as 0.5, which corresponds to the composition $CuSO_4 \cdot 3H_2O$ ($CuSO_4 \cdot H_2O : 2H_2O$). That is, exchange reaction of crystalline monohydrate under the given condition proceeds through the formation of trihydrate.

In the molar ratio region corresponding to the compositions between pentahydrate and trihydrate, the two sorts of samples of monohydrate behave similarly toward the deuterium exchange reaction. The values of $\Delta D/D$ in this region correspond to the almost complete equilibration of the monohydrate with heavy water vapor.

In this region, pentahydrate and trihydrate may be expected as the hydration product of the crystalline monohydrate, the deuterium content of the trihydrate being lower than that of the pentahydrate. As an extreme case, if the hydrate water of pentahydrate and that of trihydrate equilibrate with each other in the course of the experiment, the result is the complete equilibration of deuterium between the monohydrate and water vapor. In the case of the other extreme where pentahydrate and trihydrate are dehydrated independently without exchanging their deuterium atoms with each other, it may be easily shown by calculation that, though the value of $\Delta D/D$ is slightly lower than that of the complete equilibration, the difference is well within the range of experimental errors. Thus, if pentahydrate and trihydrate are formed as the product of hydration, the results are always the nearly complete equilibration of monohydrate with the water vapor, which may also be expected for amorphous monohydrate.

If, on the other hand, the pentahydrate alone was formed in this molar ratio region, the values of $\Delta D/D$ should be 0.25, irrespective of the values of the molar ratio, which is contrary to the results. Thus, the exchange reaction may be used to determine the composition of the hydrate formed on hydrating an anhydrate or a lower hydrate, provided that the anhydrate has an exchangeable hydrogen atom.

The increased exchangeability of amorphous monohydrate as compared with crystalline monohydrate is due to the exchange reaction between surface molecules and adsorbed water, as in the case of oxalic acid. The fractions of the amorphous monohydrate which takes part in the exchange reaction to the total amount used are calculated by the relation[1],

$$M'/M = (1/k)(\Delta D/D)/(M/M_w)$$

to be 0.75～1.08. The corresponding values obtained with oxalic acid are 0.71～0.85.

The molar ratio of the monohydrate in the surface as defined by the deuterium exchange reaction to the monohydrate of the bulk may be calculated by the relation[1],

$$\beta = [(1/k)(\Delta D/D) - x]/[(M/M_w) - x]$$

where $x$ is a constant, which has the value of 0.5 if trihydrate is formed on hydrating the amorphous monohydrate, and of 0.25 if pentahydrate is formed.

Above the value of the molar ratio corresponding to the composition of trihydrate, the dissociation pressure of the partially hydrated amorphous monohydrate is of the order of

that of monohydrate in the case of fast hydration, owing probably to the strong adsorptive power of the amorphous monohydrate, and is in the neighborhood of that of trihydrate in the case of slow hydration. It is probable that, in this region, amorphous monohydrate at first absorbs water vapor and subsequently combines with it rather slowly to form trihydrate as hydration product.

The surface to bulk ratios as given by the above relation are now calculated for the five specimens of the amorphous monohydrate whose exchange results are plotted in Fig. 1. The results are 0.44, 0.48, 0.75, 0.91 and 1.10. The values of the ratio obtained with amorphous oxalic acid are 0.60~0.70[1]. These values may compare nearly with each other. This result, together with the similarity of the results of the exchange reaction between oxalic acid and copper sulfate, confirms the view mentioned in the previous report[1] concerning the nature of the dehydration product and the relation between the degree of deuterium exchange and surface area of the product.

The results of oxygen exchange reaction are the same in essentials as those of deuterium exchange reaction. It may be concluded that interchange of water molecules as well as of protons occurs in the course of the hydration of monohydrate with heavy water vapor and subsequent dehydration of the product. Accordingly, in the dehydration of copper sulfate pentahydrate, the fifth water molecule is interchangeable with the remaining four. The discussions of the previous[1] and the present papers, concerning the nature of the dehydration products, the relation of the exchange reaction to the surface area of the dehydration products, and the mechanisms of the exchange reaction, are applicable with necessary change to the oxygen exchange reaction.

## Summary

The deuterium and oxygen-18 exchange reaction of amorphous and crystalline copper sulfate monohydrate with water in the course of the hydration of the monohydrate with heavy water vapor and the subsequent dehydration of the product has been studied.

The exchange reaction of crystalline monohydrate is associated with the formation of hydrate. Amorphous monohydrate shows an increased degree of exchange over crystalline monohydrate. This increased exchangeability of amorphous monohydrate is due to the exchange reaction between surface molecules and adsorbed water. The similarity of the results of deuterium exchange reaction between oxalic acid and copper sulfate confirms the suggestion of the previous report that anhydrous oxalic acid prepared by dehydration in vacuo at low temperatures is amorphous and the degree of deuterium exchange reaction is related to the surface area of the dehydration product.

The results of the oxygen-18 exchange reaction of copper sulfate monohydrate with water vapor are almost identical in essentials with those of the deuterium exchange reaction. The fifth water molecule of copper sulfate is interchangeable with the other four in the process of dehydration of pentahydrate and the hydration of monohydrate.

# *A Study of Dehydration and Hydration of Sodium Dihydrogen Phosphate and Racemic Acid by Means of the Deuterium Exchange Reaction*

By Nobukazu OKAZAKI and Akiko OKUMURA

(Received November 11, 1960)

In a study of dehydration and hydration of oxalic acid by means of the deuterium exchange reaction[1], the following facts have been observed; (1) the difference of exchange behavior of the anhydrate with the method of its preparation, and the amorphous character of the anhydrate prepared by dehydration in vacuo at low temperatures, (2) recrystallization of the amorphous anhydrate under the catalytic action of water vapor, and (3) deuterium

1) N. Okazaki and E. Takemura, This Bulletin, **34**, 977 (1961).

exchange reaction in anhydrate-hydrate mixture. It is the purpose of the present work to examine with other salt hydrates whether or not the phenomena are of general occurrence.

The experimental procedures were almost the same as those used in the previous work[1].

**Difference of Exchange Behavior of Anhydrate with the Method of Dehydration.** — *Sodium Dihydrogen Phosphate.* — Commercial sodium dihydrogen phosphate dihydrate (special grade reagent) was used without further purification. Two sorts of samples of the anhydrate were used; one was prepared by dehydration of dihydrate to constant weight at 130°C in a drying oven, and the other by dehydration in vacuo at ordinary temperatures. The procedures for the deuterium exchange experiment were the same as those used previously.

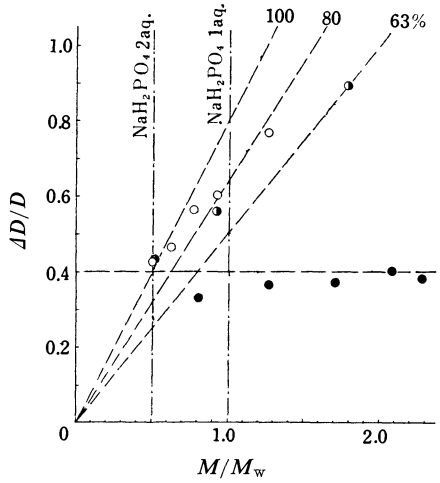

Fig. 1. Difference of the deuterium exchange reaction between anhydrous sodium dihydrogen phosphate prepared by dehydration in vacuo at ordinary temperatures (○; 20°C, ◑; 11°C) and that prepared at 130°C (●).

The results are shown in Fig. 1, in which the degree of exchange $\Delta D/D_f$ is plotted against the molar ratio of the reactants $M/M_w$ (for notations and formulas, see the previous work). As in the case of oxalic acid[1], there is a qualitative difference of exchange behavior between the two sorts of anhydrous sodium dihydrogen phosphate.

The exchange reaction of the anhydrous phosphate prepared at 130°C was studied at 11°C. In these experiments, the values of $\Delta D/D_f$ are about 0.4 for the values of the molar ratio ranging from 1.0 to 2.5. This fact means that, in these cases, the amount of the anhydrous phosphate which takes part in the exchange reaction is always in a definite ratio to the amount of water used, irrespective of the presence of the excess anhydrous phosphate. This ratio $M'/M_w$ may be calculated by the relation,

$$M'/M_w = (2/kn)(\Delta D/D_f)$$

where, $k$ is the partition coefficient of deuterium between anhydrous phosphate and water, and $n$ is the number of exchangeable hydrogen atoms in sodium dihydrogen phosphate.

The value of $k$ has been determined from the exchange reaction in solution to be 0.806 $\pm$0.008 (mean of four determinations), which is somewhat smaller than the value commonly accepted for the partition coefficient of hydroxyl hydrogen[2].

By using the above value of $k$ and taking $n=2$, the values of $M'/M_w$ are calculated to be 0.5 or 1 : 2, which corresponds to the composition $NaH_2PO_4 \cdot 2H_2O$. It may be concluded that the exchange reaction of the anhydrate prepared at 130°C proceeds through the formation of dihydrate.

The existence of monohydrate of sodium dihydrogen phosphate is known, but the formation of monohydrate was not observed under the condition of the experiments. In correspondence with this, the dehydration of dihydrate yielded anhydrate directly; dehydration curves were constructed at 11.0, 20.0 and 28.0°C, but no sign of the formation of monohydrate has been observed. The values of the dissociation pressure obtained from the dehydration curves are 3.84 mmHg at 11.0°C, 7.98 mmHg at 20.0°C, and 14.77 mmHg at 28.0°C. Each of these values is the mean of seven to ten measurements obtained at various stages of dehydration. These values gave a good linear plot of $\log p$ against $1/T$, from which the heat of dissociation of sodium dihydrogen phosphate dihydrate into anhydrate has been calculated to be 13.5 kcal. per mol. $H_2O$. In these experiments, the dissociation pressure was measured by a mercury U-tube manometer (1.8 cm. bore). The temperature was measured by a mercury thermometer graduated in 0.1°C (uncalibrated).

As exemplified by the above results, the exchange reaction in question may be used to determine the composition of the hydrate formed on hydrating an anhydrate or a lower hydrate. Another example may be found in the previous paper[3], where the hydration product of copper sulfate monohydrate was identified by this method with trihydrate or with a mixture of tri- and pentahydrate according to the condition of hydration.

The exchange reaction of the anhydrous phosphate prepared in vacuo was studied at

2) See, for example, V. Gold and D. P. N. Satchell, *Quart. Rev.*, **9**, 51 (1955).

3) N. Okazaki, A. Okumura, and K. Nakagawa, This Bulletin, **45**, 983 (1961).

two temperatures, 11 and 20°C. The increased exchangeability of the phosphate prepared in vacuo as compared with the phosphate prepared at 130°C may be seen in Fig. 1. As in the cases of oxalic acid and copper sulfate, it should be attributed to the exchange reaction between adsorbed water and the phosphate occurring in the extended surface of the latter.

The values of the degree of exchange obtained at 11°C are considerably lower than those obtained at 20°C. It is probably due to the increased adsorption of water in the reaction zone during the preliminary dehydration and the consequent increase in the degree of recrystallization of the dehydration product at the lower temperature.

The values of the ratio of the amount of the anhydrous phosphate which takes part in the exchange reaction to the total amount used, as calculated by the relation,

$$M'/M=(1/k)(\Delta D/D_f)/(M/M_w)$$

are 0.77~1.06 for the specimens of anhydrous phosphate prepared in vacuo at 20°C and 0.63~1.03 for those prepared at 11°C. The values obtained for oxalic acid and copper sulfate[1,3] are 0.71~0.85 and 0.75~1.08, respectively.

The surface to bulk ratio $\beta$ as defined by the deuterium exchange reaction may be calculated by the relation[1],

$$\beta=[(1/k)(\Delta D/D_f)-0.5]/[(M/M_w)-0.5]$$

The values obtained are 0.59~0.71 for the specimens of anhydrous phosphate prepared in vacuo at 20°C, and 0.48 for two specimens prepared at 11°C.

*Racemic Acid Monohydrate.* — Racemic acid monohydrate was prepared from *d*-tartaric acid by the usual method, and purified by repeated crystallization from aqueous solution. The specimens of anhydrous racemic acid were prepared partly by dehydration of monohydrate in vacuo at 20°C, and partly by dehydration at 100°C under atmospheric pressure.

The results are shown in Table I.

Table I. Exchange reaction of anhydrous racemic acid at 20°C

| Specimen | $M/M_w$ | $\Delta D/D_f$ | $M'/M$ | $\beta$ |
|---|---|---|---|---|
| Anhydrous racemic acid prepared in vacuo at 20°C | 1.383 | 2.34 | 0.94 | 0.71 |
| | 1.438 | 2.61 | 0.91 | 0.70 |
| | 1.851 | 3.20 | 0.86 | 0.69 |
| Anhydrous racemic acid prepared at 100°C | 1.120 | 2.22 | | |
| | 1.495 | 2.03 | — | — |
| | 1.591 | 2.27 | | |

As with the other hydrates previously studied, the degree of exchange is independent of the molar ratio in the case of the anhydrous acid prepared at 100°C, and increases with the value of the molar ratio in the case of the anhydrous acid prepared in vacuo at 20°C. The number of exchangeable hydrogen atoms is calculated to be 4, that is, two carboxyl hydrogen and two hydroxyl hydrogen atoms, from the results of the exchange reaction of anhydrous acid prepared at 100°C.

The values of the surface to bulk ratio $\beta$ as defined by the deuterium exchange reaction are calculated by[1],

$$\beta=[(1/2k)(\Delta D/D_f)-1]/[(M/M_w)-1]$$

The values obtained are compared with those of the other hydrates in Table II.

Table II

| Specimen | $\beta$ | Temp. of Dehydration °C |
|---|---|---|
| Anhydrous oxalic acid | 0.60~0.70 | 25 |
| Copper sulfate monohydrate | 0.44~1.10 | 35 |
| Anhydrous sodium dihydrogen phosphate | 0.59~0.71 | 20 |
| | 0.48 | 11 |
| Anhydrous racemic acid | 0.70 | 20 |

It will be seen that the values for four substances are comparable with each other. The copper sulfate monohydrate prepared by dehydration in vacuo at low temperature is known to be amorphous[4], and the dehydration product of oxalic acid dihydrate in the vacuum of electron microscope has also been shown to be amorphous[1]. Though the above ratio does not bear a definite physical significance, yet it would be useful for semi-quantitative discussion. Thus, the similarity of the values of the ratio suggests that the dehydration products of racemic acid, sodium dihydrogen phosphate as well as oxalic acid in vacuo at ordinary temperatures are amorphous, and adds new evidence to the postulate that dehydration of salt hydrates proceeds through the intermediate formation of an amorphous product.

**Effect of Adsorbed Water on the Recrystallization of Amorphous Anhydrous Sodium Dihydrogen Phosphate.**—The anhydrous phosphate prepared in vacuo at 20°C was exposed to water vapor of 2 mmHg in a vacuum system at 11°C for twenty minutes, liquid water maintained at −10°C being used as the source of the vapor. Then, the anhydrous phosphate was isolated from the vapor source, and kept in contact with the adsorbed water at 11°C for definite times. After a given time of contact, the anhydrous phosphate was hydrated with a known amount of water vapor of a definite pressure, and subsequently redehydrated. The water obtained on redehydration was analyzed for its deuterium content.

4) V. Kohlschütter and H. Nitschmann, *Z. physik. Chem.*, Bodensteinfestband, 494 (1931).

As in the case of the oxalic acid, the pressure of the water vapor above the anhydrous phosphate increases during the time of contact of the phosphate with adsorbed water vapor. It may be attributed to the recrystallization of the amorphous phosphate and the consequent desorption of the water vapor. The pressure begins to increase after the induction period of 30 to 40 min., and within a few hours it reaches a maximum value of about 4.8 mmHg which is well above the dissociation pressure of dihydrate (3.8 mmHg at 11°C). The pressure increase begins to decline at about 4 mmHg, which is probably due to the beginning of hydrate formation. After the maximum has been attained, the pressure decreases at first rather rapidly to about 4 mmHg, and then very slowly toward 3.8 mmHg. The amount of water liberated by the phosphate during the period of pressure increase is estimated to be $3\times10^{-4}$ mol. per mol. of the phosphate.

The results of the exchange reaction are shown in Fig. 2. The exchangeability $M'/M$ of the amorphous phosphate decreases with the time of contact of the phosphate with water vapor, while in the absence of water vapor the exchangeability decreases only slightly.

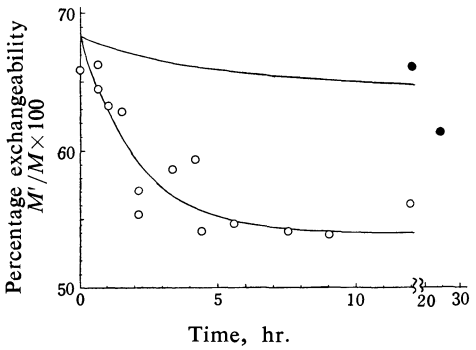

Fig. 2. Decrease in the exchangeability of amorphous anhydrous sodium dihydrogen phosphate due to recrystallization under the catalytic action of water vapor. $M/M_w=1.25$. Solid circle; in the absence of water vapor. Open circle; in the presence of water vapor.

It appears that catalysis of the recrystallization of highly dispersed dehydration intermediate by adsorbed water is of general occurrence.

The process of recrystallization may be visualized as dissolution of the energy-rich anhydrate into adsorbed water; that is, the formation of two-dimensional solution and recrystallization from it of crystalline anhydrate. Below a particular concentration of this two-dimensional solution, it comes to be in equilibrium with hydrate instead of anhydrate, that is, nucleation of hydrate begins. Thus, according to this view, the relation of recrystallization to nucleation of hydrate would be analogous to the relation of anhydrate to hydrate, each in equilibrium with its saturated solution.

**Deuterium Exchange Reaction between Unhydrated and Hydrated Phosphate in Partially Hydrated Amorphous Sodium Dihydrogen Phosphate.** — Anhydrous phosphate prepared by dehydration in vacuo at 20°C was hydrated with heavy water vapor of 9 mmHg pressure and left for a given time at 15°C. Then, it was dehydrated in vacuo at 20°C, and the water obtained was analyzed for its deuterium content.

The results are shown in Fig. 3. As in the case of oxalic acid, the degree of exchange $M'/M$ of the phosphate increases with the time

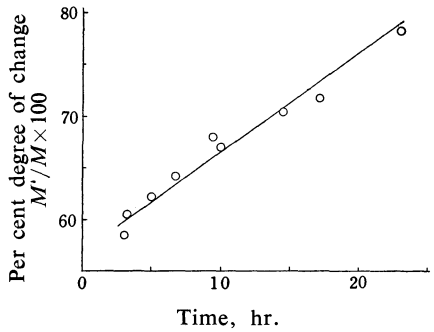

Fig. 3. Progress of deuteration of sodium dihydrogen phosphate in partially hydrated state.

during which the phosphate has been kept in the partially hydrated state. The increase is probably due to the deuteration of the primary phosphate ions in the interior of the crystallites. A possible mechanism of this process has been suggested with reference to the exchange reaction of oxalic acid[1].

## Summary

In order to examine the generality of the results obtained with oxalic acid, the following questions were studied with sodium dihydrogen phosphate and in part with racemic acid: (1) the relation between the deuterium exchange reaction and the surface area of the anhydrate, and the amorphous character of the anhydrate prepared by dehydration in vacuo at low temperatures, (2) recrystallization of the amorphous anhydrate under the catalytic action of adsorbed water, and (3) deuterium exchange reaction in anhydrate-hydrate mixture.

The results obtained with sodium dihydrogen phosphate and racemic acid are similar to those obtained with oxalic acid. It appears that formation of amorphous anhydrate in the dehydration of crystal hydrate in vacuo at low

temperatures and its recrystallization under the catalytic action of adsorbed water are phenomena of general occurrence.

The deuterium exchange reaction of crystalline anhydrate may be used to determine the composition of the hydrate formed on hydrating an anhydrate under a given condition.

The authors wish to thank Mrs. M. Kitora and Mrs. Y. Sawanobori for their assistance in part of this work.

# *The Rearrangement of N-Deuterated Aromatic Amine Hydrochloride into its Ring-deuterated Analogue in the Solid Phase: The Rearrangements of o- and m-Toluidine Hydrochlorides and the Effect of Anions on the Rate of Rearrangement of Anilinium Salts*

By Nobukazu Okazaki and Akiko Okumura

(Received November 18, 1960)

When aniline hydrochloride-*N*-*d* is heated at about 150°C or above, it rearranges into its ring-deuterated analogues[1]

The reaction may as well be regarded as the deuterium exchange reaction between the $NH_3^+$ group and the benzene nucleus in aniline hydrochloride. The rearrangement occurs well below the melting point of the hydrochloride. The deuterated positions of the benzene nucleus have been determined by the reverse rearrangement of *o*,*p*-trideuterio-aniline hydrochloride to be the ortho and the para positions[1b]. It has been suggested that the mechanism of this rearrangement is an electrophilic substitution as in the case of the liquid phase deuteration of aromatic nucleus by acidic deuterating agents[2], and that anilinium ion acts as proton acceptor at least in the state of partial dissociation in the solid phase,

Further study of this rearrangement with *p*-toluidine hydrochloride[3] has shown that the number of nuclear hydrogen atoms which take part in the rearrangement is 2, probably ortho positions, when the rearrangement takes place in the solid phase, and 4, probably ortho and meta positions, when the rearrangement takes place in the molten phase. This qualitative difference in exchange equilibria suggests that different mechnisms are responsible for the exchange reaction in the solid and for that in the molten phase, and serves to exclude the possibility that the exchange reaction in the solid phase might be caused by local melting due to the presence of a small amount of moisture or other contaminations.

The purpose of the present work is to supplement the earlier results with the study of the exchange reaction of *o*- and *m*- toluidine hydrochloride and with the comparative study of the rate of rearrangement of aniline hydrochloride and hydrobromide, in the hope of approaching the elucidation of the mechanism of this rearrangement.

## Experimental

**Materials.**—Commercial *o*-toluidine (extra pure reagent) was first treated with oxalic acid in order to exclude the possible contamination with para isomer. After repeated distillations, it was neutralized with hydrochloric acid (special grade reagent), and recrystallized twice from water.

*m*-Toluidine was synthesized partly from *p*-toluidine and partly from benzaldehyde by the usual methods. It was acetylated, and the aceto-toluidide obtained was purified by repeated recrystallization from water. Then the amine was again set free, distilled repeatedly and neutralized with hydrochloric acid. The hydrochloride was recrystallized from water twice (m. p. 215.5~216.0°C, corrected).

1) a) M. Harada and T. Titani, This Bulletin, **11**, 554 (1936). b) N. Okazaki, *J. Chem. Soc. Japan*, **62**, 52 (1941); N. Okazaki and M. Koizumi, This Bulletin, **16**, 371 (1941).

2) C. K. Ingold, C. G. Raisin and C. L. Wilson, *J. Chem. Soc.*, **1936**, 1637.

3) N. Okazaki and J. Kuroda, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kwagaku Kwaisi*), **62**, 57 (1941); This Bulletin, **11**, 417 (1941).

Commercial aniline (special grade) was neutralized with hydrochloric acid, and the salt solution was treated with steam to remove the possible contamination with nonbasic compounds. Then the amine was again set free, distilled repeatedly, and neutralized with hydrochloric acid (special grade) or redistilled hydrobromic acid (first grade). The salts were recrystallized three times from alcohol.

**Procedure.** — The experimental procedures are almost the same as those described in the earlier paper[1b]. A known amount of *N*-deuterated anilinium or toluidinium salt which was prepared by the exchange reaction with heavy water (ca. 1%) and dried in a vacuum desiccator over phosphorus pentoxide, was sealed in vacuo in a glass tube, and heated for a definite time in a vapor bath of organic liquid.

The relation between the initial and equilibrium deuterium contents, $D_i$ and $D_e$, of the $NH_3^+$ group of the salt is given by

$$nk=3(D_i-D_e)/D_e$$

where $k$ is the deuterium partition coefficient between the $NH_3^+$ group and the benzene nucleus, $n$ is the number of the nuclear hydrogen atoms which take part in the exchange reaction.

As the value of $k$ may be taken to be nearly unity, the number $n$ of exchangeable hydrogen atoms of the benzene nucleus may be judged readily from the value of $nk$.

The value of $\alpha$ defined by an analogous relation,

$$\alpha=3(D_i-D_t)/D_t$$

may be used to follow the exchange reaction, where $D_t$ is the deuterium content of $NH_3^+$ group at time $t$. At equilibrium $\alpha$ is equal to $nk$.

The deuterium content of the $NH_3^+$ group was determined by equilibrating the salt with water of known amount and known deuterium content at low temperature (ca. 60°C or below). The deuterium content of the equilibrated water was measured by the floatation method, the proportionality of the deuterium atom fraction of heavy water to its excess density being assumed.

**Kinetic Formula.**—If it is assumed that the rate of the deuteration of ortho and para positions of anilinium salt may be described by one and the same rate constant, the reaction may be treated as a first order reversible reaction with respect to the deuterium content. The appropriate rate equation is

$$k_1=(kD_e/tD_i)\ln((D_i-D_e)/(D_t-D_e))$$

where, $k_1$ is the first order rate constant of the deuterium exchange reaction between $NH_3^+$ and aromatic nucleus, or the rate of the corresponding hydrogen exchange in undeuterated salts.

In terms of $\alpha$, defined above, the rate equation becomes,

$$k_1=(2.303/t)(k/k+1)\log((\alpha+3)/(3-(\alpha/k)))$$

## Results and Discussion

**I. The Rearrangements of *o*- and *m*-Toluidine Hydrochlorides.**—Fig. 1 shows the rates of the exchange reactions, expressed by the value of $\alpha$ after one hour from the start of the exchange reaction, of *o*- and *m*-toluidine hydrochlorides at various temperatures. For comparison, the rate-temperature curves of aniline and *p*-toluidine hydrochlorides are also shown. In the latter salt, the rate is expressed by the value of $\alpha$, after 3.5 hr. from the start of the reaction.

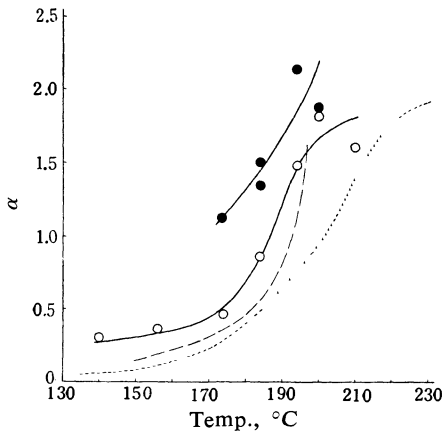

Fig. 1. Rearrangement of aniline and toluidine hydrochlorides at various temperatures. ●, *m*-Toluidine hydrochloride; ○, *o*-Toluidine hydrochloride; – – –, Aniline hydrochloride; ------, *p*-Toluidine hydrochloride

The exchange reaction of *o*-toluidine hydrochloride is measurable even at 140°C (ca. 75°C below its melting point). Apart from the exchange reaction of *m*-toluidine hydrochloride in which the methyl group cooperates with the amino group to facilitate the deuteration of the ortho and the para positions to the amino group, the ease of the exchange reactions of the hydrochlorides is in the order,

*o*-toluidine hydrochloride
> aniline hydrochloride
> *p*-toluidine hydrochloride

This corresponds to the reverse of the order of the basic dissociation constants of the amines at ordinary temperature (the values of $K_B$ are $3\times10^{-10}$, $5\times10^{-10}$ and $2\times10^{-9}$ at 25°C, respectively[4]), or to the order of the acid strengths of their conjugate acids, *o*-toluidinium, anilinium and *p*-toluidinium ions. This order of the acid strengths of the conjugate acids would probably hold even at the temperatures of the rearrangement. Thus, the ease of the exchange reaction increases with the increasing proton releasing power of the $NH_3^+$ group for the aromatic nuclei of comparative reactivities.

This fact serves to confirm the earlier view that the mechanism of this exchange reaction is an electrophilic substitution, and that anili-

4) Landolt, "Physikalisch-chemische Tabellen", Bd. II, 5te Auflage, P. 1160.

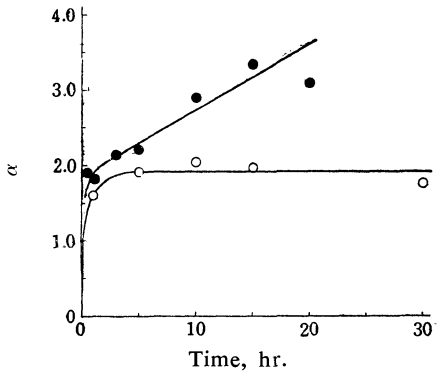

Fig. 2. Difference of equilibria between the exchange reactions of *o*-toluidine hydrochloride in the solid phase and in the liquid phase. ○, 210°C (solid phase), ●, 224°C (liquid phase)

nium or toluidinium ion acts as a proton acceptor at least in the state of partial dissociation. This is also a necessary condition for the $NH_3^+$ group to act as a proton donator.

Figure 2 shows the variation of the value of $\alpha$ with time for *o*-toluidine hydrochloride. At 210°C (below the melting point of the hydrochloride), the value of $\alpha$ reaches the equilibrium value of about 2 in less than five hours, but does not exceed 2 even after thirty hours. On the other hand, at 224°C (above the melting point of the hydrochloride) the value of $\alpha$ definitely exceeds 2 after three hours, and increases steadily towards the equilibrium value of probably 4.

The equilibrium values of $\alpha$ for the exchange reaction of *m*-toluidine hydrochloride at 200 and 218°C are shown in Table I, the melting point of the hydrochloride being 216°C.

Table I. The equilibrium values of $\alpha$ for the exchange reaction of *m*-toluidine hydrochloride at 200 and 218°C

| Temp. °C | Time hr. | *nk* | Temp. °C | Time hr. | *nk* |
|---|---|---|---|---|---|
| 200 | 5 | 2.54 | 218 | 10 | 4.20 |
| 200 | 7 | 2.82 | 218 | 15 | 4.32 |
| 200 | 10 | 2.59 | 218 | 20 | 4.07 |

Table I shows that three hydrogen atoms are exchangeable in the solid phase exchange reaction, and four hydrogen atoms take part in the liquid phase exchange.

If it were assumed that these differences in the *nk* values are due to the effect of temperature on the rate of exchange of the third or the fourth nuclear hydrogen atoms, then it should follow that, for the rearrangement of *o*-toluidine hydrochloride, the rate of this exchange at 224°C is at least ten times as fast as the rate at 210°C, and the exchange reaction is associated with an improbably large activation energy of 80 kcal. or more. The difference can not of course be attributed to the ordinary effect of temperature on the exchange equilibria. Therefore, these differences in the values of *nk* should be due to the difference of the mechanism between the solid phase and the liquid phase exchanges.

The values of *nk* found with hydrochlorides of aniline and toluidines are as follows;

| | Below the m.p. | Above the m.p. |
|---|---|---|
| Aniline hydrochloride | 3(ortho, para) | — |
| *o*-Toluidine 〃 | 2 | — |
| *m*-Toluidine 〃 | 3 | 4 |
| *p*-Toluidine 〃 | 2 | 4 |

The results are reasonably interpreted in terms of the assumption that only the ortho and the para positions of the benzene nucleus are reactive in the solid phase exchange reaction, and in the liquid phase meta positions are deuterated slowly. This lends support to the view that the mechanism of this reaction is an electrophilic substitution. The deuteration of meta positions in the liquid phase exchange may be due to toluidinium ions acting as proton acceptors. The fact that in the solid phase deuteration occurs exclusively at ortho and para positions, requires that the proton acceptor in this exchange reaction should be the molecules of toluidine or the toluidinium ions at least in the state of partial dissociation.

The crystals of toluidine hydrochlorides are probably composed of toluidinium ions and chlorine ions, by analogy with the crystals of aniline hydrochloride[5] and hydrobromide[6]. In view of this fact, it is rather surprising that meta positions are not deuterated in the solid phase exchange. Two mechanisms are possible for the exchange reaction; intermolecular and intramolecular mechanisms.

If the exchange reaction in the solid state occurs intermolecularly, probably through the intervention of lattice imperfections, for example, between two toluidinium ions, the absence of meta deuteration requires that, whenever two toluidinium ions react, the proton-accepting toluidinium ion as well as the donating one should be at least in the state of partial dissociation. This is equivalent to the requirement that almost all of the toluidinium ions in the crystal should be at least in the state of partial dissociation at the temperatures of the rearrangement, which seems improbable. The presence of an appreciable amount of toluidinium ions would make

5) J. C. Brown, *Acta Cryst.*, **2**, 228 (1949).
6) I. Nitta, T. Watanabe and I. Taguchi, *X-rays* (*Japan*), **5**, 31 (1948).

the meta deuteration observable. Moreover, if the toluidinium ions in the crystal were in the state of partial dissociation to any extent which makes the meta deuteration unobservable, they would at least remain so in the liquid phase, and the meta deuteration should be unobservable even in the liquid phase.

An alternative mechanism is an intramolecular shift of proton from the $NH_3^+$ group along the $\pi$-electron cloud of the benzene nucleus (formation of $\pi$-complex or the like) to the positions of the attack. In this case, the toluidinium ions react necessarily in the dissociated state, and the exclusive deuteration of ortho and para positions may be readily explained.

In the liquid phase, increased degrees of freedom of molecular motion would allow the toluidinium ions to collide with the proton donating species, and deuteration of meta positions takes place.

**II. The Rates of Rearrangement of Aniline Hydrochloride and Hydrobromide.** — The intramolecular character of the rearrangement of aromatic amine hydrochlorides being accepted, it is interesting to see whether the rate of rearrangement differs with the nature of the anion. As the rearrangement in the solid phase occurs in the nearly ordered arrangement of ions on which information is available from X-ray crystal analyzes[5,6], it would be suited for the study of the role of anions.

Figure 3 shows the variations of $\alpha$ with time for various temperatures for the rearrangement of aniline hydrochloride. Figure 4 is the corresponding figure for aniline hydrobromide. It will be seen that the rearrangement of the hydrochloride is considerably faster than that of the hydrobromide.

The equilibrium values of $\alpha$ are 2.72 and 2.37 for the hydrochloride and the hydrobromide respectively, the effect of temperature on the

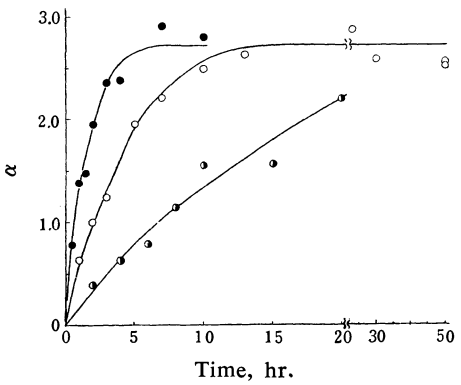

Fig. 3. Variation of $\alpha$ with time for the rearrangement of *N*-deuterio-aniline hydrochloride. ●, 194°C ○, 184°C ◑, 173°C

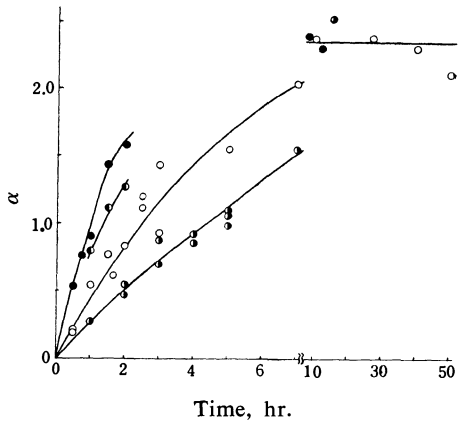

Fig. 4. Variation of $\alpha$ with time for the rearrangement of *N*-deuterio-aniline hydrobromide. ●, 225°C ◐, 222°C ○, 218°C ◑, 211°C

exchange equilibria being neglected. From this value, the number of the nuclear hydrogen atoms of the hydrobromide which take part in the exchange reaction may be determined as 3. The positions of these hydrogen atoms are probably ortho and para by analogy with the result obtained with the hydrochloride[1b]. The values of the partition coefficients $k$ are $0.90_1$ and $0.79_0$ for the hydrochloride and the hydrobromide. It cannot be decided whether the difference is real or due to some experimental errors.

The first order plots of the rearrangement of the hydrochloride and the hydrobromide are shown in Figs. 5 and 6.

The linearity of the plots is not quite satisfactory. This is at least partly due to the

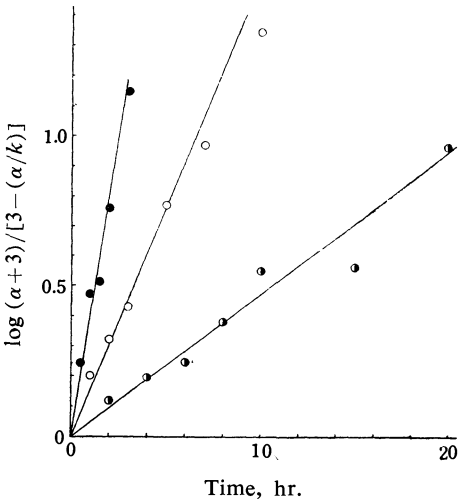

Fig. 5. First order linear plot for the rearrangement of *N*-deuterio-aniline hydrochloride. ●, 194°C ○, 184°C ◑, 173°C

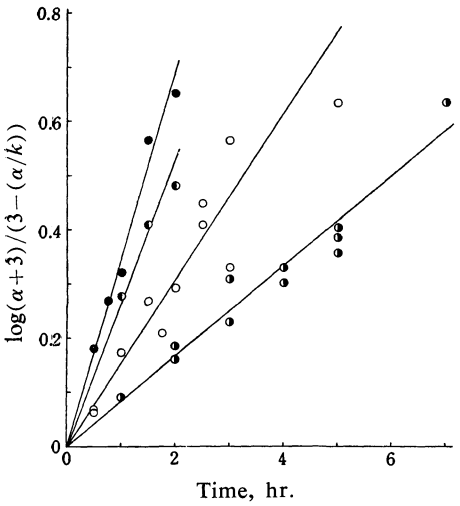

Fig. 6. Fist order linear plot for the rearrangement of *N*-deuterio-aniline hydrobromide.
●, 225°C ◐, 222°C ○, 218°C ◑, 211°C

indirect nature of the deuterium analysis (equilibration with water), and to the complicated sequence of operations. It is possible that the departure of the plots from linearity is partly caused by the failure of the assumption that the deuteration of the ortho and the para positions is characterized by the same rate constant.

Figures 7 and 8 are the Arrhenius plots. The Arrhenius parameters were determined by the method of least squares. The results are;

$$k_1^{Cl}(sec^{-1}) = 10^{16.7}\exp((44000\pm1200)cal./\boldsymbol{RT})$$

and

$$k_1^{Br}(sec^{-1}) = 10^{16.3}\exp((46000\pm2000)cal./\boldsymbol{RT})$$

for aniline hydrochloride and hydrobromide, respectively.

The entropies of activation were calculated by the equation, $A = e\cdot(kT/h)\cdot\exp(\Delta S/R)$, to be 15 and 13 cal./deg. for the hydrochloride and the hydrobromide.

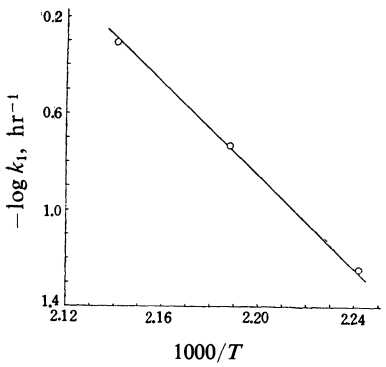

Fig. 7. Arrhenius plot for the rearrangement of *N*-deuterio-aniline hydrochloride.

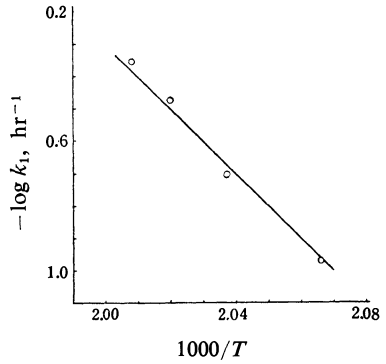

Fig. 8. Arrhenius plot for the rearrangement of *N*-deuterio-aniline hydrobromide.

Owing to the errors in the determinations of the rate constants, the accuracy of the absolute magnitudes of the energies and the entropies might not be claimed, but the order of magnitude of these values is probably correct, and they would be sufficient for the purpose of comparison.

These is no other example of the deuterium exchange reaction in the solid state to be compared with the present results. In pure liquid phase, the deuterium exchange reactions of phenol[7] and of *o*-cresol[8] have been studied. The reactions proceed through bimolecular mechanism. The values of activation energies are 34.8 kcal. for the exchange reaction of phenol and 23 kcal. for that of cresol. The value of the frequency factor for the exchange reaction of phenol is $10^{9.49}$. Comparison of these results with the present ones suggests that there is a difference in the mechanisms of nuclear deuteration between the two cases. As suggested above, the rearrangement probably proceeds through the intramolecular shift of protons from $NH_3^+$ groups to aromatic nuclei, where they attack the carbon atoms with higher electron densities. The protons leaving the $NH_3^+$ groups will move along the $\pi$-electron clouds to the nuclei, or they will combine with the halide ions to form transient molecules of hydrogen halide. The latter process is the necessary preliminary to the sublimation of the amine hydrochloride, which becomes marked side by side with the rearrangement with increasing temperature. Thus, the protons of the anilinium ions would be in a relatively free to-and-fro movement between $NH_3^+$ groups, $Cl^-$ ions, and aromatic nuclei, at high temperatures. In the course of these movements, they will come across the ortho and the para

7) A. I. Brodskii and I. I. Kukhtenko, *Zhur. Fiz. Khim.*, **25**, 920 (1951); *Chem. Abstr.*, **47**, 3814f.
8) I. I. Kukhtenko, *Doklady Akad. Nauk, S. S. S. R.*, **93**, 487 (1953); *Chem. Abstr.*, **49**, 3054.

positions and happen to attack the nuclear carbon atoms. The reaction may be formulated as,

$$C_6H_5NH_2D^+ \overset{K}{\rightleftarrows} C_6H_5NH_2+D^+(\cdots X)$$

$$C_6H_5NH_2+D^+(\cdots X) \overset{k_0}{\rightarrow} C_6H_4D\cdot NH_2+H^+(\cdots X)$$

where, $H^+(\cdots X)$ may be the proton attached to the aromatic nucleus (formation of $\pi$-complex), or it may be the transient molecule of hydrogen halide, or some form of proton which is in a relatively free state.

According to the above scheme, the first order rate constant $k_1$ of the deuterium exchange, or the rate of hydrogen exchange between $NH_3^+$ and aromatic nucleus of undeuterated salt, may be expressed as,

$$k_1=k_0(H^+)(C_6H_5NH_2)=k_0K(C_6H_5NH_3^+)$$

Therefore, the Arrhenius parameters obtained from the temperature dependence of $k_1$ contain, besides those of the rate-controlling step, the contributions from the energy and the entropy of the dissociation of the preequilibrium step, which by the nature of the reaction should have rather large positive values. Thus the large activation energies and large positive entropies of the rearrangement of anilinium halide may be interpreted qualitatively in terms of the above scheme.

The similarity of the Arrhenius parameters between the rearrangement of the two salts suggests that the role of anion in this reaction should be only subsidiary and the mechanism of the rearrangement involves primarily the anilinium ion alone, which is consistent with the intramolecular mechanism.

The difference of the rate of rearrangement between the two salts seems to be chiefly due to the difference in the activation energies, and it should be attributed to the effect of anions.

The results of X-ray crystal analysis[5,6] show that the $NH_3^+$ group is coordinated by four bromine ions, two at a distance of 3.48 Å and the other two at 3.65 Å, in the crystal lattice of the hydrobromide, and by three chlorine ions at a distance of 3.16 Å in that of the hydrochloride. The difference in the N–X distances is greater than that of the ionic radii of the halide ions, and it is expected that the chlorine ion exerts a more powerful polarizing effect upon the N–H bond. Thus, the protons of the $NH_3^+$ groups would be more loosened in the hydrochloride than in the hydrobromide in the initial state of the reaction, and this difference would contribute to the lowering of the energy of activation.

The distances between the halide ions and the ortho and the para carbon atoms may be calculated from the data of the X-ray crystal analyzes. The shortest distances are 3.87 Å for ortho and 3.98 Å for para carbon atoms in the crystal lattice of the hydrobromide, and 3.53 and 3.85 Å for ortho and para carbon atoms in that of the hydrochloride, the sum of van der Waals radii being 3.80 and 3.65 Å for hydrobromide and hydrochloride, respectively. It might be expected that the presence of the negatively charged anions in the neighborhood of the reaction centre would stabilize the positively charged activated complex. And, if it is the case, the extent of stabilization would also be in favor of the chlorine ions.

## Summary

The rearrangement of *N*-deuterated aromatic amine hydrochloride into its ring-deuterated analogues has been studied in the solid and the liquid phases with *o*- and *m*-toluidines, and studied kinetically with anilinium chloride and bromide at 173~194°C and at 210~225°C, respectively.

The ease of the rearrangement of the hydrochlorides in the solid phase is in the order,

*o*-toluidine hydrochloride
> aniline hydrochloride
> *p*-toluidine hydrochloride

which is the reverse of the order of the basic dissociation constants of the amines at 25°C. *m*-Toluidine hydrochloride is more reactive than *o*-toluidine hydrochloride.

The numbers of nuclear hydrogen atoms which take part in the rearrangement are, 2 in the solid phase and >3 in the liquid phase rearrangement of *o*-toluidine hydrochloride, and for *m*-toluidine hydrochloride 3 and 4 in the solid and the liquid phases respectively. This result, taken in conjunction with the earlier ones with aniline and *p*-toluidine hydrochlorides, confirms the view that in the solid phase rearrangement the ortho and the para positions are exclusively deuterated, and in the liquid phase deuteration of the meta positions takes place.

The rearrangement of the anilinium salts is characterized by high activation energy (ca. 45 kcal.) and large positive entropy of activation (ca. 15 cal./deg.).

These results are reasonably interpreted by the intramolecular electrophilic mechanism.

A small difference of the activation energies between the rearrangement of the two anilinium salts (ca. 2 kcal.) may be explained in terms of the different polarizing effects of the halide ions on the initial state and possibly also on the activated complex.

The authors wish to thank Professor T. Titani, Tokyo Metropolitan University, for his interest and advice.

# *The Structure of the Condensation Products of Troponoids and Ethyl Cyanoacetate*

By Shingo MATSUMURA

(Received December 2, 1960)

Nozoe and his co-workers have already reported that the condensation of 2-chlorotropone (I) and ethyl sodiocyanoacetate (II) formed 2-amino-1, 3-diethoxycarbonylazulene (III), 1-cyano-2-hydroxy-3-ethoxycarbonylazulene (IV), and a structurally unknown compound (V) of m. p. 137°C, whose analytical values correspond to the molecular formula of $C_{17}H_{18}O_5N_2$[1].

Similar condensation was carried out by Akino[2] on 2-chloro-6-methyltropone (VI) and he observed the formation of 2-amino-1, 3-diethoxycarbonyl-5-methylazulene (VII) and a compound (VIII) of m. p. 103°C, whose analytical values agree with $C_{18}H_{20}O_5N_2$.

Examinations were made on the structure of V and VIII.

The ultraviolet absorption spectra[3] of V and VIII, shown in Fig. 1, are very similar to each other and the two compounds are assumed to have a common skeletal structure.

V and VIII easily form picrates melting at 215 and 196°C, respectively. The infrared ab-

a V, b VIII, c XIII

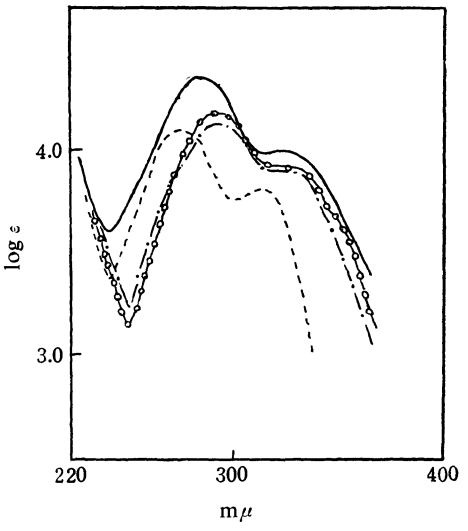
1) T. Nozoe, S. Seto, S. Matsumura and T. Asano, *Proc. Japan Acad.*, 32, 339 (1956).
2) H. Akino, to be published.
3) Ultraviolet spectra were measured with a Hitachi EPU-2A spectrophotometer by Mr. F. Sato of this Institute, to whom the author is deeply indebted.

sorption spectra[4] of V and VIII are shown in Fig. 2, a and b.

The infrared spectrum of V exhibits absorption bands at 3455 and 3323 $cm^{-1}$ for the primary amino or hydroxyl and imino group, at 2260 $cm^{-1}$ for cyano group, at 1735 $cm^{-1}$ for ester carbonyl, at 1678 $cm^{-1}$ for ester carbonyl conjugated with unsaturated bond, and at 1635 $cm^{-1}$ for absorption due to the deformation vibration of N-H group. Similar bands are found in the spectrum of VIII.

When V is warmed with dilute hydrochloric acid in ethanol for a short period, colorless crystals (IX), m. p. 93°C, are obtained. IX is also obtained on decomposition of the picrate of V with sodium hydrogencarbonate solution. Analytical values of IX agree with $C_{12}H_{10}O_4$.

The reaction of V with dilute acid for 4 hr. affords colorless crystals (X), m. p. 188°C, which are also formed on treatment of IX with dilute acid. X is an acid substance since it dissolves in sodium hydrogen carbonate solution. Analytical values of X correspond to the molecular formula of $C_{10}H_6O_4$. The ultraviolet absorption spectra of IX and X, shown in Fig. 3, are similar to the absorption curves of coumarin derivatives. Thermal decomposition of X produces colorless crystals (XI), m. p. 68°C, with an aroma. The ultraviolet absorption spectrum of XI (Fig. 3) and its melting point is identical



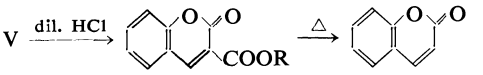


Fig. 3. Ultraviolet absorption spectra in methanol.

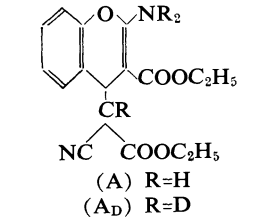
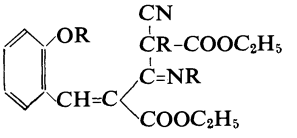
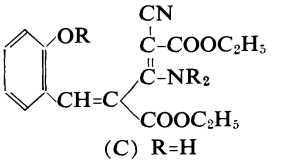


-o-o IX, -·-· X, ---- XI, —— XV

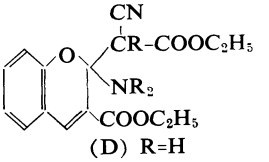
with that of coumarin and on admixture it is confirmed that XI is coumarin.



Consequently, IX is 3-ethoxycarbonylcoumarin and X is 3-carboxycoumarin. The melting points of IX and X are in good agreement with those reported in the literature.



From these experimental results, formulae A, B, C and D are taken into consideration for the structure of V.



(A) R=H
($A_D$) R=D

(B) R=H
($B_D$) R=D

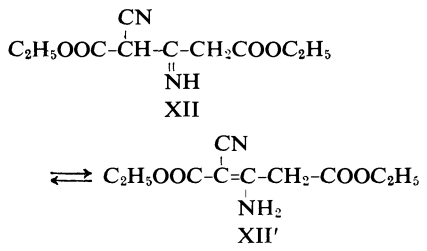
(C) R=H
($C_D$) R=D

(D) R=H
($D_D$) R=D

If formula A is correct, its ultraviolet absorption should be similar to that of *o*-alkylphenol[5]. However, V has absorption maxima at 296 and 365 mμ, differing from those of *o*-alkylphenols, so that the structure of V is not A.

The formulae B, C and D are tautomeric.

Baron[6] prepared a dimer (XII) by condensation of two molecules of ethyl cyanoacetate and gave the ketimine-type structure alone for XII, but it should also take a tautomeric amino-type structure. The infrared spectrum



4) Infrared spectra were measured with a Perkin-Elmer Model 21 double beam spectrophotometer by Mr. S. Aono of this Institute, to whom the author is deeply indebted.

5) H. F. Hunter, R. A. Morton and A. T. Carpenter, *J. Chem. Soc.*, **1950**, 441.

6) H. Baron, ibid., **85**, 1736 (1904).

of XII exhibits absorption bands at 3420 and 3300 $cm^{-1}$ for the primary amino group, at 2215 $cm^{-1}$ for the cyano group conjugated with unsaturated bond, at 1710 $cm^{-1}$ for ester carbonyl, and at 1680 $cm^{-1}$ for ester carbonyl conjugated with unsaturated bond.

These facts indicate that the dimer XII takes the amino form XII′ in crystalline state.

XII

XII′

In analogy with the above, it is more likely that V takes the amino-type C structure rather than the imino-type B. However, the infrared spectrum of V has an absorption for cyano group at 2260 $cm^{-1}$, but not of a cyano group conjugated with unsaturated bond. Moreover there is an absorption due to ester carbonyl not conjugated with unsaturated bond at 1735 $cm^{-1}$. It follows, therefore, that V has the structure of D, i.e. 2-amino-2-(cyano-ethoxycarbonyl-methyl)-3-ethoxycarbonyl-$\alpha$-benzopyrane.

VIII is a methyl derivative of V and the position of the methyl is assumed to be at 7-position, since there is absorption of C–H out-of-plane vibration at 820 $cm^{-1}$ [7].

In order to confirm the formula D for V, the deuterated compound XIII of V was prepared and its infrared absorption spectrum was examined. XIII is obtained by recrystallization of V from 50% dioxane-deuterium oxide mixture. Admixture of XIII and V shows no depression in the melting point and the ultraviolet spectra of two compounds are identical.

The infrared spectrum of XIII (Fig. 2c) shows that the absorption bands at 3455, 3323, 2937, 1635, 1528, 1490, 1418, 1280, 1175, 1037 and 1025 $cm^{-1}$ in V disappear in XIII, and new bands at 2576, 2418, 2160, 1565, 1430 and 1000 $cm^{-1}$ appear in XIII. The absorption bands at 940 and 915 $cm^{-1}$ in V shift to 934 and 900 $cm^{-1}$ with slightly increasing intensity in XIII. The fact that no ring-substitution has occurred by deuteration is proved by the absence of any change in the C–H out-of-plane deformation vibration absorption in V and XIII. If all the deuterable functional groups in B, C and D structures assumed for V have been completely deuterated, the structures $B_D$, $C_D$ or $D_D$ would be possible for XIII. The wave number ratio of 3455 $cm^{-1}$ in V and 2576 $cm^{-1}$ in XIII is 1.34, and that of 3323 $cm^{-1}$ in V and 2418 $cm^{-1}$ in XIII is 1.38. These ratios agree with the usual values of $\nu(N-H)/\nu(N-D)$.

The disappearance of the absorption band at 2937 $cm^{-1}$ and appearance of a new absorption band at 2160 $cm^{-1}$ gives a wave number ratio of 1.36, which agrees with the usual value of $\nu(C-H)/\nu(C-D)$.

The absorption band at 2937 $cm^{-1}$ in V is not due to the stretching absorption of C–H in aromatic ring or that in unsaturated double bond. This indicates that the deuterable hydrogen in the methine group of V has undergone an exchange reaction with deuetrium. Consequently, there should be no absorption band of $\nu(C-D)$ in formula $C_D$ and this formula is excluded.

Mecke et al.[8] examined infrared absorption spectra of phenol and deuterated phenol, and assigned the bands at 1399～1332 and 1230～1180 $cm^{-1}$ for characteristic absorption of $\nu(C-O)$ and $\delta(O-H)$ in phenol. They showed that new absorption bands appeared at 1300 and 980～920 $cm^{-1}$ in deuterated phenol.

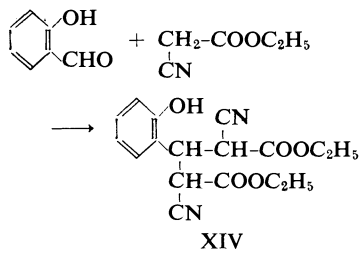
There are absorption band at 1370 and 1175 $cm^{-1}$ in V.

The band at 1175 $cm^{-1}$ is active to deuteration but that at 1370 $cm^{-1}$ is inactive. There is no absorption band due to $\delta(O-D)$ at 980～920 $cm^{-1}$ in XIII. The absorption band at 1635 $cm^{-1}$ in V is active to deuteration and this band may be assigned to $\delta(N-H)$. These facts suggest that V takes the formula D and not B.

Bechert[9] obtained a compound XIV of m. p. 140°C by condensation of salicylaldehyde and ethyl cyanoacetate with alkoxide.

Knoevenagel et al.[10] obtained XIV by the use of piperidine in place of alkoxide. Both workers gave the molecular formula of $C_{17}H_{18}O_5N_2$ for XIV.

Since the melting point of XIV is close to that of V and the molecular formula of the two compounds are identical, XIV was prepared by the method of Knoevenagel and its admixture with V showed no depression of the melting point. Further the ultraviolet absorption spectra of the two compounds were found to be identical.



Bechert and Knoevenagel et al. assigned the structure of diethyl-$\alpha,\gamma$-dicyano-$\beta$-(2-hydroxyphenyl)-glutarate as XIV, i.e. V, but this structure cannot explain the ultraviolet and infrared spectral data obtained with V.

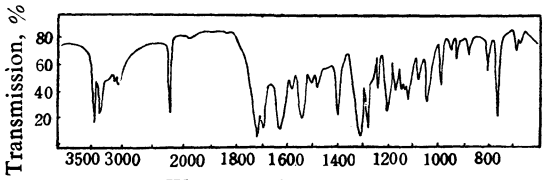
XIV

Seshadri et al.[11] found that on refluxing XIV in ethanol containing piperidine, a compound XV of m. p. 248°C, was obtained. From the identity of XV with the condensation product of 3-cyanocoumarin (XVI) and ethyl cyanoacetate, they gave the structure of ethyl 3-cyano-3, 4-dihydrocoumarin-4-cyanoacetate (E) for XV.

If Seshadri's assumption is correct, formation of XV from the proposed structure of $\alpha$-benzopyrane derivative for V cannot be explained. Therefore, re-examination was made on the structure of XV. The ultraviolet spectrum of XV, shown in Fig. 3, is similar to that of coumarin derivatives. The infrared spectrum of XV, as indicated in Fig. 4, exhibits absorption at 3410 and 3280 $cm^{-1}$ for the primary amino group, at 2210 $cm^{-1}$ for the cyano group conjugated to unsaturated bond, and at 1710 and 1680 $cm^{-1}$ for lactonic carbonyl and ester carbonyl conjugated with unsaturated bond.



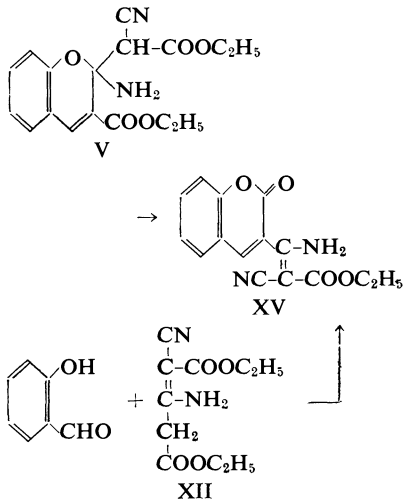


Fig. 4. Infrared absorption spectrum of XV in KBr disk.

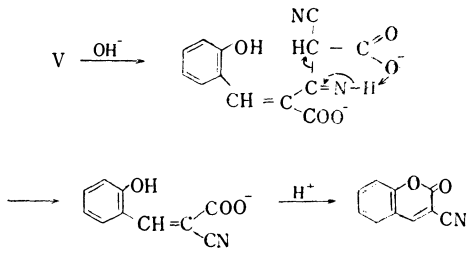
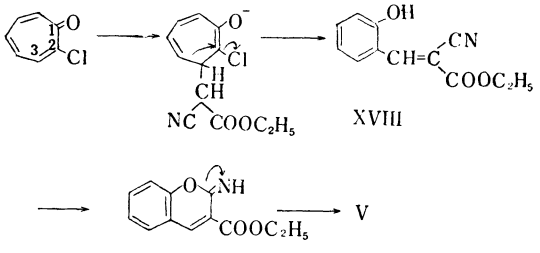


These data suggest that the structure of XV is not E as proposed by Seshadri but must be $\alpha$-amino-$\alpha$-(3-coumarinyl)-$\beta$-cyano-$\beta$-ethoxycarbonylethylene.

Condensation of salicylaldehyde and XII, in the presence of potassium hydroxide or piperidine, affords a compound corresponding to XV.



Knoevenagel et al.[10] reported the formation of 2-oxo-$\beta$-phenylpropane-$\alpha$, $\alpha$, $\gamma$-tricarboxylic anhydride (XVII) from V but re-examination of this reaction showed the formation of IX alone and not the compound corresponding to XVII.

It has been found that hydrolysis of V with ethanolic solution of potassium hydroxide produces XVI[9]. This reaction mechanism must be such as is indicated in Scheme 1.

Scheme 1.

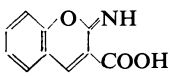
This reaction is similar to the mechanism of formation of aromatic nitrile by alkaline hydrolysis of trichloro-aryl-ketimine[12].

XIX

Scheme 2.

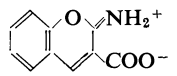
11) V. D. N. Sastry and T. R. Seshadri, *Proc. Indian Acad. Sci.*, 16A, 29 (1942); *Chem. Abstr.*, 37, 880 (1943).

12) J. Houben and W. Fisher, *J. prakt. Chem.*, 123, 313 (1929); D. T. Mowry, *Chem. Revs.*, 42, 221 (1948).



The mechanism for formation of V by the condensation of I and II is illustrated in Scheme 2.

Formation of salicylaldehyde derivatives by nucleophilic attack against tropone derivatives has already been witnessed in the reaction of 2, 7-dihalotropone with alkali[13] or ammonia[14], of 2-halo-7-phenyltropone and 2, 4, 7-tribromotropone[15,16].



Kitahara[17] assumed a reaction mechanism for this kind of rearrangement reaction in which the nucleophilic reagent attacks the 3-position of the tropone ring.

Formation of V from I is assumed to follow similar rearrangement reaction mechanism.

Formation of an intermediate XIX is supported by the following evidence. Baker et al.[18] found that heating of salicylidenecyanoacetic acid (XX) in ethanol changed it into a substance XXI sparingly soluble in ethanol, and XXI was easily soluble in water and neutralization of its aqueous solution resulted in the formation of X. They therefore assumed for XXI an imino compound like XXIa or an intramolecular salt of imino compound like XXIb.

XXIa

XXIb

## Experimental[19]

**Picrate of V.**—A saturated ethanolic solution of picric acid was added to a solution of 100 mg. of V dissolved in 3 ml. of ethanol and 150 mg. of yellow needles, m. p. 215°C (decomp.), separated out immediately. This picrate undergoes decomposition when heated in ethanol and changes into an easily soluble substance.

Found: C, 49.52; H, 3.91; N, 12.63. Calcd. for $C_{23}H_{21}O_{12}N_5$: C, 49.37; H, 3.75; N, 12.52%.

**Picrate of VIII.**—Yellow needles, m. p. 195~196°C.

Found: N, 12.53. Calcd. for $C_{24}H_{23}O_{12}N_5$: N, 12.21%.

**Reaction of V with Dilute Acids.** — a) A solution of 500 mg. of V dissolved in 10 ml. of ethanol, added with 0.2 ml. of 6 N hydrochloric acid, was boiled for 3 min. and evaporation of ethanol left prismatic crystals. The addition of water to this crystalline residue resulted in the melting of the crystals to form an oily substance which crystallized on standing. Recrystallization from ethanol afforded 250 mg. of colorless prisms (IX), m. p. 92~93°C which showed no depression on admixture with 3-ethoxycarbonylcoumarin.

Found: C, 66.38; H, 4.95. Calcd. for $C_{12}H_{10}O_4$: C, 66.05; H, 4.62%.

b) A mixture of 100 mg. of V in 3 ml. of 2 N hydrochloric acid was refluxed at 100~110°C for 1 hr., by which V dissolved gradually. Water was added to the reaction mixture under cooling and colorless crystals precipitated out. Recrystallization from ethanol afforded 40 mg. of IX.

c) A mixture of 100 mg. of V in 1 ml. of 6 N hydrochloric acid was heated on a water bath for 4 hr., water was evaporated, and the precipitate thereby formed was recrystallized from ethanol, affording 20 mg. of X, m. p. 186~188°C, which showed no depression on admixture with 3-carboxycoumarin.

Found: C, 63.02; H, 3.61. Calcd. for $C_{10}H_6O_4$: C, 63.16; H, 3.18%.

**Formation of Coumarin (X).**—Low-pressure sublimation of 50 mg. of X by heating at 200~230°C produced some crystals with an aroma. Reccystallization of the sublimate from cyclohexane gave colorless plates (X), m. p. 67~68°C, undepressed on admixture with coumarin.

**Deuteration of V.** — V was recrystallized from 50% mixture of dehydrated dioxane and deuterium oxide.

**Formation of α-Amino-α-(3-coumarinyl)-β-cyano-β-ethoxycarbonylethylene (XV).**—A suspension of 100 mg. of V in 1 ml. of ethanol, with 3 drops of piperidine added, was refluxed for 4 hr., by which V dissolved once, and colorless needle crystals began to precipitate out as the reaction proceeded. Recrystallization of these crystals from a large volume of ethanol gave 60 mg. of XV, m. p. 245~246°C.

Found: C, 63.12; H, 4.34; N, 9.85. Calcd. for $C_{15}H_{12}O_4N_2$: C, 63.38; H, 4.26; N, 9.86%.

UV. $\lambda_{max}^{MeOH}$ mμ (log ε): 280 (4.36), 318 (4.0).

**Synthesis of XV.**—A solution of 50 mg. of salicylaldehyde and 100 mg. of XII dissolved in 0.5 ml. of absolute ethanol with 1 drop of piperidine added was allowed to stand at room temperature. The crystals that precipitated out were recrystallized from ethanol and 120 mg. of XV was obtained.

The author takes this opportunity to express his deep gratitude to Professor Tetsuo Nozoe and Professor Shuichi Seto for their unfailing guidance and to Mr. Yusaku Ikegami and Mr. Kyozo Ogura for much helpful advice. Also the author expresses his thanks to Mr. S. Ohyama and Miss A. Iwanaga for the microanalyses.

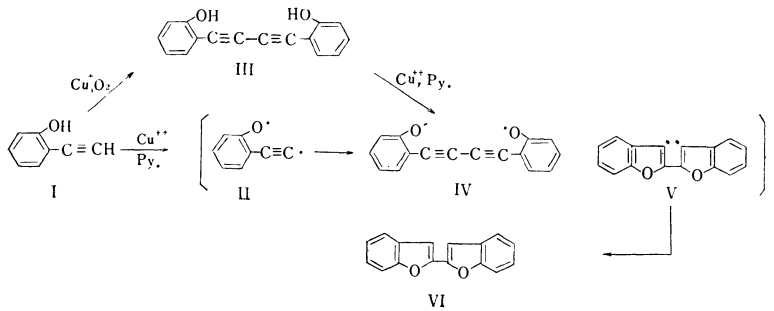
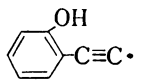
# *Oxidation of o-Hydroxyphenylacetylene and o, o'-Dihydroxydiphenyldiacetylene by Copper Ion*

By Fumio TODA and Masazumi NAKAGAWA



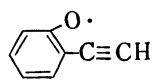
(Received December 9, 1960)

Previously the present authors have reported the quantitative formation of 2, 2'-dibenzofuranyl (VI) by the intramolecular cyclization of *o*, *o'*-dihydroxydiphenyldiacetylene (III) on treatment with basic reagents[1]. It has been found that VI is also formed quantitatively by the photodecomposition of the silver salt of III[2]. It is apparent that the former reaction involves an intramolecular nucleophilic addition of a phenoxide anion to the triple bond and the latter reaction proceeds through a radical intermediate.



The present paper deals with the formation of VI from *o*-hydroxyphenylacetylene (I) or III by the action of cupric acetate in pyridine. The treatment of I with the conventional cuprous chloride-ammonium chloride coupling reagent in an atmosphere of oxygen yielded the expected product III in a reasonable yield[1]. Unexpectedly, however, an evolution of heat was observed when I was added to a solution of cupric acetate in pyridine which is an excellent reagent of oxidative coupling of ethynyl compound proposed by Eglinton[3], and VI was isolated in a yield of 30% from the reaction mixture together with fairly large amount of an unidentified neutral oily material. A similar treatment of III with the Eglinton's reagent gave VI in quantitative yield. No change was observed when III was treated with pyridine without cupric acetate, in spite of the intramolecular cyclization of III could be caused by a weak base such as sodium carbonate or sodium hydrogen carbonate. Therefore, the presence of cupric ion is essential for the cyclization of III to VI.

Transitory formation of ethynyl radical during the course of oxidation of terminal acetylene by aqueous solution of cupric salt was postulated by Klebanski et al[4]. One electron oxidation of an ethynyl anion by cupric ion results in a transitory radical. Rapid combination of two of the ethynyl radicals forms diacetylenic product. The formation of the ethynyl radical VII seems to be probable in the course of the photochemical transformation of silver acetylide of I into coumarone[5]. Also the appearance of the phenoxyl radical IV seems to be highly probable in an intermediate stage of transformation of the silver salt of III into VI by irradiation[2]. More recently the appearance of phenoxyl radical was confirmed in several instances[6].



From the above-mentioned consideration, it appears likely that we may conclude that the reaction of I with cupric ion proceeds through the formation of free radical II. The coupling of two of II results in the new radical IV which is the same with the intermediate of the photochemical formation of VI from the silver salt of III. The oxidation of I with cupric ion may produce other radicals such as VII

VII

VIII

and VIII. Coupling two of VII and subsequent oxidation of the hydroxyl groups may be another route leading I to IV. Cyclization or other side reactions of II, VII and VIII which occur prior to the coupling reaction leading to IV may be responsible for the low yield of VI and the formation of a neutral oily by-product in the reaction of I with Eglinton's reagent.

The great difference between the mode of oxidation of I by the conventional coupling technique employing cuprous salt and that of the one by the Eglinton's procedure is remarkable, because cupric ion produced by the aerial oxidation of cuprous ion is regarded as the oxidizing agent in the former reaction[3] and also the oxidizing agent in the latter process is undoubtedly the same cupric ion. Quite recently, Hay[7] has reported that phenylacetylene and diethynylbenzenes can be coupled rapidly at room temperature with oxygen or air in a pyridine solution containing catalytic amount of cuprous chloride. He pointed out also that cupric carboxylates are catalysts for the reaction but they have far inferior catalytic activity as compared with cuprous salts. The copper ion in these coupling reagents must exist in some form of complex and it seems to be highly possible that the ethynyl compound takes the part of the ligand of the copper complex. Therefore, the marked difference of the oxidizing power of these coupling reagents is associated with the difference of the structure of copper complex formed in the particular reaction mixture.

## Experimental

**Oxidative Coupling of *o*-Hyroxyphenylacetylene by the Eglinton's Method.**—A solution of *o*-hydroxyphenylacetylene (I, 5.0 g.) in ethanol (10 ml.) was added to a deep blue solution of cupric acetate monohydrate (30 g.) in pyridine (65 g.). An appreciable elevation of the temperature of the mixture was observed and the color of the mixture rapidly changed to green. The reaction mixture was stirred for 2 hr. under cooling with running water. Stirring was continued for further 2 hr. at 50°C. After removal of the solvent under reduced pressure the residue was mixed with water and extracted with ether. The ether extract was washed with aqueous solution of cupric acetate and water, successively and dried over sodium sulfate. Tiny colorless needles suspended in an oily liquid were obtained after evaporating the solvent. The crystals were filtered, washed with ethanol and recrystallized from benzene using active charcoal giving colorless needles, m.p. 194.5~195.5°C, 1.5 g. (30%). The substance showed no depression of the melting point on admixture with a genuine sample of 2,2'-dibenzofuranyl (VI)[1].

**Oxidation of *o*, *o'*-Dihydroxydiphenyldiacetylene with the Eglinton's Reagent.**—A mixture of *o*, *o'*-dihydroxydiphenyldiacetylene (III, 0.50 g.), cupric acetate monohydrate (3.0 g.) and pyridine (20 g.) was stirred for 3 hr. at 60°C. The solvent was distilled in vacuo. The residue was mixed with water and extracted with ether. The extract was washed with aqueous cupric acetate and water, successively. The dried solution (over magnesium sulfate) was concentrated, yielding crude crystals, m. p. 194.5~195.5°C, 0.5 g. The crude material was recrystallized from benzene employing active charcoal to give colorless needles, m. p. 194.5~195.5°C, 0.45 g. (90%). This was identified as 2,2'-dibenzofuranyl (VI) by the mixed melting point determination with an authentic specimen of VI[1].

# *Aggregation of Ion-exchange Resin Particles*

By Manabu SENŌ and Takeo YAMABE

(Received December 20, 1960)

An ion-exchange resin is a crosslinked polyelectrolyte gel, which dissociates to produce cations or anions. Polystyrenesulfonic acid-divinylbenzene and polyvinylbenzyltrimethylammonium hydroxide-divinylbenzene are a typical cation-exchange resin and a typical anion-exchange resin used now, respectively. These resins exhibit a remarkable swelling behavior when the degree of crosslinking, e. g., the content of divinylbenzene is small[1]. Resins with a high degree of crosslinking scarcely swell at all and, using these resins, researches not on the swelling behavior of resins but on the aggregation behavior are able to be carried out.

The cation- and the anion-exchange resins have negative and positive charges, respectively, in the dissociated states and, therefore, it is expected that the interparticlar interaction exerts itself between two kinds of these resin particles. In practice, it is often observed that such an aggregation takes place in a mixed bed water purification apparatus. In this paper, some observation on the aggregation behavior will be presented. Independently of this investigation, Grubhofer described recently a similar observation[2]. It is believed that this behavior is of interest colloid-chemically and the ion-exchange resins are interesting samples to investigate colloid-chemical phenomena in this respect. Recently, Schenkel and Kitchener used similar particles to test the Derjaguin-Verwey-Overbeek theory[3].

## Experimental

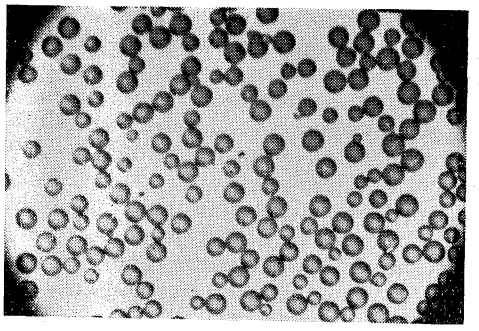
Ion-exchage resins used primarily in this experiment are commercially-available ones, Dowex 50W and Dowex 1, which are strongly acidic and strongly basic polystyrene-based resins with sulfonic acid group or quarternary ammonium group, respectively. In addition, the following resins were used; Amberlite IR-120 (strongly acidic), Amberlite IRA-400 (strongly basic), Amberlite IRC-50 (weakly acidic) and Amberlite IR-4B (weakly basic). The former two are polystyrene-type resins and the later two are polyalkene-type ones with carboxyl acid group and secondary or tertiary amino group, respectively. The $H^+$-form cation exchanger or the $OH^-$-form anion-exchanger is prepared by treating them with hydrochloric acid or sodium hydroxide solution, respectively, after conditioning them several times and washing them thoroughly with deionized water.

The aggregation behavior was observed directly with the naked eye or by microphotography and, as a measure of the degree of aggregation, the sedimentation volumes were measured. About 1 g. of air-dried resins was taken into 20 ml. of suspending media in the sedimentation tube, which is 15 cm. in height and 1.5 cm. in inner diameter. The suspending media were deionized water except when stated otherwise. After being stirred vigorously, the sedimentation tube was settled in the quiescent state overnight at room temperature, 20~25°C, and the sedimentation volume was read. By correcting for the moisture content of resins, the specific sedimentation volume was gained. The moisture content was measured gravimetrically by drying them on phosphorus pentoxide in vacuo.

## Results and Discussion

**Formation of Aggregation.**—Dowex 50W resins of hydrogen-form or Dowex 1 resins of hydroxyl-form, individually, form dense sediments in water, the specific sedimentation volume being 2.6 ml./g., respectively. When both kinds of resins are mixed, remarkable aggregation takes place; very bulky sediment is formed and the specific sedimentation volume is 21 ml./g. (volume fraction of particles in the sediment is 0.04). By observing the microscopic photograph of these systems shown in Fig. 1, it is clear that, although each kind of resins, individually, disperses uniformly, in the mixture of them both resins combine with each other to form agglomerates with large voids.

It is well-known that, the stronger is the attracting interaction between the particles, the larger is the sedimentation volume of the particles. Recently, Vold[4] calculated the sedimentation volume of the colloidal particles whose attracting range extends over a distance $r$ times larger than the particle radius from their surface. According to her calculation, the ion-exchange particles under study now have a range of attraction nearly equal to the particle radius ($r \approx 1$).



These agglomerates are formed in the systems of weakly dissociated resins, e. g., between

But the last system, e. g., the weakly acidic and the weakly basic resins, do aggregate only to less extent. The degree of aggregation of these systems is given in Table I.

Table I. Degree of aggregation of various particle systems

| System* | Degree of aggregation** |
|---|---|
| IR-120-IRA-400 | 2.8 |
| IR-120-IR-4B | 1.9 |
| IRC-50-IRA-400 | 2.5 |
| IRC-50-IR-4B | 1.3 |

* All the particles are Amberlite ion-exchange resins, 20 mesh of particle size and 1 : 1 mixture by weight.
** Degree of aggregation are defined as the ratio of sedimentation volume (aggregate) in pure water to the volume (non-aggregate) in 1 N sodium chloride.

**Effect of Addition of Salts.**—The aggregates are destroyed by addition of salts. The specific sedimentation volumes diminish on addition of salts such as sodium chloride as shown in Fig. 2. As for the breaking-down of aggregates by

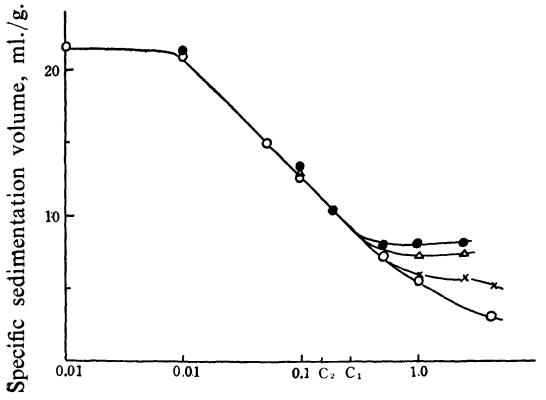

Fig. 2. Effects of addition of salts on sedimentation volume. System; Dowex 50W (200 mesh)-Dowex 1 (200 mesh), 1 : 1 by weight. -○- NaCl, -×- $MgCl_2$, -△- $Na_2SO_4$, -●- $MgSO_4$. $C_1$ and $C_2$ are saturation concentrations of Dowex 50W and Dowex 1, calculated from the total exchange capacities of resins.

addition of salts the following results are to be pointed out;

(1) The effect of destruction of agglomerates is primarily governed by equivalent concentration of salt solution, independently of variation of the kind of salts.

(2) In high concentration range of salts, in which the aggregates are completely broken down, the specific sedimentation volume changes with the variation of salts. But this difference is primarily due to the difference in the density of the salt solution, and it is finally observed that the anion-exchange resin, the lighter one, is separated from the cation-exchange resin, the heavier one, and floats up.

(3) When the saturation concentration which is calculated from the total exchange capacity of resins is reached, the hydrogen ions or the hydroxyl ions may be largely replaced for, say, the sodium ions or the chloride ions and at this concentration the aggregate is completely broken down. In the far lower concentration range than this saturation concentration, the aggregate is destroyed considerably and there is a linear relationship between the specific sedimentation volume and the logarithm of the concentration of the added salt solution.

(4) The aggregates are broken down by the addition of acids or alkaline solutions. The strongly acidic resin-the weakly basic resin (Amberlite IR-120-Amberlite IR-4B) destroyed with hydrochloric acid, and the weakly acidic resin-the strongly basic resin (Amberlite IRC-50-Amberliet IRA-400) destroyed with sodium hydroxide become to form aggregation again, on washing them with deionized water. It may be due to hydrolysis of weakly dissociated resins.

**Aggregation in Non-aqueous Media.**—As it appears that the interparticlar force is electrostatic in nature, it seems to be interesting to investigate the aggregation behavior in non-aqueous media, the dielectric constant of which is small. It is well-known that the minute amount of water influences greatly the electrostatic coagulation and the air-dried ion-exchange resins contain the considerable amount of water, for these are very lyophilic gels, and hence the air-dried resins must be dried on phosphorus pentoxide in vacuo to remove moisture from them completely. The sedimentation volume of these dried resins in dried benzene was measured and was shown in Fig. 3. As seen

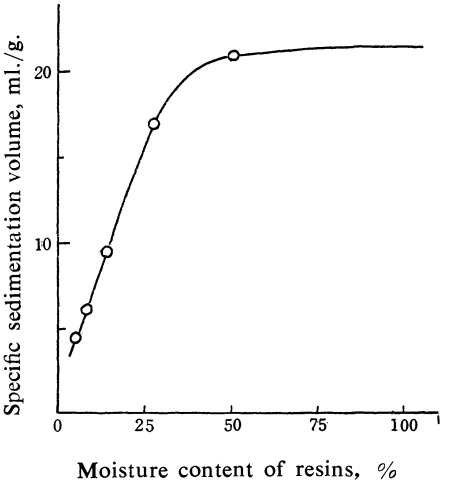

Fig. 3 Effect of moisture on sedimentation volumes of resins in benzene. Dowex 50W (200 mesh)-Dowex 1 (200 mesh)

in this figure, in which the specific sedimentation volume is plotted against the moisture content of resins, the resins do not form an aggregate in the complete absence of water.

**Mechanism of Aggregation.**—It is supported by the above-mentioned results that the interparticlar force which causes aggregation is electrostatic in nature. The agglomeration takes place between the hydrogen-form cation-exchange resins and the hydroxyl-form anion-exchange resins. A kind of neutralization reaction occurs between the particles of hydrogen-form resin and the hydroxyl-form resin and results in producing the negatively charged and the positively charged resin particles and Coulombic interaction is exerted between these charged particles. Such a coagulation behavior

was observed also between a polymeric acid and a polymeric base by Deuel et al.[5]

The presence of small additional ions such as sodium or chloride ions screens the charges on the particles and the interparticlar Coulombic attraction decreases. In benzene free from water the degree of dissociation of counterions is so small that the neutralization does not proceed between hydrogen- and hydroxyl-form particles. Hence the aggregates are not formed in such a system.

**Steric Factor on Aggregation.**—It is well-known that the steric factors such as the size and shape of particles affect greatly the aggregation behavior of colloidal particles. The ion-exchange particles used in this investigation are very large in size and spherical in shape. Therefore, it seems that the effect of size ratio of both particles participated with aggregation is more interesting than that of the size and shape itself. In Fig. 4, the aggregation behavior of the ion-exchange resin particles, Dowex 50W and Dowex 1, with different sizes is shown. As seen in this figure, the particles with the same sizes show a maximum aggregation on mixing at the equal amounts of both resins and the particles with the different sizes show a maximum aggregation on mixing at a larger amount of the larger particle and a smaller amount of the smaller particle. The weight fraction of the cation-exchange resin, Dowex 50W, that gives the maximum aggregation is shown against the ratio of radii between both of the resin particles in Fig. 5. It is clearly noticed that the difference in size between both particles influences markedly the aggregation behavior.

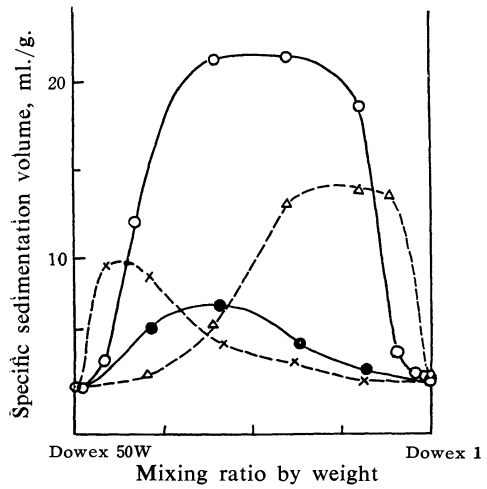

Fig. 4 Sedimentation volumes of mixtures of resins of various particle sizes.

| Mesh size; | Dowex 50 W | Dowex 1 |
|---|---|---|
| —○— | 200(0.043 mm.) | 200(0.055 mm.) |
| --×-- | 20(0.375 mm.) | 200 |
| --△-- | 200 | 40(0.190 mm.) |
| —●— | 20 | 40 |

Average radii of resin particles are given in parentheses.

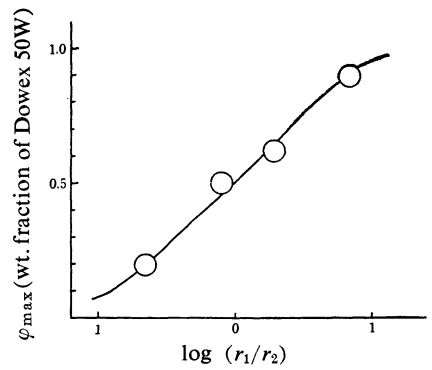

Fig. 5. Relation of the mixing ratio of maximum aggregation and the particle size ratio.

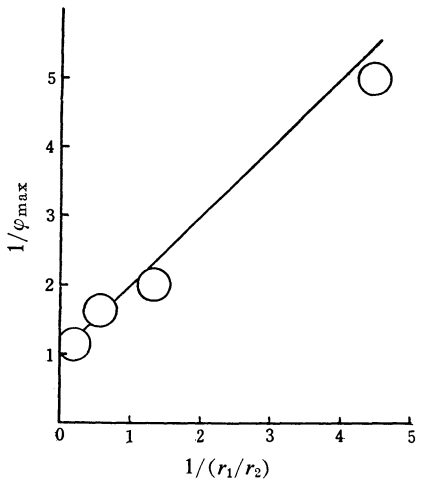

Fig. 6. Plots of $1/\varphi_{max}$ against $r_2/r_1$. Full line is the theoretical.

Now, it is assumed that the maximum aggregation takes place in the case where the total surface areas of the two kinds of particles are equal. The following formula is derived from this assumption.

$$\varphi_{max}=\frac{r_1}{r_1+r_2}$$

where $\varphi_{max}$ is the weight fraction of Dowex 50W giving maximum aggregation, and $r_1$ and $r_2$ are radii of Dowex 50W and Dowex 1 particles, respectively. In Fig. 6, the reciprocal of $\varphi_{max}$ is plotted against the reciprocal of $r_1/r_2$. If the above-mentioned assumption is valid, this plot should be a straight line

5) H. Deuel, J. Solms and A. Denzler, *Helv. Chim. Acta*, 36, 1671 (1953).

intersecting the ordinate at unity. As shown in Fig. 6, it is confirmed that this is the case in the present systems.

**Summary**

Some observations are presented on the aggregation behavior of the ion-exchange resin particles. On mixing the hydrogen-form cation-exchange resin particles with the hydroxyl-form anion-exchange resin particles, remarkable aggregation takes place. It seems that this aggregation is due to the electrostatic attraction force exerted between resin particles. This is supported by the results that the aggregation is destroyed by addition of salts and that the agglomerates are not formed in non-polar medium in the complete absence of water. Moreover, it was demonstrated that the variation of the size ratio of particles influences markedly the aggregation behavior. A simple explanation is given for such a coagulation phenomena.

*The Institute of Industrial Science*
*The University of Tokyo*
*Yayoi-cho, Chiba*

*Added in proof:*

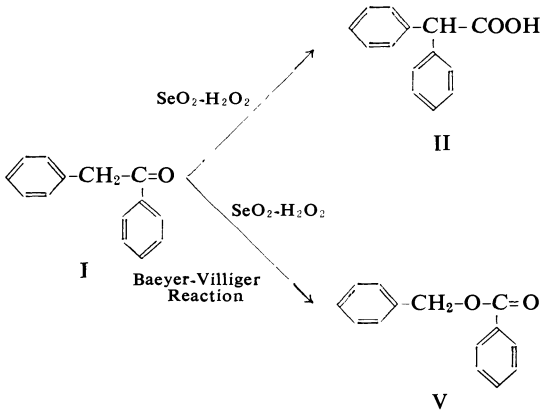
It was shown by further observations done after contribution of this paper that salt-form ion-exchange resin particles, for example, sodium-form cation-exchange resin and chloride-form anion-exchange resin aggregate in pure water where no additional salt is completely absent and also red color due to the formation of ferric thiocyanate complex does not appear when ferric-form cation-exchange resin and thiocyanate-form anion-exchange resin are mixed in pure water. From these observations it is clear that no chemical reaction takes place practically between these particles and some modifications should be applied to the coagulation mechanism proposed in the present paper. A portion of counterions distributes outside of the resin particle, so that the fixed charges of the resin are not completely neutralized by the counterions in the volume occupied by the particle. Therefore, the cation-exchange resin particles carry negative charges and the anion-exchange resin particles carry positive charges in their suspension. Electrostatic interaction is exerted between these particles. Distribution of counterions would be largely affected by the salt concentration, the dielectric constant of medium and the degree of dissociation of fixed ionized groups. The details will be reported later.

# *Hydrogen Peroxide Oxidation. V. Selenium Dioxide Catalyzed Oxidative Rearrangement Reaction of Desoxybenzoin*[1]

By Noboru SONODA and Shigeru TSUTSUMI

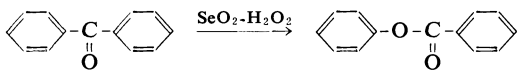
(Received December 14, 1960)

The previous papers[2-4] in this series described the fact that the selenium dioxide catalyzed hydrogen peroxide oxidation of enolizable ketones produces carboxylic acids by the intramolecular migration of alkyl or aryl group to the $\alpha$-carbon atom of the carbonyl group. The present study was undertaken to provide additional informations pertinent to active species of these reactions and the reaction processes.



For this purpose, desoxybenzoin was selected as a starting material. According to the procedure[4] previously employed for phenyl alkyl ketones, desoxybenzoin (I) was oxidized with hydrogen peroxide in the presence of a catalytic amount of selenium dioxide in tertiary butyl alcohol at 82°C. The formation of diphenyl acetic acid (II) was observed and benzoic acid was also isolated as a acidic product.

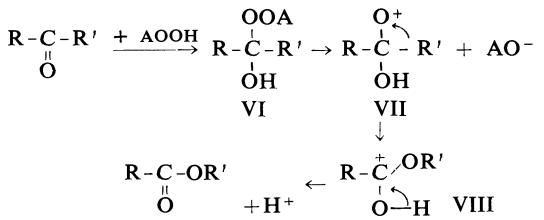
After unreacted desoxybenzoin was removed, small amounts of benzil (III) and benzoin (IV) were isolated from the neutral part of the reaction products, and an oily substance was also isolated as the residue. The strong infrared absorption bands at 1110 (sym. C-O-C), 1270 (asym. C-O-C) and 1710 $cm^{-1}$ (C=O) of the residue indicated the presence of an ester group, and it was confirmed to be benzyl benzoate (V) by gaschromatographic analysis.



Diphenyl acetic acid (II) should be produced by the migration of phenyl group to the $\alpha$-carbon atom of the benzyl group in conformity

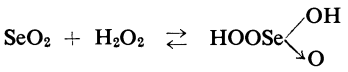
1) Reported at the Autumn Meeting of Chemical Society of Japan, Tokyo, October, 1959.
2) N. Sonoda and S. Tsutsumi, This Bulletin, 32, 505 (1959).
3) N. Sonoda, T. Yamaguchi and S. Tsutsumi, *J. Chem. Soc. Japan, Ind. Chem. Sec.* (*Kogyo Kagaku Zasshi*), 63, 737 (1960).
4) N. Sonoda and S. Tsutsumi, This Bulletin, 33, 1440 (1960).

with the reaction aptitude observed in the previous paper[4], whereas the formation of benzyl benzoate (V) may be apparently due to Baeyer-Villiger oxidative rearrangement reaction[5,6].



It was confirmed experimentally that benzyl benzoate is not an intermediate in the reaction path of the production of diphenyl acetic acid. Therefore, both the rearrangement reactions described above may proceed competitively in the same reaction system. This is also supported by the fact that the Baeyer-Villiger reaction is generally applicable to the non enolizable ketones which can not produce the rearranged carboxylic acids. For example, benzophenone was oxidized by the selenium dioxide catalyzed hydrogen peroxide yielding phenyl benzoate or its hydrolyzed products.

Baeyer-Villiger reaction is interpreted as one of the reactions of ketones with peroxyacids. The favored reaction mechanism was first proposed by Criegee[7], who assumed that the addition of peroxyacid to the carbonyl group produced a hydroxyperoxide VI (referred to as "Criegee Intermediate"), which dissociated to give an electron-deficient ion VII, and then was rearranged to form carbonium ion VIII with cleavage of a carbon-carbon bond, and VIII decomposed to the ester.



Accordingly, the formation of benzyl benzoate from desoxybenzoin may be due to some kind of peroxyacid as the active oxidizing species in the selenium dioxide-hydrogen

AOOH: peroxyacid

peroxide system, and this fact is also consistent with our previous assumption[2] that peroxyselenious acid is the most probable catalyst.

The formation of peroxyselenious acid was first assumed by Hughes and Martin[8] from the kinetic study of the oxidation of selenium dioxide with hydrogen peroxide to selenic acid.

Recently, Ogata and Tabushi[9] have reported in the kinetic study of the oxidation of dimethylaniline that a kind of peroxide such as peroxyselenious acid or  is assumed to be produced as the active oxidizing species.

Although the formation of selenic acid would be possible in this reaction system, the selenic acid might not be the active species, because desoxybenzoin was oxidized with selenic acid to yield benzil as well as in the case of the selenious acid oxidation, and no rearrangement reaction was observed. In addition, Ogata and Tabushi[9] have shown in the kinetic study that peroxyselenic acid[10] may not be an active oxidizing species.

Hawthorne and his co-workers[11] reported that the Baeyer-Villiger rearrangement of desoxybenzoin with trifluoroperoxyacetic acid gave benzyl benzoate and phenyl phenylacetate in the ratio of 51 : 39. In contrast to this result, only benzyl benzoate was isolated as ester in the selenium dioxide catalyzed hydrogen peroxide oxidation, and phenyl phenylacetate was not detected by the gas chromatography which was capable of analyzing both the esters. It is interesting to note that the rearrangement aptituds of the two possible

5) For a review of the Baeyer-Villiger reaction, see C. H. Hassall, "Organic Reactions", Vol. IX. John Wiley & Sons, Inc., New York, N. Y. (1957), pp. 73—106.

6) Recently, Hellman and Rosegay have also reported the occurrence of the Baeyer-Villiger reation from the isolation of 6-hydroxycaproic acid in the oxidation products of cyclohexanone with selenic acid-hydrogen peroxide reagent; H. M. Hellman and A. Rosegay, *Tetrahedron Letters*, 1959, No. 13, 1~3; *Chem. Abstr.*, 54, 4345 (1960).

8) F. J. Hughes and D. S. Martin Jr., *J. Phys. Chem.*, 59, 410 (1955).

9) Y. Ogata and I. Tabushi, This Bulletin, 32, 215 (1959).

10) The formation of peroxyselenic acid ($H_2SeO_5$) was assumed by several workers; (a) R. R. Worsley and H. B. Baker, *J. Chem. Soc.*, 123, 2870 (1923). (b) C. W. Smith and R. T. Holm, *J. Org. Chem.*, 22, 746 (1957). But the evidence and the other information of the peroxyselenic acid were not obtainable. See (c) W. C. Schumb et al., "Hydrogen Peroxide", Reinhold Pub., New York, N. Y (1955), p. 477.

11) M. F. Hawthorne, W. D. Emmons and K. S. McCallum, *J. Am. Chem. Soc.*, 80, 6393 (1958).

migrating groups, phenyl and benzyl groups, are largely dependent on the kind of the oxidative reagent in the Baeyer-Villiger reaction. Such a difference in the migrating aptitude was also reported by Howthorne and the co-workers[11], who showed that the greater selectivity between migrating groups was observed in the cleavage of phenyl cyclohexyl ketone with peroxyacetic acid as compared with the similar reaction with trifluoroperoxyacetic acid.

The simplest interpretation of the reaction mechanism of the diphenyl acetic acid formation may involve the electrophilic attack of the peroxyacid to a double bond formed between the carbonyl carbon and the methylene carbon atoms. The formation of this double bond was assumed from the observation[2,3,12] that the orientation of the migration of alkyl groups in the selenium dioxide catalyzed rearrangement reaction of aliphatic unsymmetrical ketones with hydrogen peroxide was comparable to the orientation of the enol form or of diketone formation with selenious acid. Accordingly, it is reasonable to say that the initial state of the attack of peroxyselenious acid to the ketone will be analogous to that of selenious acid. Although we have proposed the inferential mechanism[2] which comprises the enol formation followed by the attack of the peroxyselenious acid, the other possible reaction path will be suggested from the recent study on the mechanism of selenium dioxide oxidation of ketones, in which Corey and Schaefer[13] have pointed out that the electrophilic character to the carbonyl group may be served by 4d-orbitals of selenium in the first step of the reaction. In the present case the formation of the double bond may be induced by the electrophilic addition of the peroxyselenious acid to the carbonyl oxygen (IX), and then electrophilic attack by hydroperoxy group occurs intramolecularly (X) as shown below.

12) The detailed results were presented at the 13th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1960.

13) E. J. Corey and J. P. Schaefer, *J. Am. Chem. Soc.*, **82**, 918 (1960).

Elimination of selenious acid from X may yield hydronium ion (XI) which will be rearranged to produce the carboxylic acid (II).

Our results are not sufficient to allow a choice between the two proposed reaction paths; however, the latter may be more favorable because of the distinctive character of the peroxyselenious acid as compared with the other peroxyacids.

Since no products other than benzil have been found[13] in the oxidation of desoxybenzoin with selenious acid, the formation of benzoin might be illustrated in the path via hydronium ion intermediate (XI).

## Experimental[14]

**Materials.**—Desoxybenzoin was prepared from phenyl acetic acid, phosphorus trichloride and benzene according to the procedure of Allen and Barker[15]; b. p. 158°C (4 mmHg). A sample, m. p. 57°C, was obtained by the recrystallization from methanol.

**Reagent for Oxidation.** — A solution containing 20 ml. of 30% hydrogen peroxide and 80 ml. of tertiary butyl alcohol was dried over 60 g. of anhydrous sodium sulfate for two days. After filtration of sodium sulfate, 0.2 g. of selenium dioxide was dissolved in 25 ml. of this solution. The solution prepared was used as a reagent for oxidation.

**Oxidation of Desoxybenzoin.**—In a 15 ml. of tertiary butyl alcohol, was dissolved 4.9 g, (0.025 mol.) of desoxybenzoin by slight heating, and 25 ml. of hydrogen peroxide-selenium dioxide reagent (0.05 mol. of hydrogen peroxide and 0.2 g. of selenium dioxide) was added. The reaction mixture was refluxed for 17 hr., and was distilled under reduced pressure to remove the solvent and water. The residue was diluted with 100 ml. of ether and was filtered to remove a small amount of metallic selenium deposited. The ethereal solution was extracted with 10% potassium carbonate solution.

*Acidic Products.*—The potassium carbonate solution was acidified with 4 N hydrochloric acid and extracted with ether. The ether extract was dried over anhydrous sodium sulfate and removal of the ether left 1.3 g. of mixture of acids. Benzoic acid (0.6 g.) was separated as the soluble part of the mixture in warm water, m. p. 121°C (lit.[16] 121°C), mixed melting point with an authentic sample was not depressed.

The insoluble part (0.5 g.) was recrystallized from a small amount of benzene to remove the brown impurities and was further recrystallized from hot water. This yielded white crystals, 0.2 g. of diphenyl acetic acid (6% yield based on the unrecovered desoxybenzoin); m. p. 145°C (lit.[16] 145°C), mixed melting point with an authentic sample showed no depression.

Found: C, 79.00; H, 5.52. Calcd. for $C_{14}H_{12}O_2$: C, 79.22; H, 5.70%.

*Neutral Products.* — The ethereal solution, from which the acidic products were removed was dried over anhydrous sodium sulfate, and the ether was evaporated. On distillation of the residual brown oily liquid under reduced pressure, 3.0 g. of yellow oily products were obtained, b. p. 140~166°C (4 mmHg). After cooling overnight, crystals deposited were filtered and recrystallized from methanol giving 1.6 g. of recovered desoxybenzoin, m. p. 55°C. The filtrate was further cooled at 0°C for two days, and crystals deposited were filtered and recrystallized from ethanol giving a small amount of recovered desoxybenzoin and 35 mg. of benzil; faint yellow crystalline solid, m. p. 94~95°C (lit.[16] 95°C), undepressed when mixed with an authentic sample.

Found: C, 80.15; H, 5.11. Calcd. for $C_{14}H_{10}O_2$: C, 79.98; H, 4.79%.

The filtrate was cooled further at 0°C for 3 weeks and isolated crystalline solid was recrystallized from ethanol; 25 mg. of white crystals were obtained, m. p. 130~132°C; the infrared spectrum[17] exhibited strong absorption bands at 3320 (OH) and 1680 $cm^{-1}$ (conjugated C=O), and was identical with an authentic benzoin; vicinal hydroxy ketone test[18] by periodic acid reagent gave positive result. In the above respects this sample was confirmed to be mainly benzoin (lit.[16] m. p. 133°C).

Found: C, 79.23; H, 5.78. Calcd. for $C_{14}H_{12}O_2$: C, 79.22; H, 5.70%.

The residual liquid was redistilled under reduced pressure, and 0.9 g. of oily product, benzyl benzoate, was obtained. The infrared spectrum[17] of analytical sample, b. p. 156~157°C (3 mmHg), showed strong bands at 1710 (C=O), 1270 (asym. C-O-C) and 1110 $cm^{-1}$ (sym. C-O-C), and was identical with an authentic sample.

Found: C, 79.50; H, 5.54. Calcd. for $C_{14}H_{12}O_2$: C, 79.22; H, 5.70%.

Presence of phenyl phenylacetate was not detected by the gaschromatography which was capable of separating phenyl phenylacetate and benzyl benzoate: column, Silicone-550; column temperature, 205°C; carrier gas, $H_2$.

**Oxidation of Benzophenone.**—To a 25 ml. of selenium dioxide-hydrogen peroxide reagent (0.05 mol. of hydrogen peroxide and 0.2 g. of selenium dioxide) was added 50 ml. of tertiary butyl alcohol and 9.1 g. (0.05 mol.) of benzophenone, and the mixture was refluxed for 24 hr. After removal of the solvent from the reaction mixture, the residual products was separated into acidic and neutral parts according to the usual procedure. From the acidic part was isolated 0.2 g. of benzoic acid. For the purpose of saponification of the ester contained, the neutral product was treated with 5 g. of sodium hydroxide in 90% aqueous methanol solution at 65°C for 2 hr. After removal of the methanol, 20 ml. of water was added and the neutral substance was extracted with ether. The ether extract gave 6.8 g. of unreacted benzophenone, b. p. 124~129°C

18) Ref. 16, p. 129.

(3 mmHg). Acidification of the water soluble part yielded 0.4 g. of benzoic acid, and small amount of phenol was also isolated; the tribromide was prepared which melted at 94°C (lit.[16] m. p. 95°C), mixed melting point with an authentic sample showed no depression. The formation of phenyl benzoate was confirmed from the above experiments.

**Oxidation of Desoxybenzoin with Selenic Acid.** —To a mixed solution of 50 ml. of tertiary butyl alcohol and 50 ml. of methanol was added 9.8 g. (0.05 mol.) of desoxybenzoin. The solution was heated to 70°C, and 18 g. of 40% aqueous selenic acid (0.05 mol.) was added dropwise to the solution. After the solution was maintained at 70°C for 24 hr., metallic selenium deposited was filtered off. The filtrate was distilled to remove the solvent, and the residue was separated into acidic and neutral parts according to the usual procedure. From the acidic part was isolated 0.15 g. of benzoic acid. The neutral part gave 7.6 g. of benzil, m. p. 94~95°C, and 1.8 g. of unidentified substance (probably, some organo selenium compound).

## Summary

1) Selenium dioxide catalyzed oxidation of desoxybenzoin with hydrogen peroxide in tertiary butyl alcohol gave diphenyl acetic acid which was produced by the rearrangement of phenyl group to the methylene carbon atom.

2) Baeyer-Villiger reaction was also occurred competitively in this reaction system, and benzyl benzoate was isolated as ester from the neutral products. Such an observation shows that the active oxidizing species may be some kind of peroxyacid. This fact is consistent with our previous assumption that peroxyselenious acid is the most probable catalytic form.

3) It is assumed in the reaction path of the formation of the rearranged carboxylic acid that the initial state of the attack of the peroxyselenious acid to the ketone may be analogous to that of selenious acid. From this point of view, a possible reaction path was proposed.

The authors wish to thank Dr. Y. Odaira for his helpful suggestions and encouragement.

# *Kerr Effect in Liquid State*

By Hideo OKABAYASHI

(Received December 23, 1960)

In the calculation of a physical property of liquid on the basis of a molecular theory, a form of local (or internal)[1] field may play an important role.

A theoretical formula for the dielctric constant of liquid has been derived, in which the local field is assumed to have the following expression[2].

$$F_i=\left(1-\frac{\varphi_i\alpha_j}{v}\right)^{-1}\left(E_1+\frac{\varphi_i\mu_{0i}}{v}\right)=\gamma_i\left(E_1+\frac{\varphi_i\mu_{0i}}{v}\right)$$

$$\varphi_i=2\pi a_1a_2a_3\int_0^\infty \frac{du}{(a_i^2+u)\sqrt{(a_1^2+u)(a_2^2+u)(a_3^2+u)}} \quad (1)$$

The liquid is considered as consisting of molecules, each of which has a permanent dipole and an anisotropic polarizability. Each component of the dipole moment is denoted as $\mu_{01}$, $\mu_{02}$ and $\mu_{03}$. The component of the polarizability tensor along the principal axis is represented as $\alpha_1$, $\alpha_2$ and $\alpha_3$, respectively. The molecular shape is assumed to be ellipsoid. $2a_1$, $2a_2$ and $2a_3$ are the lengths of the principal axes. The molecular volume is $v$. Further it is assumed that the direction of each principal axis is coincident with that of each principal axis of the polarizability.

In the present paper, Eq. 1 is applied to the derivation of a theoretical formula of Kerr constant in liquid state. The numerical calculation of the Kerr constant is also made and compared with the experimental value.

**The Formula of the Kerr Constant in Liquid State.**—Generally, a liquid may be birefringent

1) M. Born used the term "das wirkende Feld"; M. Born, "Optik", Verlag von J. Springer. (1933); P. Debye used the term "das (wirksame) innere Feld"; P. Debye, "Polare Molekeln", Verlag von S. Hirzel, Leipzig (1929). J. H. Van Vleck used the term "local field", and used the term "internal field" instead of the term "self-field" in the previous paper[2]; J. H. Van Vleck, "The Theory of Electric and Magnetic Susceptibilities", Oxford Press (1932). The terminology "local field" or "internal field" is according to H. Fröhlich; H. Fröhlich, "Theory of Dielectrics", Oxford Press (1950).

2) M. Yasumi, H. Okabayashi and H. Komooka, This Bulletin, 31, 402, 673 (1958).

when an electric field is applied. The magnitude of the artificial birefringence is represented quantitatively by Kerr constant $B$ [3].

$$B=\frac{n_{\parallel}-n_{\perp}}{\lambda E^2}$$

where $n_{\parallel}$ and $n_{\perp}$ denote the refractive indices of the liquid parallel to and perpendicular to the applied field, respectively. $\lambda$ is the wavelength of light in vacuo. $E$ is the magnitude of the applied static electric field.

The theory of the Kerr effect was derived by Born[4]. According to his theory, the Kerr constant has the following expression.

$$B=\frac{\pi N_c}{3n\lambda}(n^2+2)^2\left(\frac{\varepsilon+2}{3}\right)^2(\Theta_1+\Theta_2)$$

$$\Theta_1=\frac{1}{45kT}\sum_{1,2,3}\{\alpha_i(\omega)-\alpha_j(\omega)\}\{\alpha_i(0)-\alpha_j(0)\}$$

$$\Theta_2=\frac{1}{45k^2T^2}\sum_{1,2,3}\{\alpha_i(\omega)-\alpha_j(\omega)\}\{\mu_{0i}^2-\mu_{0j}^2\} \quad (2)$$

$\varepsilon$ is the static dielectric constant of the liquid and $n$ is the ordinary refractive index. $N_c$ is the number of molecules in a unit volume. $\alpha_i(\omega)$ is the polarizability at the angular frequency of $\omega$. This formula has been successfully applied to the case of gases. A molecule of the gas may either be polar or non-polar. However, as yet no theory of Kerr effect in liquid state could explain experimental facts sufficiently[5]. The discrepancy between theory and experiment may lie in the inappropriate assumption of the local field. In the following, on the basis of the formula 1 for the local field, the Kerr constant of liquid is calculated.

The strength of the total electric field in the medium is denoted by $\vec{E}_t$, and

$$\vec{E}_t=\vec{E}+\vec{e}\cdot\exp(-i\omega t) \quad (3)$$

$\vec{E}$ is the static part and $\vec{e}\cdot\exp(-i\omega t)$ is the oscillating part. The static part of the local field is expressed as before:

$$F_i=\left\{1-\frac{\varphi_i\alpha_i(0)}{v}\right\}^{-1}\left(E_i+\frac{\varphi_i\mu_{0i}}{v}\right)$$
$$=\gamma_i(0)\left(E_i+\frac{\varphi_i\mu_{0i}}{v}\right) \quad (1)'$$

$\alpha_i(0)$ is used instead of $\alpha_i$, in order to indicate that it concerns the static field.

The oscillating part of the local filed $\vec{f}\cdot\exp(-i\omega t)$ is represented as,

$$f_ie^{-i\omega t}=\left\{1-\frac{\varphi_i\alpha_i(\omega)}{v}\right\}^{-1}e_ie^{-i\omega t}=\gamma_i(\omega)e_ie^{-i\omega t} \quad (4)$$

The expression 4 is obtained from the assumption that the liquid molecule can not follow the oscillating field.

To obtain the formula of the Kerr constant, the value of the electric moment due to the oscillating field must be known.

It is denoted by $\vec{\mu}_e\cdot\exp(-i\omega t)$, and

$$\mu_e=\frac{\vec{\mu}_e\cdot\vec{e}}{e}=\frac{\sum\alpha_i(\omega)f_ie_i}{e} \quad (5)$$

The refractive index $n_e$ along the $\vec{e}$ is related to the mean value of $\mu_e$ as follows;

$$(n_e^2-1)e=4\pi N_c\langle\mu_e\rangle \quad (6)$$

$\langle\mu_e\rangle$ is obtained according to the Boltzmann statistics.

$$\langle\mu_e\rangle=\frac{\int\mu_e\exp(-U/kT)d\Omega}{\int\exp(-U/kT)d\Omega} \quad (7)$$

$d\Omega$ represents elementary solid angle. $U$ is the potential energy under the influence of the field.

$$U=-\left\{\frac{1}{2}\sum\alpha_i(0)F_i^2+\sum\mu_{0i}F_i\right\} \quad (8)$$

Here an assumption is made that,

$$E_1,\ E_2,\ E_3\gg e_1,\ e_2,\ e_3 \quad (9)$$

In the calculation of $\langle\mu_e\rangle$, $\exp(-U/kT)$ is expressed in the power series of $E$, and only the terms proportional to $E$ and $E^2$ are retained. Two distinct cases must be considered.

(1) If the direction of the electric vector of the incident light is coincident with that of the static electric field, and $\langle\mu_e\rangle$ is denoted as $\langle\mu_{\parallel}\rangle$, then

$$\langle\mu_{\parallel}\rangle=e\left[\frac{1}{3}\sum\alpha_i(\omega)\gamma_i(\omega)\right.$$
$$+\frac{E^2}{45kT}\sum_{1,2,3}\{\alpha_i(\omega)\gamma_i(\omega)-\alpha_j(\omega)\gamma_j(\omega)\}$$
$$\times\{\alpha_i(0)\gamma_i^2(0)-\alpha_j(0)\gamma_j^2(0)\}$$
$$+\frac{E^2}{45k^2T^2}\sum_{1,2,3}\{\alpha_i(\omega)\gamma_i(\omega)-\alpha_j(\omega)\gamma_j(\omega)\}$$
$$\left.\times\{\mu_{0i}^2\gamma_i^4(0)-\mu_{0j}^2\gamma_j^4(0)\}\right] \quad (10)$$

$\langle\mu_{\parallel}\rangle$ is related to $n_{\parallel}$ as follows.

$$(n_{\parallel}^2-1)e=4\pi N_c\langle\mu_{\parallel}\rangle \quad (11)$$

3) This definition is based on the experimental method. From the theoretical standpoint, it is more convenient to define $K=B\lambda$ as the Kerr constant than $B$. However, in the present paper the quantity of $B$ is dealt with according to the traditional custom.

4) M. Born, *Ann. Physik*, **55**, 177 (1918).

5) c. g. A. Peterlin and H. A. Stuart, *Z. Physik*, **113**, 663 (1937); H. A. Stuart, "Die Physik der Hochpolymeren", Bd. I., Springer-Verlag, Berlin (1952), p. 426.

(2) If the electric vector of the light is perpendicular to the direction of the static electric field and $\langle\mu_e\rangle$ is denoted as $\langle\mu_\perp\rangle$, then

$$\langle\mu_\perp\rangle=e\Big[\frac{1}{3}\sum\alpha_i(\omega)\gamma_i(\omega) - \frac{E^2}{90kT}\sum_{1,2,3}\{\alpha_i(\omega)\gamma_i(\omega)-\alpha_j(\omega)\gamma_j(\omega)\} \times\{\alpha_i(0)\gamma_i^2(0)-\alpha_j(0)\gamma_j^2(0)\} - \frac{E^2}{90k^2T^2}\sum_{1,2,3}\{\alpha_i(\omega)\gamma_i(\omega)-\alpha_j(\omega)\gamma_j(\omega)\} \times\{\mu_{0i}^2\gamma_i^4(0)-\mu_{0j}^2\gamma_j^4(0)\}\Big] \quad (12)$$

and

$$(n_\perp^2-1)e=4\pi N_c\langle\mu_\perp\rangle \quad (13)$$

The Kerr constant $B$ is expressed as:

$$B=\frac{\pi N_c}{n\lambda}\Big[\frac{1}{15kT}\sum_{1,2,3}\{\alpha_i(\omega)\gamma_i(\omega)-\alpha_j(\omega)\gamma_j(\omega)\} \times\{\alpha_i(0)\gamma_i^2(0)-\alpha_j(0)\gamma_j^2(0)\} + \frac{1}{15k^2T^2}\sum_{1,2,3}\{\alpha_i(\omega)\gamma_i(\omega)-\alpha_j(\omega)\gamma_j(\omega) \times\{\mu_{0i}^2\gamma_i^4(0)-\mu_{0j}^2\gamma_j^4(0)\}\Big] \quad (14)$$

Because of small magnitude of $(n_\parallel-n_\perp)$, $(n_\parallel+n_\perp)$ is replaced by $2n$.

In the case when the direction of the permanent dipole moment is coincident with the direction of one of the principal axes of the molecular ellipsoid (i.e. $a_1$ axis), Eq. 14 is simplified as,

$$B=\frac{\pi N_c}{n\lambda}\Big[\frac{1}{15kT}\sum_{1,2,3}\{\alpha_i(\omega)\gamma_i(\omega)-\alpha_j(\omega)\gamma_j(\omega)\} \times\{\alpha_i(0)\gamma_i^2(0)-\alpha_j(0)\gamma_j^2(0)\} + \frac{1}{15k^2T^2}\{3\alpha_1(\omega)\gamma_1(\omega)-\sum\alpha_i(\omega)\gamma_i(\omega)\} \times\mu_0^2\gamma_1^4(0)\Big] \quad (15)$$

**Comparison of Eq. 15 with Experiments.**— In the calculation of the Kerr constant with Eq. 15, the value of permanent dipole moment, that of the component of polarizability and that of the molecular dimension must be known. Values of these quantities are taken

TABLE I. THE VALUES OF $\mu_0$, $\alpha_i(\omega)$, $(P_E+P_A)$ AND THE AXIAL RATIO OF THE MOLECULAR ELLIPSOID[a)]

from the literatures by the method similar to that written in the previous paper[2].

Contrary to the case of the calculation of the static dielectric constant, in the case of the calculation of the Kerr constant, both the values of $\alpha_i(0)$ and $\alpha_i(\omega)$ are needed. However, as yet the value of $\alpha_i(0)$ is not known. Stuart[6] and Le Fèvre[7] have assumed that $\alpha_i(0)/\alpha_i(\omega)=(P_E+P_A)/R_\lambda$. $P_E$ is electronic polarisation and $P_A$ is atomic polarization. $R_\lambda$ is molecular refraction for the wavelength of $\lambda$.

In Table I the values of the following quantities are tabulated; the value of permanent dipole moment $\mu_0$, the value of the component of polarizability $\alpha_i(\omega)$, the value of $(P_E+P_A)$ and the values of the ratios of axial lengths of the molecular ellipsoid.

The Kerr constant of about twenty substances is calculated with Eq. 15 and compared with the experimental value.

The value calculated with Eq. 2 is also compared with experimental one.

Generally speaking, the considerable discrepancy between the theoretical value and the experimental one is observed if we apply Eq. 2, and moreover, the greater the value of the dielectric constant of liquid, the greater becomes the discrepancy[8].

On the contrary, the calculated value with Eq. 15 is not very far from the experimental one.

When atomic polarization is taken in account, the coincidence is not unsatisfactory.

In Table II, the calculated and the experimental values of $B$ are tabulated. In the fourth column, the calculated values with Eq. 15 are tabulated, in which $\alpha_i(0)$ is replaced by $\alpha_i(\omega)$. In the fifth, the value of $\alpha_i(0)$ is taken in account.

In the sixth, the values of $B$ calculated with Eq. 2 are represented. The experimental values of $B$ are also represented in the seventh column. In addition, the values of $\varepsilon$ are tabulated in the eighth.

For a symmetrical top molecule the calculation which is to be described in the following is also made.

A symmetrical top molecule can be approximated as a spheroid. The shape of a spheroid can be determined by only one axial ratio. In this case, the value of the axial ratio is chosen as to fit the experimental value of the Kerr constant, and is compared with the geometrical one.

In the case of a general ellipsoidal molecule, the Kerr constant is calculated with Eq. 15, in which the value of axial ratio is taken as the value of the geometrical one.

In the following, some remarks are made on special cases.

**Spheroide Molecules.** — a) *Carbon Disulfide* —For liquid carbon disulfide the calculated value of the Kerr constant is sensitive to the assumed axial ratio. The value of axial ratio 0.48 is fitted best to the observed value of the Kerr constant. In the case of dielectric constant the value of axial ratio 0.50 is the fittest value. The geometrical value is 0.54.

b) *Benzene.* — The obtained value of the axial ratio 0.44 is smaller than the geometrical one 0.52.

c) *Chloroform.* — The value of axial ratio 1.82 is the fittest value if atomic polarization is taken in account. The geometrical value is 1.54.

**General Ellipsoid Molecules.** — a) *Benzene Derivatives.*—The calculated value of the Kerr constant gives the right magnitude, but the values for fluorobenzene[10], *p*-dichlorobenzene and nitrobenzene are excepted. As the only one exceptional case, the value for *p*-dichlorobenzene obtained with Eq. 2 is better than the value obtained with Eq. 15. The calculated value of the Kerr constant of liquid fluorobenzene is lower than the experimental one. The theoretical value for nitrobenzene is much lower than the experimental one.

b) *Pyridine.*—The calculated value is lower than the experimental one.

c) *Nitromethane.*—The value of electronic polarization and that of atomic polarization are evaluated by Le Fèvre[7] as 12.0 cc. and 6.3 cc., respectively. The calculated value of the Kerr constant coincides fairly with the observed one if atomic polarization is taken in account. However, whether the coincidence is fortuitous or not is not determined as yet.

d) *Diethyl Ether.*—For diethyl ether planer zigzag form is assumed. The value of axial ratio calculated from the molecular model is fairly consistent with the value which is fittest for the value of the Kerr constant.

e) *Ethyl Methyl Ketone.*—Also the model of planer zigzag form is adopted. The calculated value is lower than the experimental one.

6) H. A. Stuart and H. Volkmann, *Ann. Physik*, 18, 121 (1933).

7) C. G. Le Fèvre and R. J. W. Le Fèvre, *J. Chem. Soc.*, 1953, 4041. Further they have used $P_E=R_\infty$ (molecular refraction for light of infinite wavelength) instead of $R_\lambda$.

8) However, the so-called $4\pi/3$ catastrophe[9] does not arise in the Kerr effect.

9) J. H. Van Vleck, *Ann. N. Y. Acad. Sci.*, 40, 295 (1940).

10) It is interesting to note that the value of the component of the molecular polarizability of fluorobenzene is almost the same as that of benzene. Le Fèvre[7] has obtained the following values.

| | $\alpha_1\times10^{25}$ | $\alpha_2\times10^{25}$ | $\alpha_3\times10^{25}$ |
|---|---|---|---|
| Benzene | 111.4 | 111.4 | 73.6 |
| Fluorobenzene | 112.6 | 110.6 | 71.1 |

**Summary**

A formula for the Kerr constant in liquid state has been derived, in which the form of the local field is assumed to be the same as that derived previously[2]. The formnla is able to explain experimental data to some extent, although there are some exceptions.

The author is grateful to Professor Masasi Yasumi for his kind guidance and encouragement throughout this work, and to Mr. Hitoshi Komooka for his advice. Thanks are also due to the Ministry of Education for a grant in aid of this research.

# *Organic Semiconductors with High Conductivity. III. Perylene-Iodine Complex*

By Tokiko UCHIDA and Hideo AKAMATU

(Received December 24, 1960)

Polycyclic aromatic hydrocarbons with halogens form molecular complexes in solid state and those complexes of the charge transfer type possess relatively high electrical conductivity. The preliminary survey for the semiconductive properties of these complexes has been given in the first paper[1] of this series of investigations. Concerning the mechanism of electronic conduction in organic solids, the charge transfer complexes are so suggestive that their structures with their physical properties are specially interesting. In the preceding paper[2], the violanthrene-iodine system was investigated in connection with its structure. In this paper, the investigation of the perylene-iodine system, another typical example for this series of complexes, is presented.

**Preparation and Composition of Perylene-Iodine Complex.**—The formation of a solid molecular compound between perylene and iodine has been known for many years since the investigations of Clar and Brass[3], and also, by Zinke et al.[4] However, concerning the composition of this complex, these investigators did not come to agreement with each other.

When perylene is added to the benzene solution of iodine, the molecular complex is obtained as a black precipitate which consists of needle-shaped minute crystals. This complex is somewhat unstable in the atmosphere and has tendency to liberate iodine. The following procedure was employed for the determination of the composition. Perylene (100~130 mg.) and iodine (appropriate amount) were dissolved in 50 ml. of benzene. By heating this solution under reflux condenser, both components were homogeneously dissolved. Then the container was transferred into a thermostat of 20°C, and the complex was precipitated from the solution. For the purpose of keeping the equilibrium between the precipitated complex and the solution, the container was held at this temperature for more than 15 hr. being continuously vibrated. Then by a suction through a glass filter, the precipitate was separated from the solution as quickly as possible, and was kept in a desiccator. The iodine content in the solution was determined by the titration with sodium thiosulfate solution. The iodine content of the precipitate was also determined by the same method after dissolving it into benzene.

In Fig. 1, the iodine content of the benzene solution which is in equilibrium with the precipitate is plotted against the composition of the precipitate. The composition is expressed with the number of iodine molecules added to one molecule of perylene (mole ratio).

On this curve, the isotherm for the heterogeneous equilibrium of the perylene-iodine system, the horizontal part AB indicates that the precipitate should consist of two sorts of solid phase, one is perylene and the other is the complex which has the composition of

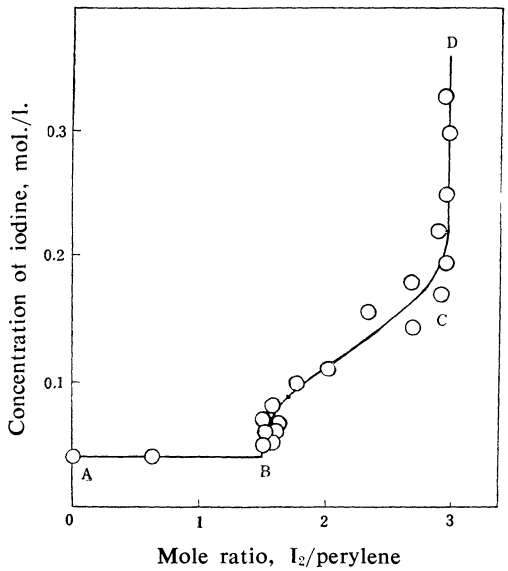

Fig. 1. The isotherm of perylene-iodine system. The concentration of iodine in benzene solution is plotted against the composition of precipitate.

Perylene·1.5 $I_2$. It can be seen directly or under a microscope that the precipitate is a mixture of yellow crystals (perylene) and black needles (complex). As will be shown in the latter section, the magnetic susceptibility measurement also verifies the existence of Perylene·1.5 $I_2$. At the vertical part CD, the precipitate is made of one phase which has the composition of Perylene·3$I_2$. Thus, there are two kinds of complexes which have different compositions. The precipitate at the intermediate part BC should be made of a solid solution of these two kinds of complexes. The shape of the curve BC is similar to that of the violanthrene-iodine system, which was discussed in the previous paper[2].

The spectrophotometric measurement was made for the mixed solution of perylene and iodine in benzene and also in chloroform, but the absorption band due to the complex formation could not be found over 3000~7000 Å range. This result implies that the molecular complex has poor solubility or it might be stable only in the solid state. Thus the equilibrium between perylene and iodine, for instance when the concentration of iodine is high enough, can be expressed as

$$\text{Perylene(soln.)} + 3I_2\text{(soln.)} \rightleftarrows [\text{Perylene}\cdot 3I_2]$$

The equilibrium constant in benzene solution has been found to be $K_c = 2.1 \times 10^5$ (in mol./l. unit, 20°C). This leads to the free energy of the complex formation, $-RT \ln K_c = -7.1$ kcal./mol.

**Electrical Properties.**—The electrical resistivity of perylene-bromine complex is not stable because of the substitution reaction of bromine as reported in the previous paper[1]. This is not the case, however, for the perylene-iodine complex; the substitution reaction does not take place between iodine and hydrogen, and the complex can be kept stable if it is sealed in the dry atmosphere.

The precipitate from the benzene solution was applied to the resistivity measurement. The specimen powder was compressed between the metal electrodes in an ebonite tube having inside diameter of 8.0 mm. The electrode surfaces were coated with platinum plates. The electrical field applied to the specimen was about 20 V./cm. and the resistance was read with an ohmmeter.

The observed resistivity was dependent on the applied pressure and it decreased with the reciprocal of pressure in a linear way when the applied pressure was above 50 kg./cm$^2$. This might be due to the presence of contact resistance between particles. Thus, the limiting value was read by the extrapolation to the infinite pressure. This value, $\rho(p=\infty)$, is assumed as the intrinsic resistivity of the sample and is shown in Table I, where the observed

TABLE I. SEMICONDUCTIVE DATA OF PERYLENE-IODINE COMPLEX

resistivity at the pressure of 116 kg./cm$^2$ is also shown for comparison.

The voltage dependence for the current was examined with the complex having the composition of Perylene·2.53 $I_2$. The linear relationship was observed between the current and the applied voltage when the voltage was not higher than 25 V./cm. In this region where the Ohm's law holds, the current was stable and quite reversible. This indicates that the conduction is the electronic one. However, when a higher voltage than this value was applied, the larger current deviating from the linear relationship was observed instantaneously and then it decreased gradually. After the external field was removed, the cell was still polarized slightly for a while.

The temperature dependence for the resistivity was observed in the range from room temperature down to −170°C. No higher temperature can be applied to the sample for it decomposes and liberates iodine.

It was observed that the resistivity increases with decreasing temperature, and a good linear relationship was found between the logarithm of resistivity and the reciprocal of temperature. This linear relation was found even in a case of which the sample consisted of two solid phases (perylene and complex) or of the solid solution, similarly as in the case of a pure simple compound (for instance perylene).

Assuming the formula $\rho=\rho_0\exp(\varepsilon/2kT)$, where $\rho$ is the resistivity and $\rho_0$ is a constant, the value of $\varepsilon$, the "energy gap" for the generation of charge carriers was estimated. This value is shown in Table I.

In Table I, it is seen that the $\varepsilon$-value is nearly constant (about 0.06 eV.) over a very wide range of the mole ratio. This might be due to the fact that the observed value was the one having the narrowest energy gap which participated predominantly in the generation of charge carriers at the low temperature range where the experiment was carried out.

There are two kinds of intermolecular compounds, as mentioned in the preceeding section, Perylene·1.5 $I_2$ and Perylene·3$I_2$. It is noticeable, however, that no important distinction can be found for the values of the energy gap between those complexes, similarly for the values of resistivity. Therefore, it can be concluded that both complexes, Perylene·1.5 $I_2$ and Perylene·3 $I_2$, possess resistivity of 9～10 ohm.cm. and an energy gap of 0.06 eV. In consequence the solid solution of these complexes possesses the same values regardless of its composition.

For the purpose of knowing the principal charge carriers, whether electrons or positive holes, the preliminary examination of the thermoelectric power of the cell was made. Both leads of the cell were connected to a galvanometer. When the one side of the cell was heated to a higher temperature than the other side, the flow of a minute current was observed. The direction of the current indicated that the warm side electrode was negative against the cold side electrode of the cell. The amount of the thermoelectric power was roughly estimated as a few micro volts per degree. This indicates that positive holes contribute to the current more predominantly than electrons.

**Magnetic Susceptibility.**—Both perylene and iodine are diamagnetic substances. In the case of the formation of the charge transfer complex, however, the magnetic susceptibility of the system shows a large deviation from the additive property of diamagnetism[5]. This offers a method to examine the composition of the intermolecular compound formed in the system. The Gouy method was employed for the susceptibility measurement at the room temperature. The observed values are summarized in Table II and illustrated in Fig. 2 as the function of iodine content.

The remarkable depression of diamagnetism from the value given by the additivity rule

Table II. The diamagnetic susceptibility of perylene-iodine system

| Wt. percentage of $I_2$ | Mole ratio $I_2$/perylene | Specific susceptibility $\chi\times10^6$ |
|---|---|---|
| 0 | 0 | −0.632±0.007 |
| 22.6 | 0.29 | −0.517±0.004 |

* International Critical Table VI, p. 355.

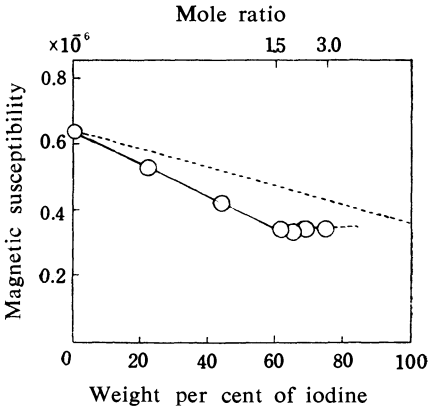

Fig. 2. The plot of the diamagnetic susceptibility of perylene-iodine system as the function of iodine content.

(the dotted line) is seen in Fig. 2. The depression proceeds in a linear way as the iodine content increases up to 60 per cent. Then, from 60 per cent up the susceptibility appears almost constant; but probably it proceeds toward the value of iodine. Thus a sharp break is found at the iodine content of 60 per cent (the mole ratio is 1.5). The linear part of susceptibility below this iodine content follows the additivity rule in regard to the mixture of pure perylene and the complex of this composition. This proves the complex formation of Perylene·1.5 $I_2$. Its molar susceptibility is $-217\times10^{-6}$, which implies that the depression from the diamagnetic additivity is $80\times10^{-6}$ per mole of perylene. However, the recognition of the formation of Perylene·3 $I_2$ is difficult from the magnetic susceptibility measurement, as its value is almost the same as the value of Perylene·1.5 $I_2$ and also is not far from the value of iodine. This suggests that in the formation of Perylene·3 $I_2$ from Perylene·1.5 $I_2$ by further addition of iodine, the electronic state of the system is not greatly influenced. The molar susceptibility of Perylene·3 $I_2$ is $-342\times10^{-6}$ and the diamagnetic depression is $92\times10^{-6}$. This is comparable to that of Perylene·1.5 $I_2$.

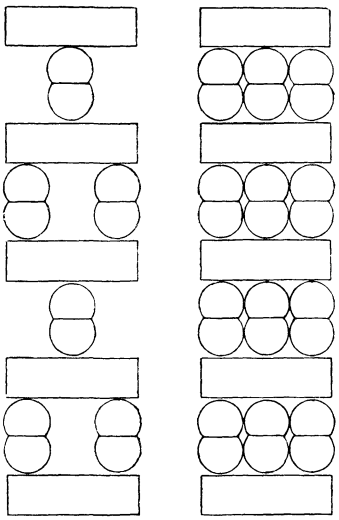
**ESR Absorption.**—The diamagnetic depression from the additivity rule should be attributed to the paramagnetic contribution of the unpaired electrons which are generated in association with the formation of charge transfer complex, as Matsunaga[5,6] has pointed out previously. The electron spin resonance absorption was examined for the perylene-iodine system as the function of iodine content. An x-band microwave spectrometer, Hitachi MPS-1 was employed. The measurement was carried out at room temperature. The spin concentration and the *g*-value were determined referring to the values of DPPH. The results are summarized in Table III.

TABLE III. THE ELECTRON SPIN RESONANCE ABSORPTION OF PERYLENE-IODINE SYSTEM (AT ROOM TEMPERATURE)

| Mole ratio $I_2$/perylene | Line width at half maximum gauss | Number of spins per g. | Number of spins per one molecule of perylene ESR | Static* |
|---|---|---|---|---|
| 0.29 | 8 | $1.8\times10^{19}$ | 0.01 | 0.01 |
| 0.78 | 8 | $2.3\times$ 〃 | 0.02 | 0.03 |
| 1.52 | 8 | $5.5\times$ 〃 | 0.06 | 0.06 |
| 1.84 | 11 | $5.2\times$ 〃 | 0.06 | 0.06 |
| 2.22 | 11 | $5.2\times$ 〃 | 0.06 | 0.06 |
| 2.53 | 13 | $3.3\times$ 〃 | 0.05 | 0.06 |
| 3.00 | 13 | $3.0\times$ 〃 | 0.05 | 0.07 |

* These values were calculated with the deviation from the additivity rule for molar susceptibility, dividing by $1270\times10^{-6}$.

The *g*-value was observed to be constant, 2.0043, regardless of the composition of the complex. The spin concentration varies with the iodine content, but the number of spins assigned to one molecule of perylene becomes nearly constant in any system whose mole ratio is more than 1.5. In the last column of the table, the number of unpaired electrons calculated from the diamagnetic depression in molar susceptibility is shown. These values are in good agreement with those observed by ESR absorption. The most interesting point in this result is that the number of unpaired electrons assigned to one perylene molecule is essentially constant for both Perylene·1.5 $I_2$ and Perylene·3 $I_2$. This suggests again, with the electrical property, that the electronic states are not greatly different from each other in those two complexes.



**On the Structure of Perylene-Iodine Complex.**—The X-ray diffraction patterns have been examined with the association of the "Geigerflex" diffractometer for the complexes which have the compositions of Perylene·1.5 $I_2$ and Perylene·3 $I_2$ respectively. Both complexes give sharp crystalline patterns which are quite different from that of perylene. This is in marked contrast to the violanthrene-iodine complex, which gives an amorphous pattern[2]. The main diffraction lines of Perylene·1.5 $I_2$ and Perylene·3 $I_2$ are in common with each other regarding the position as well as the intensity ratio. This indicates that these two complexes have structures very similar to each other.

Concerning the crystal system, no information could be obtained from the observed values of spacing alone, because it possesses low symmetry. However, three series of diffraction lines could be found in the observed principal lines. The first series consists of lines whose spacing is 13.5Å and possesses the largest intensity compared to the other series. The second and the third series consist of lines which have the spacing of 11.5 and 10.7Å respectively. In all of these series, the first order diffraction lines are weak in intensity, but the second order diffraction lines possess enough intensity and are well resolved.

Hassel and Strømme[7] have made investigation on the crystal structure of the benzene-bromine complex. It was concluded that in this solid complex the molecules of bromine and benzene are arranged alternately with each other, directing the molecular axis of bromine

5) Y. Matsunaga, This Bulletin, **28**, 475 (1955).
6) Y. Matsunaga, *J. Chem. Phys.*, **30**, 855 (1959).
7) O. Hassel and K. O. Stromme, *Acta Chem. Scand.*, **12**, 1146 (1958).

nearly perpendicular to the molecular plane of benzene. A similar structure could be assumed for the perylene-iodine complex. If an iodine molecule is sandwiched between two perylene molecules, directing its molecular axis perpendicularly to the plane of the perylene molecule, the distance between the two perylene molecules would be 10.7 Å (the thickness of aromatic molecular plane = 3.7 Å and the length of iodine molecule = 7.0 Å). This value is in coincidence with the observed spacing of 10.7 Å The molecular plane of perylene possesses enough area to accommodate three iodine molecules. Thus, it is likely that the complex is made of a structural unit such as is shown in Fig. 3. The reflection planes which have the spacing of 13.5 Å and give the strongest diffraction lines should be the planes which contain iodine molecules in the highest density, and could be constructed by stacking such structural units. However, no further information can be derived from the powder diffraction diagram alone.

(a) Perylene·1.5 $I_2$ (b) Perylene·3 $I_2$

Fig. 3. The proposed structure of perylene-iodine complex. (a) Perylene·1.5 $I_2$ (b) Perylene·3 $I_2$

The density of the perylene-iodine system has been examined. The pycnometer was employed in association with an aqueous medium containing a small amount of surfactant. In Fig. 4, the specific volume is plotted against the iodine content. The specific volume of perylene is 0.741 cc./g. and that of iodine is 0.202 cc./g. The broken line indicates the specific volume of the binary system assuming the additivity of volume. The observed values are situated above this line. This indicates that complex has the structure with interstices where water molecules can not penetrate. However, when the iodine content increases up to the composition of Perylene·3 $I_2$, the observed specific volume is 0.340 cc./g.; this value is in good agreement with the calculated value assuming the additivity law. This indicates that this complex has the most closed packing structure.

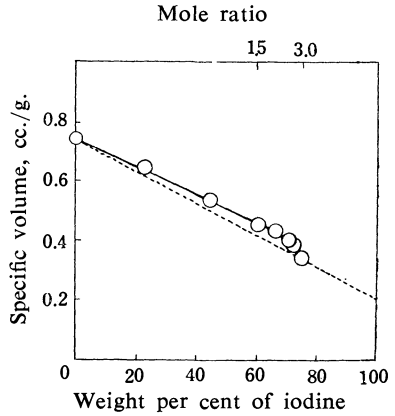


Fig. 4. The specific volume of perylene-iodine system.

## Discussion

Most organic compounds are electrical insulators, because the intermolecular coupling is so poor that electrons can hardly transfer from molecule to molecule, even in the electronic excited state. In organic semiconductors, the activation energy for generating charge carriers possesses relatively low values (1 eV. or less), whereas the resistivity possesses high values ($10^7 \sim 10^{14}$ ohm. cm.). However, if, in the formation of crystal, the condensation of molecules is caused by an interaction such as that which is associated with the exchange of electrons between molecules, it could be expected that those electrons can move throughout the crystal lattice. This could result in the drift mobility under the applied electrical field. This is the case of charge transfer complex in the solid state.

In the solid complex, in order to expect the conductance, the donor molecules (D) and the acceptor molecules (A) should be arranged alternately with each other in such a way as D·A·D·A···, thus the charge transfer interaction could be conjugated between neighboring molecules throughout the crystal lattice. The proposed model for the perylene-iodine complex illustrated in Fig. 3 is likely to be reasonable.

In the case of simple semiconductive compounds (polycyclic aromatic hydrocarbons), the resistivity and also the activation energy for generating charge carriers are depending markedly on the size of the aromatic molecule.

However, in the case of the charge transfer complex, their semiconductive property is quite independent of the size of the hydrocarbon molecule, as is seen in Table IV. This implies that the charge transfer interaction itself, between donors and acceptors, is the principal cause for generating mobile electrons which can contribute to the electrical conduction. The ESR absorption is observed commonly in charge transfer complexes and a close connection between the unpaired electrons and the charge carriers be presumed[8].

TABLE IV. THE SEMICONDUCTIVE DATA OF AROMATIC HYDROCARBONS AND IODINE COMPLEXES

| Complex | Mole ratio | $\rho_{15°C}$ ohm.cm. | $\varepsilon$ eV. |
|---|---|---|---|
| Perylene-iodine | 1 : 1.5 | 9 | 0.06 |
| Perylene-iodine | 1 : 3 | 10 | 0.06 |
| Pyranthrene-iodine | 1 : 2 | 20 | 0.09 |
| Violanthrene-iodine | 1 : 2 | 13 | 0.15 |
| Pure hydrocarbon | | | |
| Perylene | | $4.0\times10^{18}$ | 2.0 |
| Pyranthrene | | $4.5\times10^{16}$ | 1.07 |
| Violanthrene | | $2.0\times10^{14}$ | 0.94 |

The isotherm for the phase equilibrium of perylene-iodine system indicates the formation of two sorts of intermolecular compounds which have the composition of Perylene·1.5 $I_2$ and Perylene·3$I_2$ respectively. The investigation of the magnetic susceptibility also suggests the existence of the compound of Perylene·1.5$I_2$. However, concerning the electrical property almost no difference could be found between those two sorts of compounds. These two compounds possess not only the same semiconductive property but also the similar structure and almost the same number of unpaired electrons. These facts lead to the assumption that when three iodine molecules combine with two perylene molecules, not only the framework of the crystal structure but also the electronic state (for the charge transfer type of combination) are completed, and almost no further improvement takes place by adding the three more iodine molecules. Those added iodine molecules can occupy the interstices in the framework to complete the closed packed structure (mainly with non-bonding type of combination), but result in no further important change in the electronic state for the complex formation.

## Summary

Concerning the solid complex of perylene-iodine system, it has been clarified that two sorts of molecular addition compounds are formed. One has the composition of Perylene·1.5 $I_2$ (or 2 Perylene·3 $I_2$) and the other is Perylene·3$I_2$. Both complexes are semiconductive with low resistivity; the resistivity at the room temperature is 9～10 ohm.cm. and the energy gap is 0.06 eV. Concerning those values, both complexes possess almost the same values. Not only the elecrical properties and the magnetic properties, but also, both complexes possess similar crystal structures. To explain those facts, the structural units for those complexes have been proposed. These consist of the conjugation between perylene molecules and iodine molecules with the charge tranfer type of interaction.

# *Ion-exchange Behavior of Acidic and Basic Amino Acids*

By Manabu SENŌ and Takeo YAMABE

(Received December 20, 1960)

In the preceding paper[1] the ion-exchange behavior of some neutral amino acids was described and it was pointed out that amino acids are absorbed most predominantly on ion-exchange resins in the pH range near the isoelectric points of the amino acids. In this paper, some experimental results concerning the ion-exchange behavior of the acidic and the basic amino acid are presented and discussed.

## Experimental

Glutamic acid was used as an acidic amino acid and lysine monohydrochloride as a basic amino acid. These dissociation constants p$K$ and isoelectric points pI are as follows.

| | p$K_1$ | p$K_1'$ | p$K_2$ | p$K_2'$ | pI |
|---|---|---|---|---|---|
| Glutamic acid | 2.19 | 4.25 | 9.67 | — | 3.22 |
| Lysine | 2.18 | — | 8.95 | 10.76 | 9.70 |

p$K$'s are defined by equations given later. The ion-exchange resins used were Amberlite resins, IR-120, IRC-50, IRA-400 and IR-4B, the exchange capacities of which are 4.24, 10.0, 2.15 and 8.0 meq./g. dry resin, respectively.

The experimental procedures were the same as those in the preceding paper[1]. All measurements were carried out batchwise; a constant volume (50 ml.) of a solution containing a constant amount (about 2 mmol.) of an amino acid and being adjusted to a desired pH by adding hydrochloric acid or sodium hydroxide, was added onto a constant quantity (about 1 meq.) of the ion-exchange resin. The details are as follows.

| Amino acid | Total amounts $a$ mmol. | H- or OH-form resins $w$ g. (dried) IR-120 | IRC-50 | IRA-400 | IR-4B |
|---|---|---|---|---|---|
| Glutamic acid | 2.09 | 0.180 | 0.091 | 0.344 | 0.110 |
| Lysine | 2.13 | 0.170 | 0.097 | 0.336 | 0.109 |

After being allowed to stand for a few days, which were long enough for the attaining of the exchange equilibrium, the pH and the remaining amount of the amino acid in the solution phase were measured and the adsorbed amount of the amino acid was estimated. All the experiments were made at room temperature, 5~15°C.

## Results and Discussion

Experimental results were shown in Figs. 1 and 2, in which the adsorbed amounts of amino acids were plotted against the pH of the equilibrium external solution. Like the neutral amino acids, the acidic and the basic amino acid are adsorbed most intensively at pH values close to the isoelectric point and, in the lower and the higher pH range, the adsorbed amounts of the amino acids decrease sharply owing to the competitive adsorption of hydrogen or hydroxyl ions. The amounts of uptake of amino acids by sodium- or chloride-form strongly dissociated resins are less than those by hydrogen-form or hydroxyl-form resins, especially in the pH range near the isoelectric point.

The pH dependence of adsorption of amino acids is more remarkable and more characteristic, compared to the case of neutral amino acids. As shown already by several investigators[2,3], glutamic acid is adsorbed predominantly on the anion-exchange resins and lysine on the cation-exchange resins. Glutamic acid is adsorbed very intensively in the limited pH range, 3~5, on a weakly basic ion-exchanger, IR-4B, while it is well adsorbed in a wider, namely, higher pH range in the case of a strongly basic ion-exchanger, IRA-400. This is owing to the strong affinity of IR-4B to the hydroxyl ion. Lysine shows a peculiar behavior, probably because it was used in the monohydrochloride form. The resulting solution from it is acidic, and sodium hydroxide must be added to bring the solution pH to the isoelectric point of lysine. The maximum adsorption of lysine takes place in pH 2~3 on IR-120, and in pH 7~9 on IRC-50. In other words, the addition of sodium ions decreases the amount of uptake of lysine on IR-120 and increases the amount adsorbed on IRC-50. This behavior is owing to the strong affinity of IRC-50 to the hydrogen ion and that of IR-120 to the sodium ion.

The adsorption mechanism of amino acids on the ion-exchange resins was described in the preceding paper. That is to say, when the amino acid cations are adsorbed on the hydrogen-form cation-exchanger, the hydrogen ions

are liberated from resins and promote the association of the amino acid to produce the amino acid cations. These result in further exchange of the amino acid cations for the hydrogen ions. The exchange reaction attains equilibrium through such a repeating process. Similar reactions take place in other systems.

**Relations between the Adsorbed Amount of Amino Acids and the pH of the External Solution.**—The dissociation constants of the acidic amino acid are given as

$$\left.\begin{aligned} &AH^+ \rightleftarrows A^\pm + H^+ \quad K_1=\frac{[A^\pm]_s[H^+]_s}{[AH^+]_s} \\ &A^\pm \rightleftarrows A^- + H^+ \quad K_1'=\frac{[A^-]_s[H^+]_s}{[A^\pm]_s} \\ &A^- \rightleftarrows A^{2-} + H^+ \quad K_3=\frac{[A^{2-}]_s[H^+]_s}{2[A^-]_s} \end{aligned}\right\} \quad (1)$$

where the term arising from activity coefficients is neglected. In a case when the acidic amino acid is exchanged for hydrogen ions on the cation-exchanger, the selectivity coefficient is defined as

$$\left.\begin{aligned} &RH + AH^+ \rightleftarrows RAH + H^+ \\ &K_H=\frac{[AH^+]_r[H^+]_s}{[AH^+]_s[H^+]_r} \end{aligned}\right\} \quad (2)$$

where $[A]_s$ is the concentration of ion A in the equilibrium external solution in the unit, meq./ml., and $[A]_r$ is that in the resin phase in the unit, meq./g. dry resin.

Under the present experimental condition, that is; (1) the total amount of the amino acid in the system is constant, $a$ mmol., (2) the amount of the exchangeable ions in the ion-exchanger is constant, $c$ meq., $c=Cw$, where $C$ is the exchange capacity (meq./g. dry resin) of the resin and $w$ is the weight of the resin used, and (3) the volume of the external solution is constant, $v$ ml., the following relationship holds between the adsorbed amount of the amino acid, $[AH^+]_r=y$, and the hydrogen ion concentration in the external solution, $[H^+]_s=x$,

$$\left.\begin{aligned} &\frac{(a-wy)(c-wy)}{y}=\frac{vw}{K_H}f(x) \\ &f(x)=\frac{x^3+K_1x^2+K_1K_1'x+K_1K_1'K_2}{x^2} \end{aligned}\right\} \quad (3)$$

This formula is similar to that derived on the system of neutral amino acids[1].

When the acidic amino acid is adsorbed on the hydroxyl-form anion-exchanger, two species of the amino acid anions participate in the exchange reaction as follows,

$$\left.\begin{aligned} &ROH + A^- \rightleftarrows RA + OH^- \\ &K_{OH} = \frac{[A^-]_r [OH^-]_s}{[A^-]_s [OH^-]_r} \\ &2ROH + A^{2-} \rightleftarrows R_2A + 2OH^- \\ &K'_{OH} = \frac{[A^{2-}]_r [OH^-]_s^2}{[A^{2-}]_s [OH^-]_r^2} \end{aligned}\right\} \quad (4)$$

and the following formulas are derived between quantities, $[A^-]_r = y_1$, $[A^{2-}]_r = 2y_2$ and $[OH^-]_s = x'$,

$$\left.\begin{aligned} &\frac{[a - w(y_1 + y_2)]\,[c - w(y_1 + 2y_2)]}{y_1} = \frac{vw}{K_{OH}} f(x') \\ &\frac{[a - w(y_1 + y_2)]\,[c - w(y_1 + 2y_2)]^2}{y_2} \\ &\quad = \frac{vw^2}{K'_{OH}} \frac{K_w}{K_2} f(x') \\ &f(x') = \frac{K_1 K_1' K_2 x'^3 + K_1 K_1' K_w x'^2 + K_1 K_w^2 x' + K_w^3}{K_1 K_1' K_w x'} \end{aligned}\right\} \quad (5)$$

Similar formulas are obtained on the exchange reaction of a basic amino acid such as lysine, which dissociates as follows,

$$\left.\begin{aligned} &AH_2^{2+} \rightleftarrows AH^+ + H^+ \\ &K_1 = \frac{2[AH^+]_s [H^+]_s}{[AH_2^{2+}]_s} \\ &AH^+ \rightleftarrows A^\pm + H^+ \\ &K_2 = \frac{[A^\pm]_s [H^+]_s}{[AH^+]_s} \\ &A^\pm \rightleftarrows A^- + H^+ \\ &K_2' = \frac{[A^-]_s [H^+]_s}{[A^\pm]_s} \end{aligned}\right\} \quad (6)$$

where the selectivity coefficients are defined as

$$\left.\begin{aligned} &RH + AH^+ \rightleftarrows RAH + H^+ \\ &K_H = \frac{[AH^+]_r [H^+]_s}{[AH^+]_s [H^+]_r} \\ &2RH + AH_2^{2+} \rightleftarrows R_2AH_2 + 2H^+ \\ &K'_H = \frac{[AH_2^{2+}]_r [H^+]_s^2}{[AH_2^{2+}]_s [H^+]_r^2} \end{aligned}\right\} \quad (7)$$

The relationship between the quantities, $[AH^+]_r = y_1$, $[AH_2^{2+}]_r = 2y_2$ and $[H^+]_s = x$, is

$$\left.\begin{aligned} &\frac{[a - w(y_1 + y_2)]\,[c - w(y_1 + 2y_2)]}{y_1} = \frac{vw}{K_H} f(x) \\ &\frac{[a - w(y_1 + y_2)]\,[c - w(y_1 + 2y_2)]^2}{y_2} = \frac{vw^2}{K'_H} K_1 f(x) \\ &f(x) = \frac{x^3 + K_1 x^2 + K_1 K_2 x + K_1 K_2 K_2'}{K_1 x} \end{aligned}\right\} \quad (8)$$

While, in a case when the basic amino acid is adsorbed on the hydroxyl-form anion-exchanger, the simpler relation is derived between $[A^-]_r = y$ and $[OH^-]_s = x'$,

$$\left.\begin{aligned} &\frac{(a - wy)(c - wy)}{y} = \frac{vw}{K_{OH}} f(x') \\ &f(x') = \frac{K_1 K_2 K_2' x'^3 + K_1 K_2 K_w x'^2 + K_1 K_w^2 x' + K_w^3}{K_1 K_2 K_2' x'^2} \end{aligned}\right\} \quad (9)$$

It must be noted that these relationships hold for the two-component systems that contain hydrogen or hydroxyl ions besides amino acid ions.

**$f(x)$ or $f(x')$ Functions.**—As described in the preceding paper, functions $f(x)$ or $f(x')$, which appear to the right of the above equations,

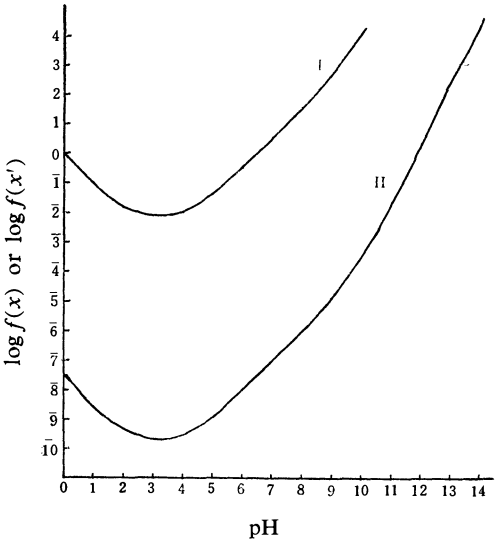

Fig. 3. $f(x)$ and $f(x')$ of glutamic acid.
I $f(x)$, II $f(x')$

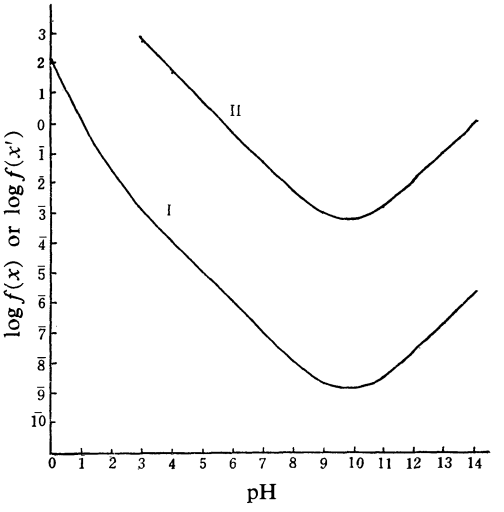

Fig. 4. $f(x)$ and $f(x')$ of lysine.
I $f(x)$, II $f(x')$

contain only a variable, the solution pH, and give the characteristic exchange behavior of amino acids. These functions have minimum values at the isoelectric points of amino acids as shown in Figs. 3 and 4, in which these are plotted against pH. At the minimum of these functions, the adsorbed amount of amino acids is the maximum. This can be shown directly by differentiating the above equations.

The amounts of adsorbed amino acids are related inversely to $f(x)$ or $f(x')$. For example, the relation derived from Eq. 3 is

$$y=\frac{ac}{w\left(a+c+\frac{v}{K_H}f(x)\right)}+\frac{a^2c^2}{w\left(a+c+\frac{v}{K_H}f(x)\right)^3}+\cdots \quad (10)$$

and the similar equation is obtained from Eq. 9. In the system where two ionic species of amino acids participate in the exchange reaction, such a simple relation can not be derived and, however, when $K'$ is not much larger than $K$ in Eqs. 7 or 8, $y_2$ is very small compared to $y_1$ in the pH range near the isoelectric point and the similar relations to Eq. 10 are derived in these cases.

This is closely related to the fact that $f(x)$ and $f(x')$ of the acidic and the basic amino acid are more strongly dependent on pH than those of neutral amino acids[1], that the ion-exchange behavior of the former has more remarkable pH effect than that of the latter. In passing, it is noticed that the exchange reaction takes place in a wider pH range in the cases where two ionic species praticipate.

**Ion Species Exchanged.**—In order to estimate the selectivity coefficients $K$ and $K'$, the ionic species exchanged for hydrogen or hydroxyl ions must be discriminated. This requires a complicated procedure experimentally[4]. Hence, it is assumed that the same dissociation equilibrium is attained in the resin phase as in the solution phase. Then, in the case of an acidic amino acid,

$$\frac{K_2}{K_w}=\frac{[A^{2-}]_r}{2[A^-]_r[OH^-]_r} \quad (11)$$

and under the present condition the following relation is obtained between $y_1$ and $y_2$,

$$y_2=\frac{K_2(c-wy_1)y_1}{w(2K_2y_1+K_w)} \quad (12)$$

Putting Ep. 12 into Eq. 5, $K_H$ and $K_{II}'$ are estimated at least in principle, if the amount (in mole) of adsorbed amino acids is known.

A similar relation is derived as that for a basic amino acid. The relation

$$K_1=\frac{2[AH^+]_r[H^+]_r}{[AH_2^{2+}]_r} \quad (13)$$

is assumed and the following formula is obtained.

$$y_2=\frac{(c-wy_1)y_1}{w(K_1+2y_1)} \quad (14)$$

It might be reasonably expected that these relations are valid for strongly dissociated ion-exchangers. In the case of weakly dissociated ion-exchangers, these relations are not always satisfied, because all the ions exchanged are not in the dissociated state[5].

From Eq. 12 or 14 and the known quantities, the numerical relation between $y_1$ and $y_2$ can estimated and the mole ratio of monovalent amino acid ion to all the exchanged amino acid ions in the resin phase, $y_1/(y_1+y_2)$, is shown against the total amino acid ions exchanges in mole in Fig. 5. Using this diagram

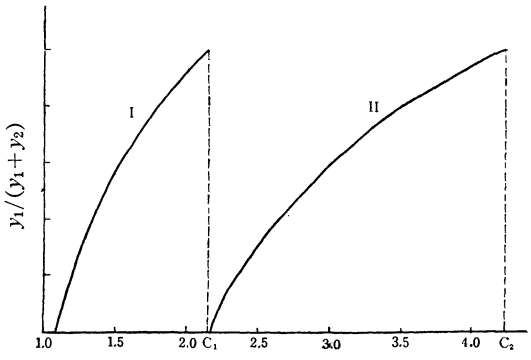

Fig. 5. Fraction of ionic species of amino acids in ion-exchange resins.
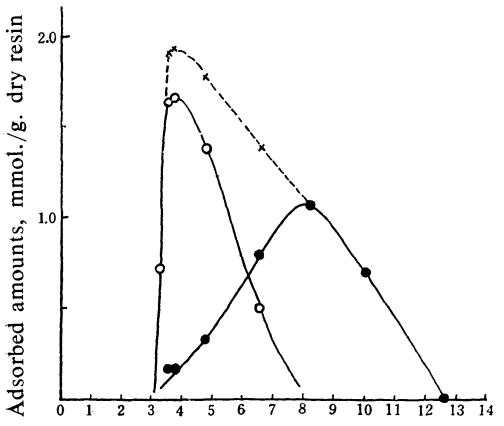
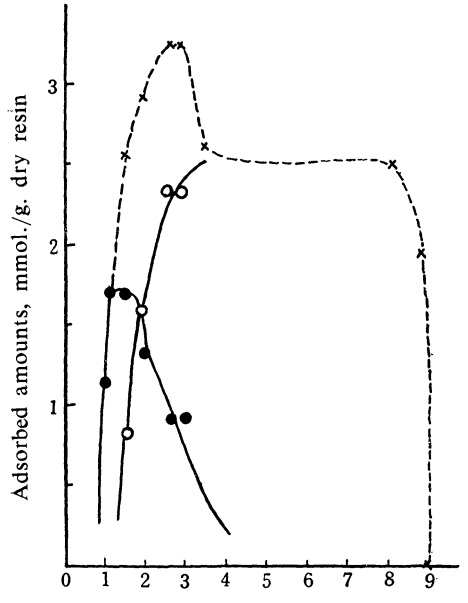
I Glutamic acid-IRA-400, II lysine-IR-120, $c_1$ and $c_2$ are the exchange capacities of IRA-400 and IR-120, respectively.

and the experimental data shown in Figs. 1 and 2, the adsorbed amino acids can be discriminated into two ionic species, mono- and di-valent ions. The result is given in Fig. 6.



It is shown by differentiating Eq. 12 that, when $y_1$ has the following value

$$y_1=\frac{1}{2}\left(\sqrt{\left(\frac{K_w}{K_2}\right)^2+2C\frac{K_w}{K_2}}-\frac{K_w}{K_2}\right) \quad (15)$$



$y_2$ has a maximum value

4) In order to discriminate ionic species of adsorbed amino acids experimentally, the adsorbed amount must be measured in the two units, mole and equivalent number. The molar quantity was measured in this experiment and the equivalent quantity will be obtained by knowing the contents of hydrogen or hydroxyl ions in the ion-exchange resin in equilibrium in an appropriate way.

5) These relations can be extended to this case by assuming that the exchange capacity $C$ is a variable which depends on the dissociation constants of the exchange sites combined with various ions adsorbed on the resins.

Glutamic acid-IRA-400, —○— $A^-$, —●— $A^{2-}$, --×-- total ($A^- + A^{2-}$)

Lysine-IR-120, —○— $AH^+$, —●— $AH_2^{2+}$, --×-- total ($AH^+ + AH_2^{2+}$)

Fig. 6. Ionic species of amino acids adsorbed on ion-exchange resins.

$$y_{2,\max} = \frac{1}{2}\left(C + \frac{K_w}{K_2} - \sqrt{\left(\frac{K_w}{K_2}\right)^2 + 2C\frac{K_w}{K_2}}\right) \tag{16}$$

Putting these values into the second equation of Eq. 5, it is shown that $y_2$ has a maximum value when

$$f(x') = K'_{OH}\frac{\left(a - \frac{1}{2}c\right)}{v} \tag{17}$$

In the case of glutamic acid-Amberlite IRA-400, using the known values and the value of $K'_{OH}$ obtained in the next section, Eq. 17 becomes

$$f(x') = 2.27 \times 10^{-7}$$

This value corresponds to pH=7.4.

A similar relation is derived in the case of lysine-Amberlite IR-120. The value of $y_2$ is maximum when

$$f(x) = K_H'\frac{\left(a - \frac{1}{2}c\right)}{v} \tag{18}$$
$$= 1.48 \times 10^{-2}$$

This corresponds to pH 2.0. All the values explain well the experimental results presented in this paper.

**Selectivity Coefficient.**—The selectivity coefficients were estimated from the above-mentioned experimental data, using Eqs. 3, 5, 8 and 9, with Eqs. 12 and 14[6]. The latter equations can not be successfully applied to the cases of weakly dissociated resins. On this account, the selectivity coefficients in the systems, glutamic acid-IR-4B and lysine-IRC-50, can be obtained immediately. However, as revealed in the systems, glutamic acid-IRA-400 and lysine-IR-120, monovalent amino acid ions play the predominant role in the pH range close to the isoelectric point and divalent amino acid ions contribute predominantly to the ion-exchange in the pH-range for from the isoelectric point[7]. It may be safely assumed that similar reactions take place also in systems of weakly dissociated ion exchangers. The selectivity coefficients thus obtained are given in Table I.

Table I. Selectivity coefficients

| | Glutamic acid | | Lysine | |
|---|---|---|---|---|
| | $\log K_H$ | $\log K'_H$ | $\log K_{OH}$ | $\log K'_{OH}$ |
| IR-120 | 0.23 | — | 1.81 | $\bar{1}$.62 |
| IRC-50 | $\bar{2}$.43 | — | $\bar{5}$.83 | $\bar{3}$.14 |
| | $\log K_{OH}$ | $\log K'_{OH}$ | $\log K_{OH}$ | $\log K'_{OH}$ |
| IRA-400 | $\bar{3}$.32 | $\bar{6}$.82 | $\bar{3}$.75 | — |
| IR-4B | $\bar{8}$.08 | — | $\bar{3}$.38 | — |

6) In this calculation, it happens that $c - w(y_1 + 2y_2)$ equals nearly zero. Then, the following formulas derived from Eqs. 12 and 14 are used.

$$c - w(y_1 + 2y_2) = \frac{K_w(c - wy_1)}{2K_2y_1 + K_w} \quad \text{(glutamic acid-IRA-400)}$$
$$= \frac{K_1(c - wy_1)}{K_1 + 2y_1} \quad \text{(lysine-IR-120)}$$

7) This situation is verified by the variation of the ionic species of amino acids due to the pH change. The predominant ionic species in solutions with various pH's are as follows.

| pH | | 2.2 | | 4.3 | | 9.7 | |
|---|---|---|---|---|---|---|---|
| Glutamic acid | $AH^+$ | | $A^\pm$ | | $A^-$ | | $A^{2-}$ |
| pH | | 2.2 | | 9.0 | | 10.8 | |
| Lysine | $AH_2^{2+}$ | | $AH^+$ | | $A^\pm$ | | $A^-$ |

In general, $K_H$'s of the amino acids are larger than $K_{OH}$'s. $K_H$ or $K_{OH}$ in the case of the weakly dissociated resins is rather small. This is owing to their strong affinity to hydrogen or hydroxyl ions and it is clear from Figs. 1 and 2 that IRC-50 of sodium-form or IR-4B of chloride-form has a strong affinity to amino acids.

## Summary

The ion-exchange behavior of the acidic and the basic amino acids was described and discussed. The maximum uptake of amino acids takes place in the pH range close to the isoelectric points and the pH effect is more remarkable and more characteristic, in comparison with the case of neutral amino acids. Theoretical treatment on ion-exchange equilibria, which takes account of the dissociation equilibria of amino acids, explains well the experimental results and the selectivity coefficients were estimated herefrom.

# *Photoreduction of Acridine in Deaerated and Aerated Ethanol Solutions*

By Shunji KATO, Shigekazu MINAGAWA and Masao KOIZUMI

(Received December 26, 1960)

Photochemical reaction of acridine was studied recently by several workers[1-6]. According to Zanker, the solution of acridine in ethanol when irradiated by ultraviolet light, yields diacridane in case when the concentration is above $10^{-3}$ M; this was confirmed by means of infrared spectrum and polarography. Zanker's result was reconfirmed by Kellman[4]. Zanker further found that when the concentration of acridine is below $10^{-3}$ M, the photoproduct consists mainly of acridane.

Zanker's remark that he studied the reaction under the presence of dissolved oxygen attracted much of our attention, because we formerly found that the photochemical reduction of eosine dissolved in ethanol is completely suppressed by the presence of a very small quantity of oxygen[7]. Nothing, however, is described in Zanker's paper about the effect of oxygen on the reaction. We made some preliminary investigations on this problem.

Although our experiments were done only under the limited condition, the results obtained are so specific that they seem to be very important for elucidating the mechanism of the reaction. At least the results must be taken into account in order to give a correct description of the photochemical behavior of acridine in ethanol. Therefore, it is worth while to report, as we believe, the results obtained and some deductions based on them.

## Experimental

**Sample.**—Tokyo Kasei's acridine was recrystallized twice from the water-ethanol mixture (3 : 2 in volume ratio). Wako Junyaku's ethanol (G. R.) was used without further purification.

**Procedure of Degassing.** — In order to exclude the air from the solution, the following procedure was employed. The sample solution was put into B (Fig. 1) and was evacuated by a diffusion pump through a trap A dipped in liquid air. Most of the dissolved air was eliminated during the distilla-

tion of the solvent from B to A. When all the solvent went to A, tap F was closed and the solvent was distilled back from A to B, dipping B in liquid air. The above procedure was repeated.

In Fig. 1, C is the reaction cell ($1\times1\times4$ cm.) and D is the inlet of sample solution.

The above procedure is superior to repeated distillation in a closed system since it requires far less time for the satisfactory degassing. The loss of the solvent is negligible.

**Apparatus.** — The apparatus is shown in Fig. 2.

- $C_2$: Cell containing pure solvent as a reference
- $S_1$, $S_2$: Shutter

The illuminating light is comparatively pure monochromatic light of 365 m$\mu$. The electric source is supplied from VOLCO-HT high-grade automatic voltage stabilizer.

The reaction is followed by the change of optical density at 365 m$\mu$, the reading of the meter being carried out during the course of the reaction.

**Quantum Yield.**—Quantum yield was determined by potassium ferri-oxalate actinometer.

## Results

**Comparison of Aerated and Deaerated Solutions.**—The experiments were done with the solution of acridine $1\times10^{-4}$ M in ethanol dissolving various amounts of oxygen from air-saturation to complete degassing. In order to check the effect of a small quantity of water contained in alcohol, the reaction was tried with the solution containing various amounts of water and it was established that a small amount of water does not affect essentially the rate of the reaction. Hence the alcohol employed was not particularly dehydrated by any chemical method.

In case the rate of the disappearance of acridine is proportional to the light absorption, the relation

$$-\frac{dc}{dt}=\frac{kI_0}{d}(1-e^{-E})\times1000 \qquad (a)$$

must hold, where $E=\alpha cd$, $c$ is the concentration of acridine, $\alpha$ the absorption coefficient at 365 m$\mu$. Integrating, one obtains

$$\ln(e^{-E}-1)=\ln(e^{E_0}-1)-1000\,k\alpha I_0 t \qquad (b)$$

Hence $\ln(e^{E}-1)$, when plotted against $t$, must give a straight line with the inclination of $1000k\alpha I_0$, which gives the relative rate of the reaction. The experimental results satisfy the above relation very satisfactorily as shown in Fig. 3, for both the air-saturated and the deaerated solution. It is seen from these results that the rate in the aerated solution is about one-third of that in the deaerated solution.

The absorption spectra of the solution were

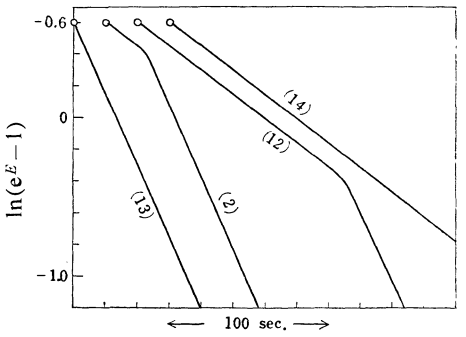

Fig. 3. Plots of $\ln(e^{E}-1)$ vs. time for typical decay. The numbers in the figure point out the experimental number in Table I.

examined immediately after the reaction, and it was found that there is no difference in the two cases, aerated and deaerated, and they are quite the same as the one reported by Zanker. Thus it can safely be concluded that the reductive photochemical reaction can occur even in the presence of oxygen. This is somewhat surprising and is in sharp contrast to the case of eosine in ethanol solution.

**The Effect of Oxygen Concentration.**—When the concentration of the dissolved oxygen is below a certain value, $\ln(e^{E}-1)\sim t$ relation shows quite a sharp breaking point at a certain point and the inclination of the line preceeding the breaking point is almost equal to that of the air-saturated solution, while the one after the breaking point is approximately equal to that for the evacuated solution. It was found that the length of the initial part with

smaller inclination becomes shortened with the decrease of oxygen concentration and yet the inclination itself remains practically constant irrespective of the oxygen concentration. Typical results are shown in Fig. 3 and the complete data are given in Table I.

TABLE I. THE EFFECT OF OXYGEN CONCENTRATION UPON THE RATE OF THE PHOTOCHEMICAL REACTION OF ACRIDINE
[Acridine] $=1\times10^{-4}$ M

| Exp. No. | $[O_2]$ $\times10^4$ M | Temp. °C | $k\alpha I_0\times10^5$ sec$^{-1}$ | |
|---|---|---|---|---|
| 13 | 0 | 13.3 | | 2.28 |
| 19 | 0 | 25.0 | | 2.16 |
| 20 | 0 | 25.0 | | 2.38 |
| 21 | 3.63 | 18.8 | 0.78 | |
| 22 | 7.75 | 14.5 | 0.86 | |
| 14 | air-saturation | 13.0 | 0.73 | |
| 18 | 〃 | 25.0 | 0.70 | |
| Average | | | 0.77 | 2.27 |
| | | | Before breaking point | After breaking point |
| 1 | 0.336 | 16.3 | 1.02 | 1.99 |
| 9 | 0.340 | 19.3 | 0.83 | 2.06 |
| 2 | 0.465 | 19.3 | 0.83 | 2.16 |
| 8 | 0.460 | 21.4 | 0.78 | 1.82 |
| 10 | 0.600 | 17.0 | 0.96 | 1.91 |
| 3 | 0.656 | 20.7 | 0.86 | 2.12 |
| 15 | 0.720 | 13.2 | 0.78 | 1.76 |
| 11 | 0.740 | 18.3 | 0.73 | 2.06 |
| 4 | 0.919 | 18.6 | 0.83 | 1.76 |
| 12 | 0.920 | 22.9 | 0.78 | 2.01 |
| 17 | 0.985 | 13.7 | 0.78 | 1.76 |
| Average | | | 0.85 | 1.95 |

Although the reproducibility is not so good, it is apparent that the rate before the breaking point is, on the average, about one third of that for the deaerated solution and that the rate after breaking point is approximately equal to that of the deaerated solution.

Further, the results in Table I seem to indicate that the rate of reaction is not so much dependent upon temperature, whether oxygen is present or not. To confirm this, the reaction rate of the evacuated solution was investigated in the wider range of temperature. The results shown in Table II establish quite definitely the temperature independence of the rate in the degassed solution.

TABLE II. THE EFFECT OF TEMPERATURE ON THE RATE FOR THE DEGASSED SOLUTION OF ACRIDINE
[Acridine] $=0.7\times10^{-4}$ M

| Temp., °C | $k\alpha I_0\times10^5$ sec$^{-1}$ | |
|---|---|---|
| 25 | 2.28 | Average |
| | 1.90 | 2.09 |
| 35 | 2.16 | |
| | 2.13 | 2.14 |
| 45 | 2.27 | |
| | 1.93 | 2.10 |

From the above results, it can be said that the rate is about one third of the deaerated solution as long as a very small amount of oxygen is present in the solution and that the oxygen is exhausted near the crossing point of the two linear parts, whence the rate gets the value of the degassed solution.

To confirm this further, the following experiment was performed using a special reaction cell. The volume of the upper part, i. e. the gaseous part of the cell was increased about three times to that of the liquid part. The area of the liquid surface was so small that the dissolution of oxygen during the course of the reaction, would be neglected in view of a rather rapid rate of the reaction. Now, if the solution of acridine in ethanol containing a proper amount of oxygen is irradiated in such a cell, one would expect the breaking point to appear after a certain time interval when the oxygen in the liquid phase is consumed. Furthermore one would expect that if one shakes the cell at this stage in order to bring on a new equilibrium of dissolution between gaseous and liquid phase, and then continue to irradiate the solution again, the rate would fall down to the original value and another breaking point would once more appear after a certain time. These expectations were in fact realized as shown in Fig. 4.

Thus one can conclude with much confidence that in the presence of oxygen the reduction of acridine and the consumption of oxygen takes place simultaneously and that the latter process is intimately connected with the recovery of acridine from a certain transient intermediate.

The decrease of acridine concentration during the consumption of dissolved oxygen can easily

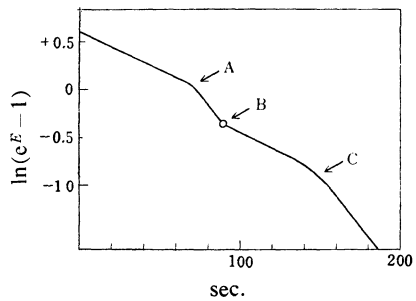

Fig. 4. A decay curve in the special cell. At the time A, dissolved oxygen would exhausted. At B, the cell was shaken and oxygen was introduced into the liquid phase, then at C it would be exhausted again.
$[O_2]=0.912\times10^{-4}$ M (35.0 mmHg), 18°C, $C_0=1\times10^{-4}$ M

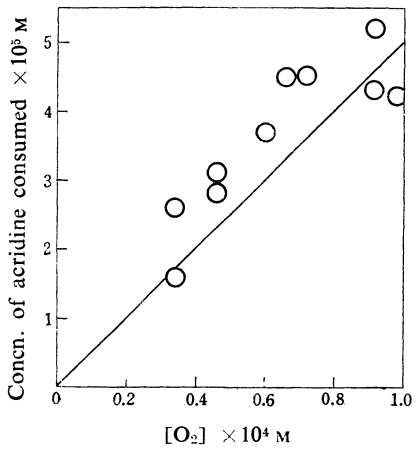

Fig. 5. Plots of the decrease of acridine concentration before the breaking point of the decay curve, vs. the initial concentration of dissolved oxygen.

be evaluated and this is plotted in Fig. 5 against the concentration of oxygen dissolved in the solution. Since the initial concentration of acridine obtained from the optical density is always a little less than $1\times10^{-4}$ M, the concentration of the prepared solution, the latter was used, though somewhat arbitarily, instead of the former.

There is an appreciable scattering of the points, but it is evident that the ratio (consumed oxygen): (reduced acridine) lies near 2 : 1.

**Quantum Yield.**—The light intensity entering into the solution was measured to be $0.156\times10^{-7}$ M $sec^{-1}cm^{-2}$. Since $\alpha$ is $1.14\times10^{4}$ at 365 m$\mu$, from the value of $k\alpha I_0$, the quantum yield for the deaerated solution was found to be about 0.13.

## Discussion

The plausible scheme for the deaerated solution may be pictured as follows

$$\left.\begin{aligned} &A+h\nu \rightarrow A^* \\ &A^*+RH_2 \rightarrow AH\cdot+RH\cdot \end{aligned}\right\} \quad (0)$$

$$AH\cdot+RH\cdot \rightarrow AH_2+R \quad (1)$$

$$AH\cdot+RH\cdot \rightarrow A+RH_2 \quad (2)$$

$$AH\cdot+AH\cdot \rightarrow AH_2+A \quad (3)$$

$$RH\cdot+RH\cdot \rightarrow HR\text{–}RH \text{ or } R+RH_2 \quad (4)$$

where A, $RH_2$, R are acridine, ethanol, acetaldehyde respectively and A* denotes the excited singlet or triplet state as the case may be.

The above scheme is essentially the same as that of Kellman[4] except that it involves the recovery of A and $RH_2$ (process 2).

At first, let us consider the molecular species X which oxygen attacks. Since the rate of the reaction is independent of the concentration of oxygen unless it is too low, the rate with which oxygen attacks X should be much faster than the rate with which X disappears in the deaerated solution. Supposing that the diffusion of oxygen is the rate-determining step of the reaction between $O_2$ and X, as is plausible, the experimental result that the rate is independent of oxygen concentration above $10^{-5}$ M leads to the conclusion that the life of X in the deaerated condition is $\sim10^{-5}$ sec. or more. Hence X can not be the singlet excited state. We have found that the fluorescence of acridine is not quenched appreciably by oxygen and this discovery also supports the above conclusion.

If X is triplet, then the formation of molecular associate $X\cdots O_2$ analogous to the intermediate of the Schenck's scheme[8] might be conceivable, but it is difficult to interpret the reductive reaction on this basis.

The possibility that T-state is quenched partially by oxygen depending on its concentration can of course be rejected on the ground that the rate is independent on the concentration of oxygen. Thus it is most plausible to assume that oxygen attacks the semi-reduced form of A produced by the process 0. In case of reductive photobleaching of eosine in ethanol, this process really takes place very rapidly*. In that case, however, the reaction was completely suppressed by a very small quantity of oxygen and the following scheme could account for the experimental results[7].

$$DH\cdot+O_2 \rightarrow D+HO_2\cdot$$

$$RH\cdot+O_2 \rightarrow RH\cdots O_2$$

$$HO_2\cdot+HO_2\cdot \rightarrow H_2O_2+O_2$$

$$RH\cdots O_2+RH\cdots O_2 \rightarrow 2\ \text{Acid}+H_2O_2$$

$$RH\cdots O_2+HO_2\cdot \rightarrow H_2O_2+\text{aldehyde}+O_2$$

But in the present case where acridine is reduced even in high oxygen concentration, one can not interpret the formation of acridan in any way by a single process in which oxygen attacks AH·. This leads to the assumption that some other intermediate such as $AH\cdots O_2$ be produced and some of them go back to A and the remainder turns into $AH_2$ through a bimolecular reaction. Perhaps $AH\cdots O_2$ may have its hydrogen attached to nitrogen, and the oxygen loosely combined with 9-carbon.

Now the scheme should further account for the following three experimental results.

8) G. O. Schenck, *Naturwissenschaften*, **40**, 212 (1953).

* From the results of the flash experiment, it is not proper to say that oxygen attacks only semiquinone. See Ref. 9.

9) S. Kato et al., This Bulletin, 33, 262 (1960).

[a] The rate of the reaction is proportional to the rate of light absorption for both the aerated and the deaerated condition.

[b] The rate in the aerated solution is about one third of that in the deaerated solution.

[c] The ratio of consumed oxygen to the reduced acridine ($=\gamma$) is about 2.

Now in the deareated condition one can easily derive the following equation by means of steady state method

$$-\frac{d[A]}{dt}=\frac{d[AH_2]}{dt}=\frac{\phi I_{abs}(k_1+\sqrt{k_3k_4})}{k_1+k_2+2\sqrt{k_3k_4}}=\phi\beta f_{abs} \quad (a)$$

$$\beta=\frac{k_1+\sqrt{k_3k_4}}{k_1+k_2+2\sqrt{k_3k_4}}$$

where $\phi$ is the quantum yield of the formation of AH· and RH·, and $k_1$, $k_2$, $k_3$ and $k_4$ are respectively the rate constants of the processes 1, 2, 3 and 4.

Assuming the formation of $AH\cdots O_2$ and $RH\cdots O_2$, the following processes may be conceivable for the aerated solution.

$$AH\cdot+O_2 \rightarrow AH\cdots O_2 \quad (5)$$

$$RH\cdot+O_2 \rightarrow RH\cdots O_2 \quad (5')$$

$$2AH\cdots O_2 \rightarrow AH_2+A+2O_2 \quad (6)$$

$$AH\cdots O_2 \rightarrow A+HO_2\cdot \quad (7a)$$

$$2RH\cdots O_2 \rightarrow 2\ Acid+H_2O_2 \quad (8)$$

$$AH\cdots O_2+RH\cdots O_2 \rightarrow AH_2+R+2O_2 \quad (9)$$

$$AH\cdots O_2+RH\cdots O_2 \rightarrow A+R+H_2O_2+O_2 \quad (10)$$

$$AH\cdots O_2+RH\cdots O_2 \rightarrow A+RH_2+2O_2 \quad (11)$$

In the presence of oxygen the reaction 5 is so fast that the reactions 1, 2 and 3 can be neglected.

To simplify the discussion, only the following two extreme cases will be considered.

**Case I.** — When $AH\cdots O_2$ disappears mainly through the reactions 6 and 7a, the reaction 8 must take place accompanied by them. If so, the formation of acridane would not be simply proportional to the rate of light absorption, because the process 7a is a first order reaction concerning $[AH\cdots O_2]$ while 6 is a second order one. This contradicts the experimental result [a]. Hence, the reaction 7a should be replaced

$$2AH\cdots O_2 \rightarrow 2A+H_2O_2+O_2 \quad (7)$$

by a bimolecular reaction and the steady state method leads to the following expression.

$$-\frac{d[A]}{dt}=\frac{d[AH_2]}{dt}=\frac{k_6\phi I_{abs}}{2(k_6+k_7)} \quad (b)$$

$$-\frac{d[O_2]}{dt}=\frac{\phi I_{abs}(2k_6+3k_7)}{2(k_6+k_7)} \quad (c)$$

Thus the result [b] requires

$$\frac{k_6}{2(k_6+k_7)}=\beta/3 \quad (d)$$

while $\gamma$ can be expressed as,

$$\gamma=\frac{d[O_2]/dt}{d[A]/dt}=\frac{(2k_6+3k_7)}{k_6}=2+3k_7/k_6 \quad (e)$$

From d and e the following relation holds,

$$\gamma=4.5/\beta-1$$

Since $\beta$ is smaller than unit, $\gamma$ should be greater than 3.5. Thus $\gamma$ does not satisfy the result [c] and we can safely reject this case.

**Case II.**—When 9, 10 and 11 are the main reactions, the steady state method leads to the following expression

$$-d[A]/dt=d[AH_2]/dt=\phi I_{abs}k_9/(k_9+k_{10}+k_{11})$$

$$-d[O_2]/dt=\phi I_{abs}k_{10}/(k_9+k_{10}+k_{11})$$

The result [b] requires that

$$k_9/(k_9+k_{10}+k_{11})=\beta/3 \quad (f)$$

and $\gamma$ is given as follows from the result [c]

$$\gamma=k_{10}/k_9=2 \quad (g)$$

From f and g

$$k_{11}/k_9=3/\beta-3 \quad (h)$$

Then, this ratio is shown for some values of $\beta$,

| $\beta$ | 1 | 0.8 | 0.6 | 0.5 | 0.4 | 0.3 |
|---|---|---|---|---|---|---|
| $k_{11}/k_9$ | 0 | 0.75 | 2 | 3 | 4.5 | 7 |

The independence of $\phi$ and $\beta$ on temperature in the deaerated solution strongly suggests that the process 1 or 3 only prevails and the process 2 does not occur appreciably. If one excludes 2, then the value of $\beta$ is limited from 1 to 1/2. The higher limit corresponds to the case in which reaction 1 prevails and the lower to the case in which reaction 3 is a chief one. In view of the fact that dimerization does not occur in diluted solution, reaction 1 seems to be more desirable than 3. Then the only possible case will be the Case II in which $\beta=1$, $k_{11}=0$. In connection with this scheme, it is to be added that there is another possibility in which a certain type of radical complex $AH\cdots RH$ with an appreciable life is formed and it is attacked by oxygen decomposing in three different ways;

1) $AH\cdots RH+O_2 \rightarrow A+RH_2+O_2$

2) $AH\cdots RH+O_2 \rightarrow A+R+H_2O_2$

3) $AH\cdots RH+O_2 \rightarrow AH_2+R+O_2$

This case is quite analogous to the above case at least kinetically.

Of course further investigations are needed to substantiate the above deduction and to

decide the scheme unequivocally. Perhaps the flash technique will be most helpfull.

## Summary

1. The deaerated solution of acridine $1 \times 10^{-4}$ M in ethanol, when irradiated by 365 mμ produces acridane with a quantum yield of about 0.13. This reductive reaction can proceed even in the air-saturated solution with the rate about one third of that of the deaerated solution. For both cases the rate is simply proportional to the absorption of light.

2. When the concentration of dissolved oxygen is more than about twice that of acridine concentration, the rate of the reaction is approximately equal to that of the air-saturated solution independent of the oxygen concentration, and at the same time oxygen is consumed at the rate about twice as great as that of the reduction of acridine. Hence, when the existent oxygen is exhausted, the rate gains the value of the deaerated solution.

3. All the above results are almost entirely independent of temperature.

4. A possible scheme was proposed in which a certain type of intermediate is formed between semireduced acridine and oxygen and, from this intermediate acridine is partially recovered accompanied with the consumption of oxygen and, in competition with this, acridane is poduced, both by a bimolecular process.

# *Electronic Structure of Benzyl Radical*[1)]

By Yuji Mori

(Received December 12, 1960)

The electronic spectrum of benzyl radical[2,3)] has been investigated theoretically by the methods of MO[4-6)] and VB[6)]. However, there is no theoretical interpretation of the correlation between the electronic structures of benzyl radical and of benzene. The purpose of the present paper is to show the electronic structure of benzyl radical in correlation with that of benzene.

The singlet states of benzene correlate with the doublet states of benzyl radical and the triplet states of benzene correlate with the doublet and quartet states of benzyl radical. Therefore, it is expected that the lowest triplet level $^3B_{1u}$ of the benzene ring will be lowered by the interaction between $\pi$-electrons of the benzene ring and methylene radical and that this will give rise to the lowest excited state $^2B_2$ of benzyl radical.

In view of this, a simpie calculation is carried out by using an approximation that the wave function of benzyl radical can be expressed in terms of the $\pi$-electron wave function of the benzene ring and that of the methylene group ($CH_2$).

## Method of Caluculation

The method of calculation is similar to the method of composite systems presented by London[7)], by Longuet-Higgins and Murrell[8)] and by the present author[9)].

The molecular orbital of the benzene ring is

$$\varphi_l(\nu)=\sqrt{6}^{-1}\sum_{t=1}^{6}\exp[-2\pi il(t-1)/6]\,\chi_t(\nu)$$

where $l=0, \pm1, \pm2, 3$ and $\chi_t(\nu)$ is the $2P\pi$ AO of the $t$th carbon atom in the benzene ring. At the carbon atom 1 the hydrogen atom is substituted by $CH_2$ and the $2P\pi$ orbital of $CH_2$ is represented by $\chi_7(\nu)$.

The wave functions oe the benzene ring are, with an obvious abbreviation,

$$\Psi_{13}=|\phi_9{}^b\cdot\chi_7|$$

* $\chi_7$ is the $2P\pi$ orbital of $CH_2$.

In order to simplify the procedure of calculation, the following assumption will be used. Namely, all of the interactions between the benzene ring and the $CH_2$ group are ignored except only that by exchange of $\pi$-electrons.

Though this is very crude and theoretically insufficient, this will not be unacceptable because the perturbation by the odd electron in the $\pi$-orbital of the $CH_2$ group is not so large that this assumption causes serious error in the results.

Neglecting non-neighbors, the interaction by electron exchange can be written

$$\iint\varphi_l(\nu)\chi_7(\mu)H\chi_7(\nu)\varphi_m(\mu)d\tau_\nu d\tau_\mu$$
$$=[l\theta H\theta m]$$
$$=1/6\iint\chi_1(\nu)\chi_7(\mu)H\chi_7(\nu)\chi_1(\mu)d\tau_\nu d\tau_\mu$$
$$=\alpha/6 \qquad (1)$$

where $\alpha$ is the exchange energy in the VB theory and $H$ is the complete electronic Hamiltonian. The value of the interaction integral is evaluated to be $-0.32$ eV. taking the value of $\alpha$ as $-1.92$ eV. as suggested by Sklar[10] and Craig[11].

## Results

The numerical values of the matrix elements are shown in Table II. In evaluating the diagonal matrix elements the energy levels of

| $^2B_2$ | 7.02 | |
| $^2A_2$ | 7.17 | |

By using the calculated wavelengths for these transitions, the oscillator strength are given

$$f_{12}=3.7\times10^{-5}$$
$$f_{16}=3.8\times10^{-3} \qquad (4)$$

## Discussion

The emission spectrum of benzyl radical has a band which was observed by Schüler[2] at about 4500 Å. This will arise from the transition between the ground state and the lowest excited state $^2B_2$(2.99 eV.). However, no absorption band which corresponds to this transition has been observed. The result that the bands arising from the lower excited states of benzyl radical will have very weak intensities will serve as an interpretation for this experimental result. By a similar consideration it will be explained that the band arising from the transition to $^2A_2$(3.42 eV.) has not been observed.

It is seen that the lower excited states of benzyl radical, $^2B_2$(2.99 eV.) and $^2A_2$(3.42 eV.), have the character of the triplet states of benzene. Then the oscillator strengths are due to the degrees of contributions from $\Psi_4$ or $\Psi_8$ which have the components of $^1E_{1u}$ of benzene. Therefore the transitions from the ground state to these excited states are almost forbidden though these are allowed by selection rule.

The small oscillator strengths to the lower excited levels were suggested by Longuet-Higgins[4] and Bingel[6] in terms of molecular orbital theory. The results of the present paper, however, differ from those by molecular orbital calculations in the order of the positions of energy levels. In the present paper, the lowest excited state is $^2B_2$(2.99 eV.). This is inconsistent with the prediction by the other calculations[4,6] that the lowest excited state of benzyl radical will be $^2A_2$. This discrepancy arises,

TABLE IV. THE ESTIMATED LOWEST EXCITED STATES OF RADICALS

| Radical | $\Delta E(T-N)$, eV. | $\lvert C_{mr}\rvert^2=\lvert C_{m'r}\rvert^2$ | $-2\lvert C_{mr}\rvert^2\cdot\alpha$, eV. | Excitation energy, eV. |

in some degree, from the difference of configuration interactions included in the calculations. In the present treatment the first order configuration interaction is that between the locally excited configurations in the benzene ring. The first order configuration interaction in molecular orbital treatment has the character of interaction between the electron transfer configurations between the benzene ring and the methylene group.

The assignment of the excited state which will give rise to the absorption band[3] at 3100 Å is uncertain, since there are two excited levels in the vicinity of 4 eV., $^2B_2$(4.18 eV.) and $^2A_2$(4.33 eV.).

The intensities of the bands arising from the higher excited states will be more intense than those of the lower ones, because larger contributions from the configurations $\Psi_4$ and $\Psi_8$ are expected.

Though the present treatment showed satisfactory results, it is difficult to undertake a more precise quantitative discussion concerning the energy levels and the intensities of the bands, because of the assumption that the effect of interaction by electron transfer is completely neglected. Therefore, the treatment in this paper may be useful for the qualitative discussion of the correlation between the electronic structures of the radical and the parent molecule, for instance, between the benzene and benzyl radicals.

As the application of this treatment, simplified consideration can be made on the lowest excited levels of some conjugated free radicals, like benzyl radical. It will be possible that the lowest excited state of a radical can be approximated by the single configuration. The component is the lowest triplet state of the parent molecule.

By this approximation, the excitation energy from the ground state to the lowest excited state of the radical will be given

$$\Delta E=\Delta E(T-N)+3/2\,[m\theta H\theta m]+1/2\,[m'\theta H\theta m']$$

In the above, $\Delta E(T-N)$ is the excitation energy from the ground state to the lowest triplet state of the parent molecule in which one electron is excited to a vacant MO $\varphi_{m'}$ from an occupied MO $\varphi_m$, and $[m\theta H\theta m]$ is the integral of interaction by the exchange of $\pi$-electron in $\varphi_m$ and the methylene group.

By using the nearest neighbor approximation, the excitation energy of the radical can be written

$$\Delta E=\Delta E(T-N)+\{3/2\,|C_{mr}|^2+1/2\,|C_{m'r}|^2\}\alpha \tag{5}$$

where $C_{mr}$ is the coefficient of $\varphi_m$ at carbon atom $r$, where the hydrogen atom is substituted by a methylene radical. In Table IV, the lowest excitation energies of the conjugated free radicals calculated by Eq. 5 are shown.

It is interesting that the excitation energy of the lowest excited state of $\alpha$-naphthylmethyl radical is lower than that of $\beta$-naphthylmethyl radical and the lowest excited states of benzyl radical and triphenylmethyl radical have the same excitation energy. Although triphenylmethyl radical is not planar, the result of this paper shows qualitative agreement with the experimental result that this radical has the first absorption band at about 5000 Å[14] with weak intensity. The lowest excitation energy of allyl radical in Table IV may be compared with those by Moffit[15], by Higuchi[16] and by Longuet-Higgins and Pople[4].

By this treatment it can be said that the lowest excited levels of each free radical in Table IV will be lower than the lowest triplet levels of the parent molecule and will give rise to a weak absorption band.

## Summary

The electronic structure of benzyl radical was shown by the approximation of the composite system in which all of the interactions

14) T. L. Chu and S. I. Weissman, *J. Chem. Phys.*, **22**, 21 (1954).
15) W. Moffit, *Proc. Roy. Soc.*, **A218**, 486 (1953).
16) J. Higuchi, *J. Chem. Phys.*, **26**, 151 (1957).

are ignored except only the interaction by exchange between $\pi$-electrons of the benzene ring and the methylene group ($CH_2$). The results are qualitively in agreement with the experimental observations[2,3] and the results of the other calculations[4,6]. The discrepancy between the results of the present paper and the other calculations are discussed.

The lowest excited states of some conjugated free radicals are also discussed.

The author is greatly indebted to professor I. Tanaka for his continuous encouragement and discussion.

## Appendix

The wave function of the ground state of triphenylmethyl radical is

$$\Psi_1=\phi_1\phi_1'\phi_1''\theta$$

where $\phi_1$, $\phi_1'$ and $\phi_1''$ are the wave functions of the ground states of the benzene rings I, II and III respectively, and $\theta$ is the $2P\pi$ orbital of carbon atom at the center of the molecule.

For the excited states, the wave functions are

$$\Psi_2^{\pm}=\sqrt{3}^{-1/2}[(\phi_3\cdot\theta)\phi_1'\phi_1'' + \exp(\pm 2\pi i/3)\phi_1(\phi_3'\cdot\theta)\phi_1'' + \exp(\pm 4\pi i/3)\phi_1\phi_1'(\phi_3''\cdot\theta)]$$

$$\Psi_3=\sqrt{3}^{-1/2}[(\phi_3\cdot\theta)\phi_1'\phi_1''+\phi_1(\phi_3'\cdot\theta)\phi_1'' + \phi_1\phi_1'(\phi_3''\cdot\theta)]$$

where $(\phi_3\cdot\theta)$, $(\phi_3'\cdot\theta)$ and $(\phi_3''\cdot\theta)$ are similar to $\Psi_3$ in the case of benzyl radical.

Therefore, neglecting non-neighbors, the lowest excitation energy is given as

$$H_{22}-H_{11}=H_{33}-H_{11} =2.95\ \text{eV}.$$

# *The Effect of Electron Transfer in the Electronic Structure of Benzyl Radical*

By Yuji MORI

(Received December 12, 1960)

In the previous paper[1], the correlation between the energy levels of benzyl radical and those of benzene has been shown by the present author, though neglecting all of the interactions between benzene ring and $CH_2$ in benzyl radical except only the interaction by exchange of $\pi$-electrons. However, there is the question as to the different results which may be obtained if the assumption of the calculation is altered. In the present paper, the purpose is to show how the results may be affected by the change of the assumption in the treatment.

In the present paper, the assumption is used that the interaction between benzene ring and $CH_2$ arises from the transfer of the electron. This assumption is introduced in the calculation by the use of the approximation of integrals suggested by Pariser and Parr[2]. This treatment is the same as the method of composite systems[3].

2) R. Pariser and R. G. Parr, *J. Chem. Phys.*, **21**, 767 (1953).
3) A. London, ibid., **13**, 396 (1945); H. C. Longuet-Higgins and J. N. Murrell, *Proc. Phys. Soc.*, **A68**, 101 (1955); Y. Mori, This Bulletin, **28**, 291 (1955).

## Calculation

The molecular orbitals of benzene ring are written in the real form as,

$$\begin{aligned}
\varphi_0(\nu) &= \sqrt{6}^{-1}\{\chi_1(\nu)+\chi_2(\nu)+\chi_3(\nu)\\
&\quad +\chi_4(\nu)+\chi_5(\nu)+\chi_6(\nu)\}\\
\varphi_1(\nu) &= \sqrt{12}^{-1}\{2\chi_1(\nu)+\chi_2(\nu)-\chi_3(\nu)\\
&\quad -2\chi_4(\nu)-\chi_5(\nu)+\chi_6(\nu)\}\\
\varphi_2(\nu) &= 2^{-1}\{\chi_2(\nu)+\chi_3(\nu)-\chi_5(\nu)\\
&\quad -\chi_6(\nu)\}\\
\varphi_3(\nu) &= \sqrt{12}^{-1}\{2\chi_1(\nu)-\chi_2(\nu)-\chi_3(\nu)\\
&\quad +2\chi_4(\nu)-\chi_5(\nu)-\chi_6(\nu)\}\\
\varphi_4(\nu) &= 2^{-1}\{\chi_2(\nu)-\chi_3(\nu)+\chi_5(\nu)\\
&\quad -\chi_6(\nu)\}\\
\varphi_5(\nu) &= \sqrt{6}^{-1}\{\chi_1(\nu)-\chi_2(\nu)+\chi_3(\nu)\\
&\quad -\chi_4(\nu)+\chi_5(\nu)-\chi_6(\nu)\}
\end{aligned} \qquad (1)$$

In the above $\chi_t(\nu)$ is the $2P\pi$ atomic orbital of $\nu$th electron at $t$th carbon atom, and $CH_2$ is attached to carbon atom 1 of benzene ring.

The unperturbed wave functions of benzyl

radical used in the present calculation are shown in Table I.

In Table I, $\chi_7(\nu)$ is the $2P\pi$ orbital of $CH_2$. The configurations from $\Psi_1$ to $\Psi_9$ are those of the previous paper[4] and these are the non-polar configuration. The electron transfer configurations from $\Psi_{10}$ to $\Psi_{25}$ (polar configurations) are neccessary to consider the effect of electron transfer.

By the use of Pariser-Parr approximation, with the neglect of penetration integral and all of the differential overlaps except resonance

4) The correlations between the electronic states of benzene and those of benzyl radical are

$\phi(^1A_{1g})-\Psi_1$; $\phi(^1E_{1u})-\Psi_2,\Psi_8$; $\phi(^1B_{1u})-\Psi_4$; $\phi(^1B_{2u})-\Psi_6$; $\phi(^3E_{1u})-\Psi_3$, $\Psi_9$, $\Psi_{29}$; $\phi(^3B_{1u})-\Psi_5$, $\Psi_{27}$; $\phi(^3B_{2u})-\phi_4$, $\phi_{28}$.

integral, the energies of the electron transfer configurations degenerate in pairs

$$H_{v,v}=H_{v+1,\,v+1}$$

where $v$ is an even number[5].

The matrix elements $H_{jk}$'s $(j\neq k)$ are not zero in the following two cases;
1) between an electron transfer configuration and a non-polar configuration of the same symmetry class both of which differ by the position of just one electron, and 2) between both electron transfer configurations of the same direction and of the same symmetry class. However, the interactions between excited electron transfer configurations are not considered, as these contribute very slightly to the energies and to the wave functions of the lower excited states of benzyl radical.

Then by taking the linear combinations

$$\left.\begin{aligned}\Psi_v^+&=\Psi_v+\Psi_{v+1}\\ \Psi_{v+1}^-&=\Psi_v-\Psi_{v+1}\end{aligned}\right\}\qquad(2)$$

each secular determinant is factored as shown in Table II. The values of the integrals are those by Pariser[6].

Then the wave functions of benzyl radical are classified into classes as follows:

The wave functions represented by the linear combinations of

a) $\Psi_1,\ \Psi_3,\ \Psi_5,\ \Psi_{11}^-,\ \Psi_{13}^-,\ \Psi_{14}^+,\ \Psi_{17}^-$
b) $\Psi_2,\ \Psi_4,\ \Psi_{10}^+,\ \Psi_{12}^+,\ \Psi_{15}^-,\ \Psi_{16}^+$
c) $\Psi_6,\ \Psi_9,\ \Psi_{18}^+,\ \Psi_{20}^+,\ \Psi_{23}^-,\ \Psi_{23}^+$
d) $\Psi_7,\ \Psi_8,\ \Psi_{19}^-,\ \Psi_{21}^-,\ \Psi_{22}^+,\ \Psi_{25}^-$
e) $\Psi_{26},\ \Psi_{27},\ \Psi_{31}^-$
f) $\Psi_{30}^+$
g) $\Psi_{28},\ \Psi_{33}^-$
h) $\Psi_{29},\ \Psi_{32}^+$

| $^4A_2$ | g | 5.12 (5.42) |
| $^2B_2$ | b | 5.29 (6.23) |

a) The values in the parentheses are those in the previous paper.

where $q(\nu)$ is the position of the $\nu$th electron, are those shown in Table III, the transitions from the ground state to the excited states of classes a and c are almost forbidden but the transitions to the excited states of classes b and d are allowed, though these four transitions are allowed by selection rule.

The energy levels of benzyl radical by the present treatment are show in Table IV.

## Discussion

The lowest excitation energy from the ground state to the lowest excited state $^2B_2$ calculated by this treatment is 2.75 eV. and this value will be compared to the transition energy 2.8 eV. of the "V"-band[7] of benzyl radical which was observed by Schüler. From the consideration on the transition moments it was shown that the transition to the lowest $^2A_2$ (3.21 eV.) of class c is almost practically forbidden and the transition to $^2A_2$ (3.75 eV.) of class d is allowed. Therefore, the absorption band observed by Porter at about 3100 Å[8] will be assigned to the excitation from the ground state to the excited state $^2A_2$ (3.75 eV.; 3300 Å).

In the present treatment, the weak intensities of the lower absorption bands are predicted though the effect of electron transfers was taken into account. There are two directions of the electron transfers. One is the electron transfer from benzene ring to $CH_2$ and the other is the reverse. Further the effect of these two electron transfers are equal in magnitude and opposite in direction, and cancel each other on the transition moments of the excitation to the states of class a. On the other hand, in the transitions to the states of class b the effect of electron transfer may be considerable, because for these transitions the two electron transfers contribute to enhance the oscillator strengths.

The effect of electron transfer on the transitions to the states of classes c and d is indirect. The directions of these transition moments are orthogonal to the direction of electron transfer. In this case, the transition moments are given by the mixing with the configuration $\Psi_8$ where the mixing arises from the electron transfer interaction. Therefore, the intensity of the transition to $^2A_2$ (3.21 eV.) may be weak, as no mixing with $\Psi_8$ occurs and $^2A_2$ (3.75 eV.) will give rise to a strong absorption band by the mixing with $\Psi_8$.

Consideration may be given to the intensities of the lowest absorption bands of radicals in which the $CH_2$ group of benzyl radical is substituted by another atom or group. By the substitution, the electronegativity of the attached group or atom is changed from that of $CH_2$. By this change the difference is given between the weights of contributions from the two opposite electron transfer states. Then the intensities of the lowest bands of these radicals may be more intense than that of benzyl radical because the effects of the two electron transfers of opposite directions do not cancel completely in such radicals.

The results of the present paper are similar to those obtained by the treatment in the previous paper[1] and also the inconsistency with the results calculated by the method of MO[9,10] is seen. This inconsistency arises from the difference of the configuration interactions included in the calculations as shown in the previous paper. The results of the present paper may be more reliable than that in the previous paper because of the improved procedure of calculation.

## Summary

The method of composite system was applied to the calculation of the electronic spectra of benzyl radical. The results are very similar to those in the previous paper[1] and there is no important difference between these two results though the procedures of calculation are different.

The effect of electron transfer on the transition moments of lower bands of some radicals was discussed.

The author wishes to express his sincere thanks to Professor I. Tanaka for his kind advice and discussions.

## Appendix

The diagonal matrix elements of the electron transfer configurations are written in the form

$$H_{jj}=E_P(j)+U(j)$$

In the above, $E_P(j)$ represents the energies of charge components in the electron transfer $j$ and $U(j)$ is the Coulomb potential between charged components.

The molecular integral are abbreviated as

$$I_{mm}=\int\varphi_m(\nu)H_{core}(\nu)\varphi_m(\nu)d\tau_\nu$$

$$[ll:mm]=\iint|\varphi_l(\nu)|^2e^2/r_{\nu\mu}|\varphi_m(\mu)|^2d\tau_\nu d\tau_\mu$$

7) H. Schüler, *Z. Naturforsch.*, **A10**, 459 (1955).
8) G. Porter and J. Norman, *Nature*, **174**, 508 (1954).
9) H. C. Longuet-Higgins and J. A. Pople, *Proc. Phys. Soc.*, **A68**, 591 (1955).
10) W. Bingel, *Z. Naturforsch.*, **A10**, 462 (1955).

$$[lm : lm] = \iint \varphi_l(\nu)\varphi_m(\nu)e^2/r_{\nu\mu}\varphi_m(\mu)\varphi_l(\mu)\mathrm{d}\tau_\nu \mathrm{d}\tau_\mu$$

$$(tt : uu) = \iint |\chi_t(\nu)|^2 e^2/r_{\nu\mu}|\chi_u(\mu)|^2 \mathrm{d}\tau_\nu \mathrm{d}\tau_\mu$$

where $\varphi_l(\nu)$ and $\varphi_m(\nu)$ are the $\pi$-electron molecular orbitals of benzene.

Applying the following relations (the last three are Eqs. 28, 46 and 47 in Ref. 6),

$$[11 : mm] = [33 : mm], \quad [22 : mm] = [44 : mm]$$

$$[12 : 12] = [34 : 34], \quad [23 : 23] = [14 : 14]$$

$$\mathbf{I}_{mm} = \mathbf{W}_{2P} - \sum_t (C_{mt})^2 \sum_{u(\neq t)} (tt : uu) + k_m\beta$$

$$2\sum_{m=0}^{2} [ll : mm] = \sum_t (C_{lt})^2 \sum_u (tt : uu)$$

$$2\sum_{m=0}^{2} \{[1m : 1m] + [3m : 3m]\}$$

$$= 2\sum_{m=0}^{2} \{[2m : 2m] + [4m : 4m]\} = (11 : 11)$$

one has

$$\mathrm{E}_P(10) = E_P(11), \qquad \mathrm{E}_P(18) = \mathrm{E}_P(19)$$

By the above equations and by the relations

$$[11 : 33] = [22 : 44], \quad [01 : 01] = [02 : 02]$$

$$[03 : 03] = [04 : 04], \quad [13 : 13] = [24 : 24]$$

the following is given

$$\mathrm{E}_P(v) = \mathrm{E}_P(v+1)$$

where $v$ is an even number.

The Coulomb potential $\mathrm{U}(j)$ is given subject to the symmetry (except U(20) and U(21)),

$$^2\mathrm{B}_2 \text{ and } ^4\mathrm{B}_2 \quad \mathrm{U}(j) = -[11 : 77]$$

$$^2\mathrm{A}_2 \text{ and } ^4\mathrm{A}_2 \quad \mathrm{U}(j) = -[22 : 77]$$

The potentials U(20) and U(21) are

$$\mathrm{U}(20) = \mathrm{U}(21) = -2[11 : 77] + [22 : 77]$$

Thus the following is given

$$\mathrm{H}_{v,\,v} = \mathrm{H}_{v+1,\,v+1}$$

# *Polarographic Determination of the Formation Constant of Sulfatonickel(II) Complex*

By Nobuyuki TANAKA and Hiroshi OGINO

(Received December 24, 1960)

In the previous paper[1], a new method for the determination of the formation constants of metal acetato complexes and its application to acetatonickel(II) complexes were presented. The method is based on the polarographic measurement of the sum of the equilibrium concentrations of hydrated metal ions and metal acetato complexes in the presence of an appropriate auxiliary complex-forming substance. Although similar functions are derived, the method is essentially different from the DeFord and Hume's method[2] that is based on the displacements of the half-wave potential of metal ions in the presence of a complex-forming substance[3].

Because of the increasing interest in the determination of the formation constants of less stable complexes, especially those with two or more different ligands, it seems worth while to generalize the treatment of the method reported in the previous paper[1] and to increase its applicability.

In the present paper, the case where a co-existing ion, $Z^{z-}$, is added to the system of Ni(II)—auxiliary complex-forming substance—acetate is dealt with. A general procedure for the determination of the formation constants of $Ni(OAc)_i^{(2-i)+}$ and $Ni(Z)_j^{(2-zj)+}$ as well as $Ni(OAc)_i(Z)_j^{(2-i-zj)+}$ is presented, and the formation constants of monosulfatonickel(II) complex, which were determined with sulfate ions used as the co-existing ion, are reported.

## Theoretical

Let us consider the acetate buffer solution which contains nickel(II)[4], nitrilotriacetate (NTA)[4] and a co-existing ion. There exist the following equilibria:

$$Ni^{2+} + X^{3-} \rightleftarrows NiX^- \quad (1)$$

$$NiX^- + H^+ \rightleftarrows NiHX \quad (2)$$

$$Ni^{2+} + i\,OAc^- + j\,Z^{z-} \rightleftarrows Ni(OAc)_i(Z)_j^{(2-i-zj)+} \quad (3)$$

1) N. Tanaka and K. Kato, This Bulletin, 32, 516 (1959).
2) D. D. DeFord and D. N. Hume, *J. Am. Chem. Soc.*, 73, 5321 (1951).
3) D. N. Hume, *Anal. Chem.*, 32, 137R (1960).
4) Nickel(II) and nitrilotriacetate may be replaced by other appropriate metal ions and complex-forming substances, respectively.

where $X^{3-}$ denotes a tervalent NTA anion and $Z^{z-}$, a co-existing ion, e. g., sulfate.

The total concentration of nickel, $[Ni]_t$, and that of NTA, $[NTA]_t$, in the solution are given in terms of the ionic and the molecular species as follows:

$$[Ni]_t = \sum_{i=0}^{n}\sum_{j=0}^{p}[Ni(OAc)_i(Z)_j^{(2-i-zj)+}] + [NiX^-] + [NiHX] \quad (4)$$

$$[NTA]_t = [NTA]_f + [NiX^-] + [NiHX] \quad (5)$$

where $\sum_{i=0}^{n}\sum_{j=0}^{p}[Ni(OAc)_i(Z)_j^{(2-i-zj)+}]$ represents the sum of the concentrations of hydrated nickel ions and complexes of nickel(II) co-ordinating with acetate and/or $Z^{z-}$ ions, and $[NTA]_f$, the sum of the concentrations of the uncomplexed NTA.

The polarographic diffusion current of nickel ions obtained in the solution which contains acetate and $Z^{z-}$ ions corresponds to the sum of the diffusion current due to the hydrated nickel ions and of those due to the complexes of nickel(II) co-ordinating with acetate and/or $Z^{z-}$ ions[1]. If the hydrated ion and the complexes have nearly the same diffusion current constants, the sum of their concentrations can be determined from the polarographic diffusion current, if necessary, after correction. Then, we write the equation as,

$$[Ni^{2+}]_{app} = \sum_{i=0}^{n}\sum_{j=0}^{p}[Ni(OAc)_i(Z)_j^{(2-i-zj)+}] \quad (6)$$

where $[Ni^{2+}]_{app}$ is the concentration that can be determined polarographically. Eq. 4 is rewritten as,

$$[Ni]_t = [Ni^{2+}]_{app} + [NiX^-] + [NiHX] \quad (7)$$

The concentrations of $NiX^-$, $Ni^{2+}$ and $X^{3-}$ are given by

$$[NiX^-] = \frac{[Ni]_t - [Ni^{2+}]_{app}}{\beta} \quad (8)$$

$$[Ni^{2+}] = \frac{[Ni^{2+}]_{app}}{\sum_{i=0}^{n}\sum_{j=0}^{p}K_{Ni(OAc)_i(Z)_j}[OAc^-]^i[Z^{z-}]^j} \quad (9)$$

$$[X^{3-}] = \frac{[NTA]_f}{\alpha} \quad (10)$$

where

$$\alpha = 1 + \frac{[H^+]}{K_{HX}} + \frac{[H^+]^2}{K_{H_2X}K_{HX}} + \frac{[H^+]^3}{K_{H_3X}K_{H_2X}K_{HX}}$$

and

$$\beta = 1 + K^H_{NiHX}[H^+]$$

$K_{H_3X}$, $K_{H_2X}$ and $K_{HX}$ represent the first, the second and the third dissociation constant of nitrilotriacetic acid, respectively, $K^H_{NiHX}$, the equilibrium constant of the reaction given by Eq. 2 and $K_{Ni(OAc)_i(Z)_j}$, the overall formation constant of $Ni(OAc)_i(Z)_j^{(2-i-zj)+}$. It may be defined that when both $i$ and $j$ are zero, the value of $K_{Ni(OAc)_i(Z)_j}$ equals unity.

The formation constant of $NiX^-$, consequently, is given as

$$K_{NiX} = \frac{[NiX^-]}{[Ni^{2+}][X^{3-}]} = \alpha\{[Ni]_t - [Ni^{2+}]_{app}\} \times \frac{\sum_{i=0}^{n}\sum_{j=0}^{p}K_{Ni(OAc)_i(Z)_j}[OAc^-]^i[Z^{z-}]^j}{\beta[Ni^{2+}]_{app}[NTA]_f} \quad (11)$$

Introducing to Eq. 11 the expression for the concentration of uncomplexed NTA given as

$$[NTA]_f = [Ni^{2+}]_{app} - [Ni]_t + [NTA]_t \quad (12)$$

the relation

$$\frac{\{[Ni^{2+}]_{app} - [Ni]_t + [NTA]_t\}[Ni^{2+}]_{app}}{[Ni]_t - [Ni^{2+}]_{app}} = \frac{\alpha}{\beta K_{NiX}}\sum_{i=0}^{n}\sum_{j=0}^{p}K_{Ni(OAc)_i(Z)_j}[OAc^-]^i[Z^{z-}]^j \quad (13)$$

is obtained. It may be obvious that both $\alpha$ and $\beta$ in Eq. 13 are constant in the solution of the given pH and the given ionic strength.

First, the values of $[Ni^{2+}]_{app}$ are determined by the polarographic method at the given pH, the given ionic strength and the given concentration of acetate, but at varied concentrations of $Z^{z-}$, with which the values for the left-hand side of Eq. 13 are calculated. In this case it may be convenient to express Eq. 13 as,

$$F_0 = \frac{\alpha}{\beta K_{NiX}}\sum_{i=0}^{n}K_{Ni(OAc)_i}[OAc^-]^i + \frac{\alpha}{\beta K_{NiX}}\sum_{i=0}^{n}K_{Ni(OAc)_i(Z)}[OAc^-]^i[Z^{z-}] + \cdots\cdots + \frac{\alpha}{\beta K_{NiX}}\sum_{i=0}^{n}K_{Ni(OAc)_i(Z)_p}[OAc^-]^i[Z^{z-}]^p \quad (13')$$

where the left-hand side of Eq. 13 is replaced by $F_0$. Eq. 13′ shows clearly that the plot of $F_0$ against the concentration of $Z^{z-}$ gives a curves of $p$th degree with respect to $[Z^{z-}]$. From extrapolation of the $F_0$ plot to the zero concentration of $Z^{z-}$, the value of $\frac{\alpha}{\beta K_{NiX}}\sum_{i=0}^{n}K_{Ni(OAc)_i}[OAc^-]^i$ is obtained. Then, the function $F_j(Z)$ $(1 \leq j \leq p+1)$ is defined as

$$F_j(Z) \equiv \frac{F_{j-1}(Z) - \frac{\alpha}{\beta K_{NiX}} \sum_{i=0}^{n} K_{Ni(OAc)_i(Z)_{j-1}} [OAc^-]^i}{[Z^{z-}]}$$

$$= \frac{\alpha}{\beta K_{NiX}} \sum_{i=0}^{n} K_{Ni(OAc)_i(Z)_j} [OAc^-]^i + \frac{\alpha}{\beta K_{NiX}} \sum_{i=0}^{n} K_{Ni(OAc)_i(Z)_{j+1}} [OAc^-]^i [Z^{z-}] + \cdots\cdots \quad (14)$$

$F_j(Z)$ is plotted against the concentration of $Z^{z-}$ and the value of $\frac{\alpha}{\beta K_{NiX}} \sum_{i=0}^{n} K_{Ni(OAc)_i(Z)_j} [OAc^-]^i$ is determined by extrapolating the $F_j(Z)$ plot to zero concentration of $Z^{z-}$. Repeating the procedure until the relation,

$$F_{p+1}(Z) = 0$$

is obtained, the value of $p$ can be determined.

Secondly, the values of $[Ni^{2+}]_{app}$ are determined by the polarographic method at the given pH, the given ionic strength and the given concentration of $Z^{z-}$, but at varied concentrations of acetate. The left-hand side of Eq. 13 is calculated and plotted against the concentration of acetate. Eq. 13 is also written as a function of the concentration of acetate:

$$F_0 = \frac{\alpha}{\beta K_{NiX}} \sum_{j=0}^{p} K_{Ni(Z)_j} [Z^{z-}]^j + \frac{\alpha}{\beta K_{NiX}} \sum_{j=0}^{p} K_{Ni(OAc)(Z)_j} [Z^{z-}]^j [OAc^-] + \cdots\cdots + \frac{\alpha}{\beta K_{NiX}} \sum_{j=0}^{p} K_{Ni(OAc)_n(Z)_j} [Z^{z-}]^j [OAc^-]^n \quad (13'')$$

From extrapolation of the $F_0$ plot to zero acetate concentration, the value of $\frac{\alpha}{\beta K_{NiX}} \sum_{j=0}^{p} K_{Ni(Z)_j} [Z^{z-}]^j$ is obtained.

The function $F_i(OAc)$ $(1 \leq i \leq n+1)$ is also defined as,

$$F_i(OAc) \equiv \frac{F_{i-1}(OAc) - \frac{\alpha}{\beta K_{NiX}} \sum_{j=0}^{p} K_{Ni(OAc)_{i-1}(Z)_j} [Z^{z-}]^j}{[OAc^-]}$$

$$= \frac{\alpha}{\beta K_{NiX}} \sum_{j=0}^{p} K_{Ni(OAc)_i(Z)_j} [Z^{z-}]^j + \frac{\alpha}{\beta K_{NiX}} \sum_{j=0}^{p} K_{Ni(OAc)_{i+1}(Z)_j} [Z^{z-}]^j [OAc^-] + \cdots\cdots \quad (15)$$

$F_i(OAc)$ is plotted against the concentration of acetate and the value of $\frac{\alpha}{\beta K_{NiX}} \sum_{j=0}^{p} K_{Ni(OAc)_i(Z)_j} [Z^{z-}]^j$ is detremined. If the procedure concerning the $F_i(OAc)$ plot is repeated at $p+1$ different concentrations of $Z^{z-}$, $(n+1)(p+1)$ pieces of equations with $(n+1)(p+1)$ unknown quantities, which are $K_{Ni(OAc)_i(Z)_j}$ $(0 \leq i \leq n,\ 0 \leq j \leq p$ except $i=j=0)$ and $\frac{\alpha}{\beta K_{NiX}}$, are yielded. Solving these equations, all of $K_{Ni(OAc)_i(Z)_j}$ can, at least theoretically, be determined.

## Experimental

**Reagents.**—A standard solution of nickel nitrate was prepared by dissolving an appropriate amount of pure nickel metal in nitric acid. The concentration of nickel was determined by the conventional gravimetric method with dimethylglyoxime[5]. A solution of disodium nitrilotriacetate was prepared from the commercial nitrilotriacetic acid (DOTITE NTA), and standardized against the standard solution of nickel(II) nitrate by amperometric titration with a similar procedure for ethylenediaminetetraacetate[6,7]. A solution of potassium sulfate was prepared from the guaranteed grade reagent. The sulfate concentration was determined by the conventional gravimetric method[8]. All other chemicals used were of analytical reagent grade.

**Apparatus and Procedure.**—A Yanagimoto PB-4 pen-recording polarograph was used for the measurement of the current-voltage curves. The dropping mercury electrode used had an $m$ value of 2.13 mg./sec. and a drop time $t_d$ of 4.07 sec., being measured in an air-free 0.2 M potassium nitrate solution containing $2 \times 10^{-6}$ M polyoxyethylene lauryl ether (LEO) at 25°C and at −0.5 V vs. SCE. The sum of the diffusion currents of hydrated nickel ions, acetatonickel(II), sulfatonickel(II) and, if any, acetatosulfatoniccolate(II) complexes were determined in the acetate buffer of pH 3.66±0.02 containing sulfate, nickel(II) and a slight excess of NTA at 15, 25 and 35°C. The concentration of acetate in the buffer was varied from 0.025 to 0.100 M at the constant concentration of sulfate of 0.03 M, while that of sulfate was varied from 0.01 to 0.05 M at the constant concentration of acetate of 0.05 M. The ionic strength of the solution was adjusted to be 0.2 with potassium nitrate. LEO was added as a maximum suppressor by $1 \times 10^{-6}$ M (at 15°C) or $2 \times 10^{-6}$ M (at 25 and 35°C) in concentration. The pH of the solution was measured

accurately, after the polarographic measurement, with a Hitachi Model EHP-1 pH meter with a glass electrode.

## Results and Discussion

The polarograms were recorded with the solution of pH 3.66 containing $1.00\times10^{-3}$ M nickel nitrate, $1.09\times10^{-3}$ M NTA and various concentrations of acetate and sulfate, unless otherwise stated. Nickel(II) gave an irreversible wave with the half-wave potential of about $-1.05$ V vs. SCE in the acetate-sulfate-nitrate media. This wave is considered to be due to the reductions of hydrated nickel(II) ions, acetatonickel(II), sulfatonickel(II) and, if any, acetatosulfatoniccolate(II) complexes. The limiting current of the wave was found to be proportional to the concentration of the electroactive species and also to the square root of the effective height of mercury column on the dropping mercury electrode. This clearly showed that the limiting current is diffusion-controlled.

The apparent diffusion current constants of nickel(II) were determined from the measurements of the diffusion current at various acetate and sulfate concentrations. The values of $[Ni^{2+}]_{app}$ of Eq. 6 were calculated, with the aid of those apparent diffusion current constants, from the limiting currents obtained with the reaction mixtures.

**Presence of Sulfato Complexes.**—The polarograms were recorded with the solutions containing 0.0500 M actate and various concentrations of sulfate at various temperatures. With the values of $[Ni^{2+}]_{app}$ obtained, the left-hand side of Eq. 13, $F_0$, was calculated and plotted against the sulfate concentration. The results are shown in Fig. 1, where it is clearly seen that the plots of $F_0$ vs. $[SO_4^{2-}]$ give straight lines. This fact indicates that $p$ is equal to 1 and no appreciable amount of complexes with two sulfates or more co-ordinated is present in the solution under the experimental conditions. From the plots in Fig. 1, the values of $\frac{\alpha}{\beta K_{NiX}}\sum_{i=0}^{n} K_{Ni(OAc)_i}[OAc^-]^i$ and $\frac{\alpha}{\beta K_{NiX}}\sum_{i=0}^{n} K_{Ni(OAc)_i(SO_4)}[OAc^-]^i$ in Eq. 13′ were determined, the former being given by the intercept at $[SO_4^{2-}]=0$ and the latter, by the slope.

**Absence of Acetatosulfato Complexes.**—The polarograms were recorded with the solutions containing 0.0297 M sulfate and various concentrations of acetate at 25°C, and the values of $[Ni^{2+}]_{app}$ were determined. The left-hand side of Eq. 13, $F_0$, was calculated and plotted against the acetate concentration. (A in Fig. 2).

A linear relation between $F_0$ and the concentration of acetate clearly indicates that $n$ is equal to 1 and no appreciable amount of complexes with two acetates or more co-ordinated is present in the solution under the experimental condition. The fact that $n$ and $p$ are equal to 1, respectively, suggests that $NiOAc^+$, $NiSO_4$ and $Ni(OAc)(SO_4)^-$ may exist in the solution under the experimental condition.

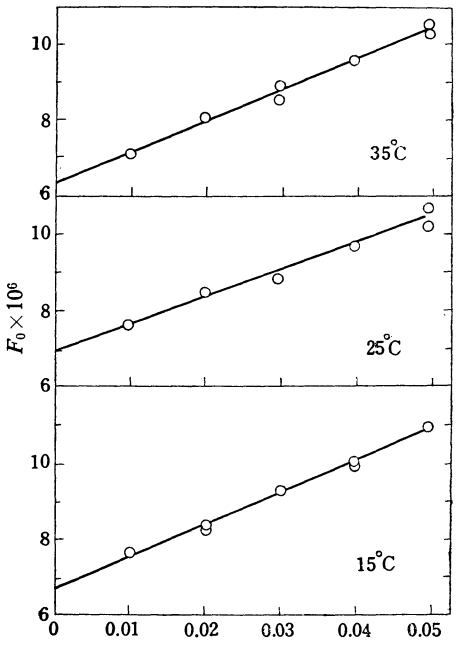

Fig. 1. Relation between the values of left-hand side of Eq. 13, $F_0$, and the concentration of sulfate at various temperatures. Acetate concentration is 0.0500 M.

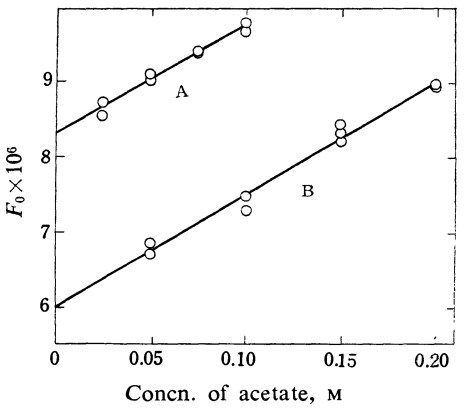

Fig. 2. Relations between the value of left-hand side of Eq. 13, $F_0$, and the concentration of acetate at 25°C, obtained in the presence of 0.0297 M sulfate (A) and in the absence of sulfate (B).

TABLE II. THE REPORTED VALUES OF FORMATION CONSTANTS OF SULFATONICKEL(II) COMPLEX

| Investigator | Method | Temp., °C | Ionic strength | $K_{NiSO_4}$ | Ref. |
|---|---|---|---|---|---|
| Money et al. | e. m. f. | 25 | 0 | 250 | 9 |
| | | | 0.2 | 22* | |
| Brown et al. | freezing point | 0 | 0 | 114～244 | 10 |
| | | | 0.2 | 8～16* | |
| Kenttämaa | freezing point | 0 | 0 | 220 | 11 |
| | | | 0.2 | 15* | |

* These are the formation constants which were calculated by the present authors with the values reported in the literature referred to.

From the following experiment, however, it is concluded that $Ni(OAc)(SO_4)^-$ is not present in an appreciable concentration: The polarograms were obtained with the solutions containing $1.00\times10^{-3}$ M nickel nitrate, $1.10\times10^{-3}$ M NTA and various concentrations of acetate but none of sulfate at 25°C and pH 3.68. The values of $F_0$ were calculated with the observed $[Ni^{2+}]_{app}$'s and plotted against the acetate concentration with a linear relation as shown by B in Fig. 2. The value of $\frac{\alpha}{\beta K_{NiX}}K_{NiOAc}$ which was determined from the slope of plot B in Fig. 2 is $1.48\times10^{-5}$, while that of $\frac{\alpha}{\beta K_{NiX}}(K_{NiOAc}+K_{Ni(OAc)(SO_4)}[SO_4^{2-}])$ obtained from the slope of plot A in Fig. 2 is $1.41\times10^{-5}$. The agreement of these two values indicates that the term $K_{Ni(OAc)(SO_4)}[SO_4^{2-}]$ is negligible and, therefore, no appreciable amount of $Ni(OAc)(SO_4)^-$ is present under the experimental condition.

**The Determination of the Formation Constant of Sulfatonickel(II) Complex.**—It has been known that nickel(II) forms only a monoacetato complex in the solution containing acetate up to 0.2 M in concentration at ionic strength 0.2 at temperature ranging from 15 to 35°C[1]. From this and the fact that $Ni(OAc)(SO_4)^-$ is considered not to be present under the experimental condition, Eq. 13′ is simplified as,

$$F_0=\frac{\alpha}{\beta K_{NiX}}+\frac{\alpha}{\beta K_{NiX}}K_{NiOAc}[OAc^-]+\frac{\alpha}{\beta K_{NiX}}K_{NiSO_4}[SO_4^{2-}]$$

The formation constant of acetatonickel(II) complex has been given as 2.6 and 2.4 at 15 and 35°C, respectively[1]. The value at 25°C was determined to be 2.5 from plot B in Fig. 2, and this value was in satisfactory agreement with that obtained previously[1]. With the aid of these values, the formation constants of sulfatonickel(II) complex at various temperatures were obtained from the intercepts and the slopes in Fig. 1. These are given in Table I.

TABLE I. FORMATION CONSTANTS OF SULFATONICKEL(II) COMPLEX AT VARIOUS TEMPERATURES

| Temp., °C | $K_{NiSO_4}$ |
|---|---|
| 15 | 14.3±0.4* |
| 25 | 11.6±0.9* |
| 35 | 14.6±0.7* |

* The accuracy of $K_{NiSO_4}$ was calculated with the standard deviations of the intercepts and the slopes of the $F_0$ plots.

The formation constants of the sulfatonickel(II) complex which have been reported by other researchers are given in Table II. The original values in their papers were corrected for ionic strength and also listed in Table II. In this calculation, the activity coefficients of nickel(II) and sulfate ions were estimated to be 0.33 and 0.27, respectively[12], at 25°C and ionic strength 0.2. At 0°C and ionic strength 0.2, they were estimated to be 0.29 and 0.23, respectively[12]. It is probably seen that the formation constants of monosulfatonickel(II) complex obtained in this study are in an essential agreement with those given in Table II.

Besides, Table I clearly indicates that the formation constants of monosulfatonickel(II) complex, $K_{NiSO_4}$, are almost independent of temperature at 15 to 35°C. The same tendency has been found for the formation constants of monoacetatonickel(II) complex reported previously[1].

## Summary

A method for the determination of the formation constants of less stable metal complexes has been developed. The method is based on the polarographic measurement of the sum of the equilibrium concentrations of

hydrated metal ions and the complexes coordinating with acetate and/or co-existing ions in the presence of an appropriate auxiliary complex-forming substance. Essential advantages of the method are those of the method that was previously reported and applied to the formation constants of acetatonickel(II) complex.

The procedure developed is applied to the study of the nickel(II) complexes present in the acetate buffer solution containing nitrilotriacetate as an auxiliary complex-forming substance and sulfate as co-existing ions. The results obtained reveal that, under the experimental condition, the monoacetatonickel(II) ions $NiOAc^+$ and the monosulfatonickel(II) $NiSO_4$ are present in the solution but not the acetatosulfatoniccolate(II) $Ni(OAc)(SO_4)^-$. The formation constants of monosulfato complex, $K_{NiSO_4}$, at ionic strength 0.2 are calculated to be 14.3±0.4 at 15°C, 11.6±0.9 at 25°C and 14.6±0.7 at 35°C.

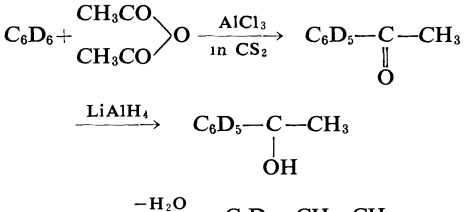
## *Infrared Spectra of Some Deuterated Crystalline Polystyrenes. III. Characteristic Bands of Isotactic Polymer from Styrene-$d_5$*



By Masamichi KOBAYASHI

(Received April 8, 1961)

In order to interpret the absorption bands characteristic of the helical conformation of isotactic polystyrene, several deuterated derivatives in which the hydrogen atoms of the skeletal chain are substituted with deuterium, such as crystalline poly-$\alpha d_1$-, poly-$\beta d_1$-, poly-$\alpha, \beta d_2$- and poly-$\beta, \beta d_2$-styrene, have been synthesized and their infrared spectra have been investigated[1,2]. It was found that the characteristic bands appearing (1) in the region of 1450~1180 $cm^{-1}$ ($1364\sigma$, $1314\sigma$, $1297\pi$ and $1195\pi$), (2) at near 1070 $cm^{-1}$ and (3) at near 900 $cm^{-1}$ were remarkably affected by the sites and the numbers of the substituted deuterium atoms. However, the frequency shifts of these bands on deuteration were not always so simple that it seemed difficult to assign them to simple vibrational modes. Although it seems reasonable to consider that the deformational vibrations of the skeletal CH and $CH_2$ groups and the stretching vibrations of the carbon chain in the helix contribute to the appearance of the characteristic bands, we could not disregard the effects of the coupling of these modes with the CH deformations of the side group, since it was known that[3] some of the characteristic bands were moderately affected by deuteration of the para position.

In order to throw some light on the problem, the infrared spectra of the polymers (both isotactic and atactic) of the monomer $C_6D_5CH=CH_2$ were investigated.

The monomer was prepared by the following scheme

$C_6D_6$ was prepared from benzene and deutero-sulfuric acid, $D_2SO_4$, by an exchange reaction, the product contained about 85 mol.% of deuterium. The monomer thus obtained was polymerized in *n*-heptane using Ziegler type catalyst, then isotactic polystrene-$d_5$ was obtained. The atactic polymer was prepared by bulk polymerization using B. P. O. as a catalyst.

In Fig. 1 the spectra of the atactic and isotactic (crystallized) polymers were compared with each other.

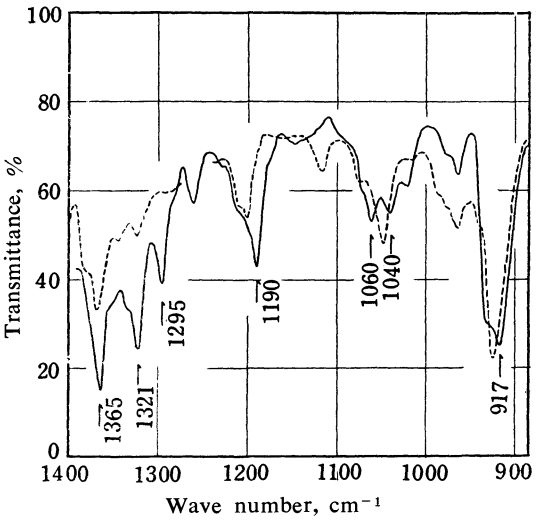

Fig. 1. Infrared spectra of polystyrene-$d_5$.
—— isotactic polymer at crystalline state
---- atactic polymer

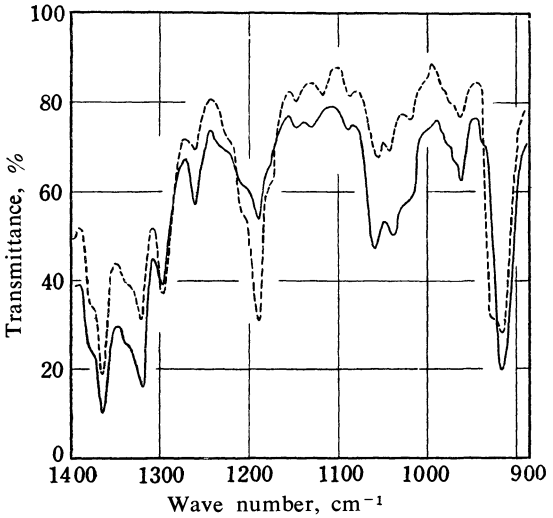

Fig. 2. Polarized infrared spectra of isotactic polystyrene-$d_5$.
—— electric vector perpendicular to elongation
---- electric vector parallel to elongation

A most noticeable feature is that the spectroscopic characters of isotactic polystyrene are observed also in our deuterated sample; the appearance of the bands at 1365, 1321, 1295 and 1190 $cm^{-1}$ and the splitting of the bands at near 1070 $cm^{-1}$ and at near 900 $cm^{-1}$ on crystallization. Especially, the bands in the region of 1450~1180 $cm^{-1}$ have almost the same frequencies and relative intensities as those of polystyrene. Moreover, as shown in Fig. 2, measurements of the polarization spectra of the oriented crystallized sample show that the polarization properties of the characteristic bands coincide with those of isotactic polystyrene.

These results may support the assumption that the CH deformations of the phenyl group have little effect upon the appearance of the characteristic bands of isotactic polystyrene, especially, those in the region of 1450~1180 $cm^{-1}$. Then, it may be concluded that the helical conformation of the isotactic polystyrene molecule reflects mainly on the absorption bands associated with the modes of the groups composing the skeletal chain.

The detail of this work will be reported in elsewhere.

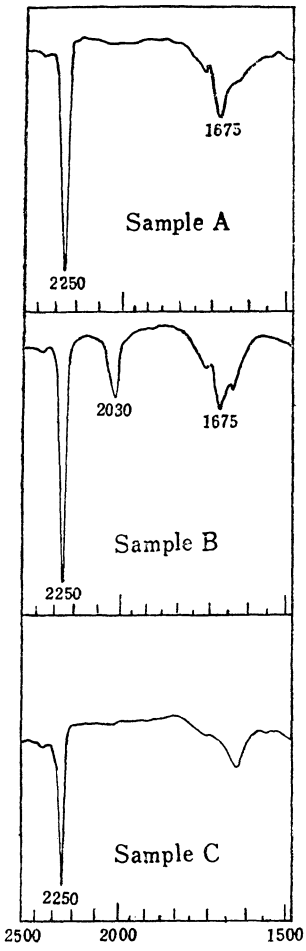
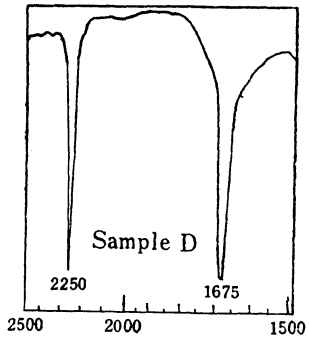
## *Infrared Spectra of Polyacrylonitrile Polymerized by Gamma-irradiation at Low Temperatures*



By Yoshizo TSUDA

(Received May 15, 1961)

In order to study the effect of polymerization condition on the infrared spectrum of polyacrylonitrile, acrylonitrile was polymerized in bulk and in various solutions by gamma-irradiation at low temperatures and it was found that the intensities of absorption bands at 1675 and 2030 $cm^{-1}$ vary according to the polymerization conditions, i. e., the solvent species and the irradiation temperatures. Figure 1 shows the infrared spectra in the 1500~2500 $cm^{-1}$ region obtained from the potassium bromide disks of some different polyacrylonitrile samples. Samples A, B and C were obtained by gamma-irradiation of pure acrylonitrile at 17, $-78.5$ and $-196$°C, respectively. Figure 2 shows that of sample D which was obtained by gamma-irradiation of acrylonitrile in triethylamine solution at $-78.5$°C. As may be seen in these figures, the absorption band at 1675 $cm^{-1}$ is much more intense in sample D than in samples A and B and this band is not observed at all in sample C. On the other hand, the band at 2030 $cm^{-1}$ which is not observed in samples A, C and D is intense in sample B. The band at 1675 $cm^{-1}$ was assigned by Liang and Krimm[1] to a vibration of an impurity. On the basis of the behavior of this band, it is sure that this band should be assigned to a vibration characteristic of a special structure of polyacrylonitrile itself.



From the copolymerization studies of acrylonitrile and styrene by gamma-irradiation at

Wave number, $cm^{-1}$

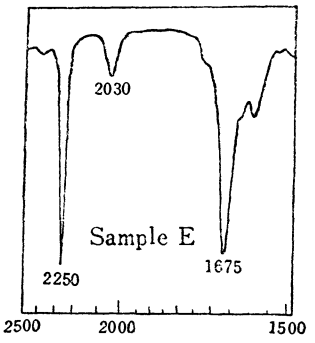

Fig. 1. Infrared spectra of polyacrylonitrile obtained by gamma-irradiation. Samples A, B and C were polymerized in bulk at 17, −78.5 and −196°C, respectively.

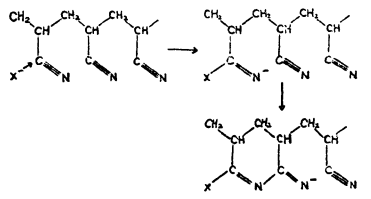
Wave number, $cm^{-1}$

Fig. 2. Infrared spectrum of polyacrylonitrile obtained by gamma-irradiation in triethylamine solution at −78.5°C.

−78.5°C[2], it was shown that the polymerization proceeds in bulk by a free-radical mechanism, on the other hand, in dilute organic solutions predominantly by an anionic mecha-



Wave number, $cm^{-1}$

Fig. 3. Infrared spectrum of polyacrylonitrile obtained by gamma-irradiation in *N*, *N*-dimethylformamide solution at −78.5°C.

nism. In view of these facts, it can be considered reasonably that the band at 2030 $cm^{-1}$ is due to the keteneimine linkage, as has been described previously[3], and the band at 1675 $cm^{-1}$ is due to the C=N linkage which comes from a reaction by an anionic mechanism. The latter band is also intense in the spectrum of polymer obtained in dimethylformamide solution as shown in Fig. 3.

In order to determine whether the C=N linkage is formed by the action of radiations on the polymer or is formed by the polymerization processes themselves, the polymer sample C which has no absorption at 1675 $cm^{-1}$ was dissolved in dimethyl formamide and then irradiated at −78.5°C. In the infrared spectrum of the irradiated polymer the band at 1675 $cm^{-1}$ was observed to be as intense as that of the sample D. When this polymer solution was irradiated at room temperature, any increase of the absorption at 1675 $cm^{-1}$ was not observed in the spectrum of the irradiated polymer. These facts indicate that the formation of C=N linkage is due to the action of radiations on the polymer in these solutions at low temperatures.

From the above consideration, the following reaction to give the conjugated C=N linkage to the polymer can be assumed to occur by gamma-irradiation at low temperatures,

where $X^-$ denotes an anion formed by the irradiation of solvent molecule at low temperatures. The formation of the same structure was also assumed recently in an anionic

polymerization of acrylonitrile[4]. This reaction proceeds easily by an anionic mechanism as shown above, however, it seems that the similar reaction proceeds also by a free-radical mechanism, the rate of formation being very small, as shown by the presence of the weak absorption at 1675 $cm^{-1}$ in the spectrum of polymer obtained in bulk.

The infrared spectra of the polymer samples were obtained using Perkin-Elmer model 21 spectrophotometer. The gamma-rays of $^{60}Co$ were used for the gamma-irradiation at the dose rate of $4 \times 10^4$ r/hr.

## *Isolation of 6-O-Methyl-D-galactose from the Agar of Ceramium Boydenii*

By Susumu HIRASE and Choji ARAKI

(Received May 27, 1961)

The chemical structure of agar has been extensively investigated in this Institute[1]. One of the present writers has assigned the linear structure consisting of D-galactose and 3, 6-anhydro-L-galactose to agarose, which is the main polysaccharide of the agar of *Gelidium amansii*[2]. Besides these two sugars, there are also contained L-galactose, xylose, D-glucuronic acid, pyruvic acid and sulfuric acid in the agar[1]. The present communication reports the isolation of 6-*O*-methyl-D-galactose in 12% yield from the hydrolysis products of the agar of *Ceramium boydenii*. This is the first reported instance of 6-*O*-methyl-D-galactose as far as agar is concerned. The synthesis of the sugar has been reported on several occasions[3-5]. It has also been isolated from the non-gelling polysaccharide of the red seaweed *Porphyra capensis*[6].

### Experimental

**Preparation of Agar.**—Agar was extracted from dry *Ceramium boydenii* with hot water and purified by freezing and thawing in the usual way. It contains 2.81% of ash and 1.18% of sulfate on the dry basis.

**Hydrolysis of the Agar.**—The agar (15 g. on the dry basis) was hydrolyzed with N-sulfuric acid (200 ml.) in a boiling water bath for 15 hr. After filtration followed by neutralization with barium carbonate and subsequent refiltration, the solution was allowed to pass through columns of Amberlite IR-120 (100 ml.) and Amberlite IR-4B (100 ml.) in succession. The resins were then washed with water (1500 ml.). All the effluents were combined and evaporated under reduced pressure to a sirup (7.5 g.). Paper chromatographic examination using *n*-butanol-ethanol-water (4 : 1 : 2 v/v) as a developing solvent and aniline hydrogen phthalate as a sprayer indicated the prensence of galactose, xylose, 6-*O*-methyl-galactose and 5-hydroxymethylfuraldehyde. The last compound would arise from 3, 6-anhydrogalactose which would have been decomposed during the hydrolysis[7].

**Isolation of 6-*O*-Methyl-D-galactose.**—The sirup obtained above afforded D-galactose on crystallization from a mixture of methanol (25 ml.) and ethanol (35 ml.); yield 2.6 g., m. p. 160~165°C; $[\alpha]_D^{24}$ +78.0° (*c* 0.80 in water). The mother liquor (4.7 g.) was then chromatographed on a charcoal-Celite column, from which a mixture (2.9 g.) of galactose and xylose was eluted with first 2 l. of water. Further elution with additional 5 l. of the same solvent afforded chromatographically pure 6-*O*-methyl-D-galactose; yield 1.8 g. (12% of the agar). The sugar was purified by recrystallization twice from absolute ethanol; m. p. 122~124°C; $[\alpha]_D^{20}$ +135°→+77.0° (*c* 1.0 in water) (Found: C, 43.15; H, 7.11; $OCH_3$, 16.15. Calcd. for $C_7H_{14}O_6$: C, 43.29; H, 7.27; $OCH_3$, 15.98%). The melting point and optical rotation reported for 6-*O*-methyl-D-galactose are: m. p. 128°C, $[\alpha]_{578}^{20}$ +114°→+77°[3]; m. p. 118°C, $[\alpha]_D^{20}$ +120°→+70°[4]; m. p. 122~123°C, $[\alpha]_D^{18}$ +112°→+66°[4]; m. p. 113~114°C, $[\alpha]_D^{18}$ +137°→+77°[5]; m. p. 122~123°C, $[\alpha]_D^{17}$ +117°→+77.3°[6]. For comparison, 6-*O*-methyl-D-galactose was prepared by the method of Freudenberg and Smeykal[3] and purified on a charcoal-Celite column. It had the same melting point and mixed melting point as that isolated above.

The sugar was also identified as its phenylosazone[3-6]: m. p. and mixed m. p. 200~201°C; $[\alpha]_D^{20}$ +140° (*c* 0.40 in pyridine) (Found: N, 14.98; $OCH_3$, 8.19. Calcd. for $C_{19}H_{24}O_4N_4$: N, 15.05; $OCH_3$, 8.33%).

# *Photoreduction of Methylene Blue by Visible Light in the Aqueous Solution Containing Certain Kinds of Inorganic Salts. I. General Features of the Reaction*

By Yoshiharu Usui, Hiroshi Obata and Masao Koizumi

(Received January 10, 1961)

In connection with the study of photoreduction of methylene blue with aliphatic amines, we did some experiments on the irreversible photodecomposition of the dye in the aerated aqueous solution[1]. It was our plan at that time to investigate systematically, varying pH of the solution, about the effect of the oxygen concentration upon the rate of this irreversible photodecomposition. But it happens that we had found the reversible photobleaching to take place with an appreciable rate in the degassed solution containing certain kinds of inorganic salts commonly used for buffering. Here "reversible" means that the dye is recovered when the air is introduced into the solution and the colorless product was confirmed to be the leuco compound of the dye. This fact which we have found seems to be of foundamental importance for the chemistry of dye in general, since the buffered solution which was found to be effective in promoting this novel photoreduction, is usually used for the dye solution. The object of this paper is to report some reults of our experiments undertaken to clarify the general nature of this extraordinary photoreduction which proceeds without any addition of particular reducing agent.

## Experimental

**Sample.** — *Methylene Blue.* — Grübler's dye was recrystallized from *n*-butyl alcohol three times and was dried in vacuum.

$$\varepsilon_{\lambda=665\,m\mu}=6.0\times10^{4}$$

*Inorganic Reagents.*—Sodium borate, sodium monohydrogen phosphate, potassium dihydrogen phosphate, sodium sulfate, sodium chloride, sodium iodide, hydrochloric acid, sodium hydroxide. All of the salts were of special grade and they were recrystallized from the redistilled water 2 or 3 times. Hydrochloric acid of special grade was distilled twice at the azeotropic point. Sodium hydroxide of special grade was used without further purification.

**Apparatus and Procedure.** — Degassing of the solution was performed in a suitable ampule by repeating freezing and evacuation 5~7 times. The solution then was poured into a reaction cell which is a spectrophotometer cell $1\times1\times4$ cm., connected to the evacuation apparatus via the tube fused to the upper part of the cell. The reaction was performed in a thermostat of $30\pm0.5$°C. The light source was a 500 W-75 V. projection lamp. It was used at $55.0\pm0.5$ V. and the intensity was checked by a photocell (PT 17 V 2) during the course of the reaction. At various time intervals, the cell was taken out and the absorption spectrum was measured by a Hitachi or a Kotaki spectrophotometer.

## Results

**1. The Irreversible Bleaching by Oxygen and the Reversible One in the Evacuated Solution.**— The feature of the photobleaching of methylene blue in the borate buffer solution containing various amounts of oxygen was examined.

The composition of the solution was as follows; methylene blue $1.2\times10^{-5}$ M, borate, $7.8\times10^{-2}$ M, hydrochloric acid $1.4\times10^{-1}$M, pH=7.62.

In case of the dye solution saturated with air, the irradiation causes a gradual decrease of the absorption spectra of methylene blue without any noticeable change of the maximum position.

When the concentration of oxygen is decreased down to $1.41\times10^{-5}$ M, the bleaching caused by irradiation is still irreversible, the introduction of air not causing any recovery of dye. It was found that the absorption maximum shifts towards violet more and more, when the oxygen concentration is decreased.

When the solution is completely degassed, the bleaching still occurs and with a much greater rate than that of the oxygen-containing solution. However, the shift of the absorption maximum is somewhat less than in the case in which the oxygen concentration is small. The notable fact in this case is that the color appreciably recovers when the air is introduced after the irradiation. The position of the absorption maximum of the aerated solution exactly coincides with that of the partially bleached solution before aeration.

The rate of bleaching is proportional to the quantity of light absorption, that is

$$k't=-\ln(e^{acd}-1)+\text{const.} \qquad (1)$$

1) H. Obata, K. Kogasaka and M. Koizumi, This Bulletin, 32, 125 (1959).

except the two cases, i. e., the completely evacuated solution and the one dissolving the least amount of oxygen.

In evaluating the value of $k'$ from Eq. 1, $\alpha$-value was conventionally chosen as $\varepsilon$-value in order to compare the results with those of the pure aqueous solution[1], and the remaining quantity of methylene blue was obtained by use of Blaisdell's[2] method. The above equation does not hold for the two exceptional cases mentioned above, the rate in these cases decreasing more rapidly than calculated by Eq. 1. In Table I are given the values of $k'$ and the shift of maximum absorption ($\Delta\lambda$) after 50 min. $k'$ for the two exceptional cases were tentative as they were calculated from the initial slope of the curve drawn according to Eq. 1.

The concentration of oxygen was analyzed by a specially designed apparatus.

Table I

| Concn. of $O_2$, M | $k'$, $min^{-1}$ | $\Delta\lambda$, m$\mu$ |
|---|---|---|
| 0 | $(2.0 \times 10^{-1})$ | 5 |
| $3.2_0 \times 10^{-5}$ | $(1.4 \times 10^{-2})$ | 9 |
| $6.76 \times 10^{-5}$ | $1.14 \times 10^{-2}$ | 8 |
| $8.58 \times 10^{-5}$ | $1.08 \times 10^{-2}$ | 5 |
| $1.13 \times 10^{-4}$ | $1.14 \times 10^{-2}$ | 3 |
| $1.53 \times 10^{-4}$ | $1.32 \times 10^{-2}$ | 3 |
| $3.40 \times 10^{-4}$ | $1.66 \times 10^{-2}$ | 0 |

As seen from Table I the value of $k'$ is not affected so much by the concentration of oxygen. The results conform well with those of the pure aqueous solution, where it was found that the rate is almost constant down to about $4 \times 10^{-5}$ M of oxygen whence the rate begins to decrease. The order of the $k'$ value is also the same as that of the pure aqueous solution, in view of the difference of the light intensity[1].

**2. Bleached Product of Methylene Blue in the Deaerated Solution.**—In order to make clear the cause for photobleaching in the evacuated solution and the recovery of color by aeration, the absorption spectra of the solution irradiated for various times were examined from 200 to 700 m$\mu$. Figure 1 shows the results obtained when the phosphate buffer solution of methylene blue was irradiated.

It is evident that accompanied with a decline of the main absorption of methylene blue, a new absorption appears in the ultraviolet region with the maximum at 255 m$\mu$. Further it is observed that the change in ultraviolet region takes place with an isosbestic point at about 273 m$\mu$. The absorption at 255 m$\mu$ coincides essentially with that of the leuco methylene blue chemically prepared, and it was almost

definitely established by Obata[3] that the bleached product is nothing but the leuco form of dye which is but partially demethylated. It is to be added here that the dotted line in Fig. 1 which represents the absorption spectra of the recovered dye after aeration, has exactly the same maximum position as that of the partially bleached solution (see Sec. 6).

In connection with the formation of leuco dye, it seems to be worthy of reconfirming and studying further what Lewis[4] et al. formerly observed. Thus they perceived a slight fall of the absorption at 660 m$\mu$ with the rise of temperature ($\Delta D/\Delta T = 0.03/40°C$) in the aqueous solution of methylene blue at three different concentrations, $9.0 \times 10^{-6}$, $1.9 \times 10^{-6}$, $6.3 \times 10^{-7}$ M, and they attributed this change to the formation of a colorless form according to the equilibrium; $D^+ + H_2O \rightleftarrows (DOH)H^+$. They, however, did not study about the change in the ultraviolet region. Hence we carefully examined the absorption spectra of the aqueous dye solution $6.3 \times 10^{-7}$ M, at various temperatures from 20 to 75°C in the region 200 ~700 m$\mu$, using a long path cell (10 cm.).

At first the aerated solution was examined at several temperatures, varying the temperature from low to high and then in the inverse direction. Three such independent experiments were done but no change beyond experimental

4) G. N. Lewis et al., *J. Am. Chem. Soc.*, 65, 1150 (1943).

error was observed. In some cases rather opposite changes were observed; thus $\varepsilon_{max}$ increased with the rise of temperature and decreased to its original value with the fall of the temperature. This would perhaps be due to the adsorption and desorption of dye on the cell wall. Thus the aerated solution did not show any sign of the phenomenon that Lewis et al. had claimed to perceive.

Next, the three analogous experiments were performed using the evacuated solution, and this time, a small depression beyond the experimental error was observed in the visible region with the rise of temperature. In addition to this change a clear reversible change was observed in the neighborhood of 250 m$\mu$. A typical result is shown in Fig. 2. It is seen that a new peak appears when the temperature is raised. Thus the formation of the colorless form that Lewis had postulated seems to be substantiated in the case of the degassed solution.

This colorless form might somehow be related to the formation of leuco dye, but there is no doubt that the change of spectra in the irradiated solution is not due to what Lewis et al. supposed to be, as was confirmed by Obata[3].

**3. Studies about the Solution Containing Various Kinds of Salts.**—Since it has become established in Sec. 2 that methylene blue is photoreduced in the presence of certain salts, the next problem is to examine whether the similar phenomena be observed for other salts and how the rate will depend upon the type of salts, including the plain aqueous solution. The salts examined were sodium borate, sodium hydrogen phosphate, potassium dihydrogen phosphate, sodium sulfate, sodium chloride, sodium iodide, hydrochloric acid and sodium hydroxide.

The results obtained were quite similar at least qualitatively in all respects, thus in regards to the spectral change, recovery of color by aeration and the maintainance of the maximum position when recovered. But the rate depends very much upon the types of salts and a quite large difference is also observed in the magnitude of the spectral shift.

In Fig. 3 some typical cases are shown.

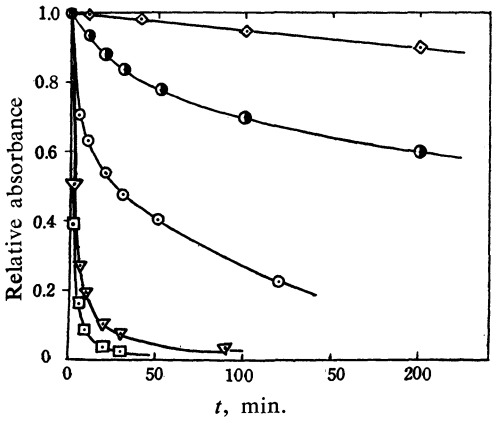

Fig. 3. Photobleaching of methylene blue in deaerated aqueous solutions containing various inorganic compounds at 30°C.

- ◈ HCl $1.0\times10^{-3}$ M (pH=3.0)
- ◑ $Na_2SO_4$ $1.0\times10^{-2}$ M (pH=6.1) (NaI, NaCl and the plain aqueous solution are similar to $Na_2SO_4$)
- ⊙ Borate buffer (pH=7.55)
- ▽ NaOH $1.0\times10^{-3}$ M (pH=10.9)
- ◙ Phosphate buffer (pH=7.57)

In the case of phosphate buffer and sodium hydroxide the rate is far greater in the order of magnitude, next comes the borate buffer and in the case of other salts and plain aqueous solution, the rate is less than one hundredth of the first class. The rate is still slower in the case of hydrochloric acid.

Experimental results are given in Table II in which $\Delta D$ and $\Delta\lambda_{max}$ are respectively the depression and the shift of the absorption maximum per twenty minutes. As for the shift, details will be described further in Sec. 6. All these solutions are of course stable in the dark.

It is well-known that methylene blue is very weak against alkali, and for caution's sake, the spectral change of methylene blue in

sodium hydroxide alkaline solution in the dark was examined.

In the case of 1 N solution, the absorption spectra in the visible region rapidly change into broader ones with a maximum near 590 mμ, whether the solution was degassed or not. When not deareated, this band remains constant after 41 hr. standing in the dark. But under the degassed condition the band gradually declines accompanied with a growth of a new peak at 250 mμ, and upon introduction of air it almost recovers its original height. When the concentration of sodium hydroxide is $10^{-3}$ N, there is no marked change observed in either aerated or deaerated solutions at room temperature. But when the temperature of the deaerated solution is raised to 60°C, a similar spectral change as in the case of 1 N sodium hydroxide (deaerated) takes place.

From the above observations it looks as if the spectral changes in the alkaline solutions are somewhat related to those in the neutral solutions caused by the temperature change. They may deserve further study but here it is enough to say that at $10^{-3}$ N sodium hydroxide scarcely any spectral changes occur in the dark at room temperature.

**4. Scrutiny about any Possible Effect of Impurity.**—In view of the rather unusual character of the present reductive reaction which proceeds without any reducing agent in the ordinary sense, it seems essential to scrutinize cautiously about the possible effect of any contaminating impurity which might act as a reducing agent, especially in cases of phosphate and borate where the rate is appreciably great. For this purpose the following experiment was performed.

Air was introduced to the nearly completely photobleached solution and the recovered dye was eliminated from the solution by adsorbing it on charcoal and filtering the solution through glass wool. Into the buffer solution thus pretreated, methylene blue was newly dissolved and the reaction was once more repeated. The rate proved to be almost the same as that of the preceeding experiment. From the above experiment any possible effect of impurity which might be contained in the buffer solution can be neglected.

Since it is very difficult to prepare a very pure sample of dye, the following special method was adopted in order to scrutinize the possible effect of any impurity contained in the dye.

According to Oster[5] the irradiation of the solution containing methylene blue, EDTA, *o*-phenanthroline and ferric salt, produces the complex between $Fe^{2+}$ and *o*-phenanthroline and the reaction persists as long as ferric salt exists in the solution. This is because the leuco form of methylene blue produced by the photochemical reaction between EDTA and dye, reduces the ferric salt, the dye being recovered by this reaction. The similar reaction should necessarily be expected in our case since the leuco dye is produced by the irradiation. Accordingly the solution containing methylene blue, borate buffer, $Fe^{3+}$ ($6.0\times10^{-4}$ M) and *o*-phenanthroline ($2.3\times10^{-3}$ M) was degassed and then irradiated. The result was that an absorption spectrum of $Fe^{2+}$-phenanthroline complex ($\lambda_{max}=510$ mμ) did appear and that the concentration of the complex produced, attained more than ten times than that of the dye. Hence it can safely be concluded that most part of the reaction is not due to any impurity contained in the dye sample. The details of this experiment will be described in Part III.

**5. Search for other Reaction Products.**—Since the dye is reduced to the leuco compound, it is naturally expected that some oxidizing substances be produced. Hence it was undertaken to detect hydrogen peroxide and oxygen.

After the reaction was performed using a cell with a breakable joint, the solvent was distilled in vacuum through the joint upon the mixed powder of ferric salt (12 mg.) and potassium ferricyanide (16 mg.). In case of borate buffer, the existence of hydrogen peroxide was in fact ascertained by a green tint, while in case of phosphate buffer no change was observed.

In case of phosphate buffer, a very small amount of gas collected (about 30% of the employed dye) after the irradiation was examined by a mass-spectrometer*. Oxygen was detected but it was interpreted to be due to the air since nitrogen and argon were also detected and the ratio of the three patterns practically coincided with that of the air. The

5) G. K. Oster and G. Oster, ibid., **81**, 5543 (1959).

* We are indebted to Professor T. Titani of Tokyo Metropolitan University for this analysis.

gas in question might have been due to the leak in the gas collection apparatus.

Thus according to this analysis no oxygen was detected. But this negative result does not necessarily deny the formation of oxygen. Because if oxygen be produced, there is no doubt that part of it must be consumed in the irreversible photo-decomposition of dye mentioned in Sec. 1. Moreover, when the phosphate buffer solution of dye partially bleached was kept in the dark for a long time, it recovered its color very gradually and this perhaps may be attributed to the existence of a very small quantity of oxygen produced during the irradiation.

**6. Relation between the Quantity of Demethylation and That of the Produced Leuco Dye.**— The shift of absorption spectra accompanied with the photobleaching can be attributed most certainly to the dimethyl amino groups[3]. Now to know the relation between these two quantities, the ratio $D/D_0$ ($D$ and $D_0$ are respectively, the optical density of maximum absorption at time $t$ and at $t=0$) is conventionally plotted against the position of maximum absorbance for all the results so far obtained. Figure 4 shows the plots for the phosphate buffer. In this case shift and bleaching apparently proceed in a parallel way and the position of absorption maximum in the final stage seems to tend toward the neighborhood of 640 m$\mu$. When the absorption spectra of a partially bleached solution is divided by Blaisdell's method into two parts, i.e. the part due to the remaining methylene blue and that of other compounds, then the absorption of the latter always has its maximum near 640~645 m$\mu$ as shown in Fig. 5.

This strongly suggests that throughout irradiation or in most periods of irradiation except

the last stage, a single molecular species is predominantly formed as a result of demethylation. In case of other salts, the relation between bleaching and shift is somewhat different from that of the phosphate buffer, as shown in Fig. 6.

There are many cases in which demethylation is appreciably delayed than bleaching. In case of borate buffer, demethylation seems to be accelerated by the increase of pH. Summarizing all the results, demethylation apparently takes place with a rate about equal to bleaching at most, or with a much smaller rate. But in all cases the band maximum of demethylated compound lies near 640~650 mμ as in the case of phosphate buffer, suggesting again the formation of a single molecular species through demethylation. An example of borate buffer is shown in Fig. 7.

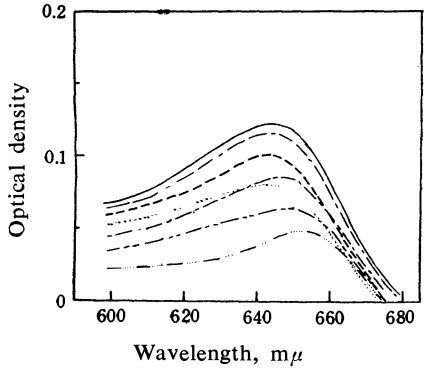

Fig. 7. The absorption spectra of the demetylated component separated by Blaisdell's treatment (in borate buffer pH=8.30).

| | | Irradiation time, min. | Opt. density remaining methylene blue at 665 mμ |

Now correct data for the absorption maximum of mono-, di-*N*, *N'*-, di-*N*, *N*- and trimethylthionine can not be found in the literature, so that the number of demethylation can not be decided from Figs. 5 and 7, though the latter two seem rather plausible.

Suspecting the possibility that a small amount of hydrogen peroxide produced might cause demethylation to occur, the effect of the addition of hydrogen peroxide was examined. Such an investigation is also desirable from the standpoint of examining the effect of the reaction product upon the entire reaction.

The experiment was done using the aqueous solution of methylene blue and the intensity of the illuminating light was chosen so great that about 90% bleaching took place in about 10 hr. Plots of $D/D_0$ against $\lambda_{max}$ are given in Fig. 8.

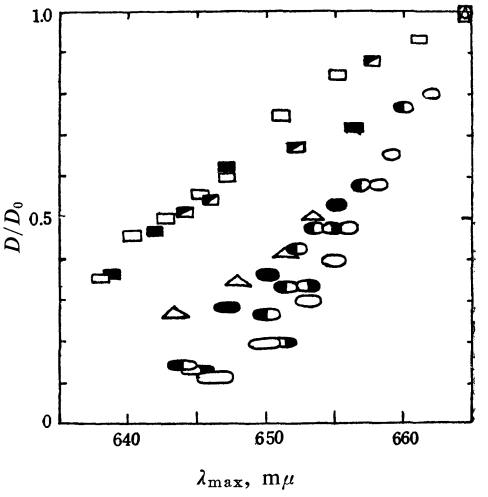

Fig. 8. Plot $D/D_0$ against $\lambda_{max}$ for the various concentrations of $H_2O_2$ in plain aqueous solution.

| | |
|---|---|
| ◩ $5.15\times10^{-4}$ M | △ $3.09\times10^{-5}$ M |
| ■ $1.03\times10^{-4}$ M | ◐ $2.58\times10^{-5}$ M |
| □ $1.03\times10^{-4}$ M | ◑ $2.06\times10^{-5}$ M |
| ● $7.20\times10^{-5}$ M | ○ 0 |

It is evident that demethylation is much accelerated when the added hydrogen peroxide exceeds $7.22\times10^{-5}$ M. But when the concentration of hydrogen peroxide is $3.9\times10^{-5}$ M or $2.5\times10^{-5}$ M, there is no noticeable effect observed. Accordingly, it is clear that demethylation occurring without added hydrogen peroxide is not due to hydrogen peroxide produced during the reaction. In the presence of a large quantity of hydrogen peroxide irreversible photodecomposition becomes marked and at $5.15\times10^{-4}$ M of the added hydrogen peroxide, the reaction consists only of the irreversible photodecomposition. But the contribution of such an irreversible decomposition is negligible when the concentration of hydrogen peroxide is $\sim10^{-5}$ M.

Of course, it was ascertained that the addition of hydrogen preoxide in the above order of magnitude does not cause any dark reaction. In connection with the above experiments, the effect of the addition of pyruvate was examined and it was found that the recovery of dye exceeds 85~90% of the original dye (measured by $D/D_0$) when it is added, as against 80% when it is not added.

## Discussion

The present reaction as a whole is very complicated and as to the dye, there occur simultaneously three types of reaction; demethylation, formation of leuco compound and the irreversible decomposition. The magnitude of the dye decomposed irreversibly is estimated at most to be about 20~30% of the entire dye disappearing (irreversible decomposition plus leuco formation), but the correct value can not be obtained since the extinction coefficient of the demethylated compound is unknown.

The fact that the magnitude of recovered dye when pyruvate is added to the plain aqueous solution (in this case no shift occurs) reaches about 90%, strongly supports the view that the greater part of the irreversible decomposition is due to some oxidative substance produced during the photoreduction. At the present stage it is not certain whether and how much the irreversible decomposition is essentially connected with the formation of leuco compound but 10% or less would be plausible from the above data.

As for the relation between demethylation and leuco formation, the following conclusions can be drawn from the experimental results. Thus the two reactions are not directly interrelated with each other but rather take place seemingly at least, as two independent simultaneous reactions; because the addition of pyruvate can almost completely suppress demethylation without essentially affecting the rate of leuco formation.

From the absorption spectra of the oxidized form of demethylated dye, the number of demethylation is perhaps one or two. The spectrum as seen in Figs. 5 and 7, rises at first and reaches a maximum when the optical density of the remaining methylene blue falls near one third of the original value and then declines gradually. The absorption spectra of the solutions which have been partially photobleached and then recolored by the introduction of air, have almost the same maximum position as that of the solution before aeration. The latter fact indicates that the ratio between methylene blue and demethylated dye in the oxidized form is quite similar to that in the reduced form. This conforms well with the fact that oxidation potential of the demethylated compound is almost the same as that of methylene blue[6]. The variation of the concentration of the oxidized form of demethylated dye, as judged from its absorption spectra, can well be interpreted, if one assumes that an equilibrium is rapidly attained between the oxidized and reduced form of methylene blue and the corresponding forms of the demethylated dye. If one further assumes that demethylation and leuco-formation have about the same rate (this situation perhaps corresponds to the case of phosphate buffer approximately) then the concentration of the oxidized form of demethylated dye will simply be given as follows.

Putting the mole fractions of the oxidized and reduced form of methylene blue as $y_1$ and $x_1$ respectively and the corresponding quantity for the demethylated dye as $y_2$ and $x_2$, then the total mole fraction of reduced form is $x=x_1+x_2$, and the total mole fraction of demethylated dye is $x_2+y_2$. From the assumption, $x_2+y_2=x_1+x_2$ or $y_2=x_1$.

If one assumes, to simplify the matter, that there is no irreversible decomposition, then $x_1+x_2+y_1+y_2=1$.

Since the percentage of the demethylated compound is the same in oxidized and reduced form, the following formula can easily be obtained, utilizing the above relations.

$$x_1/y_1=y_2/y_1=x_2/y_2=(1-y_1-y_2)/(y_1+y_2) \quad (2)$$

Hence

$$y_2=-y_1+\sqrt{y_1}$$

From the following figures calculated by Eq. 2 one can see how the changes in $y_1$ and $y_2$ are related with each other.

| | | | | | | | |
|---|---|---|---|---|---|---|---|
| $y_1$ | 0.81 | 0.49 | 0.25 | 0.16 | 0.09 | 0.04 | 0.01 |
| $y_2$ | 0.09 | 0.21 | 0.25 | 0.24 | 0.21 | 0.16 | 0.09 |

For the sake of completeness, the numerical figures will be given below when the rate of demethylation is 0.7 and 0.5 times that of bleaching, i. e. $x_2+y_2=0.7(x_1+x_2)$ and $x_2+y_2=0.5(x_1+x_2)$.

| $x_2+y_2=0.5(x_1+x_2)$ | | | | | | | |
|---|---|---|---|---|---|---|---|
| $y_1$ 0.8 | 0.6 | 0.5 | 0.4 | 0.3 | 0.2 | 0.1 | 0.04 |
| $y_2$ 0.06 | 0.104 | 0.118 | 0.125 | 0.122 | 0.106 | 0.070 | 0.034 |
| $x_2+y_2=0.7(x_1+x_2)$ | | | | | | | |
| $y_1$ 0.8 | 0.6 | 0.5 | 0.4 | 0.3 | 0.2 | 0.1 | 0.04 |
| $y_2$ 0.076 | 0.135 | 0.157 | 0.172 | 0.174 | 0.162 | 0.12 | 0.10 |

The real situation is that the irreversible decomposition always takes place more or less, but it is evident from the above data that the changes of absorption spectra of methylene blue and the demethylated dye in most cases (Figs. 5 and 7) correspond to the case that demethylation has roughly the same rate as that of bleaching.

The result that a small quantity of dissolved oxygen increases the degree of demethylation,

6) L. Rapkin, A. P. Struky and R. Wurmser, *J. Chim. Phys.*, **76**, 340 (1926); See also Part II of this series.

can be accounted for as due to the repeated reoxidation of leuco dye, since this process retards the leuco-formation, increasing the relative magnitude of demethylation.

In some cases demethylation is found to proceed noticeably at a later stage and this strongly suggests, as already mentioned, that the reduced dye is more susceptible to demethylation. Thus it is plausible that demethylation and bleaching are in this sense related with each other although they are in fact independent simultaneous reactions.

A brief structural discussion will be added at the end.

Since demethylation is related with the amino group of a side chain while the formation of leuco dye is connected with the ring nitrogen, it is natural that the two reactions take place independently. In general demethylation is considered to take place oxidatively so that it is plausible in the present case that the (transient) removal of the lone pair electrons participates in the course of demethylation. This view seems to account for the difference of salts in suppressing demethylation. Thus according to the results so far obtained less demethylation seems to occur in the presence of $SO_4^{2-}$, $Cl^-$, $I^-$, $OH^-$ when compared with borate and phosphate, and this might be due to the attachment of such simple anions to the amino group which hinders the removal of lone pair electrons. The anticipation that the leuco form is more susceptible to demethylation is compatible with the above view, since the leuco dye is electroneutral and can not combine with an anion. This might be the reason why demethylation becomes more pronounced at a later stage.

As for the formation of leuco dye, it is most plausible to consider that the primary process for the reaction consists in the acceptance of an electron by the excited dye, but it is not known at the present stage what kind of molecular species acts as an electron donor. It is conceivable that the amino group of the dye molecule plays this role, but there seems to be another possibility that hydroxide ion loosely attached to or existing in the neighborhood of ring nitrogen behaves as an electron donor. The latter possibility might be supported by the existence of a colorless form $(DOH)H^+$ which Lewis first postulated and which the present paper further supports.

At any rate there is scarcely any doubt that the ultimate fission of water by the visible light is taking place in this case. Such a possibility was formerly considered as a very unlikely event from the standpoint[7] of energy, but recently experimental evidence for such a process to occur, seems to be rather strengthened[8]; the present result, we believe, demonstrates unequivocally that it can really occur though the mechanism is still entirely unknown and is to be solved in future.

## Summary

It was discovered that the irradiation of the aqueous solution of methylene blue containing various kinds of salts, produces the leuco form of dye; accompanied with this reaction, irreversible photodecomposition of dye and demethylation occurs to some extent. Hydroxide, phosphate and borate were found to be most effective in promoting this photoreduction. Careful studies were performed to counteract the possible effect of impurity. Since the present reaction was considered most certainly to be due to the ultimate fission of water, the analysis for Oxygen and hydrogen peroxide was undertaken. The former was not detected by means of a mass-spectrograph in case of phosphate, but the latter was chemically detected in case of borate buffer. The connection between the quantity of demethylation and that of the formation of leuco dye was investigated and clarified to some extent.

# *Photoreduction of Methylene Blue by Visible Light in the Aqueous Solution Containing Certain Kinds of Inorganic Salts. II. Photobleached Product*

By Hiroshi OBATA

(Received January 10, 1961)

Koizumi, Usui and the present author have discovered[1] that the deaerated aqueous solution of methylene blue undergoes photobleaching by visible light, and they have clarified the general features of the phenomenon. The bleached solution has a well-defined absorption spectra with a new peak at 256 m$\mu$ and the color is recovered when air is introduced into the solution. It was further established that the absorption peak of the remaining oxidized form gradually shifts accompanied with the bleaching reaction. Also the recovered dye has its maximum at about 640 m$\mu$, which is essentially the same as the ultimate position of the remaining oxidized form before aeration.

As regards the photobleaching it seems most probable to attribute it to the formation of leuco dye, but if so, one has perhaps to assume the ultimate fission of water by visible light, which occurs with great difficulty for the energetic reason. If the photobleached product be some substance other than the leuco dye, this difficulty may be avoided. In connection with such a possibility it seems necessary to pay some attention to Lewis' suggestion[2] that a certain colorless form of methylene blue with the structure $(Mb^+\cdots OH^-)H^+$ ($OH^-$ is attached to ring nitrogen) exists in the aqueous solution. In case the photobleached product be such a substance or some others related with it instead of the leuco dye, then its chemical behavior would be expected to be quite different from that of the chemically prepared leuco dye which is believed to be MbH.

Secondly, as to the cause for the shift of the absorption maximum, Yoshida's work seems to be noteworthy[3]. He concludes that in the alcoholic solution methylene blue is demethylated by exposure to the visible light accompanied with the photoreduction. It seems natural to expect that the same reaction occurs in the aqueous solution, but as another possibility, the photo-hydrolysis of the dimethylamino group cannot be neglected a priori since it is well-known that in the alkaline aqueous solution, methylene blue is converted into methylene violet[4].

The present paper concerns the elucidation of the above two problems, and the investigation consists mainly of the comparison between the chemically prepared leuco dye and the photobleached product from the following three standpoints.

1) Comparison of the absorption spectra of the photobleached product with those of leucomethylene blue, benzoylleucomethylene blue and acetylleucomethylene blue. The latter two substances are considered to have a structure related with MbOH.

2) Comparison of the oxidative and reductive behavior of the photobleached product with that of leucomethylene blue.

3) Comparison of the pH dependence of the absorption spectrum of the photobleached product and that of leucomethylene blue.

The results lead to the conclusion that the photobleached product is most certainly a leuco dye partially demethylated.

## Experimental

**Materials.**—*Methylene Blue.*—Grübler's reagent was recrystallized twice from water and then once more from butanol. The molar extinction coefficient was 62000. Most experiments were done with the solution of $2\times10^{-5}$ mol./l.

*Leucomethylene Blue.*—The deaerated solution of methylene blue was reduced to the leuco form by warming the solution to about 60°C with a small amount of zinc powder. The maximum of the absorption spectrum of this solution is 256 m$\mu$ and the value agrees with that of the solution reduced by sodium hydrosulfite or hydrogen with palladium asbestos. This result ensures that the solution reduced by adding zinc powder is leucomethylene blue. The solution reduced by passing hydrogen in the presence of palladium asbestos was used for a few experiments.

**Benzoylleucomethylene Blue and Acetylleucomethylene Blue**[5].—*Leucomethylene Blue.*—A solution of 25 g. of methylene blue in 500 ml. of water was heated almost to boiling, 25 g. of zinc powder was

5) G. Cohn, *Ber.*, **33**, 1567 (1900); L. Chalkley, *J. Am. Chem. Soc.*, **47**, 2057 (1925).

added and then, during vigorous stirring, 70 ml. of pure concentrated hydrochloric acid was added as quickly as possible. After a few minutes, the color of this solution changed to pale greenish yellow. The filtrate was allowed to stand in the nitrogen atmosphere overnight; it was then cooled in an ice-bath and filtered. The precipitate obtained was well dried in a vacum desiccator. This precipitate was greenish and stable in the air for several days; yield 30 g.

*Benzoylation.*—The 4.5 g. of dry zinc salt obtained was dissolved in 9 ml. of dry pyridine, previously deoxygenated by flashing with nitrogen gas, and the solution was treated with 5 ml. of benzoyl chloride, heated for one hour in the nitrogen gas, and then allowed to stand overnight. The reaction mixture was poured into a large volume of cold water, the tarry substance that separated off was washed with 10% sodium carbonate solution and with water until it became a white powder, and then it was extracted with 10% hydrochloric acid. The acidic solution was made alkaline with aqueous ammonia and the white precipitate was collected and dried. The dried substance was recrystallized twice from alcohol. The crystalline substance obtained was pale yellow and melted at 190.5~192°C. The molar extinction coefficient was 55000.

**Acetylation.**—Acetylation was done with acetic anhydride by the same method as benzoylation. The melting point was 180.3~180.5°C, pale green. The molar extinction coefficient was 51000.

$K_3Fe(CN)_6$, $K_4Fe(CN)_6$ — G. R. reagents were recrystalized from water three times.

$SnCl_4 \cdot 5H_2O$, $SnCl_2 \cdot 2H_2O$ — G. R. reagents were used without further purification.

**Apparatus for Photobleaching and Procedures.**—Figure 1 shows the main part of the apparatus for bleaching the aqueous solution of methylene blue. As a light source, two tungsten lamps for spot light (500 W) were employed and the range of wavelength was chosen by means of a filter (Mazda VR2) and any shorter wavelength than 600 m$\mu$ was cut off completely. The reaction cell was a glass rectangular type for Beckman spectrophotometer and could be degassed. Absorption spectra were measured by a Kotaki or Hitachi spectrophotometer according to the visible or ultraviolet region. The photobleaching reaction of methylene blue was carried out in the aqueous solution without any buffered reagents at 30°C.

## Results

**Photobleaching of Aqueous Methylene Blue Solution in Vacuo.**—It required more than ten hours for the aqueous methylene blue solution to be bleached in vacuo. After the irradiation of 10 hr., there remained about ten per cent of the oxidized form and the wavelength of absorption maximum (667 m$\mu$) moved to about 640~650 m$\mu$. Further, when the bleached solution was exposed to the air, the solution regained the blue color and the position of the absorption peak was practically the same as in the case of the above value. The optical density of the recolorized solution was about 70 per cent that of the original methylene blue solution. Thus the general features of the spectral change is quite similar to that in the case of the buffered solution[1].

**Comparison of the Absorption Spectra of the Photobleached Product with Those of the Related Compounds.**—If there should exist any difference in the absorption spectra of leucomethylene blue (DH) and those of DOH, the photobleached product would easily be identified spectroscopically. But the fact is that nothing has been reported about DOH, except Lewis' proposal so far as the author knows and still less about its absorption spectra. For the purpose of getting knowledge about the absorption spectra of DOH, those of the synthesized benzoylleucomethylene blue and acetylleucomethylene blue were measured.

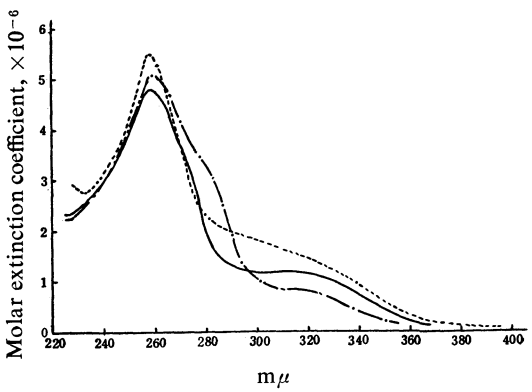

Fig. 2. Absorption spectra of leucomethylene blue and its derivatives.
—— Leucomethylene blue
----- Benzoylleucomethylene blue
—·— Acetylleucomethylene blue

These were fairly stable in the aerated condition and were expected to have the absorption band similar to that of DOH, because they are closely related with DOH in structure. The absorption spectra of benzoylleucomethylene blue and acetylleucomethylene blue were compared with that of leucomethylene blue in alcoholic solution. Figure 2 shows the absorption spectra of these three substances. They are similar in shape and the wavelengths of the maxima agree fairly completely. These results suggest that the absorption bands of DH and DOH resemble each other, hence one can not decide spectroscopically whether the photobleached product be DH or DOH.

**Comparison of the Oxidative and Reductive Behavior between Photobleached Product and Leucomethylene Blue.**—The reactivity of the photobleached product was compared with that of leucomethylene blue. The outline of the principle for this comparison is as follows. Two solutions containing respectively about equal amounts of leucomethylene blue and the photobleached product are added in vacuo, each to the same amount of solution containing a definite quantity of a suitable oxidation reduction system. Then the quantity of dye which has been oxidized is determined spectroscopically. The comparison of the ratio of the colored and colorless species in the equilibrium state for the two cases would be useful for the identification of the photobleached product. The reagents chosen are (1) $K_3Fe(CN)_6$–$K_4Fe(CN)_6$ system, (2) $SnCl_4$–$SnCl_2$ system and (3) thionine-leucothionine system.

(1) *The Reaction with $Fe(CN)_6^{3-}$—$Fe(CN)_6^{4-}$ System.*—The mixture of $K_3Fe(CN)_6$ and $K_4Fe(CN)_6$, each $1.6\times10^{-5}$ mol., was added in vacuo to 7 ml. of the solution containing the dye system (leucomethylene blue or the photobleached product). The calculated concentration of $K_3Fe(CN)_6$ and $K_4Fe(CN)_6$ in the solution thus prepared, being $2.3\times10^{-3}$ mol./l., was about 100 times that of the dye-system. As expected from the values of $E_0'$ at pH 7 (0.43 V. for $Fe(CN)_6^{3-}$-$Fe(CN)_6^{4-}$, 0.011 V. for methylene blue-leucomethylene blue)[6] the addition of $K_3Fe(CN)_6$–$K_4Fe(CN)_6$ system to the solution of methylene blue rapidly produced a blue color of the oxidized dye; but the solution gradually changed its color and turned to a green tint after a few minutes. As to the photobleached solution, a change quite similar to that above was observed.

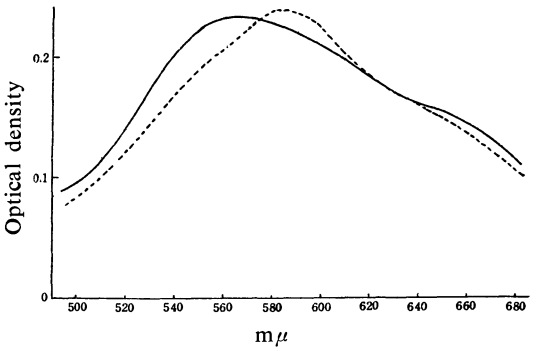

Fig. 3. Absorption spectra of the complex with $K_3Fe(CN)_6$.
—— Oxidized form of the photobleached product
---- Oxidized form of leucomethylene blue

In Fig. 3 the absorption spectra of these two solutions are shown and in addition, that of the aqueous methylene blue solution containing $K_3Fe(CN)_6$. A large shift of $\lambda_{max}$ of methylene blue suggests the formation of a certain complex between the dye and $K_3Fe(CN)_6$. A further shift for the photobleached product, ca. 15 mμ corresponds, without doubt, to that of the component dye.

(2) *The Reaction with $Sn^{4+}$—$Sn^{2+}$ System.*—In this case a more quantitative comparison can be done. Thus when a large quantity of the solution containing $SnCl_4$ and $SnCl_2$, 1 : 1 in mole ratio, is added to the solution of the reduced dye, the latter will be oxidized to such an extent that its potential attains the value of $Sn^{4+}$-$Sn^{2+}$ system, which on account of its great excess, maintains practically its original value. The concentration of oxidized form ($X_o$) and that of reduced form ($X_r$) of dye in the equilibrium state can easily be obtained spectroscopically by measuring the optical density of the above solutions in both deaerated and aerated conditions, the former providing the value of $X_o$ and the latter $X_o+X_r$. In this way the value of $X_o/X_r$ in two cases, leucomethylene blue and the photobleached product can be compared at a constant oxidation reduction potential determined by $Sn^{4+}/Sn^{2+}$ ratio.

In practice the experiment was done as follows. The stock solutions of stannic chloride and stannous chloride both in 1 N hydro chloric acid were neutralized by sodium acetate to adjust the pH value to 5. Two milliliters of 1 : 1 stannic chloride-stannous chloride solution was added to 5 ml. of reduced dye solution, the concentration of stannic chloride and stannous chloride having been suitably selected to make their ultimate concentration 0.02 mol./l. Upon mixing, the blue color immediately

6) M. Clark, "Oxidation Reduction Potential in Organic System", Williams & Wilkins Co., Balimore (1960), p. 132; L. F. Hewitt, "Oxidation-Reduction Potential in Bacteriology and Biochemistry", 6th Ed., Livingstone Ltd., Edinburgh (1950), p. 21.

appeared and its optical density was measured at 660 and 645 mμ respectively for the case of leucomethylene blue and the photobleached dye. Aerating the system the optical density was measured once more at the above wavelengths. Typical results are shown in Table I.

TABLE I. OPTICAL DENSITY OF LEUCOMETHYLENE BLUE AND THE PHOTOBLEACHED PRODUCT AFTER ADDING $SnCl_4$-$SuCl_2$ SYSTEM

| | Leucomethylene blue | Photobleached product |
|---|---|---|
| Deaerated state | 0.201 | 0.286 |
| Aerated state | 0.352 | 0.380 |
| $X_o/X_r$ | 1.331 | 3.04 |

$E_0'$ value of the photobleached product may be evaluated in the following way. The oxidation-reduction potential of the solution which is practically decided by the $Sn^{4+}/Sn^{2+}$ ratio is expressed as follows.

$$E_h = E'_{o_{Sn}} + \frac{RT}{2F} \ln \frac{[Sn^{4+}]}{[Sn^{2+}]}$$

$$= E'_{o_{Mb}} + \frac{RT}{2F} \ln \frac{X_{o_{Mb}}}{X_{r_{Mb}}}$$

$$E'_{o_{ph}} + \frac{RT}{2F} \ln \frac{X_{o_{ph}}}{X_{r_{ph}}}$$

where $E'_{o_{Sn}}$, $E'_{o_{Mb}}$ and $E'_{o_{ph}}$ are respectively the midpoint potential (the potential when the concentration of oxidant and reductant is the same) of $Sn^{4+}/Sn^{2+}$, methylene blue, and the photobleached system at pH 5. Using the value of $E'_{o_{Mb}}$ (0.101 V.)[6] in the literature and the value of $X_{o_{Mb}}/X_{r_{Mb}}$ in Table I, one can determine the $E_h$ value, which was found to be 0.1048 V. Since $E_h$ has the same value for the photobleached system, one can easily get $E'_{o_{ph}}$ from $X_{o_{ph}}/X_{r_{ph}}$. The value obtained is 0.090 V. which is close to the value of methylene blue.

(3) *The Reaction with Thionine-Leucothionine System.*—$E_0'$ of thionine is only a little higher than that of methylene blue and the light absorption by thionine is almost negligible in the concentration $10^{-5}$~$10^{-6}$ mol./l. at a wavelength of the absorption maximum of methylene blue. But, if the concentration of the thionine solution was chosen above $10^{-3}$ mol./l. in order to keep the value of $E_h$ approximately constant after mixing, then the absorption of thionine at 665 mμ would become so great that it would prevent a simple spectroscopic analysis of the methylene blue system. Moreover it is troublesome to prepare a solution containing a definite amount of thionine and leucothionine and to add it to the solution to be tested in vacuo. For this reason the analogous experiment as in the case of $Sn^{4+}$-$Sn^{2+}$ system was not undertaken in this case and the following procedure was adopted. A suitable amount of thionine solution ~$10^{-6}$ mol./l. in concentration is added to the solution to be examined in order to oxidize about a half of the existent leuco form. In case of leucomethylene blue, the concentration of oxidized form produced by the addition of thionine can easily be obtained spectroscopically. The total sum of oxidized and reduced form is also determined by measuring the optical density of the solution after aeration. From these two values the concentration of the oxidized and reduced forms of methylene blue as well as thionine in the equilibrium can easily be calculated. The use of $E_0'$ value of thionine[6] (0.068 V. at pH 6.8) enables one to decide the $E_0'$ value of methylene blue and vice versa. After having checked the above method by leucomethylene blue, it was applied to the photobleached product in order to estimate its $E_0'$ value. But in this case the exact value for the concentration of oxidized and reduced form can not be decided spectroscopically because of the lack of the molar absorbancy. As an approximation the value of the molar extinction coefficient of methylene blue at 665 mμ was provisionally used.

To illustrate by an example, the absorption spectra when 3 ml. of thionine solution was added to the solution of 5 ml. of photobleached product are shown in Fig. 4. Curves ② and

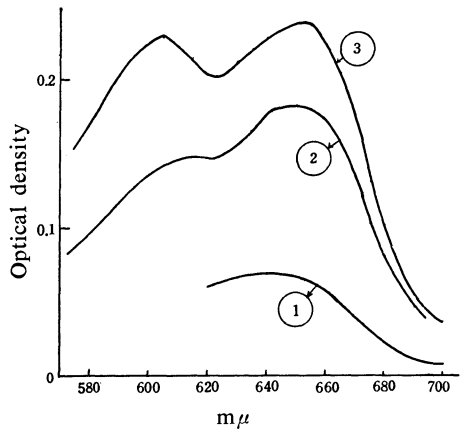

Fig. 4. Absorption spectra of the photobleached product when thionine solution added.

③ refer respectively to the deaerated and aerated solution and ① is the absorption spectrum due to the remaining oxidized form in the original photobleached solution (after having been corrected for dilution). From these data the concentration of each species in the equilibrium state was calculated and shown in Table II.

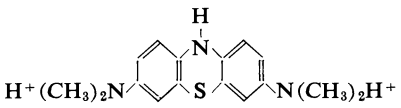

TABLE II. CONCENTRATION IN THE EQUILIBRIUM STATE BETWEEN THIONINE AND THE PHOTOBLEACHED PRODUCT

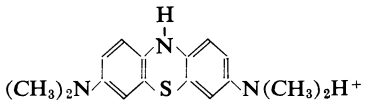
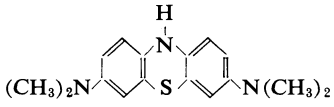
| | Oxidized form | Reduced form | $E_h$ |
|---|---|---|---|
| Thionine | $0.08\times10^{-6}$ | $2.04\times10^{-6}$ | 0.0257 |
| Photobleached product | $3.64\times10^{-6}$ | $1.10\times10^{-6}$ | |

(The oxidized form remaining in the original photobleached solution: $1.6\times10^{-6}$ mol./l.)



From the data in Table II $E_o'$ of the photobleached product was calculated to be 0.0101 V. Two other similar experiments gave the values, 0.0090 and −0.0122 V. The average is 0.0023 V. It is to be added that when 10% less value is used for the extinction coefficient of the photobleached product, $E_o'$ value in the above case varies from 0.0101 to 0.028 V.; thus the value itself is not so exact, but it is certain that it is close to that of methylene blue.

**Comparison of the pH Dependence of the Absorption Spectra between Methylene Blue and the Photobleached Product.**—Leucomethylene blue ionizes in two steps at pH 4.5 and 5.9, that is, there are three species of leucomethylene blue in respective pH regions as shown below.



(a)

pH<4.5

(b)

4.5<pH<5.9

(c)

pH>5.9

Accordingly, the absorption spectra of leucomethylene blue in three pH regions may be different from each other. This was examined and the analogous experiment was done also for the photobleached product. Five milliliters of the solution of leucomethylene blue or the photobleached product was poured into 2 ml. of the acetate buffer solution in vacuo. The pH values chosen were 3.54, 4.02, 5.00, 6.62 and 8.25 each successively corresponding to the region where the species a, a, b, c, and c are predominant.

One could find, however, no differences between methylene blue and the photobleached product both in shape and in the position of the maximum wavelength at all pH values, the latter always being at 256 mμ. But some difference was found in the molar extinction coefficient at 256 mμ, with the highest value at pH 5 and decreasing both in larger and smaller pH regions. The results are shown in Table III and Fig. 5. In Table III the optical

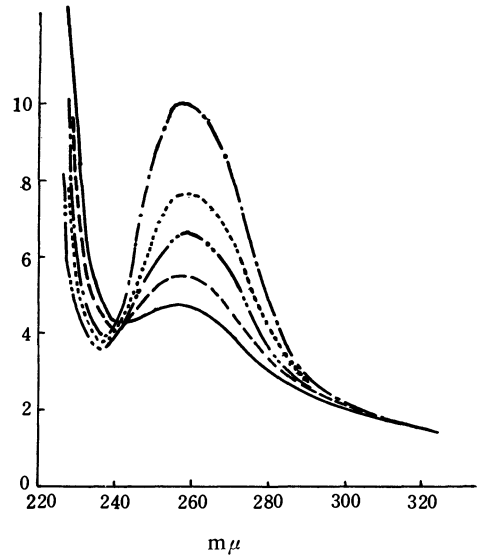


Fig. 5. Absorption spectra of the photobleached product in respective pH value.
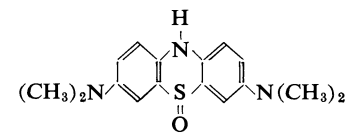
(Absorption bands in shorter wavelength than 240 mμ are caused by acetic acid.)

——— pH 3.54 ····· pH 6.62
------- pH 4.02 —·—· pH 8.62
— · — pH 5.50

density of the leuco form at the maximum absorption (256 mμ) (denoted as B), that of the oxidized form produced by aeration of the respective solution of leuco form (at 665 mμ for methylene blue and 645 mμ for the photobleached product) (denoted as A), and the ratio B/A are tabulated. The value of B/A or its relative value standardized to that at pH 5 would be a measure of the molar extinction coefficient at 256 mμ of leuco dye, because the absorption spectrum of methylene blue is essentially the same in the above pH region and the same would perhaps apply to the photobleached product.

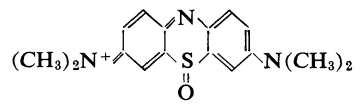
In evaluating the data in Table III it must be noted that a certain correction was made for a small amount of coexisting oxidized form in the solution of leuco dye, by making use

TABLE III. OPTICAL DENSITIES IN VARIOUS pH VALUES



| | | pH | | | | |
|---|---|---|---|---|---|---|
| | | 3.54 | 4.02 | 5.00 | 6.62 | 8.25 |
| Photobleached product | A | 0.442 | 0.335 | 0.186 | 0.380 | 0.372 |
| | B | 0.610 | 0.561 | 0.405 | 0.463 | 0.384 |
| | B/A | 1.447 | 1.675 | 2.18 | 1.22 | 1.033 |
| | Relative value | 0.663 | 0.768 | 1 | 0.559 | 0.474 |
| Leucomethylene blue | A | 0.340 | 0.243 | 0.230 | 0.160 | 0.164 |
| | B | 0.284 | 0.367 | 0.254 | 0.168 | 0.161 |
| | B/A | 0.836 | 0.992 | 1.045 | 0.730 | 0.636 |
| | Relative value | 0.798 | 0.947 | 1 | 0.698 | 0.606 |

of the fact that the ratio of the optical density at 256 m$\mu$ to that of 665 m$\mu$ or 645 m$\mu$, as the case may be, in the oxidized form is approximately 1 : 3.



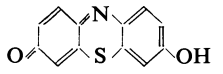
From the above results it is certain that as regards the pH dependence of the absorption spectrum there is no marked difference between leucomethylene blue and the photobleached product.

## Discussion

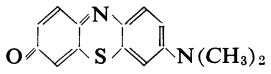
From the results obtained in the present paper which demonstrate clearly the marked resemblance between the photobleached product and leucomethylene blue both in oxidative and reductive behavior as well as acid base character, there scarcely remains any doubt that the photobleached product is a leuco form dye. Lewis' colorless species $(DOH)H^+$ [2], for which the oxidative and reductive behavior as observed would never be expected, can safely be rejected as a photoproduct. But here another conceivable substance which is speculative but somewhat fascinating will be mentioned in connection with this colorless form. This is a compound supposed to be formed, should $OH^-$ be photochemically split into $H^-$ and O (I). It may happen that this is oxidized to II by aeration. If such a compound as I were

(I)

(II)



formed, there might be a possibility that the photofission becomes more feasible and that such a reaction is accompanied by the product of neither oxygen nor hydrogen peroxide. Although there are no such substances cited in the literature, but some *S*-oxides are really known in the derivatives of phenthiazines, which are hypsochromic than their mother compounds, for example, such compounds as 2, 7 - dinitrophenthiazine - *S* - oxide[7] (yellow against dark brown of 2, 7-dinitrophenthiazine) and benzothiazino tropone-*S*-oxide[8] (380 m$\mu$ against 440 m$\mu$ of benzothiazino-tropone). Hence the compound I does not contradict the present result so far as the shift of the absorption peak is concerned.



Apart from such a speculation one may conclude that the photobleached product is a leuco dye of a certain kind.

Next, there will be discussion as to whether the accompanying photoreaction is demethylation or hydrolysis of dimethylamino group. Substances to be taken up as possible photobleached products would be the following four; methylene azur A (*N*, *N*-dimethylthionine), methylene azur B (trimethylthionine), or thionol (III), methylene violet (*N*, *N*-dimethylthionolin) (IV). Unfortunately there are few reliable data available either for the absorption spectra or for the oxidation-reduction potential of such substances, and comparison with the present results are not always possible. According to Kehrmann[9] the absorption maximum of methylene azur A and methylene azur B are respectively 638 m$\mu$ and 656 m$\mu$ and the former is rather close to this observed value. As for the reduction potential on the other hand, Rapkin et al.[10] reported that $E_o'$ of methylene azur B is about the same as that of methylene blue but their data have seemingly

7) F. Kehrmann, *Ber.*, **46**, 2809 (1913); F. Kehrmann and H. Goldstein, *Helv. Chim. Acta.*, **4**, 27 (1921).
8) Unpublished result in Prof. Nozoe's Laboratory in our Faculty.
9) F. Kehrmann, *Ber.*, **46**, 2136 (1913).

to be reexamined according to a recent investigation[11].

(III)

(IV)

Thionol was reported to have the absorption maximum at 590 or 595 mμ[4,12], which does not agree with the present value, while methylene violet has an absorption maximum at 635 mμ in the aqueous solution[4] (or 597.4 mμ in alcoholic solution[13]). As for the $E_0'$ value of the latter compounds there is evidence that it is much lower than that of methylene blue, although its reliable value is not found in the literature. Thus the $E_0'$ value of thionolin, the demethylated analogue of methylene violet, was reported to be −0.22 V. (at pH 7.11)[14], which is much lower than that of thionine (0.062 V. at pH 7.0), the demethylated analogue of methylene blue (0.011 V. at pH 7.0). From these data it would be natural to expect that the $E_0'$ value of methylene violet is smaller than −0.22 V. at pH 7. Thus the possibilities of photohydrolysis which lead to III or IV, can be denied altogether.

11) For example, as regards toluidin blue, compare Rapkin's data with B. P. Nikol'skü and V. V. Pal'chevskü, *Zhur. Fiz. Khim.*, **32**, 1280 (1958).
12) S. Granick and L. Michaelis, *J. Am. Chem. Soc.*, **69**, 2883 (1947).
13) M. Althausse und G. Krüss, *Ber.*, **22**, 2065 (1889).
14) S. Granick, L. Michaelis and M. Schubert, *J. Am. Chem. Soc.*, **62**, 1802 (1940).

To sum up the above discussion, a photobleached product is most certainly a partially demethylated methylene blue, which is perhaps methylene azur A.

## Summary

In order to identify the photobleached substances which are produced when the aqueous solution of methylene blue is irradiated with visible light, the following three kinds of experiments were carried out.

1) Comparison of the absorption spectra of the photobleached product with those of leucomethylene blue, benzoylleucomethylene blue and acetylleucomethylene blue.

2) Comparison of the oxidative and reductive behavior of the photobleached product with that of leucomethylene blue.

3) Comparison of the pH dependence of the absorption spectrum of the photobleached product and that of leucomethylene blue.

It was concluded that the photobleached product is the leuco form dye and its oxidized form is most certainly a partially demethylated methylene blue, perhaps methylene azur A.

The author wishes to express his thanks to Professor Masao Koizumi for his suggestions and criticism throughout this investigation.

# *A. C. Polarography of Thiamine Hydrochloride in Weakly Acidic Buffer Solutions**

By Koichi OKAMOTO

(Received August 31, 1960)

A number of polarographic investigations on thiamine hydrochloride have been reported[2]. Most of these studies have been carried out in highly acidic or basic solutions or in unbuffered solutions, because their D. C. reduction waves were not well-defined in weakly acidic or in neutral buffer solutions owing to the overlapping of hydrogen discharging currents or pre-sodium waves.

The stability of thiamine under such extreme conditions was not sufficient to carry out the polarographic measurements and in unbuffered solutions the real pH-values at the surface of D. M. E. could not be defined experimentally. Therefore, the investigations have to be done in buffered solutions in order to know the real polarographic reduction waves of thiamine in weakly acidic solutions.

When the A. C. polarographic method was applied, thiamine hydrochloride was found to show one or two well-defined peak currents in weakly acidic and in neutral buffer solutions. Especially the behavior of the first wave

was distinctly observed in the solutions of pH 4.75~7.0. These two waves were considered to be attributed to the reduction of two species of thiamine hydrochloride in a solution.

In this paper, these A. C. polarographic behaviors of thiamine hydrochloride will be reported.

## Experiments and Results

The polarograph used was the same as that reported in the previous paper[1]. The characteristics of the dropping mercury electrode were: $m$=0.917 mg. $sec^{-1}$, $t$=4.68 sec. (open circuit), 3.92 sec. (at −1.30 V. vs. S. C. E.), 3.85 sec. (at −1.40 V.).

The thiamine hydrochloride and other reagents used were of reagent grade.

Experiments were carried out 2 or 3 times on the same kind of sample at 25°C and the values obtained were averaged in general. All potentials and peak currents were expressed in V. vs. S. C. E. and μA, respectively.

**The Influences of pH to $i_S$ and $E_S$.** — In the buffer solutions of pH 3.0~10.0, containing $1\times10^{-3}$ mol./l. thiamine hydrochloride ($B_1$-HCl), the variation of the wave forms with pH was observed, especially in the region of pH 4.00~6.00.

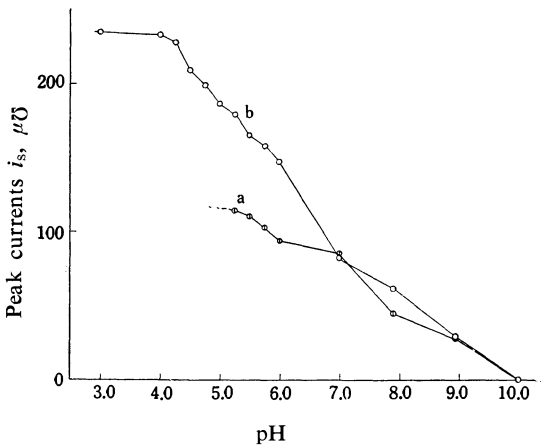

Fig. 2. The relation of the peak currents to pH.

[$B_1$-HCl] = $1\times10^{-3}$ mol./l., 25°C

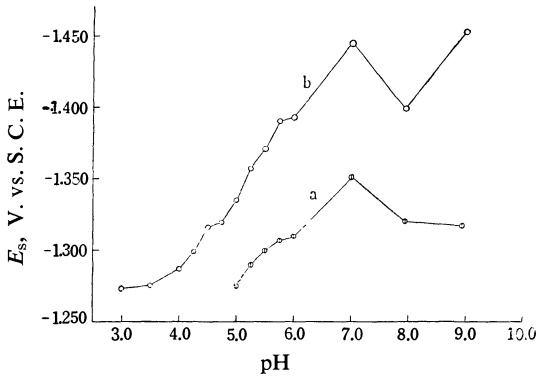

Fig. 3. The relation of $E_s$ to pH.
a: first wave b: second wave
$[B_1\text{-HCl}] = 1\times10^{-3}$ mol./l., 25°C

Some of the typical polarograms were shown in Fig. 1 and the relations of peak currents $i_s$ or of summit potentials $E_s$ to pH were summarized in Table I, Figs. 2 and 3.

Wave heights were measured following the method shown in Fig. 1.

Only one peak current was obtained in the region of pH 3.0~4.75, two peak currents were observed in the region of pH 4.75~9.0. They had the same wave heights at pH 7.0. In basic solutions of pH 7.0~10.0, these two waves changed irregularly and completely disappeared at pH 10.0.

As shown in Figs. 1 and 2, the 1st wave began to be separated at pH about 4.75 and decreased gradually with pH-increase in the same manner as the second.

Gradual negative shifts of $E_s$ of the first and the second waves with pH-increase were found, certain irregularities, however, being observed in basic solutions as shown in Fig. 3.

**The Relations of the Concentrations of $B_1$-HCl to $i_s$ and $E_s$.**—In order to know whether these two peak currents were both due to the reduction of $B_1$-HCl itself, the relation between the concentrations and $i_s$ was investigated in 0.5 M phosphate buffer of pH 6.00.

The results obtained were shown in Table II and Fig. 4. Good linearities were found for

Table II. The variations of $i_s$ and $E_s$ with the concentrations of $B_1$-HCl

| 0.40 | 41.5 | 74.7 | 1.300 | 1.369 |
| 0.60 | 68.2 | 105.2 | 1.307 | 1.386 |
| 0.80 | 93.2 | 137.0 | 1.307 | 1.384 |
| 1.00 | 119.0 | 174.5 | 1.309 | 1.390 |

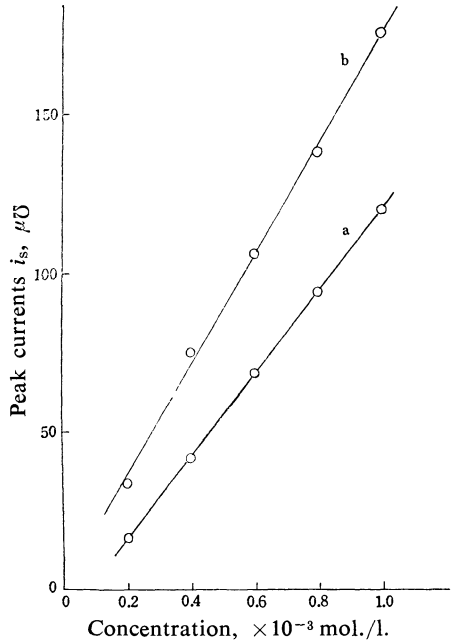

Fig. 4. The relation between the concentrations and the peak currents in 0.5 M-phosphate buffer of pH 6.00.
a: first wave b: second wave

two waves and the saturation tendencies occurred usually in cases where adsorption or desorption waves were not recognized at all.

Therefore, both of the waves seemed to be the real reduction waves of $B_1$-HCl itself.

The summit potential $E_s$ fairly shifted to negative potentials with the increase of the concentrations of $B_1$-HCl.

**Temperature Coefficients of $i_s$.**—Temperature coefficients of the first and the second wave heights were obtained as 1.64 and 1.56% respectively on 0.5 M phosphate buffer solutions of pH 6.0 containing $1\times10^{-3}$ mol./l. of $B_1$-HCl.

These coefficients coincided with the theoretical value of 1.6% of the diffusion currents.

**The Influence of Mercury Heights $H$ to $i_s$.**—The relationship of $H$ to $i_s$ was studied using the method of the plotting $\log H$ (corrected with the reverse pressure of mercury height) against $\log i_s$. The sample offered was $1\times10^{-3}$ mol./l. of $B_1$-HCl dissolved in 0.5 M phosphate buffer of pH 6.00.

The following equations were obtained:

$$\text{first wave;} \quad i_s^1 = H^{0.34} + K_1$$

$$\text{second wave;} \quad i_s^2 = H^{0.29} + K_2$$

where $K_1$ and $K_2$ are constants.

The peak currents were not proportional to the square root of $H$.

**Electrocapillary Curve.**—When strong adsorption-desorption phenomena occurred at the

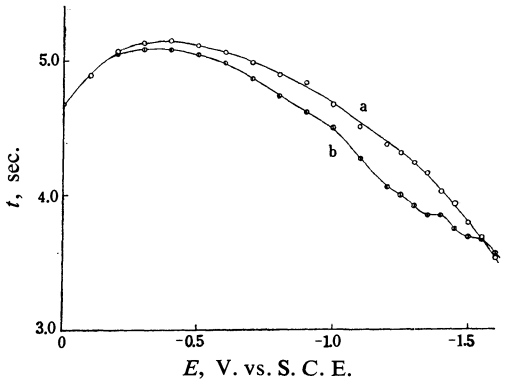

Fig. 5. Electrocapillary curves.
a: Reference; 0.5 M-phosphate buffer pH 6.00
b: 1 mmol $B_1$-HCl in reference soln. a.

surface of D. M. E., the electrocapillary curve was known to show certain irregularities.

The electrocapillary curve of $B_1$-HCl in pH 6.00 phosphate buffer solution was shown in Fig. 5.

In a very wide potential range $-0.20\sim-1.55$ V., the drop time $t$ was smaller in a solution of $B_1$-HCl than in a solution without it, and two small minima were observed at potentials $-1.35$ and $-1.50$ V. corresponding to the slightly negative potentials of each two peak current.

Weak adsorption seemed to take place at the surface of D. M. E., but it could have no remarkable effects upon A. C. polarographic waves; therefore, two A. C. waves were both considered to be not entirely so-called tensammetric waves.

## Discussion

As described in the above section, comparatively-well defined two A. C. polarographic waves of $B_1$-HCl observed in weakly acidic buffer solutions, were not the simple tensammetric, but the reduction waves with a few tensammetric properties.

When the aqueous solution of $B_1$-HCl was titrated with sodium hydroxide solution, two equivalent points were observed[3], the first point corresponding to 1 mol. equivalent of sodium hydroxide and to the process I→II (Fig. 6), another to 3 mol. equivalent of sodium hydroxide and to the process V→VI, while no point corresponding to 2 mol. of sodium hydroxide was detected. The values of $pK_1$ and $pK_2$ were 4.70~4.80 and 9.30~9.37, respectively at 25°C[2].

On the other hand, a new polarographic wave began to be observed at about pH 4.75;

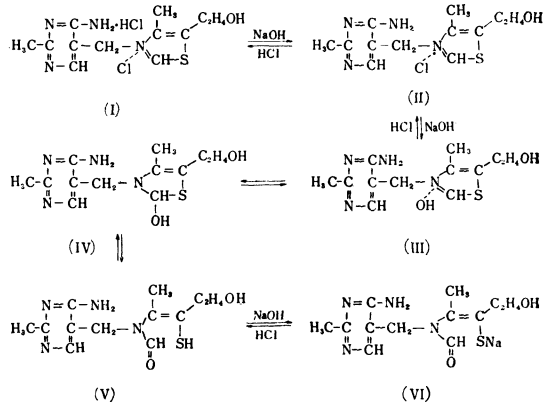

Fig. 6. The variation of $B_1$-HCl when titrated with HCl or NaOH solutions[3].

therefore, this (first wave) was considered to correspond to a reduction of species II that would increase from pH about 3.5 up to neutral range, then the second wave was to correspond to a reduction of species I that gradually decreased with pH-increase.

The first wave seemed to overlap with the second in the region of pH smaller than 4.75, but as the negative shift of the second was larger than of the first, it came to appear at pH 4.75.

At pH 4.70~4.80 the ratio of the polarographic wave heights of the first and the second should be 1 : 2 and at pH 7.0 should be 1 : 1 theoretically. Similar results were obtained experimentally as shown in Fig. 2.

The gradual decreasing of both wave heights with pH-increasing was explained as follows by the above dissociation processes (Fig. 6). If the polarographic reduction of thiamine took place at the double bond >N=C- in thiazole ring, IV, V and VI could not be reduced at D. M. E. Although these formes were not detected in the titration curve, they were considered to exist together in the solutions of pH about 5~9, so that the gradual decrease of wave heights were mainly due to this gradual increase of non-reductive IV or V.

The difference between the summit potentials of the first and second waves was up to about 100 mV., the influence of hydrochloric acid combining to pyrimidine ring or in other words to whole molecule of $B_1$, might produce this difference.

## Summary

Although in ordinary D. C. polarography no well-defined polarographic reduction waves of thiamine in weakly acidic or in neutral buffer solutions have been reported, it was found that A. C. polarographic methods would be suitable for these studies.

3) A. Watanabe and Y. Asahi, *J. Pharm. Soc. Japan* (*Yakugaku Zasshi*), 75, 1046 (1955).

A. C. polarographic waves of thiamine appeared at $-1.27\sim-1.35$ V. in buffer solutions of pH 3.0~4.75, and in the region of pH 4.75~7.0 a new wave began to be observed at more positive potentials than $-1.27\sim1.35$ V., while another wave was observed at $-1.32\sim-1.44$ V. in the same pH region. The heights of two waves decreased with the increase of pH.

In basic buffer solutions the wave forms varied irregularly and the waves disappeared completely at pH 10.0.

According to the relation of $i_s$ to temperature, mercury heights and concentrations, these two waves were both recognized as diffusion currents with a few tensammetric properties.

The nature of the first and second waves were attributed to the reductions of thiamine with $Cl^-$, and with hydrochloric acid and $Cl^-$ to each dihydrothiamine, respectively.

The author is very much indebted to Director M. Matsui of our Laboratory for affording facilities for this investigation.

# Studies on the Silk-platinum Catalyst. I. Its Preparation and Activity

By Akira Akamatsu, Yoshiharu Izumi and Shiro Akabori

(Received January 19, 1961)

Recently, Izumi[1] reported on an entirely new type of palladium hydrogenation catalyst, which is unique in that its carrier is fibers of silk-fibroin. Parlladium chloride was easily coordinated with the silk-fibroin protein and then the resulting silk-palladium chelate was hydrogenated to give the catalyst. It is assumed that the metal in the catalyst is highly dispersed and tightly fixed to the micelle structure of silk-fibroin in a finely devided state, and consequently the active surface of the metal is considerably increased. Furthermore, the catalyst has a number of characteristics due to the nature of the carrier silk-fiibroin fibers.

In addition to these characteristics, other interesting properties were expected to be found, when palladium was replaced by platinum. A brown hair-like silk-platinum chelate was successfully formed, when silk-fibroin fibers were boiled with an aqueous solution of potassium tetrachloroplatinate ($K_2PtCl_4$). Activation of this chelate by hydrogenation gave the black-colored silk-platinum catalyst.

This catalyst was found to catalyze the hydrogenation of various compounds, as will be reported in the following papers of this series[2]. In general it showed the highest hydrogenation activity for aromatic nitro compounds. In the hydrogenation of nitrobenzene to aniline, its activity was about two hundred and fifty times as high as that of a platinic oxide catalyst containing the same amount of platinum metal. Further advantages of this catalyst, as of a silk-palladium catalyst, are the facility with which it can be mixed with reactants and separated from the reaction mixture without detachment of the metal from the carrier, and the fact that it can be stored for a long period in air-dried conditions without undergoing spontaneous combustion.

The present paper describes the conditions used for the preparation of this catalyst, and its activity and stability.

## Results and Discussion

**Conditions for Preparation of the Chelate.**— In order to obtain a catalyst with high activity, as well as to minimize expensive loss of platinum, the platinum content of the chelate preparation must be increased. In the previous paper[1] Izumi reported on an "easily detachable form" of metal in the silk-palladium catalyst, which did not contribute to the activity. It is probable that this "easily detachable form" is free metal which has been reduced without forming a chelate. Similarly, platinum in the chelate is assumed to consist of "coordinated" and "not coordinated" platinum. The latter is simply deposited on the silk-fiboin fibers as the free metal. It is possible that the former is readily soluble in concentrated hydrochloric acid while the latter is insoluble. Optimal conditions not only for "the

1) Y. Izumi, This Bulletin, 32, 932 (1959).
2) A. Akamatsu, Y. Izumi and S. Akabori, in preparation.

total platinum content", but also "the coordinated platinum content" were studied; the latter estimated as the concentrated hydrochloric acid soluble part. The results are shown in Fig. 1. (a) Four hundred milligrams of silk-fibroin fibers were boiled with an aqueous solution of potassium tetrachloro-platinate. The ratio of crystalline potassium tetrachloro-platinate to silk-fibroin in the solution, and the boiling time were constant. The concentration of the solution was varied by changing the volume of the solvent. Thus, the optimum concentration was found to be about 0.75%. (b) The boiling time was also kept constant and the volume of the 0.75% aqueous solution of potassium tetrachloro-platinate was varied. Comparatively high contents of platinum were obtained using more than 20 ml. of solution. (c) An adequate boiling time was found to be 14 to 20 min. Thus, the most desirable result was obtained when 400 mg. of silk-fibroin fibers were boiled with 20 ml. of a 0.75% aqueous solution of potassium tetrachloro-platinate for 14 to 20 min. This preparation was used for the work described in the following sections of this paper. Prolonged boiling of more than 20 min. only resulted in an increase in the "not coordinated part". Another good result was obtained, when a suspension of silk-fibroin in potassium tetrachloro-platinate solution was heated at 55°C in an air bath for 17 hr., instead being boiled.

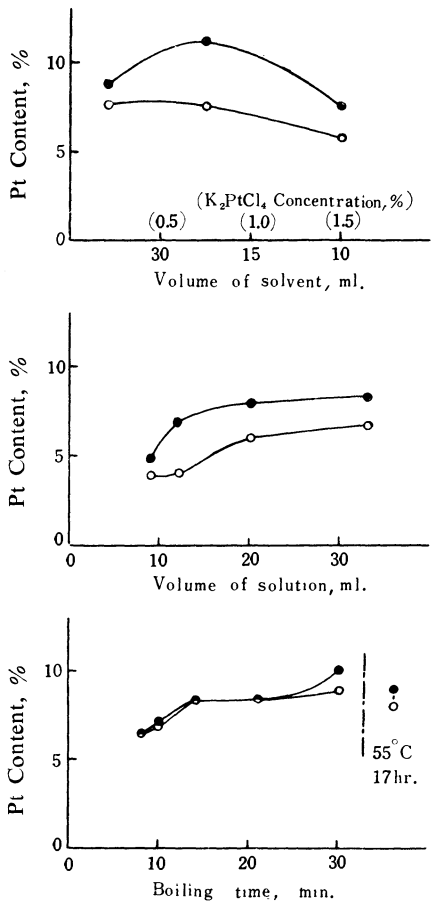

Fig. 1. Platinum content of chelate prepared under various conditions.

● Total platinum content, ○ Coordinated platinum

400 mg. of silk-fibroin was boiled (a) in an aq. solution containg 150 mg. of $K_4PtCl_4$ for 14 min., (b) in a 0.75% $K_2PtCl_4$ aq. solution for 14 min., and (c) in 20 ml. of a 0.75% $K_2PtCl_4$ aq. solution.

In the preparations described above, about 50% of the platinum in solution was used up in formation of the chelate. The remainder in the mother liquor was recovered and used for subsequent preparations.

**Conditions for Activation of the Chelate.**— The above chelate was converted to the active catalyst by reducing it with ca. 90 kg./cm$^2$ of hydrogen in an autoclave. To find the optimal conditions for activity, the hydrogenation reaction was carried out in various solvents at various temperatures for different periods. Representative experiments are summarized in Tables I to IV, in which the activity of the resulting catalysts are represented by their reaction velocity ($v$) during the hydrogenation of nitrobenzene to aniline using the same amount of catalyst in each case, and by their activity yield ($y \cdot v$.) which means their activity on the basis of the same amount of the metal in the catalyst. $v$ was calculated according to the equation; $v=100/t$, where $t$ is the time in minutes required for 70% hydrogen uptake. $y \cdot v$ was calculated as the product of the reacion velocity ($v$) and the gravity yield*[1] ($y$). The decrease in the gravity yield is due to destruction of the carrier fibroin fibers. In general, activation at high temperatures resulted in a high activity yield and low gravity yield. The former is not due only to an increase in the metal content resulting from destruction of the carrier.

When water was used as solvent during activation (Table I), carrier fibers were broken to pieces at above 150°C, and almost completely destroyed and dissolved in the solvent at 200°C. Activation for two hours gave a comparatively active catalyst. The most active catalyst was obtained at 160°C.

With diethyl succinate or methanol, less active catalysts were obtained with the silk-platinum catalyst (Table II), though in the

*[1] For example, when 100 mg. of the chelate is hydrogenated to give 50 mg. of the active catalyst, the gravity yield is 50%.

case of the silk-palladium catalyst, an exceedingly active catalyst was obtained with diethyl succinate (Table VI).

However, the use of dilute acetic acid as a solvent (Table III), increased the activation. One per cent acetic acid was the most effective among the other solvents tested. But increasing the amount of the precursor chelate in proportion to that of the solvent, failed to give satisfactory results (Cat. No. 19). So, for the repeated activation of this catalyst, the various conditions shown in Table IV were tested. Repeated hydrogenation under the same conditions resulted in an extremely high activity. Heating in an autoclave without hydrogen also gave a very active catalyst though it was less

† Calculated value

active than the former. However, boiling in a flask with 1% acetic acid was not effective. Repeated hydrogenation with 1% aqueous ammonia was not effective for increasing the total activity yield ($y \cdot y' \cdot v$), but it did increase the reaction velocity.

The present results show that the activity of the catalyst is influenced very much by the solvent used, and the temperature and time of activation. The destruction of the carrier and the increase in the metal content of the catalyst are evidently effected by these conditions, and indeed might contribute to some extent to the activity represented by the activity yied. But a low gravity yield was not always accompanied by a high actvity yield as shown by comparison of catalysts Nos. 9 and 16. It may be that these conditions directly and independently influence the activity. The solvent especially is an important factor in the activation, as Hartung et al.[3] reported concerning the effect of certain organic anions on the preparation of the palladium-charcoal catalysts. It was proved in this work that regardless of the extent of the gravity yield, use of acetic acid resulted in a very good activity, while methanol, diethyl succinate, and aqueous ammonia were not effective.

It does not seem unreasonable, as Hartung pointed out, to attribute these solvent effects on the arrangement of the crystalline structure or the spacing of the active centers on the catalyst. It should also be noted that the ratio of the volume of solvent to the amount of the precursor-chelate used influenced the activity to a large extent, though such a phenomenon was not seen in the case of the silk-palladium catalyst.

3) W. H. Hartung et al., *J. Org. Chem.*, **21**, 999 (1956).

**Stability of the Catalyst.** — In Table V are shown the reaction velocities observed in the hydrogenation of nitrobenzene to aniline, using the final catalyst*2 both immediately after its activation and after storage of the dry catalyst for several weeks in a stoppered bottle. The results clearly show the silk-platinum catalyst can be stored for a long period without loss and even with some increase of activity. No spontaneous combustion took place during the storage period.

**Activity with Aromatic Nitro Compounds.** — The activity of the silk-platinum catalyst*2 in the hydrogenation of various alkyl derivatives of nitrobenzene to the corresponding amines was compared with that of platinic oxide catalyst, silk-palladium catalyst (activated in methanol) and silk-palladium-DES catalyst (activated in diethyl succinate)*3. Table VI shows the reaction velocities for the hydrogenation of the same amount (1/30 mol.) of the various compounds, using catalysts, each of which contains the same amount (13 mg.) of metal. The silk-platinum catalyst showed the highest activity of all the catalysts with all the compounds tested. Notably in the hydrogenation of nitrobenzene in methanol, the reaction velocity was 254 times as fast as that with the platinic oxide catalyst. When methanol was used as a solvent, the reaction velocity for the silk-platinum and the silk-palladium-DES catalyst was faster than when dioxane was used, in spite of the low reaction temperature.

The ratios of the reaction velocity of alkyl nitrobenzenes to that of non-substituted nitrobenzene were calculated and are shown in

*2 This catalyst was prepared under the same conditions as that for catalyst No. 20 in Table IV. See Experimental.

*3 See Experimental.

brackets in Table VI. In the series of alkyl nitrobenzenes the ratios decreased as the alkyl groups increased in substituents and branching. This decrease is distinguishable with catalysts in which the carrier is silk-fibroin fibers. It is possible that, not only the bulkiness of the reactants, but also the characteristic structure of carrier silk-fibroin[4] exerts some steric hindrance retarding the hydrogenation.

## Experimental

**Determination of Platinum.** — Platinum was measured by the iodine method[5], after the chelated sample had been treated as follows;

*1) For Estimation of the Total Platinum Content.* —About 15 mg. of the chelated sample were accurately weighed in a crucible and heated with 0.5 ml. of concentrated nitric acid on a steam bath for 20 min. The mixture was evaporated to dryness and the residue was strongly heated to ash over a burner. After the ash had been dissolved in 0.5 ml. of aqua-regia, the soluion was evaporated to dryness. One milliliter of concentrated hydrochloric acid was added to the residue and evaporated off twice to remove the nitrate. The residue was then dissolved in water and the solution diluted to 50.0 ml. Exactly 5.00 ml. of the solution was used for each determination.

*2) For Estimation of Coordinated Platinum.* — About 15 mg. of the chelated sample were accurately weighed in a test tube and heated with 2.0 ml. of 30% hydrochloric acid on a steam bath for 30 min. The mixture was filtered through filter paper and the filter paper was washed with water. The combined filtrates were transferred to a crucible and ashed by evaporation and strong heat. Then the ash was treated in the same way as described above for the estimation of the total platinum content.

**Reaction Vessel.**—The same autoclave as described in the previous paper[1] was used for activation of the chelate and for hydrogenation reactions.

**Measurement of the Reaction Velocity.** — One thirtieth of a mole of the substrates (for nitrobenzene, 4 g.) dissolved in 50 ml. of methanol and the catalysts to be tested (for silk-platinum catalyst, 40 mg.) were placed in the autoclave, into which hydrogen was then introduced to a pressure of 90 kg./cm$^2$. The initial pressure was read after shaking to allow equilibration, and then the shaking was continued until 70% of the theoretical amount of hydrogen had been taken up.

**Preparation of Catlysts.**—*1) Silk-platinum Catalyst.*—The catalyst, used in investigations of stability and activity, was prepared by the following method; a) Twenty grams of sik-fibroin fibers previously washed with boilng water were mixed with 1 l. of an 0.75% aqueous solution of potassium tetrachloroplatinate and the mixture was boiled for 18 min. The silk-platinum chelate obtained was filtered off, washed with water, methanol and then ether, and finally dried in vacuo. b) Twenty grams of the chelate were suspended in 500 ml. of 1% acetic acid reduced with hydrogen (80 kg./cm$^2$) at 160°C for 2 hr. in a 1 l. autoclave. The catalyst obtained was filtered off, washed with water, methanol and ether, and dried in vacuo (12 g., 60%). The reaction velocity ($v$) with nitrobenzene at 16°C was 1.8. Repeated hydrogenation of 4 g. of this catalyst by the same method for 1 hr. gave the final catalyst (2.6 g., 66%). The reaction velocity ($v$) of this catalyst at 32°C was 60.7.

*2) Platinic Oxide Catalyst.*—This was prepared by the method of Ref. 6.

*3) Silk-palladium Catalyst.*—This was prepared as described in the previous paper[1].

*4) Silk-Palladium-DES Catalyst.* — Two hundred milligrams of the silk-palladium chelate[1] were suspended in 50 ml. of diethyl succinate and reduced with hydrogen (80 kg./cm$^2$) at 220°C for 2 hr. in a 100 ml. autoclave. The resulting catalyst was washed with methanol and dried in vacuo.

**Isolation of Products.** — The products on the hydrogenation of nitrobenzene and of its alkyl derivatives were isolated as follows:

*Aniline.* — This was isolated as described previously[1].

*p-Aminoisopropylbenzene, p-Amino-tert-butylbenzene.* —The reaction mixture was filtered and the filtrate distilled in vacuo. The amines obtained were acetylated and the crude acetyl derivatives were recrystallized from alcohol: *p*-Aminoisopropylbenzene; b. p. 112°C/19 mmHg (lit.[7] 225°C/760 mmHg). *p*-Amino-*tert*-butylbenzene; b. p. 117~119°C/15 mmHg (lit.[8] 120~132°C/15 mmHg). *p*-Acetaminoisopropylbenzene; m. p. 105°C (lit.[9] 105~106°C). *p*-Acetamino-*tert*-butylbenzene; m. p. 171°C (lit.[8] 171~172°C).

*3,5-Dimethyl-4-amino-tert-butylbenzene.*—The crude amine was converted to its 2-nitro derivative and this was recrystallized; m. p. 86°C (lit.[10] 88~89°C).

## Summary

1. A silk-platinum chelate, which had the highest platinum content, involving both the total platinum content and the coordinated platinum, was obtained when 400 mg. of silk-fibroin was boiled with 20 ml. of a 0.75% aqueous solution of potassium tetrachloroplatinate for 14 to 20 min.

2. The most active silk-platinum catalyst was obtained when reduction of the chelate was pepeated twice in 1% acetic acid with 90 kg./cm$^2$ of hydrogen at 160°C. The activity was much influenced by the solvent, temperature and time used for its activation.

3. The catalyst could be stored for a long

# *Reduction of Organic Compounds with Urushibara Catalysts under High Pressure. VIII*[1]. *Reduction of Acetophenone, Especially with Urushibara Nickel Catalyst Prepared by Various Modified Methods*

By Shin-ichi TAIRA

(Received December 27, 1960)

In the preceding paper[1] of this series, catalytic reduction of benzophenone with various Urushibara catalysts under various conditions was reported, and activities of Urushibara nickel, Urushibara cobalt and Urushibara copper, prepared by various methods were compared with each other.

The procedure for preparing Urushibara nickel catalyst has been successively modified since its discovery and some varieties of this catalyst were reported. The preparation of the Urushibara nickel catalyst is divided into two steps; namely, the preparation of precipitated nickel and the digestion of the precipitated nickel with acid or alkali. Varieties of the Urushibara nickel catalyst originate in methods of preparing the precipitated nickel and succesive treatment with acid or alkali. The precipitated nickel, prepared from nickel chloride or nickel acetate solution with zinc dust, gives Urushibara nickel B (U-Ni-B)[1,2] or Urushibara nickel CB (U-Ni-CB)[1] by digestion with caustic alkali. The same precipitated nickel gives Urushibara nickel A (U-Ni-A)[1,3] or Urushibara nickel CA (U-Ni-CA)[1] by treatment with acetic acid in place of caustic alkali. The U-Ni-CB and U-Ni-CA are prepared from the precipitated nickel which was obtained from nickel chloride solution and zinc dust at a low temperature. The precipitated nickel, prepared from nickel chloride solution with aluminum grains, gives Urushibara nickel BA (U-Ni-BA)[4,5] by treatment with sodium hydroxide solution, and Urushibara nickel AA (U-Ni-AA)[6] by treatment with acetic acid and sodium chloride.

In the present paper, reduction of acetophenone with various Urushibara nickel catalysts is investigated. In this connection, the possibility of preservation of the precipitated nickel retaining the activity of the catalyst therefrom was examined. The renewal of used catalyst was also examined, and it was found that a highly active catalyst can be regenerated from a used catalyst by a simple procedure.

## Experimental

**Apparatus.**—Reduction was carried out in the same autoclave (Sakashita SE-20; electro-magnetically stirring type autoclave having a capacity of 200 ml.) used in the experiments reported in the preceding paper[1].

**Materials.**—Commercially available acetophenone was purified by repeated crystallization.

**General Procedure for Reduction.**—Any catalyst, prepared so as to contain 1 g. of nickel, was carefully transferred with ethanol into the autoclave. Then the air present in the autoclave was replaced

by hydrogen gas four times. All operations were carried out under the following condition: (1) acetophenone: 30 g. (0.25 mol.), (2) ethanol: 60 ml., (3) pH: 9~11 (It has been recognized[1,7,8] that the catalytic reduction of carbonyl group with Urushibara catalyst was accelerated by a trace of alkali. When U-Ni-A or U-Ni-CA was used, 1 ml. of 10% sodium hydroxide solution was added.), (4) agitation: 40~45 strokes per minute, (5) reaction temperature: as a remarkable hydrogen uptake was found to begin at about 60°C in reduction of carbonyl group[7], agitation was started when the temperature in the autoclave reached about 60°C, and the temperature was kept between 60 and 70°C throughout the operation, (6) pressure: as it had been found that, in the case of the reduction of carbonyl group under high pressure, the velocity of reduction was only slightly affected by the initial pressure under 100 kg./cm$^2$ [1,7], the effect of the initial pressure was ignored and (7) when the pressure in the autoclave dropped to 20~30 kg./cm$^2$, supplementary hydrogen gas was charged two or three times in every course of the operation, and the reduction was continued until the hydrogen uptake ceased. Pressure was observed at intervals of five minutes.

After the reduction was finished, the catalyst was filtered off and washed with ethanol. From the combined filtrate, the major part of the ethanol was removed by distillation on a water bath, and the residual liquid was distilled under reduced pressure. The fraction, distilling at 89~91°C/15 mmHg, was collected. The yield of methylphenylcarbinol was 91~95 per cent of the theoretical amount.

**Preparation of Catalysts.** — The U-Ni-B[1,2], U-Ni-CB[1], U-Ni-BA[4,5], U-Ni-A[3] and U-Ni-CA[1] were prepared by the methods described in the references cited. Regenerated Urushibara nickel catalyst was prepared from any used catalyst by the following methods. The used catalyst was recovered by filtration after the previous reaction, and dried at about 100°C and stored.

(A) To well-mixed zinc dust (5 g.) and recovered U-Ni-A (1.3 g.) with water (3 ml.) was added 80 g. of 10% sodium hydroxide solution. The mixture was occasionally stirred for 20 min. at 50~55°C and then 5 min. at 75~80°C. At the end of this process, generation of hydrogen gas ceased and grayish white zinc compounds were deposited. The upper liquor was removed by decantation and the residual solid was washed with 200 ml. of hot water and then with two 50 ml. portions of ethanol. Every washing was decanted.

(B) Recovered U-Ni-A (1.3 g.), used in Exp. No. 113 and left standing for 55 days, was well mixed with zinc dust (10 g.) and water (5 ml.). The mixture was treated with 160 g. of 13% acetic acid for about 5 min. As hydrogen gas was vigorously generated at first, good agitation by hand was required to prevent the contents from running over. In this case the solid did not come up to the surface of the solution which was green in color. The solid was collected on a glass filter and washed with 200 ml. of water and then with 100 ml. of ethanol.

(C) To a mixture of the recovered U-Ni-A (1.1 g.) used in Exp. No. 32, zinc dust (5 g.) and water (3 ml.) was added 80 g. of 13% acetic acid. The following procedure was similar to that described in B, and a very fine catalyst was obtained.

(D) To a mixture of recovered U-Ni-A (1.4 g.), zinc dust (2.5 g.) and water (2.5 ml.) was added 40 g. of 13% acetic acid. The following procedure was similar to that described in B.

(E) The recovered U-Ni-B (7.3 g.) used in Exp. No. 11 was treated with 160 g. of 13% acetic acid until the solid came up to the surface of the solution which had turned green. Since the major part of the zinc dust had been removed in the previous preparation of the U-Ni-B, only a small quantity of hydrogen gas was evolved in this process. The solid was collected on a glass filter, and washed with 200 ml. of water and then with 100 ml. of ethanol.

(F) The recovered U-Ni-CB (7 g.) used in Exp. No. 19 was treated with 160 g. of 13% acetic acid. Generation of hydrogen gas was hardly observed, and the solution turned black owing to the suspension of fine solid. After about 8 min. the solid was separated by centrifuge from the solution which was green in color. The solid was washed with two 200 ml. portions of water and then two 50 ml. portions of ethanol in the centrifugal tube. The washings were decanted.

(G) To a mixture of recovered U-Ni-A (1.4 g.) and water (2 ml.) was added 50 g. of 20% acetic acid. The mixture was then digested at 70~75°C for one minute on a boiling water bath. The U-Ni-A reacted vigorously with acetic acid at this temperature. Then solid, adsorbing hydrogen gas, came up to the surface of the solution which was green in color. The solid was collected on a glass filter and washed with 200 ml. of water and then with 100 ml. of ethanol.

(H) The weight of recovered U-Ni-A, prepared so as to contain 1 g. of nickel, being ordinary 1.3 ~1.4 g., the recovered U-Ni-A (0.9 g.) used in Exp. No. 37 was supplemented by 0.5 g. of recovered and stored U-Ni-A. To this was added 2 ml. of water and the mixture was treated as is described in G.

(I) To a mixture of recovered U-Ni-A (1.4 g.) and water (2 ml.) was added 50 g. of 10% acetic acid. The mixture was digested at 75~80°C for one minute on a water bath. The following procedure was similar to that described in G.

In all procedures, distilled water was used for washing, and the obtained catalyst was protected from contact with air as far as possible.

## Results and Discussion

As reported in the preceding paper[1] on the reduction of benzophenone, the activity of various Urushibara nickel catalysts in the reduction of acetophenone was studied by comparing the time required for the completion

e) 1 ml. of 10% sodium hydroxide solution was added.

of reduction under nearly the same condition.

A series of experiments shown in Table I was carried out to confirm the activity of each catalyst and to offer the standard of reference for the subsequent experiments. The reduction of acetophenone was effectively achieved with U-Ni-B, U-Ni-BA, U-Ni-CB, U-Ni-A and U-Ni-CA, among which U-Ni-A proved to be the most useful. The U-Ni-B, prepared from nickel acetate and zinc dust, which had been found to be similarly active in the reduction of benzophenone, was also effective for the reduction of acetophenone though somewhat less active (Exp. Nos. 15 and 16). The U-Ni-BA, which had been proved to be specially useful for hydrogenation of aromatic nucleus[4,5], was not so particularly active (Exp. Nos. 17 and 18) as it was in the reduction of

e) About 0.7 g. of nickel was found to be contained by analysis.

benzophenone[1]. The activities of U-Ni-CB and U-Ni-CA were found to be fairly high, though they were somewhat inferior to that of U-Ni-A.

The usual Urushibara nickel catalysts B and A can be prepared by a simple operation in only one hour or less. Supposing the relation of the precipitated nickel to Urushibara nickel catalyst is similar to that of Raney alloy to Raney nickel catalyst, the operation of preparing Urushibara nickel catalyst is certainly more simplified when precipitated nickel can be stored in the state ready to use. It has been claimed that precipitated nickel is inherently provided with active nickel surfaces and acid or alkali is not effective to create any active state on the surfaces, and that the rôle of acid or alkali is to remove the basic zinc chloride which has been formed by the reaction of zinc dust with nickel chloride solution[3]. It is presumable in this view that exposure of precipitated nickel to air for a long time may cause the deactivation or lowering of activity of the catalyst prepared from it. Some experiments on the preservation of precipitated nickel have already been reported in regard to the preparation of U-Ni-BA[5]. Precipitated nickel prepared from nickel chloride solution with aluminum grains was preserved in distilled water, 99% ethanol or dry state under reduced pressure. The U-Ni-BA, prepared from the preserved precipitated nickel, was unexpectedly shown to have practically the same activity as that which the catalyst prepared from freshly prepared precipitated nickel has.

The present author tried reduction of acetophenone with the U-Ni-B and U-Ni-A obtained from precipitated nickel, which was prepared from nickel chloride solution with zinc dust by the ordinary methods[2,3], dried at about 100°C, and left standing for a week in the air. The results are shown in Table II. These results do not differ from those obtained with the normally prepared U-Ni-B and U-Ni-A. Therefore, contact with air is safely permitted for precipitated nickel. It may not be necessary for the water for washing to be distilled in the preparation of precipitated nickel.

One of the features of the Urushibara nickel catalyst is that it is not self-inflammable by contact with air under ordinary conditions. Consequently, nickel can be recovered from such waste catalyst as nickel chloride which can be used again for the preparation of the Urushibara nickel catalyst. But the operation may be troublesome and expensive. If recovered Urushibara nickel can be repeatedly used in place of the precipitated nickel, the time for preparing the precipitated nickel and the cost of nickel chloride will be saved. For the purpose of attaining this request a series of experiments was carried out to regenerate the active catalyst directly from recovered catalyst (Table III).

First, the U-Ni-B was prepared from the mixture of recovered U-Ni-A and zinc dust by treatment with sodium hydroxide solution. The regenerated catalyst was found to be useful enough for the reduction of acetophenone though it was somewhat less active (Exp. No. 31). The cause of this reactivation was considered to result from the removal of adsorbed substances on the surfaces of nickel particles by hydrogen gas generated from zinc dust with caustic alkali. Then the catalyst prepared from recovered U-Ni-A and zinc dust by

treatment with acetic acid was also expected to have considerable activity. In fact, such a catalyst proved to be highly active and gave a better result than that obtained with the original U-Ni-A (Exp. No. 32). To save the amount of zinc dust, the next catalysts were prepared by using one half or one fourth the amount of zinc dust as the quantity used for preparing the catalyst in Exp. No. 32. They had also high activities (Exp. Nos. 33 and 34), and gave practically the same results as those obtained with the normally prepared U-Ni-A (cf. Exp. Nos. 112—115 in Table I). If the existence of a small amount of zinc is enough to reactivate the recovered catalyst, the recovered U-Ni-B and U-Ni-CB may become active by being treated with acetic acid. Actually, each of the catalysts prepared from the recovered U-Ni-B and U-Ni-CB used in Exp. Nos. 11 and 19, gave a better result than those obtained with the original catalysts (Exp. Nos. 35 and 36). As the recovered U-Ni-B and U-Ni-CB contain only a small quantity of zinc, only a little hydrogen gas is evolved by the digestion with acetic acid. Accordingly, zinc dust is supposed to be excluded from the reagents necessary for the renewal of the catalyst. Thus some catalysts were prepared from recovered U-Ni-A by being treated with acetic acid only, and these catalysts were also found to be highly active (Exp. Nos. 37, 38 and 39). In these cases, however, nickel itself reacted vigorously with hot acetic acid, and solid, adsorbing hydrogen gas, came up to the surface of the green solution. In consideration of the results described above, acetic acid must have, in case of preparing the U-Ni-A, some activating effect on the surfaces of nickel particles besides the chemical function of generating hydrogen gas and removing deactivating substances (basic zinc chloride and others). Probably one important function of acetic acid may consist in eroding the surfaces of nickel particles and creating new ones. This assumption accounts for the reactivation of recovered catalysts and also for the fact that the U-Ni-A has not high activity, when the digestion with acetic acid is interrupted before the solution turns green by the formation of nickel ion[1]. The discussion as to whether or not the precipitated nickel has inherently active nickel surfaces seems not to be important.

## Summary

Catalytic reduction of acetophenone with various Urushibara nickel catalysts was studied under high pressure. The U-Ni-A with a small amount of alkali was found to be the most useful. The U-Ni-CB and U-Ni-CA were also highly active as they were in case of the reduction of benzophenone. The activity of the U-Ni-A and U-Ni-B, prepared from preserved precipitated nickel, was the same as that of the catalysts obtained from the freshly prepared precipitated nickel. In addition, it was found that the recovered Urushibara nickel catalyst could be repeatedly used after a simple regeneration process especially in the form of U-Ni-A. Such a regenerated catalyst had practically the same activity as that of the normally prepared U-Ni-A.

The author wishes to express his thanks to Professor Kazuo Hata for his continuous encouragement throughout this work.

# *A Theoretical Treatment of Molecular Complexes. I. Silver-Aromatic Hydrocarbon Complexes*

By Kenichi FUKUI, Akira IMAMURA, Teijiro YONEZAWA and Chikayoshi NAGATA

(Received January 11, 1961)

Theoretical researches of molecular complexes have become active since Mulliken combined the old concepts of molecular compound and established a new theory[1]. Prior to this research many qualitative discussions on molecular complexes had been presented. These are the covalent bond theory by Bennett and Willis[2], the polarization aggregate theory by Briegleb[3], the ionic complex theory by

1) R. S .Mulliken. *J. Am. Chem. Soc.*, **74**, 811 (1952).

2) G. M. Bennett and G. H. Willis, *J. Chem. Soc.*, **1929**, 256.

3) G. Briegleb, *Z. physik. Chem.*, **B16**, 249 (1932).

Weiss[4], and the complex resonance by Brackmann[5]. Weiss had pointed out that molecular complexes have an ionic structure $B^+A^-$, so that the lower the ionization potential for an electron donor is, and the higher the electron affinity for an electron accceptor is, the more easily the molecular complex is formed. Brackmann regarded the structure of complex as a resonance hybrid to which no-bond and dative structures contribute.

$$D:A \leftrightarrow D^+:A^-$$

Based upon these concepts, Mulliken presented a quantum mechanical theory on the charge transfer spectra of molecular complex[1]. Further, Mulliken predicted the configuration of benzene-iodine complex, benzene-silver complex and $BF_3$-$N(CH_3)_3$ complex, and his assumption was proved to be correct except in the case of benzene-iodine complex. With regard to benzene-iodine complex, Aono discussed Mulliken's model and presented a corrected one[6]. It may be true that in spite of these successes, Mulliken's procedure is not very useful to discuss the relative ease of complex formation among different molecules. There are often found some trials of discussing this problem by comparing the magnitude of ionization potentials of electron donors. For example, with respect to the silver-aromatic molecular complex, a correlation between the magnitude of ionization potential of methyl derivatives of 1,2-benzanthracene and their equilibrium constants in complex formation was pointed out by Nakajima[7]. However, this treatment has only a limited application since the ionization potential is not the sole factor relating to the ease of complex formation, and is hence not suitable in discussing the configuration of complex.

In the present paper we make use of the delocalization method in order to approach the conformation of molecular compound, finding a clear correlation between the equilibrium constant and the calculated value of the delocalization energy for silver-aromatic hydrocarbon complexes.

## Model and Formulation

In this paper the delocalization method was applied to silver-aromatic hydrocarbon complexes. Since it has been confirmed by X-ray diffraction that in silver-benzene complex silver cation is located above the middle of a carbon-carbon bond of benzene plane[8], we assume that silver cation approaches from above the molecular plane to the middle of a carbon-carbon bond of a benzene ring in aromatic hydrocarbons to form the molecular complex. The $\pi$ electronic stabilization energy due to delocalization from the occupied orbitals of the aromatic hydrocarbon to the lowest vacant orbital of the silver cation is calculated by the perturbation theory. This procedure is quite similar to the one which has been used in the frontier electron theory presented by some of the present authors[9]. When the aromatic molecule is confined to alternant hydrocarbons and their derivatives, and the silver cation is combined with the $r$th and the $s$th carbon atoms of the aromatic hydrocarbon by a weak bond, the secular equation of the $\pi$ part of the total system which includes the silver cation and the aromatic molecule is written in the simple LCAO MO treatment (overlap neglected) as follows:

$$D(\lambda)=\begin{vmatrix} h-\lambda & 0 & 0 \cdots\cdots 0 & \gamma & \gamma & 0 \cdots\cdots 0 \\ 0 & a_{11}-\lambda & a_{12}\cdots\cdots & a_{rr} & a_{1s} & \cdots\cdots a_{1n} \\ 0 & a_{21} & a_{22}-\lambda\cdots & a_{2r} & a_{2s} & \cdots\cdots a_{2n} \\ \vdots & & & & & \\ 0 & & & & & \\ \gamma & a_{r1} & a_{r2}\cdots\cdots & a_{rr}-\lambda & a_{rs} & \cdots\cdots a_{rn} \\ \gamma & a_{s1} & a_{s2}\cdots\cdots & a_{sr} & a_{ss}-\lambda & \cdots\cdots a_{sn} \\ 0 & & & & & \\ \vdots & & & & & \\ 0 & a_{n1} & a_{n2}\cdots\cdots & a_{nr} & a_{ns} & \cdots a_{nn}-\lambda \end{vmatrix}$$

$$=(h-\lambda)\Delta(\lambda) -\gamma^2\{\Delta_{rr}(\lambda)+\Delta_{ss}(\lambda)-2\Delta_{rs}(\lambda)\} \quad (1)$$

where

$$\Delta(\lambda)=\begin{vmatrix} a_{11}-\lambda & a_{12} & \cdots\cdots & a_{1n} \\ a_{21} & a_{22}-\lambda & \cdots\cdots & a_{2n} \\ \vdots & \vdots & & \vdots \\ a_{n1} & a_{n2} & \cdots\cdots & a_{nn}-\lambda \end{vmatrix} \quad (2)$$

is the secular determinant for the isolated aromatic molecule, and $\Delta_{rr}(\lambda)$, $\Delta_{ss}(\lambda)$, and $\Delta_{rs}(\lambda)$ are the minors of $\Delta(\lambda)$ corresponding to $(rr)$, $(ss)$ and $(rs)$ elements, respectively; $a_{ii}$ and $a_{ij}(i\neq j)$ are the Coulomb and the resonance integrals, respectively; and $h$ and $\gamma$ are the Coulomb integral of the silver cation and the resonance integral between the silver cation and the $r$th and the $s$th atoms of the aromatic molecule at which the delocalization of $\pi$ electron takes place, respectively. In presenting the value of energies, we make the zero point equal to the Coulomb integral of

benzene carbon and express them in units of $(-\beta)$ which is the resonance integral of the benzene C-C bond. If we designate the roots of $\Delta(\lambda)=0$ and $D(\lambda)=0$ as

$$\lambda_1, \lambda_2, \cdots\cdots \lambda_n\ ;\ \lambda^{(1)}, \lambda^{(2)} \cdots\cdots^{(n)}, \lambda^{(h)}$$
$$(\lambda_1 > \lambda_2 > \cdots\cdots > \lambda_n)$$

respectively, among which $\lambda^{(h)}$ will be very close to the value of $h$ and $\lambda^{(j)}$ to $\lambda_j$ $(j=1,2 \cdots\cdots n)$ since $\gamma$ is small. Namely $\lambda^{(j)}$ and $\lambda^{(h)}$ can be written as $\lambda^{(j)}=\lambda_j+\delta_j$, $\lambda^{(h)}=h+\delta_h$ in which $|\delta_j|$ and $|\delta_h|$ are small. For simplicity, we exclusively treat the following two cases in which $\Delta(\lambda)$ has no multiple root.

Case 1: When $h$ is not equal to any $\lambda_j$, we can obtain $\delta_j$ as

$$\left.\begin{aligned}\delta_j &= 2\left\{\frac{\Delta_{rr}(\lambda_j)}{(h-\lambda_j)\Delta'(\lambda_j)}+\frac{\Delta_{ss}(\lambda_j)}{(h-\lambda_j)\Delta'(\lambda_j)}-\frac{2\Delta_{rs}(\lambda_j)}{(h-\lambda_j)\Delta'(\lambda_j)}\right\}\gamma^2+[\gamma^4] \\ &\qquad (j=1,2\cdots\cdots n) \\ \delta_h &= -\sum_{j=1}^{n}\left\{\frac{\Delta_{rr}(\lambda_j)}{(h-\lambda_j)\Delta'(\lambda_j)}+\frac{\Delta_{ss}(\lambda_j)}{(h-\lambda_j)\Delta'(\lambda_j)}-\frac{2\Delta_{rs}(\lambda_j)}{(h-\lambda_j)\Delta'(\lambda_j)}\right\}\gamma^2 \\ &\quad +[\gamma^4]\end{aligned}\right\} \quad (3)$$

where $[\gamma^4]$ denotes the higher terms. The delocalization energy, $\Delta E$, is defined as follows:

$$\Delta E = 2\sum_{j=1}^{m}(\lambda^{(j)}-\lambda_j) \quad (4)$$

$$=2\sum_{j=1}^{m}\left\{\frac{\Delta_{rr}(\lambda_j)+\Delta_{ss}(\lambda_j)-2\Delta_{rs}(\lambda_j)}{(h-\lambda_j)\Delta'(\lambda_j)}\right\}\gamma^2+[\gamma^4]$$

$$=-2\sum_{j=1}^{m}\frac{(C_r^j+C_s^j)^2}{h-\lambda_j}\gamma^2+[\gamma^4] \quad (5)$$

where $j=1,2\cdots\cdots m$ denote the occupied orbitals, and the $r$th and the $s$th carbon atoms are adjacent to each other. And $C_r^j$ is the coefficient of the $r$th atomic orbital in the $j$th molecular orbital of the isolated aromatic molecule. When $h$ is equal to zero, then the total delocalization energy becomes

$$\Delta E=\{S_r^{(E)}+S_s^{(E)}+2S_{rs}^{(E)}\}\gamma^2+[\gamma^4] \quad (6)$$

where $S_r^{(E)}$, $S_s^{(E)}$ are superdelocalizabilities at the $r$th and the $s$th carbon atoms for the electrophilic reaction[9], and $S_{rs}^{(E)}$ is given in Eq. 7 and may be named bond-delocalizability of the bond $rs$.

$$S_{rs}=\sum_{j=1}^{n}\frac{(\nu_j-\nu)C_r^jC_s^j}{\lambda_j} \quad (7)$$

where $\nu_j$ is the number of $\pi$ electrons in the $j$th molecular orbital and $\nu$ is the number of $\pi$ electrons in the approaching orbital to or from which the delocalization of electrons occurs. $S_{rs}^{(E)}$ designates $S_{rs}$ in which $\nu=0$.

The formula obtained by Eq. 5 indicates that the magnitude of delocalization energy depends sensitively upon the local symmetry of the molecular orbital; that is to say, when $C_r^j$ and $C_s^j$ have same signs, the magnitude of delocalization energy is large, while it is small in case of different signs. It may be stressed that a conclusion similar to that of Mulliken has thus been derived by the present treatment.

Case 2: When $h$ is equal to the energy of the highest occupied orbital of the isolated aromatic molecule $\lambda_f$,

$$\left.\begin{aligned}\delta_j &= 2\left\{\frac{\Delta_{rr}(\lambda_j)}{(h-\lambda_j)\Delta'(\lambda_j)}+\frac{\Delta_{ss}(\lambda_j)}{(h-\lambda_j)\Delta'(\lambda_j)}-\frac{2\Delta_{rs}(\lambda_j)}{(h-\lambda_j)\Delta'(\lambda_j)}\right\}\gamma^2+[\gamma^4] \\ &\qquad (j=1,2,\cdots\cdots n) \\ \left.\begin{matrix}\delta_h\\ \delta_f\end{matrix}\right\} &= \pm\sqrt{-\frac{\Delta_{rr}(h)+\Delta_{ss}(h)-2\Delta_{rs}(h)}{\Delta'(h)}} \\ &\quad \times\gamma+[\gamma^2]\end{aligned}\right\} \quad (8)$$

and the delocalization energy depends dominantly upon the term of first order. Hence, we obtain

$$\Delta E=2\sqrt{-\frac{\Delta_{rr}(h)+\Delta_{ss}(h)-2\Delta_{rs}(h)}{\Delta'(h)}}\gamma+[\gamma^2]$$
$$=2|C_r^f+C_s^f|\gamma+[\gamma^2] \quad (9)$$

It may be remarked that in case 2, the magnitude of $\Delta E$ depends upon the local symmetry of the highest occupied orbital, the frontier orbital at the bond to be attacked.

Then the following conclusion can be derived. When $h$ is not equal to any $\lambda_j$, the larger the value of $-\sum_j\frac{(C_r^j+C_s^j)^2}{h-\lambda_j}$ is, the easier the molecular complex formation is, and when $h$ is equal to $\lambda_f$, the reactivity is proportional to $|C_r^f+C_s^f|$.

## Results and Discussion

The easiness of the molecular complex formation depends upon many factors such as delocalization energy, dispersion energy, exchange repulsion energy and electrostatic energy. Therefore, the reactivity should be discussed under consideration of all these factors. In discussing the relative easiness of complex formation of a series of similar compounds, however, it is expected that the energies, other than delocalization energy, contributing to the activation energy, may be approximately constant or negligible. In such a case, the delocalization energy is considered to play a dominant role.

In the present paper, an attempt is made to

TABLE I. THE VALUES OF THE INDEX FOR COMPLEX FORMATION AND THE EQUILIBRIUM CONSTANT FOR THE COMPLEX BETWEEN SILVER CATION AND AROMATIC COMPOUNDS

With regard to toluene and xylene, and carbon-carbon bond adjacent to the methyl group is not taken into account for the sake of steric circumstances.

$K_1$ is the equilibrium constant for the following reaction

$$Ag^+ + Ar = AgAr^+ \qquad K_1 = (AgAr^+)/(Ag^+)(Ar)$$

explain the reactivity of complex formation of a series of similar compounds by the consideration of the delocalization energy only. The delocalization energies calculated by the formulas stated above are tabulated in Table I together with the equilibrium constants of the first step of the molecular complex formation between silver cation and aromatic compound[10]. A clear parallelism is seen between the index and the equilibrium constant. The parameters used in calculation for methyl group are as follows.

$\alpha_{CH_3}$ (Coulomb integral for methyl group in Eq. 1) = 3

$\beta_{C\text{-}CH_3}$ (resonance integral for $CH_3$-C bond in Eq. 1) = 1

The energies of the highest occupied levels thus obtained are compared with the observed ionization potentials in Table II. At a glance at this table, a good parallelism is observed between the ionization potential and the energy of the highest occupied level. This implies that the adopted parameters should be appropriate.

TABLE II. RELATION BETWEEN THE IONIZATION POTENTIAL AND THE HIGHEST OCCUPIED LEVEL IN AROMATIC COMPOUNDS

|  | 1.33 | 1.900 | −0.452 |
|  | 1.30 | 1.737 | −0.568 |
|  | 1.09 | 1.798 | −0.605 |

Thick lines in the figure of aromatic compounds indicate the bonds with maximum value of the index, which are assumed to be the positions of attack by silver cations.

$K_1$ is the equilibrium constant for the following reaction.

$$Ag^+ + Ar = AgAr^+ \qquad K_1 = (AgAr^+)/(Ag^+)(Ar)$$

the assumption that this compound has a plane structure. Experimental data show that this compound is not planar. If two benzene nuclei are but little conjugated with each other, the value of the equilibrium constant for this compound may reasonably be expected to be approximately twice as large as that of benzene as was pointed out by Andrews et al.[10] On the other hand, the index is scarcely affected by the degree of conjugation between two benzene nuclei. On the occasion of comparison with the value of the index, therefore, the observed value of equilibrium constant must be divided by a factor which is larger than unity and smaller than two. This is the reason why the observed value of the equilibrium constant seems too large in comparison with the magnitude of the index calculated.

It seems that also the value of energy of the highest occupied orbital can be a good measure for complex formation. This fact shows that the ionization potential is also useful as a rough index to discuss the easiness of complex formation, though it is impossible to predict the position of attack as stated above.

Furthermore, the complex formation in polycondensed aromatic hydrocarbons is treated in a similar manner and the results are shown in Table III. In this series the parallelism between the value of index and equilibrium constant[11] is not so good. In these polycondensed aromatic hydrocarbons their molecular size is not uniform. The coordination with silver cations may take place at more than one positions in a molecule which has more than one positions of equal or nearly equal reactivity. One silver cation which has already added to a position in a hydrocarbon molecule will not exert a substantial influence upon the later addition of another silver cation to another position in the same molecule, provided these two positions are sufficiently apart from each other. In such a case, in order to be compared with the calculated value of the theoretical index, the observed value of the equilibrium constant must be modified by considering the number of sites in one molecule as is stated above in the case of biphenyl.

Another factor influencing the easiness of the complex formation is the polarizability which may be different in various cases. This means that ion-induced dipole interactions are not uniform from molecule to molecule, and it is indispensable for the prediction of reactivity to take the ion-dipole interaction into account. This point will be discussed in future.

# *Infrared Spectra of Cyclohexanoxime and Cyclohexanoxime-d*

By Masao KIMURA, Yoko KURODA, Osamu YAMAMOTO* and Masaji KUBO

(Received January 17, 1961)

Although several studies have been made on the infrared spectra of oximes, most of them have dealt with OH and C=N stretching vibration. Other vibrational frequencies of the functional group of oximes such as those of the NO stretching, the OH bending, etc. have attracted less attention. The infrared spectra of diacetyl monoxime and isonitrosoacetone have already been reported[1]. The study was undertaken in an attempt to inquire into the character of the absorption spectra of oximes. However, each molecule of these compounds has a carbonyl group in conjugation with a C=N bond. Moreover, the type of hydrogen bondings in these compounds could not be determined uniquely, because both a nitrogen atom and an oxygen atom in an oxime group as well as the oxygen atom of a carbonyl group may take part in hydrogen bonds as a proton acceptor. In the present study, it is attempted to assign the observed bands of cyclohexanoxime and cyclohexanoxime-*d* to various modes of the functional group. These compounds are devoid of conjugate systems. In addition, the crystal structure of cyclohexanoxime has already been determined by X-ray analysis[2]. It is reported that the crystal consists of trimers linked by O-H···N hydrogen bonds. Accordingly, all absorption bands, at least those observed in the spectra of the solid, can be interpreted as arising from the vibrations of assciated molecules linked by hydrogen bonding of this type.

The infrared spectrum of cyclohexanoxime has been recorded by Cross and Rolfe[3], Palm and Werbin[4], Califano and Lüttke[5], Matsui[6] and Bredereck et al.[7], but no complete assignment of bands has been carried out as yet.

## Experimental

A commercial preparation of cyclohexanoxime was purified by recrystallization from a solution in ligroin. A deuterated sample was prepared by exchanging hydrogen of OH groups with deuterium from heavy water. These samples were dried before use.

The spectra were taken with a Hilger H-800 spectrophotometer equipped with rock-salt and potassium bromide prisms, the region scanned covering 4000~500 $cm^{-1}$. Both potassium bromide disks and Nujol or hexachlorobutadiene mulls were employed for taking the spectra of solids. Solutions of various concentrations in carbon tetrachloride and carbon disulfide were also used in order to observe changes in absorption intensity with concentration. All the infrared spectra were recorded at room temperature.

## Assignment and Discussion

All absorptions associated with the functional group -C=N-OH of oximes except for the C=N stretching vibration are expected to show an appreciable concentration dependence, just as is observed in the spectra of diacetyl monoxime and isonitrosoacetone[1]. On deuteration, new bands arising from OD groups should appear in place of all bands attributable to OH groups. Therefore, attention was paid especially to the concentration dependence of absorption intensity as well as to the disappearance of certain bands on deuteration. Bands involving changes in intensity with concentration are listed in Table I. The C=N stretching frequency is also given in Table I, since it is considered to be a frequency characteristic of the functional group of oximes.

**OH and OD Stretching Frequencies, $\nu$(OH) and $\nu$(OD).**—For the OH stretching vibration, a single sharp band and a composite broad band consisting of two sub-maxima were observed in the range 3600~3000 $cm^{-1}$ (Fig. 1). The intensity of the latter band became strong with increasing concentration at the expense of that of the former. Only the broad band was present in the spectrum of the solid. These bands shifted towards much lower frequencies on deuteration (Table I). The band of the OD stretching vibration showed a general pattern and a concentration change almost identical with those of the OH stretching

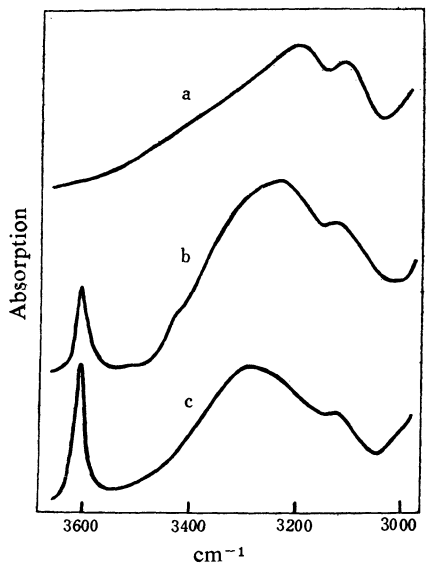

Fig. 1. Infrared absorption spectra of cyclohexanoxime. (a) Solid in a KBr disk, 2 mg./200 mg. KBr. (b) 0.24 mol./l. $CCl_4$ solution, 0.2 mm. cell. (c) 0.10 mol./l. $CCl_4$ solution, 0.53 mm. cell.

vibration. However they were masked by the absorption bands of carbon dioxide to such an extent that it was not feasible to locate them exactly. The single sharp band and the broad band were ascribed to the stretching vibrations of the OH or OD bond of free molecules and associated molecules, respectively.

The broad band of bonded OH groups at about 3200 $cm^{-1}$ showed nearly the same appearance regardless of the state of the samples (Fig. 1), indicating that the type of hydrogen bonding formed in solution was -OH···N=C<. The appearance of the band was almost independent of the concentration of solutions. Accordingly, the presence of two sub-maxima in the bonded OH stretching band observed in solutions is not attributable to different kinds of hydrogen bondings or to various polymeric molecules involving hydrogen bondings of various extents. In the spectra of diacetyl monoxime and isonitrosoacetone, similar composite absorptions having few sub-maxima were observed for the bonded OH stretching vibrations. In the previous paper, the form of hydrogen bonding was presumed for these compounds to be of the -OH···O=C< type. However, unlike the behavior of the stretching band of bonded OH groups in cyclohexanoxime, the shape of the bands and the position of the sub-maxima in the spectra of diacetyl monoxime and isonitrosoacetone changed to some extent with the state of aggregation and also with the concentration of solutions. The frequency shift of the OH stretching vibration caused by association was about 240 $cm^{-1}$ in diacetyl monoxime and isonitrosoacetone, whereas it was about 400 $cm^{-1}$ in cyclohexanoxime. This suggests that the

hydrogen bonds in cyclohexanoxime are different from and stronger than those in diacetyl monoxime and isonitrosoacetone.

**C=N Stretching Frequency, $\nu$(C=N).** — Only one absorption band of medium intensity could be observed in the range 1750～1500 $cm^{-1}$ (Table I). Accordingly, this absorption was assigned to the C=N stretching vibration. The band showed no change in its intensity with concentration and state, although deuteration caused a slight lowering of the frequency.

The value of 1662 $cm^{-1}$ for the C=N stretching vibration is in agreement with 1669 $cm^{-1}$ reported by Cross and Rolfe[3], 1662 $cm^{-1}$ by Palm and Werbin[4] and 1665 $cm^{-1}$ by Bredereck et al.[7] These values are characteristic of unconjugated oximes such as acetaldoxime and formaldoxime and are higher than those of conjugated oximes such as diacetyl monoxime (1630 $cm^{-1}$) and isonitrosoacetone (1613 $cm^{-1}$). Since in cyclohexanoxime, diacetyl monoxime and isonitrosoacetone, association caused no frequency shift of the C=N stretching band while deuteration was accompanied by a shift of only about 10 $cm^{-1}$, a separation between the C=N stretching frequencies of conjugated and

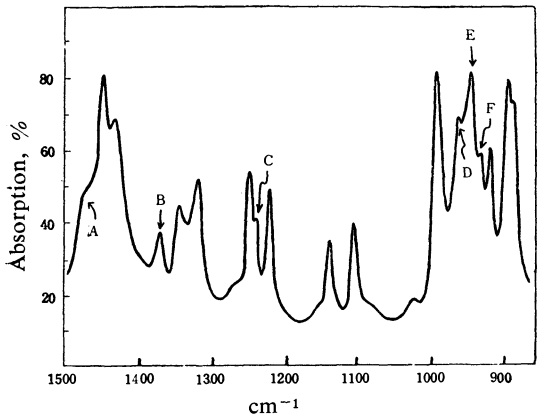

Fig. 2a.

unconjugated oximes is presumably due to the difference in the double bond character of the C=N bond. In fact, the C=N bond of *p*-benzoquinone monoxime involving a very strong conjugation absorbs at 1555 $cm^{-1}$, which is much lower than the corresponding wave number of diacetyl monoxime and isonitrosoacetone[8].

**OH and OD In-plane Bending Frequencies, $\delta$(OH) and $\delta$(OD), and Out-of-plane Bending Frequencies, $\gamma$(OH) and $\gamma$(OD).** — Bands disappearing on deuteration and the corresponding bands of the deuterated compound are associated with the absorptions by OH and OD groups, respectively (Table I). Such bands appearing below 1500 $cm^{-1}$ can be classified into two groups on the basis of their frequencies and the widths. One of them includes bands showing a distinct absorption peak in the higher frequency region except for a band at 1480 $cm^{-1}$, which was partly masked by a strong absorption due to the $CH_2$ bending. The other is comprised of relatively diffuse bands appearing in the lower frequency region. Bands at 1480, 1372 and 1237 $cm^{-1}$ and the corresponding bands of the deuterated compound at 1080, 1015 and 971 $cm^{-1}$ belong to the former group and must be ascribed to the in-plane bending vibration of the OH and OD groups, respectively, because they are in a wave number range, in which this kind of vibration is usually expected (Figs. 2 and 3). The band of cyclohexanoxime near 750 $cm^{-1}$ and that of the deuterated compound at about 550 $cm^{-1}$ belong to the latter group and were assigned to the out-of-plane bending vibration of the OH and OD groups, respectively (Figs. 4 and 5). No absorption band arising from the OH out-of-plane bending vibration of free molecules will be observed in the potassium

bromide region. Generally speaking, the OH or OD bending frequency of associated molecules of organic compounds is higher than that of free molecules. Bands arising from free molecules must be absent in the spectra of solids. Thus, the band of cyclohexanoxime at 1480 $cm^{-1}$ and that of the deuterated compound at 1080 $cm^{-1}$ were reasonably assigned to the vibration of associated molecules. This assignment is consistent with the change of intensity with concentration.

Two bands were found to be associated with the OH in-plane bending vibration of free molecules. A similar situation was observed in some alcohols by Tarte and Deponthière[9] and Maclou and Henry[10]. For instance, Tarte and Deponthière have reported two bands at 1243 and 1030 $cm^{-1}$ for ethanol vapor and assigned them to the OH in-plane bending vibration of free molecules, because these bands were replaced by two bands at 890 and 790 $cm^{-1}$ on deuteration. As was pointed out Tarte and Deponthière, two reasons are conceivable for the origin of the appearance of two bands: rotational isomerism about a C-O bond and some coupling such as Fermi resonance. Pritchard and Nelson[11] interpreted the bands of *tert*-butanol in solutions at 1329 and 1141 $cm^{-1}$ as the coupled bands of the $CH_3$ rocking and the OH in-plane bending of free molecules. However, such coupling seems unlikely to exist in cyclohexanoxime. The ratio of the product of two frequencies for the OH in-plane bending vibration and that for the OD in-plane bending vibration is 1.72 rather than $\sqrt{2}$ as expected from the product rule. The value seems to favor an interpretation of the double band in terms of rotational isomerism about an N-O bond. Such double OH bending frequency was not observed for diacetyl monoxime and isonitrosoacetone. In these compounds, a lower frequency band due to free OH groups might be masked by other strong absorption bands, although it is conceivable that these compounds have a single OH in-plane bending band. Califano and Lüttke did not mention the double character of the free OH bending vibration in their study on acetaldoxime and formaldoxime. Further examination is required in order to elucidate this problem.

Bands at 795 and 580 $cm^{-1}$ observed in the crystals of cyclohexanoxime and cyclohexanoxime-*d*, respectively, could not be observed even in concentrated solutions. However, new very broad bands appeared at 740 and 535 $cm^{-1}$. The frequency difference between crystals and solutions will be due to the different molecular environments.

**NO Stretching Frequeny, $\nu$(NO).**—Bands at 961, 948 and 933 $cm^{-1}$ and the corresponding bands of the deuterated compound at 955, 944 and 930 $cm^{-1}$ can be assigned unequivocally to the NO stretching vibrations (Figs. 2 and 3). From their concentration dependence, it is evident that the band of cyclohexanoxime at 961 $cm^{-1}$ and that of the deuterated compound at 955 $cm^{-1}$ are due to the NO stretching vibration of associated molecules.

Two bands were assigned to the NO stretching vibration of free molecules. They can possibly be ascribed to the respective NO stretching absorptions of two isomers. This fact provides an indirect but additional evidence in favor of the presence of rotational isomers. Deuteration gave rise to a slight shift of the NO stretching frequency to a lower frequency, while association caused a shift to a higher frequency by about 13 $cm^{-1}$, which is nearly equal to the amount of shift observed in diacetyl monoxime and isonitrosoacetone[1]. The NO stretching frequency observed in the present study is lower than those of *p*-benzoquinone monoxime and naphthoquinone monoximes[8] at about 1000 $cm^{-1}$, but is much higher than those of alkyl nitrites[12] covering a range 814 $\sim$751 $cm^{-1}$.

**Summary**

The infrared absorption bands due to the functional group of cyclohexanoxime and cyclohexanoxime-*d* were reasonably assigned by taking into account the concentration dependence of these bands in solutions. Cyclohexanoxime having no conjugate system showed a spectral feature different in many respects from that of diacetyl monoxime or isonitrosoacetone already studied. The type of hydrogen bonding is -OH···N=C< both in solutions and in the solid state. Consequently, the stretching frequency of bonded OH groups of cyclohexanoxime is different from those of diacetyl monoxime and isonitosoacetone. The doubling of absorption bands was observed for both the OH in-plane bending vibration and the NO stretching vibration of free molecules. This suggests the presence of rotational isomers. The wave numbers of the C=N stretching vibration is higher, while that of the NO stretching vibration is lower than those of the corresponding vibrations of diacetyl monoxime and isonitrosoacetone. This indicates that the double bond character of the C=N bond in cyclohexanoxime is greater than that in oximes having a conjugate system.

# *Dye-sensitized Photopolymerization of Vinyl Compounds. Polymerization of Acrylonitrile by Stannous Chloride and Acriflavine. I**

By Ai WATANABE and Masao KOIZUMI

(Received January 17, 1961)

The photochemical polymerization of vinyl compounds in the presence of a dye and a suitable reducing agent has been found by Oster[1], and it has been proposed that the initiation step is due to a certain kind of radical produced by the action of the oxygen upon leuco dye, which has been formed by the reduction of the original dye. It seems that most of the reactions can be well interpreted by this scheme, and yet there are only a few cases in which detailed kinetic studies have established the above scheme.

For example, the photopolymerization of acrylonitrile in the presence of a dye and a metallic ion such as $Sn^{2+}$, has not yet fully investigated, though it has been established by Oster that such systems are excellent for the preparatory purpose[2].

In the course of the preliminary investigations upon such systems which include more than twenty dyes and various reducing agents such as potassium thiocyanate, thiourea (TU), ascorbic acid (AA), sodium thiosulfate, stannous chloride etc., it was felt that a different scheme may occur in certain cases, especially in cases

where stannous chloride is used as a reducing agent. Hence using acriflavine which was found to be most efficient in combination with stannous chloride, we have examined kinetically the effect of various factors upon the rate of photopolymerization. This paper pertains to the results obtained when the system containing dimethylformamide (DMF), water, acrylonitrile (AN), acriflavine (Af or D) and stannous chloride was irradiated in the presence of oxygen.

## Preliminary Experiment

More than twenty dyes were tested preliminarily for examining their efficiency in promoting the polymerization, when they were added to the mixture of AN, water, methanol (2 : 1 : 1.2 in volume) containing potassium thiosulfate, TU, AA, sodium thiosulfate or stannous chloride as reducing agents. The samples in test tubes were irradiated by a 100 V.-500 W projection lamp (used at 80 V.) placed 10 cm. apart from the tubes for 1 hr. The magnitude of polymerization was visually judged from the quantity of the precipitate produced. The purpose of the experiments was to find extremely prominent cases, and the exact comparison of the result is of course impossible on account of crudeness in procedure, observation etc. In Table I are given the results obtained for the three types of dyes, about which the oxidative and reductive behavior have been examined to some extent. It is evident from the above table that there exists no parallelism between the magnitude of polymerization and the easiness in bleaching and recovery of color. For example, thiazine dyes which are easily reduced as well as rapidly reoxidized by oxygen, have rather a small power of initiating the polymerization. It is ture that the excess of oxygen will inhibit the polymerization since it has been confirmed by the suppression of polymerization by bubbling the air through the solution. But it is expected that the consumption of oxygen during the reoxidation of leuco dye will soon realize the situation in which the polymerization may take place rather smoothly. The above results in thiazine dyes contradict this expectation altogether. On the other hand xanthene dyes, of which the leuco form shows a great resistance against reoxidation by oxygen, can have some power of inducing polymerization when coupled with proper reducing agents. Acridine dyes, which lie between the above two classes as judged from our unpublished results which demonstrate that these dyes make reversible bleaching in the aqueous solution containing $Sn^{2+}$ whether oxygen exists or not, show a very pronounced efficiency for promoting polymerization when used with stannous chloride.

All these facts suggest that the photopolymerization induced by dyes would some in cases go via a different scheme from Oster's, especially in case of acriflavine and stannous chloride.

From such a viewpoint the quantitative investigation upon the system acriflavine-stannous chloride was undertaken.

## Experimental

**Materials.**—Acrylonitrile from American Cyanamide Co. was distilled after dehydrating with calcium chloride, b. p. 76.5°C. Dimethylformamide

(DMF) from Du Pont was dehydrated by potassium carbonate and then distilled, b. p. 151~151.5°C. $SnCl_2 \cdot 2H_2O$ (G. R) and $SnCl_4 \cdot 3H_2O$ (G. R) were used without further purification. Acriflavine from Merck was also used without purification.

**Procedure.**—As a light source a projection lamp 100 V.-500 W was used at 80 V. The distance between the light source and a reaction cell placed in a thermostat is 33 cm. Mazda Color Filter V-Y3C which cuts off $\lambda <$ ca. 420 m$\mu$ is set in front of the reaction cell. In the experiments for studying the effect of light intensity, neutral filters were used. A reaction cell is made of terex glass $1 \times 1 \times 4.5$ cm. and it is connected with a capillary utilized as a dilatometer. The drop of meniscus in the capillary due to polymerization was followed by use of a travelling microscope. All the experiments were done at 35°C except otherwise described.

To prepare the sample for reaction, (1) acrylonitrile, (2) the aqueous solution of dye and (3) DMF dissolving stannous chloride were mixed in a proper ratio. The concentration of dye and stannous chloride in the latter two solutions are adjusted to get a desired composition of the ultimate sample. In studying the effect of [AN], the ratio of 1 and 3 was changed keeping the quantity of 2 as constant, while for investigating the effect of [$H_2O$] the ratio of 2 and 3 was changed keeping the quantity of 1 as constant. It is to be noted that DMF solution of stannous chloride must be prepared prior to the experiment in order to get a good reproducibility.

In order to separate the polymer the sample, after the reaction, was poured into a large quantity of methanol and the precipitate was washed with methanol containing hydrochloric acid (concentrated hydrochloric acid : methanol = 0.0015 : 1 in volume) and after washing once more with methanol was dried at 40°C in vacuo. The molecular weight of the polymer thus obtained was determined by measuring the viscosity of the solution of DMF containing about 0.1% of polymer at 25°C. To calculate the intrinsic viscosity Schulz and Sing's formula[3] was employed.

$$[\eta] = \frac{\eta_{sp}/c}{1 + 0.28\eta_{sp}}$$

The average molecular weight was evaluated from the following relation[4].

$$[\eta] = 3.92 \times 10^{-4} \overline{M}^{0.75}$$

## Results

When the sample containing stannous chloride and acriflavine is irradiated, the polymerization usually commences at once, but when the sample contains only either of the two the polymerization does not occur in fact. There is no dark reaction perceived even when a large quantity of stannous chloride and acriflavine are added. In Fig. 1, curve 1 represents the rate for the sample, AN : $H_2O$ : DMF = 4 : 3 : 4.2 (in volume), [$SnCl_2$] = $2.73 \times 10^{-2}$ M, [Acriflavine] = $2.73 \times 10^{-4}$ M. Accompanied with the polymerization, the solution becomes turbid due to the precipitation of the polymer. When the concentration of stannous chloride is small a certain period of induction appears and after that the curve becomes linear (curve 2). As regards curve 3 mention will be made later. In case of a small concentration of dye the rate begins to decrease earlier than in other cases. In all cases the rate was evaluated from the initial linear portion of the curve. It is to be noted that when the same cell was used for a long period of time, the cell walls gradually became opaque and it had to be renewed occasionally. Therefore, it is not always possible to compare and to correlate the data of a different series of experiments described below.

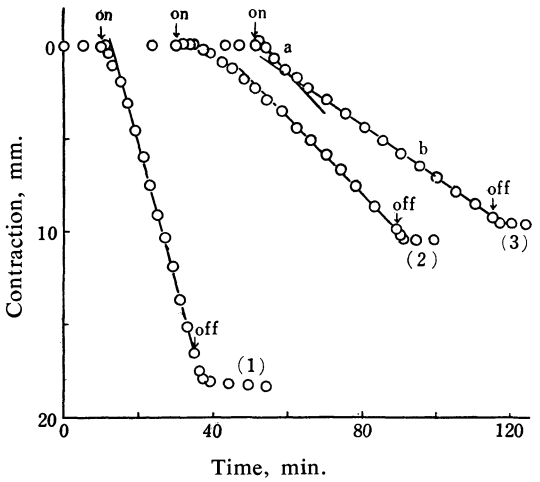

Fig. 1. The contraction-time curves.

| | [D] $10^{-4}$ M | [$SnCl_2$] $10^{-3}$ M | AN : $H_2O$ : DMF (in volume) |
|---|---|---|---|
| (1) | 2.73 | 27.3 | 4 : 3 : 4.2 |
| (2) | 2.73 | 1.71 | 4 : 3 : 4.2 |
| (3) | 3.00 | 11.0 | 3.6 : 0.51 : 5.89 |

**1. The Effect of Evacuation.** — The relative rates of the cautiously degassed samples were 1.02, 1.16 as compared with 1.49, 1.52, 1.46 of the aerated ones ([Acriflavine] = $1.0 \times 10^{-4}$ M, [$SnCl_2$] = $1.25 \times 10^{-2}$ M, AN : $H_2O$ : DMF = 3.3 : 2.0 : 4.7 (in volume)). It is evident that the polymerization does take place in the evacuated sample though the rate is somewhat smaller than the aerated solution. The ratio of the rates in two cases being about 1 : 1.4, it seems rather plausible to consider that the effect of oxygen is of the secondary importance (see Discussion). Tentatively assuming the above viewpoint and to orient the investigation, the effect of various factors upon the rate was examined in the first place using aerated solution. Another reason for this was to avoid

3) G. V. Schulz and G. Sing, *J. Prakt. Chem.*, **161**, 161 (1942).
4) P. F. Onyon, *J. Polymer Sci.*, **22**, 13 (1956).

the troublesome procedure for repeated evacuation. The results given below concern only with such aerated samples.

**2. The Effect of Dye Concentration.** — The variation of the rate when the concentration of acriflavine is changed from zero to $1.4\times10^{-4}$ M is shown in Fig. 2. It is apparent from the

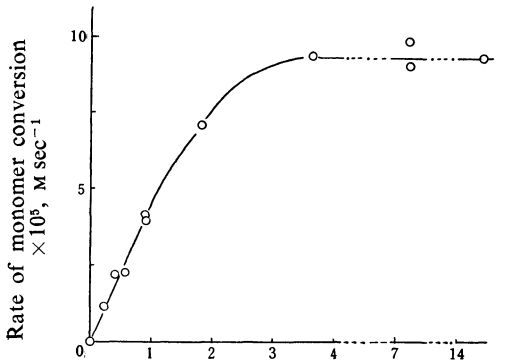

Fig. 2. Dependence of rate on acriflavine concentration.
$[SnCl_2]=1.8\times10^{-2}$ M; AN : $H_2O$ : DMF = 4 : 3 : 4.2 (in volume)

figure that in the region of $\sim10^{-6}$ M of dye, the rate linearly increases with the dye concentration. This was further confirmed by log (rate)$\sim$log[AF] curve, which gave the slop of 0.9. When the concentration of dye exceeds ca. $3.5\times10^{-5}$ M, the rate remains constant. From the above results it is concluded that, at a small concentration of dye, the rate is proportional to the dye concentration and it appears to be proportional also to the absorbed light but it will be shown below that it is not the fact (see Sect. 7).

**3. The Effect of the Concentration of Stannous Chloride.**—The effect of the concentration of stannous chloride on the rate is shown in Fig. 3. Although there exists some scattering of the experimental points, it is still evident that in the low concentration region ($<$ ca. $3.5\times10^{-3}$ M) the linearity holds between the rate and $[SnCl_2]$, and this fact was also confirmed by the slope of 0.9 for log (rate)$\sim$log $[SnCl_2]$ plot. Above ca. $10^{-2}$ M of stannous chloride the rate remains constant. It is to be added that in the case of a high concentration of $[SnCl_2]$ the polymer deposits throughout the entire cell while in case of low concentration, the polymer adheres to the lower half of the front wall of the vessel.

**4. The Effect of Monomer Concentration.**— In Fig. 4, the rate is plotted against the square of the monomer concentration. It is apparent that the rate $\propto[AN]^2$. Another series of experiments gave a similar result. log(rate)$\sim$log[AN] plot gave a straight line of slope 1.9$\sim$2.05.

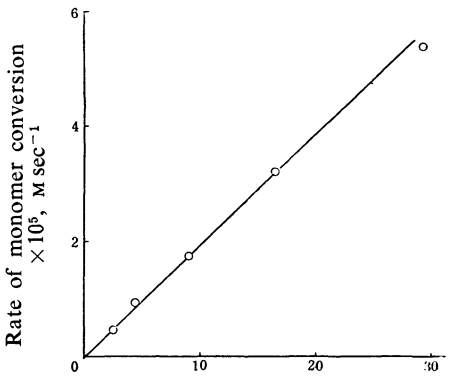

Fig. 4. Dependence of rate on acrylonitrile concentration.
$[D]=3.00\times10^{-4}$ M; $[SnCl_2]=1.37\times10^{-2}$ M; $[H_2O]=14.9$ M

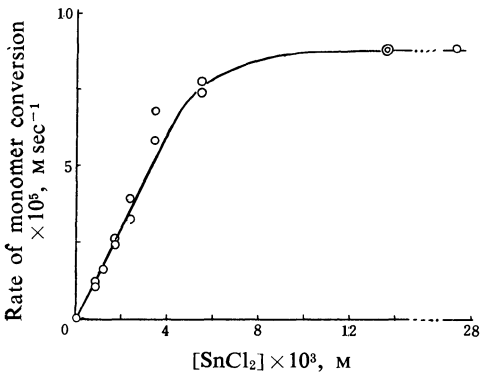

Fig. 3. Dependence of rate on stannous chloride concentration.

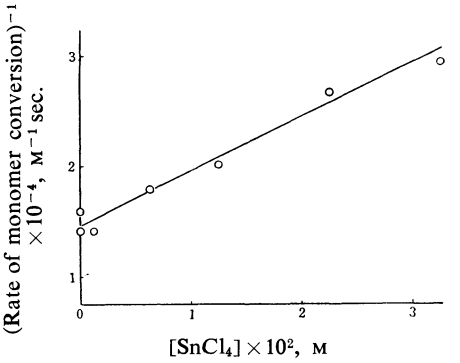

Fig. 5. Dependence of rate on stannic chloride concentration.
$[D]=2.00\times10^{-4}$ M; $[SnCl_2]=1.25\times10^{-2}$ M; AN : $H_2O$ : DMF = 3.6 : 2.5 : 4.0 (in volume)

**5. The Effect of the Concentration of Stannic Chloride.** — When $SnCl_4$ is added, the rate is decreased. As shown in Fig. 5, there exists an approximate linearity between the reciprocal of the rate and the concentration of stannic chloride.

**6. The Effect of Water Content.** — It was found that the polymerization can occur without any water being added, and the effect of water content on the rate was investigated in some detail. Time plots in the case of a large quantity of water were simple as shown in Fig. 1 (1), but they were curved as shown in Fig. 1 (3) when the content of water was low. Corresponding to this anomaly the polymer did not appear at first; the above phenomenon may perhaps be connected with the precipitation of the polymer. In Fig. 6 the rate is plotted against $[H_2O]/[DMF]$; × and ○ represent respectively the rates evaluated from parts a and b of the curve. It is apparent from

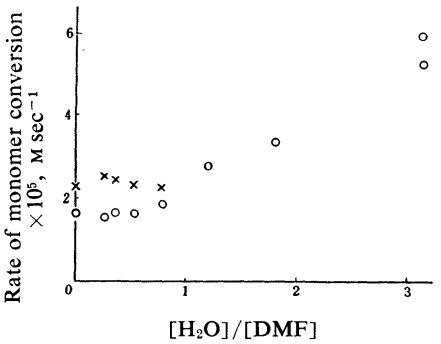

Fig. 6. Dependence of rate on $[H_2O]/[DMF]$.
$[AN]=5.4$ M; $[D]=3.0\times10^{-4}$ M; $[SnCl_2]=1.1\times10^{-2}$ M

the figure that the addition of water up to about $[H_2O]/[DMF]=1$ scarcely affects the rate but a larger quantity causes an increase to some extent. It is known that 1 : 1 complex is formed between DMF and water[5], and the above result might be correlated with this phenomenon.

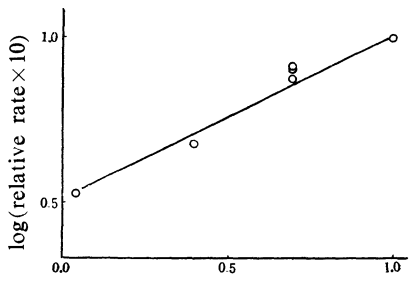

Fig. 7. The intensity exponent.
$[D]=2.00\times10^{-4}$ M; $[SnCl_2]=1.25\times10^{-2}$ M;
AN : $H_2O$ : DMF = 3.6 : 2.5 : 4.0 (in volume)

5) A. D. Jenkins and R. Johnston, ibid., 39, 81 (1959).

**7. The Effect of Light Intensity.** — The intensity of the exciting light was changed to 50, 25 and 11% of the standard light by use of neutral filters. As seen from Fig. 7 the rate is nearly proportional to the root of light intensity. Although these experiments were done only for the samples containing such a large quantity of dye as to absorb almost all the effective light, there is scarcely any doubt that this relation also holds for the case of a small concentration of dye.

**8. Average Degree of Polymerization.**—The effect of the monomer concentration on the degree of polymerization was examined. As shown in Fig. 8, linear relation holds approximately between $\bar{P}$ and [AN]. The effect of the addition of stannic chloride on $\bar{P}$ was also

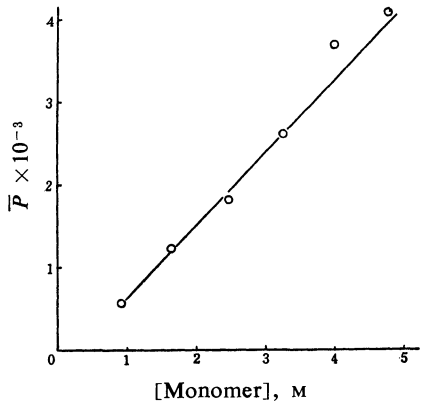

Fig. 8. Dependence of average degree of polymerization on acrylonitrile concentration.
$[D]=2.00\times10^{-4}$ M; $[SnCl_2]=1.25\times10^{-2}$ M; $[H_2O]=13.9$ M

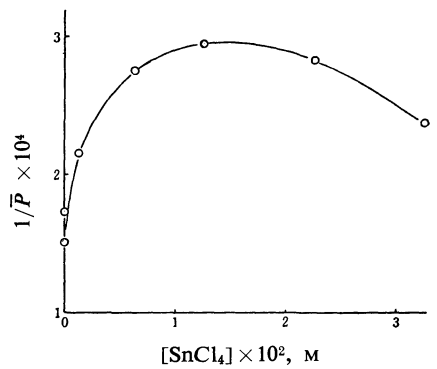

Fig. 9. Dependence of average degree of polymerization on stannic chloride concentration.
$[D]=2.00\times10^{-4}$ M; $[SnCl_2]=1.25\times10^{-2}$ M; AN : $H_2O$ : DMF = 3.6 : 2.5 : 3.9 (in volume)

examined. The result is shown in Fig. 9. If stannic chloride only takes part in the termination or chain transfer process, $1/\bar{P}$ should increase monotonously with $[SnCl_4]$, so that it is certain that stannic chloride interferes with other processes, particularly with the initiation step.

**9. Activation Energy.**—The temperature dependence of the rate was measured in the region from 16.5 to 40°C. The Arrhenius plot is shown in Fig. 10. The rate is almost independent of temperature between 25 and 40°C. But below about 25°C, the rate decreases with the fall of temperature. The apparent activation energy is evaluated to be 7±2 kcal./mol.

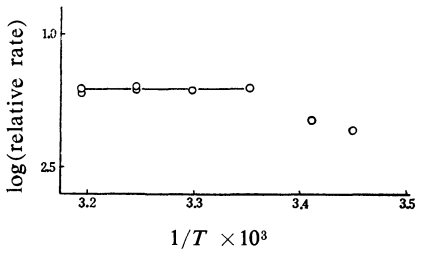

Fig. 10. Arrhenius plot.
$[D]=2.00\times10^{-4}$ M; $[SnCl_2]=1.25\times10^{-2}$ M; AN : $H_2O$ : DMF = 3.6 : 2.5 : 4.0 (in volume)

## Discussion

From the result that the polymerization takes place in the degassed solution and with the same order of rate as that of the aerated one, it is certain that the existence of oxygen is not of primary importance for the reaction to occur. Hence it is tentatively assumed that oxygen is not involved in the essential steps of the reaction, particularly in the early stages of the initiation. Then the molecular species which participate in the initiation step would be stannous chloride, acriflavine and AN, since both water and stannic chloride do not affect the rate so much. Thus the addition of stannic chloride as much as $3\times10^{-2}$ M only decrease the rate to about a half and 15 M of water increases the rate only 3~4 times, a small amount scarcely affecting the rate. It may be certain that stannous chloride employed contains a small amount of stannic chloride, but its effect may be neglected from the experimental results. Hence attention will be paid only on the dependence of the rate upon $[SnCl_2]$, [D], [AN] and intensity of light $I_0$.

Now the overall rate of polymerization is in general expressed by the following equation if the condition of steady state is satisfied.

$$v=k_p[R][M] \qquad (I)$$

where [R] and [M] are the concentrations of growing polymer and monomer. [R] can be expressed by II or III according as the termination process is the first order or the second order in regard to [R].

$$[R]=v_i/k_t \qquad (II)$$

$$[R]=(v_i/k_t)^{1/2} \qquad (III)$$

The experimental rate formula satisfies the following condition

$$v \propto [D][SnCl_2][M]^2$$

and

$$v \propto I_0^{1/2}$$

when [D] and $[SnCl_2]$ are small.

Hence $v_i$ in this case must be expressed as follows:

case II, $v_i \propto [D]^{1/2}[D^*]^{1/2}[SnCl_2][M]$

case III, $v_i \propto [D][D^*][SnCl_2]^2[M]^2$

where D* is the excited dye. Case III however can be rejected since it was found experimentally that the following relation holds,

$$\bar{P} \propto [M]$$

and in general $\bar{P}$ may be equated to $v/v_i$ at least approximately (unless the rate of chain transfer is quite appreciable). Thus the initiation processes must be those that satisfy the following relations.

When [D] and $[SnCl_2]$ are small

$$v_i \propto [D]^{1/2}[D^*]^{1/2}[SnCl_2][M] \qquad (IV)$$

When both [D] and $[SnCl_2]$ are large

$$v_i \propto [M]I_0^{1/2} \qquad (V)$$

The equations IV and V look rather unusual and these suggest the peculiar character of the reaction scheme.

Here we propose the following two schemes as plausible ones.

A. $D \xrightarrow[(1)]{h\nu} D^* \xrightarrow[(3)]{D} D^t \xrightarrow[(5)]{Sn^{2+}} (D^- \cdots\cdots Sn^{3+})$

$D^*$ —(2)→ D; $D^t$ —(4)→ D; $(D^- \cdots\cdots Sn^{3+})$ —(6′)→ $D+Sn^{2+}$; —(6)→ $Leuco+Sn^{4+}$

$\xrightarrow[(7)]{Sn^{2+}} D + Sn^+ + Sn^{3+} \xrightarrow{(8)} D + 2Sn^{2+}$

(or $D^- + Sn^{3+}$) (or $D + Sn^{2+}$)

$Sn^{3+} + M \xrightarrow[(9)]{k_1} R$

(or $Sn^+ + M \longrightarrow R$)

B. $D + Sn^{2+} \underset{(0)}{\overset{K_0}{\rightleftarrows}} (DSn^{2+}) \xrightarrow[(1)]{h\nu} (D^*Sn^{2+})$

$(D^*Sn^{2+})$ —(2)→ D

$\xrightarrow[(3)]{D} (D^tSn^{2+}) \xrightarrow[(5)]{} (D^- \cdots\cdots Sn^{3+})$

$(D^tSn^{2+})$ —(4)→ D; $(D^- \cdots\cdots Sn^{3+})$ —(6′)→ $D+Sn^{2+}$; —(6)→ $Leuco+Sn^{4+}$

$\xrightarrow[(7)]{Sn^{2+}}$ same as above

In scheme A, $Sn^{2+}$ participates in the steps 5 and 7 while in scheme B a complex is formed between $Sn^{2+}$ and D and the corresponding scheme to 5 in A is lacking. In both schemes it is assumed that the transition from singlet excited state (D*) to triplet ($D^t$) is induced by the ground state dye molecule. Although this is plausible and in fact such a process has also been accepted by Oster for the case of acridine dyes[6], it is noteworthy that there is another possibility that the excimer[7] be formed between D and D*. The discrimination may however be impossible only from the rate formula. ($D^- \cdots\cdots Sn^{3+}$) is supposed to be a charge transfer complex or the like.

For both schemes A and B the essential point is that two kinds of molecular species of radical nature produced by process 7, react almost exclusively in such a way as to produce stable molecular species and only a small fraction of them react with monomer to produce an initiator of polymerization 9. Thus when $D^-$ and $Sn^{3+}$ are produced by 7 electron transfer should rapidly occur between them, recovering D and $Sn^{2+}$, while when D, $Sn^+$ and $Sn^{3+}$ are produced, the analogous electron transfer should take place between $Sn^+$ and $Sn^{3+}$ (8), $Sn^+$, $Sn^{3+}$, $D^-$ (this is rather unplausible) or all of them may initiate the polymerization. In fact such schemes as above seem almost indispensable to interpret the following relations consistently.

$$v_1 \propto I_0^{1/2}, \qquad v \propto [M]^2, \qquad \bar{P} \propto [M]$$

From the above schemes, the following rate formulas can be derived.

Case A

$$v_1 = \left[\left\{\frac{k_1 I_0 k_3 [D]}{k_2 + k_3 [D]}\right\}\left\{\frac{k_5 [Sn^{2+}]}{k_4 + k_5 [Sn^{2+}]}\right\} \times \left\{\frac{k_7 [Sn^{2+}]}{k_6 + k_6' + k_7 [Sn^{2+}]}\right\}\right]^{1/2} \frac{k_9}{k_8^{1/2}} [M] \qquad (VI)$$

Case B

$$v_1 = \left[\left\{\frac{I_0 k_1 K_0 [Sn^{2+}]}{1 + K_0 [Sn^{2+}]}\right\}\left\{\frac{k_3 [D]}{k_2 + k_3 [D]}\right\}\left\{\frac{k_5}{k_4 + k_5}\right\} \times \left\{\frac{k_7 [Sn^{2+}]}{k_6 + k_6' + k_7 [Sn^{2+}]}\right\}\right]^{1/2} \frac{k_9}{k_8^{1/2}} [M] \qquad (VII)$$

Both VI and VII can express the experimental results satisfactorily as in the following way.

i) Large [D]: $v$ is independent of [D].

$$v \propto I_0^{1/2}$$

ii) Small [D]: $k_1 I_0$ may be put approximately proportional to [D]. Hence

$$v \propto [D]$$

iii) Large $[Sn^{2+}]$: $v$ is independent of $[Sn^{2+}]$.

iv) small $[Sn^{2+}]$: $v \propto [Sn^{2+}]$

v) In all cases, $v \propto [M]^2$

As for the effect of water, both hydration of D and the formation of a certain ion pair from $Sn^{2+}$ and $OH^-$ would favor the reaction. For example the formation of $(SnOH)^+$ would promote processes 5 and 7 in both case A and case B; moreover the hydration of D would also be favorable for these process and in addition, for 3 and 0 (in case B). All these effects together should cause the rate to increase with the content of water. But these effects are of secondary importance in the reaction scheme and to not affect the rate very much.

In connection with the above schemes, it may be worthy of adding here some discussions about the rate of dye bleaching in the absence of acrylonitrile. Provided that process 7 be neglected, the rate of bleaching of dye will be given as follows:

Case A

$$\frac{k_1 I_0 k_3 [D]}{k_2 + k_3 [D]} \cdot \frac{k_5 [Sn^{2+}]}{k_4 + k_5 [Sn^{2+}]} \cdot \frac{k_6}{k_6 + k_6'} \qquad (VIII)$$

Case B

$$\frac{k_1 I_0 K_0 [Sn^{2+}]}{1 + K_0 [Sn^{2+}]} \cdot \frac{k_3 [D]}{k_2 + k_3 [D]} \cdot \frac{k_5}{k_4 + k_5} \cdot \frac{k_6}{k_6 + k_6'} \qquad (IX)$$

Thus the similar relation in respect to [D] and $[Sn^{2+}]$ will hold for two cases. But when the process 7 participate in the reaction the rate would decrease when the concentration of $Sn^{2+}$ exceeds a certain value. It may be possible to examine this effect experimentally.

If Oster's mechanism holds in the present case, which postulates the formation of leuco dye prior to the initiation process, the rate formula of initiation would be similar to VIII and IX which contradicts the experimental results altogether. Thus three relations $v \propto I_0^{1/2}$, $v \propto [M]^2$ and $\bar{P} \propto [M]$ can not be interpreted satisfactorily on this basis. Analogous discussion may be extended to the effect of oxygen on the rate, the increase amounting to about 40% of that of the evacuated solution. If this increase is due to the participation of the process $D + SnCl_2 \rightarrow Leuco + SnCl_4$, $Leuco + O_2 \rightarrow$ active radical, then the kinetic order in respect to $[SnCl_2]$ and [D] would be the average of the two simultaneous reactions and

7) B. Stevens and E. Hutton, *Nature*, **186**, 1045 (1960).

would not be the whole number as experimentally obtained. Hence it seems more plausible that oxygen interferes with the intermediate ($D^- \cdots\cdots Sn^{3+}$) rather than its attack on leuco dye. The discrimination between cases A and B may perhaps be made by spectroscopic investigation. Further investigations are now under way to confirm the above schemes more definitely and to select case A or case B.

## Summary

When the aerated solution of acrylonitrile, acriflavine and stannous chloride in the mixture of water and dimethylformamide is irradiated by the visible light, the polymerization of acrylonitrile immediately takes place. The presence of water and oxygen was found to be unnecessary for the reaction to occur. The dependence of rate on the concentration of each species and on the light intensity ($I_0$) can be summarized as follows.

| | |
|---|---|
| Acriflavine | $<$ca. $1\times10^{-5}$ M, 1st order; |
| | $>$ca. $3.5\times10^{-5}$ M, const. |
| Stannous chloride | $<$ca. $3.5\times10^{-3}$ M, 1st order; |
| | $>$ca. $1.2\times10^{-2}$ M, const. |
| Acrylonitrile, | 2nd order |
| $I_0$, | 1/2th order |

It was further found that the average degree of polymerization is proportional to the monomer concentration. The scheme involving the photoreduction of dye by stannous chloride and its recovery by the existent oxygen cannot explain the present result. It was proposed as a new mechanism that a transient metallic ion of tin with an odd valency is formed and this, interacting with acrylonitrile, initiates the polymerization.

The present research was mostly performed by Ai Watanabe at Osaka City University and was finished during her stay at Sendai as a visiting research fellow. The authors express their cordial thanks to Professor R. Fujishiro of Osaka City University for his interest and encouragement.

# *The Photovoltaic Behavior in Organic Compounds*

By Hiroo INOKUCHI*, Yusei MARUYAMA* and Hideo AKAMATU

(Received January 17, 1961)

The study on the photo-electrical behavior in organic semiconductors produced by excitation accompanying absorption of light, especially the investigation of the photoconduction, has been carried out by several workers[1]. However, relatively little is known about the photovoltaic phenomena of these organic compounds[2].

In one of the few articles on this subject, Nelson[3] reported a photovoltaic behavior of junctions between organic compounds and cadmium sulfide in association with optical sensitization in photography. The author proposed that the induced photovoltage is related to the difference in energy between the conduction band of the organics (dye) and that of cadmium sulfide. On the other hand, Calvin and Kearns[4] reported interesting results on photovoltaic organic junctions: Mg-phthalocyanine || tetramethyl-*p*-phenylene diamine and coronene || chloranil junctions.

In this paper, we show that the photovoltaic behaviors have been observed with a simple cell, consisting of a junction between aromatic compounds and metal or stannic oxide. Further, in comparison with other semiconductive behaviors of polycyclic aromatic compounds, the produced electromotive force will be discussed.

## Experimental Procedures

For an observation of photo-electromotive force between organic semiconductor and metal or metal

oxide, a sandwich-type cell was applied. This cell was made by sandwiching aromatic compounds between two electrodes: The evaporated film of aromatic compounds was deposited onto a glass plate which had been coated in advance with a thin metal film or onto a stannic oxide conducting layer to provide a junction electrode. The specimen film was usually one or two microns in thickness. Further, the second electrode was evaporated onto the specimen film. The conducting path between these electrodes extended through the specimen film. The resulting construction of the cell was illustrated in Fig. 1 of the previous report[5].

For the preparation of alkali metal-aromatics junction, as shown in Fig. 1, the alkali metal, evaporated onto organic film as a second electrode under less than $10^{-5}$ mmHg, acted as a junction electrode. After the evaporation of alkali metal, all observations of their electromotive forces were carried out under a high vacuum to avoid a decomposition of the alkali metal by an action of moisture. However, a fluctuation was frequently introduced concerning the direction of electromotive force. For the elimination of this fluctuation, the construction of a more precise apparatus is in due course.

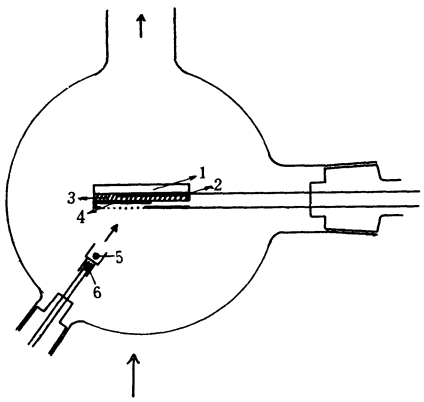

Fig. 1 The arrangement for preparation of alkali metal-aromatics junction. (1) Pyrex glass plate, (2) terminal electrode, (3) aromatic compound, (4) junction metal (alkali metal), (5) nickel dish, and (6) electric heater for evaporation.

The sandwich-type aromatics-aromatics junction was made by the successive evaporation of two sorts of aromatic compounds, kept in the vessel 5 of Fig. 1, onto a conducting glass plate without an intrusion of air into the contact area between these two compounds.

The illumination of white light was produced from a tungsten lamp onto the side of the junction metal. The measurement of induced photovoltage had to be associated with a vibration-reed electrometer because its produced electric power was extremely low. By means of a quartz-prism monochrometer and also of interference filters, a spectral response of photo-electromotive force in the range from 350 m$\mu$ to 1300 m$\mu$ was observed.

The applied aromatic compounds, perylene, violanthrene and violanthrone, were provided from Drs. T. Handa and also J. Aoki. Coronene, a seven membered aromatic hydrocarbon, was provided from Badisch Anilin und Soda Fabrik, Germany. These organic compounds were purified with a combination of three methods; recrystallization, sublimation and chromatography.

## Results and Discussions

When the contact between an organic semiconductor and a metal was illuminated with white light from a tungsten lamp, the induced electromotive force reached immediately a saturated value and this was kept quite steadily for a long period. However, in the alkali metal-aromatics junction it was found that its electromotive force decreased to a value smaller than the original one. This behavior would be introduced from a high reactivity of alkali metal with moisture and/or from a formation of charge transfer complex between the metal and the aromatic compound.

For the noble metal-aromatics junction, the observed photoelectromotive force varied from a few millivolts to 10 mV. depending on the sorts of metals applied to the junction and also on the condition of preparation technique as illustrated in Table I. In all of these photocells, the junction metal acted as a negative electrode against the terminal electrode; thereby, at the junction, electrons flowed from the hydrocarbons to the junction metals under the illumination.

On the other hand, a quite stable photovoltage was produced at the contact between perylene and stannic oxide, and its saturated value reached 80 mV. when a light was incident on it through the transparent stannic oxide electrode (electrical conducting glass electrode). The spectral response of this electromotive force was a curve which is in good coincidence with the optical absorbance curve and also with the response curve of photoconduction for solid perylene as illustrated in Fig. 2.

Similar behavior of the photovoltaic effect was found in the junction between coronene, violanthrene or violanthrone and stannic oxide, whose electromotive forces were 20, 450 and 80 mV. respectively. These four hydrocarbons acted as electron acceptors with respect to stannic oxide under illumination of panchromatic light. However, the spectral response of photovoltage of violanthrone junction was a quite peculiar one as shown in Fig. 3. Its threshold value was found to be around 0.9 eV., which is in agreement with that of the photoconduction of its aromatic compound.

TABLE I. THE PHOTOVOLTAGE OF METAL-AROMATICS JUNCTIONS

| Photovoltaic junction | | Photo-emf | |
|---|---|---|---|
| Aromatics (sign) | Metal (sign) | Voltage, mV. | Wattage, W. |
| Violanthrene (+) | Pt (−) | 2∼ 3 | $\sim 10^{-17}$ |
| Violanthrene (+) | Au (−) | 6∼ 9* | $\sim 10^{-16}$ |
| Violanthrene (+) | Ag (−) | Detectable | |
| Violanthrene (+) | Sn (−) | 2∼ 8 | $\sim 10^{-16}$ |
| Violanthrene (+) | Pb (−) | 4∼14 | $\sim 10^{-16}$ |

* As a special case, emf reached to 50 mV.

TABLE II. THE PHOTO-ELECTROMOTIVE FORCE OF ALKALI METAL-AROMATICS JUNCTIONS

| Photovoltaic junction | | Photo-emf | | |
|---|---|---|---|---|
| Aromatics (sign) | Metal (sign) | Voltage, V. | Wattage, W. | $\Delta\varepsilon/2$, eV. |
| Perylene (−) | Li (+) | 0.3∼1.0 | $\sim 10^{-10}$ | 1.0 |
| Coronene (−) | Li (+) | 0.3 | $\sim 10^{-10}$ | 0.8 |
| Violanthrene (−) | Li (+) | 0.3∼0.8 | $\sim 10^{-9}$ | 0.43 |
| Violanthrone (−) | Li (+) | 0.2∼0.9 | $\sim 10^{-10}$ | 0.39 |
| Perylene (+) | Na (−) | 0.3∼1.0 | $\sim 10^{-11}$ | 1.0 |
| Violanthrene (+) | Na (−) | 0.3∼0.8 | $\sim 10^{-10}$ | 0.43 |
| Violanthrone (±) | Na (∓) | 0.1∼0.5 | $\sim 10^{-8}$ | 0.39 |
| Perylene (±) | K (∓) | 0.2∼0.9 | $\sim 10^{-10}$ | 1.0 |
| Violanthrene (+) | K (−) | 0.2∼0.8 | $\sim 10^{-10}$ | 0.43 |
| Violanthrone (−) | K (+) | 0.2∼0.5 | $\sim 10^{-9}$ | 0.39 |

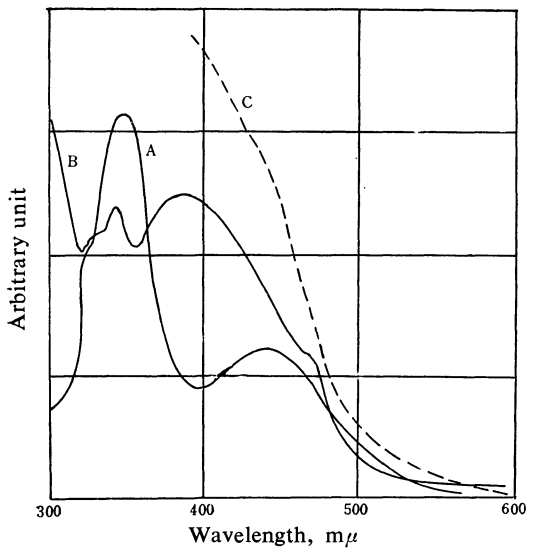

Fig. 2 The spectral response curves of photoconductivity (A), absorption spectrum (B) and photovoltage (C) for perylene in solid phase.

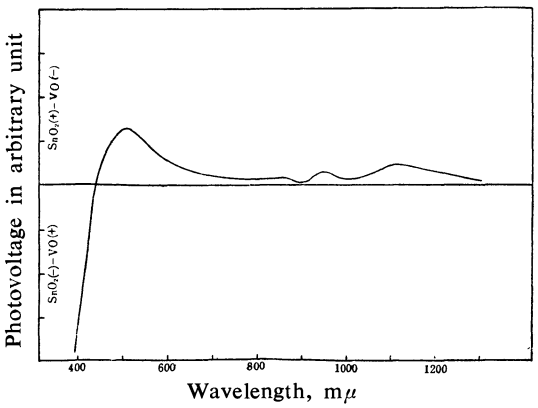

Fig. 3 The spectral response curve of photovoltage for the $SnO_2$-violanthrone ($SnO_2$-VO) junction.

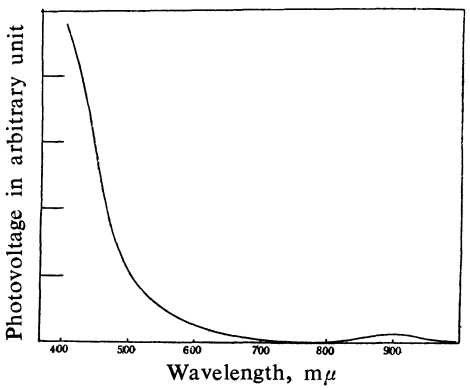

Fig. 4 The spectral response of photovoltage produced at the junction between sodium metal and violanthrene.

These results imply that the spectral responses of the photovoltage are predominated by the electronic structure of polycyclic aromatic compounds but not by that of stannic oxide. In this connection, no optical absorption in stannic oxide film was found in a visible region longer than 390 mμ.

In the alkali metal-aromatics junction, the induced photo-electromotive force reached to almost one volt as listed in Table II. Its

spectral response was a curve falling monotonously from short wavelength to long wavelength side. An extrapolation of this decrement found a tentative threshold value, which is sited in a range from 600 to 700 m$\mu$ as shown in Fig. 4.

A weak but definite response of photovoltage was found in a longer wavelength region than the extrapolation value. However, further investigations are restricted by fluctuation concerning the direction of electromotive force and also by the lack of stability of the force. In the lithium-aromatics junction, the metal acted as a positive electrode relative to the terminal electrode. Most of the aromatic compounds in the sodium-aromatics junction, however, acted as a positive electrode with respect to sodium; that is to say, electrons were transferred from the hydrocarbons to the junction metal at the junction and then the organic solids acted as electron donors. In the potassium-aromatics junction, the direction of photo-electromotive force was changed depending on the sorts of organic solids and also on the wavelength of incident light.

These values of photovoltage decreased to a small value in time. This decrease may be introduced from the complex formation between aromatic compound and alkali metal and/or may be produced by a decomposition of the junction. These fluctuations on the observed values may be eliminated by means of the application of ultra-high vacuum.

As a preliminary work of aromatics-aromatics junction, we have found that a fairly large electromotive force ($10\sim10^2$ mV.) was produced at the contact between two pure aromatic hydrocarbons; for instance, perylene and violanthrene, under illumination. The details of this work will appear elsewhere.

When a contact between semiconductive material (band gap : $\Delta\varepsilon$) and metal is made, it is believed that the flow of charge carrier, $I_o \exp[-\Delta\varepsilon/2kT]$, happended at the contact and a potential barrier occurs at the boundary layer. On illuminating the contact of junction, the flows of forward and backward currents, $I_f$ and $I_b$, are expressed as

$$I_f = I_o \exp[-(\Delta\varepsilon/2 - eV_{op})/kT] \quad (1)$$

$$I_b = I_o \exp[-(\Delta\varepsilon/2)/kT] + I_L \quad (2)$$

respectively, where $I_L$ is the excess flow of charge carrier under illumination and $V_{op}$ is photo-electromotive force, measured for an open circuit condition. At an equilibrium condition, $V_{op}$ is expressed as

$$V_{op} = \frac{kT}{e} \ln\left[1 + \frac{I_L}{I_o \exp[-(\Delta\varepsilon/2)/kT]}\right] \quad (3)$$

because of $I_f = I_b$.

When the induced current $I_L$ under illumination of light is large, Eq. 3 is rewritten as

$$V_{op} \fallingdotseq \frac{\Delta\varepsilon}{2e} + \frac{kT}{e} \ln\frac{I_L}{I_o} \approx \frac{\Delta\varepsilon}{2e} \quad (kT \ll e) \quad (4)$$

$$V_{op} \fallingdotseq \frac{kT}{e} \frac{I_L}{I_o} \exp[-(\Delta\varepsilon/2)/kT] \ll 1 \quad (5)$$

For the alkali metal-aromatics junction, it is expected the produced photovoltage, $V_{op}$, follows Eq. 4 because the excess flow of illuminated current is great. On the contrary, the minute photovoltage for the noble metal-aromatics junctions is explained by Eq. 5 tentatively.

## Summary

When a contact between a semiconductive material and a metal is made, it is expected that a potential barrier occurs at the boundary layer and the photovoltaic effect which is observed with illumination on this barrier. It has been found that this is the case for organic semiconductors. The photovoltaic cell was made with aromatic compounds sandwiched between two metal layers or metal and stannic oxide. One of them was a terminal electrode and the other, the junction electrode, was made with evaporated film of platinum, gold, silver, tin, lead or alkali metal. All observations of photovoltage were carried out in vacuo or in an atmosphere of inert gas.

With the illumination of white light from a tungsten lamp, the induced photovoltage varied from several millivolts to one volt, depending on the sorts of metals applied to the junctions. In most of these junctions, the organic solids acted as positive electrodes with respect to the junction metal.

In the alkali metal-aromatics system, a fluctuation was frequently observed concerning the direction of electromotive force, but the value of photovoltage was generally much higher than in the case of the other metals; thus the spectral response of the voltage was measurable. This response was less dependent on the sorts of organic solids but dependent on the sorts of metals. On the other hand, the spectral response in the junction between organic solid and stannic oxide, was a curve which is in good coincidence with the optical absorption curve for solid organics.

The cost of this research has been defrayed from the Grant in Aid for Fundamental Scientific Research from the Ministry of Education, to which the author's thanks are due.

# *Isolation of 2, 3-Cyclopenteno-5-methylpyridine from Coal Tar Bases*

By Hajime SUZUMURA

(Received January 24, 1961)

It was previously reported that 3, 4, 5-collidine and 2, 3-cyclopenteno-6-methylpyridine were isolated from the tertiary amine fraction boiling about 210°C in coal tar bases and their chemical structure were confirmed[1]. On further investigation, a $C_9H_{11}N$ base was isolated by solvent extraction and picrate formation from bases boiling about 220°C. This was identified as 2, 3-cyclopenteno-5-methylpyridine, comparing the physical properties of the isolated base and its derivatives with those of the synthesized base[2].

2, 3-Cyclopenteno-5-methylpyridine

The presence of this base in coal tar and petroleum distillates has not hitherto been reported. In Table I is shown the comparison of the isolated base with the synthesized compound.

## Experimental

**Original Material.** — The material used in the present investigation is a coal tar base fraction called "toluidine-xylidine fraction" ($TX_n$) furnished by Yawata Chemical Industry Co., Kyushu, Japan. The boiling point range of the material is shown in Table II. This sample contains 10% of neutral oil and 34% of primary amines determined as xylidines by diazotization-titration, therefore the content of the tertiary amines which constitute the rest of the sample is approximately 56%.

**Separation of the Tertiary Amines.**—A mixture of 6 kg. $TX_n$ and 1350 cc. of concentrated sulfuric acid was steam-distilled and neutral oil and a small amount of tar acids were respectively removed as a distillate. By addition of sodium hydroxide to the residual acidic solution, 4.84 kg. of the base was recovered. Then, 2.9 kg. of acetic anhydride was added and refluxed to remove the primary amines. The reaction mixture was distilled through a 30 cm. column and the distillate up to 250°C was collected and made alkaline with sodium hydroxide and steam-distilled. The disillate, after being dried over solid sodium hydroxide, was distilled in vacuo through a fractionating column[1] with a reflux ratio of 20 : 1 and divided into the fractions shown in Table III.

In the fractions Nos. 5 and 6, which were to be examined, the primary amines were still present to a minor extent and the acetylation procedure was repeated.

**Isolation of 2, 3-Cyclopenteno-5-methylpyridine.** —As the chromatographic separation using a column of cupric chloride-aluminum oxide and also the urea adduct method were ineffective, the separation by solvent extraction was carried out. As the solutes, the fractions Nos. 5' and 6' of Table IV were used. A countercurrent extraction apparatus of semiautomatic type equipped with one hundred distribution tubes was employed. The volume of each tube was 20 cc. Ligroin was introduced into the apparatus as the light phase and the acidic sodium phosphate buffer solution (pH 4.78) as the heavy phase. By a single withdrawal procedure, the ligroin layers were transferred successively, giving a series of fractions, and from those fractions the bases were collected as the picrates. Results of the extractions using Nos. 5' and 6' as the solutes are shown in Table V.

The melting points shown in the table were determined on the picrates once recrystallized from ethanol. From Table V, it was observed that the new component was, next to quinoline, not easily soluble in the buffer solution; the base had a relatively large distribution coefficient.

In order to obtain a large amount of the base to work with, the extraction whose scheme is shown in Table VI was carried out using a 300 cc. separating funnel. Twenty-five grams of the fraction No. 6' was diluted with ligroin to 100 cc., to which 100 cc. of the buffer solution was added, shaken for 3 min., then allowed to settle. The heavy phase

Crude picrates from Nos. 5—9 were combined and after recrystallization from ethanol, 0.1 g. of picrate was obtained, m. p. 201~202°C.

Base from Nos. 1, 2 and 3 were identified as quinoline by their picrates and tartrates.

was drawn off and the new buffer solution was added; the extraction was repeated three more times in the same manner as described above. After the bulk of the solvent was removed by distillation, the raffinate was purified as a picrate. Recrystallization from ethanol yielded 1.7 g. of picrate, which melted at about 200°C. This picrate, when admixed with the picrate of quinoline, m. p. 198~200°C (uncorr.), showed a large melting point depression amounting to 20°C, hence it is obviously different from that of quinoline.

TABLE VI. EXTRACTION USING A SEPARATING FUNNEL

From 20 g. of fraction No. 5' by the same procedure, 0.9 g. of picrate, m. p. 196~198°C (uncorr.), was obtained. The picrate, recrystallized from ethanol melted at 201~202°C (uncorr.). This purified picrate was decomposed by addition of sodium hydroxide and the regenerated base was recovered by steam distillation followed by extraction with ether. The ether extract of the distillate was concentrated to give colorless plates, m. p. 38.5~41°C.

**Properties, Derivative and Absorption Spectra of the Isolated Base.**—*Neutralization Equivalents.*—The base (0.073 g.) was titrated by 0.1 N hydrochloric acid (F 0.999) using bromophenol blue as an indicator and measuring the pH of the solution. For the neutralization of the base, 5.45 cc. of 0.1 N hydrochloric acid was required.

Found: 134. Calcd. for $C_9H_{11}N$; 133.

*The Picrate.*—Several recrystallizations from ethanol yielded yellow needles, m. p. 205.2~206.2°C.

Found: N, 15.16. Calcd. for $C_{15}H_{14}N_4O_7$: N, 15.47%.

*The Picrolonate.*—It was prepared from equimolar quantities of picrolonic acid and the base in ethanol. Recrystallization from ethanol yielded yellow needles which decomposed at 211.5~212.5°C.

*The Ultraviolet Absorption Spectrum.*—The spectrum in cyclohexane is shown in Fig. 1.

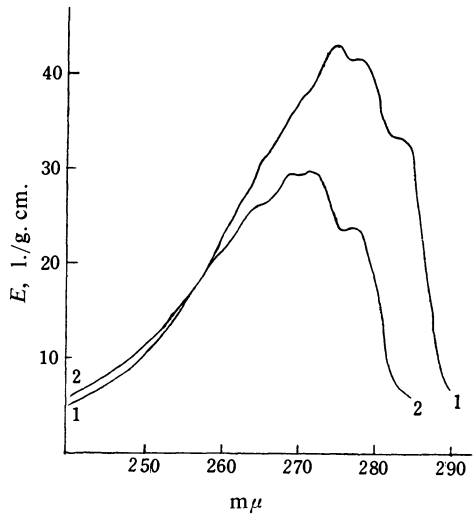

Fig. 1.
1, 2,3-Cyclopenteno-5-methylpyridine
2, 2,3,5-collidine

The ultraviolet spectrum of 2,3-cyclopenteno-5-methylpyridine ($\lambda_{max}$ 276 mμ) has the same similarity to that of 2,3,5-collidine ($\lambda_{max}$ 271 mμ) as the spectrum of 2,3-cyclopenteno-6-methylpyridine ($\lambda_{max}$ 275 mμ) has to that of 2,3,6-collidine ($\lambda_{max}$ 270 mμ)[1,2].

*The Infrared Absorption Spectrum.*—The spectrum in carbon disulfide is shown in Fig. 2.

Characteristic absorption bands at 13.7 μ and 14.1 μ are similar to those of 2,3,5-collidine. This similarity may well be explained by the relationship between absorption bands and the position of substituents of alkyl pyridines[3].

3) H. Shindo and N. Ikekawa, *Pharm. Bull.* (*Tokyo*), **4**, 192 (1956).

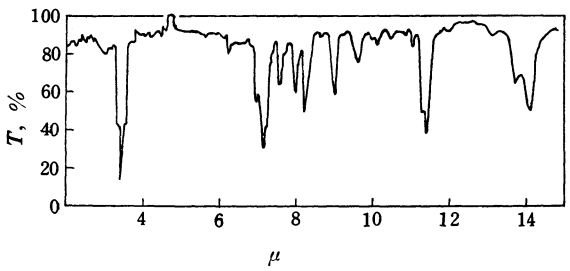

Fig. 2.

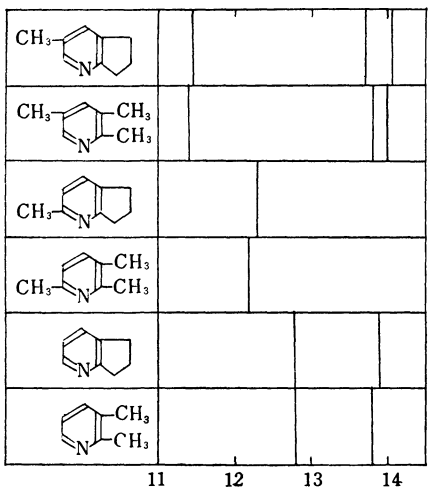
In Fig. 3 are shown the specific absorption bands appearing in the fingerprint region of cyclopenteno-pyridine, 2,3-dimethylpyridine, 2,3-cyclopenteno-6-methylpyridine and 2,3,6-collidine.



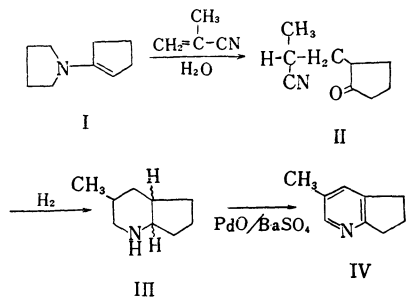


Fig. 3.

**The Synthesis of 2,3-Cyclopenteno-5-methylpyridine.**—In order to compare the isolated base from coal tar with the authentic sample of the base, a synthesis was carried out in the manner similar to that described by Lochte et al.[2]. The procedure is schematically shown below.

*Cyclopentano-pyrrolidine Enamine (I).*—A solution of 10 g. of cyclopentanone and 26 g. of pyrrolidine in 140 cc. of dry benzene was refluxed for 6 hr. in a flask fitted with an azeotropic water separator. The benzene and the excess of pyrrolidine were distilled off leaving a viscous liquid, 15.8 g., which was used without further purification in the subsequent reaciton.

*2-(2-Methyl-2-cyanoethyl)-cyclopentanone (II).*—Methacrylonitrile* (9.5 g.) was added to a solution of the enamine I in 100 cc. of dimethylformamide. The resulting solution was refluxed for 31 hr. in a flask fitted with a tower of calcium chloride. The bulk of the solvent was then removed by distillation and to the residue were added 57 cc. of water and 4 cc. of glacial acetic acid. This solution was refluxed for 2 hr. 40 min., cooled and extracted four times with benzene. The combined benzene extracts were washed three times with 10% hydrochloric acid, twice with 10% potassium carbonate solution, and once with water and dried over sodium sulfate. After removal of the benzene, the residue was distilled in vacuo giving 4.6 g. of a liquid boiling at 125~126°C (5 mmHg), $n_D^{25}$ 1.4580 and 1.1 g., $n_D^{25}$ 1.4709 (reported $n_D^{25.5}$ 1.4624). The semicarbazone prepared from the two fractions melted at 195.4°C and 189~190°C respectively (reported 195°C).

*Hexahydro-2,3-cyclopenteno-5-methylpyridine (III).*—Raney nickel** was added to a solution of II in absolute ethanol. This mixture was hydrogenated at an initial $H_2$ pressure of 34 kg./cm² and 120°C in a 100 cc. autoclave equipped with an elecromagnetic stirring device. The Raney nickel was filtered off and the solvent was removed by distillation in vacuo. The residual liquid was distilled in a Claisen flask yielding a corless liquid, b. p. 85°C (21 mmHg).

The experimental results are shown in Table VII.

*2,3-Cyclopenteno-5-methylpyridine (IV).*—In the present experiment, III was dehydrogenated in the liquid phase with palladium oxide/barium sulfate in place of palladium-carbon described in the literature cited. A mixture of equal amounts by weight of the base and the catalyst (palladium oxide/barium sulfate) was placed in a flask and refluxed in a nitrogen stream in an oil bath. The cooled mixture was extracted with ether and the ether extract was concentrated to give the crude base.

The experimental result was shown in Table VIII. The pure base was obtained by the decomposition of the recrystallized picrate as described above.

*Preparation of Palladium Oxide/Barium Sulfate*[5].—Palladium chloride (0.3 g.) was dissolved in a mixture of 15 cc. of 2 N sulfuric acid and 120 cc.

* Preparation of methacrylonitrile—commercial methacrylamide (17.0 g.) and 20 g. of $P_2O_5$ were thoroughly mixed and heated in a flask over free flame. The distillate, after treatment with a small amount of $K_2CO_3$, was distilled to give a fraction, 8 g., boiling at 89~89.5°C, $n_D^{22}$ 1.4001 (reported[4] $n_D^{20}$ 1.4007).

4) Rohm and Haas, G. m. b. H., U. S. Pat. 2210320 (1940).

** Raney nickel—one gram of commercial alloy (Ni : Al = 50 : 50) was gradually added with stirring to 10 cc. of 20% sodium hydroxide solution in a beaker placed in a water bath maintained at 50°C, over a period of about 50 min. After the addition was complete, the resulting Raney nickel was washed with water to the neutral pH, then with 95% ethanol and finally with absolute ethanol.

| | $H_0$ kg./cm² | $\Delta P$ kg./cm² | Temp. °C | Period | Wt. g. | $n_D^{25}$ | Yield % |
| 2.9 | 33.8 | 10.8 | 108～120 | 4 hr. 35 min. | 3.75 | 1.4820 | 63 |
| 3.4 | 34.1 | 15.7 | 108～118 | 5 hr. 30 min. | | | |

Table VIII. Dehydrogenation

| Hexahydro-base(III) g. | $PdO/BaSO_4$ g. | Conditions | | Product | |
|---|---|---|---|---|---|
| | | Temp., °C | Period | Yield, g. | M. p., °C |
| 0.37 | 0.37 | 180 | 6 hr. | 0.35 | below 20 |
| 0.52 | 0.52 | 200～210 | 8 hr. 15 min. | 0.35 | 35～37 |

of water which was kept at 80°C. After the solution was allowed to settle for 20 min., it was poured with vigorous stirring into 165 cc. of 0.2 N barium hydroxide yielding a precipitate. It was filtered off by suction, washed with 240 cc. of water and dried in vacuo. Pale brown powder was obtained; 3.7 g.

**Derivatives of the Synthesized Base.** — *The Picrate.* — Yellow needles, m. p. 204.8～205.8°C. From 900 mg. of the picrate, 250 mg. of the base, m. p. 38.7～41°C was regenerated by addition of sodium hydroxide followed by steamdistillation.

*The Picrolonate.*—It was prepared in the same manner as described in the case of the isolated base. Recrystallization from ethanol yielded yellow needles which decomposed at 211.5～212.5°C.

**Confirmation.** — The isolated 2,3-cyclopenteno-5-methylpyridine, the picrate and the picrolonate when admixed with the corresponding synthesized sample gave no melting point depression. The infrared absorption spectrum of the isolated base and that of the synthesized base were superimposable.

# *Fischer-Tropsch Synthesis with Tubular Reactor of 18.1 l. Catalyst Bed. II. Reactor with Temperature Gradient along Out-side Wall*

By Michio KURAISHI*, Minoru KURITA, Tadasuke HOSOYA, Hideo ICHINOKAWA, Kiyoshi OGAWA and Hiroshi UCHIDA

(Received January 18, 1961)

A previous paper[1] in this series described the Fischer-Tropsch synthesis with the reactor whose out-side wall temperature was kept constant along the whole length by means of a heat transfer medium of flowing oil. However, the catalyst bed temperature tended to rise very high, and the product yield remained below that to be expected from the synthesis results with the reactor of the same design but of a much smaller catalyst bed of 2 l. A closer investigation in this respect disclosed that the large magnitude of temperature rise was mainly due to a high heat transfer resistance across an oil film on the out-side wall of the reactor. For the better performance, therefore, the reactor ought to be modified in construction in order that the heat transfer efficiency across the oil film might be improved. By the use of the reactor which has been improved along this line, the present synthesis experiments are conducted.

The previous paper, in addition, dealt with

the calculation of the temperature profile in the catalyst bed on the basis of the concentration gradient determined along the heights of the catalyst bed. Because of the temperature gradient already present in the oil surrounding the reactor, the method of the calculation, however, can be applied with difficulty to the result with the present reactor. In this paper the calculating method with the result is proposed.

## Experimental

In an effort to improve the heat transfer efficiency across the oil film on the out-side wall of the previous reactor, the previous reactor system was subjected to some modifications. Fig. 1 shows a

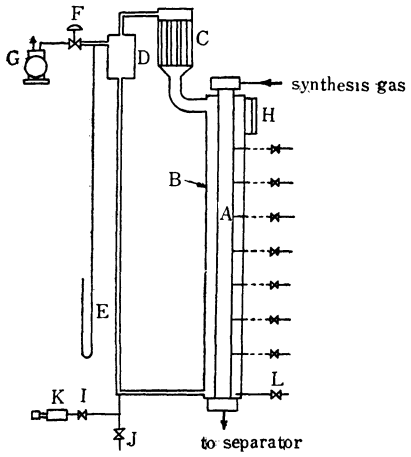

Fig. 1. Schematic diagram of reactor system.

F, Magnetic valve
G, Pump
H, Level indicator
I, J, L, Needle valves
K, Dowtherm feeder

schematic diagram of the system after the modifications. The main modification made was that the reactor (A, 10 m. high by 50 mm. I. D.) was placed in a cylinder (B) which was filled with oil (Dowthem) boiling under a reduced nitrogen pressure, whereas the previous reactor had been held in the oil under forced circulation at a fixed flow rate under an atmospheric pressure of nitrogen. A small amount (ca. 200 l./hr.) of nitrogen was always being introduced from a valve (L) into the oil bath by way of a number of openings (0.8 mm. diameter) perforated along two semi-circular tubes placed, opposite to each other, at the bottom of the cylinder. The nitrogen gas passed upwards through the oil, and could easily be controlled at a fixed pressure by means of a leak opened by a magnetic valve (F) which was coupled with a mercury contact manometer (E).

The top zone of the oil bath was equipped with a level indicator (H), by the aid of which the oil was maintained at a constant level by either introducing or withdrawing a small quantity of oil through a valve (I) or (J), respectively. A condenser (C) was placed directly above the top of the cylinder, in which the oil vapor accompanying the nitrogen stream was refluxed back into the oil bath. A reservoir (D) served to avoid a sudden change in the nitrogen pressure. After passing through C, D and F, the gas was finally drawn out by a pump (G).

In view of the kind of reactor type called rectification cooling type, which was originated by Dorschner[2], the present reactor may also be known as such, but it differs from Dorschner's reactor in some respects.

Besides the sintered catalyst (designated catalyst A hereafter) in the previous paper[1], a fused iron catalyst (designated catalyst B hereafter) of the same promoter-composition was employed in this study. Granules of the catalyst ranging from 5 to 2 mm. in size were used, and the catalyst bed of 18.1 l. contained 39.41 kg. of the granules after reduction. The technique of the catalyst pretreatment as well as of the synthesis was essentially the same as was described elsewhere[3] in detail.

## Results and Discussion

**Results.** — Table I shows, together with the synthesis variables, results from a series of five experiments, among which two experiments were carried out by using catalyst A while the other three ones by using catalyst B. Numerals listed in the column of nitrogen pressure serve as a measure to estimate roughly the oil bath temperature: the higher the pressure is, the higher the temperature rises. Further, the axial temperature profiles in the catalyst bed as well as in the oil bath are exemplified in Figs. 2A, B, C and D for experiments Nos. 1, 2, 6 and 7, respectively.

It was after the experiment described in the previous paper[1] (hereafter simply called experiment A) had been made that the bed of catalyst A was used in this study, and hence the bed had already undergone an activity decrease to some extent. In this connection, a much higher yield of the product (oil plus wax) may have not been produced in experiment No. 1 as compared with the yield (14.14 kg./day) in experiment A, in spite of the improvement made for the heat transfer efficiency[4]. Nevertheless, one can yet recognize the effects of the improvement clearly. One of the effects is the axial temperature gradient

in the oil bath, increasing continuously from top to bottom. The appearance of the gradient arises from the fact that the boiling temperature of oil is continuously increased with gravity of increasing amounts of oil in the oil bath cylinder from top to bottom. The temperature gradient thus produced along the oil bath may have helped the catalyst bed temperature to rise with the distance ($x$) from the top of the bed. In contrast to the above, the temperature profile in the bed of experiment A showed a downward tendency along the lower half of the bed. Another effect is the smaller magnitude of temperature difference between the oil bath and the reactor axis, in other words, the smaller magnitude of the bed over-temperature (hereafter denoted by $(t-t_b)$, where $t$ and $t_b$ are the temperatures measured along the axis of catalyst bed and along the oil bath, respectively), which was 15°C at a maximum for experiment No. 1 while 25°C for experiment A.

By using a fresh bed of catalyst B in place of the deteriorated one of catalyst A, much higher yields of the product, attaining from 24 to 26 kg./day, were produced (refer to the results of experiments Nos. 6 and 7), even though the nitrogen pressure was kept below that of experiment Nos. 1 and 2. Moreover, the magnitude of $(t-t_b)$ remained comparatively small: at the region of a maximum $(t-t_b)$, 22 and 30°C for experiments Nos. 6 and 7, respectively. The somewhat larger magnitude of $(t-t_b)$ observed with the latter experiment may be accounted for by a lower

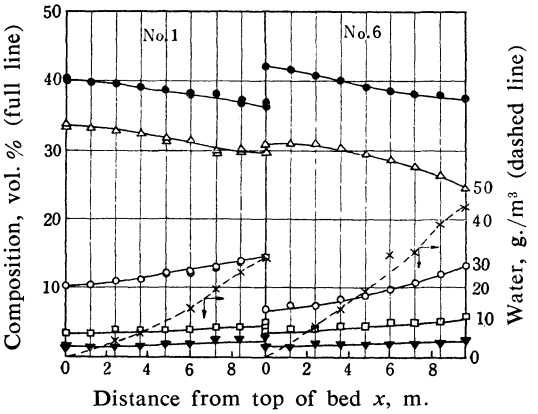

Fig. 3. Concentration gradient along catalyst bed.

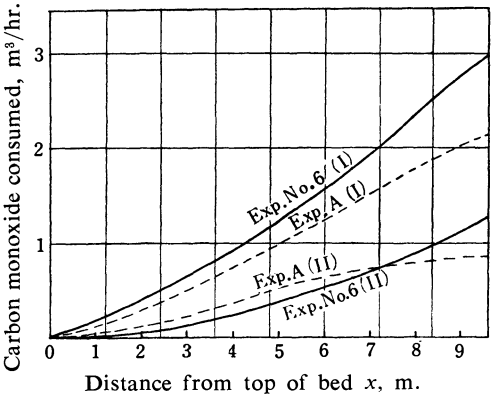

Fig. 4. Carbon monoxide consumed by either reaction (1) or (2) as a function of $x$.

space velocity of the inlet gas, details of which will be stated later.

The concentration gradient of the individual components along the reactor was determined in the same manner that was made in experiment A[1]. Among the results the gradient for experiment No. 6, for instance, is shown in the right half of Fig. 3, while the gradient for experiment A is given again in the other half. Starting with the results of Fig. 3 and following the procedure as reported in the previous paper[1], one can calculate amounts of carbon monoxide consumed with the progress of the synthesis either by $2H_2+CO \rightarrow >CH_2+H_2O\cdots$ (1) or by $CO+H_2O \rightarrow CO_2+H_2\cdots$(2). Fig. 4 illustrates plots of the amount vs. $x$, together with the recited ones for experiment A. The figure discloses that although the amounts of carbon monoxide consumed by the reaction 1 in the top zone of the catalyst beds differ slightly from each other the amount at the end of the bed in experiment No. 6 attains 3/2.1 times as large as the amount in experiment A. In view of the fact it can be seen that in experiment No. 6 better use was made of the lower half of the catalyst bed than that in experiment A.

**Method of Calculating Temperature Profiles in Catalyst Bed.**—Because of the presence of the temperature gradient along the oil bath, the solution to the heat balance equation, as cited in the previous paper[1], is to be made under the different boundary conditions from the previous ones. The equation is then given as follows.

$$C_pG\frac{\partial t}{\partial x}=\frac{1}{r}\left[\frac{\partial}{\partial r}\left(\lambda_r\cdot r\frac{\partial t}{\partial r}\right)+\frac{\partial}{\partial x}\left(\lambda_x\cdot r\frac{\partial t}{\partial x}\right)\right]+Q \quad (1)$$

with the following boundary conditions,

$$t=t_0 \quad \text{at} \quad x=0$$

$$\lambda_r\partial t/\partial r+U(t-t_b)=0 \quad \text{at} \quad r=r_2$$

and $\partial t/\partial r=0$ at $r=r_1$

where $C_p$ is the heat capacity per unit mass of fluid, $G$ is the mass velocity based on an empty tube, $r$ is the distance in lateral direction, $\lambda$ is the effective thermal conductivity of the catalyst bed system, $Q$ is the reaction heat, $U$ is the overall heat transfer coefficient, $r_1$ and $r_2$ are the inner and the outer radii of the catalyst bed, respectively.

A numerical solution of Eq. 1 may be possible. However, the calculation will be very time-consuming since $t_b$ varies with $x$. As a compromise, it would be rather convenient for the present purpose to start with a more simplified equation of the heat balance, in which the temperature is assumed to be radially uniform at every cross section of the bed that an average temperature[5] ($t_{av}$) over the bed cross section may simply be taken into account. The solution then gives the axial temperature profile. Once the axial temperature profile has been drawn, Eq. 1 can be solved more easily with respect to a cross section, in the neighborhood of which the axial temperature is kept essentially constant. The solution gives the radial temperature profile.

Under the assumption of uniform temperature across the bed, the following equation of the heat balance can be established,

$$G_pG\mathrm{d}t/\mathrm{d}x+2\pi r_2U'(t-t_b)/S=Q \qquad (2)$$

with the boundary condition that $t=t_0$ at $x=0$. The symbol $S$ in the equation is the cross sectional area of the bed, and the second term in the left-hand side of the equation concerns the heat transfer across the tube wall of the reactor held in the oil bath whose axial temperature gradient is assumed to be given by a linear function of $x$, namely $t_b=t_{bo}+ax$, where $t_{bo}$ is the oil bath temperature at $x=0$. The constant $a$ takes a value characteristic of the gradient in the oil bath. It should further be noted that $U'$ is to be distinguished from $U$ in Eq. 1. The calculation of $U'$ is made by taking the tube wall coefficient of the heat transfer based on $t_{av}$ (denoted by $h'$) into account whereas $U$ by taking the coefficient based on $t$ at $r=r_2$ (denoted by $h$) into account. In this paper, $h'$ with respect to the present annular shaped cylinderical bed was evaluated by making use of the formula[6] proposed by Maeda et al.[7] for $h'$ with a cylindrical bed, while $h$ by the aid of the formula[8] by the Hatta et al.[9] In the latter formula, $\lambda_r$ is taken into consideration.

In Eq. 2, $Q$ is again approximated to

$$Q=C_1\mathrm{e}^{-Mx}-C_2\mathrm{e}^{-Nx} \qquad (3)$$

where $C_1$, $C_2$, $M$ and $N$ are constants. Combination of 2 with 3, and subsequent rearrangement give

$$\mathrm{d}t/\mathrm{d}x+A(t-t_{bo}-ax)=G_1\mathrm{e}^{-Mx}-G_2\mathrm{e}^{-Nx} \qquad (4)$$

in which the following abbreviations are introduced.

$$A\equiv 2\pi r_2U'/C_pGS,\quad G_1\equiv C_1/C_pG$$
$$G_2\equiv C_2/C_pG \qquad (5)$$

The solution of Eq. 4 is given by

$$t=t_{bo}+\mathrm{e}^{-Ax}\left[t_0-t_{bo}+\frac{G_1}{A-M}\left\{\mathrm{e}^{(A+1)x}-1\right\}-\frac{G_2}{A-M}\left\{\mathrm{e}^{(A-N)x}-1\right\}\right]+a\left\{x-\frac{1}{A}(1-\mathrm{e}^{-Ax})\right\} \qquad (6)$$

On the other hand, under the assumption of $\mathrm{d}t/\mathrm{d}x=0$, Eq. 1 is reduced to a simpler form of

$$\lambda_r\{\mathrm{d}^2t/\mathrm{d}r^2+(1/r)(\mathrm{d}t/\mathrm{d}r\}+Q=0 \qquad (7)$$

with the boundary conditions that $\mathrm{d}t/\mathrm{d}r=0$ at $r=r_1$, and $\lambda_r\mathrm{d}t/\mathrm{d}r+U(t-t_b)=0$ at $r=r_2$. The solution results in Eq. 8.

$$t=t_b+\frac{Qr_2^2}{4\lambda_r}\left[\left\{1-\left(\frac{r}{r_2}\right)^2\right\}+2\left(\frac{r_1}{r_2}\right)^2\ln\frac{r}{r_2}+\frac{2\lambda_r}{Ur_2}\left\{1-\left(\frac{r_1}{r_2}\right)^2\right\}\right] \qquad (8)$$

By the aid of Eqs. 6 and 8 both the axial and the radial temperature profiles can be drawn.

Let us make an approximate check on the accuracy of the present calculation method by performing a profile calculation. The calculation is carried out on the basis of the experimental data of experiment A, and the resulting profiles are shown in Fig. 5 with the dotted and dashed lines, of which the radial one is given for the cross section at $x=6$ m. In the neighborhood of the cross section, the axial temperature has been found nearly constant. For the sake of comparison, the figure is included with the previous profiles (dashed lines) calculated by using the solution with no simplification of Eq. 1. The respective profiles calculated by either one of the two

5) The average temperature ($t_{av}$) is defined by

$$t_{av}=\int_{r_1}^{r_2}t\cdot 2\pi r\mathrm{d}r/\pi(r_2^2-r_1^2)$$

6) $h'D/k=4.90(R_{ep})^{0.60}\mathrm{e}^{-2.2d_p/D}$, where $D$ is the diameter of bed, $k$ is the thermal conductivity of fluid, $R_{ep}$ is the modified Reynolds number, and $d_p$ is the diameter of catalyst granules (4 and 3.4 mm. for catalysts A and B, respectively). In the evaluation of $h'$, $D_{eq}$ defined by $D_{eq}=D_2-D_1$ is used in place of $D$.

7) S. Maeda and K. Kawazoe, *Chem. Eng. Japan* (*Kagaku Kogaku*), **17**, 276 (1953).

8) $\lambda_r/k=0.209(R_{ep})^{0.87}$ and $hD_{eq}/\lambda_r=127(R_{ep}\cdot d_p/D_{eq})^{-0.87}$.

9) S. Hatta and S. Maeda, *Chem. Eng. Japan* (*Kagaku Kikai*), **13**, 79 (1949).

different methods show a good approximation with each other. However, it should be noted that the present method of calculating the axial temperature profile is available only when $\lambda$ is so high that the radial temperature gradient can be ignored. It otherwise may lead to errors, for instance, in such a case that the synthesis is made by the once-through operation where the mass velocity of the inlet gas, as a consequence, $\lambda$ is usually much lower.

**Calculation of Temperature Profile.** — Before proceeding to the profile calculation, the coefficient ($h_L$) of heat transfer referred to the out-side wall of present reactor, over which the oil film is kept under nucleated boiling, has to be evaluated. Although there have appeared a few papers[10] dealing with the heat transfer phenomenon considered, none of them except for the paper by Nishikawa[11] is available for the calculation. Accordingly, a rough estimation of $h_L$ is made for experiment No. 2 by means of Nishikawa's formula, which results in the value of 4800 kcal./m² hr. °C. By using this value the profile calculation is made[12]. The profiles thus drawn are shown in Fig. 2B with the dotted and dashed lines, which appear to be in a poor agreement with the experimental profiles: the calculated axial temperature profile rises more rapidly in the top zone while it lies below the experimental one in the lower half of the catalyst bed, and in addition the radial temperature profile at the cross section of $x=8$ m. shows a maximum temperature across the bed of 284.3°C, in contrast to the measured one of 289°C. The disagreement may probably be due to too high an estimated value of $h'_L$, consequently of $U'$.

The calculation is then repeated with other different values of $h'_L$ for a better agreement between the measured axis-temperature in the bed and the calculated one, and finally $h'_L=600$ kcal./m² hr. °C, consequently $U'=391$ kcal./m² hr. °C, is conveniently chosen, by the choice of which the temperature of 289.5°C is attained. The value of $h'_L$ has thus appeared only one eighth of the value afore-cited[13], but it is still 3.5 times as much as the value in the previous reactor. The axial profile calculations have then been made, and an improvement in the accordance between the calculated and the measured profiles is obtained (refer to the dashed line in Fig. 2B). The same calculations made on the basis of the data of the other experiments of Nos, 1, 6 and 7 results in the profiles as cited in Figs. 2A, C and D, respectively. The profiles are in a good agreement with measured ones, except for a small intermediate range where the measured profile lies somewhat below the calculated one. Moreover, the radial temperature profile is visualized by the calculation as shown in the figure, and a comparison of the profile with that in Fig. 5 is suggestive of the improving effect of the present procedure on the heat transfer efficiency across the out-side wall. In this study, however, no experimental evidence is available for the radial profile.

It should be noted that the present procedure of improving the heat transfer efficiency can effectively be applied only when the difficulty exists in the heat transfer resistance across the liquid film on the out-side wall of the reactor. In this respect, a comparison between the results of experiment Nos. 6 and 7 shows that the magnitude of $(t-t_b)$ is a

11) K. Nishikawa, *Trans. Jap. Soc. Mech. Eng.*, No. 120, **22**, 551 (1956).

12) In fact, the temperature gradient in the oil bath is convex upwards instead of being a linear function of $x$, as shown in Figs. 2A, D. In the calculation of the profile, a few axial step lengths are chosen, and the solution is applied to each of the steps successively. Although the integration constant in the solution remains the same in the first step where the boundary condition is $t=t_0$ at $x=0$, it differs in value for the succeeding steps because the different boundary condition that $t$ at the end of the first step is equal to $t$ at the top of the second step, and so forth, are established.

13) We are not as yet certain of the accurate reason why the value of $h'_L$ thus chosen is far smaller than that obtainable from Nishikawa's formula.

little smaller for experiment No. 6 which was conducted under the essentially same operating conditions, except for the greater $G$, than those in experiment No. 7. As regards the present two experiments where $h'_L$ is as high as 600 kcal./m$^2$ hr. °C, the greater value of $\lambda$[14], which is necessarily accompanied by the increasing $G$, may therefore become rather responsible for the smaller magnitude of $(t-t_b)$. The effect of varying values of $G$ on $(t-t_b)$ can be seen more clearly when the results of the once-through operation is considered[15].

Dorschner[2] has already pointed out that the outside wall temperature gradient increasing from top to bottom exerts an advantageous effect on an efficient use of the catalyst bed. For the purpose of producing such a temperature gradient, he employed a bath of an oil mixture consisting of hydrocarbons of different boiling points, whereas in the present procedure one kind of oil, Dowtherm, is simply used. In addition, the procedure has another advantage of providing a better means of temperature control: the oil bath temperature has to be increased successively to follow the deterioration of the catalyst activity, which can be done by a simple regulation of the nitrogen pressure. However, it suffered from the following limitation that a considerable magnitude of the temperature difference (for example, ca. 20°C from top to bottom in the present reactor) can not be produced until the reactor reaches as high as 10 m.

14) The values of $\lambda$ for experiment Nos. 6 and 7 were 5.09 and 4.03 kcal./m.·hr. °C, respectively.
15) The results will be reported elsewhere.

**Summary**

The present experiments on the Fischer-Tropsch synthesis have been made with the reactor which was placed in a bath of oil boiling under a reduced nitrogen pressure. The heat transfer efficiency referred to the out-side wall of the reactor has been improved considerably, and, as a consequence, the magnitude of the bed over-temperature remains comparatively small, in spite of the high yield of the product attaining 24~26 kg./day.

The axial and the radial temperature profiles have been separately calculated on the basis of the concentration gradient determined along the heights of the reactor: first the calculation of the former profile under the assumption of uniform temperature across the bed, and secondly that of the latter profile at a cross section in the neighborhood of which the axial temperature is approximately constant. By the convenient choice of 600 kcal./m$^2$ hr. °C for the tube wall coefficient of heat transfer referred to the out-side wall of the present reactor, the calculated axial temperature profile is in good agreement with the experimental profile except for a small intermediate range.

The authors are grateful to Mr. M. Oba, Mr. A. Matsuda, Mr. H. Imai and Mr. K. Shimomura for their assistance in the synthesis experiments.

# *Organoboron Compounds. I. On the Reaction of n-Butylboronic Acid with Polyvinylalcohol*

By Seiji KATO, Yojiro TSUZUKI and Shigenobu KITAJIMA

(Received October 17, 1960)

It is well-known that boric acid reacts with various diols and sugars, giving more acidic complexes, and thus boric acid can be titrated with standard sodium hydroxide in the presence of mannitol. One of the authors[1] previously studied the reactions polarimetrically and showed that the formation of the complexes is a reaction of ionic nature. Boric acid, reacting with polyvinylalcohol, also forms polyvinyl borate ester. Owing to this reaction a remarkable change is observed on the viscosity of aqueous polyvinylalcohol on the addition of boric acid, hence boric acid is available as a modification agent of the viscosity of aqueous polyvinylalcohol when filaments are spum from it. In a similar manner esters of boronic acid with polyols can be formed, which have been known as arneboronates. Kuivila[2] prepared

1) Y. Tsuzuki, This Bulletin, **16**, 23 (1941).

2) H. Kuivila, *J. Org. Chem.*, **19**, 780 (1954).

them by the reaction of some arylboronic acid with numerous diols and sugars.

The present paper deals with the reaction of *n*-butylboronic acid with polyvinylalcohol, and discusses the experimental method, esterification grade, and some properties of the products.

## Experimental

**Preparation of *n*-Butylboronic Acid.** — *n*-Butylboronic acid was prepared in an atmosphere of nitrogen, practically according to Johonson's method[3], in the following way:

$$n\text{-Bu-MgBr}+B(OCH_3)_3 \rightarrow n\text{-Bu-B}(OCH_3)_2+MgBrOCH_3$$

$$n\text{-Bu-B}(OCH_3)_2+H_2O \rightarrow n\text{-Bu-B}(OH)_2+CH_3OH$$

From 80.6 g. (0.50 mol.) of *n*-butylmagnesiumbromide and the equivalent quantity of methylborate (52 g.) was obtained *n*-butylboronic acid as fine crystals, m. p. 92~94°C, yield ca. 50 g. (ca. 50% of the theory).

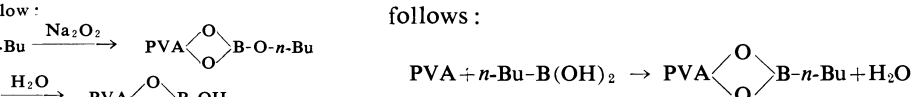
**Esterification of Polyvinylalcohol with *n*-Butylboronic Acid.** — Purified polyvinylalcohol (PVA) which has the polymerization grade of about 1500 and was reprecipitated by the usual method is dissolved in water, the concentration of which is always kept constant (2.5%). The concentration of boronic acid solutions varied from experiment to experiment. The solution of boronic acid is placed in a 500 ml. four-necked flask with a reflux condenser, and a 2.5% solution of PVA is dropped from a separating funnel at a temperature from 40 to 70°C during one hour, and stirring is continued for one more hour. An insoluble product appears as a white emulsion. On salting out this emulsion, a gum-like material is produced. This product is dried in vacuo and reprecipitated from benzene solution into cold methanol for purification.

**Determination of Boron.**—Although a number of methods for the analysis of boron have been proposed, they are for the most part troublesome. The present authors have modified the method of Martin in the following way[4], which is proved to be easier and more practical.

The sample is refluxed with a sodium peroxide solution for several hours until it is dissolved. The solution is exactly neutralized to pH 6.9 with hydrochloric acid by the help of a pH-meter and on adding mannitol the solution is titrated back until the pH-meter exactly indicates the mark of 6.9. The content of boron can be estimated from the data*.

**Infrared Spectra.** — *n*-Butylboronate ester is dissolved in carbon tetrachloride and a thin film is made on a mercury dish. The thickness was about 0.03 mm. The apparatus used was a Hitachi spectrophotometer EPI-2.

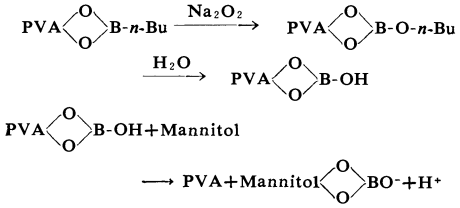
## Results and Discussion



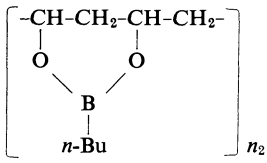
Polyvinylalcohol (PVA) reacts with *n*-butylboronic acid instantly in aqueous solution. The product is obtained in a state of emulsion, but after salting out, it can be obtained as a solid. If the concentration of *n*-butylboronic acid is varied against the constant concentration of PVA, the products are varied in form from gum-like to transparent white hard solids. The materials obtained are all insoluble in water, but dissolve in many organic solvents. These differences chiefly depend upon the boron content of the products. The solubility of the products increases with the increasing boron content. Table I shows the solubility in several organic solvents, of the product which contains the highest quantity of boron.

TABLE I. THE SOLUBILITY OF PVA-*n*-BUTYLBORONATE

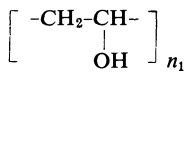
| Solvent | Solubility | Solvent | Solubilty |
|---|---|---|---|
| Methanol (in hot) | s | Chloroform | ss |
| Ethanol | s | Benzene | ss |
| Buthanol | s | Toluene | ss |
| Ether | ss | Nitrobenzene | sw |
| Tetrahydrofuran | ss | Phenol | sw |
| Petroleum-ether | sw | Chlorobenzene | s |
| Acetone | sw | Aniline | is |
| Ethylacetate | s | Pyridine | s |
| Carbon disulfide | ss | Formic acid | is |
| Carbon tetrachloride | ss | Acetic acid | sw |



Note, s: soluble ss: very soluble
is: insoluble sw: swelling



It has been known that in acetalization of PVA, the product acetalized dissolves in various organic solvents, and that the solubility increases with the acetalization grade. In view of these phenomena, the authors have estimated the esterification grade of PVA-boronates by determining the boron content of the products, the formation of which is formulated as follows:



In the above reaction PVA is partially esterified with boronic acid; hence the product may be represented as consisting of the following two parts:

3) J. R. Johnson et al., *J. Am. Chem. Soc.*, **60**, 115 (1938).
4) J. R. Martin, *Anal. Chem.*, **24**, 182 (1952).
* While PVA-borate is produced as the result of oxidation and hydrolysis, it gives free PVA on adding mannitol as seen below:

Mol. wt. = 153.8

Mol. wt. = 44

Then,

$$N = 2n_2 + n_1$$

where $N$ is the polymerization grade of PVA, and

$$B\% = (10.8\, n_2)/(153.8\, n_2 + 44\, n_1) \times 100$$

$$E_g = 2n_2/N \times 100$$

where $E_g$ is the esterification grade.

From the above three equations, it follows that

$$E_g = (133.74 \times B\%)/(16.41 - B\%)$$

Flory[5] has shown from the statistical theory that the maximum grade of acetalization is 86.47%; that is to say, 13.53% of the hydroxyl groups in PVA remains unreacted. While Noma and his coworkers[6] obtained experimentally the maximum value of acetalization, they used the reaction of PVA with diethylchloroacetal, and by determining the chlorine content by the Carius method, they found that the acetalization grade is not affected by the concentration of diethylchloroacetal, and the maximum value is in reality less than 85%. As to the reaction of PVA with *n*-butylboronic acid, the esterification grade $E_g$ increases with concentration of the latter. Table II shows the relation between the concentration of *n*-butylboronic acid and $E_g$, where the concentration of PVA is fixed to be 2.5%.

Table II. Relation between concentration of reactant and $E_g$

| No. | *n*-Butylboronic acid | Molar ratio | B% | $E_g$, % |
|---|---|---|---|---|
| B-1 | 1.25 | 1/2 | —* | — |
| B-2 | 2.50 | 1 | 5.97 | 75.4 |
| B-3 | 5.00 | 2 | 6.17 | 80.6 |
| B-4 | 7.50 | 3 | 6.31 | 83.6 |
| B-5 | 10.00 | 4 | 6.39 | 85.6 |

* Not salted out.

As seen from Table II the molar ratio of PVA to *n*-butylboronic acid is varied from one half to four. Above this concentration *n*-butylboronic acid dissolves incompletely, and hence the reaction does not proceed normally.

It is, however, to be remarked that the maximum value of $E_g$ agrees with the values obtained by Flory[5] and Noma[6]. The structure of PVA has been studied by many authors[7] and is generally considered to be of 1, 3-glycol form, but in the above equations the forms of 1, 2- and 1, 4-glycol, are not effective in estimating the value of $E_g$, because the molecular weight of the unit is equal.

Observing the fact that these esters in benzene as well as carbon tetrachloride can be spun into poor solvents and that the esters are very soluble in various solvents it may be considered that PVA reacts with boronic acid to form no didiol complexes II of so-called network structure but yields a monodiol I. This presumption is supported by the investigations of PVA-borate by Irany[8] and by Deuel[9]. Sakurada and Okada[10] previously reported on the reaction of PVA with boric acid, showing the structure of the product by means of X-ray diffraction, that the trivalent hydroxyl groups in boric acid form a cyclic structure such as III and when the relative concentration of boric acid to PVA becomes higher, a didiol structure II should also be taken into consideration.

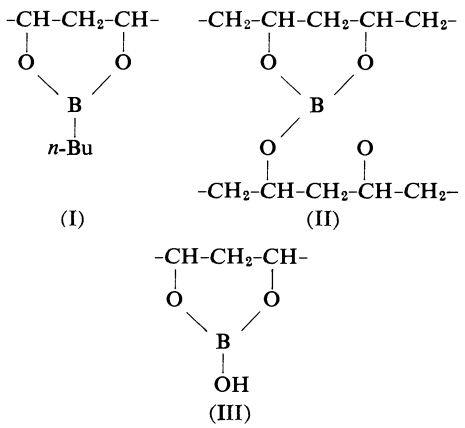


Fig. 1

In the case of *n*-butylboronic acid, however, a structure as II is not conceivable, for boronic acid is of divalent character and the boron atom is sterically hindered by the *n*-butyl group greater than the hydroxyl of boric acid.

**The Effect of Catalyst and Temerature.** — While in acetalization of PVA, an acid catalyst is fundamental for determining the reaction velocity[11], but the reaction of this esterification

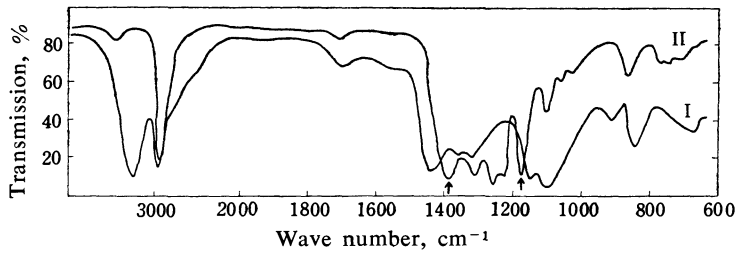

Fig. 2. Infrared spectra of polyvinylalcohol (I) and polyvinyl *n*-butylboronate (II).

proceeds instantly, and the determination of $E_g$ showed that the influence of $H^+$ on the reaction was not noticeable. Of course in alkaline solution, esterification does not proceed; the ester, if produced, may be saponified as soon as it is formed.

**The Effect of Temperature.** — The effect of temperature on $E_g$ is remarkable. In the range of 40 to 70°C, the values of $E_g$ rise as the temperature is raised, as shown in Table III.

TABLE III

| Temp., °C | 40 | 50 | 60 | 70 |
|---|---|---|---|---|
| $E_g$, % | 69.3 | 71.9 | 80.3 | 85.6 |

**Infrared Spectra.** — In order to study the structure of the esterification products, deeper infrared spectra were taken in the form of films prepared from carbon tetrachloride solutions of the esters on a mercury dish, the results of the observation being shown in Fig. 2.

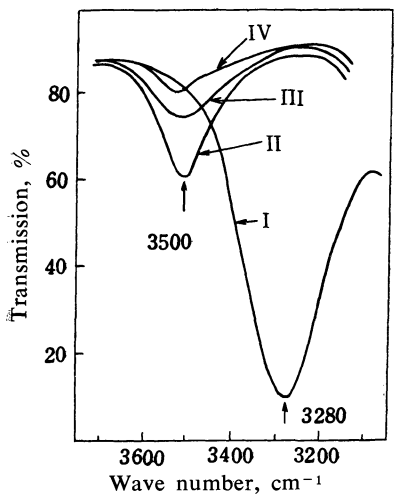

Fig. 3. Shifts of OH absorption band.
I: PVA II: B-2 III: B-4 IV: B-5

Curve I in Fig. 2 shows the spectrum of PVA unreacted. On treating with *n*-butylboronic acid it shows new absorption bands in the region of 1000 to 1500 $cm^{-1}$. In this region 1190 and 1390 $cm^{-1}$ can be assigned respectively to -B-C and -B-O bonds[12-14]. At the same time the OH stretching absorption band at 3280 $cm^{-1}$ of PVA shifts to a higher frequency by treatment with boronic acid and decreases in intensity with the increasing value of $E_g$ as shown in Fig. 3.

As seen in Fig. 3, it is observed that the decrease in intensity is related to $E_g$ qualitatively, and quantitative treatments will be reported in a later paper.

## Summary and Conclusion

It has been shown that PVA is partially esterified with *n*-butylboronic acid, giving products of the form of PVA  B-*n*-Bu.

The esterification grade, $E_g$, of the products is estimated from the boron content. $E_g$ increases with the increasing concentration of *n*-butylboronic acid used, the maximum $E_g$ being 85.6%. $E_g$ rises from 69.3 to 85.6% as the reaction temperature is elevated from 40 to 70°C.

On treating with *n*-butylboronic acid PVA shows new absorption bands 1190 and 1390 $cm^{-1}$ in deeper infrared spectra, which are assigned respectively to -B-C and -B-O bonds. At the same time the OH stretching absorption band at 3280 $cm^{-1}$ of PVA shifts to a higher frequency, and decreases in intensity with the increasing $E_g$.

# *A New Quantum-mechanical Reactivity Index for Saturated Compounds*

By Kenichi FUKUI, Hiroshi KATO and Teijiro YONEZAWA

(Received January 24, 1961)

In our previous paper[1], the frontier electron density[2] was shown to become a good intramolecular index of the reactivity in a metathetical reaction of saturated compounds.

In the present paper, we treat several lower paraffins and halomethanes by using the same method as that used in the previous treatment[1], and attempt to derive a new intermolecular index of the reactivity, which is hereafter referred to as the delocalizability, $D_r$. This index is similar to the superdelocalizability[3] of conjugated molecules. It is found that the magnitude of $D_r$ in these compounds has an intimate correlation with the value of activation energy observed in metathetical reactions.

## Electronic Structure of *n*-Paraffins and Methyl Fluoride

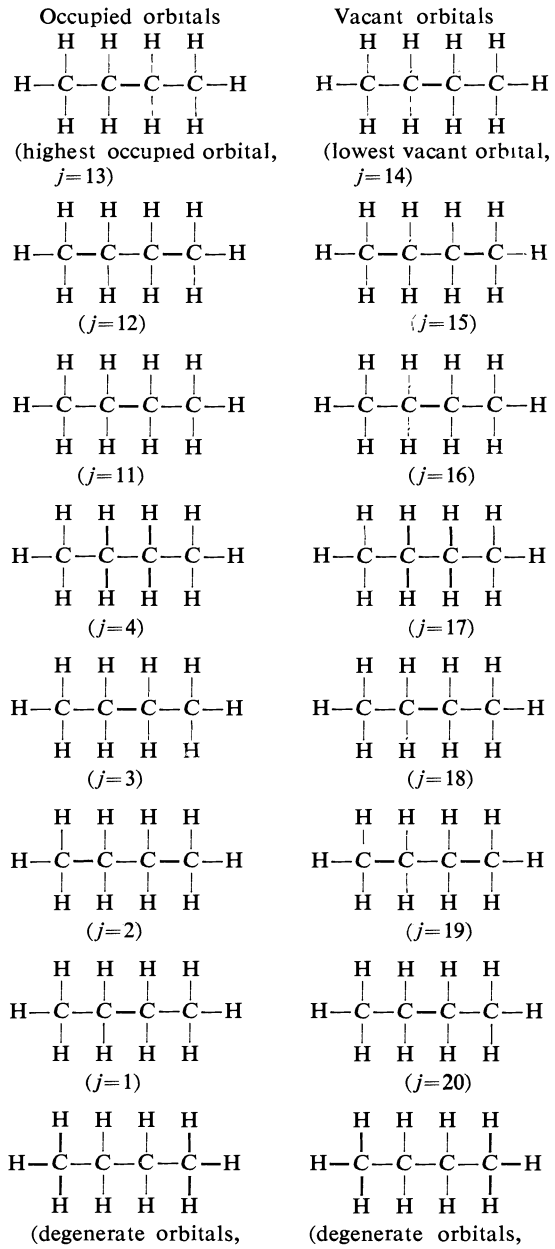
The calculated values of orbital energies and electron distributions in methane, ethane, propane, *n*-butane and methyl fluoride are listed in Table I.

With regard to *n*-paraffins, we can point out the following characteristics:

(1) The bonding electrons tend to localize in the particular bonds in each molecular orbital. For example, the electrons in the highest occupied and the lowest vacant orbitals in these compounds except methane, have a general trend to localize in the central C-C bonds as shown in Fig. 1*.

(2) The electron distributions of occupied and unoccupied orbitals are almost symmetrical with respect to the energy equal to $\alpha$ (see below) as is seen in Fig. 1.

(3) The distances of levels of molecular orbital energy in these compounds are much larger than those of conjugated molecules. The excitation energy of the N-V transition in a simple LCAO MO sense is, therefore, estimated to be 9~10 eV. referring the presumed value



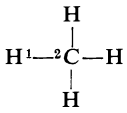


Fig. 1. The electron distributions of *n*-butane.
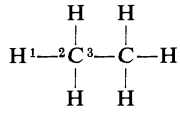
(Thick lines denote the most densely populated bonds of bonding electrons.)



1) K. Fukui, H. Kato and T. Yonezawa, This Bulletin, 34, 442 (1961).
2) See e. g. K. Fukui, T. Yonezawa, C. Nagata and H. Shingu, *J. Chem. Phys.*, 22, 1432 (1954).
3) K. Fukui, T. Yonezawa and C. Nagata, This Bulletin, 27, 423 (1954).
* This result suggests that in lower *n*-paraffins their first ionization can be attributed to the removal of one electron localized in C-C bonds.

* doubly degenerate

of $-\beta$ (6~7 eV.). This excitation energy is consistent with the spectroscopic data[4].

The characteristics of orbital energies and of the electron distribution stated above agree with the properties observed experimentally in saturated compounds and also with calculated results obtained by Lennard-Jones and Hall's equivalent orbital method[5].

In the doubly degenerate highest occupied orbitals of methyl fluoride, the bonding electrons localize dominantly in the methyl group. In the next highest occupied orbital, an exceedingly large density is observed on the fluorine atom in accordance with the facts pointed out by Frost and McDowell[6], who measured the ionization potentials of methyl halides.

The Coulomb and resonance integrals used in the present paper are summarized in the following table.

| | |
|---|---|
| $\alpha_H=\alpha-0.2\beta$ | $\beta_{cc}=0.34\beta$* |
| $\alpha_F=\alpha+0.9\beta$ | $\beta_{CH}=1.1\beta$ |
| $\alpha_{Cl}=\alpha+0.5\beta$ | $\beta_{CF}=0.5\beta$ |
| $\alpha_{Br}=\alpha+0.45\beta$ | $\beta_{CCl}=0.65\beta$ |
| $\alpha_I=\alpha+0.40\alpha$ | $\beta_{CBr}=0.58\beta$ |
| $\alpha_C=\alpha$ | $\beta_{CI}=0.53\beta$ |

* $\beta_{cc}$ refers to the resonance integral between two $sp^3$ orbitals attached to one and the same carbon atom.

## A New Reactivity Index for Radical Reactions of Saturated Compounds, $D_r^{(R)}$

The radical reactions of alkyl compounds are covered by the general equation

$$R\text{-}X+Y\cdot\rightarrow[R\cdots X\cdots Y]\rightarrow R\cdot+X\text{-}Y \qquad (1)$$

where R is an alkyl group, X is the group to be extracted and Y is an attacking radical or atom. The bracket in the equation refers to the transition state.

The secular determinant for the activated complex, [R-X···Y], is written

$$\Delta_\sigma=\begin{vmatrix} \alpha_Y-\varepsilon & \gamma\beta & 0 & 0 & 0 & 0 & 0 \\ \gamma\beta & \alpha_X-\varepsilon & \beta_{CX} & 0 & 0 & 0 & 0 \\ 0 & \beta_{CX} & \alpha_C-\varepsilon & \beta_{CH} & \beta_{cc} & & \\ 0 & 0 & \beta_{CH} & \alpha_H-\varepsilon & 0 & & \\ 0 & 0 & \beta_{cc} & 0 & \alpha_C-\varepsilon & & \\ 0 & \multicolumn{6}{l}{\text{(The secular equation for the R-X molecule)}} \end{vmatrix}$$

where $\alpha_A$ refers to the Coulomb integrals of atom A, $\beta_{AB}$ is the resonance integral between bonding orbitals of atom A and B, and $\gamma$ is a parameter for the resonance integral of the X-Y incipient bond in the transition state.

By using the perturbation theory, we can derive a new reactivity index, named $D_r$, for metathetical radical reactions in saturated compounds, in place of the superdelocalizability ($S_r$) in our previous paper[3].

$$D_r^{(R)}=\sum_j^{occ}\frac{(C_r^j)^2}{\varepsilon_j-\alpha}\beta+\sum_j^{unocc}\frac{(C^j_r)^2}{\alpha-\varepsilon_j}\beta \qquad (3)$$

where $C_r^j$ is the coefficient of the $r$th atomic orbital in the $j$th molecular orbital, $\varepsilon_j$ is the $j$th molecular orbital energy, $\alpha$ is the Coulomb integral of a $sp^3$ orbital in a carbon atom, and $\beta$ is the resonance integral between two $sp^3$ orbitals in a C-C bond.

In the derivation of Eq. 3, we assume that $\alpha_X$ is equal to $\alpha$, and the values of $\alpha$ and $\beta$ in the activated complex are the same as those of the isolated molecule.

It may be worthy of notice that $D_r^{(R)}$ represents the stabilization energy due to $\sigma$ type interaction in a radical reaction, while $S_r^{(R)}$ denotes the stabilization energy which

* $k_C$ means the rate constant divided by the number of H atoms of the same kind.

arises from the hyperconjugation taking place between a reagent and a conjugated molecule.

## Results and Discussions

In our previous paper[1], the magnitudes of the frontier electron densities at hydrogen atoms in several saturated hydrocarbons ran parallel with the experimental reactivities[7] of hydrogen atoms in metathetical reactions. The frontier electron density for radical attack was shown to be a good intramolecular index of reactivity. This index, however, does not indicate the correct order of reactivity in different molecules. Therefore, we adopt $D_r^{(R)}$ which is useful not only as an intramolecular index but also as an intermolecular index. The calculated values of $D_r^{(R)}$ in several saturated compounds are listed together with the observed values of activation energy[8,9] in various metathetical reactions in Tables II and III.

TABLE III. THE VALUES OF $D_r^{(R)}(H)$ AND ACTIVATION ENERGIES OF HALOMETHANES IN METATHETICAL REACTIONS

(a) $CH_nCl_{4-n}+CH_3\cdot \rightarrow CH_{n-1}Cl_{4-n}\cdot+CH_4$

**Hydrogen Extraction Reaction.**—In the case of reaction $RH+R'\cdot \rightarrow R\cdot+R'H$, results of calculation and experiments are cited in Table II (a) and (b), where R and R′ are two different alkyl groups. The values of $D_r^{(R)}$ at hydrogen atoms in several lower paraffins indicate a tendency that the larger the molecule RH is, the smaller is the magnitude of activation energy, this being in accord with experiments[8]. Furthermore, these values of $D_r^{(R)}$ agree with the activities of various kinds of hydrogen atoms estimated by Trotman-Dickenson[7] as shown in Table II (b).

In Table III (a), (b) and (c), the calculated values of $D_r^{(R)}$ at hydrogen atoms in various halomethanes are listed together with the observed activation energies[9]. In Table III (a), the radical reactions between methyl radical and chlorine-substituted methanes are indicated. The greater the number of chlorine atoms in methane is, the smaller is the activation energy, and also the magnitude of $D_r^{(R)}$ at hydrogen atoms increases with the number of chlorine atoms. The results on fluorine-substituted methanes are shown in Table III (b), and

| $CHBr_3$ | 4.889 | 0.3 |

in various halomethanes and the observed values of activation energy in the halogen extraction reactions[9]. In Table IV (a), a good agreement is observed between the values of $D_r^{(R)}$ and the activation energies of various monosubstituted halomethanes. In Table IV (b), the values of $D_r^{(R)}$ at chlorine atoms in various chlorine-substituted methanes and the activation energies in the hydrogen-atom reactions are indicated. In Table IV (c), the values of $D_r^{(R)}$ at bromine atoms in several bromomethanes are compared with the activation energies in the sodium-atom reaction.

In spite of the fact that this is the first attempt of the quantum-mechanical investigation of the reactivity of saturated compounds, the agreement of the theory with experience is almost satisfactory, and hence the new quantum-mechanical quantity $D_r^{(R)}$ can be a useful index for predicting the reactivity of saturated compounds, equally with $S_r$ in conjugated molecules. There remain, however, some points to be checked in future. These are summarized as follows:

(1) We assume that $\alpha_x$ is equal to $\alpha$ to derive $D_r$. Meanwhile, a slight change in activation energy is experimentally observed according to the species of attacking reagents. Hence, if the values of $\alpha_x$ would be modified according to the change of the attacking reagent, this effect can be interpreted in the present procedure.

(2) In the present treatment, we do not take into account the stabilization energy due to the resonance in an attacking alkyl radical or the radical formed. It has been made clear that this resonance energy has a remarkable influence on the magnitude of the activation energy[10]. In this connection, the present treatment should be modified so as to involve the contribution of this kind of resonance to the activation energy.

(3) A disagreement between the values of $D_r^{(R)}$ in methyl halides and the experimental activation energies is observed. This is probaly because the energies of the vacant orbitals of some methyl halides are nearly equal to $\alpha$. Thus, the values of the $D_r^{(R)}$ become extremely large. If carefully selected values of parameters for halogen atoms should be adopted, these disagreements may be avoidable.

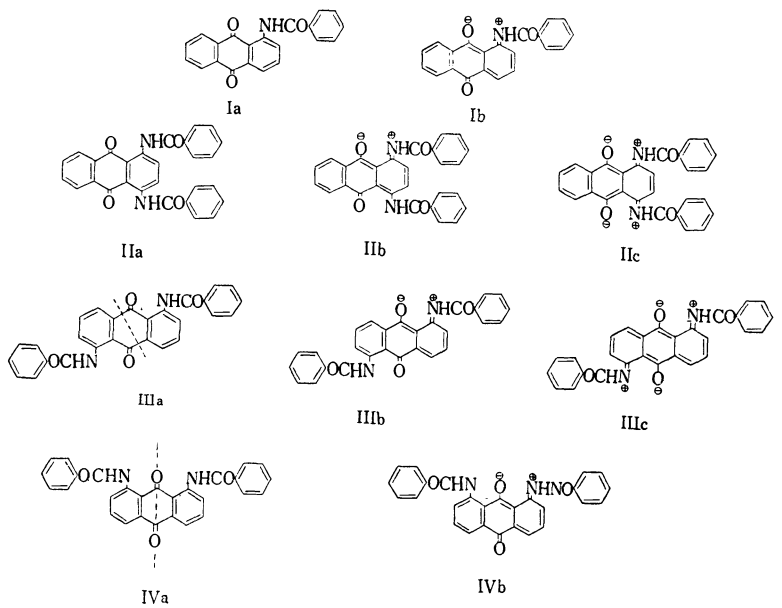
# *Studies on the Diacylaminoanthraquinone Dyes*

By Takayuki HAYASHI and Reiko SHIBATA



(Received September 20, 1960)

In our previous papers[1-5], 1-acylamino-, 1,4-, 1,5- and 1,8-diacylaminoanthraquinones having $NO_2$, Cl, OMe, $SO_2N(Me)_2$ or $NH_2$ (X or Y)* as a substituent in the acyl group were prepared. Visible and infrared absorption spectra of these dyes were measured in solution and in solid, respectively, and cotton was dyed with them, and their light fastness on cotton was tested. On the basis of these results, the effects of X and Y substituent groups were discussed with their various properties, such as wavelengths of absorption maxima, relative difficulties of vatting, color tones of vat solutions, shades of dyed cotton, and light fastness. In this paper, the above-mentioned properties have been discussed correlatively for all of these dyes.

## Results and Discussion

**Visible Absorption Spectra.**—Visible absorption spectra of 1-acylamino-, 1,4- and 1,5-diacylaminoanthraquinone series were observed and discussed by Peters and Sumner[6]. In this paper, from the results of visible absorption for 1-acylamino-, 1,4-, 1,5- and 1,8-diacylaminoanthraquinones, the relation between wavelengths or intensities of the absorption maximum and positions of acyl groups has been discussed. Furthermore, for each series of 1-acylamino-, 1,4-, 1,5- and 1,8-diacylaminoanthraquinones the effect of the substituent (X or Y) in the acyl group upon the wavelength and intensity of the absorption maximum has been considered.

The absorption maxima[1-4] of 1-benzoylamino-, 1,4-, 1,5- and 1,8-dibenzoylaminoanthraquinones appeared at 421, 502, 448 and 455 m$\mu$ in *o*-dichlorobenzene with the peak molar extinction coefficient of 5900, 7600, 12000 and 11000, respectively. Since the molecule of the 1,5-derivative is divided into two halves diagonally as in III, simple additivity is established between two chromophoric systems within it, and one to three benzene rings in

the anthraquinone nucleus increase their quinonoid character, thereby reducing the aromaticity, but the extent of the contribution of a structure IIIc to the resonance is exceedingly small. For the 1-derivative, on the other hand, one to two benzene rings in the anthraquinone nucleus increase their quinonoid character as in I, thereby reducing the aromaticity, and only one carbonyl group of the anthraquinone nucleus takes part in conjugation, this being different from the 1, 5-derivative. The wavelength of the absorption maximum for the 1, 5-derivative should therefore be somewhat longer than for the 1-derivative, but the intensity of the former should be approximately twice that of the latter. Since the molecule of the 1, 8-derivative is divided into two halves vertically as in IV, simple additivity is established between two chromophoric systems within it as the 1, 5-derivative, but one to two benzene rings in the anthraquinone nucleus increase their quinonoid character, thereby reducing the aromaticity, this being different from the 1, 5-derivative. Though one carbonyl group is held by two chromophoric systems in common for the 1, 8-derivative, mesomeric shifts of electrons within the chromophoric systems are suppressed, owing to cross conjugation of two systems, in which case the extent of the contribution of a structure IVb to the resonance should be a little greater than for a structure IIIb. The effective area of $\pi$-electron systems[7,8] for IV is also slightly smaller than for III. The wavelength of the absorption maximum for the 1, 8-derivative should therefore be somewhat longer than for the 1, 5-derivative, and the intensity of the former should be a little lower than for the latter but approximately twice that of the 1-derivative. For the 1, 4-derivative one to two benzene rings in the anthraquinone nucleus increase their quinonoid character, thereby reducing the aromaticity, and the extent of the contribution of a structure IIc to the resonance is more marked. The 1, 4-derivative shows no such simple additivity as indicated in III owing to interaction between their two chromophoric systems, probably producing a new one, and an effective area of $\pi$-electron systems for II is smaller than for III or IV. The wavelength of the absorption maximum for the 1, 4-derivative should therefore be the longest among them and the intensity should lie between those of 1- and 1, 8-derivatives. Such relations should be established similarly among 1-acylamino-, 1, 4-, 1, 5- and 1, 8-diacylaminoanthraquinones with the same substituent in the acyl group.

From results[1-4] of the bands for each series, it was known that electron-attracting substituents mainly showed a +I effect and electron-donating substituents mainly a −T effect and the *p*-dimethylsulfamyl group showed a +I effect similar to a *p*-nitro group, this being different from the result of the *p*-sulfamyl group obtained by Zollinger[9]. For the bands of each series, it was shown that the shifts of the absorption maximum complied with Hammett's rule[10] and that the relationship between the wavelengths of the absorption maximum and Brown's $\sigma^+$ values[11,12] was

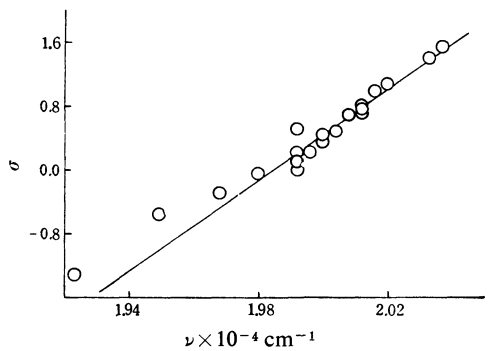

Fig. 1. The relationship between wave-number ($\nu$) of the maximum absorption and Hammett's $\sigma$ value on the 1,4-diacylaminoanthraquinone series.

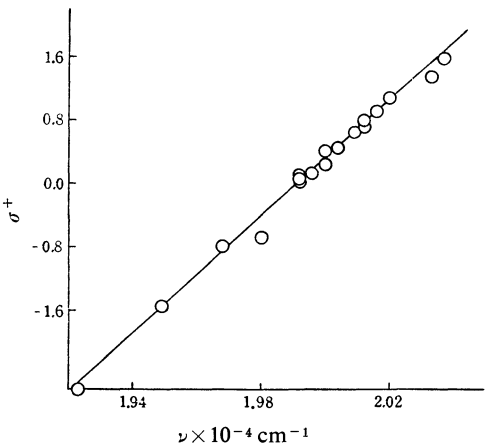

Fig. 2. The relationship between the wave-number ($\nu$) of the maximum absorption and Brown's $\sigma^+$ value on the 1,4-diacylaminoanthraquinone series.

more linear than that between them and Hammett's $\sigma$ values[10] as indicated in Figs. 1 and 2 for the 1,4-diacylaminoanthraquinone series. Accordingly it is possible to estimate a shift from Brown's $\sigma^+$ value of a substituent in the acyl group and obtain an expected shift of the absorption maximum by introduction of an adequate substituent with known Brown's $\sigma^+$ value to the acyl group. Hammett's $\sigma$ value of *p*- and *m*-dimethylsulfamyl groups were 0.70 and 0.53, and Brown's $\sigma^+$ values of these were 0.86 and 0.68, respectivery, from Figs. 1 and 2.

For each series, dyes with *o*-chloro, *o*-methoxy or *o*-nitro groups, besides an *o*-amino group, as X and Y, showed a considerably hypsochromic shift and a decreasing intensity in their absorption maxima. Both the wavelengths and the intensities were almost independent of all combinations of substituents in two acyl groups for each series. As indicated in Table I, the absorption maximum of 1,5-diacetylaminoanthraquinone agreed with those of 1,5-di-*o*-substitutes. This fact was admitted on the other *o*-substitutes. The effect of the *o*-substituted phenyl group should therefore be much the same as that of the methyl group, and this fact shows that the benzene ring has been twisted around the C-C linkage between

Table I. Visible absorption bands of *o*-substituted benzoylamino- and acetylamino-anthraquinones[1-4]

| | *o*-Substitute | Acetylamino-anthraquinone |
|---|---|---|
| 1-Derivative | 407~411 (5300~6000)** | 415 (5300) |
| 1,4-Derivative | 483~486 (6950~7100) | 487 (7550) |
| 1,5-Derivative | 437~439 (10500~11500) | 438 (11000) |
| 1,8-Derivative | 438~441 (9700~10200) | 440 (10400) |

the *o*-substituted phenyl and the carbonyl group in the acyl group. The twisting may be attributed to the steric hindrance between the *o*-nitro and the carbonyl group or to the repulsion between the *o*-chloro or *o*-methoxy and the carbonyl group in the acyl group. The wavelengths of the absorption maximum of 1-*o*-amino-, 1,4-, 1,5- and 1,8-di-*o*-amino-substitutes were 436, 514, 460 and 463 m$\mu$ in *o*-dichlorobenzene, respectively. As these absorption peaks do not show a hypsochromic shift, they are different from the ones of the other *o*-substitutes, such the interesting twisting of the benzene ring as in *o*-substitutes may not arise.

** Wavelength, m$\mu$ (molar extinction coefficient).

**Infrared Absorption Spectra.**—Three and six $\mu$ bands of infrared absorption spectra for some acylaminoanthraquinones have been observed as powders suspended in Nujol on account of their limited solubility and were discussed by Flett[13]. In this work, infrared absorption spectra of 1-acylamino-, 1,4-, 1,5- and 1,8-dibenzoylaminoanthraquinones have also been observed as powders suspended in Nujol and information has been gained about their structures in the solid. This information may be, to some extent, similar to deduction for the structure of the dye molecule in cotton dyed with them.

As indicated in Table II, a C=O frequency in the peri-position of the benzoyl group for 1,4-dibenzoylaminoanthraquinone is lower than for the 1,5-isomer, and then the C=O bond of the former is more weakened than for the latter. This fact may generally suggest that the shade of the 1,4-diacylaminoanthraquinone series on cotton is more bathochromic than in the case of the 1,5-isomer. As 3 $\mu$ bands of 1,5-dibenzoylaminoanthraquinone almost agree with those of the 1,8-isomer, the effect of imino groups on the whole of the molecule is much the same in both cases. This fact may generally suggest that a shade of the 1,5-diacylaminoanthraquinone series on cotton is approximately the same with that of the 1,8-isomer.

Table II. 3 and 6 $\mu$ bands of solid benzoylaminoanthraquinones[5]

| | 3 $\mu$ bands $cm^{-1}$ | 6 $\mu$ bands $cm^{-1}$ (C=O frequencies) |
|---|---|---|
| 1-Derivative | 3175 | 1681, 1669, 1637 |
| 1,4-Derivative | 3125, 3086, 3058 | 1686, 1639 |
| 1,5-Derivative | 3226, 3195, 3125[a] | 1689, 1639 |
| 1,8-Derivative | 3226, 3185, 3125[a] | 1701, 1681, 1631 |

a) 3 $\mu$ bands obtained from KBr discs of 1,5- and 1,8-derivatives were all the same (3257, 3226, 3125 $cm^{-1}$).

Though it is known that the question, whether or not shifts of a C=O frequency comply with Hammett's rule, must be generally discussed in regard to the result obtained from the dilute solution of a nonpolar solvent, the results obtained from the solid of the 1-acylaminoanthraquinone series have been examined on account of its limited solubility in the present work. Shifts in the C=O frequency of the acyl groups were in harmony with Hammett's rule, as indicated in Fig. 3. Shifts in the C=O frequency of the peri-position of the acyl groups lay on the S-shaped curve against

13) M. S. C. Flett, *J. Chem. Soc.*, **1948**, 1441.

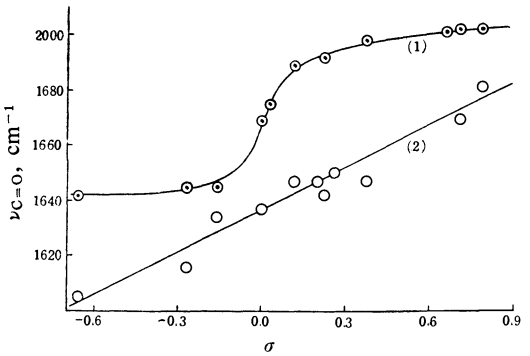

Fig. 3. The relationship between the C=O frequency ($\nu_{C=O}$) and Hammett's $\sigma$ value on the 1-acylaminoanthraquinone series.
(1) The quinone-type C=O frequency in the peri-position of the acylamino group.
(2) The C=O frequency in the acyl group.

Hammett's $\sigma$ value, as indicated in Fig. 3, and the latter C=O bond was therefore strengthened to much the same degree for the dyes with any of the electron-attracting substituents and the reverse was found to be true for the dyes with any of the electron-donating substituents. For the 1-derivative with a *p*- or *m*-dimethylsulfamyl group which is intensely electron-attracting, the C=O bonds of its molecule in solid have been strengthened to the extent indicated on the curve of Fig. 3.

As C=O frequencies[5] of (*o*-nitrobenzoyl)-aminoanthraquinone agree with those of 1-acetylaminoanthraquinone[13], the effect of the *o*-nitrophenyl group on them is thought to be of the same degree as that of the methyl group. This fact shows that the benzene ring of the former has been twisted around the C-C linkage between the *o*-substituted phenyl and the carbonyl group in the acyl group, and that the twisting may be attributed to steric hindrance between the *o*-nitro and the carbonyl group in the acyl group. For the *o*-nitro-substitute, this interpretation of its molecular structure in solid is the same as the deduction on that in solution on the basis of the results of the visible absorption. From shifts in the C=O frequency[5] of the acyl group for *o*-chloro- and *o*-methoxy-substitutes, however, it seems probable that such twisting of the benzene ring does not arise on the molecule in solid, this being different from the molecule in solution. Though the benzene ring of the *o*-chloro- or *o*-methoxy-substitute in solution has been twisted by repulsion between the *o*-chloro or *o*-methoxy and the carbonyl group in the acyl group, such twisting may be suppressed in a solid where the molecules are paked closely. From the result of infrared absorption, it seems likely that for the *o*-amino-substitute in solid the benzene ring also does not twist, this being identical with the deduction on its molecular structure in solution on the basis of the results of the visible absorption.

**Relative Difficulties of Vatting.**—It has been concluded that from the interpretation of visible absorption for the acylaminoanthraquinone series, an electron density of the quinone-type carbonyl group within the chromophoric system decreases in the order of 1, 4-, 1, 8- and 1, 5-isomers, and that it decreases in the order of 1, 4- and 1, 5-isomers from examinations of their infrared absorption. From both these bits of information and a reduction mechanism of anthraquinone[14], it is deduced that difficulty of reduction, namely difficulty of vatting, should naturally increase in the order of 1, 4-, 1, 8- and 1, 5-isomers. The result has also been obtained from our experiments[2-4] showing that difficulty of vatting increases in the order of 1, 4-, 1, 8- and 1, 5-isomers and vatting of the 1, 8-isomer is no more difficult than vatting of the 1, 4-isomer.

The result has been obtained from our experiments[2-4] that, for each seris of 1, 4-, 1, 5- and 1, 8-diacylaminoanthraquinones, the effect of X or Y on the difficulty of vatting increases in the order of *p*-$SO_2N(Me)_2$, *m*-$SO_2N(Me)_2$, *m*-OMe, *m*-Cl, *p*-OMe, *p*-Cl, *m*-$NO_2$, *p*-$NO_2$. But difficulties of vatting of *m*-methoxy-, *m*-chloro- and *p*-methoxy-substitutes have been of much the same degree as that of the non-substitute and those of dimethylsulfamyl-substitutes have been especially small[2-4]. It is known that the relative difficulty of vatting, namely the relative difficulty of reduction,

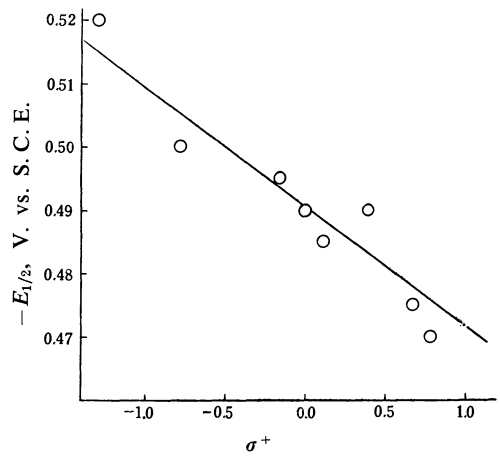

Fig. 4. The relationship between the first half-wave potential ($-E_{1/2}$) in ethanol and Brown's $\sigma^+$ value on the 1-acylaminoanthraquinone series.

14) T. Vickerstaff, "Physical Chemistry of Dyeing", Oliver & Boyd, London (1954), p. 282.

is dependent on both the magnitude of the reduction potential and the degree of the rate of reduction[14]. For the reduction potential, shifts of the reduction potential for 2-substitutes of 1, 4-naphthoquinone or for 3-substitutes of phenanthrenquinone were in harmony with Hammett's rule[2], and a relationship between the first half-wave potentials of 1-acylaminoanthraquinone series and Brown's $\sigma^+$ values were also in accordance with Hammett's rule, as indicated in Fig. 4. From these results, there seems likely to be a correlation between the magnitude of the reduction potential and Hammett's $\sigma$ or Brown's $\sigma^+$ value of the substituent for each series of acylaminoanthraquinones. On the contrary, from our results described above, it is evident that the effect of X or Y on the difficulty of vatting has been dependent not only on Hammett's $\sigma$ or Brown's $\sigma^+$ value but also on the hydrophilic or hydrophobic property of X or Y. Therefore, it seems likely that for each series the relative difficulty of vatting is dependent on both the magnitude of the reduction potential and the degree of the rate of reduction, and that the rate of reduction bears a relation to the hydrophilic or hydrophobic property of X or Y.

**Color Tones of Vat Solutions.** — For leuco salts of these dyes, as two electron-donating substituents ($O^-$) occupy 9- and 10-positions where they have the maximum conjugation with the anthracene nucleus, the effect of these substituents is considerably greater than that of such substituents as acyl groups occupying the other positions. Therefore, the entire visible absorption curve, that is, color tones of vat solution for all of 1,4-, 1,5- and 1,8-diacylaminoanthraquinone series should be similar to one another. Such deduction has been consistent with our results[2-4], that is, the color tones of vat solution for all of them, except for di-*o*-substitutes, were from reddish violet-blue to reddish violet. Waters[15] and Venkataraman[16] also reported that for the vat solutions of anthraquinone, aminoanthraquinone, acylaminoanthraquinone and others the visible absorption curves with maximum absorption bands at 425 and 515 m$\mu$ were given, being approximately similar to one another.

**Shades of Dyes.**—The 1, 4-diacylaminoanthraquinone series was a red dye, and 1, 5- and 1, 8-derivatives were yellow dyes but the shade of the latter on cotton was somewhat more bathochromic than that of the corresponding isomer of the former[2-4]. For all of the dyes with a nitro group as X or Y, the shades on cotton were from brown to intensly brownish on account of the amino group (reduction of the nitro group)[2-4]. The fact that the shade is hypsochromic in the order of 1, 4-, 1, 8- and 1, 5-isomers, is explained in the same way by electronic interpretations on shifts in visible absorption bands for these dyes in solution. It was admitted that for each series of diacylaminoanthraquinones a shade of the XY type*** was in the middle between shades of the corresponding XX type and of the YY type, and this fact has shown that the effects of X and Y on the shift of the shade are additive. An electron-donating substituent in the acyl group causes the bathochromic shift of the shade and the reverse is found for electron-attracting substituents. Though *p*- and *m*-dimethylsulfamyl groups were found to be intensly electron-attracting from examinations of the visible absorption, the shades of dyes with these groups as X or Y have merely shown a change from the weak hypsochromic to the weak bathochromic shift. For 1,4- and 1,5-diacylaminoanthraquinone series, an effect of X or Y on enhancement of brilliance of the shade has been shown to be greater in the *m*- than in the *p*-position within the acyl group, as described in the PB Report[17], but such a difference has not been found for the 1,8-derivative. Generally speaking, the degree of brilliance on the shade of the XY type for each series of diacylaminoanthraquinones was higher than that of the corresponding XX or YY type.

It is known that adsorption of leuco vat dyes on cellulose is dependent on both their affinity and rate of diffusion[18], but as the rate of diffusion may be independent of a kind of X or Y for the acylaminoanthraquinone series, it seems likely that adsorption of leuco acylaminoanthraquinones is dependent on their affinity, and, therefore, the greater the affinity is, the greater is the depth of the shade. From affinities of some acylaminoanthraquinones for cotton, it has been concluded that for any one of these series there is little difference in affinity between the *m*- and *p*-substitutes but their affinities are greater than that of a non-substitute and a great reduction in affinity is shown on the *o*-substitutes[8,18]. From these bits of information, the depth of the shade of the non-substitute should be less than those of *m*- and *p*-substitutes and those of the *o*-substitutes should be especially small for each series. Such deductions have been consistent with our results[2-4] obtained from comparison

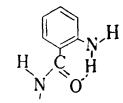
*** The XX or YY type denotes the diacylaminoanthraquinone with the same two acyl groups and the XY type that with two different acyl groups.
17) BIOS 987 (PB 75860) p. 185.
18) T. Vickerstaff, loc. cit., p. 299.

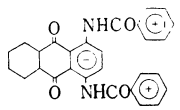


with the depth of the shade for many sets of the same shade. It is known that there is a definite correlation between affinity and molecular weight for these dyes, except for *o*-substitutes[8,18], but for dyes with a dimethylsulfamyl group as X or Y, the depth of the shade has been less in spite of the increase of molecular weight with the increasing surface area. This fact is due to a reduction of van der Waals force based on a decreasing coplanarity which is attributed to the bulky volume of the dimethylsulfamyl group.

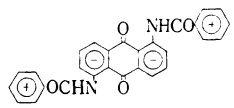
***o*-Substitutes.**—It has been known from our experiments[2-4] that vatting of *o*-substitutes is more difficult than for *m*- and *p*-substitutes and the color tones of the vat solution for the former are more hypsochromic and pale than for the latter, and the former has dyed cotton with more difficulty.

From interpretations of visible absorption bands for *o*-substitutes, it has been concluded that mesomeric shifts of electrons within their chromophoric system are suppressed by the *o*-substituents, namely the *o*-substituents lower the electron density of the quinone-type carbonyl group. In consideration of both this fact and the vatting mechanism of *o*-substitutes, it is natural that these dyes have increasing difficulty in vatting, as described above. For leuco *o*-substitutes the hypsochromic shifts in the color tone of their vat solutions, described above, are attributed to the reduced conjugation between the anthracene nucleus and *o*-substituted benzoyl groups, and the palenen of vat solutions may be due to a decrease in an effective area of the $\pi$-electron system for *o*-substitutes. For *o*-chloro- and *o*-methoxybenzoylaminoanthraquinones, Valentin[19] has partially attributed their reduced affinities to internal chelation within acylamido groups, as indicated in Va and Vb, but the reduced affinity of *o*-methylbenzoylaminoanthraquinone[8,18] can not be explained satisfactorily from his suggestion, and the presence of the internal chelation is inconsistent with the information about the molecular structure obtained from their visible absorption. As *o*-substituents make it difficult for the *o*-substitutes to attain a planar configuration as indicated by this information, these dyes may dye cotton with diffiiculty, as described above, on account of the reduction of van der Waals force with the decreased affinity.

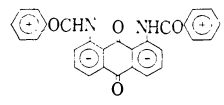
Va



Vb



Vc



From interpretations on their visible absorption, it seems likely that *o*-amino-substitutes (reduction of the *o*-nitro-substitutes) have maintained coplanarity of the molecule, but the *o*-aminosubstitutes have also dyed cotton with difficulty. These results may be taken to show that the *o*-amino group prevents the hydrogen bond formation between the amido group and the cellulose hydroxyl group on account either of the steric hindrance of the *o*-amino group or the internal chelation as indicated in Vc.

**Light Fastness.** — Several relations between chemical constitutions of 1,4-, 1,5- and 1,8-diacylaminoanthraquinone series and their light fastness have been drawn from the results[2-4] of the light fastness test for them. In the first place, grades of light fastness on cotton for 1,4-, 1,5- and 1,8-dibenzoylaminoanthraquinones were 7, 6 and 5, respectively. The light fastness of the diacylaminoanthraquinone series on cotton has generally become lower in the order of 1,4-, 1,5- and 1,8-isomers. The shades of these dyes on cotton, except for *p*-substitutes of the 1,4-diacylaminoanthraquinone series, have not shown fading, but have shown a sign of turning brown under sunlight. For 1,5- and 1,8-diacylaminoanthraquinone series the light fastness of *p*-substitutes was generally higher than that of corresponding *m*-substitutes, which was higher than that of corresponding *o*-substitutes for each series of 1,4-, 1,5- and 1,8-diacylaminoanthraquinones. For each series of them, in comparison with the light fastness of a non-substitute, the dyes with a chloro group as X have shown almost no lowering, but the dyes with a methoxy or dimethylsulfamyl group have shown slight lowering, and all of the dyes with a nitro group (an amino group on cotton) evident lowering.

It is know that for a group of dyes of the

VIa

VIb

VIc

19) L. Valentin, *J. Soc. Dyers Colorists*, **72**, 286 (1956).

same type, for example simple azo dyes, in general, the greater the difference is of an electron density on two parts within a molecule of the dye, the higher the light fastness of the dye is. For dibenzoylaminoanthraquinones it seems likely that an electron density of the benzene ring in the benzoyl group is lower than that of the benzene ring within the anthraquinone nucleus, as indicated in VIa, VIb and VIc, from both pieces of information about mesomeric shifts of electrons within the chromophoric systems and examinations of some reactions of the dyes with reagents. For 1,4-dibenzoylaminoanthraquinone two chromophoric systems hold one benzene ring within the anthraquinone nucleus in common, but for 1,5- and 1,8-dibenzoylaminoanthraquinones two chromophoric systems bear relations with different benzene rings in the anthraquinone nucleus respectively. The difference between electron densities of the benzene ring in the benzoyl group and of the benzene ring in the anthraquinone nucleus for the 1,4-derivative should therefore be greater than for the 1,5- or 1,8-derivative. From interpretations of both visible and infrared absorption for 1,5- and 1,8-derivatives, it has been concluded that an electron density of the quinone-type carbonyl group on the peri-position of the benzoylamido group for the latter is somewhat higher than for the former. As two chromophoric systems of the 1,8-derivative holding one carbonyl group in common are cross conjugation, mesomeric shifts of electrons within them are suppressed by each other; but, on the other hand, two chromophoric systems of the 1,5-derivative bear almost no relation to each other. The extent of the mesomeric shift of electrons within one chromophoric system for the former is therefore less than for the latter, and then the difference between electron densities of the benzene ring in the benzoyl group and of the benzene ring in the anthraquinone nucleus for the former is less than for the latter. Finally, the difference between electron densities of two benzene rings decreases in the order of 1,4-, 1,5- and 1,8-isomers, and this order may be responsible for the lowering of light fastness in the order of 1,4-, 1,5- and 1,8-isomers, described above. An alternative possibility is that the 1,5-isomer being transform it probably packs more compactly than the 1,8-isomer which is in cis-form in the solid of the dye within the fiber, and also that the light fastness of the former may be higher than that of the latter.

The effects of Cl, OMe or $NH_2$ as X on light fastness, described above, were similar to the results[20] already known concerning many dyes. Though a dimethylsulfamyl group is intensely electron-attracting, shades of the dyes with this group as X or Y have only shown changes from weak bathochromic to weak hypsochromic shifts in comparison with the shade of the non-substitute, and further the dimethylsulfamyl group has an appearance of a weak electron-attracting or weak electron-donating group in these cases. This fact may bear some relation to the lowering of the light fastness of these dyes described above. The lowering of light fastness may be due to the fact that these dyes can not pack compactly in the solid of the dye within the fibre owing to the bulky volume of the dimethylsulfamyl group.

The authors wish to express their sincere thanks to Professor Yoshio Nagai and Dr. Shimpachiro Kato of Tokyo University for their helpful suggestions and encouragement in the course of this work. They also wish to thank the Tokuyama Research Laboratory of Idemitsu Kōsan Co. for infrared measurements.

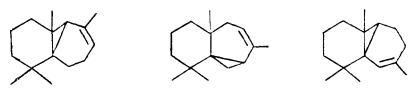
# *Polyterpenes. III*[1]. *The Structure of Thujopsene**

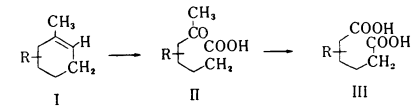
By Hiroshi KOBAYASHI, Shizuo NAGAHAMA and Saburo AKIYOSHI



(Received November 19, 1960)

Thujopsene, the main component of Hiba wood oil, has attracted much attention in the last few years[2]. Hirose and Nakatsuka[3] pointed out that widdrene[4], which was later shown to be widely distributed in *Cupressaceae*[5], was identical with thujopsene. Erdtman and Norin[6] confirmed this identity and proposed structure Ia for this compound. Independently we also arrived at the same conclusion and proposed structure Ia and Ib[7], of which the former is preferred[5]. Subsequently Erdtman and Norin[9] presented further evidence and revised their structure to Ib. Sisido and Nozaki[10] proposed structure Ic for thujopsene, but later withdrew their suggestion[11] in favor of Erdtman and Norin's proposal. In view of the evidence presented[12] we also consider that the properties of thujopsene are best explained by the formula Ib.

We now wish to present our findings which have already been outlined in our short communication[8].



Thujopsene (I) possesses the molecular formula $C_{15}H_{24}$ and is a tricyclic hydrocarbon compound having an unsaturated bond. On the permanganate oxidation in acetone, it gives ketocarboxylic acid, $C_{15}H_{24}O_3$ (II), as a main product in addition to other by-products. Ozonolysis of thujopsene gives the same acid II. This acid II is therefore considered as the primary product to which thujopsene cleaves at the unsaturated bond without any other change. Thus, the purpose of the studies comes to determine the structure of acid II.

Hypobromite oxidation of II affords a dicarboxylic acid, $C_{14}H_{22}O_4$ (III), which shows the presence of the $CH_3$-CO- group in the keto acid II, and these results, when considered together with the preceding data, seem

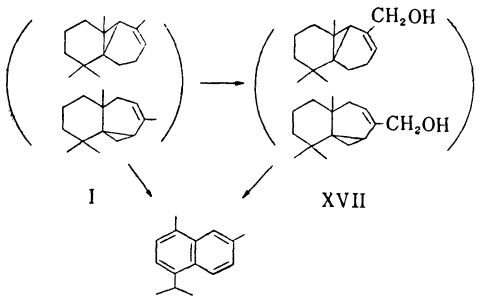

Fig. 4

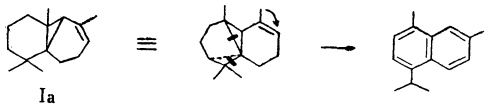

Fig. 5

to indicate the presence of the structure $CH_3-\underset{\underset{C-}{|}}{C}=C-$ in thujopsene.

The keto acid II is, when treated with mineral acid, easily isomerized to a ketolactone (carbonyl absorptions 1774 and 1724 $cm^{-1}$) accompanied with a cleavage of a ring in the keto acid II. It possibly indicates the presence of a small ring in the keto acid II.

The $C_{14}$-dicarboxylic acid (III) gives two different monomethyl esters, $C_{15}H_{24}O_4$, one (IV) of which is obtained by acid catalyzed esterification with methanol and the other (V) by hydrolysis of dimethyl ester (VI) with methanolic potassium hydroxide. The former (IV) is also obtained from the methyl ester of II, when treated with hypobromite in aqueous dioxane, and it seems therefore that one of the two carboxyl groups in III is much more hindered than the other and that the former results from $CH_3-CO-$ group in II.

The $C_{14}$-dicarboxylic acid (III) is dehydrated to an anhydride, $C_{14}H_{20}O_3$ (VII) (carbonyl adsorptions 1799 and 1752 $cm^{-1}$), which is easily pyrolyzed at about 300°C to a cycloketone, $C_{13}H_{20}O$ (VIII), accompanying decarboxylation[13].

Calcium and barium salt of dicarboxylic acid III also give cycloketone VIII by pyrolysis but they do so in poor yield.

Cycloketone VIII is condensed with ethyl formate in the presence of sodium metal to an enol, $C_{14}H_{20}O_2$ (IX), and is oxidized to a yellow 1,2-diketone, $C_{13}H_{18}O_2$ (X), with selenium dioxide in dioxane. Each of these two characteristic reactions results in the quantitative formation of the corresponding product and exclusively of only a single corresponding species. It seems therefore that the carbonyl group in VIII connects to a methylene group at one side and to a more substituted carbon atom at the other side. This presumption becomes more certain by the fact that 1,2-diketone (X) is converted into a dicarboxylic acid, $C_{13}H_{20}O_4$ (XI), without loss of the carbon atom when treated with alkaline hydrogen peroxide.

The $C_{13}$-dicarboxylic acid (XI) gives the corresponding anhydride, $C_{13}H_{18}O_3$ (XII), by heating. All attempts to get $C_{12}$-cycloketone from XI have failed.

XII shows infrared absorptions of the carbonyl group at 1799 and 1754 $cm^{-1}$. Therefore XII is considered to be of glutaric anhydride type, and the cycloketone to be of structure VIII, and further the ring containing an unsaturated bond in thujopsene is six-membered.

$C_{13}$-dicarboxylic acid (X), like acid III, also easily gives two different monomethyl esters, $C_{14}H_{20}O_4$, one (XIII) by esterification and the other (XIV) through hydrolysis of dimethyl ester.

Cycloketone VIII gives an alcohol, $C_{13}H_{22}O$ (XV), when reduced with lithium aluminum hydride. It is of interest that the reduction with lithium aluminum hydride proceeds stereospecifically and the epimer of XV does not occur[14].

Alcohol XV is dehydrogenated by selenium to 1-methylnaphthalene with loss of two carbon atoms. If the two carbon atoms eliminated on dehydrogenation are regarded as that of one methyl of the geminal dimethyl group and that of the angular methyl group, the skeleton of alcohol XV is considered as formula XV. The position of the hydroxyl group is determined as follows. By means of methyl magnesium iodide, a methyl group is introduced on the carbon atom of the carbonyl group in VIII, which leads to a corresponding alcohol, $C_{14}H_{24}O$ (XVI). Selenium dehydrogenation of alcohol XVI gives 1,6-dimethylnaphthalene. The methyl group introduced is on 6-position unless a migration of the methyl group occurs on dehydrogenation, and thus the groups in question are considered to be on the position indicated.

The enlarging of the five-membered ring in alcohol XV to the six-membered ring by aromatization, when considered together with the acid-catalyzed cleavage of a ring in the keto acid II, seems to indicate the presence of the

13) This ketone was first reported by T. Ozeki, S. Seto and T. Nozoe at the 10th Annual Meeting of the Chemical Society of Japan, Tokyo, 1957, and called "pyroketone" by them. On the preparation of this ketone by another route, see previous paper, Ref. 1.

14) The epimer of alcohol XV was obtained from lead tetraacetate oxidation product of thujopsene, see Ref. 1.

cyclopropane ring fused to the five-membered ring in XV. In addition, the infrared and ultraviolet spectral data of keto acid II, its methyl ester and cycloketone VIII are corroborative of the conjugation of the ketonic group with the cyclopropane ring[15].

Thus Ia or Ib is proposed for the structure of thujopsence. The fact that the dehydrogenation of thujopsene and its alcoholic derivative, $C_{15}H_{24}O$ (XVII), afford 1,7-dimethyl-4-isopropylnaphthalene is unfavorable for structure Ib which is less amenable to the rearrangement in regard to the naphthalene derivatives.

## Experimental

**Ester of Ketocarboxylic Acid II.**—Methylation with diazomethane gave a methyl ester which was purified by distillation under reduced pressure, b. p. 151~158°C/7 mmHg, m.p. 42~43°C. Infrared max. (Nujol) 1700 and 1735 $cm^{-1}$; ultraviolet max. 222 m$\mu$ ($\varepsilon$ 3160) and 284 m$\mu$ ($\varepsilon$ 40). $[\alpha]_D^{26}$ −94.0° (*c* 1.54).

Found: C, 71.96; H, 9.84. Calcd. for $C_{16}H_{26}O_3$: C, 72.14; H, 9.84%.

**Esters of Dicarboxylic Acid III.**—Dimethyl ester VI was prepared through methylation with diazomethane in ether. The solution was evaporated to dryness, and the residue was purified by recrystallization from methanol, m. p. 72~73°C. Infrared max. (carbon tetrachloride) 1737 $cm^{-1}$.

Monomethyl ester IV was prepared from dicarboxylic acid III by esterification with methanol. The details were presented in the previous paper. Melting point 59~60°C. Infrared max. (Nujol) 1700 and 1736 $cm^{-1}$. This monomethyl ester was also obtained by treating the methyl ester of the ketocarboxylic acid II (2.50 g.) with excess of sodium hypobromite solution (aqueous dioxane 1 : 1) for 2.5 hr. at room temperature. The reaction mixture was diluted with water, acidified and extracted with ether. The ethereal extract was washed twice with water, extracted with aqueous sodium bicarbonate (7%) and then with aqueous sodium hydroxide (5%). When the sodium bicarbonate extract acidified, dicarboxylic acid III was mainly obtained, m. p. 209~210°C, mixed melting point with dicarboxylic acid III undepressed. From the sodium hydroxide extract the monomethyl ester (1.30 g.) was obtained, m. p. 58~59°C and mixed melting point with that obtained by esterification of III undepressed.

**Monomethyl Ester V.**—The dimethyl ester prepared by methylation with diazomethane was refluxed in methanolic potassium hydroxide (5%) for 6 hr. The reaction mixture was diluted with water, washed with ether, acidified, and extracted with ether. The last ethereal extract was washed with water, and extracted with aqueous sodium bicarbonate (7%) and then with aqueous sodium hydroxide (5%). The sodium bicarbonate extract was acidified and extracted with ether. The extract was washed with water, evaporated to dryness, the residue being recrystallized from aqueous methanol, m. p. 208~209°C. Mixed melting point with dicarboxylic acid III (m.p. 209~210°C) was undepressed. The sodium hydroxide extract was acidified and then treated as above. The product obtained was a monomethyl ester of m. p. 114.5~115.5°C. Infrared max. (chloroform) 1693 and 1720 $cm^{-1}$.

Found: C, 67.02; H, 9.02. Calcd. for $C_{15}H_{24}O_4$: C, 67.13; H, 9.02%.

This monomethyl ester was reconverted to dimethyl ester VI by methylation with diazomethane in ether.

**Cycloketone VIII.**—The acid anhydride VII (5.0 g.) was pyrolyzed at 280~320°C for 40 min. under air-cooling reflux; distillation of the product gave 3.4 g. of a distillate, which was refluxed in methanolic potassium hydroxide (5%) for an hour. The reaction mixture was diluted with water, extracted with ether, and the ethereal extract was washed with water and then the solvent was removed to dryness. The residue was steam-distilled and ketone VIII separated as crystalline precipitates was dissolved in ether and dried over sodium sulfate. After the solvent was removed to dryness, the residue was recrystallized from petroleum ether, m.p. 117~118°C, and was further purified by sublimation under reduced pressure, m.p. 118~119.5°C, yield 1.7 g.. Infrared max. (Nujol) 1727 $cm^{-1}$. Ultraviolet max. (ethanol) 278 m$\mu$ ($\varepsilon$ 55.5). $[\alpha]_D^{26}$ +62.2° (*c* 0.602).

This ketone was also obtained by pyrolysis of calcium salt and of barium salt of III.

**Hydroxymethylation of VIII, Enol IX.**—The cycloketone VIII (600 mg.) and ethyl formate (700 mg.) were allowed to react in cold benzene solution (8 ml.) in the presence of sodium dust (200 mg.) for two days, when methanol was added to decompose the residual sodium metal. Water was added and the aqueous layer was acidified. The crude enol was collected (250 mg., m. p. 97~98°C) and decolorized with active charcoal. Recrystallization from aqueous ethanol gave white needles of m.p. 105~106°C, which gave purple color in the ferric chloride test. Infrared max. (chloroform) 1668 $cm^{-1}$, (Nujol) 1681 and 2680 $cm^{-1}$.

Found: C, 75.63; H, 9.22. Calcd. for $C_{14}H_{20}O_2$: C, 76.32; H, 9.15%.

From the benzene layer, the starting material (330 mg.) was recovered.

**Diketone X.**—Cycloketone VIII (130mg.), selenium dioxide (130 mg.) and dioxane (2.5 ml.) were heated in a sealed tube for 6 hr. at 200°C. Selenium was filtered off and washed with petroleum ether. The filtrate and washings were combined and water (30 ml.) was added to it; the yellow diketone was dissolved in ethereal layer. The aqueous layer was extracted with petroleum ether until the extract was no longer colored yellow. The combined extract was washed with water and dried over sodium sulfate. After the solvent was removed from the dried solution the residue solidified

15) E. N. Trachtenberg and G. Odian, *J. Am. Chem. Soc.*, **80**, 4018 (1958); R. J. Mohrbacher and N. H. Cromwell, ibid., **79**, 401 (1957).

immediately. Yield of crude product 130 mg., m.p. 170~171°C. Recrystallization from petroleum ether raised the melting point to 180~181°C. Infrared max. (Nujol) 1736 $cm^{-1}$.

Found: C, 75.78; H, 8.87. Calcd. for $C_{13}H_{18}O_2$: C, 75.69; H, 8.80%.

**Dicarboxylic Acid XI**[16].—To the mixture of diketone X (50 mg.), ethanol (6 ml.) and hydrogen peroxide (30%, 2 ml.) was dropwise added aqueous sodium hydroxide (10%, 2 ml.), and after being allowed to stand for half an hour, the reaction mixture was warmed at 80°C in a water bath for a few minutes and, after being cooled, was acidified and the crystalline precipitatates wese recrystallized from aqueous ethanol, m.p. 210~211°C. The dicarboxylic acid XI was dehydrated to the acid anhydride XII with acetic anhydride, and recrystallized from benzene-petroleum ether, m.p. 211~212°C.

No ketone formation was observed during the pyrolysis of the acid anhydride XII, which was also true in the cases of calcium- and barium dicarboxylate XI.

**Alcohol XV.**—An ethereal solution of lithium aluminum hydride (30 mg.) was added with swirling into an ethereal solution of cycloketone VIII (500 mg.). After being allowed to stand overnight, a small amount of water was added to decompose the residual lithium aluminum hydride. The resultant mixture was extracted with an additional amount of ether. The ethereal extract was washed with dilute sulfuric acid the then several times with saturated salt solution, and was dried over sodium sulfate. The solvent was evaporated to dryness and the residue was crystallized immediately, yield 450 mg., and recrystallized from petroleum ether, m.p. 132~133°C. Infrared max. (Nujol) 3280 $cm^{-1}$. $[\alpha]_D^{26}+19.2°$ (*c* 0.802).

Found: C, 80.30; H, 11.68. Calcd. for $C_{13}H_{22}O$: C, 80.35; H, 11.41%.

Alcohol XV (2.0 g.) was oxidized to cycloketone VIII by treatment with sodium bichromate (1.5 g.), water (2 ml.) and acetic acid (16 ml.) for 30 hr. at room temperature. The reaction mixture was diluted with water and was extracted with ether. The ethereal extract was washed several times with aqueous sodium bicarbonate (7%), with water and dried over sodium sulfate. After the solvent was removed to dryness the residue was crystallized immediately. Repeated recrystallization from petroleum ether gave m.p. 117~118°C. This substance was identified as being the original cycloketone VIII by mixed melting point test and infrared spectrum comparison.

**Dehydrogenation of Alcohol XV.**—The alcohol XV (2.0 g.) and selenium (3.0 g.) were heated under reflux at 400°C for 165 hr. The oily product was distilled and the main fraction (b.p. 230~240°C) was eluted from alumina (50×70 mm. column) with petroleum ether, yield 0.30 g., $n_D^{17}$ 1.5803. The picrate of the above hydrocarbon compound was orange needles and recrystallizations from ethanol afforded the material of m.p. 137~138°C. The pure hydrocarbon compound was regenerated from picrate by elution from alumina with petroleum ether. $n_D^{17}$ 1.6125.

Found: C, 92.86; H, 7.33. Calcd. for $C_{11}H_{10}$: C, 92.91; H, 7.09%.

Picrate of the purified material showed m.p. 138~139°C, and mixed melting point with the picrate of 1-methylnaphthalene[17] (m.p. 139~140°C) was undepressed.

Found: C, 54.89; H, 3.63; N, 11.39. Calcd. for $C_{17}H_{13}O_7N_3$: C, 54.99; H. 3.53; N, 11.32%.

**Methylcarbinol XVI.**—The ethereal solution of cycloketone (4.3 g.) was dropwise added to ethereal methyl magnesium iodide (from methyl iodide (3.6 g.), magnesium (0.6 g.) and ethyl ether (13 ml.)). The Grignard complex was decomposed by treatment with aqueous ammonium chloride. The methylcarbinol was extracted with an additional ether from the above reaction mixture, yield 4.2 g., and was purified by recrystallization from petroleum ether and sublimation under reduced pressure, m.p. 62~63°C. $[\alpha]_D^{20}+14.3°$ (*c* 1.87). Infrared max. 3245 $cm^{-1}$.

Found: C, 80.92; H, 11.76. Calcd. for $C_{14}H_{24}O$: C, 80.71; H, 11.61%.

**Dehydrogenation of Methyl Carbinol XVI.**—Methyl carbinol XVI (2.0 g.) and selenium (3.0 g.) were heated at 400°C for 104 hr. The same treatment as that of alcohol XV yielded an oily product (0.3 g.), the main fraction distilling at 240~250°C. The infrared spectrum of the hydrocarbon compound coincided with that of 1,6-dimethylnaphthalene and its picrate recrystallized from ethanol was of m.p. 111~112°C. The pure hydrocarbon compound was regenerated from picrate by means of elution from alumina with petroleum ether. $n_D^{12}$ 1.6047.

Found: C, 92.13; H, 8.02. Calcd. for $C_{12}H_{12}$: C, 92.26; H, 7.74%.

**Esters of the Dicarboxylic Acid XI.**—The dimethyl ester was prepared by methylation with diazomethane by a method similar to the case of the dicarboxylic acid III. M. p. 70~72°C.

**Monomethyl Ester XIII.**—Dicarboxylic acid anhydride XII (490 mg.) was refluxed in methanol (2 ml.) containing two drops of concentrated sulfuric acid for half an hour. The reaction mixture was diluted with water and extracted with ether. The ethereal extract was washed with water and extracted with aqueous sodium bicarbonate (7%). The aqueous extract was washed with ether, acidified and extracted again with ether. The last ethereal extract was evaporated to dryness and the solid residue was recrystallized from aqueous methanol to give a compound, m.p. 58~62°C, which decomposed at about 90°C and again solidified and melted at 208~209°C. The decomposed product was identical with the dicarboxylic acid anhydride XII (mixed melting point test and infrared spectrum comparison).

The monomethyl ester was converted to the dimethyl ester with diazomethane, and hydrolyzed

16) The same dicarboxylic acid had been obtained in the series of lead tetraacetate oxidation of thujopsene and the chemical data of acid XI and its anhydride XII had been presented in Ref. 1.

17) An authentic sample was synthesized according to the direction of O. Grummitt et al., *J. Am. Chem. Soc.*, 65, 295 (1943).

to the original dicarboxylic acid with aqueous potassium hydroxide.

**Monomethyl Ester XIV.**—Dimethyl ester (1.0 g.) prepared by methylation with diazomethane was refluxed in methanolic potassium hydroxide (10%, 25 ml.) for 5 hr. The reaction mixture was diluted with water, and the neutral oil which separated, on solidification, was filtered off. The aqueous portion was acidified and the crystalline precipitates collected, yield 300 mg., were recrystallized from petroleum ether, m.p. 145~145.5°C, which was reconverted to the starting material by the methylation.

**Dehydrogenation of Thujopsene.**—Thujopsene (5.0 g.) and selenium (10.0 g.) were heated at 330°C for 190 hr. The oily product obtained on distillation (b.p. above 120°/5 mmHg) was eluted from alumina (50×50 mm. column) by petroleum ether, yield 0.54 g., $n_D^{18}$ 1.5702; the product when chilled on dry ice gradually solidified. Repeated recrystallizations from methanol afforded colorless plates of m.p. 60~61°C. The infrared spectrum of the hydrocarbon compound agreed with that of 1,7-dimethyl-4-isopropylnaphthalene.

Found: C, 90.72; H, 9.41. Calcd. for $C_{15}H_{18}$: C, 90.85; H, 9.15%.

The picrate was recrystallized from ethanol and had m.p. 88~89°C.

Found: C, 58.96; H, 4.96; N, 9.85. Calcd. for $C_{21}H_{21}O_7N_3$: C, 59.01; H, 4.95; N, 9.83%.

**Aldehyde**[18].—Thujopsene (9.5 g.) was added to the ethanol solution of selenium dioxide (5.2 g. of selenium dioxide in 60 ml. of absolute ethanol). The mixture was gently refluxed for 20 hr. at boiling point. The reaction mixture, after the selenium (2.2 g.) was filtered off, was concentrated to about 20 ml. under reduced pressure and a large amount of water was added to the remainder, the organic portion of which was extracted by benzene. The benzene extract was washed twice with saturated salt solution, with saturated aqueous lead acetate and again with salt solution three times, and dried over sodium sulfate. After the solvent was removed the remainder was fractionated. The aldehyde was obtained from the fraction of b.p. 133~134.5°C/3.5 mmHg, yield of crude product 7.1 g.. Repetition of recrystsllization raised the melting point to 74~75°C. Infrared max. (Nujol) 1683 $cm^{-1}$.

**Alcohol XVII.**—The warm solution of aldehyde (5.54 g. of aldehyde in 26 ml. of methanol) was added to the solution of sodium borohydride (0.344 g. of the hydride in 3 ml. of methanol). After being heated for ten minutes, the mixture was left to cool at room temperature for two hours. Aqueous acetic acid was added to the reaction mixture to decompose the residual hydride. When the resulting mixture was diluted with water, the product was immediately solidified. The crystalline precipitates were collected and washed with water thoroughly. White needles of m.p. 102.5~103.5°C were obtained by recrystallization from petroleum ether. $[\alpha]_D^{20}-109°$ ($c$ 0.90). Infrared max. (Nujol) 3320 $cm^{-1}$.

Found: C, 81.84; H, 11.01. Calcd. for $C_{15}H_{24}O$: C, 81.76; H, 10.98%.

**Dehydrogenation of Alcohol XVII.**—Alcohol XVII (5.0 g.) and selenium (10.0 g.) were heated at 330°C for 30 hr. The oily product obtained (b.p. above 120°C/4.5 mmHg) was eluted from alumina (20×100 mm. column) with petroleum ether, yield 0.20 g., $n_D^{18}$ 1.5642. Though the picrate was prepared, its melting point could not be raised to that reported by Sörm[19]. The infrared spectrum of the hydrocarbon compound which was regenerated from the crude picrate coincided to a fair extent with that of 1,7-dimethyl-4-isopropylnaphthalene. The regenerated hydrocarbon compound was semi-solid, and rigid determination of its melting point was not conducted owing to the lack of a sample.

# *Mercury Photosensitized Decomposition of Carbon Dioxide by 1849 Å ($Hg^*6^1P_1$)*

By Yuji MORI

(Received January 24, 1961)

Few studies[1,2] have been made of reactions induced by the 1849 Å mercury resonance line, because of the difficulty of eliminating the effect of the other resonance line of mercury at 2537 Å.

In the case of carbon dioxide most of the above difficulties may be reduced. The possibility of direct photolysis by 2537 Å is eliminated since carbon dioxide is transparent above 1850 Å. The excitation energy of $6^3P_1$ of mercury, 112.2 kcal., is insufficient to bring about the reaction

$$CO_2+Hg^*(6^3P_1) \rightarrow CO+O+Hg(^1S_0)$$

and the reaction

$$CO_2+Hg^*(^3P_1) \rightarrow CO+HgO$$

is slow and has no important effect[3] on the photosensitized decomposition by $6^1P_1$ of mercury. The excitation energy of $6^1P_1$ of mercury, 153.9 kcal., is sufficient to bring about the decomposition of carbon dioxide.

Therefore, it is possible to investigate the photosensitized decomposition and the direct photolysis of carbon dioxide induced by the resonance line at 1849 Å without any important interference caused by the resonance line at 2537 Å.

## Experimental

**Photosensitized Decomposition.**—Carbon dioxide obtained from sodium bicarbonate was dried by passing it over calsium chloride and magnesium perchlorate. Then the gas was stored after purification by bulb to bulb distillation, using dry ice and liquid nitrogen. Before each run, gases noncondensable in ilquid nitrogen were remonved by pumping in liquid nitrogen.

The reaction was carried out in a cylindrical fused quartz cell (5 cm. in diameter 10 cm. long) illuminated by the radiation from a low pressure mercury lamp operated at a constant current 90 ma. from a 2000 V. leakage transformer. The gas saturated with mercury vapor by passing it over a mercury surface in a heated U tube, was introduced into the reaction cell. To keep the gas saturated with mercury vapor throughout a run, liquid mercury was intoduced into the reaction cell. When no liquid mercury was introduced in the cell, the reduction of the rate of the reaction was observed by the depletion of mercury due to the formation of the oxide of mercury. The temperature of the reaction cell was kept at room temperature.

The gaseous products, noncondensable in liquid nitrogen, were analysed in a conventional analysis system. The amount of noncondensable gas was measured by compressing it into a constant volume burette using a small mercury diffusion pump backed by a Töepler pump. The volume of carbon monoxide in the noncondensable products was determined by means of copper oxide heated at around 300°C.

**Direct Photolysis.**—In the investigation of the direct photolysis, the carbon dioxide used was prepared in a system completely free from mercury vapor in order to eliminate the mercury photosensitization. The pressure of carbon dioxide in the reaction cell was measured by means of a Bourdon gauge. After the photolysis, the gaseous products noncondensable in liquid nitrogen, were analysed by connecting the reaction cell to an analysis system by means of a ground joint.

Since the absorption coefficient of carbon dioxide at 1849 Å is very small[4], the investigation was carried out in a higher pressure region than in the case of photosensitization. The reaction was carried out at room temperature.

## Results

**Photosensitization.**—Carbon monoxide was the only product which was noncondensable in liquid nitrogen, and no oxygen was detected. This means that the rate of formation of oxygen is at most a few percent of that of carbon monoxide. A colored substance, assumed to be an oxide of mercury, was found on the surface of the front window of the reaction cell. This was soluble in dilute sulfuric acid and was removed by flaming in vacuum.

The average rate of production of carbon monoxide, (amount of carbon monoxide produced)/(irrandiation time), depends on the time of irradiation and the pressure of carbon

1) C. C. McDonald, A, Kahn and H. E. Gunning, *J. Chem. Phys.*, **22**, 908 (1954).

2) J. D. McGilvery and C. A. Winkler, *Can. J. Chem.*, **30**, 194 (1952).

3) In fact, the formation of an oxide of mercury and carbon monoxide was observed in the experiment using a filter which cuts off the light below 2300 Å. But the rate of this reaction was very slow and showed that its effect would be negligible.

dioxide as shown in Table I and in the plots in Fig. 1.

The gradual decrease of transparency of the front window of the reaction cell by the formation of the oxide of mercury, decreases the rate of production of carbon monoxide (i. e., the rate of decomposition of carbon dioxide) with the increase of irradiation time $t$. Therefore, the initial rate $r_0$ was obtained by extrapolation to $t=0$ assuming the formula

$$r = r_0 + at + bt^2$$

where the constants $a$ and $b$ depend on the pressure of carbon dioxide.

The initial rates for various pressures are given in Table I (last column) and the plots in Fig. 2.

**Direct Photolysis.** — The products, non-condensable in liquid nitrogen, were oxygen and carbon monoxide in a ratio around 1 : 5, which is far from the stoichiometric ratio of 1 : 2. No solid deposit was found on the front window of the reaction cell. The results are shown in Table II and in Fig. 3. It will be

* The reaction cell was flamed and pumped before introduction of carbon dioxide.

seen from the data in Table II that the rate of oxygen formation was markedly reduced when the reaction cell was flamed in pumping before a run.

## Discussion

In the case of direct photolysis, the deficiency of oxygen produced is greatly affected by the flaming in pumping. Therefore this deficiency of oxygen could be explained by assuming the wall reaction

$$O+O+\text{Wall} \rightarrow O_2\ (\text{Wall})$$

In the investigation of photodecomposition of carbon dioxide by the resonance radiation from the xenon lamp, Wijnen[5] and Tanaka[6] observed that oxygen and carbon monoxide were obtained in the ratio 1 : 9 at room temperature and 1 : 3 at 300°C. This increase of oxygen production at a higher temperature can be explained by the decrease of oxygen adsorbed (or absorbed) on the wall of the reaction cell.

Some of the deficiency of oxygen may be the result of the formation of ozone by the reaction

$$O_2+O+M \rightarrow O_3+M$$

Mahan[7] observed that ozone was formed in his experiment of the photodecomposition of carbon dioxide by the xenon lamp. Since ozone absorbs the resonance line at 2537 Å and is then decomposed, the deficiency of oxygen can not be explained entirely by the formation of ozone.

In the photosensitized decomposition, no oxygen was detected and the oxide of mercury was deposited on the window of the cell. Therefore, the possible reactions which will form the oxide of mercury may be as follows:

a) $CO_2+Hg^*(6^1P_1) \rightarrow CO+HgO$

or

b) $CO_2+Hg^*(6^1P_1) \rightarrow CO_2^*+Hg(^1S_0)$

$CO_2^* \rightarrow CO_2+h\nu$

$CO_2^* \rightarrow CO+O$

$O+Hg+M \rightarrow HgO+M$

$O+O+\text{Wall} \rightarrow O_2\ (\text{Wall})$

Callear, Patrick and Robb[8] suggested that the oxide of mercury was formed in the mercury photosensitized reaction of oxygen by the following

$$O_3+Hg^* \rightarrow O_2+HgO$$

In the present investigation, however, it is unlikely that the oxide of mercury was formed by the above reaction, since the concentration of oxygen in the reaction cell was very low.

The approximate value of the quenching cross section ($\sigma^2$) of carbon dioxide for excited mercury atoms $Hg^*(6^1P_1)$ may be obtained by assuming that the rate of production of the carbon monoxide is equal to the rate of decomposition and to the rate of the quenching reaction of excited mercury atoms by carbon dioxide. From this view point, the mechanism is assumed to be the following:

$$Hg+h\nu \rightarrow Hg^*(6^1P_1) \qquad I_{abs}$$

$$Hg^*(6^1P_1) \rightarrow Hg+h\nu \qquad k_1$$

$$Hg^*(6^1P_1)+CO_2 \rightarrow CO+HgO \quad \text{or} \quad \rightarrow Hg+CO+O \qquad k_2$$

Thus the relation between the initial rate of production of carbon monoxide and the pressure of carbon dioxide will be written as

$$1/r_0 = 1/I_{abs} + k_1/I_{abs}k_2P \qquad (1)$$

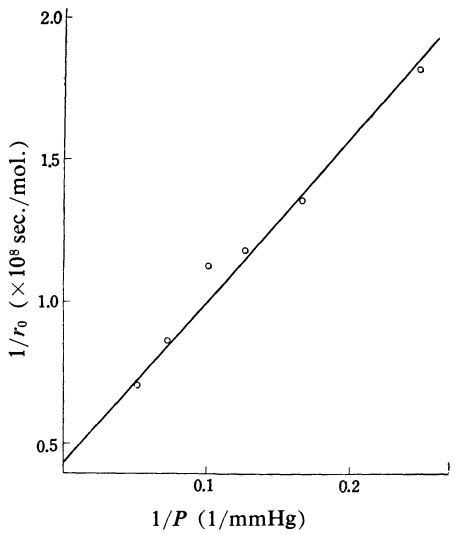

Fig. 4. The plots of $1/r_0$ against $1/P$.

where $r_0$ is the initial rate of production of carbon monoxide and $P$ is pressure of carbon dioxide. The plots of $1/r_0$ against $1/P$ is linear as shown in Fig. 4. Therefore, utilizing Eq. 1 and from the result shown in Fig. 4, it was found that $\sigma^2=320$ or 64 Å$^2$ according to whether the life time of excited mercury atom, $Hg^*(6^1P_1)$, is $0.3\times10^{-9}$ or $1.6\times10^{-9}$ sec.[9]

It will be difficult to determine the correct value of the quenching cross section even if the exact life time of the excited mercury atom is given. The value of the apparent quenching cross section calculated by Eq. 1 will be smaller than the correct one when other quenching reactions which do not form carbon monoxide are not negligible. Another

9) A. C. G. Mitchel and M. W. Zemansky, "Resonance Radiation and Excited Atoms", The McMillan Co., New York (1934).

difficulty will be in the uncertainty in the effective life time of excited mercury atom due to reabsorption of the resonance radiation of 1849 Å. The resonance radiation emitted by an excited mercury atom will be absorbed by another mercury atom in the ground state, with some probability. This leads to an increase of the effective life time of the excited mercury atom and to an increase in the apparent quenching cross section.

However, it is possible to think that the quenching cross section of carbon dioxide for $Hg^*(6^1P_1)$ is larger than 2.48 $Å^2$ for $Hg^*(6^3P_1)$[10].

This is supported by the consideration that the attractive interaction between the excited mercury atom $Hg^*(6^1P_1)$ and carbon dioxide is stronger than that between $Hg^*(^3P_1)$ and carbon dioxide. The lower excited singlet states of carbon dioxide have higher energies than $Hg^*(6^1P_1)$[11]. The lowering of the energies of the excited states of mercury atom due to the induced dipole-dipole interaction at large intermolecular distance is written

$$\Delta E_k = \sum_j W(\mu_k \cdot \mu_j)/E_k - E_j$$

where $E_k$ is the energy of the excited state $k$ of the mercury atom, $E_j$ is the energy of the excited state $j$ of carbon dioxide and $W(\mu_k \cdot \mu_j)$ is the interaction energy between transition moment of the mercury atom $\mu_k$ and that of carbon dioxide $\mu_j$. Therefore, this induced dipole-dipole interaction has a much stronger effect for $Hg^*(6^1P_1)$ than for $Hg^*(6^3P_1)$ because of their energies and transition moments. In a similar consideration the charge transfer interaction is more effective in $Hg^*(6^1P_1)$ since the energy difference between $Hg^*(6^1P_1)$ and the charge transfer state is smaller than in the case of $Hg^*(6^3P_1)$.

## Summary

The photosensitized decomposition of carbon dioxide by $Hg^*(6^1P_1)$ and the direct photolysis by 1849 Å was investigated by the static method.

The product in photosensitization was carbon monoxide and no oxygen was detected. The deficiency of oxygen in the product may be due to the formation of an oxide of mercury which was deposited on the front window of the reaction cell.

In photolysis of carbon dioxide, carbon monoxide and oxygen were produced in the ratio around 5 : 1. The deficiency of oxygen may be due to the wall effect and partly due to the formation of ozone.

The apparent quenching cross section was obtained by assuming a simple mechanism. The large value of the apparent quanching cross section of $Hg^*(6^1P_1)$ is discussed from the point of view of intermolecular interaction between the excited mercury atom and carbon dioxide in the ground state.

The author is greatly indebted to Professor Ikuzo Tanaka for his continuous encouragement and discussions.

# *Kinetic Studies on Solvolysis. VI. Kinetic Evidence of the Distinct Rôle of the Hydrogen Atom of Hydroxylic Solvent Molecules as an Attacking Center at the First Ionization Stage*

By Kunio OKAMOTO and Haruo SHINGU

(Received October 22, 1960)

Acceleration by hydroxylic groups has been well known for solvolytic reactions of several secondary and tertiary halides[1], and it was previously pointed out[1a,2] that this kind of acceleration would be a specific driving force by hydrogen-bonding to the leaving halide ion and that it was superimposed on the acceleration by general solvent effect which was assumed to be proportional to the reciprocals of dielectric constants of the solvents[2]. However, previous investigations[1,2] have not given any evidence of the distinct rôle of the hydrogen atom as a reactive center in the

hydroxyl group. In the present investigation linear catalysis by ortho- and para-substituted phenols, mono- and di-hydric alcohols and several polar molecules in acetolysis of *tert*-butyl bromide has been examined in order to see if the intramolecularly fixed, or chelated, hydrogen atom of the hydroxyl group would lose its accelerating function as a hydrogen-bonding center, and also to ascertain if there was co-operating acceleration by two adjacent hydroxylic groups in a molecule. Furthermore, the solvolysis rates of *tert*-butyl bromide in phenol-carbon tetrachloride mixtures have been quantitatively discussed from the point of view that the hydrogen atoms of the various species of "associated" phenol molecules would be operative as the key atoms at the first ionization stage of the solvolysis in these phenolic solvents.

When *tert*-butyl bromide was subjected to acetolysis in acetic acid-carbon tetrachloride mixture (1 : 3 by vol.) in the presence of sodium acetate, it was found that several phenols, glycols, and some other polar molecules showed linear catalysis, as has previously been known in the case of the unimolecular reaction in nitromethane[1b]. In Table I the catalytic constants of these hydroxylic molecules are compared. The catalytic constants of the ortho-substituted phenols in which the hydroxyl groups are intramolecularly fixed by a hydrogen bridge are smaller than those of corresponding para-derivatives, as evidenced by the data for nitro-, chloro-, hydroxy- and methyl derivatives of phenols. Among them the effect of the *o*-nitro group is particularly striking in that the catalytic constant of *o*-nitrophenol is the smallest and comparable to that of nitrobenzene, while that of *p*-nitrophenol is the largest one. These observations may lead to the conclusion that the hydrogen atom in the free, or non-chelated, hydroxyl group is the center of reaction in the first ionization stage of the $S_N1$-type solvolysis.

TABLE I. CATALYTIC CONSTANTS OF PHENOLS, ALCOHOLS AND SEVERAL POLAR AND NON-POLAR COMPOUNDS IN ACETOLYSIS OF *tert*-BUTYL BROMIDE IN ACETIC ACID-CARBON TETRACHLORIDE MIXTURE (1 : 3 BY VOL. AT 25.0°C) AT 70.0°C

For this acetolysis the catalytic order of the substituted phenols is qualitatively, but not quantitatively, the same as the acidity order, while for the solvolysis in nitromethane[1b] this correlation was found to be quantitatively applicable. This inconsistency would probably be due to the complexity resulting from the hydrogen-bonding interaction between these phenols and acetic acid.

In this connection it is noteworthy that even non-hydroxylic polar molecules, e. g., toluene, chlorobenzene, nitrobenzene, and acetone, and also benzene could give small but definitely positive catalytic constants which were comparable to that of acetic acid per se. This may be explained on the basis that these molecules would modify the self-hydrogen-bonding interaction of the acetic acid molecules to the extent that a certain increase of their free hydrogen atoms and, therefore, relative enhancement of ionizing power of acetic acid would result.

The negative catalytic constant for dioxane can be explained on a basis similar to the above consideration by supression of the catalytic action of acetic acid due to the hydrogen-bonding, or hydrogen-accepting, nature of dioxane.

A further evidence of the necessity of free hydroxyl groups is revealed by the following fact: that in intramolecularly hydrogen-bonded methyl salicylate solvent, *tert*-butyl bromide did not show any hydrogen bromide evolution for 4.0 hr. at 70°C, while in phenolic solvent this bromide was easily solvolysed even at room temperature.

For dihydroxylic compounds, like 1,2-cyclohexanediols, ethylene glycol, catechol and water, the catalytic constants are greater than

* Calculated from interpolated values of $\alpha_n$'s using Eq. 2.
** For phenol polymer species with more than eleven phenol molecules. The average number of $n$ was assumed to be thirteen.

twice those of monohydroxylic compounds, like cyclohexanol, ethanol, phenol and methanol, respectively (cf. Table I). Although some electronic effect, especially in the dihydroxylic phenols, might be responsible for these results, the marked acceleration would be mostly attributed to the sterically co-operating attack of two adjacent hydroxyl groups in these molecules.

On the basis of the foregoing discussion, it appears to be reasonable to reconsider the solvent effect of hydroxylic compounds from the point of view that the ionization is controlled by the co-operating attack of hydroxyl groups of the various species of associated hydroxylic molecules. For a discussion of this problem the data for the association degree of those compounds are required. Fortunately the calculated results for the distribution of various associated phenol species in carbon tetrachloride at 20.0°C are available[3]. Therefore, the solvolysis rates of *tert*-butyl bromide in various phenol-carbon tetrachloride mixtures were measured in the presence of sodium phenolate at 20.0°C and after suitable correction for the initial concentrations of sodium phenolate (see Experimental) the data were tested by the following equations which were derived in order to correlate the observed solvolysis rates with the concentrations of the various species of associated phenol molecules.

Provided that reacting phenols are short-lived polyhydroxylic polymers with various degrees of association, the total rate of the solvolysis may be expressed in the Eq. 1,

$$\text{rate}=(\sum_1^n k_n[S_n])[\text{RX}]=k[\text{RX}] \qquad (1)$$

where $S_n$ represents the time-average concentration of a phenol polymer species $n$, and $k_n$ represents the rate constant for the phenol polymer species $n$. Furthermore, the $S_n$ in the Eq. 1 is expressed by Eq. 2,

$$S_n=(\text{Phenol conc.})\times\alpha_n/n\times100 \qquad (2)$$

where $\alpha_n$ represents the percentage of the number of the phenol molecules forming polymer species $n$ to the total number of the phenol molecules. Thus, using the values of $\alpha_n$'s given by Kempter and Mecke[3] and of the observed rate constants for the corresponding phenol-carbon tetrachloride mixtures, we can estimate the approximate values for $k_n$'s. In Table II the values for the coefficients of $k_n$'s, i. e., the values of $S_n$'s in Eq. 1, are shown along with the corresponding eleven interpolated values of observed total rate constants.

In examining the relation between the observed total rate constants and the $S_n$'s in eleven simultaneous equations obtained from the values in Table II, it is obvious that an increasing series of values for $k_n$'s is required for good agreement between the observed total rate constants and those calculated from the right side of Eq. 1, and one of such series for the $k_n$'s is shown in the following: $k_1, k_2=0.05\times10^{-4}$, $k_3, k_4=0.1\times10^{-4}$, $k_5, k_6=0.3\times10^{-4}$, $k_7, k_8=1\times10^{-4}$, $k_9, k_{10}=6\times10^{-4}$, $k_{>10}=18\times10^{-4}$ ($sec^{-1}$). Using these $k_n$'s the calculated values for the total rate constants are compared with the observed ones in Fig. 1.

Thus, on the basis of Mecke's polymer distribution values[3] for phenol polymer species in carbon tetrachloride, we may conclude that

3) H. Kempter and R. Mecke, *Z. physik. Chem. Abt. B*, **46**, 229 (1946).

⊙ Observed × Calcd. from Eq. 1

the phenol polymer species with higher association degree should show more effective acceleration presumably because of their cooperative action as a kind of polyhydroxylic molecule. This would be a more detailed expression of the "polymolecular"[4] acceleration in solvolysis.

## Experimental[5]

**Materials.**—*tert*-Butyl bromide[6], *cis*-[7] and *trans*-[8] cyclohexanediol were prepared by published procedures. Sodium phenolate was previously prepared[9]. Sodium acetate[9], dioxane[9], phenol[9] and acetic acid[10] were purified by a previously reported method. All the reagents employed were of reagent grade quality, and purified by fractional distillation or by recrystallization. *o*-Cresol, m. p. 30.0~31.0 °C; *p*-cresol, m. p. 33.0~34.0°C; *p*-nitrophenol, m. p. 113.0~114.0°C; *o*-nitrophenol, m. p. 44.0~45.0°C; *p*-chlorophenol, m. p. 41.0~42.0°C; catechol, m. p. 104.0~105.0°C; hydroquinone, m.p. 172.0°C; *cis*-1,2-cyclohexanediol, m. p. 97.5~98.0 °C; *trans*-1,2-cyclohexanediol, m. p. 103.5~104.0 °C; *tert*-butyl bromide, b. p. 73.0°C; methanol, b. p. 64.0~65.0°C; ethanol, b. p. 78.0°C; phenol, b. p. 180.0~181.0°C; cyclohexanol, b. p. 161.0°C; ethylene glycol, b. p. 197.0~198.0°C; *o*-chlorophenol, b. p. 175.0~176.0°C; benzene, b. p. 80.0°C; toluene, b. p. 110.0°C; acetone, b. p. 56.0°C; dioxane, b. p. 101.0°C; carbon tetrachloride, b. p. 76.0°C; chlorobenzene, b. p. 132.0°C; nitrobenzene, b. p. 210.0~211.0°C; acetic acid, b. p. 117.0°C.

The solvent for the kinetic determinations of the acetolysis rates consisted of one volume of acetic acid and three volumes of carbon tetrachloride at 25.0°C. The solvents for the phenolysis were prepared at 25.0°C.

**Rate Measurements.**—A) *Acetolyses in Carbon Tetrachloride-Acetic Acid (3 : 1 by vol.).*—A sealed-ampoule technique was used. The reaction mixtures were prepared by mixing the weighed amounts of *tert*-butyl bromide and aliquots of solutions of known concentrations of sodium acetate and of hydroxylic compounds in carbon tetrachloride-acetic acid mixutre at 25.0°C. Each ampoule contained 1.000 cc. of aliquot of the reaction mixture. The thermostat was controlled to ±0.01° at 70.0°C. After reaction for appropriate lengths of time, the ampoules were cooled. Each sample was run into a flask and after being rinsed with about 5 cc. of acetic acid the unchanged sodium acetate was titrated with 0.050 N perchloric acid solution in acetic acid with crystal violet indicator. Rate constants were calculated graphically assuming that the reaction was of the first order. Decrease of sodium acetate associated with solvolysis of *tert*-butyl bromide in each run obeyed good first-order kinetics, this being illustrated graphically in Fig. 2 for several runs.

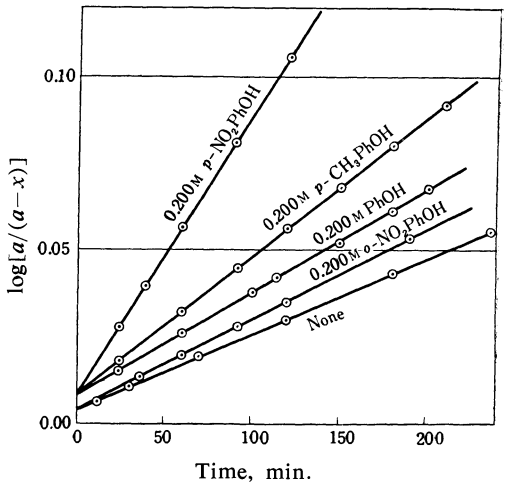

Fig. 2. Rates of acetolyses of *tert*-butyl bromide in acetic acid-carbon tetrachloride (1 : 3 by vol., at 25.0°C) in the presence of phenols at 70.0±0.01°C, 0.100 M *t*-BuBr, 0.0500 N NaOAc.

B) *Solvolyses in Phenol-Carbon Tetrachloride Mixtures.*—A weighed amount of *tert*-butyl bromide and an aliquot of the solution of a known concentration of sodium phenolate in an appropriate mixture of phenol and carbon tetrachloride were mixed in a measuring flask placed in a thermostat kept at 20.0±0.01°C. At appropriate time intervals, aliquot portions (1.000 cc.) were pipetted into 2 cc. of cold acetic acid at 15°C and the solutions were titrated according to the method described in section A. Rate constants were calculated from the first

order rate equation by a graphical method, and satisfactory first order behavior was observed for each run, this being shown graphically in Fig. 3.

## Results

The rate constants of acetolyses used for the calculation of catalytic constants of phenols, alcohols, and several polar and non-polar compounds are summarized in Table III. The catalytic constants were calculated by Eq. 3.

$$k_1(\text{obs.}) = k_1^\circ + k_2(\text{Conc. of the accelerating substance}) \quad (3)$$

where $k_1^\circ$ represents the standard rate constant and $k_2$ represents the catalytic constant.

The first order rate constants for the solvolyses of *tert*-butyl bromide in phenol-cardon tetrachloride mixtures depended on the initial concentrations of sodium phenolate and at high concentrations they increased reaching the maximum values which were previously concluded to be the rates of the first ionization step of *tert*-butyl bromide[9]. According to the total rate expression[9] for the phenolysis of this compound, these maximum values for the rate of ionization were estimated from the plots of the reciprocals of observed rate constants vs. those of the initial concentrations of sodium phenolate. In Table IV, the observed rate constants are summarized along with the estimated maximum values for the rate of ionization ($k_1$, N=∞).

## Summary

The catalytic constants of phenols, alcohols, and several polar and non-polar molecules in acetolysis of *tert*-butyl bromide were measured in acetic acid-carbon tetrachloride (1:3 by vol., at 25.0°C) in the presence of sodium acetate at 70.0°C. Ortho substituted ($NO_2$, Cl, $CH_3$, OH) phenols gave smaller constants than those of corresponding para derivatives, and among them *o*-nitrophenol gave the smallest one which was comparable to that of nitrobenzene. Dihydroxylic compounds, like 1,2-cyclohexanediols, ethylene glycol, catechol and water, gave constants greater than twice those of the corresponding monohydroxylic compounds, like cyclohexanol, ethanol, phenol and methanol, respectively. It was concluded that, in view of the lack of catalytic action of intramolecularly hydrogen-bridged hydroxylic compounds, the hydrogen atom of those hydroxylic molecules was distinctly the center of attack in the first ionization stage of the solvolysis and that two adjacent hydroxyl groups in dihydric compounds sterically co-operated in this stage. On these bases, similar accelerating action of various species of associated phenol molecules was suggested and illustrated by the analysis of the data of solvolysis rates of *tert*-butyl bromide in phenol-carbon tetrachloride mixtures at 20.0°C. It was shown that phenol polymer species with higher association degree exhibited more effective acceleration.

The authors are indebted to Mr. Ken-ichi Takeuchi who measured part of the phenolysis rates.

# *Kinetic Studies on Solvolysis. VII. On the Kinetic Resolution at the First Stage of the $S_N1$-type Solvolysis of α-Phenethyl Chloride in Optically Active Carboxylic Acid Solvents*

By Kunio Okamoto, Ken-ichi Takeuchi and Haruo Shingu

(Received November 21, 1960)

In the previous paper[1] we have demonstrated that the acetolysis of *tert*-butyl bromide proceeds with some linear rate acceleration in the presence of *p*-nitrophenol and some other *p*-substituted phenols, while the presence of *o*-substituted phenols in which the hydroxyl groups are fixed by intramolecular hydrogen-bridge does not cause any catalytic acceleration. From this it was concluded that the free hydroxyl group was distinctly the center of the reaction in those hydroxylic molecules including alcohols, phenols, carboxylic acids and water. It is, therefore, clear that they play a rôle not only as a general solvent but also as a kind of reactant molecule in the first ionization stage of the $S_N1$-type solvolysis.

Thus it may be anticipated that, when the $S_N1$-type solvolysis of a racemic halide is carried out in an optically active solvent, there would be observed a kinetic resolution in the first stage of the solvolysis with the result that the unchanged asymmetric halide may have some optical activity. This possibility of asymmetric solvolysis of $S_N1$-type was examined in the case of the solvolysis of (±)-α-phenethyl chloride in (+)-α-methyl hydrogen camphorate and in (−)-pinonic acid. This paper presents evidence in support of the existence of such kinetic resolution in those optically active solvents.

**$S_N2$-type Kinetic Resolution of (±)-α-Phenethyl Chloride in Dioxane.**—The rate studies on the $S_N1$-type solvolysis in these optically active solvents in the presence of 0.1 M of triethylamine showed that both of the reactions were of the first order in α-phenethyl chloride and of zero order in the added base, this being illustrated in Figs. 1 and 2. Although these results indicate that the reactions proceed predominantly by $S_N1$ mechanism, they do not exclude a slight, presumably less than 1%, concurrency of $S_N2$ mechanism[2].

As a control experiment, thererfore, the extent and direction of the $S_N2$-type kinetic resolution of α-phenethyl chloride was examined under the reaction conditions comparable to those of the $S_N1$-type resolution. For this purpose the $S_N2$-reaction of α-phenethyl chloride and triethylammonium salt of the optically active carboxylic acid was carried out in dioxane, which is a favorable solvent for the

Table I. Summary of optical purities of the recovered α-phenethyl chloride and of α-phenethyl alcohol in the $S_N1$-type solvolysis of (±)-α-phenethyl chloride

| Solvent | Nucleophile | Temp. °C | Time[a] hr. | Optical purity, % α-Phenethyl chloride (recovered) | Optical purity, % α-Phenethyl alcohol[b] |
|---|---|---|---|---|---|
| (+)-α-Methyl hydrogen camphorate $[\alpha]_D^{15}$ 58.0° | Triethyl-ammonium (+)-α-methyl camphorate | 98~100 | 7.5 | L[c] 0.54±0.13 | L 2.24±0.28 |
| | | 98 | | L 0.58±0.09 | L 2.95±0.74 |
| | | 100 | | (L 2.82±0.01[d]) | (D[c] 10.6 ±0.09) |
| (−)-Pinonic acid $[\alpha]_D^{18}$ −10.9° | Triethyl-ammonium | 70 | 15 | D 0.27±0.08 | D 0.57±0.07 |
| $[\alpha]_D^{20}$ −51.5° | | 70~80 | 15.5 | D 0.20±0.05 | D 1.04±0.25 |
| $[\alpha]_D^{18}$ −76.1° | | 70 | 15 | D 0.13±0.02 | L 1.56±0.39 |
| Acetonitrile | Anilinium (+)-α-methyl camphorate[e] | 85 | 4.85 | 0.00±0.02 | — |
| | Anilinium (−)-pinonate[f] | 85 | 4.35 | 0.00±0.03 | L 3.22±1.38 |
| Dioxane[g] | Triethyl-ammonium (+)-α-methyl camphorate[e] | 100 | 9[h] | L 0.08±0.01 | (L)[i] |
| | Triethyl-ammonium (−)-pinonate[f] | 70 | 16[h] | L 0.15±0.01 | (L)[i] |

a) Approximately the half life time for each reaction.
b) The alcohol obtained from α-phenethyl ester.
c) Configuration.
d) The run with L-(+)-α-phenethyl chloride; $[\alpha]_D^{15}$ 30.4°, optical purity 28.7%.
e) The acid, $[\alpha]_D^{15}$ 58.0°, chloroform.
f) The acid, $[\alpha]_D^{20}$ −75.0°, chloroform.
g) The reaction under $S_N2$ mechanism.
h) The reaction time for the stage of 5% conversion of the chloride.
i) Deduced from the principle that the inversion of configuration occurs in the $S_N2$-type reaction.

$S_N2$ mechanism. In the reaction with triethylammonium (−)-pinonate (the acid $[\alpha]_D^{20}$ −75°), about 5% of (±)-α-phenethyl chloride was consumed in 16 hr. at 70°C and the unchanged chloride of 0.15% optical purity (L configuration) was obtained (cf. Table I). A similar reaction was carried out with triethylammonium (+)-α-methyl camphorate (the acid $[\alpha]_D^{15}$ +58°) and the unchanged α-phenethyl chloride showed 0.08% of optical purity (L configuration) after 9 hr. at 100°C at the stage of about 5% conversion. These values would indicate the extent of the kinetic resolution caused by the supposedly co-existing $S_N2$ mechanism in the $S_N1$-type reactions in these optically active carboxylic acid solvents.

**Possibility of the Induced Resolution Caused by Kinetic Resolution at the Second Stage of $S_N1$-type Solvolysis.** — The slight resolution observed in the $S_N2$ condition would indicate another mechanism for interpretation of the results of the $S_N1$-type resolution. Since the intermediate in the $S_N1$-type solvolysis is converted to the product by a process quite similar to the $S_N2$ mechanism, the starting chloride which is in equilibrium with the intermediate may also become optically active, even if the intermediate was kinetically resolved by an optically active nucleophile at the second stage of solvolysis, instead of being resolved at the first ionizing stage.

In order to examine this possibility, another control experiment was carried out under conditions that should cause kinetic resolution only at the second stage, i.e., the product forming stage. For this purpose acetonitrile, which does not react with the intermediate, was used as a solvent for the solvolysis of α-phenethyl chloride. As is expected from the $S_N1$ mechanism, the solvolysis rates optically active nucleophiles (anilinium (−)-pinonate and (+)-α-methyl camphorate) were found to obey good first order kinetics at 85°C, this being shown in Figs. 3 and 4. Half way through the reactions the recovered α-phenethyl chloride did not give any optical activity for either

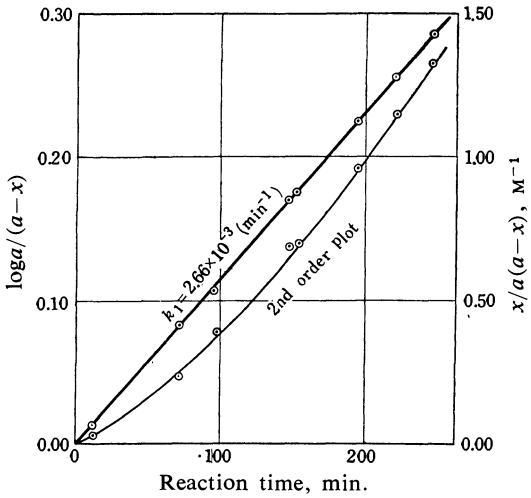

Fig. 3. Solvolysis rate of (±)-α-phenethyl chloride in acetonitrile in the presence of 0.675 N anilinium (−)-pinonate at 85.0±0.1°C. The initial concentration of the chloride, 0.675 M.

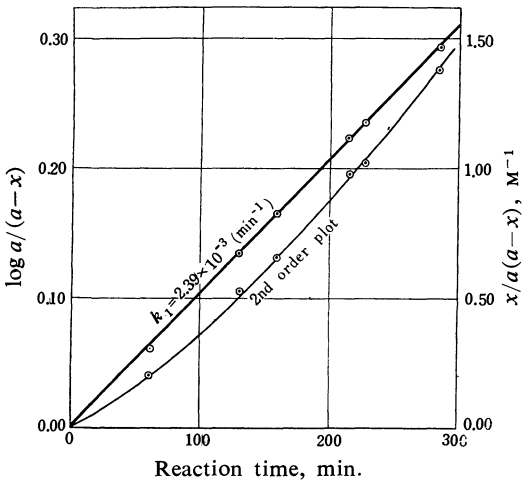

Fig. 4. Solvolysis rate of (±)-α-phenethyl chloride in acetonitrile in the presence of 0.682 N anilinium (+)-α-methyl camphorate at 85.0±0.1°C. The initial concentration of the chloride, 0.682 M.

of the nucleophiles within the experimental error, while the small amount of α-phenethyl alcohol obtained after hydrolysis of α-phenethyl pinonate showed about 5% of optical purity (D-configuration) (cf. Table I). This eliminates the possibility that the kinetic resolution at the second stage of the $S_N1$-type solvolysis can induce any preceptible resolution at the first ionization stage.

**Kinetic Resolution at the Ionization Stage of the $S_N1$-type Solvolysis.**—With these considerations in mind, we first carried out the $S_N1$-type solvolysis in (+)-α-methyl hydrogen camphorate in the presence of triethylamine at 98~100°C for 7.5 hr. until about 50% of α-phenethyl chloride was consumed, and the unchanged chloride had 0.54±0.13% of optical purity (L-configuration) (cf. Table I). In a similar experiment at 98°C for 9.5 hr., α-phenethyl chloride of 0.58±0.09% of optical purity (L-configuration) was recovered. Although the direction of the rotation of the recovered chlorides was the same as in the above mentioned reaction of the $S_N2$ mechanism in dioxane, the degree of optical purity, i. e., the extent of the kinetic resolution, is obviously greater than the one expected in the $S_N2$-type reaction under the corresponding reaction conditions, even after the correction of optical purity for the difference of the reaction percentage in both of the mechanisms. Hence it is evident that the optical rotation in the recovered chloride was predominantly caused by the kinetic resolution at the first ionization stage of the $S_N1$-type solvolysis in (+)-α-methyl hydrogen camphorate.

In a similar manner analogous experiments on the $S_N1$-type solvolysis of α-phenethyl chloride in the other optically active solvent was carried out in the presence of triethylamine in (−)-pinonic acids of various optical rotations for 15 hr. at about 70°C. In pinonic acid of optical rotations, $[\alpha]_D^{18}$ −10.9°, $[\alpha]_D^{20}$ −51.5° and $[\alpha]_D^{18}$ −76.1°, the unreacted chlorides showed 0.27±0.08, 0.20±0.05 and 0.13±0.02% of optical purity (D-configuration), respectively.

As above mentioned, in the resolution of the $S_N2$ mechanism with triethylammonium (−)-pinonate in dioxane the direction of rotation of the unreacted chloride was that of L-configuration, and this is just opposite to the one (D-configuration) observed in the reactions carried out in (−)-pinonic acid. This result clearly indicates that the kinetic resolution occurred at the first ionization stage of the $S_N1$-type solvolysis in this optically active solvent.

Finally, the kinetic resolution at the ionization stage of these $S_N1$-type solvolyses may be considered as a further evidence for the solvent molecule playing a rôle as a kind of reactant in this stage[1].

**Configuration of the Optically Active α-Phenethyl Alcohol Derived from α-Phenethyl Esters of Optically Active Carboxylic Acids.**—In the reactions in (+)-α-methyl hydrogen camphorate the isolated β-(α-phenethyl) α-methyl camphorate was hydrolysed with alcoholic sodium hydroxide or reduced with lithium aluminum hydride, and the optical purity of the recovered α-phenethyl alcohol

Table II. Relationship between configurations of recovered α-phenethyl chloride and α-phenethyl alcohol derived from α-phenethyl ester obtained in the $S_N1$-type solvolysis of (±)-α-phenethyl chloride in optically active carboxylic acids

| Configuration of recovered α-phenethyl chloride | Resolution controlling stage for α-phenethyl alcohol | Configuration for α-phenethyl alcohol derived from α-phenethyl esters | Optically active carboxylic acids as a solvolytic solvent |
|---|---|---|---|
| L | first | L | (+)-α-Methyl hydrogen camphorate |
| | second* | L | —— |
| D | first | D | (−)-Pinonic acid, $[\alpha]_D$ −10.9° and −51.5° |
| | second* | L | (−)-Pinonic acid, $[\alpha]_D$ −76.1° |

* It is assumed that the resolution at the second stage gives the alcohol with L-configuration by the $S_N2$ mechanism (see text).

amounted to 2.24±0.28 and 2.95±0.74% (L-configuration) for each run (cf. Table I), while α-phenethyl alcohols derived from α-phenethyl (−)-pinonate by alkaline hydrolyses showed optical purities of 0.57±0.07 (D-configuration), 1.04±0.25 (D-configuration) and 1.56± 0.39% (L-configuration) for the reactions in (−)-pinonic acid with optical rotations, $[\alpha]_D^{18}$ −10.9°, $[\alpha]_D^{20}$ −51.5° and $[\alpha]_D^{18}$ −76.1°, respectively (cf. Table I).

In these reactions the directions of rotation for the α-phenethyl alcohols derived from the ester of the optically active carboxylic acids doubtless controlled, generally, by two factors, namely, the kinetic resolution caused by the attack of the optically active nucleophile at the second stage of the solvolysis and the resolution in the intermediate determined by the electrophilic attack by optically active solvent molecules at the first ionization stage.

The resolution at the first ionization stage has already been discussed in the previous section. For the discussion of the results of the resolution at the second stage the knowledge about the steric behavior of α-phenethyl chloride at this stage is required, since it is uncertain whether the configuration of the chloride would invert at the second stage of the $S_N1$-type reaction in these optically active carboxylic acids. Thus, the solvolysis of originally optically active chloride, L-(+)-α-phenethyl chloride, was carried out in (+)-α-methyl hydrogen camphorate in the presence of triethylamine at 100°C. Half way through the reaction α-phenethyl alcohol of 37% inversion, 63% racemization of configuration was obtained after reductive hydrolysis of β-(α-phenethyl) α-methyl camphorate (cf. Table I)[3].

This indicates that at the second stage of this solvolysis the chloride reacted predominantly with inversion of the configuration. This is consistent with the results previously known in the reaction of this chloride in the other hydroxylic solvents[4].

Considering this inversion of configuration of α-phenethyl chloride at the second stage of the $S_N1$-type solvolysis, we may expect that the direction of the second stage resolution would be the same as that of the resolution by the $S_N2$-type mechanism. This is verified by the fact that the $S_N1$-type resolution of (±)-α-phenethyl chloride with anilinium (−)-pinonate in acetonitrile, used as a solvent in which the resolution occurs only at the second stage, gives alcohol with L-configuration which is the same type obtainable in the $S_N2$-type resolution, e. g., in dioxane (cf. Table I).

Assuming that the direction of second stage resolution in the $S_N1$-type solvolysis in the optically active carboxylic acids would be the same as in acetonitrile, we can determine the resolution controlling stage, first or second, for the α-phenethyl alcohol derived from the esters by comparing the direction of resolution for the recovered chloride with those of the alcohol obtained, this being indicated in Table II.

In Table II it is shown that in (−)-pinonic acids, $[\alpha]_D$ −10.9° and −51.5°, the configuration of the resolved α-phenethyl alcohol (cf. Table I) is predominantly determined at the first ionization stage, while in almost optically pure (−)-pinonic acid with $[\alpha]_D$ −76.1° it is determined at the second stage of the reaction. In α-methyl hydrogen camphorate it seems likely that the configuration of α-phenethyl alcohol (cf. Table I) is predominantly controlled at the first ionization stage, since the

3) The recovered α-phenethyl chloride was mostly racemic and retained only 10% of the original optical purity, as is expected from the reversibility of the ionization process at the first stage of the $S_N1$-type solvolysis.

4) E. D. Hughes, C. K. Ingold and A. D. Scott, *J. Chem. Soc.*, 1937, 1201.

resolution percentage of α-phenethyl chloride at the $S_N2$ condition, i. e., in dioxane, is considerably less than that observed at the $S_N1$-type reaction in this optically active solvent.

## Experimental[5]

**Specific Rotations in Chloroform for Optically Pure α-Phenethyl Alcohol and α-Phenethyl Chloride.**—Because of the lack of previously reported data, specific rotations in chloroform for α-phenethyl alcohol of the rotations $\alpha_D$, neat, −37.0° (at 15.0°C), +19.4° (at 24.4°C) and −40.1° (at 25.4°C), *l* 1 dm. for all, were measured, and the following results were obtained: $[\alpha]_D$ −47.5° (at 15.0°C, *c* 16.0), +24.8° (at 24.4°C, *c* 6.70) and −50.7° (at 25.4°C, *c* 6.70), respectively. From these values and the reported value[6] for neat rotation of optically pure α-phenethyl alcohol ($\alpha_D^{25}$ 43.7°, *l* 1 dm.), a specific rotation in chloroform for the optically pure alcohol was estimated to be 55.9° (at 15~25°C, *c* 6.70~16.0). In a similar manner, a specific rotation in chloroform for optically pure α-phenethyl chloride was estimated to be 105~107° (at 17~25°C, *c* 6.8~6.9) from the following data: reported value[7] for neat rotation of optically pure chloride, $\alpha_D^{25}$ 126~129°, *l* 1 dm.; observed specific rotations in chloroform for α-phenethyl chloride of neat rotations $\alpha_D$ −34.8° (at 17.0°C, *l* 1 dm.) and +17.8° (at 25.7°C, *l* 1 dm.): −28.9° (at 17.0°C, *c* 6.83) and +14.9° (at 25.7°C, *c* 6.90), respectively.

**Reaction of (±)-α-Phenethyl Chloride and Triethylammonium (−)-Pinonate in (−)-Pinonic Acid.**—(−)-Pinonic acid was prepared by potassium permanganate oxidation of α-pinene according to the previously reported method[8]. A mixture of pinonic acid (35.0 g., b. p. 152~156°C/4 mmHg, $[\alpha]_D^{18}$ −10.9°, *c* 10.9, chloroform), triethylamine (7.0 g., b. p. 88~89°C) and (±)-α-phenethyl chloride (10.45 g., b. p. 92.0°C/36 mmHg) was kept at 70°C for 15 hr. After addition of ether (50 cc.) the ethereal solution containing crystals of triethylammonium hydrochloride was washed successively with two 50 cc. portions of 10% aqueous sodium hydroxide and two 50 cc. portions of water, dried, and concentrated. The residue was fractionally distilled in vacuo, giving α-phenethyl chloride (6.9 g., b. p. 77.0~78.0°C/18 mmHg., $n_D^{20}$ 1.5265, $\alpha_D^{18}$ −0.180±0.005°, $[\alpha]_D^{18}$ −0.287°, *l* 2 dm., *c* 31.4, chloroform, Found: C, 68.18; H, 6.27. Calcd. for $C_8H_9Cl$: C, 68.33; H, 6.45%). The residual mass was refluxed with a mixture of 20% aqueous sodium hydroxide (15 cc.) and ethanol (10 cc.) for 4 hr. and distilled with steam. The distillate (about 100 cc.) was extracted with two 50 cc. portions of ether. Concentration of the combined ether solutions afforded an oily material which was distilled in vacuo to give α-phenethyl alcohol (2.2 g., b. p. 80.0~81.0°C/7 mmHg, $n_D^{20}$ 1.5245, $\alpha_D^{17}$ −0.040 ±0.005°, $[\alpha]_D^{17}$ −0.320°, *l* 2 dm., *c* 6.23, chloroform, Found: C, 78.62; H, 8.26. Calcd. for $C_8H_{10}O$: C, 78.65; H, 8.25%).

The second run carried out under similar conditions, 70~80°C, 15.5 hr., with pinonic acid (20.0 g., b. p. 152.0°C/7 mmHg, m. p. 70~80°C, $[\alpha]_D^{20}$ −51.5°, chloroform), triethylamine (5.0 g.) and (±)-α-phenethyl chloride (7.0 g.) afforded α-phenethyl chloride (3.3 g., b. p. 58.0°C/7.5 mmHg, $\alpha_D^{15}$ −0.100±0.025°, $[\alpha]_D^{15}$ −0.21°, *l* 2 dm., *c* 23.8, chloroform) and α-phenethyl alcohol (2.2 g., b. p. 80~82.0°C/9 mmHg, $\alpha_D^{18}$ −0.105±0.025°, $[\alpha]_D^{18}$ −0.58°, *l* 2 dm., *c* 9.1, chloroform, Found: C, 78.58; H, 8.06%).

Starting from pinonic acid (25.0 g., m. p. 65.0~75.0°C, $[\alpha]_D^{18}$ −76.1°, *c* 9.63, chloroform), triethylamine (5.0 g.) and α-phenethyl chloride (6.75 g.), the third run afforded at 70°C for 15 hr. α-phenethyl chloride (4.0 g., b. p. 58.0~59.0°C/9 mmHg, $n_D^{20}$ 1.5230, $\alpha_D^{18}$ −0.040±0.005°, $[\alpha]_D^{18}$ −0.141°, *l* 2 dm., *c* 14.2, chloroform, Found: C, 68.38; H, 6.59%) and α-phenethyl alcohol (0.50 g., b. p. 68.0~69.0°C/3 mmHg, $n_D^{20}$ 1.5210, $\alpha_D^{18}$ 0.020±0.005°, $[\alpha]_D^{18}$ 0.872°, *l* 2 dm., *c* 1.15, Found: C, 78.35; H, 8.44%).

**Reaction of (±)-α-Phenethyl Chloride and Triethylammonium (+)-α-Methyl Camphorate in (+)-α-Methyl Hydrogen Camphorate.**—α-Methyl hydrogen camphorate was obtained by esterification of camphoric acid according to the previously reported method[9]. To a mixture of α-methyl hydrogen camphorate (52.5 g., m. p. 56.0~57.0°C, $[\alpha]_D^{15}$ 58.0°, chloroform) and triethylamine (10.0 g.), (±)-α-phenethyl chloride (14.0 g.) was added. After being kept at 98~100°C for 7.5 hr., the reaction mixture was taken into ether (100 cc.), and washed successively with water (100 cc.), three 50 cc. portions of 10% aqueous sodium hydroxide, and two 50 cc. portions of water. The ethereal solution was dried with anhydrous sodium sulfate and concentrated. The oily material was fractionally distilled in vacuo, giving a fore-run (1.0 g.), containing styrene and a small amount of α-phenethyl chloride, α-phenethyl chloride (5.6 g., b. p. 53.0 ~ 55.0°C / 8.5 mmHg, $n_D^{20}$ 1.5274, $\alpha_D^{13}$ 0.020±0.005°, $[\alpha]_D^{13}$ 0.57°, *l* 2 dm., *c* 1.71, chloroform, Found: C, 68.14; H, 6.58%) and β-(α-phenethyl) α-methyl camphorate (10.4 g., b. p. 165~168°C/2 mmHg, $n_D^{20}$ 1.5052).

Found: C, 71.41; H, 8.11. Calcd. for $C_{19}H_{26}O_4$: C, 71.67; H, 8.23%.

β-(α-Phenethyl) α-methyl camphorate was reduced with lithium aluminum hydride. A mixture of lithium aluminum hydride (5.0 g.) and dry ether (250 cc.) was stirred for 1 hr. under a nitrogen atmosphere and treated with β-(α-phenethyl) α-methyl camphorate (10.0 g.) dissolved in ether (50 cc.) over a period of 5 min. After being stirred for 5 hr. and being kept overnight at 15°C, the mixture was treated with water (10 cc.) which was added over a period of half an hour. The precipitated material was filtered and washed with ether (100 cc.), and the combined ether solution was concentrated. The residue was distilled under reduced pressure to give α-phenethyl alcohol (2.6 g., b. p. 70.0~71.0°C/7 mmHg, $n_D^{20}$ 1.5260, $\alpha_D^{17}$

5) Microanalyses by Microanalytical Center, Kyoto University. Melting points are not corrected. For the measurement of optical rotations "Zeiss Winckel, Kreispolarimeter, 0.01°" was used.

0.400+0.005°, $[\alpha]_D^{17}$ 1.25°, *l* 2 dm., *c* 16.0, chloroform. Found: C, 78.75; H, 8.36%).

The second run carried out at 98°C for 9.5 hr. with α-methyl hydrogen camphorate (23.0 g.), triethylamine (5.0 g.), and (±)-α-phenethyl chloride (7.0 g.), afforded α-phenethyl chloride (1.9 g., b. p. 49.0~51.0°C/6 mmHg, $\alpha_D^{15}$ 0.13±0.02°, $[\alpha]_D^{15}$ 0.62°, *l* 2 dm., *c* 10.5, chloroform) and after alkaline hydrolysis of the ester α-phenethyl alcohol (0.15 g., b. p. 80.0°C/9 mmHg, $\alpha_D^{15}$ 0.04±0.01°, $[\alpha]_D^{15}$ 1.65°, *l* 2 dm., *c* 1.21, chloroform) was obtained.

**Reaction of (+)-α-Phenethyl Chloride and Triethylammonium α-Methyl Camphorate in (+)-α-Methyl Hydrogen Camphorate.**—(±)-α-Phenethyl alcohol was resolved according to the published method[6] and the first crop of brucine salt of α-phenethyl hydrogen phthalate gave (−)-α-phenethyl alcohol, $[\alpha]_D^{15}$ −47.5°, *c* 16.0, chloroform, From the first mother liquors (+)-α-phenethyl alcohol ($[\alpha]_D^{13}$ 37.0°, *c* 15.4, chloroform) was obtained. From this (+)-alcohol (+)-α-phenethyl chloride ($[\alpha]_D^{15}$ 30.4°, *c* 7.15, chloroform) was prepared by chlorination with thionyl chloride according to the previously reported method[3]. The reaction was carried out with (+)-α-methyl hydrogen camphorate (50.0 g.), triethylamine (4.5 g.) and (+)-α-phenenethyl chloride (5.6 g., $[\alpha]_D^{15}$ 30.4°) at 100°C for 8 hr. After treatment similar to the previous experiment with (±)-α-phenethyl chloride, α-phenethyl chloride (2.4 g., b. p. 51.0~52.0°C/6 mmHg, $n_D^{20}$ 1.5268, $\alpha_D^{15}$ 0.450±0.01°, $[\alpha]_D^{15}$ 2.98°, *l* 2 dm., *c* 7.55, chloroform, Found: C, 68.40; H, 6.37%) was recovered.

After reduction with lithium aluminum hydride, β-(α-phenethyl) α-methyl camphorate (4.6 g., b. p. 173°C/2 mmHg, $n_D^{20}$ 1.5034, Found: C, 71.88; H, 8.31%.) afforded α-phenethyl alcohol (0.9 g., b. p. 63.0~67.0°C/3 mmHg, $n_D^{20}$ 1.5169, $\alpha_D^{15}$ −0.580±0.005°, $[\alpha]_D^{15}$ −5.93°, *l* 2 dm., *c* 4.90, chloroform, Found: C, 78.48; H, 8.43%).

**Reaction of (±)-α-Phenethyl Chloride and Triethylammonium (+)-α-Methyl Camphorate in Dioxane.** — Triethylammonium (+)-α-methyl camphorate was prepared by mixing the equivalent amounts of triethylamine and (+)-α-methyl hydrogen camphorate in dioxane. A mixture of triethylamine (5.0 g.), (+)-α-methyl hydrogen camphorate (10.6 g.), dry dioxane (24.5 g.) and (±)-α-phenethyl chloride (7.0 g.) was kept at 100°C for 9 hr. The reaction percentage of the chloride was estimated to be about 5% from the aliquot titration of unchanged triethylammonium α-methyl camphorate with acetic acid solution of perchloric acid. After addition of ether (100 cc.) the mixture was washed with four 100 cc. portions of water, dried with anhydrous sodium sulfate, and concentrated. The residue was fractionally distilled under reduced pressure to give α-phenethyl chloride (5.8 g., b. p. 89.0°C/38 mmHg, $n_D^{20}$ 1.5264, $\alpha_D^{20}$ 0.055±0.005°, $[\alpha]_D^{20}$ 0.086°, *l* 2 dm., *c* 31.8, chloroform, Found: C, 68.58; H, 6.52%).

**Reaction of (±)-α-Phenethyl Chloride and Triethylammonium (−)-Pinonate in Dioxane.** — A mixture of triethylamine (5.0 g.), (−)-pinonic acid (9.2 g., $[\alpha]_D^{20}$ −75.0°, chloroform), dry dioxane (25 cc.) and (±)-α-phenethyl chloride (7.0 g.) was kept at 70°C for 16 hr. The reaction percentage of the chloride was estimated to be about 5% from the titration of unchanged triethylammonium pinonate. After addition of ether (100 cc.) the mixture was treated in a manner similar to the reaction with triethyl ammonium α-methyl camphorate. The recovered α-phenethyl chloride gave the following constants; b. p. 89.0°C/37 mmHg, $n_D^{20}$ 1.5272, $\alpha_D^{20}$ 0.09±0.005°, $[\alpha]_D^{20}$ 0.16°, *l* 2 dm., *c* 28.0, chloroform, Found: C, 68.58; H, 6.52%.

**Reaction of (±)-α-Phenethyl Chloride and Anilinium (+)-α-Methyl Camphorate in Acetonitrile.** — Anilinium α-methyl camphorate solution (0.750 N) was prepared from equivalent amounts of aniline and (+)-α-methyl hydrogen camphorate ($[\alpha]_D^{15}$ 58.0°) in acetonitrile. (±)-α-Phenethyl chloride (4.92 g.) was dissolved in the anilinium salt solution and diluted to a volume of 50 cc. with the solution. The mixture was kept in a sealed tube for 291 min. (half life time of the reaction) at 85.0°C. Ether (100 cc.) was added to the cooled reaction mixture, and the mixture washed with water (50 cc.). After evaporation of ether the residual oily mass gave α-phenethyl chloride (2.3 g., b. p. 55.0~56.0°C/6 mmHg, $n_D^{20}$ 1.5251, $\alpha_D^{21}$ 0.00± 0.02°, *l* 1 dm., neat). In the distillation residue no ester was found.

**Reaction (±)-α-Phenethyl Chloride and Anilinium (−)-Pinonate in Acetonitrile.**—In a manner similar to the reaction with anilinium (+)-α-methyl camphorate (±)-α-phenethyl chloride (5.81 g.) was kept with 0.750 N anilinium (−)-pinonate (the acid $[\alpha]_D^{20}$ −75.0) solution for 261 min. (half life time of the reaction) at 85.0°C. The recovered chloride (2.22 g.) gave the following constants; b. p. 53.0°C/ 2 mmHg, $n_D^{20}$ 1.5239, $\alpha_D^{21}$ 0.00±0.03°, *l* 1 dm., neat, Found: C, 68.63; H, 6.60%. The higher boiling fraction (5.24 g., 137~140°C/0.8 mmHg) was hydrolysed with 20% aqueous sodium hydroxide (15 cc.) and ethanol (10 cc.) for 4 hr., and distilled with steam. The recovered α-phenethyl alcohol (0.05 g.) gave slight optical activity ($\alpha_D^{20}$ 0.07±0.03°, $[\alpha]_D^{20}$ 1.8°, *l* 1 dm. *c* about 4, chloroform).

**Kinetic Measurement.**—The reactions in (+)-α-methyl hydrogen camphorate ($[\alpha]_D^{15}$ 58°) and (−)-pinonic acid ($[\alpha]_D^{20}$ −51.5°) were carried out in a 15 cc. measuring flask placed in a thermostat. To a weighed amount of α-phenethyl chloride in the flask the optically active carboxylic acid solution of triethylamine was added to the volume of 15 cc. at the reaction temperature. After various periods of time, aliquot portions (1.000 cc.) were pipetted into 5 cc. of cold acetic acid and the solutions were titrated with 0.0672 N perchloric acid in acetic acid with crystal violet indicator. The rates in acetonitlile were measured by a sealed-ampoule technique. Each sample (1.000 cc.) was titrated with 0.245 N perchloric acid in acetic acid. The rate constants were calculated from the first order rate equation by a graphical method.

## Summary

1) In $S_N2$ displacement reactions of (±)-α-phenethyl chloride with triethylammonium (+)-α-methyl camphorate and with triethylammonium (−)-pinonate in dioxane, α-phenethyl chloride of 0.08% of optical purity (L-

configuration) and of 0.15% of optical purity (L-configuration) were recovered at the stage of about 5% conversion, respectively.

2) In $S_N1$-type solvolysis of (±)-α-phenethyl chloride with anilinium (+)-α-methyl camphorate and (−)-pinonate in acetonitrile, the recovered α-phenethyl chlorides showed no perceptible optical activity on the half way for each of the reactions. From this, the possibility of the induced resolution caused at the first stage by kinetic resolution at the second stage of the $S_N1$-type solvolysis was eliminated.

3) In $S_N1$-type solvolysis of (±)-α-phenethyl chloride in (+)-α-methyl hydrogen camphorate and in (−)-pinonate, about half of the chloride was converted to the ester at the similar reaction conditions (temperature and time) to the $S_N2$ displacement reactions carried out in dioxane. The recovered chloride in the reaction in hydrogen camphorate showed optical purity of 0.54~0.58% (L-configuration). In pinonic acids with various optical activities the recovered chlorides possessed optical purity of 0.13~0.27% (D-configuration).

4) In comparing the configurations and optical purities in $S_N1$- and $S_N2$-conditions, it is concluded that optically active solvent molecules, like (+)-α-methyl hydrogen camphorate and (−)-pinonic acid, can cause kinetic resolution in the first ionization stage of the $S_N1$-type solvolysis and therefore they obviously play a rôle as a kind of reactant molecule which controls the steric course of the solvation reaction in the first stage of this solvolysis.

5) In the $S_N1$-type solvolysis of optically active α-phenethyl chloride in presence of triethylamine in (+)-α-methyl hydrogen camphorate, optically active β-(α-phenethyl)-α-methyl camphorate gave optically active α-phenethyl alcohol of 37% inversion, 63% racemization of configuration. From this it was concluded that $S_N2$-like spatial orientation predominates at the second stage of this solvolysis.

6) For each of the resolution results of α-phenethyl chloride under $S_N1$- and $S_N2$-conditions, the relationship between the configuration of the resolved alcohol and the resolution-controlling stage was predicted on the basis of the observed inversion at the second stage of the solvolysis. The configurations observed for the α-phenethyl alcohols were found to be consistent with the predictions.

The authors wish to thank Mr. Ryôichi Kanô for his assistance in preparation of (−)-pinonic acid.

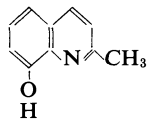
# *Study on Metal Complexes of Analytical Importance. I. Vanadium Complexes of 8-Quinolinol and 2-Methyl-8-quinolinol*[1]

By Hiroji NAKAMURA, Yoichi SHIMURA and Ryutaro TSUCHIDA



(Received November 24, 1960)

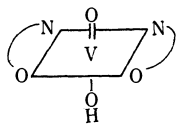
8-Quinolinol (A) is a popular analytical reagent, being used in the analysis of vanadium.

A

8-Quinolinol
(symbol: oxinH)

B

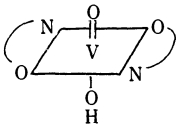
2-Methyl-8-quinolinol
(symbol: $CH_3$-oxinH)



The reaction of vanadate with 8-quinolinol in aqueous solution at pH 4~5 produces a bluish-black complex. This complex dissolves in lower aliphatic alcohols to give red solutions, while in chloroform it gives a violet one[2]. From boiling alcohol solutions saturated with this complex is deposited a brownish black complex on cooling, which dissolves in chloroform to show red color instead of violet.

Bielig and Bayer[2] reported that these two complexes were geometrical isomers which had a molecular formula $[VO(OH)(oxin)_2]$, and they named the bluish-black complex "violet form" and the brownish black complex "red form" by the colors of the chloroform solutions of these complexes.

1) A part of this study was presented at the Symposium on Coordination Compounds of the Chemical Society of Japan, Sendai, September, 1960.



2) H.-J. Bielig and E. Bayer, *Ann.*, **584**, 96 (1953).

Based on rather weak experimental evidences, they reported that the violet form had the cis structure and that the red form had the trans structure which are shown in Fig. 1.

cis structure

Fig. 1 (a)

trans structure

Fig. 1 (b)

Contrary to their conclusion, Blair and Pantony[3] assumed that the red form had the molecular formula [VO(O-R)(oxin)$_2$] (R is an alkyl group), namely that the complex was an alkyl ester of [VO(OH)(oxin)$_2$]. As for the violet form, Blair and Pantony explained that it had the trans structure, but no experimental evidence was given.

In order to decide the configurations of the complexes, we have prepared new complexes of 2-methyl-8-quinolinol, and from experimental data of these complexes have discussed the problem.

## Results and Discussion

**Complexes of 2-Methyl-8-quinolinol with Vanadium(V).**—As will be seen in the experimental part, 2-methyl-8-quinolinol produces with vanadate a yellow complex, not a black one. In the case of 8-quinolinol a bluish-black complex (violet form) is separated under the same conditions. In this respect, the yellow complex resembles neither the violet nor the red form.

Recrystallization of the yellow complex from 98% methanol also produces a yellow complex. The complex thus obtained is yellow in crystalline state, but shows red color in absolute methanol giving an absorption band at 60.6 $\times 10^{13}$ sec$^{-1}$ (Fig. 2a). The solution in 98% methanol gives a weaker band at the same frequency (Fig. 2b). The higher the water content of the solvent is, the weaker is the absorption band (Fig. 2b-f). Thus, the color in 90% methanol solution is almost yellow.

Elementary analysis of the yellow complex shows that it has the formula of VO(OH)(CH$_3$-oxin)$_2$·2H$_2$O, and over phosphorus pentoxide in vacuo the complex gradually changes black with decrease of its weight. In three weeks the color changes completely to black, and the decrease of weight corresponds to two molecules of water. The black complex thus obtained has the empirical formula VO(OH)(CH$_3$-

3) A. J. Blair and D. A. Pantony, *J. Inorg. Nucl. Chem.*, 5, 316 (1958).

oxin)$_2$. Accordingly it is clear that the difference between the yellow and the black colors is due to the water molecules. Judging from the marked change of the color, the water molecules are not merely of crystallization character but are coordinated. The black complex cannot have the cis structure owing to the steric hindrance between the methyl groups of the ligands. It is considered to have the trans structure (Fig. 1).

Since the maximum coordination number of the quinquevalent vanadium is six, the yellow complex [VO(OH)(CH$_3$-oxin)$_2$(OH$_2$)$_2$] must have an octahedral configuration. Consequently the two 2-methyl-8-quinolinol ions are coordinated as unidentate ligands. The difference between 8-quinolinol and 2-methyl-8-quinolinol is only that the latter has a methyl group at the carbon atom adjacent to the nitrogen atom. Therefore, it seems that the nitrogen atoms are not bound to the vanadium ion. Infrared absorption spectra of these two complexes show that this consideration is correct.

Both the yellow and the black complexes exhibit a strong band of C–O stretching[4] at the same wave number 1108 cm$^{-1}$ (Fig. 3). This shows that in each complex, oxygen atoms are bound to the vanadium ion. If the bond V–O were broken in the yellow complex, the position of the C–O stretching band of the complex would differ from that of the black. Moreover, these complexes show four bands over the region between 1640 and 1500 cm$^{-1}$ which are considered to be C=N or C=C stretching vibrations[5] in the ligands. Considerable differences are recognized between the corresponding bands of the two complexes not only in their positions, but also in intensities (Fig. 3). These differences suggest that in the yellow complex the nitrogen atoms are not bound to the central vanadium ion.

Now we have been led to the conclusion that the yellow complex [VO(OH)(CH$_3$-oxin)$_2$(OH$_2$)$_2$] has an octahedral structure and that the 8-quinolinol ions are not bidentate but unidentate ligands which are bound to the central vanadium ion by their oxygen atoms.

**Structure of the Red Form.**—As was described in the preceding section, the black complex [VO(OH)(CH$_3$-oxin)$_2$] has the trans structure. Therefore, the comparison of the absorption spectrum of [VO(OH)(CH$_3$-oxin)$_2$] with those of the red and the violet forms may give us some suggestions about the structures of these complexes.

The absorption spectra of these three complexes in chloroform are shown in Fig. 4. [VO(OH)(CH$_3$-oxin)$_2$] shows two bands at $60.6\times10^{13}$ and $80.6\times10^{13}$ sec$^{-1}$. The positions

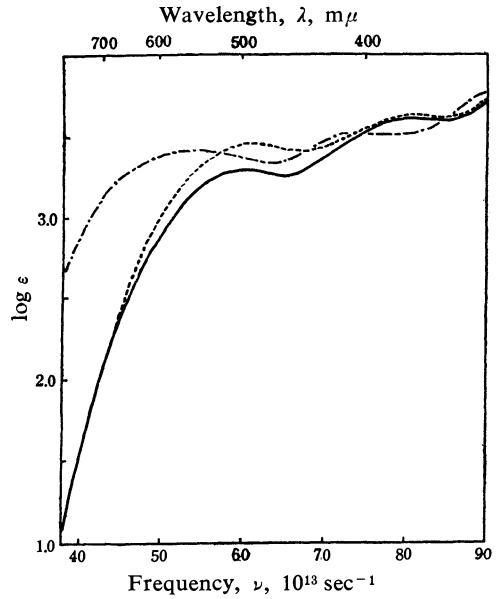

Fig. 4. Absorption spectra of 8-quinolinol-vanadium complexes and 2-methyl-8-quinolinol-vanadium complex in chloroform.
—·— violet form
---- red form
—— [VO(OH)(CH$_3$-oxin)$_2$] (trans)

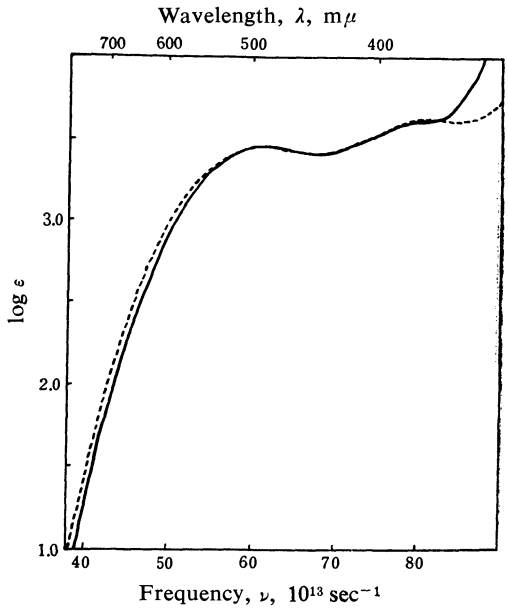

Fig. 5. Absorption spectra of [VO(OH)(oxin)$_2$] (red form) (——) and [VO(O-CH$_3$)(oxin)$_2$] (----) in benzene. The enhancement of the curve (——) at the shorter wavelength region is owing to the absorption of 8-quinolinol which is added in excess.

4) R. G. Charles, H. Freiser, R. Friedel, L. E. Hillard and W. D. Johnstone, *Spectrochim. Acta*, **8**, 1 (1956).
5) L. J. Bellamy, "The Infrared Spectra of Complex Molecules", 2nd ed. (1958), pp. 270-286.

of the bands coincide with those of the red form. Accordingly it seems that the red form has the trans and the violet form has the cis structure. In this respect, these results support Bielig's opinion. But as will be seen in the experimental part, Blair's opinion that the red form has a formula $[VO(O\text{–}R)(oxin)_2]$ is also correct. 8-Quinolinol complexes which are recrystallized from boiling methanol and isopropyl alcohol respectively have the empirical formulae corresponding to $[VO(O\text{–}CH_3)(oxin)_2]$ and $[VO(O\text{–}C_3H_7)(oxin)_2]$. To obtain a red 8-quinolinol complex without using alcohols, we examined many solvents. No solvent, however, was effective. Next, the reaction between vanadium(V) quinaldinate and 8-quinolinol in benzene was tried. Instantly the color changed to red and the absorption spectrum of the solution was quite like that of the red form which was obtained from boiling methanol solution (Fig. 5).

Now we can conclude that the violet form has the cis structure, while the red form has the trans structure, and further that the esterification of the red form does not induce any striking change of color.

**Yellow 8-Quinolinol Complex.** — Both the violet and the red forms are almost black in the crystalline state, as was described in the preceding section. But a yellow 8-quinolinol complex can also be obtained, which is prepared as a sodium salt at higher pH[2]. Bielig and Bayer gave the formula $Na[VO(O)(oxin)_2]\cdot H_2O$ to the yellow complex salt. They carried out the chemical analysis of the yellow complex after drying it over phosphorus pentoxide at 100°C in a high vacuum. The sodium salt which was dried in air has an empirical formula $NaVO(O)(oxin)_2\cdot 4H_2O$. The yellow color of this salt may be understandable on the assumption that it has the formula $Na[VO(O)(oxin)_2(OH_2)_2]\cdot 2H_2O$ corresponding to the yellow 2-methyl-8-quinolinol complex $[VO(OH)(CH_3\text{-}oxin)_2(OH_2)_2]$.

## Experimental

**Preparation of 2-Methyl-8-quinolinol Complexes of Vanadium.**—The yellow complex was prepared as follows: 3.2 g. of 2-methyl-8-quinolinol was dissolved in 60 ml. of 1 N acetic acid and was diluted to 250 ml. To the solution was added drop by drop 2.0 g. of sodium metavanadate tetrahydrate ($NaVO_3\cdot 4H_2O$) dissolved in 100 ml. of 0.2 N sodium hydroxide. A muddy yellow precipitate appeared. The pH of the mixture was adjusted to 5.0 by the use of 1 N acetic acid and it was digested for two hours at 70°C. The crude complex thus obtained was recrystallized three times from 98% methanol by evaporating the solvent at 40°C in vacuo. The yellow complex obtained as pure crystals was dried over calcium chloride. For analyzing the coordinated water of this complex, heating is not suitable, since the complex decomposes at a high temperature. Therefore, drying over phosphorus pentoxide was adopted for the analysis of the coordinated water.

Found: $H_2O$, 8.10; C, 54.96; H, 4.85; N, 6.40; V, 11.51. Calcd. for $C_{20}H_{17}O_4N_2V\cdot 2H_2O = [VO(OH)(CH_3\text{-oxin})(OH_2)_2]$: $H_2O$, 8.26; C, 55.04; H, 4.85; N, 6.42; V, 11.68%.

The complex is soluble in lower aliphatic alcohols, cyclohexanone, pyridine and diluted solution of alkali, and insoluble in ethyl ether, 2-butanone, cyclohexane, benzene, chloroform, carbon tetrachloride and water.

The black complex was prepared by expeling the water molecules of the yellow complex over phosphorus pentoxide in vacuo.

Found: C, 60.04; H, 4.18; N, 7.10; V, 12.65. Calcd. for $C_{20}H_{17}O_4N_2V = [VO(OH)(CH_3\text{-oxin})_2]$: C, 60.00; H, 4.28; N, 7.00; V, 12.73%.

The black complex is soluble in chloroform, benzene and whatever the yellow complex is soluble in, sparingly soluble in ethyl ether, insoluble in cyclohexane, carbon tetrachloride and in water, and soluble with decomposition in dioxane, acetone and 2-butanone.

**Violet Form of 8-Quinolinol-Vanadium Complex.** —This complex was prepared by the method of Bielig and Bayer[2] and also of Blair and Pantony[3].

**Red Forms of 8-Quinolinol-Vanadium Complex.** —The methyl ester was prepared as follows: 1.0 g. of violet form was refluxed for 90 min. with 400 ml. of methanol. After filtration, the solution was concentrated to about 40 ml. The brownish black crystals then separated were filtered and dried in air.

Found: C, 59.16; H, 4.20; N, 7.35; V, 13.01. Calcd. for $C_{19}H_{15}O_4N_2V = [VO(O\text{–}CH_3)(oxin)_2]$: C, 59.09; H, 3.91; N, 7.25; V, 13.19%.

The isopropyl ester was prepared in almost the same way as was the methyl ester.

Found: C, 61.61; H, 4.66; N, 6.81; V, 12.08. Calcd. for $C_{21}H_{19}O_4N_2V = [VO(O\text{–}C_3H_7)(oxin)_2]$: C, 60.80; H, 4.62; N, 6.80; V, 12.30%.

**Yellow 8-Quinolinol Complex of Vanadium.**— This complex was prepared by the method of Bielig and Bayer[2] and was analyzed after being dried in air.

Found: C, 45.52; H, 4.25; N, 5.91; V, 10.60. Calcd. for $C_{18}H_{20}O_8N_2NaV = Na[VO(O)(oxin)_2(OH_2)_2]\cdot 2H_2O$: C, 45.87; H, 4.27; N, 5.94; V, 10.81%.

**Preparation of Sodium Salt of 2-Methyl-8-quinolinol-Vanadium Complex.**—The same method as that used in the preparation of $Na[VO(O)(oxin)_2(OH_2)_2]\cdot 2H_2O$ was not effective for the preparation of this complex. So the desired complex was prepared as follows: 2.1 g. of $[VO(OH)(CH_3\text{-oxin})_2(OH_2)_2]$ was dissolved in 200 ml. of 0.2 N sodium hydroxide. After being filtered, the solution was concentrated at 50°C in vacuo to 20 ml. The complex salt thus obtained was recrystallized twice from 98% methanol.

Found: C, 48.59; H, 4.65; N, 5.42; V, 10.05. Calcd. for $C_{20}H_{24}O_8N_2NaV = Na[VO(O)(CH_3\text{-oxin})_2(OH_2)_2]\cdot 2H_2O$: C, 48.59; H, 4.89; N, 5.67; V, 10.30%.

**Absorption Spectrum of the Red Form which is Not Esterified.**—For the first time, vanadium quinaldinate was prepared as follows: 0.97 g. of $NaVO_3 \cdot 4H_2O$ was dissolved in 50 ml. of 2 N sodium hydroxide. To this solution was added 1.73 g. of quinaldinic acid dissolved in 50 ml. of 2 N sodium hydroxide. This mixture was acidified with 10 ml. of 2 N acetic acid. The white precipitate which appeared was separated by filtration after it had been digested for two hours at 60°C.

The benzene solution of this complex was colorless. To the solution was added a benzene solution of 8-quinolinol (almost colorless). The solution instantly became red, which was quite similar to the color of the solution of the red form prepared from the violet form by the use of methanol (Fig. 5). The same behavior was recognized in dioxane too.

**Measurements.**—Visible and ultraviolet absorption spectra were determined with a Beckman DU and a Hitachi EPU-2A spectrophotometers using the cells which have 1 and 10 cm. light paths.

Infrared absorption measurements were made by the pressed disk technique in a Hitachi EPI-2 infrared spectrophotometer, the disks being 200 mg. of dried potassium bromide containing 1.5 mg. of complexes.

## Summary

New complexes, $[VO(OH)(CH_3\text{-oxin})_2]$, $[VO(OH)(CH_3\text{-oxin})_2(OH_2)_2]$ and $Na[VO(O)(CH_3\text{-oxin})_2(OH_2)_2] \cdot 2H_2O$ have been prepared and discussed in relation to the structures.

From experimental evidences of these complexes and of 8-quinolinol-vanadium complexes, we have concluded that the violet form of 8-quinolinol-vanadium complex has a cis configuration and that the red form has a trans one.

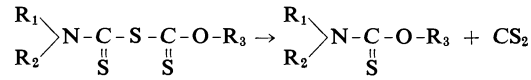
# *Studies on the Thiocarbamoylthiocarbonates. II. Synthesis and Thermal Decomposition of Aryl Thiocarbamoyltrithiocarbonates*

By Aritsune KAJI

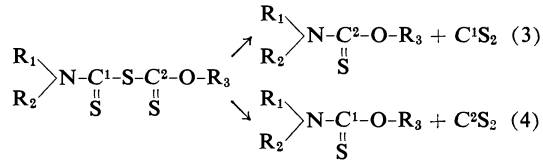
(Received November 24, 1960)

The syntheses and characteristics of *N, N*-disubstituted *O*-aryl *S*-thiocarbamoyldithiocarbonates have been reported previously[1]. Aryl esters of *N, N*-disubstituted thiocarbamoyltrithiocarbonic acid were also synthesized by the reaction of aryl chlorodithioformates with sodium or ammonium salts of *N, N*-disubstituted dithiocarbamic acid as shown in Eq. 1.



(1)

In this way, various compounds were obtained in good yields as shown in Tables I—IV.

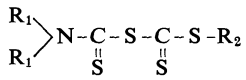


*N*-Monosubstituted aryl thiocarbamoyltrithiocarbonates could not be obtained, however, by this method, owing to their probable decomposition during the reaction.

As has been described in the previous paper[1], aryl ester of *N, N*-disubstituted *S*-thiocarbamoyldithiocarbonic acid, when kept at a temperature higher than its melting point, decomposes into *N, N*-disubstituted *O*-aryl thionocarbamate liberating carbon disulfide (Eq. 2).

(2)

It is easily seen that two ways are possible to eliminate carbon disulfide, which can be shown in Eqs. 3 and 4.



(3)

(4)

In order to decide the preferable course of the elimination reaction, the thermal decomposition of the compounds labeled with radioactive sulfur was studied. By the thermal decomposition of *O*-(4-tolyl) *S*-(*N, N*-dimethylthiocarbamoyl)dithiocarbonate (I), in which

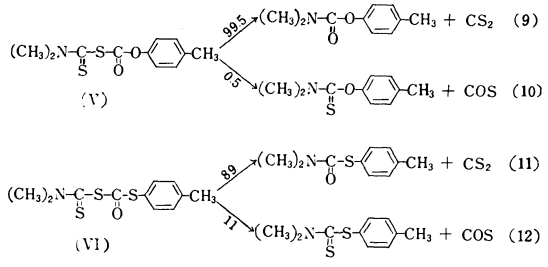
two S atoms in the thiocarbamoylthio group were labeled with $^{35}_{16}S$, radio-active *O*-(4-tolyl) *N,N*-dimethylthionocarbamate (II) was produced. The relative activity of II against I was found to be 0.2625, while the theoretical value, based on Eq. 5 should be zero, and based on Eq. 6, it should be 0.5000.

But this result may be explained if one postulates that the two courses of decomposition (Eqs. 5 and 6) occur simultaneously at the rate of 47.5 : 52.5.

*N,N*-Disubstituted aryl thiocarbamoyltrithiocarbonates were found to decompose, when kept at temperatures higher than their melting points, into *N,N*-disubstituted aryl dithiocarbamates liberating carbon disulfide. The crystalline decomposition products of some trithiocarbonates are listed in Table V.

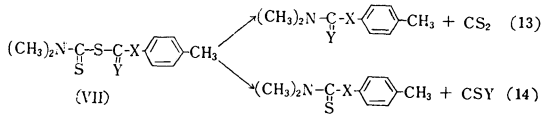
By the thermal decomposition of *S*-(4-tolyl) *S*-(*N,N*-dimethylthiocarbamoyl) trithiocarbonate (III) in which the two S atoms were labeled with $^{35}_{16}S$ similarly as in the case of I, radio-active 4-tolyl *N,N*-dimethyldithiocarbamate (IV) was given. But the relative activity of IV against III was found to be 0.3305. Thus the proportion of the two courses was concluded to be 33.9 : 66.1 (Eqs. 7 and 8) in this case.



These facts show that the two courses of decomposition can occur simultaneously, but the rate of their occurrence is strongly influenced by substituting O atom with S atom.

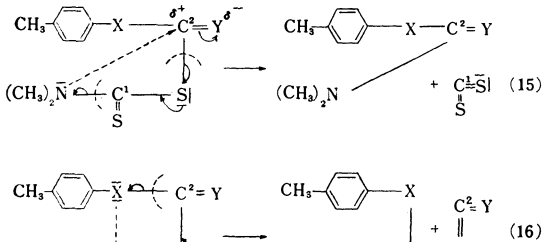
To discover what influences would appear when another one of the S atoms was substituted with an O atom, the thermal decomposition of the compounds containing $>C^2=O$ in place of $>C^2=S$ (cf. Eqs. 3 and 4) was studied. This could produce carbon disulfide if the reaction occurred as Eq. 3, or carbon oxysulfide if the reaction followed Eq. 4. By the thermal decomposition of V and VI, both carbon disulfide

and carbon oxysulfide were evolved as decomposition fragments in each case (cf. Eqs. 9—12). Also, the volume rates of $CS_2$ : COS were found to be 99.5 : 0.5 and 89 : 11 respectively, by gas-chromatographic analyses of the above fragments.



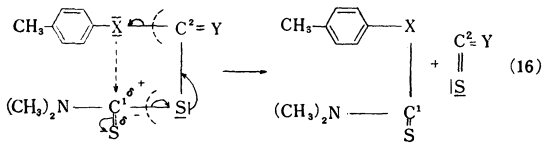
These results show that the proportions of the two courses in each case should be 99.5 : 0.5 (Eqs. 9 and 10), and 89 : 11 (Eqs. 11 and 12).

(9) (10) (11) (12)



These results show that the proportion of the occurrence of reaction 13 against reaction 14 increases according to the variation of X and Y to S or O atom as follows.

$$X=Y=O>X=S,\ Y=O>X=O,\ Y=S>X=Y=S$$



(13) (14)

Summarizing the decomposition reactions mentioned above, it may be concluded that there are two reaction mechanisms on the thermal decomposition reaction of *N*, *N*-disubstituted aryl thiocarbamoylthiocarbonates, which can be written as follows.

(15)

(16)

(X, Y : O and/or S)

Reaction 15 occurs by co-ordination of $(C^2)^+$ to $\overline{N}$, and reaction 16, by co-ordination of $(C^1)^+$ to $\overline{X}$. The electron density on $C^2$ and electro-negativity of -X-, which vary according to the variation of X and Y to S or O atom, may have some influence on the reaction courses.

By comparison of the electron densities on $C^1$ in $>N-\overset{1}{C}=S$ and $C^2$ in $-X-\overset{2}{C}=Y$, when both X and Y are O atoms, the electron density on $C^2$ is far smaller than that on $C^1$, owing to the greater polarization of $>C=O$ than that of $>C=S$ and greater electro-negativity of -O- than that of -S-. Thus reaction 15 may occur almost exclusively in this case. When X is an S atom, however, the electron density on $C^2$ increases, for the electro-negativity of -X- becomes smaller owing to replacement of O atom by S atom. This will make not only the co-ordination of $(C^2)^+$ to $\overline{N}$ unfavorable, but also the co-ordination of $(C^1)^+$ to $\overline{X}$ favorable. Thus reaction 16 may occur to some extent in this case. When Y is an S atom, the difference of the electron densities on $C^1$ and on $C^2$, due to the respective polarity of $>C=Y$ and $>C=S$, will disappear. Thus the two sorts of co-ordination become concurrent. When X is also an S atom, reaction 16 occurs most easily for the reasons mentioned above.

These situations may explain the relationships between the mechanisms of thermal decomposition of the compounds VII and their structures.

## Experimental

**Starting Materials.**—Sodium or ammonium salts of *N*, *N*-disubstituted-dithiocarbamic acid were synthesized by the known methods[1]. Aryl esters of chlorodithioformic acid were synthesized similarly to aryl chlorothionoformates which were previously reported[1], by the reaction of thiophosgen, thiophenol and sodium hydroxide.

**4-Tolyl *N*, *N*-Dimethylthiocarbamoyltrithiocarbonate.** — To a solution of 14.3 g. (0.1 mol.) of sodium dimethyldithiocarbamate in 100 cc. of water, was added gradually 20.3 g. (0.1 mol.) of 4-tolyl chlorodithioformate, keeping the temperature at 10～15°C during the reaction period of 2 hr. The reaction mixture produced 25 g. (yield, 87%) of orange crystals with m. p. 105～106°C. Recrystallization from acetone-ethanol gave orange needles of m. p. 107～108°C.

**4-Tolyl *N*-Methyl-*N*-phenylthiocarbamoyltrithiocarbonate.**—To a suspension of 20 g. (0.1 mol.) of ammonium *N*-methyl-*N*-phenyldithiocarbamate in 100 cc. of acetone, was added gradually 20.3 g. (0.1 mol.) of 4-tolyl chlorodithioformate, keeping the temperature at 5～10°C during the reaction period of 1 hr. The reaction mixture poured into 200 cc. of cold water produced 30 g. (yield, 86%) of orange crystals with m. p. 96～99°C. Recrystallization from acetone-ethanol gave orange prisms with m. p. 98～99°C.

The other esters shown in Tables I—IV were synthesized similarly to the synthesis of the above examples.

***S*-(4-Tolyl) *S*-(*N*, *N*-Dimethylthiocarbamoyl)dithiocarbonate (VI).**—This could also be synthesized in a similar way, by reacting 27.1 g. (0.1 mol.) of *S*-(4-tolyl) chlorothiolformate with 14.3 g. (0.1 mol.) of sodium dimethyldithiocarbamete in 150 cc. of acetone. Yield : 27.8% ; Yellow needles of m. p. 69～70°C.

Found: C, 48.66; H, 4.72; N, 5.33. Calcd. for $C_{11}H_{13}NOS_3$: C, 48.71; H, 4.80; N, 5.17%.

**Thermal Decomposition of V and VI.** — In a sealed flask (1000 cc. in volume) which was filled with nitrogen gas at 10 mmHg., 2 g. of V or VI was fused at 160°C for 1 hr. After the subsidence of evolution of gas, nitrogen gas was led into the flask until the pressure became 760 mmHg. Further, the ratio of carbon oxysulfied and carbon disulfide, in the gas obtained, was measured by gas-chromatography (column: tricresyl phosphate, at 42.5°C; carrier: $H_2$).

**Thermal Decomposition of Radio-active 4-Tolyl *N*, *N*-Dimethylthiocarbamoyltrithiocarbonate (III).** —In an oil bath, 0.575 g. of III (specific activity: 47.84 mc./mol.), synthesized by the reaction between 4-tolyl chlorodithioformate and radio-active sodium *N*,*N*-dimethyldithiocarbamate in which the two S atoms were labeled with $^{35}_{16}S$, was fused at 160°C for 1 hr. in nitrogen atmosphere of 10 mmHg. After the subsidence of evolution of radio-active carbon disulfide, the decomposition product was twice recrystallized from 2.4 cc. of ethanol and produced 0.327 g. (yield, 77.5%) of radio-active 4-tolyl *N*,*N*-dimethyldithiocarbamate (VI), of which the specific activity was 15.81 mc./mol. with m. p. 112~113°C. The relative specific activity of VI against III was 0.3305 (=15.81/47.84).

By the thermal decomposition of radio-active *O*-(4-tolyl) *S*-(*N*,*N*-dimethylthiocarbamoyl)dithiocarbonate (I) (specific activity: 23.85 mc./mol.), radio-active *O*-(4-tolyl) *N*,*N*-dimethylthionocarbamate (II) (specific activity: 6.26 mc./mol.) was produced in a similar way. Thus the relative activity of II against I was 0.2625.

The author wishes to express his sincere thanks to Professor Dr. Ryozo Goto, Kyoto University, for his guidance and encouragement throughout this work. The author also thanks Professor Dr. Hiroshi Watanabe, Konan University, for his helpful advice. He is also grateful to Dr. N. Oda, Mr. M. Kubo, Mr. K. Norishima, Mr. G. Tsuchihashi, Mr. S. Ono and Mr. A. Nomura for gas-chromatographic and elemental analyses, to Dr. K. Taniguchi for his guidance, and to Mr. K. Miyazaki, Mr. K. Hashimoto and Mr. Y. Aoki for their assistance with the experimental work.

# *Benzylideneaniline. III. Anils of Substituted Benzaldehydes*

By Nozomu EBARA

(Received January 21, 1961)

In the first paper of this series[1] a non-planar structure was proposed for benzylideneaniline, where the benzene ring of aniline part is almost perpendicular to the rest of the molecule (Fig. 1). In such a case the ultraviolet absorption spectrum of this molecule would be closely allied to those of benzaldehyde type I and aniline type II molecular halves, and it was assumed that the absorption maxima at 263 m$\mu$ (A) and at 315 m$\mu$ (B) is due to I and II respectively. The effects of substituents upon these bands were examined and it was found that the substituents on II had little to do with band A, whereas marked shifts were experienced by band B.

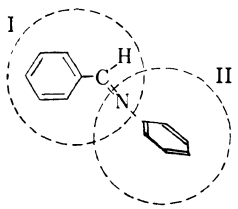

Fig. 1. Assumed structure of benzylideneaniline.

In the present paper, derivatives of benzylideneaniline of which the substituents are on aldehyde ring I, together with anils bearing aliphatic halves, were synthesized and their spectral features as well as other properties were examined.

**Ultraviolet Absorption Spectra.**—Ultraviolet absorption spectra of anils were measured in *n*-heptane, ethyl alcohol and 50% mixture of hydrochloric acid and ethyl alcohol. The spectra in *n*-heptane are illustrated in Fig. 2 and pertinent data are listed in Table I.

*Bands A.*—Bands A shift markedly as substituents vary, in contrast to the case where the substituents are on II. Moreover, they shift furthermore towards longer wavelengths when alcohol is used as solvent. In acidic

medium, the blue shift is again observed with these bands as in the former case[1], but their maxima are by no means at the same position, but vary in a manner similar to those of corresponding anils and aldehydes. These facts are in good accordance with the above proposal that band A is largely of the nature of CT band of I.

*Bands B.*—Unfortunately the behavior of bands B is not quite obvious as anils bearing the electron-donating groups at the ortho position of I exhibit the expected maxima of enhanced intensities at the longer wavelength region (presumably the second CT bands[2] from I) and the positions of bands B become obscure. But in cases where they are observable, they are in general almost at the same position. It is perplexing, however, that substitution at the para position of I by $NO_2$ group also gives rise to a new band at the longer wavelength region, of which the explanation is not yet deduced.

There remains another discrepancy as to the intensities of bands B, which are too much enhanced to be largely of the nature of $A_1-B_2$ transition of II.

**Comparison with the Anils Bearing Aliphatic Halves.** — Benzylidene-*n*-butylamine, anisylideneisopropylamine, *p*-dimethylaminobenzylideneisopropylamine, salicylideneisopropylamine and *n*-butylideneaniline were synthesized and their spectra were measured (Fig. 3).

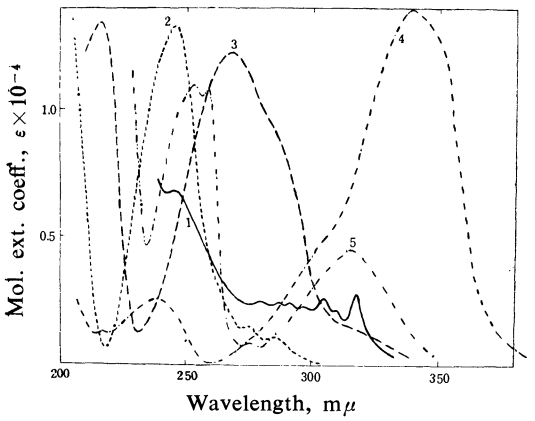

Fig. 3. Spectra of aliphatic anils in *n*-heptane:
1) 
2) 
3) 
4) 
5) 
(Intensity of 4 is in half scale).

Anils of aliphatic amines and aromatic aldehydes exhibit intense bands in the proximity of those of aldehydes, which may therefore be correlated to bands A of aromatic anils. Bands B vanish completely in these anils.

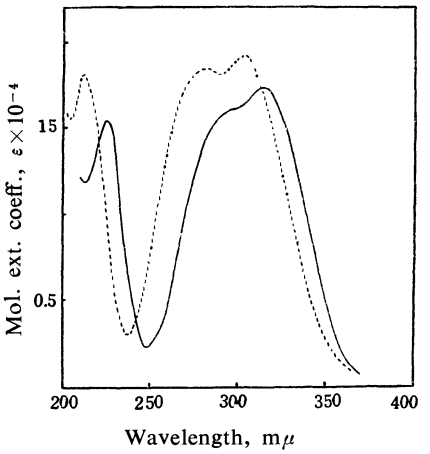
*n*-Butylideneaniline shows an intense band at 2470 Å and a weak one with a structure between 2820 and 3200 Å, which should correspond to those of aniline. The position of the latter band coincides almost exactly with band B of benzylideneaniline, although their intensities differ considerably. It is not certain whether *n*-butylideneaniline assumes benzaldehyde type or aniline type structure (presumably, the former), but apart from this, it may be concluded that $A_{1g}-B_{2u}$ transition of benzene at 2600 Å rises to this position in the presence of the perturbation of R–CH=N– and that this band shifts no more towards longer wavelengths when R turns from aliphatic to aromatic groups.

Therefore, no substantial difference seems to exist between the spectra of aliphatic and aromatic anils.

**Spectra of *N*-Methylated and Protonated Anils.**—Similar spectra are observed with *N*-methylated anils and with *N*-protonated anils. Bands B vanish completely, whereas bands A shift towards shorter wavelengths: the explanation of the latter phenomenon was given tentatively in terms of hybridization change in the previous paper[1].

No anils giving rise to second CT bands of I miss these bands when they are methylated or protonated.

***p*-Hydroxybenzylidene- and Anisylideneaniline.**—Striking are the features of the spectra of



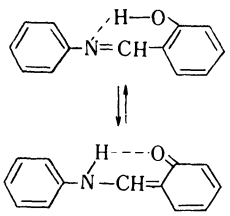


Fig. 4. Spectra of 1)  and 2)  in $C_2H_5OH$.

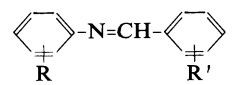
2) J. Tanaka and S. Nagakura, *J. Chem. Soc. Japan, Pure Chem. Sec. (Nippon Kagaku Zasshi)*, **78**, 1200 (1957).

*p*-hydroxybenzylidene- and anisylideneaniline, where the spectra are very greatly different in alcohol as compared with those in *n*-heptane, the latter exhibiting the ordinary shape of anils (Fig. 4). In contrast to this, the spectra of anils bearing these substituents on II are free from any remarkable solvent effect. It seems plausible to assume that the bands A at 2750 Å and at 2790 Å of these compounds in *n*-heptane, presumably the CT band of I, shift to 3140 and 3030 Å in alcohol, respectively, owing to the pronounced stabilization of the solvated excited states where there are large resonance polarizations due to strongly electron-donating substituents at the para positions. These molecules decompose very quickly in alcohol, as will be described in a following section, and the bands near 2800~2900 Å may be attributed to the inevitably present decomposition products.



**Salicylidene- and *o*-Methoxybenzylideneaniline.** —Another peculiar feature is that of salicylideneaniline, where three bands are observed above 3010 Å, which are too conspicuous to be the vibrational structure. It had been reported that strong hydrogen bonding exists between hydroxyl hydrogen and azomethine nitrogen atoms[3], and that this would be responsible for the unusual spectrum of this molecule[4]. But it is highly improbable that a hydrogen bonding would cause such a large variation in the spectrum as the appearance of new bands.

In phenylazonaphthol a tautomerism is known to exist between azo and hydrazone forms[5], whereas *o*-hydroxyazobenzene does not exhibit this tautomerism[6]. To see whether this is the case or not with salicylideneaniline, and to examine whether or not some of these bands correspond to the tautomeric enamine form, the temperature dependence of the ultraviolet absorption spectrum was examined. The

spectrum was measured at several temperatures between −60 and 47°C, but no remarkable change was observed except for the ordinary sharpening and broadening of the peaks accompanying the temperature change. The infrared spectrum was also examined in carbon tetrachloride solution and in solid state, but there was observed no band attributable to C=O stretching vibrational mode. Moreover the spectra in the solution and in the solid state resemble each other very closely, indicating that the molecular structure is not so greatly different in these two states, and that there seemes to exist no tautomeric equilibrium between the above two structures. The shift of C=N stretching vibration from that of unsubstituted benzylideneaniline is considerably great as compared with other anils where the shifts are at most within a few $cm^{-1}$ (Table II). OH stretching vibration is hidden under the lower frequency side of CH stretching vibration. Deuterated salicylideneaniline was synthesized. This gives rise to a very broad band between 2020~2180 $cm^{-1}$, doubtless attributable to OD stretching vibration, from which the position of the original OH band is calculated to lie between 2800~3000 $cm^{-1}$, showing an unusual shift towards lower frequencies.

TABLE II. WAVE NUMBERS OF C=N STRETCHING VIBRATIONS

in $CCl_4$

| R | R′ | Wave number, $cm^{-1}$ |
|---|---|---|
| H | H | 1629 |
| *p*-$OCH_3$ | H | 1626 |
| *o*-Cl | H | 1630 |
| *m*-Cl | H | 1631 |
| *p*-Cl | H | 1628 |
| *m*-$NO_2$ | H | 1631 |
| H | *p*-$OCH_3$ | 1624 |
| H | *o*-$OCH_3$ | 1620 |
| H | *m*-$NO_2$ | 1629 |
| H | *p*-$NO_2$ | 1629 |
| H | *o*-OH | 1616 |

Presumably a large resonance coupling would exist between azomethine and enamine forms, the former still being predominant. The molecule may safely be referred to as existing almost exclusively in azomethine form rather than in enamine form in the solution as well as in the solid state, and the new ultraviolet absorption bands might not be ascribed to the tautomerism.

Ionization equilibrium might exist in this molecule between phenolic and phenolate structures, and some of the bands might be attributed to anion form. But this seems also not to be the case, as the change of solvent, as well as of temperature, proves no evidence of the noticeable variation in the ionization constant. Moreover, in alkaline solution, the

6) e. g., D. Hadži, *J. Chem. Soc.*, **1956**, 2143.

bands above 3010 Å disappear and a new band comes out at 3800 Å, which is raised too much to be led back to any of the bands of salicylideneaniline.

It turns out that an intense band exists at 3220 Å in the spectrum of *o*-methoxybenzylideneaniline. This is all but congruent with that at 3210 Å of *o*-methoxybenzaldehyde and is presumably the second CT band of I. Salicylaldehyde, salicylaldoxime[7], salicylaldimine[7] and bis-salicylidene-ethylenediamine[8] as well as *N*-methyl-salicylideneanilinium ion exhibit similar bands. All of these bands may demand their replica in the spectrum of salicylideneaniline: the band at 3415 Å is the most adequate for this, though it is conflicting that this band experiences the blue shift when alcohol is used as solvent.

One of the other two bands at 3010 and 3180 Å, preferably the latter, may be assigned as band B, which comes from I of the molecule.

**Hydrolyzation Reaction of *p*-Hydroxybenzylidene-, Anisylidene- and *o*-Methoxybenzylideneaniline.**—These three compounds decompose very quickly in alcoholic solutions. The reaction rates were found to depend upon the water content of alcohol, and would conceivably be hydrolyzation reactions. The rates of these reactions were measured at several temperatures by tracking their spectral changes, and it was found that the reactions are first-order as to the concentrations of anils in the presence of excess water. The results are shown in Table III and in Figs. 5, 6 and 7.

Table III. Hydrolyzation reaction rates in $C_2H_5OH(2)+H_2O(1)$

| Temp., °C | $k\times10^2$ | $E$, kcal./mol. | A |
|---|---|---|---|
| *o*-Methoxybenzylideneaniline | | | |
| 31.6 | 9.90 | 7.72 | $1.6\times10^4$ |
| 26.0 | 7.92 | | |
| 20.6 | 6.40 | | |
| 12.0 | 4.40 | | |
| *p*-Hydroxybenzylideneaniline | | | |
| 45.6 | 5.87 | 6.56 | $2.5\times10^3$ |
| 40.1 | 4.95 | | |
| 25.85 | 2.97 | | |
| 13.95 | 1.89 | | |
| Anisylideneaniline | | | |
| 45.5 | 5.16 | 6.11 | $1.0\times10^3$ |
| 39.7 | 4.28 | | |
| 24.5 | 2.62 | | |
| 13.85 | 1.77 | | |

It is probable that owing to the strongly electron-donating properties of the substituents, the addition of proton at the nitrogen atom, or conceivably the heterolytic fission of OH bond of hydrogen-bonded water at the nitrogen atom, accompanied by the addition of $OH^-$ to the azomethine carbon atom, would proceed easily.

The activation energies are almost equal in these three cases, whereas the frequency factor is the largest in *o*-methoxybenzylideneaniline. One tentative explanation is that owing to the closely standing hydrogen-bonded *o*-methoxyl group, the chance of the reaction in which water participates is greater in this case.

1) 

2) 

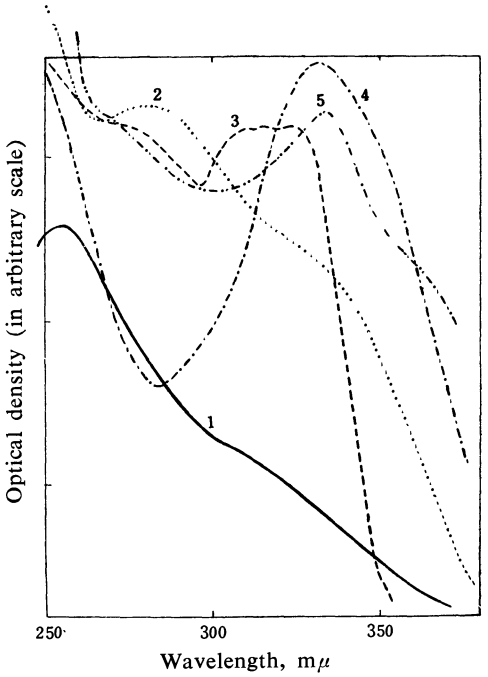
3) 

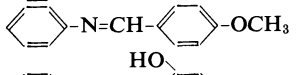
When the substituents are on II, hydrolyzation reaction does not take place, presumably because the substituents would only affect the C=N bond through the participation in the migration aptitude of nitrogen non-bonding electrons.

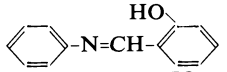
**Spectra in the Solid States.**—The spectra of benzylideneaniline, anisylideneaniline, salicylideneaniline, salicylidene-*p*-chloraniline and salicylidene-*p*-bromoaniline were measured in the solid states by means of either the potassium chloride disk method or the film method (Fig. 8). In the former three cases the spectra are very similar to those in *n*-heptane solutions, indicating that the molecular shapes are not greatly different in these two states, provided that the ignorance of the effect due to the orientation of the crystal axis may be permitted in the latter method. In the latter two cases, single peaks are always observed above 3000 Å instead of three, though their spectra in the solution are very similar to that of salicylideneaniline. It is not certain whether this is due to the variation in molecular shapes or due to the difference in crystal structures, or in turn due to the preferred orientation of crystal axis against the plates, which tends to favor the absorption band whose transition moment is perpendicular to it.

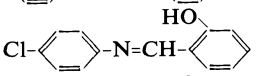
**Trial Interpretation of UV Spectrum on the Basis of Planar Model.** — Because of some discrepancies arising in the above consideration, the interpretation of the ultraviolet spectrum of benzylideneaniline is intended tentatively to be regarded on the basis of the planar model.

The symmetry $C_{2v}$ may be assigned to the molecule, so far as the $\pi$ electrons are concerned. In this approximation, the allowed









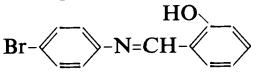


Fig. 8. Spectra in solid states,

4) 

5) 

electronic transitions are $A_1-A_1$ and $A_1-B_2$ ($A_1-B_1$ may be excluded, because the $\pi$ electronic levels are always constructed with atomic 2p orbitals).

Following the method of Nagakura and Tanaka[9], the perturbation diagram of this molecule is drawn, where the ionization potential and electron affinity of C=N group are assumed to lie between those of C=O and C=C, largely approaching the former (Fig. 9). Although the coefficients of atomic orbitals at N and C atoms in the MO of C=N group differ from each other, the resulting molecular energy level diagram might not be so far from those of stilbene and azobenzene at least in the lower region, and the lower excitations should be $\pi-\pi^*$ (or $A_1-A_1$) and $\pi-\phi^*$ (or $A_1-B_2$)[10]. The former should involve the charge transfer from two benzene rings to the

9) S. Nagakura and J. Tanaka, *J. Chem. Phys.*, **22**, 236 (1954).

10) The energy diagram is drawn by taking account of Jaffé's calculations (see Ref. 11).

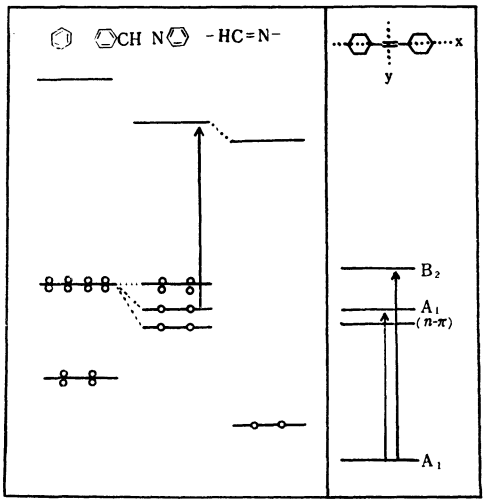

Fig. 9. Energy level diagrams of planar benzylideneaniline molecule.

central C=N part, although the mixing with other configurations would in part reduce it. The latter has much in common with benzene $A_{1g}-B_{2u}$ transition except that it becomes allowed by the perturbation. The intensity of the former should be reduced by the unsymmetrically situated central N atom and that of the latter would be much lower.

Two bands, A and B, arising in the spectrum of benzylideneaniline must be interpreted from the above standpoint. Jaffé[11] had assumed that they are $\pi-\phi^*$ and $\pi-\pi^*$, respectively.

In the present experiment, however, it was found that band A has the character of CT band, whereas band B does not, and that the nitrogen non-bonding electrons are responsible for the appearance of band B. Moreover this band is too intense to be $A_1-B_2$ transition. These findings go behind with Jaffé's interpretation.

An alternative interpretation in which band A is assigned as $\pi-\pi^*$ does not hold, as the energy of this transition might not be so great.

Thus, the planar model presents more discrepancies with regard to the ultraviolet spectrum of the molecule.

## Conclusion

The results obtained here can be explained adequately by the non-planar model proposed in the previous paper. In particular, the coincidence in the ultraviolet spectrum seems to be excellent. But the explanation is not unique and leaves many discrepancies. It remains in doubt whether or not the failure of explaining the spectrum of this molecule with the hitherto believed planar model might be ascribed to the misestimation or ignorance of some quantities which will arise in the calculation of molecular energies.

The molecule seems to assume the same conformation in the solid state as in the solution. The X-ray crystal analysis is now in progress. This will provide indisputable information with regard to the precise conformation of benzylideneaniline molecule.

## Experimental

**Materials.**—Benzylidene-, *p*-hydroxybenzylidene-, *p*-chlorobenzylidene-, *p*-nitrobenzylidene, *m*-nitrobenzylidene-, anisylidene-, *p*-dimethylaminobenzylidene- and salicylideneaniline were prepared by the direct condensation of aniline with corresponding aldehydes, without any dehydrating agent and were recrystallized from ethyl or isopropyl alcohol. M. p. 63, 193~194, 61~62, 90~90.5, 64.5~65, 51.5~52, 67~68 and 50~50.5°C, respectively.

*o*-Methoxybenzaldehyde was prepared from salicylaldehyde by methylating it with dimethyl sulfate. The distilled and crystallized aldehyde was readily submitted to condensation reaction with aniline, affording *o*-methoxybenzylideneaniline. The product was dehydrated and distilled and then recrystallized from isopropyl alcohol. M. p. 39~40°C.

Salicylidene-*p*-chloraniline and -*p*-bromaniline were synthesized by the condensation of salicylaldehyde with corresponding anilines and recrystallized from ethyl alcohol. M. p. 100 and 107°C, respectively.

*n*-Butylideneaniline, benzylidene-*n*-butylamine and anisylidene-, salicylidene- and *p*-dimethylaminobenzylideneisopropylamine were prepared by the following procedure. Equimolecular amounts of corresponding amines and aldehydes were put into a round-bottomed flask equipped with a good condenser. Vigorous reaction took place and water was separated out. The mixture was heated on a water bath for about one hour, then shaken with ether, dried over calcium chloride and distilled under reduced pressure. B. p. 118°C/13 mmHg, 111°C/17 mmHg, 119~120°C/14 mmHg., 155°C/25 mmHg, respectively.

**Deuterated Salicylideneaniline.** — Deuterated ethyl alcohol was prepared from sodium ethoxide and deuterium oxide, and this alcohol was again used for the preparation of sodium ethoxide. The procedure was repeated so as to reduce the hydrogen content of the resulting alcohol. Salicylideneaniline was dissolved in this alcohol and the solvent was evaporated at room temperature under reduced pressure. The moisture was carefully excluded throughout the whole process.

***N*-Methylated Anils.**—Excess amounts of methyl iodide were added in the solutions of anils and they were kept standing for several hours. The absorption spectra were measured at times in order to check the degree of completion of the reaction. The intense absorbancy due to methyl iodide was compensated for, but the spectra below 3000 Å could not be measured. Another method is

11) H. H. Jaffé, Si-Jung Yeh and R. W. Gardner, *J. Molecular Spectroscopy*, 2, 120 (1958).

employed as well, in which anils were dissolved in pure methyl iodide, kept standing for a night, desiccated to dryness, dissolved in alcohol and subjected to the measurements of absorption spectra.

**Measurements.**—Ultraviolet spectra were measured by means of a Cary 14-type self-recording spectrophotometer using 1 cm. quartz cell. To follow the reaction rate, the spectra were measured by the use of Hitachi EPU 2-type spectrophotometer.

**Hydrolyzation Reactions.**—The anils were dissolved in alcohol containing one-third the amount of water, and immersed in a thermostat. The absorbances of the solutions were measured at times in the vanishing band region. The final absorbances were also measured from which a rate equation could be derived. The plotted points fell on straight lines in very good coincidence.

Infrared spectra were measured by means of Nihon-bunko self-recording spectrophotometer model 301, using sodium chloride prism and sodium chloride cells of 0.1 mm. in thickness. Solid samples were prepared by allowing the melt to cool between sodium chloride plates pressed together.

Solid samples for the ultraviolet measurements were prepared either by allowing the melt to cool between quartz plates or by pressing the mixtures of finely powdered materials with specially prepared potassium chloride crystals[12].

The author wishes to express his sincere thanks to Professor Saburo Nagakura of the University of Tokyo for his kind guidance throughout this study.

# *Abnormal Acceleration of the Rate of Bulk Polymerization of Styrene**

By Norio NISHIMURA

(Received November 21, 1960)

It is well known that an acceleration in rate can be observed during polymerization reactions. In the early stage of this investigation, Trommsdorff et al.[1] ascribed this phenomenon to the increase in viscosity of the reaction system. It is now currently accepted that the increase in both rate and degree of polymerization is brought about by a decrease in termination constant due to the gel effect (or Trommsdorff effect). In a viscous solution, the termination constant is affected first. Propagation and transfer reactions involving small monomer and catalyst molecules are less affected by viscosity.

There have been some investigations on the effect of viscosity on the reaction rate and the individual rate constants[1-4].

Recently, Tobolsky et al.[5] have shown that the limiting fractional conversion at infinite time of a radical initiated vinyl polymerization could be predicted from a knowledge of the kinetic rate constants under certain conditions where the gel effect does not invalidate the theory.

## Experimental

**Reagents.** — Commercial 2,2'-azobisisobutyronitrile was recrystallized twice from ether solution m. p. 103~103.5°C. Styrene monomer was washed with 10% sodium hydroxide and then with water. After drying over calcium chloride, the monomer was distilled and stored in the dark. Just before use, it was fractionated at 25 mmHg and the middle fraction was used. Benzene was washed in turn with concentrated sulfuric acid, dilute sodium hydroxide and water. Then it was dried over calcium chloride, then over metallic sodium wire and distilled. *n*-Butanol of reagent grade was used after distillation.

**Procedure.**—All polymerizations were carried out in glass dilatometers, the type of which was similar to that used before[6]. After being filled with the requisite amounts of catalyst and monomer, the tubes were connected to a vacuum line and sealed off. The tubes were then held in a thermostat at 60°C.

The volume contraction of the solution was

* Presented at the Local Meeting of the Chemical Society of Japan, Hiroshima, November, 1960.

followed with a travelling microscope. At high conversion where dilatometric technique could not be applied because of high viscosity, the gravimetric method was used. In order to calculate the degree of conversion from the contraction of the solution, the densities of polystyrene in the monomer (solution polymer density) and styrene monomer at 60°C were taken as 1.0563 and 0.869[7], respectively. Hence, for bulk polymerization of styrene, 100% conversion corresponds to a 17.7% contraction in volume of the original monomer.

The induction period could not be observed in every experiment. At specified times, the contents of the tubes were properly dissolved in benzene and then poured dropwise into a much greater quantity of ice-methanol. The precipitate was filtered off and dried in vacuo.

The intrinsic viscosities of the benzene solutions of polystyrene were determined at 30±0.01°C using an Ostwald viscometer. The number average degree of polymerization was estimated from the following equation[8]

$$\bar{P}_n = 1770[\eta]^{1.40}$$

In order to obtain the distribution of the degrees of polymerization at high conversion, *n*-butanol was slowly added to the benzene solution of the polymer (about 1.5%). The addition of the *n*-butanol was stopped before precipitation of the polymer appeared. By slow evaporation of the relatively volatile benzene, the solution becomes richer in less volatile *n*-butanol, and the precipitation of polystyrene results. After temperature equilibrium was attained in a thermost at 30°C, the precipitate in a gel state was separated by decantation from the solution and the same procedure was repeated. The precipitate was then dissolved again in benzene and poured into ice-methanol followed by drying in vacuo. This method is almost the same as that adopted by Chitani et al.[9]

## Theoretical

Notation

$M$—Number of moles of monomer,
$P$ —Number of moles of polymer,
$I$ —Number of moles of catalyst,
$f$ —Catalyst efficiency,
$k_p$—Rate constant for propagation,
$k_t$—Rate constant for termination,
$k_d$—Rate constant for the first order decomposition of catalyst,
$\alpha$ —Total volume shrinkage for the complete conversion of monomer to polymer,
$\bar{P}_n$—Cumulative value for number average degree of polymerization,
$\bar{\bar{P}}_n$—Instantaneous value for number average degree of polymerization.

It is well known that the rate of radical polymerization initiated by a catalyst is expressed as

$$-\frac{d[M]}{dt} = K[I]^{1/2}[M] \tag{1}$$

where

$$K \equiv \frac{k_p}{k_t^{1/2}} k_d^{1/2} f^{1/2} \tag{2}$$

If the decomposition rate of the catalyst is of the first order with respect to its concentration, then the conversion $x$ at time $t$ may be expressed by

$$x = 1 - \exp\{A(e^{-(1/2)k_d t} - 1)\} \tag{3}$$

where

$$A \equiv \frac{2K}{k_d}[I]_0^{1/2} \tag{4}$$

The value of $K$ can easily be obtained from the slope of the initial rate of polymerization against the square root of the catalyst concentration. From Eq. 3 it may be seen that the fractional conversion $x$ reaches a limiting value $x_\infty$ when $t \to \infty$.

$$x_\infty = 1 - \exp(-A) \tag{5}$$

Tobolsky[10] showed this relationship and compared it with experimental results. In the previous paper[6], which describes the polymerization of vinyl acetate in the benzoyl peroxide-iron(II)-benzoin redox system, the same concept of the limiting conversion was proposed by us. Later Tobolsky et al.[5] proposed a modified form of the kinetic expressions. The equations derived above have not been corrected for a net volume shrinkage of the system. If the volume shrinkage is taken into account, then the effective monomer and catalyst concentrations are

$$[M] = \frac{[M]_0}{(1-\alpha x)}(1-x) \tag{6}$$

$$[I] = \frac{[I]_0}{(1-\alpha x)} e^{-k_d t} \tag{7}$$

respectively. From Eqs. 1, 6 and 7, one obtains

$$\frac{(1-\alpha x)^{3/2}}{(1-x)} dx = K[I]_0^{1/2} e^{-(1/2)k_d t} \cdot dt \tag{8}$$

Integration of Eq. 8 leads to

$$\frac{2}{3}y^3 + 2a^2 y + a^3 \ln\frac{(y-a)}{(y+a)} = Ae^{-(1/2)k_d t} + C \tag{9}$$

where

$$\left.\begin{aligned} C &\equiv \frac{2}{3} + 2a^2 + a^3 \ln\frac{(1-a)}{(1+a)} - A \\ y &\equiv (1-\alpha x)^{1/2}; \quad a \equiv (1-\alpha)^{1/2} \end{aligned}\right\} \tag{10}$$

8) D. H. Johnson and A. V. Tobolsky, ibid., **74**, 938 (1952).
9) T. Chitani, G. Meshitsuka and Y. Matsui, *High Polym. Chem.* (*Kobunshi Kagaku*), **10**, 175 (1953).
10) A. V. Tobolsky, *J. Am. Chem. Soc.*, **80**, 5927 (1958).

Eqs. 8 and 9 are somewhat different from the similar expressions derived by Tobolsky et al.[5]

It is rather complex to calculate the limiting conversion $x_\infty$ from Eq. 9. But if the corresponding value of $y$ is expressed by $y_\infty$, then from Eq. 9,

$$Z \equiv \frac{2}{3}(y^3-y_\infty^3)+2a^2(y-y_\infty) + a^3 \ln \frac{(y-a)(y_\infty+a)}{(y+a)(y_\infty-a)} = Ae^{-(1/2)k_d t} \quad (11)$$

or taking the logarithm,

$$\ln Z = \ln A - \frac{1}{2}k_d t \quad (12)$$

Therefore, if the values of $K$ and $k_d$ are accurately known, it is possible to draw an $x \sim t$ curve over the whole course of polymerization and compare it with the experimental curve. And if a deviation between them is seen, it might be explained as indicative of a change in circumstance such as gel formation. In a case where no such deviation occurs, one can obtain $K$ and $k_d$ directly by applying Eq. 12. In Eq. 12, if $\ln Z$ is plotted against time $t$, a straight line should be obtained and the slope and the intercept will give $(1/2)k_d$ and $\ln A$, respectively.

The number average degrees of polymerization of a polymer instantaneously formed and cumulatively formed are related to each other by Eq. 13.

$$\bar{\bar{P}}_n = \frac{\bar{P}_n}{1-\frac{x}{\bar{P}_n}\cdot\frac{d\bar{P}_n}{dx}} \quad (13)$$

Applying Eq. 13, one can calculate $\bar{\bar{P}}_n$ from the $\bar{P}_n \sim x$ curve which can be obtained experimentally. Eq. 13 was derived by Schulz et al.[11] and Wall et al.[12], independently.

It is of great interest to note that according to Eq. 13, the value of the instantaneous degree of polymerization will become infinitely large when the value of $(x/\bar{P}_n)\cdot(d\bar{P}_n/dx)$ approaches unity. So, one can tentatively refer $\bar{\bar{P}}_n \to \infty$ as a measure of gel formation.

In a bulk polymerization of vinyl monomer, if chain transfers to monomer and initiator are both neglected, $\bar{P}_n$ may be expressed as

$$\bar{P}_n = \frac{[M]_0-[M]}{f\{[I]_0-[I]\}} \quad (14)$$

for combination termination.

In a case where volume shrinkage can be neglected,

$$\bar{P}_n = \frac{[M]_0}{f[I]_0}\cdot\frac{x}{1-\exp(-k_d t)} \quad (15)$$

Taking the volume shrinkage into account, it follows that

$$\bar{P}_n = \frac{[M]_0}{f[I]_0}\cdot\frac{x}{1-\alpha x-\exp(-k_d t)} \quad (16)$$

It was pointed out by Robertson[13] that the catalyst efficiency $f$ started to decrease rapidly as bulk polymerization proceeded in the case of styrene and methyl methacrylate. In this case, remembering that $\bar{P}_n$ is a cumulative value for the number average degree of polymerization, the catalyst efficiency $f$ in Eq. 14 must also be a cumulative one. Then, rearranging Eq. 14 and inserting $\bar{f}$ instead of $f$,

$$\bar{f} = \frac{[M]_0-[M]}{\bar{P}_n([I]_0-[I])} \quad (17)$$

The true value of $f$ at conversion $x$ may be expressed by

$$f = \bar{f} + x\frac{d\bar{f}}{dx} \quad (18)$$

It is well known that an abnormal explosive reaction is followed by an increase in the degree of polymerization. Hence, the comparison of the experimental molecular weight distribution with the theoretical one will offer interesting information.

According to rigorous kinetics, the molecular distribution for combination termination is given by[14]

$$r[M_r] = \frac{1}{2}R_i\delta^2\left[\left(\frac{r}{[M]_0}+\frac{1}{R_i^{1/2}\delta}\right)\exp\left\{-\frac{R_i^{1/2}\delta}{[M]_0}(r-1)\right\} - \left(\frac{r}{[M]}+\frac{1}{R_i^{1/2}\delta}\right)\exp\left\{-\frac{R_i^{1/2}\delta}{[M]}(r-1)\right\}\right] \quad (19)$$

where $M_r$ is the number of moles of a polymer having $r$ monomer nuits, $\delta$ a quantity approximated to $k_t^{1/2}/k_p$ and $R_i$ the rate of initiation.

## Results and Discussion

The bulk polymerizations of styrene catalyzed by 2, 2′-azobisisobutyronitrile were carried out at 60°C, and the fractional conversion $x$ was

11) G. V. Schulz and G. Harborth, *Makromol. Chem.*, **1**, 106 (1947).

plotted against time $t$ over the whole course of polymerization as shown in Fig. 1.

The initial rates of the reaction $R_0$ obtained from the figure were plotted against the square root of the initial concentrations of the catalyst, giving a straight line as expected from Eq. 1. This is shown in Fig. 2. From the slope, the value of $K$ was found to be $0.86\times10^{-4}$ $mol^{-(1/2)}\,l^{1/2}\,sec^{-1}$, which is in good agreement with the value obtained by Tobolsky et al.[8] The spontaneous decomposition of 2,2'-azobisisobutyronitrile has been widely studied and various values for the rate constant $k_d$ have been reported. Using the $^{14}C$ labelled initiator, Bevington[15] proposed the value of $1.20\times10^{-5}\,sec^{-1}$ as the best. Using this value together with the above-mentioned value of $K$, one can calculate the whole course of the

* $K=0.86\times10^{-4}\,mol^{-(1/2)}\,l^{1/2}\,sec^{-1}$, $k_d=1.20\times10^{-5}\,sec^{-1}$ and $\bar{f}=0.70$ was used.

polymerization by Eq. 3 or, exactly, by Eq. 9. Some experimental and calculated values of $x$ at various times are listed in Table I and Table II, and predicted $x\sim t$ curves are also shown in Fig. 1, $\alpha=0.177$ being used in Eq. 9.

As seen in the figure, these two calculated curves coincide with each other almost perfectly below 20% conversion, and above it, they separate gradually. At high convertion, the difference becomes fairly appreciable. Such a fact must be taken into account when polymerization, are followed by large valume shrinkage as seen in the bulk polymerization of vinyl acetate. Comparing the predicted and experimental values of $x$ in each catalyst concentration, it seems that, at very low conversion, these values agree fairly well. In the second step, however, there appears a clear deviation between them which seems to appear at lower conversion in lower initial catalyst concentration. The accelerated polymerizations proceed almost linearly with respect to time. Then, there is a third step where the rate of the polymerization becomes explosive, and at the beginning of the step, production of gas bubbles was always seen. It made the dilatometric analysis impossible. Above 90% conversion, the viscous solution changed into hard plastic and the reaction ceased few percent less than perfect conversion. Since this anomalous rate acceleration cannot be considered as associated with change in $k_d$, it must be owing to change in $K$. The values of $K$ at any fractional conversions can be calculated by Eq. 8, in which the slope $dx/dt$ at $x$ may be obtained from Fig. 1, the value of $k_d$ being taken again as $1.20\times10^{-5}\,\mathrm{sec}^{-1}$ and as constant at any conversions. It must be noted that in deriving the values of $K$ from Eq. 8, it was tacitly assumed that the steady state for radicals holds even at the explosive step.

Remembering that $K=k_pk_d^{1/2}f^{1/2}/kt^{1/2}$, the values of $f^{1/2}k_p/kt^{1/2}$ were plotted against $x$ as shown in Fig. 3. The form of the curves in the figure is quite similar to one which was reported by other investigators[5,13].

From Fig. 3, it is obvious that the values of $f^{1/2}k_p/k_t^{1/2}$ are almost constant up to 20~30% conversion in every initial catalyst concentration. They increase gradually and then rapidly as $x$ increases. It is clear that the increase in $f^{1/2}k_p/k_t^{1/2}$ occurs at lower fractional conversion the lower the initial catalyst concentration is. The reasonable explanation is as follows: As has been pointed out by some investigators, the termination constant $k_t$ including two large growing polymer chains is first diffusion-controlled. The lower the catalyst concentration, the greater becomes the degree of polmerization and hence the viscosity of solution. If $k_t$ is affected first, the increase in viscosity will result in the decrease in $k_t$.

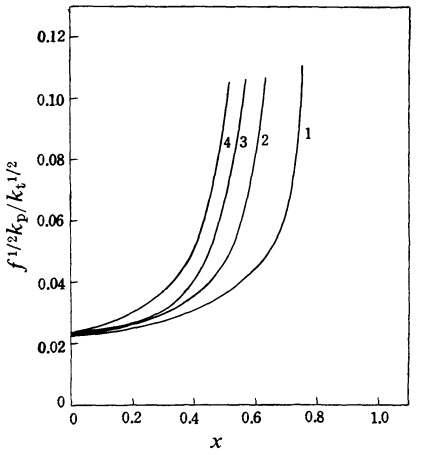

Fig. 3. $f^{1/2}k_p/k_t^{1/2}$ determined from the rate of polymerization data (Eq. 8) vs. $x$.
$[I]_0\times10^2$ mol./l.: 1, 5.00; 2, 2.00; 3, 1.00; 4, 0.36

The increase in $f^{1/2}k_p/k_t^{1/2}$ may also be reflected on the fact that the experimental conversions were higher than the predicted ones in each experiment with one exception. According to Eq. 5, as $A$ and hence $f^{1/2}k_p/k_t^{1/2}$ increase, the value of $x$ approaches unity.

The explosive polymerization is usually followed by an increase in the degree of polymerization. In the polymerization of styrene, the chain transfer to monomer is small and so, its contribution to the degree of polymerization may be neglected if catalyst concentration is properly chosen.

Since chain termination by combination is exclusive in the polymerization of styrene, the cumulative number average degree of polymerization $\bar{P}_n$ may be expressed approximately by Eq. 14. In Figs. 4 and 5, $\bar{P}_n$ is plotted against $x$.

Applying Eq. 14 ($f=0.7$ was used), the theoretical plots of $\bar{P}_n$ vs. $x$ are expressed by curves I and I′ in each figure, the volume shrinkage being neglected for simplicity. As seen in the figure, the predicted value of $\bar{P}_n$ is not so much affected by the fractional conversion unless the catalyst concentration is extremely small or very large. The experimental plots of $\bar{P}_n$ vs. $x$ which are denoted by curves II and II′, show that the values of $\bar{P}_n$ in each run agree fairly well with the predicted value up to 20~30% conversion. With $[I]_0=0.0036$ mol./l., the deviation is the greatest. However the value of $\bar{P}_n$ increases gradually thereafter, then more rapidly toward the last.

According to Eq. 14, $\bar{P}_n$ is a function of

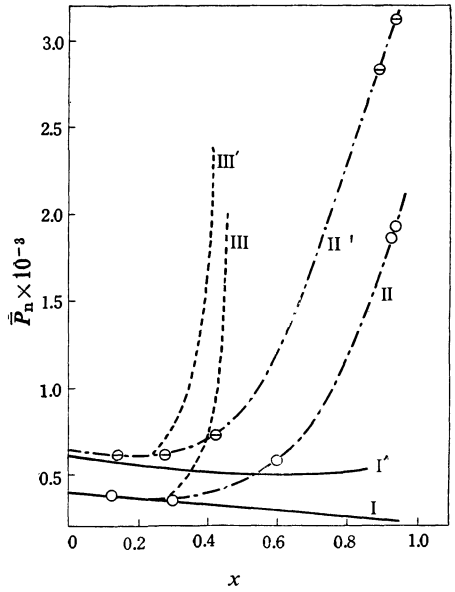

Fig. 4. Cumulative and instantaneous average degree of polymerization $\bar{P}_n$ and $\bar{\bar{P}}_n$ vs. $x$.

monomer and catalyst concentrations and catalyst efficiency. Accordingly, the (cumulative) catalyst efficiency $\bar{f}$ can be obtained on inserting the experimental values of $\bar{P}_n$, $[M]$ and calculated values of $[I]$ into Eq. 17. In Table I are listed some values of $\bar{f}$ which were calculated by Eqs. 15 and 16, the volume shrinkage being taken into account in the latter equation. As may be seen in Fig. 6, the values of $\bar{f}$ are plotted against $x$. The average value of $\bar{f}$ at low conversion is about 0.7, which is very close to the value obtained by Tobolsky et al.[5] It is of interest to note that the catalyst efficiency $\bar{f}$ seems to depend only upon conversion and not upon the initial concentration of the catalyst. The instantaneous catalyst efficiency $f$ which was calculated by Eq. 23 may also be seen in Fig. 6.

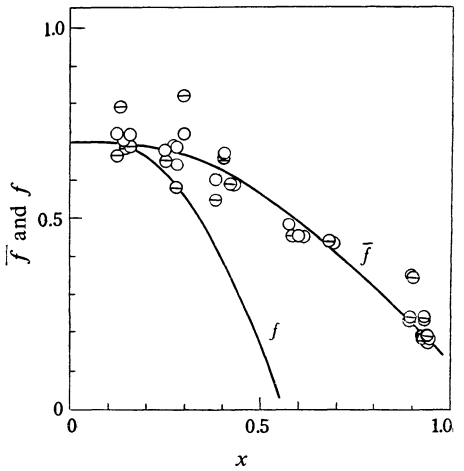

Fig. 6. Apparent dependence of cumulative and instantaneous catalyst efficiency $\bar{f}$ and $f$ upon $x$.
○ calcd. by Eq. 15; ⊖ calcd. by Eq. 16

The shape of the curves is similar to but somewhat different from that obtained by Robertson[13]. This true value of catalyst efficiciency at any $x$ decreases rapidly with increasing conversion. There is a doubt as to whether or not the catalyst efficiency is much affected by change in environment such as an increase in viscosity. Since the dimensions of the catalyst and the monomer are very small compared with the dimension of the polymer, it is unlikely that those molecules suffer an effect of diffusion in such a low conversion step. Hence it is very doubtful whether the catalyst efficiency is diffusion controlled. In deriving Eq. 16, it was tacitly assumed that the chain transfer to polymer does not take place and hence each polymer produced is a long chain molecule which has two catalyst fragments at its ends. If this is not so and the chain transfer to already dead polymers might occur

considerably Eq. 16 would no more be applied. If the chain transfers to polymers occur in such a manner as to cross-link together the polymers previously formed, a rapid increase in the average degree of polymerization will result. The apparent decrease in $f$ might be owing to this fact.

The instantaneous degree of polymerization $\overline{\overline{P}}_n$ at any conversion may be calculated by Eq. 15. In Figs. 4 and 5, $\overline{\overline{P}}_n$ is plotted against $x$ as shown in curves III and III'. As seen in these figures, each value of $\overline{\overline{P}}_n$ increases steeply toward infinity as $x$ increases. Above 40~50% conversion, the value of $\overline{\overline{P}}_n$ takes a negative value in each experiment.

This interesting phenomenon was first observed by Wall et al.[12] According to them, the formation of cross-linking of polymer molecules not only increases the average molecular weight, but simultaneously, diminishes the number of polymer molecules, thus accounting for the observed results. It is clear from the definition $\overline{\overline{P}}_n = -dM/dP$ that $\overline{\overline{P}}_n$ takes a negative sign when $dP$ is negative.

On account of the fact that any polymers produced by chain reactions must have a certain dispersion of molecular sizes, the study of size distribution in polymers is of great importance in connection with the kinetic mechanisms of polymerizations. Among several experimental techniques for the fractionation of polymers, those based on solubility are most generally used. However, the fractions obtained in any experimental techniques are always heterogeneous with respect to molecular weight and, so far, the problem of the overlapping of the polymer species has never been overcome.

The fractionations of two samples were carried out in order to obtain the distribution of molecular sizes at high conversion, and the results are listed in Table III. As an approximation, the degrees of polymerization in each fraction were calculated from the data of viscosity measurements, using the relation $\bar{P}_n = 1770 [\eta]^{1.40}$ which was applied for the unfractionated polymers.

TABLE III. FRACTIONATION RESULTS OF POLYMERS

| Fraction No. | Weight, g. | % | $\overline{DP}$ |
|---|---|---|---|
| Unfractionated | 6.000 | | 6853 |
| 1 | 1.347 | 22.7 | 26980 |
| 2 | 0.575 | 9.7 | 11480 |
| 3 | 1.174 | 19.7 | 9820 |
| 4 | 0.369 | 6.2 | 5681 |
| 5 | 0.745 | 12.5 | 4142 |
| 6 | 1.277 | 21.5 | 2258 |
| 7 | 0.455 | 7.7 | 818 |
| Unfractionated | 5.523 | | 3123 |
| 1 | 0.465 | 8.4 | 14090 |
| 2 | 0.788 | 14·3 | 8048 |
| 3 | 0.392 | 7.1 | 4508 |
| 4 | 1.279 | 23.2 | 2501 |
| 5 | 1.112 | 20.1 | 1183 |
| 6 | 1.140 | 20.7 | 652 |
| 7 | 0.344 | 6.2 | 242 |

The integral weight distribution curves were obtained by plotting the weight of each fraction as a function of the degree of polymerization, adding the weight of each fraction to the weight of the preceding fraction. The smooth lines drawn in Fig. 7 are the integral and differential weight distribution curves. The latter lines were obtained by taking the slope of the integral weight distribution curves as a function of the degree of polymerization.

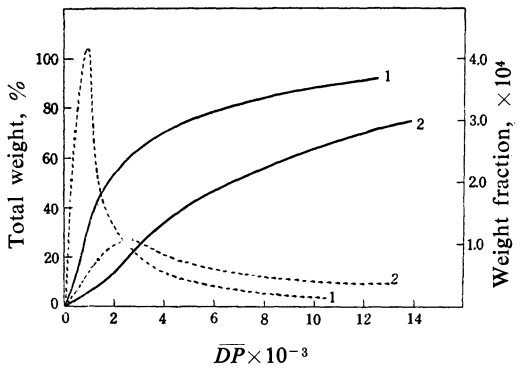

Fig. 7. Molecular weight distribution.
—— integral, ----- differental weight distributions
1: $[I]_0 = 0.02$ mol./l., $x = 0.941$, $\bar{P}_n = 3123$
2: $[I]_0 = 0.0036$ mol./l., $x = 0.903$, $\bar{P}_n = 6853$

It was pointed out by Guzmán[16] that this classical method of approaching the problem about molecular weight distribution is rather imperfect because there is an inevitable source of error such as the overlapping of polymer species. He compared the results obtained by the classical procedure with those obtained statistically, based on the same experimental data, and showed that there was a considerable difference between them. In spite of being more logical and reasonable, the statistical approach involves a great labor of mathematical computation and is not easy to handle.

Instead, the size distribution curves of the polymer at conversion $x = 4\%$ were drawn as shown in Fig. 8 in accordance with Eq. 21 which was derived from the kinetic mechanism of the initial polmerization step alone.

16) G. M. Guzmán, *J. Polymer Sci.*, **19**, 519 (1956),

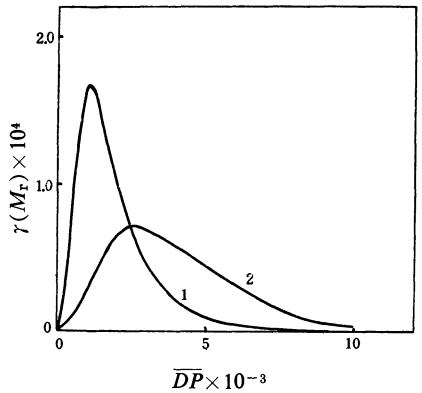

Fig. 8. Theoretical differential weight distributions (Eq. 19) at $x=0.04$.
1: $[I]_0=0.02$; 2: $[I]_0=0.0036$ mol./l.

It is clear from Figs. 7 and 8 that there is a considerable difference between experimental and calculated differential weight distributions. The shape of the corresponding curves up to the maximum weight fraction is very similar. However, beyond this, the experimental curves fall much less rapidly and unsymmetrically than do the calculated ones.

It may reasonably be assumed that the experimental molecular weight distribution consists of two parts, normal and abnormal distributions of molecular species. The part of the normal distribution may correspond to that which can be obtained from the initial stage of polymerization, while the part of the abnormal distribution may arise from the explosive polymerization. The kinetic treatment of such abnormal weight distribution may be complex. Nevertheless, it is of great interest that the result of explosive polymerization is reflected on such weight distribution.

From the study of the molecular weight distribution, it seems that the abnormal increase of the degree of polymerization at high conversion is not owing to the chain transfer to the already dead polymers, but is, probably, owing to the burying of the growing polymer radicals, because the produced polymer at high conversion involves a considerable part of low molecular weight.

## Summary

The bulk polymerization of styrene initiated by 2, 2′-azobisisobutyronitrile was carried out up to high conversion at 60°C. The comparison of the experimental conversion~time data with calculated ones showed that there was a considerable deviation between them. The rate of the polymerization became explosively great toward the last.

Assuming the combination termination, the cumulative degree of polymerization was calculated and the values were compared with those obtained experimentally. The deviation at high conversion might be owing to the decrease in the catalyst efficiency as suggested by Robertson. However, the assumption that the polymer molecules have been produced only by combination is very doubtful.

The study of the molecular weight distribution suggested that the abnormal increase in the rate and the degree of polymerization seemed to be owing to the burying of the growing polymer radicals in themselves in the highly viscous solution.

The author wishes to express his thanks to Professor Shigeo Hasegawa and Professor Nishio Hirai for helpful suggestions and encouragement.

# *On the pd Hybridization of the Sulfur Atom in Thiothiophten. II. The Contraction of the d Orbital*

By Kôgorô MAEDA

(Received December 27, 1960)

In the previous paper of this series[1], the pd hybridization was proposed on the central sulfur atom in thiothiophten to compose the full $\sigma$ skeleton of condensed ring system of the molecule. It was shown that the above configuration of electrons on the central sulfur atom is favored in accounting for both the so-called abnormal length of the bond between two sulfur atoms and the right angle of S-S-C, and that the electronic structure of thiothiophten can be treated according to the usual LCAO $\pi$ approximation without considering the $\sigma$ skeleton, unlike the procedure proposed by Giacometti and Rigatti[2]. Further, the possibility of participation of the d orbital in the hybridization was examined from the standpoint of overlap criterion, giving the values of the overlap integrals. As the result of the inspection, however, it turned out that one might not except any participation of the d orbitals in bonding to occur through the hybridization. It was pointed out there that this may be due to the straightforward application of Slater's rule[3] to the estimation of the effective nuclear charges for the d orbitals. As already mentioned, since the maximum of the radial function of the d orbital with its effective nuclear charge required by Slater's rule lies at 9 atomic units, the orbital may be regarded as including the full $\sigma$ skeleton of thiothiophten, so that it would be impossible to avoid the influence of the neighboring atoms in the molecule. The charges of the atoms may contract the d orbital and enlarge its nuclear charge, leading to a value of overlap integral comparable to that of 3p orbital. Contraction of this kind was once examined in the case of the d orbital in thiophene[4], where it might be expected that as the result of the contraction by the perturbation of neighboring carbon atoms, the participation of the d orbitals in bonding would take place to a greater extent than predicted by the direct application of free atom parameter by Slater's rule.

In the present paper, following the treatment about the d orbital of the sulfur atom in thiophene, the influence of neighboring atoms upon the d orbital will be examined on the central sulfur atom in thiothiophten and the possibility of the participation in the hybridization will be inquired into from the standpoint of overlap criterion, comparing the values of overlap integral.

**Orbital Contraction.**—A model is employed here, in which a single d electron on the central sulfur atom is supposed to move in the field of the nucleus of charge $Z_S$, and upon this hydrogen-like atom system a perturbation is superposed consisting of three positive charges of the neighboring atoms of thiothiophten. The positive charges come because the field of an atom capable of forming a covalent bond is substantially electron-attracting. The perturbing charges are composed of those of the two sulfur atoms of magnitude $Z_A(=Z_B)$ at the distance of S-S bond, 4.461 atomic units ($\sigma_A(=\sigma_B)$) and of the carbon atom of $Z_C$ at the distance of central C-S, 3.440 atomic units ($\sigma_C$). These charges will be treated, not as three hydrogen-like atoms, but just as point charges of respective magnitudes. The actual potential of the perturbation is very intricate because it involves many factors, the attraction of the surrounding nuclei, the coulomb repulsions of their electrons, exchange terms, and others; hence the dependence on distance of the potential will not follow the $r^{-1}$ law at all closely. The system being thus too complicated to be considered, the point charge model is employed as approximation in this paper. The magnitudes of the perturbing charges will be treated rather as parameters, values plausible in a wider range being involved.

Under this point charge approximation, the potential by the outlying charges may be expanded as a sum in the usual $1/r$ series[5] as follows:

For the two charges of sulfur atoms,

4) K. Maeda, This Bulletin, 33, 303 (1960); The idea of orbital contraction was first given by D. P. Craig and E. A. Magnusson, *J. Chem., Soc.*, **1956**, 4895.
5) H. Eyring, J. Walter and G. E. Kimball, "Quantum Chemistry", John Wiley & Sons Inc., New York (1944), p. 369.

$$V_{A,B}(r>\sigma_A) = -(2Z_A/r)\{1+(1/2)(3\sin^2\vartheta \times\cos^2\varphi-1)(\sigma_A/r)^2+\cdots\cdots\}$$
$$V_{A,B}(r<\sigma_A) = -(2Z_A/\sigma_A)\{1+(1/2)(3\sin^2\vartheta \times\cos^2\varphi-1)(r/\sigma_A)^2+\cdots\cdots\}$$

and for the carbon atom,

$$V_C(r>\sigma_C) = -(Z_C/r)\{1+\sin\vartheta\sin\varphi\,(\sigma_C/r) +(1/2)(3\sin^2\vartheta\sin^2\varphi-1) \times(\sigma_C/r)^2+\cdots\cdots\}$$
$$V_C(r<\sigma_C) = -(Z_C/\sigma_C)\{1+\sin\vartheta\sin\varphi\,(r/\sigma_C) +(1/2)(3\sin^2\vartheta\sin^2\varphi-1) \times(r/\sigma_C)^2+\cdots\cdots\}$$

The perturbation energy due to the outlying potential is given by $\int\psi v\psi d\tau$, where $\psi$ is the d electron wave function of the usual Slater type. As the wave function, two for the d orbital are taken, $3d_z$ and $3d_{xy}$ (notation of Pauling and Wilson[6]), which were discussed in the previous paper[2]. In integrating the two orbitals, one must pay some attention to the orientation of the $3d_z$ orbital, because in the present consideration the Z-axis is taken to be normal to the molecular plane, and the Y-axis goes along the central C-S bond. The oribital should be rotated by 90° about the Y-axis. After the rotation, the angular part of the orbital, $(3\cos^2\vartheta-1)$, turns into $(3\sin^2\vartheta\times\cos^2\varphi-1)$. Hereafter, the orbital is described as $3d_{x(z)}$ in this paper.

The total perturbation energy is given as the sum of the energies by the above three positive charges, and the terms higher than the 2nd of the potential may be neglected because of their small contributions to the energy. Hence, after the integration, the respective energies of the two orbitals are given as follows:

For $3d_{x(z)}$

$$E = -(2Z_A/\sigma_A)\{\sigma_A R^0_{33}(\alpha\sigma_A) +(2/7)\sigma_A R^2_{33}(\alpha\sigma_A)\} -(Z_C/\sigma_C)\{\sigma_C R^0_{33}(\alpha\sigma_C) -(1/7)\sigma_C R^2_{33}(\alpha\sigma_C)\}$$

and for $3d_{xy}$

$$E = -(2Z_A/\sigma_A)\{\sigma_A R^0_{33}(\alpha\sigma_A) +(1/7)\sigma_A R^2_{33}(\alpha\sigma_A)\} -(Z_C/\sigma_C)\{\sigma_C R^0_{33}(\alpha\sigma_C) +(1/7)\sigma_C R^2_{33}(\alpha\sigma_C)\}$$

where $R^p_{nn}(\alpha\sigma)$ is the auxiliary function which was used in the case of thiophene[4], and its explicit form is

$$R^p_{nn}(\alpha\sigma) = (1/\sigma)(2\alpha\sigma/n)^{2n+1}\{1/(2n)!\} \times\{(2n+p)!\times(n/2\alpha\sigma)^{2n+p+1} -A_{2n+p}(2\alpha\sigma/n)+A_{2n-p-1}(2\alpha\sigma/n)\}$$

where

$$A_n(\omega) = \int_1^\infty r^n\exp(-\omega r)dr$$

In the above expressions, $\alpha$ is a parameter to be determined to minimize the total energy which is the sum of the perturbation energy and the unperturbed given by

$$W = (\alpha/3^2)(\alpha/2-Z_s)$$

for the hydrogen-like orbital of free atom parameter $Z_s$; that is, the procedure to be performed now is to find the new value of effective nuclear charge for which the total energy is a minimum for given magnitudes of $\sigma_A$, $\sigma_C$, $Z_A$ and $Z_C$. The new value of the charge will offer an appropriate basis for the discussion about the d orbital under the perturbation.

In conducting the procedure, it is necessary to set the values of $Z_s$, $Z_A$ and $Z_C$. As the value of $Z_s$, 1 and 2 are chosen, and for $Z_c$ three values are taken, 1, 2 and 3, which were used in the case of thiophene[4]. With respect to the value of $Z_A(=Z_B)$, four values are assigned, 1, 3, 5 and 6. All the above values are to be treated as tentative parameters. In the real system, it is difficult to determine the straightforward values of the parameters equivalent to the outlying potential, because, as mentioned above, the real field is not truly coulombic but much more complicated. Furthermore, there is, in general, a considerable difference between so-called potential- and field-determined nuclear charge on the same atom[7]. Hence, in this paper, some attention will be paid rather to a variation in $\alpha$ by adopting the values of the above parameters in wider range. In finding the minimum of the total energy, it is necessary to know the values of $\sigma R^p_{nn}(\alpha\sigma)$, which are taken from the table in the previous paper[4].

In Table I are given the results. From this table it is found that the new values of the effective charges under perturbation are considerably greater compared with those of free atom parameters, without exception, and furthermore that there are only small variations between these values despite the adoption of a wider range of the parameters. In the case of thiophene, it was shown that the magnitude of the new value is more sensitive to the bond distance $\sigma$ than to the parameters for the outlying potential, and that it is little altered

| 2 | 2 | 2.90 | 3.10 | 3.15 | 3.20 |
| 2 | 3 | 3.05 | 3.10 | 3.25 | 3.30 |

II. $3d_{x(z)}$

| | | | | | |
|---|---|---|---|---|---|
| 1 | 1 | 2.34 | 2.63 | 2.75 | 2.82 |
| 1 | 2 | 2.50 | 2.70 | 2.83 | 2.88 |
| 1 | 3 | 2.63 | 2.80 | 2.86 | 2.94 |
| 2 | 1 | 2.68 | 2.88 | 2.96 | 3.00 |
| 2 | 2 | 2.90 | 3.02 | 3.02 | 3.05 |
| 2 | 3 | 3.05 | 3.12 | 3.15 | 3.10 |

by the charges of neighboring atoms in the range 2~3 when $\sigma=3$ and 4. In the present consideration, with respect to the bond distance $\sigma$, the fixed values are assigned, $\sigma_A(=\sigma_B)$ and $\sigma_C$, which are taken from the actual distances in thiothiophten, obtained from the X-ray analysis study by Bezzi, Mammi and Garbuglio[8]. Considering the above situation in thiophene, therefore, the present results may be convincing in regard to making fast the values of $\sigma$. This fact is worthy of notice, because to obtain the same results through the different starting points of $Z_s$ might indicate the existence of a self-consistent value of $\alpha$ appropriate for the perturbation in which the geometrical configuration of the outlying potential to the atom in question is settled. In fact, the values given in the Table would serve as the first steps of the procedure to the self-consistent value. The value would probably remain settled near 3~4. Of course, it must be emphasized that this discussion on the effective value for $\alpha$ is by all means of tentative character under the present point charge approximation. Furthermore, the value of $\alpha$ appropriate to the real system should be determined precisely with respect to the whole energy of the molecule. The values in the Table, however, may be used as useful clues to the studies about the behavior of the d orbital on the central sulfur atom in thiothiophten.

From these discussions, it might be inferred in any case that the effective nuclear charge for the d orbital on the central sulfur atom in thiothiophten would not bear the free atom parameter, but it should bear a greater value considering the influence by the surrounding nuclei, probably near 3~4. As suggested earlier in this paper, the value for the d orbital will furnish an appropriate basis of the discussion about the orbital.

**Overlap Integral.** — In the previous section, the influence of the surrounding nuclei upon the d orbital was examined, and the results were given in Table I. Using these results, the overlap integral with the 3p $\sigma$ orbital of the neighboring sulfur atom were estimated for the corresponding values of $Z_s$, $Z_A$ and $Z_C$. These are given in Table II. In calculating these values, the tables of the integrals given in the previous paper[1b] were used, and as the effective nuclear charge for the 3p orbital, the direct value through Slater's rule was assigned, because it was shown that the value for 3p is little affected by the outlying perturbing charges when $\sigma=3$ and 4, and moreover, because, although it was accurate in the case of thiophene[4], in general, the contraction of the orbital is great only when the orbital with high screened and loosely bound electrons lies under the perturbation.

TABLE II. OVERLAP INTEGRALS OF 3d ORBITALS WITH 3p ORBITALS OF NEIGHBORING S ATOM

I. $3d_{xy}$

| $Z_s$ | $Z_c$ | $Z_A(=Z_B)$ 1 | 3 | 5 | 6 |
|---|---|---|---|---|---|
| 1 | 1 | 0.082 | 0.129 | 0.148 | 0.163 |
| 1 | 2 | 0.113 | 0.145 | 0.161 | 0.166 |
| 1 | 3 | 0.138 | 0.161 | 0.170 | 0.172 |
| 2 | 1 | 0.141 | 0.173 | 0.173 | 0.178 |
| 2 | 2 | 0.161 | 0.178 | 0.181 | 0.185 |
| 2 | 3 | 0.173 | 0.178 | 0.189 | 0.192 |

II. $3d_{x(z)}$

| | | | | | |
|---|---|---|---|---|---|
| 1 | 1 | 0.092 | 0.143 | 0.162 | 0.173 |
| 1 | 2 | 0.121 | 0.154 | 0.175 | 0.181 |
| 1 | 3 | 0.143 | 0.170 | 0.178 | 0.190 |
| 2 | 1 | 0.151 | 0.181 | 0.192 | 0.195 |
| 2 | 2 | 0.183 | 0.197 | 0.197 | 0.200 |
| 2 | 3 | 0.200 | 0.206 | 0.210 | 0.204 |

The values in Table II are all positive and of the order of 0.1~0.2. Craig et al.[9] once proposed that for significantly strong binding a value of the overlap integral of about 0.1 or greater is necessary. According to this proposition, one might expect some significant binding to take place between the 3d and the 3p orbitals. The participation of the d orbital to bonding is performed through the pd hybridization in the present problem, and whether the d orbital is to be used or not depends, amongst other factors, upon whether the overlap integral involving the d orbital is comparable

to that of 3p in terms of overlap approximation employed here. Therefore, the integral between $3p\sigma$ orbitals of S-S bond in thiothiophten was estimated, for the sake of comparison, using free atom parameters, and it was obtained as 0.243. In estimating this value, Table III given in the present paper was used. The overlap integral $S(3p\sigma-3p\sigma)$ was once given by Mulliken et al. for $t=0$[10], and also by Craig et al., who evaluated the values with parameters $p$ and $t$ in the ranges of 2∼10 and 0∼0.5 at the respective intervals of 1.0 and 0.1[11]. In the present paper, the values with $p$ in the wider range of 0∼10 at the intervals of 0.5 were calculated, and in Table III are given the results obtained.

From the above estimation of the overlap integrals, it is found that almost comarable values are obtained for both the integrals involving the 3p and the 3d orbitals. These values would become more close when the so-called self-consistent value above mentioned may be used as the effective nuclear charge for the d orbital. Then, it may be said that the participation of the d orbital in the hybridization is more favorable than predicted through the direct employment of free atom parameters by Slater's rule, and that the extent to which the d orbital participates in bonding through the hybridization will be of the order nearly the same as, or at least not much less than, that of the 3p orbital. These results may be somewhat deficient in precision under the present point charge and overlap approximations employed in this paper. However, they may be sufficiently valid for discussing semi-quantitatively how the d orbital behaves under the perturbation in the actual molecule.

It is of interest to notice that the values of the overlap integral for the 3d orbital lie very nearly at the corresponding maxima for the respective effective nuclear charges of the orbital (see Tables I and III in Ref. 2). These values approach more nearly to the maxima when the self-consistent values under the present perturbation, 3∼4, may be used, or when a larger value of the distance between the orbitals is adopted. This is because the parameter $p$ in the calculation of overlap integral involves the distance between the orbitals. Hence the so-called abnormal length of S-S bond in thiothiophten may be rather consistent to give the greater possibility of participation of the d orbital in the hybridization.

**Hybrid Orbitals.** — From the above considerations, it is found that the d orbitals on the central sulfur atom in thiothiophten might be able to participate in the hybridization to the same as, or at least to an extent comparable to that of the 3p orbital. Then the hybrid orbitals may be written with the same mixing coefficient for the two d orbitals in question as follows:

For $3d_{xy}$,

$$(1/\sqrt{2})\,(\psi_{3d_{xy}}\pm\psi_{3p})$$

10) R. S. Mulliken, C. A. Rieke, D. Orloff and H. Orloff, *J. Chem. Phys.*, **17**, 1248 (1949).
11) D. P. Craig, A. Macoll, R. S. Nyholm, L. E. Orgel and L. E. Sutton, *J. Chem. Soc.*, **1954**, 332.

and for $3d_{x(z)}$,

$$(1/\sqrt{2})(\psi_{3d_{x(z)}} \pm \psi_{3p})$$

The mixing coefficient is fortunately compatible with the conditions required from the linear bond of S-S-S in thiothiophten and the symmetrical skeleton of the molecule[12]. The approximate forms of the hybrid orbitals were already shown in Fig. 2 of the previous paper[1b].

Of the two sets of hybrid orbitals, those involving the $3d_{x(z)}$ orbital may be more probable for participating in the hybridization to form the S-S-S bond in thiothiophten, because the values of the overlap integral are greater for the $3d_{x(z)}$ than for the $3d_{xy}$ with corresponding $p$ and $t$ values.

All the above discussions are those under the point charge approximation and within the framework of the overlap criterion. Therefore it is more or less inevitable that the results obtained in this paper should not be so readily sufficient for an accurate discussion of the formation of the possibe bond in thiothiophten. Furthermore, in fact, the accurate discussion dealing with the final determining factor in bonding, that is, on balancing of energy should be taken up for consideration with respect to the whole molecule of thiothiophten. Nevertheless, the results obtained above will be valuable enough for approximate and semi-quantitative discussion about the possibility of participation of the d orbital in the central sulfur atom in thiothiophten. Therefore it can now be said that the structure of thiothiophten is not one involving the no-bond resonance structure proposed by Bezzi et al.[8], but rather it may be the condensed ring system of the full $\sigma$ skeleton involving the hybrid orbitals on the central sulfur atom of the molecule.

# *Studies on Organophosphorus Compounds. II. On Phosphite Cuprous Halide Complex Compounds*[*1]

By Yoshihiko NISHIZAWA

(Received November 26, 1960)

Although many workers have studied complex compounds having phosphorus atom, many of them reported on phosphine[*2] complex compounds such as phosphine platinum halides[1], phosphine cuprous iodides[2] and phosphine chromium halides[3], while phosphite complex compounds were reported on only by Arbuzov[4] and others.

Arbuzov has reported that phosphites give phosphite cuprous halide complex compounds which have two experimental formulae, $(RO)_3PCuX$(I) and $[(RO)_3P]_2CuX$ (II), and that *O,O*-dialkyl phosphonates give no complex compounds. Therefore, this reaction has been utilized as an identification of phosphite from phosphonate.

The present author separated two compounds having formulas I and II and measured their molecular weights in various organic solvents. It was made clear as a result, that these complex compounds showed an interesting behavior in organic solvents and reacted with pyridine, aniline and their analogues and produced new complex compounds having phosphites and amines.

**Preparation of Phosphite Cuprous Halide Complex Compounds.**—Phosphite cuprous halides were prepared by the reaction of phosphite with cuprous halide in a benzene solution. After cuprous halides were dissolved in benzene, the benzene was evaporated under reduced pressure, the complex compounds were obtained as white crystals or colorless oil.

Changing the mole ratio of phosphites to cuprous halides obtained two complex compounds, namely, phosphite cuprous halides I and bis-phosphite cuprous halides II. Triphosphite cuprous halide could not be prepared from three moles of phosphite and one mole

It is clear from the following experimental facts that these complex compounds I and II have the phosphite group in their molecules. These compounds reacted with acetyl chloride in benzene solution to give *O,O*-dialkyl-acetyl phosphonates (A) and cuprous halides. The melting point of *p*-nitrophenylhydrazone of the phosphonate A coincided with that of *p*-nitrophenylhydrazone of the product prepared from trialkyl phosphite and acetyl chloride by Arbuzov's reaction[5].

$$[(RO)_3P]_nCuX \xrightarrow{n\cdot CH_3COCl} n\cdot(RO)_2\overset{\overset{O}{\|}}{P}-COCH_3 + CuX + n\cdot RCl$$

(A) → *p*-Nitrophenylhydrazone

$$(RO)_3P + CH_3COCl \rightarrow (RO)_2\overset{\overset{O}{\|}}{P}-COCH_3 + RCl$$

(*n* is 1 or 2 and R is alkyl group).

The infrared absorption spectra*3 of these

compounds I and II showed the absorption band of *P-O*-isopropyl group at 1010 $cm^{-1}$ or *P-O*-phenyl group at 1200 $cm^{-1}$ according to the kinds of phosphites in complex compounds I and II. (see Figs. 1 and 2).

However, the absorption bands of P-O stretching vibration[6] of phosphite at 857 and 769 $cm^{-1}$ shift to 879 and 779 $cm^{-1}$ respectively. Form this shift, it is considered that P-O bonds are shortened by the formation of the complex, namely, the bonding strength of P-O in these complex compounds becomes stronger than that of phosphite (see Figs. 1 and 2).

In the ultraviolet absorption spectra*4 of these complex compounds, absorption maximum $\lambda_{max}$ of phosphite at 263.5 shifts to 265 and absorption bands became more broad by the formation of complex (see Fig. 3). This shift seems to show the usual correlation between the coordination compound and its donor[7].

**Molecular Weights of Phosphite Cuprous Halide Complex Compounds.**—The molecular weights of these complex compounds were measured by the cryoscopic method[8] in benzene, bromoform and cyclohexane, which are all prepared by purification of guaranteed reagents in the usual manner[9].

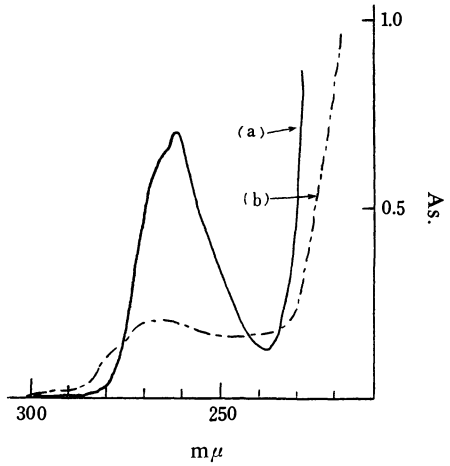

Fig. 3. Ultraviolet absorption spectra (in ethanol) of (a) triphenyl phosphite and (b) bis-(triphenyl phosphite) cuprous Chloride (IIb).

The results of these experiments are shown in Tables III and IV.

It is clear from Tables III and IV that the complex compounds I form associated molecules in organic solvents and that the degree of association are changed according to the kinds of halogens or solvents; on the contrary, the complex compounds II form simple molecules in organic solvents unconcerned with the kinds of halogens or solvents.

It seems to be possible that the apparent values of molecular weights will become smaller, if the associated molecules are dissociated in organic solvents. These possibilites are supported by the fact the degrees of association in nonpolar solvents are greater than that in polar solvent.

So, the present author prepared phenyl phosphonite, which is an analogue of phosphite but has the property of phosphine to a slight degree, and leads[10] to the complex compounds III and IV.

**Preparation and Molecular Weight of *O, O*-Diisopropylphenyl Phosphoniten Cuprous Halides (III) and (IV).**—Complex compounds III and IV were prepared from *O, O*-diisopropylphenyl phsophonite[11] and cuprous halide by the same method as phosphite I and II. The yield, the melting points and the microanalytical data of the complex compounds III and IV are shown in Table V.

As is clearly shown in Table VI, phenyl phosphonite cuprous halides (III) form tetramer and bis-(phenyl phosphonite) cuprous halides (IV) form dimer in organic solvents irrespectively of the kinds of halogens or solvents.

From the above results of Table VI and phosphine cuprous iodide which is reported as tetramer[2], it may be considered that complex compounds I will also be tetramer and complex compounds II dimer but these compounds I and II will be dissosiated in organic solvents.

But the real structures of these compounds must be determined by x-ray analysis.

**Phosphite Cuprous Halide Amine Complex Compounds.**—It was mentioned already that phosphite cuprous halides I reacted with more one mole ratio of phosphite and gave bis-phosphite cuprous halides II. In this reaction when aniline, pyridine and their derivatives are used instead of the phosphite, new complex compounds were prepared[12] on the contrary bis-phosphite cuprous halides II did not react with the above amines.

That is to say, to the acetone solution containing one mole of phosphite cuprous halides I, one mole of aniline, pyridine or their derivatives wasadded and thus, white crystals were obtained. These crystals had sharp melting points and showed the experimental formula of $(RO)_3PCuX\cdot$ Amine.

$$\underset{(I)}{(RO)_3PCuX} + \text{Amine} \rightarrow \underset{(V),\ (VI)}{(RO)_3PCuX\cdot\ \text{Amine}}$$

Changing the mole ratio of amines to phosphite cuprous halides I neither phosphite cuprous halide bis-amines $(RO)_3PCuX(Amine)_2$

nor bis-amine cuprous halides $(Amine)_2CuX$ were obtained.

The yields, the melting points and the microanalytical data of these new complex compounds V and VI are shown in Table VII. The infrared absorption spectra of these complex compounds V and VI showed that these compounds V and VI have both the amine molecule and the phosphite molecule. Infrared absorption spectrum of triethyl phosphite cuprous iodide $\alpha$-picoline (Ve) is shown in Fig. 4 as a representation.

It was interesting to see that ortho-substituted anilines, *O*-chloroaniline, *O*-toluidine, *O*-anisidine etc., did not give these complex compounds VI. The cause may be considered from models of complex molecules to be a steric hindrance owing to the ortho-substituent in aniline.

In the pyridine series, all derivatives gave new complex compound, irrespective of the position of substituents.

It was also made clear by the present author that all of the above mentioned compounds I, II, III, IV, V and VI had strong fungicidal activities[13], and the data of their biological activities will be reported in other paper.

## Experimental

**Preparations of Phosphites.**—Trialkyl or triphenyl phosphites were prepared by Ford-Moore's methods[14] and their yields, physical constants and microanalytical data are shown in Table VIII.

**Preparation of Diisopropyl Phenyl Phosphonite.**—This phosphonite was prepared from phenyl dichlorophosphine and isopropyl alcohol by Arbuzov's method[11]. The boiling point is 110°C/0.5 mmHg, the refractive index is $n_D^{25}$ 1.5000 and the yield is 84%.

Found, P, 13.7; C, 63.59; H, 8.59. Calcd. for $C_{12}H_{19}O_2P$, P, 13.7; C, 63.72; H, 8.41%.

**Preparation of Phosphite or Phosphonite Cuprous Halides I or III.**—The following example illustrates the preparation of phosphite or phosphonite cuprous halides I or III. Other examples are shown in Tables I and V and their molecular weights are shown in Tables III and VI.

**Preparation of Diisopropyl Phenyl Phosphonite Cuprous Chloride (IIIa).**—To a solution of 14.3 g. (0.05 mol.) of diisopropyl phenyl phosphonite in 50 ml. of benzene was gradually added 4.95 g. (0.05 mol.) of cuprous chloride. The temperature rose gradually and cuprous chloride was dissolved in benzene. After one hour's stirring, the trace of insoluble matter was filtered off and concentrated under reduced pressure. White crystals (18.9 g,.

13) J. Hattori and Y. Nishizawa, Japan. Pat. Applied No. 36382 (1958), 3506, 22572, 22573 (1959).

14) A. H. Ford-Moore, "Organic Syntheses", Vol. 31, John Wiley & Sons, New York, (1951), p. 111.

98.5%) were obtained and recrystallized from petroleum ether, m. p. 141~142°C.

Found: Cl, 10.88; P, 9.4; Cu, 19.8. Calcd. for $C_{12}H_{19}O_2PCuCl$: Cl, 10.92; P, 9.5; Cu, 19.5%.

**Preparation of Bis-phosphite or Bis-phosphonite Cuprous Halides II or IV.**—The following example illustrates the preparation of bis-phosphite or bis-phosphonite cuprous halides II or IV. Other examples are shown in Tables II and V and their molecular weights are shown in Tables IV and VI.

**Preparation of Bis-(diisopropyl Phenyl Phosphonite) Cuprous Chloride (IVa).**—The compound was prepared from 28.5 g. (0.1 mol.) of diisopropyl phenyl phosphonite and 4.95 g. (0.05 mol.) of cuprous chloride in benzene solution as above mentioned. White crystals (32.9 g., 98.4%) were obtained and melted at 144~145°C (from ligroin).

Found: Cl, 6.39; P, 11.0; Cu, 11.9. Calcd. for $C_{24}H_{38}O_4P_2CuCl$: Cl, 6.44; P, 11.2; Cu, 11.5%.

**Reaction of Triisopropyl Phosphite Cuprous Chloride (Ia) with Triisopropyl Phosphite.**—To a solution of 15.3 g. (0.05 mol.) of triisopropyl phosphite cuprous chloride (Ia) in 50 ml. of benzene was added 10.4 g. (0.05 mol.) of triisopropyl phosphite. The temperature did not rise during this addition. The benzene was evaporated under reduced pressure, white crystals (23.8 g.) were obtained and melted at 69~70°C. A mixture of the crystals and the authentic bis-(triisopropyl phosphite) cuprous chloride which was prepared from two moles of triisopropyl phosphite and one mole of cuprous chloride, melted at 69~70°C.

**Reaction of Triethyl Phosphite Cuprous Chloride[4] with Triphenyl Phosphite.**—Triphenyl phosphite (15.5 g., 0.05 mol.) was added to a solution of 13.3 g. (0.05 mol.) of triethyl phosphite cuprous chloride in 50 ml. of benzene. After the benzene was evaporated off, white crystals of triethyl phosphite triphenyl phosphite cuprous chloride (IIg) (28.1 g, 97.8%) were obtained and melted at 75~76°C.

Found: Cl, 6.15; P, 11.2; Cu, 10.8. Calcd. for $C_{24}H_{30}O_6P_2CuCl$: Cl, 6.17; P, 10.9; Cu, 11.0%

**Reaction of Bis-(triisopropyl phosphite) Cuprous Chloride (IIa) with Cuprous Chloride.**—There was added 4.95 g. (0.05 mol.) of cuprous chloride to a solution of 25.7 g. (0.05 mol.) of bis-(triisopropyl phosphite) cuprous chloride (IIa) in 50 ml. of benzene. After cuprous chloride was dissolved in benzene, the reaction mixture was filtered off and concentrated. White crystals (29.6 g) were obtained and melted at 117°C.

This melting point coincides with that of the authentic triisopropyl phosphite cuprous chloride (Ia) prepared from one mole ratio of triisopropyl phosphite and one mole ratio of cuprous chloride, and the mixed melting point was not depressed.

**Reaction of Triethyl Phosphite Cuprous Iodide (Ie) with Acetyl Chloride.**—To a solution of 17.8 g. (0.05 mol.) of triethyl phosphite cuprous iodide (Ie) in 50 ml. of benzene, there was gradually added 3.9 g. of acetyl chloride. The temperature of the reaction mixture rose and white inorganic compounds were precipitated. After one hour's refluxing, the precipitates were filtered off and the filtrate was concentrated. The residual oil was fractionated under reduced pressure. The main product was distilled at 78~79°C/3 mmHg, and yielded 7.7 g.

$n_D^{20}$ 1.4209. Found: P, 17.1; C, 39.81; H, 7.34. Calcd. for $C_6H_{13}O_4P$: P, 17.2; C, 40.00; H, 7.22%. *p*-Nitrophenylhydrazone of the aforesaid main product was prepared from *p*-nitrophenylhydrazine in the usual manner.

This hydrazone melted at 131~132°C (recryst. from ethanol) and the mixed melting point with authentic *p*-nitrophenylhydrazone of *O,O*-diethyl-acetyl phosphonate prepared from triethyl phosphite and acetyl chloride was not depressed.

Found: P, 9.6; C, 45.59; H, 5.89; N, 13.31. Calcd. for $C_{12}H_{18}N_3O_5P$: P, 9.8; C, 45.71; H, 5.71; N, 13.33%

**Pyrolysis of Bis-(triisopropyl Phosphite) Cuprous Chloride (IIa).**—The compound IIa (25.8 g., 0.05 mol.) was set in a distillation flask (50 ml.) which was combined with a trap cooled at −50°C and heated at 100°C under 0.3 mmHg for 6 hr.

The crystals IIa melted and then crystallized again. The product was recrystallized from petroleum ether and melted at 116~117°C. This melting point coincides with that of the authentic triisopropyl phosphite cuprous halide (Ia) prepared from one mole ratio of triisopropyl phosphite and one mole ratio of cuprous chloride and the mixed melting point was not depressed.

On the other hand, colorless oil which was captured in a trap, was distilled at 60~62°/9mmHg and yielded 7.7 g, $n_D^{28}$ 1.4081.

Found: P, 14.6; C, 15.80; H, 10.35. Calcd. for $C_9H_{21}O_3P$: P, 14.9; C, 15.92; H, 10.10%

This oil was added to a benzene solution containing 5.3 g. of cuprous chloride and gave white crystals which melted at 116~117°C. The melting point of these crystals coincided with the authentic triisopropyl phosphite cuprous chloride (Ia) and the mixed melting point was not depressed.

**Reaction of Phosphite Cuprous Halides I with Amines.**—The following example illustrates the preparation of phosphite cuprous halide amine complex V or VI. Other examples are shown in Table VII.

**Reaction of Triethyl Phosphite Cuprous Chloride with Pyridine.**—To a solution of 26.5 g. (0.1 mol.) of triethyl phosphite cuprous chloride in 100 ml. of acetone was added 7.9 g. (0.1 mol.) of pyridine.

The acetone was evaporated off under reduced pressure and light green crystals (33.9 g.) were obtained. White needles were recrystallized from ligroin and melted at 56~57°C.

Found: N, 4.22; Cl, 10.00; P, 8.9; Cu, 19.1. Calcd. for $C_{11}H_{20}ClNO_3PCu$: N, 4.07; Cl, 10.32; P, 9.0; Cu, 18.5%

## Summary

Phosphites or phosphonites react with cuprous halides in one to one or two to one mole ratio to give phosphite, phosphonite, bis-phosphite or bis-phosphonite cuprous halides complex compounds. Their molecular weights

in various organic solvents showed that these compounds formed polymer.

Phosphite cuprous halides react with pyridine, aniline or their derivatives and gave new complex compounds having phosphite, cuprous chloride and amine.

The author wishes to express his thanks to Professor Shinichiro Fujise and Professor Taro Yamazaki of Tohoku University and Professor Ryutaro Tsuchida of Osaka University for their helpful suggestions in the preparation of this manuscript. He also wishes to thank the Sumitomo Chem. Co., Ltd. for permission to publish this work. He is indebted to co-workers in the analytical section of this laboratory. He also wishes to express his thanks to Messrs. M. Nakagawa and Y. Suzuki for their never failing assistance.

# *An Attempt to Discuss Reactivities of Excited Molecules by the Molecular Orbital Method*

By Kenichi FUKUI, Keiji MOROKUMA and Teijiro YONEZAWA

(Received December 29, 1960)

In order to elucidate the mechanisms of reactions of conjugated or non-conjugated organic compounds which are in their ground state, a number of quantum mechanical, especially molecular orbital, studies have been performed and have achieved remarkable success in predicting theoretically their chemical reactivities[1-4]. In connection with the recent advance of techniques of photochemical investigation, chemical reactivities of electronically excited molecules have aroused our interest.

Because of the complicated characters and the multifariousness of reactions of excited molecules, only a few theoretical discussions have ever been made. As regards the problem of their self-dissociation, some qualitative discussions in terms of the potential energy curve have prevailed[5]. For discussing the energy transfer reaction between an excited molecule and an unexcited one, the collision theory has prevailed as a powerful tool[6]. On account of the lack in systematic experimental data and, in addition, because of the difficulties in the theoretical treatment, only a few quantum chemical studies have been presented on excited molecules involved in the addition reactions of large organic molecules. Photopolymerization of hydrocarbons has been discussed in terms of free valence of the molecules in their lowest excited state. The intramolecular orientation in the reaction of anthracene or naphthacene has been explained well[7]. But that of acenaphthylene has not been[8]; free valence of its lowest excited states is greatest at positions 5 and 6, and, on the contrary, the photodimer of the componud is produced through positions 1 and 2.

In the present paper, as was previously done with reference to the molecules in their ground state by the present authors[9,10] and by Brown[11], the reactivites of excited molecules are assumed to be parallel with the $\pi$ stabilization energy at the transition state due to the interaction of the molecule with the reagent (molecule, ion or radical) through the position of attack. Under this assumption the reactivity indexes are derived by the use of the molecular orbital method.

## Formulation and Comparison with Experiments

Reactions of an excited molecule with an unexcited molecule are classified into several cases from the point of view of the spin multiplicity of reactants. The assumptions, the formulations and general considerations of the present molecular orbital treatments leading to the theoretical measures of reactivity will be described rather circumstantially in the first few cases, and in other cases only the indexes of reactivity derived will be given.

**Reaction of an Excited Triplet Molecule with an Unexcited Radical.**—First of all, attention is paid to the reaction of an excited triplet molecule ($^3$A) with an unexcited radical ($^2$B), where the numbers on the left shoulder refer to the multiplicity of the molecules. Here it would be rational for practical purposes in treating photochemical reactions to assume that the molecule $^3$A has only one excited electron. Then the wave functions of these molecules are written as follows:

$$\Psi(^3\mathrm{A}) = A\left[\cdots(\phi_1\alpha)^{m-3}(\phi_1\beta)^{m-2}(\phi_{01})^{m-1}(\phi_{02})^{m} \times \begin{Bmatrix} \alpha(m-1)\alpha(m) \\ \beta(m-1)\beta(m) \\ (1/\sqrt{2})\{\alpha(m-1)\beta(m)+\beta(m-1)\alpha(m)\} \end{Bmatrix}\right] \quad (1)$$

$$\Psi(^2\mathrm{B}) = A\left[\cdots(\phi_1\alpha)^{n-2}(\phi_1\beta)^{n-1}\begin{Bmatrix}(\phi_0\alpha)^n \\ (\phi_0\beta)^n\end{Bmatrix}\right]$$

where $\phi_i$ and $\phi_j$ are the molecular orbitals of molecules A and B, respectively, whose numbering is schematically shown in Fig. 1, 01 and 02 denoting the lower and the higher half-occupied levels, of A, respectively, and (0) denoting the half-occupied level of the radical B; $m$, an even integer, is the number of electrons of the molecule A and $n$, an odd number, is that of the radical B; $A$ is the antisymmetrizing operator including the normalization constant; and each line in braces may constitute one wave function.

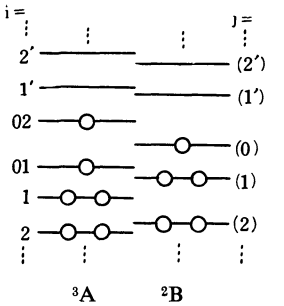

Fig. 1. Numbering of molecular orbitals.

The states of the total system consisting of the triplet A and the doublet B would be a quartet and a doublet. But the quartet, which would be proved later to be less significant in this discussion, is abandoned. The doublet wave function for $M_S=1/2$* is

$$^2\Psi_{1/2}[^2(\mathrm{AB})] \equiv \Psi[0] = A[\cdots(\phi_1\alpha)^{m-3}(\phi_1\beta)^{m-2} \cdots(\phi_1\alpha)^{m+n-2}(\phi_1\beta)^{m+n-1}(\phi_{01})^{m-1}(\phi_{02})^{m} \times(\phi_0)^{m+n}\{(\alpha\beta+\beta\alpha)\alpha-2(\alpha\alpha)\beta\}/\sqrt{6}] \quad (2)$$

where, for example, $\alpha\beta\alpha$ means $\alpha(m-1)\beta(m)\alpha(m+n)$. That for $M_S=-1/2$ is not written because the energetical argument is similar. Thus the state $\Psi[0]$ is assumed to correspond to the initial system of the reaction in question. If A and B are far separated from each other, the energy of the state is the same as that of the product function $\Psi(^3\mathrm{A})\cdot\Psi(^2\mathrm{B})$. The molecular orbitals may include all $\pi$ ones and $\sigma$ ones, but in this paper we consider the reactions in company with only the $\pi$ electron excitation, and hence $\sigma$ orbitals will rationally be omitted as making an invariant framework.

At the transition state of the reaction the two molecules, $^3$A and $^2$B, will stay at a distance, making a weak interaction through the atoms at which the reaction takes place. This interaction is assumed to be a kind of $\pi-\pi$ conjugation and in this simple LCAO MO approach it will be represented by a small resonance integral $\gamma\beta$ between the atomic $\pi$ orbitals $r$ and $s$ of the reactants, A and B, respectively, where $\beta$ is the resonance integral of the C-C $\pi$ bond in benzene. This perturbation makes the initial state $\Psi[0]$ come to the direct or indirect interaction with various electronic configurations of the combined system. Of these configurations only those, which have energy matrix elements with the initial state in scope of the simple LCAO MO approximation, are taken into account. This means that the configurations (of course, doublet and $M_S=1/2$) in which one electron transfers from $^3$A to $^2$B and vice versa have concern with the transition state of the reaction, whereas those which correspond to intramolecular one-electron transitions do not.

Under these assumptions the electron configurations to be taken into account are those corresponding to the following one-electron transfers, represented by $l\rightarrow m$, from an occupied or half-occupied orbital, $l$, to an unoccupied or half-occupied orbital, $m$:

$$\begin{aligned} &02\rightarrow(0),\ 02\rightarrow(j'),\ 01\rightarrow(0),\ 01\rightarrow(j') \\ &i\rightarrow(0),\ i\rightarrow(j'),\ (0)\rightarrow01,\ (0)\rightarrow02 \\ &(0)\rightarrow i',\ (j)\rightarrow01,\ (j)\rightarrow02,\ (j)\rightarrow i' \end{aligned} \quad (3)$$

* $M_S$ denotes the eigenvalue of $S_z$, the $z$ component of the spin momentum operator.

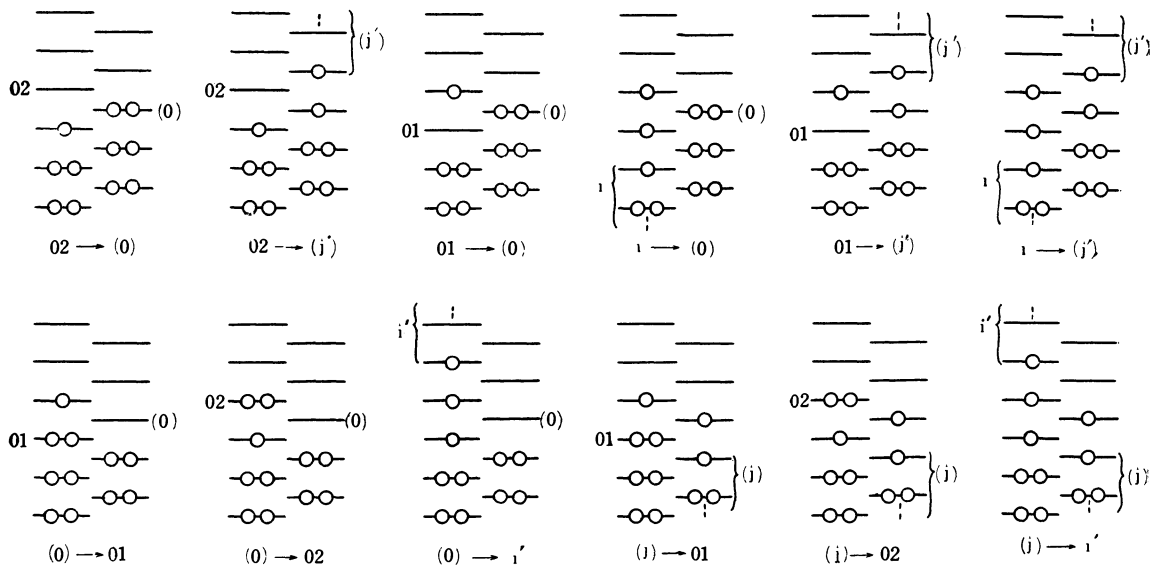

Fig. 2. Electronic configurations taken into account.

where

$i=1, 2, \cdots$ (occupied orbitals of $^3$A)

$i'=1', 2' \cdots$ (unoccupied orbitals of $^3$A)

$(j)=(1), (2), \cdots$ (occupied orbitals of $^2$B)

$(j')=(1'), (2'), \cdots$ (unoccupied orbitals of $^2$B)

They are schematically illustrated in Fig. 2. For an illustration, the configuration associated with the transfer 02→(0), will have the following wave function:

$$\Psi[02\rightarrow(0)] = \boldsymbol{A}[\cdots(\phi_0\alpha)^{m+n-2}(\phi_0\beta)^{m+n-1}(\phi_0\alpha)^{m+n}] \quad (4)$$

The energy matrix element between these configurations and the initial state can be expressed in terms of the integral $\gamma\beta$. For example,

$$\left|\int \Psi^*[02\rightarrow(0)]\, H\Psi(0)\mathrm{d}\tau\right| = |\, c_r^{02} d_s^{0} \gamma\beta\,| \quad (5)$$

where $c_r^k$ and $d_s^l$ are the coefficient of the atomic orbitals $r$ and $s$ in the molecular orbital $k$ and $l$ of the molecules A and B, respectively.

The transition state of the reaction is the lowest energy state resulting from the interaction mentioned above. The difference in $\pi$ electronic energy, i. e. the stabilization energy, between the initial state and the transition state, was assumed in the preceding section to parallel the activation energy, of the reaction, and accordingly the reactivity of the excited molecule. This stabilization energy would be expanded in powers of $\gamma$ by regarding it to be small. There arise three main subcases according to the mutual relation of the energy levels 01 and 02 of the molecule $^3$A and (0) of the molecule $^2$B*. In the following $Y_{k,l}$ denotes the energy in units of $(-\beta)$ turned out in one electron transfer from the molecular orbital $k$ of the one molecule to the molecular orbital $l$ of the other one. That is, $Y_{k,l}$ is positive if the level $k$ is higher than the level $l$ and vice veras. Thus we reach the final reactivity indexes of excited molecules.

(a) If $Y_{02,0}>Y_{0,01}>0$, that is, if the half-occupied level of the molecule $^2$B lies between the levels 01 and 02 of $^3$A and is nearer to 01 than to 02, as is shown in Fig. 3 (a), the stabilization energy to the second order of $\gamma$ is written in the following expression**:

$$\Delta E=\left[Y_{02,0}+\frac{(3/2)(c_r^{02})^2(d_s^0)^2}{Y_{02,0}}\gamma^2\right](-\beta) \quad (6)$$

From this formula some general conclusions on reactivities of excited molecules may be

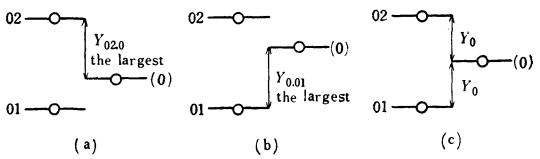

Fig. 3. Mutual relation of molecular levels.

* Some rare cases, for instance, $Y_{0.02}>0$ or $Y_{01.0}>0$, are not included for the sake of brevity.

** In general the stabilization energies for each $M_S$ component may differ from each other. In the surroundings of reaction no magnetic field being applied, no specialization of the component is possible and the mean of all components would be significant as a real stabilization energy. In this case the energy for $M_S=1/2$ is the same as that for $M_S=1/2$; also the mean energy becomes the same.

TABLE I. RATE CONSTANT AND $\pi$ STABILIZATION ENERGY OF POLYMERIZATION OF STYRENE

| Reaction[a] | Rate constant[b] $k$ (l. mol$^{-1}$ sec$^{-1}$) | $\pi$ Stabilization energy (in units of $-\beta$) |
|---|---|---|
| R·+$^3$A→RA· | $\sim 10^{11}$ | $0.414+0.801\gamma^2$ (position 9) |
| | | $0.414+0.400\gamma^2$ (position 1) |
| | | $0.414+0.200\gamma^2$ (position 2) |
| R·+A→RA· | $3.4\times 10^2$ | $0.926\gamma^2$ |
| R·+M→R· | $1.2\times 10^2$ | $0.932\gamma^2$ |
| RA·+M→R· | 0.8 | $0.739\gamma^2$ |

a) Abbreviations, R·: polymer radical of styrene; $^3$A: triplet anthracene; A: anthracene; M: styrene.
b) Taken from Ref. 10.

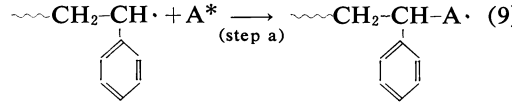
derived. In most reactions between unexcited molecules, terms first appear in the second order of $\gamma$, whereas in Eq. 6 the term in zero order exists. The appearance of the zero order term is universal in all the following cases and subcases, making clear the reason why the reactions including excited molecules proceed so fast. The difference in reactivity of several excited molecules would thus dominantly be decided by this term. The intramolecular orientation, on the other hand, depends on the term in the second order. More minutely, so far as attention is paid to the lowest excitation of the molecule A as is expected in real photochemical reactions of conjugated molecules, the atom where $(c_r^{02})^2$, the frontier electron density for a nucleophilic attack in the ground state, is the greatest is the most reactive in an excited molecule. The coefficient (3/2) is characteristic to the triplet A molecule. If the molecule A is excited in the singlet state it amounts to (1/2), as will be mentioned in the next section. The difference would not necessarily mean the difference in reactivity of these two states, since the approximation is too simple to discuss at this point, on which there will be some discussion in a later section.

To the transition state the electron configuration corresponding to the one-electron transfer 02→(0) has the greatest contribution, since the other configurations have the first contribution to $\Delta E$ in the fourth order. Therefore, the direction of charge transfer is from molecule A to molecule B.

(b) If $Y_{0,01}>Y_{02,0}>0$, i. e., if the half-occupied level of $^2$B lies between the levels 02 and 01, and nearer to 02 than to 01, as shown in Fig. 3 (b), then

$$\Delta E=\left[Y_{0,01}+\frac{(3/2)(c_r^{01})^2(d_s^0)^2}{Y_{0,01}}\gamma^2\right](-\beta) \quad (7)$$

In this subcase also the rate of reaction is great and the intramolecular orientation of the excited molecule is controlled by $(c_r^{01})^2$, the frontier electron density for an electrophilic attack in the ground state. The most contributive configuration in this subcase corresponds to the transition (0)→01, resulting in a charge transfer from B to A.



(c) If $Y_0\equiv Y_{02,0}=Y_{0,01}>0$, i. e., if the level (0) is just in the midst of the levels 01 and 02, as shown in Fig. 3 (c), then

$$\Delta E=\left[Y_0+\frac{(3/2)[(c_r^{01})^2+(c_r^{02})^2](d_s^0)^2}{Y_0}\gamma^2\right]\times(-\beta) \quad (8)$$

A large rate constant is confirmed also in this subcase, and $[(c_r^{01})^2+(c_r^{02})^2]$, the frontier electron density for a radical attack in the ground state, comes to the point.

So far as alternant hydrocarbons are concerned, however, the equality $(c_r^{01})^2=(c_r^{02})^2$ holds in the simple LCAO MO approximation, so that in all subcases and the following cases the most reactive position in a molecule in its lowest excited state is the same as that in the ground state. This explains the great reactivity of meso position of anthracene. Further experimental studies are anticipated with respect to the intramolecular orientation in nonalternant hydrocarbons and heterocyclic compounds where the equality mentioned above no more exists.

Here a comparison with experimental data may be given. Excited triplet anthracene was reported by Norrish et al.[12] to enter into the chain of polymerization of styrene in the following way:

(9)

Observed rate constant, $k_a$, and calculated $\pi$ stabilization energy $\Delta E$ are tabulated in Table I. The stabilization in the reaction a is calculated by using Eq. 8. Those of other reactions in which only molecules in their ground state participate are given by the usual formula for stabilization energy[10]:

12) V. S. Anderson and R. G. W. Norrish, *Proc. Roy. Soc.*, **A251**, 1 (1959); R. G. W. Norrish and J. P. Simons, ibid., **A251**, 4 (1959).

$$\Delta E=\left[\sum_{j}^{\text{unocc}}\sum_{i}^{\text{all}}\nu_i-\sum_{j}^{\text{occ}}\sum_{i}^{\text{all}}(2-\nu_i)\right]\times\frac{(c_r^i)^2(d_s^j)^2}{Y_{ji}}\gamma^2(-\beta) \qquad (10)$$

where $\nu_i$ is the number of electrons in the $i$th molecular orbital of A. The extraordinary great magnitude of rate constant of reaction a is well understood in connection with the presence of the zero order term. Further, the position 9 is the most active, at which anthracene would enter into the polymer chain. An appropriate choice of the value of $\gamma$ ($=0.7$) makes the $\log k_a-\Delta E$ plots practically linear.

The wave functions (Eq. 1) of $^3$A and $^2$B may be combined so as to construct a quartet instead of the doublet (Eq. 2). The quartet state has matrix elements with some configurations in Eq. 3, only to give the stabilization energy in the second order. Because of the lack of the zero order terms and, accordingly, because of the instability of the transition state, reactions would not be considered to proceed by way of the quartet transition state.

**Reaction of an Excited Singlet Molecule with an Unexcited Radical.**—The reaction of an excited singlet molecule ($^1$A) with an unexcited radical ($^2$B) can be discussed in a way similar to that of a triplet molecule ($^3$A) mentioned in the preceding reaction. The doublet wave function for $M_S=1/2$ of the combined system is, in place of Eq. 2 in the triplet case,

$$\Psi[0]=\mathcal{A}[\cdots(\phi_{01})^{m-1}(\phi_{02})^{m}(\phi_0)^{m+n}\times\{(\alpha\beta-\beta\alpha)\alpha\}/\sqrt{2}] \qquad (11)$$

Also, we are led to the same equations as Eqs. 3, 4 and 5, excepting that the numerical coefficient in the second term should be read (1/2) in this case, instead of (3/2). The meanings of the frontier electron density and the direction of charge transfer in each subcase are entirely the same as in the last case; and therefore discussions may be omitted for brevity.

**Reaction of an Excited Tripled Molecule with an Unexcited Molecule.**—The reaction of an excited triplet molecule ($^3$A) with an unexcited singlet molecule ($^1$B)* now comes to our attention. Discussions are almost alike, so that the only important formulas would be summarized in this case and in the following case. The numbering of molecular orbitals is illustrated in Fig. 4. The states of the combined system at the initial stage of reaction are represented by a set of three triplet wave functions, one with $M_S=1$, one with $M_S=0$ and the other with $M_S=-1$, as follows:

* The singlet molecule $^1$B may be an ion whose spin is singlet.

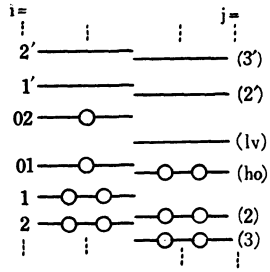


Fig. 4. Numbering of molecular orbitals. lv and ho mean the lowest unoccupied and the highest occupied orbitals, respectively.

$$\left.\begin{aligned}
{}^3\Psi_1&=\mathcal{A}[\cdots(\phi_{01})^{m+n-1}(\phi_{02})^{m+n}\times\alpha(m+n-1)\alpha(m+n)]\\
{}^3\Psi_0&=\mathcal{A}[\cdots(\phi_{01})^{m+n-1}(\phi_{02})^{m+n}\times(\alpha(m+n-1)\beta(m+n)+\beta(m+n-1)\alpha(m+n)\}/\sqrt{2}]\\
{}^3\Psi_{-1}&=\mathcal{A}[\cdots(\phi_{01})^{m+n-1}(\phi_{02})^{m+n}\times\beta(m+n-1)\beta(m+n)]
\end{aligned}\right\} \qquad (12)$$

Electronic configurations which are taken into account in the perturbation calculation are summarized in Fig. 5 with illustrations. Each $M_S$ component of the functions 12 will have matrix elements with the same $M_S$ component of the wave functions for the configurations

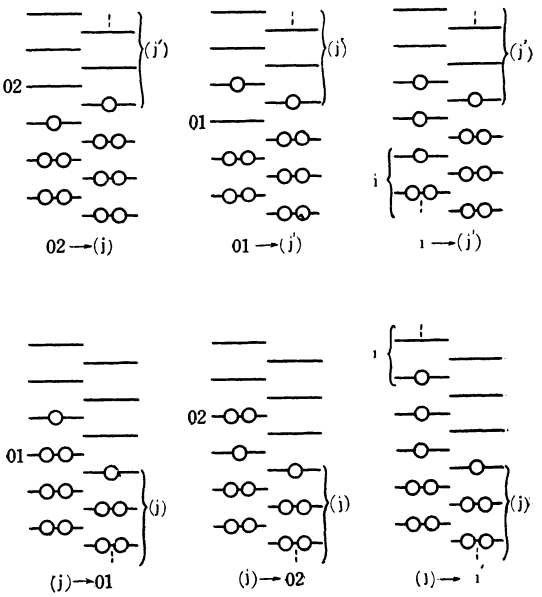

Fig. 5. Electronic configurations taken into account.
$i=1,2,\cdots$ (occupied orbitals of $^3$A); $i'=1',2',\cdots$ (unoccupied orbitals of $^3$A); $j=$ ho, 2, $\cdots$ (occupied orbitals of $^1$B); and $j'=$ lv, 2', $\cdots$ (unoccupied orbitals of $^1$B).

TABLE II. $\pi$ STABILIZATION ENERGY IN PHOTODIMERIZATION OF POLYACENES AND ACENAPHTHYLENE

| Compound | Pairs of positions to react with | $\pi$ Stabilization energy (in units of $-\beta$) |
|---|---|---|
| Anthracene | 9-9, 10-10 (central) | $0.547\gamma$ |
| | 1-1, 4-4 (end) | $0.273\gamma$ |
| Naphthacene | 5-5, 12-12 (central) | $0.417\gamma$ |
| | 1-1, 4-4 (end) | $0.159\gamma$ |
| Pentacene | 6-6, 13-13 (central) | $0.400\gamma$ |
| | 5-5, 14-14 | $0.299\gamma$ |
| | 1-1, 4-4 (end) | $0.100\gamma$ |
| Acenaphthylene | 1-1, 2-2 | $0.568\gamma$ |
| | 5-5, 6-6 | $0.375\gamma$ |

in Fig. 5. Then the stabilization energy* is obtained as follows, according to the mutual relation of energy levels:

(a) If $Y_{02,1v}$ is positive and the most positive of all $Y$'s, then

$$\Delta E=\left[Y_{02,1v}+\frac{(c_r^{02})^2(d_s^{1v})^2\gamma^2}{Y_{02,1v}}\right](-\beta) \qquad (13)$$

This is the case for most electrophilic reagents (cations) serving as $^1B$.

(b) If $Y_{ho,01}$ is positive and the most positive of all $Y$'s, then

$$\Delta E=\left[Y_{ho,01}+\frac{(c_r^{01})^2(d_s^{ho})^2\gamma^2}{Y_{ho,01}}\right](-\beta) \qquad (14)$$

Most nucleophilic reagents (anions) as $^1B$ are included in this subcase.

(c) If $Y_{02,1v}=Y_{ho,01}$, and they are positive (then of course the most positive), then, putting them equal to $Y_0$,

$$\Delta E=\left[Y_0+\frac{\{(c_r^{02})^2(d_s^{1v})^2+(c_r^{01})^2(d_s^{ho})^2\}\gamma^2}{Y_0}\right]\times(-\beta) \qquad (15)$$

Such a conjugated molecule as has its lowest excitation energy smaller than the excitation energy to the triplet of the molecule A would be classified in this subcase.

(d) If all $Y$'s are negative, then

$$\Delta E=\left[\sum_j^{unocc}\sum_i^{all}\nu_i-\sum_j^{occ}\sum_i^{all}(2-\nu_i)\right]\frac{(c_r^i)^2(d_s^j)^2\gamma^2}{Y_{ji}}\times(-\beta) \qquad (16)$$

In this subcase the stabilization energy begins in the second order terms, predicting a slow rate in the process of reaction.

(e) If $Y_{02,1v}=0$ and the others are negative, then

$$\Delta E=\left[\,|\,(c_r^{02})(d_s^{1v})\,|\,\gamma+\left\{\sum_j^{unocc}\sum_i^{all}\nu_i-\sum_j^{occ}\sum_i^{all}(2-\nu_i)\right\}'\frac{(c_r^i)^2(d_s^j)^2\gamma^2}{2Y_{ji}}\right](-\beta) \qquad (17)$$

* Each $M_S$ component gives the same stabilization energy, and the mean is, therefore, the same.

where the mark $'$ on the summation tells to omit the set ($j$=1v, $i$=02).

(f) If $Y_{ho,01}=0$ and others are negative, then, similarly

$$\Delta E=\left[\,|\,(c_r^{01})(d_s^{ho})\,|\,\gamma+\left\{\sum_j^{unocc}\sum_i^{all}\nu_i-\sum_j^{occ}\sum_i^{all}(2-\nu_i)\right\}'\frac{(c_r^i)^2(d_s^j)^2\gamma^2}{2Y_{ji}}\right] \qquad (18)$$

$'$ indicating the neglect of the set ($j$=ho, $i$=01).

(g) If $Y_{02,1v}=Y_{ho,01}=0$ and others are negative, we obtain

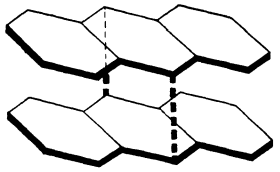
$$\Delta E=\left[\sqrt{(c_r^{02})^2(d_s^{1v})^2+(c_r^{01})^2(d_s^{ho})^2}\,\gamma+\left\{\sum_j^{unocc}\sum_i^{all}\nu_i-\sum_j^{occ}\sum_i^{all}(2-\nu_i)\right\}'\times\frac{(c_r^i)^2(d_s^j)^2\gamma^2}{2Y_{ji}}\right](-\beta) \qquad (19)$$

neglecting in the summation the sets ($j$=ho, $i$=01) and ($j$=1v, $i$=02) In the latter three subcases the stabilization is of the first order, and for the lowest excited molecule the frontier electron density controls a main part of the reactivity indexes. The subcase g includes reactions of an excited molecule with an unexcited molecule of the same kind.

The photodimerization of aromatic hydrocarbons has been considered to pass through the following mechanism:

$$A^*+A \underset{\text{(step b)}}{\longrightarrow} (AA^*) \underset{\text{(step c)}}{\longrightarrow} AA \qquad (20)$$

Though the detail of the intermediate (AA*) is not clear, assuming the present type of complex for the transition state of step b, one can discuss the reactivity of this reaction as belonging to the subcase g. In Table II calculated values of the $\pi$ stabilization energy are collected. In that table, reagents are assumed to make two weak bondings through two meso positions, as illustrated in Fig. 6; the assumption of one bonding would only need to divide the values by the factor 2.



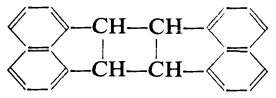


Fig. 6. Model of transition state of photodimerization of anthracene.

Anthracene is well known to make a photodimer at 9 and 10 positions, in accord with our calculation. Also in other polyacenes the most central meso-positions have the largest stabilization energy. This result is compatible with the experiment[13]. Bowen and Marsh[14] studied the photodimerization of acenaphthylene, finding that the structure of the photodimer was

This finding was first theoretically discussed by Crawford and Coulson[8]. They calculated the free valence of this molecule in its lowest excited state and found that the values of positions 5 and 6 (0.62) are greater than those of positions 1 and 2 (0.57), which conflicted with the above experimental results. Thus they stated that the free valence is not a sufficient guide to reactivity. Recently this experiment has been interpreted successfully by the present authors in terms of the frontier electron density for a radical reaction[15]. The frontier electron density of positions 1 and 2 is greater than that of positions 5 and 6. In that paper the excited acenaphthylene was regarded as an ordinary radical reagent attacking an acenaphthylene molecule in the ground state. At this time it would be interesting to apply the present theory which involves an explicit consideration of the excitation. This belongs to the subcase g. As is seen in Table II the stabilization energy of the reaction through pairs of positions 1-1 and 2-2 is greater than that through 5-5 and 6-6, in accordance with the experiment.

In intermolecular comparison it is said that the ease of photodimerization is greater in pentacene than in anthracene[13]. But this is not a direct comparison of the rate constant $k_b$ of the step b but a rough estimation from the amount of dimers produced. The total rate of dimer formation would be affected not only by the rate constant $k_b$ but also by various competitive reactions such as the collisional or spontaneous degradation of the excited A molecule, dissociation of (AA*), and so forth. To measure and compare the rate constant with calculated stabilization energy would be interesting.

**Reaction of an Excited Singlet Molecule with an Unexcited Molecule.**—The method and the results of the treatment for this kind of reaction is exactly the same as that in the last case if only the wave function, Eq. 12, is replaced by the following equation:

$$^1\Psi_0 = \boldsymbol{A}[\cdots(\psi_{01})^{m+n-1}(\psi_{02})^{m+n}\{\alpha(m+n-1) \times\beta(m+n)-\beta(m+n-1)\alpha(m+n)\}/\sqrt{2}] \quad (21)$$

Eqs. 13 to 20 are also valid in this case.

**Reaction of an Excited Molecule with Another Excited Molecule.**—We derived also the equations giving the stabilization energy in a reaction of an excited molecule (singlet or triplet) with another excited molecule (singlet or triplet) in a similar way. But as they are less meaningful for practical purposes and rather intricate, we do not give their explicit forms. It would be noteworthy that in this case also the frontier electron densities decide the intramolecular orientation.

## Discussion

We have derived formulas giving the $\pi$ stabilization energy and the reactivity index, discussing the rate of reactions of excited molecules. But we do not, at all, regard this theory as complete but merely as a simple pioneering attempt in the molecular orbital method; the assumptions included may have to be subjected to some improvements in future. For discussing the difference in rate constant caused by the difference in multiplicity of states, interactions of electrons should be explicitly taken into account. For discussing various dissociation reactions, attention would have to be paid to $\sigma$ electrons in the bond to be broken. Furthermore, in order to understand all the figures of reactions of an excited molecule, discussions on relations between various elementary steps involved in the reaction would be expected.

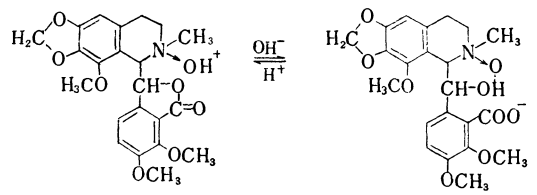
# *Polarography of Narcotine-N-oxide**

By Yutaka ASAHI



(Received January 7, 1961)

It has been reported by Kirkpatrick[1] that narcotine, an opium alkaloid, shows a catalytic hydrogen wave as do the other alkaloids, and according to Holubeck[2], narcotine and hydrastin can be determined quantitatively with the the reduction wave of their oxidation product, opianic acid. It is known that *N*-oxides such as pyridine-*N*-oxide[3] and nitrogen mustard *N*-oxide[4] are reduced polarographically to the corresponding amines, but the polarography of narcotine-*N*-oxide has not been reported yet.

In this paper the polarographic determination of narcotine-*N*-oxide in the oxidation products of narcotine is attempted and further-more, the electrode reaction and behaviors of narcotine-*N*-oxide in aqueous solutions are examined by means of DC- and AC-polarography, electrocapillarity, potentiometric titration and ultraviolet absorption spectrometry. Narcotine-*N*-oxide shows 2-electron reduction waves of *N*-oxide, which are complicated by the adsorption on the electrode, the kinetic current of protonation and the reversible cleavage of lactone.

## Experimental

The Yanagimoto pen-recording polarograph model PA 2, the Beckman pH meter model G and Beckman spectrophotometer model DU or DK 2 were used. The dropping mercury electrode has such characteristics as $m=0.817$ mg. $sec^{-1}$, $t=3.94$ sec., $m^{2/3}t^{1/6}=1.097$ and $h=70$ cm. Polarograms were taken in buffer solutions of acetate, phosphate,

(I) (II)

borate, hydrochloric acid and sodium hydroxide at 25±0.1°C after bubbling nitrogen gas, using N calomel electrode as the external reference electrode.

Narcotine hydrochloride and its *N*-oxide were given by Dr. H. Matsumaru of the Tokyo factory of our company.

## Results

**Catalytic Hydrogen Wave.** — Narcotin-*N*-oxide shows a great increase of current from about −1.2 V. and generally a maximum wave in a buffer solution of pH 1～9. (Fig. 1e) The maximum wave height ($i_m$) is greatest at about pH 7 (Fig. 2 (5)) and tends to reach a limiting value at higher concentrations. The height ($i_m$) in a 0.2 mM solution of the *N*-oxide is supressed from 56 μamp. to 40 and 20 μamp. in the presence of 0.01 and 0.05% gelatin, respectively. The maximum potential ($E_m$), −1.4～−2 V., becomes more negative in higher wave heights and higher concentrations: $E_m$ −1.44 V., $i_m$ 0.09 μamp. $c$ 0.05 mM; $E_m$ −1.55 V., $i_m$ 7.6 μamp., $c$ 0.2 mM; $E_m$ −1.70 V., $i_m$ 38.2 μamp., $c$ 0.6 mM at pH 9.2. The temperature coefficient of $i_m$, 8% deg.$^{-1}$, is very high. The height decreases with the increase of mercury head ($h$) : $i_m$ in a 0.1 mM solution of pH 9.2 is 1.62, 1.19 and 0.89 μamp. at 48, 68 and 88 cm. of $h$ respectively.

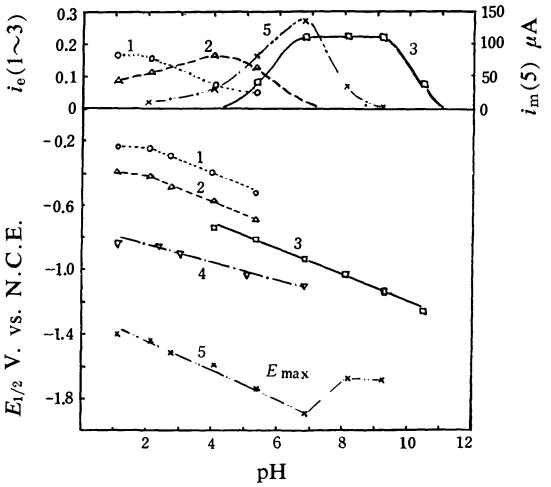

Fig. 2. $E_{1/2}$-pH curves (lower) and wave height-pH curves of narcotine-*N*-oxide (0.1 mM).
1) Absorption wave, 2) Reduction wave of cation, 3) Reduction wave of free base, 4) Reduction wave of hydroxy-carboxylic acid form, 5) Catalytic hydrogen wave.

**Reduction Wave of Lactone type Narcotine-*N*-oxide (I).**—0.1 mM narcotine-*N*-oxide hydrochloride in a buffer solution of pH 1～10 shows 1～3 steps of reduction waves at the potential more positive than that of the catalytic hydrogen wave (Fig. 1a). The total wave height is independent of pH in a range of 1～9, but decreases at above pH 9 (Fig. 2 (1～3)). In 0.1 N hydrochloric acid, the total wave height ($i_d$) of 3 steps is proportional to the concentration ($c$) in a range of 0.1～1 mM and the diffusion current constant ($k_D$) is calculated as 2.3 (μamp. mM$^{-1}$ mg$^{-2/3}$ sec$^{1/2}$).

Their 1st step is considered as an adsorption wave since the relationships between the wave height ($i_1$) and the concentration ($c$) fulfil the equation $i_1 = a \cdot b \cdot c/(1+b \cdot c)$ with $a$=1.25 $b$=2.67 mM$^{-1}$.

In acetate buffer of pH 4, 3 steps of reduction waves are also obtained in low concentration (0.05～0.23 mM), but in higher concentration (0.24～1 mM) an anomalous minimum wave in some potential range is obtained (Fig. 1, b, c). Thus the current is strongly suppressed in the potential range of −0.42～−1.04 V. at 1 mM and −0.6～−0.7 V. at 0.24 mM. The limiting current at −1.1 V. corrected for the residual current is, however, proportional to the concentration.

At pH 6.8～9.2, one reduction wave is observed near a catalytic hydrogen wave. Since the wave height tends to a limiting value (0.3 μamp.) at higher concentration (0.05～0.6 mM) and its temperature coefficient is small (0.4% deg$^{-1}$), this wave is assumed to be an adsorption wave.

When the pH value increases from 4 to 7, the wave heights of the 1st and the 2nd steps decrease and that of the 3rd step increases (Fig. 2). The apparent p$K$ of I is assumed to be 5.6 from the pH in which the 1st and 2nd wave height is equal to the 3rd one.

$E_{1/2}$-pH curves can be shown by the equation $E_{1/2} = E_0 + a$ pH, where $E_0$ are −0.08, −0.26 and −0.30 V. for 1st, 2nd and 3rd waves, respectively and $a$ is about −0.08 V. (Fig. 2).

The slope of the reduction wave of narcotine-*N*-oxide at −0.2～−0.9 V. in 0.25 mM solution of pH 3.7, becomes steep and the foot of the wave shifts toward the negative side in the presence of 0.1～2 mM narcotine. The potential range of the anomalous wave observed at −0.47～−0.89 V. in 0.5 mM at pH 4.1 becomes more negative and less wide (−0.63～−0.92V.) in the presence of 2 mM narcotine. In both cases the total wave height is also proportional to the concentration of the *N*-oxide and is not altered with narcotine. Similar phenomena are observed in the coexistence of 0.01～0.02% gelatin and 0.2～1 mM the *N*-oxide.

**Change of Polarograms of Narcotine-*N*-oxide by Alkali and Acid.**—The reduction wave of narcotine-*N*-oxide hydrochloride (I) disappears gradually in alkali. From the current-time curve at a fixed potential, the reaction is estimated to be of the 1st order. Its velocity constant ($k_1$) is proportional to [OH$^-$] ion concentration. The reaction product II gives no wave above pH 9 but a reduction wave at more negative potential than that of I at pH

1～7 (Fig. 1d) and reverse to the original one I by acid. The velocity constant ($k_2$) of the reverse reaction is proportional to [$H^+$] ion concentration (Fig. 3).

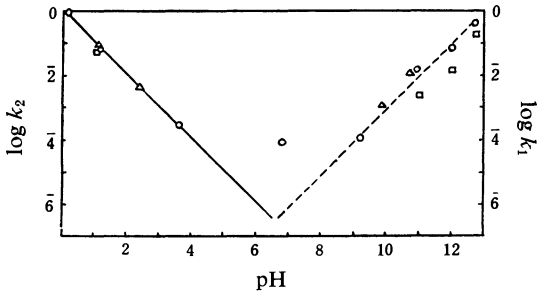

Fig. 3. Relationships between pH and reaction velocity constant of cleavage of the lactone ($k_1$) and of its formation ($k_2$) of narcotine (□) or its *N*-oxide (○, △) observed by reduction wave height (△) or $\varepsilon_{313m\mu}$ (○, □) at 25°C.

**Change of Ultraviolet Absorption Spectra of Narcotine and its *N*-oxide by Alkali and Acid.**—Narcotine hydrochloride gives a peak with $\lambda_{max}$ 313 m$\mu$ ($\varepsilon$ 4000) and a shoulder at 290 m$\mu$ in 20% ethanol solution (pH 5). The spectra change gradually to $\lambda_{max}$ 282 m$\mu$ ($\varepsilon$ 3200) in alkali.

Narcotine-*N*-oxide gives $\lambda_{max}$ 313 m$\mu$ ($\varepsilon$ 4000) and shoulders at 290 and 240 m$\mu$ in acid, and $\lambda_{max}$ 278 m$\mu$ ($\varepsilon$ 2800) in alkali. These changes occur reversibly and in measurable speed. The velocity constant of the 1st order reaction observed by absorbance at 313 m$\mu$ is proportional to [$OH^-$] in alkali and [$H^+$] in acid, and is in good agreement with that obtained by polarography (Fig. 3).

**A. C. Polarography.**—0.2 mM Narcotine-*N*-oxide in a buffer solution of pH 4 gives a large A. C. Polarogram ($i_p$ 710 $\mu\bar{v}$) at the potential $E_p$ −1.67 V. corresponding to the catalytic hydrogen wave but no wave at the potential of reduction of *N*-oxide. At higher concentration (1 mM) in the same buffer, the A. C. polarogram is suppressed in the potential range −0.5～−1 V. as D. C. polarogram.

**Electrocapillary Curve.**—The relationships between the applied potential and drop time of the mercury electrode in an acetate buffer of pH 4 is shown in the electrocapillary curve with a maximum at −0.6 V. (Fig. 4 ——). In the presence of 0.2 mM narcotine-*N*-oxide, the surface tension of the electrode is suppressed at −0.2～−1.4 V. and the curve extends to negative at −1.5～−1.7 V. because of the ohmic drop with the large catalytic current (Fig. 4------).

**Potentiometric Titration.**—Titration of 1 cc. of 10 mM narcotine-*N*-oxide·HCl with 0.1 cc. of

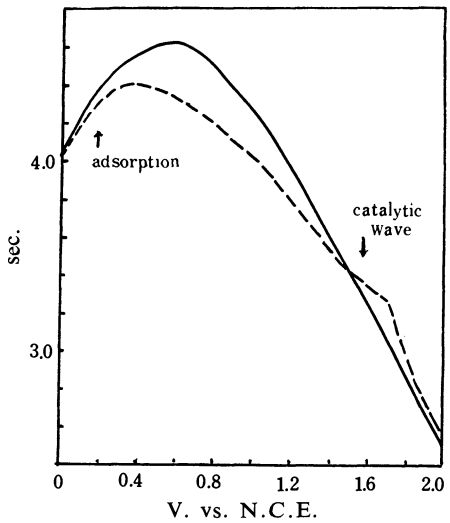

Fig. 4. Electrocapillary curves of acetate buffer (pH 4, ——) and with 0.2 mM narcotine-*N*-oxide (------).

0.1 N sodium hydroxide at 25°C reveals it to be an acid of p$K$ 3.75. After an alkaline (5 mM the *N*-oxide, 0.02 N sodium hydroxide, 10 cc.) is heated at 100°C for 5 min., two acid groups of p$K$ 6.0 and below 3 are observed by titration with 0.1 N hydrochloric acid or sodium hydroxide in nitrogen atmosphere and the product shows an absorption maximum at 280 m$\mu$. When the solution of pH 2.7 is heated at 100°C for 30 min., an acid group of p$K$ 3.7 and an absorption maximum at 313 m$\mu$ is obtained again. This alternation is ascribed to the reversible cleavage of the lactone. A similar phenomenon is also observed in narcotine, where the lactone type gives p$K$ 6.1 and the hydroxycarboxyl type gives p$K$ 9.4 and below 3.5 in 50% ethanol solution.

## Discussion

The maximum wave of narcotine-*N*-oxide at about −1.4～−2 V. is considered to be a catalytic hydrogen wave as narcotine and other alkaloids. This is useful for a microdetermination of pure alkaloid because of its high sensitivity, but can not be used for the specific determination of each alkaloid.

The reduction wave of narcotine-*N*-oxide must be due to the *N*-oxide group as this wave is not observed in narcotine. The total wave height of the *N*-oxide in acetate buffer solution of pH about 4 can be utilized for its determination in the mixture of alkaloids. Applying Ilkovič's equation, $k_D=607\ nD^{1/2}=i_d$. $c^{-1}m^{-2/3}t^{-1/6}$, with $k_D=2.3$ at pH 1～9 and $D=4.1\cdot10^{-6}$ ($cm^2\ sec^{-1}$) which is estimated from the molecular weight, $n=1.88\fallingdotseq2$ is obtained.

As the wave is very flat and no A. C. polarogram is obtained at the corresponding potential, the electrode process may be irreversible. In strong acid solutions, narcotine (p$K$ 6.1) and its $N$-oxide (p$K$ 3.75) exist as proton adducts with lactone moiety I. Then the 1st and 2nd steps at pH 1~5 are assumed to be due to the following reaction.

$$\left(\rangle N\rightarrow O\right)H^+ + 2e + 2H^+ \rightarrow \rangle NH^+ + H_2O$$

The fact that the apparent p$K$ 5.6 obtained from the wave height-pH curves is greater than p$K$ 3.75, is explained by the kinetic current due to the protonation of the base on the electrode. The 3rd wave at pH 5~10 may be ascribed to the reduction of the $N$-oxide base to narcotine.

$$\rangle N\rightarrow O + 2e + 2H^+ \rightarrow \rangle N + H_2O$$

It is clear from the hysteresis of potentiometric titration curve and ultraviolet absorption spectra in acid and alkali that narcotine and its $N$-oxide change reversibly from lactone types I in acid to hydroxy-carboxylate types II in alkali. Because of this reaction, the wave height of the 3rd step decreases at pH above 10. The $N$-oxide with a hydroxy-carboxylate group II give more negative $E_{1/2}$ than that of lactone type I, perhaps because the $N$-oxide is stabilized by the formation of hydrogen bond $\left(\rangle N\rightarrow O\cdots HO-\right)$.

The 1st step of the $N$-oxide with lactone ring has the character of an adsorption wave and disappears in the presence of narcotine or gelatin. Moreover the fact that the surface tension of the mercury electrode is suppressed in more negative potential than the 1st wave, confirms the adsorption of the reduction product, narcotine, on the electrode surface. Applying Brdička's equation[5], $z = i_a t / nF\Delta q$, with $i_a = 0.3\,\mu$ amp. (pH 9.2), $t = 3.94$ sec. and $\Delta q = 0.85\ (mt)^{2/3} = 0.0185\,cm^2$, the maximum number of adsorbed molecule ($z$) is estimated to be $3.3\times10^{-10}$ mol. $cm^{-2}$ and the cross-sectional area of a narcotine molecule on the electrode surface ($A$) is calculated as 50 Å$^2$. From $i_a = 1.25\,\mu$ amp. in 0.1 N hydrochloric acid, $A$ is estimated to be 12 Å$^2$. These values are comparable to the minimum cross-sectional area of a molecule packing closely on the mercury surface.

The curious polarograms in higher concentration at pH about 4 are ascribed to the inactivation of the mercury electrode by the adsorption layer.

## Summary

Narcotine-$N$-oxide shows a catalytic hydrogen wave as narcotine and other alkaloids. The reduction waves of narcotine-$N$-oxide are ascribed to the 2-electron reduction of the $N$-oxide to narcotine. Their 1st step is an adsorption wave of the reductant. The adsorped film disturbs the further electrode reaction, an anomalous minimum wave is observed in higher concentration. The 2nd step in pH 1~5 corresponds to the proton adduct of the $N$-oxide with lactone and the 3rd step in pH 5~10 to the base of the $N$-oxide.

Narcotine and its $N$-oxide change reversibly to hydroxycarboxylate type in alkali, which gives more negative reduction potential of the $N$-oxide and an absorption maximum in shorter wavelength. The velocity constants of cleavage of the lactone and of the reverse reaction are proportional to [$OH^-$] and [$H^+$], respectively.

# *A Novel Synthetic Route of 3,6-Dimethyl-2,3-dihydro-1H-cyclopent-[a]anthracene and 6-Methyl-2,3-dihydro-1H-cyclopent[a]anthracene*

By Masao NAKAZAKI, Kikuo YAMAGAMI and Sachihiko ISOE

(Received December 26, 1960)

Tsuda and coworkers[1] reported the isolation of a hydrocarbon ($C_{19}H_{18}$, oil, melting point of the picrate, 133~134°C) among the products of selenium dehydrogenation of the phenol II which they obtained by the dienone-phenol rearrangement of 7-keto-5,8(9)-cholestadien-3$\beta$-yl acetate. The same compound was isolated by them[2] from the selenium dehydrogenation products of the anthrasteroid III from 5,8(9)-cholestadien-3$\beta$-ol.

Starting from 1-methyl-2-naphthoic acid (IV) we[3] succeeded in preparing 3,6-dimethyl-2,3-dihydro-1*H*-cyclopent[*a*]anthracene (I). This structure I was assigned by Tsuda and coworkers to their dehydrogenation product, but the comparison of the ultraviolet absorption spectra of synthetic I and the dehydrogenation product indicated that the latter was considerably contaminated with non-anthranoid impurities. Having established the structure of anthracholestatetraene, proposed by Mosettig[4], by an excellent method[5], Burgstahler and Mosettig[6] prepared *dl*-5,7,9,14-anthratetraen-17-one (V) to study a possible general synthetic route to anthrasteroids as well as to examine their carcinogenic properties. Sodium borohydride reduction of ketone V afforded alcohol VI, but the dehydrogenation which was expected to be accompanied by the migration of the 18-methyl group to 17-position to give I was found fruitless[7].

Since 3,6-dimethyl-2,3-dihydro-1*H*-cyclopent-[*a*]anthracene (I) is an analog of Diel's hydrocarbon usually obtained by the dehydrogenation of steroids, and since we happened to need a considerable amount of it for biological experiments, we explored a simpler route to compound I. In the present paper a new synthetic route to compound I and its nor-compound XIIIb is described.

Our synthesis, shown in Fig. 1, employs the

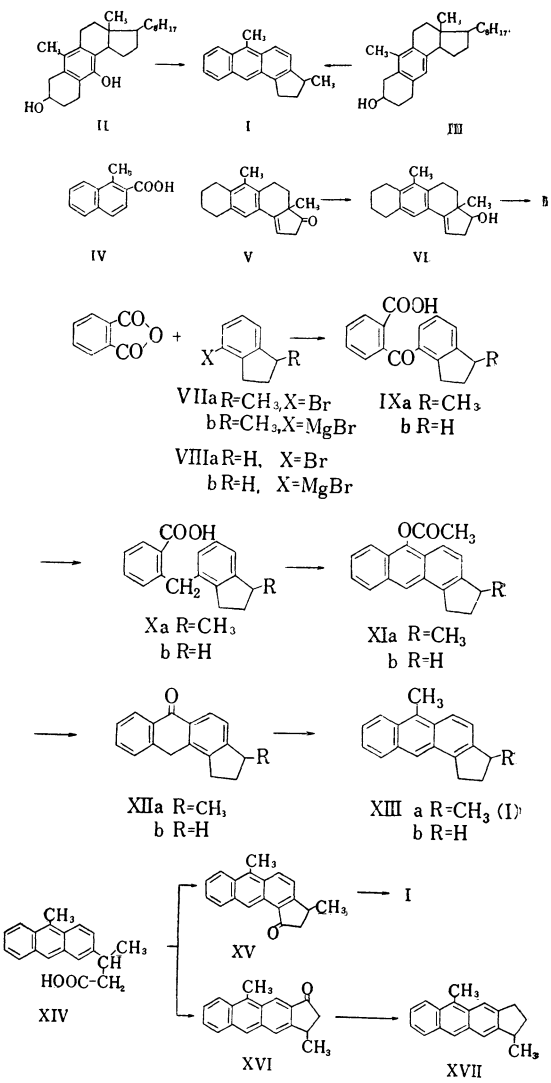

Fig. 1

method developed by Fieser and Hershberg[8] for the general synthesis of 9-alkylanthracene derivatives. Since the syntheses of I and XIIIb are similar, that of I is described at length. 4-Bromo-1-methylindan (VIIa), our starting substance, had been obtained by Hoyes[9] by

reduction with hydriodic acid and phosphorus of 4-bromo-1-hydroxy-1-methylindan (b. p. 135~136°C/25 mmHg, m. p. 33~34°C), prepared from 4-bromo-1-indanone and methylmagnesium bromide. When we carried out the reaction of methylmagnesium bromide with the bromoketone, we obtained unsaturated 7-bromo-3-methylindene (b. p. 137~139°C/19 mmHg) which did not show an OH band in infrared spectrum but could be hydrogenated in a good yield to saturated 4-bromo-1-methylindan (VIIa) (b. p. 75~77°C/1.5 mmHg) in the presence of platinum oxide.

Although Kon and Woolman[10] observed that 4-bromoindan (VIIIa) could be converted with difficulty into a Grignard complex even under the condition elaborated by Fieser and Hershberg[8], bromide VIIa could be made to react smoothly with magnesium to afford Grignard compound VIIb, which gave 2-(1-methylindan-4-carbonyl)benzoic acid (IXa) (m. p. 123.5~124.4°C) with phthalic anhydride. The conversion into 2-(1-methylindan-4-ylmethyl)-benzoic acid (Xa) (m. p. 126~127°C) was effected by the high pressure catalytic hydrogenation with a copper chromite catalyst.

Heating with zinc chloride in acetic anhydride and acetic acid accomplished the ring closure of acid Xa to 6-acetoxy-3-methyl-2, 3-dihydro-1*H*-cyclopenta[*a*]anthracene (XIa) (m. p. 161~161.5°C), which, because of its instability toward acid and alkali, was hydrolyzed indirectly according to Fieser and Hershberg's method[8].

The reaction of methylmagnesium bromide with acetate XIa provided 3-methyl-6-oxo-2, 3, 6, 11-tetrahydro-1*H*-cyclopent[*a*]anthracene (XIIa) (m. p. 99~100°C), accompanied by a high melting compound (m. p. 221~223°C). The latter, in spite of its sparing solubility in benzene, always appeared in the mother liquor of recrystallization of even the purest sample of anthrone XIIa from benzene. From this behavior, together with other evidences (molecular weight, ultraviolet spectrum and infrared spectrum) it appears that the substance is a condensation product from two anthrone molecules, analogous to the high melting products obtained by Fieser and Hershberg[8] in their synthesis of 10-isopropyl-1', 2', 3', 4'-tetrahydro-1, 2-benzanthracene.

The product from the Grignard reaction of anthrone XIIa with methylmagnesium bromide was decomposed with an acid and extraction with ether gave a highly blue-green fluorescent oil, which was purified by chromatography on alumina to afford pale yellow needles, m. p. 80.5~81°C. The substance was identified with 3,6-dimethyl-2,3-dihydro-1*H*-cyclopent[*a*]anthracene (I) prepared previously[3] by mixed melting point determination, comparison of infrared and ultraviolet spectra and mixed melting point determination of the trinitrobenzene complex.

In our previous synthesis of I, there remained a question whether the ring closure of acid XIV took place at 1-position to give XV or at 3-position to give XVI. Then, structure XVI was ruled out mainly on account of two observations, i. e. the 1-position of the anthracene nucleus is much more reactive toward electrophilic substitution, and the keto compound (XV) (m. p. 142~143.5°C) obtained showed a markedly similar ultraviolet spectrum with 1-acetylanthracene and exhibited an absorption at 12.2 $\mu$ in infrared spectrum which could be attributed to the presence of two adjacent hydrogen atoms in the anthracene nucleus[11]. The present synthesis with no such ambiguity can be taken as a support to the above view.

The synthesis of 6-methyl-2,3-dihydro-1*H*-cyclopent[*a*]anthracene (XIIIb) was carried out in a way analogous to that described above, m. p. 127~128°C; melting point of the trinitrobenzene complex, 149.5~150.5°C; melting point of the picrate, 144~145°C, ultraviolet spectrum overlapping that of I (see Fig. 2 and Table I).

## Experimental*

**Ethyl *o*-Nitrocinnamate**[12]. — Cinnamic acid was nitrated to give a mixture of *o*- and *p*-nitrocinnamic acids, which were esterified with ethanol and hydrogen chloride gas. From the mixture of ethyl *o*- and *p*-nitrocinnamates, the *o*-isomer was separated by virtue of its facile solution in m. p. 42°C, yield, 21.4%.

**Hydrocarbostyril.**—Ethyl *o*-nitrocinnamate (30 g.) was dissolved in 300 cc. of ethanol and hydrogenated in the presence of 4~5 g. of Raney nickel W-6 at 55~60°C and 47 atms. for 5~7 hr. Hydrocarbostyril was obtained in a yield of 79%, m. p. 163°C, (literature[13]: m. p. 165~166°C).

**β-(2-Bromophenyl)propionic Acid (XVIII)**[14].—*a. From Hydrocarbostyril*[15]. — A mixture of 30 g. of hydrocarbostyril, 97 g. of crystalline barium hydroxide and 400 cc. of water was refluxed for 20 hr. in a stream of nitrogen. The solution was diluted with 500 cc. of water and a stream of carbon dioxide was passed through it to precipitate barium carbonate.

After being freed from barium carbonate, the solution was made just alkaline to phenolphthalein with 10% sodium carbonate solution. The precipitated sodium salt, after being dried and washed with acetone, weighed 64.7 g. (yield, 84%), m. p. 155°C. A solution of 18.7 g. of this sodium salt and 6.9 g. of sodium nitrite in 100 cc. of water was added dropwise into 42 cc. of 48% hydrobromic acid chilled at 0~5°C in an ice bath. Cuprous bromide was precipitated by adding 6.3 g. of sodium sulfite to a mixture of 25 g. of cupric sulfate, 14.6 g. of sodium bromide and 100 cc. of water, and was dissolved by adding 6 cc. of 48% hydrobromic acid, and the solution was kept boiling. Onto this boiling solution, the above-mentioned diazonium bromide solution was added in four portions and the whole was refluxed for 30 min. The precipitated bromo acid was taken into ether, and the ethereal solution was washed with water and dried with anhydrous sodium sulfate. After removal of the solvent, the residue was recrystallized from aqueous acetic acid, m. p. 91~93°C, 5.6 g. The mother liquor was distilled and the fraction which boiled at 127~128°C/1 mmHg solidified on standing, m. p. 90°C, 1.2 g.

*b. From o-Bromobenzyl Bromide.*—*o*-Bromotoluene was brominated according to the procedure of Weizman and Patai[16], affording *o*-bromobenzyl bromide, m. p. 30°C (yield, 78%). To ethanolic sodium ethoxide prepared from 9.25 g. of sodium and 300 cc. of absolute ethanol, was added 28.5 g. of ethyl malonate and the mixture was heated for 15 min. on a water bath. After a solution of *o*-bromobenzyl bromide in 100 cc. of ethanol was added with stirring during 1 hr., the solution was stirred and refluxed for 3 hr.

The solvent was removed and the residue was diluted with ice water, and then concentrated hydrochloric acid was added to make the solution acidic to Congo red. After extraction with ether, the ether extract was washed with water and dried with anhydrous sodium sulfate. Removal of the solvent afforded a residue which was distilled to give ethyl *o*-bromobenzylmalonate boiling at 165~170°C/3 mmHg, 64.7 g. (yield, 82%)[10,14]. This malonate (64.5 g.) was hydrolyzed by boiling with 150 g. of potassium hydroxide, 175 cc. of ethanol and 300 cc. of water for 1 hr. After the ethanol was removed 250 cc. of concentrated hydrochloric acid was added to precipitate *o*-bromobenzylmalonic acid, which was collected and dried, 87 g. The malonic acid (87 g.) was decarboxylated by boiling with 400 cc. of water for 5 hr.

A heavy red oil which separated was extracted with ether and the ethereal solution was washed with water. After drying with anhydrous sodium sulfate, the solvent was removed to give β-(2-bromophenyl) propionic acid, m. p. 90°C. The yield was about 80% from the malonic ester.

**4-Bromo-1-indanone (XIX).**—Although Miersch[17] reported the formation of the bromoindanone XIX in a yield of 10% by the cyclization with concentrated sulfuric acid, XVIII did not give XIX with polyphosphoric acid[18] either under a rather mild condition (130°C, 20 min., recovery) or under a drastic condition (250°C, 20 min., polymerization). A mixture of 8.9 g. of crude XVIII and 15.6 g. of thionyl chloride was refluxed for 3 hr. After the excess of the thionyl chloride was removed, the residue, β-(2-bromophenyl)propionyl chloride, b. p. 120~123°C/2 mmHg, was dissolved in 240 cc. of carbon disulfide, and the solution was chilled at 5°C. To the stirred solution, 7.6 g. of aluminum chloride was added during 1.5 hr. After being allowed to stand at room temperature for 1.5 hr., the reaction mixture was refluxed for 15 min., and then a mixture of 100 cc. of concentrated hydrochloric acid and 300 cc. of water was added to decompose the reaction complex. The bromindanone was steam-distilled and recrystallized from ethanol, colorless needles, m. p. 95~96°C, (literature[15], m.p. 98~99°C), 6.2 g. (yield, 85%).

* All melting points are uncorrected. All ultraviolet spectra were measured with an EPS-2 Hitachi autorecording spectrophotometer and infrared spectra with a Perkin Elmer Model 12C. The analyses were performed in the microanalytical laboratory of the Institute of Polytechnics, Osaka City University.

**4-Bromoindan (VIIIa)**[10,14].—To a solution of 11.0 g. of XIX and 110 cc. of ethanol, 99 g. of amalgamated zinc was added with 70 cc. of concentrated hydrochloric acid. While the mixture was refluxed for 3 hr., 60 cc. of concentrated hydrochloric acid was added in three portions, and refluxing was further continued for 2 hr. The reaction mixture was diluted with water and, after the excess of zinc was removed, was extracted with ether. After drying with anhydrous sodium sulfate, the solvent was removed to give a liquid, which was distilled in vacuo, b. p. 75~77°C/2 mmHg, 8.7 g. (yield 85%), (literature, b. p. 118°C/18 mmHg[14], 100°C/1.5 mmHg[10]).

**7-Bromo-3-methylindene (XX)**[9].—Methyl bromide gas was introduced into a stirred mixture of 6.1 g. of magnesium and 200 cc. of ether until the magnesium disappeared. To the Grignard reagent, a solution of 2.5 g. of XIX in 500 cc. of ether was added during 1 hr., and the mixture was refluxed for 2 hr. While the solution was cooled in an ice bath, a mixture of 100 cc. of concentrated hydrochloric acid and 500 cc. of ice water was added, and the solution was extracted with ether. After the extract was washed with water and dried with anhydrous sodium sulfate, the solvent was removed to give an oil, which was distilled in vacuo, b. p. 137~139°C/19 mmHg, 11.1 g. (yield, 45%).

**4-Bromo-1-methylindan (VIIa).**—To a solution of 11.1 g. of XX in 50 cc. of ethanol, 0.2 g. of platinum oxide was added and the mixture was shaken in an atmosphere of hydrogen. Hydrogen was absorbed rapidly, and after 2 hr. the solution was freed from the catalyst. Removal of the solvent gave an oil, which was distilled in vacuo, b. p. 75~77°C/1.5 mmHg, 9.4 g. (yield, 84%), (literature[9], b. p. 245°C).

**2-(1-Methylindan-4-carbonyl)benzoic Acid (IXa).**—When a mixture of 5 drops of ethyl iodide and 10 drops of VIIa was added to a stirred mixture of 2.16 g. of magnesium and 5 cc. of ether, ebullition of ether was observed to indicate the start of the Grignard reaction. With stirring and heating on a water bath, a solution of 9.4 g. of VIIa in 80 cc. of ether was added during 3 hr., and the mixture was refluxed for 15 hr. in an atmosphere of nitrogen.

The Grignard solution was transferred into a dropping funnel with the aid of the pressure of nitrogen from a tank; then the reaction flask was washed with 100 cc. of ether, and the washing was transferred again into the funnel.

To a solution of 11.4 g. of phthalic anhydride in 200 cc. of benzene, the above Grignard solution was added during 1.5 hr. with stirring and refluxing, and the mixture was stirred and refluxed for 2 hr. in an atmosphere of nitrogen. Dilute hydrochloric acid was added to decompose the Grignard complex, and the solution was steam-distilled. The precipitate which separated from the distillated was dissolved in 10% sodium carbonate solution, and the resulting solution was again steam-distille. The turbid solution was filtered through a layer of Hyflo and was made acidic with dilute hydrochloric acid to precipitate IXa, which was recrystallized from benzene, m. p. 114~120°C. Recrystallization from benzene-ligroin yielded pure carboxylic acid, m. p. 123.5~124.5°C, 4.5 g. (yield, 36%). IR spectrum: 5.95 and 6.0 $\mu$.

Found: C, 77.15; H, 5.89. Calcd. for $C_{18}H_{16}O_3$: C, 77.12; H, 5.75%.

**2-(1-Methylindan-4-ylmethyl)benzoic Acid (Xa).**—A mixture of 3.5 g. of IXa and 140 cc. of ethanol was refluxed with a small amount of Raney nickel. The Raney nickel was filtered off, and the solution was hydrogenated with 0.5 g. of a copper chromite catalyst in a steel bomb at 149~155 atms. and 210~220°C for 4 hr. After the bluish green solution was freed from the catalyst, hydrogen sulfide was introduced to remove copper and chromium ions, and precipitated sulfides were filtered off through a layer of Hyflo. Removal of the solvent from the filtrate gave crystals, which were recrystallized from ethanol, m. p. 126~127°C, 3.2 g. IR spectrum: 5.9 $\mu$

**6-Acetoxy-3-methyl-2,3-dihydro-1*H*-cyclopent[*a*]anthracene (XIa).**—To a mixture of 3.2 g. of Xa, 30 cc. of acetic anhydride and 20 cc. of acetic acid, was added 0.27 g. of fused zinc chloride. After the brown mixture was refluxed for 1 hr., 50 cc. of water was added and the precipitated crystals were recrystallized from ethanol, m. p. 137~138°C, 2.5 g. (yield, 72%). IR spectrum: 5.7 $\mu$. UV spectrum: see Table I.

Found: C, 82.87; H, 6.64. Calcd. for $C_{20}H_{18}O_2$: C, 82.73; H, 6.25%.

**3-Methyl-6-oxo-2,3,6,11-tetrahydro-1*H*-cyclopent[*a*]anthracene (XIIa).**—To a Grignard reagent, prepared from 0.755 g. of magnesium, 30 cc. of ether and methyl bromide gas, 2.3 g. of XIa was added with 90 cc. of benzene. After the ether was removed, 90 cc. of benzene was added and the mixture was refluxed for 30 min. To the yellow solution, 100 cc. of diluted hydrochloric acid was added and the product was extracted with ether. After the ether extract was washed with water and dried with anhydrous sodium sulfate, the solvent was removed and the crystals were recrystallized from ethanol-ligroin, m. p. 86~93°C. For the preparation of an analytical sample, the product was recrystallized from methanol, m. p. 99~100°C.

Found: C, 86.11; H, 6.26. Calcd. for $C_{18}H_{16}O$: C, 87.06; H, 6.50%.

The mother liquor gave sparingly soluble crystals which were recrystallized from benzene-ethanol, m. p. 221~223°C.

**3,6-Dimethyl-2,3-dihydro-1*H*-cyclopent[*a*]anthracene (I).**—To the Grignard reagent, prepared from 0.252 g. of magnesium, 30 cc. of ether and methyl bromide, 427 mg. of XIIa was added with 50 cc. of benzene. After the ether was removed, the reaction mixture was refluxed on a water bath for 30 min. While the solution was chilled in an ice bath, 50 cc. of 2 N hydrochloric acid was added and the product was extracted with ether. The greenish blue fluorescent ether extract was washed with water and dried with anhydrous sodium sulfate. Removal of the solvent gave an oil which was chromatographed on 10 g. of alumina. Elution with benzine-benzene gave crystals which were recrystallized from methanol, pale yellow crystals, m. p. 80.5~81°C, 177 mg. (yield, 42%). The substance was found identical with I previously

prepared[3] by the comparison of the infrared spectra and the mixed melting point determination. UV spectrum: see Table I.

Found: C, 92.14; H, 7.60. Calcd. for $C_{19}H_{18}$: C, 92.63; H, 7.37%.

The trinitrobenzene complex was prepared from 35 mg. of I and 30 mg. of trinitrobenzene in benzene, and recrystallized twice from ethanol, reddish scarlet needles, m. p. 141.5~142°C. The mixed melting point determination (m. p. 140.5~142.5°C) confirmed the identity with the trinitrobenzene complex previously prepared[3] (m. p. 142~142.5°C).

Found: C, 65.37; H, 4.60; N, 9.15. Calcd. for $C_{25}H_{21}O_6N_3$: C, 65.35; H, 4.61; N, 9.15%.

**2-(4-Indancarbonyl)benzoic Acid (IXb).** — To a suspension of 2.05 g. of magnesium in 5 cc. of ether, was added a mixture of 2 drops of ethyl iodide and 10 drops of VIIIa to start the Grignard reaction. When ebullition of ether was observed, a mixture of 8.7 g. of VIIIa and 60 cc. of ether was added dropwise during 4 hr. After the solution was refluxed and stirred for 20 hr., the solution was transferred into a dropping funnel by means of the pressure of nitrogen from a tank, then the flask was washed with 100 cc. of ether and the washing was also transferred into the dropping funnel. To a solution of 11.3 g. of phthalic anhydride in 120 cc. of benzene, was added the above Grignard solution during 1.5 hr., and the mixture was refluxed for 30 min. A mixture of concentrated hydrochloric acid and 300 cc. of ice water was added to the reaction mixture and the whole was steam-distilled to remove volatile by-products. Ketoacid IXb was separated and dissolved in 150 cc. of a 10% sodium carbonate solution and the solution was steam-distilled for 2 hr. Fifty cubic centimeters of concentrated hydrochloric acid was added to the solution to give IXb, which was collected and recrystallized from benzene, m. p. 174~175°C. For the preparation of an analytical sample, the substance was recrystallized from benzene, m. p. 175~176°C, 6.8 g. (yield, 58%). IR spectrum: 6.01 and 5.94 $\mu$.

Found: C, 76.29; H, 5.54. Calcd. for $C_{17}H_{14}O_3$: C, 76.67; H, 5.30%.

**2-(4-Indanylmethyl)benzoic Acid (Xb).**—A solution of 6.2 g. of IXb in 125 cc. of ethanol was refluxed with a small amount of Raney nickel. The solution, after the catalyst was filtered off, was hydrogenated in a steel bomb with 0.3 g. of a copper chromite catalyst at 199~202 atoms. and 215°C for 4 hr. The solution was separated from the catalyst and treated with hydrogen sulfide to remove copper and chromium ions as the sulfides. The solution was filtered through a layer of Hyflo and the filtrate was concentrated under reduced pressure to afford crystals, which were recrystallized from benzene, m. p. 146~146.5°C, 5.42 g. (yield, 72%). IR spectrum: 6.01 $\mu$.

Found: C, 81.00; H, 6.24. Calcd. for $C_{17}H_{16}O_2$: C, 80.92; H, 6.39%.

**6-Acetoxy-2, 3-dihydro-1*H*-cyclopent[*a*]anthracene (XIb).**—To a mixture of 4.2 g. of Xb, 30 cc. of acetic acid and 20 cc. of acetic anhydride, was added 0.35 g. of zinc chloride and the solution was refluxed for 1 hr. To the brown solution, 200 cc. of water was added to precipitate a dark brown solid mass, which was continuously extracted with benzene to remove a brown insoluble by-product. The benzene extract was concentrated to afford yellow crystals, which were recrystallized from benzene, yellow prisms, m. p. 161~161.5°C, 3.4 g. (yield, 74%). IR spectrum: 5.70 and 12.35 $\mu$. UV spectrum: see Fig. 1 and Table I.

Found: C, 82.69; H, 6.12. Calcd. for $C_{19}H_{16}O_2$: C, 82.58; H, 5.84%.

**6-Oxo-2,3,6,11-tetrahydro-1*H*-cyclopent[*a*]anthracene (XIIb).** — To the Grignard reagent, prepared from 1.15 g. of magnesium, 60 cc. of ether and methyl bromide, was added 3.4 g. of XIb in three portions, which was followed by 40 cc. of benzene and then the ether was distilled off. The yellow reaction complex was decomposed with 100 cc. of water, while the solution was chilled in an ice bath, and the product was extracted with ether. After the ether extract was washed with water and dried with anhydrous sodium sulfate, the solvent was removed to give crystals, m. p. 115~140°C, which were recrystallized from benzene, m. p. 160~163°C. For the preparation of an analytical sample, the substance was recrystallized from benzene, m. p. 165~166°C, 0.981 g. (yield, 34%). IR spectrum: 6.10 $\mu$. UV spectrum: see Fig. 1.

Found: C, 86.68; H, 6.25. Calcd. for $C_{17}H_{14}O$: C, 87.15; H, 6.02%.

The mother liquor gave pale yellow needles, which were sparingly soluble in benzene, m. p. 222~223.5°C.

Found: C, 86.40; H, 5.63%.

**6-Methyl-2,3-dihydro-1*H*-cyclopent[*a*]anthracene (XIIIb).**—To the Grignard solution, prepared from 0.488 g. of magnesium, 30 cc. of ether and methyl bromide, was added 0.98 g. of XIIb, which was followed by 50 cc. of benzene. After the ether was distilled off, the benzene solution was refluxed for 30 min. After diluted hydrochloric acid was added to decompose the Grignard complex, the solution was extracted with ether. The bluish green fluorescent ether extract was washed with water and dried with anhydrous sodium sulfate. Removal of the solvent gave orange yellow needles, which were recrystallized from benzene to give pale yellow needles, m. p. 127~128°C. The mother liquor was concentrated and the residue was chromatographed on 10 g. of alumina affording an additional crop, with made the total yield of XIIIb 434 mg. (yield, 56%). UV spectrum: see Fig. 1 and Table I.

Found: C, 92.83; H, 6.85. Calcd. for $C_{18}H_{16}$: C, 93.06; H, 6.94%.

The trinitrobenzene complex was prepared from 20 mg. of XIIIb and 20 mg. of trinitrobenzene, and was recrystallized from ethanol, reddish scarlet needles, m. p. 149.5~150.5°C.

Found: C, 64.92; H, 4.35; N, 9.59. Calcd. for $C_{24}H_{19}O_6N_3$: C, 64.71; H, 4.30; N, 9.34%.

The picrate was recrystallized from benzene, brownish black needles, m. p. 144~145°C.

Found: C, 62.87; H, 4.19; N, 8.88. Calcd. for $C_{24}H_{19}O_7N_3$: C, 62.47; H, 4.15; N, 9.11%.

# SHORT COMMUNICATIONS

## *Manganese(III) Complexes with Ethylenediaminetetraacetic Acid*

By Yukichi Yoshino, Yoshikazu Tsunoda and Akira Ouchi

(Received June 1, 1961)

Although there have been some papers[1-3] on the analytical use of maganese(III) complexes with ethylenediaminetetraacetic acid (EDTA), little is known of the nature of the complex compounds. The authors had studied the critical condition of their formation in solution and could isolate the crystalline solid.

Three methods of the preparation of Mn-(III)-EDTA complexes from compounds of manganese in higher valency states have been examined. (1) Manganese dioxide suspended in water was mixed with solid ethylenediaminetetraacetic acid ($H_4Y$) under vigorous stirring. (2) In place of the free acid, a mixture of disodium salt of EDTA ($Na_2H_2Y \cdot 2H_2O$) and acetic acid was added to manganese dioxide. (3) Mn(II)-EDTA complex solution and manganese dioxide were mixed. Of these methods, the first was found to be the most suitable.

The relation between the mole ratio of manganese dioxide to EDTA and that of manganese dioxide to the produced Mn(III)-EDTA was shown in Fig. 1. Through the reaction a little of EDTA was lost and this may be due to its oxidation by manganese dioxide. However the mole ratio of Mn(III) to EDTA in the complex was approximately 1 : 1. Of course permanganate can also be

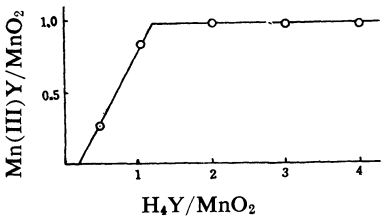

Fig. 1. Relation between the mole ratio of EDTA ($H_4Y$) : $MnO_2$ and the mole ratio of Mn(III)-EDTA : $MnO_2$ ($MnO_2$ : $2.69 \times 10^{-4}$ mol.).

used in place of manganese dioxide in all of these three methods.

The general method used to prepare the solid complex was as follows: to manganese dioxide precipitated by reducing potassium permanganate with ethanol, EDTA (in the acid form) was added in a ratio of little less than 1 : 1. On vigorous stirring reaction took place, evolving carbon dioxide, and a deep red solution was obtained. Filtering off the excess manganese dioxide, an equal volume of cold ethanol was added to the filtrate. The solution was allowed to stand for 1~2 hr. Deep red crystals thus obtained were washed with 90% ethanol and then with ethyl ether. Finally it was dried in the air in cold dark place; yield: 45~55%.

The crystal is deep red in color and decomposes easily in the light or on heating, giving carbon dioxide. The decomposition rate seems to be increased by the presence of Mn-(II) ion. The oxidation equivalent of the complex was evaluted as 435±3 by iodometric titration. It is very soluble in water but insoluble in most of organic solvents. When a sample was heated with gradual elevation of temperature, 12~13% of weight loss took place at 25~130°C. This value may correspond to the sum of the weight of the water of crystallization and of EDTA partially decomposed. The remaining EDTA was completely

3) R. Přibil and E. Hornychova, *Chem. Listy*, **40**, 101 (1950).

decomposed at 260~300°C. The solid gave the analysis: K, 9.50; Mn, 12.52; C, 28.56; H, 3.57; N, 6.53%. From these results the formula $K[Mn(EDTA)(OH_2)_2]\cdot H_2O$ was tentatively given as in the case of Cr(III)-EDTA complex[4].

Visible absorption spectra of the complex in acetic acid-sodium acetate buffer solutions of various pH were illustrated in Fig. 2. In the solution of pH 2.5~4.0 the maximum absorption was observed at 500 mμ, while in the higher pH region the color turned yellow and the maximum shifted to 450 mμ. By plotting the extinction against pH of the solution, the p$K$ value between the red and the yellow species was evaluated as 5.3. It was also found that the red complex was strongly adsorbed on an anion-exchange resin in the chloride form. On titrating the complex with sodium hydroxide the curve in Fig. 3 was obtained. This curve has a single inflection at a neutralization point with approximately 1 mol. of sodium hydroxide per 1 mol. of the chelate. The pH of the half-neutralized solution is 5.5; which agrees fairly well with the p$K$ value obtained from spectral data.

## *The Electron Spin Resonance Absorption of Vanadium Pentoxide Catalysts*

By Kimio TARAMA, Shiichiro TERANISHI, Satohiro YOSHIDA and Hiroshi YOSHIDA

(Received June 2, 1961)

Kozyrev[1] and Pecherskaya et al.[2] studied the electron spin resonance (ESR) absorption of $VO^{2+}$ in organic solvents at room temperature and observed that its spectrum consisted of eight hyperfine components, while Sands[3] reported the ESR absorption of $V^{4+}$ ions in glass, and Faber et al.[4] observed the hyperfine structures of $VO^{2+}$ ions on the ion exchangers. But no one has ever reported the ESR absorption of vanadium pentoxide.

The ESR method was used in order to study the magnetic properties of vanadium pentoxide and the binary system of vanadium pentoxide-potassium pyrosulfate.

Vanandium pentoxide was prepared by calcining ammonium metavanadate at 450°C, and vanadium pentoxide-potassium pyrosulfate

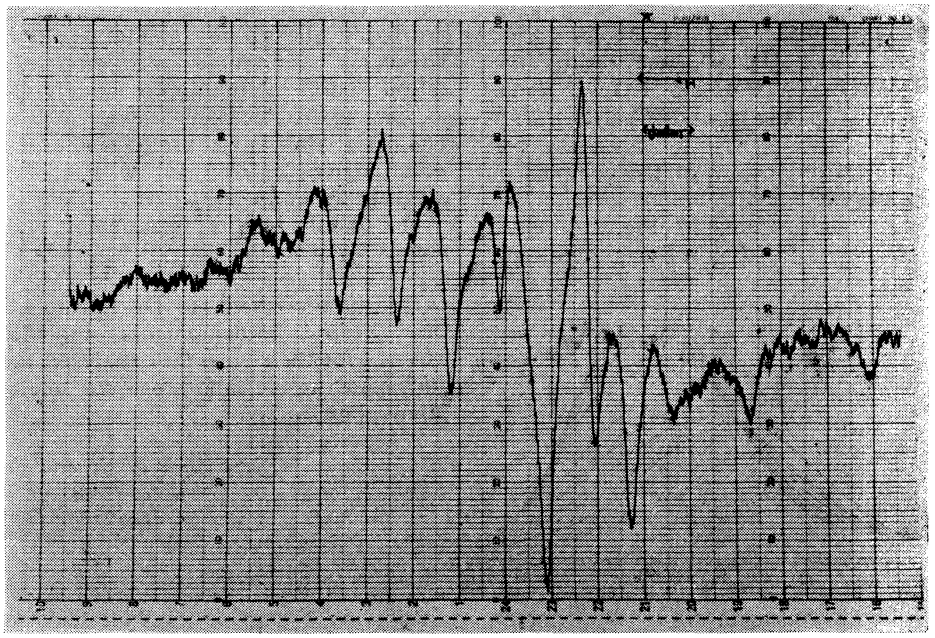

Fig. 1. ESR spectrum of the solid solution of vanadium pentoxide and potassium pyrosulfate.

samples were prepared by calcination of the mixture vanadium pentoxide and potassium pyrosulfate which contained vanadium pentoxide 10, 15, 25, 40, 50 and 70 mol. % respectively at 450°C, in closed glass vessels. Vanadium pentoxide-potassium pyrosulfate samples containing vanadium pentoxide less than 40 mol. % melted completely, and changed into amorphous substances of dark brownish color.

The spectrometer used in this research was of reflecting-type, and its resonance frequency was 9410 Mc. The observation were carried out at room temperature and also at liquid oxygen temperature.

In the case of vanadium pentoxide, an asymmetric ESR signal was observed and the $g$-value was 1.96. The line width ($\Delta Hmsl$) was 89 gauss at 16°C and 173 gauss at −183°C.

ESR signals of vanadium pentoxide-potassium pyrosulfate samples containing vanadium pentoxide less than 25 mol. %, showed the well-resolved hyperfine structures at room temperature. Fig. 1 shows the hyperfine structure of the sample consisting of vanadium pentoxide 15 mol. % and potassium pyrosulfate 85 mol. %. Eleven components are observed and its central eight components are stronger than the others.

In the case of the samples containing vanadium pentoxide more than 25 mol. %, the spectrum was not so well-resolved as Fig. 1.

The analysis of this spectrum according to Kozyrev's method shows that the $g$-value and the coupling constant for the central eight components are 1.98 and 98 gauss, and for the other three components are 1.92 and 320 gauss respectively.

The spectrum of vanadium pentoxide-potassium pyrosulfate is quite similar to that of $VO^{2+}$ ions on the ion exchangers observed by Faber et al.[4] and this fact shows that the observed paramagnetic absorption results from $VO^{2+}$ ions.

The authors wish to thank Professor Seizo Okamura, Kyoto University, for allowing one of the authors to use the ESR absorption apparatus.

## *Synthesis of* D-*Threosamine and* D-*Erythrosamine*[1]

By Juji YOSHIMURA, Yoshiaki OHGO and Tetsuo SATO

(Received June 27, 1961)

In the course of studies on the glycosylation of aminosugars[2], the requirement of a lower 2-aminosugar had arisen, so we attempted to synthesize 2-amino-D-tetroses. Recently, the synthesis of them was reported by Kuhn et al.[3], in which the hydrochlorides of D-threosamine and D-erythrosamine were obtained by catalytic half reduction of *N*-benzyl-D-tetrosaminonitriles ($III_b$ and $IV_b$) prepared by acidic hydrolysis of corresponding acetone derivatives ($I_b$ and $II_b$).

It prompts us to record further observations related to their work. To obtain *N*-substituted-D-tetrosaminonitriles (III and IV) two paths shown in Fig. 1 were examined. By treatment of D-glyceraldehyde[4] with amines (aniline, benzylamine and isopropylamine respectively) and hydrogen cyanide, *N*-phenyl-D-threosaminonitrile ($IV_a$), m. p. 114~116°C, $[\alpha]_D$ −247.2° (*c* 0.72, ethanol), Found: C, 62.38; H, 6.30; N, 14.5, Calcd. for $C_{10}H_{12}O_2N_2$: C, 62.48; H, 6.29; N, 14.58%, and *N*-isopropyl-D-erythrosaminonitrile ($III_c$), m. p. 103~104°C, $[\alpha]_D$ + 48.1° (*c* 0.21, methanol), Found: C, 53.43; H, 8.90; N, 17.48. Calcd. for $C_7H_{14}O_2N_2$: C, 53.14; H, 8.92; N, 17.71%, were obtained as colorless needles.

On the other hand, when acetone-D-glyceraldehyde[5] was treated in the same manner, two epimeric pairs of the corresponding acetone-aminonitriles ($I_a$, $II_a$, $I_b$ and $II_b$) were separated in crystalline forms (acetone-*N*-phenyl-D-erythrosaminonitrile ($I_a$), m. p. 124°C, $[\alpha]_D$ +157.9° (*c* 0.69, methanol), yield 7.4%, Found: C, 66.30, H, 6.85; N, 12.06, Calcd. for $C_{13}H_{16}O_2N_2$: C, 67.22; H, 6.94; N, 12.06%, acetone-*N*-phenyl-D-threosaminonitrile (IIa), m. p. 100~102°C, $[\alpha]_D$ −149.4° (*c* 0.86, methanol), yield 30%, Found: C, 67.40; H, 7.04; N, 11.94. Calcd. for $C_{13}H_{16}O_2N_2$: C, 67.22; H, 6.94; N, 12.06%. The physical properties of *N*-benzyl derivatives, $I_b$ and $II_b$, are entirely consistent with those of the substances reported by Kuhn et al.[3] respectively.

In addition to them, a trace of rhombic colorless crystal, m. p. 115~116°C, $[\alpha]_D$ +15° (*c* 0.77, methanol), having the same analytical values as the epimeric pair (Found: C, 67.06; H, 7.02; N, 11.92%) in the case of *N*-phenyl derivatives and a small amount of crystals corresponding to $C_{13}H_{18}O_4N_2$, m. p. 255~256°C, and $C_{16}H_{16}O_2N_2$, m. p. 216~218°C in the case of *N*-benzyl derivatives were obtained.

To prepare *N*-substituted D-tetrosaminonitriles the above acetone derivatives were subjected to hydrolysis in a mineral acid, to which *N*-benzyl derivatives ($I_b$ and $II_b$) showed such an extraordinary resistance that it was impracticable to obtain hydrolyzates of $I_b$ and $II_b$ even in 2 N hydrochloric acid solution of 80% ethanol at room temperature for 24 hr., although Kuhn et al. carried out successfully by exsiccating the 2 N hydrochloric acid solution of $I_b$ or $II_b$ on phosphorus pentoxide at room temperature. *N*-Phenyl derivatives ($I_a$ and $II_a$) changed gradually in their optical rotation in a 1 N mineral acid solution of 80% ethanol at room temperature [$I_a$: $[\alpha]_D$ +107° (5 min.)→ +156° (3 hr.)→+165° (22 hr. approximately const.), $II_a$: $[\alpha]_D$ −164° (3 min.)→−177° (1 hr.) →−220° (20 hr.)→−222° (41 hr.)→−228° (92 hr. const.)]. Colorless needles, m. p. 114~116°C, obtained from the reaction mixture of $II_a$, was agreed with $IV_a$ described above.

The presumption whether these aminonitrile derivatives belong to the threo-type or the erythro-type was deduced from the general survey on their yields and their optical rotational data. In general, an epimer in which -NHR group has trans configuration to the hydroxyl gronp attached to the adjacent carbon precedes the cis isomer in their yield[6]. Moreover, the one having -NHR group on the right hand in the Fischer projection shows generally more positive optical rotation than the other, when they are measured in an inert solvent. This relationship seems to be closely akin to the acid-amide rule[7] in the sugar series. Fortunately, Kuhn et al. established the configurations of $I_b$ and $II_b$ by converting them into the configurationally known α-amino-β, γ-dihydroxybutyric acid[8], and the result coincides with the above mentioned presumption.

To obtain pure epimeric pair of aminosugars,

workers. In nitric acid medium, thorium-234 was separated by anion exchanger Amberlite IRA-400[11]. Recently, Korkisch et al.[12] reported that the adsorption of thorium onto anion-exchange resin is very strong, but that of uranium is rather weak, in a nitric acid-alcohol mixed solution.

The author studied the procedure of the preparation of carrier-free thorium-234 using an anion exchanger Dowex 1-X8. The preparation procedure is as follows. One gram of commercial reagent grade uranyl nitrate hexahydrate crystal was dissolved without further purification in 5~6 ml. of 0.2 N nitric acid-ethyl alcohol 80%, mixed solution*, and the solution was passed through Dowex 1-X8 resin column (100~200 mesh, 1.0 g., 0.70 $cm^2$ ×2.8 cm., pretreated with a few milliliters of the nitric acid-alcohol mixed solution) at a flow rate 0.7 ml. per min., and then the column was washed with 30~40 ml. of the nitric acid-alcohol mixed solution. The elution of thorium from the resin column could be attained with a small amount of 0.2 N nitric acid or water. When the elution was carried out with 0.2 N nitric acid, thorium was almost completely eluted with 4~5 column volumes of the nitric acid solution at a flow rate 1.0 ml. per min.

The result shown in Fig. 1 was obtained using the procedure described above. The activity measurement of the solution was as follows; an aliquot of the solution was transferred to a glass counting dish, and evaporated to dryness. The $\alpha$ and $\beta$ activities were counted using a gas flow proportional counter and G-M counter respectively. In Fig. 2, decay curve of the eluate is shown.

The yield of thorium-234 from one gram of uranyl nitrate crystal was $4.6\times10^5$ d.p.m.($^{234}$Th $+^{234}$Pa), and the radiochemical impurities were not observed by $\beta$ and $\gamma$ energy measurements.

# *Studies on Polymerization and Depolymerization of ε-Caprolactam Polymer. IX*. Reformation Reaction of ε-Caprolactam from Poly-ε-capramide*

By Naoya OGATA

(Received January 24, 1961)

The mechanism of the polymerization reaction of ε-caprolactam in the presence of water has been studied in detail by many investigators[1-6]. It has been generally accepted that the initial reaction of the polymerization is caused by the hydrolysis of ε-caprolactam and that the chain growth occurs mainly through the addition of ε-caprolactam to $-NH_2$ end-groups, being catalyzed by -COOH end-groups. If this mechanism is correct, ε-caprolactam is reformed in the depolymerization reaction rolling out successively from $-NH_2$ end-groups of the polymer chain because the polymerization is an equilibration reaction. Therefore, no ε-caprolactam can be expected from poly-ε-capramide having modified end-groups. In the previous paper[6], however, it was presumed that the addition reaction of ε-caprolactam would take place even on amide groups near the center of the polymer chain. In this case the reverse process of this intramolecular amide-interchange reaction called "Einrollung Reaktion"[1] as shown below is responsible for the reformation of ε-caprolactam from poly-ε-capramide.

## Experimental

ε-Caprolactam with water content less than 0.01% was polymerized in the presence of 1/20, 1/50 or 1/100 mol./mol. of hexamethylenediamine or adipic acid at 257°C. Polymers were washed with boiling water, and then heated in a solid phase at 180°C for 10 hr. at 1 mmHg pressure. The analytical results of the polymers having almost exclusively $-NH_2$ or -COOH end-groups thus obtained are shown in Table I. The polymer having $-NH_2$ end-groups was heated in refluxing acetic anhydride for 4 hr. and $-NH_2$ end-groups were acetylated almost completely. The polymer having $-NH_2$ end-groups was also dissolved in phenol and $-NH_2$ end-groups in the polymer were neutralized by titrating with aqueous hydrochloric acid in the presence of thymol blue as an indicator. The polymer having -COOH end-groups was dissolved in hot benzyl alcohol and the solution was neutralized by titrating with alcoholic sodium hydroxide solution in the presence of phenolphthalein. The polymers having $-NH_3^+Cl^-$ or -COONa end-groups were precipitated by adding methanol to the neutralized solutions.

TABLE I. THE ANALYTICAL RESULTS OF THE POLYMERS

| Kind of end-group | Basic group mol./mol. | Acidic group mol./mol. | $[\eta]$ |
|---|---|---|---|
| $NH_2$—$NH_2$ | $9.8\times10^{-2}$ | $3.9\times10^{-4}$ | 0.21 |
| | $16.5\times10^{-2}$ | $7.2\times10^{-4}$ | 0.16 |
| HOOC—COOH | $11.8\times10^{-4}$ | $9.5\times10^{-2}$ | 0.20 |
| | $8.2\times10^{-4}$ | $7.8\times10^{-2}$ | 0.20 |
| NaOOC—COONa | 0 | 0 | 0.22 |
| | $2.7\times10^{-4}$ | 0 | 0.27 |
| | 0 | 0 | 0.41 |
| | 0 | 0 | 0.50 |
| $ClH\cdot H_2N$—$NH_2\cdot HCl$ | 0 | — | 0.25 |
| AcHN—NHAc | $8.8\times20^{-4}$ | $2.3\times10^{-4}$ | 0.23 |
| | $9.3\times10^{-4}$ | $2.7\times10^{-4}$ | 0.27 |
| | 0 | 0 | 0.43 |
| | $3.4\times10^{-4}$ | 0 | 0.52 |

Each of the polymers was washed with refluxing methanol and dried at 110°C in vacuo of 2 mmHg for 24 hr. in order to decrease the water content to less than 0.01%. The polymer samples, each 2 g. in weight, were sealed within glass tubes under a nitrogen atmosphere and heated for a certain period of time at 230 or 257°C in a vapor bath of thymol or Dowtherm A. The amount of ε-caprolactam reformed from the polymers was determined for the extract in chloroform. The number of end-groups in the polymers was determined and the intrinsic viscosity $[\eta]$ for the polymers was measured in 98% sulfuric acid. The polymerization degree $\bar{P}_n$ of the polymers was calculated by the following equation[7].

$$\bar{P}_n = 124[\eta] - 5$$

## Results

The rates of reformation of ε-caprolactam from the polymers are shown in Tables II—V.

No change in the number of end-groups was observed during the heat treatment. As shown in Tables II—V, at 230°C, ε-caprolactam is reformed from the polymer of which the end-groups are exclusively -COOH or $-NH_2$ while no ε-caprolactam is reformed from the polymer having -NHAc or -COONa end-groups. However, at 257°C, ε-caprolactam is reformed even from the polymer having -NHAc or -COONa end-groups. The rate of the reformation of ε-caprolactam is not influenced by the polymerization degree of the modified polymers. The rate of the reformation of ε-caprolactam from the polymer having $-NH_3^+$ end-groups is very fast.

## Discussion

The re-equilibration of poly-ε-capramide has been studied[8-11] on the dry polymers having modified end-groups. It has been reported[8,9] that the rate of reformation of ε-caprolactam from the acetylated polymer is very much slower than that of normal polymer. From these results, it seems very probable that no re-equilibration would take place in a dry polymer having all its end-groups modified.

As shown in the experimental results, no ε-caprolactam is formed at 230°C from the polymer having COONa or -NHAc end-groups. However, above 230°C, it is presumed that the addition or reformation of ε-caprolactam must take place on the amide groups in the polymer chain through the intramolecular amide-interchange reaction. As the rate of the reformation of ε-caprolactam from the polymer having $-NH_3^+$ end-groups is very fast, it is ascertained[2,5] that the addition or the reformation of ε-caprolactam on the $-NH_2$ end-groups, catalyzed by the hydrogen ion, occurs fast.

Assuming that reformation reaction of ε-caprolactam from the polymer having modified end-groups may be caused by the intramolecular interchange reaction between two adjacent

8) S. Smith, *J. Polymer Sci.*, **30**, 459 (1958).
9) G. M. Van der Want, ibid., **37**, 547 (1959).

amide groups in polymer chain, it can be expressed as follows:

$$M_n \underset{k_2}{\overset{k_1}{\rightleftarrows}} M_{n-1}+L \quad (1)$$

where $M_n$ and $M_{n-1}$ are polymer chains, L is ε-caprolactam, $k_1$, $k_2$ the rate constant of the reformation or addition reactions, respectively. The rate of the reformation reaction of ε-caprolactam can be expressed as follows, when the concentration of polymer chain is expressed in mole fraction of structural unit:

$$dx/dt=k_1(1-x)-k_2x \quad (2)$$

where $x$ is the mole fraction of ε-caprolactam reformed at $t$ hr. At equilibrium,

$$k_2=k_1(1-x_\infty)/x_\infty \quad (3)$$

where the equilibrium concentration of ε-caprolactam $x_\infty$ is about 0.07[4] and $(1-x_\infty)$ can be fixed as equal to 1. Then, from Eqs. 2 and 3,

$$dx/dt=k_1(1-x/x_\infty) \quad (4)$$

Integration of Eq. 4 gives Eq. 5.

$$2.303 \log x_\infty/(x_\infty-x)=k_1t/x_\infty \quad (5)$$

From Eq. 5, the rate constant of the reformation reaction of ε-caprolactam can be calculated for the polymer having modified end-groups, as shown in Table VI. The values of $k_1$ are roughly the same, being independent

of the polymerization degree of the polymer. The mean value of $k_1$ is $0.23\times10^{-2}$ mol./mol.hr. Yumoto[4] reported that the rate constant of the reformation of ε-caprolactam from the polymer $[\eta]_{cresol}=1.1$ was $2.26\times10^{-2}$ mol./mol.hr. at 257°C. In this case, as the number of amino- or carboxyl-groups in the polymer is $(0.5\sim0.7)\times10^{-2}$ mol./mol., it is presumed that the reformation of ε-caprolactam may be caused mainly by the reaction rolling out ε-caprolactam succesively from the ends of the polymer chain.

Compared with this value, the reformation velocity of ε-caprolactam from the polymer having modified end-groups is about 1/10 and it can be found that the end-groups of the polymer play a very important role for the addition or the reformation reactions of ε-caprolactam. However, the rate of the reformation of ε-caprolactam from the polymer having modified end-groups is independent of the polymerization degree of the polymer and it is presumed that ε-caprolactam is reformed also by the reaction between two adjacent amide groups in the polymer chain.

In the previous paper[6], it was reported from the results of the amide-interchange reaction of an *N*-alkyl acid amide and ε-caprolactam,

that the rate constant of the reformation reaction of ε-caprolactam at 252°C was $3.6\times10^{-2}$ mol./mol.hr. This value is considerably greater than that for the polymer having modified end-groups. This is probably due to the difference in activity of the components.

It is concluded for the polymerization and reformation reactions in the system of ε-caprolactam and poly-ε-capramide that the reaction occurs predominantly on the end-groups of the polymer and that the intramolecular amide-interchange reaction between two adjacent amide groups in the polymer chain occurs slowly.

## Summary

The reformation reaction of ε-caprolactam from poly-ε-capramide having modified end-groups has been studied. It was found that no ε-caprolactam was reformed at 230°C from the polymer of which all of the end-groups were -COONa or -NHAc groups, while ε-caprolactam was reformed slowly at 257°C. The rate of the reformation of ε-caprolactam from the polymer having -COONa or -NHAc end-groups is about 1/10 of that from the polymer having normal end-groups at 257°C and it is independent of the polymerization degree of the polymer.

The polymerization and the depolymerization reactions of ε-caprolactam polymer occur predominantly on the end-groups and the interchange reaction between two adjacent amide groups in the polymer chain occurs slowly.

The author wishes to express his sincere gratitude to Dr. H. Kobayashi for his permission to publish these results and also to Dr. T. Yoshino and Mr. T. Takayanagi for their helpful discussion. He is indebted to Mr. S. Yoshikawa for his assistance in the experiments.

# *Studies on Organophosphorus Compounds. III. On Phosphite Copper Cyanide Complex Compounds*[*1]

By Yoshihiko NISHIZAWA

(Received January 27, 1961)

In a previous paper[1], it has been reported on a few new properties of phosphite[*2] cuprous halide complex compounds. During the course of an investigation of organophsphorus complex compounds, the present author has also found that phosphites react with copper cyanide to give new complex compounds[2] having strong fungicidal action[3].

There has been no report on copper cyanide complex compounds having the phosphorus atom, but recently Birum[4] prepared independently the same compounds as those of the present author and reported that they have insecticidal activity towards a few insects.

**Preparation of Phosphite Copper Cyanide Complex Compounds.**—Phosphite copper cyanides were prepared from phosphites and copper cyanides in a benzene solution. After copper cyanide was dissolved in benzene solution, and the benzene was evaporated under reduced pressure, the complex compounds were obtained as white crystals or colorless oil.

According to the mole ratio of phosphites to copper cyanide two complex compounds were obtained; namely, phosphite copper cyanide (I) and bis-phosphite copper cyanide (II), but tri-phosphite copper cyanide could not be prepared from three moles of phosphite and one mole of copper cyanide; instead, a product was one mole of bis-phosphite copper cyanide (II) and one mole of phosphite was unreacted.

$$(RO)_3P + CuCN \rightarrow (RO)_3PCuCN \quad (I)$$

$$2(RO)_3P + CuCN \rightarrow ((RO)_3P)_2CuCN \quad (II)$$

[*1] Presented at the Annual Meeting of Chemistry of Complex Compounds of Japan, Fukuoka, October, 1959.

[*2] The phosphorus compounds in this paper were named according to the Drake Committee's Report (*Chem. Eng. News*, **30**, 4515 (1952)).

1) Y. Nishizawa, This Bulletin, **34**, 1170 (1961).

2) Y. Nishizawa, and M. Nakagawa, Japanese Pat. Applied No. 12895 (1959).

3) J. Hattori and Y. Nishizawa, Japanese Pat. Applied No. 12896 (1959).

4) G. H. Birum, U. S. Pat., 2909544 (1959).

$$3(RO)_3P + CuCN \rightarrow ((RO)_3P)_2CuCN + (RO)_3P$$
(II)

Phosphite copper cyanides (I) gave bis-phosphite copper cyanides (II) by adding one mole ratio of phospite and II gave also I by adding one mole ratio of copper cyanide, and II were converted to phosphite copper cyanide (I) by heating under a reduced pressure.

$$(RO)_3PCuCN + (RO)_3P \rightarrow ((RO)_3P)_2CuCN$$
(I) (II)

$$((RO)_3P)_2CuCN + CuCN \rightarrow 2(RO)_3PCuCN$$
(II) (I)

$$((RO)_3P)_2CuCN \xrightarrow{heat} (RO)_3PCuCN + (RO)P\uparrow$$
(II) (I)

It is clear from the following experimental facts that these complex compounds have the phosphite group in their molecules. The compounds I and II reacted with benzoyl chloride in benzene solution to give *O,O*-dialkylbenzoyl phosphonates (A) and copper cyanide. The melting point of 2,4-dinitrophenylhydrozone of the phosphonate A coincided with that of 2,4-dinitrophenylhydrazone of the product prepared from trialkyl phosphite and benzoyl chloride by Kosolapoff's method[5]

$$((RO)_3P)_nCuCN + n\ C_6H_5COCl$$

(5)

The infrared absorption spectra*3 of these compounds, I and II, showed the absorption band of P–O-isopropyl group at 1010 $cm^{-1}$ (see Fig. 1). But the absorption bands of P–O stretching vibration[6] of phosphite at 857 and 769 $cm^{-1}$ shift to 879 and 779 $cm^{-1}$, respectively. From this shift, it is considered that P–O bonds are shortened by formation of the complex; namely, P–O bonds in these complex compounds become stronger than that of phosphite (see Fig. 1).

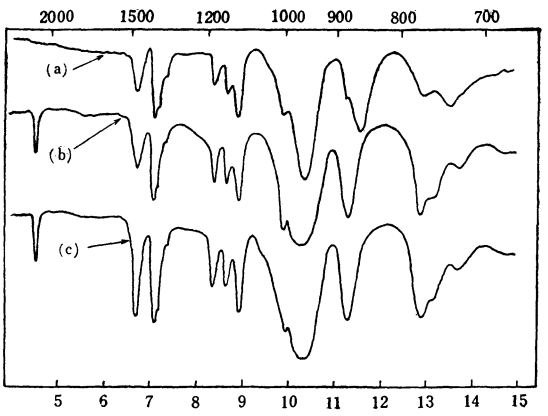

Fig. 1. (a) Infrared absorption spectrum of triisopropyl phosphite (in Nujol). (b) Infrared absorption spectrum of triisopropyl phosphite copper cyanide (Id) (in Nujol). (c) Infrared absorption spectrum of bis-(triisopropyl phosphite) copper cyanide (IId) (in Nujol).

In the ultraviolet absorption spectra*4 of these compounds, the absorption maximum did not appear.

**Molecular Weights of Bis-phosphite Copper Cyanide Complex Compounds.**—In many cases, it has been reported that organometallic cyanide complex compounds form the polymer[7,8], so the present author measured the molecular weights of the crystalline bis-phosphite copper

cyanide as represented in these compounds. Molecular weights of these complex compounds were measured by the cryoscopic method[9] in benzene, bromoform, and cyclohexane and by the ebullioscopic method[10] in benzene. All of these solvents were prepared by purification of guaranteed reagents in the usual manner[11].

The results of these experiments are shown in Table II.

It is made clear from Table II that the complex compounds having methyl or ethyl groups as alkyl form tetramer in benzene solution at the freezing point and that they form dimer in other solvents, such as bromoform and cyclohexane, and moreover by the ebullioscopic method in benzene they also form dimer.

With isopropyl group as alkyl, the compound forms dimer in all cases.

It seems to be possible that the apparent values of molecular weights may be smaller, if the associated molecules dissociate in organic solvents. These possibilities are supported by the fact that the degree of association in non-polar solvents are greater than that in a polar solvent. So the present author measured the molecular weight of bis-(trimethyl phosphite) copper cyanide (IIa) by cryoscopy in cyclohexane in various concentrations ranging from 0.3 to 5 per cent.

If the associated molecules dissociate in organic solvents, the apparent values of molecular weight will become greater with the increase of concentration.

As shown in Table II, an increase of apparent values of molecular weight could not be found in the above range of concentration. So it seems to be right that the compound IIa forms dimer in cyclohexane, and does not form dimer from the dissociation of tetramer.

These problems of their structures or degree of association must be determined by X-ray analysis.

## Experimental

**Preparation of Phosphites.**—Trialkyl phosphites were prepared by Ford-Moore's method[12] and their yields, physical constants and microanalytical data are shown in Table III.

**Preparation of Phosphite or Bis-phosphite Copper Cyanides.**—The following examples illustrate the preparations of phosphite and bis-phosphite copper cyanides, I and II. Other examples are shown in Table I and their molecular weights are shown in Table II.

**Preparation of Triethyl Phosphite Copper Cyanide (Ib).**—To a solution of 33.2 g. (0.2 mol.) of triethyl phosphite in 50 ml. of benzene was gradually added 17.8 g. (0.2 mol.) of copper cyanide. The temperature rose gradually and copper cyanide dissolved in benzene. After stirring one hour, the reaction mixture was filterd and concentrated under reduced pressure. Colorless oil (49.6 g.) was obtained, $n_D^{25}$ 1.5031.

Found: N, 5.63; P, 12.2; Cu, 25.1. Calcd. for $C_6H_{15}O_3PCuCN$: N, 5.47; P, 12.1; Cu, 24.9%.

To a solution of 8.5 g. of Ib in 20 ml. of benzene, was added 5.6 g. of triethyl phosphite. The temperature did not rise. After concentrating the benzene solution, 13.9 g. of a white crystalline substance were obtained and the melting point of this substance was 121°C upon recrystallization from ligroin. This melting point coincided with that of authentic bis-(triethyl phosphite) copper cyanide (IIb) and a mixed melting point showed no depression.

**Preparation of Bis-(trimethyl phosphite) Copper Cyanide (IIa).** — This compound was prepared from 24.8 g. (0.2 mol.) of trimethyl phosphite and 8.9 g. (0.1 mol.) of copper cyanide in benzene solution as above mentioned. White crystals (33.5 g. 99.3%) were obtained and melted at 60~61°C.

Found: N, 4.15; P, 18.3; Cu, 18.6. Calcd. for $C_6H_{18}O_2P_2CuCN$; N, 4.15; P, 18.4; Cu, 18.8%.

To a solution of 11.2 g. of the compound IIa in 20 ml. of benzene was added 4.3 g. of trimethyl phosphite. After the benzene was evaporated, 15.1 g. of colorless oil were obtained and gave $n_D^{26}$ 1.5296. The refractive index, the infrared spectrum and the microanalytical data of this compound coincided with authentic trimethyl phosphite copper cyanide (Ia).

**Pyrolysis of Bis-(triethyl phosphite) Copper Cyanide (IIb).** — The compound IIb (21.1 g. 0.05 mol.) was set in a distillation flask (50 mol.) which was combined with the trap cooled at −50°C, and heated at 130°C under 0.1 mmHg pressure for 8 hr.

The colorless oil which was captured in the trap,

12) A. H. Ford-Moore, "Organic Syntheses", Vol. 31 (1951), p. 111.

was 7.1 g. and was distilled at 55~56°C/19 mmHg, $n_D^{20}$ 1.4133.

Found: P, 19.7; C, 46.05; H, 9.18. Calcd. for $C_6H_{15}O_3P$: P, 19.9; C, 46.15; H, 9.04%.

To a solution of 4.1 g. of this oil in 5 ml. of benzene was added 1.1 g. of copper cyanide. After filtering and concentrating, 5.0 g. of white crystals were obtained and melted at 121°C (recryst. from petroleum ether). This melting point coincided with that of authentic bis-(triethyl phosphite) copper cyanide (IIb) and the mixed melting point did not go down. So it was made clear that this oil was triethyl phosphite.

On the other hand, residual oil in a distillating flask gave 11.6 g. and had $n_D^{25}$ 1.4999, and the microanalytical data and the infrared absorption spectrum of this oil coincided with that of authentic triethyl phosphite copper cyanide.

Found: P, 12.5; N, 5.21; Cu, 24.6. Calcd. for $C_6H_{15}O_3PCuCN$: P, 12.1; N, 5.48; Cu, 24.9%.

To a solution of 5.1 g. of this oil in 10 ml. of benzene was added 3.3 g. of triethyl phosphite. After the benzene was evaporated off, 8.0 g. of white crystals were obtained and melted at 121°C. This melting point coincided with that of authentic bis-(triethyl phosphite) copper cyanide (IIb) and the mixed melting point did not go down. So, it was determined that the residual oil was triethyl phosphite copper cyanide (Ib).

**Reaction of Triethyl Phosphite Copper Cyanide (Ib) with Benzoyl Chloride.** — To a solution of 5.1 g. of triethyl phosphite copper cyanide (Ib) in 10 ml. of ether was added gradually 2.8 g. of benzoyl chloride. The temperature rose and copper cyanide was precipitated. The reaction mixture was filtered and concentrated. The residual oil was distilled under reduced pressure, b. p. 140°C/2.5 mmHg, $n_D^{23}$ 1.5068, yield 3.6 g.

Found: P, 12.6; C, 54.39; H, 6.18. Calcd. for $C_{11}H_{15}O_4P$: P, 12.8; C, 54.55; H, 6.20%.

2,4-Dinitrophenylhydrazone of this product was prepared in the usual manner and melted at 171~172°C (recryst. from ethanol). This melting point coincided with that of 2,4-dinitrophenylhydrazone of authentic *O,O*-diethylbenzoyl phosphonate[4] and mixed melting point did not go down.

## Summary

Trialky phosphite reacts with copper cyanide to give phosphite or bis-phosphite copper cyanides according to the mole ratio of phosphite to copper cyanide.

It is made clear from their molecular weights that these products form polymer in various organic solvents. Moreover, these products have strong fungicidal action but this will be reported in another paper.

The author wishes to express his thanks to Professor Shinichiro Fujise and Professor Taro Yamazaki of Tohoku University and to Professor Ryutaro Tutida of Osaka University for their helpful suggestions in the preparation of this manuscript. He also wishes to thank the Sumitomo Chem. Co., Ltd. for permission to publish this work. He is indebted to coworkers in the analytical section in this laboratory. He also wishes to express his thanks to Mr. M. Nakagawa for his assistance.

# *Infrared Spectra of Isotactic Poly-α-olefins**

By Hiroyuki TADOKORO, Tohru KITAZAWA**, Shun'ichi NOZAKURA and Shunsuke MURAHASHI

(Received January 18, 1961)

In the previous paper[1], we have reported that the infrared absorption bands at 1364, 1314, 1297 and 1185 $cm^{-1}$ of isotactic polystyrene (IPS) and its derivatives are considered to be closely associated with the helical structure of the isotactic polymers (mainly due to the $CH_2$, CH and C-C vibrations of the main chain having the alternate sequence of gauche and trans conformations) and that these bands may be used as the criterion for the isotactic structure. Furthermore, it has been confirmed from the infrared spectra of the mixture of IPS and isotactic poly-α, β, β-trideuterostyrene (IPTDS) that these bands are originated from the intramolecular interactions in the helical chain[2]. In this communication we wish to report the results obtained

* Presented at the 9th Annual Meeting of the Society of Polymer Science, Osaka, May, 1960.

** Present address: Research Laboratories, Kanegafuchi Spinning Co., Ltd., Tomobuchi-chô, Miyakojima-ku, Osaka.

from the infrared spectra measured on the following polymers in order to examine whether similar bands appear or not.

*Polypropylene.*—We have used the ethyl ether extract of Moplen MS as the atactic sample (APP), and its *n*-heptane residue as the isotactic sample (IPP).

*Isotactic and Atactic Poly-3-deuteropropene-1 (IPP-3D and APP-3D)* $-(-CH_2-\underset{\displaystyle CH_2D}{\underset{|}{CH}}-)_n-$.—Prepared according to the following scheme, and separated by the same procedure as in the case of polypropylene:

$$CH_2{=}CH{-}CH_2Cl \xrightarrow{Mg} CH_2{=}CH{-}CH_2MgCl \xrightarrow{D_2O}$$

$$CH_2{=}CH{-}CH_2D \xrightarrow{\text{Natta catalyst}} -(-CH_2-\underset{\displaystyle CH_2D}{\underset{|}{CH}}-)_n-$$

*Polybutene-1.*—Polymerized with Ziegler catalyst. We used the ethyl ether extract as the atactic sample (APB), and its residue as the isotactic sample (IPB).

*Isotactic Polyvinylcyclohexane (IPVCH) and Poly-α-deuterovinylcyclohexane (IPDVCH)* —$-(-CH_2-\underset{\displaystyle H}{\underset{|}{CD}}-)_n-$.—(kindly given by Professor C. G. Overberger of the Polytechnic Institute of Brooklyn).

Figure 1 shows the infrared dichroism (LiF optics) of IPP, IPP-3D and IPB as well as IPS for reference. The bands in the 3$\mu$ region appear at nearly the same frequencies as the characteristic values of the $CH_2$ and $CH_3$ stretching modes of *n*-paraffins (2960(∥) 2953 (⊥): $\nu_a$ ($CH_3$), 2920(⊥) : $\nu_a$ ($CH_2$) (*E*), 2905 (∥): $\nu_a$ ($CH_2$) (*A*), 2876(⊥) : $\nu_s$ ($CH_3$) (*E*), 2844(no): $\nu_s$ ($CH_2$) (*A* and *E*) for IPP). As we have already reported, no (or weak) dichroism of the 2849 $cm^{-1}$ $\nu_s$ ($CH_2$) band and the distinguished perpendicular dichroism of the 2924 $cm^{-1}$ $\nu_a$ ($CH_2$) band of IPS may be interpreted by the inclination of the $CH_2$ group. This dichroic feature may be expected to be found in the spectra of all kinds of helical isotactic polymers[3]. In fact, this feature has been

3) S. Murahashi, S. Nozakura and H. Tadokoro, This Bulletin, 32, 534 (1959).

observed in the spectra of IPP and IPP-3D. Although IPP-3D has another $CH_2$ group in the side chain besides the $CH_2$ group in the main chain, it will be clear from a simple consideration that the dichroism of the $\nu_s$ ($CH_2$) band may be absent, if the $CH_2$ group assumes the three stable positions about the C-$CH_2$D axis with equal probability. This dichroic feature is obscured in the cases of IPB, IPVCH and IPDVCH, because of the complexity due to the existence of $CH_2$ groups in the side chain. In the spectra of IPS and IPP, there are appreciable shifts between perpendicular and parallel components of the $\nu_a$ ($CH_2$) band, and furthermore the perpendicular component occurs at higher frequencies and parallel ones at lower in both spectra. The splitting of the perpendicular and parallel components are also observed in the $\nu_a$ ($CH_3$) bands in the spectra of IPP and IPB, but in these cases the perpendicular ones occur at lower frequencies. The splitting of the $\nu_a$ ($CH_2$) bands may be explained from the factor group consideration reported already in the case of IPS[4]. The band splitting of the $\nu_a$ ($CH_3$) modes involves an interesting problem in relation to the perturbation of the environment to the local degeneracy of the $CH_3$ group.

Figure 2 is the infrared spectra (1600~700 $cm^{-1}$) of isotactic poly-α-olefins rewritten on the scale of molecular extinction coefficient. In Fig. 3, the spectra of the isotactic and atactic samples of poly-α-olefins at room temperature were compared with those of the molten states of the isotactic samples. Figure 4 shows the infrared dichroism (NaCl region) of isotactic poly-α-olefins. We have found that several bands at 1400~1100 $cm^{-1}$ region of the spectra of isotactic poly-α-olefins show behavior similar to that of the bands of IPS and its derivatives mentioned at the beginning of this article. The bands observed at 1364

$cm^{-1}$ in the spectra of IPS and its derivatives[1,3,5] appear also in the spectra of IPP, IPP-3D, IPB and IPP-3, 3, $3D_3$[6] at the same frequency, and moreover exhibit the same characteristic behavior: (1) the perpendicular dichroism, (2) similar intensity (2~5 in molecular extinction coefficient), (3) absence in the cases of the atactic samples and (4) decrease of the intensity with heating and disappearance at molten state. This band is not observed in the spectra of IPTDS, isotactic poly-$\alpha D_1$-styrene[7], IPP-1, $1D_2$[6], IPP-2D[6]. The above mentioned inference for this band may be considered to be supported strongly by these experimental evidences. Especially, the constancy of the frequency (1365~1360 $cm^{-1}$) extending over the various samples of IPS, its derivatives and isotactic poly-$\alpha$-olefin swill suggest the approximate localization of the vibrations in the skeleton and the attached hydrogen atom, comparing them to the bands described subsequently. Some bands similar to the 1185 $cm^{-1}$ band of IPS (and 1183 $cm^{-1}$ of isotactic poly-*p*-deuterostyrene, 1184 $cm^{-1}$ of isotactic poly-*p*-methylstyrene, 1190 $cm^{-1}$ of isotactic poly-*m*-methylstyrene, 1184 $cm^{-1}$ of isotactic poly-*p*-trimethylsilylstyrene) are observed in the spectra of IPP (1167 $cm^{-1}$), IPP-3D (1216 $cm^{-1}$), IPB (1217 $cm^{-1}$) and IPVCH (1217 $cm^{-1}$) with the same parallel dichroism, the similar intensity (2.5~4.5 in molecular extinction coefficient) and the similar band shapes. In addition this band is absent in the spectra of atactic samples and IPTDS, IPDVCH, IPP-1, $1D_2$[6], IPP-2D[6] and IPP-3, 3, $3D_3$[6]. Consequently these bands are considered to be due to similar origin. In spite of the approximate constancy of the frequency in the case of IPS and its derivatives, the frequency differs considerably in the spectra of poly-$\alpha$-olefins. This fact suggests that in the mode assignable for this type of band the vibration in the main chain would couple with those of the side chain appreciably in the cases of poly-$\alpha$-olefins, while it would not do so with the phenyl side group.

# *Molecular Rotations of Polyhydroxycyclohexanes in Relation to their Structures. II*[1]. *(−)-1, 2, 3, 5/4-Cyclohexanepentol*

By Shukichi YAMANA

(Received February 6, 1961)

$[M]_D^{20}$(W) of (−)-1, 2, 3, 5/4-cyclohexanepentol ((−)-epi-quercitol[2]) was calculated by using PM-method and Whiffen's method[3], respectively. The orientation of the unit groups, (OH). in the molecule is shown in Table I (Fig. 1).

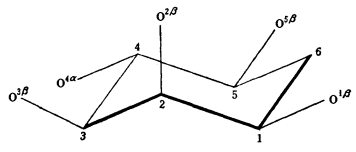

Fig. 1. Perspective drawing of the molecular model of (−)-1,2,3,5/4-cyclohexanepentol.

TABLE I

| Name | Orientation of unit group, (OH) | Calcd. $\sum[\mu]_{D\,obs}^{20}$ | Calcd. Whiffen |
|---|---|---|---|
| Cyclohexane | | | |
| (−)-1,2,3,5/ 4-pentol | [(1β), (2β), (3β), (4α), (5β)] | −6.8 (−10.9)[5] | 0 |

**PM-Method.**— $[M]_D^{20}$(W) of (−)-1, 2, 3, 5/4-cyclohexanepentol$\equiv\sum[\mu]_{D\,obs}^{20}$ of (−)-1, 2, 3, 5/4-cyclohexanepentol = (1β) Λ (2β) + (1β) Λ (3β) + (1β) Λ (4α) + (1β) Λ (5β) + (2β) Λ (3β) + (2β) Λ (4α) + (2β) Λ (5β) + (3β) Λ (4α) + (3β) Λ (5β) + (4α) Λ (5β) = $A+0+0+0-A-B+0-A+0+A$[4] = $-B=-6.8$ $(-10.9)$[5].

1) Part I: S. Yamana, This Bulletin, 33, 1741 (1960).
2) "Advances in Carbohydrate Chemistry", Vol. 14, Academic Press, New York (1959), p. 190.
3) D. H. Whiffen, *Chem. & Ind.*, 1956, 964.
4) Table II in the previous paper[1] is used, here.
5) The values, calculated by supposing that the optical center of (OH) is located at its O atom, are given in parentheses.

**Whiffen's Method.**

along $C^1-C^2$
C|C−C|O+O|O−O|H+H|H−H|C
along $C^2-C^3$
C|H−C|C+O|C−O|O+H|O−H|H
along $C^3-C^4$
C|C−C|H+O|H−O|O+H|O−H|C
along $C^4-C^5$
C|H−C|C+O|O−O|H+H|C−H|O
along $C^5-C^6$
C|C−C|H+O|H−O|H+H|H−H|C
along $C^6-C^1$
C|H−C|C+H|C−H|O+H|O−H|H
Total=0

As seen above, $[M]_D^{10}$(W) of (−)-1, 2, 3, 5/4-cyclohexanepentol is presumed to be −6.8 (−10.9)[5] (by PM-method) or 0 (by Whiffen's method). The corresponding observed value has not been found in any referential literatures, but $[M]_D$(W) was observed at 27°C as −8.9[6]. This is nearly equal to −6.8 (−10.9)[5], the value calculated by PM-method at 20°C. This fact indicates that in this case also, PM-method is more suitable for estimating $[M]_D^{20}$ (W) than Whiffen's method.

# *Studies on Surface Heterogeneity in Adsorption of Carbon Dioxide on Nickel by Use of the Isotopic Desorption Method*[1]

Kozo Hirota, Yasushi Kobayashi* and Jitsuo Kiji

(Received January 30, 1961)

A number of printed works on the active center of catalysts have appeared, since Taylor proposed the idea in 1925. However, though its existence on actual catalysts is recognized unequivocally by most researchers, some ambiguities remain yet as to its nature. In some cases the experimental grounds in favour of the active center may be explained by other causes, i. e., by the "induced heterogeneity" or by the mutual interaction between adsorbed molecules. Such situations regarding this important problem of catalysis may be brought about because researchers have taken it up by the kinetic or calorimetric methods, which are deficient in giving decisive conclusions.

Therefore, in order to attack the problem, now called heterogeneity of catalyst surface, it seems interesting to apply the isotopic desorption method of Roginsky[2], who applied it with success by the use of deuterium to determine the heterogeneity of nickel, when hydrogen was chemisorbed[3]. The process of the method consists in two procedures: firstly successive chemisorption of two gaseous portions of isotopically labelled and non-labelled species, to the catalyst to be investigated, and secondly, determination of the isotopic composition of the gases desorbed from the catalyst. Now, if the isotopic composition of the desorbed gases is the same as that of the mean of the chemisorbed gases, it is highly probable that the catalyst surface is homogeneous, while if it is not the same, the catalyst surface is likely to be heterogeneous. Since then, the method has been applied by others; e. g., chemisorption of carbon monoxide on a promoted iron catalyst by Kummer and Emmett[4], making radioactive carbon as the tracer, and chemisorption of hydrogen on nickel-silica by Schuit[5], who, however refused to accept the result of Roginsky.

Such being the situation it will be interesting to apply it to other systems under the condition of least ambiguity, so as to check the criticism against this method. In the present paper, the heterogeneity of nickel surface will be investigated by use of carbon dioxide,

making heavy carbon dioxide $CO^{18}O$ as the labelled species of adsorbent, and effecting desorption at the adsorbed temperatures. Selection of this adsorbate may be appropriate, because, besides its possible immobility on the surface, it will evolve little adsorption heat, as compared with hydrogen and carbon monoxide hitherto selected, so that the disturbing effect of evolved heat would be small on adsorption.

## Experimental

**Apparatus.**—The apparatus used in the measurement is shown in Fig. 1. During the experiment, caution was always taken that no mercury vapor might penetrate into catalyst A by constant use of trap T kept at ca. −78°C.

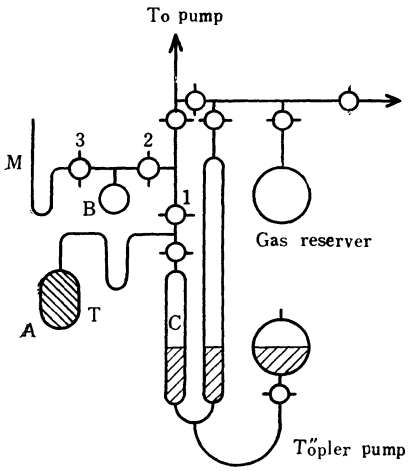

Fig. 1. Apparatus.

**Nickel Catalyst.**—Nickel carbonate, obtained by the reaction of aqueous nickel nitrate solution with an ammonium carbonate solution, was washed with water, dried and heated in the air for 10 hr. at 300°C. Nickel oxide thus prepared was turned into nickel powders by reducing it with hydrogen for 80 hr. at 350~380°C. Before each experimental run, the nickel powders were treated with hydrogen followed by evacuation at the same temperature at $10^{-6}$ mmHg. The specific area of the catalyst determined by the BET method (adsorbate, nitrogen) was 1.18 $m^2/g$.

**Gases.**—Heavy carbon dioxide $CO^{18}O$ was prepared in the present laboratory by the thermal diffusion method[6]. Its concentration was 29.9~15.2 atom %. Normal carbon dioxide was obtained by evaporation of commercial dry ice, and purified with aqueous sodium chromate, followed by dehydration with liquid nitrogen and phosphorus pentoxide. The hydrogen used for reduction was prepared by electrolysis of aqueous sodium hydroxide solution, and was purified finally by being effused through a palladium filter. The last treatment was indispensable for the reproducibility of the result.

**Adsorption Isotherm.**—For the sake of discussion, the adsorption isotherm for carbon dioxide on the nickel powders (28.1 g.) which were used in the experiment was determined at −78°C. This is shown in Fig. 2. It was found that 0.17$_8$ cc./g. was necessary in order to complete the monomolecular layer.

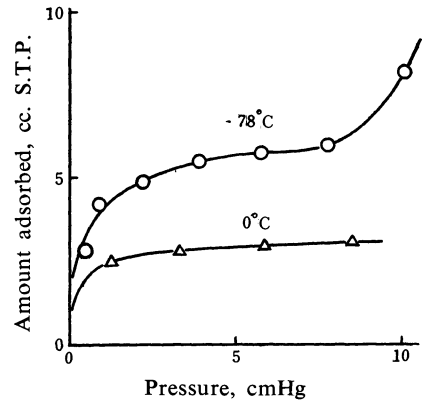

Fig. 2. Adsorption isotherms for carbon dioxide at 0 and −78°C (cat. 28.1 g.)

**Reduction of Nickel Surface.**—In order to determine the permissible degree of reduction the amount of adsorbed oxygen was measured with the isotopic dilution method by use of $CO^{18}O$, i. e., introducing the gas to the vessel which contained nickel and determining the degree of dilution in the gas collected from the vessel. When the $O^{18}$% of the original $CO_2$ was 15.2 atom % and when the reduction at 380°C was continued for 20 hr., the collection was made at two temperature intervals, the result being as follows :—between 0°C and room temperature, 0.3 cc. and 14.2%, and between room temperature and 300°C, ca. 1 cc. and 12.2%. Dilution of the original carbon dioxide occurred to such an extent that the residual oxygen was found not to be negligible by the above treatment of reduction, suggesting that the nickel surface did not reach a state sufficiently free from oxygen. However, it was found that eighty hours of reduction as actually adopted in the experimental runs was found to be satisfactory so that the heterogeneity could be discussed by this method. Such difficulty in cleaning the surface as was found above has been pointed out already, e. g., recently by Roberts and Sykes[7].

**Exchange Reaction.**—After the nickel catalyst charged in the reaction vessel A was reduced with hydrogen, it was evacuated and was kept at the adsorption temperature, which was adopted to be −78°C if otherwise not stated. Then a known amount $V_1$ of heavy carbon dioxide (or normal carbon dioxide) was introduced into the vessel A from the measuring pipette C. After the scheduled time which was set at 30 min. of contact, the gaseous sample was collected by opening the taps

6) K. Hirota, Y. Kobayashi et al., "Isotopes and Radiation" (Tokyo), 2, 235 (1959); Y. Kobayashi et al., "Mass-spectroscopy" (Japan), No. 13, 79 (1959).

7) M. W. Roberts and K. W. Sykes, *Trans. Faraday Soc.*, 54, 548 (1958).

1 and 2, and being condensed in the trap B cooled at −78°C. Amount $v$ of the condensed gas was determined by evaporating it in the known volume of space between the taps 3 and 2 with the manometer M. The residual carbon dioxide adsorbed tightly on the nickel could be calculated as the difference between $V_1$ and $v$. Then normal carbon dioxide (or heavy carbon dioxide), the amount of which was measured to be $V_2$, was again introduced to the catalyst already covered to some extent by heavy carbon dioxide. After the scheduled time of contact, the gaseous part of the carbon dioxide was again condensed in B, and was measured by the same procedure as described above. This procedure was done several times. The first desorption was made at the same temperature as the adsorption, and subsequent desorption was carried out by raising the temperatures gradually up to 300°C. The isotopic abundance and gaseous composition of each collected gas were determined by a mass-spectrometer.

## Results

For the sake of making the effect evident, the adsorption was carried out at temperatures as low as possible, i. e., mostly at −78°C and also at 19 and 0°C. However, the amount of the desorbed gas was determined at several temperatures up to 300°C. Experimental data are summarized in Table I in the order of the runs actually carried out. The first and second portions, denoted as I and II in Table I, of the gas introduced into the vessel are heavy and normal carbon dioxide if otherwise not stated. The numerals marked by→after $V_1$ denote the amount of the gas strongly adsorbed after desorption at the adsorption temperature.

The reproducibility of the experiment may be shown by the residual amount of the gas remaining after evacuation in Nos. 1 and 4, where the adsorbed and desorbed temperatures were the same (−78°C) while other experimental conditions were practically identical with each other. It is noteworthy that such strongly adsorbed gas amounted to ca. 1.85 cc. in both runs in spite of the difference of the first portion introduced. The tendency that

the first portion was adsorbed more tightly than the second could be observed in No. 2, where heavy carbon dioxide was made the second portion. From the comparison of Nos. 1 and 4 with No. 2, the residual gas at −78°C is evidently small in the case where heavy carbon dioxide was introduced as the second gas. This may be explained by the isotopic effect of adsorption. Though the discussion along this line is interesting, it will not be taken up in the present report, because there may be some accidental error*.

By comparing the result Nos. 3 and 6 where the adsorption and first desorption were carried out at 0°C and 19°C, respectively, with those of Nos. 1 and 4, it is clear that the strongly adsorbed carbon dioxide increases in amount as the temperature of adsorption becomes higher.

In order to obtain knowledge on the state of adsorption of carbon dioxide, a similar experiment was attempted making carbon monoxide the second gas in No. 5. Since carbon monoxide can be adsorbed on nickel very strongly as shown by the great heat of adsorption (35 kcal.)[8], carbon dioxide which has been adsorbed may be expelled from a nickel surface. Such an effect is moreover possible due to the heat evolution when carbon monoxide is chemisorbed. However, as described in Table I, the amount of the desorbed carbon dioxide was only ca. 0.1 cc., though carbon monoxide was desorbed more than carbon dioxide ($5.1_8$ cc.). This suggests a firm bonding of carbon dioxide with nickel. However the fact that $^{18}O$ concentration of carbon monoxide in the desorbed gas could not be neglected will become a matter of discussion; i. e. it was 1.0%. This indicates the occurrence of an exchange reaction such as

$$CO^{18}O + CO \rightarrow CO_2 + C^{18}O \qquad (I)$$

on nikel surface in parallel with desorption.

Such a firm bonding between the first chemisorbed* carbon dioxide and nickel can be concluded also from the isotopic balance of heavy oxygen in each run. According to No. 1, where 0.40 cc. of heavy carbon dioxide was chemisorbed as the first gas, only a part of it could be desorbed at each desorbing procedure, as shown in Table II, where the nautral abundance of $^{18}O$ was taken to be 0.2%. The same tendency can be seen also in No. 4, where 0.56 cc. of heavy carbon dioxide was first chemisorbed. It will be noteworthy that though the absolute amount of heavy carbon dioxide adsorbed at −78°C is different in both runs, their ratios to those at 300°C is the same i. e., 0.65. A similar result is found easily, in others runs, by the same method of calculation.

## Discussion

As pointed out above, a part of the nickel surface has a nature to chemisorb carbon dioxide so strongly that carbon monoxide added as the second gas can not expel the carbon dioxide practically from the surface. This nature of the nickel surface will be supported also from the fact that the molecules once chemisorbed at low temperature were not desorbed even by evacuation at 300°C. By use of the data of No. 1, the situation will be shown quantitatively. The residual amount 1.87 cc at the desorbed temperature corresponds to surface coverage ($\theta$) of 0.37, which decreases gradually down to $\theta$=0.18 (0.9 cc.) after the desorption process at 300°C, because the amount of carbon dioxide necessary to cover the catalyst surface monomolecularly is 5.0 cc.

Now the nature of such a special surface, which extends to about one third of BET area of the nickel, will be discussed from the standpoint of isotopic exchange of heavy oxygen with regard to possible occurrence of the induced heterogeneity. The data of No. 1 will be taken up again. If the bonding of carbon dioxide to nickel is extremely firm on

* The residual gas remaining at 300°C is only 0.18 cc. in No. 2. Such a small numeral will probably be brought out by an increased error due to the large amount of the second gas ($12.1_8$ cc.).

8) O. Beeck, "Advances in Catalysts", 2, 151 (1950).

* Chemisorption will hereafter be used often as a technical term not defined to be clearly different from adsorption.

some special sites on the surface, it may be possible that $^{18}O$ concentration in the first portion of desorbed gas is natural, i. e. 0.2%, because $V_1$ was 1.35 cc., which was less than the volume corresponding to the chemisorption on the special sites (1.87 cc.), leaving some vacant sites for the second gas. Actually, dilution of $^{18}O$ in the strongly adsorbed carbon dioxide occurred up to 2.0%, as shown in the last column of Table I. The degree of dilution will be given approximately as follows: 0.096/0.40=0.24. This suggests that there occurred some exchange of oxygen between strongly adsorbed carbon dioxide and that which was weakly adsorbed.

Now it is natural to assume that the difference of adsorptive power or the surface mentioned above might be due to the primary property of sites but not induced secondarily by the mutual interaction of absorbed molecules. This is because if the difference is brought about by the latter reason, the degree of the exchange reaction II between adsorbed carbon dioxide would occur much more markedly and increase according as the adsorption temperature rises, and evacuation at 300°C would take away most of the adsorbed carbon dioxide, due to a relatively weak interacting energy. Another fact will be shown against the induced heterogeneity by use of the data of No. 2, where heavy carbon dioxide added as the second gas ($3.6_5$ cc.) was taken out from the surface practically without exchange by the first desorption at the adsorption temperature, due to the weak bonding of the second gas with adsorptive sites.

Since the surface heterogeneity is confirmed, its nature will be discussed in more detail. According to the analysis of the data, it has been shown that even the special sites extending as much as one third of the total are not of a homogeneous nature in adsorptive power, three fourths of it making firmer bonding to carbon dioxide than the remaining one third. The existence of such heterogeneity is possible also from the data of No. 5, which can be explained by an exchange reaction I of weakly adsorbed carbon monoxide and strongly adsorbed carbon dioxide. Assuming that the amount of the strongly adsorbed carbon dioxide is 1.85 cc. and also that $^{18}O$ concentration of the strongly adsorbed carbon monoxide ($7.0_6$ cc.) is the same as that of the desorbed one, $^{18}O$ lost from carbon dioxide by the contact of carbon monoxide will be approximately equal to $(1.0\times12.24/1.85\times15.2)\times100\%=22\%$. It is noteworthy that this numeral nearly equals that (24%) obtained in the discussion of the above paragraph. Here it will be mentioned that no exchange of this type I could be observed on silver catalyst even at 220°C[9], suggesting that there was a difference in the chemisorped state between nickel and silver. The result may be caused by the chemisorptive power of nickel to carbon monoxide which is so strong that they can form stable carbonyl compounds, though the chemisorptive power of both metals to carbon dioxide is not very different, so that the exchange reaction

$$O_2^*+CO \rightarrow CO_2^*+O_2 \qquad \text{(III)}$$

proceeds at the same order of temperature 100~200°C[10].

In short, it can be concluded that there are two or three types of sites on nickel surface differing in chemisorptive power. It will be our next problem to investigate the real nature of these special sites, e. g., to see whether they exist as groups or as isolated ones. However, the problem of surface heterogeneity is very complicated, and the present data can not give an answer to all the questions to be discussed. Here it will be mentioned that, since the ratio of the active surface to the total is considerably large and reproducibility of the catalytic activity is very good, the heterogeneity here observed may be brought about by the different catalytic activity of each crystal plane and not by isolated sites on some planes. Further discussion concerning the nature of heterogeneity is to be continued in the investigation which will be reported soon.

## Summary

By applying the isotopic desorption method of Roginsky under the experimental condition of least ambiguity, heterogeneity of nickel surface has been studied on the chemisorption of carbon dioxide by making heavy oxygen as the tracer. It has been shown that about one third of the surface can chemisorb carbon dioxide very strongly at −78, 0 and 19°C, and a part of carbon dioxide chemisorbed is not desorbed even by the evacuation at 300°C. Considering the isotopic balance of heavy oxygen, it can be said that the above effect is brought about by the primary heterogeneity of surface sites but not by the "induced heterogeneity" of adsorbate. However, it has been found difficult to make the detailed nature of such heterogeneity by the present data alone.

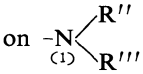
# *A New Method for the Preparation of Piperazines. III. Mechanism of Ring-closure Reactions with Elimination of Ester*

By Kazuo NAKAJIMA

(Received January 11, 1961)

The new synthesis of piperazines proposed by the author in the preceding papers[1], consists in heating a compound A to obtain a piperazine-derivative B under elimination of an ester C, as can be seen from the following over-all Scheme 1;

[A] [B]



$$+ \mathrm{RCOOR'''} \qquad (1)$$

[C]

The compound A is an ester. It is generally accepted that the alkyl-ogygen bond in carboxylic acid ester of primary or secondary alcohols remains unattacked in hydrolysis or in other reactions in which these esters are concerned. However, esters of tertiary alcohols in some of their reactions may suffer the rupture of the alkyl-oxygen bond. For example, *tart*-butyl acetate, heated under reflux, is completely converted by dry hydrogen chloride into *tart*-butyl chloride and acetic acid, while *n*- and *sec*-butyl acetate undergo no reaction by the same treatment.

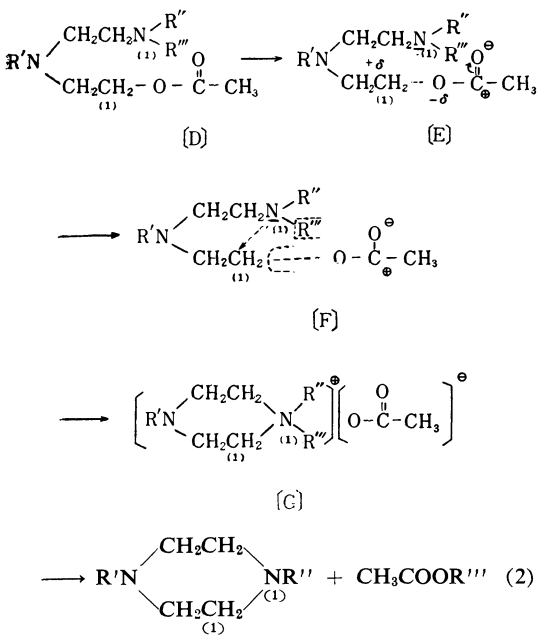
According to Eq. 1, however, the $C_{(1)}$-O bond should break up and the liberated acetoxyl group should combine with an alkyl group which comes out of $N_{(1)}$ to build up an ester molecule C, thus leaving a piperazine-ring system B.

The $-C-C_{(1)}-$ linkage in A may be regarded as an alkyl, so the piperazine-ring formation 1 may be considered to be a reaction which involves a replacement of R''' by $-C-C_{(1)}-$ grouping.

In other words, the ester part of A reacts as an alkylating reagent on  to drive out R'''.

In order to see the reactivities of alkyl acetates with tertiary amines, triethylamine and dimethylaniline were heated with *n*-butyl acetate under reflux for 20 hr.

However, no reaction could be observed and the starting materials were recovered unchanged. An attempt in an autoclave (at 280°C for 3 hr.) gave the same result.



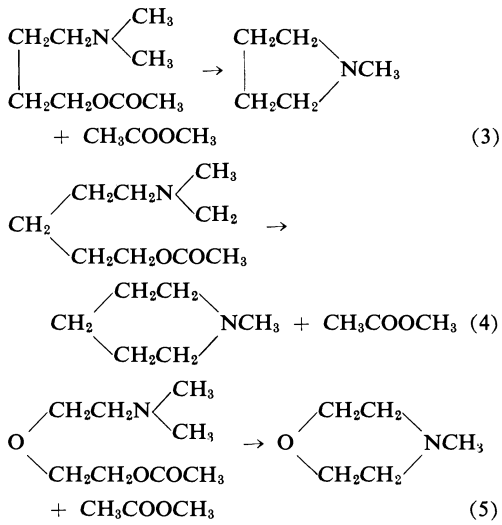
Even when *tert*-butyl acetate which has tendency to rupture at the alkyl-oxygen bond was used, reaction between the ester and triethylamine or dimethylaniline did not proceed.

In contrast to the very smooth progress of reaction 1 (R', R'', R''': $CH_3$), a ring-closure reaction for obtaining the same product by heating *N*, *N*, *N'*, *N'*-tetramethylethylenediamine and ethylenediacetate in an autoclave for 3 hr. at 280°C proved to be a failure.

In reaction 1 (R', R'', R'''; $CH_3$), the dialkylated amino group and the ester grouping are held in one molecule and are able to stay very close to each other on account of their special configuration. This proximity of the two groups is the most remarkable difference between the two cases of cyclization reaction and it seems to be plausible to attribute the cause of reaction 1 to the close situation of these groups.

The mechanism of the piperazine-ring formation might be written as follows;

1) K. Nakajima, This Bulletin, 34, 651, 655 (1961).



The first stage of the reaction mechanism is assumed to be the formation of a polarized state in the molecule D under the influence of heat as shown in E. In the second stage the union of $N_{(1)}$ and $C_{(1)}$ takes place and the carboxyl group is released as an anion. Then in the third stage the salt-like compound G thus formed is considered to be broken into a piperazine-derivative H and an ester $CH_3COOR'''$ at that elevated temperature. The decomposition of G may be regarded as a similar type of reaction to the thermal decomposition of the quarternary ammonium halides, which was reported by Hofmann[2].

This assumption for the similiarity can be explained by the fact that ease in liberation of the alkyl group R''' is identical to that of Hofmann's reaction, as briefly refered to in preceding report[1].

On inspecting the reaction mechanism shown in Scheme 2, an important question naturally arises as to what kind of compounds having a disubstituted amino and an ester-grouping in suitable positions in the molecule can undergo cyclization in the same way as these described above.

In order to give an answer to this question, several trials have been made with 4-dimethylamino-*n*-butyl acetate, 5-dimethylamino-*n*-pentyl acetate and β-acetoxy-β'-dimethylaminodiethyl ether. They have successfully proved that these compounds also undergo similar ring-closure reaction at about 200°C with elimination of an ester, giving *N*-methylpyrrolidine (3), *N*-methylpiperidine (4) and *N*-methylmorpholine (5), respectively.

These reactions make it easy to suppose that β-acetoxy-β'-dimethylaminodiethyl sulfide may have the possibility of being converted into *N*-methylthiomorpholine under similar conditions.

Synthesis of the sulfide, however, has not yet been attained.

## Experimental

***tert*-Butyl Chloride from *tert*-Butyl Acetate by Hydrogen Chloride.**—Dry hydrogen chloride was passed into *tert*-butyl acetate boiling in a flask fitted with a fractionating column, at such a rate that *tert*-butyl chloride formed distilled over at 50~60°C.

The reaction proceeded smoothly, leaving acetic acid in the reaction flask. *n*-Butyl and *sec*-butyl acetate remained intact by the same treatment.

***N*-Methylpyrrolidine from 4-Dimethylamino-*n*-butyl Acetate.**—*4-Dimethylamino-1-butanol.*—A mixture of 22 g. (0.2 mol.) of tetramethylene chlorohydrin and 50 g. of a 40% aqueous solution of dimethylamine was allowed to react in a bottle, plugged with a stopper holding a thermometer and an outlet tube connected to another bottle fed with water. By occasional shaking and timely cooling in water, the exothermic but moderate reaction was regulated so that no methylamine gas came to the bottle with water.

After adding 9 g. of powdered sodium hydroxide cautiously in small portions, the mixture was distilled. The crystals of sodium chloride which prevented the further distillation were removed by filtration and the filtrate was submitted to a careful fractionation. There was obtained about 15 g. of 4-dimethylamino-1-butanol as a colorless, viscous liquor boiling at 184°C.

Found: N, 11.82. Calcd. for $C_6H_{15}ON$: N, 11.95%.

*4-Dimethylamino-n-butyl Acetate.*—Twelve grams (0.12 mol.) of acetic anhydride was gradually

2) A. W. Hofmann, *Proc. Roy. Soc.*, **1860**, 10, 595.

added to 12 g. (0.12 mol.) of 4-dimethylamino-1-butanol with stirring and cooling in water. The reaction mixture was then dissolved in about 50 cc. of water and neutralized with sodium bicarbonate added in small portions until no more evolution of carbon dioxide was observed. The resultant solution was extracted with ether in a continuous extraction apparatus.

Distillation of the ether followed by a careful distillation in vacuo gave a 90~95% yield of the acetate.

Colorless liquid, b. p. 85°C/15 mmHg. Picrate, m. p. 126°C.

Found: N, 8.69. Calcd. for $C_8H_{17}O_2N$: N, 8.80%.

*N-Methylpyrrolidine.*—Sixteen grams (0.1 mol.) of 4-dimethylamino-*n*-butyl acetate was distilled slowly and carefully using a small Claisen flask, which is equipped with two thermometers, one being inserted in the liquid through the straight neck of the flask to read the internal temperature and the other fitted in the side neck to read the distillation temperature. When the internal temperature was raised to above 200°C, boiling commenced with the splitting into *N*-methylpyrrolidine and methyl acetate, both of which distilled over at 50~100°C as they were formed.

Redistillation of the distillate gave about 6 g. (about 75%) of pure *N*-methylpyrrolidine. *N*-Methylpyrrolidine is a well-known compound, a colorless liquid, b. p. 80~81°C. Picrate, m. p. 218°C.

**N-Ethylpyrrolidine from 4-Diethylamino-*n*-butyl Acetate.** — *4-Diethylamino-1-butanol.* — A mixture of 27 g. (0.25 mol.) of tetramethylene chlorohydrin and 36.5 g. (0.5 mol.) of diethylamine was boiled under reflux for 10 hr. The crystals of diethylamine hydrochloride, gradually formed during the heating, were filtered off and the filtrate was fractionally distilled. After a forerun of tetrahydrofuran (ca. 5 g.) formed in a side reaction 6, there was obtained about 15 g. of 4-diethylamino-1-butanol boiling at 208°C, as a colorless, viscous liquid.

$$HO(CH_2)_4Cl + HN(C_2H_5)_2 \rightarrow \begin{array}{l} CH_2\text{-}CH_2 \\ | \quad | \\ CH_2 \quad CH_2 \\ \diagdown \quad \diagup \\ \quad O \end{array} + (C_2H_5)_2NH\cdot HCl \qquad (6)$$

Found: N, 9.51. Calcd. for $C_8H_{19}ON$: N, 9.64%.

*4-Diethylamino-n-butyl Acetate.*—Obtained similarly as in the methyl derivative mentioned above. Colorless liquid, b. p. 98°C/12 mmHg.

Found: N, 7.31. Calcd. for $C_{10}H_{21}O_2N$: N, 7.48%.

*N-Ethylpyrrolidine.* — Obtained in the same way as in the methyl derivative above. Colorless liquid, b. p. 104~106°C. Picrate, m. p. 185°C.

**N-Methylpiperidine from 5-Dimethylamino-*n*-pentyl Acetate.**—On the whole, the actual procedure here is analogous to that of *N*-methylpyrrolidine.

*5-Dimethylamino-1-pentanol.*—A mixture of 24.5 g. (0.2 mol.) of pentamethylene chlorohydrin and 50 g. of a 40% aqueous solution of dimethylamine was allowed to react. After the reaction was completed the resultant homogenous solution was distilled until the internal temperature indicated 180°C. To the cooled mixture was added a concentrated solution of potassium hydroxide in methyl alcohol and the precipitate of potassium chloride was filtered off and the filtrate was distilled.

Colorless, viscous liquid, b. p. 205~206°C. Yield 21 g. (80%).

Found: N, 10.39. Calcd. for $C_7H_{17}ON$: N, 10.68%.

*5-Dimethylamino-n-pentyl Acetate.* — The procedure described in the case of the corresponding butyl derivative was also employed here.

Colorless oily liquid, sparingly soluble in water, b. p. 114°C/22 mmHg.

Found: N, 7.78. Calcd. for $C_9H_{19}O_2N$: N, 8.09%.

*N-Methylpiperidine.*—This compound was obtained by the slow distillation of 5-dimethylamino-*n*-pentyl acetate followed by the fractionation of the distillate, and was identified by comparison with the authentic sample.

Colorless liquid, b. p. 107°C.

**N-Ethylpiperidine from 5-Diethylamino-*n*-pentyl Acetate.** — *5-Diethylamino-1-pentanol.*—From 24.5 g. (0.2 mol.) of pentamethylene chlorohydrin and 30 g. (ca. 0.4 mol.) of diethylamine, about 25 g. (ca. 80%) of this compound was obtained as a colorless viscous liquid boiling at 127~130°C/22 mmHg.

Found: N, 8.75. Calcd. for $C_9H_{21}ON$: N, 8.80%.

*5-Diethylamino-n-pentyl Acetate.* — Colorless oil, sparingly soluble in water, b. p. 127°C/22 mmHg.

Found: N, 7.02. Calcd. for $C_{11}H_{23}O_2N$: N, 6.96%.

*N-Ethylpiperidine.* — The acetate above was split into *N*-ethylpiperidine and ethyl acetate at a temperature higher than 200°C. The reaction proceeded slowly but steadily. *N*-Ethylpiperidine is, of course, a well-known compound.

**N-Methylmorpholine from β-Acetoxy-β'-dimethylaminodiethyl Ether.**—*β-Hyroxy-β'-dimethylaminodiethyl Ether.*—The ether was prepared by the reaction of 2 mol. proportions of ethylene oxide on 1 mol. proportion of aqueous solution of dimethylamine.

In 110 g. (1 mol.) of a 40% aqueous solution of dimethylamine was absorbed ethylene oxide, generated by dropping a solution of 80 g. (2 mol.) of sodium hydroxide in 160 cc. of water onto a boiled mixture of 200 g. (2.5 mol.) of ethylene-chlorohydrin and 100 cc. of water under reflux. The reaction between ethylene oxide and dimethylamine is exothermic.

Suitable control of the dropping rate of the sodium hydroxide solution and occasional water-cooling were applied in order to bring the ethylene oxide entirely into action. The gain in weight of the reaction mixture was about 90 g. and indicated that in this way about 2 mol. of ethylene oxide could be generated and be made to enter into the reaction.

To the brown and viscous mixture was added portion-wise about 60 g. of anhydrous potassium

3) I. G. Farfen Ind., D. R. P. 432803; *Chem. Zentr.*, **1926**, II. 1693.

carbonate. Then there were formed two layers, of which the upper was separated and distilled fractionally. There was obtained about 15 g. of β-dimethylamino ethyl alcohol (b. p. 130~135°C) and about 50 g. of β-hydroxy-β'-dimethylamino-diethyl ether (b. p. 205°C).

Found: N, 10.68. Calcd. for $C_6H_{15}O_2N$: N, 10.52%.

*β-Acetoxy-β'-dimethylaminodiethyl Ether.* — Acetic anhydride (26 g. 0.25 mol.) was added dropwise to 35 g. (0.2 mol.) of β-hydroxy-β'-dimethylamino-diethyl ether with cooling in water.

After heating to boiling under reflux and subsequent cooling to room temperature, the mixture was dissolved in about 100 cc. of water, neutralized with about 30 g. of sodium bicarbonate added in small portions and extracted with ether in a continuous extractor. Distillation of the ether followed by fractionation of the residual liquid under reduced pressure gave almost a quantitative yield of β-acetoxy-β'-dimethylaminodiethyl ether as a colorless liquid boiling at 132°C/50 mmHg or 110°C/30 mmHg.

*N-Methylmorpholine.*—Distillation of β-hydroxy-β'-dimethylaminodiethyl ether, carried out slowly and carefully at atmospheric pressure, gave a mixture of methyl acetate and *N*-methylmorpholine in a good yield.

The *N*-methylmorpholine was identified by an authentic sample.

Colorless liquid, b. p. 215~216°C. Picrate m. p. 220°C. Chloroplatinate, m. p. 225~226°C.

**N-Ethylmorpholine from β-Acetoxy-β'-diethylaminodiethyl Ether.**—The procedure employed was substantially analogous to that of the methyl derivative.

*β-Hydroxy-β'-diethylaminodiethyl Ether**.—Obtained by the action of ethylene oxide on β-diethylaminoethyl alcohol in equimolecular proportions, or on an aqueous diethylamine solution in mole proportions of 2 to 1. Colorless, viscous oily liquid, b. p. 142°C/52 mmHg.

Found: N, 8.57. Calcd. for $C_8H_{19}O_2N$: N, 8.69%.

*β-Acetoxy-β'-diethylaminodiethyl Ether.*—Colorless oily liquid, b. p. 143~145°C/42 mmHg.

Found: N, 6.60. Calcd. for $C_{10}H_{21}O_3N$: N, 6.89%.

Chloroplatinate, yellow plates from concentrated solution, decomposed at 174°C.

Found (for chloroplatinate): Pt, 24.00. Calcd. for $(C_{10}H_{21}O_3N)_2 \cdot H_2PtCl_6$: Pt 23.90%.

*N-Ethylmorpholine.*—Obtained by a slow distillation of the above ether. The formation of *N*-ethylmorpholine proceeded very slowly but in an excellent yield. Colorless liquid, b. p. 139°C. Picrate, m. p. 190°C. Chloroplatinate, orange-yellow needles, m. p. 198°C. These data were identified with the authentic samples.

The auther wishes to express his heartfelt thanks to Professor Dr. Ryozo Goto, Kyoto University for his encouragement and numerous suggestions throughout this work.

# *Reaction of Trypsin with S-Methylisothiourea and with S-Methylglucosylisothiourea*

By Kazuyuki MAEKAWA and Kyoko ISHIMOTO

(Received January 16, 1961)

*O*-Methylisourea has long been used to introduce amidyl residue into amino acids and peptides. The reaction of *O*-methylisourea with proteins takes place only in ε-amino group of lysine, and homoarginine is produced by the hydrolysis of the product[1]. Hughes et al. have shown that in treating serum albumin with *O*-methylisourea, the more the value of Sakaguchi's reaction increased, the less amino nitrogen became[2]. Roche and his associates treated bovine serum albumin, casein, and ovalbumin etc. with *O*-methylisourea in concentrated ammonium hydroxide, and after the hydrolysis of the reaction products, they identified homoarginine by means of paper chromatography[3]. Lately Chervenka et al. demonstrated that all of the 13 lysines changed into homoarginine and no more changes were caused in the reaction of chymotrypsin with

1) R. M. Herriott, "Advances in Protein Chem.", III, Acad. Press Inc., New York (1947), p. 215.

3) J. Roche, M. Mourgue and R. Baret, *Bull. Soc. chim. biol.*, **36**, 85 (1954).

*O*-methylisourea[4]. On the other hand, Schütte employed *S*-methylisothiourea instead of *O*-methylisourea[5]. Later on, this reaction was applied to the δ-amino group of ornithine[6].

By the application of a similar reaction, that is, the condensation reaction which liberates mercaptan from substituted isothiourea, Micheel et al. have treated case in and gelatin etc. with *S*-methylglucosylisothiourea. They supposed that the ε-amino group of lysine undergoes the reaction, since the amount of combined sugar runs parallelly only to the lysine content of protein[7].

It has already been illustrated that concerning the reaction of *S*-methylglucosylisothiourea upon histidine, the carbon of position 4 or 2 in the imidazole ring is more reactive than the α-amino group of amino acids or the ε-amino group of lysine[8].

Authors have undertaken the study of the reaction of *S*-methylglucosylisothiourea and trypsin as an enzyme, as it has already been suggested that histidine is an essential site of the enzymatic activity[9].

In respect to trypsin, various active and inactive derivatives have already been reported[10-16], but no work on the reaction of *S*-methylisothiourea and *S*-methylglucosylisothiourea has been reported yet.

The results showed that trypsin molecule[17] was combined with 6~7 mol. of glucosylamidyl residue, and yet the enzymatic activity was retained, but the autodigestion was remarkably depressed. The amidinated trypsin was more stable than the glucosylamidyl derivative. These facts described in this report were not owing to the mercaptan produced by the reaction, but evidently owing to glucosylamidination or amidination. The mercaptan produced during the reaction had no part in the stabilization of trypsin, which fact is consistent with the result obtained by using 2, 3-dimercapto-1-propanol[18].

## Experimental

**Amidination and Glucosylamidination of Trypsin.** — One hundred milligrams of crystalline trypsin (Motida Pharm. Co.) was dissolved in 20 ml. of 1/15 M phosphate buffer, pH 8.0 (or Palitzsch's borate buffer) in the presence of 0.01 M calcium chloride[12,19]. The protein concentration of trypsin was determined spectrophotometrically, using values proposed by Green and Neurath[20]. Thus, enzyme solution was 0.695 mg./ml. Five milliliters of this enzyme solution was added to 3 ml. of aqueous solution of *S*-methylglucosylisothiourea hydroiodide (70 mg./ml.) and to the equal volume of *S*-methylisothiourea (50 mg./ml.) respectively. Then the reaction mixture was adjusted to pH 8 with a few ml. of 0.1 N sodium hydroxide, and covered with ether to dissolve mercaptan evolving. The solutions were allowed to stand at 10°C.

**Determination of Combined Glucosylamidyl Residue.**—To 1 ml. of the solution described above, which was taken out at certain time intervals, 5 ml. of 0.4 M solution of trichloroacetic acid (TCA) was added, and the mixture was warmed for a while at 50°C. The enzyme derivative precipitated was collected by centrifuge, then washed several times with TCA in order to remove the sugar compound which did not react. As for the precipitate, the

combined glucosylamidyl residue was determined by the modified Brückner's method[21] as follows: Namely, 1 ml. of water and 1 ml. of 4% aqueous solution of orcinol were added to the resulting precipitate of enzyme-derivative. Then, 8 ml. of 31.2 N sulfuric acid, cooled with cold water, was added to it. After mixing them completely, it was heated in a boiling water bath exactly for 5 min., then cooled with tap water. The absorbance of the solution was measured at 530 mμ, using a whole blank solution which contains the same concentration of untreated enzyme and which has been treated similarly in the reference cell. The value of the combined glucosylamidyl residue was calculated by multiplying the molecular ratio for the value obtained from the estimation of glucosylamidyl glycine.

**Measurement of the Activity.**—One half milliliter of the reaction mixture was transferred into 10 ml. of 1/15 M phosphate buffer, pH 7.1 at certain time intervals. By using 1 ml. of this diluted solution, the enzymatic activity was measured according to the modified Anson's method by using casein as substrate[22].

▲—▲ Ga-trypsin heated for 60 min. at 100°C
●—● Ga-glycine

**Determination of the Guanidino-group and Amino Nitrogen.**—The guanidino-group was determined by Sakaguchi's reaction. The sample was treated in the same manner as described in the determination of glucosylamidyl residue, because the Sakaguchi's reaction was inhibited by *S*-methylisothiourea and *S*-methylglucosylisothiourea. Namely, 0.5 ml. from the reaction mixture described above was pipetted out and the enzyme was precipitated by adding TCA solution and washed several times with TCA solution, then further washed with absolute alcohol. The precipitate was dissolved in 0.1 N sodium hydroxide and the guanidino-group was determined by Weber's method[24].

The amino group of the precipitate which was prepared by the same method as in the determination of glucosylamidyl residue was determined by ninhydrin reaction according to the method of Troll and Cannan[23].

**Absorption Spectrum and Optical Rotation.**—The sample for measurement of absorption spectrum was prepared by exhaustive dialysis against water of pH 3 (with hydrochloric acid). The optical rotation was determined by using the sample prepared as follows. A large amount of the reaction mixture was brought to pH 3.4 with hydrochloric acid, and precipitated at 70 per cent saturation of ammonium sulfate and washed several times with 70% ammonium sulfate. The precipitate was dissolved in water.

| Casein | 82 | 93 | 100 |
| Glucosylamidyl casein | 70 | 79 | 93 |

* Enzyme preparation of trypsin and the two trypsin derivatives were taken from the incubating mixture in 24 hr. from starting.

## Results and Discussion

The results are shown in Tables I to III. Under the condition presented, trypsin (mol. wt. 23800)[15,16] was combined with 6~7 mol. of glucosylamidyl residue in 4 days. As the result, the color intensity of ninhydrin reaction decreased about 14 per cent. The Sakaguchi's reaction has no change by being combined with glucosylamidyl residue. By the reaction of trypsin and *S*-methylisothiourea, the guanidino group of enzyme derivative clearly increases.

By glucosylamidination or amidination of trypsin, the enzyme does not suffer from the loss of the enzymatic activity, but becomes rather stable against the autodigestion. It is well known that peptide linkage which involves $\alpha$-amino group of lysine becomes less easily digested by trypsin, by blocking the $\varepsilon$-amino group of the substrate with acetyl group and others[25,26]. From the result reported here, it is proved that glucosylamidyl casein and amidyl casein are resistive to the tryptic digestion, in accordance with a report of Weil et al.[26]

On the other hand, amidyl trypsin and glucosylamidyl trypsin have enzymatic activity, but it seems likely that homoarginine or glucosylhomoarginine linkage which exists in the modified enzyme molecule is not digested by trypsin and the modified trypsins.

It is probably deduced that $\varepsilon$-amino group of lysine and other groups which are to be glucosylamidinated or amidinated have nothing to do with the tryptic activity.

The authors wish to express their thanks to Mr. N. Aizawa of the Motida Pharm. Co. for a generous supply of trypsin.

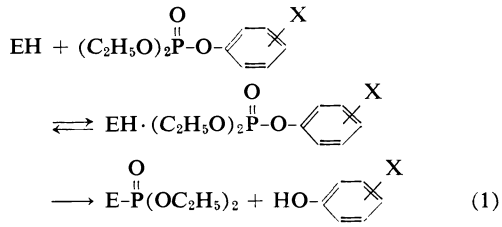
# *Electronic Structure and Biochemical Activities in Diethyl Phenyl Phosphates*

By Kenichi FUKUI, Keiji MOROKUMA, Chikayoshi NAGATA and Akira IMAMURA

(Received February 2, 1961)



In the recent fifteen years thousands of organo phosphorus compounds have been found to be endowed with effective insecticidal properties and some of them—TEPP, parathion, paraoxon and so forth—are now in practical use[1]. It become apparent that the toxicity of these compounds to insect or to human being is mainly related to the reaction with the cholinesterase enzyme system in the body[2-5].

Diethyl substituted phenyl phosphates, which are treated in the present paper, have been tested in detail of their toxicities to insects, their effciencies of cholinesterase inhibition[3-5] and their hydrolysis constants[5-7], and each of the three has been found to be in line with the other[1,5,7]: phosphates are more toxic when their inhibiting activities are larger and when their hydrolysis constants are larger.

Diethyl phenyl phosphates are bound by a covalent bond to the esteratic site of cholinesterase in an irreversible phosphorylation, this inhibiting the hydrolysis of acetyl choline in a normal biochemical cycle. The enzyme-inhibiting mechanisms are proposed by Aldridge

et al.[7-10] to be such as represented by the following scheme:

(1)

where EH is the enzyme, and the second step is assumed to be rate-determining. It was often said that the initial stage of the step is the attack of the electron-releasing, that is, the nucleophilic site or atom of cholinesterase on the P–O bond of phosphates, and this mechanism seems to be analogous to that of the alkali hydrolysis of the phosphates[1] and that the enzyme-inhibitory activity of the phosphate is, therefore, related to the lability of P–O bond[5,7]. And furthermore Aldridge estimated the strength of the bond by the ionization constant of the hydrolysis product[7]; the esters derived from strongly acidic phenols are highly toxic and vice versa. According to his opinion, paraoxon is toxic because *p*-nitrophenol is a strong acid.

In contrast with phosphates, it is interesting that highly purified parathion and its homologues—diethyl substituted phenyl thionophosphates— are little active as inhibitors of enzyme systems. They are oxidized in the tissue to the corresponding phosphates, which attack the cholinesterase, showing the poisoning action in vivo experiments[2,11,12].

The present authors have established the frontier electron theory, one of the quantum mechanical theories of chemical reactivity, of conjugated molecules, and found that the superdelocalizability, the index of reactivity in the theory, represents the experimental results better than those in other theories[13-15]. The theory has been successfully applied to biochemical problems as well, for instance, the carcinogenic activity of condensed aromatic hydrocarbons[16] and azo dyes[17], the plant growth activity of substituted benzoic acids[18], the nicotine-like activity of choline phenyl ethers[19] and the fungicidal activity of quinoline-*N*-oxides[20]. It is noteworthy, as theoretically indicated by the present authors, that these activities are directly related to the interaction of the conjugated molecule with a nucleophilic (electron releasing) atom or group of the tissue; and in this connection a discussion will be given in a later section.

Superdelocalizability on the *r*th atom of phenyl phosphates that is to be used in this paper is that for a nucleophilic reaction (the reagent attacking phosphates has been considered nucleophilic in nature[1,8]) and has the following form:

$$S_r^{(N)} = 2\sum_{j}^{\text{unocc}} \frac{(C_r^j)^2}{-\lambda_j} \qquad (2)$$

where $C_r^j$ is the coefficient of the *r*th atomic orbital in the *j*th molecular orbital, $\lambda_j$ is the coefficient of its energy $\varepsilon_j = \alpha + \lambda_j\beta$, $\alpha$ and $\beta$ are the standard coulomb and resonance integrals, and the summation covers unoccupied orbitals. The larger its magnitude is, the more reactive the molecule is. The phosphorus atom is considered to offer one orbital and one electron conjugable with other atoms, as has been discussed in our previous paper on ATP[21]. The coulomb integral of the atom X and the resonance integral between the atoms X and Y are written as $\alpha + a_X\beta$ and $l\beta$, respectively; and in Table I are listed the energy parameters used in the paper, which are not so different from those in previous papers[17,18,21],*.

## Results and Discussion

We calculated the superdelocalizability and the electron density on various positions of fifteen diethyl substituted phenyl phosphates, assuming that in the enzyme-inhibition the intermediate complex formation does not affect the electronic structure, and comparing with experimental results, found that the super-

*1 Taken from Ref. 5.
*2 Estimated from the data of Ref. 6.
*3 Deduced from the data of median lethal dosage to various insects of Refs. 3, 4 and 5. ++: very highly active, +: highly active, +: active, ±: less active, −: almost inactive.

delocalizability for a nucleophilic reaction on the phosphorus atom has close correlations with the case of alkali hydrolysis, and therefore, with the cholinesterase (ChE) inhibitory power and insecticidal activity, as is clearly seen in Table II. The total electron density on the phosphorus atom seems to show similar relations but even the largest difference is 0.004 at the utmost and would not be enough to elucidate large differences in the hydrolysis constants. Indexes of other positions or for other kinds of reaction (electrophilic and radical) had no such parallelism. These results suggest that in the alkali hydrolysis of phosphates the attack of hydroxyl anion to the phosphorus atom is rate-determining and the susceptibility of P–O bond to hydrolysis is nothing but the reactivity of the phosphorus atom, and would support the existing interpretation that both to the enzyme-inhibitory and to the insecticidal activities the hydrolytic attack of a nucleophilic site, probably of the esteratic site of cholinesterase, makes a controlling contribution.

Interactions of the substrates with the anionic site of cholinesterase, which become important in the hydrolysis of acetylcholine, are also probable for some phosphates; and they will

serve as a cause of discrepancy between activities of alkali hydrolysis and of esterase-inhibition, since in the former the reagent is a hydroxyl group only and has no subsidiary anionic site. In this series of compounds, however, these interactions do not seem to be significant, for we could find no such index on any atom in the substituted phenyl group, sterically suitable for the interactions, that would rationary explain the discrepancy.

In Table II, 2,4-dinitrophenyl phosphate is less toxic to insects than expected from the inhibitory power, this being explained as that it would be hydrolytically deactivated in its way to the effective site because of its too large reactivity[5]. This situation is well understood in terms of the superdelocalizability and its threshold for an effective insecticide seems to lie between 1.20 and 1.25. The lack of insecticidal toxicity of *p*-formylphenyl phosphate which could not be elucidated by experimental results[5] is difficult to explain even by this theoretical study, and some other factors would have to be considered.

Furthermore the striking difference of activities between phosphates and thionophosphates is to be discussed. We calculated as an example the superdelocalizability on the phosphorus atom of diethyl *p*-nirophenyl thionophosphate, which amounted to 1.056. Comparing this value with those of diethyl *p*-nitrophenyl phosphate (1.119) and other phosphates discussed above (1.132~1.094), one would clearly see the reason why the thionophosphate in itself is inactive in the inhibition of the enzyme system in vitro. As most thionophosphates substituted by other substituents are less reactive than the *p*-nitro compound, they are well understood to be inactive. The metabolic oxidation to phosphates thus has a meaning, we may say, in elevating the reactivity for a nucleophilic attack.

The nucleophilic nature of the cholinesterase inhibition and toxicity of phenyl phosphates, that is, the nature that the phosphate is attacked by an electron-releasing group, is very interesting in connection with our theoretical indication that the carcinogenic activity and at the same time the anti-tumor activity of conjugated compounds appear to be nucleophilic in their essential character as well as some other biochemical activities, for instance, the anti-fungal activity[20] or nicotine like activity[19]. The high nucleophilic reactivity of the phosphates in question suggests to us, that they would be endowed with the carcinogenic ability or with the carcinostatic ability, though the active site in the tissue will be different in each activity. In fact, paraoxon was found to have the carcinostatic activity[23]. On this point a more elaborate discussion will be given elsewhere[24].

# *Mass Spectra at Low Ionizing Voltage and Bond Dissociation Energies of Molecular Ions from Hydrocarbons*

By Itiro OMURA

(Received January 18, 1961)

Since Eyring and co-workers[1] first introduced the statistical theory to the interpretation of mass spectra of hydrocarbons, several authors[2-4] have reported similar results on simple organic molecules. King and Long[3] pointed out that the theory is inadequate at low ionizing voltages although it seems qualitatively satisfactory at high ionizing voltages such as 70 V. except for some of the rearrangement and hydrogen abstraction processes. Hence, it seems very important for the purpose of clarifying ion dissociation mechanisms to study mass spectra at low ionizing voltages.

In this paper, the experimental results on the mass spectra of some paraffins and olefins, especially on the characteristic features of ion yield in relation to the ionizing voltages, are

presented, and discussion is carried out on the bond dissociation of molecular ions.

## Experimental

The instrument used in this work is a Hitachi mass spectrometer: type RMS-3, of a single focusing, 60° sector type with a radius of 100 mm. Positive ions going into the ion collector are detected through a negative feedback amplifier with an electrometer tube, Raytheon 5886 tetrode. In order to measure appearance potentials, however, some slight modifications are made in the ion source and the electric circuit belonging to it. A shielding electrode is inserted between the filament and the ionization chamber of an ordinary ion source, the filament is heated by DC currents and the ionizing voltage can be changed by 0.1 V. step by means of a potentiometer.

In the experiment, the pressure in the sample reservoir and the operating conditions, except the ionizing voltage, of the ion source are kept nearly constant.

The extrapolation method[5] is applied to obtain the appearance potentials, and krypton (ionization potential spectroscopically obtained: 14.03 eV.[6]) is used as the calibrating gas.

## Experimental Results

**Paraffins.**—The appearance potentials obtained for straight and branched paraffins are shown in Table I together with bond energies calculated from the appearance potentials. Numerals under the chemical formula of ions represent the appearance potentials in electron volts and those above the arrows the bond energies or the activation energies in unimolecular decomposition. These energy values are in good agreement with the values reported by Field and Franklin[7].

In Figs. 1, 2 and 3, relative yields of principal ions are shown in relation to the ionizing voltage. The abscissa, $V_e-I$, is the excess energy of the ionizing electron over the ionization potential of the parent molecules. Since M/e 29 peak in a mass spectram of isobutane results from the summation of a rearrangement peak ($C_2H_5^+$) and isotopic peaks, correction is necessary for the estimation of

the $C_2H_5^+$ yield from the spectrum. The curve for $C_2H_5^+$ in Fig. 3 is a curve corrected by Washburn's method[8].

8) G. P. Barnard, "Modern Mass Spectrometry", the Institute of Physics, London (1953), p. 201.

These curves can be classified into four types, though it is difficult to classify some ions because they show medium aspects between two neighboring types. Type I curves are for those ions whose relative yield is very high at very low excess energies and decreases rapidly with the increase of ionizing voltage. Type II curves are for those ions whose relative yield rises rapidly to a maximum at an excess energy of 5~10 eV., and decreases to a nearly constant value. Type III curves are for those ions whose relative yield rises to a nearly constant value without passing a distinct maximum or after passing through a slight maximum at an excess energy higher than 10 eV. Type IV curves are for those ions whose relative yield increases slowly and does not level off until much higher ionizing voltages.

Parent ions and fragment ions of low activation energies belong to Type I. The activation energies of ions belonging to Type II are in a range between about 0.3. and 2 eV., and those to Type III in a range between about 2 and 3.5 eV., while those to Type IV are larger than 3 eV. The classification of principal ions from four paraffins are listed in Table II.

Table II. Classification of principal ions

| Type | Substance | | | |
|---|---|---|---|---|
| | Ethane | Propane | *n*-Butane | Isobutane |
| I | $C_2H_6^+$ | $C_3H_8^+$ | $n$-$C_4H_{10}^+$<br>$C_3H_7^+$<br>$C_3H_6^+$ | iso-$C_4H_{10}^+$<br>$C_3H_6^+$ |
| II | $C_2H_5^+$<br>$C_2H_4^+$ | $C_3H_7^+$<br>$C_3H_6^+$<br>$C_2H_4^+$ | $C_4H_9^+$<br>$C_2H_4^+$ | $C_4H_9^+$<br>$C_3H_7^+$ |
| III | $C_2H_3^+$<br>$C_2H_2^+$ | $C_3H_5^+$<br>$C_3H_4^+$<br>$C_2H_6^+$<br>$C_2H_5^+$ | $C_4H_8^+$<br>$C_3H_5^+$<br>$C_2H_5^+$ | $C_4H_8^+$<br>$C_4H_7^+$<br>$C_3H_5^+$<br>$C_2H_5^+$ |
| IV | $CH_3^+$ | $C_3H_3^+$<br>$C_3H_2^+$<br>$C_2H_3^+$<br>$C_2H_2^+$<br>$C_2H^+$<br>$CH_3^+$ | $C_4H_7^+$<br>$C_3H_3^+$<br>$C_2H_3^+$ | $C_3H_4^+$<br>$C_3H_3^+$<br>$C_2H_4^+$<br>$C_2H_3^+$ |

**Olefins.**—Similar results are obtained for straight olefins. The appearance potentials and the activation energies obtained are shown in Table III. These data are also in good agreement with the values of Field and Franklin[7]. Comparing Table III with Table I, the ionization potentials of olefins are considerably lower than those of paraffins with the same carbon numbers. This may be caused by the fact that $\pi$-electrons are concerned in the ionization of olefins. Activation energies, on the other hand, are higher for olefins than for paraffins.

TABLE III. APPEARANCE POTENTIALS AND ACTIVATION ENERGIES OF OLEFINS, eV.

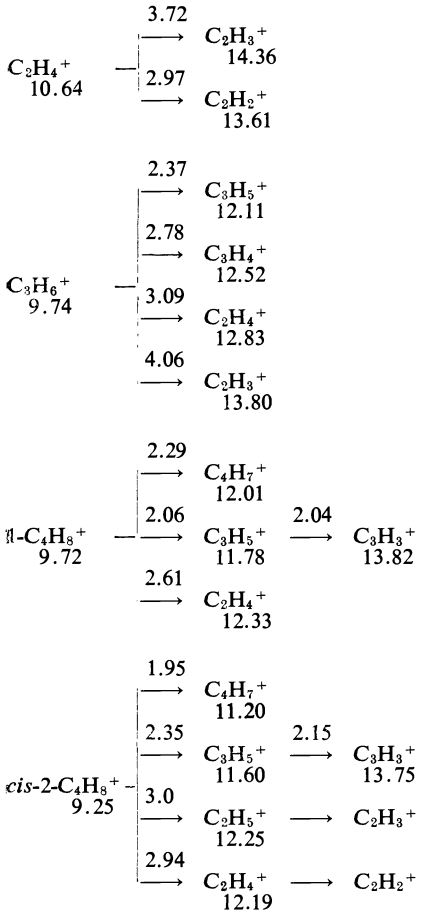

TABLE IV. CLASSIFICATION OF PRINCIPAL IONS

| Type | Substance | | | |
|---|---|---|---|---|
| | Ethylene | Propylene | 1-Butene | *cis*-2-Butene |

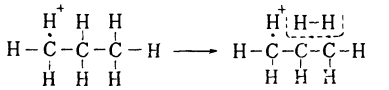
Relative yields of principal ions are shown in Figs. 4, 5 and 6. The $C_2H_5^+$ yield in Fig. 6 is a corrected curve by Washburn's method[8]. As in the case of paraffins, the curves can be classified into four groups and the activation energies generally become larger from Type I to Type IV.

## Discussion

It has been believed that the statistical theory of unimolecular reaction[1] can be applied to the interpretation of decomposition of molecular ions by the impact of electrons with comparatively high energies. The theory is based on the presumption that molecular ions do not decompose instantaneously into ionized and neutral fragments, but the electron energies are uniformly distributed to whole bonds of molecular ions and then they are concentrated in a specific bond, causing the decompotision related with the electronic state of fragment ions.

According to the theory, a positive charge is distributed to a C-C or C-H bond and the bond rupture of a molecular ion is closely related with the distribution of the positive charge[7]. For instance, a parent ion of propane is presumed to be a hybrid of the following three structures[1] explained in terms of resonance:



$$H_3{\equiv}C\dot{+}CH_2{-}C{\equiv}H_3 \qquad (1)$$

$$H_3{}^+{\doteq}C{-}CH_2{-}C{\equiv}H_3 \qquad (2)$$

$$H_3{}^+{\doteq}C{-}\underset{H}{\overset{H}{CH}}{=}CH_2 \qquad (3)$$

Fragment ions $C_2H_5^+$ and $C_3H_7^+$ can be expected from simple primary decompositions of the first and second structures, respectively. If a neutral molecule H-H is removed from the third structure, an ionic structure would be expected, $H_3{}^+{\doteq}C\text{-}CH{=}CH_2$, regarded as an olefinic molecular ion[9]. Thus the ionic structures concerned with the distribution of positive charge are very important for the primary rupture of C-C or C-H bond.

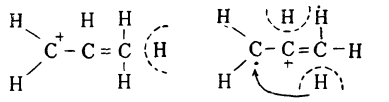
As mentioned above, a probable process for the $C_3H_6^+$ creation from $C_3H_8^+$ is a primary decomposition as follows:

(4)

or simply

$$C_3H_8{}^+ \longrightarrow C_3H_6{}^+ + H_2 \qquad (5)$$

As seen in Table I, the activation energy of $C_3H_6^+$ is a little less than twice the activation energy of $C_3H_7$. This seems to be an energy transfer effect showing that the energy in the rearrangement of hydrogen atoms is given away from a hydrogen molecule to a resonant ion. From the relation of decomposition energy, the $C_3H_6^+$ ions can not be expected through a secondary decomposition given by[9]



$$C_3H_8{}^+ \longrightarrow C_3H_7{}^+ + H \longrightarrow C_3H_6{}^+ + 2H \qquad (6)$$

The fragment ions $C_3H_5^+$, on the other hand, are expected through a secondary decomposition as follows:

$$\begin{aligned} C_3H_8{}^+ &\longrightarrow C_3H_7{}^+ + H \\ &\longrightarrow C_3H_5{}^+ + H_2 + H \end{aligned} \qquad (7)$$

In this case, energy transfer may also take place between a neutral hydrogen molecule and a resonant ion.

The $C_3H_5^+$ ions from paraffins are caused by a secondary decomposition, but those from olefins by a primary decomposition. For instance, the $C_3H_5^+$ ions from propylene are produced through both or either of the following process:

(8)

These two ionic structures are based on the assumption of electron migration[10], though

9) D. P. Stevenson and J. A. Hipple, Jr., *J. Am. Chem. Soc.*, 64, 1586 (1942).
10) G. R. Lester, "Advances in Mass Spectrometry", Symposium Publications Division, Pergamon Press (1959), p. 287.

unfortunately their relative importance has not been exactly proved by experiment. The positive charge is distributed more probaly on C-C bond than on C-H bond, but the principal ions intensities have shown that the "no-bond structures" give an effect of greater importance for the bond rupture. In case of butene, however, the rupture of C-C bond is more probable. The reason may be in the fact that the effects of double bond or no-bond structures are weaker in case of butene than in case of propylene.

It was reported that there might be a simple relation between the yield of fragment ions caused by the rupture of C-H bond of the parent ions and the number of bonds[11], but this theory has not been proved by experiment[1]. The results of the present experiment shown in Table V also contradict the theory. If the

TABLE V. RELATIVE AMOUNT OF PRINCIPAL IONS TO TOTAL IONS AND RATIO OF C-H BONDS TO TOTAL BONDS IN A HYDROCARBON

| Substance | $\frac{\text{C-H bonds}}{\text{Total bonds}}$ | $\frac{C_nH^+{}_{2n+1}}{\text{Total ions}}$ | $\frac{C_nH^+{}_{2n-1}}{\text{Total ions}}$ |
|---|---|---|---|
| $C_2H_6$ | 0.87 | 0.09 | |
| $C_3H_8$ | 0.80 | 0.08 | |
| $n$-$C_4H_{10}$ | 0.77 | 0.007 | |
| iso-$C_4H_{10}$ | 0.77 | 0.008 | |
| $C_2H_4$ | 0.8 | | 0.24 |
| $C_3H_6$ | 0.75 | | 0.24 |
| 1-$C_4H_8$ | 0.74 | | 0.05 |
| *cis*-2-$C_4H_8$ | 0.74 | | 0.05 |

distribution of positive charge on C-C and C-H bonds are calculated more precisely by the orbital theory, the process of decomposition of molecular ions might be explained more clearly.

Since the fragment ions $C_2H_4^+$ from isobutane are believed to be of olefinic structure and can not be expected to result from $C_2H_5^+$ ions, the process may be as follows:

$$\text{iso-}C_4H_{10}^+ \longrightarrow CH_3-\dot{C}H^+ + CH_3-CH_3$$
$$\longrightarrow CH_2\therefore CH_2^+ + C_2H_6 \qquad (9)$$

The energy necessary for reaction 9 is about 3.84 eV. The fragment ions $C_2H_5^+$ from isobutane also seem to be caused by primary decomposition; and a referred process may be as follows:

$$\text{iso-}C_4H_{10}^+ \longrightarrow CH_3-\dot{C}H^+ + CH_3-CH_3$$
$$\longrightarrow CH_3-CH_2^+ + C_2H_5 \qquad (10)$$

The energy necessary for the $C_2H_5^+$ creation is about 3.57 eV. and a little less than that for the $C_2H_4^+$. These processes 9 and 10 may be explained by the presumption of hydrogen transfer and rearrangement respectivly.

The $C_2H_4^+$ and $C_2H_5^+$ ions from *cis*-2-butene may be produced through the following processes, respectively:

$$\textit{cis}\text{-}2\text{-}C_4H_8^+ \longrightarrow CH_3-\dot{C}H^+ + CH-CH_3$$
$$\longrightarrow CH_2\therefore CH_2^+ + C_2H_4 \qquad (11)$$

and

$$\textit{cis}\text{-}2\text{-}C_4H_8^+ \longrightarrow CH_3-\dot{C}H^+ + CH-CH_3$$
$$\longrightarrow CH_3-CH_2^+ + C_2H_3 \qquad (12)$$

Hydrogen migration and rearrangement are related, as in cases of the reactions 9 and 10. Contrary to the case of isobutane, the activation energy for $C_2H_5^+$ ions is much greater than that for the $C_2H_4^+$ ions. This may be one of the double bond effects. Another double bond effect is shown in Table VI. The

TABLE VI. DOUBLE BOND EFFECT OF OLEFINS

| Substance | Ionization potential | Activation energy C-H | Activation energy C-C | Type of total ion yield C-H | Type of total ion yield C-C |
|---|---|---|---|---|---|
| $n$-$C_4H_{10}$ | 10.23 | 1.57 | 0.63 | 2 | 1 |
| 1-$C_4H_8$ | 9.72 | 2.29 | 2.06 | 2 | 2 |
| *cis*-2-$C_4H_8$ | 9.25 | 1.95 | 2.35 | 2 | 2 |

activation energy for a bond rupture is greater in cases of 1-butene and *cis*-2-butene than in the case of *n*-butane, especially for the rupture of C-C bond.

In order to examine chain branching effects, the results on propane, *n*-butane, and isobutane are compared in Table VII. The

TABLE VII. CHAIN BRANCHING EFFECT OF PARAFFINS IONS

| Substance | Ionization potential | Activation energy C-H | Activation energy C-C | Type of total ion yield C-H | Type of total ion yield C-C |
|---|---|---|---|---|---|
| $C_3H_8$ | 11.20 | 0.56 | 1.04 | 2 | 3 |
| $n$-$C_4H_{10}$ | 10.23 | 1.57 | 0.63 | 2 | 1 |
| iso-$C_4H_{10}$ | 10.23 | 1.37 | 0.93 | 2 | 2 |

activation energies for both C-C bond rupture and C-H bond rupture of iso-$C_4H_{10}^+$ are between those of $C_3H_8^+$ and $n$-$C_4H_{10}^+$, respectively.

## Summary

Relative yields of parent and principal fragment ions from four paraffins and olefins by electron impact are measured for the first time. The characteristic features of the ion yields can be classified into four types related with the ionizing voltages. The decomposition processes for some fragment ions can be explained under some assumptions, and those for forbidden ions $C_2H_5^+$ from isobutane and *cis*-2-butene under the assumption of hydrogen rerrangement.

# *Rheological Properties of Hydrogels of Agar-agar*

By Kiyoshi ARAKAWA

(Received February 1, 1961)

Hydrogels of agar-agar are typical examples of polymeric thermo-reversible gels, and have long been the objects of the researches in colloid chemistry for these several decades[1]. Much remains unknown, however, concerning these gels even at present. In the study of thermo-reversible gels rheological methods are the most appropriate ones, and especially, the recent development of rheology has brought to light many new means for that purpose. The author has made a series of rheological studies on thermo-reversible gels[2,3], and a stress relaxation experiment has been made on the hydrogels of agar-agar, a part of the result of which was reported previously[2]. In this paper more comprehensive results and discussion are given.

## Experimental

**Sample.** — Sample I was given by Nihon Kaiso Kogyo Co., whose specification is shown in Table I together with that of sample II used in the previous experiment[2] for comparison. The intrinsic viscosity $[\eta]_{25}$ at 25°C of the aqueous solution of agar-agar was obtained by means of a capillary viscometer of the Ostwald type, and the molecular weight was calculated from the value of the intrinsic viscosity according to the following formula 1[4].

$$[\eta]_{25} = (3.7 \times 10^{-4}) M_v \qquad (1)$$

The obtained molecular weight is, however, an approximate one, because the reproducibility in the viscosity measurement at 25°C is not so good as that in the measurement at 60°C described below. The preparation of cylindrical gels for the stress relaxation experiment was made as follows. A powder sample was mixed with water in a vessel, and was dissolved by heating on an oil bath with a reflux condenser for two hours, and then was poured into cylindrical moulds. After the surfaces of the cylinders were covered with liquid paraffin in order to avoid the evaporation of water, the specimens were annealed in a thermostat. After 24 hr. specimen gels were taken out from the moulds and were aged at room temperature for more than two weeks. The dimension of the specimen was about 3 cm. in height and 2 cm. in diameter. The preparation of the solution for the measurement of viscosity was made according to the same procedure as that described above, and the measurement was made directly after the preparation.

**Apparatus.**—A chainomatic relaxometer was used to measure the relaxation of Young's modulus of the cylindrical gels, which was the same one as that used previously[2,3].

TABLE I. SAMPLES

| | Sample I | Sample II |
|---|---|---|
| Ashes, % | 2.9 | 1.5 |
| $[\eta]_{25}$, 100 cc./g. | 16.1 | 2.9 |
| Molecular weight | 40000 | 8000 |

## Results and Discussion

**Viscosity of Agar-agar Solution.** — The data of viscosity for the solution of sample I at 60°C are given in Fig. 1. As is seen in Fig. 1, the curve of $\eta_{sp}/C$ vs. $C$ relation rises with decrease of concentration after passing through a minimum point. This is the characteristic of the solution of polyelectrolyte in general and the same behavior of solutions of agar-agar was reported recently by Sakamoto and Kishimoto[5].

**Stress Strain Relation.** — The setress $\sigma$ of 2.6% gel of sample I at 25°C is plotted against the compressional strain $\gamma$ in Fig. 2. The stress $\sigma$ was measured accurately 2 min. after the instant of loading for all strains. It is

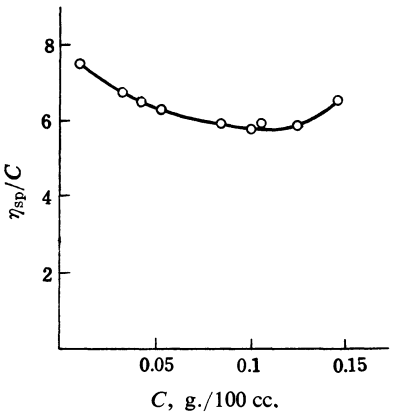

Fig. 1. Viscosity vs. $C$ relation.

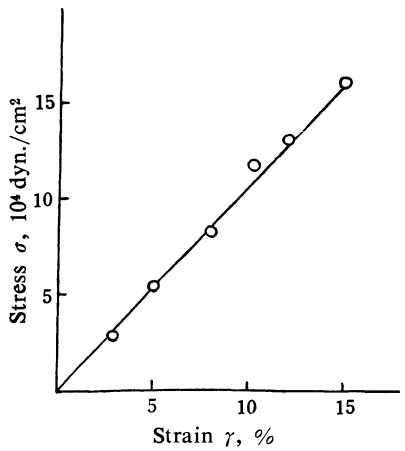

Fig. 2. Stress strain curve at 25°C.

clearly seen in Fig. 2 that the stress strain relation is linear within the amount of strain, 15%.

**Stress Relaxation.** — The relaxation Young's modulus $E_r(t)$ of 2.6% gel of sample I under constant strain at various temperatures is plotted against $\log t$ in Fig. 3, where $t$ is time and $E_r(t)$ is $\sigma/\gamma$. The amount of the imposed strain $\gamma$ is 5% for all temperatures, which is within the range of the linear relation between stress and strain.

The data of stress relaxation on the hydrogel of sample II of the same concentration, which were reported previously[2], are plotted again in Fig. 4 for comparison, but without the multiplication factor $298/T$ in this case. The relaxation curves in Fig. 3 show the inversion of the mutual position with lapse of time. It may be said that in the short time region and at the comparatively low temperature rubber elasticity appears predominantly, but with the lapse of time the junction cleavage occurs more frequently at the higher temperatures. However, in Fig. 4 no inversion is seen. This

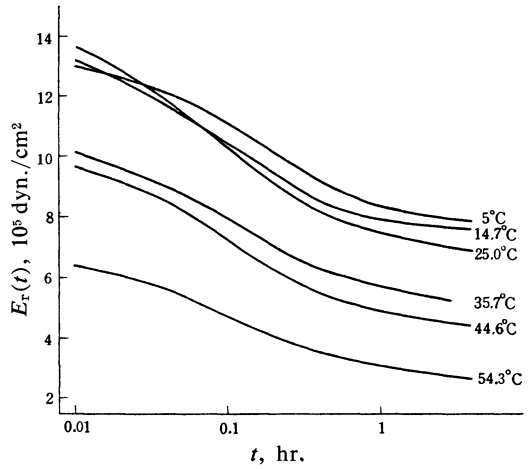

Fig. 3. Relaxation Young's modulus of 2.6% gel (sample I).

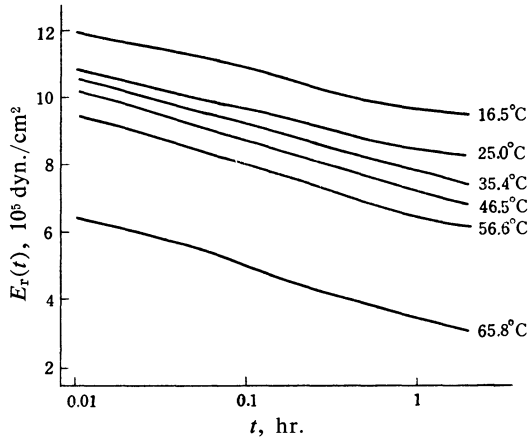

Fig. 4. Relaxation Young's modulus of 2.6% gel (sample II).

may be partly attributed to the difference in the molecular weight of agar-agar.

**Analysis of Relaxation Data by Mechanical Model.** — The mechanical behavior of these gels is represented by the 6-elements mechanical model shown in Fig. 5. According to this model, $E_r(t)$ under constant strain is expressed by Eq. 2,

$$E_r(t) = E_1 e^{-t/\tau_1} + E_2 e^{-t/\tau_2} + E_3 e^{-t/\tau_3} \qquad (2)$$

where $\tau_1 = \eta_1/E_1$, $\tau_2 = \eta_2/E_2$, and $\tau_3 = \eta_3/E_3$.

The results obtained from the curves in Fig. 3 and Fig. 4 by means of Eq. 2 are given in Table II. The calculation of the model constants was made by repeating the procedure described in the previous paper[2], when the following condition (3) was assumed.

$$\tau_1 \gg \tau_2 \gg \tau_3 \qquad (3)$$

As seen in Table II, this is satisfied.

The Maxwellian element of the relaxation time $\tau_1$ may be regarded as the representation

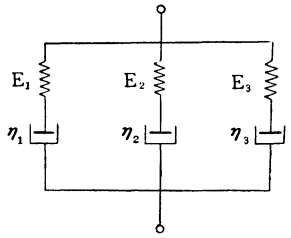

Fig. 5. Mechanical model.

| 56.6 | 7.0 | 1.8 | 1.2 | 17 | 12 | 0.8 |
| 65.8 | 3.9 | 1.4 | 1.7 | 9.8 | 17 | 1.4 |

of the main network structure. The linkage supporting this network may be of secondary nature, considering that the hydrogel of agar-agar makes sol-gel transition reversible, and the bond cleavage process in the gels under constant strain may occur at the junctions in the network, not along the network chains. From the $\tau_1$ vs. $1/T$ relation shown in Fig. 6, the average activation energy $\Delta\overline{H}$ is obtained for the dotted line, and is given in Table III, together with the values calculated from the previous data[2] for 4.0 and 1.0% gel of sample II.

$$\Delta H = R\frac{\partial \ln \tau_1}{\partial(1/T)} \qquad (4)$$

In the agar-agar gels the chain skeleton is composed of the chain of galactose. In natural cellulose the activation energy for the cleavage of hydrogen bonds along a-axis in crystalline region is 7~8 kcal./mol.[6] The value given in Table III is 4.5~6.6 kcal./mol., which is smaller than the above value in natural cellulose, and is camparable with the activation energy of the hydrogen bond between water molecules, 4.5 kcal./mol., and that for ethyl alcohol, 6.2 kcal./mol.[7] From the above consideration it may

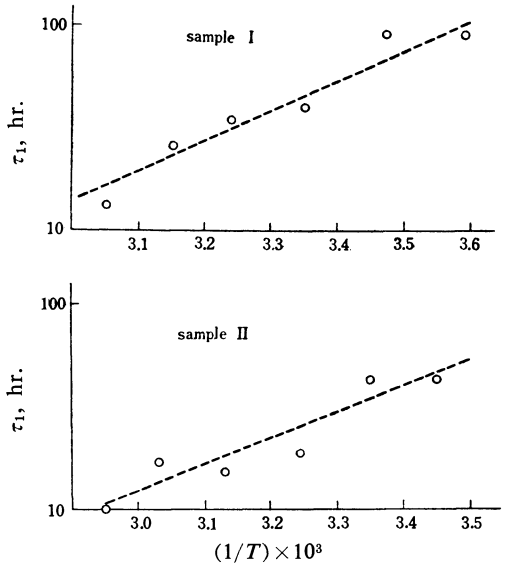

Fig. 6. $\tau_1$ vs. $1/T$ relation of 2.6% gel.

TABLE III. AVERAGE ACTIVATION ENERGY $\Delta\overline{H}$

| | Sample I | | Sample II | |

| $\Delta\overline{H}$, kal./mol. | 6.6 | 4.8 | 5.8 | 4.5 |

be said that in the hydrogel of agar-agar the secondary bond between each agar-agar molecule which constructs the gel structure is the hydrogen bond between galactose, and that the bond is a little weakened by the effect of solvent molecule, compared with the hydrogen bond in the micelle of natural cellulose.

## Summary

A rheological study was made for the hydrogels and the solution of agar-agar. The viscosity vs. concentration relation exhibits the character of polyelectrolyte. From the stress relaxation data obtained by a chainomatic balance relaxometer the following results were obtained.

1) The behavior of hydrogels of agar-agar is represented by the 6-elements mechanical model.

2) The activation energy of the secondary bond between agar-agar molecules which constructs the gel structure is 4.5~6.6 kcal./mol.

Then, there was some discussion on the structure of the hydrogels of agar-agar.

The author is indebted to Mr. Mineo Watase for his cooperation in carrying out this study.

# *Studies on Long Chain Alkyl Amides of Water-soluble Poly-α-amino Acids. I. Amphipathic Properties of Poly-DL-alanine Dodecylamide*

By Toshizo ISEMURA, Shoichi IKEDA, Fumikatsu TOKIWA* and Junzo NOGUCHI**

(Received February 3, 1961)

It has been established that poly-α-amino acid can be synthesized by the polymerization of *N*-carboxy-α-amino acid anhydride[1,2], and a basic substance such as sodium hydroxide, sodium methoxide or organic amines (e. g., *n*-hexylamine, triethylamine) initiates the polymerization effectively[1-3]. The polymerization reaction, initiated by a base (HB) capable of generating an active hydrogen, proceeds as a stepwise addition of amino acid residues in the following manner:

$$\rightarrow \text{H-(-NH-}\underset{\text{R}}{\text{CH}}\text{-CO-)}_x\text{-B} + x\ CO_2$$

The free amino group of poly-α-amino acid produced in each step of the reaction reacts with another molecule of *N*-carboxy anhydride. The stepwise polymerization then goes on until all the *N*-carboxy anhydride molecules are consumed, and the resulting poly-α-amino acid would have a number average degree of polymerization ($x$) equal to the initial anhydride-initiator molar ratio ([A]/[I]).

The poly-α-amino acid prepared in this way would have a basic residue (B) at the terminal carboxyl group linked by an amide bond, if an organic amine such as primary alkyl amine has been chosen as the initiator for polymerization. Thus an amphipathic poly-α-amino acid amide, which has both hydrophilic and hydrophobic groups in a molecule, may be readily synthesized by the above method, if the following conditions are satisfied. The poly-α-amino acid is soluble in water, the basic residue is composed of a hydrophobic group such as long paraffin chain, and the hydrophility of the poly-α-amino acid part is well balanced with the hydrophobicity of the basic residue, i. e., the initial [A]/[I] ratio is properly chosen.

Aside from the difference in chemical structure, the chain conformation and other related properties of poly-α-amino acid are greatly dependent on the constituent amino acid residue[4] as well as on the degree of polymerization, medium and temperature. The manifold possibility in the use of various water-soluble poly-α-amino acids would make the studies of amphipatic poly-α-amino acid alkylamide significant for elucidating the hydrophilic nature of different amino acid residues and the effect of the type of residue on the properties of amphipathic polymer and its hydrogen bonding nature. Furthermore, it is expected that the polymers would find practical uses as surface active agents.

It is noted that the reaction mechanism of polymerization of *N*-carboxy-α-amino acid anhydride is apparently analogous to that of ethylene oxide[5] and the structure of poly-α-amino acid amide resembles that of polyoxyethylene alkyl amine or ether.

The present paper deals with the synthesis and amphipathic nature of poly-DL-alanine alkyl amide, especially, of poly-DL-alanine dodecylamide, in relation to the degree of polymerization of polyamino acid part in a molecule.

## Synthesis

*N*-Carboxy-DL-alanine anhydride (DL-alanine NCA) was prepared from DL-alanine by the phosgene method[6]. The polymerizations were initiated with either dodecylamine, cetylamine or *N*-myristyl-β-alanine at [A]/[I] ratios which varied from 5 to 30. The polymers obtained were dodecylamide (I), cetylamide (II) or *N*-carboxyethyl-myristylamide (III) of poly-DL-alanine:

$$C_{12}H_{25}NH\text{-(-CO-}\underset{\text{CH}_3}{\text{CH}}\text{-NH-)}_x\text{-H} \qquad \text{(I)}$$

$$C_{16}H_{33}NH\text{-(-CO-}\underset{\text{CH}_3}{\text{CH}}\text{-NH-)}_x\text{-H} \qquad \text{(II)}$$

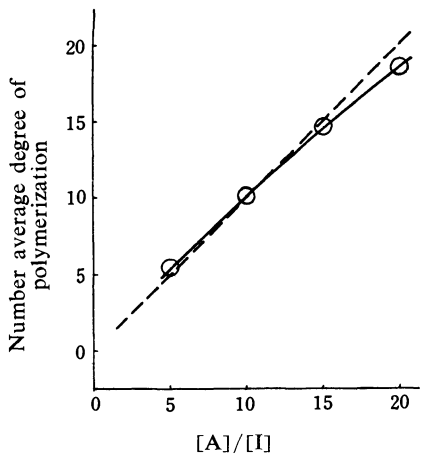
a) 0.75 g. sample in 100 ml. water



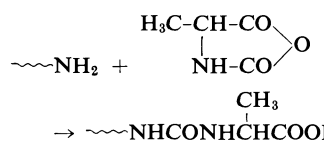


Fig. 1. PADA from polymerization in dioxane with dodecylamine initiator; number average degree of polymerization ($x$) as a function of anhydride-initiator ratio ([A]/[I]), (dashed line represents "theoretical" $x$-[A]/[I] relationship).

The number average degree of polymerization of PADA was determined by the titration of a terminal amino group with perchloric acid[7]. It should be equal to the [A]/[I] value, and Table I and Fig. 1 show that this relation is nearly fulfilled. Hereafter, the designation $x$ is used instead of [A]/[I] for specifying a PADA preparation, although the value of $x$ is not strictly equal to that of [A]/[I]. Values of $x$ were slightly lower than the [A]/[I] value at higher [A]/[I] ratios. The discrepancy may be ascribed either to the error in the titration which is enhanced at higher [A]/[I] ratios or to the presence of a few thermal carboxyl groups which has been formed in a termination reaction during the polymerization in the following manner[7]:

The results of the terminal amino analysis and infrared data as described below confirm the formation of PADA, i. e., poly-DL-alanine linked with dodecylamine in its terminal carboxyl group, in the case of the polymerization of *N*-carboxy-DL-alanine anhydride initiated with dodecylamine.

PADA is insoluble in ordinary organic solvents such as acetic acid, chloroform, and dimethylformamide, but is soluble in formic acid, dichloroacetic acid and *m*-cresol.

PADA of $x > 17$ is soluble in water, but PADA of $x < 17$ gives a turbid solution in water, the turbidity increasing with decreasing $x$. Polyoxyethylene dodecylamine becomes soluble in water for the degree of polymerization higher than 8[8]. However, PADA of any $x$ value is soluble in an aqueous acid solution, the free terminal amino group being ionized.

While the aqueous solutions of polyoxyethylene derivatives are known to exhibit the clouding phenomenon when heated[9], no such phenomenon is observed for PADA solution. This may be attributed to the formation of stronger hydrogen bonding between DL-alanyl residue and water molecule than that between oxyethylene residue and water molecule, the former being kept unbroken even at high temperatures.

## Experimental

***N*-Carboxy-DL-alanine Anhydride.** — DL-Alanine (20 g.) was suspended in dry dioxane (300 ml.), stirred and phosgene bubbled in for about 3 hr., maintaining the temperature at 35~40°C. After the completion of the reaction carbon dioxide was passed through the solution until free of phosgene. The solvent was removed at reduced pressure. Then anhydrous ether was added and evaporated under reduced pressure, and this procedure was repeated several times. Dry petroleum ether was poured into an oily residue, and DL-alanine NCA was recrystallized after keeping the oil for 24 hr. at −15°C. DL-Alanine NCA was recrystallized from ether-petroleum ether. M. p. 45°C, yield 80%.

8) T. Otsuka, personal communication.

9) L. Raphael, *Ist. Int. Cong. on Surface Active Agent*, **1**, 52 (1954).

**Poly-DL-alanine Dodecylamide.**—After an appropriate amount of dodecylamine (for example, 1.6 g. at [A]/[I]=10) was dissolved in dry dioxane (200 ml.), DL-alanine NCA (10 g.) was added to it at room temperature. Polymerization was allowed to proceed for several hours. The suspension of PADA was poured into a large amount of ether, the precipitate was gathered by centrifugation and dried in vacuo.

**Other Derivatives of Poly-DL-alanine.**—Poly-DL-alanine cetylamide and poly-DL-alanine *N*-carboxyethyl-myristylamide were synthesized in the same manner as described above, using cetylamine and *N*-myristyl-β-alanine as initiator, respectively. Poly-DL-alanine was prepared by polymerizing with triethylamine-initiation at [A]/[I]=50, the average $x$ of which was found to be 28.8 by end-group analysis.

**Titration of Terminal Amino Groups.** — A N/20 perchloric acid solution was prepared by adding calculated amount of 70% perchloric acid to glacial acetic acid. After standing overnight, this solution was standardized by titration with pure sodium carbonate in glacial acetic acid, using crystal violet (0.2% glacial acetic acid solution) as indicator.

A sample of 50~80 mg. was weighed into a 50 ml. Erlenmeyer flask, dissolved in 2 ml. of dichloroacetic acid, and then 8 ml. of glacial acetic acid was added to the solution. The solution was titrated to green end-point of crystal violet indicator with the standard perchloric acid solution which was delivered from a 5 ml. micro-burette; the titer of solvent alone was subtracted from sample titer.

To check the procedure, a known amount of dodecylamine was titrated, and the agreement with calculated value was obtained at the green end-point. The point of color change was made somewhat obscure in the presence of dichloroacetic acid, but the accuracy of titration was within about 5%.

**Infrared Measurements.** — All infrared measurements were performed on a Shimadzu Type AR-275 double beam spectrometer using a sodium chloride prism. The samples for infrared measurements were prepared as dispersions either in potassium chloride disks or in Nujol.

**Titration with an Aqueous Hydrochloric Acid Solution.** — pH measurements were made with a Horiba Type M-3 pH-meter. A given amount of sample was dispersed or dissolved in distilled water, and titrated with a standard hydrochloric acid solution (0.06 N) to obtain a titration curve. Concentration of each sample was 0.75 g. polymer in 100 ml. solution.

**Measurements of Surface Tension.** — Surface tension was measured by drop weight method. The apparatus was placed in a thermostat of 25.0°C. The observed values were corrected by using the correction factor of Harkins and Jordan. The pH of sample solutions was adjusted to pH 5.0 by hydrochloric acid, unless otherwise stated, because all the samples were soluble at this pH.

**Measurements of Surface Pressure.** — Surface pressure was measured by a balance of hanging plate type at room temperature. Samples were spread from solutions in a mixed solvent, formic acid-isopropyl alcohol-water (1 : 2 : 7), on distilled water and on an aqueous solution of 0.01 M potassium carbonate or 0.2 M potassium chloride.

## Results and Discussion

**Infrared Absorption Spectra.** — The infrared spectra of PADA and poly-DL-alanine were recorded in the solid state from potassium bromide disks and Nujol suspensions. Some of the infrared data are summarized in Table II.

The absorption bands at 2970 and 2930 $cm^{-1}$ from a potassium bromide disk are assigned to the C-H stretching modes of $CH_3$ and $CH_2$ groups, respectively. The intensity of the former, relative to that of the latter, becomes stronger with increasing $x$, and is the strongest for poly-DL-alanine. This observation supports the formation of poly-DL-alanine linked with dodecylamine.

PADA and poly-DL-alanine show amide I absorption at 1661 and 1629 $cm^{-1}$ and amide III absorption at 1240 and 1220 $cm^{-1}$. The lower frequency in the amide III band was observed in Nujol suspension but not in potassium bromide disk. A band due to N-H stretching lies at 3310 and 3280 $cm^{-1}$. The lower frequency appeared in potassium bromide disk for PADA of $x=5$ but not in Nujol suspension. In amide I band the higher frequency

a) from KBr disk, b) from Nujol suspension

of the two amide bands is characteristic of the random conformation of polypeptide and the lower is of the β-conformation[10-13],*. The dependence of the relative intensity of two frequencies in the amide III and the N–H stretching bands upon the value of $x$ is also related to the presence of these two conformations. In all the three bands the intensity of the higher frequency of PADA relative to that of the lower increases with $x$, and poly-DL-alanine absorbs the higher frequency strongly. The results indicate that the random conformation is predominant for PADA with higher $x$ ($x \geq 20$) and poly-DL-alanine, the portion of the β-conformation increases with lowering $x$, and PADA with $x=5$ is mostly in the β-conformation**.

However, the above correlation of infrared frequency with the conformation of polypeptides could not be found in amide II band.

**Titration with an Aqueous Hydrochloric Acid Solution.** — When PADA or poly-DL-alanine is dispersed or dissolved in water, the solution shows an acidic pH. Poly-DL-alanine gives the most acidic pH, 3.7. Table I shows the pH's of the solution of 0.75 g. polymer in 100 ml. A value of pH, 2.8, of poly-DL-alanine ($x=30$) solution has been reported already[15]. This might be ascribed partly to the presence of the terminal carboxyl groups produced by the termination reaction during polymerization, as mentioned before[7].

The solution of PADA exhibits lower pH with increasing $x$, because an equal gram of polymer contains less terminal amino groups with increasing $x$. This effect is enhanced by the more complete solubility of PADA with higher $x$, since the amino groups of insoluble molecules would remain unionized.

When the solution of PADA is titrated with an aqueous hydrochloric acid solution, the pH is gradually lowered and then suddenly decreases. Fig. 2 shows the pH of solution plotted against mole of hydrochloric acid added when 0.75 g. PADA is dispersed or dissolved in 100 ml. solution. On this titration curve, a

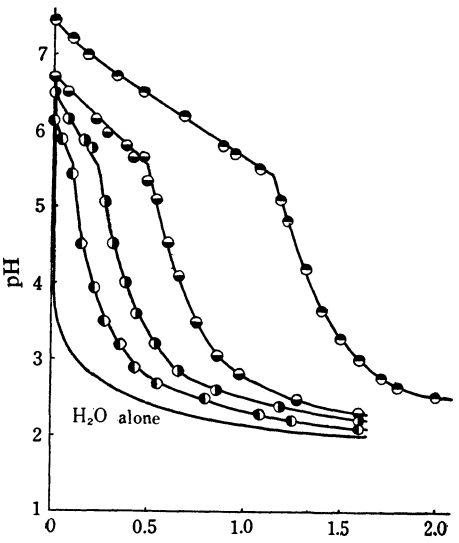

Fig. 2. Plots of pH of PADA solution against added amout of hydrochloric acid at 25°C. ◓, $x=5$; ◒, $x=10$; ◑, $x=15$; ◐, $x=20$

break point exists at about pH 5.5, irrespective of $x$. At this point the turbid dispersion of PADA with $x<17$ becomes almost transparent. If all the terminal amino groups could be titrated with hydrochloric acid, the break point should be the end point, and the mole of hydrochloric acid consumed should be equal to mole of terminal amino groups obtained from anhydrous perchloric acid titration. Nevertheless, the former was found to be considerably smaller than the latter. The discrepancy might arise from the fact that the PADA molecules in aqueous acid media aggregate into a "micelle". The micelle is composed of ionized molecules together with unionized molecules, the latter being not titratable with hydrogen ions. Evidence for the micelle formation is provided by surface tension data and preliminary experiments of ultracentrifugation and solubilization.

**Surface Tension.** — The surface tension of aqueous solutions of PADA together with poly-DL-alanine and dodecylamine hydrochloride was measured at pH 5.0. Dodecylamine hydrochloride was a sample recrystallized several times from acetone-benzene. The surface tension vs. concentration curves at pH 5.0 are shown in Fig. 3. The result obtained for dodecylamine hydrochloride was in good agreement with that already reported[16].

The surface tension of PADA solution is

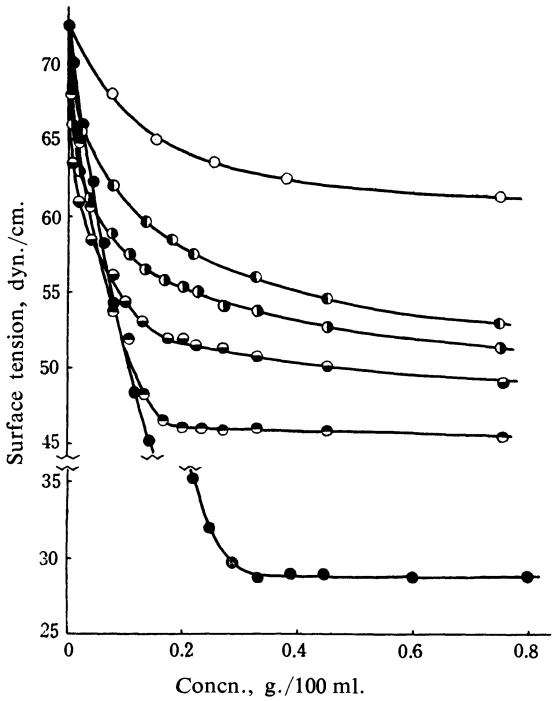

Fig. 3. Surface tension vs. concentration curves for aqueous solution of PADA, poly-DL-alanine and dodecylamine hydrochloride at pH 5.0 25°C. PADA: ◓, $x=5$; ◒, $x=10$; ◑, $x=15$; ◐, $x=20$; ○, poly-DL-alanine; ●, dodecylamine hydrochloride

characterized by a sharp initial decrease followed by a gradual flattening, as the concentration becomes higher. This behavior is commonly observed for surface active agents. The break point corresponds to the critical micelle concentration, although it becomes obscure for PADA of higher $x$. The critical micelle concentration of PADA lies in more dilute concentration than that of dodecylamine hydrochloride, and shifts towards lower concentration as $x$ increases.

In a PADA molecule, a sequence of DL-alanyl residues is between the dodecyl group and the ionized or unionized hydrophilic amino group at pH 5.0, where PADA is partially ionized. In this case the part of poly-DL-alanine reduces the repulsion between ionized hydrophilic groups due to the intermolecular hydrogen bonding. Thus the micelle formation takes place readily at lower concentration as $x$ increases. It is noticeable that the critical micelle concentration of PADA lies at about $10^{-3}$ mole per liter which is compared with

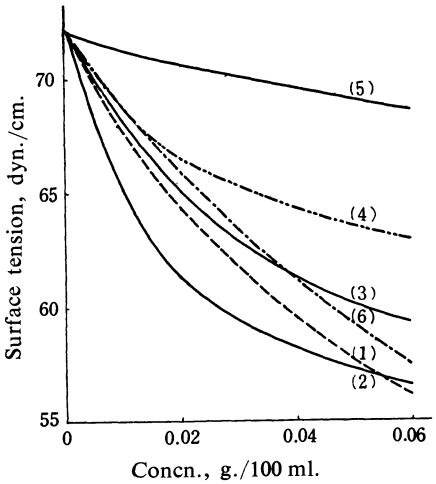

Fig. 4. Surface tension vs. concentration curves of PADA, poly-DL-alanine and dodecylamine hydrochloride at dilute concentrations. pH 5.0, 25°C. PADA: (1) $x=5$, (2) $x=10$, (3) $x=15$, (4) $x=20$, (5) poly-DL-alanine, (6) dodecylamine hydrochloride

that of polyoxyethylene derivatives with long alkyl chain, $10^{-4}$ mol. per liter[17].

At low concentrations the slope of surface tension vs. concentration curve is the steepest for PADA of $x=10$ and is more gentle when $x$ is either smaller or larger than this value, as shown in Fig. 4. For $x<10$, the explanation is as described before. For $x>10$ the attraction

17) L. Hsioa, H. M. Dunning, P. B. Lorenz, *J. Phys. Chem.*, **60**, 657 (1956). E. Gonick and J. W. McBain, *J. Am. Chem. Soc.*, **69**, 334 (1947).

due to hydrogen bonding between DL-alanyl residues predominates over van der Waals cohesion between alkyl chains and the characteristics of poly-DL-alanine become obvious and reduce the effect of alkyl chain, thus surface tension being less lowered.

Fig. 5 show the effect of acid on surface tension of PADA. The more acidic the solution of PADA is, the lower the surface tension becomes and the break point shift to more dilute concentration. This fact indicates that the excess acid added beyond pH 5.5 remains free in solution and behaves like a simple neutral salt, suppressing the electrostatic repulsion between ionized amino groups.

**Surface Film of PADA.** — Fig. 6 illustrates surface pressure vs. area curves of PADA and poly-DL-alanine films on distilled water. They are of condensed type. The limiting area, $A_{\Pi\to 0}$ ($m^2$/mg.), of PADA increases with $x$, tending to that of poly-DL-alanine, as listed in Table III. The film of PADA occupies a larger area on the aqueous subphase containing salt than on distilled water, as shown in Fig. 7, but salt has no influence on poly-DL-alanine film.

The limiting area expressed in $m^2$/mg. is reduced to that in $Å^2$ per average DL-alanyl residue by

$$A_{\Pi\to 0}(Å^2/\text{residue}) = \frac{10^{23}}{N}\left(M_A + \frac{M_B}{x}\right) A_{\Pi\to 0}\ (m^2/\text{mg.}) \quad (1)$$

if the residue weight of dodecylamine is equally distributed over alanyl residues. Here $N$ is the Avogadro number, and $M_A$ and $M_B$ are residue weight of alanine (71) and dodecylamine (184), respectively. In Eq. 1 $x$ is assumed to be infinite for poly-DL-alanine film.

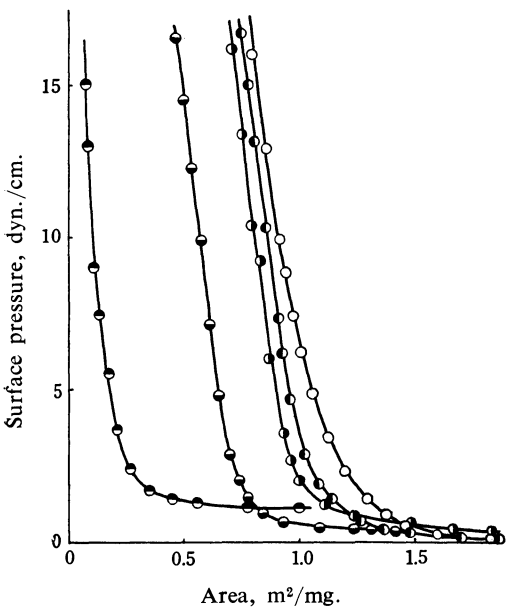

Fig. 6. Surface pressure vs. area curves of PADA and poly-DL-alanine on distilled water at 18°C. PADA: ◓, $x$=5; ◒, $x$=10; ◑, $x$=15; ◐, $x$=20; ○, poly-DL-alanine

TABLE III. LIMITING AREAS AND $f$ VALUES OF PADA AND POLY-DL-ALANINE

| $x$ | On distilled water $A_{\Pi\to 0}$ | | | On 0.01 M $K_2CO_3$ $A_{\Pi\to 0}$ | | | On 0.2 M KCl $A_{\Pi\to 0}$ | | |
|---|---|---|---|---|---|---|---|---|---|
| | $m^2$/mg. | $Å^2$/residue | $f$ | $m^2$/mg. | $Å^2$/residue | $f$ | $m^2$/mg. | $Å^2$/residue | $f$ |
| 5 | 0.26 | 4.7 | 0.05 | — | — | — | — | — | — |
| 10 | 0.74 | 11.0 | 0.64 | 0.89 | 13.3 | 0.81 | 1.07 | 15.9 | 0.99 |
| 15 | 0.98 | 13.5 | 0.87 | 1.09 | 15.0 | 0.98 | 1.11 | 15.3 | 1.00 |
| 20 | 1.06 | 14.1 | 0.94 | — | — | — | — | — | — |
| Poly-DL-alanine | 1.18 | 14.0 | — | — | — | — | 1.18 | 14.0 | — |

Since the limiting area of long chain alkylamine or alkylamide is about 20 Å$^2$ per molecule[18] and that of poly-DL-alanine is 14 Å$^2$ per residue, PADA should have a limiting area

$$A_{\Pi\to 0}(\text{Å}^2/\text{residue}) = \frac{20+14x}{x} \qquad (2)$$

if it spreads completely as a monomolecular film. While the observed value of the limiting area of PADA on aqueous salt solution such as 0.01 M potassium carbonate or 0.2 M potassium chloride is found to agree with the value calculated from Eq. 2, that obtained on distilled water is smaller than the calculated value. In the latter case, a part of hydrophilic poly-DL-alanine part might be submerged into water. If it is assumed that $xf$ DL-alanyl residues and a dodecylamino residue in a PADA molecule form a surface film and $x(1-f)$ DL-alanyl residues are submerged into water the limiting area of PADA may be expressed by

$$A_{\Pi\to 0}(\text{Å}^2/\text{residue}) = \frac{20+14xf}{x} \qquad (3)$$

Substituting the observed values of limiting area for $A_{\Pi\to 0}$(Å$^2$/residue) in Eq. 3, the values of $f$ are obtained as given in Table III.

It is interesting to note that, while PADA becomes more hydrophilic and more soluble in water as $x$ is larger, in surface film it spreads more; that is, more DL-alanyl residues in a molecule exist on an aqueous surface. This observation may be interpreted as follows: When PADA of lower $x$ is compressed, the van der Waals attraction between dodecyl groups is so strong that some of DL-alanyl residues are forced to be submerged into water. For PADA of higher $x$, however, a hydrogen-bonded conformation[19-21] of poly-DL-alanine part will remain unbroken on compression, since the hydrogen bonding is more predominant than van der Waals cohesion.

**Summary**

Poly-DL-alanine alkyl amide has been synthesized by the polymerization of *N*-carboxy-DL-alanine anhydride initiated with alkyl amine at different anhydride-initiator ratios ([A]/[I]). The amphipathic properties of poly-DL-alanine dodecylamide (PADA) with [A]/[I] = 5 to 20 have been investigated in comparison with poly-DL-alanine.

The degree of polymerization of poly-DL-alanine part can be easily controlled by the initial [A]/[I] ratio. The number average degree of polymerization ($x$) is found to be approximately equal to [A]/[I].

The solubility of PADA in water is higher as $x$ increases, and PADA with $x>17$ is transparently soluble. PADA with any $x$ value is soluble in aqueous acid solutions, the pH of which is lower than 5.5. The titration curve with an aqueous acid solution shows a break at this pH.

The infrared spectra of PADA in the solid state indicate that PADA with higher $x$ is almost in the random conformation and the portion of the $\beta$-conformation increases as $x$ becomes lower.

Surface tension of PADA in aqueous acid solution exhibits typical characteristics of amphipathic substances. The degree of surface tension lowering at low concentration region is the largest for PADA of $x=10$.

The surface film of PADA is of condensed type and the limiting area is larger as $x$ increases. PADA with higher $x$ becomes more spread as surface film, more DL-alanyl residues being on the aqueous surface.

# *On the Temperature Dependence of Spectra of Solvated Anions*

By Akira MARUYAMA*, Mitsuo SHIMOJI and Kichizo NIWA

(Received February 20, 1961)

Recently it has been noticed that the ultraviolet spectra of solvated halide ions depend upon the temperature. The bands in the ultraviolet region are considered to be due to the charge transfer from the ion to the solvent. However, with respect to the details of the mechanism, different models have been proposed by several authors. In particular, these models seem to lead to different conclusions on the effect of temperature.

In this paper, it is shown that the differences existing among the previous theories are only apparent in character, and some experimental data on the temperature dependence of the ultraviolet spectra of solvated iodide ions are given.

## Experimental and Results

Measurements of absorption spectra were carried out with a Hitachi EPU-2 type spectrophotometer. The temperature was varied in the range 5~60°C and was kept constant within ±1°C, circulating the thermostatted water in the cell box by means of a small pump.

The absorption spectra for potassium iodide, ammonium iodide, codmium iodide, cobalt(II) iodide and bismuth(III) iodide in their aqueous solutions ($10^{-5}$ mol./l.) have a common maximum wavelength irrespective of the cations (for example 225 mμ at 12°C) in agreement with the data of many authors[1,2]. As is well known, this maximum can be ascribed to the existence of the iodide ion in such dilute solutions. In Table I the values of

TABLE I. WAVELENGTHS OF MAXIMUM ABSORPTION (mμ) OF IODIDES ($10^{-5}$ M IN WATER) AT SEVERAL TEMPERATURES

| Temp., °C | KI | $CdI_2$ | $BiI_3$ |
|---|---|---|---|
| 6.5 | 225.4 | 225.3 | 225.2 |
| 25.2 | 226.1 | 226.0 | 226.0 |

the maximum wavelength ($\lambda_{max}$) of potassium iodide, cadmium iodide and bismuth(III) iodide ($10^{-5}$ mol./l. aqueous solution) are shown with the error of ±0.2 mμ. In Fig. 1 the temperature dependence of the energy maximum ($h\nu_{max}$) calculated from $\lambda_{max}$ obtained is recorded. The slope in Fig. 1 gives $d(h\nu_{max})/dT = -32$ cal. deg$^{-1}$ mol$^{-1}$, where $h$ is Planck's constant. This is in agreement with the value of Smith and Symons[2]. Present results, that $d(h\nu_{max})/dT \approx -30$ cal. deg$^{-1}$ mol$^{-1}$ in these solutions, are in agreement with those obtained in many solvent systems[2-4]. Some theoretical considerations for this fact, i. e. the shift to longer wavelength with increasing temperature, will be given in the next section.

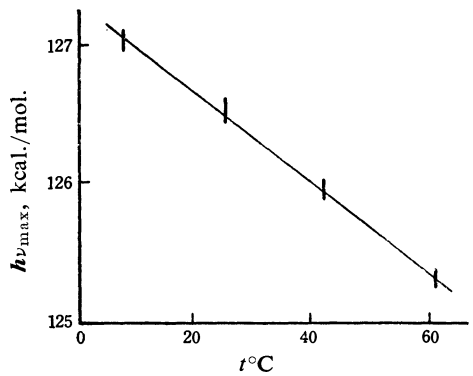

Fig. 1. $h\nu_{max}$ of $I^-$ in aqueous solution ($10^{-5}$ mol./l.).

## Discussion

Many anions dissolved in polar liquids such as water exhibit absorption spectra in the ultraviolet region. These spectra are considered to be due to an electron transfer from the solvated anion to a quantum state, which is yielded by the resultant atom, the adjacent water molecules, and the external polarized dielectrics. The electron transfer is so fast that the positions of all atomic nuclei in all solvent molecules may be regarded as fixed throughout the transition process in accordance with the Franck-Condon principle. In other words the process may be regarded as a sort of non-equilibrium state associated with electron transition. From this point of view Platzman and Franck[5] calculated the positions of the absorption bands of the aqueous halide

ions. Their theoretical expression for the energy of the absorption $h\nu$ is as follows.

$$h\nu = E_x + L_{x^-} + \{\chi - L_x\} - B \quad (1)$$

Here $E_x$ is the electron affinity of the atom X, and $L_x$ and $L_{x^-}$ are the differences of energies associated with the solvation of the atom and of the ion, respectively. $\chi$ is the energy required to form the average solvation configuration of the solvent molecules (i. e. the correction term based on the Franck-Condon principle), and $B$ is the energy of the excited electron resulting from the Coulombic force of the polarized solvent (i. e. hydrogen-like states) and from the electronic polarization induced by the electron in the excited state.

$$B = \frac{2\pi^2 me^4}{h^2 2^2} Z^2_{\text{eff}} + \frac{1}{3}\frac{\pi^2 e^4 m}{h^2} Z_{\text{eff}}\left(1 - \frac{1}{D_{\text{op}}}\right) \quad (2)$$

and

$$Z_{\text{eff}} = \left(\frac{1}{D_{\text{op}}} - \frac{1}{D_s}\right) \quad (3)$$

where $D_{\text{op}}$ and $D_s$ are the optical and static dielectric constants, $m$ is the mass of an electron. The values of $h\nu$ calculated by using Eq. 1 were in good agreement with the experiment.

However, Smith and Symons[6,7], and Stein and Treinin[8] pointed out that the theory of Platzman and Franck fails to explain changes in the position of the absorption bands caused by changing temperature or solvent. Smith and Symons attempted to avoid the difficulties by adopting the "square well" model. According to this theory the electron after detachment from the ion still remains in the cavity previously occupied by the ion. Then the energy of the absorption $h\nu$ is given by

$$h\nu = E_x + \frac{h^2}{8mr_o^2} \quad (4)$$

where $r_o$ is an empirical parameter which was introduced by Smith and Symons. This parameter may roughly be regarded as the radius of the spherical cavity. However, it is unlikely that the order of magnitude of $r_o$ corresponds to any physically meaningful value, because it is greater (for example 4Å for $I^-$) than any value that may be reasonably expected. Stein and Treinin[8] modified the Platzman-Franck theory by introducting the concept of a variable radius parameter $r^*$ as suggested by Smith and Symons. Their equation is given as

$$h\nu = E_x + (S_{\text{ion}} + E_p) - L_x - B \quad (5)$$

where

$$S_{\text{ion}} + E_p = \frac{e^2}{r^*}\left(\frac{1}{2} + \frac{1}{2D_{\text{op}}} - \frac{1}{D_s}\right) \quad (6)$$

The difference between Platzman-Franck's Eq. (1) and Smith-Symon's (5) is that $(S_{\text{ion}} + E_p)$ in Eq. 5 takes the place of $(I_{x^-} + \chi)$ in Eq. 1. According to Stein and Treinin the valnes of the radius parameter $r^*$ obtained from the spectroscopic data on the basis of Eq. 5 were in good agreement with the apparent ionic radii estimated from partial ionic volumes. The temperature dependence of $h\nu$ was also explained in terms of the change of the radius of the cavity (or ionic radii), $dr^*/dT$. They emphasized that Franck and Platzman's procedure, taking into account $L_{x^-}$ and $\chi$, is inadequate for the treatment of the temperature dependence.

However, the concept of ionic radii in liquids corresponds to the rigid sphere model of liquids, and may be regarded as an appoximation for the behavior of liquids. The apparent ionic radii should be determined more rigorously from the relation between the total energy and ion-molecule distances. Thus Eq. 5 should in principle coincide with Eq. 1 apart from minor differences of mathematical expressions. Hence, the temperature dependence of $h\nu$ will be considered here without using the concept of the radius parameter $r_o$.

In Platzman-Franck's equation the effect of temperature may be prominent in the terms $L_{x^-}$, $\chi$ and $L_x$, since these factors strongly depend on the positions of nuclei. The terms caused by the electronic polarization or the electronic motion can be unimportant, since $dD_{\text{op}}/dT$ and $dD_s/dT$ are so small that the calculated value for $d(h\nu_{\max})/dT$ is at most about 1/10 of the observed values. Thus one can write

$$\frac{d(h\nu)}{dT} = \frac{d\{L_{x^-} - (I_x - \chi)\}}{dT} \quad (7)$$

It seems to be impossible to define $d(L_x - \chi)/dT$ in Eq. 7 by the usual thermodynamic method, though $d(L_{x^-})/dT$ simply denotes the change of the thermodynamic specific heats $\Delta C_{x^-}$ as the following:

$$\frac{d(L_{x^-})}{dT} = \Delta C_{x^-} = C^g_{x^-} - C^s_{x^-} \quad (8)$$

where $C^g_{x^-}$ and $C^s_{x^-}$ show the specific heats of the ion in vacuo and in the solvent, repectively. As was noted by Stein and Treinin, $\Delta C_{x^-}$ of the process $X^-$ (in solvent) $\rightarrow X^-$ (in

6) M. Smith and M. C. R. Symons, *Discuss. Faraday Soc.*, **24**, 206 (1957).
7) M. Smith and M. C. R. Symos, *Trans. Faraday Soc.*, **54**, 346 (1958).
8) G. Stein and A. Treinin, ibid., **55**, 1086 (1959).

vac.) can be positive. On the other hand, for the neutral atom X one can write

$$\frac{d(L_x-\chi)}{dT}=\Delta C_{x^*}=C^g{}_{x^*}-C^s{}_{x^*} \qquad (9)$$

corresponding to Eq. 8. However, $C^s{}_{x^*}$ does not denote the specific heat of the ion in the solvent to be defined in the equilibrium state, since $(L_x-\chi)$ does not correspond to the stable configuration for the atom. Substituting Eqs. 8 and 9 into Eq. 7, one obtains

$$\frac{d(h\nu)}{dT}=(C^g{}_{x^-}-C^g{}_{x^*})-(C^s{}_{x^-}-C^s{}_{x^*}) \qquad (10)$$

Approximately $C^g{}_{x^-}$ is equal to $C^g{}_x$, because both ion and atom are monatomic particles in the gaseous phase and the contribution of electronic states may be disregarded in the range of room temperature. Thus

$$\frac{d(h\nu)}{dT}\approx-(C^s{}_{x^-}-C^s{}_{x^*}) \qquad (11)$$

The configuration of the atomic nuclei, including the solvent molecules, will be similar in $C^s{}_{x^-}$ and $C^s{}_{x^*}$, though the ion-dipole interaction in $C^s{}_{x^-}$ may disappear in $C^s{}_{x^*}$ (i. e. only van der Waals interaction and the exchange repulsive energy). This means that the energy of interaction between the solute and the solvent will be much smaller in $C^s{}_{x^*}$ than in $C^s{}_{x^-}$. Then it is assumed that i) the ion-dipole interaction is so strong that the potential energy between the ion and the solvent molecule can be regarded as a classical vibration energy, and that ii) the interaction between the atom and the solvent molecule is negligibly weak compared with the ion-dipole interaction. Hence, it may be concluded that $(C^s{}_{x^-}-C^s{}_{x^*})$ is mainly due to the vibrational heat capacities (in the sense of classical mechanics) being proportional to the number of solvated molecules (or dipoles), $n$. Thus, from Eq. 11

$$\frac{d(h\nu)}{dT}\approx-kn \qquad (12)$$

where $k$ is the Boltzmann constant. As the order of magnitude of $n$ is usually 10 (for example, 6 to 8 for the first layer of hydration in aqeous solution[9]), $d(h\nu)/dT$ calculated may be about $-20$ cal. deg$^{-1}$ mol$^{-1}$ in agreement with the observed values. The present consideration (12) will, essentially, not be different from the Smith-Symons and Stein-Treinin theories, since the increase of the radius of cavity $r_0$ should correspond to the change in the free energy of the solvated ion caused by the temperature rise. Examples of this sort are found in the models of the free volume for liquids i. e. the harmonic oscillator model and smoothed potential model[10].

## Summary

The effect of temperature on the ultraviolet spectra of solvated anions is examined experimentally and theoretically. The shift of the spectrum to the longer wavelength with increasing temperature can be explained in terms of the oscillator model of the solvent molecules. This corresponds to the increase of the ionic radii (or the radius of the cavity) with the temperature rise.

# *The Absolute Configuration of Rotenone*[1]

By Masao NAKAZAKI and Hisao ARAKAWA

(Received February 9, 1961)

Rotenone, one of the most powerful vegetable insecticides, was first isolated by Nagai[2] from *Milletia taiwaniana* Nagai, a native of Formosa, and was found to be identical with tubotoxin[4] obtained from *Derris elliptica* which is now widely cultivated.

I

The accepted formula I[5] was advanced independently by Takei[6], Butenandt[7] and LaForge[8] at about the same time (1932).

To study the interesting relationship between the insecticidal action of rotenone and its stereochemistry, the establishment of the absolute configuration is essential. This contribution is concerned with the determination of the absolute configuration at C-5′ carbon atom of rotenone (I).

Tubaic acid (IIa) obtained by the alkaline degradation of rotenone was catalytically hydrogenated to give (−)-dihydrotubaic acid (IIb)[10], which was dissolved in acetic acid and exhaustively ozonolyzed[11] by passing ozone through it for 25 hr. After further oxidation with hydrogen peroxide, oxalic acid was removed as the calcium salt and the solution was passed through the column of Amberite IR-120 to be freed of the excess of calcium ions. The solvent was removed in vacuo and crude 3-hydroxy-4-methyl-pentanoic acid (III) (or IV in Fischer projection) was esterified with diazomethane to give the methyl ester IVb, b. p. 77~86°C/18 mmHg, $[\alpha]_D$+19.0°.

To correlate IVb with D-valine, the methyl ester IVb was converted into the hydrazide IVc, m. p. 152~153°C, $[\alpha]_D$+43°, which was treated with nitrous acid[12] to give (−)-5-isopropyloxazolidone (V), m. p. 113~114°C, $[\alpha]_D$ −44.5°, the structure of which was confirmed by the comparison of the infrared spectrum with the racemic V, m. p. 87~88°C, prepared from the racemic hydroxylic acid IVa[13,14].

(−) Methyl 2-hydroxy-3-methylbutanoate (VIIb), b. p. 62~63°C/15 mmHg, $[\alpha]_D$ −1.4°, which was prepared from D-valine (VI)[15] with retention of configuration[16], was treated with liquid ammonia in a steel bomb to give the (+)-amide VIIc, m. p. 99~101°C, $[\alpha]_D$ +65.10. Lithium aluminumhydride redcution of the amide VIIc afforded the aminoalcohol VIIIa

1) A preliminary note appeared in This Bulletin, **34**, 453 (1961).

8) F. B. LaForge and H. L. Haller, *J. Am. Chem. Soc.*, **54**, 810 (1932).

9) The configurations of carbon atoms at 6a and 12a seem not to be crucial to the insecticidal action; e. g. (−)-deguelin shows almost the same physiological action as that of (±)-deguelin (S. Takei and S. Miyajima, *Scientific Papers Inst. Phys. Chem. Research* (*Tokyo*), **12**, 946 (1933)). Cahn and coworkers (R. S. Cahn, R. F. Phillipers and J. J. Boam, *J. Chem. Soc.*, **1938**, 513). obtained (+)-isorotenone, the enantiomer of (−)-isorotenone which keeps the original configuration of rotenone at 6a and 12a carbon atoms, from "mutarotenone"; but there seems to have been no study on the comparison of the physiological properties between them. Although Miyano amd Matsui (M. Miyano, A. Kobayashi and M. Matsui, *Chem. Ber.* in press) reported the total synthesis of natural rotenone, the effect of the configuration C-5′ carbon atom has remained unknown, since the enantiomer of natural rotenone could not be prepared.

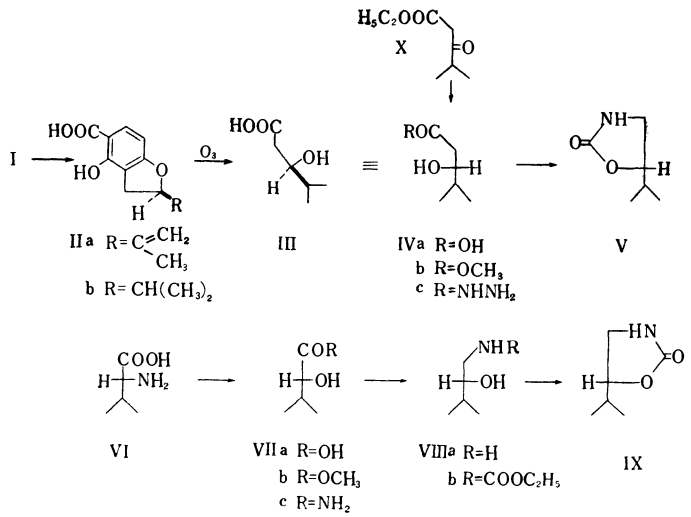

Fig. 1.

which was transformed, via the carbamate VIIIb, into (+)-5-isopropyloxazolidone (IX), m. p. 113~114°C, $[\alpha]_D$ +44.2°.

The fact that 5-isopropyloxazolidone (V and IX) were enatiomorphous was established by comparison of their intrared spectra, which can be superimposed in every detail, moreover, a mixed melting point determination of the 5-isopropyloxazolidone synthesized from the racemic hydroxylic acid IVa with the racemic compound prepared by mixing equal parts of (−)-5-isopropyloxazolidone from rotenone and (+)-5-isopropyloxazolidone from D-valine and recrystallization from benzene showed no depression. These facts clearly show, as can be seen from Fig. 1, that rotenone has (R)-configuration at the carbon atom C-5′ as illustrated in I.

During the course of this investigation, Büchi and Crombie[14] published a short communication in which they reported the same conclusion. They ozonolyzed (−)-dihydrotubaic acid (IIb) to obtain (+)-3-hydroxy-4-methylpentanoic acid (IVa). In order to secure enough starting material, they synthesized (±)-IVa and resolved via the quinine salt obtaining (−)-acid (enantiomer of III from rotenone) which they converted via three steps into (−)-2-methylpenta-3-ol with known configuration.

Thus we could confirm Büchi and Crombie's result[17], although our approach appears more direct and simple, giving well defined crystalline compounds in each step, which will be proved to be useful as key compounds in establishing absolute configuration of other compounds.

17) They also succeeded in establishing (S)-configuration at 6a carbon atom by the exhaustive ozonolysis of acetyldihydrorotenone to obtain D-glyceric acid in the form of its *p*-bromophenacyl ester. See Ref. 14.

## Experimental

**Dihydrotubaic Acid (IIb).**—IIb was prepared according to Takei and Koide's procedure, m. p. 166°C, $[\alpha]_D^{25}$ −103.7° (*c* 1.08, methanol).

Found: C, 64.88; H, 6.25. Calcd. for $C_{12}H_{14}O_4$: C, 64.85; H, 6.35%. (literature[10], m. p. 168°C, $[\alpha]_D$ −82.67°, chloroform).

**Exhaustive Ozonolysis of Dihydrotubaic Acid (IIb).**—To a solution of 4.4 g. of dihydrotubaic acid (IIb) in 70 cc. of 95% acetic acid, was passed ozone at room temperature for 25 hr. The color of the solution changed from colorless to brown after 5 min., and pale yellow after 30 min. and then colorless again. After 8 cc. of 30% hydrogen peroxide was added, the solution was kept at room temperature for 17 hr, then 50 cc. of water was added with a small amount of palladium-carbon to decompose the excess of hydrogen peroxide. In order to remove oxalic acid, 2 g. of calcium acetate was added and the resulting precipitate was filtered. After the solution was freed from excess calcium ion by passing through a column of Amberite IR-120, the solution was concentrated in vacuo to give a syrup which was dried in a vacuum desiccator overnight. The viscous hydroxylic acid III was dissolved in a small amount of methanol and esterified with excess diazomethane solution in ether. After being allowed to stand overnight and being dried over anhydrous sodium sulfate, the solution was concentrated, giving a pale yellow residue which was distilled in vacuo, b. p. 77~86°C/18 mmHg, 0.95 g. $[\alpha]_D^{20}$ +19.0° (*C* 5.77, ethanol).

**(+)-3-Hydroxy-4-methylpentanhydrazide (IVc).**—To a solution of 0.95 g. of the methyl ester IVb in 20 cc. of ethanol, 2 g. of 80% hydrazine hydrate solution was added and the mixture was heated on a water bath for 1 hr. After standing in a refrigerator overnight, the solid mass obtained was

recrystallized from ethanol giving crystals, m. p. 151~153°C, $[\alpha]_D^{19}$ +38~−40° (ethanol), 0.32 g. To prepare an analytical sample the product was recrystallized from ethanol, m. p. 152~153°C, $[\alpha]_D^{19}$ +43°) (*c* 1.01, ethanol).

Found: N, 19.14. Calcd. for $C_6H_{14}O_2N_2$: N, 19.17%.

**(−)-5-Isopropyloxazolidone (V).**—After 10 cc. of benzene was added to a solution of 0.3 g. of the hydrazide IVc in 10 cc. of 1N hydrochloric acid, a solution of 1.5 g. of sodium nitrite in 2 cc. of water was added during 10 min. at 5~6°C with stirring. After being kept at room temperature for 1 hr., the benzene layer was separated and washed with saturated aqueous sodium hydrogen carbonate and dried over calcium chloride for 30 min. When the benzene solution, being freed from the drying reagent, was heated on a water bath at 75°C, generation of nitrogen was observed, and the solution was refluxed for 30 min. Removal of the solvent gave crystals (0.22 g.) which were recrystallized from benzene to afford an analytical sample, m. p. 113~114°C, $[\alpha]_D^{18}$ −44.5° (*c* 1.01, ethanol), 70 mg. infrared spectrum (solvent: chloroform) was found completly superimposable on the one of (−)-isomer IX prepared from D-valine.

Found: C, 55.93; H, 8.55; N, 10.98. Calcd. for $C_6H_{11}O_2N$: C, 55.79; H, 8.58: N, 10.84%.

**(−)-Methyl 2-Hydroxy-3-methylbutanoate (VIIb).**—According to Fischer's procedure[16], 4.9 g. of D-valine ($[\alpha]_D^{16}$ −27.6° *c* 2.68, 6N hydrochloric acid) was converted into 2-hydroxy-3-methylbutanoic acid (VIIa). The hydroxylic acid was esterified with diazomethane in ether and the methyl ester VIIb was distilled to give an oil, boiling at 62~63°C/15 mmHg, $[\alpha]_D^{17}$ −1.4° (*c* 9.18, ethanol), 2.4 g.

**(+)-2-Hydroxy-3-methylbutanamide (VIIc).**—A mixture of 2.4 g. of methyl ester VIIb and 8 cc. of liquid ammonia was placed in a steel bomb and kept at 30°C overnight. After heating at 40~45°C for 2 hr., the excess of ammonia was evaporated, giving a residue, which was dissolved in ethanol. Removal of the solvent gave a viscous oil which was caused to solidify by trituration with benzene, m. p. 98~100°C, $[\alpha]_D^{15}$ +62° (*c* 1.0, methanol), 620 mg. The mother liquor was concentrated and the residue was again ammonolyzed with 80 cc. of liquid ammonia by heating at 140°C for 1 hr., and at 100°C for 15 hr. to give 600 mg. of the amide. The crude amides were recrystallized from ethanol-benzene to give crystals, m. p. 95~100°C, $[\alpha]_D^{15}$ +50° (*c* 1.02, methanol), 370 mg. For an analytical sample, the product was recrystallized from benzene, then from methanol, m. p. 99~101°C, $[\alpha]_D^{15}$ +65.1° (*c* 0.76, methanol).

Found: N, 11.82. Calcd. for $C_5H_{11}O_2N$: N, 11.96%.

**(+)-5-Isopropyloxazolidone (IX).**—In the thimble of a modified Soxhlet extractor inserted between the reflux condenser and the reaction flask which contained a slurry of 900 mg. of lithium aluminum-hydride in 100 cc. of tetrahydrofurane, was placed 940 mg. of the amide VIIc. After refluxing for 6 hr., a small amount of water, just enough to decompose the reaction complex, was added and the precipitated aluminum hydroxide was filtered. The aluminum hydroxide was continuously extracted with tetrahydrofurane for 2 hr., and the extract was combined with the filtrate. After 2 cc. of concentrated hydrochloric acid was added, the solvent was removed in vacuo, water was added to the residue and the solution was washed with ether three times. The acidic solution was made alkaline with 6 cc. of 50% potassium hydroxide and saturated with potassium carbonate, and then extracted with ether. After the ether extract was dried over anhydrous potassium carbonate, the solvent was removed to give the aminoalcohol VIIIa, which has an odor reminiscent of amine. The oil was dissolved in 15 cc. of benzene and was allowed to stand overnight. After the precipitated amide (140 mg.) was recovered, 0.7 cc. of pyridine was added with a solution of 0.65 g. of ethyl chloroformate in 4 cc. of benzene. After stirring for 1 hr., the reaction mixture was allowed to stand at room temperature for 1 hr. Ten cubic centimeters of water was added and the aqueous layer, after separating from the benzene layer, was extracted twice with benzene. The combined benzene extract was washed twice with 1 cc. of 1N hydrochloric acid and then with water. After the solvent was removed in vacuo, 10 cc. of benzene was added and evaporated to remove any trace of water by azeotropic distillation giving the carbamate VIIIb, 450 mg. To a sodium methoxide solution which was prepared from 50 mg. of sodium and 3 cc. of methanol, 10 cc. of toluene was added and the methanol was removed by heating with free flame. A solution of 450 mg. of the carbamate VIIIb in 17 cc. of toluene was added to the sodium methoxide suspension and heated at 100~105°C for 1 hr. with stirring. The reaction mixture was chilled in an ice bath and 10 cc. of water was added with stirring. The aqueous layer which separated from the toluene layer, was extracted twice with toluene. The combined toluene extract was concentrated to 5 cc. in vacuo to precipitate crystals which were recrystallized from benzene-benzine (b. p. 70~80°C), m. p. 111~112°C, 200 mg. Recrystallization from benzene raised the melting point to 113~114°C. $[\alpha]_D^{14}$ +44.2° (*c* 1.04, ethanol).

Found: C, 56.18; H, 8.68; N, 11.13. Calcd. for $C_6H_{11}O_2N$: C, 55.79; H, 8.58; N, 10.84%.

**(±)-Ethyl 3-Hydroxy-4-methylpentanoate.**—To a chilled solution of 8 g. of ethyl isobutyroylacetate in 40 cc. of methanol, 5 g. of sodium borohydride was added with stirring during 1 hr., and the reaction mixture was allowed to stand at room temperature for 1 hr. After the methanol was evaporated, water was added and the whole was extracted with choloroform. The chloroform extract was washed with diluted sulfuric acid and then with saturated sodium hydrogen carbonate solution. After drying over anhydrous sodium sulfate, the solvent was removed to give an oil, which distilled at 92~93°C/20 mmHg, 2.9 g.

**(±)-3-Hydroxy-4-methylpentanhydrazide.**—To a solution of 2.6 g. of the above-mentioned ester in 6 cc. of ethanol, was added 6 g. of 80% hydrazine hydrate and the reaction mixture was heated on a water bath for 1 hr. and allowed to stand in a refrigerator overnight. The precipitated crystals

were recrystallized from ethanol yielding crystals, m. p. 148～149°C, 1.72 g.

Found: N, 19.22. Calcd. for $C_6H_{14}O_2N_2$: N, 19.17%.

**(±)-5-Isopropyloxazolidone.**—Following the procedure described for the preparation of the (−)-isomer V, 1.7 g. of the racemic hydrazide was converted into (±)-5-isopropyloxazolidone, m. p. 87～88°C, 0.65 g.

Found: C, 55.88; H, 8.50; N, 11.12. Calcd. for $C_6H_{11}O_2N$: C, 55.79; H, 8.55; N, 10.84%.

The mixed melting point of the synthetic (±)-5-isopropyloxazolidone, m. p. 87～88°C, with the racemic compound, m. p. 87～88°C, which was prepared by mixing equal amounts of (−)-isomer V, m. p. 113～114°C from rotenone and (+)-isomer IX, m. p. 113～114°C from D-valine and recrystallization from benzene, was 87～88°C.

We are indebted to Mr. Mitsuru Notake for his effort in obtaining *Derris elliptica*, and to Nitto Kasei Co. for financial support.

# *On Some Dark-colored Chlorocuprates(I, II) and Related Compounds. III. X-Ray Study and Reflectance Measurements*

By Masayasu MORI

(Received February 20, 1961)

In the majority of mixed valence compounds that exhibit abnormal light absorption, the metal atoms in different valence states are bound by atomic bridges or metal-metal bonds[1]. The abnormal light absorption in these compounds is explained as due to an electron transfer through these bonds or bridges[2]. In certain mixed valence halometallates as e. g. $Rb_2SbCl_6$, however, such bonds or bridges are hardly conceivable from crystallographic data, though they also are highly colored. The mechanism of interaction absorption in these compounds may not be essentially different, but is probably more complicated. Examples of such compounds are few: as far as the author is aware they are represented by one of the two general formulae, $M_2SbX_6$[3] and $[M^{III}A_6][PbCl_6]$[4,5]. The X-ray study which will be described below has proved that compounds, $[M^{III}A_6][CuCl_5]_x[CuCl_4]_{1-x}$,[6] constitute another such series. Diffuse reflectance of powdered chlorocuprates was also measured in order to examine the existence and the qualitative feature of the light absorption in these compounds, especially in connection with the problem of interaction color.

## Experimental

**Samples.**—The samples of chlorocuprates used for measurements of reflection were prepared according to the method described in the previous paper. The crystal used in the X-ray analysis was obtained by digesting the precipitate in the mother liquor at 30~40°C.

Hexamminechromium(III) chloride monohydrate which was used in the reflectance measurement and in the preparation of chlorocuprates was prepared by a procedure analogous to that for the preparation of $[Cr(NH_3)_6]_2(SO_4)_3 \cdot 2H_2SO_4 \cdot 3H_2O$, reported previously[7]. At the stage of precipitating the complex, 300 ml. of 12 N hydrochloric acid was used instead of 200 ml. of 12 N sufuric acid, and the yield of the chloride was 23~24 g. (48~50%). The undesirable effect of the impurities in zinc, pointed out in the previous paper could be minimized by amalgamation of metal surfaces by warming granular or mossy zinc in ca. 5% solution of mercury(II) chloride in 1 N hydrochloric acid.

Potassium copper(II) chlorides were prepared by Meyerhoffer's method[8]

**Reflectance Measurements.**—The diffuse reflectance, $R_d$, of chlorocuprates, i. e. the ratio of the

quantity of light reflected by a powdered sample to the quantity of light reflected by magnesium oxide powder was measured with a Shimazu spectrophotometer, Type QR-50, with its integration sphere attachment, in the wave number range of $(1.4\sim3.0)\times10^4$ cm$^{-1}$.

**Crystal Analysis.**—Oscillation photographs of a small crystal of $[Cr(NH_3)_6][CuCl_5]_x[CuCl_4]_{1-x}$ were taken using Cu-$K\alpha$ radiation. The relative intensities of reflections were visually estimated and corrected for Lorenz and polarization factors by means of Cochran's chart[9]. The observed structure factors obtained in this way were compared with the calculated factors by the trial and error method. The lattice constant was determined with an X-ray diffractometer using Cu-$K\alpha_1$ radiation ($\lambda=1.5405$ Å).

## Results and Discussion

**The Crystal Structure of $[Cr(NH_3)_6][CuCl_5]_x[CuCl_4]_{1-x}$.**—From the oscillation data the crystal was found to have an $O_h$ symmetry, and only those reflections were observed which fulfilled the following conditions:

1) $h+k=2n$, $k+l=2n$, $l+h=2n$;

2) $h+k=4n$ for $(h\,k\,0)$ reflections;

3) $h\neq k$, $k\neq l$, $l\neq h$ for odd indices.

The space group is therefore determined to be $O_h^8$–Fd3c. The unit cube edge is $a=22.19+0.02$ Å, and the unit cell contains 32 of the above formula units. The observed density was 1.89 g./cc. and the calculated density is 1.84 g./cc. for $x=0.5$ and 1.92 g./cc. for $x=1$. There has been an ambiguity as to the $x$ value, i. e. the ratio, Cu(II)/Cu(total) for the sample used in X-ray work*.

General features of the intensity distribution were found to be similar to those observed for the chlorocuprate(II) of the same complex cation studied by Mori, Saito and Watanabe[10]. In the latter compound, 160 chlorine atoms in the unit cell are classified into two groups, those in 64 (e) equivalent positions and those in 96 (g) equivalent positions. In the case of chlorocuprate(I, II) the number of chlorine atoms should be smaller than 160 by $32(1-x)$. An attempt was made to obtain the value of $x$ by the method of least square, on the assumption that in chlorocuprate(I, II), either (e) or (g) equivalent positions are incompletely occupied. However, either assumption gave an $x$ value slightly greater than unity ($\sim1.03$). It is ridiculous to assume an $x$ value greater than unity, but it is probable that $x$ has been close to unity, for the sample crystal was prepared by a long digestion of the precipitate in the mother liquor, during which the quantity of univalent copper has probably decreased by air oxidation. The observed structure factors were, therefore, compared with those calculated on a tentative assumption of $x=1$ and the same atomic coordinates as those obtained for the chlorocuprate(II) (Table I). This comparison gave a fairly low $R$ (reliability factor) value, namely 0.152 for $(h\,k\,0)$ reflections (unobserved reflections included as $F_0=0$), and 0.212 for $(h\,k\,l)$ reflections up to $l=8$ (unobserved reflections excluded). Thus the present research could not find out the difference between the crystal structure of chlorocuprate (I, II) and that of chlorocuprate(II), although the sample crystal of chlorocuprate(I, II) appeared almost black in contrast to the yellow chlorocuprate(II) crystal. Because of the presence of heavy atoms, further refinement including the determination of the structure of chlorocuprate(I) ion probably necessitates more accurate intensity data for a sample with a higher Cu(I) content as well as a simultaneous study of chromium and cobalt compounds.

Table I. Atomic coordinates in chlorocuprate(I, II)

32 Cu: (b), 1/4, 1/4, 1/4, etc.
32 Cr: (c), 0, 0, 0, etc.
(64) Cl: (e), $u$, $u$, $u$ ($u=0.190$), etc.
(96) Cl: (g), 1/4, $v$, $-v$ ($v=0.075$), etc.
192 N: (h), $x$, $y$, $z$ ($x=0.070$, $y=0.050$, $z=-0.030$), etc.
$B$ (overall temperature factor): 2.5.

The information obtained is, therefore, that in hexamminechromium(III) chlorocuprate(I, II), too, the Cr and Cu atoms are arranged in the NaCl type and that the ionic species of Cu(II) is the trigonal-bipyramidal $[CuCl_5]^{3-}$ ion, the same ion as is found in the chlorocuprate(II). The chart prepared with a self-recording X-ray diffractometer for a powder sample of chlorocuprate(I, II) for which $x$ was nearly equal to 0.5 also showed relative intensities similar to those for the chlorocuprate(II). The essential feature of the crystal structure of chlorocuprate(I, II), therefore, seems to be unaltered even when $x$ approaches 0.5**. In particular, the Cu–Cu distance should remain about the same ($\sqrt{2}a/4=7.79$ Å), since any change in the Cu coordinate must result in a remarkable change in the structure factors. It

9) W. Cochran, *J. Sci. Instr.*, **25**, 253 (1948).

* Attention was not at first paid to this problem, for it was some time later that the author found the composition of the chlorocuprate(I, II) to be changeable.

10) M. Mori, Y. Saito and T. Watanabe, This Bulletin, **34**, 295 (1961).

** For $x$ below this value the ratio Cu/Cr is not 1:1 any more (Ref. 6).

is, therefore, difficult to assume anything like an atomic bridge between copper atoms in hexamminechromium(III) chlorocuprate(I, II) of a low Cu(I) content.

**Reflectance of Powdered Chlorocuprates.**—In presenting the data of reflectance measurements it seems convenient to use Kubelka and Munk's expression[11], $f(R_d)=(1-R_d)^2/2R_d$, for there is a certain parallelism between this quantity and the extinction coefficient of the crystal—they should be proportional to one another when the effect of the specular reflection at crystal surfaces is small compared with the diffuse reflection. Kortüm and Schöttler[12] stated that this condition is nearly fulfilled for potassium permanganate and its mixed crystals when the powder is very fine. Kondo and others[13] examined this problem in detail by comparing the reflection data with the absorption curve of a single crystal and found that even when the powder is sufficiently fine some effect of specular reflection makes the curve of $(1-R_d)^2/2R_d$ somewhat different from the true extinction curve of potassium permanganate, and that some caution must be exercised when reflectance is measured for substances of varying refractive indices.

In the present research, use was made of this powder method, because: (1) the process of measurement is very simple and the experiment is at any rate possible even when the compound does not crystallize in thin plates; (2) the light reflected from crystal surfaces of most chlorocuprates studied appeared white to the naked eye, so that at least in the visible region the effect of the specular reflection was thought to be smaller than in the case of potassium permanganate, in which case the light reflected from crystal surfaces seems green; and (3) the main purpose was to examine the existence and the qualitative feature of usually very broad interaction absorption in the visible region. In Figs. 1—4 is plotted the quantity, $\log[(1-R_d)^2/2R_d]$ for various chlorocuprates against wave number.

*Hexamminechromium(III) Chlorocuprate(I, II), Hexamminechromium(III) Chlorocuprate(II) and Hexamminechromium(III) Chloride Monohydrate (Curves $A_1$, $B_1$ and $C_1$ Respectively in Fig. 1).*— Curve $A_1$ of the chlorocuprate(I, II) shows an existence of interaction absorption in the entire visible region, which is not observed in the case of the chlorocuprate(II) (curve $B_1$) or the chloride (curve $C_1$). At the same time both curves $A_1$ and $B_1$ show very great value of $\log[(1-R_d)^2/2R_d]$ (poor reflection) in the neighborhood of $2.7\times10^4$ cm$^{-1}$, suggesting the existence of strong absorption bands. It seems difficult to determine the exact positions of their peaks, owing to the insufficient accuracy of this method for low reflection values*, to the probable contribution of the specular reflection in this region and also to the effect of the complex cation; but there seems to be little doubt as to their high intensity. These absorption bands are probably charge transfer spectra[14,15] of $[CuCl_5]^{3-}$ ion; the chloride shows no such strong absorption in this region (curve $C_1$). That similar bands are observed for both chlorocuprate(II) and chlorocuprate(I, II) seems to be consistent with the result of X-ray analysis, which shows that in either compound the ionic species of Cu(II) included is the trigonal-bipyramidal $[CuCl_5]^{3-}$ ion.

The qualitative features of curves $A_1$ and

---- Curve $C_5$, 0.0216 M $[Cr(NH_3)]Cl_3$
* ε is expressed on the basis of g. ion Cu or Cr.

* Prof. Yukio Kondo of St. Paul's University kindly suggested that measurements with samples diluted with white substances are effective in these instances. The present author, therefore, wishes to apply this method to a more comprehensive study of halocuprates(II) as soon as possible.

14) E. Rabinowitch, *Rev. Modern Phys.*, 14, 112 (1942).
15) L. E. Orgel, *Quart. Rev.*, 8, 422 (1953).

$B_1$ are somewhat similar to those of the absorption curves of systems, copper(II)-copper (I) and copper(II) respectively, in concentrated calcium chloride solution, studied by Doehlemann and Fromherz[16], when the effect of the complex cation is taken into account (cf. also curves $A_5$ and $C_5$ in Fig. 5). The resemblance is probably not sufficient to prove that the ionic species is the same, but it may be worth noting that the compounds of this series are the only chlorocuprates in which an interaction color of copper(I) and copper(II) is observable, just as in the case of chloride solution.

Usefulness of reflectance measurements for samples with weak absorption bands may be exemplified by the comparison of the $\log f(R_d)$ curve of the powder sample (curve $C_1$, Fig. 1) with the $\log \varepsilon$ curve of an aqueous solution (curve $C_5$, Fig. 5) for the same stable complex compound, $[Cr(NH_3)_6]Cl_3 \cdot H_2O$. The peaks of the two absorption bands are found at almost the same positions although the heights of the peaks are found to be somewhat different. Moreover, a low peak is clearly perceptible at $1.55 \times 10^4$ cm$^{-1}$ in curve $C_1$, which probably corresponds to the transition of the $d_\varepsilon$ electron. It is not easy to find this peak even by absorption measurements when a sample solution is dilute.

*Hexamminecobalt(III) Chlorocuprate(I, II), Hexamminecobalt(III) Chlorocuprate(II) and Hexamminecobalt(III) Chloride (Curves $A_2$, $B_2$ and $C_2$, Respectively in Fig. 2).*—The general feature of the curves is quite similar to that of the corresponding chromium(III) compounds, except in the case of the difference of the position of the absorption peaks of hexammine complex cation.

*Hexamminecobalt(III) and Hexamminechromium(III) Chloroplumbates(II, IV) (Curves $A_3$ and $B_3$ Respectively in Fig. 3).*—Reflectance is very small in the entire visible region showing an existence of interaction absorption of Pb(II) and Pb(IV).

*Hexamminechromium(III) Pentabromocuprate (II) (Curve $A_4$ in Fig. 4).*—Reflectance is very small in the visible region, but it increases a little toward the lower wave number region. The relationship is somewhat similar to the absorption curve of $CuSO_4$ in 48% hydrobromic acid (curve $B_5$, Fig. 5)**. The flattening of the curve at the range of low reflectance is probably due to the effect of the specular reflection.

*Dipotassium Copper(II) Tetrachloride Dihydrate and Potassium Copper(II) Trichloride (Curves $B_4$ and $C_4$ Respectively in Fig. 4).*—Reflectance of these salts was measured for comparison with that of chlorocuprates described above. The former compound, which is known to have the structure, $[CuCl_2(H_2O)_2] \cdot 2KCl$[17,18], shows much weaker absorption in the neighborhood of $2.7 \times 10^4$ cm$^{-1}$ than do the chlorocuprates described above, and the charge transfer band seems to lie at the region of higher wave number. This has been ascertained by measurements up to wave number $3.0 \times 10^4$ cm$^{-1}$, though the curve is given only in the range, $(1.4 \sim 2.6) \times 10^4$ cm$^{-1}$.

In the case of $KCuCl_3$ the curve obtained is very different from those of other chloro complexes of copper studied in the present research or the absorption curve of copper(II) in a solution of high chloride concentration. This difference suggests that in $KCuCl_3$, copper(II) exists in a state quite different from those in the usual chlorocomplexes;—a polynuclear structure with chlorine bridges might, for example, be assumed as in the case of $CsCuCl_3$[19].

## Summary

The ionic species of Cu(II) in hexamminechromium(III) chlorocuprate(I, II) has been found to be a trigonal-bipyramidal $[CuCl_5]^{3-}$ ion. Reflectance measurements have shown the existence of diffuse interaction absorption in some chlorocuprates(I, II) and chloroplumbates (II, IV). A strong charge transfer band of $[CuCl_5]^{3-}$ was also found in the neighborhood of $2.7 \times 10^4$ cm$^{-1}$ for hexamminechromium(III) chlorocuprate(I, II) and hexamminechromium (III) chlorocuprate(II).

The present author is pleased to express his sincere thanks to Dr. Masayoshi Nakahara of St. Paul's University who kindly advised him to undertake reflectance measurements of chlorocuprates. He is grateful to Professor Yoshihiko Saito of the University of Tokyo for his kind guidance in X-ray study. The research would never have been possible without many valuable suggestions and constant encouragement accorded by Professor Shin'ichi Kawaguchi of our Institute. The author could utilize the spectrophotometer through the kindness of the Faculty of the Science of Living of our University.

# *Solvent Extraction of Inorganic Nitrates with Diphosphonate Ester. II. Thorium and Uranyl Nitrates*

By Hideo SAISHO

(Received March 10. 1961)

In the previous paper[1], was studied the solvent extraction behavior of zirconium, yttrium and several lanthanide elements (cerium, promethium, europium and lutetium) with tetra-*n*-butyl ethylene-diphosphonate* (TBEDP), $(BuO)_2P(O)(CH_2)_2(O)P(BuO)_2$. The distribution ratio of each element between nitric acid solution and TBEDP diluted with kerosene was determined in the range of nitric acid concentration from 0.01 to 13 M and TBEDP concentration from 0.1 to 0.2 M. The extractability of zirconium increased with increasing acidity. However, in the extraction of yttrium and lanthanide elements, the distribution ratios were very high in the low acidity region and decreased sharply with increasing acidity. This extracting reagent is very excellent for the extraction of trivalent elements such as lanthanide elements especially in the low acidity region.

The present paper describes in detail the solvent extraction behavior of thorium and uranium in the system of TBEDP-kerosene and nitric acid solution.

Infrared absorption studies have also been undertaken to obtain the information on the organic phase containing uranium.

## Experimental

**Sources of Materials.**—TBEDP received from the Tama Chem. Co., Tokyo, Japan was used without any further purification. TBEDP was diluted to the desired concentrations with kerosene, which had its flash point above 60°C and was not specially purified. Nitric acid solutions were prepared by diluting concentrated nitric acid, special grade. The acidity was checked volumetrically, whenever necessary.

Uranyl nitrate was of guaranteed reagent grade, and was used as $1.24\times10^{-3}$ M solution in the whole acidity region studied.

Thorium-234 ($UX_1$) separated from uranium was chosen to study the extractability of thorium by TBEDP. Thorium-234 tracer[2] was obtained as nitrate by means of the usual ethyl ether extaction method followed by cation exchange.

**Determination of Distribution Ratios.** — The details of the method used in the previous report[1] were also adopted in the present study. The distribution ratio was measured after shaking the two phases for thirty minutes in a thermostat kept at 25±0.5°C.

The uranium concentration in the aqueous phase was determined colorimetrically or by fluorimetry and that in the organic phase was measured in the same way after extraction into an aqueous solution of sodium carbonate. For colorimetry, the oridinary hydrogen peroxide method[3] was employed. The method adopted for fluorimetry was similar to that of Grimaldi et al.[4] The procedure was as follows: Aliquot portions containing uranium were transferred to a small platinum dish and carefully dried up under an infrared lamp. Fluoride flux was then added to the dish and the flux was melted for about five minutes in an electric furnace kept at 700°C. After cooling the melt, the fluorescence was measured, using excitation by radiation of 365 mμ wavelength. A blank and a standard were run at the same time. The fluoride flux used here consisted of 9% sodium fluoride, 45.5% sodium carbonate and 45.5% potassium carbonate, which were fused in platinum at about 500°C and then thoroughly ground and mixed. Both colorimetric and fluorimetric measurements were made with a Shimadzu recording photoelectric spectrophotometer, type RS.

Amounts of thorium-234 were determined radiochemically in the same way as those described in the previous paper[1]. Infrared spectra were measured with a Hitachi EPI-II double-beam infrared spectrophotometer equipped with a sodium chloride prism. All the measurements were made in the liquid state.

## Results and Discussion

**Effect of Nitric Acid Concentration.**—Figures 1 and 2 show the variation of distribution ratio, $K_d$, of uranium(VI) and thorium(IV) in the range of nitric acid concentration from 0.1 to 13 M, keeping the TBEDP concentration 0.1 M. Other authors'[5,6] results for both elements in the extraction with TBP from nitric acid are added for comparison.

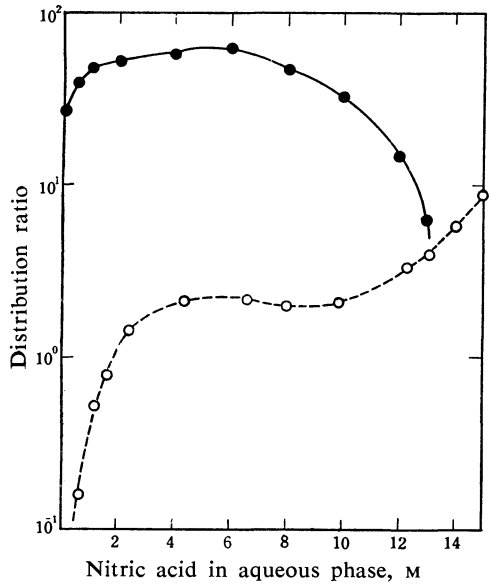

Fig. 2. Distribution ratio of thorium(IV).
—●—●—: 0.1 M TBEDP in kerosene
--○--○--: McKay et al.[6], 19% TBP in kerosene

As shown in Fig. 1, the acid dependence curves for TBEDP and TBP have a considerable resemblance; maximum extractions of uranium-(VI) from nitric acid solutions are observed at about 6 M nitric acid concentration in both cases.

As Fig. 2 shows, similarity in the shape of the acid dependence curves for TBEDP and TBP is also found in the acidity range up to about 6 M nitric acid; the $K_d$ values for thorium-(IV) increase with increasing acidity. In the higher acidity range, the $K_d$ values by TBEDP tend to decrease gradually, whereas those by TBP have an increasing tendency, especially in the acidity region over about 10 M nitric acid.

**Effect of TBEDP Concentration on Extraction of Uranium(VI).** — Figure 3 shows two series of results in the range of $1\times10^{-3}$ to $1\times10^{-1}$ M TBEDP concentration in the organic

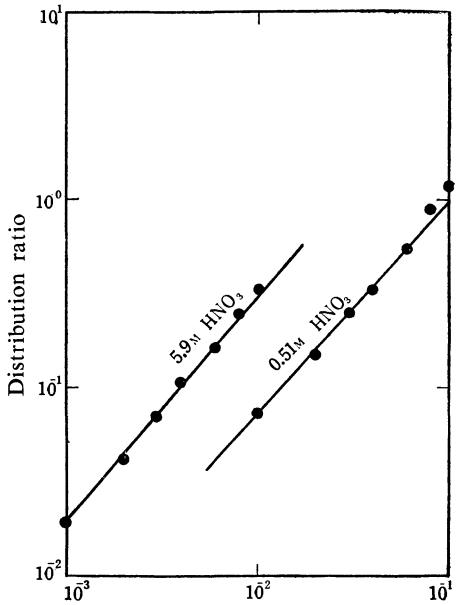

Fig. 3. Power dependence of distribution ratio on TBEDP concentration.

phase, keeping the acidity of the aqueous phase constant. In the plots of log $K_d$ vs. logarithmic TBEDP concentration, the slope of the lines through the points is 1.1 for both 0.51 and 5.9 M nitric acid up to about $6\times10^{-2}$ M TBEDP concentration. The first power dependence of the $K_d$ values on the TBEDP concentration indicates the 1 : 1 TBEDP to uranium ratio. The complex formed in the organic phase may be $UO_2\cdot(NO_3)_2\cdot$TBEDP, analogous to the corresponding uranium(VI) compound in TBP extraction[5,7]. It is in good agreement with the results obtained by Healy and Kennedy[8] for benzene solutions of diphosphoryl reagents containing the group =P(O)Y(O)P= (where Y

is oxygen, methylene or ethylene), saturated with uranyl nitrate.

**Infrared Studies on the Organic Phase.** — Infrared absorption studies may provide some information on the extracting behavior of uranyl nitrate by TBEDP. Infrared spectra were recorded for the following samples: (I) kerosene, (II) pure TBEDP, (III) 0.2 M kerosene solution of TBEDP, (IV) 0.2 M kerosene solution of TBEDP after being shaken with 6 M nitric acid, and (V) 0.2 M kerosene solution of TBEDP after being shaken with 0.5 M uranyl nitrate solution in 6 M nitric acid. The spectra in the region of 900 to 1700 $cm^{-1}$ are illustrated in Fig. 4.

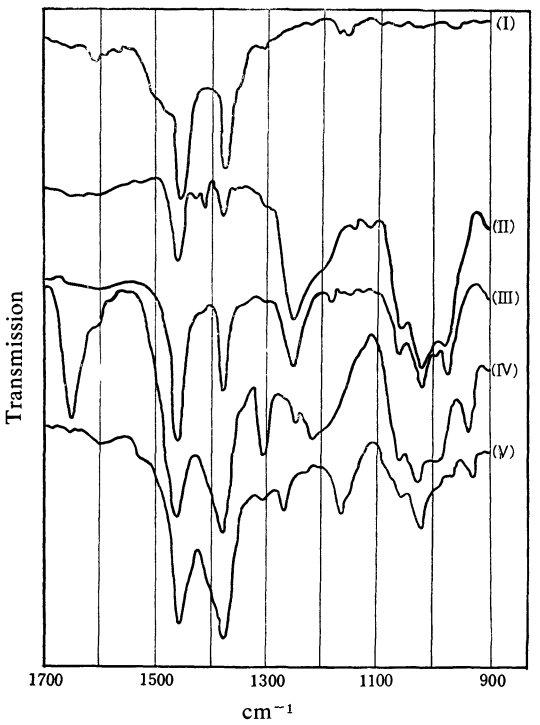

Fig. 4. Infrared absorption spectra of samples I—V.

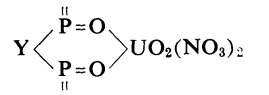
(I) Kerosene
(II) Pure TBEDP
(III) 0.2 M Kerosene solution of TBEDP
(IV) 0.2 M Kerosene solution of TBEDP after being shaken with 6 M nitric acid
(V) 0.2 M Kerosene solution of TBEDP after being shaken with 0.5 M uranyl nitrate in 6 M nitric acid

The spectrum of the sample III can be explained as a mixture of the samples I and II. In the spectrum of III, the bands at 1462 and 1380 $cm^{-1}$ are assigned to the deformation vibrations of methyl groups in TBEDP and kerosene. The band at 1255 $cm^{-1}$ and the bands in the region of 1100 to 950 $cm^{-1}$ are due to TBEDP. The 1255 $cm^{-1}$ band is assignable to the P=O stretching frequency, while the other bands are associated with the stretching vibrations of the P-O-C linkage and the C-C bond.



In the spectrum of IV, three new absorption bands were observed at 1649, 1305 and 944 $cm^{-1}$. According to Peppard et al.[9], four absorption bands are found in the infrared spectrum of 100% nitric acid at 1680, 1308, 924 and 769 $cm^{-1}$. The addition of water to 100% nitric acid causes the appearance of bands at 828 and 1380～1410 $cm^{-1}$ which have been attributed to the nitrate ion[10-13]. Thus, these three new bands are possibly due to nitric acid. The band due to the nitrate ion in the 1380～1410 $cm^{-1}$ region appears to overlap the 1380 $cm^{-1}$ band observed for TBEDP. These results indicate that nitric acid is extracted into the TBEDP organic phase.

The P=O stretching band, which appears at 1255 $cm^{-1}$ in pure TBEDP, shifts to about 1220 $cm^{-1}$. The corresponding band in the spectrum of V is observed at 1169 $cm^{-1}$. On the other hand, the bands near 1030 $cm^{-1}$ do not show any change in the spectra for III, IV and V. Therefore, the P=O bond takes part in the extractability of nitric acid and uranyl nitrate by TBEDP, but the P-O-C linkage does not appear to participate.

It is noticeable that the strong band of nitric acid observed at 1649 $cm^{-1}$ for IV disappears in the spectrum of V. The bands at 1305 and 944 $cm^{-1}$, which are also due to nitric acid, can not be found. Consequently, nitric acid seems to be nearly absent in V. These results suggest that uranium(VI) is extracted into the TBEDP organic phase more predominantly than nitric acid.

A band at 937 $cm^{-1}$ is observed in the spectrum of V instead of the absence of 944 $cm^{-1}$. This band may be assignable to the U=O stretching frequency[14-16].

Healy and Kennedy[8] have proposed the structure

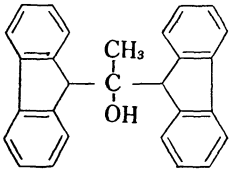
# *Über die Einwirkung von Brom auf 9-Acetylfluoren*



Von Mitsuo MASAKI und Masaki OHTA

(Eingegangen am 21 Februar, 1961)

Die Halogenierung von Fluorenen[1] oder Dibenzofulvenen[2] ist ausführlich berichtet worden. Über 9-Acylfluorene fehlen unseres Wissens aber bisjetzt entsprechende Untersuchungen.

Um das Ziel, 9-Glycylfluoren darzustellen, das durch Umsetzung von 9-Bromacetylfluoren mit Amin erhalten werden mag, haben wir zunächst Bromierung von 9-Acetylfluoren ins Auge gefasst. Es schien uns auch interessant zu sein, die Halogenierungsfähigkeit der 2-, 7- und 9-Stellungen des Fluorenrings, in dessen 9-Stellung Acetylgruppe vorliegt, und der Acetylgruppe aufzuschliessen.

Über die Synthese von 9-Acetylfluoren (I) sind von Miller u. a.[3] die Umsetzung von 9-Fluorenyl-lithium mit Acetylchlorid und von Wagner u. a.[4] die Claisen-artige Ester-Kondensation von Fluoren mit Essigsäureäthylester berichtet worden. Nach dieser Methode haben wir I erhalten können. Da auf jener Methode es aber einige Fragen[4,5] gibt, haben wir die Reaktion von 9-Fluorenyl-lithium mit Acetylchlorid versucht. Dabei erhält man nicht I, sondern eine Substanz vom Schmp. 182°C, deren Molekularformel $C_{28}H_{22}O$ darstellt. Durch Infrarot-Absorptionen bei 1060 und 3570 $cm^{-1}$ wie die typischen Banden beim tertiären Alkohol (Abb. 1) und durch Ultraviolet-Spektren wurde die Struktur der Substanz als $\alpha$-Di-9-fluorenyl-äthanol (II) festgestellt, das

(II)

offenbar durch weitere Einwirkung von 9-Fluorenyllithium auf primär gebildetes 9-Acetylfluoren entstanden war.

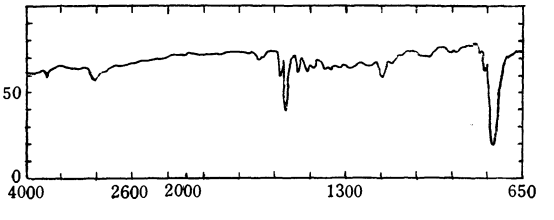


Abb. 1. Infrarot-Spectrum von II.

Nach Schlenk[6] entsteht bei der Einwirkung von Benzoylchlorid auf 9-Fluorenyl-lithium neben 9-Benzoylfluoren Di-9-fluorenyl-phenyl-carbinol. Bei Acetylchlorid erhält man jedoch nur II selbst dann, wenn 9-Fluorenyl-lithium

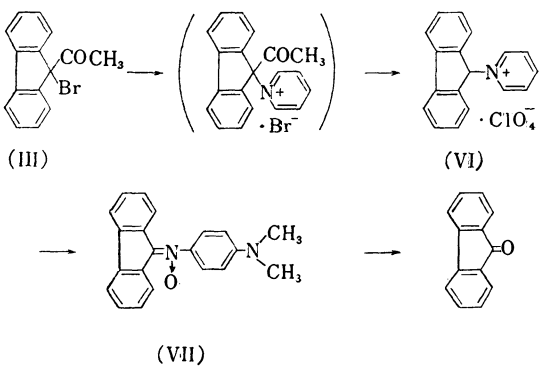
6) W. Schlenk und E. Bergmann, *Ber.*, **62**, 745 (1929).



sich zur ätherischen Lösung von überschüssigem Acetylchlorid langsam hinzutropfen lässt. Daher kann man sich so vorstellen, dass die Reaktion von 9-Fluorenyl-lithium mit 9-Acetylfluoren in bestimmten Temperatursbereichen schneller als die mit Acetylchlorid sei.

Bei der Einwirkung von äquivalentem Brom auf I in Äther bei Raumtemperatur erhält man zwei Produkte, nähmlich Monobrom-körper (III) vom Schmp. 109～110°C (9.1 Tl.) und Dibrom-körper(IV) vom Schmp. 162～164°C (0.9 Tl.).

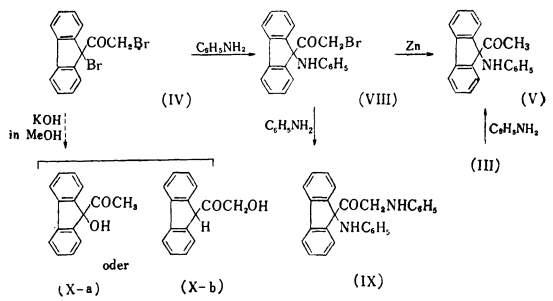
Beim Erhitzen mit Anilin liefert III Anilino-Körper(V), der in Säure unlöslich ist. Beim längeren Erwärmen von III in Pyridin erhält man eine schwarzbraune Substanz, die man sich als Pyridiniumsalz von III vorstellen kann. Aber die Elementaranalyse des Perchlorats zeigt, dass diese Molekularformel $C_{18}H_{14}O_4N$ darstellt, dass also unter Hydrolyse im Verlauf der Reaktion Acetylgruppe sich abspalten lässt und daher dass das Bromatom in III an einen Fluoren-Kern gebunden ist.

Die Konstitution des Perchlorates(VI) ergibt sich aus seiner Umsetzung über Nitron zum 9-Fluorenon.

Bei der Einwirkung von *p*-Nitroso-dimethyl-anilin auf VI in Pyridin erhält man entsprechendes Nitron (VII), das sich mit Säure zu 9-Fluorenon zersetzen lässt.

(III) (VI) (VII)

Aus den oben erwähnten Tatsachen und Ultraviolet-Absorptions-spektren kann geschlossen werden, wie in der Abbildung gezeigt, dass VI das Pyridiniumsalz des 9-Bromfluorens ist, und also dass die Verbindung vom Schmp. 109～110°C (III) 9-Brom-9-acetylfluoren darstellt.



Erhitzt man Dibrom-körper vom Schmp. 162～164°C (IV), der auch bei der Einwirkung von 2 Mol Broms auf I quantitativ entsteht, mit überschüssigem Anilin in Benzol, so erhält man neben Anilinhydrobromid, ein Mono-anilino-monobrom-derivat (VIII), das sich bei der Reduzierung mit Zinkpulver Monoanilino-derivat überführen lässt, das nicht anders als die aus III gewonnene Verbindung (V) ist. Der Dibrom-körper enthält also eins der zwei Bromatome in 9-Stellung.

Beim längeren Erhitzen mit Anilin setzt sich VIII zu Dianilino-körper (IX) um. Aus dieser Tatsache und aus der Umsetzung von IX mit Kaliumhydroxyd in Alkohol ergibt sich die Stellung des zweiten Broms.

Bei der Einwirkung von methanolischem Kaliumhydroxyd auf IV bei Raumtemperatur erhält man das bromfreie Produkt, dessen Bruttoformel $C_{15}H_{12}O_2$ darstellt.

Nach einigen Vorschlägen[1a,7] kann man sich leicht vorstellen, dass das an 2- oder 7-Stellung von Fluoren-kern gebundene Brom nicht unter den oben erwähnten Bedingungen reagieren könne, und dass die Brome in IV nicht an 2- oder 7-Stellung gebunden sei: So sei die Verbindung (IV) 9-Brom-9-bromacetylfluoren, und diese Vermutung wurde durch Ultraviolet-Absorptionsspektren bestätigt.

Als Konstitution des oben erwähnten Produkt ($C_{15}H_{12}O_2$) kann man sich Formel X-a oder X-b vorstellen, die aber noch jetzt untersucht wird.

(IV) (VIII) (V) (III) (X-a) (X-b) (IX)

Die Bromierung von I mittels *N*-Bromsuccinimids ist uns nicht gelungen.

Es ist bemerkenswert, dass Acetylfluoren sich mit Brom zuerst in die 9-Stellung bromieren lässt und keine Bromierung mit NBS stattfindet, indessen Fluoren selbst sich bei der Einwirkung von Brom bei 0～5°C in 2- oder 2-, 7-Stellung[1a] bromieren lässt und bei der Bromierung mit NBS 9-Bromfluoren[1c] entsteht.

### Beschreibung der Versuche

***α*-Di-9-fluorenyl-äthanol (II).** — Eine ätherische Lösung von 9-Fluorenyl-lithium, aus 8 g Fluoren nach der Methode von Burtner und Cusic[8] dargestellt, wird unter mechanischem Rühren zu einer eisgekühlten Lösung von 5 g Acetylchlorid in 30 ccm abs. Äther langsam hinzugetropft, die Reaktionslösung lässt sich noch 2 Std bei Raumtemperatur rühren und darauf in ein Gemisch von Eis und Ammoniumacetat giessen. Die ätherische Schicht wird zusammen mit dem mit wässeriger

7) J. Schmidt und K. Bauer, ebenda, **38**, 3751 (1905).
8) R. R. Burtner und J. W. Cusic, *J. Am. Chem. Soc.*, **65**, 264 (1943).

Schicht noch 2 Mal geschüttelten Äther mit Natriumsulfat getrocknet. Der nach dem Abdamppen des Äther erhaltene Rückstand wird 2 Mal mit Petroläther und darauf mit wenigem Äthanol gewaschen, und aus Äthanol umkristallisiert. Hellrötliche Nadeln vom Schmp. 182°C. Ausb. 3.5 g.

Gef.: C 89.16; H 6.07. Ber. für $C_{28}H_{22}O$: C 89.84; H 5.88%.

**9-Brom-9-acetylfluoren (III).**—Man versetzt einer Lösung von 7.2 g des nach der Methode von Von und Wagner[4] erhaltenen 9-Acetylfluorens in 120 ccm Äther mit 5.5 g Brom bei Raumtemperatur und schüttelt das Gemisch um: Sofort verliert sich die Farbe des Broms. Nach 4~5 stündigem Stehen bei Raumtemperatur wird der abgeschiedene Niederschlag durch Dekantierung abgetrennt, der 1.3 g wiegt, nach dreimaligen Umkristallisierungen den Schmp. 160~161°C und bei Mischprobe mit IV keine Depression zeigt, und die ätherische Reaktionslösung ergibt beim Abdampfen des Äthers das kristallinische Produkt. Ausb. 8.3 g. Farblose Nadeln vom Schmp. 109~110°C (aus Äthanol, Essigsäure oder Ligroin).

Gef.: C 62.90; H 4.04. Ber. für $C_{15}H_{11}OBr$: C 62.72; H 3.83%.

**9-Brom-9-bromacetylfluoren (IV).**—Zu einer Lösung von 5.3 g 9-Acetylfluoren in 100 ccm abs. Äther setzt man unter Umschütteln langsam 8.2 g Brom zu. Nach eintägigem Stehen der Mischung wiegen die abgeschiedenen delben Nadeln 7 g und werden aus Äthanol umkristallisiert. Farblose Nadeln vom Schmp. 162~164°C.

Gef.: C 50.25; H 2.86. Ber. für $C_{15}H_{10}OBr_2$: C 49.18; H 2.73%.

**Einwirkung von Pyridin auf 9-Brom-9-acetylfluoren.** — In 10 ccm reinem trocknem Pyridin löst man 2.1 g III, wobei es sich leicht erwärmt, verschliesst den Kolben mit einem Calciumchlorid-Rohr, lässt es 3 Std bei Raumtemperatur stehen, darauf erwärmt man dieses ungefähr 3~4 Std auf dem Wasserbad und dann fügt man 200 ccm Benzol hinzu. Das ausgefallene, harzförmige Produkt wird nach der Entfernung von der benzolischen Lösung durch Dekantierung mit 80 ccm heissem Wasser extrahiert. Nach dem Erkalten versetzt man die wässerige Lösung mit Aktivkohle, filtriert sie ab und fügt eine Lösung von Perchlorsäure zum Filtrat hinzu. Im Eisschrank scheidet sich *N*-9-Fluorenyl-pyridiniumperchlorat (VI) vollständig ab. Es wird abfiltriert und aus Äthanol umkristallisiert. Blass-orange Nädelchen vom Schmp. 213~214°C. Ausb. 1.1 g.

Gef.: N 4.18. Ber. für $C_{18}H_{14}O_4NCl$: N 4.08%.

**9-Fluorenon-(*p*-dimethylaminophenyl)nitron (VII).** — In 6 ccm Pyridin löst man 0.7 g VI auf, versetzt es mit 0.27 g *p*-Nitrosodimethylanilin und fügt 1.8 ccm 2 N Natriumhydroxyd unter Umschütteln hinzu. Unter leichter Erwärmung scheidet sich ein Niederschlag ab. Nach 5~6 Std wird er abfiltriert und aus Äthanol umkristallisiert. Ausb. 0.5 g. Orange Prismen vom Schmp. 237~239°C.

Gef.: N 9.27. Ber. für $C_{21}H_{18}ON_2$: N 8.92%.

**Hydrolyse von VII.** — Im Scheidetrichter werden 0.5 g VII mit 20 ccm 3 N Salzsäure durchge schüttelt und 2~3 mal mit je 20 ccm Äther ausgeschüttelt. Den vereinigten Ätherextrakt wäscht man mit Wasser, trocknet mit Natriumsulfat und dampft ein. Es bleiben 0.22 g 9-Fluorenon, das als Hydrazon festgestellt wurde hinter. Schmp. 149~150°C (Lit.[9]: 149~150°C).

Gef. N 14.10%.

**9-Anilino-9-acetylfluoren (V).**—Zu einer Lösung von 0.4 g Anilin in 20 ccm Äthanol setzt man 1 g III zu, erwärmt dieses 4 Std bei 60~70°C auf dem Wasserbad, nach der Versetzung mit Aktivkohle erhitzt man dies im Rückfluss und darauf filtriert man das Gemisch ab, aus dem sich beim Erkalten Schuppen auskristallisieren. Ausb. 0.9 g. Aus Äthanol umkristallisiert, verwandeln sie sich in farblose Prismen vom Schmp. 142~144°C.

Gef.: N 4.55. Ber. für $C_{21}H_{17}ON$: N 4.68%.

**9-Anilino-9-bromacetylfluoren (VIII).**—Zu einer Lösung von 5 g Anilin in 40 ccm trocknem Benzol setzt man 5 g IV zu und erhitzt sie 2 Std auf dem Wasserbad. Nach der Entfernung des gebildeten Anilinhydrobromids nach dem Erkalten lässt sich die Lösung unter vermindertem Druck einengen und mit Äthanol versetzen, wobei langsam farblose

# *The Viscosity of Concentrated Aqueous Solutions of Strong Electrolytes*

By Takeshi SATOH and Koreaki HAYASHI

(Received October 29, 1960)

It has been pointed out that the viscosity $\eta$ of aqueous solutions of strong electrolytes can be expressed by the following empirical equation given by Jones and Dole[1],

$$\eta/\eta_0 = 1 + Ac^{1/2} + Bc \qquad (1)$$

where $\eta_0$ is the viscosity of pure water, $A$ and $B$ are parameters independent of concentration $c$ (mol./l. solution). Moreover, it is indicated that contrary to the positive value of $A$, the $B$-parameter can possess either sign corresponding to each pair of individual ionic species, and that the magnitude of $B$ is several times greater larger than that of $A$. It is noteworthy that the second term in Eq. 1 can be derived from the Debye-Hückel limiting law, and that the accord of theoretical derivation with the $A$-parameter obtained experimentally is very satisfactory. This excellent work focused in the ion-ion interaction was done by Falkenhagen and his coworkers[2]. On the other hand, the consideration of the parameter $B$ has probably been treated more qualitatively compared with $A$. It is generally accepted that $B$ may be determined additively from the specific value of the individual ion[3] and its temperature coefficient can be used as a measure indicating the effect of ion-solvent interaction in flow[3,4]. However, we should bear in mind the fact that the above-mentioned consideration should be limited to a narrow range of extremely dilute solutions. Frank and Thompson[5] have recently given fundamental reconsideration to some thermodynamic quantities and called our attention to the limit of the validity of the Debye-Hückel theory. According to their conclusion the Debye-Hückel formalism breaks down around the critical concentration $c_0$ owing to

the failure of the fine-grainedness* of the ion cloud. It is estimated that $c_0 \approx 10^{-3}$ mol./l. for 1-1 electrolytes at 25°C.

The aim of this paper is directed to the concentrated range reaching the saturation specified at a given temperature.

* It is noticeable that the various quantities defined in the ion cloud are to be essentially nonfluctuating. Let us consider one volume element in the cloud. Then, the frequency with which one ion happens to exist there should be sufficiently small. They introduce a new term of "fine-grainedness" to express the degree of averaging. Of course, in the limiting case of extremely dilute solution this requirement would be strictly justified.—The ion cloud would have the character of infinitely fine-grained matter.

## Experimental

The measurements of viscosity were made with conventional Ostwald viscometers in a water bath. According to the Hagen-Poiseuille law, the viscosity can be generally determined by

$$\eta = K\rho t \qquad (2)$$

where $\rho$ is the density of solution; $t$ is the efflux time and $K$ is a constant of the viscometer for a constant charge of liquid. Kinetic energy correction term $K'\rho/t$ ($K'$=constant) can be omitted in our present systems because the amount is negligible. The values of $K$ of two viscometers used were $3.214\times10^{-5}$ and $2.895\times10^{-5}$, respectively. These

values were determined by blank tests with pure water at different temperatures. The density $\rho$ of each solution was measured with a picnometer.

Lithium chloride, lithium bromide, sodium bromide, sodium iodide, potassium fluoride, potassium bromide, potassium iodide and cesium chloride were used as electrolytes. These samples were all special-grade commercial products. They were dried in a thermostat long enough before they were made into solutions.

## Results

Our experiments were carried out at room temperature by varying the concentration of solutions.

Suryanarayana and Venkatesan[6] have already reported the viscosities of sodium chloride solutions from 1 molal to saturation and from 30 to 55°C. Kume and Tanaka[7] have also presented a paper on some kinds of electrolytic solutions, in which the data of sodium chloride and potassium chloride are included. Consequently, for sodium chloride and potassium chloride we can utilize these data. In Table I our results are listed together with some of them. All the results are also shown in Fig. 1.

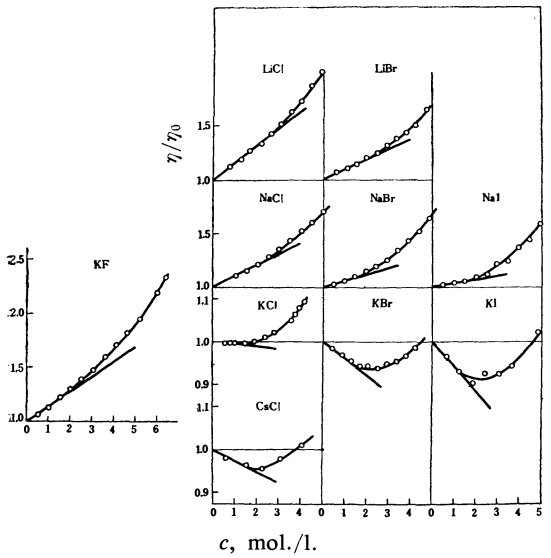

Fig. 1. Plots of relative viscosity against concentration.

## Discussion

One might easily admit that the relative viscosity vs. concentration curves could be generally classified into two groups. In the first type the relative viscosity varies almost linearly with the concentration in the dilute range (the slope is all positive) and then deviates clearly from the linearity after passing a critical point of concentration. The second type is one that indicates so-called negative viscosity — the behavior as a whole is not greatly different from the former, but it can be distinguished on one point, namely that its slope in the dilute range is negative. We would claim that the concentration corresponding to deflection point might be closely related with a critical concentration that is characterized in our model concerning the structure of electrolytic solutions. As general tendencies, with increasing temperature the absolute value of the tangent becomes greater and the deflection point moves to a higher concentration. But the displacement of the latter is so small that it can be neglected in the present problem. Derived from the data by Suryanarayana and Venkatesan[6] the temperature coefficient of the displacement under consideration is estimated as the order of 0.02 mol./l. deg$^{-1}$. These behaviors are shown in Fig. 2.

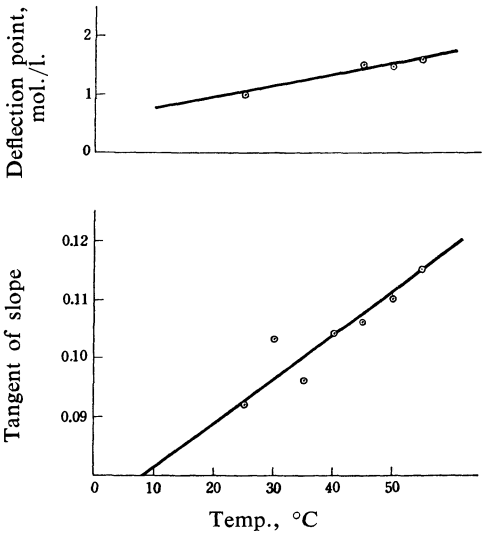

Fig. 2. Temperature coefficient of deflection point and tangent of slope against concentration (NaCl solution). After Suryanarayana and Venkatesan.

Let us continue the consideration in more detail. It is convenient to take series, e.g. anion series—in one series a cation is substituted corresponding to a fixed anion. In Fig. 3 the dependence of the ionic radius upon the tangent is plotted. One may notice the general feature that the tangent becomes smaller with increasing ionic radius (at a virtual value** its sign changes from positive

6) C. V. Suryanarayana and V. K. Venkatesan, *Trans. Faraday Soc.*, **54**, 1709 (1958).

7) T. Kume and M. Tanaka, *J. Chem. Soc. Japan, Pure Chem. Sec. (Nippon Kagaku Zasshi)*, **81**, 534 (1960).

** It is interesting to note that a critical value may probably satisfy a condition, in which a sum of both radii of the ions involved in one series is equal to 3.1~3.3Å. In the Cl series $K^+$ is incidentally fitted in this relationship.

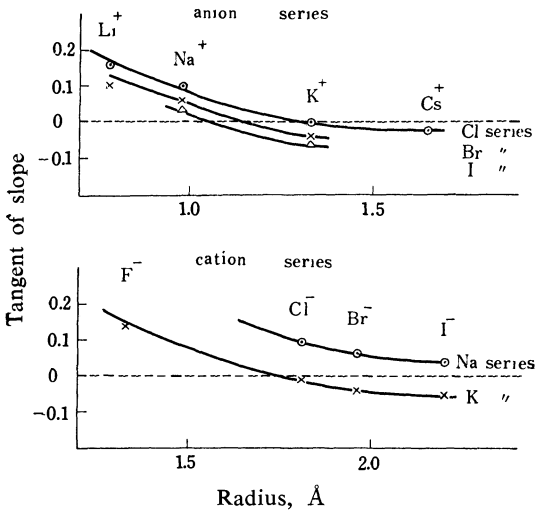

Fig. 3. Tangent of slope vs. ionic radius.

to negative) and the deflection point moves to a lower concentration***. Concerning the dilute range in which the viscosity varies linearly with the concentration, we would conform to Broersmas' treatment[8]. According to his assumption of local viscosity, the viscosity $\eta$ can be set,

$$\eta \approx \eta_{0-0} + 2\sum \frac{n_i v_i}{N v_0}(\eta_{i-j} - \eta_{0-0}) \qquad (3)$$

where $\eta_{i-j}(=\eta_{j-i})$ is a local viscosity in a region containing neighboring water molecules in the $i$th and $j$th hydration layers, consequently $\eta_{0-0}$ is a local viscosity in a region containing both free waters; $v_i$, $n_i$ and $v_0$, $n_0$ are the volume and the number per unit volume of water molecules existing in these respective states. $N$, the total number of water molecules per unit volume can be written:

$$N = n_0 + n(n_{1(+)} + n_{1(-)} + n_{2(+)} + n_{2(-)})$$

where $n_{1(+)}$, $n_{1(-)}$ and $n_{2(+)}$, $n_{2(-)}$ are the hydration numbers of primary and secondary layers surrounding a cation and an anion respectively. Equation 3 is considered to be based upon the following fundamental concepts. Local friction force is proportional to the total cross-sectional area of the molecules which are proportional to their volumes and the velosity gradient (a const) and the resultant of these effects contribute to the bulk viscosity. Factor 2 enters because the layers considered are identical so that element $i$ and $j$ can meet either way. The higher terms containing more than the square of concentration, $(n_i/N)^2$, are neglected. In other words the bulk viscosity is assumed to be givin by averaging the effect of local viscosity with the weights of relative volume and concentration of the water molecule in different state.

From the standpoint of our model Eq. 3 can be written,

$$\begin{aligned}\eta \approx \eta_{0-0} &+ 2\frac{n_{1(+)} n v_{1(+)}}{N v_0}(\eta_{1(+)-2(+)} - \eta_{0-0}) \\ &+ 2\frac{n_{2(+)} n v_{2(+)}}{N v_0}(\eta_{2(+)-0} - \eta_{0-0}) \\ &+ 2\frac{n_{1(-)} n v_{1(-)}}{N v_0}(\eta_{1(-)-2(-)} - \eta_{0-0}) \\ &+ 2\frac{n_{2(-)} n v_{2(-)}}{N v_0}(\eta_{2(-)-0} - \eta_{0-0}) \qquad (4)\end{aligned}$$

If we assume that $\eta_{1(+)-2(+)} \approx \eta_{1(-)-2(-)}$, $\eta_{2(+)-0} \approx \eta_{2(-)-0}$, the equation can be transformed to,

$$\begin{aligned}\frac{\eta}{\eta_0} \approx 1 + 2\frac{n}{N}\Bigg[&(n_{1(+)} + n_{1(-)})\frac{v_1}{v_0}\left(\frac{\eta_{1-2}}{\eta_{0-0}} - 1\right) \\ &+ (n_{2(+)} + n_{2(-)})\frac{v_2}{v_0}\left(\frac{\eta_{2-0}}{\eta_{0-0}} - 1\right)\Bigg] \qquad (5)\end{aligned}$$

Since $n = cN/1000$, where $N$ is the Avogadro number, we find that the relative viscosity varies linearly with the concentration. The factor of the linear term can clearly possess either sign. Since an inequality $\eta_{1-2} > \eta_{0-0}$ is admitted as being always valid, the correlation between $\eta_{2-0}$ and $\eta_{0-0}$ is likely to have a casting vote in the determination of the sign. When $\eta_{2-0} > \eta_{0-0}$, the sign shows positive. When $\eta_{2-0} < \eta_{0-0}$, the sign shows positive or negative corresponding to the inequality:

$$(\eta_{1-2} - \eta_{0-0})/(\eta_{0-0} - \eta_{2-0}) \gtrless (v_2/v_1)(n_{2(+)} + n_{2(-)})/(n_{1(+)} + n_{1(-)})$$

It turns out, therefore, that the condition of negative viscosity is given by

$$\eta_{2-0} < \eta_{0-0},\ (\eta_{1-2} - \eta_{0-0})/(\eta_{0-0} - \eta_{2-0}) < 5 \qquad (6)$$

in rough approximation[9].

It should be understood that the above-mentioned consideration does not contradict Eq. 1. As the concentration reaches nearly 0.1 mol./l., the linear term becomes predominant compared with the Debye-Hückel-Falkenhagen term. Of course, we could not express the relationship exactly only with a linear term. Kaminsky[10] has recently clarified the fact that we have to supply a quadratic term in order to obtain a more precise formula even in the range up to 0.5 mol./l. However, since the factor of linear term is larger than two other

*** This facts can be deduced from our data in spite of slight differences of temperature.

terms by one degree of order of magnitude, it is apparent that it plays a leading role in the concentrated range over 0.1 mol./l.

Suryanarayana and Venkatesan[6] have proposed that if one plotted a function $\ln(\eta/\eta_0)/C_*$ against reduced concentration $C_*$, where $C_*$ is the ratio of the mole fraction to that at saturation, one could probably represent the entire behavior except in dilute solutions. We suppose that the breakdown in their formalism may be essentially due to our critical phenomenon.

## Summary

The coefficients of the viscosity of concentrated aqueous solutions of 1-1 type electrolytes were measured at room temperature. Judging from the relationship between relative viscosity and concentration the electrolytes would be classified into two groups. One is normal and the other shows negative viscosity. It is the linear term that makes the most predominent contribution in the dilute range. We analyzed its factor by the use of Broersma's concept of local viscosity. From the expression obtained, a condition of negative viscosity was derived as 6 in approximation. According to our interpretation, negative viscosity does not result from individual characters of ions of each electrolyte in question, but from delicate correlations between the local viscosities of neighboring hydration layers.

The authors are very grateful to Professor Tatsuro Watari for his valuable and stimulating discussions. They also wish to thank Mr. Tatsundo Hakuya warmly for his assistances throughout the course of this work.

# *Physicochemical Properties of Dilute Aqueous Solutions of Amylose. Optical Rotatory, Viscometric and Osmometric Studies*

By Takashi KUGE* and Sôzaburo ONO

(Received February 15, 1961)

Amylose is metastable in a neutral aqueous solution, and tends to retrograde. In the retrograded precipitates, amylose molecules take linear extended configurations and form well-ordered crystallites[1]. It has also been well known that amylose can be precipitated as complexes having a helical configuration from the aqueous solutions by the addition of various complexing agents[1]. Hence, it is natural to suppose that the configuration as well as the degree of aggregation of amylose molecules in solution can be changed, depending on the condition under which they are dissolved[2]. Accordingly, it may be inferred that a dilute aqueous solution of amylose has characteristic properties due to the high tendency to associate and the possibility of the transition among various probable configurations of amylose molecules. However, there have been very few experiments[3] concerning the physicochemical properties of the solution. Therefore, in the present experiments, in order to obtain further knowledge of the properties of dilute aqueous solutions of amylose, optical rotatory power, viscosity and osmotic pressure of the solution at various temperatures have been investigated.

## Experimental

**Materials.** — Amylose was obtained from potato strach by a selective precipitation method with *n*-butyl alcohol and isoamyl alcohol[4]. This amylose was recrystallized twice from boiling water in the presence of excess butanol and the resulting pure amylose was used in this investigation unless otherwise indicated. The $\beta$-limit dextrin used was prepared from glutinous rice starch by digestion with soyabean $\beta$-amylose which was given by Dr. Yamamoto of Osaka City University. The method of digestion was essentially similar to that described

by Meyer and Bernfeld[5]. The β-limit dextrin obtained was found to be a 41% degraded product of the parent material by measuring the reducing power of the digested mixture.

**Optical Rotatory Power.** — A Rudolph photoelectric polarimeter model 200 was used for the measurements of the dispersion of rotatory power. A Hitachi polarimeter having a vernier scale of one handredth degree, was used for the measurements of the temperature dependence of rotatory power with a jacketed polarimeter tube which enables thermoregulated water to circulate. All measurements were made with two-decimeter tubes.

About 500 mg. of the amylose was dispersed in 70 ml. of 0.5 M aqueous potassium hydroxide and allowed to stand overnight to complete the dispersion and then filled up to 100 ml. with the same solvent. The solution thus obtained was diluted 2.5-fold either with distilled water, after neutralization (pH 5.4~6.0) with hydrochloric acid, or with the 0.5 M potassium hydroxide. The solutions were filtered and the filtrates were used for measurements. Likewise, the β-limit dextrin was also used.

For the measurements of the variations of rotatory power with temperature, the temperature of the circulating water was changed at an average rate of 3 degrees per 10 min. The temperature of the solution investigated was read from a thermometer immersed in the circulating water. The temperature seemed to be controlled to ±1.0°C. At a given constant temperature six readings were made and the average was taken.

**Viscosity.**—A usual Ostwald type viscometer was used throughout this investigation. For the solutions investigated the viscometer had flow times of 123~271 sec. at the experimental temperatures. Temperature control within ±0.01°C could be achieved by keeping a thermostated water-bath in an outer larger thermostat.

The procedure used for determining the viscosities was as follows: The amylose solution prepared as described in the above section was filtered through a glass filter. Ten milliliters of the filtrate was pipetted into the viscometer which was placed in the thermoregulated water-bath set at 25.0°C and allowed to stand for 20 min. The flow time was then determined three times and the average was taken. Thereafter the temperature of the water-bath was raised to another given temperature and after a further 20 min. the flow time was determined. This process was repeated at 5 degree intervals, until 50.0°C. The temperature was then decreased and the flow time was redetermined in the same way. This required approximately seven hours. Another aliquot of the solution was allowed to stand at 25.0°C during the period of the above experiment and thereafter its viscosity was also measured.

**Osmotic Pressure.** — Amylose obtained by a method similar to that described by Azumi and Nakajima[6] was recrystallized three times from water by the addition of *n*-butanol and the resulting pure potato amylose was used in this experiment.

The amylose was first dissolved in 0.5 M aqueous potassium hydroxide solution by stirring under nitrogen atmosphere for about two hours in a flask having a glass stopper which was then sealed and stored at 5.0°C for a night. This stored solution was then neutralized with hydrochloric acid and diluted with distilled water to yield 0.2 M solution with respect to potassium chloride containing 0.1~0.5% amylose which was used for the measurements. The concentration of amylose was calculated from the dry weight of the sample dissolved.

The osmometer employed was a modified Zimm-Myerson type osmometer[7,8]. The inner diameter of the measuring capillary was about 0.8 mm. The amount of the solution required to fill the osmometer was about 9 ml. Toluene was used as a pressure indicator, for the solutions examined tended to stick in the measuring capillary. Collodion membranes prepared in the manner described by Fuoss[9] could be useful in this study.

Setting the meniscus in an appropriate position, the measuring apparatus was allowed to stand at a given temperature controlled within ±0.05°C. The approach of the meniscus to equilibrium was followed by a cathetometer. The equilibrium value was attained within six hours in this case. The experimental error with regard to the equilibrium value was within ±0.1 cm.

## Results and Discussion

Specific rotations obtained at room temperature at different wavelengths using solutions of 0.2% concentration are given in Table I. The rotatory dispersions of the amylose and the β-limit dextrin were normal. That is, when the reciprocal of the specific rotation was plotted against the square of the wavelength, the points lay on a straight line (Fig.

TABLE I. SPECIFIC ROTATIONS OF AMYLOSE AND β-LIMIT DEXTRIN AT VARIOUS WAVELENGTHS

| Wavelength mμ | Specific rotation | | | |
|---|---|---|---|---|

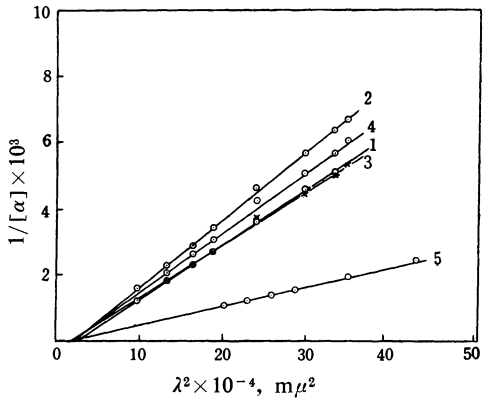

Fig. 1. The rotatory dispersions of amylose, $\beta$-limit dextrin and D-glucose. The date for D-glucose are taken from International Critical Table. Only for glucose, the ordinate scale should be read in one tenth of the presented. 1, amylose in 0.2 M KCl; 2, amylose in 0.5 M KOH; 3, $\beta$-limit dextrin in 0.2 M KCl; 4, $\beta$-limit dextrin in 0.2 M KOH; 5, D-glucose in $H_2O$.

1). Hence, the variation in the rotation measured can be expressed by a single term Drude equation

$$[\alpha]_\lambda = A/(\lambda^2-\lambda_c^2) \qquad (1)$$

where $[\alpha]_\lambda$ is the specific rotation at a given wavelength, $\lambda$, and $A$ and $\lambda_c$ are the rotation constant and the critical wavelength, respectively. $A$ and $\lambda_c$ can be obtained from the slope and the intercept of the straight line with the abscissa, respectively. Their values calculated by the least square method are given in Table II. Already determined correlations between rotatory properties and molecular structure make it apparent that optical rotatory dispersion is one of the best qualitative methods for detecting changes in configuration of very large optically active molecules[10]. Particularly, the helical configuration of protein and polypeptide could be well reflected in $\lambda_c$. Murakami[11] pointed out from a theoretical viewpoint that the helical structure in which many identical groups are asymmetrically arranged shifts apparently an original $\lambda_c$ corresponding to random structure towards longer wavelengths. Hence, it may be considered that amylose taking a helical configuration should possess a distinctively different $\lambda_c$ from that of amylose which has no helical configuration. All of the $\lambda_c$ found for the amylose and the $\beta$-limit dextrin in the two solvents are in close agreement with each other. It seems that the $\beta$-limit dextrin never takes a helical configuration because of its highly branched structure[1]. Moreover, D-glucose has also a nearly equal $\lambda_c$, as can be seen in Fig. 1 and Table II. Wolff et al.[12] also gave 147 m$\mu$ for $\lambda_c$ of corn amylose in 1 M potassium hydroxide, though they obtained 103 m$\mu$ for corn amylopectin. Hence, it can be stated that the wavelength near 140 m$\mu$ is an intrinsic $\lambda_c$ for D-glucopyranose residue, and the amylose in the two solvents at room temperature does not take a well-oriented helical configuration. Although there are some possibilities that right handed and left handed helices exist in the same amount, this seems to be rather rare.

TABLE II. CRITICAL WAVELENGTH AND ROTATION CONSTANT

| Substance | Solvent | $\lambda_c$, m$\mu$ | $A$ |
|---|---|---|---|
| Amylose | 0.2 M KCl | 151 | 60.2 |
| | 0.5 M KOH | 145 | 48.8 |
| $\beta$-Limit dextrin | 0.2 M KCl | 134 | 62.1 |
| | 0.5 M KOH | 141 | 54.4 |
| D-Glucose | $H_2O$ | 141[a] | |

a) The value was calculated from the data given in International Critical Table.

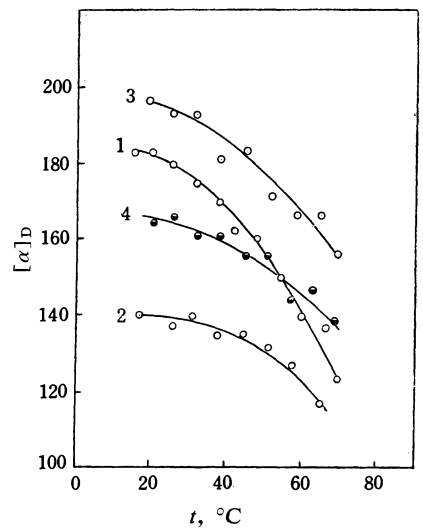

Fig. 2. The temperature dependences of specific rotations: 1, 0.2% amylose in 0.2 M KCl; 2, 0.2% amylose in 0.5 M KOH; 3, 0.2% $\beta$-limit dextrin in 0.2 M KCl; 4, 0.2% $\beta$-limit dextrin in 0.5 M KOH.

Figure 2 shows temperature dependence of the specific rotations of the amylose and $\beta$-limit dextrin in the two solvents at a wavelength 589 m$\mu$ (Na-D line). Although the rotation of the amylose in 0.2 M potassium

10) For a review, see C. Djerassi, "Optical Rotatory Dispersion, Applications to Organic Chemistry", McGraw Hill Book Co., Inc., New York (1960), Chapter 17.
11) H. Murakami, *J. Chem. Phys.*, **27**, 1231 (1957).
12) I. A. Wolff, P R. Watson and C. E. Rist, *J. Am. Chem. Soc.*, **74**, 3064 (1952).

chloride solution is considerably larger than that of the amylose in 0.5 M potassium hydroxide at 25°C, the former approaches the latter with increasing temperature, having a large temperature coefficient of negative sign. The rate of the change of the specific rotation is $-1.4°/°C$ in the region of the most rapid change, which is unusually large compared with those of carbohydrates of low molecular weight; for example, sucrose has the rate $\sim 0.01°/°C$[13].

Changing temperature can affect the optical rotation in four possible ways: 1) Configuration of the chain of amylose might change, namely, the helix-coil transition might occur. This was seen in cases of proteins and polypeptides[10]. 2) Ring conformation of glucopyranose residue might differ. Reeves[14] considered that the different specific rotations of corn amyloses in neutral aqueous solution and alkaline solution may be ascribed to different conformations of their glucopyranose rings, that is, B1 may be the conformation in neutral solution and 3B in alkaline solution (the symbols follow Reeves' convention). 3) The vicinal action of solvent might change[15]. This generally decreases with increasing temperature. 4) Hindrance to free rotation around bond axis might change. This would change axial symmetry.

Among these possibilities, the first is unlikely, since the $\beta$-limit dextrin also shows qualitatively the same behavior as to temperature dependence as the amylose does (Fig. 2). In addition, the specific rotation at the higher temperature is close to that of $\alpha$-D-glucose, which may suggest no contribution due to the helical structure to the rotation at the higher temperature. The second and the third possibilities are not clear at present. However, judging from the small temperature coefficients of the rotations of the carbohydrates having low molecular weights, the possibilities appear to be unimportant. Even if the transition between the two ring conformations mentioned above occurs, that would not explain the whole change of the rotation without other causes, since the rotation in neutral solution (corresponding to B1) becomes smaller than that in alkaline solution at room temperature (corresponding to 3B) with increasing temperature. The fourth seems to be most important in the present case. According to Kauzmann and Eyring[15], those influences which tend to restrict freedom of orientation about bonds connecting groups to the asymmetric carbon atom will tend to increase the order of magnitude of the optical activity, causing the first order contribution defined by them. At the lower temperature, the ability of free rotation around bonds such as C–O–C, C–OH and $C\text{-}CH_2\text{-}OH$ in amylose molecule seems to be strongly hindered owing to hydrogen bonds occurring between hydroxyl groups which come close to each other. This will lead to the higher rotation due to the first order contribution. With increase in temperature, the hydrogen bonds will be more or less ruptured and the free rotation will become easier. This process must also be taken into consideration in order to explain the anomalous behavior of viscosity of amylose, as can be seen later. Consequently, the lower rotation of amylose at the higher temperature may be ascribed to the vanishing of the first order contribution.

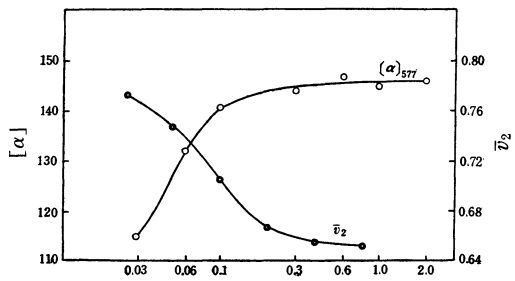

Fig. 3. The variations of specific rotation, $[\alpha]_{577}$, and partial specific volume, $\bar{v}_2$, of amylose in 0.5 M KOH with change in the concentration of amylose. $[\alpha]_{577}$ was measured by the Rudolph photoelectric polarimeter.

In Fig. 3 the variation of the specific rotation with that of partial specific volume which was found by Yoshikawa[16] by measuring density of amylose solution, is shown. Although the experimental error increases as the concentration becomes lower, it may be said that both the specific rotation and the partial specific volume sharply alter with decreasing concentration in the region of low concentration below 0.1%. These facts seem to be explained by the decrease of segment-segment interaction with decreasing concentration, and support the authors' opinion concerning the temperature dependence of the rotatory power.

From the point of view given above, it may be suggested that the large rotation of the $\beta$-limit dextrin compared with that of amylose would arise from the inability of free rotation around the bonds between carbon 5 and carbon 6 at branch points in the $\beta$-limit dextrin; besides, the highly branching structure would

13) T. R. P. Gibb, Jr., "Optical Methods of Chemical Analysis", McGraw Hill Book Co., Inc., New York (1942), Chapter 8.

increase segment-segment interaction occurring inside the molecule. On the contrary, in amylose which has no branch point, all of the bonds between carbon 5 and carbon 6 can rotate freely unless the hydrogen bond at carbon 6 is formed with another segment which comes into contact with it. The well known fact that amylopectin shows a greater rotation than that of amylose may be explained by the same consideration.

As for the viscosity, its change may be qualitatively parallel with that of the rotation. Figures 4 and 5 show the variations of the reduced viscosities of 0.2% amylose in 0.2 M potassium chloride and 0.5 M potassium hydroxide, respectively. Arrows marked on the curves in these figures indicate directions of the temperature change. Cross marks in the figures represent viscosities of the samples allowed to stand at 25.0°C for seven hours. It can be seen in these figures that the reduced viscosities in the two solvents decrease with increase in temperature, independent of the

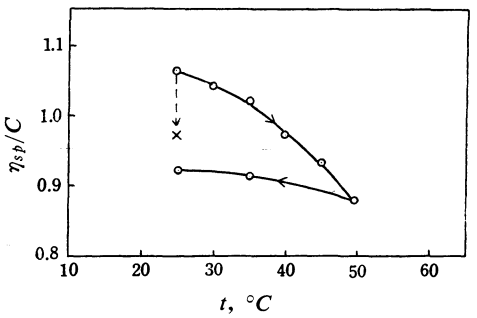

Fig. 4. The variation of reduced viscosity of 0.2% amylose in 0.2 M KCl with temperature.

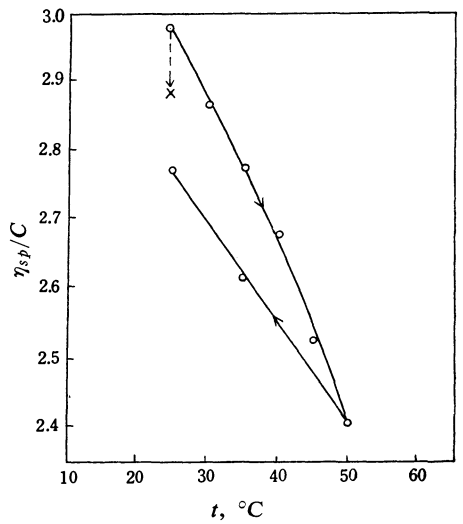

Fig. 5. The variation of reduced viscosity of 0.2% amylose in 0.5 M KOH with temperature.

nature of the solvents used. In a poor solvent, the intrinsic viscosity should increase with increasing temperature, according to the theory of viscosity. Flory[17] gave the following expression for intrinsic viscosity of polymer, assuming a random coil configuration.

$$[\eta] = \Phi(\bar{r}_0^2/M)^{3/2} M^{1/2} \alpha^3 \quad (2)$$

$$\alpha^5 - \alpha^3 = 2C_M \psi_1 (1-\theta/T) M^{1/2} \quad (3)$$

$$\theta = \kappa_1 T/\psi_1 \quad (4)$$

where meanings of the letters are the same as those given by Flory. Although a change in temperature may affect the intrinsic viscosity through alteration of both $(\bar{r}_0^2/M)^{3/2}$ and $\alpha^3$ occurring in Eq. 2, the change of the latter of these factors is likely to be dominant in a usual case. In a poor solvent, where both $\kappa_1$ and $\psi_1$ generally are positive, $\theta$ also will be positive, while negative $\kappa_1$ and positive $\psi_1$ in a good solvent will result in a negative $\theta$. Consequently, in general, the intrinsic viscosity of polymer in a poor solvent should increase with increasing temperature, since $\alpha$ should increase with increasing temperature according to Eq. 3. The increase of $\alpha$ should be most rapid in the immediate vicinity of $T=\theta$.

The viscosity of the amylose even in the aqueous potassium chloride solution, which is a poor solvent having a $\theta$-temperature of 25°C[3d], decreases with increase in temperature, though the reduced viscosity instead of the intrinsic viscosity is dealt with. The anomalous behavior of the viscosity should be accounted for by assuming that $(\bar{r}_0^2/M)$ of the amylose displays an unusually rapid alteration with temperature. $\bar{r}_0^2$ is modified by hindrance to free rotation around bond linking monomers, being greater with increase in the restriction. It is probable that the free rotation around glycosidic bond is strongly hindered by hydrogen bondings between segments through many hydroxyl groups of amylose. With increasing temperature, these hydrogen bonds will be ruptured and the restriction will decrease, which in turn will result in the decrease of $\bar{r}_0^2$. That is, the flexibility of the amylose chain seems to be considerably increased with increasing temperature through the decrease of the degree of the hydrogen bonding.

In the potassium hydroxide solution the possibility of the degradation of the amylose due to oxidation might be considered; however, in the potassium chloride solution the possibility can be ruled out[18]. Figure 4 shows that the solution recooled to 25.0°C does not completely recover its viscosity, and the viscosity

of the solution after aging at 25°C is lower than that of the solution before aging. These facts may probably arise from the metastability of the amylose solutions having a tendency to retrograde. Possibly the change of the state of the amylose including hydrogen bonding cannot be completely reversible.

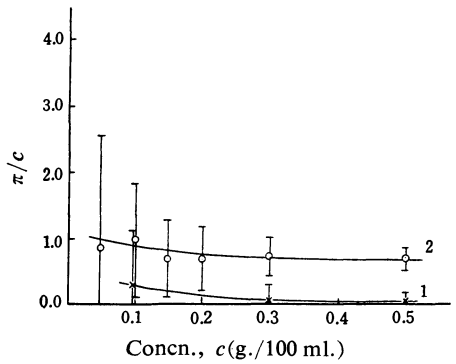

Fig. 6. $\pi/c$ ratio plotted against concentration of amylose in 0.2 M KCl: 1, at 25°C; 2, at 35°C. The vertical lines drawn represent the ranges of experimental error.

In Fig. 6, the ratio of the osmotic pressure to the concentration of the amylose, $\pi/c$, is plotted against the concentration, $c$. The vertical lines drawn in the figure represent the ranges of experimental error. The results of the osmotic measurements are not satisfactory because the experimental error is relatively great compared with the observed osmotic pressure. It may be, however, stated from Fig. 6 that osmotic pressure at 35°C is greater than that at 25°C, and the initial slopes of the curves of $\pi/c \sim c$ plot are negative. These facts seem to indicate that a significant amount of association of amylose occurs in the solutions examined. The amount may decrease with increase in temperature, and also decrease with decrease in concentration. It should be considered that the solutions used by Everett and Foster[3d] (solutions of amylose in aqueous potassium chloride, aqueous potassium hydroxide and dimethyl sulfoxide) to investigate molecular configuration of amylose in solution, are by no means molecularly dispersed solutions, judging from the above results. Therefore, their conclusion concerning the molecular configuration should not be accepted without modification.

Thus it may be said that all of the anomalous phenomena observed, indicate that hydrogen bonding plays a significant role in the properties of the dilute aqueous amylose solutions used in these experiments just as in those of more concentrated solutions or pastes[19]. In other words, any interpretation of the behavior of amylose aqueous solutions may be impossible without postulating hydrogen bondings, even in the case of such dilute solutions as 0.1% or so. At present, however, it is unfortunate that intermolecular and intramolecular hydrogen bondings can not be distinguished with respect to their effects acting on the described properties of the solution except in the case of osmotic pressure. The osmotic measurements may show the existence of the intermolecular hydrogen bondings. However, it seems natural to suppose that the intramolecular hydrogen bondings also exist and have great influence on the properties of the solution together with intermolecular hydrogen bondings.

As already stated above, the well-oriented helix of the amylose in the neutral aqueous solution can be excluded. However, the possibility of the existence of the deformed helix of amylose suggested by Holló and Szejtli[20] remains uncertain, and it seems worth while to reconsider this problem. According to them, the viscosity of acid solution of amylose is unchanged by the addition of iodine, as far as the added iodine is taken up to form the complex. Only when excess iodine is added, is the viscosity changed. If the configuration were substantially altered by the addition of iodine, it would affect the viscosity of the solution. Therefore keeping in mind the helical configuration in amylose-iodine complexes, the configuration of amylose in the solution should not be supposed to be substantially different from the helical configuration. The amylose in the neutral aqueous solutions may be permitted to take the deformed helical configuration, if it is assumed that the deformed helix has no contribution to the optical rotation. In the previous paper[21], the present authors suggested that the vanishing of the blue color of amylose-iodine complex at high temperature (70°C or so) appears to be ascribed to the random configuration of the amylose molecules. Considering these facts with the ease of the amylose-iodine reaction at room temperature, it seems probable that the amylose in neutral solution at room temperature may take the configuration of the deformed helix, which may easily be transformed into the well-oriented helix, rather than take a quite disordered random configuration. The deformed helical molecules appear to be more disordered with increasing temperature. Accordingly, the helical configuration of amylose in the solution at higher temperature may be

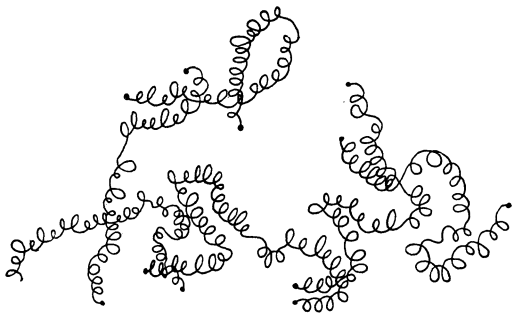
more unreasonable than that at lower temperature.

Although Everett and Foster[3d] suggested a random coil configuration of amylose in aqueous neutral solutions from the studies of viscosity and light scattering, their results should be reconsidered, taking the above stated high degree of molecular association of amylose into account. If we assume the high degree of association of molecules having some flexibility, it may be reasonably supposed that the molecules must behave as a random coil in appearance, since a real polymer chain that is restricted in free rotation may be approximated by an equivalent freely jointed chain[22]. Associated amylose molecules, as a whole, may be statistically equivalent to a random coil polymer having great molecular weight.

As a consequence, the most probable configuration of amylose molecules dissolved in neutral aqueous solutions at room temperature, seems to be associated deformed helix which is tentatively drawn in Fig. 7.



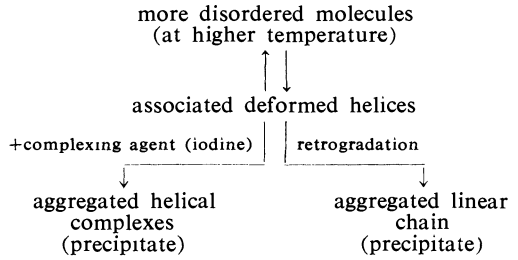


Fig. 7. Supposed configuration of amylose molecules dissolved in aqueous solutions. Dot drawn represents the end of molecule. The length of chain corresponding to each molecule is conveniently drawn to be shorter than that of real molecule.

It should be noted that amylose is metastable in neutral aqueous solutions. Hence, the supposed configuration drawn in Fig. 7, which seems to correspond to "native aggregate" proposed by Paschall and Foster[3a], is a metastable form and then may be stabilized by retrogradation (phase separation). Paschall and Foster also found that the native aggregate can not retrograde at room temperature without first undergoing at least partial disaggregation, and the disaggregation continues along with retrogradation. Therefore, the linear extended configuration of amylose seems to be formed only when retrogradation (crystallization) takes place. Consequently, the following scheme for molecular configuration change of amylose in aqueous solution may be proposed;

## Summary

Optical rotatory power, viscosity and osmotic pressure of dilute aqueous solutions of amylose have been studied. Optical rotatory dispersions of amylose and $\beta$-limit dextrin in 0.2 M potassium chloride and 0.5 M potassium hydroxide are normal and can be well expressed by a single term Drude equation. All of the $\lambda_c$ obtained from the analysis of the dispersion curves are close to 140 m$\mu$ which may be considered as a characteristic value of glucopyranose residue. This seems to indicate that there is no well-oriented helix of amylose in the solutions. With increasing temperature, the optical rotations of amylose and $\beta$-limit dextrin decrease. Amylose, especially in a neutral aqueous solution, has an unusually great temperature coefficient of specific rotation amounting to $-1.4°/°C$ as the largest value. Parallel with this change, the viscosities of the amylose solutions decrease with increasing temperature. These results seem to be well explained by assuming that the flexibility of amylose molecules is considerably influenced by temperature through the change of the degree of hydrogen bonding between segments of the molecules. Osmotic measurements have given evidence to prove the occurrance of the association of amylose molecules in the solution examined. The degree of the association has been found to decrease with increasing temperature. These facts indicate that hydrogen bonding plays a significant role in the properties of the dilute aqueous solution.

The molecular configuration of amylose in aqueous solutions has been discussed. It seems to be most probable that amylose molecules in the solutions take the configuration of deformed helix, and associate highly with each other. No linear extended configuration is possible. The figure of the supposed configuration is drawn.

# *Thermodynamical Studies on Binary Systems Consisting of Polar and Non-polar Liquids. I. Construction of a Semi-automatic Microcalorimeter Suitable for the Rapid Measurement of Heats of Mixing of Binary Solutions*

By Kazuo AMAYA*

(Received March 1, 1961)

For the full understanding of thermodynamical properties of binary systems, it seems to be very important to know about the relation between the termodynamical properties of binary systems and the structure of the constituent molecules.

The accumlation of this knowledge may contribute not only to the development of the theory of solutions but also to the application of it to practical purposes. To see how the dipole moment of polar molecules affects the thermodynamical properties of binary systems containing them, the measurements of heats of mixing for binary solutions consisting of polar and non-polar liquids were attempted.

The main obstacles which prevent the systematic study of heats of mixing for a large number of binary systems of non-electrolytes have been the difficulty, and the laboriousness, of the precise measurement of the small amount of heat evolved or absorbed on mixing two kinds of liquids of non-electrolytes.

Therefore, in designing a calorimeter the following points are taken into account.

1) Ease of the measurement, particularly the shortening of the time required for one measurement by an economical use of waiting time. It is essentially necessary to perform a large number of measurements in a short time.

2) Saving of the amounts of the samples required for each measurement.

3) Elimination of the errors due to evaporation or condensation of the components on mixing.

4) Durability for continuous operation of the thermostat for a long period.

By bearing the above points in mind, a semi-automatic microcalorimeter with the following features is constructed.

1) Five removable mixing vessels are attached to the calorimeter. They can be fitted to or removed from the calorimeter from the outside of the calorimeter chamber without seriously affecting its thermal equilibrium. This device cuts down the time required for the calorimeter to reach thermal equilibrium, after which the next measurement can be carried out, and hence is capable of shortening the waiting time required for each measurement.

2) An automatic measurement of the integrated time from $10^{-4}$ to 100 sec. during which the electrical current is passed through the calorimeter heater is carried out with an electronic counter, a gate circuit and a standard crystal oscillator.

3) An automatic thermal compensation is possible when the system is endothermic.

4) The quantities of samples required for each measurement are less than 1 cc. for each component.

5) The vapor phase is completely eliminated. This eliminates the error due to evaporation or condensation of the components.

## Principle of the Construction of the Apparatus

The whole apparatus consists of a thermostat, a calorimeter, a thermister resistance thermometer, an automatic thermal compensation circuit composed the of constant current supply for the calorimeter heater and a relay circuit which exchange connection of a constant current supply from a dummy heater to the calorimeter heater, the automatic time measuring apparatus consisting of an electronic

* Present adress: Government Industrial Research Institute, Tokyo, Shibuya-ku, Tokyo.

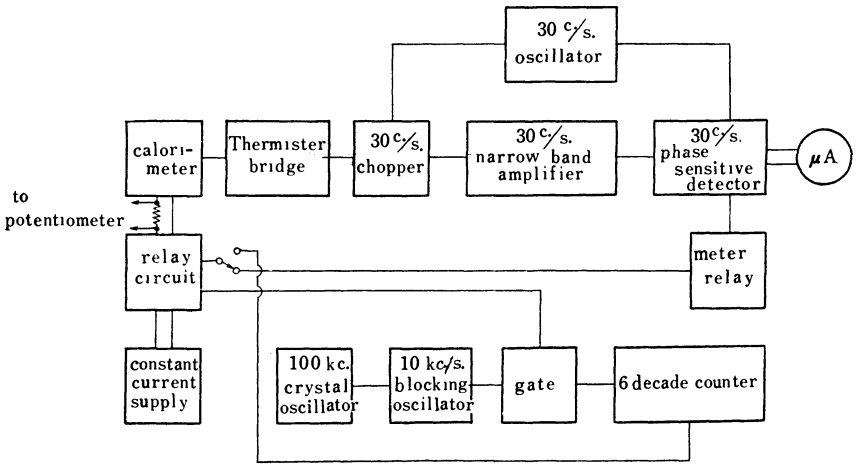

Fig. 1. Block diagram of the apparatus.

counter and the standard crystal oscillator and the gate, and a potentiometer for measuring the electric current of the calorimeter heater. The block diagram of the whole apparatus is shown in Fig. 1. The principle of the operation is as follows.

When the endothermic change occurs in the calorimeter, the signal from the thermometer is amplified by the vacuum tube amplifier and its output automatically operates the relay and changes the connection of the switch from the dummy heater to the calorimeter heater and supplies electrical energy to the calorimeter. At the same time, the gate circuit of the counter is opened and the signal of constant frequency of 10 kc. from a blocking oscillator synchronized by the 100 kc. crystal oscillator enters into the counter and begins to register the time. When sufficient energy has been supplied, the relay returns to its original position and ceases the supply of electrical energy to the calorimeter, and at that instance, the gate circuit is closed, and the integral value of the time during which the current is passed through the calorimeter heater is registered on the counter. For the part of the heat change which is not compensated perfectly, correction is made thereafter. For exothermic reaction, the change of temperature is plotted against time and the temperature change is referred to that caused by feeding a known amount of electrical energy.

### The Details of the Apparatus

**The Calorimeter.** — The calorimeter consists of the mixing vessel holder rotatable around the horizontal axis, the removable mixing vessels, and the mixing vessel container. All of these are contained in the calorimeter chamber which consists of a liquid-tight

cylindrical brass chamber with a large Dewer vessel in it. By this calorimeter a large number of measurements can be made without much labor. The calorimeter from which the mixing vessel is taken away is shown in Fig. 2.

Inside the holder, the removable mixing vessel is just fitted. This can be placed or removed the by use of a long bakelite rod. The mixing procedure is to make the holder upside down by turning it around the pivot P through the manipulation of the handle from the outside of the calorimeter chamber.

**The Mixing Vessel Holder.** — The mixing vessel holder is shown in Fig. 3. A is the

mixing vessel holder made of a brass cylinder closed at one end and equipped with the pivot P. The cylinder is 3 cm. in inner diameter, 3.4 cm. in outer diameter, and 3.3 cm. in height. Around the outside wall of the cylinder, the calorimeter heater H of double silk covered manganin wire was wound non-inductively, and was fixed by Araldite resin. The resistance of the manganin wire is 45.850 Ω. The outside of the bottom wall of the mixing vessel holder is equipped with a thermister T of about 100 kΩ in resistance at 25°C. The thermister is enclosed in a thin polyvinyl chloride tube and sandwiched between the bottom of the holder and the cupper plate with a brass plate spacer of 2 mm. thickness with a slot, into which the thermister is just fitted, in order that the thermister may not be crushed. The pivot P, made of bakelite for thermal insulation, is fixed to the holder by a male screw extruding from the wall of the holder.

The pivot P is held by a bearing. The holder can be rotated around the pivot P through a bebel gear by rotating the pivot P with the handle outside the calorimeter chamber.

The leads of the thermister and the calorimeter heater are passed through the small holes bored along the axis of the pivot P and are drawn from the one end of the pivot P in order not to be entangled by the turning over of the holder.

The outside of the holder is all covered by foam styrene for thermal insulation.

**The Container for the Mixing Vessels.** — In a large space of the Dewer vessel, there is the mixing vessel container E which can contain four mixing vessels. The five mixing vessels filled with liquid samples to be mixed, are introduced into the calorimeter at one time. One of the five is held in the mixing vessel holder, and the other four are held in the mixing vessel container. When one measurement is finished, the mixing vessel in the holder is taken out of the calorimeter chamber and the one in the container is placed into the mixing vessel holder within the calorimeter chamber by the long bakelite rod without affecting the thermal equilibrium inside it.

**The Mixing Vessel.** — The mixing vessel is shown in Fig. 4. The mixing vessel consists

lid. The mixing vessel is a cylindrical iron vessel 2.6 cm. in inner diameter, 3.2 cm. in outer diameter and 3.1 cm. in height. The vessel is filled with mercury and then the two kinds of liquid to be mixed are introduced into two glass bells by two syringes, one for each liquid; therefore they are confined above the mercury separately.

To prevent the bells from being raised above the surface of the mercury by bouyancy when the liquids are introduced into them, two spring steel plates the length of each being a little longer than the inner diameter of the iron vessel, are stuck to the inner wall of the vessel by their restoring force across the diameter of the vessel and the bells are clamped by them.

The syringe used in introducing the liquid into the bell is the usual one modified by attaching a screw driver and by bending the end of the needle.

The upper side of the lid is equipped with a male screw and a nut.

The male screw is used when the mixing vessel is placed into, or is removed from the holder from the outside of the calorimeter chamber by the long bakelite rod, at the one end of which there is a female screw just fitted to the male screw. The nut clamps the iron pin which prevents the mixing vessel from falling down out of the holder when it is turned upside down.

Through the upper part of the wall of the holder a small hole is bored, into which the pin at the upper side of the mixing vessel is put (see Fig. 3).

Before placing the mixing vessel into the holder, the iron pin is loosely held between the nut and the upper side of the lid. When the vessel is put into the holder, the end of the pin is guided into the hole above mentioned by a small piece of permanent magnet, held at the other end of the long bakelite rod described above, and then the nut is screwed by a nut driver from the outside of the calorimeter chamber. After these procedures have been finished, the upper side of the mixing vessel is covered with a foam-stylene lid. The lid is fixed to the mixing vessel by fitting a rubber cap put at the center of the lid to the top of the male screw attached to the lid of the mixing vessel. The rubber cap prevents the foam styrene lid from falling off when the vessel holder is turned. Thus all sides of the calorimeter are covered by foam styrene, and good thermal insulation is assured. The inside of the calorimeter chamber can be illuminated by a miniature lamp in order that these procedures can be performed with ease.

**The Thermometer.**—The thermometer bridge, the converter and the thermister resistance thermometer are the same as those described in the previous paper[1]. The amplifier is also similar to that previously described except that the first stage vacuum tube 6SH7 is replaced by 12AT7 tube in which the two triode plate load resistors are wire wound resistors of 100 kΩ. By the use of the wire wound resister as the plate load, the excess noise is reduced and the signal to noise ratio is raised about three times higher than before.

**The Electrical Circuit for the Automatic Thermal Compensation.** — The electrical circuit for the automatic thermal compensation consists of the constant current supply, the dummy heater, the calorimeter heater, and the relay which converts the connection of the constant current supply from the dummy heater to the calorimeter heater by a lowering of the temperature of the calorimeter.

The electrical circuit is shown in Fig. 5.

The output of the phase sensitive detector

of the thermometer amplifier is fed to a meter relay with sensitivity of 200 μA. When the needle of the meter relay touches the one contact point, the grid of the 1/2·6SN7 tube is connected to high potential through a neon discharge tube and the increased plate current operates the microswitch B and changes the path of electric current from the dummy heater to the calorimeter heater. This operation occurs when the temperature of the calorimeter changes by about $10^{-4}$°C.

A standard 10 Ω resistor is connected in a series with both the dummy and the calorimeter heater. The current which passes through the calorimeter heater is obtained by measuring the electric potential across the 10 Ω standard resistor with the potentiometer. The constant current supply is a heavy duty battery of 6 V. terminal voltage.

The terminal of the microswitch which is connected to the calorimeter heater has a lead to the grid of the gate tube, and when the switch operates, the potential of 6 V. is applied to the grid of the gate tube. $R$ and $R'$ are pairs of resistors having the same resistance and are connected in series with the calorimeter and the dummy heater respectively. By changing the position of the arm of the rotary switch, the total resistance of $R$ and $R'$ is changed, with the resistance kept equal to each other and thereby the current is adjusted from about 15 mA to 120 mA in five steps.

The dummy heater is the resistor having an almost equal value of resistance to the calorimeter heater. Before starting the experiment, the current is passed through the dummy heater and the battery is made to be at a steady state. By the operation of the switch, the total load is nearly the same and the steady state is not disturbed.

**The Time Measuring Apparatus.**—It consists of the standard 10 kc. oscillator with the gate circuit and the six decade electronic counter. The electrical circuits of the former is shown in Fig. 6.

The standard 10 kc. oscillator is a blocking oscillator synchronized by the standard 100 kc. crystal oscillator. The frequency of the 100 kc. crystal oscillator is not corrected by the standard frequency. The gate tube is a 6AS6 tube. The 10 kc. signals from the blocking oscillator are fed to the third grid of the 6AS6 tube. When no voltage is applied to the first grid of 6AS6, a 10 kc. signal sufficiently large to operate the counter is not produced across the plate load resistor of the 6AS6 tube. But, when the gate signal of 6 V. is applied to the first grid of 6AS6, the 10 kc. signal, sufficiently large to operate the counter, comes out. This operation follows in an instant when the electric current from the constant current supply is passed through the calorimeter heater, and so there occurs no delay. By this electronic device, the errors otherwise introduced, of individual persons caused by delay of pushing stop watches or a delay caused by the mechanical inertia of electromagnetic switches, are completely eliminated.

The six decade electronic counter is made of six discharge tube type decatrons of multi-output type manufactured by Japan Radio Communication Co. For the first stage a single pulse decatron is used which responds to signals of up to 20 kc./sec., and the other five are the double pulse decatrons which respond only to signals of up to 5 kc./sec.

By this counter the integral time from $10^{-4}$ to 100 sec. can be measured with an error of $\pm 10^{-4}$ sec. multiplied by the number of operations of the gate circuit.

The counter is also able to pass electrical current through the calorimeter heater for a

pre-determined time from 0 to 100 sec. in steps of $10^{-2}$ sec. But between the actual time and that pre-determined there is a difference of $3\times10^{-2}$ sec. due to the mechanical inertia of the mechanical switch system.

The device stated above is convenient for supplying a known amount of electrical energy to the calorimeter.

**The Thermostat.** — The thermostat and the regulator are practically the same as those described previously. The only improvement is the replacement of the leather belt-pulley type stirrer with the V-belt gear driven one by which the continuous operation for about three months was made possible.

The temperature of the thermostat was kept constant within $10^{-4}$°C at 25±0.1°C.

## Procedures

**Filling of the Bells with the Samples.** — The mixing vessel with two glass bells in it is immersed into a pool of mercury and is turned two or three times in order to exclude the air in the bells and fill them completely with mercury.

Making sure that no air remains in the bells, the two kinds of liquid to be mixed are introduced into each of the two bells by two syringes one for each component.

The quantity of the liquid introduced is determined by weighing the difference of the weight of the syringe by a chemical balance to 0.5 mg. before and after introducing the liquids into the bells.

After the liquids are introduced into the bells, mercury is poured into the vessel until the mercury overflows the edge of the mixing vessel.

Then the round sheet of polyethylene, the size of which is sufficient to cover the whole cross section of the mixing vessel, is placed over the surface of the mercury in the mixing vessel. Making sure that no air exists between mercury and the sheet of polyethylene, the lid of the mixing vessel is put on it and is tightly screwed.

Similar procedures are carried out for the other four mixing vessels containing the same kinds of liquid but of different ratios. The amount of the liquids taken is so chosen that the concentration of the resultant mixture is made about 10, 30, 50, 70 and 90% in voluo.

**The Measurement of the Temperature Change on Mixing.**—The five mixing vessels filled with the sample are introduced into the calorimeter chamber, which is immersed into the thermostat, and one of the five into the mixing vessel container. Then the end of a pin on the lid of the mixing vessel placed in the mixing vessel holder is guided to the hole of the mixing vessel holder and tightly clamped. Then the foam styrene lid is fixed over it. They are then left over night.

After thermal equilibrium is attained, the resistance of the thermister is read every minute and then the liquids are mixed. The mixing is performed by rotating the mixing vessel holder by 180°C, and then by rocking it within a small angle for several times with the handle, from the outside of the calorimeter chamber. Before mixing, the battery for the constant current supply to the calorimeter heater is connected to the dummy heater in order to keep it in a steady state.

When the heat of mixing is endothermic, the thermal compensation takes place automatically. In this case the current passes through the calorimeter heater intermittently from two to four times according to the rate of heat evolution and to the magnitude of electric current passed, until the heat absorbed is nearely compensated for. Then the operation of the automatic thermal compensation circuit is stopped and the resistance of the thermister is read every minute for 15 to 20 min. by manually adjusting the resistance box of the thermometer bridge so as to make the output of the phase sensitive detector null.

The current which has passed through the calorimeter heater is measured to a fraction of second desimals of mA within the interval during which the thermal compensation operates and the current is passed through the calorimeter heater.

The integrated time during which the current is passed through is automatically registered on the electronic counter. Then the known small amount of electrical energy is supplied to the calorimeter to evaluate the part of the heat not perfectly compensated. And again the values of resistance are read for 15 to 20 min. to construct a resistance-time curve.

When the heat of mixing is exothermic, automatic thermal compensation is impossible. In this case the resistance of the thermister is read for 15 to 20 min. after mixing and the resistance-time curve is constructed. Then again a known amount of electrical energy which is nearly equal to the heat evolved on mixing is supplied to the calorimeter and the resistance-time curve is constructed in a way similar to what was done before.

**Calculation of the Heats Evolved or Absorbed by the Use of Resistance-time Curves.**—Typical plots of resistance versus time for endothermic heat of mixing with automatic thermal compensation are shown in Fig. 7.

Within the intervals during which the automatic thermal compensation circuit is in

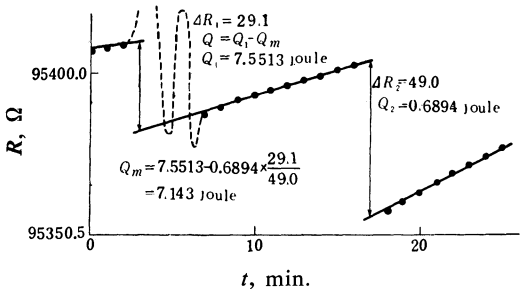

Fig. 7. Typical resistance vs. time curve for endothermic heat of mixing with automatic thermal compensation.

operation, the resistance of the thermister cannot be measured. The dotted line in the figure shows the plot that would be expected if it were actually made.

As the plots of resistance versus time after the thermal compensation ceases to operate are almost linear, it is extrapolated linearly to the time when the mixing was done.

This change of resistance, corresponding to the net change after mixing and the thermal compensation is denoted by $\Delta R_1$, and the total electrical energy supplied by thermal compensation by $Q_1$, and the change of resistance after supplying a known amount of electrical energy $Q_2$ is denoted by $\Delta R_2$, which is obtained by the similar procedure. The change of temperature is very small and the $\Delta R_1$ and $\Delta R_2$ is assumed to be proportional to the corresponding temperature change $\Delta T_1$ and $\Delta T_2$. Then the heat of mixing $Q_m$ is given by

$$Q_m = Q_1 - \Delta R_1/\Delta R_2 \cdot Q_2$$

Typical plots of resistance versus time for the exothermic change, are shown in Fig. 8. In this case the change of resistance on mixing

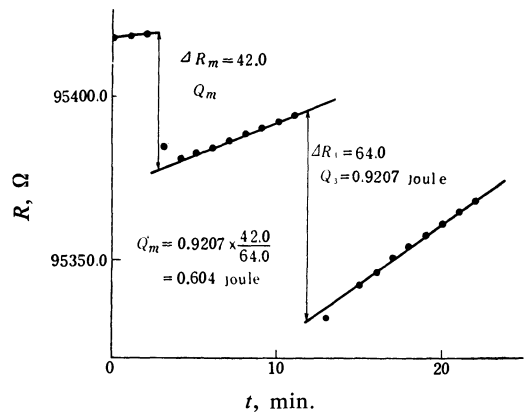

Fig. 8. Typical resistance vs. time curve for exothermic heat of mixing.

$\Delta R_m$ is obtained by linear extrapolation of the plots of resistance-versus time as described above. If the change of resistance due to the supply of a known amount of electrical energy $Q_3$ be $\Delta R_3$, the heat of mixing for this case is given by,

$$Q_m = \Delta R_m/\Delta R_3 \cdot Q_3$$

by assuming again that $\Delta R_m$ and $\Delta R_3$ are proportional to the corresponding change of temperature $\Delta T_m$ and $\Delta T_3$.

**The Sensitivity and the Errors.** — The heat sensitivity is about $10^{-2}$ joule/Ω and the change of resistance can be measured precisely to 0.1 Ω, and thus the change of heat of $10^{-3}$ joule can be detected.

The errors in the final result may arise from the following sources;

1) the error due to the measurement of time,

2) that due to the measurement of the current which passes through the calorimeter heater,

3) that due to the weighing and the filling of the samples,

4) that due to the omission of the correction of heat exchange between the calorimeter and the surroundings.

For 1 the frequency of the crystal oscillator is precise to $\pm 10^{-5}$, and the error in counting is $\pm N$ count, where $N$ is the number of operation of the gate circuit. $N$ is usually within five, and one count corresponds to $10^{-4}$ sec. and the integral time registered on the counter is from 10 to 100 sec., the relative error in the measurement of time is between $5\times10^{-5}$ and $5\times10^{-6}$.

Thus the total number of errors due to 1 is at most $\pm 5\times10^{-5}$.

For 2 the potential drop acrose the 10 Ω standard resistor is measured accurately to $\pm 0.5\times10^{-4}$ V. The current is of the order of a few to several tens of mA, then the potential drop across the standard 10 Ω resistor is of the order of several tenths of a volt. The relative error is at most $\pm 5\times10^{-4}$.

The resistance of the calorimeter heater is measured accurately to ±0.005 Ω in about 50 Ω. The relative error in the precision is $\pm 10^{-4}$.

For 3 the weighing of the samples is performed with the error of 0.5 mg. and the minimum weight of the samples taken is of the order of 100 mg. Then the relative errors would be at most $\pm 5\times10^{-3}$.

In the filling processes is sometimes occurs that a very small quantity of mercury enters into the needle of the syringe which can not be noticed until the next filling. When it is noticed, the drop of mercury is taken into a

weighing bottle and is weighed and the correction is made to the former weight of the liquids.

If it is left unnoticed or noticed in the fillings after the next or further filling, then the correction cannot be made and this amounts to a few milligrams. In this case, the errors from this source may amount to a few per cent at most.

For 4 no quantitative evaluation can be made because during the course of thermal compensation the temperature versus time relation can not be recorded by this apparatus.

In a course of inspection of the data, it was noticed that when the compensation currents had been large, the values of heats absorbed obtained by the above mentioned procedure were a little greater than that when the compensating current had been small.

The errror due to the heat exchange in the endothermic cases might be a few per cent. In the exthermic cases the error due to linear extrapolation might be a few per cent, and in endothermic cases this kind of error may be extremely small due to thermal compensation.

The final error arising from all these sources above mentioned, though the errors from 3 and 4 are the largest, may amount to a few per cent.

**Summary**

A semi-automatic microcalorimeter is constructed which is convenient for a large number of the measurements of heats of mixing of two kinds of liquid.

The calorimeter is equipped with a removable mixing vessel, its holder, and a container, by which the efficiency of the measurement is much increased. Automatic registering of the time intervals during which the electrical current is supplied to the calorimeter, as well as automatic thermal compensation for endothermic systems, are performed. It is another feature of the apparatus to require only less than 1 cc. of each component for each measurement. The elimination of the vapor phase of the liquids in the mixing vessel makes the results certain. The heat sensitivity is $10^{-3}$ joule.

The author wishes to express his thanks to Professor R. Fujishiro of Osaka City University and to Professor Y. Morino of the University of Tokyo for their constant encouragement throughout this work.

# *Thermodynamical Studies on Binary Systems Consisting of Polar and Non-polar Liquids. II. The Measurement of the Heats of Mixing for Binary Systems of Polar and Non-polar Liquids*

By Kazuo AMAYA*

(Received March 1, 1961)

The heats of mixing for 22 binary systems of polar and non-polar liquids were measured. Each pair of polar and non-polar liquids had nearly equal molecular volume. This was done in order to see how the magnitude of the dipole moment of the constituent polar molecules relates to the thermodynamical properties of the binary systems.

## Samples

**Selection of the Pairs of Polar and Non-polar Liquids.**—In selecting pairs of polar and non-polar liquids which are suitable for use in investigating the effect of the dipole moments of the constituent molecules on the heats of mixing the following points were taken into account.

1) The molecular volumes of polar and non-polar components in each pair are nearly equal to each other. This eliminates the effect of the difference of molecular size and makes the effect of the dipoles as clear as possible.

2) The polar molecules have various degrees of magnitudes of dipole moment.

The pairs of polar and non-polar components for which the heats of mixing were measured are shown in Table I with their molar volumes and dipole moments.

It is considered that the observed heats of

| Methylcyclohexane | 128.38 | Chlorocyclohexane | 119.37 | 2.07 |
| | | Bromocyclohexane | 124.43 | 2.15 |
| *trans*-Dichloroethylene | 77.28 | *cis*-Dichloroethylene | 76.12 | 1.89 |
| Benzene | 89.40 | Pyridine | 81.31 | 2.20 |
| 1,4-Dioxane | 85.80 | Pyridine | 81.31 | 2.20 |

mixing of polar and non-polar liquids contain both contributions from the non-electrostatic dispersion forces and those from the electrostatic dipolar and higher multipolar forces.

The former contribution may be small if the pair of polar and non-polar molecules have molecular structures similar to each other except in the case of the dipole moment. For such binary mixtures, the observed heats of mixing may be considered to be approximately equal to the contribution only from the dipoles of the polar molecules.

Thus at the beginning of the experiment, the measurements were made for the pairs of polar and non-polar molecules not only of similar molecular volume but also of similar molecular structure such as toluene—benzene derivatives (chlorobenzene, bromobenzene, nitrobenzene and benzonitrile), benzene—pyridine, *trans*-dichloroethylene—*cis*-dichloroethylene, methylcyclohexane—halocyclohexanes and cyclohexane—cyclohexanone systems. Although toluene is not strictly non-polar, its polar effect may be small enough to regard it as non-polar.

In the course of the experiment, anomalies were noticed in a group of the systems which contain aromatic compounds.

To make clear whether these anomalies come from the aromatic character of its polar component or of the non-polar component of the pairs of liquids, the experiment was extended to the pairs of aromatic non-polar—aliphatic polar as well as aliphatic non-polar—aromatic polar molecules.

TABLE II. BOILING POINT OF THE SAMPLES

| Substance | B. p. (obs.), °C | B. p. (lit. value), °C |
|---|---|---|
| Chlorobenzene | 131.5~131.6 | 131.687 |
| Bromobenzene | 155.7~155.8 | 155.908 |
| Nitrobenzene | 207.9~208.1 | 210.80 |
| Benzonitrile | 188.7~189.0 | 191.10 |
| *n*-Butylchloride | 78.2~ 78.3 | 78.44 |
| *n*-Butylcyanide | 140.0~140.8 | 142.25 |
| Diethylketone | 101.7~101.8 | 101.70 |
| Methyl propyl ketone | 101.8 | — |
| Cyclohexanone | 155.2~155.3 | 155.65 |
| Chlorocyclohexane | — | |
| Bromocyclohexane | — | |
| Pyridine | 115.0 | 115.58 |
| *cis*-Dichloroethylene | 60.3~ 60.4 | 60.36 |
| Cyclohexane | 80.4 | 80.4 |
| Toluene | 110.3~110.4 | 110.623 |
| Benzene | 80.1 | 80.103 |
| Methlycyclohexane | 100.8 | — |
| 1,4-Dioxane | 101.2 | 101.32 |
| *trans*-Dichloroethylene | 47.3 | 47.67 |

Cyclohexanone, diethyl ketone, and methyl propyl ketone were selected to show the effect of molecular shape and that of the position of the dipole in the molecule.

**Purification of the Samples.** — Most samples were purified from the commercially available purest products according to the methods described in the literature[1] and were finally distilled under normal pressure, with a concentric vaccum jacketed column of about 40 theoretital plates.

Bromocyclohexane and chlorocyclohexane were kindly donated by Dr. M. L. Huggins of the Eastman Kodak Co. Both compounds decompose at their boiling point under normal pressure, so they were used without further purification.

In Table II the boiling points of the samples are shown with the values given in the literature. The thermometer used for the distillation was not corrected by a standard thermometer. Also the boiling points were not corrected for the atmospheric pressure.

## Results and Discussion

The results of the heat of mixing for the 22 binary systems of polar and non-polor liquids are shown in Tables III and IV, in which the following notations are used.

$v_2$: Volume fraction of the polar liquids.

$x_2$: Mole fraction of the polar liquid.

$w_2$: Weight of the polar component taken for the measurement in grams.

$w_1$: Weight of the non-polar component taken for the measurement in grams.

$\Delta H_{\mathrm{m\ obs}}$: The observed heat of mixing in joule.

$\Delta H_{\mathrm{m}}$/cc.: The observed heat of mixing per unit volume of the mixture in joule.

$H^{\mathrm{E}}$: The heat of mixing per mole of the mixture in joule.

$\alpha$: The coefficient of the van Laar formula for heats of mixing of liquids. It is related to the heat of mixing by the relation

$$\Delta H_{\mathrm{m}} = \alpha \cdot V(1-v_2) \cdot v_2$$

where $V$ is the total volume of the mixture.

The volues of $\alpha$ are plotted against $v_2$ in Figs. 1 and 2, $\Delta H_{\mathrm{m}}$/mol. is plotted against $x_2$ in Figs. 3 and 4.

For the systems in which the non-polar component is non-aromatic, the coefficient $\alpha$ can be expressed approximately by the following quadratic expressions except for nitrobenzene-cyclohexane systems. For the systems in which the non-polar component is aromatic, $\alpha$ cannot be expressed by a simple formula.

It is obvious from the above figures that for the systems where non-aromatic molecules such as cyclohexane and methyl cyclohexane are selected for the non-polar component (denoted as group I hereafter) the values of $\alpha$ are positive and increase smoothly as the volume fractions of polar component $v_2$ decrease. It is in sharp contrast to the cases of mixing of two non-polar liquids where the values of $\alpha$ are nearly constant over the whole range of concentrations[2].

The larger the dipole moment of the polar molecules the larger the variation of the values of $\alpha$ with concentration. This suggests that

the change of the values of $\alpha$ with concentration originated from the effect of the dipoles of the polar constituents.

However, for the systems in which aromatic compounds such as toluene or benzene are the non-polar components (denoted as group II hereafter), most of the values of $\alpha$ decrease with the decrease of $v_2$ in most concentration ranges, and their variation seems to have no aparent relation with the dipole moment of the polar components.

Furthermore the values of $\alpha$ are much smaller than the corresponding systems of group I containing the same polar component and cyclohexane and are negative for most of these systems. This is a marked difference in comparison with group I.

It is difficult to interpret these differences by electrostatic energy only, for the dielectric constant of toluene does not differ so much from that of cyclohexane, and the electrostatic energy for both can also not be expected to differ greatly. It is concluded from the experimental results that the structural difference between aliphatic and aromatic non-polar liquids is responsible for these differences, for these anomalies are independent of whether the polar components are aromatic or not. This is in accordance with the fact that benzene shows an anomalous solvent effect in dielectric measurement.

As is seen from Fig. 2, for the systems of group II non-polar components, most of the values of $\alpha$ are negative, and if positive, these are small and do not change greatly with concentration as those systems in group I.

The effect of the dipole of the polar component, as is observed in the systems of group I, is also shown for such systems of group II as contain polar molecules of large dipole moment, in which the values of $\alpha$ begin to

increase with the decrease of $v_2$ at low concentrations of polar molecules. This may be interpreted as follows: in the systems of group II two effects must be taken into account; the one is that governed by the magnitude of the dipole moment of the polar component, and is similar to that observed in the systems of group I and the other is a kind of stabilizing effect, specific, or coherent to the aromatic character of non-polar liquids such as toluene or benzene.

For *cis*-dichloroethylene—*trans*-dichloroethylene and pyridine—dioxane systems the values of $\alpha$ are smaller than that of the other group of the systems of polar-non-aromatic non-polar pairs. This may be due to the quadrupole of their components.

## Summary

The heats of mixing were measured for 22 binary systems of polar and non-polar liquids where the pairs of liquids have similar molecular sizes.

For the systems in which the non-polar components are non-aromatic, the van Laar coefficients $\alpha$ are positive and increase smoothly as the concentration of polar liquids decrease. This variation of $\alpha$ with concentration is attributed to the effect of dipole of the polar component.

However, for the systems where the non-polar components are aromatic, the values of $\alpha$ are smaller than that of the corresponding non-aromatic system and are even negative for most of the cases and decrease with concentration of polar component in most concentration ranges.

The sharp difference between two groups of the binary systems, was attributed to the structural difference of aromatic and non-aromatic non-polar components.

The effect presumably due to the quadrupole of the non-polar components was noticed.

The author wishes to express his thanks to Professor R. Fujishiro of Osaka City University and to Professor Y. Morino of the University of Tokyo for their constant encouragement and discussions.

# *Studies on Leucomycin. V. Isolation of Mycarose-4-isovalerate from Leucomycin $A_1$*

By Tetsuo WATANABE, Hisao NISHIDA and Kazuo SATAKE

(Received February 21, 1961)

Leucomycin $A_1$ is a main component of the basic antibiotic complex produced by *Streptomyces kitasatoensis Hata*[1,2]. As described in the previous papers, the main antibiotic isolated from the complex by counter current distribution with the use of a solvent system composed of benzene, chloroform, methanol and water[3], possessed one nitrogen and gave an amino sugar, mycaminose ($C_8H_{17}NO_4$) on drastic acid-hydrolysis[4]. In this paper, we wish to report the isolation of another sugar moiety from the mild acid-hydrolyzate and the identification of it as mycarose-4-isovalerate or its steric isomers.

By the action of methanolic hydrogen chloride, leucomycin $A_1$ ($C_{46}H_{81}NO_{17}$, m. p. 135~138°C, $pK'_a$ 7.1) was split into another basic compound I ($C_{34}H_{59}NO_{13}$, m. p. 154~155°C, $pK'_a$ 8.1) and a neutral oily substance II ($C_{13}H_{24}O_5$, b. p. 115~117°C/1.5 mmHg). The latter oil showed reducing properties only after the removal of the one acid-labile *O*-methyl group. These facts seemed to indicate that there had occurred a methanolysis of the neutral sugar moiety of leucomycin $A_1$. The methyl glycoside possessed an intense infrared absorption at 1745 $cm^{-1}$ and did not consume periodic acid under usual conditions*1. On alkaline hydrolysis at room temperature, however, II gave a mixture of two isomeric methyl

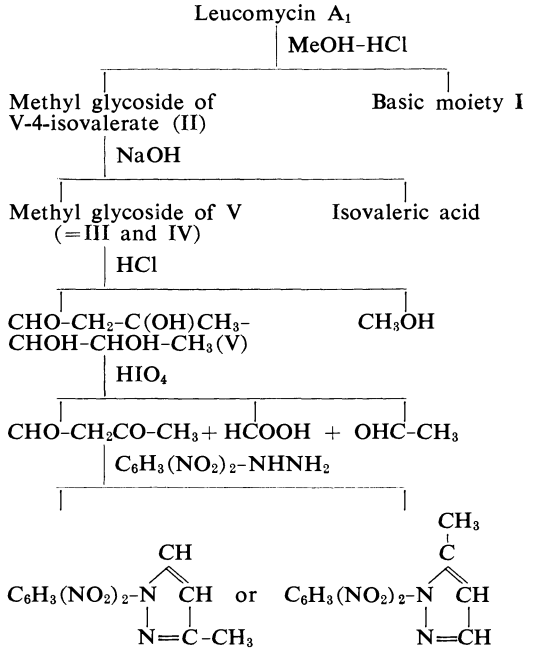
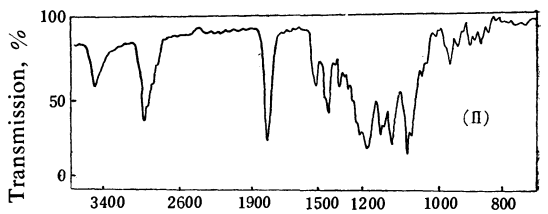
4) T. Watanabe, ibid., 34, 15 (1961).

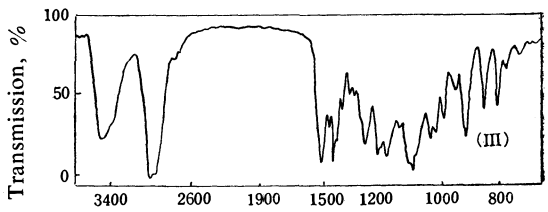
*1 The present author had no evidences to presume whether II was $\alpha$-, $\beta$- or a mixture of both glycoside isomers.



glycosides, III ($C_8H_{16}O_4$, m. p. 59~61°C) and IV ($C_8H_{16}O_4$, b. p. 115°C/1.5 mmHg), both of which consumed periodic acid; isovaleric acid was also obtained which was identified as the *S*-benzylthiouronium salt (m. p. 153°C). These results indicate that II is an isovarelyl ester of a neutral sugar glycoside.



The *O*-methyl group of III was easily split with dilute mineral acid at room temperature, giving a reducing sugar V ($C_7H_{14}O_4 \cdot H_2O$, m. p. 89~90°C). The sugar V which possessed two *C*-methyl groups and three hydroxyl groups, gave a positive iodoform reaction, and rapidly consumed one mole of slightly alkaline iodine, indicating that V was a branched deoxyaldose. The sugar V dissolved in concentrated sulfuric acid with an intense red brown color, a behavior similar to that of intact leucomycin[3,4], and V as well as II showed a characteristic color with vanillineperchloric acid reagent on paper, which had been reported to be specific to 2-desoxyaldose[5].



Upon periodate-oxidation, the sugar V consumed one mole of the oxidant rather rapidly and an additional one mole slowly, and produced one mole each of formic acid and acetaldehyde. The former was identified as the *p*-bromophenacyl ester (m. p. 100~101°C) and determined quantitatively by alkaline titration, while the latter was identified as the 2, 4-dinitrophenylhydrazone (m. p. 160~161°C) and assayed photocolorimetrically with the use of *p*-hydroxybiphenyl[6]. Beside the abovementioned two products, 1-(2, 4-dinitrophenyl)-3(or 5)-methylpyrazole ($C_{10}H_8N_4O_4$, m. p. 139~140°C) could be isolated from the reaction mixtures of periodate-oxidized products*2 of V with 2, 4-dinitrophenylhydrazine, indicating the formation of acetacetaldehyde from V[7,8].

These results seemed to indicate that the sugar V was a 2, 6-deoxy-3-methylaldose, thus mycarose which had already been isolated from magnamycin by Woodward et al.[9], or its steric isomer.

Isovaleric acid liberated from II by the action of alkali seemed to be originally attached to the C-4-position of V as the ester. This was because the derivative II, unlike the free V, had an intense infrared absorption at 1745 $cm^{-1}$ (see Fig. 1) presumably due to the presence of the ester linkage and because it did not

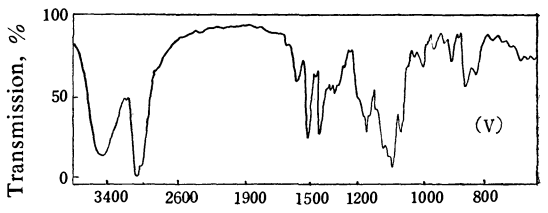


Fig. 1. Infrared absorption spectrum of II, III and V.

*2 An oxidized mixture resulted from one mole of periodate per mole of V, as the mixture contained acetaldehyde in a much lower ratio.

consume periodate under the usual conditions.

Intact leucomycin $A_1$ has one *O*-methyl group, that is acid-stable[10], while the methyl glycoside II derived from leucomycin $A_1$ with methanolic hydrogen chloride at room temperature is acid-labile. Accordingly the neutral sugar moiety (V-4-isovalerate) appears to be linked with another moiety I containing the basic mycaminose residue, as a glycoside, and to be methanolyzated by the above-mentioned treatment. In this respect, a marked difference should be emphasized among the $pK'_a$ of the basic moiety I ($pK'_a$ 8.1), intact leucomycin $A_1$ ($pK'_a$ 7.1) and diacetyl leucomycin $A_1$ ($pK'_a$ 5.1)*[3,11]. Sucha stepwise decrease in the $pK'_a$ values of the dimethylamino group[4] of mycaminose residue, might be interpreted by a successive blocking effect of two hydroxyl groups adjacent to the dimethylamino group. Thus V-4-isovalerate might be linked to the 4- or 2-position of mycaminose residue.

## Experimental

**Leucomycin $A_1$.**—The leucomycin complex used in this experiment was a commercial bulk, Lot No. 9LM-47, which was kindly given by the Research Institute, Toyo Jozo Co., Ltd. Leucomycin $A_1$ was isolated from the complex by a counter current distribution technique, as already reported by the present authors[3].

**Methanolysis of Leucomycin $A_1$.**—Leucomycin $A_1$ (20 g.) was dissolved in 100 ml. of methanol containing 1% hydrogen chloride and the solution mixture was allowed to stand for 18 hr. at 5°C. Thereafter, the reaction mixture was neutralized to pH 4 with diluted sodium hydroxide, concentrated under reduced pressure to remove methanol, diluted with water and extracted with ether (three times, 200 ml.-, 100 ml.- and 100 ml.-portions). The ether extract gave 4 g. of colorless oily liquid II, b. p. 115~117°C/1.5 mmHg, $[\alpha]_D^{25}$ −9.87 (*c* 3 in chloroform).

Found: C, 59.38; H, 9.59; $OCH_3$, 11.51. Calcd. for $C_{13}H_{24}O_5$: C, 59.98; H, 9.29; $OCH_3$, 11.90%. From the remaining aqueous layer, 8 g. of I was crystallized out on adjusting the pH to 8, m. p., 154~155°C (recrystallized from acetone-water)+.

Found: C, 59.14; H, 8.73; N, 1.97. Calcd. for $C_{34}H_{59}NO_{13}$: C, 59.22; H, 8.56; N, 2.03%.

**Alkaline Hydrolysis of II.**—Two grams of II was dissolved in 40 ml. of aqueous sodium hydroxide (1 N) and the solution was allowed to stand for 3 days at room temperature. The hydrolyzate was neutralized to pH 7 with hydrochloric acid, concentrated to dryness in vacuo and the residue was extracted continuously with chloroform. The chloroform extract gave 700 mg. of III (b. p., 76~78°C/1.5 mmHg, m. p., 59~61°C) and 500 mg. of IV (b. p., 115~116°C/1.5 mmHg, not solidified).

Found (for III): C, 54.76; H, 8.97; $OCH_3$, 17.03. Calcd. for $C_8H_{16}O_4$: C, 54.63; H, 9.15; $OCH_3$, 17.62%.

Found (for IV): C, 54.70; H, 9.02; $OCH_3$, 17.23%.

The chloroform-insoluble residues were dissolved into 0.1 N sulfuric acid and steam-distillated. The distillate gave a crystalline *S*-benzylthiouronium salt (m. p., 152~153°C, recrystallized from ethanol) which showed no depression on admixture with authentic *S*-benzylthiouronium isovalerate.

Found: C, 57.95; H, 7.39. Calcd: for $C_5H_9O_2 \cdot C_8H_{11}N_2S$: C, 58.24; H, 7.42%.

**Acid Hydrolysis of III.**—Seven hundred milligrams of III was dissolved in 40 ml. of 0.1 N sulfuric acid and allowed to stand for 45 min. The hydrolyzate was neutralized with aqueous barium hydroxide and the filtrate from barium sulfate was condensed in vacuo to 5 ml. and extracted with ether. The ether layer gave 580 mg. of crystalline solid V, m. p., 89~90°C (recrystallized from ethanol), $[\alpha]_D^{25}$ −25.08 (*c* 3 in water)

Found: C, 46.60; H, 9.40. Calcd. for $C_7H_{14}O_4 \cdot H_2O$: C, 46.41: H, 9.39%.

**Periodate Oxidation of V.**—*Quantitative Oxidation.*—The oxidation was achieved in 0.5% acetic acid at 20°C, with the uses of 0.52 mM of the sugar V and of 4.8 mM of sodium metaperiodate, and an aliquot of the reaction mixture was pipetted out after a given period, for the following analysis. The amounts of periodate consumed, was determined, after the addition of potassium iodide, by the titration with thiosulfate. The amounts of acetaldehyde formed was determined spectrophotometrically with *p*-hydroxbiphenyl[6]. The amounts of formic acid formed was determined by the alkali-titration on the oxidation mixture in aqueous solution instead of 0.5% acetic acid solution. Acetaldehyde and formic acid in the reaction mixture were identified as the 2, 4-dinitrophenylhydrazone (m. p., 160~161°C) and the *p*-bromophenacyl ester (m. p., 100~101°C), respectively. The melting points of these derivatives showed no depression on admixture with each authentic sample, respectively.

*Identification of 1-(2, 4-Dinitrophenyl)-3(or 5)-methylpyrazole with One Mole of Periodate.*—Five hundred milligrams of sugar V (2.78 mM) was dissolved in 50 ml. of water and 600 mg. (2.86 mM) of sodium periodate was added. The solution was allowed to stand for 20 min., then treated with 2, 4-dinitrophenylhydrazine. The bright red precipitate appeared in the solution, was purified on a column of silicagel (1.5×40 cm.) with a mixture of benzene, ethanol and petroleum ether as the developer. The second main band eluted from column gave 75 mg. of a crystal, m. p., 139~140°C (recrystallized from ethanol-ether). Admixture with authentic sample (1-(2, 4-dinitrophenyl)-3(or 5)-methylpyrazole synthesized from acetacetaldehyde and 2, 4-dinitrophenylhydrazine) caused no lowering of the melting point.

Found: C, 48.67; H, 3.60; N, 22.89. Calcd. for $C_{10}H_8N_4O_4$: C, 48.39; H, 3.25; N, 22.57%.

*3 Free mycaminose, itself, possessed a $pK'_a$ at 8.1[4].

# *Thermo-magnetic Study of Mercury and Dilute Amalgams of Sodium and Potassium*

By S. SRIRAMAN and V. SHANMUGASUNDARAM

(Received February 9, 1961)

The idea of the probable existence of definite compounds between mercury and an alkali element has been suggested by several investigators from their work on vapor pressure[1], surface tension[2] and electrical conductivity[3] measurements of these amalgams. But similar investigations by different authors[4-8] on these amalgams have failed to show any such compound formation. Rao and Aravamuthachari[9] have studied the magnetic susceptibility of dilute alkali amalgams at room temperature. At very low concentration of amalgams lithium showed an increase of diamagnetic susceptibility while the other alkali metals indicated a decrease. Klemn and Hauschulz[10] made magnetic measurements on alkali amalgams at 20 and $-180$°C. The maximum and minimum in $\chi$-concentration curves have been explained as due to the formation of compounds. The magnetic study of dilute alkali amalgams at higher temperatures may throw more light on the structure of the alkali amalgams. Hence the present investigation has been taken up.

## Experimental

Sodium, potassium and mercury used in this investigation were of the highest purity. The amalgams were prepared in vacuum with a specially prepared pyrex apparatus (Fig. 1) by distillation.

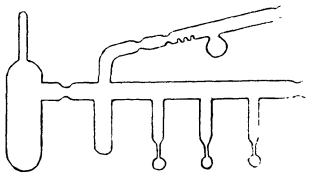

Fig. 1. The pyrex apparatus to prepare the amalgam.

The estimation of alkali content was carried out in accordance with improved procedure for the alkalimetric titration given by Lewis Adams and Lanman and described in detail by Rao and Aravamuthachari[9].

The specific susceptibilities of mercury, the two alkali metals and the amalgams were found by the Curie retorsion method using the vacuum arrangement described by Venkateswarlu and Sriraman[11]. For each specimen $\chi$ values were determined for four different field currents. Graphs were drawn between $\chi$ and $1/H$ for each specimen and in all cases the points were found to plot themselves in a horizontal straight line showing the complete

TABLE I. SUSCEPTIBILITY OF MERCURY, SODIUM AND POTASSIUM

| Substance | Number of bulbs studied | $\chi_s$ Observed | $\chi_s$ by others | | | |
|---|---|---|---|---|---|---|
| Mercury | 5 | −0.169 | −0.1675[12] | −0.166[9] | −0.1610[13] | −0.1667[10] |
| Sodium | 4 | +0.599 | +0.644[10] | +0.60[11] | +0.60[9] | +0.59[14] |
| Potassium | 4 | +0.462 | +0.532[10] | +0.460[11] | +0.52[9] | +0.51[14] |

absence of ferromagnetic impurities. For the calculation of $\chi$ the value for benzene ($0.702\times10^{-6}$) is taken as standard.

## Results

The results obtained for mercury and the two alkali metals are given in Table I. The values of susceptibility given in this report indicate those in $10^{-6}$ c. g. s. units.

Two mercury bulbs were studied at different temperatures between 30°C and 240°C. The results obtained are given in Table II. The fall in $\chi$-values of mercury is found to be slightly larger than reported by Bates and Baker[12].

TABLE II. $\chi_s$ (DIA) OF MERCURY AT DIFFERENT TEMPERATURES

obtained. Four of the above sodium amalgam bulbs and seven of the above potassium amalgam bulbs have been subjected to temperature study in the range 30°C to about 210°C. The results obtained (Table IV) show that, for each specimen, the $\chi_s$ values of the two amalgams remain practically constant at all temperatures.

## Discussion

When very small quantities of a metal goes into solution in mercury one of the three things may hapen; (1) a compound may be formed (2) the metallic atoms may exist in a state of solid solution in mercury and (3) the metal may get dispersed into atoms, each atom, being surrounded by a group of mercury atoms forming a complex molecule.

Bent and Hildebrand[1] suggest the presence of a compound $NaHg_{16}$ as it would explain both vapor pressure and electromotive force data. Inoue[15] and his co-workers claim to identify a compound $NaHg_{14}$ by electrolyzing a saturated sodium chloride solution with mercury cathode. These compounds correspond to about 5.5 and 6.5 atomic per cent of sodium. If such compounds are really formed a pronounced change in the susceptibility will normally be obtained at these concentration. Our results show only a very broad minimum at about 6 atomic per cent as illustrated in Fig. 2. In the case of potassium amalgam the variation of susceptibility at very low concentrations is so rapid (Fig. 3) that compound formation could not account for the change. A study of susceptibility of amalgams at these concentrations and at different temperatures may give us some indications regarding the formation or otherwise of a compound. Our results (Table IV) do not show any such indication. The $\chi_s$ values for amalgams of these concentrations are found to be practically constant at all temperatures. It may be observed that for potassium amalgams the minimum is fairly sharp at 0.3 atomic per cent of potassium. The magnetic investigations of alkali amalgams at 18°C by Klemn and Hauschulz[10] have not indicated the formation of compounds at such low concentrations.

According to Rao and Aravamuthachari[9] the alkali atoms do not even exist in a state of solid solution and they have advanced reasons from electrical conductivity data. Inoue and his co-workers[16] have discussed the structure of sodium amalgam with reference to the amalgamation potential, equilibrium potential, electrophoresis, surface tension and viscosity. The structure of the amalgam was considered as a colloidal state.

Rao and Aravamuthachari[9] suggest that when an exceedingly small quantity of an alkali metal is introduced into mercury it is likely that it is dispersed into atoms and each atom is surrounded by a group of mercury atoms forming a complex molecule. It seems quite probable that the initial fall in the diamagnetic susceptibility of mercury is due to this cause. As concentration increases the alkali atoms join in pairs and these pairs of alkali atoms are surrounded by a group of mercury atoms, the decrease of diamagnetism would rapidly disappear and diamagnetism increases. For these to occur, single atoms of the alkali elements should possess a high paramagnetic component and double atoms a strong diamagnetic component. Ample evidence for the former property is borne out by the experiments of Bates and Tai[17], who find that many metals which are diamagnetic in the solid state appear to possess a large paramagnetic component in the amalgam. Also a few metals like manganese which are paramagnetic in the solid state appear to possess nearly 20 times the paramagnetic susceptibility when dissolved in mercury. That two paramagnetic atoms joining together producing a

15) Y. Inoue and A. Osugi, *J. Electrochem. Soc. Japan*, **20**, 502-513 (1952).

16) Y. Inoue, A. Osugi and T. Amawa, ibid., **22**, 121-6 (1954).

17) L. F. Bates and L. C. Tai, *Proc. Phys. Soc.*, **48**, 795 (1936); ibid., **49**, 230 (1937).

diamagnetic molecule is illustrated by the example of hydrogen. Both the amalgams studied exhibit these effects though in the case of sodium amalgam the initial fall is not as rapid as in potassium amalgam.

The problem could be considered from the point of view of the influence of change in the specific volumes. Maey[18] has shown that the specific gravity of alkali amalgam diminishes rapidly even at low concentrations. The addition of only 0.6% by weight of sodium changes the specific gravity from 13.596 to 12.956. This change corresponds to what would have been obtained, if the mercury had been heated from 0 to 260°C. According to Stoner such an increase in volume would be accompanied by an increase of the paramagnetic susceptibility component of the free electrons. The fall observed in the susceptibility of the mercury at higher temperatures may be due to this cause.

As the amalgam is heated the volume increases. From the above argument this expansion should lead one to expect a further decrease in susceptibility. But the values for the two amalgams for the concentrations studied are not affected by rise of temperature. Is it possible that the lowering of susceptibility due to heating might be compensated by the rise in diamagnetic susceptibility due to the formation of more pairs of alkali atoms in the amalgam? This will mean that such pair formation is induced by temperature.

## Summary

The susceptibility of pure mercury was determined at different temperatures. Sodium and potassium amalgams were prepared in a pure state and the susceptibility of the amalgams of different concentrations at different temperatures was studied. The $\chi$-values of amalgams were found to be practically constant in the range of temperature employed.

The authors wish to express their grateful thanks to Dr. K. Venkateswarlu for his keen and continued interest throughout this investigation.

# *Note on the Electron Spin Resonance of Cupric Oxide-Alumina Catalysts*

By Yoshio MATSUNAGA*

(Received February 20, 1961)

Cupric oxide-alumina is one of the supported catalyst systems examined by Selwood's susceptibility-composition isotherm method. The presence of a plateau of susceptibility of cupric ion at low concentrations is characteristic in this oxide system. The plateau found in the isotherm seemed to suggest that the cupric ions are effectively isolated from each other at low concentrations. However, the paramagnetism which is to be expected for isolated copper atoms in the reduced catalyst samples was not observed[1,2]. Here we wish to present the results of an electron spin resonance study of this oxide catalyst system.

Pure gamma-alumina was impregnated with cupric nitrate solution. The mixture was filtered after standing overnight, dried without washing, and heated in a stream of air at 400°C for six hours. The catalysts containing 0.44 to 16.6 per cent of copper were prepared. Using a Gouy balance as described previously, the magnetic susceptibility measurements were carried out at room temperature[3]. The alumina used in this study was found to have a value of $-0.36\times10^{-6}$ per gram. The gram susceptibility of the cupric ion was estimated on the assumption that the magnetic susceptibilities of cupric, aluminum, and oxide ions are additive and those of the latter two are independent of the composition of catalysts. Curve A in Fig. 1 shows the susceptibility of

cupric ion plotted against the copper concentration. The value below three per cent of copper appears to be nearly constant. The general feature of curve A is quite similar to the curve reported by Jacobson and Selwood[2].

The electron spin resonance absorption was recorded on a spectrometer made by Japan Electron Optics Laboratory Ltd. at room temperature and at a frequency of 10 kMc./sec. No resonance absorption was found in massive cupric oxide with a field modulation of 15 gauss; on the other hand, the derivative of resonance absorption as shown in Fig. 2 was obtained from all of our catalysts. The spectrum seems to arise from the cupric ions with random orientation of tetragonal symmetry axes. The value of $g_\perp$ was estimated to be 2.05 using the method proposed by Kneubühl[4].

4) F. K. Kneubühl, *J. Chem. Phys.*, 33, 1074 (1960).

This absorption must be attributed to the cupric ions in the dispersed state and its intensity can be a measure of the amount of such cupric ions. The relative intensity was given by the ratio of the peak-to-peak intensity to the copper concentration, see $I_p$ of the derivative curve of resonance absorption in Fig. 2. Curve B in Fig. 1 gives the plot of relative intensity to the copper concentration. If our supported cupric oxide consists of a mixture of massive crystalline oxide and the cupric ions which contribute to the resonance absorption, curve B must show a plateau at low concentrations. The relative intensity of resonance absorption was found in a sharp increase in the range where the susceptibility value was nearly constant. Therefore, we may conclude that the above view is incorrect. The presence of another kind of dispersed state, in which the cupric ions do not give resonance absorption but do contribute to the increase of susceptibility value observed at low concentrations, must be taken into consideration. We may assume that the decrease of copper concentration is accompanied by a continuous diminution in the average number of neighboring cupric ions surrounding each cupric ion. At low concentrations each cupric ion may have only a few paramagnetic neighbors, possibly separated farther than in massive crystalline oxide. The interaction between such dispersed cupric ions may be too weak to affect the susceptibility value of these cupric ions, but may contribute to the broadening of resonance absorption to some extent. It seems likely that the observed asymmetric resonance absorption arises from the completely isolated cupric ions, probably dissolved in alumina in the course of the preparation of catalysts, and the cupric ions dispersed on the surface of a carrier and under the weak interaction with neighboring cupric ions give too broad resonance absorption to be detected.

The author wishes to express his hearty thanks to Professor Shizuo Fujiwara for his interest and encouragement.

# *Note on the Oxidation of Perylene in Strong Acids*

By Yoshio MATSUNAGA*

(Received February 20, 1961)

The color reaction in concentrated sulfuric acid is one of the characteristic properties of polycyclic aromatic hydrocarbons and quinones, and has been used by organic chemists for their identification. Handa has measured the absorption spectra of a number of aromatic compounds dissolved in sulfuric acid of various concentrations, and attempted to estimate their basicities[1]. On the other hand, it has been pointed out by several authors that aromatic hydrocarbons in sulfuric acid show ESR absorption[2,3]. The paramagnetic species has been assigned by Weissman as a positive ion formed by oxidation. Hoijtink and Weijland have reported that the visible spectrum of a perylene solution in sulfuric acid resembles very closely that of a mononegative ion of this hydrocarbon[4].

In order to elucidate the nature of the species existing in sulfuric acid we attempted to study the oxidation of perylene by the optical and ESR methods. We examined the absorption spectrum of perylene dissolved in 70 per cent perchloric acid and observed two bands, at 503 and 530 m$\mu$, which are located at nearly the same position as the one in sulfuric acid (see Fig. 1a and c.). We attempted also the oxidation of perylene in perchloric acid using potassium ferricyanide and the isolation of the product. Weiss reported in 1941 that the salts of some other aromatic hydrocarbons were prepared by oxidation in strongly acidic media[5]. The black reaction mixture was washed with a slightly diluted perchloric acid, in which the oxidized perylene was found to be only very sparingly soluble, and examined by an ESR spectrometer at a frequency of 9 kMc./sec. and at room temperature. A sharp line with a width of about 2.4 gauss at a half power was found. The $g$-value corresponding to the center of the line was estimated, by comparison with DPPH, to be $2.0025\pm0.0003$. The solubility of the product in 70 per cent perchloric acid was found to be much higher than that of the original hydrocarbon, so the main product seems to be ionic, probably the hydrocarbon perchlorate as described by Weiss. Unfortunately the solubility is still not high enough to examine ESR absorption in the dissolved state.

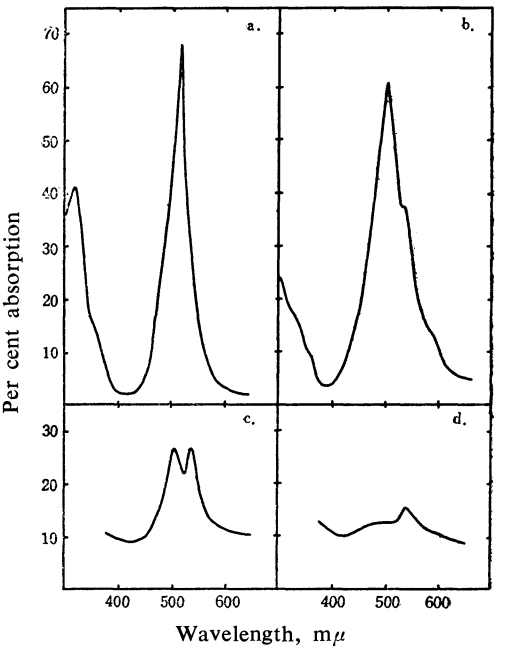

Fig. 1. Absorption spectrum of perylene in strong acids.
a, Dissolved in concentrated sulfuric acid
b, Oxidized perylene in 70 per cent perchloric acid
c, Dissolved in 70 per cent perchloric acid
d, After warming of c for a short time

The spectrum of the oxidized perylene has two bands which are located exactly at the same positions as those obtained by the direct dissolution of the hydrocarbon in perchloric acid. However, as shown in Fig. 1b, after oxidation the intensity of the band at lower wavelength became appreciably higher than the other. Although Dallinga and others have observed a similar spectrum of perylene by the dissolution in hydrogen fluoride and by the contact with oxygen, the band at higher wave-

length was found to be stronger in their case[6]. It seems to be evident that the band at lower wavelength is due to the paramagnetic ion formed by oxidation and the other is due to some other species derived from perylene. It is unlikely that the latter species is the protonated perylene, because no strong band was observed in this region of the spectrum of perylene in oxygen-excluded hydrogen fluoride[6]. The oxidation of perylene without the addition of an oxidizing reagent seems to be due to the presence of molecular oxygen dissolved in perchloric acid or combined with the hydrocarbon**. An attempt to accelerate the oxidation reaction of perylene in perchloric acid was made by warming. However, the band at 503 m$\mu$ decreased its intensity quickly (see Fig. 1d.). This observation shows that the band at the low wavelength side is due to a unstable species and seems to be not inconsistent with the above conclusion.

As it is convincing that only a part of perylene dissolved in concentrated sulfuric acid is paramagnetic[2,7], there must be again two or more species derived from perylene. Therefore, it seems likely that, as shown by the presence of a shoulder on the low wavelength side, the band due to the monopositive ion in sulfuric acid overlaps the band due to some other species.

The author attempted also the oxidation of tetracene in perchloric acid using ferricyanide and obtained a deep green solution and an unstable black precipitate. The absorption spectra of tetracene oxidized in perchloric acid and tetracene dissolved in sulfuric acid are rather complicated and the intensity ratios of bands depend on the time. Although the complete assignment has not yet been made, it appeared that there are three or more common species in these two solutions.

# *Reduction of Organic Compounds with Urushibara Catalysts under High Pressure. IX*[1]. *Reduction of Some Carbonyl Compounds with Urushibara Catalysts Prepared by Various Modified Methods*

By Shin-ichi TAIRA

(Received March 17, 1961)

In the preceding paper[1] of this series, catalytic reduction of acetophenone with various Urushibara nickel catalysts, especially with the catalyst prepared from preserved precipitated nickel and with the regenerated catalyst, was reported. The procedure for preparing the Urushibara catalysts has been successively modified and some varieties of the catalysts, namely, U-Ni-B[2-7], U-Ni-BA[5,6,8], U-Ni-$NH_3$[9], U-Ni-CB[7], U-Ni-A[3-7,10], U-Ni-AA[11], U-Ni-CA[7], U-Co-B[7,9,12,13], U-Co-CB[7], U-Co-A[7,13], U-Co-CA[7], U-Cu[7] and U-Cu-C[7], were developed. Each of them has intrinsic characteristics and can be used properly in accordance with the substance to be reduced. The preparation of the Urushibara catalysts is divided into two steps, that is, the preparation of precipitated metals and the digestion of them with acid or alkali. Therefore the

nature of an Urushibara catalyst is decided by the method of preparation and digestion of precipitated metal.

In the present paper, reductions of deoxybenzoin, benzoin, benzil and furil with the Urushibara catalysts prepared by various methods are studied, and the further modifications of the preparation of the catalyst are presented.

## Experimental

**Apparatus.**—Reductions were carried out in an electro-magnetically stirring type autoclave having a capacity of 100 ml. (the Sakashita SE-10 type). For the reduction of furil, SE-20 (200 ml. capacity) was used.

**Materials.**—Deoxybenzoin was prepared from phenylacetyl chloride and benzene by the Friedel-Crafts reaction[14]. The crude material was purified by distillation under reduced pressure and then recrystallized from methanol, b. p. 159.5~160.5°C/6 mmHg, m. p. 55~56°C.

Benzoin was prepared from benzaldehyde[15]. The crude product was recrystallized three times from ethanol, m. p. 133~134°C.

Benzil was prepared by catalytic oxidation of the benzoin with ammonium nitrate[16]. The raw product was recrystallized from methanol, m. p. 96.5~97°C.

Furil was obtained by the same manner from furoin prepared from furfural[17], m. p. 165°C.

**General Procedure for Reduction.**—Catalyst was carefully transferred with ethanol into the autoclave. Then the air present in the autoclave was replaced by hydrogen gas four times. Most operations were carried out under the following conditions: (1) Catalyst was prepared so as to contain 0.5 g. of nickel metal. (2) Sample; 0.05 mol. (deoxybenzoin 9.8 g., benzoin 10.6 g., benzil 10.5 g., furil 9.5 g.). (3) Solvent; ethanol (99%) 50 ml. (4) pH; 9~11. When U-Ni-A, U-Ni-CA or U-Cu-C was used, 0.5 ml. of 5% sodium hydroxide solution was added. (5) Agitation; 40~45 strokes per minute. (6) Reaction temperature; 60~68°C. Agitation was started when the temperature in the autoclave reached 60°C. The heating of the autoclave was regulated so as to get to 60°C within 30~35 min., and then the temperature was kept between 60 and 68°C throughout the operation. (7) Initial pressure; 50~100 kg./cm². As it has been recognized[7] that initial pressure affected only slightly the velocity of reduction of the carbonyl group under 100 kg./cm², the effect of initial pressure was ignored. Depression of pressure was observed at intervals of 5 min. When U-Cu-C was used, reduction was carried out with the catalyst prepared so as to contain 1 g. of copper and at about 130°C.

**Reduction Products.**—*Phenylbenzylcarbinol.*—After the reduction of deoxybenzoin was finished, the catalyst was filtered off and washed with ethanol. The major part of ethanol was distilled off and the hot residue was poured into hot water with stirring and the mixture was cooled in an ice-bath. The precipitate was filtered off and dried. It was recrystallized from petroleum benzin into colorless needles, m. p. 66~67°C. Yield, 91~94% of the theoretical.

*Hydrobenzoin.* — After the reduction of benzoin was finished, the catalyst, mixed with some crystals separated out, was filtered off and washed with hot ethanol to dissolve the crystals. From the combined filtrate, the major part of ethanol was removed by distillation. The hot residue was poured into hot water with stirring. After cooling, the crude hydrobenzoin was filtered off and dried. It was recrystallized from aqueous ethanol into colorless scales, m. p. 139~140°C. Yield, 90~93% of the theoretical.

**Benzoin.**—After the partial reduction of benzil was finished, the contents were filtered off and washed throughly with hot ethanol. After removal of the major part of ethanol from the combined filtrate, benzoin crystallized in prisms, m. p. 132~134°C. Yield, 76~80% of the theoretical.

*Furoin.*—After the reduction of furil, the product was treated by the same procedure as is described above. Pale yellow prisms, m. p. 137~138°C. Yield, 79~81% of the theoretical.

**Preparation of Catalysts.**—The U-Ni-B[2-6], U-Ni-A[3-6,10], U-Ni-CB[7] and U-Ni-CA[7] were prepared by the methods described in the references cited. The others were prepared by the methods described below.

*Precipitated Nickel Prepared by a Simplified Method.*—To the well mixed zinc dust (10 g.) and water (4 ml.) placed in a 50 ml. beaker 4.04 g. of the crystals of commercially available nickel chloride ($NiCl_2 \cdot 6H_2O$) is added at once and the mixture is stirred with a glass rod. Soon reaction begins and a vigorous reaction takes place suddenly within a few minutes. The reaction mixture swells up into a slushy mass. It is washed with 200 ml. of cold water, and then the washing is filtered or removed by decantation. Thus about 13.5 g. of precipitated nickel, containing about 1 g. of nickel contaminated with a quantity of zinc, zinc oxide and basic zinc chloride, was obtained.

*U-Ni-B* was prepared from the above described precipitated nickel (containing 0.5 g. of nickel) by digesting with 80 g. of 10% sodium hydroxide solution at about 50°C for 15 min. The upper liquor was decanted and the residue was washed with two 50 ml. portions of water and then with the same amount of ethanol. The obtained catalyst was less bulky than the usual U-Ni-B and carried a black color (the usual U-Ni-B has rather grayish appearance). Every washing was removed by decantation.

*U-Ni-A* was prepared from the same precipitated nickel (containing 0.5 g. of nickel) by treatment with 75 ml. of 20% acetic acid at ordinary temperature until the generation of hydrogen gas subsided and a solid came up to the surface of the green solution. The solid was collected on a glass filter and washed with each 100 ml. portions of water and ethanol.

17) W. W. Hartman and J. B. Dickey, ibid., **55**, 1228 (1933).

*U-Ni-A Obtained by Treatment of the Precipitated Nickel with Hydrochloric Acid, Abbreviated as U-Ni-A(HCl).*—The precipitated nickel (containing 0.5 g. of nickel), prepared by normal or simplified method, was digested with 240 ml. of 0.75 N hydrochloric acid at ordinary temperature for about one minute until a solid came up to the surface of the green solution. The solid was collected on a glass filter and washed with 200 ml. of water and then with 100 ml. of ethanol.

*U-Cu-C.*—The precipitated copper was prepared by the same way as was reported in the previous paper[7]. It was treated with 200 ml. of 20% acetic acid on a boiling water bath at 80~90°C for about 20 min. At the end of the digestion a solid, adsorbing hydrogen gas, came up to the surface of the solution likely in case of preparing the U-Ni-A. The solid was collected on a glass filter and washed with 200 ml. of water and then with 150 ml. of ethanol. About 2.3~2.5 g. of bulky catalyst, containing copper (about 1 g.) and zinc, was obtained.

In all procedures, distilled water was used for washing except for the preparations of precipitated metals. The solid should be protected from contact with air as far as possible after the treatment of precipitated metals with acid or alkali.

## Results and Discussion

In the reduction of benzophenone[7] and acetophenone[1] to the corresponding alcohols with various Urushibara catalysts, the U-Ni-A was found to be the most useful catalyst. The same conclusion was confirmed also in the reduction of deoxybenzoin, benzoin and benzil. The U-Ni-CB was also found to be highly active (Tables I, II and III).

**Modification of the Preparation of the Catalyst.**—As was reported in the preceding paper[1], the preparation of the Urushibara nickel catalyst was fairly simplified. The

TABLE I. REDUCTION OF DEOXYBENZOIN

Deoxybenzoin 9.8 g. (0.05 mol.); solvent: ethanol (99%, about 50 ml.)

| Exp. No. | Catalyst[a] | Total weight of catalyst, g.[b] | Initial press. kg./cm² | Initial temp. °C | Reaction temp. °C | Time[c] min. |

a) Each U-Ni catalyst was prepared so as to contain 0.5 g. of nickel. The U-Cu catalyst was prepared so as to contain 1 g. of copper
b) The figures were obtained by weighing the dried catalysts after use for reduction.
c) The figures in the parentheses are the time required for reducing each carbonyl group, the first figures being for the first carbonyl group.
d) The catalyst was prepared from the newly developed precipitated nickel (c. f. Experimental part).
e) 0.5 ml. of 5% sodium hydroxide solution was added.
f) Supplementary hydrogen gas was charged three times when the pressure dropped to 30 kg./cm².

activity of U-Ni-A or U-Ni-B, prepared from the preserved precipitated nickel, being the same as that of the catalyst obtained from the freshly prepared precipitated nickel, time can be saved to prepare the catalyst if a large quantity of the precipitated nickel is previously reserved. On the other hand, the recovered Urushibara nickel catalysts can be repeatedly used by a simple process of regeneration, especially in form of the U-Ni-A.

As the process for the preparation of the Urushibara nickel catalyst is divided into the preparation of the precipitated nickel and the treatment of it with acid or alkali, the modification of preparing a catalyst can be devised in each of both procedures. Already many modifications have been accomplished, and varieties of the catalyst were reported. The precipitated nickel prepared at low temperature gives a highly active Urushibara nickel C. But the preparation of it requires so much time, that a favorable feature of the Urushibara catalysts to be prepared in a short time is lost. In case of preparing the precipitated nickel from hot aqueous nickel chloride solution and zinc dust on a boiling water bath, a vigorous exothermic reaction is observed. If the heat of the reaction is utilized, the time for preparing the precipitated nickel will be shortend and the procedure may be simplified. For the purpose of attaining this request, it may be suitable to use the concentrated solution of nickel chloride in place of the diluted solution used in the usual preparation. Thus, the first attempt was the addition of a very concentrated nickel chloride solution onto a dry zinc dust, but this method was unsuccessful as the reaction was so vigorous that an uniform agitation was impossible and an uniform deposition of nickel metal on the particles of zinc could not be expected. After several trials, it was found that the most profitable method consists in adding crystals of nickel chloride to the mixture of zinc dust and a little water, and a good precipitated nickel could be prepared in a few minutes.

In the preparation of the U-Ni-A by digesting the precipitated nickel with acid, acetic or propionic acid has been used and formic, butyric and hydrochloric acids had been regarded as unprofitable[3,4,10]. Supposing the action of the acid is to activate the precipitated nickel by generating hydrogen gas, removing the deactivating substances and eroding the surfaces of nickel particles[1], there is no reason that hydrochloric acid cannot be applicable except for some special poisonous action to a nickel catalyst. Therefore the nickel catalyst obtained from the precipitated nickel by treatment with hydrochloric acid is expected to have ability of hydrogenation though it may be lower than those of the other Urushibara nickel catalysts.

**Comparison of the Activities of Various Catalysts.**—The results of reduction of benzoin and benzil with the usual Urushibara nickel

TABLE IV. PARTIAL REDUCTION OF α-DIKETONES

| Exp. No. | α-Diketone | Solvent | Catalyst[a] | Initial press. kg./cm² | Reaction temp. °C | Time min. | Reduction product | Yield % |
|---|---|---|---|---|---|---|---|---|

| 44 | Furil 9.5 g. (0.05 mol.) | Ethanol (100 ml.) | U-Ni-A[b] | 60 | 60～62 | 100 | Furoin | 79 |

a) Each catalyst was prepared so as to contain 0.5 g. of nickel, and in each operation 0.5 ml. of 5% sodium hydroxide solution was added.
b) The catalyst was prepared from the newly developed precipitated nickel (cf. Experimental part).

catalysts and with the newly developed ones are tabulated in Tables II and III. In consideration of the condition of preparing the newly developed precipitated nickel, it is expected that it possesses both natures of the precipitated nickels prepared in hot and in cold conditions. Accordingly the nature of the catalyst obtained from it may be situated between those of the usual Urushibara nickel and the Urushibara nickel C. When the Urushibara nickel catalysts of B type (prepared by digestion with alkali) are used for the reduction in an autoclave, the rates of reduction are influenced by the factors such as the fineness and dispersability of the catalyst, the bulk and the kind of carrier (e. g. zinc, zinc oxide) ete. On the other hand, as the Urushibara nickel catalysts of the A type (prepared by digestion with acid) contain only small quantities of zinc and zinc compounds, if any, and are less bulky than the B type, the inherent activities of the catalysts may dominate the velocities of reduction. In consideration of these facts, the time required for the completion of reduction with various Urushibara nickel catalysts is compared with each other. The activity of each catalyst is not always constant, but it can be approximately estimated by repeated experiments. Both for the reduction of benzoin and benzil, the usual U-Ni-A gives the best results. The U-Ni-A prepared from the newly developed precipitated nickel is somewhat inferior to the usual U-Ni-A, but has enough activity for practical use. The activity of the Urushibara nickel catalysts has been studied[3,18], in connection with the size of their crystallites, which was estimated by X-ray diffraction method. According to the authors, the more vigorous the reaction to prepare the precipitated nickel takes place, the smaller the crystallites of the obtained catalyst become, and the activity of the catalyst is lowered with the growth of the size of crystallites. The size of crystallites of the highly active Urushibara nickel catalysts was reported to be about 40 Å and the same as that of the Raney nickel catalyst. The values obtained by the present author were 39～45 Å for the usual U-Ni-A, and 33～41 Å for the modified U-Ni-A obtained from the newly developed precipitated nickel. On the whole the size of crystallites of the modified U-Ni-A was found to be smaller than that of the usual U-Ni-A. Therefore, the activities of the freshly prepared catalysts may not be discussed only from a standpoint of the size of crystallites, although the catalyst used in Exp. No. 39 gave a smaller value (33 Å) than that (37 Å) of the catalyst used in Exp. No. 310.

The U-Ni-A prepared by digesting the precipitated nickel with hydrochloric acid was proved to be still active though it was inferior to the other U-Ni-A. The cause may be partly due to the small contents of nickel metal and partly to the adsorption of some chlorine compound on the surface of the catalyst. As it has been previously reported[7], the Urushibara copper catalyst has an activity for reduction of a carbonyl group and the U-Cu-C is superior. But the treatment of the precipitated copper with acetic acid at room temperature requires much time. If the temperature of digesting the precipitated metal with acid affects the activity only slightly, it is advantageous to operate the digestion at high temperature. The results obtained with such catalyst are given as Exp. Nos. 213 and 311 in Tables II and III.

**Partial Reduction of α-Diketones.**—In every experiment on the reduction of benzil, a sudden fall of hydrogen uptake was observed after a certain quantity of hydrogen had been absorbed. It is conceivable that the reduction of one carbonyl group of the two has been finished at this point. Then, the partial reduction of α-diketones to α-ketols is expected to be possible under suitable condition. It was realized in the reduction of benzil and furil,

18) Y. Urushibara, M. Kobayashi, S. Nishimura and H. Uehara, *Shokubai*, 12, 107 (1956).

and the results of the partial reduction are shown in Table IV. In case of reducing a carbonyl group to the corresponding alcohol, it has been noticed that the velocity of hydrogen uptake increases at about 60°C and that the reduction is promoted by a trace of an alkali. The reduction in neutral solution being presumed to require a long time for the completion[7], the reduction of benzil to benzoin was carried out with the U-Ni-A added with a little quantity of alkali at room temperature. On the other hand, the partial reduction of furil was practised at about 60°C and in a large quantity of ethanol, as furil dissolves only slightly in ethanol at room temperature.

## Summary

The catalytic reduction of deoxybenzoin, benzoin, benzil and furil with various Urushibara catalysts under high pressure were studied. It was found that benzil and furil was converted into the corresponding $\alpha$-ketols by the partial reduction under proper condition.

Some modifications for the preparation of the Urushibara catalyst were attained. The newly developed precipitated nickel prepared by a very simple way proved to give a catalyst as active as the usual Urushibara nickel catalyst for practical use. Hydrochloric acid was found to be applicable for the digestion of the precipitated nickel in place of acetic acid.

The author expresses his sincere gratitude to Professor K. Hata for his helpful advice and encouragement throughout this work.

# *Conformation and Reactivity of 4-Methylcyclohexylmethyl p-Tosylates*

By Nobuo Mori

(Received January 23, 1961)

The important relation between conformation and reactivity in a cyclohexane system which contains a departing group directly bound to the cyclohexane ring and in an acyclic system has been applied in many areas of organic chemistry[1].

The present work desires to confirm the effect of conformation on the reactivity in a cyclohexane system which contains a departing group bound through a methylene group to the ring, especially by means of substituted cyclohexylmethyl *p*-tosylates. For this purpose, novel *cis*- and *trans*-4-methylcyclohexylmethyl *p*-tosylates have been prepared from the corresponding carbinols which form the basis of the *p*-tosylates, and they were solvolyzed. The *cis*- and *trans*-4-methylcyclohexylcarbinols are prepared by hydrogenolysis of the corresponding 4-methylcyclohexanecarboxylic acid esters under severe conditions, at 250°C under 200 atm. in the presence of copper-barium-chromium oxide catalyst for 10 hr.[2] The author has used advantageously lithium aluminum hydride in dry ether for conversion of the esters into the carbinols.

1) For example, see M. S. Newman, "Steric Effects in Organic Chemistry", John Wiley & Sons, Inc., New York (1956).

## Experimental

**Samples.**—*Cyclohexylmethyl p-Tosylate.*—Benzaldehyde (20 g.) in ethanol (30 cc.) was hydrogenated under 80 initial atm. at a temperature gradually raised to 100°C in the presence of Raney nickel (10 g.) until no more hydrogen was absorbed. The filtered solution was distilled under reduced pressure to give the cyclohexylcarbinol, b. p. 74.5°C/20 mmHg. The carbinol was treated with an equimolecular amount of *p*-toluenesulfonyl chloride in pyridine at 0~5°C, to give the *p*-tosylate as needles, m. p. 30.5°C after recrystallization from aqueous methanol.

Found: C, 62.65; H, 7.51. Calcd. for $C_{14}H_{20}O_3S$: C, 62.55; H, 7.44%.

*cis*-4-*Methylcyclohexylmethyl p-Tosylate.*—A neutral solution of *p*-toluic acid (15 g.) in 10% sodium hydroxide solution in an autoclave was hydrogenated at 180~200°C under 90 initial atm. in the presence of Raney nickel (10 g.) for 2.5 hr. until no more hydrogen was absorbed. The filtered solution was worked up in the usual way, by making it acid with concentrated hydrochloric acid,

extracting the separated oily product with ether, evaporating the ether and distilling the residue under reduced pressure, to give the semi-solid mass (12 g.), b. p. 129~130°C/15 mmHg, which melted at 107~108°C (reported 111°C[3]) after one recrystallization from aqueous methanol. The acid (1.5 g.) so obtained was esterified by refluxing it in ethanol (30 cc.) containing concentrated sulfuric acid (1 g.) for 2 hr., to give the ethyl ester (1.6 g.), b. p. 92~93°C/28 mmHg. The ester in dry ether (5 cc.) was added stepwise into a suspension of lithium aluminum hydride (0.5 g.) in dry ether (50 cc.) at 0~5°C. After stirring for another half an hour, the reaction mixture was treated with a small volume of dilute sulfuric acid sufficiently to make the ether layer clear, and the layer was dried over potassium carbonate and evaporated to dryness. The oily product, which consisted mainly of *cis*-4-methylcyclohexylcarbinol, was treated with *p*-toluenesulfonyl chloride (1.5 g.) in pyridine (3 cc.) and after 3 hr. poured into a mixture of concentrated hydrochloric acid and ice to separate the oily mass which solidified after a few minutes. The solid was recrystallized from aqueous methanol to give the *cis*-tosylate (1.3 g.) as plates, m. p. 44.5~44.7°C.

Found: C, 64.00; H, 8.05. Calcd. for $C_{15}H_{22}O_3S$: C, 63.79; H, 7.85%.

*trans-4-Methylcyclohexylmethyl p-Tosylate.*—*p*-Toluic acid (8 g.) in glacial acetic acid (60 cc.) which had previously been treated with potassium permanganate, was hydrogenated at 70~80°C under atmospheric pressure in the presence of Adams platinic oxide catalyst (0.5 g.)[4] for about 2 hr. without any aeration of the catalyst until no more hydrogen was absorbed. The acetic acid was removed from the filtered solution under reduced pressure and the residue was distilled to give the hexahydro-acid (5 g.), b. p. 133~134°C/20.4 mmHg (reported 135°C/20 mmHg[3]). The acid (2 g.) was similarly converted into the *trans*-tosylate as needles, m. p. 30.5~31.0°C and yield 1 g. after recrystallizations with slight difficulty from methanol in a dry ice-acetone bath.

Table I. Summary of rate constants at 99.8°C

| 4-Substituent | Tosylate $\times 10^2$ mol./l. | Solvent | $k_1 \times 10^4$ $min^{-1}$ |
|---|---|---|---|
| H | 1.57 | HAcO | 2.27 |
| | 1.60 | EtOH | 8.42 |
| *cis*-$CH_3$ | 1.78 | HAcO | 4.34 |
| | 1.79 | EtOH | 7.68 |
| *trans*-$CH_3$ | 1.80 | HAcO | 1.79 |
| | 1.79 | EtOH | 11.0 |
| Ethyl tosylate* | 3.8~4.3 | HAcO | 5.08 |
| Isobutyl tosylate* | 2.5~2.8 | HAcO | 2.28 |

* Calculated from $8.47 \times 10^{-6}$ $sec^{-1}$ and $3.79 \times 10^{-6}$ $sec^{-1}$ respectively in Ref. 6.

3) G. H. Keats, ibid., 1937, 2003.

4) This catalyst was prepared according to the method described in "Organic Synthesis", Coll. Vol. 1 (1948), p. 463.

Found: C, 63.75; H, 7.84. Calcd. for $C_{15}H_{22}O_3S$: C, 63.79; H, 7.85%.

Solvolysis rates were measured at 99.8°C in ethanol (98.5% by weight) and in acetic acid containing a slight excess of acetic anhydride by the usual ampoule technique[5]. The reactions were followed by titrating at intervals for the sulfonic acid liberated during the solvolysis to ca. 50% completion because of slow velocity. The observed kinetics were nicely first order and the precision of the measurements was usually better than 5%. The calculated first order rate constants for the tosylates and also alkyl tosylates for a comparision are summarized in Table I.

## Discussion

Difference in reactivity between the two departing groups restricted respectively in axial and equatorial orientation depends on the difference in energy of the ground state, rather than the transition state; and when the departing group is axial, there is a compensating steric acceleration due to relief of crowding between this axial group and the axial hydrogen atoms in $\gamma$-position, and as a result of this the solvolysis should be quite facile for the axial group, for example as shown by the typical fact[7] that *cis*-4-*tert*-butylcyclohexyl *p*-tosylate is solvolyzed at a rate about 3 times as fast as the corresponding trans-isomer. As a matter of course, the difference disappears in the isomeric 1,2-dimethylcyclohexyl bromides[8] which are nearly equal in the energy of their ground states, and also in the isomeric 1,3-dimethylcyclohexyl chlorides[9].

Thus, in general, the high steric repulsion acting on the departing group as described above results in fast departure of the group, provided the transition state for solvolysis does not include at least any higher electronic effect, such as the inductive effect by substituents especially in $\beta$-position or internal participation of neighboring groups or hydrogens, as shown in the fact[10] that *tras*-2-acetoxylcyclohexyl *p*-tosylate is acetolyzed much faster than the corresponding cis-isomer. Such an electronic effect is probably not included in the transition states of the isomeric tosylates used in the present work.

**Preferred Conformation and Acetolysis.**—The possible chair conformations of the isomeric tosylates used in the present work are as follows:

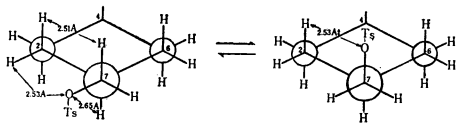
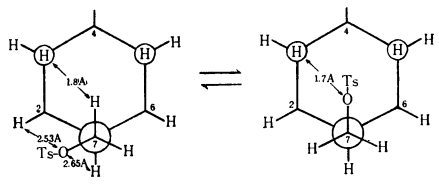
10) S. Winstein et al., ibid., **70**, 821 (1948).



*trans*-(I) *trans*-(II)

*cis*-(I) *cis*-(II)

Fig. 1



where Ts is the *p*-toluenesulfonyl group. The *trans*-(I) should be more stable than the *trans*-(II). On the other hand, the difference in stability between the *cis*-(I) and *cis*-(II) may be very small, and thus the cis-isomer is in the form of the *cis*-(I) in a considerable ground state concentration. Moreover, a favorable conformation of the *p*-toluenesulfoxymethyl group is very important, and for one in equatorial orientation it may be represented by the *e*-(III) and *e*-(IV) in Fig. 2, which are projected along the $C_7$ to $C_1$ axis and also accompanied by distances between non-bonded atoms in question,

*e*-(III) *e*-(IV)

Fig. 2

in which the conformation *e*-(III) will be more stable than *e*-(IV), because in the former only the bulky tosyl group eclipses the equatorial hydrogen on carbon atom 2 while in the latter the tosyl group eclipses the two axial hydrogens on carbon atoms 2 and 6. On the other hand, the toluenesulfoxymethyl group in axial orientation has two possible conformations which are represented respectively by the *a*-(III) and *a*-(IV) in Fig. 3, similarly projected

*a*-(III) *a*-(IV)

Fig. 3

The former, in which only the bulky tosyl group and equatorial hydrogen on carbon atom 2 are opposite one another, should be of lower energy than the latter, in which the distance between the tosyl group and the two axial hydrogens on carbon atoms 3 and 5 is very short. Thus, in such preferred conformations *e*-(III) and *a*-(III), the magnitude of repulsive action on the tosyl group in the axial toluenesulfoxymethyl group may be of the same order as that in the equatorial one; and therefore it will be expected that the isomeric 4-methylcyclohexylmethyl *p*-tosylates are solvolyzed at a nearly equal rate, if only the steric repulsion in the ground states is the governing factor. However, in the present work, the solvolysis in acetic acid as a poor nucleophilic solvent gave the result that the ratio of $k_{cis}/k_{trans}$ was 2.4. The fact may be explained on the possible assumption that, if the solvolysis is a simple carbonium ion process and the solvolysis of the cis-isomer proceeds, at least in part, via the conformation *a*-(III), the difference in energy between the ground state and the consequent possible carbonium ion, such as the *a*-(V) in Fig. 4, for the cis-isomer is very low as compared to that between the ground state *e*-(III) and the carbonium ion *e*-(V) for the trans-isomer. This assumption is probably right, since the high strain on the hydrogen atom in the methylene group in the ground state can substantially disappear in the consequent transition state, though the simple carbonium ion process is not always the governing consideration.

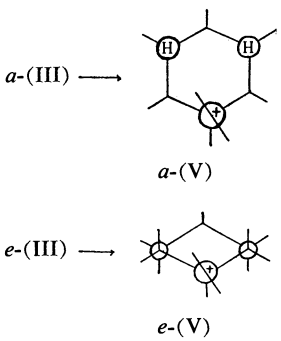


Fig. 4

**Solvent Effect and Ethanolysis.**—The rate of solvolysis of a given compound is generally altered by the solvating power or nucleophilic nature of a given solvent and the solvolysis includes usually solvation of the carbonium ion intermediate and nucleophilic assistance from the solvent molecules. Primary alkyl tosylates tend to be solvolyzed more rapidly in nucleophilic solvents such as ethanol than in acetic acid, and further the relative rates of $k_{EtOH}/k_{HAcO}$ for linear lower alkyl tosylates is higher than that for $\beta$-branched alkyl tosylates. For example, the ratio[6] at 75°C is 39 for ethyl tosylate, 6.2 for isobutyl tosylate and

0.28 for neopentyl tosylate. This would be partly due to the fact that variation from primary tosylate to $\beta$-branched alkyl tosylate would decrease the amount of nucleophilic assistance from the solvent. As the tosylates used in the present work are represented as the $\beta$-branched alkyl compounds in structure, it is expected that behavior of the tosylates in various solvents is approximately in agreement with that of isobutyl tosylate.

From Table II, it is seen that the rate of solvolysis of the trans-form increases according as the solvent changes from acetic acid to ethanol, in agreement with the behavior of primary alkyl tosylates, and the rate enhancing degree, that is, the ratio of $k_{EtOH}/k_{HAcO}$ is 6.1. This rate increasing trend is partly due to the fact that, in the conformation *e*-(III) of the trans-form, ethanol molecules approach more easily to the reaction center atom $C_7$, along the $C_1-C_6$ axis through the two hydrogens on carbon atom 6 in a back side attack manner.

On the other hand, the rate for the cis-form increases slightly under the same solvent sequence and the ratio is 1.7. This lower ratio would be mainly due to that in the conformation *a*-(III) of cis-form the axial hydrogen on carbon atom 5 hinders a similar entrance of solvent molecules along the $C_1-C_6$ axis.

TABLE II. RELATIVE RATES IN DIFFERENT SOLVENTS

| 4-Substituent | H | *cis*-$CH_3$ | *trans*-$CH_3$ |
|---|---|---|---|
| $k_{EtOH}/k_{HAcO}$ | 3.7 | 1.77 | 6.1 |

# *Studies on the Silk-platinum Catalyst. II. General Properties*

By Akira AKAMATSU, Yoshiharu IZUMI and Shiro AKABORI

(Received February 27, 1961)

In the previous paper[1] of this series, the preparation of a silk-platinum catalyst, and its activity and stability were reported. This catalyst is extremely active for the hydrogenation of aromatic nitro compounds.

In the present work it was found that this catalyst was relatively less active for the hydrogenation of other compounds, and showed behaviors in the catalytic reactions, quite unlike the so far known reactions of other platinum catalysts. It is probable that the difference is mainly due to the nature of the carrier silk-fibroin in this catalyst. Various reactions of this catalyst with poisons of catalysts are also described in the present paper.

## Catalytic Efficiency with Various Compounds

In order to examine the catalytic efficiency of the silk-platinum catalyst[1], various compounds were tested for their power of reduction of 200 mg. of the catalyst per mole of hydrogen theoretically taken up, with 90 kg./cm$^2$ of hydrogen, in a 100 ml. autoclave. The results are summarized in Table I, in which are recorded the conditions used for the hydrogenation reaction, the ratios of hydrogen taken up to the theoretical amount, and reaction products and their yields.

**Hydrogenation of Ketones.**—This catalyst was found to be capable of catalyzing the hydrogenation of acetone and ethyl methyl ketone to the corresponding alcohols, but was quite inactive for the cardonyl groups of mesityloxide and acetophenone. In general, it is probable that simple aliphatic ketones can be reduced in the presence of this catalyst, while reduction of carbonyl groups, conjugated with the C=C double bonds and attached to aromatic rings, may be impossible.

**Hydrogenation of Aldehydes.**—A very interesting phenomenon was observed on the hydrogenation of both acetaldehyde and benzaldehyde in the presence of this catalyst. When hydrogen was introduced into the reaction vessel before the reactant had been heated to the reaction temperature, reduction of these aldehydes did not take place. But, when previously heated reactant was shaken with hydrogen (indicated by an asterisk* in the

* Hydrogen was introduced into the autoclave, after the reactant had been heated to this temprature.
** Estimated directly by gas-chromatography of the reaction mixture.

table), the reaction occurred. Moreover, benzaldehyde could be reduced even at room temperature. As a matter of further interest, it was found that the catalyst which was recovered after having failed to catalyze the reduction of benzaldehyde, showed a considerable increase in activity to hydrogenate nitrobenzene. Its reaction velocity ($v$)[1] was 100 at 21°C.

Unlike the case with ketones, this catalyst seems to be more active for the reduction of aromatic aldehydes than for that of aliphatic aldehydes, as shown by comparison of the reduction of acetaldyde and benzaldehyde shown in the table. With the aliphatic aldehyde groups conjugated with the C=C double bonds in acrolein and crotonaldehyde, hydrogen uptake hardly occurred.

**Hydrogenation of the C=C Double Bonds.**—Tests on the redudtion of allyl alcohol and maleic acid showed that this catalyst is rather active in hydrogenating the C=C double bonds. In the hydrogenation of allyl alcohol, the reaction velocity was influenced by the pressure of hydrogen. The reaction proceeded slowly at a low pressure of hydrogen. On the other hand, it was somewhat difficult to reduce the C=C double bonds conjugated with the carbonyl groups in mesityloxide, acrolein and crotonaldehyde. The double bonds in benzene rings were not reduced in the presence of the catalysts.

**Reduction of Aliphatic Nitro Compounds.**—This catalyst was found to be extremely active in hydrogenating nitro groups attached to aromatic rings, as described in the previous paper[1]. However, nitromethane and diethyl nitro malonate in acetic anhydride were both reduced much more slowly to give methyl acetamide and diethyl acetaminomalonate, respectively.

**Reduction of Acetophenoxime.**—Hydrogenation of acetophenoxime took place rather slowly with this catalyst, yielding $\alpha$-phenethyl amine and some $\alpha, \alpha'$-diphenethyl amine.

**Reduction of Ethyl Cyanide.**—Ethyl cyanide could not be reduced at all in the presence of this catalyst.

**Reductive Amination of $\alpha$-Ketoglutaric Acid.**—It was expected that this catalyst would convert $\alpha$-ketoglutaric acid to glutamic acid in the presence of ammonia and hydrogen, but the result was negative.

As seen in the results described above, the catalytic reactions effected by the silk-platinum catalyst are quite different from the known reductions effected by other platinum catalysts. It may be inferred that the difference is due to

the characteristic spacing of the active centers on the silk-platinum catalyst, which are the result of the structure of the carrier fibroin protein.

The difference between the catalytic efficiency of the silk-platinum and that of the platinic oxide catalyst in the hydrogenation of aromatic nitro compounds, was described in the previous paper[1] of this series.

### Poisoning of the Catalyst

The silk-platinum catalyst was found to be sensitive to poisonous substances or to chemical treatments. But the behavior towards catalytic poisons were somewhat different from that of the silk-palladium catalyst[2]. In examining these inhibitory effects, hydrogenation of nitrobenzene to aniline was adopted as the test system and the reaction velocity ($v$) was calculated as previously described[1].

**Inhibition by Carbon Monoxide.**—Activity of the silk-platinum catalyst in hydrogenating nitrobenzene in the presence of carbon monoxide was tested in comparison with that of the silk-palladium catalyst. For this purpose, carbon monoxide was mixed with hydrogen in various proportions, and introduced into the reaction system. The results obtained are shown in Table II.

Table II. Inhibition by carbon monoxide

| Catalyst | Addition of CO % | Temp. °C | React. vel. $v$ |
|---|---|---|---|
| Silk-Pt (40 mg.) | 0 | 19 | 41.7* |
| | 0.1 | 23 | 8.3* |
| | 0.1 | 50 | 35.7 |
| | 5.0 | 21 | 0 |
| | replaced with pure $H_2$ | 21 | 8.2 |
| | 5.0 | 110 | 5.0 |
| | 10.0 | 100 | 0 |
| | (recovered cat.) 0 | 16 | 15.0 |
| Silk-Pd (200 mg.) | 0 | 30 | 11.1 |
| | 0.1 | 30 | 0.12** |
| | replaced with pure $H_2$ | 30 | 0 |
| | 1.0 | 80 | 0.34 |

* See Fig. 1. ** Calculated value.

The silk-palladium catalyst was much more inhibited by carbon monoxide than the silk-platinum catalyst. The silk-platinum catalyst that had no catalytic action in the presence of carbon monoxide, recovered its activity to some extent in the absence of carbon monoxide. Furthermore, when little carbon monoxide was added (0.1%), the activity was restored even in the course of the reaction, as shown in Fig. 1. It is probable that carbon monoxide is adsorbed by the active metals, sometimes forming coordinate linkages, thus preventing the catalytic action. The activity may be restored when the adsorption is partially removed by hydrogenation of the carbon monoxide (as in the case shown in Fig. 1), or by washing the poisoned catalysts with methanol. It seems that palladium adsorbs carbon monoxide more easily than platinum, and thus the silk-palladium catalyst was more inhibited than the silk-platinum catalyst.

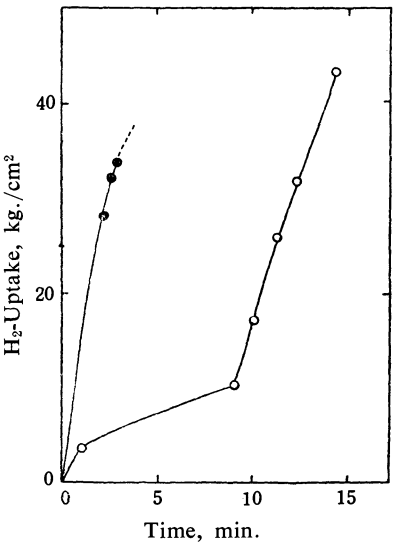

Fig. 1. Hydrogenation of nitrobenzene,
● in the absence of CO, at 19°C,
○ in the presence of 0.1% CO, at 23°C.

**Inhibition by Benzyl Mercaptan.**—As shown in Table III, treatment of the catalyst with benzyl mercaptan and its addition to the substrate resulted in a remarkable decrease in the catalytic activity in hydrogenating nitrobenzene. It is probable, that the mercaptan inhibits the catalyst by directly blocking active platinum, as in the case of the silk-palladium catalyst[2].

Table III. Inhibition by benzyl mercaptan

| Treatment | Addition | React. vel. $v$ at 32°C |
|---|---|---|
| — | — | 48.2 |
| $CH_3OH$ | — | 33.8 |
| $C_6H_5CH_2SH$*/$CH_3OH$ | — | 1.5 |
| — | $C_6H_5CH_2SH$ 2 mg.** | 1.1 |

* 1 mol. per mol. of platinum in the catalyst used.
** 0.25 mol. per mol. of platinum in the catalyst used.

**Inhibition by Metal Ions.**—In the case of the silk-palladium catalyst[2], the activity was greatly lowered in the presence of ferric and cupric ions supplied as nitrates. Cupric ion

2) Y. Izumi, ibid., 32, 936 (1959).

was somewhat more toxic than ferric ion. The silk-platinum catalyst was scarcely inhibited by ferric ion, as shown in Table IV. Cupric ion inhibited this catalyst considerably. The catalyst could not be reactivated by treatment with ethylenediamine tetra-acetic acid (EDTA). When the silk-palladium catalyst was similarly treated, however, it showed very powerful catalytic activity. These metal ions may form chelate linkages, though in a manner different from that of the silk-palladium catalyst, with the carrier protein to prevent the reactant from approaching the active platinum atoms.

TABLE IV. INHIBITION BY METAL IONS

| Metal ion | | React. vel. $v$ at 32°C |
|---|---|---|
| — | | 48.2 |
| $Fe(NO_3)_3 \cdot 12H_2O$ | 8 mg. ($10^{-4}$ mol.) | 36.8 |
| | 40 mg. | 26.5 |
| $Cu(NO_3)_2 \cdot 3H_2O$ | 5 mg. ($10^{-4}$ mol.) | 20.3 |
| | 10 mg. | 8.8 |
| | (treated with EDTA)* | 2.6 |
| | 25 mg. | 1.0 |

* The catalyst was recovered (80%) and treated with 0.5% ethylenediamine tetra-acetic acid.

**Effect of Acetylation.**—The activity of this catalyst remained unaffected by acetylation; the reaction velocity ($v$)[1] with an acetylated silk-platinum catalyst was 33.0 at 32°C. This is not the case with the silk-palladium catalyst[2].

## Experimental

**Preparation of the Catalyst.**—The catalysts used in this work were prepared by the method of Ref. 1 for the silk-platinum, and Ref. 3 for the silk-palladium catalyst.

**Isolation of the Products.**—*Reduction of Acetone.*—The reaction mixture was filtered and the filtrate was distilled; b. p. 80~82°C. The product was identified as isopropyl alcohol by means of gaschromatography.

*Reduction of Ethyl Methyl Ketone.*—The product was isolated as above (b. p. 97.5~98.5°C), and identified as *sec*-butyl alcohol by gaschromatography.

*Reduction of Acetaldehyde.*—The reaction mixture was filtered and the filtrate was treated by gaschromatography. The product was identified as ethyl alcohol, and the yield estimated.

*Reduction of Benzaldehyde.*—The products were identified as benzyl alcohol and toluene and their yields were estimated by gaschromatography.

*Reduction of Allyl Alcohol.*—The product distilling at 97~98°C was identified as *n*-propyl alcohol by means of gaschromatography.

*Reduction of Maleic Acid.*—An aqueous solution of maleic acid adjusted to pH 7.0 with sodium hydroxide was subjected to reduction. The reaction mixture was filtered and the filtrate evaporated to 20 ml. It was then acidified with 20 ml. of concentrated hydrochloric acid. After standing overnight, 9.5 g. of succinic acid (m. p. 184°C) was obtained. It was confirmed by ultraviolet spectroscopy that the product was devoid of unsaturated bonds.

*Reduction of Mesityloxide.*—The reaction mixture was filtered and the filtrate was subjected to gaschromatography. The product was identified as methyl isobutyl ketone, and the yield estimated. Unreacted mesityloxide was also detected.

*Reduction of Nitromethane.*—After filtration of the reaction mixture, the filtrate was fractionally distilled under reduced pressure. The product, boiling at 95~96°C/17 mmHg, was identified as methyl acetamide by gaschromatography and infrared spectroscopy.

*Reduction of Diethyl Nitro Malonate.*—The reaction mixture was filtered and the filtrate evaporated to 20 ml. Thirty milliliters of water were added. After standing overnight, 14 g. of diethyl acetamino malonate (m. p. 93~95°C) was obtained.

Found: N, 6.41. Calcd. for $C_9H_{15}O_5N$: N, 6.45%.

*Reduction of Acetophenoxime.*—The reaction mixture, from which the catalyst had been removed, was evaporated to 30 ml. To this was added 15 ml. of concentrated hydrocholoric acid and then 30 ml. of ether. After standing the solution in a refrigerator overnight, the crystals were filtered off, recrystallized from water, and identified as $\alpha$, $\alpha'$-diphenethyl amine hydrochloride (sublimed above 240°C).

Found: C, 73.52; H, 7.73; N, 5.22; Cl, 13.56. Calcd. for $C_{16}H_{20}NCl$: C, 73.55; H, 7.66; N, 5.32; Cl, 13.47%.

The filtrate was evaporated to dryness and the residue dissolved in 20 ml. of methanol, to which was added 30 ml. of ether. After standing overnight, $\alpha$-phenethyl amine hydrochloride was obtained. It was recrystallized from alcohol and ether; m. p. 158°C.

Found: C, 61.04; H, 7.80; N, 8.75, Cl, 22.45. Calcd. for $C_8H_{12}NCl$: C, 60.95; H, 7.68; N, 8.89; Cl, 22.49%.

**Poisoning of the Catalyst.**—The reaction velocity ($v$) of the hydrogenation of nitrobenzene to aniline was measured and calculated by the method of the previous paper[1].

*Inhibition by Carbon Monoxide.*—Carbon monoxide was mixed with hydrogen in varying proportions and introduced into the reaction system.

*Preparation of Inhibited Catalyst.*—Two hundred milligrams of the silk-platinum catalyst (containing 1/3000 mol. of platinum) was suspended in 100 ml. of methanol or in 100 ml. of 0.04% benzyl mercaptan methanol solution (containing 1/3000 mol. of mercaptan), stirred for 15 min. washed with methanol and ether, and then dried in vacuo. Forty milligrams of this catalyst was used for the test.

*Treatment of the Inhibited Catalyst by Ethylenediamine Tetra-acetic Acid (EDTA).*—The inhibited catalyst was boiled with a 0.5% aqueous solution of EDTA for 5 min., filtered, washed with water, methanol, and then ether, and finally dried in vacuo; 32 mg. (80%).

3) Y. Izumi, ibid., 32, 932 (1959).

*Acetylation of the Catalyst.*—One hundred milligrams of the catalyst was boiled with 50 ml. of acetic anhydride for 2 hr., filtered, washed with ether, and dried in vacuo. Forty milligrams of this catalyst was used for the test.

## Summary

1. The silk-platinum catalyst showed quite different behaviors with various compounds from that of other platinum catalysts. The difference is probably due to the characteristic spacing of the active centers on the silk-platinum catalyst, due to the structure of the carrier silk-fibroin protein.

2. The catalyst was found to catalize the hydrogenation of some aldehydes, unconjugated aliphatic ketones and C=C double bonds, aliphatic nitro groups and oxime, more weakly, than that of the aromatic nitro groups.

3. Carbon monoxide, benzyl mercaptan and cupric ion poisoned the catalyst, and the activity of the catalyst inhibited by cupric ion, was not recovered by treatment with ethylenediamine tetra-acetic acid.

4. Ferric ion scarcely inhibited the catalyst and acetylation of the catalyst scarcely decreased its activity, unlike that of the silk-palladium catalyst.

# *Studies on the Composition and Properties of Less Familiar Metal Cyano Complexes. I. Composition of Nickel and Cobalt Octacyanomolybdates by Electrometric Methods*

By Wahid U. MALIK and S. Iftikhar ALI

(Received December 27, 1960)

The chemical literature abounds in references on the properties and composition of metal complexes of alkali ferro- and ferricyanides but very little attention appears to have been paid to the study of the metal complexes of alkali octacyanomolybdates. The only work worth mentioning is that of Wardlaw and co-workers[1] who carried out studies on the metal complexes of silver, thallium, copper, etc. by the method of chemical analysis. It is a well known fact that the physical methods have got certain advantages over the methods of chemical analysis in as far as that they not only provide precise information of the composition of the freshly precipitated complex but are able to eliminate the errors which might creep in during the washing and drying of precipitate possessing adsorptive and hydrolytic properties. Attention to this point was drawn by Bhattacharya[2] on the basis of the work carried out by him and his students on metal ferro- and ferricyanides. Since the metal complexes of alkali octacyanomolybdates appear to belong to the class of metal ferrocyano complexes, it was thought worthwhile to employ physical methods for the elucidation of their composition.

The present communication deals with our studies on the nickel and cobalt complexes of potassium octacyanomolybdate employing conductometric, potentiometric and amperometric methods. Moreover these complexes have not so far been studied and are likely to open a new field for the physico-chemical studies on metal cyano complexes.

## Experimental

The method recommended by Fieser[3] was followed for the preparation of potassium octacyanomolybdate. All chemicals, molybdenum(VI) oxide, potassium thiocyanate, pyridine and potassium cyanide, used were A. R. samples. The crystallized product (golden yellow in color) was dried over calcium chloride in a vaccum dessicator. It was dissolved in water twice distilled by a all-glass apparatus and its concentration was determined by titrating potentiometrically against the potassium permanganate solution of a known concentration. Potassium octacyanomolybdate(V) was prepared by the method

1) W. Wardlaw and co-workers, *J. Chem. Soc.*, **1927**, 2981.

2) A. K. Bhattacharya, "Proc. Symp. Coordination Compounds, Part I", National Academy of Science, India (1959), p. 139.

3) L. F. Fieser, *J. Am. Chem. Soc.*, **52**, 5204 (1930).

recommended by Kolthoff[4] and standardized potentiometrically against potassium ferrocyanide.

Nickel and cobalt chlorides of A. R. grade were used for preparing their solutions and their concentrations were estimated gravimetrically after precipitating as nickel dimethylglyoxime and cobalt ammonium phosphate respectively.

Conductometric titrations were done with the help of Cambridge conductivity bridge (No. L-350140) with a bridge type conductivity cell (No. L-355234 and cell constant 0.36). Potentiometric titrations were performed with Tinsley potentiometer (Type 338713) with a lamp and scale arrangement. The indicator electrode was the $K_4Mo(CN)_8 \rightleftarrows K_3Mo(CN)_8 + e$ couple obtained by dipping a bright platinum electrode in a solution of potassium octacyanomolybdate(IV) containing a little potassium octacyanomolybdate(V).

In order to carry out amperometric studies, the constant potential to be applied during the course of titrations was first of all determined, taking in the polarographic cell 1 cc. of 0.1 M salt solution in 0.1 M potassium chloride as supporting electrolyte, 0.0003% sodium methyl red for nickel(II) and 0.01% gelatin for cobalt(II) as maximum suppressor, the total volume made up to 20 cc. The current was measured with Fischer Elecdropode in conjunction with Multiflex galvanometer (type MGF 2, sensitivity 1 : 10), in the external circuit. Polarograms were drawn and from the plateau the potentials to be applied for the amperometric titrations were found out. The potential applied during the course

of titrations for nickel(II) and cobalt(II), being −1.2 and −1.4 V. respectively. Electrodes used were the dropping mercury electrode and the S.C.E. Pure nitrogen was passed in order to maintain the inert atmosphere. All measurements were made at 30±0.1°C. Both direct (salt solution in the cell) and reverse ($K_4Mo(CN)_8$ in the cell) titrations were performed with different concentrations of the reactants.

The results are summarized below. A few typical curves are shown in Figs. 1A, 1B, 2A, 2B and 3A, 3B.

## Discussion

The reaction between nickel chloride/cobalt chloride and potassium molybdocyanide may be represented by the following stoichiometric equations:

$$MCl_2 + K_4Mo(CN)_8 = K_2MMo(CN)_8 + 2KCl \quad (1)$$

$$3MCl_2 + 2K_4Mo(CN)_8 = K_2M_3(Mo(CN)_8)_2 + 6KCl \quad (2)$$

$$2MCl_2 + K_4Mo(CN)_8 = M_2Mo(CN)_8 + 4KCl \quad (3)$$

$$MCl_2 + xK_4Mo(CN)_8 = K_2MMo(CN)_8 \cdot (x-1)K_4Mo(CN)_8 + 2KCl \quad (4)$$

(adsorption complex)

The results on conductometric, potentiometric and amperometric titrations summarized in the foregoing paragraph give a ratio of $2M^{2+}$ : $1Mo(CN)_8^{4-}$ pointing towards the formation of the complex $M_2Mo(CN)_8$ (M being Ni/Co) in accordance with Eq. 3 given above. Further, a ratio of 1 : 1 for the reactants is also found in the case of conductometric titration when the metal salt is added to the potassium molybdocyanide in the conductivity cell. For this ratio the complex formed would have the composition $K_2MMo(CN)_8$.

The combining ratios (both 2 : 1 and 1 : 1) show a slight discrepancy from the stoichiometric equations. For almost all the different concentrations of the reactants employed for these titrations, the amount of potassium molybdocyanide required is larger than the theoretical values. This behavior can well be explained by assuming that the freshly precipitated complexes have got the property of adsorbing $Mo(CN)_8^{4-}$ ion. An indirect proof of the adsorptive capacity of the complexes was forthcoming from our preliminary experiments. There it was found that the green precipitate of nickel molybdocyanide can be transformed into a stable sol when nickel chloride is added to a little excess of potassium molybdocyanide. However, mixing in the reverse order ($K_4Mo(CN)_8$ to $NiCl_2$) resulted in a thick precipitate rather than a sol. A similar behavior was found with cobalt molybdocyanide which could be obtained in the form of a stable orange colored sol by using excess of potassium molybdocyanide.

The potentiometric studies need a special mention here. We observed that potentiometric titrations for this precipitation reaction can be successfully performed by employing a $Mo(CN)_8^{4-} \rightleftarrows Mo(CN)_8^{3-} + e$ couple at bright platinum electrode. Typical curves (Fig. 2A) are obtained when the metal solution is added to the solution of potassium molybdocyanide containing a little potassium molybdicyanide. But in the case of reverse titrations (Fig. 2B) the curves are of a different nature, the e. m. f. increasing in the initial stages before showing a downward slope. This behavior points towards the fact that the molybdo-molybdicyanide couple attains equilibrium condition when an optimum amount of the reagent is present in the titrating cell. When sufficient amount of molybdocyanide has been added from the burette the curves have got the typical nature.

Amperometric titrations carried out with potassium molybdocyanide in the polarographic cell are different in shape than those which should be obtained on theoretical considerations, for such titrations (reducible ions added to non-reducible ions in the cell). The current increases appreciably on adding the titrant (Fig. 3B) and this is more so for $Co^{2+}$ solution (results not given). It was thought that the increase in current might be due to the formation of some intermediate soluble complex. The products of interactions at different stages in this region were taken separately and polarograms drawn. The $E_{1/2}$ in each case corresponded to the $E_{1/2}$ of $Ni^{2+}$ (−1.1 V.) and $Co^{2+}$ (−1.2 V.) thereby showing the non-existence of a soluble complex in between. Titrations with the metal solution in the cell (Fig. 3A) were of the same nature as required on theoretical grounds. It is quite likely that the colloidal nature of the solution in the former case influence the performance of the dropping mercury electrode and typical curves are not obtained there.

## Summary

The composition of the freshly precipitated nickel and cobalt cyano molybdates was determined using conductometric, potentiometric and amperometric methods. The nickel compound is green in color and its composition may be represented as $Ni_2Mo(CN)_8$. The orange precipitate of the cobalt cyano molybdate has also got the composition $Co_2Mo(CN)_8$. Reverse conductometric titration (salt solution added to molybdocyanide) give evidence of the complexes $K_2NiMo(CN)_8$ and $K_2CoMo(CN)_8$. These titrations provide information of the adsorption of $Mo(CN)_8^{4-}$ ions by the freshly precipitated complex. Both the compounds show tendency to pass into the colloidal state when the salt solution is added to excess of potassium octacyano molybdate.

# *Studies on the Composition and Properties of Less Familiar Metal Cyano Complexes. II. Composition of Copper Octacyano Molybdate and the Existence of the Redox System* $Cu^{+}+Mo(CN)_8^{3-} \rightleftharpoons Cu^{2+}+Mo(CN)_8^{4-}$

By Wahid U. MALIK and S. Iftikhar ALI

(Received December 27, 1960)

In continuation to our studies on the composition of the complex molybdocyanides of heavy metals by electrometric methods (Part I, this Bulletin*), investigations were extended to the copper complexes. The study of such complexes, besides providing information regarding the composition of cupric molybdocyanide, opens a new aspect for further investigation, viz., the existence of redox potential in the system $Cu^{+}+Mo(CN)_8^{3-} \rightleftarrows Cu^{2+}+Mo(CN)_8^{4-}$. Little work has been done in this direction even for the well-known metal ferrocyanogen complexes and very few references are available in the literature on this aspect of the problem.

For the first time Davidson[1] in 1937 drew attention towards the existence of $Fe^{3+}+Fe(CN)_6^{4-} \rightleftarrows Fe(CN)_6^{3-}+Fe^{2+}$ couple in the slow formation of ferric-ferrocyanide while carrying out experiments on the iron blues. Very recently systematic studies on these lines have been carried out by Malik[2] for systems like $Cu^{+}+Fe(CN)_6^{3-} \rightleftarrows Fe(CN)_6^{4-}+Cu^{2+}$; $Mn^{3+}+Fe(CN)_6^{4-} \rightleftarrows Fe(CN)_6^{3-}+Mn^{2+}$; $Cr^{2+}+Fe(CN)_6^{3-} \rightleftarrows Cr^{3+}+Fe(CN)_6^{4-}$ etc., applying amperometric methods.

The present communication deals with two aspects of the problem of copper complexes of alkali cyanomolybdates: i) the composition of the freshly precipitated cupric molybdocyanide by electrometric methods and ii) the study of the cuprous chloride potassium molybdicyanide reaction employing a cuprous-cupric couple at the bright platinum electrode.

## Experimental

Solutions of potassium molybdo- and molybdicyanide were prepared and standardized as given in Part I. Copper sulfate solution was prepared by dissolving a weighed amount of A. R. crystals of the salt in redistilled water and its concentration determined iodometrically[3]. Cuprous chloride[4] was prepared and a weighed amount of it dissolved in 1 M potassium chloride solution (acidified with a little hydrochloric acid). The solution was kept under a layer of paraffin to avoid oxidation. The concentration of the solution was determined by titrating against 0.1 M ammonium thiocyanate, using ferric alum[5] as the indicator.

Conductometric, potentiometric and amperometric titrations between copper sulfate and potassium molybdocyanide were carried out as described earlier. Potentiometric titrations between cuprous chloride and potassium molybdicyanide were carried out, using $Cu^{+} \rightleftarrows Cu^{2+}+e$ couple, obtained by dipping bright platinum electrode in a solution of cuprous chloride containing a little cupric chloride.

All the experiments were performed in the dark room and the vessels were also wrapped with black paper to avoid the decomposition of potassium molybdicyanide.

The results are summarized below. A few typical curves are shown in Figs. 1A, 1B, 2, 3A, 3B and 4A, 4B.

## Discussion

Conductometric titrations between copper sulfate and potassium molybdocyanide (Figs. 1A and 1B) give the ratio $Cu^{2+}$ to $Mo(CN)_8^{4-}$ as 2 : 1. Potentiometric titrations carried out with copper sulfate solution in the cell did not give typical titration curves and there was a sharp rise in potential on the addition of even a small amount of molybdocyanide (containing a little molybdicyanide) from the burette. Titrations carried out in the reverse manner, viz., by adding copper sulfate solution to the molybdocyanide in the cell ($Mo(CN)_8^{4-} \rightleftarrows Mo(CN)_8^{3-} + e$ couple at the bright platinum electrode) gave very satisfactory results (Fig. 2) and here too a ratio of 2 : 1 was found to exist. However, both these methods gave a little more of potassium molybdocyanide than required by the stoichiometric equation: $2 \cdot CuSO_4 + K_4Mo(CN)_8 = Cu_2Mo(CN)_8 + 2K_2SO_4$ for the formation of the complex. Here this may also be attributed to the adsorption of $Mo(CN)_8^{4-}$ by the freshly precipitated complex although the adsorption effect is not so marked as in the case of cobalt and nickel complexes (Part I). The behavior of copper molybdocyanide is also slightly different from those of cobalt and nickel molybdocyanides in as much as that the precipitate of the latter pass into colloidal solution more readily than the former. Amperometric titrations (Figs. 3A and 3B) both

direct and reverse give the ratio 2 : 1, again pointing towards the formation of the complex $Cu_2Mo(CN)_8$.

Conductometric titrations as well as the amperometric titrations were unsuccessful in investigating the reaction between cuprous chloride and potassium molybdicyanide. In the latter suitable potential to be applied could not not be found while in the former sharp points of intersection at the equivalence point were not realized. However, potentiometric titrations at the $Cu^+ \rightleftarrows Cu^{2+}+e$ couple (Pt electrode dipped in a solution of cuprous chloride containing a little cupric chloride) gave typical titration curves with two sharp breaks (Figs. 4A and 4B). The values for the ratio $Cu^+$ : $Mo(CN)_8^{3-}$ being nearly 1 : 2 and 1 : 1 respectively.

Before assigning a particular formula to the complex formed by this reaction it is important to consider the oxidation reduction reaction : $Cu^+ + Mo(CN)_8^{3-} \rightleftarrows Cu^{2+} + Mo(CN)_8^{4-}$. Taking the redox potentials of $Mo(CN)_8^{4-} \rightleftarrows Mo(CN)_8^{3-}+e$ as $-0.82$ V. and that of $Cu^+ \rightleftarrows Cu^{2+}+e$ as $-0.17$ V., the equilibrium constant of the above mentioned redox reaction comes out to be $1.5\times10^{12}$. It means that during the interaction of cuprous chloride and potassium molybdicyanide, a large amount of cuprous is oxidized to the cupric state and the molybdicyanide is reduced to the molybdocyanide.

On the basis of the above explanation the reaction should take place in the following two steps.

$Cu_2Cl_2+2K_3Mo(CN)_8+2KCl=2CuCl_2+2K_4 \cdot Mo(CN)_8$ followed by, $2CuCl_2+2K_4Mo(CN)_8= 2K_2CuMo(CN)_8+2KCl$. The ratio 1 : 2 ($Cu^+$ : $Mo(CN)_8^{3-}$) found on the basis of potentiometric titration support the above mechanism since the overall reaction would be $Cu_2Cl_2+ 2K_3Mo(CN)_8=2K_2CuMo(CN)_8+2KCl$, giving the complex $K_2Cu^{II}Mo^{IV}(CN)_8$.

Whether an oxidation-reduction equilibrium ($K=1.5\times10^{12}$) can completely hold good in the case of precipitation reactions is rather difficult to say. It is quite probable that some of the cuprous chloride is precipitated by potassium molybdicyanide before mutual oxidation reduction takes place and some cuprous molybdicyanide is also formed. Under these conditions a ratio of 1 : 1 for the reactants should be realized. This is what we actually get from the second break of the direct and the first break of the reverse titrations. To sum up it may be said that the products of interaction between cuprous chloride and potassium octacyanomolybdate(V) are predominantly $K_2Cu^{II}Mo^{IV}(CN)_8$ although a little amount of $KCu_2^{I}Mo^{V}(CN)_8$ is also formed.

## Summary

The reaction between copper sulfate and potassium molybdocyanide was studied using conductometric, potentiometric and amperometric methods. The stoichiometric ratio of 2 : 1 for $Cu^{2+}$ to $Mo(CN)_8^{4-}$ correspond to the formation of $Cu_2Mo(CN)_8$. The interaction of cuprous chloride and potassium molybdicyanide resulted in the formation of $K_2Cu^{II}Mo^{IV}(CN)_8$. Evidence for the existence of a redox potential in the system $Cu^+ + Mo(CN)_8^{3-} \rightleftarrows Cu^{2+}+Mo(CN)_8^{4-}$ could be obtained for the latter reaction on the basis of potentiometric titrations.

# *On the Erlenmeyer Reaction. I. Mechanism of Threo-β-phenylserine Formation**

By Takeo KANEKO and Kaoru HARADA**

(Received December 9, 1960)

The Erlenmeyer reaction[1] of glycine with benzaldehyde in the presence of excess of alkali results in the formation of *N*-benzal-β-phenylserine alkali salt and *N*-benzal-α, β-diphenyl-β-hydroxyethylamine. Recently many stereochemical studies of β-phenylserine have been published in connection with chloramphenicol. Vogler[2] has determined chemically that the structure of Erlenmeyer's phenylserine was only of the threo-type. The diastereoisomeric erythro-β-phenylserine was first isolated in pure state by Shaw and Fox[3] in 1950. They prepared pure erythro-β-phenylserine using a new method for separation of the threo and erythro isomers, and they also found a paper chromatographic solvent (S-F solvent) to separate these two diasteromers.

An interesting point in the Erlenmeyer synthesis of β-phenylserine is that the threo isomer is the predominant product. The erythro isomer, which is expected to form in the aldol condensation of glycine and benzaldehyde, has not been isolated from the final crystalline product. Shaw and Fox found by use of their paper chromatographic solvent that the threo isomer increased and the erythro isomer decreased during the reaction.

Quantitative analyses of the threo- and the erythro-phenylserine and glycine in the reaction mixture at different intervals of the reaction time have now been carried out to determine the ratio of these three amino acids. Table I shows the ratio of these three amino acids produced in the Erlenmeyer reaction.

TABLE I. AMINO ACID RATIO IN THE ERLENMEYER REACTION

| hr. | Gly | Threo-phe. ser. | Erytho-phe. ser. |
|---|---|---|---|
| 1/4 | 48 | 28 | 24 |
| 1/2 | 39 | 39 | 22 |
| 1 1/2 | 23 | 52 | 25 |
| 4 1/2 | 18 | 62 | 20 |
| 24 | 11 | 73 | 16 |
| 50 | 9 | 77 | 14 |

From the results of the analyses, it may be inferred that the erythro isomer is converted into the threo isomer during the reaction.

In order to prove the hypothesis, either erythro or threo-phenylserine was mixed with ethanol, water, benzaldelyde and sodium hydroxide as in the Erlenmeyer reaction. It was found that if equimolar or less sodium hydroxide was used, threo- or erythro-phenylserine was not converted into its diastereomer. The resulting reaction mixture gave only the original threo or erythro isomer, which was identified by paper chromatography using the S-F solvent. However, by the use of an excess of alkali as in the Erlenmeyer reaction, both threo- and erythro-phenylserine were converted into a mixture of the isomers. When threo-, erythro- or a mixtuer of threo- and erythro-phenylserine were treated under Erlenmeyer's condition, one of the sodium salts of isomeric *N*-benzal-phenylserine crystallized out from the reaction mixture as the predominant product. After debenzalation of the crystalline

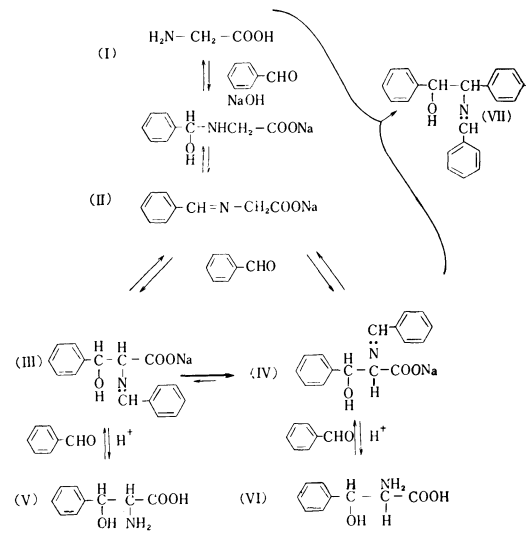

Fig. 1. Flow sheet of postulated mechanism of Erlenmeyer reaction.

product, paper chromatography showed that the product consisted of only the threo isomer. Each of the mother liquors arising from the above mentioned three different reactions, however, contained glycine and the threo- and erythro-phenylserine. These results suggest a possible-mechanism for the formation of Erlenmeyer's threo-phenylserine. The postulated pathways of the reaction are shown in Fig. 1.

Glycine (I) reacted with benzaldehyde to yield benzal glycine (II). The resulting II reacted again with benzaldehyde forming erythro-*N*-benzal-phenylserine (III) and threo-*N*-benzalphenylserine (IV). In solution both III and IV exist as a mixture. However,

(A) if the solubility of IV is small and it crystallizes easily, and

(B) if there is an equilibrium between III and IV under the reaction conditions,

the erythro isomer III is converted in to threo isomer IV by crystallization. Erlenmeyer's threo-phenylserine formation may be considered as a typical asymmetric transformation reaction.

In the conversion of V→III→IV, about 65～75% of the threo isomer was isolated in crystal form IV. It is necessary to use more than twice the equivalent of alkali to crystallize IV in the conversion of erythro to threo isomer. The filtrate of the crystalline reaction product contains III, IV and glycine, the last being an alkali degradation product of phenylserine. The reaction yielded *N*-benzal-$\alpha$, $\beta$-diphenyl-$\beta$-hydroxyethylamine (VII) as a by-product. Paper chromatography showed that a longer reaction time resulted in an increased formation of VII.

In the conversion reaction, the $\alpha$- or $\beta$-carbon atom or both carbon atoms must be racemized or inverted. Optically active erythro-phenylserine was used to determine which carbon atom racemized or inverted during the reaction. When D-erythro-phenylserine was treated with benzaldehyde and alkali as in Erlenmeyer's reaction, condition, the mixture had a very high rotatory power which decreased rapidly as is shown in Fig. 2. After about 4.5 hr., the solution lost almost all optical activity and crystals were precipitated out. The expected optically active threo isomer was not obtained, but the crystal was identified as sodium salt of racemic *N*-benzal-threo-phenylserine (IV).

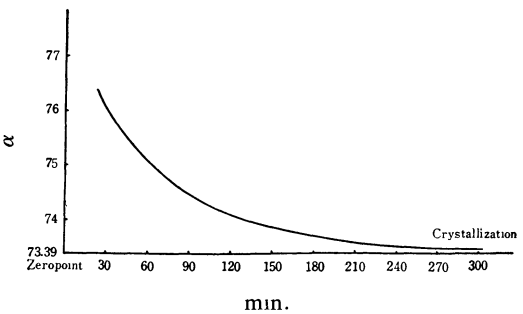

Fig. 2. Mutarotation of D-erythro-$\beta$-phenylserine.

This study showed that both the $\alpha$- and $\beta$-carbon atoms were racemized during the reaction. In the absence of benzaldehyde, D-erythro-phenylserine did not racemize so rapidly and it retained more than 75% of its optical activity after 4.5 hr. The racemization at the $\alpha$- and $\beta$-carbon atoms is not only due to the alkali but the *N*-benzal residue, which is important in the conversion process. Such knowledge suggests the equilibrium between III and IV as is shown in Fig. 3.

Optically active erythro-phenylserine has been isolated by Fone[4] using an enzymic method and he determined its configuration

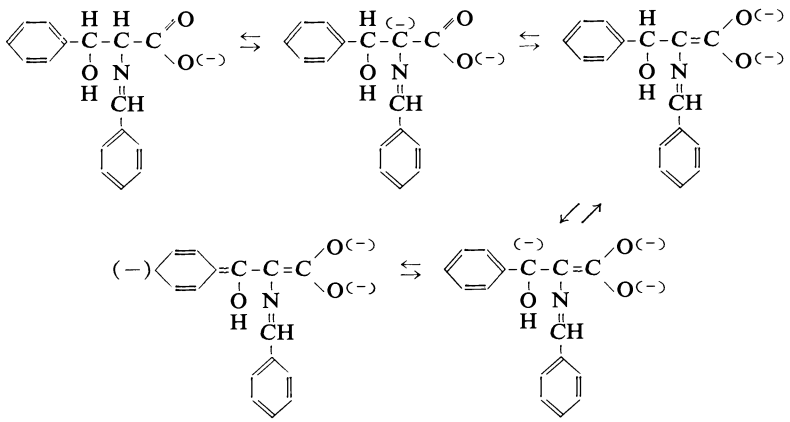

Fig. 3. Equilibrium between III and IV.

4) W. S. Fone, *J. Biol. Chem.*, **204**, 323 (1953).

biologically. In this study D- and L-erythro-phenylserine were prepared by resolution of *N*-benzoyl-DL-erythro-phenylserine using quinine. The D-isomer was isolated in an optically pure state but the L-isomer had only 75% of its optical activity. The configuration of these isomers was also determined chemically. The (−)-erythro-phenylserine was reduced with hydrogen iodide and red phosphorus giving D(+)-phenylalanine. The (−)-erythro isomer has a sweet taste, and (+)-erythro-phenylserine has a bitter taste. These results show that the (−)-erythro isomer has the $D_S$-configuration and (+)-erythro isomer has the $L_S$-configuration.

## Discussion

The fact that the mechanism of threo-phenylserine formation is based on the racemization of $\alpha$- and $\beta$-carbon atoms has been mentioned above. However, another explanation is possible: the $\alpha-\beta$ carbon linkage could be cleft during the reaction and the resulting benzaldehyde and *N*-benzal-glycine could react again to reform the threo isomer IV. Such a mechanism is conceivable since the linkage of the $\alpha-\beta$ carbon is not stable in the alkaline condition; phenylserine is completely decomposed to glycine and benzaldehyde after boiling for 1 hr. with 1 N sodium hydroxide. Elphimoff-Felkin[5] studied the transformation of ethyl threo-*p*-nitro-$\beta$-phenylserinate to the corresponding erythro isomer in alcoholic solution. The conversion reaction was explained by the cleavage of the $\alpha-\beta$ carbon bond of the threo isomer and consequent reforming of the erythro isomer from the resulting *p*-nitro-benzaldehyde and glycine ethylester. However, the explanation can not be applied successfully in the Erlenmeyer reaction. In the reaction of threo-*p*-nitro-phenylserine[6] with benzaldehyde and alkali, the sodium salt of *N*-benzal-threo-*p*-nitro-penylserine was crystallized out easily from the reaction mixture. The mother liquor contained threo- and erytho-*p*-nitro-phenylserine and only a trace amount of glycine. After two days' standing at room temperature, however, the mother liquor of the reaction mixture contained threo- and erythro-*p*-nitro-phenylserine, glycin and also a small amount of phenylserine, the last being a reaction product of benzaldehyde and glycine produced by the cleavage reaction. These results showed that the cleavage and resynthesis of phenylserine are not so important in the cases of short reaction time, although it may be important in the cases of prolonged reaction time. The fact that the phenylserine was not formed rapidly in the reaction of *p*-nitro-phenylserine and benzaldehyde, suggests that the mechanism shown in Figs. 1 and 3, which contains racemization of the $\alpha$- and $\beta$-carbon atoms and asymmetric transformation is a more reasonable pathway in the Erlenmeyer reaction.

The *N*-benzal residue in the reaction is important in the racemization and also in the formation and stabilization of many equilibrium systems. The $\beta$-carbon atom connected with the hydroxyl group is also interesting in regard to the formation of the conjugated double bond system from the $\beta$-phenyl residue to the *N*-benzal residue or to the carboxylate group. In the same reaction condition, L-tyrosine was not racemized at all with benzaldehyde and alkali.

The racemization mechanism of the Erlenmeyer reaction is complex. Two asymmetric carbons are racemized simultaneously. The observed data by rotatory power showed that the racemization proceeded as a pseudo 1st order reaction; the racemization constant, *K*, is 0.156 $min^{-1}$. The specific rotation of *N*-benzal D-erythro-phenylserine at zero time has a tremendously high value $[\alpha]_D^{27} = 13000°$ which is calculated from the racemization constant.

## Experimental

**Quantitative Analysis of the Amino Acid in the Erlenmeyer Reaction.**—A mixture of glycine (37.0 g.), water (400 ml.) and sodium hydroxide (70.0 g.) was shaken vigorously with a mixture of ethyl alcohol (100 ml.) and benzaldehyde (1.06 g.) under cooling. The mixture became clear and then a crystalline paste was formed gradually which solidified after several hours. About 0.5 g. of aliquot was taken from the reaction mixture after 15 min., 30 min., 1.5 hr., 4.5 hr., 24 hr. and 50 hr. These samples were acidified immediately with acetic acid, and a small amount of water was added. The resulting benzaldehyde was extracted with ether. The aqueous layer was adjusted to pH 10 with sodium carbonate solution, then extracted with ether to eliminate diphenylethanolamine. The aqueous solution was neutralized and evaporated in vacuo, and the residue was subjected to paper chromatography and also to dinitrophenylation of glycine and phenylserine. The ratio of glycine to phenylserine was determined by paper chromatography (solvent: *n*-BuOH : AcOH : $H_2O$/4 : 1 : 1). The corresponding spots were cut off and these were eluted with hot water. The ratio of glycine to phenylserine was determined colorimetrically, using the standard ninhydrin method[7]. The threo- and erythro-phenylserines were isolated by the Seki's method[8]. The DNP-amino acid mixture of each

sample was columnchromatographed, using Amberlite IR-112 resin ($Na^+$) and an elution solvent composed of pH 3.1 citric acid buffer (1/10 M) : ethyl methyl ketone : tetrahydrofurane/10 : 1 : 1.

Eluted solutions were collected with a fraction collector. The DNP-derivatives were separated into 3 fractions; the first band was composed of DNP-erythro-phenylserine and DNP-glycine, the second was dinitrophenol and the third was DNP-threo-phenylserine. The second band at 430 mμ disappeared on acidification to pH 1. The ratio of glycine and erythro-phenylserine to threo-phenylserine was determined colorimetrically at 430 mμ. The ratios of glycine, threo- and erythro-phenylserine were calculated from the data measured above. The results are shown in Table I.

**Reaction of Phenylserine with Benzaldehyde and Alkali.**—(A) *When a Small Proportion of Alkali was Used.*—In either case threo-phenylserine monohydrate (1.0 g.) or erythro-phenylserine (0.91 g.) was mixed with water (15 ml.), sodium hydroxide (0.2 g.), benzaldehyde (1.0 ml.) and ethanol (6 ml.). The mixture was shaken until it became clear and was allowed to stand overnight. The reaction mixture was diluted with hydrochloric acid; the resulting benzaldehyde was extracted with ether. The solution was neutralized and then examined by paper chromatography with the S-F solvent. Neither the threo nor the erythro isomer was converted.

(B) *When a Large Proportion of Alkali was Used.*—(1) Threo-phenylserine monohydrate (1.0 g.) was mixed with water (5 ml.), sodium hydroxide (0.6 g.), benzaldehyde (1 ml.) and ethanol (2 ml.). The clear solution began to deposit crystals after 1 hr. It was allowed to stand overnight at room temperature. After filtration and washing with ethanol, 1.30 g. of the crystalline *N*-benzal derivative IV was obtained. The IV was treated with 1 N hydrochloric acid and the resulting benzaldehyde was extracted with ether and the aqueous layer was evaporated to dryness. The phenylserine hydrochloride in the residue was extracted with absolute alcohol. After evaporation of the alcohol, the residual syrup was treated with silver carbonate and hydrogen sulfide to eliminate hydrochloric acid. The aqueous solution was evaporated. The resulting crude phenylserine was recrystallized from water, 0.75 g. of the threo-phenylserine monohydrate was obtained. The isolated phenylserine was shown to consist of pure threo isomer by paper chromatography with the S-F solvent (Found: N, 7.07%).

(2) A mixture of threo-phenylserine monohydrate (0.50 g.) and erythro-phenylserine (0.46 g.) was treated with sodium hydroxide (0.7 g.), water (5 ml.), benzaldehyde (1 ml.) and ethanol (2 ml.) as in the previous experiment. The clear solution began to deposit crystals after 2 hr. or earlier on seeding with IV. After standing overnight at room temperature, 0.95 g. of IV was isolated. The crystals were treated in the same way as above, 0.62 g. of pure threo-phenylserine monohydrate was isolated (Found: N, 7.18%).

(3) Erythro-phenylserine (0.91 g.) was treated with sodium hydroxide (1.0 g.), water (5 ml.), benzaldehyde (1 ml.) and ethanol (2 ml.). After 2 hr. crystallization began. The crystallization proceeded more rapidly after seeding of IV, 1.0 g. of crystals was isolated. It was treated as above, 0.65 g. of pure threo-phenylserine monohydrate was isolated. The threo isomer was converted into its copper complex.

Found: N, 6.48. Calcd. for $(C_9H_{10}O_3N)_2Cu$: N, 6.43%.

(4) D(−)-Erythro-phenylserine dioxane adduct (89.8 mg.) and benzaldehyde (80 mg.) were dissolved in 5 ml. of a mixture of water (10 ml.), ethanol (2 ml.) and sodium hydroxide (0.8 g.). The rotatory power of the solution was observed. In the first 30 min. of the reaction, the value of $[\alpha]_D$ was too great to observe. The mutarotation curve is shown in Fig 2. After 4.5 hr. the $[\alpha]_D$ reached almost zero and crystallization began in the solution. The crystals were filtered off. The analytical data of the crystals, paper chromatography and the rotatory power (in 2 N hydrochloric acid) of the isolated phenylserine showed that the crystal was the pure DL-threo-*N*-benzal-phenylserine sodium salt.

Found: N, 4.74. Calcd. for $C_{16}H_{14}O_3NNa$: N, 4.81%.

In the above reaction without benzaldehyde, D(−)-erythro-phenylserine maintained about 76% of its optical activity after 4.5 hr. of treatment.

**Reaction of Threo-*p*-nitro-phenylserine with Benzaldehyde and Alkali.** — The threo-*p*-nitro-phenylserine was prepared by the method of Ehrhart[6]. Threo-*p*-nitro-phenylserine (1.13 g.) was treated with sodium hydroxide (0.2 g.), water (15 ml.), benzaldehyde (1 ml.) and ethanol (4 ml.). The clear solution began to deposit crystals after 2 hr. The crystals were filtered off after 6 hr., and were converted into free *p*-nitro-phenylserine. The product was found to consist of the pure threo isomer by chromatography. The mother liquor of the reaction mixture contained both the threo- and the erythro-*p*-nitro-phenylserine and a trace amount of glycine. However, after 50 hr. of standing at room temperature, the mother liquor was found to contain phenylserine and an increased amount of glycine in addition to the threo- and erythro-*p*-nitro-phenylserine.

**Benzoyl Erythro- and Threo-phenylserine.**—Benzoyl-DL-erythro-phenylserine was prepared by the method of Shaw and Fox. Erythro-phenylserine was treated with benzoylchloride in the usual manner. M. p. 183~183.5°C (decomp.).

Found: C, 67.53; H, 5.48; N, 4.81%.

Benzoyl-DL-threo-phenylserine was prepared as above. M. p. 158°C (decomp.).

Found: C, 67.40; H, 5.43%.

**Resolution of Benzoyl-DL-erythro-phenylserine.**—*N*-Benzoyl-DL-erythro-phenylserine (28.5 g.) and quinine (27.2 g.) were dissolved in hot mixture of methanol (60 ml.) and acetone (40 ml.). When the solution had cooled down, crystallization of quinine salt began after seeding with an authentic specimen which was obtained during the crystallization experiment. After standing overnight in a refrigerator, the crystals were collected by filtration. The product after washing with cold acetone weighed 17.0 g. The quinine salt was recrystallized from 300 ml. of

99% ethanol, 14.0 g. of the quinine salt was obtained; m. p. 214~217°C (decomp.). The mother liquor from the recrystallization was combined with original mother liquor. From this, an additional 7.7 g. of quinine salt was isolated.

Found: C, 70.63; H, 6.31; N, 6.88. Calcd. for $C_{36}H_{39}O_6N_3$: C, 70.91; H, 6.45; N, 6.89%.

$[\alpha]_D^{22} = -105.0°$ (*c* 0.401, 99% ethanol).

Fifteen grams of the quinine salt was dissolved in ethanol, and to this solution, concentrated aqueous ammonia was added. The solution was then evaporated in vacuo to remove alcohol. The aqueous ammonia was added again and the evaporation was repeated until the ethanol was completely removed. The separated quinine base began to crystallize. The mixture was allowed to stand for a few hours for complete precipitation. The quinine was filtered off, then the filtrate was extracted three times with ether in order to remove residual quinine. The aqueous solution was concentrated in vacuo to 80 ml. and then acidified with 6 N hydrdrochloric acid to pH 2. The precipitated optically active benzoyl-erythro-phenylserine was filtered off. It was recrystallized from 35% ethanol, 5.7 g. of active benzoyl-erythro-phenylserine was obtained. M. p. 188~189°C (decomp.).

$[\alpha]_D^{23} = -29.3°$ (*c* 0.647, 99% ethanol).

Found: C, 67.27; H, 5.38; N, 4.90. Calcd. for $C_{16}H_{15}O_4N$: C, 67.36; H, 5.30; N, 4.91%.

**D-Erythro-phenylserine.**—(−)-*N*-Benzoyl-erythro-phenylserine (8.0 g.) was heated under reflux with 90 ml. of 15% hydrobromic acid for 3 hr. After hydrolysis, the solution was extracted three times with ether. After evaporation of the aqueous fraction under reduced pressure, water was added and the process repeated to remove the excess of hydrobromic acid. The residue was treated with silver carbonate and hydrogen sulfide. The dehydrobrominated solution was evaporated in vacuo, and the residue was dissolved in 15 ml. of hot water, then 15 ml. of dioxane was added to the solution. Two and a half grams of (−)-erythro-phenylserine dioxane adduct was crystallized out.

$[\alpha]_D^{26} = -53.7°$ (*c* 1.091, 2 dm, 2 N hydrochloric acid).

Found: C, 58.65; H, 6.70; N, 6.19. Calcd. for $(C_9H_{11}O_3N)_2C_4H_8O_2$: C, 58.65; H, 6.71; N, 6.22%.

Free (−)-erythro-phenylserine was prepared from the aqueous solution of the free amino acid by addition of much ethanol. The (−)-erythro-phenylserine has a sweet taste.

M. p. 193°C (decomp.). $[\alpha]_D^{25} = -68.0°$ (*c* 0.426, 2 N hydrochloric acid).

Found: C, 59.61; H, 6.12; N, 7.74. Calcd. for $C_9H_{11}O_3N$: C, 59.66; H, 6.12; N, 7.73%.

**Reduction of (−)-Erythro-phenylserine.**—A half gram of (−)-erythro-phenylserine dioxane adduct was heated at 150~160°C for 2 hr. with 15 ml. of hydrogen iodide and 0.6 g. of red phosphorus. The reaction mixture was filtered. It was then evaporated under reduced pressure, water was added and the process was repeated to remove the excess of hydrogen iodide. The residue was treated with silver carbonate and hydrogen sulfide, 160 mg. of D-phenylalanine was obtained.

$[\alpha]_D^{25} = +31.4°$ (*c* 0.780, 2 dm., water)

Found: C, 65.53; H, 6.65; N, 8.46. Calcd. for $C_9H_{11}O_2N$: C, 65.44; H, 6.71; N, 8.48%.

**L-Erythro-phenylserine.** — *N*-Benzoyl-L-erythro-phenylserine was isolated from the mother liquor of the quinine salt as shown above for the separation of D-erythro isomer, (+)-*N*-benzoyl-erythro-phenylserine, m. p. 182~183°C (decomp.).

$[\alpha]_D^{25} = +22.6°$ (*c* 0.973, 99% ethanol).

Found: C, 67.52; H, 5.44; N, 4.97. Calcd. for $C_{16}H_{15}O_4N$: C, 67.36; H, 5.30; N, 4.91%.

L-Erythro-phenylserine, m.p. 179~183°C (decomp.).

The L-erythro isomer has a bitter taste.

$[\alpha]_D^{25} = +51.2°$ (*c* 0.757, 2 N hydrochloric acid).

Found: N, 7.59. Calcd. for $C_9H_{11}O_3N$: N, 7.73%.

The authors wish to express their thanks to Professor Y. Yukawa of the Institute of Scientific and Industrial Research of this University for his helpful suggestions.

# *Forschung über den katalytischen Abbau des Kolophoniums*

Von Akira MITSUTOMI

(Eingegangen am 26. September, 1960)

Seit Berichterstattung durch Schulze[1] in 1877 über den thermischen Abbau des Kolophoniums sind mehr als 90 Jahre verflossen, aber wir haben vor uns nur ungefähr 10 Mitteilungen über das betreffende Thema. Vezes Dupont[2], Chevalier und andere[3] haben entweder durch direkte Kolophonium-Destillation oder seine Destillation mit organischen Säuren das Leichtöl für Brennstoff gewonnen. Es ist ruhig anzunehmen, dass es sich bei der Operation um einen thermischen Abbau des Kolophoniums bei 350～360°C handelt. Es ist beachtenswert, dass das brennstoffliche Leichtöl aus Kolophonium durch diese Forschung gewinnbar geworden ist. Tsukamoto[4] stellt auch bei Trockendestillation des Kolophoniums im gemeinsamen Einsatz von Aktivkohle und der japanischen Säureerde gasförmige und flüssige Produkte dar und ermittelt bei dem Letzteren Anthracen, Phenanthren, Reten u. s. w. Als Erster hat Newbery[5] den Abbau nach dem Gasphase-Verfahren vorgenommen. Als Katalysator wurde Aluminiumoxyd eingesetzt, wobei zweierlei flüssige Produkte, Sdp. 27～170°C oder 50～250°C, gewonnen wurden. Fast zu der gleichen Zeit hat Hoge[6] unterm Einsatz des Aluminiums als Katalysators bei 370～590°C den Abbau vorgenommen. Später in 1936 hat Lee[7] unterm Einsatz von Calciumoxyd, Ätzkali, der japanische Säurerde mit Calciumoxyd das Kolophonium abgebaut und Benzin, Kelosin u.s.w. dargestellt.

Es wurde durch solche Forschungsergebnisse klargemacht, dass durch Abbau des Kolophoniums Benzin-analoges Leichtöl zu gewinnen ist und die weitere Forschung hat ergeben, dass das Gasphase-Verfahren dabei das erfolgreichste Verfahren ist. Desalbres[8] berichtet, dass man unterm Einsatz der Fullererde den gesättigten Kohlenwasserstoff von Sdp. 60～130°C und flüssige Produkte von Sdp. 130～200°C gewinnen und diese Letzteren zum trocknenden Öl verwenden kann. Es ist aber Brodshi[9], der als Erster von den bisherigen Forschern den Reaktionszustand beim nach dem Gasphase-Verfahren erfolgenden Kolophonium-Abbau genau verfolgt hat. Er hat unterm Einsatz des Kupfers bei 500～700°C Kolophonium abgebaut und die Alkohole von Sdp. 30～200°C und flüssige Produkte von Sdp. 200°C und darüber erfasst. Er hat ferner jene Alkoholen auf analoge Weise abgebaut und ein Gemisch aus den aromatischen und ungesättigten Kohlenwasserstoffe von Sdp. 30～200°C dargestellt. Er hat bei den flüssigen hochsiedenden Produkten Naphthalin, Anthracen, Phenanthren, Reten nachgewiesen.

Wie oben beschrieben, sind durch Abbau des Kolophoniums die aus aromatischem Kohlenwasserstoff bestehenden flüssigen Produkte erhältlich. Annehmbar ist, dass diese für Brennstoff, Lösungsmittel, Schmierstoff, Emulgiermittel und andere Gebiete auch nützlich zu verwenden sind. Aber für einen kontinuierlich nach dem Gasphase-Verfahren erfolgenden Abbau des Kolophoniums vermisst man diesbezügliche Forschungsarbeiten. Fundamentale genaue Untersuchung ist erforderlich.

Es sollen nämlich in verschiedenen Punkten noch ergründet werden: Die Auswahl der haltbarsten Katalysatoren, die Festlegung der optimalen Temperatur, die nur den Abbau des Kolophoniums selbst einleitet, ohne aber dabei die Katalysatoren abbauen zu lassen, und die Ermittelung der ausbeutemässigen Veränderlichkeit der flüssigen Produkte bei kontinuierlichem Einsatz der Katalysatoren, sowie die Ermittelung der Zusammenhänge der katalysatorischen Einsatzmale mit der Anlagerungsmenge freien Kohlenstoffs an den Katalysatoren. Zur Gewinnung nützlicher flüssiger Produkte hat der Verfasser über den kontinuierlichen Abbau des Kolophoniums und des rohen Kieferharzes nach dem Gasphase-Verfahren Untersuchung gestellt.

## Experimentelle Vorrichtung und Operation

Die zu dieser Forschung herangezogene Vorrichtung wird in Abb. 1 gegeben. D stellt das verzinkte Eisenrohr von 90 ccm Länge und 2.8 ccm

Durchmesser dar. Das mit gewisser Menge Katalysatoren eingefüllte Reaktionsrohr wird in den Elektroofen eingebracht und 3~5 Std erhitzt, damit die Katalysatoren aktiviert werden. Dann wird gewisse Menge wasserfreies Benzol (100 oder 200 ccm) in $A_1$ in 1 eingegossen und unter Regelung des Hahns $C_1$ und mit vorgeschriebener Raumgeschwindigkeit ununterbrochen abtröpfeln gelassen. Die flüssigen Reaktionsprodukte werden in $A_2$ und $A_3$ gesammelt, während die gasförmigen Produkte in den Gassammler H zugeführt werden. Währenddessen sollen die Oberflächen der Flüssigkeiten inner- und ausserhalb des U-Rohrs S stets unter einem vermindertem Druck gehalten bleiben. Unter dieser Regelung wird der ganze Versuch durchgeführt.

Nach dem fertigen Abtröpfeln der ganzen Probenmenge in das Reaktionsrohr wird die Erhitzung eine weitere Stunde fortgesetzt. Die flüssigen Produkte werden dann destilliert, nach verschiedenen Siedepunkten eingeteilt und analysiert.

**Zubereitung der Proben.**—Da das in der Wärme verflüssigte Kolophonium auch bei über 150°C behaltener Temperatur zufolge eventuell eintretenden Temperaturabsinken weitgehende Viskositätsveränderung erfährt, ist es äusserst schwierig, das Kolophonium mit einer konstanter Raumgeschwindigkeit in das Reaktionsrohr zu bringen.

Rohes Kieferharz ist auch mit der ähnlichen schwierigkeit verbunden. Diese Schwierigkeiten wurden von uns dadurch behoben, dass das Kolophonium und das rohe Kieferharz jeweils in gewisser Menge Benzol zuerst gelöst und als solche Lösungen in das Reaktionsrohr eingebracht werden.

Es wurde 500 g davon in absolutem Benzol gelöst und 1 Liter Lösung wurde erhalten. Eine Entnahme dieser Lösung wurde auf dem Wasserbad bei der möglichst niedrigen Temperatur abgedämpft und das gemessene Gewicht des Rückstandes wurde zum Gewicht des Kolophoniums gemacht.

**Zubereitung des Katalysators.**—Es wurden beim Versuche 12 Sorten Katalysatoren eingesetzt. Einzelkatalysatoren: Japanische Säureerde, Kieselgur, Bimsstein, Kaolin und Bentonit.

Mischkatalysatoren: Japanische Säureerde—Aluminiumoxyd (70 : 30), —Aktivkohle (50 : 50), —Zinkoxyd (70 : 30), —Titanoxyd (70 : 30), Eisenoxyd (70 : 30), —Kieselsäureanhydrid (70 : 30), Zinksulfat (70 : 30).

Die Mischkatalysatoren wurden folgenderweise zubereitet. Zinkoxydpulver wurde, z. B., mit Wasser von ca. 50°C gut gerührt und im Mörser unter Zusetzung mit der japanischen Säureerde möglichst homogen vermischt. Anschliessend werden davon Kugeln von 5~8 mm Durchmesser hergestellt, bei 60°C 2 Std angetrocknet, weiter bei 110~120°C 1 Std vollständig abgetrocknet. Dann werden sie nach Packung im Reaktionsrohr bei 500°C ca. 3 Std zur Aktivierung erhitzt.

**Berechung der Ausbeute.** — Das Kolophonium besteht hauptsächlich aus Harzsäure, Abietinsäure und Dextropimarsäure, während das rohe Kieferharz daneben noch Terpene gemischt enthält. Daher ist mit Recht zu erwarten, dass als seine Abbauprodukte gesättigte und ungesättigte aliphatische Säuren und aromatische Kohlenwasserstoffe u. s. w. gegeben sind. In folgerichtiger Überlegung, dass diese Substanzen nach weiterem Abbauen auch Benzole bilden würden, wurde noch vor Einschickung der Proben-Benzollösung in dem Reaktionsrohr eine gewisse Menge absolutes Benzol ins Rohr eingeschickt und unter gleichen Bedingungen wie bei der Probelösung erhitzt. Die als Destillate auslaufenden Benzolmengen wurden bestimmt und das an Katalysatoren absorbierten Benzol gemessen, um die Resultate dem Berechnen in dem richtigen Versuche zugrunde zu legen.

Es wird z. B. angenommen, dass als Katalysator japanische Säureerde benutzt und bei 450°C reagieren gelassen wird. Zuerst werden $A$ ccm absolute Benzol zugegeben und erhitzt, wobei $b$ ccm Produkte als Destillate erhalten werden. Und $d$ ccm Benzol werden davon festgestellt.

Andererseits werden $M$ ccm Kolophonium-Benzollösung gleicherweise reagieren gelassen, wobei $E$ ccm als Destillate von dem Vorlauf bis 85°C aufgefangen werden. Dann ist die Menge der flüssigen Reaktionsprodukte, die bis zur Temperatur von 85°C tatsächlich zu erhalten sind, mit folgender Gleichung auszudrücken:

$$E-M\times\frac{107}{200}\times\frac{d}{A}\text{ ccm}$$

Werden die Destillate von 85 bis 200°C zu $F$ ccm und solche über 200°C zu $G$ ccm gesetzt, so ist die Gesamtmenge der Destillate, $N$ ccm, folgenderweise ausdrückbar:

$$N=\left(E-M\times\frac{107}{200}\times\frac{d}{A}\right)+F+G$$

Für das rohe Kieferharz wurde es auch anhand obiger Methode berechnet. Es ist bekannt, dass Benzol bei ihrer Druckströmung durch erhitztes Eisenrohr zufolge der dann eintretenden Polymerisation Diphenyl und Triphenyl erzeugen. Da aber diese Bildung nur insgesamt weniger als 1% bezogen auf die eingesetzten Benzole geschieht war in dieser Versuchsreihe solcher Fehler unberücksichtigt.

Falls Zinkoxyd—japanische Säureerde und Zinkchlorid—japanische Säureerde als Katalysatoren benutzt wurden, wurden Abbauprodukte zweifelsohne festgestellt, die niedriger sieden als Benzol. Diese Tatsache wurde natürlich bei Durchführung der Versuche berücksichtigt.

TABELLE I. ERGEBNISSE DER KONTINUIERLICHEN VERSUCHE*

| Sorten der Katalysatoren | Kieselgur | | | Japanische Säureerde | | | Japanische Säureerde und Aluminiumoxyd (70 : 30) | | |

Abb. 2. Zusammenhang zwischen der Reaktionstemperatur und Gewinnungsverhältnisse der flüssigen Produkte von niedrigem Siedepunkte.

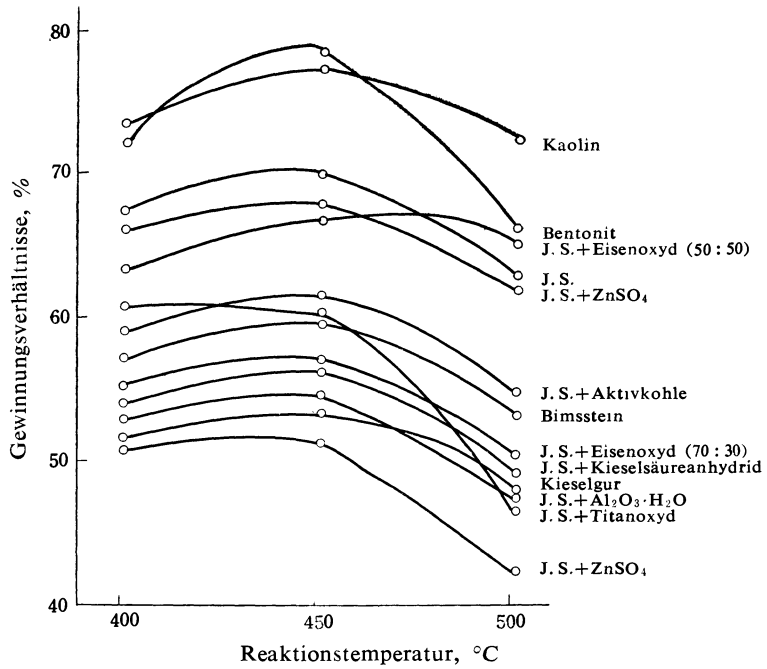

Abb. 3. Zusammenhang zwischen der Reaktionstemperatur und Gewinnungsverhältnisse der flüssigen Produkte.

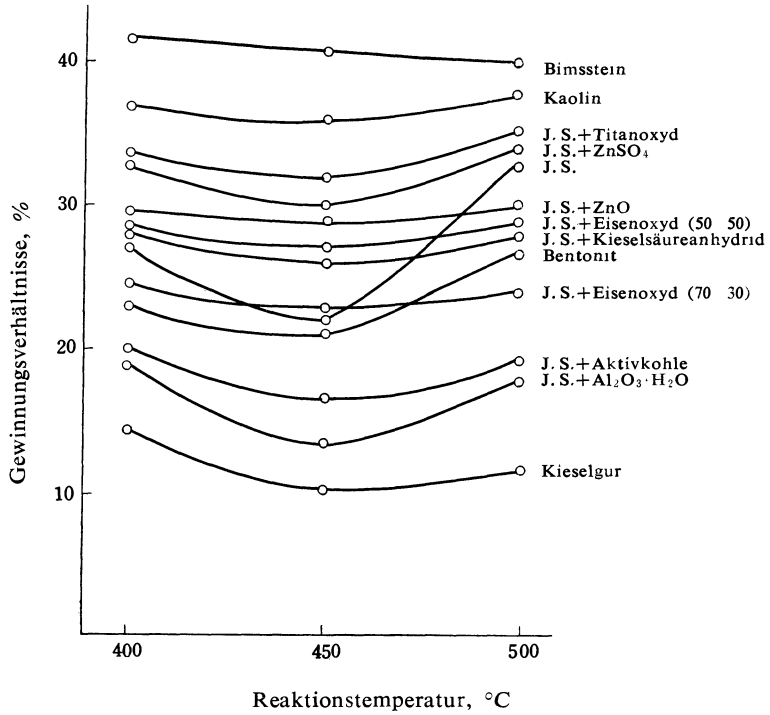

Abb. 4. Zusammenhang zwischen der Reaktionstemperatur und Gasentwicklungsmenge.

Flüssige Produkte in Abb. 1 — $A_2$ werden nach mehrmaligem Wäschen der Feindestillation unterzogen, und zwar dreiteilig abdestilliert, nämlich von dem Vorlauf bis zu 85°C, von 85 bis zu 200°C und von 200°C bis zu Trockenpunkt.

Der Destillationsverlust wurde nämlich nur bei dem niedersiedenden Fraktionen berücksichtigt. Der Verlust während des Wäschens und Abtrockenens ist aber über dis ganzen Fraktionen gleichmässig, so dass er zu $W$ ccm und der Destillationsverlust zu $L$ ccm gesetzt wird. Nach folgender Gleichung wird die Ausbeute berechnet:

Fraktion bis zu 200°C.....

$$\left(E-M\times\frac{107}{200}\times\frac{d}{A}\right)+F+L+W\times\frac{E+F}{E+F+G}$$

Fraktion über 200°C hinaus.....

$$G+W\times\frac{G}{E+F+G}$$

Gasförmige Produkte werden aus der Flasche H genommen, nach dem Hempel'schen Verfahren Kohlendioxyd etc. mengenmässig geprüft, dann mit 64% Schwefelsäure auf Isobutylen, mit 87% Schwefelsäure auf Butylen und Propylen, ferner mit 100% Schwefelsäure auf Äthylen analysiert.

## Versuchsergebnisse

Kolophonium besteht hauptsächlich aus Harzsäure, ferner Abietinsäure und Dextropimarsäure. Bei katalytischem Abbau trennt sich die Carboxyl-Gruppe los, um sich in Kohlendioxyd, Wasserstoff und Kohlenmonoxyd oder Wasser umzuwandeln. In Tabelle I sind mit der Beziehung als „diverse Gase" ihr Produktionsverhältnis angegeben. Bei diesen Gasen handelt es sich meistens um Kohlenmonoxyd und Wasserstoff mit geringem Anteil an Paraffin von niedriger Klasse. Bekanntlich ist aus Dextropimarsäure die Äthylen-Gruppe und aus Abietinsäure die Isopropyl-Gruppe leicht abspaltbar. Bei der katalytischen Abbau wie in vorliegendem Versuch müssen aber äusserst komplizierte Änderungen wie Polymerisation oder Verschiebung der Doppelbindung geschehen. Somit wird es nicht angebracht sein, direkt aus dem Bildungsverhältnis von Olefin auf des Abbauvermögen der Katalysatoren zu schliessen.

Kurz gefasst, ist es aus dem Versuchsergebnissen klar geworden, dass es zwischen der Ausbeute der flüssigen niedersiedenden Produkte und der Entwicklungsmenge der diversen Gase einen untrennbaren Zusammenhang besteht. Es wird demnach zu folgern, dass die geeignetesten Bedingungen für die Abbaureaktion mit vorzüglichen Katalysatoren eine erhöhte Bildung der niedersiedenden Fraktion und eine verminderte Gasentwicklung logischerweise ergeben.

Um zu finden, wie sich die Ausbeute an niedrigsiedenden flüssigen Produkten in Anhängigkeit von Reaktionstemperaturen verändert, wurden verschiedene Katalysatoren zum Abbau des Kolophoniums eingesetzt. Die Ergebnisse dieser Versuche wurden in Abb. 2

und 3 abgebildet, während die Gasentwicklungsmengen in Abb. 4 miteinander vergleichend gezeigt sind.

Die Ergebnisse der 8-malig kontinuierten Reaktion sind in Tabelle II aufgestellt. Es sei noch bemerkt, dass sich die an den Katalysatoren sich anlagernde freie Kohlenstoffmenge bei 3-maliger und 8-maliger kontinuierlicher Anwendung jeweils als 11 und 45 aufwies.

Die Ergebnisse bezüglich der Haltbarkeit, des Vermögens und der Regenerierbarkeit der Katalysatoren zeigen, dass als Katalysator für Abbau des Kolophoniums die Kieselgur der Beste ist. Dabei wird nämlich die höchste Produktionsmenge von flüssigen Fraktionen von niedrigem Siedepunkt schon bei verhältnismässig niedriger Temperatur erzielt. Andererseits liefern japanische Säureerde und das Gemisch derselben mit Aluminiumoxyd (70 : 30) gleiche gute Ergebnisse wie Kieselgur, sie besitzen aber den Nachteil einer kürzeren Haltbarkeit.

Von den Mischkatalysatoren zeigen das Gemisch der japanischen Säureerde mit Kieselsäureanhydrid (70 : 30) und dasselbe mit Zinksulfat (70 : 30) sowie dasselbe mit Titanoxyd (70 : 30) verhältnismässig gute Ergebnisse, sie liegen aber hinter der obengenannten Kieselgur zurück.

### Kohlenstoffanlagerung

Die Bestimmung der Anlagerung freien Kohlenstoffs an 100 g Katalysator bei Abbau von 100 g Kolophonium ergab die Ergebnisse in Tabelle III. In der Annahme, dass nach dem bei gleicher Temperatur erfolgten Abbau die Katalysatoren an ihrem eignen Gewicht keine Veränderung erfahren, wurde die Gewichtszunahme der Katalysatoren mit der angelagerten Kohlenstoffmenge gleichgestellt. Mit dieser Methode ist allerdings die aktuelle Anlagerungsmenge des Kohlenstoffs nicht zu ermitteln, aber sie ist insofern anwendar, als das „anscheinende Gewicht" nur zum Vergleich der Katalysatoren untereinander in Frage kommt. Diese zeigen, dass die Kieselgur oder das Gemisch von japanischer Säureerde mit Aktivkohle als Katalysator die geringste Anlagerung und Kaolin die nächst-geringste ergibt.

TABELLE III. ZUSAMMENHANG ZWISCHEN DEN KATALYSATORENSORTEN UND KOHLENSTOFF ANLAGERUNGSMENGE BEI DER ABBAUREAKTION VON KOLOPHONIUM

| Katalysatoren, 100 g | | A | B °C | C g |

A: Mischverhältnis
B: Reaktionstemperatur
C: Kohlenstoffanlagerung bezogen auf 100 g Einsatz des Ausgangsmaterials

### Haltbarkeit der katalysatorisch eingesetzten Kieselgur

Um die Kieselgur auf ihre katalysatorische Haltbarkeit zu prüfen, ein Zapfen für Umschaltung angebracht wurde, um bei fertigem Tröpfeln einer gewissen Menge des Kolophoniums jedesmals die flüssigen Produkte und Gas aufzufangen. Die flüssigen Produkte wurden destilliert und in 2 Fraktionen bis 200°C und über 200°C eingeteilt. Von den Gasen wurden die Anteile an Kohlendioxyd, Wasserstoff, Olefinen, Parafinen und so weiter prozentual analytisch bestimmt.

Als Katalysator wurden 108 g Kieselgur, eingesetzt und 100 g Kolophonium mit einer Raumgeschwindigkeit von 18 ccm/Std ins Reaktionsrohr bei 450°C geschickt.

Die an dem Katalysator angelagerte Menge freien Kohlenstoffs betrug nur 64 g erst nach dem beendeten Abbau von 1700 g Kolophonium. Daher ist anzunehmen, dass die Haltbarkeit dieses Katalysators verhältnismässig lang ist.

### Bestandteilmässige Untersuchung der flüssigen Produkte

Es wurden die flüssigen Produkten zuerst in die zwei Fraktionengruppen, nämlich in die bis zu 200°C und die däruber, eingeteilt. Die Erste wurde weiterer Feindestillation unterworfen. Hiervon wurden die Fraktion von Sdp. 85～90°C in Eisessig gelöst, brominiert, destilliert, um Brombenzol ergeben zu lassen, damit Benzol ermittelt wurde.

Auch zur Ermittelung des Toluols wurden die Fraktion von Sdp. 108～115°C weiterer Feindestillation unterzogen und in 2,4-Dinitrotoluol überführt. Dann wurde die Fraktion von Sdp. 128～145°C weiterer Feindestillation unterzogen, oxydiert, wonach Terephthalsäure zur Ermittelung des *p*-Xylol erfasst wurde. Von der Fraktion von Sdp. 149～159°C

wurde Cumol, von derselben von Sdp. 159～171°C Pseudocumol, und von derselben *p*-Cumol als sulfonsaures Barium gesondert und ermittelt. Trennung weiterer Bestandteile war äusserst erschwert, so dass eine Reindarstellung unmöglich war.

Als Bestandteile der flüssigen Produkte von höherem Siedepunkt als 200°C wurden Naphthalin, Anthracen, Phenanthren, Reten ermittelt. Naphthalin war von den Kondensaten bei Sdp. 215～235°C leicht als Pikrat ermittelt.

Die aus dem Kondensat von Sdp. 320～360°C ausgeschiednen Kristalle konnten nach Umkristallisierung aus Alkohol mit anschliessender Oxydation zu Anthrachinon als Anthrachinon nachgewiesen wurde. Ferner wurde Phenanthren nachgewiesen, indem die aus der Mutterlauge der Anthracen-Umkristallisierung erhaltenen Kristalle mit Chromsäureanhydrid zu Phenanthrachinon oxydiert wurden.

Die Trennung des Retens war äusserst schwierig. Die Kondensate über Sdp. 360°C wurden nämlich stark abgekühlt. Die dabei ausgeschiedenen Kristalle wurden getrennt. Durch ihre Umkristallisation wurde das dabei zuerst zur Abscheidung kommende Anthracen getrennt. Die Mutterlauge wurde mit Pikrinsäure-Benzollösung zugesetzt, wodurch Retenpikrat zur Ausfällung kam. Dies wurde durch Mischprobe nachgewiesen.

**Zusammenfassung**

Es wurden gefunden, dass als Katalysator zur Herstellung nützliche Kohlenwasserstoffe beim katalytischen Abbau des Kolophoniums nach dem Gasphaseverfahren bei gewöhnlichem Druck die Kieselgur auch für kontinuierliche Arbeit der Hervorragendste ist.

Die Reaktionstemperaturen um 450°C sind die Optimalen, wobei der prozentuale Gewinnungssatz für die flüssigen Produkte 53.7% beträgt. Diese flüssige Produkte werden in die Fraktion bis zu 200°C und dieselbe darüber eingeteilt. Aus der Vorderen wurden Benzol, Toluol, Xylol, Cymol, Pseudocymol, *p*-Cymol nachgewiesen, während aus der Letzteren Naphthalin, Anthracen, Phenanthren, Reten ermittelt wurden.

Bei den gasförmigen Produkten betrug der prozentuale Gewinnungssatz 8.6%. Sie bestanden hauptsächlich aus Kohlendioxyd, Olefine, Kohlenmonoxyd, Wasserstoff und Paraffinen.

Zum Schluss sei es noch bemerkt, dass die vorliegende Arbeit unter der Leitung von Herrn Professor Dr. Eiichi Funakubo an der Technischen Fakultät der Universität zu Osaka durchgeführt wurde.

# *Forschung über den katalytischen Abbau des rohen Kieferharzes*

Von Akira MITSUTOMI

(Eingegangen am 26. September, 1960)

Da das rohe Kieferharz als Gemisch aus Kolophonium und Terpenen gehalten werden kann, hat der Verfasser zum Versuch genau dieselbe Vorrichtung wie beim Kolophonium eingesetzt und fast gleicher Weise der katalytische Abbau des rohen Kieferharzes durchgeführt. Dabei wurde natürlich genau geprüft, ob die Kieselgur auch als Katalysator für kontinuierliche Abbau nach dem Gasphaseverfahren angepasst ist, wie es bei dem Kolophonium der Fall ist, und welche andere Katalysatoren dann die besten Ergebnissen darbringen.

### Zubereitung der Katalysatoren

Es wurden für vorliegende Versuchsreihe 17 folgende Katalysatoren eingesetzt.

Japanische Säureerde Nr. 1: Mit Wasser zugesetzt, verformt und aufgetrocknet.

Japanische Säureerde Nr. 2: In 10% Salzsäure eingetränkt, ca. 5 Std lang erhitzt, durch Dekantierung von Salzsäure getrennt mit Wasser gewaschen, bis das Spülabwasser neutral wird, und dann aufgetrocknet.

Japanische Säureerde Nr. 3: Mit 38% Salzsäure, wie oben beschrieben, behandelt.

Kupferoxyd: Marktbefindliches Kupferoxyd in Wasser aufgelöst, mit Ätznatronlauge behandelt: Nach Abspülen des gebildeten Hydroxyds erhitzt.

Zinkoxyd: Marktbefindliches Zinkoxyd behandelt, wie oben beschrieben.

Mischkatalysatoren:

Japanische Säureerde-Aluminiumoxyd (80 : 20), (70 : 30), (50 : 50), (30 : 70).

Japanische Säureerde-Zinkoxyd (90 : 10), (70 : 30).

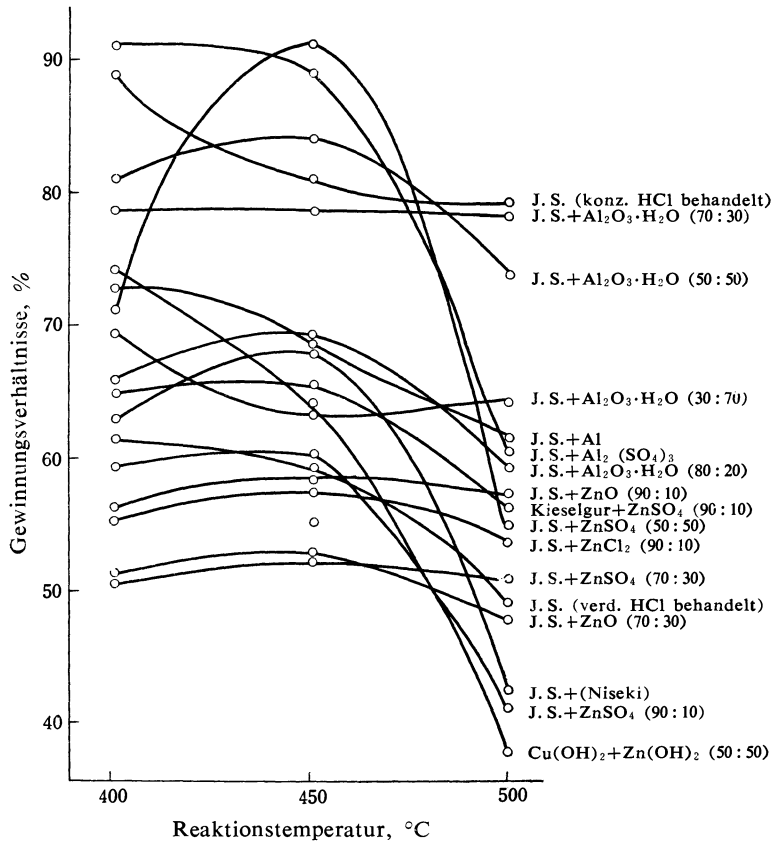

Abb. 1. Zusammenhang zwischen der Reaktionstemperatur und dem Gewinnungsverhältnisse der flüssigen Produkte.

J. S. : Japanische Säureerde

Japanische Säureerde-Zinkchlorid (90 : 10).
Japanische Säureeerde-Zinksulfat (90 : 10), (70 : 30), (50 : 50).
Japanische Säureerde-Aluminiumsulfat (70 : 30).
Japanische Säureerde-Magnesiumoxyd (70 : 30).
Kieselgur-Zinksulfat (90 : 10).
Kupferoxyd-Zinkoxyd (50 : 50).

Die oben genannten Katalysatoren wurden zu Kugeln mit gleich grossem Durchmesser vorformt wie es beim Abbau von Kolophonium der Fall war, und in gleichförmige Reaktionsanlage eingefüllt, vorgehitzt und aktiviert.

### Versuchsergebnisse und Beitrag darüber

Unter Verwendung gleichartiger Reaktionsvorrichtung wie bei vorher beschriebenem Kolophonium, wurde das rohe Kieferharz bei 400, 450 und 500°C Erhitzung gespaltet. Gleichzeitig mit Bestimmung des Gesamtvolumens der dabei produzierten Gase, des prozentualen Gehaltes an Kohlendioxyd, Olefinen, Wasserstoff, Paraffinen u. s. w. wurden flüssige Produkte auf ihr Bildungsverhältnis geprüft, indem sie in zwei Franktionen von denselben von 85 bis 200°C und über 200°C eingeteilt wurden.

Aus diesen Werten wurde das Abbauverhältnis von rohem Kieferharz errechnet. Daraufhin wurde das Abbauvermögen der Katalysatoren miteinander verglichen. Die Ergebnisse sind zum erleichterten Vergleich in Abb. 1 und 2 veranschaulicht. Basierend auf diesen Ergebnissen wurde folgende Batrachtung gestellt. Es war der Zweck der Versuche, rohen Kieferharz dem katalytischen Abbau zu unterziehen und das Gemisch von verschiedenen Kohlenwasserstoffen vom Siedepunkt unterhalb von 200°C mit guter Ausbeute darzustellen. Aus diesem Standpunkt ist zu finden, dass, zwar mit einigen Ausnahmen, der Abbau bei 450°C das beste Ergebnis lieferte. Alle als Katalysatoren eingesetzten Stoffe ergaben mit Ausnahme von dem Gemisch des Kupferoxyds mit Zinkoxyd gute Resultaten, und zwar wurde die Ausbeute von durchschnittlich 35 bzw. 50% erhalten. Vor allem erwies sich das Gemisch der japanischen Säureerde mit Aluminiumoxyd (50 : 50) als das Beste. Die dreimalig kontinuierlich erfolgte Spaltung von je 100 g rohem Kieferharz bei 450°C wies für flüssige

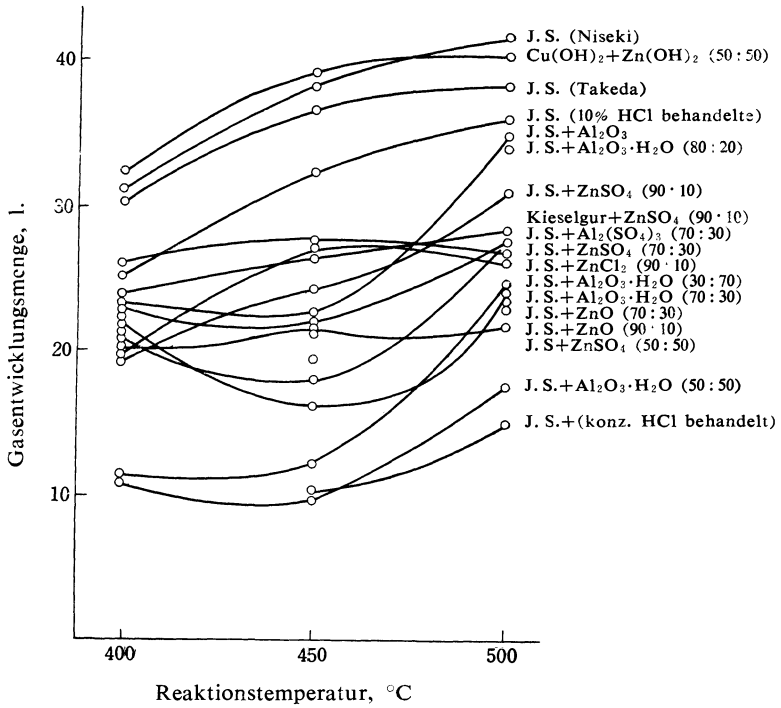

Abb. 2. Zusammenhang zwischen der Reaktionstemperatur und der Gasentwicklungsmenge.
J. S. : japanische Säureerde

Produkte von niedrigem Siedepunkt die Ausbeute von 44.5, 58.8 und 65.4% jeweils auf. Dabei wurde ferner bei Beendigung der dritten Reaction die Anlagerung freien Kohlenstoffs auf dem Katalysator nur als 10 g verwogen.

Als der nächstbeste erwies sich die mit konz. Salzsäure behandelte japanische Säureerde. Der bei 400°C und 450°C dreimal fortgesetztem Abbau von je 500 g Ausgangsmaterial zeigte für niedrigsiedende flüssige Produkte einen Mittelwerte von 50% Ausbeute auf.

Demgegenübre wurde bei dem Mischkatalysator von japanischer Säureerde und Zinksulfat (50 : 50), japanischer Säureerde und Zinkoxyd (90 : 10) eine Durchschnittsausbeute von 45% erzielt, aber eine erhöhte Anlagerung freien Kohlenstoffs auf den katalysatoren wurde mit weniger Haltbarkeit ermittelt.

**Anlagerung des Kohlenstoffs.** — Messung der Anlagerung freien Kohlenstoffs auf 100 g Katalysator beim Abbau von 100 g Roh-Kieferharz ergab die Ergebnisse von Tabelle I. Aus diesen Ergebnissen ist klar geworden, dass bei Katalysatoren aus Aluminiumoxyd, vor allem bei japanische Säureerde und Aluminiumoxyd Gemisch, die geringste Anlagerung freien Kohlenstoffs mit der längsten Haltbarkeit zu finden ist. Beim Gemisch der japanischen Säureerde mit Zinkchlorid wurde die höchste Anlagerung freien Kohlenstoffs mit dem Angriff des durch Abbau des Katalysators zu bildenden Chlors auf die Reaktionsanlage bestätigt, so dass dasselbe als katalysator unmöglich anzuwenden ist.

**Haltbarkeit des Mischkatalysator aus japanischer Säureerde und Aluminiumoxyd.** — Nach den obigen Untersuchungsergebnissen hat es sich herausgestellt, das der Mischkatalysator der japanischen Säureerde mit Aluminiumoxyd als Abbauskatalysator für rohes Kieferharz das geeigneteste ist.

Die Prüfung der Haltbarkeit erfolgte in gleicher Vorrichtung wie es bei Kolophonium der Fall war; 178 g Mischkatalysator aus japanischer Säureerde und Aluminiumoxyd (70 : 30), 223 ccm nach Volumen, wurden ins Reaktionsrohr eingeschickt. Dadurch wurden 2 kg rohes Kieferharz mit 18 ccm/Std Raumgeschwindigkeit bei 450°C gespaltet. Die Ergebnissen sind in Tabelle II verzeichnet. Nach diesen Versuchsergebnissen kann man wissen, dass sich die Ausbeute für niedrigsieden den flüssigen Produkte bei Auftragung von 500 g rohes Kieferharz als maximal erweist. Von

A : Abtröpfelungsmenge des rohen Kieferharzes
B : Reaktionsdauer
C : Entwicklungsvolumen
D : $CO_2$
E : Olefine
F : Diverse Gase

dem erreichten fertigen Abbau des 900 g Roh-Kieferharzes an weist nunmehr der Abbau ein ungefähr konstantes Bild auf. Aber nachher verschlechtert sich der Abbau selbst. Es erweist sich endlich die Ausbeute von den flüssigen Produkten mit niedrigem Siedepunkt als 30%. Die während dieses ganzen kontinuierlichen Abbaus auf den Katalysatoren angelagertin Menge des freien Kohlenstoffs betrug nur 84 g.

**Bestandteile der flüssigen Produkte.** — Das rohe Kieferharz ist als Kolophonium mit Terpenen-Zusatz zu betrachten. Bei den durch den katalytischen Abbau hergestellten Produkten zeigt das Klophonium keinen grösseren Unterschied von dem rohen Kieferharz. Insbesondere bei Abbau bei einer hohen Temperatur über 400°C können die meisten Terpenen mit grosser Möglichkeit in gasige Substanzen ungewandelt werden. Dieser Umstand ist leicht einzusehen, wenn man die gebildete Gasmenge bei dem 450°C kontinuier-lichen Kolophonium-Abbau unter Verwendung der Kieselgur als Katalysator und dieselbe von der gleicherweise erfolgten Roh-Kieferharzspaltung bei 450°C vergleicht.

Die Untersuchnng der durch Abbau des rohen Kieferharzes dargestellten flüssigen Produkte stellte Benzol, Toluol, Xylol, Cumol, Pseudocumol, *p*-Cymol, Naphthalin, Anthracen, Phenanthren und Reten fest. Es waren also gleiche Ergebnisse wie bei dem bereits beschriebenen Kolophonium.

Als gasförmige Produkte wurde Wasserstoff, Kohlendioxyd, Kohlenoxyd, Olefinen festgestellt. Aber die chemische Zusammensetzung der Olefine wurde nicht geforscht.

## Zusammenfassung

Für kontinuierliche Gewinnung der flüssigen Produkte von niedrigem Siedepunkte durch den katalytischen Abbau des rohen Kieferharzes hat sich das Verfahren mit den Mischkatalysator aus der japanischen Säureerde und Aluminiumoxyd anzuwenden als das Erfolgreichste erwiesen.

Die Reaktionstemperatur wird am besten 450°C gewählt, wie es bei Kolophonium der Fall war. Es ist interessant, dass die Kieselgur, die sich bei Kolophonium bewährt hat, bei dem rohen Kieferharz nicht so sehr gute Ergebnisse dargebracht hat. Es wurde erkannt, dass es sich bei den Abbauprodukten bestandteilmässig fast um die gleichen Verbindungen wie bei dem Kolophonium.

Zum Schluss sei es noch bemerkt, dass die vorliegende Arbeit unter der Leitung von Herrn Professor Dr. Eiichi Funakubo an der Technischen Fakultät der Universität zu Osaka durchgeführt wurde.

# *An Analysis of Ishikawa's Equation of State as Applied to the Critical Region of Isopentane*

By Tetsuya ISHIKAWA and Minoru IKEDA

(Received September 29, 1960)

In the last report of this series of study[1], one of the present authors (Ishikawa) made a close investigation of his equation of state: for one mole of gas

$$p+\frac{a}{V^{2-\varepsilon}}=\frac{RT}{V-b}$$

where $a=3p_cV_c^2$, $b=V_c/3$ and $\varepsilon$ is an empirically determinable parameter which depends upon molecular association, its factor, $A$, being defined by him as the ratio of observed $P_cV_c/RT_c$ to its van der Waals' value 8/3, or $A=(1+3V_c^{\varepsilon})/4$ at the critical point. He remarked that $\varepsilon$ varies but little with the volume and that $\varepsilon$-$V$ curves of xenon and neopentane, $C(CH_3)_4$, in the critical region appear alike to

consist of three parts, the first part being concave up to the critical point, or more precisely speaking, at first probably showing a minimum which is situated at the volume corresponding to the minimum of $p$-$V$ curve plotted by his equation, taking $\varepsilon$ to be that at the critical point, and finally a nearly straight line, the second part being undoubtedly a long straight line starting from the critical point; or, at the critical point the second and higher derivatives of $\varepsilon$ with respect to the volume appear to be zero, and the third part being convex upward to the maximum which may correspond to the volume at which the other form of van der Waals' equation ($b=V_c/3$) takes the critical pressure. This paper is intended to analyze the $\varepsilon$-$V$ curve by making use of Young's precise $PVT$-measurements on

isopentane at the temperature range of 170～200°C, the critical temperature being 187.8°C[2].

### Analysis of $\varepsilon$-$V$ Curves

For the estimation of $\varepsilon$ at each isotherm of isopentane, we take the following values: $T_c$=187.8+273.16°K, $p_c$=25000 mmHg (32.89 atm.), $d_c$=0.2343 cm$^3$ g$^{-1}$, these values being quoted from the same observer's values on the border curve of this substance[3], $M$=72.151, $R$=82.06 cm$^3$ atm. deg$^{-1}$ mol$^{-1}$, log $a$=6.9711254, and $b$=102.68 cm$^3$ mol$^{-1}$.

In the liquid portion below the critical temperature, it is highly probable as estimated that $\varepsilon \times V^{1/3}$ is constant at each isotherm, the mean values being 0.4674 (2.4～2.5), 0.4564 (2.4～2.7), 0.4513(2.4～2.8) and 0.4472(2.4～3.0) at 170, 176, 180 and 185°C, respectively, the numbers in the parentheses showing volume ranges in cm$^3$ g$^{-1}$, and so we have conducted similar operation on the $\varepsilon$ values at and above the critical temperature, 187.8, 190, 195 and 200°C, their mean values being 0.4455(2.4～3.0), 0.44305(2.4～3.0), 0.4376(2.4～2.8) and 0.4320 (2.5～2.6), respectively. These constants are denoted by $c_1$'s.

All these values except that at 170°C, multiplied by each temperature in the absolute scale $T$, gave a constant value 204.89±0.34 (0.17% probable error), and therefore each value can be written as $204.89/T$. Let $\varepsilon$ in the liquid portion be denoted by $\varepsilon_l$, then $\varepsilon_l$ is the product of the above obtained value at each isotherm by $V^{-1/3}$ or is briefly expressed by $204.89/TV^{1/3}$. In the region of liquid and gaseous coexistence, however, $\varepsilon$ may become very complicated as supposed from the critical isotherm stated above, so we will make trial by taking the sum of $\varepsilon_l$ and $\varepsilon$ in this region to search for $\varepsilon$ in gaseous form in this region which is denoted $\varepsilon_g$. Unfortunately as Young's data are lacking in this region, we are obliged to study the functional form of $\varepsilon_g$ in the isotherms of from 187.8 to 200°C, above which the constant range of $\varepsilon \times V^{1/3}$ in the liquid portion apparently disappears.

As seen from Table I, the values of $(\varepsilon_l+\varepsilon_{obs})$ decrease at first, then approach nearly a constant, and again decrease.

For a supplementary test we will quote from the later $PVT$-measurements[4] on neopentane by Beattie, Douslin and Levine together with their earlier measurements[5] at 160.50～160.70°C, the critical temperature being 160.60°C already treated (see Table II). The constancy of $\varepsilon \times V^{1/3}$ in the liquid portion, $V$=142.9～222.2 cm$^3$·mol$^{-1}$, is not so good as those which appeared in Table I, yet we dare take their geometric mean values as 0.4246. The constant range in the region of coexistence distinctly occurs between 304.9 and 400 cm$^3$ mol$^{-1}$, their mean value being 0.13721, the range of which is a little beyond the upper limit of coexistence at 160.00°C as referred to Fig. 1 in the earlier paper of these observers.

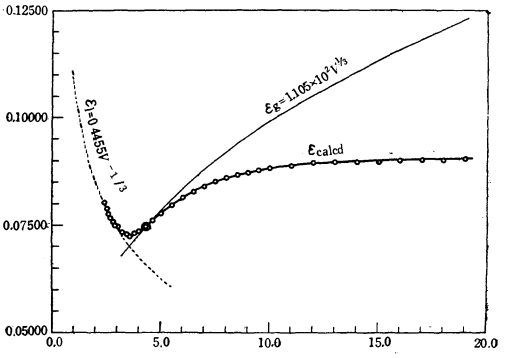

Fig. 1. $\varepsilon$-$v$ Diagram of isopentane at 187.8°C.

The existence of a constant range of $(\varepsilon_l+\varepsilon_{obs})$ as observed in this example has given us a clue for analyzing the first decreasing range up to a constant range: Putting the value $\varepsilon_{obs}-\{(\varepsilon_l+\varepsilon_{obs})-0.13721\}$, where $\varepsilon_l=0.4246V^{1/3}$, to be the form $c_2V^n$, $n$ and $c_2$ being constants, we have obtained $n=1/3$ and $c_2=1.106\times10^{-2}$. Similar calculations have given us the respective values for isopentane as follows: $n=1/3$ for all the cases and $c_2$'s are 1.105, 1.097, 1.081 and $1.064\times10^{-2}$ at 187.8, 190, 195 and 200°C, respectively, and $c_2=1.1145\times10^{-2}$ at 185°C has been graphically obtained from the preceding values which are quite linear against temperature. At the critical temperature where $V=V_c$, for neopentane $1.106\times10^{-2}\,V_c^{1/3}$ ($V_c$=303.0 cm$^3$ mol$^{-1}$)=0.07429, which is fairly coincident with the observed $\varepsilon$=0.07411, for isopentane $1.105\times10^{-2}\,V_c^{1/3}$ ($V_c$=4.268 cm$^3$ g$^{-1}\times$72.151=307.94)=0.07479, which is also coincident with the observed $\varepsilon$=0.07486. Thus it is highly probable that the common form of $c_2V^{1/3}$ obtained above is no other than the required $\varepsilon_g$ in each isotherm. This result shows us that in the critical isotherm $\varepsilon_l+\varepsilon_g$=a constant for the volume range up to the critical volume, or in other words, the molecular complexities of liquid and gaseous states are in equilibrium for this range.

In the isotherms above the critical temperature, the same phenomenon is also observed,

but the constant range becomes short and shifts to greater volume than the critical volume.

In these ranges $\varepsilon_{calcd}$ can be estimated from a transformed relation: $\varepsilon_{calcd}=\varepsilon_{obs}-(\varepsilon_1+\varepsilon_g-\text{a constant})$, without doing the direct analysis of $\varepsilon_{obs}$. Next we consider $\varepsilon$-$V$ curve beyond the critical volume. Since in the critical isotherm of isopentane $\varepsilon_g=1.105\times10^{-2}V^{1/3}$ coincides numerically with the observed $\varepsilon$ in case $V=V_c$ and so $\varepsilon_1=0.4455\,V^{-1/3}$ vanishes as would be expected, we may put the change in molecular complexity in gaseous state to be the difference between the thus computed $\varepsilon_g$ and $\varepsilon_{obs}$ at the same volume, and assume that this difference is proportional to $V^n$, or $\varepsilon_{obs}=\varepsilon_g-c_3V^n$, $n$ and $c_3$ being constants. This calculation necessitates dividing the $\varepsilon$-$V$ curve into at least six parts: $n=4$ and $c_3=6.115\times10^{-14}$ (6.0~7.0), $n=3$ and $c_3=3.124\times10^{-11}$ (7.5~9.0), $n=2$ and $c_3=2.103\times10^{-8}$ (9.5~14), $n=4/3$ and $c_3=2.131\times10^{-6}$ (15~19), $n=1$ and $c_3=2.398\times10^{-5}$ (20~40), and $n=2/3$ and $c_3=3.416\times10^{-4}$ (50~100), the parentheses being volume range in $cm^3\,g^{-1}$. Similarly $n$'s and $c_3$'s of other isotherms have been obtained with expected results. For an example of the above results, we adopt from Table I (critical isotherm) with Fig. 1, in which $\varepsilon_{obs}$ is denoted by ○, $\varepsilon_{obs}$ at the critical point by ◎, $\varepsilon_{calcd}$ by a thick line, $\varepsilon_1=0.4455\cdot V^{-1/3}$ and $\varepsilon_g=1.105\times10^{-2}V^{1/3}$ by dotted and fine lines respectively.

## Discussion of the Results

Ishikawa's equation of state, though it is superior to most of the hitherto published equations of state, does not hold quantitatively in the critical region, so long as $\varepsilon$ is assumed to be a constant throughout the whole range of volume. However, if we consider it to consist of sets of volume functions having one ($c_1$ for the liquid portion) or two ($c_1$ and $c_2$, $c_2$ and $c_3$ for the coexistence and gaseous portions) constants analytically obtained from $\varepsilon_{obs}$, his equation holds for a certain range of volume during which the same molecular complexity continues.

In the liquid portion the increase in $V^{1/3}$ or in average molecular distance (if it is assumed that a molecule is spherical with a diameter $\sigma$, $V=\pi\sigma^3N/6$ where $N$=Avogadro's number, and average molecular distance is the distance

between the centers of the nearest molecules) causes the decrease in $\varepsilon$, this being consistent with the ordinary physico-chemical conception, whereas in the liquid and gaseous coexistence portion up to the critical volume the increase in average molecular distance causes the decrease in $\varepsilon$ of liquid form, $\varepsilon_l$, and at the same time the increase in $\varepsilon$ of gaseous form, $\varepsilon_g$, this being a case which is usually explained by the LeChatelier principle of mobile equilibrium. In the gaseous portion the decreasing rate from $\varepsilon_g$ is propotional to the $n$th power of average molecular distance thus: $n=12$ for 1.15~1.18 times, $n=9$ for 1.21~1.28 times, $n=6$ for 1.31~1.45 times, and $n=4$ for 1.50~1.67 times the average molecular distance at the critical point (9.95 Å according to the above assumption).

According to Warren's study[6] from Stewart's X-ray diffraction measurements on normal paraffins from pentane to pentadecane[7], the long-chain molecules are straight in liquids and neighboring molecules are roughly parallel, 5.65 Å apart from each other, as if it were the diffraction of diatomic molecules, and also according to Müller the diffraction ring in normal paraffins observed by Stewart is due to assemblages of molecules (cybotactic groups), the average distance of the nearest approach near their melting points being 4.5~5.0 Å[8]. As computed from the relation $A=(1+3V_c^e)/4$, the molecular association factors of neopentane, isopentane and *n*-pentane at their critical points are estimated to be 1.395, 1.402 and 1.471, respectively, the last being the value quoted from the critical constants measured by Beattie, Levine and Douslin[9]. These values are near to slightly polar substances such as methyl acetate (1.45), ethyl acetate (1.46) and propyl acetate (1.47) than to diatomic molecules such as nitrogen (1.29), oxygen (1.20), chlorine (1.35) and bromine (1.30). As a summery of the present analyses, we give in columns 10 and 11 in Table I the thus computed pressures, $p_{calcd}$, and their percentage deviations from the observed pressures, $p_{obs}$. On the whole, these deviations are so small that they are supposed to be experimental errors, since they are within less than 0.27% on the average up to 19~20 $cm^3g^{-1}$.

It is worth mentioning that Ishikawa's equation of state to which the thus suitable analyses are applied yields no such discrepancy from experiments in the critical region as all other equations of state generally do. Fig. 2 shows

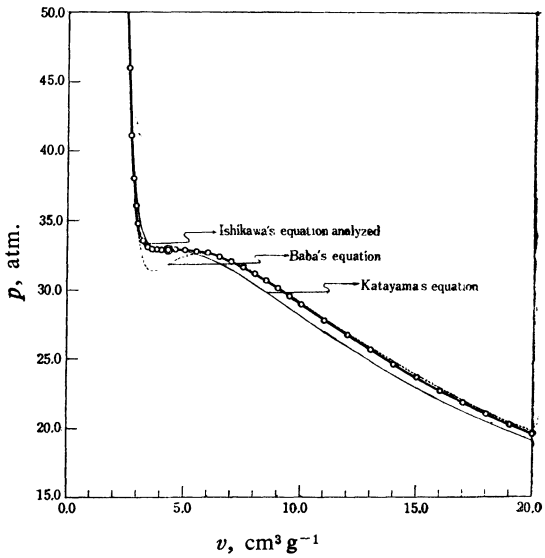

Fig. 2. Critical isotherm of isopentane.

the comparison of Ishikawa's equation adopted from Table I (thick line, 0.21% deviation up to 19 $cm^3g^{-1}$) with Katayama's equation[10] (fine line, 1.81% deviation up to 20 $cm^3g^{-1}$) and Baba's equation[11] (dotted line, 1.96% deviation up to 19 $cm^3g^{-1}$) which were applied by themselves to the same Young's data of isopentane.

## Conclusion

The above results lead to the following conclusions (1) that liquid associated molecules still exist at least 12°C above the critical temperature, and that they are assembled up to the critical volume, as judged from the coexistence condition for liquid and gaseous states: $\varepsilon_l+\varepsilon_g=$ a constant, where $\varepsilon_l=c_1V^{-1/3}$ and $\varepsilon_g=c_2V^{1/3}$, the former corresponding to the functional form of $\varepsilon$ for liquid assemblages and the latter to the base functional form of $\varepsilon$ for gaseous assemblages, (2) that gaseous associated molecules exist from the lower point on the border curve to the gaseous region, and are disassembled from the base functional form proportional to the average distance stepwise with volume increase by van der Waals' forces of the 12th, 9th, 6th, 4th, 3rd and 2nd powers of average distance for their respective volume ranges, and therefore (3) that the nature of the $p$-$V$ curve is, from the analytical standpoint of view, not continuous but discontinuous, and a clear difference in the functional forms between $\varepsilon_l$ and $\varepsilon_g$, and

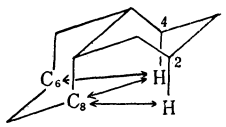
# *The Effect of Conformation on Reactivity. III*[1]. *Acetolysis of the cis-Decalyl p-Toluenesulfonates*

By Ichiro MORITANI*, Shinya NISHIDA and Masuo MURAKAMI

(Received January 14, 1961)

It has been shown that the strain arising from the compression between the tosyl group and the hydrogen atom in the 1, 3-diaxial positions to each other in the 1- and 2-*p*-toluenesulfonates of *trans*-decalol plays an important role in controlling the rate of acetolysis[1].

Theoretically no isomeric forms would be possible with the *trans*-decalin molecule due to its rigid comformation[1], but some rotational isomers are found to exist with the *cis*-decalin, the case being analogous to the cyclohexane system. Introduction of a substituent into the *cis-trans*-2-decalin molecule would give the following two conformations, the equatorial I and the axial II. Each of the three other *cis*-



I II

*cis-trans*-2-Decalyl derivative

decalyl derivatives will give similar conformational isomers[2]. Therefore it would not be possible to utilize the interpretation given for the *trans*-decalyl system in predicting reactivities of the *cis*-decalyl derivatives.

The *cis*-decalin was found to be less stable than the *trans*-decalin[3]. This instability would be due to a non-bonded interaction between the atoms which constitute the *cis*-decalin ring. In other words, 1, 3-diaxial interactions are regarded as being responsible for the instabilities. This is apparent by the examination of the structure represented by III; there

III

*cis*-Decalin

is a steric compression between the $CH_2$ group at $C_6$ and the hydrogen atoms in the axial position at $C_2$ and $C_4$. The group involved in giving rise to strains in the system under consideration differs therefore, as seen above, from that found to be participating in the system previously studied, i. e., the $CH_2$ group rather than the tosyl group. It is of considerable interest to see how this type of 1, 3-diaxial interaction will affect *cis*-decalyl derivatives.

Hückel[4] has made studies on the methanolysis of *cis*-decalyl *p*-toluenesulfonates[4], but has not correlated the reactivities with conformations.

It seems desirable therefore to study the reaction on a quantitative basis to find the relationships between conformation and reactivity. In this regard, we have undertaken a study on rates of acetolysis of the four isomers of the *cis*-decalyl *p*-toluenesulfonates.

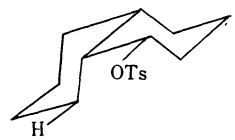
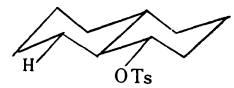
TABLE III. PERCENTAGE OF OLEFIN FORMED ON THE ACETOLYSIS OF DECALYL *p*-TOLUENESULFONATES at 100°C



| Decalyl *p*-toluenesulfonate | Conformation | Percentage of Olefin, % |
|---|---|---|
| *trans-trans*-1 | 1 e | 66 |
| *trans-cis*-1 | 1 a | 90 |
| *trans-cis*-2 | 2 e | 68 |
| *trans-trans*-2 | 2 a | 80 |
| *cis-trans*-1 | | 81 |
| *cis-cis*-1 | | 100 |
| *cis-cis*-2 | | 79 |
| *cis-trans*-2 | | 74 |

The rates of acetolysis of *cis-cis*-1, *cis-trans*-1, *cis-cis*-2, *cis-trans*-2-decalyl *p*-toluenesulfonate were measured at several temperatures. The results are given in Table I. Straight-line relationships between the rate constants and reciprocal of the absolute temperatures were obtained.

The rates of acetolysis of the *cis*-decalyl derivatives were found to be always faster than those of the *trans*-decalyl derivatives. The rate acceleration in the *cis*-decalyl system appears to be due to 1, 3-diaxial interaction, consisting of a strain between ring A and B (Table II).



To provide further evidence, the products formed in the acetolysis of the *p*-toluenesulfonates were determined and the results are summarized in Table III. The acetolysis of *cis-cis*-1-decalyl *p*-toluenesulfonate yielded—octalin as the principal product. The olefin obtained gave only the white nitroso chloride, m. p. 138°C (decomp.), of $\Delta^{1,9}$-octalin[5] by treatment with amyl nitrite and concentrated hydrochloric acid. The olefin was also identified by the infrared and ultraviolet absorption spectra* (Figs. 1 and 2).

On the other hand, *cis-cis*-2-decalyl *p*-toluenesulfonate gave 80% of an olefin which was identified to be disubstituted by the ultraviolet absorption spectrum, Fig. 2 and 20% of acetate. The rate of acetolysis of *cis-cis*-1-decalyl *p*-toluenesulfonate is expected to be comparable to that of *trans-trans*-1-decalyl *p*-toluenesulfonate as illustrated in IV and V.

IV
*cis-cis*-1-Decalyl tosylate
70

:

V
*trans-trans*-1-Decalyl tosylate
1

However, the rate of the former was found to be 70 times faster than that of the latter. This marked difference in reactivity would then be ascribed to characteristics inherent to the ring systems or their conformation, since it has been known that *cis*-decalin is less stable than the *trans*-decalin by 2.2 kcal./mol.[3]. It would then be reasonable to suppose that the 1, 3-diaxial interaction present in the ground state of *cis*-decalin ring system is responsible for the exceedingly fast rate of the *cis*-decalyl derivatives. The mechanism involved contains obviously a weakening of the strain in the course of attaining the transition state by loosening the carbon-hydrogen bond at $C_9$ with simultaneous formation of a partial double bond between $C_1$ and $C_9$. This decrease in strain is due to a displacement of $C_9$ from the axial to the equatorial position with respect to the A ring as shown in

5) A. C. Cope and G. Holzman, *J. Am. Chem. Soc.*, **72**, 3062 (1952).

* An olefin obtained from an acetolysis of *trans-cis*-1-decalyl *p*-toluenesulfonate showed exactly the same infrared and ultraviolet absorption spectra as those of the olefin obtained in this study.

VI
*cis-cis*-1-Decalyl tosylate
(more strained)

VII
(transition state)
(less strained)

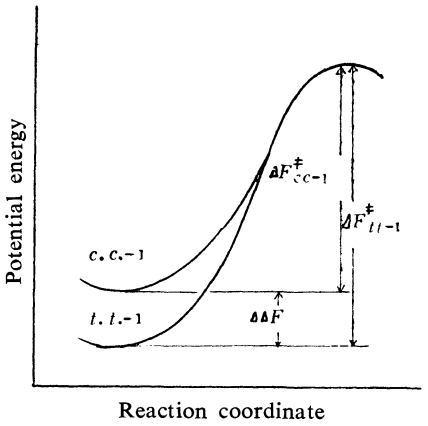

Fig. 3

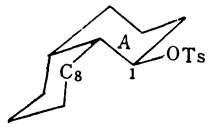
VI and VII. Supposing the conformation of the transition state of *trans-trans*-1- to be similar to that of *cis-cis*-1-, the free energy of activation which controls reactivity can be represented as shown in Fig. 3, in which $\Delta F^{\ddagger}_{cc-1}$ indicates the free energy of activation for *cis-cis*-1- and $\Delta F^{\ddagger}_{tt-1}$ for *trans-trans*-1-decalyl *p*-toluenesulfonate. The energy difference between *cis*- and *trans*-decalin in the ground state would then be $\Delta\Delta F$. Thus *cis-cis*-1-decalyl *p*-toluenesulfonate should contain less free energy of activation than does the *trans-trans*-1-decalyl *p*-toluenesulfonate by $\Delta\Delta F$ indicating a higher reactivity of the former.



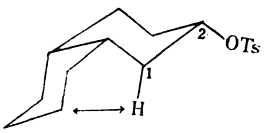
This rate-accelerating factor participates only in the elimination reaction. In other words, the rate-accelerating factor is operating only when $\Delta^{1,9}$-octalin is formed as a result of the cleavage of the *cis*-decalin ring. Our result that the acetolysis of *cis-cis*-1-1-decalyl *p*-toluenesulfonate yielded only $\Delta^{1,9}$-octalin is

6) A. C. Cope, R. J. Cotter and G. G. Roller, *J. Am. Chem. Soc.*, 77, 3594 (1955).
7) P. Bladon, H. B. Henbest and G. W. Wood, *J. Chem. Soc.*, 1952, 2737.

well in accord with the interpretation based on the above consideration.

*cis-trans*-1-Decalyl *p*-toluenesulfonate, an epimer of *cis-cis*-decalyl *p*-toluenesulfonate, was found to be less reactive than the *cis-cis*-1-decalyl derivative, the former being 17 times less reactive than the latter.

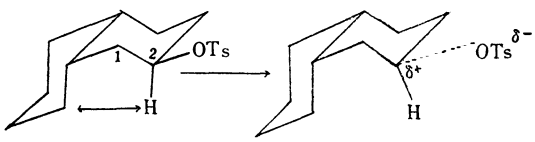
The preferred conformation of the *cis-trans*-1-decalyl derivative is represented by VIII and it will be seen that the $C_8$ is in the equatorial position with respect to ring A*). Accordingly,



VIII
*cis-trans*-1-Decalyl tosylate

in the transition state a partial double bond should be formed between $C_1$ and $C_9$, in conformity with the explanation given for the *cis-cis*-1-decalyl derivative. But the decrease of the strain of the *cis*-decalin ring will be expected to be much smaller than that observed with the *cis-cis*-1-decalyl derivative. Thus, the contribution of strain in the acceleration of the reaction rate would be exceedingly small. This prediction was well supported by our experimental results, which showed that reactivity of *cis-trans*-1-decalyl *p*-toluenesulfonate was smaller than that of *cis-cis*-1-decalyl *p*-toluenesulfonate but greater than that of *trans-trans*-1-decalyl *p*-toluenesulfonate by a factor of 3.9, and that the olefin obtained in 80% yield consisted of a mixture of tri- and disubstituted octalin instead of trisubstituted $\Delta^{1,9}$-octalin as a major product (Fig. 2).

The distance between the carbon atom at the reaction center and the site of the ring fusion at $C_9$-$C_{10}$ in the *cis*-2-decalyl derivatives is not sufficiently small to affect their reaction rates, as observed with the 1-decalyl derivatives, but strains of the type we have proposed are considered to participate in giving higher reactivities compared with the *trans-cis*-2-decalyl derivative (2-equatorial).



The preferred conformation of the *cis-cis*-2-decalyl *p*-toluenesulfonate shows that the hydrogen in the axial position at $C_1$ or $C_3$ is involved in giving rise to 1, 3-diaxial interaction. In the transition state, there will be a decrease in strain by partial breaking away of the hydrogen in the axial on either $C_1$ or $C_3$ after having formed a partial double bond between $C_1$ and $C_2$ or $C_3$. This requires less free energy of activation and consequently *cis-cis*-2-decalyl *p*-toluenesulfonate is expected to be more reactive than *trans-cis*-2-decalyl *p*-toluenesulfonate with which no such situation is possible. The prediction is well supported

IX
*cis-cis*-2-Decalyl tosylate
(more strained)

by the results that *trans-cis*-2-decalyl *p*-toluenesulfonate gives the olefin in only 68% while *cis-cis*-2-decalyl *p*-toluenesulfonate 80%.

Since the $C_2$ in the *cis-trans*-2-decalyl *p*-toluenesulfonate molecule, represented by X as the preferred conformation, takes a planar structure in the transition state in both the

X
*cis-trans*-2-Decalyl tosylate (more strained)

XI
(transition state)
(less strained)

substitution and elimination reactions, a decrease of 1, 3-diaxial interaction which has been present in the ground state would be expected, resulting in the increased reactivity. This is well demonstrated by the results of the kinetic studies; the *cis-trans*-2-decalyl derivative is 4.3 and 1.4 times more reactive than *trans-cis*-2-decalyl *p*-toluenesulfonate (2-equatorial) and *trans-trans*-decalyl *p*-toluenesulfonate (2-axial), respectively.

The present study with the *cis*-decalyl *p*-toluenesulfonates and the previous one with the *trans*-decalyl sulfonates point to the fact that 1, 3-diaxial arrangement, rather than the nature of the atoms or groups, is important in giving rise to strain. The data presented here and the foregoing discussion have provided further evidence to support the importance of 1, 3-diaxial interaction in controlling reactivities of the conformational isomers of the decalin derivatives.

## Experimental

**Materials.** — *cis-cis-1-Decalol.* — α-Naphthol was reduced with Raney nickel and the crystalline material formed in the reaction mixture after

* The other conformation (Ref. 2) of *cis-trans*-1-decalyl *p*-toluenesulfonate is expected to show a reactivity comparable to that of *cis-cis*-1-derivative. This is not the case however. Our results were not in agreement with this.

collection and recrystallization from petroleum ether, had m. p. 92~93°C[8].

*cis-trans-1-Decalol.*—The last fraction collected from the distillation of the reduction product of α-naphthol was distilled through a 45-cm. distilling column, under reduced pressure and the fraction boiling at 130~132°C/20 mmHg was collected. *cis-cis*-1-Decalol was removed by collecting crystalline material from a solution of the distillate in petroleum ether (50~60°C) and also crystals formed on concentrating the mother liquor. The oily filtrate weighing 6 g. was allowed to react with 5.8 g. of phthalic anhydride for 6 hr. at 135~140°C. The solid product obtained on cooling was recrystallized three times from benzene, twice from carbon tetrachloride and once from benzene, to give 7 g., m. p. 140~142°C[9].

The ester weighing 7 g. was hydrolyzed with 100 ml. of a 5% alcoholic solution of potassium hydroxide under reflux for one hour. After addition of water, it was extracted five times with 50 ml. portion of ether. The combined ether extracts were washed with water and dried over anhydrous magnesium sulfate. The ether was removed by distillation and the residue distilled to give 3 g. (83% yield), b. p. 116~117°C/20 mmHg.

*cis-cis-2-Decalol.*—A solution of 300 g. of β-naphthol in 300 ml. of ethanol was hydrogenated at 140~145°C under 200 atmospheric pressure, using 25 g. of Raney nickel as catalyst. The reaction mixture contained some crystalline material. The product was liquified by warming and the catalyst separated by filtration while warm. After cooling solution, the crystalline needles were collected and recrystallized once from alcohol and once from petroleum ether to give 80 g. of *cis-cis*-2-decalol, m. p. 104~105°C[10].

*cis-2-Decalone*[10].—To a solution of 30 g. (0.19 mol.) of *cis-cis*-2-decalol in 120 ml. of glacial acetic acid was added cautiously 15 g. (0.15 mol.) of chromium trioxide in a concentrated aqueous solution so that the temperature did not rise above 50°C. After allowing the reaction mixture to stand for two days at room temperature, it was heated on a water bath for two hours. It was cooled and a solution of 40 g. of potassium hydroxide in 200 ml. of water was added dropwise under ice cooling. The reaction mixture was extracted four times with ether and the ether solution washed with a saturated solution of sodium bicarbonate, followed by a saturated solution of sodium chloride. After drying the ether solution over anhydrous magnesium sulfate, the ether was removed and the residue distilled to give 24 g. (81% yield) of material, b. p. 124.5~125.5°C/20 mmHg, $n_D^{41}$ : 1.4945.

*cis-trans-2-Decalol*[11].—To a solution of 5.3 g. (0.035 mol.) of *cis*-2-decalone in 100 ml. ethanol was added 5 g. (0.22 mol.) of metallic sodium. When the reaction was complete, water was added and the oil which had separated was extracted five times with ether. The combined ether extracts were washed with water, dried over anhydrous magnesium sulfate, the ether removed, and the residue distilled to give 4 g. (75% yield) of material, b. p. 120~121°C/13 mmHg. After standing overnight the distillate, *cis-cis*-2-decalol in crystalline form (2.5 g.) was separated from the oil (1.5 g).

A reaction product formed by treating 4.3 g. of the oil with 4.3 g. of phthalic anhydride for six hours at 135~140°C was treated with petroleum ether to give a solid product. It was dissolved in a small amount of acetone to remove some insoluble material and the crystalline material obtained upon adding some petroleum ether was recrystallized from ethyl acetate to give 7.7 g. of the phthalate of *cis-trans*-2-decalol, m. p. 151~152°C[12].

The fraction boiling at 134~135°C/20 mmHg, 13.5 g., obtained from the reduction product of β-naphthol was treated with 13 g. of phthalic anhydride for six hours at 135~140°C. After treating the reaction product in the manner described above, 11 g. of the ester was obtained, m. p. 146~150°C.

Upon hydrolysis of the phthalic acid ester as described previously, 4.3 g. (75% yield) of the fraction boiling at 120~123°C/12 mmHg was obtained.

*cis-trans*-2-Decalyl *p*-nitrobenzoate[12] was prepared by the reaction of the fraction obtained above with *p*-nitrobenzoyl chloride in dry pyridine, m. p. 73~74.5°C.

Found : C, 67.35 ; H, 7.26 ; N, 4.49. Calcd. for $C_{17}H_{21}O_4N$ : C, 67.31 ; H, 6.98 ; N, 4.62%.

A solution of 7 g. (0.023 mol.) of the *p*-nitrobenzoate in 100 ml. anhydrous ether was added dropwise to a mixture of 3.5 g. (0.092 mol.) of lithium aluminum hydride in 50 ml. anhydrous ether and the reaction mixture refluxed for six hours. After allowing it to stand overnight, the excess hydride was decomposed by adding a small piece of ice and 100 ml. of 6 N hydrochloric acid. The ether layer was separated, washed with water, and dried over anhydrous magnesium sulfate. After removing the ether, the residue was distilled to give 3 g. (84% yield) of material, b. p. 121~123°C/12 mmHg.

*cis-Decalyl p-Toluenesulfonates*[4]. — The method employed was identical with that described for the preparation of the *trans*-decalyl *p*-toluenesulfonates. However, for the preparation of *cis-cis*-2-decalyl *p*-toluenesulfonate, it was found necessary to use 1.5 mol. equivalent of *p*-toluenesulfonyl chloride for one mole of the decalol in order to obtain a pure product. *cis-cis*-1-Decalyl *p*-toluenesulfonate was found to be very unstable and the analytical results obtained did not check closely with the calculated values, but the melting point of the decalol and the *p*-toluenesulfonate were in good agreement with those reported.

*cis-trans*-1-Decalyl *p*-toluenesulfonate was purified by recrystallizing from methanol to remove *cis-cis*-1-decalyl-*p*-toluenesulfonate, which was readily

**Rate Measurements.**—The rate determinations were made by the procedure previously described[1]. A typical kinetic run is shown in Table V.

**Determination of the Proportion of Unsaturated Products.** — Amounts of unsaturated substances formed in the reaction were determined by the bromide-bromate method[13].

**Acetolysis of *cis-cis*-1-Decalyl *p*-Toluenesulfonate.**—Twelve grams of *cis-cis*-1-decalyl *p*-toluenesulfonate were dissolved in 290 ml. of an acetic acid solution of 14 g. of potassium acetate. This solution was warmed for fifteen minutes at 100°C on a steam bath. After cooling 250 ml. of 25% aqueous solution of sodium hydroxide was added to the above solution. The solution was extracted with ether, dried over anhydrous magnesium sulfate, the ether was removed and distilled to give 4 g. (76% yield) of material, b.p. 84~86°C/23 mmHg. The acetate was not obtained.

One gram of this product was mixed with 3 ml. of acetic acid solution of two grams of isoamyl nitrite. Cooling the solution, 2 ml. of concentrated hydrochloric acid was added dropwise with swirling. The white precipitate was separated by filtration and washed with a few milliliters of acetone. The residual white nitrosochloride of $\Delta^{1,9}$-octalin (0.9 g.) had 128~130°C (decomp.)[14]. Two recrystallizations of this white nitrosochloride from acetone gave an analytically pure substance, 138°C (decomp.)[14]. The blue nitrosochloride of $\Delta^{1,9}$-octalin was not obtained from the acetone filtrate.

Found: C, 59.16; H, 7.88; N, 6.98. Calcd. for $C_{10}H_{16}NOCl$: C, 59.55; H, 8.00; N, 6.95%.

This work was supported partly by the grant in aid provided by the Ministry of Education and we express our gratitude.

# SHORT COMMUNICATIONS

## *The Polymerization of Vinyl Acetate Catalyzed by Iodine*

By Kozo HIROTA and Fukuo TAKEMURA

(Received July 12, 1961)

Recently it was reported by the present authors[1] that $\alpha$-methylstyrene ($\alpha$MS) could be polymerized with iodine, making an example of iodine-catalyzed high-polymerization in addition to vinylether[2]. Now, it has been confirmed that vinyl acetate (VAc) also belongs to another monomer of this kind. Since the polymerization of this monomer, however, is slightly different from those of $\alpha$MS and vinylether, and moreover, the peculiar behavior of iodine in polymerizing VAc was not mentioned at all by Bartlett et al.[3] who studied rather the role of iodine as inhibitor at its low concentration, essential points of this reaction will be reported.

Vinyl acetate was sealed in glass tubes together with iodine after degassed and dehydrated. The reaction was carried out at room temperature by shaking the tubes, because the reaction system remained heterogeneous in the case of a large amount of iodine. Besides the increase of viscosity the polymerization could be recognized by gradual precipitation of deep violet substance on the wall from the solution, but the precipitation did not occur so rapidly, e. g. it occurred after a day in the solution of 9 wt.% iodine. Such a tendency of separating colored "polymers" was not observed in the case of $\alpha$MS, where the polymers could be separated by the addition of methanol. Conversions of the monomer obtained at 160 hr. are plotted against the initial concentration of iodine in Fig. 1. Iodine begins to exhibit its polymerizing power at the concentration of 1 wt.% as suggested by the shape of the curve and this fact agrees with the finding of Bartlett and Kwait[3] as mentioned above.

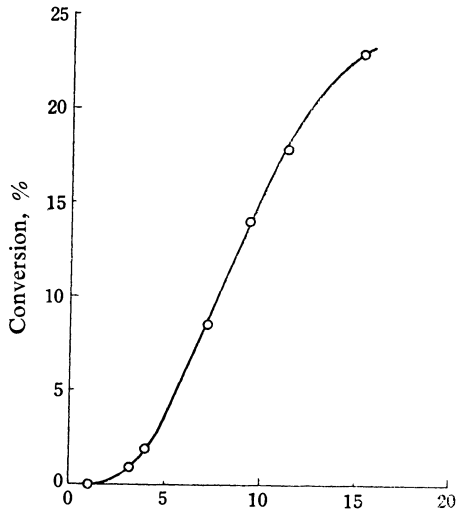

Fig. 1. Conversion of vinyl acetate to the insoluble polymer against the concentration of iodine.

The polymer is hard, brittle and amorphous, according to the X-ray pattern. It does not melt below 310°C. Iodine content is about 14~18%, though the concentration of iodine in the solution is varied from 4~15%. Infrared spectrum of the polymer shows that this polymer includes carbonyl and methyl groups. It is insoluble in ordinary organic solvents*, and hardly soluble even in aqueous potassium iodide solution at 80°C, suggesting that iodine is firmly occluded or bonded to the polymer. The molecular weight therefore can not be determined yet. This result presents a sharp contrast to the case of vinylether. According to preliminary measurement, this polymer seems to have specific resistance of about the order of $10^8$~$10^9$ ohm/cm.

We express our sincere thanks to Dr. Kenji Osaki of the Physical Department for the

## *On the Formation of Benzoin by the Reaction of Carbon Monoxide with Organometallic Compounds**

By Membo RYANG and Shigeru TSUTSUMI

(Received July 20, 1961)

In the previous papers, the present authors reported that the reaction of carbon monoxide with organometallic compounds produced a coordinate complex as an intermediate, followed by the formation of the carbon monoxide adducts A.

$$RM+CO \longrightarrow (\text{Coordinate complex}) \longrightarrow R\text{-}\underset{\underset{O}{\|}}{C}\text{-}M$$

where M=MgX[1], Li[2], Na[3]. (A)

The adduct A is reactive and further reacts with excess of organometallic compounds, producing various reaction products, in which included acyloin, the dimerization product of the adducts A.

$$2\ R\underset{\underset{O}{\|}}{C}\text{-}M \longrightarrow 2\ R\text{-}\underset{\cdot\cdot}{C}\text{-}OM \longrightarrow$$

$$R\text{-}\underset{\underset{M}{|}}{\overset{\overset{O}{|}}{C}}\!=\!\underset{\underset{M}{|}}{\overset{\overset{O}{|}}{C}}\text{-}R \longrightarrow R\text{-}\underset{\underset{O}{\|}}{C}\text{-}\underset{\underset{OH}{|}}{CH}\text{-}R \qquad (1)$$

Fisher and Stoffers already reported the formation of acyloin by the reaction of carbon monoxide with Grignard reagents at high temperature and elevated pressure[4].

This report deals with an attempt to prepare acyloin under more mild conditions and it was found that, in the reaction of carbon monoxide with phenylmagnesium bromide in ethyl ether solution at −35°C, the addition of cobalt(II) chloride led to the formation of benzoin as a main product (Table run 3).

TABLE. THE REACTION OF CARBON MONOXIDE WITH PHENYLMAGNESIUM BROMIDE IN THE PRESENCE OF COBALT(II) CHLORIDE

| | Temp. °C | Time hr. | Theoretical yields of products, % | | | |
|---|---|---|---|---|---|---|
| | | | Diphenyl | Benzoin | Benzophenone | Triphenylcarbinol |
| 1. | −10 | 1 | 80 | trace | 5.5 | trace |
| 2. | −25 | 2 | 44.2 | 12.5 | 22 | 12 |
| 3. | −35 | 2 | 30 | 35 | trace | 5 |

On the other hand, the absence of cobalt(II) chloride under the same conditions gave a very poor yield.

From the above results, it is considered that although phenylcobalt chloride, which is formed by the reaction of phenylmagnesium bromide with cobalt(II) chloride (Eq. 2), is unstable, it reacts with carbon monoxide at low temperature, producing benzoin as a main product.

$$PhMgBr+CoCl_2 \longrightarrow PhCoCl+MgBrCl \qquad (2)$$

On the other hand, when reaction temperature is rather high (−10 or −20°C), phenyl radical is formed as a result of homolytic cleavage of the carbon-cobalt bond and dimerizes to diphenyl (run 1) or reacts with carbon monoxide in producing benzophenone (run 2).

$$PhCoCl \longrightarrow Ph\cdot + \cdot CoCl$$

$$2\ Ph\cdot \longrightarrow Ph\text{-}Ph$$

$$2\ Ph\cdot + CO \longrightarrow Ph\text{-}\underset{\underset{O}{\|}}{C}\text{-}Ph$$

Furthermore, in the reaction of carbon monoxide with phenyl potassium, which is prepared by the reaction of anisole with metallic potassium in pentane solution, benzoin (25%), benzhydrol (2.3%), benzoic acid (4%) and benzaldehyde (trace) are produced.

All these results mentioned above seem to support the opinion that, in the reaction of carbon monoxide with organometallic compounds, the carbon monoxide adduct A is formed and dimerizes to acyloin or further reacts with excess of organometallic compounds, producing various reaction products.

## *A Novel Resin Spot Test for Copper(II) Using a Chelating Resin**,[1]

By Masatoshi FUJIMOTO

(Received August 10, 1961)

"Resin spot test[2]" has proved its widespread utilities by many interesting works of the present author and other chemists[3]. This sensitive test is based mainly on the intense coloration of a few grains of light-colored ion exchangers by the up-take of trace amounts of colored substances from outer solution phase, and are easily attained much higher sensitivities as compared with those of ordinary spot test[4].

In this communication the author suggests a new possibility to lend high selectivities to the resin spot tests through applications of a sort of special resins having chelate-forming groups as functional groups. The resin used here is "Dowex A-1 Chelating Resin", a resin of styrene-divinylbenzene basis with imino-diacetate group, whicih adsorbs preferentially palladium(II) and copper(II) at about pH 5[5].

The commercial resin supplied as sodium form, 50—100 mesh, was packed in a column, converted into ammonium form via free-acid form, washed with de-ionized water, and dried at room temperature. A buffer solution of pH

4.7 was prepared from 1 F acetic acid and 1 F ammonium acetate.

In Table I are shown colorations of the resin beads with diverse metal ions under various conditions. In some cases the coloration in the resin beads for copper(II) was found to be rather improved in a slightly acid medium added with phosphoric acid. The following procedure was thus proposed for the specific detection of minute amount of copper(II) with the chelating resin without any specific reagents added.

In a depression of a white spot plate mix a few grains of Dowex A-1 Chelating Resin in the ammonium form with a drop (0.04 ml.) of the 1 F acetate buffer of pH 4.7. (Minute amount of tiny resin beads can easily be added in the depression only by touching a clean tip of a thin glass rod with the resin beads in a reservoir and by tapping gently the rim of the deppression with the tip portion of the rod). After a few minutes, add a drop of the test solution and allow to stand for about ten minutes. Then observe a more or less intense yellowish green to light greenish blue color developed in the *edge* of the resin beads under magnification. If the beads are covered with some other colors, add a drop of 1 F phosphoric acid and again observe the change in color at the edge of the resin beads. Since the chelate formation in the resin phase seems to be somewhat delayed, it would be desired to wait for an hour or more, preferably overnight, the spot plate being kept in a moist chamber free from any dust. It is also recommended to use the "resin centrifuge method[1]" to attain rapidly the highest sensitivity (see Table II). The time-dependency of the limit of identification for copper(II) in the present test is shown in Table II.

The influences of diverse metal ions on the present test are also summarized in Table I, in which are shown the limits of identification for copper(II) and limiting proportions in the presence of other metal ions. Further details for the proposed method will be reported elsewhere.

The author is indebted to Dr. A. J. Barnard, Jr., The J. T. Baker Chemical Company, and to Dr. J. R. Skidmore, Dow Chemical Company, for their kindness supplying him a sample of Dowex A-1 Chelating Resin and many valuable informations through the data sheet.

## *Effects of High Energy Ionizing Radiation on Crystallinities of Cellulose II, III and IV*

By Hiroshi Sobue and Yoshitami Saito

(Received July 24, 1961)

Several reports of the effects of ionizing radiation on cellulose I[1] are known. In this communication, the effects of ionizing radiation on the crystalline regions of cellulose II, III and IV were reported.

We used viscose rayon as cellulose II. Cellulose III was prepared by treatments of the cellulose II in liquid ammonia at about $-78°C$ for four hours, and the ammonia was removed above $0°C$, and then the sample was dried at room temperature. Cellulose IV was made from cellulose II by treatments in glycerin at $260\sim265°C$ for one hour, then glycerin was washed off with ethanol and then the sample was dried in vacuo.

The samples were wrapped with aluminum foil and irradiated, cooling at about $-78°C$ with dry ice, by electron beam from a van de Graaff till total dosages were attained to $10^7$, $5\times10^7$, $10^8$ and $3\times10^8$ rad.

The crystallinities of the samples were determined by acid hydrolysis method and also by X-ray diffraction method, estimating the crystallinity by the ratio of crystalline diffraction areas to total diffraction areas (Hermans method[2]).

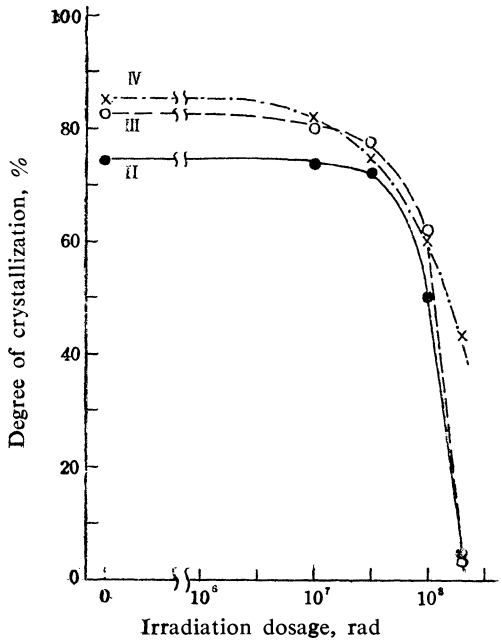

Fig. 1. The relationship between irradiation dosage and crystallinities by acid hydrolysis of celluloses.

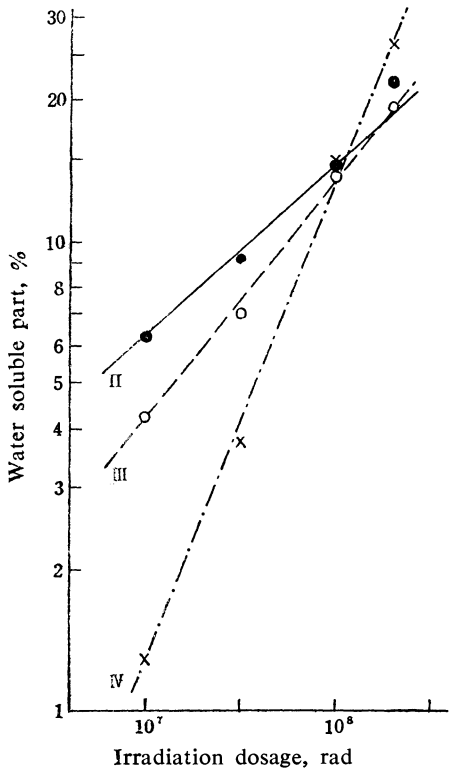

Fig. 2. The relationship between irradiation dosage and water soluble parts of celluloses.

The relationship between dosage and crystallinties by acid hydrolysis of celluloses is shown in Fig. 1. By the irradiation up to $5\times10^7$ rad, the decrease of crystalline regions is not observed for all celluloses. But by the irradiation of above $5\times10^7$ rad, in all types of celluloses remarkable lowering of crystallinities was observed.

The relationship between dosage and crystallinities by X-ray diffraction method is illustrated in Table I. There are not remarkable differences between X-ray diffractive crystallinities of unirradiated samples and those of samples irradiated with $10^7\sim3\times10^8$ rad.

Thus, the crystallinities of these celluloses are quite different depending on the measuring methods. The reason is explained as follows; large crystallites in the samples are degraded into small ones by the irradiation, but total crystalline areas determined by X-ray diffraction almost do not change. However, the velocity of acid hydrolysis becomes much greater as the crystallites are smaller.

TABLE I

| Radiation Dose (rad) | Crystallinities by X-ray diffraction method, % | | |
|---|---|---|---|
| | Cellulose II | Cellulose III | Cellulose IV |
| Unirradiated | 62.9 | 73.5 | 62.7 |
| $10^7$ | 62.0 | 78.1 | 63.2 |
| $5\times10^7$ | 62.2 | 65.0 | 64.2 |
| $10^8$ | 61.7 | 65·8 | 59.9 |
| $3\times10^8$ | 61.7 | 62.5 | 59.0 |

In Fig. 2, plots of water-soluble parts of celluloses versus dosage are shown. For each cellulose, the water soluble part increases rapidly by irradiation of above $10^8$ rad. Saeman et al.[3] reported that almost all parts of cotton linter become water soluble by $5\times10^8$ roentgen of Cathode ray in the Resonant-Transformer. From these results it is clear that cellulose is degraded to lower molecular weight substance by $3\sim5\times10^8$ rad.

## *Transformation of Swertiamarin to Gentiopicrin. The Structure of Gentiopicrin*

By Takashi KUBOTA and Yutaka TOMITA

(Received July 17, 1961)

In a preceding communication, it was reported that swertiamarin, the bitter component of *Swertia japonica* Makino, is represented by structure I[1], and that dehydration of the tertiary hydroxyl group of swertiamarin acetate (II) with potassium bisulfate and acetic anhydride affords monoanhydroswertiamarin acetate, $C_{24}H_{28}O_{13}$ (III), m. p. 143~144°C which shows bands in its ultraviolet absorption spectrum at 246 mμ log ε 3.44 and 269 μ log ε 3.37[1].

However, on further purification by chromatography and by recrystallization the melting point of II was raised to 151~152°C (IIIA), and the ultraviolet absorption spectrum showed a band at $\lambda_{max}$ 245 mμ log ε 3.65 and no band at 269 mμ. On the other hand, II treated with $BF_3$ in AcOH at low temperature for 3 hr. afforded a dehydrated product (IIIB) as colorless plates, m. p. 137~138°C. The ultraviolet absorption spectrum showed a band only at 270 mμ log ε 3.8 and none at 246 mμ. Therefore, the monoanhydroswertiamarin acetate (III) described in the previous paper[1] is a mixture of IIIA and IIIB and from the ultraviolet absorption spectra the following formulae are given for IIIA and IIIB respectively. (Fig. 1). The fact that a greater amount of IIIA is produced by the dehydration reaction with potassium bisulfate than the more stable triene type isomer IIIB, indicates the relationship between the hydroxyl group at $C_4$ and the hydrogen atom at $C_5$ to be in cis to each other. In the case of the dehydration reaction with $BF_3$, double bond migration of IIIA occurs by the action of $BF_3$ and consequently II gives the stable IIIB.

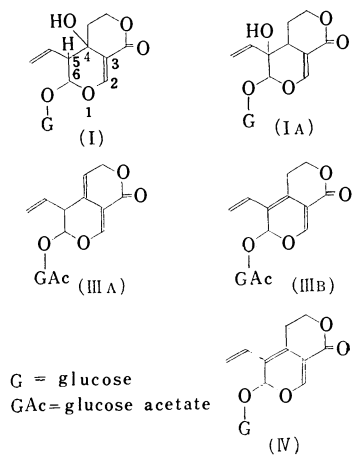

Fig. 1

The infrared absorption spectrum of IIIA shows a band at 12.2 μ which is due to the tri-substituted double bond. Therefore the tertiary hydroxyl group of I must exist at $C_4$ and not at $C_5$. From these results, an alternative structure of swertiamarin IA[1] can be excluded.

In order to establish the structure of gentiopicrin a detailed study on its degradation reactions was carried out by Asahina, Asano, Tanase and Ueno[2]. On the basis of their data the several possible structures were suggested by Sakurai[3], Korte[3] and Canonica and Pelizzoni[4], respectively. Although, Canonica and Pelizzoni[5] have recently proposed the formula IV as the most probable structure for gentiopicrin, the definite evidence for its carbon skeleton is lacking in their paper. If the structure IV is correct, IIIB, a monoanhydro derivative of II should be identical with gentiopicrin acetate.

Now it has been confirmed that IIIB and the acetate, m. p. 139°C, of gentiopicrin, extracted from the root of *Gentiana scabrae*, are identical in their infrared absorption spectra.

Concerning the structure of swertiamarin, the correctness of the carbon skeleton of I has been definitely demonstrated by synthesis of erythrocentaurin[6], the hydrolysis product of swertiamarin with emulsin, and by transformation of swertiamarin to gentianin[7] as reported in the previous papers. Although several structures were suggested for gentiopicrin, the structure IV proposed by Canonica and Pelizzoni has been established to be correct from the above-mentioned results.

## *Reactions of Picryl Ether with Amino Compounds*

By Kazuo SATAKE, Masaru TANAKA, Yasuharu TSUZUKIDA and Shoji SHIMA

(Received June 26, 1961)

The cleavage of phenyl ether linkage, either in acidic or alkaline medium, has been achieved only under vigorous conditions. In this respect, ammonolysis of picryl ether was proved to be an exceptional case. Picryl ether (TNP-$OC_2H_5$* m. p. 77.5~78.5°C[1]; TNP-$OC_6H_5$ m. p. 151~152°C[2]) gave picramide (m. p. 187~188°C; $\lambda_{max}$ m$\mu$ ($\varepsilon \times 10^{-4}$): 325 (1.14), 415 (0.86)) and *N*-methylpicramide (m. p. 109~110°C; $\lambda_{max}$ m$\mu$ ($\varepsilon \times 10^{-4}$): 346 (1.60) with a marked shoulder at 418 m$\mu$) only by dissolving the ether into hydrated ethanol solution of ammonia (7.5 N) and methylamine (5 N), at room temperature, respectively. The results of spectrophotometric investigation[3], as illustrated in Fig. 1, indicated that the ammonolysis of picryl ether proceeded almost immediately with quantitative yield.

The most remarkable fact was different behaviors of the both picryl ethers with dimethylamine; thus the phenyl ether gave *N*, *N*-dimethylpicramide (m. p. 137~138°C[4]; $\lambda_{max}$ m$\mu$ ($\varepsilon \times 10^{-4}$): 380 (1.38)) immediately, while the ethyl ether did not even after 24 hr. under the conditions described in Fig. 1. With the use of excess amounts of dimethylamine (Tokyo Chemical Industry Co., Ltd.; Guaranteed Reagent), there was observed some formation of *N*-methylpicramide, presumably being originated from the contaminated methylamine.

Reaction of the same type occurred in much less alkaline medium (pH 8), and not only with amine but also with amino acid. Thus equimolar mixtures of glycine and picryl ethyl ether and of proline and picryl phenyl ether in borate buffer (pH 8.0) at room temperature gave TNP-glycine (m. p. 161°C; $\lambda_{max}$ m$\mu$ ($\varepsilon \times 10^{-4}$): 340 (1.25)[5]) and TNP-proline (m. p. 164~165°C; $\lambda_{max}$ m$\mu$ ($\varepsilon \times 10^{-4}$); 362 (1.29)[5]) with excellent yield, respectively. Some typical results on the reaction in analytical scale are summarized in Fig. 2, together with those of

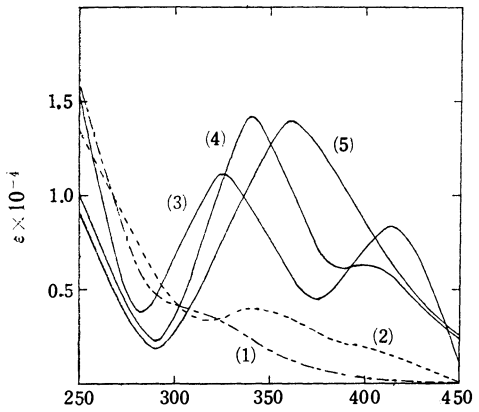

Fig. 1. Aminolysis of picryl phenyl ether (1) TNP-$OC_6H_5$ in N/10 HCl in 50% ethanol TNP-$OC_6H_5$ was previously dissolved into (2) N NaOH, (3) 7.5 N $NH_3$, (4) 5 N $CH_3NH_2$ and (5) 3.6 N $(CH_3)_2NH$, in 50% ethanol, and the mixture was acidified with HCl exactly after 1 min. Final concentrations were $1.0 \times 10^{-4}$ M in all cases. The spectra (3), (4) and (5) were just the same as those of picramide, *N*-methyl- and *N*, *N*-dimethylpicramide of $1.0 \times 10^{-4}$ M, respectively. The spectrum (2) indicated some formation of picric acid under the action of alkali.

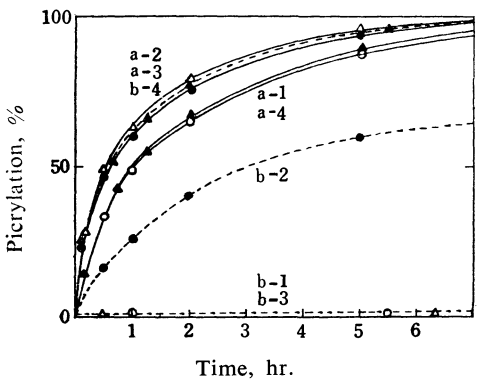

Fig. 2. Picrylation of glycine (——) and proline (----)
1) with TNP-$OC_2H_5$ (—○—)
2) with TNP-$OC_6H_5$ (—●—)
3) with TNP-$SO_3H$ (—△—)
4) with TNP-Cl (—▲—)

The initial concentrations of amino acid and picryl compounds were $1.0 \times 10^{-4}$ M in an equi-volume mixture of M/15 borate buffer (pH 8.0) and ethanol.

The picrylations of glycine (a) and proline (b) were estimated from the increment of optical density at 340 m$\mu$ and at 360 m$\mu$ respectively (see Fig. 1).

trinitrophenylations with TNP-Cl[5] and TNP-$SO_3H$[5,6] under the similar conditions.

It will be of interest that picryl ether is a powerful trinitrophenylating agent even under physiological condition. The ether as well as the chloride, a well-known trinitrophenylating reagent of protein, has been already reported to produce allergic dermatitis and to produce an antibody which reacts with TNP-protein on their repeated contact with skin[7]. The facts described in this paper will explain why picryl ether is a precursor of antigenic TNP-protein in vivo.

The details on trinitrophenylation of protein with picryl ether will be described elsewhere.

## *New Catalysts for the Nucleoside Synthesis by Fusion Method*

By Yoshiharu Ishido and Tetsuo Sato

(Received June 27, 1961)

Recent studies[1] in this laboratory indicated that purine nucleosides could be synthesized merely by fusing a mixture of purine and 1-*O*-acyl sugar derivatives under reduced pressure in the presence of *p*-toluenesulfonic acid or zinc chloride. For example, the synthesis of 9-β-D-ribofuranosyl 2-methylthio-6-chloropurine (III) from 2-methylthio-6-chloropurine (I) and 1,2,3,5-tetra-*O*-acetyl-β-D-ribofuranose (II) may be formulated as follows:

For the synthesis of *O*-glycosides by the similar fusion method, various acidic catalysts have been used[2].

Recently, Helferich et al.[3] scrutinized the catalytic effect of several acids, including newly hydrochloric acid, sulfuric acid, oxalic acid and phosphoric acid, for the *O*-glycoside formation and found anhydrous methanesulfonic acid to be the most effective catalyst as far as being examined.

The present authors wish to report that anhydrous methanesulfonic acid was less effective than concentrated sulfuric acid and that concentrated phosphoric acid was almost ineffective for nucleoside (*N*-glycoside) synthesis.

7-β-D-Ribofuranosyl theophylline (VI):—To a fused mixture of an equivalent amount of theophylline (V) and II, concentrated sulfuric acid was added, and the mixture was subjected to react at 130～140°C for about ten minutes, in vacuo. The cooled reaction mixture was then dissolved into chloroform, and a small amount of unchanged V was filtered off. After neutralization of the filtrate with methanolic ammonia, the solvent was removed in vacuo to dryness, and then deacetylated with methanolic ammonia in the usual manner. The deacetylated syrup was crystallized by trituration with a small amount of ethanol and recrystallized from ethanol. IV was obtained as fine needles in 48% yield of theoreticals, m. p. 189～190°C, $[\alpha]_D^{15}+25°$ (*c* 0.50, water). This showed no depression on admixture with an authentic specimen[4]. When anhydrous methanesulfonic acid was used as a catalyst, the yield was 41% theoreticals (m. p. 182～186°C).

In the similar manner, III (in both cases of concentrated sulfuric acid and of anhydrous methanesulfonic acid, the yields were 39 and 15%

# *Thermodynamical Studies on Binary Systems Consisting of Polar and Non-polar Liquids. III. Calculation of the Electrostatic Part of the Thermodynamic Excess Functions due only to the Dipole of the Polar Molecule for the Binary System Composed of Polar and Non-polar Liquids according to Onsager's Model*

By Kazuo AMAYA

(Received March 4, 1961)

In the previous paper it has been shown that in the systems containing non-aromatic non-polar components, the increase of van Laar coefficient with the decrease of the concentration of the polar component may be due to its dipole moment and that a kind of stabilizing effect exists in the systems containing aromatic non-polar components. In order to confirm the fact that such a variation of the van Laar coefficient with concentration in the former group of the systems is due to the dipoles of the polar components and to elucidate the cause of the stabilization effect in the latter group of the systems, theoretical formulas based on Onsager's model of polar liquids are derived to explain the electrostatic part of the excess thermodynamic quantities due only to the dipole of the polar component, by neglecting the effect of higher multipoles for a binary system of polar and non-polar liquids, and are applied to the actual systems for which the heats of mixing were measured.

## Derivation of Theoretical Expressions

In deriving the expressions of the electrostatic part of the thermodynamic excess functions due only to the dipole of the polar component for a binary system of polar and non-polar liquids, the following assumptions are made according to Onsager[1]:

1) The polar molecules is spherical.
2) The dipole is a point dipole and is located at the center of the molecule.
3) The medium surrounding the polar molecule is a continuous one having macroscopic isotropic dielectric constant.
4) The polarizability of the polar molecule is isotropic.

Then further the following assumption is imposed:

5) There is no volume change on mixing.

If a molecule of dipole moment $\mu$ and of polarizability $\alpha$ is placed at a cavity of radius $a$ in a medium of dielectric constant $\varepsilon$, the reaction field $R$ due to the dielectric is

$$R=\mu\cdot g \tag{1}$$

where $g$ is given by

$$g=\frac{2(\varepsilon-1)}{2\varepsilon+1-(2\alpha/a^3)(\varepsilon-1)}\cdot\frac{1}{a^3} \tag{2}$$

The electrostatic work $w$ required for the formation of a dipole $\mu$ in the medium is given by

$$w=-1/2\cdot g\cdot\mu^2 \tag{3}$$

Then according to Barker[2], the electrostatic part of the free energy of mixing $F^{\mathrm{Eel}}$, which is equal to $G^{\mathrm{Eel}}$ for a condensed system, for 1 mol. of a binary mixture in which the two components have the same molecular size and polarizability but different dipole moments $\mu_1$ and $\mu_2$, is given by

$$F^{\mathrm{Eel}}=G^{\mathrm{Eel}}=\frac{1}{2}N_{\mathrm{A}}(\mu^2{}_1-\mu^2{}_2)\times\left(x_1\int_{x_1}^{1}g\mathrm{d}x_1-x_2\int_{0}^{x_1}g\mathrm{d}x_1\right) \tag{4}$$

where $N_{\mathrm{A}}$ is the Avogadro Number, $x_1$ and $x_2$ denote the mole fraction of the components 1 and 2 respectively. For a binary solution in which one component is polar and the other is non-polar, the electrostatic part of the free energy of mixing is given by

$$G^{\mathrm{Eel}}=\frac{1}{2}N_{\mathrm{A}}\mu^2\left\{x_2\int_{x_2}^{1}g\mathrm{d}x_1-(1-x_2)\int_{0}^{x_2}g\mathrm{d}x_2\right\} \tag{5}$$

where $\mu$ denotes the dipole moment of the polar molecule, and $x_2$ the mole fraction of the polar component in the solution.

Then other thermodynamic functions may be derived from the well-known thermodynamic relations:

$$H^{\mathrm{Eel}}=G^{\mathrm{Eel}}-T\cdot\frac{\partial G^{\mathrm{Eel}}}{\partial T}$$

1) L. Onsager, *J. Am. Chem. Soc.*, **58**, 1486 (1936).

2) J. A. Barker, *Proc. Roy. Soc.*, **A219**, 367 (1953).

$$S^{\mathrm{Eel}}=-\frac{\partial G^{\mathrm{Eel}}}{\partial T}$$

and the following expressions are obtained.

$$H^{\mathrm{Eel}}=\frac{1}{2}N_{\mathrm{A}}\mu^2\left\{x_2\int_{x_2}^{1}h\mathrm{d}x_2-(1-x_2)\int_{0}^{x_2}h\mathrm{d}x_2\right\} \tag{6}$$

$$S^{\mathrm{Eel}}=\frac{1}{2}N_{\mathrm{A}}\mu^2\left\{x_2\int_{x_2}^{1}s\mathrm{d}x_2(1-x_2)\int_{0}^{x_2}s\mathrm{d}x_2\right\} \tag{7}$$

where

$$h=g-T\cdot\partial g/\partial T \tag{8}$$

and

$$s=-\partial g/\partial T \tag{9}$$

If the polarizability $\alpha$ of the polar molecule is expressed by

$$\frac{{n_2}^2-1}{{n_2}^2+2}=\frac{4}{3}\pi N\alpha \tag{10}$$

where $N$ is the number of polar molecules in a unit volume of the pure liquid and $n_2$ is the refractive index of the polar liquid, and the molar volume of the polar molecule, $V_{\mathrm{M}}$ is taken as $4/3\cdot\pi N_{\mathrm{A}}a^3$. Then $g$ is expressed as

$$g=\frac{8}{3}\pi\frac{1}{V_{\mathrm{M}}}\cdot N_{\mathrm{A}}\cdot\frac{\varepsilon(x_2)-1}{2\varepsilon(x_2)+{n_2}^2}\cdot\frac{{n_2}^2+2}{3} \tag{11}$$

For 1 mol. of solution the above quantities are given as follows.

$$G^{\mathrm{Eel}}=\frac{4}{3}\pi\frac{{N_{\mathrm{A}}}^2}{V_{\mathrm{M}}}\cdot\frac{{n_2}^2+2}{3}\mu^2\times\left\{x_2\int_{x_2}^{1}\frac{\varepsilon(x_2)-1}{2\varepsilon(x_2)+{n_2}^2}\mathrm{d}x_2-(1-x_2)\int_{0}^{x_2}\frac{\varepsilon(x_2)-1}{2\varepsilon(x_2)+{n_2}^2}\mathrm{d}x_2\right\} \tag{12}$$

$$H^{\mathrm{Eel}}=\frac{4}{3}\pi\frac{{N_{\mathrm{A}}}^2}{V_{\mathrm{M}}}\cdot\frac{{n_2}^2+2}{3}\mu^2\times\left\{x_2\int_{x_2}^{1}\frac{\varepsilon(x_2-1)}{2\varepsilon(x_2)+{n_2}^2}(1-A(x_2)\cdot T)\mathrm{d}x_2-(1-x_2)\int_{0}^{x_2}\frac{\varepsilon(x_2)-1}{2\varepsilon(x_2)+{n_2}^2}\times(1-A(x_2)\cdot T)\mathrm{d}x_2\right\} \tag{13}$$

$$S^{\mathrm{Eel}}=\frac{4}{3}\pi\frac{{N_{\mathrm{A}}}^2}{V_{\mathrm{M}}}\cdot\frac{{n_2}^2+2}{3}\mu^2\times\left\{x_2\int_{x_2}^{1}\frac{\varepsilon(x_2)-1}{2\varepsilon(x_2)+{n_2}^2}A(x_2)\mathrm{d}x_2-(1-x_2)\int_{0}^{x_2}\frac{\varepsilon(x_2)-1}{2\varepsilon(x_2)+{n_2}^2}A(x_2)\mathrm{d}x_2\right\} \tag{14}$$

where $A(x_2)$ is given by

$$A(x_2)=\frac{1}{V_{\mathrm{M}}}\frac{\mathrm{d}V_{\mathrm{M}}}{\mathrm{d}T}+\left(\frac{1}{\varepsilon(x_2)-1}-\frac{2}{2\varepsilon(x_2)+{n_2}^2}\right)\frac{\mathrm{d}\varepsilon(x_2)}{\mathrm{d}T}+\left(\frac{1}{{n_2}^2+2}-\frac{1}{2\varepsilon(x_2)+{n_2}^2}\right)2n_2\frac{\mathrm{d}n_2}{\mathrm{d}T} \tag{15}$$

which is easily derived by taking the logarithm of $g$ and differentiating it with temperature. In the above expressions the following notations are used:

$\varepsilon(x_2)$: the dielectric constant of the solution in which the mole fraction of the polar component is $x_2$,

$n_2$: the refractive index of the polar liquid,

$N_{\mathrm{A}}$: Avogadro's number,

$V_{\mathrm{M}}$: the molar volume of the polar liquid, and

$T$: absolute temperature.

## The Application of the Theory to the Actual Systems

**The Necessary Data for the Calculation.**—In applying the theory to the actual systems, it is necessary to have the numerical values of the following quantities:

1) the thermal expansion coefficient of the polar liquid,

2) the dielectric constant of the pure polar liquid, $\varepsilon_2$,

3) the temperature dependence of $\varepsilon_2$, $\mathrm{d}\varepsilon_2/\mathrm{d}T$,

4) the refractive index of the pure polar liquid, $n_2$,

5) the temperature dependence of $n_2$, $\mathrm{d}n_2/\mathrm{d}T$,

6) the density of the pure polar liquid, $d$,

7) the dipole moments of the polar component in vacuum, $\mu$,

8) the dielectric constant of the solution, $\varepsilon_{12}$, and

9) the temperature dependence of $\varepsilon_{12}$, $\mathrm{d}\varepsilon_{12}/\mathrm{d}T$.

It is preferable to use the values of these constants which are determined experimentally, but unfortunately they are not available for all the systems considered in this experiment. In fact, for 1, 2, 4, 6 and 7 the values are available for all the components, but for 3 and 5 the values are only partly available and for 8 and 9 none of the values are available for all the systems. For those which are not available in the literature, they are derived from the relevant values on reasonable assumptions or the experimental rules as described in the following.

**The Derivation of the Values of the Quantities which are not Available in the Literature.**—(1) The temperature dependence of the dielectric constant of the polar liquid. According to Onsager, the dielectric constant of a

| | 0.134 | 233.5 | 394.9 | 161.4 |
| | 0 | 0 | 0 | 0 |

polar liquid $\varepsilon_2$ is related to temperature as

$$\varepsilon_2-n_2^2=\frac{3\varepsilon_2}{2\varepsilon_2+n_2^2}\cdot\frac{(n_2^2+2)^2}{3}\cdot\frac{4\pi N}{3kT}\mu^2 \quad (16)$$

By assuming that the dipole moment $\mu$ of the polar molecule is independent of temperature, we obtain the following expression, by taking the logarithm of both sides of the formula 16 and differentiating it with the temperature:

$$\left(\frac{1}{\varepsilon_2-n_2^2}+\frac{2}{2\varepsilon_2+n_2^2}-\frac{1}{\varepsilon_2}\right)\frac{d\varepsilon_2}{dT}+\left(\frac{1}{2\varepsilon_2+n_2^2}-\frac{1}{\varepsilon_2-n_2^2}-\frac{2}{n_2^2+2}\right)2n_2\frac{dn_2}{dT}=\frac{1}{N}\cdot\frac{dN}{dT}-\frac{1}{T} \quad (17)$$

where $1/N\cdot dN/dT$ is the thermal expansion coefficient of the polar liquid reversed in sign. All the values in the above expression are available except $d\varepsilon_2/dT$. Then the values of $d\varepsilon_2/dT$ can be derived by the relevant values such as $\varepsilon_2$, $n_2$, $dn_2/dT$, $T$ and the thermal expansion coefficient.

(2) The temperature dependence of the refractive index of the liquid. The refractive index $n$ of a liquid can approximately be expressed as $(n^2-1)/(n^2+2)\cdot 1/\rho=\text{const.}$ where $\rho$ is the density of the liquid. Differentiating it with temperature, we obtain

$$\frac{dn}{dT}=\frac{(n^2-1)(n^2+2)}{6n}\cdot\frac{1}{\rho}\cdot\frac{d\rho}{dT} \quad (18)$$

$1/\rho\cdot d\rho/dT$ is the thermal expansion coefficient of the liquid reversed in sign. Then we can derive the values of $dn/dT$ from the refractive index and the thermal expansion coefficient of the liquid.

(3) The dielectric constant of the solution, $\varepsilon_{12}$. According to Onsager, the dielectric constant of a binary solution of polar and non-polar liquid is expressed as

$$\frac{3(1-v_2)(\varepsilon_{12}-n_1^2)\varepsilon_{12}}{2\varepsilon_{12}+n_1^2}+\frac{3v_2(\varepsilon_{12}-n_2^2)}{2\varepsilon_{12}+n_2^2}=\frac{4\pi Nv_2\mu^2}{3kT}\left\{\frac{\varepsilon_{12}(n_2^2+2)}{2\varepsilon_{12}+n_2^2}\right\}^2 \quad (19)$$

where $v_2$ is the volume fraction of the polar components.

By replacing $\mu^2$ in the above expression with

$$\frac{9(\varepsilon_2-n_2^2)(2\varepsilon_2+n_2^2)kT}{\varepsilon_2(n_2^2+2)^2\cdot 4\pi N}=\mu^2 \quad (20)$$

which is obtained from Onsager's expression of the dielectric constant for a pure polar liquid, we obtain[3]

6. Benzonitrile—Cyclohexane

$$\frac{\varepsilon_{12}-\varepsilon_1}{2\varepsilon_{12}-n_1^2}\cdot(1-v_2)+\frac{(\varepsilon_{12}-\varepsilon_2)(2\varepsilon_{12}\varepsilon_2+n_2^4)}{\varepsilon_2(2\varepsilon_{12}+n_2^2)^2}v_2=0 \tag{21}$$

where $\varepsilon_1$ and $n_1$ are the dielectric constant and refractive index of the non-polar liquid respectively, other notation being the same as those already described. All the values in the above expression 21 are known except $\varepsilon_{12}$ and $v_1$. The dielectric constant of the solution $\varepsilon_{12}$ can be calculated from the expression 21 for any given values of concentration $v_2$.

(4) The temperature dependence of $\varepsilon_{12}$, $d\varepsilon_{12}/dT$. It is approximated by a weighted mean such as

$$\frac{d\varepsilon_{12}}{dT}=\frac{\varepsilon_2-\varepsilon_{12}}{\varepsilon_2-\varepsilon_1}\cdot\frac{d\varepsilon_1}{dT}+\frac{\varepsilon_{12}-\varepsilon_1}{\varepsilon_2-\varepsilon_1}\cdot\frac{d\varepsilon_2}{dT} \tag{22}$$

$d\varepsilon_1/dT$ is the temperature dependence of the dielectric constant of the non-polar liquid. If $d\varepsilon_1/dT$ is not available, it is derived by using the following expression

$$\frac{\varepsilon_1-1}{\varepsilon_1+2}\cdot\frac{1}{\rho}=\text{constant} \tag{23}$$

By differentiation with temperature, we obtain

$$\frac{d\varepsilon_1}{dT}=\frac{1}{\rho}\frac{d\rho}{dT}\frac{(\varepsilon_1-1)(\varepsilon_1+2)}{3} \quad (24)$$

which can be calculated from the values of $\varepsilon_1$ and the thermal expansion coefficient of the non-polar liquid.

The values used for the calculations are shown in Table I.

## The Results and Discussions

The calculation is carried out for the systems for which the heats of mixing were measured. For the systems where toluene is the non-polar component, it is assumed that the dipole-moment of toluene is zero. No serious difference occurs even if the finite value of its dipole moment is taken into account (the difference being only 4% at most). The results obtained are shown in Tables II and III and some of them are shown in Figs. 1—3.

As is seen from the above tables, the electrostatic part of the excess free energy and the excess enthalpy of mixing for the above systems derived on the Onsager model, are all positive over all the concentrations and the quantities for 1 mol. of mixture deviate from the parabola expressed by $Kx_2(1-x_2)$, where $K$ is a constant and $x_2$ is the mole fraction of the polar components. The larger the dipole moments of the polar components are, the larger are the deviations and the larger the shift of $x_{max}$, $x_{max}$ designating the concentration where these quantities are maximum.

The electrostatic part of the excess entropy of mixing for 1 mol. of the mixture shows a specific behavior. For the systems containing polar components of small dipole moments, they are positive over the whole concentration, but for those of large dipole moments, the values are negative over the range of larger values of $x_2$, and rapidly increase and take very large positive values as $x_2$ decreases.

It is naturally expected that these values do not differ so much if the non-polar component, cyclohexane, is replaced by toluene, because of the similar dielectric constant, since according to the assumption of the theory the values are the function of dielectric constant only.

The calculated values of the electrostatic part of van Laar coefficients $\alpha^{el}_{calcd}$ were also calculated by the relation: $\alpha^{el}_{calcd}=H^{Eel}_{calcd}/v_2(1-v_2)\cdot V$, where $V$ is the molar volume of the mixture. They are shown in Tables IV and V.

It is seen from the results that the values of $\alpha^{el}_{calcd}$ are positive and increase with the decrease of concentration $x_2$ of polar component, and the larger the dipole moments, the larger the values of $\alpha^{el}_{calcd}$ as well as their variations with concentration.

## Summary

The electrostatic part of the excess functions for 21 binary systems consisting of polar and non-polar liquids were calculated according to Onsager's model. The electrostatic part of the excess free energy and excess enthalpy are positive over all the concentrations for all of these systems and these quantities are unsymmetric with regard to the mole fractions $x$ against the value at the point $x=0.5$.

The concentrations $x_{max}$ where these quantities have maximum values, shift to a lower concentration of polar component. The larger the dipole moment of the polar components, the larger the maximum values and the shifts are. The electrostatic part of excess entropies have positive values over the whole concentration for systems consisting of a polar component of small dipole moment, but for those consisting of one with a larger dipole moment, these quantities take negative values for a high concentration of polar component, but take positive values for a low concentration range. The electrostatic part of van Laar coefficients is also calculated and these values increase with the decrease of concentration of polar component.

The author wishes to express his thanks to Professor R. Fujishiro of Osaka City University and to Professor Yonezo Morino of the University of Tokyo for their constant encouragement and discussions.

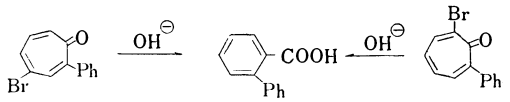
# *Studies on the Mechanism of Rearrangement Reaction of 2-Phenyl-4-bromotropone to 2-Phenylbenzoic Acid*[1]

By Yoshio KITAHARA, Ichiro MURATA and Tadashi MUROI*

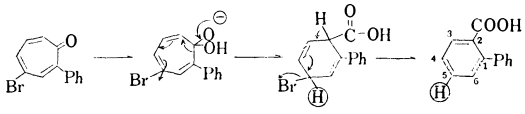
(Received January 26, 1961)



It had been found in the early period of studies on troponoid chemistry that the tropone derivatives having the halogen or methoxyl group in the 2-position undergo rearrangement to benzoic acid derivatives when treated with bases[2]. This rearrangement reaction has often been utilized for deriving unknown troponoid to known benzene derivatives to determine the position of various substituents in the seven-membered ring by the organic chemical method[2].

X=halogen, methoxyl

Two kinds of mechanism may be considered for this rearrangement reaction. One, route-A, involves the attack of the base on the carbonyl carbon (C-1), followed by ring contraction concerted with liberation of the substituent in C-2 as an anion[3]. The other, route-B, is the attack of the base on C-2 and subsequent rearrangement[4]. If the rearrangement proceeds through route-A, the carbon atom in the carboxyl group of the benzoic acid produced corresponds to the carbonyl carbon of tropone, and if the reaction goes through route-B, it will be the carbon atom at C-2 of the tropone. An investigation of the rearrangement with carbonyl-labeled 2, 7-dibromo- and 2, 4, 7-tribromotropone proved that the modified mechanism of route-A is the correct one[5].



One of the authors (T. M.) found that the product obtained by treatment of 2-phenyl-4-bromotropone (I) with alkali was unexpectedly 2-phenylbenzoic acid (III), the same as the rearrangement product of 2-phenyl-7-bromotropone (II)[6].

I III II

Differing from II, I does not possess any group easily liberated as an anion at the carbon adjacent to the carbonyl group and the rearrangement product, III, no longer possesses bromine atom. Consequently, the mechanism proposed by Doering and Denney[5] cannot be applied to this rearrangement reaction.

The following mechanism was considered for this abnormal rearrangement reaction and tracer technique using heavy water was utilized to prove this assumption.

If the rearrangement proceeds through this route, the reaction carried out in a system containing deuterium as an origin of hydrogen should give a product with the carbon-bound deuterium only in the 5-position of the biphenyl formed.

A solution of I dissolved in a solution of deuterium oxide[7], sodium hydroxide-*d*, and methanol-*d*[8] was refluxed for 30 min. and 2-phenylbenzoic acid was isolated from the acid portion. To remove deuterium from the carboxyl group, the acid was converted into its methyl ester with diazomethane and the ester was hydrolyzed to deuterated 2-phenylbenzoic acid (III) of m. p. 108~110°C[9]. The

9) Under this rearrangement condition, 2-phenylbenzoic acid was proved to be free from secondary deuteration on aromatic nucleus, since the infrared absorption spectrum of the product obtained by treatment of 2-phenylbenzoic acid under the same conditions as for rearrangement of I was identical with that of the original substance. D. J. G. Ives (*J. Chem. Soc.*, **1938**, 81) also reported that deuteration did not take place on the benzene ring when benzoic acid was treated in a deuterium oxide-sodium hydroxide-*d* system.

* IR spectra are measured using a Perkin-Elmer Model 21 double beam spectrophotometer in KBr pellet.

infrared absorption spectrum of III (Table I.) was different from that of III'[10], and this fact indicated that it contained the deuterium atom.

In order to determine the position of the deuterium atom in III, the following reaction was carried out. III was allowed to react with thionyl chloride at room temperature and the resulting acid chloride, treated with ammonia water, gave the amide (IV), m. p. 172.5~173°C. The Hofmann reaction of IV by the method of

III: X=COOH, Y=D
IV: X=$CONH_2$, Y=D
V: X=$NHCOCH_3$, Y=D
VI: X=$NHCOCH_3$, Y=Br
III': X=COOH, Y=H
IV': X=$CONH_2$, Y=H
V': X=$NHCOCH_3$, Y=H

Graebe[11] yielded the corresponding amine and the product was acetylated to give deuterated 2-acetamidobiphenyl (V), m. p. 113~114°C. The infrared absorption spectra of IV and V so obtained (Table I) and determination of deuterium by mass analysis (cf. Experimental) indicated that the deuterium atom has remained during the series of these reaction steps.

Bromination of V and V' with 1 mol. of bromine in glacial acetic acid gives the known 2-acetamido-5-bromobiphenyl (VI)[12] of m. p. 127.5~128.5°C in a quantitative yield from both. The infrared absorption spectra of VI derived from both V and V' were entirely identical, indicating that the deuterium atom in V had been substituted with a bromine atom in this bromination procedure. VI is a known substance and the position of its bromine atom has already been determined. These facts have proved that the deuterium atom in II, IV and V is in 5-position in the biphenyl ring and, consequently, the reaction mechanism assumed for this abnormal rearrangement might be proved to be correct.

## Experimental[13]

**Rearrangement Reaction of 2-Phenyl-4-bromotropone (I) in Heavy Water System.**—To a solution of sodium (1.38 g.) dissolved in methanol-*d* (35 ml.), deuterium oxide (25 ml.) and I (4.9 g.) were added and the mixture, provided with a calcium chloride tube, was refluxed for 30 min. on a water bath. Methanol was evaporated in a reduced pressure, the residue was diluted with 10 ml. of water, and extracted with chloroform to remove the neutral portion. The aqueous layer was acidified with hydrochloric acid to Congo red, the precipitated acid portion was extracted with chloroform, and the extract was washed with water. After drying over magnesium sulfate, chloroform was evaporated from the extract and the residue was sublimed in reduced pressure, from which 2.3 g. of crude crystals, m. p. 99~104°C, was obtained.

Without further purification, this product was dissolved in ether and ether solution of diazomethane was added to effect esterification. The residue obtained on evaporation of ether was dissolved in ethanol (30 ml.), 2 N sodium hydroxide (10 ml.) was added, and the mixture was refluxed

10) The same reaction was carried out in parallel, using 2-phenylbenzoic acid synthesized from fluorene[11]. The compounds not containing deuterium are represented by the same compound number as the corresponding deuterated compounds but with a prime.

11) C. Graebe and A. S. Rateanu, *Ann.*, **279**, 257 (1894).

12) H. A. Scarborough and W. A. Waters, *J. Chem. Soc.*, **1927**, 89.

13) All melting points are uncorrected.

for 2.5 hr. to effect hydrolysis. Ethanol was evaporated, the residue was acidified with diluted hydrochloric acid extracted with chloroform. The crystals obtained from this extract were sublimed in reduced pressure and afforded 2.15 g. (61.6%) of crystals melting at 95~103°C. Recrystallization from cyclohexane gave III m. p. 108~110°C.

Found: D, 8.93. Calcd. for $C_{13}H_9DO_2$: D, 10.00 atom%.

**2-Carbamoylbiphenyl-5-*d* (IV).**—The addition of thionyl chloride (2 ml.) to III (1.9 g.) resulted in vigorous reaction with evolution of hydrogen chloride. The mixture was allowed to stand at room temperature for 1.5 hr., excess thionyl chloride was distilled off in reduced pressure, and the oily residue was added to 28% ammonia water under ice-cooling, by which white precipitates formed at once. The precipitates were collected and the crude amide (1.8 g) of m. p. 145~158°C so obtained was recrystallized from hydrous ethanol to IV, m. p. 172.5~173°C.

Found: D, 8.37. Calcd. for $C_{13}H_{10}DNO$: D, 9.08 atom%.

**2-Acetamidobiphenyl-5-*d* (V).**—IV (1.75 g.) was triturated with water (10 ml.) in a mortar and transferred to a beaker. A solution of sodium hypobromide, prepared from bromine (1.75 g.), sodium hydroxide (3.5 g.), and water (22 ml.) at 0°C, was added into the beaker with ice-cooling and the mixture was stirred for 1 hr. A trace of insoluble matter was removed by filtration, the filtate was heated at 50~55°C for 1 hr., and submitted to steam distillation. The distillate was extracted with chloroform, the extract was washed with water, dried, and chloroform was evaporated. The residue (1 g.) was dissolved in dehydrated pyridine (3 ml.) and acetyl chloride (0.7 g.) was added dropwise under ice-cooling. The mixture was allowed to stand for 30 min. and poured into 2 N hydrochloric acid containing cracked ice. The crystals that separated out were collected by filtration (1.1 g.), m. p. 104~108°C. Recrystallization from hydrous ethanol gave V, m. p. 113~114°C.

Found: D, 6.60. Calcd. for $C_{14}H_{12}DNO$: D, 7.70 atom%.

**2-Acetamido-5-bromobiphenyl (VI).**—A solution of bromine (390 mg.) in glacial acetic acid (2 ml.) was added to a solution of V (500 mg.) dissolved in glacial acetic acid (3 ml.), with stirring, and the mixture was allowed to stand overnight. The mixture was then poured into ice-water, and crude crystals (750 mg.) of m. p. 115~118°C were sublimed in reduced pressure. Recrystallization of the sublimate from hydrous ethanol gave V as colorless needles m. p. 127.5~128.5°C.

Found: C, 57.64; H, 4.40; N, 4.37. Calcd. for $C_{14}H_{12}ONBr$: C, 57.93; H, 4.17; N, 4.83%.

The determination of deuterium by mass analysis was carried out by Dr. Sumio Horibe, Faculty of Science, Tokyo Metropolitan University, and the infrared spectral measurement was made by Mr. Hideji Aono of this Institute, to both of whom the authors express their sincere gratitude.

# *Condensation Reaction of Troponoids and Ethyl α-Cyano-β-aminoglutaconate. I*

By Shingo MATSUMURA

(Received February 2, 1961)

Nozoe and others have studied the reaction mechanism whereby azulene derivatives are formed by condensation of troponoids and cyanoacetic ester, and have considered the formation of an intermediate A during the course of this reaction[1]. There is also a possibility, in addition to the above mechanism,

(A)

of formation of a dimer of cyanoacetic ester followed by its condensation with troponoids in the formation of 2-aminoazulene derivatives.

This paper describes some results obtained on examination of this point.

Reaction of 2-chlorotropone (I) and a dimer[2] of ethyl cyanoacetate, i. e. ethyl α-cyano-β-aminoglutaconate (II) in absolute ethanol, in the presence of sodium ethoxide, affords red needles (III), m. p. 165°C, orange scales (IV), m. p. above 260°C, and colorless scales (V), m. p. 197°C. The use of a tertiary amine as the condensation agent results in the formation of III and IV but not of V.

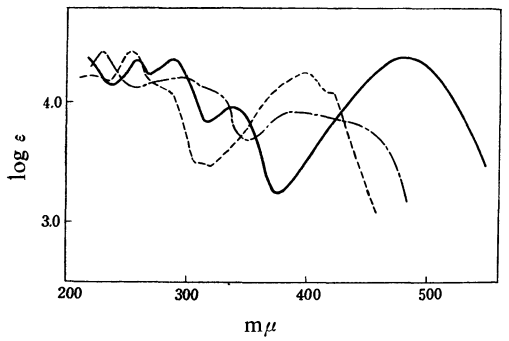

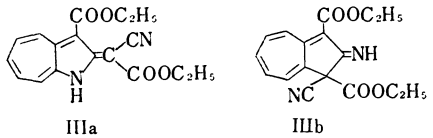

Fig. 1. UV absorption spectra of III, IV and V in methanol.
—— III, ----- IV, -·-·- V

Examinations were made on the structure of these products. The ultraviolet absorption spectra[3] of III, IV and V are given in Fig. 1.

These absorption spectra indicate that these products are not 2-aminoazulene derivatives. The analytical values of III correspond to molecular formula of $C_{17}H_{16}O_4N_2$ and structures like IIIa and IIIb may be assumed from this molecular formula.

The infrared absorption spectrum[4] of III, as indicated in Fig. 2a, exhibits absorption bands at 3220 $cm^{-1}$ for the imino or hydroxyl group, at 2200 $cm^{-1}$ for the cyano group conjugated with unsaturated bond, at 1688 $cm^{-1}$ for ester carbonyl conjugated with unsaturated bond, and at 1650 $cm^{-1}$ for stretching vibration of ester carbonyl conjugated with unsaturated bond or that due to NH deformation vibration.

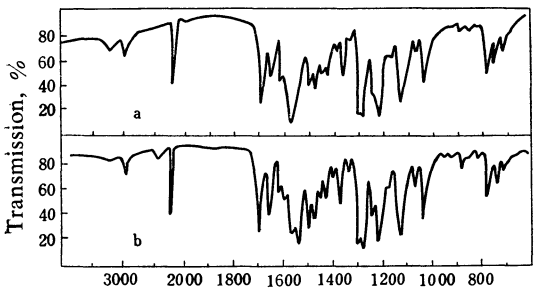

Fig. 2. IR absorption spectra of III (a) and $III_D$ (b) in KBr.

The structure of III which satisfies these infrared spectral results is the formula IIIa.

III undergoes reaction with sodium alkoxide to form a red substance (VI) which is decomposed by water or dilute acid to revert to III. This shows that VI is a sodium salt of III.

III does not form a picrate on addition of an ethanolic solution of picric acid but a prolonged heating of such a solution produces a picrate of m. p. 156°C (decomp.), sparingly soluble in ethanol. III easily reacts with dilute hydrochloric acid to form a labile product of red needles (VII), m. p. 155°C.

Other structurally unknown substances of various colors are obtained but they are all unstable and cannot be isolated in pure form. VII forms a picrate of m. p. 156°C.

The passage of dry hydrogen chloride gas through dehydrated benzene solution of III gives yellow needles (VIII) assumed to be the hydrochloride of III. VIII is extremely labile and decomposes when left in the air. The neutralization of VIII with sodium hydrogen carbonate solution liberates VII, whose ultraviolet absorption spectrum, as indicated in Fig. 3, is similar to that of 1-azaazulene derivatives.

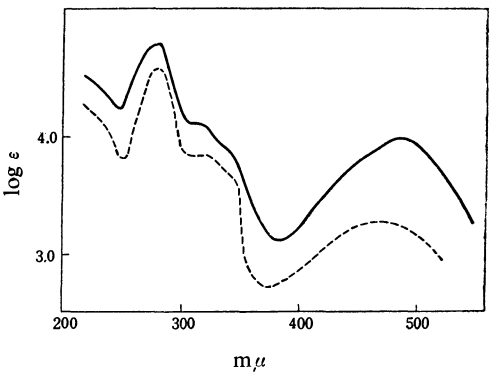

Fig. 3. UV absorption spectra of VII (——) and 3-ethoxycarbonyl-2-(diethoxycarbonylmethyl)-1-azaazulene (----) in methanol.

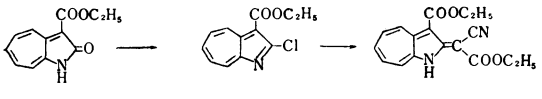
III is insoluble in water but dissolves in an aqueous solution of potassium hydroxide, from which it is extracted with an organic solvent. These foregoing facts show that III is an amphoteric substance and its behavior resembles that of pyrrole or indole to acids and alkalis.

These experimental results support the structure of IIIa for III.

Recently, Seto and others[5] prepared 2-chloro-3-ethoxycarbonyl-1-azaazulene (X) from 3-ethoxycarbonyl-1-azaazulan-2-one (IX) and



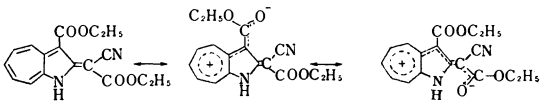
3) Measured by a Beckman Model DU spectrophotometer.

4) IR spectra are measured using a Perkin-Elmer Model 21 double beam spectrophotometer by Mr. S. Aono of this Institute, to whom the author is deeply indebted.

5) S. Seto et al., to be published.

obtained corresponding condensates by condensation of X with diethyl malonate and ethyl cyanoacetate.

Comparative examination of III with the condensate, m. p. 165°C, of X with ethyl cyanoacetate showed that they are the same substances. Consequently, III was proved to have IIIa structure, i. e. 2-(cyano-ethoxycarbonylmethylene)-3-ethoxycarbonyl-1-azaazulane.



IX X III

Further examination was made on the absorption band at 1650 $cm^{-1}$ in the infrared spectrum of III to see whether it is due to the ester carbonyl conjugated with unsaturated bond, stretching vibration of C=C, or to deformation vibration of N–H group. In order to confirm this point, a deuterated compound ($III_D$) of III was prepared.

$III_D$ was easily obtained on decomposition of VI with deuterium oxide. Admixture of $III_D$ with III showed no depression in the melting point and the ultraviolet absoption spectrum of $III_D$ in anhydrous cyclohexane agreed with that of III. The infrared spectrum of $III_D$, indicated in Fig. 2b, shows that the absorption bands at 3220, 1225 and 710 $cm^{-1}$ in III have disappeared and new bands have appeared at 2420, 1533 and 1186 $cm^{-1}$ in the spectrum of $III_D$, with decreased intensity of the absorption band at 1563 $cm^{-1}$.

The wave number ratio of 3220 $cm^{-1}$ in III and 2420 $cm^{-1}$ in $III_D$ is 1.330, which approximately agrees with the usual value of $\nu$(N–H)/$\nu$(N–D)[6]. Since the absorption band at 710 $cm^{-1}$ in III is active to deuteration, this absorption can be assigned to the out-of-plane deformation vibration of the N–H group. The absorption band at 1650 $cm^{-1}$ in III is still present in $III_D$ so that it is not due to any deformation vibration of the N–H group but should be the stretching vibration of ester carbonyl or the exo-methylene group. If it were due to the carbonyl, the absorption has a very much lower frequency for that of unsaturated ester carbonyl. This fact indicates that there is a large contribution of ionic structures such as those shown in Scheme 1 in III.

In oder to determine the assignment of absorption bands at 1688 and 1650 $cm^{-1}$, 2-(dicyanomethylene)-3-ethoxycarbonyl-1-azaazulane (XI) and 2-(cyano-ethoxycarbonylmethylene)-3-cyano-1-azaazulane (XII) were prepared and their infrared spectra were measured. Condensation of X and sodiomalononitrile in dry dioxane afforded lustrous red crystals XI, m. p. above 260°C.

Scheme 1.

Condensation of 2-chloro-3-cyano-1-azaazulene (XIII) and ethyl sodiocyanoacetate in dehydrated dioxane produced dark red crystals (XII), m. p. 230°C. The ultraviolet absorption spectra of XI and XII are indicated in Fig. 4 and the infrared spectra of XI and XII are shown respectively in Fig. 5a and b. These infrared spectra exhibit an absorption band due to ester carbonyl at 1690 $cm^{-1}$ in XI and at 1645 $cm^{-1}$ in XII.

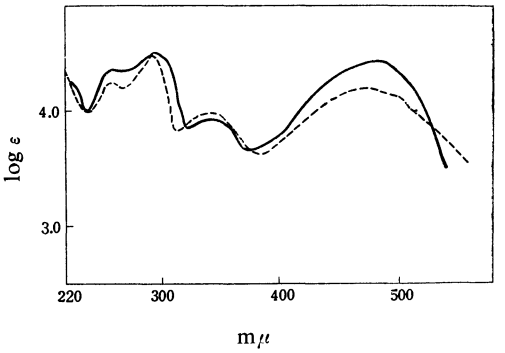


Fig. 4. UV absorption spectra of XI and XII in methanol.
—— XI, ----- XII

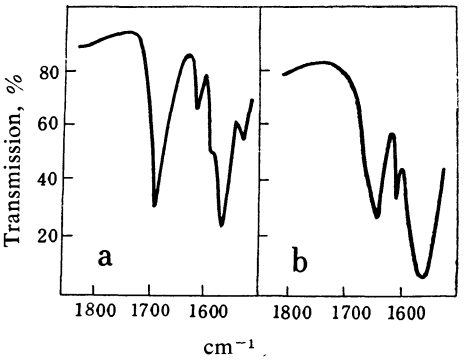

Fig. 5. IR absorption spectra of XI (a) and XII (b) in KBr disk.

These facts prove that the absorption band at 1688 $cm^{-1}$ in III is due to the carbonyl group in the ester at 3-position and that at 1650 $cm^{-1}$ is the absorption of the ester carbonyl group bonded to the methylene group

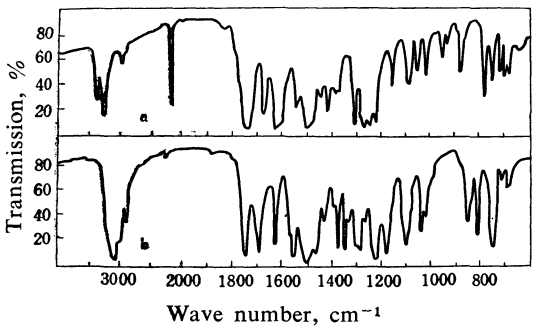
6) L. J. Bellamy, "The Infrared Spectra of Complex Molecules", Methuen (1958), p. 257.

and that it is not due to the stretching vibration of exo-methylene.

Analytical values of IV correspond to the molecular formula of $C_{15}H_{12}O_4N_2$ and its ultraviolet spectrum is similar to the absorption curve of 1-oxaazulan-2-one or 1-azaazulan-2-one derivatives. The infrared spectrum of IV, as indicated in Fig. 6a, exhibits the absorptions at 3380 and 3278 $cm^{-1}$ for primary amino group, at 2205 $cm^{-1}$ for cyano group conjugated with unsaturated bond, at 1740 $cm^{-1}$ for carbonyl in unsaturated $\gamma$-lactone, and at 1675 $cm^{-1}$ for ester carbonyl conjugated with unsaturated bond. From these results, IV is assumed to be a 1- oxaazulan-2-one derivative.

Seto obtained 1-oxaazulan-2-one (XIV), by decomposition of 3-ethoxycarbonyl-1-oxaazulan-2-one or 3-acetyl-1-oxaazulan-2-one with concentrated sulfuric acid.[7]

The same decomposition of IV with concentrated sulfuric acid afforded XIV, m. p. 69°C, and this has proved that IV is $\alpha$-amino-$\alpha$-(1-oxaazulan-2-on-3-yl)-$\beta$-cyano-$\beta$-ethoxycarbonyl-ethylene.



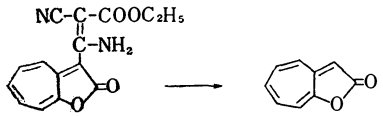


Fig. 6. IR absorption spectra of IV(a) and V(b) in KBr disk.

IV XIV

Analytical values of V correspond to the molecular formula of $C_{17}H_{18}O_5N_2$ and the infrared spectrum of V, indicated in Fig. 6b, exhibits a strong and broad absorption band at around 3100 $cm^{-1}$, absorption of cyano group at 2260 $cm^{-1}$, that of ester carbonyl at 1740 $cm^{-1}$, and that due to ester carbonyl conjugated with unsaturated bond at 1688 $cm^{-1}$.

Sometimes V is not obtained by condensation of I and II and the yield of V is generally poor. Further examination of this product was not made.

7) S. Seto, *Sci. Repts. Tohoku Univ.* (*I*), 37, 367 (1953).

Reaction of 2-methoxytropone (XV) and II in the presence of an alkoxide results in almost complete recovery of XV and III, IV and V are not obtained.

From the foregoing results, it was shown that 2-aminoazulene derivative was not formed in the condensation of troponoids with II.

## Experimental

**Reaction of 2-Chlorotropone (I) and Ethyl $\alpha$-Cyano-$\beta$-aminoglutaconate (II).**—a) To a solution of sodium ethoxide, prepared from 250 mg. of metallic sodium and 10 ml. of absolute ethanol, 2.45 g. of II was added and a solution of 1.5 g. of I dissolved in 30 ml. of absolute ethanol was added to it with stirring under ice-cooling. The solution colored red immediately. The mixture was allowed to stand at room temperature for 3 hr. and the red crystals that separated out were collected by filtration. The collected crystals were dissolved in benzene to separate them from colorless inorganic salt and evaporation of benzene left red crystals of m. p. 155~159°C. Repeated recrystallization from ethanol afforded 800 mg. of red needles (III), m. p. 163~165°C.

The reaction mixture left after the removal of the above crystals was evaporated to dryness under reduced pressure and the residue separated into crystalline and oily substances. This residual mixture was dissolved in benzene to be separated into benzene-soluble and insoluble portions.

The benzene-soluble portion afforded 350 mg. of III.

Found: C, 65.52; H, 5.38; N, 8.56. Calcd. for $C_{17}H_{16}O_4N_2$: C, 65.37; H. 5.16; N, 8.97%.

UV $\lambda_{max}^{MeOH}$ m$\mu$ (log $\varepsilon$): 260 (4.32), 289.5 (4.37), 340 (3.98), 490 (4.37).

Addition of water to the benzene-insoluble portion precipitated 200 mg. of orange crystals insoluble in water. This substance is extremely sparingly soluble in various organic solvents. Its recrystallization from a large quantity of chloroform afforded orange-yellow scales (IV), m. p. above 260°C.

Found: C, 63.58; H, 4.01; N, 9.85. Calcd. for $C_{15}H_{12}O_4N_2$: C, 63.38; H, 4.26; N, 9.86%.

UV $\lambda_{max}^{MeOH}$ m$\mu$ (log $\varepsilon$): 254 (4.43), 282 (4.14), 399 (4.27).

The water-soluble portion of this mixture produced, upon neutralization with dilute nitric acid, 750 mg. of brown precipitate and five recrystallizations from ethanol afforded 150 mg. of colorless scales V, m. p. 195~197°C.

Found: C, 61.85; H, 5.71; N, 8.83. Calcd. for $C_{17}H_{18}O_5N_2$: C, 61.81; H, 5.49; N, 8.48%.

UV $\lambda_{max}^{MeOH}$ m$\mu$ (log $\varepsilon$): 230 (4.43), 300 (4.21), 388 (3.92).

b) To a solution of 1 g. of I and 1.7 g. of II dissolved in 30 ml. of absolute ethanol, 1.4 g. of tributylamine was added under ice-cooling and the solution changed from orange to red. After allowing the mixture to stand for 5 hr. at room

8) All melting points are uncorrected. The microanalyses were carried out by Mr. S. Ohyama and Miss. Y. Endo of this Institute, to whom the author is deeply indebted.

temperature, the red leaflet crystals that separated out were collected by filtration and treated with chloroform to be separated into chloroform-soluble and insoluble portions.

Red needle crystals separated from the chloroform-soluble portion and recrystallization from ethyl acetate gave 550 mg. of III. The solid sparingly soluble in chloroform was recrystallized from a large quantity of chloroform to 420 mg. of orange-yellow crystals IV.

The reaction mixture after separation of the above products was evaporated, the residue was dissolved in chloroform, and the solvent was evaporated to dryness from the chloroform extract. The red crystalline residue thereby obtained was recrystallized from ethanol to 140 mg. of III.

**Sodium Compound (VI) of III.**—A solution of sodium ethoxide, prepared from 10 mg. of metallic sodium and 1 ml. of absolute ethanol, was added to the solution of 100 mg. of III dissolved in 1 ml. of dehydrated benzene by which 100 mg. of amorphous orange-red solid (VI), m. p. above 260°C, formed immediately. The solid was collected, washed with benzene, and dried.

VI was dissolved in water and extracted with benzene. The benzene extract was dried over anhydrous sodium sulfate and evaporation of benzene left 70 mg. of III. The residual aqueous solution was adjusted to pH 7 and extracted with benzene. The benzene extract was dried over anhydrous sodium sulfate and evaporated, leaving 20 mg. of III.

Found: N, 8.46. Calcd. for $C_{17}H_{15}O_4N_2Na$: N, 8.35%.

**Reaction of III and Picric Acid.**—a) A mixture of 50 mg. of III and saturated solution of picric acid in ethanol was warmed on a water bath to effect solution and the solution was allowed to stand at room temperature. The red needle crystals that separated out were recrystallized from ethyl acetate and 40 mg. of III was recovered.

b) A mixture of 50 mg. of III and 100 mg. of picric acid was placed in a test tube and the tube was heated in a water bath at 90°C to effect solution. Addition of ethanol to this solution separated 120 mg. of orange-yellow crystals, m. p. 156~158°C (decomp.), sparingly soluble in ethanol.

Found: N, 12.81. Calcd. for $C_{23}H_{19}O_{11}N_5$: N, 12.79%.

**Action of Aqueous Alkali Solution on III.**—A solution of 20 mg. of III dissolved in 1 ml. of 10% potassium hydroxide aqueous solution was heated on a water bath for 1 hr., cooled, and adjusted to pH 7. The red crystals thereby produced were recrystallized from ethanol and ca. 15 mg. of III was recovered.

**Action of Acetic Anhydride on III.**—A solution of 50 mg. of III dissolved in 1 ml. of acetic anhydride to which was added 1 drop of pyridine was heated at 120°C for 3 hr. Acetic anhydride was evaporated and the residue was recrystallized from ethanol, by which 30 mg. of III was recovered.

**Action of Diazomethane of III.**—The excess of ether solution of diazomethane was added to the solution of 20 mg. of III dissolved in 30 ml. of ether and the mixture was allowed to stand at room temperature for 4 hr. Evaporation of ether left crystals which were recrystallized from ethyl acetate and III was recovered.

**Action of Acid on III.**—a) Dropwise addition of 0.2 ml. of 2 N hydrochloric acid to a solution of 50 mg. of III dissolved in 1 ml. of ethanol by application of heat resulted in yellowing of the solution. Ethanol was evaporated from this mixture, the residue was neutralized with sodium hydrogencarbonate solution, and the dark red precipitate that formed was extracted with benzene. The benzene extract was dried over anhydrous sodium sulfate and passed through a column of alumina, by which the product separated into red, blue and green bands.

Elution of the red band with benzene afforded ca. 5 mg. of red leaflets VII, m. p. 153~155°C.

Elution of the green band with ethyl acetate failed to give any crystalline product.

VII formed a picrate of m. p. 156~158°C on addition of saturated ethanol solution of picric acid.

Found: N, 13.02. Calcd. for $C_{23}H_{19}O_{11}N_5$: N, 12.79%.

b) Dry hydrogen chloride gas was passed through a solution of 50 mg. of III dissolved in dehydrated benzene and the yellow needle crystals (VIII) that separated out were collected by filtration. This product underwent a change by atmospheric moisture. The product was dissolved in water, neutralized with sodium hydrogencarbonate, and the precipitate was extracted with benzene from which 10 mg. of a substance agreeing with VII, m. p. 153~155°C, was obtained.

**Deuterated Compound ($III_D$).**—A solution of 100 mg. of VI dissolved in 1 ml. of deuterium oxide to which was added 1 drop of acetic anhydride was allowed to stand at room temperature for 1 hr. The red needle crystals that separated out were recrystallized from dehydrated benzene-cyclohexane mixture and 60 mg. of $III_D$, m. p. 163~164°C, undepressed on admixture with III, was obtained.

**Synthesis of 2-(Dicyanomethylene)-3-ethoxycarbonyl-1-azaazulane (XI).**—To a sodium ethoxide solution prepared from 50 mg. of metallic sodium and 2 ml. of absolute ethanol, 250 mg. of malononitrile was added to form its sodio compound and ethanol was evaporated completely. The residue was suspended in 2 ml. of dehydrated dioxane, 250 mg. of 2-chloro-3-ethoxycarbonyl-1-azaazulene (X) was added to it, and the mixture was heated at 90°C for 1 hr. The reaction mixture colored dark red and orange precipitate separated gradually. Dioxane was evaporated from this mixture, the residue was dissolved in water, and the solution was acidified with acetic acid by which a lustrous crystalline precipitate was produced. Recrystallization from acetone gave 120 mg. of lustrous red crystals XI, m. p. above 260°C.

Found: C, 67.74; H, 4.08; N, 15.98. Calcd. for $C_{15}H_{11}O_2N_3$: C, 67.91; H, 4.18; N, 15.84%.

UV $\lambda_{max}^{MeOH}$ mμ (log ε): 259 (4.23), 295 (4.47), 340 (3.92), 483 (4.43).

**Synthesis of 2-(Cyano-ethoxycarbonylmethylene)-3-cyano-1-azaazulane (XII).**—To a suspension of 50 mg. of sodium in 2 ml. of dehydrated dioxane,

400 mg. of ethyl cyanoacetate was added and the mixture was warmed to form the sodio compound. A mixture of this sodio compound and 200 mg. of 2-chloro-3-cyano-1-azaazulene (XIII) was heated at 90°C for 1 hr., by which the solution became dark red and a reddish orange precipitate began to separate out. Dioxane was evaporated, the residue was dissolved in water, and the aqueous solution was acidified with acetic acid. The dark red precipitate thereby formed was recrystallized from acetone and 280 mg. of dark red needles XII, m. p. 230°C (decomp.), was obtained.

Found: C, 67.83; H, 4.26; N, 15.67. Calcd. for $C_{15}H_{11}O_2N_3$: C, 67.91; H, 4.18; N, 15.84%.

UV $\lambda_{max}^{MeOH}$ $m\mu$ (log $\varepsilon$): 256 (4.21), 293 (4.46), 340 (3.80), 490 (4.18).

**Formation of 1-Oxaazulan-2-one (XIV).** — A solution of 100 mg. of IV dissolved in 0.2 ml. of concentrated sulfuric acid was heated on a water bath for 1 hr. and the brownish orange solution that formed was diluted with water. This was extracted with benzene, the extract was washed thoroughly with water, and dried over anhydrous sodium sulfate. Evaporation of benzene left an oily substance with aroma.

This residue was digested with hot cyclohexane, the orange crystals thereby obtained were sublimed in reduced pressure, and the sublimate was recrystallized from cyclohexane, affording XIV, m. p. 69~71°C.

The author takes this opportunity to express his sincere gratitude to Professor Tetsuo Nozoe and Professor Shuichi Seto for their kind guidance throughout the course of this work, and to Mr. Fumio Sato for his cooperation in carrying out the experiments.

# *Studies on Micro-paraffin. III. Properties and Spectra of Each Fraction of Micro-paraffin Separated by Urea Method and Chromatography*

By Kazuo NEGORO

(Received December 20, 1960)

Since Bengen's discovery in 1940[1,2], it has been observed with interest that crystalline molecular compounds, that is to say, urea adductible components, were formed by urea and organic compounds of straight-chain structure and numerous studies on this reaction have been reported. The application of this reaction has been remarkably developed as one of the excellent separation methods of organic compounds[3]. Phillips[4] explained that 20~90% of urea adductible compenents were contained in microcrystalline waxes.

Molecular compounds, formed by urea and ordinary paraffin waxes, were previously reported[5,6], and the studies on micro-paraffins will be explained in this report. The micro-paraffin was separated into two groups of compounds; one was of the straight-chain structure forming adducts with urea and the other was of the non-straight-chain structure forming no adducts. Then, each group was separated into three fractions soluble in pentane, benzene, and alcohol, successively, by chromatography with silica gel. The crystal properties of each soluble fraction were studied and its ultraviolet and infrared absorption spectra were measured.

As a result of these experiments, it was confirmed that it was reasonable to consider that the cause of the micro-crystallization of the so-called micro-paraffin should be not essential, but derived by secondary factor. It was also confirmed that about 60% of the micro-paraffins obtained from the tank residue of Arabian crude oil (Aramo oil in Saudi-Arabia)[7] consisted of urea adductible paraffins which had higher melting points and lower refractive indices than those of non-adductible ones. However, it was found when the ultraviolet spectra of each soluble fraction was separated by chromatography that small quantities of various aromatics were mixed with the fractions and an absorption band due to the double band was observed on the infrared

spectrum of the benzene soluble fraction. After recrystallization of each fraction with ethyl alcohol, it was observed by the microscope that the adductible paraffin formed plate crystals, and the fractions soluble in pentane and benzene separated from micro-paraffin by chromatography also formed plate crystals. These phenomena were proved by the infrared spectra indicating that each fraction showed the characteristic crystal band[8] in the wavelength of 13.7~13.9 $\mu$ (wave number of 730~710 $cm^{-1}$).

On the contrary, the non-adductible paraffin showed a micro-crystalline state; the only exception was the pentane soluble fraction separated from non-adductible micro-paraffins by chromatography, which formed plate crystals.

## Experimental

**Formation of Urea Adducts.**—Micro-paraffin was dissolved in benzene and treated with solid urea. The activators for the reaction were water and methyl alcohol. The formed molecular compounds of urea and straight chain paraffins (urea adducts) were separated from the non-adductible paraffin with urea by a suction filter with a vacuum pump.

The adducts were dried to constant weight watching the temperature to avoid decomposition, and finally, were decomposed with hot water. The adductible paraffins were separated from urea by dissolving them in hot water.

They were separated by filtration as they solidified with the drop of temperature. They were completely dried in a desiccator and weighed. The so-called urea reject or adductible paraffin, was weighed after benzene, methyl alcohol and water were expelled by solvent recovery apparatus. The conditions of the experiments are shown in Table I.

TABLE I. UREA ADDUCTS REACTION

| | |
|---|---|
| Micro-paraffin | 112.5 g. |
| Benzene | 1700 cc. |
| Urea | 450.0 g. |
| Methyl alcohol for activator | 45 cc. |
| Water | 4.5 cc. |
| Reaction temp. | 33°C |
| Reaction time | 50 min. |
| Drying temp. of adducts | 35~45°C |
| Drying time of adducts | 60 hr. |
| Hot water | 6000 cc. |
| Temp. of hot water | 70~80°C |

The materials used in the experiment were as follows:

Methyl alcohol: b. p. 65°C, refined from commercial first grade product by distillation.

Benzene: b. p. 80°C, refined from commercial product by ordinary method[9].

Urea: m. p. 132.6°C, refined by recrystallization method.

**Chromatography.** — Each of the adductible and non-adductible paraffins was dissolved in a large quantity of pentane.

Twenty grams of the adductible paraffin was weighed out and dissolved in 16 l. of pentane; and 20 g. of the non-adductible paraffin was weighed out as above and dissolved in 12 l. of pentane.

Each of the two was charged into the column for chromatography, and treated with pentane, benzene, and ethyl alcohol to be separated into their soluble fractions.

The column used was a glass tube of 160 cm. in length and 6 cm. in diameter, and packed with 3 kg. of 80 mesh silica gel that had been dried for 8 hr. at 120°C.

**Measurement of Physical Properties.** — *Mean Molecular Weight.*—Measured by the depression of freezing point[10] in refined benzene.

*Melting Point.*—Measured by the method of dropping point[11].

*Refractive Index.*—Measured by an Abbe refractometer at 70°C (higher than melting point of paraffins).

**Observation of Crystals**[12].—The adductible and non-adductible paraffins and their pentane, benzene and ethyl alcohol soluble fractions separated by chromatography were recrystallized with solvent (ethyl alcohol; b. p. 78°C). The crystals were observed with ordinary or phase-contrast microscopes. One gram of each paraffin sample was dissolved in 300 cc. of ethyl alcohol and the solution was warmed to 70°C in a thermostat. Then, it was gradually cooled to room temperature and recrystallized.

**Measurement of Ultraviolet Absorption Spectrum.** — A photo-electric spectrophotometer of Type EPU-2 manufactured by Hitachi Mfg., Co. was used for the measurement of ultraviolet absorption spectrum. About 0.5 g. of the sample was taken and weighed accurately, and then dissolved in 5 g. of refined *n*-hexadecane to make up the solution of concentration of 10 wt. %. The solution was diluted to a tenth its former strength by the weighing method, successively, to make concentrations of 1, 0.1 and 0.01%. The ultravioled spectra of these solutions were measured at room temperature. *n*-Hexadecane, refined from commercial special grade product by the same process as the previous report[13], was confirmed to be fit for a diluent by measuring the degree of transparency in the range of wavelength of 220~420 m$\mu$.

**Measurement of Infrared Absorption Spectrum.** — A infrared spectrophotometer of Perkin Elmer Model-21 was used for the measurement of infrared spectrum. The sample of the adductible or non-adductible paraffins and each fraction separated by chromatography were applied on the spectrophotometer and measured.

## Results and Discussions

**Results of Urea Adducts Formation.** — The micro-paraffins which were obtained from the tank residues of Arabian crude oil were treated with urea, and the results are shown in Table II.

TABLE II. UREA TREATMENT OF MICRO-PARAFFIN

| Material | Weight, g. | Yield, % |
|---|---|---|
| Micro-paraffin | 112.5 | 100.0 |
| Urea adductible paraffin | 69.5 | 61.8 |
| Urea non-adductible paraffin | 33.1 | 28.9 |
| Loss | 9.9 | 9.3 |

According to Philips[4], it was reported that micro-crystalline waxes contained 20~90% of urea adductible components. Turner et al.[14] reported that ordinary crystalline waxes contained 80~90% of *n*-paraffin by the results of the examination by mass-spectra on 16 sorts of paraffins. As results of the above reports, it is considered that the so-called micro-paraffins have higher molecular weight than that of the ordinary crystalline waxes and that the former contain side chain substances in a larger amount than the latter. It seems to be reasonable to consider that isoparaffins which have some side chains and the paraffins which have one or two aromatic or naphthene rings form adducts with urea as reported by Zimmerschied[15].

It will not be stated that all the components of such urea adductible paraffins consist of *n*-paraffin alone (small quantities of side-chain paraffins may be contained). The above consideration will also be confirmed by the results of chromatography, ultraviolet spectroscopy, and infrared spectroscopy as mentioned below.

**Results of Chromatography and Properties of Each Fraction.** — The adductible and non-adductible paraffins were separated by chromatography with silica gel.

The yields of each fraction are shown in Table III.

Great differences of the yields of each fraction were not seen between the two paraffins. However, there were great differences between the results of the physical properties of each fraction as shown in Table IV.

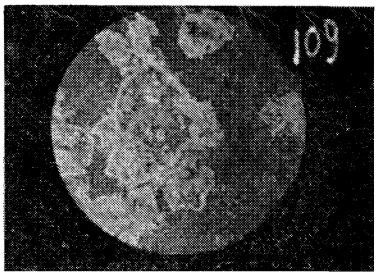
The non-adductible paraffins have higher mean molecular weights, lower melting points, and very much higher refractive indices than the adductible paraffins. Then, it was shown that in micro-paraffins, straight-chain hydrocarbons were separated effectively from substances having side-chains and aromatics.

TABLE III. RESULTS OF CHROMATOGRAPHY

| | Micro-paraffin | Urea adductible paraffin | Urea non-adductible paraffin |
|---|---|---|---|
| Pentane soluble fraction | 75.4 (76.8)* | 79.0 (86.8) | 76.5 (84.5) |
| Benzene soluble fraction | 17.0 (17.3) | 9.5 (10.4) | 9.5 (10.5) |
| Ethyl alcohol soluble fraction | 5.8 (5.9) | 2.5 (2.8) | 4.5 (5.0) |
| Loss | 1.8 (—) | 9.0 (—) | 9.5 (—) |
| Total | 100.0 (100.0) | 100.0 (100.0) | 100.0 (100.0) |

* The values in ( ) show the yield (%) of each fraction, from which loss is subtracted.

TABLE IV. PHYSICAL PROPERTIES OF EACH FRACTION



| | Mean molecular weight | | M. p., °C | | Refractive index, $n_D^{70}$ | |
|---|---|---|---|---|---|---|
| | A Urea adductible paraffin | B Urea non-adductible paraffin | A | B | A | B |
| Base micro-paraffin | 613 | 620 | 67.0 | 54.4 | 1.4400 | 1.4460 |
| Pentane soluble fraction | 607 | 636 | 65.0 | 54.0 | 1.4390 | 1.4410 |
| Benzene soluble fraction | 591 | 602 | 20 | 20 | 1.5050 | 1.5200 |
| Alcohol soluble fraction | 636 | 627 | 67.0* | 46.5* | —** | —** |

* Though each fraction was dropped at 57.0 or 46.5°C in measuring, some parts of the residues were solid. It was difficult to determine the melting point.

** Measurements were impossible.

In particular, by the fact that the non-adductible paraffins have very high refractive indices, it should be suggested that they consist of complicated compounds[16].

It has already been known that hydrocarbons with side-chains and aromatic or naphtheric substances have lower melting points and higher refractive indices[17,18].

**Results of the Observation of Crystals.**—Each fraction obtained by chromatography from the non-adductible paraffins was recrystallized with ethyl alcohol and observed through a microscope.

The results of the observation are shown in Figs. 1—8. Figure 1 shows the adductible paraffin which forms plate crystals smaller than those of the ordinary crystalline paraffin wax.

On the other hand, the non-adductible paraffin is in a very micro-crystalline state as shown in Fig. 2.

The growth of plate crystals of the pentane soluble fraction of urea adductible paraffin (Fig. 3) has progressed further than those of base paraffin, and the pentane soluble fraction of urea non-adductible paraffin (Fig. 4) also develops to plate crystals. The benzene soluble fraction of urea adductible paraffin from plate crystals as shown in Fig. 5, but that of urea non-adductible paraffin is microcrystalline as shown in Fig. 6. The ethyl alcohol soluble fractions of the two (adductible and non-adductible) were very fine and amorphous as shown in Figs. 7 and 8. These were very different from the other fractions.

The results of such observations through the microscope conformed to the results of measurement of infrared spectra of each paraffin, and these facts are interesting for the investigation on microcrystallization of micro-paraffin.

**Results of Measurement of Ultraviolet Spectrum.** — Each fraction of urea adductible or non-adductible paraffins was diluted with *n*-hexadecane, and its degree of transparency

($T\%$) was measured; the results are shown in Figs. 9 and 10.

The ultraviolet spectra of the two paraffins are shown in Figs. 11 and 12, in which ordinate means $\log \varepsilon$ and abscissa wavelength ($m\mu$) calculated from the above results.

As [the results of such ultraviolet spectra, it is considered that both of the urea adductible and non-adductible paraffins contain various aromatics though their quantities are small.

**Results of Measurement on Infrared Spectrum.** —The results of the infrared spectra measured on each fraction of urea adductible and non-adductible paraffins are shown in Figs. 13—20. Though it is difficult to analyze any spectra on each fraction, the assignment of the main

vibrations has been considered as shown in Tables V—XII in reference to the results of Randall and others[19].

It was reported in our previous paper[7,8] that the results of the observation by microscope was noteworthy, showing that any substances in plate crystals had a crystal band in the range of wave number of 710~730 $cm^{-1}$ (or wavelength of 13.7~13.9 $\mu$).

## Conclusion

Comparing the urea adductible with non-adductible paraffin, there have been considerable differences in each fraction. In particular, it is very interesting that the alcohol fraction has the spectrum assigned to O-H streching vibration, which has been suggested to be the cause of micro-crystallization. It is considered that the substances which are the cause of micro-crystallization shall be contained in the alcohol fraction of urea non-adductible paraffins.

The author expresses his sincere appreciation to Professor Ryozo Goto and Professor Saburo Yagi, Kyoto University, for their cordial guidance in these studies, and is also grateful to the personnel in Osaka Ind. Tech. Lab., who co-operated with the author on the experiments of infrared spectrum.

# *Studies on Micro-paraffin. IV. On the Transformation of Paraffin Crystal by Addition of Pure Substances*

By Kazuo NEGORO

(Received January 23, 1961)

Numerous phenomena, concerning the micro-crystallization of microparaffin derived by secondary cause, were previously reported[1]. Many investigations were made for the crystal growth of paraffin wax in the field of lubricating oils, because it was supposed to have great effects on the pour points of oils[2]. The pour points of lubricating oils are not the melting points of oils, but it seems to be reasonable to consider that the pouring phenomenon happens when the whole fluidity of lubricating oils is lost by the crystallization of wax components contained in the oils. Therefore, additional agents are used for pour point depressants to keep the fluidity of lubricating oils in low temperature inhibiting the crystal growth of paraffin waxes. They are supposed to inhibit the crystal growth of paraffin waxes, because they are adsorbed by paraffin waxes rather than oils.

The addition of any inorganic and organic substances to ordinary crystalline paraffin waxes were examined and their structure which should inhibit the crystal growth of paraffin waxes. In particular, as seen in the report[3], the cause of micro-crystallization of microparaffins was considered to be affected by substance with hydroxyl groups derived by the results of studies on ultraviolet and infrared spectra, etc. of the components separated from the microparaffin by a propane deasphalting method, urea adducts method, and chromatography: hence, the behavior of various organic compounds having OH groups should be noticed. Then, many pour point depressants for lubricating oils, additional agents to paraffin waxes[4], and direct dyes[5] were examined at the same time. Furthermore, pure organic substances considered to be effective for the crystal growth of paraffin waxes were studied at the base of pure *n*-dotriacontane (forming plate crystals), and their effects on crystal growth of *n*-hydrocarbon (simple substance, but not mixture) were investigated.

As the above results, such as Santopour or pour point depressants for lubricating oils, picric acid, *p*-hydroxydiphenyl, and some direct

dyes were found to be the substances affected on the transformation of crystal growth of paraffins.

These behaviors shall be cleared by future studies, they are now being investigated by X-ray diffraction, and infrared spectra of microparaffins. However, it is very interesting that the existence of the above organic substances with hydroxyl groups and similar molecular structure, affects the transformation of the crystal of paraffin waxes. It was found, also, that there was a difference between the paraffin waxes (mixture of various hydrocarbons) and *n*-dotriacontane for such effects of addition. Therefore, the composition of paraffin was considered to be effective for the micro-crystallization of microparaffins.

## Experimental

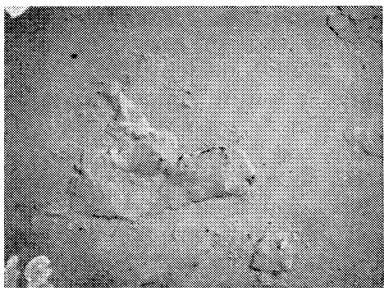
**Materials.**—*Crystalline Paraffin.*—The sample of wax was made in the Funakawa Refinery, Nippon Mining Co., m. p. 53.5°C, and refractive index $1.4308^{70.0}$.

*n-Dotriacontane.*—The product of Fischer Scientific Co., and purchased from Pacific Gulf Oil Co.,[6] m. p. 69.2°C, sp. gr. $0.7831^{70.0}$, and refractive index $1.4308^{70.1}$.

*n*-Dotriacontane was of a high purity, but a content of some impurities was recognized by the result of the ultraviolet spectrum (wavelength 220~400 mμ) measurement with purified *n*-hexadecane as diluent. Accordingly, purification was conducted with 10% of activated clay at 75°C (yield of 78%). Such purified *n*-dotriacontane was confirmed to contain no impurities by a measurement of the ultraviolet spectrum as above, m. p. 69.5°C and refractive index $1.4315^{73.0}$.

The above values were confirmed to be almost equal to those in the literature[7].

*Chemicals.*—Many inorganic and organic chemicals, added to the crystalline paraffin or *n*-dotriacontane, were of special or 1st grade made by Kanto Kagaku Co.



*Solvents.*—Ethyl alcohol was purified by a general method[8], and its boiling point was 78.0°C.

**Crystallization.**—Crystalline paraffin or *n*-dotriacontane was weighed accurately on a chemical balance; and 10, 1 and 0.1 wt.% of each inorganic or organic chemicals (as additive) were also weighed accurately. Both the paraffin and the additive were placed in an Erlenmeyer's flask and melted at 80°C in a thermostat. Even when there were some chemicals not melted at 80°C, the next operation was started; 1 g. of purified ethyl alcohol was added to 300 cc. of each sample with a pipette, and was warmed at 75±1°C in the thermostat to make the sample soluble in ethyl alcohol with intermittent stirring. Then, it was gradually cooled to room temperature for the growth of the crystal of the paraffin.

**Observation of Crystals by Microscope**[9].—The crystal of each sample was placed on a slide glass with a syringe, and was observed with an ordinary or phase-contrast microscope; and then, photographs of the state of each crystal were taken.

## Results and Discussion

**Effects of Various Substances on Crystallization of Crystalline Paraffin.**—*Effects of Inorganic Substances.*—The effects of the existence of various inorganic substances on the crystallization of crystalline paraffin were investigated. The crystalline paraffin at the base forms thin and large plate crystals as shown in Fig. 1, which mainly consists of *n*-paraffin (containing 88~90% of the straight chain adductible paraffin), and it is supposed that the average number of carbon chains of hydrocarbons contained to be 27*[1].

×225

Fig. 1. Crystals of crystalline paraffin.

In the case of each 10% of various metals, oxides, acids, alkalis, salts, etc., such as sulfur, zinc powder, manganese dioxide, silica, zinc oxide, aluminum chloride, sodium bicarbonate, potassium chlorate, alum, silver nitrate, ammonium vanadate, sulfuric acid, hydrochloric acid, sodium hydroxide, etc., existed with crystalline paraffin, no transformation were observed in the crystallization of the crystalline paraffins.

*Effects of Organic Substances.*—Next, the effects of 0.1~10% of various pure organic substances on crystalline paraffin were also examined. Experiments were conducted on various organic compounds; and at the same time, as explained above by the investigation of the crystal properties[1,3], ultraviolet spectra and infrared spectra on each fraction of microparaffin separated by the application of propane deasphalting method, urea adducts method, chromatography etc., the compound with hydoroxyl or carbonyl groups was considered

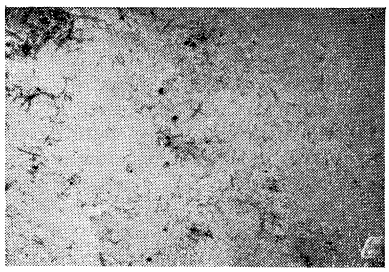
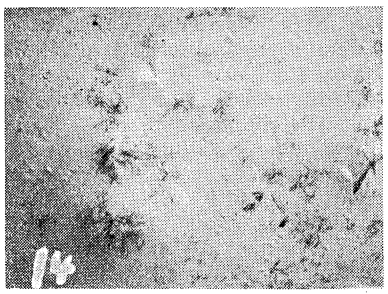
to give effects on the micro-crystallization of microparaffin. Under the above circumstances, in particular, the various types of organic compounds with functional groups such as hydroxyl or carbonyl group were examined in a wide scope. In the case of each 10% of various aromatics, alcohols, aldehydes, ketones, acids, esters, salts, phenols, amines, nitrogen compounds, sulfur compounds, etc., such as naphthalene, *tert*-butyl alcohol, cetyl alcohol, cholesterol, phenol, $\alpha$- and $\beta$-naphthol, resorcinol, glycerine, pyrogallol, *p*-hydroxydiphenyl, picric acid, *m*- and *p*-nitrophenol, *o*-, *m*- and *p*-dinitrobenzene, aniline, lauril amine, triethanolamine, phenylhydrazine, azobenzene, methyl orange, hydroxyazobenzene, dinitrophenyl hydrazine, benzaldehyde, glucose, methylisobutyl ketone, acetophenone, $\alpha$- and $\beta$-naphthoquinone, quinizarine, benzoic acid, acetic acid, naphthenic acid, oleic acid, stearic acid, oxalic acid, adipic acid, 2.3- and 2.5-dihydroxybenzoic acid, salicylic acid, calcium acetate, calcium, barium and aluminum stearate, lead oleate, zinc and lead naphthate, amyl acetate benzyl acetate, ethyl chloride, trichloroethylene, methylchlorostearate, *n*-heptyl mercaptane, dibenzyl disulfide, etc. exist with crystalline paraffin, were observed in the crystallization of the crystalline paraffin, were observed in the crystallization of the crystalline paraffins. Each of the various organic compounds which transformed the crystalline properties of paraffin when being added to it, are shown in Table I.

The substances having hydroxyl groups combined with an alkyl group or a benzene ring, were hardly affected on crystallization of paraffins. Glycerine, ethylene glycol, pyrogallol, etc.[2] which were said to drop the pour points of lubricating oils when being added, were not much affected on the crystal growth of paraffins. However, in the case of *p*-hydroxydiphenyl and picric acid, the crystal growth of crystalline paraffins was evidently inhibited as shown in Figs. 2 and 3, respectively, and it is very interesting that they show a microcrystalline state.



×225

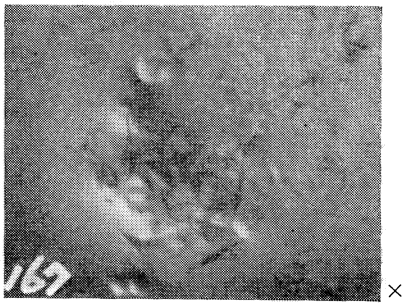
Fig. 2. Transformation of crystals of crystalline paraffin caused by the addition of *p*-hydroxydiphenyl.



×225

Fig. 3. Transformation of crystals of crystalline paraffin caused by the addition of picric acid.

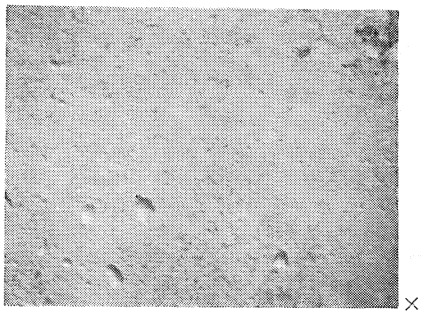
In the next stage, nitrogen compounds such as compounds having nitro, amino or azo groups, etc. were examined. But almost no effects were observed on such compounds as shown above. As the results of investigations on the compounds having aldehyde or ketone groups, quinizarine (having two hydroxyl groups in addition to ketone groups and



×225

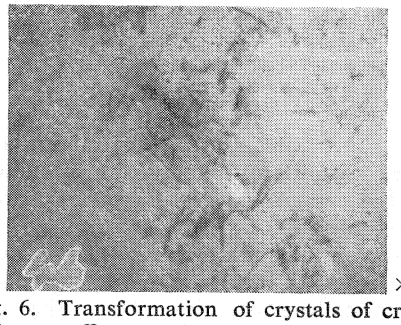
Fig. 4. Transformation of crystals of crystalline paraffin caused by the addition of quinizarine.

benzene nucleus) formed the microcrystallization of crystalline wax as shown in Fig. 4. Almost no effects were given by various types of organic acids having hydroxyl groups. However, in the presence of metallic salts of stearic or naphthenic acid, microcrystalline crystals were found accompanied by plate crystals of crystalline paraffin. The metallic soaps of fatty acids are used for the pour point depressant of lubricating oils[10], and they are said to have larger effects when their molecular weights are larger. For instance, the effects of the existence of metallic salts of stearic and naphthenic acids on the crystals of a crystalline paraffin are shown in Figs. 5 and 6, respectively.



×225

Fig. 5. Transformation of crystals of crystalline paraffin caused by the addition of calcium stearate.



×225

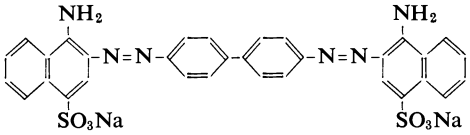
Fig. 6. Transformation of crystals of crystalline paraffin caused by the addition of zinc naphthate.

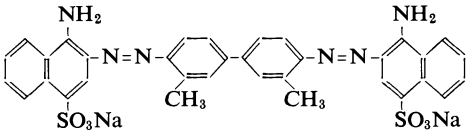
Though effects of the addition of a few compounds of sulfur were investigated, so far, substances inhibiting the crystal growth of crystalline paraffins have not been found.

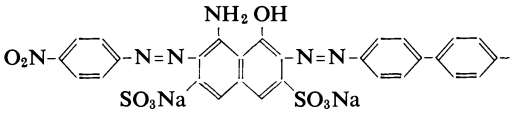
The substances giving effects on the transformation of crystallization are shown in Table I.

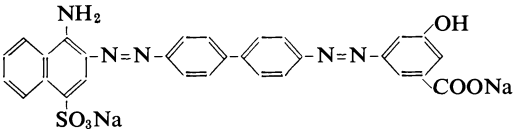
*Effects of Addition Agents.*—The results of the investigations on addition agents of paraffin waxes had been already reported[11]. The effects of the existence of such agents on the crystals of paraffin waxes were examined. Also the pour point depressants, recently being in practical use in the field of lubricating oils, are considered to have effects on keeping the fluidity of lubricating oil in lower temperature[2] by inhibiting the growth of paraffin crystals mixed in oils. Then, the effects of depressants on sale upon the crystallization of crystalline paraffins when mixed in the paraffins were also examined as above, and the results are shown in Table II.

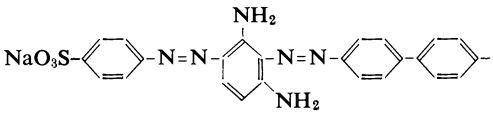
It was found that the substance, having the most remarkable effect on the change of the crystals of paraffin wax, was Santopour. In

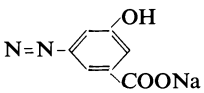


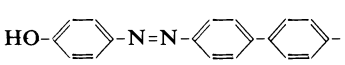


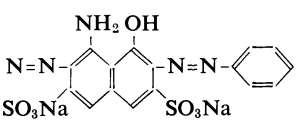












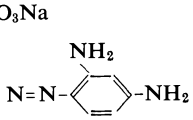


Table II. Effects of addition agents on the crystallization of paraffin

| Sample | Effects on crystallization of paraffins | Summary |
|---|---|---|
| Polyethylene | no | Improver of m. p. which micronizes the structure of paraffin |
| Acra wax c | no | Synthetic paraffin. Improver of m. p. |
| Carbo wax | no | Poly (ethylene glycol) (mol. wt. 4000) |
| Vistac | no | Polybutene (mol. wt. 1100 and 3400) |
| Ar wax | no | Paraffin added by polyethylene |
| Stroba wax | no | Paraffin mixed with a small quantity of resin |
| Adva wax | Somewhat transformation | Microparaffin added by polyethylene |
| Chloro-naphthalene | Transformation | Chlorinated naphthalene |
| Santopoid 23RI | no | Addition agents of lubricating oils |
| Ionol | no | Addition agents of lubricating oils |
| Santopour | Transformation (micro-crystallization) | Addition agents of lubricating oils |
| Santolube 70 | no | Addition agents of lubricating oils |

Table III. Effect of direct dyes

| Sample | Structural formula | Effects on crystallization of paraffin |
|---|---|---|
| *p*-Aminodiphenyl |  | no |
| Congo red |  | no |
| Benzopurprine |  | no |
| Nippon green B conc. |   | Transformation (micro-crystallization) |
| Nippon orange R |  | Transformation |
| Nippon brown 3G |   | Transformation |
| Nippon dark green B conc. |   | Transformation |
| Nippon deep black ex. conc. |   | Transformation |

this case, the phenomenon of micro-crystallization as picric acid, *p*-hydroxydiphenyl, etc. was confirmed by microscopy as shown in Fig. 7.

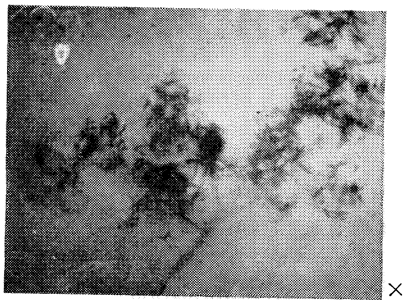
Santopour is the product made from phenol and paraffin wax[12], and it is said to form the following structure. It is attractive that the structure is similar to that of picric acid which caused the crystals of the crystalline paraffins to micro-crystallize.

(W; paraffinic chain)

Chloronaphthalene*, which was made by blowing chlorine into naphthalene, was added to the crystalline paraffin. Then, the crystal growth of paraffin was inhibited, and almost no crystal of paraffin appeared by cooling under the same condition; it was attractive

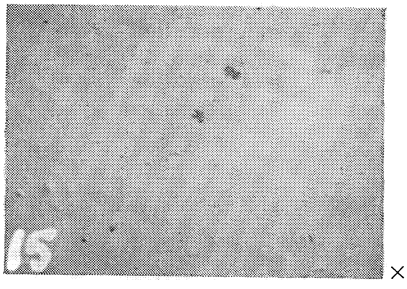
12) N. Iimure, "Guide-book of Petroleum Products", Sangyo Tosho, Tokyo (1956), p. 162.

* The trial product by K. Hashizume (Fukushima Paraffin Paper Co.), was used and its composition is obscure.



×225

Fig. 7. Transformation of crystals of crystalline paraffin caused by the addition of Santopour.



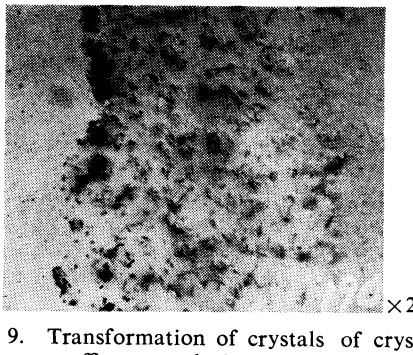
×225

Fig. 8. Transformation of crystals of crystalline paraffin caused by the addition of chloronaphthalene.

that only a small amount of amorphous crystals was observed as shown in Fig. 8.

*Effects of Direct Dyes.*—It has been reported[5] that the direct dyes having functional groups such as hydroxyl group, amino group, etc. made the gelatin of methyl cellulose by bridge-making through each molecule. Then, the effects of such dyes on crystal growth of the paraffin were examined. The results of experiments on 9 sorts of dyes are shown in Table III.

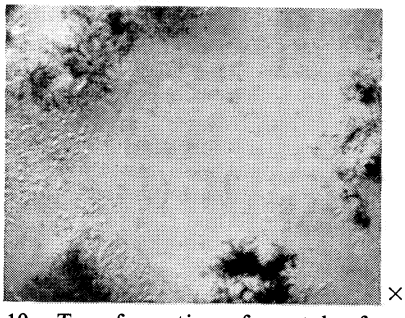
It is very interesting that in the case of direct dyes also, only the compounds having hydroxyl groups gave effects on crystal growth of the crystalline paraffin.



×225

Fig. 9. Transformation of crystals of crystalline paraffin caused by the addition of Nippon green B conc.

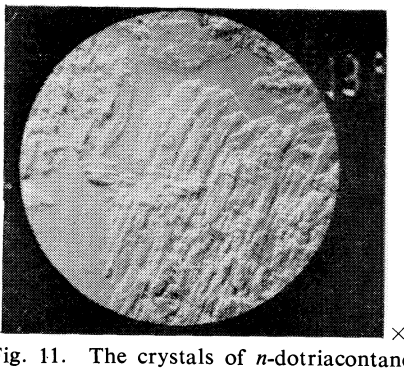
*Effects of Asphalt Components.*—Similarly, the asphalt component separated from heavy oil containing microparaffin[1] by propane deasphalting method was added to the crystalline paraffin. Then, the crystals of the paraffin were microcrystallized as shown in Fig. 10, and it was interesting that the micro-crystalline state was very closely similar to that caused by the addition of Santopour, picric acid, *p*-hydroxydiphenyl, etc.

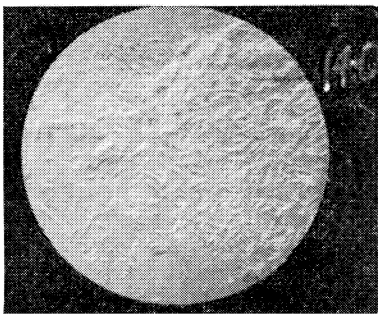


×225

Fig. 10. Transformation of crystals of crystalline paraffin caused by the addition of asphalt component.

**Effects of Various Substances on Crystallization of *n*-Dotriacontane.**—Each of the various organic compounds which transformed the crystalline properties of paraffin when being added to it, were added to a purified *n*-dotriacontane (formed thin plate crystals as shown in Fig. 11) as the above examination. Then, its effects on the crystallization of *n*-dotriacontane were investigated. These results are shown in Table IV.





×225

Fig. 11. The crystals of *n*-dotriacontane.

The phenomena of micro-crystallization which gave effects on the crystal when *p*-hydroxydiphenyl or picric acid was added to *n*-dotriacontane are in Figs. 12 and 13, respectively. Figure 14 shows the photograph of crystal transformations of *n*-dotriacontane when Santopour, addition agent of lubricating oils, was added to it, and it is easy to find out crystals of needles.

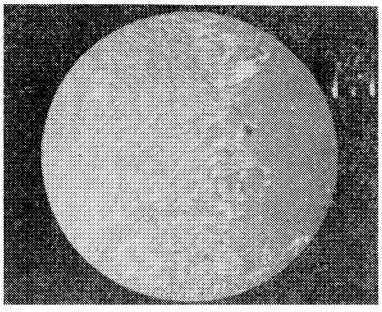


Table IV. Effects of various organic substances on the crystallization of *n*-dotriacontane

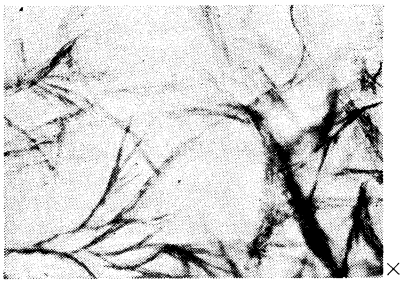
| Sample | Effects on crystallization of *n*-dotriacontane | Sample | Effects on crystallization of *n*-dotriacontane |
|---|---|---|---|
| *p*-Hydroxydiphenyl | Transformation (micro-crystallization) | Adva wax | Almost no transformation |
| Picric acid | Transformation (micro-crystallization) | Santopour | Transformation (micro-crystallization) |
| Glucose | Almost no transformation | Nippon green B conc. | Transformation |
| Quinizarine | Almost no transformation | Nippon orange R | Almost no transformation |
| Calcium stearate | Almost no transformation | Nippon brown 3G | Almost no transformation |
| Barium stearate | Almost no transformation | Nippon dark green B conc. | Almost no transformation |
| Aluminum stearate | Almost no transformation | Nippon deep black ex. conc. | Almost no transformation |
| Zinc naphthate | Almost no transformation | Chloronaphthalene | Almost no transformation |
| Lead naphthate | Almost no transformation | Asphalt component | Transformation |

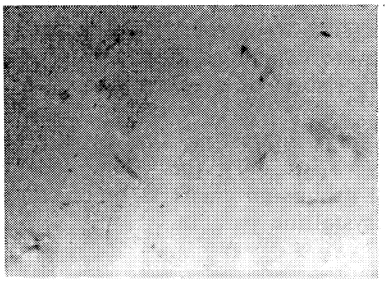
×150

Fig. 12. Transformation of crystals of *n*-dotriacontane caused by the addition of *p*-hydroxydiphenyl (micro-crystallized).



×150

Fig. 13. Transformation of crystals of *n*-dotriacontane caused by the addition of picric acid (micro-crystallized).

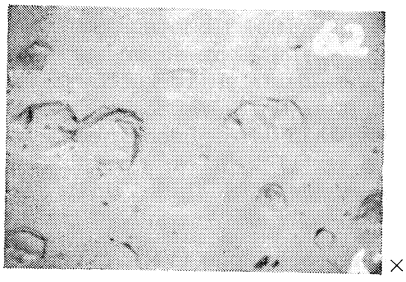


Though the dyes in general gave no remarkable effects, only in the case of "Nippon green B conc." formed micro-crystallization in some parts as shown in Fig. 15.

The examples of almost no effects were the results of photomicrographs of the addition of chloronaphthalene or barium stearate to *n*-dotriacontane, which are shown in Figs. 16 and 17, respectively.

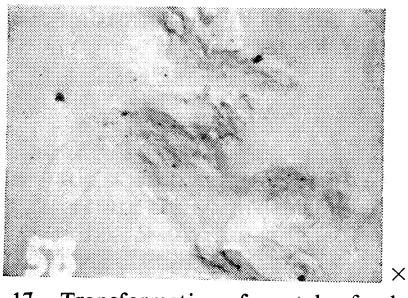
×225

Fig. 14. Transformation of crystals of *n*-dotriacontane caused by the addition of Santopour (micro-crystallized).



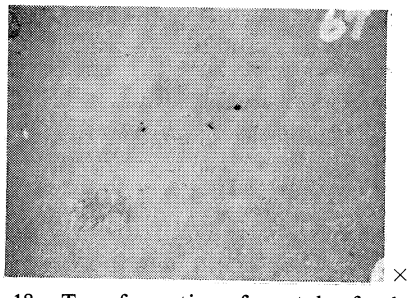
×225

Fig. 15. Transformation of crystals of *n*-dotriacontane caused by the addition of "Nippon green B conc." (hardly micro-crystallized).



In the case of the asphalt component obtained by propane deasphalting method, its effect was not so remarkable though a little transformation of the crystals of *n*-dotriacontane was seen (Fig. 18).

As mentioned above, two cases were considered; one was of crystalline paraffin, a mixture of various hydrocarbons, in which the



×225

Fig. 16. Transformation of crystals of *n*-dotriacontane caused by the addition of chloronaphthalene (almost no change).

×225

Fig. 17. Transformation of crystals of *n*-dotriacontane caused by the addition of barium stearate (almost no change).

×225

Fig. 18. Transformation of crystals of *n*-dotriacontane caused by the addition of asphalt component (hardly micro-crystallizad).

content of straight paraffins was nearly 90% and containing paraffin side chains, naphthene rings, and aromatic rings; and other was of *n*-dotriacontane, *n*-paraffin series hydrocarbon of carbon number 32. Then, the effects of addition of various organic compounds were different between both, and the composition of the paraffin gave effects on the facility of micro-crystallization of the paraffin. It had already been found[3] that the content of the adductible compounds of the straight chain in the microparaffin was nearly 60%. Accordingly, the easiness of micro-crystallization of microparaffin should be considered to be caused by the existence of more side chains of paraffin in microparaffin than in the crystalline paraffin wax. By observation with the microscope, the phenomenon of micro-crystallization is seemd to be that very fine crystals of plate are rolled up to make minute crystals of needle.

It was found that Santopour, picric acid, *p*-hydroxydiphenyl, and a few direct dyes formed a considerable micro-crystallization of pure hydrocarbons of a straight chain too. It is interesting that all these compounds contain hydroxyl groups and being in somewhat similar structures. Essential investigation will be made by X-ray diffraction, infrared spectrum, observation by electron microscope etc. with regard to the reason why these substances form micro-crystallization of the crystals of paraffin. It should be caused by the fact that the properties of paraffin molecules arranging regularly and growing up to the fundamental crystal of plate are inhibited or obstructed. However, it will be cleared in detail by future studies.

The author expresses his sincere appreciation to Professor Ryozo Goto and Professor Saburo Yagi, Kyoto University, for their cordial guidance and discussion throughout this research.

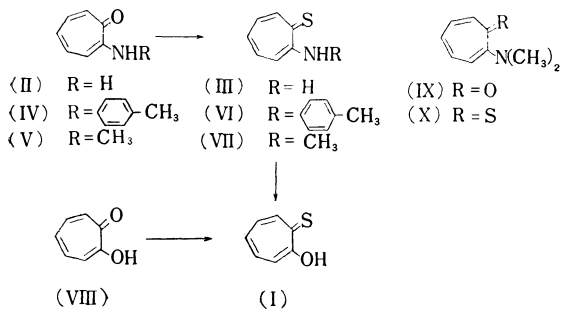
# *On 2-Aminotropothione Derivatives*

By Tetsuo Nozoe and Kazuo Matsui

(Received March 22, 1961)



2-Mercaptotropone (I) with two possible tautomeric structures, A and B, was synthesized in 1953 in our laboratory[1,2]. Although the structure of 2-mercaptotropone (B) was assigned at that time from its chemical behaviors, further examinations on its physicochemical properties as well as those of its homologs suggested that I should take the structure A of 2-hydroxytropothione rather than B, in a static state[3].

(A) (B)

As another type of tropothione derivatives, 2-aminotropothiones (1-amino-7-thioxo-1, 3, 5-cycloheptatrienes) were recently synthesized by Brasen et al.[4] from 2-aminotroponeimines (1-amino-7-imino-1, 3, 5-cycloheptatrienes) by the action of hydrogen sulfide. This report deals with another synthesis of 2-aminotropothiones, probably identical with Brasen's compounds and reactions thereof.

Heating 2-aminotropone (II) with excess of phosphorus pentasulfide in pyridine for 2 hr. on a water bath yields 2-aminotropothione (III) as orange red prisms, m. p. 135~136°C, in 60% yield. III is neutral substance and stable in air, and gives benzoate, m. p. 136~137°C. Hydrolysis of III with excess of potassium hydroxide in ethanol affords I.

(II) R=H (III) R=H (IX) R=O
(IV) R=C6H4-CH3 (VI) R=C6H4-CH3 (X) R=S
(V) R=CH3 (VII) R=CH3

(VIII) (I)

Similarly, 2-*p*-toluidinotropothione (VI), orange red plates of m. p. 98~99°C, and 2-methylaminotropothione (VII), orange needles of m. p. 67~68°C, are obtained respectively from 2-*p*-toluidinotropone (IV) and 2-methylaminotropone (V). Both VI and VII are stable substances and benzene layer colors dark red with cupric acetate by the formation of chelate compound.

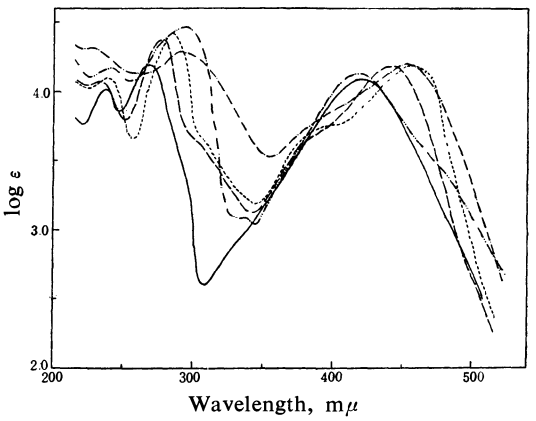


Fig. 1. Ultraviolet absorption spectra of I (——), III (——), VI (-·-·), VII (----) and benzoate of III (-···-) in methanol.

Reaction of tropolone (VIII) with phosphorus pentasulfide gives I even in a lower yield. But 2-dimethylaminotropone (IX) failed to give any objective 2-dimethylaminotropothione (X) except resinous materials by the same method.

These facts imply that hydrogen bond formation between C=S and NH or OH group considerably affects the stability of tropothione derivatives.

As electrophilic substitution, bromination of III in acetic acid was carried out, but only a yellow complex was obtained and heating of it with water ended in decomposition with the recovery of the original substance (III).

There can be two tautomeric structures, C and D, for each III, VI and VII. But their ultraviolet spectra fairly resemble that of 2-hydroxytropothione (I) (structure A) (Fig. 1). This fact suggests, that all these should exist as 2-aminotropothiones (structure C).

(C) (D)

1) T. Nozoe, M. Sato and K. Matsui, *Proc. Japan Acad.*, **29**, 22 (1953).
2) Idem., *Sci. Repts. Tohoku Univ., Ser. I*, **37**, 211 (1953).
3) T. Nozoe and K. Matsui, This Bulletin, **34**, 616 (1961).
4) W. R. Brasen, H. E. Holquist and R. E. Benson, *J. Am. Chem. Soc.*, **82**, 995 (1960).

Infrared spectrum of III is shown in Fig. 2. Absorption assignable to SH group usually seen at 2600~2550 $cm^{-1}$ is absent, and according to Mecke's law,[5] strong absorption at 1045 $cm^{-1}$ must correspond to $\nu_{C=S}$. Thus, the infrared spectrum also supports the structure C for III. This result is in agreement with that obtained by Brasen from nuclear magnetic resonance studies[4].

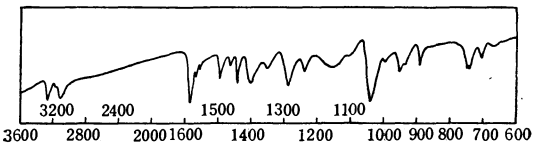

Fig. 2. Infrared absorption spectum of III (KBr disk).

It is known that although I takes structure A in the static state, it behaves like 2-mercaptotropone (structure B) during various reactions, affording only *S*-substituted derivatives[1,2]. However, the possibility of the structure of 2-mercaptotroponeimine (D) for III is excluded even during chemical reactions from its inertness toward diazomethane and the formation of *N*-benzoate as described below.

Two possible structures are assumed for benzoate of III, i. e. *N*- and *S*-benzoate. Its ultraviolet spectrum, however, considerably resembles that of III itself (Fig. 1), and $\nu_{C=S}$ appears at 1065 $cm^{-1}$ in its infrared spectrum. It has therefore been clarified, that this must be *N*-benzoate.

These experiments thus show an essential difference in the chemical properties between I and III.

## Experimental[6]

**2-Aminotropothione (III).**—A mixture of 0.5 g. of 2-aminotropone (II), 1.5 g. of phosphorus pentasulfide and 5 ml. of pyridine was stirred on a water bath for 2 hr. After removal of pyridine under a reduced pressure, water was added to the residue and separated crystals were collected by filtration and dried. This was extracted with methanol for 1 hr. and left cooling. Precipitated crystals were filtered off and methanol was evaporated. The residue was extracted with hot benzene and the crystals obtained was recrystallized from benzene to give 0.3 g. of III as orange red prisms, m. p. 136~137°C.

Found: C, 61.42; H, 4.83; N, 10.00. Calcd. for $C_7H_7NS$: C, 61.27, H, 5.15, N, 10.21%.

Benzoate: Prepared from III and benzoyl chloride in pyridine, and recrystallized from ethanol to red leaflets, m. p. 136~137°C.

Found: C, 69.66; H, 4.45; N, 5.40. Calcd. for $C_{14}H_{11}ONS$: C, 69.68; H, 4.59; N, 5.81%.

**Hydrolysis of III; Formation of 2-Mercaptotropone (I).**—A mixture of 30 mg. of III, 1 ml. of 20% potassium hydroxide and 4 ml. of ethanol was refluxed for 6 hr., ethanol was evaporated under a reduced pressure, water was added to the residue and the solution was treated with activated carbon. The filtrate thereby obtained was acidified with 6 N sulfuric acid and the crystals that separated out were collected by filtration. Sublimation of this product under 3 mmHg pressure afforded I as orange red crystals m. p. 54~55°C. Yield, 15 mg. This was identified by mixed fusion with authentic sample.

**2-*p*-Toluidinotropothione (VI).**—A mixture of 0.3 g. of 2-*p*-toluidinotropone (IV), 1 g. of phosphorus pentasulfide and 5 ml. of pyridine was stirred on a water bath for 2 hr. Pyridine was removed under a reduced pressure, water was added to the residue and extracted with chloroform. Extract was washed with 2 N hydrochloric acid and the solvent was evaporated in vacuo. The residue was extracted with hot ethanol, and the substance so obtained was recrystallized first from cyclohexane then from ethanol to give VI as orange red plates, m. p. 98~99°C. Yield, 50 mg.

Found: C, 74.31; H, 5.49; N, 5.85. Calcd. for $C_{14}H_{13}NS$: C, 73.99; H, 5.76; N, 6.17%.

**2-Methylaminotropothione (VII).**—A mixture of 0.3 g. of 2-methylaminotropone (V), 1.5 g. of phosphorus pentasulfide and 5 ml. of pyridine was stirred on a water bath for 1.5 hr. Pyridine was removed under a reduced pressure, water was added to the residue and extracted with chloroform. After evaporation of chloroform, the residue was triturated with 5 ml. of methanol and insoluble materials were filtered off. Methanol was evaporated in vacuo and the residue was extracted with hot cyclohexane. Extracted material was recrystallized two times from cyclohexane to give 50 mg. of VII as orange needles, m. p. 67~68°C.

Found: C, 63.92; H, 5.68; N, 9.27. Calcd. for $C_8H_9NS$: C, 63.53; H, 6.00; N, 9.27%.

**Reaction of Tropolone (VIII) and Phosphorus Pentasulfide; Formation of I.**—A mixture of 0.2 g. of VIII, 0.5 g. of phosphorus pentasulfide and 5 ml. of pyridine was stirred on a water bath for 30 min. Pyridine was evaporated under a reduced pressure, 10 ml. of 2 N potassium hydroxide was added to the residue, and the solution was treated with activated carbon. The filtrate thereby obtained was acidified with 6 N sulfuric acid and the crystals that separated were collected by filtration. Sublimation of this product under 3 mmHg pressure and recrystallization of the sublimate from petroleum ether afforded I as orange red prisms, m. p. 53~55°C. Yield, 20 mg. This was identified by admixture.

**Reaction of Dimethylaminotropone (IX) and Phosphorus Pentasulfide.**—To a solution of 1 g. of IX dissolved in 5 ml. of pyridine, 1.5 g. of phosphorus pentasulfide was added under stirring. The solution colored red immediately and darkened after a short time. After stirring for 1.5 hr. at room temperature, pyridine was evaporated under a reduced pressure, water was added to the residue and separated dark

6) All m. p. are uncorrected. The microanalyses were carried out by Miss A. Iwanaga and Miss M. Suzuki to whom the authors express their deep gratitude.

crystals were collected by filtration. This was extracted with methanol for 1 hr., but only small amounts of resinous materials were obtained.

**Bromination of III.**—A solution of 40 mg. of bromine in 0.5 ml. of acetic acid was added to 30 mg. of III dissolved in 3 ml. of acetic acid under stirring. Yellow crystals that separated were collected by filtration. This substance, m. p. over 280°C, is insoluble in benzene or ethanol. By heating it with water, followed by extraction with chloroform and sublimation of the extract under 3 mmHg pressure, 15 mg. of III, m. p. 130~135°C, was recovered, identified by mixed fusion.

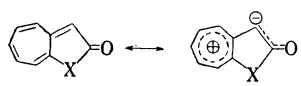
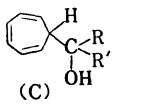
# *Synthesis of Some 8, 8-Disubstituted Heptafulvene Derivatives*[1]



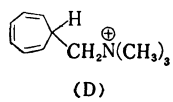
By Tetsuo NOZOE, Toshio MUKAI, Kazutoshi OSAKA*
and Nobuyuki SHISHIDO**

(Received March 23, 1961)

Heptafulvene (methylenecycloheptatriene) (A) can be regarded as a methylene analog of tropone and is also one of the typical non-alternant hydrocarbones with a cyclic conjugated double bond system. Its structure suggests more or less the contribution of a 6-$\pi$



(A)



(B)

electron system as tropylium ion. Consequently, it seems of interest to examine the aromaticity and reactivity of this type of compounds comparing with those of azulenes and azulane-2-one type of compounds (B: X=O or NH)[2]. Theoretical interests on the unique ring system attracted also much attention of physical chemists as well as organic chemists and calculation by molecular orbital method has been carried out by Berthier and Pullman[3], Bergman et al.[4] and Julg and Pullman[5,6].

Attempts have already been made for synthesis of heptafulvene derivatives. In 1953, Grundmann, Ottman and Gollner[7], and van Aardt[8] in 1954, attempted the elimination of water from tropyl carbinols (C) but a facile formation of a polymer or styrenes as a rearrangement product was observed and the desired compound could not be obtained. In 1954, Doering and Wiley[9] succeeded in obtaining heptafulvene by the Hofmann elimination of

(C)

(D)

the quaternary ammonium salt (D), obtained from norcaradienecarboxamide, under special conditions. Recently details of this work have been published[10]. According to Doering and Wiley, heptafulvene is a very unstable compound and easily undergoes polymerization but its structure has been proved from the formation of methylcycloheptane by hydrogenation and of dimethyl azulene 1, 2-dicarboxylate by addition with dimethyl acetylene dicarboxylate followed by oxidation. Matteson, Drysdale and Sharkey[11] also obtained heptafulvene, though in a minute amount, by pyrolytic decomposition of methylenecycloheptadienes.

The reason for the larger lability of heptafulvene compared with tropone is considered to be due to the difference in the electron-withdrawing power of the carbonyl and methylene

group, that is, the difference in the contribution of the tropylium-type structure. If this is the case, it may be anticipated that a more stable heptafulvene derivative would be obtained by the introduction of an electron-withdrawing group, such as cyano or ethoxycarbonyl, into the 8-position of heptafulvene. The present series of work was undertaken on such assumption.

Condensation of tropylium ion and active methylene compound has been reported by Vol'pin, Ahrem and Kursanov[12], and by Conrow[13]. Similar to their method, reaction of tropylium ion and malononitrile gave tropylmalononitrile (I) and ditropylmalononitrile (II). Further reaction of I with tropylium ion also afforded II. Such a fact and the ultraviolet and infrared spectra in Table I supported the structures of I and II to be correct.

Condensation of tropylium ion and ethyl cyanoacetate proceeded in the same way by which ethyl tropylcyanoacetate[12] (III) and ethyl ditropylcyanoacetate (IV) were obtained. IV was also obtained by the reaction of III with tropylium ion. The structures of III and IV were supported by their ultraviolet and infrared spectroscopic data given in the Table.

It is already known that diethyl tropylmalonate (V) is obtained by the reaction of tropylium ion and diethylmalonate[12,13], but the reaction of V with tropylium ion failed to afford diethyl ditropylmalonate. This is probably rather attributed to the smaller electron-withdrawing power of the ethoxycarbonyl group than that of the cyano group or to the steric hindrance of the bulky ethoxycarbonyl group.

As was expected, application of a dehydrogenation agent to the tropilidene derivatives, I, III and V, successfully afforded the desired 8,8-disubstituted heptafulvenes. Application of one mole of bromine to I in chloroform, and subsequent heating of the bromide thereby obtained, resulted in the formation of reddish crystals (VI), $C_{10}H_6N_2$, m.p. 200°C, in 50% yield, with liberation of hydrogen bromide. Oxidation of I with *N*-bromosuccinimide in *tert*-butanol containing pyridine and water also gave VI, in 70% yield, accompanying a small amount of rearrangement product, benzalmalononitrile (VII)[14]. VI could be obtained by refluxing I with chloranil in xylene. The infrared absorption of the cyano group in VI shifted to a smaller wave number by 55 $cm^{-1}$ than in I (cf. Table) and shows there is a fair degree of conjugation of the cyano group with the unsaturated system. The ultraviolet spectrum of VI is similar to that of 1-oxa-azulan-2-one derivatives (Fig. 1). These facts

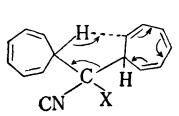
support that VI possesses the structure of 8, 8-dicyanoheptafulvene (heptafulvene-8, 8-dicarbonitrile). Heating of ditropylmalononitrile (II) at 140~150°C for 30 min. resulted in formation of VI and tropilidene in an almost quantitative yield. This reaction is considered to proceed through the intermediate depicted below (four-centered type reaction)[15].

(II) X=CN (VI) X=CN
(IV) X=$CO_2Et$ (VIII) X=$CO_2Et$

8-Cyano-8-ethoxycarbonylheptafulvene (VIII) as red crystals, m. p. 63.5°C was successfully synthesized in about a 40% yield by dehydrogenation of ethyl tropylcyanoacetate (III) with chloranil in boiling xylene. Pyrolysis of ethyl ditropylcyanoacetate (IV) gave also VIII in about a 25% yield. The reason why IV gave a poorer yield of VIII than in the case of pyrolysis of II can be attributed to the smaller electron-withdrawing power of ethoxycarbonyl than in the cyano group to split the bond between the tropyl group and the carbon atom to which it is attached. It was found that the reaction of III with *N*-bromosuccinimide under the condition described previously for I gave ethyl α-cyanocinnamate[16] (IX) rather than the expected VIII in a good yield. The absorption maxima of the infrared spectrum of VIII are given in the Table I. The shift of absorption bands of the carbonyl and cyano groups to a smaller wave number than those of III indicates the conjugation of these functional groups with the unsaturated system. On comparison of the infrared spectra of the two kinds of heptafulvenes, VI and VIII, it is learned that there are some absorption maxima characteristic to them. (indicated by an asterisk in the Table).



8, 8-Diethoxycarbonylheptafulvene (X) was obtained as a red oil by dehydrogenation of diethyl tropylmalonate (V) with chloranil. X was somewhat more labile than VI or VIII and tended to undergo polymerization on being left in the air. The structure of X is evident from the similarity of its ultraviolet spectrum with those of VI and VIII, and from the presence of absorption bands in its infrared spectrum characteristic to heptafulvenes (see Table 1). The absorption of carbonyl in X shifted to a small wave number from that of V. Bromination-dehydrobromination of diethyltropylmalonate (V) gave 3-ethoxycarbonyl-1-oxaazulan-2-one (XI)[17] whose formation may have passed through X as an intermediate, but this point requires further examination.

(X) (XI)

In parallel with this work, Doi synthesized 3, 4-dihydroxy-8, 8-dicyanoheptafulvene by the reaction of 3-iodotropolone and malononitrile in the presence of sodium amide in liquid ammonia[18]. A few months later, Kitahara and Doi et al. successfully synthesized VI by condensation of tropone and malononitrile[19], and recently they obtained VI, VIII and X from tropylium ion and bromo compounds of malononitrile, ethyl cyanoacetate and diethyl malonate[20]. Their examination of the properties of heptafulvenes revealed some interesting facts as mentioned in Refs. 21 and 24.

15) A similar reaction mechanism involving an intermediate of a five membered ring can be possible. The examples of this type of reaction mechanism can be found in the explanation of the Cope Rearrangement. A. C. Cope, K. E. Hoyle and D. Heyl, *J. Am. Chem. Soc.*, 63, 1843 (1941); E. G. Foster, A. C. Cope and F. Daniels, ibid., 69, 1893 (1947).

18) Paper presented at the Local Meeting of Tohoku District of the Chemical Society of Japan, Yamagata, June, 1959.

19) Paper presenteted at the General Meeting of Tohoku District of the Chemical Society of Japan, Akita, October, 1959.

20) Paper presented at the General Meeting of Hokkaido District of the Chemical Society of Japan, Sapporo, July, 1960.

8,8-Dicyanoheptafulvene (VI) is sparingly soluble in organic solvent and has a fairly high melting point, but 8-cyano-8-ethoxycarbonyl- (VIII) and 8,8-diethoxycarbonylheptafulvene (X) are more soluble than VI. VI and VIII do not form perchlorate, picrate, styphnate, or trinitrobenzene complex. VI and VIII are fairly stable to acids and do not change on being refluxed for 2 hr. with 6 N hydrochloric acid, while VI changes into a yellow solid on being heated with 75% sulfuric acid. On the other hand, VI and VIII are labile towards alkali[21]. Such behavior of 8,8-substituted heptafulvenes is different from that of heptafulvene (A)[10]. This is reminiscent of the fact that cyano and ethoxycarbonyl groups situated at 1- or 3-position of azulene are also difficult to hydrolyse with acids[22]. VI is stable to bromination and neither substitution nor addition reaction occurs on application of excess bromine in chloroform. These facts can be explained by the great contribution of the 6-$\pi$ electron structures E and F due to electron-attracting groups at 8-position. In fact, as has been published[23], measurement of the dipole moment has shown that the value are 7.49 D (dioxane, 25°C) for VI and 4.40 D (benzene, 25°C) for VIII.

(E) (F)

In order to examine the aromaticity and double bond character of heptafulvenes, Diels-Alder reaction and hydrogenation were carried out. 8,8-Diethoxycarbonylheptafulvene (X) tends to undergo polymerization, while 8,8-dicyanoheptafulvene (VI) does not form an adduct even on being refluxed with maleic anhydride in xylene. 8-Cyano-8-ethoxycarbonylheptafulvene (VIII) shows an intermediate reactivity and partially undergoes addition reaction with maleic anhydride to form the adduct (XII), which has an absorption at 247 m$\mu$. VI resists catalytic hydrogenation over palladium carbon but easily absorbs three moles of hydrogen by the use of platinum oxide as catalyst and forms a pale yellow oil[24], which still retains the absorption at 239 m$\mu$ in its ultraviolet spectrum. On the other hand, X easily absorbs 4 mol. of hydrogen and forms an octahydro compound XIII, which was converted to cycloheptylmalonic acid[25] on hydrolysis.

These experimental results have shown that the stability of 8,8-disubstituted heptafulvenes depends on the nature of the substituent present and the high stability of the compound with a strongly negative group like the cyano group which agrees with the presumption.

## Experimental[26,27]

**The Condensation Reaction of Tropylium Bromide and Malononitrile.**—To a solution of 2.41 g. (0.037 mol.) of malononitrile in 30 ml. of pyridine was gradually added 6 g. (0.035 mol.) of crude tropylium bromide[28] with stirring for 30 min. After stirring for 2 hr. at room temperature, the mixture was poured into 110 ml. of 6 N hydrochloric acid and extracted with benzene. The benzene extract was washed with water, diluted sodium hydrogen carbonate and water, dried over sodium sulfate and evaporated. The brown oily residue crystallized partly on standing. Addition of ethanol and cooling afforded 1.6 g. of crystals, m.p. 58~60°C, as first crop, 1.4 g. of crystals, m.p. 89~99°C, as second crop, and 2 g. of crystals, m.p. 38~48°C containing oil as third crop. Recrystallization of the first crop from benzene gave 1.24 g. (yield 22.7 %) of tropylmalononitrile (I) as colorless crystals, m.p. 61~62°C, which showed m.p. 62.8~63.5°C on recrystallization from benzene once more.

Found: C, 77.38; H, 5.26; N, 17.73. Calcd. for $C_{10}H_8N_2$: C, 76.90; H, 5.16; N, 17.94%.

The solution of the third crop in petroleum ether-benzene (1 : 2) was chromatographed through a column containing 40 g. of alumina. An elution with the same solvent gave 0.64 g. of crystals, m. p. 94~105°C. This substance and the second crop were combined and recrystallized from ethanol to give ditropylmalononitrile (II) as colorless prisms, m. p. 107~108°C.

Found: C, 82.78; H, 5.57; N, 11.15. Calcd. for $C_{17}H_{14}N_2$: C, 82.90; H, 5.73; N, 11.37%.

**The Condensation Reaction of Tropylium Bromide and Tropylmalononitrile (I).**—To a solution of 0.31 g. (2 mmol.) of I in 6.3 ml. of pyridine 0.35 g. (2 mmol.) of crude tropyl bromide was added and the solution resulted was heated on a water bath for 1.5 hr. After addition of 21.7 ml. of 6 N hydrochloric acid under ice-cooling, the mixture was extracted with benzene. The benzene extract was washed with diluted sodium hydrogen carbonate and water, dried over sodium sulfate and distilled to give 0.39 g. (yield 80%) of crystals, m.p. 102~104°C. Recrystallization from ethanol gave colorless crystals, m.p. 104~105.5°C, which showed no depression on admixture with II.

21) Y. Kitahara et al. reported that VI and VIII rearranged to the corresponding styrene derivatives on treating with dilute alkali.

24) Y. Kitahara et al. found that VI absorbed 4 mol. of hydrogen to give an octahydro compound which on hydrolysis gave cycloheptylmalonic acid.

25) I. Vogel, *J. Chem. Soc.*, **1928**, 2025.

26) All melting points and boiling points were uocorrected.

27) The microanalyses were performed by Mr. S. Azumi and Miss A. Iwanaga to whom the authors expressed their gratitude.

28) Tropylium bromide was synthesized from tropilidene by the method of Doering and Knox. *J. Am. Chem. Soc.*, **79**, 352 (1957).

**The Condensation Reaction of Tropylium Bromide and Ethyl Cyanoacetate.**—To a solution of 16.4 g. (0.145 mol.) of ethyl cyanoacetate in 150 ml. of pyridine, 20.4 g. (0.12 mol.) of crude tropyllium bromide was gradually added with stirring under ice-cooling. The reaction mixture was allowed to stand overnight at room temperature to which 260 ml. of concentrated hydrochloric acid was added dropwise under ice-cooling. The acidic solution was extracted with ether and the ether extract was filtered off, washed with diluted sodium hydrogen carbonate and water, and dried over sodium sulfate. Evaporation of ether gave 22.30 g. of a brown oil which crystallized partially on standing. Filtration afforded 6.3 g. of crystals, m.p. 115~117°C, which were recrystallized from ethanol to give 5.3 g. (yield 15%) of ethyl ditropylcyanoacetate (IV) as colorless prisms, m.p. 124~125°C.

Found: C, 78.12; H, 6.35; N, 4.84. Calcd. for $C_{19}H_{19}O_2N$, C, 77.79; H, 6.53; N, 4.77%.

Distillation of the filtrate in reduced pressure gave 10.97 g. (yield 45.0%) of ethyl tropylcyanoacetate (III) as orange viscous oil, b.p. 130~135°C /4 mmHg. After one more distillation, the oil of b.p. 125~130°C/2 mmHg was submitted for microanalysis and spectrum determination.

Found: C, 70.22; H, 6.45; N, 7.06. Calcd. for $C_{12}H_{13}O_2N$. C, 70.91; H, 6.45; N, 6.89%.

**The Condensation Reaction of Tropylium Bromide and Ethyl Tropylcyanoacetate (III).**—A solution of 0.43 g. (2.5 mmol.) of crude tropyl bromide and 0.5 g. (2.5 mmol.) of III in 10 ml. of pyridine was warmed at 40~50°C in a water bath for 30 min. Under ice-cooling, the reaction mixture was neutralized by adding 36 ml. of 6 N hydrochloric acid and extracted with benzene. The benzene extract was washed with water, dried over sodium sulfate and evaporated. Recrystallization of residual crystals from ethanol gave 0.57 g. (yield 78%) of colorless crystals, m. p. 122~123°C, which were proved to be identical with IV by mixed melting point determination.

**Bromination and Dehydrobromination of Tropylmalononitrile (I).**—A solution of 0.32 g. (2 mmol.) of bromine in 0.3 ml. of chloroform was added dropwise to a solution of 0.31 g. (2 mmol.) of I in 3 ml. of chloroform at room temperature. During stirring for 40 min., the color of bromine disappeared and evaporating chloroform in reduced pressure at room temperature gave a pale orange oil. Heating the oil in a boiling water bath for 10 min., it changed to orange red crystals with the evolution of hydrogen bromide gas. Addition of ethanol and filtration affored 150 mg. (yield 50%) of reddish crystals, m.p. 180~185°C, which on recrystallization from ethanol gave 8, 8-dicyanoheptafulvene (VI) as red needles, m.p. 198~199°C.

Found: C, 78.09; H, 4.20; N, 17.77. Calcd. for $C_{10}H_6N_2$: C, 77.90; H, 3.92; N, 18.17%.

**Dehydrogenation of Tropylmalononitrile (I) with *N*-Bromosuccinimide.**—Five hundred milligrams (3.2 m mol.) of I and 550 mg. (3.0 m mol.) of *N*-bromosuccinimide were added to a solution of 11 ml. of *tert*-butanol, 2 ml. of pyridine and 1 ml. of water and the mixture was allowed to stand at room temperature for 90 hr. During this period, reddish needles separated. The filtration gave 250 mg. of red needles, m.p. 194~199°C. After adding 60 ml. of water, the filtrate was extracted with ether. The ether extract was washed with water, dried over magnesium sulfate and evaporated to 160 mg. red needles, m. p. 195~198°C and the filtrate was dissolved in benzene and chromatographed using 3 g. of alumina. After evaporation, the first elutes with benzene gave 65 mg. of colorless needles, m. p. 81~82°C, (VII) which showed no depression on admixture with benzalmalononitrile, m. p. 83°C[14]. The second elutes with benzene gave 60 mg. of red needles, m. p. 194~198°C. Three hundred and fifty milligrams (yield 70%) of total red needles were combined and recrystallized from ethanol to give red needles, m. p. 198~199°C, which is identical with VI.

**Dehydrogenation of Tropylmalononitrile (I) with Chloranil.**—Three hundred milligrams (1.9 mmol.) of I and 510 mg. (2.1 mmol.) of chloranil were added to 5 ml. of xylene and the mixture was refluxed for 2 hr. The dark brown precipitate separated on cooling was filtered and dissolved in benzene. The benzene solution was washed with 1 N sodium hydroxide solution and water and dried over sodium sulfate. Epaporation of benzene gave 60 mg. of orange red crystals, m. p. 179~188°C. Recrystallization from ethanol gave 50 mg. (yield 17%) of red needles, m. p. 189~199°C, which showed no depression on admixture with the authentic sample VI.

**Thermal Decomposition of Ditropylmalononitrile (II).**—One gram (6.4 mmol.) of II was placed in the sublimation apparatus with a cold-finger condenser and heated at 140~150°C in an oil bath for 30 min. Sublimation in 2 mmHg at the same temperature gave 540 mg. (yield 86%) of red needles, m.p. 188~193°C. Recrystallization from ethanol afforded red crystals, m.p. 199~200°C, which showed to be identical with VI on admixture with the authentic sample. During thermal decomposition and sublimation, about 200 mg. of a yellowish oil was caught in a trap cooled with dry ice-acetone. One hundred and twenty five milligrams of this oil and 147 mg. (1.5 mmol.) of maleic anhydride were added to 1.5 ml. of xylene and the mixture was refluxed for 4.5 hr. An addition of 5 ml. of petroleum ether to the solution gave 110 mg. (yield 41%) of pale yellow crystals, m. p. 98~99°C, on cooling. Recrystallization from carbon tetrachloride afforded crystals, m. p. 99~100°C, which showed no depression on admixture with adduct, m. p. 99~100°C. of tropilidene and maleic anhydride[29].

**Dehydrogenation of Ethyl Tropylcyanoacetate (III) with Chloranil.**—To 100 ml. of xylene, 19.6 g. (0.08 mol.) of chloranil and 10 g. (0.051 mol.) of III were added and the mixture was refluxed for 1.5 hr., while a lot of dark brown crystals separated. The crystals (A) obtained by filtration were digested several times with methanol (B) and then benzene (C). Thus 7.1 g. of chloranil was recovered as an insoluble part. The residue obtained from ethanol washings (B) by evaporation was digested with benzene (D) to give 2.1 g. of dihydrochloranil. The washings C and D were

29) K. Alder and G. Jacobs, *Ber.*, **86**, 1528 (1953).

combined and chromatographed through a column containing 60 g. of alumina. Elution of a dark red band with benzene and evaporation of benzene gave 2.84 g. of dark red oil (E) which crystalized partially. The xylene filtrate from A was evaporated in reduced pressure and the residue obtained was washed with methanol (F) to give 2.1 g. of chloranil. Methanol washings were evaporated and the residue was dissolved in benzene and chromatographed using 60 g. of alumina. Evaporation of red benzene eluates affored 1.66 g. of red crystals (G), m.p. 46~54°C. Four and a half grams (yield 45%) of the combined red crystals, E and G were dissolved in benzene and chromatographed again using alumina to give 8-cyano, 8-ethoxycarbonylheptafulvene (VIII) as red crystals, m. p. 61~63°C. Recrystallization from petroleum ether gave red prisms, m. p. 63.5°C.

Found: C, 72.06; H, 5.50; N, 6.78. Calcd. for $C_{12}H_{11}O_2N$: C, 71.62; H, 5.51; N, 6.9%.

**Thermal Decomposition of Ethyl Ditropylcyanoacetate (IV).**—One gram (3.4 mmol.) of IV in a small Claisen flask was heated at 170~195°C in an oil bath and distilled in 2 mmHg at the same temperature to give a red viscous oil. Addition of a little amount of ethanol afforded yellow crystals, m.p. 118~120°C, which proved to be starting IV, by mixed m.p. determination. The red filtrate, after evaporating ethanol, was dissolved in benzene and chromatographed using alumina. An elution of a red absorption band with benzene and evaporation of benzene gave 150 mg. (yield 22%) of a red oil which crystallized on standing and showed m.p. 55~60°C. Repeated recrystallization from petroleum ether gave red prisms, m.p. 63°C, which showed no depression on admixture with VIII.

**The Reaction of Ethyl Tropylcyanoacetate (III) and *N*-Bromosuccinimide.** — Four hundred milligrams (2 mmol.) of III and 420 mg. (2.4 mmol.) of *N*-bromosuccinimide were dissolved in a mixture of 10 ml. of *tert*-butanol, 2 ml. of pyridine and 1 ml. of water. The reaction mixture was allowed to stand at room temperature for about 1 week, then poured to 30 ml. of water and extracted with ether. The ether extracts were washed with diluted hydrochloric acid and water, dried over magnesium sulfate and evaporated to 340 mg. of brown oil. On adding a small amount of ethanol. it crystallized to give 300 mg. of crystals, m.p. 45~47°C. Recrystallization from petroleum ether afforded colorless plates (IX), m. p. 49~50°C, which showed no depression on admixture with authentic ethyl α-cyanocinnamate, m. p. 50°C[16].

**Dehydrogenation of Diethyl Tropylmalonate (V) with Chloranil.**—To boiling xylene were added 7.5 g. (0.03 mol.) of V and 8.8 g. (0.036 mol.) of chloranil and the reaction mixture was refluxed for 1.5 hr. After cooling, dark red crystals separated, and this was filtered to give 2.8 g. of dihydrochloranil as crystals, m.p. 228°C. Distillation of xylene from the filtrate under reduced pressure afforded precipitates from which 2.0 g. of chloranil, m.p. 285°C, were obtained by washing with methanol (A). The washings A were evaporated and the residue was dissolved in benzene and chromatographed through a column containing 50 g. of alumina. An elution of a red band with benzene and evaporation of solvent gave 4.1 g. of red oil (B). It seemed to contain a little amount of starting material, because of the presence of infrared absorption at 705 and 740 $cm^{-1}$ due to tropilidene nucleus. The distillation of the oil (B) in reduced pressure gave the following fractions. 1) 0.32 g. of oil, b.p. 122~130°C/3 mmHg. 2) 1.00 g. of red oil, b.p. 130~140°C/3 mmHg. 3) 0.63 g. of red oil, b.p. 140~150°C/3 mmHg and a considerable amount of residue.

Found: C, 67.77; H, 6.54 (for fr. 3); C, 67.42; H, 6.91 (for fr. 2). Calcd. for $C_{14}H_{16}O_4$: C, 67.73; H, 6.50%.

Fraction 2 (0.68 g.) was allowed to stand at room temperature for about 2 weeks, thereby red gelatinous material was obtained. On being dissolved in hot ethanol and cooled, it gave 0.35 g. of pale yellow amorphous product which softens at about 120°C. This is sparingly soluble in ether and ethanol, but soluble in acetone, benzene and ethyl acetate. It has a weak absorption maximum at 255 mμ.

Found: C, 67.46; H, 6.24. Calcd. for $C_{14}H_{16}O_4$: C, 67.73; H, 6.50%. mol. wt.: 1000 (by Rast method using camphor).

**Bromination and Dehydrobromination of Diethyl Tropylmalonate (V).**—To a solution of 0.96 g. (4 mmol.) of V in 5 ml. of chloroform was added a solution of 0.64 g. of bromine (4 mmol.) in 2 ml. of chloroform. After stirring for 30 min., the solvent was evaporated from the mixture to give 1.5 g. of a pale yellow oil. Heating the oil in a boiling water bath for 60 min. resulted in evolution of hydrogen bromide gas to give 1.1 g. of a brownish oil. It was dissolved in benzene and the benzene layer was washed with diluted sodium hydrogen carbonate and water, dried over sodium sulfate and chromatographed through a column containing 20 g. of alumina. The evaporation of benzene elutes gave 350 mg. of red oil which has an ultraviolet absorption maxima at 274 and 355 mμ. An elution with ethyl acetate afforded 300 mg. of brown oil which crystallized. Recrystallization from ethanol gave 50 mg. of yellow crystals (XI), m.p. 130°C, which proved to be identical with 3-ethoxycarbonyl 1-oxaazulan-2-one, m.p. 130°C, by mixed melting point determination[17].

**Behavior of 8,8-Disubstituted Heptafulvene, VI and VIII against Acid and Alkali.** — a) 6 N Hydrochloric acid and ethanol: 60 mg. of VI was dissolved in a mixture of 3 ml. of concentrated hydrochloric acid and 3 ml. of ethanol and the solution was refluxed for 2 hr. On cooling, red needles were crystallized and 40 mg. of starting material, m.p. 198°C, was collected by filtration.

One hundred miligrams of VIII was treated in the same way as above and the reaction mixture was poured into 50 ml. of water and extracted with benzene. The benzene extracts were washed with water, dried over sodium sulfate and evaporated to 85 mg. of red oil which crystallized and showed m.p. 59~61°C. Recrystallization from petroleum ether gave red prisms, m.p. 62~63°C, which was proved to be identical with starting VIII.

b) 75% sulfuric acid: 100 mg. of VI was added to 2.5 ml. of 75% sulfuric acid and the mixture was heated in a boilding water bath. After 6 hr.,

all crystals were dissolved and no carbon dioxide evolved. Dilution with 5 ml. of water and addition of sodium hydrogen carbonate to pH 2.5 separated an yellow amorphous material which is sparingly soluble in water or ether, but soluble in sodium hydrogen carbonate.

c) 2 N potassium hydroxide and ethanol solution: 50 mg. of VI was dissolved in 1 ml. of 6 N potassium hydroxide and 2 ml. of ethanol and the resulted mixture was refluxed for 1 hr. 20 mg. of solid resinous material separated. Extraction of the filtrate with benzene gave no starting VI.

**Bromination of 8, 8-Dicyanoheptafulvene (VI).**—To a solution of 80 mg. (0.55 mmol.) of VI in 3 ml. of chloroform was added a solution of 160 mg. of bromine (1 mmol.) in 0.6 ml. of chloroform and the reaction mixture was stirred at room temperature for 4 hr. Bromine still remained. Evaporation of chloroform at room temperature gave 70 mg. of red needles, m.p. 192~194°C, which were recrystallized from ethanol to give a starting material (VI) as crystals, m.p. 199~200°C.

**Reaction of 8-Cyano, 8-Ethoxycarbonylheptafulvene (VIII) and Maleic Anhydride.**—A solution of 300 mg. (1.5 mmol.) of VIII and 176 mg. (1.8 mmol.) of maleic anhydride in 6 ml. of xylene was refluxed for 34 hr. After xylene was distilled under reduced pressure and a small amount of methanol was added, a red viscous oil crystallized. Sixty milligrams (yield 13.4%) of light yellow crystals, m. p. 170~174°C, were obtained by filtration and recrystallized from methanol to give an adduct (XII) as crystals, m.p. 177°C.

Found: C, 63.67; H, 4.08; N, 4.62. Calcd. for $C_{16}H_{13}O_5N$: C, 64.21; H, 4.38; N, 4.68%. $\lambda_{max}^{MeOH}$ 297 mμ (log ε 4.23).

Evaporation of methanol from the filtrate gave 250 mg. of a red oil which was dissolved in benzene and chromatographed through column containing 6 g. of alumina. An elution with benzene afforded 100 mg. (yield 33%) of VIII as red crystals, m.p. 50~55°C.

**Reaction of 8, 8-Dicyanoheptafulvene (VI) and Maleic Anhydride.**—Two hundred and fifty milligrams (1.7 mmol.) of VI and 190 mg. (1.9 mmol.) of maleic anhydride was added to 6 ml. of xylene and the resulted mixture was refluxed for 13 hr. On cooling, red needles crystallized. Evaporation of xylene and addition of ethanol to residue gave 200 mg. of starting VI as red needles, m. p. 195°C.

**Catalytic Reduction of 8, 8-Dicyanoheptafulvene (VI).**—a) One hundred milligrams (0.65 mmol.) of VI was dissolved in 40 ml. of ethanol and hydrogenated in the presence of 30 mg. of Pd-carbon (5%) at ordinary temperature and pressure. Only 20 ml. (0.9 mmol.) of hydrogen was absorbed for 6 hr. Treated in the usual way, 90 mg. of red needles, m.p. 184~188°C were obtained which was identical with VI.

b) With Pt-oxide. A solution of 120 mg. (0.82 mmol.) of VI in 55 ml. of ethanol was hydrogenated in the presence of 15 mg. of Pt-oxide at ordinary temperature and pressure. After 42 ml. (2.3 mmol.) of hydrogen had been absorbed, the color of the solution changed and at 57 ml. (3.1 mmol.) of hydrogen the velocity became slow and at 61 ml. (3.3 mmol.) hydrogenation was stopped. Catalysts were filtered and the filtrate was evaporated to give 120 mg. of yellow oil which showed infrared absorption at 3345, 3445 $cm^{-1}$ due to $NH_2$ group. It was dissolved in benzene and passed through a column containing 9 g. of alumina. Evaporation of the benzene eluate gave 30 mg. of a colorless oil which has no infrared absorption maximum due to $NH_2$ or NH group, but showed an absorption maximum at 239 mμ in methanol. Evaporation of the ether eluates gave 45 mg. of a brown oil which has infrared absorption at 3345 and 3445 $cm^{-1}$.

**Catalytic Reduction of 8, 8-Diethoxycarbonylheptafulvene (X).**—A solution of 500 mg. (2 mmol.) of X in 40 ml. of ethanol was hydrogenated in the presence of 10 mg. of Pt-oxide as catalyst at ordinary temperature and pressure. After 107 ml. (4.9 mmol.) of hydrogen had been absorbed, the red color of the solution disappeared and the absorption of hydrogen almost ceased at 175 ml. (7.8 mmol.). The filtrate obtained by removal of the catalyst was evaporated to 400 mg. of an yellow oil (XIII). It has no absorption maximum in the ultraviolet spectrum.

Two hundred and fifty milligrams of XIII was added to a mixture of 2.5 ml. of 6 N potassium hydroxide and 2.5 ml. of ethanol and the solution was refluxed for 2 hr. After evaporating ethanol and diluting with water, the reaction mixture was acidified with diluted hydrochloric acid and extracted with ether. The ether extracts were washed with water, dried over sodium sulfate and evaporated to 200 mg. of colorless crystals, m. p. 145~149°C (decomp.). Repeated recrystallization from a mixture of carbon tetrachloride and acetone gave colorless crystals, m. p. 160~161°C (decomp.).

Found: 60.49; H, 7.72. Calcd. for $C_{10}H_{16}O_4$: C, 59.98; H, 8.05%.

Reported melting point for cycloheptylmalonic acid is 164.5°C[25].

The authors express their gratitude to Shell Petroleum Company for the kind donation of tropilidene used as the starting material, and to Sankyo Co., Ltd. for donation of a research fund which covered a part of the expenses for this work. The authors also thank Mr. H. Tsuruta for repeating some experiments.

# *Intramolecular Interaction between Hydroxyl Group and π-Electrons. XIII*[1]. *$\nu_{O-H}$ Absorption of 2,6-Diphenylphenol and the Related Compounds*

By Michinori Ōki, Haruo Hosoya and Hiizu Iwamura

(Received March 27, 1961)

It has been clarified, by a series of reports[2] from this laboratory, that, if a hydroxyl group and the π-electrons are located at suitable positions, the intramolecular interaction takes place to the extent which is determined by the structure of the molecule, the strength of the proton-donor, and the strength of the proton-acceptor. Thus, in a usual case, two O-H stretching ($\nu_{O-H}$) absorption bands corresponding to the free and the interacting hydroxyl groups appear in the 3μ region. The above consideration leads to the deduction that, if the steric factors force the hydroxyl group to approach the π-electrons, there would be no free hydroxyl group. Tribenzylcarbinol[3] will be one of the examples in this category.

Pauling suggested[4] that the hydrogen atom of the phenolic hydroxyl group is located in the plane of the aromatic nucleus because of the resonance stabilization. Later, the suggestion was found to be true when 2,6-dichlorophenol was found[5] to possess only an O-H··· Cl bonded hydroxyl group from the O-H stretching absorption in the infrared region and the microwave data also[6] led to the same conclusion as Pauling's suggestion. Therefore, if a phenol carries two groups at both ortho-positions of the hydroxyl group, which contain π-electrons, the compound can be another example which has no free hydroxyl group. In this paper, 2,6-diphenylphenol and the related compounds are taken as examples and absence or presence of the free hydroxyl group will be discussed in terms of the steric factor.

## Experimental

**Measurement and Calculation.** — The measurement of the absorption in the 3μ region was carried out with a Perkin Elmer 112G grating spectrometer and quartz cells of 2 and 5 cm. lengths as required. Carbon tetrachloride was used as a solvent. The concentration was $1\sim2\times10^{-3}$ mol./l. and the spectral slit width 1 $cm^{-1}$ in this region. The calculation of the band intensities was performed as reported previously[7], the integrated intensities being the authors' choice. However, on some occasions, the assumption that the appearance of the two peaks or the asymmetric curve indicates the overlap of the two symmetric curves, each of which is expressed by the Lorentz function, is proved to be false, suggesting the presence of the third band. In such cases, the molecular extinction coefficients were taken instead of the integrated intensities for the convenience of the calculation.

**Materials.**—The compounds used for this work are known unless otherwise mentioned and their physical constants agreed with those reported in the literature.

*4-Nitro-2,6-diphenylphenol.* — This compound was prepared by condensation of nitromalonaldehyde and dibenzyl ketone according to the method described by Hill[8]. The melting point of the compound was 115°C after four recrystallizations from ethanol. However, the melting point was suddenly raised up to 135°C when a large crystal was scratched, and the compound melting at 115°C has never been obtained thereafter. This phenomenon must be a type of polymorphism but the physical measurement was not carried out with the unstable form because of the lack of the sample. The melting point of the stable form was 135~136°C (lit.[8], 135~136°C).

*3,5-Dimethyl-2,6-dipropenylphenol.* — A mixture of 20 g. (0.123 mol.) of 2-allyl-3,5-dimethylphenol, 15.7 g. (0.13 mol.) of allyl bromide, 18.0 g. (0.13 mol.) of potassium carbonate and 50 ml. of acetone was refluxed for ten hours. The filtrate from the reaction mixture was fractionated and gave 22 g. (87%) of allyl 2-allyl-3,5-dimethylphenyl ether, b. p., 148~150°C/15 mmHg. The ether was refluxed with an equal amount of *N,N*-diethylaniline for three hours and, after cooling, the mixture was diluted with petroleum ether. The solution was shaken with dilute hydrochloric acid to remove *N,N*-diethylaniline and then extracted with Claisen's alkali. When the alkaline solution was diluted with water, an oil separated, which was distilled to give 83% 2,6-diallyl-3,5-dimethylphenol, b. p., 105~106°C/2 mmHg, $n_D^{19}$ 1.5410.

Found: C, 82.94; H, 9.05. Calcd. for $C_{14}H_{18}O$: C, 83.12; H, 8.97%.

The phenol (10 g.) was dissolved in 30 ml. of

methanol containing 10 g. of potassium hydroxide and the solvent was evaporated until the temperature of the solution rose to 130°C. The mixture was refluxed for twenty hours at that temperature, cooled, diluted with water and extracted with ether. The ethereal extract was dried over potassium carbonate and fractionated to give 7.3 g. of 3,5-dimethyl-2,6-dipropenylphenol, b. p., 155°C/18 mmHg. The compound solidified and was recrystallized from petroleum ether. The melting point was 59~60°C.

Found: C, 83.04; H, 9.12. Calcd. for $C_{14}H_{18}O$: C, 83.12; H, 8.97%.

## Results and Discussion

The $\nu_{O-H}$ absorptions of substituted 2,6-diphenylphenols and of 2-chloro-6-phenylphenol are summarized in Table I. As expected, these phenols did not possess absorption at the position (ca. 3600 $cm^{-1}$) where ordinary phenols do, but at the position which is too low a wave number to be assigned to the free hydroxyl group. Absorptions of 4-substituted 2,6-diphenylphenols are symmetric and appear at lower wave numbers as the substituent at 4 position is more electronegative, the phenomenon being common for the ordinary phenols[9] and 4-substituted 2,6-di-*tert*-butylphenols[10].

TABLE I. $\nu_{O-H}$ ABSORPTIONS OF PHENOLS [2,4,6-XY($C_6H_5$)$C_6H_2$OH]

| Substituent X | Substituent Y | $\nu_{max}$ $cm^{-1}$ | $\varepsilon_{max}$ | $A\times10^{-4}$ $mol^{-1}$ l. $cm^{-2}$ |
|---|---|---|---|---|
| $C_6H_5$ | $NO_2$ | 3531.2 | 366 | 2.54 |
| $C_6H_5$ | H | 3553.3 | 305 | 1.93 |
| $C_6H_5$ | $NH_2$ | 3567.9 | 305 | 1.85 |
| Cl | H | 3550.2<br>3535.6 | 41<br>184 | 0.30<br>1.22 |

Since the hydroxyl group of the 4-substituted 2,6-diphenylphenols is considered to be all interacting with the $\pi$-electrons of the adjacent phenyl groups, it may be interesting to compare the absorptions of these compounds with those of the corresponding phenols in benzene. Thus the $\nu_{O-H}$ absorption of *p*-nitrophenol was measured in benzene solution, the absorption maximum being at 3527.4 $cm^{-1}$. The difference (3.8 $cm^{-1}$) from 4-nitro-2,6-diphenylphenol is rather small and supports the above mentioned idea. However, it must be considered that this difference is the combination of the solvent effect and the electronic effect of the substituent. 4-Nitro-2,6-diphenylphenol in benzene showed the $\nu_{O-H}$ absorption at 3523.3 $cm^{-1}$. Therefore, the difference between 3527.4 $cm^{-1}$ and 3523.3 $cm^{-1}$ may be attributed to the effect of two phenyl groups at *o*-positions. Phenol in benzene is known to show its $\nu_{O-H}$ maximum at 3562 $cm^{-1}$ [11]. The deviation from 3553.3 $cm^{-1}$ may be interpreted similarly.

2-Chloro-6-phenylphenol has its $\nu_{O-H}$ absorption maximum at 3535.6 $cm^{-1}$ but the curve shows a shoulder at the higher wave number side. Therefore, the curve was divided into two, assuming that it was an overlap of two symmetric curves which could be expressed by the Lorentz function (Fig. 1). The authors

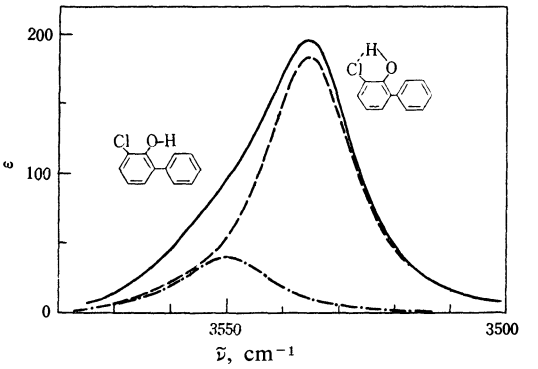

Fig. 1. $\nu_{O-H}$ absorption of 3-chloro-2-hydroxybiphenyl.
——— the observed curve
– – – O-H···Cl
—·—· O-H···$\pi$

have data, concerning the interacting form of 2-hydroxybiphenyl and the hydrogen-bonded form of *o*-chlorophenol, which reveal the fact that the former is located at 3565.0 $cm^{-1}$ and the latter at 3547.0 $cm^{-1}$. Then it will be most probable to assign the band maximum at 3535.6 $cm^{-1}$ to the hydrogen-bonded form of the hydroxyl group with ortho chlorine atom and that at 3550.2 $cm^{-1}$ to the interacting form with $\pi$-electrons. The lowering of the wave number must be derived from the effect of the electron-drawing substituents. As to the integrated intensities of each component, the O-H···Cl bonded form is apparently large, but it may not necessarily mean that the molecule having the hydrogen bond between the hydroxyl group and the chlorine atom is greatly in the majority, since it is a well-known fact that the absorption intensity per molecule becomes stronger on O-H···Cl hydrogen bond formation.

As the source of the $\pi$-electrons, the propenyl group might be considered equally effective with the aromatic nucleus. Thus, various phenols containing propenyl groups are prepared and their $\nu_{O-H}$ absorptions examined. The results are summarized in Table II. As is clear from Table II, replacement of a phenyl

| | i | 3563.2 | 241.6 | |

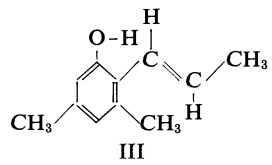
* f and i denote the free and the interacting forms, respectively.

group by a propenyl group gives rise to the appearance of an absorption due to the free form of the hydroxyl group and this phenomenon is enhanced when two propenyl groups are introduced in place of the phenyl groups of 2,6-diphenylphenol. One of the possibilities which reasonably explains the phenomenon is the concept of the rotational isomerism. *o*-Propenylphenol is taken as an example for the explanation, because of its simplicity. In this case, the consideration of the cis form[4] will suffice to cover the possibilities, since 2,6-dipropenylphenol contains only this form whichever direction the O-H points.

I

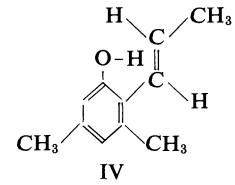
II

The authors are assured that *o*-propenylphenol assumes the trans form with respect of the ethylenic linkage[12]. Then there will be two rotational isomers about the $C_{Ph}-C_\alpha$ axis, being represented by I and II. Structure II will possess a free hydroxyl group, if a pair of π-electrons are necessary for the interaction and/or if the hydrogen atom of the hydroxyl group must approach from the upper side to the π-electron cloud in order to establish the interaction. Thus, structure I may be the only form which possesses the interaction in *o*-propenylphenol. The availability of the π-electrons of 2,6-diphenylphenol, on the other hand, will not be altered no matter what rotational position is taken, because the structure corresponding to I is always involved in this compound. If the above assumption is correct, a compound which is forced to take structure I will have no free hydroxyl group. The enforcement may be given by the steric hindrance. 3,5-Dimethyl-2-propenylphenol and 3,5-dimethyl-2,6-dipropenylphenol were chosen as examples. The results are shown in Table III.



12) It is supported by the fact that *o*-propenylphenol possesses an absorption at 968.6 $cm^{-1}$ due to C-H out-of-plane deformation.

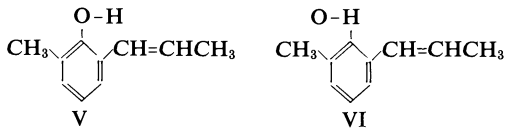
Table III. $\nu_{O-H}$ absorptions of 6-substituted 3,5-dimethyl-2-propenylphenols



[6,3,5,2-X$(CH_3)_2$($CH_3CH{=}CH$)$C_6H$-OH]

| X | O-H | $\nu_{max}$ $cm^{-1}$ | $\varepsilon^a{}_{max}$ | $\Delta\nu_{max}$ $cm^{-1}$ |
|---|---|---|---|---|
| H | f | 3607.7 | 19.4 | 68.5 |
| | i | 3539.2 | 101.9 | |
| $CH_3CH{=}CH$- | f | — | — | — |
| | i | 3526.5 | 120.2 | |

The steric effect of the methyl group may be too great to assume structure III and the structure IV becomes favorable. Therefore, the structure of 3,5-dimethyl-2-propenylphenol may be represented by IV. The structure IV is, at the same time, favorable for the internal interaction and these considerations predict that 3,5-dimethyl-2-propenylphenol contains more interacting molecules than 2-propenylphenol in spite of the fact that the methyl group is the electron-donating group which weakens the proton donating power of the phenols. Comparison of the data in Tables II and III indicates that this is really the case. Since 2,6-dipropenyl-3,5-dimethylphenol has two propenyl groups which are sterically enforced to take the structure as IV, it is naturally expected that this compound will possess single $\nu_{O-H}$ absorption at a rather low frequency. Actually a perfectly symmetrical band is found at 3526.5 $cm^{-1}$. Hence, it is proved that the propenyl group can also be the source of the π-electrons which give th $\nu_{O-H}$ absorption at extraordinarily low frequency.



III

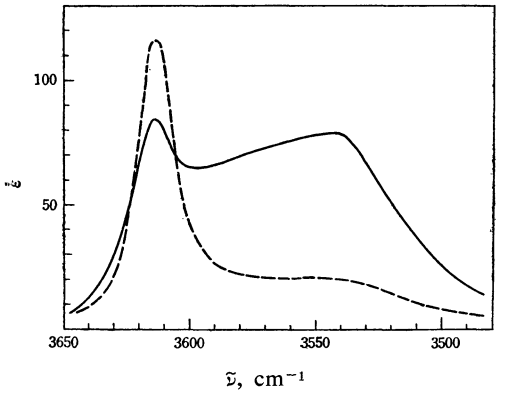
IV

As to the steric effect on the interaction, it may also be interesting to examine the $\nu_{O-H}$ absorption of 2-methyl-6-propenylphenol. Since the hydroxylic hydrogen atom is located on the plane of the benzene nucleus, it is reasonably expected that, in *o*-cresol, the molecule will be more stable when the hydroxylic hydrogen is located on the opposite side of the methyl group. Therefore, in 2-methyl-6-propenylphenol, the contribution of structure V may be more than that of structure VI. This consideration suggests that there will be more molecules, which have the intramolecular interaction between the hydroxyl group and π-electrons, in 2-methyl-6-propenylphenol than in 2-propenylphenol. The former compound has one absorption maximum at 3617.0 $cm^{-1}$

($\varepsilon^a_{max}=83.8$) and another at 3548.3 $cm^{-1}$ ($\varepsilon^a_{max}=39.3$). Comparison of the results with these compounds indicates that the above consideration is correct, since both $\Delta\nu_{max}$ and $\varepsilon_i/\varepsilon_f$ are greater in 2-methyl-6-propenylphenol.

V VI

The $\nu_{O-H}$ absorptions of the precursors of the propenyl compounds, the phenols carrying allyl groups, are also examined in connection with the freedom of rotation and the basicity of the ethylenic linkage. The results are shown in Table IV. The diagrams of the $\nu_{O-H}$ absorptions of 2-allyl-3, 5-dimethylphenol and 2, 6-diallyl-3, 5-dimethylphenol are also given in Fig. 2, because of the difficulty of understanding the matter from the mere numericals. The $\varepsilon_i/\varepsilon_f$ of the phenols carrying allyl groups are always greater than those of the propenylphenol derivatives unless they carry methyl groups at 3 and 5 positions. This will mean that the effect of the basicity of the ethylenic



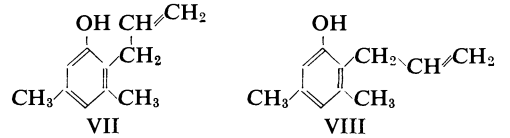


Fig. 2. The apparent $\nu_{O-H}$ absorption of 2, 6-diallyl-3, 5-dimethylphenol (——) and 2-allyl-3, 5-dimethylphenol (– – –).

* Four place number is given because of the uncertainty due to the broadness of the band (see Fig. 2).

bond plays the major role and the rotation about $C_{Ph}-C_\alpha$ axis the minor role, for the interaction. This is because the basicity of the ethylenic linkage in the propenylphenols is rather low due to the conjugation with the benzene nucleus. In contrast with the above situation, when methyl groups are present at 3 and 5 positions, the allylphenols show smaller $\varepsilon_i/\varepsilon_f$ value than those of the corresponding propenylphenols. This is without doubt caused by the freedom of rotation. That is, it is possible for "cis" 2-allyl-3, 5-dimethylphenol to take the conformations illustrated, for example, by VII and VIII, which are unfavorable for the intramolecular interaction. The possibilities of taking these unfavorable structures are owing to the rotation about $C_{Ph}-C_\alpha$ and $C_\alpha-C_\beta$ axes, while, in 3, 5-dimethyl-2-propenylphenol, the rotation about the $C_{Ph}-C_\alpha$ is at least partially restricted due to the resonance stabilization and the steric interference of the methyl group, possibly causing all the cis forms to be the interacting. Baker and Shulgin[13] have mentioned that the steric effect of the methyl group in 2-allyl-3, 5-dimethylphenol is favorable for the interaction, when compared with 2-allylphenol, probably because the contribution of structures such as VIII is less. Nevertheless, the conclusion is not contradictory, since it may be possible for

VII VIII

structure VIII to be present to a small extent and it is out of the question at the present time which structure is the main contribution for the free cis form.

When an asymmetrical band is assumed to be an overlap of the symmetrical bands, the compounds which contain one or two propenyl groups at ortho positions of the hydroxyl group usually possess three $\nu_{O-H}$ bands unless the absorption corresponding to the interacting form is very strong. In the case of 2-phenyl-6-propenylphenol, the three bands may be reasonably assigned to the free, the interacting with the phenyl group, and the interacting with the propenyl group. However, the situation must be further studied with other compounds before obtaining a general conclusion.

The authors are indebted to Professors Yoshiyuki Urushibara and Saburo Nagakura for their valuable advice and encouragement throughout this work. A part of the cost

# *Intramolecular Interaction between Hydroxyl Group and π-Electrons. XIV*[1]. *Electronic Effect of the Substituents on the Interaction in 2-Hydroxybiphenyls*

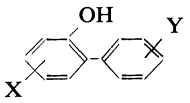
By Michinori Ōki and Hiizu Iwamura

(Received March 27, 1961)

Since the observation by Wulf and his co-workers[2], it has been occasionally reported that 2-hydroxybiphenyl shows doublet O–H stretching band in the infrared absorption spectrum. The phenomenon was explained on the assumption that 2-hydroxybiphenyl would be composed of cis and trans isomers. Such an explanation had been adopted by Pauling[3] for the like phenomenon observed in the infrared spectrum of *o*-chlorophenol. As the cis isomer seems to be less stable because of

the steric interference, there must exist a cause which makes the appearance of this form possible. Wulf and his co-workers attributed stabilizing force to the approach of the hydroxyl group to the first carbon atom of the benzene ring which is ortho to the hydroxyl group and to the consequent attraction between them, but failed to show the true nature. Later, Mecke[4] explained the phenomenon from the polarizable nature of the π-electrons in the benzene nucleus and assumed that a so-called π-complex was formed intramolecularly, without giving further details. Recently Musso and von Grunelius[5] reported some $\nu_{O-H}$ absorptions of 2,2′-dihydroxybiphenyl and their derivatives and discussed the competitive intramolecular hydrogen bond formation between O–H···O and O–H···π systems, with special reference to the geometrical consideration. The examples are, however, too complicated to help us to understand the nature of the latter interaction separately.

The present authors have preliminarily reported[6] that the energies of the intramolecular interaction between the hydroxyl group and the π-electrons in 2-hydroxy-4- and -4′-nitrobiphenyls are 2.5 and 0.9 kcal./mol., respectively. The present study was initiated on the expectation that the electronic effect of the substituents on the interaction will provide additional informatin in regard to the true nature of the interaction.



## Experimental

Measurement and treatment of the infrared spectra were carried out as described previously[7]. The known samples were prepared according to the literature, and the new as described below. Their physical constants and analytical data are listed in Table I.

**Materials.** — *2-Hydroxyl-4-methoxybiphenyl.* — 2-Amino-4-methoxybiphenyl[13] (0.02 mol., 4.0 g.) was dissolved in aqueous sulfuric acid (4.5 ml. of concentrated sulfuric acid and 6 ml. of water) and diazotized with 1.5 g. of sodium nitrite in 3 ml. of water. The excess of nitrite was decomposed by a lump of urea and the solution was poured into 20 ml. of boilng 30% aqueous sulfuric acid. The separated dark oil was taken up in ether and the ether layer was extracted thrice with 20% aqueous sodium hydroxide solution. The alkaline extract was acidified and extracted with ether. The ether extract was treated with active charcoal, filtered and evaporated. The tarry residue was extracted with hot petroleum ether and the extract deposited prisms after cooling. The pure sample was obtained by recrystallization from petroleum ether.

*4-Chloro-2-hydroxybiphenyl.*—A half moles (86.3 g.) of 4-chloro-2-nitroaniline[14] was diazotized in 150 ml. of concentrated hydrochloric acid with 35 g. of sodium nitrite in 50 ml. of water, and decomposed in the presence of 2 l. of thiophene free benzene by adding an excess of sodium acetate. Stirring was continued over-night. The benzene layer was washed with aqueous sodium hydroxide and the solvent evaporated. 4-Chloro-2-nitrobiphenyl distilled at 160~166°C/2 mmHg, and solidified in the receiver. It was recrystallized from petroleum ether-benzene to give prisms melting at 53°C (lit.[15], 52~53°C). The nitro-compound (23 g., 0.1 mol.) was catalytically hydrogenated over platinized Raney nickel[16] in ethanol, 6.5 l. of hydrogen being absorbed in 2 hr. 2-Amino-4-chlorobiphenyl was, without further purification, diazotized in aqueous sulfuric acid with sodium nitrite and decomposed by pouring into 30% aqueous sulfuric acid. 4-Chloro-2-hydroxybiphenyl was recrystallized from carbon tetrachloride to form prisms.

*5-Ethyl-2-hydroxybiphenyl.*—To a solution of 5 g. of 5-acetyl-2-hydroxybiphenyl[10] in 100 ml. of acetic acid was added a few drops of 3 N hydrochloric acid and 100 mg. of platinum oxide. On shaking under hydrogen atmosphere, 1.1 l. of hydrogen was absorbed under the atmospheric pressure and at the room temperature. The solvent was evaporated under reduced pressure and the residue was distilled at 122°C/2 mmHg, giving the desired phenol, $n_D^{15}$ 1.5893.

*2-Hydroxy-5-methoxycarbonylbiphenyl.*—5-Acetyl-2-hydroxybiphenyl[10] in pyridine was oxidized with iodine to the corresponding β-ketoalkylpyridinium iodide, which was cleft by aqueous alcoholic sodium hydroxide to 2-hydroxybiphenyl-5-carboxylic acid, as is specified by King[17]. The carboxylic acid was recrystallized from benzene to give plates melting at 148°C (lit.[18], 148~149°C). A suspension of 8 g. of the hydroxycarboxylic acid in 100 ml. of methanol was saturated with hydrogen chloride, refluxed on a water bath for two hours and then poured into 500 ml. of ice-water. The crystals were collected and recrystallized from benzene to give plates.

*2-Hydroxy-3'-methoxybiphenyl.*—To a mixture of 30 g. of *m*-bromoanisole and 50 g. of *o*-nitrochlorobenzene was added in five portions 50 g. of copper bronze at 200°C. The temperature was kept at 200~240°C for five hours longer. After cooling, the solid mass was extracted with acetone and the extract was fractionally distilled under diminished pressure, the fraction boiling at 150~175°C/1~2 mmHg being collected. On fractional recrystalliza-

tion of the distillate from methanol, 10 g. of 3'-methoxy-2-nitrobiphenyl, melting at 83~84°C was obtained. Found: N, 6.28. Calcd. for $C_{13}H_{11}O_3N$: N, 6.11%. Catalytic reduction of the nitrocompound gave 2-amino-3'-methoxybiphenyl which was characterized as the acetyl derivative (m. p., 114°C) and analyzed. Found: C, 74.88; H, 6.48; N, 5.81. Calcd. for $C_{15}H_{15}O_2N$: C, 74.66; H, 6.27; N, 5.81%. Diazotization of the amine and the subsequent hydrolysis gave 2-hydroxy-3'-methoxybiphenyl.

*2-Hydroxy-3'-methoxycarbonylbiphenyl.*—2-Amino-3'-methoxycarbonylbiphenyl[19] was diazotized in aqueous sulfuric acid and decomposed at 80°C. The oily layer was extracted with ether and washed with aqueous sodium carbonate solution. The solvent was evaporated and the residue was recrystallized from carbon tetrachloride, to give prisms.

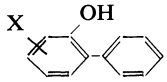
*2-Hydroxy-3'-nitrobiphenyl.*—To a solution of 3 g. of 2-methoxy-3'-nitrobiphenyl (m. p., 68.5~69°C)[20] in 50 ml. of acetic acid was added 20 ml. of 48% aqueous hydrobromic acid. The mixture was warmed on a water bath for five hours, when the oily layer disappeared. The solution was concentrated under reduced pressure and the residue was diluted with 50 ml. of water. Brown oil was extracted with benzene and the benzene layer was extracted with 20% aqueous sodium hydroxide. The aqueous layer was acidified and the product recrystallized from methanol to form needles.

*2-Hydroxy-4'-methoxybiphenyl.*—4'-Methoxy-2-nitrobiphenyl[21] (2.3 g., 0.01 mol.) was reduced with 13 g. of stannous chloride dihydrate and 15 ml. of concentrated hydrochloric acid in 20 ml. of alcohol by refluxing for two hours. The amine[22] in 30 ml. of water and 2 ml. of sulfuric acid was diazotized with 0.7 g. of sodium nitrite in 2 ml. of water and hydrolyzed as usual to the desired phenol. The phenol was recrystallized from a mixture of carbon tetrachloride and petroleum ether (1 : 1).

*2-Hydroxy-4'-iodobiphenyl.*—4'-Amino-2-hydroxybiphenyl[23] (3.7 g., 0.02 mol.) was diazotized in aqueous sulfuric acid (2.4 g. of concentrated sulfuric acid and 20 ml. of ice-water) with 1.5 g. of sodium nitrite in 3 ml. of water. The diazonium solution was added dropwise to the boiling aqueous potassium iodide solution (4 g. of potassium iodide in 5 ml. of water) and the separated brown oil was extracted with ether. On evaporation the ether extract gave heavy oil which was heated with hot petroleum ether and decanted. Repetition of the process gave thick prisms.

*2-Hydroxy-4'-methoxycarbonylbiphenyl.*—To a mixture of 50 g. (0.32 mol.) of *o*-nitrochlorobenzene and 26 g. (0.1 mol.) of methyl *p*-iodobenzoate, heated at 230~240°C, was added 80 g. of copper bronze for three hours. After cooling, the mass was extracted with acetone using a Soxlet extractor. The acetone extract deposited a large amount of 2,2'-dinitrobiphenyl, which was filtered off. The mother liquor was evaporated and the residue was refluxed with 500 ml. of ethanol and 160 ml. of 10% aqueous sodium hydroxide for three hours. The mixture was diluted with water to make up 1 l. and boiled for several minutes with active charcoal and then filtered. The filtrate was acidifed and the precipitate was collected. Recrystallization from acetic acid gave 6 g. of 2-nitrobiphenyl-4'-carboxylic acid, melting at 247°C (lit.[24], 250°C). It was catalytically hydrogenated over platinum oxide, as described in the literature[24]. The aminocarboxylic acid was diazotized and hydrolyzed as usual. The crude hydroxycarboxylic acid was used, without further purification, for the preparation of the corresponding ester. Esterification was carried out by saturating the methanolic suspension with hydrogen chloride nd refluxing the mixture for two hours. Recrystallization from carbon tetrachloride gave prisms.

## Results and Discussion



It must be confirmed in the first place that two bands which appear in the 3 μ region in the infrared are not derived from the intermoleculer hydrogen bonding but from the intramolecular origin. With 2-hydroxybiphenyl, the infrared spectra were measured over the concentration range from 0.5 to 0.001 mol./l. in carbon tetrachloride. At concentration of over 0.1 mol./l., a third band appears at 3460 $cm^{-1}$, which is assigned to the $\nu_{O-H}$ of the associated hydroxyl group, but, below 0.01 mol./l., this band disappears and the ratio of intensities of the remaining ones scarcely depend upon concentraion. All the following data were obtained in these conditions, usually 0.001 mol./l. solution being employed.

The absorption at the higher wave number of 2-hydroxybiphenyl is located at 3607 $cm^{-1}$ and, referring to the free $\nu_{O-H}$ of phenol, 3610 $cm^{-1}$ [25], is assigned to the trans form of the molecule having the free hydroxyl group (f). The other absorption at the lower wave number is tentatively assigned to the cis form having the intramolecular interaction with π-electrons of another benzene ring and having a less force constant of the O-H stretch (i). The intensities and the maxima of these two bands vary considerably with different substituents on each benzene ring. The apparent effect of the substituents on the infrared absorption spectra is shown in Figs. 1 and 2, and the numerical data are in Tables II and III. If the varied band properties can be explained reasonably in terms of the intramolecular interaction with π-electrons, the above assignment will be justified.

Substitution has been confined to the positions at 4, 5, 3' or 4' of the hydroxyl group

Added in proof: After this paper had been received, W. Beckering (*J. Phys. Chem.*, **65**, 206 (1961)) reported O-H$\cdots\pi$ interaction in some of the examples included in the present study.

at 2-position in biphenyl skeleton in order to avoid either another intramolecular hydrogen bond[1] and/or steric influence[26], which make the consideration more complex. For the sake of convenience, the substituted 2-hydroxybiphenyls are calssified into two groups; one is those with the substituent on the benzene ring (A) which bears the hydroxyl group and the other those on the other ring (B).

The varied $\Delta\nu_{max}$ and $A_i/A_f$ in Tables II and III may be considered to correspond to the strength of the interaction, since the former is known to be approximately proportional to the enthalpy (Eq. 1)[27] and the latter to the equilibrium constant (Eq. 2)[28] of the interaction. Therefore, neither value should be independent of the other and the relation between $\Delta\nu_{max}$ and $\log(A_i/A_f)$ must be linear (Eq. 3) if $\Delta S$ of the interaction, and the constants $a$ and $b$ are independent of the

substituents. The case is realized from Fig. 3. Strictly speaking, however, the line has a little convex curvature upwards, which may be attributed to the second order term neglected in

$$-\Delta H = a\Delta\nu_{max} \quad (1)$$

$$K = bA_1/A_f \quad (2)$$

$$RT\cdot\ln(A_1/A_f) = a\Delta\nu_{max} + (T\Delta S - RT\cdot\ln b) \quad (3)$$

the approximation, assuming the constancy of $a$, $b$ and $\Delta S$. From the gradient of the line, a constant $a$ in the equation can be estimated to be 0.057 kcal.cm$^{-1}$ at the measured temperature. It may be expressed otherwise by saying that the wave number shift of 18 cm$^{-1}$ corresponds to the energy of the interaction of one kcal./mol. Compared with the ordinary hydrogen bonding, in which displacement of $\nu_{O-H}$ by 40 cm$^{-1}$ corresponds to one kcal./mol. of the enthalpy change[27], these interactions seem to have the characteristic that a smaller $\Delta\nu_{max}$ corresponds to an appreciable enthalpy change. This is, however, overestimated, since the term $T\Delta S$ in Eq. 3 is some what dependent on $\Delta\nu_{max}$ and the greater $\Delta\nu_{max}$ makes the absolute value of $\Delta S$, which is inherently negative, greater. It will tend to make its value less.

It is further shown in Fig. 3, that the points representing 2-hydroxybiphenyls substituted on the B-ring spread wider by about five times than those having the substituent on the A-ring; that is, the effect of the substituents on the phenomenon is more fully developed in the B-ring. As the first approximation, the strength of the intramolecular interaction between the hydroxyl group and π-elctrons is expected to be influenced by the substituent on the B-ring by directly affecting the π-electron density and the proton accepting character of the B-ring, while the substituent on the A-ring will not touch the π-electron density of the B-ring but affect the proton donating character of the hydroxyl group. The above observation means that the former effect is predominant.

As to the latter effect, it is well known that acid dissociation constant ($pK_a$) of phenols[29] and spectroscopically free $\nu_{O-H}$ of phenols in carbon tetrachloride solution[30], are in linear relationship with Hammett's sigma constants of the substituents. The free $\nu_{O-H}$ of 2-hydroxybiphenyls substituted in the A-ring have been examined in this connection and the results are presented in a Hammett sigma-rho plot in Fig. 4. A line with rho value of −13.8 is

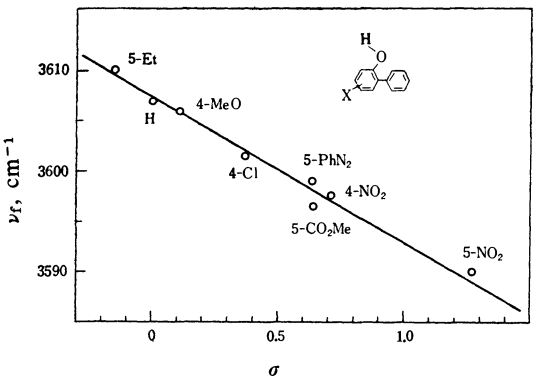

Fig. 4. $\nu_{O-H}$ frequencies of the free hydroxyl group in 2-hydroxybiphenyls substituted in the A ring versus the Hammett sigma constants.

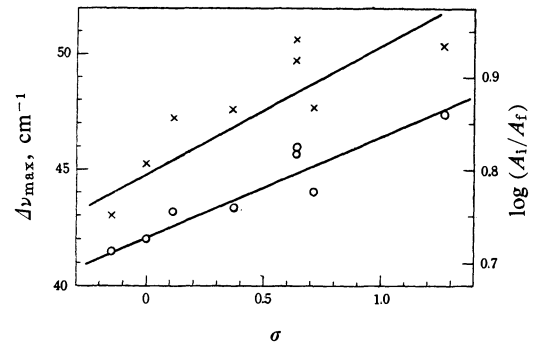

Fig. 5. Dependence of the two band properties, $\Delta\nu_{max}$ (the circles to the left ordinate) and $\log(A_i/A_f)$ (the crosses to the right ordinate) on the substituents in A-ring.

obtained, comparable to $\rho=-12.6$ in the substituted phenols[30]. This suggests that the substituents in the A-ring are really pertaining to the proton donating character of the hydroxyl group just as in phenols and thus must be affecting the strength of the intramolecular interaction. In Fig. 5, it is illustrated to what extent the strength of the interaction, i.e., $\Delta\nu_{max}$ and $\log(A_i/A_f)$ depends on the sigma constants of the substituents. It can be concluded from Figs. 4 and 5, that the intramolecular interaction between the hydroxyl group and $\pi$-electrons strengthens as the electron drawing power of the substituents or the acidity of the hydroxyl group enhances, and weakens with the electron-donating substituents.

As the substituents on the ring B govern the density and polarizability of $\pi$-electrons acting as the hydrogen accepter, it is natural that the variation in the B-ring substituent causes a salient change in the degree of the interaction in such a direction that the electron donating substituents (e.g., methoxyl) enhance the interaction, while the electron-attracting substituents (e.g., nitro) disfavor the interaction. Two kinds of band properties, $\Delta\nu_{max}$ and $\log(A_i/A_f)$ have again been tested for Hammett's sigma-rho relation, in the expectation that $\pi$-electron density and/or polarizability at the site of the interaction will be expressed in terms of sigma values, just as in the case of the electrophilic nuclear substitution reaction[31]. Although Wulf et al.[2] suggested that the hydroxyl group would approach the first carbon atom (1′-carbon), there is no a priori reason which of the 3′- or 4′- substituents may be regarded as *m*- or of *p*-position in respect of the site of the interaction. In the previous papers[32,33] the authors have succeeded in assigning the position of the hydroxylic proton in the interaction in benzyl and phenethyl alcohols by plotting $\log(A_i/A_f)$ against Hammett's sigma values considering the various possibilities, and by choosing the assignment of better linearity. The trial has again been applied to the present system but failed to obtain the precise linearity in either case. In Fig. 6 is shown the relation between $\log(A_i/A_f)$s' relative to that for 2-hydroxybiphenyl and the Hammett sigma constants, *m*- and *p*-values of which are allotted to 4′- and 3′-substituents, respectively. These are

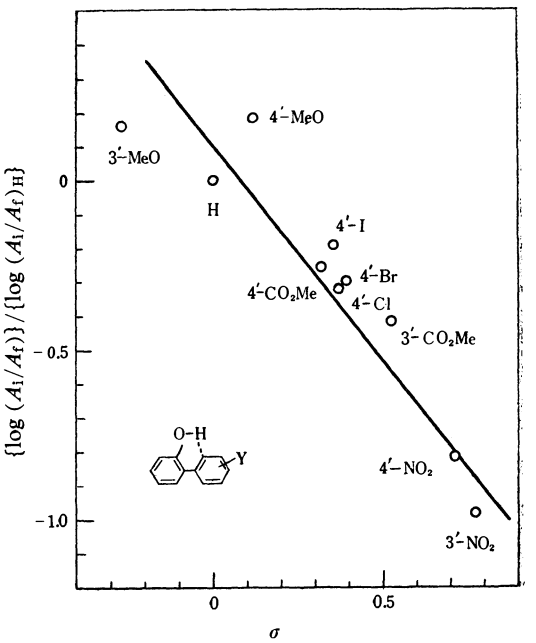

Fig. 6. Relation between $\{\log(A_i/A_f)\}/\{\log(A_i/A_f)_H\}$ and the Hammett sigma constants in 2-hydroxybiphenyl substituted in B-ring.

in better linearity than the reverse assignment in so far as 3′-electrophilic substituents (e. g., nitro) disfavor the interaction more than the 4′-ones. Here it may be said that the hydroxylic proton is more concerned with π-electrons at 2′-carbon than at the 1′. Methoxyl group at 3′- and 4′-positions, however, favors the interaction equally, in spite of the fact that their sigma constants are of opposite sign and differ by 0.38. If the interaction is solely concerned with π-electrons at 2′-carbon, the methoxyl group at 4-position would not have favored the interaction. Putting the emphasis upon the last observation and regarding the difference in the electrophilic substituents minor, it may tentatively be concluded that the hydroxylic proton is concerned with π-electron density between 1′ and 2′ carbon atoms, like the structure of the complex formed between silver ion and benzene[34].

It has been assumed that the electronic effect of the substituents might be confined to the ring to which it is attached. Biphenyls are, however, characteristic of its conjugation between two phenyl rings, and a considerable conjugation has been demonstrated by the kinetic study[35] and the ultraviolet spectroscopy[36], even when it is substituted at one ortho-position by a rather small group[37]. Although there is no datum available for the 2-hydroxybiphenyl system, if the conjugation exists between two rings in this system, the free $\nu_{O-H}$ must also be dependent on the substituents on the B-ring. In Fig. 7 the wave number where the free $\nu_{O-H}$ appears is plotted to Hammett's sigma constants, *m*- and *p*-sigma values being alloted to the substituents at 3′- and 4′-positions, respectively. A line having an inclination of −3.9 is obtained and, compared with that of Fig. 4, −13.8, it can be

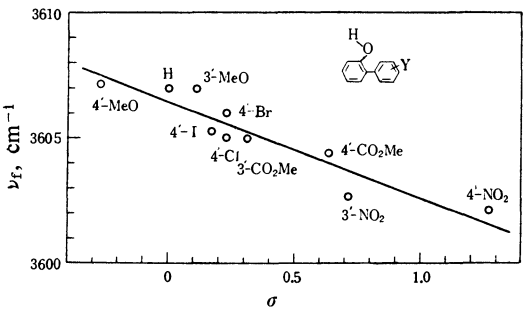

Fig. 7. $\nu_{O-H}$ frequencies of the free hydroxyl group in 2-hydroxybiphenyls substituted in the B-ring, versus the Hammett sigma constants.

stated that in 2-hydroxybiphenyls 28% of the electronic effect of the substituents can be transmitted across the pivot bond through mesomerism and/or induction. The degree of conjugation is rather great in spite of the ortho substitution when compared with biphenyls free from the substituent[35,36], because Berliner obtained, for example, $\rho=0.37$ from the dissociation constants of the substituted biphenyl-4-carboxylic acids, deducing 37% propagation of the substituent effect[38]. This may be reasonable, however, because the data obtained for 2-hydroxybiphenyls are for free $\nu_{O-H}$ of trans configration, which, unlike cis form, has only a little excessive steric hindrance compared with a hydrogen atom.

With these new informations of conjugative effect, the effect of the substituents at the A and the B-rings on the electron donating power of the B-ring and on the proton donating character of the hydroxyl group, respectively, must be reevaluated. Since the effect of the substituents is more strongly exerted by affecting the proton accepting power than the proton donating one, as shown in Fig. 3, the effect of the B-ring substituents on the apparent interaction by affecting the proton donating character of the hydroxyl group of the A-ring may be neglected. On the other hand, the effect of the A-ring substituents on the proton accepting character of the B-ring must be taken into account, since it amounts to 28% of that caused by the B-ring substituents and has as much influence on the interaction as the effect on the proton donatining power of the hydroxyl group. The electron attracting substituents (e. g., nitro), for example, influence the interaction as a result of two opposing effects. That is, they favor the interaction by strengthening the proton donating character of the hydroxyl group and disfavor it by lessening the proton accepting charactor of the B-ring. Although it is as yet impossible to separate the two competing effects quantitatively, it is clear that the pure effect of A-ring substituents on the proton donating character of the hydroxyl group is more pronounced than is estimated from Fig. 3.

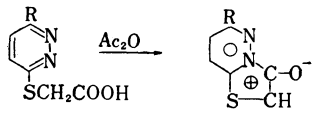
# *Studies on Meso-ionic Compounds. XIV*[1]. *Synthesis of Meso-ionic Compounds from Pyridazine Derivatives Having a Carboxymethylmercapto Group*

By Masaki OHTA and Kimio KISHIMOTO

(Received April 3, 1961)

In the previous paper of this series, the reaction of several kinds of azoles (5-phenyl-1, 3, 4-triazole, 5-phenyl-1, 3, 4-oxadiazole, 1, 5-diphenyl-1, 3, 4-triazole, benzothiazole, benzoxazole, cyclohexeno- and cyclopentenothiazoles) having a carboxymethylmercapto group with acetic anhydride was reported[2]. Although no formation of pigments had been reported by Duffin et al.[3], it was demonstrated that not only the corresponding meso-ionic compounds but also pigments are formed in the reaction.



In this paper, the present authors further extended this reaction to pyridazine derivatives and studied whether the meso-ionic compounds are obtained or not from the pyridazine derivatives possessing a carboxymethylmercapto group by the loss of one mole of water. The structure of the resulting meso-ionic compounds from pyridazine derivatives was confirmed by infrared absorption, hydrolysis, and the reaction of the compounds with phenylhydrazine or mercuric chloride.

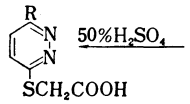
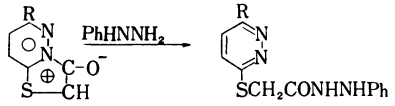
a: R=$CH_3$ d: R=Cl
b: R=$SCH_3$ e: R=Ph
c: R=$SCH_2Ph$ f: R=SH

Pyridazine derivatives possessing a carboxymethylmercapto group[4] were prepared from the corresponding mercapto pyridazine derivatives by the reaction with monochloroacetic acid. By the action of acetic anhydride or acetic anhydride-pyridine on 3-methyl-6-(carboxymethylmercapto)-pyridazine (IIa), violet pigment, which was not prosecuted for detailed investigation because of its difficult purification, was formed, and no corresponding meso-ionic compound was formed. But the present authors have found that IIa reacts readily with acetic anhydride-pyridine-triethyl amine to give a red meso-ionic compound IIIa by the loss of one mole of water, and in the same manner as in the case of IIa the other meso-ionic compounds IIIa—IIIe are obtained from those corresponding parent acids IIa—IIe, respectively. Unlike those reported previously[2], however, the present compounds are not formed in the absence of triethylamine as a more basic tertiary base, and by moisture in the air or in the solvent of recrystallization the new red compounds IIIa—IIIe immediately are turned into pale yellow compounds of which analytical values show their structures to be meso-ionic compounds IIIa—IIIe having a water of crystallization and which reversibly return to the red compounds of IIIa—IIIe on drying. These



II (a—e) III (a—e)



meso-ionic compounds are heat-unstable solids which are readily soluble in polar and non-polar solvents. For example, meso-ionic compounds give yellow aqueous solutions with the exception of IIIe and red solution in absolute ethanol or dry benzene. The influence of the substituent in 3-position of pyridazine on the ring closure of II by acetic anhydride was scarecely observed. Only 3-mercapto-6-(carboxymethylmercapto)-pyridazine (IIf) gave no mese-ionic compound. On storage, IIIa deteriorated and became black after about two weeks at room temperature. Though the other compounds IIIb—IIIe are stable, IIIa—IIIe turn black in pyridine or 10% aqueous sodium hydroxide. The infrared spectra of IIIa—IIIe respectively, in comparison with those of the parent acids, have a new strong absorption at 1630～1650 $cm^{-1}$ with the disappearance of a band near 1700 $cm^{-1}$ due to carbonyl vibration of the carboxy group. This similar remarkable change of the spectra of meso-ionic compounds from these pyridazine derivatives has been observed also in infrared spectra of meso-ionic

compounds derived from 2-(carboxymethylmercapto)-pyridine, whose structure had been confirmed synthetically[3], and from azoles having a carboxymethylmercapto group[2]. By 50% aqueous sulfuric acid IIIa—IIIe were easily hydrolyzed to the corresponding parent acids IIa—IIe respectively. The meso-ionic compounds IIIa, IIIb and IIIe reacted with

II (a—e)

III IV(a, b and e)

mercuric chloride in methanol respectively to give pale yellow precipitates, whose analytical values suggest the structures to be IIIa+2$HgCl_2$, IIIb+HgCl and IIIe+HgCl respectively[5,6], but in the case of the parent acids IIa—IIe no such precipitates were formed. When meso-ionic compounds IIIa, IIIb and IIIe were heated with phenyl hydrazine in ethanol, the corresponding phenylhydrazides (IVa, IVb and IVe) were obtained. The fact that the corresponding phenylhydrazones were not formed, suggests that the C-O bond of the meso-ionic compounds has no ketonic character.

## Experimental

**3-Benzylmercapto-6-mercaptopyridazine.**—A solution of benzylchloride (0.8 g.) in methanol (2 ml.) was poured into a solution of 3,6-dimercaptopyridazine[4] (0.8 g.) and sodium hydroxide (0.2 g.) in methanol (14 ml.). The solution was heated at 70°C on a water bath for 5 min., and 10% aqueous sodium hydroxide was added. The insoluble substance was filtered off. The filtrate was neutralized with aqueous hydrochloric acid to precipitate 3-benzylmercapto-6-mercaptopyridazine. Recrystallization from glacial acetic acid gave pale yellow needles (0.9 g.), m. p. 178~179°C. Yield 68.7%.

Found: N, 11.90. Calcd. for $C_{11}H_{10}N_2S_2$: N, 11.96%.

The alkali insoluble substance described above was recrystallized from ethanol to give white needles of 3,6-bis(benzylmercapto)-pyridazine, m. p. 121~122°C.

Found: N, 8.74. Calcd. for $C_{18}H_{16}N_2S_2$: N, 8.64%.

**3-Methyl-6-(carboxymethylmercapto)-pyridazine (Ia).**—A solution of chloroacetic acid (3.75 g.) and sodium hydroxide (1.6 g.) in water (16 ml.) was

added to a solution of 3-methyl-6-mercapto-pyridazine (5.0 g.)[4] and sodium hydroxide (1.6 g.) in water (16 ml.). The solution was warmed on a water bath at 60~65°C for an hour. After cooling, the reaction mixture was neutralized with 10% aqueous hydrochloric acid and the resulting precipitate was filtered off. Recrystallization from ethanol gave white plates (4.3 g.) m. p. 138~139°C. Yield 58.9%.

Found: C, 45.50; H, 4.52; N, 14.90. Calcd. for $C_7H_8O_2N_2S$: C, 45.65; H, 4.34; N, 15.22%.

**IIb, IIc, IId, IIe and IIf[4].** — These acids were prepared by the same procedure as used for Ia. The following Table I set forth these results.

**Meso-ionic Compound IIIa from IIa.**—The acid IIa (4.0 g.) was dissolved at room temperature in a mixture of acetic anhydride, pyridine and triethylamine (volume ratio of 1 : 1 : 1) (5 ml.). The solution immediately turned red and after a few minutes orange crystals were separated, which were filtered off, and completely washed with ether. Recrystallization from ethanol-ligroin gave pale yellow needles, m. p. 106°C (decomp.), which have a water of crystallization.

Found: C, 45.60; H, 4.45; N, 15.14. Calcd. for $C_7H_6ON_2S \cdot H_2O$: C, 45.65; H, 4.38; N, 15.21%.

When this compound was heated at about 65°C under reduced pressure, the water of crystallization was removed, affording red crystals of IIa, m. p. 135°C (decomp.). Yield 2.0 g. (50.0%).

Found: C, 50.30; H, 3.72; N, 16.54. Calcd. for $C_7H_6ON_2S$: C, 50.60; H, 3.64; N, 16.87%.

**Meso-ionic Compound IIIb, IIIc, IIId and IIIe Derived from Acids IIb, IIc, IId and IIe Respectively.**—In exactly the same manner as in the case of IIa, these meso-ionic compounds were obtained from the corresponding parent acids IIb, IIc, IId and IIe respectively, and are listed in Table II.

**Action of Aqueous Sulfuric Acid on IIIa.**—A suspension of IIIa (0.3 g.) in 50% aqueous sulfuric acid (1 ml.) was refluxed gently for 5 min. The solution slowly turned red to yellow. After cooling, the solution was neutralized with 10% aqueous sodium hydroxide and was concentrated under diminished pressure. Absolute ethanol (50 ml.) was added to the concentrated solution and the resulting precipitate was filtered off. Crude crystals obtained by concentration of the filtrate were recrystallized twice from ethanol, to afford white plates (0.15 g.), m. p. 139°C, which were undepressed by admixture with an authentic sample of IIa.

**Action of Aqueous Sulfuric Acid on IIIb and IIIe.**—The reaction product, from IIIb or IIIe by a method similar to that for IIa, was undepressed by the admixture with authentic sample of IIb or IIe. Yield of IIb, 81.7% and that of IIe 40%.

**Action of Aqueous Sulfuric Acid on IIIc.** — A suspension of IIIc (0.1 g.) with 50% aqueous sulfuric acid (2 ml.) was gently boiled for 10 min., and after cooling, the solution was neutralized with 10% aqueous sodium hydroxide and was extracted with ether. The extract was dried over anhydrous sodium sulfate and was evaporated to dryness. The residue was recrystallized from glacial acetic acid affording 0.07 g. of white plates m. p. 108~109°C, which showed no depression on admixture with an authentic specimen of IIc.

**Action of Aqueous Sulfuric Acid on IIId.** — In the same manner as in the case of IIIc, the parent acid IIc was obtained.

**Reaction of IIIa, IIIb and IIIe Respectively, with Mercuric Chloride[5,6].** — The solution of IIIa (0.7 g.) and sodium acetate (0.7 g.) in 50% aqueous methanol (20 ml.) was added to a solution of mercuric chloride (1.1 g.) in 50% aqueous methanol (5 ml.). The solution immediately turned yellow to separate a yellow precipitate (1.3 g.). Recrystallization from ethanol gave pale yellow crystals, m. p. > 230°C.

Found: N, 4.22. Calcd. for $C_7H_6ON_2SHg_2Cl_4$: N, 3.94%.

Yellow precipitate from IIIb or IIIe was prepared by the same method as used for IIIa and yellow precipitate from IIIb has m. p. > 300°C.

Found: N, 6.71. Calcd. for $C_7H_5ON_2S_2HgCl$: N, 6.47%. M. p. 250°C (decomp.) from IIIe, Found: N, 5.73, 5.71. Calcd. for $C_{12}H_7ON_2SHgCl$: N, 6.05%.

**Action of Phenylhydrazine on IIIa.**—A solution of phenylhydrazine (0.1 g.) in absolute ethanol (1 ml.) was added to a solution of IIIa (0.1 g.) in absolute ethanol (2 ml.) and the solution was refluxed on a water bath for 15 min. and decolorized with charcoal. The residual oil obtained by evaporation of alcohol solidified giving crude crystals (0.1 g.), m. p. 125~126°C, on cooling in an ice bath for 1 hr. Twice recrystallization from ethanol-ligroin yielded a pure sample of the corresponding phenylhydrazide (IVa) as orange needles, m. p. 138~139°C.

Found: C, 56.43; H, 5.21; N, 20.32, 20.24. Calcd. for $C_{13}H_{14}ON_4S$: C, 56.92; H, 5.15; N, 20.43%.

**Action of Phenylhydrazine on IIIb and IIIe.**—In exactly the same manner as described above, phenylhydrazides (IVb and IV) were prepared, IVe was plates (33.9%), m. p. 181~181.5°C.

Found: C, 64.14; H, 4.93; N, 16.42. Calcd. for $C_{18}H_{16}ON_4S$: C, 64.27; H, 4.80; N, 16.66%. IV, m. p. 152~153°C. Found: N, 18.75. Calcd. for $C_{13}H_{14}ON_4S_2$: N, 18.29%.

# *The Crystal Structure of Orthorhombic Aniline Hydrobromide, $C_6H_5NH_3Br$*

By Isamu NITTA*, Tokunosuké WATANABÉ and Inao TAGUCHI†

(Received March 13, 1961)

It has been reported in the previous paper[1], that aniline hydrobromide, $C_6H_5NH_3Br$, shows a phase transition of $\lambda$-type in the neighborhood of room temperature. It is monoclinic below 27.5°C, and is orthorhombic above this temperature. In the present paper, the crystal structure of the high temperature modification will be given.

## Experimental

Crystals of aniline hydrobromide were obtained by slow evaporation from methanol solutions. They were made into small cylindrical rods parallel to the b- and c-axis, less then 0.1 mm. in diameter, by partial dissolution with filter paper moistened with methanol. The hot air stream method[2] was applied to take oscillation and Weissenberg photographs. The temperature of the crystals was maintained at $70\pm1$°C during exposure.

The unit cell containing four formula units was found to have the following dimensions:

$$a=16.77\pm0.06\,\text{Å}$$

$$b=6.05\pm0.03\,\text{Å}$$

and

$$c=6.86\pm0.03\,\text{Å}$$

The space group was uniquely determined, from missing reflections, to be $D_{2h}^{10}$-Pnaa.

In order to collect intensity data, unfiltered Cu-$K$ radiations were used for taking Weissenberg photographs. This allowed us to make use of $K\beta$ in addition to $K\alpha$[3]. The multiple-film technique was applied, and the relative intensities of reflections were visually estimated by comparison with standard intensity scales for each series due to $K\alpha$ and $K\beta$. Corrections for Lorentz and polarization factors were made in the usual way. Corrections for absorption were made using Bradley's method for cylindrical specimens[4]. The linear absorption coefficients for Cu-$K\beta$ were calculated using Walter's rule[5] from the values for Cu-$K\alpha$. The extinction effect was more or less minimized by putting larger weights on the relative intensity values obtained from smaller specimens.

## Structure Determination

Since there are four formula units in the unit cell, four bromine atoms must lie on one of the four-fold equivalent positions, a, b, c and d, given by $D_{2h}^{10}$-Pnaa[6]. Two of these, a and b, have the eigen symmetry $C_i$-$\bar{1}$, and the other two, c and d, have $C_2$-2. Inspection of the observed intensities of reflections ($h\,0\,0$) ruled out the possibility of placing these four bromine atoms either on a or b, hence they must lie either on c or d. There are four aniline molecules in the unit cell and their longest molecular axis on which lie the atoms, N, $C_1$ and $C_4$ must occupy either c or d. Now neither the bromine atoms nor aniline molecules can occupy simultaneously the same equivalent positions, neither c nor d, since the axial length $a$ is too short to be accommodated with these. This case is definitely eliminated also by a qualitative disagreement between observed and calculated structure factors ($0\,k\,l$) even for lower order reflections. Therefore, if the bromine atoms are placed on c, the atoms N, $C_1$ and $C_4$ must be placed on d, or vice versa. The choice of these two alternatives is immaterial, since it depends only on the choice of origin. Thus, the atomic coordinates for each atom are those given in Table I.

The number of positional parameters to be determined is ten in all. However, if we assume the usual bond distances and bond angles for the aniline molecule, they can be reduced to only three. They are $x_{Br}$, $x_N$ and $\alpha$, the last one representing the angle between the benzene ring and the plane (010). An approximate value 0.025 for $x_{Br}$ was easily obtained from the Patterson synthese, $P(xz)$ and $P(xy)$. Using this value, trial and error methods gave

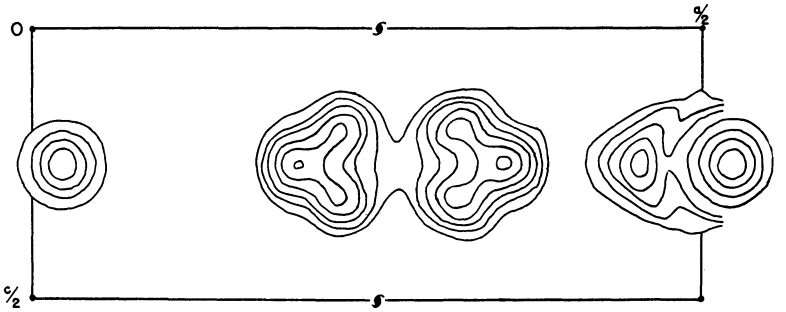

Fig. 1. Electron density projection along the b-axis. Contours for the carbon and nitrogen atoms are drawn at intervals of 1 $Å^{-2}$, starting at the 3 e$Å^{-2}$ level. Contours for the bromine atom are drawn at intervals of 10 e$Å^{-2}$, starting at the 10 e$Å^{-2}$ level.

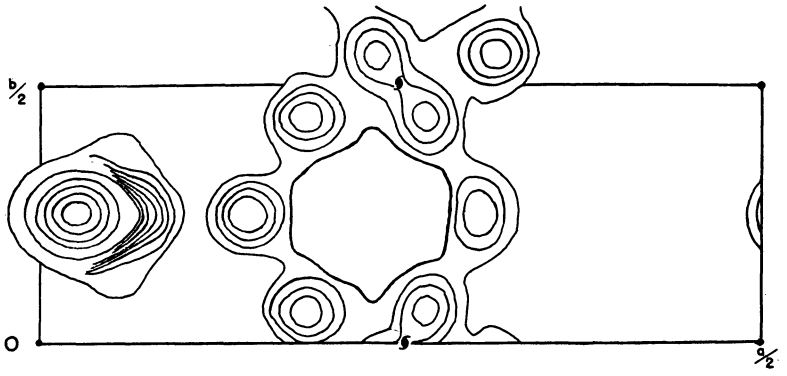

Fig. 2. Electron density projection along the c-axis. Contours intervals are the same as in Fig. 1.

approximate values, $x_N=0.43$ and $\alpha=25°$, from $(0kl)$ reflections.

The electron density projections along the b- and c-axis were then calculated, based on this trial structure, a few terms of doubtful sign being ommitted. They showed all the atoms except nitrogen. Afer three cycles of refinement, there were no terms whose signs were to be changed. The final electron density projections, $\rho(xz)$ and $\rho(xy)$, are shown in Figs. 1 and 2. From the $\rho(xz)$ projection, a more accurate value for $x_{Br}$ was obtained assuming the Gaussian curvature near the peak. Those of the carbon atoms were also obtained graphically from these two projections. As the nitrogen atom in these projections is partially masked by the bromine atom, the location of the nitrogen atom was evaluated by subtracting the observed electron density distribution of the bromine atom from $\rho(xz)_{z=(1/4)}$, assuming that the former has the same distribution along $+X$ and $-X$ from $x_{Br}$. Using the atomic coordinates thus obtained, the discrepancy factors were found to be 11.5% for $(h0l)$ and 11.2% for $(hk0)$ reflections, the overall temperature factor being assumed to be isotropic, with a value 4.0 $Å^2$.

### Refinement of the Structure

Two difference syntheses, $D(xz)$ and $D(xy)$, prepared at this stage indicated an appreciable anisotropy of thermal vibration of the bromine atom, in addition to a slight shift of the atomic coordinates for each atom. The bromine parameter was refined, using mainly $(h0l)$ reflections, and those of the other atoms were made, using both $(h0l)$ and $(hk0)$ reflections. Since the direction of the maximum vibration of the bromine atom is along the c-axis, its atomic scattering factor can be given by[7]

$$f_{Br}=f_{Br}\text{ (free atom) }\exp(-\gamma)$$
$$\gamma=(A+B\sin^2\varphi)\sin^2\theta/\lambda^2$$

where $\varphi$ is the angle between $\boldsymbol{a}$ and $\boldsymbol{h}$, and $A$ and $B$ are unknown quantities to be determined. In order to allow for the anisotropic vibration of the bromine atom, the variation of the temperature parameter with $\varphi$ was first determined

7) E. W. Hughes, *J. Am. Chem. Soc.*, 63, 1717 (1941).

in the following way. The contributions of the carbon and nitrogen atoms were subtracted from the observed structure factors to give a set of $F'_O$ values. These $F'_O$ values were divided into groups with $\varphi=0\sim15°$, $15\sim30°$,……, $75\sim90°$, and for each group $\gamma$ was obtained from a plot, log $F_{Br}/F'_O$ against $(\sin\theta/\lambda)$, where $F_{Br}$ stands for the calculated bromine contribution without temperature factor. Further refinement followed, assuming that the temperature factors for the carbon and nitrogen atoms were the same and isotropic.

At this stage, the secondary extinction effect was corrected using the equation[8], $I_o=I_c \exp(-gI_c)$.

Finally the contributions of the hydrogen atoms were allowed for. It was assumed that the hydrogen atoms attached to the carbon atoms were located in the outward directions bisecting the angle between consecutive C–C bonds, at a distance 1.05 Å, and that the hydrogen atoms attached to the nitrogen atom were distributed tetrahedrally with respect to the C–N bond, at a distance 1.01 Å. It was further assumed that these hydrogen atoms were rotating freely around the C–N bond as in the case of methylammonium chloride[9]. Now the contribution from the rotating hydrogen atoms to the structure factor can be written by

$$\pm 12 f_H \exp -(\sin\theta/\lambda)^2 B_H \times J_o(K \sin\theta/\lambda) \begin{matrix}\cos 2\pi h x_H \\ \sin 2\pi h x_H\end{matrix}$$

where $J_o$ is the zeroth order Bessel function and the argument $K$ is $4\pi r_o \sin\theta_o$. In this expression, $r_o$ and $\theta_o$ are the radius of the orbit and the angle between $\boldsymbol{a}$ and $\boldsymbol{h}$ respectively, and $x_H$ is the common $x$ parameter for hydrogen atoms. The temperature factor for hydrogen, $B_H$, was assumed to be isotropic with a value 6.5 Å$^2$. The agreement between observed and calculated strucrure factors was found definitely improved especially for lower order reflections. The discrepancy factors were decreased to 7.9% and 6.5% for $(h0l)$ and $(hk0)$ reflections, including all the non-observed terms up to $\sin\theta/\lambda = 0.67$. The final positional parameters and temperature factors for each atom are listed in Table II. The interatomic distances and bond angles calculated from these positional parameters are given in Tables III and IV. In Tables V and VI, the observed and calculated structure factors for $(h0l)$ and $(hk0)$ reflections are given.

## Discussion

The crystal structure of aniline hydrobromide can be said to belong to a distorted CsCl-type, consisting of bromine and anilinium ions. The $C_2$–$C_3$ distance in the benzene ring is slightly shorter than the other C–C distances. The $C_1$–N distance is 1.47 Å, suggesting a single bond nature.

The structue can also be described as built up with alternating layers, parallel to the (100) plane, one layer containing anilinium ions and the other bromine ions. The structure may further be taken as a superstructure along the a-axis, since every other layer contains anilinium ions in different orientations, as can be seen in Fig. 4. The inclination of the benzene ring to the plane (010) is ±22.5°, so that the angle between the neighboring benzene rings is 45°. The bromine ions lie nearly on the same plane, the deviation from the plane being 0.386 Å.

The shortest intermolecular atomic distances are found between carbon atoms. These distances (see Table IV) are somewhat shorter than the usually accepted van der Waals' contact, 3.70 Å.

Between the consecutive layers, the strongest interactions will be those between the bromine ion and the nitrogen atom of the anilinium ion. Each bromine ion is surrounded by four nitrogen atoms, and each nitrogen atom by four bromine ions, which from a rhomb parallel to

···Br. The cleavage plane, (001), is also perpendicular to this longer distance.

Since the anilinium ion in this structure should have the two-fold rotational symmetry demanded by the space group, the three hydrogen atoms bound to the nitrogen atom must occupy statistical positions by some means.

Two plausible models of arrangement of these three hydrogen atoms are shown in Fig. 5. Case A, in Fig. 5, includes two strong and one weak hydrogen bonds. On the other hand, in case B there are one strong and two weak hydrogen bonds. These are the two extremes. A model of free rotation around the C–N axis is another extreme. This model of free rotation was incorporated into the structure factor calculations as described in the section of refinement.

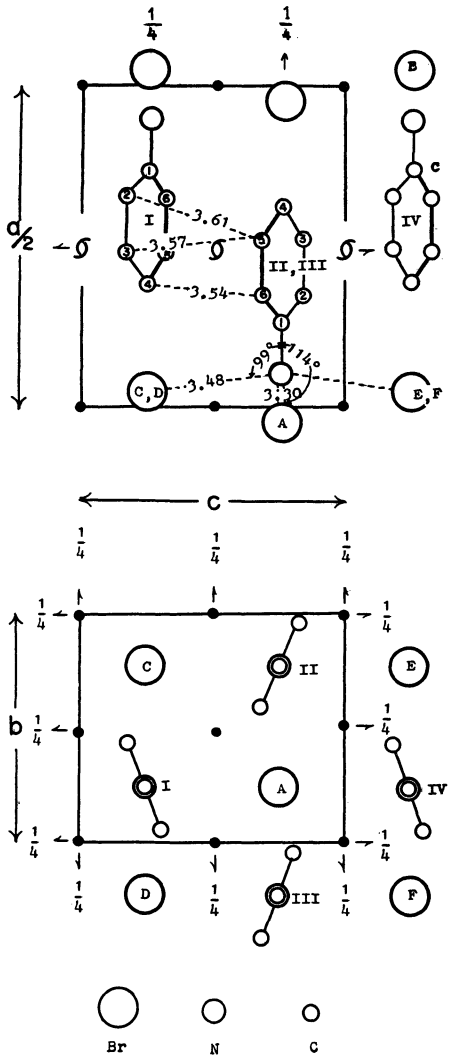

Fig. 3. The structure of the orthorhombic aniline hydrobromide projected on to the (010) and (100) planes.

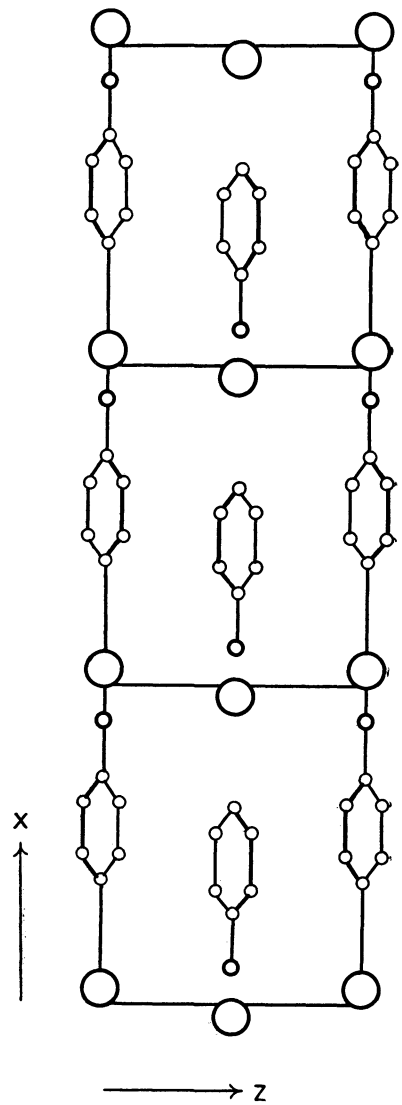

Fig. 4. A schematic representation of the superstructure along the b-axis.

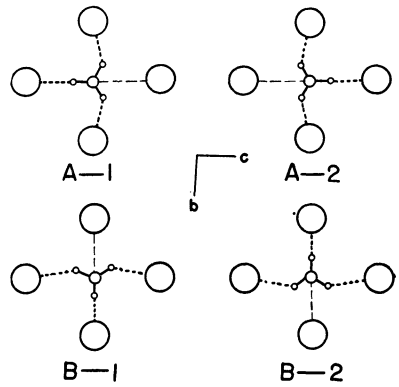

Fig. 5. Statistical arrangements of the three hydrogen atoms bound to the nitrogen atom.

Now, the actual structuer may be represented by an average of all the possible states arising from these extremes stated above, with an appropriate weight on each. Such a statistical arrangement of the hydrogen atoms will vanish when the phase transition takes place.

The mean temperature factor is 5.8 Å$^2$. This value is considerably large for a crystal whose melting poing is as high as 283°C. The temperature factors and melting points of several related compounds are listed in Table VI. That these amine hydrohalides have large thermal vibration and relatively high melting points will probably be due to the partially ionic and partially molecular character of these compounds. The large thermal motion will arise from their molecular character, whereas the ionic character will be responsible for their high melting points. It is interesting to note that these amine hydrohalides have these common characteristics notwithstanding their different crystal structures.

Let us now compare the crystal structure of aniline hydrobromide with those of alkylamine hydrohalides. Both methyl- and propyl-ammonium chlorides crystallize in the tetragonal system, and the alkylammonium ions are characterized by the four-fold axial symmetry. In methylammonium chloride, the three hydrogen atoms attached to nitrogen occupy statistical positions, or they are in rotation. In propylammonium chloride, not only these hydrogen atoms but also the nitrogen and carbon atoms, too, are rotating. The difference between the four-fold axial symmetry of the alkylammonium ions and the two-fold axial symmetry of the anilinium ions may be due to the difference in their molecular shape. All these crystals are apolar, so that their structures can be described as an alternating disposition or antiparallel arrangement of dipoles along their principal axes. The nitrogen atoms in these alkylammonium chlorides have four halogen atoms as their immediate neighbors, so also the nitrogen atoms in aniline hydrobromide, though these four distances in the latter are not exactly the same.

There are some indications of a possible hindered oscillation of the anilinium ion around its longest axis. The final difference projection, $D(xz)$, shows that the temperature factors of $C_2$ and $C_3$ are larger than those of $C_1$ and $C_4$. Some reflections such as (112) whose structure factors have contributions from $C_2$ and $C_3$ alone are associated with diffuse spots, presumably due to the thermal motion stated above.

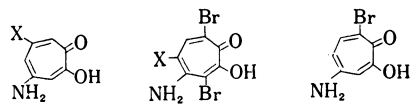
# *Some Electrophilic Substitution Reactions of 4-Aminotropolone**

By Kozo Doi



(Received March 29, 1961)

In the course of investigations of 4-aminotropolone (I) and its derivatives, the author has established general methods of their syntheses, which include amination of 3-iodotropolones with potassium amide in liquid ammonia[1], applications of the Schmidt reaction to acetyl-, formyl- and isopropenyltropolones[2] and of the Curtius reaction to 4-carboxytropolones[1], and amination of 4-bromotropolone with aqueous ammonia[3].

On the other hand, there have been little informations on reactivities of 4-aminotropolones except on a diazotization of 4-amino-6-methyltropolone (II)[4], whereas the reactions of the isomeric 3- and 5-amino derivatives have been much investigated[5]. Recently the author has reported in brief the synthetic applications of I, involving preparations of some pyridotropolones[6] and of 4-aminotropone[7]. In this communication the author wishes to take up some electrophilic substitution reactions of the aminotropolone (I).

I: X=H III: X=Br IV
II: X=Me V: X=H

On bromination the aminotropolone (I) has been found to give nuclear substitution products in the same manner as many other tropolones. For example, in the presence of sodium acetate as a hydrogen bromide acceptor, I consumes three molar equivalents of bromine to afford in a good yield the tribromotropolone (III). On the other hand, in the absence of any hydrogen bromide acceptor, I reacts with one molar equivalent of bromine to give not only a monobromo derivative, IV, which was identified with that obtained from an application of the Schmidt reaction to the known 6-acetyl-3-bromotropolone[2], but also a dibromo compound, V, whose respective yield is better in the latter than the former. Such a preferential formation of dibromo compound by one molar equivalent of bromine has also been observed in the case of tropolone itself[5].

In Fig. 1 are indicated the ultraviolet absorption spectra of the above two substitution products, III and V, comparing with that of the monobromo compound IV. Tsuboi[8] observed that an introduction of one bromine atom into the 3 (or 7)- and 5-position of tropolone caused a red shift of the maximum in the longest wavelength by 10 and 15 mμ, respectively. Now, the above three bromotropolones (III, IV and V) have the maximum in the longest wavelength at 410, 380 and 390 mμ, respectively. The difference of the maxima of V and IV is 10 mμ, and that of III and V is 20 mμ, the fact of which suggests that the dibromotropolone (V) may be a 3, 7-dibromo derivative rather than a 3, 5-dibromo one.

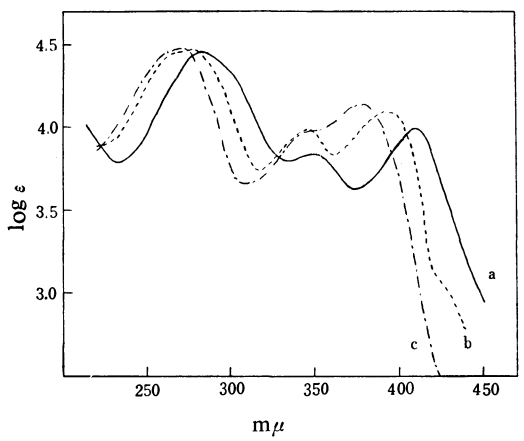

Fig. 1. The ultraviolet absorption spectra.
(a): 4-Amino-3, 5, 7-tribromotropolone (III)

(c): 6-Amino-3-bromotropolone (IV)

8) M. Tsuboi, This Bulletin, 25, 369 (1952).

The position of the two bromine atoms of the dibromo compound V is also understood from a comparison of the characteristic bands due to the CH out-of-plane vibration (864cm$^{-1}$) with those of some other 3, 4, 7-trisubstituted tropolones, which possess bands in the 820~875 cm$^{-1}$ region[9], in the infrared absorption spectra. Table I indicates frequencies of the CH out-of-plane vibration of V, comparing with those of some other 3, 4, 7-trisubstituted tropolones.

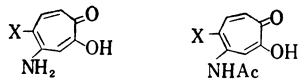

Table I. Frequencies of the CH out-of-plane vibration of some 3,4,7-trisubstituted tropolones

| Compound | $\nu_{CH}$ cm$^{-1}$ | Ref. |
|---|---|---|
| 4-Amino-3, 7-dibromotropolone (V) | 864 | |
| 4-Isopropyl-3, 7-dibromotropolone | 835 | 10 |
| 7-Bromo-3-iodo-4-methyltropolone | 847 | 11 |
| 7-Bromotropolone-3, 4-dicarboxylic anhydride | 872 | 12 |
| 7-Hydroxytropolone-3, 4-dicarboxylic anhydride | 882 | 12 |

4-Aminotropolone (I), differing from its isomeric 3- and 5-amino derivatives, has been found to be fairly stable in pace of the action of nitric acid. Thus an attempt to obtain a nitro compound from I in an usual reaction condition for nitration of tropolones causes to yield not any substitution product but merely a nitrate, possessing a composition of $C_7H_7O_2N \cdot HNO_3 \cdot H_2O$. With fuming nitric acid, however, I reacts vigorously to form in a poor yield 4-amino-5-nitrotropolone (VI), whose structure was confirmed by the fact that the ultraviolet absorption is practically identical with that of the product obtained by an application of the Schmidt reaction to 4-acetyl-5-nitrotropolone[2].

In order to obtain further informations with respect to orientation of electrophilic substitution, nitration has also been carried out on 4-acetylaminotropolone (VII), which is readily prepared from the reaction of I and acetyl chloride in pyridine. Nitration of VII with fuming nitric acid in an acetic acid solution gives also a 5-nitro derivative, VIII, whose structure is confirmed by the formation of VI on its alkaline hydrolysis.

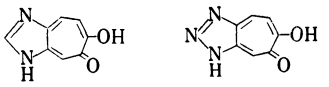
VI: X=$NO_2$ VII: X=H
IX: X=$NH_2$ VIII: X=$NO_2$
X: X=*p*-Tolylazo



The absorption maximum at 400 mμ (log ε 3.90) of VIII indicates more decreased values both in wavelength and absorption intensity than that at 435 mμ (log ε 4.41) of 5-nitrotropolone itself[13]. This is not consistent with the bathochromic effect of the acetylamino group, having been attributed recently to the steric inhibition of resonance between the nitro group and the tropolone nucleus by the adjacent acetylamino group[14].

From a catalytic hydrogenation of the 5-nitro derivative VIII over palladized charcoal, 4,5-diaminotropolone (IX) is readily obtained. In the previous paper[2], the author found that an application of the Schmidt reaction to 4-acetyltropolone resulted in the formation of 4-aminotropolone sulfate instead of the expected acetylamino derivative VII, attributing this mechanism to the hydrolyzable nature of VII in the condition employed. Actually it has now been found that the acetylamino compound VII affords easily 4-aminotropolone sulfate on being merely dissolved in concentrated sulfuric acid even at room temperature. This fact justifies the previous mechanism in the Schmidt reaction of the acetyltropolones.

Bromination and nitration of 5-aminotropolones have already been reported, but in no cases has isolation of the substitution products been described[15]. With 3-aminotropolone, some electrophilic substitutions involving bromination, nitration, and azo coupling have been attempted with no isolation of any reaction products[16]. On the contrary, 4-aminotropolone (I) gives easily nuclear substitution products in some electrophilic reactions. This fact is probably considered to be connected with that the amino and hydroxyl groups in the aminotropolone (I) are situated at the positions where they cooperate with each other to increase the reactivity of the tropolone ring, whereas the two groups in the 3- and 5-isomers are not in such positions.

The aminotropolone (I), similarly to the other tropolones, undergoes azo coupling to give a nuclear substitution product of red dyestuff, not a diazoamino derivative. Thus on being treated with diazotized *p*-toluidine in an alkaline solution, I affords in a good yield 4-amino-5-*p*-tolylazotropolone (X), whose hydrogenolysis leads to the diaminotropolone (IX).

In a similar manner to *o*-phenylenediamine, the diamino compound IX gives an imidazole, XI, on being heated with formic acid, and a

XI XII

triazole, XII, on being diazotized. Informations on tautomerism between these reaction products and their possible isomers of the aza-azulene type have not been obtained in detail, but it is probably concluded that they may not be their possible dihydroxy-azaazulene derivatives, since their respective ultraviolet absorption is resembling that of imidazolo[d]tropone[17] and of triazolo[d]tropone[18] (Fig. 2).

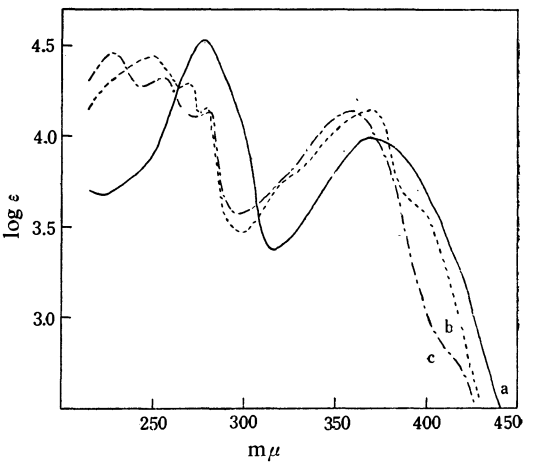


Fig. 2. The ultraviolet absorption spectra.

(c): Triazolo[d]tropolone (XII)

## Experimental

All of the ultraviolet absorption spectra were measured in methanol solution with a Beckman model DU quartz spectrophtometer. The infrared spectra were measured on potassium bromide disks with a Perkin-Elmer model 21 infrared spectrometer, using a rock salt prism.

**Tribromination of 4-Aminotropolone (I).**—To a stirred mixture of I (70 mg.), sodium acetate trihydrate (200 mg.) and methanol (2 ml.) was added dropwise a cold solution of bromine (240 mg.) in methanol (2 ml.). The reaction mixture was

diluted with water, and the precipitated solid, after collection by filtration, sublimation in vacuo, and subsequent recrystallization from acetic acid, gave 4-amino-3, 5, 7-tribromotropolone (III, 160 mg.) as yellow needles, m. p. 203°C.

Found: N, 3.80. Calcd. for $C_7H_4O_2NBr_3$: N, 3.75%.

$\lambda_{max}$ mμ (log ε): 282 (4.47), 350 (3.84), 410 (4.00).

**Monobromination of I.**—To a stirred cold solution of I (0.41 g.) in methanol (10 ml.) was added dropwise a solution of bromine (0.48 g.) in methanol (2 ml.). After 30 min., the solution was evaporated in vacuo, the residue was diluted with water (5 ml.), and the deposited solid, after collection by filtration, was crystallized fractionally from methanol to give less soluble 4-amino-3,7-dibromotropolone (V, 016 g.) as yellow prisms, m. p. 224~225°C.

Found: N, 5.01. Calcd. for $C_7H_5O_2NBr_2$: N, 4.75%.

$\lambda_{max}$ mμ (log ε): 276 (4.46), 345 (3.99), 390 (4.10). From the more soluble portion, 6-amino-3-bromotropolone (IV) as yellow needles, m. p. and mixed[2] m. p. 214°C, was obtained. Further bromination of the preceding products, IV and V, afforded respectively the tribromotropolone (III).

**Nitration of 4-Aminotropolone (I).**—a) To a stirred solution of I (0.41 g.) and acetic acid (3 ml.) was added dropwise at room temperature a solution of fuming nitric acid (0.2 g., *d* 1.84) and acetic acid (1 ml.). After evaporation of the solvent, the residual solid was recrystallized from a mixed solvent of acetic acid and methanol to give 4-aminotropolone nitrate (0.26 g.) in the form of colorless needles, m. p. 163~164°C (decomp.).

Found: C, 41.96; H, 4.06; N, 13.80. Calcd. for $C_7H_7O_2N \cdot HNO_3 \cdot H_2O$: C, 42.00; H, 4.03; N, 14.00%. This substance is soluble in water and its aqueous solution decomposes sodium hydrogen carbonate.

b) Addition of fuming nitric acid (0.2 g.) to the aminotropolone (I, 0.41 g.) resulted in a vigorous reaction to form a deep red solution, which was immediately chilled in ice and allowed to stand for 30 min. Then this solution was diluted with water (2 ml.), the residual solid was collected by filtration, and crystallized from acetic acid to yield 4-amino-5-nitrotropolone (VI) as yellow needles, m. p. above 300°C, which was identified with an authentic specimen[2] through ultraviolet absorption.

**4-Acetylaminotropolone (VII).**—After acetyl chloride (3.1 g.) was added dropwise during 10 min. to a stirred cold solution of I (2.8 g.) in pyridine (10 ml.), the reaction mixture was allowed to stand for 4 hr. The mixture was diluted with water, allowed to stand overnight, and then acidified to Congo red with dilute hydrochloric acid. The solid which separated on chilling this mixture was collected and recrystallized from methanol to afford 4-acetylaminotropolone (VII, 2.2 g.) as colorless needles, m. p. 166~167°C.

Found: C, 55.43; H, 5.33; N, 7.14. Calcd. for $C_9H_9O_3N \cdot H_2O$: C, 54.82; H, 5.62; N, 7.10%.

$\lambda_{max}$ mμ (log ε): 267 (4.54), 365 (3.84).

**4-Acetylamino-5-nitrotropolone (VIII).**—To a stirred mixture of VII (1.3 g.) and acetic acid (4 ml.) was added dropwise at room temperature a solution of fuming nitric acid (0.5 g.) and acetic acid (1 ml.), the deep red solution so formed was allowed to be stirred for further 1 hr., diluted with water (40 ml.), and extracted with four 25-ml. portions of ether. The ether extract, after evaporation of the solvent followed by recrystallization from a mixed solvent of acetic acid and methanol, gave VIII (0.46 g.) as yellow needles, m. p. 230°C (decomp.).

Found: C, 48.53; H, 3.88; N, 12.31. Calcd. for $C_9H_8O_5N_2$: C, 48.53; H, 3.60; N, 12.50%.

$\lambda_{max}$ mμ (log ε): 274 (4.53), 400 (3.90).

**Hydrolysis of VIII.**—A mixture of VIII (0.2 g.), potassium hydroxide (0.2 g.), and water (8 ml.) was heated at 60°C on a water bath for 30 min., and then the resulting red solution was acidified with dilute hydrochloric acid to separate the aminotropolone (VI, 0.15 g.), whose structure was confirmed by the comparison of the ultraviolet absorption with that of an authentic sample[2].

**4, 5-Diaminotropolone (IX).**—A mixture of the nitroamine (VI, 0.18 g.), 5% palladium-on-carbon (50 mg.) and methanol (100 ml.) was shaken in an hydrogen atmosphere until the uptake of hydrogen had ceased. Then the catalyst was removed by filtration, the filtrate evaporated in vacuo, and the residue crystallized twice from ethyl acetate to give 4,5-diaminotroplone (IX, 60 mg.) as yellow prisms, m. p. 215°C (decomp.).

Found: C, 54.98; H, 5.21; N, 18.57. Calcd. for $C_7H_8O_2N_2$: C, 55.25; H, 5.30; N, 18.41%.

$\lambda_{max}$ mμ (log ε): 278 (4.54), 371 (3.99).

**4-Amino-5-*p*-tolylazotropolone (X).**—A diazonium chloride solution prepared from *p*-toluidine (2 g.) was added dropwise during 10 min. to a stirred cold solution of I (2.8 g.), potassium hydroxide (6 g.) and water (100 ml.). After 30 min., the reaction mixture was acidified with acetic acid, the solid which separated was collected, and recrystallized from ethyl acetate to afford X (4.5 g.) of red needles, m. p. 230°C (decomp.).

Found: N, 16.22. Calcd. for $C_{14}H_{13}O_2N_3$: N, 16.46%.

$\lambda_{max}$ mμ (log ε): 260 (4.37), 300 (4.38), 375 (4.11), 470 (4.41).

Hydrogenation of X in methanol over 5% palladized carbon afforded easily a diamino derivative IX.

**Imidazolo[d]tropolone (XI).**—A mixture of IX (0.15 g.) and 80% formic acid (10 ml.) was heated under reflux for 2 hr., the solvent was evaporated to dryness, and the residue, after sublimation in vacuo, was recrystallized from acetic acid to give XI (60 mg.) of colorless prisms, m. p. above 275°C

Found: C, 59.08; H, 3.55; N, 17.60. Calcd. for $C_8H_6O_2N_2$: C, 59.26; H, 3.73; N, 17.28%.

$\lambda_{max}$ mμ (log ε): 250 (4.44), 268 (4.28), 280 (4.14), 372 (4.14).

**Triazolo[d]tropolone (XII).**—A solution of sodium nitrite (60 mg.) in water (1 ml.) was added dropwise during 5 min. to a stirred cold solution of IX (0.15 g.), acetic acid (0.2 ml.), concentrated hydrochloric acid (0.4 ml.) and water (6 ml.). After 2 hr., the mixture was diluted with water (40 ml.), neutralized with sodium hydrogen carbonate, and extracted continuously with ether for 5 hr. The ether extract, after evaporation of the solvent, sublimation of the residue in vacuo followed by

crystallization from acetic acid, gave XII (50 mg.) of colorless prisms, m. p. 265°C (decomp.).

Found: C, 51.20; H, 2.98; N, 25.78. Calcd. for $C_7H_5O_2N_3$: C, 51.54; H, 3.09; N, 25.76%.

$\lambda_{max}$ m$\mu$ (log $\varepsilon$): 228 (4.48), 256 (4.34), 282 (4.14), 360 (4.17).

The author wishes to express his sincere gratitude to Professor Yoshio Kitahara for his kind guidance throughout the course of the present experiment, to Mr. Hideji Aono for the infrared spectral measurements, and to Messrs. Shin-ichi Ohyama, Kuni Kato and Ayako Iwanaga for microanalyses.

# *Molecular Rotations of Terpenes in Relation to their Structures. I. The Internal Conformation of Isopropyl Group in Menthol-like Substance*[1]

By Shukichi YAMANA

(Received December 27, 1960)

In liquid or dissolved state, $C^9H_3$ and $C^{10}H_3$ in the isopropyl group of menthol-like substance are considered to be free to rotate about the axis of $C^4$-$C^8$ bond and the position which has minimal potential and makes these methyl groups rest, may be decided by steric repulsions and intramolecular van der Waals' forces etc. between the atoms in the molecule (Fig. 1).

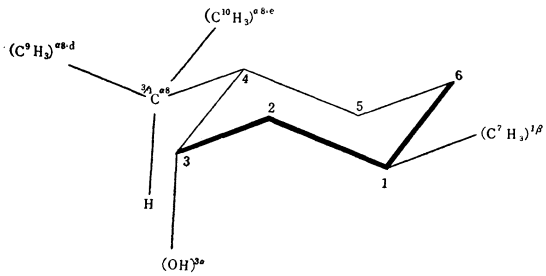

Fig. 1[2]. Perspective drawing of the molecular model of (+)neomenthol.

On the other hand, by uing the PM-method, the author recently tried to explain the molecular rotations of polyhydroxycyclohexanes[3,4]. From the standpoint of the fact that a menthol-like substance is a kind of polyhydroxy (or monohydroxy)-cyclohexane, the type of the internal conformation of its isopropyl group at an equilibrium state, above mentioned, is discussed in this article.

1) Presented at the Symposium on the Structural Chemistry of the Chemical Society of Japan, Sapporo, August, 1960.

2) $C^{\alpha 8}$-Atom is $C^8$-atom which is situated in $\alpha$-orientation (i. e. under the cyclohexane-ring in Fig. 1). $(CH_3)^{\alpha 8}$ means the $CH_3$ group which combines with $C^{\alpha 8}$-atom. Concerning the symbols, d- and e-, refer to "Method Proposed" in this article.

3) S. Yamana, This Bulletin, 33, 1741 (1960).

## Molecular Model and Data Used

According to Jefferies' investigation of menthol-like substances by infrared spectrum[5], it was concluded that in their molecules, isopropyl group usually takes equatorial orientation and that two methyl groups repulse each other. Referring to Jefferies' work, only the compounds which have a six-membered ring of C 1 conformation are treated in this article.

The unit groups in their molecules and their corresponding molecular rotations are given in Table I.

The molecular model and the optical properties of the hydroxyl group (except the value of $\zeta$-coefficient), used in the preceding article[3] were adopted here without any correction. Values of mean polarizability $\alpha$ and of anisotropy ratio $\beta$ of methyl group are $2.27\times10^{-24}$ (cc.) and 0.35 respectively[17]. The optical

4) In the previous paper[3], by using $[M]_D^{20}$(W) of (−) 1, 3/2, 4 cyclohexanetetrol, the value of $(\zeta_{OH})^2$ was calculated as 3.6402 $\{3/(n^2+2)\}$. But strictly speaking, it was apparent there that if 3.6402 $\{3/(n^2+2)\}$ is used, $\sum[\mu]_{Dobs}^{20}$ of (−)1/2 cyclohexanediol becomes somewhat smaller than its corresponding $[M]_D^{20}$(W) and $\sum[\mu]_{Dobs}^{20}$ of (+) 3, 5, 6/1, 2, 4 cyclohexanehexitol becomes somewhat larger than its corresponding $[M]_D^{20}$(W). That fact can be explained superficially by the assumption of the changeability of $(\zeta_{OH})^2$ according to the number of hydroxyl groups in a molecule. When $[M]_D^{20}$(W) of (−) 1/2 cyclohexanediol is used, the value of $\zeta_{OH}^2$ is calculated as follows;

$$\sum[\mu]_{Dobs}^{20} \text{ of } (-)\ 1/2 \text{ cyclohexanediol} = (OH)\cdot {}^{1\beta}\chi(OH)^{2\alpha} + (OH)^{1\beta}\chi\text{ch.R} + (OH)^{2\alpha}\chi\text{ch.R}$$

$$= -11.73\{(n^2+2)/3\}\zeta_{OH}^2 + 0 + 0 \equiv -48.2$$

$$\therefore\ \zeta_{OH}^2 = 4.1091\{3/(n^2+2)\} \qquad (4)^*$$

(Ref. Tables I and II of the previous paper[3]).

center of a unit group is located at the center of the mass of its corresponding bond. In order to simplify the calculations, the refractive indices of the homogeneous substances and of the solutions under discussion are all assumed to be about 1.46[18].

## Method Proposed

Strictly speaking, as isopropyl group has no optical axis of cylindrical symmetry, the calculations of $[\mu]^{20}_{D\,calcd}$ which are concerned with isopropyl group are impossible. In order to avoid this difficulty, the following two simplifications are introduced.

Simp. I

$$(iso\text{-}C_3H_7)^{4\alpha} = (C^8H)^{4\alpha} + (C^9H_3)^{\alpha 8} + (C^{10}H_3)^{\alpha 8} \simeq^{2)} (C^8H_3)^{4\alpha} + (C^9H_3)^{\alpha 8} + (C^{10}H_3)^{\alpha 8}$$

Simp. II

$$(iso\text{-}C_3H_7)^{4\alpha}\chi A = \{(C^8H)^{4\alpha} + (C^9H_3)^{\alpha 8} + (C^{10}H_3)^{\alpha 8}\}\chi A \simeq (C^8H)^{4\alpha}\chi A + (C^9H_3)^{\alpha 8}\chi A + (C^{10}H_3)^{\alpha 8}\chi A$$

From Simps. I and II,

$$(iso\text{-}C_3H_7)^{4\alpha}\chi A \simeq (C^8H_3)^{4\alpha}\chi A + (C^9H_3)^{\alpha 8}\chi A + (C^{10}H_3)^{\alpha 8}\chi A \quad (1)$$

Next, the positions of minimal potential for $(C^9H_3)^{\alpha 8}$ or $(C^{10}H_3)^{\alpha 8}$ will be mentioned. Referring to the steric repulsion between one of these methyl groups and the C-atom in the cyclohexane-ring ($C^3$- and $C^5$-atoms), it can be easily understood that there should be three positions of minimal potential for methyl groups. The author names these three positions d-, e- and f-positions, respectively (Fig. 2).

But, d-position is trans to $C^4$–$C^5$ bond and e-position is trans to $C^4$–$C^3$ bond and f-position is gauche to both $C^4$–$C^5$ and $C^4$–$C^3$ bonds. As

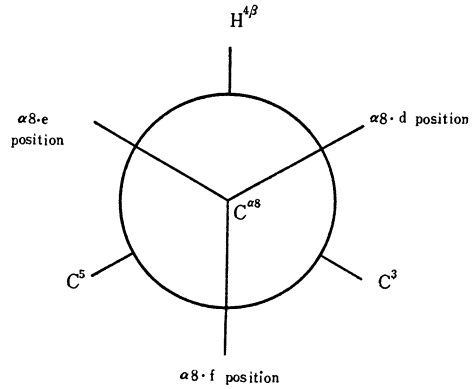

Fig. 2. Positions of minimal potential of $CH_3$ in $iso\text{-}C_3H_7$, viewed along $C^{\alpha 8}$–$C^4$ axis.

6) $[M]^{20}_D$ of pure materials in liquid state or of chloroform solutions are adopted, preferentially. Some values were presumed from $[M]_D$ which had been observed in the neighborhood of 20°C. (Ref. 3).

7) ch. R is an abbreviated symbol of a cyclohexane-ring.

17) S. Yamana, This Bulletin, **31**, 564 (1958).

18) The refractive index, $n$, is as follows; homogeneous state (1.46), chloroform solution (1.45), acetone solution (1.36), ethyl alcohol solution (1.36). If $n$ changes from 1.46 to 1.36, $\{(n^2+2)/3\}$ changes by $\partial/\partial n\{(n^2+2)/3\}\delta n \simeq 0.0973$. The magnitude of this value of $\{(n^2+2)/3\}$-change is about 7% of the value of $\{(n^2+2)/3\} \simeq 1.3772$.

movable groups in isopropyl group are $(C^9H_3)^{\alpha 8}$, $(C^{10}H_3)^{\alpha 8}$ and one H atom, it is obvious that any two of these three positions (d-, e- and f-positions) must be occupied by two methyl groups and the remaining one position should be occupied by one H atom. Then, the following three types of the internal conformation of $(iso\text{-}C_3H_7)^{4\alpha}$ are possible (Table II).

TABLE II. THE TYPE OF THE INTERNAL CONFORMATION OF $(iso\text{-}C_3H_7)^{4\alpha}$

| Name of type | $\alpha 8$·d-Position | $\alpha 8$·e-Position | $\alpha 8$·f-Position |
|---|---|---|---|
| Symmetrical | $CH_3$ | $CH_3$ | H |
| Unsymmetrical I | H | $CH_3$ | $CH_3$ |
| Unsymmetrical II | $CH_3$ | H | $CH_3$ |

**Substances which Have $(OH)^{3\alpha}$.**—It is apparent in Table III that the distance between O-atom in $(OH)^{3\alpha}$ and f-position is 2.52 Å and is shorter than the sum of van der Waals' radius of methyl group and that of $(OH)^{3\alpha}$.

TABLE III. THE DISTANCES BETWEEN O-ATOM IN $(OH)^3$ AND THREE POSITIONS OF MINIMAL POTENTIAL OF METHYL GROUP IN $(iso\text{-}C_3H_7)^{4\alpha}$

| | $\alpha 8$·d-Position | $\alpha 8$·e-Position | $\alpha 8$·f-Position |
|---|---|---|---|
| $(OH)^{3\alpha}$ | 3.49 Å | 4.30 Å | 2.52 Å |
| $(OH)^{3\beta}$ | 2.52 Å | 4.30 Å | 3.49 Å |

Then, owing to the steric repulsion, $(OH)^{3\alpha}$ may refute the idea that any movable methyl group in isopropyl group stays at f-position. In this case, the symmetrical type is only one possible type of the internal conformation of isopropyl group. For these reasons, it is concluded that in $(iso\text{-}C_3H_7)^{4\alpha}$ of (+)neomenthol in the liquid or dissolved state, two $(CH_3)^{\alpha 8}$'s are forced to stay at d- and e-positions (Fig. 1).

$$\therefore\ (iso\text{-}C_3H_7)^{4\alpha} = (C^8H)^{4\alpha} + (C^9H_3)^{\alpha 8\cdot d}\ ^{20)} + (C^{10}H_3)^{\alpha 8\cdot e} \simeq (C^8H_3)^{4\alpha} + (C^9H_3)^{\alpha 8\cdot d} + (C^{10}H_3)^{\alpha 8\cdot e}\ ^{21)} \quad (2)$$

Referring to Table I and Eq. 2, $\sum [\mu]^{20}_{D\ obs}$ of (+)neomenthol can be calculated by the following equation.

$$\begin{aligned}\sum [\mu]^{20}_{D\ obs} \text{ of (+)neomenthol} &= (CH_3)^{1\beta}\text{⅄}(OH)^{3\alpha} + (CH_3)^{1\beta}\text{⅄}(CH_3)^{4\alpha} + (CH_3)^{1\beta}\text{⅄}(CH_3)^{\alpha 8\cdot d} + (CH_3)^{1\beta}\text{⅄}(CH_3)^{\alpha 8\cdot e} \\ &+ (CH_3)^{1\beta}\text{⅄ch. R} + (OH)^{3\alpha}\text{⅄}(CH_3)^{4\alpha} \\ &+ (OH)^{3\alpha}\text{⅄}(CH_3)^{\alpha 8\cdot d} + (OH)^{3\alpha}\text{⅄}(CH_3)^{\alpha 8\cdot e} \\ &+ (OH)^{3\alpha}\text{⅄ch. R} + (CH_3)^{4\alpha}\text{⅄}(CH_3)^{\alpha 8\cdot d} \\ &+ (CH_3)^{4\alpha}\text{⅄}(CH_3)^{\alpha 8\cdot e} + (CH_3)^{4\alpha}\text{⅄ch. R} \\ &+ (CH_3)^{\alpha 8\cdot d}\text{⅄}(CH_3)^{\alpha 8\cdot e} + (CH_3)^{\alpha 8\cdot d}\text{⅄ch. R} \\ &+ (CH_3)^{\alpha 8\cdot e}\text{⅄ch. R} \quad (3)\end{aligned}$$

On the other hand, $[\mu]^{20}_{D\ calcd}\{3/(n^2+2)\}$, caused by the dynamical coupling effect between any two members of unit groups in menthol-like substance, can be calculated by using the theoretical formulae[19]. The results of calculation are shown in Table IV.

By using Table IV, Eq. 3 is rewritten as follows;

$$\begin{aligned}\sum [\mu]^{20}_{D\ obs} \text{ of (+)neomenthol} &= (-4.04\zeta'_{CH_3}\zeta'_{OH}{}^{22)} + 0 - 4.41\zeta'^2_{CH_3} + 4.41\zeta'^2_{CH_3} + 0 + 25.30\zeta'_{CH_3}\zeta'_{OH} + 3.09\zeta'_{CH_3}\zeta'_{OH} - 4.04\zeta'_{CH_3}\zeta'_{OH} + 0 + 0 + 0 + 0 + 0)\{(n^2+2)/3\} + D - D \\ &= 20.31\zeta'_{CH_3}\zeta'_{OH}\{(n^2+2)/3\}\end{aligned}$$

The corresponding observed value is 30.6[23].

$$\therefore\ 20.31\zeta'_{CH_3}\zeta'_{OH}\{(n^2+2)/3\} \equiv 30.6$$

or

$$\zeta'_{CH_3}\zeta'_{OH} = 1.5066\{3/(n^2+2)\} \quad (4)$$

On the other hand, the value of $\zeta_{CH_3}\zeta_{OH}$ in the case of hydroxycyclohexane can be calculated by using (−)*trans*-2-methylcyclohexanol as below;

$$\begin{aligned}\sum [\mu]^{20}_{D\ obs} \text{ of (−)}trans\text{-2-methylcyclohexanol} &= (OH)^{1\beta}\text{⅄}(CH_3)^{2\alpha} + (OH)^{1\beta}\text{⅄ch. R} + (CH_3)^{2\alpha}\text{⅄ch. R}^{23)} \\ &= -25.30\{(n^2+2)/3\}\zeta_{CH_3}\zeta_{OH} + 0 + 0^{24)} \\ &\equiv -42.4\end{aligned}$$

$$\therefore\ \zeta_{CH_3}\zeta_{OH} = 1.6759\{3/(n^2+2)\} \quad (5)$$

The value of $\zeta'_{CH_3}\zeta'_{OH}$ of menthol-like substance, shown in Eq. 4 is almost equal to that of $\zeta_{CH}\zeta_{OH}$ of methylcyclohexanol given in Eq. 5. This fact indicates that the value of $\zeta'_{CH_3}\zeta'_{OH}$ in Eq. 4 is trustworthy. Moreover, by using Eq. 4, $\sum [\mu]^{20}_{D\ obs}$ of (+)*trans*-2-hydroxyneomenthol which has $(OH)^{3\alpha}$ in its molecule is calculated to be 69.5. This calculated value is almost equal to the corresponding observed value, 70.3. This fact may mean that the value of $\zeta'_{CH_3}\zeta'_{OH}$ in Eq. 4 is a suitable one for the calculation of $\sum [\mu]^{20}_{D\ obs}$ of menthol-like substances.

Next, by using a method similar to that described above, an equation can be obtained as follows;

19) S. Yamana, This Bulletin, 30, 203 (1957).

20) $(CH_3)^{\alpha 8\cdot d}$ means $(CH_3)^{\alpha 8}$ which stays at d-position, and so on (Ref. 2).

21) Simp. I is used here.

22) $\zeta'$ is $\zeta$-coefficient of a unit group in the case of menthol-like substance.

23) Ref. Table I.

24) Table IV is used, here.

TABLE IV. $[\mu]^{20}_{D\,calcd}\{3/(n^2+2)\}$, CAUSED BY THE DYNAMICAL COUPLING EFFECT BETWEEN ANY TWO MEMBERS OF UNIT GROUPS IN MENTHOL-LIKE SUBSTANCE OF C 1 CONFORMATION

| | $(CH_3)^{\alpha 8\cdot f}$ | $(CH_3)^{\alpha 8\cdot e}$ | $(CH_3)^{\alpha 8\cdot d}$ | $(CH_3)^{4\alpha}$ | $(OH)^{3\beta}$ | $(OH)^{3\alpha}$ | $(OH)^{2\beta}$ | $(OH)^{2\alpha}$ |
|---|---|---|---|---|---|---|---|---|

| $(CH_3)^{\alpha 8\cdot f}$ | 0 | 0 | 0 | | | | | |

Note: $D$ cannot be calculated, theoretically.

TABLE V. $\sum[\mu]^{20}_{D\,obs}$ OF MENTHOL-LIKE SUBSTANCE

| Name | Type S | Type I | Type II |
|---|---|---|---|
| (−)*trans*-2-Hydroxymenthol | −12.8 | $-29.4-D$ | $-33.0+D$ |
| (−)*cis*-2-Hydroxymenthol | −43.4 | $-45.5-D$ | $-63.4+D$ |
| (−)Isomenthol | −25.7 | $-31.3-D$ | $-35.5+D$ |
| (−)Menthol | −32.0 | $-34.3-D$ | $-45.1+D$ |
| (−)Carvomenthol | −31.0 | $-42.9-D$ | $-40.5+D$ |
| (+)*cis*-1,2-Menthanediol | 19.2 | $6.2-D$ | $10.8+D$ |
| (+)Neocarvomenthol | 38.9 | $41.4-D$ | $29.5+D$ |
| (+)*trans*-1-Hydroxyneocarvomenthol | 38.9 | $40.3-D$ | $30.6+D$ |

S: Symmetrical type, I: Unsymmetrical I type, II: Unsymmetrical II type.

$$\sum[\mu]^{20}_{D\,obs} \text{ of } (-)cis\text{-2-hydroxyneomenthol} \equiv(-11.73\zeta'^{2}_{OH}-0.25\zeta'_{CH_3}\zeta'_{OH}) \times\{(n^2+2)/3\}\equiv-50.6 \quad (6)$$

Combining Eq. 4 with Eq. 6,

$$\zeta'^{2}_{OH}=4.2796\{3/(n^2+2)\} \quad (7)$$

or

$$\zeta'_{OH}=2.0687\{3/(n^2+2)\}^{1/2} \quad (7')$$

The value of $\zeta'^{2}_{OH}$ in Eq. 7 is nearly equal to that of $\zeta^{2}_{OH}$, $4.1091\{3/(n^2+2)\}$ which was obtained for the case of (−)1/2 cyclohexanediol[25]. This fact can easily be understood by considering that both (−)*cis*-2-hydroxyneomenthol and (−) 1/2 cyclohexanediol have only two hydroxyl groups which are adjacent to each other in their molecules. Thus, the value of $\zeta'^{2}_{OH}$ Eq. 7 seems to be reliable. From Eqs. 4 and 7′,

$$\zeta'_{CH_3}=0.7283\{3/(n^2+2)\}^{1/2}$$

and

$$\zeta'^{2}_{CH_3}=0.5304\{3/(n^2+2)\} \quad (8)$$

**Substances which Have $(OH)^{3\beta}$.** — Referring to Table III, the nearest position from O-atom in $(OH)^{3\beta}$ is $\alpha$8·d-position. Then, owing to the steric repulsion, $(OH)^{3\beta}$ may refute the idea that any movable $(CH_3)^{\alpha 8}$ in $(iso\text{-}C_3H_7)^{4\alpha}$ stays at $\alpha$8·d-position. In this case, the internal conformation of $(iso\text{-}C_3H_7)^{4\alpha}$ may be forced to take the unsymmetrical I type. But if an atom or group which combines whith $C^2$-atom attracts $(OH)^{3\beta}$ off $\alpha$8·d-position, the influence of $(OH)^{3\beta}$ on the type of the internal conformation of $(iso\text{-}C_3H_7)^{4\alpha}$ may be greatly weakened. Now, by using Eqs. 4 and 7, $\sum[\mu]^{20}_{D\,obs}$ of the menthol-like substances which have $(OH)^{3\beta}$ are calculated in each type of the internal conformation of $(iso\text{-}C_3H_7)^{4\alpha}$. The results of calculation are shown in the upper part of Table V.

For lack of experimental data in relation to the cyclohexane-ring, $D$ cannot be calculated theoretically. Then, the author resorted to a quasi-empirical evaluation of it. (−)Menthol has $(OH)^{3\beta}$ but it has no atom or group which combines with the $C^2$-atom and attracts $(OH)^{3\beta}$. And moreover, as the orientation of its $(CH_3)^{1\beta}$ is equatorial, the influence of $(CH_3)^{1\beta}$ on the type of the internal conformation of its $(iso\text{-}C_3H_7)^{4\alpha}$ will be very small. Then, the internal conformation of its $(iso\text{-}C_3H_7)^{4\alpha}$ is expected

25) Ref. Eq. 4* in the foot-note 4.

TABLE VI. COMPARISON OF $[M]_D^{20}$ WITH $\sum[\mu]_{D\,obs}^{20}$

| Name | at $C^3$ | $[M]_D^{20}$ [23] | $\sum[\mu]_{D\,obs}^{20}$ S | I | II | % |
|---|---|---|---|---|---|---|

| (−)*cis*-2-Hydroxyneomenthol | $(OH)^{3\alpha}$ | −50.6 | −50.6 | | | 100% S |
| (+)*trans*-2-Hydroxyneomenthol | $(OH)^{3\alpha}$ | 70.3 | 69.5 | | | 100% S |
| (−)*trans*-2-Hydroxymenthol | $(OH)^{3\beta}$ | −16.0 | −12.8 | −72.6 | 10.2 | 95% S + 5% I |
| (−)*cis*-2-Hydroxymenthol | $(OH)^{3\beta}$ | −56.7 | −43.4 | −88.7 | −20.2 | 71% S +29% I |
| (−)Isomenthol | $(OH)^{3\beta}$ | −39.4 | −25.7 | −74.5 | 7.7 | 72% S +28% I |
| (−)Menthol | $(OH)^{3\beta}$ | −77.5 | −32.0 | −77.5 | −1.9 | 100% I |
| (−)Carvomenthol | none | −41.2 | −31.0 | −86.1 | 2.7 | 82% S +18% I |
| (+)*cis*-1,2-Menthanediol | none | 24.1 | 19.2 | −37.0 | 54.0 | 86% S +14% II |
| (+)Neocarvomenthol | none | 65.2 | 38.9 | −1.8 | 72.7 | 22% S +78% II |
| (+)*trans*-1-Hydroxyneocarvomenthol | none | 79.2 | 38.9 | −2.9 | 73.8 | 100% II |

S: Symmetrical type, I: Unsymmetrical I type, II: Unsymmetrical II type.

to be of the unsymmetrical I type. Accordingly, by referring to Table V, $\sum[\mu]_{D\,obs}^{20}$ of (−) menthol should be $(-34.3-D)$. The corresponding observed value is −77.5[23].

$$\therefore \quad -34.3-D\equiv -77.5$$

or

$$D=43.2 \qquad (9)$$

By using Eq. 9, Table V can be rewritten into Table VI.

The seventh column of Table VI indicates the percentage of two types in order to explain the corresponding observed value. But, as the observed value, $[M]_D^{20}$, has some probable errors and the calculated value, $\sum[\mu]_{D\,obs}^{20}$, was obtained by using some assumptions, the absolute values of the percentage in the seventh column should not be considered to be conclusive. Thus, it becomes apparent that even in this series, the symmetrical type can be prevalent when there are some groups which attract $(OH)^{3\beta}$ or to not allow any $(CH_3)^{\alpha 8}$ to say at the $\alpha 8$·f-position. But the ratio of these two types is affected greatly by the orientations of the other atoms or groups in the molecules.

**Substances which Have no (OH)$^3$.**—By using a method similar to those mentioned above, $\sum[\mu]_{D\,obs}^{20}$ of the substances which have not $(OH)^3$ are calculated and the results are shown in the lower parts of Tables V and VI. In this case also, the symmetrical type is prevalent. But it is strange that in (+)neocarvomenthol and (+)*trans*-1-hydroxyneocarvomenthol, the unsymmetrical II type is prevalent among the three types. This may mean that there is a kind of intramolecular (or intermolecular) van der Waals' attractive force between $(CH_3)^{\alpha 8}$ and the hydroxyl group which combines with the $C^2$- or $C^1$-atom, but this point is left for future study.

## Summary

From the standpoint of the fact that a menthol-like substance is a kind of hydroxycyclohexane, the molecular rotations of menthol-like substances are calculated by using the PM-method. A comparison of the calculated values with the corresponding observed values seems to make it possibe to presume the type of the internal conformation of $(iso\text{-}C_3H_7)^{4\alpha}$.

# *Structure of Enteromycin. I*. Derivatives and Products in Various Reactions of Enteromycin*

By Kōmei MIZUNO

(Received April 4, 1961)

*Streptomyces albireticuli* isolated by Nakazawa[1] in 1951 produces several biologically active antibiotics including eurocidine[2], enteromycin[3], carbomycin[4] (magnamycin)[5,6] and tertiomycin[7], which are different from each other in properties and they all show low toxicity. Nakazawa et al. isolated eurocidin[2] from a methanolic extract of the mycelium of the microorganism and carbomycin[4] from an ethyl acetate extract of the filtered broth which had been made alkaline beforehand, and Miyake et al. obtained tertiomycin[8] from the mother liquor of carbomycin. Nakazawa et al. also isolated enteromycin, an antibiotic active against Gram-negative bacteria, from the ethyl acetate extract of the above filtered broth which had been made acid, and assigned to it an empirical formula of $C_6H_8O_5N_2$, but its structure has so far remained unclarified. The present author, however, from the results of experiments to be published in four reports hence, has made clear that the antibiotic is *N*-(*O*-methyl-*aci*-nitroacetyl)-3-aminoacrylic acid. It is a peptide-type[9] compound and seems to be the first so far isolated from natural products as a substance having a *O*-methyl-*aci*-nitro group.

Enteromycin (I) is sparingly soluble in water and other solvents, but can be recrystallized from plenty of hot methanol and gives two kinds of interchangeable crystals Ia and Ib according to the extent of cooling. The p*K*a of this compound is 4.3, and from its molecular weight calculated from the amount of the alkali consumed and from its analytical values the molecular formula of $C_6H_8O_5N_2$ was assigned to it. Enteromycin has a methoxy group, and is optically non-active and negative to the phenolic OH reaction (referred to as Barton[10] reaction hereafter) by the ferric chloride-potassium ferricyanide reagent, but reduces the Fehling's reagent. A methanolic solution of this compound exhibits three absorption maxima at $\lambda$ 230 m$\mu$ ($\varepsilon$ 9000), 275 m$\mu$ ($\varepsilon$ 13000) and 298 m$\mu$ ($\varepsilon$ 16000) (Fig. 1), and the infrared spectra of Ia and Ib show absorptions at the following wavelengths ($\nu_{max}^{Nujol}$ $cm^{-1}$): 3300~3330 (NH), 2560~2670 (COOH), 1680~1690 (CO), 1620~1640 (conj. C=N), 1600 (conj. C=C), 1560 (-CO-NH-), 992 (Ia), 988 (Ib) (trans C=C). When methylated with diazomethane Ia and Ib gave the same product II [m. p. 141°C (decomp.), $C_7H_{10}O_5H_2$] and the infrared spectrum (Fig. 4) of the product clearly exhibited the absorption (1720 $cm^{-1}$) of COOR. II, having two methoxy groups, is obviously the methyl ester of I and so I seems sure to have a methoxy group detectable by the Zeisel method and a free carboxyl group, and therefore the formula A was assigned to it.

$$C_6H_8O_5N_2 \quad (C_4H_4O_2N_2)\rightarrow\begin{matrix}-COOH\\-OCH_3\end{matrix}$$

A

Since further reaction of II with diazomethane yielded a product (III) [m. p. 121°C (decomp.), $C_8H_{12}O_5N_4$] suspected to be a molecular compound from its molecular formula, the skeleton of I was assumed to have one or more double bonds.

I is unstable to heat, acid and alkali, and when heated with water it gave off formaldehyde (IV), acetaldehyde (V), carbon dioxide (VI), and others. In addition to V and VI, I also produced ammonia (VII), glyoxylic acid (VIII), oxalic acid (IX), etc. by heating with diluted hydrochloric acid, and acetaldehyde when reacted with hydroiodic acid, but no formaldehyde was yielded in these acid decompositions. Heating of I with sodium hydrogen carbonate solution afforded oxamic acid (XI). When subjected as such to thermal decomposition, I changed, under evolution of formaldehyde, into a substance which was positive to

the Barton reaction and easily soluble in water and methanol. The substance was recrystallized from water in plates (XII) [m. p. 175°C (decomp.), $C_5H_6O_4N_2$] and needle-like crystals XIII [m. p. 169°C (decomp.), $C_{11}H_{14}O_9N_4$], and XII further afforded two kinds of interchangeable products XIIa and XIIb when recrystallized from water. XII (p*K*a 4.3 and 8.3) is an acid substance consuming two moles of alkali, and it is positive to the Barton reaction and reduces the Fehling's reagent but has no methoxyl group detectable by the Zeisel method. A methanolic solution of this substance exhibited two absorption maxima at $\lambda$ 225 m$\mu$ ($\varepsilon$ 16500) and 280 m$\mu$ ($\varepsilon$ 18000), and from infrared spectra of XIIa and XIIb (Figs. 6, 7) the presence of OH (3450 $cm^{-1}$), NH (3330), COOH (2560~2670), CO (1680), conj. C=N (1630), conj. C=C (1610) and trans C=C (975, 990) was presumed.

XIII has a methoxy group and from its ultraviolet spectrum (Fig. 8) and antibiotic activity,

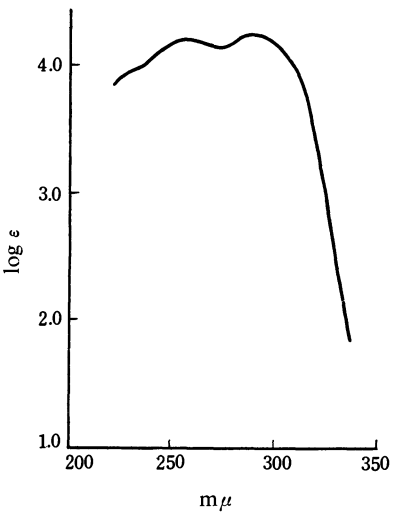

Fig. 11. Ultraviolet absorption spectrum of XIV in methanol.

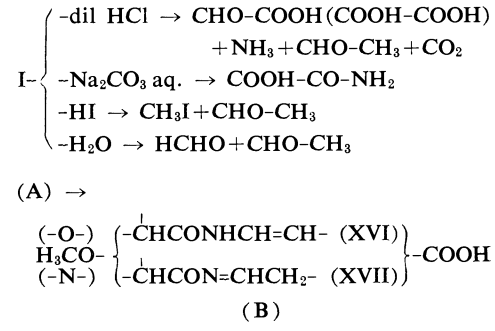
it is assumed to be a molecular compound consisting of I and XII, and this assumption was confirmed by the infrared spectrum (Fig. 9) of the product prepared from equimolecular amounts of the two components. Demethoxylation** of I by heating afforded XII or XIII as mentioned above depending on the temperature and time of heating, and from the kind and amount of the product the progress of the demethoxylation could be checked. The thermal decomposition proceed to a considerable extent when I was left standing at 30°C for some ten days. However, since neither formaldehyde nor a substance positive to the Barton reaction was produced when I was allowed to stand in a methanolic solution of trimethylamine at 0°C for a long time, I seems to have no such a group as $-CH_2OH$ which produces formaldehyde by general dehydroxymethylation. Considered together with the results of decompositions of I with acid and water, the methoxy group detectable by the Zeisel method appears to be split off as formaldehyde, and therefore I is assumed to have a specific functional group including a methoxy group. So XII may be called demethoxyenteromycin. Amidation of I produced light yellow crystals, m. p. 163°C (decomp.) (neither urotropine nor IV was found in the mother liquor), which were converted into stable prisms (XIV) [m. p. 208°C (decomp.), $C_5H_7O_4N_3$], when treated with diluted acetic acid. As this product was positive to the Barton reaction and its infrared spectrum (Fig. 10) exhibited various absorptions characteristic of amides, it may be called enteromycin amide. The ultraviolet spectrum (Fig. 11) of the product showed two maxima at $\lambda$ 255 m$\mu$ ($\varepsilon$ 15000) and 290 m$\mu$ ($\varepsilon$ 18000), but as the spectrum did not resemble that of I, the product is likely to have a structure considerably different from that of I.

As mentioned before, I seems to have one or more double bonds, so it was subjected to catalytic reduction to make its skeleton clear, whereupon XII was produced first but the final product was XV [m. p. 225°C (decomp.), $C_5H_{10}O_3N_2$]. This product has no methoxy group and is positive to the ninhydrin reaction, and it may be called dehydroxytetrahydrodemethoxyenteromycin from its molecular formula.

From the above results the methoxyl group of I appears to be split off by catalytic reduction, and though I seems apparently to be amidated, it has no $COOCH_3$ group, so the amidation must be due to a specific functional group mentioned before. The carbon dioxide produced in the acid decomposition of I seems to have derived from the COOH group, and since acetaldehyde was produced in the same decomposition, the molecule of I ought to have $-CH=CH-$ or $-CH_2-CH=$ combination. Further the fact that ammonia, oxalic acid, and glyoxylic acid were produced in the decomposition and that oxamic acid was obtained in the alkali decomposition seems to suggest that I has $-NH-CO-\overset{|}{C}H-$ or $=N-CO-\overset{|}{C}H-$ combination.

Chart 1.



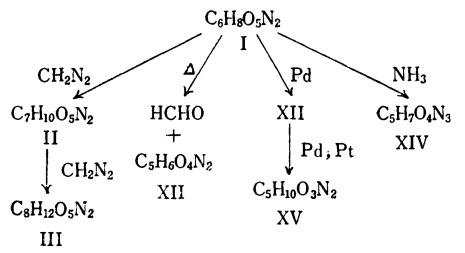


Chart 2.

## Experimental

**Enteromycin (I).** — A hot solution of 1 g. of enteromycin in 500 cc. of methanol was filtered with 100 g. of decolorizing charcoal and the filtrate was left standing, separating 500 mg. of long needle-like crystals Ib. Concentration of the mother liquor gave an additional crop of 300 mg. A solution of 200 mg. of Ib in 150 cc. of hot methanol was concentrated to about 50 cc. under reduced pressure and cooled to yield fine prisms Ia. Working up of the mother liquor afforded another crop, making the total yield 180 mg. Ia and Ib were clearly distinguishable in infrared spectrum. They dissolved in aqueous sodium hydrogen carbonate solution with evolution of carbon dioxide and colored yellow at 142°C, brown at 158°C and melted at 172°C with decomposition.

Found: C, 38.21; H, 4.41; N, 15.14; O-$CH_3$, 16.14. Calcd. for $C_6H_8O_5N_2$: C, 38.30; H, 4.29; N, 14.89; O-$CH_3$, 16.54% (one O-$CH_3$).

The p$K$a of this compound is 4.3 and its molecular weight is 180±10 when calculated from the amount of the alkali consumed.

** Whether this phenomenon is to be called demethoxylation or deformaldehyde reaction was unknown at first, but preference was given to the former as experiments proceeded.

**Enteromycin Methylester (II).**—To a suspension of 600 mg. of pure I in 60 cc. of ethanol was added an ether solution of diazomethane produced from 5 g. of nitrosomethylurea in several portions at 10~15°C. When evolution of nitrogen subsided, the almost colorless reaction mixture was concentrated under reduced pressure, giving 630 mg. of white crystals, which melted at 141°C (decomp.) after recrystallization from ethanol. This product gives off no carbon dioxide in sodium hydrogen carbonate solution and is negative to the ferric chloride-potassium ferricyanide reaction.

Found: C, 41.86; H, 4.75; N, 13.48; O-$CH_3$, 30.01. Calcd. for $C_7H_{10}O_5N_2$: C, 41.58; H, 4.99; N, 13.86; O-$CH_3$, 30.70% (two O-$CH_3$).

**Diazomethane Addition Product of Enteromycin Methylester (III).**—To a solution of 200 mg. of II in 20 cc. of ethanol was added a solution of diazomethane in 50 cc. of ether which was produced from 2 g. of nitrosomethylurea, and the reaction mixture was left standing at room temperature for 10 hr. and then concentrated at low temperature under diminished pressure to precipitate crystals. The crystals, after washing with ethanol, were dissolved in hot methanol, the solution was filtered, and the crystals obtained from the filtrate were recrystallized from ethanol, giving 100 mg. of needles, m. p. 121°C (decomp.). This compound is positive to the ferric chloride-potassium ferricyanide reaction and gives orange-red color with the Dragendorff[11] reagent.

Found: C, 39.40; H, 5.02; N, 22.50; O-$CH_3$, 25.02. Calcd. for $C_8H_{12}O_5N_4$: C, 39.24; H, 4.95; N, 22.94; O-$CH_3$, 25.42% (two O-$CH_3$).

**Decomposition of Enteromycin with Hot Water.**—A suspension of 100 mg. of I in 6 cc. of water was heated at 100°C for 1 hr. in vessel A under introduction of nitrogen. The aldehydes and carbon dioxide evolved were collected in receivers B and C containing pure water and baryta water, respectively. After the reaction, about 25 mg. of barium carbonate was obtained. A solution of 20 mg. of 2,4-dinitrophenylhydrazine in 5 cc. of concentrated hydrochloric acid was added to the receiver B, the mixture was allowed to stand for 3 hr. and the resulting hydrazones were extracted with ethyl acetate. The extract was washed with water, dried over anhydrous sodium sulfate and concentrated at low temperature under reduced pressure, separating 25 mg. of yellowish orange 2,4-dinitrophenylhydrazones (referred to as 2,4-DNPH hereafter). Paper chromatography of a solution of the products in chloroform-acetone (1 : 1) by the method of Gasparic[12] gave the two yellow spots at $R_f$ 0.25 and 0.38, which were identified as of 2,4-DNPH of formaldehyde (IV) and that of acetaldehyde (V).

**Decomposition of Enteromycin with Hydrochloric Acid.**—A suspension of 200 mg. of I in 2 cc. of 1 N hydrochloric acid was treated as above at 95°C for 1 hr. In addition to 140 mg. of barium carbonate, the following substances were obtained.

*Acetaldehyde (V).*—The aldehyde produced was converted to 2,4-DNPH with a solution of 2,4-dinitrophenylhydrazine in hydrochloric acid and the resulting crude product, m. p. 141°C (ca. 40 mg.) was purified by recrystallization from ethanol, when m. p. rose to 160°C. The $R_f$ value in paper chromatography and infrared spectrum of the product where in complete accord with those of 2,4-DNPH of synthetic acetaldehyde, and a mixed melting point determination of both substances showed no depression.

Found: C, 43.37; H, 3.73; N, 24.83. Calcd. for $C_8H_8O_4N_4$: C, 42.86; H, 3.60; N, 24.99%.

*Oxalic Acid (IX).*—The reaction mixture was extracted with 20 cc. of ether and the extract was concentrated to give 20 mg. of white crystals, m. p. 96°C, which was subjected to paper chromatography by the method of Stark[13] et al. (solvent: 75% phenol containing 1% of formic acid), affording a spot at $R_f$ 0.20, suspected to be of oxalic acid. The sodium salt of the product was converted to *S*-benzylthiuronium salt and purified by recrystallization from ethanol, m. p. 193°C.

Found: N, 13.17. Calcd. for $C_{18}H_{22}O_4N_4S_2$: N, 13.27%.

*Glyoxylic Acid (VIII).*—A solution of 2,4-dinitrophenylhydrazine in hydrochloric acid was added to the reaction mixture which had been extracted with ether, and after 3 hr. the resulting hydrazone was extracted with ethyl acetate. Concentration of the extract yielded a small amount of yellow crystals, which when paper-chromatographed in parallel with 2,4-DNPH of synthetic glyoxylic acid, gave a spot of 2,4-DNPH of glyoxylic acid at $R_f$ 0.40.

*Ammonia (VII).*—The reaction mixture from which 2,4-DNPH of glyoxylic acid had been separated was made alkaline and steam-distilled. The evolving basic gas was collected in diluted hydrochloric acid and the solution was evaporated to dryness to yield some plates. The product was identified as ammonium chloride because it gave, on paper chromatography (solvent: the upper layer of a mixture of *n*-butanol, acetic acid and water (4 : 1 : 5)), a spot at $R_f$ 0.14 which was positive to the ninhydrin reaction and took on a grayish brown color with the ammonical silver nitrate solution.

**2, 4-DNPH of Glyoxylic Acid.**—One and three tenths grams of ethyl diethoxyacetate, $(EtO)_2CH$-COOEt, synthesized by Moffett's method[14] was hydrolyzed by heating in 5 cc. of 5 N sodium hydroxide at 65°C for one hour and the reaction mixture, after neutralizing with hydrochloric acid, was shaken with ether to remove the unreacted material. One gram of 2,4-dinitrophenylhydrazine was dissolved in the aqueous layer, 25 cc. of concentrated hydrochloric acid was added, the mixture was stirred for 30 min. at 80°C, yielding 1.5 g. of yellow crystals. The crystals were dissolved in a solution of 1.5 g. of sodium bicarbonate in 30 cc. of water, the solution was acidified with hydrochloric acid and extracted with ethyl acetate, and the extract, after being washed with water and dried, was evaporated under reduced pressure, leaving 1.1 g. of a residue, which crystallized from hot methanol into yellow needlelike crystals, m. p. 193°C (decomp.).

Found: C, 37.89; H, 2.66; N, 21.79. Calcd. for $C_8H_6O_6N_4$: C, 37.80; H, 2.38; N, 22.05%.

**Paper Chromatography of 2,4-DNPH of Glyoxylic Acid.** — Each of 2,4-DNPH of various aldehydes, dissolved in a 1 : 1 mixture of chloroform and acetone, was developed by the ascending method on a piece of Tōyō filter paper No. 7 (4×45 cm.) acetylated by Micheel's method[15], using a solvent of cyclohexane-benzene-chloroform-ethyl acetate-acetone (5 : 5 : 10 : 1 : 5). $R_f$ values of various 2,4-DNPH at the time when the solvent front migrated about 20 cm. from the starting point were as shown below.

| Substance | $R_f$ value |
|---|---|
| 2,4-Dinitrophenylhydrazine | 1.00 |
| 2,4-DNPH of acetone | 0.90~0.95 |
| 〃 of formaldehyde | 0.84 |
| 〃 of acetaldehyde | 0.73 |
| 〃 of glyoxylic acid | 0.40 |

Under ultraviolet rays all the spots were observed as light absorbing spots and all of them exhibited a peculiar brownish purple color when immersed in 90% ethanol containing 2% of sodium hydroxide.

**Decomposition of Enteromycin with Hydroiodic Acid.** — Fifty milligrams of I was heated with 4 cc. of the hydroiodic acid mixture (hydroiodic acid-phenol-propionic anhydride) at 60~80°C for 40 min. and at 80~120°C for 2 hr. under introduction of nitrogen, and the aldehyde in the distillate was converted to 2,4-DNPH. On paper chromatography as before, the 2,4-DNPH gave a single yellow spot at $R_f$ 0.35, which was identified as 2,4-DNPH of acetaldehyde.

**Decomposition of Enteromycin with Alkali Carbonate.** — *Oxamic Acid (XI).* — A mixture of 500 mg. of I and 5 cc. of 10% sodium carbonate solution was heated on the water bath and after being concentrated to 1.2 cc. cooled to yield ca. 100 mg. of crystals. The crystals were dissolved in 3 cc. of water, the solution was passed through a column of Amberlite IR-120 (H-form), and the effluent, after concentration under reduced pressure, was mixed with a little ethanol to separate 50 mg. of yellowish white crystals. The crystals were dissolved again in water and reprecipitated with ethanol, giving 30 mg. of white crystals, m. p. 203°C (decomp.). The product, melting at 210°C after drying at 120°C for 2 hr. in vacuo, was identified as oxamic acid having one mole of water of crystallization.

**Thermal Decomposition of Enteromycin (1).** — Three hundred milligrams of I was heated at 110~120°C for 40~50 min. in a 5 cc. flask connected through a Liebig condenser with a vessel containing 5 cc. of cold pure water, under gentle introduction of nitrogen which was washed with an alkaline pyrogallol solution and dried with calcium chloride. And the following substances were obtained.

*Demethoxyenteromycin (XII).* — The yellow contents of the flask were dissolved in 3 cc. of methanol and the solution, after being filtered to remove the unreacted material (70 mg.), was evaporated at low temperature under diminished pressure. The white residue was dissolved in 2 cc. of hot water and cooled to separate about 40 mg. of needles XIII. The mother liquor from the needles was concentrated, yielding 140 mg. of prisms XIIa, which, after several recrystallizations from water, gave about 40 mg. of plates XIIb. Both kinds of the crystals colored brown at 157°C and melted at 175°C with decomposition. They were positive to the ferric chloride-potassium ferricyanide reaction and could be distinguished from each other by their infrared spectra.

Found (XIIa): C, 37.82; H, 3.91; N, 17.85. Found (XIIb): C, 37.78; H, 3.97; N, 17.97; O-$CH_3$, undetected. Calcd. for $C_5H_6O_4N_2$: C, 37.98; H, 3.83; N, 17.72%.

*Formaldehyde (IV).* — The aldehyde collected in the water-containing vessel was converted to 2,4-DNPH (ca. 30 mg.), which afforded a single yellow spot at $R_f$ 0.25 on paper chromatography[12]. The product melted at 168°C after recrystallization from methanol and it was identified as 2,4-DNPH of formaldehyde from its infrared spectrum and by mixed melting point determination.

Found: C, 40.38; H, 3.08; N, 27.00. Calcd. for $C_7H_6O_4N_4$: C, 40.00; H, 2.88; N, 26.66%.

**Thermal Decomposition of Enteromycin (2).** — *Enteromycin Demethoxyenteromycin Molecular Compound.* — When I was left standing at room temperature for more than several months, it gave off the smell of formaldehyde and colored yellow. The product was treated as in the case of XII to give needle-like crystals (XIII), m. p. 169°C (decomp.), which were positive to the ferric chloride-potassium ferricyanide reaction and had about one half antibiotic activity of that of I.

Found: C, 38.52; H, 3.88; N, 16.68. Calcd. for $C_{11}H_{14}O_9N_4(C_6H_8O_5N_2 \cdot C_5H_6O_4N_2)$: C, 38.10; H, 4.05; N, 16.20%.

Fifty milligrams of I and 50 mg. of XII were dissolved in 5 cc. of hot water and the solution was cooled to yield needle-like crystals having the same infrared spectrum as XIII.

*Non-dehydroxymethylation.* — A solution of 50 mg. of I in 5 cc. of 1% methanolic trimethylamine solution was left standing at 5°C for one week and concentrated at low temperature under reduced pressure. The residue (ca. 50 mg.) was dissolved in 3 cc. of water and the solution was acidified with several drops of acetic acid, giving about 45 mg. of crystals showing the same infrared spectrum as I.

**Enteromycin Amide (XIV).** — A solution of 500 mg. of I in 100 cc. of methanol saturated with ammonia was allowed to stand overnight at room temperature, and the solvent was distilled off, leaving 450 mg. of crude crystals. The crystals were dissolved in 7 cc. of water and the solution was filtered and made acid with acetic acid to separate 380 mg. of crystals, m. p. 196~203°C (decomp.). The product, after recrystallization from methanol, melted at 208°C (decomp.) and was positive to the ferric chloride-potassium ferricyanide reaction.

Found: C, 34.59; H, 4.02; N, 24.50; O-$CH_3$,

15) F. Micheel and H. Schweppe, *Microchim. Acta*, **1954**, 60.

undetected. Calcd. for $C_5H_7O_4N_3$: C, 34.68; H, 4.08; N, 24.24%.

A solution of 30 mg. of 2,4-dinitrophenylhydrazine in 10 cc. of concentrated hydrochloric acid was added to the above acid mother liquor and the mixture, after being heated at 100°C for 10 min. and left standing for one hour, was extracted with ethyl acetate. The 2,4-DNPH obtained from the extract showd the spot of 2,4-DNPH of acetaldehyde at $R_f$ 0.35 on paper chromatography[12].

**Catalytic Reduction of Enteromycin.**—*Demethoxyenteromycin (XII).* — A solution of 300 mg. of I in 300 cc. of hot pure methanol was rapidly cooled and catalytically reduced on palladium-carbon, when one mole of hydrogen was absorbed in about 30 min. The catalyst was filtered off and the filtrate was concentrated at low temperature under reduced pressure, separating crystals. The mother liquor from the crystals was further concentrated and a solution of the residue (ca. 200 mg.) in 5 cc. of hot water was allowed to stand to deposite needle-like crystals. The crystals were filtered and the filtrate was concentrated to about 3 cc., yielding ca. 150 mg. of plates, m. p. 175°C (decomp.). The infrared spectrum of the product was in complete agreement with that of XIIa.

Found: C, 38.10; H, 4.00; N, 17.62. Clacd. for $C_5H_6O_4N_2$: C, 37.98; H, 3.83; N, 17.72%.

*Dehydroxytetrahydrodemethoxyenteromycin (XV).*— A solution of 300 mg. of I in 300 cc. of hot pure methanol was cooled and reduced in the presence of 100 mg. of Adams platinum oxide when 4 mol. of hydrogen was absorbed about 2 hr. The catalyst was filtered and washed well with water, and the combined filtrate and washing were concentrated at low temperature under reduced pressure. The resulting white crystals (200 mg.), after recrystallization from aqueous methanol, melted at 225°C and were positive to the ninhydrin reaction.

Found: C, 40.97; H, 7.11; N, 18.92; $-NH_2$, 11.55. Calcd. for $C_5H_{10}O_3N_2$: C, 41.09; H, 6.90; N, 19.17; $-NH_2$, 10.45% (one-$NH_2$).

On paper chromatography by the method of Consden[16] et al. (80 g. phenol, 19.3 cc. water and 0.7 cc. concentrated aqueous ammonia) the product afforded a spot at $R_f$ 0.68, which with the ninhydrin reagent gave a color changing from yellow to blue.

## Summary

In order to know its functional groups and the combining state of the groups, enteromycin was subjected to such reactions as methylation, amidation, degradation, and catalytic reduction, and the properties of the products were investigated.

# *Structure of Enteromycin. II*. Derivatives and Products in Various Reactions of Dimethoxyenteromycin*

By Kōmei MIZUNO

(Received April 4, 1961)

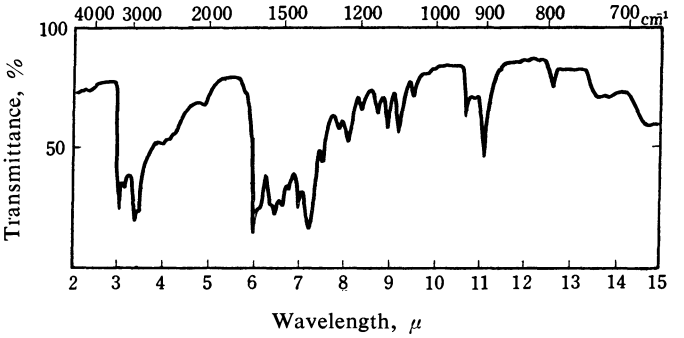
Dehydroxytetrahydrodemethoxyenteromycin (XV)[1] obtained by the catalytic reduction of enteromycin (I) or demethoxyenteromycin (XII) seems to have the same skeleton as that of the latter two. And from the course of changes of I, XII appears to be in the closest relation with I. In the present work, the structure of XV was established, and the functional group of XII and its derivatives were investigated in detail.

The infrared spectrum (Fig. 1) of XV exhibited the absorptions of NH, COOH and $COO^- \cdot NH_3^+$ (2100, 1620, 1370 $cm^{-1}$), but its ultraviolet spectrum showed no specific absorption at the long wave region beyond $\lambda$ 220 m$\mu$. Also, an amino group was detected in this compound by azotometry. Since the compound was considered to be a saturated peptide in view of the above facts, it was hydrolyzed with hydrochloric acid and the product was subjected to paper chromatography, detecting glycine (XXIII) and $\beta$-alanine (XXV). The DNP derivatives[2] of both amino acids were also confirmed by paper chromatography. Hydrolysis of the DNP derivative of XV produced no DNP-amino acid, but since $\beta$-alanine was obtained as a free amino acid, XV was.

* This constitutes part XXXVI of a series entitled "Studies on Antibiotics" by S. Tatsuoka, and was reported at the Forum on Natural Organic Compounds held on October 16, 1960.

1) K. Mizuno, This Bulletin, **34**, 1419 (1961).

2) W. W. Bromer, *J. Am. Chem. Soc.*, **79**, 2794 (1957).



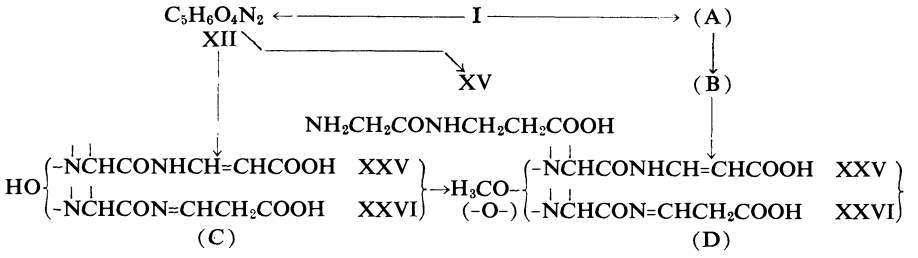


Fig. 1. Infrared absorption spectrum of dehydroxytetrahydrodemethoxyenteromycin (glycyl-β-alanine) (XV).

assumed to be glycyl-β-alanine. So *N*-formylglycine was condensed with β-alanine ethyl ester in the presence of dicyclohexylcarbodiimide and the resulting *N*-formylglycyl-β-alanine ethyl ester was hydrolyzed with sodium hydroxide to give *N*-formyl-β-alanine. The product was deformylated by the method of Miyamoto[3] et al., and the infrared spectrum, melting point (decomp.), and $R_f$ value in paper chromatography of the resultant product were found to be in full accord with those of XV. From these results the formula C was presumed for XII and the formula D for I.

The two acidic groups[1] in XII were confirmed by acetylation and methylation of XII. The product was obtained as prisms (XVIII) [m. p. 181°C (decomp.), $C_7H_8O_5N_2$] negative to the Barton reaction, and since its infrared spectrum (Fig. 2) showed a clear absorption of >NO-COR[4] (1775 $cm^{-1}$), it was called *O*-acetyldemethoxyenteromycin.

Reaction of XII with diazomethane products, one of which (XIX) [m. p. 159°C, $C_7H_{10}O_4N_2$] was obtained as prisms and had a methoxy group and the other (XX) [m. p. 137°C, $C_7H_{10}O_4N_2$] was yielded as needles and had two methoxy groups. As the infrared spectra (Figs. 3 and 4) of both products showed the absorption of COOR (1710 $cm^{-1}$), they were called *N*-methyldemethoxyenteromycin methyl ester and *O*-methyldemethoxyenteromycin methyl ester, respectively.

From the formation of these compounds, it is obvious that XII representable by the formula C has a phenolic hydroxyl group in addition to a free carboxyl group. Decomposition of XII with hydrochloric acid produced acetaldehyde (V), carbon dioxide (VI), ammonia (VII), and glyoxylic acid (VIII), but not formaldehyde, and boiling of XII with water also afforded no formaldehyde, and therefore the structure of XII would be almost the same as that of I, except the special functional[1] group including a methoxy group. Amidation of XII gave a compound (XXI) m. p. 168°C (decomp.), $C_5H_9O_4N_3$] as needles, which positive to the ninhydrin reaction and reverted to the original compound by treatment with heat, water, or diluted acetic acid. And as the infrared spectrum (Fig. 5) of this product exhibited the absorption characteristic of amides, it was called demethoxyenteromycin amide. Also similarity of the ultraviolet spectrum of the product to that of XII suggested that it has a structure considerably different from that of entromycin amide (XIV).

Finally the course of the change of XII to XV by catalytic reduction was investigated in detail. Namely, catalytic reduction of XII on palladium-carbon first yielded prisms (XXII) [m. p. 203°C (decomp.), $C_5H_8O_3N_2$] which were sparingly soluble in cold water and gave a

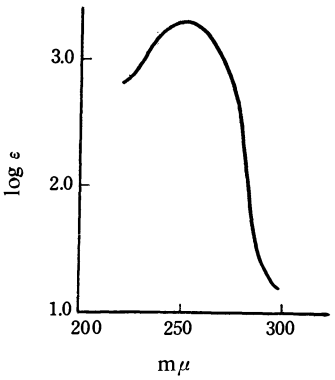

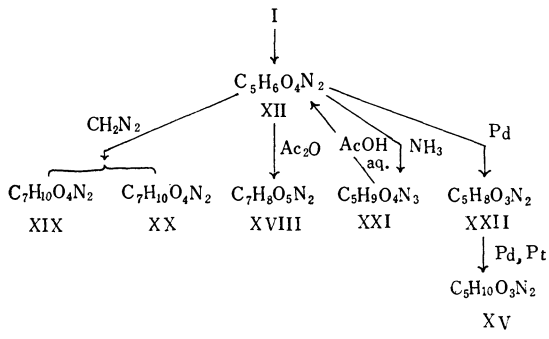

Fig. 7. Ultraviolet absorption spectrum of XXII in water.

yellow ninhydrin reaction, and further reduction resulted in the formation of glycyl-β-alanine (XV). From its molecular formula, XXII was called dehydroxydihydrodemethoxyenteromycin, and since its infrared spectrum (Fig. 6) exhibited the absorptions of NH, COOH and $COO^- \cdot NH_3^+$, it was considered to be a peptide. The ultraviolet spectrum (Fig. 7) of the compound showed a single absorption maximum ($\varepsilon_{max}$ 2000) at $\lambda_{max}$ 250 mμ.

## Experimental

**Hydrolysis of Dehydroxytetrahydrodemethoxyenteromycin (XV).**—A solution of 10 mg. of XV in 1 cc. of 6 N hydrochloric acid was heated at 110°C for 5 hr. in a sealed tube, the air in which was replaced with nitrogen. The reaction mixture was evaporated to dryness, the residue was dissolved in 1 cc. of water, and part of the solution was subjected to paper chromatography according to the method described in Report I, giving two spots at $R_f$ 0.42 and 0.65. The former spot colored brownish pink with ninhydrin and the latter, blue, and they were identified as glycine and β-alanine, respectively. Five tenths cc. of the above aqueous solution was adjusted to pH 8 with 30 mg. of sodium hydrogen carbonate, the mixture was allowed to react with a solution of 8 mg. of 1-fluoro-2,4-dinitrobenzene in 0.5 cc. of ethanol, and the product was extracted by the method of Bromer[2]. The product was developed in the dark on filter paper, Whatman No. 1, with the upper layer of *n*-butanol-0.1% aqueous ammonia (1 : 1), giving two yellow spots at $R_f$ 0.28~0.33 and 0.37~0.40. They were identified as DNP-glycine and DNP-β-alanine. Each of the two spots was extracted with 4 cc. of hot water, and the absorption of the extracts was measured, finding that the two products were contained in the material in equimolecular amounts.

**Hydrolysis of DNP-Dehydroxytetrahydrodemethoxyenteromycin.**—To a solution of 10 mg. XV in 2 cc. of water was added a solution of 7 mg. of 1-fluoro-2,4-dinitrobenzene in 2 cc. of ethanol, followed by 20 mg. each of sodium hydrogen carbonate and sodium carbonate, and the mixture was treated as in the preceding experiment. The reaction mixture was extracted first with ether at acid pH to remove 2,4-dinitrophenol and then with isobutanol to obtain the DNP-derivative of the peptide compound. Part of the product was subjected to two dimensional paper chromatography; namely it was, developed first with the same solvent system as in the preceding experiment to detect a yellow spot at $R_f$ 0.26, which migrated to $R_f$ 0.26 in the second development with a solution of sodium dihydrogen phosphate (1 M) and disodium hydrogen phosphate (0.5 M) in 1 l. of water. The above DNP-derivative was hydrolyzed by heating with 0.5 cc. of 10 N hydrochloric acid at 100°C for 3 hr. and the ether soluble portion of the product was chromatographed as above, detecting the spot of 2,4-dinitrophenol at $R_f$ 0.44~0.49 (in the first development) and 0.26 (in the second development) and the spot of 2,4-dinitroanilin at 0.85~0.95 (in the first development) and 0.00 (in the second development), but no spot of DNP-glycine was observed. The acid solution from which the ether solube portion had been separated was evaporated to dryness and the residue was chromatographed as in the preceding experiment, whereupon a spot coloring blue with ninhydrin was detected at $R_f$ 0.65, which was identified as β-alanine.

**Synthesis of Glycyl-β-alanine.**—To a solution of 2.1 g. of *N*-formylglycine in 20 cc. of ethanol was added 2.4 g. of β-alanine ethyl ester, followed by

4.2 g. of dicyclohexylcarbodiimide, and the mixture was allowed to stand overnight with cooling. The separated urea derivative was filtered off, the filtrate was evaporated under reduced pressure, and the residue was dissolved in 20 cc. of ethyl acetate. The solution was filtered and the needle-like crystals, m. p. 72°C (ca. 2.5 g.) obtained from the filtrate was purified by recrystallization from ethyl acetate. The product melted at 75°C.

Found: C, 47.81; H, 7.09; N, 14.13. Calcd. for $C_8H_{14}O_4N_2$ (*N*-formylglycyl-β-alanine ethyl ester): C, 47.52; H, 6.97; N, 13.85%.

One gram of the product dissolved in 20 cc. of dioxane was hydrolyzed by standing with 6~7 cc. of 1 N sodium hydroxide at room temperature, the reaction mixture was passed through a column of Amberlite IR-120 (H-form) to remove sodium ion, and the effluent was concentrated under diminished pressure to give white crystals, which were recrystallized from ethanol in prisms, m. p. 121°C (600 mg.).

Found: C, 41.68; H, 5.81; N, 15.84. Calcd. for $C_6H_6O_4N_2$ (*N*-formylglycyl-β-alanine): C, 41.38; H, 5.79; N, 16.09%.

To a solution of 450 mg. of the product in 2 cc. of methanol was added 0.25 cc. of hydrazine hydrate (80%), and the mixture was heated for 5 hr. on the water bath. The resulting crystals were washed with methanol and recrystallized from aqueous methanol, yielding 250 mg. of prisms, m. p. 225°C (decomp.). The infrared spectrum, $R_f$ value in paper chromatography and coloration in the ninhydrin reaction of the product were in complete agreement with those of XV described in Report I.

Found: C, 40.75; H, 7.10; N, 18.84. Calcd. $C_5H_{10}O_3N_2$ (glycyl-β-alanine): C, 41.09; H, 6.90; N, 19.17%.

**O-Acetyldemethoxyenteromycin (XVIII).**—To a solution of 300 mg. of demethoxyenteromycin (XII) in 15 cc. of hot water was added dropwise 2 cc. of acetic anhydride at 55~60°C over a period of about 15 min. with vigorous stirring. The mixture once became clear, but white crystals m. p. 180°C (decomp.) (ca. 320 mg.), gradually separated there from, which were recrystallized from methanol in prisms, m. p. 181°C (250 mg.). The product is negative to the ferric chloride-potassium ferricyanide reaction and resists ester exchange with methanol and decomposes when dried at a temperature over 70°C in vacuo.

Found: C, 42.33; H, 4.33; N, 13.97; -$COCH_3$, 20.50. Calcd. for $C_7H_8O_5N_2$: C, 42.00; H, 4.03; N, 14.00; -$COCH_3$, 21.50%.

**N-Methyldemethoxyenteromycin Methyl Ester (XIX).**—To a solution of 600 mg. of XII in 30 cc. of ethanol was added a solution of diazomethane (produced from 7 g. of nitrosomethylurea) in 80 cc. of ether and the mixture was left standing at room temperature for 10 hr. The solvent was distilled off and the resulting white crystals, m. p. 120°C (150 mg.) were recrystallized from 1.5 cc. of methanol in needles (XIX), m. p. 159°C (ca. 60 mg.). This product is negative to the ferric chloride-potassium ferricyanide reaction.

Found: C, 45.16; H, 5.21; N, 15.22; O-$CH_3$, 16.38. Calcd. for $C_7H_{10}O_4N_2$: C, 45.16; H, 5.41; N, 15.05; O-$CH_3$, 16.67%.

**O-Methyldemethoxyenteromycin Methyl Ester (XX).**—The mother liquor from XIX was concentrated to 0.7 cc. and left standing, separating 70 mg. of needles, which after crystallization from methanol melted at 137°C. Like XIX, the product is negative to the phenolic OH reaction, and its molecular weight is 180±20 when measured by the Rast method, using camphor as solvent.

Found: C, 45.15; H, 5.45; N, 15.04; O-$CH_3$, 32.45. Calcd. for $C_7H_{10}O_4N_2$: C, 45.16; H, 5.41; N, 15.05; O-$CH_3$, 33.30%.

**Decomposition of Demethoxyenteromycin with Hydrochloric Acid.**—According to the method described in Report I, a mixture of 100 mg. of XII and 3 cc. of 1 N hydrochloric acid was heated in the atmosphere of nitrogen at 100°C for about one hour in flask A, which was connected with vessel B containing pure water and vessel C containing baryta water. The reaction mixture changed from brown to redish brown and plenty of barium carbonate deposited. After the reaction, the aldehyde in the vessel B was converted to the 2,4-DNPH derivative with a solution of 2,4-dinitrophenylhydrazine in hydrochloric acid, and the product was chromatographed as before, detecting a single spot of the 2,4-DNPH of acetaldehyde at $R_f$ 0.38.

A solution of 2,4-dinitrophenylhydrazine in hydrochloric acid was added to one half of the contents of the flask A, the resulting 2,4-DNPH derivative was extracted with ethyl acetate, and the extract was shaken with sodium hydrogen carbonate solution. The aqueous layer was made acid and extracted again with ethyl acetate, and the extract, after washing with water and drying, was concentrated under reduced pressure to give yellow crystals, which on paper chromatography exhibited the spot of the 2,4-DNPH derivative of glyoxylic acid at $R_f$ 0.42. The remaining half of the contents of the flask A was made alkaline and steam-distilled, and the distillate neutralized with hydrochloric acid was evaporated to dryness, affording white crystals, which, when paper chromatographed as described in Report I, gave the spot of ammonium chloride at $R_f$ 0.14.

**Demethoxyenteromycin Amide (XXI).**—An amount of 500 mg. of XII was dissolved in 100 cc. of methanol saturated with ammonia and the solution, after standing overnight, was concentrated in the atmosphere of nitrogen at low temperature under reduced pressure, giving about 200 mg. of a residue which became light yellow prisms melting at 168°C (decomp.) after washing with a mixture of acetone and ethanol. The same treatment of the mother liquor yielded 250 mg. of unchanged XII. The product, m. p. 168°, colors blue with ninhydrin and is positive to the ferric chloride-potassium ferricyanide reaction. It produces XII quantitatively when treated with diluted acetic acid or hot water.

Found: C, 34.54; H, 5.49; N, 23.93. Calcd. for $C_5H_9O_4N_3$: C, 34.28; H, 5.18; N, 23.99%.

**Dehydroxydihydrodemethoxyenteromycin (XXII).**—A 200 mg. portion of XII dissolved in 20 cc. of pure methanol was reduced on 150 mg. of palladium

carbon (1 : 10) until about 2 mol. of hydrogen was absorbed. The catalyst was filtered and washed with hot water, the combined washing and filtrate were concentrated under reduced pressure, and methanol was added to the concentrate, giving about 150 mg. of crystals. The product was treated with a little cold water and the insoluble portion was recrystallized from water, yielding 70 mg. of prisms, m. p. 203°C (decomp.), which colored yellow with ninhydrin and gave a spot at $R_f$ 0.63 on paper chromatography[2].

Found: C, 41.46; H, 5.79; N, 19.48; $-NH_2$, 11.06. Calcd. for $C_5H_8O_3N_2$: C, 41.66; H, 5.59; N, 19.44; $-NH_2$, 9.86%.

Catalytic reduction of a solution of 30 mg. of XXII in 10 cc. of a mixture of glacial acetic acid and methanol on about 30 mg. of Adams platinum oxide (or palladium-carbon) afforded about 20 mg. of glycyl-β-alanine.

**Summary**

The structure of dehydroxytetrahydrodemethoxyenteromycin was established to be glycyl-β-alanine. Demethoxyenteromycin yielded *O*-acetyldemethoxyenteromycin by acetylation, *N*-methyl- and *O*-methyldemethoxyenteromycins by methylation, and demethoxyenteromycin amide by amidation. Catalytic reduction of demethoxyenteromycin gave first dehydroxydihydrodemethoxyenteromycin and then glycyl-β-alanine. Acid decomposition products of demethoxyenteromycin were the same those of enteromycin, except methyliodide.

# *Infrared Absorption Spectra of Water of Crystallization in Cobaltous Chloride Hexa- and Dihydrate Crystals*

By Itaru GAMO

(Received February 13, 1961)

The infrared absorption spectra of cobaltous chloride hexahydrate and dihydrate have been separately subject to two investigations[1,2]. However, there has been no comparative study of the two crystals in relation to their structural difference.

In the present paper, observed spectra were examined in relation to the difference of the binding states of the water molecules in them. The two crystals have an advantage over the hydrated salts of oxy-acids such as hydrated sulfates, because all the observed bands can be attributed to the vibrations of water molecules without ambiguity except for those due to the skeletal vibrations of the metal atom and ligands. Furthermore their structures are well determined by X-ray diffraction[3] and by electron diffraction[4] respectively.

## Experimental

**Preparation.** — Commercial cobaltous chloride hexahydrate of guaranteed grade was recrystallized from water. Cobaltous chloride dihydrate was obtained by keeping the purified hexahydrate over calcium chloride at ordinary temperature for 24 hr.[5]

**Measurement.**—Spectra were recorded by means of a Kôken DS 301 infrared spectrophotometer using a sodium chloride or potassium bromide prism. The potassium bromide disk technique was employed.

## Results

The spectra are given in Fig. 1. In the 3 $\mu$ region one peak is observed for the hexahydrate at 3430 $cm^{-1}$, and one shoulder and two peaks for the dihydrate at 3564, 3444 and 3226 $cm^{-1}$. These are comparable to the peaks of various inorganic hydrated salts[6] in this region, and can be assigned to the O–H stretching vibrations of water molecules affected by coördination on a cobalt atom and by the hydrogen bonding with a chlorine atom or an oxygen atom of an outer water molecule. Overlapping of several stretching bands is probably responsible for the broadness of the band for the hexahydrate. In the 6 $\mu$ region, two bands of medium intensity are observed at 1625 and 1599 $cm^{-1}$ for the hexahydrate. The latter is fairly sharp. Both can be assigned to the bending mode of water molecules, the former being presumably due to a ligand water

molecule and the latter to a water molecule free from coördination. For the dihydrate, one band of medium intensity is observed at 1610 $cm^{-1}$. It can be assigned to the bending mode of a ligand water molecule. In the 9 $\mu$ region, the spectrum of the hexahydrate shows a very broad weak band at 1090 $cm^{-1}$, and that of the dihydrate shows a similar one at 1100 $cm^{-1}$. The origins of these bands cannot be decided at present. Probably they are the combinations or overtones of some restricted rotation modes of water molecules. The band observed at 790 $cm^{-1}$ for the dihydrate can be attributed to the wagging vibration of a ligand water molecule affected by hydrogen bonding, because of its position, intensity and shape. The bands so far reported were observed in the sodium chloride region.

In the potassium bromide region, no band was observed for the hexahydrate. For the dihydrate only one very broad band was observed at 642 $cm^{-1}$. It is tentatively attributed to the rocking mode of the water molecule which is responsible for the wagging band at 790 $cm^{-1}$, because the twisting band of a water molecule is usually too weak to be observed. It cannot be assigned to any skeletal vibration of the metal atom and ligands since the skeletal vibration bands should appear in a lower frequency region.

Tables I and II summarize these results.

Table I. Observed frequencies of $CoCl_2 \cdot 6H_2O$

| Wave number, $cm^{-1}$ | Assignment |
|---|---|
| 3430 s | O-H stretch. |

## Discussion

According to X-ray analysis[3], four water molecules and two chlorine atoms in cobaltous chloride hexahydrate are coördinated on the cobalt atom, making an octahedron with the cobalt atom at the center. Two other water molecules are far distant from the cobalt atom, and each of their oxygen atoms forms a hydrogen bond with one of the two O–H bonds of a ligand water molecule. The other O–H bond of this water molecule forms another hydrogen bond with a chlorine atom of a neighboring octahedron (for details, see Fig. 2).

An electron diffraction study[4] shows that two water molecules and two chlorine atoms in

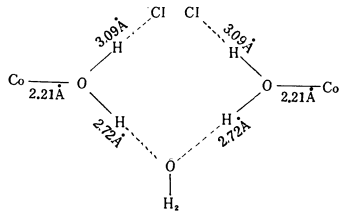

Fig. 2. Arrangement of atoms in $CoCl_2 \cdot 6H_2O$.

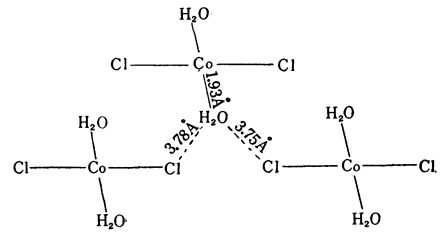

Fig. 3. Arrangement of atoms in $CoCl_2 \cdot 2H_2O$*.

* The three parallelograms are respectively in different planes. The values 3.75 and 3.78 Å were calculated from the data in Ref. 4.

cobaltous chloride dihydrate are coördinated on the cobalt atom, making a parallelogram with the cobalt atom at the center (Fig. 3).

As in the previous studies[6,7], it shall be assumed that the water frequencies are influenced by coördination and hydrogen bonding.

As is seen from Fig. 2, at least four O–H stretching frequencies are expected theoretically for the hexahydrate: one for the O–H bond of the ligand water molecule which forms the hydrogen bond O–H···Cl, one for the bond O–H···O, and two (symmetric and antisymmetic) for the almost free water molecule. The peak observed at 3430 $cm^{-1}$ probably corresponds to either one of the first two, because the frequency shift from the value of the vapor state is of the same order as in many cases[6] where the water molecule is affected by coördination and hydrogen bonding. The last two frequencies should appear in a higher region since they correspond to an almost free water molecule. Probably they are weak and hidden in the above-mentioned band.

In the dihydrate, the nearest distance between a ligand water molecule and a chlorine atom of a neighboring parallelogram is 3.75 Å, and the next to the nearest distance is 3.78 Å. The two observed bands, at 3444 and 3226 $cm^{-1}$ can be explained in relation to the crystal structure by the following assumption: one of the O–H bonds of the ligand water molecule forms a hydrogen bond with one of these two chlorine atoms, and the other is free from hydrogen bonding. We can correlate the 3226 $cm^{-1}$ band with the fomer O–H bond and the 3444 $cm^{-1}$ band with the latter since hydrogen bonding lowers the stretching frequency and the coördination effects are equal in the two cases. It is unlikely that one of the O–H bonds forms a hydrogen bond of distance 3.75 Å and the other forms a hydrogen bond of distance 3.78 Å respectively with each of the two chlorine atoms, because the frequency difference of 218 $cm^{-1}$ is far too great to be explained by the difference of the hydrogen bond distances 0.03 Å since the stretching frequency is relativery insensitive to the hydrogen bonding effect. The shoulder at 3564 $cm^{-1}$ cannot be interpreted for the present.

For the bending vibration in the hexahydrate two frequencies are observed. They can be explained readily from the crystal structure. The higher frequency (1625 $cm^{-1}$) can be attributed to the mode of the coördinated and hydrogen bonded water molecule, and the lower frequency (1599 $cm^{-1}$), the value of which is almost equal to that of the vapor state frequency (1595 $cm^{-1}$), can be assigned to the almost free water molecule since in general the two effects are likely to increase the bending frequency[8]. For the dihydrate there is observed only one bending frequency (1610 $cm^{-1}$), corresponding to the fact that there is only one kind of water molecule in the unit cell of the crystal. It is 15 $cm^{-1}$ lower than that for the ligand water molecule in the hexahydrate. This indicates that the additive effect of coördination and hydrogen bonding is greater in the hexahydrate than in the dihydrate although the coördination distance between the cobalt atom and the water molecule is somewhat shorter, and so the coördination effect is greater in the dihydrate.

The position and the shape of the wagging band at 790 $cm^{-1}$ for the dihydrate are reasonable as compared with those in the usual cases. For the hexahydrate no band was observed in this region. (These results suggest that the band at 781 $cm^{-1}$ reported for the hexahydrate in a previous paper[6] may be in fact due to the dihydrate which may have happened to be produced by partial dehydration of part of the hexahydrate during the vacuum process in the preparation of the KBr disk.)

The position and the shape of the rocking band at 642 $cm^{-1}$ for the dihydrate seem also to be reasonable. The frequencies of the wagging and the rocking band are somewhat lower than the corresponding frequencies for aluminum sulfate octodecahydrate[8] respectively.

## Summary

The observed spectra of the water of crystallization were interpreted by the effects of coördination and hydrogen bonding. The total difference in the spectra of the two crystals was explained in relation to the difference in their atomic arrangements.

# *Infrared Absorption Spectra of Water of Crystallization in Ferrous Chloride Tetrahydrate Crystal*

By Itaru GAMO

(Received February 13, 1961)

The crystal structure of ferrous chloride tetrahydrate has been determined in detail by X-ray diffraction[1]. Therefore it is possible to correlate the infrared absorption spectra of the water of crystallization with the structure.

In the present study, the characteristic bands of the water of crystallization in the crystal were determined for this purpose. Like cobaltous chloride hexahydrate and dihydrate[2], the crystal has an advantage in that observed bands can be attributed to the vibrations of water molecules almost uniquely. The spectra have an interesting feature in the bending region that has not been observed in other cases in this series of studies[2-6].

## Experimental

**Preparation.**—Commercial ferrous chloride tetrahydrate of guaranteed grade was recrystallized from water.

**Measurement.** — Spectra were recorded by a Kôken DS 301 infrared spectrophotometer equipped with a sodium chloride prism. The potassium bromide disk technique was employed.

## Results

The spectra are given in Fig. 1. In the 3 $\mu$ region, one peak is observed at 3442 $cm^{-1}$ and one shoulder at 3238 $cm^{-1}$. These are comparable to the peaks of various inorganic hydrated salts in this region, and can be assigned to the O–H stretching vibrations of water molecules affected by the interaction with an iron atom and by the hydrogen bonding with a chlorine atom. The overlapping of several stretching bands is probably responsible for the somewhat broad feature of the band. In the 5 $\mu$ region, a broad and very weak band is observed at 2301 $cm^{-1}$. It can be assigned to the combination of the bending and the wagging mode of a water molecule. It is somewhat overlapped by the carbon dioxide band at 2352 $cm^{-1}$. A similar band observed at 1740 $cm^{-1}$ is probably due to an overtone of some restricted rotation mode or a combination of such modes. In the 6 $\mu$ region, two remarkably sharp peaks of medium intensity are observed at 1626 and 1603 $cm^{-1}$, the former being a little weaker than the latter. They are assigned to the bending vibrations of water molecules affected by the same effects as in the cases of streching modes. They are the sharpest bending bands that have been observed in this series of studies. Hitherto only one bending band was observed or in the case of two peaks at least one was not sharp[2,4]. This is not because the present instrument is better in resolving power than that used in most of the previous measurements. An infrared study of the crystal by the latter instrument gave two equally sharp bands in the same region. The shoulder at 1492 $cm^{-1}$ is too low to be assigned to the bending mode and therefore should be attributed to the first overtone of the wagging mode (see below). Probably the weak band at 1229 $cm^{-1}$ has its origin in a combination or an overtone. The 755 $cm^{-1}$ band can be

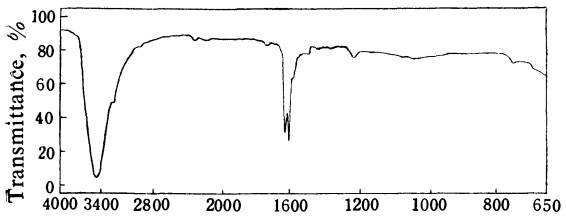

Fig. 1. Observed bands of $FeCl_2 \cdot 4H_2O$.

TABLE I. OBSERVED FREQUENCIES OF $FeCl_2 \cdot 4H_2O$

| Wave number, $cm^{-1}$ | Assignment |

assigned to the wagging mode of a water molecule because of its position and shape.

Table I summarizes these results.

## Discussion

According to X-ray analysis[1], the crystal is monoclinic and belongs to space group $P2_1/c$ with $a=5.91$, $b=7.17$, $c=8.44$ Å and $\beta=112°10'$. The structure consists of discrete groups, two per unit cell. Each group contains one iron atom, four water molecules, and two chlorine atoms. It is a distorted octahedron. There are two iron-oxygen distances: 2.09 and 2.59 Å. Hereafter the corresponding oxygen atoms will be called oxygen I and II, and the corresponding water molecules will be called type I and type II, respectively. The distance 2.59 Å is considerably greater than the sum of the ionic radii of iron and oxygen (2.16 Å). Therefore oxygen II is very weakly held in the group. The analysis suggests that oxygen I forms a pair of hydrogen bonds with two chlorine atoms in the manner shown in Fig. 2, and in oxygen II two hydrogen atoms are used to form three hydrogen bonds (Fig. 3). Therefore they are likely to be more or less bifurcated.

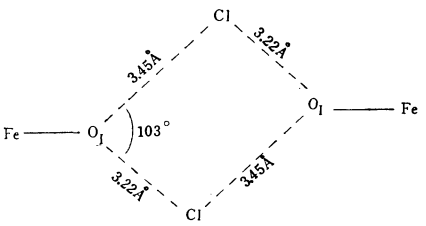

Fig. 2. Suggested hydrogen bonds for $O_I$. The error in each bond length is ±0.04 Å.

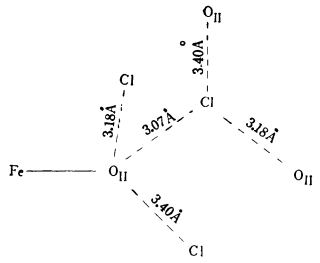

Fig. 3. Suggested hydrogen bonds for $O_{II}$. The error in each bond length is ±0.025 Å.

As in the previous studies[2-5], it will be assumed that the water frequencies are influenced by coördination and hydrogen bonding.

Figure 2 may suggest, at first sight, couplings between vibrations of two water molecules of type I due to hydrogen bonding. But it is unlikely because of the considerable difference between the distances of the two hydrogen bonds connected by the same chlorine atom. The situation is similar in the case of type II (Fig. 3). Therefore the observed two stretching frequencies are not due to splitting by hydrogen bonding. Further, there is a considerable difference between two O-H distances in each molecule because the corresponding hydrogen bonds are different in length. This suggests that the observed bands are not due to the symmetric and the antisymmetric vibration respectively.

The stretching frequency of water is in general likely to decrease by the effect of coördination, as suggested by comparison of the frequency of the ammonium ion with that of the ammonia molecule[7]. Hydrogen bonding of course lowers the frequency; therefore the two effects will be additive.

From this standpoint, it will first be assumed that the observed two bands at 3442 and 3238 $cm^{-1}$ are both due to water of type II. Since the metal-to-oxygen bond is almost purely electrostatic in this case, we have only to take into account the hydrogen bonding effect. Then, from Glemser's relationship[8] between the stretching frequency and the hydrogen bond length, the corresponding O-H···Cl distances are estimated to be 3.32 and 3.11 Å, respectively. Both values seem to be compatible with the above-mentioned suggestion concerning hydrogen bonding for oxygen II, indicating the validity of the assumption. Bands due to water of type I should appear in a lower region because the coördination effect is fairly large (distance 2.09 Å). Probably they escape detection due to their weak intensity.

The two effects influence the bending frequency also. Hydrogen bonding increases the frequency as seen in the case of ice. The observed two frequencies 1626 and 1603 $cm^{-1}$ are lower than the value 1644 $cm^{-1}$ in ice, which is free from coördination. This suggests that coördination lowers the bending frequency. The situation may be similar to that in the case of the degenerate deformation frequency of the ammonia molecule in a metal ammine complex[9], which is somewhat lower than the corresponding value of the vapor state. Probably in the case of water in general the effect of coördination should cancel partly the effect of hydrogen bonding. This seems to be responsible for the relatively small change in the bending frequency by the two effects, as compared with that in the stretching frequency.

From the above-mentioned standpoint, the stronger coördination results in the lower

7) I. Gamo, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), 73, 594 (1952).
8) O. Glemser and E. Hartert, *Naturwiss.*, 42, 534 (1955).
9) G. F. Svatos, D. M. Sweeny, S. Mizushima, C. Curran and J. V. Quagliano, *J. Am. Chem. Soc.*, 79, 3313 (1957).

bending frequency. Thus the observed bands at 1626 and 1603 $cm^{-1}$ can be reasonably attributed to water molecules of type II and of type I, respectively, since the coördination is considerably weaker in the former and the hydrogen bonding effects are approximately equal in the two cases. For the present, their remarkable sharpness cannot be correlated with the crystal structure.

Experimental results[3,5] show that either of the two effects increases the wagging frequency. The band at 755 $cm^{-1}$ is reasonably attributed to the wagging mode of water of type I, the metal-oxygen distance being 2.09 Å. The wagging band due to type II should appear in a lower region, because in this case the coördination effect is very small (distance 2.59 Å) and the hydrogen bond strength is of the same order as in ice, which is free from coördination and has a wagging band near 600 $cm^{-1}$.

**Summary**

The observed spectra of the water of crystallization were correlated with the crystal structure determined by X-rays. They were interpreted as affected by coördination and hydrogen bonding. The coördination was concluded to lower the bending frequency of water in general. Two remarkably sharp bending bands were found.

The author wishes to express his thanks to Professor Takehiko Shimanouchi of the University of Tokyo for his helpful guidance.

# *Absorptiometric Determination of Micro-amounts of Iron in Nuclear Grade Graphite and Urania-Graphite Fuel; Nitroso R Salt Method after Coprecipitation of Iron with Manganese Dioxide**

By Masatoshi MIYAMOTO

(Received January 24, 1961)

It has been necessary, in the author's laboratory, to determine micro-amounts of iron in nuclear grade graphite and urania-graphite fuel for a nuclear reactor. Spectrographic methods have been used to estimate the iron impurity in graphite. Recently[1], the impurity in graphite of high purity was determined after concentration by a chemical method. Little literature on absorptiometric determination of the impurity in nuclear grade graphite and urania-graphite fuel is seen at present. The author has applied a method with nitroso R salt, sodium 1-nitroso-2-naphthol-3, 6-disulfonate[2,3], to these samples because the reagent has the highest sensitivity to iron at present giving very stable green color[4]. In this paper, the effect of diverse ions, preliminary separation and contamination with foreign iron are discussed.

## Experimental

**Apparatus and Materials.** — A Hitachi spectrophotometer, model EPU-2, was used for all measurements of absorbancy, matched 1 cm. cells being used. A Beckman pH-meter, model H-2, was used for acidity measurements. An electric furnace used for the ashing of samples was equipped with a protector assembled with fused silica plates to keep the sample out of possible contamination with dust from the wall of the furnace.

All the chemicals were of JIS special grade including starting materials in the following preparation of chemicals unless otherwise stated. Nitroso R salt was recrystallized from 50% aqueous ethanol. Hydrochloric acid and aqueous ammonia were purified by distillation. Cobalt sulfate was prepared by the pyrolysis of chloropentaminecobalt(III) chloride followed by furming with sulfuric acid and recrystallization. The cobalt complex was prepared according to the description by M. Biltz and W. Biltz[5]. Manganese chloride was prepared from iron-free potassium permanganate by reduction with

ethanol and dissolution of resulting manganese dioxide followed by recrystallization. For the removal of iron impurity, the permanganate was dissolved in water containing a small amount of aluminum sulfate followed by the precipitation of aluminum hydroxide with aqueous ammonia.

*Standard Iron Solution.* — A solution containing 2 mg. of iron per milliliter was made by dissolving ammonium ferric sulfate in 0.1 N hydrochloric acid. The iron concentration was checked titrimetrically with a standard permanganate solution after the reduction of iron by stannous chloride. The iron solution was appropriately diluted in time for use.

*Nitroso R Salt Solution.* — 0.500 g. of the reagent was dissolved in 100 ml. of water.

*Buffer Solution.* — A 4.00 M solution of recrystallized sodium acetate.

*Hydroxylamine Sulfate Solution.* — 5.00 g. of the salt was dissolved in 100 ml. of water.

*Manganese Solution.*—A 0.2 M solution of manganese chloride.

*Ammonium Carbonate Solution.*—A 0.1 M solution was made by dissolving the salt in 0.3 N aqueous ammonia followed by standing over night and filteration.

*Acidified Hydroxylamine Solution.*—Three parts of the hydroxylamine sulfate solution were mixed with 1 part of 6 N hydrochloric acid.

**Method.** — The absorptiometric determination of iron was made as follows unless otherwise stated: a test solution was taken in a 25 ml. volumetric flask and neutralized with dilute aqueous ammonia either against a drop of a methyl orange indicator solution or till just before the precipitation of iron. Two milliliters of 0.1 N hydrochloric acid and 1.0 ml. of the hydroxylamine sulfate solution were added and the liquid was swirled well followed by dilution to about 20 ml. Two milliliters each of the reagent solution and the buffer solution were added in the order with stirring. The liquid was diluted to the mark. The flask was immersed in boiling water for about 10 min. followed by cooling to room temperature with running water. The intensity of the resulting color was measured at 715 and 650 mμ., the wavelength widths being 1.0 mμ.

The coprecipitation of iron with manganese dioxide was made as follows unless otherwise stated: to a test solution, 10 ml. of the manganese solution was added and the solution was diluted to about 100 ml. Ten milliliters of the ammonium carbonate solution was added. Five milliliters of about 3% hydrogen peroxide was added with stirring and the solution was heated on a boiling water bath for 30 to 40 min. The resulting precipitate was centrifuged at 3,000 r. p. m. for 10 min. followed by washing with about 15 ml. of water. It was dissolved in 5 ml. of the acidified hydroxylamine solution. The resulting solution was transferred into a quartz dish and evaporated on a water bath till dryness. The residue was taken with 2.0 ml. of hot 0.1 N hydrochloric acid and transferred into a 25 ml. volumetric flask for the determination of iron.

## Results and Discussion

In the following discussions, a deviation within 2% was allowed.

**Adjustment of Acidity and Effect of Diverse Ions.**—An optimum pH-range for the full color development was reported by the present author[3] to be 5.3 to 6.5. The acidity of a test solution, which contains 0.5 to 4.0 ml. of 0.1 N hydrochloric acid can be satisfactorily adjusted within the optimum range by the addition of 2.0 ml. of the buffer solution.

Griffing and Mellon[6] reported the effect of many diverse ions. The present results obtained with several ions are shown in Table I. According to the previous workers, vanadium-(V) interferes strongly because of its color formation. The present result, however does not indicate any interference with the color intensity of iron complex by the presence of at least 10 p. p. m. of the ion. Manganese(II) gives an absorption band around 440 mμ. The strong effect of an increased amount of the reagent or the metal ion on the intensity of the band suggests that the manganese(II) complex formed is unstable. The instability of the complex permits the presence of a large amount of the metal ion without interference in the color development of iron. An intense red color of cobalt(III) complex, which has disappeared by the heating for completion of the color reaction of iron, gradually appears again when the solution is left to stand. Fortunately, the red complex does not give absorption at 715 mμ. Because of the high stability of the red complex, however, the use of increased amounts of the reagent is required for the full color development of iron. Uranium(VI) does not give any absorption in long wavelength region. The presence of a very large amount of the ion is thus permitted. This is parallel with Nageswara Rao and

TABLE I. EFFECT OF DIVERSE IONS ON THE DETERMINATION

Each test solution contains 2.00 p. p. m. of iron at the final concentration.

| Diverse ions* added, p. p. m. | | Errors, % 715 mμ | Errors, % 600 mμ | Amounts of the reagent soln. used, ml./25 ml. |
|---|---|---|---|---|
| Sodium | 4,600 | −0 | 1 | 2.00 |
| Vanadium(V) | 10 | 1 | 0 | 2.00 |

Raghava Rao's results[7] on the reaction of uranyl ion with the reagent.

**Removal of Diverse Ions by Coprecipitation of Iron with Manganese Dioxide.** — Dean and Lady[8] selectively decomposed colored complexes of diverse ions with hydrazine under a carefully controlled condition without affecting the color intensity of the iron complex. Very recently, Ishii[9] extracted iron with tributyl phosphate for absorptiometric determination of iron impurity in uranium metal with 1, 10-phenanthroline. The present author coprecipitated iron with manganese from an ammoniacal carbonate solution leaving the diverse ions as well as uranium in the solution. The manganese was precipitated as dioxide by the oxidation of manganese(II) ion. The method is simple and appropriate for the extraction of iron out of sample solutions which contain "concentrated" uranium. Coprecipitation of iron with aluminum hydroxide was found unsuitable for the present purpose because of the resistance of the precipitate to dissolution in a dilute acid and of possible precipitation of aluminum hydroxide at the stage of the color development of the iron.

*Coprecipitation of Iron.*—Figure 1 shows the completeness of the coprecipitation of iron with 1.2 mg. of manganese. Increases in the blank absorption at 715 and 600 m$\mu$. may be attributed to iron impurity in the reagents used. Figure 2 shows the amounts of manganese required for complete precipitation of iron. It also indicates that 2 ml. of bromine water may be used as an oxidizing agent instead of hydrogen peroxide when the solution is boiled for 10 to 15 min. Hydrogen peroxide, however, is superior to bromine water because the former gives a well coagulated precipitate by warming on a water bath. Three milliliters of 3% hydrogen peroxide is sufficient for complete precipitation of manganese(II) ion. Precipitation of manganese by the reduction of permanganate[10] with formate, sulfite or ethanol[11] was found unsuitable for the present purpose because of difficulty in the collection of a very fine precipitate formed.

Filteration of the precipitate by a filter paper is unsuitable because of possible contamination with foreign iron from the filter. The amounts of iron impurity found in the Toyo, No. 5B (7 cm.) were 0.6 to 2.6 $\mu$g. per each filter. The precipitate is dissolved in the acidified hydroxylamine solution with ease. The minimum amount of the solvent required to dissolve the precipitate is 1.25 ml. A hot hydrogen peroxide solution containing hydrochloric or sulfuric acid, as the solvent, is inferior to the former.

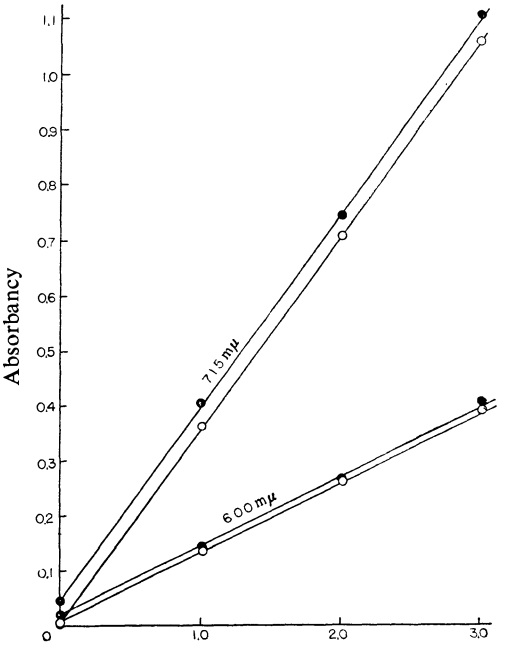

Fig. 1. Amounts of iron and color intensity. The final volume was 25 ml. ○, coprecipitation was not made; ●, coprecipitation with 1.2 mg. of manganese was made.

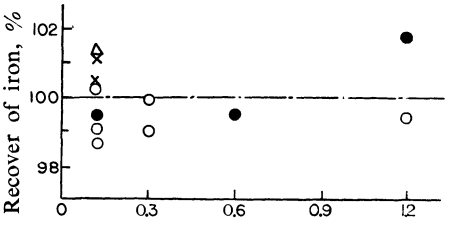

Fig. 2. Amounts manganese and recovery of iron by the coprecipitation.

Amounts of iron taken are: ●, 50 $\mu$g. (oxidation with bromine water); △, 25 $\mu$g.; ○, 50 $\mu$g. and ×, 75 $\mu$g.

*Separation of Iron from Diverse Ions.* — Results shown in Table II indicate that the separation by this method is effective to eliminate the diverse ions. One fourth milligram of platinum associated with uranium is satisfactorily removed from iron (cf. No. 5 in Table

II) while the presence of the same amount of platinum associated with many diverse ions altogether tends to give a slight positive error (cf. No. 7). The removal of cobalt is not effective (cf. No. 3). Sixty five to seventy-one percent of the original cobalt was found in manganese dioxide precipitated from a solution containing 0.25 mg. of cobalt and 50 $\mu$g. of iron.

**Determination of Iron Impurity in Nuclear Grade Graphite and Urania-Graphite Fuel.** — Copper and Chromium, which may strongly interfere with the absorptiometry, are scarcely found in appreciable amounts in nuclear grade graphite. This enables us to apply the method to samples of the graphite without any preliminary separation. The method can be applied to samples of ordinary grade graphite in the same way because iron forms the greater part of the impurities in general. In this case, absorption at 600 m$\mu$. may be used to check the degree of interference by diverse impurities comparing the intensity of the absorption with that obtained at 715 m$\mu$. Preliminary separation is required in the case of urania-graphite fuel because of comparatively large amounts of impurities in the urania component.

*Sampling.*—Contamination with foreign iron should be avoided during the sampling of analytical specimens. The use of a drill tipped with a tungsten-cobalt alloy, G2[12], is suitable for the sampling from graphite blocks by drilling. In the author's experience, the weight loss of the drill was 1.2 mg. when 2 kg. of graphite was pulverized by the drilling while the loss of an alloyed steel drill was about 6 mg. (3 p. p. m. as to the graphite) under the same conditions. The average hardness of the graphite blocks used was 27.3 by Shore unit. Crashing with a press and pulverizing in an agate mortor may also be done.

*Contamination with Foreign Iron from Platinum Crucibles.* — It was said that[11] platinum wares contain iron impurity which may be dissolved out with hot acids, giving erroneous results in determinations of micro-amounts of iron. The present author evaporated 4 ml. each of 18 N sulfuric acid in platinum crucibles on a hot plate till dryness. The crucibles were cleaned by pyrosulfate fusion and immersion in 1 to 1 hydrochloric acid successively before use. Each residue was taken with 1 ml. of hot water followed by the determination of iron. Results are shown in Fig. 3. The amounts of iron extracted from the platinum crucibles do not depend on the fuming time. This was confirmed by a statistical treatment of the data. The average amount of the iron extracted is 1 $\mu$g. which is the same amount as that found in the sulfuric acid used. From the results, platinum crucibles cleaned carefully may be used for ashing of samples and fuming with sulfuric or perchloric acid. Porcelain crucibles, "SCP" Brand, may also be used. The above fuming test applied to the crucibles gave substantially

the same results as those obtained in the case of the platinum crucibles.

*Recommended Procedure.* — Five grams of a graphite sample is ashed in a platinum crucible at about 800°C. Washed oxygen gas may be introduced into the furnace, if necessary. The ash is treated with 2 ml. of 6 N hydrochloric acid on a water bath and evaporated to dryness. The ash dissolves during the evaporation. Colored insoluble matter, if any, should be completely dissolved with the aid of 1 ml. of hydrofluoric acid followed by fuming with 1 ml. of perchloric or sulfuric acid till dryness. The resulting residue is taken with 10 ml. of 0.1 N hydrochloric acid. The solution is diluted to 50.00 ml. Ten milliliter portions of the test solution are taken in a 25 ml. volumetric flask. One milliliter of the hydroxylamine sulfate solution is added and the determination is made as described in the section "Experimental", the color intensity being measured at 715 mμ. For the preparation of the working curve a set of standard iron solutions containing 0, 1, 2 and 3 p. p. m. at the final concentrations is used.

The amount of a sample to be taken may be reduced to less than 1 g. depending on the content of iron impurity in the sample when the whole of the test solution is used for the color development. The author, however, recommends the use of 5 g. of a sample, which contains a very small amount of iron impurity, to reduce errors due to contamination and segregation of the iron impurity. The lower limit of the determination may be expected to be 2 p. p. m.

In the case of samples of urania-graphite fuel, the coprecipitation of iron should be made as described in the section "Experimental." In this case, the fuming with perchloric acid is made prior to the coprecipitation to convert chromium impurity into chromate ion. Blank tests are required when either or both the fuming and the coprecipitation are carried out.

Iron impurities in several samples determined by the method are shown in Table III. Results obtained at 600 mμ. are also shown for comparison. In the case of samples of the urania-graphite fuel, low results were obtained when the removal of diverse ions was ommitted. They are thought to be due to the consumption of the reagent by large amounts of diverse ions present.

## Summary

An absorptiometric determination of micro-amounts of iron with nitroso R salt was satisfactorily applied to the routine analysis of nuclear grade graphite. An ashed sample is brought into a solution and the color of iron is developed by the reagent with the aid of hydroxylamine sulfate. Adjustment of pH to the optimum range is easily made by the addition of a definite amount of an acetate buffer. The intensity of the color is measured at 715 mμ. The range of the determination covers 2 to 75 p. p. m. when 1 g. of a sample is taken, the final volume being 25 ml. In the case of a sample of urania-graphite fuel, the ash is fumed with perchloric acid and a preliminary separation is made by coprecipitation with manganese dioxide which is produced by the oxidation of manganese(II) ion with hydrogen peroxide in a hot ammoniacal carbonate solution. The recovery of

iron is quantitative and the removal of diverse ions is satisfactory. All of the uranium is also removed here. Contamination with foreign iron from a drill used for sampling and from the platinum or percelain crucibles used is negligible. The effect of diverse ions on the absorptiometry was also examined.

The author is indebted to Mr. H. Nihei and Miss Fukamachi for their experimental work. Acknowledgment is made to Drs. K. Ono and Y. Oka, Professors of Tohoku University, for their encouragement and also to Tokai Electrode Mfg. Co. Ltd. for their permission to publish the results.

# *Photochemical Processes due to n-π* and π-π* Transitions of 2-Picoline N-Oxide in the Vapor Phase*

By Norisuke HATA*1

(Received February 8, 1961)

As reported in the previous paper[1], the main photolytic product of pyridine *N*-oxide due to irradiation by 3261 or 2537 Å was pyridine in both cases. We observed a remarkable difference in the relation between the quantum yield of pyridine produced and the temperature.

In the case of 2-picoline *N*-oxide, however, it may be expected that the introduction of a methyl group in the 2-position of the pyridine ring might cause photochemical behavior different from that of pyridine *N*-oxide. In order to investigate the effect of 2-methyl substitution on the photolysis of pyridine *N*-oxide, the present author carried out the gaseous photolysis of 2-picoline *N*-oxide by irradiating with the 3261 Å (Cd $^3P_1$) or 2537 Å (Hg $^3P_1$) resonance line, which corresponds to absorption due to an $n$-$\pi^*$ or a $\pi$-$\pi^*$ transition of this substance, respectively. It was found from this experiment that 2-picoline *N*-oxide undergoes a photochemical rearrangement to isomerize to 2-pyridinemethanol at 3261 Å and a fission of N→O bond to produce 2-picoline at 2537 Å.

## Experimental

The 2-picoline *N*-oxide used in this experiment was prepared by the method described by Ochiai and purified by vacuum distillation several times[2]. B. p., 105~106°C/4 mmHg.

A pyrex cadmium resonance lamp was used as a light source for the photolysis in the $n$-$\pi^*$ absorption region, while a quartz mercury resonance lamp was used in the $\pi$-$\pi^*$ absorption region, and these lamps were those used for the photolysis of pyridine *N*-oxide.

The gaseous photolysis of 2-picoline *N*-oxide was carried out by a procedure similar to that of pyridine *N*-oxide described in the previous paper[1]. Photolytic products were also divided into fractions A, B, C and D just as those of pyridine *N*-oxide, where

Fraction A: Gaseous product not condensed at −196°C (liquid nitrogen).

Fraction B: Gaseous product condensed at −196°C and not condensed at −95°C (liquid nitrogen in methanol).

Fraction C: Liquid product condensed at −95°C and not condensed at −75°C (dry ice in methanol).

Fraction D: Dark brown polymer.

The pressures of fractions A and B were each measured with a Toepler-gauge, and analyzed by using a mass-spectrometer and a low-pressure gas-chromatograph (column: benzyl ether). The analysis of fraction C was done with a Shimadzu quartz spectrophotometer QB-50 and also a Shimadzu gas-chromatograph GC-1A (column: cetyl alcohol). The analysis of fraction D was not carried out.

## Results and Discussion

The ultraviolet absorption spectra of several methylpyridine *N*-oxides have been measured in polar solvents by Ikekawa et al.[3], where they discussed a relation between the maximum of $\pi$-$\pi^*$ absorption and the position of the methyl group in the pyridine ring. The author has also observed a weak shoulder absorption

with three isomeric picoline *N*-oxides in a non-polar solvent and in the vapor[4]. The absorption was regarded as due to an $n$-$\pi^*$ transition. Figure 1 shows the vapor spectrum of 2-picoline *N*-oxide which was measured with a Cary recording spectrophotometer 14 M*[2].

As described in the experimental part, the photolytic products at 3261 or 2537 Å irradiation were divided into fractions A, B, C and D. Fraction A was mainly hydrogen but included a small amount of oxygen, and fraction B was identified as carbon dioxide. Fraction C obtained as a liquid product was 2-pyridinemethanol at 3261 Å irradiation, whereas it was 2-picoline in the case of 2537 Å irradiation. The experimental results were expressed as quantum yields of fractions A, B and C at different temperatures as shown in Figs. 2 and 3.

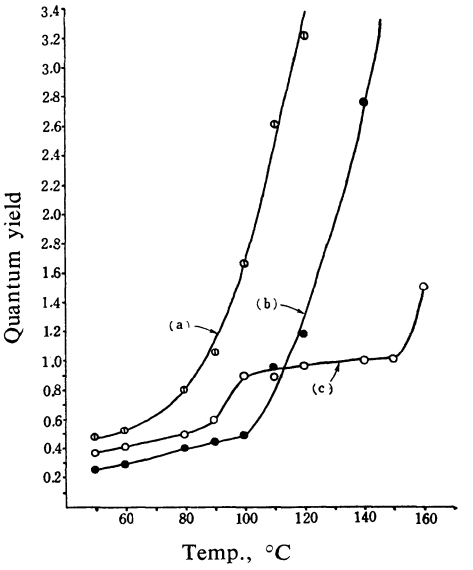

Fig. 2. Quantum yields of products versus temperature in the case of 2537 Å irradiation.

(c) —○—: Fraction C

The processes succeeding to a $\pi$-$\pi^*$ transition of 2-picoline *N*-oxide may be expressed as follows, assuming that the excited molecule passes through a triplet state as in the case of pyridine *N*-oxide[1]. That is,

(1)

4) N. Hata, This Bulletin, to be published.

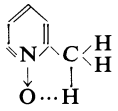
(2)



(3)

(4)

(5)

(* and *t denote the excited singlet and triplet states, respectively.)

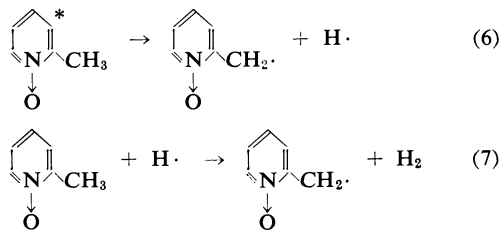


Fig. 2 indicates how the quantum yield of each photolytic product at 2537Å irradiation changes with temperature. Although the quantum yield of fraction C (2-picoline) is 0.4~0.5 at low temperatures, it increases steeply at about 90°C to a saturated value (0.9~1.0) at temperatures above 100°C. (Such a temperature dependence of the quantum yield has not been observed in the case of pyridine *N*-oxide at 2537Å irradiation, in which case the quantum yield of pyridine produced did not change substantially with temperature.) This observation suggests that an activation energy would be required for the production of 2-picoline. This may be interpreted qualitatively as follows. Excited 2-picoline *N*-oxide, due to a $\pi$-$\pi^*$ transition, presumably passes into a triplet state crossing with the excited singlet state to dissociate to 2-picoline and atomic oxygen in a predissociative manner as in the case of pyridine *N*-oxide (cf. Fig. 3 in Ref. 1). Since, for the pyridine *N*-oxide[1] or 3-picoline *N*-oxide[5] which does not possess a methyl group in the 2-position of the pyridine ring, the quantum yield of fraction C is independent on the temperature, the temperature dependence observed in the case of 2-picoline *N*-oxide must be associated with the interaction between the methyl group and the N→O group. The N→O bond energy of 2-picoline *N*-oxide is approximately the same as in pyridine *N*-oxide, i. e. ca. 110 kcal. $mol^{-1}$, although it may be smaller than 110 kcal. $mol^{-1}$ owing to the decrease of N→O double bond character caused by the hyperconjugative effect of 2-methyl group. Therefore, the process 3, by which the excited triplet 2-picoline *N*-oxide dissociates to 2-picoline and atomic oxygen, possibly does not need an activation energy. Thus, process 4 which is the alternative reaction producing 2-picoline is probably influenced by the interaction between the 2-methyl group and the N→O group. Investigation of the ultraviolet absorption spectrum of 2-picoline *N*-oxide[3,4], suggests the formation of a weak hydrogen bond between the methyl group and N→O group as shown in A. Such a weak

(A)

hydrogen bond formation may bring about a retarding effect for process 4 at low temperatures. Since the hydrogen bond is broken by the thermal perturbation caused by the increasing temperature, however, the abstraction reaction 4 would be facilitated by increasing temperature. Therefore, it is expected that the quantum yield of 2-picoline may rapidly increase to become about twice the value at low temperature. Figure 2 indicates distinctly the existence of such a tendency. The activation energy necessary for the production of 2-picoline estimated from the temperature-dependence of the quantum yield is about 1.1 kcal. $mol^{-1}$.

2-Picoline *N*-oxide gives rise also to substantial amounts of hydrogen upon irradiation with 2537Å, where the quantum yield increases remarkably with rising temperature as shown in Fig. 2. This is probably due to a participation of the following processes in addition to the process 5.

(6)

(7)

Although $D(CH_2\text{-}H)$ in 2-picoline *N*-oxide is not known, it is reasonable to assume processes 6 and 7, since the gaseous photolysis of toluene produces hydrogen[6].

In addition to processes 6 and 7, the production of fractions A, B and D probably resulted from the process 5 between excited 2-picoline *N*-oxide and oxygen produced by process 4 as in the case of pyridine *N*-oxide. To confirm the correctness of this reaction the gaseous photolysis was attempted for the mixture of 2-picoline *N*-oxide and oxygen, expecting that the 2-picoline would decrease and other products

(a) —●—: Fraction B
(b) —○—: Fraction C

would increase with increasing oxygen pressure. The experimental results are expressed as amounts of fractions B (carbon dioxide) and C (2-picoline) in the decomposed products under the different pressures of oxygen. The results support clearly the occurence of process 5 described above.

In the case of 3261 Å irradiation ($n$-$\pi^*$ transition), 2-picoline *N*-oxide isomerizes to 2-pyridinemethanol by a rearrangement of the oxygen atom of N→O group to the methyl group as shown in process 8 and the production of fractions A, B and D were very small.

(8)

As seen from Fig. 3, the quantum yield of fraction C shows a maximum value at about 70°C and approximate temperature-independence at temperatures greater than 100°C. The fact that the quantum yield is affected by changes in temperature seems to indicate that process 8 requires some activation energy. Its activation energy estimated from the quantum yield and the temperatures*3 is about 3.4 kcal. $mol^{-1}$. This production of 2-picoline from its *N*-oxide at 3261 Å irradiation requires, presumably, an activation energy of about 11～12 kcal. $mol^{-1}$, considering the fact that the activation energy for the production of pyridine[1] or 3-picoline[5] from its *N*-oxide is about 11～12 kcal. $mol^{-1}$. Since the activation energy necessary for the photoisomerization of 2-picoline *N*-oxide to 2-pyridinemethanol is estimated to be about 3.4 kcal. $mol^{-1}$, however, the excited triplet molecule resulting from 3261 Å irradiation may largely undergo process 8 involving a smaller potential barrier than that for the N→O bond split.

If the photochemical behavior due to $n$-$\pi^*$ transition is only the rearrangement process described above, its products should be 2-pyridinemethanol alone. However, the fact that small amounts of decomposed and polymerized products are detected in the products as seen in Fig. 3 seems to indicate that processes 3—7 occur simultaneously with process 8. The experimental results of the photolysis for the mixture of constant amounts of 2-picoline *N*-oxide and different pressures of oxygen suggest that the above assumption is reasonable. That is, as seen from Figs. 4 and 5 the fact that fraction B increases rapidly and fraction C decreases with increasing pressures of oxygen

*3 The quantum yield of 2-pyridinemethanol (fraction C) decreases at temperatures above 80°C, which may probably be ascribed to the increase of quenching of the excited molecule with increasing pressures of 2-picoline *N*-oxide. Therefore, the calculation of the activation energy necessary for the production of 2-pyridinemethanol was performed by using some of the quantum yields at temperatures below 80°C.

may be regarded as evidence for the reaction between excited 2-picoline *N*-oxide and oxygen.

**Summary**

The gaseous photolysis of 2-picoline *N*-oxide was carried out by irradiation with the 3261 Å (Cd $^3P_1$) or 2537 Å (Hg $^3P_1$) resonance lines corresponding to an $n$-$\pi^*$ or a $\pi$-$\pi^*$ absorption of this substance, respectively.

In the case of 3261 Å irradiation, the major product was 2-pyridinemethanol, whose quantum yield showed a marked temperature-dependence. The activation energy necessary for the production of 2-pyridinemethanol was estimated to be about 3.4 kcal. mol$^{-1}$.

On the other hand, the photolytic products at 2537 Å irradiation were 2-picoline and other decomposition products and polymers. The quantum yield of 2-picoline showed a marked temperature-dependence, which may be attributed to the interaction between the 2-methyl group and the N→O group. The activation energy necessary for the production of 2-picoline was estimated to be about 1.1 kcal. mol$^{-1}$.

In conclusion, the author wishes to express his hearty thanks to Professor Ikuzo Tanaka for his kind guidance and encouragement. Thanks are also due to Mr. Y. Mori and Dr. K. Naiki for their helpful discussions during the course of this work.

# *Photochemical Processes due to n-π* and π-π* Transitions of 3-Picoline N-Oxide in the Vapor Phase*

By Norisuke HATA*1

(Received February 15, 1961)

The photochemical reactions caused by an $n$-$\pi^*$ or a $\pi$-$\pi^*$ transition of pyridine *N*-oxide and 2-picoline *N*-oxide were previously studied in the vapor phase[1,2], by irradiating with the 3261 Å (Cd $^3P_1$) or 2537 Å (Hg $^3P_1$) resonance line, respectively. As reported in the previous paper[2], the introduction of the 2-methyl group in pyridine *N*-oxide strongly influences the photochemical behavior of pyridine *N*-oxide both in $n$-$\pi^*$ and $\pi$-$\pi^*$ transitions. However, it is considered that the photochemical reactions of 3-picoline *N*-oxide are similar to those of pyridine *N*-oxide, because the hyperconjugative effect and also the interaction with the N→O group could be neglected with the 3-methyl group. Therefore, the present author has attempted the gaseous photolysis of 3-picoline *N*-oxide by irradiation with 3261 Å (Cd $^3P_1$) and 2537 Å (Hg $^3P_1$) resonance lines, each of which corresponds respectively to the absorption region due to an $n$-$\pi^*$ or a $\pi$-$\pi^*$ transition of 3-picoline *N*-oxide.

## Experimental

The synthesis of the 3-picoline *N*-oxide used in this experiments was done by a method similar to that of pyridine *N*-oxide*2. The product was purified by vacuum distillation several times[3]. B. p., 123°C/5 mmHg.

The light sources employed for the photolysis in the $n$-$\pi$ or $\pi$-$\pi^*$ absorption region were a pyrex cadmium resonance lamp or a quartz mercury resonance lamp, respectively, which were used in the case of pyridine *N*-oxide[1] and 2-picoline *N*-oxide[2].

Since the experimental methods are similar to those of pyridine *N*-oxide and 2-picoline *N*-oxide as reported in a previous paper[1], the description of the experimental techniques are omitted in this paper. The photolytic products were divided into fractions A, B, C and D just as in the photolysis of pyridine *N*-oxide or 2-picoline *N*-oxide, where

Fraction A: Gaseous products not condensed at −196°C (liquid nitrogen).

Fraction B: Gaseous products condensed at −196°C and not condensed at −95°C (liquid nitrogen in methanol)

Fraction C: Liquid products condensed at −95°C and not condensed at −75°C (dry ice in methanol).

Fraction D: Dark brown polymers.

The pressures of fractions A and B were each measured with a Toepler-gauge, and analyzed by using a mass-spectrometer and a low pressure gas-chromatograph (column: benzyl ether). The analysis of fraction C was done with a Shimadzu

quartz spectrophotometer QB-50 and also a Shimadzu gas-chromatograph (column: cetyl alcohol). The analysis of fraction D was not carried out.

## Results and Discussion

3-Picoline *N*-oxide has two absorption systems in the region of the near ultraviolet both in the solution of a non-polar solvent and in the vapor[4]. Figure 1 shows the absorption curves of 3-picoline *N*-oxide in the vapor phase, which was measured with a Cary recording spectrophotometer 14 M*[3]. As seen from Fig. 1, there are two absorption regions between 28000 and 40000 $cm^{-1}$, one of which is the weak absorption at about 30000 $cm^{-1}$ and the other a stronger absorption at about 35500 $cm^{-1}$. As will be described in a later paper[4], the weak absorption at the longest wavelength which consists of sharp vibrational structures having an O–O band at 29368 $cm^{-1}$ corresponds to the $n$-$\pi^*$ absorption due to an excitation of non-bonding electrons localized on the oxygen atom to the antibonding $\pi$-orbital. On the other hand, the strong absorption having its absorption maximum at about 35703 $cm^{-1}$ is considered to be due to a $\pi$-$\pi^*$ transition.

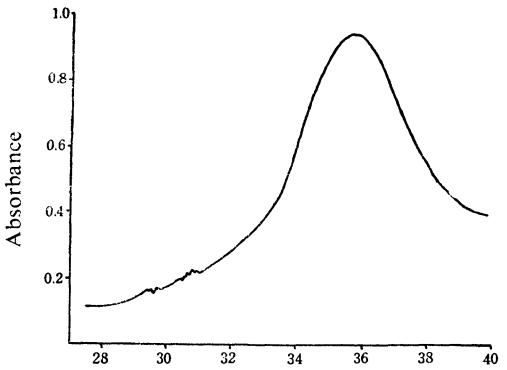

Fig. 1a. Vapor spectrum of 3-picoline *N*-oxide at 70°C. (Absorption region due to $n$-$\pi^*$ and $\pi$-$\pi^*$ transitions.)

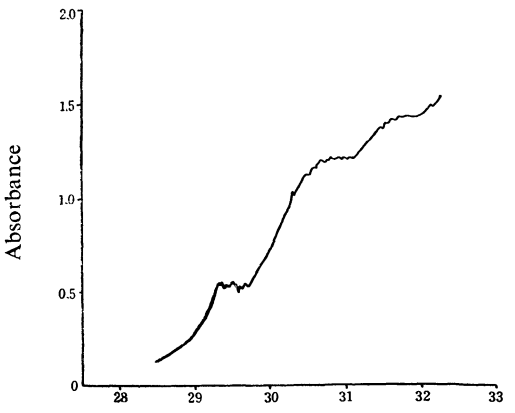

Fig. 1b. Vapor spectrum of 3-picoline *N*-oxide at 100°C. (Absorption region due to $n$-$\pi^*$ transition.)

As described in the experimental part, the photolytic products due to irradiation with 3261 or 2537 Å were divided into fractions A, B, C and D. Fraction A was largely hydrogen, although small amounts of oxygen were detected in this fraction. Fraction B was identified as carbon dioxide. Fraction C, obtained as a liquid product, was 3-picoline. The experimental results were expressed as the quantum yield of fractions A, B and C at different temperatures as shown in Figs. 2 and 3. The quantum yields of the products at temperatures greater than 160°C were not shown in these figures, because the thermal decomposition of 3-picoline *N*-oxide occurs simultaneously with the photochemical decomposition at these higher temperatures.

The experimental results of the photolysis for 3-picoline *N*-oxide are summarized as follows.

*a) A Relation between the Quantum Yield of Fraction C (3-Picoline) and the Temperature.* —In the case of 3261 Å irradiation ($n$-$\pi^*$ transition), the quantum yield increases markedly at about 80~100°C, although it has a comparatively low value at temperatures below 80°C. A further increase of the temperature causes a decrease in the quantum yield to some extent. On the other hand, the quantum yield at 2537 Å irradiation ($\pi$-$\pi^*$ transition) is independent of the temperature, and has a value of about 0.55.

*b) A Relation between the Quantum Yield of Fraction A (Mainly Hydrogen) or Fraction B (Carbon Dioxide) and the Temperature.* — The quantum yields of fractions A and B increase continuously with rising temperature with both 3261 and 2537 Å irradiation.

*c)* In either case (i.e., 3261 and 2537 Å) comparatively greater amounts of fraction D (dark brown polymer) are obtained.

*d)* When the photolysis of a mixture of 3-picoline *N*-oxide and oxygen was carried out at different pressures of oxygen, the amount of fraction B markedly increased with increasing oxygen pressure, but that of fraction C decreased.

From the experimental results described above, it is concluded that the photochemical reaction of 3-picoline *N*-oxide is quite similar to that of pyridine *N*-oxide, but not to that

of 2-picoline *N*-oxide. This fact suggests that the hyperconjugative effect of methyl group or the interaction between N→O group and methyl group may be neglected in the photolysis of 3-picoline *N*-oxide. Therefore, it may be considered that the mechanism of the photochemical reaction of 3-picoline *N*-oxide would be similar to that of pyridine *N*-oxide. Thus, we assumed the following mechanism as the processes succeeding to an $n$-$\pi^*$ and a $\pi$-$\pi^*$ transitions of 3-picoline *N*-oxide.

(1)

(2)

(3)

(4)

(5) Decomposition and polymerization

(* and *t denote the excited singlet and triplet states, respectively.)

First the 3-picoline *N*-oxide molecule is excited to the corresponding excited singlet state due to an $n$-$\pi^*$ or a $\pi$-$\pi^*$ transition caused by an absorption of 3261 or 2537 Å radiation. (Cf. the schematic potential curves for pyridine *N*-oxide as depicted in Fig. 4 of Ref. 1 for the succeeding description). Such an excited molecule probably decomposes to 3-picoline and atomic oxygen in a predissociative manner, in which a triplet state crossing with the first excited state exists presumably as a short lived intermediate. As seen from Figs. 2 and 3, the quantum yield of 3-picoline at 3261 Å irradiation shows a remarkable temperature dependence as pointed out in the experimental results a, while at 2537 Å irradiation it is independent of the temperature. This fact means that activation energy would be required for the production of 3-picoline at 3261 Å, but not at 2537 Å. The activation energy necessary for the production of 3-picoline in the case of 3261 Å irradiation is about 11.5 kcal. $mol^{-1}$, which was estimated from the relation between the quantum yield of produced 3-picoline and the temperature, and this value coincides nearly with that of pyridine *N*-oxide. Of the processes 3 and 4, which are possibly the essential reactions producing 3-picoline, the process 3 might be the only reaction requiring an activation energy. If an appreciable activation energy is required for process 4, the quantum yield of 3-picoline must also depend on the temperature even at 2537 Å irradiation. (However, the experimental results do not show any temperature-dependence of the quantum yield of 3-picoline at 2537 Å irradiation). As reported in a previous paper for the case of 2-picoline *N*-oxide[2], the temperature-dependence of the quantum yield of 2-picoline observed at 2537 Å irradiation was attributed to the interaction between the 2-methyl group and the N→O group as one of the main factors. Therefore, in the case of 3-picoline *N*-oxide the experimental result obtained at 2537 Å irradiation

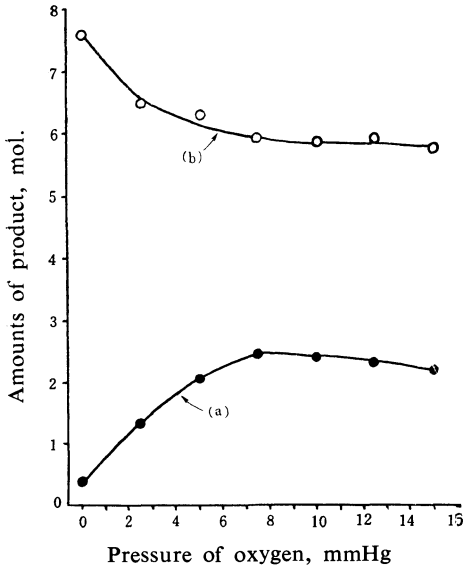

Fig. 4. Amounts of products versus oxygen pressure in the photolysis of mixtures of 3-picoline *N*-oxide and oxygen at 3261 Å (irradiation time: 2 hr., temperature: 100°C).
(a) —●—: Fraction B
(b) —○—: Fraction C

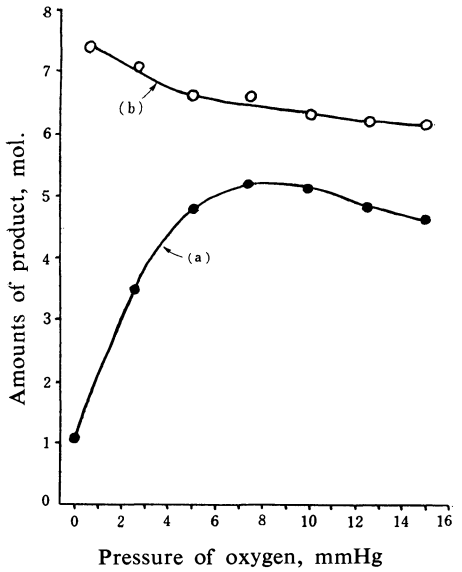

Fig. 5. Amounts of products versus temperature in the photolysis of mixtures of 3-picoline *N*-oxide and oxygen at 2537 Å (irradiation time: 10 min., temperature: 80°C).
(a) —●—: Fraction B
(b) —○—: Fraction C

(which is similar to that of pyridine *N*-oxide) supports the idea of the importance of the interaction between 2-methyl group and N→O group in the photolysis of 2-picoline *N*-oxide.

The results of the photolysis of mixtures of constant amounts of 3-picoline *N*-oxide and different pressures of oxygen are shown in Figs. 4 and 5 for the cases of 3261 and 2537 Å irradiations, respectively. These results indicate that the amounts of 3-picoline decrease and that of fraction B (carbon dioxide) increases with increasing oxygen pressure. This is regarded as evidence for the occurrence of the reaction 5 between the excited molecule and oxygen. In Figs. 4 and 5, the tendency for the amounts of products observed at oxygen pressures greater than about 7.5 mmHg to approach a saturated value may be ascribed to collisional deactivation of the excited molecule by oxygen with increasing pressures of oxygen.

## Summary

Gaseous photolysis of 3-picoline *N*-oxide was attempted by irradiation with the 3261 Å (Cd $^3P_1$) or 2537 Å (Hg $^3P_1$) resonance line corresponding to an $n$-$\pi^*$ or a $\pi$-$\pi^*$ absorption region, respectively, of this substance. In either case, the photolytic products were mainly 3-picoline, and we observed a remarkable temperature-dependence for the quantum yield of 3-picoline in the case of 3261 Å irradiation but not in the case of 2537 Å irradiation. This observation suggests that an activation energy would be required for the production of 3-picoline at 3261 Å only. The activation energy estimated from the relation between the quantum yield of produced 3-picoline and the temperature at 3261 Å irradiation was about 11.5 kcal. mol$^{-1}$, which is almost about the same value as that of pyridine *N*-oxide. The reactions succeeding to an $n$-$\pi^*$ or a $\pi$-$\pi^*$ transition of 3-picoline *N*-oxide were considered to be similar to the case of pyridine *N*-oxide.

In conclusion, the author wishes to express his hearty thanks to Professor Ikuzo Tanaka for his kind guidance and encouragement. Thanks are also due to Mr. Y. Mori and to Dr. K. Naiki for their helpful discussion during the course of this work.

# *Infrared Spectra of Acyclic Imides. IV. Effects of Alkali Halides on the Infrared Spectra of Diacetamide*

By Toyozo UNO, Katsunosuke MACHIDA and Ikuko HAMANAKA

(Received February 6, 1961)

Anomalies in the infrared spectra of some polar molecules in the alkali halide disk technique have often been reported[1]. In case of benzoic acid[2], potassium iodide disks have been recommended to obtain the same infrared spectra as those of pastes. On the other hand, molecules containing the -CONHCO- group such as succinimide[3], cyanuric acid[4] and barbituric acid[5], have been reported to undergo spectral changes depending on the method of preparation of samples. In the present paper, we will report that diacetamide ($CH_3$-CONHCO-$CH_3$), which has been revealed to exhibit dimorphism[6], also shows an analogous anomaly. An inversion of configuration of the -CONHCO- group is suggested to take place in the course of this spectral change. The ionic radii of the anions and the cations of alkali halides involved as well as the amount of water contained in the sample have been proved to influence the spectral change. The effect of compression in the disk technique has also been examined.

## Results and Discussion

**Alkali Halide Anomaly and Dimorphism of Diacetamide.** — The crystal of diacetamide in form A undergoes marked changes in infrared spectra on the addition of various alkali halides. This phenomenon was observed at first for potassium iodide, in the course of measurements in the disk technique. As reported in the preceding paper[6], diacetamide in form A shows two C=O stretching bands at 1734 and 1700 $cm^{-1}$, the stronger one being the band at 1700 $cm^{-1}$. This was always the case for Nujol or hexachlorobutadiene pastes. For potassium bromide disks however, both of these bands sometimes underwent changes in relative intensities so that the band at 1734 $cm^{-1}$ became the stronger one. In an attempt to prevent this spectral change, the use of potassium iodide as the matrix[2] was made to result in a marked spectral change of different type over the whole region measured.

On the other hand, another crystal form (form B) was found for diacetamide[6] and a close similarity in infrared spectra was observed between pastes of the form B and potassium iodide disks of form A. Furthermore, form A and form B were proved to involve the trans-cis and the trans-trans -CONHCO- group respectively, giving rise to infrared spectra markedly different from each other. Thus, the above fact concerning potassium iodide suggests that the configuration of the -CONHCO- group is changed from the trans-cis to the trans-trans configuration in the course of preparation of potassium iodide disks from form A. To confirm this, further investigations with the use of various alkali halides have been made and the following results have been obtained.

**Effects of Various Alkali Halides.** — *1) Potassium Iodide, Sodium Iodide and Sodium Bromide.*—The presence of these alkali halides gives rise to analogous changes in infrared spectra of the form A of diacetamide not only in the disk technique but also in the paste method. Here, the paste method means the technique in which the mixture of diacetamide in form A and one of potassium iodide, sodium iodide and sodium bromide (the molar ratio being approximately one to one) is mulled with Nujol or hexachlorobutadiene. It is seen from this fact that the primary factor for the spectral change is not in the disk technique itself but in the alkali halide used. By the application of the paste method, the effect of water adsorbed on alkali halides or other impurities can be made negligible since in this case the amounts of diacetamide and alkali halide are comparable to each other. Furthermore, the paste method is preferable to examine the corresponding spectral changes for diacetamide-*d* since the infrared spectra of highly pure diacetamide-*d* can be obtained only with a rapid technique such as the paste method. Considering these advantages of the paste method, we have carried out the measurements in the present study mainly on the

pastes of the two-component systems of diacetamide and various alkali halides[7].

The infrared spectra of the two-component systems containing potassium iodide and sodium bromide are shown in Figs. 1, (a) and (b) respectively. It is obviously seen that these spectra resemble that of diacetamide in the form B[6]. These two-component systems show the sharp symmetric imide I band near 1750 $cm^{-1}$ as well as the weak but well resolved antisymmetric imide I band near 1700 $cm^{-1}$. The latter band has been supposed to be overlapped by the broad symmetric imide I band in the spectrum of the undeuterated species in form B[8]. Furthermore, the low-frequency shift of the antisymmetric imide I band on deuteration is obviously observed for these two-component systems. There is only a little difference in the corresponding characteristic frequencies between the system containing sodium iodide and that containing potassium iodide. The system containing sodium bromide shows however, the infrared spectrum in which some characteristic frequencies related mainly to the N-H bond are appreciably different from those observed for the systems containing iodides. The similarity in the infrared spectra between form B and the two-component system containing one of these alkali halides is also observed in the case of diacetamide-*d*.

*2) Potassium Bromide, Potassium Chloride and Sodium Chloride.*—The infrared spectrum of the two-component system consist of form A and one of these alkali halides is identical with that of form A. In other words, these alkali halides bring about no spectral change. The comparison of alkali halides described in 1 and 2 suggests that both the cation and the anion of alkali halides participate in the spectral change under consideration.

*3) Lithium Iodide, Lithium Bromide and Lithium Chloride.*—These lithium salts bring about the spectral change. Infrared spectra analogous to Figs. 1, (a) and (b) are obtained for the systems containing lithium iodide and lithium bromide respectively. The infrared spectrum of the system containing lithium chloride is shown in Fig. 1, (c), which is appreciably different from either (a) or (b) in the regions 3600 to 2000 $cm^{-1}$ and 1000 to 700 $cm^{-1}$. Since lithium halides adsorb an appreciable amount of water during the preparation of pastes, the examination of the spectral change for diacetamide-*d* on addition of lithium halides seriously suffers from the interference of the undeuterated species. Consequently, the characteristic bands of diacetamide-*d* in the two-component systems containing lithium halides could hardly be identified except for the N-D stretching band.

On the basis of the above fact, those infrared spectra obtained by the addition of these alkali halides may be conveniently classified into three types $B_1$, $B_2$ and $B_3$ according to the anion involved. Thus, we have three iodides, two bromides and one chloride giving rise to the spectral types $B_1$, $B_2$ and $B_3$ in that order. Differences among the types $B_1$, $B_2$ and $B_3$, as represented by Figs. 1, (a), (b) and (c) respectively, are mainly in the N-H (and N-D) stretching and the imide V (and V′) frequencies[6,8,9]. Table I shows these frequencies for each spectral type. The other characteristic frequencies[8] of diacetamide in the two-component systems are shown in Table II. Discussions on these frequencies will be given later.

avoid the adsorption of water during the preparation of pastes, the effect of a small amount of water on this spectral change must be taken into account if lithium halides are involved. Instead of removing water from the systems containing lithium halides, the other alkali halides were re-examined in the presence of a small amount of water[10]. The result was such that sodium chloride and potassium bromide partly give rise to the spectral change in the presence of water while potassium chloride does not.

These results are summarized in Table III, from which it is seen that the presence of water favors this spectral change. This may

* A is the identical spectrum with that of form A. B's are the spectra analogous to that of form B. Suffices differentiate the features of the N-H stretching and the imide V band (see text and Table I).

be understood in connection with the fact that the recrystallizing solvent for form B is water[6]. It is also seen however, that the ionic radii of the anion and the cation are concerned with this spectral change in both samples with and without water. In the alkali halide disk technique, the contamination of water is hardly avoidable since an excess of alkali halides which are usually hygroscopic must be used in comparison with the sample. As seen from Table III, the spectral change of diacetamide in the two-component system containing potassium bromide takes place only in the presence of water. Situations may be analogous for potassium bromide disks. The water adsorbed on the matrix partly gives rise to the spectral change related to the changes in intensities of the C=O stretching bands at 1734 and 1700 $cm^{-1}$ previously mentioned.

**Effect of Compression in the Disk Technique.**— When the disk technique is applied to form B of diacetamide with potassium bromide or potassium chloride as the matrix, it is observed that the absorption bands due to form A appear partly[11]. This fact may be interpreted in terms of the degradation of crystal lattices under pressure as has been reported for substances with melting points below 90°C[3]. Since diacetamide (m. p. 81°C) is crystallized in form A from the molten liquid[6], it is not surprising that the degradation of form B is followed by the formation of form A. Thus, in the potassium bromide disk technique, the presence of water favors the change from form A to form B[12] while the compression favors the reverse change. The infrared spectra of diacetamide in potassium bromide disks may vary with changes in these two factors.

**Interaction between Diacetamide and Various Alkali Halides.** — Differences in the characteristic frequencies among the two-component systems under consideration may be interpreted in terms of interaction between the -CONHCO- group and the ions of alkali halides. As seen from Table I, the N-H (and N-D) stretching and the imide V (and V′) frequencies depend only on the anion. This fact suggests the occurrence of an ion-dipole interaction between the imide hydrogen atom and the anion. Such an interaction, if any, is expected to become weaker as the ionic radius of the anion increases. The tendency of frequency shifts shown in Table I is in accord with this expectation. As the anion is changed from $Cl^-$ through $Br^-$ up to $I^-$, the N-H (and N-D) stretching frequency increases while the imide V (and V′) frequency decreases. On the other hand, as seen from Table II, the frequencies of the bands due mainly to the vibrations of the C=O or C-N bonds depend on both the cation and the anion, suggesting that there occurs another ion-dipole interaction between the C=O oxygen atoms and the cation of alkali halides. If otherwise, the frequencies shown in Table II should depend also only on the anion. Thus, the frequency differences shown in Tables I and II suggest that the ion-dipole interaction between the anion and the N-H bond and that between the cation and the C=O bonds occur simultaneously. Table II shows that the imide I frequency increases with the ionic radii of both the anion and the cation, while the imide II, III and II′ frequencies show the reverse shifts. The frequency shifts of the characteristic bands of monosubstituted amides depending on the polarity of the molecule have been well investigated[13]. Since similar shifts on the change of polarity are expected for the corresponding characteristic frequencies of acyclic imides, the above fact may be taken as indicating that the polar

10) Estimation of the amount of water added was described in Experimental Part 3.

11) For the conditions of preparations of disks, see Experimental Part 4.

12) Strictly speaking, a certain form in which the -CONHCO- group takes a configuration similar to that in form B.

13) T. Miyazawa, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), 77, 321, 619 (1956).

character of the molecule of diacetamide becomes more predominant as the ionic radii of the anion and the cation of alkali halide decrease. Furthermore, the symmetric imide I frequencies shown in Table II are higher than that of form B of diacetamide (1734 $cm^{-1}$). This fact means that the bond order of the C=O bond involved in the ion-dipole interaction with the cations is greater than that of the C=O bond involved in hydrogen bond in form B. The ion-dipole interaction between the cations and the C=O bonds seems to be so weak that this does not affect the nature of the N-H bond appreciably, resulting in the independence of the frequencies shown in Table I on the cation.

All the molecules of diacetamide in the two-component system under consideration can be involved in the ion-dipole interactions supposed from the spectral change only if the crystal lattice of form A degrades completely. This was confirmed by the powder X-ray diffraction measurement. Figure 2, (a) shows the diffraction pattern of the intimate mixture of diacetamide and potassium iodide (the molar ratio being approximately one to one)[14]. The diffraction pattern of diacetamide in form A is shown in Fig. 2, (b). It is seen that no diffraction line in (a) appears in (b). Thus, the crystal lattice of form A of diacetamide does not remain in the two-component system with potassium iodide. Furthermore, the appearance of new diffraction lines in (b) obviously indicates the formation of different lattices. These results give support to the explanation of the spectral change in terms of the ion-dipole interactions suggested above.

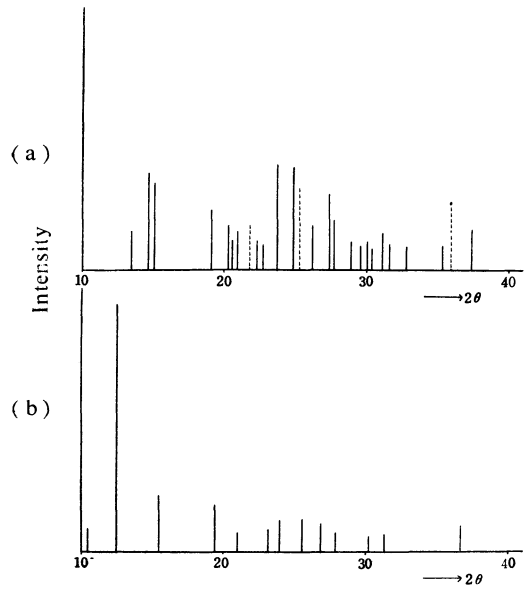

Fig. 2. Powder X-ray diffraction patterns.
(a) Diacetamide-KI system (Broken lines indicate the lines due to KI).
(b) Diacetamide in form A.

Table III shows that larger anions and smaller cations are favorable to give rise to the spectral change. Discussions will now be conducted regarding this fact on the basis of the ion-dipole interactions. The spectral change under consideration seems to be the evidence for the change in the configuration of the -CONHCO- group. Owing to the repulsive force between two oxygen atoms of the -CONHCO- group in the trans-trans configuration, the molecule in this configuration is expected to be less stable than that in the trans-cis configuration. In fact, as reported in the preceding paper[6], this is true for diacetamide. However, if a large anion such as $I^-$ approaches the hydrogen atom of a molecule in the trans-cis configuration, a strong repulsive force will be exerted between this anion and the oxygen atom at the cis position with respect to the hydrogen atom This repulsive force may be expected to increase with the ionic radius of the anion. On the other hand, if a cation approaches the oxygen atoms of a molecule in the trans-trans configuration, the repulsive force between these two oxygen atoms will be partly compensated for by the attractive forces between this cation and the oxygen atoms. The smaller the cation is, the more closely it can approach these oxygen atoms, so that the repulsive force between these two oxygen atoms decreases with the ionic radius of the cation. Thus, the simultaneous effects of the cation and the anion will give rise to the inversion from the trans-cis configuration to the trans-trans one and, as the experiment shows, the larger the anion and the smaller the cation of alkali halide are, the more easily the inversion takes place.

The actual situation in the crystalline state may be somewhat different from the monomolecular model for the ion-dipole interaction supposed above. However, it is noticed here that such a simplified model is sufficient for the qualitative elucidation of the marked spectral change. From the above discussions, it is expected that the energy difference between the trans-cis and the trans-trans configuration is rather small for diacetamide. Besides the electrostatic and the steric contribution to the energy, the energy of the formation of hydrogen bond must be taken into account to estimate the energy difference between these two configurations. However, as the problem is related to the solid state, it is difficult to determine which of these two configurations has the greater advantage for the formation of

14) See Experimental Part 5.

hydrogen bond, whose natures may be very different from each other for these two configurations.

## Conclusion

It has been found that the alkali halide disk technique gives rise to marked changes in infrared spectra of diacetamide under some conditions. This phenomenon has been proved to be related to the contamination of water, to the compression in this technique and to the ionic radii of the anion and the cation of alkali halide used. Similar spectral changes of diacetamide on the addition of various alkali halides have been interpreted in terms of the inversion of the -CONHCO- group from the trans-cis to the trans-trans configuration. In a qualitative consideration on the basis of both the electrostatic interactions and the steric effect, it has been pointed out that the possibility of the inversion is closely related to the ionic radii of both the cation and the anion.

## Experimental

1) **Materials.** — Commercially available G. P. grade sodium chloride and potassium chloride were purified according to Hales' method[15]. Commercially available E. P. grade lithium iodide and lithium bromide, G. P. grade potassium iodine, potassium bromide, sodium iodide, sodium bromide and lithium chloride were used without further purification. These alkali halides were ground to 200 mesh, dried over phosphorus pentoxide at 150~200°C, in 5~10 mmHg for 10~15 hr., and stocked over phosphorus pentoxide in a vacuum desiccator. The preparation of form A and form B of diacetamide and diacetamide-*d* has been described[6].

2) **Preparation of Pastes.** — Each of the alkali halides (2~3 mg.) described in 1 was added on a drop of Nujol or hexachlorobutadiene in an agate mill and ground by hand carefully. Then form A of diacetamide or diacetamide-*d* (2~3 mg.) was added and ground by hand rapidly for ca 30 sec. The pastes thus obtained were immediately subjected to measurement. The preceding paper will be referred to for the details of the measurement[6].

3) **Effect of Water.** — Water was added with a thin glass rod on the sample containing each of potassium iodide, potassium bromide, potassium chloride, sodium iodide, sodium bromide and sodium chloride, and pastes were prepared as described in 2. The amounts of both water and diacetamide were adjusted so that the relative intensities of the O-H and the N-H stretching bands were similar to those of the corresponding bands observed for the samples containing lithium halides. In most cases the transmittance for the band maxima near 3400 and 3200 $cm^{-1}$ were 60~70% and 30~50% respectively.

4) **Preparation of Disks.** — Potassium chloride or potassium bromide (ca. 500 mg.) and diacetamide in form B (1~2 mg.) were ground by hand in an agate mill for 3~5 min., and pressed under 120 kg./$cm^2$ in 2~3 mmHg for ca. 5 min. to prepare a disk.

5) **X-Ray Diffraction Measurement.** — Form A of diacetamide (ca. 500 mg.) and potassium iodide (ca. 830 mg.) were ground by hand carefully for 20~30 min., allowed to stand in a vacuum desiccator containing phosphorus pentoxide for a day, and subjected to the diffraction measurement (Fig. 2, (a)). Form A of diacetamide was treated similarly except for the addition of potassium iodide (Fig. 2, (b)). A Rigaku Denki X-ray diffractometer with GM counter was used and the Cu-$K_\alpha$ line was adopted.

The authors express their thanks to Dr. Tatsuo Miyazawa of Osaka University for his kind advice. Thanks are also due to Dr. Kiyoshi Nakamura of Research Laboratory, Dainihon & Co. Ltd. for his kind advice and for X-ray diffraction measurements.

# *Some Observations on the Process of Dehydration and Rehydration of Gypsum by Means of Proton Magnetic Resonance*

By Tatsuo SAITO

(Received February 15, 1961)

In the previous paper[1], the proton resonance spectra of thermally dehydrated products of alumina trihydrate in vacuo and their rehydrated specimens were measured and the relations between the phase transformation and the movements of bound water were investigated.

In the present paper, the process of thermal dehydration of natural gypsum in vacuo and their rehydration by saturated water vapor were investigated by the variation of line shapes of proton resonance spectra.

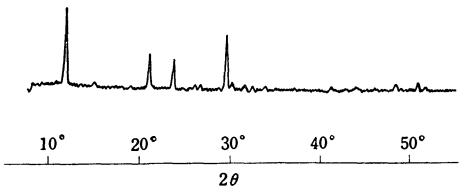
On the study of the process of dehydration and rehydration of gypsum extensive literatures have appeared. Several authors[2-8] deduced that the hemihydrate obtained from the partial dehydration of gypsum has a zeolitic type of structure such that water molecules can enter and leave it without destroying the lattice. Other authors[9] deduced that the calcium sulfate hemihydrate has a definite chemical composition and that the process of dehydration is not zeolitic in character. On the other hand, Mitsuki[10] and Razouk[8] explained that the dehydration of gypsum in vacuo leads directly to the formation of a soluble anhydrite.

The present author found by the observations of the proton resonance spectra that the soluble anhydrite produced by the thermal dehydration of gypsum occludes some quantity of movable water in the space of its crystal lattice and that the hemihydrate obtained by the rehydration of dehydrated gypsum has a definite crystal water and some quantity of movable water.

## Experimental

**Experimental Apparatus.**—The NMR measurements were performed at room temperature using the modulation technique described by Bloembergen, Purcell and Pound[11]. The detecting apparatus[12] has the ordinary constitution, which is composed of an r−f oscillator, an r−f amplifier, a detector, an audio frequency amplifier, a lock-in amplifier and a recorder. The pole face diameter of the permanent magnet is 140 mm. and the air gap length is 40 mm. The magnet has the field intensity of 4140 gauss, with a uniformity of $2\times10^{-5}$ over the whole sample volume. Continuous variation of the static magnetic field linear with time was achieved by an automatic current scanning apparatus[13].

**Specimens.**—The starting material used in this experiment was fibrous gypsum (Produces in Iwasawa, Iwate Prefecture) containing the stoichiometric amount of water according to the formula, $CaSO_4 \cdot 2H_2O$. The X-ray diffraction diagram of this material is shown in Fig. 1.



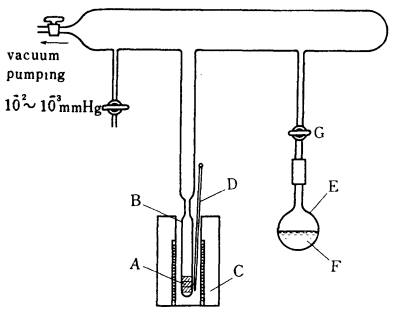


Fig. 1. X-ray diagram of the starting material, gypsum.

Each dehydration-specimen or rehydration-specimen was prepared in the vacuum system illustrated in Fig. 2. To prepare each specimen by thermal dehydration in vacuo, about 2 g. of powdered gypsum was pressed in the form of small cakes A and put into the resonance sample tube B which was connected to the high vacuum system. This sample tube B was heated from outside by an electric furnace C for 3 hr. in a high vacuum and was then sealed off. The dehydration temperatures were 70, 80, 90, 95, 100, 105, 110, 115, 125, 150 and 200°C. For the preparation of rehydration-specimens, each sample after the treatment of the thermal dehydration in vacuo was immediately exposed for 15 hr. to saturated water vapor which was introduced through the cock G from the flask E at room temperature. Then, each sample tube containing this rehydrated specimen was pumped out to a high vacuum for 12 hrs. at room temperature and was then sealed off. In this experiment, the temperature of the dehydration in vacuo was 80, 95, 110, 125, 135, 150, 165, 180, 220, 250 and 300°C.

X-Ray powder diffraction was made with a "Geigerflex" recording X-ray spectrometer using filtered $CuK_\alpha$ radiation.

## Results and Discussion

**Thermal Dehydration in vacuo.**—The experimental derivative curves of the proton resonance obtained from the dehydrated products are shown in Figs. 3 and 4. The photographs of a and b in Fig. 4 show the recorded spectra of the typical derivative curves.

As is seen in Fig. 3, the derivative curve of the starting material shows a typical line shape of two spin system[14] with broad width of about 14 gauss. While in the line shape of the specimen dehydrated at 70°C a single peak appeared overlapping the line of the starting material at its center, for the specimen dehydrated at 90°C only the center peak was observed. This characteristic single sharp peak was also observed for the specimen dehydrated at 150°C, while for the specimen dehydrated at 200°C no proton resonance signal was observed. It is known that this single sharp peak of proton resonance originates from the water molecules which are in the thermal motion.

Fig. 5. Variation of water contents in the dehydration or rehydration-specimens the dehydration temperature.

14) G. E. Pake, *J. Chem. Phys.*, **16**, 327 (1948).

To compare the above results with the change of chemical composition, the water content of each dehydration-specimen was measured and the values of percentage of weight loss at 800°C were plotted in Fig. 5 as the function of the dehydration temperature.

As is seen in Fig. 5, the water content decreases suddenly at about 70°C from the value corresponding to dihydrate to the value of 1~2% corresponding to soluble anhydrite, while the remaining water can not be completely removed even at 150°C and in this process of dehydration the steps corresponding to the formation of hemihydrate were not observed. This is in agreement with the results obtained by other authors[8,10].

In the X-ray diffraction studies, the crystallographical phase transformation was observed for the dehydration at about 70°C as shown in Fig. 6.

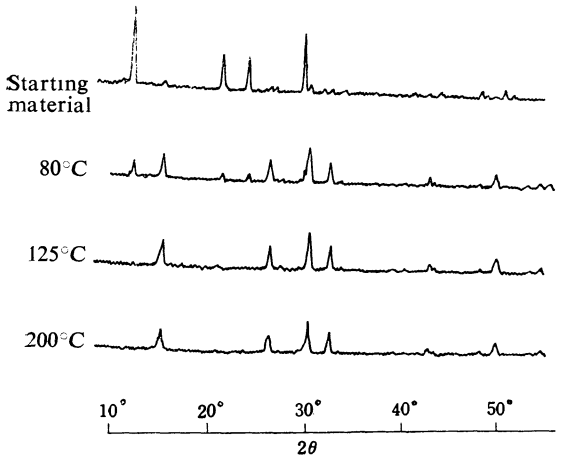

Fig. 6. X-ray diffraction diagrams of the dehydration-specimens.

From these experimental results, it is assumed that the decomposition of this gypsum occurs at 60~70°C, that some quantity of water released during the dehydration remains in the space of the crystal lattice which is introduced by the dehydration and that this movable water is gradually removed with rises of temperature, having no influence upon the crystal lattice.

On the other hand, the crystal structure of gypsum[15] may be described as a complex layer structure in which the layers are bound together by bonds from water molecules, each of which is joined to a $Ca^{2+}$, 0 atom of a $SO_4^{2-}$ ion of one layer and an 0 atom of $SO_4^{2-}$ ion of an adjacent layer.

It might be concluded from the experiments described above that these O-H-O bonds are so weak that the crystal structure of gypsum can be broken down even at low temperature and that the evolution of the binding water may occur at the same time, while some quantity of this water may remain in the space of the lattice which is introduced by the decomposition at low temperature.

**Rehydration of the Dehydration-Specimens in vacuo.**—The NMR measurements were carried out on the specimens prepared by the rehydration of gypsum thermally dehydrated in vacuo. The typical experimental derivative curves obtained from these measurements are shown in Fig. 7.

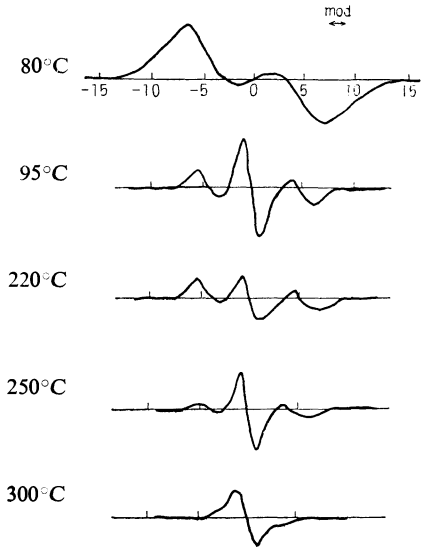

Fig. 7. Experimental derivative curves of proton resonance in the rehydration-specimens.

As is seen in Fig. 7, the rehydrated specimens of gypsum dehydrated at the temperature from 95 to 250°C show the same line shapes. The photograph of c in Fig. 4 shows the recorded spectrum of this typical derivative curve, while the rehydrated specimen of gypsum dehydrated at 80°C shows the same line shape as that of the starting material. From the measurements of the water content of these rehydrated specimens, it was found that the line shapes observed for the rehydrated specimens of gypsum dehydrated from 95 to 250°C correspond to the phase of hemihydrate, $CaSO_4 \cdot 1/2\,H_2O$. The values of the water content of these specimens were also plotted in Fig. 5 as the function of the dehydration temperature.

While these rehydration-specimens corresponding to hemihydrate were crystallographically quite similar to the dehydrated gypsum corresponding to soluble anhydrite from the result of the X-ray study, the line

15) A. F. Wells, "Structural Inorganic Chemistry", Oxford University Press, London (1950), p. 440.

shapes observed for these rehydration-specimens are different from that for the dehydrated gypsum and are presumably understood as the signal of three spin type with an intensive center peak. The line width of this line shape (the separation between peaks in side band) was about 11～12 gauss.

The product obtained from this hemihydrate by the thermal treatment at 100°C for 3 hr. in vacuo showed only the single center peak corresponding to the movable water. This movable water may also be explained as the zeolitic water existing in the space of the crystal lattice which was introduced by the dehydration of hemihydrate.

On the other hand, the rate of rehydration of gypsum dehydrated at 125°C by saturated water vapor was examined by NMR measurements and it was found that all the specimens obtained from the rehydration for one to 48 hr. showed the same line shapes as that corresponding to hemihydrate. This result means that hemihydrate is considerably stable against saturated water vapor and that the rate of hydration of soluble anhydrite is very high. This result is in agreement with the result obtained by other authors[8].

However, gypsum dehydrated at 80°C is easily rehydrated by saturated water vapor directly to dihydrate. This fact means that the product dehydrated at 80°C has the pseudolattice of gypsum and transforms easily to the phase of dihydrate by the addition of water molecules.

## Summary

1) On the thermal dehydration in vacuo, the characteristic single sharp peak of proton resonance was observed for the specimens dehydrated at the temperature from 70 to 150°C.

It is assumed that this single sharp peak is attributed to the zeolitic water probably existing in the space of the crystal lattice of soluble anhydrite and that this zeolitic water can be interpreted as being a part of the water molecules which originate from dihydrate during the thermal decomposition.

2) Calcium sulfate hemihydrate was formed by the rehydration of gypsum dehydrated in vacuo. This hemihydrate showed the proton resonance spectrum corresponding to the signal of three spin type with an intensive center peak. This intensive center peak can be interpreted as an indication of the movable water existing in the space of the crystal lattice of hemihydrate.

3) This hemihydrate was considerably stable under the atmosphere of saturated water vapor. This was ascertained by the NMR measurements.

The author wishes to express his sincere thanks to Dr. Y. Kotera of this Institute for his kind advice.

The author also wishes to express his hearty thanks to Professor Tokutaro Hagiwara of Hiroshima University for his kind direction and also to Professor Tunahiko Sidei and Dr. Syukuro Yano of Kyoto University for their continual guidance and encouragement throughout this study.

# *Studies on the Surface Structure of Porous Materials*

By Akie TSURUIZUMI

(Received December 29, 1960)

It has been generally accepted that the adsorption of gases on adsorbents such as active carbon and silica gel is both physical and chemical in nature, the latter being caused by the formation of complex surface compounds with residual active groups as well as by an ion exchange effect on the surface. The chemisorption plays a role in the earlier stage of the adsorption process, while the general behavior of the adsorption is characterized by the physical behavior.

Pore structure of the surface, which is important for both the theoretical and practical studies, could be visualized by combining

various methods such as porosimetries and adsorption measurements. A preferential physical adsorption of adsorbates with various molecular sizes could be used most effectively for classification of the pore-sizes.

In the present paper, the pore structures of various adsorbents such as active carbon and silica gel were studied. The results of adsorption measurements with water vapor and various organic vapors, the BET method using nitrogen, and mercury and water prosimetry were analyzed, and the size, shape and chemical nature of the pores were discussed in detail.

An emphasis was placed on the deviations from the prevailing theories, which are based on a simple pore model such as the cylindrical one. The analysis of the deviations enabled us to depict the shape of the pore, being of narrow-neck or ink-bottle shape. In addition, a new term, 'sieving coefficient' was proposed, which would be quite profitable for classification of the adsorbents.

## Theoretical

The pores are classified into the following three groups: micro-pores, ca. 10 Å in radii; transitional pores, 100~500 Å; micro-pores, 10000 Å. The transitional and micro-pore distributions are determined empirically by a mercury porosimetry[1]. The micro-pore distribution is calculated by Thomson's formula,

$$r=-\frac{2v\sigma\cos\theta}{RT\ln P/P_0} \qquad (1)$$

where $v$ is the molecular volume, $\theta$ the contact angle, $\sigma$ the surface tension, $r$ the pore radius, $P$ the vapor pressure of the meniscus, and $P_0$ that of the bulk phase.

A total volume of pores with a radius in a range between $r$ and $r+dr$ is represented by

$$dv=D(r)dr \qquad (2)$$

where $v$ is the total volume of the pores, and $D(r)$ the distribution function of the pore radii. The function $D(r)$ is obtained by graphical differentiation of a curve drawn by plotting the total amount of adsorption against the radii of the pores. A plot of $dv/d\log r$ vs. $\log r$ was similar to the Gaussian probability curve.

Thomson's equation is implicitly based on the following assumptions: i) Adsorption of water is caused by the capillary condensation. ii) The pore is cylindrical in shape with a uniform diameter. iii) The water adsorbed in the pore has the same density as that in bulk phase.

Cohan[2], McBain[3] and Higuchi[4] have pointed out that the size distribution function of pores having diameters less than 10 Å can not be calculated by Thomson's equation. If the radii of pores are less than 10 Å, the condensation of water vapor inside the pore is impossible, because the diameter of the void space in the pore is reduced to 2~3 molecular sizes by preliminary formation of a monolyer on the inside wall in the earlier stage of the adsorption process.

In the range of higher radius, a minor correction for pore radius less than six per cent is necessary[5]. This is due to the reduction of the pore space by the formation of the adsorption film on the wall. This correction was, however, not applied in the present study. Actually, pore-size distribution curves obtained by using Thomson's equation are in good agreement with those obtained from the adsorption of nitrogen as has been shown by Joyer[6], with those obtained by the adsorption of benzene vapor and by the mercury porosimetry reported by the present author[7].

The radius of a cylindrical pore is given by the equation[8]

$$pr=2\pi\sigma\cos\theta \qquad (3)$$

where $p$ is the applied pressure to press the mercury into the pore, $\sigma$ the surface tension of mercury, $r$ the redius of the pore and $\theta$ the contact angle.

Expressing $p$ in kg./cm$^2$, $r$ in cm., and putting $\delta=480$ dyn./cm. and $\theta=140°$C[9,10], Eq. 3 is reduced to

$$pr=7.5\times10^{-4} \qquad (4)$$

If the pores are ink-bottle or bottle-neck shaped, the appearent radii obtained by the porosimetry are those of narrow-neck shape, being less than the true ones.

IRA 400 and IRC 120) repeatedly until its electrical conductivity was reduced to as low as 4~6 $\mu\mho$/cm. The crystals of the sugar purified by recrystallization from ethanol were dried at 40°C under 5~10 mmHg. The ashes in 10 g. of the purified sugar were undetectable with a chemical balance. The sugar placed on a quartz boat in a quartz combustion tube in an electric furnace was carbonized in a stream of nitrogen gas with a flow rate of 20~30 ml./min. The traces of oxygen in this were removed beforehand by passing through a layer of heated reduced copper. The temperature of the furnace was raised at a rate of 5°C/min., and then kept at a required temperature for 30 min. The rate of temperature rise was a factor to determine the pore structure. Carbonization temperatures and yields were as follows: $S_3$, 800°C and 23.44%; $S_4$, 1000°C and 21.30%. Granules of 70~100 meshes were collected with sieves. Spectroscopic analysis: Al (−), Si (+),·····.

$SZ_3$, $SZ_4$: A mixture of 10 g. of the purified sugar and 20 g. of zinc chloride (G. P. grade) with a few drops of hydrochloric acid was heated to 200°C on a evaporating dish. The charcoals obtained by the same carbonization process as that mentioned above from the residues were boiled with hydrochloric acid (1 : 1) to remove zinc chloride, washed with distilled water till pH values of the filtrates became 5~6, and dried for 4~6 hr. at 150~170°C. Granules of 70~100 meshes were collected. Ashes in 1 g. of the sample were undetectable with a chemical balance. No traces of zinc were detected by the dichizon method[12]. Spectroscopic analysis: Al (−), Mg(±), Si(+).

*Molecular Sieve 5A**. — Composition: $Me^{12}/n\{(AlO_2)_{12}-(SiO_2)_{12}\}27-30H_2O$, (Me: Ca, Na). Highly polar. Pore diameter noted by the manufacturer was 5 Å.

*Silica Gel No. 28.* — A gel precipitated from 3 N sodium silicate and 4 N sulfuric acid at a controlled pH of 5.5 was washed with water, electrodialized for 100 hr., dried at 20~30°C, and finally at 120~150°C. 70~100 meshes.

*3SZ$_4$, 6SZ$_4$.*—A sample of $SZ_4$ impregnated with 2 per cent nitrobenzene solution of polyvinyl chloride (Geon 103EP) was carbonized by the same method as that mentioned above at 1000°C. The process was repeated three times for $3SZ_4$ and six times for $6SZ_4$. The pore volumes and internal total wall areas were shown in Tables I and II.

TABLE II. TOTAL PORE VOLUME BY WATER OR MERCURY DISPLACEMENT METHODS

| Sample | F Water displ. vol. cc./g. | G Mercury displ. vol. cc./g. | H Total pore vol. G−F cc./g. |
