 cc. of alkaline-ammoniacal silver nitrate solution (prepared by dissolving 0.3 g. of silver nitrate in 3 cc. each of concentrated aqueous ammonia and 10% sodium hydroxide solution) was heated on a water bath for 30 min. After removal of the precipitate that formed, the filtrate was acidified and the crystals that separated out were collected by filtration. Recrystallization from dilute ethanol gave colorless prisms (XV), m. p. 108~109°C. Treatment of XV with concentrated sulfuric acid at room temperature yielded crystals (XVI), m. p. 80~82°C. XV and XVI were identified as *o*-biphenylcarboxylic acid and fluorenone, respectively, by the mixture melting point determination.

**Action of Concentrated Sulfuric Acid on XIVa.**—Addition of 0.3 cc. of concentrated sulfuric acid to 30 mg. of XIVa at room temperature resulted in deep reddish purple solution under evolution of gas. After being warmed slightly on a water bath, the reaction mixture was poured onto crushed ice. The crystals that separated out were collected by filtration and recrystallized from dilute ethanol to give yellow prisms (XVI), m. p. 80~82°C, with undepressed melting point on admixture with fluorenone.

**Catalytic Reduction of XIVa.**—a) A solution of 250 mg. of XIVa dissolved in 10 cc. of methanol was catalytically reduced at ordinary temperature and pressure, with the addition of 30 mg. of Adam's catalyst. Absorption of hydrogen was 35 cc. After removal of the catalyst by filtration, methanol was removed, and the crystalline residue was recrystallized from methanol to give colorless needles (XVIIa) of m. p. 223~224°C (decomp.). Yield, 100 mg.

Found: C, 67.77; H, 5.53. Calcd. for $C_{14}H_{14}O_4$; C, 68.28; H, 5.73%.

*Dimethyl Ester (XVIIb).*—Colorless needles, m. p. 81~82°C.

Found: C, 69.68; H, 6.25. Calcd. for $C_{16}H_{18}O_4$: C, 70.05; H, 6.61%.

*Anhydride (XVIII).*—Acid (XVIIa) was heated above its melting point for one minute and cooled. The crystalline mass was recrystallized from methanol to give colorless needles of m. p. 125~127°C.

Found: C, 72.71; H, 5.17. Calcd. for $C_{14}H_{12}O_3$: C, 73.67; H, 5.30%.

b) A solution of 150 mg. of XIVa dissolved in 5 cc. of methanol was catalytically reduced at ordinary temperature and pressure, with the addition of 100 mg. of palladium-charcoal (5%). The absorption of hydrogen was about 30 cc. After removal of the catalyst by filtration, methanol was removed, and the crystalline residue was washed with a small amount of ether. These crystals of m. p. 160~170°C were, without further purification, converted to their dimethyl ester (XIX) by the action of ethereal diazomethane. Recrystallization from methanol gave colorless prisms, m. p. 77~78°C. These crystals showed depression of the melting point on admixture with XVIIb.

Found: C, 69.88; H, 7.13. Calcd. for $C_{16}H_{20}O_4$: C, 69.54; H, 7.30%.

**Reaction of 2-α-Naphthyltropone-7-carboxylic Acid (VIb) and Alkali.**—Similar treatment of VIb as in the case of VIa gave 1-α-naphthylcyclohexadiene-1, 2-dicarboxylic acid (XX) as colorless prisms, m. p. 237~238°C (decomp.).

Found: C, 73.68; H, 5.00. Calcd. for $C_{18}H_{14}O_4$: C, 73.46; H, 4.80%.

**Action of Sulfuric Acid on XX.**—Similar treatment of XX with concentrated sulfuric acid as in the case of XIVa gave yellow needles (XXI), m. p. 169~170°C, with undepressed melting point on admixture with benzanthrone.

**Reaction of 5-Bromo-2-phenyltropone-7-carboxylic Acid (X) and Alkali.**—A solution of 20 mg. of X dissolved in 0.4 cc. of 1 N sodium hydroxide was heated for one hour on a water bath and acidified with dilute hydrochloric acid. The crystals thereby obtained were collected by filtration and recrystallized from ethanol to give colorless crystals (XV), m. p. 105~108°C, with undepressed melting point on admixture with *o*-biphenylcarboxylic acid. By treatment with concentrated sulfuric acid, XV was converted to fluorenone (XVI) and identified by mixture melting point determination.

The author wishes to express his sincere thanks to Professor Tetsuo Nozoe of Tohoku University for his guidance and encouragement throughout this work, as well as to Professor Shuichi Seto, Professor Yoshio Kitahara and Assistant Professor Toshio Mukai of Tohoku University for their kind advice and suggestions. He is also grateful to Mrs. Kuniko Kodaira for the measurements of ultraviolet absorption spectra and to Mr. Shinichi Ohyama and Miss Ayako Iwanaga for the elemental analyses.

# *Infrared and Raman Spectra of Dialkoxymethanes in Various Phases and the Assignment of Spectra of Methoxyethoxymethane*

By Kenkichi NUKADA

(Received March 23, 1961)

The study of internal rotation around the C–C bond has been carried out in great detail by several authors[1], but detailed discussion of that arround the C–O bond has not been carried out so far.

In this paper, the rotational isomerism of compounds containing two C–O bonds such as dialkoxymethanes ($R_1OCH_2OR_2$) is discussed from the spectroscopical point of view. Infrared spectra of vapor, liquid and solid phases and Raman spectra of liquid phase were obtained, and the possible interpretation of these results was given by referring to other available data such as dipole moment.

With the conclusion thus obtained, the assignments of vibrational frequencies of dimethoxymethane and diethoxymethane are reported in the other papers[2,3], and that of methoxyethoxymethane is presented in this paper.

## Experimental

The samples used were dimethoxymethane (DMM, $CH_3OCH_2OCH_3$), methoxyethoxymethane

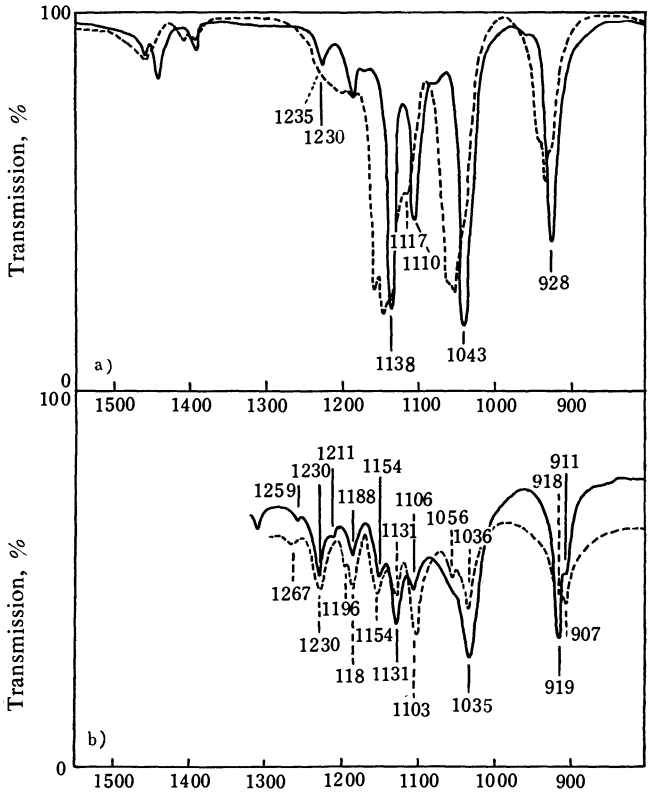
1) S. Mizushima, "Structure of Molecules and Internal Rotation", Academic Press, New York (1954).

2) K. Nukada, *Spectrochim. Acta*, to be published.

3) K. Nukada, This Bulletin, to be published.

(MEM, $CH_3OCH_2OC_2H_5$), diethoxymethane (DEM, $C_2H_5OCH_2OC_2H_5$) and diisopropoxymethane (DPM, $(CH_3)_2CHOCH_2OCH(CH_3)_2$). All the compounds were synthesized in our laboratory and their purity was checked by gas chromatography[4,5].

Infrared spectra of vapor and liquid phases were obtained by means of Perkin Elmer 21 spectrophotometer and those of solid phase were obtained by means of Perkin Elmer 12C spectrophotometer, both equipped with a sodium chloride prism. Infrared spectra at an elevated temperature were obtained with a gas celll designed and constructed by Mr. H. Tomita of our laboratory[6]. Because dialkoxymethanes are rapidly decomposed at high temperature by oxygen in air, care should be taken to remove oxygen as completely as possible from a gas cell in a high temperature experiment. Solid infrared spectra were obtained with a low temperature cell designed by us[7].



Raman spectra were taken by means of Cary 81 spectrophotometer. The degree of depolarization was measured by wrapping two types of polaroids around a Raman tube.

## Results and Discussion

**Infrared Spectra of Dimethoxymethane in Various Phases.** — The spectra of vapor and liquid phases are shown in Fig. 1a.

The intensity of vapor bands at 1235 and 1110 $cm^{-1}$ shows an appreciable decrease as compared with that of liquid bands. Of these, the liquid band at 1110 $cm^{-1}$ is known as a branch of "methylal's doublet", and it is a remarkable fact that in vapor phase a branch of the doublet turns to be a shoulder. As will be described in the following section and in the other paper[8], in other dialkoxymethanes and in ethylidene dialkyl ethers ($R_1OCH(CH_3)OR$) the smae behavior of spectra were also observed.

The low temperature infrared spectra are shown in Fig. 1b. It was found that two types of spectra are obtained at low temperature below melting point. It is dependent upon

Wave number, $cm^{-1}$

the critical condition of freezing the material. An example of freezing procedure is as follows: After cooling gradually, spectrum A (solid line in Fig. 1b) was obtained at −150°C, then after once melting and cooling again, spectrum B (dashed line in Fig. 1b) was obtained at −134°C. The last procedure was repeated and spectrum B was obtained again. After once melting and cooling again, spectrum A was obtained at −135°C. Lastly, on raising the temperature, spectrum B was obtained at −110°C. It is not clear at present that the difference of these spectra is due either to the difference of crystallized states between two types of solid phase, or is due to the fact that one of them is in a super-cooled state. Spectrum A is more similar to that of the solution except for the band at 1230 $cm^{-1}$, the relative intensity of which is greater than that of liquid phase spectrum, and for new bands at 1259, 1211, 1051 and 911 $cm^{-1}$, appearing as shoulders. Spectrum B is, on the other hand, quite different from that of the solution, that is, the intensity ratio of the band at 1131 $cm^{-1}$ to one at 1103 $cm^{-1}$ changes appreciably.

From these results the following assumption seems to be possible. In DMM, two rotational isomers exist, namely $\alpha$ and $\beta$ forms. The bands at 1138, 1043 and 928 $cm^{-1}$ are due to vibrations belonging to the $\alpha$ form, and the bands at 1230 and 1110 $cm^{-1}$ are due to vibrations belonging to the $\beta$ form. If this assumption is true, both forms are mixed moderately in liquid phase and the $\alpha$ form exists predominatingly in vapor phase. In solid phase, both forms are still mixed but the abundance ratio of the two forms changes as compared with that in the case of the liquid phase, that is, the $\beta$ form is more predominant. The possible forms may be gauche-gauche form (or less polar form), two methyl groups of which rotate about 120° from the central OCO plane in an anticlockwise sence, and trans-trans form (or more polar form), the COCOC skeleton of which is planar.

If this assumption is ture,

1) The dipole moment of vapor and liquid phase should be considerably different at room temperature,

2) Some solvent effect is expected since the dipole moments of two isomers are considerably different, and

3) The appearance of the vapor spectrum should change to some extent with increasing temperature.

In the following description, the above-mentioned assumption is examined by checking these three items in detail.

1) In his prewar paper, Kubo illustrated the diagram showing the correlation between dipole moment and azimuthal angles of rotation of methyl groups in DMM[9]. From this diagram together with the observed value of dipole moment, Kubo has concluded that in the vapor phase DMM has one stable configuration, in which two methyl groups rotate to the opposite sides of central OCO plane (gauche-gauche form). Recently, Uchida et al. measured the dipole moment of DMM in liquid phase at 25°C (0.67D) and found that it is in good agreement with the value of vapor extrapolated to 25°C (0.69D)[10]. Uchida et al. has concluded that DMM is a mixture of rotational isomers, most of which is helical or almost helical in structure (gauche-gauche form). These results lead to a definite conclusion that at least at room temperature, the abundance ratio of isomers are, if they exist, almost equal in vapor and liquid phases.

Therefore, the cause of appreciable change between infrared spectra of vapor and condensed phases is not due to the change of abundance ratio of isomers between two phases, but due to some other kind of effect such as the change of intermolecular interaction between two phases.

2) In Fig. 2, the infrared spectrum of acetonitrile solution of DMM is shown. As acetonitrile is a very polar solvent (dielectric constant of which is 38), there must be some systematic change of spectra between acetonitrile solution and non-polar solvent solution, if the rotational isomerism actually exists in solution. From Fig. 2, the ratio of absorbance of the band at 1140 $cm^{-1}$ to that of the band at 1111 $cm^{-1}$ ($K_{1140}/K_{1111}$) is calculated to be 0.374.

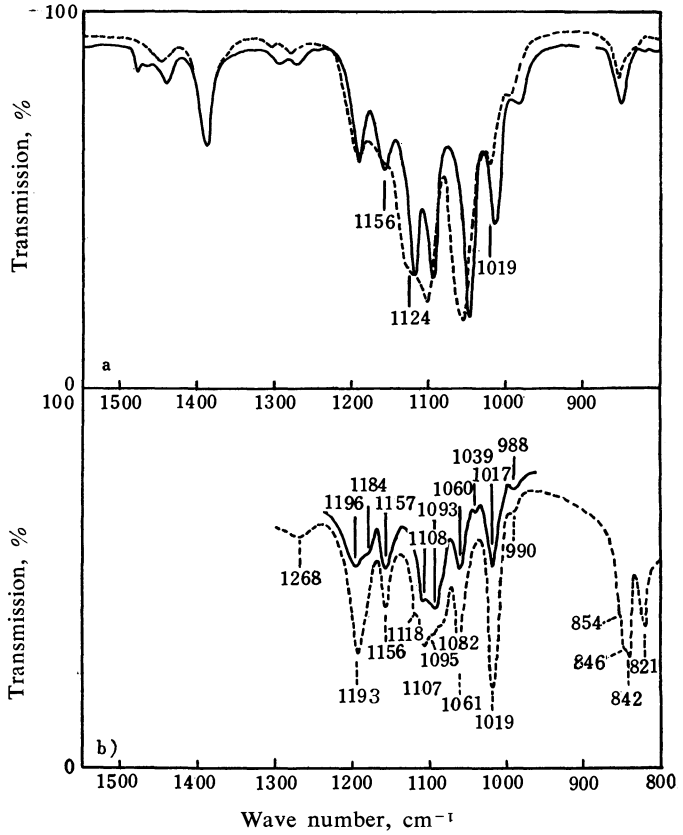

Fig. 3. Infrared spectra of diethoxymethane ($C_2H_5OCH_2OC_2H_5$).

a) Solid line, $CCl_4$ and $CS_2$ solutions, cell thickness: 0.15 mm., 2%. Dashed line, vapor.
b) Solid phase spectra, solid line, cell thickness: 0.015 mm. Dashed line, cell thickness: 0.05 mm.

The ratio is also calculated to be 0.331 in the case of carbon tetrachloride solution. Though it is impossible to obtain such a ratio in the case of vapor (Fig. 1a), it is clear that is has a very high value. Hence if these two bands belong to another type of rotational isomers, a more polar form must be predominant in the vapor phase, but this is inconsistent with the measurement of dipole moment[9]. From these considerations, it is reasonable to assume that these two bands belong to the same type of isomers.

3) Vapor spectra of DMM were taken at the temperature range between 24 and 100°C. No change in the appearance of the spectra was observed. The dipole moment of the vapor varies with the temperature as mentioned by Uchida et al., and they have explained this as the change of abundance ratio between isomers with temperature variation[10]. The present observation seems to be inconsistent with the conclusion of them. The most reasonable interpretation to make a compromise between the results of infrared spectra and those of dipole moment is as follows. This molecule has one form (gauche-gauche form) below 100°C, both in the vapor and liquid phases. The variation of dipole moment with temperature is due to the increase of amplitude of torsional oscillation, while the change of appearance of spectra among three phases is due to the change of intermolecular interaction.

As will be described in detail in the other papers[2,3], the change of band intensity among different phases is sometimes a useful measure in assigning spectra. One example is as follows. If an infrared band is strong in the liquid phase but weak in the vapor phase and the corresponding Raman band is strong and polarized, this band is safely assigned to a totally symmetrical vibration. The change of band intensity between vapor and liquid phases is also observed in the case of DMM-$d_2$ ($CH_3 \cdot OCD_2OCH_3$), DMM-$d_6$ ($CD_3OCH_2OCD_3$), DMM-$d_8$ ($CD_3OCD_2OCD_3$), DEM and DEM-$d_2$ ($C_2H_5OCD_2OC_2H_5$). The author has found that in all cases the above-mentioned rule can be used in the assignment of spectra.

**Infrared and Raman Spectra of Diethoxymethane in Various Phases.** — Since DEM has four internal rotational axes, a possible number of rotational isomers may be larger than that of DMM. But from the spectroscopical point of view, isomers concerning C–ethoxy axes are important and those concerning C–C axes are less important.

In Fig. 3a, infrared spectra of vapor and liquid phases of DEM are shown. As in the case of DMM, the appearance of spectra is rather different between two phases, that is, the intensity of vapor bands at 1156, 1124 and 1019 $cm^{-1}$ shows an appreciable decrease as compared with those of liquid phase spectra.

Solid infrared spectra of DEM are shown in Fig. 3b. Just as in the case of DMM, two types of spectra, namely A and B, are observed according to the slight change of the critical condition of freezing the material. In the type A spectrum, the intensity of the bands at 1193, 1019, 842 and 821 $cm^{-1}$ shows an appreciable increase and that of the band at 1095 $cm^{-1}$ shows a decrease as compared with those of carbon tetrachloride solution. The appearance of the type B spectrum is similar to that of the carbon tetrachloride solution, except for the doublet at 1100 $cm^{-1}$.

In Fig. 4, the infrared spectrum of acetonitrile solution is shown. There exists no difference between the spectra of carbon tetrachloride and of acetonitrile solutions.

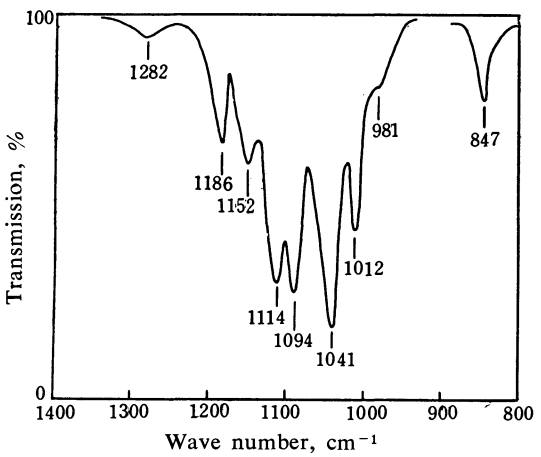

Fig. 4. Infrared spectrum of diethoxymethane ($C_2H_5OCH_2OC_2H_5$). Acetonitrile solution.

In Fig. 5, Raman spectra of carbon tetrachloride and acetonitrile solutions of DEM are shown. The intensity of the band at 1047 $cm^{-1}$ increases and that at 1187 $cm^{-1}$ decreases in acetonitrile solution. There is, however, no other experimental evidence that the former band belongs to the more polar form and the

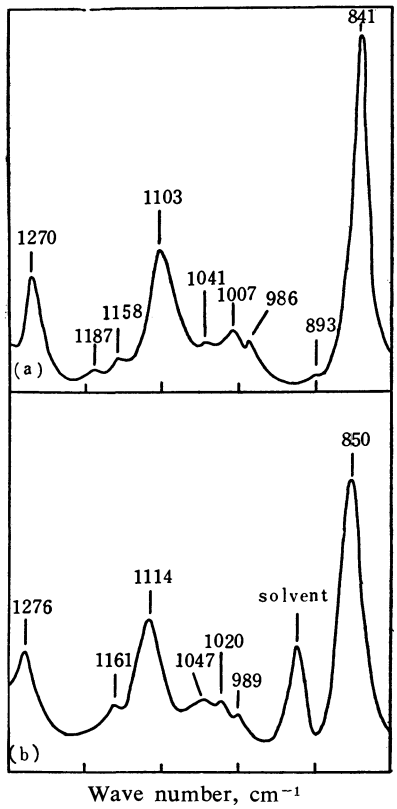

Fig. 5. Raman spectra of diethoxymethane ($C_2H_5OCH_2OC_2H_5$).

a) Pure liquid.
b) Acetonitrile solution (60%).

latter to the less polar form, hence the intensity change is probably due to simple solvent effect, that is, is due to the difference of intermolecular interaction between two kinds of solutions.

Vapor spectra of DEM were taken at the temperature range between 24 and 100°C. As no change was observed in the appearance of spectra within the temperature range, DEM has almost one and the same form in vapor phase below 100°C.

According to the measurement of Kubo, dipole moment of DEM is, in vapor phase, 1.22D at 56°C and slightly increases with rising temperature (1.26D at 203°C). Kubo has concluded that this molecule has one stationary form in vapor and that the difference of dipole moment between DMM and DEM (0.5D) is due to the difference of azimuthal angles of alkyl groups from the central OCO plane[11]. Since there is no dipole measurement on liquid phase the molecular structure of DEM of liquid phase is not clear, but from the analogy

11) M. Kubo, *Sci. Papers Inst. Phys. Chem. Research*, **30**, 169 (1936).

with DMM one could assume that the molecular form is the same both in vapor and liquid phases (nearly gauche-gauche form, but that the azimuthal angles of ethyl groups from central OCO plane are smaller than those of methyl groups in DMM), and that the change of appearance of spectra among different phases is dependent on the difference of intermolecular interaction. The detail of assignment will be reported elsewhere[3].

**Infrared Spectra of Methoxyethoxymethane in Various Phases.**—In Figs. 6 and 7, infrared spectra of vapor, liquid and solid phases of MEM are shown.

The vapor bands at 1131 and 926 $cm^{-1}$ become weaker as compared with the liquid bands, and the doublet at 1112 $cm^{-1}$ (and 1096 $cm^{-1}$) in the liquid phase is distorted in the vapor phase,that is, it becomes singlet in the vapor phase. The solid bands at 1218 $cm^{-1}$ and 1013 $cm^{-1}$ become much stronger and one at 1135 $cm^{-1}$ becomes weaker as compared with the liquid bands.

It is quite hard, as in the case of DMM and DEM, to interpret such a complicated change of spectra among various phases as the change of abundance ratio of the rotational isomers. It is better to assume that from the analogy of

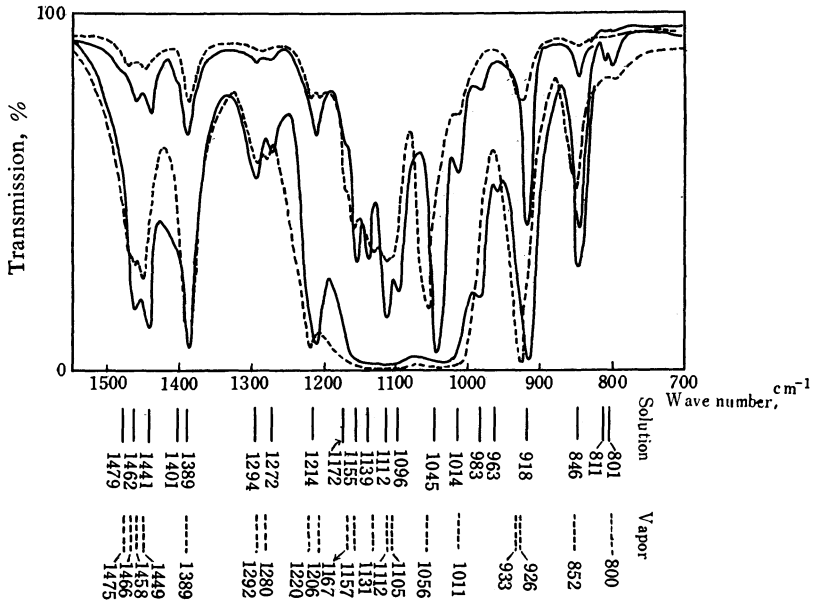

Fig. 6. Infrared spectra of methoxyethoxymethane ($CH_3OCH_2OC_2H_5$).

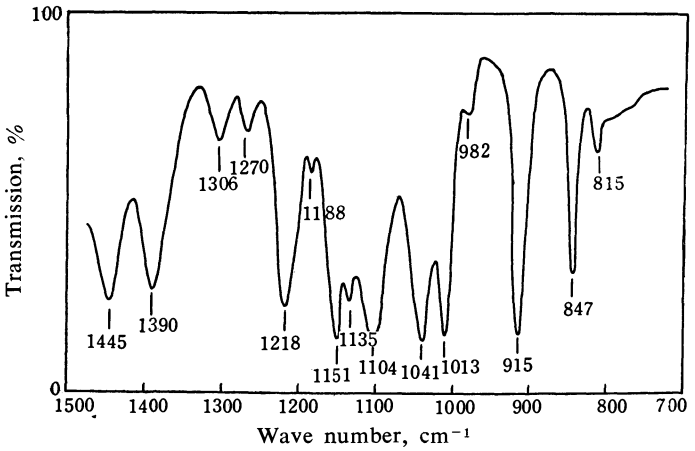

Fig. 7. Infrared spectrum of methoxyethoxymethane ($CH_3OCH_2OC_2H_5$).
Solid, cell thickness: 0.015 mm.

DMM, MEM has also one form in the liquid and vapor phases at least near room temperature. If the dipole moment of the vapor and liquid phases are observed, one can establish the validity of the above-mentioned assumtion.

**Assignment of Infrared and Raman Spectra of Methoxyethoxymethane.** — In this section the assignment of the infrared and Raman spectra (Fig. 8) of MEM is given by assuming that this molecule has only one form in its vapor and liquid phases.

The assignment of bands at 3000 $cm^{-1}$ has

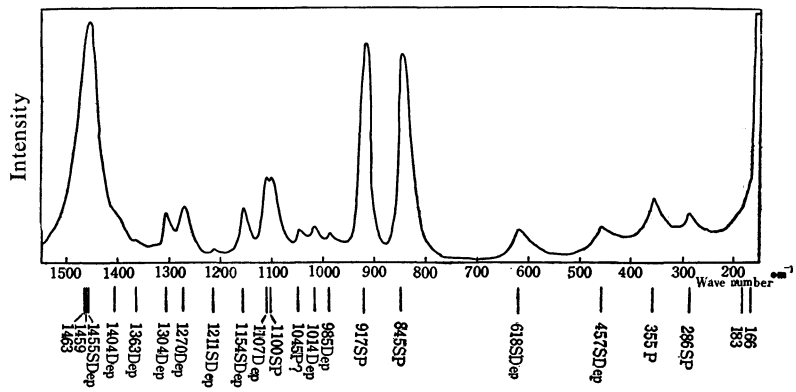

Fig. 8. Raman spectrum of methoxy ethoxy methane ($CH_3OCH_2OC_2H_5$).

already been given by the same author[12].

The appearance of infrared spectra between 1500 and 1250 $cm^{-1}$ is quite similar to that of DEM and DEM-$d_2$, except for the lack of a very weak band a 1360 $cm^{-1}$. It means that the absorbance of bands in the ethoxyl group is greater than that of the methoxyl group. The appearance of Raman bands is, on the other hand, slightly different from that of DEM and DEM-$d_2$, that is, the intensity of the band at 1404 $cm^{-1}$ decreases and that at 1304 $cm^{-1}$ increases.

As the interaction between methoxyl and ethoxyl groups may be weak, the spectra of MEM within this region may be reasonably explained by assuming the simple superimposition of spectra, of methoxyl and ethoxyl compounds as shown in Table I.

A medium infrared band at 1214 $cm^{-1}$ (having a corresponding weak Raman band) is assigned to the methyl rocking of methoxyl group. This is consistent with the fact that at this frequency many compounds containing methoxyl group have a medium infrared band and that the homologues of these compounds having no methoxyl group have no infrared band[2,3,13,14].

Spectra between 1150 and 800 $cm^{-1}$ are very complicated not only in this molecule but in many other molecules containing oxygen atoms such as ethers, other dialkoxymethanes, ethyldene alkyl ethers, 2,2-dialkoxypropane and orthoaliphatic acid esters. The skeletal COCOC stretching should clearly exist within this region. As shown in the discussion of DMM and its deuterated compounds[2], DEM and DEM-$d_2$[3] and dimethyl ether and dimethyl ether-$d_6$[15,16], skeletal stretchings are mixed with CH deformation vibrations to some extent, and from inspection without exact calculation it is quite hard to give a rigorous assignment. Nevertheless, some bands could be assigned reasonably from the strong similarity of spectra among homologues.

The strong liquid infrared band at 1096 $cm^{-1}$ (having no vapor infrared band and a strong and strongly polarized Raman band) is assigned to the symmetrical COCOC stretching. In DMM and DEM, liquid infrared bands around 1100 $cm^{-1}$ have a corresponding very weak vapor infrared band and a medium or strong and strongly polarized Raman band. They have been assigned to the symmetrical COCOC stretching in good agreement with the present assignment.

The strongest infrared band at 1045 $cm^{-1}$ (having a corresponding weak Raman band) is assigned to the asymmetrical COCOC stretching by the analogy with DMM.

Two very strong and strongly polarized

b) Solid, solid line, cell thickness: 0.015 mm. Dashed line, cell thickness: 0.05 mm.

Raman bands at 917 and 845 $cm^{-1}$ (having corresponding strong and weak infrared bands, respectively) are assigned to the methyl rocking of the methoxy group and the symmetrical COCOC stretching, respectively. The basis of the assignment will be described in other papers[2,3].

The assignment of the remaining bands between 1150 and 800 $cm^{-1}$ is very difficult only from the comparison of the spectra of homologues. They may be mixtures of asymmetrical COCOC stretchings, CC stretching, methylene rocking of ethoxyl group, and methyl rocking of methoxyl and ethoxyl groups.

The bands below 700 $cm^{-1}$ are due to the skeletal deformation and torsional vibrations.

In DMM, DMM-$d_2$, DMM-$d_6$, DMM-$d_8$[2], DEM and DEM-$d_2$[3], three medium Raman bands appear at 640~560 $cm^{-1}$ (depolarized), 450~370 $cm^{-1}$ (depolarized) and at 325~295 $cm^{-1}$ (polarized). The present data of MEM are completely consistent with these results. Therefore, they could be assigned to the asymmetrical, symmetrical (central angle OCO and two terminal angles COC vibrate in the opposite phases) and symmetrical (all angles vibrate in the same phase) COCOC skeletal deformations, respectively, from the analogy with the case above mentioned. In DEM and DEM-$d_2$, an additional strongly polarized Raman band appears at 240 $cm^{-1}$. In MEM, the band at 286 $cm^{-1}$ is strongly polarized and the origin of this band is probably like that of the band at 240 $cm^{-1}$ in DEM and DEM-$d_2$, hence this band is assigned to OCC deformation as in the case of DEM and DEM-$d_2$.

Torsional vibrations are expected to exist below 250 $cm^{-1}$, and Raman bands at 183 and 166 $cm^{-1}$ may be assigned to these vibrations, although the assignment is somewhat doubtful as these bands are very weak and appear as a shoulder of very strong exciting line.

**Infrared Spectra of Diisopropoxymethane in Various Phases.**—Infrared spectra of DPM in vapor and liquid phases are shown in Fig. 9. As in the case of other dialkoxymethanes, the intensity of some bands (1175, 1129 and 1094 $cm^{-1}$) become smaller in the vapor phase.

No appreciable difference is found between the spectra of carbon tetrachloride and acetonitrile solutions (Fig. 10a).

Solid infrared bands have at least two different shapes, which are dependent on the critical condition of freezing the material, as shown in Fig. 10b.

The vapor spectra were taken at the temperature range between 24 and 106°C, but no change was observed.

The results are thus very similar to those in the case of DMM, DEM and MEM. Therefore, the same assumption as the above-mentioned one may also be held in this case. Because DPM has great bulk at the terminals (isopropyl groups) and the steric repulsion between isopropyl groups and the central methylene group is expected to be very large, this molecule may take a nearly planar zig-zag form.

## Summary

The rotational isomerism of dialkoxymethanes ($CH_3OCH_2OCH_3$, $CH_3OCH_2OC_2H_5$, $C_2H_5OCH_2OC_2H_5$ and $(CH_3)_2CHOCH_2OCH\cdot(CH_3)_2$) is discussed from the spectroscopical point of view. The experimental results are as follows.

1) The appearance of infrared spectra is appreciably different among the vapor, liquid and solid phases. Of these, the solid spectrum gives the most complicated figure.

2) No solvent effect is obtained in acetonitrile solution.

3) No change is observed in the vapor infrared spectrum between room temperature and 100°C.

It is concluded from these results and data of dipole moment that dimethoxymethane exists as one configuration in the liquid and vapor phases, the terminal methyl groups of which are rotating about 120° anticlockwise sense from the central OCO plane.

The configuration of other dialkoxymethanes are assumed to be of one form by the analogy of experimental results.

Finally, the assignment of vibrational spectra of methoxyethoxymethane is presented.

The author wishes to express his sincere thanks to Dr. Y. Mashiko for his valuable discussion.

# *Infrared and Raman Spectra of Diethoxymethane and Diethoxymethane-$d_2$*

By Kenkichi NUKADA

(Received March 30, 1961)

In previous papers, the author has reported the characteristic vibrations of infrared spectra of dialkoxymethanes[1] and ethylidene dialkyl ethers[2], and more recently the assignment of vibrational spectra of dimethoxymethane ($CH_3OCH_2OCH_3$) and its deuterated compounds[3].

In this paper, infrared and Raman spectra of diethoxymethane (DEM, $C_2H_5OCH_2OC_2H_5$) and diethoxy methane-$d_2$ (DEM-$d_2$, $C_2H_5OCD_2 \cdot OC_2H_5$) are presented and the assignment of spectra are given by referring to the above-mentioned results[1-3].

DEM has four internal rotational axes and there is a possibility of more than two rotational isomers existing in it. The author has examined the rotational isomerism of dialkoxymethanes and concluded that dimethoxymethane, the simplest homologue of DEM, takes one form in vapor and liquid phases near room temperature. He did not obtain such a definite conclusion in the case of DEM, but from the similarity of the change of infrared spectra among various phases between dimethoxymethane and DEM, he suggested that DEM also takes one and the same form in vapor and liquid phases (two ethoxyl groups rotate about 120° in an anticlockwise sense from the central OCO plane) near room temperature[4]. In this paper, the assignment is given with the assumption mentioned above.

## Experimental

DEM and DEM-$d_2$ were prepared from ethanol and formaldehyde, and from ethanol and formaldehyde-$d_2$, respectivity. The detailed description of the prepatation will be reported elsewhere[5].

Infrared spectra were obtained by means of a Perkin Elmer 12C spectrophotometer equipped with a lithium fluoride prism and a 21 spectrophotometer equipped with a sodium chloride or a cesium bromide prism.

Raman spectra were obtained by means of a Cary 81 spectrophotometer. In the case of DEM-$d_2$, a capillary tube, the capacity of which is 0.2 cc. was used. The degree of depolarization was measured by wrapping two kinds of polaroids around a Raman tube.

The spectra thus obtained are illustrated in Figs. 1—3.

## Results and Discussion

**C-H and C-D Stretching Vibrations.** — The features of the Raman spectra of DEM and DEM-$d_2$ are quite similar in the 3000 $cm^{-1}$ region. They have two strongly polarized bands at 2929～2931 $cm^{-1}$ and at 2873～2875 $cm^{-1}$, and one depolarized band at 2972～2974 $cm^{-1}$. The features of the infrared spectra are, on the other hand, slightly different from each other. Thus, the intensity ratios of the bands at 2928～2929 $cm^{-1}$ to those at 2896～2900 $cm^{-1}$ are different in these two compounds.

The strongest infrared bands at 2977～2975 $cm^{-1}$ in DEM and DEM-$d_2$ (the corresponding Raman bands being strongly depolarized) are assigned to the asymmetrical methyl stretching of the ethoxyl group[2].

The strong infrared bands at 2870～2878 $cm^{-1}$, having corresponding strongly polarized Raman bands, in DEM and DEM-$d_2$ are assigned to the symmetrical methyl stretching[1].

In dimethoxymethane-$d_6$ ($CD_3OCH_2OCD_3$), bands at 2932 and 2887 $cm^{-1}$ are assigned respectively to the asymmetrical and the symmetrical methylene stretchings of $OCH_2O$ group[3]. The corresponding $CD_2$ stretchings

Pure liquid

are found in dimethoxymethane-$d_2$ ($CH_3OCD_2 \cdot OCH_3$) to be at 2188 (strongly depolarized in Raman) and at 2080 $cm^{-1}$ (strongly polarized in Raman), respectively. In DEM-$d_2$, two strong infrared bands appear at 2214 (the corresponding Raman band being strongly depolarized) and at 2080 $cm^{-1}$ (the corresponding Raman band being strongly polarized); hence they are assigned to the asymmetrical and the symmetrical $CD_2$ stretchings of the $OCD_2O$ group, respectivery, on the analogy of the above mentioned results. The asymmetrical and symmetrical methylene stretchings of the $OCH_2O$ group in DEM are then expected to appear near 2930 and 2890 $cm^{-1}$, respectively. The relative intensity of the infrared band at 2928~2929 $cm^{-1}$ becomes lower in DEM-$d_2$ as compared with the one in DEM, while that at 2870~2878 $cm^{-1}$ does not chow an appreciable change between DEM and DEM-$d_2$. Then it is certain that the asymmetrical methylene stretching of the $OCH_2O$ group exists at 2930 $cm^{-1}$ in DEM, and that it is probably overlapped by the other type of vibration. The overlapping band is presumably the asymmetrical methylene stretching of ethoxy group[2]. The bands at 2870~2878 $cm^{-1}$ in DEM and DEM-$d_2$ are assigned to the symmetrical methylene stretching of the ethoxyl group, overlapped by the symmetrical methylene stretching of the $OCH_2O$ group, as described above, and also by the symmetrical methyl stretching of the ethoxyl group. Since the intensity of these bands does not alter appreciably between DEM DEM-$d_2$, the absorbance of the symmetrical methylene stretching

of the $OCH_2O$ group is concluded to be small.

The possibility of the Fermi resonance occurring between two types of methylene groups may be small, because the interaction between them is believed to be negligible.

The remaining weak bands may be overtone and/or combination.

**Skeletal Stretching and C–H and C–D Deformation Vibrations.** — The appearance of the spectra of DEM and DEM-$d_2$ is quite similar in the range between 1480 and 1270 $cm^{-1}$ both in infrared and Raman. Therefore, the absorbance of the ethoxyl group is more predominant than that of the $OCH_2O$ group in this frequency region.

Medium infrared and Raman bands appear at 1477~1481 $cm^{-1}$ both in DEM and DEM-$d_2$. In ethylidene diethyl ether ($C_2H_5OCH(CH_3)\cdot OC_2H_5$), ethylidene methyl ethyl ether ($CH_3OCH(CH_3)OC_2H_5$), 2, 2-diethoxypropane ($C_2H_5OC(CH_3)_2OC_2H_5$)[6], triethyl orthoformate ($HC(OC_2H_5)_3$) and in triethyl orthopropionate

* P. and Dep. mean "polarized" and "depolarized", and S. means "strongly".

$(C_2H_5C(OC_2H_5)_3)$[7], a weak or medium infrared band is observed in this region. But in diisopropoxymethane $((CH_3)_2CHOCH_2OCH\cdot(CH_3)_2)$[8], ethylidene dimethyl ether $(CH_3\cdot OCH(CH_3)OCH_3)$, trimethyl orthoformate $(HC(OCH_3)_3)$, trimethyl orthoacetate $(CH_3C\cdot(OCH_3)_3)$ and in trimethyl ortho-*n*-valerate $(CH_3(CH_2)_3C(OCH_3)_3)$[7], no band exists in this region. Hence the bands at 1477~1481 $cm^{-1}$ are assigned to the methylene vibration of the ethoxyl group, certainly the scissoring vibration. The methylene scissoring of the $OCH_2O$ group can also exist at this frequency[3], but the absorbance of the latter may probably smaller than that of the former and it is hard to observe it.

All compounds containing oxygen atoms which the author has studied[1-4,6-8] have weak infrared and strong and depolarized Raman bands around 1460 $cm^{-1}$ except for dimethoxymethane and dimethoxymethane-$d_8$ $(CD_3\cdot OCD_2OCD_3)$. The last two compounds contain no methyl group, thus the bands in this region should be due to the methyl group. Therefore the bands at 1455~1466 $cm^{-1}$ (very weak in infrared and strong and depolarized in Raman) in DEM and DEM-$d_2$ are assigned to the asymmetrical methyl deformation of the ethoxyl group.

The origin of infrared bands at 1440~1443 $cm^{-1}$ both in DEM and DEM-$d_2$ is not clear, but they must be due to the vibration of the ethoxyl group, or the combination or overtone of skeletal vibrations.

The medium infrared and polarized Raman bands at 1389~1393 $cm^{-1}$ both in DEM and DEM-$d_2$ are assigned to the symmetrical methyl deformation of the ethoxyl group. From the result on dimethoxymethane and its deuterated compounds[3] the methylene wagging of the $OCH_2O$ group could exist in this region. So in DEM, these two bands may probably overlap.

The very weak infrared and weak Raman bands at 1359~1362 $cm^{-1}$ in DEM and DEM-$d_2$ are assigned to the methylene wagging of the ethoxyl group.

The features of doublet at 1292~1307 $cm^{-1}$ and 1270~1274 $cm^{-1}$ do not alter strongly between DEM and DEM-$d_2$, thus these bands are also due to the ethoxyl group. Of these, the former bands are assigned to the methylene rocking and the latter to the methylene twisting, because the Raman intensity of the latter is greater than that of the former and it is expected that the twisting vibration, the species of which is A, should give a stronger band.

In conclusion, it becomes clear that bands due to the ethoxy group are at 1477~1481, 1455~1466, 1441~1443, 1389~1393, 1361~1364, 1292~1307 and at 1270~1274 $cm^{-1}$ (all the values are those of liquid phase). The skeletal vibrations may not appear in such a high frequency region.

The weak Raman band at 1230 $cm^{-1}$ (having a corresponding very weak infrared band) in DEM-$d_2$ may be due to $CD_2$ vibration coupled with the COCOC skeletal vibration. Since the Raman band is polarized, it is assigned to the $CD_2$ scissoring or twisting, being coupled with an A type skeletal stretching, to some extent.

The medium bands at 1187~1192 $cm^{-1}$ both in infrared and Raman in DEM disappear in DEM-$d_2$ (in which a very weak infrared band appears at 1178 $cm^{-1}$, though the origin of this band may be different as the intensity is too low). Hence these bands are due to the methylene vibration of the $OCH_2O$ group, probably the twisting or wagging.

The bands at 1156~1158 $cm^{-1}$ in DEM both in infrared and Raman disappear in DEM-$d_2$. In dimethoxymethane and dimethoxymethane-$d_6$, weak infrared bands at this freqencey are assigned to the methylene rocking of the $OCH_2O$ group[3]. According to these results, these bands are assigned to the methylene rocking of the $OCH_2O$ group.

From the study on dimethoxymethane and its deuterated compounds, the skeletal COCOC stretching should exist between 1150~800 $cm^{-1}$ [3]. In DEM and DEM-$d_2$, the additional skeletal stretchings due to CC bonds could exist in this region. But the absorbance of the latter ones may be smaller than that of the former, hence the features of the spectra of DEM and DEM-$d_2$ are actually similar to those fo dimethoxymethane at this frequency region.

The infrared bands at 1117 and at 1136 $cm^{-1}$ in DEM and DEM-$d_2$ are the next strongest bands in the liquid phase, and the corresponding Raman bands are very weak. In dimethoxymethane and its deuterated compounds, the strong infrared bands around 1140 $cm^{-1}$, the corresponding Raman bands of which are extremely weak, are assigned to the asymmetrical skeletal stretching[3]. These bands are then assigned to one of the asymmetrical COCOC stretchings.

The Raman band at 1115 $cm^{-1}$ in DEM-$d_2$ is due to the $OCD_2O$ methylene vibration. As it is strongly polarized, it may be assigned to the scissoring or twisting being coupled with the symmetrical skeletal stretching to some extent.

The strong infrared band at 1095 $cm^{-1}$ in

7) K. Nukada, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **81**, 1028 (1960).
8) K. Nukada, This Bulletin, to be published.

DEM corresponds to the band at 1072 $cm^{-1}$ in DEM-$d_2$. As the corresponding Raman bands are strong and strongly polarized (in DEM), these bands are assigned to one of the symmetrical COCOC stretchings.

The strong infrared band appears at 1048 $cm^{-1}$ in DEM, but no corresponding band exists in DEM-$d_2$ near that frequency. In DEM-$d_2$, the remaining band, the intensity of which is rather high, is the band at 987 $cm^{-1}$. Furthermore the intensity of the corresponding Raman bands is not so high in both cases, thus it is reasonable to correlate the two bands as the same type of skeletal vibration. The remaining modes are one symmetrical and one asymmetrical vibration, but as described in detail later the symmetrical one should appear at 800~850 $cm^{-1}$ both in DEM and DEM-$d_2$. Accordingly these bands are assigned to the asymmetrical COCOC stretching.

The bands at 1015 and 984 $cm^{-1}$ in DEM and those at 940 and 969 $cm^{-1}$ in DEM-$d_2$, may be due to CC stretchings. The former ones are assigned to the symmetrical mode and the latter to the asymmetrical one, respectively, since the intensity of the corresponding Raman bands of the former is higher than that of the latter.

The strongest and strongly polarized Raman bands exist at 841 and 814 $cm^{-1}$ in DEM and DEM-$d_2$, respectively. In dimethoxymethane, its deuterated compounds[3], methoxyethoxymethane and in diisopropoxymethane[9], there appear the strongest and strongly polarized Raman bands, being assigned to the symmetrical skeletal stretching, between 900 and 800 $cm^{-1}$. Thus these bands are also definitely assigned to the symmetrical COCOC stretching. Just as in the case of dimethoxymethane and its deuterated compounds[3], the corresponding infrared bands are not so strong, and in the vapor phase its intensity becomes lower than that of the liquid phase. As already mentioned in the study of dimethoxymethane, the mode of this vibration is such that two terminal ethoxyl groups vibrate symmetrically and the central OCO group does not move much.

**Skeletal Deformation Vibrations.** — It is expected that five skeletal angle deformations appear over 200 $cm^{-1}$ and six torsional vibrations below 250 $cm^{-1}$. At the present, no infrared band below 280 $cm^{-1}$ is obtained because of the experimental limitation and Raman band below 200 $cm^{-1}$ is hardly observable since the strong exiting line disturbs the observation of weak Raman band. All the skeletal deformations could then be observed either in infrared or in Raman, while the torsional vibrations are hardly observable.

There are three pairs of strong Raman bands in DEM and DEM-$d_2$, namely at 634 and 614, 471 and 441, and 349 and 351 $cm^{-1}$. In dimethoxymethane, its deuterated compounds[3] and in methoxyethoxymethane[4], there appear such pairs of Raman bands. The appearance of infrared spectra is also quite similar between DEM and DEM-$d_2$, that is, three pairs of strong infrared bands appear at the same frequency regions. Hence they are certainly due to the skeletal deformations

Of these, the bands at 349~351 $cm^{-1}$ are strongly polarized in Raman, so they are assigned to the symmetrical COCOC deformation. As in the case of dimethoxymethane and its deuterated compounds, these are the vibrations all skeletal angles of which move in the same phase.

The degree of depolarization of the remaining two bands is not clear, but on the analogy of dimethoxymethane the bands at 614~634 $cm^{-1}$ in DEM and DEM-$d_2$ are assigned to the asymmetrical deformation and the last bands at 441~470 $cm^{-1}$ to the other symmetrical one, two COC angles and the OCO angle of which vibrate in the opposite phases.

As the Raman bands at 235~243 $cm^{-1}$ in DEM and DEM-$d_2$ are strongly polarized, they are assigned to the symmetrical OCC deformation. The assignment of the asymmetrical one is not clear.

The remaining weak bands may be overtone and/or combination of torsional vibrations.

## Summary

Infrared spectra between 3000 and 280 $cm^{-1}$ (vapor and liquid phases) and Raman spectra (liquid phase) of diethoxymethane ($C_2H_5 \cdot OCH_2OC_2H_5$) and of diethoxymethane-$d_2$ ($C_2H_5OCD_2OC_2H_5$) were observed and the assignment of the spectra is presented with the assumption that these molecules take one form both in the vapor and liquid phases. In the assignment, that of the homologues such as dimethoxymethane, its deuterated compounds, methoxyethoxymethane and diisopropoxymethane, are taken into consideration.

The author wishes to express his sincere thanks to Dr. Y. Mashiko for his valuable discussions.

# *Structure of Enteromycin. III.* Structure of Demethoxyenteromycin*

By Kōmei MIZUNO

(Received April 4, 1961)

The present work was initiated with a view to knowing the structure of dehydroxydihydrodemethoxyenteromycin (XXII)[1] and establishing the structure of demethoxyenteromycin (XII) by making clear the partial structures of *O*-acetyldemethoxyenteromycin (XVIII), *N*-methyldemethoxyenteromycin methyl ester (XIX), and *O*-methyldemethoxyenteromycin methyl ester (XX).

XXII has a molecular formula having one mole less hydrogen than dehydroxytetrahydrodemethoxyenteromycin (XV), namely glycyl-$\beta$-alanine, and its hydrolysis with hydrochloric acid gives glycine, acetaldehyde and others. The infrared spectum (Report II, Fig. 6) of this compound shows the absorption of C=C and the ultraviolet spectrum (Report II, Fig. 7) inhibits an adsorption similar to that of $\alpha, \beta$-unsaturated carboxylic acids. Further the infrared spectra (Report II, Figs. 2 and 4) of XVIII and XX reveals the clear absorption of NH. From these facts it is reasonable to assign the structure of *N*-glycyl-3-aminoacrylic acid to XXII. Accordingly, of the presumptive formulas, D

$$NH_2CH_2CONHCH=CHCOOH \qquad (XXII)$$

and C, for enteromycin and demethoxyenteromycin described in Report II, the $\alpha, \beta$-unsaturated ones would be preferential.

Catalytic reduction of XVIII on Adams platinum oxide yielded acetic acid (XXVII) and glycyl-$\beta$-alanine, and this fact ascertained the presence of $\rangle$NOAc in XVIII. On the other hand, the position of the $\rangle$NOH group in XII was clarified to be at the terminal N in the formula C. Catalytic reduction of XIX and hydrolysis of the resulting viscous substance (ester) (XX) yielded sarcosine (XXIX) and $\beta$-alanine. The same treatment of XX gave glycine and $\beta$-alanine. From these results, it is proper to think that the remaining hand of the hydroxyimino group (HO-N$\langle$C) in XII is not used for a N-N combination (the infrared spectra of XVIII and XX reveal the absorption of NH) or for a N-C combination (in a N-C combination is present, it must be split off by catalytic reduction before the formation of XXII which is a readily saturable unsaturated compound). In other words, the terminal N of XII ought to participate in aldoxime. Since thus XII is a strongly phenolic aldoxime compound, it gives two methyl derivatives ($CH_3$-$\overset{\overset{O}{\uparrow}}{N}$=CH- and $H_3CO$·N=CH-) as Fuson[2] pointed out, and XIX is understood as the *N*-methyl derivative taking

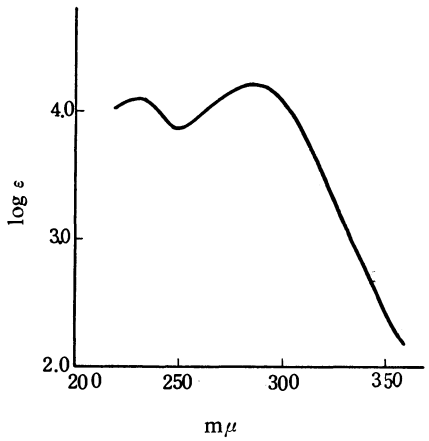

Fig. 1. Ultraviolet absorption spectrum of *O*-methyldemethoxyenteromycin methyl ester (XX) in methanol.

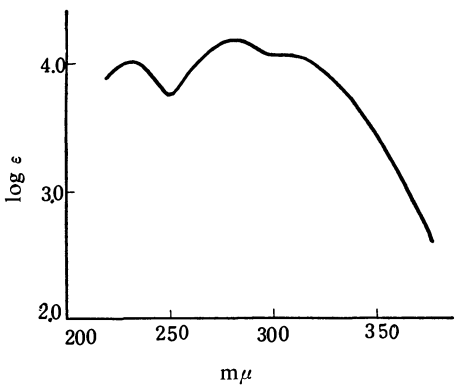

Fig. 2. Ultraviolet absorption spectrum of *N*-methyldemethoxyenteromycin methyl ester (XIX) in methanol.

* This constitutes Part XXXVII of a series entitled "Studies on Antibiotics" by S. Tatsuoka, and was reported at the forum on Natural Organic Compounds, October 1960.

1) K. Mizuno, This Bulletin, 34, 1425 (1961).

2) R. C. Fuson, "Advanced Organic Chemistry" (1950), p. 515.

oxide-form, and XX as the *O*-methyl derivative taking ether-form. The ultraviolet spectrum (Fig. 1) of XX, like that of XVIII, showed such strong absorptions at $\lambda$ 225 m$\mu$ and 280 m$\mu$ as those of diketone[3] compounds, whereas the ultraviolet spectrum (Fig. 2) of XIX exhibited such a strong absorption at $\lambda$ 295 m$\mu$ as the conjugate nitrone-form[4] may show. These facts seem to be in good accord with the above-mentioned structures.

Namely, the structure of XII must be *N*-(hydroxyiminoacetyl)-3-aminoacrylic acid,

$$HON=CHCONHCH=CHCOOH \quad (XII)$$

and consequently the structure of methyl *N*-(*N*-oxy-methyliminoacetyl)-3-aminoacrylate

$$H_3\overset{\overset{O}{\uparrow}}{C}N=CHCONHCH=CHCOOCH_3 \quad (XIX)$$

is presumed for XIX, and the structure of methyl *N*-(*O*-methylhydroxyiminoacetyl)-3-aminoacrylate

$$H_3CON=CHCONHCH=CHCOOCH_3 \quad (XX)$$

for XX.

## Experimental

**Acid Decomposition of Dehydroxydihydrodemethoxyenteromycin.**—A solution of 30 mg. of dehydroxydihydrodemethoxyenteromycin (XXII) in 3 cc. of 6 N hydrochloric acid was heated at 100°C for 6 hr. in a sealed tube, the air of which was replaced with nitrogen. One half of the reaction mixture was allowed to react with 2, 4-dinitrophenylhydrazine dissolved in hydrochloric acid, and the product was subjected to paper chromatography to detect the spot of the 2, 4-DNPH of acetaldehyde at $R_f$ 0.35. The remaining half was evaporated to dryness and the residue was chromatographed, finding a single spot of glycine at $R_f$ 0.40.

**Catalytic Reduction of *O*-Acetyldemethoxyenteromycin.** — A solution of 30 mg. of *O*-acetyldemethoxyenteromycin in 50 cc. of pure methanol was reduced in the presence of 20 mg. of Adams platinum oxide. The reaction mixture was diluted with 20 cc. of pure water and filtered, and 10 cc. of the filtrate was passed through a column of Amberlite IR-120 (H-form). The effluent, after addition of aqueous ammonia, was concentrated under diminished pressure and the residue was chromatographed by the method of Kennedy et al[5]. (solvent system: 95% ethanol containing ammonia. Detective reagent: a solution of B.P.B. in 70% ethanol, made acid with citric acid) to detect a blue spot, which was identified as ammonium acetate, and hence the presence of acetic acid in the reaction mixture was confirmed. It is evident that the spot is not formic acid because it does not reduce the ammoniacal silver nitrate solution of Brown et al.[6] The remaining filtrate (60 cc.) was concentrated under reduced pressure, giving 10 mg. of crystals, m.p. 225°C (decomp.), the infrared spectrum and $R_f$ value in paper chromatography of which were in complete accord with those of glycyl-$\beta$-alanine.

**Catalytic Reduction of *N*-Methyldemethoxyenteromycin Methyl Ester and Hydrolysis of the Product.**— A solution of 30 mg. of *N*-methyldemethoxyenteromycin methyl ester in 10 cc. of pure methanol was reduced on 20 mg. of Adams platinum oxide. The reaction mixture was filtered and concentrated under reduced pressure, leaving a small amount of a very viscous substance (XXVIII). The infrared spectrum of the substance showed the absorption of COOR, but its ultraviolet spectrum revealed no specific absorption in the long wave region beyond $\lambda$ 220 m$\mu$. Part of the substance was hydrolyzed with 6 N hydrochloric acid and the resulting free amino acid was investigated by the ninhydrin reaction and paper chromatography, whereupon a blue spot was detected at $R_f$ 0.65 and a pink spot at $R_f$ 0.73. The former spot was identified as $\beta$-alanine and the latter as sarcosine. The substance, after dinitrophenylation, gave three yellow spots; i.e. a spot at $R_f$ 0.37 in the first development, at $R_f$ 0.30 in the second development, a spot at $R_f$ 0.52 in the first development, at $R_f$ 0.28 in the second development, and a spot at $R_f$ 0.40 in the first development, at $R_f$ 0.43 in the second development, and they were identified as DNP-alanine, 2, 4-dinitrophenol, and DNP-sarcosine, respectively. The spots of DNP-$\beta$-alanine and DNP-sarcosine were extracted with hot water, and from the absorptions of the extracts the two compounds were found to be contained in equimolecular amounts.

The rest of the substance (XXVIII) was dinitrophenylated and the ether soluble portion of the product was hydrolyzed with hydrochloric acid and chromatographed, when no spot of DNP-sarcosine was detected, and the presence of only free $\beta$-alanine was confirmed.

**Catalytic Reduction of *O*-Methyldemethoxyenteromycin Methyl Ester and Hydrolysis of the Product.**— A solution of 30 mg. of *O*-methyldemethoxyenteromycin methyl ester in 10 cc. of pure methanol was reduced on 20 mg. of Adams platinum oxide. The reaction mixture was filtered and concentrated under reduced pressure to give a viscous substance. The product was hydrolyzed with hydrochloric acid and chromatographed as before, detecting glycine and $\beta$-alanine.

## Summary

The structure of dehydroxydihydrodemethoxyenteromycin was assumed to be *N*-glycyl-3-aminoacrylic acid. From the fact that catalytic reduction of *O*-acetyldemethoxyenteromycin afforded acetic acid and glycyl-$\beta$-alanine, and that *N*-methyl- and *O*-methyldemethoxyenteromycin methyl ester have the partial structures of *N*-(*N*-oxy-methyliminoacetyl)- and *N*-(*O*-

# *Structure of Enteromycin. IV**

By Kōmei MIZUNO

(Received April 4, 1961)

As reported in the previous papers[1-3], enteromycin (I) differs from demethoxyenteromycin (XII) in molecular formula only by $CH_2O$, but they are greatly different in property. From the fact that enteromycin is demethoxylated by heating under evolution of formaldehyde, and from the results of the decomposition of I and XII, enteromycin seems to have a specific functional group containing a methoxyl group. Therefore, the clarification of the functional group was considered to be the most important problem for establishing the structure of I. So the course of the conversion of I to XII by catalytic reduction was restudied first of all. On the other hand, attempts were made to know the position of the functional group by clarifying the structure of the amido compounds, XIV[1] and XXI[2], of I and XII.

Enteromycin methyl ester[1] (II) is soluble in many solvents and its catalytic reduction gives prisms (XXX) [m. p. 196°C (decomp.), $C_6H_8O_4N_2$], which are positive to the reaction of Barton et al.[1] The product has a methoxyl group, and though its infrared spectrum (Fig. 1) shows no absorption of $COOCH_3$ (1710 $cm^{-1}$), its ultraviolet spectrum exhibits two absorption maxima at $\lambda$ 225 m$\mu$ ($\varepsilon$ 11000) and 280 m$\mu$ ($\varepsilon$ 16000). However, as the product was positive to the Barton reaction, it was assumed to be demethoxyenteromycin methyl ester and the assumption was confirmed by the following experiments. Acetylation of XXX with acetic anhydride in warm water afforded prisms (XXXI) [m. p. 127°C, $C_8H_{10}O_5N_2$] negative to the Barton reaction. As the infrared spectrum (Fig. 2) of this product showed a clear absorption of $\equiv NOCOCH_3$ (1775 $cm^{-1}$), it was assumed to be *O*-acetyldemethoxyenteromycin methyl ester, and the assumption was confirmed by the formation of the same compound by methylation of *O*-acetyldemethoxyenteromycin (XVIII) with diazomethane. From the above fact, it was found that II is demethoxylated only by catalytic reduction without heating, and that such a phenomenon seems to be due to the specific position of the methoxyl group in the functional group in I and II.

Catalytic reduction of enteromycin amide (XIV) on palladium-carbon yielded prisms (XXXII) [m. p. 179°C (decomp.), $C_5H_9O_4N_3$] and the product was called dihydroenteromycin amide. It was positive to the Barton reaction but negative to the ninhydrin reaction and the reaction of the hydrazino group[4], and though its ultraviolet spectrum (Fig. 3) showed an absorption maximum at $\lambda$ 250 m$\mu$ ($\varepsilon$ 5100), its infrared spectrum (Fig. 4) exhibited no absorption of C=C. Hydrolysis of the product with hydrochloric acid afforded $\beta$-alanine but neither glyoxylic acid nor acetaldehyde, and alkaline

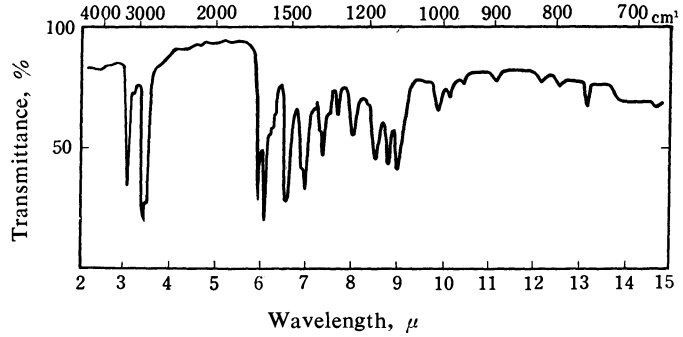

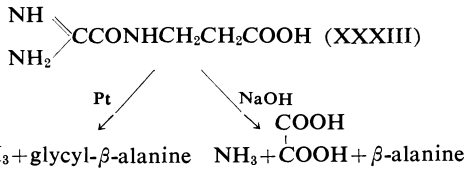

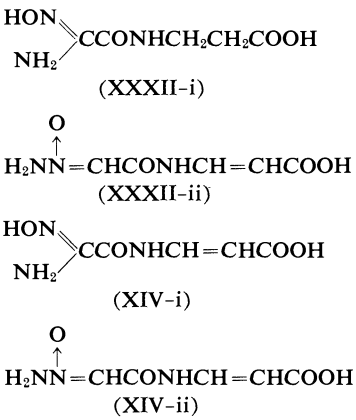

Fig. 5. Infrared absorption spectrum of a pyrazoline derivative (III) of enteromycin methyl ester.

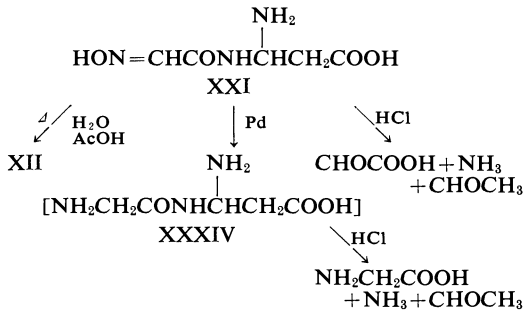
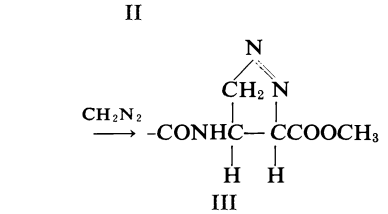
hydrolysis of the product furnished β-alanine and oxalic acid under evolution of a basic gas.

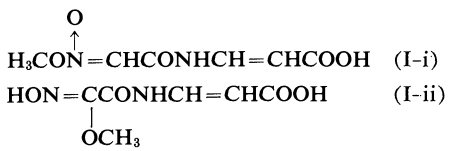


Catalytic reduction of XXXII for a long time in the presence of palladium-carbon gave a light pink product readily soluble in water (XXXIII) [m. p. 213°C (decomp.), $C_5H_9O_3N_3$], which was negative to the Barton reaction but positive to the ninhydrin reaction. The product was hydrolyzed with alkali, and in the reaction mixture were detected β-alanine, ammonia and oxalic acid, by paper chromatography. Further reduction of the above product on Adams platinum oxide produced ammonia and glycyl-β-alanine. From these results, amidinocarbonyl-β-alanine was assigned as the structure of XXXIII.

Accordingly, XXXII was considered to have the structure of *N*-(hydroxyamidinocarbonyl)-β-alanine (XXXII-i) and XIV the structure of *N*-(hydroxyamidinocarbonyl)-3-aminoacrylic acid (XIV-i) among the four formulas shown below:



An aqueous solution of the product (XXXIV) obtained by catalytic reduction of demethoxy-enteromycin amide (XXI) on palladium-carbon showed no specific absorption in the long wave region beyond λ 220 mμ, and hydrolysis of the product with hydrochloric acid produced acetaldehyde, ammonia and glycine. On the other hand, XXI furnished acetaldehyde and glyoxylic acid when hydrolyzed with hydrochloric acid, and its infrared spectrum (Report II, Fig. 5) exhibited no absorption of C=C. From this fact, XXI was presumed to be 3-amino *N*-(hydroxyiminoacetyl)-β-alanine.



The amidation product of XII has not the same structure as that (XIV-i) of enteromycin amide. Judging from the structure of XIV-i, it is evident that the $-OCH_3$ group of the functional group characteristic of I is situated on the HO-N=CH-CO- side of XII and its position seems to be the nitrogen of the oxime or the α-carbon atom.

To make clear that enteromycin also has a 3-amino acrylic acid portion, the structure of the diazomethane addition product[1] (III) of enteromycin methyl ester was investigated. Catalytic reduction of III on Adams platinum oxide and hydrolysis of the product with hydrochloric acid yielded glycine but not β-alanine. The infrared spectrum (Fig. 5) of III exhibited no absorption of C=C. From these results the addition product was considered to be a pyrazoline[5] derivative formed by addition of diazomethane to the α, β-double bond. This suggested that II also has such a double bond.

Namely, enteromycin also contains a 3-amino-acrylic acid portion.

From these results and considerations, the following two formulas were presumed as the structure of enteromycin.

Of the two formulas, (I-i) was preferred from the following experimental data.

i) Glyoxylic acid was produced by acid hydrolysis.

5) K. V. Auwers and O. Ungemach, *Ber.*, **66**, 1205 (1933)

ii) Methylation with diazomethane gave not *N*- or *O*-methyl compound but a pyrazoline derivative.

iii) The products obtained in various stages of catalytic reduction had no methoxy group[6].

iv) Ultraviolet Spectrum showed at $\lambda$ 298 m$\mu$ a strong absorption suspected to be due to conjugated nitrone.

v) To be negative to the reaction of Barton et al. for the phenolic hydroxyl group.

vi) Infrared spectra of I and II exhibited no absorption of -OH.

vii) Only one acidic group was observed.

Arndt et al.[7] once synthesized *O*-methyl-*aci*-nitroacetate and found that this compound was converted by heating into the corresponding oxime under evolution of formaldehyde. Gilman[8] explained the mechanism as this; a proton of the methoxyl is attracted by the coordinating oxygen and as a result the methoxyl converts into formaldehyde, while the corresponding oxime is formed. The formula I-i, having such a functional group, well explains the mechanism of the demethoxylation of enteromycin by heating. Since formation of formaldehyde from a methoxyl group may not be possible in any other group than the functional group, the formula I-i seems to be conclusively right from this point alone.

The problem still to be solved is whether or not amidation of a compound having such a specific structure as I-i furnishes a substance similar to XIV-i.

To clarify this point, ethyl *O*-methyl-*aci*-nitroacetate $C_5H_9O_4N$; $H_3CO\overset{O}{\uparrow}N=CHCOOC_2H_5$ synthesized by the method of Arndt et al. was amidated under the same conditions as in I and detailed investigation was made on the product (XXXV) [m. p. 171°C (decomp.), $C_2H_5O_2N_3$]. The product was positive to the Barton reaction and its ultraviolet spectrum (Fig. 6) showed an absorption at $\lambda$ 250 m$\mu$ ($\varepsilon$ 5100), which was in accord with that of dihydroenteromycin amide (XXXII). Alkaline hydrolysis of XXXV evolved a basic gas and produced oxalic acid, and acetylation of it with acetic anhydride in warm water gave an *O*-acetyl compound [m. p. 168°C (decomp.), $C_4H_7O_3N_3$], which was negative to the Barton reaction and the infrared spectrum of which showed the absorption of AcON= (1755 cm$^{-1}$).

Next, XXXV was reduced for a long time in the presence of palladium-carbon, and the light pink product (XXXVI) yielded ammonia and oxalic acid when hydrolyzed with alkali, and oxamide (XXXVII) when treated with hot water. Since, however, XXXVI was not isolated, the following experiments were carried out. XXXV was reduced on Adams platinum oxide and the product was hydrolyzed with hydrochloric acid, giving glycine. Catalytic reduction of the *O*-acetyl derivative of XXXV with palladium-carbon in acetic anhydride yielded a light pink product assumed to be *N*, *N'*-diacetyldiaminoacetamide [m. p. 257°C (decomp.), $C_6H_{11}O_3N_3$], and the structure was confirmed from the formation of glyoxylic acid by the hydrolysis of the product with hydrochloric acid.

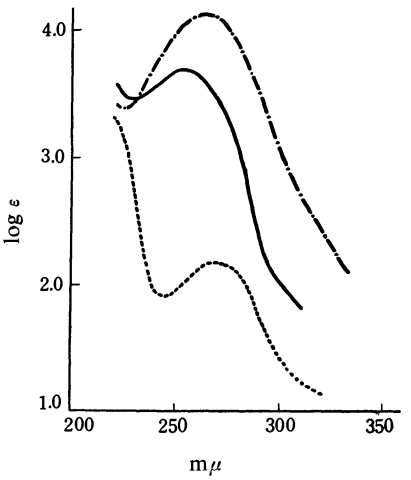


Fig. 6. Ultraviolet absorption spectra of ethyl *O*-methyl *aci*-nitroacetate (-·-·-), oxamide monoxime (XXXV) (——), and ethyl nitroacetate (----) in methanol.

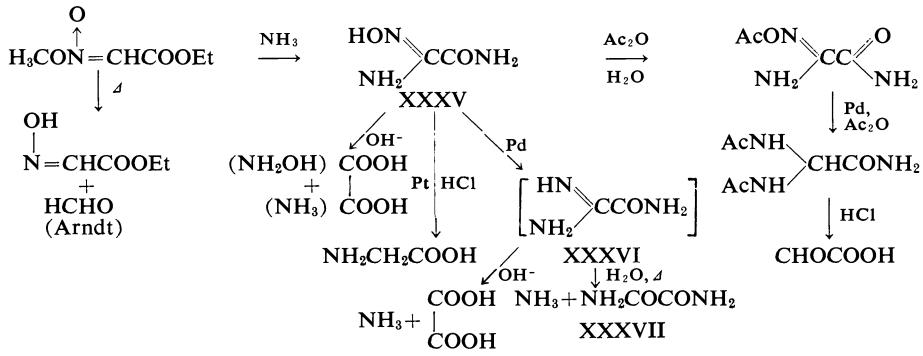
From these results, XXXV is represented by the formula below and may be called oxamide monoxime. Thus XXXV was found to have a structure similar to XIV-i.

Thus, conversion of I-i to XIV-i was considered possible, and hence the plane structure of enteromycin was established as *N*-(*O*-methyl-*aci*-nitroacetyl)-3-aminoacrylic acid (I-i).



The steric configuration of I was investigated next. The infrared spectra of III, XXI, XXXII and XXXIII, which are considered to be saturated in the 3-aminoacrylic acid portion, scarcely showed the absorption of trans[9] C=C (960~990 cm$^{-1}$), whereas I, II, XII, XIV, XVIII, XIX, XX, XXII, XXX and XXXI, which are considered to be unsaturated in the portion, exhibited the absorption without exception, and therefore the configuration of the portion is assumed to be trans.

XII is an aldoxim and takes two crystal forms, but its *O*-acetyl derivative (XVIII) takes only one crystal form. Treatment of XVIII with alkali carbonate afforded XIIa but not the corresponding nitrile.

According to the rule proposed by Hantzsch et al.[10] and corrected by Brady et al.[11,12] and Meisenheimer et al.[13,14], and if all the compounds of the present work follow the rule, the configuration of the hydroxyiminoacetyl group of XII is assumed to be *syn*, and the hydrogen attached to the $\alpha$-carbon atom is on the same side of the double bond as the coordinating oxygen in the *aci*-nitroacetyl group of I-i, and therefore** XXXVIII and XXXIX may be assigned to enteromycin and demethoxyenteromycin, respectively.

## Experimental

**Demethoxyenteromycin Methyl Ester (XXX).**—A solution of 200 mg. of enteromycin methyl ester (II) in 40 cc. of pure methanol was reduced on 80 mg. of Adams platinum oxide until 0.8~0.9 mol. of hydrogen was absorbed. The catalyst was filtered off and the filtrate was evaporated at low temperature under reduced pressure, leaving about 150 mg. of crystals, m. p. 178°C (decomp.), which were recrystallized from methanol to give ca. 70 mg. of needles, m. p. 196°C (decomp.). The product is positive to the ferric chloride·potassium ferricyanide reaction.

Found: C, 42.00; H, 4.87; N, 15.86; O-$CH_3$, 18.29. Calcd. for $C_6H_8O_4N_2$: C, 41.86; H, 4.68; N, 16.28; O-$CH_3$, 18.03%.

***O*-Acetyldemethoxyenteromycin Methyl Ester (XXXI).**—a) To a solution of 50 mg. of XXX in 3 cc. of hot water was added several drops of acetic anhydride and the mixture, after standing for 10 min., was adjusted to pH 6.0 with sodium hydrogen carbonate and extracted with ethyl acetate. The extract was washed with water and evaporated at low temperature under reduced pressure, and the residual prisms, m. p. 116°C (ca. 20 mg.) were recrystallized from acetone. The product melted at 127°C.

b) A suspension of 300 mg. of *O*-acetyldemethoxyenteromycin (XVIII) in 7 cc. of ethyl acetate was allowed to react with a solution of diazomethan (produced from 1 g. of nitrosomethylurea) in 20 cc. of ether for 30 min. and the colorless reaction mixture was evaporated at low temperature under reduced pressure to leave a syrupy substance. The syrupy substance was left standing with a little ether and the resulting crystals (ca. 250 mg.) were recrystallized from acetone in prisms, m. p. 127°C. The product and that in a) gave the same infrared spectrum and their mixed melting point showed no depression.

Found: C, 45.16; H, 4.86; N, 12.76; O-$CH_3$, 13.96. Calcd. for $C_8H_{10}O_5N_2$: C, 44.86; H, 4.71; N, 13.08; O-$CH_3$, 14.36%.

**Dihydroenteromycin Amide (XXXII).**—A solution of 500 mg. of enteromycin amide (XIV) in 400 cc. of hot pure methanol was cooled and reduced on 150 mg. of palladium-carbon (1 : 10) until about one mole of hydrogen was absorbed (ca. 90 min.). The reaction mixture was evaporated at low temperature under reduced pressure, the syrupy residue was dissolved in 10 cc. of methanol, and ether was added to the filtered solution to deposit light pink crystals. The crystals were filtered off, the filtrate was concentrated, and ether was added to the syrupy residue, separating about 380 mg. of crystals, m. p. 176°C (decomp.), which were recrystallized

** Recently, Nishikawa et al.[15] conducted infrared spectroscopic analysis on the compounds of the present work and on their deuterium-substituted derivatives and reported that the intramolecular hydrogen bond observed between NH and coordinating oxygen in enteromycin methyl ester (II) could be explained only by its *anti*-configuration. If their assumption is right, the configuration of enteromycin is in reverse with that of XXXVIII and does not apply to the rule of Hautzsch et al.

15) M. Nishikawa et al., *J. Pharm. Soc. Japan* (*Yakugaku Zasshi*), in press.

from methanol in white plates, m.p. 179°C (decomp.) (250 mg.). The product is positive to the ferric chloride-potassium ferricyanide reaction, gives yellowish brown color with ninhydrin, and furnishes a spot at $R_f$ 0.55 on Consden's paper chromatography described in Report I.

Found: C, 34.56; H, 5.49; N, 24.18. Calcd. for $C_5H_9O_4N_3$: C, 34.28; H, 5.18; N, 23.99%.

**Decomposition of Dihydroenteromycin with Hydrochloric Acid.** — A solution of 10 mg. of XXXII in 1 cc. of 6 N hydrochloric acid was heated under reflux at 100°C for one hour. In one half of the reaction mixture 5 mg. of 2,4-dinitrophenylhydrazine was dissolved and the solution was investigated by paper chromatography to detect no 2,4-DNPH of acetaldehyde or of glyoxylic acid. The remaining half of the reaction mixture was evaporated to dryness and the residue was chromatographed, giving the spot of β-alanine at $R_f$ 0.65.

**Decomposition of Dihydroenteromycin with Alkali.**—A solution of 10 mg. of XXXII in 1 cc. of 1 N sodium hydroxide was refluxed for one hour, when a basic gas evolved copiously. The reaction mixture was passed through a column of Amberlite IR-120 (H-form) and the effluent was subjected to paper chromatography, detecting the spot of oxalic acid at $R_f$ 0.20. The substance adsorbed on Amberlite IR-120 was eluted with 1 N ammonium hydroxide and the solution was chromatographed as above to give a spot of β-alanine.

**Dehyroxydihydroenteromycin Amide (XXXIII).** —A solution of 700 mg. of XXXII in 40 cc. of acetic acid was catalytically reduced for about 40 hr. in the presence of 200 mg. of palladium-carbon and the reaction mixture was concentrated at low temperature under reduced pressure in the atmosphere of nitrogen, leaving crystals, which, after washing first with ether and then with methanol, afforded about 350 mg. of light pink crystals, m.p. 205°C (decomp.). The product is positive to the ninhydrin reaction (light blue color) and gives a spot at $R_f$ 0.77 on paper chromatography (Consden's method).

Found: C, 38.02; H, 6.00; N, 26.86. Calcd. for $C_5H_9O_3N_3$: C, 37.73; H, 5.70; N, 26.41%.

Addition of 1 cc. of 1 N sodium hydroxide to 20 mg. of the product evolved a gas, which was basic to pH test paper and reddened the Nessler's reagent, suggesting that it is ammonia. The mixture was boiled for one hour under reflux and subjected to paper chromatography, detecting oxalic acid and β-alanine.

**Desaminodehydroxytetrahydroenteromycin [Glycyl-β-alanine] (XV).** — A solution of 30 mg. of XXXIII in 5 cc. of 70% methanol was reduced on 20 mg. of Adams platinum oxide and the reaction mixture, after being filtered, was concentrated, leaving about 13 mg. of glycyl-β-alanine.

**Catalytic Reduction of Demethoxyenteromycin Amide and Hydrolysis of the Product.**—A solution of 30 mg. of demethoxyenteromycin amide (XXI) in 10 cc. of pure methanol was reduced on 15 mg. of palladium-carbon. The reaction mixture was neutral and evolved no ammonia, and it exhibited no specific absorption in the long wave region beyond 220 mμ. The reaction mixture was diluted with 3 cc. of water, the catalyst was filtered off, and the filtrate was concentrated at low temperature under reduced pressure, leaving a white residue, which was hydrolyzed by heating with 4 cc. of 3 N hydrochloric acid at 100°C for 2 hr. A 2 cc. portion of the reaction mixture was allowed to react with 2,4-dinitrophenylhydrazine and the resulting 2,4-DNPH was chromatographed to find the spot of the 2,4-DNPH of acetaldehyde at $R_f$ 0.36. The rest of the reaction mixture was evaporated to dryness under diminished pressure and the residue was also chromatographed, detecting a large amount of glycine and traces of β-alanine.

**Ethyl *O*-Methyl-*aci*-nitroacetate.**—An amount of 2.7 g. of ethyl nitroacetate ($K_p$ 79~81°C) prepared from ethyl acetoacetate by the method of Arndt et al.[8] was dissolved in 10 cc. of ether, and the solution was left standing with 40 cc. of an ether solution of diazomethane produced from 5 g. of nitrosomethylurea. The reaction mixture was evaporated at low temperature under reduced pressure, leaving an oily substance showing an absorption maximum (ε 13500) at λ 262 mμ.

Found: C, 41.05; H, 6.45; N, 9.02. Calcd. for $C_5H_9O_4N$ (ethyl *O*-methyl-*aci*-nitroacetate): C, 40.81; H, 6.17; N, 9.52%.

**Oxamide Monoxime (XXXV).**—To a solution of 1.5 g. of ethyl *O*-methyl-*aci*-nitroacetate in 10 cc. of methanol was added 50 cc. of methanol saturated with ammonia, and the yellowish orange-colored mixture, after standing at room temperature overnight, was concentrated at low temperature under reduced pressure, giving 1 g. of light yellow crystals, m.p. 165°C (decomp.). The crystals were dissolved in hot methanol, decolorized with carbon, and the solution was cooled to furnish about 600 mg. of colorless prisms, m.p. 171°C (decomp.), positive to the ferric chloride-potassium ferricyanide reaction but negative to the ninhydrin reaction.

Found: C, 23.58; H, 4.83; N, 40.27. Calcd. for $C_2H_5O_2N_3$: C, 23.30; H, 4.89; N, 40.77%.

An amount of 20 mg. of the product was boiled with 2 cc. of 1 N sodium hydroxide for one hour, when a basic gas evolved copiously. The reaction mixture was passed through a column of Amberlite IR-120 (H-form) and the effluent was chromatographed, giving the spot of oxamide at $R_f$ 0.20.

***O*-Acetyloxamide Monoxime.**—To a solution of 2.5 g. of oxamide monoxime (XXXV) in 7 cc. of hot water was added dropwise 2 cc. of acetic anhydride at 60°C with vigorous stirring. After about 20 min. the reaction mixture was concentrated at low temperature under reduced pressure and the separated crystals were recrystallized from acetone in prisms, m.p. 168°C (decomp.).

The product was negative to the ferric chloride-potassium ferricyanide reaction and showed the infrared spectrum characteristic of =NOCOR (1755 $cm^{-1}$).

Found: C, 33.32; H, 4.83; N, 29.04. Calcd. for $C_4H_7O_3N_3$ (*O*-acetyloxamide monoxime; $CH_3COON{=}C(NH_2)CONH_2$: C, 33.10; H, 4.86; N, 28.96%.

***N*, *N'*-Diacetyldiaminoacetamide.**—A solution of 1 g. of *O*-acetyloxamide monoxime $AcON{=}C(NH_2)\cdot CONH_2$ in a mixture of 20 cc. of glacial acetic acid and 7 cc. of acetic anhydride was reduced on 500 mg.

of palladium-carbon (1 : 10) for about 6 hr. The reaction mixture, after addition of water, was concentrated under reduced pressure, and the part sparingly soluble in hot acetone of the product was recrystallized from water to give about 800 mg. of light pink crystals, m. p. 257°C (decomp.).

Found : C, 41.51 ; H, 6.49 ; N, 24.41. Calcd. for $C_6H_{11}O_3N_3$ *N*,*N'*-diacetyldiaminoacetamide, $(CH_3CO\cdot NH)_2CHCONH_2$ : C, 41.61 ; H, 6.60 ; N, 24.27%.

A solution of 50 mg. of the product in about 1 cc. of water was heated with a solution of 2,4-dinitrophenylhydrazine in hydrochloric acid for about 2 hr. to hydrolyze and at the same time to produce the 2,4-DNPH derivative. The reaction mixture was extracted with ethyl acetate and the extract was shaken with a sodium hydrogen carbonate solution. The alkaline solution was made acidic and extracted again with ethyl acetate, and the extract, after washing with water and drying, was evaporated at low temperature under reduced pressure, giving yellowish white needles, m. p. 192°C. The infrared spectrum of the product was in accord with that of the 2,4-DNPH of glyoxylic acid and the product showed the same color reaction (orange-brown with alkali) and the same $R_f$ value (0.40) in paper chromatography as the 2,4-DNPH of glyoxylic acid.

**Oxamide (XXXVII).**—Catalytic reduction of a solution of 700 mg. of XXXV in a mixture of 10 cc. of methanol and 10 cc. of glacial acetic acid absorbed one mole of hydrogen in about 30 min. The reaction mixture had not the absorption maximum at $\lambda$ 250 m$\mu$ and gave a light blue color with ninhydrin. The reaction mixture was concentrated at low temperature under reduced pressure and the syrupy residue was crystallized by addition of ether. The product was washed with ether, treated with cold water and warm water successively, and recrystallized from hot water to give about 200 mg. of crystals, m. p. above 300°C, negative to the ninhydrin reaction.

Found : C, 27.27 ; H, 4.76 ; N, 31.84. Calcd. for $C_2H_4O_2N_2$ (oxamide) : C, 27.27 ; H, 4.58 ; N, 31.81%.

The ninhydrin positive substance (XXXVI) detected immediately after the reduction could not be isolated.

**Catalytic Reduction of Oxamide Monoxime.**—A solution of 10 mg. of XXXV in 10 cc. of glacial acetic acid was reduced to 20 mg. of Adams platinum oxide for about 2 hr. The reaction mixture was concentrated under reduced pressure and hydrolyzed by heating with 3 cc. of 6 N hydrochloric acid at 100°C for about one hour. Paper chromatography of the white residue of the hydrolysis mixture gave a spot of glycine.

**Decomposition of *O*-Acetyldemethoxyenteromycin with Sodium Carbonate.**—A mixture of 100 mg. of *O*-acetyldemethoxyenteromycin (XVIII) and 4 cc. of 5% sodium carbonate solution was allowed to stand at room temperature for 70 min. The reaction mixture was neutralized with acetic acid and extracted with ethyl acetate. The plates, m. p. 175°C (decomp.) (70 mg.) obtained from the extract were positive to the ferric chloride-potassium ferricyanide reaction and exhibited the same infrared spectrum as demethoxyenteromycin (XII).

Found : C, 38.12 ; H, 3.77 ; N, 17.52. Calcd. for $C_5H_6O_4N_2$ : C, 37.98 ; H, 3.83 ; N, 17.02%.

## Summary

Catalytic reduction of enteromycin methyl ester afforded demethoxyenteromycin methyl ester. Since demethoxyenteromycin amide was presumed to be 3-amino-*N*-(hydroxyiminoacetyl)-$\beta$-alanine, while enteromycin amide was considered to be *N*-(hydroxyamidinocarbonyl)-3-aminoacrylic acid, the two presumptive formulas, I–i and I–ii, were proposed for enteromycin. As the amido compound prepared by amidation of synthetic ethyl *O*-methyl-*aci*-nitroacetate was assumed to have the structure of hydroxyamido carbonyl amide (oxamide monoxime) and as enteromycin was demethoxylated by heating under evolution of formaldehyde, the formula I–i was found to be preferential, considering together other properties of the compound, and therefore the plane structure of enteromycin was established to be *N*-(*O*-methyl-*aci*-nitroacetyl)-3-aminoacrylic acid. The steric configuration of the 3-amino acrylic acid seems to be trans and that of the *O*-methyl *aci*-nitroacetyl group (the configuration of the hydrogen attached to the $\alpha$-carbon atom and of the coordinating oxygen) to be syn.

The author is grateful to Dr. S. Kuwada, Director of the Laboratories for his kindness to give the chance to conduct the present work and for his encouragement throughout the work. Thanks are to Drs. K. Tanaka, A. Miyake, M. Miyamoto, Y. Ueno, J. Ueyanagi and T. Kanzawa for their kind advice. The author is also indebted to Messrs. Y. Kawamatsu, T. Yoshikawa for their kind assistance, to Dr. K. Nakazawa, Messrs. M. Shibata, M. Inowe and their coworkers who gave the starting material, to Messrs. M. Nishikawa, H. Nakamachi for their infrared spectroscopic analyses, to Dr. Y. Asahi for his measurement of dissociation constants, to Messrs. M. Kan, H. Kashiwagi and Mrs. Y. Tsukamoto, Misses F. Suzuki, M. Ueda, and H. Nabekura for their elementary analyses and Mr. T. Nakata for his azotometric determination.

# *Oxidation of Ferrous Ions in Aqueous Solutions by Cobalt-60 Gamma Rays. II*[1]. *Effect of Anions at High Dose*

By Hiroshi HOTTA and Shin-ichi OHNO

(Received April 18, 1961)

It is well-known that the Fricke dosimeter ($G(Fe^{3+})=15.6$) is the best secondary standard dosimeter, but it has the upper limit of applicable doses due to the solubility of oxygen in the solution. The air-free system may also be applicable up to higher doses as a good dosimeter ($G(Fe^{3+})=8.2$) for the same kind of radiations with the Fricke dosimeter, if the procedure of degassing oxygen is not minded. For this purpose, the property at high dose was examined.

The reaction scheme for the air-free system is usually assumed as follows:

$$Fe^{2+}+OH=Fe^{3+}+OH^- \quad (1)$$

$$Fe^{2+}+H_2O_2=Fe^{3+}+OH^-+OH \quad (2)$$

$$Fe^{2+}+H+H^+=Fe^{3+}+H_2 \quad (3)$$

As the dose increases, $G(Fe^{3+})$ decreases gradually above a certain dose due to re-reduction of ferric ion produced, by the reaction

$$Fe^{3+}+H=Fe^{2+}+H^+ \quad (4)$$

competing with reaction 3. However, this reaction may not be so simple, for ferric ion is usually associated with anions in the solution, as discussed later.

On the other hand, sodium chloride is usually added by 0.001 M as a stabilizer for the Fricke dosimeter to suppress the effect of organic impurities, for chloride ion scavenges OH radical, which reacts with the impurities, like

$$Cl^-+OH+H^+=Cl+H_2O \quad (5)$$

and this reaction does not affect the $G(Fe^{3+})$ due to the following reaction[2]

$$Fe^{2+}+Cl=Fe^{3+}+Cl^- \quad (6)$$

The effect of anions, especially halide ions, on the radiolysis of ferrous solutions at high dose was investigated in the present study to obtain the detailed information of reaction 4.

## Experimental

The preparation of solutions and the irradiation method by 10 kc. cobalt-60 gamma rays were the usual ones as was mentioned in Part I[1]. The composition of the solutions used is listed in Table I. All the solutions containing halide salts were dissolved in the "standard solution", which contained 0.04 M ferrous ammonium sulfate in 0.8 N sulfuric acid.

The concentration of ferric ion was usually measured by a Shimadzu spectrophotometer. The molar extinction coefficient of ferric ion at 304 m$\mu$, which was 2150 $cm^{-1}$ at 24°C, was constant between 0.2 N and 1.2 N sulfuric acid, but increased by 0.8% for

TABLE I. COMPOSITION OF SOLUTIONS USED IN M AND THEIR $k_4/k_3$ IN Eq. iii

the rise of one degree centigrade between 13 and and 38°C. However, this was measured by the titration method of potassium permanganate for solutions containing fluoride ion or a large amount of ferric ion.

## Results

**Dependence of the Concentration of Ferrous and Sulfate Ions.**—The oxidation of ferrous ion in the nitrogen-saturated solution of 0.5 M ferrous ammonium sulfate in 0.8 N sulfuric acid is shown as "a" in Fig. 1. The $G(Fe^{3+})$ was initially 8.2, and gradually decreased above $7\times10^6$r (0.05 M in ferric ion). The result for the 0.1 M ferrous solution, measured up to 0.09 M in ferrous ion, was almost the same as solution a. The $G(Fe^{3+})$ for the 0.04 M ferrous solution began to come down at $4\times10^6$ r (0.03 M in ferric ion). The decrease of $G(Fe^{3+})$ at high dose is due to reaction 4 as mentioned in the "Introduction". On the other hand, the reaction

$$OH+H_2=H+H_2O \qquad (7)$$

may promote reaction 4 at high dose, at which hydrogen molecules are accumulated in the closed medium. The conversion ratio of ferric ion to initial ferrous ion at the bending point of the $(Fe^{3+})$-dose curve is different between the above solutions.

The effect of sulfate concentration on $G(Fe^{3+})$ at high dose in nitrogen-saturated 0.5 M ferrous ammonium sulfate solutions is shown in Fig. 1, that is, solutions b, c and d were dissolved in 2.8, 4.8 and 8 N sulfuric acid, respectively, and solution f contained 1 M sodium sulfate in 0.8 N sulfuric acid. The decrease of $G(Fe^{3+})$ is considerably suppressed by 2.8 N sulfuric acid, but this effect does not increase much by the more concentrated sulfuric acid. Sulfuric acid is more effective than sodium sulfate as compared between solutions b and e which contained the same amount of sulfate group (1.4 M).

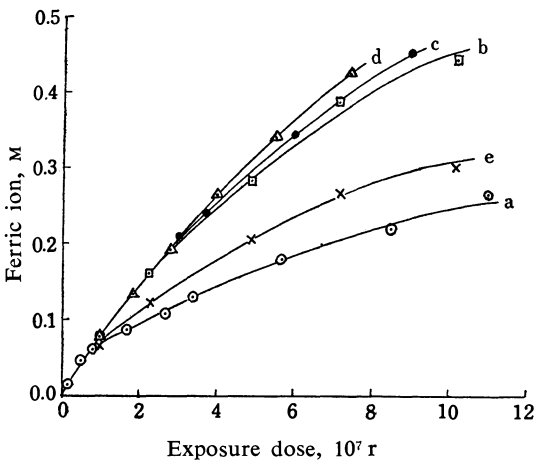

Fig. 1. Oxidation of ferrous ion in the nitrogen-saturated solutions a (⊙), b (▣), c (●), d (△) and e (×).

**Effect of Halide Ions.** — The oxidation of ferrous ion in the nitrogen-saturated standard solutions containing f 0.001 M, g 0.01 M, h 0.1 M and i 0.5 M sodium chloride, respectively, is shown in Fig. 2. As the concentration of of sodium chloride increases, the observed points depart at the lower dose from the straight line of solution f, and the $G(Fe^{3+})$ decreases with the increase of the dose.

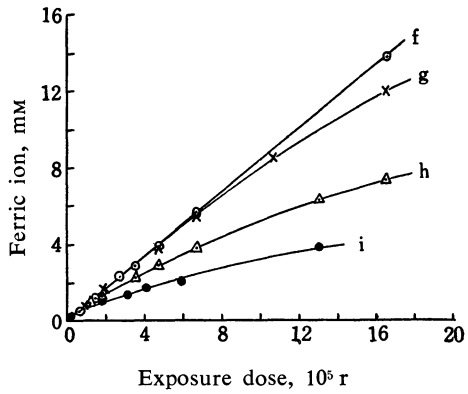

Fig. 2. Oxidation of ferrous ion in the nitrogen-saturated solutions f (⊙), g (×), h (△) and i (●).

On the other hand, the oxidation of ferrous ion in the oxygen-saturated standard solutions containing j 0.001 M, k 0.01 M, and l 0.1 M sodium chloride, respectively, is shown in Fig. 3. The thermal air oxidation of ferrous ion catalyzed by chloride ion, corrected in Fig. 3, were $(2.5\pm0.5)\times10^{-4}$ M in these solutions. The effect of chloride ion as seen in Fig. 2 does not appear even in solution l till oxygen is consumed.

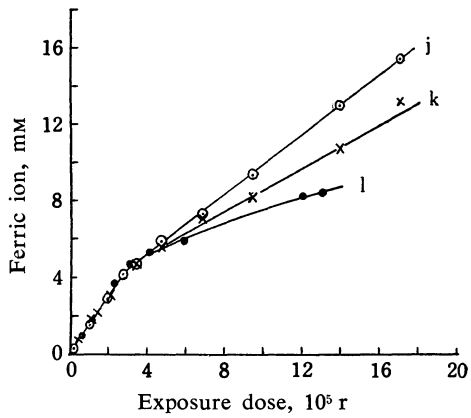

Fig. 3. Oxidation of ferrous ion in the oxygen-saturated solutions j (⊙), k (×) and l (●).

TABLE II. CONCENTRATION OF COMPLEXES IN M

| Run | X | $Fe^{III}$ | $Fe^{3+}$ | $FeSO_4^+$ | $Fe(SO_4)_2^-$ | $FeX^{2+}$ | $FeX_2^+$ | $FeX_3$ | $X^-$ |

TABLE III. ASSOCIATION CONSTANT OF FERRIC COMPLEXES AT 25°C

| Ligand | $K_1$ | $K_2$ | $K_3$ | Ionic strength | Reference |
|---|---|---|---|---|---|
| $SO_4$ | 95 | 9.4 | — | 1.0 | 5 |
| F | $1.62\times10^5$ | $8.9\times10^3$ | 500 | 0.5 | 4 |
| Cl | $4.2\pm0.2$ | $1.3\pm0.4$ | $0.04\pm0.02$ | 1.0 | 6 |
| Br | 0.5 | — | — | 1.0 | 6 |

Note: $K_n=\frac{(FeX_n^{n-3})}{(FeX_{n-1}^{n-4})(X^-)}$

Furthermore, the effect of 0.1 M various halide ions, namely, h sodium chloride, m potassium bromide n potasium fluoride, and p nothing, in the nitrogen-saturated standard solution, was studied as shown in Fig. 4. The effectiveness on the $G(Fe^{3+})$ is in the order of

$$Cl^- > Br^- > SO_4^{2-} > F^- \qquad \text{(i)}$$

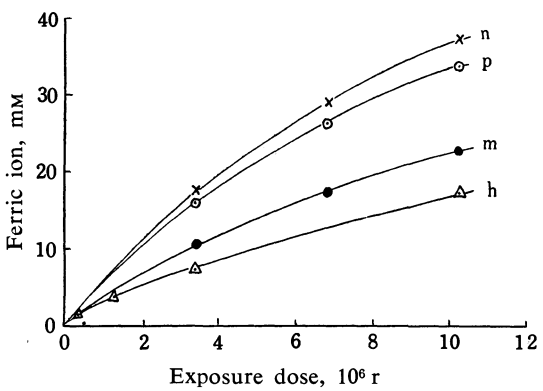

Fig. 4. Oxidation of ferrous ion in the oxygen-saturated solutions h (△), m (●), n (×) and p (⊙).

## Discussion

If chloride ion is only a scavenger for OH radicals as mentioned in the "Introduction", the $G(Fe^{3+})$ should not be affected by the excess of chloride ion. However, the $G(Fe^{3+})$ in the air-free systems decreases at high dose with increase of chloride ion in Figs. 2 and 3. On the other hand, as mentioned already, ferric ions are more or less associated with anions; for example, as $FeCl^{2+}$, $FeCl_2^+$, $FeCl_3$ etc., and even if bare, hydrated with water molecules. Therefore, it is supposed that the reduction rate is different between those ferric complexes.

When the present hypothesis is correct, the observed series i for the effectiveness of various anions on the reduction of ferric ion might be understood by the properties and concentration of the complexes in the solutions. The concentrations of respective complexes in the irradiated standard solutions containing 0.1 M halide salt and 0.01 M ferric species are estimated in Table II without correction of activity on the asumption that ferrous and ammonium ions do not associate with any ion. The concentration of $SO_4^{2-}$ is assumed to be 0.30 M in those solutions from Kerker's result[3]. Furthermore, the association constants of respective complexes in Table III[4-6] are used directly in the evaluation, for the association constant is usually not so changed between 0.5 and 1.0 of ionic strength expected from the above estimation for sulfuric acid.

Ferrous ion is considered to be also associated with hydrogen ion in the acidic solution through the oxygen atom of a water molecule like

$$Fe^{2+}\cdots O\begin{matrix}H\\ \cdots H^+\cdots H\end{matrix} \qquad \text{(ii)}$$

3) M. Kerker, *J. Am. Chem. Soc.*, **79**, 3664 (1957).
4) J. Hudis and A. C. Wahl, ibid., 75. 4153 (1953).
5) R. A. Whiteker and N. Davidson, ibid., **75**, 3081 (1953).
6) E. Rabinowitch and W. A. Stockmayer, ibid., **64**, 335 (1942).

and the approach of a hydrogen atom to the hydrogen ion is assumed to be the rate-determining step of reaction 3. Therefore, if the effect of reaction 7 is ignored, the reaction scheme in the "Introduction" leads to the equation for the rate of oxidation in the mixture of ferric and ferrous ions[7].

$$\frac{d(F^{III})}{d(Dose)} = 2G(H_2) + \frac{2G(H)}{1+\frac{k_4(Fe^{III})}{k_3(Fe^{II})}} \quad \text{(iii)}$$

where $k_3$ and $k_4$ are the rate constants of reactions 3 and 4, respectively, and $(Fe^{III})$ and $(Fe^{II})$ are the concentration of ferric and ferrous species obtained by chemical analysis, respectively. Then, the appearent ratios, $k_4/k_3$, without considering complex formation, are obtained as listed in Table I as the measure of relative reduction rates. The larger value is more reliable.

Exactly speaking, since $(Fe^{III})$ and $(Fe^{II})$ do not always mean their free ion concentration $(Fe^{3+})$ and $(Fe^{2+})$, due to complex formation or imperfect dissociation, the apparent ratio should be rewritten as

$$\frac{k_4(Fe^{III})}{k_3(Fe^{II})} = \frac{1}{k_3(Fe^{2+})}\sum(c_i)k_4' \quad \text{(iv)}$$

where $c_1$ and $k_4'$ are the concentration and rate constant of reduction reaction in reference to the $i$'th ferric complex, respectively, as

$$FeX^{2+} + H = Fe^{2+} + X^- + H^+ \quad (8)$$

instead of reaction 4. If the difference between $(Fe^{II})$ and $(Fe^{2+})$ is ignored, the relative rate constant to reaction 3, the $k_4'/k_3$, for respective ferric complexes are obtained in Table IV

Table IV. Relative reduction rate and standard oxidation-reduction potential of ligand

| Ligand | $k_4'/k_3$ in Eq. iv | Standard oxidation-reduction potential V. |
|---|---|---|
| Br | 3000 | 1.065 |
| Cl | 3400±300 | 1.385 |
| $H_2O$ | 20~70 | 1.77 |
| $SO_4$ | <2 | 1.98 |
| F | ≈0 | 2.85 |

from the estimation in Table II. The contribution except for $Fe^{3+}$, $FeSO_4^+$, $FeX^{2+}$ is also ignored in the evaluation, for the concentration or reaction rate of ignored complexes is small in comparison with those species. The value for $FeCl^{2+}$ is obtained from $k_4/k_3$ of solutions g, h and i. The value of hydrated ferric ion corresponds to free ferric ion in Table II. The assumption for the concentration of $SO_4^{2-}$ is effective for the values in Table IV, but not effective for the ratio between them. It is concluded from Table IV that the reduction rate of ferric chloride and bromide complexes by hydrogen atom is more than fifty times as great as hydrated ferric ions. Also that ferric sulfate complexes are much less reductive than hydrated ferric ion, and ferric fluoride complexes are scarcely reductive at all. It is also understood by the lower reductivity of ferric sulfate complexes why the dose-yield curve is straight ($G(Fe^{3+})=8.2$) up to high dose in spite of the production of ferric ion.

The quantitative analysis is impossible for the result of the concentrated solutions as shown in Fig. 1 for the lack of fundamental constants. However, since the $k_4/k_3$ of sulfuric acid solution is approximately proportional to the ratio of concentration, $(Fe^{3+})/(Fe^{III})$ from Eq. iv, this ratio can give some information for those systems. That is, the ratio, $(Fe^{3+})/(Fe^{III})$, is a function of the concentration of sulfate ion, which suppresses the concentration of free ferric ion by the formation of ferric sulfate complexes as less-reductive species, including the dependence of association constant on ionic strength[5,8]. It is concluded from the ratios in Table I that the concentration of free ferric ion in the solutions decreases and that of free sulfate ion increases with increase of sulfuric acid up to 1 M, but neither concentration changes so much in the more concentrated sulfuric acid solution. The fact is confirmed by the study of the dissociation of sulfuric acid[3,9]. Sodium sulfate is not so effective as sulfuric acid for the suppresion of the reduction reaction in comparison between solutions b and e containing the same amount of sulfate group, for the dissociation of sulfuric acid is suppressed by sodium sulfate. The difference of $k_4/k_3$ between solutions a and p containing the same amount of sulfuric acid may be due to the effect of direct reaction with thermerized electron as suggested by Weiss[10] or other reactions in a hot track in the concentrated solution.

On the other hand, in Fig. 3, the $G(Fe^{3+})$ in the presence of oxygen is not affected by chloride ion even in solution till oxygen is consumed. It is because all hydrogen atoms from the radiolysis of water associate rapidly with oxygen as $HO_2$ which is an oxydizing reagent. According to Rothschild and Allen, the association rate is more than one hundred times as fast as the rate of reaction 3[7].

7) W. G. Rothschild and A. O. Allen, *Radiation Research*, **8**, 101 (1958).

8) B. N. Mattoo, *Z. phys. Chem.*, **19**, 156 (1959).

10) J. Weiss, *Nature*, **186**, 751 (1960).

Silverman and Dodson reported that the rate of electron exchange reaction between ferric chloride complex and ferrous ion is about ten times as fast as that between free ferric and ferrous ions[11]. For such a case, the ligand atom gives a chance for multi-charged ions to anchor easily at the same site, and also serves as the bridge of electron transfer. Brown[12] suggested that the effectiveness may be a function of the electronegativity and polarizability[13]. Since the reactivity of the hydrogen atom for the present reaction is not due to electrostatic force but due to unpaired electron, some difference is expected between the two cases. In fact, the electron exchange reaction between $Tl^+$ and $Tl^{3+}$ is promoted in sulfuric acid[14], but ferric sulfate complex is less reductive for hydrogen atom than hydrated ferric ion as shown in Table IV. Anyhow, it is necessary for the reaction

$$Fe^{3+}-X^- + H \longrightarrow Fe^{2+} + XH \qquad (9)$$

even if XH is dissociated afterwards, that the ligand X loss one electron. The standard oxidation-reduction potential of the ligand to do so, $\Delta E$, which may be a function of electronegativity and polarizability, corresponds to the reductivity of complexes in Table IV. The discrepancy for the order of bromide complex may be due to the uncertainty of its association constant. When the reduction rate of complexes might be expressed as

$$k = A \exp\left(-\frac{\Delta E}{RT}\right) \qquad (v)$$

the $k_4'/k_3$ of fluoride complex is expected to be the order of 0.01.

## Summary

The $G(Fe^{3+})$ of air-free acidic ferrous sulfate solutions decreases gradually with the increase of dose due to the re-reduction of ferric ion produced. The decrement depends on the property of anion as well as sulfuric acid in the solution in the order of

$$Cl^- > Br^- > SO_4^{2-} > F^-$$

The relative reduction rate of ferric complexes is obtained in Table IV as a result of the estimation of respective complexes in the solution; that is, ferric chloride and bromide complexes promote the reduction of ferric ion, and ferric sulfate and fluoride complexes suppress it.

# *Synthesis of Several Tertiary Alcohols from Propanol-2 and Ethylene by Gamma-ray Irradiation**

By Kozo HIROTA and Motoyoshi HATADA

(Received April 22, 1961)

In previous reports[1,2], it was found that several higher ketones can be synthesized by a chain telomerization from acetaldehyde and terminal olefins by $\gamma$-ray irradiation with high $G$ values. Similar telomerization may also occur with a high yield in the system of propanol-2 and ethylene, considering Urry's research[3] on the peroxide- and light-induced additions of several alcohols to olefins. The chain-carrying radical of this system, however, is $(CH_3)_2\dot{C}OH$ instead of $CH_3\dot{C}O$ in the systems of acetaldehyde and olefins, as will be shown as follows:

Initiating step:

$$(CH_3)_2CHOH \rightsquigarrow (CH_3)_2\dot{C}OH + H$$

Propagating step:

* Chain Telomerization Induced by Gamma-rays. II.

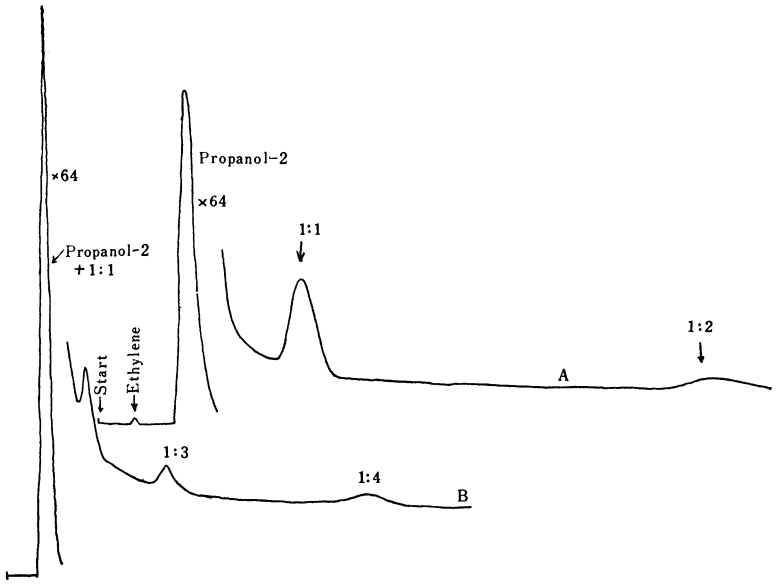

Fig. 1. Gaschromatograms of the samples after irradiation.
Curve A was obtained by using D. O. P. 3 m. column at 107°C.
Curve B was obtained by using H. V. O. 6 m. column at 180°C.

$$(CH_3)_2\dot{C}OH + C_2H_4 \xrightarrow{k_{p0}} (CH_3)_2C(OH)CH_2\dot{C}H_2$$

$$(CH_3)_2C(OH)CH_2\dot{C}H_2 \xrightarrow{+C_2H_4, k_{p1}}$$

$$+(CH_3)_2CHOH \swarrow^{k_{d1}} \quad (CH_3)_2C(OH)(CH_2)_3\dot{C}H_2$$

$$(CH_3)_2(C_2H_5)COH + (CH_3)_2\dot{C}OH$$

By a similar scheme $(CH_3)_2C(OH)(CH_2)_3\text{-}\dot{C}H_2$ will produce $(CH_3)_2\text{-}(OH)(CH_2)_3$ and $(CH_3)_2\cdot C(OH)(CH_2)_3CH_2CH_2\dot{C}H_2$ with velocity constants $k_{d2}$ and $k_{p2}$, respectively, etc.

It is the object of the present paper to report that the expected telomerization proceeds even at room temperature.

## Experimental

Commercial pure propanol-2 was used after distillation, while commercial ethylene (research grade) was used without further purification. No impurity was found in the gases by either gaschromatographical or mass-spectral analyses.

Every sample for irradiation was degassed and distillated into glass tubes (1.2 cm. in diameter; ca. 20 cm. in length), equipped with a breakable joints. After the tubes were sealed, they were irradiated by $\gamma$-rays from the Co-60 source (700 c) installed in this laboratory. Dosimetry was based on a ferrous oxidation yield of 15.5. After the irradiation, the samples were taken out through the breakable joint and were put through gaschromatographic analysis (Apparatus; Shimadzu GC1A type).

The initial ratios of propanol to ethylene in the sample were about ten if otherwise not described. These ratios will be denoted as $R$ hereafter, which, however, is not necessarily equal to that in solution, because ethylene is hardly soluble.

## Results

In the sample irradiated, *tert*-amyl alcohol (1 : 1 telomer) and *tert*-heptyl alcohol (1 : 2 telomer) were identified by the use of a 3.0 m. column of dioctyl phthalate, while *tert*-nonyl alcohol (1 : 3 telomer) and *tert*-undecyl alcohol (1 : 4 telomer) were also detected by the use of a 6.0 m. column of high vacuum-oil (Fig. 1). However, the existence of higher telomers will be estimated, especially when $R$ is large, as is done in the discussions.

In Fig. 2, the amount of the 1 : 1 telomer produced is plotted against the irradiated time. After an induction period is observed in the initial part of the curve, a linear increase is found in the amount. It is interesting to note that a similar induction period was also observed[4] in the gamma-ray-induced telomerization of acetaldehyde and ethylene. Such an effect may be due to the presence of some undetectable impurities, e. g. oxygen or other radical-scavengers. The $G$ value calculated from the linear part of the curve is ca. 1.2×

$10^2$, suggesting that this reaction proceeds by a chain mechanism. Figure 3 shows the relation between $R$ and $G$ values of the product at 9°C, where other variables are kept constant. By use of the data of Fig. 3 molar fraction $F_i$ of the $1:i$ telomers to the total telomers is plotted in Fig. 4, making $R$ as the ordinate. The full curves in the figure will be explained in the discussion.

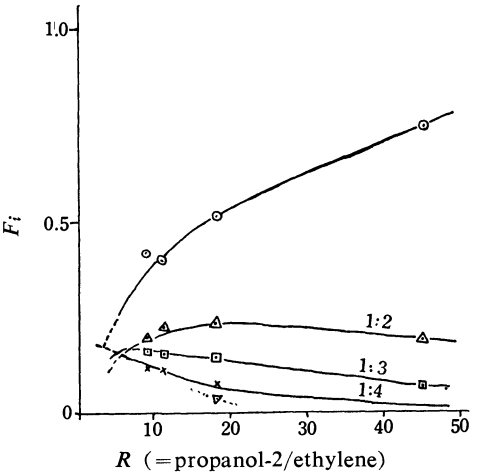

Fig. 4. Distribution of the telomers corresponding to the data of Fig. 3.
—— Calculated by

$$F_i=\frac{C_nR}{\prod_{i=1}^{n}(C_iR+1)}$$

▽ Assumed value for 1 : 5 telomer

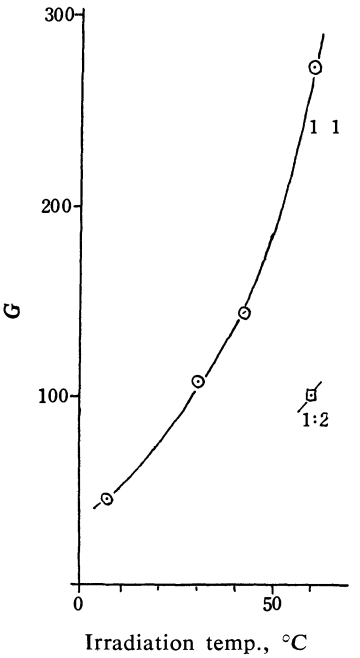

Fig. 5. *tert*-Amyl alcohols vs. irradiation temp.

Temperature dependency of $G$ values on the amount of the products is shown in Fig. 5. It is clear that the higher is the reaction temperature, the more *tert*-amyl alcohol is produced and $G$ value reaches about 300 at 60°C. Plots of logarithms of the $G$ values vs. $1/T$°K give a straight line as shown in Fig. 6, by which an activation energy of 6.3 kcal./mol. can be determined. This value, however, is not necessarily that of the reaction, but is of complex nature, because the solubility of ethylene into alcohol changes when the reaction temperature is changed as is seen in our experiment.

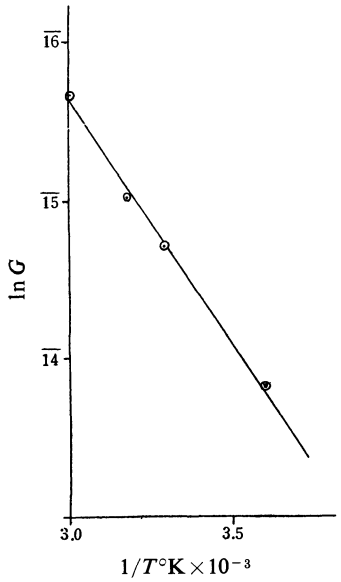

Fig. 6. $\ln G$(*tert*-amyl alcohol) vs. $1/T$°K. $E_A=6.3$ kcal./mol.

## Discussion

If the telomerization proceeds by the reaction scheme shown in the introduction, the distribution of the telomers produced will be given as molar fractions $F_i$ by the theoretical relation[5]:

$$F_i=\frac{C_iR}{\prod_{i=1}^{n}(C_iR+1)}$$

where $C_n$'s$=k_{dn}/k_{pn}$ are transfer constants. Assuming that the molar ratio of alcohol to ethylene in the solution is the same as that ($R$) of the starting material and that higher telomers are produced though small in amount, chain transfer constants $C_i$'s were calculated from the observed $F_i$'s in the sample of $R=18$, and were found to be 0.062, 0.056, 0.073 and 0.12 for $i=1$, 2, 3 and 4, respectively, if $G$ value of 1 : 5 telomer is assumed to be 8. The mean value of $C_1$, $C_2$ and $C_3$, i. e. 0.062, resembles Urry's average transfer constant, 0.057[3], obtained at 115~130°C, using di-*tert*-butyl peroxide as initiator. This means that the chain-propagating step of the radiation-induced reaction is similar to that of the reactions induced by chemical initiators, although the reaction temperatures, pressure and $R$ values are different in the two reactions.

However, exactly speaking, plots of $F_i$ determined from the observed data vs. $R$ do not lie on the full curves calculated from the above $C_i$'s so completely as shown in Fig. 4. Similar comparison of the theory and experiment was better in the systems of acetaldehyde and propylene[1] or isobutylene[2]. The discrepancy in this system may be brought about by the assumptions adopted in the calculation i. e., $G$ value of 1 : 5 telomer and neglect of the change of solubility of ethylene to propanol-2 with pressure. Though a better coincidence may be obtained by the introduction of solubility data, this correction could not be carried on, because of the absence of such data. On the other hand, production of higher alcohols, corresponding to $1:i$ telomer ($i\geq 5$), ought to be considered, as assumed to some extent in the calculation, because if they are completely neglected, the coincidence became more than that shown in Fig. 4.

The overall activation energy obtained above (6.3 kcal./mol.) nearly equals that of the abstraction reaction of hydrogen atom from $\alpha$-carbon of propanol-2, i. e., 7.3 kcal./mol.[6] Considering the ambiguity included in the former value, such a degree of coincidence indicates that the step which produces the chain-carrying radical may be regarded as being the rate-determining one in the above mechanism.

In the irradiated samples containing a small amount of iodine ($10^{-3}$ mol. in propanol-2), not even a trace of telomers was found, probably due to the radical-scavenging action of iodine. This finding may serve as an evidence of the radical mechanism as assumed by us. However, since formation of $CH_nI^+$ and $CH_4OI^+$ was recently observed mass spectrometrically by the ion-molecule reactions[7];

$$CH_n^+ + I_2 \rightarrow CH_nI^+ + I$$
$$\text{or}\quad CH_n^+ + I_2 \rightarrow CH_{n-1}I^+ + HI$$
$$CH_3OH^+ + I_2 \rightarrow CH_4OI^+ + I$$

an ion-scavenging action of iodine can be taken into account. It is possible therefore that some ion or ions also play some role in the

present reaction, but probably in some intermediate step which preceeds the production of $(CH_3)_2\dot{C}OH$. Then the initiating step above the mechanism will be composed of several elementary ones.

Though the $G$ value of this telomerization is of the same order of magnitude as the system of acetaldehyde and propylene or isobutylene, it is smaller by one or two orders of magnitude at the same temperature than that of the system where acetaldehyde was used instead of propanol-2[4]. This may be attributed to the difference in nature between the chain-carrying radicals, i. e., acetyl radical and isopropyl radical in both systems.

## Summary

Tertiary amyl and higher tertiary alcohols have been synthetized at 6~60°C by irradiating gamma-rays on mixture of propanol-2 and ethylene enclosed in glass vessels. It has been found that as the irradiation temperature the $G$ value of these telomers increases markedly, e. g. up to ca. 300 at 60°C. It has been concluded from the distribution of the telomers produced that this reaction proceeds by a chain mechanism, making isopropyl radical $(CH_3)_2\dot{C}OH$ as the chain-carrying radical. It has been estimated that the characteristic of gamma-rays will be found in the step prior to the production of the isopropyl radical. If the rays can play some role in this reaction.

The authors wish to express their sincere thanks to Mr. Hiroshi Ochi for his help in performing the present research.

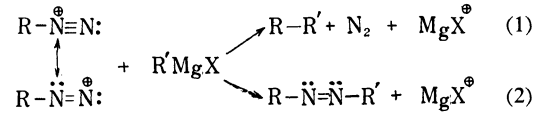
# *Syntheses and Ultraviolet Spectra of Aromatic Azo Compounds. I. Bromo-methylazobenzenes*

By Yujiro NOMURA



(Received April 22, 1961)

The reaction of Grignard reagents with aromatic diazonium salts was first investigated by Hodgson and Marsden[1], who found that the addition of the zinc chloride double salts of several diazonium chlorides to arylmagnesium bromides in refluxing dry ether gave azo compounds in low yields.

Oda and Nakano[2], on the other hand, reported that the zinc chloride double salt of benzenediazonium chloride reacted with alkyl- or arylmagnesium bromides in ether at 0°C to give 6~34% of the theoretical amount of alkyl- or arylbenzenes.

Curtin and Ursprung[3] reinvestigated these reactions following the procedure of Oda et al. and observed that azo compounds were formed in 2~35% yields and no significant amounts of biaryls, reported by Oda et al. to be products of these reactions, could be obtained. They postulated that small amounts of metal impurities might be contained in magnesium employed by Oda et al. which catalyzed the reaction in an abnormal way.

The formation of biarly or azo compound in the reaction of Grignard reagent with diazonium ion may be represented by the following equations:

(1)

(2)

If the reaction proceeded according to 1, the same mole of nitrogen as biaryl R-R′ should be evolved. But no significant amounts of nitrogen have been observed to evolve in these reactions in accordance with the observations of Curtin et al. Since azobenzenes initially formed by the reaction 2 might react further

* Based on bromocompound used.

with excess Grignard reagent to yield hydrazobenzenes[4] and their derivatives[5], it was suspected that the attack of Grignard reagents on azobenzenes might be responsible for the rather poor yields of azo compounds.

The present study was carried out for the purpose of applying the reactions of Grignard reagents with diazonium salts to the preparations of various azo compounds and always the excess of diazonium salts over Grignard reagents were used expecting better yields of azo compounds.

**General Procedure.**—The ethereal solution of tolylmagnesium bromide prepared from 1 mol. of bromotoluene and the excess of magnesium was added slowly with vigorous stirring to the suspension of 1.3~1.5 mol. of the zinc chloride double salt of bromobenzenediazonium chloride at a rate necessary to maintain refluxing. The resulting dark red mixture was stirred for an additional 60 min. at room temperature and then poured onto ice-cold dilute hydrochloric acid. The ether layer was separated and washed with water and dried. Evaporation of the ether gave a solid or oil, which crystallized upon standing. The crude bromo-methylazobenzenes thus obtained were recrystallized from alcohol or distilled in vacuo, followed by recrystallization from alcohol.

In the syntheses of 4-bromo-2-methylazobenzene (X), 4-bromo-3-methylazobenzene (XI) and 2-bromo-4-methylazobenzene (XII), phenyl magnesium bromide and the excess of the zinc chloride double salts of bromotoluene-diazonium chlorides were used.

The bromo-methylazobenzenes prepared by this method were shown in Table I. They are all new compounds except 4-bromo-4'-methylazobenzene (IX)[6] and 4-bromo-3-methylazobenzene (XI)[7], which showed no depression of their melting points on admixture with a respective authentic specimen prepared according to the literature.

Electronic absorption spectra were measured in an alcoholic solution. The maxima of the absorption spectra of bromo-methylazobenzenes were listed in Table II. It can be seen that the *K*-bands of bromo-methylazobenzenes shift

towards a longer wavelength than unsubstituted azobenzene ($\lambda_{max}$ 318 m$\mu$, $\varepsilon_{max}=20900$ in alcohol) especially when methyl or bromine is in ortho or para positions. On the other hand, the molecular extinction coefficients ($\varepsilon_{max}$) became larger when methyl or/and bromine was situated in ortho, meta and para positions, in this order.

## Experimental

Ultraviolet absorption spectra were measured by a Hitachi EPU 2 type spectrophotometer using a 1 cm. quartz cell.

**Preparation of the Zinc Chloride Double Salt of Diazonium Chloride.**—The mixture of 1 mol. of amine and 3~4 mol. of hydrochloric acid (1 : 1) was diazotized at 0°C with sodium nitrite dissolved in a small amount of water. To the resulting solution of diazonium chloride was added a cold saturated solution of zinc chloride (200 cc.) with stirring, when the zinc chloride double salt of diazonium chloride was separated out. After being allowed to stand in ice water for some time with occasional stirring, the double salt was filtered by suction and washed several times with a little ice-cold alcohol and then with ether. The double salt was spread in air and then dried in vacuum desiccator. The yield was excellent in most cases.

A few examples of the preparation of the zinc chloride double salt of diazonium chloride was shown below.

Thirty two grams of 2-amino-5-bromotoluene were added to 100 cc. of dilute hydrochloric acid (1 : 1), and the resulting suspension of the amine hydrochloride was diazotized at 0°C. A saturated solution of zinc chloride (about 40 cc.) was added to the diazotized solution with stirring. The yield of the double salt was 40 g. or 98% of the theoretical. In the same manner, from 17.2 g. of *p*-bromoaniline was obtained 28.0 g. (95% yield) of the double salt, and from 17.2 g. of *m*-bromoaniline was obtained 28.3 g. of the double salt.

**Preparations of Bromo-methylazobenzenes.**—Twelve bromo-methylazobenzenes were prepared following the general procedure described above. An example is given below in the preparation of 2-bromo-2'-methylazobenzene (I).

Seventeen grams of the zinc chloride double salt of *o*-bromobenzenediazonium chloride and 150 cc. of dry ether were put in a 300 cc. flask equipped with an efficient stirrer, a reflux condenser and a dropping funnel. A Grignard solution prepared from 7 g. of *o*-bromotoluene and 1.3 g. of magnesium in ether and diluted to about 40 cc. with dry ether was introduced from the dropping funnel to the suspension of the diazonium salt with vigorous stirring over a period of 15 min. without external cooling. Exothermic reaction occurred and gentle reflux continued for some time after all the Grignard solution was added. The mixture was diluted to double its volume with ether and shaken with cold dilute hydrochloric acid and then with water, dried over calcium chloride and evaporated to give the red crystals, which were recrystallized from ethanol with a small amount of decolorizing charcoal. The yield of 2-bromo-2'-methylazobenzene was 7 g. or 64% of the theoretical amount based on *o*-bromotoluene.

## Summary

1) Twelve bromo-methylazobenzenes have been synthesized by the reactions of Grignard reagents with zinc chloride double salts of diazonium compounds. Ten of them are new compounds.

2) The ultraviolet absorption spectra of bromo-methylazobenzenes have been measured and some regularities of the absorption maxima have been observed in them.

The author is indebted to Dr. Nozomu Ebara for the determination of the ultraviolet absorption spectra.

# *Photoreduction of Methylene Blue by the Visible Light in the Aqueous Solution Containing Certain Kinds of Inorganic Salts. III. Kinetic Treatment of the Reaction*

By Yoshiharu Usui and Masao Koizumi

(Received April 13, 1961)

It has been established in the previous papers[1] that upon irradiation of the aqueous solution of methylene blue containing various kinds of salts by visible light, the formation of leuco dye takes place accompanied by demethylation and the irreversible decomposition of dye; and in particular its rate is quite high in the presence of phosphate, sodium hydroxide and borate. Leuco formation and demethylation proceed as simultaneous reactions and in most cases the rate of the former is higher than that of the latter, which can be suppressed almost completely under suitable conditions.

Now it is very remarkable that the leuco-formation can occur without any reducing agents in the ordinary sense, and how this occurs still awaits further studies and is a very important problem to be solved. In the previous paper two possibilities were suggested for the primary process, i. e., the reaction of the excited dye and that of the ground state on one hand and the reaction between the excited dye and hydroxide ion on the other. Of course the problem must be attacked from various standpoints, and the present paper is chiefly concerned with the investigation from the reaction kinetics.

## Kinetic Treatment

The present reaction as a whole is too complicated to be treated exactly, but it is desirable to get an approximate rate formula which can reproduce the experimental results, as a means for studying further the reaction scheme. Now the most reliable data supplied by the experiments are the decline of the main absorption band of the dye. But as already stated, the formation of leuco dye is accompanied with demethylation which causes the shift of the maximum toward the shorter wavelength. Therefore, by applying the minimum ratio method of Blaisdell[2] to the absorption spectra of the irradiated solution, the one due to the remaining methylene blue was evaluated and its analysis was undertaken. The decrease in dye concentration obtained from the above treatment is, of course the sum due to leuco-formation, demethylation and irreversible decomposition, but in view of the fact that these reactions take place with about the same ratio for a particular system during the most part of one run, the rate derived therefrom may well correspond to that of leuco-formation. It is necessary however, to pay due attention to this point when the rates for different systems are compared; for example, in case of phosphate the rate of demethylation is of about the same order of that of leuco-formation, while in case of sodium hydroxide the former is quite a good deal smaller than the latter.

In Fig. 1 plots of $\varepsilon_{max}$ against time are given for the typical results so far obtained, in which $\varepsilon_{max}$ pertains to the maximum of the absorption spectra of methylene blue after

1) Y. Usui, H. Obata and M. Koizumi, This Bulletin, 34, 1049 (1961); H. Obata, ibid., 34, 1057 (1961).
2) B. E. Blaisdell, *J. Soc. Dyers. & Colorists*, 65, 619 (1949).

Blaisdell's treatment*. It is seen that broadly speaking, they are classified into three groups on the grounds of the magnitude of bleaching. The first group with a very small rate contains sodium sulfate, sodium iodide, sodium chloride and the pure aqueous solution. The second group with a medium rate contains only borate buffer, and the third one with the largest rate are phosphate buffer and sodium hydroxide solution. As stated below the first and the second groups have the rate formula which is approximately of the first order in respect to dye while for the third group the second order rate formula fits the experimental data quite satisfactorily. Hence the first and second group may be lumped together. In the following the rate for borate buffer and that for phosphate buffer will be separately discussed, each as a representative of the two groups.

**Borate Buffer Solution.**—Approximately, the rate is represented as of the first order with respect to dye, but as the reaction proceeds it becomes progressively smaller than that calculated from the simple first order rate formula. The cause for this retardation may supposedly be due to the interference of a certain reaction product; for example, such a product as hydrogen peroxide and this was really confirmed by the following experiment. Thus into the solution of methylene blue of which 80~90% had previously been photobleached, a suitable quantity of dye was newly dissolved in vacuo to make the concentration about equal to that of the previous one. Using such a solution the photoreaction was once more repeated and its rate was compared with that of the previous experiment.

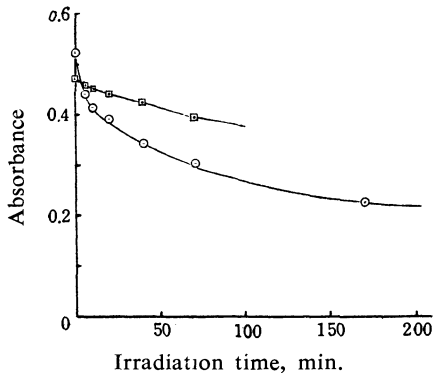

Fig. 2. Retardation by reaction product(s) in borate buffer at 30°C.
(◉: 1st run, ▣: 2nd run)

* Since the optical density of the solution during the course of the reaction is relatively small, the inner filter effect of the demethylated dye need not be taken into account.

As shown in Fig. 2, the rate in the second run is much smaller than that in the first one. On the basis of this result we now propose the following scheme as a tentative one.

$$\begin{array}{ccccccccc} \mathrm{MB} & \xrightarrow{h\nu} & \mathrm{MB^*} & \rightarrow & \mathrm{MB^t} & \cdots\cdots & \xrightarrow{a} \mathrm{X} & \xrightarrow{k_1} & \mathrm{P} \\ & & \downarrow & & \downarrow & & \downarrow k_d \quad \searrow^{k_2} & & +\mathrm{P} \\ & & \mathrm{MB} & & \mathrm{MB} & & \mathrm{MB} & & \mathrm{MB} \end{array} \qquad \text{(A)}$$

In this scheme it is assumed that the dye molecule goes via the triplet state to a certain intermediate X, and $a$ is a fraction of excited dye which attains to X. X then is assumed to react in three different ways, i.e., the product-forming reaction of the (apparent) first order (rate constant; $k_1$) the usual deactivation process (rate constant; $k_d$) and a process of particular deactivation caused by the attack of some reaction product (rate; $k_2[\mathrm{P}][\mathrm{X}]$). In fact it is entirely unknown how the reaction product may interfere with the reaction, but here the above scheme may conventionally be adopted rather as a trial one, partially because of the simplicity of the formula obtained therefrom.

If the reaction proceeds in a steady state according to the above scheme, the rate formula may be expressed as follows;

$$-\frac{\mathrm{d}[\mathrm{MB}]}{\mathrm{d}t}=k_1[\mathrm{X}]=\frac{ak_1C}{k_1+k_d+k_2(C_0-C)} \qquad (1)$$

in which $C_0$ is the initial concentration of dye. In the absence of the retarding effect of the product, this equation is reduced to the following,

$$-\frac{\mathrm{d}[\mathrm{MB}]}{\mathrm{d}t}=\frac{ak_1C}{k_1+k_d}$$

Here it is to be added that the absorption of light is assumed to be approximately proportional to the dye concentration $C$.

Below it will be shown that the above trial formula is satisfactory to some extent.

Integration of 1 leads to

$$\frac{\ln C_0-\ln C}{C_0-C}=\frac{k_2}{k_1+k_d+k_2C_0}+\frac{ak_1}{k_1+k_d+k_2C_0}\cdot\frac{t}{C_0-C} \qquad (2)$$

This equation requires a linear relation between $(\ln C_0-\ln C)/(C_0-C)$ and $t/(C_0-C)$, which in fact is well satisfied by most of the experimental results within the experimental error. This is shown in Fig. 3.

It is also evident from the figure that Eq. 2 does not hold in the case of phosphate buffer. The values for intercept, $S=k_2/(k_1+k_d+k_2C_0)$, inclination, $\alpha=ak_1/(k_1+k_d+k_2C_0)$ and the ratio of the latter to the former, $ak_1/k_2(=\alpha/S)$,

* Analytical concentration of the initial solution.

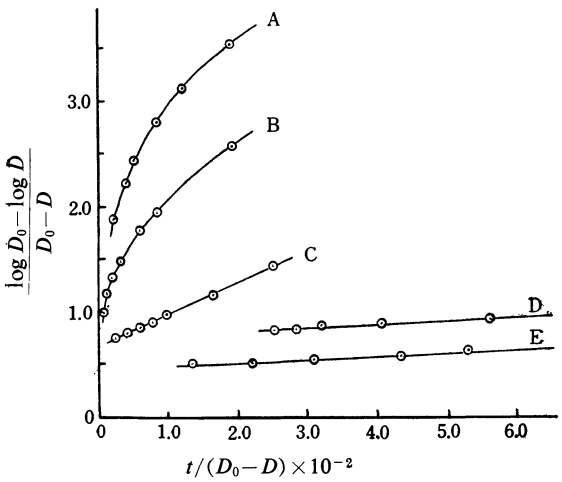

Fig. 3. Application of Eq. 2 for various salt solutions.
A. Phosphate buffer
B. NaOH aq. soln.
C. Borate buffer
D. $Na_2SO_4$ aq. soln.
E. aq. soln.

are summarised in Table I except for phosphate and sodium hydroxide for which Eq. 2 does not hold.

For the further support of Eq. 2, the effect of the initial concentration on the rate was examined in case of borate buffer. From Eq. 2 the reciprocal of the intercept ($=1/S$) should satisfy the following equation,

$$\frac{1}{S}=\frac{k_1+k_d}{k_2}+C_0 \qquad (3)$$

hence the plot of $1/S$ against $C_0$ should be a straight line of slope 1. The slope experimentally obtained is about 0.91 as shown in Fig. 4.

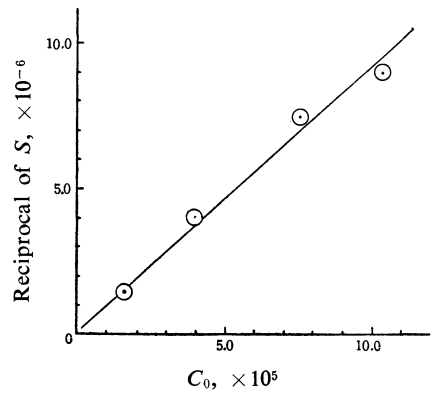

Fig. 4. Plot of $1/S$ against initial concn. $C_0$.

Further, the reciprocal of inclination of Eq. 2 being represented as follows,

$$\frac{1}{\alpha}=\frac{k_1+k_d}{ak_1}+\frac{k_2}{ak_1}C_0 \qquad (4)$$

the plot of $1/\alpha$ against $C_0$ should be linear with the inclination of $k_2/ak_1$. This was in fact satisfied by the experimental data, the value obtained being $4.4\times10^{8}$ ($mol^{-1}$ l. sec.)

which agrees approximately with the mean value of (e)—(h) in Table I ($S/\alpha=4.0\times10^8$).

Thus the reliability of Eq. 2 was substantiated to some extent, and so the effect of pH on the rate, which was examined in the region of pH, 7.40~9.15 keeping the concentration of borate ion constant, was analyzed by Eq. 2. The values of $\log \alpha/S(\alpha/S=ak_1/k_2)$ for the various pH values are shown in Table II.

Table II

| pH | log[OH⁻] | log $\alpha/S$ |
|---|---|---|
| 9.15 | −4.85 | −7.28(−7.69) |
| 8.30 | −5.70 | −7.97 |
| 7.85 | −6.15 | −8.32 |
| 7.55 | −6.45 | −8.63 |
| 7.40 | −6.60 | −8.48 |

It is apparent that the value of $\alpha/S$ increases approximately proportionally to the concentration of [OH⁻].

**Phosphate Buffer Solution.** — It is assumed that the essential difference against the case of borate lies only in the bimolecular reaction of X and MB, which leads to the production of leuco dye, all the other steps being quite similar as in the previous one. Thus

$$\mathrm{MB} \xrightarrow{h\nu} \mathrm{MB^*} \rightarrow \mathrm{MB^t} \cdots\cdots \xrightarrow{a} \mathrm{X} \xrightarrow[k_1']{\mathrm{MB}} \mathrm{P}$$

$$\mathrm{MB^*} \rightarrow \mathrm{MB}, \quad \mathrm{MB^t} \rightarrow \mathrm{MB}, \quad \mathrm{X} \xrightarrow{k_d'} \mathrm{MB}, \quad \mathrm{X} \xrightarrow{k_2'} \mathrm{P}$$

whence the rate is expressed as follows,

$$-\frac{\mathrm{d[MB]}}{\mathrm{d}t}=\frac{2ak_1'C^2}{k_1'C+k_d'+k_2'(C_0-C)}=\frac{2ak_1'C^2}{k_d'+(k_1'-k_2')C+k_2'C_0} \quad (5)$$

In view of the fact that the experimental data can quite satisfactorily be reproduced by the second order rate formula, it may be permissible to put $k_1'=k_2'$. Then,

$$-\frac{\mathrm{d[MB]}}{\mathrm{d}t}=\frac{2ak_1'C^2}{k_d'+k_2'C_0}=2kC^2 \quad (6)$$

where

$$k=\frac{ak_1'}{k_d'+k_2'C_0}$$

Some examples for the relation $1/C\sim t$ are shown in Fig. 5. Most of the experimental results satisfy the linear relation. (Table III).

When the initial concentration is varied, the following relation should hold between the reciprocal of $k$ and $C_0$

$$\frac{1}{k}=\frac{k_d'}{ak_1'}+\frac{k_2'}{ak_1'}C_0 \quad (7)$$

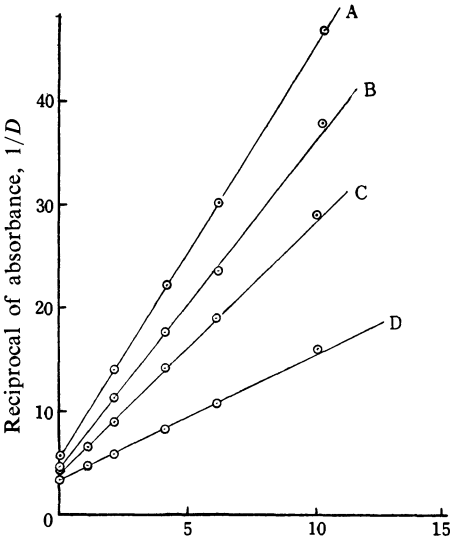

Fig. 5. Plot of the reciprocal of absorbance (D) against the irradiation time at constant pH.

| pH | log[OH⁻] | log $k$ |
|---|---|---|
| 8.81 | −5.19 | 3.17 |
| 8.07 | −5.93 | 3.11 |
| 7.71 | −6.29 | 3.06 |
| 7.52 | −6.48 | 3.02 |
| 6.94 | −7.06 | 2.97 |

In contradistinction to the case of borate buffer, the rate is scarcely affected by the variation of pH.

### The Effect of Some Added Substances

**The Behavior when Ferric Chloride and *o*-Phenanthroline are Added.** — In the previous paper it was reported that when these substances are added to the borate buffer solution of methylene blue and irradiated, the complex between $Fe^{2+}$ and *o*-phenanthroline is formed, the quantity of which attains to more than ten times that of the dye. Thus, it was concluded from the above result, that no impurity contained in dye participates essentially in the reaction. In addition to this conclution, the investigation of this system is important with regard to the quantitative relation between the leuco-formation and the irreversible photodecomposition. So further description will be given below.

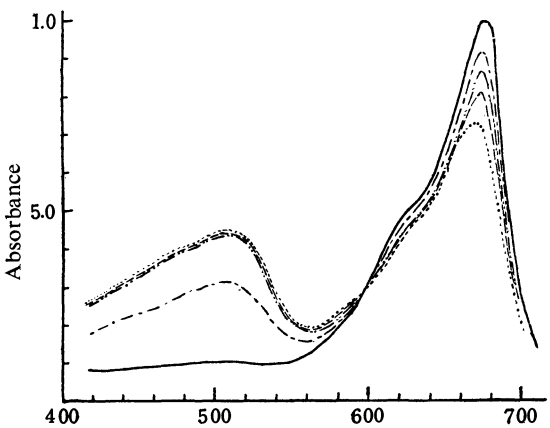

Fig. 7. The spectral change of the mixture of methylene blue-borate buffer, *o*-phenanthroline and ferric chloride solution when irradiated.
—— initial
– – – 2 min.-irradiation
—·— 5 min.-irradiation
—·· 20 min.-irradiation
····· 50 min.-irradiation

A typical result is shown in Fig. 7, in which the absorption band of 510 mμ is due to trisphenanthroline iron(II) complex. In this experiment the concentration of the complex produced by 2 min. irradiation is about fourteen times that of the decrease in dye concentration. This decrease is due to the irreversible bleaching, the solution not being decolorized by aeration. Thus it may be judged that if the formation of leuco dye takes place only by the accompanying irreversible decomposition of dye, then one molecule of dye decomposed ought to be able to produce more than ten molecules of leuco dye. This makes the above view highly improbable.

It is to be added that when the irradiation is continued after all the $Fe^{3+}$ has been consumed to produce trisphenanthroline iron(II) complex, the bleached dye partially recovers its color upon the introduction of air. Therefore it is certain that as long as $Fe^{3+}$ exists the produced leuco dye reduces $Fe^{3+}$, but after the disappearance of $Fe^{3+}$ the existence of the reduced dye persists.

It is regrettable that no such experiment can be performed for the phosphate solution on account of the small solubility of $Fe^{3+}$ salt.

**The Effect of the Addition of Pyruvate.** — It was reported in the previous paper that a small quantity of hydrogen peroxide was detected in case of borate buffer but not in phosphate buffer. Now it is well known that in general hydrogen peroxide is rapidly decomposed by the addition of pyruvate, and it is interesting to investigate the effect of the addition of pyruvate upon the rate and to compare the two cases when the phosphate or borate buffer is used. The concentrations of pyruvate ($C_{py}$) added to the borate buffer are $1.2\times10^{-4}$, $2.2\times10^{-4}$, and $2.4\times10^{-4}$ M. The results are shown in Fig. 8.

It is apparent from the figure that the slope becomes steeper with the increase of the concentration of pyruvate. Further, when $\alpha/S$-values for the two cases, one with pyruvate and the other without it but otherwise in the similar conditions are compared, the value for the former is definitely larger; thus from Fig. 8 for $C_{py}=2.2\times10^{-4}$ M, $\alpha/S=7.57\times10^{-9}$ and for $C_{py}=0$, $\alpha/S=2.97\times10^{-9}$(mol. $l^{-1}$ $sec^{-1}$). The above results are well comprehended if the $k_2$-value in the second term on the right side of Eq. 2 gets smaller with the addition of pyruvate. Although the possibility for other steps to be affected might not be neglected, it seems most plausible that the

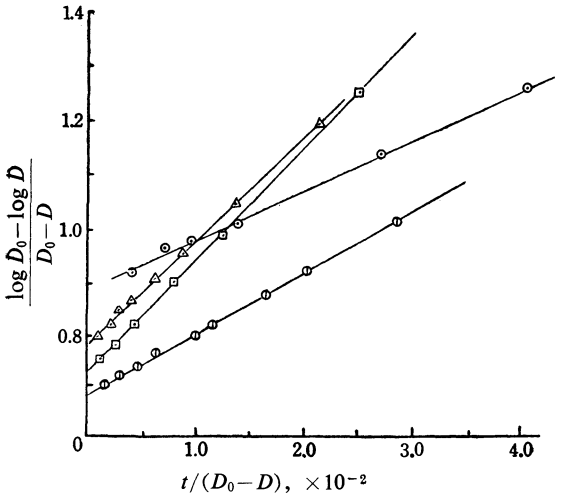

Fig. 8. The effect of the addition of pyruvate on Eq. 2 ($D$……optical density).

⊙ [Pyr]=0
① [Pyr]=$1.2\times10^{-4}$ M
△ [Pyr]=$2.2\times10^{-4}$ M
◙ [Pyr]=$2.4\times10^{-4}$ M

addition of pyruvate chiefly affects the $k_2$-value in view of the result obtained for phosphate buffer (described below).

When ten times as much pyruvate as the concentration of methylene blue was added to phosphate buffer, the rate was also represented as of the second order with respect to dye and the $k$ value of Eq. 6 was evaluated to be $5.3\times10^2$ ($mol^{-1}$ l. $sec^{-1}$). This is slightly smaller than $6.2\times10^2$, which is the $k$-value in the absence of pyruvate but otherwise having similar conditions. It is evident that the addition of pyruvate to the phosphate buffer scarcely affects the rate.

Thus the effect of pyruvate-addition is quite different in the case of phosphate and borate, and this is just what is expected from the results already obtained.

**The Effect of the Addition of Quinone.** — It was reported in the previous paper that in the case of phosphate buffer, neither hydrogen peroxide nor oxygen was detected. But it is premature to deny the formation of oxygen only on the basis of this analysis, because the produced oxygen may be consumed in the irreversible photodecomposition of dye. In order to detect the oxygen formed, it seems rather essential to make the experiment under conditions such that the oxygen which might be produced, be accumulated so rapidly that it is scarcely consumed in the photooxidation of dye.

With this view in mind and from the analogy of the Hill reaction in photosynthesis, the addition of quinone was tested. Thus if the quinone does not attack the excited dye but only oxidizes the leuco dye produced as in the case of the Hill reaction, the oxygen is expected to be accumulated.

Preliminary tests demonstrated, however, that the addition of quinone, the quantity being up to several times (in mole) that of the dye induces a quite complicated spectral change of methylene blue when the evacuated solution is irradiated. In addition, spectra of methylene blue in the above solution were found to change even in the dark though the rate was much slower.

Thus there is no doubt that the direct photoreaction does take place between dye and quinone. This reaction seems to be interesting from a different point of view, but it is clear that quinone is too reactive to be used for the above object. Hence further studies have been abandoned. Other kinds of quinones or other types of oxidants more mild in character should be searched.

## Quantum Yield

In both buffer solutions, the quantum yield ($\gamma$) for the initial stage was evaluated by using the inclination of the curve of optical density against time, and the number of photons ($I_{abs}$) absorbed by the solution, both in the initial stage. The latter quantity was measured with the combination of the thermopile (Moll and Burger standard thermopile) and White single potentiometer (Leeds and Northrup).

The following table shows the results obtained for borate and phosphate buffer solutions.

Table V. Quantum yield

| Condition | | $I_{abs}$ (photons. $sec^{-1}$ $cc^{-1}$) | $\Delta D/\Delta t$ ($D$, $min^{-1}$) | $\gamma$ |
|---|---|---|---|---|
| a) | Phosphate buffer | $7.2\times10^{15}$ | 0.089 | $9.2\times10^{-4}$ |
| | | $6.9\times10^{16}$ | 0.029 | $7.1\times10^{-4}$ |
| b) | Borate buffer | $3.5\times10^{15}$ | 0.006 | $3.0\times10^{-4}$ |
| | | $8.7\times10^{15}$ | 0.010 | $2.2\times10^{-4}$ |

## Discussion

It was found in the previous paper that the general feature of the reaction is somewhat different in borate and phosphate buffer. Now in the present paper additional differences were found from the kinetic standpoint. Thus the rate in borate buffer is approximately of the first order in dye while that of the phosphate buffer, is of the second order, and moreover the pH effect is quite different in two cases. Therefore, two cases will be separately discussed, anticipating the essential difference in mechanism.

In case of borate the rate being of the first order in dye, the interaction of two dye molecules of which one acts as an electron-donor and the other as an acceptor can safely be neglected. The result of the experiment pertaining to the formation of trisphenanthroline iron(II) chloride also denies such an interaction. Thus one cannot but consider that in this case the oxidation of water is taking place under some cooperative action of the salt. In fact, as reported in the previous paper, a small quantity of hydrogen peroxide was detected.

As regards the photofission of water by visible light, Yamafuji reported a long time ago[3] that hydrogen peroxide was produced when the solution of eosine or chlorophyll was irradiated by the solar light. Their experiments, however, were criticized by Rabinowitch[4] and at present their results seem to be judged to be doubtful.

Indeed the decomposition of water by the visible light by virtue of the following scheme

$$H_2O \rightarrow H+OH$$

or

$$HO^- \rightarrow e+OH \qquad (6)$$

must be almost impossible from the energetic reason, except for the case in which the absorption of more than two photons takes part in one act. However, if the reaction in the following molecular mechanism occurs,

$$D^+ + 2OH^- \rightarrow DH + HO^-_2 \qquad (7)$$

the free enthalpy change is not so great. It is ca. $\Delta G^\circ_{298}=49.65$ kcal./mol. so that with an efficient use of the energy of photon absorbed, ca. 43.0 kcal., only 6.6 kcal. needs to be provided for the reaction 7 to occur. If borate ion can afford a certain amount of free enthalpy in some way, then the quantum yield experimentally obtained would be attained by the process 7.

In connection with this it is tempting to recall that borate is an electron deficient substance and to suppose that some of the borate ions may be in a certain energy-rich state combining with hydroxide ion. Alternatively there might be a possibility that a certain species of dye such as $(D\cdots OH)H^+$ which Lewis[5] proposed, takes part in the reaction to make it energetically feasible. The result that the rate is approximately of the first order in $[OH^-]$ in spite of the second order for the stoichiometric equation, might be related with this.

Next the case of phosphate will be discussed. In this case neither hydrogen peroxide nor oxygen was detected and the reaction proceeds in the second order with regards to dye. These facts seem at first strongly to suggest that the initial process is the interaction of the excited dye with the ground-state-dye molecule, the electron transfer taking place between them according to

$$D^* + D \rightarrow D^- + D^+ \qquad (8)$$

and resulting in the leuco-formation from one dye molecule and the irreversible decomposition of another. But judging from the result that 70~80% of the bleached dye is recolorized by the introduction of air, it seems necessary that one molecule of dye decomposed ought to be able to reduce about three dye molecules and that the reducing power of the substances produced by dye-decomposition should be much larger; otherwise the quantity of reduced dye would be much less. Hence the above scheme would not be accepted unless it is confirmed experimentally that the above requirements are really satisfied. At the present stage it seems rather improbable that the leuco-formation only occurs through 8 though it may contribute to some extent.

On the other hand, the reaction

$$2D^+ + 2OH^- \rightarrow 2DH + O_2 \qquad (9)$$

seems not entirely impossible from the energetic view point. Thus its $\Delta G^\circ_{298}$ is 55.93 kcal. and taking the energy of photon, 43.0 kcal. into account, the free enthalpy is evaluated to be about 6.4 kcal. for one dye molecule. Should the phosphate ion be able to provied energy in some way, reaction 9 would be realized just as reaction 7.

The role of phosphate ion must be clarified irrespective of wether the reaction goes via 8 or 9.

The photoreduction which has been confirmed in this series of investigation would be expected to occur in other thiazine dyes and this has really been ascertained in the case of thionine. Since the demethylation need not be taken into account for thionine, the quantitative study would be more feasible particularly as regards the interrelation between leuco-formation and irreversible decomposition. These are now in course of study.

## Summary

Kinetic treatment was undertaken for the photobleaching of the aqueous solution of methylene blue containing various inorganic salts.

If a certain kind of inhibiting action due to

some reaction product(s) is taken into consideration, the rate for borate buffer is satisfactorily reproduced as the first order of excited dye, while for phosphate buffer it is second order with regard to dye. It was further found from this analysis that the rate of the essential step (or steps) of the reaction for the case of borate is approximately proportional to the concentration of $OH^-$, while for the case of phosphate it is almost independent of pH.

The quantity of irreversible decomposition of dye in case of borate buffer was estimated to be very small against that of the reversible bleaching, the former being a few tenths of the latter from the experimental results obtained when ferric chloride and *o*-phenanthroline were added to the borate buffer solution.

Judging from the results hitherto obtained, it is most plausible that the photoreduction of methylene blue in case of borate takes place through the decomposition of water. But in case of phosphate, there still remains some possibility that the reaction commences by the interaction of excited dye and ground state dye, electron transfer taking place between them.

The quantum yield of the bleaching reaction was measured and found to be $(2\sim3)\times10^{-4}$ for borate buffer and $(7\sim9)\times10^{-4}$ for phosphate buffer.

Thanks are due to Dr. Shunji Kato and Mr. Hiroshi Obata for helpful discussions.

# *Raman Spectra of p-Dichlorobenzene and p-Dichlorobenzene-$d_4$*

By Shinnosuke SAËKI

(Received April 3, 1961)

The molecular spectra of *p*-dichlorobenzene have been studied by many investigators, and the author has reported on the infrared absorption spectra of ordinary and deuterated *p*-dichlorobenzene previously[1]. In this paper, the Raman spectra of the same substances will be reported upon, for it is essential for the assignment of the molecular vibration to study the Raman spectra as well as the infrared spectra.

As the molecule of *p*-dichlorobenzene has the center of symmetry, the thirty normal vibrations are divided into two groups according to the rule of mutual exclusion. Consequently, fifteen vibrations are active in Raman effect and eleven vibrations are active in infrared absorption spectrum. Though this fact does much to simplify the molecular spectra of this substance, the Raman spectrum of this substance is still rather complicated with the appearence of the overtone lines, combination lines and lines due to the Fermi resonance in addition to the above-mentioned eleven fundamental lines.

Concerning the Raman spectrum of *p*-dichlorobenzene, a number of papers have been published since many years ago[2-4]. In these papers, the assignment of the lines was carried out inductively, comparing the spectrum with those of other benzene derivatives of the same type and observing a frequency change between them for each corresponding band or line. Since the number and the variety of the treated substance were extensive, and since the conclusions were made after prudent examinations, one can put much confidence in most of the results obtained by this method. However, since in a different molecule the strength to the interatomic bonds (force constants) changes as well as the masses of atoms, a slight ambiguity appears to be left in the assignment which resulted from such inductive studies. Actually the proposed assignments of some Raman lines of *p*-dichlorobenzene seemed to be somewhat indefinite and arbitrary.

In the study reported here, as the Raman spectra were observed for completely deuterated *p*-dichlorobenzene as well as for the ordinary one, the product rule could be applied in order

to verify the assignment proposed. In addition to the frequencies, the qualitative depolarization ratio of each line was also observed by the two exposure method using the polaroid cylinders in order to obtain more definite assignments than previous ones.

## Experimental

Ordinary *p*-dichlorobenzene of extra pure grade on the market was recrystallized three times from the ethanol solution, and then sublimed before being used for the measurement of the Raman spectra. The melting point of the obtained substance was 53°C.

The deuterated one was prepared and purified as follows. Ordinary *p*-dichlorobenzene was stirred at 105°C for six hours in heavy sulfuric acid. The reaction mixture was poured on ice and the precipitate filtered off and washed with water and dried. The exchange with heavy sulfuric acid was repeated until the strongest band of $C_6HD_3Cl_2$ could hardly be observed in the infrared absorption spectrum of the substance. It was necessary to repeat the exchange reaction two or three times in order to attain such purity. Then the obtained substance was further purified in the same way as that for ordinary *p*-dichlorobenzene, but because of the smallness of the quantity, the purification could not be carried out so thouroughly as in the case of ordinary *p*-dichlorobenzene. The deuterated substance was probably a little less pure than the ordinary one.

The Cary model 81 automatic recording Raman spectrophotometer was used for the measurements, of which the source was the mercury arc lamp of Toronto type, and the dispersion of the grating was 4 Å/mm. at 5000 Å.

The spectra were measured in the solution of 1 g. *p*-dichlorobenzene in 5 ml. carbon tetrachloride. The qualitative depolarization ratios were measured by placing the polaroid cylinder around the Raman tube and by polarizing the exciting light to the directions parallel or perpendicular to the axis of the tube.

## Results

The observed Raman spectra are shown in Figs. 1—4. As are shown in Figs. 3 and 4, the base lines of the spectra of deuterated *p*-dichlorobenzene rose gradually towards the higher frequency ends of the spectra, showing remarkable backgrounds. It might probably be caused by the slight resinous impurity, which could not be removed completely by the purification because of the small quantity of deuterated substance available, as we mentioned previously.

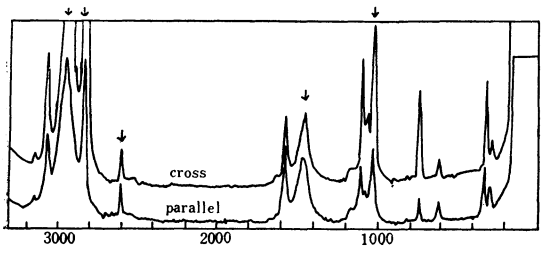

Fig. 1. Raman spectra of *p*-dichlorobenzene (1 g. in 5 ml. methanol).

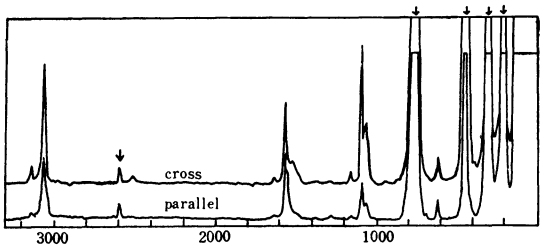

Fig. 2. Raman spectra of *p*-dichlorobenzene (1 g. in 5 ml. carbon tetrachloride).

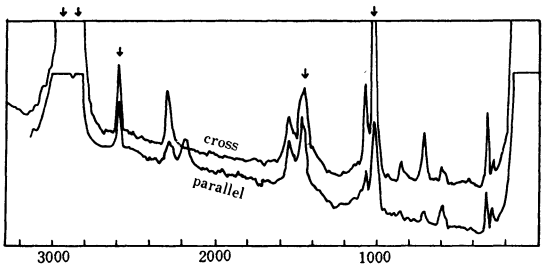

Fig. 3. Raman spectra of *p*-dichlorobenzene-$d_4$ (1 g. in 5 ml. methanol).

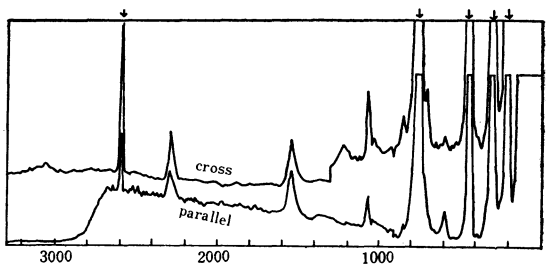

Fig. 4. Raman spectra of *p*-dichlorobenzene-$d_4$ (1 g. in 5 ml. carbon tetrachloride).

The observed frequencies and intensities of Raman lines are listed in Tables I and II. The intensities are described by the heights of lines measured on the chart. The notation "masked" means that the line could not be observed, due to the masking effect of a strong Raman line of the solvent in the spectra of that solution while it was observed in the other solution. Though the Raman spectra of the substances were observed in the solution in methanol or in carbon tetrachloride, there is no possibility that a Raman line is masked in both methanol and carbon tetrachloride solutions, for there is no frequency region

where both methanol and carbon tetrachloride have a strong Raman line. The only exception is the region between a line at 1460 $cm^{-1}$ of methanol and a line at 1530 $cm^{-1}$ of carbon tetrachloride. But fortunately, as neither of these lines was very strong, there was little possibility that a line would escape observation even in this region, so long as its intensity is not extremely weak.

The notation "unobserved" in the tables means that the line was not observed in one of the solutions while it was observed in the other solution. As all of these lines had very small intensities, it was not unreasonable that they were unobservable in one of the solutions. However, they could still not be adopted uncritically as the Raman lines of solute.

The notation "sh." means a line observed as a shoulder of a strong Raman line of the solute itself or the solvent, and "p." and "dep." represent a line which apparently changed and apparently did not change its intensity when excited by incident light polarized parallel and perpendicular to the axis of the Raman tube, respectively.

## Discussion

The molecule of *p*-dichlorobenzene belongs to a point group $V_h$, and its fifteen Raman active normal vibrations are factored into six of the species $A_g$ (in-plane), five of the species $B_{3g}$ (in-plane), one of the species $B_{1g}$ (out-of-plane) and three of the species $B_{2g}$ (out-of-plane). Therefore six polarized (and probably strong) lines and nine depolarized lines were expected to be observed in the Raman spectrum. The modes of these normal vibrations are shown in Table III.

TABLE III. THE MODES OF THE NORMAL VIBRATIONS OF *p*-DICHLOROBENZENE

| Species | No.* | Mode |
|---|---|---|
| $A_g$ | $\nu_1$ | C-H or C-D stretching |
| | $\nu_2$ | Ring stretching |
| | $\nu_3$ | C-H or C-D in-plane bending |
| | $\nu_4$ | Ring stretching |
| | $\nu_5$ | C-Cl stretching |
| | $\nu_6$ | Ring in-plane deformation |
| $B_{1g}$ | $\nu_9$ | C-H or C-D out-of-plane bending |

| | $\nu_{16}$ | Ring out-of-plane deformation |
| | $\nu_{17}$ | C-Cl out-of-plane bending |
| $B_{3g}$ | $\nu_{23}$ | C-H or C-D stretching |
| | $\nu_{24}$ | Ring stretching |
| | $\nu_{25}$ | C-H or C-D in-plane bending |
| | $\nu_{26}$ | Ring in-plane deformation |
| | $\nu_{27}$ | C-Cl in-plane bending |

* The normal vibrations were numbered after Herzberg.

***p*-Dichlorobenzene.** — Seventeen Raman lines are observed in the spectrum of this substance. Therefore the number of observed lines exceedes the number of Raman active normal vibrations. However, since there were several lines which were apparently considered to be overtones or combinations, this fact does not mean that all of the Raman active normal vibrations have been observed.

As we mentioned previously, six polarized lines were expected to be observed, but actually nine polarized lines were found in the observed spectrum, as is shown in Table I. Considering its frequency value, one of these polarized lines observed at 2522 $cm^{-1}$ *1 must be explained as an overtone or a combination. The number of remaining observed lines was still more than the number of expected lines. Considering the vibrational modes shown in Table III, these six lines belonging to the species $A_g$, one was expected to appear near 3000 $cm^{-1}$, one at about 1500 $cm^{-1}$, and two between 1300 and 1000 $cm^{-1}$. Though the vibrational mode of $\nu_4$ was described as the ring stretching, it proved to be the "breathing" vibration of the benzene ring on closer examination. Therefore its frequency might be relatively low and expected to appear in this region, and two below 1000 $cm^{-1}$. Accordingly it was clear that the line at 3071 $cm^{-1}$ had to be assigned to C–H stretching vibration, the line at 1531 $cm^{-1}$ to the ring stretching vibration, the line at 774 $cm^{-1}$ to the C–Cl stretching vibration, and the line at 331 $cm^{-1}$ to the ring in-plane deformation vibration.

Concerning the assignment of the lines observed in the region 1000~1300 $cm^{-1}$, there were some points of discussion. While only two of the totally symmetric normal vibrations were expected to appear in this region, four polarized Raman lines were actually observed at 1067, 1080, 1103 and 1163 $cm^{-1}$ *2. As the line at 1103 $cm^{-1}$ had much greater intensity than the other three, this line may the most plausibly be assigned to the breathing vibration of the ring. From the facts that the line at 1067 $cm^{-1}$ was very close to the line at 1080 $cm^{-1}$, and that these two lines were hardly resolved in the spectrum of the methanol solution, these two lines might be considered to be brought out by a Fermi resonance between a fundamental and an overtone or a combination vibration (for example 545($b_{1u}$)[1] $\times 2 = 1090$ ($A_g$), 744 ($a_g$) + 331 ($a_g$) = 1075 ($A_g$)). Then the frequency of the in-plane bending vibration of C–H bonds was estimated to be about 1075 $cm^{-1}$, the mean value of these two frequencies. Provided that the two normal vibrations were assigned in such a way, the line at 1163 $cm^{-1}$ had to be considered as an overtone or a combination, or a fundamental which belongs to a species other than $A_g$. However it was also possible to take the line at 1163 $cm^{-1}$ for the in-plane bending vibration of C–H bonds, and to take the lines at 1067 and 1080 $cm^{-1}$ for the above-mentioned combination and overtone respectively. This alternative assignment seems to be somewhat unreasonable taking into account their relative intensities, nevertheless this could not be considered to be absolutely impossible. The superiority of one to the other will be revealed later by the application of the product rule.

The next step is to assign the other lines to the normal vibrations which belong to species other than $A_g$. These normal vibrations consist of four out-of-plane vibrations which belong to the species $B_{1g}$ or $B_{2g}$, and five in-plane vibrations which belong to the species $B_{3g}$. As is shown in Table II, two of the four out-of-plane vibrations are those of C–H bonds, and their frequencies must be higher than 819 $cm^{-1}$, which is the frequency of the infrared active out-of-plane vibration of C–H bonds (species $B_{3u}$[1]) in which the four C–H bonds vibrate from the plane of the molecule up and down in the same phase. Though the frequencies of these vibrations were estimated to be between 819 and 1100 $cm^{-1}$, no depolarized line was observed in this region. Since naturally too much confidence should not be put in the observed degrees of depolarization, it would not be impossible to assign the lines at 1067 and 1080 $cm^{-1}$ to these out-of-plane vibrations. However, since these lines had been well explained as a combination and as an overtone, as was mentioned above, and since the observed degrees of depolarization were not consistent with the above assignments, it appears better to consider that the normal vibrations in question were not observed and to assign the above lines to a combination and an overtone than to make a strained assignment. Further discussion concerning these lines will be seen later.

The other two out-of-plane vibrations are those of the ring and of the C–Cl bonds. Since the frequency of the former was expected to be about 400 $cm^{-1}$, the line observed at 400 $cm^{-1}$ in the solution of carbon tetrachloride was assigned to it. But it should be mentioned here that there remained a little ambiguity in this assignment, since the intensity of the line was so weak that it was not observed in the solution of methanol. As the out-of-plane bending vibrations of C–Cl bonds were expected to be observed in lower frequency region —probably in the vicinity of 300 $cm^{-1}$, the line at 294 $cm^{-1}$ was assigned to this vibration.

*1 As a slight discrepancy was generally seen between the frequency observed in methanol solution and that oserved in carbon tetrachloride solution, the mean value of these two was used in this paper as a rule. However, in the case that an apparent difference existed between the accuracies of two observed frequencies, the more accurate one was used.

*2 Since the second and the fourth lines were observed much more clearly in carbon tetrachloride than in methanol as is seen in Figs. 1 and 2, the frequencies observed in carbon tetrachloride solution were adopted as is mentioned in the last foot-note.

The last five normal vibrations to be assigned are those which belong to the species $B_{3g}$. The frequency of the stretching vibration of C–H bonds was naturally a little higher than 3000 $cm^{-1}$, and in the observed spectra a weak line was found at 3147 $cm^{-1}$ in addition to the strong line at 3071 $cm^{-1}$ which was already assigned to the vibration of the species $A_g$. The observation of the qualitative depolarization ratio showed that this weak line was considerably polarized. In addition to this fact, the frequency 3147 $cm^{-1}$ appeared to be too high even for an aromatic C–H stretching vibration. Therefore this line had to be assigned not to the C–H stretching vibration, but to the overtone of the ring stretching vibration of 1572 $cm^{-1}$ which will be discussed below. The C–H stretching vibration of the species $B_{3g}$ should be considered to overlap with that of the species $A_g$ at 3071 $cm^{-1}$.

Three of the remaining normal vibrations are the stretching vibration of the ring, the in-plane deformation vibration of the ring and the in-plane bending vibration of C–H bonds. There might be no objection to assigning three depolarized lines observed at 1572, 1285 and 623 $cm^{-1}$ to them respectively. As for the last remaining normal vibration, that is, the C–Cl in-plane bending vibration, there was no observed line except a very weak line at 349 $cm^{-1}$ to be assigned to it. Though the intensity of this line was very low, this line had been observed also by Whiffen et al.[2] And since there were no lines observed in the spectra to be assigned to the C–Cl bending vibrations except the two lines observed at 349 and at 294 $cm^{-1}$, it appeared to be quite plausible to assign the former line to the in-plane, and the latter line to the out-of-plane bending vibration of C–Cl bonds respectively.

A brief discussion should be given here concerning the lines which had not yet been treated above that is, the weak lines at 2520, 1630 and 1378 $cm^{-1}$, of which the degrees of depolarization could not be measured with adequate certainty. The line at 2520 $cm^{-1}$, though observed to be polarized, could not be explained as a line belonging to the species $A_g$. This line might probably be a combination line of the species $B_{3g}$, that is, 1405 ($b_{2u}$) + 1091($b_{1u}$). The line at 1630 $cm^{-1}$ was measured as a depolarized line, and explained as being 1091($b_{1u}$) + 545($_{3u}$). The line at 1378 $cm^{-1}$ was easily explained as 819($b_{3u}$) + 544($b_{3u}$).

**Deuterated *p*-Dichlorobenzene.** — The Raman lines observed for deuterated *p*-dichlorobenzene was not so many as for an ordinary one. The observed eleven lines were shown in Table II. According to the measurement of the qualitative polarization ratios, six of these lines were polarized. But the result obtained for the line at about 1520 $cm^{-1}$ was a little ambiguous, because its intensity was so weak that the observation of the depolarization ratio was very difficult even qualitatively. However, these six polarized lines were unambiguously assigned to the six normal vibrations of the species $A_g$, as is shown in Table IV. The comparison of this assignment with that for ordinary *p*-dichlorobenzene will be given later.

The remaining five observed lines are to be assigned to the remaining nine normal vibrations, of which four out-of-plane vibrations belong to the species $B_{1g}$ or $B_{2g}$, and five in-plane vibrations belong to the species $B_{3g}$. It might be apparent that two of the out-of-plane vibrations concerning C–D bonds have frequencies higher than 695 $cm^{-1}$, the frequency of the C–D out-of-plane vibration of the species $B_{3u}$ observed in the infrared absorption spectrum[1]. However no corresponding line was observed in such a region of frequency, so it had to be concluded that these vibrations had too low intensities to be observed. The other two out-of-plane vibrations were expected to appear from 350 to 400 $cm^{-1}$ and at about 250 $cm^{-1}$ respectively, considering their vibrational modes (Table III). But there was no line to correspond to the former vibration. The line corresponding to the latter vibration was observed at 288 $cm^{-1}$ with remarkable intensity, but it was difficult to determine whether this line was to be assigned to the out-of-plane or in-plane vibration of C–Cl bonds.

Concerning the in-plane normal vibrations belonging to the species $B_{3g}$, there might be no difficulty in assigning the line at 2285 $cm^{-1}$ to the C–D stretching vibration and the line at 1553 $cm^{-1}$ to the ring stretching vibration. As for the in-plane bending vibration of C–D bonds, since the corresponding vibration of ordinary *p*-dichlorobenzene was observed at 1285 $cm^{-1}$ with relatively low intensity, the frequency was expected to be a little lower than 1000 $cm^{-1}$ in the case of a deuterated one. No distinct line was observed in this frequency region at first sight, but the closer examination of the spectra revealed a very weak line at 937 $cm^{-1}$, the intensity of which was so weak that the line could hardly be distinguished from the noises. It might be a little questionable to consider it as a real Raman line. but if we remember that the line at 1285 $cm^{-1}$ of ordinary *p*-dichlorobenzene was also very weak and that the corresponding line of deuterated *p*-dichlorobenzene has to appear in the region of 900~1000 $cm^{-1}$, this line could be assigned to the C–D in-plane bending vibration.

The line at 607 $cm^{-1}$ was easily assigned to

the ring in-plane deformation vibration.

To the C–Cl in-plane bending vibration, it is possible to assign the line at 288 $cm^{-1}$, but, as is mentioned above, it might also be possible to assign it to the in-plane bending vibration of C–Cl bonds. As in the case of ordinary *p*-dichlorobenzene, the decision of the assignment for these vibrations appear to be impossible at this point.

**The Product Rule.**—According to the Teller-Radlich product rule, the theoretical ratios of the products of the frequencies for each substance are 1.998 for the species $A_g$, 1.249 for the species $B_{1g}$, 1.408 for the species $B_{2g}$ and 1.969 for the species $B_{3g}$, where the calculations were carried out using the following values for molecular constants:

| | |
|---|---|
| $m_H = 1.0081$ | (in physical atomic weight) |
| $m_D = 2.0147$ | (in physical atomic weight) |
| $m_C = 12.0038$ | (in physical atomic weight) |
| $m_{Cl} = 34.9801$ | (in physical atomic weight) |
| $r_{C-H} = 1.08$ | (Å) |
| $r_{C-Cl} = 1.68$ | (Å) |
| $r_{C-C} = 1.39$ | (Å) |

and 120° for all of the bond angles.

The assignments for the six normal vibrations of the species $A_g$ were unambiguously determined in the case of ordinary *p*-dichlorobenzene, but in the case of a deuterated substance there remained a question which of the two lines at 1163 $cm^{-1}$ and 1075 $cm^{-1}$ was to be assigned to the in-plane vibration of C–H bonds. If the ratio of the products of the frequencies was calculated assuming the latter assignment, the result was 1.825, a little less than the theoretical value 1.998. On the contrary, if the former assignment was assumed, the ratio became 1.991, in good accordance with the theoretical value. This result led us to the conclution that it was the line at 1163 $cm^{-1}$ to be assigned to the C–H bending vibration of the species $A_g$.

Here, in connection with this assignment a comment should be mentioned about the exchange of the vibrational modes. As was stated above, according to this assignment, $\nu_3$'s were 1163 and 1078 $cm^{-1}$ for ordinary and deuterated *p*-dichlorobenzene respectively, and $\nu_4$'s were 1103 and 863 $cm^{-1}$ for ordinary and deuterated ones respectively. The fact that the line at 1103 $cm^{-1}$ was much more intense than the line at 1163 $cm^{-1}$ in the spectra of ordinary *p*-dichlorobenzene suggests to us that the mode of the former is the breathing of the benzene ring and that of the latter is the C–H in-plane bending vibration. However, in the case of a deuterated substance, it was clear from the consideration of the frequency that

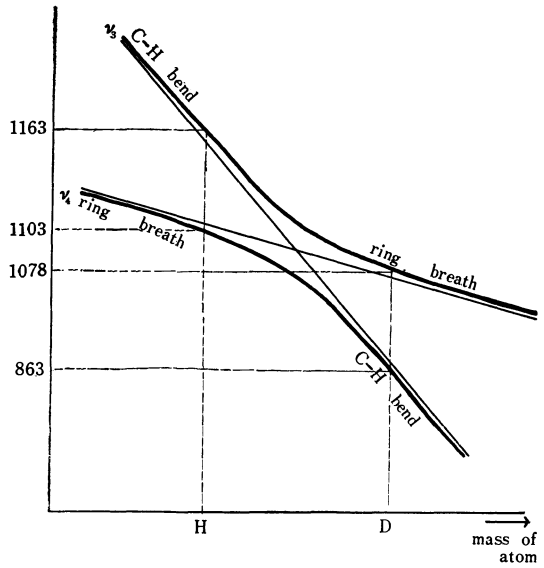

Fig. 5. The variation of vibrational mode with atomic mass.

the line at 1078 $cm^{-1}$ was the breathing of the benzene ring and that the line at 863 $cm^{-1}$ was the C–D in-plane bending vibration. Thus the exchange of the vibrational modes shown in Fig. 5 took place in the case of these molecules. This consideration suggested that the breathing vibration of the benzene ring strongly couples with the C–H or C–D in-plane bending vibration in these molecules, and that the modes of these vibrations are by no means simple, but rather complicated combinations of some simple modes.

It was impossible to apply the product rule to the species $B_{1g}$ and $B_{2g}$ because of the insufficient number of the observed lines. As was already stated above, only one normal vibration—the C–H or C–D out-of-plane vibration—belongs to the species $B_{1g}$. Therefore, provided that the line at 1067 or 1080 $cm^{-1}$ of ordinary *p*-dichlorobenzene corresponds to this vibration, the frequency of the corresponding vibration of deuterated substance could be estimated at about 850 $cm^{-1}$ by utilizing the product rule. As is shown in Table II, a remarkable line was indeed observed at 863 $cm^{-1}$ in the spectra of deuterated substance, but it was already assigned to a vibration of the species $A_g$, because the measurement of the depolarization ratio showed it to be polarized. In addition to such a lack of a corresponding line, both lines at 1067 and 1080 $cm^{-1}$ of the ordinary substance were themselves polarized, and so it seemed to be unreasonable to assign either of them to the vibration of the species $B_{1g}$.

As the C–Cl in-plane bending vibration of

TABLE IV. ASSIGNMENTS OF RAMAN LINES OF ORDINARY AND DEUTERATED *p*-DICHLOROBENZENES

| Species | No. | $\tilde{\nu}$ $C_6H_4Cl_2$ | $\tilde{\nu}$ $C_6D_4Cl_2$ | Mode |
|---|---|---|---|---|
| $A_g$ | $\nu_1$ | 3071 | 2301 | C-H or C-D stretching |
| | $\nu_2$ | 1531 | ca. 1520 | Ring stretching |
| | $\nu_3$ | 1163 | 1078 | C-H in-plane bending / Ring breathing |
| | $\nu_4$ | 1103 | 863 | Ring breathing / C-D in-plane bending |
| | $\nu_5$ | 744 | 708 | C-Cl stretching |
| | $\nu_6$ | 329 | 324 | Ring in-plane deformation |
| $B_{1g}$ | $\nu_9$ | — | — | C-H or C-D out-of-plane bending |
| $B_{2g}$ | $\nu_{15}$ | — | — | C-H or C-D out-of-plane bending |
| | $\nu_{16}$ | 400? | — | Ring out-of-plane deformation |
| | $\nu_{17}$ | 295 | 288 | C-Cl out-of-plane bending |
| $B_{3g}$ | $\nu_{23}$ | 3071 | 2285 | C-H or C-D stretching |
| | $\nu_{24}$ | 1572 | 1553 | Ring stretching |
| | $\nu_{25}$ | 1285 | 937? | C-H or C-D in-plane bending |
| | $\nu_{26}$ | 623 | 607 | Ring in-plane deformation |
| | $\nu_{27}$ | 349 | — | C-Cl in-plane bending |

deuterated *p*-dichlorobenzene, which corresponds to the line at 349 $cm^{-1}$ of the ordinary substance, was not observed, the exact application of the product rule was impossible for the species $B_{3g}$ also. However, the ratio of products of the frequencies calculated from four pairs of observed frequencies alone was 1.963, which was very near to the theoretical value 1.969 irrespective of the omission of the fifth pair. Generally speaking, a vibration directly concerned with C–H bonds naturally shows the sensitive frequency shift with the substitution of the hydrogen atoms by deuterium atoms. The other vibrations—especially when their frequencies are very different from the frequency of C–H vibration—show little frequency shift. Therefore the C–Cl bending vibration of deuterated *p*-dichlorobenzene was expected to have a frequency nearly equal to that of the corresponding vibration of ordinary *p*-dichlorobenzene, 349 $cm^{-1}$. This means that the ratio of the frequencies for the fifth vibration of the species $B_{3g}$ is probably little larger than 1, and therefore, if the above-mentioned calculation had been carried out taking account of this pair of frequencies, the result would be still in good accordance with the theoretical value. This consideration means that the application of the product rule could prove the correctness of the assignment for the species $B_{3g}$ too.

The assignment which was determined above is shown in Table IV.

## Summary

The Raman spectra of ordinary and deuterated *p*-dichlorobenzene were measured in solutions. The qualitative depolarization ratios of observed Raman lines were also measured by the two exposure method using the polaroid cylinders. On the basis of these results, the assignments of normal vibrations for these substances were determined. The assignments for the in-plane normal vibrations (species $A_g$ and $B_{3g}$) were verified applying the product rule.

The author gratefully acknowledges the encouragement and advice given him by Dr. Y. Mashiko.

# *Decomposition of Mono- and Diethanolamine Carbamate in Glycerol Solution*

By Mamoru MATSUDA

(Received May 4, 1961)

Monoethanolamine (MEA) and diethanolamine (DEA) provide excellent methods to remove acidic gases from natural and refinery gases. At normal temperatures these amines have strong affinity for the gases, while at higher temperatures these amines are recovered by expulsion of the acidic gases.

Many papers have been published on the absorption reaction of carbon dioxide with MEA or DEA[1-5], and a few on the reverse reaction[6,7]. However, no kinetic study of the decomposition of the MEA and DEA carbamate or carbonate has hitherto been carried out.

The present paper reports the activation energies for decomposition and absorption obtained from the rate of decomposition, and the heats of formation, together with equilibrium constants, over the temperature range of 110 to 140°C.

## Experimental

**Chemicals.** — MEA, DEA and glycerol were of reagent grade and fractionally distilled in vacuo. Solvents such as xylene, *n*-butyl acetate, *n*-butyl alcohol, acetic acid, and toluene were also of reagent grade. Carbon dioxide from a steel cylinder was purified by passing through concentrated sulfuric acid and anhydrous calcium chloride.

**Preparation of Samples.** — MEA (1 part) was dissolved in glycerol (2 parts). The reaction between the solution, $n_D^{20}$ 1.4680, $d_{20}^{20}$ 1.187, and carbon dioxide took place by bubbling the latter through the former gently for 3 hr. The sample thus obtained had carbon dioxide 0.06385 g./g. sample (0.334 mol. $CO_2$/mol. MEA), $n_D^{20}$ 1.4803, $d_{20}^{20}$ 1.250. The DEA glycerol solution (1 : 2 by vol.), $n_D^{20}$ 1.4729, $d_{20}^{20}$ 1.211, was treated with the same procedure as above; 0.02485 g. $CO_2$/g. sample (0.220 mol. $CO_2$/mol. DEA), $n_D^{20}$ 1.4779, $d_{20}^{20}$ 1.228.

**Apparatus and Technique.** — The apparatus for the decomposition of the sample was shown in Fig. 1. The reaction tube R was a 50 ml. test tube, 2.5 cm. in diameter, charged with glass rods, 0.4 cm. $\phi \times 1.0$ cm. The manometer M was provided with an entraining liquid, a saturated aqueous solution of sodium chloride acidified with sulfuric acid containing a few drops of methyl orange. The cooling zone N was an effective, comparatively large, about 100 ml., heat exchanger, and the temperature of it was maintained constant by circulating water at 20°C. The graduated glass tube G, 3 mm. in diameter, lying horizontally, was calibrated exactly by measuring the length of mercury of known weight.

The experiment was carried out as follows: the apparatus consisting of R, M, N and G, was filled with pure carbon dioxide. About 9 g. of mercury was employed to stop the open end of the graduated glass G. The reaction temperature was maintained within ±0.2°C by the vapor of the boiling solvent which was heated by an oil-bath thermostat O regulated to ±1°C. When the system reached an equilibrium, as shown by a steady state of the colored solution inside the U-tube M and the mercury plug P, all the variables—barometric pressure, temperatures of cooling water $T_5$, of the room $T_3$, of the reaction tube $T_2$, and of the solvent vapor $T_1$—were recorded. Then the plug was set to zero

by means of a two way cock C and a syringe S. A weighed sample was poured from 2 ml. syringe into the reaction tube through an open glass tube I. The glass tube was closed with a rubber plug. It took less than 3 seconds. The temperature in the tube did not substantially decrease. The sample began to evolve carbon dioxide pushing the mercury plug. The syringe S was operated manually to maintain the inside and outside pressures equal at all times by reading the manometer M. The position of the mercury plug, time, and other variables were recorded at short intervals. The experiment was repeated two or three times at the same temperature.

Gravimetric analyses of carbon dioxide of the fresh and the heated samples which still retained carbon dioxide were carried out. The apparatus and technique were the same as those of Knorr's method[8].

## Results and Discussion

Figures 2 and 3 are graphs of the increase in volume of the gases formed as a function of time due to the decomposition of the samples over the temperature range of about 110 to 140°C. It can not be assumed that the increase in volume was due only to the evolution of carbon dioxide. Vapor of the amines and the solvent, the change of atmospheric pressure and room temperature may affect the measurements. The temperature and the pressure were substantially constant during the experiments. As to the vapor of the amines and the solvent, a blank test showed that the vapor increased the volume by about 0.3 ml./g. sample at 136°C for the initial period of the reaction, in about half a minute. After that period the reaction system reached an equilibrium.

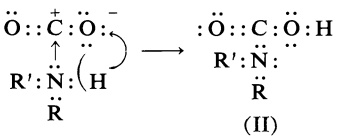
| At room temp. | — | 12.58±0.05 |

Concerning the reaction mechanism of the amines and carbon dioxide, Van Krevelen and Hoftijzer suggested that in aqueous solution the complete reaction took place in two steps, the first being a dissociation of the amine and the second the combination of the fragments, and the reaction was a third order[4]. As to

8) W. W. Scott, "Scott's Standard Method of Chemical Analysis", D. Van Nostrand Co., Inc., New York (1939), p. 235.



the reaction order a similar conclusion was reached by Cryder and Maloney[2], and Smola[9]. The work of Mason and Dodge[1], and of Shneerson and Leibush[3], showed that the concentration of carbon dioxide in aqueous solution of the amine at equilibrium varied about 0.5 to 0.9 mol. per amine as the temperature decreased from about 75 to 0°C, and the absorption would take place as follows:

$$2RR'NH + H_2O + CO_2 \rightleftarrows (RR'NH_2)_2CO_3$$

$$(RR'NH_2)_2CO_3 + CO_2 + H_2O \rightleftarrows 2RR'NH_2HCO_3$$

$$R = HOCH_2CH_2;\ R' = R \text{ or } H$$

Goodridge interpreted the reaction in terms of zero order as tentative, and presented the following mechanism in the absence of water[5]:

(II)

The amine carbamates in glycerol solution were decomposed, according to the following reactions:

$$RR'NCOONH_2RR' \underset{k_2}{\overset{k_1}{\rightleftarrows}} 2RR'NH + CO_2 \quad (1)$$

MEA $R = HOCH_2CH_2,\ R' = H$

DEA $R = R' = HOCH_2CH_2$

The partial pressure of carbon dioxide was constant at 1 atmospheric pressure. The reaction was reversible as the formula 1, and the following differential equation will be valid:

$$du/dt = k_1(a_0 - u) - k_2(a_0' + 2u)^2 p_{CO_2} \quad (2)$$

$$= k_1(a_0 - u) - k_2'(a_0' + 2u)^2 \quad (3)$$

where

$a_0$ = initial concentration of MEA or DEA carbamate, mol./g. sample,

$a_0'$ = initial concentration of MEA or DEA, mol./g. sample,

$k_1$ = rate constant of decomposition of the carbamate,

$k_2$ = rate constant of absorption of the MEA or DEA,

$u$ = moles of the decomposed carbamate at the time $t$, and

$p_{CO_2}$ = partial pressure of carbon dioxide.

When $u=0$ at $t=0$ and $u=u_e$ at $t=\infty$, the solution of the Eq. 3 is:

$$(Ka_0 - a_0'^2)/u = (\sqrt{K^2 + 8K(2a_0 + a_0')}/2) \cdot \coth(k_2' t \sqrt{K^2 + 8K(2a_0 + a_0')}/2) + (K + 4a_0')/2 \quad (4)$$

where $K = k_1/k_2' = (a_0' + 2u_e)^2/(a_0 - u_e)$ (5)

$$k_2' = k_2 p_{CO_2} \quad (6)$$

A relation between rate constants, $k_1$ and $k_2'$, and equilibrium constant $K$, should be expressed as $k_1/k_2' = K^{1/\nu(r)}$, where $\nu(r)$ = the number of occurrence of a rate determining step necessary to complete an overall reaction formula[10]. At present, however, $\nu(r) = 1$, as will be explained.

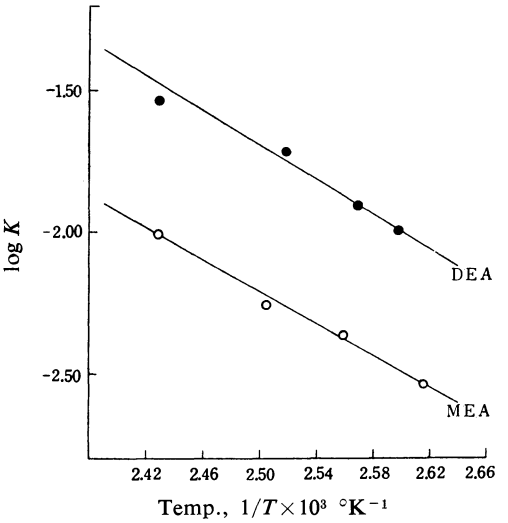


Fig. 4. Temperature dependence of equilibrium constant $K$; $\log K$ vs. $1/T$ ($\times 10^{-3}$).

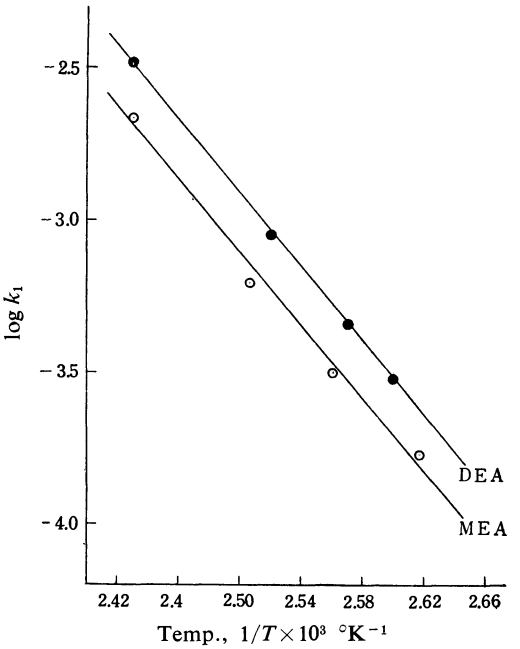

Fig. 5. Temperature dependence of rate constant $k_1$; $\log k_1$ vs. $1/T$ ($\times 10^{-3}$).

9) A. Smola, *Mitt, chem. Forsch.*, **2**. 38 (1948); **2**, 43 (1948).

10) J. Horiuti, *Chem. & Chem. Ind.* (*Kagaku to Kogyo*) **9**, 355 (1956).

On the basis of the amount of carbon dioxide at equilibrium, equilibrium constants were calculated. The temperature dependence of the equilibrium constants was shown in Fig. 4. From the slopes of the lines the heats of the reaction were calculated by the van't Hoff's equation, and were found to be 12.9 and 13.4 kcal./mol. $CO_2$ for MEA system and DEA system, respectively. Since $a_0$, $a_0'$, $K$, $t$ and $u$ were known by the experiment, the rate constants, $k_1$ and $k_2'$, at each temperature, were calculated. After the initial period the values of the rate constants became equal within the limits of experimental error. The calculated values of $u$ obtained from Eq. 4, using these rate constants and the others, were plotted against the time. The agreement with the experimental values supports the validity of Eqs. 1 to 6. The values of $\log k_1$ and $\log k_2'$ were plotted against the reciprocals of corresponding absolute temperatures, as shown in Figs. 5 and 6, and the Arrhenius' energies of activation of the decomposition and the absorption were calculated over the temperature range of 110 to 140°C, and were found to be 27.5 and 14.4 kcal./mol. for the MEA system, 27.8 and 13.6 kcal./mol. for DEA system, respectively.

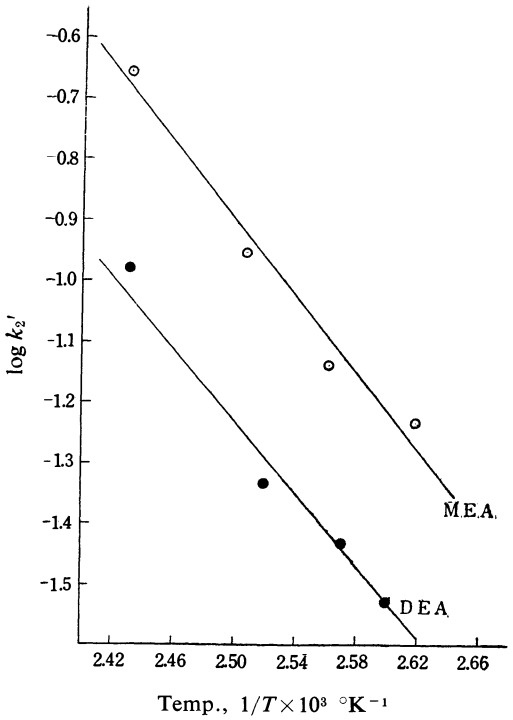

Fig. 6. Temperature dependence of rate constant $k_2'$; $\log k_2'$ vs. $1/T$ ($\times10^{-3}$).

As to the samples, the reaction products should have the formula $RR'NCOONH_2RR'$ (I), since the solution had still excess amine which would eventually change the products of the type RR'NCOOH (II), if present, to the type (I).

The author wishes to express his sincere thanks to Mr. Shûzô Kishida for his encouragement. This paper is published by the permission of the Technical Research and Development Institute, Defense Agency.

# *Photoconductivity of Polycyclic Aromatic Compounds*

By Mizuka SANO

(Received May 10, 1961)

Since Akamatu and Inokuchi reported the photoconductivity of violanthrone[1], a number of investigations have been made on the photoconductive phenomena in aromatic compounds[2-7]. These investigations, however, have been concentrated mainly on compounds consisting of a small number of rings, such as anthracene and pyrene, which possess resistivities as high as $10^{20}$ ohm. cm. at room temperature[3]; hence, they may be classified as insulation photoconductors rather than semiconductors. Recently Kallmann and Pope[8] showed

that the injected holes from an electrode contributed to the major conduction in anthracene, and Moore and Silver[9] concluded that anthracene is an extrinsic photoconductor rather than the intrinsic one.

On the other hand, relatively little work has been done on the photoconductive behaviors in multi-ring compounds, though it is known that the semiconductive properties are enhanced with the increase of the number of rings.

## Experimental

**Materials.**—Most of the materials were synthetized by Drs. Handa and Aoki in our laboratory. All of them were carefully purified by recrystallization from solutions. To the final process of the purification the vacuum sublimation method was applied repeatedly.

**Procedures.** — Two types of photocells, i. e., the surface-type cell and the sandwich-type cell, were employed for the investigation of photoconduction. The surface-type cell consisted of a uniform film of aromatic compound with a thickness of about one micron and an area of $15\times15$ mm$^2$. The film was deposited on a pyrex glass plate (the dimension of which was 20 mm.$\times$25 mm.) by slow sublimation in vacuo. Colloidal graphite, "Aquadag", was applied on the film to serve as the electrodes, which were 1 cm. in length and about 3 mm. in width, with a gap of 1 mm. between them. The sandwich-type cell was formed by sublimation of the compound onto a pyrex plate on which a transparent aluminum conducting film had been previously deposited. The second aluminum film, lying entirely on the organic film, completed a photocell with an area of $10\times5$ mm$^2$ and a thickness of a few microns.

The sublimation of organic compounds was carried out in vacuo ($10^{-3}$ mmHg) without decomposition over temperatures ranging from 80 to 380°C. The growth of a film was followed by observing the color of reflected light, and in this way the thickness could be estimated accurately enough to prepare an appropriate film for photoconduction.

Most of the aromatics employed absorb the light intensely in the spectrum region extending from near ultraviolet to near infrared, so that a tungsten lamp is one of the most convenient light sources. The Mazda 750-watt projector lamp was used, being associated with second-order interference filters to isolate narrow particular wavelength regions. The maximum transmissive wavelengths of the regions, which were 9~16 m$\mu$ in half band width, ranged from 392 to 1324 m$\mu$, with an interval of 50~100 m$\mu$.

Absolute measurements of intensity of incident light on an organic photocell were made with the Nihonbunko vacuum thermopile which was placed at the position of the photocell. The sensitivity of the thermopile was 5.6 microvolts per one microwatt with the time constant of 33 milliseconds and the resistance of 4.2 ohm. A germanium phototransistor and a PbS photocell were used as auxiliary instruments for the measurement of light intensity, because these detectors endure a higher intensity of light better than the thermopile. The maximum intensity, $6\times10^{18}$ photons/sec·cm$^2$, was obtained for the light which was isolated by the 1324 m$\mu$ filter.

Measurements of electric current were made with association of the Takeda Model V-IM dc amplifier. The ampplifier has the input resistance ranging from $4.5\times10^5$ to $4.4\times10^{11}$ ohm. The voltage source applying to an organic photocell was a battery of dry elements with voltage of up to 700 V.

The apparatus, as illustrated in Fig. 1, consisted of five parts; the outer glass cylinder, the liquid nitrogen container with the photocell holder, the radiation shield, the optical windows and four conducting leads. The photocell was mounted on the holder by being pressed with a polystyrene plate and nuts.

Measurements of temperature were made with the germanium resistor which had been calibrated with a pentane direct-readings thermometer. The resistance of the resistor changed from 27 to 10 ohm. following the temperature change from +15 to −196°C. The complete evacuation and the heat radiation shield prevented condensation of moisture on the surface of optical window. The apparatus was placed in a metal box, which served for shutting out the photocell from light and also for preventing electrical disturbance.

## Results

**Change in Photocurrent with Electric Potential.** —The electric current was measured as a function of applied potential under the illumination of monochromatic light. Most of the observations were made with surface-type photocells in vacuo, to avoid the effects of space charge which were occasionally observed with sandwich-type photocells.

The current responded to potential variation instantaneously and then remained constant with time. The potential dependence of photocurrent was reproducible, as in the case of dark current similarly. When the logarithm of the current $i$ was plotted against the logarithm of the applied potential $V$, a linear relationship was obtained. This is illustrated in Fig. 2 for pyranthrene. From this, the potential-current relation could be expressed by the following formula,

$$i \propto V^{\alpha}$$

The values of $\alpha$ for pyranthrene, violanthrene and perylene are shown in Table I. In this table, it is seen that $\alpha$ is approximately unity, under different conditions of illumination with regard to wavelength and intensity of light. Hence, it can be concluded that the photocurrent obeys Ohm's law over the range of potential applied up to $7\times10^3$ V./cm.

**Change in Photocurrent with Light Intensity.** — The photocurrent in surface-type photocells was observed as a function of light intensity. The relation between photocurrent and light intensity yielded two regions generally, as illustrated in Figs. 3 and 4. In each region, the relationship between the photocurrent $i_p$ and the light intensity $L$ could be expressed by the formula,

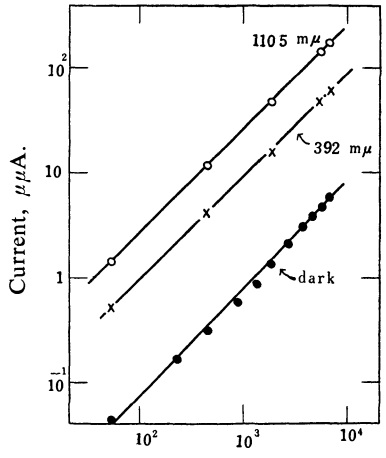

Fig. 2. The relation between current and applied potential for pyranthrene.

TABLE I. THE $\alpha$-VALUE FOR SURFACE-TYPE PHOTOCELLS

| | Illumination: Wavelength mμ | Illumination: Intensity photons/sec. cm² | α-Value |
|---|---|---|---|
| Pyranthrene (film) | Dark | — | 1.05 |
| | 392 | $10^{15}$ | 1.01 |
| | 529 | $10^{13}$ | 1.14 |
| | 1055 | $10^{15}$ | 1.10 |
| | 1105 | $10^{17}$ | 1.00 |
| Violanthrene (film) | Dark | — | 1.11 |
| | 557 | $10^{13}$ | 1.15 |
| Perylene (film) | 470 | $10^{13}$ | 1.20 |
| Perylene (single crystal) | 392 | $10^{16}$ | 1.17 |
| | 403 | $10^{16}$ | 1.15 |
| | 502 | $10^{16}$ | 1.17 |
| | 502 | $10^{17}$ | 1.19 |

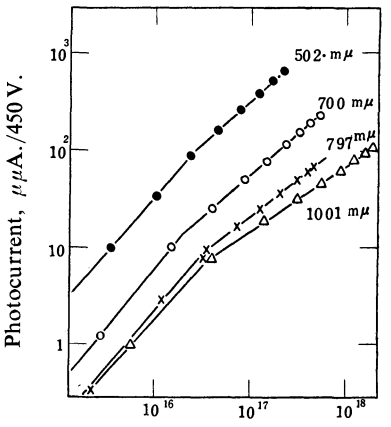

Fig. 3. The relation between photocurrent and light intensity for pyranthrene (surface-type photocell).

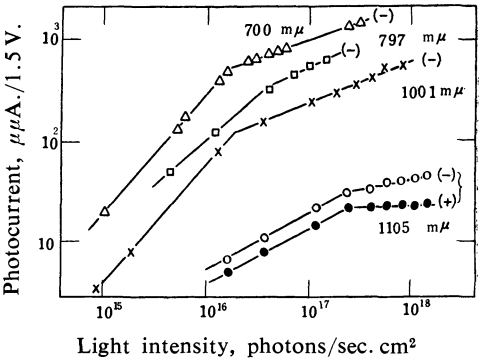

Fig. 4. The relation between photocurrent and light intensity for pyranthrene (sandwich-type photocell).

Illuminated electrode was biased positively, (+) and negatively (−).

$$i_p \propto L^n$$

In the region of low light intensity, usually not much exceeding $10^{16}$ photons/sec. cm$^2$, the photocurrent changed approximately in linearity with the light intensity, i. e., the exponent $n$ was nearly unity. This relation was seemingly independent of the wavelength of incident light, the atmosphere, the applied potential and the temperature.

While in the region of high light intensity, $n$ possessed a smaller value than unity, and was dependent on the wavelength of illumination. Nevertheless, no appreciable difference of $n$-value was noted according to the variation of temperature, potential, or atmosphere. The $n$-values are summarized in Table II.

No indication of saturation was observed with surface-type photocells even in the region of the highest light intensity, around $10^{18}$ photons/sec. cm$^2$. However, sandwich-type photocells showed the saturation of photocurrent at the light intensity of $2\times10^{17}$ photons/sec. cm$^2$, as illustrated in Fig. 4.

TABLE II. THE $n$-VALUE FOR PYRANTHRENE AND PERYLENE SURFACE-TYPE PHOTOCELLS IN THE REGION OF HIGH LIGHT INTENSITY

* $10^{-3}$ mmHg after being flushed with argon gas.

**Change in Photocurrent with Temperature.**—The temperature dependence for photocurrent was measured over the range from 173 to 290°K. The surface-type photocell was employed with association of the apparatus which is shown in Fig. 1. The photocurrent increased with an increase in the temperature. Plots of the logarithm of photocurrent $i_p$ against the reciprocal of temperature gave a straight line

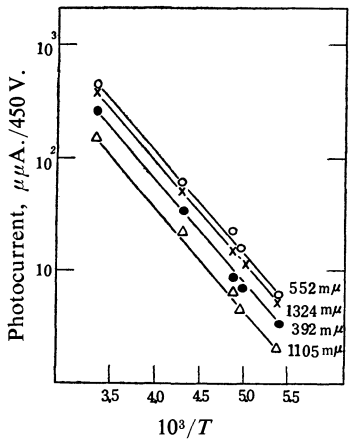

Fig. 5. The photocurrent vs. temperature for pyranthrene (surface-type photocell).

(Fig. 5), and the relation follows the equation,

$$i_p = i_0 \exp(-E/kT)$$

where $E$ is the activation energy of photocurrent.

It is of interest that the activation energy, e. g., 0.18 eV. for pyranthrene, was found to be independent of the intensity and the wavelength of incident light over the range from 392 to 1324 mμ employed.

**Generation of Charge Carriers.**—An attempt was made to measure the photocurrent which was produced by the illumination onto a limited area of the aromatic film between the electrodes of surface-type photocell. Aquadag electrodes were painted on the pyranthrene film with a gap of 7 mm. between them. When the whole area between the electrodes was illuminated, the maximum photocurrent, of the value of $12\times10^{-12}$ A./450 V., was observed. When the illumination was made onto the half part of the area between the electrodes by masking the other half, the magnitude of photocurrent was smaller than that expected if the photons in the same number had been uniformly distributed over the whole area. When the illumination was focused onto one of the electrodes alone, the increase of current was hardly observed. In addition, when the light fell onto a small limited area of the film, the magnitude of photocurrent assigned per unit area was nearly equal to that of the photocurrent produced by the illumination on the half area. Consequently it might be concluded that the charge carriers are not produced in a particular portion such as the Aquadag electrode or the contact area, but in the area between both elctrodes. Nevertheless, there is no explanation for the fact that the maximum photocurrent was produced by the illumination on the whole area. Probably the difference is

related to the decay pocess of charge carriers.

The photocurrent produced by an asymmetric illumination with respect to the polarity of ppalied potential was also measured. Onto a pyranthrene surface-type cell an image of slit of monochromatic light was collimated so that the illuminated strip lay parallel to the electrodes. Keeping the applied potential ($2.25\times\times10^2$ V./cm.) and light intensity ($2.8\times10^{17}$ photons/sec. cm$^2$ for 552 m$\mu$ illumination) constant, the photocurrent was measured as the image was moved from one electrode to the other. The photocurrent was always greater when the illuminated portion was located close to the negatively biased electrode. In this case, the photoelectromotive force due to the asymmetric illumination was undetectable, even under the illumination of the highest light intensity.

Also, a sandwich-type photocell possesses the asymmetry in itself, because the light intensity of illumination is diminished successively along the electric potential. The photocurrent of a pyranthrene film (about 10 $\mu$ in thickness), which was sandwiched between two evaporated aluminum films, was 1.5 times greater when the illuminated side was negatively biased than when it was positively biased at the applied potential of $1.5\times10^3$ V./cm.

The thermoelectromotive force, which was observed with compressed powder of isoviolanthrone, was of the order of $10^{-4}$ V./deg., indicating conduction predominantly by electrons.

## Discussion

The semiconductive behaviors of polycyclic aromatic compounds have been fairly extensively studied, but the theoretical interpretation of their electronic conduction has not been completed, because the intermolecular interactions in the solid state are scarcely known. However, a significant part of the behavior of organic semiconductors can be discussed, for convenience, in terms of the band model. It may be postulated that the empty band and the full band are formed from the energy levels of the excited states and the ground state of $\pi$-electrons of the molecule respectively. In this case, the band widths might be narrow; especially the width of the full band is so narrow because of poor overlapping of the wave functions for the ground state, that the full band may be regarded as a series of discrete levels. Consequently it is quite probable that the holes are almost confined to the particular molecules in which they are generated, and most of the electric current is conducted by electrons through the crystal. The model was supported by the signs of the thermoelectromotive force and the polarity for the maximum photocurrent which was produced by an asymmetric illumination. In addition, as the ohmic nature of photocurrent as well as the experiment on the limited-area illumination indicated, the generation of charge carriers took place in the bulk of aromatic film, neither from the electrode nor the electrode-film contact. Hence, the multi-ring compounds are seemingly intrinsic photoconductors. The light intensity dependence for photocurrent has been usually accounted for by the concept of the trapping process of charge carriers. For instance, Rose[10] explained the variation of the exponent $n$ from 1 to 0.5 by the population of the effective trapping centers which varies depending on the intensity of illumination. Our result showed that $n$ possesses unity at a low light intensity and possesses a smaller value than unity at a high light intensity. This result is coincident qualitatively with that shown by Rose. The temperature dependence for photocurrent can not be easily interpreted because more than one parameter can change with temperature. However, the activation energy of photocurrent was independent on the wavelength of light. This result seems to indicate that the activation energy is not associated with the formation of charge carriers, such as the dissociation of electron-hole pairs, but with the transport process of carriers. If the trapping centers are assumed to be of the same depth below the empty band, and the temperature dependence could be ascribed to the variation of the mobility of carriers, the activation energy indicates the depth of trapping center. However, the nature of the centers has not been established. As suggested by Nelson[11] for the case of cationic dyestuff, every molecule might be regarded as a trapping center in the polycyclic aromatic compounds.

## Summary

The voltage, light intensity, and temperature dependences for photocurrent in multi-ring compounds were studied as well as the photocurrent produced by the limited-area illumination. The photocurrent was found to be ohmic over the range of voltage employed. The photocurrent increased linearly with the intensity of light in the region of low light intensity, while it increased as the fractional power of the light intensity in the region of high intensity. The photocurrent increased with an increase of the temperature, and the activation energy of the photocurrent was found to be independent of the wavelength and the intensity of illumination.

11) R. C. Nelson, *J. Chem. Phys.*, **30**, 406 (1959).

The signs of the thermoelectric power as well as the polarity for the maximum photocurrent, and the experiment on the limited-area illumination indicated that the conduction in polycyclic aromatic compounds was due predominantly to electrons which were generated in the bulk of aromatic film.

The author expresses his hearty thanks to Professor Hideo Akamatu for his kind direction and advice, and also to Dr. Hiroo Inokuchi for his continuous advice in this work. # *Stereoregular Polymers. IX. Polymerization of Optically Active α-Olefins**

By Shun'ichi NOZAKURA, Shigeru TAKEUCHI, Heimei YUKI and Shunsuke MURAHASHI

(Received April 18, 1961)

In their previous work[1], the authors polymerized styrene with anionic catalysts containing the optically active alkyl group such as optically active amylsodium or triamylaluminum combined with titanium trichloride. The purpose was to obtain optically active polystyrene, in which one helical configuration (either right- or left-handed screw helix) presumably induced by the active group might be predominantly present. However, the attempt was not successful.

X-Ray analyses of various isotactic polymers have shown that the crystalline structure of the polymer, and accordingly the crystallinity and the melting temperature are largely dependent on the side group of the chain[2]. In other words, the type of helix, i.e. the number of monomeric units or of turns in the identity period, may be decided definitely by the shape and size of the substituent group of the chain.

The present work was carried out as one of the programs of attempting to regulate the direction of helical configuration of polymer chain in its screw sense. Two optically active α-olefins, *l*-4-methyl-1-hexene and *d*-3-methyl-1-pentene, were polymerized by the Ziegler catalyst and the nature of the polymer was examined in anticipation that the asymmetric substituent might induce the helical configuration, which exists with only one (right- or left-handed) screw sense, in the polymer chain.

## Experimental

**Preparation of Monomers.**—*l-2-Methyl-1-butanol.*—Commercial fusel oil was fractionally distilled by Stedman type column (about seventy theoretical plates) repeatedly. *l*-2-Methyl-1-butanol thus obtained showed b. p. 128°C and $\alpha_D^{28}$ −9.36° (*l*=20 cm.) (optical purity 98.7%)[3].

*d-1-Chloro-2-methylbutane.*—The alcohol was converted to the chloride by thionyl chloride. Yield 78.7%, b. p. 99°C, $[\alpha]_D^{30}$ +1.63° (optical purity 97%)[4].

*Optically Active 1-Bromo-2-ethoxy-4-methylhexane.*—2-Methylbutylmagnesium chloride derived from optically active *d*-1-chloro-2-mehthylbutane was made to react with α, β-dibromo ethyl ether[5] to give 1-bromo-2-ethoxy-4-methylhexane[6]. Yield 60.3%, b. p. 91~93°C/15 mmHg.

*l-4-Methyl-1-hexene*[7].—The ethoxyheptyl bromide gave *l*-4-methylhexene in 61% yield by refluxing an alcoholic solution with zine powder for 10 hr.

B. p. 87～88°C, $[\alpha]_D^{31}$ −2.50° (optical purity 94%)[8] $n_D^{31}$ 1.3970, $d_4^{31}$ 0.692.

*5-Methyl-1-hexene.*— It was synthesized similarly from commercial isoamyl alcohol via isoamyl chloride in 16% yield based on the chloride. B. p. 83～85°C. The isoamyl chloride showed an optical activity ($[\alpha]_D^{22}$ +0.33°), which corresponded to that calculated for a mixture of 81% pure isoamyl chloride and 19% *d*-1-chloro-2-methylbutane[9].

*d-3-Methyl-1-pentanol.*—Optically active 3-methyl-1-pentanol was synthesized from formaldehyde and 2-methylbutylmagnesium chloride derived from *d*-1-chloro-2-methylbutane (b. p. 99～100°C, $[\alpha]_D^{10}$ +1.71°, optical purity ca. 100%), which was obtained from optically pure *l*-2-methyl-1-butanol, b. p. 127.5～128.5°C, $[\alpha]_D^{11}$ −9.55° (*l*=20 cm.). Gaseous formaldehyde was bubbled through the ethereal solution of the Grignard reagent with dry nitrogen. The subsequent decomposition and steam-distillation of the product gave *d*-3-methyl-1-pentanol in 38.3% yield, b. p. 147～149°, $[\alpha]_D^{10}$ +8.41° (literature[8]: $[\alpha]_D^{19.5}$ +8.53°).

*d-3-Methylpentyl Acetate.*— The acetate was obtained from the alcohol by using *p*-toluenesulfonic acid as a condensing catalyst, yield 69%, b.p. 156～158°C, $[\alpha]_D^{8}$ +8.53° (literature[8]: $[\alpha]_D^{19}$ +8.30°).

*d-3-Methyl-1-pentene.* — The methylpentyl acetate was dropped with a stream of nitrogen through a quartz tube packed with glass pieces at 500°C. The pyrolysis gave *d*-3-methyl-1-pentene in 36% yield. b. p. 54～55°C, $[\alpha]_D^{12}$ +32.95° (literature[8]: $[\alpha]_D^{17}$ +32.86°).

*dl-3-Methyl-1-pentanol.*—Ethylene oxide was bubbled through an ethereal solution of *sec*-butylmagnesium chloride using nitrogen as a carrier gas. The product was decomposed by saturated aqueous ammonium chloride and steam-distilled to give *dl*-3-methyl-1-pentanol. Yield 52%, b. p. 148～150°C.

*dl-3-Methyl-1-pentene.* — The racemic 3-methyl-1-pentene was obtained from the racemic methylpentanol via its acetate similarly as described on the optically active methylpentene. Yield 35% based on the alcohol, b. p. 54～56°C.

**Polymerization.** — The heptene monomers, *l*-4-methyl-1-hexene and 5-methyl-1-hexene, were polymerized in a five-necked flask described previously[10]. The vessel was flushed with dry nitrogen, and charged with *n*-heptane, titanium tetrachloride and aluminum triethyl (*n*-heptane solution), and the monomer was injected by a hypodermic syringe through a rubber cap fitted on the vessel. The mixture was heated for 10 hr. at 70°C. All procedures were done in a stream of dry nitrogen. The reaction mixture was then poured into a large volume of methanol containing a small amount of hydrochloric acid to decompose the catalyst. After being allowed to stand overnight the precipitated polymer was collected by centrifugation, washed with methanol, and dried.

The hexene monomers, *d*- and *dl*-3-methyl-1-pentene, were polymerized by analogous procedures but using a sealed tube as the reaction vessel and at 50°C for longer periods, 40 hr. for racemic and 144 hr. for *d*-monomer.

The results of polymerization were summarized in Table I.

The polyheptenes were soluble in chloroform, carbon tetrachloride, toluene, benzene, decalin, carbon disulfide, and hot *n*-heptane, and insoluble in ether, alcohol and acetone.

Poly-*d*-3-methyl-1-pentene was almost insoluble in usual organic solvents. This was slightly soluble above its melting point in petrolatum liquid, dibutyl phthalate and dioctyl phthalate. The solution in petrolatum liquid was maintained clear and stable even after it had cooled to room temperature, but the polymer precipitated from the phthalate solutions below about 290°C and no appreciable amount of polymer appeared from the liquid phases by adding methanol.

On the other hand, the polymeric product of *dl*-3-methyl-1-pentene was found to be largely contaminated with polyethylene produced from the Ziegler catalyst itself and was fractionated successively by boiling toluene and by boiling decalin. The toluene-soluble fraction (68%) containing a considerable amount of polyethylene melted between 130 and 190°C. The decalin-soluble fraction (17%) and the remaining insoluble fraction (15%) melted at 225～226°C and 245～247°C, respectively. The solubility of decalin-insoluble fraction seemed

8) P. Pino and L. Lardicci, *Chem. & Ind.*, **1959**, 483.
9) F. C. Witmore and J. H. Olewine, *J. Am. Chem. Soc.*, **60**, 2570 (1938).
10) S. Murahashi, S. Nozakura, M. Sumi and K. Hatada, This Bulletin, **32**, 1094 (1959).

to be slightly greater than that of poly-*d*-3-methyl-1-pentene but was about the same.

**Optical Rotation.**— For the determinations of optical rotatory dispersion and optical purity a Rudolph high-precision photoelectric spectropolarimeter model 200S-80 was used.

The observed optical rotation of a solution of poly-*d*-3-methyl-1-pentene in petrolatum liquid was $\alpha_D^{24}$ +4.68° ($l$=20 cm.) at $c$=0.0745. The petrolatum liquid, however, had an optical rotation $\alpha_D^{24}$ +2.15° ($l$=10 cm.), and the specific rotation of the polymer, $[\alpha]_D^{24}$ +255°, was calculated from the difference of rotations of the solution and the solvent.

**Density.**—Determination of polymer density was carried out by a density gradient tube using methanol and water as media.

**Melting Point.**—The polymer sample was placed on a metal block under the microscope. The metal block was heated by a hot plate and the melting point of the sample was measured.

## Results

The dependence of the optical rotation on the concentration of poly-*l*-4-methyl-1-hexene was examined in four solvents, toluene, decalin, carbon tetrachloride and carbon disulfide. The results are shown in Fig. 1. The linear ralationships between the rotation and the polymer concentration were obtained in each solvent. These led to the values of specific rotation $[\alpha]_D^{27.5}$ +251° (toluene), $[\alpha]_D^{24}$ +268° (decalin), $[\alpha]_D^{25}$ +236° (carbon tetrachloride) and $[\alpha]_D^{13}$ +290° (carbon disufide).

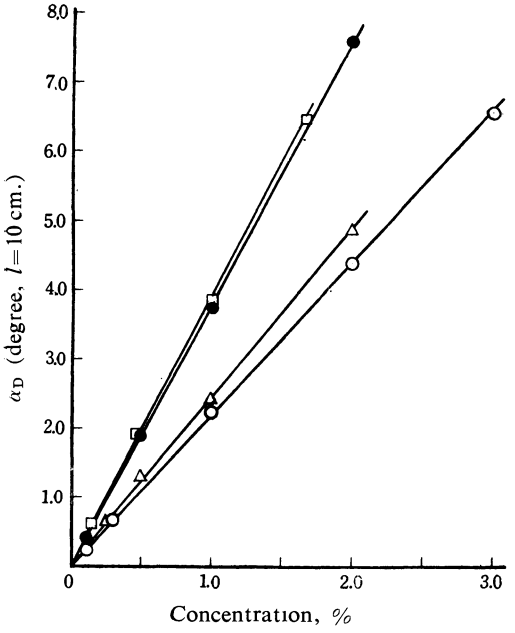

Fig. 1. Optical rotation vs. concentration of poly-*l*-4-methyl-1-hexene in various solvents: ○ in toluene at 27.5°C; △ in decalin at 24°C; □ in carbon tetrachloride at 25°C; ● in carbon disulfide at 13°C.

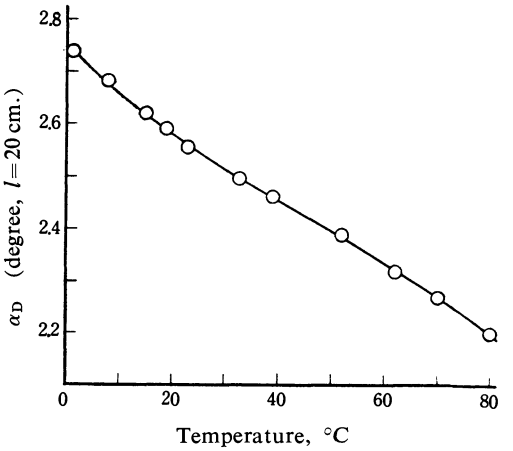

Fig. 2. Temperature dependence of optical rotation of 0.5% poly-*l*-4-methyl-1-hexene solution in decalin.

The plots of the optical rotation of 0.5% poly-*l*-4-methyl-1-hexene solution in decalin vs. temperature are shown in Fig. 2. The rotation decreased almost linearly with the elevation of temperature from 2 to 80°C.

To the toluene solution of the polymer (concentration 1.05%) *n*-heptane, a poor solvent for the polymer, was added successively and the change of optical rotation of the solution was followed. Similarly *n*-butanol, a precipitant against the polymer, was added in another series of this experiment. The results showed that the rotation was rather strictly linear to the concentration of the polymer alone (Fig. 3). In these experiments the ageing of the

solution caused no change in the optical rotation after adding the poor or the bad solvent.

The optical rotatory dispersion was measured with the polymer in two solvents, decalin ($c=0.4\%$, $l=10$ cm.) and toluene-*n*-heptane mixture (1 : 1 vol./vol., $c=0.6\%$, $l=10$ cm.). The results are shown in Figs. 4 and 5. The plots $\alpha_\lambda\lambda^2$ vs. $\alpha_\lambda$, where $\alpha_\lambda$ is the optical rotation at a wavelength $\lambda$, were linear as shown in Fig. 5, and no abnormal dispersion was observed.

All the polymers obtained here gave sharp crystalline X-ray patterns except the toluene-soluble fraction of poly-*dl*-3-methyl-1-pentene. The patterns given by poly-*d*-3-methyl-1-pentene and the decalin-insoluble fraction of poly-*dl*-3-methyl-1-pentene were completely different. The spacings obtained from the powder X-ray diagrams are summarized in Table II.

## Discussion

Both of the optically active polymers, poly-*l*-4-methyl-1-hexene and poly-*d*-3-methyl-1-pentene, showed enormously large optical rotations compared with those of the monomers. The large optical rotations seemed to be contributed not only by the neighboring groups around the asymmetric carbon atom of the side group but also by the molecular asymmetry of the helical configuration of the main chain, more practically by a predominant concentration of either right- or left-handed helix in the solution.

It is doubtful that the isotactic polymer such as poly-$\alpha$-olefin still maintains its helical structure in the solution. However, Takeda and his collaborators[11] recently stated from their infrared absorption study that in carbon disulfide isotactic polystyrene retained its helical structure[12] even in the solution state. This encouraged us to investigate the optical rotation of poly-*l*-4-methyl-1-hexene in solution by varying the conditions in order to learn its exact nature.

The concentration of the helix might vary with the concentration of the polymer, if it remained in the solution in any extent. The temperature might also affect the concentration of the helix. The concentration of the helix would be considered to be related to the interaction between the molecules of polymer and solvent. A good solvent may release the helical configuration of the polymer to transform it into a randomly coiled structure and, on the other hand, poor solvent might probably coil up the chain to a helix as shown by

11) M. Takeda, K. Iimura, A. Yamada and Y. Imamura, ibid., 32, 1150 (1959).

Doty and his coworkers[13] for poly(γ-benzyl L-glutamate).

However, the concentration, the temperature and the addition of bad solvent gave no distinct change in the specific rotation of the polymer in solution, compared with the large change observed in the helix-coil transformation of poly (γ-benzyl L-glutamate). In addition, the plots of optical rotatory dispersion fitted the equation $\alpha_\lambda\lambda^2=\lambda_c^2\alpha_\lambda+A'$[13] derived from the simple one-term Drude equation $[\alpha_\lambda]=A/(\lambda^2-\lambda_c^2)$, where $\lambda_c$, $A$ and $A'$ are the constants, respectively, and no complex dispersion was found. These facts strongly suggest that the optical rotation of this polymer is attributed to only one species, the asymmetric carbon atom of the substituent group, at least in solution.

The polymer formed from the 5-methyl-1-hexene monomer had a specific rotation $[\alpha]_D^{22}$ $+54^\circ$ in toluene. Obviously this was caused by *l*-4-methyl-1-hexene units in the polymer which had been contained in the monomer used. Reding[14] has reported that the polymer produced from a mixture of 4-methyl-1-pentene and 3-methyl-1-butene was a copolymer but not a mixture of the homopolymers of each monomer. Therefore, it may be preferable to consider the polymer obtained here as being also the copolymer of 5-methyl-1-hexene and *l*-4-methyl-1-hexene. It must be noted that the specific rotation of this polymer was about 20% of that of poly-*l*-4-methyl-1-hexene and the percentage was coincident with the content of *d*-1-chloro-2-methylbutane in amyl chloride mixture used as the starting material of the monomer, although many steps had been taken in the way from the chloride to the polymer.

The optical rotatory behavior of poly-*l*-4-methyl-1-hexene gave no positive evidence either for the existence of helical configuration in solution or, if any, for a predominant existence of right- or left-handed helices. This might be caused by the absence of strong intramolecular attraction such as hydrogen bond to coil up the chain to a helix in solution. Even if the helix was maintained in solution, the one carbon atom inserted between the main chain and the asymmetric carbon atom would weaken the steric influence of the neighboring groups around the asymmetric carbon atom. This might result in no regulation of the direction of helical configuration in a single screw sense.

The density of poly-*l*-4-methyl-1-hexene was coincident with the value reported for poly-*dl*-4-methyl-1-hexene by Natta[2]. The melting point was also approximately the same as those observed by Natta (188°C)[2] and Campbell (157~160°C)[15] with the polymer formed from the racemic monomer. These facts seem to suggest that there is almost no difference in the crystalline structure of either the optically active or the racemic polymer even in the solid state.

On the contrary, the melting point of poly-*d*-3-methyl-1-pentene is distinctly higher than that of the decalin-insoluble fraction of poly-*dl*-3-methyl-1-pentene, which seemed to have almost the same crystallinity and stereoregularity as those of the former polymer from its solubility behavior. Furthermore, the X-ray diffraction patterns of these two polymers are so different that the polymers appeared to be constituted with completely different monomeric units from each other.

The low conversion and also the very low stereospecificity in the polymerization of *dl*-3-methyl-1-pentene suggest the difficulty of isotactic propagation of this monomer. This may be caused by the copolymerization of the *d*- and *l*-monomers, in which the asymmetric tertiary carbon atoms are adjacent to the vinyl groups.

In the polymerization of racemic monomer three types are probable in the formation of its polymer: a mixture of homopolymers of *d*- and *l*-monomer each, a random copolymer and a block-copolymer of these. Furthermore, each type of these is able to form isotactic, atactic and stereo-block polymers in regard to the main chain of the polymer.

For the polymer of *dl*-3-methyl-1-pentene the authors obtained three fractions according to the solubility difference. The problem as to which of the above mentioned types correspond to the respective fractions is very interesting, although this is not certain at the present stage of this work.

In poly-3-methyl-1-pentene the asymmetric carbon atom of side chain is adjacent and so close to the main chain of the polymer that it may affect the configuration of the chain, contrary to the case of poly-4-methyl-1-hexene. Therefore, the predominant or exclusive formation of either the right- or left-handed helix may be expected in much more probability for poly-*d*-3-methyl-1-pentene than for poly-*l*-4-methyl-1-hexene. Unfortunately, the detailed investigation on the optical rotation of poly-*d*-3-methyl-1-pentene could not be done due to the extremely low solubility of the polymer, although the polymer showed a

very large specific rotation, $[\alpha]_D^{24}$ +255°, in petrolatum liquid.

After the completion of this work, papers by Pino and Lorenzi[16], and Bailey and Yates[17] appeared, which described the same subject independently. Bailey and Yates reported that the specific rotation of poly-*d*-3-methyl-1-pentene $[\alpha]_D^{25}$ was −257° in 1,1-ditolylethane. The present sample of the same polymer showed distinctly dextro rotation also in 1,1-ditolylethane, but the exact value could not be obtained, because the concentration of the solution was too small to be measured, due to the extremely low solubility of the polymer in 1,1-ditolylethane at room temperature. Pino and Lorenzi reported that the various soluble fractions of poly-*d*-3-methyl-1-pentene, which seemed to be atactic or stereoblock, had dextro rotations.

Pino and Lorenzi concluded in their paper that in dilute solution and in the molten state the isotactic and stereo-block polymers of optically active α-olefins may be at least in part spiralized and that helices of a single screw sense may largely prevail, because of the remarkable dependence of the optical rotation on stereoregularity and temperature. However, the temperature coefficient of optical rotation must also be dependent on the magnitude of specific rotation itself and in this respect the temperature coefficients of the optical rotation of optically active poly-α-olefins may be considered to be not so large. Other considerations seem to be necessary to explain the large optical rotations of these isotactic polymers formed from optically active α-olefins.

The authors wish to thank Dr. Yōzō Chatani for his help in the X-ray investigation.

# *Studies on Phenolic Resins. IV. Physical and Chemical Properties of Coating Films of Japanese Lac (Urushi) (Rigidity Modulus-Temperature Relations Measured by Torsional Pendulum Method)*

By Tsutomu KUWATA, Jū KUMANOTANI and Seiji KAZAMA

(Received April 17, 1961)

Japanese lac (*urushi*) has been used as a natural coating material for more than two thousand years in Japan and China. It has been recognized that the coating film prepared from Japanese lac has many excellent properties and utility. The decorative coating film for artificial and wooden articles has a beautiful color tone and as the protective coating film, it is known by experience to have outstanding physical and chemical properties, compared with the films of the usual paints or varnishes. Traditional wooden crafts coated with *urushi* are very famous and used with appreciation all over the world, but our country imports a large quantity of raw Japanese lac from other Asian countries, because it produces only five per cent of the demand. Therefore, it has been hoped to make up industrial processes to synthesize some substance that can be used in place of natural Japanese lac, or some kind of compounding component or filler for it. There were two ways of attempting this aim.

One attempt was to synthesize the compouds chemically identical with the natural substance. The substance which is usually called Japanese lac is a sap of Rhus vernicifera D. C., produced in Japan and China. Chemical identification of urushiol, the principal component and polymerization unit of Japanese lac, was carried out by Majima[1] and Dawson[2] and the latter established that urushiol was composed of four

derivatives of catechol, substituted at 3-position with paraffinic, olefinic, diolefinic, and triolefinic straight chains of 15 carbons, and the average number of double bonds in the mixture were about two for one molecule. Some of these compounds were synthesized by Dawson[3] and Yukawa[4] but their processes cannot be applied to industrial production. Many chemically analogous compounds were synthesized in the past but they could not be used practically.

Another attempt was made in the industrial field for the purpose of obtaining substitutes or fillers for Japanese lac, and several kinds of coating materials, which formed a film apparrently similar to that of Japanese lac, were prepared and commercialized as "synthetic Japanese lac". But the interesting and important feature of Japanese lac, which must be taken into account, is that it contains an oxidation-reduction enzyme, laccase, and air-drying of Japanese lac proceeds through a characteristic oxidation-polymerization of urushiol with oxygen in the air, catalyzed with laccase[5]; also that the characteristic reaction is thought to be one of the factors that give good properties to the film. Though the molecular structure and reaction mechanism of laccase are not yet known, it was proved to act only on *ortho-* or *para*-polyhydroxy or polyamino aromatic compounds[5]. Therefore commercialized so-called "synthetic Japanese lacs", which are oil varnishes, are not affected by laccase, and they degrade the mechanical properties of the film when used as fillers for Japanese lac.

In another paper the authors studied the preparative method of compounds capable of polymerizing at room temperature together with urushiol, affected with laccase equally to it, when added to natural Japanese lac as fillers[6].

Evaluation of those compounds should be carried out in respect of the physical and mechanical properties of the coating films formed from the mixtures of them and Japanese lac, as compared with the properties of Japanese lac film.

Although it is well known by experience that the coating films of Japanese lac have ideal physical and mechanical properties, scientific studies have been limited to the subjects of resistance to chemical reagents and electrical insulation, and no data were available about the mechanical properties.

In this paper the authors first studied, by means of the torsional pendulum method, the mechanical properties of coating films, prepared through various processes from Japanese lac. This method had been developed to study the visco-elastic behavior of polymers, and in spite of its being a simple operation, it presented useful data such as rigidity modulus and decrement of oscillation at any temperature, and glass transition temperature of the film.

As the results of the observation of the mechanical properties of the coating films which were the oxidation polymerization products of urushiol under the action of laccase or heat, it was revealed that the Japanese lac films had excellent, characteristic properties, never found in other kinds of coating films.

Then the authors determined the mechanical data of three coating film samples each prepared from the mixtures of 10 parts of Japanese lac and 6 parts of the synthetic compound. These three compounds were chosen from a series of catechol derivatives, which had been synthesized by the authors for the purpose of obtaining a good filler for Japanese lac. It was evidently approved by the properties of the film samples that those compounds were excellent fillers for Japanese lac and able to be used in place of urushiol.

## Experimental by Torsional Pendulum Method

The torsional pendulum method developed by Inoue[7] to investigate the mechanical characteristics of polymer films is simple in operation, and gives reliable data. Torsional pendulum apparatus has as the main part an inertia bar attached at its center to the lower end of a pending sample film strip, and a mirror is set below the center. The period and the amplitudes of damping oscillation of the bar are measured by the lamp-and-scale system. Rigidity modulus ($G$) and logarithmic decrement ($\lambda$) are calculated from these data.

**Procedure.**—Torsional pendulum apparatus with sample film was set in a low temperature thermostat, slowly heated up to 40°C and kept at this temperature for 40 min. This duration was necessary for the internal structure of the sample to reach equilibrium at this temperature. Then the temperature was cotinuously dropped at the rate of 1°C/2 min. down to −60°C, while measuring the amplitudes and the period of 3~6 oscillation cycles every 5 or 10°C. The temperature was slowly raised to room temperature, and the apparatus with sample was kept there overnight. Next day it was set in an electric heating thermostat, and the temperature was continuously raised at the rate of 1°C/2 min. to about 150°C and the measurement was carried out every 5 or 10°C.

The rigidity modulus ($G$) of the sample film was calculated from the period, and the logarithmic

decrement ($\lambda$) was calculated from the amplitude change.

$G$ and $\lambda$ were plotted against temperature, and the temperature where $\lambda$ was maximum was glass transition temperature ($T_g$) of the sample film.

TABLE I. LIST OF SAMPLES

| No. | Sample film |
|---|---|
| 1 | Air-dried film of kiurushi |
| 2 | Baked film of kiurushi |
| 3 | Air-dried film of sugurome urushi |
| 4 | Baked film of sugurome urushi |
| 5 | Air-dried film of sugurome urushi |
| 6 | Tested strip of sample No. 5, heated at 100°C for 2 hr. after measurement up to 110°C |
| 7 | Sample No. 5, kept in air for 25 days |
| 8 | Sample No. 1, kept in air for 30 months |
| 9 | Tested strip of sample No. 8, kept in air overnight after measurement up to 150°C |
| 10 | Sample No. 2, kept in air for 30 months |
| 11 | Sample No. 3, kept in air for 30 months |
| 12 | Tested strip of sample No. 11, kept in air overnight after measurement up to 150°C |
| 13 | Sample No. 5, kept in air for 30 months |
| 14 | Air-dried film of Thailand-sugurome urushi, kept in air for 30 months |
| 15 | Air-dried film of sugurome processed mixture of kiurushi and distilled urushiol (1 : 1 part) kept in air for 7 months |
| 16 | Air-dried film of sugurome-processed mixture of kiurushi (10 parts) and linseed oil (3 parts) |
| 17 | Air-dried film of sugurome-processed mixture of kiurushi (10 parts) and linseed oil (6 parts) |
| 18 | Sample No. 16, kept in air for 30 months |
| 19 | Air-dried film of sugurome-processed mixtre of kiurushi (10 parts), linseed oil (2 parts) and ester gum (1 part) |
| 20 | Baked film of sugurome-processed mixture of kiurushi (10 parts), linseed oil (2 parts) and ester gum (1 part) |
| 21 | Sample No. 20, kept in air for 30 months |
| 22 | Air-dried film of sugurome-processed mixture of kiurushi (10 parts) and catechol derivative A (6 parts) |
| 23 | Air-dried film of sugurome-processed mixture of kiurushi (10 parts) and catechol derivative B (6 parts) |
| 24 | Air-dried film of sugurome-processed mixture of kiurushi (10 parts) and catechol derivative C (6 parts) |
| 25 | Air-dried film of oil varnish of reactive *o*-cresol resin |
| 26 | Air-dried film of oil varnish of nonreactive *o*-cresol resin |

The inertia bar used in the experiment was made of aluminum, the length being 20.64 cm., weight 34.01 g. moment of inertia 1210 g. cm$^2$. The periods measured were 3~15 sec. It had been reported that in order to obtain reliable data the periods should lie in the range from 2 to 17 sec.[8]

**Sample Films.**—The sample films are listed in Table I. The meanings of several terms which are unique to Japanese lac are as follows.

*Kiurushi* (raw Japanese lac); this is the sap of the plant.

*Sugurome process*; this is a unique process in the preparation of usual commercial coating material of Japanese lac in Japan. Raw Japanese lac, alone or with other substances, is stirred in a wooden vessel for a time, then heated at about 38°C for about 7 hr. under stirring. During the process dehydration and partial oxidation of the lac take place.

*Sugurome urushi*; *sugurome-processed* Japanese lac. The raw Japanese lac of Samples Nos. 1—4, 8—12, 15—24, was taken from a lot produced in Moppo, China. The Samples Nos. 5, 6, 7, 13, were taken from another lot. Sample No. 14 was the film formed from Thailand lac, the main component of which is not urushiol but thithiol.

*Sugurome-proscess* in the preparation of Sample No. 5, was a little different from that of Sample No. 3, but details were not ascertained.

The torsional pendulum method required the sample film strip, of which the breadth $b$ was about 1 cm. and the thickness $h$ was more than 0.02 cm. because $b/h$ ratio should be 10~50 in order to obtain reliable data. But the thickness of the uniform film formed by one coating was 0.002~0.004 cm. The authors prepared the sample coating films by coating the sample lacs on tin plates (25 cm. × 15 cm.), repeating the coating and drying to touch-free state five to ten times until the films formed became thick enough.

Air-drying was carried out in a wet atmosphere in order to activate laccase. In case of baking, every coat was heated by an infrared lamp (40~60°C) to give a touch-free surface, and finally the film was heated at 100°C for 1 hr. in an electric drier.

The sample film thus formed on the tin plate was cut into strips, about 1 cm. broad, and these strips were torn off after amalgamation of the tin surface. The dimensions of the test strips we used were 13~15 cm. in length and 30~60 in $b/h$.

Samples Nos. 22—24 were the air-dried films of *sugurome-processed* mixtures of *kiurushi* (10 parts) and catechol derivatives (6 parts). Catechol derivative A was the ester of homoprotocatechuic acid and linseed oil alcohol; B, mixed glyceride of protocatechuic acid and linseed oil fatty acid (1 : 2); C, allyl ester of addition product of catechol and linseed oil fatty acid.

Samples Nos. 25 and 26 were the films of varnishes of phenolic resins, observed in comparison with Japanese lac.

All sample films except those of which the duration of exposure to air are noted in Table I were examined within 10 days after preparation.

## Results and Discussion

The results of the experiments are shown in Table II and Figs. 1—5. The following abbreviations are used: $T$, temperature in °C; $G$, rigidity modulus in dyn./cm²; $\lambda$, logarithmic decrement; $T_g$, glass transition temperasure; $G_g$, rigidity modulus at glass transition temperature; $G_r$, rigidity modulus at 20°C; $G_h$, high temperature rigidity modulus or the minimum rigidity modulus above $T_g$; $\lambda_{max}$, the maximum logarithmic decrement shown at $T_g$. ($T_g$ was defined as the temperature at which $\lambda$ reached the maximum)

**Characteristic *G-T* Relations of Coating Films of Japanese Lac.**—All kinds of coating films formed from synthetic resins show glass transition phenomena. Not to mention the films of thermoplastic resins[9], those of cross-linked polymers, such as epoxy[10], alkyd[11] and phenolic resin varnish[12] change markedly in physical and mechanical properties as the temperature changes through $T_g$, over a relatively narrow temperature range. Below $T_g$ they are in the glassy state, being rigid and a little brittle, and values of $G$ are about $10^{10}$ dyn./cm². Above $T_g$ they are in the rubbery state, being soft and flexible, and values of $G$ range between $10^7$ and $10^8$ dyn./cm², so they lack in mechanical strength. The abrupt change in properties depending upon temperature is undesirable for practical use and, therefore, each kind of coating film can be used in a limited range of temperature.

But it is revealed by the authors' experiment that the coating films of Japanese lac were quite different from and superior to those from usual synthetic resins in their properties.

As shown in Fig. 1, in temperature range around $T_g$, temperature dependence of $G$ of air-dried and baked films of *kiurushi* and *sugurome-urushi* was less than that of Samples Nos. 25 and 26, which were air-dried films of oil varnishes of *o*-cresol resins presented as examples of phenolic resin. $G$ of Japanese lac films changed so mildly with temperature from lower to higher temperature ranges, as $T_g$ could not be determined distinctly from *G-T* curve. $T_g$ was determined from the $\lambda$-$T$ relation and the $\lambda$-$T$ curve, too, was smooth compared with that of the synthetic resin film.

At room temperature, three coating films, except the baked film of *kiurushi*, had ample flexibility in spite of their great rigidity modulus, compared with synthetic resin films.

9) Y. Inoue, *J. Chem. Soc. Japan, Ind. Chem. Sec.* (*Kogyo Kagaku Zasshi*), **63**, 1427 (1960).
10) K. Ueki, ibid., **64**, 1425 (1961).
11) L. W. Chen, unpublished.
12) J. Kumanotani, unpublished.

Among them the air-dried film of *sugurome-urushi* was the most rigid but as flexible as samples Nos. 25 and 26, which were in the rubbery state and had smaller values of $G_r$. Values of $G_h$ of Japanese lac films were, generally, larger than those of synthetic resin films, in which case it was reported that films with $G_h$ greater than $10^8$ dyn./cm$^2$ were insufficient in flexibility[13]. These data of mechanical properties of Japanese lac films showed that the films had an excellent tolerance to temperature change and good adaptability as protective coating films over a wide temperature range.

By $G$-$T$ and $\lambda$-$T$ relations, $G_h$ and $T_g$, we are able to know the deformation behavior of a polymer substance when loaded by mechanical force, and assume the internal polymeric structure of the polymers. $T_g$ increases with the increase of intermolecular forces caused by the polar group, and of the density of the cross-link of polymer molecules. This is because $T_g$ shows the temperature at which thermal energy becomes sufficient to allow segments of polymers to move beyond energy barriers of environments. $G_h$ increases with increase of density of cross-link, the deformation of polymer substance being restricted only by cross-links of molecules at the temperatures enough above $T_g$.

Japanese lac films are cross linked polymers formed by oxidation-polymerization of urushiol, activated with laccase or heat. The cross-linking points are catechol nucleus and double bonds of side chains of urushiol molecules. Therefore the films are considered to have some complicated three dimensional structure. In case of air-drying, the action of laccase contributes to the formation of this characteristic structure. The films are in transitional state, some parts being in the glassy state and the others in the rubbery state over a wide range of temperature and they do not show sharp glass transition. Also the rubber parts increase with the rise of temperature, $G$ and $\lambda$ changing smoothly.

The ideal combination of rigidity and flexibility of the films is also considered to be owing to the characteristic polymer structure of polymerized urushiol with rigid benzene ring and flexible long side chain.

The large values of $G_h$ of Japanese lac films suggested high density of cross-link, but it must be noted that the density of cross-link at high temperature was higher than that at room temperature, because thermal cross-linking reaction took place during the measurement up to the temperature at which $G_h$ was given. This fact was pointed out from comparison of $T_g$ and $G_h$ between Samples No. 8 and No. 9, and between No. 11 and No. 12. And it may be mentioned that the increase of $G$ with temperature above the temperature at which $G_h$ was given was due to both entropy elasticity effect and the increasing density of cross-link.

The above mentioned two characteristics in physical properties of Japanese lac films (1. They do not show sharp glass transition phenomenon. 2. They have ideally combined flexibility and rigidity.) are unique to them.

The films from synthetic Japanese lac may be necessary to be characterized by these points in order to exceed films from other synthetic resins. These characteristics were retained in Samples Nos. 5—21, which are used in practice as Japanese lac films.

**Effect of *Sugurome-process* on Physical and Chemical Properties of Coating Films.**— Coating films from *sugurome-urushi* (Samples Nos. 3, 4, 5, 11, 13) were more fiexible and had lower values of $T_g$, $G_r$ and $G_h$ than films from *kiurushi* (Samples Nos. 1, 2, 8 and 10). The differences in those physical properties were remarkable between them either in case of air-dried films (between No. 1 and No. 3) or baked (between No. 2 and No. 4), or after they were kept in air for 30 months (between No. 8 and No. 11). $T_g$ of baked film from *kiurushi* was valued at 85°C and it lacked in flexibility at room temperature. The cause of the difference is not clear but it may be due to the characteristic unit of polymerization induced by laccase-oxygen(air)-polymerization. Further investigation is needed about the chemical change during the *sugurome-process*. But this traditinal process proved to be very advantageous in preparing qualified coating material of Japanese lac to form air-dried film with a large value of $G_r$ and ample flexibility (Sample No. 3).

Sample No. 5 was also air-dried film of *sugurome-urushi*, but it differed from Sample

No. 3 in physical properties, because the lot of *kiurushi* and conditions of *sugurome-process* and drying process were respective for each. The properties of Sample No. 5 lay between those of Sample No. 1 (from *kiurushi*) and No. 3, and this relationship was retained after time elapsed (Samples Nos. 8, 11 and 13). The quality of Japanese lac may be modified to various extents by changing the condition of the *sugurome-process*.

**Effect of Fillers.**—Linseed oil is used today commonly as a filler for Japanese lac. A mixture of *kiurushi* and linseed oil is *sugurome-processed* and commercialized. Sample No. 16 which was air-dried film of *sugurome-processed* mixture of *kiurushi* (10 parts) and linseed oil (3 parts), had a lower value of $T_g$, about the same value of $G_r$ and a higher value of $G_h$ than Sample No. 3 (from *sugurome-urushi*). No considerable difference was found between *G-T* curves of the two (Figs. 1 and 4), and they were almost identical in mechanical properties. The decrease of $T_g$ was due to the decrease of intermolecular force caused by the addition of the drying oil, and the increase of $G_h$ was due to the increase of cross-link density induced by the reaction of the double bonds.

But in the case of Sample No. 17 (*kiurushi* 10 parts, linseed oil 6 parts), $T_g$ was much depressed to $-45°C$ and values of $G_r$ and $G_h$ also depressed. At high temperatures the oil oozed out of the film. The small values of $\lambda_{max}$ of these samples were due to their plasticity. Those facts indicate that if a large amount of linseed oil is added to Japanese lac, its plasticizing effect deteriorates the physical properties of the film.

*Sugurome-processed* mixture of *kiurushi*, linseed oil and ester gum is called "*shuai-urushi*" and is of general use. Owing to the polar group and polycondensed ring of ester gum, the $T_g$ of air-dried film of *shuai-urushi* (sample No. 19) was rather high but the small value of $G_h$ indicated the small density of cross-link. In baked film (Sample No. 20) values of $G_r$ and $G_h$ were greater than those of baked film from *sugurome-urushi*.

Sample No. 15 was air-dried film from *sugurome processed* mixture of 10 parts of *kiurushi* and 10 parts of urushiol isolated by molecular distillation of alcohol extract from kiurushi, and kept in air for 7 months. The content of laccase of the mixture equalled a half of that of No. 3 (*sugurome-urushi*). The film had a strong esthetic appeal and excellent flexibility, and what is more, values of $T_g$, $G_r$ and $G_h$ were higher than those of Sample No. 11 (Sample No. 3, kept in air for 30 months). Contrary to the case of linseed oil, laccase acted on urushiol very effectively, and it is concluded that if any compound similar to urushiol is obtained, a great amount can be added to Japanese lac.

The principal component of Thailand lac is not urushiol but thithiol, a mixture of 4-heptadecenylcatechols with 1.5~2 double bonds in average. It contains laccase but the content is less than in Japanese lac, and 4-substituted catechol seems to be inferior to 3-substituted catechol in chemical reactivity. Therefore its film formation takes a long time and it is used as a filler for Japanese lac. Sample No. 14 was air-dried film of *sugurome-processed* Thailand lac, kept in air for 30 months. The film was bad in its physical properties and color. Compared with No. 11 (*sugurome-urushi* of Japanese lac), values of $T_g$, $G_r$ and $G_h$ were lower, showing low density of cross-link.

**Effect of Heat and Exposure to Air.**—There are two ways of drying, namely, air-drying and baking. In most cases *sugurome-urushi* is air-dried on articles. Samples Nos. 2, 4 and 20 were baked films of *kiurushi*, *sugurome-urushi* and *shuai-urushi* respectively. Compared with Samples Nos. 1, 3 and 19 (air-dried films), baked films had higher values of $T_g$, $G_r$ and $G_h$, lower value of $\lambda_{max}$ and were less flexible and less glossy than the corresponding air-dried films. These differences in properties between them were also found in the case of No. 8 and No. 10 (after 30 months). The reaction mechanism in film formation is considered to be respective for each drying process.

Samples Nos. 1, 2, 3, 5, 16 and 20 were kept in air for 30 months to investigate changes in physical and chemical properties with time. They were Samples Nos. 8, 10, 11, 13, 18 and 21 respectively. As shown in Table II, changes of values of $T_g$ and $G_r$ for each were as follows:

| Sample | $T_g$, °C | $G_r \times 10^{-9}$, dyn./cm$^2$ |
|---|---|---|
| Air-dried film of kiurushi | 70→100 | 5.2→7.7 |
| Baked film of kiurushi | 85→130 | 7.1→9.7 |
| Air-dried film of sugurome-urushi (No. 3) | 30→ 83 | 1.2→5.4 |
| Air-dried film of sugurome-urushi (No. 5) | 45→ 95 | 5.0→6.8 |
| Air-dried film of sugurome-processed mixture of kiurushi (10 parts) and linseed oil (3 parts) | 10→ 81 | 1.4→6.2 |
| Air-dried film of shuai-urushi | 35→ 86 | 3.6→8.3 |

But concerning the values of $G_h$ of these samples, they were almost unchanged except in the case of air-dried film of *kiurushi* whose $G_h$ changed from $4.8\times10^8$ to $1.1\times10^9$ dyn./cm$^2$.

These facts indicated that the films were oxidized in air, polar groups being formed in polymer molecules. On account of the increase of intermolecular forces caused by the polar groups, the films became rigid at room temperature and values of $T_g$ rose. However, cross-liking did not take place during the exposure except in air-dried film of *kiurushi*. This phenomenon may be associated with the effect of heating or sugurome-process when the film was formed.

Even in the films kept in air for 30 months, thermal cross-linking occurred during the measurement up to 150°C, and as shown in Fig, 3, values of $T_g$, $G_r$ and $G_h$ increaed. (No. 8→ No.9, No. 11→No. 12)

**Evaluation of Synthetic Catechol Derivatives as Fillers.**—As reported in another paper[6], the authors synthesized a series of catechol derivatives for the purpose of obtaining good fillers for Japanese lac. From them the next three compounds were chosen;

A. Ester of homoprotocatechuic acid and linseed oil alcohol
B. Glyceride prepared from 1 mol. of protocatechuic acid, 2 mol. of linseed oil fatty acid and 1 mol. of glycerine.
C. Allyl ester of addition product of catechol and linseed oil fatty acid.

Mixtures of 10 parts of *kiurushi* and 6 parts of catechol derivatives were *sugurome-processed*, and air-dried films shown in Table I were formed, namely, Samples Nos. 22, 23 and 24 respectively. Velocity of the drying was not slow.

Physical data of these samples mesured by the torsional pendulum method are given in Table II and Fig. 5.

Values of $T_g$ of these samples ranged from 0∼10°C, closing that of Sample No. 16 (*kiurushi* 10 parts and linseed oil 3 parts) and far above that of No. 17 (*kiurushi* 10 parts and linseed oil 6 parts, $T_g$; −45°C). Therefore it was evidently approved that these catechol derivatives were much more advantageous than linseed oil as fillers for Japanese lac. Especially the $G-T$ curve of Sample No. 22 was almost identical with that of Sample No. 3 (*sugurome-urushi*). It is considered that catechol derivative A polymerizes together with urushiol under the action of laccase, to form a film almost identical with the film of pure Japanese lac in physical properties.

## Summary

As to Japanese lac some reports are found in literature concerning chemical identification of the lac component, or electrical insulation and resistance of the film to chemical reagents, but no physical and chemical properties related to internal polymer structure of the film had ever been investigated. In this paper the authors studied the physical and chemical properties of the film of Japanese lac by means of the torsional pendulum method.

As the results of the experiment, the following characteristics of the films prepared by various processes from Japanese lac were revealed:

1. The films do not show sharp glass transition phenomenon and are durable as a protective coating over a wide range of temperature.
2. The films from *sugurome-processed* Japanese lac have ample flexibility and considerable rigidity, ideally combined.
3. During exposure to air, the films are oxidized with formation of polar group in polymer molecules. But cross-linking does not take place except in air-dried film of raw Japanese lac.

The above mentioned physical and chemical properties of the film account for the characteristic, complicated three dimensional polymer structure caused by action of laccase and chemical structure of urushiol, and such excellent properties can not be found in any other films from synthetic resins. The results obtained are of practical use and they should be taken into consideration in the study of preparation of fillers or substitutes for Japanese lac.

Catechol derivatives synthesized by the authors were confirmed to be fairly good fillers.

The authors wish to thank Professor Y. Inoue of the Tokyo Institute of Technology for his valuable advice. They are also indebted to the Saitō Shōten, Ltd. for the preparation of the sample films.

# *Non-Empirical Calculation of the π-Electronic Structure of Cyclobutadiene Molecule by Valence Bond Method*

By Shozaburo TAKEKIYO

(Received October 21, 1960)

Non-empirical calculation of the energy levels of the cyclobutadiene molecule was first made by Craig[1] from the point of view of molecular orbital method and later a calculation by valence bond method was performed, by McWeeny[2-4] using orthogonalized atomic orbitals[5].

In the calculation by Craig a complete basis of antisymmetric molecular orbital configurations was taken into considerations and, on the other hand, in the working of McWeeny a complete set of canonical structures was included. Energy levels in both of the methods, therefore, should arrive at a complete agreement theoretically*. But it was pointed out by Shida and Kuri[6] that the numerical value 11.1289 eV. of molecular integral $\gamma_{22}$ in the paper of Craig should be corrected to 10.5586 eV. The difference between these two values may have some effects on the energy levels.

In this paper, therefore, the calculation of the π-electronic energy levels and the wave functions of the molecule is made by valence bond method, including the complete set of canonical structures and considering all kinds of overlap, single exchange, and multiple exchange integrals. The results are compared with those due to ASMO CI calculation.

Calculations are also made in the way of the orthogonalization of atomic orbitals, and Slater functions, and thus the magnitude of the ionic character of the molecule is found. The results are discussed in comparison with those due to the non-orthogonal orbitals.

## Calculation

Cyclobutadiene was assumed to be a square molecule in which the bond distance between two neighboring carbon atoms is 1.40 Å. Slater $2p_\pi$-orbitals were used for the atomic orbitals of the four carbon atoms, with the screening constant $Z_C = 3.18$. π-Electron repulsive integrals were taken from Craig[1] and penetration and core integrals were calculated directly by the present author according to the method of Parr and Mulliken[7]. The canonical structures and the corresponding energies are shown in Fig. 1.

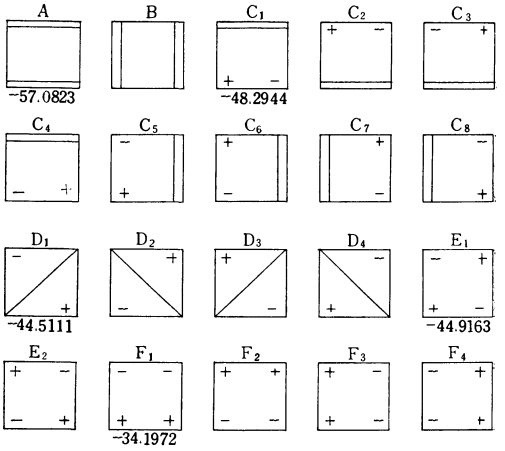

Fig. 1. Canonical structures and the energy values for the structures. (Energies are in electron volts and are relative to $4W_{2p}$, where $W_{2p}$ is the energy of a $2p_\pi$-electron of a carbon atom in its valence state.)

Bases $\Psi_i$'s for irreducible representations of the group, to which the molecule belongs, are given in Table I, where $N_i$ is the normalization constant and $\Psi_K$ is the normalized bond eigenfunction for structure K.

In our approximation the Hamiltonian operator $H$ is expressed in the form

$$H = \sum_i H_{\text{core}}(i) + (1/2)\sum_{\substack{i,\ j \\ i \neq j}} (e^2/r_{ij})$$

where

$$H_{\text{core}}(i) = T(i) + U_{\text{core}}(i)$$

$T(i)$ is the kinetic energy operator for electron $i$ and $U_{\text{core}}(i)$ is the potential energy operator for this electron in the field of the core.

TABLE II. WAVE FUNCTIONS FOR THE MOLECULE AND THE CORRESPONDING ENERGY VALUES

Based on non-orthogonal atomic orbitals

$$\Phi_1({}^1B_{2g})=0.80023\Psi_9+0.26085\Psi_{10}-0.01111\Psi_{11} \qquad E_1=4W_{2p}-58.3517\ \text{eV}.$$
$$\Phi_2({}^1A_{1g})=0.75393\Psi_1+0.32697\Psi_2-0.11784\Psi_3+0.09264\Psi_4-0.00386\Psi_5 \qquad E_2=4W_{2p}-56.3627\ \text{eV}.$$
$$\Phi_3({}^1B_{1g})=0.68396\Psi_6+0.24527\Psi_7+0.21925\Psi_8 \qquad E_3=4W_{2p}-52.6519\ \text{eV}.$$

Based on orthogonalized atomic orbitals

$$\bar{\Phi}_1({}^1B_{2g})=0.82284\bar{\Psi}_9+0.55729\bar{\Psi}_{10}-0.11117\bar{\Psi}_{11} \qquad \bar{E}_1=4\bar{\alpha}+41.8774\ \text{eV}.$$
$$\bar{\Phi}_2({}^1A_{1g})=0.78562\bar{\Psi}_1+0.55233\bar{\Psi}_2-0.01629\bar{\Psi}_3+0.25304\bar{\Psi}_4+0.11591\bar{\Psi}_5 \qquad \bar{E}_2=4\bar{\alpha}+44.0248\ \text{eV}.$$
$$\bar{\Phi}_3({}^1B_{1g})=0.75721\bar{\Psi}_6+0.49877\bar{\Psi}_7+0.42174\bar{\Psi}_8 \qquad \bar{E}_3=4\bar{\alpha}+46.9387\ \text{eV}.$$

are given in Table II. In the table, $\bar{\Phi}_i$'s are the wave functions for the molecule, obtained in the way of the orthogonalization of the atomic orbitals, $\bar{E}_i$'s are the corresponding energy values, and $\bar{\alpha}$ is as follows:

$$\bar{\alpha}=\int\bar{k}(i)H_{\text{core}}(i)\bar{k}(i)\mathrm{d}v_i$$

where $\bar{k}(i)$ is the orthogonalized expression of atomic orbital $k(i)$ of electron $i$ on atom $k$ and $\mathrm{d}v_i$ is the volume element of this electron.

## Ionic Character

Now, ionic characters, evaluated on the basis of non-orthogonal atomic orbitals are generally different from the values, obtained in their orthogonalized representation[5],*1.

Probabilities $P_K$'s of structure K's in both of the ground ${}^1B_{2g}$ state and the first excited ${}^1A_{1g}$ state were calculated from the following expression and the results are shown in Table III.

$$P_K=C_K\sum_L C_L\int\Psi_K\Psi_L\,\mathrm{d}\tau$$

where $C_K$ is the coefficient of normalized bond eigenfunction $\Psi_K$ in $\Phi_1({}^1B_{2g})$ or $\Phi_2({}^1A_{1g})$ and $\mathrm{d}\tau$ is the product of the volume element for all the $\pi$-electrons.

*1 It does not appear that considerations of such discrepancies for $\pi$-electronic systems have been made.

TABLE III. PROBABILITIES OF STRUCTURES

Based on non-orthogonal atomic orbitals

| $A=B$ | $C_i$ | $D_i$ | $E_i$ | $F_i$ |
|---|---|---|---|---|
| Ground ${}^1B_{2g}$-state | | | | |
| 0.3924 | 0.0265 | 0.0008 | 0 | 0 |
| First excite ${}^1A_{1g}$-state | | | | |
| 0.3503 | 0.0300 | 0.0054 | 0.0194 | −0.0002 |

Based on orthogonalized atomic orbital

| $A=B$ | $C_i$ | $D_i$ | $E_i$ | $F_i$ |
|---|---|---|---|---|
| Ground ${}^1B_{2g}$-states | | | | |
| 0.3385 | 0.0388 | 0.00309 | 0 | 0 |
| First excited ${}^1A_{1g}$-state | | | | |
| 0.3086 | 0.0381 | 0.0001 | 0.0320 | 0.0034 |

From these results, ionic characters are

$$
{}^1B_{2g}\text{ state}\begin{cases}
21.517\% & \text{based on } k(i)\\
32.293\% & \text{based on } \bar{k}(i)
\end{cases}
$$

$$
{}^1A_{1g}\text{ state}\begin{cases}
29.946\% & \text{based on } k(i)\\
38.280\% & \text{based on } \bar{k}(i)
\end{cases}
$$

In the ${}^1B_{2g}$ and ${}^1A_{1g}$ states the ionic characters based on $\bar{k}(i)$ are larger than on $k(i)$ by 10.776% and 8.334%, respectively.

Bond orders $B_{ij}$'s between neighboring two carbon atoms $i$ and $j$ were evaluated by formula

$$B_{ij}=\sum_K P_K(n_{ij}^K+1)$$

where $n_{ij}^K$ is the number of the $\pi$-electronic

covalent bonds between carbon atoms $i$ and $j$ in structure K. The results are

$^1B_{2g}$ state { 1.445 based on $k(i)$ ; 1.416 based on $\bar{k}(i)$

$^1A_{1g}$ state { 1.410 based on $k(i)$ ; 1.385 based on $\bar{k}(i)$

Double bond characters based on $k(i)$ are larger by 2.92% and 2.52% than these based on $\bar{k}(i)$ the $^1B_{2g}$ and $^1A_{1g}$ states, respectively.

## Discussion

Energy levels of the molecule, calculated by various methods, are shown diagrammatically in Fig. 2.

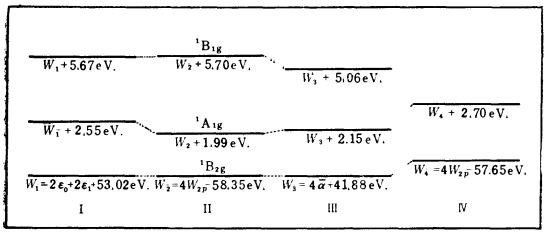

Fig. 2. Comparison of energy levels.

I. ASMOCI method[1]. II. VB method (based on non-orthogonal atomic orbitals). III. VB method (based on orthogonalized atomic orbitals). IV. Heitler-London method.

The $^1A_{1g}$ level evaluated by the present author (II) is lower by 0.56 eV. relatively than that of Craig. But influences of the difference in the values of the molecular integral on the other levels hardly appear at all*2.

One of the causes for the discrepancies of the ionic characters in the two ways is that, in the cases of the use of the orthogonalized atomic orbitals, exchange integrals which appear in the interactions of covalent structures give generally repulsive forces.

Actually, in the case of an exchange integral $\bar{J}$,

$$\bar{J}=\int\cdots\cdots\bar{a}(1)\bar{b}(2)\bar{c}(3)\bar{d}(4)\cdots\cdots H \cdots\cdots\bar{a}(1)\bar{c}(2)\bar{b}(3)\bar{d}(4)\cdots\cdots d\tau$$

is expanded as follows and $\bar{J}$ is, therefore, equal to $(\bar{b}\bar{c}|\bar{b}\bar{c})$.

$$\bar{J}=\sum_{\substack{k\\ k\neq b,\,c}}\bar{\alpha}_k\bar{S}_{bc}^2+2\bar{\beta}_{bc}\bar{S}_{bc}+(1/2)\sum_{\substack{k,\,l\\ k\neq b,\,c\\ l\neq b,\,c,\,k}}(\bar{k}\bar{k}|\bar{l}\bar{l})\bar{S}_{bc}^2+2\sum_{\substack{k\\ k\neq b,\,c}}(\bar{k}\bar{k}|\bar{b}\bar{c})\bar{S}_{bc}+(\bar{b}\bar{c}|\bar{b}\bar{c})$$

where

$$\bar{\alpha}_k=\int\bar{k}(i)H_{\mathrm{core}}(i)\bar{k}(i)\,dv_i\text{*3}$$

$$\bar{\beta}_{kl}=\int\bar{k}(i)H_{\mathrm{core}}(i)\bar{l}(i)\,dv_i$$

$$\bar{S}_{kl}=\int\bar{k}(i)\bar{l}(i)\,dv_i$$

$$(\bar{k}\bar{l}|\bar{p}\bar{q})=e^2\int(1/r_{ij})\bar{k}(i)\bar{l}(i)\bar{p}(j)\bar{q}(j)\,dv_i\,dv_j$$

From similar analyses multiple exchange integrals lead to zeros. In the use of the orthogonalized atomic orbitals, therefore, the weight of the covalent structures appears generally smaller than in the use of the non-orthogonal orbitals.

Accordingly, when $\pi$-electron densities or bond orders etc. are considered as the measure of chemical reactivities, it will be necessary for attention to be given to the discrepancies of these values in the two ways.

## Summary

$\pi$-Electronic energy levels, probalities of the resonance structures, and bond orders of cyclobutdiene molecule have been calculated by the valence bond method on the bases of two ways, one is based on non-orthogonal atomic orbitals and the other on their orthogonalization. Calculated ionic characters are 21.517% (ground $^1B_{2g}$ state), 29.946% (first excited $^1A_{1g}$ state) in the former and 32.293%, 38.280% in the latter. Bond orders between neighboring carbon atoms are 1.445, 1.410 and 1.416, 1.385 respectively.

The author wishes to express his hearty thanks to Professor Kyosuke Omori, Kyushu University, for his kind guidance and encouragement throughout this study.

Thanks are also due to Professor Saburo Nagakura, the University of Tokyo, for his valuable advice.

*Faculty of Liberal Arts*
*Nagasaki University*
*Ohashi, Nagasaki*

*2 Relative differences of levels between II and III in Fig. 2 seem to be due to the approximate orthogonalization of atomic orbitals[4,5].

*3 Since atoms except carbon are generally included in $\pi$-electronic system, $\bar{\alpha}_k$ is here to be distinguished from $\bar{\alpha}$ in the previous paragraph.

# *Statistical Thermodynamics of Solutions of Optically Active Substances. I. Excess Free Energy of Binary Solution of d- and l-Isomers*

By Kazuo AMAYA

(Received March 1, 1961)

In recent years considerable progress has been made in the field of the theory of solutions and the fundamental features of various types of binary solutions such as polymer solutions, and associated solutions, etc. were explained theoretically. However, there seem to be no papers which treat the problem of of the solutions containing optical isomers. In this paper the idea of interaction of surface points in groups will be introduced to elucidate the fundamental features of the solution consisting of optical isomers.

## The Model of the Solutions of Optical Isomers

In the statistical mechanical lattice theory of solutions of anisotropic molecules, the model usually adopted is that the surface of the molecule is devided into a definite number of contact points and each contact point is grouped into an energetically equivalent element and the number of contact points belonging to each group has a definite value. The configurational energy of the system is a sum of interaction energies of the pairs of each contact point. In such a model, however, the mutual configuration of different kinds of elements in one and the same molecule is not taken into account.

According to the above model, the molecules of *d*- and *l*-optical isomers have the same number of contact points of the same kind of elements, so that these two kinds of molecules cannot be distinguished. In order to distinguish one isomer from the other, mutual configuration of contact points of different kinds in one and the same molecule must be introduced into the above model, and at least three contact points of different kinds of elements must interact in groups at a time.

To meet the above requirement the following model is proposed.

(1) The molecule is a regular polyhedron composed of $z$ planes of which one consists of $a$-element and the remaining $z-1$ ones are consist of $b$-elements, and further, the $a$-element is composed of three sub-elements 1, 2, 3, the arrangement of these three elements, viewed toward the plane from the outside of the molecule along the direction normal to it, is in the order, 1, 2, 3 clockwise for *d*-isomers and 1, 3, 2 for *l*-isomers, the mirror image of *d*-isomers.

(2) Each molecule occupies one site of the quasi-crystalline lattice of $z$ nearest neighbors, and the molecular axis which passes the center of the molecule and the $a$-plane composed of $a$-element can take $z$ directions. When the direction is specified, it can take 3 further different arrangements by the rotation around the axis and thus the molecule at one site can have $3z$ orientational freedom in all*.

(3) The molecules contact with plane to plane and the total configurational energy of the system is the sum of the interaction energy of pairs of planes, the kind of pair of planes is $a-a$, $a-b$ and $b-b$ and the $a-a$ pair contains 6 kinds of sub pairs, 11, 22, 33, 12, 13 and 23 and ab pair 3 kinds of sub pairs, $b1$, $b2$ and $b3$. If $a$-elements of *l*-isomers and *d*-isomers are denoted by $a_l$ and $a_d$ respectively, the $a_l-a_l$ pair can take 3 configurations $\begin{pmatrix}1&2&3\\1&3&2\end{pmatrix}$, $\begin{pmatrix}1&2&3\\2&1&3\end{pmatrix}$ and $\begin{pmatrix}1&2&3\\3&2&1\end{pmatrix}$ with interaction energy $\omega_{11}+2\omega_{23}$, $2\omega_{12}+\omega_{33}$ and $2\omega_{13}+\omega_{22}$ respectively, where $\omega_{ij}$ denotes the interaction energy of a pair of $i$ and $j$ element.

For $a_d-a_d$ pair the same value of interaction energy is obtained for each configuration. For $a_l-a_d$ pair, three configurations are represeted $\begin{pmatrix}1&2&3\\1&2&3\end{pmatrix}$, $\begin{pmatrix}1&2&3\\3&1&2\end{pmatrix}$ and $\begin{pmatrix}1&2&3\\2&3&1\end{pmatrix}$ with interaction energy $\omega_{11}+\omega_{22}+\omega_{33}$, $\omega_{12}+\omega_{13}+\omega_{23}$ and $\omega_{12}+\omega_{13}+\omega_{23}$ respectively, can take place.

$\begin{pmatrix}1&2&3\\1&2&3\end{pmatrix}$ means the configuration in which sub elements 1, 2 and 3 of $a_d$ plane of *d*-isomers interact with sub element of 1, 2 and 3 of $a_l$ plane of *l*-isomers forming sub pairs 11, 22 and 33. Generally, distinguishable pairs are obtained by cycling the lower row of numbers without permutation.

## The Configurational Partition Function and the Excess Free Energy

Using the above model, the configurational partition functions and the excess free energy

* Strictly speaking the regular polyhedron must have a symmetry of $C_{3n}$ around all of $z$ axes passing through the center of the molecule and that of each of $z$ planes.

of the binary system of *d*- and *l*-optical isomers were derived based on the method of expansion of Kirkwood[1].

Generally configurational partition function $\Omega$ is, by definition, expressed as

$$\Omega=\sum e^{-E/kT} \tag{1}$$

where $E$ denotes the potential energy of a system for a particular configuration and summation is carried out over all configurations.

For the system of pure *l*-isomers, its configurational partition function $\Omega_l$ is represented

$$\begin{aligned}\Omega_l&=\sum e^{-E_l/kT}=e^{-\bar{E}_l/kT}(\sum e^{-(E_l-\bar{E}_l)/kT})\\&=e^{-\bar{E}_l/kT}(\sum e^{-W_l/kT})\end{aligned} \tag{2}$$

where $E_l$ denotes the potential energy of the system of pure *l*-isomers and $\bar{E}_l$ denotes the unweighted average of $E_l$ over all configurations and $W_l$ denotes $E_l-\bar{E}_l$. If $g_l$ denotes the number of distinguishable configurations of the system consisting of $N_l$ molecules of *l*-isomer, then the configurational partition function of the system is expressed, following Kirkwood[1], as

$$\ln\Omega_l-\ln g_l-\frac{N_l\chi_l}{\boldsymbol{kT}}=\sum\ln\frac{1}{g_l}\sum e^{-W_l(N_l)/kT} \tag{3}$$

where $N_l\chi_l=\bar{E}_l$ and $g_l$ according to the above model, is equal to $(3z)^{N_l}$.

By the use of an auxiliary quantity $h_l$ defined by

$$h_l=1-\frac{1}{g_l}\sum e^{-W_l(N_l)/kT} \tag{4}$$

Eq. 3 can be rewritten as

$$\begin{aligned}&\ln\Omega_l-N_l\ln 3z-\frac{N_l\chi_l}{\boldsymbol{kT}}\ln(1-h_l)\\&=-h_l-\frac{1}{2}h_l^2-\frac{1}{3}h_l^3-\frac{1}{4}h_l^4-\cdots\cdots\end{aligned} \tag{5}$$

If the $h_l$ in Eq. 4 is expanded in powers of $W_l(N_l)/\boldsymbol{kT}$, the following formula is obtained.

$$\begin{aligned}h_l=&\frac{\langle W_l(N_l)\rangle_{Av.}}{\boldsymbol{kT}}-\frac{\langle W_l^2(N_l)\rangle_{Av.}}{2!\ (\boldsymbol{kT})}\\&+\frac{\langle W_l^3(N_l)\rangle_{Av.}}{3!\ (\boldsymbol{kT})^3}-\cdots\cdots\end{aligned} \tag{6}$$

where $\langle W_l(N_l)\rangle_{Av.}$ denotes the unweighted average of $W_l(N_l)$ over all configurations, and similarly $\langle W_l^t(N_l)\rangle_{Av.}$ denotes the unweighted average of the $t$ th power of $W_l(N_l)$ over all configurations. Substituting 6 into 5 the following expression is obtained.

$$\begin{aligned}&\ln\Omega_l-N_l\ln 3z-\frac{N_l\chi_l}{\boldsymbol{kT}}=-\frac{\langle W_l(N_l)\rangle_{Av.}}{\boldsymbol{kT}}\\&-\{\langle W_l(N_l)\rangle^2_{Av.}-\langle W_l^2(N_l)\rangle_{Av.}\}/2!\ (\boldsymbol{kT})^2\\&-\{\langle W_l^3(N_l)\rangle_{Av.}\\&-3\langle W_l(N_l)\rangle_{Av.}\langle W_l(N_l)\rangle_{Av.}\}/3!\ (\boldsymbol{kT})^3\\&-\{2\langle W_l(N_l)\rangle^3_{Av.}\}/3!\ (\boldsymbol{kT})^3-\cdots\cdots\end{aligned} \tag{7}$$

As $\bar{E}_l$ is the unweighted average of $E_l$, it follows that

$$\langle W_l(N_l)\rangle_{Av.}=\overline{(E_l-\bar{E}_l)}=\bar{E}_l-\bar{E}_l=0 \tag{8}$$

Then Eq. 7 is rewritten as

$$\begin{aligned}&\ln\Omega_l-N_l\ln 3z-\frac{N_l\chi_l}{\boldsymbol{kT}}=\frac{\langle W_l^2(N_l)\rangle_{Av.}}{2!\ (\boldsymbol{kT})^2}\\&-\frac{\langle W_l^3(N_l)\rangle_{Av.}}{3!\ (\boldsymbol{kT})^3}-\cdots\cdots\end{aligned} \tag{9}$$

Similarly, for the system of $N_d$ *d*-isomers, the following expression is obtained.

$$\begin{aligned}&\ln\Omega_d-N_d\ln 3z-\frac{N_d\chi_d}{\boldsymbol{kT}}=\frac{\langle W_d^2(N_d)\rangle_{Av.}}{2!\ (\boldsymbol{kT})^2}\\&-\frac{\langle W_d^3(N_d)\rangle_{Av.}}{3!\ (\boldsymbol{kT})^3}-\cdots\cdots\end{aligned} \tag{10}$$

In the following, it will be shown that $\chi_l$ is equal to $\chi_d$. As $\chi_l$ is the unweighted average of $E_l$ over all configurations, $\chi_l$ is proportional to

$$\bar{\omega}_{a_l-a_l}+2(z-1)\bar{\omega}_{a_l-b}+(z-1)^2\bar{\omega}_{b-b} \tag{11}$$

and similarly $\chi_d$ is proportional to

$$\bar{\omega}_{a_d-a_l}+2(z-1)\bar{\omega}_{a_d-b}+(z-1)^2\bar{\omega}_{b-b} \tag{12}$$

where $-$ denotes the unweighted average and $\omega_{a_l-a_l}$, $\omega_{a_l-a_d}$, $\omega_{a_l-b}$, $\omega_{a_d-b}$ and $\omega_{b-b}$ denote the interaction energy of $a_l-a_l$, $a_d-a_d$, $a_l-b$, $a_d-b$ and $b-b$ plane pairs respectively.

Further, according to the assumption made above, the following relation is obtained.

$$\begin{aligned}\bar{\omega}_{a_l-a_l}&=\frac{1}{3}\{\omega_{11}+\omega_{22}+\omega_{33}+2(\omega_{12}+\omega_{23}+\omega_{31})\}\\&=\bar{\omega}_{a_d-a_d}\end{aligned} \tag{13}$$

Thus each of three different configurations of $a_l-a_l$ $a_d-a_d$ pair of plane have the same interaction energy. Further

$$\bar{\omega}_{a_l-b}=\omega_{1b}+\omega_{2b}+\omega_{3b}=\bar{\omega}_{a_d-b} \tag{14}$$

From 11, 12, 13 and 14, we obtain

$$\chi_l=\chi_d=\chi_0 \tag{15}$$

As is stated above, the interaction energy of the pairs of planes in *l*-isomers $\omega_{a_l-a_l}$, $\omega_{a_l-b}$ and $\omega_{b-b}$ and in *d*-isomers $\omega_{a_d-a_d}$, $\omega_{a_d-b}$ and $\omega_{b-b}$ have the same value, and the total energy $E$ is the sum of such interaction energies of pairs of planes. Further for one specified configuration in the system consisting of $N_0$ molecules of *l*-isomers, with a specified number of pairs of $a_l-a_l$, $a_l-b$ and $b-b$ plane contacts,

1) J. G. Kirkwood, *J. Chem. Phys.*, **6**, 70 (1938).

there exists the corrsponding configuration in the system contisting of $N_0$ molecules of *d*-isomers, for, one to one correspondence exists between both isomers.

Then the total configurational energy for one specified configuration for *l*-isomers is equal to that of the corresponding configuration in $\alpha$-isomers, that is

$$E_l = E_d \tag{16}$$

and hence

$$W_l(N_0) = W_d(N_0) = W_0(N_0) \tag{17}$$

For $d-l$ mixtures consisting of $N_l$ *l*-isomers and $N_d$ *d*-isomers, the configurational partition function $\Omega_{dl}$ is expressed as

$$\begin{aligned}
&\ln \Omega_{dl} - N\ln 3z - \ln \frac{N!}{(Nx)!\,\{N(1-x)\}!} \\
&- N\cdot\chi_{ld}(x)/\boldsymbol{kT} = -\langle W_{dl}(N,x)\rangle_{Av.}/\boldsymbol{kT} \\
&- \{\langle W_{dl}(N,x)\rangle^2_{Av.} \\
&- \langle W^2_{dl}(N,x)\rangle_{Av.}\}/2!\,(\boldsymbol{kT})^2 \\
&- \{\langle W^3_{dl}(N,x)\rangle_{Av.} - 3\langle W^2_{dl}(N,x)\rangle_{Av.} \\
&\cdot\langle W_{dl}(N,x)\rangle_{Av.}\}/3!\,(\boldsymbol{kT})^3 \\
&- 2\langle W_{dl}(N,x)\rangle^3_{Av.}/3!\,(\boldsymbol{kT})^3
\end{aligned} \tag{18}$$

where $N=N_l+N_d$ and $N\cdot\chi_{dl}(x)$ is the unweighted mean of interaction energy of the system and $x=N_l/N$. Since $\chi_{dl}(x)$ is proportional to

$$\begin{aligned}
&x^2\{\bar{\omega}_{a_l-a_l} + 2(z-1)\bar{\omega}_{a_l-b} + (z-1)^2\omega_{b-b}\} \\
&+ 2(1-x)x\{\omega_{a_l-a_d} + (z-1)(\omega_{a_l-b}+\omega_{a_d-b}) \\
&+ (z-1)^2\omega_{b-b}\} + (1-x)^2 \\
&\{\omega_{a_d-a_d} - 2(z-1)\bar{\omega}_{a_d-b} + (z-1)^2\omega_{b-b}\}
\end{aligned} \tag{19}$$

$\bar{\omega}_{a_l-a_d}$ is the mean of three interaction energies

$$\omega_{11}+\omega_{22}+\omega_{33},\ \omega_{12}+\omega_{23}+\omega_{31},\ \omega_{12}+\omega_{23}+\omega_{31}$$

Each term differs from that of $\omega_{a_l-a_l}$ or $\omega_{a_d-a_d}$ but the unweighted mean over these three configurations, becomes the same value as follows:

$$\begin{aligned}
\bar{\omega}_{a_d-a_l} &= \frac{1}{3}(\omega_{11}+\omega_{22}+\omega_{33}+\omega_{12}+\omega_{23}+\omega_{31} \\
&\quad +\omega_{12}+\omega_{23}+\omega_{31}) \\
&= \frac{1}{3}\{\omega_{11}+\omega_{22}+\omega_{33}+2(\omega_{12}+\omega_{23}+\omega_{31})\} \\
&= \omega_{a_l-a_l} = \omega_{a_d-a_d}
\end{aligned} \tag{20}$$

Hence, from 19, 20, 11 and 12, we have

$$\chi_{dl}(x) = \chi_l = \chi_d = \chi_0 \tag{21}$$

$$\langle W_{dl}(N,x)\rangle_{Av.} = \overline{(E_{dl}-\bar{E}_{dl})} = \bar{E}_{dl} - \bar{E}_{dl} = 0 \tag{22}$$

For the system consisting of $N$ *d*-isomers or $N$ *l*-isomers, free energy is expressed as

$$\begin{aligned}
F_d = F_l &= -\boldsymbol{kT}\ln\Omega_0 = N\boldsymbol{kT}\ln 3z + N\chi_0 \\
&+ \frac{\langle W^2_0(N)\rangle_{Av.}}{2!\,(\boldsymbol{kT})} - \frac{\langle W^3_0(N)\rangle_{Av.}}{3!\,(\boldsymbol{kT})^2} + \cdots\cdots
\end{aligned} \tag{23}$$

For $d-l$ mixtures consisting of $N_l(=Nx)$ molecules of *l*-isomer and $N_d$ $(=N(1-x))$ molecules of *d*-isomer, we obtain

$$\begin{aligned}
F_{dl} &= -\boldsymbol{kT}\ln\Omega_{dl} = N\boldsymbol{kT}\ln 3z + N\chi_0 \\
&+ N\boldsymbol{kT}\{x\ln x + (1-x)\ln(1-x)\} \\
&+ \frac{\langle W^2_{dl}(N,x)\rangle_{Av.}}{2(\boldsymbol{kT})} - \frac{\langle W^3_{dl}(N,x)\rangle_{Av.}}{3!\,(\boldsymbol{kT})^2} \\
&+ \cdots\cdots
\end{aligned} \tag{24}$$

As each configuration has a different energy, that is $W_{dl}=(N,x)\neq W_0(N)$, then the free energy of mixing $\Delta F_m$ is represented as

$$\begin{aligned}
\Delta F_m &= N\boldsymbol{kT}\{x\ln x + (1-x)\ln(1-x)\} \\
&+ \frac{1}{2(\boldsymbol{kT})}\{\langle W^2_{dl}(N,x)\rangle_{Av.} - \langle W^2_0(N_l)\rangle_{Av.} \\
&- \langle W^2_0(N_d)\rangle_{Av.}\} - \frac{1}{3!\,(\boldsymbol{kT})^2} \\
&\times\{\langle W^3_{dl}(N,x)\rangle_{Av.} - \langle W^3_0(N_l)\rangle_{Av.} \\
&- \langle W^3_0(N_d)\rangle_{Av.}\} + \cdots\cdots
\end{aligned} \tag{25}$$

Then the problem is reduced to a calculation of second and heigher powers of $W_{dl}(N,x)$, $W_0(N_l)$ and $W_0(N_d)$. Now $\langle W^2_0(N_l)\rangle$, $\langle W^2_0(N_d)\rangle$ and $W^2_{dl}(N)$ will be considered.

According to the model mentioned above, potential energy $E$ of the system consisting of $N$ molecules of *l*- or *d*-isomers with the particular configuration having $N_{bb}$ *bb* pairs, $N_{ab}$ *ab* pairs, $N_{aa_1}$ $aa_1$ pairs, $N_{aa_2}$ $aa_2$ pairs and $N_{aa_3}$ $aa_3$ pairs, where $aa_1$, $aa_2$ and $aa_3$ denote three kinds of *aa* contact, is expressed as

$$\begin{aligned}
E &= N_{bb}\omega_{bb} + N_{ab}\omega_{ab} + N_{aa_1}\omega^0_{aa_1} + N_{aa_2}\omega^0_{aa_2} \\
&+ N_{aa_3}\omega^0_{aa_3}
\end{aligned} \tag{26}$$

where $\omega^0_{aa_1}$, $\omega^0_{aa_2}$ and $\omega^0_{aa_3}$ denote those interaction energies corresponding to $aa_1$, $aa_2$ and $aa_3$ pairs respectively and these values are $\omega_{11}+2\omega_{23}$, $\omega_{22}+2\omega_{13}$ and $\omega_{33}+2\omega_{12}$ respectively. Then the average value $E$ becomes

$$\begin{aligned}
E &= \bar{N}_{bb}\omega_{bb} + \bar{N}_{ab}\omega_{ab} + \bar{N}_{aa_1}\omega_{aa_1} \\
&+ \bar{N}_{aa_2}\omega_{aa_2} + \bar{N}_{aa_3}\omega_{aa_3} \\
&= \frac{1}{2}zN\left\{\frac{(z-1)^2}{z^2}\omega_{bb} + \frac{2(z-1)}{z^2}\omega_{ab}\right. \\
&\left. + \frac{1}{z^2}\cdot\frac{1}{3}(\omega_{aa_1}+\omega_{aa_2}+\omega_{aa_3})\right\}
\end{aligned} \tag{27}$$

As $W_0(N)$ means the difference between the

potential energy of the system of particular configuration and that averaged over all configurations, $W_0(N)$ for the particular configuration mentioned above becomes

$$W_0(N)=E-\bar{E}=\left\{N_{bb}-\frac{1}{2}N\frac{(z-1)^2}{z}\right\}\omega_{bb}+\left\{N_{ab}-\frac{N(z-1)}{z}\right\}\omega_{ab}+N_{aa_1}\omega^0_{aa_1}+N_{aa_2}\omega^0_{aa_2}+N_{aa_3}\omega^0_{aa_3}-\frac{1}{6}\frac{N}{z}(\omega^0_{aa_1}+\omega^0_{aa_2}+\omega^0_{aa_3}) \quad (28)$$

In calculating $\langle W_0^2(N)\rangle_{Av.}$, we must strictly take the average over all possible configurations. However, since of all configurations the configurations with $N_{bb}=\bar{N}_{bb}$, $N_{ab}=\bar{N}_{ab}$ and $\sum_{i=1}^{3}N_{aa_i}=\bar{N}_{aa}$ occupy the predominant part, and the average over these configurations, may differ very little from that over all configurations, we approximately take the former average in place of the latter. Then

$$W_0(N)=\sum_{i=1}^{3}{}'N_{aa_i}\omega^0_{aa_i}-\frac{1}{6}\frac{N}{z}(\sum_{i=1}^{3}\omega^0_{aa_i}) \quad (29)$$

where $\sum'$ donates the summation under the restriction that $\sum_{i=1}^{3}N_{aa_i}=1/2\cdot N/z$ and $\langle W_0^2(N)\rangle_{Av.}$ becomes

$$\langle W_0^2(N)\rangle=\overline{(\sum_{i=1}^{3}{}'N_{aa_i}\omega^0_{aa_i})^2}-2\sum_{i=1}^{3}{}'N_{aa_i}\omega^0_{aa_i}\times\frac{1}{6}\frac{N}{Z}(\sum_{i=1}^{3}\omega^0_{aa_i})+\left(\frac{1}{6}\frac{N}{z}\sum_{i=1}^{3}\omega^0_{aa_i}\right)^2=(\sum_{i=1}^{3}{}'N_{aa_i}\omega^0_{aa_i})^2-\left(\frac{1}{6}\frac{N}{z}\sum_{i=1}^{3}\omega^0_{aa_i}\right)^2 \quad (30)$$

As all configurations of *aa* pair can take place with equal probability the first term of 30 becomes

$$(\sum_{i=1}^{3}{}'N_{aa_i}\omega^0_{aa_i})^2=\left(\frac{1}{2}\frac{N}{z}\right)^2\int_0^1\int_0^y[\{\omega^0_{aa_1}x+\omega^0_{aa_2}(y-x)\}+\omega^0_{aa_3}(1-y)]^2dxdy=\left(\frac{1}{2}\frac{N}{z}\right)^2\frac{1}{6}(\omega^{0^2}_{aa_1}+\omega^{0^2}_{aa_2}+\omega^{0^2}_{aa_3}+\omega^0_{aa_1}\omega^0_{aa_2}+\omega^0_{aa_2}\omega^0_{aa_3}+\omega^0_{aa}\omega^0_{aa_1}) \quad (31)$$

Substituting 31 into 30 the following formula is obtained:

$$\langle W_0^2(N)\rangle_{Av}=\left(\frac{1}{2}\frac{N}{z}\right)^2\cdot\frac{1}{36}\{(\omega^0_{aa_1}-\omega^0_{aa_2})^2+(\omega^0_{aa_2}-\omega^0_{aa_3})^2+(\omega^0_{aa_3}-\omega^0_{aa_1})^2\} \quad (32)$$

For the system consisting of $N_l$ molecules of *l*-isomers and $N_d$ molecules of *d*-isomer, $\langle W_{dl}^2(Nx)\rangle$, where $N=N_l+N_d$ and $x=N_l/(N_l+N_d)$, can be obtained in a similar way. In this case the average may be taken over the configurations in which $N^{ll}_{aa}=\overline{N^{ll}_{aa}}=Nx^2/2z$, $N^{dl}_{aa}=\overline{N^{dl}_{aa}}=Nx(1-x)/z$ and $N^{dd}_{aa}=\overline{N^{ll}_{aa}}=N(1-x)^2/2z$ where $N^{ll}_{aa}$, $N^{dl}_{aa}$ and $N^{dd}_{aa}$ are the number of pairs of $a_l-a_l$, $a_l-a_d$ and $a_d-a_d$ respectively. The $a_l-a_d$ pair can have three different configuration with corresponding interaction energies $\omega^{ld}_{aa_1}$, $\omega^{ld}_{aa_2}$ and $\omega^{ld}_{aa_3}$. As mentioned above $\omega^{ld}_{aa_1}=\omega_{11}+\omega_{22}+\omega_{33}$, $\omega^{ld}_{aa_2}=\omega^{ld}_{aa_3}=\omega_{12}+\omega_{13}+\omega_{23}$, then

$$\sum_{i=1}^{3}\omega^{ld}_{aa_i}=\omega_{11}+\omega_{22}+\omega_{33}+2(\omega_{12}+\omega_{13}+\omega_{23})=\sum_{i=1}^{3}\omega^{ll}_{aa_i}=\sum_{i=1}^{3}\omega^{dd}_{aa_i}=\sum_{i=1}^{3}\omega^0_{aa_i} \quad (33)$$

From 33 the following expressions are obtained.

$$W_{dl}(N,x)=\sum_{i=1}^{3}{}'(N^{ll}_{aa_i}\omega^{ll}_{aa_i}+N^{dd}_{aa_i}\omega^{ld}_{aa_i}+N^{dd}_{aa_i}\omega^{dd}_{aa_i})-\frac{1}{6}\frac{N}{z}(\sum_{i=1}^{3}\omega^0_{aa_i})=\sum_{i=1}^{3}{}'\left\{N^{ll}_{aa_i}\omega^{ll}_{aa_i}-\frac{Nx^2}{2z}\left(\frac{1}{3}\sum_{i=1}^{3}\omega^{ll}_{aa_i}\right)\right\}+\sum_{i=1}^{3}{}'\left\{N^{ld}_{aa_i}\omega^{ld}_{aa_i}-\frac{Nx(x-1)}{z}\left(\frac{1}{3}\sum_{i=1}^{3}\omega^{dl}_{aa_i}\right)\right\}+\sum_{i=1}^{3}{}'\left\{N^{dd}_{aa_i}\omega^{dd}_{aa_i}-\frac{N(1-x)^2}{2z}\left(\frac{1}{3}\sum_{i=1}^{3}\omega^{dd}_{aa_i}\right)\right\} \quad (34)$$

where $\sum'$ denotes the summation under the restrictions that $\sum_{i=1}^{3}N^{ll}_{aa_i}=Nx^2/2Z$, $\sum_{i=1}^{3}N^{dl}_{aa_i}=Nx(1-x)/z$ and $\sum_{i=1}^{3}N^{dd}_{aa_i}=(1-x)^2/2z$. Since the mean values in $\{\ \}$ of 34 become zero, then

$$\begin{aligned}\langle W_{dl}^2(N,x)\rangle_{Av}=&\left(\frac{1}{2}\frac{N}{z}x^2\right)^2\cdot\frac{1}{36}\{(\omega^{ll}_{aa_1}-\omega^{ll}_{aa_2})^2+(\omega^{ll}_{aa_2}-\omega^{ll}_{aa_3})^2+(\omega^{ll}_{aa_3}-\omega^{ll}_{aa_1})^2\}\\&+\left\{\frac{Nx(1-x)}{z}\right\}^2\cdot\frac{1}{36}\{(\omega^{dl}_{aa_1}-\omega^{dl}_{aa_2})^2+(\omega^{dl}_{aa_2}-\omega^{dl}_{aa_3})^2+(\omega^{dl}_{aa_3}-\omega^{dl}_{aa_1})^2\}\\&+\left\{\frac{1}{2}\frac{N}{z}(1-x)^2\right\}^2\cdot\frac{1}{36}\{(\omega^{dd}_{aa_1}-\omega^{dd}_{aa_2})^2+(\omega^{dd}_{aa_2}-\omega^{dd}_{aa_3})^2+(\omega^{dd}_{aa_3}-\omega^{dd}_{aa_1})^2\}\\=&\left(\frac{1}{2}\frac{N}{z}\right)^2\{x^4+(1-x)^4\}\cdot\frac{1}{36}\times\{(\omega^0_{aa_1}-\omega^0_{aa_2})^2+(\omega^0_{aa_2}-\omega^0_{aa_3})^2+(\omega^0_{aa_3}-\omega^0_{aa_1})^2\}+\left(\frac{N}{z}\right)x^2(1-x)^2\times\frac{1}{36}\{(\omega^{dl}_{aa_1}-\omega^{dl}_{aa_2})^2+(\omega^{dl}_{aa_2}-\omega^{dl}_{aa_3})^2+(\omega^{dl}_{aa_3}-\omega^{dl}_{aa_1})^2\}\end{aligned} \quad (35)$$

If the terms higher than second power of $W$ in 25 are neglected, free energy of mixing $\Delta_m F$ or excess free energy $F^E$ may be expressed as

$$\begin{aligned}\Delta_m F - NkT\{x\ln x+(1-x)\ln(1-x)\} &= F^E \\ &= -\frac{1}{2kT}\left[\left(\frac{1}{2}-\frac{N}{z}\right)^2\{x^4+(1-x)^4 \right. \\ &\quad -x^2-(1-x)^2\}\times\frac{1}{36}\{(\omega^0_{a_1a_1}-\omega^0_{a_2a_2})^2 \\ &\quad +(\omega^0_{a_2a_2}-\omega^0_{a_3a_3})^2+(\omega^0_{a_3a_3}-\omega^0_{a_1a_1})\} \\ &\quad \left.+\left(\frac{N}{z}\right)^2 x^2(1-x)^2\times\frac{1}{36}\{(\omega^{dl}_{a_1a_1}-\omega^{dl}_{a_2a_2})^2\right. \\ &\quad \left.+(\omega^{dl}_{a_2a_2}-\omega^{dl}_{a_3a_3})^2+(\omega^{dl}_{a_3a_3}-\omega^{dl}_{a_1a_1})^2\}\right] \qquad (36)\end{aligned}$$

## Discussions

As is seen from the above result the principal term of excess free energy $F^E$ is inversely proportional to absolute temperature. This is due to the fact that the optical *d*- and *l*-isomers are energetically identical in random mixture (see Eqs. 21 and 22), so that the first order terms are dropped in the expansion. It is in remarkable contrast to that of the usual binary solutions where the principal terms of $F^E$ are independent of temperature.

Dependency of the term on mole fraction $x$ of one component is complicated and is higher than quadratic in $x$. This is another feature of the system of optically active substances.

The term is usually very small and is quite negligible.

However, if the difference $|\omega^0_{a_ia_i}-\omega^0_{a_ja_j}|$ or $|\omega^{dl}_{a_ia_i}-\omega^{dl}_{a_ja_j}|$ happens to be great, the contribution from these terms may become appreciable. For instance consider an optical active molecule whose sub elements 1, 2 and 3 are $-NH_2$, $-C{=}O$ and $-OH$ group respectively. Then hydrogen bonding is formed between the pairs 1−2, 1−3, 2−3 and 3−3 but is not formed between pairs 1−1 and 2−2.

If we assume that interaction energies of these pairs which form hydrogen bonding are all equal and 5 kcal./mol. and those of the pairs which do not form hydrogen bonding are neglected, then $F^E$ becomes according to 36.

$$F^E \approx \frac{1.45}{(2z)^2}\ \text{kcal./mol.}$$

$$\text{at } T=300^\circ\text{K and } x=0.5$$

If we assume that $Z=4$, $F^E$ becomes $F^E\approx 22$ cal./mol. Although the value 22 cal./mol. obtained above is quite approximate because of the neglect of higher orders than the second, the order of magnitude of the value may not differ from that obtained by rigorous calculation.

## Summary

A statistical mechanical theory of solutions consisting of *d*- and *l*-optical isomers is developed based on a new model of optically active molecules, and the excess free energy of the system is also derived and the order of magnitude of this quantity is examined.

The auther wishes to express his hearty thanks to Peofessor Yonezo Morino of the University of Tokyo for his helpful discussions.

# *Forschung über die katalytische Entwässerung des Isoamylalkohols. III. Prüfung über die Bestandteile der durch Zinksulfat-Katalysator-Entwässerung entstehenden Produkten*

Von Akira MITSUTOMI

(Eingegangen am 8. April, 1961)

Die im vorangehenden Bericht[1] beschriebenen Versuche zeigten klar, dass der Zinksulfat-Katalysator der Beste ist, wenn aus Isoamylalkohol die hauptsächlich aus Trimethyläthylen bestehenden Olefinen hergestellt werden sollen. Dass diese unter Anwendung des genannten Katalysators aus Isoamylalkohol hergestellten Olefine ein Gemisch aus Trimethyläthylen, Isopropyläthylen und Methyläthyläthylen darstellen, ist allerdings nach ihrem Siedepunkt und weiteren physikalischen Konstanten anzunehmen, ist aber keineswegs nach exakter Prüfung der Bestandteile bestätigt.

Der Verfasser schreibt im folgenden die

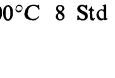
1) A. Mitsutomi, Dieses Bulletin, 34, 1525 (1961).

Ergebnisse der Forschung zur Bestimmung der Bestandteile nieder.

### Beschreibung der Versuche

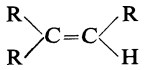
Als Katalysatoren wurde nach den Versuchsergebnissen bis zu der II. Mitteilungen das Gemisch aus 330 g Zinksulfat ($ZnSO_4 \cdot 7H_2O$) und 770 g japanischer Säureerde mit Zusatz 100 ccm 28% Ammoniak eingesetzt, danach noch in Kugelformen verarbeitet, zuerst bei 60°C 2 Std, dann bei 120°C 5 Std erhitzt und aufgetrocknet, anschliessend ins Reaktionsrohr eingefüllt und bei 500°C 8 Std aktiviert.

TABELLE I. ERGEBNISSE DER FEINDESTILLATION VON DEN REAKTIONSPRODUKTEN



| Nummerierung der Fraktion | Destillationstemp. (Korr.) °C | Prozentuales Destillationsverhaltnis, % | $n_D^{20}$ |
|---|---|---|---|
| 1 | 21.7~30.8 | 14.4 | 1.3708 |
| 2 | 30.8~33.8 | 5.0 | 1.3852 |
| 3 | 33.8~35.8 | 6.6 | 1.3880 |
| 4 | 35.8 | 13.0 | 1.3880 |
| 5 | 35.8~42.8 | 5.0 | 1.3970 |
| | Rückstand | 32.0 | 1.4028 |

Probe $n_D^{20}=1.4059$



Ganz gleichartige, aber verkleinerte Versuchsanlage, wie sie im vorangehenden mitteilung beschrieben ist, wurde herangezogen und die Reaktionstemperatur auf 350~400°C eingestellt.

Zuerst wurden flüssige Reaktionspodukte der Feindestillation unterworfen, wodurch fünf Fraktionen erhalten wurden. Sie sind in Tabelle I aufgestellt.

**Prüfung der ersten Fraktion.**—Das Infrarotspektrum der ersten Fraktion ist in Abb. 1 gezeigt.

Es sind die für Isopropyl-Gruppe charakteristischen Gerüstschwingungen 6.9 $\mu$ und 7.27 $\mu$, die intensiv erscheinen. Ferner sind 10.1 $\mu$, 11.03 $\mu$, 11.32 $\mu$ usw. für  spezifisch bemerkbar.

Diese Umstände unterstreichen das Vorhandensein des Isopropyläthylens.

Ferner ist die Absorption 12.53 $\mu$ für  festzustellen, ausserdem sind 9.33 $\mu$, 8.25 $\mu$ für Trimethyläthylen schwach dargestellt.

Diese Umstände lassen beurteilen, dass diese Fraktion neben viel Mengen Isopropyläthylen das Mitvorhandensein geringer Menge Trimethyläthylen zulässt.

**Prüfung von Fraktion Nr. 2.**—Das Infrarotspektrum von Fraktion Nr. 2 ist in Abb. 2 gezeigt.

Die Besichtigung dieses Infrarotspektrums lässt

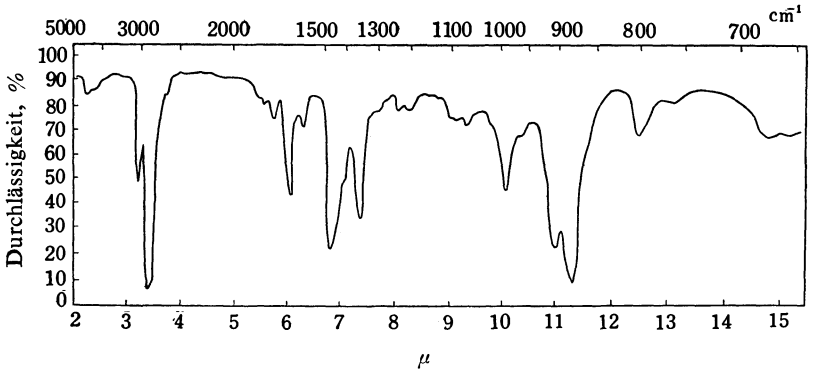


Abb. 1. Infrarotspektrum von Fraktion Nr. 1.

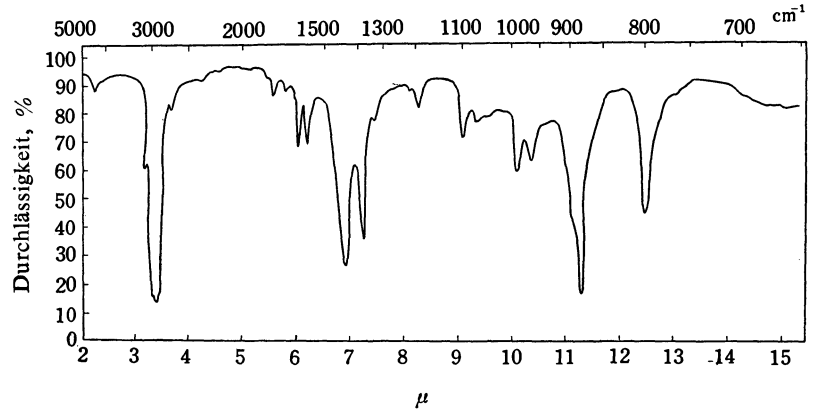

Abb. 2. Infrarotspecktrum von Fraktion Nr. 2.

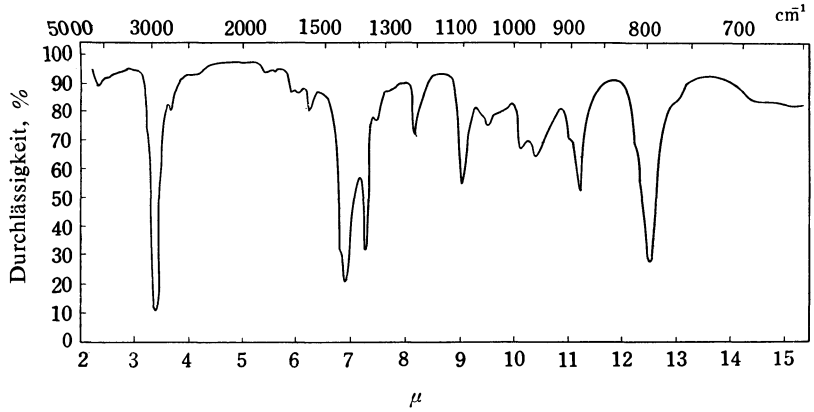

Abb. 3. Infrarotspektrum von Fraktion Nr. 3.

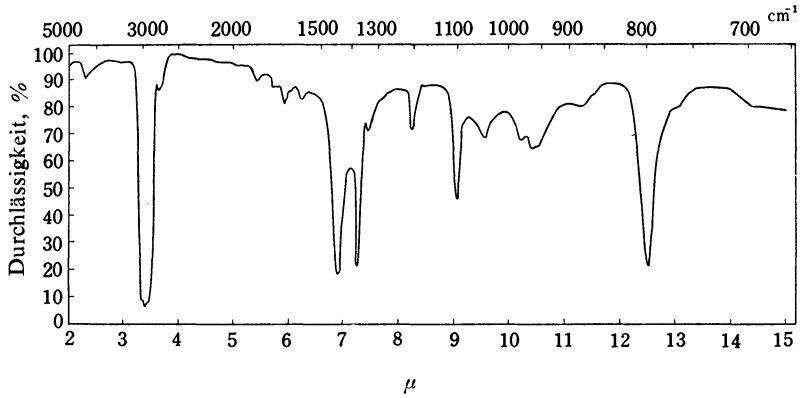

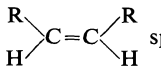

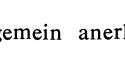

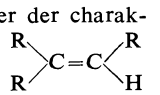

Abb. 4. Infrarotspectrum von Fraktion Nr. 4.

wissen, dass ausser der für  spezifischen 12.50 $\mu$ Wellenlänge die bei den obengenannten und unterstrichenen Wellenlängen mit den charakteristischen Gerüstschwingungen bei Trimethyläthylen gut übereinstimmen.

Ferner zu beachten ist die Absorption von 11.28 $\mu$, die als charakteristische Gerüstschwingung für Bindung von  allgemein anerkannt ist. Der Umstand, dass dies stark hervortritt, lässt wissen, dass die Fraktion Nr. 2 das Gemisch aus Trimethyläthylen und Methyläthyläthylen fast in gleichen Anteilen darstellt.

**Prüfung von Fraktion Nr. 3.**—Das Infrarotspektrum diesser Fraktion (Abb. 3) zeigt gute Übereinstimmung der Absorptionsstellungen mit denen in Abb. 2, nur dass die 12.50 $\mu$ stärker ist als bei Abb. 2, während die 11.28 $\mu$ schwächer ist, woraus mit Recht zu schliessen ist, dass diese Fraktion das Gemisch aus vielen Mengen Trimethyläthylen und geringer Menge Methyläthyläthylen darstellt.

**Prüfung von Fraktion Nr. 4.**—Der Brechungsindizes $n_D^{20}=1.3880$ dieser Fraktion ist fast mit den Literaturangaben von Trimethyläthylen $n_D^{20}=1.3874$, identisch, was annehmen lässt, dass es sich hierbei doch um reines Trimethyläthylen handelt. Bei ihrem Ultrarotspektrum (abb. 4) sind ausser der charakteristischen Gerüstgchwingungen für  die Gesamtkurvenverzeichnungen fast mit denen für Trimethläthylene übereinstimmend. Kein Vorhandensein anderer Verbindungen ist anzunehmen.

**Bestandteilmässige Untersuchung des Destillationsrückstandes.** — Wenn Reaktionstemperaturen der Entwässerung von Isoamylalkohol variieren und dabei die flüssigen Produkte (Rückstand von der Tabelle I) hinsichtlich ihres Brechungsindies miteinander verglichen werden, so lassen sich annähernd ein konstanten Wert finden (Tabelle II), dieser zeigt dass die Produkte bestandteilmässig keinerlei grössere unterschiede aufweisen.

Tabelle II. Zusammenhang der Reaktionstemperaturen mit den Brechungsindizien der Reactionsprodukte

| Reaktionstemperatur, °C | 375~425 | 350~400 | 325~375 |
|---|---|---|---|
| $n_D^{20}$ | 1.4050 | 1.4059 | 1.4048 |

Da ihre bestandteilmässige Untersuchung tatsächlich keine grösseren Unterschiede voneinander ergab,

TABELLE III. DESTILLATIONSERGEBNISSE VON DESTILLATIONSRÜCKSTANDGEMISCH

| Fraktion-nummern | Destillations-temperatur °C/mmHg | Destillate-menge ccm | $n_D^{20}$ | Anmerkung |
|---|---|---|---|---|
| 1 | 92～94/760 | 5 | 1.3961 | farblos, klar, stechendes Geruch |
| 2 | 94～96/760 | 7.5 | 1.3961 | ditto |
| 3 | 96～102/760 | 3.5 | 1.3993 | ditto |
| 4 | 50～72/46 | 3 | 1.4292 | hellgelb, aromatisches Geruch |
| 5 | 72～80/46 | 3.5 | 1.4326 | ditto |
| 6 | 931～15/7 | 1.5 | 1.4648 | gelbbraun, aromatisches Geruch |
| | Rückstand | 6 | | pechartig, dickklebrig |

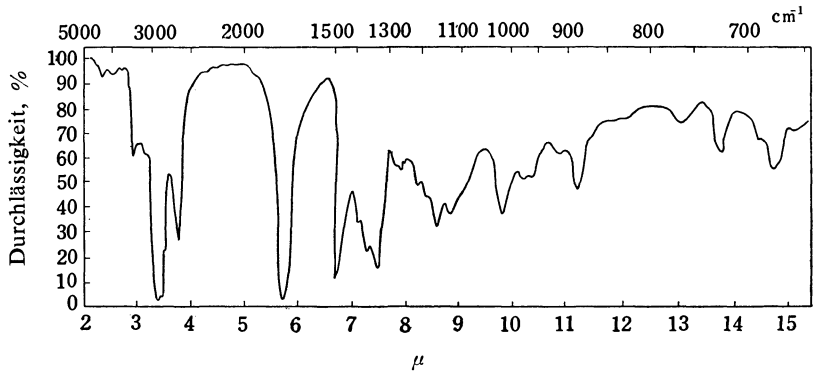

Abb. 5. Infrarotspektrum von Fraktion Nr. 2 (Tabelle III).

wurden diese drei Reaktionsprodukte voneinander abgesondert destilliert und die jeweiligen Destillate wurden zusammengebracht und dieses Rückstandsgemisch wieder der destillation unterzogen. Die Ergebnisse sind in Tabelle III aufgestellt.

Die Fluoreszenz-Indikator-Adsorptionsanalyse an der Fraction Nr. 2 hiervon ergab, dass das Gemisch aus Olefin 3.7%, aromatischartige Verbindungen 2.9% und gleich wie Alkohol polarisierte Substanzen 93.4% besteht.

Aus dem Infrarotspektrum der Fraktion Nr. 2 (Abb. 5) ist zu sehen, dass die für Aldehyde bzw. Keton-Radikal charakteristische Gerüstschwingungen

3.7 $\mu$ und 5.8 $\mu$ sowie die für  Radikal spezifischen 7.25 $\mu$ und 7.3 $\mu$ alle ausdrucksvoll in Erscheinung treten, das weist klar auf, dass Isovaleraldehyde in vielen Mengen enthalten sind. Die Absorption 2.9 $\mu$ zeigt das Vorhandensein des OH Radikals auf, während die 3.4 $\mu$ und 3.5 $\mu$ für Alkyl-Radikal klarsichtlich auftreten. Die Zusammenfassung dieser Tatsachen lässt beurteilen, dass diese Fraktion das Gemisch aus Isovaleraldehyde in vielen Mengen und unverwandte Isoamylalkohol in geringer Menge darstellt.

Ferner wurde nach chemischer Untersuchung erkannt, dass die Fraktionen von Nr. 1 bis 3, welche vollkommen gleiches stechendes Geruch besitzen, bestandteilmässig vollständig gleich sind wie die Fraktion Nr. 2. Wie aus Tabelle III ersichtlich, sind die Brechungsindizien miteinander fast identisch. Erst bei der Fraktion Nr. 4 steigt der Indizies etwas an und zwar immer höher mit den erhöhten Siedepunkten. Das Geruch geht von dem Stechenden nebenbei zum Aromatischen über. Hieraus ist das Vorhandensein der Polymere anzunehmen. Hinsichtlich der Tatsache, dass bei qualitativer Analyse des Schwefels mittels Nitroprussidnatrium und der Doktor-Lösung die Fraktionen Nr. 5, 6 und der Rückstand positiv sind, wurden die ebengenannten Nr. 5 und 6 gründlich gewaschen. Nämlich, bei der Fraktion Nr. 5 wurden 110 ccm Doktor-Lösung auf 3.1 ccm Proben in mehr als 10 Portionen eingeteilt angewandt und gewaschen. Die öligen Schichten blieben aber trotz des Waschens immer noch gelblich oder hellbraunlich, wurden nicht farblos.

Nun wurde 15 ccm der Fraktion Nr. 5 mit 500 ccm Doktor-Lösung in 20 Portionen gewaschen, aber die Farbtönung blieb immer noch unverändert. Der Brechungsindizies war $n_D^{20}=1.4550$ und die qualitative Analyse des Schwefels zeigte sich als positiv.

TABELLE IV. DESTILLATIONSERGEBNISSE DES GEWASCHENEN ÖLS (FRAKTION NR. 5 DER TABELLE III)

| Fraktionen | Destillations-temperatur °C/10 mmHg | $n_D^{20}$ | Schwefel-versuche | Anmerkung |
|---|---|---|---|---|
| 1 | 46～ 67 | 1.4420 | ± | Gelb |
| 2 | 67～ 85 | 1.4392 | + | 〃 |
| 3 | 112～135 | 1.4443 | + | 〃 |
| | Rückstand | | + | Schwarzbraunlich, dickklebrig |

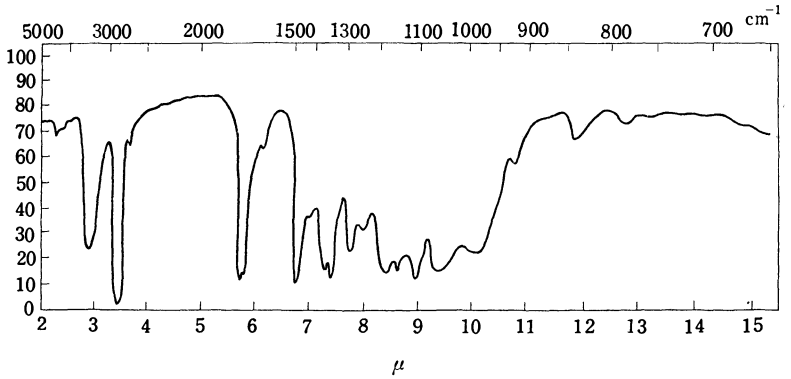

Abb. 6. Infrarotspektrum von Fraktion Nr. 3. (Tabelle IV)

Das gewaschene Öl wurde unterm verminderten Druck destlliert. Die Ergebnisse sind in Tabelle IV verzeichnet.

Bei infrarotspectraler Untersuchung (Abb. 6) der Fraktion Nr. 3 der Tabelle IV erwiesen sich die für Aldehyd oder Keton spezifischen Absorption 3.42 $\mu$ und 5.8 $\mu$ intensiv, während im Übrigen die weiteren Absorptionen mit denen als Isovaleraldehyde im grossen und ganzen übereinstimmten. Die Feststellbarkeit der Absorptionswellenlänge 2.9 $\mu$ für OH Radikal und der Absorption für Isopropyl-Radical ist klarer Nachweis für Isoamylalkohol. Es ist daher anzunehmen, dass es sich bei diesen öligen Substanzen um ein Gemisch aus Isovaleraldehyd und Isoamylalkohol handelt.

Die obigen Ergebnisse lassen für den Destillationsrückstand auf das Folgende schliessen.

Die Fluoreszenz-Indikator-Adsoptionsanalyse an dem ungewaschen Rückstand ergab, dass die jeglichen Fraktionen fast gleiche Zusammensetzung haben,

Tabelle V. Aufstellung der Ergebnisse bei Fluoreszenz-Indikator-Adsorptionsanalyse von dem ungewaschnen Rückstand der Tabelle IV

| Franktionsnummern | Olefine % | Schwefelverbindungen % | Gemisch von Isovaleraldehyde und Isoamylalkohol, % |
|---|---|---|---|
| 1 | 7.8 | 2.8 | 89.4 |
| 2 | 3.7 | 2.9 | 93.4 |
| 3 | 3.9 | 4.7 | 91.4 |
| 4 | 5.7 | 0.3 | 94.0 |

wie die Tabelle V zeigt. Die Untersuchungsergebnisse bei der Fraktion Nr. 2 können ruhig für die übrigen Fraktionen als gültig betrachtet werden. Damit könnte eine jeweilige untersuchung erübrigt sein.

Ferner bei dem gewaschenen Rückstand ist zu finden, dass ausser Isovaleraldehyd und Isoamylalkohol etwa mit Waschen leicht unentfernbare, nämlich fest gebundene Schwefelverbindungen wenn auch in geringer Menge vorhanden sind. Diese Schwefelverbindungen stammen zwar aus thermischer Zerlegung des Katalysators, aber ihr Urwesen konnte zufolge mengenmässiger Geringfügigkeit nicht festgestellt werden.

Ferner ist annehmbar, dass noch weitere hochsiedende Polymere mitvorhanden sind.

Zusammenfassung der obigen Ausführungen lautet wie folgt: Wenn Isoamylalkohol in Gegenwart des Zinksulfates als Katalysator das Wasser entzogen wird, entsteht ausser in einem Gemisch befindlichen vieren Mengen Trimethyläthylen mit geringer Menge Methyläthyläthylen sowie Isopropyläthylen, Isovaleraldehyd strukturmässig unbekannte Polymere und Schwefelverbindungen.

Zum Schluss sei noch davon erwähnt, dass die vorliegende Arbeit der Leistung von Herrn Professor Dr. Eiichi Funakubo an der Technischen Fakultät der Universität zu Osaka verdankt ist.

# *Forschung über die katalytische Entwässerung des Isoamylalkohols. IV. Quantitative Untersuchung der durch unterm Einsatz des Zinksulfat-Katalysators erfolgende Dehydratisierung gebildeten Produkte auf ihre Bestandteile*

Von Akira MITSUTOMI und Eiichi FUNAKUBO

(Eingegangen am 8. April, 1961)

Um die Zusammensetzung der aus Isoamylalkohol dargestellten Olefine zu bestimmen, wurden unterm Einsatz des Zinksulfat-Katalysators, gleich wie in der letzten Mitteilung[1], durch Fluoreszenz-Indikator Adsorotionsanalyse und Silicagel Adsorption die betreffenden gesättigten Kohlenwasserstoffe und Olefine getrennt.

Daraufhin wurde durch Infrarot-Absorptionsspektrum und Gaschromatographie an den Feindestillaten das Wesentliche ermittelt, dann quantitativ der Verbreitungszustand von den Olefinen untersucht, schliesslich die Zusammensetzung derselben klargemacht und gleichzeitig über den Bildungsmechanismus thermodynamische Betrachtung durchgeführt. Die vorliegende Mitteilung beschreibt den Verlauf der Versuchsdurchführung.

## Beschreibung der Versuche

*Operation.*—Die Vorrichtung ist in Abb. 1 gezeigt. Es wird Isoamylalkohol in 100 ccm Glaszylinder (4) mit Skalen eingefüllt. Daraus wird je eine gewisse Menge hiervon in Verdampfer (III) abgegeben und drin mit Mantelerhitzer verdampft. Der Alkoholdampf wird beim Aufsteigen in Wärmeaustauscher (II) durch aus Reaktionsrohr (I) austretendes Gas stets bei 155～165°C erhitzt und in Reaktionsrohr (I) geführt.

Die Temperatur in Reaktionsrohr konnte während der ca. 6 Tage gedauerten kontinuierlichen Reaktion stets bei 350±3°C gehalten bleiben.

Die in Wärmeaustauscher kondensierten hochsiedenden flüssigen Substanzen laufen in Vorlage (IV) zusammen, während die übrigen gasförmigen Substanzen von Wärmeaustauscher her in Vorlage (V). Vorlage (V) wird auf Wasserbad auf 80°C erwärmt, so dass unveränderter Isoamylalkohol und durch Reaktion gebildetes Wasser kondensiert werden, während Olefine und weitere niedrigsiedende flüssige Substanzen, indem sie durch über Erhitzer (6) einlaufendes heisses Wasser in Kühler (VI), von aussen her gewärmt werden, aufsteigen und anschliessend in Kühler stark abgekühlt und in Sammler (VIII) angesammelt werden.

Gase werden über Messer mengenmässig erfasst und in Sammler aufgefangen. Als die Gesamtmenge der Probe eingetan und die Reaktion zum Abschluss gebracht wurde, wurde Stickstoffgas aus Zylinder ins Reaktionssystem eingedrückt, wodurch Reaktionsprodukte alle in Vorlage gebracht wurden, indem jeglicher Verlust weitgehendst verhindert wurde.

Als Katalysator wurde das Gemisch aus 3 Teilen Zinksulfat $ZnSO_4 \cdot 7H_2O$ und 7 Teilen japanischer Säureerde herangezogen, welches mit zugesetztem 28%igen Ammoniakwasser angeteigt, zu Klumpen gemacht, bei 60°C 2 Std und dann bei 120°C 5 Std aufgetrocknet, anschliessend in Reaktionsrohr eingepackt und durch 1 stündige Erhitzung bei 500°C aktiviert wurde.

Als Probe wurde handelsübliche Ware Isoamylalkohol abdestilliert, deren Fraktion bei Sdp 127～130°C angesammelt wurde.

Bei vorliegendem Versuche wurde darauf Wert gelegt, die Reaktionstemperatur bei 350±5°C zu behalten. In der Wirklichkeit gelang es uns daher, während der für Reagieren der ganzen Probenmenge von 4800 ccm benötigten Dauer von 115 Std und 50 Min die Temperatur bei 350±3°C zu sichern.

Durchmesser eines Teilchens vom Katalysator……durchschnittlich 6 mm
Gesamtpackungsmenge des Katalysators……1.505 kg, 1.723.9 ccm
Durchlaufgeschwindigkeit der Proben……41.44 ccm/Std
Raumgeschwindigkeit……1.44 ccm/Min

## Versuchsergebnisse

Nach der von uns vorgeschlagenen Methode* wurde die Typenanalyse an rohen Olefinen vorgenommen, deren Ergebnissen in Tabelle I, II, aufgestellt. Daraufhin wurde durch das Silicagel-Adsorptionsverfahren gesättigter Kohlenwasserstoff getrennt und die Gewinnung der reinen Olefinen vorgenommen. Zu diesem Zweck wurden 200 gm Silicagel** in das Adsorptions-Trennungsrohr eingepackt, darauf 80 ccm rohe Olefine zugegeben. Der Ansatz wurde unter

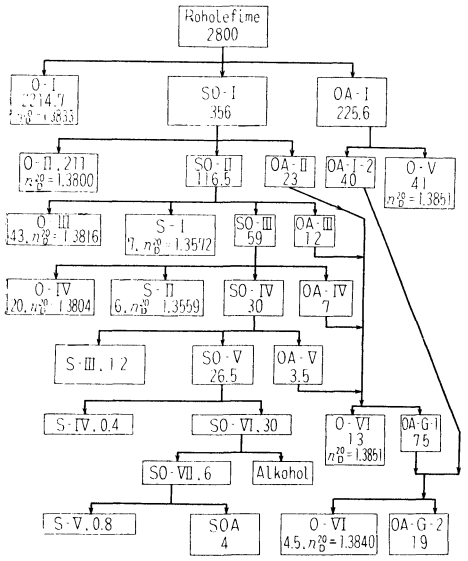
Anwendung des Äthanols der Austauschentwicklung unterzogen. Tabelle III zeigt die Reinigungsergebnisse.

Dann wurde 60 ccm von dem auf diese Weise erhaltenen SO-(I) weiter abpipettiert und in das mit 200 g Silica-gel eingepackte Rohr eingegossen. Mit Äthanol wurde die Austauschentwicklung ausgeführt. Die erhaltenen Ergebnisse sind in Tabelle IV aufgestellt. Dieses Reinigungs verfahren wurde weiter wiederholt und die Ergebnisse sind in Abb. aufgestellt. Da die Olefine hinsichtlich ihrer Brechungsindizien zusammensetzungsmässige Ähnlichkeit zu zeigen schienen, wurde sie gaschromatographisch auf ihre Zusammensetzung untersucht (Tabelle V).



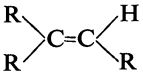


Abb. 2.*

* Nummer in ccm, S: gesättigte Kohlenwasserstoffe, O: Olefine.
Gesamtsumme S: 15.4 ccm, O: 2547.2 ccm.

Wie aus Tabelle V ersichtlich, hat die Probe O-(I) im Vergleich mit drei weiteren Proben anderes Mischverhältnis der Bestandteile aufgezeigt. Dementsprechend wurde darauf eingestellt, dass Olefin O-(I) alleine, O-(II), O-(III) und O-(IV) gemeinsam, auch O-(V), O-(VI), und O-(VIII) gemeinsam, gruppenweise gesondert destilliert werden. Um aber noch festzustellen, wurden die durch vorherige Destillation erhaltenen Fraktionen gaschromatographisch analysiert und der Verbreitungszustand der Bestandteile untersucht. Die Ergebnisse sind in Tabelle VI verzeichnet. Es wurde dabei erkannt, dass die drei Bestandteile B, C und E vorwiegend vorhanden sind, wobei die Beziehung der Siedepunkte auf Gehaltsmenge klar vortritt.

Von diesen Fraktionen sind diejenigen mit Sdp 36.9~37.1°C 100%ig reine E-Bestandteile, deren Brechnungsindies mit den Literaturangabe, von Trimethyläthylen $n_D^{20}=1.3874$, 1.3876 identisch ist.

Wegen weiterer Feststellung dieser Annahme wurde das Infrarot-Absorptionsspectrum gemessen. Dabei liess es sich finden, dass, wie Abb. 3 zeigt, das ganze Bild mit Standardsbild des 2-Methyl-2-buten übereinstimmt und die spezifische Absorptionswellenlänge 12.53 $\mu$ für

Type intensiv auftritt. Dadurch

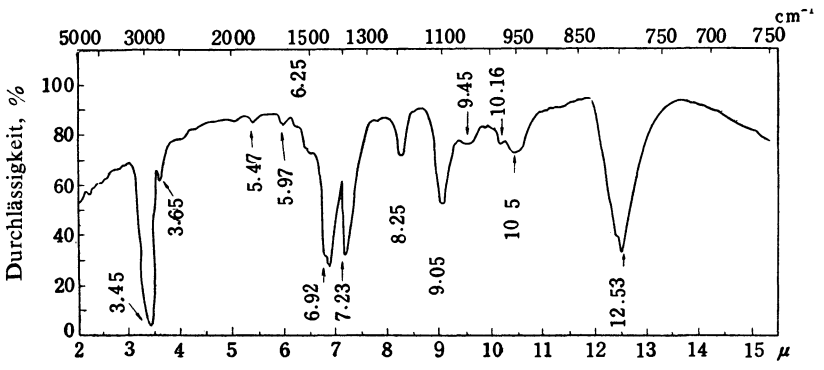

Abb. 2. Infrarot-Absorptionsspektrum von Fraktion Nr. 14.

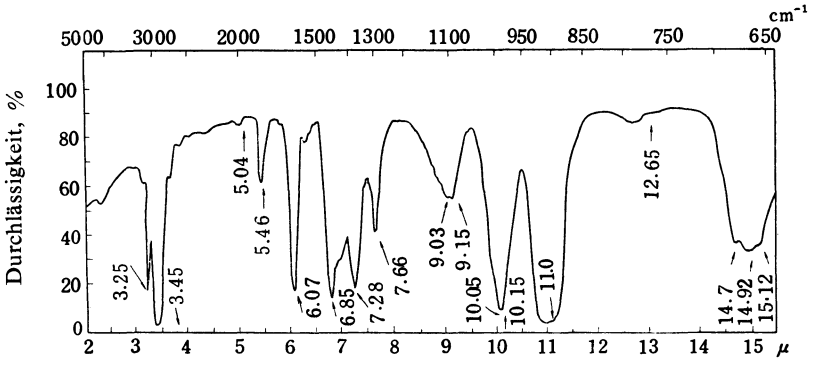

Abb. 3. Infrarot-Absorptionsspektrum von B-Bestandteil.

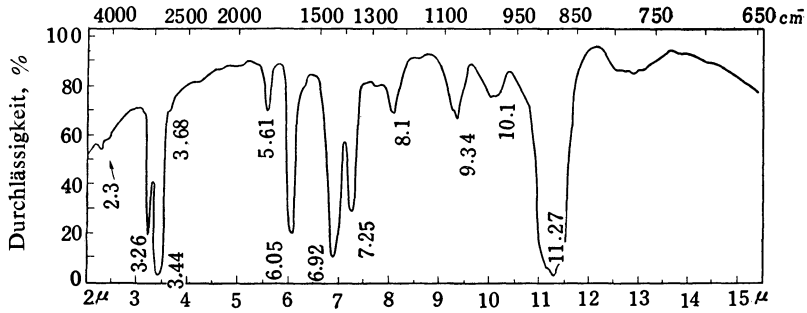

Abb. 4. Infrarot-Absorptionsspektrum von C-Bestandteil.

ist entschieden worden, dass der Bestandteil E Trimethyläthylen darstellt.

Die erste Fraktion, Sdp 18~19.5°C, zeigte das Brechungsindies, welches mit der Literaturangabe von 3-methyl-1-buten $n_D^{15}=1.3677$ übereinstimmt. Ausserdem zeigten die Messungen des Infrarot-Absorptionsspektrums (Abb. 4) einwandfreie Übereinstimmung mit dem Standardsbild für 3-Methyl-1-buten. Als spezifische Absorptionswellenlänge von $\begin{matrix}R\\H\end{matrix}\!\!>\!C$ $=CH_2$ sind die Werte von $10.05\pm0.02\,\mu$, und $10.98\pm0.02\,\mu$ nach K. E. Kitson und $10.98\pm0.02\,\mu$ nach J. A. Anderson order $10.95\pm0.02\,\mu$ nach E. L. Sailer angegeben und diese alle sind auch in unserem Bild als intensive Absorptionen aufgetreten. Demnach haben wir entschieden, dass der Bestandteil B 3-Methyl-1-buten ist. Im Infrarot-Absorptionsspektrum (Abb. 4) der Fraktion Nr. 5 tritt die spezifische Absorption, $11.27\,\mu$, fur $\begin{matrix}R\\R\end{matrix}\!\!>\!C=CH_2$ intensiv auf. Ausserdem stimmt das genze Spektraldiagramm mit dem Standardsdiagramm von Methyläthyläthylen einwandfrei überein. Aus dieser Tatsache und dem Messwerte von Brechungsindies ist entscheiden, dass der C-Bestandteil Methyläthyläthylen darstellt.

Die in Tabelle VI aufgezeichneten gaschromatohraphischen Analysenergebnisse zugrunde nehmend, wurde mengenmässige Verteilung der einzelnen Bestandteile in den einzelnen Fraktionen rechnerisch festgestellt. Kurz gefasst, gaschromatographische und infrarotabsorptionsspektrale Analyse an den durch Feindestillation fraktionierten Destillaten hat ergeben, dass die durch Silicagel-Adsorption gereinigten Olefine folgende Zusammensetzung besitzen: Trimethyläthylen 74.77, Methyläthyläthylen 19.96, Isopropyläthylen 4.78, und Olefine von unbekennter Konstitution 0.49%.

Dann wurden die Olefine O-(II), O-(III) und O-(IV), deren Brechungsindizien einander nähern, zusammengebracht und der Feindestillation unterzogen. Gaschromatographische Analyse an den Fraktionen ergaben die Resultaten in Tabelle VII.

Die Zusammensetzung von rein Olefin in dem Gemisch aus O-(II), O-(III) und O-(IV), war wie folgt: Trimethyläthylen 65.98, Methyläthyläthylen 21.95, Isopropyläthylen 11.63, und Unbekannte Olefin 0.44%.

Die Zusammensetzung von reinem Olefin in dem, Gemisch aus O-(V), O-(VI)und O-(VII), war von Tabelle VIII errechnet wie folgt: Trimethyläthylen 66.35, Methyläthyläthylen 30.17, Isopropyläthylen 0.43, und unbekannte Olefin 3.05%.

**Untersuchung auf das durch Reaktion gebildete Wasser.**—Von dem durch Reaktion gebildeten Wasser wurden 550 ccm genommen und destilliert. Verlauf der Destillation und Eigenschaften der Fraktionen sind in Tabelle IX aufgestellt.

Die Fraktionen von Nr. 3 bis 5 waren homogene Flüssigkeiten, enthielten kein Wasser, verhielten den Schiff'schen Reagenz äusserst indifferent.

Bei den Fraktionen Nr. 1 und 2, die der Schiff'schen Reagenz intensiv positiv waren, wurde ihre organische Phase mit *p*-Nitrophenylhydrazin einwirken gelassen.

Von 0.2 ccm der Fraktion Nr. 1 wurden 275 mg *p*-Nitrophenylhydrazon Schmp 101.5～104°C, und von 0.5 ccm der Fraktion Nr. 2 619 mg derselben, aber Schmp 103～108°C, erhalten. Nach Umkristallisation wandelte sich das Vordere in Schmp 105.5～110°C, und das Letztere in Schmp 105～108°C um. Die Beiden wurden durch die Mischschmelzpunktsbestimmung als Isovaleraldehyd mit Sicherheit festgestellt.

**Thermodynamische Betrachtung über Isomerisationsgleichgewicht und Zusammenfassung.** — Mit der Absicht, aus Isoamylalkohol die vorwiegend aus Trimethyläthylen bestehenden Olefinen kontinuierlich zu fabrizieren, wurde das Gas-Phase Verfahren erforscht.

Zuerst wurden Katalysatoren aus 15 Sorten Substanzen ausgearbeitet, indem diese entweder als Einzelkörper oder als Kombination eingesetzt wurden. In 122 Versuchen wurde auf das katalysatorische Vermögen gründlich untersucht. Dabei haben wir den geeignetesten Katalysator in der Zinksulfat-japanischer Säureerde-Kombination gefunden. Dieser besteht aus 3 Teilen Zinksulfats und 7 Teilen japanischer Säureerde. Dieser Ansatz wird unter Zusatz von Ammoniak angeteigt, zu Kugeln verarbeitet, und aktiviert. Das auf diese Weise behandelte Material entwickelt ausgezeichnetes katalysatorisches Vermögen und zeigt auch nach 246 Std langem kontinuierlichem Einsatz und Behandlung des 52 betragenden Alkohol-Durchsatzes fast kein Nachlassen an der Wirkung.

Unter Anwendung der Reaktionsröhre von mittelgrossem und grossem Format wurden 290 Male Versuche angestellt, um die optimalne Reaktionsbedingungen zu finden. Die durch

Tabelle X. Vergleich der mehreren Versuchsergebnisse von hohen Ausbeuten

| Reaktionstemperatur °C | Ausbeute in % der einzelnen Fraktionen | | | |
|---|---|---|---|---|
| | ～30°C | 30～35°C | 35～41°C | Summe |
| 330～360 | 4.6 | 17.7 | 67 | 89.3 |
| 330～350 | 4.0 | 16.2 | 67 | 87.2 |
| 285～345 | 0.7 | 22.6 | 67.8 | 91.1 |
| 350～370 | 2.1 | 18.9 | 70 | 91.0 |
| 360～390 | 3.7 | 18.3 | 72.5 | 94.5 |
| 300～315 | 0 | 17.3 | 75.2 | 92.5 |

Reaktion erhaltenen rohen Olefine wurden einfach hinsichtlich der Siedepunkte in drei Gruppen eingeteilt, deren Ausbeute festgestellt wurde. Mehrere Sorten mit hohen Ausbeuten wurden beispielsweise in Tabelle X aufgestellt.

Daraus ist die Beurteilung entstanden, dass bei Fabrikation des Trimethyläthylens aus Isoamylalkohol die Ausführung der Reaktion bei 350°C und dergleichen die opimalen Ergebnisse ergibt. Darauf wurde die Reaktion von 4800 ccm Isoamylalkohol bei 350±3°C vorgenommen. Die dabei erhaltenen Reaktionsprodukte wurden durch solche verschiedene Methoden wie Fluoreszenz-Indikator Adsorptionsanalyse, Feindestillation, Infrarot-Absorptionsspektrum, Gaschromatographie usw., auf ihre Bestandteile geprüft, und zwar mit folgenden Ergebnissen: Trimethyläthylen, 74.77～75.14, Methyläthyläthylen, 19.96～20.06, und Isopropyläthylen, 4.78～4.80%.

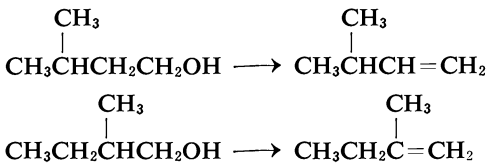
Für diese dreien Olefine sind schon von Kistiaskowsky[2] zuverlässige thermodynamische Ergebnisse vorgebracht worden. Wir haben anhand dieser Ergebnisse nach folgender Formel theoretische Werte des Isomerisationsgleichgewichtes für die vorliegende Reaktion zu bildende Olefine gesucht.

$$\Delta F = -RT \ln K$$

worin $\Delta F$: Innere Energie, $R$: Gaskonstante, $K$: Gleichgewichtskonstante, $T$: Absolute Temperatur.

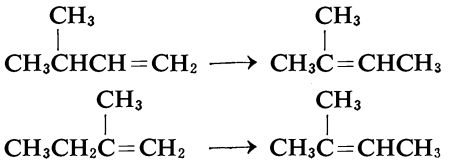
Für $\Delta F$ haben wir die folgende von Kistiaskowsky gefundene Hydrierungswärme herangezogen.

| | $-\Delta F$ (Cal./Mol.) | $K$ bei 350°C |
|---|---|---|
| Trimethyläthylen-Methyläthyläthylen | 1571 | 3.56 |
| Trimethyläthylen-Isopropyläthylen | 3416 | 15.8 |
| Methyläthyläthylen-Isopropyläthylen | 1845 | 4.44 |



Aus diesen Ergebnissen wird das theoretische prozentuale Verhältnis der Bildung für die Dreien wie folgt abgeleitet:

| | Theoretische Werte (bei 350°C), % | Experimentelle Werte (bei 350°C), % |
|---|---|---|
| Trimethyläthylen | 74.45 | 75.14 |
| Methyläthyläthylen | 20.91 | 20.06 |
| Isopropyläthylen | 4.64 | 4.80 |



Es ist sehr interessant, dass die genannten theoretischen Werte mit den von uns experimentell erhaltenen Ergebnissen ganz einwandfrei übereinstimmen. Diese Tatsache dürfte eine interessante Hinweisung auf den Mechanismus dieser Reaktion und die Eigenschaften des Katalysators, geben.

Das Bildungsverhältnis von den durch diese Arbeit erhaltenen Olefinen ist nämlich mit dem thermodynamisch zu findenden Verhältnis identisch. Mit anderen Worten, das stimmt mit dem thermodynamisch zu findenden stabilen Gleichgewichtszustand der Isomerisation überein. Die herrschende Annahme ist es, dass der Hauptbestandteil des zu entwässernden Isoamylalkohols Isobutylcarbinol sei, während die Gehalte an *gem*-Methyläthyläthylalkohol geringfügig seien.

Wenn die Entwässerung ohne Isomerisationsreaktion erfolgt, würde aus Isobutylcarbinol Isopropyläthylen und aus *gem*-Methyläthyläthylalkohol Methyläthyläthylen gebildet.

Da nun Isopropyläthylen und Methyläthyläthylen ebenfalls die Isomerisation in Trimethyläthylen mit sich bringen, entstehen die folgenden Formeln.

Nun wird die Orientierung dieser Isomerisation im allgemeinen thermodynamisch bedingt. Mit anderen Worten, dies besagt, dass das Unstabile ins Stabile isomerisiert wird. Die Reihenfolge der Stabilität ist nach Kistiakowsky wie folgendes: Trimethyläthylen > Methyläthyläthylen > Isopropyläthylen. Wenn diese Stabilität elektronentheoretisch betrachtet wird, so ist sie abhängig von dem Hyperkonjugationseffekt, wie Ingold[3] bereits erwähnt. Somit ist die Annahme der Isomerisation von Isopropyläthylen in Trimethyläthylen und von Isopropyläthylen in Methyläthyläthylen begründet.

Wenn jetzt ein anderer Gesichtspunkt genommen wird, nämlich über das Isomerisationsvermögen des Katalysators Betrachtung geübt wird, so ist es zu sagen, dass derjenige Katalysator, der Theorie übereinstimmende Isomerisationsverhältnis aufzeigt, der Ausgezeichnete ist. Die Tatsache, dass das Isomerisationsverhältnis mit dem theoretischen

2) G. B. Kistiaskowsky et al., *J. Am. Chem. Soc.* **57**, 65, 876 (1935); **58**, 137, 146 (1936); **59**, 831 (1937).

3) M. L. Dhar, E. D. Hughes, C. K. Ingold, A. M. M. Mandour, G. A. Mow and L. I. Woolf, *J. Chem. Soc.*, **1948**, 2093.

Zahlenwert identisch ist, wie es bei der vorliegenden Arbeit der Fall ist, liefert den Beweis dafür, dass das dabei eigesetze Zinksulfat ausgezeichnetes katalysatorisches Vermögen bei Entwässerungsisomerisation ausübt.

Aus den obigen Betrachtungen ist es anzunehmen, dass bei der vorliegenden Entwässerungsisomerisation das thermodynamische Isomerisationsgleichgewicht erreicht worden ist, indem unabhängig von Verunreinigungen des zu entwässernden Alkohols die gebildeten Olefine isomerisiert werden (obgleich es unklar ist, ob die Isomerisierung gleichzeitig mit der Entwässerung oder erst nach der erfolgten Bildung der Olefine geschieht).

# *Hot-atom Chemistry of Hexamminechromium(III) Nitrate in the Solid State*

By Nagao IKEDA, Kenji YOSHIHARA, Hiroshi EBIHARA and Kiyomi SUZUKI

(Received November 21, 1960)

The hot-atom effect in trisethylenediaminechromium(III) nitrate[1,2] and hexamminecobalt-(III) nitrate[3] has been studied, but the same effect in hexamminechromium(III) nitrate has not yet been reported. Recently, the present authors succeeded in enriching $^{60}Co$ and $^{60m}Co$ recoil atoms produced in neutron-irradiated hexamminecobalt(III) nitrate with a high efficiency[4]. The method used by the authors was based on the heterogeneous extraction; the neutron-irradiated fine powders were shaken with a liquid which did not dissolve the target but dissolved the recoil species. As this method is very simple and rapid, it has sometimes been used for the enrichment of radioisotopes produced by (n, p)- and (n, $\alpha$)-reactions[5,6]. In the case of (n, $\gamma$)-reaction[7], however, it does not usually give a high yield because of the short recoil range. Therefore the results in the previous paper were rather striking. In this paper, we investigated a similar heterogeneous extraction method on hexamminechromium(III) nitrate and discussed the mechanism of the extraction process. This complex is insoluble in concentrated nitric acid, but chromic ion and chromate or dichromate ion are soluble in it. Therefore, recoil atoms of $^{51}Cr$ should be extracted and enriched in the aqueous phase by shaking the target powder with concentrated nitric acid.

On the chemical form of the recoil chromium, some results heve already been reported; e.g., in the case of chromium azo-dye Palatine Fast Blue GGN[8], 83% of the radioactive chromium is present as chromium(III) and 11% of it as chromium(VI)*. In the present paper, chemical forms of recoil chromium atoms were also investigated.

## Experimental

**Target Material.** — Hexamminechromium(III) nitrate was prepared by Mori's method[9].

**Irradiation.**—The cyclotron at the Institute of Physical and Chemical Research, Tokyo, and the nuclear reactor JRR-1 at the Japan Atomic Energy Research Institute were used for irradiation. The hot-atom effect of $^{55}Cr$ (half-life: 3.5 min.) was investigated by using the cyclotron, and that of $^{51}Cr$ (half-life: 27.8 day) by using the nuclear reactor. In the cyclotron, neutrons were generated by bombardment of beryllium with accelerated deuterons, and slowed down by a paraffin block. The neutron flux at the position of irradiation was about $10^6 \sim 10^7$ n/cm$^2$ sec.* The reactor, JRR-1 was operated at 50 kW/hr., and the neution flux

9) M. Mori, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **74**, 253 (1953).
* Contribution of fast neutrons to the radioactivation did not exceed about 5%.

was of the order of $10^{11}$ n/cm² sec. at the irradiation**. Temperature at the position did not exceed about 50°C.

**Measurement of Radioactivity.**—As $^{55}$Cr emitted only $\beta$-particles (2.85 MeV.), the radioactivity was measured by a GM-counter made by the Institute of Physical and Chemical Research, (end window type, mica window thickness: 1.4 mg./cm²). Radioactivity of $^{51}$Cr was measured by a single channel $\gamma$-ray spectrometer made by the Atomic Instrument Co., Model 810A, (well type, NaI crystal, $1^3/_4'' \phi \times 2''$). $\gamma$-Ray of 0.32 MeV. of $^{51}$Cr was measured at the photo-peak by this counter.

**Measurement of Solubility of Hexamminechromium(III) Nitrate in Nitric Acid.**—The solubility of hexamminechromium(III) nitrate in nitric acid was determined in advance. Each 0.2 g. of the sample was shaken with 25 ml. of nitric acid of various concentrations for two or four minutes at 20°C. Results are listed in Table I. The solubility was about 1 mg./25 ml. for the acidity of 8~12 N at 20°C, but it was slightly greater for 6 N. Therefore the acidity of 8~12 N is preferable for this extraction process.

TABLE I. SOLUBILITY OF HEXAMMINECHROMIUM-(III) NITRATE IN NITRIC ACID (20°C)

| Concentration of $HNO_3$, N | Shaking time min. | Solubility, mg. $[Cr(NH_3)_6](NO_3)_3$/ 25 ml. |
|---|---|---|
| 6 | 2 | 3.1 |
| 6 | 4 | 3.4 |
| 8 | 2 | 1.2 |
| 8 | 4 | 1.1 |
| 10 | 2 | 1.0 |
| 10 | 4 | 0.91 |
| 12 | 2 | 0.89 |
| 12 | 4 | 0.89 |

**Determination of Chromium.**—Amounts of extracted chromium in the liquid phase were determined colorimetrically. After the liquid phase was centrifuged, the complex salt in it was destroyed by boiling with concentrated nitric acid repeatedly, and tervalent chromium was oxidized to the sexivalent state with silver peroxide and the amounts of sexivalent chromium were determined by the diphenylcarbazide method[10]. The enrichment factors, $E$ were calculated by the following formula:

$$E = \frac{a}{a_t} = \frac{M}{m} Y$$

where $a$ and $a_t$ denote specific activities in the liquid phase and in the irradiated complex salt before the process, respectively. $M$ and $m$ denote the amounts of chromium in the original salt and in the liquid phase, respectively. $Y$ is the yield of $^{51}$Cr in the liquid phase.

**Extraction of Enriched $^{55}$Cr.**—About 1 g. of hexamminechromium(III) nitrate was bombarded with neutrons produced by the cyclotron for about an hour or two. After irradiation, the target was divided into two portions. One was subjected to the measurement of radioactivity by a GM-counter tracing its decay (Sample I), and the other to the extraction of $^{55}$Cr with 20~50 ml. of 8 N nitric acid in an Erlenmeyer flask by being shaken vigorously for 2 min. After the extraction and centrifugal separation, the solid was washed with ethanol and dried in air. Its radioactivity was measured by a GM-counter tracing its decay (Sample II). Samples I and II were weighed, and the retention was calculated from the ratio of the specific activities of the two samples at the same time. The extraction yield was given by subtracting the retention value from 100%. The results are listed in Table II. The extraction yield higher than 60% was obtained and the enrichment factor of 200~400 was obtained. The enrichment of $^{55}$Cr has been attained by these simple and rapid procedures.

**Preparation of Enriched $^{51}$Cr.**—Enrichment of $^{51}$Cr was studied in the same way as in the case of $^{55}$Cr. About 1 g. of the sample was irradiated in the pneumatic tube in the nuclear reactor for 2 hr. After irradiation, the sample was shaken with 50 ml. of 8 N nitric acid in an Erlenmeyer flask for 2 min. After being centrifuged from the solid, an aliquot of the liquid phase was subjected to the measurement of radioactivity by a $\gamma$-ray spectrometer. The solid was dissolved in water, and the radioactivity of an aliquot of the solution was measured by a $\gamma$-ray spectrometer. The yield of $^{51}$Cr was calculated from these values. The results are shown in Table III. A yield of 57~73% was obtained. The enrichment factor was 24~41 which was much lower than the values of $^{55}$Cr.

**Extraction Curves on Repeated Extraction.**—In order to investigate the extraction mechanism, extraction curves on repeated extractions were observed. An outline of the procedures for the repeated extractions is illustrated in Fig. 1. About 0.2 g. of the sample was irradiated in the pneumatic tube in JRR-1, and treated according to the

procedures shown in Fig. 2, where the values of extraction yield at 20°C are plotted against the repetition number of extraction. The extraction yield was very large at the first extraction, and decreased first rapidly and then slowly. As is shown in Fig. 2, tails of the extraction curves are higher with the increasing concentration of nitric acid. The total extraction yield of five fold extraction is shown in Table IV. These values increase

TABLE IV. TOTAL RADIOCHEMICAL YIELD OF CHROMIUM-51 ON REPEATED HETEROGENEOUS EXTRACTIONS

| Series | 8 N $HNO_3$ % | 10 N $HNO_3$ % | 12 N $HNO_3$ % |
|---|---|---|---|
| No. 1 | 71.4 | 73.8 | 75.0 |

| No. 3 | 63.6 | 72.5 | 78.1 |

with the increasing concentration of nitric acid. In all experiments mentioned above, nitric acid was used for extraction. Howevere, as the target material is slightly soluble in nitric acid, it is necessary to investigate whether this small solubility plays an important role on the extraction process or not. Nitric acid solution saturated with hexamminechromium(III) nitrate was used as an extracting agent in order to suppress the dissolution of the target. The results are shown in Fig. 3. As a whole, no large difference is found between the results in Figs. 2 and 3, but the tails of the extraction curves seem to be slightly affected by using nitric acid saturated with the complex salt. All the extraction curves in Fig. 3 are similar in shape.

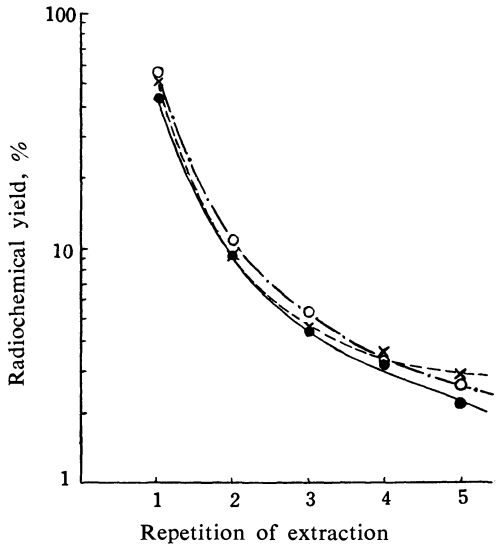

Fig. 3. Relationship between the radiochemical yield and the repetition of extraction (nitric acid saturated with hexamminechromium(III) nitrate).

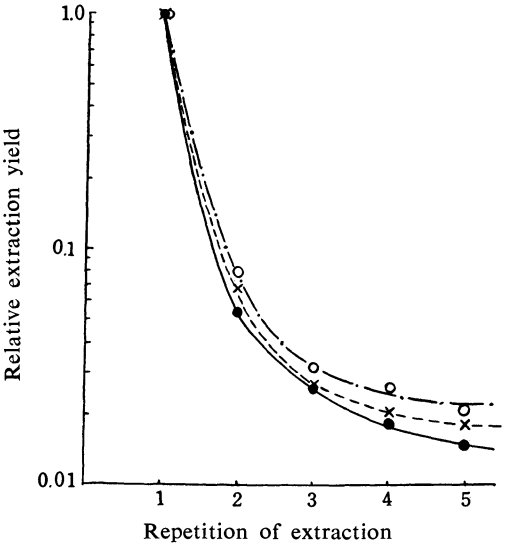

Fig. 4. Effects of shaking time on the extraction. 8 N $HNO_3$ was used for the extraction; shaking time: —●— 1 min. -·-○·- 10 min. ···×··· 6 min.

The effect of shaking time on the extraction yield was investigated, using 8 N nitric acid without addition of the complex salt as the extracting agent. The sample was shaken for 6 or 10 min. The results are shown in Fig. 4. The tails of the extraction curves become higher with the increase of shaking time.

**Determination of Enrichment Factors.** — To calculate the enrichment factor of $^{51}Cr$ in each extract, chromium was determined colorimetrically as described before. The results are listed in Table V. The chromium found in the aqueous phase is derived from the dissolved complex salt or of radiation- and thermal-decomposition of the complex salt in the reactor. In Table V, "amount of chromium" (in 25 ml. extract) represents the amount of chromium calculated in the form of the complex salt. Comparing the amounts of chromium in Table V with those of dissolved chromium in Table I, it is shown that the solubility of the irradiated complex salt was much greater than that of the salt before irradiation. Even if radiation- and thermal-decomposition of the compolex in the reactor was considered, this could not account for the increase of the amount of chromium in the aqueous phase. At the first extraction, the enrichment factor was the largest, and it fell down with the repetition of extraction. The effect of concentration of nitric acid is distinctly seen on the fourth and the fifth extraction in the table.

TABLE V. ENRICHMENT FACTORS OF CHROMIUM-51 ON EACH EXTRACTION

| Extraction number | | Amount of chromium, mg. $[Cr(NH_3)_6]\cdot(NO_3)_3$ | Enrichment factor |
|---|---|---|---|
| 8 N $HNO_3$ | 1 | 5.4 | 20 |
| | 2 | 2.8 | 5.4 |
| | 3 | 2.7 | 2.8 |
| | 4 | 3.0 | 1.5 |
| | 5 | 3.7 | 0.9 |
| 8 N $HNO_3$ | 1 | 5.6 | 20 |
| | 2 | 2.9 | 6.5 |
| | 3 | 2.5 | 3.2 |
| | 4 | 2.4 | 2.4 |
| | 5 | 2.1 | 2.3 |
| 8 N $HNO_3$ | 1 | 5.8 | 20 |
| | 2 | 3.0 | 5.5 |
| | 3 | 1.8 | 5.5 |
| | 4 | 1.9 | 3.7 |
| | 5 | 2.0 | 3.4 |

As dissolution of a small amount of the target is inevitable, the enrichment factor drops more or less in the heterogeneous extraction. Therefore, the enrichment factor of chromic ion which is the predominant species produced by the hot-atom effect was determined by the following procedures. The irradiated target was dissolved in water and an iron(III) carrier as well as chromate ion as a hold-back carrier was added to the solution. Ammonia was added to the mixture to precipitate ferric hydroxide with which chromic ion coprecipitates. After being washed with a very dilute aqueous ammonia, the precipitate was dissolved in hydrochloric acid and again ferric hydroxide was precipitated with ammonia. After being washed the precipitate was dissolved in 9 N hydrochloric acid, and the solution was extracted twice tri-*n*-butyl phosphate to remove the iron. The aqueous phase was washed twice with benzene to remove tri-*n*-butyl phosphate. The chromium content in the aqueous phase was determined colorimetrically. The enrichment factor of $^{51}Cr$(III) thus obtained was 150~230. As an enrichment factor of 20 was

obtained at the first extraction in Table V, dissolution of target material plays an important role in diminishing the enrichment factor of $^{51}Cr$ in the heterogeneous extraction.

**Determination of Chemical Forms of Recoil Products.**— In the hot-atom effect of chromium complex salts, formation of chromate ion besides chromic ion was observed[8]. Harbottle[11] suggested that ammonium ion might act as a reducing agent on the recoil event in chromate. As hexamminechromium(III) nitrate has six ammonia molecules in it, it was considered interesting to note whether sexivalent chromium was formed in the target or not.

This was investigated in the following way. At first, the percentage of chromium(III) was determined. After adding 10 mg. of iron(III) carrier as well as 20 mg. of chromate as a hold back carrier to the aqueous solution of the irradiated target, ammonia was added to this mixture to precipitate ferric hydroxide. By this procedure, $[Cr(NH_3)_6](NO_3)_3$ and chromium(VI) were not precipitated while chromium(III) was coprecipitated with ferric hydroxide almost completely. The precipitate was separated and the radioactivity was measured by a $\gamma$-ray spectrometer.

Next, formation of chromium(VI) was tested by the following two methods; one is based on the precipitation of lead chromate in the presence of chromic ion as a hold-back carrier, and the other on the extraction of chromate with tri-*n*-butyl phosphate[8]. The latter method was preferable because of its exactness, and was adopted to determine the percentage of chromate. The aqueous solution of the irradiated target was made to 1 N by hydrochloric acid, and it was extracted with tri-*n*-butyl phosphate. Chromate was extracted into the tri-*n*-butyl phosphate phase, while the complex salt and chromic ion were left in the aqueous phase. The radioactivity of the organic layer was measured by a $\gamma$-ray spectrometer. Thus the distribution of the chemical forms of the recoil products were determined; chromium(III) fraction 98~99%, chromium(VI) fraction $<0.2\%$ and the retention 1~2%.

**Measurement of the Surface Area of the Target***.— The surface area of the target was measured by the nitrogen adsorption method before and after irradiation. Before irradiation, the mean grain size of 140~300 m$\mu$ was obtained, and this value was not substantially changed by irradiation.

## Discussion

On heterogeneous extraction of recoil atoms in hexammimechromium(III) nitrate, extraction curves were affectd neither by concentration of nitric acid, nor by the extraction time. Therefore the extraction mechanism in this method is considered to be mainly due to the surface process, because if the leaching process from the interior part of the target were a principal feature, great changes would be brought about in the extraction curve by changing the concentration of nitric acid or the extraction time. However, the tail of the extraction curve becomes higher at the higher concentration of nitric acid or at the longer extraction time. These results may be interprete by assuming that the leaching process more or less contributes to the whole process.

If the surface process were a predominant one, the following problems would arise. (1) How does the slight dissolution of hexamminechromium(III) nitrate into nitric acid affect the whole process? The previous experiment will furnish an answer to this problem. The extraction curve is not markedly changed even though the extraction is done with the use of nitric acid saturated with the complex salt. Perhaps this shows that slight dissolution of the target in the aqueous phase does not markedly affect the whole process of the extraction. (2) In order to obtain a large extraction yield such as several times ten per cent by the surface process, the grain size of the target must be vevy small and must be of the comparable order to the recoil range[12]. However, the mean grain size of the target used in these experiments was 140~300 m$\mu$ (This value was not substantially changed by irradiation.). This value is much greater than the value of 10 m$\mu$ or less which is considered to be a recoil range of the (n, $\gamma$)-reaction. How is this fact interpreted?

It is difficult to solve this problem clearly, but we may assume as follows: Hexamminechromium(III) nitrate is relatively unstable to heat and is apt to be decomposed beyond 100°C. In the case of the $^{50}Cr$ (n, $\gamma$) $^{51}Cr$ reaction, the recoil energy of the order of 300 eV. is dissipated in the neighborhood of the recoil atom, and therefore high temperature appears locally around it. For example, Harbottle[13] suggested that several thousands of atoms around the recoil atom attain to several hundred degrees in a molecular crystal. The thermal decomposition by heat liberated locally is considered to be very probable in this case. Chromium nitrate and ammonia molecules would be irregularly present in this "thermal spike". This part would be easily dissolved into the aqueous phase on contact with nitric acid. This part may be considered to be the path to nitric acid. A recoil atom present in this "thermal spike" would be expected to be carried into the nitric acid solution on extraction, and a crack which reaches the

surface after irradiation or on the extraction may be possible. Since ammonia is produced by decomposition of the complex salt, local high pressure may appear in the neighborhood of the "thermal spike". Calculating from the data of the recoil energy of the (n, $\gamma$)-reaction and the dissociation energy of the complex salt, ammonia molecules of the order of $10^4$ must be present around the "thermal spike". This high pressure may be apt to make a crack at the time of the extraction.

Owing to a thermal spike and/or a crack, the recoil atom would be extractable beyond the recoil range. A similar explanation is possible in the case of the hot-atom effect in hexamminecobalt(III) nitrate.

The heterogeneous extraction is applicale to the rapid separation of recoil atoms. Especially, it is very effective to separate the radioisotope such as $^{55}Cr$ which has a very short half-life. However, a very high enrichment factor is not expected by this method.

The authors wish to express their hearty thanks to Dr. Kenjiro Kimura, the Director of the Japan Atomic Energy Research Institute for his kind guidance and encouragement throughout this work, to Dr. Izumi Higuchi, Professor of Tohoku University for the measurement of the surface area of the target, to the members of the cyclotron group at the Institute of Physical and Chemical Research, Tokyo, for the bombardment of the samples, and also to Mr. Michimasa Arai for his helpful assistance. A part of the expense for this work was defrayed by a grant from the Ministry of Education, to which the authors' thanks are due.

# *Spectroscopic Studies on Molecular Configurations of Some Aliphatic Dinitriles. I. Infrared Spectra of Succinonitrile and Bis(succinonitrilo)copper(I) Nitrate*

By Ikuo MATSUBARA

(Received April 24, 1961)

Although the infrared spectra of many substances with polymethylene chains of the type $X-(CH_2)_n-X$ have been studied in relation to their molecular configurations[1], no detailed spectroscopic studies seem to have been made on the series of aliphatic dinitriles except for the case of succinonitrile[2,3]. An interpretation of the spectra of such compounds is always a difficult problem because of the complexity caused by the existence of a number of rotational isomers. By the use of low-temperature techniques, however, the spectra of single rotational isomers in the crystalline solid state may be obtained. It is true that the spectra in the solid state may be explained in part by comparing them with those of like molecules, but it would be of great value if the direct determination of their molecular configurations in the crystalline solid state could be made by other physical methods such as by X-ray crystal structure analysis. Incidentally aliphatic dinitriles form stable copper(I) complexes of the type $[Cu\{NC-(CH_2)_n-CN\}_2]NO_3$ $(n=2, 3\cdots)$[4]. The crystal structures of the first few members of this homologous series were studied recently by X-ray method and the configuration of the ligand dinitrile molecule in the crystals of each complex was determined[5-7]. The infrared spectra of these complexes, which may be analyzed on the basis of these results, would supply much useful data for the complete understanding of the spectra of dinitrile molecules. Naturally a rigorous analysis of the spectrum of a complex compound would be a complicated problem. Therefore, it should

first be assumed that the interaction forces between the ligand molecules are so small that the main features of the spectrum may be explained from the consideration of an isolated ligand molecule[8].

This paper will report on the study of the infrared spectrum of bis(succinonitrilo)copper-(I) nitrate, $[Cu(NC-CH_2-CH_2-CN)_2]NO_3$, in connection with the configuration of the ligand succinonitrile. The result of X-ray analysis[5] shows that in the crystals of this complex the ligand succinonitrile molecule is coordinated tetrahedrally with its nitrogen atoms of both ends to two different copper atoms and takes the gauche configuration. Therefore, the infrared data of this complex may be of interest in relation to the results of the spectroscopic studies on succinonitrile by Fitzgerald and Janz[2], and Nakagawa and Tokumaru[3], who concluded that this molecule exists as a mixture of two rotational isomers, trans and gauche, the latter being the more stable configuration at low temperatures. The spectral changes due to decomposition of the complex as a result of interaction with alkali halides have been of help in assigning the vibrational frequencies of succinonitrile. The assignments of the skeletal deformation vibrations were successfully carried out on the basis of the result of a normal coordinate treatment.

## Experimental

The method of preparation and the properties of bis(succinonitrilo)copper(I) nitrate are as described in the previous paper[5].

The infrared spectra of the complex and of succinonitrile in the 4000~400 $cm^{-1}$ region were obtained using a Perkin-Elmer Model 21 and a Perkin-Elmer Model 13 spectrophotometer (with sodium chloride and potassium bromide optics, respectively). Spectra in the cesium bromide region were also obtained using a Perkin-Elmer Model 21 spectrophotometer*. The spectrum of succinonitrile was recorded at room temperature and at −50°C. A low-temperature transmission cell of the type described by Nukada[9] was used to obtain the spectra at low temperatures. The results shown in Figs. 1a and 1b are essentially the same as those obtained by Fitzgerald and Janz[2]. The spectrum of the complex was obtained using both Nujol mull and potassium bromide disk techniques. Nujol mulls of the complex gave different spectra depending on the type of alkali halide cell windows used as supporting plates. The spectrum obtained by using KRS-5 plates and that obtained by using sodium chloride plates were at first identical with each other, but the latter soon began to change gradually with time. This suggests that some interaction exists between the complex and sodium chloride plates. When potassium bromide plates were used the reaction occurred so rapidly that the spectrum changed while it was being recorded. These changes are clearly seen in Fig. 2. The spectrum in Fig. 2a is that obtained by using KRS-5 plates. The spectra in Figs. 2b and 2c are those obtained respectively by the use of sodium chloride and potassium bromide plates. (These were recorded after the specimens had been placed in the laboratory for one day.) These two spectra are in some respects different from each other, showing that the reaction products are not the same in the two cases. The spectrum obtained from a potassium bromide disk of the complex is shown in Fig. 3, which agrees quite well with that obtained from a Nujol mull by the use of potassium bromide plates (Fig. 2c). This means that the same type of reaction occurred between the complex and potassium bromide in the two cases. The absorption frequencies of succinonitrile and bis(succinonitrilo)copper(I) nitrate are listed in Table I together with the assignment.

In Table II are included the absorption frequencies due to the nitrate ion in the complex.

## Results and Discussion

The spectral simplification that occurred when succinonitrile was cooled down to $-50°C$ is clearly seen in Fig. 1. In the $1400\sim400\ cm^{-1}$ region there are four absorption bands that disappear at low temperatures. Fitzgerald et al.[2] and Nakagawa et al.[3] assigned these bands, which are at frequencies of 1271, 917, 761 and $527\ cm^{-1}$, to the vibrations of the trans form (symmetry $C_{2h}$) and assigned all the remaining bands to the vibrations of the gauche form (symmetry $C_2$). As long as the ligand succinonitrile takes the gauche form in the crystals of bis(succinonitrilo)copper(I) nitrate[5], the spectrum of this complex should be closely correlated with that of succinonitrile at low the temperatures. In complete agreement with expectation, the Nujol mull spectrum of the complex (Fig. 2a) corresponds well with the low-temperature spectrum of succinonitrile (Fig. 1b) except for the regions where absorptions due to nitrate vibrations or skeletal vibrations of the complex take place. The fact that no absorptions occur at the four frequencies which were ascribed by the previous authors[2,3] to the vibrations of the trans form gives additional support to their conclusion. On the other hand, the spectra in Figs. 2b, 2c and 3 have absorptions corresponding to the trans vibrations and show spectral features similar to that of succinonitrile at room temperature (Fig. 1a). This means that splitting of copper-nitrogen coordinate bonds occurred and succinonitrile was isolated as a result of the interaction between the complex and alkali halides. The intense bands observed at 1348 and $830\ cm^{-1}$ in Fig. 2a must be ascribed to infrared active fundamentals of the nitrate ion in the complex. The weak doublet with peaks at 1757 and $1751\ cm^{-1}$ must be a certain combination band of the nitrate ion, because some

b) See Ref. 10 in text.

inorganic nitrates show weak absorptions in this region[10]. As a result of reaction with sodium chloride these nitrate bands have decreased in their intensities and new absorptions appeared at 1795, 1375/51 and 836 $cm^{-1}$ as shown in Fig. 2b. The reaction with potassium bromide caused the appearance of new bands at 1770, 1377 (or 1381) and 824 (or 826) $cm^{-1}$ as shown in Figs. 2c and 3. These new bands observed in the two cases correspond quite well with those of sodium nitrate and potassium nitrate, respectively (see Table II). Considering these results the reaction of the complex with alkali halides should be ascribed largely

10) F. A. Miller and C. H. Wilkins, *Anal. Chem.*, **24**, 1253 (1952).

to an ion interchange between the two phases. A weak band observed at 1043 $cm^{-1}$ in the spectrum of the complex may correspond to an infrared inactive frequency of the nitrate ion which may have become active due to the effect of the crystalline field of the complex.

The remaining bands of the complex are assigned to the vibrations of the gauche form of succinonitrile with reference to the results of the previous authors[2,3]. Thus the bands observed at 1310 and 1242 $cm^{-1}$ should be assigned to the B and A $CH_2$ wagging modes, respectively. The bands at 1202 $cm^{-1}$ should correspond to the A $CH_2$ twisting mode. On the other hand, the B $CH_2$ twisting mode remains unidentified. According to the result of the normal coordinate treatment by Nakagawa et al.[3] the B $CH_2$ twisting mode should have a frequency lower than that of the A counterpart, but no appropriate band is found either in the spectrum of the complex or in that of succinonitrile. The weak band at 1027 $cm^{-1}$ and the strong band at 1001 $cm^{-1}$ in the spectrum of succinonitrile are assigned to the A C–C stretching and the B C–CN stretching modes, respectively. This is in agreement with the expectation that a symmetrical skeletal stretching mode is generally weaker than an asymmetrical one in the infrared spectrum. The Raman counterparts of these bands are found at frequencies of 1027 and 1006 $cm^{-1}$ (see Table VIII in Appendix). The fact that the former is much stronger than the latter supports the above assignment because a totally symmetric vibration is expected to be strong in the Raman spectrum. At low temperatures the 1027 $cm^{-1}$ band increases in intensity relative to the 1001 $cm^{-1}$ one (Fig. 1b), showing that the A C–C stretching mode is susceptible to the effect of crystalline field. In the spectrum of the complex a relatively strong band is observed at 1021 $cm^{-1}$. This band may be assigned to the A C–C stretching mode. To the B C–CN stretching mode may correspond the weak band at 1010 $cm^{-1}$. The fact that the intensity relation of these two bands is reverse to what is observed in the case of succinonitrile seems not to be in harmony with this assignment, but we may tentatively ascribe it to the effect of the crystalline field of the complex. The strong band at 966 $cm^{-1}$, which corresponds to the 962 $cm^{-1}$ band in succinonitrile, is assigned to the A $CH_2$ rocking mode. The 818 $cm^{-1}$ band of succinonitrile with a shoulder at 813 $cm^{-1}$ splits into two components at low temperatures as shown in Fig. 1. One of the components at 820 $cm^{-1}$ is ascribed to the B $CH_2$ rocking mode and the other at 810 $cm^{-1}$ to the A C–CN stretching mode. In the spectrum of the complex no well-defined band maxima corresponding to these vibrations are observed, due to overlapping by the strong nitrate band at 830 $cm^{-1}$. However, the shoulder bands at 826 and 813 $cm^{-1}$ are assigned with confidence to the B $CH_2$ rocking and the A C–CN stretching modes, respectively. The $CH_2$ rocking frequencies of 1, 2-disubstituted ethanes are known to change conspicuously depending on the azimuthal angle of internal rotation, and therefore can be used to determine the molecular configurations of rotational isomers[11]. The azimuthal angle of internal rotation of succinonitrile in the crystals of the complex has been determined by X-ray analysis to be 53° taking the cis position as the origin[5]. The gauche angle of free succinonitrile must be close to this value, for the two $CH_2$ rocking frequencies of this molecule agree quite well with the corresponding values of the complex. This conclusion is also in good agreement with what is expected from the calculated frequencies of these vibrations[3].

Assignment of the skeletal deformation vibrations are made with reference to the result of a normal coordinate treatment (see Appendix). The 615 and 490 $cm^{-1}$ bands of the complex correspond each to the 603 and 480 $cm^{-1}$ bands of succinonitrile which are assigned to the B and A C–C–C bending modes, respectively. The weak band at 527 $cm^{-1}$ of succinonitrile which disappears at low temperatures and has no counterpart in the spectrum of the complex (Fig. 2a) corresponds to the $B_u$ C–C–C bending mode of the trans form. The bands at 385 and 356 $cm^{-1}$ of succinonitrile are assigned to the A and B C–C≡N (out-of-plane) bending modes of the gauche form, respectively. The 385 $cm^{-1}$ band may also have some contribution from the $A_u$ C–C≡N out-of-plane bending mode of the trans form. As shown in Fig. 2a the spectrum of the complex has an absorption band at 369 $cm^{-1}$ which probably corresponds to the Cu–N stretching mode, and the shoulder band at 360 $cm^{-1}$ may be correlated with the B C–C≡N bending mode. The absorption corresponding to the A C–C≡N bending mode is not observed, probably due to the overlapping by the 369 $cm^{-1}$ band. The $B_u$ C–C≡N in-plane bending mode of the trans form has a calculated frequency of 145 $cm^{-1}$, while the A and B C–C≡N (in-plane) bending modes of the gauche form have calculated frequencies of 178 and 247 $cm^{-1}$, respectively (see Table VIII in Appendix). The values for the gauche form are in good agreement with the observed Raman frequencies, while the infrared data in the region below 300 $cm^{-1}$ are

11) I. Nakagawa, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **76**, 813 (1955).

not available for this investigation. The fact that the C–C–C bending modes of nitriles such as acrylonitrile[12], malononitrile[13] and propionitrile[14] always appear in a region as high as 600~450 $cm^{-1}$ and that the C–C≡N (in-plane) bending modes lie in a region as low as 250~150 $cm^{-1}$ suggests that there must be considerable mixing of the two bending coordinates in these skeletal deformation vibrations and no single coordinate may be associated with the individual frequencies. Calculation of the potential energy distributions for the skeletal deformation vibrations has shown that the energies associated with the C–C–C bending and the C–C≡N (in-plane) bending motions are of the same order in these two types of vibration (see Appendix). In the spectrum of succinonitrile there are three absorptions in the 800~700 $cm^{-1}$ region other than that corresponding to the $CH_2$ rocking mode of the trans form. These bands with peaks at 780, 750 and 718 $cm^{-1}$ are observed to increase remarkably in their intensities at low temperatures (Fig. 1b). As Fujiyama and Shimanouchi[15] suggested, these may be attributed to overtones or combinations of some skeletal deformation vibrations of the gauche form. The proposed assignments for these vibrations are included in Table I.

The sharp band observed at 2283 $cm^{-1}$ in the Nujol mull spectrum (Fig. 2a) may correspond to the C≡N stretching vibration of the complex. The C≡N vibrational shift of 26 $cm^{-1}$ towards higher frequencies as compared with the free succinonitrile may be understood by considering the structure of the complex. X-Ray analysis of this complex[5] has revealed that the carbon-nitrogen bond distance is 1.14 Å and that the Cu–N–C–$CH_2$ group is close to linear, from which it is expected that the carbon-nitrogen bond is essentially of a triple-bond character, the contributions of polar resonance structures such as $-C^+=N^-$ being decreased, and the C≡N stretching frequency is thereby increased. Califano et al.[16] have shown that in the cases of nitriloxides, R–C≡N→O, the C≡N stretching frequencies are about 70 $cm^{-1}$ higher than those of the corresponding nitriles and have explained this as due to the coupling with the N→O stretching vibration. In the case of this complex the effect of the interaction between the C≡N stretching and the Cu–N stretching vibrations, though small, may also contribute to the increase in the C≡N stretching frequency.

## Summary

The infrared spectrum of bis(succinonitrilo)-copper(I) nitrate, $[Cu(NC-CH_2-CH_2-CN)_2]NO_3$, has been studied in relation to the molecular configuration of the ligand succinonitrile, which is known from X-ray analysis to be the gauche form. The spectral features of this complex are quite similar to those of free succinonitrile at −50°C in agreement with the conclusion of the previous workers that the gauche isomer of succinonitrile is stable at low temperatures. Thus all the main absorption bands of the complex were satisfactorily explained as due to the vibrations of the gauche isomer. Decomposition of the complex occurs as a result of interaction with alkali halides such as sodium chloride and potassium bromide, which causes the appearance of absorption bands corresponding to the vibrations of the trans isomer. Considering the frequency shifts of the nitrate vibrations the reaction of the complex with alkali halides should be ascribed largely to an ion interchange between the two phases. The increase of 26 $cm^{-1}$ in the C≡N stretching frequency by complex formation may be understood from the linear structure of the Cu–N–C–$CH_2$ group which suggests that the carbon-nitrogen bond is essentially of a triple-bond character, the contributions of polar resonance structures such as $-C^+=N^-$ being decreased. Assignment of the skeletal deformation frequencies has been made with the help of a normal coordinate treatment which also made possible discussions concerning the nature of these vibrations.

The author wishes to express his sincere thanks to Professor S. Imanishi of Kyushu University for his kind encouragement in the course of this study. He also wishes to thank Dr. H. Murata of Hiroshima University and Dr. I. Nakagawa of the University of Tokyo for many valuable discussions. He is also grateful to Mr. D. Miura of Toyo Rayon Co., Ltd. for carrying out the mechanical calculations and to Messrs. T. Ito, H. Kataoka and K. Shirasaki of Toyo Rayon Co., Ltd. for their assistance in experiments.

## Appendix: Calculation of Skeletal Vibrations

The skeletal vibrations of succinonitrile were calculated as a six-body problem. The in-plane skeletal vibrations of propionitrile (symmetry $C_s$) were also calculated as a four-body problem in order to obtain more information on the nature of the skeletal deformation vibrations of aliphatic nitriles. A potential function of the Urey-Bradley

type[17] was used, and the values of force constants were transferred from other related molecules as shown in Table III. The symmetry coordinates of propionitrile and succinonitrile listed in Tables IV and V were constructed from the internal coordinates shown in Figs. 4 and 5, respectively. In the trans form of succinonitrile (symmetry $C_{2h}$) there is no coupling between the C-C≡N in-plane bending and out-of-plane bending motions, because they belong to different classes (see Table V). In the gauche form (symmetry $C_2$), however, these two motions belong to the same classes and accordingly a coupling occurs between them. In the Urey-Bradley type of potential function no cross term corresponding to the interaction between the two C-C≡N bending coordinates is considered, while such an interaction term, $k(C\text{-}C\equiv N)$, was introduced in this calculation to obtain better agreement with the observed frequencies. The value of $k(C\text{-}C\equiv N)$ used in this case is also included in Table III. For the calculation of the kinetic energy matrices the assumed bond lengths of $r(CH_3\text{-}CH_2)=1.54$ Å, $r(CH_2\text{-}CH_2)=1.54$ Å, $r(CH_2\text{-}C)=1.50$ Å and $r(C\equiv N)=1.15$ Å and the bond angle of 109°28′ were used. The result obtained for the in-plane vibrations (A′) of propionitrile agrees well with the observed values[14] as shown in Table VI. In Table VII are listed the diagonal terms of the potential energy distribution[18], which show that the energies associated with the coordinates $S_4$(C-C-C bending) and $S_5$(C-C≡N bending) are of the same order in the two skeletal deformation vibrations. The signs of

the L matrix elements have revealed that the vibrations assigned to the C-C-C bending and the C-C≡N bending modes correspond respectively to the in-phase and the out-of-phase coupling of the above two coordinates. The calculated and the observed frequencies of succinonitrile are compared in Table VIII, and the diagonal terms of the potential energy distribution for the trans and the gauche forms are listed in Tables IX and X, respectively. In the case of the trans form, where no coupling between the in-plane ($A_g$ and $B_u$) and out-of-plane ($A_u$ and $B_g$) vibrations occurs, situation is the same as in propionitrile and energetically the contributions of both the coordinates $S_4$(C-C-C bending)

and $S_5$(C-C≡N bending) or those of $S_9$(C-C-C bending) and $S_{10}$(C-C≡N bending) are important in producing two each of the skeletal deformation vibrations belonging to class $A_g$ or $B_u$. It is shown from the signs of the L matrices that the vibrations assigned to the C-C-C bending modes (600~450 $cm^{-1}$) correspond to the in-phase coupling and those assigned to the C-C≡N bending modes (250~150 $cm^{-1}$) to the out-of-phase coupling of the two types of bending coordinate. The potential energy distributions show that the $A_g$ vibration which corresponds to the symmetric C-CN stretching mode has a large contribution from the C-C-C bending motion. This is in agreement with the result obtained in the case of 1,2-dichloroethane[19]. In the case of the gauche form coupling occurs between $S_4$, $S_5$ and $S_6$ or $S_9$, $S_{10}$ and $S_{11}$ to produce three each of the skeletal deformation frequencies belonging to class A or B. However, it may be noted that the contribution of $S_6$ or $S_{11}$ (C-C≡N out-of-plane bending) is predominant in the vibrations assigned to the C-C≡N bending modes (400~350 $cm^{-1}$). As in the case of the trans form the energetical contributions of both $S_4$ and $S_5$ or of both $S_9$ and $S_{10}$ are important in two each of the remaining skeletal deformation vibrations belonging to class A or B. The signs of the L matrix elements show that the vibrations assigned to the C-C-C bending modes (600~450 $cm^{-1}$) correspond to the in-phase coupling and those assigned to the C-C≡N bending modes (250~150 $cm^{-1}$) to the out-of-phase coupling of the two types of bending coordinate.

# *Spectroscopic Studies on Molecular Configurations of Some Aliphatic Dinitriles. II. Infrared Spectra of Glutaronitrile and Bis(glutaronitrilo)copper(I) Nitrate*

By Ikuo MATSUBARA

(Received April 24, 1961)

In the preceding paper[1] the author has reported on the analysis of the infrared spectrum of bis(succinonitrilo)copper(I) nitrate, which proved to be quite useful for the understanding of the spectrum of succinonitrile. As a continuation of the spectroscopic studies on the series of aliphatic dinitriles, the infrared spectrum of bis(glutaronitrilo)copper(I) nitrate, $[Cu\{NC-(CH_2)_3-CN\}_2]NO_3$, has been investigated in connection with the molecular configuration of glutaronitrile. This molecule has four possible spectroscopically distinguishable rotational isomers, *TT*, *TG*, *GG* and *GG'*[2], and the complexity of its spectrum in the liquid state, which may be ascribed to the coexistence of these rotational isomers, makes its analysis almost impossible. Recently the author has studied the infrared spectrum of glutaronitrile by the use of low-temperature techniques and found that this molecule forms two different crystalline solid phases, depending on the mode of crystallization[3]. Determination of the molecular configuration of glutaronitrile in each crystalline solid phase has been made possible by comparing the two solid-state spectra with that of bis(glutaronitrilo)copper(I) nitrate, the X-ray analysis of which has revealed that in the crystals of this complex the ligand glutaronitrile molecule takes the *GG* configuration[4]. The detailed analysis of the infrared spectrum of this complex which will be presented in this paper has been undertaken to interpret the whole spectrum of glutaronitrile both in the liquid and in the crystalline solid states. Calculation of the skeletal vibrations for each isomeric form of glutaronitrile also proved useful in determining the configuration of this molecule.

## Experimental

Bis(glutaronitrilo)copper(I) nitrate was prepared in the same way as that described in the previous paper[4].

The infrared spectra in the 4000~400 $cm^{-1}$ region of glutaronitrile and the complex were recorded using a Perkin-Elmer Model 21 and a Perkin-Elmer Model 13 spectrophotometer (with sodium chloride

and potassium bromide optics, respectively). The spectrum of glutaronitrile in the liquid state is shown in Fig. 1a. As has already been reported[3], glutaronitrile can form two different crystalline solid phases. By rapid cooling of the liquid down to −60°C a metastable crystalline form is obtained. This has the spectrum shown in Fig. 1b. When the solid is warmed up to −40°C an irreversible transition occurs giving a more stable crystalline form which has the spectrum shown in Fig. 1c. The spectrum of bis(glutaronitrilo)copper(I) nitrate was obtained using both Nujol mull and potassium bromide disk methods. The spectrum obtained from a Nujol mull of the complex by using KRS-5 supporting plates is shown in Fig. 2a. The spectrum in Fig. 2b is that obtained from a Nujol mull of the complex by using potassium bromide plates. (This spectrum was recorded after the specimen had been placed in the laboratory for one day.) These two spectra are very different from each other, showing that a reaction occurred between the complex and potassium bromide as in the case of bis(succinonitrilo)copper(I) nitrate[1]. The use of sodium chloride plates resulted in a spectrum identical with that in Fig. 2a and no time dependent change of the spectrum was observed. Potassium bromide disks of the complex gave different spectra depending on the pressure applied to prepare the disk. In Figs. 3a and 3b are shown the spectra obtained from the disks which were prepare by applying pressures of 8 tons and 10 tons, respectively. The potassium bromide disk having the spectrum shown in Fig. 3a, when repressed under a pressure of 10 tons, undergoes an irreversible change and

comes to exhibit a spectrum identical with that shown in Fig. 3b. The absorption frequencies of glutaronitrile and bis(glutaronitrilo)copper(I) nitrate are listed in Table I together with the assignment.

## Results and Discussion

The symmetry types and the selection rules for the fundamental vibrations of glutaronitrile in the 1400~400 $cm^{-1}$ region[5,6] are given in Table II. All the fifteen fundamental vibrations in this region are expected to be infrared active for the *TG*, *GG* and *GG'* isomers, while for the *TT* isomer two $CH_2$ twisting and one $CH_2$ rocking modes belonging to class $A_2$ are infrared inactive. As long as the ligand glutaronitrile takes the *GG* configuration in the crystals of bis(glutaronitrilo)copper(I) nitrate[4], its spectrum should be explained as due to the vibrations of the *GG* form of glutaronitrile. The spectrum obtained from a Nujol mull of this complex by using KRS-5 supporting plates (Fig. 2a) seems to be in good agreement with the selection rules for the *GG* isomer of glutaronitrile. On the other hand, the Nujol mull spectrum obtained by the use of potassium bromide plates (Fig. 2b) and the potassium bromide disk spectrum (Fig. 3a) are very different from the spectrum in Fig. 2a and are quite similar to that of the liquid glutaronitrile (Fig. 1a). This means that free glutaronitrile has been produced as a result of interaction between the complex and potassium bromide. This interaction caused the shifts of the nitrate bands of the complex observed at 1748, 1361 and 830 $cm^{-1}$ in Fig. 2a to 1770, 1385 and 826 $cm^{-1}$, respectively, as shown in Figs. 2b and 3. The latter frequencies agree quite well with those of potassium nitrate[7], showing that the mechanism of reaction of the complex and potassium bromide should be ascribed largely to an ion interchange between the two phases as in the case of bis-(succinonitrilo)copper(I) nitrate[1].

As reported in the previous paper[3] the spectrum of glutaronitrile in the stable crystalline form (Fig. 1c) is closely correlated with that of bis(glutaronitrilo)copper(I) nitrate shown in Fig. 2a. The one to one correspondences between the individual bands of the two spectra are almost complete except for the regions where absorptions due to nitrate vibrations or skeletal vibrations of the complex take place. From this result it has been concluded that glutaronitrile takes the *GG* configuration in the stable crystalline solid state[3]. The vibrational assignment of these two spectra, though tentative in nature, are made with reference to the work of Brown and Sheppard[8] on trimethylene halides which were also found to take the *GG* configuration in the crystalline solid state. Thus, the bands observed at 1350, 1316 and 1250 $cm^{-1}$ in the spectrum of the stable solid form (Fig. 1c) may be assigned to the $CH_2$ wagging modes and those at 1287/79, 1190 and 1125 $cm^{-1}$ to the $CH_2$ twisting modes. The behaviors of the $CH_2$ wagging modes are somewhat anomalous in the case of the complex (Fig. 2a). There are quite intense bands at 1334 and 1300 $cm^{-1}$ but no band is observable around 1250 $cm^{-1}$. Although this may be ascribed to the effect of the crystalline force field of the complex, no further discussions will be made at this stage. The bands observed at 1271, 1188 and 1130 $cm^{-1}$ in the spectrum

b) The disk was prepared by applying a pressure of 10 tons.

of the complex are assigned to the $CH_2$ twisting modes. Absorptions corresponding to the C–C stretching modes are found at 1065, 1026, 1010 and 873 $cm^{-1}$ in the spectrum of the stable solid form and at 1066, 1027, 1009 and 880 $cm^{-1}$ in the spectrum of the complex. To the $CH_2$ rocking modes may correspond the bands observed at 903, 837 and 768/54 $cm^{-1}$ in the spectrum of the stable solid form and those observed at 913, 830 and 778/67 $cm^{-1}$ in the spectrum of the complex.

The configuration of glutaronitrile in the metastable crystalline solid state must be the *TG* form as the *TT* form can be excluded from

consideration of the selection rules and the existence of the *GG'* form is considered improbable from steric reasons[3]. The vibrational assignment of the spectrum shown in Fig. 1b was made on this basis. Thus, the bands observed at 1364, 1328 and 1289/82 $cm^{-1}$ may be assigned to the $CH_2$ wagging modes, and those at 1300, 1224/14 and 1181/74 $cm^{-1}$ to the $CH_2$ twisting modes of the *TG* form. The bands at 1060, 1045, 1009 and 859 $cm^{-1}$ correspond to the C-C stretching modes and those at 943, 839/35 and 757/51 $cm^{-1}$ must be ascribed to the $CH_2$ rocking modes.

The majority of the bands in the liquid-state spectrum of glutaronitrile (Fig. 1a) can be satisfactorily explained as due to the vibrations of the *TG* and the *GG* isomers, and a few remaining bands must be ascribed to the vibrations of the *TT* form, because one of them at 737 $cm^{-1}$ certainly corresponds to the $CH_2$ rocking vibration of the methylene chain of the planar all-trans configuration[5,9]. These conclusions are further confirmed by the calculation of the skeletal deformation vibrations for each isomeric form of glutaronitrile (see Appendix). The results of the calculation show that each isomer should have two C-C-C bending frequencies in the 650～450 $cm^{-1}$ region. From the potential energy distributions it is shown that the energetical contributions of both the C-C-C bending and the C-C≡N (in-plane) bending motions are important in these skeletal deformation vibrations as in the case of succinonitrile[1]. The frequencies of 586 and 511 $cm^{-1}$ observed in the spectrum of the metastable solid form (Fig. 1b) agree quite well with the values of 567 and 507 $cm^{-1}$ calculated for the *TG* form. The frequencies of 588 and 537 $cm^{-1}$ observed in the spectrum of the stable solid form (Fig. 1c) and those of 586 and 544 $cm^{-1}$ in the spectrum of the complex (Fig. 2a) are in excellent agreement with the values of 590 and 535 $cm^{-1}$ calculated for the *GG* form. In the spectrum of the liquid glutaronitrile there are weak bands at 565 and 481 $cm^{-1}$ which disappear at low temperatures. These frequencies correspond well with the values of 546 and 441 $cm^{-1}$ calculated for the *TT* form. The values of 616 and 510 $cm^{-1}$ calculated for the *GG'* form seem not to be appropriate to explain the observed frequencies in all cases. The potassium bromide disk spectrum of the complex shown in Fig. 3b is different from the spectrum in Fig. 3a in that the absorptions corresponding to the vibrations of the *TT* form as described above are anomalously intense. It seems that the applied pressure of 10 tons must have favored the selective formation of the *TT* isomer in the reaction of the complex with potassium bromide. The spectrum in Fig. 3b shows a few other anomalously intense bands besides those mentioned above. These bands must also correspond to the vibrations of the *TT* form which could not be identified in the spectrum of the liquid glutaronitrile because of the overlapping of absorptions due to the *TG* or the *GG* form.

Spectral features of the complex in the C≡N stretching frequency region are similar to those of bis(succinonitrilo)copper(I) nitrate[1]. The sharp band observed at 2278 $cm^{-1}$ in the Nujol mull spectrum (Fig. 2a) should correspond to the C≡N stretching mode of the complex. The C≡N vibrational shift of 29 $cm^{-1}$ towards higher frequencies as compared with the free glutaronitrile may be explained from a consideration of the structure of the complex. From X-ray analysis of this complex[4] it has been found that the carbon-nitrogen bond distance is 1.14 Å and that the Cu-N-C-$CH_2$ group is close to linear. This suggests that the carbon-nitrogen bond is essentially of a triple-bond character, the contributions of polar resonance structures such as $-C^+=N^-$ being decreased, and the C≡N stretching frequency is thereby increased. The effect of coupling between the C≡N stretching and the Cu-N stretching vibrations, though small, may also contribute to the increase in the C≡N stretching frequency. As shown in Figs. 2b and 3, reaction with potassium bromide results in the appearance of the band at 2252 $cm^{-1}$ which corresponds to the C≡N stretching frequency of the free glutaronitrile. The band observed at 2353 $cm^{-1}$ in

9) H. Tschamler, *J. Chem. Phys.*, 22, 1845 (1954).

the Nujol mull spectrum is considered to be characteristic of the tetrahedral configuration of the complex as in the case of bis(succinonitrilo)copper(I) nitrate[1]. The origin of the band observed at 2208 $cm^{-1}$ is hard to explain, because its intensity tends to vary from specimen to specimen and no other homologues of this series of complex show any absorption at the corresponding frequency. For the present, it may be ascribed to a certain combination vibration or to a vibration of some impurities in the complex.

## Summary

The infrared spectra of glutaronitrile and bis(glutaronitrilo)copper(I) nitrate, $[Cu\{NC-(CH_2)_3-CN\}_2]NO_3$, have been studied. The spectrum of the complex has been analyzed on the basis of the result of X-ray analysis which disclosed that the ligand glutaronitrile takes the *GG* configuration in the crystals of this compound. This complex reacts with alkali halides such as potassium bromide, resulting in the isolation of free glutaronitrile. Considering

the frequency shifts of the nitrate vibrations the reaction of the complex with potassium bromide should be ascribed largely to an ion interchange between the two phases. The increase of 29 $cm^{-1}$ in the C≡N stretching frequency by complex formation may be understood from the linear structure of the Cu–N–C–$CH_2$ group which suggests that the carbon-nitrogen bond is essentially of a triple-bond character, the contributions of polar resonance structures such as $-C^+=N^-$ being decreased. Glutaronitrile can form two different crystalline solid phases, depending on the mode of crystallization. From comparison of the two solid-state spectra with that of the complex and from consideration of the vibrational selection rules it has been concluded that glutaronitrile takes the *GG* configuration in one crystalline solid state and the *TG* in the other, and that it exists as a mixture of three isomers, *GG*, *TG* and *TT* in the liquid state. Calculation of the skeletal deformation frequencies for each isomeric form has given the results which support this conclusion. Vibrational assignment of glutaronitrile in various states has been made satisfactorily on the basis of the above results.

The author wishes to express his hearty thanks to Professor S. Imanishi of Kyushu University for his kind encouragement in the course of this study. He is also indebted to Dr. H. Murata of Hiroshima University for many helpful discussions and to Mr. D. Miura

of Toyo Rayon Co., Ltd. for carrying out the mechanical calculations. The assistance of Messrs. T. Ito, H. Kataoka and K. Shirasaki of Toyo Rayon Co., Ltd. in experiments is also acknowledged.

## Appendix: Calculation of Skeletal Vibrations

The skeletal vibrations of glutaronitrile were calculated as a seven-body problem. Calculations were carried out on all the four isomeric forms, $TT(C_{2v})$, $GG(C_2)$, $GG'(C_s)$ and $TG(C_1)$. A potential function of the Urey-Bradley type[10] was used, and the values of force constants were transferred from succinonitrile[1] as shown in Table III. The symmetry coordinates of glutaronitrile listed in Table IV were constructed from the internal coordinates shown in Fig. 4. Except for the case

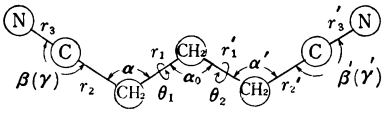

Fig. 4. Internal coordinates of glutaronitrile. $\beta$ (or $\beta'$) and $\gamma$ (or $\gamma'$) denote bending of C≡N bond in and out of the plane of the adjacent C-C-C linkage, respectively. $\theta_1=\theta_2=180°$ for $TT$, $\theta_1=\theta_2=60°$ for $GG$, $\theta_1=-\theta_2=60°$ for $GG'$, and $\theta_1=180°$ and $\theta_2=60°$ for $TG$.

of the $TT$ form, coupling between the C-C≡N in-plane and out-of-plane bending motions occurs. As in the case of succinonitrile[1] a cross term $k$(C-C≡N) corresponding to the interaction of the two C-C≡N bending coordinates was introduced into the potential function (Table III). For the calculation of the kinetic energy matrices the assumed bond lengths of $r(CH_2\text{-}CH_2)=1.54$ Å, $r(CH_2\text{-}C)=1.50$ Å and $r(C\equiv N)=1.15$ Å and the bond angle of 109°28′ were used.

The calculated frequencies are listed in Table V, in which the observed frequencies for the skeletal deformation vibrations are also included, although the observed data are not available for the region below 400 $cm^{-1}$. For each isomeric form there exist two vibrations corresponding to the C-C-C bending modes in the 650~450 $cm^{-1}$ region. The potential energy distributions listed together with the signs of the corresponding L matrix elements in Tables VI—IX show that these vibrations correspond to the in-phase coupling of the C-C-C bending and the C-C≡N (in-plane) bending motions. The agreement between the observed and the calculated frequencies of these vibrations are satisfactory, showing that the skeletal deformation frequencies of glutaronitrile are quite useful in determining the configurations of rotational isomers of this molecule.

# *Synthesis and Physical Properties of Normal Higher Primary Alcohols. IV. Thermal and X-Ray Studies on the Polymorphism of the Alcohols of Even Carbon Numbers from Dodecanol to Tetratriacontanol**

By Akira WATANABE

(Received April 20, 1961)

Since X-ray study on a series of normal paraffins was reported by Müller[1], several investigations have been made on the transition phenomenon of many long-chain compounds including acids[2-5], esters[3,6], bromides[7], and alcohols[8]. In these compounds, phase change is known to occur just below their freezing points accompanying the changes in a number of physical properties such as crystal structure, thermal property, and dipole moment in polar compounds. Recently nuclear magnetic resonance studies were also reported[9]. The $\alpha$ phase, which appears at the high temperature side, has been found to possess molecular freedom, the molecule being assumed to rotate about the long axis because of the characteristics of symmetrical crystal structure and high dielectric constant in this phase.

Although Hoffman et al.[10] recently summarized the results of the several investigations mainly on paraffins and bromides, some problems seemed to remain to be solved. The results on the higher alcohols appearing in the literature seemed to be somewhat ambiguous and the data for the alcohols with odd carbon atoms and with more than eighteen carbon atoms are too scanty to permit generalization of the series. On the other hand, the transition phenomenon has been known to be affected by the presence of extremely small amounts of impurities as well as variations in the technique of measurements and in thermal histories of the materials. Therefore it was felt to be important to examine the phenomenon with a series of pure compounds under conditions as comparable as possible. In view of these facts, the author has undertaken a study of synthesis and physical properties of normal higher alcohols with more than ten carbon atoms in order to establish the existence of transition in each member and its dependency on chain length. The reports on the synthesis have been published[11] and in this paper investigation of thermal analyses and X-ray studies on the alcohols of even carbon atoms from dodecanol to tetratricontanol are reported.

**Nomenclature of the Phases.**—*$\alpha$-Form.*—This form obtained on crystallization from the melt is somewhat transparent and on further cooling changes to the more opaque $\beta$ or $\gamma$ form at the transition point. X-Ray analysis indicates that the hydrocarbon chain is vertical to the plane of the end groups and the dielectric constant is higher than those of the $\beta$ or $\gamma$ or liquid phase. It has also been known that this form is unstable and gradually transforms into a more stable $\gamma$ form on standing.

*$\beta$-Form.*—This form, in which the hydrocarbon chain is vertical to the plane of the end groups, appears below the transition point mainly in odd members and in shorter members of the even alcohols. In the latter case, gradual transformation from $\beta$ to $\gamma$ form is known to exist in some of the members.

*$\gamma$-Form.*—This form, in which the hydrocarbon chain inclines to the plane, appears below the transition point only in even compounds and is stable at low temperature.

The correspondence of the present nomenclature to those adopted by other workers is as follows.

* This study has been carried out at the Department of Physics, Faculty of Science, Kyoto University, as a part of the cooperative research on "Synthesis and Physical Properties of Long Chain Compounds".

## Experimental

**Purity of the Materials.**—The alcohols used in this study were all prepared by the lithium aluminum hydride reduction of the corresponding fatty acids or their ethyl esters, the acids above octadecanoic being synthesized from the commercially available lower acids which were initially purified by fractional distillation followed by recrystallization. Since it is difficult to purify the compounds in high purity or to obtain a reliable method to establish their purity when the carbon chain is considerably long, the present efforts were made especially toward the purification of the alcohols above tetracosanol.

As is generally known, elemental analysis data which were presented in previous papers[11], are poor criterions for judging the purity of the compounds with more than about eighteen carbon atoms. It was found, however, in the present study that the transition point rather than the melting point proved to be reliable because repetition of the purification process resulted in the raising or disappearance of the transition points though the melting point did not vary noticeably. Table I gives the melting, freezing and transition points of pure and mixed alcohols.

X-Ray examinations also revealed the interesting facts that the presence of as much as 0.5% of hexadecanol in octadecanol resulted in the apparance of $\beta$ spacing while only $\gamma$ spacing was found in octadecanol assumed to be pure. Similar states were found in higher members. Fig. 1 shows this phenomenon clearly.

The purification of the final products were carried out extensively by means of high-vacuum distillation followed by recrystallization until the melting points, transition points and X-ray spacings became constant.

The facts that the melting points and transition points of the alcohols obtained fell on smooth curves (Fig. 8) and the X-ray spacings of the alcohols above hexadecanol gave only $\gamma$ form, indicate the high purity of the materials.

**Time-heating Curves.** — The melting points and transition points were determined by thermal analysis. A small drop of the molten substance was put on a junction of thermocouple which is made of copper and constantan of about 0.01 mm. in diameter and it was inserted into a doubly air-jacketed tube placed in a water bath.

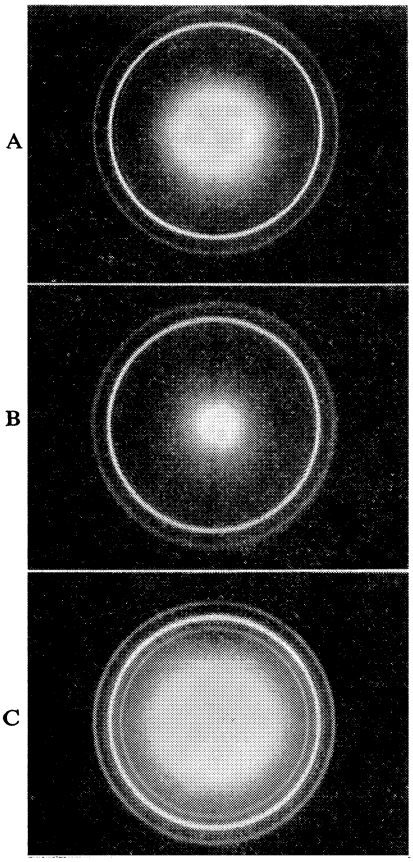

Fig. 1. X-Ray diffraction patterns of pure and mixed alcohols.
A Pure $C_{18}H_{37}OH$

C $C_{22}H_{45}OH$ containing 1% $C_{24}H_{49}OH$

Since a higher heating rate was found to be advantageous for good determination of the temperature, the measurements were carried out at the rate of about 2.0°C per minute, readings being taken every 10 sec. Each compound was run at least five times and the reproduciblity of the data was good. Probable errors of the temperatures determined on heating were estimated as being 0.1 to 0.3°C depending on the sharpness of the inflexion points and on the errors on calibration of

The temperature was measured by capillary method and uncorrected.
The heating or cooling speed was 1°C per minute.

the thermocouple, but those of cooling were about 1°C because the high temperature forms tended to supercool before the transitions, as may be seen in Fig. 4.

**X-Ray Pattern Measurements.**—It is known that the crystal spacings of the alcohols so far investigated here consist of $\beta$ and or $\gamma$ modifications in their low temperature forms and $\alpha$ modification in their high temperature form. The three modifications indicate different long spacing depending on different angles of inclination of hydrocarbon chains with respect to the planes of end groups. The most inclined $\gamma$ form shows the shortest spacing. The short spacing also indicates a greater value in $\alpha$ and $\beta$ forms because the molecules are more loosely packed in these forms than in the $\gamma$ form. The data of all the compounds were reported in a previous paper[12] and are represented graphically here (Fig. 2). In the present investigation emphasis was laid on changes of spacings under various conditions especially on the correlations with thermal analyses using the same materials. The X-ray photographs were all taken using Cu-K radiation at 40 KV. and 20 ma. Camera distances and exposure times were varied depending on the chain lengths of the compounds.

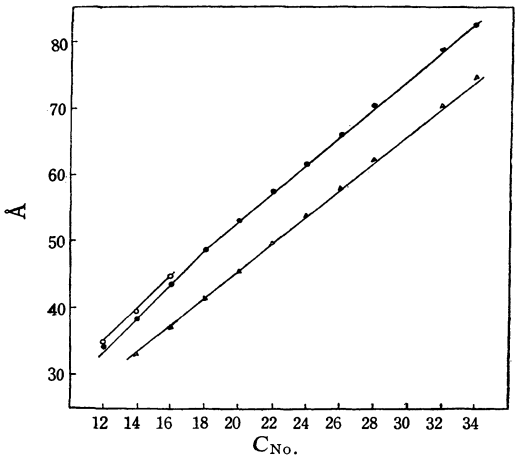

Fig. 2. Long spacings of *n*-higher alcohols.

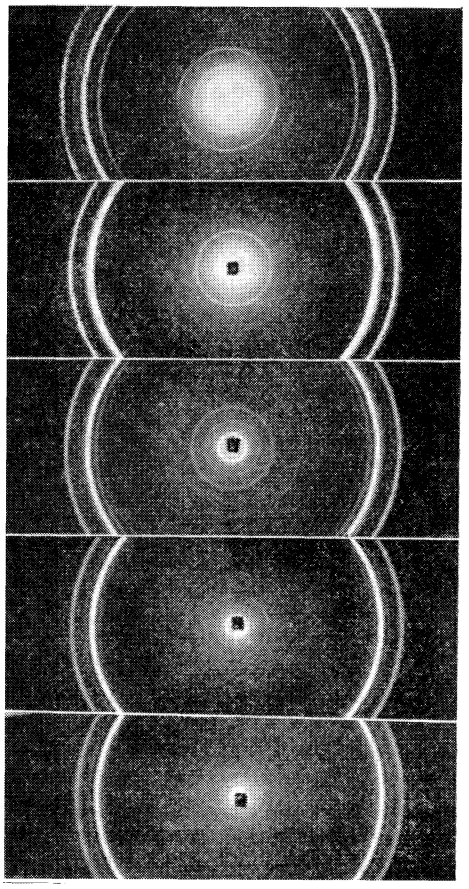

Fig. 3. Representative X-ray diffraction patterns of alcohols. The patterns in discending order are from $C_{12}$, $C_{16}$, $C_{18}$, $C_{24}$, $C_{28}$ alcohols.

Patterns such as Fig. 3 were taken by the method of sampling as follows. The melted samples were mounted on aluminum rings with about 1.2 mm. diameter and 0.8 mm. width and then solidified in the air. The beam was irradiated perpendicularly to the plane of the sample.

An effective method for the detection of $\alpha$ or $\beta$ form in $\gamma$ form was found to be the measurement of the short spacing rather than that of the long spacing. To prepare specimens for these measurements the melted materials were drawn into thin-walled capillary tubes of about 0.2 mm. diameter. The rapidly cooled specimens were obtained by plunging the capillary tube containing the melt into an ice bath. On taking a photograph the capillary tubes were rotated during exposure. An electrically heated brass furnace in which the capillary tube was inserted was used, if necessary. Accuracy of the temperatures measured by means of a copper-constantan thermocouple was within 0.5°C.

## Results and Discussion

The transition temperatures on cooling which were obtained by visual observation have been presented in earlier paper[11], but in this method it was experienced to be difficult to

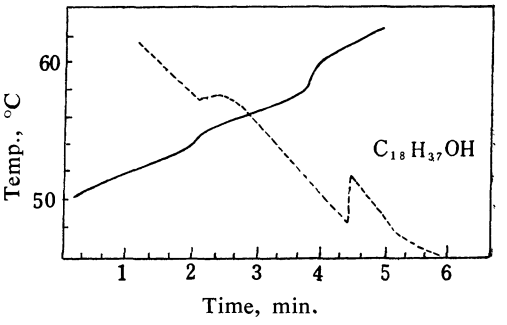

Fig. 4. Time-temperature curves for octadecanol.

12) a) K. Tanaka, T. Seto and T. Hayashida, *Bull. Inst. Chem. Res. Kyoto. Univ.*, 35, 123 (1957). b) K. Tanaka, T. Seto and A. Watanabe and T. Hayashida, ibid., 37, 281 (1959).

identify the transition point on heating. By the present study more reliable and detailed results could be obtained.

**Rotational Transition.**—Typical thermograms obtained for octadecanol are given in Fig. 4. Phase transitions, which occur at 54.5°C on heating and at 52.5°C on cooling, are shown by the break in the curves, latent heat absorption or evolution being indicated. Evidently the transition is of the first order and reversible. The previous X-ray diffraction patterns[12] and dipole moment measurements[13] indicated that the transition is rotational. For the alcohols from tetradecanol to hexacosanol similar thermograms were obtained as those presented above in contrast with the results of Phillips and other workers[8a,f] who reported the transitions only on cooling in most of these alcohols. However, the present results were very reproducible even when the thermal histories of the samples had been varied and, furthermore, the data were consistent with those obtained by the previous X-ray patterns[12],*.

Although the present thermal studies for tetradecanol and hexadecanol could not reveal three formes, the previous X-ray studies[12] indicated that these compounds are trimorphic in the solid state and the low temperature forms which consisted of $\beta$ and $\gamma$ forms, transform them into high temperature form ($\alpha$) at the different temperatures, the lower temperatures being the $\beta$ to $\alpha$ transition point; the alcohols above hexadecanol showed the simple $\gamma$ to $\alpha$ transitions.

The break in the heating curve of hexacosanol was barely detectable and the interval

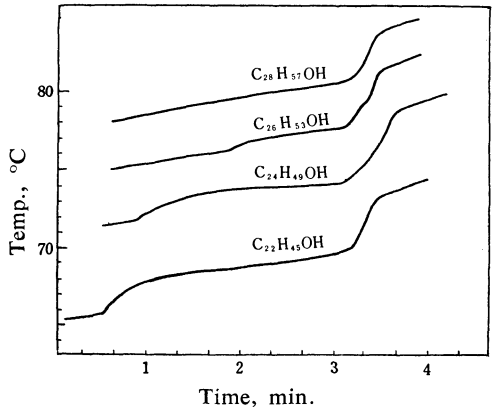

Fig. 5. Time-temperature curves for $C_{22}$, $C_{24}$, $C_{26}$, $C_{28}$ alcohols.

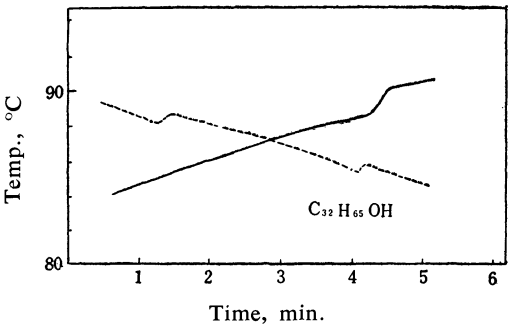

Fig. 6. Time-temperature curves for dotricontanol.

between the melting and transition points is narrow (1.2°C) (Fig. 5). The behaviors of the alcohols above hexacosanol differ markedly from those of the lower members of the series. The curves for octacosanol and dotriacontanol showed that the transitions on heation are missing while those on cooling are still present, However, both transitions were found to disappear at tetratriacontanol. These results are consistent with those by the present X-ray data, according to which in two shorter members ($C_{28}$, $C_{32}$) the $\gamma$ form persisted up to the melting points and in the last member ($C_{34}$) only the $\gamma$ form appeared at the temperature just below its freezing point.

Concerning the existence of transition in dodecanol some disagreements can be found in the literature[8ac,9ab,12a,14-16]. In the present study, non-existence of the transition was verified by the method such as thermal analysis using rapidly or slowly cooling technique, or X-ray pattern measurements made just below the freezing point with an exposure time of 15 min., and dielectric constant measurements

It appears to be interesting that variations in properties of the $\alpha$ forms were observed as the chain length of the compounds increased. In the previous and present studies the following observations have been obtained.

I) Opacities of $\alpha$ forms increase in visual inspections.

II) Inflexions at the transition points become smaller (Fig. 5).

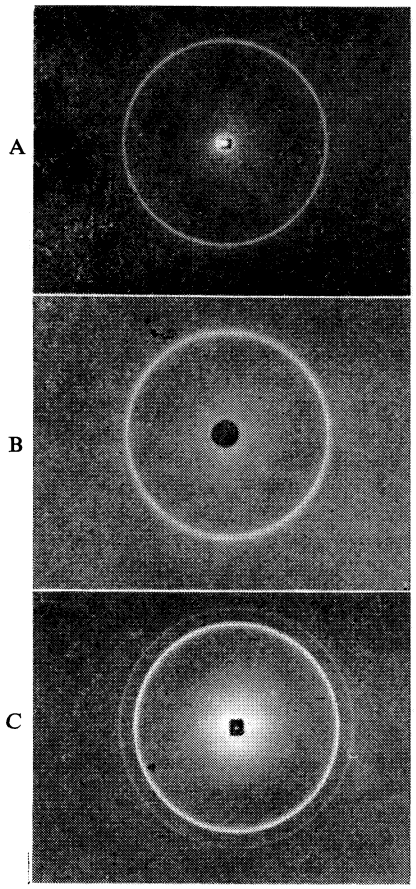

Fig. 9. X-Ray diffraction patterns of the $\alpha$ forms. The photographs were taken after the samples had been standing at the temperatures just below their freezing points for 2 hr.
A $C_{16}H_{33}OH$ C $C_{14}H_{29}OH$
B $C_{26}H_{53}OH$

III) Side spacings of $\alpha$ forms split into two lines (Fig. 9).

IV) In $\alpha$ forms inclination of the hydrocarbon chain to the plane of the ends increases (Fig. 2).

These facts would suggest that deviations in configurations or molecular motions from the typical rotational state may increase as the chain lengthens. Although it is necessary for complete interpretations of the data to await to obtain further data, a possible surmise is that molecular vibration around the axis, rather than rotation, may be caused in such longer compounds.

**$\beta$ to $\gamma$ Transformation***.—It was reported by Smyth et al.[8c] to explain their result by dielectric constant measurements that in octadecanol and other alcohols rotational transition

* According to Hoffman, the term transformation will be used here to denote phase changes such as $\beta$ to $\gamma$ or $\alpha$ to $\gamma$ which occur spontaneously on storage.

appeared when the sample was heated immediately after it was cooled from the melt while the transition failed to appear on heating the stored sample. Their argument suggests that the $\beta$ form obtained on cooling may transform into the $\alpha$ form but the transformation of this $\beta$ form into the $\gamma$ form which has occurred during the storage, may make it difficult for the transition to take place. The latter X-ray investigation made by Kolp and Lutton[8f] seemed to substantiate this fact although there appeared to remain some doubts in their thermal analysis. As described above, however, the present thermal studies showed that heating transitions invariably appeared in the materials which had been prepared under various conditions such as rapid cooling, slow cooling, or prolonged storage and X-ray data also revealed the existence of $\gamma$ to $\alpha$ transitions.

Apart from the facts described above, examination with $\beta$ to $\gamma$ transformation seemed to be so interesting that more detailed X-ray studies were undertaken. The results of the experiments with tetradecanol and hexadecanol indicated that this transformation took place as evidenced by the increasing intensity of the $\gamma$ spacings. They appeared to be very gradual, occurring over a wide temperature range. For example, after being kept at 42°C for 24 hr. a sample of hexadecanol showed nearly equal amounts of $\beta$ and $\gamma$ forms in their low temperature form which had consisted of about $2/3\beta$ and $1/3\gamma$ forms before the heating. Both compounds indicated no transformation on storage at about 25°C for 24 hr. It was also found that the low temperature forms of these alcohols contained more $\gamma$ forms when they were cooled slowly from the melt as compared with when they were cooled rapidly. This may be partly due to the $\beta$ to $\gamma$ transformations which occurred during the cooling and partly due to the $\alpha$ to $\gamma$ transformations which will be discussed in the next section.

Because of the absence of the $\beta$ form in alcohols above hexadecanol, this transformation can not be considered in these compounds. It may be concluded that the $\beta$ to $\gamma$ transformation exists only in tetradecanol and hexadecanol but it is so slow as to provide no appreciable effects on rotational transitions in qualitative measurements.

**$\alpha$ to $\gamma$ Transformation.**—This transformation, as well as $\beta$ to $\gamma$ transformation, was reported by Smyth, Kolp and other workers[8cf]. Recently Asai[13] demonstrated the stability of the $\alpha$ form in octadecanol in his dielectric constant measurements. In the present X-ray investigations the behaviors of $\alpha$ forms in the series were examined by careful control of the temperatures of the samples. It was found that the high temperature form of tetradecanol consists of $\alpha$ and $\gamma$ forms, the former being the less stable. The data were obtained by holding the compound at the temperature just below its freezing point for about 2 hr., indicating that about 2/3 of the initially existing $\alpha$ form was transformed into the $\gamma$ form (Fig. 9). In hexadecanol evidence of a smilar behavior was found at the temperature 1°C above its transition point, but at the temperature 1°C below its freezing point the observed spacing indicated only the $\alpha$ form. This $\alpha$ form proved to be stable so that no transformation could be observed within a few hours (Fig. 9). The $\alpha$ forms appearing in the alcohols above hexadecanol showed a considerable stability over the entire region of the temperatures. The relationship described above is illustrated diagrammatically in Fig. 10. It

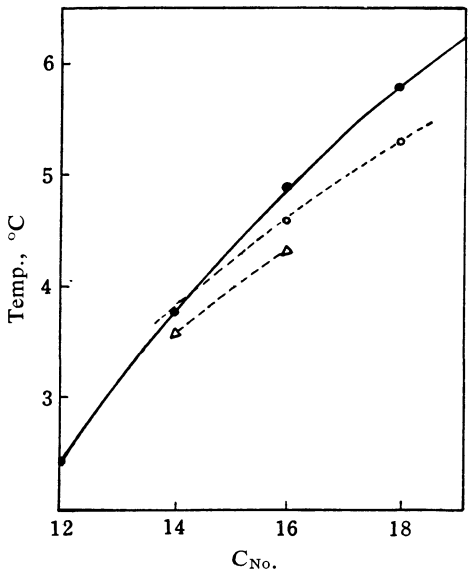

Fig. 10.

● Melting point
○ $\gamma$ to $\alpha$ transition point
△ $\beta$ to $\alpha$ transition point

will be apparent that $\gamma$ to $\alpha$ transition points are higher than $\beta$ to $\alpha$ transition points and that the $\alpha$ form is unstable only when it coexists with the $\gamma$ form but once $\gamma$ to $\alpha$ transformations have taken place the resulting $\alpha$ form is stable.

It is expected that the $\alpha$ form obtained only on cooling may be somewhat unstable. However, the X-ray examinations show that the $\alpha$ form in dotriacontanol is stable at least within about 2 hr.

## Summary

1. Determination of the melting points and transition points of the even carbon numbered alcohols from $C_{12}$ to $C_{34}$ was made by thermal analysis. The transition points of the alcohols above $C_{18}$, except $C_{22}$, have never been reported.

2. The reversible transition sets in at $C_{14}$ and terminates at $C_{26}$. The transition of $C_{28}$ and $C_{32}$ is irreversible, appearing only on cooling and both transitions disappear at $C_{34}$. Probably the pure sample of dodecanol may indicate no transition in any methods of measurements.

3. Properties of the $\alpha$ forms gradually change with increasing chain lengths.

4. The $\beta$ to $\gamma$ and $\alpha$ to $\gamma$ transformations were examined by X-ray pattern measurements and the results were discussed.

5. Transition points and X-ray spacings may be reliable criteria of purity of higher alcohols, and probably of some other long chain compounds.

The author wishes to express his sincere thanks to Professor Ryozo Goto and Professor Kenzo Tanaka of Kyoto University for their continual guidance and encouragement. He is also grateful to Dr. Tsuneo Seto of Kyoto University for his kind direction and criticism in the X-ray diffraction measurements. Thanks are also tendered to Dr. Kenjiro Asai of Kyoto University for his kind direction in the dielectric constant measurements.

# SHORT COMMUNICATIONS

## *A New Rapid Method of Determining Molecular Weight of Water Soluble Linear Polymers by the Measurement of Rate of Settling of Clay Suspensions*

By Yūkichi TOYOSHIMA

(Received April 25, 1961)

During the past decade it has been reported that certain water-soluble linear polymers can give rise to the aggregation of clay particles in a state of aqueous suspension[1,2]. In this communication this fact was investigated in a more quantitative manner by observing the relation between the rate of (hindered[3]) settling $v$ of clay suspensions under addition of a linear polymer and the molecular weight of the polymer.

Itaya clay (product of Yamagata Prefecture) levigated and after removing pebbles and large aggregates, was dried and used as suspensoid. Polymers used in this study were purified as described in a previous article[4].

The suspension was introduced in a sedimentation tube of 67.3 cm. long, which was agitated by rotating the tube for 15 min. at a speed of 5 revolutions per minute. After stopping agitation, settling rate of the suspension was measured at $30.0\pm0.1$°C. Intrinsic viscosity of the polymer freshly dissolved in aqueous 1 M sodium nitrate solution was also measured at $30.00\pm0.01$°C in a capillary viscometer of the Ubbelohde type, and the molecular weight of the polymer was determined from it.

In Figs. 1 and 2 $v\sim[\eta]^{30°C}_{1\,M\,NaNO_3}$ relation was shown for thy system in which 0.02% (to the amount of clay) of polymer was added to the 5% clay suspension. A linear relationship between $v$ and $[\eta]^{30°C}_{1\,M\,NaNO_3}$ was confirmed. A similar linearity was also found for a different content of polymers (below 0.02%) and a different concentrations of clay suspensions (above 5%) so long as the other experimental conditions were kept constant. We may discuss in details the mechanism of aggregation

of clay particles referring to this linearity in a separate reports*. Here we should like rather to draw attention to the fact that using this relation between $v$ and $[\eta]^{30°C}_{1\,M\,NaNO_3}$ together with the known relation between $[\eta]^{30°C}_{1\,M\,NaNO_3}$ and molecular weight $M$ of the polymer, we can correlate $v$ with $M$, and that using such a relationship we can determine the molecular weight from the measurement of sedimentation velocity, which is easier to practise than a similar and well known method of molecular weight determination by the measurement of intrinsic viscosity.

In the case of polyacrylamide, $v \sim [\eta]$ relation is expressed as

$$v = K[\eta]^{30°C}_{1\,M\,NaNO_3} + a \quad (1)$$

while that of $[\eta]$ and $M$ is

$$[\eta]^{30°C}_{1\,M\,NaNO_3} = 3.73 \times 10^{-4} M^{0.66} \quad (2)$$

therefore we obtain from 1 and 2,

$$\log(v-a) = 0.66 \log M + \log(3.73K \times 10^{-4}) \quad (3)$$

where $K$ is a constant, and $a$ the rate of settling without the addition of polymer. Measurement of $[\eta]^{30°C}_{1\,M\,NaNO_3}$, $v$ and $a$ shows that such a linear relationship really holds as shown in Fig. 3. Hence it enables a rapid

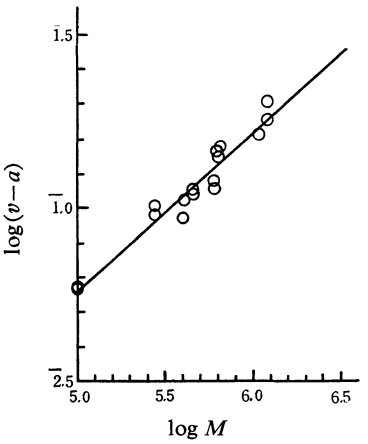

Fig. 3. The relationship between log $M$ and $\log(v-a)$ for polyacrylamides.

determination of the molecular weight of unknown polyacrylamide from the simple determination of rate of settling under the definite condition of sedimentation test using the clay suspension of the same origin. As for the other various water-soluble linear polymers, for instance, partially hydrolyzed polyacrylamide, polyvinyl alcohol, sodium carboxymethylcellulose, polyvinylpyrrolidone, dialdehyde starch, agar, gelatin, and polyethylene oxide, the same linear relationship as in Fig. 1 was also obtained as shown in Fig. 2. Hence their molecular weights can be rapidly determined from the rate of settling of

* The details will be published in a near future.

clay suspensions as in the case of polyacrylamide if the relationships between $[\eta]^{30°C}_{1\ M\ NaNO_3}$ and molecular weights for these polymers are determined previously by the method, for instance, of light scattering or osmotic pressure. As a routine procedure for product control, this new method is perhaps one of the rapid and simple methods for determining molecular weights of water-soluble linear polymers.

## *Cation-exchange Properties of Phosphoantimonic(V) Acid*

By Takuji Ito and Mitsuo Abe

(Received June 9, 1961)

Limitation of the use of organic ion-exchange resins, in recent years, brought much attention to the development of synthetic inorganic ion exchangers[1,2].

This paper describes some of the ion-exchange properties of phosphoantimonic(V) acid recently discovered. The experimental results indicate that the material is one of the very promising ion exchangers.

Experiment was made with an attempt to obtain the precipitate which was composed of antimony pentoxide and phosphoric acid. When antimony pentachloride was poured in the aqueous solution of phosphoric acid, the rate of formation of the precipitate obtained by the hydrolysis of the said chloride became extremely slow as the concentration of phosphoric acid increased. In case that the concentration of phosphoric acid was suitable relative to that of antimony pentachloride, gelatinous precipitate which was very difficult to filter was gradually formed in warming the solution. After filtering under suction and drying at 80°C, glassy materal was obtained. The material was physically and chemically stable against water, salt solutions and solutions of strong mineral acids, and showed strong cation-exchange properties even in dilute acid solutions.

When the material was added to 0.1 M ammonium nitrate solution its pH fell rapidly at first and then reached to a stational value (approximately 1.8), due to the liberation of $H^+$ produced by exchange with the cation in the solution. The adsorption of $NH_4^+$ on the material was 1.4 meq./g.

The analytical results of the glassy material indicate that the mole ratio of antimony pentoxide to phosphorus pentoxide contained was about 2 : 1.

This new material was provisionally given a name of "Phosphoantimonic Acid". This glassy acid was able to exchange reveresibly its $H^+$ with $NH_4^+$, alkali, alkaline earth and other metal ions (e. g. Ag, Cu etc.).

As one example of ion-exchange reversibility, 0.1 M ammonium nitrate solution was passed down a column (0.8 $cm^2 \times 7$ cm.) filled with this glassy ion exchanger of H-form. $H^+$ was liberated as a result of quantitative adsorption of $NH_4^+$. The adsorbed $NH_4^+$ was quantitatively eluted by treatment with 3 N nitric acid.

Extremely interesting is the strong adsorption of $K^+$ on the material in acid solutions. When the 0.01 M potassium chloride solution

1) K. A. Kraus, H. O. Philips, T. A. Carlson and J. S. Johnson, Paper 1832 presented at the 2nd International Conference of the Peaceful Uses of Atomic Energy, Geneva, 1958.
2) C. B. Amphlett, L. A. McDonald and M. J. Redman, *J. Inorg. & Nuclear Chem.*, 6, 220 (1958).

was added to a column in H-form, $K^+$ was adsorbed very easily and completely just as $NH_4^+$ done. The adsorbed $K^+$ could not eluted even by treatment with 3 N hydrochloric acid or 3 N nitric acid and it was, however, easily eluted with 1 M ammonium nitrate solution. It seemed to us that the abnormal absorbability on this material in strong acid solution might be perhaps attributed to the unordinary structure of phosphoantimonic acid.

The pH-titration curve of the glassy material showed that it was a strong monobasic acid (Fig. 1). It seems extremely possible that phosphoantimonic acid shows strong acid cation-exchange property, because antimonic acid (formally, hexahydroxyl antimonic acid $H[Sb(OH)_6]$) itself is monobasic and has the same strength of acidity as that of acetic acid (viz. dissociation constant; $H[Sb(OH)_6] = 4 \times 10^{-5}$, $CH_3COOH = 1.66 \times 10^{-5}$).

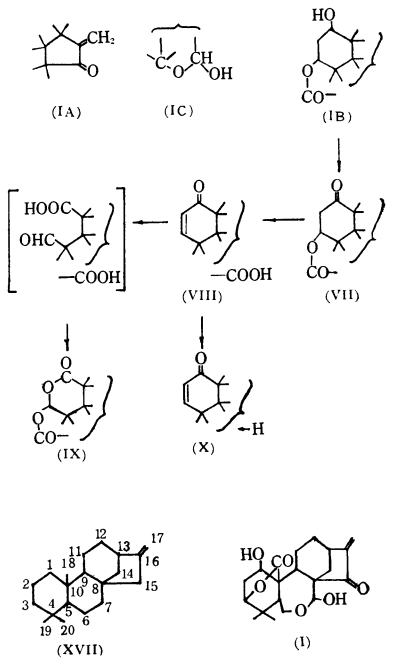
## *Chemical Constitution of Enmein a Bitter Principle from Isodon trichocarpus Kudo*



By Takashi KUBOTA, Teruo MATSUURA
Tsutomu TSUTSUI and Keizo NAYA

(Received September 11, 1961)

The partial structure IA was suggested by Takahashi, Fujita and Koyama[1] for enmein[2] (isodonin[3]), $C_{20}H_{26}O_6$, m. p. 274~275°C, $[\alpha]_D$ −156° (acetone). We now wish to propose the structure I for enmein from the following evidences.

Reduction reactions, carried out by us and by other investigators[1,2], of enmein are summarized as follows. Catalytic hydrogenation of enmein ($\lambda_{max}^{EtOH}$ 232.5 m$\mu$ ($\varepsilon$ 7400)) affords a mixture of dihydroenmein-a (IIa), $C_{20}H_{28}O_6$, m.p. 256~257°C (decomp.) ($\lambda_{max}^{EtOH}$ 297 m$\mu$ ($\varepsilon$ 36); $\nu_{max}$ 2.90, 5.72, 5.87 $\mu$), and dihydroenmein-b (IIb), $C_{20}H_{28}O_6$, m. p. 215~216°C (decomp.) ($\nu_{max}$ 2.82, 5.72, 5.82 $\mu$). On mild treatment with sodium borohydride IIb is epimerized to IIa. Dihydroenmein-a is also obtained by the sodium borohydride reduction of enmein in methanol at room temperature. Both dihydroenmeins give the same diacetate (III), $C_{24}H_{32}O_8$, m. p. 231~232°C (decomp.), which is obtained also by the reduction of diacetylenmein (IV), $C_{24}H_{30}O_8$, m. p. 221~223°C (decomp.). Both enmein and dihydroenmein are reduced with sodium borohydride in ethanol at 60°C to yield tetrahydroenmein (V), $C_{20}H_{30}O_6$, m. p. 260°C (decomp.) ($\nu_{max}$ 2.91, 5.86 $\mu$), (triacetate (VI), $C_{26}H_{36}O_9$, m. p. 193°C ($\nu_{max}$ 5.78 $\mu$, no hydroxyl)). Since dihydroenmein-a (IIa) ($\nu_{max}$ 5.87 $\mu$; exalted $\delta$-lactone) is recovered unchanged after consuming one mole of alkali on hydrolysis, it is suggested that enmein has a $\delta$-lactone group.

The partial structure IB is deduced from following results. Chromium trioxide-oxidation of dihydroenmein-a (IIa) affords bisdehydrodihydroenmein (VII), $C_{20}H_{24}O_6$, m. p. 251~253°C (decomp.), (monosemicarbazone, $C_{21}H_{27}O_6N_3$, m. p. 225~226°C). Bisdehydrodihydroenmein consumes one mole of dilute alkali (1/60 N) on hydrolysis to yield an acid (VIII),

$C_{20}H_{24}O_6 \cdot 1/3H_2O$, m. p. 233°C (decomp.) ($\nu_{max}$ 5.64, 5.75, 5.86, 6.01 $\mu$), (monomethylester, $C_{21}H_{26}O_6$, m.p. 245~246°C, monosemicarbazone, $C_{21}H_{27}O_6N_3$, m. p. 265~267°C (decomp.). Inspection of the ultraviolet spectra of VIII ($\lambda_{max}^{EtOH}$ 225 m$\mu$ ($\varepsilon$ 9600)) and its monosemicarbazone ($\lambda_{max}^{EtOH}$ 278 m$\mu$ ($\varepsilon$ 14300)) shows that the acid VIII possesses an $\alpha,\beta$-unsaturated

1) M. Takahashi, T. Fujita and Y. Koyama, *J. Pharm. Soc. Japan* (*Yakugaku Zasshi*), **78**, 699(1958); **80**, 594, 696(1960).
2) T. Ikeda and S. Kanatomo, ibid., **78**, 1123 (1958).
3) K. Naya, *J. Chem. Soc. Japan, Pure Chem. Soc.* (*Nippon Kagaku Zasshi*), **79**, 885 (1958). In comparison of infrared spectra, isodonin was identical with enmein which was kindly supplied by Dr. S. Kanatomo, Kanazawa University.

ketone group, –CO–CH=CH–. Ozonolysis of VIII affords a crystalline neutral substance (IX), $C_{19}H_{22}O_7$, m. p. 249~251°C (decomp.), which consumes two moles of dilute alkali (1/50 N) on hydrolysis, gives positive color reactions for an aldehyde and shows no more absorption of the enone group in its ultraviolet spectrum. On pyrolysis VIII is decarboxylated to yield a neutral substance (X), $C_{19}H_{24}O_4$, m. p. 169~172°C ($\lambda_{max}^{EtOH}$ 225 mμ (ε 8500)).

Bisdehydrodihydroenmein (VIII) consumes two moles of alkali (1/5 N) to yield an amorphous acid, while the neutral substance X is recovered unchanged after consuming one mole of alkali on hydrolysis. Therefore it is suggested that a lactone group is newly formed in oxidation of IIa to VII. On the other hand, treatment of dihydroenmein-a (IIa) with ethanolic sulfuric acid affords an *O*-ethyl derivative (XI), $C_{22}H_{32}O_6$, m. p. 193~195°C, (monoacetate, $C_{24}H_{34}O_7 \cdot 1/2C_6H_6$, m. p. 103~105°C, (no hydroxyl in its infrared spectrum)). Treatment of IIa with methanolic hydrogen chloride affords *O*-methyldihydroenmein(XII), $C_{21}H_{30}O_6$, m. p. 192~193°C, which reverts to dihydroenmein-a (IIa) on acid-catalyzed hydrolysis. The presence of a methoxyl group in XII was confirmed by the Zeisel analysis and the NMR spectrum (τ 6.68; three protons) of dehydro-*O*-methyldihydroenmein (XIII), $C_{21}H_{28}O_6$, m. p. 218~220°C, which is obtained from XII by chromium trioxide-oxidation. On hydrolysis XIII consumes one mole of alkali to yield a crystalline acid (XIV), $C_{21}H_{28}O_6 \cdot H_2O$, m. p. 190~192°C (decomp.) ($\lambda_{max}^{EtOH}$ 230 mμ (ε 9700); $\nu_{max}$ 5.75, 5.85, 5.97, 6.17 μ), (monomethyl ester $C_{22}H_{30}O_6$, m. p. 189~192°C ($\lambda_{max}^{EtOH}$ 228 mμ (ε 10400)), monosemicarbazone $C_{22}H_{31}O_6N_3 \cdot H_2O$, m. p. 205°C (decomp.) ($\lambda_{max}^{EtOH}$ 277.5 mμ (ε 14900)). Conversion of XII to XIV (via XIII) is easily recognized as the transformation, IB→VII→VIII, of the part IB in XII. From these results, it is concluded that the remaining oxygen atoms in the enmein molecule exist as a cyclic hemi-acetal group IC.

Recently two important degradation products were isolated by Kanatomo[4], namely 1-ethyl-4-(3, 3-dimethylcyclohexyl)benzene (XV) on dry distillation of enmein with baryta and retene (XVI) on selenium dehydrogenation of the lithium aluminum hydride-reduction product of dihydroenmein. Kanatomo suggested that enmein has the carbon skeleton of phyllocladene (XVII) and the ketonic and lactonic carbonyl groups exist at the $C_{15}$- and $C_{18}$-positions of XVII, respectively.

However, from the molecular formula and the partial structure, IA, IB and IC, of enmein, it is apparent that enmein must have a tricarbocyclic ring. Our proposed structure I for enmein is supported by the following evidences. The NMR spectra of diacetyldihydroenmein (III) and dehydro-*O*-methyldihydroenmein (XIII) show that the number of protons attached to the carbon atom, to which one or two oxygen atoms are bonded, is five (at the $C_1$-, $C_3$-, $C_6$- and $C_7$-positions) in III and four (at the $C_3$-, $C_6$- and $C_7$-positions) in XIII. Furthermore a sharp singlet (τ 3.80; one proton equivalent) attributed to the $C_7$-proton of the hemiacetal acetate[5] in III shows that the carbon atom adjacent to the hemiacetal group in enmein must have no hydrogen atom. From the biogenetic point of view, it is suggested that the hemiacetal group in the ring B may be formed from a 7-keto-diterpene by the Bayer-Villiger type oxidation followed by the reduction of a lactone formed.

## *Tritium and Carbon-14 in the Tree Rings*

By Kunihiko KIGOSHI and Yoshio TOMIKURA

(Received September 25, 1961)

The data on the atmospheric carbon-14 and tritium in recent years can be expected to furnish new information on the circulation problems of geophysics.

There are several data on the concentration of carbon-14 in the atmospheric carbon dioxide and of tritium in the rain water[1-3]. This note presents the results of measurements of the concentration of carbon-14 and tritium in the tree rings of recent years. The purpose of the measurements was to obtain the annual mean concentration of the atmospheric carbon-14 and of the tritium in the rain water.

TABLE I. TRITIUM AND CARBON-14 CONCENTRATION IN TREE RINGS

| Interval of growth of tree ring | Trritium concentration, $T/H \times 10^{18}$ | | Carbon-14 concentration** | |
|---|---|---|---|---|
| | Pine ; grown in Hiroshima* | Paulownia ; grown in Tokyo | Pine ; grown in Hiroshima* | Paulownia ; grown in Tokyo |
| Aug. 1953~Sept. 1954 | 92.2±6.2 | | 0.975±0.009 | |
| Aug. 1954~Sept. 1955 | 54.5±4.2 | 96.3±8.1 | 0.967±0.009 | 1.032±0.012 |
| Aug. 1955~Sept. 1956 | 80.7±8.9 | | 1.006±0.008 | |
| Aug. 1956~Sept. 1957 | 67.3±2.6 | 65.6±2.2 | 1.060±0.009 | 1.024±0.012 |
| Aug. 1957~Sept. 1958 | 138.7±3.9 | | 1.101±0.008 | 1.153±0.012 |
| Aug. 1958~Sept. 1959 | 304.4±3.0 | 261 ±3 | 1.192±0.012 | 1.196±0.013 |
| Aug. 1959~Sept. 1960 | 138.7±2.8* | 111 ±2.8 | 1.221±0.013- | 1.187±0.013 |

* This tree was cut down in April 1960, therefore the last tree ring corresponds to the period between Aug. 1959 and April 1960.

** The data are normalized to the concentration of Carbon-14 of the hypothetical modern wood which would not have been affected by industrial effect and nuclear tests.

The tree ring samples were previously dried in a vacuum desiccator at 110°C for several hours. The hydrogen in the tree ring was collected as water by combustion of the gas evolved by strong heating of the dried sample. The water obtained (100~150 ml.) was purified and electrolyzed in order of enrich the tritium. After the reduction of the volume of the water to about one hundredth, the deuterium content of the concentrate was measured by buoyancy method. The tritium disintegration rate was measured by an external quenched Geiger-Counter filled with hydrogen and propane. The preparation of hydrogen from the water and the operation of the counter were done in the similar manner to those developed by Östlund[4].

In Table I the measured tritium concentrations of the tree rings are shown together with the carbon-14 concentrations in the same tree rings. The carbon-14 concentrations were measured in the same manner as described in the previous paper[5]. The concentration of carbon-14 and tritium in the tree ring may be regarded as an annual mean value of the carbon-14 concentration in the atmosphere and that of the tritium concentration in the rain water respectively. The data on the carbon-14 presented here and in previous paper show a tendency of decrease after 1960 and seem to have a maximum value at the beginning of 1960.

The annual mean concentration of tritium in the rain water descreases after 1959 with the half life of about one year. Since the tritium in the troposphere has short mean life[2], the amount of tritium in the troposphere may be proportional to the amount of supply of tritium to the troposphere from the stratosphere. The observed decrease of tritium after 1959 and the annual variation of carbon-14 after 1959 suggest a stratospheric residence time of 1~2 years for these nuclides.

## *Variation of the Atmospheric Carbon-14 in Recent Years at Tokyo*

By Kunihiko KIGOSHI and Kunihiko ENDO

(Received September 25, 1961)

This note presents the results of measurements made in recent years of the atmospheric carbon-14. The data are expected to furnish informations about the circulation problems of geophysics as well as to contribute to the evaluation on the hazard from the man-made radionuclides. The atmospheric carbon dioxide was collected in Tokyo by means of the absorption in the sodium hydroxide solution. The radioactivities were measured by an acetylene filled proportional counter as described in the previous paper[1].

The results obtained are shown in Table I. The unit of the values of the carbon-14 concentration listed in the table is a concentration of atmospheric carbon-14 at eighteenth century

* The unit is a concentration of the atmospheric carbon-14 at eighteenth century.

calculated from the measured concentration of carbon-14 in the tree rings growing at that time.

Rafter and Fergusson[2] reported the carbon-14 concentrations in the atmosphere in New Zealand which showed regular increase of atmospheric carbon-14 concentration between December 1955 and December 1957 by nuclear tests. Compared to these data, Table I shows large fluctuation which might be due to the nature of the air mass at the collection date in Tokyo. The air mass into which carbon-14 from the stratosphere has been supplied at the latest time must have a high concentration of carbon-14. The exchange of carbon dioxide between the air and the surface ocean water may play an important role to surppress the atmospheric carbon-14 concentration. It has been observed by several authors[2-4] that the carbon-14 concentration in the surface ocean water showed large fluctuation due to the mixing of the surface water with the deep sea water. If this fluctuation has strong influence on the atmospheric carbon-14 concentration, the consideration on this line has to be taken for the evaluation of the Suess Effect and of the annual variation of the cosmic ray intensity measured by using the tree ring samples.

## *Dipole Moment and Infrared Spectrum of 2, 3, 5, 6-Tetraisopropylnitrobenzene*

By Ruka NAKASHIMA, Setsuo WATARAI and Toshio KINUGASA

(Received September 30, 1961)

Dipole moment and infrared spectrum of 2, 3, 5, 6-tetraisopropylnitrobenzene were examined. The process of the dipole moment measurement is the same as that described in the articles[1].

The dipole moment of this compound is 3.57D (in benzene solution, at 25±0.01°C), and is actually less than that of nitrobenzene (3.97D)[2], but not so different from that of nitrodurene (3.60D)[3].

The small value of the dipole moment observed is attributed, as generally accepted, to the decrease of the resonance moment of the nitro-group due to steric hindrance.

The infrared spectra were measured with a Perkin-Elmer Model 21 spectrophotometer (with rock salt prism) in chloroform solution in the region from 1670 to 1250 $cm^{-1}$.

Fig. 1 shows the infrared spectra of nitrodurene and 2, 3, 5, 6-tetraisopropylnitrobenzene, and the data are shown in Table I.

TABLE I

| Compound | N-O stretch. vib. Asym. $cm^{-1}$ | N-O stretch. vib. Sym. $cm^{-1}$ | Diff. from $C_6H_5$-$NO_2$ $\Delta As$ $cm^{-1}$ | Diff. from $C_6H_5$-$NO_2$ $\Delta S$ $cm^{-1}$ |
|---|---|---|---|---|
| $C_6H_5$-$NO_2$ | 1527 | 1348 | — | — |
| Nitrodurene | 1526 | 1378 | −1 | 30 |
| Nitro-tetra-iso Pr-$C_6H_5$ | 1524 | 1389 | −3 | 41 |

1) S. Mizushima and K. Higashi, *J. Chem. Soc. Japan (Nippon Kwagaku Kwaishi)*, **54**, 226 (1933).

2) Our observed data.

3) L. E. Sutton et al., *Rec. trav. chim.*, **78**, 790 (1959); In their paper, the dipole moment of nitrodurene was reported as 3.62 D, but they neglected $P_A$. So we recalculated their value in consideration of $P_A$ (≒5% of $P_E$) to fit to our data.

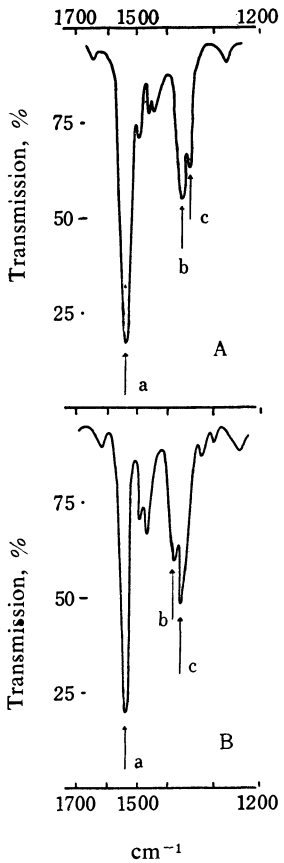

Fig. 1. Infrared spectra of nitrobenzenes (A: Nitrodurene, B: 2,3,5,6-tetra-isopropylnitrobenzene) in chloroform solution.

a: $\nu_{N-O}$ asym., b: $\nu_{N-O}$ sym., c: $\delta_{CH}$ in $-CH_3$

According to our previous observations on the general behavior of N–O sym. and asym. stretching vibrations of alkyl- and halogenonitrobenzenes[4], the N–O sym. was sensitive to the co-planarity of the nitro-group with the benzene plane, on the other hand, N–O asym. was affected by the polarity of substituents.

The infrared spectrum data obtained in the present investigation clearly reveal the general features mentioned above.

In comparing the value of $\Delta S$, which seemed to represent the magnitude of steric hindrance, it may be suggested that a larger steric hindrance was in 2, 3, 5, 6-tetraisopropylnitrobenzene than in nitrodurene.

There was a little discrepancy between the results obtained from the study with infrared spectrum and those from dipole moment.

A similar disagreement is found also in the series of the measurements of alkyl- and halogenonitrobenzenes, which will be discussed in elsewhere.

# *On the pH Dependence of Transport Behavior of Weak Acids and Weak Bases across Ion-exchange Membranes*

By Manabu Senō and Takeo Yamabe

(Received October 10, 1961)

We have pointed out that the transport behavior of weak acids and bases across ion-exchange membranes depends remarkably on the solution pH[1]. It is noticed that there is a range of pH at which the maximum transport takes place. This behavior is due to the suppression of dissociation of acids in the lower pH range, and to the contribution of the competitive transport of hydroxide ions in the higher pH range, in the case of weak acids for example. In this communication, this problem is treated in general and some useful conclusions are derived.

Let us consider the three-component system consisting of strongly dissociated ions $A^-$, e.g., chloride ions, weak acid ions $B^-$, and hydrogen or hydroxide ions. It is assumed that the concentration of each component of the sample solution remains unchanged in course of the electrodialysis experiment and all the electrolytes which are adsorbed in the membrane are in the dissociated state. Then, the permselectivity coefficient $T^{B}_{A+OH}$ is defined and written in terms of constant or known quantities as follows:

$$T^{B}_{A+OH}=\left(\frac{\bar{t}_B}{\bar{t}_A+\bar{t}_{OH}}\right)\Big/\left(\frac{C_{B_0}}{C_A+C_{OH}}\right)$$
$$=T'^{B}_{A}\cdot\frac{KC_{OH}}{1+KC_{OH}}\cdot\frac{1+(C_{OH}/C_A)}{1+T^{OH}_{A}(C_{OH}/C_A)} \quad (1)$$

1) T. Yamabe, M. Senō and N. Takai, This Bulletin, 32, 1383 (1959); *J. Chem. Soc. Japan, Ind. Chem. Sec.* (*Kogyo Kagaku Zasshi*), 64, 556 (1961); I. Kamii, T. Tanaka and T. Yamabe, *J. Pharm. Soc.* (*Yakugaku Zasshi*), 81, 931 (1961).

where $t$ transport number, $C$ concentration, $K=K_B/K_W$, $K_B$ and $K_W$ dissociation constants of weak acid BH and water, and

$$T'^{B}_{A}=\left(\frac{\bar{t}_B}{\bar{t}_A}\right)\Big/\left(\frac{C_B}{C_A}\right),\quad T^{OH}_{A}=\left(\frac{\bar{t}_{OH}}{\bar{t}_A}\right)\Big/\left(\frac{C_{OH}}{C_A}\right)$$

are permselectivity coefficients* which are constant independently of experimental conditions, and the absence and presence of bar above symbols refer to the solution and the membrane phase respectively. Subscript $B_0$ means total acid molecules in dissociated and undissociated states, and B weak acid ions.

The ratio of transport numbers which expresses the relative amount of weak acid transferred across an anion-exchange membrane is

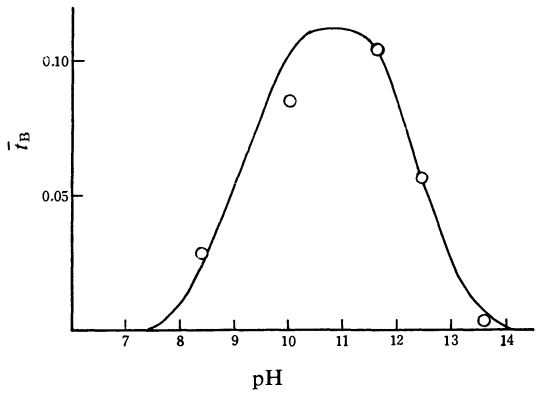

Fig. 1. Transport of boric acid across an anion-exchange membrane.
○ Experimental, —— Theoretical
Experimental conditions ; A five-compartment cell, 0.33 mA./cm², 1 hr.; Membranes, heterogeneous ones made from Amberlite IR-120 or IRA-400 ; Stock solution, 0.05 M $H_3BO_3$, 0.05 M NaCl, NaOH (for adjustment of pH).

$$\frac{\bar{t}_B}{\bar{t}_A+\bar{t}_B+\bar{t}_{OH}}=\frac{T^{B}_{A+OH}C_{B_0}}{C_A+T^{B}_{A+OH}C_{B_0}+C_{OH}} \qquad (2)$$

The experimental verification of these expressions was obtained in the case of boric acid across an anion-exchange membrane as shown in Fig. 1. The experimental procedure was the same as that in the preceding papers[1]. The transport number $t_B$ is the amount (equivalent**) of boric acid transferred across the anion-exchange membrane by passage of the electricity of 1 faraday. The theoretical curve was drawn according to Eqs. 1 and 2, in which quantities were estimated as follows; $T^{OH}_{Cl}$ is 2, $T'^{B}_{Cl}$ is 0.2*, $\bar{t}_{Cl}+\bar{t}_B+\bar{t}_{OH}$, the transport number of anions across the anion-exchange membrane***, is 0.7 and $K_B$ is $7.3\times10^{-10}$**.

This treatment leads us to the following general conclusion. The minimum pH at which the appreciable transport of a weak acid occurs depends primarily on its dissociation constant and nearly equals to $pK_B-1$, and the maximum transport takes place in the pH range between $pK_B+1$ and 12~13. The smaller is $T^{OH}_{A}$ and the larger are $C_A$ and $C_B$, the higher is the maximum pH. The same treatment can be applied to weak bases. The details will be presented in near future.

The authors express their thanks to Mr. Katuya Yanase for his experimental cooperation.

*The Institute of Industrial Science*
*The University of Tokyo*
*Yayoi-cho, Chiba*

* These are practically dependent on the current densities. $T'^{B}_{A}$ is known from the electrodialysis experiment in the pH range higher than $pK_B+1$, where $T^{B}_{A}=(\bar{t}_B/\bar{t}_A)/(C_{B_0}/C_A)=T'^{B}_{A}$.

** Only the dissociation of boric acid in the first step was considered. Further dissociations are so weak (dissociation constants $1.8\times10^{-13}$ and $1.6\times10^{-14}$) that these contributions are neglected in the pH range smaller than 13 and in the larger pH range the contribution of hydroxide ions becomes overwhelming.

*** Strictly, it contains the contribution of the transport number of anions across the adjacent cation-exchange membrane.

# *A New Method for the Determination of Boron by Spectrophotometry with Pyrocatechol Violet*

By Kazuo HIIRO

(Received December 7, 1960)

For the photometric determination of boron, most of the reagents such as oxyanthraquinones are used in concentrated sulfuric acid media, in another case using curcumin, the sample solution should be evaporated with the reagent solution under carefully controlled conditions for color development. Since these procedures are very tedious and time consuming, it would seem very useful if the color development could be substantiated simply and rapidly in aqueous media.

In previous publications it has been reported that some of the colorimetric reagents such as polyvinylalcohol[1,2], chromotropic acid[3], victoria violet[4,5] and H-resorcinol[6] can be used in aqueous media, and that some reagents are applied to indirect methods. However, many of them are not always applicable to routine work, as they are less accessible reagents, and in the case of chromotropic acid the measurements must be carried out in the ultraviolet region.

Pyrocatechol violet, a kind of sulfophthalein dye, is generally used as a metallochromic indicator for chelatometry and as photometric reagent for many metal ions such as zirconium[7,8], thorium[9], copper[10], bismuth[11], aluminum[12] and yttrium[13]. Patrovský[14] studied the detection of boron, niobium, germanium and tantalum using this reagent.

In this paper the application of the reagent to the determination of boron has been described, and the proposed method is very convenient and useful, because the procedure is carried out in an aqueous medium and the absorbance can be measured in the visible region. In this study, the absorption curves of dilute pyrocatechol violet solutions with various pH values were taken, and the existence of an isosbestic point at 494 m$\mu$ was confirmed, various facts including the effect of pH and of the reagent concentration, stability of the color and effect of temperature and of the sort of buffer solutions were examined. The interference of diverse metal ions is masked by adding ethylenediaminetetra-acetate solution as a sequestering agent. Beer's law is obeyed in the range 0.2 to 2.0 p. p. m. of boron at 494 m$\mu$.

## Experimental

**Apparatus.** — Spectrophotometric measurements were made with a Shimadzu quartz spectrophotometer, Model QB-50, with 1 cm. glass transmission cells. A Horiba glass electrode pH meter, Model H-3 was used for all pH measurements.

**Materials.**—*Standard Boron Solutions.* — Dissolve 0.5716 g. of reagent grade boric acid in 1000 ml. of water. One milliliter of the solution corresponds to 100 $\mu$g. of boron. Dilute an aliquot of the solution with water, and prepare 10.0 p. p. m. and 5.0 p. p. m. of standard boron solutions.

*Pyrocatechol Violet Solution.* — Prepare a $2\times10^{-3}$ M aqueous solution (Dotite PV).

*Buffer Solutions.*—Prepare an ammonium chloride-ammonium hydroxide buffer solution by mixing 8 parts of 0.5 M ammonium chloride solution and 1 part of 0.5 M aqueous ammonia solution, and adjust the pH to 8.55~8.60. Veronal buffer solution is prepared as follows. To 100 ml. of mixed solution of M/7 sodium diethylbarbiturate and M/7 sodium acetate add 40 ml. of 0.85% sodium chloride solution and 25 ml. of 0.1 N hydrochloric acid, and adjust to pH 8.55~8.60.

*Ethylenediaminetetraacetate Solution.* — Dissolve disodium ethylenediaminetetraacetate (dihydrate) in water to make the concentration of $5\times10^{-2}$ M.

Other various salt solutions are prepared from analytical grade reagents.

**Measurement of Absorption Spectra of Pyrocatecholviolet.** — Twenty milliliters of $10^{-4}$ M pyrocatechol violet solutions were mixed with 5 ml. of veronal buffer solutions of various pH values and diluted to 50 ml. with water. The absorption spectra of these solutions were measured with water as reference.

**Procedure.**—Pipet the boron solution containing

25 μg. or 50 μg. of boron into a 25 ml. measuring flask, add 5 ml. of $2\times10^{-3}$ M pyrocatechol violet solution and 5 ml. of buffer solution at pH 8.55~8.60, and dilute to the mark with water. Measure the absorption at 494 mμ; use a mixed solution containing 5 ml. of pyrocatechol violet and buffer in 25 ml. as reference.

In order to study the effect of diverse salts, color developments were made using 25 μg. of boron with various amounts of 4% salt solutions, and measurements were made for the solution with 50 μg. of several cations.

The effect of the temperature upon the absorbance was investigated as follows. Solutions containing 2.0 p. p. m. of boron were warmed in a water bath at a proper temperature for 15 min., and the absorbance of the solutions was measured against a reference treated similarly. For the solutions containing 1.0 p. p. m. of boron, absorbance and temperature of the warm solutions were measured at proper intervals.

## Results

**Absorption Spectra of Pyrocatechol Violet Solution.**—Fig. 1 shows the absorption curves of $4\times10^{-5}$ M pyrocatechol violet solutions at various pH values. It is found that, as the pH of the solution decreases, a maximum (450 mμ) appears, while when the pH increases absorbance at the absorption maximum (600 mμ) increases, and there is an isosbestic point at 494 mμ. Since the absorbance at the isosbestic point is not affected by the pH value of solutions, and the absorbance of reagent blank is always constant at the wavelength, the use of this isosbestic point is very advantageous for the determination of boron.

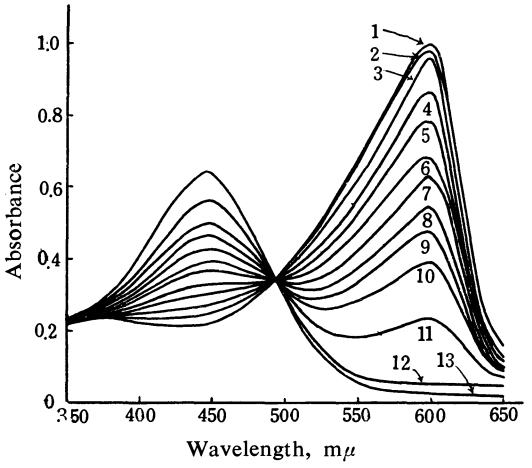

Fig. 1. Absorption spectra of pyrocatechol violet solution at various pH's.

| | | | | | |
|---|---|---|---|---|---|
| 1 | pH 9.32 | 6 | pH 8.21 | 11 | pH 7.21 |
| 2 | 8.98 | 7 | 8.10 | 12 | 5.80 |
| 3 | 8.72 | 8 | 7.95 | 13 | 4.55 |
| 4 | 8.53 | 9 | 7.79 | | |
| 5 | 8.41 | 10 | 7.63 | | |

**Effect of pH.** — As shown in Fig. 2, it is found that the maximum absorptions were obtained at pH range of 8.3~8.6.

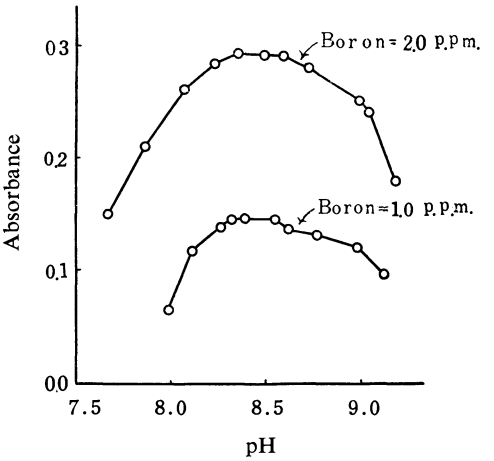

Fig. 2. Effect of pH value.
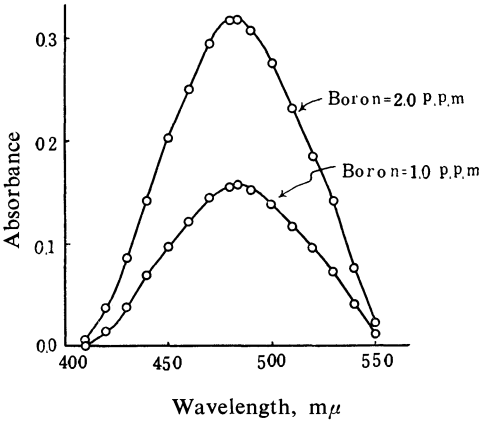
$2\times10^{-3}$ M Pyrocatechol violet soln.; 5.0 ml.,
Veronal buffer soln.; 5.0 ml.,
Measured at 494 mμ

**Absorption Spectra of Colored Boron-Pyrocatechol Violet Solution.**—Fig. 3 shows the absorption curves of the boron-pyrocatechol-violet solutions, obtained by the standard procedure. The maximum absorption is shown at 484 mμ.



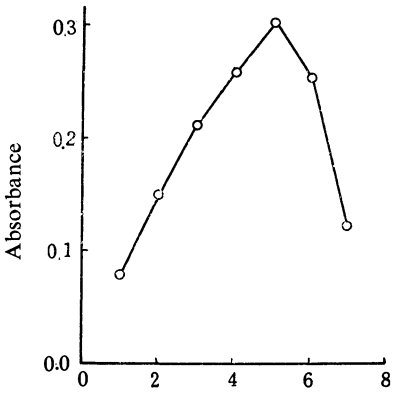


Fig. 3. Absorption spectra of colored boron-pyrocatechol violet solutions.
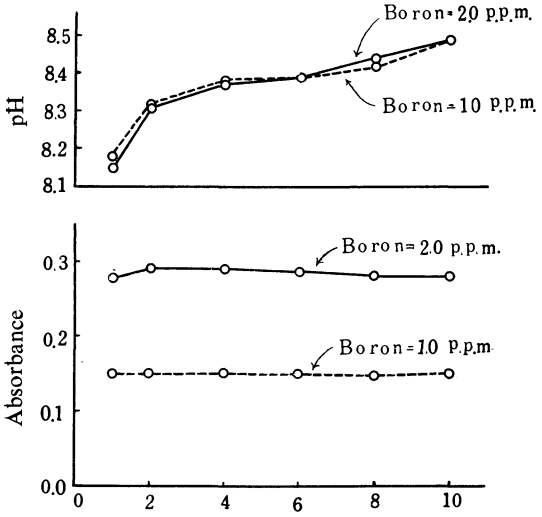
$2\times10^{-3}$ M Pyrocatechol violet soln.; 5.0 ml.
$NH_4Cl$-$NH_4OH$ buffer soln.; 5.0 ml.

**Reagent Concentration.**—In order to test the effect of concentration of pyrocatechol violet, a series of the absorbances was measured under various concentrations of the reagent, using the reagent blanks of the same concentration



as references. As shown in Fig. 4, 5 ml. of $2\times10^{-3}$ M pyrocatechol violet solution in 25 ml. is the optimum amount.

$2\times10^{-3}$ M P. V. soln. added, ml.

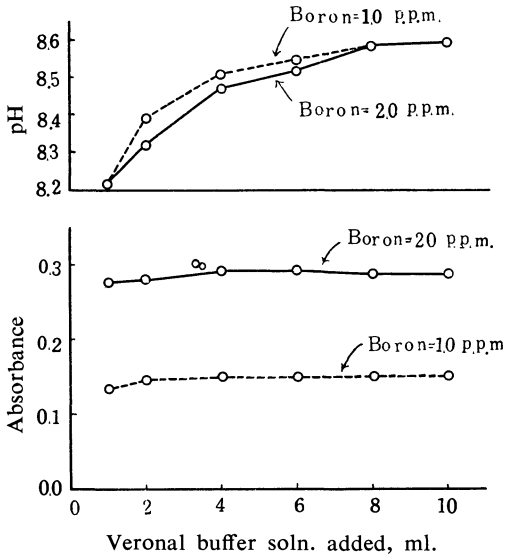


Fig. 4. Effect of pyrocatechol violet concentration.
Boron concentration; 2.0 p. p. m.
$NH_4Cl$-$NH_4OH$ buffer soln.; 5.0 ml.
Measured at 494 mμ.

**Effect of Buffer Solutions.** — The effect of buffer solution was tested with varying amounts of 0.5 M ammonium chloride-ammonia buffer solution or veronal buffer solution. At least 2 ml. of both buffer solutions are essential, as shown in Figs. 5 and 6, and 5 ml. is preferable, for the purpose of avoiding the pH change due to the addition of various salts in the following experiments.

$NH_4Cl$-$NH_4OH$ buffer soln. added, ml.

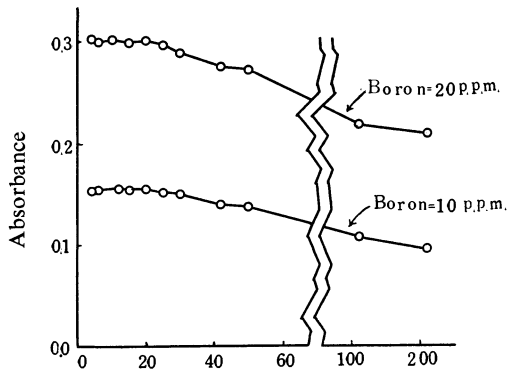

Fig. 5. Effect of buffer solution (I). In the case of ammonium chloride-ammonium hydroxide buffer solution.
$2\times10^{-3}$ M Pyrocatechol violet soln.; 5.0 ml.
Measured at 494 mμ

Veronal buffer soln. added, ml.

Fig. 6. Effect of buffer solution (II). In the case of veronal buffer solution.
$2\times10^{-3}$ M Pyrocatechol violet soln.; 5.0 ml.
Measured at 494 mμ

**Color Stability.**—Fig. 7 shows that the absorbance of colored solutions is constant for 20 min. Consequently the measurements should be done within 20 min. after color development.

Time of standing, min.

Fig. 7. Color stability of boron-pyrocatechol violet solutions.
$2\times10^{-3}$ M Pyrocatechol violet soln.; 5.0 ml.
Veronal buffer soln.; 5.0 ml.
Measured at 494 mμ
Temperature; 26~27°C

**Temperature.**—It is observed that the absorbance is affected by temperature, that is, the intensity of absorbance increases as temperature is lowered, and there is an apparent linear relationship between absorbance and temperature as shown in Fig. 8. The temperature coefficients are $0.927\times10^{-2}$/°C for 2.0 p. p. m. and $0.330\times10^{-2}$/°C for 1.0 p. p. m. of boron.

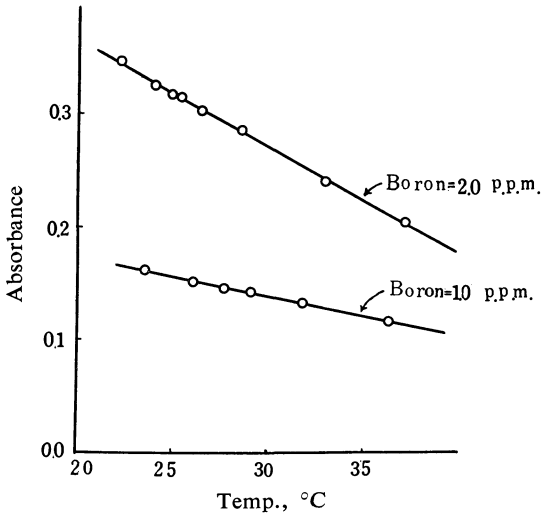

Fig. 8. Effect of temperature.

$2\times10^{-3}$ M Pyrocatechol violet soln.; 5.0 ml.
Veronal or $NH_4Cl$-$NH_4OH$ buffer soln.; 5.0 ml.
Measured at 494 mμ

**Stability of Pyrocatechol Violet Solution.**—The solution of pyrocatechol violet is stable for more than one month, as shown in Fig. 9.

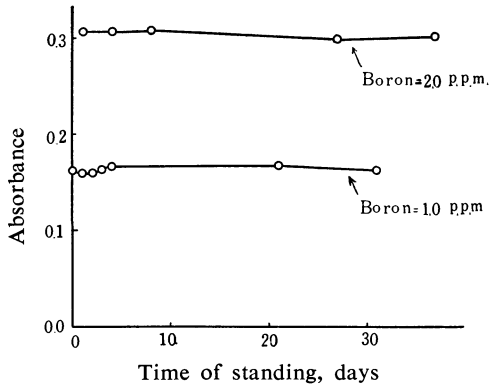

Fig. 9. Stability of pyrocatechol violet solution.

$2\times10^{-3}$ M Pyrocatechol violet soln.; 5.0 ml.
Veronal or $NH_4Cl$-$NH_4OH$ buffer soln.; 5.0 ml.
Measured at 494 mμ

**Diverse Salts.**—The results are presented in Table I. It was found that the presence of such salts as potassium fluoride, sodium chloride, potassium iodide, sodium sulfate, disodium hydrogenphosphate and potassium sodium tartrate do not interfere even at a concentration of 200 mg. per 25 ml. But sodium sulfite

and potassium nitrate interfere when 40 mg. per 25 ml. are present.

**Diverse Metal Ions.**—As shown in Table II, the following ions interfere seriously: Magnesium, zinc, copper(II), manganase(II), nickel, cobalt(II), cadmium and aluminum. Since these cations form stable chelates with ethylenediaminetetraacetate, when disodium salt of ethylenediaminetetraacetate is present in concentration of $10^{-3}$ M, they are masked effectively and do not interfer even at the concentration of 20 p. p. m. However, the interference of aluminum can not be eliminated.

**Calibration Curve.**—Measurements were made for the solutions containing various amounts of boron. Beer's law is obeyed up to 2.0 p. p. m. of boron as shown in Fig. 10. The sensitivity of this method was 0.006085/$\mu$g. and the mean error was 1.59%. Standard deviation was 0.002528 in absorbance for ten reproducible measurements for each 1.0 p. p. m. of boron.

## Discussion

The proposed new photometric method for the determination of boron by using pyrocatechol violet as a color reagent is simple in procedure as compared with the other methods.

From Fig. 1, considerations can be made as follows. Because pyrocatechol violet is a tetrabasic acid and consequently can release four protons, it may be formulated as $H_4F$, the absorption band with peak at 450 m$\mu$ can be considered as belonging exclusively to $H_3F^-$, and the peak at 600 m$\mu$ must be due to $H_2F^{2-}$ form.

As shown in Fig. 3, for the spectrophotometric measurements it is desired to choose the maximum wavelength at 482 m$\mu$, but because the absorbance of pyrocatechol violet solution is not affected by pH value at the isosbestic point 494 m$\mu$ it is preferable that the isosbestic point be chosen for the determination of boron, although photometric sensitivity is lowered slightly.

The proposed method has the feature of no preliminary separation of diverse ions, because many of them may be masked by ethylenediaminetetraacetate. This method can thus effectively be used for the determination of boron in such samples as metals, metallic oxides and alloys.

In this procedure, however, color intensity is considerably affected by temperature, so the absorption measurements must be done under constant temperature. Fortunately the effect of temperature difference will be corrected, provided that the calibration curves are made simultaneously.

Investigations for the effects of other diverse salts and metal ions and also the determination of boron for many metallic samples are now proceeding in this laboratory.

The author is indebted to Dr. Yuroku Yamamoto, Kyoto University, for his guidance and to Dr. Isao Muraki, Chief of the 5th Department of our Institute, for his useful suggestions.

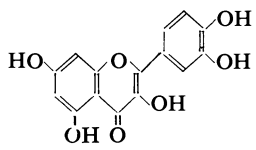
# *A New Method for the Spectrophotometric Determination of Boron with Quercetin*

By Kazuo HIIRO



(Received January 12, 1961)

In previous publications it was reported that morin, a kind of oxyflavone, was used as a reagent for the fluorimeric and spectrophotometric determination of boron[1,2]. By an analogous consideration on the basis of the chemical constitution of the reagent, it may be said that there is a possibility of using quercetin instead of morin for the photometric determination of boron.

The formula for both compounds are:

Morin

Quercetin

In the field of photometry, quercetin was already used as a coloring reagent for germanium[3,4], zirconium[5] and molybdenum[6] etc. in previous publications. Wilson formerly reported the reactivity of boron with several kinds of flavone compounds including only a brief description on quercetin[7].

On the result of preliminary experiments the present author was confident that quercetin could be applicable to the determination of boron. In this paper, therefore, the application of the reagent to a new photometric method for boron has been described. The effects of reagent concentration, oxalic acid, and hydrogen ion concentration are examined. In addition, various conditions including temperature, duration of heating, and vessel material for evaporation of sample solution, and stability of the color, solvent of dried residue and diverse salts and the stability of the reagent solution have been investigated. It was found that the colored complex of boron-quercetin has a mole ratio of 1 : 1 under the proposed condition, and that Beer's law was obeyed over the range 0.00 to 0.50 p. p. m. of boron at 445 mμ.

The new photometric method for determination of boron was applied to graphite samples, and satisfactory results were obtained.

## Experimental

**Apparatus.** — Spectrophotometric measurements were made with a Shimadzu quartz spectrophotometer, Model QB-50, using 1 cm. glass transmission cells. For the operation of color development a water bath of 50×35×35 cm. and an air bath of ordinary type were used.

**Materials.** — Dissolve 0.5716 g. of reagent grade boric acid in 1 l. of water to make a solution corresponding to 100.0 μg. of boron per 1.0 ml. Dilute an aliquot of the solution with water, and prepare standard solutions containing 5.0 p.p.m. and 2.0 p.p.m. of boron. Prepare a 0.2% ethanolic quercetin solution. Dissolve oxalic acid of analytical reagent grade in 95% ethanol to make a 20% solution. Prepare 1 N hydrochloric acid solution. All other salt solutions are prepared from reagents of analytical grade.

**Standard Procedure.**—Pipet an aliquot of the boron solution containing about 5.0 μg. of boron into a 100 ml. quartz beaker, add a suitable amount of water up to 2.0 ml. and add successively 1.0 ml. of 1 N hydrochloric acid, 3.0 ml. of 20% oxalic acid solution and 1.0 ml. of quercetin solution. Mix thoroughly and evaporate the contents to dryness on a water bath at 55±3°C. Subsequent to complete dryness, place the beaker in an air bath at 60~90°C, and keep it there for about 1 hr. to make sure of complete color development. After cooling to room temperature, dissolve the residue in 10 ml. of acetone and measure the absorbance at 445 mμ with acetone as reference.

To ascertain the stability of the color, read absorbance of the solution at proper intervals of time after color development. In order to study the effect of diverse salts, color developments were made using 2.0 μg. of boron in the presence of various amounts of 0.5 or 2.0% salt solutions.

Measurements of absorption spectra were made in respect to the solution obtained by the abovementioned procedure at every 5 mμ intervals of wavelength.

**Determination of Boron in Graphite Samples.**— Determination of boron in graphite samples was

made as follows[8]. Weigh powdered sample into a platinum boat, add 2.0 ml. of 3% calcium hydroxide aqueous suspension and mix well. Evaporate the graphite to dryness on a small heater, introduce the boat into a combustion tube in an electric furnace heated at 900°C and ash the sample in a current of oxygen. After cooling, remove carefully the ash into a distillation apparatus and distil off boron as methyl borate into a 100 ml. quartz beaker containing 1.4 ml. of 0.2 N sodium hydroxide solution and 9.0 ml. of water. Evaporate the contents in a quartz beaker to dryness on a water bath warmed at 40~50°C, and add 1.4 ml. of 0.2 N sulfuric acid to the dried residue and then treat as mentioned above.

## Results

**Absorption Spectra of the Complex.**—The absorption curves of colored solutions obtained by standard procedure are shown in Fig. 1. There is a maximum at 445 mμ, which suits for the spectrophotometric measurements.

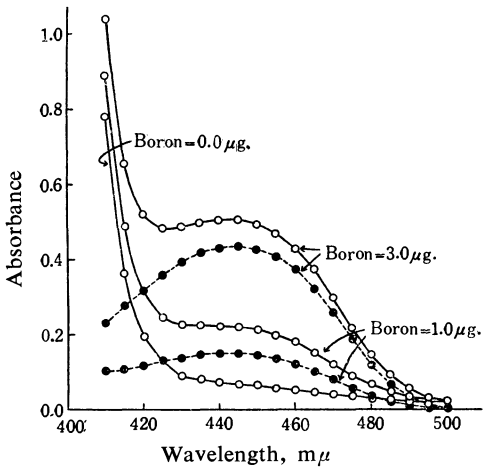

Fig. 1. Absorption spectra of colored complex of boron-quercetin.
Boron; 3.0 μg., 1.0 μg. and 0.0 μg.
Quercetin; 0.2% soln., 1.0 ml. (A-lot)
Oxalic acid; 20% soln., 3.0 ml.
HCl; 1 N soln., 1.0 ml. Water; 3.0 ml.
—○— Obtained against acetone as reference
—●— Obtained against blank as reference

**Reagent Concentration.**—Absorbances of a series of solutions contained 1.0 and 3.0 μg. of boron were measured in the presence of various amounts of the reagent. As shown in Fig. 2, 1.0 ml. of 0.2% quercetin solution is the optimum amount.

**Oxalic Acid Concentration.**—A test was made using 1.0 and 3.0 μg. of boron in the presence of varying amounts of 20% oxalic acid solution. The results indicate that 3.0 ml. of oxalic acid is recommended as shown in Fig. 3.

Quercetin; 0.2% soln., 1.0 ml. (A-lot)
Oxalic acid; 20% soln., 3.0 ml.
Water; 3.0 ml.

**Hydrochloric Acid Concentration.**—As shown in Fig. 4, it appears that the maximum absorption is obtained when 1.0 ml. of 1 N hydrochloric acid is used.

**Effect of Water.**—The absorbances were affected by the amount of water. As shown in Fig. 5, 3.0~4.0 ml. of water is always needed for complete color development in this procedure.

**Effect of Drying Conditions on Color Formation.**—As shown in Table I, the absorbance of the resulting solution containing 2.0 μg. of boron is affected by drying conditions for color development. Most satisfactory results were obtained when evaporation was made first on a water bath at 55±3°C for 4 hr. and then in an air bath at 60 to 90°C for 1 hr.

The effect of the kind of vessel on evaporation was tested. It was desired to use a quartz beaker or a platinum basin as shown in Table II. In the cases of a glass or polyethylene beaker some interferences were observed.

**Effect of the Kind of Solvent on Colored Complex.**—Various kinds of solvent for extraction of boron-quercetin colored complex are tested with 2.0 μg. of boron. Fig. 6 shows that the best results are obtained in the case of pure acetone as a solvent.

**Color Stability.**—The absorbance of colored solutions is almost constant within 10 min., and then decreases slightly as shown in Fig. 7. It is thus desired to measure the absorbances within 10 min. after colored complex is dissolved with acetone.

**Stability of Quercetin Solution during Storage.**—It is found that the absorbance is increased as the duration of storage increases after preparation of the quercetin solution, and becomes constant after about 10 days as shown in Fig. 8. Hence, it is advisable to use the reagent solution after standing for about 10 days. It may be used at least 20 days after preparation.

**Effect of Diverse Salts.**—The effect of diverse ions on the spectrophotometry was examined. These salts cause interference seriously as shown in Fig. 9.

**Mole Ratio of Boron to Quercetin in Colored Complex.**—As shown in Fig. 10, maximum

—●— Obtained after separation of boron by distillation

absorbance of the complex is obtained when the mole ratio of boron to quercetin has a value of 1 to 1[9].

**Calibration Curves.**—Measurements of absorbance were made with a number of the colored solutions containing varying amounts of boron. The results show that Beer's law is obeyed over the range 0.00 to 0.50 p. p. m. of boron as shown in Fig. 11. The sensitivity of this method, mean error and molar extinction coefficient were 0.204 $\mu$g., 4.90% and 22100 respectively. Even in the presence of 20 mg. of sodium sulfate, Beer's law is also obeyed over the range 0.00 to 0.50 p. p. m. of boron, but the sensitivity is decreased to 0.101 $\mu$g. in this case. After distillation of varying amounts of boron and evaporation of the distillate containing alkali and water to dryness, absorbances of the solutions of the dried residues were measured. As shown in Fig. 11, Beer's law is obeyed over the range 0.00 to 0.30 p. p. m. of boron.

**Determination of Boron in Graphite Samples.**—The results obtained by the above-mentioned experiments are presented in Table III.

TABLE III. RESULTS OF DETERMINATION OF BORON IN GRAPHITE SAMPLES

| Sample | Taken g. | Absorbance | Boron found $\mu$g. | Boron determined p.p.m. | Results obtained by curcumin method p.p.m. |
|---|---|---|---|---|---|

## Discussion

A sensitive new photometric method for the determination of boron by using quercetin as color reagent is proposed. The constitution of the boron-quercetin colored complex is considered to have the mole ratio of 1 : 1. In this procedure, if a different lot of quercetin, even though from the same maker, is used for color development, the absorbance is also varied, hence the determination of boron must be made using the calibration curve obtained by the same lot of quercetin as is used in the working operation. In this procedure, the color intensity of the solution is considerably affected by diverse salts, but the calibration curves are quite linear in the presence of a definite amount of salts. For the determination of boron in many kinds of practical samples, the proper separation of boron is desired. From the results of determination of boron in graphite samples, it was found that there is satisfactory agreement of the results obtained by the proposed method with those by the curcumin method in the limit of experimental error. This method may thus also be utilized for the determination of boron in other samples after preliminary separation of boron by distillation.

# *Normal Vibrations of Dimethyldimethoxysilane*

By Toshio TANAKA

(Received November 5, 1960)

The dipole moment of dimethyldimethoxysilane was previously reported to be 1.33 D at 25°C and 1.35 D at 50°C[1]. If ∠Si-O-C in this molecule was about 130° and the rotation about two Si-O bonds was free, the observed moment agreed with that calculated from bond moments. However, the ∠Si-O-C assumed there seems to be somewhat too large compared with that in tetramethoxysilane[2]. It was suggested, therefore, that the Si-O bond would perhaps rotate under some hindrance[1]. Thereafter, the Raman and the infrared spectra of dimethyldimethoxysilane were measured, and the probable form of this molecule was discussed. As the result,

1) A. kotera, K. Matsumura, H. Nomura, Y. Nakano and U. Maeda, presented at the Symposium on Organosilicon Compounds, Osaka, October, 1956, and private communication.

2) M. Yokoi, This Bulletin, **30**, 106 (1957).

it was concluded that this molecule would be *GG* form in the solid state* and have no rotational isomers[3].

This paper reports the calculation of the fundamental frequencies of this molecule and their normal mode of skeletal vibrations, under the assumption that this molecule belongs to the point group $C_{2v}$. In the calculation, a methyl group was regarded as a point mass. The normal coordinate treatment was carried out by the Wilson *FG* matrix method[4] with a Urey-Bradley potential function. No calculation of the normal vibration for $Y_2M(XZ)_2$ type molecules has been reported as far as the author knows.

## Normal Coordinate Treatment

The normal coordinate treatment has been carried out for parameters which are shown in Fig. 1. The symmetry of the molecule was assumed as $C_{2v}$. The interplanar angle for a Si-O-C plane and a C-Si-O plane including the same Si-O bond were also assumed to have an interplanar angle of $+60°$ or $-60°$.

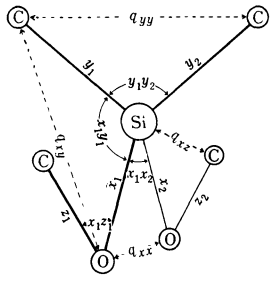

Fig. 1. Internal coordinates of the skeletal of dimethyldimethoxysilane.

According to the group theory, this molecule has fifteen skeletal vibrations, six of $a_1$, two of $a_2$, four of $b_1$ and three of $b_2$ species. Each one of the skeletal vibrations of $a_2$ and $b_2$ species is the torsional oscillation of a (Si-)$OCH_3$ group*. All vibrations of the $a_1$, $b_1$ and $b_2$ species are active both in infrared and Raman spectra, and those of the $a_2$ species are Raman active but infrared inactive.

From the internal coordinates indicated in Fig. 1, the following orthonormal symmetry coordinates have been found:

for the $a_1$ vibrations,

$$R_1=\Delta(z_1+z_2)/\sqrt{2}$$
$$R_2=\Delta(x_1+x_2)/\sqrt{2}$$
$$R_3=\Delta(y_1+y_2)/\sqrt{2}$$
$$R_4=\Delta(x_1z_1+x_2z_2)/\sqrt{2}$$
$$R_5=\Delta(x_1x_2-y_1y_2)/\sqrt{2}$$
$$R_6=\Delta(2x_1x_2+2y_1y_2-x_1y_1-x_1y_2-x_2y_1-x_2y_2)/\sqrt{12}$$

for the $a_2$ vibration,

$$R_7=\Delta(x_1y_1-x_1y_2-x_2y_1+x_2y_2)/2$$

for the $b_1$ vibrations,

$$R_9=\Delta(z_1-z_2)/\sqrt{2}$$
$$R_{10}=\Delta(x_1-x_2)/\sqrt{2}$$
$$R_{11}=\Delta(x_1z_1-x_2z_2)/\sqrt{2}$$
$$R_{12}=\Delta(x_1y_1+x_1y_2-x_2y_1-x_2y_2)/2$$

and for the $b_2$ vibrations,

$$R_{13}=\Delta(y_1-y_2)/\sqrt{2}$$
$$R_{14}=\Delta(x_1y_1-x_1y_2+x_2y_1-x_2y_2)/2$$

The numbering of these symmetry coordinates corresponds to the numbering of the fundamentals in Table I.

From the coefficients of the symmetry coordinates and the potential constants in a Urey-Bradley force field[5], the *F* matrix elements are obtained as follows:

for the $a_1$ vibrations,

$$F_{11}=K_z+s_{zx}{}^2F_{xz}+t_{zx}{}^2F_{xz}'$$
$$F_{12}=s_{xz}s_{zx}F_{xz}-t_{xz}t_{zx}F_{xz}'$$
$$F_{14}=(s_{zx}t_{xz}F_{xz}+s_{xz}t_{zx}F_{xz}')x$$
$$F_{22}=K_x+2s_{xx}{}^2F_{xx}+2s_{xy}{}^2F_{xy}+s_{xz}{}^2F_{xz}+2t_{xy}{}^2F_{xy}'+t_{xz}{}^2F_{xz}'$$
$$F_{23}=2(s_{xy}s_{yx}F_{xy}-t_{xy}t_{yx}F_{xy}')$$
$$F_{24}=(s_{xz}t_{zx}F_{xz}+s_{zx}t_{xz}F_{xz}')z$$
$$F_{25}=s_{xx}t_{xx}(F_{xx}+F_{xx}')x$$

$$F_{1111}=(H_{xz}+t_{xz}t_{zx}F_{xz}-s_{xz}s_{zx}F_{xz}')xz$$

$$F_{1212}=(H_{xy}+t_{xy}t_{yx}F_{xy}-s_{xy}s_{yx}F_{xy}')xy + 3\kappa/\sqrt{8}$$

$$F_{912}=F_{1112}=0$$

and for the $b_2$ vibrations,

$$F_{1313}=K_y+2s_{yx}^2F_{xy}+2t_{yx}^2F_{xy}'+2t_{yy}^2F_{yy}'$$

$$F_{1314}=\sqrt{2}\,(s_{yx}t_{xy}F_{xy}+s_{xy}t_{yx}F_{xy}')x$$

$$F_{1414}=(H_{xy}+t_{xy}t_{yx}F_{xy}-s_{xy}s_{yx}F_{xy}')xy + 3\kappa/\sqrt{8}$$

where the following abbreviations have been adopted:

$s_{xx}=4x/3q_{xx}$ $\quad t_{xx}=\sqrt{8}\,x/3q_{xx}$

$s_{yy}=4y/3q_{yy}$ $\quad t_{yy}=\sqrt{8}\,y/3q_{yy}$

$s_{xy}=(3x+y)/3q_{xy}$ $\quad t_{xy}=\sqrt{8}\,y/3q_{xy}$

$s_{yx}=(3y+x)/3q_{xy}$ $\quad t_{yx}=\sqrt{8}\,x/3q_{xy}$

$s_{xz}=(x-z\cos\theta)/q_{xz}$ $\quad t_{xz}=z\sin\theta/q_{xz}$

$s_{zx}=(z-x\cos\theta)/q_{xz}$ $\quad t_{zx}=x\sin\theta/q_{xz}$

and the symbols used for the equilibrium values of the interatomic distances and of the interbond angles are $x$=Si—O, $y$=Si—C, $z$=O—C, $q_{xx}$=O···O, $q_{yy}$=C···(Si)···C, $q_{xy}$=O···C, $q_{xz}$=Si···C and $\theta=\angle$SiOC.

The $G$ matrix elements are obtained by the use of the table of Decius[6] and the method of Crawford[7]. Using the notations $\rho_x$, $\rho_y$ and $\rho_z$ for the reciprocals of Si—O, Si—C and O—C bond lengths, and $\mu_{Si}$, $\mu_O$ and $\mu_C$ for the reciprocals of the masses of silicon and oxygen atoms and methyl group, respectively, the following $G$ matrix elements have been obtained:

for the $a_1$ vibrations,

$$G_{11}=\mu_O+\mu_C$$

$$G_{12}=\mu_O\cos\theta$$

$$G_{14}=-\rho_x\mu_O\sin\theta$$

$$G_{15}=-\rho_x\mu_O\sin\theta$$

$$G_{16}=-\sqrt{3}\,\rho_x\mu_O\sin\theta/\sqrt{2}$$

$$G_{22}=2\mu_{Si}/3+\mu_O$$

$$G_{23}=-2\mu_{Si}/3$$

$$G_{24}=-\sqrt{8}\,\rho_x\mu_{Si}/3$$

$$G_{25}=-\sqrt{8}\,(\rho_x+\rho_y)\mu_{Si}/3$$

$$G_{26}=-2(\rho_x-\rho_y)\mu_{Si}/\sqrt{3}$$

$$G_{33}=2\mu_{Si}/3+\mu_C$$

$$G_{34}=\sqrt{8}\,\rho_x\mu_{Si}/3$$

$$G_{35}=\sqrt{8}\,(\rho_x+\rho_y)\mu_{Si}/3$$

$$G_{36}=2(\rho_x-\rho_y)\mu_{Si}/\sqrt{3}$$

$$G_{44}=4\rho_x^2\mu_{Si}/3+\rho_z^2\mu_C+(\rho_x^2+\rho_z^2 - 2\rho_x\rho_z\cos\theta)\mu_O$$

$$G_{45}=4\rho_x(\rho_x+\rho_y)\mu_{Si}/3+\rho_x(\rho_x-\rho_z\cos\theta)\mu_O$$

$$G_{46}=\sqrt{8}\,\rho_x(\rho_x-\rho_y)\mu_{Si}/\sqrt{3} + \sqrt{3}\,\rho_x(\rho_x-\rho_z\cos\theta)\mu_O/\sqrt{2}$$

$$G_{55}=4(\rho_x+\rho_y)^2\mu_{Si}/3+\rho_x^2\mu_O+\rho_y^2\mu_C$$

$$G_{56}=\sqrt{8}\,(\rho_x^2-\rho_y^2)\mu_{Si}/\sqrt{3} + \sqrt{3}\,(\rho_x^2\mu_O-\rho_y^2\mu_C)/\sqrt{2}$$

$$G_{66}=2(\rho_x-\rho_y)^2\mu_{Si}+3(\rho_x^2\mu_O+\rho_y^2\mu_C)/2$$

$$G_{13}=0$$

for the $a_2$ vibration,

$$G_{77}=3(\rho_x^2\mu_O+\rho_y^2\mu_C)/2$$

for the $b_1$ vibrations,

$$G_{99}=\mu_O+\mu_C$$

$$G_{910}=\mu_O\cos\theta$$

$$G_{911}=-\rho_x\mu_O\sin\theta$$

$$G_{912}=\rho_x\mu_O\sin\theta/\sqrt{2}$$

$$G_{1010}=4\mu_{Si}/3+\mu_O$$

$$G_{1011}=\sqrt{8}\,\rho_x\mu_{Si}/3-\rho_z\mu_O\sin\theta$$

$$G_{1012}=-2(\rho_x+3\rho_y)\mu_{Si}/3$$

$$G_{1111}=\rho_z^2(\mu_O+\mu_C)+\rho_x^2(2\mu_{Si}/3+\mu_O) - 2\rho_x\rho_y\mu_O\cos\theta$$

$$G_{1112}=-\sqrt{2}\,\rho_x(\rho_x+3\rho_y)\mu_{Si}/3 - \rho_x(\rho_x-\rho_z\cos\theta)\mu_O/\sqrt{2}$$

$$G_{1212}=(\rho_x^2\mu_O+3\rho_y^2\mu_O)/2+(\rho_x+3\rho_y)^2\mu_{Si}/3$$

for the $b_2$ vibrations,

$$G_{1313}=4\mu_{Si}/3+\mu_C$$

6) J. C. Decius, ibid., **16**, 1025 (1948).
7) B. Crawford, ibid., **21**, 1108 (1953).

$G_{1314} = -2(\rho_x + \rho_y/3)\mu_{Si}$

$G_{1414} = (3\rho_x{}^2\mu_O + \rho_y{}^2\mu_C)/2 + (3\rho_x + \rho_y)^2\mu_{Si}/3$

The molecular and potential constants used in the calculation are listed in Table I. These values are the same as those in the preceding paper[8] except $H_{yy}$, $F_{yy}$ and $\kappa$. The potential constants of $H(CH_3\text{-}Si\text{-}CH_3)$ and $F(CH_3\cdots CH_3)$ in tetramethylsilane[9] have been adopted for the $H_{yy}$ and $F_{yy}$ in the molecule under consideration. The $\kappa$ in this molecule has been assumed to be the mean between that in tetramethylsilane[9] and that in tetramethoxysilane[10]. The values of $F'$ have been assumed to be equal to $-F/10$ in the usual way.

Table I. Molecular and potential constants of dimethyldimethoxysilane

### Assignments of the Observed Frequencies

From the $F$ and $G$ matrix elements given above, the fundamental frequencies have been calculated by the use of the molecular and the potential constants listed in Table I, and the results are shown in Table II, together with the observed wave numbers[3] of the Raman and the infrared bands in the region of the skeletal vibrations. The skeletal vibrations have been assigned by the calculation of the potential energy distribution in the symmetry coordinates.

In the present calculation, the wave number of the Si-O symmetrical stretching vibration($a_1$) is higher than that of the Si-O nonsymmetrical stretching vibration($b_1$). Nevertheless, the observed frequencies near 690 and 735 $cm^{-1}$ have been assigned as $\nu_2(a_1)$ and $\nu_{10}(b_1)$, respectively (Table II), considering the intensities of Raman and infrared bands.

As is shown in Table II, the calculated values of $\nu_2$ and $\nu_{10}$ are considerably higher than the observed ones, respectively. In order to get a better agreement between the calculated wave number and the observed, it is necessary

Table II. Raman and infrared data, calculated wave numbers and the assignment for dimethyldimethoxysilane

| $\nu$. Obs. | | $\nu$. Calcd. | Assignment | Mode of vibration |

to adopt a lower value of $K_x$(Si—O), than the 3.25 md./Å of methyltrimethoxysilane[8]. Accordingly, it seems that the value of $K_x$(Si—O) in dimethyldimethoxysilane is rather lower than that in methyltrimethoxysilane. This may correspond to the tendency for the bond energy of Si-O bond which decreases as the number of oxygen atoms attached to silicon decreases; $-E_{Si-O}$ in $SiO_4$ unit $>-E_{Si-O}$ in $CSiO_3$ unit $>-E_{Si-O}$ in $C_2SiO_2$ unit, as reported by the present author[11].

The $L$ matrices and the distribution of potential energy in symmetry coordinates have been calculated for the skeletal normal modes; the results are shown in Tables III and IV, respectively. As shown in Table IV, some of the symmetry coordinates of totally symmetric species are related to several normal modes to a considerable extent; the $R_2$ and $R_3$ coordinates to both modes of $\nu_2$ and $\nu_3$, and the $R_4$ and $R_5$ coordinates to a mode of $\nu_4$.

The author wishes to express his sincere thanks to Professor Takeo Watase of this University, Professor Hiroshi Azumi of Tohoku University and Dr. Hiroshi Murata of Hiroshima University for much valuable discussion.

# *Thermodynamic Studies on Cobalt Complexes. VIII. Some Information about Diaquotetramminecobalt(III) Complexes and Thermal Dissociation of the Corresponding Chloride**

By Motoshichi MORI, Ryokichi TSUCHIYA, Shuji TAKEMURA and Eisei MATSUDA

(Received December 19, 1960)

Although there have been a few reports[1,2] on the visible and ultraviolet absorption spectra of diaquotetramminecobalt(III) complexes, none can be found on the infrared absorption spectra of cobalt(III) diaquo-complexes except in the cases of $[Co(NH_3)_2(OH_2)_2Cl_2]Cl$ and $[Co\,en(OH_2)_2Cl_2]Cl$[3] containing chloride ions as the ligand. The investigation of diaquotetramminecobalt(III) complexes by X-ray diffraction method has never been reported. In the present study the infrared absorption and the X-ray diffraction of diaquotetramminecobalt(III) and aquopentamminecobalt(III) complexes were measured. From these some information about their crystal structures was brought out. Since little has been reported concerning the thermochemical properties of cobalt(III) diaquo-complexes, some of them will be described, with special reference to the thermal dissociation of the diaquotetramminecobalt(III) chloride.

## Experimental

Diaquotetramminecobalt(III) chloride, sulfate and perchlorate were prepared[4] by the aquation of carbonatotetramminecobalt(III) nitrate with hydrochloric, sulfuric and perchloric acids respectively. Their visible and ultraviolet absorption spectra were measured with a Hitachi EPU-2 type spectrophotometer. The infrared absorption of diaquotetramminecobalt(III) and aquopentamminecobalt(III) perchlorates were measured by the Nujol mull method with an Ōyō Kōgaku Kenkyūsho DS-201 infrared spectrophotometer, and the X-ray diffraction, with a Rigaku Denki X-ray diffractometer. The results obtained were compared with those of hexamminecobalt(III) perchlorate.

The thermal analysis was carried out for diaquotetramminecobalt(III) chloride, sulfate and perchlorate with a Shimadzu thermobalance. The thermal dissociation pressure of diaquotetramminecobalt(III) chloride was measured in vacuo with a mercury manometer.

## Results and Discussion

**Thermal Analyses of Diaquotetramminecobalt(III) Chloride, Sulfate and Perchlorate.**— In order to verify the fact that the complexes obtained were actually the desired ones, chemical analyses, determinations of coagulation values and thermal analyses were made with them. The weight losses of the complexes upon heating are plotted against the temperature in Fig. 1. It is presumed that the chloride and sulfate decompose according to the following schemes:

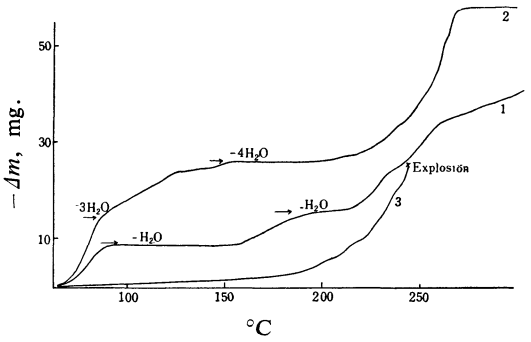

Fig. 1. The relationships between the weight loss and the temperature upon heating diaquotetramminecobalt(III) chloride (1), sulfate hydrate (2) and perchlorate (3). Both the weights of the chloride and of the perchlorate used are 0.2 g. respectively and that of the sulfate hydrate is 0.1 g. The expressions of $-nH_2O$ show the steps of dehydration of $n$ g molecule of water from oneg ram molecule of those complexes.

$$[Co(NH_3)_4(OH_2)_2]Cl_3 \xrightarrow[70\sim90°C]{-H_2O} [Co(NH_3)_4\cdot (OH_2)Cl]Cl_2 \xrightarrow[150\sim170°C]{-H_2O} cis\text{-}[Co(NH_3)_4Cl_2]Cl \xrightarrow[200\sim234°C]{} CoCl_2$$

* Read at the Symposium on Coordination Compounds of the Chemical Society of Japan, Sendai, September, 1960.

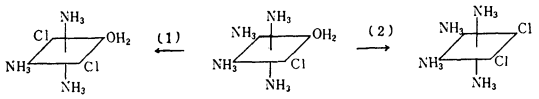
4) S. M. Jörgensen, *Z. anorg. Chem.*, **2**, 296 (1892).



$$[Co(NH_3)_4(OH_2)_2]_2(SO_4)_3\cdot 3H_2O \xrightarrow[80°C]{-3H_2O} [Co(NH_3)_4(OH_2)_2]_2(SO_4)_3 \xrightarrow[90\sim150°C]{-4H_2O} [Co(NH_3)_4SO_4]_2SO_4 \xrightarrow[240\sim260°C]{} 2CoSO_4 + (NH_4)_2SO_4$$

The perchlorate begins to decompose gently at about 190°C and explodes at 243°C. The decomposition of the perchlorate does not take place in a stepwise manner as does the chloride and sulfate.

*trans*-Aquodichlorotriamminecobalt(III) chloride, $[Co(NH_3)_3(OH_2)Cl^{(1)}_{2(6)}]Cl$, does not decompose at 100°C, whereas even at this temperature the corresponding *cis*-chloride changes to trichlorotriamminecobalt(III) complex releasing water as shown below:

There has been a report[5] that this phenomenon might be explained by the so-called trans-effect[6]. If the trans-effect is to be applied to the decomposition of aquochlorotetramminecobalt(III) chloride, the product must be *trans*-aquodichlorotriamminecobalt(III) chloride, $[Co(NH_3)_3(OH_2)Cl^{(1)}_{2(6)}]Cl$. But the product actually obtained in our experiment is *cis*-dichlorotetramminecobalt(III) chloride, $[Co(NH_3)_4Cl^{(1)}_{2(2)}]Cl$; i. e. process 1 did not occur, but process 2 did take place:

This shows that the trans-effect can not be applied to this process. A better explanation may be that *cis*-dichlorotetramminecobalt(III) chloride is more stable than the corresponding trans-chloride in the same way as that *cis*-dinitrotetramminecobalt(III) chloride is thermodynamically more stable than the corresponding *trans*-chloride[7].

**Visible and Ultraviolet Absorption Spectra of Diaquotetramminecobalt(III) Complexes.**—The visible and ultraviolet absorption spectra of diaquotetramminecobalt(III) complex which have already been reported by Tsuchida and his co-worker[1] and Kiss and his co-worker[2] are not in agreement with each other. That is, the maxima of both the first and second absorption bands of the complex reported by the former workers* are remarkably lower than those by the latter. The absorption of the complex measured by us are given in Fig. 2. The maxima of the first and second absorption bands of the complex are found at $\nu_1=59.0\times10^{13}$ sec$^{-1}$ ($\log\varepsilon_1=1.73$) and $\nu_2=84.5\times10^{13}$ sec$^{-1}$ ($\log\varepsilon_2=1.66$) respectively, where $\nu$ is the frequency and $\varepsilon$ is the molar extinction coefficient.

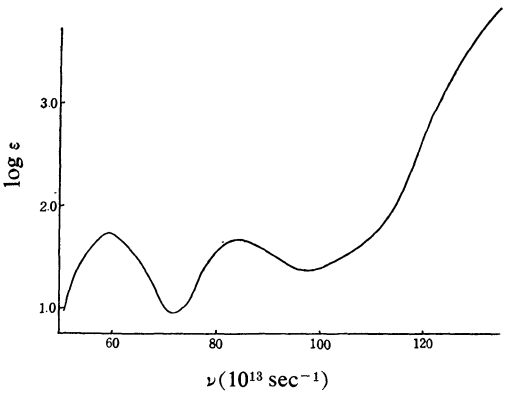


Fig. 2. The absorption spectrum of diaquotetramminecobalt(III) perchlorate.

**Dissociation Pressure of Diaquotetramminecobalt(III) Chloride.**—It was found above that diaquotetramminecobalt(III) chloride decomposed at 70~90°C as follows:

$$[Co(NH_3)_4(OH_2)_2]Cl_3(s) = [Co(NH_3)_4(OH_2)Cl]Cl_2(s) + H_2O(g)$$

The vapor pressure or dissociation pressure of diaquotetramminecobalt(III) chloride was measured at 7~36.5°C with the apparatus already described[8]. The results are listed in Table I.

The logarithm of the dissociation pressure, $p_{mm}$, is plotted against the reciprocal of the absolute temperature in Fig. 3. A straight

TABLE I. DISSOCIATION PRESSURE OF DIAQUOTETRAMMINECOBALT(III) CHLORIDE

| Temp. C° | $1/T\times10^3$ | Dissociation pressure $p_{mm}$ | $\log p_{mm}$ |

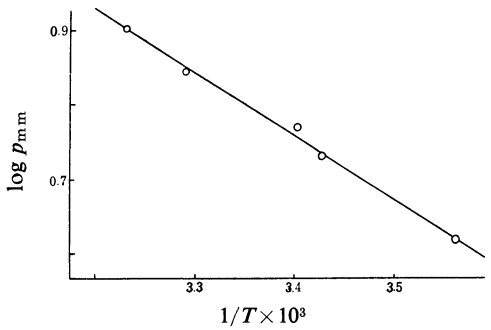

Fig. 3. The relationship between the dissociation pressure of diaquotetramminecobalt(III) chloride and the temperature.

line is obtained. The equation of the straight line is calculated by the method of least squares as,

$$\log p_{mm}=3.669-856.1/T$$

The free energy change for the dissociation is obtained as,

$$\Delta G^\circ=3916-3.604\,T,\quad \Delta G^\circ_{298}=2842\text{ cal.} \qquad (1)$$

From the free energy change for the dissociation of hexamminecobalt(III)[8] and aquopentamminecobalt(III) chlorides[9], the free energy change for the reaction in which one gram equivalent of $NH_3$ is replaced by one gram equivalent of $H_2O$ in the coordination sphere is calculated as below:

$$[Co(NH_3)_6]Cl_3(s)+H_2O(g)=[Co(NH_3)_5\cdot OH_2]Cl_3(s)+NH_3(g)$$
$$\Delta G^\circ=-296+8.32\,T \qquad (2)$$

The entropy change is $\Delta S^\circ=-8.32$ e. u. If it is assumed that the entropy change of the reaction,

$$[Co(NH_3)_5OH_2]Cl_3(s)+H_2O(g)=[Co(NH_3)_4(OH_2)_2]Cl_3(s)+NH_3(g) \qquad (3)$$

in which one gram equivalent of $NH_3$ in the reactant is replaced by one gram equivalent of $H_2O$, is equal to the entropy change of the reaction 2, i. e. $-8.32$ e. u., then the free energy change for reaction 3 is obtained by using the value of the above entropy change and the heats of formation of the substances[10,11] concerning the reaction as:

$$\Delta G^\circ=-1140+8.32\,T \qquad (4)$$

Since the free energies of formation of aquopentamminecobalt(III) chloride, water vapor and ammonia are known, from these values and Eq. 4 the free energy of formation of diaquotetramminecobalt(III) chloride in the solid state is calculated as,

$$\Delta G^\circ_f=-360600+363.2\,T$$
$$\Delta G^\circ_{f298}=-252300\text{ cal.} \qquad (5)$$

The free energy of formation of aquochlorotetramminecobalt(III) chloride, which is the decomposition product of diaquotetramminecobalt(III) chloride, is obtained from Eqs. 1 and 5 as follows:

$$\Delta G^\circ_f=-298900+349.0\,T$$
$$\Delta G^\circ_{f298}=-194900\text{ cal.}$$

From the above results the free energies of the reaction in which an ammonia molecule is successively replaced by a water molecule in the coordination sphere of hexamminecobalt(III) chloride are calculated and from these relationships it is concluded that the thermodynamic stabilities of these complexes are in the order:

$$[Co(NH_3)_6]Cl_3>[Co(NH_3)_5OH_2]Cl_3>[Co(NH_3)_4(OH_2)_2]Cl_3>[Co(NH_3)_4(OH_2)\cdot Cl]Cl_2>[Co(NH_3)_5Cl]Cl_2$$

**Infrared Absorption Spectra of Cobalt(III) Aquoammine-complexes.**—The infrared absorption spectra for diaquotetramminecobalt(III) and aquopentamminecobalt(III) perchlorates are listed in Table II together with those for hexamminecobalt(III) perchlorate already reported[12].

From the table it is seen that the wave numbers of the stretching vibration of N-H, $\nu_{N-H}$ for aquo-complexes are lower than those for hexammine-complex, whereas the wave numbers of the degenerate bending vibration, deg. $\delta_{NH_3}$, and the symmetric bending vibration, sym. $\delta_{NH_3}$, of $NH_3$ for the former are higher than those for the latter. The wave numbers of the rocking vibration of $NH_3$, $\rho_{NH_3}$, are remarkably higher for the former. This means that the coordinate bond character of Co—N in the coordination sphere of cobalt(III) ammine-complexes increases when one or two water moleclues coordinate in place of ammonia molecules.

**X-Ray Diffraction Data for Cobalt(III) Aquoammine-complexes.**—Some reports have been published on the X-ray diffraction for

hexamminecobalt(III) chloride[13] and perchlorate[14], but none for cobalt(III) aquoammine-complexes except $[Co(NH_3)_5(OH_2)]I_3$[15] and $[Co(NH_3)_4(OH_2)_2][TlCl_6]$[16]. The results of the X-ray diffraction measurement for aquopentamminecobalt(III) and diaquotetramminecobalt(III) perchlorates are shown in Table III. In this table $d$ is interplanar spacing, $I/I_0$, relative intensity, and $hkl$, indices of lattice planes.

The crystals of these complexes belong to the cubic system like $(NH_4)_3[FeF_6]$[17] and the number of chemical units in a unit cell is $Z=4$. By comparing the length of the edge of a unit cell, $a$, and the density, $D$, for the above two cobalt(III) aquoammine perchlorates with those for hexamminecobalt(III) perchlorate, $a=11.41$ Å and $D=2.048$[14], as already reported, it is found that the dimension of the unit cell becomes smaller when one gram equivalent of $NH_3$ is replaced by one gram equivalent of $H_2O$ in the coordination sphere of hexamminecobalt-(III) or aquopentamminecobalt(III) perchlorate. Such a tendency can be seen also in the cases of $[Co(NH_3)_6][TlCl_6]$ ($a=11.42$ Å)[18] and $[Co(NH_3)_4(OH_2)_2][TlCl_6]$ ($a=11.30$ Å)[16]. It makes us suppose that the change of the bond distance of Co–N is closely related to the increase of the coordination bond character which can be detected from the infrared absorption spectra.

## Summary

The visible and ultraviolet absorption spectra of diaquotetramminecobalt(III) perchlorate were measured and its decomposition process was discussed on the basis of the thermal analytical data.

The decomposition pressure of diaquotetramminecobalt(III) chloride was measured and the free energy of formation of aquochlorotetramminecobalt(III) chloride which was the product of the decomposition was calculated.

The infrared absorption and X-ray diffraction were measured for diaquotetramminecobalt(III) and aquopentamminecobalt(III) perchlorates and the relationships between the dimension of the unit cell and the coordinate bond strength, Co–N, were discussed.

# *Thermodynamic Studies on Cobalt Complexes. IX. Chemical Equilibrium between Diaquotetramminecobalt(III) Complex and Oxalate Ion**

By Motoshichi MORI, Ryokichi TSUCHIYA and Eisei MATSUDA

(Received December 19, 1961)

The method of Schramm[1] has been well known for a long time as a general method of preparing oxalatotetramminecobalt(III) complexes. It depends on the reaction of oxalic acid upon diaquotetramminecobalt(III), hydroxoaquotetramminecobalt(III), chloroaquotetramminecobalt(III) or carbonatotetramminecobalt(III) complexes. However, the thermodynamic properties of the oxalatotetramminecobalt(III) complex thus formed have never been reported. In order to get information about these properties the chemical equilibrium between diaquotetramminecobalt(III) ion and oxalate ion was studied spectrophotometrically.

## Experimental

Diaquotetramminecobalt(III) complex was prepared as the perchlorate by the reaction of carbonatotetramminecobalt(III) nitrate with perchloric acid. The identity of the sample was confirmed by chemical and thermal analyses, the measurements of the coagulation values and those of absorption spectra[2]. Oxalic acid and potassium and ammonium oxalates were purified by recrystallization.

At first oxalic acid was added to a solution of diaquotetramminecobalt(III) perchlorate as the source of oxalate ion. But the reaction hardly proceeded at all even when the solution was heated. On the other hand, when potassium oxalate was used, the diaquo-complex was decomposed owing to the strong alkalinity of the solution. When ammonium oxalate was used in place of oxalic acid or potassium oxalate, the reaction with diaquotetramminecobalt(III) perchlorate did occur. But, in this case, oxalatotetramminecobalt(III) complex was not produced but cobalt(III) oxalatoammine complex which contained the oxalate ion as an unidentate ligand was obtained. This fact will be described later in detail.

At last, the mixed solution, or the buffer solution, of oxalic acid and potassium oxalate was used. Although the reaction between the buffer solution and diaquotetramminecobalt(III) perchlorate did not proceed at room temperature, it did when heated to 65°C, producing oxalatotetramminecobalt(III) ion.

From the above preliminary experiments the following method of the determination of the chemical equilibrium between the diaquo-complex and oxalate ion was selected. The mixture of 50 ml. of a solution of diaquotetramminecobalt(III) perchlorate and 50 ml. of a buffer solution consisting of oxalic acid and potassium oxalate was kept in the flask at 65°C for ten minutes and then it was immersed in the thermostat at 25°C. When the equilibrium was attained after about six hours, the absorbancy of the solution was measured with a Hitachi EPU-2 type spectrophotometer. The maximum of the first absorption band of diaquotetramminecobalt(III) ion is at $\nu=59.0\times10^{13}\,\mathrm{sec}^{-1}$ ($\log\varepsilon=1.73$)[2] and that of oxalatotetramminecobalt(III) ion, at $\nu=58.7\times10^{13}\,\mathrm{sec}^{-1}$ ($\log\varepsilon=1.91$)[3], where $\nu$ is the frequency and $\varepsilon$, the molar extinction coefficient. The measurement of absorbancy of the solution at equilibrium was made at 510 m$\mu$.

Since cobalt(III) oxalato-complexes are readily decomposed by sunlight, a brown flask was employed in order to protect the solution from the photodecomposition. The range of the initial concentration of the diaquotetramminecobalt(III) complex was 1/500~1/800 F and that of the oxalate ion was 1/80~1/5000 F. In order to diminish the ionic strength, the concentration of the diaquo complex must be lowered. But if it is lowered below 1/800 F the error of measurement of the absorbancy will grow larger. Therefore the concentration of the diaquo-complex could not be lowered below 1/800 F. The measurement of pH of the solution was made with a Horiba HRL Model M pH meter.

## Theoretical

The reaction between diaquotetramminecobalt(III) and oxalate ions is expressed by:

$$[Co(NH_3)_4(OH_2)_2]^{3+}(aq.)+C_2O_4^{2-}(aq.) = [Co(NH_3)_4C_2O_4]^{+}(aq.)+2H_2O(l) \quad (1)$$

If the initial concentration of the diaquo-complex ion is expressed by $C$, its concentration at equilibrium, by $C_1$ and the concentration of oxalatotetramminecobalt(III) ion at equilibrium, by $C_2$, then

$$C=C_1+C_2 \quad (2)$$

If the molar extinction coefficients of the diaquo-complex and oxalate ions at 510 m$\mu$ are expressed by $\varepsilon_1$[2] and $\varepsilon_2$[3] respectively, and the value corresponding to the molar extinction coefficient calculated from the absorbancy

* Read at the Symposium on Coordination Compounds of the Chemical Society of Japan, Sendai, September, 1960.

2) M. Mori, R. Tsuchiya, S. Takemura and E. Matsuda, This Bulletin, **34**, 1757 (1961).

3) Y. Shimura and R. Tsuchida, ibid., **29**, 312 (1956).

measured at the chemical equilibrium of reaction 1 is expressed by $\varepsilon$, there exists the relationship:

$$C\varepsilon = C_1\varepsilon_1 + C_2\varepsilon_2 \tag{3}$$

From Eqs. 2 and 3, the concentration of each complex ion is obtained by

$$C_1 = C\frac{\varepsilon_2 - \varepsilon}{\varepsilon_2 - \varepsilon_1} \quad \text{and} \quad C_2 = C\frac{\varepsilon - \varepsilon_1}{\varepsilon_2 - \varepsilon_1} \tag{4}$$

In the mixed solution of the diaquo-complex with oxalic acid and potassium oxalate, it is considered that the following three equilibria exist together with the equibrium 1;

$$H_2C_2O_4 \rightleftarrows H^+ + HC_2O_4^- \tag{5}$$

$$HC_2O_4^- \rightleftarrows H^+ + C_2O_4^{2-} \tag{6}$$

$$K_2C_2O_4 \rightleftarrows 2K^+ + C_2O_4^{2-} \tag{7}$$

The first and second dissociation constants of oxalic acid, $K_1$ and $K_2$, are given as follows respectively[4]:

$$K_1 = \frac{C_{H^+} \cdot C_{HC_2O_4^-}}{C_{H_2C_2O_4}} = 5.9\times10^{-2} \quad \text{and}$$

$$K_2 = \frac{C_{H^-} \cdot C_{C_2O_4^{2-}}}{C_{HC_2O_4^-}} = 6.4\times10^{-5}$$

where $C_{H_2C_2O_4}$, $C_{HC_2O_4^-}$, $C_{C_2O_4^{2-}}$ and $C_{H^+}$ are the concentrations of oxalic acid, hydrogenoxalate ion, oxalate ion and hydrogen ion at equilibrium respectively.

The concentrations of the species in the aqueous solution at equilibrium were calculated in the following two cases separately. The first is the case when the concentration of potassium oxalate is relatively small and the oxalate ion in the solution at equilibrium consists of those formed from potassium oxalate by the ionization process 7 and from oxalic acid by process 6. The second is the case when the concentration of potassium oxalate is relatively large and not only the oxalate ion at equilibrium is all formed from potassium oxalate alone but also a part of the hydrogenoxalate ion in process 5 is given by potassium oxalate.

The calculation in the first case is carried out in the following way. The oxalate ion is assumed to consist of those formed by the ionization of potassium oxalate 7 and the second ionization process of oxalic acid 6. So, if the initial concentration of potassium oxalate and the concentration of oxalate ion formed by process 6 are expressed by $C^\circ_{K_2C_2O_4}$ and $C_x$ respectively, the concentration of the oxalate ion at equilibrium is obtained by $C^\circ_{K_2C_2O_4} + C_x - C_2$, since the concentration of the oxalate ion consumed by the reaction with diaquo-complex is $C_2$. When the initial concentration of oxalic acid and the concentration of hydrogenoxalate ion are expressed by $C^\circ_{H_2C_2O_4}$ and $C_y$ respectively, the concentration of the oxalic acid remaining unionized at equilibrium is obtained by $C^\circ_{H_2C_2O_4} - (C_y + C_x)$ and therefore the first and second dissociation constants of oxalic acid are given by the following equations respectively.

$$\left.\begin{aligned} K_1 &= \frac{C_{H^+} \cdot C_y}{C^\circ_{H_2C_2O_4} - (C_y + C_x)} \\ K_2 &= \frac{C_{H^+}(C^\circ_{K_2C_2O_4} + C_x - C_2}{C_y} \end{aligned}\right\} \tag{8}$$

In these equations, $C^\circ_{H_2C_2O_4}$ and $C^\circ_{K_2C_2O_4}$ are known and $C_2$ is calculated by Eq. 4. The two variables, $C_x$ and $C_y$, can be obtained by solving the above Eq. 8 with respect to $C_x$ and $C_y$ as follows:

$$\left.\begin{aligned} C_x &= \frac{\left(K_1K_2C^\circ_{H_2C_2O_4} + (C_2 - C^\circ_{K_2C_2O_4})\right) \times (C^2_{H^+} + K_1C_{H^+})}{C^2_{H^+} + K_1C_{H^+} + K_1K_2} \\ C_y &= \frac{K_1C_{H^+}(C^\circ_{H_2C_2O_4} + C^\circ_{K_2C_2O_4} - C_2)}{C^2_{H^+} + K_1C_{H^+} + K_1K_2} \end{aligned}\right\} \tag{9}$$

The method of determining $C_{H^+}$ will be described later.

The apparent equilibrium constant, $K_C$, for reaction 1 is given as below,

$$K_C = \frac{C_2 \cdot C^2_{H_2O}}{C_1 \cdot C_{C_2O_4^{2-}}} = \frac{C_2 \cdot C^2_{H2O}}{C_1(C^\circ_{K_2C_2O_4} + C_x - C_2)} \tag{10}$$

where $C_{H_2O} = 1000/18 = 55.5$. This constant varies with the ionic strength of the solution. The ionic strength must be known to find the thermodynamic equilibrium constant. The concentrations and the ionic strengths of each ion at equilibrium are given as follows:

| | Concentration | Ionic strength |
|---|---|---|
| $[Co(NH_3)_4(OH_2)_2]^{3+}$ | $C_1$ | $(9/2)C_1$ |
| $[Co(NH_3)_4C_2O_4]^+$ | $C_2$ | $(1/2)C_2$ |
| $3ClO_4^-$ | $3(C_1+C_2)$ | $(3/2)(C_1+C_2)$ |
| $H^+$ | $C_{H^+}$ | $(1/2)C_{H^+}$ |
| $K^+$ | $2C^\circ_{K_2C_2O_4}$ | $C^\circ_{K_2C_2O_4}$ |
| $C_2O_4^{2-}$ | $C^\circ_{K_2C_2O_4} + C_x - C_2$ | $2(C^\circ_{K_2C_2O_4} + C_x - C_2)$ |
| $HC_2O_4^-$ | $C_y$ | $(1/2)C_y$ |

The total ionic strength, $\mu$, in the solution is calculated by

$$\mu = 6C_1 + 3C^\circ_{K_2C_2O_4} + 1/2C_{H^+} + 2C_x + 1/2C_y \tag{11}$$

The calculation in the second case is performed in the following manner. In this case the concentration of the oxalate ion ionized by reaction 7 is high enough to combine with

4) R. Gane and Ch. K. Ingold, *J. Chem. Soc.*, **1931**, 2153.

diaquo-complex to form oxalatoammine-complex and to compose a part of hydrogenoxalate ion. When the concentrations of hydrogenoxalate ion produced from potassium oxalate and oxalic acid are expressed by $C_y$ and $C_z$ respectively, the concentrations of hydrogenoxalate ion, unionized oxalic acid and oxalate ion at equilibrium are obtained as $C_y+C_z$, $C^\circ_{H_2C_2O_4}-C_z$ and $C^\circ_{K_2C_2O_4}-C_2-C_y$ respectively and therefore the first and second dissociation constants are given as follows:

$$K_1=\frac{C_{H^+}(C_y+C_z)}{C^\circ_{H_2C_2O_4}-C_z}$$
$$K_2=\frac{C_{H^+}(C^0_{K_2C_2O_4}-C_2-C_y)}{C_y+C_z} \qquad (12)$$

The two variables, $C_y$ and $C_z$, can be obtained by solving the above two Eq. 12 as below:

$$\left.\begin{aligned} C_y&=\frac{\left(\begin{array}{c}((C^2_{H^+}+K_1C_{H^+})(C^\circ_{K_2C_2O_4}-C_2))\\ -K_1K_2C^\circ_{H_2C_2O_4}\end{array}\right)}{C^2_{H^+}+K_1C_{H^+}+K_1K_2}\\ C_z&=\frac{\left(\begin{array}{c}-C^2_{H^+}(C^\circ_{K_2C_2O_4}-C_2)+K_1C_{H^+}\\ C^\circ_{H_2C_2O_4}+K_1K_2C^\circ_{H_2C_2O_4}\end{array}\right)}{C^2_{H^+}+K_1C_{H^+}+K_1K_2}\end{aligned}\right\} \qquad (13)$$

Therefore the concentration of hydrogenoxalate ion at equilibrium, $C_{HC_2O_4^-}$, is given by

$$C_{HC_2O_4^-}=C_y+C_z=\frac{\left(\begin{array}{c}K_1C_{H^+}(C^\circ_{H_2C_2O_4}+C^\circ_{K_2C_2O_4})\\ -C_2)\end{array}\right)}{C^2_{H^+}+K_1C_{H^+}+K_1K_2} \qquad (14)$$

The apparent equilibrium constant, $K_C$, is given as below:

$$K_C=\frac{C_2\cdot C^2_{H_2O}}{C_1\cdot C_{C_2O_4^{2-}}}=\frac{C_2\cdot C^2_{H_2O}}{C_1(C^\circ_{K_2C_2O_4}-C_2-C_y)} \qquad (15)$$

The total concentrations and the ionic strengths of each ion in this aqueous solution at equilibrium are given as follows:

| | Concentration | Ionic strength |
|---|---|---|
| $[Co(NH_3)_4\cdot(OH_2)_2]^{3+}$ | $C_1$ | $(9/2)C_1$ |
| $[Co(NH_3)_4\cdot C_2O_4]^+$ | $C_2$ | $(1/2)C_2$ |
| $3ClO_4^-$ | $3(C_1+C_2)$ | $(3/2)(C_1+C_2)$ |
| $H^+$ | $C_{H^+}$ | $(1/2)C_{H^+}$ |
| $K^+$ | $2C^\circ_{K_2C_2O_4}$ | $C^\circ_{K_2C_2O_4}$ |
| $C_2O_4^{2-}$ | $C^\circ_{K_2C_2O_4}-C_2-C_y$ | $2(C^\circ_{K_2C_2O_4}-C_2-C_y)$ |
| $HC_2O_4^-$ | $C_y+C_z$ | $(1/2)(C_y+C_z)$ |

The total ionic strength, $\mu$, in the solution is calculated by

$$\mu=6C_1+3C^\circ_{K_2C_2O_4}+1/2\,C_{H^+}-2C_y+1/2(C_y+C_z) \qquad (16)$$

## Results and Discussion

At first by measuring the absorbancy of the solution at equilibrium, the concentrations of diaquoammine complex and oxalatoammine-complex, $C_1$ and $C_2$, were calculated by Eq. 4. By using these values, the initial concentrations of oxalic acid and potassium oxalate, $C^\circ_{H_2C_2O_4}$ and $C^\circ_{K_2C_2O_4}$, the values of the first and second dissociation constants of oxalic acid, $K_1$ and $K_2$, and, by using the activity of hydrogen ion, $a_{H^+}$, in place of the concentration, $C_{H^+}$, the approximate concentrations of oxalic acid and hydrogenoxalate ion, $C_x$ or $C_y$, were estimated by Eq. 9 or 13. The approximate ionic strengths of the solution at equilibrium were also calculated by Eq. 11 or 16.

In order to know the true concentrations of oxalate and hydrogenoxalate ions, the above calculation must be carried out by using the concentration of hydrogen ion. In spite of it the value obtained by pH measurement is not the concentration of hydrogen ion but the activity. Therefore by finding the activity coefficient of hydrogen ion in each solution having the above approximate ionic strengths from Kielland's table[5], the concentration of hydrogen ion was obtained and the concentrations of oxalate ion and hydrogenoxalate ion and the ionic strengths were again calculated by Eqs. 9 and 11 or 13, 14 and 16 respectively.

Then the apparent equilibrium constant, $K_C$, was calculated by Eq. 10 or 15. These values calculated are all summarized in Table I.

The logarithm of the apparent equilibrium constant, $K_C$, is plotted against the square root of the ionic strength, $\mu$, in Fig. 1. If it is assumed that this plotting gives a quadratic curve, the equation of the curve is calculated by the method of least squares as,

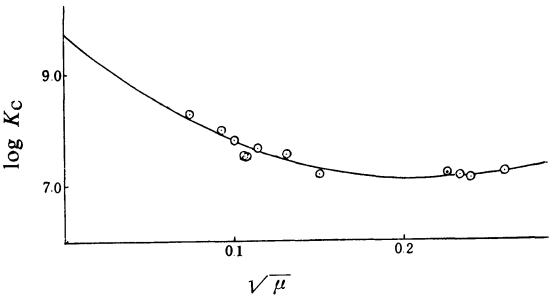

Fig. 1. The relationship between the apparent equilibrium constant of the reaction, $[Co\cdot(NH_3)_4(OH_2)_2]^{3+}+C_2O_4^{2-}=[Co(NH_3)_4C_2O_4]^+ +2H_2O$, and the ionic strength in the solution.

$$\log K_C=65.24\,\mu-25.98\sqrt{\mu}+9.687$$

The value of log $K_C$ at $\sqrt{\mu}=0$ is obtained by the extrapolation of this curve as,

$$\log K=9.7$$

This is the thermodynamic equilibrium constant of the reaction between diaquotetramminecobalt(III) and oxalate ions. The free energy change of the reaction is obtained as,

$$\Delta G^\circ_{298}=-13.2\text{ kcal.} \qquad (17)$$

Since the free energies of formation of diaquotetramminecobalt(III) ion, oxalate ion and water in unit activity are known as $-152.8$ kcal.[6], $-161.8$ kcal.[7] and $-56.69$ kcal.[8] respectively, the free energy of formation of oxalatotetramminecobalt(III) ion in unit activity is calculated as

$$\Delta G^\circ_{f298}=-213.9\text{ kcal.}$$

The heat of reaction between diaquotetramminecobalt(III) and oxalate ions is calculated as,

$$\Delta H=6.8\text{ kcal.} \qquad (18)$$

by using the heats of reaction of each compound concerned, i. e., $-235.7$ kcal.[9] for diaquotetramminecobalt(III) ion, $-197.0$ kcal.[7] for oxalate ion, $-68.32$ kcal.[8] for water and $-289.3$ kcal. for oxalatotetramminecobalt(III) ion. The last value is estimated from $\Delta H=-146.0$ kcal.[10] for hexamminecobalt(III) ion

6) A. B. Lamb and A. T. Larson, ibid., 42, 2038 (1920).
7) F. D. Rossini et al., "Selected Values of Chemical Thermodynamic Properties", United States Government Printing Office, Washington (1952), p. 120.
8) F. D. Rossini et al., l. c., p. 9.
9) K. B. Yatsimirskii, "Thermochemie von Komplexverbindungen", Akademie-Verlag, Berlin (1956), p. 178.
10) K. B. Yatsimirskii, l. c., p. 161.

and $\Delta H = -575.8$ kcal.[11] for trisoxalatocobaltate(III) ion. By using 17 and 18 the entropy change for the reaction between diaquotetramminecobalt(III) and oxalate ions is obtained as

$$\Delta S = 67.1 \text{ e. u.}$$

This large value suggests the great stability of oxalatotetramminecobalt(III) ion due to the chelate formation by oxalate ion.

The absorbancy of the solution produced by the reaction of diaquotetramminecobalt(III) perchlorate with ammonium oxalate was measured, and the spectra of the solution are shown in Fig. 2. The absorption spectra of oxalatopentamminecobalt(III) ion and oxalatotetramminecobalt(III) ion are also shown in the same figure. It is found that the absorption spectra of the compound produced at room temperatures by the reaction of the diaquo-complex with ammonium oxalate resembles that of oxalatopentamminecobalt(III) ion, whereas, when the reaction is promoted upon heating to 60°C, a shoulder of the absorption curve appears in the range of wavelengths corresponding to the second absorption band of oxalatotetramminecobalt(III) ion. It is presumed that a part of oxalate ion coordinated as a unidentate ligand at room temperatures undergoes transition to a bidentate ligand.

## Summary

The equilibrium of the reaction, $[Co(NH_3)_4(OH_2)_2]^{3+} + C_2O_4^{2-} = [Co(NH_3)_4C_2O_4]^+ + 2H_2O$ (1), was measured spectrophotometrically and the free energy of formation of oxalatotetramminecobalt(III) ion was calculated. The large increase of the entropy for the above reaction was interpreted by the chelate effect of oxalate ion.

When the mixture of oxalic acid and potassium oxalate reacts with diaquotetramminecobalt(III) complex, oxalate ion is coordinated as a bidentate ligand, whereas it is coordinated as an unidentate ligand when ammonium oxalate reacts with the same diaquo-complex.

# *Chemical Studies on Radioactive Indicators. XXIV. Separation of Rhenium from Technetium by the Distillation Method*

By Mutsuo KOYAMA

(Received December 22, 1960)

It has been considered that technetium has much resemblance in chemical properties to rhenium and the latter element has often been used as a carrier in the analysis of the former. An appropriate method is needed for the separation and the determination of technetium which is supposed to be present in natural ores or meteorites and also for the preparation of carrier-free rhenium or technetium produced by the bombardment of nuclear particles. Although several methods for separation, i. e., precipitation method[1], ion exchange method[2] and paper chromatography[3] have been proposed, it can not be said that any one of them is satisfactory in the analysis of the samples containing technetium and rhenium over a wide range of quantity.

The distillation of rhenium as $Re_2O_7$[4,5] has been a powerful method in the isolation from various elements other than technetium but the attempt to separate rhenium from technetium has not appeared yet.

In the previous paper[6], the author pointed out that the distillation of technetium from sulfuric acid is promoted by the addition of an oxidizing agent, such as nitric acid or potassium bichromate, and delayed by the addition of a reducing agent, such as hydroxylamine.

The resistance for the distillation of technetium in the presence of a reducing agent would be due to the formation of a lower oxidation state than +7. A similar experiment was performed on rhenium and it was found that reducing agent showed no effect on the distillation.

In this experiment, several kinds of gas were passed through the distilling flask as carrier and it was found that steam was the most effective on the separation of rhenium from technetium. The experiments were carried out with the solutions of carrier-free $^{95m}Tc$, $^{97m}Tc$, $^{183}Re$ and $^{184}Re$ in the presence or the absence of rhenium carrier.

The results were quite satisfactory as shown in Tables I and II.

## Experimental

**Reagents and Apparatus.**—*Isotopes.*—$^{95m}Tc$(60d) and $^{97m}Tc$(90d) were isolated as pertechnetate, from the proton-bombarded molybdenum target[6]. $^{183}Re$(71d) and $^{184}Re$(50d) were isolated as perrhenate from the proton-bombarded tungsten target[7].

*Stable Rhenium.*—Metallic powder of rhenium was obtained from Yokozawa Chemicals Co. and was converted to perrhenate by fusing it with sodium hydroxide and sodium peroxide in a nickel crucible.

*Distilling Apparatus.*—A pyrex glass distilling apparatus shown in Fig. 1 was prepared. Junctions were connected without grease.

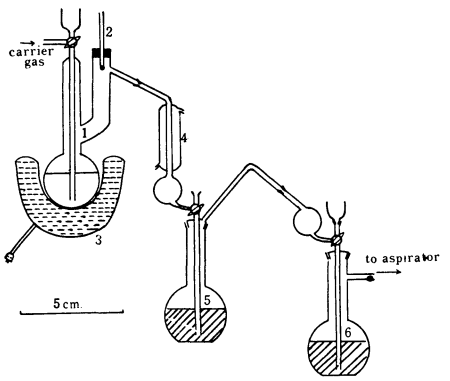

Fig. 1. Distilling apparatus.
1. Distilling flask 2. Thermometer
3. Mantle heater 4. Cooler
5. Receiver-1 (10 ml. of water)
6. Receiver-2 (20 ml of 4 N NaOH)

*Counters.*—A single channel $\gamma$-ray spectrometer (crystal: NaI(Tl), 1×1 inch) made by Kobe Kogyo Co., Ltd. and a G. M. counter (Tube: G. M. 132A, mica window 1.95 mg./cm$^2$) made by Metro Denki Co., Ltd. were used.

**Procedure.**—Six milliliters of the sample solution was taken in the distilling flask and heated with a mantle heater whose temperature was controlled with a transformer.

Carrier gas was conducted at the rate of 60

bubbles per minute. Receivers were cooled with ice water, whenever necessary. Any adhering activity inside the cooler was washed out into the receiver with a small amount of water before the measurements of the activities of the distillate. All the solutions were brought to a known volume in a volumetric flask and an aliquot was taken in a 5 ml. glass counting dish and was mounted for the $\gamma$-ray measurement.

## Results and Discussion

**Effect of the Concentration of Sulfuric Acid.** —Carrier-free rhenium was used in the experiments for testing the effect of the concentration of sulfuric acid on the distillation of rhenium. Rhenium was not distilled out from the pure water solution. On heating the sulfuric acid solution, the temperature remained at about 98~100°C during the distillation of water. After the water was distilled over, the temperature decreased once and again rose gradually to about 250°C, while sulfuric acid began to be distilled. The distilling temperature (250°C) was changeable depending on the heating and bubbling conditions.

In Fig. 2, the amounts of distilled rhenium are plotted against the amounts of distilled sulfuric acid. When 60% of the total amount of sulfuric acid was distilled, nearly 100% of rhenium was distilled out, irrespective of the initial concentration of sulfuric acid. The rate of distillation of rhenium was the greatest with 6 N sulfuric acid and the smallest with 30 N sulfuric acid. However, no quantitative distillation could be expected by the use of dilute sulfuric acid, because the volume of distilling solution became too small to dissolve the residual materials in the course of distillation.

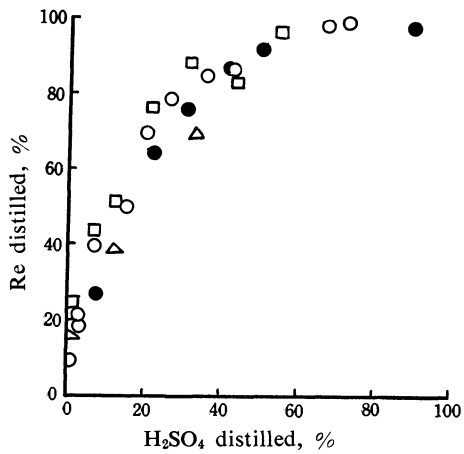

Fig. 2. Relationship between amount of Re distilled and that of $H_2SO_4$.
△ 6 N $H_2SO_4$ ○ 18 N $H_2SO_4$
□ 24 N $H_2SO_4$ ● 30 N $H_2SO_4$

Therefore, 18 N sulfuric acid was used in the following experiments.

**Effects of Reducing Agent and Carrier Gas on the Distillation of Rhenium and Technetium.** —In order to examine the effects of the atmosphere in the distilling flask on the distillation rate of rhenium and technetium, three kinds of gas, i.e., air, hydrogen and carbon dioxide, were bubbled respectively through the flask during the distillation.

Stannous chloride and hydroxylamine were used as the reducing agent, but the former

was partially distilled out. In Fig. 3, it can be seen that the distillation rate of rhenium from sulfuric acid is independent of the presence of hydroxylamine and bubbling gas. The fact that the addition of hydroxylamine had no effect on the distillation rate of rhenium shows that hydroxylamine can not reduce perrhenate[8].

In the case of technetium, the decrease in the distillation rate was distinctly observed by the addition of hydroxylamine, even when air was used as carrier gas.

In the same experiment, the bubbling of hydrogen or carbon dioxide caused a marked decrease in the distillation rate, especially in the period of the distillation of water, little technetium being found in the receiver.

The difference of the distillation rates between the use of air and that of carbon dioxide or hydrogen seems to be due to the difference of oxidizing ability against hydroxylamine. After the water was consumed in the flask, technetium gradually came to appear in the distillate. The increase in the amounts of hydroxylamine caused the decrease of the distillation rate of technetium.

**Separation of Rhenium from Technetium.**— In the foregoing method, as an appreciable amount of hydroxylamine is decomposed by heating with sulfuric acid solution, much hydroxylamine has to be added for the quantitative separation of rhenium from technetium.

To achieve smooth distillation, it is desirable to keep the amount of hydroxylamine as small as possible. Utilizing the fact that much rhenium but no technetium could be found in the distillate, the steam distillation method in the presence of hydroxylamine was examined.

Table I shows the distillation rates of rhenium obtained by steam distillation in the presence or the absence of hydroxylamine. It was found that by passing steam only at 100°C, little rhenium was distilled out, however, with gentle heating of the flask above 105°C, rhenium came to be distilled out with the steam.

8) S. Tribalat, *Ann. chim.*, 4, 289 (1949).

After distillation for 60 min., more than 99% of the rhenium was recovered. In the case when the distillation was carried out with stable rhenium, a spot test for the rhenium[9] remaining in the flask proved to be less than 1$\gamma$ of rhenium as shown in Table I.

The presence of hydroxylamine also had no effect on the distillation rate of rhenium in this method. In Table II, the distillation rates of technetium in the same condition as in the case of rhenium are shown. Distillation rates of technetium from 18 N sulfuric acid were smaller than that of rhenium even in the absence of hydroxylamine. In the presence of hydroxylamine no technetium appeared in the receivers, while most of the rhenium had been distilled off.

On the other hand, it was also observed that the presence of nitric acid promoted the distillation of technetium in the steam distillation. Therefore the separation of rhenium from technetium followed by the separation of technetium from other non-volatile materials by the distillation method could be attained by the proper use of hydroxylamine and nitric acid.

9) E. B. Sandell, "Colorimetric Determination of Traces of Metals", Interscience Publishers, New York (1959), p.754.

## Summary

The separation of rhenium from technetium was investigated. Pertechnetate is reduced to non-volatile species by the use of hydroxylamine, but perrhenate is not reduced by such an agent. Rhenium is distilled out with steam from sulfuric acid medium and technetium remains in the solution containing hydroxylamine. Rhenium from carrier-free amounts up to 10 mg. can be separated quantitatively from technetium by this method.

The author desires to express his hearty thanks to Professor Masayoshi Ishibashi and Professor Taitiro Fujinaga for their helpful advice and encouragement throughout this work. The author is also grateful to Dr. Kazuo Saito of the Institute for Nuclear Study, the University of Tokyo, for making preparation of radio-isotopes convenient.

# *Chemical Use of the Absorption of Soft $\gamma$-Rays, $\beta$-Ray-excited X-Rays and K-Capture X-Rays*. I. Improvement in Fundamental Technique and Introduction of a Differential Absorption Method*

By Tadashi NOZAKI

(Received December 20, 1960)

Soft $\gamma$-rays, $\beta$-ray-excited X-rays and K-capture X-rays are absorbed mainly by the photoelectric effect in most cases, the absorption coefficient depending much on the atomic number of the absorber material. The mass absorption coefficient ($\sigma$) for the photoelectric absorption of a photon whose energy is over the absorption edge of the absorber material is expressed by[1]

$$\sigma = C(Z^5/A)E^{-\lambda} \qquad (8/3 < \lambda < 7/2) \quad (1)$$

where $Z$ and $A$ are respectively the atomic number and the atomic weight of the absorber material and $C$ is a constant.

This phenomenon is to be applied to a vast field of chemistry as well as radiography. Recently, several kinds of works by the use of the absorption of such photons have been published[2-4], including the determination of sulfur in petroleum, of chlorine and bromine in solid organic substances, and of uranium and heavy metal salts. The thickness and density of several kinds of material were also measured by similar techniques. The fundamental technique which has been adopted in these works, however, is useful only for either of the following two cases; (1) when a monoenergetic photon-beam source of a suitable

* A part of this paper was reported at the 2nd Isotope Conference of Japan, February, 1958.

energy is used (i. e. when the exponential absorption law holds), and (2) when a relationship between the absorbance and the quantity (or concentration) of the element (or substance) to be determined can easily be obtained empirically under a given condition.

To extend the applicability of the absorption phenomenon, according to the present author's opinion, it is essential to improve the fundamental technique so that an exponential absorption curve and an accurate absorption coefficient could be obtained for a photon-beam even when it is not exactly mono-energetic.

Thus, the following studies have been undertaken: (1) examination of a source giving photons of required energy, (2) examination of a detector which enables an efficient measurement of the radiation and gives an absorption curve as near as possible to the exponential with a given absorber, (3) introduction of the differential absorption method which is useful for obtaining a better absorption curve and a more accurate absorption coefficient in the presence of photons of different energies, (4) examination of apparent change in the absorption coefficient with geometrical arrangement, and (5) establishment of an empirical relationship between the absorption coefficient and the photon energy.

**Photon-beam Source.** — Absorptiometry in quantitative analysis is usually based on Lambert-Beer's law, regardless of the photon-beam energy (wavelength). For a mono-energetic photon-beam an exponential absorption curve can be obtained easily. Radio-isotopes emitting such photons are desirable as the source, and have been used in several works[2-4]. Various nuclides including the following are useful for this purpose: $^{51}Cr$, $^{133}Ba$, $^{203}Hg$, $^{139}Ce$, $^{141}Ce$, $^{185}W$, $^{153}Gd$, $^{97m}Tc$, $^{170}Tm$, $^{109}Gd$, $^{204}Tl$, $^{241}Am$, $^{145}Sm$, $^{73}As$, $^{210}Pb$ (RaD), $^{125}I$, $^{93}Mo$, $^{68}Ge$, $^{59}Ni$, $^{55}Fe$ and $^{49}V$. (The photon energy decreases in the order given.) In using a radio-isotope emitting also $\beta$-rays for the source, the Bremsstrahlung should be made as weak as possible with a suitable enveloping substance (e. g. polystyrene).

Since a relatively small number of nuclides among those written above are usually accessible, another kind of source, generating $\beta$-ray-excited X-rays, is required for increasing the energy variety. With $\beta$-ray-excited X-rays as the source, such improvements in the fundamental technique as shown later are necessary, as they are not exactly mono-energetic. The yield and the purity (absence of photons of unsuitable energies) depend on the target (converter) and the arrangement of the generator. For the present purpose the purity of the X-rays and the ease in the change of the target material are more important than the yield. A reflection-type generator with a $K_\beta$-filter holder, (Fig. 1) serves conveniently.

Figure 2 shows the spectra observed by a scintillation counter (sodium iodide $1'' \times 1''$ crystal with aluminum cover), and Fig. 3 those by the scintillation and a proportional counter.

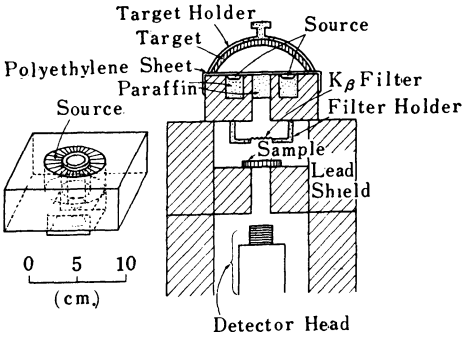

Fig. 1. Generator of $\beta$-ray-excited X-rays.

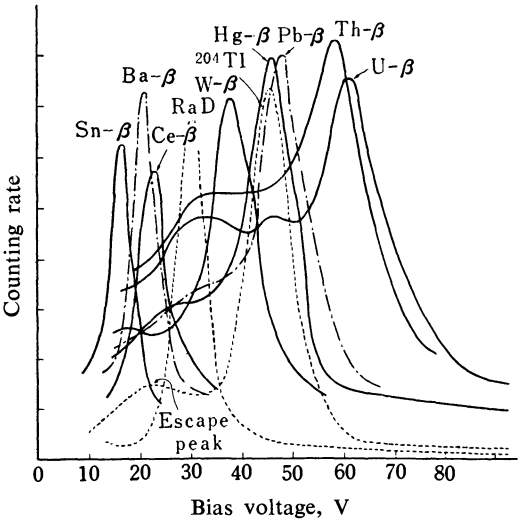

Fig. 2. Spectra of photon-beam sources.

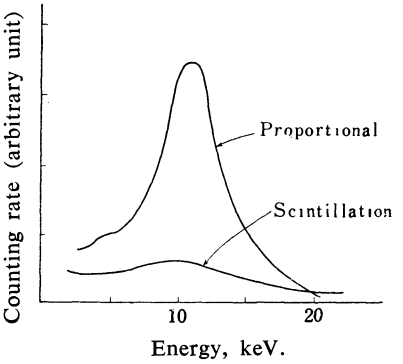

Fig. 3. Spectra of Br-$\beta$.

(For convenience, β-ray-excited X-ray of element M is written as M-β in this paper.)

**Detector.** — The counting efficiency and the shape of the absorption curve depend much on the detection method. When $^{55}Fe$ is used as a source, a simple G-M counter works satisfactorily. But this counter is a poor detector for a photon-beam having a higher energy than 10 keV. and the pulse height cannot be discriminated. Thus, an ordinary G-M counter can be used only for a few sources: e. g. $^{55}Fe$, $^{59}Ni$.

Measurement of photon-beams by counting only a narrow region of photo-peak (photo-peak counting) by a low-noise scintillation counter with a single channel analyzer offers a better result in general; the efficiency is high for photons of 20 to 300 keV. and the absorption curve is more similar to a typical exponential curve. For a photon having an energy under 20 keV., however, the following three problems are encountered: (1) the absorption by the cover of the scintillator, (2) the multiplier noise, and (3) the broadening of photo-peak (e. g. those in Fig. 2). The first can be made small by the use of a beryllium-covered crystal, which, however, is not always readily available. On the other hand, a proportional counter tube filled with xenon, krypton or a mixture of these serves, as a still better detector for such a measurement. Fig. 3 shows the spectra of Br-β measured by a xenon-filled proportional counter and by the scintillation counter. No marked photo-peak is observed by the latter. Though the photo-peak obtained by the proportional counter is not so sharp as inferred from literature[5], probably owing to the end effect, the counter is proved to be a very useful detector for such a photon-beam. A krypton-filled tube works as either a proportional or a G-M counter according to the applied voltage, though the dead time of the G-M tube is as long as 1 millisecond. By the use of an external quenching circuit, however, such a tube could be used also as a G-M tube and provides a cheaper technique for measuring photons below 50 keV.

In Fig. 4 the absorption curves of photon-beam from $^{204}Tl$ and of Hg-β are shown. Both emit the characteristic X-rays of mercury. The curve measured by a usual G-M counter is far from the exponential curve; the absorption coefficients are much larger at the initial stage, and an absorption tail is observed. The former phenomenon can be attributed to the L-series X-rays which are more sensitive to counter than the *K* X-rays. The same is seen

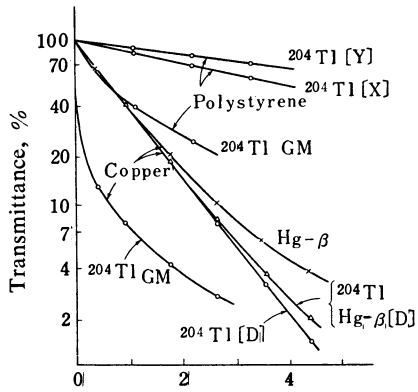

Fig. 4. Absorption curves.
GM; Measured by a G-M counter
[D]; The differential absorption curve
[X]; Absorber at the position in Fig. 1
[Y]; Absorber on the scintillator

with $^{203}Hg$, which emits a γ-ray and characteristic X-rays of thallium owing to internal conversion. The tailing should be due to the Bremsstrahlung. The curves obtained by the photo-peak counting with a scintillation counter are greatly superior. For $^{203}Hg$, the curve maintains the exponential form even when the counting rate decreases to 1/1000 of the initial. For other sources, especially for β-ray-excited X-rays, however, the absorption tailing exists to a considerable degree.

The energy resolution of the counter should be taken into account, since $K_\alpha$ X-rays of the β-ray-excited X-ray are always accompanied with $K_\beta$ rays and Bremsstrahlung of similar energies. On measuring a mono-energetic photon-beam by a scintillation or a proportional counter, the photo-peak is expressed by the Gaussian distribution curve,

$$R = k \exp[-h^2(E_m - E)^2] \quad (2)$$

where $R$ is the counting rate, $E$ is the energy, $E_m$ is the observed energy giving maximum $R$ on the spectrum, and $k$ and $h$ are constants. And,

$$(\Delta E)_{1/2} = C\sqrt{E_m} \quad (3)$$

where $(\Delta E)_{1/2}$ is the full width of photo-peak at 1/2 counting rate and $C$ is a constant. By the use of a good source, i. e. RaD, the value $C$ in Eq. 3 can be determined, and from this value and Eq. 2 the fraction of $K_\beta$ involved in the measurement range is calculated under a given experimental condition. For a common experimental condition described in the experimental part, the effect of $K_\beta$ is usually of less significance in case of a source giving a higher

5) W. Parrish et al., *Rev. Sci. Instr.*, **27**, 795 (1956).

energy than Hg-$\beta$, but must be considered for a source giving a lower energy than Ce-$\beta$. In the latter case a $K_\beta$ filter is useful to some extent; the shape in a higher energy region than the top of the photo-peak is improved and the photo-peak itself becomes sharper.

**Differential Absorption Method.** — As mentioned above, the absorption curve obtained by the above technique is in general not entirely satisfying for an accurate work. Inevitably there is absorption tailing to a certain degree, which is a nuisance when trying to obtain an accurate absorption coefficient, especially when the absorbance is large.

Two useful methods for the removal of the effect of absorption tailing (differential method and auxiliary absorption method) are presented, which have been devised anew in consideration of the causes of the tailing.

There must be three causes:

(1) Photons of a higher energy suffer the Compton scattering in the detector and escape with an energy loss in the vicinity of the measurement range.

(2) The same scattering also occurs in the absorber and surrounding materials, and a part of the scattered photons can have a similar energy as that of the main photo-peak and enter the detector.

(3) The escape-peak of a photon whose energy is higher by the energy of the $K_\alpha$ of the detector material appears in the measurement range.

For effects 1 and 2, the following relationship is known[6].

$$E_e = h\nu_0 \frac{2h\nu_0/mc^2}{1h+2\nu_0/mc^2} \tag{4}$$

where $E_e$ is the maximum energy that an electron can obtain after a collision. When $E_e$ is smaller than $mc^2/5$, $h\nu_0/E_e$ is greater than 7/2. This relathionship shows that photons giving the effect 1 must have had much higher energies than the observed range, when the photons were subjected to only one scattering. The chance of multiple scattering giving rise to effect 1 must be very small.

The effect 2 must result either from a small-angle scattering or from a multiple scattering. When the measurement is made in an arrangement shown in Fig. 1, the probability of the latter is negligible. A photon scattered with a small change of direction (e. g. a few degree), $\theta$, loses so small an amount of energy that it is hardly ever distinguished from the unscattered photon. The following familiar equation elucidates such a relationship[7]

$$h\nu = \frac{h\nu_0}{1+(h\nu_0/mc^2)(1-\cos\theta)} \tag{5}$$

where $h\nu$ and $h\nu_0$ are respectively the energy of the photon after and before the scattering. Thus, the tailing due to effect 2 is not serious.

Complete elimination of the effect 3 is practically impossible. But when the geometrical arrangement is so adjusted as to make the photon-beam enter the center of the detector, the escape-peak is less distinct.

Thus, the main cause of the tailing should be the single Compton scattering (in the detector) of photons having much higher energies.

*Differential Method.* — Several sheets of absorber made of the same material and having the same thickness are prepared. The counting rate is measured, the number of the sheets being changed one by one. When the decrease in the counting rate caused by placing one additional sheet is plotted against the number of the sheets used, the curve is more similar to an ideally exponential than the ordinary curve.

That curve, which is tentatively called "differential absorption curve" can be formulated as follows: the ordinary absorption curve is generally expressed by

$$R = A\exp(-\Phi T) + B(T) \tag{6}$$

where $\Phi$ and $T$ are respectively the absorption coefficient and the absorber thickness and $A$ is a constant, and $B(T)$ is written as

$$B(T) = \sum_n B_n \exp[-\Phi_n T] \tag{7}$$

For simplicity, the following case is considered.

$$B(T) = B\exp[-\Phi' T] + C \tag{8}$$

That is to say, the source gives only two kinds of photon, and there is a constant back ground. Then, the difference between the counting rates measured through $n$ and $n+1$ sheets of the absorber of thickness $\Delta T$ is expressed by

$$\begin{aligned} R_n - R_{n+1} &= A\exp(-\Phi n\Delta T)[1-\exp(-\Phi\Delta T)] \\ &\quad + B\exp(-\Phi' n\Delta T)[1-\exp(-\Phi'\Delta T)] \\ &= [1-\exp(-\Phi\Delta T)]\left[A\exp(-\Phi T)\right. \\ &\quad \left. + \frac{1-\exp(-\Phi'\Delta T)}{1-\exp(-\Phi\Delta T)} B\exp(-\Phi' T)\right] \end{aligned} \tag{9}$$

where $T = n\Delta T$. Comparison of Eq. 9 with Eq. 6 shows that the effect of a photon of a higher energy is reduced with the aid of the differential curve by a factor of $[1-\exp(-\Phi'\Delta T)]/[1-\exp(-\Phi\Delta T)]$. With an infinite number of

6) e. g. Ref. 1, p. 319.
7) e. g. ibid., p. 318.

infinitely thin absorbers this factor becomes $\Phi'/\Phi$, the ratio of the absorption coefficient for the photon of the higher energy to that for the lower energy. This ratio must be much less than unity. Because, as mentioned above, the energies of the two photons should differ largely from each other, and the absorption, at least for the photon of the lower energy, is mostly due to photoelectric effect. This is why the differential absorption curve is superior to the ordinary absorption curve. Such a consideration also holds in an actual case, where the source gives more photons of varying energies than shown in Eq. 8. When the counts taken are large enough in each measurement with varying numbers of the absorber sheet, the secondary differential absorption curve offers a still better result.

The differential absorption curves of $^{204}$Tl and Hg-$\beta$ with copper are shown in Fig. 4. For other kinds of source and absorber material a similar improvement is observed.

*Auxiliary Absorber Method.*—For the measurement of the differential absorption curve, several sheets of the same absorber material having the same thickness are required. Practically, this requirement is hardly fulfilled. The "auxiliary absorber method" finds more general use. A thin foil of a certain material (auxiliary absorber) having as large an absorption coefficient as possible specifically for the photon in question is placed in the path of the photon-beam. Further, the decrease in the counting rate caused by this absorber is measured both in the presence and the absence of the sample. When the decrease in counting rate in the presence of the sample is divided by that in its absence, the quotient gives a fairly accurate transmittance (denoted by fraction and not by percentage) of the photon through the sample. This is true even when the absorbance of the sample is considerably great. This can be explained by the following equations. (Subscript A indicates figures for auxiliary absorber.)

$$R(T)=A\exp(-\Phi T)+B(T)$$
$$R(0)=A+B(0)$$
$$R(T_A)=A\exp(-\Phi_A T_A)+B(T_A)$$
$$R(T+T_A)=A\exp(-\Phi T-\Phi_A T_A)+B(T+T_A)$$

Hence, the quotient $D$ becomes

$$D=\frac{R(T)-R(T+T_A)}{R(0)-R(T_A)}=\frac{\left(\begin{array}{c}A\exp(-\Phi T)\,[1-\exp(-\Phi_A T_A)]\\+B(T)-B(T+T_A)\end{array}\right)}{A[1-\exp(-\Phi_A T_A)]+B(0)-B(T_A)} \quad (10)$$

When

$$\left.\begin{array}{l}B(0)=B(T_A)\text{ and }B(T)=B(T+T_A)\\D=\exp(-\Phi T)\end{array}\right\} \quad (11)$$

The larger the $\Phi_A$ is and the smaller the $T_A$ is, the better are satisfied the assumptions in Eq. 11. It is clear from a similar argument given in the "differential absorption method" that the auxiliary absorber method offers an improved absorption curve. This curve is also always superior to the differential absorption curve. The differential method can be regarded as a special case of the auxiliary absorber method, each of the absorbers in the former being itself the auxiliary absorber in the latter.

Absorption curves of a solution of barium chloride (0.114 g./ml.) in dilute hydrochloric acid are shown in Fig. 5 with the absorption curve of hydrochloric acid containing the same quantity of chlorine. The auxiliary absorber is a thin tin foil, through which about 53% of photons transmit.

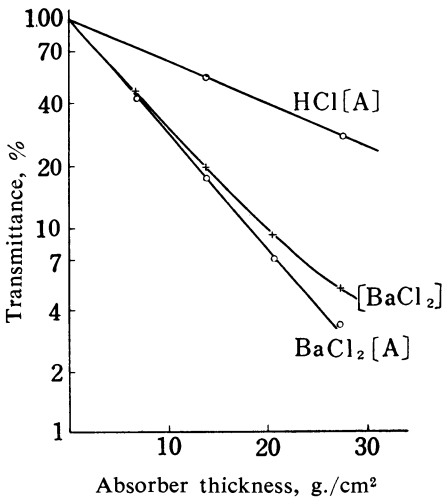

Fig. 5. Absorption curves. $BaCl_2$ [A] and HCl [A] are the auxiliary absorption curves. [$BaCl_2$] is the ordinary absorption curve.

**Effect of Geometrical Arrangement.**—A change of apparent absorption coefficient is clearly observed for an absorber having a small absorption coefficient according to the geometrical arrangement. For such an example, absorption curves of polystyrene for the photon from $^{204}$Tl are shown in Fig. 4. The curve denoted by [X] means that the absorber is placed as shown in Fig. 1, and the one denoted by [Y] means that it is placed on the scintillator. When a detector, an absorber and a source are placed close to one another, the apparent absorption coeffieient is small, and

increases toward a definite value with the increase in the distances between the source and the absorber and between the absorber and the detector.

This effect is attributable to the small-angle Compton scattering with a negligible energy loss. With such an absorber, the photolectric effect and the coherent scatterings contribute only slightly, and the absorption is caused almost entirely by the Compton scattering. However, the addition of the correction value, which can be obtained from the theoretical result[8], offers a definite value independent of the geometrical arrangement, unless the source, absorber and detector are close to one another. Such a corrected value is thought to be the true absorption coefficient. For the geometrical arrangement shown in Fig. 1, the correction value to be added is 0.007 $cm^2/g.$ for atoms in the absorber having an equal number of protons and neutrons. This value is about 1/20 of the total Compton-scattering cross section of the atom for a photon of 100 keV. Thus, this correction value can be used for all kinds of absorber material and for all kinds of photon-beam with quite a little final fractional error, so far as the absorption is mainly due to the photoelectric effect.

**Relationship between the Absorption Coefficient and the Photon Energy.** — Fairly good absorption curves and accurate absorption coefficients are obtained with the aid of techniques described above. The total cross section of the Compton scattering by an electron is almost independent of the binding state. The relationship between the total cross section of the Compton scattering and the photon energy is found in various literatures.

Amidst the coherent scatterings of photons[9] with which we are concerned here, only the Rayleigh scattering has a significant contributions, though its cross section is much smaller than that of the photoelectric absorption. The dependence of Rayleigh-scattering cross section on the photon energy is not greatly different from that of the photoelectric effect.

Thus, $\phi$, the absorption coefficient excluding the contribution of the Compton scattering is proportional to $E^{-\lambda}$, or,

$$\phi = kE^{-\lambda} \qquad (13)$$

where $8/3 < \lambda < 7/2$, and $k$ is a constant.

The experimental results shown in Fig. 6 agree with Eq. 13. They agree also with other absorber materials such as tungsten, neodymium, barium, iodine and aluminum. These experimental results indicate that Eq. 13 is valid not only above but also under the K-absorption edge, with a change of the magnitude of $k$ at the edge. This relationship plays an important role in further extension of the present study. However, it is doubtful, whether an extrapolation of a curve in Fig. 6 to a region of much lower energy (e. g. $^{55}Fe$ as the source) provides a correct value.

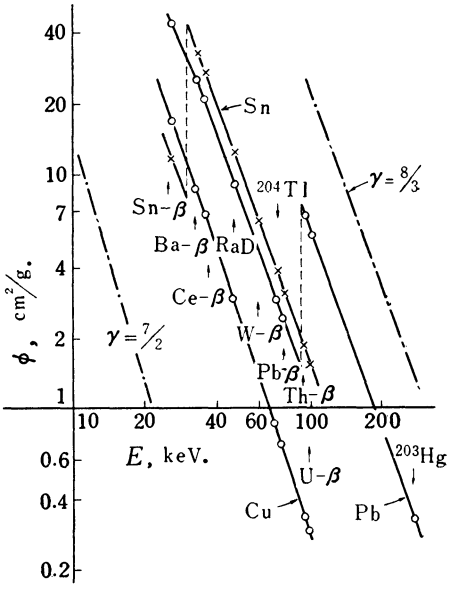

Fig. 6. Relationship between Absorption coefficient and photon energy.

There are numerical tables and charts calculated theoretically for the absorption coefficient against the photon energy. The value, however, is not entirely trustworthy for a photon having an energy not much larger than the binding energy of an electron in the absorber material, because of the invalidity of the Born approximation[10]. For the region under the K-absorption edge, the experimental values are usually considerably larger than the theoretical.

## Experimental

**Photon-beam Source.** — A solution containing radioisotopes of high specific activity emitting useful photons together with $\beta$-rays, was dried up in a hole dug in a small piece of polystyrene block, and the hole was filled with solid paraffin. When such a radioisotope was dried up in an iron dish or kept without $\beta$-ray absorber, the absorption curve, deviated further from the exponential curve. To improve the absorption curve, a solution containing $^{204}Tl$ was dried up on a crossing of polystyrene fibers at the center of a cubic polystyrene box of 5 cm. dimension, and the air in the box was replaced by hydrogen. However, only a little improvement was observed.

8) e. g. K. Siegbahn, "Beta- and Gamma-ray Spectroscopy", North Holland Pub. Co., Amsterdam (1954), p. 33.
9) e. g. ibid., p. 528.
10) e. g. ibid., p. 857.

About 50 mc. of $^{90}Sr$ of a high specific activity was dried up on a ring-formed filter paper for use as a $\beta$-ray source of the $\beta$-ray-excited-X-ray generator. It was essential to shield the detector from scattered photons by thick lead blocks. Targets of the generator were prepared as follows. Metal plates of a suitable thickness were formed as shown in Fig. 1, for use as the target. For other materials, compounds with lighter elements, such as uranium oxide, thorium oxide, mercury(I) chloride, tungsten oxide, cerium(IV) oxide, barium carbonate and ammonium bromide were placed on polystyrene target holders to a layer of due thickness with the aid of a benzene solution of polystyrene. The polyethylene sheet covering the lead block of the generator suffered radiation damage and had to be renewed with great care within a year.

**Detector.**—A scintillator (NaI, $1''\times1''$, Harshow) was mounted with the aid of a silicone oil on a photomultiplier tube (du Mont 6292), which was selected out of several tubes by examining their stability and thermal noise (a thinner crystal would be preferable for some cases). Heater voltage for the linear amplifier and preamplifier must be stabilized. The unit having the longest resolving time in the counter assembly was the pulse-height analyzer (5 $\mu$sec.), others having much smaller resolution time. Throughout the work, the gain of the linear amplifier and the preamplifier and the applied voltage to the photomultiplier tube were kept constant, unless a $\gamma$-ray having a higher energy than 200 keV. was measured. The scale in the abscissa of Fig. 2 was the bias voltage (base line) of the single channel analyzer under that condition. The window width for the photo-peak counting was 5.4 V. for a source of a higher energy than RaD and 3.6 V. for that of a lower energy than Ce-$\beta$ respectively under the same condition. The counting rate without absorber was about $10^4$ to $2\times10^4$ c. p. m. in other cases than $^{203}Hg$, in which the rate was about $10^5$ c. p. m.

Under the condition of the photo-peak counting, the fraction of $K_\beta$ rays appearing in the measurement range was as follows (denoted by percentage); U-$\beta$ 9, Th-$\beta$ 9, Pb-$\beta$ 15, Hg-$\beta$ 17, W-$\beta$ 22, Ce-$\beta$ 33, Ba-$\beta$ 35 and Sn-$\beta$ 44. For $K\beta$-filter, barium carbonate powder and iodoform were used for Ce-$\beta$ and Ba-$\beta$ respectively, both being painted on a thin filter paper in viscous benzene solution of polystyrene.

Proportional counter tubes (1.6 cm. diameter, 10 cm. effective length) of end-window type (1.9 mg./cm$^2$ mica) filled with methane (4 cm.Hg) and xenon, krypton or a mixture of these (ca. 40 cm.Hg) were set up and their characteristics measured. The output pulse of the tube was preamplified and introduced into the same electronic devices as those used with the scintillation head. The tube was also connected to a simple G-M counter circuit.

**Absorbers and Measurement of Absorption Coefficient.**—Metal-plate absorbers of aluminum, copper, tin, molybdenum and lead were obtained commercially or by rolling the pure metal to a desired thickness. A known quantity of pure iodine was dissolved in ethanol and made up to a definite volume. Pure barium and neodymium carbonates were dissolved in hydrochloric acid of a suitable concentration, and the content of the element was determined gravimetrically. Absorption curves of both the solution and the solvent were determined, and the absorption coefficient of the element was calculated, volume change due to the dissolution being taken into account.

## Summary

Studies for the improvement of fundamental techniques for the chemical use of the absorption of soft $\gamma$-rays, $\beta$-ray-excited X-rays and K-capture X-rays were undertaken. The exponential absorption curve, which is essential for the measurement of the accurate absorption coefficient and for many quantitative works, was obtained by the use of a proper detection method and the differential absorption technique, even in the presence of some photons having various energies. The relationship between the absorption coefficient thus obtained and the photon energy proved to agree with the theoretical result.

# *Visible Absorption Spectra of 1, 3, 5-Trinitrobenzene and its Derivatives in Aqueous Alkaline Acetone*

By Takehiro ABE

(Received January 16, 1961)

In a previous short communication[1] it was reported that when an acetone solution of 1, 3, 5-trinitrobenzene was treated with aqueous sodium hydroxide intense 460 and weak 510~590 mμ bands appeared and when ammonia water was applied an intense 505 mμ band came out. In the present work, the same spectroscopic investigation has been made on similar reactions of aqueous sodium hydroxide and of aqueous ammonia with 1, 3, 5-trinitrobenzene derivatives of 1, 3, 5-trinitrobenzene, 2, 4, 6-trinitrotoluene, tetryl (2, 4, 6-trinitrophenylmethylnitramine) and picryl chloride, in acetone.

## Expermental

Commercial extra pure grade trinitro compounds and commercial grade acetone were purified by the same methods as in the previous paper[2]. Sodium hydroxide and ammonia water (ca. 28%) of commercial grade were used without further purification.

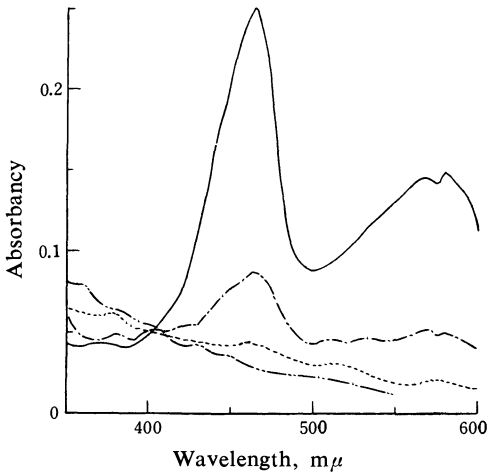

Fig. 1. Absorption spectra of 1,3,5-trinitrobenzene ($1.06\times10^{-5}$ M) in acetone (containing 4% water by volume) in the presence of sodium hydroxide ($4.16\times10^{-2}$ N) at room temperature.

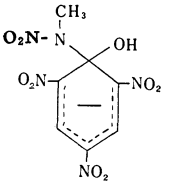
acetone solutions of these trinitro compounds initially show similar absorption curves 1. The analogy among the absorption curves 1 in Figs. 1–4 is not in perfect accord with Kimura's results[3]. He reported that a spectral pattern of a colored solution produced by treating trinitrobenzene with sodium hydroxide in a mixture of acetone and methanol (50% by volume) was different from patterns similarly made from trinitrotoluene and picryl chloride, and that the former was due to structure I while the latter ones were due to both structures I (mainly) and II.

I



II

A change in an absorption curve of the aqueous alkali-treated colored solution of tetryl with time is indicated in Fig. 5. The colored solution made by adding a drop of aqueous

3) M. Kimura, *Pharm. Bull. (Japan)*, 3, 75 (1955).

sodium hydroxide solution (1 N) to a dilute aqueous solution of tetryl is decolorized at the highest measurable rate at room temperature among those of the four trinitro compounds. The decolorized solution shows an absorption curve 5 similar to that of picrate anion. It is well known that tetryl reacts with aqueous alkali to form picrate. Accordingly, as mentioned in the previous paper[2], a curve in Fig. 5 is expected to be due to Meisenheimer's intermediate III in the process of substitution reaction of tetryl to picric acid.

III

Recently such Meisenheimer's intermediates have been presented for many colored products of polynitrobenzene derivatives with alkalies*. From the close similarity of the absorption curves 1 in Figs. 1–4 with that 1 in Fig. 5 it seems likely that the curves 1 in Figs. 1–4 do not correspond to products such as I or II but do to such Meisenheimer's type complexes, III, formed between the trinitro compounds and sodium hydroxide.

When the colored solutions for Figs. 1–4 are allowed to stand for several hours, they become turbid. Their spectra can not, therefore, be measured thereafter. Figs. 3 and 4 suggest that both the colored species from tetryl and picryl chloride are gradually converted into a substance giving an absorption band at about 390 mμ. Picric acid in acetone also gives an absorption band at the same region in the presence of sodium hydroxide[4]. Accordingly, the colored species from tetryl and picryl chloride in acetone as well as in water are probably converted mainly into picric acid. On the other hand, the colored solutions of trinitrobenzene and trinitrotoluene do not have distinct bands at about 390 mμ even after decoloration, as indicated in Figs. 1 and 2. Therefore, those from trinitrobenzene and trinitrotoluene would undergo further complicated reactions like the reaction of trinitrobenzene with sodium carbonate in methanol, finally giving 3, 5-dinitroanisole through the formation of the Meisenheimer's intermediate[5].

**Absorption Spectra of the Trinitro Compounds in Acetone Containing Ammonia Water (Figs. 6-9).**—Figs. 6–9 show that colored solutions initially produced by additions of ammonia water to the acetone solutions of the trinitro compounds give absorption curves 1 similar to these for the colored solutions obtained by

the addition of sodium hydroxide, except in the case of the solution from trinitrotoluene, and that the initially produced colored solutions change to the other solutions having different stable intense bands. The absorption curve 1 in Fig. 7 is the only one which does not correspond to the curve 1 in Fig. 2, but does to the curve[6,7] for a colored solution formed from trinitrotoluene in ethanol by the action of sodium ethoxide. Caldin et al.[6,7] have suggested a proton-transfer reaction. Miller and Wynne-Jones[8] also observed that a mixture of trinitrobenzene with diethylamine in acetone or in ethanol produced at first an intensely colored solution having absorption maxima at 470, 515 and 570 mμ and that the solution changed after a considerable period to that having an absorption band only at 515 mμ.

One can see from Fig. 10 that both ammonia water and sodium hydroxide react identically

with tetryl in water. From the similarity of the absorption curves 1 in Figs. 1–5 and 10, the absorption curves 1 in Figs. 6, 8 and 9 are perhaps due to the colored intermediates such as III, except for the case of trinitrotoluene. These initially formed colored intermediates may further react to produce a stable colored species giving the final absorption curves 4 in Figs. 6–9. The stable colored species were provisionally considered to be Meisenheimer's intermediates in the previous paper[9]. However, it has not yet been proved that the stable colored species are converted further into picric acid. Therefore, at present one can not conclude that they are the Meisenheimer's intermediates. Kimura[10] reported that a darkish purple substance obtained by adding sodium bicarbonate to the acetone solution of trinitrobenzene was a product similar to II.

## Summary

The visible absorption spectra of the colored solutions produced by adding aqueous sodium hydroxide solution or ammonia water to the acetone solutions of 1, 3, 5-trinitrobenzene and its derivatives (2, 4, 6-trinitrotoluene, tetryl and picryl chloride) were measured at room temperature in order to investigate the difference of the chemical actions between stong-alkaline sodium hydroxide and weak-alkaline ammonia water.

These trinitro compounds in acetone containing sodium hydroxide show spectra similar to that of the aqueous sodium hydroxide solution of tetryl. The spectrum of this aqueous colored solution is considered to be due to an intermediate of the Meisenheimer type in the process of the substitution reaction of tetryl to picric acid. Consequently, all the spectra of the colored solutions from the trinitro componds are also probably due to the intermediates of the Meisenheimer type.

Each colored solution of the trinitro compounds in acetone containing ammonia water initially shows the same spectrum as that with sodium hydroxide, except for the case of trinitrotoluene, and changes to the other colored solution having an intense and stable band entirely different from the initial spectrum. The initially formed colored solutions of these trinitro compounds, except the solution from trinitrotoluene, may also be due to the Meisenheimer intermediates.

The author is particularly indebted to Professor Yōkan Nomura for helpful discussions.

# *Sur la Dissolution des Minerais Sulfurés en Divers Milieux. V. Dissolution de la Sphalérite*

Par Masami ICHIKUNI et Hiroshi KAMIYA

(Reçu le 20 Janvier 1961)

Lorsqu'on aborde le problème de la désagrégation des minerais sulfurés par voie chimique, on s'intéresse notamment aux réactions qui ont part à ce phénomène. Bien que de nombreux articles soint déjà parus à ce propos, ces études sont faites, dans la plupart des cas, avec l'utilisation des minerais et non des minéraux. L'interprétation des résultats était très difficile, car les analyses chimiques n'ont donné que l'aspect global du phénomène composé de nombreuses réactions qui s'avançaient chacune à vitesse différente. Il faut qu'on sache quelles réactions peuvent avoir lieu et ont lieu au cours de la désagrégation.

Pour l'analyse des résultats, la sphalérite semble se munir d'un caractère favorable grâce à la simplicité de sa composition chimique. Kuz'minykh et Yakhontova[1] ont déjà étudié l'extraction du zinc à partir de ce minéral en utilisant le sulfate de fer (III) comme réactif. Il s'agit de la dissolution du minéral en milieu extrêmement oxydant ; ce milieu ne représenterait pas celui de la nature. Ohashi[2] a examiné la dissolution des minéraux sulfurés dans les

eaux saturées d'air, mais il est regrettable que cet auteur n'ait pas montré les réactions de dissolution. Récemment, du point de vue électrochimique, Sato[3] a donné le mécanisme de la décomposition des minéraux sulfurés dans une solution choisie.

Les présents auteurs voudraient montrer les réactions de la décomposition de la sphalérite en diverses solutions et préciser les conditions qui favorisent la désagrégation, tout en tenant compte des composants mineurs en solution. Il est probable que ces derniers se chargent du rôle de catalyseur dans la nature. L'accélération des réactions est souvent due uniquement à l'action du catalyseur. On tâtonne encore quelles substances peuvent être un catalyseur dans la désagrégation des minerais sulfurés.

### Méthode d'Expérience

On suspend 500 mg. de sphalérite pulvérisée dans 200 ml. de liqueur à l'aide d'un agitateur magnétique, et effectue le prélèvement de 5 ml. de liqueur à des intervalles appropriés au cours de 2 hr. de traitement. Le ballon à fond plat à 300 ml. contenant la liqueur est plongé dans un bain-marie dont la température est maintenue constamment à 50°C. Le ballon est bien bouché avec un bouchon de caoutchouc, persé de 2 tuyaux de verre : le plus long, dont le bout de dessous se munit d'un hémisphère de verre fritté qui touche presque le fond du ballon, sert à produire de nombreuses petites bulles d'air dans la liqueur, lorsqu'on relie à une trompe le tuyau le plus court qui ne s'enfonce pas dans la liqueur. Le débit de l'air est réglé à 0,4 l./min.

La sphalérite produite à la mine de Hosokura, département de Miyagi, est pulvérisée et passée au tamis 60. Le Tableau I montre le résultat d'analyse de l'échantillon. Une certaine teneur en plomb s'explique par la présence de la galène qui est une des impuretés minéralogiques les plus communes. On a préparé ici deux échantillons en pulvérisant de nouveau de la sphalérite tamisée dans un mortier d'agate. Un échantillon qui a été utilisé pour l'examen de l'influence du pH sur la dissolution de ce minéral était moins fin que l'autre avec lequel on a effectué les autres expériences.

3) M. Sato, *Econ. Geol.*, 55. 1202 (1960).

La liqueur prélevée est immédiatement filtrée et amenée à 25 ml. Sur cette solution diluée on effectue le dosage du zinc, et s'il y a lieu, du fer et du cuivre. Le dosage du zinc et du cuivre est fait par voie colorimétrique au moyen de la dithizone, et celui du fer, au moyen de l'*o*-phénanthroline. Le dosage de l'hydrogène sulfuré a été effectué par l'iodométrie après une filtration soigneuse de liqueur. L'ion sulfate est examiné avec une solution de chlorure de baryum.

### Résultats

**Effets du pH.**—Quand on a introduit de l'air, la vitesse de dissolution du zinc dépendait dans une grande mesure de l'acidité du milieu. La sphalérite s'est dissoute rapidement au début du traitement, et dont la vitesse de dissolution a ralenti graduellement et elle est devenue constante dans une demi-heure (voir la Fig. 2). Cette vitesse constante servait à établir une échelle de comparaison entre toutes les conditions des expériences.

Le résultat des expériences est indiqué sur la Fig. 1. Comme elle l'indique, la vitesse de dissolution décroit avec la diminution de l'acidité du milieu. L'ion sulfate n'a été décelé en aucun cas. On remarque donc une réaction qui suit :

$$(1) \qquad ZnS + 2H^+ \rightarrow Zn^{2+} + H_2S$$

A part de cette réaction, on en a une autre qui conduit à la formation du soufre libre :

$$(2) \quad ZnS + 2H^+ + O \rightarrow Zn^{2+} + S + H_2O$$

Comme la formation du soufre libre était négligeable, on admet que la première réaction est prédominante sous les conditions des expériences. On n'arrive pourtant pas à décider si la formation du soufre libre est attribuable à l'oxydation de l'hydrogène sulfuré, formé par la première réaction, ou à l'oxydation directe du minéral.

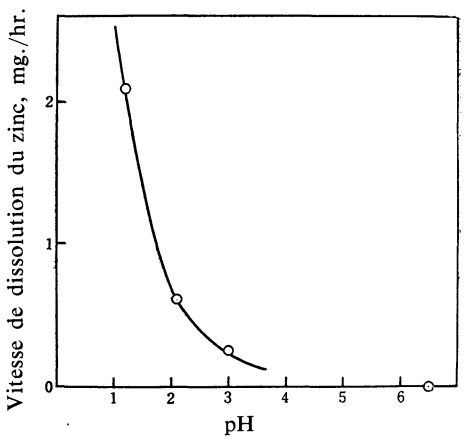

Fig. 1. Vitesse de dissolution de la sphalérite en fonction du pH (expériences effectuées avec barbotage d'air de 400 ml./min.).

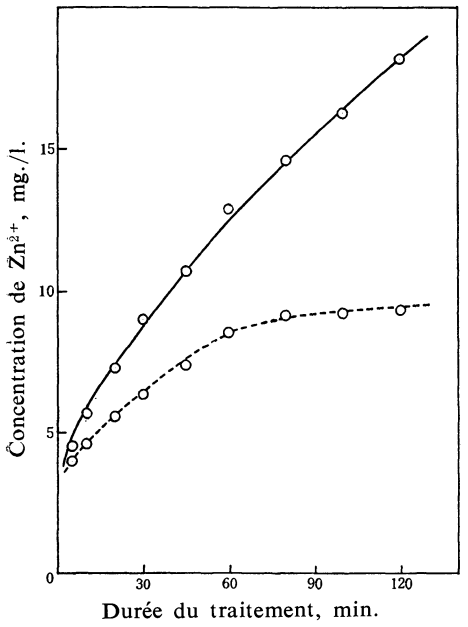

Fig. 2. Variation de concentration de $Zn^{2+}$ en fonction de la durée du traitement.
Trait plein : expérience effectuée avec l'introduction de l'air
Trait discontinu : expérience effectuée sans introduction de l'air

Il faut qu'on tienne compte de la granulométrie de l'échantillon utilisé dans cette expérience, lorsqu'on compare ce résultat avec celui des expériences exposées ci-après qui ont été effectuées avec l'échantillon plus fin.

**Effets du Barbotage de l'Air.**—Il faut qu'on sache d'abord si l'oxygène barboté agit en oxydant du minéral et de l'hydrogène sulfuré, ou simplement en entraîneur de celui-ci. A cet effet, deux expériences ont été entreprises: l'une, avec l'introduction de l'air, dont le débit était de 0,4 l./min., et l'autre, sans introduction de l'air. Dans la dernière expérience, l'air ne se comportait pas en entraîneur, et cela ne signifie pas l'expulsion entière de l'oxygène. Les deux ont été effectuées en milieu d'acide chlorhydrique 0,01 N et à la température de 50°C. Dans la Fig. 2, on dessine la concentration de zinc en fonction de la durée du traitement. Comme on voit dedans, deux courbes, correspondant chacune aux deux expériences décrites ci-dessus, s'approchent l'une de l'autre au début de la dissolution, cependant, elles s'éloignent rapidement avec le temps. La différence des deux expériences peut s'expliquer par l'accumulation de l'hydrogène sulfuré. Cette supposition sera très compréhensible, si l'on admet que le barbotage de l'air, entraînant avec celui-ci l'hydrogène sulfuré formé, favorise une dissolution remarquable du minéral. En fait, sans introduction de l'air, la teneur en hydrogène sulfuré a atteint une valeur de 2,1 mg./l. au bout de 2 hr. de traitement.

Examinons ensuite la possibilité de l'oxydation de l'hydrogène sulfuré par l'oxygène dissous. Si la réaction d'oxydation de ce composé s'avançait avec une vitesse considérable, l'empêchement de la dissolution n'aurait pas lieu, tout au moins, pendant un certain temps, car la liqueur contenait 5,0 mg./l. d'oxygène dissous avant l'addition du minéral. Au bout de 2 hr. de traitement, on a trouvé une concentration de zinc de 9,3 mg./l., correspondant à la formation de l'hydrogène sulfuré de 4,8 mg./l. Ce chiffre ne suffit pas à consumer entièrement l'oxygène dissous, même si l'hydrogène sulfuré soit complètement oxydé en soufre libre par l'oxygène contenu dans la liqueur. D'ailleurs la surface de la liqueur étant toujours en contact avec l'atmosphère, il n'y a aucune raison de croire que l'accumulation de l'hydrogène sulfuré a été causée par manque d'oxygène libre.

Par suite de ces considérations, on conclut que l'oxydation de l'hydrogène sulfuré par l'oxygène libre s'avance très lentement, et que l'hydrogène sulfuré ralentit la décomposition de la sphalérite, même en présence de l'oxygène atmosphérique. Il va sans dire qu'à l'état d'équilibre, la présence de l'hydrogène sulfuré n'est pas compatible avec celle de l'oxygène libre. Le système réalisé par les expériences était hors de l'équilibre, comme l'indique la co-présence de l'hydrogène sulfuré et de l'oxygène. La théorie de l'équilibre chimique ne sera pas très utile à expliquer le mécanisme des réactions qui ont lieu au cours du traitement.

Calculons ici le produit de concentration de zinc par celle d'ion sulfure avec les chiffres qu'on a obtenus sur l'expérience effectuée sans introduction de l'air, au bout de 2 hr. de traitement :

$$[Zn^{2+}] = 9{,}3 \text{ mg./l.} = 1{,}4 \times 10^{-4} \text{ mol./l.}$$

$$[H_2S] = 2{,}1 \text{ mg./l.} = 0{,}62 \times 10^{-4} \text{ mol./l.}$$

Comme $[H^+]^2[S^{2-}]/[H_2S] = 10^{-21}$, où $[H^+] = 10^{-2}$, on a :

$$[S^{2-}] = 0{,}62 \times 10^{-21} \text{ mol./l.}$$

donc,

$$[Zn^{2+}] \cdot [S^{2-}] = 0{,}87 \times 10^{-25}$$

Cette valeur est beaucoup moins grande que le produit de solubilité de la sphalérite : $10^{-23{,}3}$. On notera ici que la vitesse de dissolution du minéral est déjà très ralentie sous cette condition.

**Effets des Ions $Fe^{2+}$.**—Cet essai s'est fait à 50°C, en milieu d'acide chlorhydrique 0,01 N, avec l'introduction de l'air dont le débit était de 0,4 l./min. On a préparé une solution

étalon de $Fe^{2+}$ en dissolvant du chlorure de fer(II) hydraté dans l'acide chlorhydrique 0,01 N. Elle contenait 1,000 mg./l. de $Fe^{2+}$.

Les ions $Fe^{3+}$ exercent une action particulière sur la dissolution du minerai sulfuré, dans ce cas ils se réduisent en ions $Fe^{2+}$. Une solution qui est en contact avec un gisement de minerais sulfurés trouve son fer presque entièrement à l'état divalent. Les ions $Fe^{3+}$ se forment dans la nature par l'oxydation des ions $Fe^{2+}$ au moyen de l'oxygène atmosphérique. On a effectué ces expériences en prenant le mécanisme de la formation des ions $Fe^{3+}$ dans la nature en considération. Par l'introduction de l'air dans une solution contenant des ions $Fe^{2+}$, on a essayé de reproduire en quelque sorte la formation des ions $Fe^{3+}$. On avait déjà noté que l'action des ions $Fe^{2+}$ et de l'oxygène atmosphérique favorisait une forte dissolution de la chalcopyrite, et on l'avait attribué à la formation des ions $Fe^{3+}$ [4].

On montre sur la Fig. 3 un exemple tiré des expériences: la présence des ions $Fe^{2+}$ ralentit considérablement la dissolution du zinc. Même une teneur en ions $Fe^{2+}$ à 100 mg./l. produit le même effet, comme on voit sur la Fig. 4. Lorsqu'on dit vitesse de dissolution, il s'agit toujours de celle qui est mesurée à l'état stationnaire de dissolution. Ce résultat ne s'accorde pas avec celui de la chalcopyrite.

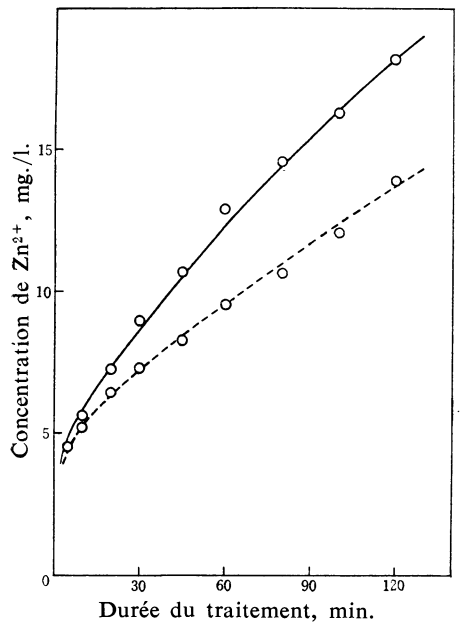

Fig. 3. Variation de concentration de $Zn^{2+}$ en fonction de la durée du traitement.
Trait plein: en l'absence des ions $Fe^{2+}$
Trait discontinu: en présence de 1.000 mg./l. de $Fe^{2+}$

4) M. Ichikuni, Ce Bulletin, 33, 1159 (1960).

**Effets des Ions $Fe^{3+}$.**—Cet essai a été effectué à 50°C, en milieu d'acide chlorhydrique 0,01 N, avec l'introduction de l'air, dont le débit restait toujours le même que les essais précédents. La solution étalon de $Fe^{3+}$ a été préparée à partir du chlorure de fer(III) hydraté. On en a dissous dans l'acide chlorhydrique, de manière à ce que la solution contienne 100 mg./l. de $Fe^{3+}$.

La réaction entre la sphalérite et des ions $Fe^{3+}$ est exprimée par l'équation suivante[1]:

$$(3)\quad ZnS + 2Fe^{3+} \rightarrow Zn^{2+} + S + 2Fe^{2+}$$

où la dissolution de 1 mol. de zinc correspond à la réduction de 2 mol. de $Fe^{3+}$ en $Fe^{2+}$. L'examen du résultat d'expériences, montré

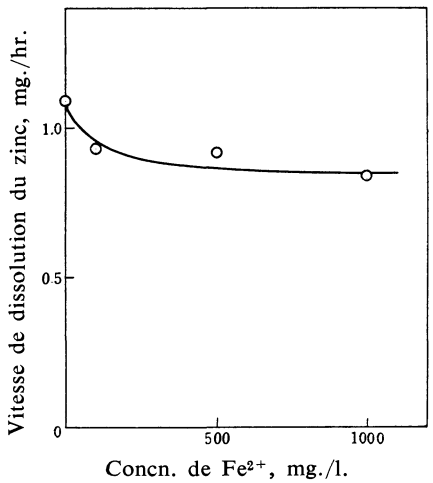

Fig. 4. Vitesse de dissolution de la sphalérite en fonction de la concentration en ions $Fe^{2+}$ de la liqueur.

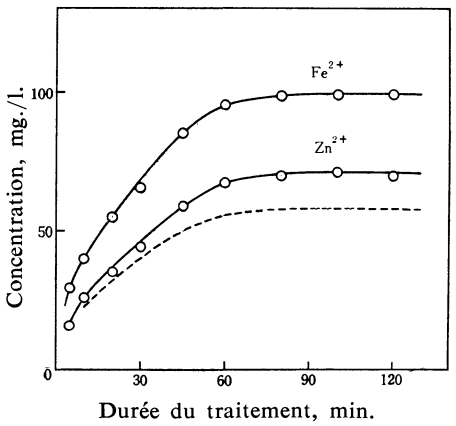

Fig. 5. Dissolution de la sphalérite par l'action des ions $Fe^{3+}$.
Trait plein: concentration de zinc dissous et defer réduit
Trait discontinu: concentration théorique de zinc, calculée à partir de la concentration trouvée de $Fe^{2+}$

sur la Fig. 5, révèle que la quantité dissoute de zinc est toujours supérieure à la quantité théorique de zinc, calculée d'après la réaction 3 à partir de la quantité trouvée de $Fe^{2+}$. Il est certain qu'une partie de zinc a été dissoute d'après la réaction 1, où l'hydrogène sulfuré a été partiellement entraîné par le courant d'air, sans être oxydé en soufre libre par l'action des ions $Fe^{3+}$.

**Effets des Ions $Cu^{2+}$.**—Il est bien connu que les ions de métaux lourds, notamment $Cu^{2+}$, jouent un rôle de catalyseur dans de diverses réactions. Comme les ions $Cu^{2+}$ se trouvent très fréquemment dans les eaux de mine, il est probable qu'ils contribuent d'une certaine manière à l'accélération ou à la retardation des réactions de désagrégation.

Bien que l'action des ions $Cu^{2+}$ ait été remarquée par certains chercheurs[5], la connaissance en est encore peu suffisante. Le comportement des ions $Cu^{2+}$ trouvé dans cette expérience permettra de révéler la fonction qu'ils exercent dans la désagrégation. Cet essai a été effectué sous les mêmes conditions que les précédents, sauf la présence des ions $Cu^{2+}$ qui ont été ajoutés saus forme du sulfate.

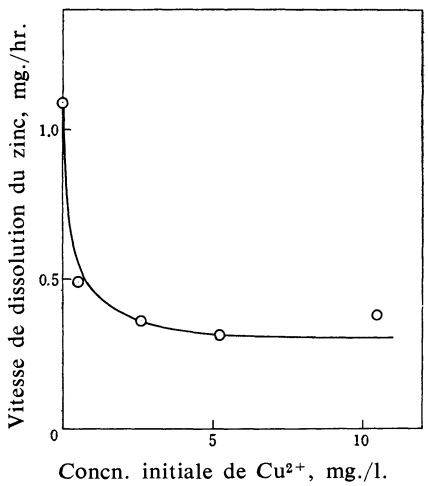

Fig. 6. Influence des ions $Cu^{2+}$ sur la dissolution de la sphalérite.

La vitesse de dissolution du zinc a été mesurée dans des solutions de diverses teneurs en $Cu^{2+}$. La Fig. 6 représente le résultat de l'essai. Les ions $Cu^{2+}$ ralentissent la dissolution. Une variation faible de concentration en $Cu^{2+}$ révélé qu'une petite portion de $Cu^{2+}$ avait disparu au cours de l'expérience. La diminution en a atteint 0,5 mg./l. près au bout de 2 hr. de traitement. Le cuivre aurait précipité sous forme du sulfure, dont la formation est attribuable au dégagement de l'hydrogène sulfuré, libéré par la décomposition du minéral. Toutefois la quantité fixée de cuivre était très faible par rapport à celle d'hydrogène sulfuré formé. On peut en déduire que la condition oxydante défavorise la fixation du cuivre, même en présence des ions sulfure. Comme le cuivre ajouté restait presque entièrement à l'état dissous, on admet qu'une réaction d'échange du zinc avec le cuivre n'avait pas lieu. Si la réaction d'échange intervenait, il y aurait une tendance d'augmenter la vitesse de dissolution à mesure que la concentration en $Cu^{2+}$ augmente.

Or, généralement dit, des solutions formées dans la zone d'oxydation du gisement des minerais sulfurés contiennent encore d'autres ions que les ions $Cu^{2+}$. La caractéristique des solution est donc la co-présence de divers ions, tels que des ions $Fe^{2+}$, $Fe^{3+}$, $Cu^{2+}$, $Mn^{2+}$ et ainsi de suite. L'action des ions $Cu^{2+}$ devrait être examinée en présence d'autres ions, notamment des ions de fer.

**Effets des Ions $Fe^{3+}$ et $Cu^{3+}$.**—Il est bien connu que les ions $Fe^{3+}$ sont efficaces à la décomposition des minerais sulfurés, mais il n'y a presque aucune étude sur la contribution des ions $Cu^{2+}$ à ce phénomène. Seulement Garrels et Thompson[6] ont mentionné que l'attaque des ions $Fe^{3+}$ contre la pyrite n'était pas accélérée par la présence des ions $Cu^{2+}$. On a entrepris ici un essai de dissolution de la sphalérite au moyen des ions $Fe^{3+}$ en présence des ions $Cu^{2+}$, et en a comparé le résultat avec celui de l'essai précédent qu'on avait effectué

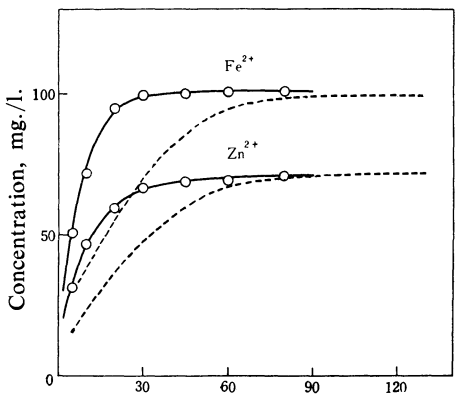

Fig. 7. Effets des ions $Cu^{2+}$ sur la dissolution de la sphalérite par l'action des ions $Fe^{3+}$.
Trait plein : expérience effectuée en présence de 5,25 mg./l. de $Cu^{2+}$
Trait discontinu : expérience effectuée en l'absence des ions $Cu^{2+}$

5) S. Koch et Gy. Grasselly, *Acta Univ. Szegediensis, Acta Mineral. Petrog.*, 6, 23 (1952).

6) R. M. Garrels et M. E. Thompson, *Am. J. Sci.*, **258** A, 57 (1960).

dans une liqueur contenant 100 mg./l. de $Fe^{3+}$, mais qui était exempte de cuivre.

La Fig. 7 donne les résultats de cet essai et du précédent. On voit que la présence des ions $Cu^{2+}$ favorise une décomposition rapide de la sphalérite. On ajoute encore que la diminution de concentration en $Cu^{2+}$ n'avait pas lieu au cours du traitement, tant que les ions $Fe^{3+}$ restaient en solution.

**Effets des Ions $Fe^{2+}$ et $Cu^{2+}$.**—Les résultats des essais précédents nous ont conduit à l'entreprise d'un autre essai mis sous les conditions qui ne sont das trop éloignées de celles de la nature. En considérant les eaux de mine, où les ions $Fe^{2+}$ sont prédominants dans la plupart des cas, on a imaginé que l'essai de la dissolution en présence des ions $Fe^{2+}$ et $Cu^{2+}$ réaliserait les réactions réelles dans la nature.

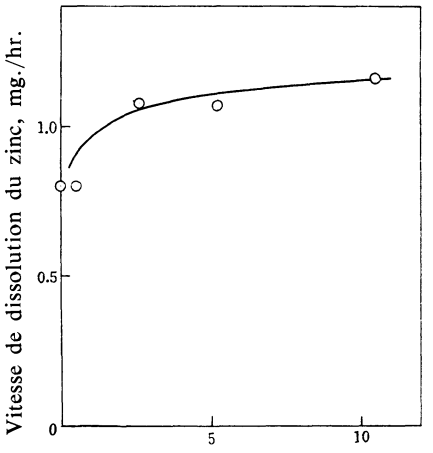

Fig. 8. Vitesse de dissolution de la sphalérite en présence de 700 mg./l. de $Fe^{2+}$ et de quantité variable de $Cu^{2+}$.

La Fig. 8 montre le résultat. Dans cette série d'expériences, la concentration de $Fe^{2+}$ était fixée à 700 mg./l. et celle de $Cu^{2+}$ variait de 0,53 à 10,5 mg./l. La concentration de $Cu^{2+}$ a diminué très lentement au cours du traitement. La diminution s'en est élevée à 0,5 mg./l. près au bout de 2 hr. de traitement. Toutefois on a remarqué une dissolution accélérée de la sphalérite, tant que l'ion cuivre restait en solution. On discutera plus loin le mécanisme possible de ce phénomène.

## Discussion

C'est le pH du milieu qui exerce une grande influence sur la décomposition du minéral, sans qu'on tienne compte des effets électrochimiques provenant du contact avec d'autres minéraux. Si le minéral existait indépendamment d'autres minéraux, il resterait assez stable en milieu neutre même en présence de l'oxygène atmosphérique.

La présence de l'oxygène libre et des ions $Fe^{2+}$ n'est pas capable d'accélérer sa décomposition, c'est que l'oxydation des ions $Fe^{2+}$ en ions $Fe^{3+}$ s'avance très lentement avec l'oxygène libre. Si les ions $Fe^{3+}$ étaient formés rapidement à partir des ions $Fe^{2+}$ par l'action de l'oxygène, l'introduction de l'air rendrait la décomposition du minéral d'autant plus facile que la teneur en ions $Fe^{2+}$ de la liqueur est plus grande.

Les ions $Cu^{2+}$, agissant souvent en catalyseur, ne sont pas tous seuls capables d'augmenter la vitesse de décomposition du minéral, par conséquent on ne peut pas attendre une réaction d'échange du zinc avec le cuivre. Il est intéressant que les ions $Fe^{2+}$ ainsi que les ions $Cu^{2+}$, loin d'accélérer la désagrégation de la sphalérite, la retardent considérablement. Ce phénomène offre des problèmes importants à la géochimie des gisements métallifères.

L'action des ions $Fe^{3+}$ avait été bien étudiée, mais on a trouvé ici, pour la première fois, qu'une petite quantité de cuivre accélérait la réaction entre le minéral et les ions $Fe^{3+}$. Toutefois les produits de réaction étaient toujours les ions $Zn^{2+}$ et le soufre libre en milieu acide, indépendamment de la présence du cuivre. On considère pour le moment le cuivre comme catalyseur.

On a eu ainsi l'idée d'examiner la dissolution du minéral en présence des ions $Fe^{2+}$ et $Cu^{2+}$ avec l'introduction de l'air. Si ces ions se comportaient indépendamment les uns des autres, ils en retarderaient la dissolution. Mais, au contraire, leur co-présence y était efficace. Ce fait insiste qu'il y a une interaction entre les ions $Fe^{2+}$, $Cu^{2+}$ et l'oxygène. Il est probable que les ions $Cu^{2+}$ facilite l'oxydation des ions $Fe^{2+}$ en ions $Fe^{3+}$ par l'oxygène atmosphérique. Ils accélèrent également l'attaque des ions $Fe^{3+}$ contre le minéral.

On conclut donc que la présence des ions $Cu^{2+}$ est indispensable à une décomposition rapide de la sphalérite, et que les ions $Cu^{2+}$ jouent ici un rôle de catalyseur. Toutefois des composés insolubles de cuivre n'en sont pas capables. On ajoute encore que, malgré l'action catalytique du cuivre, une formation abondante d'ions $Fe^{3+}$ n'aura pas lieu, le rapport $Fe^{3+}/Fe^{2+}$ étant réglé par le potentiel d'oxydo-réduction du milieu, par conséquent on ne peut pas attendre une dissolution rapide du minéral, tant que les réactions se passent en solution.

## Résumé

Les facteurs intervenant à la décomposition chimique de la sphalérite ont été examinés. Un petit pH ainsi que l'oxydant, notamment le

fer trivalent accélèrent la décomposition. La présence de l'hydrogène sulfuré la retarde considérablement. A pH 2, celle des ions $Fe^{2+}$ ou des ions $Cu^{2+}$ empêche une dissolution rapide du minéral, même avec l'introduction de l'air. La décomposition du minéral par les ions $Fe^{3+}$ est accélérée par les ions $Cu^{2+}$. La co-présence des ions $Fe^{2+}$ et $Cu^{2+}$ favorise, avec le barbotage de l'air, une dissolution remarquable du minéral, ce qui est attribuable à l'action catalytique des ions $Cu^{2+}$ qui facilitent probablement l'oxydation des ions $Fe^{2+}$ en ions $Fe^{3+}$, et l'attaque de ceux-ci contre le minéral.

Les auteurs se permettent d'exprimer leur remerciements sincères à Monsieur le professeur K. Noguchi et à Monsieur le professeur T. Hanya qui ont bien voulu donner des conseils utiles et participer à la discussion sur l'interprétation des résultats.

# *Physicochemical Studies on Cobalt Salts of Higher Fatty Acids. I. Preparation of Cobalt Soap by Metathesis*

By Hirotaro KAMBE*

(Received February 24, 1961)

Heavy metal salts of higher fatty acids, usually called heavy metal soaps, can be made by a substitution reaction between fatty acid and the salt of weak inorganic acid such as acetate. In place of inorganic salts, oxide or hydroxide may be used. These reactions can be accelerated by fusing the reactants. This is the principle of the fusion method, which is commonly used as a means of preparation of heavy metal soaps.

Cobalt soap may be prepared by the fusion method. The melting of fatty acid with cobalt(II) acetate or cobalt(II) hydroxide is followed by the reactions:

$$Co(CH_3COO)_2+2RCOOH = Co(RCOO)_2+2CH_3COOH$$

or $$Co(OH)_2+2RCOOH=Co(RCOO)_2+2H_2O$$

The cobalt soap made by the fusion method is not crystalline powder, but a glassy mass. Molten cobalt soap is easily oxidized and often becomes dark on prolonged heating in air. For these reasons we have concluded that the fusion method is not suited for preparing pure cobalt soap.

With water soluble salts of weak acid, fatty acid may react in solution. Kaufman and Lüssling[1] reported that when they shook a solution of fatty acid in petroleum ether with an aqueous solution of cobalt(II) acetate, the upper petroleum ether layer became blue as the formed cobalt soap dissolved into petroleum ether. They obtained cobalt oleate by this method. But our preliminary experiment has shown that it is difficult to prepare cobalt stearate with this technique, for the stearate is less soluble in petroleum ether than the oleate. When we use ethyl alcohol instead of petroleum ether as the solvent, the reaction advances very smoothly in a homogeneous solution and crystalline cobalt stearate powder can be prepared. This may be another means of preparing cobalt soap, as is shown later.

Water soluble inorganic salts, either of weak acid or of strong acid, react instantaneously with alkaline soap. This type of reaction is called double decomposition or metathesis. Metathesis is most important in preparing metal soaps, and it is the basis of the so-called precipitation method. The soaps made by metathesis are generally crystalline powder.

In the case of cobalt soap, cobalt(II) chloride, nitrate, sulfate, and acetate may be used as inorganic salts in metathesis. Reactions between these and sodium or potassium soap would proceed readily in solution to form cobalt soaps. For example,

$$CoCl_2+2RCOONa=Co(RCOO)_2+2NaCl$$

Kahlenberg[2] has shown very long ago that metathetic formation of heavy metal soaps

2) L. Kahlenberg, *J. Phys. Chem.*, 6, 6 (1902).

could be carried out also in organic solvents. Koenig[3] prepared many metal soaps, including cobalt soap, by metathesis in warm water. The soap thus formed was dried in an air oven at 115~120°C for 10~12 hr., and the glassy solid obtained was then pulverized. Koenig observed a color change from pink to blue when cobalt soap was heated.

In Koenig's method an aqueous solution of sodium soap is used, and at the lower concentrations, alkaline soap may be hydrolyzed to free acid, which will contaminate the soap being formed. Whitmore and Lauro[4] proposed a method for preventing the hydrolysis of alkaline soap by the addition of ethanol to the solution.

Although Whitmore and Lauro did not prepare cobalt soap in this way, we have examined this method in detail and found that besides common pink hydrous cobalt soap, blue anhydrous and red hydrous soaps may be formed according to conditions. In this part of the study, metathetic preparation of cobalt soap was investigated, and particularly the effects of several factors on the color of the soap being formed were discussed.

## Experimental

**Materials.**—*Fatty Acids.*—Stearic, palmitic, myristic, and lauric acid were fractionally distilled products, made by Nihon Yushi Co., and were recrystallized from absolute ethanol.

*Solvents.*—Ethanol and methanol were dehydrated and distilled over anhydrous calcium oxide. Acetone was dehydrated by potassium carbonate anhydrate.

*Cobalt(II) Salts.*—Cobalt chloride, $CoCl_2 \cdot 6H_2O$, nitrate, $Co(NO_3)_2 \cdot 6H_2O$, sulfate, $CoSO_4 \cdot 7H_2O$, and acetate, $Co(CH_3COO)_2 \cdot 4H_2O$ were chemically pure reagents and were recrystallized from water. These salts, except sulfate, are very deliquescent, and they were used with some water.

**Metathesis.**—The following standard procedure was adopted to control experimental factors.

(i) Fatty acid, mostly stearic acid, was dissolved in absolute ethanol by warming in a constant temperature water-bath at 60°C, and neutralized exactly by an alkaline solution, with phenolphthalein as indicator. The alkaline solution used was usually 0.15 N potassium hydroxide solution in water or in ethanol. If necessary, some amount of either solvent was added to the alkaline soap solution to control the ratio of the volume of solvent (ethanol in this case) to that of water in the system; this is called the solvent ratio hereafter. When this ratio is comparatively low, the alkaline soap solution becomes turbid by hydrolysis of the soap. In such cases the reaction products tend to contain free fatty acid, which may be extracted, however, by acetone, as is shown below.

(ii) An excess of cobalt salt, mostly cobalt chloride, was dissolved in the same water-bath in water, or, if necessary, in pure or aqueous ethanol. The solution of cobalt chloride in water is considerably acidic, and also the solution after metathesis becomes slightly acidic. It is natural for the soap made in this way to contain some free fatty acid. When cobalt acetate is used instead of chloride, the solution is not so acidic that free acid is not included in the soap, as was pointed out by Whitmore and Lauro[4].

(iii) After both solutions were warmed to 60°C, a cobalt salt solution was stirred into the alkaline soap solution little by little. As cobalt soap is almost insoluble in the solution, it precipitated immediately. The reaction must be carried out always below 60°C, because above this temperature the reaction products become somewhat bluish.

The color of soap in the solution was observed directly after the reaction and also after having been left in the solution for some time with or without stirring. The alkaline soap solution, which had at first shown a pink color due to phenolphthalein, became blue after the addition of a little of the cobalt salt solution because cobalt ion shows a blue color in ethanol. When the whole salt solution was added, the color of the solution faded generally, and pink soap precipitated.

(iv) The precipitates were filtered off by suction, washed by absolute ethanol to remove free fatty acid, and dried overnight in a vacuum desiccator over calcium chloride anhydrate at room temperature. The color of the soap was preserved during drying in this way. The dried soaps were pulverized by an agate mortar. Free fatty acid was extracted with acetone over anhydrous potassium carbonate in a Soxhlet extractor.

## Results and Discussion

As a preliminary experiment, the colors of cobalt soaps formed at various solvent ratios, based on volume, were observed in the solution without stirring.

In pure ethanol, the yield of cobalt soap was very little. As metathesis is an ionic reaction, it is natural that the reaction is suppressed in a solvent, in which degrees of ionization of reactants are low. A solution of cobalt chloride in pure ethanol is blue, and metathesis in this solvent proceeded in a blue solution. But the reaction product was not pure blue; it seemed dark blue at first, and became pale violet after being left in the solution.

In pure water, the product was pink, but when dried, it gained a tinge of blue. If the solvent ratio was lower than 1 : 1, the color of the formed soap was pink as in pure water. When the ratio exceeded 1 : 1, although the formed soap was also pink at the beginning, often small blue particles grew overnight within pink precipitates. Sometimes the whole soap turned blue in a short time, less than an

4) W. F. Whitmore and M. Lauro, *Ind. Eng. Chem.*, 22, 646 (1930).

hour. These color changes were most rapid at a solvent ratio somewhat higher than 1 : 1.

**Effect of Stirring.**—As stated above, sometimes blue soap grew in addition to pink soap in the solution when it was left without stirring. First, we examined the effect of stirring on this color change.

In a standard procedure with the solvent ratio 5 : 1, pink soap turned blue without stirring, even if very slowly, but the color changed in 1 hr. with stirring. If some blue soap powder, prepared previously, was added to the solution, the color change was completed in 15 min.

When the solution was kept at 60°C after reaction, the color did not change even after 1 hr., but if it was taken out from the water-bath and cooled by stirring, the color began to change immediately and turned perfectly blue in 25 min.

From these facts, it is concluded that the blue soap has grown from pink soap. The addition of some blue soap advances the color change remarkably, for added soap powder forms nuclei for color change. At 60°C spontaneous occurrences of nuclei are suppressed, and the color change is not observed. Below 60°C nuclei of blue soap would appear, but they grow so slowly without stirring, that the color change proceeds locally and heterogeneously, and as a result small blue particles appear within pink precipitates. Therefore, to change color completely, cooling the solution by stirring is absolutely necessary.

The bubbling of air into the solution did not alter the speed of color change. Closing the vessel and stirring by a magnetic stirrer also did not influence the effect. It is evident that oxidation is not a cause of color change.

**Effect of Solvent Ratio.**—Next we examined again the effect of the solvent ratio on the color change, but with stirring.

Stearic acid (2 g.) was dissolved in ethanol and/or water (250 ml.) and neutralized by 0.15 N potassium hydroxide in ethanol or water (about 50 ml.). The solution was mixed at 60°C with cobalt chloride in ethanol and/or water (50 ml.), with various solvent ratios, and cooled by stirring. The time needed to turn blue was observed. The results are shown in Table I.

In series I, with larger solvent ratios, the colors of the products seemed violet or pale blue from an early stage. They did not readily turn blue and contained some white powder of potassium soap. Below the ratio 6 : 1, pink soap was formed at the beginning and changed blue soon, as stated before.

In series II, which contained more water than series I, the speed of the color change became larger with the lower solvent ratio. Sometimes blue soap turned violet soon and became red overnight. The red cobalt stearates formed in these systems are completely different in appearance from pink soaps formed directly after the reaction. When dried, they can be pulverized very easily, in contrast to plastic pink soaps.

TABLE I. EFFECT OF THE SOLVENT RATIO ON THE COLOR OF COBALT SOAPS

| System | No. | Solvent ratio based on volume | Color of product |
|---|---|---|---|
| Series I | 1 | (pure ethanol) | Bluish precipit. in blue soln., mixed with white K soap. |
| | 2 | 30 : 1 | Pale violet, turned blue in 2.5 hr., mixed with K soap. |
| | 3 | 15 : 1 | Violet, turned blue in 60 min., mixed with K soap. |
| | 4 | 9 : 1 | Reddish, turned blue in 60 min. |
| | 5 | 6 : 1 | Pink, turned blue in 60 min. |
| Series II | 6 | 5 : 1 | Pink, turned blue in 30 min. |
| | 7 | 4 : 1 | Pink, turned blue in 15 min., violet in 60 min., red overnight. |
| | 8 | 3.3 : 1 | Pink, turned blue in 15 min., violet in 40 min., red overnight. |
| | 9 | 2.8 : 1 | Pink, turned blue in 30 min. |
| | 10 | 2.3 : 1 | Pink, turned blue in 25 min. |
| Series III | 11 | 2 : 1 | Pink, turned blue in 10 min., red overnight. |
| | 12 | 1.5 : 1 | Pink, turned blue in 5 min., red overnight. |
| | 13 | 1.3 : 1 | Pink, turned blue in 10 min., red overnight. |
| Series IV | 14 | 1 : 1 | Pink, turned red overnight. |
| | 15 | 1 : 1.5 | Pink, turned red overnight. |
| | 16 | 1 : 2 | Pink, turned red overnight. |
| | 17 | 1 : 3 | Red, without change. |
| | 18 | 1 : 5 | Red, without change. |

In series III, with the greater water content, the speed of the color change became very rapid, and at the solvent ratio of about 1.5 : 1, it was at a maximum. The products turned completely red overnight.

The last series, where the solvent ratio is lower than 1 : 1, was very different from the preceding series. In this series soaps did not change blue, however long stirred, but became red gradually. The systems which contained the most little amount of ethanol were red rather than pink from the outset. It was hard to dry them in vacuum, for they contained a large amount of water.

Together with the other results obtained, the following facts were confirmed:

(i) The color of the product is determined by the solvent ratio after mixing. The addition of either solvent to the solution after reaction did not affect the color.

(ii) If the resultant solvent ratio is the same, the compositions of the reactant solutions are indifferent to the color of the product.

(iii) The extent of excess of cobalt chloride over stearic acid and the order of mixing solutions did not significantly affect the color of the soap formed.

(iv) The speed of the color change from blue to red depends on the solvent ratio and the time of stirring. Blue soap always turned red if it was left in solution for long a time.

**Effect of Degree of Neutralization.**—In these experiments, the solution of stearic acid was exactly neutralized by an alkaline solution. Next we examined the effect of the degree of neutralization on the color change of cobalt soap.

At the solvent ratio 1 : 2, when exactly neutralized, the cobalt soap did not change blue, though it later became red. If the amount of added alkaline solution was varied between 60 and 140% of the equivalent, different effects were observed. When the system was insufficiently neutralized, the products became red sooner and contained much free fatty acid. When the added alkali was more deficient, the color change became slower. However, when an excess of alkali was added to the system, the product became violet. When there is a large excess of alkali, the reaction would not readily proceed because, as will be discussed in the next part, the cobalt soap may be decomposed to free acid by the presence of much alkali.

At the solvent ratio 2 : 1, when exactly neutralized, the formed pink soap soon became blue with stirring and later turned red in the solution. But when alkali was added in excess, a color change from pink to blue was not observed and the soap turned red at last. On the contrary, when alkali was insufficient, the speed of becoming blue was more rapid. When the degree of neutralization was lower, the color change became quicker, although the yield was smaller.

As well as adding insufficient alkali to the fatty acid solution, the addition of hydrochloric acid to the cobalt chloride solution had the same effect on color change. But after the forming of the pink soap, the addition of hydrochloric acid was not effective.

From these results it is concluded that the solution must be acidic at mixing for realizing the color change.

**Effect of Using Other Solvents than Ethanol.**—Throughout the preceding experiments, the solvent was a mixture of ethanol and water. Next we used acetone and methanol in place of ethanol. Any solvent which dissolves fatty acid may be used, but when the solvent does not mix with water, as the petroleum ether used by Kaufmann and Lüssling[1], the procedure becomes somewhat difficult. With methanol or acetone, metathesis could be carried out as with ethanol. In particular, when the solvent ratio was lower than 1 : 1, only pink soaps were formed. With these solvents, even if the solvent ratio was higher than 1 : 1, the blue soap could not be obtained. But when acetone was used, the formed soap became red quickly.

**Effect of Using Other Cobalt Salts than Chloride.**—Instead of cobalt chloride we tried to use other cobalt salts. Cobalt nitrate and sulfate may be used in the same way as chloride. But cobalt acetate showed somewhat different effects.

Cobalt acetate may react directly with stearic acid in aqueous ethanol. In this substitution reaction, when the solvent ratio is 2 : 1, the color changed blue and subsequently turned red. But at the ratio 1 : 2, the color did not change at all.

The color change was suppressed markedly by the addition of alkali. If the fatty acid was exactly neutralized, that is, in metathesis, the formed pink soap did not change blue in any solvent ratio.

At the solvent ratio 2 : 1, pink soap made by metathesis turned blue in 60 min. with cobalt chloride, in 30 min. with cobalt nitrate, in 20 min. with cobalt sulfate, and never with cobalt acetate.

In a substitution reaction with cobalt acetate, the addition of alkali suppressed markedly the color change to blue. The substitution reaction could be carried out between cobalt acetate and stearic acid with acetone in place of ethanol.

However, when acetone was used, with the solvent ratio 2 : 1, pink soap turned blue, even if very slowly, but perfectly blue soap was not obtained.

**Effect of Using Other Fatty Acids than Stearic Acid.**—Other cobalt soaps may be prepared by metathesis in the same way as stearate. In place of stearic acid, palmitic, myristic, and lauric acid were used.

These reactions proceeded just the same way as with stearate. The color changes were also observed, but the speed of color change from pink to blue becomes slower, as the chain length of fatty acid decreases. The laurate could not turn blue under the same conditions.

The time for turning blue with the solvent ratio is tabulated in Table II. These reactions were obtained by stirring the solutions at 45°C for 1 hr. and later leaving them in the solution without stirring. The solutions were slightly acidic.

Table II. Time for turning blue of pink cobalt soaps

| Solvent ratio | 4 : 1 | 1.5 : 1 | 1 : 1.5 | 1 : 4 |
|---|---|---|---|---|
| Cobalt stearate | 15 min. | 10 min. | — | — |
| Cobalt palmitate | 2 days | 1~2 hr. | — | — |
| Cobalt myristate | 4~5 days | 1 day | — | — |
| Cobalt laurate | — | — | — | — |

— Did not become blue.

## Summary

As a method of preparation of cobalt soap, metathesis between alkaline soap and cobalt salt was investigated.

Cobalt stearate, palmitate and myristate were obtained in pink, blue and red forms according to conditions. Cobalt laurate in blue form was not observed.

Metathetic products were always pink at the beginning. If the system has a solvent ratio (solvent to water) higher than 1 : 1, and the solution after mixing is acidic, the color of soap will turn blue with stirring. It will change red later when left in the solution. The blue form could not be obtained with acetone or methanol as a solvent.

The speed of the color change became considerably slower with fatty acid of a shorter chain length.

In substitution reaction between stearic acid and cobalt acetate with a solvent ratio higher than 1 : 1, the same color changes were observed. But in this system the addition of some alkali suppressed markedly the color change, and at an exactly neutralized metathetic reaction the soap did not turn blue. Even in this case, when acetone was used instead of ethanol, the color change was observed, but the speed was very slow.

The author expresses his gratitude to Professor Bunnosuke Yamaguchi for his advice throughout this work and to Messrs. Itaru Mita, Hirokazu Watanabe and Hiroshi Kayano for their assistance in experiments.

# *Physicochemical Studies on Cobalt Salts of Higher Fatty Acids. II. Compositions of Cobalt Soaps*

By Hirotaro KAMBE*

(Received February 27, 1961)

Cobalt soap is generally a neutral salt between a bivalent cobalt cation and two univalent fatty acid anions. For example, the composition of cobalt stearate is ideally expressed by $Co(C_{17}H_{35}COO)_2$.

Oudemans[1] and Caspari[2] have pointed out that cobalt laurate is monohydrate. Kaufmann and Lüssling[3] found that while, under some conditions, cobalt oleate was obtained as an acidic salt, $Co(C_{17}H_{35}COO)_2 \cdot (C_{17}H_{35}COO)_2$, cobalt stearate was a neutral salt.

In the previous part of these studies[4], it was found that cobalt soaps obtained by metathesis in aqueous ethanol showed three different colors, that is, pink, blue and red.

* Present address: Aeronautical Research Institute, the University of Tokyo, Meguro-ku, Tokyo.

4) H. Kambe, This Bulletin, **34**, 1786 (1961).

In the present part they will be analyzed. As a result, it will be ascertained that different colors are principally due to the difference of hydration of the cobalt soap.

## Experimental

**Materials.**—Cobalt soaps are cobalt stearates, described in the previous paper[4]. Several specimens of each typical color were chosen from among many samples.

**Analyses.**—*Free Fatty Acid.*—Free fatty acid was extracted from soaps by the use of acetone for 1 hr. with a Soxhlet extractor. The color of the soaps was not altered by extraction. Acetone was dehydrated by anhydrous potassium carbonate. A glass cylinder was inserted around a cylindrical filter paper in order to improve the circulation of the solvent[5]. The amount of free acid was determined by evaporating the solution. The residue was dissolved in ethanol, and the solution was titrated by a standard alkaline solution.

*Combined Fatty Acid.*—Cobalt soaps were decomposed by boiling with 0.1 N sulfuric acid. Isolated fatty acid and unreacted soap melted and floated in a mass on the surface of the solution. The decomposition was continued until the molten mass became wholly colorless.

Cobalt soap can be decomposed also by a 0.1 N alkaline solution. This method was not adequate here, however, because the solution foamed so much, that it was feared that unreacted soap might overflow the vessel.

The solution was cooled, and the seperated fatty acid was filtered off. The filtrate obtained in this process was used for determining the content of the cobalt. Fatty acid was dried on filter paper, dissolved in hot ethanol, and titrated by a standard alkaline solution.

*Cobalt.*—The amount of cobalt was determined by several methods. (i) Soaps were burnt to ashes, which were weighed as $Co_3O_4$. (ii) Cobalt was precipitated from the solution as a complex salt by $\alpha$-nitroso-$\beta$-naphthol. (iii) Cobalt was deposited on a platinum electrode electrolytically. (iv) The cobalt solution was titrated by an EDTA solution.

*Burning Method.*—Cobalt soap was heated in a porcelain crucible by a Bunsen burner. Stearic acid was carbonized at first, and then the whole mass was ignited and completely oxidized by strong heating. The residue was weighed as $Co_3O_4$.

*$\alpha$-Nitroso-$\beta$-naphthol Method.*—By adding an excess of hydrogen peroxide to the acidic solution of cobalt, cobalt ions were oxidized from bivalent to tervalent. The black cobaltic hydroxide precipitated from the solution by the addition of a sodium hydroxide solution. The precipitate was dissolved again by glacial acetic acid, and the dark brown solution obtained was diluted with some warm water and mixed with the solution of $\alpha$-nitroso-$\beta$-naphthol in acetic acid. The reddish brown precipitate was filtered off, dried at 130°C, and weighed as $(C_{10}H_6ONO)_3Co$.

*Electrodeposition Method.*—Cobalt stearate (0.1 g.) was decomposed by 0.1 N sulfuric acid (20 ml.), and the separated fatty acid was filtered off. The filtrate was concentrated to 10 ml., ammonium sulfate (0.5 g.) was added, and the solution was made alkaline with 0.1 N ammonia solution (40 ml.), and sodium bisulfate (0.02 g.) was added. With platinum plates as electrodes, the golden solution was electrolyzed with a current 0.2 amp. and 3.5 V. at 60°C for 8 hr. The cobalt metal deposited on the cathode was weighed after drying in an air-oven at 110°C.

*EDTA Titration.*—Cobalt soap (30 mg.) was decomposed by 0.3 N hydrochloric acid (20 ml.). The fatty acid was solidified to a mass. The solution was diluted to 70 ml. by water, murexide (ammonium purpurate) was added as an indicator[6], and the solution was neutralized by 1 N ammonia solution in some excess. The yellow solution was titrated by 0.01 M EDTA (disodium ethylenediamine tetraacetate), until the color of the solution became pink. The concentration of EDTA solution was calibrated by a standard cuprous nitrate solution.

*Water of Hydration.*—Cobalt soaps had been dried in a vacuum at room temperature. Pink species gained a tinge of blue, but other soaps did not change their colors substantially in this process. Their colors did not change during storage in an ambient atmosphere.

Inorganic cobalt salts contain some water of hydration, some of which could not be removed in the vacuum. It is possible for cobalt soaps to have such a tightly combined water of hydration. The water content was determined (i) by a Karl-Fischer reagent and (ii) by weighing after heating in a vacuum.

*Karl-Fischer Titration.*—From among the several methods of this technique, the inverse dead-stop method with "magic eye" titrometer was carried out[7]. The titration vessel was equipped with a draining cock, as proposed by Campbell[8].

The standard methanol used was an extra pure reagent, made by Takeda Chemicals Co., the water content of which was about 0.5% by volume. The Karl-Fischer reagent was prepared as usual[9] and calibrated by sodium acetate trihydrate.

The cobalt soaps did not dissolve, but were well dispersed in mixtures of methanol and pyridine, which were basic solvents of the reagent. However, because the soap was powder, it was difficult to place it in titration vessel. This was the main origin of errors.

*Dehydration in Vacuum at Heating.*—The decrease of weights was measured by a quartz spring balance in an evacuated glass tube at $10^{-3}$ mmHg. An electric furnace was used to heat the soap up to 150°C. The sensitivity of the quartz balance was 7.54 cm./g., and its accuracy was 0.2 mg. in weight. A sample of 0.1 g. was usually taken for measurements.

## Results and Discussion

**Free Fatty Acid.**—The amounts of free fatty acid in several samples of each species of cobalt stearate were measured. The average values are shown in Table I. The amount of free acid was relatively little. It was most in pink, but very little in red, soap. The following analyses were carried out with samples, the free acid of which had been completely extracted.

Table I. Free fatty acid contents in cobalt stearates

| | |
|---|---|
| Pink | 4.14 % |
| Blue | 2.36 % |
| Red | 0.70 % |

**Compositions.**—Several analyses of each species of cobalt stearate were executed by various methods. These results are tabulated together in Table II. Although the values were scattered in some ranges, the average values of each method and their mean are shown.

Theoretical compositions calculated from several possible formulas of cobalt stearate are shown in Table III. In comparing Table II with Table III, it is certain that three forms of cobalt stearate are neither basic nor acidic salt.

The blue form corresponds to anhydrous neutral soap, for it shows no water content. The red form must be dihydrate, judging from the content of hydration water. The observed

TABLE III. CALCULATED COMPOSITIONS OF COBALT STEARATES

| | Cobalt, % | Stearic acid, % | Water, % |
|---|---|---|---|
| Neutral salts, $(C_{17}H_{35}COO)_2Co$ | 9.42 | 90.58 | — |
| Monohydrate, $(C_{17}H_{35}COO)_2Co \cdot H_2O$ | 9.15 | 88.05 | 2.80 |
| Dihydrate, $(C_{17}H_{35}COO)_2Co \cdot 2H_2O$ | 8.90 | 85.64 | 5.46 |
| Basic salt, $(C_{17}H_{35}COO)Co(OH)$ | 16.40 | 83.60 | — |
| Acidic salt, $(C_{17}H_{35}COO)_2Co(C_{17}H_{35}COOH)$ | 6.47 | 93.53 | — |

contents of cobalt of these soaps were somewhat larger than the calculated values, for some of the combined fatty acid might be hydrolyzed and removed during the extraction by acetone.

The pink form shows a composition nearer to red dihydrate than to blue anhydrate. Experimental values are particularly scattered in this species. As the pink soap is an incipient product in metathesis, it may be natural that its composition is somewhat indefinite.

**Mechanism of Color Change.**—From these results, it has been ascertained that the difference of color is due to the degree of hydration of these soaps. In the previous paper[4], it was found that under some conditions the pink soap thus formed soon turned blue and then red later in solution. This corresponds with the change of the amount of water of hydration, which first decreases and then increases again. This process seems very strange, but the following interpretation may be proposed.

The alkaline soap in aqueous ethanol takes the form of micelles, in which lyophilic ionic groups of soap molecules exist in the outer layer against solvent molecules. Ionic groups dissociate in different degrees, according to the solvent ratio in solution. When the cobalt ions are added, dissociated soap ions in the outer lyophilic layer react with cobalt ions immediately. Therefore, in the incipiently formed pink soap there remains the original micelle structure of alkaline soap, as will be discussed in the later part of these studies.

With the existence of sufficient alkali, cobalt soap turns gradually to red dihydrate, which is the most stable form in these solvents. When the alkali is insufficient, the dissociation of alkaline soap is greatly suppressed, and therefore the ionic reactions proceed limitedly. In these circumstances the yield of cobalt soap is little, and much free acid exists in the formed soap.

When the solvent ratio is higher than 1 : 1, the solvent becomes somewhat oleophilic and the formed pink soap turns blue, perhaps by an inversion of the micelle structure. In this case some of the lyophobic hydrocarbon chains appear outside. As the soap becomes less lyophilic in this system, blue crystals tend to rise to the surface of the solution.

In the following time, water molecules gradually penetrate into the interior of the micelles of blue soap and adhere to the hydrophilic cobalt ions as waters of hydration. As the penetration of water is difficult through such a thick layer of hydrocarbon chains, the change of color from blue to red generally occurs slowly.

## Summary

Pink, blue and red cobalt stearates were analyzed and their compositions were determined. From these results, it has been confirmed that blue soap is anhydrate and red soap is dihydrate. The pink soap has a rather indefinite composition nearer to red soap. A mechanism of the color changes was proposed based on the inversion of the micelle structure under some circumstances.

The author expresses his gratitude to Professor Bunnosuke Yamaguchi for his kind advice throughout this work. He is also indebted to Mr. Itaru Mita for his executions of EDTA titrations, and to Messrs. Hirokazu Watanabe, Satoshi Ayano and Takeo Ozawa for their assistance on experiments.

# *Physicochemical Studies on Cobalt Salts of Higher Fatty Acids. III. Spectrophotometric Specifications of Colors of Cobalt Soaps*

By Hirotaro KAMBE

(Received February 28, 1961)

Cobalt soaps of higher saturated fatty acids have been described generally as pink crystals. Recently Herron and Pink[1] described rose-pink cobalt laurate dihydrate and purple anhydrate, which was obtained by the dehydration of pink soap in boiling organic solvents.

In a previous paper of this series[2], three species of cobalt soap of different colors were obtained by metathesis in aqueous ethanol under some conditions. From results of analyses, it was ascertained that blue soap is anhydrate, red soap is dihydrate, and pink soap has a degree of hydration near to that of dihydrate[3].

In the present paper, the colors of these soaps will be specified by spectrophotometry. Reflection spectra and a chromaticity diagram of these colors will be shown. Relations of these colors with each other will also be discussed.

## Experimental

**Materials.**—The same samples of cobalt stearates were used as for the previous papers[2,3].

**Reflection Spectra.**—Reflection spectra of soaps were measured with a Shimadzu QR-50 quartz spectrophotometer, to which an integrating sphere was attached. Reflection coefficients expressed in percentages were plotted against wavelengths between 350 and 700 m$\mu$ to get reflection curves.

**Graphical Representation of Chromaticity.**—Reflection curves were analyzed by a method proposed by the International Commission on Illumination (I. C. I.)[4]. Tristimulus values, $X$, $Y$ and $Z$, were determined from reflection curves by graphical integrations with the thirty-selected-ordinate method[4].

$$X=0.03268\sum R_x(\lambda_n) \qquad Y=0.03333\sum R_y(\lambda_n)$$
$$Z=0.03938\sum R_z(\lambda_n) \qquad (1)$$

where $R(\lambda_n)$'s are reflection coefficients of the sample at selected wavelengths (Table I).

Trichromatic coefficients, $x$, $y$ and $z$ were calculated by the formulas

$$x=\frac{X}{X+Y+Z} \qquad y=\frac{Y}{X+Y+Z}$$

and brightnesses are also tabulated in Table II.

The dominant wavelengths $\lambda_d$ of each spectrum are shown with dotted lines. In color language, blue and red soaps must be called violet and magenta respectively.

Pink soaps (Fig. 1) show a broad absorption band with a maximum at 530~540 mμ. The dominant wavelength of pink soaps varies within a wide range, from pure pink at 520c mμ to bluish pink at 565c mμ, but it does not essentially differ from that of red soaps. Pink soaps have smaller purities and larger brightnesses than red soaps.

Blue anhydrates (Fig. 2) show a large absorption band with a broad maximum at 580~590 m$\mu$, and a shallow but sharp absorption band at 400 m$\mu$. The blue color of this species originates from a large reflection at shorter wavelengths.

Red dihydrates (Fig. 3) show a deep but relatively sharp absorption band at 540~550 m$\mu$. Sometimes the spectra of blue soaps have a small shoulder at a corresponding position, arising from the red soap also present.

When blue soap was taken out of the solution at a half-turned-red state, purple soap was obtained. Pink and red soaps also became purple when they were immersed in pure ethanol for a long time. These samples are shown in Figs. 4 and 5, and their trichromatic coefficients are tabulated in Table III.

Purple soaps have dominant wavelengths between those of pink and blue soaps. Purple soaps obtained from blue soap have relatively larger purities. In these samples the dominant wavelength seems to change abruptly from 564c m$\mu$ to 410 m$\mu$, but it is clear from the chromaticity diagram (Fig. 4) that these dominant wavelengths are continuous. The main origin of purple color changes in this range, however, from an absorption band at 560 m$\mu$ to a reflection band at 400 m$\mu$.

In this way, it is established that among cobalt soaps of different colors, red and pink soaps are the same in nature, although their colors differ in purity and brightness, and that blue soap continues to pink or red soap through purple soaps.

Cobalt stearate may be formed by metathesis in aqueous methanol instead of ethanol[2], but the color of the soaps thus formed is pale pink. Their reflection curves are very flat, with a maximum at about 500 m$\mu$, as shown in Fig. 6 and in Table III. It is characteristic for them that their purities are small and

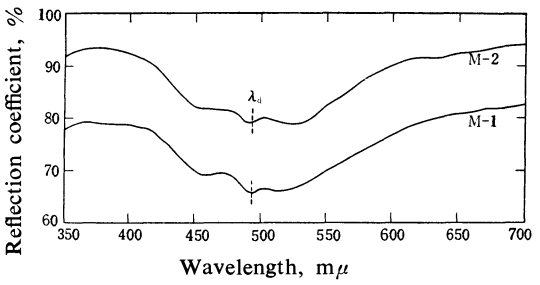

Fig. 6. Reflection curves of cobalt stearates obtained in aqueous methanol.

their brightnesses are large, and their maximum absorption occurs at a shorter wavelength.

## Summary

The colors of three species of cobalt stearates were specified by I. C. I. chromaticity coefficients. Reflection spectra have been compared with each other, and it has been found that these colors are continuous in nature.

Pink soaps have dominant wavelengths in a wide range from 520c~555c mμ and show small purities and large brightnesses. Red soaps have essentially the same dominant wavelengths as that of pink soaps at 530c~540c mμ, but they show comparatively large purities and small brightnesses, because they are darker than pink soaps. They must be called magenta in color language.

Blue soaps must be called violet rigorously, for they show dominant wavelengths at about 450 mμ. They have larger purities and smaller brightnesses. Between blue and pink, many tones of color from violet to purple exist continuously. It is certain that these colors are related to each other.

The pale pink cobalt stearates obtained in aqueous methanol were specified in the same way.

The author expresses his gratitude to Professor Bunnosuke Yamaguchi, for his advice throughout this work. He is also indebted to Messrs. Hiroshi Kayano and Teijiro Mizuno for their assistance in spectrophotometry.

# *Physicochemical Studies on Cobalt Salts of Higher Fatty Acids. IV. Ionic Nature of Cobalt Soaps, Revealed in Infrared Absorption Spectra and Magnetic Susceptibilities*

By Hirotaro KAMBE* and Itaru MITA*

(Received March 11, 1961)

In the previous papers of these studies[1-3], three forms of cobalt soap with different colors —in other words, with different degrees of hydration—were found. As they are salts of fatty acid, they must be composed of cobalt and fatty acid ions.

In the present paper, their infrared absorption spectra and magnetic susceptibilities are measured. It is concluded that as the infrared absorption bands of carboxylate ion are found, these soaps are essentially ionic in nature. Magnetic moments of cobalt ion in these soaps, calculated from magnetic susceptibilities, support this conclusion.

Infrared spectra of cobalt salts of normal fatty acids, from formic to stearic acid, were observed by Duval, Lecomte, and Douvillé[4]. They confirmed that the carboxylic groups in these salts are essentially ionic in nature.

Herron and Pink[5] measured the magnetic susceptibilities of cobalt stearate and laurate, and of cobalt laurate dihydrate. The magnetic moments of cobalt ions in these soaps were given as $\mu_{eff}=5.00$, 5.06 and 5.07 BM respectively. Moreau and Vatteroni[6] measured the magnetic susceptibilities of the cobalt salts of fatty acids with carbon numbers between 1

and 18. They have found that the susceptibilities of cobalt salts of higher fatty acids are somewhat larger than that of inorganic cobalt sulfate.

The experimental results obtained in the present paper will be discussed in comparison with these investigations.

## Experimental

**Materials.**—Cobalt stearate, palmitate, and myristate, of each typical color, obtained in the previous paper[1] were used as samples. Stearic acid, sodium stearate, and cobalt hydroxide, which had been purified as usual, were used references to the infrared investigations.

**Infrared Absorption Spectra.**—Infrared absorption spectra were measured chiefly with a Perkin Elmer Model 112 single beam spectrophotometer, using a sodium chloride or calcium fluoride prism. Some samples were measured also with a Perkin Elmer Model 12B double beam spectrophotometer at the Laboratories of Mitsubishi Kasei Co*2.

As cobalt soaps are generally insoluble in common solvents, powdered samples were used in the form of potassium bromide disks, or mulls in Nujol or in hexachlorobutadiene (HCB).

The potassium bromide disk method was used mainly in the range of wave number below 1700 $cm^{-1}$. The sample soaps and potassium bromide were carefully dried and pulverized to pass through a sieve of 200~250 meshes per inch. A small percentage was mixed with potassium bromide powder and pressed at 10,000 $kg./cm^2$ to form a disk.

Above 2700 $cm^{-1}$, the Nujol mull or HCB mull method was used exclusively. Mulls were placed between rock salt plates. Nujol shows strong absorptions of C-H bond, which overlap C-H absorptions of the soap. Although HCB is so volatile that it is difficult to make mulls with it, it was chiefly used in the range of 2700~4000 $cm^{-1}$, for it shows no absorption above 1700 $cm^{-1}$.

**Magnetic Constants.**—The magnetic susceptibility $\chi_H$ of cobalt soap, mixed with zinc oxide, was measured by Gouy's method*3. $\chi_H$ was corrected for ferromagnetic imprities by plotting susceptibilities against reciprocal field strength. Extrapolation to infinite field strength gives $\chi_\infty$, which is substantially free from ferromagnetic effects.

As the specific susceptibility of zinc oxide, $\chi_{ZnO}$, had been given as $-0.26\times10^{-6}$ c. g. s., the specific susceptibility of soap, $\chi$, was determined by the following formula:

$$\chi_\infty=\frac{w}{100}\chi+\frac{100-w}{100}\chi_{ZnO} \qquad (1)$$

in which $w$ is the concentration of soap in per cent by weight. Molar susceptibility is calculated by a formula:

$$\chi_M=M\cdot\chi \qquad (2)$$

in which $M$ is the molecular weight of soap.

The diamagnetic component of susceptibility, $\sum\chi_{dia}$, was corrected by a formula

$$\chi_M=\chi_{para}+\sum\chi_{dia} \qquad (3)$$

The diamagnetic susceptibilities of the constituents of which are shown in Table I.

The magnetic moments in Bohr magneton (BM) were calculated by a formula:

$$\mu_{eff}=2.839\sqrt{\chi_{para}\cdot T} \quad (BM) \qquad (4)$$

TABLE I. SPECIFIC DIAMAGNETIC SUSCEPTIBILITIES, $-\chi_{dia}\cdot10^6$ (c.g.s./g.)

| | |
|---|---|
| Stearate ion | 209* |
| Hydration water | 13[7] |
| Cobalt(II) ion | 12[8] |

* This value was found in magnesium, zinc and cadmium stearates[7].

## Results and Discussion

**Infrared Absorption Spectra.**—The wave numbers of the absorption maxima in the infrared spectra of cobalt soaps are assigned and tabulated in Tables II and III.

*Absorptions by Hydrocarbon Chain.* — Among species of the same color, the chain length of fatty acid did not significantly influence the spectrum. Band progression at 1200~1300 $cm^{-1}$, due to hydrocarbon chain, depends to some extent upon the length of the chain, but the absorption bands of cobalt soaps are weaker than that of stearic acid.

The absorption bands of C-H stretching vibrations, i. e. the out-of-phase vibration of $CH_2$ at 2865, the in-phase one at 2935, and the asymmetrical vibration of $CH_3$ at 2970 $cm^{-1}$, and the bands of symmetrical bending of $CH_2$ at 1465 $cm^{-1}$ were always observed in all soaps, without distinction of color. The symmetrical bending vibration band of $CH_3$ at 1375 $cm^{-1}$ was found in red soaps, but in other soaps it was not readily indentified.

*Absorptions by Carboxylate Ion.* — Absorption spectra in the range of 1250~1800 $cm^{-1}$ are shown in Figs. 1—3.

It is well known that in free fatty acid carboxyl groups of two molecules are donded by hydrogen bonds to take a dimeric form. The absorption of a carboxyl group in this state reveals its C=O stretching vibration band near 1700 $cm^{-1}$ (cf. Table III). In cobalt soaps, two absorption bands of carboxyl group were found at 1400 and 1550 $cm^{-1}$, instead of one band at 1700 $cm^{-1}$. They correspond to the symmetric and antisymmetric stretching vibrations of carboxylate ion, $-\left[C\begin{matrix}O\\O\end{matrix}\right]^-$, as

*2 With the latter instrument, measurements were executed by Mr. S. Morita.

pointed out by Duval, Lecompte and Douvillé[4]. Their conclusion was based on the deformation vibration modes of carboxylate ions, appearing at lower frequency range than ours. Their results were stated to be uncertain at a higher frequency range owing to the insufficient resolving power of their instrument.

From this result it has been concluded definitely that all cobalt soaps obtained in our experiments are ionic in nature. As a reference, spectra of free stearic acid and sodium stearate are shown in Table III. Stearic acid distinctly shows a stretching vibration of C=O at 1700

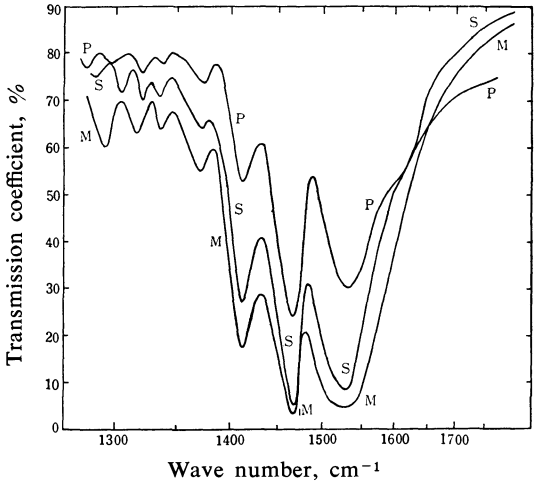

Fig. 3. Infrared absorption spectra of red cobalt soaps.

$cm^{-1}$, while no band was found at 1550 $cm^{-1}$ corresponding to the antisymmetric vibration of carboxylate ion. In place of the symmetric stretching band of carboxylate ion at 1400 $cm^{-1}$, there appeared the C–O stretching band and O–H in-plane deformation band of $-C\begin{matrix}O\\OH\end{matrix}$. Naturally, the OH stretching band at 2650 $cm^{-1}$ and the OH out-of-plane deformation band at 940 $cm^{-1}$ appeared in the spectrum of stearic acid.

Sodium stearate shows carboxylate bands at 1424 and 1560 $cm^{-1}$ and an absorption by the asymmetrical bending of $CH_3$ at 1445 $cm^{-1}$, which appears in pink soaps, exclusively. This may indicate the similarity between sodium soap and pink cobalt stearate.

*Absorptions by Hydroxyl Bond.* — In spectra of cobalt soaps with different colors of the same fatty acid, several differences were found.

In red and pink soaps, absorptions by stretching vibration of OH bonds appeared in the 3200~3400 $cm^{-1}$ region, but in blue soaps they were completely lacking. This is in accordance with the results of analyses of water content[2]. In pink soaps, a broad peak reveals itself at 3300 $cm^{-1}$, but in red soap, two peaks appear at 3260 and 3400 $cm^{-1}$.

The hydroxyl bond of cobalt hydroxide shows a very sharp band of free OH vibration at 3640 $cm^{-1}$, which does not exist in the spectrum of every soap. Liquid water shows a peak of hydrogen-bonded OH at 3410 $cm^{-1}$. In comparison with these data, water molecules in cobalt soaps were attached to cobalt ion with stronger bonds than hydrogen-bonds in

* Figgis and Nyholm[9] proposed originally this configuration, but considered later that this improbable.

free water. Therefore, it was concluded that water in cobalt soaps exists as hydration water.

**Magnetic Susceptibilities.** — Observed values of magnetic susceptibilities and magnetic moments, calculated as stated above, of red and blue cobalt stearates are shown in Table IV.

Figgis and Nyholm[9] have shown that, according to magnetic moment, cobalt(II) compounds may be classified into two types, that is, the spin-free or ionic covalent type and the spin-paired covalent type, as shown in Table V. The number of unpaired electrons, $n$, in these configurations is three and one. Therefore, the spin only value of magnetic moment, $\mu_{eff}=\sqrt{n(n+2)}$, is 3.88 and 1.73 BM, respectively. The observed values of many complexes of each type were 4.2～5.6 BM in the spin-free type, and 1.7～2.9 BM in the spin-paired type, as shown in Table V.

On the basis of these facts it has been concluded that the cobalt soaps used in the present paper were spin-free or ionic covalent complexes. This conclusion is completely consistent with the results of infrared absorption measurements.

Observed values of magnetic moments of cobalt(II) complexes are generally larger than spin only values, for the contribution of the orbital motion of electrons was not completely quenched in them owing to the presence of ligand fields and spin-orbit couping. Among ionic covalent complexes, the orbital contribution is smaller in tetrahedral $sp^3$ orbitals than in octahedral $sp^3d^2$ orbitals. This is based on the difference of multiplicities of ground states in these configurations[10].

Although our values are somewhat smaller than that of Figgis and Nyholm, blue and red cobalt soaps must correspond to the $(4s)(4p)^3$ tetrahedral four-covalent complex and the $(4s)(4p)^3(4d)^2$ octahedral six-covalent complex respectively. Holm and Cotton[10] have proposed the $(4s)(4p)^2(4d)$ square planar, ionic covalent type for some cobalt(II) complexes, but this configuration may be excluded from our cases by considerations of color.

The magnetic moments of rose-pink cobalt laurate dihydrate and purple anhydrate of cobalt stearate and laurate obtained by Herron and Pink[5] were larger than our values, as has been shown before. In contrast with our results, they found no difference in magnetic moments between anhydrate and dihydrate of cobalt laurate. As their purple anhydrate was prepared by boiling rose-pink dihydrate with solvent, it might be a glassy form recovered from a molten state. In our experiments, which will be discussed in a later part of these studies, a once-melted soap showed a somewhat larger magnetic moment than a true blue form. The orbital contribution is so much affected by a crystal field[10] that the melted form must have a different contribution of orbital motion to the magnetic moment.

Moreau and Vatteroni[6] compared the magnetic susceptibilities of cobalt soaps with that of cobalt sulfate and found that the values of cobalt soaps were somewhat larger than inorganic salt. They concluded that these soaps were regarded as structure complexes. This is also consistent with our results.

**Structure Formulas of Cobalt Soaps.**—From these results, it may be concluded that red dihydrate and blue anhydrate of cobalt stearate have a geometry of octahedral and tetrahedral coordination complex respectively. The structure formulas of these soaps may be described as shown in Fig. 4, following Herron and Pink[5]. Such a formula was proposed for cupric salts of lower fatty acids by French and Lowry[11] and opposed by Sidgwick[12]. Sidgwick's main reason for rejecting this formula was that the strain in the chelate ring of four members makes them exceedingly unstable. The alternative formula, in which the carboxyl group occupies two coordination positions attaching themselves to two different cobalt ions, so as to form a ring of more than four members, must be proposed. This was done in cupric soaps[5], but not yet for cobalt soaps.

## Summary

The infrared absorption spectra and the magnetic susceptibilities of red dihydrate and blue anhydrate of cobalt stearate were measured. The infrared spectra showed the existence of carboxylate ion in these soaps, and magnetic measurements confirmed that they are ionic in nature.

The magnetic moments of red and blue cobalt stearates showed that they are spin-free or ionic covalent complexes. The geometry of red soap is six-covalent octahedral, and that of blue is four-covalent tetrahedral. Structure formulas were proposed for them in correspondence with these geometries, but they may be improbable because of the existence of unstable rings of four members. Alternative formulas, in which a carboxyl group joins two cobalt ions, might be considered but have not yet been given.

The authors express their gratitude to Professor Bunnosuke Yamaguchi for his advice throughout this work, and to Dr. Yoshio Matsunaga and Mr. Shiro Morita for their accomplishments in magnetic and some infrared absorption measurements.

# *Statistical Thermodynamics of Solutions of Optically Active Substances. II. Solubility of d- and l-Isomers in Optically Active Solvents*

By Kazuo AMAYA

(Received March 1, 1961)

It is expected theoretically that when *d*- and *l*-optical isomers are independently dissolved in an optically active liquid, the solubilities of *d*- and *l*-isomers may be different. To elucidate the special feature of this problem, the theoretical expression for the solubilities of *d*- and *l*-optical isomers is based on the model described in a previous paper[1]. Further a possibility of optical resolution is discussed.

## Theory

Let us consider two kinds of systems, the one of which contains optically active liquid substance A and *l*-isomer of optically active molecule B (which is denoted by $B_l$) and the other contains A and *d*-isomer of optically active molecule B (which is denoted by $B_d$). For simplicity it is assumed that the two components are completely immiscible in the solid state and completely miscible in the liquid state.

The chemical potential of $B_l$ molecule in crystal $\mu^{K}_{B_l}$ is a function of absolute temperature, $T$, alone while the chemical potential of the same molecule in solution $\mu^{S}_{B_l}$ is a function of, $T$, mole fraction of $B_l$, $x_{B_l}$, and interaction parameter between A and $B_l$ molecules, $\omega_{AB_l}$. For a saturated solution of $B_l$ in A the chemical potential of $B_l$ is equal to that in the crystal, then it follows that

$$\mu^{K}_{B_l}(T) = \mu^{S}_{B_l}(T, x_{B_l}, \omega_{AB_l}) \quad (1)$$

In a similar way for a saturated solution of $B_d$ in the following expression is obtained

$$\mu^{K}_{B_d}(T) = \mu^{S}_{B_d}(T, x_{B_d}, \omega_{AB_d}) \quad (2)$$

where $\mu^{K}_{B_d}$ and $\mu^{S}_{B_d}$ are the chemical potentials of $B_d$ molecule in the crystal and in the saturated solution respectively, and $x_{B_d}$ is the mole fraction of $B_d$ in the solution and $\omega_{AB_d}$ is an interaction parameter between A and $B_d$ molecules.

As $B_l$ and $B_d$ molecules are mirror images for each other, the chemical potential of $B_l$ molecule is equal to that of $B_d$ molecule in the crystal at the same temperature. Then it follows from 1 and 2 that

$$\mu^{K}_{B_l}(T) = \mu^{K}_{B_d}(T) = \mu^{S}_{B_l}(T, x_{B_l}, \omega_{AB_l}) = \mu^{S}_{B_d}(T, x_{B_d}, \omega_{AB_d}) \quad (3)$$

Since $\omega_{AB_l}$ and $\omega_{AB_d}$ have different values, $x_{B_l}$ and $x_{B_d}$ in each saturated solution have different values. It means that the solubility of $B_d$ and $B_l$ optical isomers differ from each other. In the following, explicit expressions for $\mu^{S}_{B_l}$ and $\mu^{S}_{B_d}$ will be derived. In deriving the theoretical expressions, the following assumptions are made:

(1) Molecule A, $B_l$ and $B_d$ are equal in size and each occupies a site of quasi-crystalline lattice and has $3z$ orientational freedoms.

(2) Molecule A is covered by $z$ planes, one of which is composed of *a* element, and the others $(z-1)$ are composed of *b* elements. The *a* element is composed of three subelements 1, 2 and 3 and their arrangement is in the order 1, 2, 3 clockwise viewed from outside of the molecule.

(3) Molecule B (both $B_l$ and $B_d$) is also covered by $z$ planes, one of which is composed of $a'$ element and the others $(z-1)$ are composed of $b'$ elements. $a'$ element is composed of three subelements $1'$, $2'$ and $3'$ and their arrangement is in the order $1'$, $2'$, $3'$ clockwise for $B_l$ molecule and $1'$, $3'$, $2'$ clockwise for $B_d$ molecule viewed from outside of the molecule.

(4) The configurational energy of the system is the sum of interaction energies of plane-plane pairs.

If the interaction energy of plane $i$ and plane $j$ is denoted by $\omega_{ij}$, all possible kinds of $\omega_{ij}$ and their interaction energies become as follows.

A−A $\quad \omega_{bb}, \omega_{ab}, \omega_{aa_1} = \omega_{11} + 2\omega_{23}$
$\omega_{aa_2} = \omega_{22} + 2\omega_{13}$
$\omega_{aa_3} = \omega_{33} + 2\omega_{12}$

B−$B_l$, B−$B_d$ $\quad \omega_{b'b'}, \omega_{a'b'}, \omega_{a'a'_1} = \omega_{1'1'} + 2\omega_{2'3'}$
$\omega_{a'a'_2} = \omega_{2'2'} + 2\omega_{1'3'}$
$\omega_{a'a'_3} = \omega_{3'3'} + 2\omega_{1'2'}$

A−$B_l$ $\quad \omega_{bb'}, \omega_{ab'}, \omega_{a'b}, \omega^{l}_{aa_1} = \omega_{11'} + \omega_{23'} + \omega_{32'}$
$\omega^{l}_{aa'_2} = \omega_{22'} + \omega_{13'} + \omega_{31'}$
$\omega^{l}_{aa'_3} = \omega_{33} + \omega_{12'} + \omega_{21'}$

1) K. Amaya, This Bulletin, **34**, 1689 (1961).

$$\mathrm{A}-\mathrm{B}_d \qquad \omega_{bb'},\ \omega_{ab'},\ \omega_{a'b},\ \omega^d_{aa'_1}=\omega_{11'}+\omega_{22'}+\omega_{33'}$$
$$\omega^d_{aa'_2}=\omega_{13'}+\omega_{21'}+\omega_{32'}$$
$$\omega^d_{aa'_3}=\omega_{12'}+\omega_{23'}+\omega_{31'}$$

The total configurational energy of the system is expressed as a sum of these energies. For a system composed of $N_A$ molecules of A and $N_{B_l}$ molecules of $B_l$, the configurational partition function $\Omega_{AB_l}$ is given by

$$\ln \Omega_{AB_l}-\ln\frac{(N_A+N_{B_l})!}{N_A!\,N_{B_l}!}-\ln(3z)^{N_A+N_{B_l}}-\frac{N_A\chi_A+N_{B_l}\chi_{B_l}}{kT}$$
$$=\frac{\langle W_{AB_l}(N_A,N_{B_l})\rangle}{kT}-\frac{\langle W_{AB_l}(N_A,N_{B_l})\rangle^2-\langle W^2{}_{AB_l}(N_A,N_{B_l})\rangle}{2!\,(kT)^2}-\cdots\cdots \tag{4}$$

where

$$\chi_A=\frac{z}{2}\cdot\frac{1}{z^2}\left\{(z-1)^2\omega_{bb}+2(z-1)\omega_{ab}+\frac{1}{3}(\omega_{aa_1}+\omega_{aa_2}+\omega_{aa_3})\right\} \tag{5}$$

$$\chi_B=\frac{z}{2}\cdot\frac{1}{z^2}\left\{(z-1)^2\omega_{b'b'}+2(z-1)\omega_{a'b'}+\frac{1}{3}(\omega_{a'a'_1}+\omega_{a'a'_2}+\omega_{a'a'_3})\right\} \tag{6}$$

and $W_{AB_l}(N_A, N_{B_l})$ is the excess potential energy of the system and $\langle W_{AB_l}(N_A, N_{B_l})\rangle$ and $\langle W_{AB_l}{}^2(N_A, N_{B_l})\rangle$ denote the unweighted mean over all configurations of this quantity and of the square of it respectively. Then $\langle W_{AB_l}(N_A, N_{B_l})\rangle$ is given by

$$\langle W_{AB_l}(N_A,N_{B_l})\rangle=(N_A+N_{B_l})\{(1-x_{B_l})^2\chi_A+2x_{B_l}(1-x_{B_l})\chi_{AB_l}+x^2{}_{B_l}\chi_{B_l}\}-N_A\chi_A-N_{B_l}\chi_{B_l}$$
$$=(N_A+N_{B_l})x_{B_l}(1-x_{B_l})(2\chi_{AB_l}-\chi_A-\chi_{B_l})^* \tag{7}$$

where

$$x_{B_l}=N_{B_l}/(N_A+N_{B_l})$$
$$\chi_{AB_l}=\frac{1}{z}\left\{(z-1)^2\omega_{bb'}+(z-1)(\omega_{ab'}+\omega_{a'b})+\frac{1}{3}(\omega^l_{aa'_1}+\omega^l_{aa'_2}+\omega^l_{aa'_3})\right\}$$

In evaluating $\langle W^2{}_{AB_l}(N_A, N_{B_l})\rangle$, the average value over most probable configurations is taken as an approximation, since it is very difficult to evaluate the exact value of this quantity averaged over all possible configurations. For most probable configurations, the number of plane-plane pairs for each kind of pair becomes as shown in Table I.

The average value over the above configurations becomes as follows with a procedure similar to that described in the previous paper[1].

$$\langle W_{AB_l}(N_A,N_{B_l})\rangle^2-\langle W^2{}_{AB_l}(N_A,N_{B_l})\rangle=-\frac{(N_A+N_{B_l})^2}{4z^2}\Big[(1-x_{B_l})^4\cdot\frac{1}{36}\{(\omega_{aa_1}-\omega_{aa_2})^2+(\omega_{aa_2}-\omega_{aa_3})^2+(\omega_{aa_3}-\omega_{aa1})^2\}$$
$$+4x^2{}_{B_l}(1-x_{B_l})^2\cdot\frac{1}{36}\{(\omega^l_{aa'_1}-\omega^l_{aa'_2})^2+(\omega^l_{aa'_2}-\omega^l_{aa'_3})^2+(\omega^l_{aa'_3}-\omega^l_{aa'_1})^2\}$$
$$+x^4{}_{B_l}\cdot\frac{1}{36}\{(\omega_{a'a'_1}-\omega_{a'a'_2})^2+(\omega_{a'a'_2}-\omega_{a'a'_3})^2+(\omega_{a'a'_3}-\omega_{a'a'_1})^2\}\Big] \tag{8}$$

By substituting 8 into 4, the following expression for configurational partition function $\Omega_{AB_l}$ is obtained.

TABLE I

| The kind of pairs | | Number of pairs | |
|---|---|---|---|
| A−A | $b-b$ | $(z-1)^2/z^2\cdot N_{AA}$ | |
| | $a-b$ | $2(z-1)/z^2\cdot N_{AA}$ | $N_{AA}=\frac{1}{2}(N_A+N_{B_l})z(1-x_{B_l})^2$ |
| | $a-a$ | $1/z^2\cdot N_{AA}$ | |
| $B_l-B_l$ | $a'-b'$ | $(-1)^2/z^2\cdot N_{B_lB_l}$ | |
| | $a'-b'$ | $2(z-1)/z^2\cdot N_{B_lB_l}$ | $N_{B_lB_l}=\frac{1}{2}(N_A+N_{B_l})zx^2{}_{B_l}$ |
| | $a'-a'$ | $1/z^2\cdot N_{B_lB_l}$ | |
| $A-B_l$ | $b-b'$ | $(z-1)^2/z^2\cdot N_{AB_l}$ | |
| | $a-b'$ | $(z-1)/z^2\cdot N_{AB_l}$ | $N_{AB_l}=(N_A+N_{B_l})z\cdot x_{B_l}(1-x_{B_l})$ |
| | $a'-b$ | $(z-1)/z^2\cdot N_{AB_l}$ | |
| | $a-a'$ | $1/z^2\cdot N_{AB_l}$ | |

* Mean cohesive energy of a B molecule in an imagi- nary liquid state.

$$\ln \Omega_{AB_l}=\ln \frac{(N_A+N_{B_l})!}{N_A!\,N_{B_l}!}+\ln(3z)^{N_A+N_{B_l}}+\frac{N_A\chi_A+N_{B_l}\chi_{B_l}}{kT}\cdot\frac{(N_A+N_B)}{kT}(2\chi_{AB_l}-\chi_A-\chi_{B_l})x_{B_l}(1-x_{B_l})+\frac{1}{2(kT)^2}\frac{(N_A+N_{B_l})^2}{4z^2}\Big[(1-x_{B_l})^4\cdot\frac{1}{36}\{(\omega_{aa_1}-\omega_{aa_3})^2+(\omega_{aa_2}-\omega_{aa_3})^2+(\omega_{aa_3}-\omega_{aa_1})^2\}+4x^2{}_{B_l}(1-x_{B_l})^2\cdot\frac{1}{36}\{(\omega^l_{a'a'_1}-\omega^l_{a'a'_2})^2+(\omega^l_{a'a'_2}-\omega^l_{a'a'_3})^2+(\omega^l_{a'a'_3}-\omega^l_{a'a'_1})^2\}+x^4{}_{B_l}\cdot\frac{1}{36}\{(\omega_{a'a'_1}-\omega_{a'a'_2})^2+(\omega_{a'a'_2}-\omega_{a'a'_3})^2+(\omega_{a'a'_3}-\omega_{a'a'_1})^2\}\Big] \tag{9}$$

Then the chemical potential of $B_l$ molecules $\mu^S{}_{B_l}$ can be obtained by partial differentiating $-kT\ln\Omega_{AB_l}$ with respect to $N_{B_l}$

$$\mu^S{}_{B_l}=-\frac{\partial kT\ln\Omega_{AB_l}}{\partial N_{B_l}}=kT\ln x_{B_l}-\chi_{B_l}+(1-x_{B_l})^2(2\chi_{AB_l}-\chi_A-\chi_{B_l})-\frac{1}{36}\frac{N}{z^2}\frac{1}{kT}\Big[-(1-x_{B_l})^4\{(\omega_{aa_1}-\omega_{aa_2})^2+(\omega_{aa_2}-\omega_{aa_3})^2+(\omega_{aa_3}-\omega_{aa_1})^2\}+x_{B_l}(1-x_{B_l})^3\{(\omega^l_{a'a'_1}-\omega^l_{a'a'_2})^2+(\omega^l_{a'a'_2}-\omega^l_{a'a'_3})^2+(\omega^l_{a'a'_3}-\omega^l_{a'a'_1})^2\}+x^3{}_{B_l}(2-x_{B_l})\{(\omega_{a'a'_1}-\omega_{a'a'_2})^2+(\omega_{a'a'_2}-\omega_{a'a'_3})^2+(\omega_{a'a'_3}-\omega_{a'a'_1})^2\}\Big] \tag{10}$$

where $N=N_A+N_{B_l}$.

For the system consisting of $N_A$ molecules of A and $N_{B_d}$ molecules of $B_d$, the chemical potential $\mu_{B_d}$ for the $B_d$ molecule can be derived in quite the same way. Then $\mu^S{}_{B_d}$ becomes

$$\mu^S{}_{B_d}=kT\ln x_{dB}-\chi_{B_d}+(1-x_{B_d})^2(2\chi_{AB_d}-\chi_A-\chi_{B_d})-\frac{1}{36}\frac{N}{z^2}\frac{1}{kT}\Big[-(1-x_{B_d})^4\{(\omega_{aa_1}-\omega_{aa_2})^2+(\omega_{aa_2}-\omega_{aa_3})^2+(\omega_{aa_3}-\omega_{aa_1})^2\}+x_{B_d}(1-x_{B_d})(3\{(\omega^d_{a'a'_1}-\omega^d_{a'a'_2})^2+(\omega^d_{a'a'_2}-\omega^d_{a'a'_3})^2+(\omega^d_{a'a'_3}-\omega^d_{a'a'_1})^2\}+x^3{}_{B_d}(2-x_{B_d})\{(\omega_{a'a'_1}-\omega_{a'a'_2})^2+(\omega_{a'a'_2}-\omega_{a'a'_3})^2+(\omega_{a'a'_3}-\omega_{a'a'_1})^2\}\Big] \tag{11}$$

where

$$\chi_{AB_d}=\frac{1}{z}\Big\{(z-1)^2\omega_{bb'}+(z-1)(\omega_{ab'}+\omega_{a'b})+\frac{1}{3}(\omega^d_{aa'_1}+\omega^d_{aa'_2}+\omega_2{}^d_{aa'_3})\Big\} \tag{12}$$

Now compare 10 with 11. Since $B_l$ is a mirror image of $B_d$ and $B_l$ molecules are energetically equivalent, it follows that

$$\chi_{B_l}=\chi_{B_d} \tag{13}$$

and from the relation

$$\omega^l_{aa'_1}+\omega^l_{aa'_2}+\omega^l_{aa'_3}=\omega_{11'}+\omega_{23'}+\omega_{32'}+\omega_{22'}+\omega_{13'}+\omega_{31'}+\omega_{33'}+\omega_{12'}+\omega_{21'}=\omega_{11'}+\omega_{22'}+\omega_{33'}+\omega_{13'}+\omega_{21'}\,\omega_{32'}+\omega_{12'}+\omega_{23'}+\omega_{31'}=\omega^d_{aa'_1}+\omega^d_{aa'_2}+\omega^d_{aa'_3}$$

it follows that

$$\chi_{AB_l}=\chi_{AB_d} \tag{14}$$

Then the only difference between 10 and 11 is the second term in the bracket [ ] which contain the coefficient $x_B(1-x_B)^3$ *.

By using new notations that $\chi_B=\chi_{B_l}=\chi_{B_d}$ and $\chi_{AB}=\chi_{AB_l}=\chi_{AB_d}$, and expressing mole fractions of $B_l$ and $B_d$ molecules in their saturated solutions by $x_l$, and $x_d$ respectively, $x_l$ and $x_d$ are correlated by the following equations

$$\mu^S{}_{B_l}(x_l)=kT\ln x_l-\chi_B+(1-x_l)^2(2\chi_{AB}-\chi_A-\chi_B)-\frac{1}{36}\frac{N}{z^2}\frac{1}{kT}\{-(1-x_l)^4C_{AA}+x_l(1-x_l)^3C_{AB_l}+x_l^3(2-x_l)C_{BB}\} \tag{15}$$

$$=\mu^S{}_{B_d}(x_d)=kT\ln x_d-\chi_B+(1-x_d)^2(2\chi_{AB}-\chi_A-\chi_B)-\frac{1}{36}\frac{N}{z^2}\frac{1}{kT}\{-(1-x_d)^4C_{AA}+x_d(1-x_d)^3C_{AB_d}+x_d^3(2-x_d)C_{BB}\} \tag{16}$$

where

$$C_{AA}=(\omega_{aa_1}-\omega_{aa_2})^2+(\omega_{aa_2}-\omega_{aa_3})^2+(\omega_{aa_3}-\omega_{aa_1})^2$$

$$C_{BB}=(\omega_{a'a'_1}-\omega_{a'a'_2})^2+(\omega_{a'a'_2}-\omega_{a'a'_3})^2+(\omega_{a'a'_3}-\omega_{a'a'_1})^2$$

$$C_{AB_l}=(\omega^l_{aa'_1}-\omega^l_{aa'_2})^2+(\alpha^l_{aa'_2}-\omega^l_{aa'_3})^2+(\omega^l_{aa'_3}-\omega^l_{aa'_1})^2$$

$$C_{AB_d}=(\omega^d_{aa'_1}-\omega^d_{aa'_2})^2+(\omega^d_{aa'_2}-\omega^d_{aa'_3})^2+(\omega^d_{aa'_3}-\omega^d_{aa'_1})^2$$

* $x_B$ denotes $x_{B_l}$ or $x_{B_d}$.

## Discussions

The chemical potentials of $B_l$ and $B_d$ molecules in the solution $\mu^{S}{}_{B_l}(x)$ and $\mu^{S}{}_{B_d}(x)$ respectively, can be expressed as a function of their mole fraction $x$ by the same formula except for the term containing $C_{AB_l}$ and $C_{AB_d}$. If the common part is expressed by $F(x)$, the following formula is obtained.

$$\mu^{S}{}_{B_l}(x) = F(x) + \frac{1}{36}\frac{N}{z^2}\frac{1}{kT}C_{AB_l}x(1-x)^3 + \cdots\cdots$$

$$\mu^{S}{}_{B_d}(x) = F(x) + \frac{1}{36}\frac{N}{z^2}\frac{1}{kT}C_{AB_d}x(1-x)^3 + \cdots\cdots$$

This formula is represented schematically in Fig. 1. It is clear from the above expression that the higher the temperature the greater the difference between the two curves is. The straight line parallel to the $x$ axis representing $\mu=\mu^{K}$ crosses the curves representing $\mu^{S}{}_{B_l}(x)$ and $\mu^{S}{}_{B_d}(x)$ at points $P_l$ and $P_d$. Projections of $P_l$ and $P_d$ on $\chi$ axis represent $x_l$ and $x_d$ respectively. As these two curves generally do not coincide with each other, $x_l$ and $x_d$ have different values. This shows that the solubilities of *d*- and *l*-optical isomers in optical active solvent differ from each other and the magnitude of the difference is determined by the difference between $C_{AB_l}$ and $C_{AB_d}$. It is clear from the above argument that in principle the optical resolution is possible using the difference of solubility of *d*- and *l*-optical isomers in optical active solvents and by choosing a proper kind of molecule of A, which makes the difference of $C_{AB_l}$ and $C_{AB_d}$ large, the difference between $x_l$ and $x_d$ can be made large enough to obtain an efficient optical resolution.

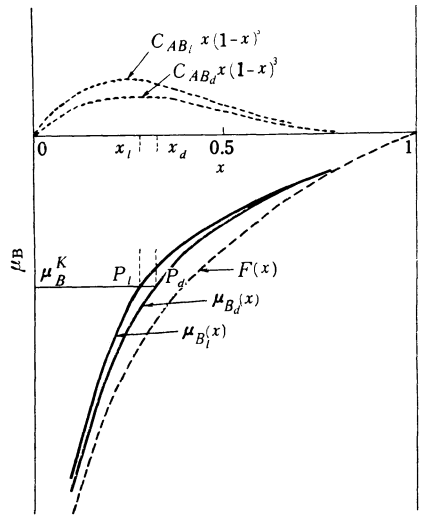

Fig. 1. Schematic diagram of $\mu_{B_l}$ and $\mu_{B_d}$ as a function of $x$.

The above argument is confined only to the mixture in which $B_l$ and $B_d$ molecules form no racemic compound. For the case where a racemic compound is formed more elaborate consideration must be made.

## Summary

The statistical mechanical expression relating the solubilities of *d*- and *l*-optical isomers in optically active solvent is derived.

It is shown that there exists a difference between these two solubilities.

The possibility of optical resolution is also discussed.

The auther wishes to express his hearty thanks to Professor Yonezo Morino of The University of Tokyo for his helpful discussions.

# *Liquid-Vapor Equilibrium of Isotope Mixture under Centrifugal Force*

By Kazuo AMAYA

(Received March 30, 1961)

In order to estimate the efficiency of concentrating one of the isotopic compounds by distillation of the mixture under centrifugal force, a theoretical expression for liquid-vapor equilibrium of the isotopic mixture under centrifugal force was derived and a concentration factor under practical condition was estimated for actual cases.

## Derivation of the Expression for the Distribution of Isotope Mixture in Liquid-Vapor Phase System under Centrifugal Force

Consider an isotopic mixture composed of $N_1$ molecules of isotope 1 of mass $m_1$ and $N_2$ molecules of isotope 2 of mass $m_2$.

If the mole fraction of isotope 1 in the mixture is denoted by $x$, then

$$N_1 = Nx \tag{1}$$

$$N_2 = N(1-x) \tag{2}$$

where $N = N_1 + N_2$.

Suppose that the mixture is confined in a closed box with cross section area $S$ and height $H$ and is placed in a field of homogeneous centrifugal force $g$*, the direction of which is perpendicular to the cross section.

If the densities of molecules of isotope 1 and 2 in the vapor phase at a distance $h^v$ from the liquid surface are denoted by $n^v_{1g}(h^v)$ and $n^v_{2g}(h^v)$ respectively and those in the liquid phase by $n^l_{1g}(h^l)$ and $n^l_{2g}(h^l)$ respectively, and suppose that the vapor density is sufficiently low and the liquid is not compressible, then following relations hold.

$$n^v_{1g}(h^v) = n^v_{1g}(0) \cdot \exp(-m_1 g h^v / kT) \tag{3}$$

$$n^v_{2g}(h^v) = n^v_{2g}(0) \cdot \exp(-m_2 g h^v / kT) \tag{4}$$

$$n^l_{1g}(h^l) + n^l_{2g}(h^l) = n^l_{1g}(0) + n^l_{2g}(0) = N_0 = \text{const.} \tag{5}$$

$$n^l_{1g}(h^l) = N_0 \cdot n^l_{1g}(0) \cdot \exp(m_1 g h^l / kT) / \{n^l_{1g}(0) \cdot \exp(m_1 g h^l / kT) + n^l_{2g}(0) \cdot \exp(m_2 g h^l / kT)\} \tag{6}$$

$$n^l_{2g}(h^l) = N_0 \cdot n^l_{2g}(0) \cdot \exp(m_2 g h^l / kT) / \{(n^l_{1g}(0) \cdot \exp(m_1 g h^l / kT) + n^l_{2g}(0) \cdot \exp(m_2 g h^l / kT)\} \tag{7}$$

where $k$ is the Boltzmann constant and $T$ is the absolute temperature of the box.

If the vaporization energy of isotope 1 is assumed to be equal to that of isotope 2, then it follows that,

$$n^l_{1g}(0) = K_T n^v_{1g}(0) \tag{8}$$

$$n^l_{2g}(0) = K_T n^v_{2g}(0) \tag{9}$$

where $K_T$ is a constant at a given temperature, $T$. From the principle of conservation of mass in a closed system, the following relations are obtained.

$$S\int_0^{H^v_g} n^v_{1g}(h^v)\mathrm{d}h_v + S\int_0^{H^l_g} n^l_{1g}(h^l)\mathrm{d}h_l = Nx \tag{10}$$

$$S\int_0^{H^v_g} n^v_{2g}(h^v)\mathrm{d}h_v + S\int_0^{H^l_g} n^l_{2g}(h^l)\mathrm{d}h_l = N(1-x) \tag{11}$$

where $SH^v_g$ and $SH^l_g$ are the volume of the space in the box occupied by the vapor and the liquid respectively at equilibrium under centrifugal force $g$ and namely $H = H^v_g + H^l_g$.

If, at equilibrium, mole fraction of isotope at the interface of liquid and vapor is denoted by $x_g$ it follows from 5 that

$$n^l_{1g}(0) = N_0 x_g \tag{12}$$

$$n^l_{2g}(0) = N_0(1-x_g) \tag{13}$$

then Eqs. 6 and 7 are rewritten as

$$\begin{aligned} n^l_{1g}(h^l) &= N_0 x_g \cdot \exp(m_1 g h^l / kT) / \{x_g \cdot \exp(m_1 g h^l / kT) + (1-x_g) \cdot \exp(m_2 g h^l / kT)\} \\ &= N_0 \Big/ \left[1 + \frac{1-x_g}{x_g} \cdot \exp\{(m_2 - m_1) g h^l / kT\}\right] \end{aligned} \tag{14}$$

$$\begin{aligned} n^l_{2g}(h^l) &= N_0(1-x_g) \cdot \exp(m_2 g h^l / kT) / \{x_g \cdot \exp(m_1 g h^l / kT) + (1-x_g) \cdot \exp(m_2 g h^l / kT)\} \\ &= N_0 \Big/ \left[1 + \frac{x_g}{1-x_g} \cdot \exp\{(m_1 - m_2) g h^l / kT\}\right] \end{aligned} \tag{15}$$

and from 3, 4, 8 and 9

* For the sake of simplicity, the values of $g$ are assumed to be constant along the direction of height.

$$n^{v}_{1g}(h^{v}) = N_0/K_T \cdot x_g \cdot \exp(-m_1 g h^{v}/\boldsymbol{kT}) \quad (16)$$

$$n^{v}_{2g}(h^{v}) = N_0/K_T \cdot x_g \cdot \exp(-m_2 g h^{v}/\boldsymbol{kT}) \quad (17)$$

Substituting 14 and 16 into 10, and 15 and 17 into 11, and integrating them, we obtain

$$Nx = N_0 S\Big[ x_g/K_T \cdot \boldsymbol{kT}/m_1 g\{1-\exp(-m_1 g H^{v}_g/\boldsymbol{kT})\} + H^{l}_g - \boldsymbol{kT}/(m_2-m_1)g \times \ln\Big\{\frac{1+(1-x_g)/x_g \cdot \exp((m_2-m_1)gH^{l}_g/\boldsymbol{kT})}{1+(1-x_g)/x_g}\Big\}\Big] \quad (18)$$

$$N(1-x) = N_0 S\Big[ (1-x_g)/K_T \cdot \boldsymbol{kT}/m_2 g\{1-\exp(-m_2 g H^{v}_g/\boldsymbol{kT})\} + H^{l}_g - \boldsymbol{kT}/(m_1-m_2)g \times \ln\Big\{\frac{1+x_g/(1-x_g)\cdot\exp((m_1-m_2(gH^{l}_g/\boldsymbol{kT})}{1+x_g/(1-x_g)}\Big\}\Big] \quad (19)$$

## Calculation of Concentration Factor for Actual Cases

Now, the change of composition of isotope in the mixture by distillation under centrifugal force will be considered. When $g=0$, Eqs. 18 and 19 become

$$Nx = N_0 S x_0 (1/K_T \cdot H^{v}_0 + H^{l}_0) \quad (20)$$

$$N(1-x) = N_0 S(1-x_0)(1/K_T \cdot H^{v}_0 + H^{l}_0) \quad (21)$$

where $H^{v}_0$, $H^{l}_0$ and $x_0$* are the values of $H^{v}_g$, $H^{l}_g$ and $x_g$ when $g=0$ respectively. By Eqs. 18 and 19 to 20 and 21 respectively and from the relation

$$H^{l}_0 + H^{v}_0 = H^{l}_g + H^{v}_g \quad (22)$$

the values of $x_g/x_0$ may be obtained in principle. However, the exact solution of these equations is very complicated.

In order to obtain a workable formula, we may expand the logarithm of the last terms in 18 and 19 in powers of $(m_2-m_1)gH^{l}_g/\boldsymbol{kT}$, and the following relations are obtained

$$x_g/K_T \cdot [\boldsymbol{kT}/m_1 g \cdot \{1-\exp(-m_1 g H^{v}_g/\boldsymbol{kT})\} + H^{l}_g] + 1/2 \cdot \{(1-x_g)-(1-x_g)^2\}(m_1-m_2)gH^{l}_g/\boldsymbol{kT} + \cdots\cdots = x_0(H^{v}_0/K_T + H^{l}_0) \quad (23)$$

$$(1-x_g)/K_T \cdot [\boldsymbol{kT}/m_2 g \cdot \{1-\exp(-m_2 g H^{v}_g/\boldsymbol{kT})\} + H^{l}_g] + 1/2 \cdot (x_g - x_g^2)(m_2-m_1)gH^{l}_g/\boldsymbol{kT} + \cdots\cdots = (1-x_0)(H^{v}_0/K_T + H^{l}_0) \quad (24)$$

If we assume that

$$|m_1-m_2| = 3,$$

$$H^{l}_g \approx 0.1 \text{ cm.}$$

$$g = 10^7 \text{ dyn.}$$

$$T \approx 300^\circ\text{K}$$

then the order of magnitude of the second term of the left side of 23 or 24 is about $1/2 \cdot |m_1-m_2| \times 10^{-5} = 1.5 \times 10^{-5}$ and can be neglected as being sufficiently small. Using the following notation

$$x_g = x_0(1+\delta) \quad (25)$$

$$H^{l}_g = H^{l}_0 + \Delta h, \quad H^{v}_g = H^{v}_0 - \Delta h \quad (26)$$

and adding 23 and 24, we obtain

$$x_0(1+\delta)\boldsymbol{kT}/m_1 g \cdot [1-\exp\{-m_1 g(H^{v}_0 - \Delta h)/\boldsymbol{kT}\}] + \{1-x_0(1+\delta)\}\boldsymbol{kT}/m_2 g \times [1-\exp\{-m_2 g(H^{v}_0 - \Delta h)/\boldsymbol{kT}\}] - H^{v}_0 = -K_T \Delta h \quad (27)$$

To obtain the approximate value of $\Delta h$, the mixture may be assumed to be of single component of mass $\bar{m} = m_1 x_0 + m_2(1-x_0)$, then

$$\boldsymbol{kT}/\bar{m}g\{1-\exp(-\bar{m}gH^{v}_0/\boldsymbol{kT}) \cdot (1+\bar{m}g\Delta h/\boldsymbol{kT})\} - H^{v}_0 = -K_T \Delta h \quad (28)$$

The value of $\Delta h$ thus obtained is then substituted into 23 and 24, and we can obtain $\delta$ from the relation

$$\frac{\boldsymbol{kT}/m_1 g \cdot \{1-(1+m_1 g\Delta h/\boldsymbol{kT})\exp(-m_1 g H^{v}_0)\} + K_T(H^{l}_0 + \Delta h)}{\boldsymbol{kT}/m_2 g \cdot \{1-(1+m_2 g\Delta h/\boldsymbol{kT})\}\exp(-m_2 g H^{v}_0) + K_T(H^{l}_0 + \Delta h)} = \frac{1-x_0(1+\delta)}{(1-x_0)(1+\delta)} \quad (29)$$

Now consider the value of $\delta$ for an actual case. For example, consider $UF_6$ and assume that

$$m_1 = 350, \quad m_2 = 353$$

$$K_T \fallingdotseq 300,^* \quad g = 10^7 \text{ dyn.}$$

$$T = 333^\circ\text{K}, \quad H^{v}_0 + H^{l}_0 = 20 \text{ cm.}, \quad H^{l}_0 = 0.1 \text{ cm.}$$

TABLE I. VALUES OF $\delta$, $x'_g$ AND THE CONCENTRATION FACTOR $(x'_g - x_0)/x_0$ AS FUNCTIONS OF ORIGINAL CONCENTRATION $x_0$ OF $^{235}UF_6$ IN $^{238}UF_6 - ^{235}UF_6$ MIXTURE WITH $g = 10^7$ dyn., $H = 20$ cm. AND $H^{l}_0 = 0.1$ cm.

| $x_0$ | $\delta \times 10^{-3}$ | $x'_g$ | $(x'_g - x_0)/x_0$ % |
|---|---|---|---|
| 0.01 | −0.95 | 0.010205 | 2.05 |
| 0.1 | −0.87 | 0.10186 | 1.86 |

| 0.9 | −0.10 | 0.90183 | 0.20 |
| 1.0 | 0 | 1.0 | 0 |

* By dividing 20 by 21, it follows that $x_0 = x$

* The vapor is assumed to be an ideal gas, and the molar volume of vapor of 22.4 l. is divided by molar volume of $UF_6$ in liquid state 75.4 cc., to obtain 22.4/0.0754 = 297.

and $\delta$ are calculated for $x_0=0.01$, 0.05, 0.1 and 0.9 and are shown in Table I. Using these values of $\delta$ we can calculate the composition of the isotope mixture at the top of the box. The composition $x_g'$ thus obtained is also shown in Table I. The concentration factors $x_g'/x_0$ are about 1.02 and the concentration of the isotope may become quite efficient by the proper design of an apparatus for successive distillation.

## Summary

Expressions for the distribution of the isotope mixture in liquid-vapor phase system under centrifugal force were derived. By the use of these expressions, the efficiency of the isotope concentration was estimated for actual cases under accessible conditions. It was found that an efficient concentration of the isotope from their mixture was possible by the proper design of an apparatus for successive distillation.

# *Adsorbabilities of Diacidotetrammine Type Cobalt(III) Complex Ions on a Cation Exchanger*[1]

By Motoshichi MORI, Muraji SHIBATA and Kuniko HORI

(Received March 3, 1961)

Since King and Walter[2] reported the separation of the cis and trans isomers of dinitrotetramminecobalt(III) ions by ion-exchange chromatography, the same kind of study has been extensively developed in our laboratory on other isomers of the diacidoteterammine type complex, and as a result it has been found that the trans isomers were, as a general rule, eluted faster than the corresponding cis isomers[3,4]. In the present work, some supplementary experiments for confirming the above rule are attempted by using the complexes which are relatively unstable in aqueous solutions. Furthermore, the adsorbabilities of all the complexes, including the previous ones, on a cation exchanger are compared.

## Experimental

**Complexes.** — All the complexes were prepared according to the literatures[5], and their identity and purity were examined with the absorption spectra in an alcoholic aqueous solution. The complexes used were as follows: the trans-cis and cis-trans isomers of $[Co\,en(NH_3)_2Cl_2]Cl$ and the trans and cis isomers of $[Co\,en_2Cl_2]$, $[Co\,en_2Br_2]Br$ and $[Co\,en_2(NO_2)Cl]Cl$.

**Elution Methods.**—A column (1×10 cm.) which contained 5 g. of Ammberlite IR-120 (50~100 mesh) in sodium form was used, and the sample solution was prepared in concentrations ranging from 0.01 to 0.06 M depending on the solubility of the complexes. Fifteen milliliters of each sample solution was applied to the column, and then the column was eluted with 0.15 M sodium chloride ethanol-water (1 : 1) solution. The velocity of elution was 0.5 ml./min. Examination of the eluted species was made by measuring the optical density of the eluted fraction at particular wavelengths. The ethanol-water solution was used as the eluant to minimize the aquation rections of the complexes.

The measurement of the optical density was carried out with a Hitachi model EPU-2 spectrophotometer.

## Results and Discussion

The elution curve of a mixture of the isomeric $[Co\,en(NH_3)_2Cl_2]^+$ is shown in Fig. 1, in which the measurement of the optical density was performed at an absorption maximum and a minimum of the trans-cis ion (460 and 560 mμ). As is seen in the figure, an elution maximum for the trans-cis ion appears in the fraction 10 and one for the cis-trans ion in the fractions 20 and 21. When only the trans-cis complex was applied to the

3) M. Mori, M. Shibata and J. Azami, *J. Chem. Soc. Japan, Pure Chem. Sec. (Nipoon Kagaku Zasshi)*, **76**, 1003 (1955).

4) M. Mori, M. Shibata and M. Nanasawa, This Bulletin, **29**, 947 (1956).

5) J. C. Bailar and D. F. Peppard, *J. Am. Chem. Soc.*, **62**, 105 (1940); A. Werner, *Ber.*, **34**, 1733 (1901); *Ann.* **386**, 48, 107, 111, 248 (1912).

column, the elution curve had its maximum in the fraction 9 and dropped to zero at the fraction 20. On the other hand, the cis-trans ion began to appear in the fraction 9 and showed the maximum elution at the fraction 21. It is, therefore, clear that each portion of the fractions 9—20 in Fig. 1 is, more or less, contaminated with both species.

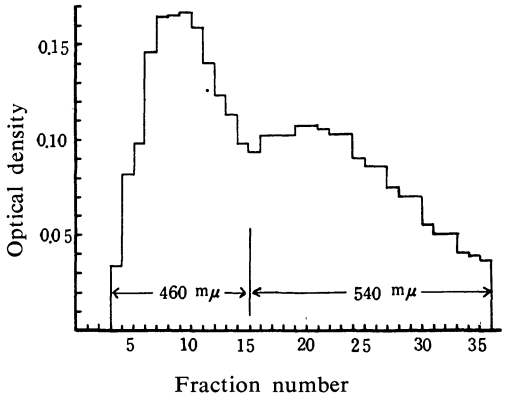

Fig. 1. Elution curve of $[Co\,en(NH_3)_2Cl_2]Cl$ isomers.

The elution curves of *trans*- and *cis*-$[Co\,en_2NO_2Cl]^+$ are shown in Figs. 2 and 3. The maximum concentration of the trans compound is observed in the fraction 8, and that for the cis in the fractions 21 and 22. The elution of a mixture of these isomers was examined, but the elution curve is omitted because the absorption spectra of both isomers are quite similar, and hence no perceptible peak was obtained.

Figure 4 is the elution curve for *trans*-$[Co\,en_2Br_2]^+$ and shows the elution peak in the fraction 7. The experiment of the elution for the cis ion was unsuccessful because of the extremely low solubility of the complex.

The elution curve for the isomeric $[Co\,en_2\cdot Cl_2]^+$ in a mixed solution is shown in Fig. 5, where the elution maxima are in the fractions

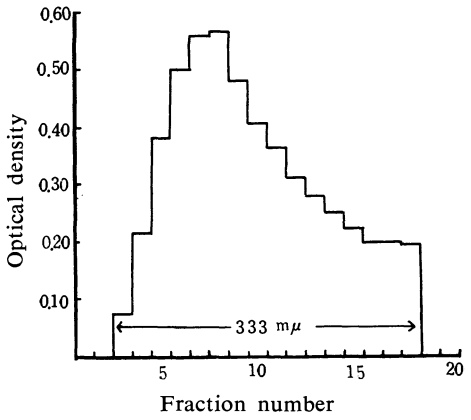

Fig. 2. Elution curve of *trans*-$[Co\,en_2NO_2Cl]Cl$.

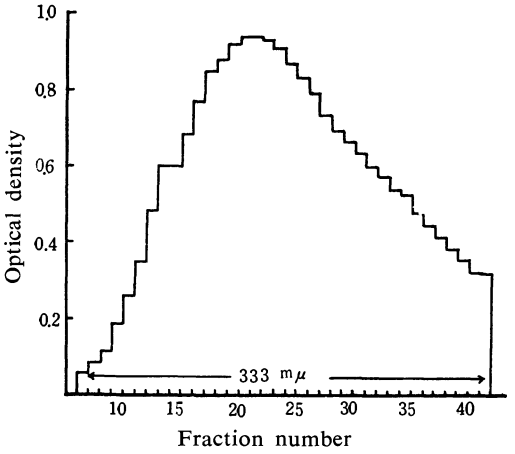

Fig. 3. Elution curve of *cis*-$[Co\,en_2NO_2Cl]Cl$.

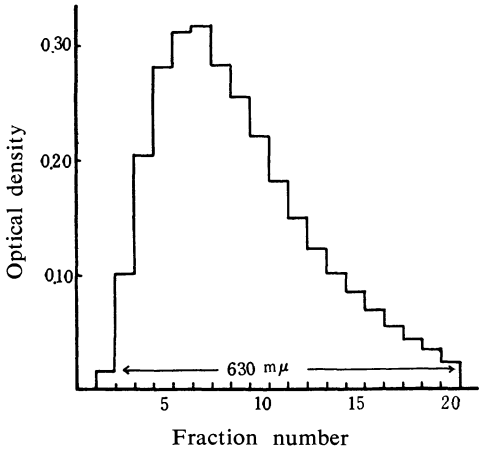

Fig. 4. Elution curve of *trans*-$[Co\,en_2Br_2]Br$.

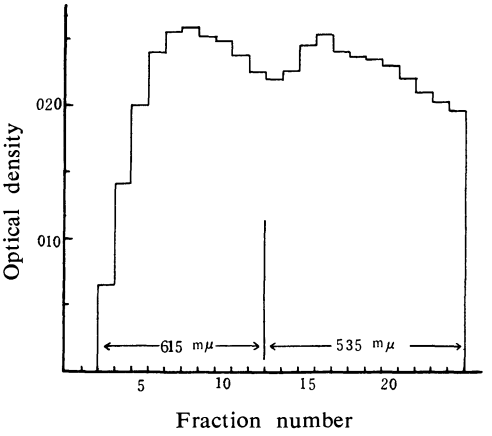

Fig. 5. Elution curve of $[Co\,en_2Cl_2]Cl$ isomers.

8 and 16. In the case of the individual solution, the trans ion was eluted with the maximum in the fraction 7 and finished its elution at the fraction 15, while the cis ion began to elute in fraction 5 and showed the maximum in the fraction 16.

From these results, it is again found that the trans ion is eluted faster than the cis ion. Furthermore, it is possible to predict the relative adsorbabilities as follows:

For the trans ions,

$$[Co\ en_2Br_2]^+ < [Co\ en_2Cl_2]^+ \simeq [Co\ en_2NO_2Cl]^+ < [Co\ en(NH_3)_2Cl_2]^+$$

For the cis ions,

$$[Co\ en_2Cl_2]^+ < [Co\ en(NH_3)_2Cl_2]^+ \simeq [Co\ en_2NO_2Cl]^+$$

Now, we are in a position to discuss the relative adsorbabilities of all the complex ions studied in the present and previous papers[3,4].

Table I. Comparison of elution maxima

| Complex ion | Eluant | Fraction no. of elution max. trans | cis |

| $[Co\ en_2(NO_2)_2]^+$ | | 11 | 31 |

* Fraction number in individual solution.

Unfortunately, it was impossible to perform all of the elutions under identical conditions. It is, therefore, difficult to derive a definite adsorbability order directly, but it is possible to predict such an order from a comparison of the elution maxima (Table I).

For the trans ions.

$$[Co\ en_2(NCS)_2]^+ < [Co\ en_2(NO_2)_2]^+ \simeq [Co\ en_2Br_2]^+ < [Co\ en_2Cl_2]^+ \simeq [Co\ en_2NO_2Cl]^+ < [Co(NH_3)_4(NO_2)_2]^+ < [Co\ en(NH_3)_2Cl_2]^+$$

For the cis ions.

$$[Co\ en_2Cl_2]^+ < [Co\ en_2(NCS)_2]^+ < [Co\ en(NH_3)_2Cl_2]^+ \simeq [Co\ en_2NO_2Cl]^+ < [Co\ en_2(NO_2)_2]^+ < [Co(NH_3)_4(NO_2)_2]^+$$

For the trans ions of the diacido-bisethylenediamine complexes, the adsorbabilities increase in the order of the dithiocyanato-, the dinitro-, the dibromo- and the dichloro-complexes; this trend may be attributed to the differences of the ionic radii of the complex ions since the distance between the cobalt and the ligand ion increases in the order $Cl^-$, $Br^-$, $NO_2^-$ and $NCS^-$. On the other hand, such a trend was not observed for the cis ions. It must, however, be said that the ammine-complexes always have a stronger affinity for a cation exchanger than the corresponding ethylenediamine-complexes; this also be due to the differences of size between ammonia and ethylenediamine molecules.

In the present work, we wanted to study many complexes of the diacido-type, but we were limited by the solubility of the complexes. However, through all the experiments it is to be noted that this kind of technique is useful for distinguishing isomeric forms of complexes, apart from the practical separation of the isomers.

## Summary

Additional elution experiments for confirming the fact that the trans ions of the diacido-tetrammine-type complexes are always eluted faster than the corresponding cis ions have been performed by using several diacido-type complexes which are relatively unstable. By comparing the elution maxima for the whole complex ions which have been used to date, the relative adsorbabilities of the isomeric ions on a cation exchanger have been predicted as follows:

For the trans ions,

$$[Co\ en_2(NCS)_2]^+ < [Co\ en_2(NO_2)_2]^+ \simeq [Co\ en_2Br_2]^+ < [Co\ en_2Cl_2]^+ \simeq [Co\ en_2NO_2Cl]^+ < [Co(NH_3)_4(NO_2)_2]^+ < [Co\ en(NH_3)_2Cl_2]^+$$

For the cis ions,

$$[Co\ en_2Cl_2]^+ < [Co\ en_2(NCS)_2]^+ < [Co\ en(NH_3)_2Cl_2]^+ \simeq [Co\ en_2NO_2Cl]^+ < [Co\ en_2(NO_2)_2]^+ < [Co(NH_3)_4(NO_2)_2]^+$$

A part of the present work was supported by a grant-in-aid from the Ministry of Education.

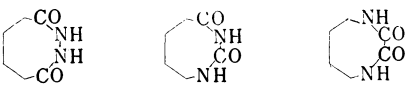
# *The Beckmann Rearrangement of 1, 2-Cyclohexane-dione Dioxime in Liquid Sulfur Dioxide*[1]

By Niichiro TOKURA, Ritsuro TADA and Kunio YOKOYAMA

(Received March 8, 1961)

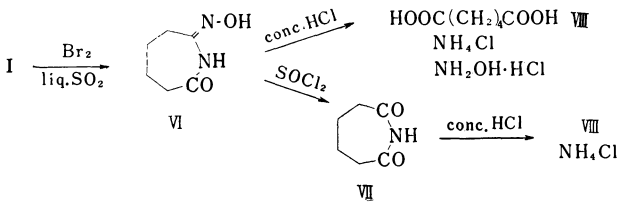
The Beckmann rearrangement of 1, 2-diketone dioxime has scarcely been reported on except in the case of benzil dioximes[2]. In the present article the authors wish to reports on the Beckmann rearrangement of 1, 2-cyclohexanedione dioxime in liquid sulfur dioxide, which resulted in a variety of interesting products.

Several examples of the Beckmann rearrangement, in which the directions of the course of the rearrangement were affected by difference in the reagents applied or conditions used have been published. In a report of Brown, van Gulic and Schmid[3], for instance, the migratory aptitude of pivalophenone oxime was found to be largely dependent upon the nature of the reagent applied, the oxime being subjected to geometrical isomerization before rearrangement[4]. The present authors have also observed that the Beckmann rearrangement of 1, 6-cyclodecanedione dioxime yielded different products accoding to the different reagents used in the rearrangement. Such complicated results have also been reported by McLaren and Schacht[5], and Yukawa and his associates[6]. However, one of the anomalies during the rearrangement, the occurrence of the syn-anti isomerization of the oximes before the rearrangement, can be largely reduced as was reported in a recent article[7] if the reaction is conducted in liquid sulfur dioxide.



In a preceding paper[8], the present authors reported on their unsuccessful attempt at the Beckmann rearrangement of 1, 2-cyclohexanedione dioxime (I) with thionyl chloride in liquid sulfur dioxide. They obtained only a dehydrated product, cyclohexano[c]-1, 2, 5-oxadiazole (II) in a yield of 70 per cent.

I II



Although the reaction with thionyl chloride was unfruitful, however, the bromine in liquid sulfur dioxide and the sulfur trioxide in sulfur dioxide afforded the rearranged products with which the present paper is concerned.

As 1, 2-cyclohexanedione dioxime (I) has not been found to have geometrical isomers and as the various reagent examined in this material have given no symptom of the presence of geometrical isomers, the problem of the possible isomer was excluded in this experiment. In view of the authors' experience with the Beckmann rearrangement, it is interesting to examine the formation of the three possible cyclic acidamide III, IV, V or the mixture of these compounds in the reaction products. But the transformation to any of these three has not been observed.

III IV V

Bromine in liquid sulfur dioxide yielded a half-rearranged product as follows:

6) Y. Yukawa, "Jikken Kagaku Koza", Vol. 18, Maruzen, Tokyo (1958), p. 426.
7) R. Tada, Y. Masubuchi and N. Tokura, This Bulletin, **34**, 209 (1961).
8) Part VII of this series, This Bulletin, **34**, 270 (1961).

The product was contaminated with a large amount of brown resinous matter from which white crystalline substances VI were isolated by acetone extraction in a yield of 32 per cent. A very small amount of II was also found in the mixture. The substance VI, m. p. 155°C, was soluble in water, acid, base, ethyl alcohol and acetone respectively but was insoluble in ether, benzene and chloroform. When VI was subjected to hydrolysis with concentrated hydrochloric acid, adipic acid, ammonium chloride[9] and hydroxylamine hydrochloride[10] were identified in the reaction mixture; no hydrazine salt was found in the mixture[11], however, the infrared spectrum of VI also proved the presence of OH and NH (2900~3200 $cm^{-1}$, strong and broad) and carbonyl (1620~1600 $cm^{-1}$, strong) groups. Moreover, the NMR spectrum of VI in dimethylsulfoxide confirmed the presence of =NOH and =NH, as in Fig. 1[12]. The peak of the oximine group was consistent with that of cyclohexanoxime, and the very low and broader absorbancy in the higher field corresponded to that of the imino group.

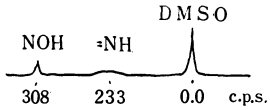

Fig. 1. NMR spectrum of VI in DMSO. c. p. s. was taken with that of DMSO as standard.

Thus the structure of VI was established as 1-aza-7-oximinocyclohepta-2-one. In order to effect the rearrangement of the remaining oximino group of VI, VI was further subjected to a reaction with thionyl chloride in ether. The resultant product seemed likely to be adipic imide (VII)[13], the oximino group being eliminated from VI without accepting further rearrangement. The hydrolysis of VII with concentrated hydrochloric acid afforded adipic acid (VIII) and ammonium chloride. The infrared spectrum of VII was agreeable with that of cyclic imide as reported by Vegstky et al.[14]

The attempted rearrangement with sulfur trioxide in liquid sulfur dioxide was accompanied by a large resinous matter. By extracting the viscous reaction mixture with ether, an orange oil (IX) was obtained. The oil boiled at 181~183°C/17 mmHg, and its yield was 23 per cent.

$$\mathrm{I} \xrightarrow[\text{liq. } SO_2]{SO_3} \underset{NH_2OH}{NC\text{-}(CH_2)_4\text{-}COOH} \xrightarrow{\text{conc.HCl}} \underset{\mathrm{IX}}{\mathrm{VIII}}$$

The compound IX was identified as δ-cyanovaleric acid from the elemental analysis, the infrared spectrum, the hydrolysis to adipic acid, the esterification and the saponification value of the ester. The present authors also found hydroxylamine in the residue of the reaction mixture by the diacetyl monoxime method[10]. Thus, the cleavage of I to IX seems likely to pass through an intermediate, 1,2-cyclohexanedione 2-monoxime (X), which might be derived through partial hydrolysis of an oximino group of I, the so-called Beckmann rearrangement of the second order being followed. An alternative explanation is also conceivable and will be discussed later.

## Experimental

**Materials.**—Commercial sulfur dioxide was dried with concentrated sulfuric acid[15] and distilled.

Bromine was dehydrated with concentrated sulfuric acid and distilled. Sulfur trioxide of extra pure grade was used without further purification. 1,2-Cyclohexanedione dioxime (I) was synthesized[8] from 2-halo-cyclohexanone by reacting with hydroxylamine in yields of 10 to 34 per cent.

**Infrared Spectrum.**—A Perkin Elmer model 21 infrared spectrophotomer was used.

**NMR Spectrum.**—A Varian Associates' type V-4300 (40 mc.) nuclear magnetic resonance spectrometer was used.

**Reaction of Bromine on I.**—The dioxime(I) (14.2 g.) and bromine (35.2 g.) were reacted in 150 ml. of liquid sulfur dioxide at room temperature for one hour. When the reaction was over, the solution was poured into ice-water, the sulfur dioxide was evaporated and the residue was extracted with ether. From the ether extract, colorless crystals were obtained after the condensation of the solution. This substance was identified as cyclohexano-[c]-1,2,5-oxadiazole (II), which had already been produced and confirmed by the reaction of thionyl chloride on I in liquid sulfur dioxide[8], by its m. p. and mixed m. p. of 25.5~26.0°C: the yield was 0.6 g. (4%). The residual solution was neutralized with sodium carbonate and extracted with chloroform. Seven grams of resinous material was obtained from the solution, but the nature of this material was obscure.

The residual solution of the chloroform extraction was condensed in vacuo and triturated with acetone. On the evaporation of acetone, 4.6 g. (32%) of colorless crystals resulted. This crystal, VI, melting at 155°C (from water or ethyl alcohol), was soluble in water, acid, base, ethyl alcohol and acetone respectively but was insoluble in ether, benzene and

chloroform. The elemental analysis showed no difference to the starting oxime I, suggesting that a rearrangement was undertaken in this reaction.

Found: C, 51.21; H, 6.85; N, 19.68. Calcd. for $C_6H_{10}O_2N_2$: C, 50.69; H, 7.07; N, 19.71%. IR $\nu_{max}^{KBr}$ 2900~3200 (strong and broad, -OH and =NH); 1660 (strong and broad, =CO) and 1620 weak, -C=N) $cm^{-1}$, respectively.

**Hydrolysis of VI.**—VI (2.0 g.) was refluxed for 2 hr. in concentrated hydrochloric acid. After the reaction, the colorless needles (III) so produced were filtered and recrystallized from ethyl alcohol, 1.1 g., m. p. 151~152°C. The mixed melting point with adipic acid showed no depression.

Found: C, 49.46: H, 6.94. Calcd. for $C_6H_{10}O_4$: C, 49.31: H, 6.90%.

The filtrate was evaporated to dryness. This residue contained ammonium chloride (Nessler test). Also hydroxylamine hydrochloride was identified[10]. No hydrazine salt was found in the residual mixture[11].

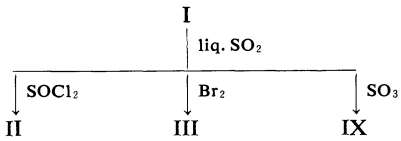
**Reaction of IV with Thionyl Chloride.**—VI(0.5 g.) was refluxed in ether (20 ml.) with thionyl chloride (0.5 g.) for fifteen minutes. The reaction mixture was poured into ice-water, and white powder (0.2 g.), m. p. 166.5°C., was yielded by the ethereal solution. This compound VII was assumed to be adipic acid imide from the elemental analysis, the infrared spectrum and the hydrolysis with concentrated hydrochloric acid to adipic acid (VIII), the melting point and the mixed melting point being 152°C.

Found: N, 1030, Calcd. for $C_6H_9O_2N$: N, 11.02%. IR $\nu_{max}^{KBr}$ 3200 and 3350, (strong, =NH), 1700 (=CO) and 2950 (=$CH_2$) $cm^{-1}$, respectively. From the reaction mixture of the hydrolysis, after the filtration of the afforded adipic acid, neither hydrazine nor hydroxylamine salt was identified by the procedure described above.

**Reaction of I with Sulfur Trioxide.**—I (7.1 g.) and sulfur trioxide (10.0 g.) were reacted in 100 ml. of sulfur dioxide for one hour at room temperature. The reaction mixture was poured into ice-water, after which the sulfur dioxide was allowed to evaporate and was then extracted with ether. The ethereal solution was washed with water, dried and evaporated. An orange-colored liquid (IX), boiling at 181~183°C/17 mmHg, $n_D^{17}=1.4452$, 1.6 g. (23%), was obtained and identified as δ-cyano-valeric acid, (literature[16], b. p. 158~160°C/5 mmHg, $n_D^{20}=1.4481$).

The residual solution after the extraction contained a large amount of resinous matter which could not be further examined.

Found: N, 10.53. Calcd. for $C_6H_9O_2N$: N, 11.02%. IR $\nu_{max}^{liq.}$, 3000~3300 (strong and broad, -OH), 2260 (medium, -CN) and 1700 (strong, =CO) $cm^{-1}$, respectively.



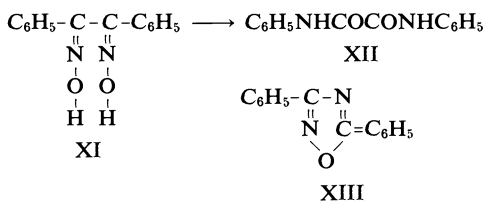
**Hydrolysis of IX**—IX(0.3 g.) was reacted with 3 ml. of concentrated hydrochloric acid by refluxing. On cooling of the reaction mixture, colorless needles were obtained in the mixture, which on admixture with adipic acid (VIII) showed no depression of the m. p. of 151~152°C.

**Esterification of IX.**—IX(2.0 g.) and two drops of concentrated sulfuric acid in 4 ml. of absolute ethyl alcohol were refluxed for 24 hr. The mixture was then mixed with water, and the separated oil was dried and distilled. An oil of b. p. 252~256°C 760 mmHg, (reportedly[16] 145~150°C/24 mmHg), was obtained. This oil was consistent with ethyl δ-cyano-valerate.

Found: C, 60.83; H, 8.37; N, 8.44, Calcd. for $C_8H_{13}O_2N$: C, 61.91; H, 8.44; N, 9.03%. Sapon. value, Found, 706.5, Calcd., 722.5.

## Discussion

When I was reacted with three different reagents, thionyl chloride, bromine and sulfur trioxide respectively, in liquid sulfur dioxide, for one hour at room temperature, three different products were obtained, viz., cyclohexano[c]-1, 2, 5-oxadiazole (II), 1-aza-7-oximino-cycloheptа-2-one (VI) and δ-cyano-valeric acid (IX) respectively, among which the first has been presented in a preceding paper[8].



If the reactions were performed without sulfur dioxide, no such simple product was obtained. Thus, thionyl chloride yielded much resinous matter, and II was obtained in a yield of zero to ten per cent. Bromine afforded only nitrosobromo compound, the presence of which was recognized by the blue color formation. Sulfur trioxide also produced a large amount of resin. This means that the reaction in liquid sulfur dioxide was greatly favored by the assistance of the solvation of this solvent, which enabled the reaction to be carried out at a lower temperature and to avoid various side reactions.

The results obtained above may be useful to enhance our understanding of the mechanism of the Beckmann rearrangement in liquid sulfur dioxide. Not only were the three products different, but the features of the respective processes were entirely different.

They were a dehydrative condensation, a Beckmann rearrangement of one of the two oximino groups, and a ring cleavage reaction respectively. The Beckmann rearrangement of 1, 2-diphenyl-1, 2-dione dioxime (benzil dioxime) which reportedly consisted of three geometrical isomers, has already been reported[17]. According to Meisenheimer and Lamparten[2], the β-isomer of XI afforded oxanilide XII, both of the two oximino groups rearranging, whereas α- and γ-isomers yielded

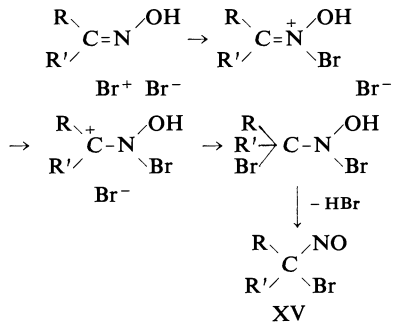
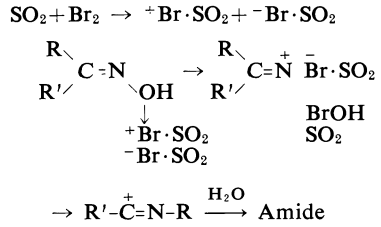
3, 5-diphenyl-1, 2, 4-oxadiazole (XIII), a product of one oximino group rearrangement followed by dehydration. The reagent used were thionyl chloride and phosphorus compounds.



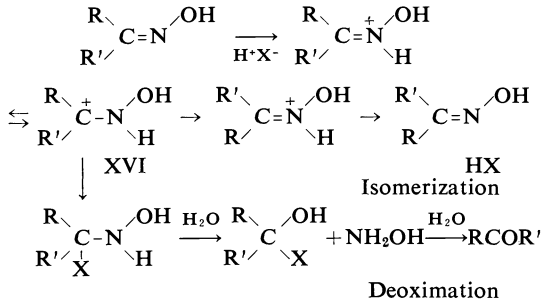
That a simple dehydration occurred by thionyl chloride from I to II indicates that the rate of the Beckmann rearrangement of I with thionyl chloride was much less than the rate of condensation with the same reagent in liquid sulfur dioxide. In such a cyclic dioxime as I, the steric impedence by the ring enlargement, if it arose, would be considerable. On the other hand, in the case of XI, no steric hindrance was anticipated, and the formation of azilinium cation favorable for the Beckmann rearrangement may be greatly assisted by the participation of the phenyl group.

The predominance of the condensation reaction between the two competitive reaction is a result of the nature of the reagent (thionyl chloride). A=N-O·SOCl group formed from a reaction between thionyl choride and a oximino group will easily produce a sulfite linkage XIV by reacting with another oximino group, for these two groups are occupying positions very close to each other. Consecutively, the formation of a sultone via the Bissinger rearrangement[18] and the conversion of the sulfite to II by elimination of the sulfur dioxide molecule would be undertaken. Very recently, Gillis[19]



has reported the formation of tetrahydrofuran from 1, 4-tetramethylene glycol with thionyl chloride via the sulfite. The derivation of II from I closely resembles this furan formation.

Here, the behavior of bromine in liquid sulfur dioxide is very interesting. When the reagent is bromine only, without sulfur dioxide, the bromine cation will attack the nitrogen atom of the oxime:



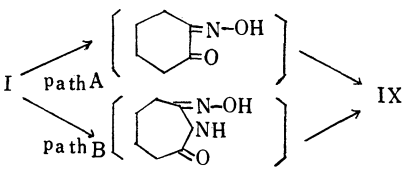
Producing a nitroso bromo compound XV which is characteristically blue in color. However, the bromine in sulfur dioxide[20] may attack the oxygen atom of the oxime, since the voluminous $SO_2$-solvated bromo-cation is liable to prefer the oxygen atom to the nitrogen atom; this would be followed by the rearrangement:

The reason why only one of the two oximino groups will accept the rearrangement is perhaps due to the steric hindrance.

Generally speaking, the attack of hydrogen acid causes some complex results in the attempted Beckmann rearrangement. The side reactions are the isomerization[5,21] of the oxime and the deoximation of the oxime (ketone formation)[21]. The origin of both arises from the same source, the formation of a carbonium ion, XVI:

18) W. Bissinger, F. E. King and C. W. Hamilton, *J. Am. Chem. Soc.*, **70**, 3940 (1948).
19) R. G. Gillis. *J. Org. Chem.*, **25**, 651 (1960).
20) N. Tokura, R. Asami and R. Tada, *J. Am. Chem. Soc.*, **79**, 3135 (1957).
21) R. Tada, Y. Masubuchi and N. Tokura, This Bulletin, **34**, 270 (1961).

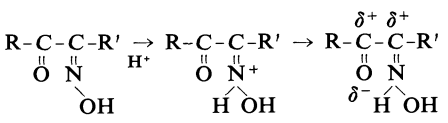
There are many examples of carbonium ion formation from oxime with hydrogen acid, such as hydrochloric acid, sulfuric acid and hydrogen cyanide[21,22]. Such a carbonium ion (XVI) cannot undertake the Beckmann rearrangement. To carry out the rearrangement, an ion-pair formation



$$=N\text{-}O\text{-} \rightarrow =\overset{+}{N}\ \overset{-}{O}\text{-}$$

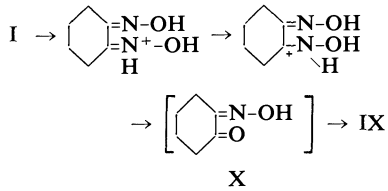
between the two atoms is necessary[23].

The cleavage of I to IX is presumed to pass through an intermediate, 1,2-cyclohexanedione monoxime (X), which may result from a partial deoximation of I, the so-called Beckmann rearrangement of the second order being followed (path A). A small amount of water remaining in the solvent (sulfur dioxide) may be responsible for the deoximation by serving as a source of the proton,



$$SO_3+H_2O+H^+ \rightarrow SO_4H^-$$

An alternate path B might be considered.



However, path B must be ruled out because this route cannot explain the presence of hydroxylamine in the reaction mixture.

The dioxime I has two oximino group sterically interferring with each other, and the elimination of one of the oximes would be a natural consequence. It is a plausible conclusion that I was cleaved to IX, via the stage of cyclohexanedione monoxime (X), the deoximation being effected by sulfuric acid mentioned above. As the result of the material balance of the IX formation, a large amount of resinous matter was recognized. Such a resinification by a dehydration reaction would supply enough water to make the proton source available for the deoximation. The Beckmann rearrangement of the second order, a well-discussed phenomenon[24], may be explained as:

$$\rightarrow R\cdot\overset{+}{C}O + R'CN \xrightarrow{OH^-} RCOOH + R'CN$$

Summarizing the above discussion, the formation of $\delta$-cyanovaleric acid (XI) may be visualized as:

## Summary

Three different reagents, thionyl chloride, bromine and sulfur trioxide in liquid sulfur dioxide were reacted on 1,2-cyclohexanedione dioxime to yield cyclohexano[c]-1,2,5-oxadiazole, 1-aza-7-oximinocyclohepta-2-one and $\delta$-cyanovaleric acid respectively. Only the bromine in liquid sulfur dioxdie effected the Beckmann rearrangement. Thionyl chloride caused a dehydrative condensation, as has been reported previously. Sulfur trioxide yielded a product resulting from a deoximative cleavage. The reasons for the different processes and the different products have been discussed.

The authors are grateful to Befu Chemical Industries Inc., for the donation of liquid sulfur dioxide.

# *Studies of Violanthrone B. I. Reduction and Oxidation of Violanthrone B*[1]

By Junji AOKI

(Receivied March 18, 1961)

When benzanthrone (I) is fused with potassium hydroxide in the presence of phenol or sodium acetate, by its own condensation, violanthrone (II) is obtained; this substance is very useful as a vat dye. On the other hand, as a by-product, a black violet compound which is worthless as vat dye is obtained; this compound is barely vattable at 65~70°C. This worthless compound was found by the study of Maki and denoted as violanthrone B[2]. Further, he suggested III as its formula with one carbonyl group. Although this assumption has been partially confirmed by studies on the condensations of benzanthrone derivatives by Maki and Nagai[3], there remain many doubtful points. Furthermore, recently it has been found by Akamatu and Maekawa[4] that this substance was paramagnetic and that it may be a new radical compound to be known as formula X. Their studies are quite interesting and valuable in the field of the chemistry of this polynuclear system.

From the result of elementary analysis and the preparation of the leucobenzoate (IV) which was obtained by the author by the addition of benzoyl chloride to the vat solution, it has been found, however, that this substance has only one carbonyl group. Following the reduction technique of Clar[5], in which violanthrone A[6] was reduced to violanthrene A (V) with zinc dust in the mixed flux of zinc chloride and sodium chloride, the author obtained the reduction product from violanthrone B. This compound resembles violanthrene A, which shows a strong yellow green fluorescence in organic solvent and is green when dissolved in concentrated sulfuric acid. It is, however, evident that this substance is apparently different from violanthrene A; the reduced compound is more soluble than violanthrene A in organic solvent and the melting point of the former is 344°C (corr.), while that of the later is higher than 360°C[5,7]. In addition, this compound is not identical with isoviolanthrene (IX)[5] either, the reduction product of isoviolanthrone (VIII) prepared by

7) E. Clar, *Ber.*, 76, 458 (1943).

the bimolecular self condensation of 3-chlorobenzanthrone (VII), because isoviolanthrene is yellow green rather than green when dissolved in concentrated sulfuric acid and melts at a temperature higher than 360°C[5,7]. From the results of his chemical analysis, the author has concluded that the reduction product is a new hydrocarbon having a "dibenzanthrene" type skeleton. We denote this hydrocarbon violanthrene B (VI).

When violanthrene A was oxidized with dilute sulfuric acid and potassium bichromate, the author obtained violanthrone A. In an effort to obtain violanthrone B, violanthrene B (VI) was oxidized, but violanthrone B (III) was not obtained. The oxidized product is readily vattable at 30°C and cotton is dyed in it a dark violet. The result of elementary analysis suggested that it may be a quinone of a dibenzanthrene type. This assumption was confirmed by the author, who synthesized its leucodibenzoate at m. p. 335~336°C (corr.).

However, he has found the more interesting fact that the quinone can also be prepared from violanthrone B (III) by a similar operation. Further, from this quinone violanthrene B (VI) was obtained again by zinc dust fusion.

In conclusion, it is reasonable to suppose that all derivatives from violanthrone B have the same polynuclear skeleton, but not those of violanthrene A and isoviolanthrene A.

On the other hand, it has been confirmed by the author that violanthrone B has only one carbonyl group, and further, it has been reported by Nagai et al. that the 6-position of benzanthrone contributes to the formation of the B-compound[3]. Consequently, the hypothetic skeleton (IV), submitted by Maki, coincides with the above facts, but the isomeric formula XI must also be re-considered for the same reason. A detailed discussion will be presented in a later report.

## Experimental

**Violanthrone A (II) and Violanthrone B (III).**—These substances were prepared by the operation stated in Maki's paper[2], but for the purpose of increasing the yield of B-compound, the condition of the alkali fusion was somewhat modified as below. Benzanthrone (I) (10.0 g.) was fused with 40 g. of 85% potassium hydroxide and 4.2 g. of phenol at 220°C for 30 min. (Ref. 2 : 81% potassium hydroxide, 12.4 g. of phenol, 1 hr.).

Violanthrone A was obtained as one product, vattable at 55°C and insoluble in chlorobenzene. Yield, 2.5 g. of violet black powder. The concentrated sulfuric acid solution shows a pure violet color.

The other product, which was barely vattable and insoluble in glacial acetic acid, was violanthrone B. Yield, 5.4 g. of violet black powder. It is soluble in concentrated sulfuric acid as a blue color[8].

Found: C, 91.47; H, 4.35. Calcd. for $C_{34}H_{18}O$ (III): C, 92.28; H, 4.10%.

**Leucobenzoate of Violanthrone B (IV).**—Violanthrone B (III) (0.50 g.) was vatted by heating with 10 g. of sodium hydroxide, 10 g. of sodium hydrosulfite and 200 ml. of water at 70°C and 5 g. of benzoyl chloride was added. The mtxture was shaked without heating for 2 hr. After being allowed to stand overnight, the precipitate was collected and washed neutral. Yield, 0.50 g. of dark brown powder. The product was recrystallized from xylene-petroleum ether, giving red brown needles, m. p. 327~328°C (uncorr.), 340~341°C (corr.). The product is soluble in organic solvent with a strong yellow green fluorescence and in concentrated sulfuric acid solution shows at first a blue color and then a blue green.

Found: C, 89.92; H, 4.19. Calcd. for $C_{41}H_{22}O_2$ (IV): C, 90.09; H, 4.06%.

**Violanthrene B (VI).**—Two gram of violanthrone B (III) in the form of fine powder, was kept with 2.0 g. of zinc dust in the mixed flux of 10 g. of zinc chloride and 2.0 g. of sodium chloride at 260°C for 20 min. Then the mixture was treated with 300 ml. of water and the insoluble material was filtered off. To remove the excess of zinc dust, it was suspended in 100 ml. of water and 30 ml. of concentrated hydrochloric acid was added. After being kept overnight, the insoluble was collected and washed neutral. The crude reduction product (1.8 g.) was sublimated in a high vaccum ($10^{-3}$~$10^{-4}$ mmHg) and recrystallized from 100 parts of *o*-dichlorobenzene, giving orange red needles, m. p. 328°C (uncorr.), 341°C (corr.). This product is soluble in organic solvent with a strong yellow green fluorescence, and in the concentrated sulfuric acid solution shows at first blue and then green, after which it changes no more.

Found: C, 95.56; H, 4.32. Calcd. for $C_{34}H_{18}$ (VI): C, 95.75; H, 4.25%.

**Violanthrene A (V).**—Synthesis was carried out by a method similar to that used for VI[9]. The crude product (1.8 g.) obtained from 2.0 g. of violanthrone A (II), was sublimated in high vaccum and refluxed with 100 g. of *o*-dichlorobenzene for 30 min. The small amount of soluble impurities was removed by hot filtration. Yield, 0.6 g. of brown red crystalline powder, m. p. 476~478°C (uncorr.)[10]. This substance is only with difficulty soluble in organic solvent and in a concentrated sulfuric acid solution shows green color.

**Isoviolanthrene A (IX).**—Synthesis was carried out by a method similar to that used for V. Yield, 32% from isoviolanthrone (VIII). Dark red crystalline powder, m. p. 506~508°C (uncorr.)[11]. The product is only with difficulty soluble in organic solvent and appears as a yellow green coloration in concentrated sulfuric acid.

**Oxidation of Violanthrene B.**—To a solution of

8) The sample was purified by means of chromatography on anhydrous sodium carbonate from *o*-dichlorobenzene.
9) Cf. also Ref. 5
10) Ref. 7, m. p. 478°C.
11) Ref. 7, m. p. 510°C.

1.00 g. of violanthrene B (VI) in 30 ml. of concentrated sulfuric acid was added, with cooling, 30 ml. of water. After cooling till the room temperature, 1.0 g. of potassium bichromate, which had been dissolved in 20 ml. of water, was added. The mixture was stirred for 3 hr. on a boiling water bath and, after being diluted with 300 ml. of water, was filtered. The unchanged VI was separated as the insoluble part by treating it with a 2% alkaline hydrosulfite solution at 30°C, and 0.95 g. of the oxidation product was obtained from the violet filtrate by air oxidation. The crude product, finely powdered, was boiled with 300 g. of *o*-dichlorobenzene with reflux for 2 hr., and insoluble impurities was removed by hot filtration. The filtrate was evaporated to a volume of about 100 ml. for crystallization. The crystal (0.65 g.) formed was recrystallized from chlorobenzene, giving black violet needles, melting point higher than 360°C. The product shows pure blue when dissolved in concentrated sulfuric acid and reddish violet in a hot organic solvent, but it is readily vattable at 30°C while III is with difficulty vatted even at 60°C.

Found: C, 88.74; H, 3.83. Calcd. for $C_{34}H_{16}O_2$; C, 89.46; H, 3.53%.

*Leucodibenzoate.* — The oxidation product (0.50 g.) was vatted by heating with 8 g. of sodium hydroxide, 10 g. of sodium hydrosulfite and 200 ml. of water at 50°C and 5.0 g. of benzoyl chloride was added. The mixture was shaked without heating for 2 hr. and allowed to stand overnight. The precipitate was then collected and the unchanged substance was removed by treating with an alkaline hydrosulfite solution as the insoluble part. The crude product (0.45 g.) was recrystallized repeatedly from *o*-dichlorobenzene-petroleum ether, giving orange brown needles, m. p. 322~323°C (uncorr.), 335~336°C (corr.). This product is only with difficulty soluble in alcohol, when dissolved in benzene, xylene and *o*-dichlorobenzene gives a strong yellow green fluorescence, and in a concentrated sulfuric acid solution gives a bluish green coloration.

Found: C, 85.96; H, 3.93. Calcd. for $C_{48}H_{26}O_4$: C, 86.47; H, 3.93%.

**Oxidation of Violanthrone B.**—By an operation similar to that used for VI, 2.00 g. of violanthrone B (III) was oxidized with 2.0 g. of potassium bichromate and diluted sulfuric acid, and 1.65 g. of crude product was obtained from an alkaline hydrosulfite vat as the soluble part (the insoluble, 0.30 g.). It was boiled with 300 g. of *o*-dichlorobenzene, and 1.00 g. of violet black needles of a melting point higher than 360°C were obtained from the filtrate after hot filtration. The product was easily vattable, was soluble in concentrated sulfuric acid, appearing as a pure blue color, and its absorption spectrum and leucobenzoate are identical with those of the oxidation product of violanthrene B.

*Reduction.* — By zinc dust fusion 0.20 g. of the above mentioned quinone was reduced. The crude product was purified by sublimation in high vacuum and recrystallization from *o*-dichlorobenzene. Yield, 0.06 g. of orange red needles, m. p. 326~328°C (uncorr.). This product was identical with violanthrene B (VI).

**Oxidation of Violanthrene A.**—By an operation similar to that used for VI, 1.00 g. of violanthrene A was oxidized with 1.0 g. of potassium bichromate and diluted sulfuric acid. The crude product was treated with 3% alkaline hydrosulfite solution at 60°C, and the unchanged substance was removed as the insoluble. From the red violet filtrate, 0.85 g. of the oxidation product was obtained. It was boiled with 100 g. of chlorobenzene for 1 hr., filtered and dried. Yield, 0.80 g. of violet black powder, melting point higher than 360°C. The product was soluble in concentrated sulfuric acid, giving a pure violet color, and, further, any other properties were also identical with those of violanthrone A (II) (Found: C, 89.11; H, 4.03%).

The author wishes to express his thanks to Professor Hideo Akamatu, Professor Hiroo Inokuchi and Professor Yoshio Nagai for their kind advice. He is also indebted to Mr. Shozo Masuda for carring out the analyses.

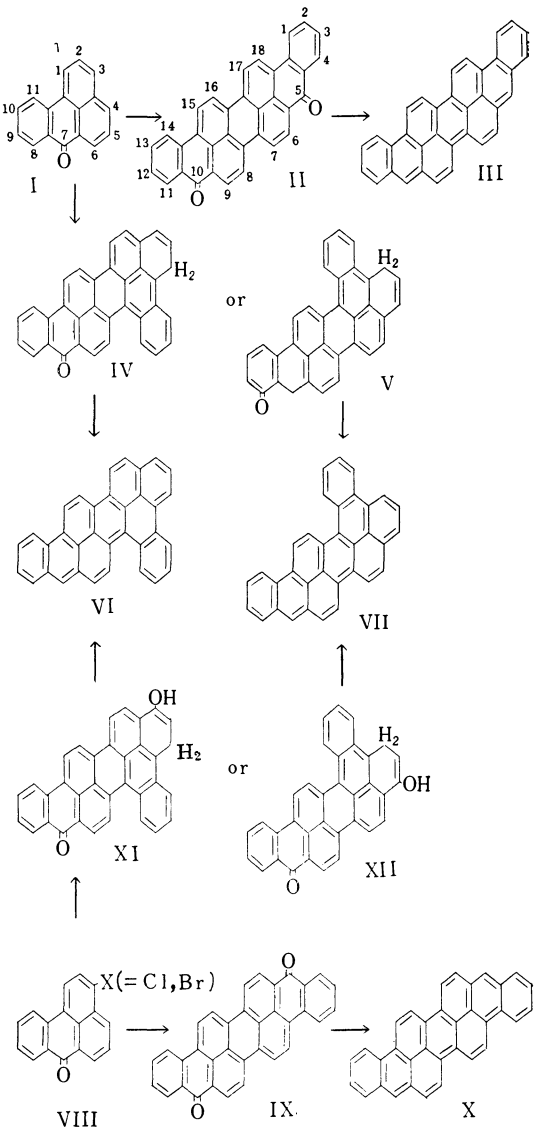
# *Studies of Violanthrone B. II. Reduction of Isoviolanthrone B*



By Junji AOKI

(Received March 18, 1961)

As described in a previous paper[1], the reduction of violanthone B resulted in obtaining the new condensed aromatic hydrocarbon, violanthrene B. Generally, when the method of alkali fussion on benzanthrone (I) derivatives (except 3-position) is applied for the purpose of obtaining the vat dyes of the violanthron (II) series, the B-compound is by-produced with violanthrone derivatives. For example, 4, 11- and 1, 14-dimethoxyviolanthrone were prepared from 8- and 11-methoxybenzanthrone respectivery by alkali fusion, and B-compounds were also obtained[2]. Violanthrone B and these B-componds resemble each other in their vattability and in their coloration with concentrated sulfuric acid. It is, therefore, suggested that the B-compounds by-produced with A-compounds of the violanthrone A type may be derivatives of violanthrone B.

Further, Nagai and Masuda have reported that the 6-position of benzanthrone contributes to the formation of B-compound because the reaction of the alkali fusion of 6-phenylbenzanthrone produces A-compound, but not B-compound[3]. According to these facts, the formula VI or VII can be applied to the skeleton of B-compound, which has only one carbonyl group[4].

On the other hand, there is another type of B-compound, that by-produced with isoviolanthrone (IX) from 3-halogenobenzanthrone (VIII) by heating with alcoholic potassium hydroxide. This B-compound, which is as barely vattable as violanthrone B, has been denoted as isoviolanthrone B by Maki and Nagai[5], and they have suggested as the formula XI, in which the halogen atom was converted into the hydroxl group. In addition, Nagai et al. have reported that the reaction of the alcoholic alkali of 3-chloro-6-phenylbenzanthrone produces A-compound of the isoviolanthrone type, but not B-compound[3].

Therefore, although the formula (XI) appears feasible the isomeric formula (XII) may be also considered, as has been mentioned for violanthrone B[6].

The author has tried to reduce isoviolanthrone B to hydrocarbon by the method of

1) J. Aoki, This Bulletin, **34**, 1817 (1961).

2) T. Maki, *J. Chem. Soc. Ind., Japan*, **38**, 1390 (1935); *Chem. Abstr.*, **30**, 2008 (1936); T. Maki and A. Kikuchi, ibid., **43**, 763 (1940); *Chem. Abstr.*, **35**, 1783 (1941).

3) Y. Nagai and M. Masuda, *J. Chem. Soc. Ind., Japan*, **47**, 529 (1944).

4) Consequently, violanthrone B may be considered as having the formula IV or V; T. Maki has suggested IV as the formula.

5) T. Maki and Y. Nagai, *J. Chem. Soc. Ind. Japan*, **37**, 493 (1934); *Chem. Abstr.*, **28**, 5435 (1934).

6) These compounds may be considered free radical because of their paramagnetism; therefore, instead of formulas IV, V, XI and XII, those which take off one hydrogen atom should be preferred. See also Ref. 1.

TABLE I. PROPERTIES OF "DIBENZANTHRENES"

| | Violanthrene B | | Isoviolanthrene B | | Violanthrene A | | Isoviolanthrene A |

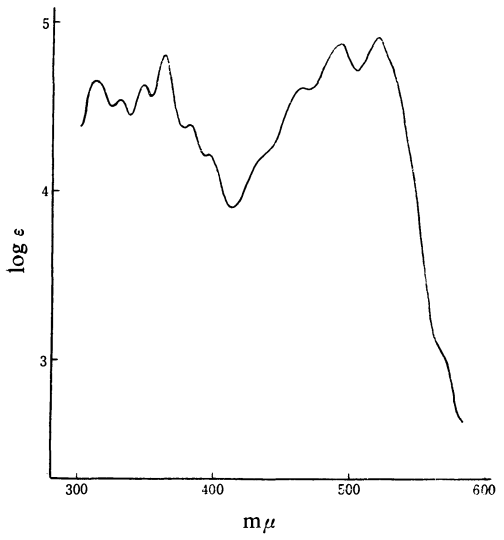

Fig. 2. Absorption spectrum of isoviolanthrene B (in benzene).

zinc dust fusion in order to find the structural formula of this compound. The hydrocarbon obtained from the above method recrystallized from *o*-dichlorobenzene in deep red needles. The meting point of this compound was 400~402°C (uncorr.), and its absorption spectrum was different from that of violanthrene B, as is shown in Figs. 1 and 2. In addition, the properties of this new hydrocarbon, which is called by the author isoviolanthrene B, are quite different from those of violanthrene B, violanthrene A (III) and also isoviolanthrene A (X), as is shown in Table I.

From these facts, we can draw the following conclusions: there are only two types of B-compound, with skeletons assumed to be the fosmulas VI and VII; one of them is violanthrene B and the other is isoviolanthrene B.

## Experimental

**Isoviolanthrone A (IX) and Isoviolanthrone B.**—A mixture of 40 g. of potassium hydroxide, 25 g. of phenol, 15 g. of ethanol and 10.0 g. of 3-chlorobenzanthrone was refluxed with stirring for 2 hr. Then the mixture was treated by the method described in Ref. 5. The yield of isoviolanthrone A was 3.2 g., and this substance is soluble in concentrated sulfuric acid, giving a blue green color. Isoviolanthrone B was obtained as the product, barely vattable and insoluble in glacial acetic acid. In the concentrated sulfuric acid solution it shows as a dark violet color. Yield, 3.0 g. of violet black powder. This sample was once more treated with an alkaline hydrosulfite solution, dissolved in hot chlorobenzene and, after hot filtration, deposited by concentrating the filtrate.

Found: C, 88.80; H, 3.58. Calcd. for $C_{34}H_{18}O_2$ (XI or XII): C, 89.06; H, 3.95%.

**Isoviolanthrene B.**—A fine powder of 1.00 g. of isoviolanthrone B was kept with 1.0 g. of zinc dust in the mixed flux of 5 g. of zinc chloride and 1 g. of sodium chloride at 260~280°C for 30 min. Then the mixture was treated with 300 ml. of water and the insoluble part filtered off. To remove the excess of zinc dust, it was suspended with 100 ml. of water, and 30 ml. of concentrated hydrochloric acid was added. After being kept overnight, the insoluble part was collected and washed neutral. The crude

reduction product (0.80 g.) was sublimated in a high vacuum ($10^{-3}$~$10^{-4}$ mmHg), and recrystallized from *o*-dichlorobenzene, giving deep red fine needles, m. p. 400~402°C (uncorr.). This product is soluble in organic solvent, giving off a strong fluorescence, and in a concentrated sulfuric acid solution shows at first as green and then as a yellow green, after which it changed no more.

Found: C, 95.56; H, 4.34. Calcd. for $C_{34}H_{18}$ (VI or VII): C, 95.75; H, 4.25%.

The author wishes to express his thanks to Professor Hideo Akamatu, Professor Hiroo Inokuchi and Professor Yoshio Nagai for their kind advice. He is also indebted to Mr. Shozo Masuda for carrying out the analyses.

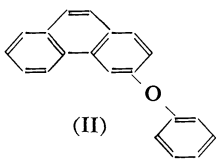
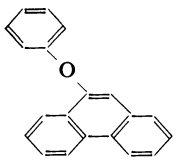
# *Synthesis of Phenanthryl Phenyl Ethers*



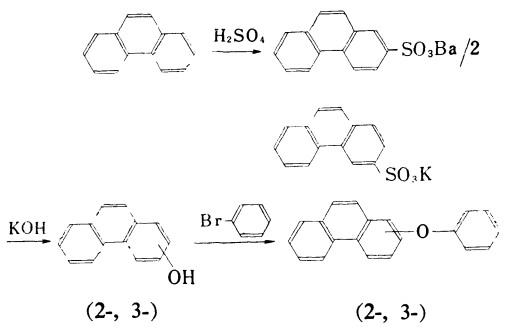
By Hajime SUZUMURA

(Received March 31, 1961)



Searching for aromatic ethers which have high boiling points and thermal stability, derivatives of phenanthrene, 2- and 3-phenanthrylphenyl ethers (Formulas I and II respectively) were synthesized and their physical properties examined. Of the phenanthrylphenyl ethers, only a 9-phenyl isomer (Formule III) has hitherto been reported on the literature[1].

(I)



(II)

(III)

The author newly synthesized 2- and 3-phenyl ethers by the scheme shown below.

TABLE I

(2-, 3-) (2-, 3-)

1) R. L. Huang, *J. Chem. Soc.*, **1955**, 3295.

Purified phenanthrene was sulfonated[2], and a mixture of monosulfonates was fused with potassium hydroxide[3], yielding phenanthrols which were then condensed with bromobenzene to give the ethers. The properties of purified specimens are shown in Table II.

TABLE II. PHENANTHRYLPHENYL ETHERS

## Experimental

**Materials.** — *Phenanthrene.* — A sample supplied by Yawata Chemical Industry Co. was purified by fusion with potassium hydroxide, followed by vacuum distillation, recrystallization from ethanol and treatment with chromium trioxide; m. p. 97~98.5°C, reported 98.7~99.5°C[4].

*Bromobenzene.* — A commercial reagent was redistilled; $n_D^{20.5}$ 1.5598, reported $n_D^{20}$ 1.5602[5].

2) "Org. Synth.", Col. Vol. II (1955), p. 482.
3) Fieser, *J. Am. Chem. Soc.*, **51**, 2466 (1929).
4) J. Heilbron, "Dictionary of Org. Compds.", Vol. IV, Oxford University Press, New York (1953), p. 84.
5) Merck Index, 7th Edition, Merck & Co. Inc., Rahway, N. J. (1960), p. 168.

*Copper Powder.*—This was precipitated from an aqueous solution of $CuSO_4 \cdot 5H_2O$ by the addition of zinc granules and was washed with water, with dilute hydrochloric acid, and finally with ethanol.

*Sulfuric Acid, Potassium Hydroxide.*—Commercial reagent.

**Synthesis of 2- and 3-Phenanthrol.** — Purified phenanthrene (50 g.)* was sulfonated by the method described in the literature[2]. From the reaction mixture, less soluble mono-sulfonic acids were separated as sodium salts, leaving disulfonates in the filtrate. By recrystallizing sodium mono-sulfonates from water, the relatively insoluble 2-isomer was first obtained, which was further purified as barium salt. From the filtrate, by concentration and the addition of potassium chloride, potassium 3-sulfonate was obtained. 2-Ba-sulfonate; 14.1 g., 16% (reported 17~21%). 3-K-sulfonate; 17.6 g., 21% (reported 24~26%). Then the sulfonates were fused with potassium hydroxide. To potassium hydroxide (about 3 parts) melted in a nickel crucible at 290~300°C, barium or potassium sulfonate (1 part) was added gradually over a period of 20 min. by stirring; the heating was continued for a further 5 min. at 320~330°C. The mixture was then allowed to cool and was dissolved in water. The addition of hydrochloric acid to this solution yielded a precipitate which was filtered off.

The precipitate was redissolved in an aqueous solution of potassium hydroxide and filtered off to remove insoluble matter. By the neutralization of the filtrate, crude phenanthrols were obtained which were filtered off and recrystallized from a mixture of ligroin and ethanol. The results of the potassium hydroxide fusion are shown in Table III.

TABLE III

| Phenanthrene sulfonate | Amount g. | Phenanthrol Amount g. | Phenanthrol M. p. °C | Reported m. p. °C |
|---|---|---|---|---|
| 2-Ba | 14 | 5.5 | 162.7~167.7<br>166~168 (purified) | 168 |
| 3-K | 17 | 10.3 | 112.6~118.5<br>116.8~118.9 (purified) | 118~119 |

**Synthesis of 2-Phenanthryl Phenyl Ether.** — A mixture of 2-phenanthrol, potassium hydroxide bromobenzene and copper powder in a flask fitted with an air condenser was placed in an oil bath and heated. The cooled mixture was first treated with a 10% aqueous solution of potassium hydroxide to dissolve unreacted phenanthrol and was then extracted repeatedly with benzene. The combined extracts were concentrated and distilled in vacuo. The distillation apparatus employed was designed for distilling solid samples and equipped with a fractionating column (10 mm.×350 mm.) packed with stainless Dixon packing 2 mm. in diameter. The distillate, which was solid melting at about 110~116°C, was recrystallized 3 times from ethanol, yielding white needles. The experimental results of the condensation reaction are shown in Table IV.

* One tenth of the amount used in Ref. 2.

Found: C, 88.69; H, 5.00; mol. wt. (Rast), 273. Calcd. for $C_{20}H_{14}O$: C, 88.86; H, 5.22%; mol. wt. 270.

*Infrared Absorption Spectrum.*—The spectrum of 2-phenanthryl phenyl ether in carbon bisulfide is shown in Fig. 1. The band appearing at 825 $cm^{-1}$

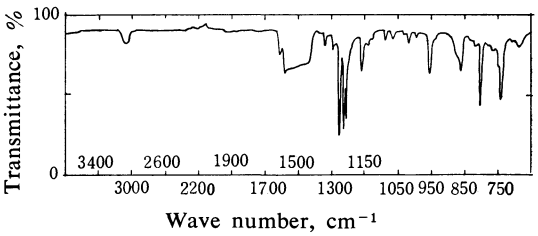

Fig. 1. 2-Phenanthryl phenyl ether.

corresponds to a 1,2,4-substitution in the benzene ring. This means a substitution in the 2- or 3-position of phenanthrene, which may be regarded as a substituted benzene. Similarly, because an absorption band at 807 $cm^{-1}$ which corresponds to a 1,2,3,4-substitution in benzene is absent, the 9- or 10-position of phenanthrene is not substituted. The absence of a strong absorption in the region of 752~753 $cm^{-1}$ shows that a 1,2,3-substitution in the benzene ring is not present; that is, there is no substitution in the 1- or 4-position of phenanthrene. The spectrum which shows characteristic absorptions of 2- or 3-substituted phenanthrene can be clearly distinguished from that of a 3-phenyl isomer, which will be described later. A band at 690 $cm^{-1}$ may be assigned to a phenoxy group. Phenoxynaphthalenes ($\alpha$, $\beta$), *p*-phenoxydiphenyl, and *p,p'*-diphenoxydiphenyl which the author prepared showed a medium absorption in the vicinity of this wave number.

*Ultraviolet Spectra.*—The spectra of the 2-phenyl as well as the 3-phenyl isomer are shown in Fig. 2.

b) Mol. % based on 3-phenanthrol employed.

The absorption maxima are different from those of 2- or 3-alkyl phenanthrene.

*Solubility.*—It is only with difficulty soluble in cold ethanol, readily soluble in benzene, and insoluble in water.

*Trinitrobenzene Complex.*—This was prepared from 2-phenanthryl phenyl ether (86 mg.) and 72 mg. of trinitrobenzene in ethanol. Three recrystallizations from ethanol yielded 45 mg. of short yellow needles, which melted at 133~134°C.

Found: N, 8.91, Calcd. for $C_{26}H_{17}O_7N_3$; N, 8.70%.

**Synthesis of 3-Phenanthryl Phenyl Ether.**—The 3-phenyl isomer was prepared and purified in the same manner as in the case of the 2-phenyl isomer. The experimental results are shown in Table V.

Recrystallization from ethanol gave white needles which melted at 86~87°C.

Found: C, 89.16; H, 5.39; mol. wt. (Rast), 273. Calcd. for $C_{20}H_{14}O$: C, 88.86; H, 5.22%; mol. wt., 270.

*Infrared Spectrum.*—The spectrum in carbon disulfide is shown in Fig. 3.

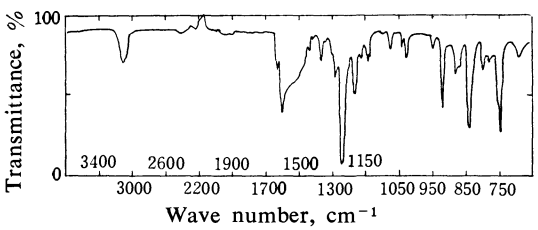

Fig. 3. 3-Phenanthryl phenyl ether.

A band at 690 $cm^{-1}$ corresponds to a phenoxyl group. Other absorption bands appearing in the finger print region are typical of 3-substituted phenanthrene, as a comparison with those of 3-ethylphenanthrene[6] shows:

| | Wave numbers, $cm^{-1}$ | | | | |
|---|---|---|---|---|---|
| 3-Phenanthryl phenyl ether | 880 | 865 | 840 | 798 | 747 |
| 3-Ethylphenanthrene | 881 | 864 | 839 | 800 | 746 |

*Ultraviolet Spectrum.*—The spectrum is shown in Fig. 2.

*Solubility.*—It is only with difficulty soluble in cold ethanol, moderately soluble in benzene, and insoluble in water.

*Trinitrobenzene Complex.*—This was prepared from ether (99 mg.) and trinitrobenzene (108 mg.) in ethanol. Three recrystallizations from ethanol yielded 73 mg. of a pale yellow adduct, m. p. 111~112°C.

Found: N, 8.96. Calcd. for $C_{26}H_{20}O_7N_3$, N, 8.70%.

The author is indebted to Professor Ryozo Goto of Kyoto University for his helpful discussions and for his criticisms of this work, and to Professor Sakujiro Kimura for his advice and encouragement.

# *Studies on Isoprenoide. XIII. Transformation of Pinene by the Action of Boron Trifluoride*

By Kimiko NAGAI

(Received March 25, 1961)

The transformation in the reaction of various reagents upon pinenes have been investigated[1-4] in detail, and the existence of camphene has been observed in the conversion products of pinene in almost all cases. The author has been engaged in a series of experiments on the reaction of boron trifluoride, an electrophilic agent, upon terpenes. It has been reported[5] that the reaction of boron trifluoride upon terpenes produces mainly polymerized products; my experiments seen to verify this.

According to another paper[6] stating that isoborneol was produced by the reaction of glacial acetic acid upon camphene with a catalyst of boron trifluoride, the author has obtained bornyl acetate in a considerable yield in the reaction of glacial and anhydrous acetic acids upon $\alpha$-pinene with a catalyst of boron trifluoride, as has been formerly communicated[7].

Because in this reaction $\alpha$-pinene is isomerized to camphene by boron trifluoride ethyl ether complex and further is esterified[6], the isomerization of $\alpha$-pinene to camphene in the absence of glacial and anhydrous acetic acids was attempted. Namely, solutions of boron trifluoride ethyl ether complex in various solvents were prepared, $\alpha$-pinene was subjected to a reaction at room temperature with various amounts of catalyst and various reaction times, and the transformation of $\alpha$-pinene and the production of camphene were investigated, taking advantage of the infrared absorption spectrum and gas chromatography.

The determination of $\alpha$-pinene and camphene based on the infrared absorption spectrum has already been investigated by Kitajima, Takeshita et al.[8], who adopted 772 $cm^{-1}$ for $\alpha$-pinene and 667 $cm^{-1}$ for camphene as a characteristic absorption in the practice of estimation. The author adopted 1130 $cm^{-1}$ for $\alpha$-pinene and 1115 $cm^{-1}$ for camphene, made a calibration curve using $\alpha$-pinene purified by distillation, and diluted solutions of camphene 10~80 per cent, for which determination was carried out on the amount of $\alpha$-pinene and camphene in the reaction products catalyzed by boron trifluoride ethyl ether complex; at the same time, this result was compared with that of gas chromatography.

When a catalyst, boron trifluoride ethyl ether complex, was used with a solvent of ligroin or benzene, and also when it was directly applied to $\alpha$-pinene without the use of any solvents, violent heat generation and polymerization occurred, and the degree of heat generation and polymerization descending from ligroin through benzene to an absence of solvents.

When ethyl ether was used as a solvent, the generation of heat was hardly observed, and it was noted from the infrared absorption spectrum that by the action of boron trifluoride ethyl ether complex, $\alpha$-pinene is converted to camphene through the Wagner-Meerwein rearrangement and that the greater the extent of isomerization to camphene the larger the amount of boron trifluoride ethyl ether complex used and the longer the reaction time.

As the infrared absorption spectrum show peaks at 817 and 827 $cm^{-1}$, the existence of a group $\begin{matrix} R \\ R' \end{matrix}\!\!>\!C=C<\!\!\begin{matrix} R'' \\ H \end{matrix}$ is presumed, and hence the formation of polymers of $\alpha$-pinene is conceivable.

Reaction products in the solvent of benzene or ligroin for which no heat generation and polymerization appeared showed such infrared absorption spectra that, while the characteristic absorption (at 1130 $cm^{-1}$) was not observed, that for camphene was observed faintly at 1115 $cm^{-1}$ and those for end-methylene and *gem*-dimethyl radical were observed at 877 and 1660 $cm^{-1}$, and at 1363 and 1384 $cm^{-1}$ respectively. Gas chromatography of these reaction products showed a small peak corresponding to camphene; also in the case of solvents of benzene or ligroin, the formation of camphene was found, though in an extremely small amount.

In this reaction, the isomerization of $\alpha$-pinene into camphene by the action of boron

trifluoride ethyl ether complex through the Wagner-Meerwein rearrangement was confirmed, and in the case of a violent reaction, although it almost polymerizes, the formation of a small amount of camphene was detected.

## Experimental

**Sample.** — α-Pinene and camphene purified by repeated distillation on metallic sodium were used. The physical constants of the samples are as follows: α-pinene b. p. 154.5~156°C, $d_4^{25}$ 0.8550, $n_D^{25}$ 1.4641; camphene b. p. 154~155°C, m. p. 47.0~47.5°C.

**The Calibration Curve of α-Pinene and Camphene.**—Camphene was diluted with α-pinene 10~80 per cent, and the characteristic absorption at 1130 and 1115 $cm^{-1}$ was selected for the infrared absorption spectra of α-pinene and camphene respectively; from the ratio of the above two absorptions, a calibration curve as seen in Fig. 1 was obtained.

TABLE I. RATIO OF ABSORPTION AT 1130 AND 1115 $cm^{-1}$

| α-Pinene % $I_1$ | Camphene % $I_2$ | $\log I_1/I_2$ |
|---|---|---|
| 100 | — | 0.5090 |
| 90 | 10 | 0.6256 |
| 80 | 20 | 0.7238 |
| 70 | 30 | 0.8443 |

$I_2$: The height of the minimum point on the absorption band of camphene

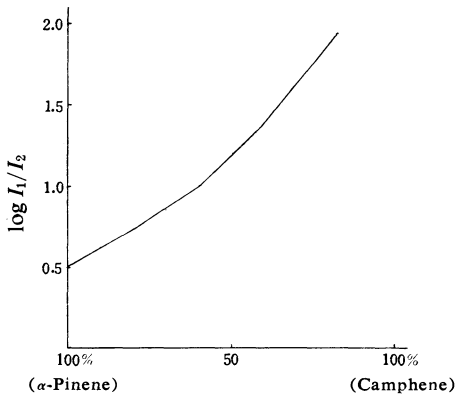

Fig. 1. Calibration curve of camphene and α-pinene.

**Reaction in the Solvent of Ethyl Ether.** — A mixture of α-pinene 10 ml. and ethyl ether 15 ml. was added to each 0.8, 1.5, 2.0 and 3.0 ml. of boron trifluoride ethyl ether complex and was allowed to react for 72 hr. at room temperature; after washing with 10% sodium carbonate and water, followed by drying, the reaction product was examined with the aid of the infrared absorption spectrum and gas chromatography. Figure 2 is the infrared absorption spectrum of the product obtained when α-pinene, camphene and 3.0 ml. of a catalyst were used. As shown from the calibration curve in Fig. 1, the yield of camphene is maximum, about 50 per cent, when 3.0 ml. of boron trifluoride ethyl ether complex was used, whereas in the reaction with 0.8 ml., the α-pinene remained almost unchanged.

Moreover, the relation between the yield of camphene and the reaction time in the case of 3.0 ml. of boron trifluoride ethyl ether complex was investigated; the result is shown in Table III, from which it can be observed that a large amount of

TABLE III. RLATION BETWEEN THE YIELD OF CAMPHENE AND REACTION TIME

| | | | | |
|---|---|---|---|---|
| Infrared absorption spectrum | Reaction time, hr. | 24 | 48 | 72 |
| | Camphene % | 49.5 | 49.9 | 50.5 |
| | Absorption coefficient | 1.210 | 1.213 | 1.225 |
| Gas chromatography | Reaction time, hr. | 24 | 48 | 72 |
| | Camphene % | 50.9 | 51.2 | 51.5 |
| | $\alpha$-pinene, % | 12.8 | 12.4 | 10.6 |

camphene is formed in the case of an hour-long reaction.

**Reaction in the Solvent of Benzene and Ligroin.**—To 10 ml. of a sample, 15 ml. of both benzene and ligroin were added, and boron trifluoride ethyl ether complex was added to the benzene solution in amounts of 0.3, 0.5 and 1.0 ml. and to the ligroin solution in amounts of 1.5, 2.0 and 3.0 ml., and after reaction ceased, treatment similar to that described above was performed. In the case of these reactions, heat generation and polymerization occurred violently; when the amount of catalyst was small, the existence of camphene was observed, but $\alpha$-pinene was not, as shown from the data of the infrared absorption spectra and gas chromatography, although the estimation of the camphene formed was nevertheless difficult.

**Reaction Without Solvents.**—This reaction shows a remarkable heat generation and polymerization, yielding reddish-brown, viscous, oily substances; because the existence of $\alpha$-pinene was still observed only on the basis of the infrared absorption spectrum and gas chromatography, the estimation was not successful.

The author wishes to express her gratitude to Assistant Professor I. Ogura for his guidance and encouragement throughout this work, and her sincere thanks to Mr. K. Machida, Kyoto University, for his services in the measurement of the infrared absorption spectrum and to Mr. K. Matsushima of our University for his help in the analysis of gas chromatography.

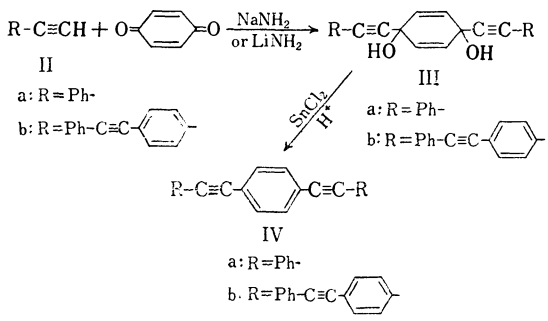
# *Alternant Conjugate Systems. I. Syntheses and Properties of Polytolans*

By Shōichi Misumi

(Received March 7, 1961)



Alternative insertion of benzene nuclei between the triple bonds of the polyacetylenic chain of $\alpha,\omega$-diphenylpolyyne constitutes an interesting conjugate system, polytolan (I). The present author has investigated the syntheses of a series of polytolans (I; $n=2$, 3, 4) to compare their ultraviolet spectroscopic properties with those of polyphenylpolyene[1] and diphenylpolyacetylene.

I

The several methods[2-4] proposed for the synthesis of tolan all seem to be inadequate to the syntheses of the higher homologues owing to the poor solubility or the difficulty in the syntheses of the intermediates.

During the course of a study concerning the reaction of quinones with acetylenes, the author has found that polytolans having an even number of $n$ can be synthesized according to the following series of reactions. For example, the reaction of sodium phenylacetylide(IIa) in

liquid ammonia with *p*-benzoquinone afforded the diacetylenic glycol (IIIa) in a yield of 31%. The reductive aromatization of IIIa with phosphorus diiodide or stannous chloride[5] resulted in the formation of distolan(IVa)[6]. Independently, IVa was synthesized by Ried according to essentially the same procedure[7]. The generalization of the reductive aromatization was achieved by his employing several kinds of quinones[7].

The present author has employed this method for the synthesis of tetrakistolan (I; $n=4$). The reaction of *p*-benzoquinone with the sodium salt of *p*-ethynyltolan (IIb) in liquid ammonia, in which IIb and its sodium salt are sparingly soluble, resulted in a recovery of the starting materials. As it was known that a lithium salt of an ethynyl compound has a larger solubility than a salt of other alkali metal[8], the reaction of the lithium salt of IIb with *p*-benzoquinone was carried out in dioxane, yielding tetra-acetylenic glycol(IIIb) in a yield of 13%. The reductive aromatization of IIIb afforded tetrakistolan (IVb) as light yellow needles with a green fluorescence. The solutions of IVb in various organic solvents exhibit an intense and characteristic violet fluorescence.

*p*-Ethynyltolan (IIb), which was used as a starting material for the synthesis of IVb, was synthesized according to the following series of reactions. A quantitative yield of the ester (VIII) was obtained by refluxing the suspension of *p*-styrylcinnamic acid (VII)[9] in methanol containing a catalytic amount of sulfuric acid. The dehydrobromination of the tetrabromide (IX) resulted in *p*-phenylethynyl-phenylpropiolic acid (X), together with a small amount of decarboxylated product (IIb). Several methods have been proposed for the decarboxylation of substituted phenylpropiolic acids[10-11], but the author has found that the acid (X) in pyridine or quinoline was smoothly decarboxylated to IIb in the presence of copper powder. Extension of the synthetic route of phenylacetylene[12] from cinnamic acid to styrylcinnamic acid (VII) was found to be unsuccessful owing to the poor solubility of the intermediate tetrabromide in various solvents.

*p*-Ethynyltolan (IIb) crystallizes in the form of colorless needles and gives amorphous yellow cuprous salt. Its mercuric acetylide was obtained in well-defined fine silky needles. As illustrated in Fig. 1, the ultraviolet spectrum of IIb was found to be closely related to tolan rather than to phenylacetylene, with a red-shift of ca. 15 mμ. The oxidative coupling of IIb according to Eglinton's method[13] afforded bis(*p*-phenylethynyl-phenyl)diacetylene (XI) as colorless plates. The disappearance of fine structure in the ultraviolet spectrum of XI as compared with that of diphenyldiacetylene is remarkable (Fig. 1).

Tristolan (I; $n=3$) was synthesized from

*p,p'*-distyrylstilbene[14] according to the procedure of Drefahl[2].

The ultraviolet spectra and the physical properties of these polytolans are presented in Fig. 2 and Table I. An examination of the ultraviolet spectra of polytolans indicates that an increase in the length of the conjugate system causes a displacement of the strongest absorption band towards a longer wavelength; this bathochromic displacement, however, becomes smaller for each additional $-C_6H_4-C\equiv C-$ grouping. Two empirical formulae ($\lambda=kn+\lambda_0$ or $\lambda=k\sqrt{n}+\lambda_0$) have been proposed to relate the number of double bonds in a conjugated chromophore group ($n$) with the wavelength of the absorption maximum ($\lambda$)[15], but the absorption maxima of polytolans could not be expressed by either of these empirical formulae, because the plot of the wavelength of the absorption maxima against $n$ or the square root of $n$ does not give a straight line, as is illustrated in Fig. 3.

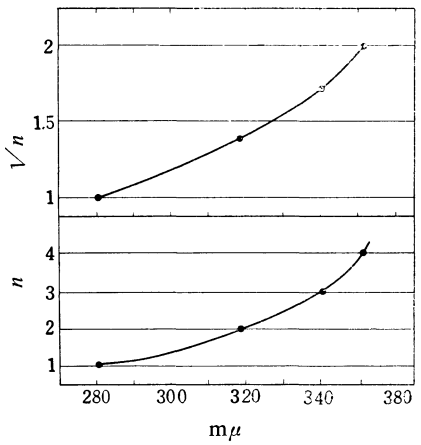

Fig. 3. Wavelength positions of the main absoption maxima plotted against number or $n\sqrt{n}$ of polytolans (I).

The spectra of tristolan (I; $n$=3) and tetrakistolan (I; $n$=4) showed absorption maxima at 256 and 279 mμ respectively. Similar maxima are also observed in the spectra of the corresponding ethylenic analogues. The occurrence of these bands can presumably be attributed to a higher order transition of the total chromophore, as is pointed out by Dale[16] and Zechmeister et al.[17].

The ultraviolet spectra of diphenylpolyacetylenes exhibit a regular bathochromic shift in accordance with the increase of the number of acetylenic linkage, also, the fine structure of the spectra becomes more and more distinct with the increase in the length of the conjugate system[18]. The same trend is also recognized in the case of diphenylpolyenes[19]. Kortüm attributed the increase in the fine structure of the spectra of diphenyl-polyyne and -polyene to the increase of the double bond character of single bonds in these conjugate systems. The increase in double bond character results

* inflexion ; a : $n$-hexane, b : benzene, c : chloroform, d : 95% alcohol

in a fixation of the molecule in a uniplanar conformation and necessarily retards the torsional vibration of the molecule[20].

On the contrary, the fine structure in the spectra of polytolans gradually becomes obscure with the increase in the length of the alternant conjugate system. The distinct fine structure observed in the spectrum of tolan can be traced in that of distolan (IVa), but the spectra of tris- and tetrakis-tolan show only a weak inflection at the corresponding positions, as is illustrated in Fig. 2. The single bond length of the $C_6H_5$-C≡ grouping has been reported to be almost identical in the series of diphenylpolyyne, whereas a distinct contraction of the single bond length inserted between two acetylenic linkages was observed in the same series, as

Table II. Single bond lengths in diphenylpolyyne Ph-(C≡C)$_n$-Ph

| $n$ | Bond length of Ph-C≡ Å | Bond length of ≡C-C≡ Å | Ref. |
|---|---|---|---|
| 1 | 1.40 | — | 21 |
| 2 | 1.44 | 1.39 | 22 |
| 4 | 1.42 | 1.37, 1.33, 1.37 | 23 |
| 5 | 1.45 | 1.39, 1.33, 1.33, 1.39 | 23 |

is summarized in Table II. These results indicate that the single bond in the $C_6H_5$-C≡ grouping has a minor degree of multiple bond character as compared with the single bond in ≡C-C≡ grouping. Consequently, an insertion of the $p$-phenylene group in a position of single bond in a conjugate polyyne chain may cause an increase of torsional vibration about the single bond of the ≡C-$C_6H_4$-C≡ grouping. Also, the increase in the number of single bond with a minor multiple bond character may increase the transition energy of photoecxitation. The disappearance of the fine structure and the hypsochromic shift of absoption maxima in the spectra of polytolans as compared with those of diphenylpolyynes seem to be attributable to the above-mentioned two reasons. This inference is also cosistent with the fact that $p$-ethynyltolan and tolan show quite similar absorption curves (Fig. 1) and the fact that the fine structure which is observed in the spectrum of diphenyldiacetylene is almost lost in the absorption curve of bis($p$-phenylethynyl-phenyl)diacetylene (XI) (Fig. 1).

The ultraviolet spectrum of distolan reported by Drefahl[2] showed a strong inflection at ca. 350 mμ which could not be observed in the spectrum of the compound prepared by the author. The presence of inflection at this wavelength seems to arise from a contamination with the starting material, $p$-distyrylbenzene ($\lambda_{max}$ 350 mμ) or $p$-styryltolan ($\lambda_{max}$ 333 ; $\lambda_{infl.}$ 352 mμ).

## Experimental*

**1, 4-Bisphenylethynyl-2, 5-cyclohexadien-1, 4-diol (IIIa).**—To a solution of sodium amide (prepared from sodium, 3.8 g., 0.167 mol.) in liquid ammonia (100 ml.) was added dropwise phenylacetylene (17 g., 0.167 mol.) in dry ether (50 ml.). After stirring for 2 hr., $p$-benzoquinone (10 g., 0.093 mol.) in dry tetrahydrofuran (70 ml.) was dropped into the mixture over a period of 3 hr. A transient development of blue color was observed on the addition of the quinone, and the entire mixture gradually changed to a deep brown solution. Ammonia was evaporated after the addition of ammonium chloride, and the residual solid was extracted with ethyl acetate. The extract was thoroughly washed with water and dried. After removal of the solvent, the residue was dissolved in ethyl acetate-benzene and passed through a short column of alumina. The crude crystals obtained on concentrating the solvent were recrystallized from benzene to give IIIa, colorless leaflets, m. p. 176~177°C, yield 8.1 g. (31.2%). (Ried[7] reported a yield of 50~55% employing lithium amide.)

Found : C, 84.47 ; H, 5.04. Calcd. for $C_{22}H_{16}O_2$ : C, 84.59 ; H, 5.16%.

* All melting points are uncorrected.

IR max($cm^{-1}$) 3320, 3260($\nu_{OH}$), 2225($\nu_{C\equiv C}$), 1007($\delta_{OH}$).

***p*-Bis(phenylethynyl)benzene [Distolan] (I : n=2)**—A solution of stannous chloride dihydrate (1.0 g.) in concentrated hydrochloric acid (3.0 ml.) was added to a stirred solution of the glycol (IIIa, 388 mg.) in tetrahydrofuran (20 ml.), and the mixture was stirred for several hours at room temperature. After standing overnight, the reaction mixture was poured into water and extracted with benzene. The extract was washed with water and dried. After removal of the solvent, the residue was dissolved in light petroleum-benzene (1 : 1, 10 ml.). The solution was then chromatographed over alumina and eluted with the same solvent, resulting in crude crystals. This was recrystallized from dry ethanol, yielding IVa, m. p. 172~175°C, 115 mg. (33.1%). Sublimation of this material in vacuo (160~175°C/15 mmHg) afforded pure IVa, colorless needles.

Found: C, 95.12; H, 5.12. Calcd. for $C_{22}H_{14}$: C, 94.93; H, 5.07%.

IVa was also obtained in a yield of ca. 20% by a reductive aromatization of IIIa with phosphorus diiodide.

***p*-Bis(β-phenylethyl)benzene.**—IVa in dry tetrahydrofuran was catalytically reduced over palladium-charcoal (5%). After removal of the catalyst, the reduction product obtained by evaporating the solvent was recrystallized twice from ethanol to yield *p*-bis(β-phenylethyl)benzene, on colorless plates, m. p. 90.5~91°C.

Found: C, 92.59; H, 7.67. Calcd. for $C_{22}H_{22}$: C, 92.26; H, 7.74%.

***p*-Stilbenealdehyde(VI).**—VI was prepared according to the procedure of Drefahl[9] with slight modifications, m. p. 113~114°C., 76% yield (lit. value, m. p. 116~117°C.).

IR max.($cm^{-1}$) 1695($\nu_{C=O}$), 1205, 1165(-CHO), 968($\delta_{=CH-}$).

***p*-Styrylcinnamic Acid (VII).**—Stilbenealdehyde (VI, 30.2 g., 0.145 mol.) and malonic acid (31 g., 0.29 mol.) were dissolved in a mixture of pyridine (60 ml.) and piperidine (1.5 ml.). A vigorous evolution of carbon dioxide was observed when the solution was warmed to 60~65°C. The solution was kept at 100°C for 3 hr. and then refluxed for 2 hr. The cooled reaction mixture was poured onto crashed ice (300 g.) containing hydrochloric acid (100 ml.). The precipitate was then filtered and washed with water. Recrystallization of this material from acetic acid yielded VII, on lustrous light yellow plates, m. p. 255~256°C, 27.5 g. (76%) (lit. value, m. p. 256~258°C, 70%)[9].

IR max.($cm^{-1}$) 1685($\nu_{C=O}$), 1427, 1278(-COOH), 959($\delta_{=CH-}$).

**Methyl *p*-Styrylcinnamate (VIII).**—A few milliliters of concentrated sulfuric acid was added to a suspension of styrylcinnamic acid (VII, 20 g.) in methanol (600 ml.), and the mixture was refluxed for 10 hr. The crystals of the acid gradually changed to pale greenish yellow plates. The cooled reaction mixture was then filtered. The crystals obtained by concentrating the filtrate were combined with the first crop and recrystallized from carbon tetrachloride, resulting in VIII, on light yellow plates, m. p. 185.5~186°C, 20.4 g. (97%).

Found: C, 81.79; H, 6.18. Calcd. for $C_{18}H_{16}O_2$: C, 81.79; H, 6.10%.

UV max(mμ) 236(ε=8,000), 345(24,000)(in 95% ethanol)

IR max($cm^{-1}$)1717($\nu_{C=O}$), 1169, 1114(-$COOCH_3$), 980, 969, 961($\delta_{=CH-}$).

**Methyl *p*-Styrylcinnamate Tetrabromide (IX).**—Bromine (30.0 g., 0.19 mol.) in chloroform (30 ml.) was gradually added to a stirred solution of the ester (VIII, 20.4 g., 0.077 mol.) in chloroform (700 ml.) under cooling with running water. The large amount of crystals deposited made the agitation of the reaction mixture impossible after about two-thirds of bromine had been added. After all the bromine had been introduced, the mixture was warmed to 40°C to complete the reaction. The crystals were filtered and washed with a small amount of chloroform, yielding the tetrabromide, 33.8 g. (75%), m. p. 235~238°C (decomp.). Further recrystallization from acetic acid afforded a pure material, colorless scale-like crystals, m. p. 242°C (decomp.).

Found: Br, 54.25. Calcd. for $C_{18}H_{16}O_2Br_4$: Br, 54.74%.

***p*-Phenylethynyl-phenylpropiolic Acid (X).**—The tetrabromide (IX, 34 g., 0.058 mol.) was intimately mixed with finely powdered potassium hydroxide (90 g., 0.6 mol.) and absolute methanol (400 ml.) was added in one portion to the mixture. After the vigorous reaction had ceased, the mixture was refluxed for 8 to 10 hr. The cooled reaction mixture was poured into water (600 ml.), and the potassium propiolate deposited was filtered and washed with a small amount of water. The combined filtrate and washing were extracted with ether. The ethereal extract was washed with water and dried. The residue obtained by removing the solvent was dissolved in light petroleum (b. p. 60~70°C.) and passed through a short column of alumina. Recrystallization of the crude crystals which were obtained by concentrating the filtrate gave IIb, pale yellow needles, 0.5 g. (4.3 %), m. p. 87~89.5°C.

The above-mentioned potassium salt was dissolved in hot methanol (400 ml.) and treated with active charcoal. On acidification of the methanolic solution with concentrated hydrochloric acid, crude *p*-phenylethynyl-phenylpropiolic acid (X) was obtained as crystals, m. p. 200~203°C, 9.7 g. (68%). Further purification was carried out by repeating the precipitation of the acid (X) from the methanolic solution with the addition of water, while a decomposition was observed when a solution of the acid is heated, especially in the presence of active charcoal. The pure material melts at 206~207°C.

Found: C, 82.67; H, 4.15. Calcd. for $C_{17}H_{10}O_2$: C, 82.91; H, 4.09%.

IR max. ($cm^{-1}$) 2205($\nu_{C\equiv C}$), 1667($\nu_{C=O}$), 1440, 1295(-COOH).

***p*-Ethynyltolan (IIb).**—To a solution of the propiolic acid (X, 1 part) in pyridine (10 parts) was added copper powder (0.1 part). The evolution of carbon dioxide was observed immediately, and in a few minutes the reaction mixture began

to froth vigorously. After the vigorous reaction had subsided, the mixture was refluxed for 40~60 min. To the cooled reaction mixture was added light petroleum (b. p. 60~70°C), and copper powder was removed by filtration. The filtrate was washed repeatedly with 2 N hydrochloric acid and then with aqueous sodium hydroxide and water successively. Concentration of the dried filtrate resulted in light brown needles, m. p. 78~83°C (yield, 76~85%). The crude ethynyltolan thus obtained was purified through chromatography over alumina, as the crude material was contaminated with a small amount of the propiolic ester. Recrystallization of the eluate from light petroleum gave pure IIb.

Found: C, 94.72; H, 4.98. Calcd. for $C_{16}H_{10}$: C, 95.02; H, 500%.

IR max.($cm^{-1}$) 3260($\nu_{\equiv CH}$).

The mercuric acetylide which was prepared according to the method of Johnson[24] was recrystallized from ethanol-benzene, yielding silky long needles, m. p. 244~245°C.

IR max.($cm^{-1}$) 2150 ($\nu_{C\equiv C}$).

**Bis(*p*-phenylethynyl-phenyl)diacetylene (XI).**—Cupric acetate monohydrate (7.5 g.) was added to a solution of *p*-ethynyltolan (IIb, 0.5 g.) in dry pyridine (50 ml.). The mixture was stirred for 8 hr. at 60~75°C. The reation mixture was diluted with benzene (200 ml.) and washed with 2 N hydrochloric acid, aqueous sodium hydroxide and water successively. The benzene solution was dried and the solvent removed, yielding a red solid. The crude material was washed twice with a small amount of light petroleum. The light yellow crystals thus obtained were recrystallized twice from benzene to give pure XI, on colorless plates.

Found: C, 95.04; H, 4.61. Calcd. for $C_{32}H_{18}$: C, 95.49; H, 4.51%.

**1, 4-Bis(*p*-phenylethynyl-phenylethynyl)-2, 5-cyclohexadien-1, 4-diol (IIIb).**—Dry dioxane (50 ml.) was added to a solution of lithium amide (prepared from lithium, 0.1 g., 14.3 mmol.) in liquid ammonia, and the ammonia was evaporated, resulting in a light pink solution. Into this solution was stirred *p*-ethynyltolan (IIb, 3 g., 14.8 mmol.) in dry dioxane (10 ml.). The color of the solution gradually changed from yellow to a transparent dark brown. After warming to 50°C for 20 min., the mixture was refluxed for 10 min. to expel the remaining ammonia and then cooled to room temperature. Under vigorous stirring, a solution of *p*-benzoquinone (0.8 g., 7.5 mmol.) in dry dioxane (20 ml.) was slowly added to the mixture over a period of 4 hr. A transient development of blue color was observed, and the color of the mixture changed to brown, forming a large amount of precipitate. The reaction mixture was stirred for ca. 20 hr. at room temperature and then refluxed for 3 hr. The cooled reaction mixture was introduced into water (500 ml.) and extracted with ethyl acetate. The extract was washed with water, dried and chromatographed over alumina. The crystalline fractions were recrystallized from benzene, yielding the glycol (IIIb), in the form of fine, long silky needles, m. p. 248~250°C., 475 mg. (12.6%).

Found: C, 88.90; H, 4.72. Calcd. for $C_{38}H_{24}O_2$: C, 89.04; H, 4.72%.

IR max.($cm^{-1}$) 3580, 3460($\nu_{OH}$), 2230($\nu_{C\equiv C}$), 1025, 1000 ($\delta_{OH}$).

**1, 4-Bis (*p*-phenylethynyl-phenylethynyl) benzene [Tetrakistolan] (IVb).**—To a warm solution of the glycol (IIIb, 245 mg.) in ethyl acetate (30 ml.) was added a solution of stannous chloride dihydrate (1 g.) in acetic acid (2 ml.) and ethyl acetate (2 ml.). The immediate deposition of a light yellow precipitate was observed. The mixture was then refluxed for 4 hr. and cooled. The precipitate was filtered (172 mg.) and dissolved in ethyl acetate. The solution was passed through a short column of alumina, and the filtrate was dried by evaporation. The residue, after recrystallization from chlorobenzene, gave tetrakistolan (IVb), in the form of light greenish yellow needles with a green fluorescence.

Found: C, 95.06; H, 4.81. Calcd. for $C_{38}H_{22}$: C, 95.37; H, 4.63%.

The author wishes to express his hearty thanks to Professor Masazumi Nakagawa for his helpful guidance throughout this work. The cost of this research was partly defrayed from the Scientific Research Expenditure of the Ministry of Education, to which author's thanks are also due.

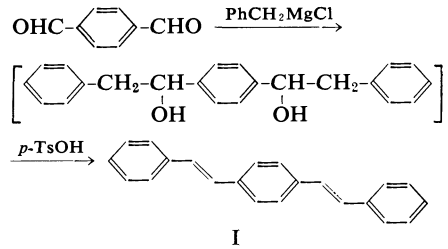
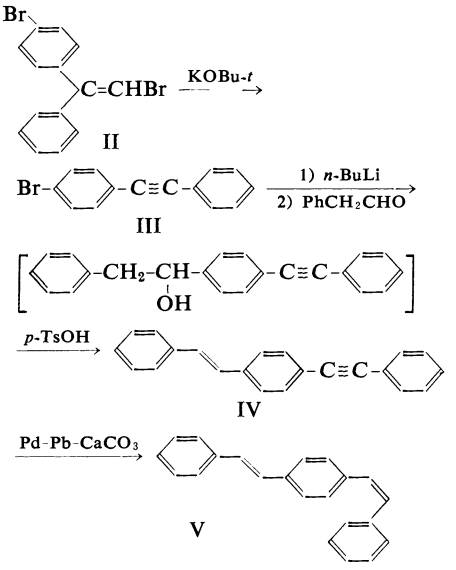
# *Alternant Conjugate Systems. II. Syntheses of Stereoisomeric p-Distyrylbenzenes and Related Compounds**



By Sōichi MISUMI, Motoyuki KUWANA, Kunie MURASHIMA and Masazumi NAKAGAWA

(Received March 7, 1961)

From a study of the ultraviolet absorption spectra of cis-trans isomeric carotenoids, Zechmeister and Pauling[1] have proposed a so-called "cis-peak rule" to correlate the molecular geometry with the spectrum. But the ultraviolet spectra of 1, 18-diphenyl-3, 7, 12, 16-tetramethyl-octadecanonaenes containing one or two sterically hindered cis-double bonds lack the cis-peak[2] which would be expected to appear according to the prediction of Zechmeister. Oroshnik[3] has also pointed out from his study of the ultraviolet spectra of sterically hindered retrovitamin A methyl ether and analogous compounds that the validity of Zechmeister's rule may be restricted to sterically unhindered cis-polyenes and that the spectra of hindered cis-polyenes cannot be explained by this rule alone.



In order to examine the validity of Zechmeister's rule with regard to stilbene derivatives containing hindered cis-double bonds, the authors have carried out the syntheses of three stereoisomers of *p*-distyrylbenzene and related compounds. The present paper deals with the syntheses of these compounds; their spectroscopic properties will be discussed together with those of *p, p'*-distyrylstilbenes and related compounds in the following paper of this series.

Among the three possible geometrical isomers of *p*-distyrylbenzene, the trans, trans-isomer was prepared by Kaufmann as early as 1917[4]. Afterward, various methods of preparation of this compound have been proposed[5]. The present authors have synthesized the trans-trans compound I according to the following series of reactions.

I

It is well-known that the ethylenic compound obtained by a dehydrohalogenation or dehydration reaction contains only a small amount of cis-isomer and that the partial hydrogenation of an acetylenic compound over Lindlar's catalyst is regarded as the most practical method obtaining cis-ethylenic compound[6]. More recently, it has been reported in some cases that the Wittig reaction[7] affords cis-compound together with trans-isomer. The authors have found during the course of the synthetical studies of stilbene homologues that the Wittig reaction is feasible for the synthesis of cis-isomer. Therefore, the second isomer, the *trans, cis-p*-distyrylbenzene (V), was prepared by the above-mentioned two methods.

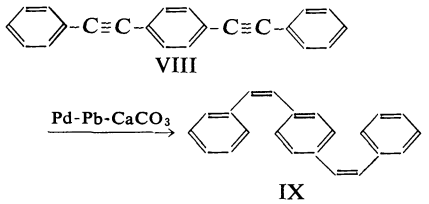
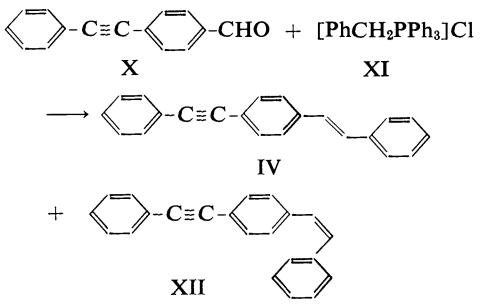
The corresponding acetylenic analogue, *p*-styryltolan (IV), was synthesized according to the following scheme from *p*-bromotolan (III), which is prepared by means of a Fritsch-Buttenberg-Wiechell rearrangement[8] of *α*-*p*-bromophenyl-*β*-bromostyrene (II).



*p*-Bromotolan (III) was also obtained by a dehydrochlorination of the ketodichloride of *p*-bromodesoxybenzoin (VI). This method has, however, been found to be less advantageous owing to the low yield of the Friedel-Crafts reaction for the preparation of VI.



*p*-Bromomethylstilbene which was derived from *p*-methylstilbene was converted to phosphonium salt VII. The reaction of the salt VII with benzaldehyde yielded *trans*, *trans*-distyrylbenzene and *trans*, *cis*-distyrylbenzene (V) in about the same yield. The trans, cis-isomer V thus obtained was found to be identical

with the trans, cis-isomer derived from acetylenic analogue by partial hydrogenation.

The third isomer, *cis*, *cis*-*p*-distyrylbenzene (IX), was prepared by the double partial hydrogenation of *p*-bisphenylethynyl-benzene (VIII)[9] over Lindlar's catalyst*.

The reaction of tolanaldehyde (X)[10] with benzyltriphenylphosphonium chloride (XI) also gave *trans*-*p*-styryltolan (IV) and *cis*-*p*-styryltolan (XII) in about equal yields. The formation of an equal amount of cis-isomer was also observed in the Wittig reaction of other stilbene homologues, which experiments will be reported on in a following paper. The formation of a four-membered cycle in an intermediate stage of Wittig reaction is generally accepted, and the formation of cis- and trans-isomers in an almost equal yield seems to be rather peculiar on the basis of this hypothesis, since the intermediate of the cis-isomer is

* Dale[5a] assigned the configuration of *trans*, *cis*-distyrylbenzene to a compound of m. p. about 95°C., which was isolated from the products of the photo-isomerization of trans, trans-isomer. However, the ultraviolet spectra of pure trans, cis- and cis, cis-compounds indicate that the compound of m. p. about 95°C is possibly a mixture of trans, cis- and cis, cis-isomers.

TABLE I. PROPERTIES OF *p*-DISTYRYLBENZENES AND RELATED COMPOUNDS

| | M. p., °C | UV spectrum, $\lambda_{max}(\varepsilon_{max})$, mμ | | | |
|---|---|---|---|---|---|
| *t*—*t* | 266 ~267 | 232 (16200) | | 350 (57000) | |
| *t*—*c* | 114 ~114.5 | 232 (20000) | 273 (12200) | 331 (36500) | |
| *c*—*c* | 86.5~ 87.5 | 232 (27600) | 270 (10900) | 314 (17700) | |
| A—A | 181.5~182 | 222 (20800) | | 318 (45400) | 337 (27000) |
| A—*t* | 211 ~211.5 | 230 (26600) | | 333 (55300) | |
| A—*c* | 78 ~ 78.5 | 227 (26800) | 271 (17700) | 312 (32900) | |

*t*, *c* and A denote *cis*-ethylenic, *trans*-ethylenic and acetylenic linkage, respectively.

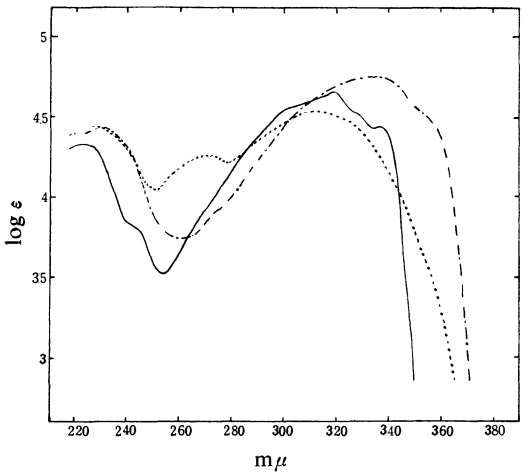

Fig. 2. The ultraviolet spectra of *p*-styryltolans (IV, *trans*, —·—·; XII, *cis*, ----) and distolan (VIII, ——) in *n*-hexane.

probably less stable than that of the trans-isomer owing to the steric interaction of two phenyl groups.

The ultraviolet spectra of the above-mentioned three stereoisomeric *p*-distyrylbenzenes and two *p*-styryltolans are presented in Figs. 1 and 2. The spectroscopic and physical properties of these compounds are summarized in Table I.

The shifts of the wavelength, where the absorption maxima of these compounds at the longest wavelength appear, represent an interesting feature. The introduction of a cis-double bond or an acetylenic bond instead of a trans-double bond caused a blue shift of ca. 18 and 16 mμ respectively. The absorption intensities of $\lambda_{max}$ at the longest wavelength of *trans-trans*, *trans*-acetylene and acetylene-acetylene compounds diminish with the increase in the amount of acetylenic linkage. Usually the absorption intensity of polyyne compound was found to be 2.6 fold as large as that of polyene compound. This phenomenon has been explained in terms of the larger number of π-electrons in triple bond and the linear geometry of polyyne compound[11]. As stated above, this is not valid for the absorption intensities of an alternant conjugate system of the styryltolan type. The decrease of absorption intensity by the introduction of aceylenic linkage seems to be attributable to an enhancement of the free rotation of the *p*-phenylene group, which may decrease the probability of transition of the full conjugate system.

The photoisomerizations and the discussions concerning the cis-peak of these compounds will be reported in the following paper together with those of the compounds of the distyrylstilbene series.

## Experimental*

***trans, trans-p*-Distyrylbenzene (I).**—*a) From Terephthalaldehyde.*—To a stirred solution of benzylmagnesium chloride (from magnesium, 3.75 g. and benzyl chloride, 20.0 g., 0.158 mol.) in dry ether (100 ml.) was added dropwise terephthalaldehyde[12] (10.0 g., 0.075 mol.) in dry tetrahydrofuran (150 ml.); this mixture was refluxed for 3 hr. A saturated aqueous solution of ammonium chloride was added to the cooled mixture and the organic layer separated by decantation. The inorganic residue was extracted with ether and the extract combined with the organic layer. The solvent was distilled from the combined solution to give the crude glycol (27 g.). A solution of the crude glycol (25 g.) in dry toluene (220 ml.) containing *p*-toluenesulfonic acid (0.8 g.) was refluxed for 2 hr. The crystals deposited from the cooled reaction mixture were filtered and recrystallized from chlorobenzene, yielding *trans, trans-p*-distyrylbenzene (I), on light greenish yellow plates, m. p. 261~262.5°C. The viscous tarry material obtained by concentration of the mother liquor was treated with chlorobenzene, yielding a second crop of I. The crude material was repeatedly recrystallized from chlorobenzene to give I. The total yield was found to be 4.3 g. (22%). Further recrystallization from the same solvent afforded pure I, m. p. 266~267°C.

Found: C, 93.59; H, 6.76. Calcd. for $C_{22}H_{18}$: C, 93.57; H, 6.43%.

*b) From p-Styrylbenzyl-triphenylphosphonium Bromide (VII).*—I was obtained from VII together with *trans, cis-p*-distyrylbenzene (V). The details will be described in section b) on the preparation of V.

***p*-Bromotolan (III).**—The bromostyrene (II) was prepared from *p*-bromoacetophenone[13] via three

* All melting points are uncorrected.

12) J. M. Snell and A. Weissberger, "Org. Synth.", Col. Vol. I (1948), p. 109.

13) R. Adams and C. R. Noller, ibid., (1955), p. 788.

steps according to the method of Bothner-By[8] in a yield of 26%, trans-form, m. p. 105.5~106.5°C. A solution of potassium *tert*-butoxide in *tert*-butyl alcohol (from potassium, 3 g. and *tert*-butyl alcohol, 40 ml.) was stirred with the finely powdered *p*-bromostyrene (II, 17 g., 0.05 mol.), and the mixture was refluxed for 3 days. To the cooled reaction mixture, *tert*-butyl alcohol (180 ml.) and water (360 ml.) were added, precipitating a colorless solid. The solid was filtered, washed with water and dried. The recrystallization of solid from light petroleum yielded III, in the form of colorless plates, m. p. 82~83°C, 10.5 g. (83%).

Found: C, 65.81; H, 3.54; Br, 30.73. Calcd. for $C_{14}H_9Br$: C, 65.39; H, 3.53; Br, 31.07%.

***trans-p*-Styryltolan (IV).** — *a) From p-Bromotolan (III).*—A little excess of *n*-butyllithium in ether (prepared from *n*-butyl chloride and lithium, the concentration being estimated by titration with 0.1 N hydrochloric acid) was slowly stirred into a solution of *p*-bromotolan (10.3 g., 0.04 mol.) in dry ether (100 ml.) in an atmosphere of pure nitrogen, and the mixture was refluxed for 2.5 hr. To the resultant orange yellow solution of tolan-lithium was added phenylacetaldehyde (6 g., 0.05 mol., freshly prepared from the dimethylacetal) in dry ether (65 ml.) at room temperature. A gradual change of the orange yellow color of the mixture to a white suspension was observed. Then the mixture was refluxed for 3 hr. to complete the reaction. A slow stream of pure nitrogen was introduced continuously into the reaction flask throughout these operations. A saturated aqueous solution of ammonium chloride (5.5 g.) and water were successively added to the cooled reaction mixture. The organic layer was separated. The organic layer and the ethereal extract were combined, washed with water and dried. The orange-colored oily residue obtained on evaporating the solvent was dissolved in dry toluene (150 ml.) containing *p*-toluenesulfonic acid (0.5 g.). The solution was refluxed, and the water formed was removed continuously by means of a water-separator. The crystals deposited on cooling the mixture were filtered and the mother liquor concentrated, resulting in the deposition of a second crop of crystals. The combined crystals were recrystallized twice from benzene, yielding *trans-p*-styryltolan, in the form of colorless leaflets, m. p. 211~211.5°C, 3.5 g. (31%).

Found: C, 94.09; H, 5.83. Calcd. for $C_{22}H_{16}$: C, 94.25; H, 5.75%.

*b) From p-Tolanaldehyde (X) by Wittig Reaction.*—The reactions described below were carried out in a dark place. *p*-Tolanaldehyde[10] (1 g., 4.85 mmol.) and benzyltriphenylphosphonium chloride (2 g., 5.15 mmol., m. p. 313~315°C) were mixed with absolute ethanol (25 ml.). To the stirred suspension was added an excess of lithium ethoxide in absolute ethanol. After stirring for 8.5 hr. at room temperature, the deposited pale yellow solid (0.7 g., a mixture of *trans-p*-styryltolan and phosphonium salt) was filtered. The solid was dissolved in benzene and the solution passed through a column of alumina to remove the phosphonium salt. The crude crystals obtained on evaporating the filtrate were recrystallized from benzene, yielding *trans-p*-styryltolan, in the form of colorless leaflets, m. p. 210~211°C, 0.5 g. (35.7%); this was found to be identical with the specimen obtained by the above-mentioned method a) by mixed melting point determination.

***cis-p*-Styryltolan (XII).** — The following operations were carried out in a dark place. The above-mentioned mother liquor of the Wittig reaction was diluted with water, precipitating a mixture of a solid and a brown oily material. The precipitate was dissolved in light petroleum. The solution was passed through a column of alumina and eluted with the same solvent. A colorless solid (m. p. 76~78°C) obtained from the eluate was recrystallized from aqueous ethanol, giving *cis-p*-styryltolan (XII), m. p. 78~78.5°C, colorless needles, 0.6 g. (49.2%).

Found: C, 93.88; H, 5.69. Calcd. for $C_{22}H_{16}$: C, 94.25; H, 5.75%.

***trans, cis-p*-Distyrylbenzene (V).** — *a) Partial Reduction of trans-p-Styryltolan (IV).*—The following operations were carried out in a dark place. Hydrogenation of the styryltolan (IV, 0.1 g.) in tetrahydrofuran (20 ml.) over Lindlar's catalyst resulted in the uptake of ca. 1 mol. of hydrogen. After removal of the catalyst, the solvent was evaporated under a reduced pressure. The residue was mixed with hot ethanol. The hot mixture was filtered to remove a small amount of insoluble trans, trans-isomer. The crystals separated on cooling the filtrate were filtered promptly. The crystals were found to be pure trans, cis-isomer V, in the form of colorless plates, m. p. 114~114.5°C.

Found: C, 93.58; H, 6.44. Calcd. for $C_{22}H_{18}$: C, 93.57; H, 6.43%.

*b) From p-Styrylbenzyl-triphenylphosphonium Bromide (VII).*—The following reactions and operations were carried out in a dark place. The phosphonium salt (VII, 2 g., 3.74 mmol.) was added to a solution of benzaldehyde (0.4 g., 3.77 mmol.) in absolute ethanol (60 ml.). Into this suspension was stirred an excess of a solution of lithium ethoxide in absolute ethanol. The mixture was stirred for 3 hr. at room temperature, and the solid was filtered (filtrate A). The solid was digested with boiling ethanol (30 ml.) and the insoluble material (solid B) filtered. The filtrate was cooled to yield trans, cis-isomer (V), m. p. 113.5~114.5°C. This was combined with the second crop, which was obtained on diluting the filtrate A with water and recrystallized from ethanol, yielding pure trans, cis-isomer (V), in the form of colorless plates, m. p. 113.5~114.5°C, 340 mg. (32.3%). This substance showed no depression of the melting point on admixture with the specimen derived by the above-mentioned method a).

Recrystallization of the solid B from chlorobenzene yielded trans, trans-isomer I, in the form of light greenish yellow plates, m. p. 253°C, 370 mg. (35.1%). The mixed melting point determination of this substance with the specimen derived from terephthalaldehyde proved the identity.

Exposure of the mother liquor of recrystallization of trans, cis-isomer to direct sunlight resulted in a deposition of crystals. This crystals were found to

be identical with trans, trans-isomer I, m. p. 255°C, 44 mg. (4%).

The total yield of the Wittig reaction was found to be 754 mg. (71.5%).

***cis, cis-p*-Distyrylbenzene (IX).**—Two moles of hydrogen were absorbed in a period of 18 min. on the hydrogenation of a solution of *p*-bis(phenylethynyl)benzene (VIII, 80 mg.) in tetrahydrofuran (20 ml.) over Lindlar's catalyst. After removal of the catalyst, the solvent was distilled under reduced pressure, yielding crystals. Repeated recrystallization of the crystals from light petroleum afforded cis, cis-isomer IX, in the form of colorless leaflets, m. p. 86.5~87.5°C.

Found: C, 93.79; H, 6.60. Calcd. for $C_{22}H_{18}$: C, 93.57; H, 6.43%.

# *Preparation and Absorption Spectra of the Cobalt(III) Complexes of Amino Acids*[1]

By Motoshichi MORI, Muraji SHIBATA, Eishin KYUNO and Mitsuhiro KANAYA

(Received March 3, 1961)

There are two isomers, $\alpha$ (violet) and $\beta$ (red), of trisglycinatocobalt(III). It has recently been ascertained from the absorption spectra by Shimura and Tsuchida[2] and also by Basolo et al.[3] that the more soluble $\alpha$-form is a trans-cis isomer and that the other is a cis-cis isomer. This assignment is supported theoretically by Nakamoto et al.[4] Furthermore, Shimura[5] came to the same conclusion with trisalaninato cobalt(III).

The present research has two main purposes: one is an investigation on the preparation of these kinds of complexes, and the other an approach to the structures of the complexes by comparing their absorption spectra with those of model compounds having cis-cis and trans-cis structures. In addition, the thermal stability and the infrared spectra of the complexes are studied.

## Experimental

**Preparation.**—i) *Method Using Cobalt(III) Hydroxide.*—This is essentially the same as the method of Ley and Winkler[6]. To a solution of the desired amino acid was added a slight excess of freshly prepared cobalt(III) hydroxide, and the mixture was heated on a water-bath until a dark red solution was obtained. The resultant solution was filtered once to remove unreacted hydroxide. The filtrate was evaporated on a water-bath almost to dryness. The residue was dissolved in a little hot water, and the solution was filtered, if necessary. On evaporating and then standing the solution, violet crystals of the $\alpha$-form were obtained. The corresponding $\beta$-form was contaminated with the $\alpha$-form, but the amount of contamination was very small. It was very easy to purify the $\alpha$-form because of the great difference between the solubilities of the two isomers. By this method the $\alpha$-isomers of glycine, *dl*-alanine and *l*-leucine were prepared with good yields. Therefore, this method may be recommended as a general method for the $\alpha$-isomer.

Found: Co, 20.7; N, 14.8. Calcd. for $\alpha$-[Co(gly)$_3$*]: Co, 20.9; N, 14.9%. Found: Co, 18.1; N, 12.8. Calcd. for $\alpha$-[Co(ala*)$_3$]: Co, 18.2; N, 13.0%. Found: Co, 11.8; N, 18.4. Calcd. for $\alpha$-[Co(leu*)$_3$]: Co, 12.8; N, 18.6%.

ii) *Method Using Hexamminecobalt(III) Chloride.*—This method was devised by us though a similar method was reported almost at the same time[7]; the principle is based on the following equation;

$$[Co(NH_3)_6]Cl_3 + 3NH_2CH_2COOH + 3KOH \rightarrow [Co(gly)_3] + 3KCl + 3H_2O + 6NH_3$$

A mixed solution of the desired amino acid with the hexamminecobalt(III) chloride was introduced

into a round flask with an air condenser, and a slight excess of 3 N potassium hydroxide was added to the mixture. The whole was heated until some crystalline materials appeared in it (it took more than 1 hr.). On cooling the contents by holding the flask in running water, fine violet crystals of the $\beta$-form separated out. In this step the $\alpha$-form was not obtained even in traces, but it was produced with a poor yield on evaporating the mother liquor.

From the experiments with glycine, *dl*-alanine and *l*-leucine, it was found that this method was convenient for the preparation of the less soluble $\beta$-form.

Found: Co, 19.6; N, 13.8. Calcd. for $\beta$-[Co(gly)$_3$]: Co, 19.7; N, 14.0%. Found; Co, 18.5; N, 12.9. Calcd. for $\beta$-[Co(ala)$_3$]: Co, 18.2; N, 13.0%. Found: Co, 12.4; N, 8.8%; Calcd. for $\beta$-[Co(leu)$_3$]: Co, 12.6; N, 9.0%.

iii) *Method Using Potassium Tricarbonatocobaltate (III).*—The reaction to this method, which was also devised by us, is as follows:

$$K_3[Co(CO_3)_3]+3NH_2CH_2COOH+3CH_3COOH\rightarrow$$
$$[Co(gly)_3]+3CH_3COOK+3H_2O+3CO_2$$

A desired amino acid was poured into a green solution of tricarbonatocobaltate(III) prepared by the method described in a previous paper[8], and the mixture was warmed on a water-bath for a little while, whereupon the color of the solution changed from green to blue. Then, 6 N acetic acid was added dropwise until the evolution of carbon dioxide ceased and the color of the solution became red-viotet. After filtering the solution, the filtrate was allowed to stand for some time in the cold. Crystals of the less soluble $\beta$-form were deposited, and then the $\alpha$-form separated out on evaporating the mother liquor over sulfuric acid. This method was applied to the same materials as those in i) and ii), and $\alpha$ and $\beta$ isomers were obtained in about equal amounts.

iv) *Ammoniatriacetatoethylenediaminecobalt(III)*, [*Co en(ata*)*]·$H_2O$.—About 3 g. of the $\alpha$-K[Co(ata)(OH)(OH$_2$)]·2H$_2$O prepared by the method described in the previous paper[9] was suspended in 20 ml. of water, and 6 ml. of a 10% solution of ethylenediamine was added to the suspension. The mixture was warmed on a water-bath until a red-violet solution was obtained. On evaporating the resultant solution over sulfuric acid, dark violet crystals of the desired complex separated out gradually. Yield, about 3 g.

Found: Co, 17.8; N, 12.7. Calcd. for [Co en(ata)]·H$_2$O: Co, 18.1; N, 12.9%.

v) *Citratotriamminecobalt(III)*, [*Co*($NH_3$)$_3$*cit***]·$H_2O$.—About 5 g. of *cis-cis*-[Co(NH$_3$)$_3$(NO$_3$)$_3$] and 2 g. of potassium citrate were dissolved separately in a little hot water, and the solutions were mixed and warmed on a water-bath for a few minutes. Then, about three volumes of ethanol was added to the solution, whereupon a violet oily material went to the bottom. After removal of the material by a separating funnel, the solution was kept in a refrigerator until fine rosy crystals separated out. This was slightly hygroscopic. Yield, about 1.5 g.

Found: Co, 17.9; N, 12.7. Calcd. for [Co(NH$_3$)$_3$cit]·H$_2$O: Co, 18.6; N, 13.1%.

Of all the complexes prepared here, the ammoniatriacetatoethylenediamine- and the citratotriamminecobalt(III) are to be regarded as new complexes. The aqueous solutions of all the complexes are very stable against acids and heat. Their solubilities in water decrease in the order of the glycinato-, the alaninato- and the leucinato-complexes; while the leucinato-complex is soluble to a certain extent in ethanol, the glycinato-complex is sparingly soluble in it.

**Thermal Decomposition and Absorption Spectra.**—The thermal decomposition was performed by using a Shimadzu thermal-balance in the same manner as that described in a previous paper[9]. The absorption spectra in solution were measured by a Hitachi EPU spectrophotometer, and the infrared spectra were obtained with a Koken DS 201 infrared spectrophotometer equipped with sodium chloride optics.

## Results and Discussion

**Thermal Decomposition.**—The decomposition curves of the glycinato-, alaninato- and leucinato-complexes are shown in Figs. 1—2 in which the weight loss per formual weight was plotted against temperature. In the case of the $\beta$-glycinato-complex, there is a certain weight loss corresponding to one molecule of water at 100~150°C, but there is no such weight loss in the corresponding $\alpha$-complex. It has been believed that the $\alpha$-complex has two molecules of water of crystallization, but the compound obtained in the present study is anhydrous. The decompositions of both isomers begin at nearly 220°C, and the weight loss corresponding to three molecules of

ammonia is clearly observed at the first stage of decomposition. In the cases of the $\alpha$- and the $\beta$-alaninato-complex there is no evidence for the existence of water of crystallization and the decomposition temperatures are about 250°C. For the $\alpha$-isomer of the leucinato-complexes, the removal of water takes place in two steps and the total amounts correspond to $2H_2O$. On the other hand, the $\beta$-isomer may be anhydrous because no distinct weight loss is observed. The decomposition temperatures are in the neighborhood of 180°C. In general, it may be said that the $\alpha$-forms are less stable than the corresponding $\beta$-forms, though the difference in the decomposition temperature is not very large.

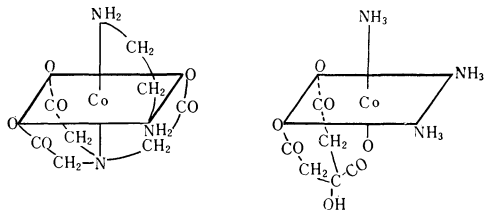
The decomosition curves for the ammoniatriacetato- and the citrato-complex are shown in Fig. 3. The former complex loses one molecule of water at a temperature below 100°C and begins to decompose at about 240°C. The latter is dehydrated at about 150°C and then decomposed when the temperature is raised.

**Visible and Ultraviolet Absorption Spectra.**— The absorption spectra of the α- and the β-forms are summarized in Figs. 4 and 5 respectively. The characteristic difference between them is seen in the first and the third bands; all of the first bands of the α-forms are more or less splitted, while those of the β-forms are normal and sharp. The third bands for the α-forms are sharper than those for the β-forms.

The absorption curves of the ammoniatriacetato- and the citrato-complex are shown in Fig. 6. The former complex has a somewhat split first band and a distinct third band, but the latter has a sharp first band and no maximum in the region of the third band.



As mentioned above, the ammoniatriacetato-complex is taken as a model for the trans-cis configuration and the citrato-complex for the cis-cis configuration, because ammoniatriacetate ion acts as a tetradentate donor and citrate ion is a tridentate ligand; consequently the most probable structures of the two complexes are thought to be those given in Fig. 7. From the similarity of the absorption spectra, it may be concluded that all the α-forms have the trans-cis structure and the β-forms, the cis-cis. The same conclusion has been reached by others[2,3,5] but a somewhat different approach was adopted in our study.

The numerical data of the absorption spectra of these complexes are summarized in Table I; the absorption maxima for the second bands reveal a general relationship between the α- and β-isomers. In the last two columns of

[Co en(ata)] [Co($NH_3$)$_3$cit]

Fig. 7. Probable structures.

the table, the values calculated by a Sone's equation[10] and the differences ($\Delta$) of the calculated values from the observed maxima are given. All of the trans-cis isomers show positive difference and the cis-cis isomers, negative difference.

**Infrared Spectra.**—The numerical data of the infrared spectra are summarized in Table II, in which the assignment is carried out with reference to papers of Nakamura and others[11]. A distinctive difference between the absorption of α- and β-isomers is observed in the region of 1580~1630 $cm^{-1}$; there is only one peak for the α-isomer, but the β-isomer has two split absorption peaks. Among the isomers of the same type, the absorption maxima shifted to longer wavelengths in the following order: the leucinato-, the alaninato- and the glycinato-complexes.

**Preparation.**—It is very interesting that the methods mentioned in the Experimental section above have preferential properties for the production of cis-cis and trans-cis isomers; the cobalt(III) hydroxide method favors the trans-cis, the hexammine method is advantageous for the cis-cis, and the tricarbonato method gives both isomers in the about the same amount. Therefore, somewhat different mechanisms may be involved in these methods and perhaps in the formation of the isomers; the decisive factor is which of the nitrogen and oxygen atoms of the incoming donor attacks the objects first.

## Summary

Three different methods were investigated of the preparation of trisglycinato-, trisalaninato- and trisleucinato-cobalt(III). The method using cobalt(III) hydroxide is convenient for the α-form, the method using hexamminecobalt(III) salt is advantageous for the β-form, and the method using tricarbonatocobaltate(III) gives both forms of the complexes. In addition, two new isomers of [Co en(ata)]·$H_2O$ and [Co($NH_3$)$_3$cit]·$H_2O$ having trans-cis and cis-cis

10) K. Sone, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **71**, 270 (1950).

configurations with respect to the coordinated atoms were synthesized.

By comparing the visible and the ultraviolet absorption spectra, it was concluded that the $\alpha$-form is a trans-cis isomer and that the $\beta$-form is a cis-cis isomer. Thermal decomposition of the complexes was performed in order to estimate the water of crystallization and the stability. The infrared spectra of the complexes were also measured.

# *Studies on Metal Complex Species Using an Anion Exchange Resin. II. On the Adsorption of Silver from Nitrate Solution*

By Hirohiko WAKI

(Received January 16, 1961)

In the previous papers[1,2] the author has derived equations for determining the composition of a metal complex by use of an anion exchange resin and applied them to mercury-(II)-nitrate complex species. Silver is, as well as mercury, adsorbed on an anion exchange resin from solutions of various nitrates or nitric acid, though its adsorption is not strong. In this paper the adsorption of silver from nitrate solutions and nitric acid was studied and its form in the resin was determined by the previously reported method[1,2] as well as by a new method.

The adsorption of silver nitrate on an anion exchanger Dowex 1-X8 was examined and compared with that of alkali nitrates. Even alkali nitrates are taken up a little in the resin, but no appreciable difference in the adsorbability between sodium and potassium is evident, as shown in Fig. 1. The apparent adsorption of alkali metals may be considered merely as a permeation of dissociated normal salts. On the other hand, the adsorbed amount of silver nitrate is considerably larger than that of alkali nitrates.

This difference in the adsorbability between silver and alkali metals is remarkable when a small quantity of these elements is used in a nitric acid medium, as shown in Fig. 2. The

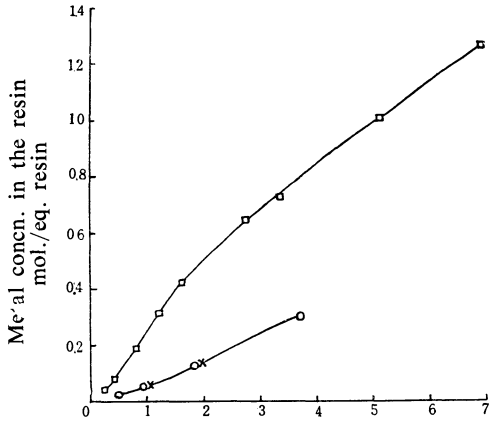

Fig. 1. Adsorption of Ag, Na and K from the solution of its nitrate only.

2) H. Waki, ibid., 34, 829 (1961).

distribution coefficient of sodium is very small and scarcely increases at all with an increase in nitric acid concentration. On the other hand, the distribution coefficient of silver in nitric acid increases rapidly in the beginning, then gradually to a maximum near 3 M nitric acid and then decreases gradually. In sodium nitrate solution, the coefficient has no maximum and is somewhat greater than that in nitric acid. Although the coefficient is considerably smaller than that of mercury[1,2], it may be reasonable to consider that the adsorption of silver is not a simple permeation of the normal salt but is related to the formation of nitrate complex species.

However, silver ion does not appear to form any nitrate complex anion in an ordinary nitrate solution, since silver nitrate may be regarded as a kind of relatively strong electrolyte, as seen from the fact that the mean activity coefficient[3] of silver nitrate is similar to that of alkali nitrate, especially that of potassium nitrate and rubidium nitrate, and at the utmost the presence of undissociated silver nitrate[4] may be considered only in concentrated nitrate solution. Even if a slight quantity of the complex anion is present in the solution, it may be difficult to consider that the adsorption of silver takes place by a successive permeation of the complex, because it takes only a short time to reach the adsorption equilibrium. Accordingly, the adsorption of silver may be explained by its movement into the resin phase as silver ion $Ag^+$ and neutral species $AgNO_3^0$, followed by the conversion into a silver-nitrate complex in the resin phase.

For the purpose of determining the composition of a metal complex by use of an anion exchange resin, the distribution coefficient $D$ of a metal element was expressed as follows[1,2]:

$$\log D=\left(n-\frac{a}{b}\right)\log[X^{b-}]-\left(m-\frac{a}{b}\right)\log(X^{b-})+K+G \qquad (1)$$

where ( ) and [ ] indicate the concentrations in the solution phase and the resin phase, $m$ and $n$ represent the numbers of an anion $X^{b-}$ binding to one metal ion $M^{a+}$ in these phases, and $K$ and $G$ represent the terms containing the complex formation constants and the activity coefficients in both phases, respectively. When the metal is present as $M^{a+}$ in the solution, Eq. 1 may be written as follows:

$$\log D=\left(n-\frac{a}{b}\right)\log[X^{b-}]+\frac{a}{b}\log(X^{b-})+K+G \qquad (2)$$

if a similar assumption is made in a silver-nitrate system, the following equation is obtained.

$$\log D-\log(NO_3^-)=(n-1)\log[NO_3^-]+K+G \qquad (3)$$

**Experiment by the Addition of an Indifferent Anion.**—This experiment was carried out in a way similar to that in the mercury-nitrate system. Two grams of an anion exchanger Dowex 1-X8 (100~200 mesh) of nitrate form was mixed with 10 ml. of a solution containing 0.3 mmol. of silver nitrate and a series of mixtures of sodium nitrate and sodium perchlorate of various mixing ratios (total concentration is 3 M). After equilibrium is reached silver and nitrate in the resin were determined. Silver was analyzed titrimetrically with a potassium thiocyanate and nitrate spectrophotometrically at 300 mμ. The amounts of silver and nitrate in the solution were estimated by subtraction from their total amounts.

The ion concentrations in the resin phase were always represented as millimoles of the ion per milliequivalent of the resin. The distribution coefficient of silver was calculated as

$$D=\frac{\text{mmol. of Ag adsorbed per meq. of the resin}}{\text{mmol. of Ag per ml. of the soln.}}$$

After the nitrate concentration in the resin was corrected as in the case of mercury-nitrate, $\log D-\log(NO_3^-)$ was plotted against the logarithm of the nitrate ion concentration in the resin. As shown in Fig. 3, in the range where nitrate is predominant, the gradient of the curve is 0.9, which corresponds approximately to $n=2$. From this result, it may be recognized that most of the silver-nitrate complex adsorbed from 3 M sodium nitrate solution has the form of $Ag(NO_3)_2^-$.

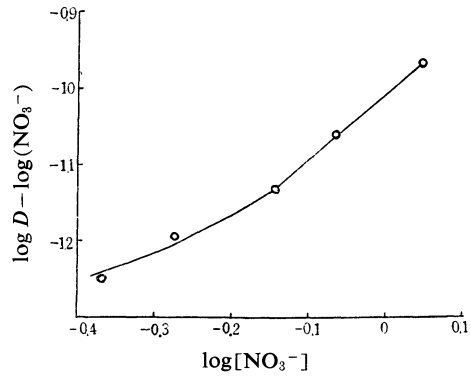

Fig. 3. Distribution coefficient of Ag as a function of the nitrate concentration in the resin phase. The measurements were carried out at the nitrate-rich range. Total concentration of the external solution is 3 M.

**Experiment by the Loading of the Complex.**— In determining the composition of a metal complex, a method in which the ratio of the adsorbed amount of the metal to the exchange capacity of the resin is determined after the resin is saturated with the metal complex anion, has often been employed[5]. This method is simple and reliable when the complex is stable and strongly adsorbed on an anion exchanger. However, it can not be used when the complex is unstable and not strongly adsorbed.

In view of this, a new loading method was studied by the present writer, which is based on Eq. 2. In the proposed method, instead of the addition of the indifferent anion, a greater amount of the same metal element is used to keep the ionic strength in the solution phase constant. The ligand ion concentration in the resin phase is therefore varied by the loading of the metal complex instead of an indifferent anion. Assuming that $MX_n^{(bn-a)-}$ is only one species for the resin phase, this concentration is expressed by

$$[X^{b-}] = [X]_t - n[MX_n^{(bn-a)-}] \quad (4)$$

where $[X]_t$ is the total ligand concentration irrespective of species. From Eq. 2 and Eq. 4 the following equation is obtained.

$$\log D = \left(n - \frac{a}{b}\right)\log([X]_t - n[MX_n^{(bn-a)-}]) + \frac{a}{b}\log(X^{b-}) + K + G \quad (5)$$

When a considerable amount of the metal is adsorbed, for the determination of $n$, $\log D/(X^{b-})^{a/b}$ can not be plotted against $\log[X^{b-}]$, because the second term in the right side of Eq. 4 can not be neglected and $n$ is unknown. Accordingly, in this case $\log D/(X^{b-})^{a/b}$ is plotted against $[MX_n^{(bn-a)-}]$ and the slope of the curve should be compared with that of the standard curves drawn by substituting 1, 2, 3, ……for $n$ in Eq. 5.

In a system of silver nitrate and sodium nitrate, Eq. 5 is written as follows:

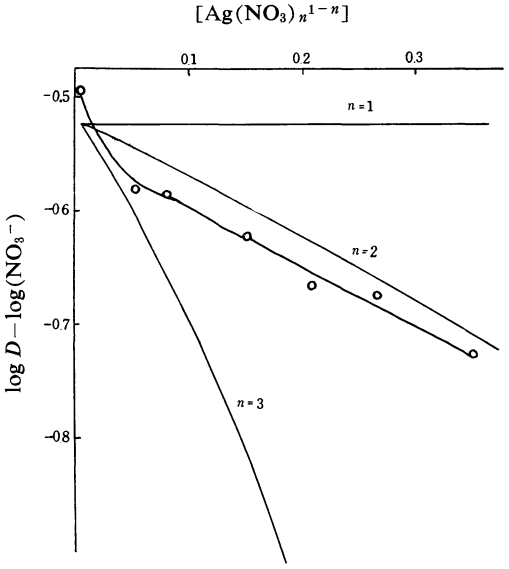

Fig. 4. Comparison with the standard curves in the system where the external initial concentration of $AgNO_3$+$NaNO_3$ is 2 M.
The standard curves are drawn in a position in which their gradients may compare with that of experimental curve.
-○- Measured —— Standard

5) For example, R. A. Horne, R. H. Holm and M. D. Meyers, *J. Phys. Chem.*, **61**, 1955 (1957).

$$\log D - \log(NO_3^-) = (n-1)\log([NO_3]_t - n[Ag(NO_3)_n^{(n-1)-}]) + K + G \quad (6)$$

The experiment was carried out by equilibrating 3 g. of an anion exchanger Dowex 1-X8 (100~200 mesh) of nitrate form with 10 ml. of a solution containing a series of mixtures of silver nitrate and sodium nitrate of various mixing ratios (total concentration is 2 M or 3 M), followed by determination of silver and nitrate in the solution phase. The silver concentration in each phase and the distribution coefficient were estimated in the same way as before. The nitrate in the solution was determined by titrating with a sodium hydroxide solution, after it was converted into nitric acid through a cation exchange column of hydrogen form. The amount of total nitrate in the resin was estimated by subtraction.

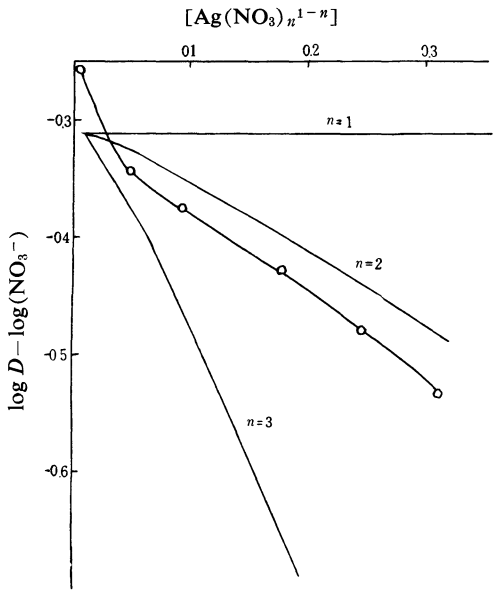

Fig. 5. Comparison with the standard curves in the system where the external initial concentration of $AgNO_3+NaNO_3$ is 3 M.
The standard curves are drawn in a position in which their gradients may compare with that of experimental curve.
-○- Measured —— Standard

The equilibrium data are tabulated in Table I and the curves for analysis are drawn in Fig. 4 and Fig. 5. Each slope of the curve is similar to that of the standard curve for $n=2$ in a wide range of the silver concentration except at a very low concentration. From this fact it may be considered that most silver in the resin phase exist as $Ag(NO_3)_2^-$ at the external nitrate concentration of about 2~3 M. This result is in agreement with that in the former experiment carried out by the addition of an indifferent anion. The high value of the gradient at the low concentration of silver is presumably due not to the presence of higher nitrate complexes, but to the inconstancy of the activity coefficient term in this region.

## Summary

1) It was found that silver was to some extent adsorbed on a strong base anion exchange resin from nitrate solutions. Its behavior was significantly different from that of alkali metals.

2) The equations derived in the previous paper were applied to a study of silver-nitrate complex. Starting from the same equation, two methods using either $NaNO_3+NaClO_4$ mixed media or the loading of the complex were employed, and the two results were in good agreement.

3) It was presumed that most silver in the resin exists as $Ag(NO_3)_2^-$ in neutral nitrate media where the external nitrate concentrations were about 2~3 M, although such anionic species may not be considered to exist in an ordinary nitrate solution.

The author wishes to express his sincere thanks to Professor Jun Yoshimura of Kyushu University for his guidance and encouragement. He also thanks Professor Hidetake Kakihana of Tokyo Technical University for his valuable suggestion.

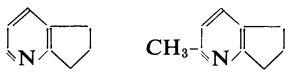
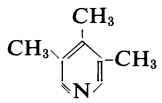
# *Separations of Lutidines, Collidines and 2, 3-Cyclopentenopyridines from Coal Tar Bases*



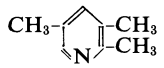
By Hajime SUZUMURA

(Received April 10, 1961)

In order to examine the tertiary amines in coal tar bases, especially in a forerunning of quinoline, methods of picrate and urea adduct formation, countercurrent extraction and chromatography were applied in order to effect the isolation of the bases. Selective separations could be carried out easily for some of the high boiling bases. From a fraction boiling at 170°C, 3, 5-lutidine[1] (I) was separated relatively easily as a zinc chloride adduct, and 2, 3-disubstituted pyridines such as 2, 3, 6-collidine[1] (II), 2, 3, 4, 6-tetramethylpyridine[2,3] (III), 2, 3-cyclopentenopyridine[2] (IV) and 2, 3-cyclopenteno-6-methylpyridine[3-5] (V) were isolated as



(I) (II) (III)



(IV) (V)

urea adducts from the fractions with corresponding boiling points. Furthermore, using a chromatographic column of cupric chloride-aluminum oxide which was effective for separations of pyridine, picolines and lutidines[6,7]

(VI)

2, 3-cyclopenteno-6-methylpyridine and 3, 4, 5-collidine[4,8-10] (VI) were separated. The latter was isolated for the first time from coal tar bases by the author[8]. With the same chromatographic column, 2, 3, 5-collidine[10] (VII) could also be separated and purified.

(VII)

The properties and physical constants of the bases which were separated are shown in the following tables.

## Experimental

**Materials.**—The materials used in the present investigation were all supplied by Yawata Chemical Industry Co.; their properties are shown below.

(2) Tertiary amines boiling at 200 and 210°C. A forerunning of quinoline (Fig. 8) was obtained when the crude quinoline was first extracted with sulfuric acid from the middle oil of coal tars and then fractionally distilled. Fractionating through a packed column 3 m. in height, this forerunning was separated into toluidine and xylidine fractions. Primary amines in these fractions were removed by acetylation, and the mixture of tertiary amines thus obtained was fractionally distilled as shown in Table VIII.

**Separation of 3, 5-Lutidine by Zinc Chloride.**— Industrial grade collidine grade 1 (Sample A) (1250

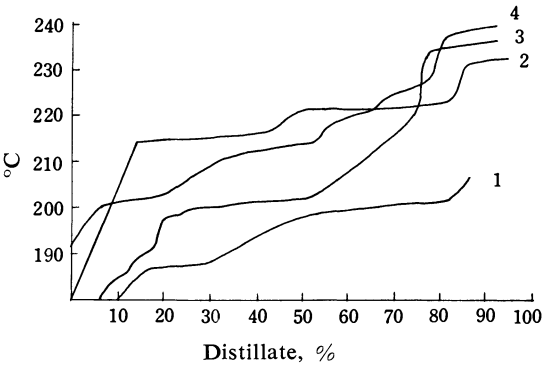

Fig. 8

1 $T_3$ ($S_1$)
2 $X_3$ ($S_1$)
3 Forerunning of quinoline ($S_1$)
4 $X_3$ ($S_4$)

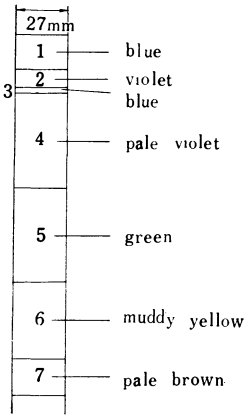

Fig. 9

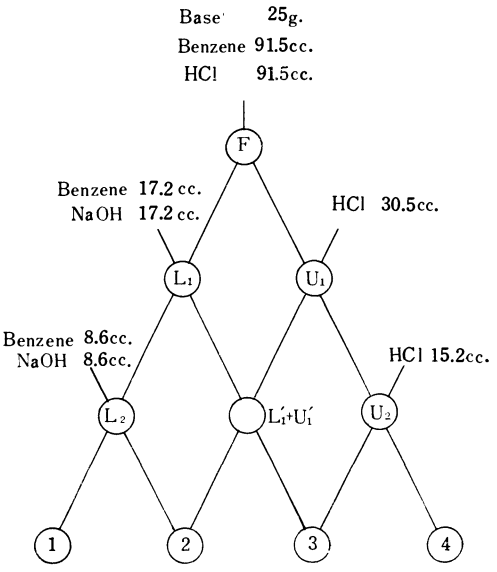

Fig. 10

cc.) was fractionated through a column 2 m. in height and packed with single turn helices, and a fraction boiling at 168~171°C (534 cc.) was obtained. When a 50% aqueous solution of zinc chloride was stirred into this fraction, a white adduct was precipitated which was washed with benzene to remove free bases and then steam-distilled. The distillate, on treatment with an aqueous solution of picric acid, gave crude picrates, m. p. 240°C, in about a 4% yield based on the fraction. The crude picrate (49 g.) was refluxed with 700 cc. of ethanol, yielding 42 g. of pure picrate, which was decomposed to give pure 3,5-lutidine.

**Separation by Urea-adduct.**—*Separation of 2,3,6-Collidine.*—One kilogram of Industrial grade collidine grade 1 (Sample B) was distilled into the following fractions:

| Fraction | up to 165°C | 165~167°C | 170~175°C |
|---|---|---|---|
| Amount, g. | 515 | 107 | 326 |

To the fraction boiling at 170~175°C (80 g.), a 50% aqueous solution of urea was added, and the resulting white adduct of m. p. 128~132°C was decomposed by steam distillation. A picrate (12 g.) melting at 147.4~148.4°C was obtained from the distillate. After being recrystallized once from ethanol, the picrate was decomposed, yielding 3.1 g. of pure 2,3,6-collidine.

*2,3,4,6-Tetramethylpyridine.*—To 16 g. of the fraction ($T_3$) boiling at 200~201°C, 43 g. of a 50% aqueous solution of urea was added, and the resulting adduct was washed with ether and decomposed by steam distillation to give a base (4.5 g.) boiling at 198°C. The picrate of this base, after three recrystallizations from ethanol, melted at 122~122.5°C. The base was also confirmed by picrolonate and ultraviolet absorption spectrum.

*2,3-Cyclopentenopyridine.*—To 36 g. of No. 3 fraction of $X_3$, a solution of urea (112 g.) in 50 cc. of water was added to form urea adduct, m. p. 124~132°C, which was decomposed, yielding 18 g. of basic material showing $n_D^{25}$ 1.5200. This was next purified as picrate, and after a recrystallization from ethanol picrate of 2,3-cyclopentenopyridine (21 g.) which melted at 178~179°C (uncorr.) was obtained. From the filtrate of urea adduct, 10 g. of the picrate of the base was recovered.

*2,3-Cyclopenteno-6-methylpyridine.*—To 5 g. of Nos. 8 and 9 fractions of $S_4$, 1 g. of a 60% aqueous solution of urea was added to yield an adduct from which 2,3-cyclopenteno-6-methylpyridine was recovered as picrate. The purified picrate did not show a melting point depression when admixed with an authentic sample. The results are shown in Table IX.

Similarly, from 50 g. of No. 9 fraction of $S_4$, 19.8 g. of picrate was obtained. The combined picrates were decomposed, yielding 7.45 g. of the free base with $n_D^{35}$ 1.5280. Bases which were recovered from the filtrate of the adduct boiled at 214°C and had $n_D^{20}$ 1.5270, and N content 10.31%.

**Chromatographic Separation.**—*Separation of 3,4,5-Collidine and 2,3-Cyclopenteno-6-methylpyridine.*—As Vignes used for the separation of pyridine, picolines and 2,6-lutidine[6], a mixture of cupric chloride (2 parts), aluminum chloride (25 parts), glycerol (6 parts) and distilled water (2 parts) was ground, dried at 50°C, and then used as an adsorbent in a chromatographic column. The adsorbent (190 g.) was packed in a column as shown in Fig. 9. No. 7 fraction (10.02 g.) from $X_3$, in Table VIII, was placed on a column and developed with 280 cc. of ether. After 5 hr., development was complete, giving various zones as shown in Fig. 9. From each zone, bases were recovered by the addition of an alkali, followed by steam distillation. While examining these bases as picrates, the author found that the bases of Nos. 4 and 5 mainly consisted of 2,3-cyclopenteno-6-methylpyridine, and a base of Nos. 1 and 2 whose picrate melted at 171~172°C (uncorr.) was identified as 3,4,5-collidine (Table X). A comparison of the properties of the base with those of the synthetic sample used in the identification of coal tar bases[10] is as follows: b.p. 210.3~210.8°C (reported 205~207°C), melting point of the picrate 173.6~174.3°C (reported 174°C), N content found 11.25% (Calcd. for $C_8H_{11}N$, 11.52%), molecular weight found 118 (Calcd. 121), and molar refractivity calculated from $d_4^{35}$ 0.9552 and $n_D^{35}$ 1.5115 38.1 (which is very close to the calculated values for collidines 38.6~38.8). The infrared spectrum in carbon disulfide and the ultraviolet spectrum in cyclohexane agreed with those of the literature cited. The base (0.4954 g.) was oxidized with 3.91 g. of potassium permanganate (used as a 2% aqueous solution) at 90°C over a period of 32 hr. Pyridine carboxylic acid was recovered as its copper salt; this was then decomposed by hydrogen sulfide to give the crude acid (0.0874 g.). After a recrystallization from water, pyridine carboxylic acid was obtained which melted with decomposition at 262.5°C (corr.).

Found: N, 5.8. Calcd. for $C_8H_5O_6N \cdot 3H_2O$: N, 5.3%.

*Separation of 2,3,5-Collidine.*—Separation of this base by picrate formation was reported in the literature, but the procedure of recrystallization was time-consuming. By using the chromatographic column described above, 2,3,5-collidine was separated easily. Bases of the fraction boiling at 183~190°C which remained in the solution after the solid urea adduct was removed were placed on the column and developed. A green zone was obtained, and from this zone was recovered a base whose picrate melted at 184~185°C and proved to be 2,3,5-collidine by the mixed melting point. Colors developed by other bases in this procedure are as follows: 3,5-lutidine (blue), 2,4,5-collidine (violet), 2,3,6-collidine (blue) and 2,3-cyclopentenopyridine (blue).

**Separation of 2,3-Cyclopentenopyridine by Countercurrent Extraction.**—2,3-Cyclopentenopyridine which was separated as urea adduct could also be separated by countercurrent extraction. The scheme of extraction, shown in Fig. 10, was similar to that described in the literature[11] using benzene and hydrochloric acid.

Using No. 2 fraction of $S_1$ as a feed, 2,3-cyclopentenopyridine was found to be concentrated in a fraction which was only with great difficulty soluble in the acid phase. The extraction was conducted

11) S. Tanaka et al., *Japan Analyst (Bunseki Kagaku)*, 5, 455, 513 (1956).

as shown in Fig. 10; bases were distributed between benzene and hydrochloric acid by shaking for 5 min. in a separatory funnel. The upper benzene layer $U_1$ was separated, hydrochloric acid (1 N) was added, and the extraction was repeated, forming upper $U_2$ and lower layer $U_1'$. To $L_1$, which was the lower layer of $U_1$, benzene and 1 N sodium hydroxide were added, and extraction was conducted to give $L_1'$ and $L_2$. $L_1'$ and $U_1'$ were combined and distributed between themselves. The extraction was continued until the 4 fractions shown in Fig. 10 were obtained. The amount, the refractive index and the melting point of the picrate of the base recovered from each fraction are shown in Table XI.

The basicity of the base was expected to decrease gradually from No. 1 to No. 4. From fraction No. 4 the picrate of 2,3-cyclopentenopyridine (4.5 g.) was separated and identified by mixed melting point with an authentic sample.

# *The Raman Spectra of 1,3,5-Trichlorobenzene and 1,3,5-Trichlorobenzene-$d_3$*

By Shinnosuke SAËKI

(Received April 12, 1961)

A report on the infrared absorption spectra of ordinary and deuterated 1,3,5-trichlorobenzene has been previously presented by the author[1], but the Raman spectra of these substances have not yet been studied in detail. In this paper the Raman spectra of these substances are reported on, and the assignment of the observed Raman lines is presented, including that of the overtones and combinations.

As the molecule of 1,3,5-trichlorobenzene has a high symmetry, ten pairs of degenerate vibrations are contained in its thirty normal vibrations, and twenty fundamental frequencies are expected to be observed in the molecular spectra of this substance. Of these twenty frequencies, fourteen are active to the Raman effect.

Hitherto the assignments of the normal vibrations of the various aromatic derivatives have been made by collecting a large number of data for many similarly substituted benzenes and by comparing and systematizing these data. In the present report, instead of referring to the data of other substances, the assignment is determined by taking the spectra of both ordinary and deuterated substances, by applying the product rule, and by referring to the results of qualitative measurements of the depolarization ratios.

## Experimental

Commercial 1,3,5-trichlorobenzene was recrystallized from ethanol solution three times, and was then further purified by sublimation. Deuterated material was prepared by stirring the ordinary 1,3,5-trichlorobenzene with deuterated sulfuric acid for eight hours at 105°C. The reaction mixture was poured on ice and recrystallized from ethanol. The progress of substitution was checked by the infrared absorption spectrum after each substitution reaction, and the reaction was repeated until the strongest absorption band of $C_6HD_2Cl_3$ could hardly be recognized. It was found that the absorption bands of $C_6H_3Cl_3$ almost completely disappeared after the first reaction, and that three repetitions of the reaction were sufficient to complete the substitution reaction*.

The instrument used for the measurements was a Cary model 81 Raman spectrophotometer. The source was a mercury arc lamp of Toronto type; the dispersion of the grating was 4 Å/mm. at 5000 Å wavelength.

Raman spectra were taken of the solution in carbon tetrachloride (1 g. solute dissolved in 5 ml. solvent) and in methanol (0.5 g. solute dissolved in 5 ml. solvent) for both ordinary and deuterated substances. As the solubilities of the substances in methanol are not sufficiently large, it was impossible to make the concentration of both solutions equal.

The depolarization ratio was measured by surrounding the Raman tube by polaroid cylinders and by polarizing the exciting light in directions parallel and perpendicular to the axis of the Raman tube.

## Results

The observed Raman spectra are shown in Figs. 1—4. In the spectrum of the methanol solution of ordinary trichlorobenzene, as the base line rose gradually with increasing frequency, it was necessary to reset the zero

1) S. Saëki, This Bulletin, 33, 1024 (1960).

* The substance in which a given band originated was easily known by following the intensity changes of that band with the repetition of the substitution reactions.

suppression of the amplifier at 1800 $cm^{-1}$. Although the cause of the shift of the base line was not found, this gave rise to no obstacle for the measurement of the frequencies of Raman lines. In the figures, the peaks pointed out by the small arrows are due to the solvents or the source lamp (D line, 2602 $cm^{-1}$).

The frequencies and intensities of the observed lines are listed in Tables I and II. The intensities are shown for the spectra excited by the polarized lights in both directions (cross and parallel). The scale of the intensity is simply the height of a Raman line measured on the chart. The notation "masked" in the tables means that the line was not observed in that solution, being masked by a strong Raman line of the solvent, while it was observed in the other solution. The notation "unobserved" means that the line was not observed in that solution, while it was observed

in the other solution. This inconstancy of observation might be due to the unequal concentrations or to different solvent effects in both solutions. In any case, it should be remembered that there might be a little ambiguity in such lines.

## Assignment

**1, 3, 5-Trichlorobenzene.**—*Species* $A_1'$. — It is universally known that the vibrations belonging to totally symmetric species give the most intense Raman lines. In the case of 1, 3, 5-trichlorobenzene, four normal vibrations belong to species $A_1'$, as is shown in Table III. The C-H stretching vibration is expected to appear about 3000 $cm^{-1}$, the breathing of the benzene ring is expected to appear about 1100 $cm^{-1}$ judging from the case of *p*-dichlorobenzene (which was reported on in our previous paper[2]), the C-Cl stretching vibration is expected to be observed in the region 700~800 $cm^{-1}$, and the deformation of the ring is expected to be observed at 300~400 $cm^{-1}$. From these estimations of the frequencies, four lines with remarkable intensities were selected from the observed Raman lines, that is, the lines at 3079, 1147, 994 and 374 $cm^{-1}$. However, as is seen in Table I, the line at 3079 $cm^{-1}$ was not very definitely polarized. In the vicinity of this line, another line was observed at 3130 $cm^{-1}$ which was apparently polarized. Therefore, it might be considered that this line corresponded to the C-H symmetric stretching vibration of the species $A_1'$ and that the above-mentioned line at 3079 $cm^{-1}$ corresponded to the C-H degenerate stretching vibration of the species E'. But this assignment conflicts with the empirical knowledge that a line belonging to a totally symmetric species is generally more intense than a line belonging to other species, and that the frequency of a degenerate stretching vibration of the C-H bonds is higher than that of a symmetric one as a general rule. Therefore, it seems to be more plausible to assign the line at 3079 $cm^{-1}$ to both degenerate and symmetric stretching vibrations of C-H bonds. Then the line at 3130 $cm^{-1}$ might well be explained as an overtone of the line at 1563 $cm^{-1}$ (e'), which will be discussed later.

The other three polarized lines were easily assigned to the other three normal vibrations

Table III. The normal modes of 1,3,5-trichlorobenzene

| Species | Mode |

| | $\nu_{20}$ | 188 ? | 188 ? | C-Cl out-of-plane bending |

N. B. The values in parentheses are the wave number which were observed in the infrared spectra.

of species $A_1'$, as is shown in Table IV. Since these lines had remarkable intensities, and no alternate lines were observed in their vicinities, the assignment was quite unambiguous. Although the frequency of the $\nu_3$, the C-Cl stretching vibration, to which the line at 994 $cm^{-1}$ was assigned, was a little higher than the expected value, it is nevertheless a quite probable value for such a vibration, considering the fact pointed out in our previous paper[3] that the strong coupling between the normal vibrations of such frequencies may often cause a large frequency shift from the empirically expected one. Consequently, this molecule might not have a normal vibration which could be called a C-Cl stretching vibration in its proper sense. However, at present such a vibration will be called a C-Cl stretching vibration for convenience.

*Species E'.* — Contrary to the easy assignment of the normal vibrations belonging to species $A_1'$, the assignment of the observed lines to the seven normal vibrations of this species was very difficult. Since the normal vibrations belonging to species E' are active in both the Raman and infrared spectra, the assignments would appear to be easily achieved by looking for the frequencies which were commonly observed in the Raman and infrared spectra. However, this could not be done so easily in practice. Actually only four frequencies were commonly observed in Raman and infrared spectra, that is, 3079 (3098), 1565 (1565), 1060 (1100 or 1055) and 425 (430). (in $cm^{-1}$. The frequencies put between parentheses are those observed in the infrared absorption spectrum in a gaseous state.) The fact that only four vibrations appeared commonly in both spectra, while seven were expected, suggested that the intensities of the Raman lines or the infrared absorption bands of the other three vibrations were to weak to be observed. But, on the other hand, the abovementioned four lines could definitely be assigned to species E'. However, the line at 1060 $cm^{-1}$ was somewhat questionable. Since the infrared absorption spectrum of the substance was measured in the gaseous state, the frequency of an observed band must be a little higher than that of the corresponding line observed in the Raman spectrum. From this consideration, it was not reasonable to consider the infrared absorption band at 1055 $cm^{-1}$ to correspond to the Raman line at 1060 $cm^{-1}$. And the other infrared band observed at 1103 $cm^{-1}$ seemed too high to be regarded as the corresponding band of this Raman line. Moreover, its depolarization ratio shown in Table I suggested that it belongs to species $A_1'$. These facts might rule out the assignment of the line at 1060 $cm^{-1}$ to the normal vibration of species E'.

As for the other three commonly observed frequencies, the line at 3079 $cm^{-1}$ was assigned to the degenerate stretching vibration of C-H bonds ($\nu_{11}$), as was mentioned above, and the line at 1565 $cm^{-1}$ was assigned to the stretching vibration of the benzene ring ($\nu_{12}$), and the line at 425 $cm^{-1}$ to the deformation vibration of the benzene ring ($\nu_{16}$), all with sufficient certainty.

As for the remaining four normal vibrations

3) S. Saëki, ibid., 33, 1021 (1960).

of this species ($\nu_{13}$, $\nu_{14}$, $\nu_{15}$ and $\nu_{17}$), the assignment of the lines was very difficult. The stretching vibration of the benzene ring, $\nu_{13}$, is empirically expected to appear in the frequency region 1400~1600 $cm^{-1}$. But, as is seen in Fig. 1 and in Table I, no Raman line was clearly observed in this region except for the line at 1565 $cm^{-1}$. A weak line observed only with difficulty at 1536 $cm^{-1}$ for the solution in carbon tetrachloride was polarized and had to be considered as an overtone or a combination belonging to species $A_1'$ (for example 1147 $(a_1')+374(a_1')$). As was already reported in our previous paper[1], the infrared absorption spectrum of this substance showed many intense absorption bands in this region of the spectrum (1412 (s), 1398 (m), 1384 (m) and 1341 (s)). The band at 1412 $cm^{-1}$ was especially clearly assigned to a fundamental because of its outstanding intensity. Consequently, although the Raman line was not observed, it appears to be plausible to assign this band to $\nu_{13}$.

The C-H in-plane bending vibration was expected to appear in the vicinity of 1000 $cm^{-1}$, where only the above-mentioned polarized line at 1060 $cm^{-1}$ was observed. In the infrared absorption spectrum[1], a remarkable band was observed at 1103 $cm^{-1}$ which showed a large frequency shift on the substitution for hydrogen atoms by deuterium atoms. Accordingly, we assigned this band to the C-H in-plane bending vibration ($\nu_{14}$).

As for the C-Cl stretching vibration $\nu_{15}$, since the coupling with other vibrational modes might shift its frequency from its usual value, as in the case of $\nu_3$, it would be necessary to examine it over a relatively wide region of frequency, such as 600~1000 $cm^{-1}$. However, no Raman line was found in spite of taking such an extremely wide region. In the infrared absorption spectrum, two intense bands were observed, that is, bands at 855 and 814 $cm^{-1}$. The former was clearly identified from the shape of its envelope* to be a band which did not belong to species E'. Consequently, the band at 814 $cm^{-1}$ was assigned to the C-Cl stretching vibration of species E' ($\nu_{15}$).

The C-Cl in-plane bending vibration $\nu_{17}$ was expected to be found about 200 $cm^{-1}$. In the neighborhood of 200 $cm^{-1}$ a remarkable line was observed at 188 $cm^{-1}$, and a less intense line was observed at 209 $cm^{-1}$. Since there exists another Raman active bending vibration of C-Cl bonds which belongs to species E'' (out-of-plane), the above-mentioned two observed Raman lines apparently originate in these two C-Cl bending vibrations. However, it was difficult to find the correspondence between these lines and these normal vibrations. It was imagined, by analogy to C-H vibrations, that the line of the higher frequency (209 $cm^{-1}$) might probably correspond to the in-plane bending vibration, and the lower one to the out-of-plane vibration. Of course, however, this was not certain.

*Species E''.*—Three out-of-plane normal vibrations belong to this species, as listed in Table III. To the C-Cl out-of-plane bending vibration $\nu_{20}$, as was mentioned above, either the line at 209 $cm^{-1}$ or the line at 188 $cm^{-1}$ —probably the latter—was to be assigned. The out-of-plane deformation vibration of the benzene ring $\nu_{19}$ was expected to be observed from 400 to 500 $cm^{-1}$, where a very weak and depolarized line was found at 526 $cm^{-1}$. Disregarding its low intensity, we assigned this line to $\nu_{19}$ for the following reasons: 1. An overtone or combination belonging to a species other than $A_1'$ might not appear in the spectrum with an observable intensity. 2. The frequency of this line (526 $cm^{-1}$) could not be derived by combining or multiplying the frequencies of other fundamentals. 3. The line at 1060 $cm^{-1}$ which was mentioned in previous paragraphs was well explained as the overtone of this line.

The C-H out-of-plane vibration $\nu_{18}$ was expected to appear in the vicinity of 800 $cm^{-1}$, but no corresponding Raman line was observed in this frequency region. This might be because the intensity of the line was probably too low to be observed.

*Overtones and Combinations.*—The overtones and combinations which have already been explained are as follows:

3132 $cm^{-1}$ $(A_1')$: 1565 $cm^{-1}$ $(e')\times 2$

1536 $cm^{-1}$ $(A_1')$: 1147 $cm^{-1}$ $(a_1')$
$+374$ $cm^{1}$ $(a_1')$ three weak lines

1060 $cm^{-1}$ $(A_1')$: 526 $cm^{-1}$ $(e'')\times 2$

In addition to these lines three weak lines were observed between 2100 and 2300 $cm^{-1}$, as is shown in Table I. Though two of these lines were easily explained as

2263 $cm^{-1}$ $(A_1')$: 1147 $cm^{-1}$ $(a_1')\times 2$

2211 $cm^{-1}$ $(A_1')$: 1103 $cm^{-1}$ $(e')\times 2$

the third line observed at 2150 $cm^{-1}$ was difficult to explain. It might probably originate. in a slight amount of impurity.

The assingment determined above is shown in Table IV.

**1, 3, 5-Trichlorobenzene-$d_3$.**—*Species $A_1'$.*—The strong and polarized Raman line at 2303 $cm^{-1}$

* Concerning the envelopes of the infrared absorption bands of these substances, a report will be presented soon.

was easily and definitely assigned to the symmetric stretching vibration of C-D bonds. The remaining three vibrations are the breathing and the deformation of the benzene ring, and the symmetric stretching of the C-Cl bonds, all of which are not much influenced by the substitution for hydrogen atoms by deuterium atoms. Therefore, these vibrations of deuterated 1, 3, 5-trichlorobenzene were expected to be observed at frequencies only a little lower than those of the corresponding lines of 1, 3, 5-trichlorobenzene, that is, at 1147, 994 and 374 $cm^{-1}$ respectively. In fact, as is shown in Table II, three strong and polarized lines were found at 1143, 951 and 374 $cm^{-1}$ in the Raman spectra of deuterated trichlorobenzene. So, the lines at 1143, 951 and 374 $cm^{-1}$ were unambiguously assigned to the ring breathing ($\nu_2$), C-Cl stretching ($\nu_3$) and ring deformation vibration ($\nu_4$) respectively. In the Raman spectrum of deuterated substance, a line was observed at 993 $cm^{-1}$ which appeared to correspond to the line at 994 $cm^{-1}$ of ordinary substance better than the line at 951 $cm^{-1}$ did. However, the requirement of fulfilling the product rule and the definite inferiority in the intensity of the line at 993 $cm^{-1}$ to the line at 951 $cm^{-1}$ ruled out the assignment of the former line to $\nu_3$. It seemed that this line should be explained as the overtone of the line at 492 $cm^{-1}$ ($e''$), which will be discussed later, just as the line at 1060 $cm^{-1}$ was the overtone of the line at 526 $cm^{-1}$ in the case of ordinary substance. Its unusually strong intensity might well be explained by the Fermi resonance with the line at 951 $cm^{-1}$.

*Species* $E'$. — As was done in the case of ordinary substance, four frequencies which were observed commonly in the Raman and infrared absorption spectra were picked up. These were 2303 (2310), 1548 (1560), 1337 (1342) and 418 (420) $cm^{-1}$. The line at 2303 $cm^{-1}$ was a polarized line and was already assigned to the C-D symmetric stretching vibration of species $A_1'$. In the neighborhood of this line was observed another weak depolarized line at 2282 $cm^{-1}$. It was difficult to determine which of these two lines was to be assigned to the C-D degenerate stretching vibration. However, since the line at 2282 $cm^{-1}$ might be explained as a combination, 952 ($a_1'$) + 1342 ($e'$, gaseous infrared band), the line at 2303 $cm^{-1}$ was assigned to the C-D degenerate stretching vibration, assuming that its frequency was equal to that of the symmetric vibration as in the case of trichlorobenzene.

The lines at 1548 and at 418 $cm^{-1}$ were assigned to the stretching and deformation vibrations of the benzene ring respectively. As these line definitely corresponded to the lines at 1565 and 425 $cm^{-1}$ of ordinary substance, there is no point of discussion in the assignment.

The line at 1337 $cm^{-1}$, though weak in Raman spectra, corresponded to the intense band at 1342 $cm^{-1}$ in the infrared absorption spectrum, and it was plausibly assigned to the stretching vibration of the ring, $\nu_{13}$, by taking account of its frequency and depolarization ratio. Other weak lines observed in its vicinity, that is, lines at 1528, 1455 and 1418 $cm^{-1}$, could not be assigned to $\nu_{13}$ from a consideration of their depolarization ratios and of correspondencies with the infrared absorption bands.

The remaining three vibrations are the in-plane bending vibration of C-D bonds, the stretching vibration and the in-plane bending vibration of C-Cl bonds. As the first two vibrations were not observed in the Raman spectra, probably because of their weak intensities, as in the case of trichlorobenzene, the frequencies of observed in the infrared spectrum had to be adopted. To the in-plane bending vibration of C-D bonds was assigned the absorption band at 843 $cm^{-1}$ observed in the infrared spectrum, for the corresponding band of the ordinary substance was observed at 1103 $cm^{-1}$. The absorption band at 799 $cm^{-1}$ was assigned to the C-Cl stretching vibration, because the band at 814 $cm^{-1}$ was assigned to the corresponding vibration of ordinary substance.

The in-plane bending vibration of C-Cl bonds was expected to be observed near 200 $cm^{-1}$, and only a remarkable line at 188 $cm^{-1}$ was observed in this region for deuterated substance. From both the intensity and the depolarization ratio, this line was considered to correspond to the line at 188 $cm^{-1}$ of ordinary substance, but it was not known at this point whether this line was to be assigned to the in-plane or to the out-of-plane vibration of C-Cl bonds. Concerning this alternate assignment, some discussion will be given later.

*Species* $E''$. — The frequency of the out-of-plane bending vibration of C-D bonds is estimated to be lower than 800 $cm^{-1}$, and a diffuse line was observed at 711 $cm^{-1}$ as a shoulder of a strong Raman line of the solvent in the spectrum of carbon tetrachloride solution of deuterated substance. This line seemed to be recognizable also in the methanol solution, but due to its low intensity it could not be clearly distinguished from the noise. However, a polarized line which seemed to correspond to the first harmonic of this vibration was observed at 1418 $cm^{-1}$. Since this line could not be explained as an overtone or as a combination of other vibrations, the line at 711 $cm^{-1}$ could be considered as a normal vibration.

It was apparent from the frequency and

the depolarization ratio that the line at 494 $cm^{-1}$ corresponds to the line at 526 $cm^{-1}$ of ordinary substance. Accordingly the line at 494 $cm^{-1}$ was assigned to the out-of-plane bending vibration of the benzene ring of deuterated substance.

As for the out-of-plane vibration of C-Cl bonds, the line at 188 $cm^{-1}$ might be assigned to it. However, as was mentioned above, it is difficult to determine whether this line is to be assigned to the in-plane or out-of-plane vibration of C-Cl bonds.

The above assignment is shown in Table IV.

*Overtones and Combinations.*—More overtones and combinations were observed in the spectra of deuterated substance than in that of ordinary substance. As was stated above, the line at 993 $cm^{-1}$ was explained as 495 ($e''$)×2, the line at 2282 $cm^{-1}$ as 952 ($a_1'$)+1337 ($e'$), and the line at 1418 $cm^{-1}$ as 711 ($e''$)×2. For the other observed Raman lines, the following explanations were possible:

1058: 535 ($a_2''$)×2

1455: ?

1528: 1337 ($e'$, from the infrared spectrum) +188 ($e'$ or $e''$)

1767: 1337 ($e'$)+418 ($e'$)

1883: 1143 ($a_1'$)+767 ($e'$) or 1337 ($e'$) +535 ($a_2''$)

2029: 1550 ($e'$)+841 ($e'$, from the infrared spectrum)

2537: 950 ($a_1'$)+1550 ($e'$)

3079, 3094: 1549 ($e'$)×2, 2303 ($a_1'$ and $e'$) +801 ($a_2''$)

Though the line observed at 1455 $cm^{-1}$ could not be well explained, the existence of such a line is quite natural, since the molecule has three normal vibrations belonging to species $A_2'$ which are active to neither the Raman nor the infrared spectrum. Some of the above-mentioned explanations of overtones and combinations were not consistent with the observed qualitative depolarization ratios* But this inconsistency might not be very significant. If too much confidence was put in the observed results of the depolarization ratio, it might sometimes lead to an erroneous assignment. However, it should be mentioned here that the above explanation of the overtones and combinations may not be absolutely correct because of the existence of the unobservable normal vibrations.

* For example, the combination of two fundamental vibrations belonging to species E′ brings out four vibrations belonging to species $A_1'$, $A_2'$ and E′ respectively, of which the one belonging to species $A_1'$ might have the highest intensity in Raman effect. Therefore, the depolarization ratio of the observed line corresponding to this combination has to be considerably small.

## Discussion

The product rule was applied to the assignment given above. For species $A_1'$, the ratio of the products of the frequencies of the ordinary and deuterated trichlorobenzenes was calculated from the observed frequencies, such as 1.401 in good agreement with the theoretical value 1.414, showing that the assignment was correct.

In species E′, it has previously been pointed out that the assignment of $\nu_{17}$ was somewhat questionable. The theoretical value of the ratio is 1.982. Assuming that the line at 209 $cm^{-1}$ of ordinary trichlorobenzene and the line at 188 $cm^{-1}$ of deuterated correspond to the in-plane bending vibrations of C-Cl bonds, $\nu_{17}$'s, the ratio calculated from the observed frequencies was 2.162, exceeding the theoretical value by about 9%. On the other hand, assuming that the line observed at 188 $cm^{-1}$ of both trichlorobenzenes corresponds to $\nu_{17}$, the calculated ratio was found to be 1.944, lower than the theoretical value by about 2%. This discrepancy of 2% could be expected from the accumulation of small errors in frequency measurements, from the shift of the fundamental lines due to Fermi reasonance, etc., but that of 9% had to be regarded as inexplicable and might suggest an erroneous assignment. Thus, it was decided that the lines at 188 $cm^{-1}$ in both substances had to be assigned to $\nu_{17}$. However, it should be mentioned here that, since there exists a possibility that an unobservably weak line corresponding to the line at 209 $cm^{-1}$ does exsist at a suitable frequency (about 205 $cm^{-1}$) in the spectrum of deuterated substance, the above assignment can not be considered absolutely correct.

For species E″, the theoretical value is 1.402. However, since $\nu_{18}$ (C-H out-of-plane bending vibration) of ordinary trichlorobenzene was not observed, the observed ratio could not be compared with the theoretical one. Accordingly, the above-mintioned question concerning the assignment of the C-Cl in-plane bending vibration could not be solved. However, if the frequency of $\nu_{20}$'s were assumed to be 188 $cm^{-1}$ for both ordinary and deuterated substances, the frequency of $\nu_{18}$ of ordinary substance could be calculated to be 936 $cm^{-1}$ by applying the product rule. However, as was stated in the previous paragraphs, no Raman line was observed in the neighborhood of this frequency.

**Summary**

The Raman spectra and the qualitative depolarization ratio of each line were observed for the solutions of 1, 3, 5-trichlorobenzene and 1, 3, 5-trichlorobenzene-$d_3$. The assignments of Raman active normal vibrations of these substances were carried out from the results of these measurements. The assignments for species $A_1'$ and $E'$ proved to be correct from the application of the product rule, showing a good accordance between theoretical and calculated ratios of products of the frequencies. However, the application of the product rule was impossible for species $E''$ because of unobserved frequencies.

The author would like to express his appreciation of the valuable advice given by Dr. Y. Mashiko.

# *Raman Spectra of 1, 2, 4, 5-Tetrachlorobenzene and 1, 2, 4, 5-Tetrachlorobenzene-$d_2$*

By Shinnosuke SAËKI

(Received May 16, 1961)

Concerning the infrared absorption spectra of 1, 2, 4, 5-tetrachlorobenzene and 1, 2, 4, 5-tetrachlorobenzene-$d_2$, a report[1] was previously presented by the author in which tentative assigments were proposed for the observed infrared absorption bands. In this paper the Raman spectra of these substances will be presented, and the assignment of these observed lines will be discussed.

The Raman spectra of ordinary 1,2,4,5-tetrachlorobenzene have already been reported on by several investigators[2]. But all of their papers have been concerned with a group of similarly substituted benzenes, 1, 2, 4, 5-tetrachlorobenzene was treated simply as a member of this group. Consequently, the molecular spectra of 1, 2, 4, 5-tetrachlorobenzene itself do not appear to have been fully studied. In this paper, instead of adopting such an inductive method, the Raman spectrum was observed for deuterated as well as for ordinary 1, 2, 4, 5-tetrachlorobenzene, and the assignment was carried out by comparing the Raman spectra for both species of the substance.

Since the molecule contains four chlorine atoms, the normal vibrations were expected to be concentrated in a lower frequency region compared with those of *p*-dichlorobenzene and 1,3,5-trichlorobenzene, which have been studied in previous papers[3-6]. As the observation of low frequency vibrations is much easier in Raman effect than in infrared spectroscopy, the product rule can be applied more completely to Raman lines. However, since a Raman line belonging to a species other than the totally symmetric one generally has a relatively low intensity and can often escape observation, this might become a new obstacle for the assignment.

## Experimental and Results

Ordinary commercial 1,2,4,5-tetrachlorobenzene of extra pure grade was recrystallized from ethanol three times, and then further purified by sublimation.

The deuterated substance was prepared in the following way: 1,2,4,5-tetrachlorobenzene was stirred with deuterated sulfuric acid for eight hours at 150°C. The reaction mixture was then poured on ice and the precipitate filtered off and dried. The degree of substitution was checked by the infrared absorption spectrum after each substitution reaction, and the reaction was repeated until the strongest absorption band of $C_6HDCl_4$ could hardly be recognized. The obtained $C_6D_2Cl_4$ was purified in the same way as that of ordinary tetrachlorobenzene.

The Raman spectra were measured by using a Cary model 81 automatic recording spectrophotometer, and the qualitative depolarization ratios were measured by the two-exposure method, using polaroid cylinders.

The measurements were carried out for the solutions in carbon tetrachloride and in benzene.

Although the Raman spectra of *p*-dichlorobenzene and 1,3,5-trichlorobenzene were measured for the solutions in methanol and carbon tetrachloride[5,6], the solubility of 1,2,4,5-tetrachlorobenzene in

methanol is so low that the spectra could not be measured in methanol solutions. Since the solubility of chlorobenzene decreases with the increasing number of chlorine atoms contained in the molecule, the concentrations of the sample solutions were not very high in this case. In the carbon tetrachloride solution, about 0.7 g. solute was dissolved in 5 ml. of solvent, while in the benzene solution about 0.6 g. solute was dissolved in 5 ml. of solvent. Irrespective of these low concentrations, the solute was not entirely dissolved at room temperature, and it was necessary to keep the Raman tube in the lamp compartment for almost an hour in order to dissolve the entire solute*.

* The temperature was 36°C in the lamp compartment.

As the concentrations of the solutions were low, a relatively high gain was required for the measurements; consequently, the signal to noise ratio in the obtained spectra was about 25, a rather low value for this spectrometer. The obtained Raman spectra are shown in Figs. 1—4, where the noises could not be well represented because of the small sizes of the figures. The base line of each spectrum, especially of the spectra of deuterated substance, rose towards the higher frequency limit of the spectrum. This was probably due to a slight amount of resinous impurity, which was unavoidable in this case. The rapid rising of the base line made necessary its resetting at several frequencies, but it produced no obstruction to the measurement of the frequencies of Raman lines.

In the figures, the Raman lines marked with small arrows are those of the solvent or of the mercury arc lamp.

The observed Raman lines are listed in Tables I and II. In the tables, the intensities are simply represented by the heights of lines measured by the scale on the chart.

## Assignment

Since the 1, 2, 4, 5-tetrachlorobenzene molecule has the symmetry $V_h$, as does the *p*-dichlorobenzene molecule, fifteen of thirty normal vibrations are active to the Raman effect. Also, as this molecule has a center of symmetry, there is no vibration which is active in both the Raman effect and infrared absorption, according to the mutual exclusion law. The fifteen Raman active normal vibrations are classified as six vibrations belonging to species $A_g$ (in-plane), five to species $B_{3g}$ (in-plane), one to species $B_{1g}$ (out-of-plane), and three to species $B_{2g}$ (out-of-plane)*. These normal vibrations and their modes are shown in Table III.

TABLE III. SPECIES AND MODES OF NORMAL VIBRATIONS OF 1,2,4,5-TETRACHLOROBENZENE

| Species | No. | Mode |
|---|---|---|
| $A_g$ | $\nu_1$ | C-H or C-D stretching |
| | $\nu_2$ | Ring stretching |
| | $\nu_3$ | Ring stretching |
| | $\nu_4$ | C-Cl stretching |
| | $\nu_5$ | Ring deformation |
| | $\nu_6$ | C-Cl in-plane bending |
| $B_{1g}$ | $\nu_9$ | C-Cl out-of-plane bending |
| $B_{2g}$ | $\nu_{15}$ | C-H or C-D out-of-plane bending |
| | $\nu_{16}$ | Ring out-of-plane deformation |
| | $\nu_{17}$ | C-Cl out-of-plane bending |
| $B_{3g}$ | $\nu_{23}$ | Ring stretching |
| | $\nu_{24}$ | C-H or C-D in-plane bending |
| | $\nu_{25}$ | C-Cl stretching |
| | $\nu_{26}$ | Ring in-plane deformation |
| | $\nu_{27}$ | C-Cl in-plane bending |

* The x-axis was taken along the two-fold axis perpendicular to the molecular plane, and the z axis was taken along the line combining the two hydrogen atoms.

Sixteen Raman lines were observed for ordinary as well as for deuterated 1, 2, 4, 5-tetrachlorobenzene, but, considering their frequencies, some of them apparently do not correspond to normal vibrations. Therefore, it seems that some of the Raman active normal vibrations were not observed on account of very low frequencies or intensities.

**1, 2, 4, 5-Tetrachlorobenzene.** — *Species $A_g$.* — The six normal vibrations belonging to species $A_g$ are seen in Table III. In the spectra obtained, the polarized and strong lines were observed in the regions expected from their modes, except for $\nu_2$ and $\nu_6$ (see Figs. 1 and 2), and the following assignment was unambiguously decided upon: $\nu_1$: 3075 $cm^{-1}$, $\nu_3$: 1162 $cm^{-1}$, $\nu_4$: 685 $cm^{-1}$ and $\nu_5$: 350 $cm^{-1}$. Considering the high intensities and low depolarization ratios of these lines, no point of discussion exists in the above assignment.

In the region around 1500 $cm^{-1}$ where the ring stretching vibration was expected to appear, a remarkable line was observed at 1567 $cm^{-1}$. However, the large depolarization ratio of this line clearly showed itself to correspond to the ring stretching vibration of species $B_{3g}$. In addition to this line, a much weaker line was with difficulty observed at 1535 $cm^{-1}$ only in the carbon tetrachloride solution. As this line was observed as a shoulder of the Raman line of the solvent at 1550 $cm^{-1}$ only in the spectrum excited by perpendicularly polarized light, its accurate frequency was difficult to measure. However, it was clear that this was a polarized line, since it entirely disappeared when excited by parallelly polarized light.

It might be indeed unusual for a line belonging to species $A_g$ to show such a weak intensity, but since no other polarized line was found in this region, this line had to be considered to correspond to the totally symmetric ring stretching vibration.

As for the last vibration of species $A_g$, $\nu_6$, the in-plane bending vibration of the C-Cl bonds, two weak lines were observed near 200 $cm^{-1}$, one at 226 $cm^{-1}$ and the other at 184 $cm^{-1}$. In the carbon tetrachloride solution, these lines were masked by a strong line of the solvent, but in the benzene solution they were observed as a shoulder of the exciting line. However, neither of these lines could be assigned to $\nu_6$, for both of them had considerable depolarization ratios. Therefore, it was concluded that $\nu_6$ might have a lower frequency and be completely masked by the Rayleigh line. By estimating from the width of the Rayleigh line, the frequency should be lower than 175 $cm^{-1}$.

*Species $B_{1g}$.*—As is seen in Table III, the only vibration belonging to species $B_{1g}$ is the out-of-plane bending vibration of C-Cl bonds, $\nu_9$. As there are four Raman active bending vibrations of C-Cl bonds, that is, $\nu_6$, $\nu_9$, $\nu_{17}$ and $\nu_{27}$, it is very difficult to determine the assignment of the two observed lines at 184 and 226 $cm^{-1}$. However, these lines were shifted to 184 and 215 $cm^{-1}$ respectively, by the deuteration; this fact suggests that the line at 226 $cm^{-1}$ of ordinary tetrachlorobenzene could not correspond to $\nu_9$, which belongs to species $B_{1g}$, for the product rule requires that the ratio of the $\nu_9$'s of ordinary and deuterated tetrachlorobenzene be 1. Consequently, the conclusion was drawn that the vibration $\nu_9$ corresponds to the line at 184 $cm^{-1}$ or lies in the unobservable low frequency region.

*Species $B_{2g}$.*—Although the out-of-plane bending vibration of C-H bonds was expected to appear in the region from 800 to 1000 $cm^{-1}$, no Raman line was observed in this region, as is seen in Table I. Since the Raman active out-of-plane vibrations of C-H bonds were not observed in the spectrum of *p*-dichloro- and 1, 3, 5-trichlorobenzene, as was reported in the previous papers[2,3], it appeared to be unobservable, in this case also on account of its low intensity.

To the out-of-plane deformation vibration of the ring, $\nu_{16}$, the line at 314 $cm^{-1}$ could be assigned. However, since there is another ring deformation vibration belonging to species $B_{3g}$ ($\nu_{26}$), it seemed also possible to assign the line at 314 $cm^{-1}$ to it. However, this latter possibility must be ruled out for a reason which will be mentioned later.

As for the out-of-plane bending vibration of C-Cl bonds, $\nu_{17}$, it is possibly unobserved. However, provided that it were observed in the spectra, the line at 184 $cm^{-1}$ or 226 $cm^{-1}$ might be regarded as the corresponding line.

*Species $B_{3g}$.*—As the stretching vibration of the benzene ring, $\nu_{23}$, was expected to appear at about 1500 $cm^{-1}$, it was clear that the above-mentioned remarkable line at 1567 $cm^{-1}$ corresponded to this vibration. This assignment is consistent with the observed qualitative depolarization ratio.

In the region 1000~1200 $cm^{-1}$ where the in-plane bending vibration of C-H bonds, $\nu_{24}$, was expected to appear, two lines of medium intensity were observed at 1190 and 1206 $cm^{-1}$. Since the latter line was polarized, as is shown in Table I, the former was assigned to $\nu_{24}$.

Although the C-Cl stretching vibration, $\nu_{25}$, was expected to appear in the vicinity of 700 $cm^{-1}$, no line was observed in this region except the strong line at 685 $cm^{-1}$ which had already been assigned to $\nu_4$. But if lines are looked for over a wider frequency region, two weak lines are found at 509 and 554 $cm^{-1}$. Although the former was a little stronger than the latter, the latter combining with the line at 685 $cm^{-1}$ ($a_g$), gave a combination line at 1236 $cm^{-1}$ which could not be explained as any other combination. Therefore, the line at 554 $cm^{-1}$ was assigned to $\nu_{25}$.

To the in-plane deformation vibration of the benzene ring, $\nu_{26}$, either the line at 467 $cm^{-1}$ or at 509 $cm^{-1}$ might be assigned. It appeared to be a little strained to assign the line at 314 $cm^{-1}$ to $\nu_{26}$, for $\nu_{26}$ probably has a frequency higher than 351 $cm^{-1}$, which was the frequency of the totally symmetric in-plane deformation vibration of the benzene ring. However, since the lines at 467 and 509 $cm^{-1}$ were both very weak, it was difficult to determine which was to be assigned to $\nu_{26}$. If one was taken for the fundamental, the other had to be explained as an overtone or a combination. However, if necessary, both of them could be explained as an overtone or a combination, that is, $467=226$ ($b_{2g}$)$\times 2$ and $509=184$ ($b_{1g}$ or $b_{3g}$)$+314$ ($b_{2g}$).

However, there was another, more plausible explanation for the line at 509 $cm^{-1}$. As was reported in our previous paper[4], a strong absorption band was observed at 507 $cm^{-1}$ in the infrared absorption spectrum of this substance. Taking account of this fact, the Raman line at 509 $cm^{-1}$ was explained as the forbidden line which was brought out by the breakdown of the rule of mutual exclusion in solution. Since it is quite probable that the rule of mutual exclusion breaks down in the condensed system, the above explanation appeared to be the most plausible. Accordingly, the line at 467 $cm^{-1}$ was assigned to $\nu_{26}$.

For the C-Cl in-plane bending vibration, $\nu_{27}$, there were two lines to be assigned, that is, the lines at 184 $cm^{-1}$ and at 226 $cm^{-1}$. As has been mentioned above, it is impossible to determine definitely the assignment of these lines. It might as possibly be that $\nu_{27}$ was not observed as that $\nu_{27}$ corresponds to one of these two lines.

*Overtones and Combinations.*—There were five observed lines which were not assigned to the fundamentals, that is, the lines at 3137, 2502, 1236, 1206 and 509 $cm^{-1}$. The lines at 1236 and 509 $cm^{-1}$ have already been explained as 685 ($a_g$)$+554$ ($b_{3g}$) and as a forbidden line which was brought out by the breakdown of the mutual exclusion law respectively.

The line at 3137 $cm^{-1}$ was clearly explained as 1567 ($b_{3g}$)$\times 2$.

Although the lines at 2502 and 1206 $cm^{-1}$ were both polarized, these could be well explained neither as an overtone nor as a combination belonging to species $A_g$. Since these

two lines were observed also in the carbon tetrachloride solution of the deuterated substance, as is shown in Table II, they should be regarded as lines due to the slight impurity contained in the solvent. Although these lines were not observed in the Raman spectrum of the pure solvent, they might quite probably appear in the spectra of sample solutions because of the extremely high gain required on the measurement of the sample solutions. Thus, these lines were removed from discussion.

**1, 2, 4, 5-Tetrachlorobenzene-$d_2$.**—*Species $A_g$.*—The line at 2301 $cm^{-1}$ corresponded apparently to $\nu_1$, the stretching vibration of the C-D bonds. Although the depolarization ratio of this line was observed to be unusually high*, there was no other remarkable line in its vicinity. Since there is no other Raman active stretching vibration of C-D bonds, there is no room for doubting this assignment.

A very weak line observed at 1520 $cm^{-1}$ was assigned to $\nu_2$, for it was apparent from the frequency and the intensity that this line corresponds to the line at 1535 $cm^{-1}$ ($\nu_2$) of ordinary 1, 2, 4, 5-tetrachlorobenzene.

For $\nu_3 \sim \nu_5$, the assignment could unambiguously be determined, as is shown in Table IV. No line was observed for $\nu_6$. This might be because its frequency was too low to be observed, as in the case of ordinary substance. A combination line was observed at 1675 $cm^{-1}$ which could well be explained by assuming the frequency of $\nu_6$ to be 155 $cm^{-1}$, as will be shown later. But, of course, this was not strong enough support for assigning 155 $cm^{-1}$ to $\nu_6$.

*Species $B_{1g}$.*—Only $\nu_9$ belongs to this species. As was already mentioned, it is not certain that the frequency of this vibration is high enough to be observed. Provided that this vibration can be observed, the line at 184 $cm^{-1}$ could be assigned to it.

*Species $B_{2g}$.*—The C-D out-of-plane bending vibration of this species, $\nu_{15}$, was not observed as in the case of the ordinary substance.

To the deformation vibration of the ring, $\nu_{16}$, the line at 315 $cm^{-1}$ was assigned. Although it is impossible that the frequency of the deuterated substance is higher than that of the ordinary substance (314 $cm^{-1}$), this might be attributed to a slight error in the measurement of the frequency because of excessive noise.

As for $\nu_{17}$, the line at 184 $cm^{-1}$ might be assigned to it. However, the assignment for such C-Cl bending vibrations is not very certain for the reason which has already been stated in the case of ordinary tetrachlorobenzene.

* The measurement was repeated three times, and the high depolarization ratio was observed every time.

*Species $B_{3g}$.*—The line at 1552 $cm^{-1}$ was easily assigned to $\nu_{23}$, the stretching vibration of the ring.

As for $\nu_{24}$, since it was observed at 1190 $cm^{-1}$ in the case of the ordinary substance, it was expected to appear near 1000 $cm^{-1}$ in the deuterated substance. But in this region only a weak and diffuse line was observed at 956 $cm^{-1}$. Since, irrespective of its low depolarization ratio, this line could not be explained as an overtone or as a combination belonging to species $A_g$, it might be assigned to $\nu_{24}$. It will be seen later that this assignment facilitates the explanation of some combination lines.

Although $\nu_{25}$ and $\nu_{26}$ of ordinary tetrachlorobenzene were observed at 554 and 467 $cm^{-1}$ respectively, those of deuterated one were not observed.

As for $\nu_{27}$, since the line at 226 $cm^{-1}$ was assigned to it in the case of 1, 2, 4, 5-tetrachlorobenzene, the line at 215 $cm^{-1}$ should be assigned to it in the case of deuterated substance.

*Overtones and Combinations.*—There were six observed lines which were not assigned to the fundamentals, that is, 1180, 1208, 1410, 1448, 1675 and 2500 $cm^{-1}$. Of these six, the two lines at 1208 $cm^{-1}$ and 2500 $cm^{-1}$ should be regarded as lines of the impurity contained in the solvent (carbon tetrachloride), as was pointed out in the previous paragraphs, and removed from discussion.

The line at 1180 $cm^{-1}$ was explained as 956 ($b_{3g}$) + 215 ($b_{2g}$). The existence of this combination line appeared to justify not only the assignment of the weak line at 956 $cm^{-1}$ to a fundamental, but also the determination of species $B_{2g}$ for the fundamental line at 215 $cm^{-1}$. For, by assuming that this line corresponds to the fundamental of species $B_{3g}$ ($\nu_{27}$), the species of the combination line at 1180 $cm^{-1}$ should be $A_g$, while the observed depolarization ratio was relatively high. However, it should be mentioned here that the certainty of this determination of the species depends on the reliability of the measurement of the depolarization ratio.

The lines at 1410 and 1448 $cm^{-1}$ were well explained as the overtones of the infrared active fundamentals of 719 and 725 $cm^{-1}$ respectively. These two overtones might perhaps resonate and be shifted away from each other.

The line at 1675 $cm^{-1}$, with a low depolarization ratio, could not be explained as an overtone, but, provided that the frequency of the unobserved $\nu_6$ of species $A_g$ is 155 $cm^{-1}$, it can be explained as a combination, 1520 ($a_g$) + 155 ($a_g$).

The assignments determined above are shown in Table IV.

TABLE IV. THE ASSIGNMENTS OF RAMAN LINES OF ORDINARY AND DEUTERATED 1,2,4,5-TETRACHLOROBENZENE

| Species | No. | $\tilde{\nu}$ | | Mode |
|---|---|---|---|---|
| | | $C_6H_2Cl_4$ | $C_6D_2Cl_4$ | |
| $A_g$ | $\nu_1$ | 3075 | 2301 | C-H or C-D stretching |
| | $\nu_2$ | ca. 1535 | 1520 | Ring stretching |
| | $\nu_3$ | 1162 | 1155 | Ring stretching |
| | $\nu_4$ | 685 | 667 | C-Cl stretching |
| | $\nu_5$ | 351 | 351 | Ring in-plane deformation |
| | $\nu_6$ | — | — | C-Cl in-plane bending |
| $B_{1g}$ | $\nu_9$ | 184? | 184? | C-Cl out-of-plane bending |
| $B_{2g}$ | $\nu_{15}$ | — | — | C-H or C-D out-of-plane bending |
| | $\nu_{16}$ | 314 | 315 | Ring out-of-plane deformation |
| | $\nu_{17}$ | 226 | 215 | C-Cl out-of-plane bending |
| $B_{3g}$ | $\nu_{23}$ | 1567 | 1552 | Ring stretching |
| | $\nu_{24}$ | 1190 | 956 | C-H or C-D in-plane bending |
| | $\nu_{25}$ | 554 | — | C-Cl stretching |
| | $\nu_{26}$ | 467 | — | Ring in-plane deformation |
| | $\nu_{27}$ | 184? | 184? | C-Cl in-plane bending |

## Discussion

According to the product rule, the theoretical values of the product of the ratios of the frequencies for each substance are 1.414, 1, 1.393 and 1.408 for species $A_g$, $B_{1g}$, $B_{2g}$ and $B_{3g}$ respectively.

For species $A_g$, although the frequencies of $\nu_6$'s were observed for neither species of substance, these could with enough security be assumed to be nearly equal*. With this assumption, the ratio calculated from the observed frequencies for species $A_g$ was 1.394 in good accordance with the above-mentioned theoretical value, showing the correctness of the proposed assignment.

For species $B_{1g}$, the assignment was determined so that the product rule might be fulfilled.

For species $B_{2g}$, as the bending vibrations of C-H and C-D bonds were not observed, the application of the product rule was impossible.

For species $B_{3g}$, the application of the product rule was also impossible because, while all normal vibrations were observed for 1,2,4,5-tetrachlorobenzene (assuming that $\nu_{27}$ is 184 $cm^{-1}$), some of those for 1,2,4,5-tetrachlorobenzene-$d_2$ were not observed.

Generally speaking, in the case of 1,2,4,5-tetrachlorobenzene, it was difficult to observe Raman lines of low intensity because of its poor solubility to the solvents. Furthermore, it is impossible, because of the mutual exclusion law, to look for these unobserved normal frequencies in the infrared absorption spectrum. Consequently, for some of the normal vibrations of this substance, there was no way of knowing their frequencies; this fact prevented the application of the product rule to verify the proposed assignment for most of the species. However, the clear explanation of observed weak lines as overtones or combinations appears to suggest that the proposed assignments might be the most reliable one at present.

## Summary

The Raman spectra of 1,2,4,5-tetrachlorobenzene and 1,2,4,5-tetrachlorobenzene-$d_2$ were measured in their dissolved states in methanol and carbon tetrachloride. The depolarization ratio of each Raman line was also observed qualitatively by the two-exposure method, using polaroid cylinders. On the basis of these experimental results, the assignment of normal vibrations was determined. The verification of the proposed assignments by means of the product rule was impossible for most of the species because of some unobserved normal vibrations. But, for species $A_g$, good agreement was obtained between the theoretical and observed values of the product of the frequencies for each substance, and the correctness of the assignment was thus verified.

The author would like to thank Dr. Y. Mashiko for helpful comments in connection with this paper.

*Shibuya-ku, Tokyo*

* The fact that the normal vibrations with low frequency were scarcely influenced by the substitution for hydrogen atoms of deuterium ones has been seen in the cases of *p*-dichlorobenzene and 1,3,5-trichlorobenzene (Refs. 5 and 6).

# *Mass-spectrometric Study on Ionization and Dissociation of Formaldehyde, Acetaldehyde, Acetone and Ethyl Methyl Ketone by Electron Impact*

By Ichiro KANOMATA

(Received March 28, 1961)

The ionization and dissociation of ethyl alcohol[1,2] and diethyl ether[3] molecules caused by electron impact have previously been studied by the present author. It has been concluded that the ionization takes place by the removal of one of the lone pair electrons of the oxygen atom and that the bond energy additivity can be applied to the ionized dissociation of these molecules by considering the trivalent character of the $O^+$.

In this report, the ionization and dissociation of formaldehyde, acetaldehyde, acetone and ethyl methyl ketone molecules, each of which has an oxygen atom as in the case of alcohols and ethers, are discussed in relation to the determination of appearance potentials of the ions produced by electron impact. In the case of formaldehyde and acetaldehyde, Reed[4,5] previously carried out an appearance potential study for the purpose of determining the dissociation energies of $D$(H–CHO), $D$(H–CO) and $D(CH_3$–CHO) and the ionization potential of CHO radical. Further, Morrison et al.[6] reported the determination of the ionization potentials of these two molecules. A similar study was also made by Kambara[7] with acetone.

## Experimental

The mass-spectrometer[8] used for this study is of a 90° sector type ($r$=12 cm.). The appearance potentials (AP) of ions were determined by the retarding potential difference method[9] (RPD). The apparatus[10] is nearly identical with Fox's[11], and its details have been described[12]. The ionization potentials and uppor break points on the ionization efficiency curves of $N_2$, CO and Kr obtained in the present study agree well with Fox's results.

The ionization potential of argon (15.77 eV.) was used as a standard for parent ions, although, owing to the RPD method, such a standard was not necessary in as much as the ion source was clean. Appearance potentials of fragment ions were determined by referring to the appearance potentials of parent ions.

The samples were chemically pure. Formaldehyde was prepared through the thermal decomposition of the polymer, and other sample gases were used after dehydration by calcium chloride.

## Results

The appearance ratios of the ions produced by 75 eV. electron impact and their appearance potentials are shown in Tables I and II respectively. Some ionization efficiency curves are illustrated in Fig. 1. Owing to the RPD method, characterized by a narrow distribution (0.2 eV.) of electron energy, fine structures appear in the ionization efficiency curves.

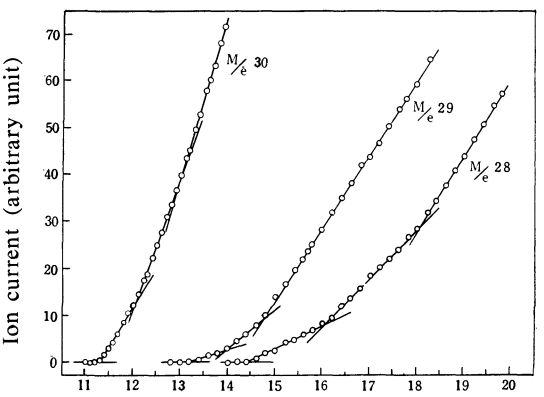

Fig. 1. Ionization efficiency curves of $HCHO^+$, $CHO^+$ and $CO^+$.

## Discussion

The production processes of ions are as follows:

*1) Formaldehyde*

**M/e=30** $HCHO^+$

The ion is a parent ion. Two distinct breaks exist in the ionization efficiency curve; the

| 27 | $C_2H_3^+$ | | 16.9 | | |
| 15 | $CH_3^+$ | $15.4\pm0.2$ | $15.53\pm0.08$<br>$17.3\pm0.15$ | $14.8_2\pm0.05$ | |

energy values corresponding to the threshold and the breaks are $10.86\pm0.02$, $11.6_6\pm0.1$ and $12.6_3\pm0.15$ eV. respectively. Sugden and Price[13] determined the first, second and third ionization potentials of HCHO as $10.8\pm0.1$, $11.8\pm0.2$ and $13.1\pm0.2$ eV. respectively through the measurement of the total ion current produced by the impact of accelerated photo-electrons. The three values obtained by the present author may be expected to correspond to these ionization potentials.

The first ionization potential of 10.86 eV. agrees well with Reed's result of 10.85 eV. obtained by electron impact[4], with Watanabe's of 10.87 eV. by photon impact[14], and with the spectroscopic value of 10.88 eV.[15] It was pointed out by McMurry[16] in his report on absorption spectra that lone pair electrons of the oxygen atom in the molecule are at the highest occupied orbital. Therefore, the first ionization potential corresponds to the energy necessary for the removal of one of the lone pair electrons.

The second ionization potential of $11.6_6$ eV., on which there are very few data[13], may relate to the ionization caused by the removal of the $\pi$-electron of the C-O bond, as has been theoretically pointed out by Foster and Boys[17] and by Sugden.

The third ionization potential of $12.6_3$ eV. is thought to correspond to the removal of a $\sigma$-electron from the C-O bond, as has also been pointed out by Foster and Boys.

The values of the first ionization potentials of parent molecules of aldehyde and ketone obtained by the present author are listed in Table III with their dipole moments. It is shown that the ionization potentials decrease by 0.5 eV. in the order of HCHO, $CH_3CHO$ and $(CH_3)_2CO$, but that the ionization potential of $(CH_3)(C_2H_5)CO$ is a little larger than that of $(CH_3)_2CO$.

TABLE III. IONIZATION POTENTIAL AND DIPOLE MOMENT

| Molecule | Ionization potential, eV. | Dipole moment* ($D$) |
|---|---|---|
| HCHO | 10.86 | 2.27 |
| $CH_3CHO$ | 10.31 | 2.72 |
| $C_2H_5CHO$ | — | 2.73 |
| $(CH_3)_2CO$ | 9.84 | 2.85 |
| $(CH_3)(C_2H_5)CO$ | 9.88 | 2.79 |

* Dipole moment: Compiled by L. G. Wesson, a publication of the Technology press. M.I.T.

13) T. M. Sugden and W. C. Price, *Trans. Faraday Soc.*, **44**, 116 (1948).
14) K. Watanabe, *J. Chem. Phys.*, **26**, 542 (1957).
15) W. C. Price, ibid., **3**, 256 (1935).
16) H. L. McMurry, ibid., **9**, 231 (1941).
17) J. M. Foster and S. F. Boys, *Rev. Mod. Phys.*, **32**, 303 (1960).

The fact that ionization potentials decrease with the increase of the number of $CH_3$ group may be due to the effect of hyper-conjugation on the ionization of the oxygen atom. That is, it is considered, in general, that the hyper-conjugation effect is predominant when the carbon atom bound with the $CH_3$ group is in an $sp^2$ configuration. The fact that the ionization potential of ethyl methyl ketone is somewhat larger than that of acetone seems to indicate that the hyper-conjugation plays an important role in the present case.

These results closely relate to the change of the dipole moments of the molecules which can be explained by the hyper-conjugation. The ionization potential decreases with the increment of dipole moment.

**M/e=29** $H\text{-}C\equiv O^+$

Two breaks exist in the ionization efficiency curve of this ion. The values of the threshold and the breaks are 12.90, 13.6 and $14.2_5$ eV. respectively.

The appearace potential of the $R_1^+$ ion produced from the $R_1R_2$ molecule is expressed as follows when excess energy (excitation and kinetic energy of $R_1^+$ and/or $R_2$) is disregarded.

$$A(R_1^+)=I(R_1)+D(R_1-R_2)$$

If the ionization takes place by the removal of one of the lone pair electrons belonging to the oxygen atom in the molecule, the energy necessary for this reaction is 10.86 eV. By inserting the value of $D$(H-CHO) (79.3 kcal./mol. or 3.45 eV.) in the above equation, the ionization potential of $R_{29}$ is obtained as 9.45 eV. (12.9 eV.$-$3.45 eV.). This value is 1.4 eV. lower than the ionization potential of the formaldehyde molecule. This may be explained by the fact that the triple bond formation can be expected between C and $O^+$ in the ionized state of CHO, while, for the ionized state of formaldehyde, only the double bond can exist. That is, the formation of the triple bond brings the stabilization of 1.4 eV. on the $CHO^+$. The value of 1.4 eV. is considerably smaller than the stabilization energy of 2.35 eV. in the case of $H_2C=O^+-C_2H_5$ produced from diethyl ether[3].

The bond energy between C and O in formaldehyde is 144 kcal./mol.[18] If it is assumed that this bond energy is not affected by the ionization of the lone pair electron of the oxygen atom in the molecule, the total bond energy of $O^+$ in the $CHO^+$ is calculated as 176.2 kcal./mol. (144 kcal./mol. $+23.06\times1.4$ kcal./mol.).

18) Y. K. Syrkin and M. E. Dyatkina, "Structure of Molecules and the Chemical Bond", Interscience Publishers, New York.

The author has previously pointed out in his discussion of the ionized decomposition of diethyl ether[3] that the total bond energies of $O^+$ in $H_2C=O^+-C_2H_5$ and in $H-C\equiv O^+$ are 204 kcal./mol. and 183 kcal./mol. respectively. The present datum (176 kcal./mol.) agrees with the previous result (183 kcal./mol.) on the whole.

The reason why the energy of trivalence in the $H-C\equiv O^+$ is smaller than that in the $H_2C=O^+-C_2H_5$ is thought to be due to the fact that the former has a smaller number of resonance structures.

**M/e=28 $CO^+$**

The observed appearance potentials of this ion are 14.1±0.05, 15.5~15.9 and 18.3±0.3 eV. respectively.

The following two processes may be considered for the creation of $CO^+$ from formaldehyde:

$$HCHO+e \rightarrow CO^+ [19]+H_2+2e$$

$$HCHO+e \rightarrow CO^+ +2H+2e$$

The heat of reaction, or the appearance potential of $CO^+$, is calculated as 14.1 eV. for the former reaction and as 18.5 eV. for the latter. These values agree well with the appearance potentials obtained in the present work.

The break between 15.5~15.9 eV. in the ionization efficiency curve is vague; it sometimes appears, and sometimes it dose not. The value is close to the ionization potential of the nitrogen molecule, so it is thought that the break is due to the ionization of $N_2$, which exists as a background in the mass-spectrometer.

On the other hand, from the thermal decomposition experiments previously made by the present author, it has been found that HCHO is thermally unstable, that it decomposes easily to the CO molecule, and that the CHO radical can not be expected through the thermal decomposition. Therefore, it is also reasonable to consider that a part of formaldehyde gas thermally decomposes into CO gas on the tungsten filament of the ion source and that the CO molecule is ionized when it enters again into ionization chamber. According to this assumption, the first appearance potential of M/e=28 corresponds to the ionization potential of the CO molecule; the experimental result does not disagree with the above conclusion. In this case, the second breaks at 18.3 eV. may correspond to the excited state of the $CO^+$ ion.

19) F. H. Field and J. L. Franklin, "Electron Impact Phenomena and the Properties of Gaseous Ions", Academic Press Inc. Publishers, New York (1957).

*2) Acetaldehyde*

**M/e=44 $CH_3CHO^+$**

The observed value of 10.31 eV. is the first ionization potential of the acetaldehyde molecule. Two breaks exist, at $11.2_4$ and 12.2 eV. on the ionization efficiency curve.

Sugden and Price[13] have previously obtained observed values of 10.4±0.1, 11.3±0.1, 12.3±0.1 and 13.5±0.2 eV. through measurement of the total ionization current. The first three values agree well with the values of the present author. At the electron energy as large as 13.5 eV., the dissociation of molecular ion certainly takes place. So Sugden's method, which dealt with only the total ionization current, is unsuitable for the determination of the higher ionization potentials of the parent molecule.

As regards the classification of the ionization potentials of $CH_3CHO$, it is reasonable to consider, as in the case of $HCHO^+$, that 10.31 eV. corresponds to the energy necessary for the removal of one of the lone pair electrons of the oxygen atom in the molecule, that $11.2_4$ eV. is the energy needed for the removal of a $\pi$-electron in the C–O bond, and that 12.3 eV. is the energy needed for the removal of an $\sigma$-electron in the C–O bond in the molecule.

**M/e=43 $CH_3CO^+$ or $CH_2CHO^+$**

The appearance potential of this ion is 11.38 eV., and breaks exist at 12.1, 12.7 and 13.7 eV. The M/e=43 ion is produced by subtracting a hydrogen atom from the parent molecular ion. The bond dissociation energy of C–H in the aldehyde radical is thought to be smaller than that in the methyl radical; moreover, if a hydrogen atom is removed from the aldehyde radical, the stabilization of energy due to the formation of a triple bond of $O^+$ may take place. Accordingly it is reasonable to conclude that the hydrogen atom is removed from the aldehyde radical in the molecule. Thus, when relation $A(R43^+)=I(R43)+D(CH_3CO-H)$ and $D(CH_3CO-H)=3.48$ eV.[20] are used, $I(CH_3CO)$ is obtained as 7.90 eV.

This value is 2.41 eV. (55 kcal./mol.) smaller than the ionization potential of the parent molecule. It can be considered that the stabilization by 2.41 eV. takes place with the formation of a triple bond of $O^+$ in this ion. If it is assumed that the bond energy between C and O atoms in acetaldehyde is not affected by the ionization of one of the lone pair electrons of oxygen atom and that the bond energy additivity is applicable to such an ionic state, the total bond energy of $O^+$ in $CH_3C\equiv O^+$ is

20) J. S. Roberts and H. A. Skinner, *Trans. Faraday Soc.*, 45, 339 (1949).

obtained as 204.5 kcal./mol. (149.5+55 kcal.) by considering that the bond energy between C and O in acetaldehyde is 149.5 kcal.[18]

On the other hand, the total bond energy of $O^+$ in $CHO^+$ was calculated as 176 and 183 kcal. by the author, as has been described above. The increase of the stabilization in the $CH_3CO^+$ ion seems to be due to the resonance between different structures, for example, $H_3{\equiv}C{-}C{\equiv}O^+$ and $H^+H_2{=}C{=}O$.

As for the second and the third ionization potentials, no information has been obtained to interpret them.

**M/e=29** $CHO^+$

As $D(CH_3\text{-}CHO)$[20] is 71.5 kcal./mol. (3.10 eV.), $I(CHO)$ is calculated as 9.43 eV. from the observed appearance potential of the ion. This value agrees well with the value of $I(CHO)$ obtained from HCHO in this report, and it is only a little smaller than Reed's value of 9.87 eV.[4] In this case the stabilization energy is obtained as follows:

$I(CH_3CHO)-I(CHO)=0.88$ eV. (20.4 kcal./mol.). Therefore, the total bond energy of $O^+$ in $H{-}C{\equiv}O^+$, calculated under the assumptions described above, is 170 kcal./mol. (149.5 +20.4 kcal./mol.). This value should more closely agree with the 183 kcal./mol. obtained from diethyl ether and with the 176 kcal./mol. from formaldehyde. However, such a discrepancy among these values is unavoidable under these loose assumptions.

**M/e=28** $CO^+$ or $C_2H_4^+$

The ionization efficiency curve of M/e=28 has an uncertain break between 15.3~15.6 eV. and a rather distinct break at 17.4 eV. The heat of reactions, or the appearance potentials of $CO^+$ from $CH_3CHO$, are obtained, by considering the heat of the formation of $CO^+$ and of the other related molecules and radicals, as follows:

$$CH_3CHO+e \rightarrow CO^+ + CH_4 + 2e \qquad 13.8 \text{ eV.}$$
$$CH_3CHO+e \rightarrow CO^+ + CH_2 + H_2 + 2e \qquad 15.8 \text{ eV.}$$
$$CH_3CHO+e \rightarrow CO^+ + H + CH_3 + 2e \qquad 18.2 \text{ eV.}$$

The calculated values do not agree with the observed appearance potentials of the M/e=28 ion. However, as the appearance ratio of this ion is very small the influence of $N_2^+$ from the background in the mass-spectrometer could be expected to be greater, and so the apparent appearance potentials should also be greater than expected. By considering such a bad observing condition, the observed values may be said to correspond closely enough to the above-estimated reactions.

On the other hand, if the reaction is assumed as $CH_3CHO \rightarrow C_2H_4^+ + O$, the heat of reaction would be 15.3 eV.

**M/e=15** $CH_3^+$

The reaction to produce $CH_3^+$ is supposed as

$$CH_3CHO+e \rightarrow CH_3^+ [19] + CHO + 2e$$
or $$CH_3CHO+e \rightarrow CH_3^+ + CO + H + 2e$$

The ionization potential of $CH_3$ radical can be estimated from various data. The mean value of the data given from various ionized decompositions of organic compounds is 10.0 eV. Moreover, the energy for direct ionization of $CH_3$ radical is also 10.0 eV. If $I(CH_3)=10.0$ eV., $D(CH_3-CHO)=3.10$ eV.[20] and $D(H-CO)=1.13$ eV.[20], the heat of reaction for these processes is calculated as 13.10 eV. and 14.23 eV. respectively. The observed value agrees with the latter calculated value by assuming that the reaction has an excess energy of 0.6 eV.

*3) Acetone*

**M/e=58** $(CH_3)_2CO^+$

Two break points exist in the ionization efficiency curve. The values of the threshold and the break points are 9.84±0.04, $10.6_7$±0.1 and $11.5_4$±0.1 eV. respectively. It is thought that these values must be compared with Sugden and Price's values, 10.2±0.1, 11.3±0.1, 12.2±0.1 and 13.6±0.2 eV., which were obtained by the measurement of the total ionization current produced by the impact of accelerated photo-electrons. The discrepancy is large. Sugden's method seems, however, to be unsuitable for the determination of the higher ionization potentials of the parent molecule because of the formation of fragment ions. The first ionization potential of the molecule was determined as 9.92 and 9.89 eV. mass-spectrometrically, by Morrison et al.[21] and Omura et al.[22] respectively, as 9.69 eV. from the measurement of the total ionization current produced by photon impact by Watanabe[23], and as 9.705 eV. spectrometrically. It is reasonable that the first, second and third ionization potentials obtained are correlated, as in the case of formaldehyde, to the ionization of the lone pair electron of the oxygen atom, of the $\pi$-electron and of the $\sigma$-electron in the C-O bond respectively.

**M/e=43** $CH_3CO^+$

There are two breaks in the ionization efficiency curve. By considering that $D(CH_3-COCH_3)$ is 3.15 eV.[20], $I(CH_3CO)$ is obtained as

21) J. D. Morrison and A. J. C. Nicholson, *J. Chem. Phys.*, **20**, 1021 (1952).
22) I. Omura, K. Higasi and H. Baba, This Bulletin, **29**, 504 (1956).
23) K. Watanabe, *J. Chem. Phys.*, **26**, 542 (1957).

7.79 eV. from the relation of $I(CH_3CO) = A(CH_3CO^+) - D(CH_3-COCH_3)$. The value is 2.05 eV. smaller than the ionization potential of acetone. By assuming the structure of this ion as $CH_3C{\equiv}O^+$, in which the trivalency is satisfied, the value of 2.05 eV. is thought to be the stabilization energy through the formation of the triple bond.

The total bond energy of $O^+$ in the ion is calculated as 202 kcal./mol. by adopting 155 kcal./mol.[18] as the bond energy between C and O in acetone. The value 202 kcal./mol. agrees well with that calculated in the case of acetaldehyde.

**M/e=28** $CO^+$ or $C_2H_4^+$

The appearance ratio of this ion is small, and the influence of $N_2^+$ in background seems to be large, so the accuracy is not great. The heat of reaction for seven processes, which are all expected to produce M/e=28, is calculated as follows:

$(CH_3)_2CO+e \rightarrow CO^+$ [19] $+C_2H_6+2e$ 14.3 eV.

$(CH_3)_2CO+e \rightarrow CO^+ + H_2 + C_2H_4 + 2e$ 15.7 eV.

$(CH_3)_2CO+e \rightarrow CO^+ + 2(CH_3) + 2e$ 17.9 eV.

$(CH_3)_2CO+e \rightarrow C_2H_4^+$ [19] $+CO+H_2+2e$ 12.2 eV.

$(CH_3)_2CO+e \rightarrow C_2H_4^+ + HCHO + 2e$ 12.1 eV.

$(CH_3)_2CO+e \rightarrow C_2H_4^+ + CHO$[20] $+H+2e$ 15.5 eV.

$(CH_3)_2CO+e \rightarrow C_2H_4^+ + CO + 2H + 2e$ 16.6 eV.

However, a conclusion as to a process suitable for the production of the M/e 28 ion could not be obtained.

**M/e=27** $C_2H_3^+$

This ion must be $C_2H_3^+$. The calculated appearance potentials for this ion are as follows:

$(CH_3)_2CO+e \rightarrow C_2H_3^+$ [19] $+H_2+CHO+2e$ 14.3 eV.

$(CH_3)_2CO+e \rightarrow C_2H_3^+ + H + H_2 + CO + 2e$ 15.5 eV.

$(CH_3)_2CO+e \rightarrow C_2H_3^+ + 3H + CO + 2e$ 19.8 eV.

These values do not agree with the observed value. Therefore, the mechanism of the production of this ion can not be found.

**M/e=15** $CH_3^+$

The calculated appearance potentials of this ion are as follows:

$(CH_3)_2CO+e \rightarrow CH_3^+$ [19] $+CH_3CO$[20] $+2e$ 13.1 eV.

$(CH_3)_2CO+e \rightarrow CH_3^+ + CH_3 + CO + 2e$ 13.9 eV.

$(CH_3)_2CO+e \rightarrow CH_3^+ + CH + H_2 + CO + 2e$ 16.3 eV.

Accordingly, the second and the third reactions would be possible if the reactions take place with excess energies (kinetic and/or excitational energies) of 1.6 and 1.0 eV. respectively. In order to know the possible reactions conclusively, however, the kinetic energies of produced ions must be measured more precisely.

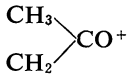
*4) Ethyl Methyl Ketone*

**M/e=72** $CH_3COC_2H_5^+$

There is a break in the ionization efficiency curve of this ion, and there seem to exist something like breaks above the first break point.

The first ionization potential is thought to be the energy by which the removal of one of the lone pair electrons of the O atom in the molecule takes place, as in the previous discussion of this report. The value obtained by the present author is a little larger than that of acetone. The fact is reasonably explained by assuming that hyper-conjugation is a little smaller in ethyl methyl ketone. This tendency was recognized also in a comparison of dipole moments.

**M/e=57** $C_2H_5CO^+$ or $CH_2CO^+CH_3$



If this ion is assumed to be $C_2H_5CO^+$, the corresponding reaction is as follows:

$$CH_3COC_2H_5 + e \rightarrow C_2H_5CO^+ + CH_3 + 2e$$

Moreover, the structure of the ion produced should be $C_2H_5-C{\equiv}O^+$, which satisfies the trivalency as in the case of $HCO^+$ from formaldehyde and of $CH_3CO^+$ from acetaldehyde as well as acetone. $I(C_2H_5CO)$ is obtained as 7.66 eV. by use of the relations, $A(C_2H_5CO^+) = I(C_2H_5CO) + D(CH_3-COC_2H_5)$ and $D(CH_3-COC_2H_5) = 3.15$ eV[20]. This value is a little smaller than the value of $I(CH_3CO)$ obtained previously in this report.

From the value of $I(C_2H_5CO)$, the stabilization energy by the formation of triple bond of $O^+$ in this ion is calculated as 2.22 eV. (9.88 eV.−7.66 eV.). Hence, the total binding energy of $O^+$ in this ion is obtained as 206 kcal./mol. (157 kcal./mol.[18] + 23.06×2.22 kcal./mol.). This value agrees quite well with the

values for $CH_3C{\equiv}O^+$ obtained in the case of acetaldehyde and acetone.

On the other hand, if this ion is assumed to be  , the ionization potential of this ion is obtained as 7.20 eV., provided that the dissociation energy between C atoms in the ethyl radical in the molecule is assumed as 3.60 eV., which is the dissociation energy of ethane. However, in this case the stabilization due to the formation of the triple bond of $O^+$ in the ion can not take place. The value of 7.20 eV. is therefore thought to be as abnormally small as the ionization of the oxygen atom in the radical.

**M/e=43** $CH_3CO^+$

The assumed reaction for the production of this ion is as follows:

$$CH_3COC_2H_5+e \rightarrow CH_3CO^+ + C_2H_5 + 2e$$

$I(CH_3CO)$ is calculated as 7.97 eV. by the use of $D(CH_3CO-C_2H_5)=3.13$ eV.[20] This value of $I(CH_3CO)$ must, of course, agree with the values of $I(CH_3CO)$ in the cases of acetaldehyde and acetone. In this case also, by assuming 1.91 eV., which is the difference between this value and the ionization potential of the parent molecule, as the stabilization energy due to the formation of the triple bond of $O^+$ in the ion, 202 kcal. is obtained as total bond energy of the $O^+$ in the $CH_3$-$C{\equiv}O^+$ ion (157 kcal. $+23.06\times1.91$ kcal.). This also agrees quite well with the values previously described in this report. Furthermore, the heat of the formation of $CH_3CO^+$ is calculated, by using the value obtained above, as 174 kcal./mol. The value agrees well with the value cited above (cf. Ref. 19).

**M/e=29** $C_2H_5^+$ or $CHO^+$

If this ion is assumed to be $C_2H_5^+$, the heat of reaction, or the appearance potentials, are calculated as follows:

$$CH_3COC_2H_5+e \rightarrow C_2H_5^+ + CH_3CO + 2e \qquad 11.8\text{ eV.}$$

$$CH_3COC_2H_5+e \rightarrow C_2H_5^+ + CH_3 + CO + 2e \qquad 12.55\text{ eV.}$$

The second process seems to take place. In this case, the reaction by which the $CH_3CO$ radical is produced is impossible, as in the case of acetone.

On the other hand, if the ion is assumed to be $CHO^+$, energetically there is some possibility as follows:

$$CH_3COC_2H_5+e \rightarrow CHO^+ + C_3H_7 + 2e \qquad 12.1\text{ eV.}$$

$$CH_3COC_2H_5+e \rightarrow CHO^+ + C_2H_4 + CH_3 + 2e \qquad 13.2\text{ eV.}$$

**M/e=28** $CO^+$ or $C_2H_4^+$

As the appearance ratio of this ion is very small, a high degree of accuracy in measurement can not be expected. The heat of reaction for the following processes is calculated:

$$MeEtCO+e \rightarrow CO^+ + C_3H_8 + 2e \qquad 14.3\text{ eV.}$$

$$MeEtCO+e \rightarrow CO^+ + CH_4 + C_2H_4 + 2e \qquad 16.35\text{ eV.}$$

$$MeEtCO+e \rightarrow CO^+ + Me + Et + 2e \qquad 17.9\text{ eV.}$$

$$MeEtCO+e \rightarrow C_2H_4^+ + CH_4 + CO + 2e \qquad 11.65\text{ eV.}$$

$$MeEtCO+e \rightarrow C_2H_4^+ + CH_3CHO + 2e \qquad 11.8\text{ eV.}$$

$$MeEtCO+e \rightarrow C_2H_4^+ + CH_3 + CHO + 2e \qquad 14.9\text{ eV.}$$

$$MeEtCO+e \rightarrow C_2H_4^+ + CH_2 + H_2 + CO + 2e \qquad 11.6\text{ eV.}$$

If the second appearance potential of 15.6 eV. is rejected for the reason described previously in the discussion on the M/e=28 ion produced from formaldehyde, the first and the third processes will probably be possible.

**M/e=15** $CH_3^+$

The heat of the reaction of the following process is calculated as 15.05 eV.

$$CH_3COC_2H_5+e \rightarrow CH_3^+ + C_2H_5 + CO + 2e$$

The appearance potential of the $CH_3^+$ agrees with the above-calculated heat of reaction if the excess energy of 0.3 eV. is permitted in the above process.

On the other hand, if the reaction is assumed to be $CH_3COC_2H_5+e \rightarrow CH_3^+ + CH_3COCH_2+2e$, and the values of $I(CH_3)$ and $D(C\text{–}C)$ to be 10.0 eV. and 3.6 eV. respectively, the heat of the reaction of this process is obtained as 13.6 eV. This does not agree with the appearance potential.

The reason why the process through which $CH_3^+$ is produced from acetone has a relatively large excess energy, while the process through which $CH_3^+$ is produced from ethyl methyl ketone has a small excess energy, is not obvious.

*5) Heat of Formation of $CHO^+$, $CH_3CO^+$ and $C_2H_5CO^+$*

The appearance potential of an ion is the heat of the reaction by which the ion is formed if no excess energy is involved, and the process may be treated by the usual methods

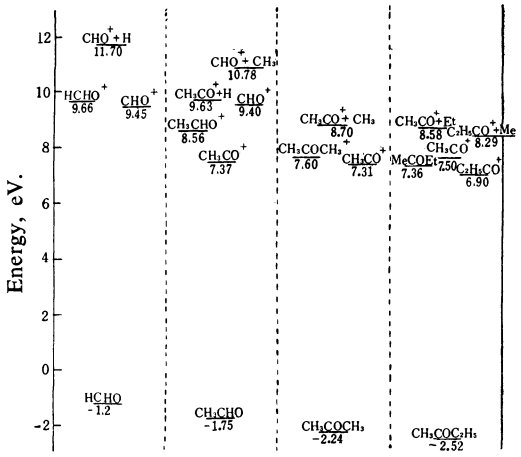


Fig. 2. Heat of formation of ions determined.

of thermochemistry. Thus, for the reaction $R_1R_2 \rightarrow R_1^+ + R_2$, the relation

$$A(R_1^+) = \Delta H_f(R_1^+) + \Delta H_f(R_2) - \Delta H_f(R_1R_2)$$

is given, provided that the reaction involves no excess energy.

By introducing the measured appearance potentials and the heat of formation of related molecules as well as radicals into the above relation, heats of formation of $CHO^+$, $CH_3CO^+$ and $C_2H_5CO^+$ are obtained, as shown in Fig. 2. The agreement between the heats of formation for the same ion produced from different molecules is very good, considering that the values are obtained through the appearance potential study.

## Summary

A study of the ionization and dissociation of formaldehyde, acetaldehyde, acetone and ethyl methyl ketone, all of which have an oxygen atom, was carried out through the appearance potential method. As appearance potentials were obtained by the retarding potential difference method, break points, which correspond to successively occurring ionization, appeared in the ionization efficiency curves of molecules and fragments. By considering the relation of energy, it is concluded that the ionization of the molecule takes place at first by the removal of one of the lone pair electrons of oxygen atom in the molecule, and that, in the formation of a fragment ion including an oxygen atom, dissociation takes place to create a triple bond, satisfying the trivalency of $O^+$ in the fragment ions.

The total bond energy of $O^+$ in $CH_3C{\equiv}O^+$ and $C_2H_5C{\equiv}O^+$ are calculated as about 200 kcal./mol., while in $HC{\equiv}O^+$ it is 170~180 kcal./mol. as in the case of diethyl ether reported previously. This fact may be explained by the number of resonance structures related.

The second and the third ionization potentials are thought to correspond to the removal of the $\pi$-electron and $\sigma$-electron in C-O bond respectively. The heat of formation of $CHO^+$, $CH_3CO^+$ and $C_2H_5CO^+$ are obtained from various reactions.

The author wishes to express his gratitude to Professor K. Kido and Professor T. Titani for their continual guidance and encouragement throughout this work, and to Professor K. Hirota of Osaka University and Professor S. Nagakura of the Institute for Solid State Physics, the University of Tokyo, for their kind advice and valuable discussion. He is also greatly indebted to Mr. Y. Kaneko and Mr. T. Oguri for their earnest co-operation.

## *The Polymerization of γ-Methyl-L-glutamate-N-carboxyanhydride Initiated with Acetic Acid*

By Tôru OKUDA and Setsuji SAKURAI

(Received August 26, 1961)

The rate of polymerization of *N*-carboxyanhydrides (NCAs) of α-amino acids and the molecular weight of polypeptides formed vary widely with the characteristic of reaction medium and initiator[1-3]. We have found that for the polymerization of γ-methyl-L-glutamate-NCA, acetic acid which has little or no initiating ability in one solvent, does act as an initiator in another solvent. Thus, when the NCA was dissolved in chloroform ($1.07\times10^{-1}$ mol. $l^{-1}$) containing acetic acid ($5.35\times10^{-2}$ mol. $l^{-1}$), rapid polymerization occurred, and completed within 130 min., while in dioxane solution no appreciable reaction was observed. Addition of dioxane (10% by volume) to the chloroform solution of the NCA caused an induction period of approximate 70 min. and a depression in rate (See Fig. 1). The evolution of carbon dioxide upon dissolution of the NCA in acetic acid was much slower than in the system chloroform-acetic acid. From the reaction mixture in acetic acid we were able to isolate only terminal-free low molecular weight peptide, which, according to the results of elementary analysis and optical rotation in dichloroacetic acid, had no acetyl group and was composed of 3 units of γ-methyl-L-glutamate residue. Found: C, 47.1; H, 6.71; N, 9.53. Calcd. for $(C_6H_9O_3N)_3\cdot H_2O$: C, 48.3; H, 6.49; N, 9.40%. $[\alpha]_D^{23}=17°$ (*c* 1.9). So far, no other products such as acetylated derivatives, diketopiperazine or cyclic peptide have been detected.

The fact that the degree of polymerization of the final polymer obtained in the polymerization in chloroform is much higher ($[\eta]=0.98$, $\overline{DP}=500\sim600$) than that expected from the initial NCA-initiator ratio of 2 indicates that only a small part of acetic acid was utilized as a true initiator. Therefore, the behavior of acetic acid as an initiator in chloroform solution seems to resemble somewhat that of tertiary amine.

Fig. 2 shows that two successive propagation rates exist. Similar change in propagation rate was observed in polymerizations of other NCAs[3-8] and explained either by conformational change (random or β-form to α-helix)

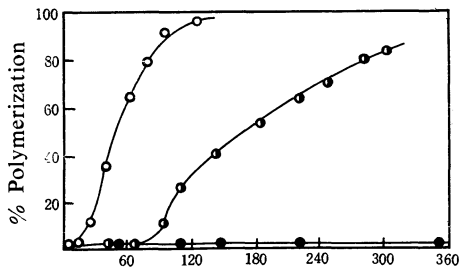

Fig. 1. Time-conversion curves for polymerization of γ-methyl-L-glutamate-NCA ($1.07\times10^{-1}$ mol. $l^{-1}$) indicated with acetic acid ($5.35\times10^{-2}$ mol. $l^{-1}$) in solution at 30°C.

in the growing polypeptide chain[4,7], or by gel effect due to precipitation of polymer or gelation[6]. In the present case, after a slow propagation rate, when about one-tenth of the NCA had been consumed the propagation shifted to a faster rate. Since the average DP of the polymer was found to be 500~600, the transition occurred when the growing polypeptide chain had reached a $\overline{DP}=50\sim60$. Because this value exceeds the one necessary for the conformational transition of poly-$\gamma$-methyl-L-glutamate (15~25 residues[5]) the gel effect might be more responsible for occurrence of the two successive propagation rates.

We wish to express our thanks to Drs. H. Oeda and T. Yoshida for permission to publish the present work.

## *Reduction of α-Pyrones with Complex Metal Hydrides*

By Kiyoyuki YAMADA, Mitsuo ISHIZAKA and Yoshimasa HIRATA

(Received November 21, 1961)

During the course of the structural investigation of aureothin[1], we obtained several derivatives that were regarded as products of unusual reactions. One of the remarkable examples is "aminol H" (II) which was produced from isoaureothamine (I) by treatment with various complex metal hydrides[2].

In order to examine whether or not the occurrence of this rather unexpected reduction is due to the complexity of the other part of the molecule, reduction of simple α-pyrones with complex metal hydrides was carried out.

4, 6-Dimethyl-α-pyrone, when treated with lithium aluminum hydride in tetrahydrofuran, gave β-methylsorbic acid, m. p. 97°C[3] (Found: C, 67.00; H, 8.10. Calcd. for $C_7H_{10}O_2$: C, 66.46; H, 7.99%. Ultraviolet spectrum, $\lambda_{max}^{EtOH}$, 260 mμ, log ε, 4.0). Reduction of 4, 6-dimethyl-α-pyrone with lithium borohydride in a similar condition also gave the same acid, whereas no reaction took place with sodium borohydride.

Further, lithium aluminum hydride reduction of 4-methoxy-6-methyl-α-pyrone, which is a good model compound for isoaureothamine (I), yielded β-methoxysorbic acid (III) (m. p. 147~149°C (decomp.)[4]. Found: C, 59.17; H, 7.13. Calcd. for $C_7H_{10}O_3$: C, 59.14; H, 7.09%. Ultraviolet spectrum, $\lambda_{max}^{EtOH}$, 264 mμ, log ε, 4.1) and a neutral product (b. p. 101~104°C/16 mmHg. One methoxyl group. Ultraviolet spectrum; $\lambda_{max}^{EtOH}$, 239 mμ) which was shown to be identical with 3-methoxy-2, 4-hexadienol (IV) obtained from β-methoxysorbic acid by lithium aluminum hydride reduction.

The relative amounts of the two products, III and IV, are considerably dependent on the reaction conditions (temperature, manner of addition, etc.), the details of which will be reported elsewhere. Thus, it was established that generally the hydrogenolysis of the 1, 6-linkage of the α-pyrone ring occurs in the reduction using complex metal hydrides.
