The tendency toward the degradation of the odd electron density becomes more apparent when R-compounds are treated by the C–C skeleton method[13,14]. That is to say, in this more simplified procedure the energy value of the σ NBMO is just equal to α[14], as it is in the NBMO of π electron systems, while in the case of straight chain R-compounds, the coefficients of the hybridized orbitals in the σ NBMO are alternately equal to zero, those of non-zero orbitals being given by $-ma$, $+m^2a$, $-m^3a$, $+m^4a$ and so forth, as is seen in Fig. 11. (m is the coefficient of the resonance integral between sp^3 hybridized orbitals of the same carbon atom.) The odd electron distribution in the more complex R- compounds can be obtained by means of this simplified procedure. The results are given in Fig. 12. The odd electron densities at the unpaired hybridized orbital of primary, secondary and tertiary carbon atoms decrease in the order

$$(C_r^N)^2_{prim} > (C_r^N)^2_{sec} > (C_r^N)^2_{tert}$$

which is in accordance with the results obtained in Section I.

A Molecular Orbital Treatment of cis- and trans-Dichloroethylenes

By Shinhachiro SAITO*

(Received March 15, 1962)

It is well known that, for the 1,3-butadienes, the trans isomer is more stable than the cis isomer. Parr and Mulliken[1] have carried out SCF MO[2] calculations for the π electrons of these molecules, confirming this view theoretically.

Dichloroethylenes are a special case in that the cis isomer has the lower energy. This fact has been investigated by many authors[3] on the basis of thermodynamic or vibrational data. Pitzer and Hollenberg[3] suggested that the anomalous stability of the cis isomer of dichloroethylene is associated with the unlike charges between those on the Cl atom for the cis isomer and for the trans isomer. For *cis*- or *trans*-dichloroethylene, no LCAO SCF treatment such as Parr and Mulliken's has ever been made. In the present paper, LCAO SCF MO calculations of the π electrons in their ground state are undertaken. The double bond characters, the ionization potentials and the energy difference between cis and trans isomers are discussed in comparing the results with experimental data.

Ground State Orbitals and Energy

The internuclear distances and the bond angles of *cis*- and *trans*-dichloroethylenes, based on microwave or electron diffraction data, are given in the literature[4,5]. They are listed in Table I. In these calculations, it has been assumed that the cis and the trans isomer have the same internuclear distances and the same bond angles. The properly-averaged numerical values based upon Table I are as follows: the skeletones Cl–C–C′–Cl′ are planar; Cl–C–C′ and C–C′–Cl′ angles, 122°; C–C′ distances, 1.38 Å; C–Cl and C′–Cl′ distances, 1.69 Å, as is shown on the last line of Table I and in Fig. 1. These values are consistent with the experimental data in Table I; also permit us to appropriate the integrals given in the literature[6] to these calculations. Bray and Barnes[7] have shown, in their nulear quadrupole resonance study of multichlorobenzenes, that, in *o*-dichlorobenzene, the out-of-plane bending of the C–Cl bonds causes an increase in the double-bond character. If the same is true for *cis*-dichloroethylene, the ground state orbitals and energy may also be affected by the out-of-plane bending of the C–Cl bond. Therefore, a trial calculation are carried out for a staggered form* (see Fig. 2) of cis isomer at the same time with the planar cis and the trans isomer. The penetration, exchange and hybrid integrals, which are not seen in the literature, have been evaluated by the use of a uniformly-charged sphere model[6,8] and of

TABLE II

Overlap integrals (dimensionless)

	Cis	Trans	Cis 18°
$S_{CC'}$	0.266	0.266	0.266
S_{CCl}	0.166	0.166	0.182
$S_{CCl'}$	0.022	0.022	—*
$S_{ClCl'}$	0.006	0.000	—*

Penetration integrals (in eV.)

	Cis	Trans
Cl' : CCl = Cl : C'Cl'	0.024	0.043
Cl : CCl' = Cl' : C'Cl	0.015	0.018
C : ClCl' = C' : ClCl	0.001	0.000
Cl' : ClCl' = Cl : ClCl'	0.090	0.005

The symbolism for the integrals adopted here is the same as in the Refs. 1 and 6.

* These values were assumed to be the same as that of cis planer form.

Mulliken's approximation[9]. The overlap integrals are calculated by the equation given by Mulliken et al.[10] Except for the integrals referred to in the literature[1,6], the estimated values of integrals are listed in Table II. Prior to SCF calculations, the starting orbitals were calculated by the simple LCAO MO method. In these calculations, the Coulomb integrals of the chlorine atoms (denoted by α_{Cl}) were evaluated by Coulson's prescription[11], and the resonance integrals between the C and the Cl atom, β_{C-Cl}, were evaluted by Wheland's expression[12]:

$$\alpha_{Cl}-\alpha_C=(X_{Cl}-X_C)\beta_{cc}$$
$$\beta_{C-Cl}=(S_{C-Cl}/S_{cc})\beta_{cc}$$

where X_{Cl} and X_C are the electronegativities of the Cl and the C atoms, and S_{C-Cl} and S_{cc}, the overlap integrals of the C–Cl and C–C' bonds respectively. The molecular orbitals were obtained as follows:

$$\left.\begin{aligned}
\phi_1&=0.4024(\chi_{Cl}+\chi_{Cl'})+0.5815(\chi_C+\chi_{C'})\\
\phi_2&=0.6612(\chi_{Cl}-\chi_{Cl'})+0.2506(\chi_C-\chi_{C'})\\
\phi_3&=0.5815(\chi_{Cl}+\chi_{Cl'})-0.4024(\chi_C+\chi_{C'})\\
\phi_4&=0.2506(\chi_{Cl}-\chi_{Cl'})-0.6612(\chi_C-\chi_{C'})
\end{aligned}\right\} \quad (1)$$

After eight trials using these orbitals, the four orthonormal SCF orbitals, ϕ_i, and the corresponding energy levels, ε_i, were found as follows:

$$\left.\begin{aligned}
\phi_1&=\begin{Bmatrix}0.2117\\0.2357\\0.2436\end{Bmatrix}(\chi_{Cl}+\chi_{Cl'})+\begin{Bmatrix}0.5688\\0.5585\\0.5518\end{Bmatrix}(\chi_C+\chi_{C'})\\
\phi_2&=\begin{Bmatrix}0.6636\\0.6614\\0.6575\end{Bmatrix}(\chi_{Cl}-\chi_{Cl'})+\begin{Bmatrix}0.1893\\0.1900\\0.1975\end{Bmatrix}(\chi_C-\chi_{C'})\\
\phi_3&=\begin{Bmatrix}0.6828\\0.6772\\0.6750\end{Bmatrix}(\chi_{Cl}+\chi_{Cl'})-\begin{Bmatrix}0.2876\\0.3072\\0.3224\end{Bmatrix}(\chi_C+\chi_{C'})\\
\phi_4&=\begin{Bmatrix}0.2786\\0.2781\\0.2984\end{Bmatrix}(\chi_{Cl}-\chi_{Cl'})-\begin{Bmatrix}0.8157\\0.8154\\0.8168\end{Bmatrix}(\chi_C-\chi_{C'})
\end{aligned}\right\} \quad (2)$$

where the upper value of the coefficients are for the trans-, the middle for planar cis-, and the lower for the staggered cis- form respectively. The orbital energies for the six π-electrons in the field of the core are (in eV.):

ε_1	cis	−18.2491
	trans	−18.5648
	cis(staggered)	−18.5445
ε_2	cis	−12.2857
	trans	−12.0196
	cis(staggered)	−12.3744
ε_3	cis	−10.1897
	trans	− 9.0793
	cis(staggered)	− 9.4966
ε_4	cis	− 6.6847
	trans	− 6.6423
	cis(staggered)	− 7.1360

while the π-electron densities on the chlorine atoms, denoted by q_{Cl}, and the bond order of C–Cl bond, P_{C-Cl}, are:

q_{Cl}	cis	1.9113
	trans	1.9109
	cis(staggered)	1.9032
P_{C-Cl}	cis	0.2854
	trans	0.2860
	cis(staggered)	0.2995

Discussion

In comparing Eqs. 1 and 2, we can see that the results obtained by the simple LCAO MO method agree qualitatively with those resulting from the LCAO SCF calculations.

Although many assumptions are included in the SCF calculations, agreement between the calculated (ε_3) and the experimental (cis: 9.61[13] or 9.66[14]; trans: 9.91[13] or 9.96[14]) values of the ionization potential is fairly good.

As has been shown in the introductory part, the energy of the cis isomer is lower than that

of the trans isomer. It is generally known that one cannot expect the energy difference between the cis and the trans isomer quantitatively with the results of the ground state energy obtained from the MO treatment mentioned above. However, for a comparison with the experimental data, the energy difference between the cis and the trans isomers is thus estimated from the ground state total π-electron energy, E_n, by the method used by Parr and Mulliken for *cis*- and *trans*-butadienes:

$$E_n \text{ (trans)} - \left\{ \begin{matrix} E_n\text{(cis) or} \\ E_n\text{(cis, staggered)} \end{matrix} \right\} \approx 11 \text{ eV}.$$

This is surprising when compared with experimental data[3], but the calculated sign agrees with the experimetal data in that the cis isomer is more stable than the trans isomer.

The numerical values of the bond order P_{C-Cl} show that the double-bond character in the cis isomer is nearly equal to that of the trans isomer, and that the P_{C-Cl} for the staggered cis form is larger than those of the planar isomers. On the other hand, the nuclear quadrupole coupling constants[15] of the ^{35}Cl atom in the solid cis isomer are smaller than those in the solid trans isomer.

If the ionic character and the *s* character[16] in the chlorine atoms are the same for both molecules, and if the C−Cl bond of the cis isomer is to be staggered from the molecular plane in the solid state, such as in Fig. 2, the difference in the nuclear quadrupole coupling constants of the cis and trans isomers (cis: 70.00 (average), trans: 71.16) may be explained in terms of the difference in the double-bond character of the two molecules.

The author wishes to express his thanks to Dr. Siro Maéda of the Defense Academy, with whom he has been able to discuss this work.

The Formation of Acetylenic Bond by the Elimination Reaction of Some Enol-esters. I. Syntheses of Enol-esters

By Masazumi NAKAGAWA, Gen NAKAMINAMI, Fumio OGURA and Hiroshi ONO

(Received March 20, 1962)

In recent years the wide distribution of various kinds of polyacetylenic compounds in the plant kingdom was well recognized[1], and considerable attention has been directed towards the mode of the formation of such a labile molecule containing a large amount of energy in a living cell. The most plausible one among the proposed several hypotheses[2] seems to be the dehydration mechanism of an enol of a β-dicarbonyl compound by way of a suitable

$$RCOCH_2COR' \rightarrow RC(OX)=CHCOR' \rightarrow RC\equiv CCOR'$$

enol derivative. This hypothesis has been supported indirectly by recent biochemical evidence which was obtained by the ^{14}C tracer technique[3].

Quite recently, Jones has suggested that the decarboxylative elimination of pyrophosphate anion from the pyrophosphate of acetylmalonyl coenzyme A is a possible route in the formation of an acetylenic bond in vivo[4], and the mechanism has been supported experimentally by the formation of phenylpropiolic acid from enol-brosylate of diethyl benzoylmalonate in an alkaline medium[5]. But the full explanation of the Jones' hypothesis and the detail of the experimental support are not ready for our hands.

Independently we have carried out the experimental confirmation of the formation of triple bond by simple elimination reaction of several enol-esters. The present paper deals with the synthesis of some enol-esters and the formation of acetylenic compounds from them will be reported in the following papers.

The following seven enol-esters were synthesized in the present work. These hitherto unknown enol-phosphates were obtained in good yield by the reaction of the sodium derivatives of the corresponding β-dicarbonyl compounds with diphenyl phosphorochloridate (V). Diphenyl 1, 3-diphenyl-2-propen-1-on-3-yl phosphate (Ia) and diphenyl β-methoxycarbonyl-α-styryl phosphate (IIa) were obtained in crystalline form, while diphenyl 1-ethoxycarbonyl-1-propen-2-yl phosphate (IIIa) and diphenyl 3-penten-2-on-4-yl phosphate (IV) were obtained in liquid form. The last one could not be purified owing to the decomposition in the attempted distillation even under a high vacuum. The structures of these compounds were confirmed by analyses except in the case of the phosphate IV, and also by the fact that all of these were insoluble in a dilute aqueous alkali solution and gave no coloration with ferric chloride. As will be reported later, elimination reaction was successfully realized in the cases of Ia and IIa affording the correspoding acetylenic compounds.

It has long been known that *C*-acylated products are mainly obtained, when sodium derivatives of various β-dicarbonyl compounds are treated with acyl halides. However, exclusive *O*-acylation was observed in the abovementioned phosphorylation, and no *C*-acylated product was detected. The usual method of *O*-acylation with acyl halides in pyridine gave no satisfactory result for the synthesis of phosphate Ia. No reaction appeared to occur, when the copper complex of methyl benzoylacetate was treated with phosphorochloridate (V).

Although many investigations were carried out until now about the reaction of the sodium derivatives of β-dicarbonyl compounds with various sulfonyl chlorides[6], the corresponding enol-sulfonates could not be obtained except at one instance. Kohler and MacDonald[6a], and Findeisen[6b] obtained sodium *p*-toluenesulfinate, ethyl chloroacetoacetate and ethyl diacetosuccinate, when the sodium derivative of ethyl acetoacetate was treated with *p*-toluenesulfonyl chloride in dry ether. The present authors carried out the reaction in acetone and obtained 4, 4'-dimethyldiphenyldisulfone[7] together with an oil. The oily material could be distilled under a high vacuum, but a small amount of chlorine containing impurity could not be removed. The distillate was insoluble in a dilute alkali solution and gave a negative test against ferric chloride and it is likely to consist mainly of enol-tosylate of ethyl acetoacetate (IIIb). The formation of the disulfone, in the present case, is attributable to the reaction of sulfonyl chloride with the sulfinate which is produced at the first stage[7].

The sodium derivative of methyl benzoylacetate was treated with *p*-toluenesulfonyl chloride in ether, yielding crude methyl *p*-toluenesulfonyloxycinnamate (IIb) in crystals. The pure material was obtained in only a few per cent yield owing to the difficulty in the removal of a considerable amount of contaminant. The assigned structure of the tosylate IIb was supported by analysis and the fact that the substance is insoluble in aqueous alkali and gives a negative test against ferric chloride*.

Treatment of dibenzoylmethane and methyl benzoylacetate with *p*-toluenesulfonyl chloride in pyridine did not afford the desired tosylates. Also the reaction of the copper complex of the above ketoester with the sulfonyl chloride gave unsatisfactory result.

β-Benzoyloxychalcone (Ib) was prepared according to the literature[8].

Experimental**

Diphenyl 1, 3-Diphenyl-2-propen-1-on-3-yl Phosphate (Ia). — A solution of dibenzoylmethane[9] (17.3 g., 0.077 mol.) in absolute ethanol (340 ml.) was added dropwise at room temperature to a stirred solution of sodium ethoxide (from 1.8 g., 0.078 g. atom, of sodium and 175 ml. of absolute ethanol).

Ethanol was evaporated (below 40°C) under reduced pressure, and the residual yellow solid was collected on a funnel, and washed with ether. A further crop was obtained from the filtrate and washings. The well dried solid was pulverized, suspended in dry ether (150 ml.), and a solution

of diphenyl phosphorochloridate[10] (V) (19.7 g., 0.074 mol.) in dry ether (150 ml.) was added dropwise with stirring at room temperature to this suspension during 30 min. The mixture was stirred for 3 1/4 hr., refluxed with stirring for 13 hr., and was then left at room temperature for 79 hr. After addition of water (90 ml.), the insoluble solid was filtered, washed with water and ether and recrystallized from ethanol to give the fairly pure phosphate Ia (20.7 g., 59% based on dibenzoylmethane), m. p. 112.5~115°C, which was further recrystallized twice from the same solvent to yield the analytical sample, light yellow cubes, m. p. 113.5~115°C.

Found: C, 70.64; H, 4.53. Calcd. for $C_{27}H_{21}O_5P$: C, 71.05; H, 4.64%.

Dibenzoylmethane (4.2 g.) was recovered from the ethereal layer of the above-mentioned filtrate and washings.

Diphenyl β-Methoxycarbonyl-α-styryl Phosphate (IIa).—The sodium compound prepared from methyl benzoylacetate[11] (10.0 g., 0.056 mol.) was mixed with diphenyl phosphorochloridate (V) (15.0 g., 0.056 mol.) according to the same manner as described above. The reaction mixture was stirred at room temperature for 6.5 hr., allowed to stand overnight and then refluxed with stirring for 4 hr. Water (90 ml.) was added to the ice-cooled reaction mixture, and the solid phosphate was filtered and washed successively with water and ether. A further crop was obtained from the ethereal solution. Recrystallization of the combined crops from light petroleum (b. p. 60~80°C) afforded almost pure material (14.2 g., 62%), m. p. 74~76°C, which was further recrystallized from the same solvent as colorless needles, m. p. 75~76°C.

Found: C, 64.75; H, 4.69; P, 7.27. Calcd. for $C_{22}H_{19}O_6P$: C, 64.39; H, 4.67; P, 7.55%.

Diphenyl 1-Ethoxycarbonyl-1-propen-2-yl Phosphate (IIIa).—The sodium derivative (10.7 g., 0.07 mol.) of ethyl acetoacetate was mixed with diphenyl phosphorochloridate (V) (18.9 g., 0.07 mol.) as described above. The mixture was stirred for 13 hr., and kept at room temperature for several hr. Water was added and the ethereal layer was washed successively with a 5% sodium hydroxide solution and a sodium chloride solution, and dried (Na_2SO_4). After evaporation of the solvent, the residue was distilled under reduced pressure to give the phosphate IIIa (16.1 g., 63.5%) as a colorless liquid, b. p.167~172°C/2×10^{-3} mmHg, n_D^{20} 1.5336.

Found: C, 59.79; H, 5.32; P, 8.48. Calcd. for $C_{18}H_{19}O_6P$: C, 59.67; H, 5.29; P, 8.56%.

Diphenyl 3-Penten-2-on-4-yl Phosphate (IV).—The sodium compound, prepared from acetylacetone (23.6 g., 0.24 mol.), and diphenyl phosphorochloridate (V) (63.2 g., 0.24 mol.) were mixed as above. The reaction mixture was stirred at room temperature for 9 hr., left overnight, and was then treated as in the case of the phosphate IIIa affording an orange oil (54.0 g., 69%). An attempt to distill the oil was unsuccessful even under a high vacuum (3×10^{-4} mmHg) because of its slow decomposition at a bath-temperature above 150°C.

Methyl β-p-Toluenesulfonyloxycinnamate (IIb).—A mixture of methyl sodiobenzoylacetate (prepared from 3.6 g., 0.02 mol. of the ester) and *p*-toluenesulfonyl chloride (3.8 g., 0.02 mol.) obtained in the manner as used for the phosphate, was stirred at room temperature for 9 hr., refluxed for 23 hr., and left at room temperature about 100 hr. After addition of water, the ethereal solution separated was washed successively with dilute aqueous sodium hydroxide and water, and dried (Na_2SO_4). Removal of the ether afforded a solid, which was separated from a concomitant oil by filtration, washed with ether, and recrystallized from methanol to give the tosylate IIb as colorless plates (0.5 g., 7.5%), m. p. 103~104°C.

Found: C, 61.26; H, 4.83; S, 9.71. Calcd. for $C_{17}H_{16}O_5S$: C, 61.43; H, 4.85; S, 9.65%.

Ethyl β-p-Toluenesulfonyloxycrotonate (IIIb).—*p*-Toluenesulfonyl chloride (38.0 g., 0.2 mol.) in anhydrous acetone was added to a suspension of sodium compound prepared from ethyl acetoacetate (26.0 g., 0.2 mol.) in the same solvent. The reaction mixture was stirred at room temperature for 6 hr., refluxed for 5.5 hr., and then allowed to stand at room temperature for 2 days. After a large amount of water was added to the reaction mixture, a white crystalline material and an oil separated which were extracted repeatedly with benzene. The combined benzene extracts were washed with a 5% sodium hydroxide solution and with a sodium chloride solution, and dried. Evaporation of benzene gave a crystalline material together with an oil. The oil was distilled under a high vacuum affording the tosylate IIIb as light yellow viscous oil (21.9 g., 38.5%), b. p. 126~128°C/4×10^{-4} mmHg, $n_D^{20.5}$ 1.5270.

Found: C, 54.12; H, 5.55. Calcd. for $C_{13}H_{16}O_5S$: C, 54.57; H, 5.97%.

The crystals were recrystallized twice from benzene yielding 4, 4'-dimethyldiphenyldisulfone as colorless needles (2.1 g.), m. p. 208.5~209.5°C (decomp.), [lit.[7], m. p. 212°C (decomp.)].

Found: C, 54.31; H, 4.54; S, 20.36. Calcd. for $C_{14}H_{14}O_4S_2$: C, 54.17; H, 4.55; S, 20.66%.

The Formation of Acetylenic Bond by the Elimination Reaction of Some Enol-esters. II. Fission of C–C Bond in α, β-Acetylenic Carbonyl Compounds by the Action of Amide Anion

By Masazumi NAKAGAWA, Gen NAKAMINAMI, Fumio OGURA and Hiroshi ONO

(Received March 20, 1962)

The nucleophilic addition of various bases to the triple bond of α, β-acetylenic carbonyl compounds has been well known. Benzoylphenylacetylene (I), for example, readily adds amines[1] or alcohols[2] in the presence of the corresponding alcoholates giving β-amino- or β-alkoxy-chalcones, respectively. Therefore the reagents and the reaction conditions, which do not cause such addition reaction, had to be found out for the study of the elimination reaction of enol-esters to yield acetylenic compounds.

Sodium amide was first examined, because its action on the ketone I had never been known. The ketone I was treated with sodium amide in liquid ammonia resulting in the formation of phenylacetylene (II), benzoic acid (III) and benzamide (IV), while any substance arising from the addition reaction

$$\underset{\text{(I)}}{2\,C_6H_5C{\equiv}CCOC_6H_5} \rightarrow 2\,\underset{\text{(II)}}{C_6H_5C{\equiv}CH} + \underset{\text{(III)}}{HO_2CC_6H_5} + \underset{\text{(IV)}}{H_2NCOC_6H_5}$$

could not be detected at all. This fact suggests the breaking of the bond between the acetylenic carbon and the carbonyl carbon atoms. Only an example of such a bond fission has been reported in which acetylphenylacetylene is decomposed to phenylacetylene and acetic acid by the action of aqueous potassium hydroxide[3]. Under similar condition, the ketone I decomposed to yield acetophenone and benzoic acid possibly via dibenzoylmethane which was produced by the hydration of the triple bond[3].

Benzoylphenylacetylene (I) was recovered unchanged in an 80% yield when it was treated with liquid ammonia in the absence of sodium amide, indicating the essential role of amide anion for the bond fission of the acetylenic ketone. If the reaction proceeds in one step by the attack of amide anion to the carbonyl carbon displacing phenylethynyl anion, only phenylacetylene (II) and benzamide (IV) ought to be produced and the corresponding free acid should not be obtained at all. The possibility of the hydrolysis of the amide IV in the course of the isolation of the reaction products was excluded by the fact that the amide IV was recovered unchanged in about 75% yield and the acid III was obtained only in a minor quantity, when IV was treated in the same manner as in the isolation procedure. Therefore, the formation of the free acid III seems to be involved in the main reaction path, but detailed studies were not undertaken.

Diphenyl 1, 3-diphenyl-2-propen-1-on-3-yl phosphate (V)[4] was treated with four equivalents of sodium amide in liquid ammonia. Expectedly, phenylacetylene (II) and benzamide (IV) were obtained. Also diphenyl β-methoxycarbonyl-α-styryl phosphate (VI)[4] was treated with sodium amide affording phenylacetylene (II). Phenylpropiolic acid (VII, R=H) or its derivative (VII, R=CH_3 or NH_2) could not

$$\underset{\text{(V)}}{C_6H_5C(OPO(OC_6H_5)_2){=}CHCOC_6H_5} \rightarrow \underset{\text{(II)}}{C_6H_5C{\equiv}CH} + \underset{\text{(IV)}}{H_2NCOC_6H_5}$$

$$\underset{\text{(VI)}}{C_6H_5C(OPO(OC_6H_5)_2){=}CHCO_2CH_3} \rightarrow \underset{\text{(VII)}}{(C_6H_5C{\equiv}CCO_2R)} \rightarrow \underset{\text{(II)}}{C_6H_5C{\equiv}CH}$$

be detected at all. Also no basic material was obtained indicating, that no nucleophilic addition occured in this reaction.

It was confirmed from the above-mentioned results, that an acetylenic linkage can be formed by the elimination reaction of enol-ester, but it was found to be difficult to isolate the corresponding α, β-acetylenic carbonyl compound without decomposition under the above stated reaction condition.

Further studies on the elimination reaction will be reported in the following paper.

Experimental*

Reaction of Benzoylphenylacetylene (I) with Sodium Amide in Liquid Ammonia. — A solution of the ketone I[5] (4.1 g., 0.02 mol.) in dry tetrahydrofuran (50 ml.) was added dropwise to a stirred suspension of sodium amide (0.022 mol.) in liquid ammonia (50 ml.) during 45 min. After stirring for a further 3 hr., ammonium chloride (1.5 g.) was added with stirring, and the ammonia was removed. Ether (50 ml.) and then saturated aqueous sodium chloride solution (50 ml.) were added to the stirred mixture under cooling by ice. A small amount of insoluble material was filtered off and washed with ether. The ethereal solution was separated from the aqueous solution, (solution A), washed successively with sodium chloride solution (solution B), dilute sulfuric acid (solution C), and sodium chloride solution, and dried ($MgSO_4$). The oily residue, obtained by removal of the solvent through a Widmer column, separated crystals on standing. A small amount of light petroleum was added to complete the crystallization. Recrystallization of the solid (0.25 g., 10%) from aqueous methanol and then from benzene afforded benzamide as colorless plates, m. p. 126.5~128°C, which was undepressed on admixture with the authentic specimen.

Distillation (at 75.5~77.5 mmHg) of the unsolidified fraction gave phenylacetylene as colorless liquid (0.7 g.) which was converted to the mercury compound according to the usual way[6]. It was recrystallized 3 times from ethanol as colorless plates, m. p. 123~124.5°C, which showed no depression in the melting point on admixture with the authentic specimen[6]. The yield of the mercury compound was 1.0 g. (25% based on the ketone I) in a fairly pure state.

A solid was separated, on acidification with sulfuric acid (Congo red) from the combined solutions of A and B. The solid was separated by filtration, and the filtrate was extracted with ether. The ethereal solution was concentrated to give a further crop of the solid (combined yield, 1.2 g., 49%). Sublimation of the solid under reduced pressure afforded benzoic acid as colorless plates, m. p. 121~122°C, undepressed on admixture with the authentic specimen.

The solution C was made alkaline with dilute sodium hydroxide and extracted with ether to give orange crystals which could not be identified owing to its minor quantity.

Treatment of Benzoylphenylacetylene (I) with Liquid Ammonia. — A solution of the ketone I (2.0 g., 0.01 mol.) in dry tetrahydrofuran (30 ml.) was added dropwise while stirring to liquid ammonia (50 ml.). After stirring for 5 min., ammonium chloride (0.6 g., 0.011 mol.) was added in a portion, and the mixture was stirred for a further 4 1/4 hr. The ammonia was evaporated, water (50 ml.) and ether (50 ml.) were added to the residue under stirring. The ethereal solution was washed successively with dilute sodium hydroxide solution, water, dilute sulfuric acid and water, and dried (Na_2SO_4). The solvent was evaporated and the residue was distilled giving a yellow liquid (1.6 g., 80%), b. p. 153.5~160°C/2 mmHg. The infrared spectrum of the liquid was identical with that of an authentic specimen of I. The entire liquid crystallized when seeded with a piece of crystal of ketone I.

Reaction of Diphenyl 1, 3-Diphenyl-2-propen-1-on-3-yl Phosphate (V) with Sodium Amide. — A solution of the phosphate V[4] (4.6 g., 0.01 mol.) in dry tetrahydrofuran was added dropwise to a stirred suspension of sodium amide (0.04 mol.) in liquid ammonia (45 ml.) during a period of 15 min. The reaction mixture was stirred for 3 1/2 hr., and the ammonia was evaporated. A saturated solution of sodium chloride was added to the residue under stirring and cooling (ice-bath). A small amount of insoluble material was removed by filtration, and the aqueous layer was extracted with ether. The combined organic solutions were washed with sodium chloride solution, and dried (Na_2SO_4). The solvent was evaporated, and the residue deposited a solid on standing. Light petroleum was added to complete the deposition. The solid (0.8 g., 66%) was separated and then recrystallized 3 times from benzene to give benzamide as white plates, m. p. 126~127°C, which was undepressed on admixture with the authentic specimen.

Found: C, 69.43; H, 5.95; N, 11.37. Calcd. for C_7H_7ON: C, 69.40; H, 5.83; N, 11.56%.

Distillation of the unsolidified part gave phenylacetylene as a colorless liquid, b. p. 60~100°C (bath)/75~77.5 mmHg, which was converted to the mercury derivative according to the usual method[6]. Recrystallization of the mercury compound gave colorless needles or plates, m. p. 123.5~124.5°C, undepressed on admixture with authentic specimen.

The Reaction of Diphenyl β-Methoxycarbonyl-α-styryl Phosphate (VI) with Sodium Amide. —A solution of the phosphate VI[4] (15.0 g., 0.037 mol.) in dry ether (500 ml.) was added dropwise to a stirred suspension of sodium amide (0.2 mol.) in liquid ammonia (250 ml.) during 1 3/4 hr. The mixture was stirred for 1 1/4 hr. The ammonia was evaporated, and a solution of ammonium chloride (12.0 g.) in water (38 ml.) was added to the residue under stirring and cooling (ice-bath). A small amount of insoluble material was filtered and washed with ether. The organic layer separated from the lower (solution A) was washed successively with dilute sodium hydroxide solution (solution B) and water, and dried. The ethereal solution was worked up yielding phenylacetylene (1.05 g., 28%) as a colorless liquid, b. p. 72~73°C/73~73.5 mmHg, whose infrared spectrum and mercury derivative (colorless needles or plates, m. p. 123~124°C) were identical with those of the authentic specimen.

Phenylpropiolic acid or its derivatives were not detected at all whether in the solution A nor in the residue in the distilling flask.

Phenol was obtained from the ether-extract of

* All melting points and boiling points are not corrected.

the acidified solution **B**. Benzoylation by Schotten-Baumann's method afforded phenyl benzoate (4.1 g., 28% based on VI), which was crystallized from ethanol yielding light yellow needles, m. p. 67.5~69.5°C, undepressed on admixture with authentic specimen.

The authors are indebted to Mr. Masakazu Okumiya for the microanalyses. A part of the expenses of this research was defrayed from the grant-in-aid of the Ministry of Education to which the authors' thanks are also due.

*Studies on trans-Dicyanodiethoxycarbonyl Ethylene. I. The Determination of the Structure**

By Ken-ichi KUDO

(Received March 28, 1962)

Cairns and coworkers[1] synthesized tetracyanoethylene containing four cyano groups and investigated its derivatives. However, there were only a few reports for the compounds of this class. Accordingly, studies on the properties and the behaviors of *trans*-dicyanodiethoxycarbonyl ethylene (I) containing two cyano and two ethoxycarbonyl groups were attempted in comparison with tetracyanoethylene in the present paper.

(I)

In 1955, Felton[2] reported that I was prepared in about 10% yield from ethyl cyanoacetate by the oxidation with selenium dioxide. Furthermore, it was also found that dicyanodiethoxycarbonyl ethane reported by Naik[3] in 1921 was identical to the ethylene compound I prepared by the Felton method. The precise structure of I, however, was not yet determined completely.

Consequently, the physical and the chemical properties of I were investigated to determine its structure. When I was dissolved in aromatic bases (e. g., benzene, toluene, xylenes, etc.), the solutions gave intense yellow colors. These colored solutions were attributed to the formation of π-comlexes between the aromatic bases and I. The π-complex spectra of I with the aromatic bases were shown in Fig. 1.

Furthermore, the concentration dependence

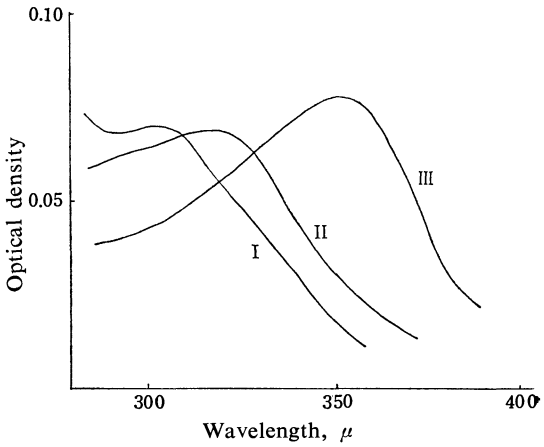

Fig. 1. The π-complex spectra of I with aromatic bases.
I (I) 0.514×10^{-4} mol./l., benzene
II (I) 0.522×10^{-4} mol./l., toluene
III (I) 0.522×10^{-4} mol./l., *o*-xylene

of these spectra was analyzed by the mothod of Keefer and Andrews[4], and Merrifield and Phillips[5]. The relation, then, is given as

$$[\mathrm{I}]\,l/\log(I_0/I) = 1/K\varepsilon\,[\mathrm{B}] + 1/\varepsilon$$

where [I] and [B] are the molar concentration of I and the mole fractions of aromatic bases, respectively, K is the association constants, log I_0/I is the optical density, and l is the cell length.

If the complex is 1 : 1 as in the case of

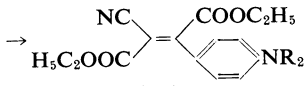
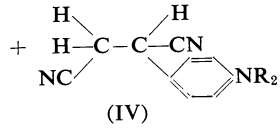
tetracyanoethylene, a plot of $[I]l/\log(I_0/I)$ vs. $1/[B]$ should be linear and yield ε as the reciprocal of the intercept, and the product $K\varepsilon$ as the reciprocal of the slope. These plots of I-aromatic complexes were shown in Fig. 2. Association constants, K, wavelength of maximum absorption, λ_{max}, and extinction coefficients for maximum absorption, ε, for nine I-aromatic complexes were listed in Table I.



From these data it appears that I is a π-acid like tetracyanoethylene[5]. However, I does not appear to be nearly as strong a π-acid; the complexes of I have an absorption maxima at shorter wavelengths than do the corresponding complexes of tetracyanoethylene. Furthermore, whereas the π-complexes of tetracyanoethylene show a progressive increase of K and λ_{max} with increasing methylation of benzene, the complexes of I do not show a similar increase.

The ultraviolet absorption spectrum of I showed a band at λ_{max} 242 mμ (log ε; 4.0313). The infrared absorption spectrum showed two bands at 1740 cm^{-1} and 1260 cm^{-1} which were attributed to the stretching vibration of C=O and C–O of ester groups, respectively, but the conjugated alkyl C≡N band at 2225±10 cm^{-1} could not be detected (Fig. 3). These results, however, are not unexpected from the fact[6] that the introduction of an oxygenated group into the molecule results in a "quenching" of the C≡N absorption intensity to a remarkable extent. The Raman spectrum showed an intense band at 1650 cm^{-1} which was attributed to the symmetrical ethylenic double bond. As a chemical evidence, the ethanolysis of I gave ethyl ethylenetetracarboxylate.



Finally, the geometrical structure of I was determined by the following manner. The reaction of I with tertiary aromatic amines

(II)

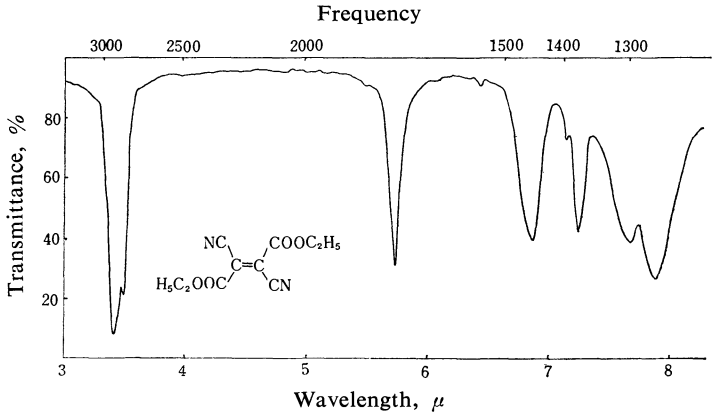
(III)

(IV)

resulted in addition of a benzene nucleus to the ethylenic double bond with the formation of 4-α, β-dicyano-α, β-diethoxycarbonyl-*N*, *N*-dialkylanilines (II). When the products II were heated with 10% aqueous sodium carbonate solution, 4-*trans*-α,β-diethoxycarbonyl-β-cyanovinyl-*N*, *N*-dialkylaniline (III) and 4-α, β-dicyanoethyl-*N*, *N*-dialkylanilines (IV) were obtained.

These addition reactions were accompanied by the production of a transient color, which would be attributed to formation of the π-complexes between I and *N*,*N*-dialkylaniline,

6) R. E. Kitson and N. E. Griffith, *Anal. Chem.*, **24**, 334 (1952).



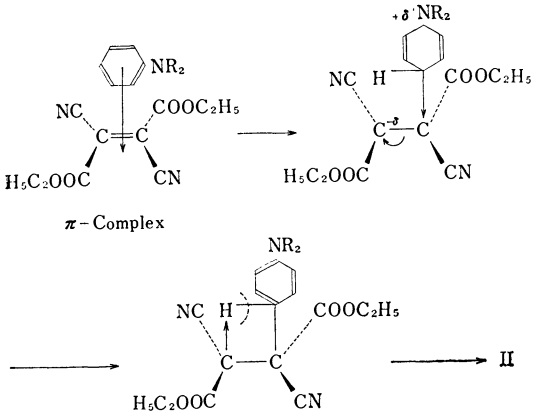


Fig. 3. Infrared absorption spectrum of I in Nujol mull.

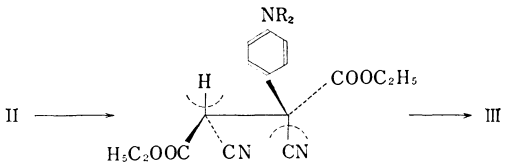


since the intense electronic absorption bands of the reaction mixture at λ_{max} 323 mμ and λ_{max} 560 mμ are attributable to neither I nor *N,N*-dimethylaniline, but to the π-complex itself as a new molecular species.

Furthermore, the course of the addition reactions was sterically specific.

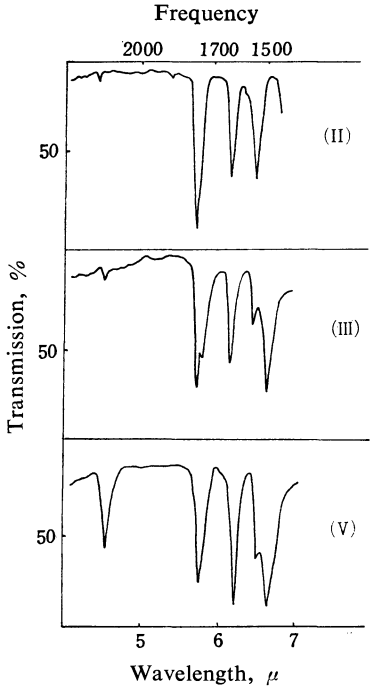
From these data it appears that the addition reactions of I with *N,N*-dialkylanilines are initiated by an ionic reaction involving electron transfer from the benzene nucleus to I. This step is probably rapid and results in th π-complex formation. The second, probably rate controlling, step in the addition reactions is a rearrangement of the π-complex to yield the adducts II. Accordingly, the course of the addition reactions would be a purely cis addition as follows:

It is generally recognized that most of the base-catalized elimination reactions, e.g., elimination of hydrogen halide or cyanide, to form a new carbon-carbon double bond proceed in a trans steric course. Accordingly, the elimination of hydrogen cyanide of II should occur in a H and a CN trans orientation (staggered form) driven by a rotation about the central carbon-carbon bond.

Thus, the evidence that the elimination product III had only a ethoxycarbonyl-ethoxycarbonyl trans geometry would drive to the conclusion that I had a trans geometry for the cyano and cyano groups.

The structures of II and IV were estimated on the basis of the infrared absorption spectra (Fig. 4). The structure of III was established definitely by the following manner. The infrared absorption spectrum of III (R ; CH_3), showed C=O bands at 1720 cm^{-1} and 1736 cm^{-1} and a C≡N band at 2220 cm^{-1} (Fig. 4). As a chemical evidence, the hydrolysis of III (R ; CH_3) with sulfuric acid gave an intramolecular acid anhydride. In addition, the structure was confirmed by the use of mixture melting points of the material with 4-*trans*-α,β-diethoxycarbonyl-β-cyanovinyl-*N,N*-dialkylaniline synthesized by an another method. Finally, the geometrical structure of III was determined on the basis of the infrared absorption spectrum. As described above, the ester C=O bands at 1736 cm^{-1} and 1720 cm^{-1} were attributed to the ester groups of α- and β-position for the benzene nucleus, respectively. Since the ester group of α-position is sterically more hindered than the other ester group, the frequency of the ester group on the α-position should shift toward a shorter wavelength from the normal position. In addition, the infrared absorption spectrum of 4-α-ethoxycarbonyl-β,β-dicyanovinyl-*N,N*-dimethylaniline[7] (V) showed an ester band at 1736 cm^{-1} (Fig. 4). The fact that the infrared absorption band of the ester on the α-position

7) B. C. McKusick et al., *J. Am. Chem. Soc.*, **80**, 2806 (1958).



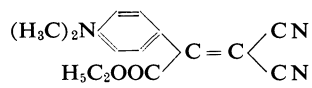


Fig. 4. Infrared absorption spectra of II, III and V.

of V coincided completely with that of the ester on the α-position of III (R ; CH_3) suggests that the α-ester group of III (R ; CH_3) is also hindered by a benzene and a cyano group, but not by an another ester group. Incidentally, Felton[8] reported that the ester C=O frequency

(V)

shifts of compounds, in which more than one ester or cyano group is attached to an ethylenic double bond, depended upon mainly the steric repulsion between these substituents. Consequently, it seems to be plausible that the configuration of III is concluded to be a trans type.

Experimental

Hydrolysis of I to Ethyl Ethylenetetracarboxylate. — A mixture of 4.4 g. of (I), 8 g. of 95% ethanol, and 8 g. of 98% sulfuric acid was heated under reflux for 7 hr. After cooling, the mixture was extracted with ether. The extract was washed with 5% sodium carbonate solution, dried with sodium sulfate, and distilled to expel ether and the residue crystallized to a colorless crystal, m. p. 54.5~55.5°C.

II(R ; CH_3).—A mixture of 22 g. (0.1 mol.) of I and 17 g. (0.14 mol.) of *N*, *N*-dimethylaniline in 50 ml. of dimethylformamide was heated at 50~60°C with stirring for 20 min. After cooling, the solvent was evaporated under reduced pressure, the residue was triturated with 50% methanol, and stood in an ice-box for several days. The solidified product was collected by filtration, washed with 50% methanol, and recrystallized from methanol-water to give 33 g. (97%) of II (R ; CH_3), m. p. 81~88°C, as colorless crystals.

Found : C, 63.07 ; H, 6.24 ; N, 12.31 ; mol. wt., 337(Rast). Calcd. for $C_{18}H_{21}O_4N_3$: C, 62.96 ; H, 6.16 ; N, 12.24% ; mol. wt., 343

Its infrared absorption spectrum had a C≡N band at 2250 cm^{-1} and a C=O band at 1760 cm^{-1}.

II(R ; C_2H_5).—In a similar procedure, II(R ; C_2H_5), m. p. 86~87.5°C, was obtained in 80% yield.

Found : C, 64.36 ; H, 6.54 ; N, 11.49 ; mol. wt., 366(Rast). Calcd. for $C_{20}H_{25}O_4N_3$: C, 64.67 ; H, 6.78 ; N, 11.31% ; mol. wt., 371.

Its infrared absorption spectrum had a C≡N band at 2250 cm^{-1} and a C=O band at 1740 cm^{-1}.

Decarbethoxylation or Elimination of Hydrogen Cyanide of II(R ; CH_3).—A mixture of 5 g. II (R ; CH_3) and 5 g. of sodium carbonate in 45 ml. of water was heated under reflux for about 20 min. to give a red oily layer. The oily layer was separated from the aqueous layer, recrystallized from benzene-petroleum benzine, and gave III (R ; CH_3), m. p. 121~122°C, as the red crystals.

Found : C, 64.45 ; H, 6.51 ; N, 8.77. Calcd. for $C_{17}H_{20}O_4N_2$: C, 64.54 ; H, 6.37 ; N, 8.86%

The crystals from the aqueous layer were collected by filtration, washed with water, and recrystallized from ethanol-water. There was obtained IV (R ; CH_3), m. p. 98~100.5°C. as yellow crystals.

Found : C, 72.25 ; H, 6.64 ; N, 21.28 ; mol. wt., 196(Rast). Calcd. for $C_{12}H_{13}N_3$: C, 72.33 ; H, 6.57 ; N, 21.09% ; mol. wt., 199.

The ultraviolet absorption spectrum of III (R ; CH_3) showed a band at λ_{max} 252 mμ (log ε ; 3.978). The infrared absorption spectrum of IV (R ; CH_3) had a C≡N band at 2250 cm^{-1} and benzene bands at 1620 cm^{-1} and 1530 cm^{-1}.

Synthesis of III (R ; CH_3) from Ethyl 4-Dimethylaminophenyl Glyoxylate.—A solution of 4 g. (0.02 mol.) of ethyl 4-dimethylaminophenyl glyoxylate, 9 g. (0.08 mol.) of ethyl cyanoacetate, and 0.5 ml. of piperidine in 7 ml. of absolute ethanol was refluxed for 30 hr. The mixture was concentrated under reduced pressure to dryness. The residue was recrystallized from benzene-petroleum benzine to give 2.8 g. (48%) of III (R ; CH_3) as red crystals, m. p. 121~122°C.

Cyclization of III (R ; CH_3) to 4-Dimethylaminophenylmaleic Anhydride.—A solution of 5 g. of III (R ; CH_3) in 40 ml. of 75% sulfuric acid was heated on boiling water for 6 hr. After cooling, the solution was poured into 100 ml. of ice-water under stirring and the aqueous mixture was neutrallized with sodium carbonate. The precipitated crystals were collected by filtration and recrystallized from acetone. There was obtained 0.8 g. (21%) of intramolecular acid anhydride in the form of dark red crystals, m. p. 179~179.5°C.

Found : C, 66.58 ; H, 5.18 ; N, 6.28 ; mol. wt., 219(Rast). Calcd. for $C_{12}H_{11}O_3N$: C, 66.35 ; H, 5.10 ; N, 6.45% ; mol. wt., 217.

8) D. G. I. Felton et al., *J. Chem. Soc.*, 1955, 2170.

Its infrared absorption spectrum showed C=O bands at 1820 cm^{-1} and 1775 cm^{-1}.

The author wishes to express his heartfelt thanks to Professor Risaburo Nakai of the Institute for Chemical Research of Kyoto University for his cordial encouragement and suggestion throughout the work. He also desires to state his sincere gratitude to Professor Ryozo Goto of Kyoto University for his invaluable advice in the course of this work. Thanks are due to Mr. Tohru Takenaka of the Institute for Chemical Research of Kyoto University for infrared spectral measurement.

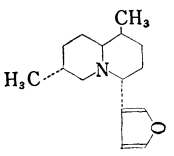
*Resolution of dl-Deoxynupharidine; The Total Synthesis of Nupharidine**

By Munio KOTAKE, Ichiro KAWASAKI, Shigeru MATSUTANI, Shiro KUSUMOTO and Takeo KANEKO



(Received April 2, 1962)

Recently we have suggested that the absolute configuration of deoxynupharidine should be represented as formula I[1]. In the course of the synthetic route of deoxynupharidine, it seems that the 7-axial methyl group has mainly been produced by catalytic reduction of the pyridine nucleus of ethyl 4-[5-methyl-pyridyl-(2)]-valerate and the 4-equatorial furyl group has been produced by catalytic reduction of 1, 7-dimethyl-4-[furyl-(3)]-dehydroquinolizidine-3. From the results that 3-methylquinolizidine obtained from 2, 5-lutidine through catalytic reduction of pyridine nucleus afforded mainly 3(a)-methyl form[2] and 4-methylquinolizidine obtained by Murakoshi's method[3] afforded only one diastereomer of 4-methylquinolizidine the synthetic mixture of deoxynupharidine[4] may be contained isomer Ia and Ib predominantly. A chromatography of the diastereoisomeric mixtures of synthetic sample on alumina[5] resulted in the separation of the following fractions. The first fraction eluted by petroleum ether gave an isomer, which was crystallized as hydrochloride. This isomer could not be lead to *N*-oxide and to iodomethylate by the same condition as used with

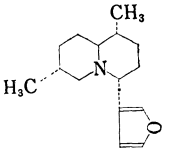


Chart I

I

Ia

Ib

success in case of a natural product. From the suggestion, that the 1(a)-methyl group of this isomer will hinder sterically the above reactions and from the evidence of NMR spectra, this isomer should be presented as 1-epimer (Ib). The fraction eluted by petroleum ether-ether, which has the infrared and NMR spectrum similar to that of natural deoxynupharidine, was oxidized with hydrogen peroxide to *N*-oxide and recrystallized as its hydrochloride (infrared spectrum in Nujol was found to be identical with that of nupharidine hydrochloride), and then reduced smoothly with palladium charcoal to give *dl*-deoxynupharidine. The treatment of *dl*-form with *l*-tartaric acid afforded *l*-deoxynupharidine *l*-tartrate as less soluble salt and the regenerated *l*-base from the tartrate oxidized to *d*-nupharidine, which was identical with a natural product in all aspects. The *d*-base also has been isolated with the aid of *d*-tartaric acid.

Experimental

To purify the reaction product, diethyl 2-[5-methylpyridyl-(2)]-allylmalonate was reduced partially with Pd-C in ethanol to diethyl 2-[5-methyl-(2)]-propylmalonate (picrate from ether, m. p. 84～85.5C, Found: C, 50.54; H, 5.01; N, 10.76. Calcd. for $C_{22}H_{26}O_{11}N_4$; C, 50.57; H, 5.02; N, 10.72%)[6] and then hydrolyzed to 4-[5-methylpyridyl-(2)]-valeric acid (m. p. 77～77.5°C, Found: C, 68.45; H, 7.88; N, 7.06. Calcd. for $C_{11}H_{15}O_2N$: C, 68.35; H, 7.82; N, 7.25%, the hydrochloride, m. p. 145～146°C, Found: C, 57.42; H, 7.06; N, 5.88. Calcd. for $C_{11}H_{15}O_2N$-HCl: C, 57.51; H, 7.02; N, 6.09%). Ethyl 4-[5-methyl-pyridyl-(2)]-valerate (b. p. 102～104°C/2 mmHg) was reduced with platinum oxide in acetic acid and then acylated with furoyl chloride immediately to give furoyl derivatives.

Natural Deoxynupharidine.—$[\alpha]_D$ −109.86° (*c* 1.16, in ethanol), the hydrochloride, m. p. 261～263°C, $[\alpha]_D$ −21.4° (*c* 0.98, in 1 N HCl).

Natural Nupharidine.—$[\alpha]_D$ +17.2° (*c* 1.10, in ethanol).

***l*-Deoxynupharidine-*l*-tartrate.** —*l*-Deoxynupharidine (0.76 g.) and *l*-tartaric acid (0.5 g.) were mixed in acetone (8 ml.) and deposited the tartrate (1.3 g.), which recrystallized from acetone-ethanol and ethyl methyl ketone, m. p. 151～152°C, $[\alpha]_D$ −14.65° (*c* 1.11, in ethanol).

Found: C, 59.26; H, 7.73; N, 3.59. Calcd. for $C_{19}H_{29}O_7N$: C, 59.51; H, 7.62; N, 3.65%.

***d*-Nupharidine-*d*-camphorsulfonate.** — *d*-Nupharidine (0.3 g.) and *d*-camphorsulfonic acid (0.3 g.) were mixed in chloroform (10 ml.) and the deposited salt (0.5 g.) recrystallized from ether-ethanol in needles, m. p. 182～183°C (decomp.), $[\alpha]_D$ +39.0° (*c* 0.9, in ethanol).

Found: C, 61.86; H, 8.25; N, 2.85. Calcd. for $C_{25}H_{40}O_6NS$: C, 62.21; H, 8.35; N, 2.90%.

Chromatography of Synthetic Deoxynupharidine. —The synthetic deoxynupharidine (42.15 g., b. p. 93～98°C/2 mmHg was chromatographed on alumina and resulted in the separation of following fractions (the fraction was checked by the infrared NMR spectroscopy);

Chromatography No. 1—1

Synthetic sample (13.3 g.) was dissolved in petroleum ether (50 ml.) and chromatographed on alumina (80 g.).

Fraction	Eluent	Volume ml.	Weight g.
1—1	Pet. ether	200	3.4
2—1	Pet. ether	200	1.7
3—1	Pet. ether	200	0.25
4—1	Pet. ether : Ether	100	0.8
5—1	Ether	100	0.65
6—1	Ether	310	0.2
7—1	Ethanol	120	4.4

Chromatography No. 1—2

Synthetic sample (15.5 g.) was dissolved in peteroleum ether (100 ml.) and chromatographed on alumina (100 g.).

Fraction	Eluent	Volume ml.	Weight g.
1—2	Pet. ether	200	2.3
2—2	Pet. ether	100	4.5
3—2	Pet. ether : Ether	100	0.8
3—2	Ether	100	1.9
5—2	Ether	200	0.3
6—2	Ether	400	0.2
7—2	Ethanol	150	4.5

Chromatography No. 1—3

Synthetic sample (13.35 g.) was dissolved in petroleum ether (100 ml.) and chromatographed on alumina (100 g.).

Fraction	Eluent	Volume ml.	Weight g.
1—3	Pet. ether	200	3.4
2—3	Pet. ether	100	4.5
4—3	Pet. ether	100	0.3
4—3	Pet. ether : Ether	100	0.5
5—3	Ether	100	2.9
6—3	Ether	200	0.3
7—3	Ethanol	150	1.9

Chromatography No. 2

Fractions except 7 of chromatography No. 1—1, 2, 3 were dissolved in peteroleum ether (50 ml.) and chromatographed on alumina (125 g.).

Fraction	Eluent	Volume ml.	Weight g.
8	Pet. ether	200	21.7
9	Pet. ether	100	2.1
10	Pet. ether : Ether	100	0.6
11	Pet. ether : Ether	100	2.8
12	Ether	225	1.5
13	Ether	200	0.5
14	Ethanol	100	0.3

Chromatography No. 3

The fractions 8 and 9 (23.8 g.) were dissolved in petroleum ether (100 ml.) and chromatographed on alumina (130 g.).

Fraction	Eluent	Volume ml.	Weight g.
15	Pet. ether	200	14.4
16	Pet. ether	100	5.2
17	Pet. ether : Ether (7 : 3)	100	0.8
18	Pet. ether : Ether (7 : 3)	100	3.7
19	Ether	100	0.3
20	Ether	300	0.05
21	Ether	120	Trace

Chromatography No. 4

The fractions 15 and 16 (19.6 g.) were dissolved in petroleum ether (80 ml.) and chromatographed on alumina (115 g.).

Fraction	Eluent	Volume ml.	Weight g.
22	Pet. ether	100	11.1
23	Pet. ether	100	4.7
24	Pet. ether : Ether (7 : 3)	100	0.7
25	Pet. ether : Ether (7 : 3)	100	2.5
26	Ether	100	0.05
27	Ether	300	0.05
28	Ethanol	125	Trace

Chromatography No. 5

The fractions 22 and 23 (15.8 g.) were dissolved in petroleum ether (60 ml.) and chromatograph on alumina (125 g.).

Fraction	Eluent	Volume ml.	Weight g.
29	Pet. ether	200	10.6
30	Pet. ether	100	2.2
31	Pet. ether : Ether (7 : 3)	100	2.2
32	Pet. ether : Ether (7 : 3)	100	1.6
33	Ether	100	Trace
34	Ether	300	Trace
35	Ethanol	120	Trace

Infrared spectra of the fractions 11, 18, 25 and 32 were similar to that of natural deoxynupharidine.

***dl*-Nupharidine Hydrochloride.**—A part (2.2 g.) of the above fractions 11, 18, 25 and 32 was dissolved in acetone and added 15% of hydrogen peroxide (2.3 g.) The reaction mixture was heated on a steam bath at 50°C for 3 hr. and then evaporated in vacuo. The residue was dissolved in ethanol (4.5 g.) and added concentrated hydrochloric acid (0.7 ml.) and ether (38 ml.) and then kept in a refrigerator to give a precipitate (m. p. 193 ~196°C), which was recrystallized from ethanol-ether in needles, m. p. 222~223°C (decomp.).

Found: C, 62.85; H, 8.29; N, 4.98. Calcd. for $C_{15}H_{23}O_2N \cdot HCl$: C, 63.03; H, 8.46; N, 4.90%.

***dl*-Deoxynupharidine Hydrochloride.**—*dl*-Nupharidine hydrochloride (1 g.) was dissolved in ethanol (30 ml.), added 10% palladium charcoal (0.4 g.) and hydrogenated at ordinary pressure and temperature. Eighty-seven milliliters of hydrogen (theoretical amount, 79 ml.) were absorbed in 2 hr. The catalyst was filtered off and the filtrate was evaporated in vacuo. The residue recrystallized from ether and ethanol gave *dl*-deoxynupharidine hydrochloride (0.85 g.), m. p. 218~220°C, yield 93%. Analytical sample obtained by further recrystallization melted at 224~225°C.

Found: C, 66.69; H, 8.84. Calcd. for $C_{15}H_{23}ON \cdot HCl$: C, 66.77; H, 8.97%.

Resolution of *dl*-Deoxynupharidine.—The *dl*-base (1.5 g.) which was obtained by several runs as above mentioned and *l*-tartaric acid (0.6 g.) were dissolved in acetone (9 ml.) and ether (ca. 0.5 ml.) and left overnight in the refrigerator. The precipitated crude tartrate (0.5 g., m. p. 141~144°C) was recrystallized several times from ethyl methyl ketone. The final product (0.2 g.) melted at 151.5 ~152°C (mixed melting point with authentic *l*-deoxynupharidine *l*-tartrate, 152~154°C) and showed $[\alpha]_D$ −11.54° (*c* 1.00, in ethanol).

Found: C, 59.30; H, 7.64; N, 3.58%.

The base recovered from the above tartrate showed $[\alpha]_D$ −68.82° (*c* 1.01, in ethanol), the hydrochloride, $[\alpha]_D$ −17.03° (*c* 1.02, in 1 N HCl), m. p. 258~261°C.

Found: C, 66.82; H, 8.96; N, 5.03%.

***d*-Nupharidine.**—The synthetic *l*-deoxynupharidine (64 mg.) was dissolved in acetone (2 ml.) and added 15% hydrogen peroxide (0.6 ml.). The mixture was kept at 50°C for 2 hr. and the solvent was evaporated under reduced pressure. The residue was dissolved in chloroform and washed with water. The residue (68 mg.) obtained from the

chloroform solution by evaporation was recrystallized from acetone in plates (8 mg.), 222°C (decomp.), $[\alpha]_D$ +13.00° (*c* 0.38, in ethanol). Found: C, 71.81; H, 9.57%. The hydrochloride, m. p. 245~246°C (decomp.).

Found: C, 63.25; H, 8.48%.

***d*-Deoxynupharidine-*d*-tartrate.** — The mother-liquor from the first crop of *l*-deoxynupharidine *l*-tartrate was evaporated, the residue dissolved in water, basified, and extrated with ether, giving the crude *d*-base (1.0 g.). This was combined with *d*-tartaric acid (0.64 g.) in ethyl methyl ketone (10 ml.) and the *d*-tartrate (0.9 g. m. p. 138~140°C) repeatedly crystallized from ethyl methyl ketone, the last fraction (0.35 g.) having m. p. 152~154°C, $[\alpha]_D$ +13.5° (*c* 1.66, in ethanol).

Found: C, 59.48; H, 7.62; N, 3.76%.

***d*-Deoxynupharidine.** — *d*-Deoxynupharidine recovered from the above showed $[\alpha]_D$ +108.58° (*c* 0.99, in ethanol), the hydrochloride, m. p. 259~261°C. Found: C, 66.50; H, 8.85; N, 5.18%.

1-(epi)-Deoxynupharidine.—Fraction 29 (10.6 g.) was dissoved in ethanol (50 ml.) and concentrated hydrochloric acid (5 ml.) and then added ether (50 ml.). The precipitated hydrochloride (7.7 g. m. p. 220~222°C) was recrystallized from acetone-methanol in prisms, m. p. 224~225°C.

Found: C, 66.65; H, 8.87; N, 5.36%.

The free base (400 mg.) was dissolved in acetone (6 ml.) and added 15% hydrogen peroxide (1 ml.). After the mixture was kept at 50°C for 2 hr., the solvent was removed in vacuo and the residue dissolved in chloroform. The chloroform solution was washed with water and then evaporated. The residual oil (400 mg.) was identical with starting material in infrared spectra.

The free base (350 mg.) was mixed with methyl iodide (5 ml.) and then left overnight. To the reaction mixture ether was added and the ethereal solution washed with bisulfite solution. By removing of solvent, starting material was recovered (350 mg.).

The author wishes to thank Mr. Naohiro Hayakawa of Japan Atomic Energy Research Institute for measurement of the NMR spectra.

On Olefin Synthesis with Phosphonate Carbanions

By Hidetaka TAKAHASHI, Kazuyoshi FUJIWARA and Masaki OHTA

(Received May 7, 1962)

A number of methods to the synthesis of olefins by using organo-phosphorus compounds have been reported.

Wittig[1] has described the conversion of a carbonyl compound into an olefin in which the oxygen atom of the carbonyl group was replaced with an alkylidene group by the reaction of an alkylidene triphenylphosphorane.

Horner and Hoffmann[2] have reported the preparation of olefins from phosphine oxides and aldehydes by refluxing the mixture in toluene for about ten hours in the presence of potassium *tert*-butoxide.

Also, Wadsworth[3] has recently reported the preparation of olefins by the reaction of phosphonate carbanions which had been prepared by the addition of the phosphonate to a slurry of sodium hydride in 1, 2-dimethoxyethane at room temperature with carbonyl compounds.

In this paper, a method of preparing phosphonate carbanions by the action of sodium amide with phosphonates and the reaction of aldehydes and ketones with the carbanions derived from diethyl carbethoxymethylphosphonate, diethyl cyanomethylphosphonate, diethyl formylmethylphosphonate diethylacetal and diethyl acetonylphosphonate are described.

Diethyl carbethoxymethylphosphonate carbanion was prepared by the reaction of diethyl carbethoxymethylphosphonate with sodium amide as a proton-accepter in tetrahydrofuran or in ether as an aprotic solvent at room temperature; it was treated with such aldehydes as *n*-butylaldehyde, crotonaldehyde, benzaldehyde and cinnamaldehyde, or with such ketones as acetone, acetophenone, benzophenone and cyclohexanone.

The reaction proceeded smoothly under mild conditions with a variety of aldehydes and ketones, resulting in α, β-unsaturated esters in fairly good yields.

The reaction can be formulated by the following scheme; the results are summarized in the Table.

1) U. Schöllkopf, *Angew. Chem.*, **71**, 260 (1959).
2) L. Horner and H. Hoffmann, *Chem. Ber.*, **92**, 2499 (1959).
3) W. S. Wadsworth, *J. Am. Chem. Soc.*, **83**, 1733 (1961).

Experimental

The phosphonates were prepared by means of the Michaelis-Arbuzov reaction[4]. The sodium amide was a commercial product.

Ethyl Cinnamilideneacetate.—Diethyl carbethoxymethyl phosphonate (11.20 g., 0.05 mol.), prepared from ethyl bromoacetate and triethylphosphite, in dry tetrahydrofuran (20 ml.) was added dropwise with stirring to a suspension of sodium amide (1.95 g., 0.05 mol.) in dry tetrahydrofuran (30 ml.) at about 20°C. The solution was then stirred at room temperature under a slow stream of nitrogen to sweep out the evolved ammonia.

Into the resulting yellow solution, cinnamaldehyde (6.60 g., 0.05 mol.) in the same solvent (20 ml.) was added dropwise over a one-hour period at 20~25°C. During this addition, a gummy precipitate appeared.

The solvent was removed, and then the residue was taken up in water. The aqueous solution was extracted with ether. The ether extract was dried over sodium sulfate and evaporated, and the residue was distilled under reduced pressure, giving 7.3 g. (72.5%) of liquid; b. p., 135~136°C/2 mmHg. This product crystallized; m. p., 26~27°C.

Found: C, 77.10; H, 6.92. Calcd. for $C_{13}H_{14}O_2$: C, 77.20; H, 6.98%.

β-Phenylcinnamonitrile (Va).—Sodium amide (1.95 g., 0.05 ml.) was placed in dry tetrahydrofuran (30 ml.). Diethyl cyanomethylphosphonate (8.86 g., 0.05 mol.), prepared from bromoacetonitrile and triethylphosphite, in dry tetrahydrofuran (20 ml.) was added dropwise with stirring to the suspension at 0~5°C, and then the resulting red solution was stirred at 15°C for about three hours under a slow stream of nitrogen. After removal of

4) G. M. Kosolapoff, "Organophosphorus Compounds", 1st. ed., J. Wiley & Sons, Inc., New York, N. Y. (1950), Chap. 7.

the ammonia, (benzophenone 9.1 g., 0.05 mol.) in the same solvent (20 ml.) was added dropwise with stirring at room temperature, and the solution was allowed to stand overnight. The solvent was removed after cooling, water was added to the residue, and the product was extracted with ether. The ether, after being dried over sodium sulfate, was removed, and the residue was distilled under reduced pressure giving 4.5 g. of liquid (b. p., 170~171°C/5.5 mmHg), which solidified, giving crystals (m. p. 43~44°C).

Found: C, 87.50; H, 5.39; N, 6.77. Calcd. for $C_{15}H_{11}N$: C, 87.77; H, 5.40; N, 6.82%.

Cinnamonitrile (Vb). — Diethyl cyanomethylphosphonate carbanion was prepared from diethyl cyanomethylphosphonate (8.86 g., 0.05 mol.) and sodium amide (1.95 g., 0.05 mol.) in the same way. Benzaldehyde (5.3 g., 0.05 mol.) in dry tetrahydrofuran (20 ml.) was added with stirring at −15~−10°C to the carbanion. After this addition, the solution was stirred for 30 min. at 15°C and allowed to stand overnight. The ether extract was dried over sodium sulfate. After removal of the ether, the residue was distilled, giving 5.5 g. of liquid (b. p., 121~123°C/9 mmHg). The liquid was hydrolyzed to give crystals of cinnamic acid (m. p., 131~133°C).

Cinnamaldehyde Diethylacetal (VII). — Diethyl formylmethylphosphonate diethylacetal (12.7 g., 0.05 mol.), prepared from bromoacetoaldehyde diethylacetal and triethylphosphite, in dry tetrahydrofuran (20 ml.) was added dropwise with stirring at 18~20°C into sodium amide (1.95 g., 0.05 mol.) in dry tetrahydrofran (30 ml.); then nitrogen was passed into the solution for several hours. After removal of the ammonia, benzaldehyde (5.3 g., 0.05 mol.) in the same solvent (20 ml.) was added dropwise with stirring at 17~18°C. The solution was stirred for an additional three hours and allowed to stand overnight. The solvent was evaporated, and the oily residue was taken up in water. The aqueous solution was extracted with ether, and the ether extract was dried over sodium sulfate and evaporated and the residue was distilled, giving 6.3 g. of liquid (b. p., 126~127°C/10 mmHg). The product was hydrolyzed and identified with the 2,4-dinitrophenylhydrazone (m. p., 149~151°C).

Benzalacetone (IX). — Diethyl acetonylphosphonate was prepared from bromoacetone and triethylphosphite. The phosphonate (9.2 g., 0.05 mol.) in dry tetrahydrofuran (20 ml.) was added dropwise with stirring at 3~5°C into a suspension of sodium amide(1.95 g., 0.05 mol.) in dry tetrahydrofran (30 ml.), and then nitrogen was passed into the solution to sweep out the ammonia. Into the solution, benzaldehyde (5.3 g., 0.05 mol.) in the same solvent was added dropwise with stirring at 5~8°C. The solution was stirred for an hour and allowed to stand overnight. The solvent was then evaporated. Steam-distillation gave IX; m. p., 39~40°C.

Found: C, 81.86; H, 7.24. Calcd. for $C_{10}H_{10}O$: C, 82.16; H, 6.90%.

We are indebted to Mr. Keiji Naruse for performing the microanalyses.

Studies on the Effects of the Substituents for 1-Arylaminoanthraquinones

By Takayuki HAYASHI and Masaki MATSUO*1

(Received May 8, 1962)

In recent years, much effort has been expended in devising a series of anthraquinone acid dyes that are resistant to decomposition by light and to severe washing. The method which has been adopted most widely is to introduce large non-sulfonated groups into established simpler dyes, thereby increasing the molecular size and the affinity for fiber and decreasing the solubility in water[1]. Prior to a discussion of the anthraquinone acid dyes, 1-arylaminoanthraquinones, the parent compounds, will be considered in this paper. Substituent groups (X) include nitro, chloro, methyl, methoxy and amino groups. Their visible and infrared absorption spectra have been measured in solution and in solid respectively. On the basis of these results, the effects of the substituent groups (X) will be discussed in view of various properties, such as wavelengths of absorption maxima and C=O and NH frequencies, similar to the previous discussion of the properties of acylaminoanthraquinones[2].

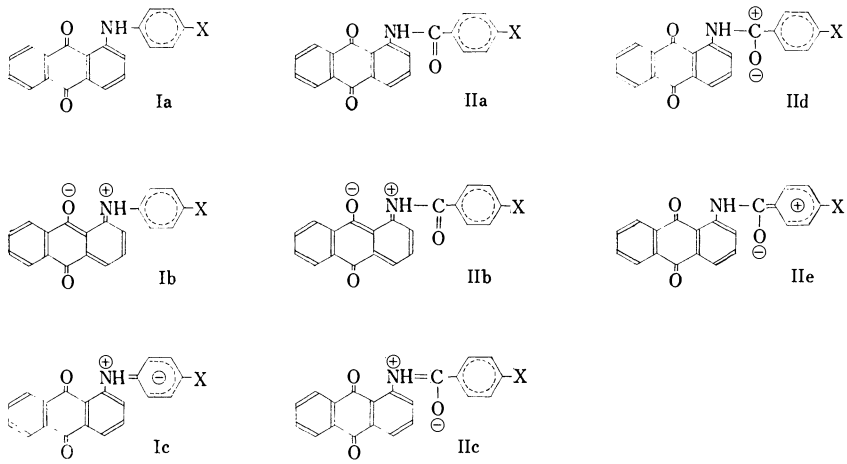
Results and Discussion

Visible Absorption Spectra.—The visible absorption spectra of some 1-arylaminoanthraquinones were observed by Hida[3] in a trichlorobenzene solution. For this paper, their spectra have been measured in an *o*-dichlorobenzene solution, and the effects of the substituents on the wavelength of the absorption maximum have been considered.



For 1-phenylaminoanthraquinone (I), the contribution of structure Ib to the resonance would be larger and, owing to the $-T$ effect of the phenyl group, the wavelength of the absorption maximum would become longer than that of 1-aminoanthraquinone*2. For 1-benzoylaminoanthraquinone (II), the contribution of structure IIb to the resonance would be the largest, but, since this is repressed by the contribution of structure IIc, the wavelength of the absorption maximum becomes shorter than that of 1-aminoanthraquinone. From the results indicated in Table I, one can see that the general pattern of effects on the absorption maxima agrees with the well-known effects[2,4-5] of substituents on the amino group.

TABLE I. VISIBLE ABSORPTION PEAKS OF 1-ARYLAMINOANTHRAQUINONES

X	Peak
H[a]	508 (5920)*3
p-NO_2[b]	487 (10700)
m-NO_2	489 (6460)
o-NO_2	483 (9370)
p-Cl	505 (7130)
m-Cl	501 (7220)
o-Cl	499 (6610)
p-NHCOMe	513 (6200)
o-NHCOMe	482 (6220)
p-Me	514 (6190)
o-Me	506 (6390)
p-OMe	516 (6000)
o-OMe	517 (5970)
p-NH_2[c]	525 (5990)
m-NH_2	515 (6910)
o-NH_2	492 (5980)

The peaks of a), b) and c) appeared at 511 (7590), 488±3 (10000) and 520 mμ (6920)*3 respectively in trichlorobenzene[3].

In the previous case of 1-acylaminoanthraquinones[2] (II), a plot of the wave numbers of the absorption maximum against the corresponding Hammett σ values[6] concaved upwards, but against the corresponding Brown σ^+ values[7,8] gave a linear relationship. For 1-arylaminoanthraquinones, on the contrary while, the plot of the wave numbers against the former does give a linear relationship, against the latter it does not do so, as is indicated in Figs. 1 and 2. In general, the electron-releasing para substituent, such as amino, methoxy and methyl groups, show the electron-release described by Hammett σ values in a nucleophilic reaction, but they show a greater electron-release than that described by them in an electrophilic reaction. In the latter, the deviations of the plots for these groups may reasonably be attributed to the differing capacities of the substituents for the resonance stabilization of a positively-charged transition state;

the positive charge must be delocalized through resonance interaction, while it is the negative charge which must so be delocalized on the former. Therefore, although some attempts to correlate electrophilic reactions with an alternative set of substituent constants have been proposed by various authors, Brown's set[7,8] is apparently the one with the most general applicability. Here, too, the same considerations as noted above are employed in the case of the shifts of absorption maxima. For 1-acylaminoanthraquinones (II), the positive charge indicated in structure IId would be delocalized through resonance with electron-releasing groups, as indicated in structure IIe, but for 1-arylaminoanthraquinones(I), unshared electrons of nitrogen in structure Ia would be delocalized through the resonance with electron-attracting groups, as indicated in structure Ic. The former is consistent with the previous data for 1-acylaminoanthraquinones[2], and the latter, with the present data for 1-arylaminoanthraquinones.

For the visible absorption spectra of 7-substituted derivatives of 3,4- and of *N*-methyl-3,4-phthaloylacridones reported by Bradley[5], a plot of the wave numbers of the absorption maximum against the corresponding Hammett σ values gives a linear relationship, as is indicated in Fig. 3. This fact shows that the type of electron displacement for 3,4-phthaloylacridone is similar to that of 1-phenylaminoanthraquinone, as was deduced from the similarity in their chemical structures. It has been suggest by Bradley[5] that 3,4-phthaloylacridone's similarity to 1-phenylaminoanthraquinone in its red-violet color, indicates that it is a true acridone, not a hydroxyacridone. The establishment of this linear relationship may also support Bradley's suggestion.

Here, too, as in the previous case of 1-acylaminoanthraquinones[2], the wavelength of the

absorption maximum is shorter for the *o*-nitro-derivative than for the *m*- and *p*-isomers; such a relation is also seen in the other *o*-derivatives, except for the *o*-methoxy derivative, as Table I indicates. The wavelength and intensity of the absorption maximum for the *o*-methyl derivative differ little from those of 1-methylaminoanthraquinone*4. The effect of the *o*-tolyl group for the former should, therefore, be much the same as that of the methyl group for the latter; this fact shows that the aryl ring is twisted around the C–N linkage between the aryl ring and the imino group in the arylamino group. The twisting may be attributed to the steric hindrance or to the repulsion between the *o*-methyl and CH groups in the 2 position of the anthraquinone nucleus. For the *o*-nitro derivative, too, the hypsochromic shift is probably due to such a twisting of the aryl ring. If it were due to the twisting of the nitro group around the C–N linkage between the benzene ring and the nitro group, the wavelengths of the absorption maxima of the *o*- and *m*-isomers would be much the same, but the wavelengths increase in the order of the *o*-, *p*- and *m*-isomers. For the *o*-amino derivative, since the wavelengths increase in the order of the *o*-, *m*- and *p*-isomers and since, moreover, the wavelength is for the first shorter than for 1-phenylaminoanthraquinone, the twisting may also arise. For the *o*-methoxy derivative, the wavelength of the absorption maximum differs little from that of the *p*-isomer; this fact shows that such twisting may not arise because of the reduced extent of the steric hindrance or because of the repulsion due to the free rotation of the methyl group in the methoxy group.

*4 A peak of 1-methylaminoanthraquinone appeared at 504 mμ (6480)*3 in *o*-dichlorobenzene.

Infrared Absorption Spectra. — Three micron infrared absorption spectra bands for a few 1,4-diarylaminoanthraquinones have been observed as Nujol mull[9], but the spectra of 1-arylaminoanthraquinones have not yet been observed. In this work, the latter were observed as Nujol mull on account of their limited solubility; then information was gained about their structure in the solid.

Table II. 3 and 6 μ-Bands of Solid 1-Arylaminoanthraquinones

frequency are assigned to the respective C=O (b) vibrations in the peri-position of the arylamino group.

For visible absorption spectra in solution, the wavelengths of the absorption maximum for 1-methylamino- and 1-dimethylaminoanthraquinones were longer than for 1-aminoanthraquinone; the wavelengths of the first and the second were alike, but their intensity decreased in the order of the first, last, and second[4]. The fact that 1-methylaminoanthraquinone had a longer wavelength than would be expected was attributed to the resonance possibility developed by the formation of the chelate structure, while the considerably reduced intensity of 1-dimethylaminoanthraquinone was thought to be due to the steric hindrance between the methyl and the C=O (b) group[4,12]. Similar phenomena have been seen in some other cases[4-5,13-14]. On the other hand, as is indicated in Table III, the fact that a C=O (b) frequency was higher for 1-methylamino- than for 1-aminoanthraquinones was attributed to the reduction of resonance by the methyl group within the former chromophoric system, and the unusually high frequency of 1-dimethylaminoanthraquinone was partly attributed to the similar reduction by methyl groups and partly to the steric hindrance between the methyl and the C=O (b) groups[11]. Similar results have been reported in some other cases[13-14]. Here, too, for visible absorption spectra in solution, the wavelength of the absorption maximum was longer for 1-phenylamino- than for 1-amino- and 1-methylamino-anthraquinones, although the C=O (b) frequency for the first was higher than for the second and was the same as that of the last. This fact may not be attributable to steric hindrance, but to the reduction by the phenyl group of resonance within the chromophoric system of the first, this being similar to the above-mentioned reduction by the methyl group for the last.

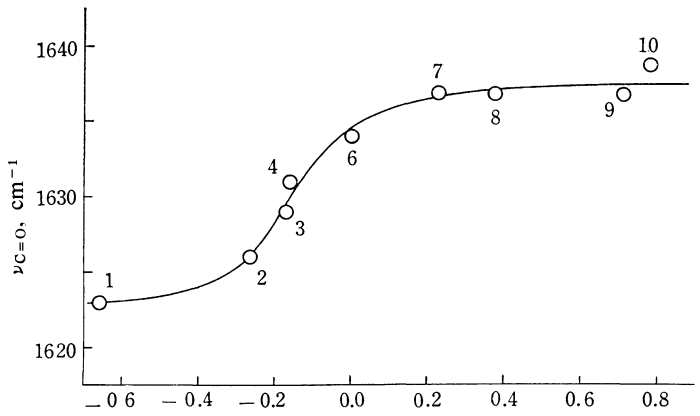

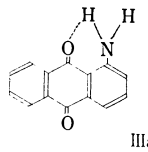

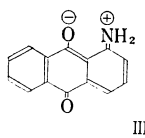

Fig. 6. Plot of C=O frequencies against Hammett σ values for 1-arylaminoanthraquinones.

As is indicated in Table III, the NH frequency lowers in the order of 1-amino-, 1-methylamino-, 1-phenylamino- and 1-benzoylamino-anthraquinones, and the reverse is found to be true for a C=O (b) frequency. For 1-aminoanthraquinone III, it seems that it is impossible to form a powerful hydrogen bonding, as in IIIa, between the amino and C=O (b) groups, and that, therefore, a contribution

IIIa

IIIb

of the ionic structure IIIb to the resonance, rather than the weak hydrogen bonding, was responsible for the considerable lowering of the C=O (b) frequency, the hydrogen bonding serving only to stabilize the ionic structure[11,15]. On the other hand, for 1-methylamino- and 1-phenylamino-anthraquinones, such resonance within chromophoric systems was reduced by the methyl and phenyl groups respectively. The above-mentioned order of the lowering of NH frequencies, therefore, suggests that the smaller the contribution of the ionic structure to the resonance becomes, the greater the contribution of the hydrogen bonding.

As is indicated in Table II, for *m*- and *p*-substituted 1-arylaminoanthraquinones, the C=O (b) frequency lowers for the ones with electron-releasing substituents, while the reverse is found to be true for the derivatives with electron-attracting groups, as in the case of those for 1-acylaminoanthraquinones[10]. These results are similar to the general pattern of substituent effects on the shift of the visible absorption maximum in solution. The effects of these substituents on the shift of the C=O (a) frequency were small, similar to those for 1-acylaminoanthraquinones[10].

A plot of the C=O (b) frequencies obtained from solids of 1-acylamino-anthraquinones against the corresponding Hammett σ values gave an S-shaped relationship; this result served to explain the shades of dyed cotton[10]. Here, too, a similar plot for 1-arylaminoanthraquinones gives the same result, as is indicated in Fig. 6. The C=O (b) bond was, therefore, strengthened to much the same degree for the derivatives with any of the electron-attracting substituents. This fact may also serve to elucidate the shades of anthraquinone acid dyes on fiber.

Here, as indicated in Table II, the C=O (b) frequency of the *o*-nitro derivative is considerably higher than those of the *m*-, *p*-isomers and 1-methylaminoanthraquinone; it is a little higher than that of 1-dimethylaminoanthraquinone, in which the unusually high C=O (b) frequency was partly attributed to steric hindrance, as has been noted above. These facts show that the aryl ring of the *o*-nitro derivative is twisted around the C–N linkage between the aryl ring and the imino group, and that the twisting may be attributed to the above-mentioned steric hindrance or to repulsion, as in the case of the molecule in solution. On the contrary, the C=O (b) frequencies of the other *o*-derivatives are 6~8 cm^{-1} higher than those of the corresponding *p*-isomers. It seems probable, therefore, that the above-mentioned twisting of the aryl rings for *o*-chloro and *o*-methyl derivatives does not arise in a solid, as in the cases of *o*-methoxy and *o*-amino derivatives, this being different from the molecule in solution. For former

15) H. Bloom, L. H. Briggs and B. Cleverley, *J. Chem. Soc.*, **1959**, 178.

o-derivatives, such twisting may be suppressed in a solid where the molecules are packed closely.

Experimental

Materials and Apparatus. — 1-Arylaminoanthraquinones with methyl or methoxy group as a substituent were prepared by condensing 1-chloroanthraquinone with substituted aniline in nitrobenzene, but nitro derivatives were prepared by condensing 1-aminoanthraquinone with the appropriate chloronitrobenzene in nitrobenzene, as has been described by Ullmann[16] and Takegawa[17]. They were obtained in good yields. Chloro derivatives were prepared in only a poor yield by either above-mentioned method. Acetylamino derivatives were prepared by acetylation of the corresponding amino derivatives with acetic anhydride, these having been prepared by reduction of the corresponding nitro derivatives with sodium dithionite at 65°C, as has been described by Ullmann[16]. All materials were purified by recrystallization and then by chromatography or hot chromatography on alumina in benzene, monochloro- or dichloro-benzene. The results are given in Table V.

j) and k) Cook[19] gives m. p. 153~154 and 177°C respectively.

The visible absorption spectra were obtained by a Shimadzu spectrophotometer, type QB-50. The infrared absorption spectra were obtained using the Nujol mull technique; a Perkin-Elmer Model 21 double beam spectrophotometer fitted with a rock-salt prism was also used. Purification of *o*-dichlorobenzene was done by the method recommended for monochlorobenzene[20].

The authors wish to express their deep thanks to Professor Yoshio Nagai and Professor Shimpachiro Kato of the University of Tokyo for their helpful suggestions and encouragement in the course of this work, and also to Mr. Akira Hara of the Tokuyama Research Laboratory of the Idemitsu Kōsan Co. for their infrared measurements.

The Mutual Interaction between Solutes in Gas Chromatography

By Kazuo AMAYA and Kazuko SASAKI

(Received March 29, 1962)

In principle, it is expected that the solutes will interact with each other in the liquid phase and that the retention volume of one component will be affected by the presence of the other components. In gas chromatography (gas-liquid partition gas chromatography), howevr, it is generally accepted that solutes do not, in fact, interact with each other in the liquid phase and that the retention volume of one solute is independent of the presence of the other components, because the concentration of each component is infinitely small. In order to elucidate the above problem, a theoretical consideration of the problem will be made from the standpoint of strictly regular solutions, and also a little experimental evidence will be given.

Theoretical Considerations

In considering the effect of the presence of other components on the retention volume of one particular component, the partial vapor pressure of the one component, which relates to its partition coefficient, in the presence of the other component must first be considered. We consider two kinds of components 1 and 2 in samples as solutes and the liquid of the stationary phase as the solvent, and we regard the portion of the stationary phase liquid in which solutes 1 and 2 are dissolved as a uniform ternary system. The system is composed of N_1 molecules of solute 1, N_2 molecules of solute 2, and N_s molecules of the solvent; for the sake of simplicity, it is also assumed that solutes 1 and 2 and the solvent have the same molecular sizes and that these molecules are arranged in $(N_1+N_2+N_s)$ sites of a quasi-crystalline lattice with z nearest neighbors. For zeroth approximation, the configurational free energy F_c of the system is given by

$$F_c=\frac{1}{2}z(N_1+N_2+N_s)\left\{\frac{N_s^2}{(N_1+N_2+N_s)^2}u_{ss}+2\frac{N_sN_1}{(N_1+N_2+N_s)^2}u_{s1}+2\frac{N_sN_2}{(N_1+N_2+N_s)^2}u_{s2}+\frac{N_1^2}{(N_1+N_2+N_s)^2}u_{11}+\frac{N_2^2}{(N_1+N_2+N_s)^2}u_{22}+2\frac{N_1N_2}{(N_1+N_2+N_s)^2}u_{12}\right\}+\boldsymbol{k}T\left(N_s\ln\frac{N_s}{N_1+N_2+N_s}+N_1\ln\frac{N_1}{N_1+N_2+N_s}+N_2\ln\frac{N_2}{N_1+N_2+N_s}\right) \quad (1)$$

where u_{ij} denotes the mutual interaction energy of the ij pair, $\boldsymbol{k}$ is the Boltzmann constant, and T is the absolute temperature. The chemical potential of solute 1 in the liquid phase, μ_1^l can be obtained by differentiating Eq. 1 with respect to N_1. μ_1^l is then expressed as

$$\left(\frac{\partial F_c}{\partial N_1}\right)=\mu_1^l=-x_s^2u_{ss}+2x_s(1-x_1)u_{s1}-2x_sx_2u_{s2}+x_1(2-x_1)u_{11}-x_2^2u_{22}+2x_2(1-x_1)u_{12}+\boldsymbol{k}T\ln x \quad (2)$$

where x, x_1 and x_2 denote $N_s/(N_1+N_2+N_s)$, $N_1/(N_1+N_2+N_s)$ and $N_2/(N_1+N_2+N_s)$ respectively. If we define the quantities w_{s1}, w_{s2} and w_{12} as

$$\left.\begin{aligned}w_{s1}&=2u_{s1}-u_{ss}-u_{11}\\w_{s2}&=2u_{s2}-u_{ss}-u_{22}\\w_{12}&=2u_{12}-u_{11}-u_{22}\end{aligned}\right\} \quad (3)$$

and use the relation that $x_1+x_2+x_s=1$, Eq. 2 can be rewritten as

$$\mu_1^l=x_{s2}w_{s1}+x_2^2w_{12}+x_2x_s(w_{12}+w_{s1}-w_{s2})+u_{11}+\boldsymbol{k}T\ln x_1 \quad (4)$$

Similarly, the chemical potential of Solute 2, μ_2^l, is given by

$$\mu_2^l=x_s^2w_{s2}+x_1^2w_{12}+x_1x_s(w_{12}-w_{s1}+w_{s2})+u_{22}+\boldsymbol{k}T\ln x_2 \quad (5)$$

For the gas phase, the solute molecules are assumed to be perfect and to have no interaction with other molecules. Therefore, if we neglect the contribution of the internal degrees of freedom to the chemical potential, the chemical potentials of solutes 1 and 2, μ_1^g and μ_2^g respectively, are given by:

$$\mu_1^g=\boldsymbol{k}T\ln N_1^g/V \quad (6)$$

$$\mu_2^g=\boldsymbol{k}T\ln N_2^g/V \quad (7)$$

where N_1^g and N_2^g denote the number of molecules of solutes 1 and 2 respectively in the gas phase of volume V. In equilibrium, the chemical potential of each species is equal in both the liquid and gas phases; therefore, by equating 4 with 6 and 5 with 7, the following relations are obtained;

$$kT \ln N_1^g/V = x_s^2 w_{s1} + x_2^2 w_{12} + x_2 x_s (w_{12} + w_{s1} - w_{s2}) + u_{11} + kT \ln x_1 \quad (8)$$

$$kT \ln N_2^g/V = x_s^2 w_{s2} + x_1^2 w_{12} + x_1 x_s (w_{12} - w_{s1} + w_{s2}) + u_{22} + kT \ln x_2 \quad (9)$$

Since the partition coefficient is the ratio of the mumber of solute molecules in the unit volume of the stationary liquid phase to that in the gas phase, the partition coefficient of solute 1, k_1^m, and that of solute 2, k_2^m, for their mixture are given by:

$$\ln k_1^m = \ln N_1 x_1 - \ln N_1^g/V = -(1/kT)\cdot\{x_s^2 w_{s1} + x_2^2 w_{12} + x_2 x_s (w_{12} + w_{s1} - w_{s2}) + u_{11}\} \quad (10)$$

$$\ln k_2^m = \ln N_1 x_2 - \ln N_2^2/V = -(1/kT)\cdot\{x_s^2 w_{s2} + x_1^2 w_{12} + x_1 x_s (w_{12} - w_{s1} + w_{s2}) + u_{22}\} \quad (11)$$

where N_1 is the number of molecules in the unit volume of the stationary liquid phase. The partition coefficients k_1^o and k_2^o for the pure solutes 1 and 2 respectively are obtained by equating x_2 or x_1 in Eqs. 10 and 11 with zero and are given by:

$$\ln k_1^0 = \ln N_1 x_{10} - \ln N_1^g/V = -(1/kT)\cdot(x_{s1}^2 w_{s1} + u_{11}) \quad (12)$$

$$\ln k_2^0 = \ln N_1 x_{20} - \ln N_2^g/V = -(1/kT)\cdot(x_{s2}^2 w_{s2} + u_{22}) \quad (13)$$

where x_{10} and x_{20} denote the mole fraction of solutes 1 and 2 respectively, and x_{s1} and x_{s2} denote the corresponding mole fraction of the solvent when only a single solute is present. From Eqs. 10, 11, 12 and 13 the ratio of partition coefficients for the mixture to that for the pure component, when there is an equal concentration in the stationary liquid phase, that is, $x_{10}=x_1$ and $x_{20}=x_2$, k_1^m/k_1^o and k_2^m/k_2^o, are given by using the relation $x_{s1}=x_s+x_2$ or $x_{s2}=x_s+x_1$:

$$\ln k_1^m/k_1^o = -(1/kT)\cdot\{x_2^2(w_{12}-w_{s1}) + x_2 x_s (w_{12} - w_{s1} - w_{s2})\} \quad (14)$$

$$\ln k_2^m/k_2^o = -(1/kT)\cdot\{x_1^2(w_{12}-w_{s2}) + x_1 x_s (w_{12} - w_{s1} - w_{s2})\} \quad (15)$$

Generally, the right sides of Eqs. 14 and 15 are not equal to zero, and k_1^m and k_2^m differ from k_1^o and k_2^o respectively; consequently, the retention volume for the mixture differs from that for the pure component.

Experimental

The experiments were performed for the equivolume mixture of chloroform-ethyl methyl ketone with a column of apiezon J and those of the chloroform-carbon tetrachloride and chloroform-toluene mixture with a column of P. E.; also, the position of each peak was compared with that obtained for the pure substances. In this case the quantity of each component was kept equal. The results obtained are shown in Table I.

Discussions

If $x_2 \ll 1$, and $x_1 \ll 1$, x_s is approximated to be equal to 1, and the term containing x_1^2 or x_2^2 is neglected as too small, and if, in expanding the exponential function, the terms higher than the second are also neglected, Eqs. 14 and 15 can be approximated as

$$k_1^m = k_1^o\{1 - (1/kT)\cdot x_2(w_{12} - w_{s1} - w_{s2})\} \quad (16)$$

Table I. Comparison of the retention time for mixtures (T_r^m) with that for pure components (T_r^o). (The quantity of each component is 25μl.)

Sample	T_r^o, min.	T_r^m, min.	ΔT_r, min.	$\Delta T_r/T_r^o$
Ethyl methyl ketone	7.60	7.83	0.23	0.030
Chloroform	10.95	11.63	0.68	0.062

Experimental Conditions —— Temp.: 52°C; Press.: 34.75 mmHg; Column: Cu pipe; Stationary phase: Apiezon J 420 g.; Support: C-22; Firebrick: 1200 g. 42~60 mesh; Carrier gas: H_2; Flow rate: 94 cc./min.

Sample	T_r^o, min.	T_r^m, min.	ΔT_r, min.	$\Delta T_r/T_r^o$
Carbon tetrachloride	4.55	4.64	0.10	0.022
Chloroform	10.16	10.35	0.19	0.019

Experimental conditions —— Temp.: 70.2°C; Press.: 26.2 mmHg; Column: Cu pipe 4 m; Stationary phase: P. E. G. 3; Support: Celite 10; Carrier gas; H_2; Flow rate: 77 cc./min.

Sample	T_r^o, min.	T_r^m, min.	ΔT_r, min.	$\Delta T_r/T_r^o$
Toluene	13.74	14.02	0.26	0.019
Chloroform	8.97	9.05	0.08	0.009

Experimental conditions —— Temp.: 70.2°C; Press.: 31.0 mmHg; Flow rate: 83 cc./min; Other conditions were the same as above.

$$k_2^m = k_2^o\{1-(1/\boldsymbol{kT})\cdot x_1(w_{12}-w_{s1}-w_{s2})\} \quad (17)$$

These equations show that the effect of interaction with a foreign substance is proportional to its concentration.

It may also be inferred that the partition coefficient in the mixture increases or decreases as the sign of $(w_{12}-w_{s1}-w_{s2})$ is positive or negative. This indicates that the position of the peak for a particular component is shifted to either the shorter or longer side according to the kind of other component in the mixture.

In the above discussions, it is tacitly assumed that the two solutes coexist and that the concentration of each solute does not change with time. However, in actuality, the concentration of each solute changes with time and the two solutes are gradually separated as they proceed through a column and are finally completely separated where the effect of interaction with the other solute does not occur. This means that the k_1^m/k_1^o or k_2^m/k_2^o ratio changes with time, even if the two solutes are always both present, if not, its value approaches 1 when the two solutes are completely separated. The time required for the value of k_1^m/k_1^o or k_2^m/k_2^o to reach 1 is dependent on the kind of solute. If the retention times of solutes 1 and 2 are denoted by T_1 and T_2 respectively, the effect of the interaction becomes larger as T_1/T_2 approaches 1.

The assumption that the solute and the solvent have the same molecular size is far from the actual case, for the molecular size of the stationary liquid phase is of an order ten times greater than that of most samples. However, the effect of the difference in molecular size is not significant if the mole fractions in the expressions are replaced by the volume fractions.

As for the experimental results, in the mixture of chloroform (1) and ethyl methyl ketone (2) it was found that the component peaks shifted to a positive direction compared with those for single component samples when an apiezon J column is used. This is interpreted as follows: the heat of the mixing of chloroform with ethyl methyl ketone may be negative, since the two components may form a hydrogen-bonded complex as chloroform and acetone do; hence, the value of w_{12} may be negative.

Further, since both component molecules, 1 and 2, have dipoles and since the stationary phase liquid apiezon J(s) is a homologue of aliphatic hydrocarbons, the heats of the mixing of s with 1 and with 2 may both be positive and the values of w_{s1} and w_{2} may be positive. Accordingly, the value $(w_{12}-w_{1}-w_{2})$ in Eqs. 16 and 17 may be negative; it therefore follows that $k_1^m > k_1^o$ and $k_2^m > k_2^o$ and the position of each component peak in the mixture may be shifted in the positive direction. This prediction coincides with the experimental results. An example of the reverse case, in which the relation $k_1^m < k_1^o$ and $k_2^m < k_2^o$ holds, has not yet been found.

For a quantitative discussion of this problem we must further derive those expressions which relate the concentration of the single component sample in the column with the time which has transpired after the sample injection under the assumption that the partition coefficient of each component varies with its concentration in the column; then we must integrate the contribution due to mutual interaction at each concentration. Further, the same procedure must be repeated for the mixture samples and the latter results compared with the former. We do not intend to deal with this problem here.

Theory predicts that the shift of each component peak due to mutual interaction will occur in the same direction. The experimental results coincide with this prediction.

It should be noted that an apparent shift in the two peaks occurs when they approach, but that the directions of the shifts are such that the two peaks come close together and are opposite each other, which effect can easily be discriminated from what originates from the mutual intearction.

Although in the present experiment a considerable quautity of samples (25μl.) was used, the relative shift of the peaks was 6% at most, which wonld be a much smaller value if much smaller quantity of samples were used. In actuality, the quantity of samples is usually of an order of a few μl. and the effect of mutual interaction can be neglected. However, when the minor component is analysed by using large amount of the sample, the effect may become important.

Summary

The influence of the mutual interaction between the molecules of different components in the sample on the retention volume of each component has been discussed from the standpoint of a strictly regular solution. The retention volume of each component in the mixture either increases or decreases, compared with that in the single component samples, according to the kinds of sample and of stationary phase liquid.

Studies on Tritium-labeled Compounds. VI[1]. *The Platinum-catalyzed Exposure Technique*

By Teruhiko MESHI and Tadao TAKAHASHI

(Received March 22, 1962)

The gas exposure technique developed by Wilzbach[2] has greatly simplified the labeling of many organic compounds, including such biologically active materials as insulin[3]. Its use is somewhat restricted, however, by the fact that multicuric quantities of tritium are required to obtain levels of activity, satisfactorily high for tracer experiments.

Up to the present, workers have tried to increase the labeling by adding to the system such external activation energy as is obtained from electric discharge[4-7], microwave discharge[7], ultraviolet irradiation[7], and γ-radiation[5]. These methods increase the specific activities remarkably, but they also produce a large amount of decomposition products. The aim of our experiments is also to obtain higher labeled products by the Wilzbach method but not by adding external activation energy. We have also tried to increase the efficiency of labeling by a larger exploitation of the β-ray energy of tritium.

Since the β-particle from tritium has a range of only 0.7 mg./cm^2, complete absorption of energy occurs within the layers of 7 μ if the organic material has a specific weight of 1 g./cm^3. Therefore, it is quite clear that labeling will occur at or near the surface of the organic compound.

The possibility of increasing the labeling efficiency by reducing the size of the particle of the organic compound is very limited, as Rosenblum et al.[8] have already shown.

Recently Wenzel et al[9] reported that higher specific activities in the range of 2~130 fold were obtained by adsorbing the compound on charcoal. When hydrogenation catalysts were applied to a salicylic acid-T_2 system, a large increase in specific activity was observed. This paper presents the results of this new modification for labeling organic compounds by the Wilzbach procedure.

Experimental

Chemicals.—All chemicals used were of analytical reagent grade and were not subjected to any further purification.

Platinum black was prepared by hydrogenation of Adams platinum oxide[10] made from chloroplatinic acid.

Palladium black was prepared by hydrogenation of palladium oxide[11] made from palladium chloride. Raney nickel was developed from a Ni-Al alloy consisting of 50% nickel by the W-2 method. The tritium gas was purchased from the Radiochemical Center, Amersham, and was 98% T_2, the rest being H_2.

Exposure. — Glass ampoules with a volume of about 5 ml. and with a breakoff seal were used for exposure.

All the samples were thoroughly mixed with 100 mg. of the catalysts and then brought into a reaction vessel. The reaction vessel was connected with the apparatus described in the previous paper[1] and was throughly degassed by pumping.

After some hours of evacuation, about 100 mc. of tritium was transferred to the reaction vessel by means of the Toepler pump, and then the capillary was sealed off. After the exposure, the reaction vessel was remounted on the apparatus, the breakoff

seal was opened, and the tritium was transferred to a storage vessel.

Purifications. — The exposed products were dissolved in a hydroxylic solvent, and the catalyst was filtered off.

The solvent was removed from the filtrate by distillation in vacuo. This operation was repeated three times to remove the exchangeable tritium completely. The residue was recrystallized from a suitable solvent and radiochemically purified through paper-chromatography, using Toyo Roshi No. 526. L-Valine and thiamine were purified with *n*-butanol-acetic acid-water (4 : 1 : 1), inositol with *n*-butanol-ethanol-water (4 : 1.1 : 1.9), and predonisolone with toluene-methanol (3 : 1). Sublimation was chosen for purification of salicylic acid, and solvent extraction for that of benzoic acid. The radiochemical purity was established by cutting the chromatograms of the labeled compounds in 10 mm. segments, extracting each segment with distilled water or alcohol, and counting the tritium activity of each extract in a windowless gas-flow counter.

Measurement of Radioactivity. — The specific activities of the tritiated products were determined by liquid scintillation counting. An aliquot of a suitable concentration of a compound in a mixture of alcohol and water was added to toluene dissolving phenylbiphenyloxadiazole (4 g./l.) and 1,4-di(2,5-phenyloxazole)-benzene (100 mg./l.) and was counted with a Pachard Tri-Carb liquid scintillation spectrometer cooled to −10°C. This system had an efficiency of approximately 13% if the sample was nonquenching.

An internal standard was used to correct for quenching and to estimate the efficiency of counting.

Results

Listed in Table I are the results of the new method of labeling with tritium catalyzed by three different typical hydrogenation catalysts.

As is shown in Table I, the platinum catalyst is the most effective in promoting tritium labeling. With platinum oxide, there is also an increase in the specific activity, but the increase is much lower because most of the tritium is used to form the tritium oxide. The addition of a small amount of platinum oxide plus platinum, however, gave a greater

Table I. Increase of the specific activity by the catalyzed exposure technique*

+Pt black	30	372	63	78	3900	21.0

* One hundred mg. of salicylic acid was exposed to about 100 mc. of tritium either in the presence or in the absence of the platinum catalyst.

TABLE III. EFFECT OF TEMPERATURE ON LABELING OF L-VALINE*

Platinum catalyst mg.	Exposure time days	Temperature °C	Specific activity μc./mg.	Increase of specific activity	Recovery %
	7	Room temp.	0.45	1	80
100	7	Room temp.	106	235	62
	4	80	0.58	1.3	68
100	4	80	2.25	5	58

* One hundred mg. of L-valine was exposed to about 100 mc. of tritium.

increase in specific activity than that of platinum alone. This is probably due to the fact that tritium gas is more readily adsorbed on platinum oxide than on platinum. The conditions employed and the results obtained in the labeling of six compounds by the catalyzed exposure technique are listed in Table I. The increase in labeling varies considerably with different compounds, but it is present in all of the compounds studied.

The aromatic compounds are more readily labeled than the aliphatic compounds. Table II shows the rates of the labeling of salicylic acid in the presence of or in the absence of the platinum catalyst.

In the absence of the catalyst, the total amount of tritium incorporated increases with the exposure time, while the amount of nonlabile tritium attached to the carbon atoms decreases with the time. In the presence of the catalyst, both the total amount of tritium (A) and the amount of nonlabile tritium (B) decrease with the exposure time beyond one hour.

These results indicate that the exposure for a longer time greatly increases the radiation damage in salicylic acid and so that the highest specific activity is obtainable when exposure is less than one hour. This is in contradiction to the report of Rydberg et al.[12] that the specific activity generally increased with the exposure time when p-aminosalicylic acid was exposed to tritium gas.

The data in Table III show the effect of temperature on labeling.

The amount of labeling increases with the exposure temperature without the catalyst, but in the presence of platinum the increase in the specific activity at 80°C is much lower than that at room temperature. Probably the amount of the adsorption of tritium gas on the platinum catalyst is substantially dependent on the temperature.

Discussion

The favorable effect of the platinum catalyst in the system is obviously related to the properties of platinum, as is shown in Table I. One probable effect of the platinum addition is to increase the absorption of β-ray energy from tritium in the system by making the contact closer between tritium and organic molecules on the catalyst surface by chemisorption.

The exchange reaction between tritium and hydrogen atoms of organic molecules is undoubtedly induced by the radioactive decay of the tritium and by the beta radiation associated therewith, as is shown below[13]:

12) J. Rydberg and A. Hanngren, *Acta Chem. Scand.*, **12**, 332 (1958).

13) T. H. Pratt and R. Wolfgang, *J. Am. Chem. Soc.*, **83**, 10 (1961).

$$T_2 \xrightarrow{-\beta^-} HeT^+ \quad (1)$$

$$RH \rightsquigarrow \text{Ions and excited species} \quad (2)$$

$$T_2 \rightsquigarrow \text{Ions and excited species} \quad (3)$$

where RH is the organic compound being irradiated.

If the tritium is to be used efficiently without adding external activation energy to the system, it is necessary to promote such ionization and excitation reactions as 2 and 3 by completely absorbing the decay energy in the system and also to increase the probability of reactions between HeT^+ and the organic compound.

When tritium and an organic compound are sealed in an ampoule without a catalyst, the beta energy is dissipated by the formation of ions and of excited molecules of both constituents and by the loss due to the absorption to the wall.

When the catalyst is present in the system, the wall loss should be small; the decay energy would be spent efficiently in the formation of the ions and of the excited molecules by the chemisorption of tritium on the catalyst.

The chemisorption of molecular tritium and organic molecules on the surface of the catalyst also increases the probability of reactions between HeT^+ and organic molecules.

Another effect of platinum addition may be seen in the catalytic exchange of hydrogen atoms, an exchange which has been employed for the preparation of tritium-labeled compounds using tritium oxide[14]. Farkas et al.[15] have already demonstrated the catalytic exchange of hydrogen atoms between molecular tritium and the nonpolar solvent, cyclohexane.

In the absence of a catalyst, the ratio of the total tritium to the nonlabile tritium attached to carbon atoms was less than one per cent, while in the presence of the catalyst, the B/A ratio increased to more than 15%, as is shown in Table II.

If the labeling is promoted only by increased absorption of the decay energy in the system, the B/A ratio must be independent of the presence of the catalyst.

Therefore, the great increase in the B/A ratio by platinum addition should be attributed to the catalytic exchange of hydrogen atoms, which presumably occurs through CH bond rupture. The relative amount of exchange for aliphatics is lower than for aromatics, as is shown in Table I. The observed tendency in the relative amount of exchange may be attributed to different strengths of chemisorption and to the fact that chemisorption of unsaturated hydrocarbons on a platinum catalyst occurs through π-complex formation.

It may be considered that chemisorption involving aliphatic compounds is relatively weak, or, alternatively, that strong chemisorption may occur only at very active, and hence less abundant, catalyst sites. In the case of salicylic acid, doubling the amount of platinum in the system increases the specific activity, but in that of valine, an increase in the amount of catalyst causes no increase in tritiation.

Furthermore, there is apparently an optimum concentration of platinum beyond which an increase in the amount of catalyst reduces the specific activity of the compound. The decrease in specific activity with the increase in platinum concentration beyond an optimum can be explained on the basis of an increasing probability of the ion neutralization and of the disappearance of the excited molecules before an effective collision (one leading to labeled-product formation) can occur.

On the other hand, charcoal also adsorbs the organic compounds, and so an increase in labeling is expected. However, a drop in the specific activity was observed when the amount of charcoal was doubled.

It could be that a part of the β-ray energy is used in vain to ionize and excite the charcoal, because the tritium gas is not adsorbed on charcoal at room temperature[9], and that consequently the efficiency of the labeling decreases.

The data in Table III indicate that the chemisorption of tritium gas on the catalyst is a very important factor in promoting the labeling. The addition of the platinum catalyst appears to promote the radiolysis of organics, but the amount of radiolysis by-products is not very large, as is shown in the recovery column of Table I.

Salicylic acid became somewhat brownish in color after 3 days of irradiation, and only 31 mg. of a radiochemically pure product could be obtained. This recovery of 31% is presumably due to the increased radiation decomposition caused by the more intense irradiation.

The low recovery in the presence of charcoal can be ascribed to the incomplete elution of the charcoal-adsorbed compound, because only about 70% of the compound used was recovered when the test blank of elution was carried out with 20 ml. of alcohol. The platinum-addition method has some advantages over the original exposure technique in that the amount of tritium required is reduced and in that the time required for labeling becomes substantially

shorter—a few day by this new technique as compared to a few weeks by the Wilzbach procedure for obtaining the same amount of activity.

Summary

To increase the efficiency of labeling according to the Wilzbach procedure by absorbing the β-ray energy of tritium in the system, three typical hydrogenation catalysts were applied to the salicylic acid-T_2 system.

The platinum catalyst was found to be most effective in promoting the labeling. The results obtained in labeling six compounds by the platinum-catalyzed-exposure technique showed that by this procedure higher specific activities in the range of 3~1880 fold were obtained.

The increase in labeling changed considerably with different compounds, and the relative amount of labeling for aromatics was higher than for aliphatics.

The authors wish to express their deep gratitude to Dr. Norio Sugimoto and Dr. Yoshio Kowa for their helpful advice and encouragement throughout this work. They are also indebted to Mr. Kiyoteru Yamada for the exposure apparatus.

Electronic States of p-Benzoquinone. VII. Intensity of the Symmetry-forbidden Electronic Absorption Bands of p-Benzoquinone

By Akira SADÔ

(Received July 26, 1961)

In Parts I[1] and II[2] of this series, we calculated the energy levels of the *p*-benzoquinone molecule and showed that the absorption bands of this molecule, appearing around 2900Å, are a superposition of three transitions, the $^1B_{1g}\leftarrow{}^1A_g$ transition, which corresponds to the π-π transition, and ^1A_u and $^1B_{2g}\leftarrow{}^1A_g$ transitions, which correspond to the n-π transitions. These transitions are all forbidden by the molecular symmetry, but are allowed through the vibronic interaction with the allowed $^1B_{2u}\leftarrow{}^1Ag$ transition. If this assignment is correct, the spectrum will appear with its transition moment along the long axis of the molecule (connecting two oxygen atoms). This is in agreement with the results of the spectroscopic studies of crystalline *p*-benzoquinone by Fixl and Schauenstein[3], Brand and Goodwin[4], and Sidman[5]. The absorption intensity around

2900Å in a *n*-hexane solution is greater than the absorption intensity around 4500Å,

$$f_{\mathrm{I}}/f_{\mathrm{II}} \fallingdotseq 1/10 \tag{1}$$

where

$$f=\int \varepsilon_{\nu} \mathrm{d}\nu \tag{2}$$

and where subscripts I and II refer to the absorption systems around the 4500Å and 2900Å regions respectively. Therefore, we may calculate the absorption intensity as a means of determining the nature of the absorption. In the description of vibronic interaction, spatially-fixed electronic wave functions are assumed.

Theoretical Considerations

The symmetry-forbidden electronic transitions are allowed by vibronic interaction with the allowed transition. This vibronic interaction has been treated by several authors[6-8]. According to the first-order perturbation method, the oscillator strength, f, for the forbidden electronic transition is described by the following formula:

$$f_{0\to k}=\sum_{s}(E_{0\to k}/E_{0\to s})C_{sk}(\boldsymbol{s})^2 f_{0\to s} \tag{3}$$

and

$$C_{sk}(\boldsymbol{s})=(W_{sk})/(E_{0\to s}-E_{0\to k}) \tag{4}$$

where $\boldsymbol{s}$ is the displacement from the equilibrium configuration in the ground electronic state, where subscript $0\to k$ indicates that the transition is from the ground state to the k state, where $0\to k$ and $0\to s$ transitions correspond to the forbidden and the allowed transitions respectively, and where $E_{0\to k}$ is the energy of the $0\to k$ transition. If we write

$$(W_{sk})_Q=\int \Theta_s^*(\boldsymbol{r})\sum_i\sum_a\{Z_a e^2 \boldsymbol{r}_a(i)\boldsymbol{s}_{Qa}/|\boldsymbol{r}_a(i)|^3\} \times\Theta_k(\boldsymbol{r})\mathrm{d}\boldsymbol{r} \tag{5}$$

then,

$$(W_{sk})^2=\sum_Q (W_{sk})_Q \tag{6}$$

where $\boldsymbol{s}_{Qa}$ is the displacement of the atom a in the normal mode Q, $\Theta_s(\boldsymbol{r})$ is the molecular electronic wave function of the quantum state, s, for the equilibrium configuration in the ground electronic state, $\boldsymbol{r}$, the symbol for the electronic coordinate, Z_a, the effective nuclear charge, and $|\boldsymbol{r}_a(i)|$, the distance from atom a to electron i. The introduction of the molecular orbital theory to give an approximate form for the electronic wave functions $\Theta_s(\boldsymbol{r})$ and $\Theta_k(\boldsymbol{r})$ leads to a considerable simplification of Eq. 5:

$$(W_{sk})_Q=\pm e^2\int \psi_1(\boldsymbol{r})\sum_a(Z_a \boldsymbol{r}_a \boldsymbol{s}_{Qa}/|\boldsymbol{r}_a|^3) \times\psi_2(\boldsymbol{r})\mathrm{d}\boldsymbol{r} \tag{7}$$

where ψ_1 and ψ_2 are the ummatched molecular orbitals in $\Theta_k(\boldsymbol{r})$ and $\Theta_s(\boldsymbol{r})$, respectively. This expression is now a one-electron integral and represents the electrostatic energy of the interaction between a set of dipoles, μ_a, and the electronic distribution, $e\psi_1\psi_2$.

If MO is constructed by the LCAO approximation, we can write

$$\psi_1=\sum_b c_{1b}\chi_b(\boldsymbol{r}) \tag{8}$$

where χ_b is the atomic orbital for atom b and c_{1b} is the coefficient of χ_b in ψ_1. From Eqs. 7 and 8,

$$(W_{sk})_Q=\pm e^2\int \sum_a\sum_b c_{1b}\chi_b(\boldsymbol{r})(\boldsymbol{r}_a \boldsymbol{s}_{Qa}/|\boldsymbol{r}_a|^3) \times\sum_c c_{2c}\chi_c(\boldsymbol{r})\mathrm{d}\boldsymbol{r} \tag{9}$$

since,

$$\boldsymbol{r}_a=\boldsymbol{r}_b+\boldsymbol{r}_{ab} \tag{10}$$

where $|\boldsymbol{r}_{ab}|$ is the distance from atom a to atom b and where it is constant, and if we neglect the differential overlap formally, we obtain,

$$(W_{sk})_Q=\pm e^2\int \sum_a\sum_b c_{1b}\chi_b(\boldsymbol{r}) \times\{(\boldsymbol{r}_b+\boldsymbol{r}_{ab})\boldsymbol{s}_{Qa}/|\boldsymbol{r}_a|^3\}c_{2b}\chi_b(\boldsymbol{r})\mathrm{d}\boldsymbol{r} \tag{11}$$

but

$$\int \chi_b(\boldsymbol{r})(\boldsymbol{r}_b \boldsymbol{s}_{Qa}/|\boldsymbol{r}_a|^3)\chi_b(\boldsymbol{r})\mathrm{d}\boldsymbol{r}=0 \tag{12}$$

and if we assume

$$\boldsymbol{r}_{ab}=\boldsymbol{r}_a \tag{13}$$

Eq. 11 becomes

$$(W_{sk})_Q=\pm e^2\int \sum_a\sum_b Z_a c_{1b}c_{2b}\chi_b(\boldsymbol{r})\boldsymbol{r}_{ab}\boldsymbol{s}_{Qa} \times\chi_b(\boldsymbol{r})\mathrm{d}\boldsymbol{r}/|\boldsymbol{r}_{ab}|^3 \tag{14}$$

Using Eq. 14, we can calculate Eq. 7 numerically.

The quantities μ_a can be evaluated by the standard method[9]:

$$\mu_a=\boldsymbol{s}_a Z_a e \tag{15}$$

Thus,

$$\boldsymbol{s}=\boldsymbol{M}^{-1}\boldsymbol{B}'(\boldsymbol{L}^{-1})'\boldsymbol{Q} \tag{16}$$

where M^{-1} is a diagonal matrix whose elements are the reciprocal masses of the appropriate atoms. B' is the transpose of the matrix B, which transforms the Cartesian displacement coordinates s into the symmetry coordinates S. $(L^{-1})'$ is the transpose of the matrix (L^{-1}), which transforms the symmetry coordinates, S, into the normal coordinates, Q. The B matrix can be evaluated from the geometry and atomic mass of *p*-benzoquinone.

Normal Coordinates

Assuming the V_h structure of the *p*-benzoquinone molecule, the transitions from the ground A_g state to the B_{2u} and B_{3u} states can appear with the transition moments along the y and x axes (both lying in the molecular plane; see Fig. 1) respectively, while the transitions to the B_{1u} state appear with moment along the z axis (perpendicular to the molecular plane)[1,2]. As is shown by Eqs. 3 and 4, the contribution of a perturbing state to the absorption intensity is inversely proportional to the energy difference between the perturbing state and the perturbed state. The absorption spectrum[3-5] of the *p*-benzoquinone crystal, using a low temperature of 20°K, appears around 2900Å with its transition moment along the y axis. Therefore, the perturbing state belongs to species B_{2u}, and we can consider vibrations belonging to b_{3u} ($B_{1g}\times b_{3u}=B_{2u}$), b_{2g}($A_u\times b_{2g}=B_{2u}$) and a_u($B_{2g}\times a_u=B_{2u}$). Since vibrations belonging to species b_{2g} and a_u have been calculated[10], we can calculate the vibration belonging to species b_{3u}.

The normal coordinate was calculated by using the method of Wilson[9]. Thereby, a matrix equation

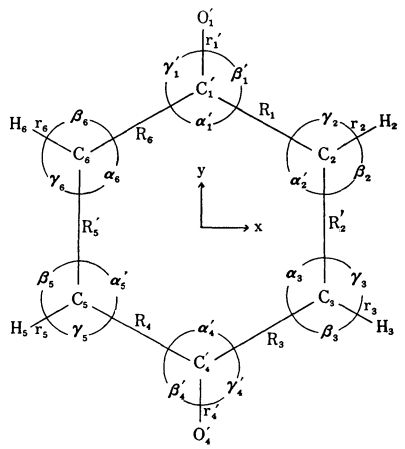

Fig. 2. Notations expressing bond angles and bond lengths and the numbering of atoms for the *p*-benzoquinone molecule.

$$(GF-\lambda I)S=0 \qquad (17)$$

was obtained. The G and F matrices are the inverse kinetic energy matrix and the force constant matrix respectively, and I is the unit matrix.

The symbols used to describe various atoms, bond lengths and bond angles in the *p*-benzoquinone molecule are shown in Fig. 2. Denoting the increase in bond lengths and angles by placing Δ in front of the symbols for these quantities, the internal symmetry coordinates, whose symbols are chosen to be as consistent as possible with those of benzene[11], are

$$\left.\begin{aligned}
S_{14} &= (1/\sqrt{6})(-\Delta R_1+\Delta R_2'-\Delta R_3+\Delta R_4 \\
&\quad -\Delta R_5'+\Delta R_6) \\
S_{15} &= (1/\sqrt{6})(-\Delta\phi_1'+\Delta\phi_2-\Delta\phi_3+\Delta\phi_4' \\
&\quad -\Delta\phi_5+\Delta\phi_6) \\
S_{18b} &= (1/\sqrt{12})(2\Delta\phi_1'+\Delta\phi_2-\Delta\phi_3 \\
&\quad -2\Delta\phi_4'-\Delta\phi_5+\Delta\phi_6) \\
S_{19b} &= (1/\sqrt{12})(\Delta R_1+2\Delta R_2'+\Delta R_3 \\
&\quad -\Delta R_4-2\Delta R_5'-\Delta R_6) \\
S_{20b} &= (1/2)(\Delta r_2+\Delta r_3-\Delta r_5-\Delta r_6) \\
S_D &= (1/2)(\Delta\alpha_2+\Delta\alpha_3-\Delta\alpha_5-\Delta\alpha_6)
\end{aligned}\right\} \qquad (18)$$

where $\Delta\phi_i=(1/2)(\Delta\gamma_i-\Delta\beta_i)$ ($i=1$, 2, 3, 4, 5 and 6).

the interatomic distances and the bond angles for the ground electronic state are used:

$$r_i'=1.23\text{Å} \qquad r_i=1.08\text{Å}$$
$$R_i=1.461\text{Å} \qquad R_i'=1.349\text{Å}$$
$$\alpha_i'=116^\circ \qquad \alpha_i=\beta_i'=\gamma_i'=122^\circ$$
$$\text{and} \quad \beta_i=\gamma_i=119^\circ$$

The source of these data may be found in a previous paper[10].

The potential function assumed was a simple valence-force field type,

$$\begin{aligned}2V=&D\{(\Delta R_1)^2+(\Delta R_3)^2+(\Delta R_4)^2+(\Delta R_6)^2\}\\&+D''\{(\Delta R_2')^2+(\Delta R_5')^2\}\\&+F\{(\Delta r_2)^2+(\Delta r_3)^2+(\Delta r_5)^2+(\Delta r_6)^2\}\\&+H\{(\Delta\alpha_2)^2+(\Delta\alpha_3)^2+(\Delta\alpha_5)^2+(\alpha\Delta_6)^2\}\\&+I\{(\Delta\phi_2)^2+(\Delta\phi_3)^2+(\Delta\phi_5)^2+(\Delta\phi_6)^2\}\\&+I''\{(\Delta\phi_1')^2+(\Delta\phi_4')^2\}\end{aligned} \tag{19}$$

The numerical values of the force constant, the same as those used in a previous paper[12] except for I'', are given in Table I. I'' is determined in such a way that a calculated value of the frequency agrees with the experimental frequency assigned to the b_{3u} C=O bending vibration ($\nu=370\,\text{cm}^{-1}$ in the ground state). The calculated and the observed frequencies are shown in Table II. The Cartesian coordinate system at each atom is defined in such a way that the positive direction of the y axis runs parallel to a line running from atom O_4 to atom O_1 and the xy plane coincides with the molecular plane. In Table III, the N' matrix is shown; it is defined by the following relation:

$$S=NX \tag{20}$$

and N' is the transpose of the matrix N. The matrix X represents the external symmetry coordinates, which are defined by using the Cartesian displacement coordinates:

$$\left.\begin{aligned}X_1&=x_{C_1'}+x_{C_4'}\\X_2&=x_{C_2}+x_{C_3}+x_{C_5}+x_{C_6}\\X_3&=x_{O_1'}+x_{O_4'}\\X_4&=x_{H_2}+x_{H_3}+x_{H_5}+x_{H_6}\\X_5&=y_{C_2}-y_{C_3}+y_{C_5}-y_{C_6}\\X_6&=y_{H_2}-y_{H_3}+y_{H_5}-y_{H_6}\end{aligned}\right\} \tag{21}$$

The L^{-1} matrix is given in Table IV.

Intensity Calculation

A dipole moment is calculated from the following formulae:

$$\mu_a=Z_a e(\overline{s_a^2})^{1/2} \tag{22}$$

and

$$\overline{s_a^2}=(\overline{x_a^2}+\overline{y_a^2}+\overline{z_a^2})\frac{h}{8\pi^2\nu_Q} \tag{23}$$

where Z_a is the "effective charge" at atom a and we use three kinds of value: (i) Z_a is the one which has been used by Murrell and Pople[11] and by Sidman[7]; (ii) each atomic displacement acts towards the π-electrons and the non-bonding electrons on its non-neighbors as a small dipole, but it is completely screened by the combined σ-electron, π-electron and non-bonding electron density from the

12) T. Anno and A. Sadô, ibid., 32, 1611 (1960).

π-electrons and non-bonding electron on its neighbors[13]. Therefore, Z_a is given the value of zero for its neighbor electron, but it is given Slater's effective nuclear charge for the 3p orbital in a negative ion of atom a (Z_C= 0.6 and Z_O=0.9) for its non-neighbors. (iii) Since the *p*-benzoquinone molecule has an unbalanced electron density, screening constants are calculated by considering the electron density. The electron densities used are given in Table V; they have been determined by the method of Moffitt[14]. The molecular orbital used for the calculation was determined in a previous paper[1]. The electronic wave functions for the equilibrium configuration were determined by a semi-empirical MO method, taking CI into account, but for the B_{2g} state only one configuration was used.

TABLE V. FORMAL CHARGE OF *p*-BENZOQUINONE (AS A RESULT OF EXCITATION)

	O_1'	C_1'	C_2

b) In the present calculation, these values are unnecessary.

Results and Discussion

For observing the absorption spectrum, a model EPS-2 Hitachi recording spectrophotometer was used, the oscillator strength was obtained graphically with a planimeter. The *p*-benzoquinone sample was prepared in the same manner as in Part V of this series[15] from hydroquinone. *n*-Hexane was used for the solvent, which was purified in the usual manner[16]. The experimental results are shown in Fig. 1.

The Cartesian displacement coordinates are given in Table VI. The calculated values of intensities are shown in Tables VII and VIII for the 4500Å and 2900Å regions respectively. From these results, we may conclude that the band around 2900Å corresponds to the transition belonging to $^1B_{1g}\leftarrow{}^1A_g$, and that the perturbing vibration is almost the b_{3u} C=O bending vibration (370 cm^{-1} in the ground state).

For the absorption band around 4500Å, the calculated intensity is very small. This is due to the facts that the interaction between the non-bonding electron of oxygen and the electronic dipole corresponds to the interaction

between an electric quadrupole and a dipole and that in the present calculation only this interaction contributes to the "n-π transition". Therefore, we considered the s-character of the non-bonding electron, but this effect was excluded from a consideration of the molecular symmetry. Assuming a V_h structure of p-benzoquinone[17,18], the non-bonding orbital of oxygene cannot be a hybridized s- and p_x-orbital, because the "s-p_x hybrid orbital" is symmetric to the yz plane. If the non-bonding orbital in oxygen is the s-orbital or the s-p_y hybrid orbital, according to the notations in Part I of this series[1], the non-bonding orbitals of p-benzoquinone ϕ_{n1} and ϕ_{n2} belong to the A_g and B_{2u} species respectively, and the $(n_1\rightarrow5)$ and $(n_2\rightarrow5)$ states belong to species B_{3g} and B_{1u}. Therefore, one of the "n-π transitions" should be an allowed transition. This fact is inconsistent with the vibrational analysis of the absorption of p-benzoquinone vapor around 4500 Å[15]. We must consider other effects or other higher-order interactions.

Summary

The intensity of the symmetry-forbidden electronic absorption band of p-benzoquinone, whose excited states belong to $^1B_{2g}$, ^1A_u and $^1B_{1g}$, has been calculated by the perturbation method. It has been concluded that the absorption band around 2900 Å corresponds to the $^1B_{1g}\leftarrow{}^1A_g$ transition, which is allowed through vibronic interaction with the allowed $^1B_{2u}\leftarrow{}^1A_g$ transition. The interaction is contributed to almost entirely by b_{3u} C=O bending vibration, whose frequency is 370 cm^{-1} in the ground state.

The author wishes to express his deep thanks to Professor Sunao Imanishi and Dr. Yoshiya Kanda of Kyushu University for their encouragement throughout this research, and to Dr. Tosinobu Anno for his helpful guidance and discussions.

Electronic States of p-Benzoquinone. VIII. Vibrational Analysis of the Vapor Absorption Spectrum around 2900 Å

By Akira SADÔ

(Received July 26, 1961)

In Part VII[1] of series, the present author showed that the absorption spectrum around 2900Å of the *p*-benzoquinone molecule due to the $^1B_{1g}\leftarrow{}^1A_g$ (π-π) transition. This transition is forbidden by molecular symmetry but allowed through vibronic interaction with the allowed $^1B_{2u}\leftarrow{}^1A_g$ transition. For this interaction, the perturbing vibration is almost b_{3u} C=O bending vibration only. Solvent effect study[2] revealed that this absorption spectrum is due to a π-π ($^1B_{1g}\leftarrow{}^1A_g$) transition. In Parts I and II[3,4], the author has calculated the energy levels of this molecule and shown that there are three transitions, ^1A_u, $^1B_{2g}$ and $^1B_{1g}\leftarrow{}^1A_g$, which are superposed in this region.

The vapor spectrum in this region has been studied by Light[5] and by Seshan[6]. Light observed 21 bands. Seshan observed 32 bands between 3145~2530Å and represented them by the following formula:

$$\nu = 31780 + 450n - 230p \qquad (1)$$

where n and p are integers, n, running 0~17, and $p=0$ or 1. However, nothing was mentioned in his paper as to the nature of the electronic transition concerned.

In order to clarify the nature of the absorption band of *p*-benzoquinone around 2900Å, the vibrational analysis of vapor spectrum of this molecule has now been investigated.

Experimental

The sample of *p*-benzoquinone from hydroquinone was prepared in the same manner as in Part V[7]. The spectrum was taken on a "Fuji process" plate. The spectrograph used was a quartz spectrograph whose dispersion was 7Å/mm. at 3000Å. The absorption cell with quartz windows was 40 cm. long; to it a small side tube was attached. The sample was immediately placed in the side tube, and the absorption cell was evacuated, while its side arm was being cooled by using a freezing mixture of ice and sodium chloride to prevent the *p*-benzoquinone sample from sublimation, and sealed off. The temperature of the absorption cell was controlled between 40 and 120°C in a manner described elsewhere[8].

Results

The absorption spectrum of *p*-benzoquinone in the region between 2580~3290Å appears at a lower temperature than that in the 4500Å region. The microphotometer tracing curves of the spectrograms of this molecule is shown in Fig. 1, while Table I contains the measured frequencies and relative intensities of the main absorption bands, together with their interpretations. We have obtained about eightly bands. From a comparison of this table with Table I in Seshan's paper[6], it can be seen that the present observation corresponds with region II of his work and that

the main bands agree with those reported by him, although his one band is resolved into several components. Moreover, we can classify the bands into two groups by their characters. One of the two groups (group 1) consists of sharp and single bands and corresponds to Sidman's (d) band[9] observed for a crystalline sample. The other band group (group 2)

9) J. W. Sidman, *J. Am. Chem. Soc.*, **78**, 2363 (1956); *J. Chem. Phys.*, **27**, 820 (1957).

consists of broad bands, each of which has two components, the frequency separation being 45 cm^{-1}

Analysis and Discussion

We have shown[3,4] that, if the *p*-benzoquinone molecule belongs to the V_h point group[10,11], three transitions (^1A_u, $^1B_{2g}$ and $^1B_{1g}\leftarrow{}^1A_g$) are superimposed in this region, and that these transitions are all forbidden by molecular symmetry but allowed through vibronic interaction with allowed $^1B_{2u}\leftarrow{}^1A_g$ transition[3,4]. If this assignment is correct, the spectrum should appear with the transition moment along the molecular axis (connecting two oxygen atoms). This is in agreement with the spectroscopic studies of crystalline *p*-benzoquinone by Fixl and Schauenstein[12], by Brand and Goodwin[13] and by Sidman[9]. The perturbing state and perturbing vibration in this case, are shown in Table II.

TABLE II. COMBINATIONS OF PERTURBED AND PERTURBING STATES OF *p*-BENZOQUINONE

Perturbing state	Perturbing vibration	Perturbed state
	b_{2g}	A_u
B_{2u}	a_u	B_{2g}
	b_{3u}	B_{1g}

In the first place, we will consider group 2. The band at 35156 cm^{-1} is taken as the origin of the analysis, which corresponds to the transition from the vibrationless ground state to the electronic excited state upon which a perturbing vibration is suberimposed by one quantum ($0+\nu''$). This band is the origin of two pregressions: one has a frequency separation of 444 cm^{-1} for a long wavelength, and the other has a frequency separation of 435 cm^{-1} for a short wavelength. They may be totally symmetric vibration frequencies in the ground and excited electronic states, as will be discussed later. Similarly, the band at 34492 cm^{-1} is the transition from the ground state upon which a perturbing vibration is superimposed by one quantum to the vibrationless electronic excited state ($0-\nu'$). The difference between the two bands is 665 cm^{-1}, and the frequencies of the perturbing vibration may be 250~400 cm^{-1}. From Table IV in Part IV of this series[14] and Table II here, the C=O bending vibration belonging to the b_{3u} species whose frequency is 370 cm^{-1} may be considered to be the perturbing vibration. This result is consistent with the absorption intensity calculation[1]. Therefore, the absorption bands of group 2 can be assigned to the $^1B_{1g}\leftarrow{}^1A_g$ transition.

The observed frequencies forming the main progressions are shown in Table III and are compared with the data of the Raman spectrum and the data from the 4500Å region absorption. The obtained frequencies, 444 in the ground state and 435, 692 and 1560 cm^{-1} in the excited state, are assigned to the a_g vibration. The 435, 692 and 1560 cm^{-1} frequencies in the excited state may correspond to the ground state frequencies of 444, 770 and 1667 cm^{-1}.

We have not been able to observe that band corresponding to the transition from the ground state in which both the perturbing vibration and the (totally symmetric) 444 cm^{-1} vibration are excited by one quantum each to the vibrationless excited state ($0-\nu''-444$), probably because this band is hidden by a band of group 1 ($\nu_I+6\times450$). The band at 36970 cm^{-1} is assigned to $0+\nu'+1125+692$, but other bands can be assigned using 1560($=1125+435$ cm^{-1}). The frequency of 1125 cm^{-1} is uncertain.

Group 1 has seven components at equal intervals of about 450 cm^{-1} between 31336 cm^{-1}

TABLE III. FUNDAMENTAL FREQUENCIES OF TOTALLY SYMMETRIC VIBRATION OF *p*-BENZOQUINONE

(ν_I) and 34032 cm^{-1} ($\nu_I+6\times450$). The shapes of these bands are sharp and they are distinguished from the shape of the bands in group 2. It is probable, though not certain, these absorption bands are due to the n-π (^1A_u or $^1B_{2g}\leftarrow{}^1A_g$) transition. The bands belonging to group 1 are shown by the form $\nu_I+n\times450$ in Table I.

Summary

The absorption spectrum of *p*-benzoquinone vapor was observed at 2900Å region and the vibrational analysis was carried out. Two absorption groups were found. The bands in group 1 are sharp and single, but the nature of the transition is uncertain. Group 2 is composed of a doublet whose frequency separation is 45 cm^{-1}. It corresponds to the $^1B_{1g}\leftarrow{}^1A_g$ transition and is allowed by vibronic interaction with the allowed $^1B_{2u}\leftarrow{}^1A_g$ transition. The perturbing vibration is a C=O bending vibration belonging to the b_{3u} species whose frequency is 370 cm^{-1} in the ground state. The vibration frequencies of the main progression are 444 cm^{-1} and 435, 692 and 1560 cm^{-1} in the ground and excited electronic states respectively.

The author wishes to express his sincere thanks to Professor Sunao Imanishi and Dr. Yoshiya Kanda of Kyushu University for their encouragement throughout this research, and to Dr. Tosinobu Anno for his helpful guidance and discussions. Thanks are also due to Dr. Ryoichi Shimada and Dr. Ikuo Matubara for guidance and assistance in the experiments.

Studies on Long Chain Alkyl Amides of Water-soluble Poly-α-amino Acids. II. Infrared Spectra of Poly-DL-alanine Dodecylamide

By Shoichi IKEDA and Toshizo ISEMURA

(Received March 30, 1962)

Infrared spectral studies of synthetic polypeptides have been an important method for elucidation of the molecular conformation. Experimental investigations have been made by Elliott[1-4], Bamford[1,5] and Blout[6-8] to correlate the conformation of various polypeptide specimens with the frequency of characteristic band in infrared spectra, and recently a semiempirical interpretation of the spectra has been developed by Miyazawa[9,10].

Blout and Asadourian[6] found that an L-polypeptide, poly-γ-benzyl-L-glutamate, consists of different amounts of the α- and β-forms, depending on the mode of preparation and the degree of polymerization. The α-form was characterized by an absorption around 1655 cm^{-1} in the amide I band, and the β-form by an absorption around 1630 cm^{-1}. Bamford, Happey and Hanby[5] reported the dependence of the infrared spectra and the conformation of copoly-1 : 1-(DL-phenylalanine, DL-leucine) on the degree of polymerization, and Robinson and Bott[11] correlated the conformation of copoly-1 : 1(γ-methyl-L-glutamate, DL-phenylalanine) with the degree of polymerization.

On the other hand, the mechanism of the polymerization reaction of *N*-carboxy-α-amino acid anhydride with primary amine initiation[12] leads us to expect that the polypeptide produced by this reaction should link with the amine residue on its terminal carboxyl group by a peptide bond. No direct evidence for such a linkage has yet been found, however. Infrared spectral study of this kind of polypeptides would also provide information to demonstrate such a terminal structure, if the

primary amine for initiation was properly chosen.

We have studied a long-chain alkyl amide of water-soluble poly-α-amino acid, which we call poly-DL-alanine dodecylamide[13]. In this paper we will report the results of the infrared spectral study on poly-DL-alanine dodecylamide (PADA) with reference to poly-DL-alanine. Our original interests have been directed towards the confirmation of the presence of a dodecyl group in the molecule and the dependence of the molecular conformation on the mode of preparation or on the degree of polymerization. For these purposes, the polymers were investigated in the solid state. However, the spectra of the polymers in Nujol mull or in potassium bromide disk were found to exhibit some complications[13]. Thus the polymers were exclusively examined in the state of film which had been cast from solutions in various solvents.

The observed infrared spectra themselves reflected the difference in structure as well as in conformation, depending on the mode of preparation. Furthermore, they were found to be also strongly dependent on the state of solution from which the film had been cast. These were interpreted as a result of conformational change of the polymer in the dissolved state.

Experimental

Materials.—Poly-DL-alanine dodecylamide was prepared as previously described, and all the specimens except one were the same as in the previous investigation[13]. PADA obtained from the anhydride/initiator molar ratio, [A]/[I], of 5 to 30 was found to have a number average degree of polymerization approximately equal to [A]/[I]. Poly-DL-alanine was prepared by triethylamine initiation or by sodium methoxide initiation.

The number average degree of polymerization of the polymers was determined by the anhydrous titration of a terminal amino group.

PADA and poly-DL-alanine were soluble in formic acid, dichloroacetic acid, trifluoroacetic acid and *m*-cresol. When PADA of [A]/[I] higher than 5 and poly-DL-alanine were dissolved in formic acid to a concentration of about 10%, the solutions gelled after a few hours to a few days. The gelation occurred faster, as the [A]/[I] value was lower. The polymer solutions in the other solvents did not show any such tendency to gel.

PADA of [A]/[I] higher than 15 and poly-DL-alanine were soluble in distilled water*. All the polymers were soluble in aqueous hydrochloric acid solution, the pH value of which was lower than 5.5. When PADA of [A]/[I] higher than 5 or poly-DL-alanine was dissolved in aqueous hydrochloric acid or in distilled water to a concentration of about 10%, the solution gelled at room temperature after several hours to several days, and the gelation occurred faster as the pH of the solution was lower. The solution gelled also by heat.

Some properties of these polymers are listed in Table I.

Infrared Measurements.—Films for infrared measurements were cast on silver chloride plates from about 10% polymer solutions in various solvents, whether they were fluid or gelled. Films cast from formic acid solution or from aqueous solution were dried at room temperature for 4 hr. or more. Dichloroacetic acid or trifluoroacetic acid could be removed from cast films with great difficulty, merely by drying them by heat (ca. 50°C) in vacuo (4 mmHg) for several hr.; the remaining solvent greatly affected the spectra and the conformation of the polymer. It was more difficult to remove the solvent, as the [A]/[I] value of the polymer was higher.

All infrared spectral measurements were performed on a Perkin-Elmer 221 spectrophotometer using a sodium chloride prism. The temperature was about 20°C, and the relative humidity was about 40%.

Results

Poly-DL-alanine. — Poly-DL-alanine obtained from [A]/[I] of 50 or more with either sodium methoxide or triethylamine initiation showed identical spectra when measured in

films cast from formic acid solution or from aqueous solution. A typical spectrum is shown in Fig. 1, curve a. This spectrum is identical with that reported by Elliott[1,4]. The characteristic absorptions at the amide I and II bands were relatively broad and were located at 1661 cm^{-1} and 1536 cm^{-1} respectively. Elliott[4,14] attributed the amide I band at 1661 cm^{-1} to the α-form. However, from the results referred to below, it is more likely that this absorption is due to the random coil form of poly-DL-alanine. Furthermore, it is now established that the amide I band of the random coil form lies at almost the same frequency as that of the α-helix[10,15]. Deuterium-hydrogen exchange experiments provide additional evidence for the random coil form of poly-DL-alanine, although it is in an aqueous solution[16].

The correlation of the amide II frequency with the polypeptide conformation is not clear. An absorption in the amide III band appeared at 1248 cm^{-1}, whatever the polypeptide conformation was, as will be described below. The N–H stretching mode was observed at a relatively high frequency, 3311 cm^{-1}. The relatively weak absorptions at 2985 and 2933 cm^{-1} may be assigned to the antisymmetric and the symmetric C–H stretching modes of the side chain methyl group respectively. The data concerning the main absorption bands are summarized in Table II.

Film cast from gel obtained by aging the solution either in formic acid or in distilled water gave an absorption spectrum as shown in Fig. 2, curve b. In comparison with curve a, obtained from a fresh, fluid solution, the amide I band had a weak shoulder at 1630 cm^{-1} in addition to the original peak at 1661 cm^{-1}. The shoulder may be assigned to the amide I band of the β-form, following Elliott[14] and after Miyazawa and Blout[10]. Thus, the gelation of the poly-DL-alanine solutions accompanies the partial conversion of the random coil form to the β-form.

Structure and Conformation of PADA.—The infrared spectra of PADA in films cast from a

formic acid solution in a fluid state (immediately after dissolution) are shown in Fig. 1, curves b, c, d and e. It should be first noted that the intensity of the antisymmetric C–H stretching mode at 2920 cm^{-1} is varied from weak to strong with decreasing the [A]/[I] ratio or the degree of polymerization. No doubt this dependence of the spectra on the [A]/[I] ratio reflects the difference in the structure of the polymer dependent on the degree of polymerization. The band may be associated with the methylene groups of the terminal dodecyl group in the PADA molecule. Since the number of mole of dodecyl group per, say, peptide group increases with decreasing the [A]/[I] ratio, the change in intensity of the band at 2920 cm^{-1} indicates the formation of a linkage between the dodecylamino group and the poly-DL-alanine part.

While poly-DL-alanine of different modes of preparation was in the random coil conformation, as has been mentioned before, PADA obtained from [A]/[I] ratios of less than 30 exhibited a different situation. The amide I absorption of the [A]/[I] 20 preparation lay at 1661 cm^{-1} with a weak shoulder at 1630 cm^{-1}, suggesting that the polymer consisted mostly of the random coil form but partly of the β-form. With decreasing [A]/[I] ratio, the absorption at 1661 cm^{-1} became weaker and that at 1630 cm^{-1} stronger. For the [A]/[I] 5 preparation, the latter band was predominant and the former appeared as a weak shoulder. The dependence of the spectra on the [A]/[I] value manifests a conformational change of PADA with the degree of polymerization. That is, a greater amount of the β-form and a smaller amount of the random coil were included in PADA, as the [A]/[I] value or the degree of polymerization was lower. The lowest [A]/[I] preparation was mostly composed of the β-form. The relative amounts of the two conformations were estimated from the ratio of the intensities of the two amide I absorptions, assuming equal molar extinction coefficients. The results are given in Table I. In addition, a shoulder at 1690 cm^{-1} became apparent as the peak at 1630 cm^{-1} became higher. This indicates that the β-form consists of antiparallel chains, provided that Miyazawa's theory[9] can be extended to such low molecular weight polypeptides.

The amide II band showed no such striking correlation of spectra with the [A]/[I] value as the amide I band, but it appeared to be slightly broader as the [A]/[I] value was decreased.

A characteristic change of spectra was also observed in the amide III band. While this band was located at 1244 cm^{-1} for the [A]/[I] 20 and 30 preparations, corresponding to 1248 cm^{-1} for poly-DL-alanine, the lower [A]/[I] preparations absorbed two frequencies, 1244 and 1222 cm^{-1}, the latter becoming stronger

with decreasing [A]/[I] value. Accordingly, the absorption at 1222 cm^{-1} should be associated with the β-form, while the one at 1244 cm^{-1} is independent of the conformation.

The N–H stretching mode at about 3300 cm^{-1} changed not in intensity but in frequency as the [A]/[I] value was varied. While poly-DL-alanine gave an absorption at 3311 cm^{-1}, the observed frequency of PADA of [A]/[I] 5 was 3279 cm^{-1} and the higher [A]/[I] preparations absorbed an intermediate frequency, 3289 to 3300 cm^{-1}. This variation also seems to accompany the conformational change with the degree of polymerization. PADA absorbed a higher frequency of the N–H stretching vibration in the random coil form, and, with an increasing amount of the β-form, it absorbed a lower frequency. This kind of behavior has already been observed for other polypeptides by Ambrose and Elliott[2].

All the above correlations of the infrared spectra with the mode of preparation are tabulated in Table II. The conformation of PADA and poly-DL-alanine can be most distinctly identified by observing the amide I absorptions at 1661 and 1630 cm^{-1}.

Film cast from dichloroacetic acid or trifluoroacetic acid solution in which the solvent was still retained always showed a stronger absorption at 1661 cm^{-1} than that from a formic acid solution. This observation suggests that PADA is strongly solvated by dichloroacetic acid or trifluoroacetic acid, which is known to be a "random coil solvent", and that PADA is more favorably stabilized in the random coil form in the presence of the solvent. The band at 1661 cm^{-1} may, therefore, be associated with the random coil form rather than with the α-helix.

Ionization of the Terminal Amino Group of PADA.—The pH value of an aqueous solution of PADA was dependent on the [A]/[I] value when dissolved or suspended in aqueous hydrochloric acid of the same concentration, since PADA combined with different numbers of hydrogen ions[13]. The pH value of the solution should be lower as the [A]/[I] value is higher. Thus the [A]/[I] 5 preparation was insoluble in 0.1 N hydrochloric acid solution, while the others were soluble. However, we may use the concentration of hydrochloric acid instead of the pH value as a measure of the ionization of the terminal group of dissolved polymer.

The infrared spectra of film cast from aqueous hydrochloric acid solution or suspension, the acidity of which was varied from 0.1 N to 0.4 N, were compared with that from formic acid solution. It was found that the spectra of PADA of [A]/[I] higher than 15 were not distinguished from those cast from the formic acid solution and were scarcely influenced by the acid strength. However, the lower [A]/[I] preparations revealed the effect of the ionization on the spectra. For the preparations of [A]/[I] 5 and 10, these changes are illustrated in Fig. 3, in which are shown the spectra of films cast from formic acid solution and from 0.1 N and 0.2 N hydrochloric

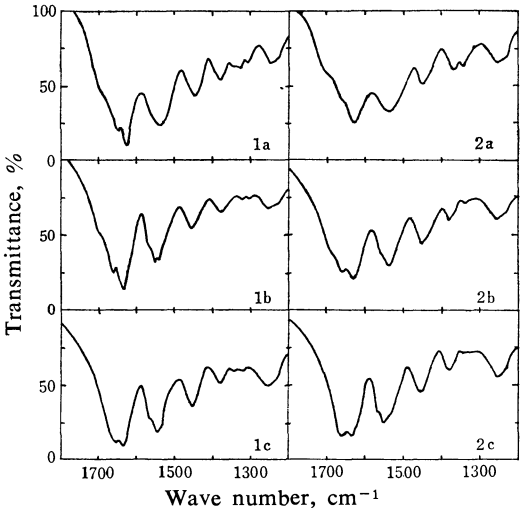

Fig. 3. Infrared spectra of poly-DL-alanine dodecylamide. Films cast from solutions in different solvents. 1. [A]/[I]=10; 2. [A]/[I]=5; a. Formic acid; b. 0.1 N Hydrochloric acid; c. 0.2 N Hydrochloric acid

acid solutions. The effect of the ionization was more enhanced as the [A]/[I] value was higher, and the absorption at 1661 cm^{-1} was stronger and the one at 1630 cm^{-1} was weaker as the degree of ionization was higher. Thus the random coil form is more stable in the ionized state than the β-form.

Gelation of PADA Solution in Formic Acid or in Aqueous Hydrochloric Acid.—When PADA was dissolved in formic acid, the lower [A]/[I] (10 and 15) preparations gelled within several hours, while the higher [A]/[I] preparations gelled after a day or two. Film cast from the gel gave a spectrum different from that obtained from the original fluid solution. With the higher [A]/[I] preparations, the absorption at 1661 cm^{-1} became weaker and that at 1630 cm^{-1} stronger, as in the case of poly-DL-alanine. Correspondingly, the bands at 1690 and 1222 cm^{-1} appeared or became slightly stronger. These are shown in Fig. 4, curves 1. Thus, the gelation of the higher [A]/[I] preparations in formic acid accompanies a conformational change characterized by the transformation of a part of the random coil to the β-form.

With the lower [A]/[I] preparations the

a) r=random coil conformation, β=β-conformation

reverse situation was encountered during the gelation. The change of the spectra by gelation is illustrated in Fig. 4, curves 2. The absorption at 1661 cm^{-1} became stronger and that at 1630 cm^{-1} weaker. Simultaneously, the bands at 1690 and 1222 cm^{-1} vanished or weakened. In the case of the lower [A]/[I] preparations in formic acid, therefore, the β-form is partly transformed into the random coil during the gelation.

When PADA was dissolved in aqueous hydrochloric acid and kept at room temperature for several days or heated on boiling water for several minutes, the solution of PADA (except for the lowest [A]/[I] preparation) became gel. Film cast from the gel was always characterized by the increased intensity of the absorption at 1630 cm^{-1} and by the decreased intensity of 1661 cm^{-1}, as compared with that from the original fluid solution. Thus the gelation of PADA in aqueous hydrochloric acid is always associated with the change of a part of the random coil form to the β-form.

All these conformational changes followed by the gelation are summarized in Table III, in which the relative amounts of the random coil and the β-form estimated as before are given.

Discussion

According to Blout and Asadourian[6], low molecular weight poly-γ-benzyl-L-glutamate produced from the *N*-carboxyanhydride by *n*-hexylamine initiation could be separated into two components, the α- and the β-forms, by the difference in solubility in formic acid. The α-polypeptide had a higher molecular weight and absorbed a frequency at 1655 cm^{-1} in the amide I band when cast in film, but the β-polypeptide was of a lower molecular weight and showed an absorption at 1630 cm^{-1}. The portion of each form in poly-γ-benzyl-L-glutamate was independent of the solvent species from which film had been cast.

According to Bamford et al.[5,17], on the other hand, low molecular weight copoly-1 : 1-(DL-phenylalanine, DL-leucine) was less soluble in benzene as the degree of polymerization was lower. The copolymer was composed of the α- and β-forms, and the decreased solubility was attributed to the increased amount of the β-form. The α-form absorbed 1655 cm^{-1}* and the β-form absorbed 1636 cm^{-1} when the copolymer was examined in a film state. Unlike as in poly-γ-benzyl-L-glutamate, however, the portions of the two forms were dependent on the solvent species and the method for the regeneration into film. Formic acid was more favorable in producing the β-form, and dichloroacetic acid preferred the formation of the α-form. Similar results were obtained for poly-DL-phenylalanine[17].

Poly-DL-alanine obtained from dodecylamine initiation, PADA, was found to consist of the random coil form and the antiparallel β-form. The former form gave an absorption at 1661 cm^{-1} in the amide I band, while the latter absorbed at 1630 cm^{-1}. The portion of the β-form was greater, and the solubility in distilled water was lower, as the degree of polymerization was lower. However, the solubility of this polymer in water might not be attributable to the conformational difference alone but also to the hydrophobicity of the dodecyl group. As compared with that from formic acid solution, film cast from dichloroacetic acid solution contained a greater amount of the random coil form, but the difference would be caused by the presence of remaining solvent and will disappears after the complete removal of the solvent. Thus, the conformation of PADA in the solid state is defined mainly by the degree of polymerization.

There are two factors to stabilize a given conformation of a polymer chain, i. e., energy and entropy contributions. The former is determined by the potential of internal rotation around backbone linkages, the hydrogen bonding between peptide bonds, etc. The latter arises mainly from the Brownian motion of the constituent residues. In high molecular weight PADA and poly-DL-alanine, the entropy contribution is greater than the energy contribution; then the random coil form is made more stable. With lowering of the degree of polymerization, the conformational entropy decreases and the energy contribution becomes predominant. The energetically stable form would be the interchain hydrogen-bonded β-form, and then the β-form becomes abundant in low molecular weight PADA. In PADA, the van der Waals cohesion between dodecyl groups should play an additional role in stabilizing the β-form, the long chain alkyl groups tending to be held together. Further, the antiparallel-chain β-form would be more stable than the parallel one, as far as the potential of the internal rotation was concerned[18].

The effect of the dissolved state on the regenerated conformation of PADA may be interpreted as follows. In dichloroacetic acid or trifluoroacetic acid solution, the polymer is probably in a solvated random coil form,

17) C. H. Bamford, W. E. Happy and F. Happey, *Proc. Roy. Soc.*, **A205**, 30 (1950).

* Elliott[4] recorded this frequency as 1661 cm^{-1}.

18) T. Miyazawa, *J. Polymer Sci.*, **55**, 215 (1961).

irrespective of the degree of polymerization, owing to the strong ability of the solvent to break hydrogen bonds, and no further conformational change occurs in the course of time. The conformation of PADA in the dissolved state is considered to be reversible to the original one in the solid state when the polymer is made free from the solvent.

In formic acid solution, however, PADA will be in a randomly coiled form immediately after dissolution. This form may be less solvated and less randomly coiled than in dichloroacetic acid solution, since formic acid is a weaker hydrogen bond-breaking agent. However, this state of dissolution is considered to be reversible to the initial solid state of the polymer. The conformation of PADA in formic acid solution is no doubt much more abundant in the random coil form than in the initial solid state. However, this solution undergoes aging, probably owing to the weak polymer-solvent interaction and the high polymer concentrations such as 10%. In the course of aging, the dissolved random coils are in contact with one another and are then linked by interchain hydrogen bonds. As a result, the random coil is partly converted into the β-form, and the formation of cross-linkages makes the fluid solution into gel. PADA in the gelled state can no longer return to the initial solid state, even if the solvent is completely removed. When the regenerated solid state is compared with the original solid state, the aging or the gelation apparently accompanies the partial conversion of the β-form to the random coil for the [A]/[I] 10 and 15 preparations, but it produces the reverse conversion for the higher [A]/[I] preparations. The chain length of PADA of [A]/[I] 5 is too short to bring about gelation.

In aqueous hydrochloric acid solution, the terminal amino groups of PADA are, at least, partially ionized, as the pH titration data indicate. The electrostatic repulsion is then operative between polymers and the polymer chain takes a random coil. From the pH titration and the surface tension data, it is evident that most of the hydrochloric acid required to make the pH value of the solution lower than 5.5 is not bound to the polymer, but merely suppresses the electrostatic repulsion as neutral electrolyte does. When the solvent is removed, however, the free hydrochloric acid or the ionic atmosphere is reduced and the interchain distance is decreased. Thus, the electrostatic repulsion is very strong in the regenerated PADA, which is partially ionized. As compared with the unionized PADA regenerated from formic acid solution, the ionized PADA regenerated from aqueous hydrochloric acid solution has a higher portion of the random coil form, since the interchain hydrogen bonds maintaining the β-form are ruptured by the electric repulsion. The effect of the repulsive force is greater, as the degree of polymerization is lower and the degree of ionization is higher.

The aqueous solution of PADA or poly-DL-alanine forms a gel by aging. The random coil form of PADA in solution will be partly converted into the β-form during this process. The cross-linkages formed by the aging will be retained even after the removal of the solvent, and the increased amount of the β-form results in the ionized PADA regenerated from the gel. In solution, the contact or the aggregation of ionized PADA is disturbed by the interchain repulsion between ionized terminal groups. In concentrated hydrochloric acid solution, however, most of ions produced from the acid are free from PADA and only serve to reduce the electrostatic repulsion, Thus, the contact of ionized PADA with one another is made easier and the gelation can occur faster, as hydrochloric acid is more concentrated.

Summary

The infrared spectra of poly-DL-alanine and poly-DL-alanine dodecylamide were measured on film cast from various solutions, and the conformation of the polymers were elucidated on the basis of the location and intensity of absorptions, mainly in the amide I and III bands.

The polymer showed an absorption at 1661 cm^{-1} in the amide I band if it was in the random coil form, but it showed two absorptions at 1630 and 1690 cm^{-1}, if it was in the antiparallel β-form. While the amide III band was located at 1244 cm^{-1} irrespective of the polymer conformation, the band had an additional absorption at 1222 cm^{-1} for the β-conformation.

From the above correlation of the spectra with the polymer conformation, it was found that poly-DL-alanine and PADA prepared with high [A]/[I] ratios are in the random coil form but that PADA of [A]/[I] ratios lower than 30 is composed of both the random coil and the antiparallel β-forms when it is regenerated from formic acid solution. PADA contained a greater amount of the β-form as the [A]/[I] value or the degree of polymerization was lower. The [A]/[I] 5 preparation was mostly in the β-form.

In the ionized PADA obtained from aqueous hydrochloric acid solution, the portion of the random coil form increased relative to that in the unionized PADA derived from formic

acid solution, and the effect of the ionization was enhanced for the lower [A]/[I] preparations.

Poly-DL-alanine and PADA in formic acid or aqueous hydrochloric acid solution underwent a partial transformation from the random coil to the β-form during the aging of concentrated solution, which process accompanied gelation. The solution of the lowest [A]/[I] preparation did not gel. In the state regenerated from gel, poly-DL-alanine and PADA, except for the unionized lower [A]/[I] preparations, had an increased amount of the β-form as compared with that from an initial fluid solution. In the lower [A]/[I] preparations obtained from formic acid solution, the reverse transformation apparently occured, when the films cast before and after the gelation were compared.

The authors wish to thank Dr. Kunio Fukushima for helpful discussion on the infrared data. The expense of this work was partly defrayed by a grant from the Ajinomoto Co.

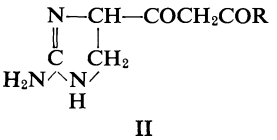
*An Attempt at the Synthesis of Roseonine**



By Tadashi SATO

(Received December 11, 1961)

In 1954, Nakanishi et al. isolated a new amino acid, roseonine, as one of the hydrolysis products of a peptide antibiotics roseothricin; they proposed that the structure was 2-amino-4-(1-carboxy-1-hydroxy-2-amino)-ethyl-2-imidazoline (I)[1]. Since the compounds firmly

I

II

identified as the degradation products of roseonine were very few in number, information about its structure was obtained mainly from a comparison of its physicochemical properties with those of many model compounds. Later, some similar amino acids were isolated from other sources and were named differently (e. g., geamine isolated from geomycin[2]), but they were proved to be identical with roseonine.

In order to confirm the structure of this amino acid, the synthesis of roseonine was attempted. As the most facile path to roseonine appeared to be through a ketonic compound II, the studies were directed to the preparation of this ketonic compound. When 2,3-diaminopropionic acid monohydrobromide (III) was treated with bromocyan in the presence of two moles of sodium hydroxide, 2-amino-2-imidazoline-4-carboxylic acid (IV) was obtained. The acetylation of IV with a mixture of acetic acid, acetic anhydride and concentrated sulfuric acid afforded a monoacetyl derivative. The acetyl derivative was formulated as V in view of the following reaction sequence. Ethanolic hydrogen chloride converted V into its ester, VI. Numerous attempts to effect the condensation of VI with ethyl acetate or acetone in order to afford II were unsuccessful. However, ethyl acetoacetate condensed with it in the presence of sodium ethylate, and the product was isolated as its hydrochloride. Based on the following physicochemical properties and reactions of this condensation product, the bicyclic structure VIIa was assigned to it. IV and V may have a dipolar structure, judging from their pK_a values (Table II). The infrared spectra of IV, V, VI and VIIa in the 1800~

* After the manuscript of this article was submitted for publication, a revised structure was proposed for roseonine: H. E. Carter et al., *J. Am. Chem. Soc.*, 83, 4297 (1961).

1500 cm^{-1} region were measured in different states and were compared with each other (Table I). The carboxylate band (1630~1608 cm^{-1} in A, C, E, G) of IV and V shifted to the carboxyl band (1735~1720 cm^{-1} in B, D, F, H) in the acidic state. Goto et al.[3] reported that the disubstituted guanidium group generally showed in the 1700~1580 cm^{-1} region, two bands separated from each other by 90 cm^{-1}; they were named guanidium I and II. The bands at 1687 and 1580 cm^{-1} of IV were, therefore, thought to be guanidium I and II; in accordance with this expectation, they shifted to a lower wave number in the deuteriated state (C, D). However, V and VI have only one band that shifted when deuteriated. It was assumed from this result that the two guanidium bands of IV were reduced to one band by acetylation. The bands at 1735~1720 cm^{-1} of V and VI, which were unaffected by the change in state, were assigned to amide carbonyl[4] overlapped by carboxyl in

3) T. Goto, K. Nakanishi and M. Ohashi, This Bulletin, 30, 723 (1957).

4) It has been reported that the amide carbonyl band shifts toward a higher wave number when the amide nitrogen atom constitutes a five-membered ring system (*N*-acetylimidazole, *N*-acetylindol, etc.): W. Otting, *Chem. Ber.*, 89, 1940 (1956); H. A. Staab, ibid., 90, 1320 (1957).

Table II. Values of pK_a's

Compound	pK_{a1}	pK_{a2}
IV	2.5	12.1
V	1.6	8.7
VI	—	7.7
VIIa	2.0	3.8
X	3.1	—

the case of F and H in Table I or by ester in the case of I and J.

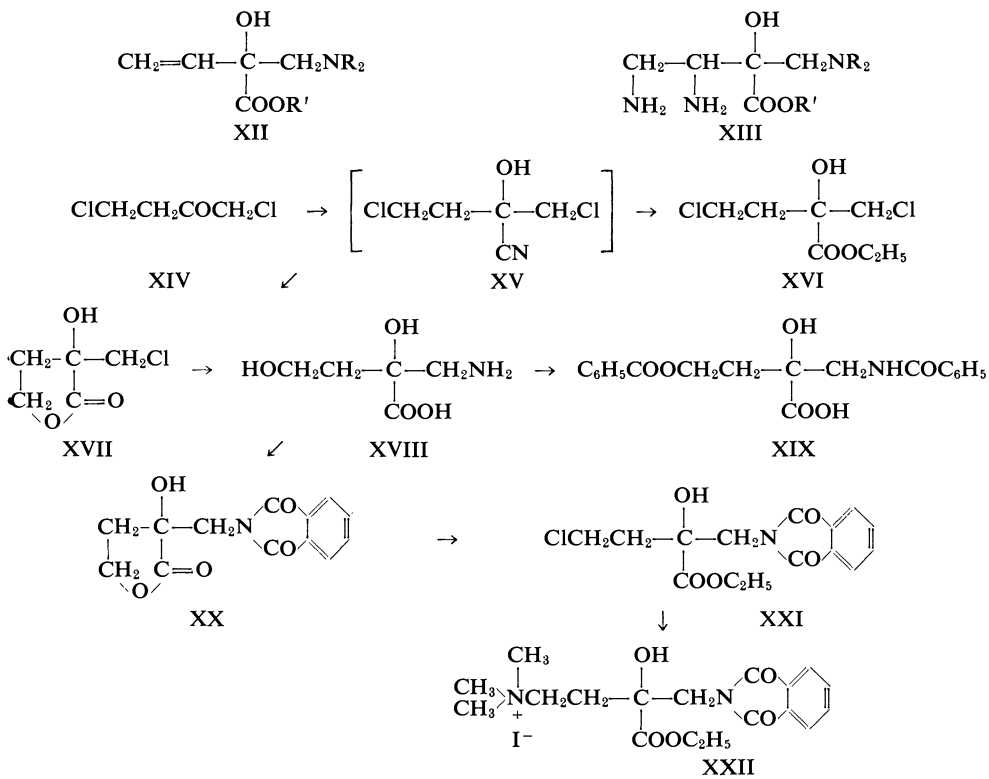
Bearing these facts in mind, the band assignments of VIIa were made as follows: 1750 cm^{-1} to amide carbonyl (shifted to a higher wave number by five-membered cyclization), 1708 cm^{-1} to carboxyl, 1665 cm^{-1} to guanidium (shifted to a lower wave number by deuterium substitution in the case of L), and 1630 cm^{-1} to a C=C double bond.

Further evidence supporting this structure (VIIa) was also obtained. Phenylhydrazine reacted with VIIa, but the product was not the phenylhydrazone, but the phenylhydrazine salt of VII (VIII), because phenylhydrazine was easily removed from VIII by the action of picric acid to afford the picrate of VII (IX). The hydrochloride VIIa was not susceptible to the acid or to alkali hydrolysis, and the titration with alkali revealed the presence of two titratable groups, which were attributable to the guanidine and carboxyl groups (see below). The acetylation of VIIa afforded the acetyl derivative X, which had only one titratable group. Although the observations described above were consistent with the bicyclic structure VIIa, the hydrochloride exhibited unexpectedly low pK_a values, 2.0 and 3.8. Even when the higher observed value of pK_a was attributed to the ionization of the guanidine group, it appeared to be too low to be regarded as the pK_a value of normal guanidine derivatives. A specific steric environment caused by the fusion of two rings is probably responsible for this unusually low pK_a value.

In order to prevent the cyclization of the acetyl derivative VI to VIIa, the benzoylation of IV was carried out. However, the dibenzoyl ester (XI or its isomer, according to the position of the benzoyl groups), which was directly obtained from IV, resisted condensation with ethyl acetate or acetone to prepare II.

As α,β-diamino compounds were found to be a convenient starting material for the synthesis of 2-amino-2-imidazoline derivatives, an artifice of synthesizing from the side chain was next adopted. As the immediate synthetic objective, an olefinic compound XII was chosen in order to prepare for the desired diamino compound XIII.

Chart 2



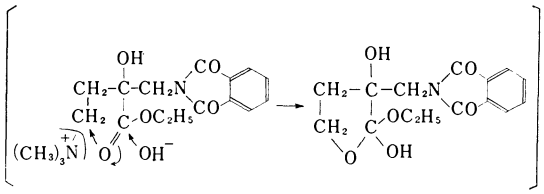


Chart 3

XXIII XXIV

When 1,4-dichloro-2-butanone (XIV) was treated with sodium bisulfite and then with potassium cyanide, an oil was obtained. This oil, despite its fairly constant boiling point, contained the starting ketone, which was detected by infrared analysis. The oil exhibited bands of hydroxyl and nitrile in its infrared spectrum and afforded a considerable amount of the starting ketone on being left standing. It may be inferred from these results that the oil is an equilibrium mixture of the cyanhydrin XV and the starting ketone XIV. Further support for the cyanhydrin structure was obtained by converting it into its chloroester XVI by ethanol and concentrated sulfuric acid, and into a chlorolactone XVII by hydrochloric acid in acetic acid. The amino acid XVIII was obtained from the lactone XVII by aqueous ammonia at 100°C. Chemical evidence for the β-amino-γ-hydroxy acid structure of XVIII was obtained by Schotten-Baumann benzoylation, which afforded the dibenzoylcarboxylic acid XIX, and by reaction with phthalic anhydride in pyridine, which afforded the phthaliminolactone XX. The amino acid XVIII has a side chain of roseonine, and its behavior in reaction against ninhydrin was similar to that of roseonine dihydrochloride. Ethanolic hydrogen chloride converted the phthaliminolactone XX into the ester XXI. As the direct dehydrochlorination of XXI was unsuccessful, it was converted into tertiary amine methiodide XXII. The Hofmann degradation of XXII afforded a glassy substance. The structure of this substance may be assumed to be the hemiacetal XXIV derived from the hydroxide XXIII by the scheme shown in Chart 3, since it afforded the starting lactone XX on treatment with dilute hydrochloric acid.

Experimental

The infrared spectra were determined on a Koken infrared recording spectrophotometer, model DS 301.

The acid constants refer to apparent values derived with a glass electrode system in water.

2-Amino-2-imidazoline-4-carboxylic Acid (IV).—Eleven grams of 2,3-diaminopropionic acid monohydrobromide were dissolved in 48 ml. of 10% sodium hydroxide and 50 ml. of an aqueous solution containing 6.3 g. of bromocyan were added. After being left standing overnight, it was evaporated to dryness in vacuo, and the residue was recrystallized from water. Yield, 3.5 g.; m. p., 303°C (decomp.).

Found: C, 36.90; H, 5.41; N, 32.80. Calcd. for $C_4H_7N_3O_2$: C, 37.21; H, 5.43; N, 32.55%.

The picrate was prepared and recrystallized from water, m. p., 208°C.

Found: N, 23.73. Calcd. for $C_{10}H_{10}N_6O_9$: N, 23.46%.

1-Acetyl-2-amino-2-imidazoline-5-carboxylic Acid (V).—Seventy milliliters of acetic anhydride and one drop of concentrated sulfuric acid were added to a solution of 8 g. of IV in 70 ml. of glacial acetic acid, and the solution was kept at 40~45°C for 45 min. After concentration in vacuo on a water bath, 200 ml. of methanol were added. The resulting crude product (m. p. 225°C (decomp.)) was recrystallized from glacial acetic acid-methanol; m. p., 232°C (decomp.).

Found: N, 24.73. Calcd. for $C_6H_9N_3O_3$: N, 24.55%.

Ethyl 1-Acetyl-2-amino-2-imidazoline-5-carboxylate (VI).—A suspension of 5 g. of the acid V in 100 ml. of ethanol was saturated with dry hydrogen chloride without cooling and then left to stand for 2 hr. After concentration in vacuo, the residue was neutralized with aqueous sodium carbonate and taken up in chloroform. The extract was dried over sodium sulfate, and the solvent was distilled. The residual ester was recrystallized from chloroform-petroleum ether; m. p., 152~154°C.

Found: C, 48.14; H, 6.72; N, 21.42. Calcd. for $C_8H_{13}N_3O_3$: C, 48.23; H, 6.58; N, 21.10%.

The picrate was prepared in water and recrystallized from ethanol; m. p., 163~165°C.

Found: N, 19.74. Calcd. for $C_{14}H_{16}N_6O_{10}$: N, 19.62%.

Bicyclic Compound VII.—A mixture of 0.3 g. of the ester VI, 0.3 g. of ethyl acetoacetate, and 1.1 ml. of a sodium ethylate solution (prepared by dissolving 1 g. of sodium in 20 ml. of ethanol) was heated at reflux for 1.5 hr. The solid was then filtered out and dissolved in a small amount of water. The solution was acidified with hydrochloric acid (1 : 1) and concentrated in vacuo. The resulting solid was recrystallized from ethanol; m. p., 242°C.

Found: C, 41.37; H, 4.56; N, 18.00. Calcd. for $C_8H_{10}ClN_3O_3$: C, 41.54; H, 4.31; N, 18.11%.

The phenylhydrazine salt VIII was obtained by heating a mixture of the hydrochloride and phenylhydrazine in ethanol for 10 min. Recrystallization from ethanol afforded white needles; m. p., 162~163°C.

Found: C, 55.65; H, 5.72; N, 23.07. Calcd. for $C_{14}H_{17}N_5O_3$: C, 55.53; H, 5.62; N, 23.11%.

The picrate IX was prepared from the hydrochloride VIIa or the phenylhydrazine salt VIII by treatment with picric acid in water; m. p., 125°C.

Found: N, 19.27. Calcd. for $C_{14}H_{12}N_6O_{10}$: N, 19.85%.

The acetyl derivative X was prepared by heating a solution of the hydrochloride in a mixture of glacial acetic acid and acetic anhydride (1 : 1) in the presence of a small amount of pyridine and then recrystallizing it from ethanol; m. p., 224°C (decomp.).

Found: C, 50.90; H, 4.70; N, 17.59. Calcd. for $C_{10}H_{11}N_3O_4$: C, 50.75; H, 4.64; N, 17.72%.

Ethyl 1-Benzoyl-2-benzoylamino-2-imidazoline-4-carboxylate (XI).—A suspension of 1 g. of IV in 20 ml. of ethanol was saturated with dry hydrogen chloride without cooling. After 2 hr., the ethanol was removed in vacuo. The resulting oil was dissolved in a small amount of ethanol, and the ethanol was again removed in vacuo. The same procedure was once repeated with ethanol and then twice with pyridine, and 3.6 g. of benzoic anhydride was added. The solution was heated at reflux for 4 hr., and the pyridine was removed in vacuo. The resulting oil, when triturated with a small amount of ethanol, crystallized; this was then recrystallized from ethanol in the form of white needles; m. p., 189~190°C.

Found: C, 65.85; H, 5.60; N, 11.80. Calcd. for $C_{20}H_{19}N_3O_4$: C, 65.74; H, 5.24; N, 11.50%.

2-Chloromethyl-2-hydroxy-4-chlorobutyronitrile (XV).—A solution of 89 g. of sodium bisulfite in 222 ml. of water was added to 62 g. of 1,4-dichloro-2-butanone (XIV), and the mixture was shaken vigorously for 20 min. To the resulting homogeneous solution, some crushed ice, 150 ml. of ether, and then a solution of 56 g. of potassium cyanide in 168 ml. of water were added. The ether layer was separated, and the aqueous layer was shaken with ether several times. The combined ether solution was dried over sodium sulfate and distilled; b. p., 102~103°C/1 mmHg.

The infrared spectrum showed bands of hydroxyl (3340 cm^{-1}) and nitrile (2219 cm^{-1}). The carbonyl band (1724 cm^{-1}) of the starting ketone was also observed.

Ethyl 2-Chloromethyl-2-hydroxy-4-chlorobutyrate (XVI).—A mixture of 5 g. of the cyanhydrin XV, 25 ml. of ethanol and 7.5 ml. of concentrated sulfuric acid was heated at reflux for 5 hr. and then poured onto crushed ice. This was shaken with ether, and the ether extract was dried over sodium sulfate. After the solvent had been removed, the residue was distilled; b. p. 111~115°C/4 mmHg.

Found: C, 38.43; H, 5.32. Calcd. for $C_7H_{12}Cl_2O_3$: C, 39.23; H, 5.58%.

The infrared spectrum showed an ester band at 1733 cm^{-1}.

α-Chloromethyl-α-hydroxy-γ-butyrolactone (XVII).—A mixture of 61 g. of the cyanhydrin (XV), 92 ml. of glacial acetic acid and 183 ml. of concentrated hydrochloric acid was heated on a water bath for 6 hr. After the ammonium chloride had been filtered off, the filtrate was concentrated in vacuo and extracted with ether. The ether extract was dried over sodium sulfate, and the solvent was removed. Vacuum distillation afforded a white viscous oil. Yield, 39 g.; b. p., 128~136°C/5 mmHg.

Found: C, 38.46; H, 4.69. Calcd. for $C_5H_7ClO_3$: C, 39.84; H, 4.65%.

The infrared spectrum showed a lactone band at 1760 cm^{-1}.

2-Aminomethyl-2,4-dihydroxybutyric Acid (XVIII).—A mixture of 6 g. of the lactone (XVII) and 120 ml. of concentrated aqueous ammonia was heated at 100°C in an autoclave for 5 hr. The solution was evaporated to dryness in vacuo, and the resulting solid was recrystallized from water. Yield, 3.5 g.; m, p. 237°C (decomp.).

Found: C, 40.39; H, 7.55; N, 9.31. Calcd. for $C_5H_{11}NO_4$: C, 40.26; H, 7.43; N, 9.39%.

The amino acid showed no color development on treatment with ninhydrin at 100°C. However, a purple-brown precipitate was obtained when the reaction was carried out at 150°C in a sealed tube.

2-Benzaminomethyl-2-hydroxy-4-benzoxybutyric Acid (XIX).—A small amount of the amino acid XVIII was dissolved in 10% aqueous sodium hydroxide and shaken with benzoyl chloride, with the solution being kept alkaline. Acidification with hydrochloric acid afforded white crystals, which were washed with ether to remove any benzoic acid. The ether-insoluble product was recrystallized from 50% ethanol; m. p., 173°C.

Found: N, 3.86. Calcd. for $C_{19}H_{19}NO_6$: N, 3.93%.

α-Hydroxy-α-phthaliminomethyl-γ-butyrolactone (XX).—A mixture of 3.5 g. of the amino acid XVIII, 5.5 g. of phthalic anhydride, 50 ml. of pyridine was heated at reflux for 6 hr. The solution was concentrated in vacuo, and water was added. The resulting solid (5.5 g., m. p. 147~149°C) was recrystallized from ethanol; m. p., 155°C.

Found: N, 5.26. Calcd. for $C_{13}H_{11}NO_5$: N, 5.37%.

Ethyl 2-Hydroxy-2-phthaliminomethyl-4-chlorobutyrate (XXI).—A suspension of 15 g. of the lactone XX in 350 ml. of ethanol was saturated with dry hydrogen chloride without cooling. After standing for 2hr. at room temperature, the solution was concentrated in vacuo. The addition of water afforded an oil which soon solidified. Recrystallization from 50% ethanol afforded white needles of XXI; m. p., 99~100°C.

Found: C, 55.47; H, 5.16; N, 4.32. Calcd. for $C_{15}H_{16}ClNO_5$: C, 55.22; H, 4.90; N, 4.28%

Ethyl 2-Hydroxy-2-phthaliminomethyl-4-dimethylaminobutyrate Methiodide (XXII).—Four grams of the chloroester XXI were dissolved in 20 ml. of ethanol containing 2.8 g. of dimethyl amine and then heated at 100°C for 4 hr. in a sealed tube. The ethanol was removed in vacuo, and the residue was extracted with ether (Soxhlet). Evaporation of the ether afforded a pale yellow viscous oil. The oil was dissolved in 50 ml. of dry acetone, and 15 g. of methyl iodide was added. A yellow solid was recrystallized from water; m. p., 219°C.

Found : C, 44.44 ; H, 5.56 ; N, 5.91. Calcd. for $C_{18}H_{25}IN_2O_5$: C, 45.31 ; H, 5.25 ; N, 5.87%.

Thermal Decomposition of the Hydroxide Obtained from XXII.—Wet silver oxide which had freshly been prepared from 1.5 g. of silver nitrate was added to a solution of 1.5 g. of the methiodide XXII in 30 ml. of water, stirred for 30 min., and filtered. The filtrate was evaporated to dryness under reduced pressure and kept at 150°C for 2 hr. (2 mmHg.). The residue was taken up in chloroform and treated with charcoal. Evaporation of the chloroform afforded a white glassy substance. Treatment of this substance with dilute hydrochloric acid afforded the lactone XX ; m. p. and mixed m. p., 155°C.

The author wishes to express his deep thanks to Professor Masaki Ohta, Tokyo Institute of Technology, for his guidance throughout this work. The author is also indebted to Professor Koji Nakanishi, Tokyo University of Education, for his helpful discussions and to Dr. Asaji Kondo for his microanalyses. Moreover, he is grateful to the Kawakami Memorial Foundation for financial support.

The Formation and Crystalline Nature of Boron Nitride in the Reaction of Boron Oxide with Sodium Amide

By Hiroaki TAGAWA and Otokichi ITOUJI

(Received March 20, 1962)

Boron nitride has extremely interesting chemical properties and physical characteristics. As the structure is very similar to that of graphite, it is sometimes called white graphite. Boron nitride is an excellent refractory material and is used as a thermal insulator in high frequency induction vacuum furnaces, as a material for the manufacture of refractory crucibles, and as an anti-sticking agent in contact with molten glass or metals. It is also an excellent lubricant and is used as a heat-resistant lubricant.

Boron nitride has been known for the more than one hundred years since it was first prepared by Balmain in 1842[1]. Since then it has been investigated by many researchers, and many methods of fabrication have been described in the literature and by patents.

Boron nitride is prepared by the reactions of a compound containing boron with a compound containing nitrogen; it the many processes by which it is produced may be summarized by the following equations:

$$4NH_3 + BCl_3 = BN + 3NH_4Cl$$[2-4]

$$2B + N_2 = 2BN$$[5]

$$B_2O_3 + 2NH_3 = 2BN + 3H_2O$$[6-8]

$$B_2O_3 + 3NaNH_2 = 2BN + NH_3 + 3NaOH$$[9]

$$B_2O_3 + 2NH_4Cl = 2BN + 2HCl + 3H_2O$$[10]

As with carbon, the physical and chemical properties of this material may vary considerably according to the nature of the starting materials and of the fabricating condition, but they may be thought of as depending mainly on such structural factors as the crystallinity and the state of the condensed system of the triboron-triazin ring.

In this article, boron oxide and sodium amide were selected as the starting materials in the preparation of boron nitride. Sodium amide is a chemically strong reducing agent; its great reactivity is coupled with the relatively low melting point of 210°C. The boron nitride which was formed in the reaction of boron oxide with sodium amide was investigated for the effect of the producing conditions on its structure and properties. The behavior of the reaction was examined by differential thermal analysis and thermogravimetry, and the crystalline nature of the boron nitride thus formed

was investigated by X-ray analysis and infrared absorption measurement.

The Nature of the Reaction of Boron Oxide with Sodium Amide

Experimental.—*Material.*—Boron oxide (Junsei Chemicals Co.) was dehydrated at 1000°C for 1hr., and then pulverized and screened with a 16 to 32 mesh sieve in a dry box. The sodium amide used in this experiment was obtained from the Kongo Chemicals Co.; it was pulverized below a 100 mesh sieve. The purity of this material was 93%; the rest was sodium hyroxide.

Differential Thermal Analysis.—A specimen, mixed to a 1 : 3 (by mol.) ratio of boron oxide to sodium amide was examined by differential thermal analysis with a three-hole nickel holder within an atmosphere of nitrogen. The difference in temperature between the sample and the reference (aluminium oxide) was measured by a thermocouple of chromel-alumel with two pairs in series. The differential thermoelectric motive force was recorded on the chart of electric recorder.

The temperature of the electric furnace was elevated continuously at a constant heating rate of 5°C/min.

Thermogravimetry.—The behavior of the reaction of boron oxide with sodium amide was also examined by using a thermogravimetric apparatus, which allowed a continuous measurement of the weight loss against the time. The apparatus consisted of a torsion type thermobalance (Shimadzu Manufacturing Co.) using a fine tungsten wire and of an electric furnace. The weight changes were measured by the rotation of the wheel, which applied sufficient torsion to the fiber to restore the arm to the null position. Its capacity and sensitivity were 1 g. and 5 mg. respectively. The thermobalance system could be evacuated.

The specimen used in this experiment was a mixture of boron oxide and sodium amide (mixing ratio, 1 : 3 by mol.). The powdered sample was placed in a nickel crucible and was suspended from the arm by a molybdenum wire. The weight changes by dehydration and nitridation were observed during the elevation of the sample temperature at a constant rate of heating of 5°C/min, within an atmosphere in nitrogen.

Results and Discussion.—*Differential Thermal Analysis.* — Differential thermograms of the reaction of boron oxide with sodium amide and of that of only sodium amide are shown in Fig. 1. The reaction of boron oxide with sodium amide in Fig. 1 (a) shows two peaks at 163 and 205°C, while in the reaction of boron oxide with sodium amide, involving 65% of sodium hydroxide, only one peak appears, at 163°C. Although the melting point of sodium amide is 210°C, it may be found in Fig. 1 (c) that the melting point is lowered in the presence of sodium hydroxide to about 165°C. The endothermic peaks at 155 and 201°C correspond with the melting of the sodium amide containing large amounts of

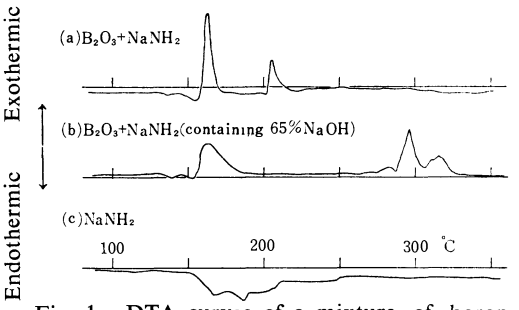

Fig. 1. DTA curves of a mixture of boron oxide and sodium amide (mixing ratio by mol. = 1 : 3).

sodium hydroxide and pure sodium amide respectively. The reaction peak at 205°C shows that the reaction of boron oxide with sodium amide occurs as soon as the sodium amide melts, which agrees with finding of Kamlet[9]. It may therefore be concluded that this reaction needs the melting of sodium amide and that the reaction temperature is lowered in the presence of sodium hydroxide, as sodium amide appears to make a solid solution with sodium hydroxide. The several peaks at about 300°C in the reaction of boron oxide with sodium amide involving large amounts of sodium hydroxide in Fig. 1 (b), seem to be due to the formation of sodium borates by the reaction of sodium hydroxide with the unreacted boron oxide.

Thermogravimetry. — The thermogravimetric curve of a mixture of 1.5 g. of boron oxide (16~32 mesh) and 2.5 g. of sodium amide is shown in Fig. 2. In this curve the weight loss observed is plotted against the temperature

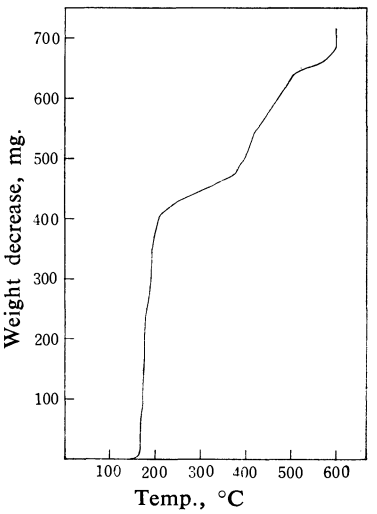

Fig. 2. Thermogravimetric curve of a mixture of boron oxide and sodium amide in hydrogen. B_2O_3; 1.5 g., $NaNH_2$; 2.5 g., heating rate; 5°C/min., retention time at 600°C; 30 min.

up to 600°C. A steep weight loss occurs in the temperature range from 170 to 200°C. The finding of this decrease in weight above 170°C is correspondent with that of the differential thermal analysis. The weight of the sample decreases gradually with the raising of the temperature, even above 200°C. At temperatures above 400°C, some sodium amide was condensed at the cold part of the quartz tube.

The mixing ratio of boron oxide was chosen as 1 : 3 by mole according to the following equation :

$$B_2O_3 + 3NaNH_2 = 2BN + NH_3 + 3NaOH$$

Theoretically, 1.5 g. of boron oxide reacts with 2.5 g. of sodium amide to form 1.1 g. of boron nitride and 0.36 g. of ammonia. The actual weight decrease is two times larger than the calculated quantity of evolved ammonia. Chemical analysis indicates that only 29.9% of the boron oxide changes into boron nitride. Consequently, this large weight loss may be due to the reaction of the sodium hydroxide formed with the amide and to the sublimation of the amide.

Crystalline Nature of the Boron Nitride Formed

Experimental.—*Preparation of Boron Nitride.*—Boron nitride for X-ray analysis and for infrared absorption measurement was produced by heating a mixture of boron oxide and sodium amide (mixing ratio, 1 : 3 by mole) at a desired temperature between 200 and 800°C in an ammonia atmosphere. The apparatus consisted of a quartz tube 50 mm. in inner diameter, a suspended crucible 30 mm. in diameter and 40 mm. in height, and an electric furnace. The tube containing the mixture could be evacuated for the exchange of atmosphere. The sample was suspended in a nickel bucket in the hot zone of the tube with fine tungsten wire from the top of the tube.

Five grams of boron oxide and 13.3 g. of sodium amide were ground together, charged into the nickel crucible, and heated in the electric furnace at temperatures from 200 to 800°C. In order to examine the behavior of the reaction during heating, a thermocouple was put in the mixture. The reaction commenced at about 170°C and proceeded vigorously at about 210°C with the evolution of ammonia. When the furnace temperature stood at 210°C, it was shown that the temperature of the mixture was temporarily brought up to 350°C. The reaction mixture was kept at the desired terminal temperature between 200 and 800°C for more than 30 minutes. The product in the crucible was obtained as a gray porous material. The substance was broken up and vigorously stirred into ice water. The insoluble boron nitride was filtered off, washed free of soluble matter with water, and then dried. The yields of boron nitride based on boron oxide were always about 30 percent in the top temperature range from 200 to 800°C. This boron nitride was analyzed for boron and nitrogen using the method mentioned by Finlay et al.[11]

X-Ray Measurement.—Changes in the interlayer spacing and crystallite growth were observed as a function of the terminal temperature. The diffraction patterns were recorded by an automatic recording X-ray spectrometer (Rigaku Denki Co.) and were calibrated by referring to a standard quartz specimen. The diffraction maximum did not directly give the true interlayer spacing for the polarization and absorption, as in the case of carbon[12], but the measured values were used.

The crystallite size was obtained from the broadening of the X-ray diffraction lines according to the procedure described by Klug and Alexander[13]. The crystallite dimension was calculated according to the following equation :

$$L = K\lambda/\beta\cos\theta$$

where L is the average effective dimension of the crystallite in a direction perpendicular to the reflecting plane at the glancing angle θ, λ is the wave length of the X-ray, K is a shape factor, and β is defined as the half-maximum line breadth. The L_c-dimension, the thickness of the parallel packets of layers, was obtained from the (002) line by using $K=0.9$. The L_a-dimension could not be obtained because of the obscure shape of the (10) band.

The diffraction conditions employed were as follows; the target was copper filtered by nickel, the filament voltage and current were 30 kV. and 15 mamp. respectively, the divergent slit was 1°, the receiving slit, 1° and 0.1 mm., the time constant, 4 sec., and the scanning speed, 2°/min.

Infrared Absorption Spectra.—The infrared spectra in the 4000 to 650 cm^{-1} region of boron nitride were obtained by using a Nippon Bunko model DS-301 spectrophotometer (with a potassium bromide prism) and by using potassium bromide pellet techniques.

Results and Discussion.—*X-Ray Analysis.*—The X-ray diffraction patterns of boron nitride formed at several temperatures between 200 and 800°C are shown in Fig. 3. Geometrically, the structure is very similar to that of graphite[14]. The peak at about 26° of the Bragg angle corresponds with the interlayer spacing. A terminal temperature of 800°C for the reaction mixture scarcely affects the yield of boron nitride, but the crystallinity increases with an increase in the top temperature. The X-ray diagrams of the boron nitride formed at 200 to 600°C show diffuse bands corresponding to the positions of the (002) and (100) lines, indicating a two-dimensional structure. In the case of boron nitride produced at 800°C, the deformation of the (10) band is already visible, and the

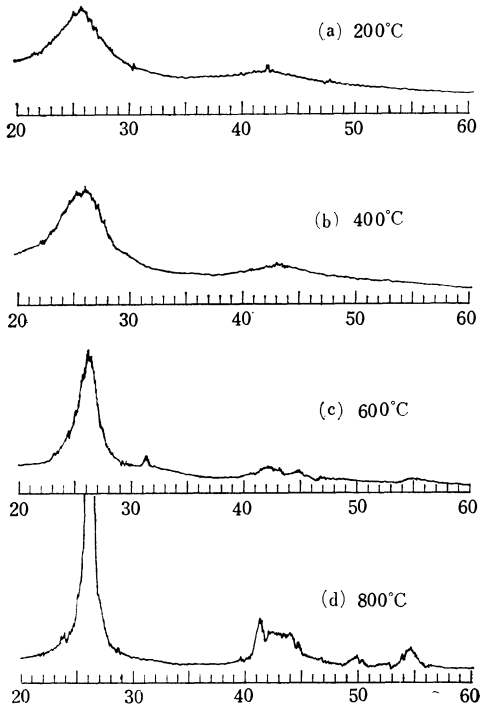

Fig. 3. X-ray patterns of boron nitride of various terminal temperatures.

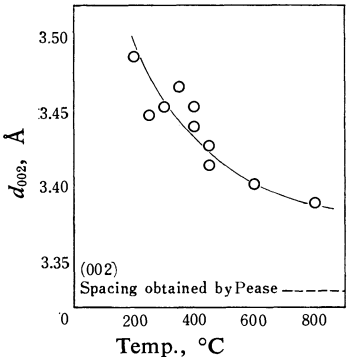

Fig. 4. Relationship between the apparent interlayer spacing and the terminal temperatures.

separation of the (100) and (101) reflexions may be clearly recognized.

By increasing the terminal temperature of the reaction mixture, the diameter of the boron nitride layers and the number of layers per parallel packet is increased, and the (002) spacing decreases. The results of these measurements are shown in Figs. 4 and 5. In the case of carbon, a decrease in the interlayer spacing, which accompanies an increase in the degree of graphitization, has already been

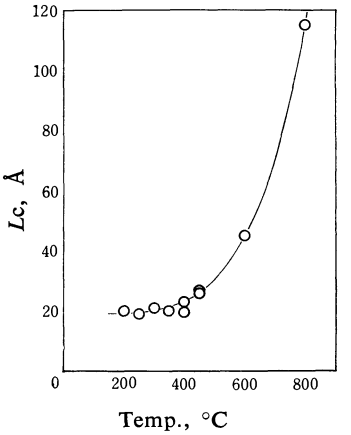

Fig. 5. Relationship between the *Lc*-dimensions of the parallel layer groups and the terminal temperature.

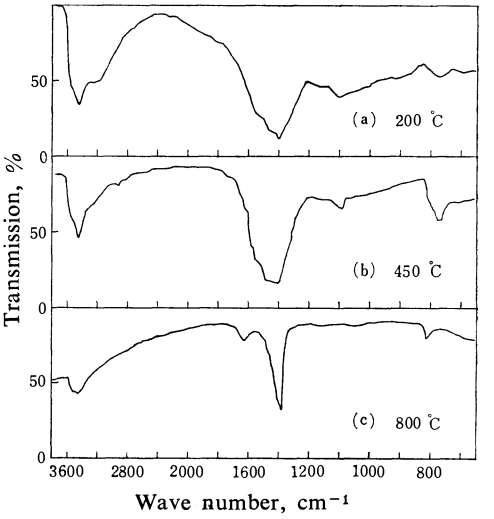

Fig. 6. Infrared absorption spectra of boron nitride of various terminal temperatures.

shown by Rooksby[15], Bacon[16] and Franklin[17]. The different graphitizing behavior of carbon may be a result of the nature of the original carbonaceous material and of the conditions under which they have been carbonized. On the other hand, the crystallization of boron nitride, like that of carbon, seems to be due to the processes and conditions of various methods of production. The increase of crystallite above 400°C, as shown in Fig. 5, is thought to be accelerated in the presence of molten salts, such as boric anhydride and sodium hydroxide.

Infrared Absorption Spectra. — The infrared absorption spectra of boron nitride formed at

200, 450 and 800°C are shown in Fig. 6. The absorption band at about 1400 cm^{-1} for boron nitride may be assigned as an in-plane B–N ring deformation. The spectrum of boron nitride obtained at 200°C, especially the B–O streching vibration at 1450 cm^{-1}, is different from the infrared absorption spectrum of boron oxide[18]. The absorption spectrum of boron nitride formed at 800°C agrees with the finding of Miller[19] and Brame[20]. The broadness of the absorption band at 1400 cm^{-1} and the O–H stretching band due to boron nitride hydrolyzed become somewhat smaller with an increase in the terminal temperature. The fundamental infrared absorption spectrum of boron nitride is scarcely influenced by the fabrication temperature. Although the melting point of boron nitride is above 3000°C, the skeletal structure of B–N hexagonal layers is complete even in the formation at 200°C, which finding agrees with the results of X-ray diffraction.

Summary

The reaction of boron oxide with sodium amide has been investigated using differential thermal analysis and thermogravimetry. The reaction occurs at 210°C, the melting point of sodium amide, while in the presence of a large amount of sodium hydroxide, the reaction temperature is lowered to 165°C. It has been shown from the results of the differential thermal analysis that the reaction of boron oxide with sodium amide commences as soon as the sodium amide melts.

The boron nitride formed completes the skeletal structure of B–N hexagonal layers even at 200°C. The fundamental infrared absorption spectra of boron nitride is very little influenced by the fabrication temperature. The crystallinity of boron nitride as shown by the interlayer spacing and the crystallite size increases with the reaction temperature.

Radiation Induced Reaction of Silicon Hydride

By Wataru ANDO and Shigeru OAE

(Received May 10, 1962)

Several publications have disclosed the addition of silicon hydrides to a number of alkenes with activated peroxide or under ultraviolet light. White and Rochow[1] obtained ethyl-, diethyl-, and triethylsilane by exposing a mixture of silane and ethylene to mercury vapor discharge. They indicated that the initial reaction is the decomposition of silane from the major amounts of products obtained by the irradiation of the mixture of silane and ethylene with mercury discharge in a flow system, and then concluded that the initial step involved must be the formation of hydrogen atom and silyl(SiH_3-) radical from silane. Fritz[2] also gave the mechanism in which the addition of the silicon hydrides to alkenes is free radical chain reaction. However, the exact course of the addition could not be determined, since further reactions of the initial products were extensive under these conditions.

The present investigation differs primarily from the above work in that the reaction was carried out at room temperature using gamma rays from 3.8 kilocurie ^{60}Co source.

No direct studies of the radiation chemistry of pure silane have been reported. The results of irradiation of pure silane and that with water, carbon dioxide and acetylene will be investigated.

Experimental

Reagents.—The reaction of silicon tetrachloride with lithium tri-*tert*-butoxaluminohydride was used for the preparation of silane[3]. In this case the reaction was carried out in a 500 ml. flask with flow of dry nitrogen. Commercially available carbon dioxide was purified by fractional distillation at low

3) S. Sujishi and J. Kieth, *J. Am. Chem. Soc.*, **80**, 4138 (1958).

temperature. Acetylene was made from the reaction of carbide and water, and was purified by repeated distillations.

Reaction Vessel.—The vessel in which the gaseous irradiations were carried out was consisted of pyrex tube of 16 mm. outside diameter and 22 mm. length, and equipped with a breakoff seal.

Analysis of Products.—Separation of products was achieved by a serial fractional distillations and condensations following the known procedure[4]. The yield of each fraction was measured by observing the pressure exerted when the entire fraction was vaporized into a calibration column. Vapor pressure at below room temperature was measured by the conventional method. The molecular weight of each product was calculated from its vapor density. Gamma field intensity was determined by the ferrous sulfate dosimeter.

Results and Discussion

Radiation Induced Reaction of Pure Silane.—The results of the irradiation of pure silane at different pressures and radiation doses are shown in Tables I and II. In these experiments, the separation of the products was achieved by taking the advantage of the different volatilities of the products; unreacted silane was distilled at −160°C, and di- and higher silanes at −111.8 and −45°C. The noncondensable gas at 196°C was introduced into a calibrated column with a Toepler pump. Higher silicon hydrides data are not shown in the following tables because of the low concentrations and the poor precision in their analyses.

In all of the reactions, the rate of hydrogen formation did decrease with the total radiation dose and the original silane pressure increased. In each experiment, a thin layer of light brown amorphous solid deposited on the wall of the reaction vessel. It was a polymeric compound having an empirical formula $(SiH_2)_x$, which was identified by measuirng the amounts of hydrogen and silicon after decomposing the solid by heating in an incinerator.

Under the described conditions, it is assumed that SiH_3, SiH_2, Si_2H_5 and H radicals or ions are formed in the irradiation of silane. These results when plotted as a function of initial silane pressure (Fig. 1) show that the rate of hydrogen formation in irradiation decreases with increasing silane pressure. At high pressure of gas the dependence of the energy absorption upon the pressure is not linear with density. This will acount for at least a part of the effect of pressure upon $G(H_2)$: i.e. Table I.

However, this relation will depend upon the composition and the geometry of the reaction vessel and the pressure of the gas in a

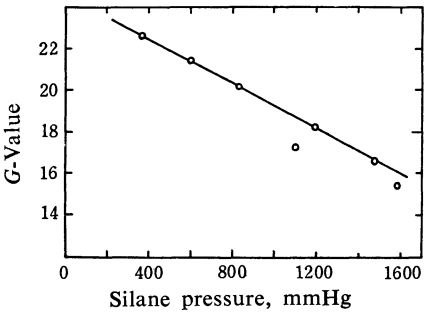

Fig. 1. Pressure dependence of hydrogen formation on the radiolysis of silane.

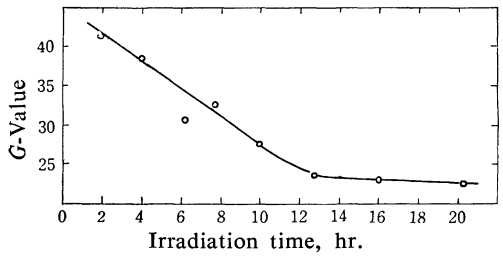

Fig. 2. Hydrogen formation as function of energy absorbed on radiolysis of silane.

complicated manner. Figure 2 shows that the rate of hydrogen formation at the low pressure (in these experimental range) decreases with irradiation time. These trend seems to favor the radical-radical reaction rather than ion-molecule reaction.

These facts suggest that unimolecular decomposition of silane might be considerd as taking place initially in two ways.

$$SiH_4 \sim\sim\sim\rightarrow SiH_2 + H_2 \quad (1)$$

$$SiH_4 \sim\sim\sim\rightarrow \cdot SiH_3 + H \quad (2)$$

There is no definite evidence as to which is primary reaction. But the energy of dissociation of reaction 1 very probably is not greater than the activation energy. On the other hand, the energy of dissociation for reaction 2 should be considerably greater than that of the activation. Hogness, Wilson and Johnson[5] have concluded that silylene radical is the primary product in the decomposition of silane. If this is the case, silyl radical becomes the secondary product arising from reaction such as

$$SiH_2 + SiH_4 \rightarrow 2 \cdot SiH_3 \quad (3)$$

In this case some of SiH_2 radical loses its energy and forms polymeric solid: $(SiH_2)_x$. The formation of hydrogen produced by radical process is probably due to the reaction; the primary process may be proposed as the reaction 1 and then 3, which is followed by the following chain propagating processes;

$$\cdot SiH_3 + SiH_4 \rightarrow Si_2H_6 + \cdot H \quad (4)$$

$$\cdot SiH_3 + Si_2H_6 \rightarrow Si_3H_8 + \cdot H \quad (5)$$

and chain ending processes

$$2H \cdot \rightarrow H_2 \quad (6)$$

$$2 \cdot SiH_3 \rightarrow Si_2H_6 \quad (7)$$

Radiation Induced Reaction of Silane with Carbon Dioxide, Water and Acetylene.—Mixtures of silane and carbon dioxide were sealed into the reaction vessels in various ratios. The results of four experiments were given in Table III, only for the hydrogen formation. Analysis of the material volatile at room temperature showed the presence of silane, disilane and higher silanes in addition to the bulk of non-condensable hydrogen at −196°C. Here again a thin layer of light brown solid deposited on the wall of the reaction vessel.

TABLE III. RADIOLYSIS OF SILANE-CARBON DIOXIDE MIXTURES*

0.455	0.		3.19	22.8
0.450	0.129	0.29	3.57	25.7
0.480	0.478	1.0	9.24	65.3
0.136	0.443	3.2	3.57	84.8

* Total dose for these experiments was 5.81×10^{20} eV./g.

The result from the radiolysis of silane with water are shown in Table IV. In case of radiolysis of a mixture of silane and acetylene, the observed G-value for the formation of hydrogen was 52.7.

TABLE IV. RADIOLYSIS ON THE MIXTURE OF SILANE AND WATER*

SiH_4 mmol.	H_2O mmol.	Product, H_2 mmol. $\times 10^3$	$G(H_2)$
0.482	3.2	17.7	119
0.487	0.005	11.1	77
0.482	0.003	7.72	52
0.422	trace	4.78	37

* Total dose was 5.81×10^{20} eV./g. in each experiment.

Striking difference was observed in the amounts of hydrogen in the radiolysis of mixiures of silane and carbon dioxide from that of pure silane even when the silane pressure and radiation dose were similar in those experiments. The increase in the G-value with carbon dioxide concentration seems to suggest that original energy absorbed by carbon dioxide somehow transfers to the silane, be it the transfer of charge or of excitation. Such transfer manifests itself as an increase in the rate of silane conversion. This effect has been noted previously in the radiolysis of acetylene[6-8], butadiene, and several inorganic gases[6].

In case of water-silane mixtures, in view of the very little reactivity of silicon hydrides toward pure water[9], the observed G-value of

hydrogen formation was extremely high as compared to that of pure silane radiolysis. The observed results is very interesting. Energy transfer from water to silane cannot be attributed as the amounts of water used was less than one per cent. One possibility would be that the excited water molecule will abstract hydrogen atom from silane by short chain reaction, but little is known about what happens to the resulting radical in the gaseous medium. The exact nature of the chain reactions is not clear.

By comparion with a simple charge transfer reaction in the radiolysis of silane-carbon dioxide system, charge transfer reaction is not possible in the radiolysis of silane-acetylene mixtures because acetylene have a lower ionization potential than that of silane. In this system, charge transfer producing chemical changes has been known to be supressed[10]. Perhaps, the compound containing vinyl group attached to the silicon might be formed by the following reactions[1].

$$\cdot SiH_3 + C_2H_2 \rightarrow \dot{C}H{=}CHSiH_3 \quad (8)$$

$$\dot{C}H{=}CHSiH_3 + SiH_4 \rightarrow CH_2{=}CHSiH_3 + \cdot SiH_3 \quad (9)$$

Summary

Silane, at various pressures, has been irradiated with 3.8 kilocuries gamma rays. In all experiments, gaseous products of the reaction were hydrogen, disilane and higher silanes, while *G*-value for the formation of hydrogen depends on initial silane pressure and total dose. Some polymeric material with the approximate empirical formula of $(SiH_2)_x$ is also formed.

Mixtures of silane with carbon dioxide, water and acetylene were also irradiated with gamma rays, and the rate of hydrogen formation was found to increase with increasing carbon dioxide and water. This was explained by a charge transfer mechanism.

*Equilibria in the $PdS-H_2-Pd_4S-H_2S$ and $Pd_4S-H_2-Pd-H_2S$ Systems**

By Kichizo NIWA, Toshio YOKOKAWA and Toshiro ISOYA

(Received January 31, 1962)

It is known that in the palladium-sulfur system there are three stable compounds, namely PdS_2, PdS and Pd_4S. The sulfur pressure associated with the dissociation of PdS_2 to PdS has been measured by Biltz and Laar[1], while the thermodynamic properties of the other two compounds are not yet known. The present studies have been undertaken to measure the dissociation pressures of PdS and Pd_4S on the basis of measurements of the equilibrium between a hydrogen-hydrogen sulfide gaseous mixture and a PdS–Pd_4S or Pd_4S–Pd solid mixture. From the experimental results, the free energies of the formation of the three sulfides were calculated.

Experimental

Materials. — PdS was prepared from palladium chloride of a guaranteed reagent. From a 5% hydrogen chloride aqueous solution of palladium chloride, PdS was precipitated by the introduction of gaseous hydrogen sulfide. Pd_4S was not prepared as a pure substance, but was produced in the solid phase in the intermediate state of a reduction of PdS to Pd (or in the sulfidization of Pd to PdS). This compound was identified by X-ray analysis.

Apparatus and Procedures.—A streaming method was employed. The reaction tube is shown in Fig. 1. In the figure, A is a pyrex tube 30 cm. in length and 1 cm. in inner diameter. The right hand portion of the tube is expanded downwards to be charged with the sulfide mixture. B is a pyrex outlet tube 9 mm. in outer diameter and 5 mm. in inner diameter. The heating element is a nichrome resistance furnace. The temperature of the furnace was controlled manually within ±1°C. The temperature was measured by a platinum vs platinum—rhodium thermocouple at

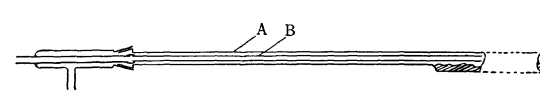

Fig. 1. Schematic diagram of the reaction tube.

* Presented at the 14th Annual Meeting of the Chemical Society of Japan, April, 1961.

the outside of the reaction tube. The temperature of the inner space of the reaction tube was proved to be equal to that of the outside by a preliminary test. Hydrogen gas was generated by electrolysis of a potassium hydroxide solution. Oxygen was eliminated by introducing the gas into a heated copper net. The hydrogen thus prepared was found by gas-chromatographic analysis to contain a trace of oxygen and about 2% nitrogen. These impurities were disregarded, since any error due to these minor quantities falls within the normal scattering of experimental results. For the sake of uniform mixing, the gas mixture of hydrogen and hydrogen sulfide was stored before use above vacuum pump oil in a glass vessel. After the reaction, the gas mixture was led into a potassium hydroxide aqueous solution and then gathered in a glass vessel, where the volume of the hydrogen was measured. The amount of hydrogen sulfide in the alkaline solution was determined by iodometric titration. The rate of gas flow appropriate for attaining equilibrium was examined at 625°K. No change in apparent equilibrium composition was detected when the flow rate was changed from 7 to 60 cc./min. Another confirmation of the attainment of equilibrium is given by the fact that the apparent equilibrium compositions of the gaseous mixture were consistent with each other, irrespective of the direction of reaction, as will be seen below.

Results

PdS–Pd_4S System. — The equilibrium was measured over the temperature range of 613 to 795°K. The ratios of the equilibrium partial pressure of hydrogen sulfide to that of hydrogen are summarized in Table I. The reaction is represented by the following equation:

TABLE I. EQUILIBRIUM CONSTANTS OF THE REACTION, $4/3\ PdS+H_2=1/3\ Pd_4S+H_2S$

Temp., °K	P_{H_2S}/P_{H_2}
612	3.68×10^{-2}
613	3.74×10^{-2}
622	3.50×10^{-2}
622	4.40×10^{-2}
622	4.29×10^{-2}
622	4.00×10^{-2}
663	8.94×10^{-2}

795	3.08×10^{-1}

* From sulfidization side

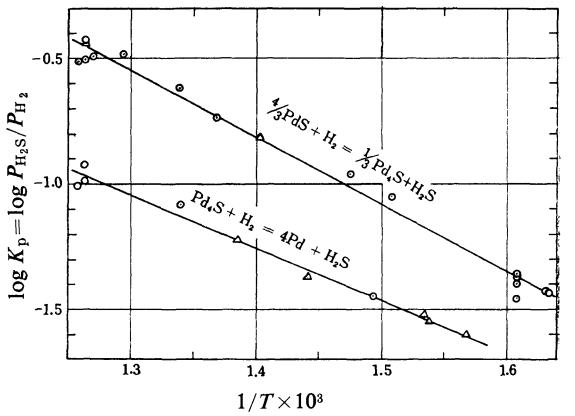

Fig. 2. Logarithm of the equilibrium constants plotted against reciprocal temperature.

$$\frac{4}{3}PdS+H_2=\frac{1}{3}Pd_4S+H_2S,\ K_p=P_{H_2S}/P_{H_2} \quad (1)$$

The logarithms of equilibrium constants are plotted against the reciprocal temperature in Fig. 2. By the least-aquare method, the following equation was derived for the standard free energy change of this reaction:

$$\Delta G^0=(12200\pm300)-(13.4\pm0.5)T$$
$$(\pm130\ \text{cal./mol. at } 613\sim798°K) \quad (1')$$

Pd_4S–Pd System.—The temperatures of the measurements ranged from 638 to 795°K. The equilibrium constants, defined below, are shown in Table II and in the lower portion of Fig. 2.

TABLE II. EQUILIBRIUM CONSTANTS OF REACTION, $Pd_4S+H_2=4Pd+H_2S$

Temp., °K	P_{H_2S}/P_{H_2}
*638	2.50×10^{-2}
*650	2.83×10^{-2}
*652	3.01×10^{-2}
670	3.57×10^{-2}
*694	4.27×10^{-2}
*722	6.00×10^{-2}
746	8.29×10^{-2}
791	1.03×10^{-1}
791	1.20×10^{-1}
795	9.87×10^{-2}

* From sulfidization side

From these values, the free energy equation can be derived as follows:

$$Pd_4S+H_2=4Pd+H_2S,\ K_p=P_{H_2S}/P_{H_2} \quad (2)$$
$$\Delta G^0=(9600\pm400)-(7.7\pm0.6)T$$
$$(\pm90\ \text{cal./mol. at } 638\sim795°K) \quad (2')$$

In Eqs. 1′ and 2′, the figures after the ± sign denote the standard deviations.

Discussion

Combining Eqs. 1 and 2 with that of the thermal dissociation of hydrogen sulfide, one can calculate the dissociation pressures of these two sulfides. Within the temperature range of this experiment, the free energy change associated with the dissociation of hydrogen sulfide is given by[2]:

$$H_2S = H_2 + \frac{1}{2}S_2 \quad (3)$$

$$\Delta G^0 = 21200 - 11.3T \quad (3')$$

Therefore,

$$\frac{3}{8}PdS = \frac{2}{3}Pd_4S + S_2 \quad (4)$$

$$\log P(\text{atm.}) = -14600/T + 10.8 \quad (4')$$

$$2Pd_4S = 8Pd + S_2 \quad (5)$$

$$\log P(\text{atm.}) = -13500/T + 8.3 \quad (5')$$

and

$$2PdS_2 = 2PdS + S_2 \quad (6)$$

$$\log P(\text{atm.}) = -7330/T + 8.45 \quad (6')$$

Here, the temperature equation for PdS_2 was calculated from the data of Biltz and Laer's measurement at three temperatures.

Next, on the basis of Eqs. 4, 5 and 6, the free energies of the formation of Pd_4S, PdS and PdS_2 are:

$$4Pd + \frac{1}{2}S_2(g.) = Pd_4S \quad (7)$$

$$\Delta G^0 = -30800 + 19.0T \quad (7')$$

$$Pd + \frac{1}{2}S_2(g.) = PdS \quad (8)$$

$$\Delta G^0 = -32800 + 23.3T \quad (8')$$

$$Pd + S_2 = PdS_2 \quad (9)$$

$$\Delta G^0 = -49700 + 41.7T \quad (9')$$

The standard free energies of the formation of these sulfides at 298°K cannot be obtained because of a lack of knowledge about their heat contents.

2) K. K. Kelley, *Bur. Mines Bulletin*, No. 406 (1937).

Summary

Equilibrium measurements were carried out by a streaming method on the systems of palladium sulfides and of hydrogen-hydrogen sulfide gaseous mixtures. From the results, the dissociation pressures of PdS and Pd_4S were calculated, and the free energies of the formation of PdS_2, PdS and Pd_4S from palladium metal and sulfur diatomic gas were obtained.

Spectroscopic Studies of Methylamine Adsorption on Gamma-alumina

By Kozo HIROTA, Kenji FUEKI and Tokuji SAKAI

(Received April 14, 1962)

In our previous reports[1], the state of formic acid adsorbed on dehydrated silica and on alumina was investigated by means of nuclear magnetic resonance and infrared absorption methods. We thereby concluded that the acid adsorbed on silica was in an undissociated state, but that the free motion of the proton bonded to oxygen was hindered markedly, while a part of the acid dissociated into formate ions on alumina similarly to the way it did on several metal catalysts[2].

As the next substance to be studied along these lines and to be reported on in this paper, methylamine, which has a basic character contrary to that of formic acid, was adopted, while gamma-alumina was adopted as the adsorbent. The present research will also be interesting because of the fact that several amines are used so as to estimate the acidities of such oxide-catalysts.

Experimental

Materials. — *Methylamine.* — Methylamine of a chemically pure grade was used after dehydration.

Deuteromethylamine CH_3ND_2. — Methylamine was deuterated by the following exchange reaction.

$$CH_3NH_2 + D_2O \rightarrow CH_3ND_2 + H_2O$$

1) K. Hirota, K. Fueki, K. Shindo and Y. Nakai, This Bulletin, **31**, 783 (1958); **32**, 1261 (1959).

2) K. Hirota, K. Kuwata and Y. Nakai, This Bulletin, **31**, 861 (1958); J. Fahrenfort and H. F. Hazebrock, *Z. physik. Chem., N. F.*, **20**, 105 (1959).

Alumina.—Aluminum hydroxide, which was prepared from aluminum nitrate, was dried at 130°C for 10 hr. Then, after drying at 450°C for 8 hr., it was further degased at the same temperature for 100 hr. in vacuo (10^{-4} mmHg). The sample thus produced was a porous powder, its apparent density being 0.49 g./cm^3. According to X-ray measurement, it was almost amorphous, and it could be concluded to be gamma-alumina.

Measurement.—The essential measurement procedures were the same as has been reported already[1]. The infrared spectrum of methylamines adsorbed on the alumina powders was obtained on the sample pressed on a NaCl plate placed in a cell with NaCl windows. The infrared apparatus was a Perkin-Elmer Model 221, installed at the Institute of Protein Research, Osaka University. The nuclear magnetic resonance (NMR) spectrum was obtained at a fixed measuring frequency of 60 Mc./sec. with a Varian-V3600 C, installed at the Japan Atomic Energy Research Institute. The chemical shift of the proton resonance spectrum was determined by employing benzene as an external reference substance in a spinning, coaxial-sample tube arrangement (the double-tube method). Other experimental details will be described when necessary.

Results

The Infrared Spectra.—The infrared spectra of the adsorbed state are shown in Fig. 1, where the contribution of gaseous amine to the spectra, if it existed, was eliminated with a compensation cell. The spectra were obtained when the surface coverage, θ, of amines was ca. 0.2. Though the s/n ratio was large, three bands due to adsorption may be clearly identified in Fig. 1. In Table I they are assigned to gaseous amines of strong intensities. A detailed assignment of the bands will be undertaken below. It must be noted that the intensity of the degenerate stretching vibration ($\nu(CH_3)$) of CH_3 is markedly decreased by adsorption as compared with those of the other two bands, $\delta(CH_3)$ and $\delta(NH_2)$.

The NMR Spectra.—Figure 2 shows the NMR spectra of the normal and deuterated amines in liquid and adsorbed states measured at room temperature. It was found that only one signal could be identified over the range up to $\theta=1.2$; i. e., the other signal became too broad. By comparing the spectra of both amines, it is evident that the observed signal corresponds to that of the proton attached to the carbon atom rather than to that attached to the nitrogen atom. As ought to be expected, the half-width of this signal decreased and became sharp with the surface coverage, θ, as is shown in Fig. 3, where θ was determined

under the assumption that the molecular cross section of methylamine was 18 Å^2. Another interesting point is the chemical shift to the adsorbed state from the liquid state. Since the so-called "bulk effect" is superposed on this effect, a quantitative discussion, besides the relation shown in Fig. 3, will be postponed to later paragraphs.

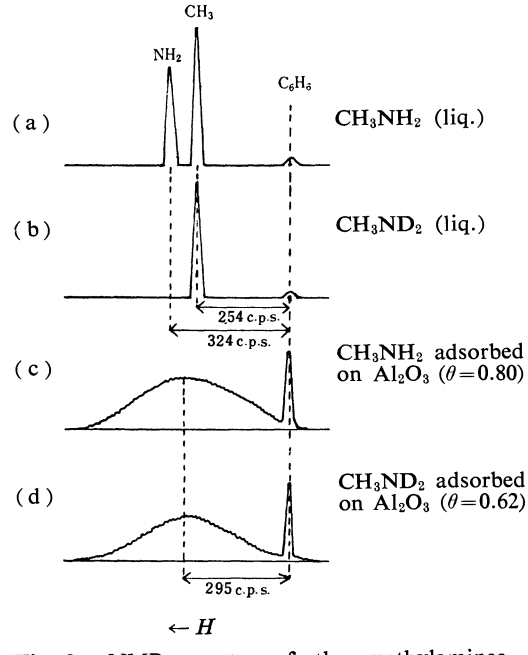

Fig. 2. NMR spectra of the methylamines adsorbed on alumina (schematic).

Discussion

Adsorbed States of Amines.—In the region between 1100~3300 cm^{-1}, three strong bands are observed on gaseous methylamine, e. g., 2961, 1473 and 1623 cm^{-1}; these are assigned to be $\nu(CH_3)$, $\delta(CH_3)$ and $\delta(NH_2)$ respectively, while the corresponding ones are observed on deuterated methylamine, CH_3ND_2, at 2961 cm^{-1} ($\nu(CH_3)$), 1468 cm^{-1} ($\delta(CH_3)$) and 1234 cm^{-1} ($\delta(ND_2)$) respectively. It is natural, therefore, to correlate them, as has been done in Table I, to the three bands observed when both amines were adsorbed. However, there were some shifts to a lower frequency in $\nu(CH_3)$, $\delta(NH_2)$ and $\delta(ND_2)$. These shifts seem to suggest the occurrence of some structural change of methylamines due to adsorption. The same conclusion will be derived from the data of the NMR spectra below.

As has already been mentioned, two marked changes were observed in the NMR spectra when either of the two methylamines was adsorbed on alumina: a disappearance of the signal of the aminyl-proton and a broadening of that of the methyl-proton.

Judging from these results, methylamine seems to be adsorbed in such a state that the hydrogen of the aminyl group is more resticted than that of the methyl group; i. e., amine is bonded to alumina via the nitrogen atom. Such a model is convenient to explain the change of the δ (NH_2) absorption band, because the bond angle between the N–H groups would be deformed due to adsorption, even though the three bonds of nitrogen atom orient one another so as to take a pyramidal structure, according to microwave-spectroscopic research[3].

The Nature of the Bond between Amines and Alumina.—It is, therefore, highly probable that both methylamines are adsorbed on alumina, making the nitrogen atom nearer to the surface than the carbon atom. Let us investigate the nature of the interaction of both atoms from the viewpoint of the adsorbent.

According to recent research[4], extremely dehydrated alumina acts as a Lewis acid; e. g., the aluminum atom of such alumina can accept a pair of electrons in its vacant *p*-orbitals, making a kind of bond with the adsorbate molecule. On the present drastically dehydrated alumina, it is natural to assume, therefore, that part of the unpaired electrons of the nitrogen atom will move to the aluminum atom. However, considering the fact that the adsorption heat is not very high, the degree of electron transfer may not be very high*.

Such an electron transfer due to adsorption may also be shown to be possible by the NMR spectra, which give the direction of the transfer by the chemical shift. As is shown by Fig. 2, the signal of the methyl proton shifts to a higher field, apparently suggesting the increase of electrons at the carbon atom, though the reverse result would be expected. The above discrepancy will disappear if the bulk-susceptibility correction is taken into consideration.

When the double-tube method was adopted, the net shift, δ, may be given from the observed shift, δ_{obs}, by the following formula[6]:

$$\delta = \delta_{obs} + \frac{2\pi}{3}(\chi_{ref} - \chi) \qquad (1)$$

where χ_{ref} and χ denote the volume magnetic

4) Cf., Actes du II Congrès International de Catalyse, Technip, Paris (1960).

* According to the results of Sakai[5], the heat of the adsorption of methylamine on alumina is 7.9 kcal./mol. at room temperature.

5) T. Sakai, K. Fueki and K. Hirota, 14th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1961, No. 3360.

6) Cf., J. A. Pople, W. G. Schneider and H. J. Bernstein, "High-resolution Nuclear Magnetic Resonance", McGraw-Hill Book Co., New York (1959), p. 81.

susceptibilities of the reference substance and of the adsorbate respectively. The chemical shift observed, Δ, corresponds to the difference in δ's between the liquid and the adsorbed state of methylamine, irrespective of the reference substance, benzene. Thus, Δ is given from Eq. 1 by

$$\Delta = (\delta_{liq} - \delta_{ads})_{obs} + \frac{2\pi}{3}(\chi_{ads} - \chi_{liq}) \qquad (2)$$

where the volume susceptibility of methylamine χ_{liq} is calculated to be -0.67×10^{-6} from the specific susceptibility[7] and its density, (0.767 g./cc.). Thus, Δ may be calculated to be 0.35 p. p. m., if the specific susceptibility of alumina is assumed to be that of a dehydrated alumina, i. e., -0.350×10^{-6} [8]. Therefore, it can be said that the net shift was to the lower field, suggesting an electron transfer from the carbon atom. Such a result will be noteworthy if compared with formic acid/silica system[1], where such a chemical shift due to adsorption may be practically neglected (+0.01 p. p. m.).

On the other hand the conclusion already mentioned is supported by the fact that electron density decreased at the carbon atom as a result of adsorption; the decrease of ν (CH_3) in wavelength can be explained by this model. However, it is difficult at the present stage of study to estimate quantitatively either the increase in electron density at the aluminum atom or the exact nature of the bond between the amine and alumina.

If the amine molecule is chemisorbed on alumina via the nitrogen atom, as has been suggested above, it is not strange that the motion of the aminyl group will be hindered so much more than that of the methyl group that the proton signal of the former may become very broad. For the same reason, it is possible that the signal of the latter may become sharp as the amount of adsorption increases. Thus, the results shown in Fig. 3 may be explained qualitatively.

Finally, it may be added that, according to our recent spectroscopic research, an aromatic amine, aniline, seems to be adsorbed also via its nitrogen atom on alumina[9], though it takes not a pyramidal but a planar structure. On the other hand, such an adsorbed model will provide other evidence on the role of the Lewis acid sites of alumina, recently proposed by Peri[10], on the isomerization catalyst.

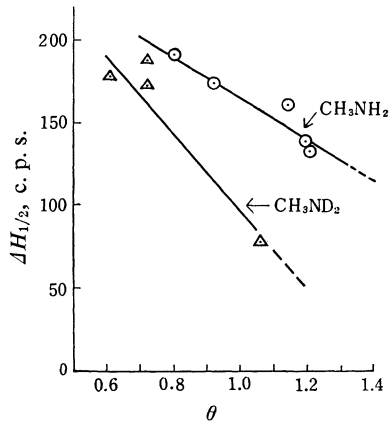

Fig. 3. Change of the half-width of NMR signal of the adsorbed methylamines.

Summary

It can be confirmed directly by means of NMR and infrared spectra that methylamine is chemisorbed on dehydrated gamma-alumina at room temperature, making a bond probably with the aluminum atom via the nitrogen atom; this conclusion is supported by the fact that the proton signal of the aminyl group cannot be observed at such a surface coverage when that of the methyl group is observed, and the fact that the deformation band of the NH_2 group and the stretching band of CH_3 group change as a result of adsorption.

The authors wish to express their deep thanks to Dr. Naohiro Hayakawa of the Japan Atomic Energy Research Institute for his NMR measurement.

Polarography of Pyridine N-Oxide and its Alkyl Derivatives[*1]

By Tanekazu KUBOTA and Hiroshi MIYAZAKI

(Received April 23, 1962)

Several authors have reported on the polarographic behavior of such aliphatic and aromatic *N*-oxides as pyridine, nitrogen mustard and narcotin *N*-oxides, showing that these *N*-oxides give one or more reduction waves involving two electrons and are reduced to the corresponding amines[1-4]. Especially, Foffani and Fornasari have found that pyridine *N*-oxide in various buffer solutions gives one reduction wave whose height decreases rapidly at above pH≈6 and disappears in alkali[4]. The mechanism of such polarographic behavior, however, has not yet been studied in detail. In order to obtain further information about this mechanism, the present authors have attempted detailed polarographic investigations.

Experimental

A Yanagimoto pen-recording polarograph, model PB-4, a Beckman pH meter, model G, and a Hitachi recording spectrophotometer, model EPS-2, were used for the measurement of polarograms, pH values, and ultraviolet absorption spectra respectively. The characteristics of the dropping mercury electrode used were: $m=1.23$ mg./sec., $h=65$ cm. and $t=4.35$ sec. (open circuit). The ionic strength of the buffer solutions used, had been adjusted to 0.45 by adding sodium chloride; these buffer solutions were as follows: NaAc+HCl (pH=1.09~3.79), NaAc+HAc (pH=3.80~5.60), KH_2PO_4+NaOH (pH=6.20~7.40), and glycocol+NaCl+NaOH (pH=8.53~11.01). Polarograms were taken in the above buffer solutions after bubbling nitrogen gas for 10 min. to remove the dissolved oxygen in the solutions, saturated calomel electrode being used as the external reference electrode. In this case, the temperature was controlled within ±0.1°C by a thermostat, and the measurements were usually made at 25±0.1°C. Experiments were carried out three times on the same electrolytic solution. The values thus obtained were averaged.

Pyridine, 4-methylpyridine and 4-ethylpyridine *N*-oxides were prepared and purified by the standard method[5], and their melting points were determined to be 66, 184~185 and 108~109°C respectively. Infrared spectra and microanalytical data show good agreement with the data in the literature[6] and with the calculated values.

Results and Discussion

Polarograms of pyridine *N*-oxide at various pH values are illustrated in Fig. 1. The pH-dependence of the limiting current in pyridine and 4-methylpyridine *N*-oxides is also shown in Figs. 2 and 3. From Figs. 1, 2 and 3, it can be clearly seen that the reduction wave decreases rapidly with the increasing pH value in pH values above 5. Since the ultraviolet absorption spectra of each of the above *N*-oxides in a region of pH≈7 to 1 N sodium hydroxide coincide almost completely in both the maximum wavelength and the intensity, no change in the structure is expected in alkali. On the other hand, the acid dissociation constants (pK_a's) of pyridine and 4-methylpyridine *N*-oxides have previously been determined by the spectrophotometric method as 0.79 and 1.29 respectively[7,8]. Moreover, the experimental results of the temperature dependence and the mercury pressure dependence on the reduction wave in the acidic pH region and in the pH region in which the limiting current decreases rapidly are shown in Table I.

1: Experimental curve
2: Calculated curve

In the case of pH 7.0, the temperature coefficient of the reduction wave is much greater than that at pH 2.91. Moreover, the mercury pressure dependence at pH 7.0 did not show a good relationship between i and $\sqrt{h}$, where i and h denote the limiting current (μA) and the height of a mercury electrode in cm. (corrected with the reverse pressure of mercury height) respectively. In the case of pH 2.91, however, a linear relationship of i to $\sqrt{h}$ was obtained. In addition, the limiting current independent of $\sqrt{h}$ is zero or vevy small at pH 2.91 on the pyridine and 4-methylpyridine *N*-oxides, as may be seen in Table I.

From the viewpoint of the recent kinetic current theory[9], therefore, it may be reasonably considered on the basis of the above experimental results that the pH dependence of the limiting current is due to the kinetic current, which can be represented as Eqs. 1 and 2, which were derived by Matsuda and by Koutecky[10,11].

$$\longrightarrow \text{N}^{+}\text{-H} + \text{H}_2\text{O} \qquad (1)$$

$$i = i_d \cdot [1/[1+1.128(\vec{k}_r \cdot t \cdot [H^+]^2/K_a)^{-1/2}]] \qquad (2)$$

Hence, i_d is the diffusion current corresponding to the total concentration of *N*-oxides. In our case, the i appearing in the region of high proton concentrations becomes equivalent to i_d, which may show the normal temperature and mercury pressure dependences, as was observed at pH 2.91 on the above *N*-oxides, because in this condition the term in the brackets on the right hand side of Eq. 2 is reduced to 1.

Using Eq. 2 and the K_a value above stated, we have determined the rate constant, $\vec{k}_r$, of the recombination process in Eq. 1, whereas for the drop time, t, the values measured under the same condition as the determination of limiting current were used, so as to satisfy the pH dependence of the limiting current; $\vec{k}_r = 3.0\times10^{12}$ and $\vec{k}_r = 3.7\times10^{11}$ (mol./l.)$^{-1}$(sec.)$^{-1}$ were obtained for pyridine *N*-oxides and 4-methylpyridine *N*-oxide respectively*2.

The rate constants thus obtained are of the same order as the theoretical value obtained by Onsager[12] and as the experimental values of the other compounds determined by other workers[11]. The current-pH relationships calculated by using these k_r values are also shown in Figs. 2 and 3. A good agreement with the experiments is obtained on the whole. Some discrepancy, however, can be found in the acidic pH region. No quantitative explanation could be made for this, but it seems that the other miscellaneous effects on the *N*-oxide

TABLE I. THE TEMPERATURE AND THE PRESSURE DEPENDENCES FOR THE REDUCTION WAVE AT VARIOUS pH'S

Compound	Temperature coefficient (deg^{-1})[a]		Pressure dependence[b]	
Pyridine *N*-oxide	pH=2.91	pH=7.0	pH=2.91	pH=7.0
	1.05%	2.42%	$i=0.476\cdot\sqrt{h}$	c)
4-Methylpyridine *N*-oxide	pH=3.30	pH=6.61	pH=3.30	pH=6.61
	1.31%	2.06%	$i=0.304\sqrt{h}+0.375$	d)

a) Calculated at compound interest method.
b) h and i denote the height of a mercury electrode in cm. (corrected against the reverse pressure) and the limiting current (μA), respectively.
c) No good relationship between i and $\sqrt{h}$ exists.
d) No rigid relationship between i and $\sqrt{h}$ is obtained, but can be roughly expressed as $i=0.71+0.092\sqrt{h}$.

group, such as the hydration and the acid catalytic reactions, may contribute somewhat in the acidic pH region*3.

The current pH relationship of 4-ethylpyridine *N*-oxide also showed the same tendency as in Figs. 2 and 3. In this case, $\vec{k_r}=5.5\times10^{11}$ $(mol./l.)^{-1}(sec.)^{-1}$ was obtained by using Eq. 2, and $pK_a\fallingdotseq1.21$, which is estimated from the relationship between pK_a and Hammett's σ values[8].

Under the conditions used here, the reduction wave corresponding to the free *N*-oxide group could not be found; this point differs from that in such aliphatic compounds as narcotin *N*-oxide. As a result of the resonance effect between $\geqslant N\rightarrow O$ group and pyridine ring, as is well known, the aromatic *N*-oxide group shows a great resistance to the reductive reaction[5,7b].

*3 In addition the error owing to the drawing figure for the determination of the limiting current may also not be neglected.

Summary

The polarographic behavior of pyridine, 4-methylpyridine and 4-ethylpyridine *N*-oxides has been investigated. The reduction wave of these *N*-oxides decreases rapidly with the increasing pH value in pH values above 5 and disappears in alkali. It was clearly shown by the polarographic and spectroscopic investigations that the main reason for this phenomenon is the kinetic current. Quantitative treatment of the pH-dependence of the limiting current was also carried out.

The authors are grateful to Professor Shinzi Koide of Mukogawa Women's University, in Nishinomiya, and to Dr. Masanosuke Takagi of University of Osaka Prefecture for various discussions.

Intramolecular Interaction between Hydroxyl Group and π-Electrons. XVI.[1] ν_{O-H} *Absorption Spectra of Aryldimethylcarbinols and Related Compounds*

By Michinori Ōki and Hiizu Iwamura

(Received March 20, 1962)

It has been shown in a previous paper[2] that the benzyl alcohols show doublet O–H stretching vibration spectra (ν_{O-H}) in the 3 μ region owing to the rotational isomerism about the C_α–O bond. The hydroxyl group in one (II) of the isomers takes part in the intramolecular interaction with π-electrons of the benzene nucleus and shows the lowered ν_{O-H} when compared with the normal one. Ring

I II

substitution at *p*- or *m*-position to the hydroxymethyl group has been found to alter considerably the apparent ν_{O-H} curve, that is, the relative amount of the two rotational isomers. Furthermore, the phenomenon has been ascribed solely to the change in the proton accepting power of the π-electrons on the benzene ring. In reference to the Hammett's sigma constants of the substituents, the π-electron density at the carbon atom to which the hydroxymethyl group is attached, has been found to have the greatest influence, and a "cis" structure is proposed for the isomer as expressed by model II.

Evans[3] has observed that in benzyl alcohol an unusual vibrational coupling takes place between the aromatic C–H in-plane deformation mode and a stretching mode of $-CH_2-O-$ group at 1020 cm^{-1}. According to the literature, this coupling should be permitted only when C_α–O bond lies in the plane perpendicular to that of the benzene ring. This configuration is in accordance with that of the "cis" structure proposed by the present authors.

There seems to be, however, another factor in the apparent substituent effects, that is, the proton donating character of the α-hydroxyl group might also be influenced by the ring substituent and the apparent substituent effects would be the result of a counteraction between the two effects just as is the case in 2-hydroxybiphenyls[4].

To clarify the ambiguity in the electronic effect, and to obtain further support on the configuration of the interacting form, aryldimethylcarbinols and the related tertiary carbinols in which the hyperconjugative electronic interaction between the hydroxyl group and the aromatic residue may be minimal, have been submitted to the ν_{O-H} spectral measurement.

Experimental

Spectral Measurement.—A Perkin Elmer 112 G grating infrared spectrometer was operated to measure ν_{O-H} absorption as described previously[5].

Materials.—They were prepared by action of an excess of methyl- or ethyl-magnesium halide on the corresponding ketones or carboxylic esters, unless otherwise stated. Decomposition of the reaction mixtures was always effected by an aqueous solution of ammonium chloride to avoid dehydration catalyzed by a trace of acid in the later process. Despite all the tests no *p*-dimethylamino derivative could be obtained, *p*-dimethylamino-α-methylstyrene, m. p., 75°C[6], being the sole product.

The two nitro derivatives were obtained by oxidation of the corresponding nitrocumenes as described for the *p*-isomer[7].

p-Methoxycarbonyl derivative was prepared by refluxing the silver salt of 2-(*p*-carboxyphenyl)-2-propanol[8] with methyl iodide in methanol.

Physical constants and analytical data, if necessary, of the samples are listed in Tables I and II.

Results and Discussion

In Fig. 1 are presented the apparent ν_{O-H} absorption curves of dimethylphenylcarbinol and the two extreme derivatives with respect to the Hammett's sigma constants of the substituents. All the numerical band properties are listed in Table III.

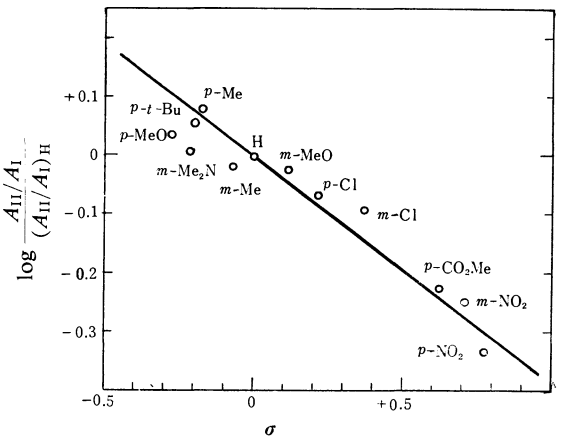

Fig. 2. Relation between $\log\frac{A_{II}/A_I}{(A_{II}/A_I)_H}$ and the Hammett's sigma constant.

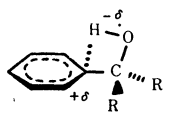
In contrast with the benzyl alcohols[2] which have the ν_{O-H}'s at 3636 and 3617 cm^{-1}, all the present carbinols have doublet ν_{O-H}'s at 3620 and 3606 cm^{-1}. This is the due consequence of the tertiary nature of the hydroxyl group[16].



The relative intensity, A_{II}/A_I, which may be put approximately equal to the equilibrium constant, K, between I and II, varies considerably as the electron-releasing substituents in the benzene ring enhance the lower lying band, while the electron-withdrawing ones reduce it, relative to the higher absorption. In Fig. 2, it is illustrated quantitatively as the relation between $\log(A_{II}/A_I)$ and the Hammett's sigma constants. The inclination expressed as $\rho = -0.357$ is as large as that of the benzyl alcohols, $\rho = -0.475$[2], and suggests a similar mechanism

of interaction. If the interaction bore a fairly polarized mechanism with considerable contribution of the intramolecularly charge-transferred structure, III, the electronic interaction between the substituent and the site of the interaction would be pronounced and the σ^+

III

proposed by Brown and Okamoto[9], rather than the original σ constants would have given the better linearity. Since this is not the case, the interaction may be considered to include but little contribution by such a structure. A slight diminution in the absolute value may be due to the weakened ability of the tertiary carbinols as proton donors rather than the primary ones.

There is no doubt about assigning the isomer II, having the intramolecular interaction with the π-electrons, to the band at lower frequency, 3606 cm^{-1}. Then the apparent variation in A_{II}/A_I may be, as a first approximation, attributed to the change in the proton attracting power of the π-electron on the benzene ring. Since the doublet ν_{O-H} maxima vary only within the experimental error, the ring substituents might be regarded to be indifferent to the force constant of the hydroxyl group. ν_f which appears at 3620 cm^{-1} can validly be said to be indifferent to the ring substituent in contrast to the substituted phenols[17] in which ν_f's are in linear relation with the sigma constants of the ring substituents. It is, however, rather dangerous to conclude from the apparent constancy in the wave number that the hydroxyl groups having the intramolecular interaction with the π-electrons are also independent of the substituents.

With the intention of making it clear that the ring substituents might not be concerned with the donor ability of the hydroxyl group,

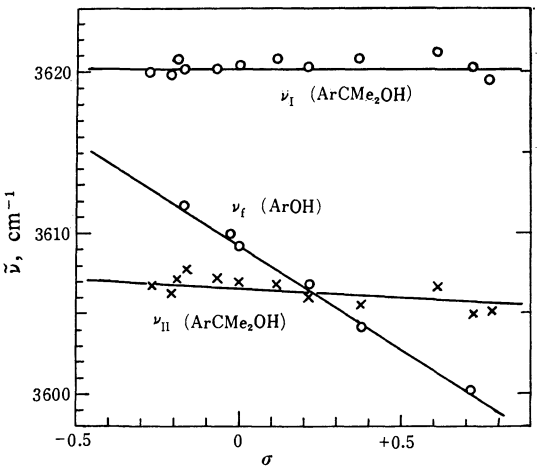

Fig. 3. The effect of the nuclear substitution on the ν_{O-H} maxima of aryldimethylcarbinols and phenols.

the denominator being estimated from the intensity of the remaining free ν_{O-H}.

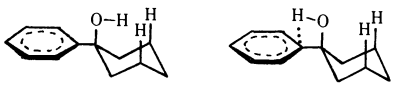
but solely with the π-electron system as the proton acceptors, the intermolecular association of these carbinols with diethyl ether as a common proton acceptor in carbon tetrachloride was investigated. Unexpectedly, the association IV was found to be dependent on the substituents as is seen from the ν_{O-H} of the hydroxyl group taking part in the association, and from the association constants (K'), in Fig. 4. The electron-withdrawing group such as nitro

$$Ar \cdot CMe_2 \cdot \overset{-\delta}{O}\text{-}H \cdots \overset{+\delta}{O}Et_2$$
IV

tends to strengthen, while the electron-releasing one weakens, the association between the aryldimethylcarbinols and diethyl ether. Compared with the free ν_{O-H}'s which are quite independent of the ring substitution, it has become reasonable to conclude here that the effect of the ring substituents on the hydroxyl group becomes the more conspicuous, when the hydroxyl group is more polarized by the formation of hydrogen bonding or the like interactions. The electronic structure of the hydroxyl group should be expressed as a resonance hybrid between V, VI and VII. The increased contribution of the structures VI and VII by any mechanism will lower the force constant of O–H which in turn makes sharper response to the electronic changes in the rest of the

R-O-H	$R\text{-}\bar{O}\text{-}\overset{+}{H}$	$R\text{-}\overset{+}{\bar{O}}\text{-}H$
V	VI	VII

molecule, R. This finding bears a resemblance to the substituent effects on the reaction kinetics and the ultraviolet spectra, in which the excited state rather than the ground state suffers from more distinguished electronic effect of the substituents.



Since the strength of, and the polarization in the hydroxyl group by, the O–H$\cdots\pi$ interaction, as realized in aryldimethylcarbinols, may be regarded to lie between the two extremes, the effect of the substituent on the proton donor character of the hydroxyl group will be medium and can not be evaluated quantitatively. The effect of the substituent in this sense will make ν_i's lower by way of strengthening the proton donor character, as the electron-withdrawing power of the substituent increases, and may be opposite to the direct substituent effect on the proton accepting ability of the π-electrons. Thus, it is rather practical to assume that the apparent constancy of ν_i's over a wide range of aryldimethylcarbinols would be the result of the counterbalance between a favorable effect on the proton donor and an unfavorable influence on the proton acceptor in the case of the electron attracting substituent. The same interpretation will also be operative of the electron releasing groups.

In Table IV are listed ν_{O-H} data of diethylphenylcarbinol, 1-phenylcyclohexanol and 1-methyl-1, 2, 3, 4-tetrahydro-1-naphthol. Though the hydroxyl groups in these compounds are in the same structural position as those of the aryldimethylcarbinols with respect to the benzene ring, and the π-electron density as a proton acceptor is common, they have the

Table IV. ν_{O-H} Absorptions of tertiary alcohols

	ν_{O-H}	ν_{max} cm^{-1}	$\Delta\nu^a_{1/2}$ cm^{-1}	A 10^3 mol^{-1} l. cm^{-2}	$\Delta\nu_{max}$ cm^{-1}	log (A_{II}/A_I)
Diethylphenylcarbinol	I	3618.2	17.8	2.71	10.0	−0.10
	II	3608.2	19.0	2.16		
1-Phenylcyclohexanol	I	3620.5	17.7	1.10	15.3	0.57

varied value of log (A_{II}/A_I). The phenomenon can not be attributed to the electronic effect, but rather to the steric effect. Taking 1-phenylcyclohexanol as an example, the hydroxyl

Ia IIa

hydrogen in Ia has a steric interference with the axial hydrogens at 3- and 5-positions of the cyclohexane ring. Thus the stability of isomer Ia relative to IIa will be diminished considerably, and the value of log (A_{II}/A_I) is the largest ever examined for a compound of this type.

The authors are indebted to Professor Yoshiyuki Urushibara for his encouragement and discussion throughout this work. The authors' thanks are also due to the Ministry of Education for the grant-in-aid for fundamental scientific research.

On Glumamycin, a New Antibiotic. IV. The Amino Acid Moiety*

By Michitaka INOUE**

(Received April 19, 1962)

As we have reported previously[1-4], glumamycin[5], a new acidic peptide-type antibiotic, is composed of seven kinds of amino acids and one mono-unsaturated fatty acid. They are aspartic acid, α(L), β-methylaspartic acid, proline, valine, glycine, pipecolic acid, α,β-diaminobutyric acid, and 3-isotridecenoic acid.

In the present work, the nature of the amino acids was determined and an investigation was made of the free amino group of glumamycin.

Experimental

Preparation of the Sample for Determination of the Amino Acids.—Ten milligrams of glumamycin purified by counter current distribution[5] were hydrolyzed with 3 ml. of 6 N hydrochloric acid in a sealed tube at 110°C for 24 hr., and the hydrolysate was then treated in the usual way to remove the excess hydrochloric acid.

Determination of the Amino Acids by the Moore-Stein Method[6]. — First the determination was carried out by Moore-Stein's method. The results are shown in Table I.

Determination of the Amino Acids by the Paper-DNP Method.—Next, determination of the amino acids was conducted by the paper-DNP method.

A definite volume of the above hydrolysate was dinitrophenylated by the method of Levy[7]. The mixture of DNP-amino acids thus obtained was subjected to two-dimensional paper chromatography (Solvent system: first, *n*-butanol saturated with 2 N aqueous ammonia, and then a 1.5 M phosphate buffer[8]). The yellow spots on the paper chromatogram (Fig. 1) were cut out and extracted with 5 ml. of 1% sodium hydrogen carbonate solution[7]. Colorimetry of the extract was effected at 360 mμ for the usual amino acids, at 385 mμ for proline, and at 395 mμ for pipecolic acid. This determination was conducted on three sheets of paper chromatogram, and the amino acid contents were calculated from the mean values of the experimental millimole extinction coefficients obtained in the next experiment. The results are shown in Table III.

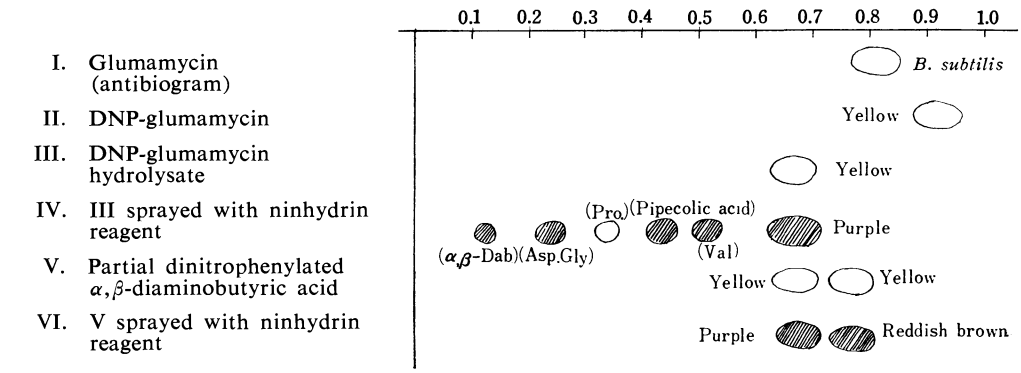

Fig. 2. Paper chromatograms of glumamycin and related compounds (Solvent system; *n*-butanol, acetic acid, water (4 : 1 : 5)).

Measurement of the Experimental Millimole Extinction Coefficients of Various Amino Acids.—Aspartic acid, glycine, proline, valine, pipecolic acid, and α, β-diaminobutyric acid were dissolved in three consecutive concentrations. The solutions, after being dinitrophenylated by Levy's method[7], were subjected to two-dimensional paper chromatography (Solvent system: the same as has been mentioned above). The yellow sports were cut out and extracted in the same way as above. The experimental millimole extinction coefficients of the amino acids were calculated from the absorptions at their respective wavelengths, and finally the mean values of the solutions in three concentrations were obtained (Table II).

Hydrolysis of DNP-Glumamycin.—Ten milligrams of DNP-glumamycin obtained by Sanger's method[9] were hydrolyzed with 3 ml. of 6 N hydrochloric acid in a sealed tube at 110°C for 24 hr. The hydrolysate was diluted and treated with ether in the usual way. No ether-soluble DNP-amino acid was obtained. The yellow aqueous layer was evaporated in a dark place, to remove the excess hydrochloric acid. The residue thus obtained was submitted to paper chromatography (Fig. 2).

Paper Chromatography.—The paper chromatograms (I—VI) in Fig. 2 were obtained by developing them with the solvent system *n*-butanol, acetic acid and water (4 : 1 : 5). All the processes were conducted by the descending method.

Partial Dinitrophenylation of α, β-Diaminobutyric Acid.—α, β-Diaminobutyric acid[8] isolated from the hydrolysate of glumamycin was dinitrophenylated by Sanger's method[9], but the reaction time was limited to 30 min. The reaction mixture was immediately shaken with ether to remove the unreacted dinitrofluorobenzene and di-DNP-α, β-diaminobutyric acid. The yellow aqueous layer thus obtained was submitted to paper chromatography.

Results and Discussion

The amino acids contents of glumamycin was estimated by the Moore-Stein method; as a result, 4 mol. of aspartic acid, 1 mol. of valine, and 2 mol. of glycine were detected, as is shown in Table I. The other amino acids were not detected, probably because α(L), β-methylaspartic acid was eluted in the same fraction as that of aspartic acid, because pipecolic acid was not colored favorably with ninhydrin, and because α, β-diaminobutyric acid was not eluted by this method. That ammonia was not detected means that asparagine does not exist therein despite the presence of 4 mol. of aspartic acid.

TABLE I. AMINO ACIDS COMPOSITION OF GLUMAMYCIN DETERMINED BY MOORE-STEIN'S METHOD

Amino acid	Calcd. ratio in 48 hr. hydrolysate	Assumed ratio of amino acid residue
Aspartic acid	4.23	4
Glycine	2.12	2
Valine	1.00	1
Proline	1.05	1
Amino N	0	0

Next, the determination was carried out by the paper-DNP method. The DNP-derivatives of the amino acids in glumamycin hydrolysate were obtained by Levy's method, and their two-dimensional paper chromatograms are shown in Fig. 2. The DNP-derivatives of the two acidic amino acids, i.e. α(L), β-methylaspartic acid and aspartic acid were not separated clearly, so their ratio could not be determined. However, the ratio of the two compounds was estimated to be about one to three or more, judging from the sizes of their spots colored with ninhydrin in the paper chromatography of the acidic amino acid fraction of glumamycin hydrolysate. The spots of the DNP-derivatives of valine and pipecolic acid also overlapped, but the ratio of their contents could be calculated since their absorption maxima were different. This method of determining amino acids was carried out

Valine	15.75	18.0	87
Proline	16.80	18.5	91
α,β-Diaminobutyric acid	20.85	29.2	71
Pipecolic acid	15.51	15.8	98

TABLE III. AMINO ACID COMPOSITION OF GLUMAMYCIN DETERMINED BY PAPER-DNP METHOD

Amino acid	Calcd. ratio	Assumed ratio of amino acid residue
Aspartic Acid	4.12	4
Glycine	1.94	2
Proline	1.00	1
Valine	0.89	1
Pipecolic acid	0.97	1
α,β-Diaminobutyric acid	1.93	2

after confirming the fact that the dinitrophenylation of each amino acid and the elution of the product were reproducible with an error of ±4%, and that, therefore, this method was usable. The results are shown in Table II. From the experimental data, the nitrogen content of the amino acids was calculated; from the recovery rate of nitrogen (108%), the molecular ratio shown in Table III seems reasonable and is in accord with the results obtained by the Moore-Stein method.

On the basis of the above results, glumamycin is considered to contain 4 mol. of aspartic acid (including α(L), β-methylaspartic acid), one mol. each of proline, valine and pipecolic acid, and 2 mol. each of glycine and α,β-diaminobutyric acid; judging from the analytical results[3], 1 mol. of an unsaturated fatty acid[4] also seems to be present.

Further, investigation was made into the free amino group of glumamycin. As is shown in Fig. 2, the water-soluble DNP-amino acid in the hydrolysate of DNP-glumamycin was identified as mono-substituted DNP-α,β-diaminobutyric acid. The results of the paper chromatography are as follows;

1) Paper chromatogram I is the antibiogram of glumamycin (microorganism; *B. subtilis*), 2) Paper chromatogram II shows the yellow spot of DNP-glumamycin, 3) Paper chromatogram III shows the yellow spot at R_f 0.68 of the DNP-amino acid in the DNP-glumamycin hydrolysate; when the chromatogram is sprayed with the ninhydrin reagent, all the amino acids contained in glumamycin are colored and the yellow spot at R_f 0.68 turns purple (paper chromatogram IV), 4) Paper chromatogram V indicates two yellow spots of partially dinitrophenylated α,β-diaminobutyric acid at R_f 0.68 and 0.75; when the paper chromatogram is sprayed with the ninhydrin reagent, the yellow spot at R_f 0.68 turns purple and the spot at R_f 0.75, reddish brown.

Judging from the color reaction paper chromatogram VI, it is assumed that the substance with R_f 0.68 is mono-DNP-α,β-diaminobutyric acid in which the α-amino group is free and that the β-amino group is dinitrophenylated, while the substance with R_f 0.75 is also the same acid, but its α-amino group is dinitrophenylated and β-amino group is free. On the basis of this assumption, the free amino group of glumamycin is assumed to be the β-amino group of α,β-diaminobutyric acid, and the α-amino group is assumed to participate in peptide linkage. In addition, as another spot of α,β-diaminobutyric acid is found at R_f 0.1 on paper chromatogram V, 1 mol. α,β-diaminobutyric acid of each two in glumamycin takes part in the peptide-linkage through both the α- and the β-amino groups.

Summary

Separatory determination was conducted on the seven amino acids contained in glumamycin. By the Moore-Stein method and by paper chromatography of the DNP-derivatives of the amino acids, 4 mol. of aspartic acid (including α(L), β-methylaspartic acid), 2 mol. each of glycine and α,β-diaminobutyric acid, and 1 mol. each of valine, pipecolic acid and proline were detected. Also, investigation was made into the free amino group of this antibiotic.

The hydrolysate of DNP-glumamycin showed one yellow spot at R_f 0.68, which spot turned purple with ninhydrin.

Compared these results with paper chromatogram of partially dinitrophenylated α,β-diaminobutyric acid, it was assumed that the β-amino group of one of the acids, is free, that the α-amino group participates in the peptide linkage in glumamycin, and that both amino groups of another α,β-diaminobutyric acid take part in the peptide linkage.

The author wishes to express his thanks to Dr. Satoru Kuwada, the Director of the Research Laboratories, Dr. Sueo Tatsuoka, Vice-Director of the Research Laboratories, and Dr. Kuniyoshi Tanaka, the Head of the Second Division of the Research Laboratories for their guidance and encouragement, and to Drs.

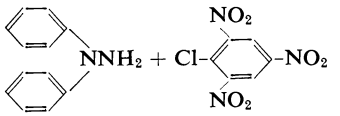
Electric Properties of the Single-crystal and Thin Film of α,α'-Diphenyl-β-picrylhydrazyl

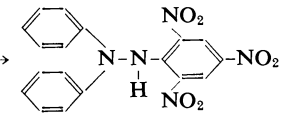
By Hiroo INOKUCHI, Yoshiya HARADA and Yusei MARUYAMA

(Received May 19, 1962)



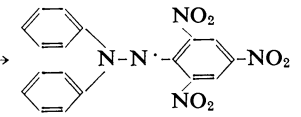
It is known that α,α'-diphenyl-β-picrylhydrazyl (DPPH) has one unpaired electron. The magnetic properties of the stable free radical have been studied by a number of investigators[1-4]. The unpaired electron localized on the nitrogen atoms of the molecule converts para-hydrogen into ortho-hydrogen at low temperature[5]. The conversion mechanism is a paramagnetic (physical) one, as absence of the hydrogen-deuterium exchange reaction rules out a dissociative chemisorption of hydrogen molecules by the free valencies of surface.

The works on the role of the unpaired electron in the interaction between free radicals and adsorbed oxygen or complexed organic solvents have been reported[6,7]. These results expressed that no change of the concentration of unpaired electrons is found with this interaction.



However, few articles concerning the electronic properties for solid free radicals have been published[5,8]. In this paper, we are presenting the electronic conduction and its related phenomena of the single crystal and the thin film of α,α'-diphenyl-β-picrylhydrazyl. Further, the relation between the orientation of molecules in the crystal and the electronic conduction will be discussed.

Experimental Procedures



α,α'-Diphenyl-β-picrylhydrazyl was prepared by reaction of α,α'-diphenylhydrazine (I) with picryl-chloride (II) in chloroform. The strong heating of this solution yielded precipitates of white crystallites, diphenylhydrazine hydrochloride. After separation of these precipitates from the solution, the addition of ether caused beautiful scarlet-red crystal, α,α'-diphenyl-β-picrylhydrazine (III), to precipitate. After the method of Goldschmidt and Renn[9], the oxidation of hydrazine with lead dioxide and anhydrous sodium sulphate, produced the violet crystal, α,α'-diphenyl-β-picrylhydrazyl (IV).

(I) (II)

(III)

(IV)

The solvent-free single crystal (dimension: 0.3×0.3×1.3 mm., weight: about 1 mg.) of the free radical was grown from the carbon disulphide solution. Two types of thin film cells of DPPH were prepared by a vacuum evaporation as described in the previous report[10]. This evaporation had to be operated rapidly at a vacuum of the order of 10^{-5} ~10^{-6} mmHg to avoid the decomposition of the free radical in specimen vessel under heating (80~130°C). The decomposition of the prepared thin free radical film was also accelerated by a contact with air and/or by an illumination of ultraviolet light. Therefore, the observation of its physicochemical properties was carried out in short period (one or two days) after preparation.

specimen were measured with an aid of vibration-reed electrometer. During the measurement, the specimen was kept in a vacuum vessel. The absorption spectra of the free radical were observed with a Cary recording spectrophotometer, model-14.

Results and Discussion

The electrical resistivity*, ρ, and its activation energy of the DPPH single crystal were fairly high in comparison with the previous results[5,8]. It was found that a great anisotropy of these values occurs in the direction of the crystal: The conductivity along the long axis (c-axis) of needle crystal is higher than that perpendicular to the axis by a factor of 10^5 as listed in Table I.

From a preliminary results, the crystal structure of DPPH is orthorhombic one, with four molecules in a unit cell of dimensions a=17.6Å, b=18.9Å and c=7.59Å and molecules in the crystal seem to be arranged perpendicular to the c-axis and the molecular planes are parallel with each other. The unpaired electron in the molecule is localized on the nitrogen atoms and the direction of its orbitals extends perpendicularly from the molecular plane as shown in Fig. 1. Therefore, the overlapping of the orbitals is expected to be large in the direction perpendicular to the molecular plane, but not in the parallel one to the plane. Since charge carriers in the free radical transfer through the overlapping, the anisotropy of conductivity might be a consequence of substantial anisotropy of the overlapping in the crystal.

As is illustrated in Table I, no direction dependency was found in the values of energy

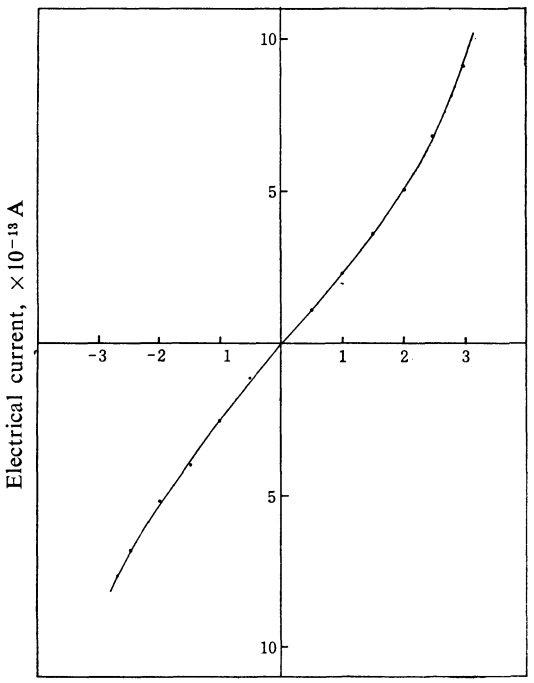
····· Photoconduction for sandwich-type cell



* The electrical resistivity, ρ, is expressed as $\rho=\rho_0\exp(\varepsilon/2kT)$.

gap, $\Delta\varepsilon$. Hence, there should be a large difference in the mobility of charge carriers depending on the direction of the crystal.

Polycyclic aromatic molecules of thin film are in alignment with their ab plane with the film surface as reported in the previous paper[10]. The DPPH thin film is expected to be a similar behaviour. The anisotropic values of the resistivity of its two directions—the direction perpendicular to the film (sandwich-type cell) and that along to the surface (surface-type cell)—are also explained by the orientation of unpaired electron orbitals.

(a)

(b)

Fig. 3. The current-voltage relation of DPPH thin film cells.
(a) I-V curve of the surface type DPPH cell.
(b) I-V curve of the sandwich type DPPH cell.

A great difference was found on the characteristics of photoconduction and current-voltage relation in these two types of cells. The photoconduction for sandwich-type cell, Al||DPPH||Al[11], was found under an illumination of visible light but little for surface type one. The spectral response for photoconduction is illustrated in Fig. 2 as a dotted line.

In comparison with the absorption spectra of the DPPH crystal, which possess two absorption peaks, 332 and 533 mμ, the spectral response for photoconduction is in a good agreement with that for optical absorption for the shorter wavelength peak of 332 mμ, but not for the longer wavelength peak of 533 mμ, which is completely missed in the response for photoconduction.

The variation of the current with the applied potential obeyed Ohm's law for the lower fields used. At the higher fields (over 10^3 V./cm.), however, its voltage dependence was strongly curved for sandwich-type cell and became more linear for surface-type one as illustrated in Fig. 3.

Summary

The electronic conductivity of two forms of α,α'-diphenyl-β-picrylhydrazyl, the single crystal and the thin film, was observed. The resistivity (ρ_{15}) at room temperature along c-axis (1×10^{10} Ω cm.) is 10^5 times lower than that perpendicular to the axis (1×10^{15} Ω cm.), but its activation energy ($\Delta\varepsilon$) against temperature is in good agreement (1.5 and 1.6 eV.). These large anisotropy may be introduced from that of the arrangement of molecules in the crystal. In the case of thin film, the values of ρ_{15} and of $\Delta\varepsilon$ are $\sim10^{10}$ Ω cm., 1.7 eV. for surface type cell and $\sim10^{13}$ Ω cm., 2.7 eV. for sandwich-type cell respectively. A great difference on the characteristics of photoconduction and on the current-voltage relation in these two types of cell was found.

*Dye-sensitized Photopolymerization of Vinyl Compounds. Polymerization of Acrylonitrile by Stannous Chloride and Acriflavine. II**

By Ai WATANABE**

(Received February 8, 1962)

In the previous paper[1], the present author and Koizumi studied the polymerization of acrylonitrile (AN), which takes place when a solution of AN, acriflavine (D) and stannous chloride in the mixed solvent of water and dimethylformamide (DMF) is illuminated by visible light. They found that neither oxygen nor water is of primary importance for the initiation of polymerization, as a mechanism they proposed that a transient tin ion of odd valency is produced and that this, by interacting with the monomer, initiates the polymerization.

The aim of the present work is to make the proposed scheme more definite by ascertaining whether it also fits the photosensitized polymerization of AN in DMF (with no addition of water and in vacuo) in the presence of stannous chloride and acriflavine.

Experimental

Materials.—AN from the Union Carbide Corporation was distilled at atmospheric pressure and was further distilled twice in an atmosphere of nitrogen under reduced pressure. Commercial acriflavine was recrystallized twice from water and dried in vacuo. Stannous chloride dihydrate (G. R) was dehydrated in vacuo at room temperature. DMF from Du Pont was purified as has been described previously[1].

Procedure.—As the light source, a tungsten projection lamp 100 V.-500 W was operated at 80 V., as has been described in Part I. The distance between the light source and the reaction cell in a thermostat was 10 cm. A Matsuda color filter V-Y3C and a heat-cutoff filter were put between the reaction cell and the light source. The reaction cells and dilatometers were the same as have been described in Part I except for the one shown in Fig. 1, which was used to study the influence of oxygen upon the rate of polymerization. The solution to be studied was poured into cell A and then degassed after being frozen in a dry-ice bath. When the degassing was complete, a definite quantity of air was introduced through B and the dilatometer was sealed off at constricted Part B. When the contents thawed, the air was dissolved by shaking the cell, and the solution was poured through capillary C into the reaction cell D by tilting the unit. The drop of meniscus in the capillary, E, was followed by the use of a travelling microscope. All the experiments were done at 30°C, and the solutions were degassed by repeating the vacuum distillation except when otherwise described.

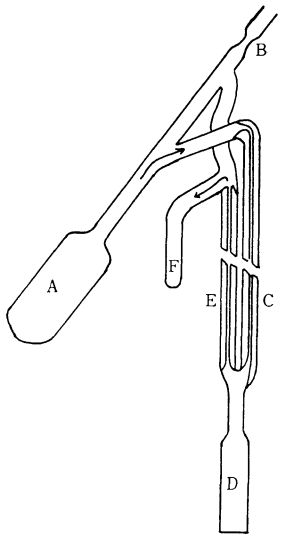

Fig. 1. Dilatometer.

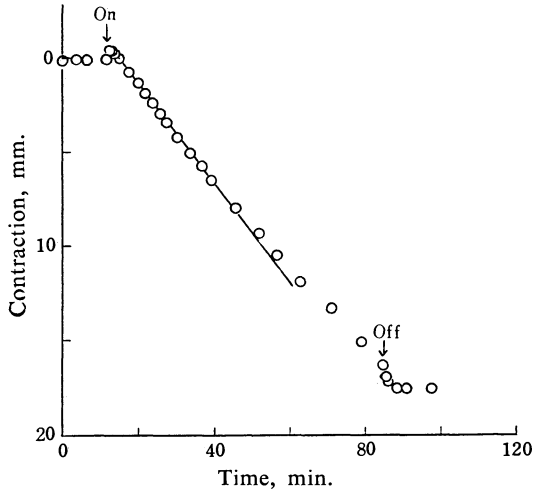

Fig. 2. The polymerization~time curve. $[D]=1.0\times10^{-4}$ M ; $[SnCl_2]=1.25\times10^{-2}$ M ; $[AN]=5.0$ M

* Presented at the 14th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1961.

** Present address: Nichiban Co., Nerima-ku, Tokyo.

1) A. Watanabe and M. Koizumi, This Bulletin, **34**, 1086 (1961).

The apparatus employed for making a sample of a bleaching reaction was almost the same as that used for the polymerization. The solutions were thoroughly degassed and were poured into two reaction cells in vacuo. They were sealed off, separately; one was used for the dark-reaction, and the other for the photo-reaction. At various time intervals during the reaction, reaction cells were taken out and the dye concentration of solutions was measured by a spectrophotometer.

Results

The Polymerization.—Induction periods were observed in almost none of the experiments, and after a short period of constant rate the rate fell off gradually. Figure 2 shows a typical curve for the polymerization. During the course of polymerization, the polymer did not deposit. In all cases, the rate was evaluated from the initial linear portion of the curve. The reproducibility of experiments was not excellent enough to correlate the data of a different series of experiments.

The Effect of Dye Concentration.—In Fig. 3 is shown the variation of the rate with the concentration of acriflavine. It is apparent from the figure that, at a concentration of dye of less than 1×10^{-5} M, the rate increases linearly with the square root of the dye concentration and that the log(rate)~log[D] curve gives the slope of 0.4. The rate decreases when the concentration of dye exceeds 1×10^{-4} M.

The Effect of the Concentration of Stannous Chloride.—The effect of the concentration of stannous chloride on the rate is shown in Fig.

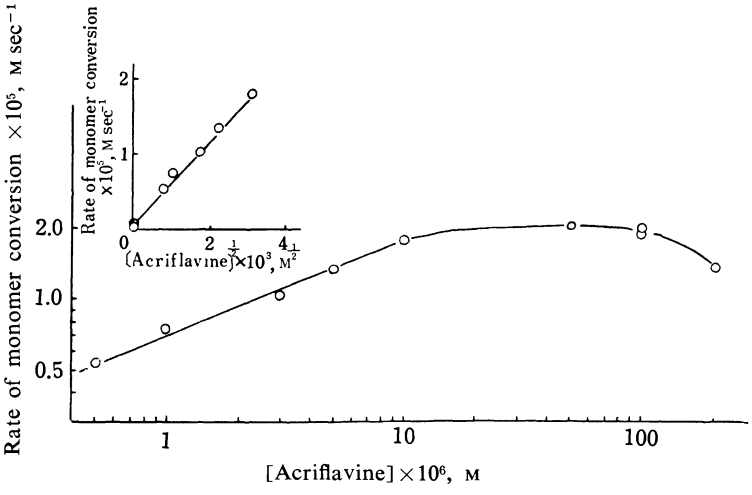

Fig. 3. The dependence of the initial polymerization rate on acriflavine concentration.
$[SnCl_2]=1.25\times10^{-2}$ M; [AN]=5.0 M

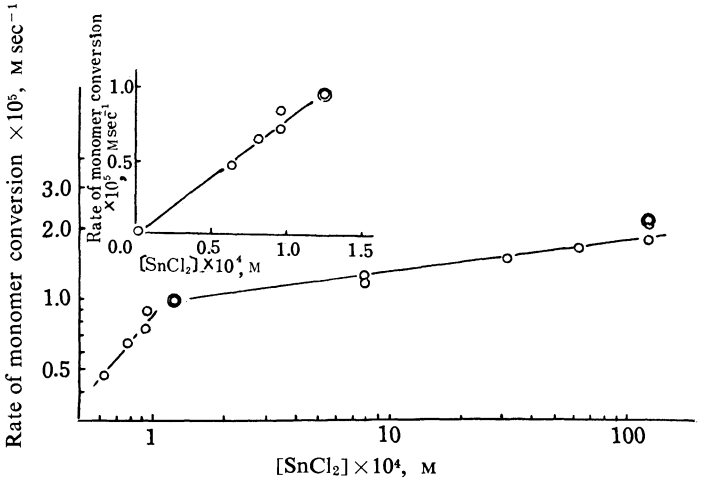

Fig. 4. The dependence of the initial polymerization rate on $SnCl_2$ concentration.
$[D]=1.0\times10^{-4}$ M; [AN]=5.0 M

4. When the concentration of stannous chloride is less than 1×10^{-4} M, the linearity holds between the rate and the concentration of stannous chloride, this being also confirmed by the slope of 0.95 for the log(rate)~log[$SnCl_2$] plot, although there exists some scattering of the experimental points. In the region where the concentration of stannous chlorde is more than ca. 1×10^{-4} M, the rate increases at a lower rate.

The Effect of the Monomer Concentration.—As is shown in Fig. 5, the rate depends on the second power of the monomer concentration. The log(rate)~log[AN] plot gives a straight line of the slope of 2.2.

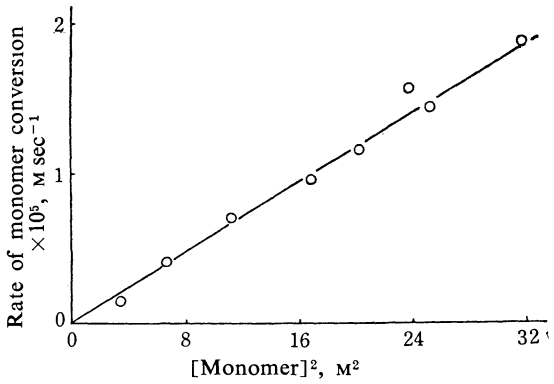

Fig. 5. The dependence of initial polymerization rate on acrylonitrile concentration.
[D]=2.0×10^{-4} M; [$SnCl_2$]=1.25×10^{-2} M

The Effect of the Pressure of Oxygen.—In Fig. 6, the rate is plotted against the pressure of oxygen. It is evident that the polymerization in the degassed solution has a rate somewhat smaller than that in the non-degassed solution, the ratio of the rate in the two cases being about 0.5. Thus, the presence of oxygen is not of primary importance for the occurrence of the reaction.

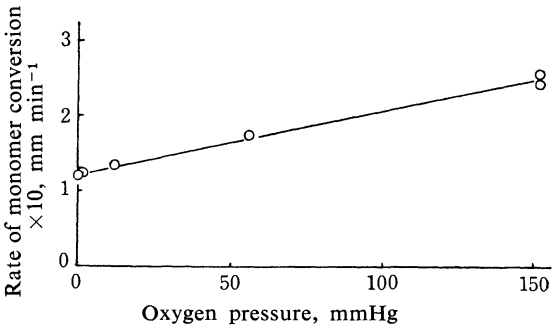

Fig. 6. The dependence of the initial polymerization rate on oxygen pressure.
[D]=1.0×10^{-4} M; [$SnCl_2$]=1.25×10^{-2} M; [AN]=5.0 M

The Effect of the Light Intensity. — The intensity of the exciting light was changed to 50, 25 and 12% of the standard light by the use of neutral filters. The samples used in these experiments contained a quantity of dye large enough to absorb almost all the effective light. As is shown in Fig. 7, the intensity exponent is about 0.35.

The Bleaching.—*The Bleaching of Dye in the DMF Solution.*—When the degassed solution of dye in DMF was illuminated, the bleaching occurred, whereas not a slight bleaching was observed in the dark. In Fig. 8 the absorption spectrum of the sample after illumination is (2), and that of the original sample is (1). A slow restoration of the absorption curve was realized even in vacuo when the illuminated sample was kept in the dark (3). On the

6 47.5 hr.-standing of (4) in the dark

introduction of air into the illuminated sample, the absorption curve was further restored to some extent.

The rate of photobleaching was reduced by the addition of stannous chloride, and it was found that the bleached solution in this case never completely regains its color upon the introduction of air. The bleaching did not occur in the dark. The reversible photobleaching was scarcely observed at about 6.25×10^{-3}M stannous chloride and the absorption spectrum showed a slight shift of λ_{max} toward a longer wavelength.

In Fig. 9, the absorbance at the wavelength corresponding to the maximum of the original sample is plotted against the reaction time. This figure does not allow a rigorous comparison of the rates of photobleaching because of the superposition of the reversible and irreversible bleaching, the latter especially giving an absorption curve due to the remaining dye and the product. However, the rates can be compared semiquantitatively from this figure, and it is clear that the rate decreases as the concentration of stannous chloride is increased.

The Bleaching of Dye in the DMF-AN Solution. —When AN is added to the DMF solution, the spectrum of dye showed little change, but the rate of photobleaching was reduced. Furthermore, the photobleaching of dye in the degassed DMF-AN solution was irreversible, and the absorption spectra of the illuminated solution showed a shift of λ_{max} to longer wavelengths. When stannous chloride is added, the rate of photobleaching is appreciably

reduced, as is shown in Fig. 10; the bleaching is irreversible. The bleaching does not occur in the dark. An example of the spectral change caused by illumination is shown in Fig. 11.

Though the feature of photobleaching is complicated and it is desirable to study it more quantitatively, some qualitative discussion may be given about the relation between photobleaching and photopolymerization on the basis of the above results. In broad outline, the photobleaching of dye occurs in the absence of stannous chloride though the photopolymerization does not occur. The rate of photobleaching is reduced by the addition of stannous chloride which, on the other hand, causes the photopolymerization to occur. Consequently, it may be concluded that the photobleaching of dye does not occur parallel with the photopolymerization.

Discussion

As expected, the polymerization of AN was initiated by visible light in the presence of stannous chloride and acriflavine in vacuo. It will be discussed below whether the experimental results can be interpreted on the basis of the schemes proposed in the previous paper. One of the schemes proposed for the initiation process involves the assumption that a complex is formed between the Sn^{2+} ion and the dye. However, this seems rather implausible in view of the finding that the shift of the absorption spectrum of dye in the visible region was not observed by the addition of stannous chloride in a DMF-AN or a DMF-AN-H_2O solution. Moreover, the essential steps are common in the two schemes. Hence, to avoid confusion, the discussion is limited to the other scheme, which is described below:

$$\begin{array}{ccccccccc} D & \xrightarrow[(1)]{h\nu} & D^* & \xrightarrow[(3)]{D} & D^t & \xrightarrow[(5)]{Sn^{2+}} & (D^- \text{ — } Sn^{3+}) & \xrightarrow[(7)]{Sn^{2+}} & \\ & & \downarrow (2) & & \downarrow (4) & & \downarrow (6') & \downarrow (6) & \\ & & D & & D & & D+Sn^{2+} & Leuco+Sn^{4+} & \end{array}$$

$$D + Sn^+ + Sn^{3+} \xrightarrow[(8)]{} D + 2Sn^{2+}$$

$$(\text{or } D^- + Sn^{3+}) \qquad (\text{or } D + Sn^{2+})$$

$$Sn^{3+} + M \xrightarrow{k_i} R$$

$$(\text{or } Sn^+ + M \rightarrow R)$$

The essential points in this scheme are that the two kinds of ionic species of a radical nature produced by process (7) react almost exclusively in such a way as to produce stable ions, and that only a small fraction of them react with the monomer to initiate the polymerization. It is assumed, in addition, that the reaction attains the steady state and that the termination of the growing polymer is spontaneous.

The experimental overall rate formula in the present case may be expressed as follows,

$$v \propto [D]^{1/2}[SnCl_2][M]^2 \qquad (I)$$

provided that [D] and $[SnCl_2]$ are small. Thus, the rate is 1/2-order with respect to the dye concentration, whereas it is first order in the previous system, containing water and oxyen, which was treated in Part I. This difference in the order of reaction with respect to the dye concentration can be explained on the assumption that the transition from a singlet (D^*) to a triplet (D^t) excited state occurs in this case as is described below, whereas this is induced by the ground state dye molecule[2] in the previous system, as was discussed in Part I:

$$\begin{array}{ccccccc} D & \xrightarrow[(1)]{h\nu} & D^* & \rightarrow & D^t & \rightarrow & \text{same as the above scheme} \\ & & \downarrow (2)(3) & & \downarrow (4) & & \\ & & D & & D & & \end{array}$$

From this scheme, the initiation rate (v_i) and v can be derived as follows:

$$v_i = \left[\left(\frac{I_0 k_1 k_3}{k_2 + k_3}\right)\left(\frac{k_5[Sn^{2+}]}{k_4 + k_5[Sn^{2+}]}\right) \times \left(\frac{k_7[Sn^{2+}]}{k_6 + k_6' + k_7[Sn^{2+}]}\right)\right]^{1/2} \frac{k_i}{k_8^{1/2}}[M] \qquad (II)$$

and

$$v = \frac{k_1 k_p}{k_t k_8^{1/2}}[M]^2\left[\left(\frac{I_0 k_1 k_3}{k_2 + k_3}\right)\left(\frac{k_5[Sn^{2+}]}{k_4 + k_5[Sn^{2+}]}\right) \times \left(\frac{k_7[Sn^{2+}]}{k_6 + k_6' + k_7[Sn^{2+}]}\right)\right]^{1/2} \qquad (III)$$

From Eq. III, the following relations are obtained, satisfying the experimental results:

i) When [D] is small, $I_0 k_1$ may be put as approximately proportional to [D]. Hence, $v \propto [D]$.
ii) When $[Sn^{2+}]$ is small, $v \propto [Sn^{2+}]$.
iii) In all cases, $v \propto [M]^2$.
iv) $v \propto I_0^{1/2}$

It is regrettable that the value of the intensity exponent experimentally obtained, i.e., 0.35 (which is much less than 0.5), can not be explained satisfactorily.

To sum up, all the features of the present reaction, except a single point mentioned above, can well be interpreted on the basis of a scheme quite similar to that proposed in the previous paper. In addition, the rate of the photobleaching of dye decreases with the increasing stannous chloride concentration, whereas the rate of the photopolymerization increases appreciably with it. This result also supports the view that the photopolymerization

2) F. Millich and G. Oster, *J. Am. Chem. Soc.*, **81**, 1357 (1959).

does not accompany the transient photobleaching of dye, which finding is naturally expected according to the proposed scheme.

Summary

The photosensitized polymerization of AN in DMF by acriflavine and stannous chloride in vacuo was investigated. The reaction rate was shown as: $v \propto [D]^{1/2}[SnCl_2][M]^2$, where [D] and $[SnCl_2]$ were small. The experiments performed examining the photobleaching of dyestuff in various conditions led to the finding that the photopolymerization does not occur by virtue of the transiently-reduced dye. The scheme proposed in Part I, in which the transient tin ion of odd valency (Sn^{3+} and/or Sn^{+}) initiates the polymerization by interacting with the monomer, was further substantiated.

The author wishes to expess her hearty thanks to Professor Masao Koizumi and Dr. Shunji Kato of Tohoku University for their helpful discussion, and to Professor Ryoichi Fujishiro for his encouragement.

Adsorption Characteristics of ^{60}Co-ions towards Polystyrene Treated with Sulfuric Acid Relative to Radioactive Decontamination

By Tsutomu SEIMIYA and Tsunetaka SASAKI

(Received April 6, 1962)

The surface treatment of plastics has drawn the attention of many investigators since it has much to do with such practical problems as anti-electrification, adhesion, radioactive decontamination, etc. It is also a problem of theoretical interest from the viewpoint of the relation of the adsorption to the nature of the surface concerned[1]. Concerning these problems, it is of basic importance to know the amount of solute adsorbed on a solid surface, about which much literature is available[2]. In such studies, however, the total uptakes of a solute have often been roughly treated as the adsorption and no due distinction has been drawn between the adsorption and adhesion[3], especially concerning practical problems, in spite of the fact that such a distinction is rather important in the practice, for instance, of decontamination. Further, as for the adsorption which is measured as a surface excess, several types have been distinguished according to their natures[4], but in practice they have also often been treated without distinction. In order to contribute to the study of such problems we have studied the details of the adsorption of cobalt ions on a polystyrene surface, and also the effect of sulfuric acid treatment on the adsorption.

Experimental

The samples of plastics used in these experiments were polystyrene ("Styron-666-General Purpose" of Asahi-Dow Ltd.) cut in $0.2\times2\times2$ cm. plates. The sulfuric acid used was of a commercial pure grade. An aqueous solution of cobaltous chloride (8×10^{-7} mol./l.) tagged with ^{60}Co-ions was used for the adsorption experiment. The specific activity under the experimental geometry was 6.7×10^{-14} g./cm^2 c.p.m. The sample plates cleaned with a soap solution were immersed under various conditions of dipping time and temperature into sulfuric acid, withdrawn, rinsed with distilled water, and dried in a desiccator. The samples thus treated were weighed and floated on the surface of 4 cc. of an aqueous solution of radioactive cobaltous chloride. After 30 minutes' contact, which was considered to be sufficient for equilibration, they were then taken out of the radioactive solution, weighed to measure the amounts of liquids which adhered to the samples, and dried using an infrared lamp. The radioactivities of the samples were then mesured with a GM-Counter (Ten Model SA-10, 100 Scaler), equipped with a GM-tube with a 2.95 mg./cm^2 mica window (Ten GM 131). The amount of adsorption was determined as the difference between the total radioactivity taken up by the plastics samples and that radioactivity due to the solution adhering to the polystyrene sample, under

the assumption that the concentration of ^{60}Co-ions is the same for both the adhering solution and the bulk of the solution. The specific activity of cobalt ions necessary for this calculation was measured at the same time under the same geometry as for the standard sample, which was prepared by evaporating a known amount of a radioactive sample solution put in 20 spots on a polystyrene sample. For the measurement of the radioactivity, only β-ray counting was used, the difference between the counting rates taken with and without a γ-ray filter. The samples of plastics were further dipped into 50 cc. of various rinsing liquids and were taken out of them after a desired immersion time. The remaining radioactivities on the plastics surface were then measured, and from the values obtained, the amount of the desorption of ^{60}Co-ions from the samples was determined. For each successive dipping, the rinsing liquid was renewed.

Results

Figure 1 shows the changes in the uptake of ^{60}Co-ions with the immersion time of polystyrene in sulfuric acid at 40°C. The desorption of cobalt ions using various rinsing liquids was measured; these results are shown in Figs. 2 and 3. The polystyrene samples appearing in Fig. 3 had been immersed in a sulfuric acid solution for 30 sec. at 85 to 88°C; those in Fig. 2 had not been so treated. The amounts of ^{60}Co-ions remaining on the plate taken as a vertical axis, were expressed as percentages of the original amount of ^{60}Co-ions adsorbed, as was stated in the preceding section. The values above 100 per cent came from the adhering portion of the liquid which was used for the cobalt ion adsorption. Here we can notice that, although the cobalt ions adsorbed initially on an untreated surface (Fig. 2) are much fewer than those on a treated surface (Fig. 3), the former as a whole is rather harder to remove by rinsing than the latter, regardless of the nature of the rinsing liquid; i. e., the steady portion of the curves of Fig. 2 attained after prolonged rinsing is higher (2.95×10^{-11} g./cm^2) than would be presumed from the small initial amount of cobalt ion uptake. This may come from the irreversible portion of the adsorption of cobalt ions due to the impurities in the original sample; the impurities may possibly be removed or altered to the center of reversible adsorption during the sulfuric acid treatment.

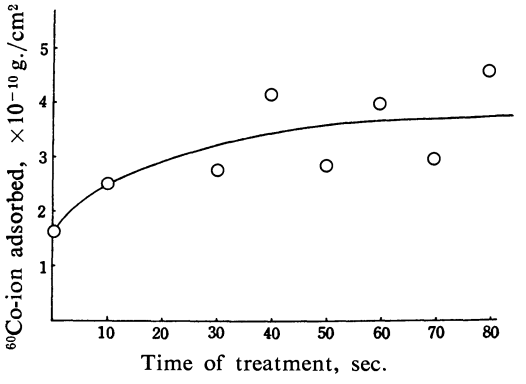

Fig. 1. Change of adsorption of ^{60}Co-ion on polystyrene with time of immersion into sulfuric acid.

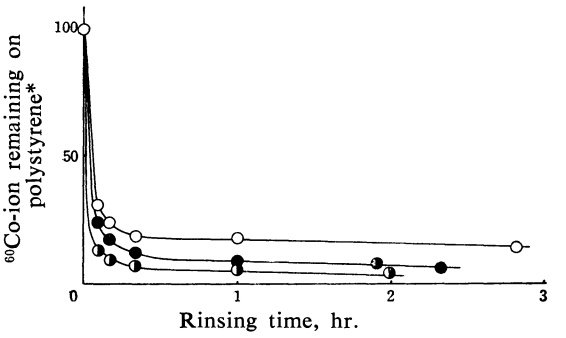

Fig. 2. Desorption of ^{60}Co-ion from polystyrene not treated with sulfuric acid.
Initial activity being 2500 c.p.m.; rinsing liquid used being 0.1 mol. aqueous cobalt chloride (○), distilled water (●) and aqueous 1 % EDTA solution all at pH 7.8 (◑).
* Relative counting rate of ^{60}Co-ion

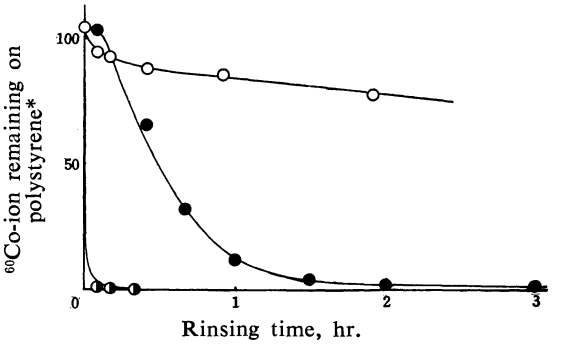

Fig. 3. Removal of ^{60}Co-ion-contamination from polystyrene treated with sulfuric acid.
Initial radioactivity; 15000~5000 c.p.m. (^{60}Co; $4.1\sim1.4\times10^{-9}$ g.) rinsing liquids; absolute ethanol (○); distilled water (●); 0.1 mol. aqueous cobaltous chloride solution (◑).
* Relative counting rate of ^{60}Co-ion

It can be seen in Fig. 3 that, in the case of treated polystyrene, the initial amount of adsorption is much larger than that of an untreated surface and that the desorption curves change markedly with the nature of the rinsing liquids. Thus, the rinsing with distilled water gradually decreases the adsorbed cobalt ions, while almost all of the cobalt ions are removed instantly by rinsing with a non-radioactive 0.1 mol. aqueous cobaltous chloride solution; this reduces the residual amount of

cobalt ion adsorption to less than 3.08×10^{-12} g./cm^2. On the basis of this desorption behavior, shown in Figs. 2 and 3, it may be concluded that the major part of the adsorption of cobalt ions by the treated (sulfonated) polystyrene is the ion-exchange adsorption. This conclusion is further confirmed by the fact that the rate of desorption by the anhydrous ethyl alcohol is smaller than that by distilled water. Here we employed ethyl alcohol because it is a nonionizing solvent, thus offering no ions for ion-exchange with the adsorbed ion, and yet it shows a larger solubility for cobaltous chloride than does distilled water. The desorption curves are also shown in Fig. 3.

In this situation, we should like to draw further attention to the problem of radioactive contamination and decontamination. Concerning these problems, Jackson and Garard made a similar experiment[5] for plastics surfaces using nuclear fission products as contaminants. The amount of adsorbed fission products they obtained, as well as the final amount of activity after rinsing the contaminated sample with 5 per cent ammonium citrate, is higher than those of our results for the sulfonated (ion-exchanging) polystyrene surface. In our case, the sulfonation of polystyrene was mainly restricted to its surface, and it was shown that, in such a case, adsorbed cobalt ions are rather readily desorbed; even a simple water (a weakly ionizing liquid) rinsing is fairly effective, as is shown in Fig. 3.

In the case of radioactive decontamination, it is the easy and widespread practice to use water, a detergent solution or an acid solution as the rinsing liquid or decontaminant. Quite often, howeve, these treatments leave some persistent contamination behind, though a large portion of contamination is readily removed. This residual contamination, though small in amount, may often be quite undesirable. Our present findings on the adsorption and desorption of ^{60}Co-ion by polystyrene have some bearing on this problem. It may be said that, if the sample of polystyrene is properly treated with sulfuric acid, such residual contamination will be reduced practically to zero even by a simple rinsing with water, though the surface is rendered rather susceptible to contamination. However, the problem still remains to find the optimum conditions, giving minimum susceptibility, for such a surface treatment.

In conclusion, we should like to emphasize that, judging from the results of the present experiment on the adsorption characteristics of cobalt ions on a polystyrene sample, the information concerning the properties of solid surfaces and the nature of the adsorption of a solute on them can properly be obtained from such experiments as sulfuric acid treatment and from the measurement of desorption curves for treated and untreated surfaces using various rinsing liquids.

Summary

The adsorption of cobalt ions by polystyrene treated with sulfuric acid was measured using the radiotracer technique. We also studied the type of adsorption of the cobalt ions by polystyrene, with or without sulfuric acid treatment, by observing the rate of desorption by the use of several rinsing liquids. It was confirmed that, although cobalt ion adsorption on an untreated surface is much less than that on a treated surface, the former is rather harder to remove by rinsing than the latter, regardless of the nature of the rinsing liquid.

Effect of Sulfuric Acid and Chromic Acid Mixture Treatments of Plastics on their Wettability towards Water

By Teruo TSUNODA, Tsutomu SEIMIYA and Tsunetaka SASAKI

(Received April 6, 1962)

The wettability of polymer surfaces has been studied by several workers with reference to the theoretical problems of surface chemistry as well as the practical processes of printing, adhesion, friction, anti-electrification, surface electrical conductivity, etc., and many problems of the surface chemical and physical treatment of a polymer substance and plastics have been studied along these lines[1].

In most of these experiments with surface treatment, however, no full attempt has been made to establish a definite relation between the amount of surface attack and the magnitude of the surface properties affected thereby. In the present experiment, the effect of the sulfuric acid treatment of polystyrene and of the chromic acid mixture treatment of polyethylene on their wettability towards water was studied.

Experimental

Materials.—The plastics used in this experiment were polystyrene ("Styron-666-General Purpose" made by the Asahi-Dow, Ltd.) and polyethylene ("Hi-Zex" made by the Mitsui Chemical Ind. Co.), both 0.2 cm. in thickness and cut into 2×1 cm. plates. Sulfuric acid of a pure grade and a chromic acid mixture prepared from commercial potassium dichromate, sulfuric acid and water in the ratio of 5 : 100 : 8 by weight were used for the surface treatment of polystyrene and polyethylene respectively.

Procedure.—Sample plates cleaned with a soap solution were immersed, under varying conditions of dipping time and temperature, into a sulfuric acid solution in the case of polystyrene and into a chromic acid mixture in the case of polyethylene; they were then withdrawn, rinsed with distilled water, dried in a desiccator, and used for the contact angle measurement by a Wilhelmy-type torsion balance, in a manner similar to that reported previously[2]. The cobalt adsorption on the treated polystyrene surface was measured by the radiotracer method, using a cobaltous chloride solution tagged with ^{60}Co. The details of this, as well as the results of the measurement, have already been reported in a preceding paper[3].

Contact Angles.—Figure 1 shows the change in the contact angles of water on polyethylene with the time of immersion in a chromic acid

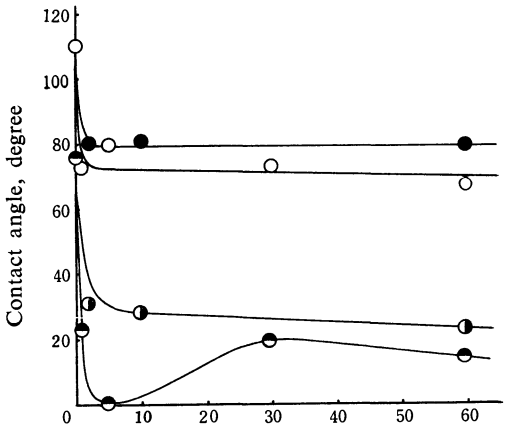

Fig. 1. Change of wettability of polyethylene towards water with time of immersion into chromic acid mixture.
- ● Advancing contact angle; immersion temperature 13°C

- ◓ Receding contact angle; immersion temperature 23°C

mixture at 23 and 13°C. In both cases, the polyethylene surfaces are rendered wettable soon after immersion into the chromic acid mixture. This can reasonably be explained by the oxidation of the polyethylene surfaces by the chromic acid mixture, as may be seen from a similar oxidation reaction which constitutes the basic reaction of the quantitative determination of the number of side chains in a polyethylene molecule[4]. A similar oxidation is observed in a surface treatment by an aqueous solution of chromic acid and

potassium permangante, while no increase in the wettability can be seen in a treatment by sulfuric acid or phosphoric acid. The relation between the contact angle of the water and the temperature of the sulfuric acid treatment for polystyrene is given in Fig. 2, which shows a zero receding contact angle for temperatures above 50°C. The higher the temperature of treatment is raised, the more wettable becomes the polystyrene surface towards water. The sulfonation of the polystyrene surface by the sulfuric acid may reasonably be considered responsible for this wettability[5]. The change in the contact angle of water on polystyrene

with the time of immersion into sulfuric acid was also measured at the immersion temperatures of 30°C, from 85 to 88°C and at 100°C (Figs. 3 and 4). For the cases of both 85 to 88°C and of 100°C, a rapid increase in wettability is observed within 10 sec. of immersion, while a rather gradual increase in wettability is exhibited at 30°C.

The Relation between Wettability and the Degree of Surface Attack.—Various equations for the relation between the wettability of a solid surface and the adsorption of the liquid or solute upon it have been proposed[6].

We ourselves have presented the following equation[2]:

$$\cos\theta = \frac{\sigma_1 + \sigma_w}{\sigma_1}(a\Gamma + b) - 1 \qquad (1)$$

where θ is the contact angle of the wetting liquid (aqueous solution) with a surface tension of σ_1 on the surface of a solid where the solute adsorption of the amount Γ takes place, σ_w, the surface tension of the solvent (water), an a and p, constants. The value a is positive or negative according to whether the adsorption renders the surface hydrophobic or hydrophilic. This equation can be reduced

6) P. A. Rhebinder et al., *Kolloid-Z.*, **65**, 268 (1933); M. A. Cook et al., *J. Phys. Colloid Chem.*, **55**, 1219 (1951); K. S. Doss et al., *Proc. Ind. Acad. Sci.*, **7A**, 117 (1938); M. Wada, *Nippon Kogyo Kaishi*, **59**, 681 (1943) (in Japanese); L. S. Bartell et al., *J. Phys. Chem.*, **64**, 514 (1960).

to Doss' Eq. 5 for wetting by a pure liquid (water) where $\sigma_1=\sigma_w$ and $\Gamma=0$.

We have already confirmed that Eq. 1 is valid both in the case of the wetting of a paraffin surface by an aqueous ethyl alcohol solution and in the case of the dewetting of a galena surface by an aqueous xanthate solution[2]. Now let us apply this equation in the present case to explain the wetting of a polystyrene surface by water. Here σ_1 is equal to σ_w and the equation is simplified to:

$$\cos\theta=2(a\Gamma+b)-1 \qquad (2)$$

In the original Eq. 1, Γ represents the amount of adsorption, which can be interpreted to be the extent of the portion of the surface suffering from the change in wetting properties. It is quite legitimate here to equate Γ with the extent of the surface rendered wettable by the sulfuric acid, or with the degree of surface sulfonation if such an expression may be used for the sake of brevity. Then we can interpret Eq. 2 as the wetting isotherm for the sulfonation of a polystyrene surface. Now if we assume that the amount of cobalt adsorption, x, for the sulfonated surface is proportional to Γ, we have

$$\cos\theta=2(apx+b)-1 \qquad (3)$$

where p is the proportionality constant. We should, however, notice that the untreated surface also gives a cobalt adsorption of the amount x_w. This, together with x, gives the total cobalt adsorption, X, namely

$$X=x+x_w \qquad (4)$$

From Eqs. 3 and 4, we obtain

$$\cos\theta=\cos\theta_w+2ap(X-x_w) \qquad (5)$$

Here $X-x_w$ expresses the net amount of surface sulfonation. From Eq. 5 we should expect a linear relation between $\cos\theta$ and $X-x_w$. Figure 5 shows the experimental results. Here the values of θ were those measured one minute after the samples were dipped in water, and the corresponding X values were measured by the radiotracer method[3]. Now, we can observe a linear relation as a whole, in the cases of both an advancing and a receding contact angle, thus confirming a linear change of wettability with the degree of sulfonation as far as the present experiment is concerned. We can, of course, expect in this diagram that the region of saturation may appear on further attack, where the incerase of $X-x_w$ will no longer result in an increase in $\cos\theta$. This may be explained chiefly by the fact that, under such a condition, the attack may proceed deep under the surface, thus contributing little to the wetting properties of the surface.

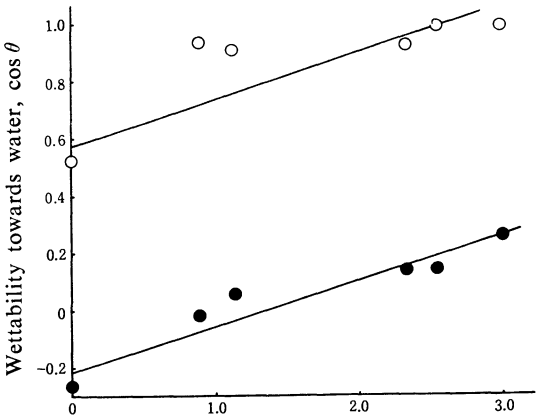

Fig. 5. Change of wettability with degree of surface attack of polystyrene.

Dissolution and Anion Exchange Behavior of the Rare Earth Elements in Potassium and Ammonium Carbonate Solutions

By Tomitsugu TAKETATSU

(Received May 21, 1962)

It has been reported by several investigators[1-4] that tracer amounts of thorium and yttrium, as well as macro amounts of uranium(VI), thorium, cerium(IV) and beryllium, are firmly adsorbed on an anion exchange resin in a carbonate solution. No systematic studies of the dissolution of rare earth carbonates and of the anion exchange behavior of macro amounts of rare earth ions dissolved in a carbonate solution have yet been reported. In the present paper, however, the relation between the amounts of rare earth elements dissolved and the concentration of potassium or ammonium carbonate will be studied. Moreover, the minimum concentration of potassium or ammonium carbonate necessary to dissolve the precipitate of the rare earth carbonate completely will be determined, and the distribution coefficients (K_d) of rare earth ions between an anion exchange resin and a potassium or ammonium carbonate solution more concentrated than the minimum will be measured. The state of the dissolution and the anion exchange behavior of the rare earth elements will be discussed using these results.

Experimental

Standard solutions of rare earth elements were prepared by dissolving the oxides of the elements in dilute hydrochloric acid, while the concentrations of the rare earth ions were determined volumetrically with ethylenediaminetetraacetic acid (EDTA) by using Xylenol Orange as the indicator.

As the anion exchange resin, Dowex 1, X-8 in carbonate form, of a 50~100 mesh, was used.

All the other chemicals used were of analytical reagent grade.

The measurements of the amounts of rare earth elements dissolved and of the distribution coefficients K_d, of rare earth ions between an anion exchange resin and a potassium or ammonium carbonate solution were carried out as follows:

A known amount of the rare earth solution was put into a glass-stoppered conical flask, and the solution was dried on a water bath to remove any excess hydrochloric acid. One hundred milliliters of a series of potassium carbonate solutions of various concentrations was added to the residue in the flask. The precipitate of basic rare earth carbonate was thereby formed. The flask was vigorously shaken by a mechanical shaker for an hour and left to stand overnight to dissolve the precipitate.

(A) When the precipitate was not dissolved completely, it was filtered with No. 5C Toyo filter paper. The precipitate on the filter paper was dissolved in dilute hydrochloric acid, and the solution was poured into a beaker. The rare earth ion in the solution was titrated with EDTA.

(B) When the precipitate was dissolved completely, one gram of the resin was added to the carbonate solution. After the solution had been shaken by a shaker for 3 to 4 hr., the resin was rapidly separated by suction from the solution with a glass filter and transferred into a column. The rare earth element adsorbed on the resin was eluted by dilute hydrochloric acid. Although at the beginning of the elution the resin bed was disturbed by the release of carbon dioxide, it gradually settled down and was packed in the column. This disturbance did not affect the elution, since only the rare earth ion was adsorbed on the resin. The amount of rare earth ion was determined by a method similar to that described above.

All the procedures in the case of ammonium carbonate solution were similar to those used for the potassium carbonate solution, except that, because of the instability of ammonium carbonate, a magnetic stirrer was used instead of a shaker to stir the solution.

All the experiments were carried out at room temperature, which was about 20°C.

Results and Discussion

The quantities of rare earth ions used in this experiment, as well as the quantities of thorium and uranyl ions used for comparison are shown in Table I.

Relation between the Concentration of Potassium or Ammonium Carbonate Added and the Amount of Rare Earth Carbonate Dissolved. —When an excessive amount of a potassium or ammonium carbonate solution was added to the rare earth chloride, the basic rare earth carbonate was precipitated; the precipitate was then dissolved partially or completely by shaking or stirring. The plots of the amounts of the rare earth ions dissolved against various concentrations of potassium and ammonium carbonate are shown in Figs. 1 and 2. The

molar concentration of ammonium carbonate is represented by the molecular formula of $NH_4CO_2NH_2 \cdot NH_4HCO_3$, but the concentration is not accurate owing to the instability of ammonium carbonate.

From these results, it can be seen that the amounts of rare earth elements dissolved increase with the increase in the concentration of carbonate, and also with the increase in atomic number, except for cerium, yttrium and scandium. For example, the precipitates of praseodymium, neodymium, samarium, gadolinium, erbium, yttrium and scandium carbonates are dissolved completely in potassium carbonate solutions more concentrated than about 0.55, 0.45, 0.35, 0.30, 0.25, 0.15 and 0.10 M respectively. The precipitate of lanthanum carbonate could not be dissolved completely even in 1.0 M. As cerium is oxidized to the tetrapositive state in a potassium or ammonium carbonate solution, its behavior differs from that of other rare earth elements. In an ammonium carbonate solution more cnocentrated than 0.2 M, cerium is able to exist as stable orange-yellowish solution; on the other hand, in a potassium carbonate solution more concentrated than 0.4 M, it is dissolved completely

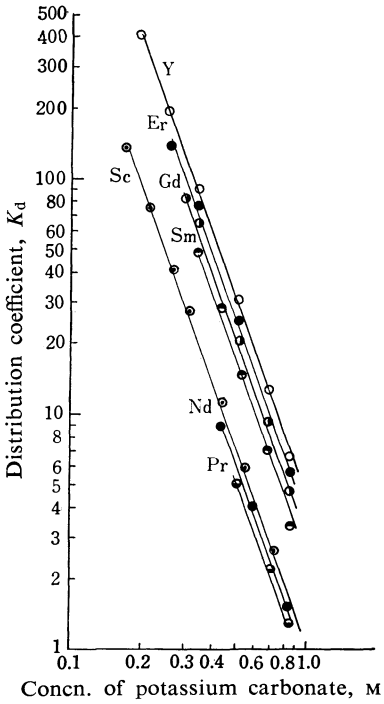

Fig. 5. Distribution coefficient of rare earth ions between Dowex 1 and potassium carbonate solution.

at first, although the precipitate of the carbonate is formed again when the solution is left over night.

Relation between the Adsorbabilities of the Rare Earth Elements and the Concentrations of Potassium and Ammonium Carbonate. — When the precipitates of rare earth carbonates were dissolved completely by the procedure described above, the anion exchange behavior of these elements was studied. The distribution coefficient, K_d, is given by:

$$K_d = [M_r]/[M_s] \quad \text{(ml./g.)}$$

where M_r and M_s represent the amount of rare earth ion in 1 g. of the resin and in 1 ml. of the solution respectively.

The plots of the distribution coefficients, K_d, of rare earth ions against various concentrations of potassium and ammonium carbonates are shown in Figs. 3 and 4. It can be seen that the adsorbability of rare earth elements decreases as the concentration of potassium or ammonium carbonate increases and that the order of the K_d values is Y> Er> Gd > Sm> Sc> Nd> Pr in a potassium carbonate solution. In an ammonium carbonate solution, the K_d value of tetrapositive cerium is larger than that of samarium and the slope of tetrapositive cerium is more similar to that of thorium than to the slopes of other rare earth elements. For purposes of comparison, the K_d values for uranyl and thorium ions in a potassium carbonate solution obtained by the same procedure as that for rare earth ion are shown in Fig. 3. From the distinct difference in the values of K_d, it is expected that the rare earth elements can be effectively separated from uranium(VI) and thorium(IV) by an anion exchange resin, with the potassium carbonate solution as the eluting agent.

A logarithmic diagram of the K_d values of rare earth ions against the concentrations of potassium carbonate is given in Fig. 5. Since the slope of the curve $\log K_d$ vs. $\log (CO_3^{2-})$ shows linearity and since the lines are parallel to one another with a negative slope, it has been concluded, according to a method developed by Kraus et al.[5] for determining the composition of metal complex species using an anion exchange resin, that the rare earth ions dissolved in a carbonate solution have an identical negative charge.

Summary

The amounts of rare earth elements dissolved in potassium and ammonium carbonate solutions of various concentrations have been

5) K. A. Kraus and F. Nelson, "Anion Exchange Studies of the Fission Products" in "Peaceful Uses of Atomic Energy", Proceedings of the International Conference in Geneva (United Nations) Vol. VII, (1955), p. 113.

determined. These amounts increase with the increase in the concentration of the carbonate and also with the increase in atomic number, except for cerium, yttrium and scandium. When the precipitates of the rare earth elements were completely dissolved in carbonate solutions more concentrated than a certain known concentration, the distribution coefficients, K_d, of the rare earth carbonate ions between an anion exchange resin of a carbonate form and potassium or ammonium carbonate solutions of various concentrations were determined. The values of K_d increased both with the decrease in the concentration of carbonate ions and with the increasing atomic number of the rare earth elements. Since the slopes of the curve $\log K_d$ vs. $\log(CO_3^{2-})$ in a potassium carbonate solution are found to be almost the same value for all the rare earth elements investigated, it has been concluded that the soluble complex of rare earth elements possesses an identical negative charge.

The author wishes to express his gratitude to Professor S. Misumi for his valuable discussions and encouragement.

Influence of Substituent Groups on Nuclear Reactivity in the Formation of Substituted Biphenyls by Reaction of Aromatic Diazo and Related Compounds with Aromatic Liquids. V. Phenylation of Nitrobenzene and Anisole

By Takashi INUKAI, Katsumi KOBAYASHI and Osamu SIMAMURA

(Received May 22, 1962)

A semi-quantitative determination of the partial rate factors for nitrobenzene in the homolytic phenylation by phenyl radicals produced by decomposition of *N*-nitrosoacetanilide and of diazobenzene hydroxide was reported in Part I[1] of this series. Subsequent quantitative experiments[2] on various substiuted benzenes using column chromatography, spectrophotometry, etc., showed that the reactivity towards the phenylation differs rather slightly from compound to compound. Consequently for the comparison of the values of partial rate factors obtained from competitive phenylation to be significant it became necessary to improve the precision of the product analysis. We accordingly have adopted the radioisotope dilution analysis as reliable means accurate enough for the desired determination, and we now report the partial rate factors for phenylation of nitrobenzene and of anisole obtained by this method.

N-Nitrosoacet(anilide-^{14}C) was allowed to decompose in a large excess of a mixture of known amounts of benzene and nitrobenzene at 20°C. The reaction mixture was analyzed for biphenyl and the three isomeric nitrobiphenyls by the isotope dilution method. The results are presented in Table I. The results of a similar experiment in a mixture of benzene and anisole at 20°C are shown in Table II. The partial rate factors, the relative rates compared with the rate for benzene and the isomer distributions derived from the data shown in these tables are listed in Table III.

The high precision of the present analytical method is evident from the agreement of two independent determinations of the yield of biphenyl in any of the three experiments, as will be seen from the last columns of Tables I and II. Such an excellent agreement, however, was not observed in the partial rate factors for nitrobenzene calculated from the data of Exps. 1 and 2. This is deemed not due to defects in the analytical method, but apparently due to incontrollable minor fluctuations in experimental conditions, which we do not intend to study further for the present.

Recently Hey, Orman and Williams[3] redetermined the relative rate of the homolytic

phenylation of nitrobenzene by phenyl radicals produced by decomposition of benzoyl peroxide and revised the former value[4], which was considered as a maximum value since it was based on results which may be subject to an error due to loss of rather volatile biphenyl during the course of the analysis. Obviously the isotope dilution analysis adopted in the present work is not liable to such errors due to fractionation of components to be determined. The revised value of 2.94 for the relative rate leads to new values for the partial rate factor of 5.5, 0.86 and 4.9 for the *o*-, *m*- and *p*-position, respectively, of nitrobenzene, whereas the present authors' corresponding values are 9.38, 1.16 and 9.05, respectively, for the phenylation by phenyl radicals produced by the decomposition of *N*-nitrosoacetanilide. The discrepancy between these two sets of values could be accounted for partly on the ground that, although both reactions are of the homolytic nature, the detailed mechanism may not necessarily be the same. But a more important cause is probably the difference in reaction temperature; the decomposition of *N*-nitrosoacetanilide was carried out at 20°C, whereas that of benzoyl peroxide at 80°C, and elevation of the reaction temperature would tend to change the partial rate factors towards unity, it being assumed that both reactions proceed

TABLE III. PARTIAL RATE FACTORS, RELATIVE RATES AND ISOMER DISTRIBUTION IN PHENYLATION OF NITROBENZENE AND ANISOLE

Compound PhX		Partial rate factors			Relative rates	Isomer distribution of $C_6H_5C_6H_4X$, %		
		o	*m*	*p*		*o*	*m*	*p*
$PhNO_2$	Exp. 1	8.95	1.14	8.82	4.83	61.8	7.8	30.4
	Exp. 2	9.80	1.17	9.28	5.20	62.8	7.4	29.8
	Mean	9.38	1.16	9.05	5.02	62.3	7.6	30.1
PhOMe		3.56	0.93	1.29	1.71	69.3	18.1	12.6

by the same mechanism and that the frequency factor in the Arrhenius equation remains constant. Thus it is readily shown that partial rate factors $f(T_1)$ and $f(T_2)$, at two temperatures, T_1 and T_2, are related with each other by the following equation:

$$T_1 \log f(T_1) = T_2 \log f(T_2)$$

Substitution of the value for the partial rate factor of the *o*-position obtained by the *N*-nitrosoacetanilide reaction and of the corresponding value by the benzoyl peroxide reaction for $f(T_1)$ and $f(T_2)$ in this equation, respectively, gives 1.31 as the value for T_2/T_1, which should actually be $353/293=1.20$. A similar substitution of the values for the *p*-position gives 1.39. The approximate agreement of these values with the actual value seems to indicate the validity of this explanation for the observed difference in the partial rate factors, although the values for the meta position give no reasonable value for T_2/T_1. Huisgen and Grashey[5] quoted a value of 2.0 for the relative rate of phenylation of anisole by means of *N*-nitrosoacetanilide at 25°C. This value is fairly close to our value of 1.71. As there are no previous data for the partial rate factors for anisole available for comparison, we have calculated, similarly to Williams's calculation[6], the partial rate factors by using the free valence values, 0.422, 0.395 and 0.406 for the *o*-, *m*- and *p*-position of phenol, respectively, derived from Sandorfy's bond order values[7]. In adopting these values as the free valence values of anisole we have neglected the polar effect of the methyl group, which tends to lower the electronegativity of the oxygen atom. The predicted values for the partial rate factors at 20°C are 4.06, 0.84 and 1.60 for the *o*-, *m*- and *p*-position, which compare favourably with the present experimental values of 3.56, 0.93 and 1.29.

Although separate experiments[8] show that the abstraction of a hydrogen atom by aryl radicals produced from *N*-nitrosoacetanilides occurs only to a very limited extent in an aromatic compound which contains no reactive methyl group, in the decomposition of *N*-nitrosoacetanilide in a mixture of anisole and benzene the phenyl radicals generated should readily abstract a hydrogen atom from the methyl group of anisole resulting in the formation of benzene-^{14}C. To examine this probability the benzene recovered from the reaction mixture was nitrated with a mixture of fuming nitric acid and concentrated sulphuric acid, and the resulting *m*-dinitrobenzene was recrystallized from ethanol to give a specimen of a constant activity of 0.018 ± 0.001 mc./mol. This value corresponds to the production of 0.30 ± 0.02 mmol. of benzene-^{14}C, and shows that 15.4% of the phenyl radicals generated and accounted for as biphenyls and benzene gave benzene by abstracting a hydrogen atom.

Experimental

All melting points are corrected.

Materials.—Thiophene-free benzene was purified by repeated fractional freezing, m. p. 5.7°C. Nitrobenzene, prepared from the above benzene by nitration, was fractionally distilled and further purified by repeated fractional freezing, m. p. 5.7°C. Anisole was prepared by methylation of purified phenol and purified by distillation and fractional freezing, m. p. −37.5°C.

Commercial biphenyl was repeatedly recrystallized from 90% ethanol and sublimed under reduced pressure, m. p. 70°C.

Nitrobiphenyls and 4-methoxybiphenyl were prepared from the corresponding nitroanilines and anisidine by the Gomberg-Bachmann reaction[9] and purified by recrystallization from methanol; the melting points were: 2-NO_2, 37; 3-NO_2, 61; 4-NO_2, 113.5; and 4-MeO, 91°C.

2-Methoxybiphenyl was similarly prepared from *o*-anisidine, recrystallized twice from petroleum ether, and converted into 2-hydroxybiphenyl, m. p. 58.5°C (from petroleum ether), by heating (210~220°C, 16 hr.) with pyridine hydrochloride[10], and

this compound was methylated with dimethyl sulphate again to afford pure 2-methoxybiphenyl, m. p. 32°C (from methanol).

3-Methoxybiphenyl was prepared from 3-nitrobiphenyl by reduction to 3-aminobiphenyl (b. p. 187~188°C/18 mmHg), diazotization and hydrolysis in diluted sulphuric acid at 65°C to give 3-hydroxybiphenyl, m. p. 76.8°C (from petroleum ether), which was then methylated with dimethyl sulphate to afford pure 3-methoxybiphenyl, b. p. 159°C (12 mmHg), a colourless oil.

N-Nitrosoacet(anilide-^{14}C) was prepared from benzene-1-^{14}C (The Radiochemical Centre, Amersham) by nitration and catalytic reduction to aniline followed by acetylation and finally by nitrosation of the resulting acetanilide. The experimental procedure is described elsewhere[11].

Decomposition of *N*-Nitrosoacet(anilide-^{14}C) in a Mixture of Benzene and Nitrobenzene.—The results are tabulated in Table I. *N*-Nitrosoacet-(anilide-^{14}C) with a specific activity of 14.45 mc./mol., (920.42 mg., 5.607 mmol.) was dissolved in a mixture of 52.0 g. of benzene (666.7 mmol.) and 82.0 g. of nitrobenzene (666.7 mmol.) maintained at 20.0°C in a thermostat and allowed to decompose until at last the nitrogen evolved reached a final value of 68% of the theoretical. A portion (A, 42.578 g.) was weighed out from the reaction mixture (133.697 g.), and to this portion were added 0.9975 g. (6.472 mmol.) of biphenyl, 1.7011 g. (8.540 mmol.) of *o*-nitrobiphenyl, and 1.0924 g. (5.484 mmol.) of *p*-nitrobiphenyl. From the resulting solution benzene and nitrobenzene were removed under reduced pressure. The residue was distilled through a Vigreux column 15 cm. in height giving a biphenyl fraction, b. p. 117~120°C (6.5 mmHg), an *o*-nitrobiphenyl fraction, b. p. 140~150°C (5 mmHg), and a *p*-nitrobiphenyl fraction, b. p. 155~160°C (5 mmHg). Biphenyl and *o*-nitrobiphenyl were purified by chromatography on activated alumina in petroleum ether, and *p*-nitrobiphenyl was purified by chromatography on acetivated alumina in 1 : 1 mixture of petroleum ether and benzene. Another portion (B, 45.335 g.) was taken from the original reaction mixture, and to this portion were added 0.4962 g. (3.221 mmol.) of biphenyl and 0.4972 g. (2.496 mmol.) of *m*-nitrobiphenyl. The mixture was worked up as above, that is, by distillation to give a biphenyl and a *m*-nitrobiphenyl fraction and by chromatography of these fractions on activated alumina in petroleum ether. The two specimens of biphenyl from portion A and portion B were finally purified by repeated recrystallizations from 90% ethanol and sublimation under vacuum (1~2 mmHg). Nitrobiphenyls were further purified by recrystallization from methanol. The purification was deemed complete when the specific activity of a specimen remained constant on further recrystallization. A second experiment was carried out in a similar way.

Decomposition of *N*-Nitrosoacet(anilide-^{14}C) in a Mixture of Benzene and Anisole.—The results are summarized in Table II. *N*-Nitrosoacet(anilide-^{14}C) with a specific activity of 14.18 mc./mol., (637.43 mg., 3.883 mmol.), was dissolved in a mixture of 18.08 g. of benzene (231.4 mmol.) and 80.22 g. of anisole (741.8 mmol.) and allowed to decompose at 20.0°C; nitrogen evolved amounted to 82.5% of the theoretical value. Two portions (A, 49.030 g., and B, 48.904 g.) were weighed out from the reaction mixture (98.296 g.). To portion A were added 0.4942 g. (3.204 mmol.) of biphenyl, 1.3061 g. (7.089 mmol.) of 2-methoxybiphenyl, and 0.7393 g. (4.018 mmol.) of 4-methoxybiphenyl, and from the resulting solution benzene and anisole were removed under reduced pressure. The residue was dissolved in a mixture of petroleum ether and benzene (4 : 1), and subjected to chromatography on activated alumina in petroleum ether to afford biphenyl, 2-methoxybiphenyl and 4-methoxybiphenyl by elution with petroleum ether (b. p. 40~60°C). To portion B above were added 0.5982 g. (3.879 mmol.) of biphenyl and 1.1281 g. (6.123 mmol.) of 3-methoxybiphenyl, and from the resulting solution benzene and anisole were removed under reduced pressure. The residue was chromatographed on activated alumina in petroleum ether to give biphenyl and 3-methoxybiphenyl. The specimens of biphenyl from portions A and B were purified by recrystallization and sublimation as in the experiments in a mixture of nitrobenzene and benzene. 2- and 4-Methoxybiphenyl were purified by repeated recrystallizations from methanol. The oily 3-isomeride was converted into 3-hydroxybiphenyl by heating with pyridine hydrochloride, and this was purified by repeated recrystallizations from petroleum ether to a constant activity of 0.281±0.002 mc./mmol.

Radioactivity Determination.—Radiocarbon assays were carried out by oxidizing samples according to the method of Van Slyke and Folch[12] and by converting the resulting carbon dioxide into barium carbonate, the activity of which was then counted with an end-window Geiger-Müller counter on an "infinitely thick" layer.

Summary

N-Nitrosoacet(anilide-^{14}C) has been decomposed at 20°C in a mixture of benzene with nitrobenzene or with anisole, and the reaction products have been analyzed for biphenyl and isomeric nitrobiphenyls or isomeric methoxybiphenyls by isotope dilution method. From these results the partial rate factors for the phenylation have been calculated to be for nitrobenzene: *o*, 9.38; *m*, 1.16; and *p*, 9.05; and for anisole: *o*, 3.56; m, 0.93; and *p*, 1.29.

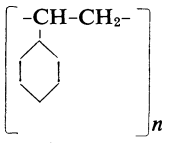
The Solution Behavior of Polystyrene Derivatives: Poly-p-chlorostyrene

By Takahide SAITO



(Received May 23, 1962)

It has been revealed by the studies of the viscosity and light-scattering characteristics of polymers that the solution behavior of polymers is, in general, affected by the polarity of the solvent, the branching of the polymer, the structure and the configuration of the monomer unit, etc. Therefore, it has been interesting for the present author to study the solution properties of polystyrene derivatives, especially the effects of the variation in monomer structure on their solution behavior.

In this paper the viscosity and light-scattering characteristics of poly-*p*-chlorostyrene in butanone and in toluene have been compared with those of polystyrene.

Poly-*p*-chlorostyrene

Polystyrene

Experimental

Materials. — *p*-Chlorostyrene[1],* was redistilled under reduced pressure (b. p., 69.0°C/20 mmHg) before use. The monomer (ca. 70 g.) was sealed in a glass tube and polymerized without an initiator for 48 hr. at 100°C. Then the polymerization product was dissolved in butanone, and the polymer was precipitated with methanol. Reprecipitation was carried out twice, and, after being washed with methanol, the polymer was dried under reduced pressure. The conversion rate was about 87%.

Butanone was refluxed with potassium permanganate for one day in order to oxidize some organic impurities. The butanone distilled from this mixture was dried with potassium carbonate for a week and then redistilled. The fraction (b. p., 79.5~80.0°C) was used. Toluene was washed successively with sulfuric acid, water, a dilute solution of sodium hydroxide, and finally again with water until it was neutralized. It was then dried with metallic sodium and distilled. The fraction which distilled at 110.0~110.5°C was used.

The sample of poly-*p*-chlorostyrene was divided into two parts; each part was independently fractionated as follows: About 20 g. of polymer was dissolved in one liter of butanone. Ten fractions were fractionally precipitated with methanol by the successive precipitation method at 35°C. Each fraction was redissolved in butanone and was precipitated to eliminate the part with a lower molecular weight. Seven fractions were used for the measurements in butanone, and six in toluene.

Measurements.—The solutions for the light-scattering and viscosity studies were rendered free from dust by centrifuging for one hour at 20000 g., using a "Spinco Ultra Centrifuge, Type E" and were filtered into the light-scattering cell or into the reservoir of the viscometer, through a sintered glass filter No. 5, just before the measurements. The viscosity measurements were carried out on the butanone solutions at 25°C and on the toluene solutions at 30°C. A conventional Ubbelohde viscometer was modified so that successive dilution could be performed. The intrinsic viscosity, $[\eta]$, and the Huggins constant, k', were obtained according to the equation:

$$\eta_{sp}/C=[\eta]+k'[\eta]^2C$$

where η_{sp} is the specific viscosity and C is the concentration of polymer in g./100 ml.

An Aminco photometer[2] was used for the measurements of the light scattering. Measurements covering the angular range of 30~140° were performed at room temperature; the wavelengths used for the measurements were 436 mμ and 546 mμ. The weight-average molecular weight, M_w, the second virial coefficient, A_2, and the z-average-root-mean-square-end-to-end distance, $<D^2>_z^{1/2}$, were calculated, using the Zimm plot, according to the equations:

$$KC/R_\theta=1/M_wP(\theta)+2A_2CP(\theta)$$

$$K=2\pi^2n_0^2(dn/dc)^2/N_A\lambda^4$$

where

$P(\theta)$: the factor expressing the reduction in scattered intensity at angle θ
λ : the wavelength of light in vacuum
N_A : Avogadro's number
R_θ : Rayleigh ratio at angle θ

R_θ is calculated according to the equation[3]:

$$R_\theta=(n_0^2/\pi h)\,Y(G_\theta/G_0^p)S_dXV$$

where

G_θ: the galvanometer reading at angle θ
G_0^p: the galvanometer reading at angle 0° when the incident beam falls to photo tube through the opal-glass standard diffuser located at the center of the cell holder
S_d: the transmittance of the opal-glass standard diffuser,
T : the total transmittance of the neutral filters used in measuring G_0^p

* The monomer used was synthetized by the author of Ref. 1.

3) D. K. Carpenter and W. R. Krigbaum, *J. Chem. Phys.*, **24**, 1041 (1956).

h : the width of the slit of the receiver
n_0 : the refractive index of pure solvent
X : a calculation constant determined by the Rayleigh ratio of benzene, 48.5×10^{-6}
V : the volume correction approximated by $1/\sin\theta$

The values of dn/dc, the increments of the refractive index of the solution with concentration, were determined by a Zeiss interferometer to be 0.212 ml./g. in butanone and 0.106 ml./g. in toluene at room temperature.

Results and Discussion

Results.—The plots of the reduced viscosity, η_{sp}/C, vs. the concentration, C, in butanone and in toluene are shown in Figs. 1 and 2 respectively, and the intrinsic viscosity, $[\eta]$, and the Huggins constant, k', are determined from these plots. The Zimm plots for A–6 in butanone and B 2–2 in toluene are shown in Figs. 3 and 4 as examples of the light-scattering measurements. The weight-average molecular weight, M_w, the second virial coefficient, A_2, and the z-average-root-mean-square-end-to-end distance, $\langle D^2\rangle_z^{1/2}$, for each fraction are determined from these figures.

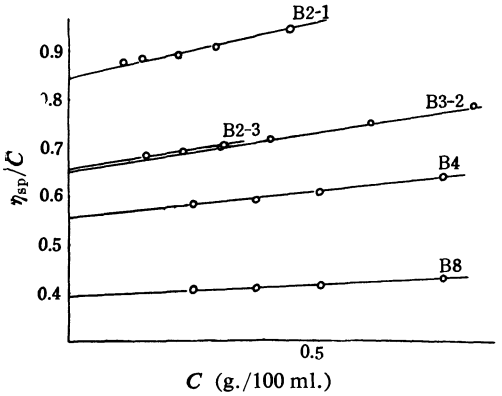

Fig. 2. Relation between reduced viscosity and concentration of poly-*p*-chlorostyrene in toluene at 30°C.

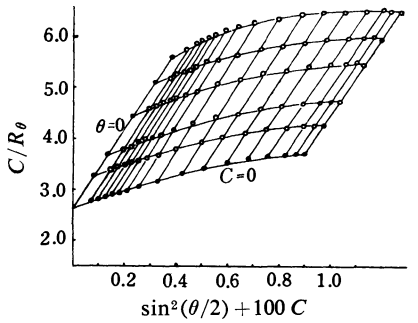

Fig. 3. Zimm plot of poly-*p*-chlorostyrene fraction A 6 in butanone for $\lambda=436$ mμ.

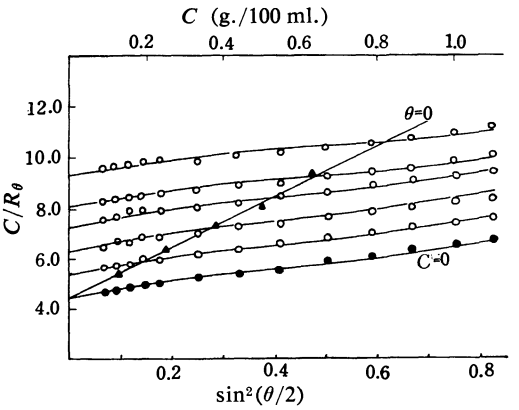

Fig. 4. Incomplete Zimm plot of poly-*p*-chlorostyrene fraction B 2-2 in toluene for $\lambda=436$ mμ. Upper abscissa shows concentration and lower abscissa shows $\sin^2(\theta/2)$. Plots of C/R_θ vs. concentration for each angle except a line for $\theta=0°$ are not shown in this figure.

The results of the viscosity and light-scattering measurements in butanone and in toluene are summarized in Tables I and II respectively.

The molecular weight (degree of polymerization) dependences of the intrinsic viscosity, $[\eta]$, the z-average-root-mean-square-end-to-end distance, $\langle D^2\rangle_z^{1/2}$, and the second virial coefficient, A_2, are usually represented by the equations:

$$[\eta]=KM_w^{\alpha} \tag{1}$$

$$\langle D^2\rangle_z^{1/2}\sim M_w^{\beta} \tag{2}$$

$$A_2\sim M_w^{\gamma} \tag{3}$$

where the constants, K, α, β and γ, are experimentally determined from a plot of $\log X$ against $\log M_w$ (or $\log P$), where X is $[\eta]$, A_2,

or $<D^2>_z^{1/2}$ *. The log-log plots of the intrinsic viscosity, the second virial coefficient and the end-to-end distance against the molecular weight are shown in Figs. 5, 6 and 7 respectively.

Equations 1, 2 and 3 for poly-*p*-chlorostyrene are

$[\eta]=2.9_4\times10^{-4}M_w^{0.59}$ in butanone at 25°C
$[\eta]=1.2_8\times10^{-4}M_w^{0.64}$ in toluene at 30°C
$<D^2>_z^{1/2}\sim M_w^{0.55}$ in butanone
$<D^2>_z^{1/2}\sim M_w^{0.60}$ in toluene
$A_2\sim M_w^{-0.17}$ in butanone
$A_2\sim M_w^{-0.40}$ in toluene

Discussion.—A solvent, the polymer solution of which shows a higher value of A_2, $<D^2>_z^{1/2}$ or $[\eta]$, is called a "*good*" solvent. In the case of poly-*p*-chlorostyrene, butanone is considered to be a better solvent than toluene according to this definition, because poly-*p*-chlorostyrene in the former solvent shows higher values of A_2 and of $<D^2>_z^{1/2}$ than in the latter.

To discuss the influence of the substituent in the para position of the benzene ring on the solution behavior, the constants, K, α, β and γ, for poly-*p*-chlorostyrene and polystyrene

- - -PS : Polystyrene-butanone
-□- : Poly-*p*-chlorostyrene-toluene
-○- : Poly-*p*-chlorostyrene-butanone

* The value shown as $<D^2>_z^{1/2}$ gives the length $\sqrt{6}$ times as long as the root-mean-square radius of gyration, and it gives the end-to-end distance only in the case of the Gaussian chain. For convenience, however, the value is used as a relative measure of chain extension in the case of the non-Gaussian chain also.

TABLE III. COMPARISON OF THE DEPENDENCES OF SOLUTION BEHAVIORS ON MOLECULAR WEIGHT FOR POLYSTYRENE AND POLY-*p*-CHLOROSTYRENE IN BUTANONE AND TOLUENE

Solvent	Polymer	$K\times10^4$	α	β	γ
Butanone 25°C	Poly-*p*-chlorostyrene	2.9	0.59	0.55	−0.17
	Polystyrene	3.9	0.58	0.58	−0.23
Toluene 30°C	Poly-*p*-chlorostyrene	1.2	0.64	0.60	−0.40
	Polystyrene	1.3	0.70	0.68	−0.33

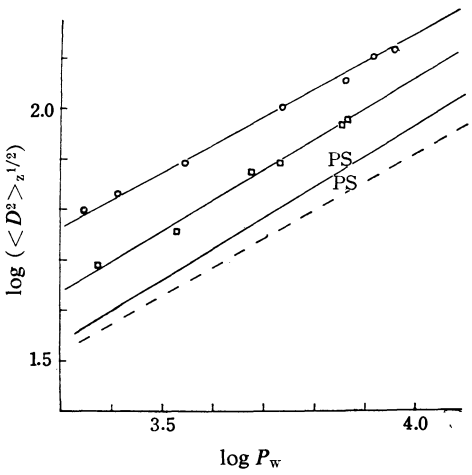

Fig. 6. Comparison of extensions of chain for poly-*p*-chlorostyrene in toluene and butanone with those of polystyrene at the same degree of polymerization.

-□-: Poly-*p*-chlorostyrene-toluene
-○-: Poly-*p*-chlorostyrene-butanone
—PS: Polystyrene-toluene
- - -PS: Polystyrene-butanone

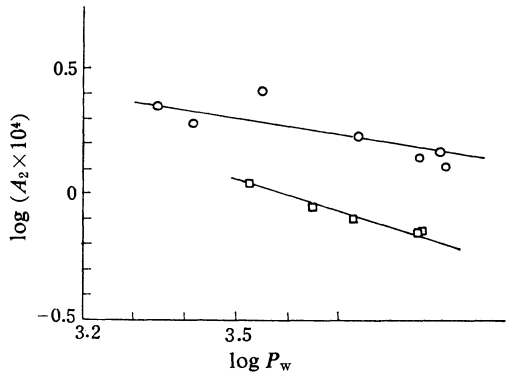

Fig. 7. Relation between second virial coefficient and degree of polymerization of poly-*p*-chloro-styrene.

-□-: Poly-*p*-chlorostyrene-toluene
-○-: Poly-*p*-chlorostyrene-butanone

are summarized and compared in Table III **.

The values of the K, α, β and γ of poly-*p*-chlorostyrene are nearly the same as those of polystyrene.

Moreover, some interesting results in their solution behavior may be deduced from a detailed comparison. (1) The value of the $[\eta]$ of poly-*p*-chlorostyrene in toluene is smaller than that of polystyrene. (2) The $[\eta]$ of polystyrene in butanone is nearly the same as that of poly-*p*-chlorostyrene. (3) The values of the $\langle D^2\rangle_z^{1/2}$ of polystyrene in butanone and toluene are all smaller than those of poly-*p*-chlorostyrene. (4) The values of $[\eta]$ and $\langle D^2\rangle_z^{1/2}$ for poly-*p*-chlorostyrene in toluene are smaller than those in butanone.

Generally speaking, it is not exact to define a solvent as a "*good*" or "*bad*" solvent only on the basis of a comparison of the chain extensions of various polymers in a solvent regardless of differences in their structures. However, when the basic structures of the chain molecules are similar to one another, a comparison of the chain extensions in a solvent may be used as a relative measure of the effects of solvent on polymer configurations.

On the basis of the third result described above, it may be said that both butanone and toluene act as better solvents for poly-*p*-chlorostyrene than polystyrene.

To show this result more clearly, the ratio for polystyrene and poly-*p*-chlorostyrene of $\langle D^2\rangle_z^{1/2}$ to D_f, where D_f is the end-to-end distance, assuming a free rotation model for the chain configuration, are compared in Table IV at the weight-average degree of polymerization of $p_w=10^4$. To obtain quantitative information on the effect of the solvent on chain extension, it is necessary to take, as a parameter to be used for comparison, a ratio of $\langle D^2\rangle_z^{1/2}/\langle D_0^2\rangle_z^{1/2}$ instead of $\langle D^2\rangle_z^{1/2}/D_f$,

** The formulas which have been reported for the dependence of the intrinsic viscosity of polystyrene are;

$[\eta]=1.7\times10^{-4}M_w^{0.69}$ in toluene at 25°C[4]
$[\eta]=1.2\times10^{-4}M_w^{0.71}$ in toluene at 30°C[5]
$[\eta]=0.92\times10^{-4}M_w^{0.74}$ in toluene at 30°C[6]
$[\eta]=3.9\times10^{-4}M_w^{0.58}$ in butanone at 25°C[4]
$[\eta]=2.3\times10^{-4}M_w^{0.62}$ in butanone at 30°C[7]

The equation quoted in Table III seems to be appropriate with regard to the temperature and to the measured range of the molecular weight.

TABLE IV. VALUES OF $<D^2>_z^{1/2}/D_f$ FOR POLYSTYRENE AND POLY-*p*-CHLOROSTYRENE IN BUTANONE AND TOLUENE AT $P_w=10^4$. VALUES OF POLYSTYRENE ARE CALCULATED FROM THE DATA IN REFS. 4 AND 5.

Polymer	$<D^2>_z^{1/2}/D_f$ Solvent	
	Butanone	Toluene
Poly-*p*-chlorostyrene	3.23	2.65
Polystyrene	1.86	2.14

where $<D_0^2>_z^{1/2}$ is a z-average-root-mean-square-end-to-end distance of an unperturbed chain, because the unperturbed extension of polymer molecules with different structures varies according to differences in the dipole-dipole interaction and in the steric effects of the substituents. However, even though the values of $<D^2>_z^{1/2}/D_f$ are directly related to the effects of solvents on the polymer configuration in solution, it should be noted that the dimensions of poly-*p*-chlorostyrene in butanone are particularly extensive compared with the dimensions of poly-*p*-chlorostyrene in toluene and/or of polystyrene in toluene and butanone.

According to Flory and Fox, the relation between the intrinsic viscosity and the end-to-end distance for a linear polymer may be expressed as follows:

$$[\eta]=\Phi\frac{<D^2>_z^{3/2}}{M_w} \qquad (4)$$

where Φ is defined as an universal constant independent of the temperature, solvent and basic structure of the polymer[8]. Therefore, when Φ is a constant regardless of the solvent, the same tendencies must exist in the relations between $[\eta]$ and solvents as in the case of $<D^2>_z^{1/2}/D_f$. However, the experimental results with reference to the intrinsic viscosity which are summarized above as results 1 and 2 are not in accord with result 3. These conflicting results are substantially derived from the differences of the Φ of poly-*p*-chlorostyrene in the two solvents, as is shown in Tables I and II. The author can not explain at present why the values of Φ in the two solvents differ.

Summary

The polar group in the para position of the benzene ring of poly-*p*-chlorostyrene has a remarkable influence on the solution behavior and that, especially, the chain in the polar solvent is particularly extensive because of the interaction between the C–Cl group in the para position and the polar solvent.

The author is deeply grateful to Professor Akira Kotera and Professor Keizo Suzuki for their helpful suggestions and discussion. He also wants to thank Dr. Hideomi Matsuda and Dr. Yuji Miyazawa, who made some of the measurements of viscosity and light scattering, and Miss Michiko Takahashi, who made the centrifuging of the solutions, for their kindness. This research was supported in part by a Scientific Research Encouragement Grant from the Ministry of Education, to which the author's thanks are due.

Electronic Interactions between Molecules and Atoms (Radicals) Involving Excited States

By Yuji MORI

(Received February 21, 1961)

A number of reactions can be discussed from the standpoint of the potential-energy surface[1]. The chemical reactivity of conjugated molecules for a radical attack can sometimes be interpreted in terms of the enegy change of the ground state of the system arising from the radical attack[2]. The quenching of excited (^{2}P) sodium by a molecule is interpreted on the basis of the potential-energy surfaces[3] of the system, involving the excited state of the sodium

2) R. D. Brown, *J. chim. phys.*, **50**, 109 (1953).

3) K. J. Laidler, "Chemical Kinetics of Excited States", Oxford University Press, London (1955).

atom. In the present paper the chemical reactivity of conjugated molecules and the quenching of excited sodium will be discussed on the basis of the electronic structures of the molecules by giving the energy change for a radical attack or the potential-energy surfaces of the system. The importance of the lowest triplet states of molecules in their chemical reactivity to a radical attack, in addition to the role of the electron-transfer states in the quenching of excited sodium, will be discussed.

In previous papers[4,5], the present author has given a theoretical interpretation of the electronic spectrum of the benzyl radical under the assumption that the benzyl radical is composed of a benzene ring and a methylene radical. Since the electronic system, composed of an atom (or a radical) and a molecule, is similar to that of the benzyl radical, a theoretical treatment similar to those of the previous papers will be undertaken in the present work.

Wave Functions

The configurational wave functions of the whole system can be written as follows:

a) Doublet states ($M_S=+1/2$)

$$\Psi_0=\phi_0\cdot\chi_0^\alpha$$

$$\Psi_S(i-l)=\phi_s(i-l)\cdot\chi_0^\alpha$$

$$\Psi_T^1(i-l)=1/\sqrt{3}\{\phi_i^0(i-l)\cdot\chi_0^\alpha-\sqrt{2}\phi_i^1(i-l)\cdot\chi_0^\beta\}$$

$$\Psi_X=\phi_0\cdot\chi_1^\alpha$$

$$\Psi_C(i-\chi_0)=(1^\alpha1^\beta\cdots\cdots i^\alpha\cdots\cdots n^\alpha n^\beta\chi_0^\alpha\chi_0^\beta)$$

$$\Psi_C(\chi_0-l)=(1^\alpha1^\beta\cdots\cdots n^\alpha n^\beta l^\alpha)$$

b) Quartet states ($M_S=+3/2$)

$$\Psi_T^2(i-l)=\phi_i^1(i-l)\cdot\chi_0^\alpha$$

where $\phi_s(i-l)$, $\phi_i^0(i-l)$ and $\phi_i^1(i-l)$ are the wave functions of the excited states of the molecule, in which one electron has been excited from an occupied MO (i) to a vacant MO (l).

$$\phi_0=(1^\alpha1^\beta\cdots\cdots i^\alpha i^\alpha\cdots\cdots n^\alpha n^\beta)$$

$$\phi_s(i-l)=1/\sqrt{2}\{(1^\alpha1^\beta\cdots\cdots i^\alpha l^\beta\cdots\cdots n^\alpha n^\beta)-(1^\alpha1^\beta\cdots\cdots i^\beta l^\alpha\cdots\cdots n^\alpha n^\beta)\}$$

$$\phi_i^0(i-l)=1/\sqrt{2}\{(1^\alpha1^\beta\cdots\cdots i^\alpha l^\beta\cdots\cdots n^\alpha n^\beta)+(1^\alpha1^\beta\cdots\cdots i^\beta l^\alpha\cdots\cdots n^\alpha n^\beta)\}$$

$$\phi_i^1(i-l)=(1^\alpha1^\beta\cdots\cdots i^\alpha l^\alpha\cdots\cdots n^\alpha n^\beta)$$

The abbreviations are as follows:

i: an occupied MO of the molecule
l: a vacant MO of the molecule
χ_0: the singly occupied orbital in the ground state of the atom (or the radical)
χ_1: an excited orbital of the atom

In the above wave functions, Ψ_0, $\Psi_S(i-l)$, $\Psi_T^1(i-l)$ and Ψ_X correspond to the ground state, the excited singlet state $\phi_s(i-l)$, the triplet state $\phi_t(i-l)$ and the excited state of the atom respectively. $\Psi_T^2(i-l)$ corresponds to the triplet state. $\Psi_C(i-\chi_0)$ and $\Psi_C(\chi_0-l)$ show the electron-transfer configurations from i to χ_0 and from χ_0 to l respectively.

The energies and wave functions of the resulting states of the whole system can be given by solving the secular determinant. However, in order to avoid complications, a simplification of the treatment will be undertaken.

Reactivity of Conjugated Molecules

The object in this section is to find the energy change of the ground state of the whole system arising from interaction, relative to that in a large intermolecular distance where there is no interaction between the molecule and the radical.

In some theories of the chemical reactivity of conjugated molecules which have dealt with the energy of the reacting system by explicitly taking into account the interaction between the molecule and the radical[2,6], only the effect of the electron transfer has been discussed; no discussion has been given of the effect of the exchange of electrons. It is supposed that interaction by exchange of electrons between the molecule and the radical is as important as that by electron transfer, because the bond between the molecule and the radical may have the character of a σ-bond rather than of a π-bond in the activated complex.

From this viewpoint, the problem will be treated by taking into account the following configurational wave functions of the whole system:

$$\Psi_0,\ \Psi_S(i-l),\ \Psi_T^1(i-l),\ \Psi_C(i-\chi_0),\ \Psi_C(\chi_0-l)$$

By applying a perturbation theory for the small interactions, the energy of the ground state, W_0, is obtained as follows:

$$W_0=(\Psi_0\mathrm{H}\Psi_0)+\sum_i^{\mathrm{occ}}\sum_l^{\mathrm{vac}}\left\{\frac{(\Psi_0\mathrm{H}\Psi_S(i-l))^2}{(\Psi_0\mathrm{H}\Psi_0)-(\Psi_S(i-l)\mathrm{H}\Psi_S(i-l))}+\frac{(\Psi_0\mathrm{H}\Psi_T^1(i-l))^2}{(\Psi_0\mathrm{H}\Psi_0)-(\Psi_T^1((i-l)\mathrm{H}\Psi_T^1(i-l))}\right\}+\sum_i^{\mathrm{occ}}\frac{(\Psi_0\mathrm{H}\Psi_C(i-\chi_0))^2}{(\Psi_0\mathrm{H}\Psi_0)-(\Psi_C(i-\chi_0)\mathrm{H}\Psi_C(i-\chi_0))}+\sum_l^{\mathrm{vac}}\frac{(\Psi_0\mathrm{H}\Psi_C(\chi_0-l))^2}{(\Psi_0\mathrm{H}\Psi_0)(\Psi_C(\chi_0-l)\mathrm{H}\Psi_C(\chi_0-l))}$$

4) Y. Mori, This Bulletin, **34**, 1031 (1961).
5) Y. Mori, ibid., **34**, 1035 (1961).
6) K. Fukui, T. Yonezawa and C. Nagata, *J. Chem. Phys.*, **27**, 1274 (1957).

Neglecting overlap integrals, the matrix elements can be written as follows:

$$(\Psi_0 H \Psi_0) = E_0 - \sum_i^{occ} k^0_{i\chi}$$

$$= E$$

$$(\Psi_S(i-l) H \Psi_S(i-l))$$

$$= E + \Delta E_s(i-l) + 1/2(k^0_{i\chi} - k^0_{l\chi})$$

$$(\Psi^1_T(i-l) H \Psi^1_T(i-l))$$

$$= E + \Delta E_t(i-l) + 3/2\, k^0_{i\chi} + 1/2\, k^0_{l\chi}$$

$$(\Psi_C(i-\chi_0) H \Psi_C(i-\chi_0))$$

$$= E - \varepsilon_i + a^0_\chi + (\chi_0 H^+_i \chi_0)$$

$$(\Psi_C(\chi_0-l) H \Psi_C(\chi_0-l))$$

$$= E - \varepsilon^0_\chi + a_l + (l H^+_X l)$$

$$(\Psi_0 H \Psi_S(i-l)) = -1/\sqrt{2}\ (i\chi_0 H \chi_0 l)$$

$$(\Psi_0 H \Psi^1_T(i-l)) = \sqrt{3/2}(i\chi_0 H \chi_0 l)$$

$$(\Psi_0 H \Psi_C(i-\chi_0)) = -(i H \chi_0)$$

$$(\Psi_0 H \Psi_C(\chi_0-l)) = (l H \chi_0)$$

where E_0 is the energy of the ground state of the system without interaction, and $\Delta E_s(i-l)$ and $\Delta E_t(i-l)$ are the excitation energies of the molecule to the singlet and triplet states respectively. The integrals in these expressions are:

$$k^0_{i\chi} = (i\chi_0 H \chi_0 i)$$

$$\varepsilon_i = (i H_0 i)$$

$$a_l = (l H_0 l) + \sum^{occ} \{2(ll : ii) - (li : li)\}$$

$$\varepsilon^0_\chi = (\chi_0 H_0 \chi_0)$$

$$a^0_\chi = (\chi_0 H_0 \chi_0) + (\chi_0\chi_0 : \chi_0\chi_0)$$

$$(\chi_0 H^+_i \chi_0) = (\chi_0 H \chi_0) - (\chi_0 H_0 \chi_0) - (ii : \chi_0\chi_0)$$

$$(l H^+_X l) = (l H l) - (l H_0 l) - (ll : \chi_0\chi_0)$$

where H and H_0 respectively the Hamiltonian of the whole system with and without interaction between the molecule and the radical.

The integrals are reduced by disregarding non-neighbors and the difference between H and H_0 as follows:

$$(\chi_0 H^+_i \chi_0) = -(ii : \chi_0\chi_0)$$

$$(l H^+_X l) = -(ll : \chi_0\chi_0)$$

$$(i H \chi_0) = C_{ir} \cdot \beta^0_{r\chi}$$

$$(l H \chi_0) = C_{lr} \cdot \beta^0_{r\chi}$$

$$(i\chi_0 H \chi_0 l) = C_{ir} \cdot C_{lr} \cdot \alpha^0_{r\chi}$$

$$k^0_{i\chi} = (C_{ir})^2 \cdot \alpha^0_{r\chi}$$

where C_{ir} and C_{lr} are the coefficients of the r-th AO in the molecular orbitals i and l respectively; $\beta^0_{r\chi}$ is the resonance integral and $\alpha^0_{r\chi}$ is the exchange energy between the redical and the r-th atom in the molecule.

Therefore, the energy change of the ground state ΔW_0 is

$$\Delta W_0 = -1/2 \cdot q_r \cdot \alpha^0_{r\chi} - \sum_i^{occ} \sum_l^{vac} \left\{ \frac{(C_{ir} \cdot C_{lr})^2}{\Delta E_s(i-l) + 1/2(k^0_{i\chi} - k^0_{l\chi})} + \frac{(C_{ir} \cdot C_{lr})^2}{\Delta E_t(i-l) + 3/2\, k^0_{i\chi} + 1/2\, k^0_{l\chi}} \right\} (\alpha^0_{r\chi})^2 - \left\{ \sum_i^{occ} \frac{(C_{ir})^2}{-\varepsilon_i + a^0_\chi - (ii : \chi_0\chi_0)} + \sum_l^{vac} \frac{(C_{lr})^2}{-\varepsilon^0_\chi + a_l - (ll : \chi_0\chi_0)} \right\} (\beta^0_{r\chi})^2 \qquad (2)$$

wher q_r is the electron density at the position of the r-th atom in the molecule.

The first term, $-1/2 \cdot q_r \cdot \alpha^0_{r\chi}$, in Eq. 2 represents the exchange repulsion between the molecule and the radical, since $\alpha^0_{r\chi}$ has a negative value. In the first bracket of Eq. 2, the first term arises from the excited singlet states, and the second term shows the effect of the triplet states of the molecule. The exchange energy gives rise to these stabilization energies. These two terms are represented by $-1/8\,\pi^S_{rr}$ and $-3/8\,\pi^T_{rr}$ respectively, which are similar to the figures for atom-atom polarizability[7]. By disregarding interelectronic interaction and exchange energy, these terms can be reduced to $-1/8\,\pi_{rr}$ and $-3/8\,\pi_{rr}$, because

$$\Delta E_s(i-l) + 1/2(k^0_{i\chi} - k^0_{l\chi}) = \varepsilon_l - \varepsilon_i$$

$$\Delta E_t(i-l) + 3/2\, k^0_{i\chi} + 1/2\, k^0_{l\chi} = \varepsilon_l - \varepsilon_i$$

The two terms in the second bracket of Eq. 2, arising from electron-transfer interaction, are similar to the figures for superdelocalizability[6,8] for a radical attack and may be abbreviated as follows:

$$\gamma^+_r = -\sum_i^{occ} \frac{(C_{ir})^2}{-\varepsilon_i + a^0_\chi - (ii : \chi_0\chi_0)}$$

$$\gamma^-_r = -\sum_l^{vac} \frac{(C_{lr})^2}{-\varepsilon^0_\chi + a_l - (ll : \chi_0\chi_0)}$$

$$\gamma_r = \gamma^+_r + \gamma^-_r$$

Using the above abbreviations, Eq. 2 can be written as follows.

$$\Delta W_0 = -1/2 \cdot q_r \cdot \alpha^0_{r\chi} + (1/8\,\pi^S_{rr} + 3/8\,\pi^T_{rr})(\alpha^0_{r\chi})^2 + \gamma_r(\beta^0_{r\chi})^2 \qquad (3)$$

If interelectronic repulsion is disregarded, we obtain:

$$-\gamma_r = Z_0/(\beta^0_{r\chi})^2$$

where Z_0 is the superdelocalizability for the radical attack.

hydrocarbons has been given by Pople[9]. Therefore, in a simple approximation, the chemical reactivity of conjugated molecules for a radical attack can be determined approximately by π_{rr} and Z_0, as has been concluded by other authors[2,7,8].

Equation 2 or 3 has an interesting feature in that the chemical reactivity of molecules is affected directly by the excited states; moreover, the triplet states are more important than the excited singlet states. The importance of the triplet states is also due to the fact that a triplet state has a lower energy than that singlet state with the same electron configuration.

Quenching of Excited (^{2}P) Sodium

The experimental work by Norrish and MacF. Smith[10] on the quenching of excited sodium by hydrocarbons shows that the hydrocarbons fall into two classes according to their cross-sections for the excited sodium, as is shown in Table I. The saturated hydrocarbons have

Table I. Quenching cross-sections*

	Cross-section, Å^2
Hydrogen	7.4
Nitrogen	14.5
Methane	0.11
Ethane	0.17
Propane	0.2
Butane	0.3
Cyclohexane	0.4
Ethylene	44.0
Propylene	52.0
1-Butene	58.0
2-Butene	58.0
Cyclohexene	59.0
Benzene	75.0

* R. G. W. Norrish and W. MacF. Smith, *Proc. Roy. Soc.*, **A176**, 295 (1940).

very small quenching cross-sections. On the other hand, the unsaturated hydrocarbons have large cross-sections. Hydrogen and nitrogen have the intermediate quenching cross-sections of 7.4 Å^2 and of 14.5 Å^2 respectively. These differences can be explained by the potential energy surfaces, as will be shown below.

The potential-energy surfaces may well be represented by taking into account the ground configuration as well as the electron-transfer configurations from the sodium atom to the molecule, because of the low ionization potential of sodium. (The excitation energy to ^{2}P of sodium is 2.12 eV., and the ionization potential is 5.14 eV.). Since the excited states of the molecules under consideration have much higher energies than the ^{2}P of sodium, the energy transfer from the sodium atom to the molecule will be disregarded. Therefore, the discussion is carried out by taking into account Ψ_0 (the ground state of the system), Ψ_X (the excited state of the sodium atom), and Ψ_C (the electron-transfer state).

Diatomic Molecules.—The quenching cross-section of hydrogen for excited sodium has been discussed theoretically by Laidler[3] and by Magee and Ri[11], who have shown the potential-energy surfaces for the sodium-hydrogen system with the aid of the VB theory. In the present work, the problem is discussed from the point of view of the transfer of the electron from the sodium atom to the molecule.

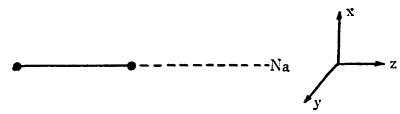

Fig. 1. The coordinate system for linear configuration in the case of diatomic molecule.

Linear Configuration. — The wave functions used are as follows[12]:

$$^2\Sigma^+ \quad \Psi_0 = \phi_0 \cdot \chi_0^{\alpha}(3s)$$

$$^2\Pi \begin{cases} \Psi_X^x = \phi_0 \cdot \chi_1^{\alpha}(3p_x) \\ \Psi_X^y = \phi_0 \cdot \chi_1^{\alpha}(3p_y) \end{cases}$$

$$^2\Sigma^+ \quad \Psi_X^z = \phi_0 \cdot \chi_1^{\alpha}(3p_z)$$

$$\Psi_C = \phi(\chi_0 - v)$$

The symmetry of the electron-transfer configuration, Ψ_C, is $^2\Sigma^+$ in the case of hydrogen and $^2\Pi$ in the case of nitrogen[13].

The diagonal matrix elements are as follows:

$$(\Psi_0 H \Psi_0) = E_0 - \sum_i^{occ} k_{i\chi}^0$$

$$(\Psi_X^x H \Psi_X^x) = E_0 + \Delta E(\chi_0 - \chi_1) - \sum_i^{occ} k_{i\chi}^x$$

$$(\Psi_X^y H \Psi_X^y) = E_0 + \Delta E(\chi_0 - \chi_1) - \sum_i^{occ} k_{i\chi}^y$$

$$(\Psi_X^z H \Psi_X^z) = E_0 + \Delta E(\chi_0 - \chi_1) - \sum_i^{occ} k_{i\chi}^z$$

$$(\Psi_C H \Psi_C) = E_0 - \varepsilon_\chi^0 + a_v + (v H_X^+ v)$$

and the non-vanishing off-diagonal elements are, for hydrogen:

$$(\Psi_0 H \Psi_X^z) = -\sum_i^{occ} (i\chi_0 H \chi_1(3p_z) \cdot i)$$

9) J. A. Pople, *Trans. Faraday Soc.*, **49**, 1375 (1953).
10) R. G. Norrish and W. MacF. Smith, *Proc. Roy. Soc.*, **A176**, 295 (1940).
11) J. L. Magee and T. Ri, *J. Chem. Phys.*, **9**, 638 (1941).
12) The lowest vacant MO of a diatomic molecule is represented by v.
13) The lowest vacant MO of hydrogen is σ_u^+, and that of nitrogen is π_g.

$$(\Psi_0 H \Psi_C) = (v(\sigma_u^+) H \chi_0)$$
$$(\Psi_X^z H \Psi_C) = (v(\sigma_u^+) H \chi_1(3p_z) \cdot i)$$

and for nitrogen:

$$(\Psi_0 H \Psi_X^z) = -\sum_i^{occ} (i\chi_0 H \chi_1(3p_z) \cdot i)$$
$$(\Psi_X^x H \Psi_C^x) = (v(\pi_g^x) H \chi_1(3p_x))$$
$$(\Psi_X^y H \Psi_C^y) = (v(\pi_g^y) H \chi_1(3p_y))$$

The potential energy surfaces of the configurational states Ψ_0, Ψ_X^x, Ψ_X^y and Ψ_X^z are repulsive toward the approach of the sodium atom to the molecule owing to the exchange repulsion[14], and that of Ψ_C(electron-transfer state) is attractive owing to the Coulomb interaction between the negatively-charged molecule and the sodium ion. The schematic potential-energy surfaces of these configurational states may be shown by the dotted lines in Fig. 2 (for hydrogen) and in Fig. 3 (for nitrogen).

The resulting potential-energy surfaces may be shown by the full lines in the figures by the consideration of the off-diagonal matrix elements.

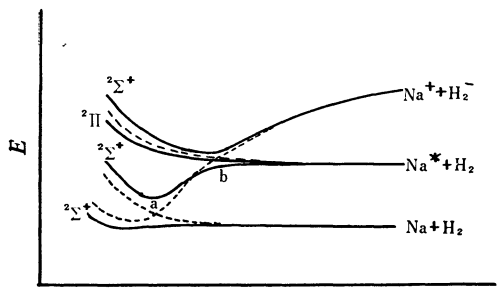

Fig. 2. The potential-energy surfaces for hydrogen (linear configuration).

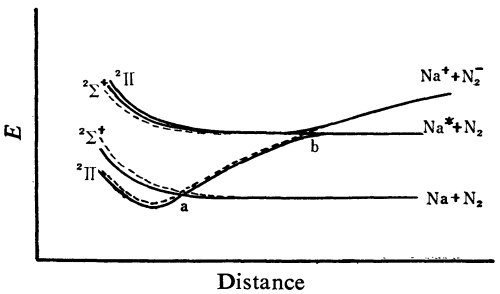

Fig. 3. The potential-energy surfaces for nitrogen (linear configuration).

14) Some of the exchange energies have positive values. In the case of hydrogen, for instance, the exchange energy $k_{1\chi}$, has a positive value, since

$$k_{1\chi}^x = (1\chi_1^x H \chi_1^x 1) = (1\chi_1^x : \chi_1^x 1)$$

Therefore, the surface of Ψ_X^x for the linear configuration of the sodium-hydrogen system may be slightly attractive, but this attractive nature of the surface is unimportant in the present discussion.

The resonance splitting at a in Fig. 2 is not small, since $(v(\sigma_u^+)H\chi_0)$, which is the off-diagonal element between Ψ_0 and Ψ_C, is given by the resonance integral between σ_u^+ and χ_0,

$$(v(\sigma_u^+) H \chi_0) = \beta(\sigma_u^+ - \chi_0)$$

In these circumstances, the reaction system on a upper surface has a small probability of passing to a lower one via crossing[3]. The resulting lower and upper surfaces do not cross, as is shown by the full lines in Fig. 2; the quenching reaction is brought about by a radiationless transition from the upper state to the lower one, which transition gives rise to a sudden acceleration of the motion of the nuclei. This radiationless transition, however, is forbidden by the Franck-Condon principle[15] and has a small probability of occurring if the energy difference between the lower and upper states is not small.

The potential-energy surfaces for the nitrogen-sodium system shows that the quenching reaction will be brought about by a transition at crossing a. The radiationless transition at a is highly probable due to the small interaction between the lower state and the upper state (electron-transfer state); this interaction may arise from the small bending distortion of the linear configuration of the nuclei.

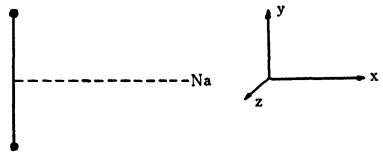

Fig. 4. The coordinate system for triangular configuration in the case of diatomic molecule.

Triangular Configuration.—In this case, the configurational wave functions and their symmetries are, for the hydrogen-sodium system, as follows:

$^2A_1$ $\quad \Psi_0 = \phi_0 \cdot \chi_0^a(3s)$
$^2A_1$ $\quad \Psi_X^x = \phi_0 \cdot \chi_1^a(3p_x)$
$^2B_1$ $\quad \Psi_X^y = \phi_0 \cdot \chi_1^a(3p_y)$
$^2B_2$ $\quad \Psi_X^z = \phi_0 \cdot \chi_1^a(3p_z)$
$^2B_1$ $\quad \Psi_C = \phi(\chi_0 - v)$

The non-vanishing interconfigurational interactions are as follows:

$$(\Psi_0 H \Psi_X^x) = -\sum_i^{occ} (i\chi_0 H \chi_1(3p_x) \cdot i)$$
$$(\Psi_X H \Psi_C) = (\sigma_u^+ H \chi_1(3p_y))$$

For considerations similar to those in the

15) G. Herzberg, "Spectra of Diatomic Molecules", 2nd Ed., D. Van Nostrand Co., New York (1950).

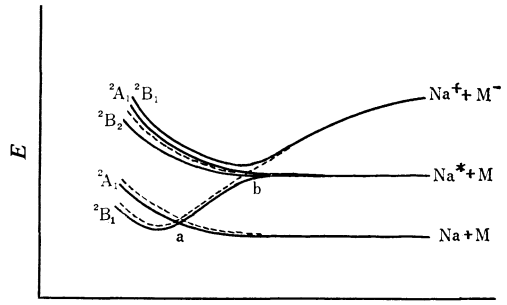

Fig. 5. The potential-energy surfaces for triangular configuration.

case of the linear configuration, the schematic potential-energy surfaces may be given as in Fig. 5. The potential-energy surface for $^2B_1$ (electron-transfer state) is cut by the surface of the lowest state. Since the interconfigurational interaction will be small, the quenching reaction may be brought about by the process:

$$H_2 + Na^*(^2P) \rightarrow H_2 \cdots Na^*(^2B_1) \rightarrow H_2^- - Na^+(^2B_1)$$
$$\rightarrow H_2 \cdots Na(^2A_1) \rightarrow N_2 + Na(^2S)$$

In the case of nitrogen, the wave functions, excepting those of the electron-transfer states, are similar to those of the hydrogen-sodium system. The wave functions of the electron-transfer states are as follows:

$$^2B_1 \quad \Psi_C^x = \phi(\chi_0 - v(\pi_g^x))$$
$$^2B_2 \quad \Psi_C^y = \phi(\chi_0 - v(\pi_g^y))$$

The features of these potential-energy surfaces are quite similar to those of the electron-transfer state of the hydrogen-sodium system. Both of these surfaces are cut by that of the lowest state, ($^2A_1$). Therefore, the reaction system on any surface of the electron-transfer states has a large probability of passing to the lowest state via the crossing, and then the quenching reaction can proceed.

Methane. — The lowest vacant orbital of methane may belong to the irreducible representation of a_1 (totally symmetrical). In the two cases shown in Fig. 6, the wave functions of the reacting system and their symmetries are as follows:

$$^2A_1 \quad \Psi_0 = \phi_0 \cdot \chi_0^\alpha(3s)$$
$$^2E \begin{cases} \Psi_X^x = \phi_0 \cdot \chi_1^\alpha(3p_x) \\ \Psi_X^y = \phi_0 \cdot \chi_1^\alpha(3p_y) \end{cases}$$
$$^2A_1 \begin{cases} \Psi_X^z = \phi_0 \cdot \chi_1^\alpha(3p_z) \\ \Psi_C = \phi(\chi_0 - v) \end{cases}$$

Since both Ψ_0 (the lowest configuration) and Ψ_C (the electron-transfer configuration) belong to the same symmetry class, ($^2A_1$), and since the interconfigurational interaction between Ψ_0 and Ψ_C is not small, it can not be expected that the resulting potential-energy surface of the upper state (the electron-transfer configuration) will be cut by that of the lowest state[16]. These circumstances are similar to those in the case of the linear configuration of the hydrogen-sodium system. The low efficiency of the quenching reaction with excited sodium will, therefore, be interpreted as due to the "non-crossing" of potential-energy surfaces.

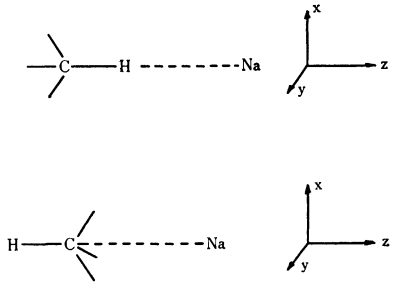

Fig. 6. The configurations for methane.

Discussion

Reactivity of Conjugated Molecules.—It has been shown that the triplet state has an effect on the chemical reactivity of conjugated molecules for a radical attack. If the energy of the lowest triplet state of a molecule is low, the role of the triplet state is clear.

The approach of a radical to a molecule causes a decrease in the exchange energy, $\alpha_{r\chi}^0$, between the radical and the r-th atom in the molecule. Since the energy difference between Ψ_0 (the lowest configuration) and $\Psi_T^1(n-n+1)$ (which corresponds to the lowest triplet state) is expressed by the relation:

$$\Delta E_T^1(n-n+1)$$
$$= (\Psi_T^1(n-n+1)\,H\Psi_T^1(n-n+1)) - (\Psi_0 H \Psi_0)$$
$$= \Delta E_t(n-n+1) + 3/2\, k_{n\chi}^0 + 1/2\, k_{n+1,\chi}^0$$
$$= E_t(n-n+1) + (3/2\,|C_{nr}|^2 + 1/2\,|C_{n+1,r}|^2)$$

the energy difference, $\Delta E_T^1(n-n+1)$, decreases with the approach of the radical to the molecule. When the radical approaches very close to the molecule, the energy of $\Psi_T^1(n-n+1)$ will be lower than that of Ψ_0 owing to the decrease in the exchange energy. In theses cases, the most important interconfigurational interaction is that between Ψ_0 and $\Psi_T^1(n-n+1)$, which is expressed by the nearest neighbor approximation as:

$$(\Psi_0 H \Psi_T^1(n-n+1)) = (C_{nr} \cdot C_{n+1,r}) \cdot \alpha_{r\chi}^0$$

16) Non-crossing may be due to the low electron affinity of methane.

where C_{nr} and $C_{n+1,r}$ are the coefficients at the r-th atom in the molecular orbitals n and $n+1$. If the activated complex or the transition state of the reaction is defined by the condition

$$\Delta E_T^1(n-n+1)=0$$

the activation energy for the reaction may be approximated as follows:

$$\begin{aligned}\Delta W_0 \fallingdotseq & -1/2\{\Delta E_t(n-n+1)/(3/2\,k_{n\chi}^0 \\ & +1/2\,k_{n+1,\chi}^0)\}\alpha_{r\chi}^0+|C_{nr}\cdot C_{n+1,r}|\alpha_{r\chi}^0 \\ = & -1/2\{\Delta E_t(n-n+1)/(3/2\,|C_{nr}|^2 \\ & +1/2|C_{n+1,r}|^2)\}+|C_{nr}\cdot C_{n+1,r}|\alpha_{r\chi}^0 \end{aligned} \quad (4)$$

The experimental work by Szwarc[17] on the radical affinity of conjugated molecules has shown that the radical affinity of a conjugated molecule depends on the energy of the lowest triplet state. This result can be interpreted by Eq. 4. Equation 4 shows that the activation energy decreases with a decrease in the energy difference, $\Delta E_t(n-n+1)$, between the ground state and the lowest triplet state.

In regard to the theoretical approximations of the present paper, the effect of the σ-bonds in the molecule was ignored completely. The use of the wave functions of the whole electron system, including the σ-electrons, would have complicated the theory and may not have affected the results greatly.

Quenching of Excited Sodium.—If the radiationless transition at a is fast, the activated state of the quenching reaction will correspond to b, which is the crossing between Ψ_C (the electron-transfer state) and Ψ_X (the excited state of sodium). The maximum value of the quenching cross section is determined by the distance between the center of the molecule and the sodium atom at b. In the case of hydrogen, the distance is found to be about 4 Å, taking the electron affinity of hydrogen as -0.28 eV.[18] This value may be compared with an experimental value of 2.7 Å $=7.4^{1/2}$ calculated from the quenching cross section (7.4 Å^2) in Table I.

The distance at b, σ, is determined mainly by the electron affinity of the molecule. Table II shows the relation between the electron affinity and the value of σ. In the calculation of the table, the small energy change of Ψ_X due to the interaction was ignored, and the integral $(v\mathrm{H}_X^* v)$ was approximated by $-e^2/R$, where R is the distance between the center of the molecule and the sodium atom. From this relation and by assuming that the activated state corresponds to b, the quenching cross sections of the molecules can be explained except in the case of the saturated hydrocarbons.

The lowest vacant orbital of ethylene will be the anti-bonding π orbital with the nodal plane between the two carbon atoms. The potential-energy surfaces and the quenching reaction process may be similar to those in the case of a triangular configuration for hydrogen, because the lowest state, Ψ_0, and the electron-transfer state, Ψ_C, have symmetry characters different from one other if the sodium atom lies in that nodal plane. Therefore, the quenching process will be as follows[19]:

$$\begin{aligned}\mathrm{C_2H_4+Na^*(^2P)} & \rightarrow \mathrm{C_2H_4\cdots Na^*(^2B_1)} \\ & \rightarrow \mathrm{C_2H_4^- - Na^*(^2B_1)} \rightarrow \mathrm{C_2H_4\cdots Na(^2A_1)} \\ & \rightarrow \mathrm{C_2H_4+Na(^2S)}\end{aligned}$$

The molecular plane of ethylene is the nodal plane of its π-orbital, but this will be unimportant since the hydrogen atoms prevent the approach of the sodium atom to the molecule.

Although the electron affinity of ethylene is unknown, the value of σ (6.6 Å) which is found from the value of the quenching cross-section in Table I can be fit into the relation shown in Table II by assuming the value of electron affinity of ethylene to be 0.9 eV.

TABLE II. THE RELATION BETWEEN σ AND ELECTRON AFFINITY

Electron affinity eV.	σ Å
−2.0	2.86
−1.0	3.57
0	4.75
1.0	7.09
2.0	13.98

The quenching cross-sections of unsaturated hydrocarbons can be explained by a consideration similar to that as in the case of ethylene. The lowest vacant orbital of the π-electrons of the unsaturated group will have the largest electron affinity in the molecule; it also has the nodal plane on which the sodium atom can approach. If the sodium atom lies in that nodal plane, the matrix element, the interconfigurational interaction between Ψ_0 and Ψ_C, is very small. The resonance splitting at crossing a will not be large, and hence, the radiationless transition can take place. The value of the quenching cross-section can, therefore, be determined by the electron affinity and by the size of the molecule.

The lowest vacant orbital of saturated hydrocarbons will have no nodal plane on which

17) M. Szwarc, *J. Chem. Phys.*, 23, 204 (1955).
18) I. Fisher-Hjalmars, *Arkiv Fysik*, 16, 33 (1959).
19) The sodium atom lies on the symmetry axis perpendicular to the molecular plane.

the sodium atom can approach. This is similar to the case of methane. The quenching cross-section of a saturated hydrocarbon may be small due to the large resonance splitting at crossing a.

It may be concluded that the efficiency of the quenching reaction with sodium (^{2}P) depends on the symmetry of the lowest vacant MO and on the electron affinity of the molecule.

Summary

In the first section, the chemical reactivity of conjugated molecules toward a radical attack has been explained. The index of chemical reactivity for a radical attack can be represented in terms of polarizability (π^S_{rr}, π^T_{rr}) and of γ_r, which is similar to the superdelocalizability for a radical attack. The role of the lowest triplet states of molecules in a radical reaction has been discussed.

Secondly, the quenching of excited (^{2}P) sodium was discussed. It has been concluded that the quenching cross-section is determined by the symmetry character of the lowest electron-transfer state and by the electron affinity of the molecule.

The author wishes to express his thanks to Professor Ikuzo Tanaka of this loboratory for his encouragement and discussion throughout this work.

Electronic Structures of Benzyl Cation and Related Compounds

By Yuji MORI

(Received February 21, 1961)

In previous papers[1,2], the author has shown a theoretical interpretation of the electronic structure of the benzyl radical, with relation to the electronic structure of a separate fragment (benzene). The calculations suggested that the lowest excited state of the benzyl radical, $^2B_2$, can be related to the lowest triplet state of benzene, $^3B_{1u}$.

Longuet-Higgins and Pople[3] have interpreted the spectra of odd alternant hydrocarbon radicals and corresponding cations on the basis of the molecular orbital theory. They have shown that odd alternant hydrocarbon radicals may have absorption bands with a weak intensity in the vicinity of the absorption bands of corresponding cations. For the benzyl radical and cation, a similar result has been reported by Bingel[4].

It will, therefore, be interesting to investigate the electronic structure of the benzyl cation from the viewpoint of the electronic structures of the separate fragments, as was done in the case of the benzyl radical.

The first problem of the present paper will be to show an interpretation of the electronic structure of the benzyl cation based on those of the composite system. This will be followed by an interpretation of the electronic spectra of diphenyl-methyl and triphenyl-methyl cations from the same standpoint, utilizing a simple treatment.

The Benzyl Cation

In the calculations, it is assumed that the system is composed of the benzene ring and the positively-charged methylene group ($-CH_2^+$). The calculations are based on the method of composite systems[5] and are carried out by taking into account the locally excited configurations in the benzene ring and the electron-transfer configurations in which an electron has been transferred from the benzene ring to $-CH_2^+$.

The LCAO MO's of benzene ring are

$$\varphi_0 = 1/\sqrt{6}\,(\chi_1+\chi_2+\chi_3+\chi_4+\chi_5+\chi_6)$$

$$\varphi_1 = 1/\sqrt{12}\,(2\chi_1+\chi_2-\chi_3-2\chi_4-\chi_5+\chi_6)$$

A similar treatment is described by Nagakura and Tanaka; S. Nagakura and J. Tanaka, *J. Chem. Phys.*, **22**, 236 (1954); S. Nagakura, ibid., **23**, 1441 (1955); J. Tanaka and S. Nagakura, ibid., **24**, 1274 (1956).

$$\varphi_2=1/2(\chi_2+\chi_3-\chi_5-\chi_6)$$
$$\varphi_3=1/\sqrt{12}(2\chi_1-\chi_2-\chi_3+2\chi_4-\chi_5-\chi_6)$$
$$\varphi_4=1/2(\chi_2-\chi_3+\chi_5-\chi_6)$$
$$\varphi_5=1/\sqrt{6}(\chi_1-\chi_2+\chi_3-\chi_4+\chi_5-\chi_6)$$

where χ_r is the $2p\pi$ AO of the r-th carbon atom in the benzene ring.

The bond is formed between the methylene group ($-CH_2^+$) and the carbon atom 1 of the benzene ring. The $2p\pi$ AO of $-CH_2^+$ is expressed by χ_7.

The electronic configurations are shown in Fig. 1, while the wave functions corresponding to these configurations are given in Table I.

TABLE I. THE WAVE FUNCTIONS OF THE BENZYL CATION

$^1A_1$ $\left\{\begin{array}{l}\Psi_1=(001122)=\phi_1\\ \Psi_2=\phi_2(1\to\chi_7)\\ \Psi_3=\phi_3(0\to\chi_7)\end{array}\right.$

$^1B_1$ $\Psi_4=\phi_4(2\to\chi_7)$

$^1A_1$ $\left\{\begin{array}{l}\Psi_5=1/\sqrt{2}\{\phi_5(1\to3)+\phi_6(2\to4)\}\\ \Psi_6=1/\sqrt{2}\{\phi_5(1\to3)-\phi_6(2\to4)\}\end{array}\right.$

$^1B_1$ $\left\{\begin{array}{l}\Psi_7=1/\sqrt{2}\{\phi_7(1\to4)+\phi_8(2\to3)\}\\ \Psi_8=1/\sqrt{2}\{\phi_7(1\to4)-\phi_8(2\to3)\}\end{array}\right.$

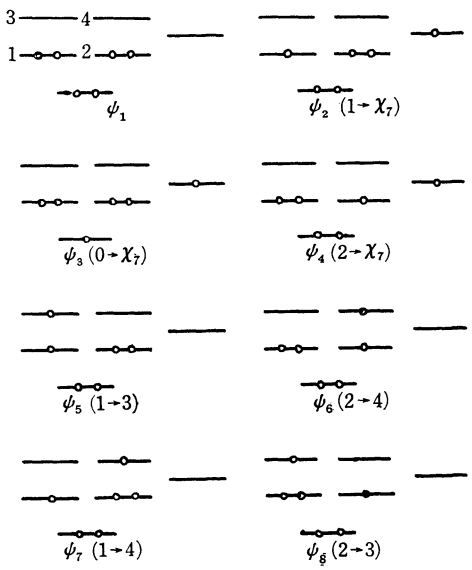

Fig. 1. The electron configurations of the benzyl cation.

In the table, Ψ_5, Ψ_6, Ψ_7 and Ψ_8, which represent the locally excited states of the benzene ring, are introduced for the purpose of considering the effect of the polarization in the benzene ring induced by $-CH_2^+$. The wave functions, Ψ_2, Ψ_3 and Ψ_4, correspond to the electron-transfer configurations, in which one electron has been transferred from the benzene ring to the $2p\pi$ AO of $-CH_2^+$.

A standard bond length, 1.39 Å, is assumed for all C–C bonds throughout the present work. The values for the molecular integrals are taken from the work of Pariser[6], and the penetration integrals from neutral carban atoms are disregarded.

The matrix elements are given in Table II, and the calculared energy levels of the benzyl cation are shown in Table III. The energy of the ground state is -61 kcal., relative to the energy of Ψ_1.

TABLE III. THE ENERGY LEVELS OF THE BENZYL CATION

Symmetry	Energy, eV.	Polarization*
$^1A_1$	0	
$^1B_1$	2.23	⊥
$^1A_1$	3.91	∥
$^1A_1$	6.24	∥
$^1B_1$	7.54	⊥

* ⊥ and ∥ mean perpendicular and parallel polarization with respect to the long axis in the benzyl cation.

The wave functions of the ground state and of the two excited states are as follows:

($^1A_1$; 0)

$$\Phi_1=0.7118\cdot\Psi_1+0.6435\cdot\Psi_2+0.1715\cdot\Psi_3+0.2121\cdot\Psi_5+0.0694\cdot\Psi_6$$

($^1A_1$; 3.91 eV.)

$$\Phi_2=0.5396\cdot\Psi_1-0.7124\cdot\Psi_2+0.4178\cdot\Psi_3+0.0639\cdot\Psi_5-0.1508\cdot\Psi_6$$

($^1B_1$; 2.23 eV.)

$$\Phi_4=0.9735\cdot\Psi_4+0.1928\cdot\Psi_7-0.1232\cdot\Psi_8$$

The calculated charge distributions of the ground state are shown in Fig. 2. In the calculation of the electron densities, it is necessary to take into account the interconfigurational electron densities. The interconfigurational electron density can be defined by the following expression for a small change in the Coulomb

6) R. Pariser, *J. Chem. Phys.*, **24**, 250 (1956).

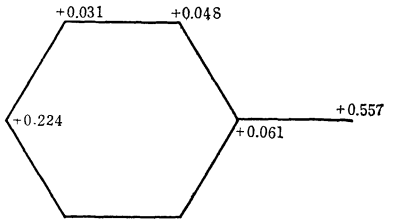

Fig. 2. The charge distribution of the benzyl cation.

integral $\Delta\alpha_r$ at the r-th atom:

$$q_r(ij)=\frac{\partial}{\partial(\Delta\alpha_r)}\Delta W_r(ij)$$

where

$$\Delta W_r(ij)=\int\Psi_i\Delta\alpha_r\Psi_j d\tau$$

Also, $q_r(ii)$ can be defined by the expression:

$$q_r(ii)=\frac{\partial}{\partial(\Delta\alpha_r)}\cdot\Delta W_r(ii)$$

Then the electron density at the carbon atom r may be written as follows:

$$q_r=\frac{\partial}{\partial(\Delta\alpha_r)}\cdot\int\Phi_1\Delta\alpha_r\Phi_1 d\tau$$
$$=\sum_i\sum_j C_iC_j\cdot q_r(ij)$$

where $\Phi_1=\sum_i C_i\cdot\Psi_i$

From the wave functions and wave numbers obtained in this section, the oscillator strengths[7] may be given as follows:

$$f_{12}=0.34$$
$$f_{14}=0.11$$

It seems that there has been no reliable experimental observation of the electronic absorption spectrum of the benzyl cation. The calculations, however, may be compared with the absorption spectrum of the carbonium ion in a sulfuric acid solution of benzyl alcohol. Grace and Symons[8] have observed that the solution shows an absorption band at 4700 Å (2.6 eV.) and so have assigned it to the benzyl cation.

The calculations show a qualitative agreement with those by Bingel[4] and by Longuet-Higgins and Pople[3]. The energy and charge distribution of the ground state are similar to the results of the calculations by Brickstock and Pople[9].

9) A. Brickstock and J. A. Pople, *Trans. Faraday Soc.*, **50**, 901 (1954).

The transition moment of the $\Phi_1-\Phi_4$ transition arises from the local transition in the benzene ring, and the direction of this is orthogonal to the long axis of the system, i. e., the direction of the electron transfer. The transition moment from Φ_1 to Φ_2 is due to the electron transfer and is parallel to the direction of the electron transfer.

The charge density on $-CH_2^+$ is +0.05 in the lowest excited state, $^1B_1$, according to the wave function obtained in the present paper. Therefore, the lowest excited state, $^1B_1$, can be represented approximately by the single configuration, Ψ_4, the electron-transfer configuration from φ_2 to χ_7. In a similar way, the approximate wave function of the ground state of the benzyl cation can be represented by the linear combination of Ψ_1 and Ψ_2, Ψ_2 being the electron-transfer configuration from φ_1 to χ_7. According to the above simple approximation, the longest absorption band of the benzyl cation may be interpreted as the band arising from the transition from the ground state to the excited state which is represented by Ψ_4. This relation is shown in Fig. 3. This simple treatment will be applied in the calculations of diphenyl-methyl and triphenyl-methyl cations in the next section.

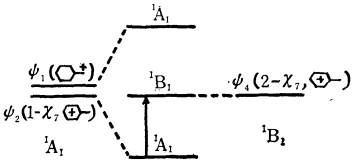

Fig. 3. Effect of electron transfer interaction in the benzyl cation.

Diphenyl-methyl and Triphenyl-methyl Cations. —In the preceding section, it was shown that the role of the electron-transfer configurations is important for the ground and the lowest excited states of the benzyl cation, and that the role of the locally excited configurations is minor. In this section, therefore, calculations will be carried out taking into account only the interactions arising from electron-transfer configurations of low energies.

The LCAOMO's of the benzene rings in the diphenyl-methyl cation are similar to those in the case of the benzyl cation. The MO which belongs to a benzene ring A or B is denoted by a subscript a or b, and the $2p\pi$ AO of $-CH^+-$ in the diphenyl-methyl cation is represented by χ_7.

The electronic wave functions of the diphenyl-methyl cation are shown in Table IV. In the table, Ψ_1 represents the state in which the positive charge is localized on $-CH^+-$, while Ψ_2, Ψ_3, Ψ_4 and Ψ_5 are the electron transfer states.

TABLE IV. THE WAVE FUNCTIONS OF THE DIPHENYL-METHYL RADICAL CATION

$$^1A_1 \begin{cases} \Psi_1 = (0_a0_a1_a1_a2_a2_a)\,(0_b0_b1_b1_b2_b2_b) \\ \Psi_2 = 1/\sqrt{2}\,\{\phi(1_a\rightarrow\chi_7)+\phi(1_b\rightarrow\chi_7)\} \end{cases}$$

$$^1B_1 \begin{cases} \Psi_3 = 1/\sqrt{2}\,\{\phi(1_a\rightarrow\chi_7)-\phi(1_b\rightarrow\chi_7)\} \\ \Psi_4 = 1/\sqrt{2}\,\{\phi(2_a\rightarrow\chi_7)+\phi(2_b\rightarrow\chi_7)\} \end{cases}$$

$$^1A_1 \quad \Psi_5 = 1/\sqrt{2}\,\{\phi(1_a\rightarrow\chi_7)-\phi(2_b\rightarrow\chi_7)\}$$

A planar configuration of the diphenyl-methyl cation is assumed in the calculation, although the system may not be planar. The possible effect of nonplanarity on the energy levels will be discussed in a later section. The matrix elements are shown in Table V. The calculated energy levels are given in Table VI.

TABLE V. THE MATRIX ELEMENTS OF THE DIPHENYL-METHYL RADICAL CATION

Values are given in eV.

	1	2	5
1	0		
2	−2.738	−0.086	
5	0	0	−0.086

	3	4
3	−0.086	
4	0	−0.086

TABLE VI. THE ENERGY LEVELS OF DIPHENYL-METHYL RADICAL CATION

Symmetry	Energy, eV.
$^1A_1$	0
$^1A_1$	2.69
$^1B_1$	2.69
$^1B_1$	2.69
$^1A_1$	5.48

The calculations may be compared with the absorption spectrum of the solution of diphenyl-methanol in the mixture of trichloroacetic acid and benzene, which has been observed by Grace and Symons[8]. They assign the absorption band at 4420 Å (2.81 eV.) to the diphenyl-methyl cation. In spite of their very simple calculations, the results seems satisfactory as an explanation of the characteristic features of the absorption band of the diphenyl-methyl cation. Also, the calculations will serve for the qualitative interpretation of the absorption band of the protonated compound of anthracene at 4100 Å[10], since this compound may have a structure similar to that of the diphenyl-methyl cation.

In the case of the triphenyl-methyl cation, a similar calculation has been carried out for the energy levels. The wave functions are shown in Table VII. The subscripts a, b and c denote the benzene rings A, B and C respectively, while χ_7 represents the $2p\pi$ AO of the carbon atom at the center of the system. The matrix elements are shown in Table VIII.

TABLE VII. THE WAVE FUNCTIONS OF THE TRIPHENYL-METHYL RADICAL CATION

$$^1A'_1 \begin{cases} \Psi_1 = (0_a0_a1_a1_a2_a2_a)\,(0_b0_b1_b1_b2_b2_b)\,(0_c0_c1_c1_c2_c2_c) \\ \Psi_2 = 1/\sqrt{3}\,\{\phi(1_a\rightarrow\chi_7)+\phi(1_b\rightarrow\chi_7)+\phi(1_c\rightarrow\chi_7)\} \end{cases}$$

$$^1A'_2 \quad \Psi_3 = 1/\sqrt{3}\,\{\phi(2_a\rightarrow\chi_7)+\phi(2_b\rightarrow\chi_7)+\phi(2_c\rightarrow\chi_7)\}$$

$$^1E' \begin{cases} \Psi_4 = 1/\sqrt{3}\,\{\phi(1_a\rightarrow\chi_7)+\exp(\pm 2\pi i/3)\phi(1_b\rightarrow\chi_7) \\ \qquad +\exp(\pm 4\pi i/3)\phi(1_c\rightarrow\chi_7)\} \\ \Psi_5 = 1/\sqrt{3}\,\{\phi(2_a\rightarrow\chi_7)+\exp(\pm 2\pi i/3)\phi(2_b\rightarrow\chi_7) \\ \qquad +\exp(\pm 4\pi i/3)\phi(2_c\rightarrow\chi_7)\} \end{cases}$$

TABLE VIII. THE MATRIX ELEMENTS OF THE TRIPHENYL-METHYL RADICAL CATION

Values are given in eV.

	1	2
1	0	
2	−3.353	−0.086

$H_{33} = -0.086$

	4	5

TABLE IX. THE ENERGY LEVELS OF THE TRIPHENYL-METHYL RADICAL CATION

Symmetry	Energy, eV.
$^1A'_1$	0
$^1A'_2$	3.27
$^1E'$	3.27
$^1E'$	3.27
$^1A'_1$	6.71

The energy levels given in Table IX are relative to the energy of the ground state. The system may not be planar, but the calculations may be compared with the absorption spectrum of the triphenyl-methyl cation, which has its first absorption band at about 4300 Å[11] (2.88 eV.). The calculated value is too high compared with the observed value. However, in view of the simple calculation and the assumed planar structure, it would be reasonable to say that this absorption band arises from the electron-transfer configuration.

Discussion

The charge distribution of the benzyl cation calculated in the present paper is similar to that calculated by Brickstock and Pople[9]. According to the prediction by the simple

10) G. Dallinga, E. L. Makor and A. A. V. Stuart, *Mol. Phys.*, **1**, 123 (1958).

11) T. L. Chu and S. I. Weissman, *J. Chem. Phys.*, **22**, 21 (1954).

MO theory, the positive charge densities are identical at the para- and ortho-positions, and there is no apparent charge at the meta-position. This charge distribution differs from that of the present calculations shown in Fig. 2. This difference may be due to the effect of polarization.

The stabilization energy, 61 kcal., of the ground state, that is, the resonance energy of the benzyl cation relative to that of benzene, is large compared to that of the benzyl radical[9,12]. Brickstock and Pople[9] have obtained a value of 21.9 kcal. for the benzyl radical. This is due to the facts that the electron affinity of $-CH_2^+$ (benzyl cation) is much larger than that of $-CH_2$ (benzyl radical), and that the largest contribution to this energy comes from the electron-transfer interaction.

The transition moment from Φ_1 to Φ_4, which is orthogonal to the direction of the electron transfer, is due to the (interconfigurational) dipole matrix elements between Ψ_3 and Ψ_4 and between Ψ_1 and Ψ_8. The dipole matrix element

$$q_{34}=e\int \Psi_3 \sum_{\nu} q(\nu)\Psi_4 \mathrm{d}V$$

corresponds to that of the one-electron transition between φ_0 and φ_2 in the positively-charged benzene ring, while q_{18} corresponds to that of the transition ($^1A_{1g}$–$^1E_{1u}$) of benzene.

A simple treatment, which deals with only the three electron-configurations, Ψ_1, Ψ_2 and Ψ_4, can interpret the characteristic features of the absorption band of the benzyl cation. However, there are some difficulties in explaining the charge distribution of the ground state and the intensity of the absorption band. The charge distribution which will be given by this simple treatment will show the same positive charge densities on the carbon atoms 1 and 4, and also on the carbon atoms 2 and 3. The transition moment from the ground state to the lowest excited state, $^1B_1$, will be zero, since no contributions from the non-vanishing dipole matrix elements, q_{34} and q_{18}, can be expected.

For the diphenyl-methyl and triphenyl-methyl cations, the planar configuration has been assumed, although the benzene rings in these systems may not be coplanar. The matrix element H_{12} (Tables V and VIII), the inter-configurational interaction between Ψ_1 and Ψ_2 (Tables IV and VII), can be expressed by the resonance integral between the benzene ring and the carbon atom at the center of the system. If the bond is twisted by an angle θ, the resonance integral $\beta(\theta)$ is given by the relation

$$\beta(\theta)=\beta(0)\cos\theta$$

Therefore, the excitation energies from the ground states to the lowest excited states of these systems will decrease with the increase in the angle of twist. However, it is difficult to determine the angle of twist for these cations from the results of the present calculations, because the calculations are so very simple that there must be some errors in them which would affect the results.

Any transition from the ground state to the excited state ($^1A_2$) of the triphenyl-methyl cation is forbidden in the planar configuration. This transition is allowed in the twisted configuration, which has a transition moment perpendicular to the σ-bonds of the central atom of the system. (This transition corresponds to that from Φ_1 to Φ_4 in the case of the benzyl cation.)

The three excited levels of the diphenyl-methyl cation have the same energy, and for the triphenyl-methyl cation a similar degeneracy of the energy levels has been found. This may be due to disregarding the configurations in which more than one electron has been transferred and the locally excited configurations in the benzene rings.

Summary

The electronic structure of the benzyl cation has been calculated on the basis of an approximation of the composite systems in order to explain the electronic spectrum of the benzyl cation from the point of view of electron-transfer interaction between the fragments. The calculations show a satisfactory agreement with the experimental observations.

For the electronic spectra of some other cations, simple calculations have been carried out as an application of the treatment for the benzyl cation. The results for the diphenyl- and triphenyl-methyl cations show qualitative agreement with the experimental results.

12) A value of 17 kcal. has been elsewhere calculated by the present author (cf. footnote 2).

The Kinetics of Substitution Reactions Involving Metal Complexes. V. Reaction between Copper(II) and Ethylenediaminetetraacetatocadmate(II) Complexes in Aqueous Solutions

By Nobuyuki TANAKA and Minoru KAMADA

(Received April 13, 1962)

The substitution reaction of copper(II) ion and ethylenediaminetetraacetatocadmate(II) complex (Cd(II)-EDTA) was first studied by Ackermann and Schwarzenbach[1]. From the polarographic measurement of the reaction rate at 0°C and ionic strength 1.0 at 5×10^{-6} to 1.4×10^{-4} M of hydrogen ion, they concluded that the reaction proceeds simultaneously through four different reaction paths. Although their measurements were carried out in acetate buffer solutions and the decrease of the reaction rate was observed with increasing concentrations of acetate ion, Ackermann and Schwarzenbach did not take consideration of this fact in the treatment of the reaction kinetics.

This observation and a series of kinetic studies on the substitution reactions involving metal complexes[2-5] carried out in this laboratory suggested us to reinvestigate the substitution reaction of copper(II) ion and Cd(II)-EDTA and to compare the mechanisms and the rate constants of those substitution reactions obtained under the same experimental conditions.

In this study, therefore, the reaction rates were measured by the polarographic method at 5 and 15°C at lower concentrations of hydrogen ion than those reported by Ackermann and Schwarzenbach. The effect of acetate ion on the reaction rate was taken into consideration. A new reaction path was found in which the rate was inversely proportional to the hydrogen ion concentration of the solution. The contribution of this reaction path was more important at lower hydrogen ion concentrations.

Experimental

Reagents.—Preparations and standardizations of the solutions of copper(II) nitrate, cadmium(II) nitrate, disodium ethylenediaminetetraacetate (EDTA) and sodium acetate-acetic acid buffers were described in the previous paper[6]. The cadmium nitrate solution was found to contain 0.08% of lead(II) ion as impurity, being determined by the a. c. polarographic method. The preliminary experiments indicated that this concentration of lead(II) ion gave no appreciable effect on the reaction rate under investigation and therefore no further purification was carried out. Other reagents used for supporting electrolytes were of guaranteed reagent grade and used without further purification.

Apparatus and Procedure.—The rate of the reaction between copper(II) ion and Cd(II)-EDTA complex was followed by measuring the change of polarographic limiting current of copper(II) ion at −0.12 V. vs. SCE with time. A Shimadzu RP-2 pen-recording polarograph was employed for the measurement of current-time curves. The dropping mercury electrode used had an m value of 2.57 mg./sec. and a drop time t_d of 3.52 sec. in an air-free acetate buffer of pH 4.7 containing 0.1 M acetate, 0.1 M potassium nitrate and 0.01% gelatin at 25°C with open circuit. A saturated calomel electrode (SCE) was used as reference electrode which was connected to the electrolytic solution with the aid of a Hume and Harris type agar bridge[7]. Dissolved oxygen in the solution was removed by bubbling nitrogen gas through the solution. Gelatin was added as maximum suppressor by 0.01% in concentration. The pH of solution was measured by means of Hitachi EHP-1 pH meter, within the accuracy of 0.02 pH unit, immediately after the measurement of current-time curve.

The reactions were initiated by injecting the known amount of the deaerated copper(II) nitrate solution at the rate of 1 ml. per second with a calibrated syringe into acetate buffer solution which contained cadmium(II) ion and Cd(II)-EDTA complex in excess. The ionic strength of the solution was adjusted to be 0.2 with potassium nitrate. The solution was thoroughly stirred by bubbling nitrogen gas for ten seconds. With this technique, a reproducible current-time curve was obtained from 20 sec. after the initiation of reaction.

Results and Discussion

Copper(II) forms mono- and diacetato complexes, whereas cadmium(II) does only monoacetato complex in the solution which contains less than 0.2 M of acetate ions. The overall substitution reaction between copper(II) ion

4) K. Kato, ibid., 33, 600 (1960).
5) N. Tanaka and K. Kato, ibid., 33, 1236 (1960).
6) N. Tanaka, M. Kamada, H. Osawa and G. Satô, ibid., 33, 1412 (1960).
7) D. N. Hume and W. E. Harris, *Ind. Eng. Chem., Anal. Ed.*, 15, 465 (1943).

and Cd(II)-EDTA complex in acetate buffer solution is represented with the following equations.

$$Cu^{2+} + 2OAc^- \rightleftarrows CuOAc^+ + OAc^- \rightleftarrows Cu(OAc)_2 \quad (1)$$

$$Cu^{2+} + CdY^{2-} \rightleftarrows CuY^{2-} + Cd^{2+} \quad (2)$$

$$Cd^{2+} + OAc^- \rightleftarrows CdOAc^+ \quad (3)$$

In Eq. 2, Y^{4-} denotes tetravalent EDTA anion. In the case when both Cd^{2+} and CdY^{2-} are present in a large excess over the copper(II) ion, Eq. 2 can be simplified to

$$Cu^{2+} \underset{k^-}{\overset{k^+}{\rightleftarrows}} CuY^{2-} \quad (4)$$

The rate equation for Eq. 4 is written as

$$-\frac{d[Cu^{2+}]_{app}}{dt} = k^+[Cu^{2+}]_{app} - k^-[CuY^{2-}] \quad (5)$$

where $[Cu^{2+}]_{app}$ is the apparent concentration of copper(II) ion that can be determined polarographically, or the sum of hydrated copper(II) ion and mono- and diacetato copper-(II) complexes.

Integrating Eq. 5

$$\ln\{[Cu^{2+}]_{app} - [Cu^{2+}]_{e,app}\} = -(k^+ + k^-)t + \ln\{[Cu^{2+}]_{0,app} - [Cu^{2+}]_{e,app}\} \quad (6)$$

is obtained, where suffixes 0 and e denote the initial and the equilibrium state respectively. At the equilibrium the following relation may be satisfied.

$$k^+/k^- = \frac{[CuY^{2-}]_e}{[Cu^{2+}]_{e,app}} \fallingdotseq K^{Cu}_{Cd,app}\frac{[CdY^{2-}]_0}{[Cd^{2+}]_{0,app}} \quad (7)$$

$K^{Cu}_{Cd,app}$ means the apparent equilibrium constant of Eq. 2 at a certain acetate concentration, and is given as

$$K^{Cu}_{Cd,app} = \frac{[CuY^{2-}]_e[Cd^{2+}]_{e,app}}{[Cu^{2+}]_{e,app}[CdY^{2-}]_e} \quad (8)$$

The values of $K^{Cu}_{Cd,app}$ were determined polarographically to be 102 at 15°C and 113 at 5°C in the presence of 0.091 M of acetate. These values were introduced in Eq. 7, and k^+ was determined from Eqs. 6 and 7.

The apparent overall rate constants of forward reaction of Eq. 4 ($k^+/[CdY^{2-}]_0$) were measured at varied initial concentrations of copper(II) ion and those of Cd(II)-EDTA complex under other conditions kept constant, and found to be independent of the variables as shown in Table I. This observation led to the conclusion that the overall substitution reaction proceeds according to the pseudo first order rate law.

Table I. $k^+/[CdY^{2-}]_0$ values at various initial concentrations of copper(II) ion or Cd(II)-EDTA complex
(15°C, μ=0.2, $[OAc^-]$=0.091 M, pH=5.50, $[Cd^{2+}]_{0,app}=1.028\times10^{-2}$ M)

$[Cu^{2+}]_{0,app}$ M×10⁴	$[CdY^{2-}]_0$ M×10³	$k^+/[CdY^{2-}]_0$ l.mol⁻¹ sec⁻¹
0.99	5.00	0.72_4
1.98	5.00	0.73_2
2.97	5.00	0.73_2
1.98	9.98	0.72_0

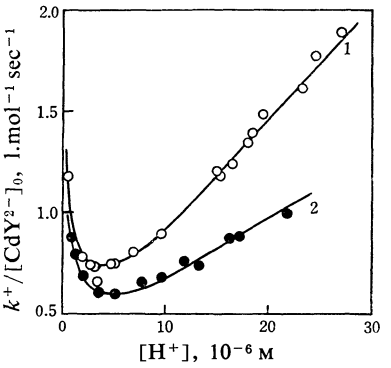

Fig. 1. $k^+/[CdY^{2-}]_0$ as a function of the hydrogen ion concentration in acetate buffer-potassium nitrate solutions of ionic strength 0.2 at 15°C. Initial concentrations are: $[Cu^{2+}]_{0,app}=1.98\times10^{-4}$ M; $[CdY^{2-}]_0=5.00\times10^{-3}$ M; $[Cd^{2+}]_{0,app}=1.028\times10^{-2}$ M (curve 1) and 2.056×10^{-2} M (curve 2). Concentration of free acetate is 0.091 M.

Two sets of $k^+/[CdY^{2-}]_0$, in each of which the values of $k^+/[CdY^{2-}]_0$ were measured at various hydrogen ion concentrations under other conditions kept constant, were obtained at two different concentrations of cadimium-(II) ion. The values obtained are plotted against the hydrogen ion concentration as shown in Fig. 1, where it should be noticed that, in the region of low hydrogen ion concentration, $k^+/[CdY^{2-}]_0$ increases with decreasing concentration of hydrogen ion.

These experimental results suggest that the substitution reaction between copper(II) ion and Cd(II)-EDTA complex proceeds simultaneously through the following four reaction paths:

i) $Cu^{2+} + CdY^{2-} \underset{k_1^+}{\rightleftarrows} CuY^{2-} + Cd^{2+}$ (9)

ii) $CdY^{2-} + H^+ \rightleftarrows CdHY^-$ (10a)

$CuHY^- + Cu^{2+} \underset{k_{II}^+}{\rightleftarrows} CuHY^- + Cd^{2+}$ (10b)

$CuHY^- \rightleftarrows CuY^{2-} + H^+$ (10c)

iii) $CdY^{2-} + H^+ \rightleftarrows Cd^{2+} + HY^{3-}$ (11a)

$Cu^{2+} + HY^{3-} \underset{k_{III}^+}{\rightleftarrows} CuY^{2-} + H^+$ (11b)

iv) $CdY^{2-} + H_2O \rightleftarrows CdOHY^{3-} + H^+$ (12a)

$$Cu^{2+} + CdOHY^{3-} \overset{k_{IV}^+}{\rightleftarrows} CuOHY^{3-} + Cd^{2+} \quad (12b)$$

$CuOHY^{3-} + H^+ \rightleftarrows CuY^{2-} + H_2O$ (12c)

If the substitution reaction is assumed to proceed only through the hydrated ions which are in equilibrium with the acetato complexes, the apparent rate of the forward reaction ($v^+ = k^+ [Cu^{2+}]_{app}$) is represented by Eq. 13.

$$v^+ = k^+ [Cu^{2+}]_{app} = \left\{ \frac{k_1^+ + k_2^+ [H^+] + k_3^+ [H^+] \frac{1 + K_{CdOAc}[OAc^-]}{[Cd^{2+}]_{app}} + k_4^+ \frac{1}{[H^+]}}{1 + \sum_{n=1}^{2} K_{Cu(OAc)_n} [OAc^-]^n} \right\} \times [Cu^{2+}]_{app} [CdY^{2-}] \quad (13)$$

$$\left. \begin{aligned} k_2^+ &= k_{II}^+ K_{CdHY}^H \qquad k_3^+ = k_{III}^+ / K_{CdY} K_{HY} \\ k_4^+ &= k_{IV}^+ K_{CdOHY} \end{aligned} \right\} \quad (14)$$

In Eqs. 13 and 14, K_{CdHY}^H means the equilibrium constant of reaction 10a, K_{CdY}, the formation constant of CdY^{2-}, K_{HY}, the fourth dissociation constant of ethylenediaminetetraacetic acid, K_{CdOHY}, the equilibrium constant for reaction 12a, and K_{CdOAc} and $K_{Cu(OAc)_n}$ represent the overall formation constants of acetatocadmium(II) and acetatocopper(II) complexes, respectively. Some of these constants were determined in our laboratory[6,8] and others were cited from literatures, if necessary, after correction for the ionic strength and/or temperature with the same procedures as described previously[2-4]. These constants are given in Table II.

TABLE II. EQUILIBRIUM CONSTANTS AT IONIC STRENGTH 0.2 AT VARIOUS TEMPERATURES

Temp., °C	5	15	20
$\log K_{CdY}$	16.53	16.34	—
pK_{HY}	10.34	10.16	—
$\log K_{CdHY}^H$	—	—	2.8
K_{CuOAc}	—	41	—
$K_{Cu(OAc)_2}$	—	190	—
K_{CdOAc}	—	27	—

From Eq. 13 is obtained,

$$K^+ / [CdY^{2-}]_0 = A[H^+] + B + C\frac{1}{[H^+]} \quad (15)$$

$$\left. \begin{aligned} A &= \frac{k_2^+ + k_3^+ \frac{1 + K_{CdOAc}[OAc^-]}{[Cd^{2+}]_{0,app}}}{1 + \sum_{n=1}^{2} K_{Cu(OAc)_n} [OAc^-]^n} \\ B &= k_1^+ / (1 + \sum_{n=1}^{2} K_{Cu(OAc)_n} [OAc^-]^n) \\ C &= k_4^+ / (1 + \sum_{n=1}^{2} K_{Cu(OAc)_n} [OAc^-]^n) \end{aligned} \right\} \quad (16)$$

8) N. Tanaka and K. Kato, This Bulletin, 33, 417 (1960).

where the initial concentrations, $[Cd^{2+}]_0$ and $[CdY^{2-}]_0$, are substituted for $[Cd^{2+}]$ and $[CdY^{2-}]$, respectively.

Rearranging Eq. 15,

$$k^+ [H^+] / [CdY^{2-}]_0 = A[H^+]^2 + B[H^+] + C \quad (17)$$

$$\left(\frac{k^+ [H^+]}{[CdY^{2-}]_0} - C \right) \Big/ [H^+] = A[H^+] + B \quad (18)$$

are obtained. Since both Cd^{2+} and CdY^{2-} are present in the reaction mixture in a large excess over the concentration of copper(II) ion, the change of their concentrations during the reaction can be neglected.

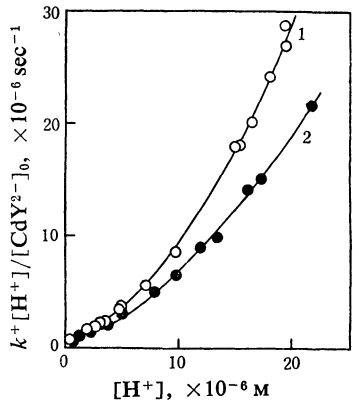

Fig. 2. $k^+[H^+]/[CdY^{2-}]_0$ as a function of the hydrogen ion concentration in acetate buffer-potassium nitrate solutions of ionic strength 0.2 at 15°C. Initial concentrations are: $[Cu^{2+}]_{0,app} = 1.98 \times 10^{-4}$ M; $[CdY^{2-}]_0 = 5.00 \times 10^{-3}$ M; $[Cd^{2+}]_{0,app} = 1.028 \times 10^{-2}$ M (curve 1) and 2.056×10^{-2} M (curve 2). Concentration of free acetate is 0.091 M.

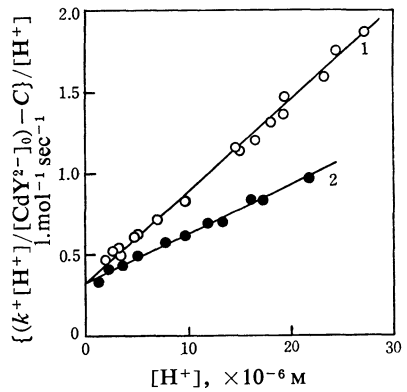

Fig. 3. $\{(k^+[H^+]/[CdY^{2-}]_0) - C\}/[H^+]$ as a function of the hydrogen ion concentration in acetate buffer-potassium nitrate solutions of ionic strength 0.2 at 15°C. Initial concentrations are: $[Cu^{2+}]_{0,app} = 1.98 \times 10^{-4}$ M; $[CdY^{2-}]_0 = 5.00 \times 10^{-3}$ M; $[Cd^{2+}]_{0,app} = 1.028 \times 10^{-2}$ M (curve 1) and 2.056×10^{-2} M (curve 2). Concentration of free acetate is 0.091 M.

TABLE III. RATE CONSTANTS IN EQ. 13 OBTAINED EXPERIMENTALLY, AND THOSE FOR REACTIONS 10b, 11b AND 12b AT IONIC STRENGTH 0.2 AT VARIOUS TEMPERATURES

Temp. °C	Rate constant					
	k_1^+ l.mol^{-1} sec^{-1}	k_2^+ l^2 mol^{-2} sec^{-1}	k_{II}^+ l.mol^{-1} sec^{-1}	k_3^+ l.mol^{-1} sec^{-1}	k_{III}^+ l.mol^{-1} sec^{-1}	k_4^+ sec^{-1}
5	0.95	$1.7_0\times10^4$	26.9	$3.7_6\times10^2$	$5.7_0\times10^8$	$9.4_5\times10^{-7}$
15	2.2	$2.9_0\times10^4$	45.9	$9.0_7\times10^2$	$1.3_2\times10^9$	$3.7_8\times10^{-6}$

In Figs. 2 an 3, $k^+[H^+]/[CdY^{2-}]_0$ and $\{(k^+[H^+]/[CdY^{2-}]_0)-C\}/[H^+]$ are plotted against $[H^+]$, respectively, using the values of k^+ obtained at various hydrogen ion concentrations. The values for *A*, *B* and *C* were determined from these plots; *A* from the slope of the plot in Fig. 3, *B* from the intercept of the plot in Fig. 3 and *C* from the intercept of the plot in Fig. 2. With these values and equilibrium constants given in Table II, the rate constants were calculated using Eqs. 14 and 16, and they are summarized in Table III.

The rate constant k_{III}^+ had been determined in the kinetic studies of the substitution reaction between copper(II) ion and lead(II)-EDTA complex[2,3], and that between copper(II) ion and zinc(II)-EDTA complex[4]. It is in reasonable agreement with the value of k_{III}^+ obtained in this study, as shown in Table IV.

TABLE IV. THE RATE CONSTANTS OF ELEMENTARY REACTIONS OF THE SUBSTITUTION REACTION, $M^{m+}+M'Y^{(m'-4)+} \rightleftarrows MY^{(m-4)+}+M'^{m'+}$, AT 15°C $\mu=0.2$ AND $[OAc^-]=0.09$ M

M	M'	k_1^+ l.mol^{-1} sec^{-1}	k_{II}^+ l.mol^{-1} sec^{-1}	k_{III}^+ l.mol^{-1} sec^{-1}
Cu^{2+}	Pb^{2+}	1.7	10	1.7×10^9
Cu^{2+}	Zn^{2+}	19	60	2.0×10^9
Cu^{2+}	Cd^{2+}	2.2	45.9	$1.3_2\times10^9$
Pb^{2+}	Zn^{2+}	4.6	800	1.0×10^{10}

Ackermann and Schwarzenbach[1] investigated the kinetics of the substitution reaction between copper(II) ion and Cd(II)-EDTA complex at 0°C in the solutions of ionic strength 1.0 containing 0.09 M of acetate ion and $5\times10^{-6}\sim1.4\times10^{-4}$ M of hydrogen ion, when they concluded that the reaction proceeds simultaneously through four different paths as follows:

$$Cu^{2+}+\left\{\begin{array}{l} CdY^{2-} \\ \downarrow\uparrow \\ CdHY^- \\ \downarrow\uparrow \\ Cd^{2+}+HY^{3-} \\ \downarrow\uparrow \\ Cd^{2+}+H_2Y^{2-} \end{array}\right\} \rightarrow Cd^{2+}+CuY^{2-}+\left\{\begin{array}{l} H^+ \\ H^+ \\ 2H^+ \end{array}\right\}$$

Their experimental conditions, however, were apparently unfavorable to find out the reaction path given by Eqs. 12a, 12b and 12c.

Equation 13 predicts that the reaction rate decreases with the increasing concentration of acetate ion. This was previously recognized experimentally by Ackerman and Schwarzenbach, who stated that the decrease in reaction rate was due to the formation of acetato copper(II) complex. Using Eqs. 15 and 16, the values of $k^+/[CdY^{2-}]_0$ were calculated at various concentrations of acetate ion with the rate constants given in Table III. These values are plotted against acetate ion concentration in Fig. 4, where the experimental values for $k^+/[CdY^{2-}]_0$ obtained at various concentrations of acetate ion are also given. Figure 4 indicates that the calculated values of $k^+/[CdY^{2-}]_0$ considerably deviate from the experimental ones. This tendency has been noticed in the studies on other substitution reactions[3-5]. The discrepancy seemed to come from the assumption that the reaction proceeds through only hydrated ions.

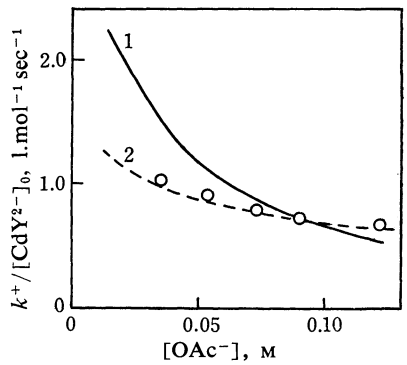

Fig. 4. $k^+/[CdY^{2-}]_0$ as a function of the acetate ion concentration in acetate buffer-potassium nitrate solutions of pH 5.50 and ionic strength 0.2 at 15°C. Initial concentrations are: $[Cu^{2+}]_{0,app}=1.98\times10^{-4}$ M; $[CdY^{2-}]_0=5.00\times10^{-3}$ M; $[Cd^{2+}]_{0,app}=1.028\times10^{-2}$ M. ○ indicates the experimental value. Curve 1 is calculated with Eq. 13 and curve 2, with Eq. 19.

Then, the reaction was assumed as to proceed through both hydrated ion and monoacetato complex. The rate-determining steps in the simultaneous substitution reaction are as follows.

$$\text{i)}\quad Cu^{2+}+CdY^{2-} \overset{k_{1h}^+}{\rightleftarrows} CuY^{2-}+Cd^{2+} \qquad (9')$$

$$CuOAc^+ + CdY^{2-} \overset{k_{1c}^+}{\rightleftarrows} CuY^{2-}+CdOAc^+ \qquad (9'')$$

ii) $Cu^{2+} + CdHY^- \overset{k_{IIh}^+}{\rightleftarrows} CuHY^- + Cd^{2+}$ (10b')

$CuOAc^+ + CdHY^- \overset{k_{IIc}^+}{\rightleftarrows} CuHY^- + CdOAc^+$ (10b'')

iii) $Cu^{2+} + HY^{3-} \overset{k_{IIIh}^+}{\rightleftarrows} CuY^{2-} + H^+$ (11b')

$CuOAc^+ + HY^{3-} \overset{k_{IIIc}^+}{\rightleftarrows} CuY^{2-} + H^+ + OAc^-$

iv) $Cu^{2+} + CdOHY^{3-} \overset{k_{IVh}^+}{\rightleftarrows} CuOHY^{3-} + Cd^{2+}$ (12b')

$CuOAc^+ + CdOHY^{3-} \overset{k_{IVc}^+}{\rightleftarrows} CuOHY^{3-} + CdOAc^+$ (12b'')

where k_{ih}^+ and k_{ic}^+ mean the rate constants of the reactions which proceed through the hydrated ion and monoacetato complex, respectively. Since it seemed extremely difficult, however, to determine all of these rate constants separately because of insufficient accuracy in the measurement, the following procedure was taken up as the first approximation. In all reactions from (9') to (12b'') the ratios of k_{ic}^+ to k_{ih}^+ (i.e. k_{ic}^+/k_{ih}^+) are assumed to be the same and denoted with x. The rate equation is written as Eq. 19.

$$v^+ = \frac{k_{1h}^+ + k_{2h}^+[H^+] + k_{3h}^+ \dfrac{1+K_{CdOAc}[OAc^-]}{[Cd^{2+}]_{app}} + k_{4h}^+ \dfrac{1}{[H^+]}}{1+\sum_{n=1}^{2} K_{Cu(OAc)_n}[OAc^-]^n} \times (1+xK_{CuOAc}[OAc^-])[Cu^{2+}]_{app}[CdY^{2-}] \quad (19)$$

Comparing Eq. 19 with Eq. 13,

$$k_i^+ = k_{ih}^+(1+xK_{CuOAc}[OAc^-]) \quad (20)$$

is derived. With the values of k_i^+ obtained experimentally at various concentrations of acetate ion k_{ih}^+ and x were determined by the graphical method. For the latter, 0.26 at 5°C and 0.37 at 15°C were obtained. The apparent rate constants $k^+/[CdY^{2-}]_0$ at various concentrations of acetate ion were evaluated with the values of k_{ih}^+ and x using Eq. 20. The results are in satisfactory agreement with the experimental values as shown in Fig. 4 (curve 2). Although this treatment is not strictly rigorous, it proves that the substitution reaction proceeds through both hydrated ions and monoacetato complexes.

Summary

The kinetic study of the substitution reaction of copper(II) and ethylenediaminetetraacetatocadmate(II) complexes in acetate buffer solutions has been carried out by the same method as reported previously[2-5]. The reaction was found, under the experimental conditions, to proceed simultaneously through four different reaction paths, and the rate constants for the elementary reactions of those reaction paths were determined at ionic strength 0.2 at 5 and 15°C. It was confirmed also that this substitution reaction proceed through both hydrated ion and monoacetato complex.

*The Crystal Structure of m-Aminobenzenearsonic Acid**

By Akira SHIMADA

(Received May 23, 1962)

The crystal and molecular structure of benzenearsonic acid and its *p*-amino derivative have been recently investigated by the present author[1,2]. These two structures are closely related in both having endless chains formed by the hydrogen bonds between arsonic acid groups, although the molecule in the latter is to be regarded as a zwitterion and although the $-NH_3^+$ group in this ion forms additional hydrogen bonds to link the chains. In connection with the above work, the crystal structure of *m*-aminobenzenearsonic acid, $H_2N \cdot C_6H_4AsO(OH)_2$, was examined as part of a program to contribute to the structural chemistry of organoarsenic compounds.

* The major part of this papar was read at the 14th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1961.

Experimental

Crystals suitable for X-ray work were selected from specimens kindly prepared and supplied by Prof. H. Nakata of Konan University. They were colorless, transparent, and lath-like needles with a long dimension in the c direction. The crystals used in this experiment had square cross sections 0.16×0.15 mm. for $(h\,k\,0)$, 0.22×0.24 mm. for $(0\,k\,l)$, and 0.26×0.29 mm. for $(h\,0\,l)$. Oscillation and Weissenberg photographs around three principal axes were taken with CuK_α radiation; it was found from an examination of them that the unit cell is monoclinic with the following dimensions:

$a=13.35$, $b=15.60$, $c=7.46$ Å and $\beta=92.7°$

This choice of axes, which makes the unit cell base-centered, is unconventional in the case of the monoclinic system, but the crystal was referred to these axes for the sake of experimental convenience, since the c axis lies along a needle direction and since the a axis is almost perpendicular to the needle direction by this choice of axes. The cell size of this crystal gave a calculated density of 1.857 g. cm^{-3} on the assumption that there are eight formula units in a unit cell. This calculated density is close to the value found for the *p*-amino derivative.

The extinctions observed, $h\,k\,l$ when $h+l$ is odd, $h\,0\,l$ when h and l is odd, and $0\,k\,0$ when k is odd, indicate that the space group is $C_{2h}^5-B2_1/a$. By comparing these results with a calibrated scale, visual intensity measurements were made with the aid of both multiple exposure and multiple-film techniques. They were corrected for the appropriate Lorentz and polarization factors, and the correction for absorption ($\mu=58.6\,cm^{-1}$) was evaluated on the assumption that the specimens were cylindrical rods.

Structure Determination

The structure was determined by making use of the heavy atom technique. Thus, the Patterson projection $P(UV)$ along the c axis was first synthesized because of the short c axis. In this projection were found trains of peaks along the b axis at approximately $U=0$ and $U=a/4$ due to vectors from the heavy arsenic atom to the lighter atoms; peaks due to vectors between arsenic atoms were also found. This striking appearance suggests that the planes of benzene rings are perhaps almost parallel to the (100) plane and pack one above the other, with a separation of one quarter of a period along the a axis. This fact was confirmed by the minimum function based on the rotation peak between arsenic atoms and also by the preliminary electron-density map, the Fourier terms of which were observed structure amplitudes with signs determined only by the approximate coordinates of arsenic atoms derivable from the Patterson function. Hence, it was not so difficult to locate plausible positions of the lighter atoms in this projection with this feature of the packing mode of benzene rings, although there was a heavy overlapping of the carbon atoms of benzene rings.

Referring to this feature of the structure, the Patterson and electron-density maps along the a axis were synthesized by the same procedure. These two maps along the a axis, together with the aid of the projection along the c axis, were sufficient to give all of the atomic positions except those of the hydrogen atoms; the projection along the b axis was also tried in order to confirm the atomic positions derived by the other projections.

Refinement of the coordinates of atoms was carried out by successive Fourier syntheses and also by difference syntheses at later stages. In the calculation of the structure factors, McWeeny's scattering curves[3] for the nitrogen atom, of "valence states" for carbon and of $1/3(f^{\parallel}+2f^{\perp})$ for the oxygen atom, were used,

while that given by Berghuis et al.[4] was used for the arsenic atom. The isotropic temperature factors were estimated to be 2.7 Å^2 for all atoms. The R indices for the final coordinates listed in Table I were 10.0, 11.8 and 11.6% for $(hk0)$, $(0kl)$ and $(h0l)$ respectively, excluding terms too weak to be observed. The observed structure factors are compared with those calculated in Fig. 1.

Description of the Structure

The configuration of a molecule and the molecular arrangement in the crystal may be seen in Figs. 2a, 2b and 2c, which represent the c, a and b axes projections for this crystal. The arsenic atom is surrounded by a group of three oxygen atoms, O_1, O_2 and O_3 of the arsonic acid, and one carbon atom C_1 of the benzene ring. The average As–O distance is 1.76 Å, and the As–C distance is 1.91 Å. The disposition of bonds from the arsenic atom appears to be nearly tetrahedral, the angles between the bonds being about 110°. The benzene ring is planar, and the average distance between adjacent carbon atoms is 1.39 Å, individual values ranging from 1.35 Å to 1.41 Å. The N–C distance is 1.49 Å, and the nitrogen atom is found to lie on the plane of a benzene ring within the limit of experimental error. This molecular configuration is considered to be in accordance with those of benzenearsonic acid and its *p*-amino derivative.

The molecules are held together by a beautiful network of hydrogen bonds. There are four hydrogen atoms available for hydrogen bonding in an asymmetric unit. Two of them come from the *m*-amino group, and two come from the arsonic acid group. There is one hydrogen bond between oxygen atoms, and there are three hydrogen bonds between oxygen and nitrogen atoms in the crystal. The hydrogen bond, with a length of 2.56 Å from the O_3

atom of I molecule to the O_1 atom of the III–B molecule, links the molecules with each other to form endless chains along the c axis. The nitrogen atom in the *m*-amino group of molecule I forms three hydrogen bonds, the first with a length of 2.95Å to the O_2 atom of II molecule, the second with a length of 2.64Å to the O_2 atom of IV+B−a−b molecule, and the third with a length of 2.66Å to the O_1 atom of the II+B molecule. This triple hydrogen-bond formation of a nitrogen atom suggests that one of the hydrogen atoms is transferred from an arsonic acid group to the *m*-amino group. On this basis, the formula of the molecule should be written as $NH_3^+ \cdot C_6H_4 \cdot AsO_2(OH)^-$, which indicates that the molecule is in the zwitterion form in the crystal.

Three hydrogen bonds around a nitrogen atom connect the chains mentioned above to form a sheet which is perpendicular to the b axis and is located around a glide plane. These sheets of hydrogen bonds are interlocked through the benzene rings, which are found to stack with each other along the a axis. This mode of packing of the molecule is similar to that of *p*-aminobenzenearsonic acid, while only hydrogen-bonded chains are packed together by van der Waals forces in benzenearsonic acid. All the intermloecular distances correspond to normal van der Waals interactions; the shorter contacts are illustrated in Fig. 2.

The author is much indebted to Professor Isamu Nitta of Kwansei Gakuin University and to Professor Tokunosuke Watanabé of Osaka University for their interest and encouragement, to Professor Hisakazu Nakata of Konan University for providing the specimens, and to Dr. Kenji Osaki of Osaka University for his sharing of his computation programs and for his instructions about structure-factor calculations using the NEAC electronic computer, which was generously made available by Dr. Shigeki Sakurai of the Electrical Communication Laboratory. Part of the computations for this study were also carried out with a KDC-I electronic computer; deep appreciation is expressed to Professor Tetsuro Tanaka, Professor Takeshi Kiyono and Mr. Koichi Toyoda of Kyoto University for their kind assistance with these calculations. The present study was supported partly by a scientific research grant from the Ministry of Education.

Semiconductivities and Charge Transfer Spectra of Solid Molecular Complexes of 1, 3, 5-Trinitrobenzene

By Haruo KURODA, Keitaro YOSHIHARA and Hideo AKAMATU

(Received April 30, 1962)

The solid molecular complexes formed by the interaction of polycyclic aromatic hydrocarbons with halogens are semiconductors of a high electrical conductivity[1]. In such molecular complexes, a charge transfer interaction between the molecules contributes to the solid formation, where halogen molecules behave as electron acceptors, while hydrocarbon molecules behave as electron donors. These solid molecular complexes exhibit a strong electron spin resonance absorption[2,3], which indicates a strong electron transfer from the donor to the acceptor molecules. There are, however, a number of charge transfer complexes which do not show any appreciable electron spin resonance absorption. In such molecular complexes, the intermolecular charge transfer between donor and acceptor molecules is relatively weak in the ground state. In these cases, Mulliken's theory of charge transfer interaction can be successfully applied to a discussion of the electronic state[4]. We shall temporarily call such complexes by the name of "loose molecular complexes". The complexes formed from polycyclic aromatic hydrocarbons, as the donor, and tetracyanoethylene or 1, 3, 5-trinitrobenzene (TNB), as the acceptor, are of this kind.

In a previous paper[5], we have shown, with a series of tetracyanoethylene-complexes, that the energy gap, twice the activation energy for the electrical conduction, determined from the temperature dependence of the electrical resistivity is approximately equal to the energy corresponding to the peak of the charge transfer band in the absorption spectrum of the crystal. In order to explain such a result, we presumed that a charge carrier is produced through a charge transfer from a donor to an acceptor molecule. If this is actually the case, a similar relation will be found with other loose molecular complexes. It seems, therefore, of interest to compare the activation energy for the electrical conduction with the frequency of the charge transfer band observed with such other loose molecular complexes as TNB-complexes.

Experimental

The TNB-complexes, in which the mole ratios of the donors to TNB were 1 : 1, were prepared by cooling hot solutions containing equivalent amounts of the donors and of TNB. The crystals of the complexes usually precipitate as fine needles.

The electrical resistivity of each complex was measured by the D. C. method. A crystalline powder of the complex was packed in a quartz cell, and the resistivity was measured under a compression of 116 kg./cm^2. The field applied externally for the resistivity measurement was below 2000 V./cm., where the resistivity obeyed Ohm's law. The temperature dependence of the resistivity was studied in a range from room temperature to a little below the melting point.

The visible and ultraviolet absorption spectra of the crystalline powders were measured by means of the KBr-pellet method with a Cary spectrophotometer.

Results

Absorption Spectra. — The absorption spectrum of the solid complex formed between *N, N, N', N'*-tetramethylbenzidine and TNB is shown in Fig. 1. The absorptions at wavelengths shorter than 500 mμ can be assigned to the excitation of either the donor or the TNB molecules, while the band extending from 500 to 800 mμ is the characteristic absorption band for the complex formation. Almost every

solid complex studied here has such a characteristic band, which is always very broad and without any fine structure, the width at half of the intensity maximum being more than 8000 cm^{-1} in wave number. The solid complex of anthracene was found to be an exception in this respect; it showed an absorption band with a fine structure which we shall mention later.

The wavelength at the peak of the characteristic band is given in Table I, together with the wavelength of the charge transfer band observed with the carbon tetrachloride solution of the complex. McGlynn and Boggus[6] have shown that the frequency of the charge transfer band of TNB-complexes of polycyclic aromatic hydrocarbons in solutions is linearly dependent on the ionization potential of the donor. The frequency of the charge transfer band in carbon tetrachloride, $\nu_{C.T.}(soln.)$, given in Table I, can be described as:

$$h\nu_{C.T.}(soln.) = 0.85I_p - 3.65 \quad [eV.] \qquad (1)$$

where I_p is the ionization potential of the donor. The relation between the frequency of the characteristic band of the solid complexes, $\nu_{C.T.}(solid)$, and the ionization potential of the donor can also be described by a similar equation:

$$h\nu_{C.T.}(solid) = 0.85I_p - 3.82 \quad [eV.] \qquad (2)$$

The regularity mentioned above implies, in the first place, that the characteristic absorption bands observed with the solid complexes are also due to the excitation associated with a charge transfer from the donor to the TNB molecules, and that, in the second place, the energy of the charge transfer excitation is, in the crystalline state, lower by an average of 0.17 eV. than that of the isolated complex in carbon tetrachloride. In other words, we can consider that the charge transfer band shows a red-shift as a result of the crystallization. The magnitude of the red-shift in each complex is given in the last column of Table I.

The absorption spectrum of the solid complex of anthracene-TNB is shown in Fig. 2. The absorption in the wavelength region of 400~500 mμ is the charge transfer band. In this band we can observe three peaks separated from each other by 1070 cm^{-1}. Lower, Hochstrasser, and Reid[7] have observed the absorption spectrum of a single crystal of

anthracene-TNB at the temperature of liquid nitrogen and have found a similar fine structure in the change transfer band. They assigned the fine structure to the TNB-ring stretching vibration, 1070 cm^{-1}, an intermolecular vibration, 250 cm^{-1}, and their combinations. This fine structure can be observed in the crystalline state only; the charge transfer band in the absorption spectrum of the complex in solution shows no structure.

Electrical Resistivity. — All the TNB-complexes studied here are poor semiconductors, exhibiting an electrical resistivity of $10^{13}\sim10^{20}$ Ω·cm. at room temperature. As is known to be the case for many organic semiconductors, the resistivity is exponentially dependent on the reciprocal of the temperature. A typical example of the temperature dependence is given in Fig. 3. The resistivity can be described, therefore, with the following equation:

$$\rho = \rho_0 \exp(E/kT) \qquad (3)$$

where E is the activation energy for the electrical conduction, and ρ_0 is a constant. The experimental results are summarized in Table II. It is to be noted that the activation energy required for the electrical conduction

α-Naphthylamine	3×10^{7}	1×10^{-4}	1.18	2.36	2.58

is very high in TNB-complexes, being comparable with or even higher than that of the donor hydrocarbons.

In Fig. 4, the energy gap, twice the activation energy for the electrical conduction, is plotted against the energy of the charge transfer excitation as determined from the frequency at the peak of the charge transfer band in the solid state. It can easily be seen in Fig. 4 that there is a very close correlation between these two values. They agree well with each other in the complexes formed with aromatic amines. In hydrocarbon-TNB complexes, the energy gap is a little lower than the energy of the charge transfer excitation, although there is a linear relation between them; it coincides, rather, with the absorption edge.

Discussion

In a previous paper[5] we have pointed out that, in several solid complexes formed between TCNE and polycyclic aromatic hydrocarbons, the energy gap, ε, determined from the temperature dependence of the electrical resistivity agrees well with the energy of the charge transfer excitation measured from the wavelength at the peak of the charge transfer band. We have confirmed in the present study that these two values are also closely related with each other in many TNB-complexes. We can not say, however, that they exactly equal one other. The relation between them may be expressed in general by the following equation:

$$\varepsilon = h\nu_{C.T.}(\text{solid}) - \Delta \qquad (4)$$

where Δ is nearly constant in a group of molecular complexes with a fixed acceptor if the donors are molecules of a same type. The average value of Δ is -0.1 eV. in polycyclic aromatic hydrocarbon-TCNE complexes, and 0.2 and 0.5 eV. in TNB-complexes of aromatic amines and in those of polycyclic aromatic hydrocarbons respectively.

Although we have compared here the energy gap with the energy corresponding to the absorption maximum, there is no theoretical reason to take that energy figure instead of the energy of the absorption edge, which is lower than the other by about 0.5 eV. in these solid complexes. We can say that, in the molecular complex mentioned above, the energy gap is equal to or a little higher than the energy of the absorption edge.

If we presume that the band model can be applied to the electronic state of the crystal of the molecular complex, and that the absorption spectrum is associated with an excitation of an electron from the highest filled energy band to the conduction band, the experimental results mentioned above can be explained rather simply. In such a case, the highest filled band may be supposed as one formed from the overlapping between the highest filled molecular orbitals of the donor molecules, and the lowest conduction band, from that of the lowest empty molecular orbitals of the acceptors. Therefore, the excitation of an electron from the filled band to the conduction band corresponds to the transfer of an electron from the donor to the acceptor; hence it is a charge transfer. According to this model, the thermal excitation needed to produce the charge carriers will be identical in its nature with the charge transfer excitation in the optical process.

It is questionable, however, whether or not the observed spectrum is actually associated with such a "band-to-band" excitation as has been postulated above. The energy of the charge transfer excitation in a (1 : 1)-complex formed in solution can be expressed by the following equation, providing the charge transfer interaction is very weak:

$$h\nu_{C.T.} = I_p - A - (e^2/\overline{R}_{D^+\cdot A^-}) - \Delta W \qquad (5)$$

where I_p is the ionization potential of the donor, A, the electron affinity of the acceptor, $\overline{R}_{D^+\cdot A^-}$, the average distance between the positive and the negative charges in the excited state, and ΔW, the energy difference which is not given by the first three terms of this equation. It can be seen that the Coulomb interaction makes quite a large contribution to determining the magnitude of $h\nu_{C.T.}$. In the crystal, on the other hand, if the electron excited from a donor molecule is not localized on the neighboring acceptor molecule, but occupies an orbital that is a little more extended over the crystal lattice, a marked decrease in the Coulomb term will result, which decrease will contribute to a blue-shift of the charge transfer band of the crystal from that of the solution. On the other hand, if the excited electron remains localized on the neighboring acceptor molecule, forming an ion pair, and if the surrounding molecules affect it as a dielectric medium, a red-shift is to be expected, since the charge transfer band of the solution is known to make a red-shift, as the refractive index of the medium is higher[8].

The wavelength of the charge transfer band in the solid complex can be determined by balancing these two opposing effects. The observation that the energy of the charge transfer excitation in the crystalline state is a

8) J. Czekalla and K.-O. Meyer, *Z. physik. Chem. N. F.*, 27, 185 (1961).

little lower in TNB-complexes than the corresponding energy of a (1 : 1)-complex in carbon tetrachloride, suggest that it is not a delocalized electron, but an neighboring ion pair, that is produced in the crystal by the charge transfer absorption. It has also been suggested by Lower, Hochstrasser and Reid[7], on the basis of their studies of the vibrational structure and of the Davydov splitting of the charge transfer band of a single crystal of anthracene-TNB complex, that the exciton in this crystal is an ion pair localized at a lattice position for a relatively long time.

if the charge transfer state in the crystal is such a one as has been discussed above, the charge carriers may not be produced directly through such an excitation process; consequently, the energy of the charge transfer need not coincide with the energy gap as determined from the electrical conduction. We can imagine a number of electronic states which can contribute to the electrical conduction in a crystal of a loose molecular complex. Let us consider a widely separated ion pair. If the distance between a positively-charged donor molecule and a negatively-charged acceptor molecule is so large that the electrostatic interaction between them is completely negligible, the positive charge can change its position from one donor molecule to another donor molecule without requiring additional energy, or at least, with a small activation energy. The same can be said about the movement of the negative charge on acceptor molecules. Thus, the widely separated ion pair can contribute to the electrical conduction. This will be the lowest conduction state; hence, the energy necessary to produce a widely separated ion pair will be equal to the energy gap. This energy can be estimated by the following energy cycle: a donor molecule is taken out from the crystal to the vacuum, then ionized and returned into the original lattice position, and a similar procedure is true for an acceptor molecule at a lattice position sufficiently separated from the positive ion of the donor. The total work necessary to complete such a process, or the energy gap, can be described as:

$$\varepsilon = I_p - A - (W_p^+ + W_p^-) \qquad (6)$$

where W_p^+ and W_p^- represent the polarization energy arising from the positive and negative ions respectively. On the other hand, the energy required to form a neighboring ion pair in the crystal can be expressed by Eq. 5. Therefore, the relation between the energy gap and the energy of the charge transfer can be expressed as:

$$\varepsilon = h\nu_{C.T.} - \delta \qquad (7)$$

$$\delta = (W_p^+ + W_p^-) - (e^2/\bar{R}_{D^+\cdot A^-} + \Delta W)$$

If the donors are molecules of a same type in a series of the complex of an acceptor, $(W_p^+ + W_p^-)$ will not change very much. δ will be nearly constant in this case. The value of δ seems to be less than 1 eV. in TNB-complexes. According to this model, ε is not necessarily equal to $h\nu_{C.T.}$, although it is linearly dependent on the other. The model given above seems to give a probable explanation for the experimental results.

Summary

A series of solid complexes of aromatic hydrocarbons and amines, with 1, 3, 5-trinitrobenzene as the common electron acceptor, were prepared. These complexes were of the loose molecular complex type, and the charge transfer bands were observed with the solid complexes, which showed only small red-shifts from the corresponding bands of the solutions. These solid complexes are poor semiconductors, and the energy gap for the excitation to the conduction state is relatively large, and is nearly coincident with the energy for the charge transfer excitation. From these results, it has been suggested that the charge transfer state in the crystal may not be very different from the corresponding state in the isolated (1 : 1)-complex in the solution. The relation between the charge transfer state and the conduction state has been discussed, and a probable model for the formation of a charge carrier has been suggested.

The cost of research has been defrayed by a Scientific Research Encouragement Grant from the Ministry of Education, to which the authors' thanks are due.

The Absorption Spectra of the Molecular Complexes of Aromatic Compounds with p-Bromanil

By Minoru KINOSHITA

(Received May 17, 1962)

The characteristic absorption spectra of molecular complexes have already been interpreted by the charge transfer theory of Mulliken[1,2]. By the approximation of the theory, the parabolic or linear relation between the energy of the charge transfer transition ($h\nu$) and the ionization potential of the donor (I_p) has been derived and experimentally confirmed[3-6].

$$h\nu = I_p - c_1 + \frac{c_2}{I_p - c_1} \quad (1)$$

$$h\nu = aI_p + b \quad (2)$$

Here, a, b, c_1 and c_2 are assumed to be characteristic constants for the complexes of any one acceptor. Equation 1 is based on Mulliken's theory more strictly than is Eq. 2. However, for weak complexes where the third term in Eq. 1 is rather small, the simple form of Eq. 2 can be a sufficient approximation.

If the coefficients in these equations are known for complexes of various acceptors, the positions of the charge transfer bands in the absorption spectra of the complexes can be predicted from the ionization potentials of donors, or vice versa; also, a comparison of the so-called "apparent electron affinities"[6] of the acceptors can be made. Therefore, it is desirable to obtain these relations in many series of complexes. In this short note, the coefficients of Eq. 2 are determined for the complexes of aromatic hydrocarbons and amines with *p*-bromanil, and the ionization potentials of several donors are estimated.

The charge transfer spectra of the complexes were measured in a carbon tetrachloride solution by the use of a Cary model-11 spectrophotometer at room temperature. The observed results are summarized in Tables I and II, along with the ionization potentials of the donors, which have been given by Watanabe[7] and by Briegleb and Czekalla[4]. Using these ionization potentials, we obtained the following relations:

$$h\nu = 0.928I_p - 4.95 \text{ eV}. \quad (3)$$

for the complexes of the polycyclic aromatic hydrocarbons in Table I, and

$$h\nu = 0.973I_p - 5.27 \text{ eV}. \quad (4)$$

for the complexes of the substituted aromatic compounds. On the other hand, Foster[6] has examined the absorption spectra for many molecular complexes with several acceptors and has shown that coefficient "a" in Eq. 2

Phenyl-α-naphthylamine	7.12
Phenyl-β-naphthylamine	7.15
α-Naphthylamine	7.39
p-Toluidine	7.58
o-Toluidine	7.69
Phenothiazine	7.28
Acridine	8.04

As is shown in Fig. 1, no serious difference is found between these equations in the I_p range from 7.0 to 8.5 eV. In consequence, a comparison of the apparent electron affinity of the acceptor can be conveniently made by using the last equation. The apparent electron affinity of *p*-bromanil is slightly larger than that of *p*-chloranil, 4.16 eV.; this seems to be quite reasonable. The ionization potentials of the donors, which were determined from the observed charge transfer energy in association with Eq. 5, are given in Table III.

Among the complexes of polycyclic aromatic hydrocarbons, perylene and pyrene gave crystalline complexes with *p*-bromanil. Their charge transfer bands were found at 755 and 650 mμ respectively, by employing the KBr-disk method. The solid complexes of some aromatic amines, such as tetramethyl-*p*-phenylenediamine, dimethylaniline, etc., with *p*-bromanil have been found to give electron spin resonance absorptions[8-10]. However, the complexes of perylene and pyrene with *p*-bromanil were found to give no electron spin resonance in their crystalline state. Considering that perylene and pyrene possess nearly the same ionization potential values as the amines, the difference in the magnetic property of the molecular complexes can not be explained simply by the difference in the ionization potential of the donors.

The author wishes to express his hearty thanks to Professor Hideo Akamatu for his kind direction and advice, and also to Dr. Haruo Kuroda for his continuous advice in the course of this work.

The Precipitation Reaction of Various Metallic Ions with Phenylarsonic Acid and its Derivatives

By Hisakazu NAKATA, Yuzuru KUSAKA and Shigeaki KIKKAWA

(Received May 11, 1962)

Phenylarsonic acid and its derivatives have been used extensively as precipitation reagents to separate and determine zirconium, titanium, thorium, bismuth, iron, tin and so on[1-4]. In these separation procedures it is very important to keep a sample solution at an appropriate acidity in order to complete the separation. For ortho, meta and para derivatives of aminophenylarsonic acid and nitrophenylarsonic acid, the pH values at which precipitation begins to occur have been reported for forty elements[3,4]. In these reports, however, the experimental conditions, such as the concentration of reagents and metallic ions and the precipitation procedure, were not described. Moreover, the exact acidities less than a pH value of 1 in which zirconium, titanium, tin and so on are precipitated were not reported.

We have studied the precipitation reactions of about twenty-five metallic elements with phenylarsonic acid and its derivatives. Under definite experimental conditions, the acidities in which the precipitation began and was then completed were measured and compared with each other. The acidities to be measured were over a broad region, such as from 12 N in hydrochloric acid to almost neutral. Phenylarsonic acid, *p*-hydroxy, *p*-amino, *o*-nitro, *m*-nitro, *p*-nitro and *p*-hydroxy-*m*-nitrophenylarsonic acid were used as the reagents. The results obtained are reported here.

Experimental

Materials.—*Phenylarsonic Acid and its Derivatives.* —These were synthesized in our laboratory, phenylarsonic acid by the Palmer-Adams method[5],

p-hydroxy phenylarsonic acid by the Jacobs-Heiderberger method[6], *p*-aminophenylarsonic acid by the Jacobs-Heiderberger-Rolf method[7], and *o*-, m- and *p*-nitrophenylarsonic acid by the Bart method[8]. Only *p*-hydroxy-*m*-nitrophenylarsonic acid was obtained already intact from Prof. Risaburo Nakai of Kyoto University. All were purified by the conventional recrystallization method.

Metallic Salts. — The usual analytical-grade reagents were used. Most of them were chlorides, except for the silver, lead, uranium and thorium as nitrates.

Measurement Instruments.—A photometric Titrator PT-1 of the Yanagimoto Co. and a pH meter M-3 of the Horiba Inst. Co. were used for the measurements. In the former, a red filter was used when the sample solution was colorless. When the solution had some color, as in the case of copper, a filter whose color was the same as that of the solution was used in the experiment. The pH meter was calibrated by Sörensen buffer solutions, solutions mixed with various ratios of 0.1 N hydrochloric acid and 0.1 M sodium citrate.

Precipitation Procedures. — For the elements which were precipitated by an arsonate reagent in pH 1.0~9.0, 8 ml. of 0.05 M metallic ion solution in 0.1 N hydrochloric acid was mixed with 24 ml. of a 0.05 M solution of the arsonate reagent in 0.1 N hydrochloric acid*. Then, by adding a 2.7 N ammonium hydroxide solution drop by drop until the pH value of the solution became 3, the precipitation phenomenon was observed. For the neutralization in more than pH 3, 0.54 N ammonium hydroxide solution was used. As the volume of these ammonia to be added did not exceed 4 ml. in all the experiments, the concentration of metallic ions in the precipitation system was in the range of 0.011~0.013 M.

The formation and the completion of precipitation were investigated with a photometric titrator which measured the transparency or the turbidity of the solution. The pH value of the solution was measured with the pH meter.

For the elements which were precipitated in a more acidic medium than with a pH value of 1, the acidities in which the precipitation occured were determined by a two-step method. First, an approximate region of the acidity was determined. Each 1 ml. of a 0.05 M metallic ion solution whose acidities were adjusted to 6, 5, 4, 3, 2 and 1 N for hydrochloric acid was put in a separate test tube, and then 3 ml. of a 0.05 M arsonate reagent solution of the same acidity as that of the metallic ion solution was added. By this technique, an approximate acidity in which the precipitation is occured was determined; for example, zirconium *p*-hydroxy phenylarsonate is precipitated in a 5~4 N hydrochloric acid solution. In the next step, the more accurate acidity was determined by a similar method. For example, 8 ml. of a 0.05 M zirconium chloride solution in 5 N hydrochloric acid was mixed with 24 ml. of a 0.05 M *p*-hydroxy phenylarsonic acid solution in 5 N hydrochloric acid. Then, 13.5 N ammonium hydroxide was added drop by drop. The arsonate precipitation phenomenon was investigated by the photometric titrator, and the acidity in the precipitation was calculated from the amount of ammonia added to the solution.

For the elements which were precipitated in a stronger acidic medium than 6 N in hydrochloric acid, the experiment was performed by almost the same method as has been described above. In this case, however, only an approximate region of the acidity was determined by a method similar to the first step in the above experiment, and the next step of determining a more accurate acidity in the precipitation was ommited, because ammonium chloride was precipitated by adding ammonia in such a strong hydrochloric acid solution.

In all cases, the experiments were performed at room temperature (about 15°C); this temperature did not exceed 20°C even in the evolution of neutralization heat.

Results and Discussion

Typical examples of the results in the experiments of lead and cadmium phenylarsonates in a weak acidic medium and of thorium and uranium *p*-nitrophenylarsonates in a strong acidic medium are shown in Figs. 1 and 2.

As these figures show, the acidities at which the precipitation began and then was completed could be elucidated by measuring the acidity and the transparency depression in the solution. The turbidity was measured only as a subsidiary means to the transparency measurement. For example, when some color change of ions, based on an acidity change in solution, occured, as in the case of chromic ion, the turbidity measurement played an important role.

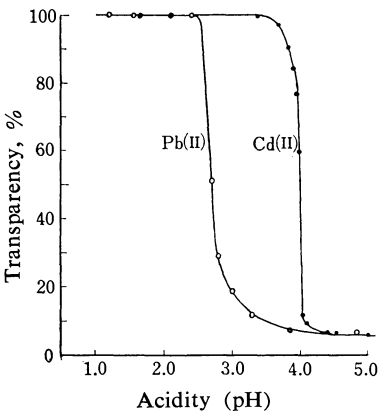

Fig. 1. Lead and cadmium phenylarsonate precipitations in weak acidic medium.

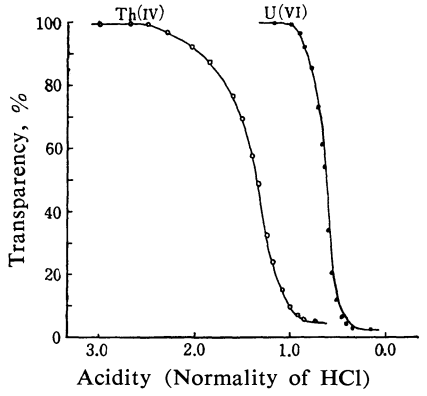

Fig. 2. Thorium and uranium *p*-nitrophenylarsonate precipitations in strong acidic medium.

The experimental results which were obtained for various metallic ions are shown in Tables I and II, in which the former is the precipitation in a strong acidic medium and the latter that in a weak acidic medium. In the tables, the numbers of the first line for each element indicate the acidity at which the precipitation began, and those of the second line indicate that point at which the precipitation is completed.

As the tables show, it seems possible to formurate some general rules on the precipitation of various elements by phenylarsonic acid and its derivatives. Although a few exceptions are found in each reagent, the general order of the elements precipitated from a strong acidic to a weak acidic medium is the order of elements shown in the tables, that is, up to down in the tables.

In each arsonate, especially when they are compared with the phenylarsonates, the nitro derivatives seem to be precipitated in a more acidic medium. In the nitro derivatives, the order is generally from the para and the meta and to the ortho form. The para hydroxy and the para amino derivatives seem to be precipitated in a more basic medium.

The authors wish to express their thanks to Messrs. Hideo Kitai, Mitsuro Tsubosaka, and Mrs. Akiko Ueshima, who contributed to this study by their synthesis of arsonic acid reagents and by their primary study of the precipitations of various metallic ions. Thanks are also due to Mr. Haruo Tsuji for his frequent assistance and to Dr. Risaburo Nakai for his gift of *p*-hydroxy *m*-nitro phenylarsonic acid.

Rotatory Dispersion and Stereochemistry of Organic Compounds. IV. On the Optical Rotatory Contribution of Hydroxyl Groups in Glucose. (Preliminary Report)*

By Yojiro TSUZUKI, Katsumi TANAKA and Koko TANABE

(Received May 25, 1962)

The rotatory dispersion of hydroxy compounds usually shows plain curves, so that the configurational environments around the asymmetric center can not be revealed by the curves. Therefore, it would be desirable to convert the hydroxyl group to one which exhibits a Cotton effect in a convenient spectral region.

The chromophore C=S, one of the most suitable for this purpose, was introduced by Tschugaeff[1] in the form of xanthates and dithiourethans; it has already been experimentally demonstrated by Lowry[2] to produce anomalous rotatory dispersion, and later Fredga[3] and Djerassi et al.[4] successfully applied it to a number of hydroxy acids.

In the present investigation, the authors have prepared various derivatives of D-glucose containing such a chromophore, namely 1,2-5,6-*O*-diisopropylidene-D-glucofuranose-3-(*S*-methyl)-xanthate (II), μ-thioglucoxazoline (III),

TABLE I. MEASUREMENT OF RD

Compound	Solvent	Concn. gr./100 cc.	Light source
I	Methanol	1.0304	Zr
II	Methanol	0.1244	Xe
III	Water	1.0132	Xe
IV	Chloroform	0.1240	Xe
V	Chloroform	0.1002	Xe

Results and Discussion

Compound I exhibits a negative, plain, rotatory dispersion curve, since in the measured wavelength region the compounds has no optically-active absorption band (Fig. 1).

C_3-OH, which is the only free hydroxyl group in this compound, has an L-configuration according to the Fischer-Tollens projection formula. The rotatory dispersion curve II of compound II, which was obtained by treating I with metallic sodium, carbon disulfide and methyl iodide in absolute ether, first exhibits a broad extreme (trough) near 500 mμ and then a sharp extreme (peak) near 375 mμ, thus producing an anomalous dispersion curve. The former trough (ca. 550 mμ) is of no special significance, but the latter sharp peak is related

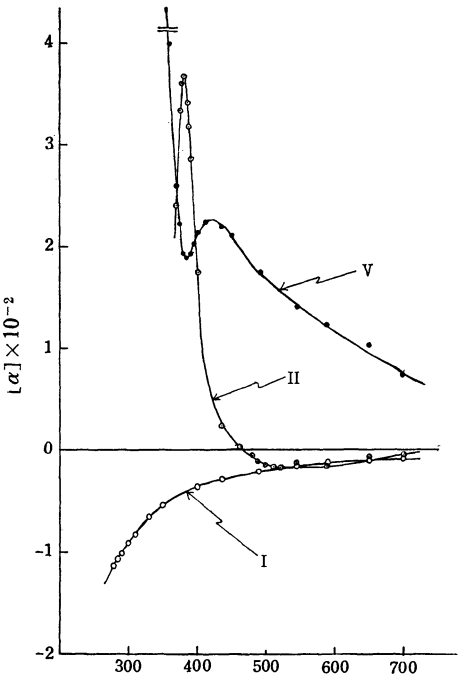

Fig. 1. RD of derivatives of glucose.
○ I, ⊙ II, ● V

to the configuration, judging from its ultraviolet absorption spectrum, which does not exhibit a peak between 400 and 700 mμ.

The ultraviolet absorption maxima appear at 280 mμ (ε=13000) and at 358 mμ (ε=49.21); the peak at 280 mμ is attributed to the C=S moiety, and the maximum at 358 mμ, to the $-\overset{S}{\overset{\|}{C}}-S-$ group.

The anomalous rotatory dispersion curve is caused by the ultraviolet, optically-active absorption band near 375 mμ due to the $-\overset{S}{\overset{\|}{C}}-S-$ group.

Although no data are available below 370 mμ, because of the difficulty of measurement, the extrapolated curve intersects the abscissa at about 360 mμ, a point which is substantially identical with the wavelength of maximum ultraviolet absorption, 358 mμ.

The positive Cotton effect seen in curve II is considered to be due to the C_3- group of the L-configuration; this would, however, be expected to give a negative partial rotation[5].

5) One of the authors has inferred from an analysis of the rotatory dispersion and various experimental facts that the OH group of L-hydroxy acids should contribute to the negative rotation, and has therefore given a rational interpretation to the anomalous behavior of the optical rotation of some hydroxy carboxylic acids. Y. Tsuzuki, *Sci. Pap. Inst. Phys. Chem. Res. (Tokyo)*, No. 890, Vol. 35, 425 (1939); No. 901, Vol. 36, 31 (1939); *J. Chem. Soc. Japan, (Nippon Kwagaku Kwaisi)*, **64**, 282, 290 (1943); Y. Tsuzuki et al., *J. Chem. Soc. Japan, Pure Chem. Sec. (Nippon Kagaku Zasshi)*, **78**, 764 (1957).

On the contrary, the xanthate group on the hydroxyl of L-types of lactic, malic and mandelic acids is clearly responsible for the positive rotation which has been demonstrated by Tschugaeff[1], by Fredga[3], and particularly by Djerassi's rotatory dispersion studies[4].

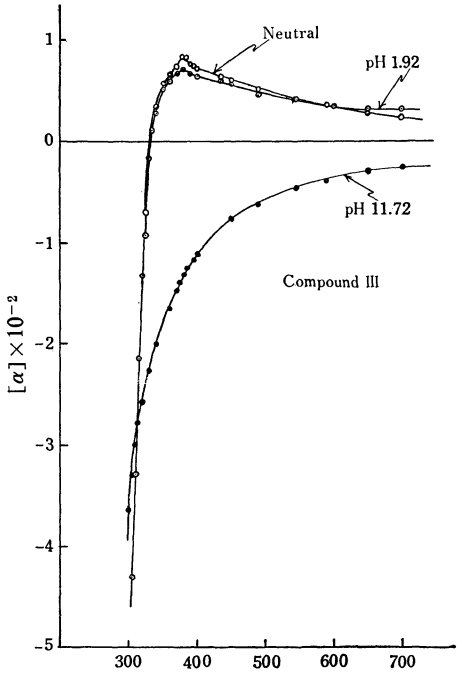
The reason for this is not clear; however, the authors think that inversion of the sign of rotation may occur when the order of the magnitude of the substituents attached to the asymmetric center is inverted, such as:

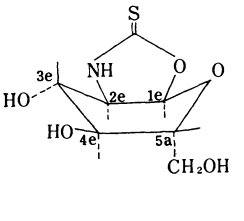
$$COOH > OH \text{ (negative)}$$

$$COOH < O\text{–}CSSR \text{ (positive)}$$

Thus, the observed rotatory contribution of the C_3 of glucose becomes comprehensible, quite in harmony with the former views and observations.

The rotatory dispersion of III, both in a neutral and in an acidic solution, exhibits obviously single Cotton effect curves (Fig. 2).





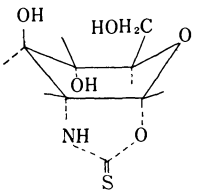


Fig. 2. RD of III.
○ Neutral, ⊙ pH=1.92, ● pH=11.72

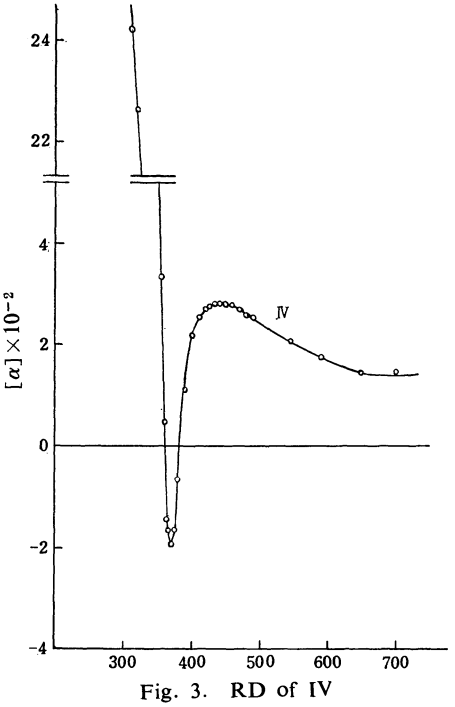
However, compound III and its acetyl derivative IV present a complicated and difficult problem for the interpretation of the rotational behavior. Undoubtedly this anomalous dispersion originates in the partial contribution of C_1 and C_2, the possible form of which may be shown as follows (IIIa):

(IIIa)

(IIIb)

The hydrogen atoms directly attached to the ring carbon atoms are ommited for the sake of simplicity. The pyranose must be at the same time of both the α- and the boat forms; otherwise, a five-membered ring including 1- and 2-carbon atoms cannot be formed. All the hydrogen atoms except C_5–H are axial. The alternate boat form, IIIb, in which the oxazoline five-membered ring and the two OH groups are axial is clearly more unstable than IIIa and is therefore to be left out of consideration.

Acetyl derivative IV of compound III also exhibits a single positive Cotton effect, however, with a larger amplitude, as may be seen by a comparison of the RD-curves of III and IV. In compound IV the thion moiety is well preserved even by acetylation, giving a maximum absorption at 345 mμ (ε=35.6) and also a nearly corresponding Cotton effect (zero rotation point at about 385 mμ) (Fig. 3). Compound III shows no ultraviolet maxima, being transparent in this spectral region. This



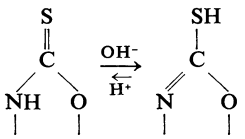


Fig. 3. RD of IV

TABLE II. DISPERSION CONSTANTS FOR GLUCOSE DERIVATIVES

$$[M]=\frac{A}{\lambda^2-\lambda_0^2}+\frac{B}{\lambda^2}$$

Compound	A	B	λ_0 mμ	Peak		Trough		UV absorption 10^{-2} mol./l.	
				mμ	[M]	mμ	[M]	mμ	ε
II	4.54	−37.82	380	380	321.54	—	—	358	49.21
III neutral	−0.11	27.73	367	385	191.49	—	—	no absorption	
III pH 1.92			308	380	154.76	—	—	no absorption	
III pH 11.72	−25.62	0.893	243	—	—	—	—	240~245	
IV	−9.99	280.24	407	445	1104.3	370	−759.17	345	35.65
V	2.53	193.09	399	410	1078.9	385	918.4	358	77.73

compound is considered to be in the non-chromatic μ-thiol form of the following tautomerism:

thion-form thiol-form

In the hydrogen chloride solution (pH=1.92) the rotatory dispersion curve was almost identical with that observed in the neutral solution except that the rotation at the peak is lower. In the sodium hydroxide solution (pH =11.72), the RD curve is shown by a negative plain curve. Thus, it is revealed by these curves that the >C=S moiety of compound III has no influence on the thion-thiol equilibrium when acidic, but in an alkaline solution the equilibrium is displaced so completely towards the enol form that the optically-active absorption band disappears and only a negative plain dispersion curve is obtained. This somewhat unexpected feature may be due to the basic rotation of the boat form.

Compound V, in which C_6 is benzylated, exhibits a rotatory dispersion curve with an obvious single positive Cotton effect near 400 mμ; however, the amplitude is small. This Cotton effect is responsible for the partial contribution of the C_5- carbon. The small amplitude implies that the effect of benzyl xanthate is lessened considerably by the intervention of the C_6-methylene group. The positive sign of this small Cotton effect is in harmony with the L-type of the C_5-$CH_2OCSCH_2C_6H_5$ group, namely, the inversion of the sign of rotation. The ultraviolet absorption maximum of compound V was found to be 358 mμ (ε=77.7), in chloroform, which absorption is responsible for the –C–S– group, perhaps being optically active. The basically strong positive rotation, the peak of which is presumably below 250 mμ, is no doubt related to the D-type of C_1-configuration (α-D-glucoside).

On the Two-term Drude Equation

It is to be expected that the dispersion data can be expressed by the two-term Drude equation:

$$[M]=\frac{A_1}{\lambda^2-\lambda_1^2}+\frac{A_2}{\lambda^2-\lambda_2^2}$$

and that the physical meaning of the values of λ_1 and λ_2 can be interpreted with relation to the chromophores of the molecules; however, for the sake of simplicity the authors have attempted for the present to see whether the experimental data conform to the following abbreviated two-term expression:

$$[M]=\frac{A}{\lambda^2-\lambda_0^2}+\frac{B}{\lambda^2}$$

The first term depends on a particular chromophore, while the second term is concerned with the sum of all the other chromophores or with the remainder of the molecule. The calculations were carrried out by means of the least square method with an electronic computer. The results are shown in Table II.

It may be seen in Table II that the optically-active absorption band in all cases shifted more or less towards wavelengths longer than the corresponding ultraviolet absorption maximum. The values of A, namely, the partial rotatory contribution of the particular chromophores, is negative in sign, in compounds III and IV, and positive in the others.

Experimental

The derivatives of glucose were prepared according to the methods of the literature.

Studies on Antibiotics and Related Substances. XV. Syntheses of Acetobromo Derivatives of 3-Amino-3-deoxyglucose and 6-Amino-6-deoxyglucose[1]

By Yukio Itō, Shinkiti Kōtō and Sumio Umezawa

(Received June 9, 1962)

Acetohalogeno derivatives of sugars are important intermediates used for the synthesis of glycosides, however, the corresponding derivatives of aminosugars represent a relatively unexplored territory. In the course of our studies on the synthesis of glycosides relating to carbohydrate-antibiotics, such as kanamycin and paromomycin, a program was instituted toward the synthesis of acetobromo derivatives of aminosugars. The synthesis of 2, 4, 6-tri-*O*-acetyl-3-amino-α-1-bromo-1, 3-dideoxy-D-glucopyranose (III), 2, 3, 4-tri-*O*-acetyl-6-amino-α-1-bromo-1, 6-dideoxy-D-glucopyranose (VII) and their derivatives is the subject of this paper.

The synthesis of III and their derivatives is outlined in the following Chart A:

Methyl 3-acetamido-2,4,6-tri-*O*-acetyl-3-deoxy-α-D-glucopyranoside (I) was synthesized by a modification of the route described by Peat and Wiggins[2]. When this route was followed, the yield of α-anomer of methyl 2, 4, 6-tri-*O*-acetyl-3-*O*-(p-toluene-sulfonyl)-D-glucoside was found to be too low to make progress in further synthesis. The difficulty has been overcome by the transformation of β-anomer to α-anomer by a modification of the method described by Ohle and Wilcke[3]. It has been found that treatment with titanium tetrachloride in chloroform transformed the β- to α-anomer in 91% yield. It has also been found that isopropanol is an appropriate solvent for the crystallization of α-anomer resulting in a

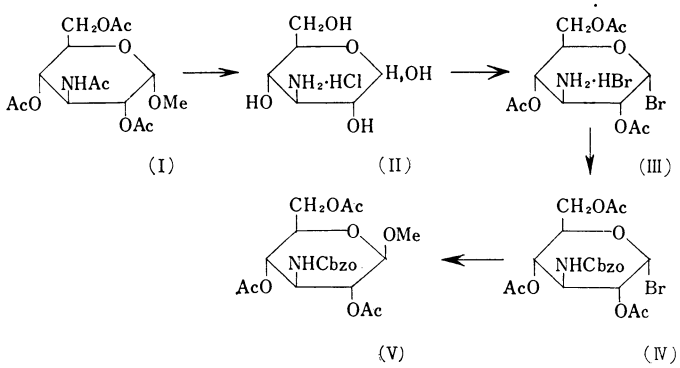

Chart A

1) Presented at the Division of Organic Chemistry of the 15th Annual Meeting of the Chemical Society of Japan, Kyoto, April, 1962.

2) S. Peat and L. F. Wiggins, *J. Chem. Soc.*, 1938, 1092, 1810.

3) H. Ohle and H. Wilcke, *Ber.*, 71, 2327 (1938).

relatively good yield (28.9%)[4]. Thus the total yield of α-anomer has been raised to 62.5%. The α-anomer has been subjected to ammonolysis by methanolic ammonia in an autoclave at 150°C, followed by acetylation, to give methyl 3-amino-3-deoxy-α-D-glucoside tetraacetate (I) by the method of Peat and Wiggins. Attempts have been made to effect ammonolysis of β-anomer by analogous procedure, followed by acetylation, but these have not been successful.

3-Amino-3-deoxy-D-glucose has been obtained by hydrolysis of the above tetraacetate. Acid hydrolysis studies revealed optimum conditions, namely, refluxing in 6 N hydrochloric acid for three hours, whereby 79.2% of the tetraacetate has been converted to 3-amino-3-deoxy-D-glucopyranose hydrochloride (II).

When treated with acetyl bromide at room temperature for three hours, 3-amino-3-deoxy-D-glucopyranose hydrochloride gave 2, 4, 6-tri-*O*-acetyl-3-amino-α-1-bromo-1, 3-dideoxy-D-glucopyranose hydrobromide (III) in a 96.2% yield.

Masking of the amino group of III with the carbobenzoxy group by treatment with carbobenzoxy chloride in potassium bicarbonate solution gave 2,4,6-tri-*O*-acetyl-α-1-bromo-3-carbobenzoxyamino-1, 3-dideoxy-D-glucopyranose (IV) in a 53.2% yield.

An attempt to prepare a glycoside from IV proved to be practical. When shaken with methanol in the presence of mercuric cyanide by Koenigs-Knorr reaction, methyl 2, 4, 6-tri-*O*-acetyl-3-carbobenzoxyamino-3-deoxy-β-D-glucopyranoside (V) has been obtained in a 77.4% yield.

Synthesis of 2, 3, 4-tri-*O*-acetyl-6-amino-α-1-bromo-1, 6-dideoxy-D-glucopyranose (VII) and their derivatives is outlined in the following Chart B:

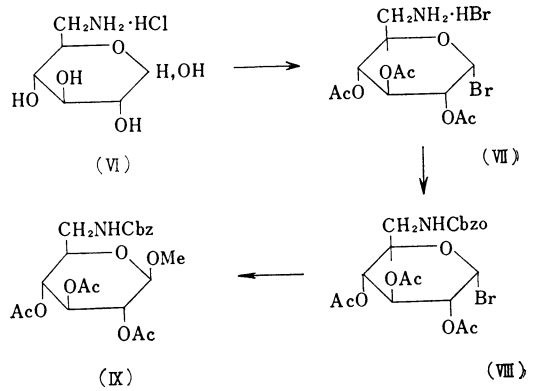

Chart B

6-Amino-6-deoxy-D-glucopyranose hydrochloride (VI) was synthesized from tetra-*O*-acetyl-α-D-glucopyranosyl bromide via benzylglucoside-derivatives by the route described by Cramer et al.[5] Reaction of VI with acetyl bromide at room temperature for seventy-four hours yielded 2,3,4-tri-*O*-acetyl-α-1-bromo-1,6-dideoxy-D-glucopyranose hydrobromide (VII), m. p. 162~164°C (decomp.), in a 96.3% yield. It should be noted that VII is almost insoluble in chloroform and other common organic solvents, while the corresponding derivative III is soluble in chloroform.

When a suspension of VII in chloroform was shaken with carbobenzoxy chloride in the presence of a saturated solution of potassium bicarbonate at 0°C for twenty minutes, the reaction product dissolved in chloroform-layer, from which 2, 3, 4-tri-*O*-acetyl-α-1-bromo-6-carbobenzoxyamino-1, 6-dideoxy-D-glucopyranose (VIII) was obtained in a 76% yield. When subjected to Koenigs-Knorr reaction, using

mercuric cyanide as a catalyst, VIII gave methyl 2,3,4-tri-*O*-acetyl-6-carbobenzoxyamino-6-deoxy-α-D-glucopyranoside (IX) in a 61.2% yield. The same reaction using silver carbonate-calcium sulfate as a catalyst gave the same product IX in a 57% yield.

Infrared spectra of the acetobromo derivatives (IV, VII, VIII) showed absorptions near 840 cm^{-1} which is characteristic of α-configuration, while the methylglucosides (V, IX) prepared from IV and VIII showed absorptions near 890 cm^{-1}, indicating that the methylglycosides have a β-configuration, as anticipated from the usual results of the Koenigs-Knorr reaction. Moreover, values of specific rotation of the above-mentioned derivatives are consistent with the spectroscopic results, as shown in Table I, where these data are shown together with those of the corresponding derivatives of 2-amino-2-deoxy-D-glucose.

Experimental

Methyl 2,4,6-Tri-*O*-acetyl-3-*O*-(*p*-toluenesulfonyl)-α-D-glucoside. — A solution of 84 g. of 1,2:5,6-di-*O*-isopropylidene-3-*O*-(*p*-toluenesulfonyl)-α-D-glucofuranose[8] in 650 g. of 2% methanolic hydrogen chloride was refluxed for 15 hr. on a steam bath. After being cooled, the reaction mixture was neutralized with basic lead carbonate, filtered and the filtrate was evaporated under reduced pressure to give a yellowish syrup. A mixture of the syrup, 67 g. of anhydrous sodium acetate and 335 ml. of acetic anhydride was heated at 110°C for 3 hr. The reaction mixture was cooled and then poured into 500 g. of ice-water, followed by stirring for 30 min. The resulting mixture was extracted with six 100 ml. portions of chloroform. The chloroform extracts were combined, washed with a saturated solution of sodium carbonate, and then with water thoroughly to give a neutral chloroform-solution, which was dried over sodium sulfate and filtered. Evaporation of the filtrate at 55°C under reduced pressure gave a reddish-brown syrup, which was crystallized from 100 ml. of ether to give 32.2 g. of methyl 2,4,6-tri-*O*-acetyl-3-*O*-(*p*-toluenesulfonyl)-β-D-glucopyranoside, m. p. 126.9~130°C., yield 33.6%.

The mother liquor separated from the above-mentioned β-anomer was evaporated to dryness to give a syrup. When dissolved in 35 ml. of hot isopropanol and allowed to stand, the syrup gave the corresponding α-anomer, the title compound, m. p. 94~95°C, yield 27.8 g. (28.9%). The crude product was used for amination. Peat and Wiggins[2] reported m. p. 97°C, $[\alpha]_D^{16}+87.1°$ ($CHCl_3$) and 19.4% yield.

Transformation of Methyl 2,4,6-Tri-*O*-acetyl-3-*O*-(*p*-toluenesulfonyl)-β-D-glucoside to its α-Anomer. —The transformation was effected by a modified method of Ohle and Wilcke[3] as follows: To a solution of 10 g. of methyl 2,4,6-tri-*O*-acetyl-3-*O*-(*p*-toluenesulfonyl)-β-D-glucoside in 120 g. of dry chloroform was added a solution of 5 g. of titanium tetrachloride in 80 g. of dry chloroform and the mixture was refluxed on a water bath for 75 min. After being cooled, the reaction mixture was poured into 200 g. of ice-water and shaken vigorously. The chloroform-layer was separated and the aqueous layer was extracted with three 10 ml. portions of chloroform. The chloroform extracts were combined, washed with water and dried over sodium sulfate. After being filtered, the chloroform solution was evaporated to dryness under reduced pressure. The resulting brown syrup was dissolved in 5 ml. of hot isopropanol and allowed to stand in the refrigerator to give a crystalline solid of methyl 2,4,6-tri-*O*-acetyl-3-*O*-(*p*-toluenesulfonyl)-α-D-glucopyranoside, m. p. 96.8~97.4°C, $[\alpha]_D^{20.7}+89°$ (*c* 2.0, $CHCl_3$), yield 9.1 g. (91%). Mixed melting point of the product with the above-described α-anomer showed no depression. The product was also used for amination.

3-Amino-3-deoxy-D-glucopyranose Hydrochloride (II).—A solution of 4.0 g. of methyl 3-acetamido-2,4,6-tri-*O*-acetyl-3-deoxy-α-D-glucoside[9] in 80 ml. of 6 N hydrochloric acid was heated on a steam bath for 3.5 hr. The reaction mixture was evaporated to dryness at 50°C in vacuo. The residue was dissolved in 2 ml. of methanol and evaporated again to dryness. The evaporation to remove water was repeated seven times to give a pale-yellow spongy residue. The residue was dissolved in 60 ml. of warm methanol, neutralized with silver carbonate and shaken with 1 g. of decolorizing charcoal for 30 min., followed by filtration. The filtrate was evaporated to dryness in vacuo at about 50°C to give 2.4 g. of a spongy residue. The residue was dissolved in 15 ml. of warm methanol, added dropwise with isopropanol until the solution became somewhat turbid and the mixture was allowed to stand in a refrigerator to give a hygroscopic powder of 3-amino-3-deoxy-D-glucopyranose hydrochloride, yield 1.2 g. (79.2%).

Found: C, 33.37; H, 6.96; N, 6.76. Calcd. for $C_6H_{13}NO_5 \cdot HCl$ (215.6): C, 33.42; H, 6.54; N, 6.50%.

Paperchromatography of the product showed a single spot by ninhydrin coloration and gave the same R_f value with that of a natural specimen which was obtained from the hydrolyzate of kanamycin.

2,4,6-Tri-*O*-acetyl-3-amino-α-1-bromo-1,3-dideoxy-D-glucopyranose Hydrobromide (III).—A mixture of 2.27 g. of 3-amino-3-deoxy-D-glucopyranose hydrochloride (II) and 10 g. of freshly distilled acetyl bromide was allowed to stand for 3 hr. at room temperature with frequent shaking. The resulting solution was subjected to distillation in vacuo to remove unchanged acetyl bromide and the residue was dried in a brown vacuum-desiccator over sodium hydroxide overnight. The residue was dissolved in 25 ml. of hot chloroform, added with 1 g. of decolorizing charcoal and refluxed for 15 min. After the mixture was filtered, 100 ml. of absolute ether was added to the solution and the mixture was allowed to stand in a refrigerator overnight to

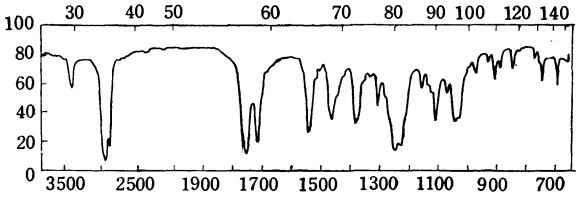

Fig. 1. Infrared spectrum of 2,4,6-tri-*O*-acetyl-α-1-bromo-3-carbobenzoxyamino-1,3-dideoxy-D-glucopyranose (IV) in Nujol.

to precipitate colorless powdery 2,4,6-tri-*O*-acetyl-3-amino-α-1-bromo-1,3-dideoxy-D-glucopyranose hydrobromide (III). The mother liquor was concentrated and added with absolute ether to obtain a second crop. The total yield was 4.56 g. (96.2%). The first crop showed m. p. 131~135°C, $[\alpha]_D^{15}$ +127.5° (*c* 1.77, $CHCl_3$).

Found: C, 31.30; H, 4.19; N, 3.38. Calcd. for $C_{12}H_{19}O_7NBr_2$ (449.1): C, 32.09; H, 4.26; N, 3.12%.

The infrared spectrum of the product in potassium bromide shows absorption bands at 3225 (νNH), 1759, (νC=O in OAc), 1593 (δNH_3^+), and 1219 (νC-O in OAc).

2, 4, 6-Tri-*O*-acetyl-α-1-bromo-3-carbobenzoxyamino-1, 3-dideoxy-D-glucopyranose (IV).—A mixture of the first and second crops of 2,4,6-tri-*O*-acetyl-3-amino-α-1-bromo-1,3-dideoxy-D-glucopyranose (III) was used for the following preparation: A mixture of 4.36 g. of III, 3 ml. of carbobenzoxy chloride (purity 58.5%), 77 ml. of chloroform and 41 ml. of saturated solution of potassium bicarbonate was stirred vigorously at −5°C for 20 min. The chloroform layer was separated and the aqueous layer was extracted with three 5 ml. portions of chloroform. The chloroform extracts were combined, washed three tmies with each 5 ml. of water and dried over 10 g. of sodium sulfate for 3 hr. The filtrate was concentrated under reduced pressure to yield a residue of colorless crystals of 2,4,6-tri-*O*-acetyl-α-1-bromo-3-carbobenzoxyamino-1,3-dideoxy-D-glucopyranose. To the residue was added 30 ml. of ether, allowed to stand overnight and then filtered; m. p. 146~148°C (decomp.), $[\alpha]_D^{10}$ +131.6° (*c* 1.77, $CHCl_3$), yield 2.59 g. (53.2%).

Found: C, 47.90; H, 4.64; N, 3.03; Br, 15.67. Calcd. for $C_{20}H_{24}O_9NBr$ (502.3): C, 47.82; H, 4.81; N, 2.79; Br, 15.91%.

The infrared spectrum of the product in Nujol shows absorption bands at 3383, (νNH), 1753 (ν C=O in OAc), 1714 (νC=O in Cbzo), 1540 (δNH), 1244, 1225 (νC-O in OAc), 848 (type 2a of pyranose ring) and 776, 748, 698 (phenyl) (Fig. 1).

Methyl 2,4,6-Tri-*O*-acetyl-3-carbobenzoxyamino-3-deoxy-β-D-glucopyranoside (V).—A mixture of 0.2 g. of 2,4,6-tri-*O*-acetyl-α-1-bromo-3-carbobenzoxyamino-1,3-dioxy-D-glucopyranose (IV) and 0.05 g. of mercuric cyanide in 1.0 ml. of absolute methanol was shaken at 27°C for 1.0 hr. to obtain a yellowish solution. The solution was cooled in ice-water and added with water dropwise, whereupon the solution became turbid and then there were colorless crystals of methyl 2,4,6-tri-*O*-acetyl-3-carbobenzoxyamino-3-deoxy-β-D-glucopyranoside deposited, which were collected and washed with water until the washings became neutral; yield 0.14 g. (77.4%), m. p. 139°C, $[\alpha]_D^{12}$ −19.6° (*c* 1.77, $CHCl_3$).

Found: C, 55.50; H, 5.99; N, 3.12; OCH_3, 6.58. Calcd. for $C_{21}H_{27}O_{10}N$ (453.5): C, 55.62; H, 6.00; N, 3.09; OCH_3, 6.84%.

The infrared spectrum of the product in chloroform shows absorption bands at 3415 (νNH), 1753 (νC=O in OAc), 1735 (νC=O in Cbzo) 1520 (δNH), 1227, 1210 (νC-O in OAc) and 895 (type 2b of pyranose ring).

2, 3, 4-Tri-*O*-acetyl-6-amino-α-1-bromo-6-deoxy-D-gulcopyranose Hydrobromide (VII).—A mixture of 0.2 g. of 6-amino-6-deoxy-D-glucose hydrochloride[5] and 0.72 g. of freshly distilled acetyl bromide was placed in a brown flask and allowed to stand for 74 hr. with frequent shakings. The resulting mixture was subjected to vacuum-distillation to remove unchanged acetyl bromide and the residue was dried thoroughly in a vacuum-desiccator over sodium hydroxide overnight. The residue was triturated with 8 ml. of chloroform to give colorless crystals of 2,3,4-tri-*O*-acetyl-6-amino-α-1-bromo-6-deoxy-D-glucopyranose hydrobromide, which were washed three times with a portion of 2.0 ml. of chloroform each, yield 0.4 g. (96.3%), m. p. 142°C (decomp.). A specific rotation pattern of the product could not be ascertained because it is not soluble enough for the determination in ordinary organic solvents. A small quantity of the product was recrystallized from a large quantity of dioxane-tetrahydrofuran for the elementary analysis; m. p. was raised to 162~164°C (decomp.).

Found: C, 31.81; H, 4.61; N, 3.04. Calcd. for $C_{12}H_{19}O_7NBr_2$ (449.1): C, 32.09; H, 4.26; N, 3.12%.

The infrared spectrum of the product in potassium bromide shows 3218 (νNH) 1765 (νC=O in OAc), 1594 (δNH_3^+), 1249, 1224 (νC-O in OAc) 843 (type 2a of pyranose ring).

2, 3, 4-Tri-*O*-acetyl-α-1-bromo-6-carbobenzoxyamino-1, 6-dideoxy-D-glucopyranose (VIII).—A mixture of 0.2 g. of 2,3,4-tri-*O*-acetyl-6-amino-α-1-bromo-6-deoxy-D-glucopyranose hydrobromide (VII), 0.12 g. of carbobenzoxy chloride, 3.5 ml. of chloroform and 1.5 ml. of a saturated solution of sodium bicarbonate was shaken at about 0°C for 20 min. Thereby the suspension of VII which is almost insoluble in both chloroform and water disappeared, resulting in two layers of clear chloroform and aqueous solutions. The chloroform layer was separated, washed with water and dried over sodium sulfate. The filtrate was evaporated under reduced

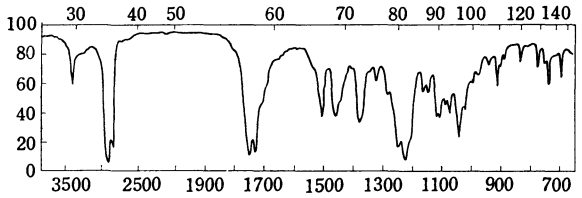

Fig. 2. Infrared spectrum of 2,3,4-tri-*O*-acetyl-α-1-bromo-6-carbobenzoxyamino-1,6-dideoxy-D-glucopyranose (VIII) in Nujol.

pressure and the resulting residue was recrystallized twice from ether-petroleum ether to give colorless tiny crystals of 2,3,4-tri-*O*-acetyl-α-1-bromo-6-carbobenzoxyamino-1,6-dideoxy-D-glucopyranose; yield 0.17 g. (76%), m. p. 89°C, $[\alpha]_D^{17}$ +156° (*c* 1.67, $CHCl_3$).

Found: C, 48.29; H, 4.72; N, 2.91; Br, 15.43. Calcd. for $C_{20}H_{24}O_9NBr$ (502.3): C, 48.72; H, 4.81; N, 2.79; Br, 15.92%.

The infrared spectrum of the product in Nujol shows absorption bands at 3390 (νNH), 1751 (νC=O in OAc), 1731 (νC=O in Cbzo), 1507 (δNH), 1249, 1222 (νC-O in OAc), 833 (type 2a of pyranose ring) and 776, 732, 739, 697 cm^{-1} (phenyl) (Fig. 2).

Methyl 2, 3, 4-Tri-*O*-acetyl-6-carbobenzoxyamino-6-deoxy-β-D-glucopyranoside (IX). — *By Mercuric Cyanide as a Condensing Reagent.*—A mixture of 0.2 g. of 2, 3, 4-tri-*O*-acetyl-α-1-bromo-6-carbobenzoxyamino-1,6-dideoxy-α-D-glucopyranose (VIII), 0.05 g. of mercuric cyanide in 1.0 ml. of absolute methanol was placed in a brown flask and shaken at 29°C for 1 hr. and then poured into 8 ml. of ice-water. The resulting viscous precipitate was taken in chloroform and washed with water. After drying over sodium sulfate, the chloroform solution was evaporated to dryness and the residue was triturated with isopropanol to start crystallization, yield 0.11 g. (61.2%), m. p. 95~100°C. Recrystallization from isopropanol raised the m. p. to 103~104°C; $[\alpha]_D^{15}$ +4.5° (*c* 2.00, $CHCl_3$).

Found: C, 55.77; H, 5.76; N, 3.11; OCH_3, 6.44. Calcd. for $C_{21}H_{27}O_{10}N$ (453.5): C, 55.62; H, 6.00; N, 3.09, OCH_3, 6.84%.

The infrared spectrum of the product in chloroform shows absorption bands at 3465 (νNH), 1764 (νC=O in OAc), 1734 (νC=O in Cbzo), 1519 (δNH), 1245, 1215 (νC-O in OAc), 903 (type 2b of pyranose ring).

By Silver Carbonate as a Condensing Reagent.—A mixture of 0.2 g. of 2,3,4-tri-*O*-acetyl-α-1-bromo-6-carbobenzoxyamino-1, 6-dideoxy-D-glucopyranose, 9.1 ml. of methanol, 1.2 g. of silver carbonate, 0.61 g. of calcium sulfate and 9.1 ml. of chloroform was sealed in a test tube to keep completely free from moisture and shaken at 29°C for 4.5 hr. The reaction mixture was filtered through active charcoal placed on a filter paper and the active charcoal was washed ten times with a portion of 2 ml of methanol. The filtrate and washings were combined and evaporated to dryness under reduced pressure. The residue was recrystallized from isopropanol to give colorless crystals of m. p. 99~101°C, yield 0.1 g. (57%). Mixed melting point of the product and the sample obtained by the above method showed no depression and the respective infrared spectra were completely superimposable.

The authors are indebted to Mr. Saburo Nakada for microanalysis and are grateful to Mr. Sadaaki Hashimoto for helping their experiments.

NOTES

Oxidaton of Tetralin with tert-Butyl Chromate

By Tamon MATSUURA, Takayuki SUGA and Takashi SAKAO

(Received April 23, 1962)

Previous works on the oxidation of cyclohexene[1a,b] and of terpenoids[2a-e] with *tert*-butyl chromate have revealed that an active methylene group adjacent to a double bond was preferentially oxidized to an α,β-unsaturated ketonic group. Also, some aromatic compounds[3] have been oxidized with the same oxidant; e. g., dihydrosafrole was mainly oxidized to piperonylic acid. The present work deals with the oxidation of tetralin with this oxidant.

Experimental

Tetralin, distilled repeatedly, was used as the sample; b. p. 90°C/18 mmHg, n_D^{25} 1.5388, d_4^{25} 0.9669. Gas chromatography using a column of P. E. G. −6000 on celite at 150°C and helium (60 cc./min.) as a carrier gas showed that the sample tetralin was contaminated by 2.9% of naphthalene.

Experiment I.—A *tert*-butyl chromate solution was prepared from 197 g. of chromic anhydride, 394.5 g. of *tert*-butyl alcohol, 1100 g. of benzene, 50 g. of glacial acetic acid and 100 g. of acetic anhydride in the same manner as in the previous report[2c] except that the oxidant solution was concentrated to 66% in volume before use. This oxidant solution was added drop by drop, to a solution of 50 g. of tetralin in 75 g. of benzene, and the oxidation was carried out under the conditions shown in Table I. Then, the whole reaction mixture was treated as usual (cf. Ref. 1b or 2c). In this manner, 44.5 g. of a neutral product and 1.8 g. of an acidic one were obtained. The latter (1.8 g.) was chromatographed on silica gel using ethyl alcohol-chloroform mixture, The first fraction gave 0.5 g. of *o*-carboxyhydrocinnamic acid (m. p. 166~167°C[4]; Found: C, 61.62; H, 5.54%) and the other fraction gave *o*-phthalic acid (m. p. and mixed m. p., 191~191.5°C).

A gas chromatogram of the neutral product showed three peaks, which corresponded to those of tetralin (retention time at 160°C: 5 min.), naphthalene (10 min.) and α-tetralone (32 min.) respectively. The chromatogram indicated the presence of 3.1% of naphthalene in the neutral product, corresponding to 2.8% for the tetralin used.

A portion (10 g.) of the neutral product was chromatographed on silica gel using mixture of ethyl acetate and *n*-hexane. The first fraction gave 5.5 g. of tetralin unchanged (b. p., n_D^{25}, d_4^{25}; the IR spectrum accorded with that of tetralin), while the second one gave 3.5 g. of α-tetralone (b. p. 124~125°C/10 mmHg, n_D^{25} 1.5655, d_4^{25} 1.0914, λ_{max}^{EtOH} 247 mμ[5]: ε 11790), which in turn gave 2, 4-dinitrophenylhydrazone (m. p. 255°C (decomp.)) (Found: N, 17.01%), semicarbazone (m. p. 219~221°C) (Found: N, 20.80%), and oxime (m. p. 102~103°C) (Found: N, 8.46%). As for the determination of the α-tetralone in the neutral product, Fujita's procedure[6] was used. The reliability of this procedure was confirmed by using a known mixture containing pure α-tetralone in tetralin.

Experiment II.—A *tert*-butyl chromate solution was prepared in the same manner as above, except that the benzene solution was concentrated to 55% in volume. To this oxidant, 50 g. of tetralin in 50 g. of benzene was added drop by drop. After the oxidation had been carried out under the conditions shown in Table I, the reaction mixture was treated as in Experiment I.

Results

The results are summarized in Table I. It was found that a methylene group adjacent to a benzene nucleus of tetralin was preferentially oxidized to a ketonic group, with *tert*-butyl chromate giving α-tetralone. However, no formation of 1,4-naphthoquinone was observed, unlike the *tert*-butyl chromate oxidation of cyclohexene, which afforded *p*-benzoquinone, and also unlike the chromic acid oxidation of α-tetralone[7], in acetic acid which gave 1, 4-naphthoquinone. A slight degradative oxidation

TABLE I. CONDITIONS AND RESULTS IN THE OXIDATION OF TETRALIN

Experiment	Reaction condition: Sample/Chromic acid	Reaction condition: Temp. °C	Reaction condition: Time day	Reaction product (wt % to the sample): α-Tetralone	o-Carboxyhydrocinnamic acid	o-Phthalic acid	Tetralin unchanged
I	1 : 5.2	18~25	16	35	1	0.6	48
II	1 : 5.2	18 then, 46~48	1 15	45	2	12	17

of α-tetralone occurred to give *o*-carboxyhydrocinnamic acid and *o*-phthalic acid. Undoubtedly, *o*-carboxyhydrocinnamic acid is the degradative product of α-tetralone through 1, 2-diketone, i. e., 3, 4-dihydro-1, 2-naphthoquinone, while *o*-phthalic acid is produced by the further oxidation of *o*-carboxyhydrocinnamic acid.

Summary

The oxidation of tetralin with *tert*-butyl chromate gave a relatively good yield of α-tetralone as the major product. Thus, it was seen that this oxidant oxidizes a methylene group of an alicyclic ring, adjacent to a benzene nucleus, to a ketonic group, forming α-ketone.

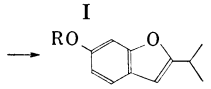
A New Method of Preparing 2-Alkylbenzofuran from 2-Alkyl-3(2H)-benzofuranone

By Yoshiyuki KAWASE and Shinnichi NAKAMOTO



(Received May 29, 1962)

For the preparation of 2-alkylbenzofurans, two methods seem to be generally applicable, by the reduction of 2-alkyl-3(2*H*)-benzofuranone oxims followed by deamination[1], and by the dehydrogenation of 2, 3-dihydro-2-alkylbenzofurans[2]. However, neither method is entirely satisfactory because of their low yields and too many steps. In the case of the 2-isopropyl derivatives, they have been prepared from 2-acetyl derivatives by the Grignard reaction[3].

Now a new, easier method for the synthesis of general 2-alkylbenzofuran from 2-alkyl-3-(2*H*)-benzofuranone has been explored; the ketone was reduced with lithium aluminum hydride or with sodium borohydride to give 2, 3-dihydro-2-alkyl-3-benzofuranol, which was then readily converted into 2-alkylbenzofuran by dehydration.

I II

III R=Me
IV R=H

Reduction of 2-isopropyl-6-methoxy-3(2*H*)-benzofuranone (I), followed by subsequent treatment with acetic acid, furnished *cis*-2, 3-dihydro-2-isopropyl-6-methoxy-3-benzofuranol (II) in the form of colorless crystals with a sharp odor. The hydroxyl group of II seems to be cis to the isopropyl group, considering its formation procedure, the difficulty with which it forms nitrobenzoate, and the easiness with which it can be dehydrated. The distillation of II or the use of hydrochloric acid in the above-mentioned reduction of I readily furnished 2-isopropyl-6-methoxybenzofuran (III). The reflux of II with anhydrous pyridine hydrochloride furnished 6-hydroxy-2-isopropylbenzofuran (IV).

Experimental*

***cis*-2, 3-Dihydro-2-isopropyl-6-methoxy-3-benzofuranol (II).**—(*a*) *By Lithium Aluminum Hydride.*—A solution of 2-isopropyl-6-methoxy-3(2*H*)-benzofuranone[4] (I, m. p. 74~75°C, IR: ν_{CO} 1675 cm^{-1} (KBr), 2 g.) in anhydrous ether (20 ml.) was stirred into a suspension of lithium aluminum hydride

* Melting and boiling points are uncorrected.

4) J. Arima and T. Okamoto, *J. Chem. Soc. Japan* (*Nippon Kwagaku Kwaishi*), **50**, 344 (1929); W. Bridge, A. J. Crocker, T. Cubin and A. Robertson, *J. Chem. Soc.*, **1937**, 1530.

(0.4 g.) in ether (80 ml.), and the mixture was then refluxed for one hour. The cooled mixture was acidified with dilute aqueous acetic acid, and the ether layer was separated and washed with dilute aqueous sodium hydroxide. The crystalline product obtained from the ethereal solution was recrystallized from petroleum benzine to give II in the form of colorless crystals; m. p., 108~109°C; yield, 1 g. (50%). IR: ν_{OH} 3220 cm^{-1} (KBr) or 3480 cm^{-1} ($CHCl_3$). Found: C, 69.24; H, 7.74. Calcd. for $C_{12}H_{16}O_3$: C, 69.21; H, 7.74%.

(*b*) *By Sodium Borohydride.*—A solution of sodium borohydride (0.5 g.) in ethanol (20 ml.) was slowly added to a solution of the ketone I (1 g.) in ethanol (30 ml.), and the mixture was heated at 65~70°C for 2 hr. In this reduction, the reaction temperature was important, for the starting material was recovered only when the temperature was lower. Most of the ethanol was removed in vacuo; the residue was acidified with dilute aqueous acetic acid and extracted with ether. The ethereal solution was washed with dilute aqueous sodium hydroxide, and the product was recrystallized from petroleum benzine; m. p., 107~109°C. Yield, 0.5 g. (50%).

2-Isopropyl-6-methoxybenzofuran (III).—Distillation of II in vacuo or treatment with dilute hydrochloric acid instead of acetic acid in the above-mentioned reduction of I gave III as a colorless oil; b. p., 130~135°C/3 mmHg. Picrate: red crystals; m. p., 60~61°C (from ethanol). Found: N, 10.75. Calcd. for $C_{18}H_{17}O_9N_3$: N, 10.02%.

6-Hydroxy-2-isopropylbenzofuran (IV).—A mixture of II (0.3 g.) and anhydrous pyridine hydrochloride (1.5 g.) was refluxed for 20 min. on an oil-bath (220°C). The cooled product was treated with dilute hydrochloric acid and extracted with ether. The ethereal solution was extracted with dilute aqueous sodium hydroxide, and the product obtained by acidifying the alkaline solution was distilled in vacuo (b. p., 130°C/0.001 mmHg) and then crystallized from petroleum benzin to give IV in the form of colorless microcrystals; m. p., 75~76°C; yield, 0.1 g. The reported m. p. is 75~76°C[1]. Found: C, 74.72; H, 7.03. Calcd. for $C_{11}H_{12}O_2$: C, 74.97; H, 6.86%.

SHORT COMMUNICATION

High Pressure Hydrogenation with Rhodium-Platinum Oxide

By Shigeo NISHIMURA and Hisaaki TAGUCHI

(Received July 23, 1962)

In previous papers[1], it was shown that the rhodium-platinum oxide of Adams' type is an excellent catalyst in activity and in selectivity in the hydrogenation of various organic compounds at ordinary temperature and pressure. The effects of platinum in the rhodium-platinum oxide were also reported[2].

Subsequently the use of the rhodium-platinum oxide under high pressure of hydrogen has been found extremely effective in many hydrogenations. Under the pressures of 70 to 100 kg./cm^2, most hydrogenations proceed rapidly at room temperature with (7 : 3) rhodium-platinum oxide (see Table I). Usually in acetic acid rapid absorptions of hydrogen begin with the reduction of the oxide almost instantly at 50°C and in 10 to 30 min. at room temperature at the pressure of 100 kg./cm^2. The rate in hydrogenation of benzene increased greatly with the increase of hydrogen pressure in the range of 75 to 132 kg./cm^2. The activity of (7 : 3) rhodium-platinum oxide under high pressures is not only much greater, but also more stable than that of platinum oxide[3]. Accordingly, with rhodium-platinum oxide only a small amount of the catalyst is required for rapid and complete hydrogenation of most unsaturated organic compounds. With

2) S. Nishimura, ibid., **34**, 1544 (1961).
3) High pressure hydrogenations with platinum oxide were reported to be effective [R. H. Baker and R. D. Schuetz, *J. Am. Chem. Soc.*, **69**, 1250 (1947)]. But in most cases, for the completion of hydrogenations within a short time, fairly a good amount of the catalyst must be used because of the decrease of the activity during hydrogenation.

TABLE I. HIGH PRESSURE HYDROGENATION WITH (7 : 3) RHODIUM-PLATINUM OXIDE[a]

Compound	Amount g.	Catalyst g.	Temp. °C	H_2 press. kg./cm^2	Time min.	Product (Yield, %)
Benzene	7.81	0.05*	24	75～49	11	Cyclohexane (Not isolated)
Benzene	7.81	0.05*	24	99～70	8	Cyclohexane (Not isolated)
Benzene	7.81	0.05*	24	132～99	5	Cyclohexane (Not isolated)
Benzene	7.81	0.025	50	99～70	6	Cyclohexane (Not isolated)
Toluene	9.21	0.05	25	99～66	12	Methylcyclohexane (85)
Ethyl benzoate	15.0	0.05	24	98～68	45	Ethyl hexahydrobenzoate (91)
Aniline	9.31	0.10*	23	75～24	76	Cyclohexylamine (68) Dicyclohexylamine (20)
Aniline	9.31	0.05	50	80～51	35	Cyclohexylamine (56) Dicyclohexylamine (29)
Phenol	9.41	0.05	32	99～65	12	Cyclohexanol (85)

Pyridine	7.91	0.05	50	100～71	20	Piperidine (Not isolated)

a) 50 ml. of acetic acid was used as solvent.
* The oxide was pre-reduced in the absence of the substrate.

the catalyst aniline gives a better yield of cyclohexylamine than with platinum oxide[4]. Phenol and acetophenone gave with good yields the corresponding saturated alcohols. Pyridine hydrogenates rather slowly at room temperature, but rapidly at 50°C. Thus, the high pressure hydrogenation with rhodium-platinum oxide is a very useful synthetic method. Its high acitivity at low temperatures may be advantageous in many selective hydrogenations. Further studies on the catalytic activity and selectivity of the rhodium-platinum oxide under high pressures are in progress.

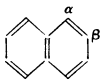
4) With platinum oxide under similar conditions, cyclohexylamine and dicyclohexylamine were obtained in yields of 17 and 23% respectively (Ref. 3); cf. G. S. Hier and R. Adams, *Ber.*, **59**, 162 (1926).

The Question of a Diversity of Mechanisms in Friedel-Crafts Acylation Reactions

By P. H. GORE

(Received March 13, 1962)

In a recent paper Yamase[1] adopted the view proposed earlier[2-4] that the literature data pertaining to Friedel-Crafts acylation reactions are consistent with a concept of a duality of mechanisms. According to the type and reactivity of reagent and substrate, the mechanism of acylation is considered to involve either an attack on the aromatic substrate by the acyl cation $RCO^{\oplus}$, or by the bulkier acyl halide complex RCOX, AlX_3. Evidence had been adduced earlier[3] in favour of the view that the latter mechanism operated in most "normal" acylation reactions, whilst attack by $RCO^{\oplus}$ would be likely only when steric circumstances become dominant.



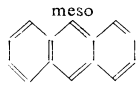
If, for instance, the acyl halide RCOX is sterically hindered, then formation of the addition complex RCOX, AlX_3 becomes energetically unfavourable*, and ionization giving the reactive acyl cation would be promoted, viz.

$$RCOX + AlX_3 \rightleftarrows RCO^{\oplus} + AlX_4^{\ominus}$$

Alternatively, when the reactive nuclear position of the substrate is sterically inaccessible, the small reagent $RCO^{\oplus}$ may be able to approach closely to the site of substitution, whilst the bulky addition complex may not. The theory of a duality of mechanisms has found a measure of general acceptance[1,6-9], whilst Brown and Jensen[6] contributed a further mechanism (i.e. involving attack by the ion-pair $(RCO^{\oplus})(AlX_4^{\ominus})$), which is not considered further here.

The data which Yamase and Goto[10,11] have recently put forward appear relevant to the concept of a duality of mechanisms. Their study of the relative reactivities of a series of acyl halides RCOX, in the presence of AlX_3, with a series of substrates, employed measurement of the "temperature of incipient reaction" (i.e. "the temperature at which the velocity of reaction becomes sufficient to cause visible bubbles (of hydrogen halide) to be evolved"), which was valuable enough in Calloway's[12] study of 1937, but which no longer can be regarded as a more than very approximate kinetic criterion.

It is of interest to consider whether the present theoretical framework of the concept of a diversity of mechanisms in the Friedel-Crafts acylation reaction would accomodate, for example, the "abnormal" substitution of naphthalene. Acylations of naphthalene[cf.4] exhibit wide variations of α- and β-isomer formation, depending on the solvent used, ranging from about 95% α- (with ethylene dichloride) to about 25% α- (with nitrobenzene). This has usually been attributed (in vague terms) to complex formation between the addition complex and solvent (S) molecules. The bulky complex RCOX, AlX_3, S would be more easily accomodated in the β-position of naphthalene[13-18]. One must admit that there is little doubt that such solvated complexes are capable of being formed under the usual reaction conditions.



The effect of such solvation would indeed be a reduction in the electron-demand (and hence of the reactivity) of the reagent, as found experimentally. However, this clear-cut and simple role of the solvent cannot, in the present view, be supported in the light of the

* This is akin to the formation of aroyl cations from aromatic carboxylic acids (ArCOOH) on dissolution in concentrated sulphuric acid, when two ortho substituents are present. (In their absence $ArCOOH_2^{\oplus}$ is formed) (Ref. 5).

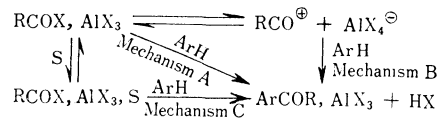
following: 1) If in nitrobenzene a bulky acylating complex is formed, why does concurrent α-substitution proceed in naphthalene, sometimes to the extent of 40%? Why can anthracene be acylated in this same solvent in its sterically hindered *meso*-position, as with benzoyl chloride in 79% yield[19], or with cinnamoyl chloride in 52% yield[4]? 2) Why



are such wide variations in isomer ratio observed with changing acyl halide? An α-/β-isomer ratio of 2.1 is obtained in the benzoylation of naphthalene in nitrobenzene, whilst under identical experimental conditions acetylation gives an isomer ratio of 0.5[13]. 3) How can appreciable β-substitution be explained in solvents such as carbon disulphide (e. g. 65% in acetylation[20]), which cannot readily solvate the aluminium chloride complexes. 4) An increase in temperature should result in increased substitution at the more sterically hindered position, whatever the solvent*. Data exist[4] for benzoylation of naphthalene, which show an increase in actual yield of β-naphthyl phenyl ketone from 24% (at 35°C) to 33% (at 150°C)[13].

The closely analogous pattern to the reversible sulphonation of naphthalene prompted the suggestion[3,4] that certain acylations may be reversible in polycyclic systems. In this theory "normal" substitution in these systems would depend on rapid precipitation of the ketone-catalyst addition complex from solution (as occurs, for example, in ethylene dichloride), whilst "abnormal" substitution would result from deacylation and resynthesis, occurring in the solution phase. Reversibility of acylation in substituted naphthalenes and higher polycyclics has now been established[4,21,22], but it appears to be of little importance[21,23] in the case of naphthalene itself, or one must surmise, with simple benzene derivatives.

The abnormal results, and the role of the solvent, in the acylations of naphthalene have not, therefore, been adequately accounted for. For this reason, and to explain recent data obtained by Jensen[23], an explanation has been sought[24] in terms of the alternative mechanisms, which may operate generally in an acylation system, viz. ArH/RCOX/S (where S = solvent).

Let it be assumed that the following reactions are possible, i. e. that the ketone ArCOR may be formed by any of three mechanistic pathways, (A) by means of the unsolvated acyl halide/catalyst complex (high reactivity, and of medium steric requirements), (B) by the free acyl carbonium ion (of high reactivity, and of low steric requirements), and (C) by a solvated acyl halide/catalyst complex (low reactivity, and of large steric requirements). It is further held that these mechanisms are not merely alternative possibilities, but that they may proceed simultaneously, their relative importance being a function of the reactivities of the reactants, and the solvating power of the solvent.

According to this view, then, α-substitution in naphthalene will proceed via mechanisms A and B, with the former predominating[3,4]. If the acyl halide is itself sterically hindered[3], mechanism B alone will operate. β-Substitution will take place by mechanisms A and C, with a trace only of B. Of these mechanisms C will become increasingly important in solvents of the type nitrobenzene, or with excess acyl halide. In solvents which tend to give "normal" (i. e. predominant α-) substitution, solvation is minimal, viz. mechanism A will operate mainly, and the product will be mostly α-, with some β- ketone. That portion of the reaction operating by mechanism B will tend to increase the percentage of α-ketone formed.

The use of excess benzoyl chloride in the benzoylation of naphthalene has recently been shown[23] to produce an increase in the proportion of β-isomer, and a marked decrease in overall yield. In the present view the effect of increasing the concentration of benzoyl chloride would here be to increase the contribution by mechanism C (at the expence of mechanism A), i. e. the proportion of β-isomer will increase. Also, since the solvated acyl complex is of low reactivity, the overall rate will decrease, and thus, presumably, will the overall yield in an equivalent experiment.

Toluene may be acetylated in ethylene dichloride solution[25] to give a p/o ratio = 83.4, whilst benzoylation[26] under similar experimental conditions involves a ratio = 9.6. It

* This assumes rate differences to be mainly due to changes in activation energy.

was concluded[25] that the steric requirements for acetylation under these conditions (with a non-coplanar configuration of the methyl group in the acetylating species) are larger than those for benzoylation.

In the present theory, it is suggested that whilst mechanism C will not operate in the solvent used[25], viz. ethylene dichloride, the ortho and para positions may both be substituted by mechanisms A and B (the former always predominating). Ionization to $RCO^{\oplus}$ will be favoured in the case of benzoyl chloride, due to resonance stabilisation, and thus the contribution of mechanism B will increase in this case, resulting here in a higher percentage ortho substitution.

Increasing concentrations of excess benzoyl chloride have been reported[23] not to affect the rate of, and the percentage ortho isomer in, the benzoylation of toluene. Since mechanism C will not operate here, this result is here to be predicted.

The data obtained by Jensen[23] led him to conclude that the acylating species for his benzoylations of toluene and naphthalene are different. We would here add the conclusion, that the differences are due in these systems to different combinations of competing substitution processes.

The Formation of Acetylenic Bond by the Elimination Reaction of Some Enol-esters. III. Formation of α, β-Acetylenic Carbonyl Compounds

By Gen NAKAMINAMI

(Received March 20, 1962)

As described in the preceding paper[1], an α, β-acetylenic ketone is readily decomposed by the action of amide anion to yield the corresponding ethynyl compound and acid amide. Therefore, in order to obtain an α, β-acetylenic carbonyl compound by the elimination reaction of enol-esters, it was hoped to employ a suitable base to avoid the cleavage reaction. The nucleophilic addition of the base to a triple bond must also be avoided. The present paper deals with the studies along this line.

According to the studies of Dufraisse and his coworkers[2], primary and secondary alcohols add readily to the triple bond in acetylenic ketone II, but *tert*-alcohols were left untouched up to now. Therefore, the action of sodium *tert*-butoxide on ketone II was examined.

When ketone II was treated with sodium *tert*-butoxide in *tert*-butanol, there was obtained β-*tert*-butoxychalcone (III), as the main product, together with minor amounts of phenylacetylene (IV) and benzoic acid (V). The formation of IV and V clearly indicated that the bond-splitting reaction[1] occured subsidiarily in II.

$$C_6H_5C(OR)=CHCOC_6H_5 \rightarrow C_6H_5C\equiv CCOC_6H_5$$
(Ia, b) (II)

$$\rightarrow C_6H_5C(O\text{-}tert\text{-}C_4H_9)=CHCOC_6H_5$$
(III)

$$+ C_6H_5C\equiv CH + HO_2CC_6H_5$$
(IV) (V)

a : R = $PO(OC_6H_5)_2$ b : R = COC_6H_5

$$C_6H_5C(OPO(OC_6H_5)_2)=CHCO_2CH_3 \rightarrow C_6H_5C\equiv CCO_2R$$
(VI) (VIIa, b, c)

$$+ C_6H_5COCH_2CO_2CH_3 + (C_6H_5O)_3PO$$
(VIII) (IX)

a : R = *tert*-C_4H_9 b : R = CH_3 c : R = H

The structure of III was confirmed by its analytical data and infrared spectrum, and supported also by the formation of dibenzoylmethane on heating the enol-ether under reduced pressure. These results indicate that neither the addition nor the bond-fission reaction can be suppressed by the use of sodium *tert*-butoxide in *tert*-butanol.

It was found after several experimentations

1) M. Nakagawa, G. Nakaminami, F. Ogura and H. Ono, This Bulletin, 35, 1488 (1962).
2) M. C. Dufraisse and P Gérald, *Bull. soc. chim. France*, [4] 31, 1285 (1922); M. C. Dufraisse and A. Gillet, *Ann. chim.*, [10] 6, 295 (1926).

that ketone II was recovered unchanged in a fair yield, when treated with sodium *tert*-butoxide in benzene, therefore all elimination reactions in the present work were carried out in benzene as the solvent. A solution of enol-phosphate was added dropwise to a stirred suspension of sodium *tert*-butoxide in benzene, and the reaction mixture was stirred further in adequate periods. Benzoylphenylacetylene (II) was obtained from the phosphate Ia[3] and the benzoate Ib[3] in 76 and 58% respectively. Not any appreciable amount of by-product could be isolated in these cases. Similarly *tert*-butyl phenylpropiolate (VIIa) was obtained in a 24% yield from the phosphate VI[3]. The structure of VIIa was inferred from its infrared spectrum in which the characteristic absorptions ascribed to a disubstituted acetylene, an ester-carbonyl group and a *tert*-butyl group were clearly indicated. The ester VIIa was converted into methyl ester by refluxing in methanol in the presence of a small amount of sulfuric acid. The ester VIIb thus obtained was hydrolyzed to give free acid VIIc, which was readily purified by sublimation followed by recrystallization. In another experiment, the acid VIIc was isolated from the reaction mixture in a 28% yield. In the reaction of phosphate VI with sodium *tert*-butoxide, triphenylphosphate IX and methyl benzoylacetate VIII were also obtained.

The formation of keto-ester VIII and phosphate IX is probably due to ester-exchange reaction. The reaction of this type was found to be the main reaction in the case of phosphate Xa[3] by the isolation of triphenylphosphate IX and phenol from the reaction products, and no elimination reaction was observed. The elimination reaction of tosylate Xc[3] under similar conditions resulted in the formation

$CH_3C(OR)=CHCO_2C_2H_5$ (Xa, c) $\quad CH_3C(OP(OC_6H_5)_2)=CHCOCH_3$ (XI)

a : $R=PO(OC_6H_5)_2$

c : $R=SO_2C_6H_4$-*p*-CH_3

of a small amount of a liquid, the main constituent of which was assigned to be ethyl tetrolate on the basis of the infrared spectrum. Alkaline hydrolysis of this material afforded a small amount of crystals, whose identification could not be performed owing to its minor quantity. The phosphate XI[3] gave no well-defined product on treatment with sodium *tert*-butoxide.

The above-mentioned results appear to provide a support for the elimination mechanism of triple bond biosynthesis through enol derivative*.

Experimental**

Action of Sodium *tert*-Butoxide on Benzoylphenylacetylene (II).—A solution of *tert*-butoxide (0.013 mol.) in dry *tert*-butanol (50 ml.) was warmed at 25~30°C. A solution of ketone II[4] (2.0 g., 0.01 mol.) in dry ether (30 ml.) was added dropwise while stirring into the above solution during 40 min. The reaction mixture was stirred for a further 2 hr. at the same temperature, and set aside at room temperature for 16 hr. A solution of glacial acetic acid (0.8 g., 0.013 mol.) in dry ether (25 ml.) was added dropwise while stirring and cooling (ice-bath), and then water (50 ml.) was added. The aqueous solution was extracted twice with ether, and combined ethereal solutions were washed successively with sodium hydrogen carbonate solution, 5% potassium hydroxide solution and water, dried (sodium sulfate) and concentrated. The residue was dissolved in ethanol (6 ml.), and treated with mercuric chloride-potassium iodide solution in the Johnson-McEwen's procedure[5]. An oil and an amorphous solid were separated. The solid was filtered, washed with 50% aqueous ethanol, pressed on a porous plate, left overnight to remove an oily material as well as possible, and recrystallized twice from ethanol to give a mercury compound of phenylacetylene as colorless needles, m. p. 122~123.5°C, undepressed on admixture with an authentic specimen.

On acidification (Congo Red) of the sodium hydrogen carbonate washings, an oil was separated and extracted with ether. The combined ether-extracts were washed with sodium chloride solution, dried (sodium sulfate), and evaporated. To the residue dissolved in acetic acid, water was added precipitating a solid (0.7 g., 57%), which was sublimed under reduced pressure and recrystallized twice from water to give benzoic acid as colorless plates, m. p. 121.5~122°C. It showed no depression in the melting point on admixture with an authentic specimen.

In another experiment using 0.04 mol. of acetic acid only 0.1 g. of the crude benzoic acid was obtained, and from the neutral part crystals (0.5 g.) of *β-tert*-butoxychalcone (III) were yielded, which were treated with charcoal in methanol and recrystallized twice from the same solvent to afford light yellow plates, m. p. 97~98°C.

Found: C, 81.54; H, 7.25. Calcd. for $C_{19}H_{20}O_2$: C, 81.39; H, 7.19%.

* As mentioned previously[3], quite recently, Jones [*Chem. & Ind. News*, **39**, No. 12, 46 (1961)] has suggested that the decarboxylative elimination of pyrophosphate anion from the pyrophosphate of acetylmalonyl coenzyme A is a possible route in the formation of an acetylenic bond in vivo, and the mechanism has been supported experimentally by the formation of phenylpropiolic acid from enol brosylate of diethyl benzoylmalonate in an alkaline medium (I. Fleming and J. Harey-Mason, *Proc. Chem. Soc.*, **1961**, 245.).

** All melting points and boiling points are uncorrected.

IR (Nujol): >C=O, 1662 cm^{-1}.

The enol-ether III gave the same deep red color as dibenzoylmethane, when it was treated with ferric chloride in ethanol, but the development of the color required several minutes. A similar behavior against ferric chloride was observed also in the case of β-methoxychalcone[2].

Thermal Decomposition of β-*tert*-Butoxychalcone (III).—The enol-ether III (0.1 g.) was heated at 180~200°C (bath) under reduced pressure (aspirator) in a sublimation apparatus. Light yellow crystals adhered gradually on the cold finger, and finally only a small amount of oil was left at the bottom of the vessel. The crystals furnished dibenzoylmethane on recrystallization from methanol as light yellow needles, m. p. 77.5~78.5°C, which showed no melting point depression on admixture with an authentic specimen[6].

Found: C, 80.62; H, 5.44. Calcd. for $C_{15}H_{12}O_2$: C, 80.33; H, 5.39%.

Elimination Reaction of Diphenyl 1, 3-Diphenyl-2-propen-1-on-3-yl Phosphate (Ia) by Sodium *tert*-Butoxide.—Sodium (0.95 g., 0.041 gram atom) was dissolved in hot dry *tert*-butanol (150 ml.), and the solvent was driven off at 50~55°C (bath) under reduced pressure as well as possible, affording almost colorless needles of sodium *tert*-butoxide. Dry benzene (150 ml.) was added to the crystals, and then the phosphate Ia (18.3 g., 0.04 mol.) in dry benzene (200 ml.) was added dropwise with stirring at room temperature to the resulting suspension during 1 hr. The mixture was stirred for a further 13.5 hr. at room temperature, and set aside for 28 hr. Water was added, and the benzene layer was washed successively with 5% potassium hydroxide solution and water and dried (sodium sulfate). All of the aqueous solutions were combined and extracted with ether. The combined ether-extracts were washed with water and dried (sodium sulfate). Evaporation of the solvent followed by distillation of the residue gave benzoylphenylacetylene (II) as a yellow oil (6.3 g., 76%), b. p. 142~144°C/0.5 mmHg, without affording any appreciable amount of low-boiling or high-boiling material. The oil was solidified completely, when seeded with a piece of crystal of authentic II, to give crystals melted at 42~47°C which was recrystallized twice from light petroleum (b. p. 40~60°C) to yield slightly yellow needles, m. p. 48~48.5°C, undepressed on admixture with an authentic specimen. Its infrared spectrum also showed the identity with that of the authentic specimen.

Found: C, 87.54; H, 5.04. Calcd. for $C_{15}H_{10}O$: C, 87.35; H, 4.89%.

A crystalline material which seemed to be diphenyl phosphate was obtained from the aqueous solution left after the extraction of ketone II.

Elimination Reaction of β-Benzoyloxychalcone (Ib) with Sodium *tert*-Butoxide.—A suspension of sodium *tert*-butoxide (0.022 mol.) in dry benzene (50 ml.) was prepared as above. A solution of the benzoate Ib[3] (6.6 g., 0.02 mol.) in dry benzene (50 ml.) was added dropwise with cooling (cold water) to the stirred suspension during 40 min. The mixture was stirred for 6 hr. with cooling by cold water, for a further 10 hr. at room temperature, and allowed to stand for about 30 hr. Water (150 ml.) was added with cooling by cold water, and the aqueous layer was extracted twice with benzene and twice with ether. The combined organic extracts were washed with sodium chloride solution and dried (sodium sulfate). Evaporation followed by distillation of the residue afforded ketone II as an oil (3.0 g.), b. p. 162~169°C/2.5 mmHg, which was solidified completely when seeded as described before. The solid so far obtained was dissolved in ether and washed successively with 5% potassium hydroxide solution and water. The ether was altered with benzene and the benzene solution was chromatographed on alumina (4.0 g.). Removal of the solvent from the eluate gave II (2.6 g., 58%) which was recrystallized from light petroleum (b. p. 40~60°C) as yellow plates, m. p. 46.5~49.5°C, and identified by infrared spectrum.

Elimination Reaction of Diphenyl β-Methoxycarbonyl-α-styryl Phosphate (VI) with Sodium *tert*-Butoxide.—A suspension of sodium *tert*-butoxide (0.044 mol.) in dry benzene (120 ml.) was prepared as above. A solution of the phosphate VI[3] (17.8 g., 0.043 mol.) in dry benzene (120 ml.) was added dropwise at room temperature to this stirred suspension during 1 hr. The mixture was stirred for a further 7 hr. at room temperature, left standing overnight, and then treated with water (120 ml.). The aqueous solution (solution A) was extracted twice with ether, and the combined organic solutions were washed successively with a 4% potassium carbonate solution (100 ml.×2), ice-cooled 0.5 N sodium hydroxide solution (100 ml.×2) and water, and dried (sodium sulfate). Evaporation followed by distillation gave a colorless liquid (product A) (2.1 g.), b. p. 93.5~96°C/1 mmHg, and an orange oily residue (product B).

The sodium hydroxide washings were acidified at 0°C, and then extracted 3 times with ether. The combined extracts were washed with sodium chloride solutionand dried (sodium sulfate). Evaporation followed by distillation afforded an oil (1.6 g., 30%), b. p. 100~101°C/1 mmHg, which was identified with methyl benzoylacetate[7] by infrared spectrum. The copper complex provided by the above oil exhibited m. p. 200~202°C and showed no melting point depression on admixture with an authentic specimen[7].

Found: C, 57.81; H, 4.42. Calcd. for $C_{20}H_{18}O_6Cu$: C, 57.48; H, 4.34%.

The above-mentioned potassium carbonate washings and the solution A afforded an oil on acidification (Congo Red) and ether-extraction. The oil appeared from its infrared spectrum as a mixture of diphenyl phosphate and a small amount of phenylpropiolic acid (VIIc), but no detailed study was taken.

Product A.—Its infrared spectrum [(liquid film): 2215, 2250 (-C≡C-); 1710 (>C=O ester); 1397, 1373 (C-H *tert*-C_4H_9); 1300, 1150 cm^{-1} (O=C-O-)] was found to be consistent with the structure of *tert*-butyl phenylpropiolate (VIIa), although the analytical

7) A. Wahl, *Compt. rend.*, **147**, 72 (1908).

data indicated the presence of an impurity. A mixture of the product A (1.0 g.), absolute methanol (20 ml.) and concentrated sulfuric acid (4 drops) was refluxed for 12.5 hr., left to stand at room temperature for about 30 hr., and poured into ice-water. An oil was separated and extracted 3 times with ether. The combined extracts were washed successively with water, sodium hydrogen carbonate solution and water, and dried (sodium sulfate). After evaporation of the solvent, the residue was distilled giving a light yellow liquid (0.8 g., 100%), b. p. 78.5~81°C/2 mmHg, (lit.,[8] b. p. 132~133°C/16 mmHg), which was proved to consist mainly of methyl ester VIIb on the basis of the infrared spectrum [(liquid film): 2220 (-C≡C-); 1715 (>C=O ester); 2820 cm^{-1} (C-H CH_3O)].

A mixture of methyl ester VIIb (0.5 g.), potassium hydroxide (0.3 g., 1.5 equiv.), ethanol (8 ml.) and water (4 ml.) was refluxed for 30 min., and cooled immediately. On addition of water (10 ml.) a small amount of oil was separated. After removal of the oil by ether-extraction, the remaining aqueous solution was acidified (Congo red) with dilute sulfuric acid at 0°C. An oil was separated, and soon began to crystallize. The product was taken up in ether, washed with sodium chloride solution and dried. Evaporation of the ether afforded phenylpropiolic acid VIIc, (0.3 g., 65%) which was sublimed under reduced pressure, and recrystallized twice from carbon tetrachloride and once from water as colorless needles, m. p. 135~137°C, (lit.[9], m. p. 137°C).

Found: C, 73.89; H, 4.22. Calcd. for $C_9H_6O_2$: C, 73.96; H, 4.14%.

IR (Nujol): 2205, 2240 (-C≡C-); 1675 (>C=O carboxyl); 3200~2400 cm^{-1} (O-H carboxyl).

Product B.—On storage in an ice-box, product B deposited some amounts of the recovered phosphate VI, which was removed by filtration. The filtrate was distilled and the fraction, boiling at 140~173°C/3×10^{-4} mmHg, was collected, then it was seeded with a piece of crystal of triphenyl phosphate[10] IX and stored in an ice-box. A solid was separated (1.4 g., 16%) and recrystallized from light petroleum (b. p. 40~60°C) to give phosphate IX as colorless needles, m. p. 48.5~50°C, which showed no melting point depresssion on admixture with an authentic specimen. Its infrared spectrum also agreed with that of the authentic specimen.

Reaction of Diphenyl 1-Ethoxycarbonyl-1-propen-2-yl Phosphate (Xa) with Sodium *tert*-Butoxide.—The phosphate[3] Xa (160.8 g., 0.44 mol.) was added dropwise at room temperature to a stirred suspension of sodium *tert*-butoxide (0.45 mol.) in dry benzene. The mixture was stirred for 20 hr., set aside for 1 day, and treated with water. The benzene layer was washed successively with 5% sodium hydroxide solution and sodium chloride solution, and dried. Benzene was removed, the residue was distilled and a fraction boiling over 130°C/3×10^{-3} mmHg, was collected. The fraction solidified, and it was recrystallized twice from light petroleum to give triphenyl phosphate (IX) as colorless needles, m. p. 49~49.5°C, identified by infrared spectrum.

A low boiling liquid obtained above was redistilled to give a liquid, b. p. 95~105°C/1×10^{-3} mmHg, n_D^{20} 1.4838, which was clearly different from the starting phosphate Xa, but its infrared spectrum resembled Xa. Although the product was supposed to be produced by ester-exchange reaction, the analytical value did not agree with the calculated ones for any possible compounds. Perhaps it is a mixture of various products at different stages in ester-exchange reaction.

From the sodium hydroxide extract stated above, some amount of phenol was obtained by acidification and ether-extraction.

Reaction of Ethyl β-*p*-Toluenesulfonyloxy-crotonate (Xc) with Sodium *tert*-Butoxide.—The tosylate Xc[3] (13.4 g., 0.047 mol.) was added dropwise at room temperature to a stirred suspension of sodium *tert*-butoxide (0.048 mol.) in dry benzene. The mixture was stirred at room temperature for 38 hr., left standing for 75 hr., and treated with water. The aqueous layer was extracted with ether, and the combined organic layers were washed successively with 5% sodium hydroxide solution and salt solution. Evaporation followed by distillation gave ethyl tetrolate as colorless, sweet smelling liquid (0.5 g.), b. p. 63~64°C/10 mmHg, (lit.[11], b. p. 164.5~165.0°C/760 mmHg).

IR (liquid film): 2240 (-C≡C-); 1712 cm^{-1} (>C=O ester).

A mixture of the liquid (0.3 g.) and 0.5 N potassium hydroxide (15 ml.) was refluxed for 40 min., cooled, and extracted with ether to remove a small amount of insoluble material. Acidification and ether-extraction afforded a very small amount of crystals, which could not however be identified.

The author wishes to express his sincere thanks to Professor Masazumi Nakagawa of Osaka University for his guidance and encouragement throughout this work. The author's thanks are also due to the Ministry of Education for the grant-in-aid.

Note added in proof (August 31, 1962).

Since this paper was submitted a short communication by J. Cymerman Craig and M. Moyle (*Proc. Chem. Soc*, **1962**, 149) has appeared in which they realized the formation of some acetylenic compounds treating the enol diethyl phosphates of the corresponding carbonyl compounds with sodium amide in liquid ammonia.

Studies of the Solvent Extraction of Niobium-95 in the Tribenzyl Amine-Hydrochloric Acid System

By Takashi OMORI and Nobuo SUZUKI

(Received February 22, 1962)

There are many reports on the solvent extraction of metals, but these extraction methods are only applicable to the particular cases described in these papers. The present authors have undertaken a quantitative investigation of solvent extraction and have made an effort to elucidate the chemical behavior of metals in the case of solvent extraction. One of the authors has already reported the quantitative treatment of the solvent extraction of ^{144}Ce with acetylacetone[1]. Recently, we both reported the mutual separation of ^{95}Zr and ^{95}Nb with acetylacetone[2].

Since about 1958 there has been a rapid developement in amine extraction, particularly for uranium extraction[3]. It has been reported that the mechanism of amine extraction is similar to that of anion exchange[3-5]. However, phenomena which can not be completely explained as anion exchange mechanism have been found in a few reports[6-8].

In the present paper, the distribution coefficients of ^{95}Nb between hydrochloric acid and amine are investigated. Based on the results, the mechanism of amine extraction and the species of niobium in hydrochloric acid are discussed.

Experimental

Reagents.—Carrier-free ^{95}Nb was separated from $^{95}Zr(^{95}Nb)$ by the anion exchange method and was stored in 18 N sulfuric acid, as has been described in a previous paper[2]. Before being used for experiments, ^{95}Nb was extracted with acetylacetone and was converted into the chloride form by back-extraction with hydrochloric acid.

Tribenzylamine (TBA) obtained from the Tokyo Kasei Co., Ltd. was of a high purity as indicated by melting point measurement and was used without further purification. A standard solution of TBA was prepared by dissolving TBA in chloroform. TBA was converted into the hydrochloride form (TBA-Cl) before being used for experiments by shaking the TBA solution in chloroform with 6 M hydrochloric acid for 30 min.

E. P. grade chloroform was treated with concentrated sulfuric acid and then purified by distillation.

All other chemicals were of guaranteed reagent grade.

Distribution Measurement. — All equilibrations were carried out in glass-stoppered tubes. These tubes were shaken with a mechanical shaking device in a constant temperature bath. The experiments were carried out at 25±0.5°C unless otherwise stated. The distribution coefficients, D, were determined as follows: ^{95}Nb was previously extracted from concentrated hydrochloric acid with TBA-Cl in chloroform. An aliquot of this organic solution, containing ^{95}Nb, was shaken for one hour with aqueous solutions of various conditions. After the phases had disengaged, the phases were transferred into two test tubes and the γ-activities of both tubes were measured with a scintillation counter. Studies of the equilibration rate have shown that complete equilibration was attained in less than 30 min.; however, the shaking time of one hour was chosen for this work.

The determination of the acidity of both phases was necessary. The aqueous phase was titrated with a standard solution of sodium hydroxide, using methyl orange as the indicator. The acid in the organic phase was titrated with a stadard sodium hydroxide solution in ethanol by the aid of a pH meter.

Results and Discussion

Extraction Mechanism and Some Related Equations. — The authors consider that the anionic species of niobium in the aqueous phase is transferred to the organic phase as follows:

$$Nb(OH)_pCl_q^{+5-p-q} + (p+q-5)RCl \rightleftharpoons R_{p+q-5}Nb(OH)_pCl_q + (p+q-5)Cl^- \quad (1)$$

followed by the reaction of the above species with TBA-Cl in the organic phase, containing large amounts of TBA-Cl:

$$R_{p+q-5}Nb(OH)_pCl_q + iRCl \rightleftharpoons R_{p+q-5}Nb(OH)_pCl_q \cdot iRCl \quad (2)$$

where RCl indicates TBA-Cl and $6 \leq (p+q) \leq 8$.

The extraction constant for Eq. 1 and the formation constant for Eq. 2 are:

$$K_{p,q} = \frac{(R_{p+q-5}Nb(OH)_pCl_q)_o(Cl^-)_a{}^{p+q-5}}{(Nb(OH)_pCl_q{}^{+5-p-q})_a(RCl)_o{}^{p+q-5}} \quad (3)$$

$$K_i = \frac{(R_{p+q-5}Nb(OH)_pCl_q \cdot iRCl)_o}{(R_{p+q-5}Nb(OH)_pCl_q)_o(RCl)_o{}^i} \quad (4)$$

where the subscripts a and o detote the aqueous and organic phases respectively.

On the other hand, the next reaction can be considered with respect to the formation of an anionic complex of niobium in the aqueous solution. For the sake of simplicity, it is reasonable to consider the typical form of $Nb(OH)_2Cl_4^-$ as the predominant species based on the following experimental results:

$$Nb(OH)_mCl_n{}^{+5-m-n}* + (m-2)H^+ + (4-n)Cl^- \rightleftarrows Nb(OH)_2Cl_4^- + (m-2)H_2O \quad (5)$$

The equilibrium constant for Eq. 5 is defined as

$$\beta_{m,n} = \frac{(Nb(OH)_mCl_n{}^{+5-m-n})_a}{(Nb(OH)_2Cl_4^-)_a \times (H^+)_a{}^{m-2}(Cl^-)_a{}^{4-n}} \quad (6)$$

The solubility of TBA-Cl in the aqueous solution can be ignored. The distribution coefficient for niobium, D, therefore, is derived in terms of activities from Eqs. 3, 4 and 6:

$$D = \frac{\sum_p\sum_q\sum_i (R_{p+q-5}Nb(OH)_pCl_q \cdot iRCl)_o}{\sum_m\sum_n (Nb(OH)_mCl_n{}^{+5-m-n})_a} = \frac{(Cl^-)_a{}^5}{\sum\sum(\beta_{m,n} \cdot (H^+)_a{}^{-m}(Cl^-)_a{}^n)} \times [\sum\sum\sum\sum(K_{p,q} \cdot K_i \cdot \beta_{p,q} \cdot (H^+)_a{}^{-p} \times (Cl^-)_a{}^{-p}(RCl)_o{}^{p+q+i-5}] \quad (7)$$

On the basis of the above equations, it is possible to indicate the factors which influence the extractability of niobium. The dependence of the hydrogen ion activity on D is given by the differentiation of Eq. 7 with respect to the hydrogen ion activity at a constant chloride level. Thus,

$$\frac{\partial \ln D}{\partial \ln (H^+)_a} = \bar{m} - \bar{p} \quad (8)$$

Proceeding as above, we obtain

$$\frac{\partial \ln D}{\partial \ln (Cl^-)_a} = 5 - \bar{p} - \bar{n} \quad (9)$$

where $\bar{m}$ and $\bar{n}$ denote, respectively, the average number of hydroxide and chloride groups per Nb in the aqueous phase, and $\bar{p}$, the average number of hydroxide groups per Nb in the organic phase.

In this experiment it is difficult to maintain the ionic strength constant; the analysis of the results obtained at such higher ionic strengths is possible only by the use of "activity" instead of "molar concentration". Therefore, the results are shown in terms of the activity. The activities for the hydrogen ion and the chloride ion are assumed to be:

$$(H^+)_a = [H^+]_a\gamma_{\pm HCl}$$
$$(Cl^-)_a = [Cl^-]_a\gamma_{\pm LiCl} \quad (10)$$

where brackets are used to indicate the molar concentrations. The mean activity coefficients for hydrochloric acid, $\gamma_{\pm HCl}$, and lithium chloride, $\gamma_{\pm LiCl}$, are calculated from the data listed in Harned and Owen[9]. For the sake of simplicity, is assumed that the species in the organic phase are monomeric and that their activity coefficients are equal to 1.

Distribution of Hydrochloric Acid.—Hydrochloric acid of various acidities ranging from 1 M to 11.4 M were shaken with a 0.1 M TBA solution in chloroform. As is shown in Fig. 1, the acid concentration in the organic phase

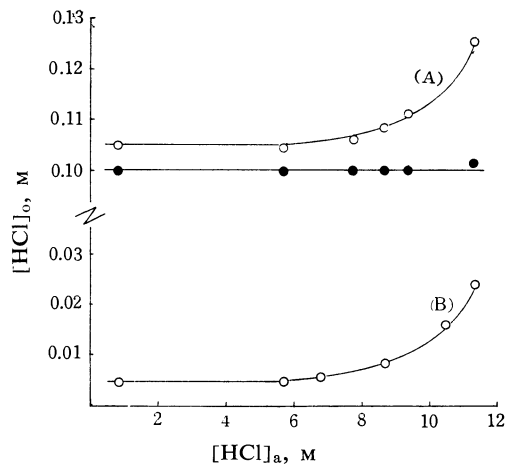

Fig. 1. Distribution of hydrochloric acid at 25°C.

○, (A) 0.100 M TBA in $CHCl_3$; (B) pure $CHCl_3$

●, Difference between curve (A) and curve (B)

abruptly increases with the increasing acidity of hydrochloric acid, but the difference in the acid concentration between the cases of TBA and pure chloroform is just 0.1 M, equivalent to the TBA concentration.

* $Nb(OH)_mCl_n{}^{+5-m-n}$ shows the general form of the niobium chloro-complex in the aqueous solution.

(1) (2) (3) (4) (5)
$[RCl]_o$: 0.200, 0.150, 0.100, 0.075, 0.050 M

Dependence of the Extractability of ^{95}Nb on Hydrochloric Acid.—The distribution of ^{95}Nb between hydrochloric acid and a TBA-Cl chloroform solution was determined. As is shown in Fig. 2, the distribution of ^{95}Nb increases with an increase in the concentration of TBA-Cl, and there is a maximum at about 10.5 M of hydrochloric acid. In this experiment, of course, the results are influenced by the concentration of hydrogen and chloride ions.

Dependence on Chloride Ion Activity. — To examine the effect of the chloride ion activity, a series of experiments were carried out. By using hydrochloric acid-lithium chloride mixtures, the concentration of hydrochloric acid was held at 7.62 M, while the chloride ion activity was varied by the addition of lithium chloride. As is shown in Fig. 4, the slope of the curve varies from 0.5 to 2.5. According to Eq. 9:

$$\frac{\partial \log D}{\partial \log (Cl^-)_a} = 5 - \bar{p} - \bar{n} \simeq 0.5 \sim 2.5 \qquad (9')$$

Dependence on Hydrogen Ion Activity.—The details of these experiments were similar to those of the above experiment, but in this case the chloride levels were held at 8.85 M and 11.4 M while the hydrogen ion activity was varied. At constant chloride levels, D is not so much affected by the hydrogen ion activity,

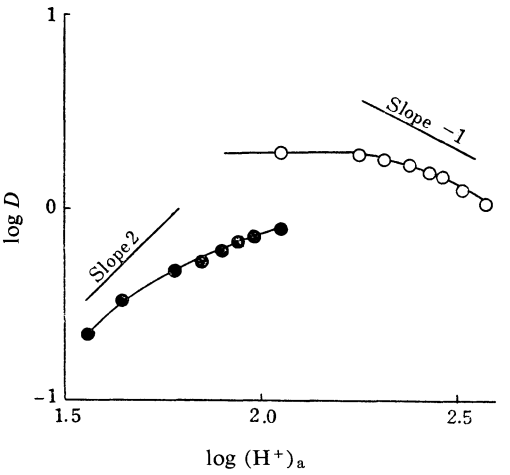

Fig. 3. Acid dependence of D values for niobium at 25°C.

○, $[Cl^-]_{a,\,total}$=11.4 M
●, $[Cl^-]_{a,\,total}$=8.85 M

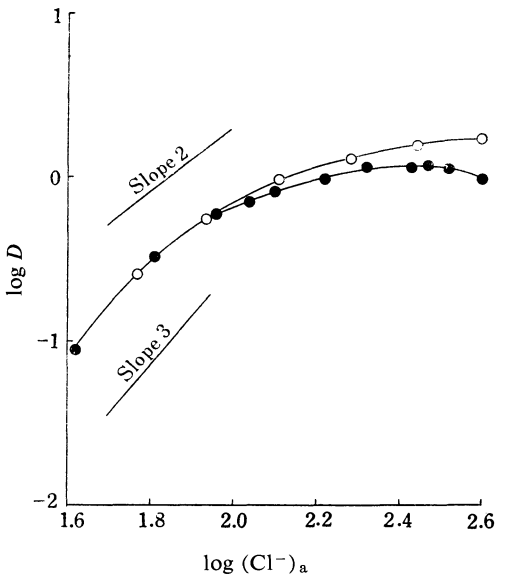

Fig. 4. Chloride dependence of D values for niobium at 25°C.

○, HCl-LiCl mixture. $[H^+]_a$=7.62 M
●, Pure HCl

as may be seen in Fig. 3. Although D remains constant at high chloride levels, 11.4 M, D decreases with a slope of −1 as the hydrogen ion activity increases. According to Eq. 8:

$$\frac{\partial \log D}{\partial \log (H^+)_a} = \bar{m} - \bar{p} \simeq 0 \sim -1.2 \qquad (8')$$

At low chloride levels, the decrease in D is suspected as being due mainly to the hydrolysis of niobium, i.e., $\bar{m} > \bar{p}$.

From Eqs. 8' and 9', we find:

$$1.2 \leq \bar{p} \leq 2.5$$

It seems reasonable, however, to consider that p $(=\bar{p})$ is constant in these conditions, probably equal to two, because the values of D are constant in the $\bar{m}=\bar{p}$ region and decrease gradually for $\bar{m} \lesssim \bar{p}$. Thus, the decrease of the D values with a slope of -1 may be explained by the following reaction (cf. the following paragraph):

$$Nb(OH)_2Cl_4^- + H^+ \rightleftharpoons Nb(OH)Cl_4 + H_2O \quad (11)$$

Species and Reaction in the Organic Phase.— In order to estimate the niobium species in the organic phase, ^{95}Nb was extracted from 10 M hydrochloric acid with various concentrations of TBA-Cl solutions in chloroform. There was no difference between the two cases of D values; viz., in one case D values were obtained by direct extraction of ^{95}Nb in hydrochloric acid with TBA-Cl, and in another case D values were obtained by the backward equilibration of the organic phase containing ^{95}Nb with hydrochloric acid. The resulting plot shown in Fig. 5 has a slope of 3.0 above 0.1 M TBA-Cl and of 2.1 below 0.1 M, indicating that one molecule of the niobium complex associates with up to three molecules of amine.

When the aqueous phase conditions are held constant, Eq. 7 can be replaced by:

$$D=A(RCl)_o+B(RCl)_o^2+C(RCl)_o^3 \quad (12)$$

where A, B and C are the constants. Therefore, if a plot of $D/(RCl)_o$ against $(RCl)_o$ fits the quadratic curve and if the intercept is not equal to zero, i. e., $K_{p,q(p+q=6)} \neq 0$, it can be considered that one molecule of amine exchages with the niobium chloro-complex.

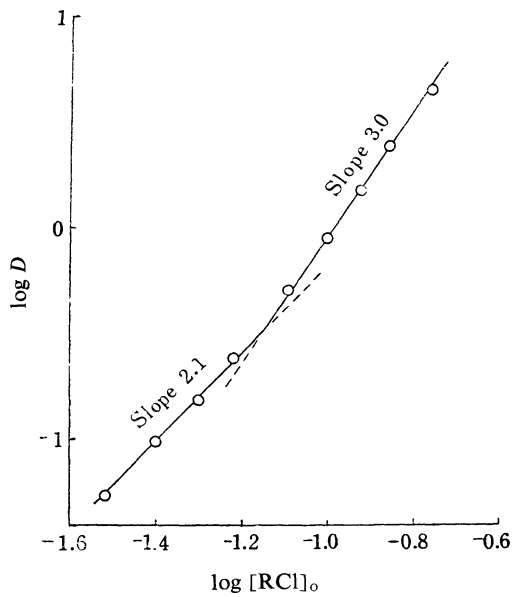

Fig. 5. TBA dependence of D values for niobium at 25°C.

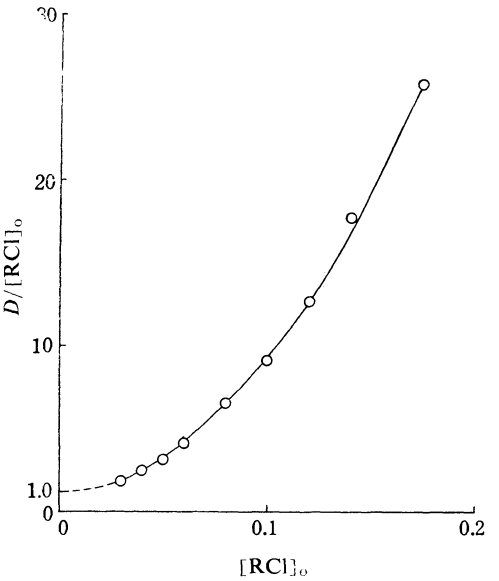

Fig. 6. Plot of $D/[RCl]_o$ vs. $[RCl]_o$.

The resulting curve is shown in Fig. 6, which indicates that the charge number of the niobium chloro-complex extracted is probably -1. It was found that the p value in the formula of $Nb(OH)_pCl_q^-$ was equal to two; therefore, this would mean that the complex in the organic phase is $RNb(OH)_2Cl_4 \cdot iRCl$ $(i=1$ and $2)$.

These considerations lead to the conclusion that the typical extractable species of niobium is $Nb(OH)_2Cl_4^-$. Other extractable species [i. e., $Nb(OH)_3Cl_3^-$, $Nb(OH)_2Cl_5^{-2}$, $Nb(OH)Cl_5^-$, etc.] will be present in very small amounts if such species exist at all. The species of niobium in hydrochloric acid have been investigated by the anion exchange method[10] and by the spectrophotometric method, indicating the presence of $Nb(OH)_2Cl_4^-$ in a 10.5 M hydrochloric acid solution[11].

From a plot of $D/(RCl)_o$ vs. $(RCl)_o$, $K_{i=1}$ and $K_{i=2}$ can be obtained as 4.4 and 786 respectively. If it is assumed that only $Nb(OH)_2Cl_4^-$ is the extractable species, $K_{p=2,\ q=4}$ can be calculated as about 940.

Temperature Effect.—There are few papers which have investigated the effect of temperature in a solvent extraction, but the authors consider that temperature is one of the most important factors. Equilibration experiments were carried out at 10 and 40°C. These results are shown in Fig. 7. At a low temperature,

10) E. H. Huffman, *J. Am, Chem. Soc.*, **74**, 4714 (1952); K. A. Kraus, ibid., **71**, 3885 (1949).
11) J. H. Kanzelmeyer, J. Ryan and H. Freund, ibid., **78**. 3020 (1956).

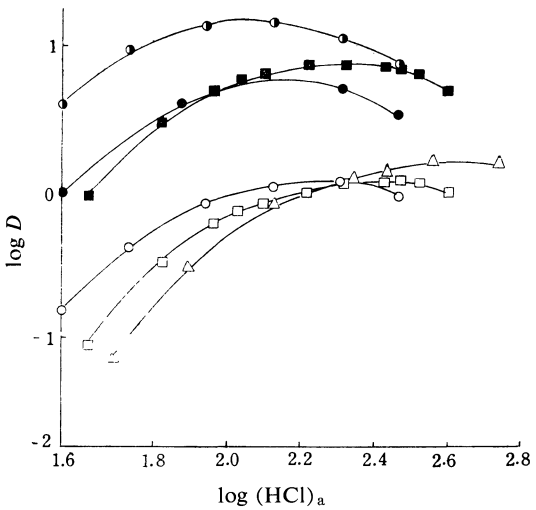

Fig. 7. Temperature dependence of D values for niobium.
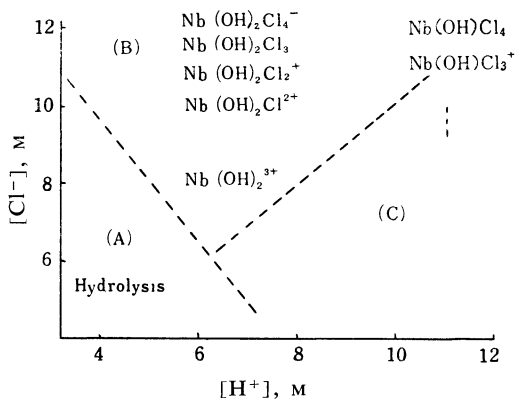
○, 40±0.5°C; □, 25±0.5°C; △, 10±0.5°C
◑, $[RCl]_0$=0.30 M; ●, 0.20 M; ■, 0.10 M

the extraction curve is similar to that shown in Fig. 4 (chloride dependence). The solubility of TBA-Cl in chloroform* is relatively small, so it is better to raise the temperature in order to use a high concentration of the TBA-Cl solution. The shapes of extraction curves are not equal to each other at different temperatures. At lower temperatures D shows a maximum in the region of higher acidity. The acidity at which it shows a maximum of D shifts to a lower acidity with an increase in the temperature. These results suggest that the reaction expressed in Eq. 11 and the formation of the niobium chloro-complex are promoted with an increase in the temperature.

Conclusion

The extraction processes of ^{95}Nb from hydrochloric acid with tribenzyl amine are shown by the following reactions:



$$Nb(OH)_2Cl_4^- + RCl \rightleftarrows RNb(OH)_2Cl_4 + Cl^- \quad K_{p=2,\,q=4}=940$$

$$RNb(OH)_2Cl_4 + RCl \rightleftarrows RNb(OH)_2Cl_4\cdot RCl \quad K_{t=1}=4.4$$

$$RNb(OH)_2Cl_4\cdot RCl + RCl \rightleftarrows RNb(OH)_2Cl_4\cdot 2RCl \quad K_{t=2}=786$$

The $K_{p=2,\,q=4}$ value is comparatively small, but it is interesting that the apparent D values are large. This fact suggests that the secondary reaction, as shown in Eq. 2, occurs in the organic phase; therefore, the overall extraction ratio increases. The formation constants for niobium chloro-complexes cannot be obtained owing to their complexity, but the authors present in Table I a scheme concerning the niobium species in the chloride system. In region A, the hydrolysis (and/or polymerization) of niobium may occur; $Nb(OH)_2Cl_n^{+3-n}$ species exist in region B and C, and $Nb(OH)Cl_n^{+4-n}$ may exist in region C only. As the temperature rises, the formation of niobium chloro-complexes will be promoted, but dehydroxylation may occur simultaneously; therefore, the situation is not simple.

Concentration and Temperature Profiles in a Tubular Reactor for Methanol Synthesis with the Outer-wall of a Uniform Temperature. II. Profiles in Reactors with a Heat Exchanger Tube in the Catalyst Bed

By Yoshisada OGINO*, Masaaki OBA, Kinya SHIMOMURA and Hiroshi UCHIDA

(Received April 12, 1962)

For better performance in methanol synthesis of the previously described tubular reactor, which was placed in a heat transfer medium of flownig oil and which was packed with a catalyst bed with no heat exchanger tube, it was pointed out that any large magnitude of temperature rise along the catalyst bed should be reduced[1]. The use of a heat exchanger tube in the catalyst bed was naturally expected to be a means of providing suitable control of the bed temperature. In this connection, several workers, such as Kodama et al.[2,3], Shindo et al.[4] and Matsuyama et al.[5], have discussed the temperature profiles in catalytic reactors equipped with various types of heat exchanger tubes, but their papers have provided no detailed experimental data on this subject. On the other hand, Kjaer[6] provided the data on the basis of which he had calculated the temperature profiles in both the catalyst bed and the heat exchanger tube, with an industrial reactor for the ammonia synthesis, but his treatment did not deal with the comparative merits of the different types of heat exchanger tubes.

In this paper, the experimental data on the profiles of methanol concentration and on the temperature measured with reactors which were individually equipped with three different types of heat exchanger tubes are presented, and their effects upon the profiles, as well as on the methanol yield, are discussed.

Experimental

The same methanol synthesis reactor as was described in the preceding paper[1] was equipped successively with three different types of heat exchanger tubes, all three types of heat exchanger tubes were copper; the first and second ones were countercurrent types (types A and B), while the last one was a concurrent type (type C). Detailed sketches of them are shown in Figs. 1A and 1B. The A-type heat exchanger tube was a single tube of 10 mm. O. D. and 8 mm. I. D.; it was placed at the center-axis of the reactor. A thermocouple protection tube of stainless steel, 5 mm. O. D. with a thickness of 1 mm., went coaxially through the heat exchanger tube and permitted scanning of the temperature along the whole length by moving the thermocouple. The heat exchangers of types B and C were double tubes of the same dimensions. They consisted of an outer tube, sealed at one end, of 10 mm. O. D. and an inner tube of 6 mm. O. D., each of them having a thickness of 1 mm. For both the B and C types of heat exchangers, the thermocouple protection

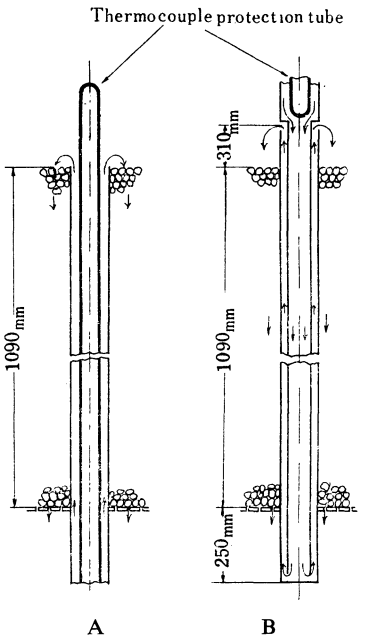

Fig. 1A. Heat exchanger tube (Type A and Type B).

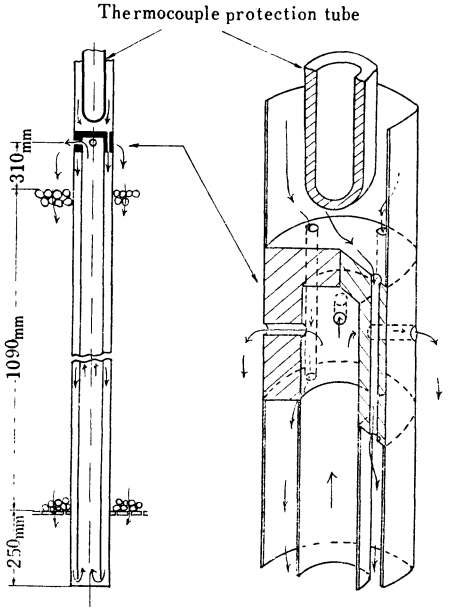

Fig. 1B. Heat exchanger tube (Type C).

tube was too thick to be inserted in the inner tube. The path of the gas stream in the reactor is indicated by arrows in the figures. It should be noted that, in the B-type heat exchanger, the synthesis gas introduced into the reactor at the top first flows downwards through the inner tube, whereas in the C-type exchanger it first flows downwards through the annular space between the outer and the inner tubes. For the sake of simplicity, the previous reactor with no heat exchanger will be hereafter denoted as the O reactor, while the individual reactors equipped with the heat exchangers of type A, type B, and type C will be termed the A, B, and C reactors respectively.

The catalyst used in the present study was a three-component catalyst (ZnO-Cr_2O_3-CuO) of the same composition and prepared by the same procedure as those of the catalyst in the preceding study[1]. Two liters of the reduced catalyst granules (3 mm. in diameter by 4 mm. high), weighing 3.012 kg., were charged into the reactor, and the catalyst bed attained as high as 1090 mm., occupying the intermediate range of the reactor between 1440 and 350 mm. from the bottom.

The operating procedure of the methanol synthesis was quite the same as has been described previously[1]. In this study, however, the bed temperature profile along the center-axis could not be measured, because the heat exchanger tube occupied the center-axis. As it was, only the off-center profiles at radial distances of 15 and 22 mm. from the center-axis were measured by means of two thermocouples in the protection tubes (5 mm. O. D. with a 1 mm. thickness) placed parallel in the bed.

The axial concentration profile was determined in the same way as in the preceding study[1], but the catalyst bed heights at which small portions of the fluid were withdrawn for the composition determinations varied somewhat according to the kinds of reactors[7].

Results

Methanol Production.—The methanol yields are listed in Table I, together with the operation variables. For the sake of comparison, the table also includes the previous data on the synthesis runs (Exps. I and I') using the O reactor. The A reactor produced a much larger amount of methanol than the O reactor, and the space-time-yield attained as much as twice the yield of the O reactor (compare Exp. I with Exp. 3), provided the synthesis gas was preheated at a higher temperature (cf. the data of Exps. 2 and 3). The B reactor could also produce a larger amount of methanol than the O reactor, but the production increase was rather low compared with that of the A reactor (compare Exp. 1 with Exp. 6). Contrary to the above findings, reliable performance data could not be collected with the C reactor until the introducing gas had been preheated to a much higher temperature (cf. Exp. 7). In this reactor, the heat exchanger tube cooled the catalyst bed so much that the bed temperature would decrease too low to allow the progress of the synthesis.

Concentration and Temperature Profiles.— Figure 2 shows the concentration and temperature profiles for the synthesis run with the A reactor (Exp. 4), while Fig. 3 shows the profiles for the runs with the B reactor (Exp. 6) and the C reactor (Exp. 7.). The major difference observed among the temperature profiles of the three reactors is that the maximum of the temperature profile appears in the upper half of the catalyst bed of A reactor whereas it appears near the bottom of the bed of B and C reactors. Moreover, the temperature at the catalyst inlet of the B and C reactors is kept considerably lower than that of the A reactor even when the gas is preheated at higher temperatures. In the bed of the A reactor, methanol has already been produced at the top zone of the bed and increases in amount rather monotonously with the bed length, whereas in the beds of reactors B and C only a small amount of methanol begins to appear after the gas has passed through more than a quarter of the bed length. The concentration and temperature profiles observed with the B and C reactors are essentially the same in tendency as those observed with the O reactor[1].

The off-center temperatures, as well as the temperature in the heat exchanger tube measured at the different bed lengths of 0, 0.44, and 0.94 m., are given as full marks in Fig. 4 for Exp. 4. A rough estimation of the radial profile from the available data leads us to expect a steep temperature rise in the middle across the annular-shaped cylindrical bed.

Discussion

Heat Transfer between Gases in the Catalyst Bed and the Heat Exchanger Tube.—Since the synthesis runs using the A reactor provide the experimental axial temperature profiles in the heat exchanger tube as well as in the catalyst bed, a quantitative treatment of the heat transfer phenomena between the gas in the catalyst bed and the gas in the heat exchanger tube will be made with this reactor. The heat balance equation for the bulk catalyst has the form:

$$S_1C_{p1}G_1dt_1/dx = S_1v\Delta H - F_{12}U_{12}(t_1-t_2) - F_{1b}U_{1b}(t_1-t_b) \quad (1)$$

while the equation for the gas in the heat exchanger tube is given by;

$$S_2C_{p2}G_2dt_2/dx = F_{12}U_{12}(t_1-t_2) \quad (2)$$

In the equations, S is the cross sectional area, C_p is the heat capacity of the gas, G is the mass velocity of the gas, v is the reaction rate based on the unit volume of the catalyst bed, ΔH is the reaction heat, F is the cooling area per unit length, and U is the overall heat transfer coefficient. Subscripts 1, 2, and b indicate the catalyst bed, the heat exchanger tube, and the oil bath respectively.

Because of the complicated nature of the first term on the right hand-side of Eq. 1, it is necessary to use a step by step integration of the differential equations. Under the assumptions that $S_1C_{p1}G_1$ and $S_2C_{p2}G_2$ are identical and that v is constant within the step length Δx, the differential equations can be directly transformed to the following difference equations:

$$A(t_{1no}-t_{1n1})/\Delta x = \Delta Q_n - F_{12}U_{12}\{(t_{1no}+t_{1n1}) - (t_{2no}+t_{2n1})\}/2 - F_{1b}U_{1b}\{(t_{1no}+t_{1n1})/2 - t_b\} \quad (3)$$

$$-A(t_{2no}-t_{2n1})/\Delta x = F_{12}U_{12}\{(t_{1no}+t_{1n1}) - (t_{2no}+t_{2n1})\}/2 \quad (4)$$

In Eqs. 3 and 4, A stands for $S_1C_{p1}G_1 = S_2C_{p2}G_2$, ΔQ_n for $S_1v_n\Delta H$ where v_n is the v in the n-th step, and the subscripts ni and no indicate the inlet and outlet of the n-th step respectively. The difference equations are solved to result in the following respective expressions of $U_{12}F_{12}/A$, t_{1no}, and t_{2no}:

$$U_{12}F_{12}/A = (t_{2n1}-t_{2no})/\Delta x\{(t_{1n1}-t_{2n1}) + \Delta t/2\} \quad (5)$$

$$t_{1no} = b/a + t_{2no}c/a \quad (6)$$

$$t_{2no} = (ap-lb)/(lc+aq) \quad (7)$$

in which the following abbreviations are introduced:

$$\Delta t = (t_{1no}-t_{1n1}) - (t_{2no}-t_{2n1}),\ a = A + F_{1b}\cdot U_{1b}\Delta\chi/2,\ b = \Delta Q + A(t_{1n1}-t_{2n1}) + F_{1b}U_{1b}\cdot \Delta x(t_b-t_{1n1}/2),\ l = B\Delta x/2,\ p = t_{2n1}\ (1\text{-}B\Delta x/2) - B\Delta x(t_{1n1}/2-t_{2n1}),\ q = (1-B\Delta x/2),\ \Delta Q = \Delta Q_n\Delta x$$

The left-hand side term of Eq. 5 corresponds to the cooling coefficient of the heat exchanger tube and will be denoted by B hereafter.

Let us calculate B by the aid of Eq. 5 on the basis of the experimental profiles of Exps. 1, 2, 3, and 4. In the calculation, t_1 is conventionally chosen to fit the arithmetic mean temperature between the two measured off-center temperatures. The step lengths used in the calculation are 0.29 m. for the first step and 0.15 m. for the other steps, corresponding to the bed heights at which small portions of the fluid in the bed were drawn for the composition determination. The B thus obtained is denoted by B_{exp} and is shown in Fig. 6 as a function of x. The figure shows that B_{exp} is different according to the bed lengths and that a maximum appears at about $x=0.4$ m.

The B_{exp}'s are then averaged over the whole bed length (denoted by $\bar{B}_{exp}$ hereafter), and the $\bar{B}_{exp}$ is compared with the value of B_{calc}, which can be calculated by usual means. In the comparison, B_{calc} averaged over the whole bed length, for the sake of convenience, is taken into account[8]; it is usually given by the following formulae:

$$B_{calcd} = U_{12}F_{12}/A \quad (8)$$

where U_{12} is defined either by

$$1/U_{12} = 1/h + (1/h_a)(r_2/r_1) + r_2/\lambda_s\ln(r_2/r_1) \quad (9)$$

or by

$$1/U_{12} = 1/h' + (1/h_a)(r_2/r_1) + r_2/\lambda_s\ln(r_2/r_1) + r_2/\lambda_e\ln(r_3/r_2) \quad (10)$$

In the above formulae, h is the heat transfer coefficient based upon the difference between the average catalyst temperature and the temperature of the outer-wall of the heat exchanger tube, whereas h' is the coefficient across

8) The calculation of individual B's at different bed lengths is very time-consuming, since the thermodynamic data must be evaluated at different bed lengths.

TABLE II. FORMULAE FOR EVALUATION OF h AND h'

the gas film on the outer surface of the tube, h_a is the coefficient from the cooling gas to the inner-wall of the heat exchanger tube material (315 kcal./m. hr. °C), λ_e is the effective thermal conductivity of the catalyst bed, r_1 and r_2 are the inner and the outer radii of the heat exchanger tube, and r_3 is the radius to give the area which is equivalent to a half of the cross sectional area of the catalyst bed. The last term on the right-hand side of Eq. 10 has no strict meaning in theory, but it is introduced conventionally because the $1/U_{12}$ should include any term of the heat transfer resistance through the catalyst bed. The term may stand for the mean value of the transfer resistance.

The evaluation of h can be made by the aid of several kinds of formulae (A[9], B[10], C[11], D[12], and E[13]), while h' can be evaluated by the aid of formula F[14], as listed in Table II. The symbols not explained earlier are as follows: R_{ep} is the modified Reynolds number, D is the equivalent diameter of the annular shaped bed, and μ is the viscosity of the gas. Moreover, either one of the following formulae can give h_a according as whether the gas flow is laminar or turbulent[15]:

9) S. Maeda and K. Kawazoe, *Chem. Eng.* (*Kagaku Kikai*), **15**, 5, 9, 312 (1951).
10) S. Hatta and S. Maeda, ibid., **12**, 56 (1948).

$$h_a = 0.023(k/D_e)(D_eG/\mu)^{0.8}(C_p\mu/k)^{0.4}$$
for a turbulent flow[16] (12)

where k is the thermal conductivity of the gas, D_e is the equivalent diameter of the heat exchanger tube, and L is the catalyst bed length. Table III summarizes the thermodynamic and other data with respect to Exps. 1, 2, 3 and 4. In Table V, $\bar{B}_{exp}$ is compared with the B_{calcd} obtained by putting into Eq. 8 the values of the heat transfer coefficients as listed in Table IV. A comparison shows that the B_{calcd}'s obtained by the use of h's from the A, C, and E formulae, and also the B_{calcd} obtained by the use of h' from formula F, are consistent with the $\bar{B}_{exp}$.

In addition, the calculation of $1/U_{12}$ by means of Eq. 10 provides the content of the overall heat transfer resistance between the gas in the catalyst bed and the gas in the heat exchanger tube; this is shown in Table VI. The table shows that the heat transfer resistance across the catalyst bed is so high as to account for about one-third of the overall heat transfer resistance.

Calculation of Axial Temperature Profiles in the A Reactor.—Under the assumption that the catalyst inlet temperature is identical with the temperature at the end of the heat exchanger tube, a step by step calculation of the axial temperature profiles in both the catalyst bed and the heat exchanger tube is possible with the aid of Eqs. 6 and 7, if ΔQ_n, U_{1b}, and B, besides the thermodynamic data, are available. In this connection, ΔQ_n is given as a function

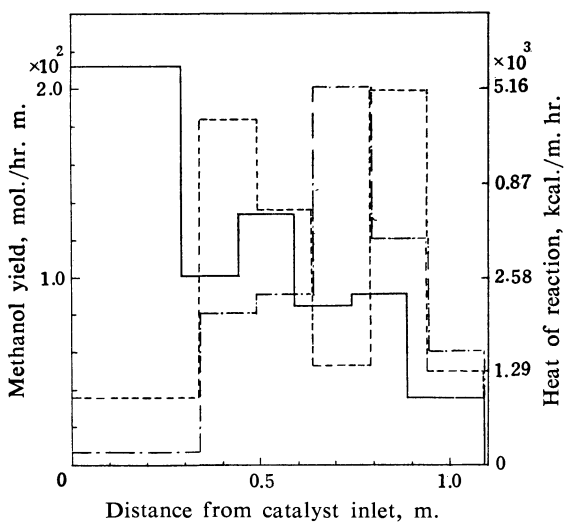

Fig. 5. Methanol yield and reaction heat of methanol synthesis as function of bed length.

of x in Fig. 5, while B_{exp} is given in Fig. 6 also as such. U_{1b} can be evaluated as a function of x by the following equation:

$$U_{1b}F_{1b}\{(t_{1ni}+t_{1no})/2-t_b\}\Delta x=\Delta Q-A\Delta t \quad (13)$$

For the sake of simplicity, however, B_{calcd} evaluated from the formula of Leva et al.[11] and U_{1b} averaged over the whole bed length are used in the present calculations. The choice of B_{calcd} is due to the afore-mentioned finding that the evaluated B_{calcd} was very approximate to the $\bar{B}_{exp}$.. The calculations are now made on the basis of the data of Exp. 4[17], and the resultant profiles are shown in Fig. 7 in comparison with the experimental ones. The accordance between the two sets of profiles is good. This indicates that an adequate value of B_{calcd} evaluated from any of the formulae thus far proposed can be used for the profile calculation without causing any serious errors.

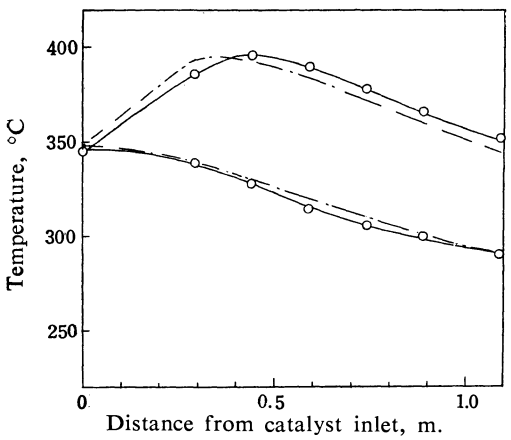

Fig. 7. Comparison between experimental and calculated temperature profiles. Exp. 4.
—○— Experimental profile.
—·—· Calculated profile.

Radial Temperature Profile across the Reactor.—Because only four measurements of the temperatures, namely, the temperatures at the center axis of the heat exchanger tube, the off-center temperatures at $r=15$ and 22 mm. in the catalyst bed, and the oil bath temperature, were made at several different bed lengths, the experimental radial profile across the reactor has not yet been obtained. In view of the estimated value of h', as well as of those of the respective heat transfer coefficients across the films on the outer and the inner surfaces of the reactor (h_L and h'')[18], steep temperature rises are expected at the outer surface of the heat exchanger tube and at the inner and the outer surface of the reactor. However, nothing decisive can be said in this respect.

Axial Temperature Profiles in B-Type and C-Type Heat Exchanger Tubes.—An attempt has been made to calculate the temperature profiles in the heat exchanger tubes of the B and C types. The calculations have been made by starting with a set of the following heat balance equations (14, 15, and 16):

$$Adt_1/dx=\Delta Q-F_{1b}U_{1b}(t_1-t_b)-F_{12}U_{12}(t_1-t_2) \quad (14)$$

$$\mp Adt_2/dx=F_{12}U_{12}(t_1-t_2)-F_{23}U_{23}(t_2-t_3) \quad (15)$$

$$\pm Adt_3/dx=F_{23}U_{23}(t_2-t_3) \quad (16)$$

The respective minus and plus signs on the left hand-side of Eqs. 15 and 16 are used as with the B-type heat exchanger tube, while the corresponding plus and minus signs are as with the C type one. The subscript 1 indicates the catalyst bed, as has been mentioned, and the subscripts 2 and 3 indicate the annular-shaped space and the inner tube of a double tube heat exchanger respectively. Since the thermodynamic as well as the mechanical data, such as C_p, U, G ΔQ, S and F, have already been

A; catalyst inlet, B; catalyst outlet.

17) In Exp. 4, the catalyst inlet temperature was 348°C. Evaluation of U_{1b} and B_{calcd} resulted in 1.524×10^2 kcal./m²hr.°C and 1.0684 m^{-1} respectively.

18) The value of h_L was estimated to be 2.091×10^2 kcal./m² hr. °C (cf. 1)), while that of h'' is evaluated, for instance, to be 2.465×10^3 kcal./m² hr. °C for the case of Exp. 4.

available and since dt_1/dx can readily be obtained from the experimental temperature profiles, t_2 can be calculated by the aid of Eq. 14. Once t_2 is obtained as a function of x, t_3 can be calculated by the substitution of the value of dt_2/dx into Eq. 15.

The calculations have been conducted on the basis of the experimental data of Exps. 6 and 7; the results are shown in Fig. 8. The values of the heat transfer coefficient necessary for the calculations are listed in Table VII, in which the symbols I, II, and III stand for the passages as indicated in Fig. 9. The figure and the table disclose that, owing to the efficient heat transfer between the gases in the II and III passages, the temperature profiles in the second passage always slope down markedly in the upper zone, and that, as a consequence, the catalyst inlet temperature is kept comparatively low. These facts may have led to the axial temperature profile in the catalyst bed being almost identical in tendency with that for the reactor with no heat exchanger tube. Taking the most favorable temperature profile for the methanol synthesis (cf. 1)) into consideration, any remarkable effect in increasing the methanol yield is scarcely to be expected from the use of heat exchanger tubes of the B and C types, unless special treatment lowers the U_{23} in the upper part of the tubes. This may have resulted in the lower methanol yields of the B and C reactors as compared with the yield of the A reactor.

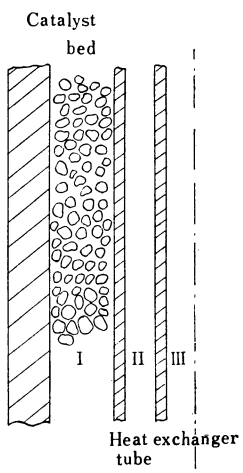

Fig. 9. Schematic diagram of flow passages.

Summary

Among the three types of heat exchanger tubes, a single tube countercurrent type, a double tube countercurrent type, and a double tube concurrent type, only the first one serves to increase the methanol production considerably compared with the effect of the previously tested reactor with no heat exchanger tube. On the basis of the experimental temperature profiles in both the catalyst bed and the single tube-heat exchanger tube, the cooling coefficient with the tube has been calculated to give the value as a function of the bed length. The value, when averaged over the whole bed length, agrees with the calculated value from the heat transfer coefficients, h or h' and h_a, available from certain formulae. By the use of this value, the average temperature profiles in the bed have been calculated on the basis of the experimental concentration profile; the resultant profile agrees well with the experimental one.

As regards the double tube-heat exchanger tubes, the temperature profiles for both the annular-shaped space and the inner tube have been calculated from the experimental bed temperature profiles. The results show that the profiles in the second passage of the tubes always slope down markedly in the upper zone and that, as a consequence, the bed temperature profiles are apt to remain almost identical with that for the previously tested reactor with no heat exchanger tube.

A Simple Molecular Orbital Method for Discussing the Electronic Structures of Stereoisomers—The Theoretical Method and ESR Hyperfine Splittings of the Terephthalaldehyde Anion

By Keiji MOROKUMA, Teijiro YONEZAWA and Kenichi FUKUI

(Received May 8, 1962)

The various different properties of the stereoisomers of organic compounds have long excited the interest of chemists in their chemical reactivities, physical properties, spectroscopic data, and so forth.

From the point of view of molecular orbital (MO) treatment, stereoisomers may be divided into two classes, one consisting of geometrical (cis- and trans-) and rotational (gauche- and trans-) isomers, and the other containing optical isomers. The following discussion will be limited to the isomers of the first class.

The electronic structures of these isomers are calculated to be identical when the simple LCAO MO method, in which electronic interactions are formally neglected, is used, for in this method the secular equation of one of the isomers is equal to that of the other. In the discussion of the differences in energy of the first class steroisomers, classical electrostatic calculation has been found useful, as has the ASMO (antisymmetrized MO) calculation, including electronic interactions. In a discussion of their electron distribution the ASMO SCF (self-consistent field) calculation is both necessary and adequate; a typical example would be the strict calculation of the π-electron distribution of trans- and cis-butadiene by Parr and Mulliken[1]. In such non-polar compounds as butadiene, indeed, such a strict but very troublesome calculation is indispensable in order to show any difference of distribution. However, in a compound containing polar groups, some differences of electron distribution between the isomers, which may be sufficient for a qualitative comparison, may be obtained by a simple LCAO MO method, with the parameters modified by considering the electronic interaction between polar groups.

In this paper, such a modified simple molecular orbital method is to be determined for conjugated molecules; it is then to be applied to the interesting differences between terephthalaldehyde anion isomers in the proton hyperfine couplings in ESR (electron spin resonance) spectroscopy recently investigated by Maki[2].

As to the structural isomers, the electronic structures are, of course, different even in the simple LCAO MO calculation. In this simple method, however, it is difficult sufficiently to take into account the effects of near-by polar groups, while actually the electronic interactions cause a considerable change in the electron distribution. The simple MO method with modified parameters which is utilized for geometrical isomers is also of use for this class of isomers. Applications to actual problems of structural isomers—nuclear coupling constants and asymmetric parameters in PQR (pure nuclear quadrupole resonance) spectra, dipole moments, etc.—will be given in the next paper[3].

Theoretical Method

In the Hückel MO theory, by solving the secular equation

$$\sum_{s=1}^{n}(a_{rs}^{0}-\lambda_i\delta_{rs})C_{ir}^{\pi}=0 \quad (r=1,2,\cdots,n) \quad (1)$$

molecular orbitals are obtained as a linear combination of atomic orbitals (AO's) as follows:

$$\phi_i^{\pi}=\sum_{r=1}^{n}C_{ir}^{\pi}\chi_r^{\pi} \quad (i=1,2,\cdots,n) \quad (2)$$

where n is the number of π AO's, χ_r^{π} is the rth π AO, C_{ir} is the coefficient of the rth AO in the ith MO, λ_i is the ith eigenvalue of Eq. 1, and a_{rr}^{0} and a_{rs}^{0} are the parameters standing for the Coulomb integral of the rth AO and the resonance integral between the rth and the sth AO's, respectively.

The molecular orbitals of σ electrons are similarly calculated as a linear combination of σ atomic orbitals (sp^2 or sp^3 hybridized orbitals on carbon atoms, hydrogen 1s orbitals

1) R. G. Parr and R. S. Mulliken, *J. Chem. Phys.*, **18**, 1182 (1950).

2) A. H. Maki, ibid., **35**, 761 (1961).

3) K. Morokuma, T. Masuda and K. Fukui, to be published in this Bulletin.

and σ atomic orbitals on substituents)[4-6]*:

$$\psi_j^{\sigma}=\sum_{t=1}^{N}C_{jt}^{\sigma}\chi_t^{\sigma} \qquad (j=1,2,\cdots,N) \quad (3)$$

with parameters b_{tt}^0 and b_{tu}^0 defined as

$$\left.\begin{array}{ll}\text{Coulomb integral} & \alpha_t^{\sigma}=\alpha_{\sigma}+b_{tt}^0\beta_{\sigma}\\ \text{resonance integral} & \beta_{tu}^{\sigma}=b_{tu}^0\beta_{\sigma}\end{array}\right\} \quad (4)$$

where N is the number of σ AO's and β_{σ} is the resonance integral of the standard C–C σ bond of benzene. From these MO's, the π and the σ electron densities, q_r^{π} and q_t^{σ} respectively, are calculated:

$$\left.\begin{array}{l}q_r^{\pi}=\sum_{i}^{\text{occ}}\nu_i^{\pi}(C_{ir}^{\pi})^2\\ q_t^{\sigma}=\sum_{j}^{\text{occ}}\nu_j^{\sigma}(C_{jt}^{\sigma})^2\end{array}\right\} \quad (5)$$

where ν_i represents the number of electrons in the ith MO.

Suppose that q_r^{π} and q_t^{σ} have already been calculated by the use of assumed parameters. We call them the densities and the parameters, respectively, of the zero order. Of course, the results are identical with respect to the cis- and the trans-isomers. If the compound has an even number of electrons (closed shell), Fock's operater of the pth atomic orbital on the Ath atom with electron-electron interaction, which corresponds to the Coulomb integral in the simple MO treatment, may be given as follows[7]:

$$F_{pp}=W_p(q_p)+\frac{1}{2}q_p\gamma_{pp}+(Z_A-1)\xi_{pA}+\sum_{r\ (\text{on }A)}^{\text{all AO's}}q_r\gamma_{pr}+\sum_{r\ (\text{not on }A)}^{\text{all AO's}}q_r\gamma_{pr}+\sum_{B\ (\neq A)}^{\text{all cores}}Z_B\xi_{pB} \quad (6)$$

The first four terms are concerned with the electrons and the core of atom A, and the last two represent the interactions with electrons and cores on the other atoms; γ_{pr} and ξ_{pB} are the electron repulsion integral and the electron core atraction integral, respectively, which are represented by

$$\left.\begin{array}{l}\gamma_{pr}=\int\chi_p^*(1)\chi_p(1)\dfrac{e^2}{r_{12}}\chi_r^*(2)\chi_r(2)\,d\tau_1 d\tau_2\\ \xi_{pB}=-\int\chi_p^*(1)\dfrac{e^2}{r_{1B}}\chi_p(1)\,d\tau_1\end{array}\right\} \quad (7)$$

γ_{pp} and ξ_{pA} are the corresponding one-center integrals, and Z_B is the charge of the core B. $W_p(q_p)$ is the energy of an electron on the pth AO in its valence state, which is a function of the electron density, q_p.

If one assumes that, when the rth and the qth AO's belong to the same atom, B, γ_{pr} is equal to γ_{pq} wherever each of them may be directed, and that, further, ξ_{pB} is equal to them (hereafter they are designated by γ_{AB}), then the latter two terms may be written as follows:

$$-\sum_{B\ (\neq A)}Q_B\gamma_{AB} \quad (8)$$

where Q_B is the net charge on atom B

$$Q_B=Z_B-\sum_{r\ (\text{on }B)}^{\text{all AO's}}q_r \quad (9)$$

The assumption is acceptable in this simple qualitative discussion. Because W_p becomes more positive and $-(1/2)q_{pp}$ more negative when q_{pp} is set larger, the sum W_p^0

$$W_p^0=W_p-\frac{1}{2}q_p\gamma_{pp}-\xi_{pA} \quad (10)$$

might be independent of the density*. Thus, the remainder of the former terms are reduced to

$$-Q_A\gamma_{AA} \quad (11)$$

Moreover, a simple expression,

$$F_{pp}=W_p^0-\sum_{B}^{\text{all atoms}}Q_B\gamma_{AB} \quad (12)$$

is obtained, W_p^0 being a constant, depending only on the kind and the hybridization of the atom (sp^2 carbon, sp^3 carbon, hydrogen, and so forth). We choose a certain atom as the standard, putting 0 on the shoulder as follows:

$$F_{qq}^0=W_q^0-\sum_{B}^{\text{all atoms}}Q_B\gamma_{DB} \quad (13)$$

At this stage, we return to the simple LCAO MO treatment, regarding the F_{pp} as the new Coulomb integral, α_p, modified with electronic interactions, and F_{qq}^0 as the standard integral, α_q^0, assumed to be equal to that of the zero order (Eqs. 1 and 4). Therefore, the new Coulomb integrals for the π electrons are:

4) K. Fukui, H. Kato and T.Yonezawa, This Bulletin, **34**, 442, 1111 (1961).
5) K. Fukui, H. Kato, T. Yonezawa, K. Morokuma, A. Imamura and C. Nagata, ibid., **35**, 38 (1962).
6) K. Morokuma, H. Kato and K. Fukui, to be published in this Bulletin.
* If the compound in question is a conjugated system, sp^2 hybridized orbitals should be used. When the compound is a saturated one, π MO's (Eq. 2) do not appear and the σ MO's are composed of sp^3 hybridized orbitals.
7) J. A. Pople, *Trans. Faraday Soc.*, **49**, 1375 (1953).

* In stereoisomers, the assumption expressed by Eq. 10 is unnecessary. The assumption is needed only in structural isomers.

$$\left.\begin{aligned} \alpha_q^0 &= \alpha_\pi + a_{qq}^0 \beta_\pi \\ \alpha_p &= \alpha_p^0 + (F_{pp} - F_{qq}^0) \end{aligned}\right\} \quad (14)$$

or the new parameters a_{pp}^1 and a_{qq}^1 are:

$$\left.\begin{aligned} a_{qq}^1 &= a_{qq}^0 \\ a_{pp}^1 &= a_{pp}^0 + (F_{pp} - F_{qq}^0)/\beta_\pi \end{aligned}\right\} \quad (15)$$

Also, for σ electrons,

$$\left.\begin{aligned} b_{qq}^1 &= b_{qq}^0 \\ b_{pp}^1 &= b_{pp}^0 + (F_{pp} - F_{qq}^0)/\beta_\sigma \end{aligned}\right\} \quad (16)$$

With these new parameters of the first order, which do, of course, differ between the two geometrical isomers, are calculated the π and σ electron distributions of the first order, showing the difference between the isomers.

Instead of Eqs. 15 and16, Eq. 17

$$\left.\begin{aligned} a_{pp}^1 &= a_{pp}^0 + k(F_{pp} - F_{qq}^0)/\beta_\pi \\ b_{pp}^1 &= b_{pp}^0 + k(F_{pp} - F_{qq}^0)/\beta_\sigma \end{aligned}\right\} \quad (17)$$

might better be used. The value of k is unity in Eqs. 15 and 16, but this value might lead to an over-estimation of the effects; therefore, so as to get nearer to self-consistency, k might be better settled as $0 < k < 1$.

ESR Hyperfine Splittings of the Terephthalaldehyde Anion

Recently an ESR spectrum of a terephthalaldehyde mononegative ion radical produced by the electrolytic reduction of the aldehyde has been observed by Maki[2]; it has been found that the hyperfine splittings of the spectrum cannot be interpreted without taking them as rising from two radical species, each of which has three pairs of protons with these coupling constants; species A: 2.08, 0.70 and 3.89 gauss, and species B: 1.54, 1.16 and 3.81 gauss (absolute value). Maki regarded them as cis- and trans-isomers of the anion radical, distinguished in the ESR spectrum because of the restricted rotation of the aldehyde groups; he suggested that species A was the cis isomer, whereas B was the trans isomer.

It would be interesting to apply the method developed in the preceding paragraph and to see which species may be assigned to which isomer and, furthermore, which coupling constant may be assigned to which proton.

As the terephthalaldehyde anion is a radical, Fock's operator in the radical is a little different from that in Eq. 6[8]. For this qualitative discussion, however, the simplified expression, Eq. 12, may rationally be adopted even for a radical; thus, no special notice to its being open shell is paid in this paragraph.

Evaluation of Atomic Integrals.—The electron repulsion integrals necessary to the evaluation of Fock's operator are estimated, in the form used by Mataga et al.[9], as follows:

$$\gamma_{AB} = \frac{14.39}{a_{AB} + r_{AB}} \text{eV.} \quad (17')$$

where a_{AB} is the distance in Å from atom A to atom B and is constant settled so as to fit experimental values at $r_{AB}=0$ (ionization potential minus electron affinity) if A and B are atoms of the same kind. When A and B are of different kinds, an arithmetical mean may roughly be adopted. The values of a_{AB} are tabulated in Table I.

The values of β_π and β_σ, standard resonance integrals, are taken as follows:

Table I. Values of a_{AB} for various pairs of atoms

B \ A	C	H	O
C	1.29	1.20	1.14
H	1.20	1.12	1.05
O	1.14	1.05	0.99

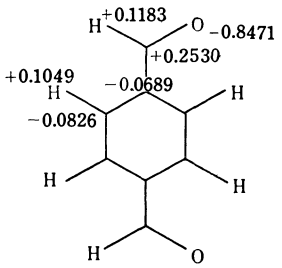
π Elctron density of the neutral aldehyde (numbering of π AO's)



π Electron density of the aldehyde anion

π Spin density of the anion

σ Electron density (numbering of σ AO's)

Net charge of the anion

Fig. 1. Electron distribution of the zero order (numbering of AO's in parentheses).

$$\left.\begin{aligned}\beta_\pi &= -2.5 \text{ eV.}\\ \beta_\sigma &= -8.0 \text{ eV.}\end{aligned}\right\} \qquad (18)$$

and k is set as unity.

The geometry of the aldehyde and its anion is considered to be planar, with bond lengths of 1.40Å for C–C (aromatic), 1.52Å for C–C (substituent), 1.08Å for C–H, and 1.22Å for C=O and with all bond angles of 120°.

Parameters of the Zero Orders.—The parameters of the zero order for the π and σ electron systems are collected in Table II. The values of a_{rr}^0 and a_{rs}^0 for π electron systems are similar to those popularly used. As to the σ system, the values in the table, except for O and C=O, are taken from a paper by the present authors[6]. The values of a_{OO}^0 and a_{CO}^0 have been settled anew by referring to the ionization potentials and electron affinities of oxygen, and to the bond energy of the C–O single bond of alcohols or ethers and the ratio of the overlap integrals for C=O and C–O bonds respectively.

Electron Distributions of the Zero Order.—In Fig. 1 are given electron distributions calculated on the basis of the parameters of the zero order. Since, of course, the results are identical for both isomers, the patterns for only the cis isomer are represented in the figure.

Parameters of the First Orders. — By using the net charge of the anion given in the Fig. 1 and the integrals of γ_{AB}, β_π and β_σ given in the foregoing section, new parameters of the first order have been derived.

As for the π electron system, as the circumstances affecting π AO's C_{II} and C_{III} are not affected by the isomerism, the a_{rr}^1's have been taken to be equal to a_{rr}^0's*. For carbons IV and V, which are indistinguishable in the zero order, new parameters have been estimated by looking tentatively on the $C_V\pi$AO in the trans isomer as a standard; for oxygens, the $O_I\pi$AO in the trans isomer has been taken as a standard.

A similar standardization and calculation of the parameters have also been carried out for σ AO's. The values of the parameters a_{rr}^1 and b_{tt}^1 of the first order thus calculated for both isomers are tabulated in Table III.

Results and Discussion. — The π and σ electron densities and the π spin density of the isomers of the terephthalaldehyde anion have been calculated with the parameters of the first order; the results are given in Fig. 2.

As would be expected from a simple electrostatic consideration, in both isomers the π electron density on C_V is larger than that on C_{IV}, since to the latter the electron-rich and, accordingly, repulsive center of oxygen is located nearer. A similar tendency is found also in σ electron densities on ring hydrogens and ring carbons. The π spin density is

* For the numbering of π AO's, see Figs. 1 and 2.

TABLE III. VALUES OF PARAMETERS a_{rr}^1 AND b_{tt}^1 OF THE FIRST ORDER*

Cis		Trans

C_{13}, C_{14}, C_{16}	+0.026	C_{13}, C_{14}, C_{16}	0 (standard)
H_{15}	−0.164	H_{15}	−0.2 (standard)

* As to numbering of AO's, see Fig. 2.

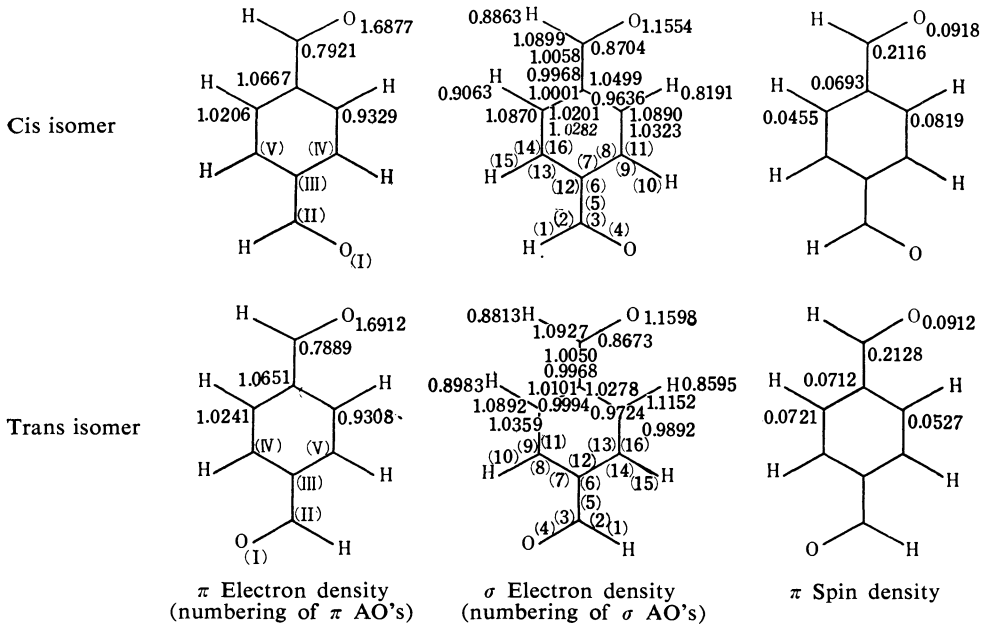

Fig. 2. Electron densities of the first order of the aldehyde anion isomers (numbering of AO's in parentheses).

calculated as the density of the half-occupied level of the anion.

In order to compare these findings in the calculations, the experimental proton hyperfine coupling constants, a_H, have been converted into spin densities on the adjacent carbons, ρ_C, by the equation

$$a_H = Q\rho_C \qquad (19)$$

where the constant, Q, is equal to −23 gauss[10]. Strictly speaking, the constancy of Q would not hold in this case, for the different polarity of each C–H bond, as may be seen in Fig. 2, would yield a different value of Q; in a qualitative discussion like this, however, such a slight difference is of little significance.

On collating the calculated spin densities with the experimental findings indicated in Table IV, we find a good mutual agreement, thus obtaining the following assignments:

(1) The A species is the cis isomer and the B species is the trans isomer, in agreement with Maki's proposition.

10) H. M. McConnell, *J. Chem. Phys.*, **24**, 632, 764 (1956).

TABLE IV. CALCULATED AND EXPERIMENTAL SPIN DENSITIES AND ASSIGNMENT OF COUPLING CONSTANTS OF TEREPHTHALALDEHYDE ANION

Calculated (cis isomer)		Experimental (species A)
Position	Spin density	Spin density
C_{II}	0.212	0.169
C_{IV}	0.082	0.090
C_V	0.046	0.030

Calculated (trans isomer)		Experimental (species B)
Position	Spin density	Spin dencity
C_{II}	0.213	0.166
C_{IV}	0.053	0.050
C_V	0.072	0.067

(2) In each isomer, the largest (in absolute value) and nearly invariant coupling constant originates from the aldehyde proton.

(3) In the trans isomer, the order of the spin density on ring carbons is $C_V > C_{IV}$. On the other hand, in the cis isomer, the spin density on C_{IV} is much larger than that on C_V. This result is of great interest because the order of the spin density is inverse to that of the total π electron density and is contradictory to a simple electrostatic presumption. On inspecting the calculated electron distribution of each molecular orbital (Table V), such a presumption seems to be attributable to the total density and to the distribution of molecular orbitals of a lower energy, but not necessarily to a distribution molecular orbitals of a higher energy or of a less bonding or antibonding nature, as the half-occupied orbital of the anion discussed here.

Summary

A new simple molecular orbital method with parameters modified by electronic interactions was developed so as to discuss simply the difference in electron distributions between stereoisomers. An application was made to the proton hyperfine coupling constants of the cis- and trans-isomers of the terephthalaldehyde anion radical, and the assignment of the constants was proposed on the basis of molecular orbital calculations.

Most of the numerical calculations were carried out on the KDC-I digital computor of Kyoto University.

Changes of the Lattice Constants and Crystallite Sizes of Various Types of Carbons with Heat Treatment

By Michio INAGAKI and Tokiti NODA

(Received June 7, 1962)

Measurements of the lattice constants and crystallite sizes of a number of raw carbon materials, heat-treated at various temperatures, have been carried out by many investigators. However, in most of the investigations, the heat treatments were made in a vacuum or in an inert atmosphere, such as of nitrogen or argon, using laboratory-type furnaces. On the other hand, the present authors thought it necessary to study the effect of the atmosphere of heat treatment on the graphitization of carbon, because it had previously been reported that carbon was only with difficulty graphitized in a vacuum[1,2]. For the present work, several kinds of raw carbon materials were heat-treated at temperatures between 1500 and 3400°C in a resistance furnace under atmospheric pressure. The lattice constants and crystallite sizes of these carbons were measured by means of the X-ray diffraction method in order to investigate their changes with heat treatment. The heterogeneity of the interlayer spacing in a parallel layer group and the relation between the crystallite size and the particle size of carbon black will also be discussed.

Experimental

Heat Treatment of Raw Carbon Materials.—The raw carbon materials used in the present work are shown in Table I, together with technical analysis data of these materials. Each of the raw carbon materials was placed in a graphite crucible and heat-treated in a carbon granular-resistance furnace of a type similar to the industrial graphitizing furnace. The temperature of the crucible was measured with an optical pyrometer focusing through a graphite tube. Because it was difficult to keep the heating temperature constant during the heat treatment, the arithmetical mean of the temperature, t_{20}, at which the crucible was kept for 20 min. and the highest temperature, t_h, in the run was taken as the temperature of the heat treatment, t_m, as is illustrated in Fig. 1. The calibration of the scale of the optical pyrometer and the correction for the absorption by the window glass of the sighting pipe were made by using a standard lamp for the optical pyrometery.

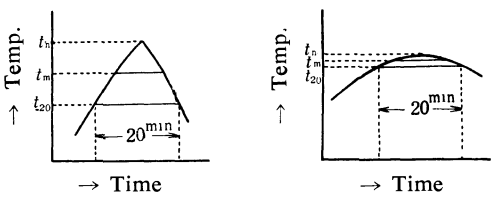

Fig. 1. Scheme of determination of heat treatment temperature.

X-Ray Diffraction Analysis.—Each sample was pulverized to pass through a 150-mesh sieve and mixed with an extra-pure silicon powder as an inner standard to the amount of 10%. The particle sizes of the standard silicon powder used were from about 20 to 40 μ, and its lattice constant, a_0, was measured as 5.4310±0.0004 Å. For X-ray diffraction analysis, a recording diffractometer and CuK_α

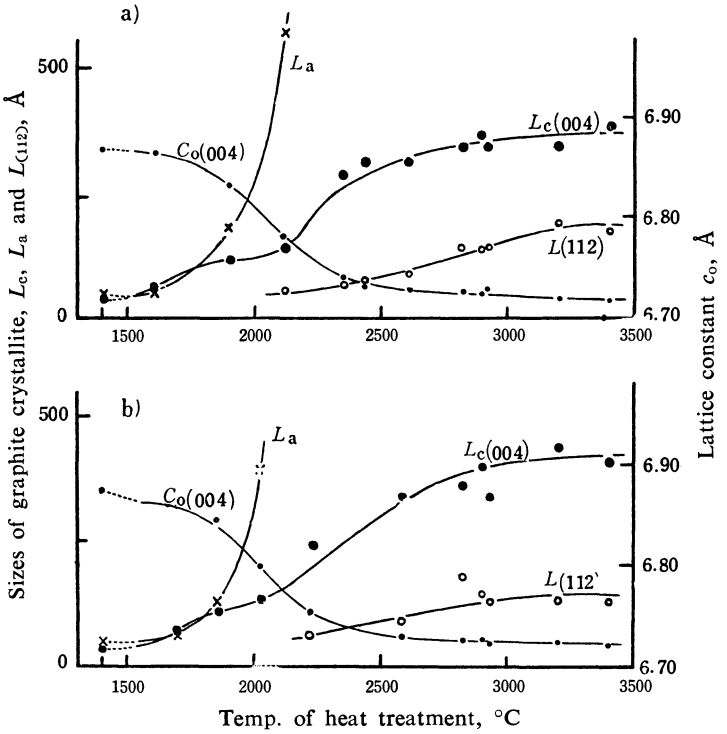
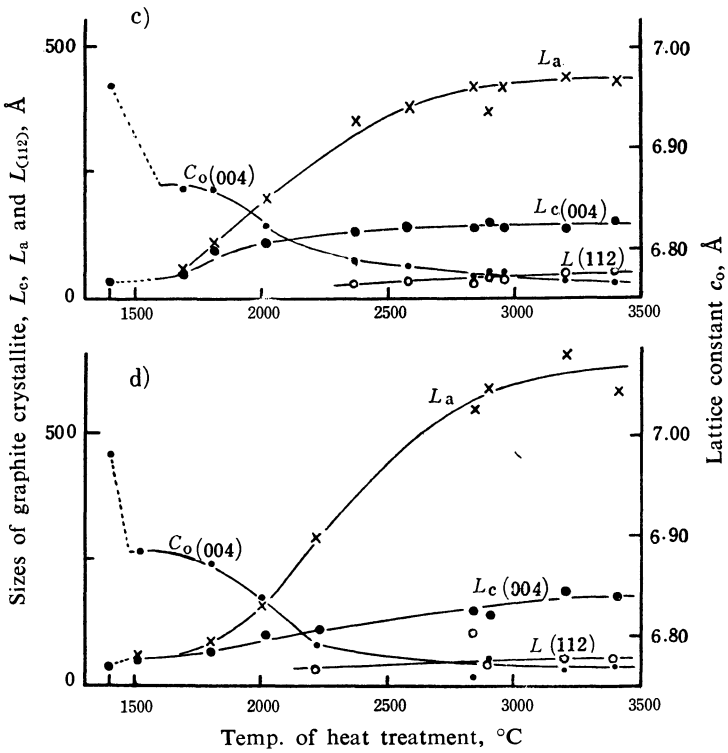
radiation were used. All the profiles of the (422) and (331) diffractions, and some profiles of the (311) diffraction, of standard silicon, were graphically separated into the α_1 and α_2 profiles by means of the Rachinger method[3], the α_1 profiles were used for the present measurements. The lattice constant, c_0, and the thickness of the graphite crystallite along the c-axis, L_c, were obtained from the (002) and (004) diffractions of carbon, the lattice constant, a_0, and the width of the crystallite along the a-axis, L_a, from the (110) diffraction, and the spacing, d_{112}, and size of three-dimensional crystallite, L_{112}, from the (112) diffraction. The crystallite sizes were calculated from half-maximum breadths of the diffraction profiles[4]. The profile of the (002) diffraction was corrected for various intensity factors, such as the Lorentz-polarization factor, the absorption factor and the square of the atomic scattering factor, by using a method similar to Ruston's[5].

Results and Discussion

Changes of Lattice Constants and Crystallite Sizes with Heat Treatment.—The lattice constant, c_0, and the crystallite sizes, L_c, L_a and L_{112}, of the samples are shown as a function of the temperature of heat treatment in Fig. 2. The c_0 and L_c values of all raw carbon materials changed very slightly at temperatures above 2500°C, apparently approaching a finite value. The c_0 values of a petroleum coke and a pitch coke, i. e., the so-called graphitizing carbons, were not less than 6.718Å, even when they were heat-treated up to 3400°C. According to Walker and Imperial, the c_0 values of four carbons heat-treated at about 3600°C under a pressure of 10 atm. of argon were not less than 6.714Å[6]. The same c_0 value as of natural graphite, 6.708Å, was obtained only when carbon was melted[7]. From the results of our experiment and of the reported experiments, it can be concluded that the graphitizability of carbon is affected by the original texture of the carbon—crystallite arrangement, pore distribution, criss-cross linkage between crystallites, etc.—even at such a high temperature as 3600°C, in the same way as at 3000°C or below.



In carbon blacks heat-treated at 3400°C, i. e., a thermal black, a lamp black, two furnace blacks, a channel black and an acetylene black, the c_0 values were 6.77, 6.76, 6.81, 6.83, 6.85 and 6.82Å, and the L_c values obtained from the (002) diffractions, were 220, 190, 110, 89, 64 and 91Å respectively. The particle sizes of these carbon blacks were about 3000, 5000, 500, 350, 300 and 300Å respectively. These experimental results revealed that the c_0 value became smaller and the L_c value larger with the increase in the particle size of carbon black. Therefore, it can be said that the degree of graphitization of carbon black depends on its particle size. This is very interesting in regard to the mechanism of crystal growth in a particle of carbon black. This subject will be discussed below in more detail.



The a_0 value increased with the increase in the temperature of heat treatment, approaching the a_0 value of natural graphite, 2.461Å. The a_0 values of the cokes heat-treated at temperatures above 2400°C and the values of the thermal black and the lamp black heat-treated above 3000°C were 2.461Å, but the values of other carbon blacks did not increase over 2.456Å even when they were heat-treated up to 3400°C.

The value of spacing, d_{112}, was always 1.156Å, independent of the temperature of heat treatment. The modulation of the (11) diffraction profile, which reveals the appearance of a three-dimensional (112) diffraction, was observed in the cokes heat-treated at temperatures above 1800°C, the L_a values of the cokes being larger than 100Å. This experimental finding coincides with Warren's observation[8]. In the thermal black and the lamp black, the (112) diffraction was observed when the L_a value was more than 150~200Å. In all the other carbon blacks, however, no (112) diffraction could be observed.

Heterogeneity of Interlayer Spacing in Crystallite.—Usually, the L_c value obtained from the (002) diffraction of a carbon, $L_{c(002)}$, is larger than that from the (004) diffraction of the same carbon, $L_{c(004)}$. The broadening of the (002) or (004) diffraction profile may be caused not only by the smallness of the crystallite but also by the heterogeneity of the interlayer spacing. The interlayer spacing of the turbostratic structure is said to be 3.44Å and that of graphite structure, 3.354Å, so the broadening for the (004) diffraction due to the heterogeneity of the spacing is twice as large as that for the (002) diffraction. The broadening due to the smallness of the crystallite should be the same for both the (002) and (004) diffractions, provided that the diffraction angle is taken into consideration. As the crystallite size is calculated from the observed broadening, the above discrepancy between $L_{c(002)}$ and $L_{c(004)}$ must be caused mainly by the heterogeneity of the spacing. If we put $\{L_{c(002)}-L_{c(004)}\}/L_{c(002)}$ as $\Delta L/L$, the

value of $\Delta L/L$ may be taken as a measure of the heterogeneity of the spacing of the graphite-like layers in a parallel layer group.

The relation between $\Delta L/L$ and the temperature of heat treatment is shown in Fig. 3. The curves of $\Delta L/L$ for the petroleum coke, the pitch coke, and the thermal black were similar. These curves might be interpreted as follows. Up to 2000°C treatment, the turbostratic structure of graphite-like layers predominates in the samples, but a part of the graphite-like layers begin to take on a three-dimensional ordering, i. e., the graphite orientation, from 1800°C treatment (this was proved by the modulation of the (11) diffraction as mentioned above). Therefore, the heterogeneity of the interlayer spacing in crystallite increases, and the value of $\Delta L/L$ increases rapidly from 1800°C upward. At temperatures above 2000°C, the graphite orientation predominates in the samples, while the turbostratic structure decreases; i. e., the heterogeneity in crystallite decreases with the increase in the temperature of heat treatment. Therefore, the value of $\Delta L/L$ becomes maximum at about 2000°C and then decreases as the temperature

of the heat treatment increases. With samples heat-treated at temperatures above 2600°C and having crystallite sizes larger than 300Å, the error in $\Delta L/L$ was very large, so a discussion of the signification of $\Delta L/L$ may become meaningless. Tagawa and Nakashima[9] obtained a similar curve by investigating the relation between the temperature of heat treatment and the activation energy of the wet oxidation reaction of heat-treated petroleum coke.

Relation between the Particle Size and the Crystallite Size of Carbon Black.—It is said that particle size is the main limiting factor for the growth of graphite crystallite in carbon black[10]. In Fig. 4, the crystallite size, L_c or L_a, of the thermal black, the two furnace blacks, and the channel black is represented as a function of the average particle size, $2R$. Because the lamp black had a peculiar distribution of particle size and because the acetylene black seemed to behave differently in its crystal growth from other carbon blacks, they were omitted from this discussion. From the two figures, it can be seen that the particle size has some effect on the crystal growth along the a-axis and also along the c-axis. This is consistent with the assumption that the minute crystallite whose layer plane is aligned parallel to the surface of the carbon black particle coalesces with its adjacencies into a larger crystallite[11] and that, in consequence, the angle between the c-axes of adjacent parallel layer group is the main limiting factor for crystal growth in carbon black. If it is the only limiting factor, the value of $L_a/2R$, which corresponds to the average angle between the c-axes of adjacent parallel layer groups, should

be the same in all carbon blacks. However, it can be seen in Fig. 5 that the value of $L_a/2R$ is larger as the particle size is smaller. Therefore, there must be another limiting factor besides the angle between the c-axes of adjacent crystallites. It might be the micropores between the crystallites.

Graphitization of Charcoal.—All diffraction profiles of charcoals heat-treated at various temperatures are asymmetrical and seem to be composite profiles[12], as is shown in Fig. 6. The profiles can be separated into three different ones by appearance, i. e., two peaks at about 3.43 and 3.36Å and a broad band.

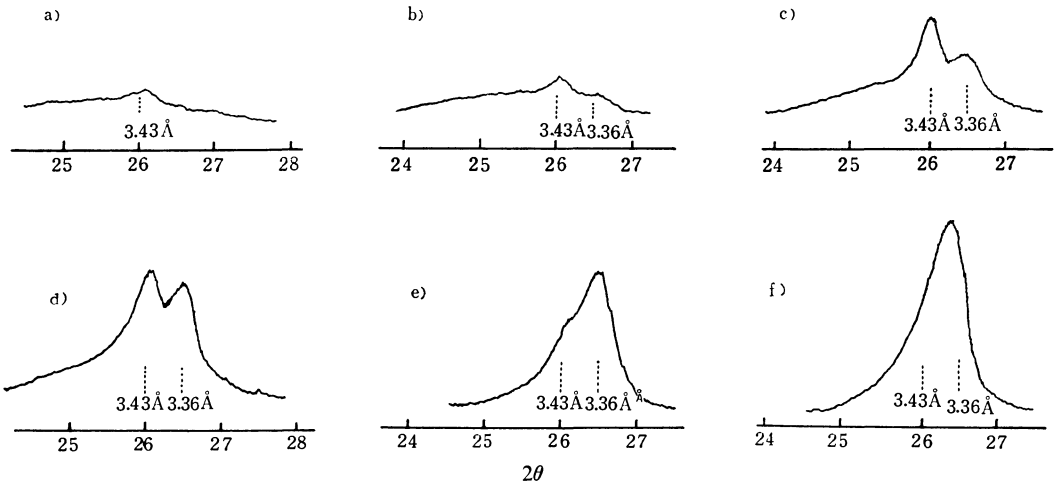

Fig. 6. Profiles of heat-treated charcoals.
a) 1820 b) 2120 c) 2370 d) 2450 e) 2820 f) 3200°C

The peak at 3.43Å increases its intensity up to 2500°C. The peak at 3.36Å, which is feeble as a temperature lower than 2000°C, increases its intensity with the increase in temperature of heat treatment and surpasses the peak of 3.43Å above 2500°C. Franklin[13] first noticed this phenomenon, calling it three-phase graphitization.

Summary

Two kinds of cokes, six kinds of carbon black and a charcoal were heat-treated at temperatures between 1500 and 3400°C in a resistance furnace under atmospheric pressure. The lattice constants and crystallite sizes of these carbons were measured by means of the X-ray diffraction method, using extra-pure silicon as an inner standard.

The c_0 values of the graphitizing carbons, such as the petroleum coke and the pitch coke, were not less than 6.718Å, even when these carbons were heat-treated at 3400°C. It was concluded that the graphitizability of carbon was affected by its original texture even at such a high temperature as 3400°C.

The c_0 value of carbon black became smaller and the value of L_c, larger with the increase in the particle size of carbon black. It has been said that the particle size is the main limiting factor for the growth of graphite crystallite in carbon black, but the experimental results suggest that such other properties as micropores may also be limiting factors.

The discrepancy between the L_c values calculated from the (002) and (004) diffractions was accounted for by the heterogeneity of the interlayer spacing in crystallite.

With the charcoal, so-called three-phase graphitization was observed.

*Nuclear Magnetic Resonance Spectra of Amino Acids and their Derivatives. I. DNP Amino Acids**

By Shizuo FUJIWARA, Yoji ARATA, Naohiro HAYAKAWA and Hironao MOMOI

(Received June 8, 1962)

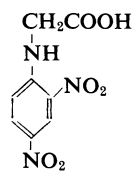
The molecular structure of amino acids has already been investigated by a variety of physical and chemical techniques. High-resolution NMR spectroscopy has also been used for this purpose. Using it, Takeda and Jardetzky[1], Jardetzky and Jardetzky[2], and Bovey and Tiers[3] have measured the proton chemical shift of NH and CH groups in amino acids.

Our aim is to study the NMR spectra of amino acids in more detail in order to compile fundamental data for the investigation of the structure of polypeptides and proteins by the NMR method.

The signal due to the NH proton of an amino acid cannot usually be observed in a water solution, since the NH proton of the amino group is subject to rapid exchange between neighboring molecules. However, in an *N*-(2, 4-dinitrophenyl) amino acid (DNP amino acid), when the sample is dissolved in dehydrated dioxane, the exchange of the NH proton is slow enough to permit the observation of the signal.

The patterns of the spectra arising from the protons on the NH and DNP groups are found to be useful for the identification of DNP amino acids.

Experimental



Materials. — All of the samples were purchased from Wako Chemicals & Co. Solutions (10%, w/v) of each DNP amino acid were prepared in dehydrated dioxane, and 2,4-dinitroaniline was dissolved in dehydrated acetone. The solutions were sealed in 5 mm. o. d. sample tubes. Sixteen kinds of DNP amino acids were used in this experiment: *N*-(2,4-dinitrophenyl) derivatives of glycine (Gly), L-alanine (Ala), L-serine (Ser), L-methionine (Met), L-threonine (Thr), L-allothreonine (Althr), L-leucine (Leu), L-isoleucine (Ileu), L-valine (Val), L-lysine (Lys), L-aspartic acid (Asp), L-glutamic acid (Glu), L-phenylalanine (Phe), L-tryptophan (Try), L-proline (Pro) and L-hydroxyproline (Hyp).

Spectrometer.—A Varian Associates model V4300C NMR spectrometer, operating at 56.44 Mc./sec., was employed for all measurements.

Calibration of the Spectra. — The frequency separations of the spectra with reference to the dioxane signal were determined by the usual side-band technique. The chemical shift data, expressed in p. p. m., are summarized in Fig. 3.

Results

The signals of the three protons of the 2, 4-dinitrophenyl group are easily identified, as is shown in the spectrum of DNP-glycine (Fig. 2). The assignment is found to be unambiguous if the spectrum is compared with that of

2, 4-dinitroaniline (Fig. 2d). In these spectra the signals due to $H_{(3)}$ and $H_{(6)}$ are both doublet; the spin-spin coupling constant between these protons (J_{36}) is estimated to be smaller than 1 c. p. s. J_{35} and J_{56} are found to be 2.8 and 9.2 c. p. s. respectively.

The signal due to the NH proton of DNP-glycine is observed as a slightly broad triplet at the high field side of the $H_{(3)}$ signal (Fig. 2a). The splitting can be attributed to the spin-spin coupling with CH_2 protons. The spin-spin coupling constant is 5.6 c. p. s. When a small amount of water is added, the signal is further broadened. This can be interpreted in terms of an increasing exchange rate of the NH proton (Fig. 2b, 2c). A detailed analysis of the broadening of the signal will be the subject of a forthcoming paper.

In all the other DNP amino acids except DNP-lysine, the NH proton signals are doublet, and in some cases they are overlapped by the $H_{(3)}$ signals. DNP-lysine gives rise to two signals of the NH protons; one is due to the α-NH proton, and the other is due to the ε-NH proton. These signals are split into doublet and triplet, respectively, by interaction with $C_{(2)}$-H and $C_{(6)}$-H protons.

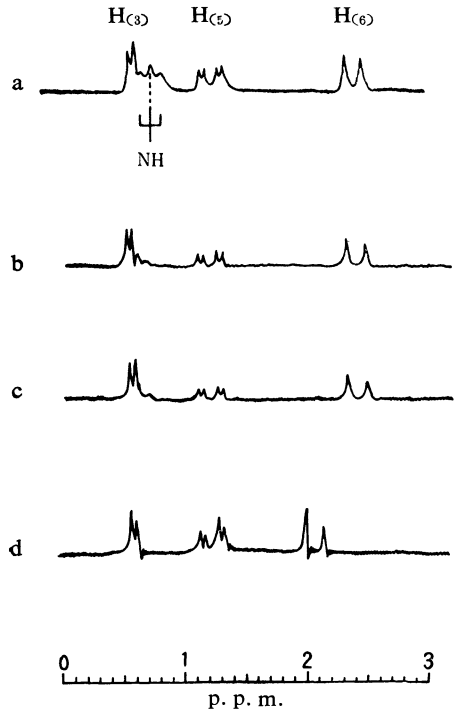

Fig. 2. The proton resonance spectra of DNP-glycine (a), (b) and (c) and of 2,4-dinitroaniline (d).
(a) Assignment of the signals. (b) Distortion of the NH proton signal caused by addition of a small amount of water. (c) The distortion by further addition of water.

In the spectra of DNP-proline and DNP-hydroxyproline, which have no NH proton, signals corresponding to those mentioned above are not observed. This also confirms the assignment of the NH proton signal.

The patterns of the spectra arising from the protons of the NH and DNP groups are sensitive to a slight change in the molecular structure. Thus, DNP-threonine and DNP-allothreonine can easily be discriminated. The same is true for DNP-leucine, DNP-isoleucine, and DNP-valine, and also for DNP-aspartic acid and DNP-glutamic acid.

In DNP-proline and DNP-hydroxyproline, the chemical shift between $H_{(3)}$ and $H_{(5)}$ is small compared with that in the other DNP

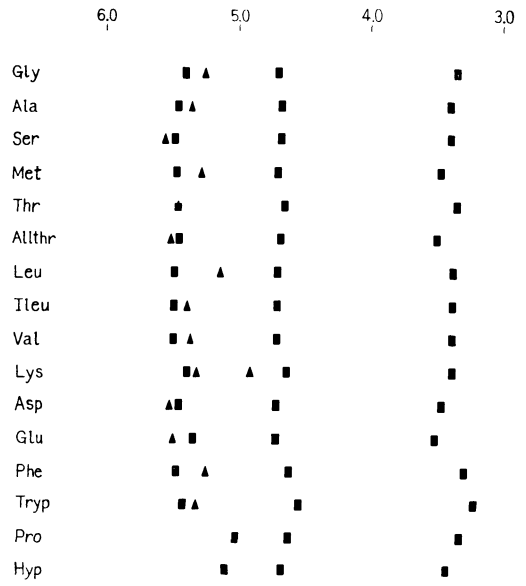

Fig. 3. Proton chemical shifts in p. p. m. of the NH and 2,4-dinitrophenyl groups referred to dioxane. Magnetic field increases from left to right. In the figure ▲ and ■ represent the center of the NH and CH proton signals, respectively.

amino acids. This may be interpreted in terms of a twisting of the NO_2 group at carbon 2 of the DNP group caused by the presence of the bulky 2-carboxy-1-pyrrolidyl group.

Signals due to alkyl chain protons cannot be identified in a dioxane solution. Therefore, an investigation of the signals of free amino acids in a D_2O solution is now in progress. The results will be discussed in the next paper.

*Accurate Determination of Interatomic Distances of Carbon Disulfide**

By Yonezo MORINO and Takao IIJIMA

(Received June 16, 1962)

In some recent studies[1,2] of molecular structure by gas electron diffraction, attentions have been paid to the physical meanings of various distance-parameters for comparing the results obtained by different techniques. In almost all cases, however, it has been impossible to show the consistency of the results of electron diffraction with those of spectroscopy because of the limited knowledge on the anharmonicity of molecular vibration.

The interatomic distances in a molecule are not constant but vary periodically because of the molecular vibrations. The distance averaged over the vibration is denoted by r_g in the sense that r_g is the center of gravity of the distribution function. In the studies of electron diffraction by gas molecules, we obtain r_g from the experimental data by a simple analytical procedure. In the spectroscopy, however, it is r_0 that is usually obtained from the rotational constant of the ground vibrational state. The r_g can be calculated if the equilibrium distance r_e and the anharmonic potential constants, especially the cubic constants, are known. Carbon disulfide is one of the simple molecules of which detailed spectroscopic data are available. The purpose of the present work is to examine if the results of the electron diffraction experiment are consistent with those of the spectroscopy by taking carbon disulfide as an example.

Among a number of spectroscopic studies for carbon disulfide, a high resolution Raman spectrum by Stoicheff[3], and an analysis of infrared rotation-vibration spectra by Guenther, Wiggins, and Rank[4], combined with another infrared study by Allen, Plyler and Blaine[5], provide us with information necessary for this work.

Calculation of r_g from Spectroscopic Data

An instantaneous distance of the C–S atom pair is expressed by

$$r = r_e + \Delta z + \frac{\Delta\rho^2}{2r_e} \tag{1}$$

in terms of internal coordinates, Δz and $\Delta\rho$, where Δz denotes the relative displacement of the atoms C and S along the molecular axis and $\Delta\rho$ is the relative displacement perpendicular to the axis. $\Delta\rho^2$ is sometimes written as $\Delta x^2+\Delta y^2$. By taking an average of Eq. 1 with respect to the distribution function, the average C–S distance r_q(C–S) is expressed by

$$r_g = r_e + \langle\Delta z\rangle + \frac{\langle\Delta\rho^2\rangle}{2r_e} \tag{2}$$

The internal coordinates Δz and $\Delta\rho$ are related to the normal coordinates by the following relations,

$$\Delta z_1 = b_1 q_1 + b_3 q_3 \tag{3a}$$

$$\Delta z_2 = b_1 q_1 - b_3 q_3 \tag{3b}$$

and

$$\Delta\rho^2 = b_{22}(q_{2a}^2 + q_{2b}^2) \tag{3c}$$

where Δz_1 and Δz_2 denote the displacements of the two C–S atompairs, respectively, and q's are the dimensionless normal coordinates which are related to the normal coordinate Q's as $q_i = 2\pi(c\omega_i/h)^{1/2}Q_i$. The coefficients b's are given by the standard treatment of normal vibrations, as

$$b_1 = \left(\frac{h\mu_s}{8\pi^2 c\omega_1}\right)^{1/2} \tag{4a}$$

$$b_3 = \left[\frac{h}{8\pi^2 c\omega_3}(\mu_s + 2\mu_c)\right]^{1/2} \tag{4b}$$

$$b_{22} = \frac{h}{8\pi^2 c\omega_2}(\mu_s + 2\mu_c) \tag{4c}$$

μ_s and μ_c are the inverse masses of S-atom and C-atom, respectively.

The $\langle\Delta z\rangle$ is thus calculated as,

$$\langle\Delta z\rangle = b_1\langle q_1\rangle \tag{5}$$

in terms of the average of the totally symmetric normal coordinate q_1, because the averages of all the linear terms of normal coordinates vanish except for the term of q_1. The general expression of $\langle q_1\rangle$ has been derived by Morino, Toyama and Oka[6], and it is reduced to the following equation for the case of a linear symmetric triatomic molecule,

TABLE I. MOLECULAR CONSTANTS OF CS_2

ω_1^e	671.36 cm^{-1}	α_1	0.000156 cm^{-1}	k_{111}	−14.90 cm^{-1}	B_0	0.10910 cm^{-1}
ω_2^e	398.62 cm^{-1}	α_2	−0.000256 cm^{-1}	k_{122}	50.10 cm^{-1}	B_e	0.10928 cm^{-1}
ω_3^e	1551.92 cm^{-1}	α_3	0.000711 cm^{-1}	k_{133}	−129.56 cm^{-1}	r_e	1.5532 Å

$$\langle q_1\rangle = -\frac{1}{2\omega_1}\left[3k_{111}\coth\frac{hc\omega_1}{2kT} + 2k_{122}\coth\frac{hc\omega_2}{2kT} + k_{133}\coth\frac{hc\omega_3}{2kT}\right] + \left(\frac{8\pi^2 c\omega_1}{h\mu_s}\right)^{1/2}\frac{kT}{f_{11}r_e} \quad (6)$$

when the potential energy expression for a CS_2 type molecule is given by,

$$V = \frac{hc}{2}[\omega_1 q_1^2 + \omega_2(q_{2a}^2 + q_{2b}^2) + \omega_3 q_3^2] + hc[k_{111}q_1^2 + k_{122}q_1(q_{2a}^2 + q_{2b}^2) + k_{133}q_1 q_3^2] \quad (7)$$

The quartic and higher-order terms are neglected in this work, because the average interatomic distances are strongly affected by the asymmetric deformation of the distribution function which is mainly dependent on the cubic terms of the potential function. The first term of Eq. 6 is due to the anharmonicity of vibrations and the second term to the centrifugal stretching for which the mean rotational energy is approximated by kT. The f_{11} is the force constant of the totally symmetric stretching vibration. The $\langle\Delta\rho^2\rangle$ is simply calculated by inserting the relation $\langle q_i^2\rangle = (1/2)\coth(hc\omega_i/2kT)$, into Eq. 3c.

The cubic potential constants k_{ijk}'s are calculated from α_i's, the variation of the rotational constants which have been obtained through the relations[7],

$$\alpha_1 = -\frac{6B_e^2}{\omega_1} - 6\sqrt{2}\left(\frac{B_e}{\omega_1}\right)^{3/2}k_{111} \quad (8a)$$

$$\alpha_2 = -\frac{B_e^2}{\omega_2}\cdot\frac{3\omega_2^2+\omega_3^2}{\omega_2^2-\omega_3^2} - 2\sqrt{2}\left(\frac{B_e}{\omega_1}\right)^{3/2}k_{122} \quad (8b)$$

and $$\alpha_3 = -\frac{2B_e^2}{\omega_3}\cdot\frac{3\omega_3^2+\omega_2^2}{\omega_3^2-\omega_2^2} - 2\sqrt{2}\left(\frac{B_e}{\omega_1}\right)^{3/2}k_{133} \quad (8c)$$

The values of α_i's used and those of k_{ijk}'s obtained from them are listed in Table I.

As the result of numerical computation, $\langle\Delta z\rangle$ was found to be 0.0013 Å, which included the contribution of the centrifugal stretching 0.0003 Å, and $\langle\Delta\rho^2\rangle/2r_e = 0.0035$ Å was obtained for $T = 288°K$. Accordingly, r_g(C–S) is calculated to be

$$r_g(\text{C–S}) = r_e + \langle\Delta z\rangle + \frac{\langle\Delta\rho^2\rangle}{2r_e} = 1.5532 + 0.0013 + 0.0035 = 1.5580\text{ Å}$$

Similarly for the S–S distance,

$$r_g(\text{S–S}) = r_e + \langle\Delta z_1 + \Delta z_2\rangle = r_e + 2\langle\Delta z\rangle = 3.1064 + 0.0026 = 3.1090\text{ Å}$$

where it is noted that $\Delta\rho$ is zero for the S–S distance.

The apparent non-linearity or the shrinkage[8] $\delta_g = 2r_g(\text{C–S}) - r_g(\text{S–S})$ is equal to $\langle\Delta\rho^2\rangle/r_e$, and it was found to be 0.0070 Å by the calculation.

According to Stoicheff[3], $\alpha_1 = 0.00018\ cm^{-1}$ may be preferable when the effect of Fermi resonance is considered. This alternative value of α_1 leads to $k_{111} = -16.27\ cm^{-1}$ and $\langle\Delta z\rangle = 0.0011$ Å. The equilibrium distance r_e is also affected by this change: it becomes 1.5530 Å. However, the average distance r_g is little altered: it was found to be 1.5579 Å. Therefore, the uncertainty in the value of α_1 due to Fermi resonance gives no serious error in the present study.

Measurement of r_g by Electron Diffraction

Experimental.—The diffraction photographs were taken by the apparatus[9,10] equipped with an r^3-sector, with the camera length of 12 cm. and the accelerating voltage of about 45 kv which was calibrated by the transmission pattern of a gold-foil. The beam current was about 0.025 μamp., and the exposure time was about 3 min. Fuji Process Plates were used to record the diffraction patterns and developed by the FD-131 developer at 20°C.

Three photographic plates were mounted in the camera at one time, fixed on a disk which was held nearly perpendicular to the main beam. Each plate was set at the exposure position one by one, by rotating the disk from outside. Photographic plates in the unit are, therefore, not exactly but only nearly perpendicular to the beam, so that the value of $L\lambda$ obtained by measuring the diameter of the gold-foil pattern recorded along the edge of the plate may differ from that of the diffraction pattern recorded on the center of the plate. The correction factor for $L\lambda$ was obtained by taking the photographs of gold-foil patterns both on the edge and on the center of the plate. The measurement was repeated

four times, that is, for twelve (4×3) plates and two gold-foil patterns on each, the corrections of $L\lambda$ were found to be,

A $-0.3\pm0.03\%$
B $0.0\pm0.05\%$
C $0.0\pm0.03\%$

for the three positions, A, B and C, of the plate on the disk, with the standard deviations among the four measurements.

In order to get the exact value of the camera length for the photograph of the gas electron diffraction, the reference gold-foil should be put at the same place as the center of the gas distribution at the nozzle. It was confirmed by an examination with a microscope that there was no considerable deficiency in the geometrical design and in the screwing mechanism of the nozzle. There is, however, an anxiety pointed out by Murata[11], that the center of the gas distribution might deviate slightly backwards, because the nozzle aperture has an asymmetric form along the beam axis, i. e., it is widened at the front side by a cone-shape cut to avoid the shielding of the scattered beam by the edge. The effect was examined by taking diffraction photographs with the nozzle turned around by 180°. The result showed no significant deviation as compared with the results of the ordinary nozzle orientation. This is in contrast to the case of $SiCl_4$[11] for which a slight deviation was really observed. The difference might be caused by the different rates of flow of gas samples.

The photographs were traced with a Rigaku-Denki MP-3 microphotometer. The full scale of the transmittancy axis on the recording chart is 24 cm. As it is not wide enough to record minute feature of diffraction patterns, an expanding device was attached to the unit to facilitate expanded recordings along the transmittancy axis, in the scale five times as large as the ordinary one.

During the tracing, the plate was rotated around the center of the pattern to average out irregularities. The recorded photometer curve became narrower as the plate was rotated more rapidly. It was observed, however, that when the pen of the recorder showed no high-frequency vibration due to the irregularities as the result of a rapid rotation, a remarkable retardation of the recording took place, presumably because of the inertia of the recording system. Accordingly, the speed of rotation was kept rather slow, about 150~500 r. p. m., and varied during the scanning so as to maintain a high-frequency vibration of the pen in an appreciable amplitude. (The width is 0.5~1 mm.)

To avoid ambiguity caused by the calibration of density into intensity of scattered electrons, the exposure was kept in the range where the linearity held between density and intensity. The linearity was shown to be valid in the range of density less than 0.6, by an application of the pair method[12] to the diffraction patterns of a gold-foil. It was confirmed for FD-131 (diluted twice in volume and developed for 5 min. at 20°C) and for D72 (diluted twice in volume, developed for 3 min. at 20°C), but the linearity was found rather poor for D76.

The nozzle was covered with a liquid-air trap though not in contact with it. The temperature decrease of the nozzle was tested with a thermocouple inserted in place of the nozzle-head. Even after the trap was charged with liquid-air, no temperature decrease was observed unless the gas was led into the apparatus. By the same rate of gas flow as in the experiment, a decrease of 5°C was observed. The temperature decrease due to adiabatic expansion of the gas was estimated to be negligibly small. Therefore it seems reasonable to assume that the temperature of gas molecules is nearly equal to the room temperature.

The lattice constant of the gold-foil used in the present study was examined by two methods. By an X-ray diffractometer, Geigerflex, the lattice constant was determined to be $a_0=4.072\pm0.003$ Å, from four diffraction peaks, (400), (331), (420) and (422), obtained by Cu-$K\alpha$. On the other hand, the lattice constant was also confirmed by the comparison of electron diffraction rings of the foil with those of thallium chloride which was proved by H. Reather* to be suitable for the use as a standard substance of wavelength measurement. An evaporated film of TlCl was deposited on a thinned gold-foil and diffraction rings of gold and TlCl were recorded simultaneously on a photographic plate by 45 kv electron beam. By taking the value of the lattice constant of TlCl, 3.8424 Å, (or 3.8347 kX[13]), the lattice constant of the gold foil was determined to be $a_0=4.067\pm0.003$ Å.

A mean of this value and that obtained by the X-ray diffraction leads to the value $a_0=4.070\pm0.002$ Å. This is 0.2% smaller than the value for pure gold, 4.078 Å**, probably became copper was contained by an amount of ca. 0.55% by weight. Chemical analysis revealed that the amount of copper in the gold-foil used in the present study was 0.47% by weight.

Analysis.—The analysis of the intensity curves to obtain molecular intensity and radial distribution curve was carried out by the same procedure as that usually applied. Elastic scattering factors given by several authors are compared in Fig. 1, and the values on the full line, those by McWeeny[16] and Berghuis et al.[15] for C-atom, and those by Tomiie and Stam[17] for S-atom, were used in the present analysis. The phase factors due to the failure of the Born approximation were obtained from the table calculated by Ibers and Hoerni[19].

--- Ref. 19

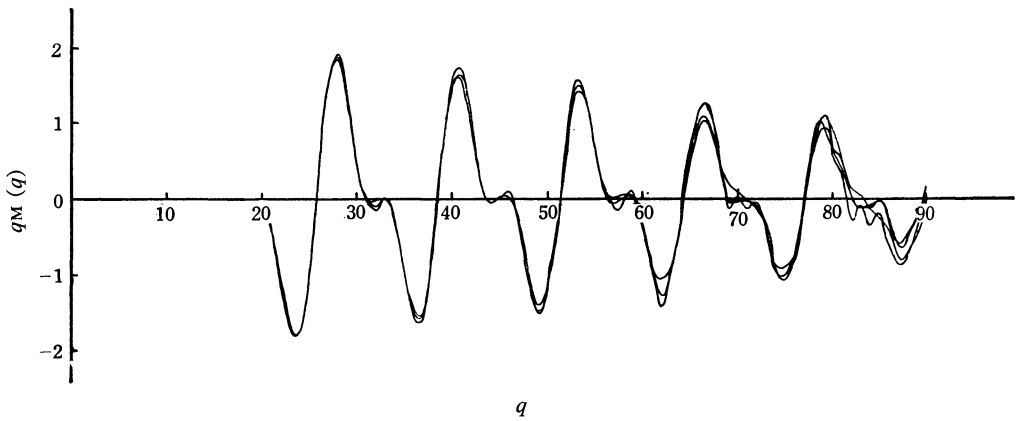

Fig. 2. The four observed molecular intensity curves of CS_2.

Inelastic scattering factors were calculated by the function given by Bewilogua[20].

Least-Squares Analysis[21,22].—Four molecular intensity curves were separately analyzed by the least-squares method described in the previous paper[21]. Each molecular intensity curve was fitted to the following equation,

$$F=i\{C_1(1/r_a'_1)\exp(-a_1s^2)\sin r_a'_1s + C_2(1/r_a'_2)\exp(-a_2s^2)\sin r_a'_2s\} \quad (9)$$

where the subscript 1 denotes the atom pair of C–S, and 2 the atom pair of S–S, and r_a' stands for $r_a-\kappa s^2$. Rigorously speaking, the r_a' in the denominators should be r_e, but it can be approximated by r_a', as adopted in the present treatment. The coefficients C's are,

$$C_1=\frac{4|F_c^e(s)||F_s^e(s)|\cos\Delta\eta}{\sum_i|F_i^e(s)|^2+\sum_i s_i(s)} \quad (10a)$$

$$C_2=\frac{2|F_i^e(s)|^2}{\sum_i|F_i^e(s)|^2+\sum_i S_i(s)} \quad (10b)$$

F_i^e and S_i denote the elastic and the inelastic scattering factors of atom i, respectively.

The distance-parameter r_a' to be determined by this method should be interpreted as the weighted mean of $r_a-\kappa s^2$, averaged over the observed range of s. It is not successful to attempt to determine κ as one of the parameters of the least-squares treatment, except for the case when κ is sufficiently large. The magnitude of κ theoretically expected is of the order of 10^{-6} A^3, and it was shown in the study of $GeCl_4$ that the magnitude of the standard deviation of κ was equal to or ten times as large as κ itself[21]. Therefore no significant value of κ can be expected to be determined.

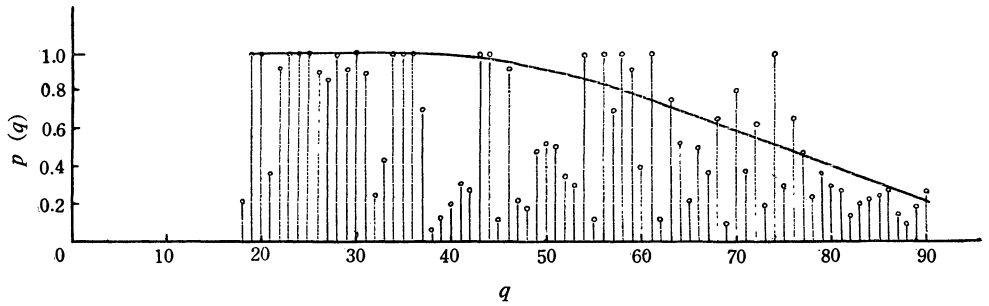

Fig. 3. The weight function: The weight determined as inversely proportional to σ^2 at each q. The smooth curve shows the general tendency.

Moreover the value of r_a may be strongly affected by the correlation between r_a and κ. Accordingly, it is more reasonable to determine the value of r_a from r_a' by the use of κ calculated from the cubic term of the distribution function.

In order to estimate the weight of the observed values of the molecular intensity at each q, $(q=(10/\pi)s)$, the standard errors of the molecular intensity were evaluated by the fluctuation among the four molecular intensity curves. The weight function was assumed to be inversely proportional to the square of the standard error at each q. It is graphically shown in Fig. 3. The results of the least squares calculation obtained by the discontinuous weight function coincided with those obtained by taking the smooth function which expresses the general tendency of the observed $1/\sigma^2$. By the second refinement of the least-squares, the convergence of the parameters was found to be sufficiently good. The results are tabulated in Table II. As the standard deviations σ are nearly the same for every intensity curve, the greatest ones are tabulated.

The standard deviations σ_{av} attached to the averaged values were evaluated from the fluctuation among the results of four intensity curves. It is expected that σ_{av} is nearly equal to $1/\sqrt{4}$ of the σ of the parameters determined for an individual curve, if sufficiently large number of plates are analyzed, or it may be somewhat greater because of the possible systematic errors independently included in each plate. The expectation that σ_{av} is almost equal to $(1/\sqrt{4})\sigma$, is nearly realized, and it may accordingly be stated that the systematic error specific to each plate is not a predominant factor.

Table II. The results of the least squares treatment

Plate	Index	r_a'(C-S)	r_a'(S-S)	l(C-S)	l(S-S)
I	0.97	1.5564	3.1085	0.0347	0.0481
II	1.00	1.5590	3.1136	0.0368	0.0484
III	1.01	1.5572	3.1121	0.0419	0.0515
IV	1.02	1.5587	3.1133	0.0368	0.0509
σ	0.02	0.0011	0.0016	0.0020	0.0022
Average	1.00	1.5578	3.1119	0.0376	0.0497
σ_{av}	0.01	0.0006	0.0012	0.0015	0.0008

Corrections.—As was stated in the preceding section, the distance r_a' is related to the r_a as,

$$r_a' \cong \langle r_a - \kappa s^2 \rangle_s = r_a - \kappa \langle s^2 \rangle_s \qquad (11)$$

where κ is related to the cubic coefficient β_3 of the distribution function as[21],

$$\kappa = l^6 \cdot \beta_3 \qquad (12)$$

and

$$\langle s^2 \rangle_s = \sum_s p(s)s^2 / \sum_s p(s) \qquad (13)$$

Thus κ for C–S was estimated to be 1.0×10^{-6} Å^3, and similarly 0.6×10^{-6} Å^3 for S–S. The weighted mean of s^2 was roughly estimated to be 250 Å^{-2}, and therefore $\kappa\langle s^2\rangle$ is 0.3×10^{-3} Å for C–S and 0.2×10^{-3} Å for S–S, respectively*. Accordingly, we have,

r_a(C–S): 1.5581 Å

and r_a(S–S): 3.1121 Å

The average interatomic distances r_g are easily obtained from r_a by the relation[21],

$$r_g = r_a + \frac{l^2}{r_e} \qquad (14)$$

With values of l^2/r_e, 0.0011 Å for C–S, and 0.0005 Å for S–S, the final results were obtained as follows,

r_g(C–S): 1.5592 Å

and r_g(S–S): 3.1126 Å

The root mean square amplitudes were corrected for the finite sample size around the

* Rigorously speaking,

$$\frac{\sum_s p(s)s^4\exp(-2as^2)\cos^2 r_a s}{\sum_s p(s)s^2\exp(-2as^2)\cos^2 r_a s}$$

should be taken in place of $\langle s^2\rangle_s$, if the correlation is assumed to be considerable only between r_a and κ. This expression was estimated to be nearly 300 Å^{-2}. Therefore the approximation by $\langle s^2\rangle_s$ is practically acceptable.

nozzle, by −0.0012Å for C–S and −0.0049Å for S–S, respectively. These corrections were calculated from the distribution of the gas molecule, which was estimated by the discrepancy of the observed background intensity from the theoretical one in the region of q larger than 70[23]. Thus the corrected values of l's are,

l(C–S) : 0.0364Å

and l(S–S) : 0.0448Å

Estimation of Reliabilities.—The reliabilities of the results of the present work are indicated by *the 99 per cent confidence intervals*, where both random and systematic errors were taken into consideration. The greater of the σ_{av} and $(1/\sqrt{4})\sigma$ of each parameter was regarded as the standard deviation originating from the random error, and 2.5 times that amount was considered to specify the 99 per cent confidence interval in the sense that the probability of finding the result of any observation outside this interval would be less than 1%[24].

The sources and the amounts of several systematic errors for both interatomic distances and root mean square amplitudes were thoroughly examined by Kuchitsu[23]. Although most of his estimates remain valid in the present work, there are required slight modifications due to some differences in experimental and analytical procedures. The systematic errors not negligible were estimated as follows corresponding to the 99 per cent confidence intervals, although there was no statistical evidence available to show that they were really so.

i) For atomic distances.

The drift of the wavelength of the primary electron beam ; 0.05%. (The accelerating voltage was regulated constant within 0.1%.)

Uncertainty of the lattice constant of the gold-foil ; 0.05%.

Errors associated with the corrections for the inclination of plates ; 0.075%. (From the standard deviations σ_A, σ_B and σ_C of the correction factors for the three plate-positions A, B and C, the standard deviation σ_P due to this correction was estimated for the average value obtained from four plates by

$$\sigma_P=\frac{1}{4}[\sigma_A{}^2+(2\sigma_B)^2+\sigma_C{}^2]^{1/2}$$

because these four consisted of one photographed at A, two at B and one at C. The 2.5 times σ_P was found to be 0.075%.)

Thus the total amounts to 0.10%, because these systematic errors are independent of each other.

ii) For root mean square amplitudes.

Errors associated with the correction for the distribution of gas molecules ; 1% for C–S, 4% for S–S. (They were tentatively taken as 50% of the correction.)

Uncertainty of the values of η in the correction for the Born approximation ; 2% for C–S.

Errors due to the arbitrary choice of the weight function[11] ; 2%.

Thus the total amounts 3% for C–S and 5% for S–S, respectively.

The confidence intervals were estimated from the square root of the sum of $(2.5\sigma)^2$ and (systematic error)^2, as summarized in Table III, and the final results of the present work are listed in Table IV, in comparison with the values calculated from the spectroscopic data.

TABLE III. ESTIMATION OF THE 99 PER CENT CONFIDENCE INTERVALS

	σ (random)	System. error	2.5σ (random)	Confidence interval
i	0.01		0.025	0.029
r_g(C–S)	0.0006	0.0016	0.0015	0.0022
r_g(S–S)	0.0012	0.0031	0.0030	0.0044
l(C–S)	0.0015	0.0012	0.0038	0.0040
l(S–S)	0.0011	0.0025	0.0028	0.0038

TABLE IV. INTERATOMIC DISTANCES, ROOT-MEAN-SQUARE AMPLITUDES AND SHRINKAGE OF CS_2 AT 15°C, WITH THE 99 PER CENT CONFIDENCE INTERVALS

	E. D.	Spectr.
Index i	1.00 ±0.03	
r_g(C–S)	1.5592±0.0022 Å	1.5580±0.0005 Å
r_g(S–S)	3.1126±0.0044 Å	3.1090±0.0010 Å
l(C–S)	0.0364±0.0040 Å	0.0391 Å
l(S–S)	0.0448±0.0038 Å	0.0412 Å
δ_g	0.0058±0.0042 Å	0.0070 Å

Conclusion

As shown in Table IV, the results obtained by electron diffraction are in good agreement with those obtained from spectroscopic data. Thus the consistency between electron diffraction and spectroscopy has been well confirmed : it gives a support to the present interpretation of the distance-parameters and the effect of molecular vibrations upon them. Moreover, it should be noted that the r_0 of the C–S distance obtained by spectroscopy is 1.5545± 0.0003Å, and r_e is 1.5532±0.0005Å[3], and they are significantly shorter than the r_g obtained by electron diffraction. This fact clearly shows that it is important to take accurately the physical meanings of various distance-parameters

into consideration, in comparing them with each other. The shrinkage effect has been confirmed as well.

The authors wish to express their gratitude to Professor Hidetoshi Takahashi and his co-workers, in the Department of Physics, for the use of PC-1 computer. Assignments of the ^{35}Cl Nuclear Quadrupole Resonance Spectra in Multichlorobenzenes by the Measurement of the Zeeman Effect

By Yonezo MORINO, Masaharu TOYAMA, Koichi ITOH* and Saburo KYONO

(Received June 26, 1962)

The ^{35}Cl nuclear quadrupole resonance lines in multichlorobenzenes were first assigned by Bray, Barnes, and Bersohn to the chlorine atoms in the molecules[1]. The assignment was, however, based on the assumption that the atoms having more numbers of ortho chlorine neighbors give rise to the resonances at the higher frequencies. This assumption is supported by the fact that the resonance frequencies in *ortho*-dichlorobenzene are higher than those in meta- and para-derivatives. The frequency shifts were interpreted in terms of the induction effect due to the substituted chlorine atoms, in particular, at the ortho neighbors. For the confirmation of this effect, it is necessary to make assignments without any assumption for the derivatives with more than two chlorine atoms. The Zeeman effect of a single crystal is suitable for this purpose, as was shown in the study of benzene hexachlorides[2].

A quadrupole resonance line splits into several Zeeman components in the presence of a static magnetic field. The splittings depend on the orientation of the applied field with respect to the principal axes of the electric field gradient at the nucleus. It has been realized that in the case of the chlorine atom in a C–Cl bond, the bond direction coincides to a high degree of approximation with that of the principal z axis, the direction giving the largest component of the electric field gradient ($|q_{xx}| \leqq |q_{yy}| \leqq |q_{zz}|$). The bond direction can, therefore, be determined by observing the angular depedence of the Zeeman effect in a single crystal. If the crystal structure is known, each resonance frequency can be assigned to one of chlorine atoms in a unit cell, by comparing the directions of the z axes with those of the C–Cl bonds, or the observed Zeeman patterns with those expected from the structure. Even when the crystal structure is unknown, the assignment is made to some extent, if the molecular structure can be inferred from other information: for instance, the resonance lines due to two chlorine atoms disposed mutually at the para positions of a benzene ring are expected to display the same Zeeman patterns at any orientation of the applied field.

The present study was originally made for the purpose to investigate the steric repulsion between the ortho chlorine neighbors in multichlorobenzenes. It was reported by Bastiansen and Hassel that the interatomic distances in hexachlorobenzene observed in electron diffraction were accounted for with assuming the distortion of the C–Cl bonds by 12° successively above and below the plane of the benzene ring[3]. The samples studied in the present work are 1, 3, 5-trichlorobenzene, 1, 2, 3, 4-tetrachlorobenzene and pentachlorobenzene. In 1, 3, 5-trichlorobenzene, the principal z axis of a chlorine atom was found to be inclined at $1.6 \pm 1.0°$ with respect to the plane determined by those of the other two[4]. Since the chlorine atoms in this

molecule are substituted at the meta positions with respect to one another, the observed distortion was attributed to the effect of crystal field. In the other compounds, it was difficult to prepare single crystals large enough for the Zeeman study. The crystals obtained were imperfect so that it was unsuccessful to perform a precise determination of the principal axes[5]. This article will present the assignments of the spectral lines for these multichlorobenzenes made in the course of the investigations.

Experimental

A self-quenched super-regenerative oscillator-detector of Dean's type[6] was used for detecting the absorption spectra. The signals detected were suitably amplified by a narrow-band amplifier, and then recorded through a phase-sensitive detector followed by a pen-recorder, for obtaining a high signal-to-noise ratio. The modulation frequency was 230 c/sec. and the quench frequency was nearly 50kc./sec. The magnet used for the Zeeman study was an air-cooled Helmholtz coil described previously[7], which supplied up to 150 gauss of magnetic field in the continuous operation. All the Zeeman experiments were carried out at room temperature.

The sample of pentachlorobenzene was synthesized from 1, 2, 4, 5-tetrachlorobenzene by Sandmeyer's method:

The product recrystallized from alcoholic solution was colorless needle-like crystals with m. p. 84~85°C. The infrared spectrum indicated little contamination in the reactants and the intermediate products. Further purification was performed by the repetition of zone-melting to remove impurities at the tracer level. The existence of such a small amount of impurities as those detected neither by the melting point nor by the infrared spectrum made the intensity of the nuclear quadrupole resonance spectrum considerably weak. For other samples, use was made of the commercial products after the purification by the similar procedures.

Single crystals were prepared by Bridgeman's method[7]. The apparatus for this purpose was an electric furnace, whose lower end was followed by a cooler place to give a large temperature gradient between the two regions. About 10 g. of each sample, put in an evacuated glass ampule with a capillary sealed at the bottom, was heated in the furnace and then slowly lowered down into the cooler place (at a rate of 2~4 mm./hr.). A single crystal gradually grew up from the bottom of the capillary, when it came to this cooler region.

Results

1, 3, 5-Trichlorobenzene

Zeeman study was made for three ^{35}Cl resonance lines designated ν_a, ν_b and ν_c in the order of increasing frequency, as was reported previously[4]. In Table I are listed the quadrupole coupling constants, the asymmetry parameters of the electric field gradients, and the direction cosines of the principal z axes with respect to the symmetry axes of the crystal, X, Y and Z. The relative orientation of the principal axes led to the unit-cell structure with the orthorhombic symmetry. The analysis of the crystal structure by X-ray diffraction was reported by Milledge and Pant[8]. As was expected from the Zeeman study, the crystal was found to be orthorhombic with the space group $P2_12_12_1$ and the unit-cell dimensions:

TABLE I. QUADRUPOLE COUPLING CONSTANTS, ASYMMETRY PARAMETERS, AND DIRECTION COSINES OF THE PRINCIPAL AXES AND OF THE CORRESPONDING C-Cl BONDS WITH RESPECT TO THE CRYSTAL AXES IN 1,3,5-TRICHLOROBENZENE

Lines (^{35}Cl)		eQq_{zz}[a] Mc./sec.	η	Direction cosines			$\Delta\alpha$[b]
				a(X)	b(Y)	c(Z)

$a=13.93$ Å, $b=13.19$ Å, $c=3.91$ Å
and $Z=4$ at 20°C

Fractional coordinates in the unit-cell were also given for each constitutive atom.

The assignment of spectral lines is made by comparing the directions of the principal z axes with those of the C–Cl bonds calculated from the fractional coordinates. The results are best explained by assigning the lines ν_a, ν_b and ν_c to the atoms Cl_3, Cl_1 and Cl_5, respectively, with the symmetry axes X, Y and Z corresponding to the crystal axes *b*, *a* and *c*, respectively. Here the suffixes 1, 3 and 5 represent the ring positions designated by Milledge and Pant. Agreement of the directions of the principal z axes with those of the C–Cl bonds is satisfactory as seen in Table I. Table II shows the mutual angles of the principal z axes of the three chlorine atoms in a molecule and those of the corresponding C–Cl bonds. It is to be noted that each principal z axis is appreciably inclined with respect to the plane determined by the remaining two, while the three C–Cl bonds are coplanar within the experimental uncertainty. In this respect the further improvement of the X-ray analysis would be desirable.

Table II. Angles between the principal z axes of the field gradients and those between the corresponding C–Cl bonds in 1, 3, 5-trichlorobenzene

	Cl_1Cl_3	Cl_3Cl_5	Cl_5Cl_1	$\Delta\theta$[a]
z Axes	120.3°	119.8°	119.9°	1.6°
C–Cl bonds	119.0°	121.3°	119.8°	0.0°

a) The angle which each z axis or each C–Cl bond makes with respect to the plane determined by the remaining two. The experimental uncertainty is estimated to be ±1.0° for the Zeeman study and ±2.5° for the X-ray study.

1, 2, 3, 4-Tetrachlorobenzene

Four resonance lines were observed by Bray et al.[1]: $\nu_a=36.297$, $\nu_b=36.333$, $\nu_c=36.635$ and $\nu_d=36.763$ Mc./sec. at 301°K; the two lower frequency lines ν_a and ν_b coalesce to one line at the liquid-nitrogen temperature. The crystal structure has not been reported. The present Zeeman study of a single crystal revealed that the lines ν_a and ν_b gave similar Zeeman patterns at any orientation of the applied magnetic field, while ν_c and ν_d gave the patterns different from any of others. The lines ν_a and ν_b are, therefore, assigned to the pair of chlorine atoms Cl_1 and Cl_4, which are substituted at the para positions with respect to each other, and the lines ν_c and ν_d to Cl_2 and Cl_3. The assignments completely agree with those expected by Bray et al.

Pentachlorobenzene

Five resonance lines were observed by Bray et al.[1] (Table III). with the single hydrogen atom bonded to the ring carbon 1, they also made a tentative assignment on the basis of Hammett sigma values and the frequency grouping: two lowest frequencies ν_a and ν_b to the chlorines 2, 6; a middle frequency ν_c to the chlorines 3, 5; two highest frequencies ν_d and ν_e to the chlorine 4. The assignment, however, seems to be very unusual. If it were true, the relative intensity of the five resonance lines should be 1 : 1 : 2 : 1/2 : 1/2 in the order of increasing frequency. In the actual spectrum, all the lines have nearly the same absorption intensities, and do not split further by the change in temperature.

The study with a single crystal indicates that the resonace lines are classified into three groups: (ν_a, ν_c), (ν_b, ν_e) and ν_d. The lines in each group show the Zeeman pratterns similar to each other but entirely different from those in other groups. The single line ν_d is then assigned to the chlorine 4 whose bond direction is different from those of other chlorines. The other line pair, (ν_a, ν_c) or (ν_b, ν_e), is assigned to either of the atom pairs, (Cl_2, Cl_5) or (Cl_3, Cl_6), the atoms in each pair being substituted at the para positions with respect to each other. Here eight possible choices of the assignments remain unexcluded, as shown in Table III. For

Table III. Assignments of the ^{35}Cl resonance frequencies in pentachlorobenzene with the single hydrogen atom bonded to carbon 1

Resonance frequency at 306°K, Mc./sec.	Assignment[a]								
	I	I′	II	II′	III	III′	IV	IV′	0
ν_a 36.782	2	6	2	6	5	3	5	3	2,6
ν_b 36.961	6	2	3	5	6	2	3	5	6,2
ν_c 37.112	5	3	5	3	2	6	2	6	3,5
ν_d 37.413	4	4	4	4	4	4	4	4	4
ν_e 37.512	3	5	6	2	3	5	6	2	4

a) The assignments I–IV′ are the possible ones revealed by the present Zeeman study, of which I and I′ are the most probable. The last column 0 presents the assignment by Bray et al.

discussing the effect of the ortho chlorine neighbors, it is necessary to assign each line to each atom in the molecule. It is, however, impossible by the present study alone. An assumption, which is not so serious as that made by Bray et al., will be employed here: the line of the highest frequency ν_e comes from one of the atoms Cl_3, Cl_4 and Cl_5, and that of the lowest one ν_a from the atom Cl_2 or Cl_6. The possible assignments are then reduced to the two cases denoted by I and I′ in Table III. These two cases are completely equivalent to each other, so long as the effect of the crystal field is ignored. The result is more reasonable than that by Bray et al., since one absorption line corresponds to one chlorine atom in a molecule. It is to be noted that the line ν_d is assigned without any assumption to the Cl_4, and the line of the highest frequency ν_e to the other one.

The angular dependence of the Zeeman patterns suggests that the orientation of the molecules in a unit-cell is symmetric with respect to three planes perpendicular to one another. It is then likely that the crystal system is orthorhombic with $Z=4$, the molecules in a unit-cell being all equivalent to one another.

Discussion

First of all it should be noted that the four resonance lines in 1, 2, 3, 4-tetrachlorobenzene have been grouped into two groups: two lower frequencies due to Cl_1 and Cl_4 and two higher ones due to Cl_2 and Cl_3; similarly the five resonance lines in pentachlorobenzene into two groups: two lower frequencies due to Cl_2 and Cl_6 and three higher ones due to Cl_3, Cl_4 and Cl_5. This fact indicates that the intramolecular effect is of predominant importance for the shifts of resonance frequencies. As for the origin of these shifts, considerations will be first made on the contribution from the charges at the neighboring atoms within the molecule. The direct field produced by the charges, which is, in general, very weak, distorts the electronic cloud around the nucleus in resonance to make a considerable contribution to the field gradient. Sternheimer has theoretically shown that the total increment of the field gradient may be approximated by the direct one Δq times a constant factor[9]:

$$\Delta q^{\text{total}} = \Delta q(1-R)$$

R is usually called Sternheimer factor which has been estimated for a Cl^- ion to be -57.7[10]. Actually, the differences in the six resonance frequencies of α-isomer of benzene hexachloride and those of γ-isomer have been satisfactorily interpreted in terms of this effect by assuming the multiplying factor $(1-R)\cong 50$[2]. Similar interpretation may be applied to the frequency differences in multichlorobenzenes.

Figure 1 presents a diagram of the observed frequencies in multichlorobenzenes plotted against the zz component of the direct field gradient calculated with disregarding the intermolecular effect. In the calculation, a formal charge placed at the center of each atom has been assumed from the information of the bond moment and of the coupling constant of the chlorine nucleus in monochlorobenzene: $-0.20e$ at the chlorine atom, $0.20e$ at the carbon atom bonded to the chlorine atom, $-0.05e$ at the carbon atom bonded to a hydrogen atom, and $0.05e$ at the hydrogen atom. The interatomic distances have been assumed to be $r(C-C)=1.39$ Å, $r(C-Cl)=1.71$ Å and $r(C-H)=1.08$ Å, and the bond angles to be all hexagonal. The plot has been made on the basis of the above assignments for 1, 2, 3, 4-tetrachlorobenzene and for pentachlorobenzene, and also of those by Bray et al.[1] for other derivatives. Roughly speaking, the frequencies are linearly correlated with Δq_{zz}, and the frequency shifts are accounted for by assuming the same multiplying factor as that in benzene hexachlorides. It will be recognized by a closer examination, however, that the frequencies are aligned on three nearly parallel lines, depending on the number of ortho chlorine neighbors. It is apparent from the trends of the three lines that the contributions from the ortho neighbors are relatively over-estimated by this direct interaction alone. Similar tendencies have been found by Bray et al. in the diagram of frequency versus Hammett sigma values[1].

Two origins should be mentioned in relation to such complicated feature of the resonance frequencies. One is the displacement of the center of the electronic charges from that of the nucleus. A simple estimate will then be attempted here for the position of the formal charge on each atom. If sp^2 hybrid orbitals are assumed for the carbon atoms, the average position of the positive charge in the C^+Cl^- bond or of the negative charge in the C^-H^+ bond is calculated by the following formula:

$$\langle z_C \rangle = (2\sqrt{2}/3)\int z_C \chi_{2s}\chi_{2pz}\mathrm{d}\tau$$

where z_C denotes the displacement of the charge measured from the center of the carbon nucleus towards that of either the chlorine or the hydrogen nucleus, and χ_{2s} and χ_{2pz} the 2s and $2p_z$ atomic orbitals of the carbon atom, respectively. The displacement of the charge

10) R. M. Sternheimer and H. M. Foley, ibid., **102**, 731 (1956).

centers also takes place in the chlorine atom of the covalent C–Cl bond: a negative charge at the center of the chlorine nucleus and a positive charge at the distance

$$\langle z_{Cl}\rangle = 2\sqrt{s(1-s)}\int z_{Cl}\chi_{3s}\chi_{3pz}d\tau$$

from the chlorine nucleus to the carbon one[11], s denoting the s character of the bonding orbital of the chlorine atom. By making use of Slater functions[12] for the atomic orbitals χ's, the equation gives $\langle z_C\rangle = 0.453$ Å and $\langle z_{Cl}\rangle = 0.376$ Å, where the s character is assumed to be 0.15 for the chlorine atom according to the estimate by Townes and Dailey[13]. This amount of displacement of the charges in the covalent C–Cl bond produces a bond moment of 1.80 D, slightly larger than the observed one[14]. The change in the field gradients thus estimated, however, rather enhances the trends of the three lines found in Fig. 1, contrary to the expectation.

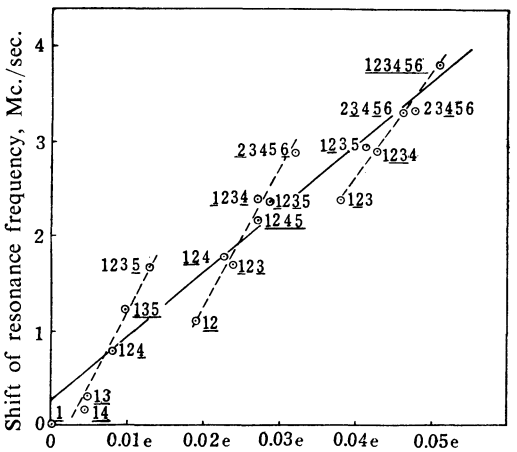

Fig. 1. Plot of the ^{35}Cl resonance frequency in multichlorobenzenes versus the direct field gradient arising from the distribution of the effective charges within the molecule. The diagram is drawn with reference to monochlorobenzene. The names of the compounds are represented by the ring positions of the substituted chlorine atoms and the assignment of each spectral line is indicated with underlines.

Another origin to be mentioned is the indirect induction effect propagated through the chemical bonds. Since chlorine is more electronegative than carbon, the bonding electrons in the C–Cl bond are, in general, attracted towards the chlorine atom. In multichloro-derivatives, however, the attractive forces of other chlorine atoms counteract that of the one in question through the bonds to produce a decrease in the ionic character of the C–Cl bond. The resonance frequency thus tends to increase with increasing number of chlorine atoms substituted in the molecule. The observed trend of the frequencies suggests that such indirect induction effect is considerably propagated to the meta and the para positions, too. An evidence for such effect was also observed in the nuclear magnetic resonance spectra[15]: the protons in monochlorobenzene, for example, give rise to a single resonance with a chemical shift $\tau = 2.756$, independent of the ring positions relative to the chlorine atom.

The contribution of the intermolecular effect has been estimated for the three resonance lines in 1, 3, 5-trichlorobenzene, on the basis of the crystal structure. Table IV shows the direct field gradients calculated by assuming an effective charge at the center of each atom in the crystal as mentioned above. The convergence has been substantially reached by the summation up to the first neighboring lattices along the a and b axes and to the third neighbors along the c axis. The sequence of the field gradients Δq_{zz} thus calculated does not agree with that of the observed coupling constants, except for Cl_3. The agreement does not seem to be attained by making any plausible

Table IV. Calculated field gradients at the chlorine nuclei directly arising from the charge distribution in crystalline 1, 3, 5-trichlorobenzene

Chlorine site	Δq_{zz}-$\Delta q_{zz}(Cl_3)$ in 10^{24} c. g. s. e. s. u.	Δq_{xx}-Δq_{yy} in 10^{24} c. g. s. e. s. u.
Cl_1	0.0130e	−0.0125e
Cl_3	0.0000e	−0.0124e
Cl_5	0.0086e	0.0015e

11) With regard to the charge distribution in the covalent C–Cl bond, one may be tempted to presume a model with the positive charge at the position of the chlorine nucleus and the negative charge at the distance $\langle z_{Cl}\rangle$ from the nucleus in the direction of the anti-bonding orbital. Such a model, however, has neglected the quadrupolar field due to the lone-pair electrons in the $3p_x$ and the $3p_y$ orbitals which is expected to have a significant influence, especially, on the ortho neighbors. In this respect, the model employed above seems more reasonable, because the positive charge has been treated as a defect of an electronic charge from the spherically symmetric configuration Cl^-.

14) Even if the s character is taken to be 0.10, the moment is only reduced to 1.52 D. The consideration suggests that the distribution of the effective charges in the C–Cl bond should be approximated by that in a purely covalent bond with an appropriate amount of s character.

TABLE V. DISTANCES BETWEEN THE CHLORINE ATOMS IN THE MOLECULE 1 AND THE ATOMS IN THE NEIGHBORING MOLECULES IN THE CRYSTAL OF 1, 3, 5-TRICHLOROBENZENE

Atoms in molecule 1[a]	Atoms in the neighboring molecules			
	Cl		H	
Cl_1	(5—6)[a)]	3.63 Å	(4—7)	2.96 Å
	(3—5)	3.75 Å		
	(1—8 and 8′)	3.91 Å		
	(5—7)	4.04 Å		
	(3—5′)	4.15 Å		
Cl_3	(1—5′)	3.75 Å	(2—5)	2.97 Å
	(3—8 and 8′)	3.91 Å	(6—3)	2.98 Å
	(5—3)	4.13 Å	(2—5′)	3.21 Å
	(1—5)	4.15 Å		
Cl_5	(1—2)	3.63 Å		
	(5—4)	3.65 Å		
	(5—4′)	3.65 Å		
	(5—8 and 8′)	3.91 Å		
	(1—3)	4.04 Å		
	(3—7)	4.13 Å		

a) The first figure in each parenthesis denotes the ring position of the neighboring atom and the second one the molecule in which the atom locates. The position of each molecule must be interpreted as follows: 1, (x,y,z); 2, $(1/2+x,1/2-y,1-z)$; 3, $(1-x,1/2+y,1/2-z)$; 4, $(3/2-x,1-y,1/2+z)$; 4′, $(3/2-x,1-y,-1/2+z)$; 5, $(1/2-x,1-y,-1/2+z)$; 5′, $(1/2-x,1-y,1/2+z)$; 6, $(-1/2+x,1/2-y,1-z)$; 7, $(1-x,-1/2+y,1/2-z)$; 8, $(x,y,z+1)$; 8′, $(x,y,z-1)$, where the fractional coordinates (x,y,z) correspond to those given by Milledge and Pant (see Table 1 in Ref. 8).

correction to the amounts nor to the position of the effective charges. The situation is quite the same for the asymmetry parameters. Since the three chlorine atoms are substituted symmetrically with respect to one another in the molecule, the intramolecular effect is not expected to produce any difference in the field gradients. The shifts of the resonance frequencies in this derivative should, therefore, be produced only through the intermolecular interactions. The disagreement may suggest either a limitation to the application of the Sternheimer theory to molecular crystals, or the existence of an extra process to propagate the effects between the neighboring molecules.

A process to be considered is the one through the distortions of the bonds. In 1, 3, 5-trichlorobenzene, however, there are no significant differences in the lengths of the C–Cl bonds, in particular, between C_1–Cl_1 and C_5–Cl_5; $r(C_1\text{–}Cl_1)=1.710$ Å, $r(C_3\text{–}Cl_3)=1.714$ Å and $r(C_5\text{–}Cl_5)=1709$ Å[8]. Considerable differences have been observed rather in the interatomic distances between the neighboring molecules. As easily seen from Table V, the number of the neighboring atoms increases in the order of positions 3, 1 and 5 for the chlorine neighbors, and in the inverse order for the hydrogen ones. Since the hydrogen atom, in general, has an electric property opposite to the chlorine atom, the observed order of the coupling constants is reasonably interpreted by considering an intermolecular induction effect independent of the directions, such as those analogous to the intramolecular one propagated through the chemical bonds. An evidence for such an extra process may also be seen in the fact that the resonance lines due to the chlorine atoms, which should be equivalent in the free molecule, are distributed over a wide range of frequency, compared with those in other chloro-derivatives of benzene.

Summary

Assignments of the ^{35}Cl nuclear quadrupole resonance spectra have been made for some multichlorobenzenes by the Zeeman studies of single crystals. Three resonance lines in 1, 3, 5-trichlorobenzene, have been assigned, in the order of increasing frequency, to Cl_3, Cl_1 and Cl_5 designated by Milledge and Pant in their X-ray study; two lower frequencies in 1, 2, 3, 4-tetrachlorobenzene to Cl_1 and Cl_4 and two higher ones to Cl_2 and Cl_3; and in pentachlorobenzene, the second highest frequency to the chlorine atom at the para position with respect to the single hydrogen atom. The shifts of the resonance frequencies have been accounted for in terms of the induction effect. It is likely that the ortho

effect is produced by the direct field arising from the charges on the neighboring atoms rather than the indirect one propagated through the chemical bonds. The interpretation of the three frequencies in 1, 3, 5-trichlorobenzene has also been attempted from the viewpoint of the intermolecular effect. It has been suggested that an induction effect independent of the directions takes place in this crystal among the neighboring molecules.

The authors would like to express their thanks to Professor Hidetoshi Takahashi, Department of Physics, the University of Tokyo, for the use of a parametron computer (PC-1) in the calculation of the crystal field in 1, 3, 5-trichlorobenzene. They are also indebted to the Ministry of Education for the expense in this experiment.

Decomposition of Peroxybenzoic Acid in Solution. I. Decomposition in Alcohols

By Katsumi TOKUMARU, Osamu SIMAMURA and Masaru FUKUYAMA

(Received June 25, 1962)

In the course of an investigation of epoxidation of olefins with peroxybenzoic acid in this Laboratory, peroxybenzoic acid was found to decompose appreciably in ethyl alcohol at room temperature[1]. Search of the literature revealed that, concerning the decomposition of organic peroxyacids in alcohols, only Swern and coworkers' report[2] was available, which stated that long chain aliphatic peroxyacids such as peroxylauric acid decomposed appreciably in methyl alcohol at 25°C. We then undertook investigation on the decomposition of peroxybenzoic acid in alcohols and some other solvents. During our research, Swern and coworkers[3] again reported the decomposition of peroxylauric acid in solvents and offered a non-radical, concerted mechanism.

After our work had been completed, Lefort, Paquot, and Sorba[4] proposed a radical mechanism for the decomposition of peroxylauric acid in petroleum ether. More recently Lefort, Sorba, and Rouillard[5] published a study on the decomposition of the same acid mainly in cyclohexane, and Heywood, Phillips, and Stansbury[6] presented a radical mechanism for the decomposition of peroxyacetic acid in hydrocarbon solutions. Further, Cohen and Edwards[7] made a kinetic study of decomposition of peroxybenzoic acid in benzene and 1-butanol in the presence of 2, 2-diphenyl-1-picrylhydrazyl and concluded a free radical cleavage of peroxybenzoic acid. We now report our results and propose a radical chain mechanism for the decomposition of peroxybenzoic acid in alcohols.

Experimental

Materials. — Peroxybenzoic acid was prepared from benzoyl peroxide according to Braun's procedure[8] as modified by Kolthoff et al.[9] Methylene chloride was used for extraction of peroxybenzoic acid. The extract was dried with sodium sulphate, the solvent removed by suction with a water-jet aspirator, and the remaining peroxybenzoic acid sublimed[10] several times under reduced pressure of a rotary vacuum pump to give samples of 96~99% purity (determined by iodometric titration[11]).

Methyl alcohol was refluxed with silver nitrate and potassium hydroxide and distilled. The distillate was refluxed with magnesium methoxide and distilled before use. Ethyl alcohol was similarly purified. Isopropyl alcohol was refluxed with 2,4-dinitrophenylhydrazine and distilled. The distillate

was refluxed with aluminium isopropoxide and distilled. *tert*-Butyl alcohol was purified by repeated partial freezing and finally distilled.

Nitrogen was freed from oxygen according to Fieser's directions[12]. Oxygen was passed through aqueous potassium permanganate acidified with sulphuric acid and dried with sulphuric acid.

Product Study.—A typical experiment for each alcohol is described.

Decomposition in Ethyl Alcohol. — Peroxybenzoic acid (9.7 g., 70 mmol.) was dissolved in 100 ml. of ethyl alcohol and left to stand in the dark for two months at room temperature until peroxybenzoic acid had been decomposed completely. The solvent was distilled, and fresh alcohol added to the residue and distilled to remove low boiling volatile matter. The combined distillates, on treatment with 2,4-dinitrophenylhydrazine, gave 2,4-dinitrophenylhydrazone of acetaldehyde (11 mmol.), m. p. (from ethyl alcohol) and mixed m. p. with an authentic sample, 168°C. Subsequent distillation of the residue under reduced pressure gave acetic acid, which was characterized as the *p*-toluidide (16 mmol.), m. p. and mixed m. p. with an authentic sample, 147°C. The residue from the distillation consisted of almost pure benzoic acid, (8.2 g., 67 mmol.), m. p. 121°C.

Decomposition in Isopropyl Alcohol.—Peroxybenzoic acid (10.3 g., 75 mmol.) was dissolved in 80 ml. of isopropyl alcohol and allowed to stand in the dark until peroxybenzoic acid had completely disappeared. The reaction mixture was distilled, and the distillate, treated with 2,4-dinitrophenylhydrazine, yielded 2,4-dinitrophenylhydrazone of acetone (42 mmol.), m. p. 126°C. The solid residue was benzoic acid (9.1 g., 75 mmol.), m. p. 121°C. When peroxybenzoic acid (0.5 g., 3.6 mmol.) was allowed to decompose in isopropyl alcohol (50 ml.) at 60°C for 4 hr., the reaction mixture, worked up as above, gave acetone, identified as 2,4-dinirophenylhydrazone (2.2 mmol.), m. p. 126°C, and benzoic acid (0.4 g., 3.3 mmol.).

Decomposition in Methyl Alcohol. — Peroxybenzoic acid (0.5 g., 3.6 mmol.) was decomposed in boiling methyl alcohol (50 ml.) for 10 hr., under a stream of nitrogen. Distillation of the reaction mixture gave formaldehyde, identified as 2,4-dinitrophenylhydrazone (1.5 mmol.), m. p. 165°C and benzoic acid (0.4 g., 3.3 mmol.).

Analysis of Gaseous Products.—A solution of peroxybenzoic acid was placed in a reaction flask. The flask was cooled with dry ice-ethyl alcohol, evacuated to remove oxygen, and let stand to warm up, and after introduction of nitrogen and chilling with the cooling mixture the system was evacuated again. After the cycle of these operations was repeated three times, the reaction was started by immersing the flask in a thermostat and gas was collected, as it evolved from the reaction mixture, on mercury in a gas burette connected to the reaction flask. When the reaction was complete, the gas was analyzed for carbon dioxide and oxygen by absorption in potassium hydroxide solution and in alkaline pyrogallol solution, respectively.

In one run, decomposition of 3.2 g. (23 mmol.) of peroxybenzoic acid in 40 ml. of isopropyl alcohol at 58°C gave 0.5 mmol. of carbon dioxide and 0.3 mmol. of oxygen.

Kinetic Measurements. — In a 200 ml. round bottomed flask equipped with a gas inlet tube and a spiral condenser carrying a calcium chloride tube at the top was placed a measured amount of an alcohol and the flask was immersed in a thermostat kept at a specified temperature. Nitrogen was passed through the alcohol to exclude oxygen, a weighed amount of peroxybenzoic acid was added, and after dissolution the concentration of the acid was determined iodometrically (normally about 0.1 mol./l.) The time of the sampling was taken as time zero for the kinetic run. Aliquots (2.00 ml.) were withdrawn at intervals and titrated in the usual manner.

At first kinetic results were not reproducible. We then found that the following treatment of reaction vessels gave tolerably reproducible results. A reaction vessel was first washed with concentrated methyl alcoholic solution of potassium hydroxide followed by water, and with concentrated nitric acid followed by water; then dilute solution of peroxybenzoic acid in the organic solvent in which the reaction was to be run was placed in the vessel and kept at 60°C for 3 hr.; and finally the vessel was thoroughly washed with this solvent and dried.

When the effect of light was investigated, a quartz flask or a glass flask coated with black enamel was used. In usual runs no special precaution was taken to exclude diffuse room light; control experiments established that this had no detectable effect upon the reaction rate.

Normally, at 30°C, an induction period ranging from ten to sixty minutes was observed, and sometimes it continued as long as three hours, but it

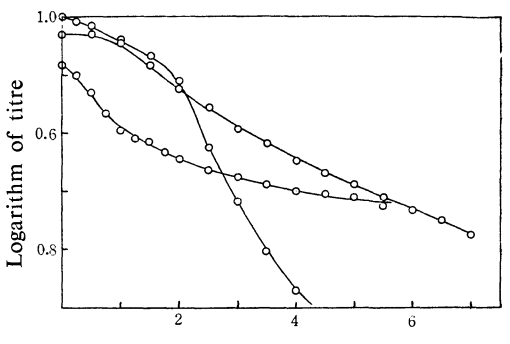

Fig. 1. Rate of decomposition of peroxybenzoic acid in isopropyl alcohol at 30°C (initial concentration of peroxybenzoic acid, ca. 0.1 mol./l.). A plot against time of logarithm of the concentration of peroxybenzoic acid expressed in titre (in ml.) of standard thiosulphate solution (0.04 N) consumed for an aliquot (2 ml.) of peroxybenzoic acid solution.

12) L. F. Fieser, "Experiments in Organic Chemistry", D. C. Heath and Co., Boston, 3rd Ed. (1955), p. 299.

seldom was observed above 50°C. The induction period was followed by a rapid and steady decomposition, but after a few hours the rate began to decrease gradually; some typical runs are shown in Fig. 1. The first-order rate constant for the decomposition was obtained from the slope of the straight part of the curve drawn through plots against time of logarithm of the concentration of peroxybenzoic acid. The mean values of the rate constants from several determinations with standard deviations are shown in Table II.

Results and Discussion

The results of the product study are shown in Table I.

The results of kinetic runs are summarized in Table II, which shows that the apparent decomposition rate in alcohols decreases in the order: isopropyl > ethyl > methyl alcohol. The rate in *tert*-butyl alcohol was nil at 30°C.

The rate of decomposition was larger in an atmosphere of nitrogen than in an atmosphere of oxygen or air for the respective alcohols. In the presence of *p*-benzoquinone in isopropyl alcohol in an atmospherere of nitrogen the decomposition took place much slower, as shown in Fig. 2. When solution of peroxybenzoic acid in isopropyl alcohol was irradiated with ultraviolet light in a quartz flask, a very rapid decomposition occurred. Acceleration by ultraviolet light was also observed in benzene solution, although it took place to a much smaller extent than in isopropyl alcohol.

These findings suggest that radicals are involved in the decomposition of peroxybenzoic acid in alcohols. It is quite natural and reasonable to assume homolytic rupture of the oxygen-oxygen bond of peroxybenzoic acid as a radical initiation process, giving a benzoyloxy and a hydroxyl radical:

$$C_6H_5C(=O)OOH \rightarrow C_6H_5C(=O)O\cdot + HO\cdot$$

The radicals thus formed attack a molecule of

solvent alcohol, abstracting a hydrogen atom α to the hydroxyl group and giving a 1-hydroxyalkyl radical, which will hereafter in this report be briefly called "solvent radical".

Since the apparent decomposition rates were different in various alcohols and the effects of oxygen and *p*-benzoquinone were observed, it is concluded that the induced decomposition of peroxybenzoic acid by solvent radicals must have occurred. If the induced decomposition had not occurred, the apparent decomposition rate of peroxybenzoic acid would have been larger in ethyl alcohol than in isopropyl alcohol, since acetaldehyde primarily formed in the former is more easily oxidized by peroxybenzoic acid than acetone formed in the latter as shown by a separate experiments.

These results suggest a mechanism comprising the following series of reactions.

$$PhCO_3H \rightarrow PhCO_2\cdot + HO\cdot \quad (1)$$

$$PhCO_2\cdot \rightarrow Ph\cdot + CO_2 \quad (1')$$

$$PhCO_2\cdot + RR'CHOH \rightarrow PhCO_2H + RR'\dot{C}OH \quad (2)$$

$$HO\cdot + RR'CHOH \rightarrow H_2O + RR'\dot{C}OH \quad (2')$$

$$PhCO_3H + RR'\dot{C}OH \rightarrow PhCO_2\cdot + RR'C(OH)_2 \quad (3)$$

$$PhCO_3H + RR'\dot{C}OH \rightarrow HO\cdot + PhCO_2CRR'OH \quad (3')$$

$$PhCO_2\cdot + RR'\dot{C}OH \rightarrow PhCO_2CRR'OH \quad (4)$$

$$HO\cdot + RR'\dot{C}OH \rightarrow RR'C(OH)_2 \quad (4')$$

$$PhCO_2CRR'OH \rightarrow PhCO_2H + RR'CO$$

$$RR'C(OH)_2 \rightarrow H_2O + RR'CO$$

Reaction 1' represents the well known decomposition of the benzoyloxy radical. It turned out, however, that this reaction did not take place to an appreciable extent in alcohols, since, the yield of benzoic acid was invariably nearly quantitative.

Reactions 2 and 2' are abstraction by radicals of a hydrogen atom from a molecule of alcohol; the former has already been proposed by Mashio and Kato[13] for the decomposition of benzoyl peroxide in alcohols, and the latter by Merz and Waters[14] for the reaction of the Fenton reagent with alcohols. They estimated the relative rate constants for reactions 2 and 2', which are shown in Table III. The relative rates decrease in the order: isopropyl > ethyl > methyl alcohol. This order can be interpreted as indicating that a larger rate constant corresponds to a larger resonance stabilization of the solvent radical formed.

Reactions 3 and 3' represent the induced decomposition of peroxybenzoic acid by solvent radicals. Although which of reactions 3 or 3' is the more important could not be determined, the results with hydrocarbons to be subsequently reported suggest that it probably is reaction 3 that took place predominantly. Similar reactions have been also proposed for the induced decomposition of benzoyl peroxide[13,15,16], acetyl peroxide[17], and persulphate[18] by 1-hydroxyalkyl radicals. It has been reported that the induced decomposition of benzoyl peroxide is readily caused by 1-hydroxyalkyl radicals or 1-alkoxyalkyl radicals among various radicals[15,16].

Mashio and Kato[13] has estimated the rate constant k_{3B} for the following reaction relative to the rate constant for reaction 4.

$$PhCO_2OCOPh + RR'\dot{C}OH \rightarrow PhCO_2CRR'OH + PhCO_2\cdot \quad (3B)$$

Since k_4's can be assumed to be nearly equal for various alcohols, the magnitude of k_{3B}/k_4 is regarded as a measure for k_{3B}. As seen from Table III, k_{3B}/k_4 is larger for isopropyl alcohol than for ethyl alcohol. It therefore

seems that k_{3B} is larger for the more electron-donating 1-hydroxyalkyl radical, since the electron-donating property decreases in the order: 1-hydroxy-1-methylethyl > 1-hydroxyethyl > hydroxymethyl radical.

Reactions 4 and 4' are written as termination reactions; the former has also been suggested for the decomposition of benzoyl peroxide[13].

Evidently, rapid decomposition of peroxybenzoic acid requires the presence of a hydrogen at the α-carbon atom in alcohol; indeed the decomposition was not noticeable in *tert*-butyl alcohol at room temperature. Table II indicates that the rate constant depends upon the nature of the α-hydrogen atom. Moreover, it is interesting to note that there seems to be a parallelism in the apparent decomposition rate between peroxybenzoic acid and benzoyl peroxide as shown by comparison of the values in Table II with those in Table III.

In the present mechanism, the induced decomposition of peroxybenzoic acid by solvent radicals is the major process which distinguishes solvents in the decomposition rate. This process is controlled, in the first place, by the stationary concentration of solvent radicals and, secondly, by their reactivity towards peroxybenzoic acid. The stationary concentration of solvent radicals would tend to increase, other things being equal, according as an α-hydrogen atom of the alcohol is abstracted more readily. The resulting 1-hydroxyalkyl radicals are resonance-stabilized in the order: 1-hydroxy-1-methylethyl > 1-hydroxyethyl > hydroxymethyl. The order of the efficiency with which they are formed from the corresponding alcohols therefore falls in the order: isopropyl > ethyl > methyl alcohol. The reactivity of solvent radicals towards peroxybenzoic acid can be assumed to be parallel to that towards benzoyl peroxide, that is, to be governed by their electron-donating property. Then for this property again the same order as above is valid, as mentioned earlier. Thus alcohols will favour the induced decomposition in the order: isopropyl > ethyl > methyl alcohol, in agreement with the findings in the rate study.

The evolution of oxygen observed in the case of the decomposition in isopropyl alcohol at 58°C might suggest participation of peroxybenzoate anions, since dissociation of peroxybenzoic acid as an acid would be favoured in a polar solvent like alcohols, and the peroxybenzoate anion has been shown to react with peroxybenzoic acid giving oxygen[19]. Oxygen is also formed from α-cumyl hydroperoxide both in aqeous alkaline solution and in cumyl alcohol[20].

Summary

Decomposition of peroxybenzoic acid was studied in methyl, ethyl, isopropyl and *tert*-butyl alcohol. The primary and the secondary alcohols were oxidized to the corresponding carbonyl compounds, which were sometimes further oxidized. The apparent decomposition rate of peroxybenzoic acid in alcohols decreased in the order: isopropyl alcohol > ethyl alcohol > methyl alcohol ≫ *tert*-butyl alcohol. For these decompositions a radical mechanism, which involves the homolytic rupture of peroxybenzoic acid and its induced decomposition by 1-hydroxyalkyl radicals derived from the respective alcohols, was proposed. A possible participation of peroxybenzoate anions in these decompositions was suggested.

Decomposition of Peroxybenzoic Acid in Solution. II. Decomposion in Hydrocarbons

By Katsumi TOKUMARU and Osamu SIMAMURA

(Received June 25, 1962)

In the preceding paper[1] we have proposed a radical chain mechanism for the decomposition of peroxybenzoic acid in alcohols. In alcohols, peroxybenzoic acid decomposes not only through the initial homolytic rupture, but also through the induced decomposition due to attack by 1-hydroxyalkyl radicals formed from alcohol molecules. In the decomposition of benzoyl peroxide, it is well known that the induced decomposition of the oxygen-oxygen bond by radicals derived from solvent molecules does not occur as readily in hydrocarbons as in alcohols or ethers[2]. Therefore, by analogy with benzoyl peroxide, we first imagined that peroxybenzoic acid might decompose in hydrocarbons with a lesser extent of the induced decomposition by solvent radicals and the apparent decomposition rate might approximate the initial decomposition rate of peroxybenzoic acid. The present report deals with the decomposition of peroxybenzoic acid in several hydrocarbons; it has turned out that peroxybenzoic acid also is extensively attacked by solvent radicals in hydrocarbons.

Experimental

Materials. — Peroxybenzoic acid was prepared according to the procedure previously described[1]. *n*-Heptane was shaken with sulphuric acid, followed by aqueous sodium hydroxide solution, dried with calcium chloride and then with sodium metal, and distilled. Cyclohexane was treated with nitric acid-sulphuric acid mixture, washed with aqueous sodium hydroxide, dried with calcium chloride and then with sodium metal, and distilled. Cyclohexanol was washed with aqueous sodium hydroxide, dried with anhydrous sodium sulphate, purified with repeated freezing, and distilled. Cumene was shaken with sulphuric acid, washed with aqueous sodium hydroxide solution, dried with calcium chloride and then with sodium metal, and distilled under an atmosphere of nitrogen. Benzene and toluene were shaken with sulphuric acid, washed with sodium hydroxide solution, dried with calcium chloride and then with sodium metal and distilled; benzene was further purified with repeated freezing and finally distilled over sodium. Carbon tetrachloride was refluxed with a mixture of aqueous potassium hydroxide solution and ethyl alcohol, washed with sulphuric acid and then with aqueous sodium hydroxide, dried with calcium chloride, and distilled.

Kinetic Measurements.—In some kinetic runs the procedure was essentially the same as described in Part I[1]. In most runs aliquots (2 ml.) of a solution of peroxybenzoic acid (0.1 mol./l.) were placed in glass tubes, the tubes were evacuated thoroughly with alternate chilling and warming to remove oxygen, sealed, and immersed in a thermostat kept at 79°C, and the contents were analyzed iodometrically for peroxybenzoic acid at intervals. Typical runs are shown in Fig. 1. Under the present experimental conditions no induction period

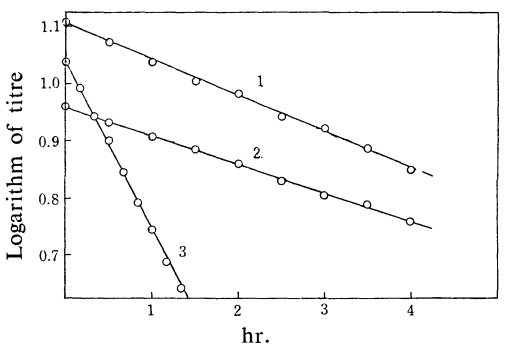

Fig. 1. Rate of decomposition of peroxybenzoic acid in hydrocarbons at 79°C (initial concentration of peroxybenzoic acid, ca. 0.1 mol./l.). 2) P. D. Bartlett and K. Nozaki, *J. Am. Chem. Soc.*, 68, 1686 (1946); K. Nozaki and P. D. Bartlett, ibid., 69, 2299 (1947).

was observed. The first-order rate constant for the decomposition was obtained from the slope of the straight part of the curve drawn through plots against time of logarithm of the concentration of peroxybenzoic acid. The mean values of the rate constants from several determinations together with deviation are shown in Table I.

Product Study.—The decomposition was carried out in a three-necked round bottomed flask equipped with an inlet tube for nitrogen and a spiral condenser, to the top of which were connected, in order of mention, a trap cooled with dry-ice ethyl alcohol, a calcium chloride tube and a potash bulb. A weighed amount of peroxybenzoic acid dissolved in a solvent was placed in the flask which was immersed in a thermostat and allowed to decompose in a slow stream of nitrogen. The decomposition was carried out until no more absorption of carbon dioxide in the potash bulb was observed. Then the reaction mixture was worked up.

For analysis of gaseous products, a solution of small amount of peroxybenzoic acid was decomposed in a closed system, and the gas evolved was analysed for carbon dioxide and oxygen by absorption method as described in Part I[1].

Decomposition in n-Heptane. — Peroxybenzoic acid (9.3 g., 67 mmol.) dissolved in 250 ml. of *n*-heptane (the initial concentration of peroxybenzoic acid, 0.27 mol./l.) was heated at 90°C for 19 hr. in a stream of nitrogen. After the decomposition was over, benzoic acid, deposited in the reaction flask, was filtered off; a little water was observed to have been formed. The filtrate was extracted repeatedly with 5% aqueous sodium hydrogen carbonate. The organic layer was dried with anhydrous sodium sulphate and distilled giving heptane and two fractions, b. p. 45~50°C at 22 mmHg (0.75 g.) and b. p. ca. 68°C at 22 mmHg (0.8 g.), respectively. The former was shown to be a mixture of heptanols and heptanones and the latter a mixture of C_7 esters, such as amyl acetate, by comparison of the infrared spectra with those of authentic specimens. The aqueous extract, on acidification with hydrochloric acid and extraction with ether, afforded benzoic acid, m. p. 121°C. The total amount of this acid formed in this reaction was 5.7 g. (46.8 mmol.).

The amount of the carbon dioxide formed as estimated from the increment of the weight of the potash bulb was 0.70 g. (15.8 mmol.). No formation of oxygen was observed in the reaction in heptane.

Decomposition in Cyclohexane. — Solution of peroxybenzoic acid (10.5 g., 76 mmol.) in 250 ml. of cyclohexane (the initial concentration, 0.3 mol./l.), was heated at 79°C for 27 hr. in a stream of nitrogen. The reaction mixture was cooled and the deposited benzoic acid filtered off; a small amount of water was noticeable in the reaction mixture. The filtrate was shaken with water; the aqueous layer, on treatment with 2,4-dinitrophenylhydrazine, gave 2,4-dinitrophenylhydrazone of cyclohexanone (trace), m. p. 158°C. It was then extracted with aqueous sodium hydrogen carbonate to isolate benzoic acid. Most of the solvent was removed from the organic layer on a water bath, and in the recovered cyclohexane benzene was detected by its characteristic ultraviolet absorption at 220~270 mμ. The residue was subjected to fractionation giving cyclohexanol (0.4 g., 4 mmol.), b. p. 68°C at 20 mmHg, which was identified by infrared spectrum measurement, and characterized as 3,5-dinitrobenzoate, m. p. 112°C, and a small amount of a colourless viscous liquid, b. p. 110°C at 2 mmHg, which was identified with ε-caprolactone by converting it into ε-hydroxycaproic acid hydrazide (Found: C, 49.31; H, 9.79. Calcd. for $C_6H_{14}N_2O_2$: C, 49.30; H, 9.63%.), m. p. 114~115°C[3,4] The residue in the distilling flask was shown to be a mixture of ε-caprolactone and its polymers by treatment with hydrazine hydrate on a boiling water-bath, ε-hydroxycaproic acid hydrazide being obtained. The total amount of ε-caprolactone in the monomeric and the polymeric form was about 2 g. (18 mmol.). In this experiment benzoic acid recovered amounted to 6.1 g. (50 mmol.) and carbon dioxide, 0.83 g. (19 mmol.). A separate small scale experiment in a closed system showed that no oxygen was formed in cyclohexane.

Decomposition in Cyclohexanol. — Peroxybenzoic acid, (1.4 g., 10 mmol.) was decomposed in cyclohexanol (40 ml.) (the initial concentration, 0.26 mol./l.) at 79°C for 1 hr. under an atmosphere of nitrogen. The reaction mixture was diluted with benzene, and extracted with water. The aqueos extract, on treatment with 2,4-dinitrophenylhydrazine, gave 2,4-dinitrophenylhydrazone of cyclohexanone (0.2 mmol.), m. p. 158°C. The organic layer was worked up as described for the experiment with cyclohexane to give benzoic acid (1.15 g., 9.5 mmol.) and ε-caprolactone (0.07 g., 0.6 mmol.), identified as ε-hydroxycaproic acid hydrazide, m. p. 114~115°C.

Decomposition in Cumene. — Peroxybenzoic acid (12.5 g., 90 mmol.) was decomposed in cumene (200 ml., the initial concentration of the acid, 0.35 mol./l.) at 79°C for 8 hr. in a stream of nitrogen. A small amount of water was detected. The reaction mixture was extracted with aqueous sodium hydrogen carbonate, and the aqueous extract gave benzoic acid (9.9 g., 81 mmol.) on acidification. The organic layer was extracted with aqueous sodium hydroxide; the aqueous extract was reddish brown, but gave no identifiable substance. Distillation of the organic layer afforded cumene and cumyl alcohol (2.1 g., 15 mmol.), b. p. 63~66°C at 2 mmHg, a considerable amount of tarry matter (ca. 0.5 g.) remaining. Cumyl alcohol was purified by repeated sublimations under reduced pressure, m. p. 33°C, (Found: C, 79.33; H, 9.05. Calcd. for $C_9H_{12}O$: C, 79.37; H, 8.88%). The infrared spectrum of the crude cumyl alcohol showed the presence of acetophenone in trace amount.

In separate experiments, oxygen was not detected by the absorption method.

Decomposition in Toluene. — Peroxybenzoic acid (3.5 g., 25 mmol.) was decomposed in toluene (70 ml., the initial concentration of the acid, 0.36 mol./l.) at 79°C for 5 hr. in a stream of nitrogen.

3) F. J. Van Natta, J. W. Hill and W. H. Carothers, *J. Am. Chem. Soc.*, **56**, 455 (1934).
4) S. L. Friess, ibid., **71**, 2571 (1949).

Extraction of the reaction mixture with aqueous sodium hydrogen carbonate gave benzoic acid (3.5 g., 28 mmol.). Distillation of the organic layer gave toluene, benzyl alcohol, (0.2 g., 2 mmol.), b. p. 105°C at 20 mmHg, and a tarry residue (ca. 0.2 g.). The benzyl alcohol was characterized by formation of 3,5-dinitrobenzoate, m. p. 112°C, and by the infrared spectrum.

Decomposition in Carbon Tetrachloride in the Presence of Iodine.—Peroxybenzoic acid (5.1 g., 37 mmol.) and iodine (10.0 g., 39.5 mmol.) were dissolved in carbon tetrachloride (130 ml.) and the solution was heated under reflux for 90 hr.

The precipitate formed was filtered off and washed with carbon tetrachloride and ethyl alcohol until the colour due to iodine was no longer observed in washings. After being dried, it was identified as diiodine pentoxide (0.4 g., ca. 1 mmol.), by determining both neutralization and oxidation equivalent (Found: neutralization equivalent, 165.9; oxidation equivalent, 27.4. Calcd. for I_2O_5: neutralization equivalent, 166.9; oxidation equivalent, 27.82.). The filtrate was shaken with aqueous sodium thiosulphate solution to remove iodine, and extracted with aqueous sodium hydrogen carbonate. The aqueous extract gave benzoic acid (4.0 g., 33 mmol.). Carbon tetrachloride was distilled, and the residue from the distillation was subjected to steam distillation. From the distillate hexachloroethane (0.1 g.). was obtained and identified by infrared spectrum measurement, m. p. (from ethyl alcohol) and mixed m. p. with an authentic sample measured in a sealed tube, 185°C.

Results and Discussion

The results of kinetic runs are shown in Table I. The apparent decomposition rates varied from solvent to solvent, and the tendency of variation was not always similar to that in the case of benzoyl peroxide[2].

When a small amount of *p*-benzoquinone was added in *n*-heptane solution of peroxybenzoic acid, apparent decomposition was retarded: at 90°C, with an initial concentration of 0.1 mol./l. of peroxybenzoic acid, k_1 was 1.5×10^{-4} sec^{-1} in the absence of *p*-benzoquinone, and 1.4×10^{-5} sec^{-1} in its presence ($0.6\sim1.2\times10^{-2}$ mol./l.).

The results of the product study are summarized in Table II. The sum of the amounts in which benzoic acid and carbon dioxide were formed is a measure of the amount of the CO_3H group decomposed, and it amounted nearly to 100% of the peroxybenzoic acid used, as seen from this table. However, in the reaction in toluene, the yield of benzoic acid exceeds the amount of the peroxybenzoic acid decomposed. This suggests that part of the benzoic acid probably was formed by the oxidation of toluene by way of benzyl alcohol and benzaldehyde.

As in the case of the reaction in alcohols, the radical nature of the decomposition of peroxybenzoic acid in hydrocarbons is indisputable. On the basis of the results of the kinetic and the product analysis, the following series of reactions are postulated which include the induced decomposition (reaction 3) of peroxybenzoic acid by solvent radicals (S·) generated from molecules of a hydrocarbon (SH) by abstraction of a hydrogen atom (reactions 2, 2′ and 2″).

$$PHCO_3H \rightarrow PhCO_2\cdot + HO\cdot \quad (1)$$

$$PhCO_2\cdot \rightarrow Ph\cdot + CO_2 \quad (1')$$

$$PhCO_2\cdot + SH \rightarrow PhCO_2H + S\cdot \quad (2)$$

$$HO\cdot + SH \rightarrow H_2O + S\cdot \quad (2')$$

$$Ph\cdot + SH \rightarrow PhH + S\cdot \quad (2'')$$

$$PhCO_3H + S\cdot \rightarrow SOH + PhCO_2\cdot \quad (3)$$

$$S\cdot + HO\cdot \rightarrow SOH \quad (4)$$

$$S\cdot + PhCO_2\cdot \rightarrow PhCO_2S \quad (4')$$

$$S\cdot + S\cdot \rightarrow S_2 \quad (4'')$$

$$SOH \rightarrow \text{Oxidation products} \quad (5)$$

TABLE II. YIELDS (IN %) OF PRODUCTS FORMED IN DECOMPOSITION OF PEROXYBENZOIC ACID IN SOME SOLVENTS

Solvent	Temp. °C	Products from solvents	Benzoic acid	Carbon dioxide	Remark
n-Heptane	90	Heptanols Heptanones C_7-Ester	69	23	Water detected
Cyclohexane	79	Cyclohexanol 5 Cyclohexanone trace ε-Caprolactone 24	66	25	Water and benzene detected
Cyclohexanol	79	Cyclohexanone 2 ε-Caprolactone 6	95		
Cumene	79	α,α-Dimethyl-benzyl alcohol 17 Distillation residue	89	8	Water detected
Toluene	79	Benzyl alcohol 8 Benzoic acid Distillation residue	112		

Reaction 1′ is the well known decomposition of the benzoyloxy radical. This reaction takes place to an appreciable extent in hydrocarbons, competing with the abstraction of a hydrogen atom from a solvent molecule (reaction 2). Reaction 1′ is less important in cumene and toluene, which possess a hydrogen atom at the α position available for ready abstraction by the benzoyloxy radical; in fact in these hydrocarbons the yield of benzoic acid was nearly quantitative. In contrast to this, the yield of benzoic acid was lower and that of carbon dioxide higher in cyclohexane and heptane; in these hydrocarbons hydrogen atoms are not as liable to attack as the α-hydrogen atom in cumene and toluene. However, in cumene and toluene, such possibility could not be excluded that the oxidation of the aromatic nucleus by peroxybenzoic acid through an ionic or molecular mechanism may occur in which peroxybenzoic acid transfers an atom of oxygen to the aromatic nucleus, being itself converted into benzoic acid.

Radicals generated in the reacting solution abstract a hydrogen atom from a molecule of hydrocarbon (SH) giving rise to a hydrocarbon radical (S·), which appears to react mainly by decomposing peroxybenzoic acid. The products from this induced decomposition are the corresponding alcohol (SOH) and the benzoyloxy radical. The alcohol may further be oxidized (reaction 5) to the corresponding carbonyl compound, carboxylic acid and ester according to the scheme set forth in Part I[1]. In fact, the successive oxidation of cyclohexanol, the primary product from cyclohexane, to cyclohexanone and ε-caprolactone was borne out as described in the experimental part.

The retarding action of *p*-benzoquinone indicates that the induced decomposition is important. In the absence of the induced decomposition water ought to have been formed in much larger amount than actually found, and the benzoate ester ($PhCO_2S$) derived from the hydrocarbon would have been formed at least in an amount comparable to that of the alcohol (SOH, reactions 4 and 4′), because hydroxyl radicals would abstract a hydrogen atom from a molecule of hydrocarbon more efficiently than benzoyloxy radicals do, the stationary concentration of the latter radical thus becoming larger than that of the former. In fact no such benzoate ester was detected at all.

A similar mechanism has recently been postulated by other workers for the induced decomposition of other organic peroxyacids. Thus, Lefort, Paquot and Sorba[5] have found that decomposition of peroxylauric acid in petroleum ether gave *n*-undecanol in a good yield and postulated attack of a *n*-undecyl radical generated by decomposition of a lauroyloxy radical on a molecule of peroxylauric acid giving a molecule of *n*-undecanol and a lauroyloxy radical.

$$C_{11}H_{23}\cdot + C_{11}H_{23}CO_3H \rightarrow C_{11}H_{23}OH + C_{11}H_{23}CO_2\cdot$$

More recently Heywood, Phillips and Stansbury[6] have studied decomposition of peroxyacetic acid in several solvents and proposed a radical chain mechanism very similar to ours. There, the induced decomposition of peroxyacetic acid by solvent radicals (S·) has also been postulated, giving rise to a molecule of the corresponding alcohol and a acetyloxy radical, which decomposes to a methyl radical and carbon dioxide.

$$S\cdot + CH_3CO_3H \rightarrow SOH + CH_3CO_2\cdot$$

Further, Lefort, Sorba and Rouillard[7] have presented a similar mechanism for the formation of cyclohexanol in the decomposition of peroxylauric acid in cyclohexane.

It is noteworthy that peroxybenzoic acid is, as shown in the present work, readily attacked at the peroxidic oxygen atom even by the radical derived from hydrocarbon, which is usually regarded as rather inefficient in causing the induced decomposition of benzoyl peroxide[2] compared with radicals from ethers and alcohols. In this respect, peroxybenzoic acid is rather similar to hydroperoxides than to benzoyl peroxide. Thus, Fordham and Williams[8] have postulated the attack of α,α-dimethylbenzyl radicals on α,α-dimethylbenzyl hydroperoxide to produce a molecule of α,α-dimethylbenzyl alcohol and an α,α-dimethylbenzyloxy radical in decomposition of α,α-dimethylbenzyl hydroperoxide in cumene. Further, Bateman and Hughes[9] have assumed induced decomposition of cyclohexenyl hydroperoxide by cyclohexenyl radicals giving cyclohexenol and a cyclohexenoxy radical, whereas in the decomposition of benzoyl peroxide in cyclohexane[10,11], such a mode of decomposition does not seem to be significant.

As regards the initiation process in alcohols and hydrocarbons, we have proposed a unimolecular homolysis of the oxygen to oxygen

bond of peroxybenzoic acid producing a benzoyloxy radical and a hydroxyl radical (reaction 1). Since peroxybenzoic acid was found to be consumed very slowly in carbon tetrachloride, it was at first thought that the rate of the homolysis of the oxygen to oxygen bond had been measured, the induced decomposition by the solvent radical, the trichloromethyl radical, having hardly occurred. If peroxybenzoic acid decompose by a similar reaction scheme in carbon tetrachloride to that in alcohols and hydrocarbons, the benzoyloxy radical initially formed will predominatly decompose to carbon dioxide and a phenyl radical, which abstracts a chlorine atom from carbon tetrachloride and yields chlorobenzene and a trichloromethyl radical; the latter will then give hexachloroethane by dimerization or phosgene and hydrogen chloride through its attack on peroxybenzoic acid or its combination with a hydroxyl radical. In fact the decomposition products in carbon tetrachloride contained only negligible traces of chlorobenzene, hexachloroethane and phosgene[12]. These findings therefore lead us to conclude that the decomposition rate of peroxybenzoic acid observed in carbon tetrachloride cannot be regarded as representing the unimolecular homolysis of peroxybenzoic acid.

If peroxybenzoic acid decomposed in benzene predominantly by the radical path, biphenyl and phenol ought to have been obtained. Actually, among the decomposition products in benzene neither biphenyl nor phenol was detected and only a trace of carbon dioxide was formed[12], indicating that the benzoyloxy radical was produced only to a limited extent. It is true that any phenol produced might have been further oxidized by peroxybenzoic acid[13], but the above findings strongly suggest that most part of peroxybenzoic acid reacted by oxidizing the benzene nucleus through a mechanism other than homolytic.

In order to get a deeper insight into the initiation process, decomposition of peroxybenzoic acid in carbon tetrachloride in the presence of iodine was carried out with the intention of catching benzoyloxy radicals according to Hammond's[14] procedure used in his study on benzoyl peroxide. However, in the present experiment, unexpectedly, diiodine pentoxide was obtained, showing that peroxybenzoic acid oxidized iodine to diiodine pentoxide, and that this method was not suitable for the study of the unimolecular homolytic decomposition of peroxybenzoic acid.

14) G. S. Hammond and L. M. Soffer, *J. Am. Chem. Soc.*, **72**, 4711 (1950).

Meanwhile in this laboratory peroxybenzoic acid has been shown to initiate a radical polymerization of methyl methacrylate[15] and kinetic measurements of this polymerization have yielded the following expression for the rate constant of the initiation, the initiation efficiency of unity being assumed:

$$2.11\times10^{4}\exp(-15400/\boldsymbol{RT})\,\mathrm{sec}^{-1}$$

This rate constant may well be taken to be that for the initial homolytic rupture of the oxygen to oxygen bond in peroxybenzoic acid. Indeed it is extremely striking that both activation energy and frequency factor are so small as compared with the corresponding values for other organic peroxides. Thus, for example, with benzoyl peroxide, the following value[16] is reported.

$$3.0\times10^{13}\exp(-29600/\boldsymbol{RT})\,\mathrm{sec}^{-1}$$

Recently Cohen and Edwards[17] have carried out kinetic study of decomposition of peroxybenzoic acid in the presence of 2, 2-diphenyl-1-picrylhydrazyl in benzene or in *n*-butyl alcohol at 60 and 65°C, estimated the rate constant of the free-radical cleavage of peroxybenzoic acid and calculated the activation energy to be about 30 kcal./mol. in benzene. Since there is no cogent reason for assuming that there exists no interaction at all between peroxybenzoic acid and 2, 2-diphenyl-1-picrylhydrazyl other than the latter is consumed by being attacked by radicals generated from the former, the values obtained by the American workers must be accepted with some reservation. However, if this value of 30 kcal./mol. is correct for the activation energy for the unimolecular homolysis of the oxygen to oxygen bond in peroxybenzoic acid, the abnormal value obtained by us suggests that the initiation might occur rather through some interaction between peroxybenzoic acid and the vinyl monomer. Moreover, the alternative possibility can not be overlooked that peroxybenzoic acid may decompose by interaction with a molecule of solvent (H–S), producing radicals, as represented in reaction (1a).

$$PhCO_3H + H\text{–}S \rightarrow PhCO_2\cdot + H_2O + S\cdot \qquad (1a)$$

A similar mode of decomposition has been

suggested by Semenov[18] and Thomas and Harle[19] for the decomposition of hydroperoxides.

Summary

Decomposition of peroxybenzoic acid was studied in *n*-heptane, cyclohexane, cumene, and toluene. The hydrocarbons were oxidized to the corresponding alcohols, which were often oxidized further. For these decompositions, a radical chain mechanism was proposed, which involves the homolytic rupture of the oxygen-oxygen bond of peroxybenzoic acid as the initiation process and an induced decomposition of this bond by solvent radicals derived from hydrocarbon molecules.

Spectrophotometric Determination of Cerium(III) and Some Rare Earths with Xylenol Orange[1]

By Kôichi TONOSAKI and Makoto OTOMO

(Received July 9, 1962)

Since xylenol orange was first prepared by Körbl and others[2,3] as a metallochromic indicator of the "complexone type", this reagent has widely been used by a number of investigators in complexometric titrations. However, only a few workers have applied this reagent to the spectrophotometric determination of metals; zirconium, hafnium, iron and bismuth have been thus determined by Cheng[4-8], and recently bitsmuth, by Onishi and Ishiwatari[9].

The present investigation was undertaken to evaluate the applicability of xylenol orange as a spectrophotometric reagent for various metal cations. From the results, a new spectrophotometric method for the determination of cerium(III) and of some rare earth elements is proposed. As in the other cases[4-9], the molar ratio of the complex between rare earth and this reagent is also 1 : 1.

Experimental

Reagents. — Stock solutions of rare earths were prepared separately by dissolving the purified oxide of rare earths (cerium, lanthanum, neodymium and yttrium) and were standardized by EDTA titration, using xylenol orange as an indicator[10].

About 10^{-3} M of a xylenol orange solution was prepared by dissolving Dotite XO reagent Dôjindô) & Co., Kumamoto) in distilled water. According to Ueno[11], this solution is stable for several months.

Apparatus. — All the absorption measurements were made with a Hitachi model EPU-2A spectrophotometer, using 1 cm. cells.

Procedure. — From 0 to 100 μg. of one of the rare earths was transferred to a 25 ml. volumetric flask. (When cerium was to be determined, 1 ml. of a 0.5% solution of ascorbic acid was added to prevent oxidation of the cerium(III) to the ceric state). Three to four milliliters of a xylenol orange solution and 15 ml. of an acetate buffer solution (pH 6.1±0.1, 0.17 M as acetate ions) were then added. After the mixture had been diluted to the mark with water and mixed, the absorbance of the solution was measured at the wavelengths mentioned below.

Results and Discussion

Absorption Spectra. — Figure 1 shows the absorption spectra of xylenol orange and its cerium complex at a pH of 6.1. Both the reagent and the complex have an absorption maximum at about 580 mμ. When a correction for the reagent blank is applied, an absorption peak of the complex is found at 575 mμ. A wavelength of 575 mμ, therefore, has been

adopted in the determination of cerium. (At this wavelength the absorbance of the complex is about six times that of the reagent itself.) The complexes of lanthanum, neodymium and yttrium exhibit similar tendencies with the cerium complex. Their absorption peaks are found at 576 mμ for lanthanum and 578 mμ for neodymium and yttrium.

Effect of pH.—The effect of pH on the color development of the cerium complex was studied with solutions varying in pH value from 4 to

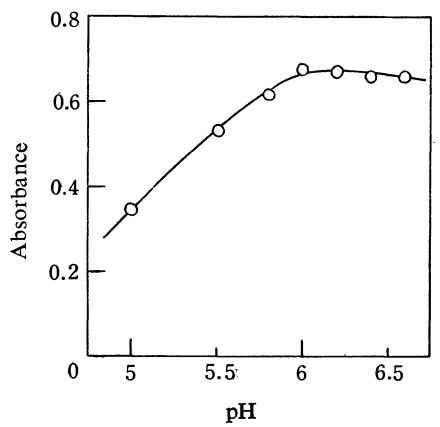

Fig. 2. Effect of pH on color development.
Ce: 65 μg.

7. Figure 2 shows that the maximum color development is obtained over the pH range of 6.0 to 6.5. Similar results are also obtained for the other rare earths.

Effect of Xylenol Orange. — A practically constant absorbance is obtained by adding 3

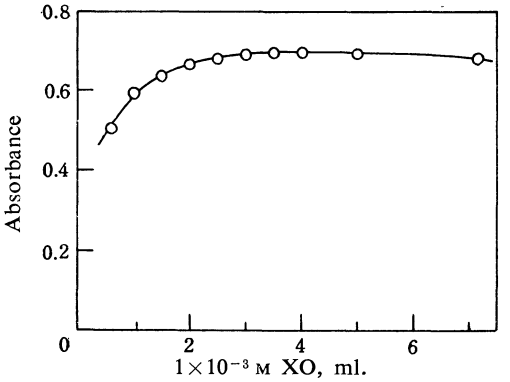

Fig. 3. Effect of addition of xylenol orange.
Ce: 65 μg.

to 5 ml. of a 1×10^{-3} M xylenol orange solution (Fig. 3). Too large amounts of the dye tend to decrease the absorbance. It seems, therefore, that in the presence of a large excess of the dye, these rare earths may form a complex other than a 1 : 1 complex.

Stability of Complex.—Figure 4 shows the stability of the colored complex of cerium. Since the color is stable at room temperature for at least 2 hr., no particular attention need be paid to the time of standing.

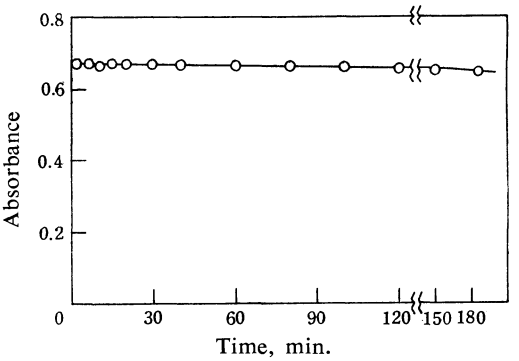

Fig. 4. Stability of Ce-XO complex.
Ce: 65 μg.

Calibration Curve. — As is shown in Fig. 5, a linear relationship exists between the absorbance and the rare earth concentration over the range investigated. The optimum concentration range was then determined by Ringbom's procedure[12] and was found to lie between 20 to 100 μg. cerium. At the measured wavelength, the molar extinction coefficients of the xylenol orange complexes of lanthanum, cerium, neodymium and yttrium are 32000, 31000, 38000 and 48000 respectively. From these high sensitivities, xylenol orange is found to be the

12) A. Ringdom, *Z. anal. Chem.*, **115**, 332 (1938/9).

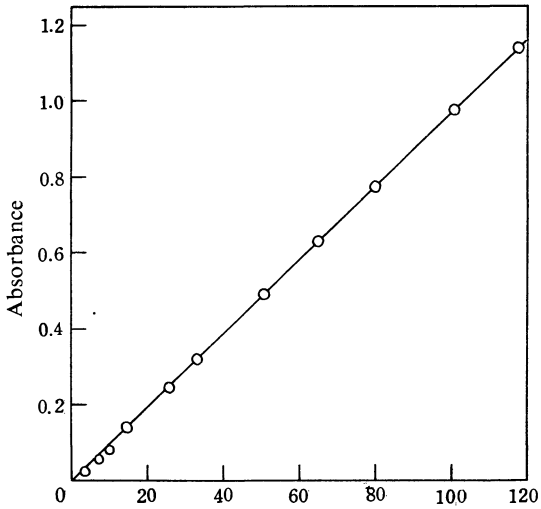

Fig. 5. Calibration curve.

most convenient reagent for spectrophotometric determination of trace amounts of rare earths.

Formation Constant.—The mole ratio method and the continuous variation method (Job's method) were applied to establish the mole ratio of the complex in solution. From Figs. 6 and 7, it is evident that cerium forms a 1 : 1 complex with xylenol orange. The formation constant was calculated from the curves shown in Fig. 7, based on the method described by Cheng[5] and et al. It was found to be 3×10^5 at 25°C. Because of its low formation constant, it is easily understood why xylenol orange has been successfully used as an indicator in the EDTA titration of rare earths. Lanthanum, neodymium and yttrium also form a 1 : 1 complex with xylenol orange; their formation constants are calculated to be 7×10^5, 1×10^6 and 3×10^5 respectively. These values are slightly lower than those of zirconium-[5], hafnium-[6] and bismuth-xylenol orange[8,9] complexes.

TABLE I. EFFECT OF ANIONS ON CERIUM DETERMINATION

Anion		Cerium	
Present	Added μ mol.	Taken μg.	Found μg.
Chloride	250	98.1	98.1
	500		97.0
Fluoride	1	92.5	88.4
	5		74.1
	10		46.5
Nitrate	250	98.1	96.6
	500		99.5
Sulfate	250		100.3
	500		99.7
Thiosulfate	8	97.4	96.3
	20		93.3
Oxalate	2.5		88.3
	5		82.2
Phosphate	1	98.1	43.5
	2.5		15.5
	5		5.2
Tartrate	5	97.4	91.9
Citrate	0.2		91.7
	1		88.0
NTA	0.5	92.5	92.3
	1.5		81.9
EDTA	0.01		73.0
	0.05		2.0
	0.2		1.0

Effect of Anions.—Table I indicates the effect of anions on the determination of cerium. Chloride, nitrate, sulfate and thiosulfate do not interfere. Large amounts of fluoride, oxalate, tartrate and citrate decrease the absorbance considerably. NTA (nitrilotriacetic

acid) and EDTA, which may form a stable complex with the rare earths, seriously inhibit the color development of the complex.

Summary

A method has been described for the spectrophotometric determination of 20 to 100 μg. of a rare earth element using xylenol orange. The complexes of cerium(III), lanthanum(III), neodymium(III) and yttrium(III) with xylenol orange have an absorption maximum at 575 to 578 mμ vs. the reagent blank. Each of them is a 1 : 1 complex and has a formation constant of approximately 10^5 under the conditions studied. Anions such as NTA and EDTA inhibit the color development of the complexes.

The authors wish to express their thanks to Miss Iku Mizuki for her assistance in the measurements.

*The Stereoregularity of Poly-p-bromostyrene Polymerized by the Ziegler Catalyst**

By Koichi HATADA, Takao NIKI, Shun-ichi NOZAKURA and Shunsuke MURAHASHI

(Received January 10, 1962)

Since stereospecific polymerization was discovered by Natta[1] in 1955, many crystalline structures have been investigated and determined on a number of stereoregular polymers. Crystallizability is not always dependent on the stereoregularity of the polymer, and some of the polymers polymerized by the so-called stereospecific catalysts appear to be amorphous, it not being certain whether they are stereoregular or not[2]. For instance, poly-*p*-methylstyrene and poly-*m*-methylstyrene polymerized by the Ziegler catalyst were originally considered to be amorphous. Later it was found, from the infrared spectroscopic study of these polymers, that the polymers might have stereoregularity[3]. This led to the preparation of effectively oriented samples of the polymers and to the determination of their crystalline structures[4].

Natta and his coworkers found that poly-*p*-chlorostyrene polymerized by the stereospecific catalyst was amorphous, but the polymer was proved to be stereoregular by its giving of crystalline polyvinylcyclohexane as the result of catalytic hydrogenation. They ascribed the noncrystallinity of the original poly-*p*-chlorostyrene to the steric effect of the chlorine atom in crystalline orientation[5]. Poly-*p*-chlorostyrene polymerized by the Ziegler catalyst was found by Nagai to contain a small fraction of the polymer insoluble in cold xylene; this fraction gave an infrared spectrum different from that of the amorphous fraction soluble in cold xylene[6].

For the present work, the authors investigated the stereoregularity of poly-*p*-bromostyrene polymerized by the Ziegler catalyst and were led to the conclusion that the polymer was, in this particular case, not stereoregular, this conclusion being different from Natta's for poly-*p*-chlorostyrene.

Experimental

Materials. — *p-Bromostyrene.* — *p*-Bromoacetophenone was prepared from bromobenzene and acetic anhydride using aluminum chloride as the catalyst[7] and was purified by recrystallization from methanol-water to make it free from the ortho isomer. The pure *p*-bromoacetophenone (m. p., 49.5~50.0°C) was reduced to the corresponding carbinol by the Meerwein-Pondorf method[8]. The carbinol was

dehydrated to *p*-bromostyrene by potassium bisulfate[9]. The product was dried over calcium chloride and distilled under reduced pressure. A fraction boiling at 69~92°C/13 mmHg was collected and fractionally crystallized several times, about one-sixth of the product being discarded each time as an unfrozen liquid. Pure *p*-bromostyrene was obtained by redistillation of the residue of the final crystallization; b. p., 90.5~91.0°C/13 mmHg, n_D^{20} 1.588.

n-Heptane.—Commercial *n*-heptane was purified in the usual manner[10], dried, and stored over metallic sodium.

Aluminum Triethyl.—Aluminum triethyl was supplied by the Mitsui Chem. Ind. Co. and was used without further purification.

Titanium Tetrachloride.—The titanium tetrachloride was a product of the Osaka Titanium Co.

Titanium Trichloride.—A commercial product (Stauffer Chem. Co.) was washed three times with *n*-heptane before use.

n-Butyllithium.—A benzene solution was prepared according to Ziegler's method[11] from *n*-butylchloride and lithium.

Lithium Aluminum Hydride.—The lithium aluminum hydride was a commercial product of Metal Hydride Inc.

Tetrahydrofuran.—Tetrahydrofuran was refluxed and distilled over sodium before use.

Polymerization.—The polymerization was carried out in a method similar to that described in a previous paper[12]. After the vessel had been flushed by dry nitrogen, 20 ml. of *n*-heptane and 0.38 g. of titanium tetrachloride were introduced into the vessel. While the solution was boiled gently, 0.225 g. of triethylaluminum was added slowly; the heating was continued for a further 5 min. and then the solution was cooled. After the precipitation of a solid complex, the supernatant liquid was removed by a syringe under dry nitrogen. The solid was washed three times with 20 ml. of *n*-heptane, and 20 ml of *n*-heptane and 0.225 g. of triethylaluminum were added. The monomer was then added to the catalyst suspension and polymerized.

When the catalyst was prepared from titanium trichloride and aluminum triethyl, 0.20 g. of triethylaluminum was added to 1.5 g. of titanium trichloride suspended in 20 ml. of *n*-heptane at room temperature.

The polymer produced was precipitated by pouring the reaction mixture into methanol containing hydrochloric acid, washed thoroughly with methanol, and dried in vacuo at 130~150°C.

Reaction of Poly-*p*-bromostyrene with *n*-Butyllithium.—A three-necked flask was fitted with a reflux condenser, a separatory funnel and a glass tube equipped with a rubber cap. After the flask had been flushed by dry nitrogen, 20 ml. of benzene and a benzene solution of *n*-butyllithium (600 mg.) were introduced with a hypodermic syringe through the rubber cap. While the solution was stirred with a magnetic stirrer and maintained at the reaction temperature, a solution of about 200 mg. of poly-*p*-bromostyrene in 20 ml. of benzene was slowly added, drop by drop, over a period of from 2 to 4 hr. After the addition was complete, stirring was continued for 2 hr.; then the mixture was poured into a large amount of methanol to hydrolyze the lithiated polymer. After the mixture had stood overnight, the polymer was collected, washed with methanol, and dried in vacuo at 70~100°C.

Reduction of Poly-*p*-bromostyrene by Lithium Aluminum Hydride.—A mixture of about 300 mg. of poly-*p*-bromostyrene and 0.5 g. of finely powdered lithium aluminum hydride in 300 ml. of tetrahydrofuran was brought to solution by warming; the solution was then refluxed under dry nitrogen for about 6 days. In the course of the reaction, two portions of 5 ml. of benzene each were added to the reaction mixture in order to solubilize the partially debrominated polymer and to complete the reaction. The reaction mixture was poured into 300 ml. of methanol containing a small amount of hydrochloric acid to decompose the excess lithium aluminum hydride and to precipitate the polymer. The product was then purified by reprecipitation from toluene and methanol.

Measurements of Softening Points and Viscosities.—Softening points were measured using a hot-stage microscope. Intrinsic viscosities are measured in benzene at 20°C using a Ubelhode-type dilution viscometer.

Results and Discussion

It was reported in a previous paper that bromobenzene does not impair the isotactic polymerization of styrene with the Ziegler catalyst[12]. This fact prompted us to prepare the isotactic polymer of *p*-bromostyrene with the catalyst.

p-Bromostyrene was easily polymerized with the catalyst to give a high polymer in good yields. The results of the polymerization are summarized in Table I. Polymerization with the addition of thiophene to the catalyst system gave almost the same results. The addition of thiophene was tried since a good stereospecificity was observed with it in the case of the polymerization of styrene[12]. The polymer showed an amorphous X-ray pattern and the same infrared spectrum as that of the polymer obtained by radical polymerization.

In order to determine the stereoregularity of poly-*p*-bromostyrene, the polymer was reduced to polystyrene and the properties of the resulting polystyrene were compared with those of isotactic and amorphous polystyrenes. Debromination was attempted by two methods, i. e., halogen-metal conversion with butyllithium, followed by hydrolysis (Braun's method)[13] and reduction with lithium aluminum hydride.

d) Elemental analysis was given for the soluble part of the reduction product.

Braun demonstrated the recovery of an isotactic polystyrene from an amorphous iodinated product which had been derived by the iodination of isotactic polystyrene[14]. He attempted to apply the method to the determination of the stereoregularity of poly-*p*-chlorostyrene and poly-*p*-bromostyrene, resulting in incomplete dehalogenation.

In the present work it was also ascertained that the lithiation of poly-*p*-bromostyrene with butyllithium could not be accomplished satisfactorily. The results of the reduction of poly-*p*-bromostyrene by butyllithium are shown in Table II. When the reaction temperature of 20°C was employed, only a half of the bromine of the polymer was removed. The three successive reactions at the same temperature gave a product still 3.49% bromine. When the reaction was carried out at the boiling point of benzene, the debromination was almost complete, but 90% of the product was insoluble and infusible. This must be a cross-linked polymer produced by the Wurtz-Fittig coupling between the lithiated phenyl group and the bromophenyl group in the polymer chains.

Prolonged reduction of poly-*p*-bromostyrene using lithium aluminum hydride as a reducing agent gave a polystyrene containing a negligible amount of bromine, although in this reaction a large excess of lithium aluminum hydride was required[15]. The results of the reduction are shown in Table III. Elemental analysis of the product showed a good agreement with that of polystyrene except that a trace of ash could not be removed from the samples.

14) D. Braun, *J. Polymer Sci.*, **40**, 578 (1959).

15) The necessity of a large excess of lithium aluminum hydride may be explained, according to Bailey[15], as follows: as the reduction proceeds, the produced aluminum tribromide reacts with lithium aluminum hydride and gives aluminum hydride. Both aluminum hydride and lithium aluminum hydride may cause a ring cleavage of the solvent tetrahydrofuran and may thus be consumed. (W. J. Bailey and F. Marktscheffel, *J. Org. Chem.*, **25**, 1797 (1960).)

From PPBS	$LiAlH_4$	150~5	+	+	Amorph.
From PPBS[g]	$LiAlH_4$	146~9	+	+	Amorph.

a) Amorphous part of the polymer obtained by the polymerization of styrene with the Ziegler catalyst
b) Isotactic part of the polymer obtained by the polymerization of styrene with the Ziegler catalyst
c) PPBS: Poly-*p*-bromostyrene
d) +: Soluble, −: Insoluble
e) EMK: Ethyl methyl ketone
f) The soluble fraction of the polymer reduced at 80°C
g) A specimen obtained by the reduction of a thermally polymerized poly-*p*-bromostyrene

The polystyrene obtained by the reduction was not separated into fractions having different properties with usual organic solvents. The polymer was heat-treated at 100°C for eight hours, but no crystallization by the treatment was detected. It was soluble in ethyl methyl ketone, gave only amorphous X-ray patterns, and showed a softening point of 150~155°C and the same infrared spectrum as that of atactic polystyrene. In the infrared spectrum, no absorption band was observed at 1364 and 1297 cm^{-1}, which bands had been proved to be characteristic of isotactic polystyrene[16]. A comparison of the reduced polymers with isotactic and atactic polystyrenes is shown in Table IV.

It may well be assumed that no change in the steric configuration of the main chain occurred through the reduction process. On the basis of these results, we may draw the conclusion that poly-*p*-bromostyrene polymerized with the Ziegler catalyst is substantially atactic in the steric configuration of the main chain. A major factor in the lack of stereoregularity may be the disturbance of stereoregulation at the site of polymerization by the bulky bromine atom attached to the para position of the benzene ring.

It is also to be noted that the polystyrene obtained by the reduction of poly-*p*-bromostyrene has a softening temperature of about 150°C. This is about 40°C higher than that of the conventional atactic polystyrene (ca. 110°C). Similarly, a polystyrene which was obtained by the lithium aluminum hydride reduction of thermally polymerized poly-*p*-bromostyrene showed the unusual softening point of 146~149°C. Therefore, there may be a possibility that the elevation of the softening point is due to a minor change in the chemical structure during the reduction, to, that is, for instance, a small extent of cross-linking.

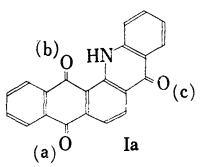
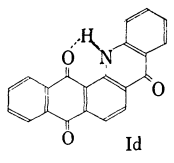
Spectroscopic Studies of 1, 2- and 3, 4-Phthaloylacridones



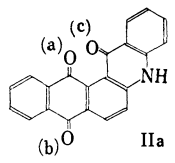
By Takayuki HAYASHI and Jun-ichirō MAEHARA*

(Received May 19, 1962)



Phthaloylacridones are compounds of a high melting point and a low solubility in organic solvents. 1, 2-Phthaloylacridone, quite similar to acridone in its orange color, is a relatively strong acid which dissolves in alcoholic potassium hydroxide with a violet color[1]. The *N*-methyl derivative is non-acidic, more soluble in organic solvents, and lower-melting than 1, 2-phthaloylacridone, the properties of which are probably the result of intermolecular hydrogen bonding[2]. 3, 4-Phthaloylacridone is similar to 1-phenylaminoanthraquinone in its red-violet color, which indicates that its molecule exists in a true acridone, not a hydroxyacridone, structure, and it is lower-melting and more soluble in organic solvents than isomeric 1, 2-phthaloylacridone, suggesting the occurrence of intramolecular hydrogen bonding[2]. As the infrared, visible and ultraviolet regions of the spectra might yield more interesting information, it seemed desirable to investigate the spectra of these phthaloylacridones and their related compounds.

Results and Discussion



Visible Absorption Spectra.—For 1-benzoylaminoanthraquinone, a IIIb structure has been largely discredited[3]; also, its molecule could not exist in structure IIIc, since amide-type resonance is not possible for IIIc[4]. 1-Benzoylaminoanthraquinone is the resonance hybrid of the forms IIIa, IIId and IIIe[4]. The phthaloylacridones are chemically closely similar to the acylaminoanthraquinones[5], and 3, 4-phthaloylacridone is a vinylog of 1-benzoylaminoanthraquinone. It seems probable, therefore, that the molecule of the former can not exist in either the structure Ib or Ic, that the former is the resonance hybrid of the forms

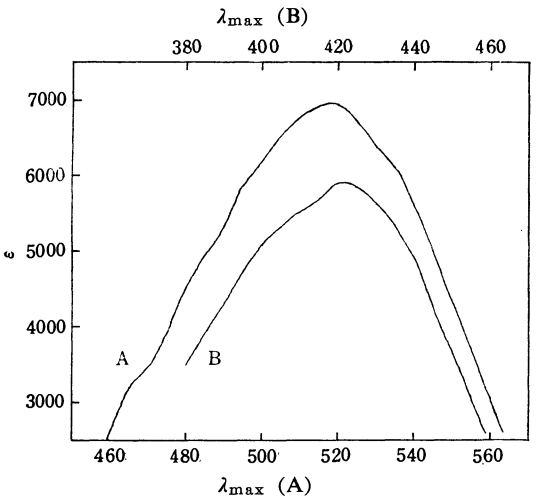

Fig. 1. Visible absorption spectra.
A: 3,4-Phthaloylacridone
B: 1-Benzoylaminoanthraquinone

Ia, Ie and If and that the carbonyl group in the nitrogen-bearing ring for the former shows an insulating effect similar to that in the benzoylamino group for the latter[4]. Their spectra in the visible region are shown in Fig. 1. As in the case of 5,6-phthaloyl-1,2-benzacridone[6], 3,4-phthaloylacridone gives a absorption curve broadly similar to that of 1-benzoylaminoanthraquinone, illustrating the insulating effect of the carbonyl group in the nitrogen-bearing ring. Such a fact is consistent with the above-mentioned deduction that both visible absorption bands are due to the same chromophore.

As is indicated in Table I, a comparison of the peaks of 3,4-phthaloylacridone and 1-benzoylaminoanthraquinone indicates a bathochromic shift of 95 mμ; the peak of the former shifts towards a longer wavelength than those of 1-aminoanthraquinone-2-carboxylic acid and 1-(*o*-carboxyphenyl)- and 1-phenyl-aminoanthraquinones. This fact can probably be attributed to the increased coplanarity of the molecule owing to the existence of the nitrogen-bearing ring for 3,4-phthaloylacridone. This interpretation is supported by the following thesis: the coplanarity on the molecule of 5,6-phthaloyl-1,2-benzacridone should be the same degree as for 3,4-phthaloylacridone, and therefore the effective area of the π-electron system[11] seems to be larger for the former than for the latter. As is clear from the results in Table I, the peak of the former appears at the same wavelength as for the latter, and the intensity is greater for the former than for the latter.

This fact is also deduced from the following results: though a comparison of the peaks of 3,4-phthaloylacridone and 1-aminoanthraquinone indicates a bathochromic shift of 53 mμ, that of 1,2-phthaloylacridone and 2-aminoanthraquinone makes only a slight hypsochromic shift of 13 mμ. For 1-amino-, 1-benzoylaminoanthraquinones[4,12] and 1,1'-dianthrimide[8], mesomeric shifts in their chromophoric systems contributed mainly to the shifts of their absorption peaks. Therefore, as will be clear from the results of the study of the infrared

spectra of 3,4-phthaloylacridone, the carbonyl group is hydrogen-bonded with the imino group, though probably hydrogen bonding is not the main cause of such a large difference between the shifts of 3,4- and 1,2-phthaloylacridones. Such a hypsochromic shift of the peak for 1,2-phthaloylacridone is, therefore, to be attributed to the reduced mesomeric shift, leading to the IIc structure, owing to the decreased coplanarity of the molecule, which is due to the repulsion between two vicinal carbonyl-type oxygen atoms.

In aminoanthraquinones and phthaloylacridones, the protonation of their carbonyl oxygen atoms can occur, but it is not possible to say positively whether one, two or three carbonyl oxygen atoms are protonated[9,13]. As is indicated in Table I, the peaks of 1- and 2-aminoanthraquinones in concentrated sulfuric acid are shifted to shorter wavelengths and lower intensities compared with anthraquinone, and appear at shorter wavelengths than those in organic solvents. These hypsochromic shifts are most probably caused by the protonation of the amino group. On the contrary, as is indicated in Table I, 1,2-phthaloylacridone absorbs at a greatly longer wavelength in concentrated sulfuric acid than in pyridine. Similar phenomena were also seen in indanthrone. The absorption peaks of indanthrone appeared at 371, 422, 482, 554, 598 and 635 mμ in ethanol[6], at about 620, 675 and 740 mμ in 1,2,4-trichlorobenzene[14], and at 390, 462 and 818 mμ in concentrated sulfuric acid[8]. Its absorption peak at the longest wavelength indicates a marked bathochromic shift at the last. Furthermore, in concentrated sulfuric acid indanthrone absorbed at longer wavelengths than did 1,2-diaminoanthraquinone. This fact was attributed to the strong amide-type resonance in the former persisting in concentrated sulfuric acid and to the inhibited protonation of the imino groups, though the amino groups of the latter were protonated[8]. On the contrary, since the phthaloylacridones are chemically closely similar to the acylaminoanthraquinones[5], the amide-type resonance for the former is not so strong as for indanthrone; therefore, the protonation of the imino nitrogen atoms of the former can occur. Consequently, the absorption peak at the longest wavelength in concentrated sulfuric acid for 1,2- and 3,4-phthaloylacridones should be attributed to the production of new chromophoric systems by protonation. In concentrated sulfuric acid, two absorption peaks of 1,2-phthaloylacridone appear at respectively longer wavelengths than do corresponding ones of 3,4-phthaloylacridone, but in pyridine the reverse is found to be true.

15) M. S. C. Flett, *J. Chem. Soc.*, **1948**, 1441.

This bathochromic shift is probably due to the fact that, since the molecule of the former has a decreased coplanarity compared with the latter, the reduced effect of the strongly electron-attracting $-NH_2^+-$ group contributes to the resonance hybrid.

Infrared Absorption Spectra.—Three and six μ bands of aminoanthraquinones and phthaloylacridones suspended in Nujol are shown in Table II, and the spectra in the 6 μ region of the latter are shown in Fig. 2. As 3, 4-phthaloylacridone is a vinylog of 1-benzoylaminoanthraquinone, the 1672, 1650 and 1613 cm^{-1} bands for the former are assigned, respectively, to vibrations of the C=O(a), C=O (b) and C=O(c) groups indicated in Ia, similar to those of the latter[4,16]. In the same manner, the 1675 cm^{-1} band for 1, 2-phthaloylacridone is assigned to vibrations of both the C=O(a) and C=O(b) groups indicated in IIa, and the 1623 cm^{-1} band, to the vibration of the C=O(c) group. In such unsymmetrically substituted anthraquinones as amino- and hydroxy-derivatives, two bands appear, since the strengths of the two C=O bonds are unequal, but unsymmetrically substituted anthraquinones such as nitro-, chloro-, methoxy- and methyl-derivatives, on which the absorption peaks hardly appear in the visible region, give a single C=O frequency, since the dissymmetry is insufficient for two separate bands to be observed[15]. Therefore, two carbonyl groups of the anthraquinone nucleus for 1, 2-phthaloylacridone, the visible absorption peak of which appears at 400 mμ, seem to give only one band in the infrared region. On the contrary, those of 3, 4-phthaloylacridone, the visible absorption peak of which appears at 516 mμ, give two bands. Its C=O(c) frequency agrees with the C=O(b) frequency of 1-aminoanthraquinone IVa, and a relation between If and IVb for them corresponds to that between the IId of 1, 2-phthaloylacridone and the IVd of 2-aminoanthraquinone. It is probable, therefore, that the frequency at 1623 cm^{-1} for 1, 2-phthaloylacridone, being equal to the C=O(b) frequency for 2-aminoanthraquinone, may be assigned to the vibration of the C=O(c) group. Such facts about the C=O frequencies of 1, 2-phthaloylacridone are to be attributed to the reduced mesomeric shift leading to the IIc structure owing to the above-mentioned decreased coplanarity of the molecule. This interpretation is supported by the fact that the C=O(c) frequency of 1, 2-phthaloylacridone is about the same as for *N*-methyl-γ-quinolone[17], the C=O frequency of which appeared at 1625 cm^{-1}.

The absorption of both the 1, 2- and 3, 4-phthaloylacridones obtained using the potassium bromide disk technique occurred at 1580 cm^{-1}. Frequencies for the C=N groups[18] are most probably found in the frequency range 1690 to 1640 cm^{-1}, and the influence of conjugation is usually small. The observed frequencies in

16) T. Hayashi. *J. Chem. Soc. Japan, Ind. Chem. Sec.* (*Kogyo Kagaku Zasshi*), **63**, 1985 (1960).

17) P. I. Ittyerah and F. G. Mann, *J. Chem. Soc.*, **1958**, 467.

18) L. J. Bellamy, "The Infrared Spectra of Complex Molecules", John Wiley & Sons, Inc., New York (1958), p. 267.

phthaloylacridones at 1580 cm^{-1} appear, therefore, at too low a frequency to be normally attributed to the C=N vibration. Furthermore, when C=N and C=C groups are in conjugation, particularly in cyclic systems, it is doubtful whether either group can be regarded as retaining its individual character; therefore, the assignment of C=N frequencies under such circumstances is not reliable[18]. The 1575 cm^{-1} band for 1, 1'-dianthrimide was not attributed to the C=N vibration, but to the ring vibration[8]. The 1582 cm^{-1} band for 1-benzoylaminoanthraquinone was also attributed to the ring vibration[16]. Furthermore, since not only amino-substituted anthraquinones, indanthrones, and anthraquinoneazines, but also anthraquinone, had medium to strong bands in the vicinity of 1587 cm^{-1}, the 1580 cm^{-1} band of indanthrone could not be reasonably assigned to the C=N vibration; these bands were, rather, attributed to ring vibrations[14]. Thus, there is no precedent for assigning the 1580 cm^{-1} band of phthaloylacridones to the C=N vibration; it also is probably to be assigned to the ring vibration. Consequently, this band can not be used to support the structures containing the C=N bond (Ib, Ic, IIb). This interpretation of the molecular structure in a solid is the same as the deduction on that in solution on the basis of the results of the visible absorption; moreover, chemical evidence does not favor the Ib, Ic and IIb structures.

The spectra in the 3 μ region of 1, 2- and 3, 4-phthaloylacridones mulled in Nujol are shown in Fig. 3. The frequencies for the O–H groups are usually found in the frequency range of 3450~3650 cm^{-1}, and the influence of conjugation is quite large[19]. Many of the frequencies for O–H groups of oxanthrone, anthraquinol and their substituted derivatives in a solid[15] were found in the 3300~3500 cm^{-1} frequency range. Moreover, neither the 3175 cm^{-1} band of 1-benzoylaminoanthraquinone nor the 3165 cm^{-1} band of indanthrone was assigned to the O–H vibration; rather, both were assigned to the N–H vibration[4,14]. For indigo and 5, 5', 7, 7'-tetrabromoindigo, in which an amide-type resonance contributes greatly to their resonance hybrids, the 3268 cm^{-1} band for the former and the 3367 cm^{-1} band for the latter were both assigned to the N–H vibration[20]. Broad and distinct bands at 3226 and 3195 cm^{-1} for 3, 4-phthaloylacridone may appear, therefore, at too low a frequency to be normally assigned to the O–H vibration; therefore, this band can not be used to support

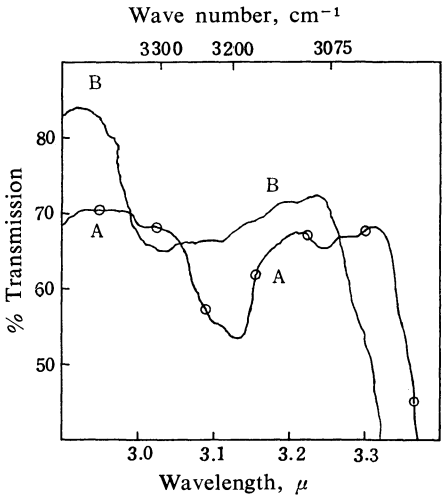

Fig. 3. 3 μ-Region of infrared absorption spectra.
A: 3, 4-Phthaloylacridone
B: 1, 2-Phthaloylacridone

the structures Ib and Ic. Consequently, the 3195 cm^{-1} band should be assigned to the N–H vibration of the true acridone structure. This interpretation of the molecular structure in a solid is the same as the deduction on that in solution on the basis of the results of the visible absorption; moreover, chemical evidence favors the true acridone structure. According to this view, the molecules of 1, 2-phthaloylacridone should also exist in a true acridone structure, in a way similar to that of the 3, 4-phthaloylacridone molecules.

It may be clearly seen in Fig. 3 that 1, 2-phthaloylacridone has two bands at 3300 and 3215 cm^{-1}. 2-Naphthylamine and 2-aminoanthraquinone in a solid gave a triple N–H band; therefore, these phenomena might not be attributable to the C=O group, but to intermolecular interactions between NH_2 groups[15]. 1-Benzoylaminoanthraquinone as a potassium bromide disk[16] also gave a double N–H band at 3226 and at 3115 cm^{-1}. Both of two bands for 1, 2-phthaloylacridone, therefore, may be attributed to the N–H vibration; therefore, the 3215 cm^{-1} band is assigned to the intermolecularly hydrogen-bonded N–H vibration. It is not possible, however, to state whether or not the occurrence of the 3300 cm^{-1} band is caused by intermolecular interaction between NH groups. The frequencies and broad shapes of the two N–H bands of 3, 4-phthaloylacridone at 3226 and 3195 cm^{-1}, similar to those of 1-benzoylaminoanthraquinone as Nujol mull[16], indicate some degree of hydrogen bonding. This view is supported by the fact that acridone in a carbon tetrachloride solution[21] gives a

19) L. J. Bellamy, ibid., p. 96.
20) G. M. Wyman, *J. Am. Chem. Soc.*, **78**, 4599 (1956); W. R. Brode, E. G. Pearson and G. M. Wyman, ibid., **76**, 1034 (1954).
21) A. V. Karyakin and A. V. Shablya, *Doklady Akad. Nauk S. S. S. R.*, **116**, 969 (1957); *Chem. Abstr.*, **52**, 4324 (1958).

N–H band at 3440 cm^{-1}. The proximity of the C=O and NH groups and the possibility for the formation of a six-membered ring suggest that one bonding is intramolecular, as is indicated in Id. Furthermore, 1-benzoylaminoanthraquinone as Nujol mull[16] gave a intramolecular N–H band at 3175 cm^{-1}, and the frequency of 3, 4-phthaloylacridone at 3226 cm^{-1} is in the vicinity of the intermolecular hydrogen-bonded N–H frequency of 1,2-phthaloylacridone at 3215 cm^{-1}. Therefore, the 3226 and 3195 cm^{-1} bands are most probably to be assigned to intermolecularly and to intramolecularly hydrogen-bonded N–H vibration respectively. This view is supported by the general tendency that, for β-amino-α, β-unsaturated ketones, the intramolecular hydrgen-bonded N–H bands occur at lower frequencies than the intermolecular hydrogen-bonded N–H bands[22]. The extent of conjugation between the imino and the C=O group in the nitrogen-bearing ring should be higher for *N*-phenylacridone than for 3, 4-phthaloylacridone, but the C=O frequency of the latter is lower than that of the former[23], this being 1632 cm^{-1}. This lowering seems also to be caused by intermolecular interaction between the NH and the C=O group for the latter.

Experimental

Materials and Apparatus.—The compounds used in this investigation were purified by repeated crystallization and then by chromatography or hot chromatography on alumina in suitable solvents.

The visible absorption spectra were obtained by a Shimadzu spectrophotometer type QB-50. The infrared absorption spectra were obtained using the Nujol mull technique; a Perkin-Elmer Model 21 double beam spectrophotometer fitted with a rock-salt prism was also used. *o*-Dichlorobenzene was purified by the method recommended for monochlorobenzence[24].

The authors wish to express their deep gratitude to Mr. Akira Hara of the Tokuyama Research Laboratory of Idemitsu Kōsan Co. for his infrared measurements.

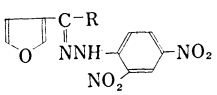
*Ultraviolet Spectra of β-Furyl Ketone and its Derivatives**

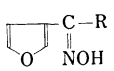
By Teruo MATSUURA, Keizo NAYA, Nobutaka ICHIKAWA and Takashi KUBOTA

(Received May 28, 1962)

Koltzin and Bulfson[1] have reported that β-furyl ketones of the A and B types have an ultraviolet absorption maximum at 240~270 mμ and 442~460 mμ respectively. Since these types of compounds possess another chromophoric group which is unconjugated or conjugated to the β-furoyl group, the present authors hoped to examine the ultraviolet spectrum of simple β-furyl ketones. For the present paper, the ultraviolet spectra of fifteen β-furyl ketones and their derivatives, which have been isolated from natural sources or have been synthesized in this laboratory, have been examined; the results are listed in the Table I.

Simple β-furyl ketones (I–V) have a broad absorption maximum at 205~208 mμ which is regarded as due to the furan nucleus[2], and also a considerably sharp maximum at 251~255 mμ (ε 3000~8000). The latter maximum, in the longer wave length region, is considered to be usable for analytical purposes as the maximum characteristic of a β-furyl ketone. The β-furyl ketone band of the VI acid appears as a shoulder under the influence of the strong band of the *a*, β-unsaturated acid group at 218 mμ.





The longest wavelength bands of the semicarbazones (VII–IX) at 265 mμ and of the 2, 4-dinitrophenylhydrazones (X–XII) at about 380 mμ are located at almost the same position as those of the semicarbazone and the

2, 4-dinitrophenylhydrazone of α, β-unsaturated ketones[3,4]. On the other hand, the bis-2, 4-dinitrophenylhydrazones, XIII and XIV, which have the additional 2, 4-dinitrophenylhydrazone group of a saturated ketone in the molecule, show a maximum at about 370 mμ with twice the absorption intensity. This hypsochromic shift is apparently due to the overlapping of the band of the unsaturated ketone derivative with the band of the saturated ketone derivative[5,6].

The ultraviolet absorption maxima[7] of egomaketone (β-dehydroperillaketone) (XVI) and of its ketonic derivatives show a good agreement with those discussed above.

Analysis of Complex Species Produced by the Szillard-Chalmers Process from Hexaquo-chromium Chloride $Cr(H_2O)_6Cl_3$ and Tetraquo-chromium Chloride $[Cr(H_2O)_4Cl_2]\cdot Cl\cdot 2H_2O$

By Niro MATSUURA, Yoshimi KURIMURA and Yoshikazu TSUNODA

(Received May 17, 1960)

Radioactive ^{51}Cr compound of a high specific activity can easily be obtained in a reactor by the Szillard-Chalmers process, using as a target an inner complex salt of chromium[1]. For example, Harbottle et al.[2] obtained hexavalent chromate or bichromate salt with a retention value of more or less 90%, depending on the nature of the counter-cation. They also obtained similar retention values for several trivalent chromium compound. In our present work, the retention of the chromium aquo-complex was investigated with a view to finding the way the energy of radioactive recoil is dissipated under the influence of a complex ligand field. Two different kinds of chromium chloride isomers were used as targets in this work, and neutron irradiation was effected in the JRR-1 reactor of the Japan Atomic Energy Research Institute. The activated products were separated into several portions of complex species by ion-exchange chromatography, and two samples of the separated portions were put into radiometric analysis for determining the ^{51}Cr yields and into colorimetric analysis for determining the total chromium content.

Experimental

Preparation of Chromium Complex.—Hexaquo- (purple) and tetraquo- (green) chloride complex salts were prepared by the method described in "Inorganic Synthesis"[4]; confirmation of the

purity was made with a Beckman D. U.-type spectrophotometer using the salts absorption spectra. Two pure stable salts of chromium chloride isomers were obtained; however, they could not be stored, even in a sulfuric acid desiccator, without partial degradation. It was found that the one isomer changed into the other by the degradation, even at room temperature. For obtaining the net yield of the radiolytic decomposition of the Szillard-Chalmers reaction, we must know the yield of natural degradation, probably caused by thermal and photochemical reactions, as a function of the time elasped before irradiation.

Irradiation.—The irradiation was effected in a closed silica or polyethylene tube containing several grams of silica gel, which was used as a desiccating agent. For neutron irradiation the target sample was placed in the No. 12 hole of JRR-1, which provided a thermal neutron flux of 2×10^{11} n/cm^2/sec. together with a γ flux of 4.5×10^5 r/hr. For γ irradiation, the sample was placed 20 cm. apart from the ^{60}Co source of 1000 curie in the Radiochemical Laboratory, the Institute of Physical and Chemical Research; this provided a dose rate of 4.5×10^4 r/hr.

Separation of Complex Species. — About 0.1 mequiv. weight of the target chromium complex was dissolved in thrice-distilled water, and the 0.1 M solution thus prepared was passed through a cation-exchange resin column 1.5 cm. in diameter and 15 cm. in length, with 12 g. of air-dried Amberlite IR-120. Then, the resin column was washed successively with water, 0.05 N perchloric acid, a 0.05 N sodium hydroxide solution, and 2 N hydrochloric acid. These eluants, proposed by Gustavson and Kawamura[6], permitted us to separate the complex species in the order given below:

Chromate, tetraquo-dichloro chromim(III), pentaquo-monochloro chromium(III) and hexaquo chromium(III) complex.

Colorimetry of the Total Chromium.—The solutions of each effluent from the cation-exchange resin column were made alkaline with 0.2 N sodium hydroxide, and the resulting alkaline solutions were treated with hydrogen peroxide in order to convert chromium(III) into chromium(VI). The developed yellow color was measured with a Beckman D.U.-type spectrophotometer[7].

Radioactivity Measurement.—After cooling for two weeks, the neutron-irradiated sample was dissolved in a small quantity of water. Then, the species of the chromium complex tagged with radioactive ^{51}Cr were separated by ione-xchange chromatography. For measuring the radioactivity due to ^{51}Cr in the separated fractions, a given amount of inactive chromium(III) salt was added as a carrier: this provided uniform precipitates of a given thickness for radioactive assay. Chromium-(III) was converted into hexavalent chromate by oxidation with hydrogen peroxide in an alkaline medium, and lead chromate was precipitated. The yellow precipitates of lead chromate, containing ^{51}Cr, were filtered off, dried and mounted for radioactivity measurement. A bell-type G. M. counter was generally used for the activity measurement, but a dipping-type counter with a wall thickness of 37 mg./cm^2 was also used when simultaneous determinations of the total and of the radioactive chromium were needed. The main radioactive impurity was ^{35}S, produced by (n, p) reaction from ^{35}Cl in chromic chloride. This interference could be avoided by absorbing the soft β rays with an aluminum absorber 8.9 mg./cm^2 thick. The radioactive ^{32}P, even if produced by a fast neutron by a (n, α) reaction with an cross section of 0.13 barn, did not interfere with our measurement of ^{51}Cr, because anionic phosphate could be eliminated during the chemical separations by cation-exchange resin and by precipitation. Actually, ^{32}P was not detected in such an amount as to affect the determination of ^{51}Cr.

Results

Separation and Recovery by Ion-exchange Chromatography.—A synthetic mixture of pure tetraquo- and hexaquo-complex salts was dissolved in water to produce a 0.2 M solution with regard to each component, and the complex species were adsorped on a hydrogen-form cation-exchange resin column. The separation was effected by the eluants as described above (Experimental). The elution chromatogram in Fig. 1 shows the quantitative recovery of two isomers.

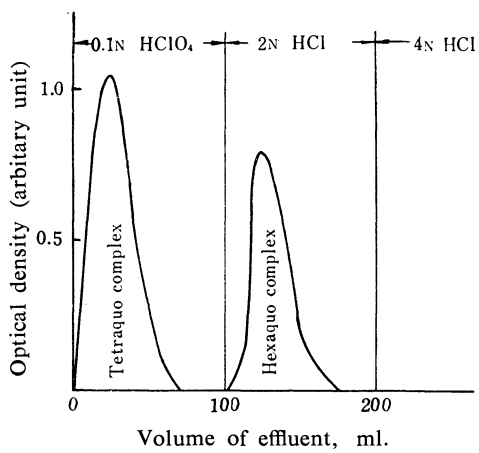

Fig. 1. Elution curve of a mixture of tetraquo- and hexaquo-complex.

Radioactive Species.—The yields of radioactive chromium complex species produced by neutron activation were determined radiochemically after separaion by ion-exchange chromatography. Each 5 ml. portion of the effluents was taken for counting the radioactivity in the course of the elution. The results of the measured radioactivity and the calculated enrichment factors are presented in Fig. 2.

The first effluent of the ion-exchange chromatograms contains unknown neutral and anionic species. The second activity peak in Fig. 2 indicates the presence of tetraquo-dichloro chromium-51, corresponding to the Szillard-Chalmers retention value. Similarly, the third peak shows the eluted pentaquo-monochloro chromium-51. The last effluent, obtained by a hydrocholoric acid stronger than 2 N, is ascribed to the hexaquo chromium-51 fraction according to the results of the preliminary test on the ion-exchange chromatography. The observed specific activities or enrichment factors of the first and third peaks were nearly the same, but each was a hundred times as large as that of the second. This is because of the partial degradation of the tetraquo-complex into the hexaquo-complex during the times of irradiation and storage. Besides, the treatment with a 0.05 N sodium hydroxide solution for eluting pentaquo-complex species causes a sort of degradation of the hexaquo-complex in the resin phase, forming a species which can not easily be eluted with 2 N hydrochloric acid. The effect of the natural degradation of the

TABLE II. PERCENT YIELD OF ^{51}Cr BY THE ELUTION WITH HCl MORE THAN 2 N. COMPARISON WAS MADE BETWEEN THE YIELDS WITH AND WITHOUT PRETREATMENT USING 1/20 N NaOH

Treatment	Eluant: 4 N HCl	Eluant: 6 N HCl
Yield with treatment	17%	12%
Yield without treatment	less than 3%	less than 3%

tetraquo-complex target on the yield of radioactive complex species can be clearly seen in Table I; and the similar effect of pretreatment with 0.05 N sodium hydroxide is shown in Table II.

It is supposed that an unstable chlomium complex in a valency state higher than three might be produced by neutron activation and that the absorption of this species on the resin is too strong to be eluted with 2 N hydrochloric acid. If chromium(IV) or chromium(V) were formed in the irradiated sample, then the chloride of chromium trichloride would act as a reducing agent against chromium-(IV) or chromium(V) which is probably a powerful oxidizing agent. For this reason, an elution was carried out with 2 N hydrochloric acid in the presence of excess sulfurous acid, but no appreciable change was observed in the elution characteristics; the conclusion was drawn that there was no chromium(IV) or chromium(V).

Radioactive Complex Species Produced from the Hexaquo- and Tetraquo-complex Target.— The yield of radioactive chromium complex species produced by neutron activation from two different targets, the hexaquo- and tetraquo-complex isomers, is presented in Figs. 3 and 4. Beside these, the amount of chromium found in each fraction of chromatograms, as

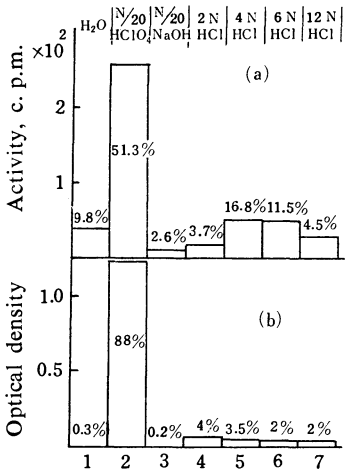

Fig. 3. Irradiated tetraquo-complex.
(a) Comparison of the amount of ^{51}Cr (expressed in radioactivity), (b) the amount of the total chromium (expressed in optical density) in the sample.

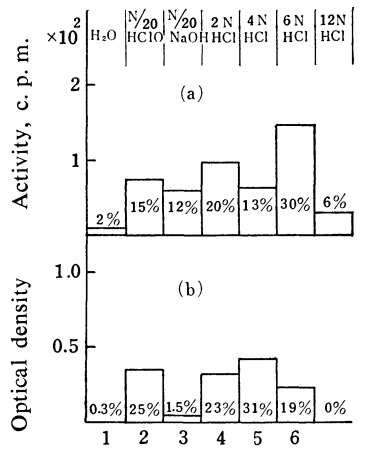

Fig. 4. Irradiated hexaquo-complex.
(a) Comparison of the amount of ^{51}Cr (expressed in radioactivity), (b) the amount of the total Cr (expressed in optical density) in the sample.

determined by colorimetric analysis, is shown in Figs. 3 and 4.

As the hexaquo-complex is much more labile than the tetraquo-complex, not only to radiation decomposition but also to natural degradation in air, the contribution of the latter effect must be considered in order to obtain the correct yield of the radiation decomposition of the hexaquo-complex. However, this effect is so small for the tetraquo-complex that the correction is not necessary. The corrected yields for the radioactive chromium species are shown in Fig. 5 for the hexaquo-chromium target and in Fig. 3 for the tetraquo-chromium target.

Anionic Species of the Activated Chromium Complex.—The first effluent produced by exchange chromatography was passed through a column filled with anion-exchange resin, Dowex 1-X8. Less than 8% of the radioactive chromium was adsorbed on the anion-exchange resin. Therefore, the remaining 92% is considered to be present in a non-ionic form, but the chemical species of the latter was not identified. As to the anionic species, the extraction of chromium as perchromic acid by ethyl acetate was undertaken from acetic acid and a sodium acetate buffer solution at pH 1.6 in order to prove the presence of the chromate anion. The extracted radioactivity was less than 5% of the total present in the first effluent produced by cation-exchange chromatography.

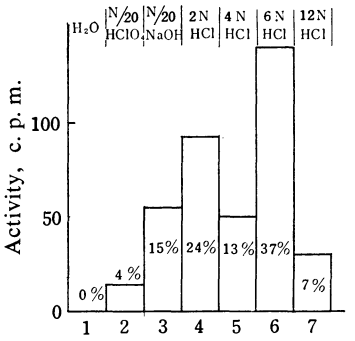

Fig. 5. Corrected distribution of ionic species for neutron irradiated hexaquo-complex.

Discussion

The yields of complex species of radioactive chromium(III) are summarized in Table III. As the retention values for two different isomers differ greatly from one another, we

TABLE III. SUMMARY OF YIELD

hoped from stereochemistry of the complex to get some information about the energy dissipation of the recoil chromium atom under the influence of the ligand field. The energy liberation by the process $^{50}Cr(n, \gamma)^{51}Cr$ was evaluated to be 9.2 MeV. from the atomic mass difference between ^{50}Cr and ^{51}Cr. From this, the recoil energy imparted to the ^{51}Cr atom by the emission of γ rays is estimated to be 839 eV. This energy must be imparted to the surrounding ligand atoms in different ways depending on the geometrical arrangement of the ligand in the chromium chloride complex. The actually observed Szillard-Chalmers effect is not the same with respect to the yield of the radioactive chromium complex for the two different isomers, hexaquo- and tetraquo-chromium chloride.

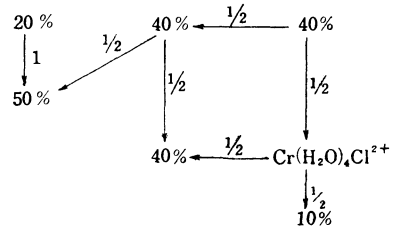
As the positively charged (+3e) recoil chromium atom is so heavy compared to the surrounding ligand atoms, the former can not escape from the interior of the crystal without any interaction. First, we suppose the recoil energy is imparted equally to three ligand atoms on the same plane of the octahedral surface; therefore these atoms will be expelled out of the complex crystal and caught by some interstitial site of the crystal. The radioactive recoil chromium atom will then recombine by statistical chance with an atom or a water molecule at the nearest neighbor's forming a certain species of the complex. As six water molecules and three chloride ions are the nearest neigbors in the present case, the yield of the radioactive complex species can be ruled out by simple statistics. With this assumption, the radioactive chromium complex yields must be 2/10 for the formation of the hexaquo-complex species, 3/10 for that of the pentaquo-complex, and 2/10 for that of the tetraquo-complex, regardless of the target complex. However, this hypothesis can not account for the experimental results shown in Table IV.

Secondly, the whole energy is transferred to one special ligand atom by head-on collision, and the kinetic energy of the recoil atom is effectively absorbed by this ligand atom. If the recoil energy is not greater than the binding energy between the central metal ion and the ligand atom, the retention value can be estimated as follows. The binding energy of one ligand water molecule to the central chromium atom is estimated to be $48/6=8$ eV. from the hydration energy of the chromium ion. However, this value must be multiplied by the factor of M°/M, for the available energy for bond-breaking is smaller than the recoil energy by this factor since momentum partition between the water molecule and the recoil chromium atom takes place. Therefore, the minimum energy is $8\times(159/18)=70.6$ eV. for breaking one ligand bond. The energy, required to remove successively one more ligand water amounts to $70.6\times(141/18)=555$eV. From this consideration, the recoil atom having less energy than this threshold energy of 70.6 eV. must retain its initial ionic form of the complex. Similarly, in the recoil chromium atom having between 70.6 and 555 eV. of energy the yields of radioactive chromium complex are different in ligand number by one from the initial form of the target complex. In the case of the tetraquo-complex as the terget the energy necessary to remove one chlorine atom from the complex crystal field can be estimated from the absorption spectroscopic data to be one-half of the energy needed for the water molecule. However, the reduction factor of the available energy for bond-breaking, M/M°, is twice as large as that of the water molecule. Therefore, the threshold energy for breaking the ligand chlorine bond is nearly one-fourth that of the evaluated energy for ligand water.

Table IV. Comparison of the Szillard-Chalmers yield of chromium chloride complex with the theoretical yield based on complete dissociation and statistical rearrangement of ligand atoms

Target complex	Tetra isomer	Hexa isomer	Theoretical
Product		yield, %	
Tetra form	50 (Retention)	4	28.5
Penta form	3	15	43
Hexa form	37	80 (Retention)	28.5

The Effect of the Multicascade of γ Emission. —The calculation of the recoil energy is not so simple as has been discussed above, since γ emission in the neutron gamma process generally takes place through several steps in cascade. In this discussion, we treat the problem as if γ emission occurred in two steps, since the final result does not differ essentially from that of multicascade emission. Assuming that successive γ photons of the same energy are emitted in two directions with an angle α, we can expect the relation between the recoil energy with no cascade, E°, and with a two-steps cascade, E', given by the Eq. 1:



$$E'=E^\circ\cos^2(\alpha/2) \quad (1)$$

As successive γ emission takes place in a random direction, the angle α divided by π gives a probability of the event where a successive γ emission occurs between 0 and α. In Fig. 6 the α/π value is plotted against the

Table V. The effect of multicascade γ emission on the Szillard-Chalmers reaction yields. The tentative calculation of the yields for recoil intermediates and final products was based on the spatial recoil energy distribution by two successive γ emission

$Cr(H_2O)_5Cl^{2+}$ (3%)				
$Cr(H_2O)_6^{3+}$ (37%)				

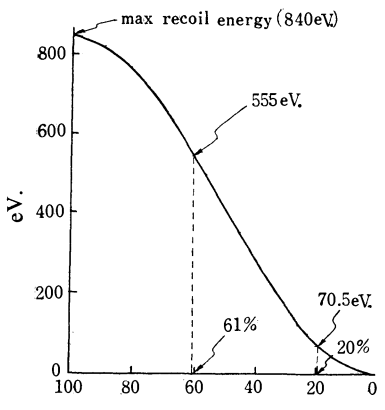

Fig. 6. Recoil energy of ^{51}Cr calculated from Eq. 1 vs. $(1-\alpha/\pi)\times 100$ which represents percentage of ^{51}Cr having recoil energy E'.

recoil energy, E', for a two-cascades emission of γ rays by the aid of Eq. 1. Taking the threshold energy value, E', for bond-breaking, we can determine the probability, α/π, from the curve shown in Fig. 6, which gives the yield of the complex species of radioactive chromium produced by neutron-gamma reaction. The α/π fraction for the given threshold, E', insufficient to break one bond, gives the retention yield of radioactive chromium. Similarly, the α/π value for the threshold corresponding to the breaking of two or more bonds, gives the yield of the complex species of radioactive chromium differing by one or more ligand atom. An intermediate complex, lacking one or more ligand atom, reproduces a normal six-ligand complex species by picking up either a water molecule or a chlorine atom depending on the relative abundance of the surrounding ligand species. For example, an intermediate $Cr(H_2O)_5^{3+}$ will reproduce either one of two stable complex six-ligand species, $Cr(H_2O)_5^{3+}$ or $Cr(H_2O)_6Cl^{2+}$, with equal probability. Therefore, on the basis of the above assumption, the final products of the radioactive chromium complex can be

estimated; the schemata are presented in Table Va for a hexaquo target and in Table Vb for a tetraquo target.

The tables show that double γ emission schema plausibly improve the agreement between the calculated and observed results more than the simple cascade scheme does.

Studies on Modified Hydrogenation Catalyst. I. Selective Hydrogenation Activity of Modified Raney Nickel Catalyst for Carbonyl Group and C=C Double Bond

By Hideaki FUKAWA, Yoshiharu IZUMI, Shinichiro KOMATSU and Shiro AKABORI

(Received February 1, 1962)

Recently, Izumi et al.[1-3] developed an entirely new series of hydrogenation catalysts, which are unique in that silk fibroin serves as carrier for metals. These catalysts have highly selective hydrogenation activity, having high activity for unsaturated compounds and aromatic nitro compounds but no activity for aliphatic carbonyl compounds. It was suggested that the specificity of these catalysts resides in the special structure of the carrier, silk fibroin.

It therefore seemed possible that if Raney nickel (R-Ni) catalyst is treated with amino acid, peptide or protein, these modified R-Ni catalysts may possess selective hydrogenation activity similar to that of the silk-metal catalyst. Isoda and Ichikawa[4] have, in fact reported the occurrence of asymmetric hydrogenation with the use of R-Ni catalyst on which optically active amino acids had been adsorbed.

As is well known, enzymatic reactions are highly specific, but their velocities can be modified by means of various reagents. Accordingly, methods of competitive inhibition or antagonism in enzymology should also be applicable to the study of non-enzymatic catalytic reactions. On the basis of these conceptions, the hydrogenation activity of the R-Ni catalyst modified with amino acids and other chelating agents has been systematically studied.

R-Ni catalyst treated with these reagents had diminished hydrogenation activity only for the carbonyl group. In particular, R-Ni catalyst modified by various amino acids, possessed this property to a greater extent than that modified by other reagents. The present paper describes the hydrogenation activity and some characteristics of the modified R-Ni catalyst.

Results and Discussion

Allyl alcohol and ethyl methyl ketone were used as substrates for most of this investigation. As modifying agent, L-glutamic acid or its monosodium salt was generally used because of its selectivity.

As summarized in Table I, the hydrogenation activity of R-Ni catalyst for ethyl methyl

○ With unsaturated catalyst
● With modified catalyst (0.5% Glu)

ketone was almost lost at 10°C when the catalyst was treated with a solution of L-glutamic acid or sodium L-glutamate of greater concentration than 0.5%, and was greatly diminished at 60°C. On the other hand, no appreciable change in its hydrogenation activity for allyl alcohol occurred upon treatment with sodium L-glutamate solutions in concentration up to 4%. When the catalyst was treated with sodium L-glutamate at concentrations greater than 4%, the hydrogenation activity for ethyl methyl ketone was almost lost even at higher temperatures. Figure 1 shows a typical hydrogenation curve of ethyl methyl ketone (a) and allyl alcohol (b) carried out with untreated and modified R–Ni catalyst.

The effect of modifying the time of immersion of R–Ni catalyst in L-glutamic acid solution on hydrogenation activity is shown in Table II. Immersion for 15 min. was sufficient to cause a pronounced decrease in hydrogenation activity for ethyl methyl ketone. Further treatment resulted in a more gradual decrease in activity. It thus appears that most of the modifying effect of L-glutamic acid took place in the first 15 min. On the other hand, immersion of R–Ni catalyst in water as long as 5 hr. did not change its hydrogenation activity.

TABLE II. TIME OF MODIFYING

Modifying reagent	Time of immersion	Hydrogenation activity EMK 10°C	EMK 60°C	AA 10°C
0.5% L-Glu	15 min.	0	4	34
	2 hr.	0	3	—
	16 hr.	0	2	30
4% L-MSG	2 hr.	0	1	16
	16 hr.	0	0	14

Treatment with various other amino acids and some other types of compounds has been carried out, and the results are summarized in Table III. All of the amino acids tested gave selective hydrogenation activity to R–Ni catalyst. Dibasic amino acids and phenylalanine had the greatest effect among the α-amino acids tested to date. Other types of chelating agents had a lesser effect than amino acids.

An interesting finding was, that the hydrogenation activity of R–Ni catalyst for allyl alcohol was promoted by the treatment with dimethylglyoxime. As will be described below, it was observed, that the hydrogenation activity of the modified R–Ni catalyst increased to three times that of the untreated catalyst in the hydrogenation of nitrobenzene. The surface of the catalyst modified with dimethylglyoxime turned pink in color. This change suggests the formation of a chelated complex between nickel and dimethylglyoxime.

Table IV summarizes the results of the hydrogenation of various ketones and unsaturated compounds with the modified R–Ni catalyst. The catalyst in these experiments was prepared by immersion in 2% sodium L-glutamate solution for 2 hr. at 10°C. The hydrogenation activity at low temperature for ketones was lost by this treatment, and even at 60°C the activity decreased from one tenth

d) Losses of carbonyl group in the products were 11% and 3%, respectively.

to one sixth of that of the untreated catalyst. Hydrogenation activity of R-Ni catalyst for unsaturated compounds was almost unchanged by this treatment, and the activity increased in the case of hydrogenation of maleic acid. Similarly, the rates of hydrogenation of ethyl maleate and of ethyl acrylate were increased by this treatment.

When mesityl oxide was the substrate of hydrogenation, hydrogen uptake ceased, when the uptake of hydrogen was one mol. per mol. of substrate, and isobutyl methyl ketone was obtained in high yield. This result shows that the C=C double bond was predominantly hydrogenated while the carbonyl group was almost unaffected when mesityl oxide was hydrogenated with this modified catalyst.

This conclusion was confirmed by examining the infrared spectrum and determining the carbonyl content of the hydrogenated products. The only negative result occurred with cinnamaldehyde. Neither its C=C double bond nor its carbonyl group was hydrogenation activity of R-Ni catalyst for nitrobenzene was depressed by treatment with amino acid as shown in Table V, but was increased two-fold by treatment with dimethylglyoxime.

The results thus for obtained suggest the possibility that the surface of activated R-Ni catalyst is inhomogeneous and that C=C and

* % Hydrogen uptake (%) in initial 10 min.

C=O bonds are reduced at different hydrogenating centers on the surface. When the catalyst was modified with an amino acid capable of chelating with nickel ion, the hydrogenated centers for carbonyl compounds were inhibited, whereas the centers for C=C double bond remained unaffected.

In this investigation, carbonyl-containing substrates used were limited to some ketones, and the conditions of hydrogenation were also limited. In order to obtain further information concerning the mechanism of this modification and to provide a basis for its practical application, further studies are required. It is expected that such studies will shed some light on the mechanism of catalytic hydrogenation reactions.

Experimental

Preparation of Catalyst. — The catalyst used in this work, was prepared by the following method. One and a half grams of Raney nickel alloys (aluminum content 45%, manufactured by Kawakami Lab. Co. Ltd.,) was added to 20 ml. of 20% sodium hydroxide solution in small portions during a period of 5 min., and was allowed to stand for 45 min. at 80°C. The activated catalyst was washed several times with water. All of hydrogenation reaction in this work was carried out with this quantity of R-Ni catalyst.

Modification of Catalyst. — Fifty milliliters of an amino acid solution was added to the activated catalyst, and the mixture was allowed to stand with occasional shaking at room temperature (10~15°C) for 2 hr. After the modifying solution was removed by decantation, the catalyst was washed once with water and two times with methanol, and centrifuged. Dry weight of the catalyst was about 0.7 g. Glycylglycine hydrochloride and acetic acid were used after their solution were adjusted to pH 5 by dilute alkali. Dimethylglyoxime was used in methanol solution.

Reaction Vessel.—A shaking autoclave of 100 ml. capacity was used as the vessel for hydrogenation reaction.

Activity of Catalyst. — Hydrogenation activity was measured by the rate of hydrogen uptake at the initial period of reaction and was represented as percent of theoretical hydrogen absorption per specified period of time.

Hydrogenation Reaction. — *1) Hydrogenation of C=C Double Bonds. — a) Hydrogenation of Allyl Alcohol.*—Seventeen grams (0.3 ml.) of allyl alcohol

were hydrogenated with hydrogen 95 kg./cm² at 10°C with R-Ni prepared from 1.5 g. alloy. Reaction velocity was represented by percent hydrogen uptake in the initial 5 min.

b) Hydrogenation of Cinnamic Acid, Maleic Acid, Ethyl Acrylate and Diethyl Maleate.—7.5 g. cinnamic acid in 50 ml. methanol, 17.5 g. maleic acid in 50 ml. methanol, 15 g. ethyl acrylate in 40 ml. methanol and 17.2 g. diethyl maleate in 50 ml. methanol were hydrogenated by the same procedure as allyl alcohol.

2) Hydrogenation of Ketones.—a) Hydrogenation of Ethyl Methyl Ketone.—Twenty grams (0.3 mol.) of ethyl methyl ketone were hydrogenated with hydrogen (70 kg./cm²) at 10°C. Reaction velocity represented hydrogen uptake in the initial 30 min. Temperature of the reaction was initially maintained at 10°C for 3 hr. and then was raised to 60°C.

b) Hydrogenation of Acetone.—Acetone (11.6 g., 0.2 mol.) was hydrogenated by the same procedure as ethyl methyl ketone.

c) Hydrogenation of Acetophenone.—Twelve grams (0.1 mol.) of acetophenone dissolved in 50 ml. methanol were hydrogenated by the same procedure as ethyl methyl ketone.

d) Hydrogenation of Cyclohexanone.—Cyclohexanone (19.6 g., 0.2 mol.) was hydrogenated by the same procedure as ethyl methyl ketone, except that the hydrogenation at higher temperature was carried out at 80°C instead of 60°C.

3) Hydrogenation of Mesityl Oxide. — Mesityl oxide was purified by fractional distillation (128~130°C, b. p.) after being washed with dilute alkali to remove contaminating iodine. Purified mesityl oxide (19.6 g., 0.2 mol.) was hydrogenated with hydrogen 90 kg./cm² initially at 10°C. After the hydrogen uptake was 0.2 mol., temperature was raised to 60°C and reaction was continued still further for 2 hr. Reaction velocity was represented by hydrogen uptake in the initial 5 min. at 10°C and during the first 30 min. at 60°C and was expressed as percentage of the theoretical amount for each radical.

4) Hydrogenation of Nitrobenzene. — Four grams (0.03 mol.) of nitrobenzene dissolved in 50 ml. methanol were hydrogenated with hydrogen (80 kg./cm²). The temperature, which initially was 10°C, rose to 40°C during the reaction. Reaction velocity was presented by percent hydrogen uptake in the first 10 min.

Determination of the Carbonyl Group. — The carbonyl group was assayed by the hydroxylamine method after Fritz and Yamamura[5].

Summary

Hydrogenation activity of the Raney nickel catalyst for carbonyl compounds was greatly diminished, when the catalyst was treated with a solution of amino acid. On the other hand, no appreciable change in its hydrogenation activity for C=C double bonds occurred upon this treatment. When mesityl oxide was used as a substrate, selective hydrogenation was most clearly demonstrated.

The effect of conditions of modification, such as concentration of the modifying solution, immersion time and kind of modifying reagent on the activity of the modified catalyst, were investigated.

Studies on the Silk-Rhodium Catalyst

By Akira AKAMATSU*, Yoshiharu IZUMI and Shiro AKABORI

(Received May 16, 1962)

A series of the hydrogenation catalysts, composed of highly dispersed metal on fibers of silk fibroin, has recently been studied. The silk-palladium[1] and silk-platinum[2] catalysts, have shown a number of interesting properties that probably depend upon the nature of the carrier silk-fibroin fibers. In particular, catalysts of this type are highly selective with respect to the reactions that they catalyze. The metal used in the present study was rhodium which was recently found to be an excellent catalyst for the reduction of aromatic or heterocyclic double bond. The silk-rhodium catalyst was prepared by boiling silk-fibroin fibers with an aqueous solution of rhodium chloride and then hydrogenating the resulting silk-$RhCl_3$-complex.

The silk-palladium catalyst selectively hydrogenated the C=C double bond without reducing

the carbonyl group in an aliphatic molecule, which contains both groups. In the case of silk-rhodium catalyst, it appears that the selectivity was much increased. In the present work, it was found that this catalyst easily catalyzes the hydrogenation of C=CHCH$_2$OH and C=CHCOOH type of the C=C double bonds, while carbonyl groups, including those of aromatic compounds, could not be hydrogenated at all. This catalyst was relatively less active for the hydrogenation of the other type of the C=C double bonds, such as C=CHCO–R, and of nitro groups.

Results and Discussion

Conditions for Preparation of the Catalysts. — In order to obtain a catalyst with high activity and to minimize expensive loss of rhodium, optimal conditions were sought for the preparation of the silk-rhodium chelate and for the activation of the resulting chelate to the catalyst.

In Fig. 1a the rhodium contents in the chelate prepared in the different preparations are shown: when 400 mg. of silk-fibroin fibers were boiled with an aqueous solution containing 100 mg. of rhodium chloride ($RhCl_3$) for 25 min. The concentration was varied by changing the volume of water, and maximum chelation occurred in a mixture containing 100 mg. of silk-fibroin fibers in 0.5% aqueous $RhCl_3 \cdot H_2O$.

The optimal volume of the 0.5% $RhCl_3$ solution and boiling time was then determined. The results are summarized in Figs. 1b and 1c. Two hundred milligrams of each of the resulting chelate was activated by reduction in an autoclave, with ca. 90 kg./cm^2 of hydrogen in 50 ml. of water at 160°C for 1.5 hr., and the activities of the obtained catalysts were measured. The activity yield ($y \cdot v$), the product of the reaction velocity (v) and gravity yield (y)[2] is a measure of activity of the catalyst for a given amount of the metal in the catalyst. Reaction velocity (v) was measured during hydrogenation of allyl alcohol to propyl alcohol with the same amount of catalyst, and was calculated by the equation; $v=100/t$, where t is the time in minutes required for 70% uptake of hydrogen.

As can be seen from data described here, the most favorable result was obtained, when 400 mg. of silk-fibroin fibers were boiled with 30 ml. of a 0.5% aqueous solution of rhodium chloride for ca. 30 min. The obtained silk-rhodium chelate consisted of golden-colored fibers which contained approximately 3.6% of the metal. This preparation was used for the work described in the following section of this paper.

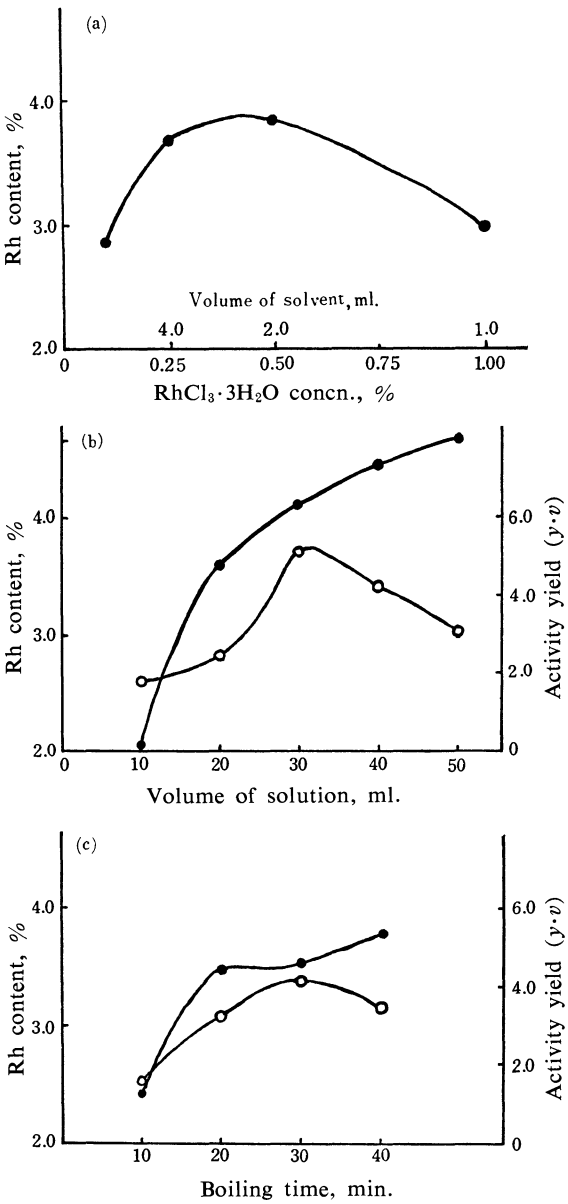

Fig. 1. Rhodium content of chelate under various conditions and activity yield of activated catalyst.
● Rhodium content
○ Activity yield
Silk-fibroin 400 mg. was boiled (a) in an aq. solution containing 100 mg. of $RhCl_3 \cdot 3H_2O$ for 25 min., (b) in a 0.5% $RhCl_3 \cdot 3H_2O$ aq. solution for 25 min., and (c) in 30 ml. of the solution.

Table I is a summary of experiments in which chelate was activated by reduction in an autoclave with ca. 90 kg./cm^2 of hydrogen in 50 ml. of water at various temperatures for different periods. The activity of the obtained catalyst, represented by the reaction

velocity (v) and the activity yield ($y \cdot v$) during the hydrogenation of allyl alcohol to propyl alcohol, was as dependent upon the temperature and time of activation as that of the silk-platinum catalyst. Increasing the amount of the precursor chelate used with respect to the amount of the solvent (water) did not influence the activity.

Stability of the Catalyst.—The reaction velocities measured by the method described above are shown in Table II. The catalyst was used both immediately after its activation and after it was dried and stored for several days in a stopped bottle. Storage of the catalyst for a long period resulted in considerable increase of activity.

Table II. Stability of catalyst

3	8.5
8	15.2
15	14.2
47	9.0

The activity of the silk-rhodium catalyst was strongly inhibited by some substances. The inhibitory effects of certain poisons on the hydrogenation of 0.1 mol. of allyl alcohol in methanol in the presence of 20 mg. (containing ca. 10^{-5} mol. of Rh) of the catalyst was investigated. The results are shown in Table III. The behavior of this catalyst towards metal ions was similar to that of the silk-platinum catalyst. It was found that silk-rhodium catalyst poisoned with both ferric and cupric ions could be reactivated by treatment with ethylenediaminetetraacetic acid (EDTA).

Selectivity of the Catalyst.—The catalytic efficiency of the silk-rhodium catalyst on various substrates was examined. For each mole of hydrogen required for complete reduction, 200 mg. of the catalyst were used under ca. 90kg./cm^2 of hydrogen in a 100 ml. autoclave. The results are summarized in Table IV.

In an earlier study it was observed that hydrogenation of both acetaldehyde and benzaldehyde did not take place in the presence of a silk-platinum catalyst, when hydrogen was introduced into the reaction vessel before the reactant had been heated to a reaction temperature; however, when catalyst and aldehyde were pre-heated and then hydrogen was introduced, the reaction occurred. All the compounds tested in the present work, were heated before introduction of hydrogen.

Hydrogenation of the Carbonyl Group.—In the presence of this catalyst the carbonyl group was not hydrogenated in any of the aldehydes and ketones listed in the Table IV.

Hydrogenation of the C=C Double Bonds.—This catalyst is extremely active in hydrogenating C=C double bonds in compounds of the types C=CHCOOH and C=CHCH$_2$OH, such as allyl alcohol, maleic acid, and cinnamic acid. On the other hand, the hydrogenation of the C=C double bonds attached to an ester group or conjugated with a carbonyl group seems to be difficult with this catalyst, and hydrogen uptake by diethyl maleate, cinnamaldehyde and crotonaldehyde was very low. Mesityl oxide absorbed a small amount of hydrogen, yielding only isobutyl methyl ketone, and preserving its carbonyl group intact. The C=C double bond in acrolein, which is conjugated with carbonyl group, behaved typically in that it could be easily hydrogenated at low temperature. The carbonyl group was not attacked, and propionaldehyde was produced in a nearly quantitative yield.

Thus it appears that the silk-rhodium catalyst is capable of easily catalyzing the hydrogenation of the aliphatic C=C double bonds in some molecules leaving unaltered their coexisting carbonyl groups. The double bonds in benzene rings were not hydrogenated in the presence of this catalyst.

Reduction of Nitro Groups.—The hydrogenating activity of silk-platinum catalyst was reported to be extremely high for nitro groups attached to aromatic rings and low for aliphatic nitro groups and C=C double bonds. In the present work, however, the catalyst showed comparatively little activity in the hydrogenation of aromatic nitro groups, and the aliphatic nitro groups of nitromethane and diethyl

nitromalonate were not reduced at all in the presence of acetic anhydride.

Nitrobenzene was not reduced except at high temperature, but the substituted nitrobenzenes, *p*-nitrotoluene and *m*-nitrocinnamic acid, were easily reduced.

2-Butyne-1, 4-diol.—It was easily hydrogenated to give 1, 4-butanediol quantatively.

Experimental

Determination of Rhodium.—Rhodium was determined by the stannous iodide method[3], after the chelated sample had been treated as follows; about 25 ml. of the chelated sample was accurately weighed in a test tube and heated with 0.5 ml. of concentrated nitric acid on a steam bath for 1 hr. The mixture was diluted with 4 N hydrochloric acid to 50.0 ml. Exactly 5.00 ml. of the solution was used for each ascertainment.

The standard curve was made with a solution containing accurately weighed rhodium chloride trihydrate to which was added a certain amount of silk-fibroin decomposed by the method described above for the chelated sample.

Measurement of the Reaction Velocity.—Twenty milligrams of the catalyst to be tested and 5.8 g. (0.1 mol.) of allyl alcohol dissolved in 50 ml. of methanol were placed in a 100 ml. autoclave. Hydrogen was then introduced to a pressure of 90 kg./cm^2, and the time required for 70% of the theoretical hydrogen uptake measured.

Preparation of Catalyst. — Five grams of the silk-rhodium chelate prepared as described previously were reduced in a 300 ml. autoclave with 90 kg./cm^2 of hydrogen in 150 ml. of water, at 140°C for 3 hr. The catalyst obtained was washed with water, methanol, and ether in succession, and then dried in vacuo; yield: 3.2 g. (65%), rhodium content: ca. 5.4% (calculated from rhodium content in the precursor chelate and the yield).

Treatment of the Inhibited Catalysts by Ethylenediaminetetraacetic Acid (EDTA). — The inhibited catalyst was boiled with 100 ml. of 0.5% aqueous solution of EDTA for 5 min., filtered, washed with water, methanol and ether, and finally dried in vacuo.

Acetylation of the Catalyst.—One hundred milligrams of the catalyst were boiled with 50 ml. of acetic anhydride for 2 hr., filtered, washed with ether, and dried in vacuo. The activity of this catalyst was measured by the same procedure used in testing nonacetylated catalyst.

Isolation of the Product.—*Hydrogenation of Allyl Alcohol, Acrolein and Mesityl Oxide.*—The reaction mixture was filtered and the filtrate was treated by gas chromatography; the products were identified as propyl alcohol, propionaldehyde, and isobutyl methyl ketone, respectively, and the yield estimated.

Hydrogenation of Maleic Acid.—The reaction mixture was filtered, the filtrate evaporated to 20 ml., and to this was added 20 ml. of water. After standing overnight, 3.7 g. of succinic acid (m. p. 179~181°C) was obtained. It was confirmed by infrared spectroscopy that the product had no unsaturated bond.

Found: C, 41.25; H, 5.17. Calcd. for $C_4H_6O_4$: C, 40.68; H, 5.12%.

Hydrogenation of Cinnamic Acid.—(i) The reaction mixture was filtered, the filtrate evaporated to 10 ml., and to this was added 20 ml. of 1 N hydrochloric acid. After standing in a refrigerator overnight, 6.4 g. of 2-phenylpropionic acid (m. p. 47.5°C) was obtained.

Found: C, 72.36; H, 6.74. Calcd. for $C_9H_{10}O_2$: C, 72.98; H, 6.71%.

(ii) An aqueous solution of cinnamic acid adjusted to pH 7.0 with sodium hydroxide, was subjected to hydrogenation. The reaction mixture was evaporated to 20 ml., and then acidified with 15 ml. of 2 N hydrochloric acid. After standing in a refrigerator overnight, 2.7 g. of 2-phenylpropionic acid (m. p. 49°C) was obtained.

Found: C, 72.15; H, 6.62. Calcd. for $C_9H_{10}O_2$: C, 71.98; H, 6.71%.

These products were proved to have no unsaturated bond, by infrared spectroscopy.

Reduction of Nitrobenzene and p-Nitrotoluene.—After filtration of the reaction mixture 10 g. of acetic anhydride was added to the filtrate. It was evaporated to dryness and the residue treated with a small amount of water. After standing 2.7 g. of acetanilide (m. p. 113~115°C) and 3.5 g. of *p*-acetotoluidide (m. p. 149°C) was obtained from aniline and *p*-toluidine, respectively.

Acetanilide. Found: N, 10.30. Calcd. for C_8H_9NO: 10.37%.

p-Acetotoluidide. Found: N, 9.28. Calcd. for $C_9H_{11}NO$: 9.39%.

Reduction of m-Nitrocinnamic Acid.—The reaction mixture was evaporated, and to this was added 25 ml. of 2 N hydrochloric acid. Obtained precipitate was filtered off, washed with water and dried in vacuo. (Dried weight, 800 mg.). The fiiltrate was concentrated to 50 ml., to the residue was added 2.5 g. of acetic anhydride and 2 g. of sodium acetate, and the mixture was stirred for 3 hr. Then, a mixture of *m*-acetaminocinnamic acid and 2-*m*-acetaminophenylpropionic acid was precipitated. *m*-Acetaminocinnamic acid content was estimated to be 49.5% by measuring hydrogen uptake on further hydrogenation of this mixture in methanol with Pd-C catalyst.

The mixture. Found: C, 63.15; H, 6.21; N, 6.83. Calcd. for $C_{11}H_{13}O_3N+C_{11}H_{11}O_3N$ (1 : 1): C, 64.07; H, 5.68; N, 6.80%.

Hydrogenation of 2-Butyne-1, 4-diol.—After filtration of the reaction mixture, the solvent was removed from the filtrate by evaporation, and the residue was dried in vacuo. The product was identified as 1, 4-butanediol by infrared spectroscopy.

Summary

1) The most active catalyst was obtained when 400 mg. of silk-fibroin was boiled with 30 ml. of 0.5% aqueous solution of rhodium chloride for ca. 30 min., and the resulting chelate was then reduced.

3) E. B. Sandell, "Colorimetric Determination of Traces of Metals", Interscience Publishers, New York (1959), p. 774.

2) The activity of this catalyst was not influenced significantly by the conditions for its preparation and was maintained or even increased greatly on storage for a long period. Benzyl mercaptan, ferric and cupric ions poisoned the catalyst, but the inhibition by the metal ions could be restored by ethylenediaminetetraacetic acid.

3) This catalyst was extremely active for the hydrogenation of the types C=C double bonds $C{=}CHCH_2OH$ and $C{=}CHCOOH$ but inactive for carbonyl groups. For the hydrogenation of other types of C=C double bonds and of nitro groups, the catalyst seems to be less active.

The authors are indebted to Dr. Heavey A. Itano of the National Institutes of Health, U. S. A., for his advice on preparing this manuscript. The authors wish to express their sincere thanks to Mr. Masami Imaida for his technical assistance throughout this investigation and to Miss Kiku Koike and Miss Masako Kawakita of this Institute for the elemental analysis.

The Anodic Behavior of Tin in an Alkaline Solution

By Masayoshi KATOH

(Received February 1, 1962)

In this paper, the anodic behavior of tin in an alkaline solution will be described.

Lowenheim[1] demonstrated that tin is anodically polarized through two potential stages in an alkaline solution. In the first stage, the anodic film of tin dissolves into the alkaline solution to form stannite ions at a relatively less noble potential. In the second stage, the anode becomes passive and shows quite a noble potential. Wakked[2] observed the same two stages, and he also showed that the film in the first stage consists of stannous hydroxide.

In contrast with the results of these previous investigators, in the present experiment the author has found three clearly distinguishable potential stages in the anodic polarization curves. This paper presents not only the polarization curves but also the nature of the film in each stage. The rate-determining step in the anodic dissolution process is also discussed.

Experimental

The study of the anodic polarization curves was carried out in a 100 ml. beaker containing a sodium hydroxide solution. The anode was polarized against a platinum cathode, and the anodic potentials were measured against a Hg-HgO reference electrode. The cell was sealed from the atmosphere and was so constructed as to bubble nitrogen or oxygen gas into the electrolytic solution through finely sintered glass.

A circular tin plate was used as the anode. Before being used, this specimen was polished with different grades of emery paper, and then its surface was rubbed with degreased cotton which had been wet by hot water. Finally it was rinsed with ethyl alcohol. Immediately after this treatment, the specimen was placed between two methacrylic resin plates. One of the plates had a circular hole, 0.3 cm^2 in area; this sized area was, therefore, exposed to the electrolytic solution as an anodically polarized electrode.

Results and Discussion

The Anodic Polarization Curves.—The anodic polarization curves of tin in a 0.1 N sodium hydroxide solution are shown in Fig. 1. It may be seen that these curves show three stages of dissolution potentials.

In order to examine the current efficiency and potential variation with time, experiments on the anodic dissolution of tin were carried out for several hours, under constant current densities at the potentials selected within the potential ranges of each stage in Fig. 1. These results are shown in Figs. 2 and 3.

In addition to these experiments, reversible

F: 2.2 mA, Curr. eff.=7.6%

potentials calculated from thermodynamic data[3] were taken into consideration. These values are given in Table I.

It will be seen from Fig. 1 that potentials in the former two stages nearly correspond to those listed in the first and the second lines, respectively, of Table I although the experimental values are slightly more noble than the table values. In the third stage, however, the anode indicates its passive state; here the potential becomes considerably more noble compared with any value listed in Table I. Since the first line of Table I shows the reversible potential value of the tin-stannous hydroxide system, the anodic film in the first stage seems to be stannous hydroxide. This was supported by the fact, shown in Fig. 2, that the current efficiencies in the first stage were nearly equal to 100%, if the current efficiencies were determined from the actual weight loss of anode and from the theoretical weight loss calculated by Faraday's law, assuming that tin was dissolved as a divalent species, i. e., stannous ion. In another experiment, the concentration of stannite ion and the total of tin in the electrolytic solution were determined after the electrolysis; the ratio between the two was found to be 0.9. This provides another evidence as to the nature of the anodic film mentioned above.

TABLE I. REVERSIBLE POTENTIALS OF HALF CELLS CALCULATED EROM FREE ENERGY

Half cell	Potential vs. Hg-HgO-0.1 N NaOH V.
$Sn-Sn(OH)_2$-0.1 N NaOH	−0.973
$Sn(OH)_2-Sn(OH)_4$-0.1 N NaOH	−0.873
$Sn-Sn(OH)_4$-0.1 N NaOH	−0.923
Sn-SnO-0.1 N NaOH	−1.036
$SnO-SnO_2$-0.1 N NaOH	−1.193

3) W. M. Latimer, "The Oxidation States of the Elements and their Potentials in Aqueous Solutions", Prentice-Hall Inc., New York (1952), p. 148.

In the second stage, the potential nearly corresponds to that of the stannous hydroxide-stannic hydroxide system, as can be seen from Table I. This result may allow us to suppose that the film consists of stannic hydroxide under which stannous hydroxide is present. However, it was found from the experiment represented by Fig. 2 that the film dissolved into both stannite and stannate ions, since the current efficiencies in that stage were about 70 to 80% and the ratio, defined as before, was about 0.64 in a nitrogen atmosphere. Moreover, the film did not have the characteristic white appearance of stannic hydroxide, but, rather, was black. The film in the second stage, therefore, can not be stannic hydroxide; it is more appropriate to consider that the film consists of some sorts of reaction products from stannic and stannous hydroxides. In order to ascertain this, another experiment was performed in which four kinds of half cells were constructed from freshly prepared components. The potentials of these cells are tabulated in Table II. The results indicate that the potential at the second stage in Fig. 1 approximately coincides with that of the third line in the table, although the former potential is slightly more noble than the latter, probably owing to ohmic polarization. This confirms the reasonableness of the consideration described above.

Table II. Potentials of half cells which were freshly prepared

Half cell	Potential vs. Hg-HgO-0.1 N NaOH V.
$Sn-Sn(OH)_2$-0.1 N NaOH	−0.980
$Sn-Sn(OH)_4$-0.1 N NaOH	−0.73～−0.75
$Sn-Sn(OH)_2$ and $Sn(OH)_4$ mix. −0.1 N NaOH	−0.86～−0.89

Some other knowledge of the nature of the film can be derived from Figs. 2 and 3. As can be seen from Fig. 2, the open circuit potential of tin in a nitrogen atmosphere is the same as that of the fourth line in Table I, so that a protective layer of stannous oxide, which is sparingly soluble, may be presumed to exist on the tin surface. In an oxygen atmosphere, however, the open circuit potential corresponds well to that of the first lines in both Tables I and II. This indicates that stannous hydroxide is present on the tin surface even as a result of simple immersion; thus, it can easily be supposed that stannous hydroxide is formed not only by electrochemical reaction but also by chemical reaction. The abnormally high current efficiency, over 100% in the oxygen atmosphere, as shown in Fig. 3,

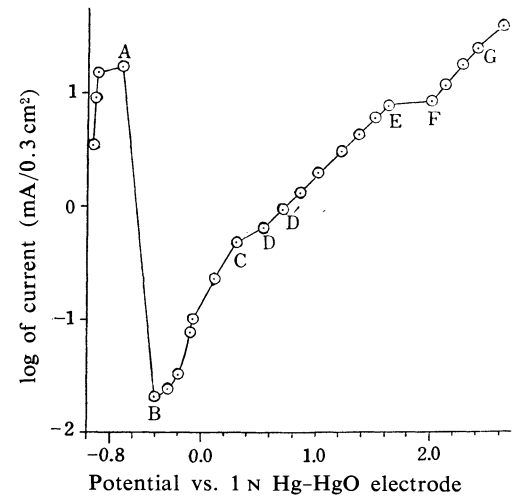

Fig. 4. Anodic polarization curve in 1.0 N sodium hydroxide solution.

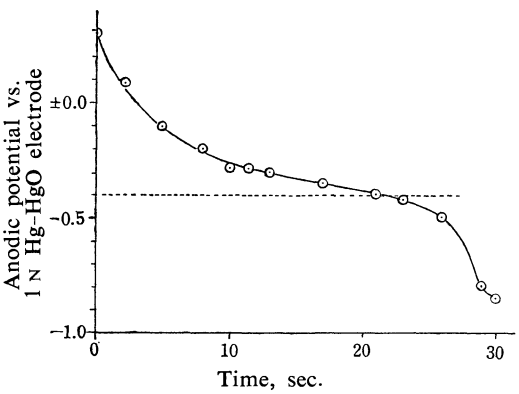

Fig. 5. Decay curve after cutting off the current at C in Fig. 4.

can be attributed to such a chemical process. It may also be found from Figs. 2 and 3 that a long duration of electrolysis at the first or the second stage does not give any passivity to the anode which might be caused by the growth of the film.

When the current density was increased beyond the second stage to reach the third stage, passivation occurred in which oxygen evolved at the anode. The process of this passivation can be more clearly observed in Fig. 4, in which the logarithm of current density is plotted against the anodic potential. The potential bordered on activation and passivation, which is generally known as the Frade potential, can be seen to be −0.400 V.

vs. the 1 N Hg–HgO reference electrode, which is indicated at B in Fig. 4. A decay curve of the potential after the current at C in Fig. 4 had been cut off was also drawn from the measured values, where a stagnation was observed at about −0.40 V., as is shown in Fig. 5. This potential coincides well with the potential at B in Fig. 4. As the anode was polarized beyond the Frade potential, three different stages were observed, the first of which was in BC before the oxygen evolution. If the anodic potential reached D', oxygen was evolved and a bright yellow surface was observed until the potential was raised to E. Further polarization, however, altered the surface state considerably; the color of the film changed to dark black from bright yellow and a different Tafel line appeared. The yellow film in the D'E region was found to be relatively more soluble compared with the dark film in FG and dissolved to give a stannate ion with about a 10% current effiiciency. In the electroplating process of tin, the anode is generally controlled to maintain the yellow color in order to obtain the stannate ion, and so it can be seen that this state corresponds to that of the D'E region.

Relation between the Alkaline Concentration and the Limitting Current Density.—The same type of polarization curves as shown in various alkaline concentrations, so that the limiting current densities reaching the second or the third stage from the first or the second stage could be measured for various concentrations. The experiment was carried out under atmospheric conditions, and the electrolytic solution was not stirred. These results are shown in Fig. 6.

It has been seen from the previous experiments that the limiting current density is governed by the transference of the hydroxide ion from the bulk of the solution to an active site where the anode takes part in the reaction. In this case, it is not necessary to make consider the diffusion of the stannate or stannite ions from the active site to the bulk of the solution, because changes in the concentration of either ion did not appreciably alter the limiting current density. According to Fick's law, the current density I, which responds to the transference of the hydroxyl ions from the bulk of the solution to the surface of the film, is given by[4]:

$$I=\frac{D\cdot nF}{(1-t_{OH^-})\delta}(a-a_c) \tag{1}$$

where t_{OH^-} and D represent the transference number and the diffusion coefficient of the hydroxide ion respectively, δ is the thickness of the diffusion layer in the solution, a and a_c are the activities of the ion in the bulk of the solution and at the surface of the film respectively, and n is the valency of the ion.

In order for the anodic reaction to take place, the hydroxide ion must reach the active site by passing through the film. Although the mechanism concerning such an ionic transference is little known, Fick's law may also be adopted in this case; it so, the current density I in the film may be expressed by the following equation:

$$I=\frac{D'\cdot nF}{(1-t'_{OH^-})\delta'}(a_c-a_d) \tag{2}$$

where t'_{OH^-} and D' are the transference number and the diffusion coefficient of the hydroxide ion in the film respectively, δ' is the thickness of the film, and a_d is the activity of the hydroxide ion at the active site. Since the current densities I in both Eqs. 1 and 2 should be equal, Eq. 1 can be combined with Eq. 2, in which case the current density I may be rewritten as:

$$I=\frac{a-a_d}{(1-t_{OH^-})\delta/D\cdot nF+(1-t'_{OH^-})\delta'/D'\cdot nF} \tag{3}$$

When the current density is increased to the maximum value, which is represented by I_L, a_d should be almost epual to zero, and hence I_L is given by:

$$I_L=\frac{a}{(1-t_{OH^-})\delta/D\cdot nF+(1-t'_{OH^-})\delta'/D'\cdot nF} \tag{4}$$

It follows from this equation that the relation of the limiting current density to the concentration of the hydroxide ions would be a linear function provided that the denominator of Eq. 4 is constant. As can be seen from Fig. 6, this relation is actually satisfied in the region

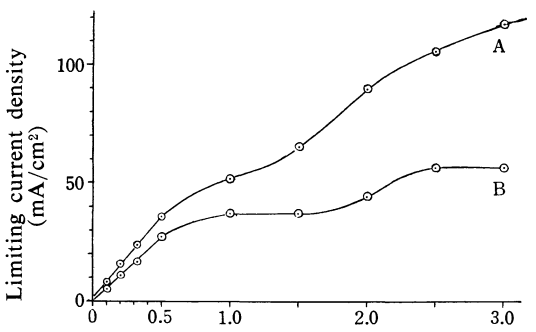

Fig. 6. Relation between alkaline concentration and limiting current density, I_L.
A I_L, from the second stage to the passive stage
B I_L, from the first stage to the second stage

of 0~0.5 N sodium hydroxide. In the denominator of Eq. 4, it is considered that the first and the second terms correspond to resistances for the transference of hydroxide ions throughout the diffusion layers in solution and in film respectively. Therefore, if each term is known, it can be determined in which layer the rate-determining step exists. In the case of the limiting current density reaching the third stage from the second stage, the first term was calculated to be 0.44×10^{-2} up to a 0.5 N concentration at 30°C by introducing the following values:

$t_{OH^-}=0.817$, $F=96500$ coulombs,

$\delta=0.05$ cm.[4], $D=2.14\times10^{-5}$ cm$^2\cdot$sec^{-1}

The sum of the first and the second terms in the denominator of Eq. 4 (i. e., a/I_L), could be obtained from the slope of the straight line in Fig. 6; it was 1.0×10^{-2} up to a 0.5 N concentration. Thus, the second term could be evaluated by subtracting the first term from a/I_L; it was found to be 0.56×10^{-2}. From these values, it may be stated that the diffusion layers in solution and in film both equally resist the transference of hydroxide ions up to a 0.5 N concentration.

As the concentration is increased beyond 0.5 N, however, the slope in Fig. 6 tends to become less steep, although still not proportional to the concentration, and the linear function no longer obtains. This indicates that the denominator of Eq. 4 begins to increase and shows no constant value. According to one table[5], any value in the first term is almost independent of the alkaline concentration. This means, therefore, that the second term tends to increase and is not constant. Since the increase of the second term means an increase of δ' and a decrease of D', it follows that thickening of the film should occur. Therefore, it can be concluded that the rate-determining step is the process in which hydroxide ions reach the active site by passing through the film.

The limiting current density reaching the second stage from the first stage can be treated in the same manner as above. Equation 4 may still be employed, because the electrode process still proceeds by replenishment of the hydroxide ions.

Since a linear function was obtained in the region of 0~0.5 N sodium hydroxide solutions, the first and the second terms of the denominator in Eq. 4 were calculated to be 0.44 and 1.19 respectively. This indicates that the rate of the transference of the hydroxide ion is practically determined by the rate of its passage through the film of stannous hydroxide; that is, the film of the first stage resists the transference of the hydroxide ion more intensely than the film of the second stage.

Relations between the Electronic Absorption Spectra and the Spatial Configurations of Conjugated Systems. XII. The Intensity and the Shape of the Conjugation Band

By Hiroshi SUZUKI

(Received June 22, 1962)

The preceding parts[1] of this series dealt mainly with a rather restricted aspect of the theme. That is, they dealt mainly with the relation between the wavelength position of the absorption maximum of the conjugation band and the most probable configuration of the molecule in some conjugated hydrocarbon systems, such as biphenyl, styrene and stilbene. In the present paper, other aspects of the subject, especially the relations between the intensity, as well as the shape of the conjugation band, and the spatial configuration of the molecule, are discussed for the foregoing systems as representatives of alternant hydrocarbon systems.

1) H. Suzuki, This Bulletin, (I) **32**, 1340; (II) 1350; (III) 1357 (1959); (IV) **33**, 109; (V) 379; (VI) 389; (VII) 396; (VIII) 406; (IX) 410; (X) 613; (XI) 619 (1960).

Calculation of the Transition Moment as a Function of the Angle of Twist

It is well known that in such conjugated hydrocarbon system as the foregoing, steric hindrance to the planarity of the system exerts a hypochromic as well as a hypsochromic effect on the conjugation band.

The steric hindrance may be considered to be relieved, to a first approximation, only by a twist of the formally single bond or bonds, e.g., the co-annular bond in the biphenyl system, the bond linking the phenyl group to the ethylenic carbon atom in the styrene system, and the similar bonds in the stilbene system. (These "single" bonds are referred to as the pivot bonds.) On the basis of this assumption, in the preceding parts of this series, the energy of a one-electron transition from the highest occupied π-orbital, ψ_{+1}, to the lowest vacant one, ψ_{-1}, was calculated, by the simple LCAO MO method, as a function of the angle of the twist of the pivot bond for each of these systems and was correlated with the wavelength of the maximum of the conjugation band for a number of the compounds of the system. In spite of the simplicity of the method used, the correlation was almost completely satisfactory. Thus, it may be said that an almost satisfactory explanation of the steric hypsochromic effect in these conjugated systems was obtained. Therefore, it may be of some interest to see whether the steric hypochromic effect, i.e., the reduction of the intensity of the band due to steric hindrance to the planarity of the conjugated system, can be explained by extending the simple MO treatment.

The resonance integral of the atomic orbitals χ_i and χ_j is denoted by $\rho_{ij}\beta$, β representing the π-π resonance integral for adjacent carbon atoms in the benzene ring. The parameter, ρ_{ij}, is determined by the distance, R_{ij}, between atoms i and j as well as by the angle of twist, θ_{ij}, of the bond, i.e., the angle by which the axes of χ_i and χ_j are twisted with respect to each other. If it is assumed that the bond length, R_{ij}, is constant, ρ_{ij} can be taken to be proportional to $\cos\theta_{ij}$.

On the basis of the orbital energies calculated as functions of ρ_{piv} in the preceding parts of this series, the coefficients of the atomic orbitals in the molecular orbitals ψ_{-1} and ψ_{+1} and then the transition moment, $M_{-1,+1}$, have been calculated as functions of ρ_{piv}. The transition moment is, needless to say, expressed as:

$$M_{-1,+1}=\sqrt{2}\int\psi_{-1}\,q\psi_{+1}\mathrm{d}\tau$$

where q and $\mathrm{d}\tau$ are the position coordinate of the electron and the volume element of the space of the coordinate respectively. By the way, the subscript $-1,+1$ refers to quantities concerning the transition from ψ_{+1} to ψ_{-1}, while the subscript piv refers to quantities concerning the pivot bond. These subscripts are subsequently often omitted for the sake of brevity if no confusion is possible. In the calculations, the relation between ρ and θ as well as R assumed in the preceding parts has been used for each system, and all the bond angles at the carbon atoms in the conjugated skeleton have been assumed to be 120°. The results are shown in Fig. 1, in which the values of the square of the transition moment, namely, the dipole strength of the transition (in units of Å^2), are plotted against θ_{piv}.

The oscillator strength, f, is related to the transition moment by the usual equation;

$$f=1.085\times10^{-5}\nu M^2$$

where ν is the wave number (in cm^{-1}) at which the absorption due to the transition occurs. In the previous papers, the wave number to be observed was correlated with the transition energy, ΔE, calculated as a function of θ for each of the systems. Accordingly, by the use of the relation, the f-value can be calculated as a function of θ for each system. The calculated f-value, which is designated as f_{theor}, for the stilbene system is also graphed in Fig. 1.

It can be clearly seen in this figure that the dipole strength of the transition, as well as the oscillator strength, of each system becomes

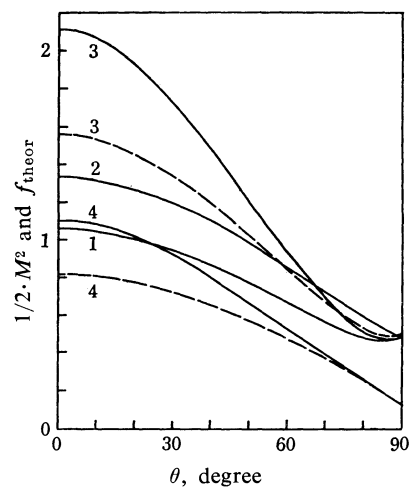

Fig. 1. Relations between the transition moment, M, as well as the calculated oscillator strength, f_{theor}, of the conjugation band and the angle of twist of the "single" bond, θ. Solid lines are for $1/2\cdot M^2$ (in Å^2); broken lines, for f_{theor} 1, styrene 2, biphenyl 3, *trans*-stilbene 4, *cis*-stilbene.

smaller as the value of θ becomes larger. This means that the intensity of the conjugation band will become lower as the deviation from the planarity of the conjugated system increases, a trend which is in agreement with observation. It may be noted here that the variation in the dipole strength of the transition associated with the variation of ρ_{piv} is roughly linear in each of the systems.

A Comparison of the Theoretical Values with the Experimental Values of Oscillator Strength

The oscillator strength can be estimated from the absorption curve by means of the usual equation:

$$f=4.317\times10^{-9}\int\varepsilon_{\nu}\mathrm{d}\nu$$

where ε_{ν} is the molar extinction coefficient at wave number ν and the integral is the integrated intensity of the absorption band concerned. The value of the oscillator strength estimated from the observed spectrum is designated as f_{exp}.

In Table I, for some compounds of the conjugated systems under consideration and, in addition, for butadiene, the values of f_{theor} and f_{exp} are listed, together with some relevant data.

The f_{theor}-Values.—The values of θ are those evaluated from the wavelengths of the absorption maxima in the previous parts of this series, and the transition moments have been calculated on the basis of these θ values. That is, the transition moment of each compound has been calculated for the most probable configuration of the conjugated system, and no electronic (probably small hyperchromic) effects which the substituents may exert on the absorption intensity have been taken into account.

For tetraphenylethylene, the model in which all of the phenyl groups are rotated out of the plane of the central ethylenic bond to the same extent was used as the basis for the calculation of the transition moment, according to the conclusion made in Part VI of this series.

For butadiene, the calculation has been carried out on the basis of the planar s-trans model in which the lengths of the "double" bonds and of the "single" bond are 1.34Å and 1.48Å respectively.

The f_{exp}-Values.—The f_{exp}-values for most compounds were estimated from the absorption spectra reported in Parts I, II, V and VII of this series. The spectra of biphenyl, tetraphenylethylene and tolan reported in Parts I and VI were found to be somewhat inaccurate with respect to the absorption intensity. Accordingly, the f_{exp}-values for these compounds (the entry numbers 4, 13 and 14) were estimated on the basis of the newly redetermined spectra. The experimental data for the entry

14	Tolan	280	316	0	4.804	1.862	0.700	2.66	222	233

The notation is as follows: λ and ε, the wavelength and the molar extinction coefficient of the maximum of the conjugation band respectively; θ, the angle of twist of the "single" bond in the most probable configuration; M, the calculated transition moment; f_{theor} and f_{exp}, the theoretical and the experimental oscillator strength respectively; $\Delta\nu$, the wave number interval between the absorption maximum and the point of half the maximum intensity at a longer wavelength than the maximum.

numbers 1[2,3], 2[4], 3[5] and 5[6] have been taken from papers of other authors. All the spectral data are for the solution in *n*-heptane at room temperature except where otherwise indicated.

It is difficult to determine unambiguously the intrinsic band envelope and, hence, the integrated intensity of the conjugation band as differentiated from neighboring bands. For each of the compounds of entry numbers 4, 7, 10, 13 and 14, the area under the absorption curve at wave numbers lower than the absorption minimum between the conjugation band and the neighboring band lying at higher wave numbers was taken as an approximation of the integrated intensity of the conjugation band, since with these compounds the conjugation band is comparatively well resolved from its neighbor.

With the compounds of entry numbers 6, 8, 9, 11 and 12, the conjugation band itself is situated at quite a high wave number and has quite a low intensity; hence, the resolution of the band from the neighboring band is very unsatisfactory. Therefore, for these compounds, twice the area under the absorption curve at wave numbers lower than the absorption maximum was taken as a rough appoximation of the integrated intensity of the conjugation band.

Comparison of f_{theor}- and f_{exp}-Values.—It is well known that the value of f calculated by the simple MO method is in general too high by a factor of about 2~3. This general tendency is considered to be due to the essential character of the method, which does not take account of interactions among electrons and hence tends to over-estimate the delocalization of the molecular orbitals[7]. This appears to be inevitable when any one single electronic configuration is used. In this respect, the present calculation is not an exception. Thus, the ratios of f_{theor} to f_{exp} are about 2~3.

Apart from the discrepancy in the absolute values, quite a good correspondence is found between the f_{theor} values and the f_{exp} values. This can be seen more clearly in Fig. 2, in which the f_{theor} values are plotted against the corresponding f_{exp} values. Considering the uncertainty involved in the estimation of the f_{exp} values, as well as the simplification made in the calculation of the f_{theor} values, it may be said that the correspondence is rather

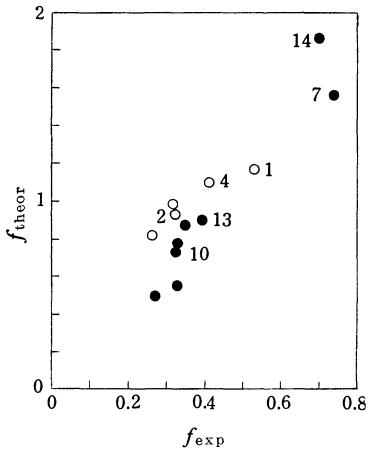

Fig. 2. Relations between the theoretical values, f_{theor}, and the experimental values, f_{exp}, of the oscillator strength of the conjugation band. ○, for the compounds of the entry numbers 1—6 in Table I; ●, for the compounds of the entry numbers 7—14 (the compounds of the stilbene system, including tolan).

unexpectedly good. Especially, it may be noted that the points for the compounds belonging to the stilbene system (entry numbers 7, 8, 9, 10 and 13), with the exception of two *cis*-dialkylstilbenes and tolan, fall nearly on a smooth line passing through the origin.

This almost satisfactory correspondence of the f_{theor} values to the f_{exp} values may be considered to validate the present treatment. Thus, it may be concluded that the reduction of the intensity, as well as the shift toward shorter wavelengths, of the conjugation band caused by steric hindrance to the planarity of the conjugated system has been almost satisfactorily explained solely by the change in the π-electronic states of the molecule associated with the change of the most probable configuration.

Basic Assumptions in the Present Treatment

One of the basic assumptions underlying the treatment developed throughout the present series of papers is that the steric hindrance to the planarity of the conjugated system is relieved to a first approximation only by a twist of the formally single bond or bonds. Any twist of such a bond should not affect the σ-bond energy, and, since such a bond has a relatively low π-bond order in the electronic ground state, the loss of the delocalization energy of the π-electrons associated with the twist should be relatively small. Furthermore, it is expected that such a twist will, in most cases, rapidly reduce the steric repulsion

between non-bonding atoms. The above assumption is quite admissible.

Two other important underlying assumptions are that the molecules with the most probable configuration in the electronic ground state make the most important contribution to the absorption band and that the absorption maximum corresponds to the vertical transition in such molecules. These assumptions might appear to be self-evident. However, since the explanations of the steric hypochromic effect proposed by some other authors seem to be based on an idea quite opposed to this assumption, and, further, in order to provide a basis for a later discussion of the shape of the band, they will be discussed here in some detail.

The potential energy curve of any electronic state for the twist of a "single" bond can be considered to be determined primarily by the sum of the π-electronic energy of the state and of the steric repulsion energy as functions of the angle of twist. Such a potential energy curve may be relatively shallow; hence, the separations of the vibrational levels may be relatively small, compared, for example, with those for the stretching vibrational mode of a "double" bond.

According to the classical theory, the molecules in each vibrational level can be considered to stay predominantly at the turning points of the vibrational motion. Therefore, according to the Franck-Condon principle, the most probable of the electronic transitions which a molecule in a vibrational state associated with the electronic ground state can give rise to should be the transition vertically upward in the potential energy diagram from each of the turning points of the vibrational level to the point on the potential energy curve of the electronic upper state. The energy of such a vertical transition is the difference between the potential energies of the two points and, hence, should be equal to the difference between the π-electronic energies in the configuration characterized by the angle of twist, the contributions of other factors such as steric repulsion energy and σ-electronic energy to the potential energies of the two points being considered to be identical because the transition does not involve any change in the spatial configuration of the molecule. This consideration justifies that treatment in the present series by which the energy difference between the two π-orbitals, ψ_{-1} and ψ_{+1}, calculated as a function of θ, namely, $\Delta E_{-1,+1}(\theta)$, has been correlated directly with the wave number of the observed absorption band.

The wave number corresponding to $\Delta E(\theta)$ is denoted by $\nu(\theta)$, and the transtion moment and the oscillator strength of this transition are denoted by $M(\theta)$ and $f(\theta)$ respectively. The population ratio of the configuration characterized by θ in the electronic ground state is denoted by $P^G(\theta)$. The value of θ at which the value of $P^G(\theta)$ is at its maximum is denoted by θ^G_{max}, which may be considered to agree approximately with the value of θ at the minimum of the potential energy curve, namely, θ^G_{eq}, in which the subscript eq is an abbreviation for "equilibrium".

The contribution of any configuration to the absorption is proportional to the product of the population ratio of the configuration and the transition probability in the configuration. Accordingly, the absorption intensity, $\varepsilon(\theta)$, at the wave number, $\nu(\theta)$, can be taken to be approximately proportional to $f(\theta)\cdot P^G(\theta)$.

The value of f, as well as that of M^2, decreases comparatively slowly as the value of θ becomes larger, as is seen in Fig. 1. Roughly speaking, the larger the value of θ, the larger the increase of f as well as of M^2 associated with a decrease of θ. Thus, in the conjugated hydrocarbon systems treated in the present paper, the variation of f as well as of M^2 is approximately linear to cos θ.

On the other hand, the distribution curve of $P^G(\theta)$ versus θ may be relatively steep. Thus, the value of $P^G(\theta)$ may decrease comparatively rapidly as the value of θ is separated in both directions from that of θ^G_{max}. In cases where steric hindrance is involved, the larger the steric hindrance, the larger the value of θ^G_{max} and, probably, the larger the decrease of $P^G(\theta)$ associated with a decrease of θ from θ^G_{max}.

Therefore, it is quite reasonable to expect that the angle of twist, θ, at which the value of $f(\theta)\cdot P^G(\theta)$ is at its maximum agrees almost completely with θ^G_{max}, i. e., the angle of twist in the most probable configuration. Thus, the maximum of the absorption band may be considered to originate in molecules with the most probable configuration.

The oscillator strength of the band should be expressed as:

$$f=\int f(\theta)\cdot P^G(\theta)\cdot d\theta$$

Judging from the above-mentioned feature or the dependence of $f(\theta)$ as well as of $P^G(\theta)$ on θ, it is evident that f can be well approximated by $f(\theta^G_{max})$.

On Some Other Explanations of the Steric Hypochromic Effect

The Explanation of Jaffé and Orchin.—Jaffé and Orchin[8] recently proposed a "Franck-Condon effect" as an important cause of the

8) H. H. Jaffé and M. Orchin, *J. Chem. Soc.*, 1960, 1078.

steric hypochromic effect observed with the conjugation band of such sterically hindered compounds as sterically hindered stilbenes. Their basic theory is that only the vertical transitions to the lowest vibrational level of the electronic upper state should be allowed. Thus, according to them, if the values of θ at the turning points of the lowest vibrational level of the twisting mode of the "single" bond in the electronic excited state are denoted by $\theta^{E}_{<}$ and $\theta^{E}_{>}$, only the molecules with the value of θ in the range between $\theta^{E}_{<}$ and $\theta^{E}_{>}$ in the electronic ground state can give rise to a transition to the electronic excited state, and any transition in the molecules with θ outside the range is forbidden. Accordingly, the observed intensity of the band should be reduced below the value predicted from the theoretical oscillator strength by the ratio of the number of the molecules with θ in the range to the whole number of the molecules in the electronic ground state. The greater the steric hindrance, the smaller this ratio will be. This is the gist of Jaffé and Orchin's explanation of the "Franck-Condon effect".

This explanation is in conflict with the basic assumptions of the present treatment. From the considerations given above, it is evident that the explanation by Jaffé and Orchin is invalid. In addition, they seem to confuse the probability density distribution in the lowest vibrational state in the electronic ground state with the distribution of population among various vibrational states in the electronic state; furthermore, it seems not to be clear whether they discuss the intensity of the absorption maximum or the integrated intensity of the entire band.

The Explanation of Braude.—The argument of Jaffé and Orchin is similar to the explanation by Braude of the so-called type 1 steric effect, i. e., the decrease in the intensity of the conjugation band without any appreciable accompanying wavelength displacement of the band observed with sterically hindered compounds, e. g., *o*-substituted acetophenones, as compared with the sterically unhindered parent compound. Braude and his co-workers[9,10] ascribed this decrease in the intensity to the decrease in the population ratio of the planar or near-planar configuration in the electronic ground state. This theory means that, with sterically hindered compounds, the maximum absorption does not originate in the most probable non-planar configuration but in the less probable, energetically unfavorable, planar or near-planar configuration; this is contrary to the basic assumptions of the present treatment. The theory of Braude is evidently based on the concept that the absorptions at nearly identical wavelengths should be due to the transitions in the nearly identical configurations; it also tacitly involves the assumption that the transition in non-planar configurations is impossible or nearly so.

In general, the direction and the magnitude of the change of the transition energy caused by a twist of a bond depend on the sign and the magnitude of the change in the π-bond order of the bond associated with the transition[11,12] and, hence, essentially on the nature of the orbitals between which the transition occurs[13]. In some cases, it is possible that a quite large change of the molecular configuration results in substantially no change or a very small change in the transition energy. Therefore, absorptions at the identical wavelength do not necessarily mean that they originate in the identical configuration.

As is shown above, the transition moment varies continuously with θ in the cases of the conjugated hydrocarbon systems. As will be discussed later in this series, the situation is not so very different in the case of the phenylcarbonyl system, i. e., the acetophenone or benzaldehyde system, which was cited by Braude as representative of the systems exhibiting the so-called type 1 steric effect. The assumption that the transition in non-planar configurations is substantially impossible is untenable. Furthermore, it has been demonstrated experimentally by Waight and Erskine[14] that the maximum absorption should be considered to originate in the transition in the most probable non-planar configuration, even in the case of sterically hindered acetophenones.

The Shape of the Conjugation Band

Potential Energy Curves for the Twisting Mode.—It is a notable fact that the conjugation band of *trans*-stilbene exhibits a well-resolved vibrational fine structure, even at room temperature, whereas the bands of sterically-hindered related compounds are structureless. A similar situation can be found in many other conjugated systems.

We shall now attempt, on the basis of the considerations so far described, to relate the shape of the conjugation band to the steric hindrance to the planarity of the conjugation system. With this end in view, the potential

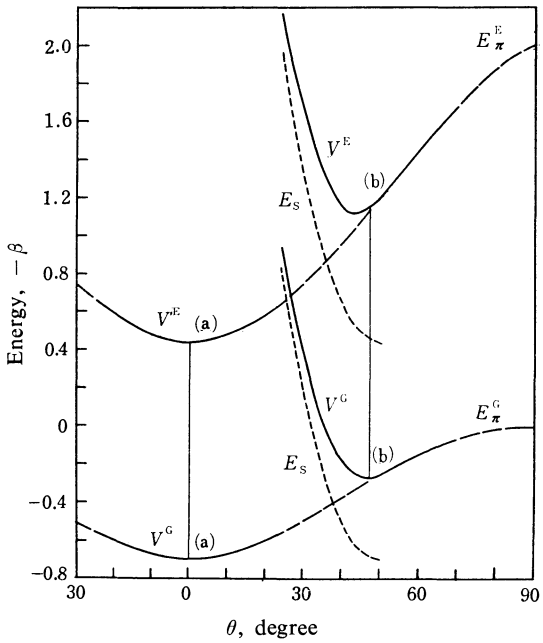

Fig. 3. Potential energy diagram for the stilbene system. V, potential energies (solid lines) as functions of the angle of twist of the "single" bonds, θ: (a) for the sterically unhindered compound; (b) for a sterically hindered compound. E_π, π-electronic energies (broken lines). E_S, steric repulsion energy (dotted lines).

energy curves for the twisting of the pivot bonds are first examined.

In Fig. 3, the calculated π-electronic energy ($E^G{}_\pi$) of the ground state of the stilbene system and that ($E^E{}_\pi$) of the excited state which arises from the transition of an electron from ψ_{+1} to ψ_{-1} are plotted against θ, these curves being shown as broken lines. In this figure, the energy of the ground state when θ is 90° is taken as the reference zero energy, while the unit of energy is $-\beta$. By the way, the superscripts G and E refer to the electronic ground state and the electronic excited state respectively throughout the present paper. The quantity $-E^G{}_\pi$ is the so-called extra-resonance energy and is approximately proportional to $\rho^2{}_{piv}$ and, hence, to $\cos^2\theta_{piv}$. The difference between $E^E{}_\pi$ and $E^G{}_\pi$ is the transition energy and increases, roughly speaking, linearly with the decreasing value of ρ_{piv} and, hence, of $\cos\theta_{piv}$. The $E^E{}_\pi$-curve is, of course, steeper than the $E^G{}_\pi$-curve.

Also in Fig. 3, the curves for the steric repulsion energy (E_S) as a function of θ for a hindered case are arbitrarily depicted as dotted lines. The curves for the resultant potential energy (V) as the sum of E_π and E_S for the unhindered case and for the hindered case are shown as solid lines.

In the unhindered case, the V-curves coincide with the E_π-curves; therefore, $\theta^G{}_{eq}=\theta^E{}_{eq}=0°$, where θ_{eq} represents the equilibrium angle of the twist, i.e., θ at the minimum of the V-curve.

In the hindered case, the V of each electronic state is regarded as the sum of E_π of the state and E_S, which is considered to be identical in both the states. Since $E^E{}_\pi$ increases more rapidly than $E^G{}_\pi$ does as θ becomes larger, there must be this relation: $\theta^G{}_{eq}>\theta^E{}_{eq}>0°$.

The E_S-curve may be quite steep. The E_π-curves are steeper at a larger value of θ, except when θ is extremely large. Therefore, if the steric hindrance is not so slight, the V-curves in the sterically hindered case may be steeper than the corresponding ones in the unhindered case. At least, there seems to be no reason to believe that the latter should be distinctly steeper than the former.

Distribution of Configurations in the Ground State.—As has been mentioned above, the V^G-curve in the sterically hindered case may be steeper than that in the unhindered case. Accordingly, the distribution curve of the population of configurations characterized by θ in the electronic ground state, namely, the $P^G(\theta)\sim\theta$ curve, which can be considered to have its maximum at $\theta^G{}_{eq}$, may be broader in the unhindered case than in the hindered case.

However, if $P^G(\theta)$ is plotted against $\Delta E(\theta)$ or $\nu(\theta)$ instead of θ, a distribution curve with quite different features will result. As has been mentioned already, the configuration characterized by θ can be considered to be characterized also by $\Delta E(\theta)$ or $\nu(\theta)$. $\Delta E(\theta)$ and $\nu(\theta)$ vary roughly linearly with ρ and, hence, with $\cos\theta$. Therefore, if $\theta^G{}_{eq}$ is small, even though the distribution curve with respect to θ is comparatively broad, the distribution curve with respect to $\Delta E(\theta)$ or $\nu(\theta)$ will be quite steep. This means that, in this case, even quite a wide variation of θ will give rise to the transition in quite a narrow range of wave numbers. On the other hand, if $\theta^G{}_{eq}$ is fairly large, even if θ varies within a comparatively limited range around $\theta^G{}_{eq}$, the variation of θ will give rise to the transition in a comparatively wide range of wave numbers. Thus, from the consideration of the distribution of configurations in the electronic ground state, it may be expected that the conjugation bands of the sterically hindered compounds are broader than that of the unhindered parent compound.

By the way, since $-E^G{}_\pi$, i.e., the extra-resonance energy, can be considered to be approximately proportional to $\cos^2\theta$, it can be roughly related with $\Delta E(\theta)$ and $\nu(\theta)$ as follows:

$$-E^{G}{}_{\pi}(\theta) \propto [\Delta E(90°) - \Delta E(\theta)]^2$$
$$\propto [\nu(90°) - \nu(\theta)]^2$$

Intensity Distribution among Transitions of Vibrational Progression.—The total probability of the transition from a vibrational state associated with the electronic ground state to the electronic excited state is distributed among transitions to vibrational states associated with the electronic excited state in proportion to the square of the overlap integral of the eigenfunctions of the two vibrational states involved.

The vibrational quantum number is represented by v and, as has been mentioned already, the electronic states are denoted by the superscripts G and E respectively. The lowest vibrational state associated with the electronic ground state, i. e., the state for which v^G is 0, is admittedly most densely populated, and the transition from this state should make the most important contribution to the absorption band, as has been discussed above.

In general, for $v=0$, there is a broad maximum of the probability density distribution approximately above the minimum of the potential energy curve. On the other hand, for $v \neq 0$, there is a broad maximum of the probability density distribution in the neighborhood of each of the classical turning points of the vibrational motion, but lying somewhat more toward the center. In a series of transitions from the state for which $v^G=0$, the overlap integral has a maximum value for the transition to the v^E state which has the broad maximum of its probability distribution vertically above the minimum of the potential energy curve of the electronic ground state. Therefore, the further the minima of the potential energy curves of the two electronic states are separated from each other, and the steeper the upper potential energy curve, the higher the v^E-value of the most probable transition from the $v^G=0$ state will be and the greater the variety of v^E states will be, among transitions to which the total transition probability is distributed[15].

As has been mentioned above, in the unhindered case, $\theta^G{}_{eq}=\theta^E{}_{eq}=0°$. Therefore, in this case, the transition probability from the $v^G=0$ state will be concentrated mostly in the 0−0 band. On the other hand, in the hindered case, $\theta^G{}_{eq} > \theta^E{}_{eq} > 0°$, and the upper potential energy curve may be steeper than that in the unhindered case. Therefore, in this case, the transition probability from the $v^G=0$ state will be broadly distributed among transitions to a comparatively large number of v^E states.

The Shape of the Band.—From the considerations of both the distribution of the population of configurations in the electronic ground state and of the intensity distribution among transitions from the most probable vibrational state associated with the electronic ground state to various vibrational states associated with the electronic excited state, it is expected that, in the unhindered case, the absorption will occur over a comparatively narrow range of wavelengths and that the greater the steric hindrance, the wider the range of wavelengths over which the absorption will occur. Thus, as far as the twisting mode about the single bonds is concerned, it is expected that the absorption band will be broadened by the steric hindrance.

This expected effect of steric hindrance in broadening the absorption band may be of two kinds: (a) a broadening of the whole band system or (b) a broadening of individual absorption lines originating in the other kind of vibrational mode and, consequently, a blurring of the fine structure of the band.

The half-band-width, as well as the ratio of the integrated intensity or the oscillator strength to the intensity of the absorption maximum, may be taken as a measure of the broadness of the band as a whole. In Table I, instead of the half-band-width, the wave number interval between the absorption maximum and the point of half the intensity of the maximum at a longer wavelength than the maximum, which is referred to as $\Delta\nu$, is presented, together with the $f_{exp}/\varepsilon_{max}$ ratio for each compound.

It seems that there is, in gross, a trend in conformity with the above expectations, although it is doubtful, because of uncertainty involved in the estimation of these data, whether much significance can be attached to this apparent trend. Thus, the effect of steric hindrance of broadening the band as a whole is not clear, although its possibility can not be excluded.

On the other hand, the effect of blurring the fine structure of the band and, eventually, of making the band structureless seems to be more convincing.

As was shown in Fig. 1 of Part V of this series, the conjugation band of *trans*-stilbene exhibits quite a well-resolved fine structure. The separations of the fine structure are about 1340 cm^{-1} at 20°C; these become 1480 cm^{-1} at −130°C[16]. The conjugation bands of *p*-phenylstilbene, *p*,*p'*-diphenylstilbene[I-IX] and styrene[4] exhibit a similar, though somewhat more blurred, fine structure. In contrast with the conjugation bands of these probably

15) See, for example: G. Herzberg, "Molecular Spectra and Molecular Structure, I. Spectra of Diatomic Molecules", 2nd ed., D. Van Nostrand Company, Inc., New York (1950), p. 193 ff.

16) R. N. Beale and E. M. F. Roe, *J. Chem. Soc.*, 1953, 2755.

unhindered compounds, the bands of probably nonplanar related compounds are almost perfectly structureless. (By the way, the conjugation band of biphenyl is structureless.)

According to Beale and Roe[16], the fine structure of the conjugation band of *trans*-stilbene is considered to originate in an ethylenic C=C stretching frequency. This bond undergoes the largest change in π-bond order on the excitation of the molecule; hence, the minima of the potential energy curves of the electronic ground state and of the electronic excited state for the stretching vibration of this bond are probably at values of the bond length considerably different from each other. (Since the π-bond order decreases on the excitation, the equilibrium bond length in the upper state is probably longer than that in the lower state.) Therefore, it must be possible for transitions from the lowest vibrational level of the electronic ground state to several vibrational levels of the electronic excited state to occur and, since the energy separations of the vibrational levels must be comparatively large, they will probably be revealed as the progression of the fine structure.

As has been mentioned above, the transition probability is considered to be concentrated in a considerably restricted wavelength range in the unhindered case, in so far as the twisting mode about the single bonds is concerned. Consequently, in this case, the progression originating in the C=C stretching mode is not so blurred and will reveal itself as a comparatively well-resolved fine structure.

On the other hand, in the case of hindered molecules, the transition probability is considered to be distributed among a greater variety of transitions covering a wider range of wavelengths; the fine structure will thereby be blurred. The same explanation will be applicable to the other systems.

Summary

The moment of the transition from the highest occupied orbital to the lowest vacant orbital has been calculated, by the simple LCAO MO method, as a function of the angle of the twist of the " single " bond for biphenyl, styrene and stilbene, each as a representative of alternant hydrocarbon systems. Thereby, it has been shown that the decrease in the intensity of the conjugation band observed with sterically hindered compounds, as compared with the band of the sterically unhindered parent compound, can be explained almost entirely satisfactorily by the decrease in the transition moment associated with the deviation of the most probable configuration of the molecule from the planarity. In this connection, Jaffé and Orchin's explanation, as well as Braude's explanation, of the steric hypochromic effect has been criticized.

From a consideration of the potential energy curves of the electronic ground state and of the electronic excited state for the twist of the "single" bond, an explanation has been suggested of the notable fact that the conjugation bands of sterically hindered stilbenes are almost structureless in contrast with the band of *trans*-stilbene, which has quite a well-resolved fine structure.

*Relationship between Acid Dissociaiton Constants of N_1-Arylsulfanilamides and the Hammett Equation**

By Mitsuru YOSHIOKA, Kaname HAMAMOTO and Tanekazu KUBOTA

(Received June 25, 1962)

It has been known that there are close and important relationships between acid dissociation constants of sulfa drugs and such chemotherapeutic properties as bacteriostatic activity[1], absorption[2], excretion[2], and so on. The general formula of the drugs is as follows:

* Presented in part at the Symposium on the Electronic States of the Molecule, Sapporo, August, 1960, and in part at the Symposium on the Mechanism of Organic Reactions, Sendai, October, 1961.

1) P. H. Bell and R. O. Roblin, Jr., *J. Am. Chem. Soc.*, **64**, 295 (1942).

2) L. S. Schanker, "Annual Review of Pharmacology", Vol. I, Annual Reviews. Inc. California (1961), p. 29.

where R are usually heterocyclic substituents.

Therefore, it seems very important to investigate in detail a effect of the substituent R on the acid dissociation constant. In the case of heterocyclic compounds, a quantitative investigation of the effect would involve various, complicated problems. On the other hand, in the case of N_1-arylsulfanilamides (R: Ar; $ArNHSO_2C_6H_4NH_2$), such an investigation could be carried out by applying the Hammett equation (Eq. 1).

$$\log (k/k_0) = \rho\sigma \qquad (1)$$

In this equation k and k_0 are equilibrium (or rate) constants for a meta or para-substituted and for the unsubstituted aromatic compounds respectively. σ is the substituent constant, which depends solely on the substituent, and ρ is the reaction constant, which depends on the specific reaction. A different substituent constant, σ^-, for a para electron-attracting group has been used on dissociations (or reactions) of anilines and phenols. Little examination of dissociation of anilides, however, has been made so it is not clear whether or not σ^- [3] should be used with the dissociation of sulfanilamides which belong to the anilides[4]. The purpose of this paper is to clear up this point and to make a quantitative examination of a relationship between the acid dissociation constants of N_1-arylsulfanilamides and the Hammett equation.

Experimental

Materials.—N_1-Arylsulfanilamides were prepared by known procedures[5] and were purified by repeated recrystallizations from aqueous alcohol.

Dissociation Constant Determination.—Bell and Roblin[1] have reported that all the sulfanilamides used in their study, except for the very acidic ones, are in the "non-zwitter ion" form. Accordingly, acid dissociation of the sulfanilamides used here can be expressed by Eq. 2:

$$\underset{BH^+}{Ar\cdot NH\cdot SO_2C_6H_4NH_2} + H_2O \rightleftharpoons \underset{B}{Ar\cdot N^-\cdot SO_2C_6H_4NH_2} + H_3O^+ \qquad (2)$$

The acid dissociation constant, K_{NH}[6], can be given by Eq. 3:

$$K_{NH} = [Ar\cdot N^-\cdot SO_2C_6H_4NH_2][H_3O^+]/Ar\cdot NH\cdot SO_2C_6H_4NH_2] = [B][H_3O^+]/[BH^+] \qquad (3)$$

Equation 4 can be obtained easily by applying Lanbert and Beer's law to Eq. 3:

$$pK_{NH} = pH - \log \frac{E_{BH^+} - E_{obs}}{E_{obs} - E_B} \qquad (4)$$

where E_{BH^+}, E_B and E_{obs} are optical densities of BH^+, B, and a mixture at a given pH, in the same concentration at a wavelength. Therefore, we can accurately determine pK_{NH} ($-\log K_{NH}$) values by the spectrophotometric method. The ultraviolet spectra of N_1-phenylsulfanilamide and determination of its pK_{NH} value by applying Eq. 4 are shown in Figs. 1 and 2 as typical examples.

A stock solution (2 cc.) of sulfanilamides in an aqueous 0.001 N sodium hydroxide solution or in

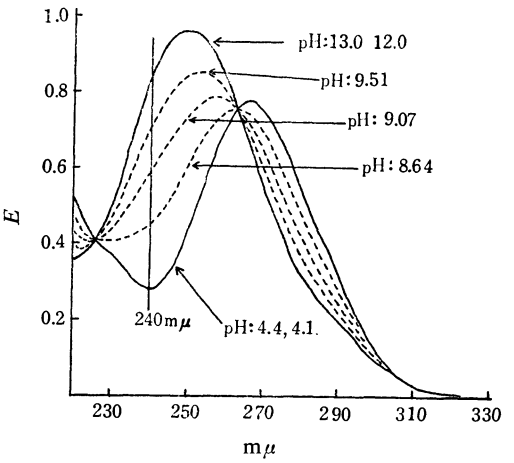

Fig. 1. Ultraviolet spectra of N_1-phenylsulfanilamide at various pH in 4.74×10^{-5} M solution.

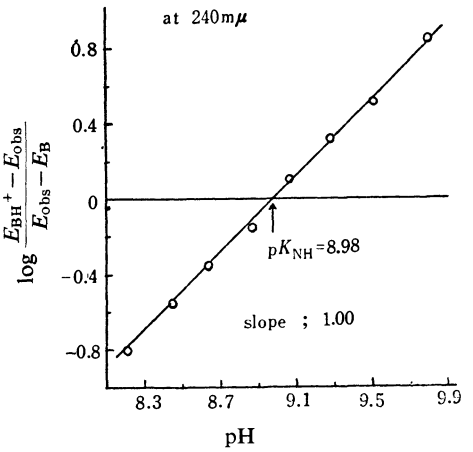

Fig. 2. Determination of the pK_{NH} value of N_1-phenylsulfanilamide at 240 mμ: The mean value of pK_{NH} values at 240, 243, 246 and 249 mμ, is given to be 8.97.

3) This constant, σ^-, is the same as Jaffé's σ^*[4].

4) H. H. Jaffé, *Chem. Revs.*, **53**, 191 (1953).

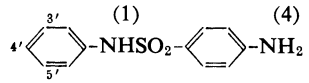
5) A. E. Senear et al., *J. Org. Chem.*, **11**, 378 (1946); H. Kaplan and G. W. Leubner, *J. Am. Chem. Soc.*, **67**, 1076 (1945); J. H. Gorrin, *J. Chem. Soc.*, **1945**, 734.

6) There is another dissociation constant of the sulfanilamides, $K_{NH_3^+}$, as is shown in the following equations:

$$ArNHSO_2\cdot C_6H_4\cdot NH_3^+ + H_2O \rightleftharpoons ArNHSO_2\cdot C_6H_4\cdot NH_2 + H_3O^+$$

$$K_{NH_3^+} = [ArNHSO_2\cdot C_6H_4\cdot NH_2][H_3O^+]/[ArNHSO_2\cdot C_6H_4\cdot NH_3^+]$$

Examination of this dissociation will appear elsewhere.



an aqueous 0.033 N ethanolamine solution[7] was diluted to 25 cc. with Britton-Robinson's universal buffer solutions[8], the ionic strength of which had been adjusted to 0.2 by adding sodium chloride. The pH values of sample solutions were measured with a Beckman model G pH meter at 25±2°C, and the spectra were recorded with a Hitachi model EPS-2 recording spectrophotometer at 27±2°C, using a 1 cm. cell. An improved spectrophotometric method[9] was applied for the pK_{NH} determination of the sulfanilamides with a SO_2NH_2 group, because they have overlapping dissociation constants (pK_{NH} and $pK_{SO_2NH_2}$).

Results and Discussion

Acid Dissociation Constants and Melting Points of Sulfanilamides. — The dissociation constants, pK_{NH}, and the melting points are listed in Table I. The elementary analysis of each compound listed here agrees well with the corresponding formula unless otherwise stated.

TABLE I. pK_{NH} AND MELTING POINTS OF N_1-ARYLSULFANILAMIDES

Substituent[a]	pK_{NH}	M. p. °C
3',5'-$(NO_2)_2$	6.19	206.0~209.0
3'-NO_2, 5'-Cl	6.92	201.0~202.0
4'-NO_2	6.97	167.0~169.0

b) The analysis fits the formula $C_{12}H_{13}O_4 \cdot N_3S_2 \cdot {}^1/_2H_2O$

c) The formula $C_{12}H_{13}O_4N_3S_2 \cdot {}^1/_2C_2H_5OH$ was indicated by analysis.

Substituent Constants (σ and σ^-). — Since Jaffé's[4] evaluation of normal substituent constants (σ values), they have been re-evaluated by McDaniel, and Brown[11] and by Bekkum et al.[12] We have examined their papers and have selected McDaniel's σ values[11] except for the *m*- and *p*-substituents of SO_2NH_2 and NMe_2, because McDaniel's values have been evaluated from dissociation constants of substituted benzoic acids and so seem to be most reliable and reasonable. It seems to us that McDaniel made a mistake in evaluating the σ values of *m*- and *p*-SO_2NH_2, so Zollinger's original values[13] are adopted for them. At present, the σ values for *m*- and *p*-NMe_2 are quite complicated. McDaniel has given −0.83 for *p*-NMe_2, whereas Jaffé and Bekkum respectively, have given −0.60 and −0.266[14] for it. McDaniel's values for NMe_2 were evaluated from dissociation constants of dimethylaminobenzoic acids, which exist to some extent as the zwitterions. Jaffé's value for *p*-NMe_2 is an average of seventeen values ranging from −1.049 to −0.206. Bekkum calculated the σ value of *p*-NMe_2 from equilibria involving anilines. Therefore, Bekkum's value for *p*-NMe_2 is most reliable and his values for *p*- and *m*-NMe_2 are selected here.

As for σ^- values, Jaffé's estimates are adopted for *p*-NO_2, *p*-CN and *p*-$COCH_3$ and

13) H. Zollinger and C. Wittmer, *Helv. Chim. Acta*, **39**, 351 (1956).

14) A σ value from equilibria involving anilines.

Zollinger's estimate is adopted for p-SO_2NH_2, because there is no other value for these groups.

Table II lists the substituent constants (σ and σ^-) we have selected.

Plot of log K_{NH} ($-pK_{NH}$) against σ (or σ^-). —Figure 3 represents a relation of the dissociation constants of sulfanilamides with the substituent constants. A good, linear relationship between log K_{NH} and σ is obtained except for p-NO_2, p-CN, p-$COCH_3$ and p-SO_2NH_2. For these electron-attracting groups, neither σ values nor σ^- values give a good fit. This result clearly indicates that neither σ nor σ^- for these groups may be applicable to the dissociation of sulfanilamides.

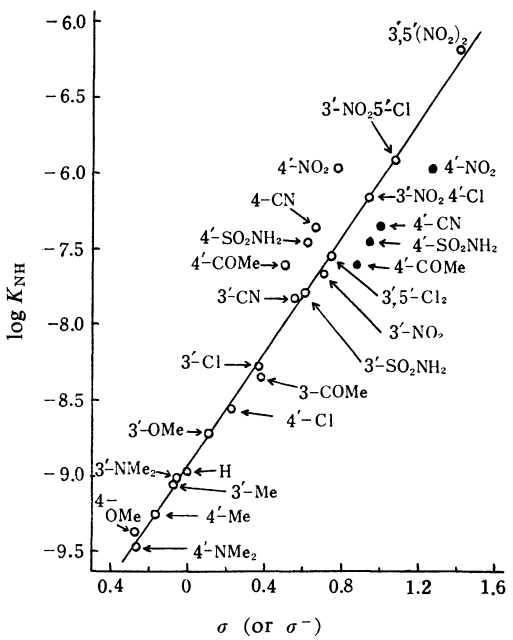

Fig. 3. Plot of log K_{NH} against substituent constants. Open circles, σ ; Closed circles, σ^-

A Modified Hammett Equation. — The only other known irregular relationship of this kind for electron-attracting groups in nucleophilic reactions ($\rho > 0$) is in the case of thiophenols[4]. In electrophilic reactions ($\rho < 0$), however, a similar irregular relationship for such electron-releasing groups as p-NH_2, p-OCH_3 and p-CH_3 has been observed in many reactions and equilibria. Yukawa and Tsuno have proposed the following modified Hammett relationship (Eq. 5) ; this relationship has been applied successfully to many electrophilic reactions[15] ($\rho < 0$).

$$\log (k/k_0) = \rho(\sigma + r\Delta\sigma_R^+)$$
$$\Delta\sigma_R^+ \equiv \sigma^+_{\text{Brown and Okamoto}} - \sigma \qquad (5)$$

where r is a reaction constant describing the degree of the transition state resonance and $\Delta\sigma_R^+$ is a substituent constant suggesting the resonating capacity of an electron-releasing substituent at the para-position

A similar modification could be made in nucleophilic reactions[16], and a modified Hammett equation can be expressed by Eq. 6 for nucleophilic reactions and equilibria ($\rho > 0$) :

$$\log (k/k_0) = \rho(\sigma + r'\Delta\sigma_R^-)$$
$$\Delta\sigma_R^- \equiv \sigma^- - \sigma \qquad (6)$$

Here r' (a resonance reaction constant), $\Delta\sigma_R^-$ (a resonance substituent constant of an electron-attracting p-substituent), and σ^- for nucleophilic reactions correspond to r, $\Delta\sigma_R^+$, and σ^+ Brown and Okamoto respectively for electrophilic reactions.

This modified equation (Eq. 6) may be connected with mesomeric para interactions in nucleophilic reactions (or equilibria), as is shown in the following limiting structures:

R : NO_2, CN, etc. Y : NH_2, SH, etc.

Consequently, Eq. 6. can be applied to the acid dissociation of sulfanilamides. In this case, the ρ value should be calculated only from the data of the m-substituted sulfanilamides. However, the data for such p-substituents as CH_3O, CH_3 and Cl may be used also, for in these groups the mesomeric para interactions are very weak for the sulfanilamides discussed here. On the other hand, the data for such substituents as m-SO_2NH_2, m-NMe_2 and p-NMe_2 should be excluded from the calculation of the ρ value, because σ values for these groups[17] have not been determined definitely and are less reliable than for other groups. Thus, the ρ value was calculated by means of the least square method, using the data for m-substituents of NO_2, CN, and CH_3CO, m- and p-substituents of Cl, CH_3, and CH_3O and H. The calculated values of ρ, log $K_{0,NH}$, S[18], and the correlation

TABLE III. $\Delta\sigma_R^-$ VALUES

16) Y. Yukawa and Y. Tsuno, "Progress in Organic Reaction Mechanisms", Vol. I, Maki-shoten, Tokyo (1958), p. I (in Japanese).

17) It is worth noting that the selected values for these groups in Table II give a good fit, as is shown clearly in Fig. 3.

18) The standard deviation of experimental results from the regression line.

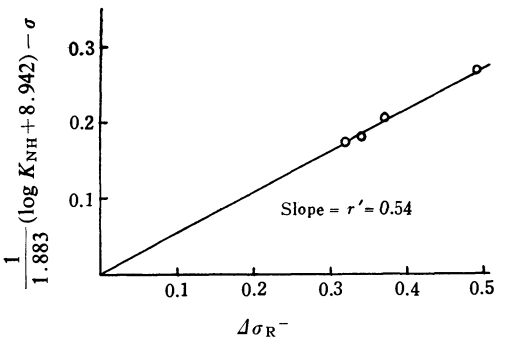

Fig. 4. Determination of r' for the dissociation of N_1-arylsulfanilamides.

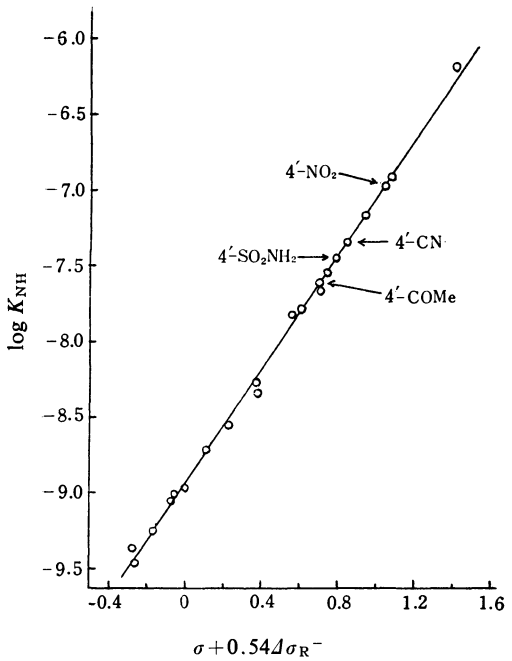

Fig. 5. Correlation of the dissociation of N_1-arylsulfanilamides with the modified Hammett equation.

coefficient are 1.883, −8.942, 0.07 and 0.998 respectively. In Table III are given the $\Delta\sigma_R^-$ values calculated from the substituents constants listed in Table II. From the plot of $[(1/\rho)\log(K_{NH}/K_{0,NH})-\sigma]$ against $\Delta\sigma_R^-$, as shown in Fig. 4, r' is given as 0.54. As is seen in Fig. 5, the acid dissociation of N_1-arylsulfanilamides is expressed well by Eq. 7:

$$\log K_{NH}=1.883(\sigma+0.54\ \Delta\sigma_R^-)-8.942 \quad (7)$$

Dissociation of *N*-Arylbenzenesulfonamides ($ArNHSO_2C_6H_5$). — Willi[19] has reported a relationship between dissociation constants of *N*-arylbenzenesulfonamides and the Hammett equation. He has concluded that σ^- should be applied for the electron-attracting groups at the para-position in the case of these sulfonamides. These compounds have a –NH– group of the same type as that of the N_1-arylsulfanilamides discussed above, so the modified Hammett equation (Eq. 6) may be applied also to the dissociation of *N*-arylbenzenesulfonamides. Willi's data were treated as in the case of sulfanilamides. The σ values[12] selected for p-COO^-, and p-NH_2 are 0.120 and −0.423, and the σ^- value for p-COO^- is 0.367[20]. The ρ value, $\log K_0$, S[18], and the correlation coefficient are calculated to be 1.833, −8.285, 0.059 and 0.998 respectively, using the data for m-NO_2, p-Cl, H, p-CH_3, p-OCH_3 and p-NH_2. From Fig. 6, r' is given as 0.68.

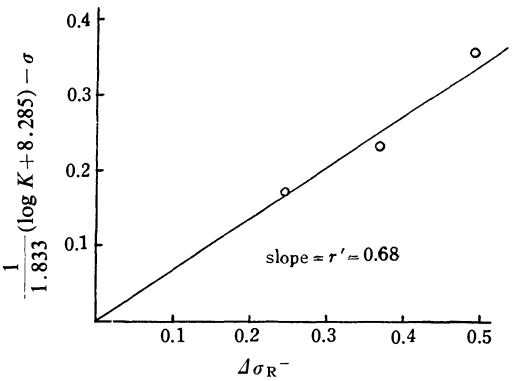

Fig. 6. Determination of r' for the dissociation of *N*-arylbenzenesulfonamide.

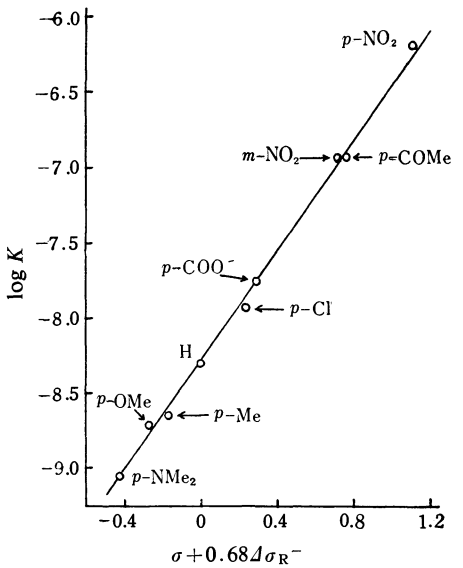

Fig. 7. Correlation of the dissociation of *N*-arylbenzenesulfonamide.

19) A. V. Willi, *Helv. Chim. Acta*, **39**, 46 (1959).

20) A. V. Willi and T. F. Stocker, ibid., **38**, 1279 (1955). In this paper the σ^- value of p-COO^- has been given as 0.335; this is an average of the 0.367 obtained from dissociation of phenols and the 0.335 obtained from that of $ArNHSO_2C_6H_5$. Only the former value should be adopted.

Therefore, the dissociation of *N*-arylbenzenesulfonamides can be expressed well by Eq. 8, as is shown in Fig. 7:

$$\log K = 1.833(\sigma + 0.68\ \Delta\sigma_R^-) - 8.285 \qquad (8)$$

Since the number of the substituents is only eight and some of them are not reliable enough, the values of ρ and r' will be somewhat uncertain. Nevertheless, clearly the modified Hammett equation (Eq. 6) can be applied also to the dissociation of these sulfonamides.

The results obtained from the sulfanilamides ($ArNHSO_2C_6H_4NH_2$) and the benzenesulfonamides ($ArNHSO_2C_6H_5$) show that the modified Hammett relationship for nucleophilic reactions should be applied to the dissociation of Ar–NH–SO_2– type anilides.

Summary

1. Acid dissociation constants of twenty-one N_1-arylsulfanilamides ($ArNHSO_2C_6H_4NH_2$) were exactly determined by the spectrophotometric method at 27±2°C and in an ionic strength of 0.2.

2. A modified Hammett relationship for nucleophilic reactions (Eq. 6) can be applied to acid dissociation of N_1-arylsulfanilamides and also of *N*-arylbenzenesulfonamides ($Ar\cdot NHSO_2C_6H_5$).

3. These results show that the modified Hammett relationship should be applied to the dissociation of Ar–NH–SO_2– type anilides.

The authors wish to thank Professor Yasuhide Yukawa of Osaka University for his valuable advice, Mr. Tsunetoshi Honma for his assistance in the preparation of the samples, and Mr. Hiroshi Miyazaki and Mr. Itaru Tanaka for their ultraviolet spectral measurements.

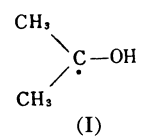
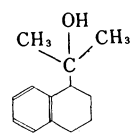
Studies of the Photochemical Reactions. IV. The Synthesis of Dimethyl-α-tetralylcarbinol by the Photochemical Reaction of Acetone in Tetralin[1]



By Kensuke SHIMA, Yasuo SHIGEMITSU and Shigeru TSUTSUMI

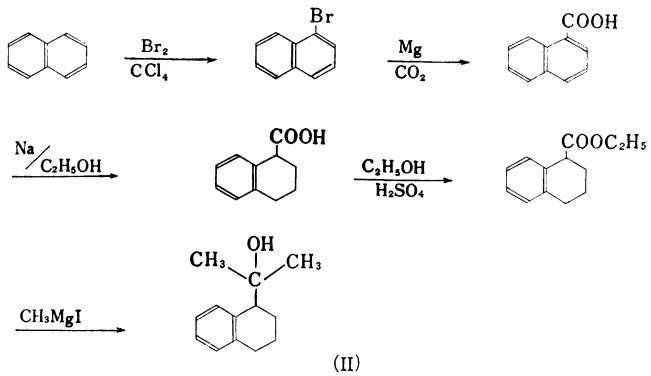
(Received June 2, 1962)



In a previous paper[2], the reactions of photoactivated acetone in cyclohexane or methylcylclohexane was reported on. In these reactions, it was ascertained that photoactivated acetone abstracted hydrogen from the hydrogen donor solvent to form an intermediate radical, the dimethylhydroxymethyl radical (I).

In order to use this radical (I) for synthetic purposes, tetralin, having the reactive α-hydrogen for autoxidation[3] or other radical reactions[4], was chosen as the hydrogen donor solvent. The present paper reports on the synthesis of dimethyl-α-tetralylcarbinol (II), which can only with considerable difficulty be prepared by other methods[5].

In this experiment, an ultraviolet light from a 400 W high pressure mercury lamp was used. A mixture of acetone and tetralin (mole ratio: 1 : 4 and 1 : 2 respectively) was irradiated in a nitrogen atmosphere at 10～15°C for 100, 25 and 10 hr., and then the reaction products were fractionated and analyzed chromatographically.



(I)

(II)

From the lower boiling fraction, isopropyl alcohol was obtained, and the fraction (b. p. 124～126°C/4 mmHg) was identified as dimethyl-α-tetralylcarbinol (II), the adduct of the (I) radical and the α-tetralyl radical. The infrared spectrum, shown in Fig. 2, was identical with that of an authentic sample, and the mixed melting point of its phenyl urethane was not depressed. The authentic sample was prepared by the following procedure[5]:

* Isopropyl alcohol, II, and high boiling residue.

The reaction conditions and the yields of the products are summarized in Table I. The amounts of unreacted acetone and isopropyl-alcohol were estimated by gaschromatographic analysis.

It is of interest to note that dimethyl-α-tetralylcarbinol (II) is easily produced in a fairly high yield by the photochemical reaction of acetone in tetralin.

Experimental[6]

Materials.—Tetralin was purified by fractional distillation over sodium ; b.p., 81.5~83°C/14 mmHg, n_D^{20} 1.5380. Acetone was purified by the ordinary method[7] ; b. p. 56.5~57°C, n_D^{20} 1.3588.

The Photochemical Reaction of Acetone in Tetralin.—A mixture of acetone (45 g., 0.77 mol.) and tetralin (201.3 g., 1.53 mol.) was placed in a 300 ml. reaction vessel and irradiated at 10~15°C in a nitrogen atmosphere for 25 hr. The reaction apparatus is shown in Fig. 1. After this irradiation, the reaction product was fractionally distilled under atmospheric and reduced pressure to give the following fractions :

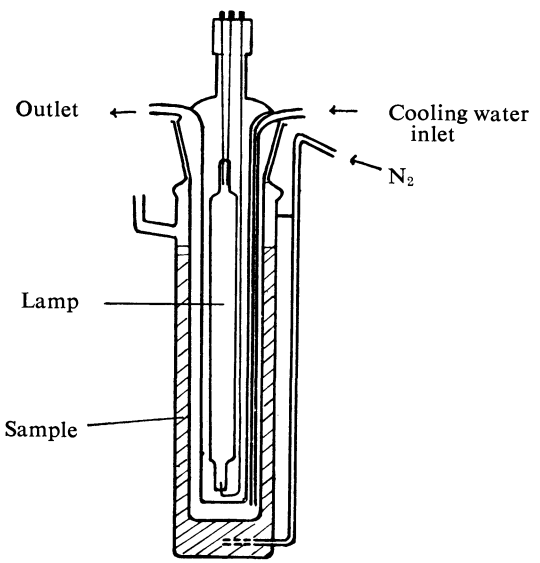

Fig. 1. Reaction apparatus.

	B. p.	Weight g.	n_D^{20}
(1)	57.5~59°C	20.5	1.3588
(2)	59.5~83°C	7.7	1.3645
(3)	~30°C/14 mmHg	6.0	1.3838

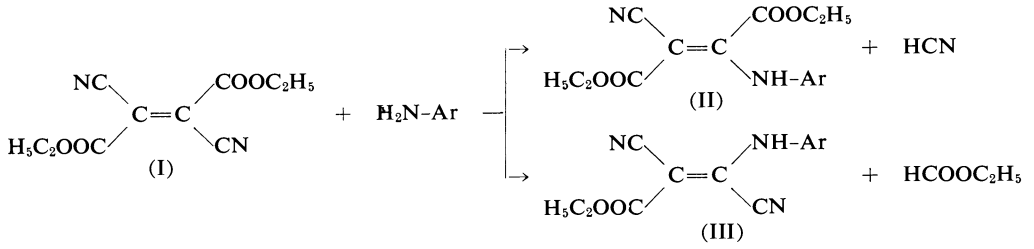
*Studies of trans-Dicyanodiethoxycarbonylethylene. II. Reactions with Ammonia and Primary Aromatic Amines**

By Ken-ichi KUDO

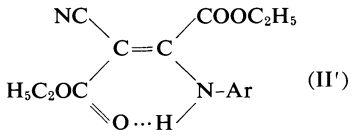


(Received May 22, 1962)

As has been described in a previous paper[1], the reactions of *trans*-dicyanodiethoxycarbonylethylene (I) with tertiary aromatic amines resulted in the addition of a benzene nucleus to the ethylenic double bond with the formation of 4-α, β-dicyano-α, β-diethoxycarbonyl-*N*, *N*-dialkylanilines. In the present paper, the reactions of I with ammonia or primary aromatic amines are investigated.

Reactions with Primary Aromatic Amines. — When a mixture of primary aromatic amine

* This work was presented at the 14th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1961.



1) Part I, K. Kudo, This Bulletin, 35, 1490 (1962).

II Ar; *p*-CH_3O-C_6H_4, *p*-CH_3-C_6H_4, or *p*-Cl-C_6H_4
III Ar; *p*-CH_3O-C_6H_4, *p*-CH_3-C_6H_4, *p*-Cl-C_6H_4, *m*-NO_2-C_6H_4, or β-$C_{10}H_7$

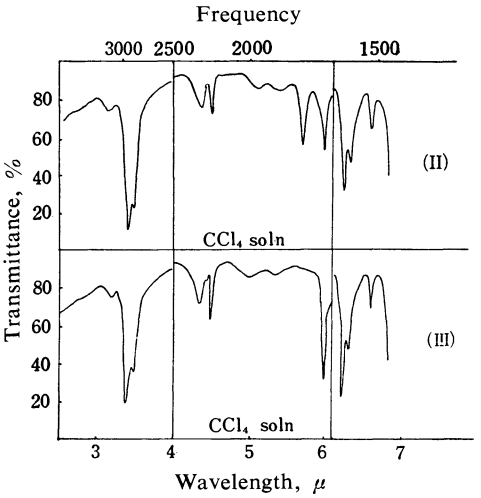
and I in an organic medium was heated, *N-trans*-α, β-diethoxycarbonyl-β-cyanovinylamines (II) and *N-trans*-α, β-dicyano-β-ethoxycarbonylvinylamines (III) were obtained. In these reactions, when the molar ratio of I to primary amine was 1 : 2, II products, resulting from the substitution of a cyano group with an amine group, predominated. On the other hand, III products, resulting from the substitution of an ethoxycarbonyl group, predominated when the molar ratio of I to primary amine was 2 : 1. Neither II nor III products were obtained by the reaction of I with α-naphthylamine or *p*-nitroaniline, while with *m*-nitroaniline or β-naphthylamine only III products were obtained. These results are shown in Table I.

The structures of III and II were determined in the following manner. By the hydrolysis of II or III with a 10% aqueous sodium hydroxide solution, the parent amine was recovered in a good yield. This result suggests that the vinyl group is attached to the nitrogen atom rather than to the carbon atom. The infrared absorption spectrum of III (Ar; *p*-CH_3-C_6H_4) showed an NH band at 3115 cm^{-1}, C≡N bands at 2227 and 2247 cm^{-1}, and a C=O band at 1680 cm^{-1} (Fig. 1). The infrared absorption spectrum of II (Ar; *p*-CH_3-C_6H_4) showed an NH band at 3185 cm^{-1}, a C≡N band at 2227 cm^{-1}, and C=O bands at 1672 and 1754 cm^{-1} (Fig. 1). The facts that the ester groups of II showed two bands at 1672 and 1754 cm^{-1} and that of III only a band at 1680 cm^{-1} suggest that the bands at 1754 and 1672 cm^{-1} are to be attributed to the ester groups attached to the α- and β-carbon atoms in the aromatic amine group respectively. Similarly, it is expected that the C≡N bands at 2247 and 2227 cm^{-1} are to be attributed to the C≡N groups attached to the α- and β-carbon atoms respectively. (Incidentally, it is generally known that the carbonyl and nitrile frequencies are shifted from their normal positions toward longer wavelengths by conjugation with the vinyl group and also by strongly electronegative substituents on the α-carbon atom, while the α,β-unsaturated carbonyl and nitrile frequencies shift from their normal position toward shorter wavelength in the case of sterically hindered compounds[2].) The geometrical structures of II and III were established on the basis of the considerations of the C=O frequencies of the β-esters of II and III. It was already known that a C=O frequency of β-amino-α, β-unsaturated ester is shifted toward a low frequency by the formation of a chelate hydrogen-bond structure[3]. Thus, the evidence that the β-ester of II had a lower C=O frequency than that of

(II')

III would indicate that II had an intramolecular chelate structure II'. Accordingly, it should be concluded that II and III have ester-ester and nitrile-nitrile trans geometries respectively.

Further chemical evidence for II was obtained



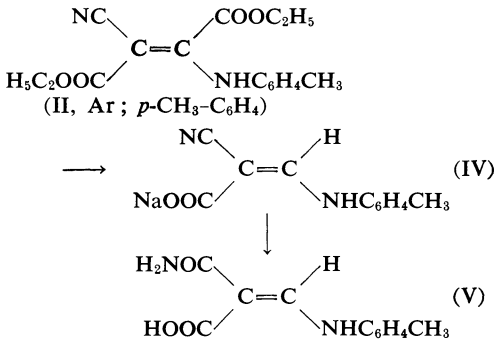


Fig. 1. The infrared absorption spectra of (II, Ar; *p*-CH_3-C_6H_4) and (III, Ar; *p*-CH_3-C_6H_4). A lithium fluoride prism was used for the measurement of C=O and C≡N bands in carbon tetrachloride and one of rock salt for the other bands in Nujol mull.

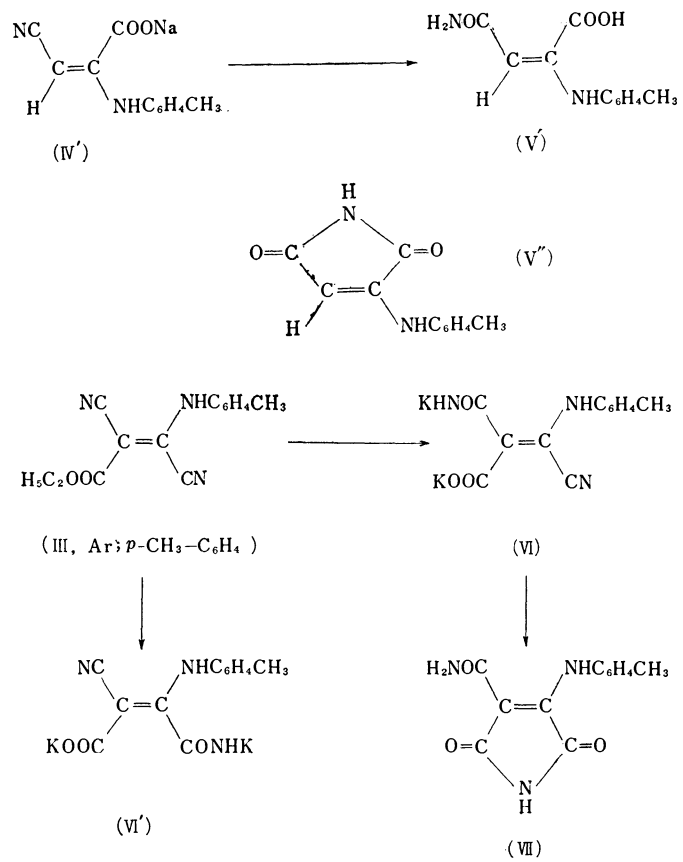
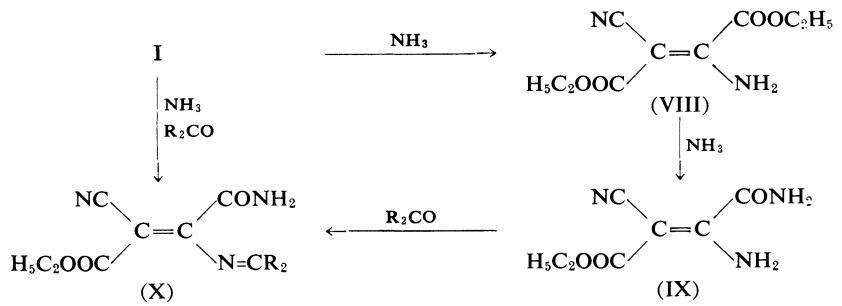
by step by step hydrolysis and decarboxylation of II (Ar; p-CH_3-C_6H_4) to β-p-toluidino-α-carbamoylacrylic acid (V) via sodium β-p-toluidino-α-cyanoacrylate (IV). While the



(II, Ar; p-CH_3-C_6H_4)

infrared absorption spectra of IV and V did not exclude the possibility that these compounds may possess the corresponding isomeric forms, IV' and V', this possibility was rejected when cyclic imide V'', the expected product from IV', was not obtained by the hydrolysis of IV' with dilute hydrochloric acid.



III (Ar; p-CH_3-C_6H_4) was also hydrolyzed with a 10% methanolic potassium hydroxide solution to give potassium β-p-toluidino-β-cyano-α-potashcarbamoylacrylate (VI). When the solution of VI was acidified, α-p-toluidino-α'-carbamyl maleimide (VII) was formed readily by the intramolecular cyclization of the CN and COOH groups. If the VI' structure were correct, the C=O frequency would be shifted toward a shorter wavelength by deviation from the planar configuration which was attributed to the steric repulsion between the aryl and the amide C=O groups. Consequently, the VI' structure should be excluded on the evidence that the spectrum showed its low frequency at 1650 cm^{-1}.

Kissinger and Ungnade[4] discovered that α, α-dinitro-ester, $RC(NO_2)_2COOC_2H_5$, undergoes the substitution of an ethoxycarbonyl group with alcoholic hydrazine hydrate. Thesing[5] and Dornow[6] described how the displacement of a nitrile group of acylcyanides occurs readily in reaction with nucleophilic reagents in a neutral and especially in a weak alkaline

(IV') (V') (V'') (III, Ar; p-CH_3-C_6H_4) (VI) (VI') (VII)

solution. Thus, as indicated by Middleton[7], if the $\rangle C{=}C\langle^{CN}_{COOC_2H_5}$ group may be analogous to the $\rangle C{=}O$ group in its electron-drawing effects, the formation of II or III respectively by the substitution of C≡N or $COOC_2H_5$ with aromatic amine derivatives seems to be reasonable.

The mechanism of these substitution reactions would be similar to the reaction mechanism of the formation of 4-*trans*-α, β-diethoxycarbonyl-β-cyanovinyl-*N*, *N*-dialkylaniline from I described in the previous paper[1]. Namely, these reactions would be initiated by the formation of the π-complexes between I and primary aromatic amines, since the intense electronic absorption bands of the reaction mixture at λ_{max} 315~365 mμ and λ_{max} 440~510 mμ are attributable to neither the I products nor to the primary aromatic amines, but to the π-complex itself as a new molecular species. The second step in the reaction appears to be an addition of primary aromatic amine to give an adduct, although the adduct as an intermediate was not isolated. The final step is an elimination of hydrogen cyanide or ethyl formate to yield II or III respectively.

Reaction with Ammonia.—The reaction of I and ammonia with a molar ratio of 1 : 1 gave only one product, *trans*-α, β-diethoxycarbonyl-β-cyanovinylamine (VIII), in a good yield. By a similar procedure, α-carbamoyl-β-cyano-β-ethoxycarbonylvinylamine (IX) was obtained from I via VIII by ammonolysis of an ester group with the excess of ammonia in a good yield, but diamide derivatives of VIII were not obtained. The infrared absorption spectrum of VIII showed NH bands at 3401 and 3279 cm^{-1}, a C≡N band at 2212 cm^{-1}, and C=O bands at 1761 cm^{-1} (α-ester) and 1687 cm^{-1} (β-ester) (Fig. 2). The infrared absorption spectrum of IX had NH bands at 3448, 3356, 3257 and 3185 cm^{-1}, a C≡N band at 2222 cm^{-1}, and C=O bands at 1695 (β-ester) and 1667 cm^{-1} (α-amide) (Fig. 2). In these spectral data, the evidence that the β-esters of VIII and IX had low C=O frequencies is to be attributed to the formation of an intramolecular hydrogen-bond[3] between the C=O and amino groups. Further chemical evidence for VIII and IX was supplied by the synthesis of the acetyl derivatives and by the formation of Schiff bases X respectively. X products were also obtained directly from I. The X structures were established on the bases of the synthesis of the acetyl derivatives and supported by the fact that X products were hydrolyzed with an aqueous sodium hydroxide solution to give the parent ketone, which would indicate that the ketone was attached to the nitrogen atom rather than to the carbon atom.

The mechanism of the formation of VIII products would be similar to the reaction mechanism of the formation of II products described above.

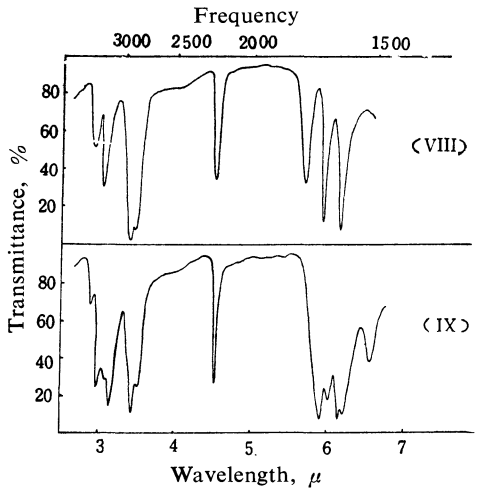

Fig. 2. The infrared absorption spectra of VII and IX.

Experimental

***N*-*trans*-α, β-Dicyano-β-ethoxycarbonylvinylamines (III).**—III products were generally prepared by the reaction of primary aromatic amines with the excess of I in dimethylformamide at 50~60°C. Other solvents, such as pyridine, acetonitrile and ethyl formate, were also used. In a typical experiment, a mixture of 4.3 g. (0.04 mol.) of *p*-toluidine

* In the media of dimethylformamide

and 18 g. (0.08 mol.) of I in 30 ml. of dimethylformamide was heated at 50~60°C while being stirred for 30 min. The solvent was distilled off in vacuo, and the red residue was kept in an ice-box for several days. The solidified residue was recrystallized from ethanol-water to give 9 g. (92%) of III (Ar; p-CH_3-C_6H_4) (m. p. 116.5~117°C) in the form of yellow crystals (Table I).

***N*-*trans*-α, β-Diethoxycarbonyl-β-cyanovinylamines (II).**—II products were prepared from I with an excess of primary aromatic amines by a similar procedure. For example, from 12 g. (0.06 mol.) of I and 12 g. (0.12 mol.) of p-toluidine, II (Ar; p-CH_3-C_6H_4) (m. p. 103~104°C) was obtained in a 5 g. (28%) yield (Table I).

Hydrolysis of III (Ar; p-Cl-C_6H_4) to p-Chloroaniline.—A mixture of 1 g. of III (Ar; p-Cl-C_6H_4) and 50 ml. of a 10% sodium hydroxide solution was refluxed for 3.5 hr. and then steam distilled. The distillate was cooled to give 0.3 g. (77%) of p-chloroaniline; m. p., 68~69°C. The p-chloroaniline was dissolved in a solution of 4 ml. of pyridine and a small quantity of ether. The addition of 0.3 ml. of acetyl chloride to the solution gave p-chloroacetanilide (m. p. 177~179°C, alone or mixed with an authentic sample). Similarly, the other II and III products also gave the corresponding parent amines.

Hydrolysis of II (Ar; p-CH_3-C_6H_4) to Sodium β-p-Toluidino-α-cyanoacrylate (IV).—A mixture of 3 g. of II (Ar; p-CH_3-C_6H_4) and 5 g. of sodium carbonate in 45 ml. of water was heated under reflux for 2.5 hr. and then cooled to 0°C. The precipitated IV was filtered off and recrystallized from ethanol-water to give colorless crystals (m. p. 232~233.5°C (decomp.)).

Found: C, 58.82; H, 4.23. Calcd. for $C_{11}H_{19}O_2N_2Na$: C, 58.93; H, 4.05%.

Its infrared absorption spectrum had bands at 3230 cm^{-1} (NH), 2200 cm^{-1} (C≡N) and 1640 cm^{-1} (C=O).

Hydrolysis of Sodium β-p-Toluidino-α-cyanoacrylate (IV) to β-p-Toluidino-α-carbamoylacrylic Acid (V).—A clear solution of 2 g. of IV in 100 ml. of water was acidified with hydrochloric acid to pH 3. The precipitated crystals were recrystallized from ethanol. There was obtained 1 g. of V (m. p. 166.5~168.5°C) as yellow crystals.

Found: C, 60.08; H, 5.48. Calcd. for $C_{11}H_{12}O_3N_2$: C, 59.99; H, 5.49%.

Its infrared absorption spectrum showed bands at 3330 cm^{-1} and 3170 cm^{-1} (NH), and 1655 and 1645 cm^{-1} (C=O).

Hydrolysis of III (Ar; p-CH_3-C_6H_4) to Potassium β-p-Toluidino-β-cyano-α-potashcarbamoylacrylate (VI).—A mixture of 2.6 g. of III (Ar; p-CH_3-C_6H_4), 5 g. of potassium hydroxide, 25 ml. of methanol, and 25 ml. of water was heated on a boiling water bath for 2 hr. After cooling, the precipitated crystals were recrystallized several times from ethanol-water to give 1.3 g. of VI (m. p. 274~275°C) as colorless crystals.

Found: C, 42.20; H, 3.43; N, 12.40. Calcd. for $C_{12}H_{11}O_4N_3K_2$: C, 42.45; H, 3.27; N, 12.38%.

Its infrared absorption spectrum showed peaks at 3480, 3340, 3200, 2160 and 1650 cm^{-1}.

Cyclization of Potassium β-p-Toluidino-β-cyano-α-potashcarbamoylacrylate (VI) to α-p-Toluidino-α'-carbamoylmaleimide (VII).—A solution of 3 g. of VI in 100 ml. of water was acidified with hydrochloric acid. The precipitated crystals were collected, washed with water, and recrystallized from dimethylformamide-ethanol to give VII (m. p. 276~277°C) as yellow crystals.

Found: C, 58.77; H, 4.60; N, 17.25. Calcd. for $C_{12}H_{13}O_3N_3$: C, 58.77; H, 4.52; N, 17.14%.

Its infrared absorption spectrum showed bands at 3420 and 3200 cm^{-1} (NH), 1760 and 1730 cm^{-1} (succinimide type C=O), and 1665 cm^{-1} (amide C=O).

***N*-*trans*-α, β-Diethoxycarbonyl-β-cyanovinylamine (VIII).**—*With Ammonium Hydroxide.*—Three grams (0.05 mol.) of 28% ammonium hydroxide were slowly stirred into a mixture of 11 g. (0.05 mol.) of I and 60 ml. of acetonitrile at 5~8°C. The solvent was evaporated at room temperature, and the residue was crystallized to give 10 g. (94%) of VIII (m. p. 78~79°C).

Found: C, 50.82; H, 5.65; N, 13.33. Calcd. for $C_9H_{12}O_4N_2$: C, 50.94; H, 5.70; N, 13.20%.

With Ammonia Gas.—A mixture of 2.8 g. (0.013 mol.) of I and 15 ml. of acetonitrile was placed in a 50 ml. three-necked flask equipped with a mechanical stirrer and a gas inlet tube. After the flask had been cooled in an ice-salt bath at −10~15°C and the mechanical stirring had been started, ammonia gas was slowly passed into the mixture for 2~3 min. until an orange color appeared; the reaction was then allowed to proceed for 20 min. When the acetonitrile was removed by vacuum distillation, the residue solidified to give 2.1 g. (75%) of VIII (m. p. 78~79°C) as colorless crystals.

α-Carbamoyl-β-cyano-β-ethoxycarbonylvinylamine (IX).—A mixture of 11 g. (0.05 mol.) of I and 60 ml. of acetonitrile was placed in a three-necked flask equipped with a sealed mechanical stirrer, a gas inlet tube, and a gas outlet tube protected with a calcium chloride tube. Ammonia gas was vigorously passed for 2 hr. into the mixture, which had been cooled throughly in an ice-salt bath. The solvent was removed by distillation, and the residue was crystallized. After recrystallization from alcohol, the yield of IX (m. p. 145~146°C (decomp.)) as colorless crystal was 7.5 g. (82%).

Found: C, 46.09; H, 5.03; N, 22.66. Calcd. for $C_7H_9O_3N_3$: C, 45.90; H, 4.95; N, 22.94%.

Preparation of Schiff Bases (X).—*From I.*—A mixture of 11 g. (0.05 mol.) of I and 100 ml. of acetone was treated with ammonia gas by a procedure similar to that used in the preparation of IX. The yield of X (R; CH_3) (m. p. 235~236°C) as colorless crystals was 3.2 g. (30%).

Found: C, 53.82; H, 6.02; N, 18.77. Calcd. for $C_{10}H_{13}O_3N_3$: C, 53.80; H, 5.87; N, 18.83%.

The infrared absorption spectrum of X (R; CH_3) had bands at 3322, 3226, 2220, 1733 and 1692 cm^{-1}.

In a similar procedure, X (R; C_2H_5) was obtained in a 84% yield.

Found: C, 57.06; H, 6.90; N, 16.75. Calcd. for $C_{12}H_{17}O_3N_3$: C, 57.38; H, 6.82; N, 16.72%.

From N-trans-α, β-Diethoxycarbonyl-β-cyanovinylamine (VIII) and α-Carbamoyl-β-cyano-β-ethoxycarbonylvinylamine (IX).—In a similar procedure, the yields of X from VIII and from IX were 86 and 79% respectively.

Hydrolysis of Schiff Bases (X).—A mixture of 1 g. of X and 100 ml. of a 5% aqueous sodium hydroxide solution was placed in a two-necked flask equipped with a gas inlet tube and a condenser with a gas outlet tube leading to a trap containing a 2,4-dinitrophenylhydrazine solution. The mixture was refluxed, and nitrogen gas was slowly passed into the mixture. Acetone 2,4-dinitrophenylhydrazone (m. p. 126°C) was precipitated as red needle crystals.

Acetylation of *N*-*trans*-α, β-Diethoxycarbonyl-β-cyanovinylamine (VIII).—*With Acetic Anhydride.*—A mixture of 4.2 g. (0.02 mol.) of VIII, 10 ml. of acetic anhydride, and three drops of concentrated sulfuric acid was heated under reflux for 8 hr. After cooling, the dark brown residue was crystallized to give 1.8 g. (33%) of α-ethoxycarbonyl-α'-diacetylaminomaleimide (m. p. 173~174°C) as colorless crystals.

Found: C, 49.45; H, 4.95; N, 10.52. Calcd. for $C_{11}H_{12}O_6N_2$: C, 49.25; H, 4.51; N, 10.45%.

Its infrared absorption spectrum had bands at 3344, 1812, 1779, 1745, 1704 and 1681 cm^{-1}.

With Acetyl Chloride.—A two-necked flask, equipped with a dropping funnel and a reflux condenser protected with a calcium chloride tube, was charged with 17 g. (0.08 mol.) of VIII and 200 ml. of acetone. The mixture was heated under reflux, and 150 ml. of acetyl chloride was added over a period of a few minutes. After the mixture had been refluxed for an additional 2 hr., the solvent was removed by vacuum distillation at room temperature and a dark red residue was crystallized. By recrystallization several times from acetone, α, β-diethoxycarbonyl-β-cyanovinylacetylamine (m. p. 215~216°C) was obtained in a 2.2 g. (11%) yield.

Found: C, 51.90; H, 5.42. Calcd. for $C_{11}H_{14}O_5N_2$: C, 51.96; H, 5.55%.

Its infrared absorption spectrum had bands at 3226, 2222, 1802, 1709 and 1654 cm^{-1}.

Acetylation of Schiff Bases X with Acetyl Chloride.—A mixture of 1 g. (0.004 mol.) of X, 10 ml. of acetic anhydride, and a few drops of concentrated sulfuric acid was refluxed for 10 min. After cooling, the mixture was crystallized to give α-*N*-acetylcarbamoyl-β-ethoxycarbonyl-β-cyanovinylisopropylidenamine (m. p. 200~201°C) in a 10% yield.

Found: C, 54.38; H, 6.05; N, 15.80. Calcd. for $C_{12}H_{15}O_4N_3$: C, 54.33; H, 5.70; N, 15.84%.

The author wishes to express his gratitude to professor Risaburo Nakai of the Institute for Chemical Research, Kyoto University, for his cordial encouragement and suggestions throughout this work. He also desires to state his gratitude to Professor Ryozo Goto of Kyoto University for his invaluable advice in the course of this work. Thanks are also due to Mr. Tatsuo Azuma of the Institute for Chemical Research, Kyoto University for his earnest assistance.

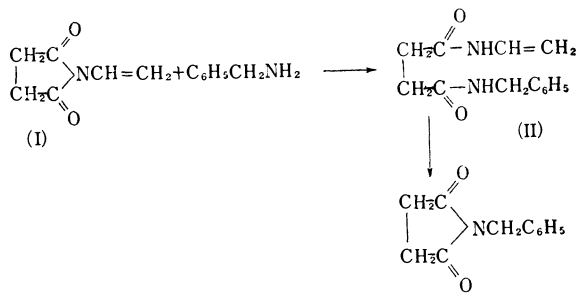
NOTES

Synthesis of N-Vinylsuccinamides

By Kiyoshi KATO



(Received February 19, 1962)

In 1959 Yanagi[1] reported a reaction of *N*-vinylsuccinimide with amines at room temperature. Under his experimental conditions, a white precipitate was given as an addition product, and he presumed the addition of amines to occur on the vinyl double bond. However, the reaction of *N*-vinylsuccinimide with amines may take place in two ways, to yield either an addition product to the double bond or *N*-vinylamide by the opening reaction of the imide ring.

Therefore, the present author has tried to prepare *N*-vinylamide derivatives through the latter reaction. When *N*-vinylsuccinimide (I) was treated with benzylamine at room temperature, a reaction occurred immediately and gave a solid flake (II), m. p. 172~173°C (decomp.). II was converted into *N*-benzylsuccinimide by the thermal decomposition. The infrared spectrum of II (Fig. 1) showed the absorption bands[2] at 3.02, 6.10 and 6.50 μ which suggested the existence of an amide radical. The existence of a double bond in the product was recognized by the Baeyer test and by bromination. Thus, II was concluded to be *N*-vinyl-*N'*-benzylsuccinamide.

Similarly, *N*-vinylsuccinimide reacted with various primary and secondary aliphatic, aromatic and heterocyclic amines and gave the respective vinyl compounds (see Table I).

N-Vinylsuccinamide copolymerized readily with such a monomer as methyl methacrylate or acrylonitrile.

Experimental

Only a few typical procedure are described in detail.

The physical properties and analyses of products are collected in Table I.

Preparation of *N*-Vinyl-*N'*-benzylsuccinamide.—A mixture of 1.1 g. of *N*-vinylsuccinimide and 1.25 g. of benzylamide was kept at room temperature for thirty minutes. The purified sample melted at 172~173°C (decomp.) and weighed 2.21 g. (95.2%).

2) L. J. Bellamy, "The Infrared Spectra of Complex Molecules", John Wiley and Sons, Inc., New York (1954), p. 176.

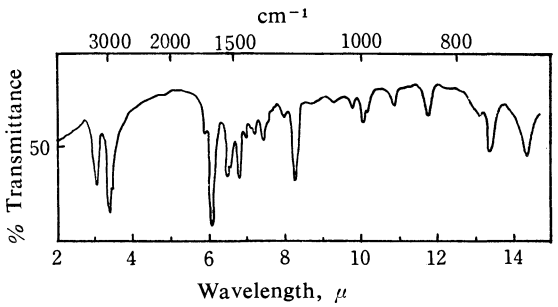

Fig. 1. Infrared spectrum of II (Nujol).

Thermal Decomposition of *N*-Vinyl-*N'*-benzylsuccinamide.—When II was heated at about 180°C for a few minutes, a red liquid was obtained. After recrystallization of the product from methanol, crystals were obtained; m. p. 98~99°C, undepressed by admixture with an authentic compound (Found: N, 7.28%).

Synthesis of *N*-Vinyl-*N'*-2-hydroxyethylsuccinamide.—A mixture of 1.25 g. of *N*-vinylsuccinimide and 0.6 g. of monoethanolamine in 2 ml. of benzene was kept at room temperature for few minutes. The precipitate was then filtered and dried. The product was recrystallized from benzene-ethanol. The purified sample melted at 134.5~135.5°C (decomp.); the yield was 1.75 g. (94.8%).

Reaction of *N*-Vinylsuccinimide with Morphorine.—*N*-Vinylamide was expected to be produced in this run, too, but it was not obtained in an analytically pure state. In the infrared spectrum of the crude material, absorption bands were observed at 3.02, 6.58 and 10.06 μ; these were assigned to the NH stretching vibration of a secondary amide and to CH out-of-plane deformation.

Copolymerization of *N*-Vinyl-*N'*-*n*-propylsuccinamide with Methyl Methacrylate.—A solution of 0.2 g. of *N*-vinyl-*N'*-*n*-propylsuccinamide, 1.8 g. of methyl methacrylate and 0.02 g. of benzoyl peroxide in 7 ml. of dioxane was heated at 65~66°C in a water bath for 6 hr. The polymer solution was poured into 70 ml. of methanol. After filtration and drying, the polymer weighed 0.41 g. (N, 1.69%). It was soluble in acetone, tetrahydrofurane, dioxane, benzene, toluene, chloroform, tetrachloroethane and ethyl acetate.

The author is indebted to Professor Niro Murata of the University of Osaka Prefecture for his invaluable advice and encouragement. Thanks are also due to Dr. Seibei Yoshikawa for his encouragement.

Ultracentrifugal Determination of Micellar Molecular Weights of Polyoxyethylene Dodecyl Ether

By Fumikatsu TOKIWA* and Toshizo ISEMURA

(Received May 15, 1962)

Several investigations[1-5] of non-ionic detergents in aqueous solutions have shown that the micellar molecular weights are highly dependent on the structures of the detergents. The chain-lengths of the polyoxyethylene of non-ionic detergents are also considered to be one of the factors that affect the micellar molecular weights.

An analytical ultracentrifuge provides a convenient method for the determination of the micellar molecular weights of non-ionic detergents. The transient-state method of determining micellar molecular weights in the analytical ultracentrifuge may be useful in avoiding independent determinations of the diffusion coefficients[6], and the synthetic boundary method may be used to determine relative optical concentrations without independent determinations of specific refractive increments[7]. The treatment of the data obtained from the Schlieren optics of analytical ultracentrifuge has already been given in detail[5,8] and will not be repeated here. The equation required for weight-average micellar molecular weight determination by the transient-state method is:

$$M=\frac{RT}{(1-\bar{V}\rho)\omega^2}\left(\frac{dc/dx}{xc}\right)_{m \text{ or } b}$$

Here M is the molecular weight, R the gas constant, T the absolute temperature, $\bar{V}$ the partial specific volume of the solute, ρ the density of the solution, ω the angular velocity, c the solute concentration, and x the distance from the axis of rotation to some point in the

c) See the text.

solution; the values of c and dc/dx must, on the other hand, be determined. The symbols m and b denote the meniscus and the bottom of the liquid column respectively.

Experimental

The detergents studied were polyoxyethylene dodecyl ether (abbreviated to PODE), $C_{12}H_{25}O\cdot(CH_2CH_2O)_nH$, which were prepared from dodecyl alcohol of high purity. The average degrees of the polymerization of ethylene oxide in these samples used are listed in Table I. The purification of the detergents was carrried out by an extraction method[9] using water-saturated *n*-butanol and *n*-butanol-saturated water. It was confirmed, by testing through paper chromatography[10], that the purified samples contained no detectable free polyethyleneglycol (abbreviated to PEG). The molecular weights of the samples (m) were determined by the freezing point depression of their benzene solutions. PEG (Carbowax 4000) was purchased from the Carbide and Carbon Chemicals Co. The detergent solutions were prepared by weight in freshly distilled water and stored for a few days.

The ultracentrifugal experiments were performed in a Hitachi model UGA-1 type ultracentrifuge. Centrifugations were done at 18 ± 0.2°C or 21 ± 0.2°C. In the present work, micellar molecular weights were determined only from the meniscus of the column, because it was found that the detergent solutions gave insufficient refractive-index gradients to permit measurement of the micellar molecular weight at the bottom of the column.

Partial specific volumes were determined from pycnometric measurements of solution densities at the same temperature as centrifugation was performed. The values of partial specific volumes are given in Table I.

Results and Discussion

The results for the micellar molecular weight (M) determination of PODE having various chain-lengths of polyoxyethylene are summarized in Table I. As expected, the micellar molecular weight or the aggregation number (the number of molecules per micelle, M/m) is highly dependent on the chain-length of polyoxyethylene. The aggregation number represented by M/m is used here as a measure of the degree of the aggregation, since the molecular weights of PODE should always have some distribution and the molecular weights obtained from different methods differ from one another. The aggregation number decreased with an increase in the chain-length, and PEG, a high molecular weight condensate composed of hydrophilic ethylene oxide, was found to be dissolved as a single molecule. Concerning the effect of polyoxyethylene chain-lengths on the aggregation numbers, Nakagawa et al.[4] have obtained similar results from light-scattering and diffusion-viscosity experiments over a relatively limited range of chain-lengths, using methoxy polyoxyethylene decyl and dodecyl ether. It would be desirable to have data for lower concentrations, but even a small error in reading the concentration gradient curves for concentrations lower than about 0.8~1.0 g./100 ml. would introduce much error.

The finding that the aggregation number decreases with the increase in the chain-length of polyoxyethylene indicates that the micelle formation of non-ionic detergents has some relation with the steric effect of the polyoxyethylene chain as well as with the hydrophility of the polyoxyethylene chain. It is a doubtful postulate that ordinary micelles are formed in a solution of such a non-ionic detergent as is encountered in ionic detergent solutions if the polyoxyethylene chain becomes sufficiently long. In the case of PODE of $n=67.3$ the aggregation number is only 6.5, and it is doubtful that a micelle, in the generally accepted meaning of the term, could be formed with

such an insufficient number of molecules. PEG shows no micelle formation, assuming that the molecular weight reported for the PEG studied is correct. Such behavior is not unexpected since light-scattering[1] and ultracentrifugal[5] experiments have shown that similar compounds, Pluronics, which are high molecular weight condensates of ethylene and propylene oxides, do not form micelles.

The authors express their hearty thanks to Mr. K. Kakiuchi for his measurements of ultracentrifugal sedimentation.

Recoil Reactions in Irradiated Tris-(nitrosonaphtholato)- and Tris-(dimethylglyoximato)-cobalt(III) Complexes

By Nobufusa SAITO, Takeshi TOMINAGA and Hirotoshi SANO

(Received May 28, 1962)

Hot-atom chemistry of radiocobalt has been studied by several authors on the irradiated octahedral cobalt(III) complexes of the formula, CoA_3, containing organic bidentate ligands, A (A=glycinate, acetylacetonate, oxinate, etc.)[1-4]. With a view to clarifying the relationship between distribution of induced ^{60}Co activity in various chemical forms and any chemical or physical property of the ligand, the present authors have selected, in addition to those mentioned above, three complex compounds of the similar type, tris-(α-nitroso-β-naphtholato)-,

TABLE I. PERCENTAGE OF ^{60}Co ACTIVITY SEPARABLE AS Co(II)

tris-(β-nitroso-α-naphtholato)- and tris-(dimethylglyoximato)-cobalt(III) complexes, and investigated the recoil reactions of radiocobalt in such compounds.

These crystalline complex compounds were irradiated in an experimental hole in JRR-1 reactor for one or five hours at ambient temperature. Thermal neutron flux was approximately 3×10^{11} n/cm^2·sec. All bombardments were made in the presence of air.

After the bombardments tris-(nitrosonaphtholato)-cobalt(III) complexes were dissolved in chloroform, and shaken four times with (1 : 1) nitric acid. The ^{60}Co activity as cobalt(II) was extracted into aqueous phase with enrichment factors more than 150, while ^{60}Co as complexes remained in organic phase.

The irradiated tris-(dimethylglyoximato)-cobalt(III) complex was dissolved in water and ^{60}Co-labeled species were separated by means of procedures involving paper electrophoresis (in acetate buffer or in 1% sodium chloride solution), solvent extraction (cobalt(II) extracted into benzene as β-nitroso-α-naphtholato-complex), precipitation, or ion exchange. By the solvent extraction method, ^{60}Co was extracted into benzene with enrichment factors more than 100. For the dimethylglyoximato-complex, the ^{60}Co activity separable as cobalt(II) was considerably decreased unless the irradiated complex was dissolved in water containing cobalt(II) carrier beforehand. Since no isotopic exchange was observed in practice between ^{60}Co(II) and tris-(dimethylglyoximato)-cobalt(III) complex within 6 hr. (at 24.5°C), the decrease might be mainly attributed to consumption of ^{60}Co(II) (in micro quantities) due to probable comlpex formation with free dimethylglyoximate ions present in the solution. Therefore adequate amounts of cobalt(II) carrier was added beforehand to minimize the loss of activity.

The percentages of ^{60}Co activity separable as cobalt(II) for samples irradiated and stored for varied times were summarized in Table I.

As seen in Table I, nitrosonaphtholato-cobalt(III) complexes showed considerably low percentages for cobalt(II) fraction. Since it was reported that more than 70% of the induced ^{60}Co activity could be separated as cobalt(II) from most of the CoA_3 type complexes freshly irradiated*, such a low extractability seemed to be rather unusual.

It is worthy of mentioning that α-nitroso-β-naphtholato-complex represented higher extractability of radiocobalt as cobalt(II) than β-nitroso-α-naphtholato-complex. This fact might possibly be related to some differences in configuration of their ligands or chemical properties of these complexes.

Hongo, Tokyo

* Based on the values reported in the papers cited above (1—4) as well as those for tris-(dimethylglyoximato)-cobalt(III) reported in the present paper. Though the irradiation condition employed by different authors were not identical the integrated neutron flux and gamma flux in the present experiment were estimated rather lower than those employed by other authors. Most irradiations by the other authors were also made at pile temperature.

Self-diffusion of the Sulfate Ion in Gelatin Gels

By Hirondo KURIHARA*1, Hiroshige HIGUCHI*2, Takeshi HIRAKAWA*3 and Ryohei MATUURA

(Received May 28, 1962)

The self-diffusion of ions in gels has not been studied so extensively as in aqueous solutions. In general, the diffusion process in gels is made more complicated than in liquid systems by such factors as the geometry of the diffusion path and the adsorption of the ion by the gel substance. Clearly these factors are closely related to the structure of gels. It is expected that the study of the self-diffusion of ions will give us useful information about the structure of gels as well as the nature of the transport phenomena in gels. In this paper the self-diffusion of the sulfate ion in gelatin gels will be investigated.

Experimental

The gelatin used in the present experiment was Merck's reagent for chemical use. In order to minimize its salt content, the aqueous solution (sol) of the gelatin was passed through an ion-exchange column. After that the salt content was found to be 0.3%. ^{35}S labeled sodium sulfate was obtained from the Radiochemical Center, England, as a carrier-free material. It was isotopically diluted to a proper concentration and purified by recrystallization.

For the measurement of diffusion, the layer analysis method was used. The diffusion cell was almost identical with that of Nachtrieb and Petit[1],

although some details were modified. The cell was made up of six disks (denoted from the top as disk No. 1 to disk No. 6) of poly(methyl methacrylate) Each disk, 40 mm. in diameter and 5 mm. in thickness, could be rotated around a common vertical axis. Disks No. 2 to No. 5 bore holes 5 mm. in diameter at a point 1 cm. from the center. They were aligned by means of a locating pin so that they formed a straight diffusion column. The two ends of the diffusion column were covered by disks No. 1 and No. 6, which bore no holes.

The gelatin sol, which contained inactive sodium sulfate of a known concentration, was poured into the holes of disks No. 3 to No. 5, which had been aligned. The same sol also containing radioactive sodium sulfate of the same concentration as above was poured into the hole of disk No. 2. They were then left to stand in a constant temperature bath. After complete gelation, the two gel blocks were placed in contact with each other by rotating the disks and by aligning the holes by the locating pin, as has been stated above. This time of contact was taken as time zero for diffusion. After an appropriate time (usually, 4 to 5 hr.), the cell was taken out of the bath and each disk was rotated with respect to its neighbor in order to shear the column of gel into four sections. The radioactivity of the sodium sulfate in each section (C) was measured after it had been mounted on a porcelain dish as a uniform film. The self-absorption correction was not made, since each disk contained exactly the same amount of gelatin and we needed only the relative intensity of radioactivity with respect to the initial one in disk No. 2 (C_0). The self-diffusion coefficient of the sulfate ion was thus calculated from the observed value of C/C_0 with the aid of the Stefan-Kawalki Tables[2].

The temperature of most of the diffusion, experiment was 25°C. For the measurement of the activation energy for self-diffusion, the temperature ranged from 10 to 28°C with 11% gelatin gel containing sodium sulfate of 0.001 mol./l.

Results and Discussion

In Fig. 1 the self-diffusion coefficient of the sulfate ion in gelatin gels, D_g, at 25°C is plotted against the square root of the concentration of sodium sulfate in the gel. Each value of the diffusion coefficient is a mean of three separate runs. The standard deviation was less than 3%. For the sake of comparison, the self-diffusion coefficient of the sulfate ion in aqueous solutions at 25°C, D_w, as measured by Nielsen et al.[3], is also shown in Fig. 1.

It may be seen from Fig. 1 that the D_g value in 11% gel is about half as large as D_w when the concentration of sodium sulfate is very low, but at higher concentrations of sodium sulfate the two values approach each other. As the gel concentration increases, the D_g value decreases; also, the dependence of the D_g value on the

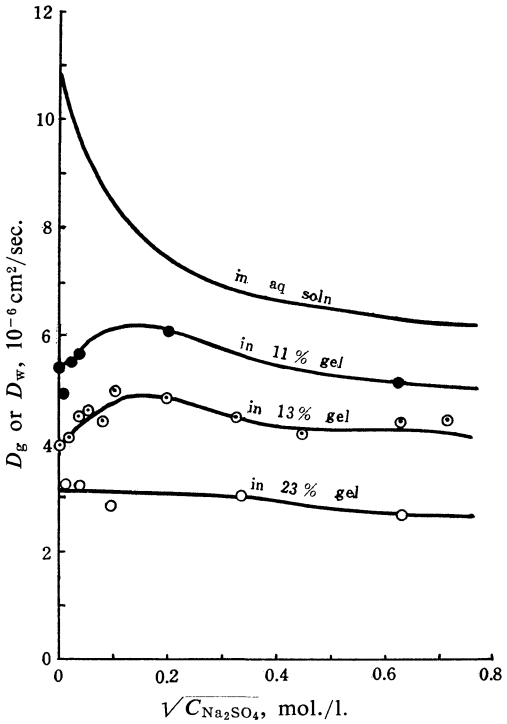

Fig. 1. Self-diffusion coefficient of sulfate ion vs. square root of concentration of Na_2SO_4 in gelatin gels (D_g) and in aqueous solutions (D_w) at 25°C.

concentration of sodium sulfate becomes smaller. The initial linear decrease of the D_w value with respect to the square root of the concentration of sodium sulfate in aqueous solutions may be explained in terms of the Onsager theory of ionic diffusion[4,5]. This behavior is quite different in gels, where the D_g initially increases a little but decreases slightly as the concentration of sodium sulfate increases further. In 23% gel, no initial increase in the D_g is observed.

It has reasonably been assumed that the sulfate ion is adsorbed strongly by the gelatin molecule to form intra- or intermolecular cross-linking. Indeed, we found that the "melting point" of gelatin gel[6] increases as the addition of sodium sulfate increases. The activation energy for the self-diffusion of the sulfate ion in 11% gel at the sulfate concentration of 0.001 mol./l. was found to be 5.9 kcal./mol. This value is of the same order of magnitude as that for the self-diffusion of ions in ion-exchange resins[7]. It is to be concluded, therefore, that the self-diffusion of the sulfate

ion in gelatin gels proceeds via the exchange of the adsorbed ion. Of course, the geometry of the diffusion path plays an important role in the diffusion of the adsorbed ion, since the self-diffusion coefficient decreases appreciably as the concentration of gel increases.

Bloksma[8] measured the self-diffusion of sodium and iodide ions and of urea in clay pastes. He separated two labyrinth factors, geometry and adsorption, and proposed to determine them. It is, however, not easy to determine each factor separately unless some assumptions are made. Probably the combined effects are responsible for the curious dependence of the D_g value on the concentration of sodium sulfate.

*NMR Spectra of α-Glycols**

By Shin-ichiro FUJISE, Genjiro HAZATO, Tsuneo IKENOUE, Shin-ichi SASAKI and Yasuhisa SENDA

(Received June 7, 1962)

We wish to report that the NMR spectra of α-glycols show a deviation caused by the differences in the steric configurations of the hydroxyl groups.

In the spectra of α-glycols, a characteristic difference between two isomers appeared in the chemical shift of the hydroxyl protons. The experimental results are shown in Table I. These findings are very interesting in comparison with those reported by Kuhn[1].

1) In α-glycol, which is in a liquid state at ordinary temperatures, the signal of the hydroxyl proton of the erythro-isomer was generally observed at a lower magnetic field than that of the threo-isomer, and in the trans rather than in the cis state.

2) When α-glycols are dissolved in a basic solvent, these hydroxyl protons are exchanged with the base; therefore, their signals show a single peak and the chemical shifts show a curve with a shape like that of Fig. 1, without exception between two isomers.

3) In organic acid, the protons of the carboxyl group and the hydroxyl group are exchanged, and their signals appear as a concentration shift. The shape of the curve in the two-phase system is different from that in a basic solvent (Fig. 2), but its behavior between two isomers is the same as in those cases without a solvent or in a base.

The following are the exceptions to our experimental rule which were observed.

4) In the spectrum of five-membered ring compounds such as cyclopentane-1,2-diol or α,β-dihydroxyvalerolactone, which take the planar conformation, the signal of the hydroxyl proton of the cis-isomer in acidic solvents was less shielded than that of the corresponding

trans-isomer in areas of a higher acid content (Figs. 3 and 4). This fact was recognized when trifluoroacetic acid instead of acetic acid was used as a solvent, a smaller amount of trifluoroacetic acid being sufficient to show this experimental fact, it is also well known that triflouroacetic acid is weaker than acetic acid in acidity.

The NMR spectra were obtained with a Varian V-4300 high resolution spectrometer at a fixed frequency of 40 Mc./sec., and the chemical shifts of the hydroxyl proton were relative to the signal of the proton of the group which was seen at the highest field in the spectra.

4-Chloro-3-methylcrotonic Acid Derivatives and Phosphonates

By Kazuyoshi FUJIWARA, Hidetaka TAKAHASHI and Masaki OHTA

(Received June 15, 1962)

3-Methylcrotonic acid derivatives are important intermediates for the synthesis of Vitamin A or of carotenoid. The present authors have found a very convenient procedure for the preparation of 4-chloro-3-methylcrotonic acid derivatives by the use of phosphonates. Recently, Wadsworth and Emmons[1] described how carbonyl compounds reacted with phosphonates by the action of sodium hydride to give olefinic compounds. In this study, ethyl

1) W. S. Wadsworth and W. D. Emmons, *J. Am. Chem. Soc.*, **83**, 1733 (1962).

4-chloro-3-methylcrotonate and 4-chloro-3-methylcrotononitrile were obtained from chloroacetone and appropriate phosphonate by the aid of sodium amide or of hydride in dry ether or tetrahydrofuran.

$$ClCH_2\overset{CH_3}{\overset{|}{C}}O + (EtO)_2\overset{O}{\overset{\|}{P}}CH_2R \rightarrow ClCH_2\overset{CH_3}{\overset{|}{C}}=CHR \quad (I)$$

(R, CO_2Et or CN)

Phosphonate in dry ether or tetrahydrofuran was stirred into a slurry of sodium amide or hydride in the same solvent at about 20°C. After this addition, the solution was stirred at room temperature while the evolved gas was removed under a slow stream of nitrogen. To the yellow solution, maintained below 25°C, chloroacetone in the same solvent was added drop by drop, a gummy precipitate appearing. After the reaction mixture had been stirred at room temperature for 1 hr., much excess water was added and then the product was extracted with ether. The ether, after being dried over sodium sulfate, was removed and the residue distilled under reduced pressure. I, R=CO_2Et; yield, 58%; b. p., 83~84°C/15 mmHg. Found: C, 51.38; H, 6.47; Cl, 21.41. Calcd. for $C_7H_{11}ClO_2$: C, 51.70; H, 6.82; Cl, 21.81%. I, R=CN; yield, 72%; b. p., 89~90°C/22 mmHg. Found: C, 51.92; H, 5.31; N, 12.09. Calcd. for C_5H_6ClN: C, 51.96; H, 5.23; N, 12.12%.

The 4-chloro-3-methylcrotonic acid derivatives condensed with triethyl phosphite at 180~200°C to give phosphonates. II, R=CO_2Et; yield, 81%; b. p., 157~158°C/8 mmHg. Found: C, 49.68; H, 8.11. Calcd. for $C_{11}H_{21}O_5P$: C, 49.99; H, 8.01%. II, R=CN; yield, 89%; b. p., 135~136°C/4 mmHg. Found: C, 49.58; H, 7.44; N, 6.44. Calcd. for $C_9H_{16}NO_3P$: C, 49.76; H, 7.43; N, 6.45%.

$$ClCH_2\overset{CH_3}{\overset{|}{C}}=CHR + (EtO)_3P \rightarrow (EtO)_2\overset{O}{\overset{\|}{P}}CH_2\overset{CH_3}{\overset{|}{C}}=CHR \quad (II)$$

Further investigation into the reaction between haloketones and phosphonates is now in progress; details will be presented elsewhere.

ν_{O-H} *Absorption and Rotational Isomerism of Fluoro-alcohols*[1]

By Michinori Ōki and Hiizu Iwamura

(Received June 15, 1962)

In a previous paper[2] it was presented that the ordinary saturated alcohols possess doublet character of O–H fundamental stretching vibration (ν_{O-H}). Considering the lack of this character in methanol and *tert*-butyl alcohol, and classifying the ν_{O-H} frequencies in reference to the types of the alcohols, the authors have succeeded in a tentative explanation that the occurrence of the doublet bands should be due to the rotational isomerism about the C–O bond as an axis.

In the meantime, Piccolini and Winstein[3] have been led to the same conclusion based on the measurement with some seventy saturated alcohols. Partly because of the fact that they took advantage of the spectra in the first overtone 1.4 μ region, their data are not always in quantitative agreement with the present authors'. In this respect, it seems desirable to add another example to confirm the existence of the rotational isomers about the C–O bond in alcohols.

I II II'

Of the three rotational isomers, I, II and II', in primary alcohols, relative stabilities will be determined by the interaction between the hydroxyl group and group R. As far as R is an alkyl group, only the van der Waals repulsive force is to be considered, hence I is expected to be predominant over II and II'. In this connection it was shown[2] that the intensity of the band corresponding to I is about twice as stronger as that of (II+II'), in spite of just the reverse statistical factor, and that the ratio of the integrated intensities, A_I/A_{II}, amounts to 6.0 when R is *tert*-butyl. Since it is unlikely that the molar absorption intensity

	II	3619.8	23.6	8.60	

of ν_{O-H} differs appreciably in I and II, A_I/A_{II} may be a good estimate of the population ratio between I and II. Then it comes out that I is about 400 cal./mol. more stable than II. The ratio, B_1/B_2, of ca. 8 by Piccolini and Winstein[3] will produce unreasonably great energy difference between the two rotational isomers.

When a hetero-atom is introduced in group R, another situation will arise in addition to the mere repulsive force. The apparent absorption curves and ν_{O-H} data of the fluorinated primary alcohols measured in dilute carbon tetrachloride solution (ca. 0.003 mol./l.) are shown in Fig. 1 and in Table I, respectively. They were determined with a Perkin-Elmer 112G grating IR spectrometer with the spectral slit width of 1 cm^{-1} [4,5].

All three show doublet ν_{O-H} at 3635 and 3620 cm^{-1}, respectively. The former is as high as that of methanol and can validly be assigned to the conformation I of the ordinary primary alcohols. According to the generalization put forward in the previous paper[2], conformational isomer II should have its ν_{O-H} at 3626~3629 cm^{-1}. There is a slight shift to the lower frequency in the present examples. The intensities of the doublet bands have suffered from more conspicuous effect. Contrary to the corresponding ethanol and 1-propanol, the lower-lying bands have acquired superiority over the higher ones, as shown in the A_I/A_{II} column in Table I. These data are in accord with the idea of the rotational isomerism around the C–O bond and may be explained as follows.

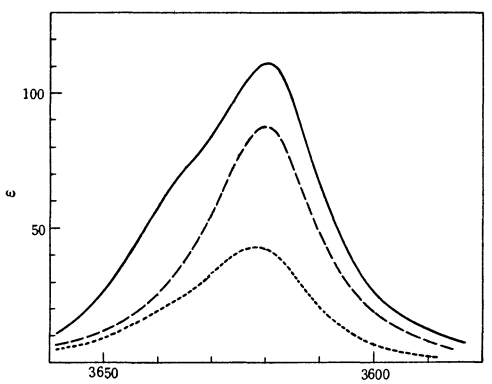

Fig. 1

····· FCH_2CH_2OH
– – – $CF_3CH_{20}OH$
—— $CF_3CF_2CH_2OH$

In isomers II and II′, it is possible for the hydroxyl group to take part in some kinds of O–H···F interaction which stabilizes the molecule. In ethylene fluorohydrin there seems to be no apparent energy difference between I and II, because A_I/A_{II} is nearly equal to the frequency factor of 1/2. However, the statement is not strictly true, since (II+II′) contains further isomerism with respect to the $C_\alpha-C_\beta$ axis. Band II, therefore, consists of the sum of these isomers and it is the mean energy of them that is comparable with that of I. When the number of the fluorine atoms at β-carbon atom is raised to three, rotational degree of freedom about the $C_\alpha-C_\beta$ bond produces no isomerism and all conformations belonging to (II+II′) have O–H···F interaction with the consequence of almost exclusive population in these isomers. In pentafluoropropanol, the existence of one or two of the rotational isomers in respect of the $C_\alpha-C_\beta$ axis in type (II+II′) become impossible, because of overcrowding of the CF_3 and OH groups. This effect disfavors the residence of the molecule in conformation (II+II′) relative to I, and has already been observed in a pair of ethanol and 1-propanol which have their A_I/A_{II} of 1.8 and 2.6, respectively[2]. The rates of the increase in the relative intensity are 1.44 in ethanol—1-propanol, and 6.9 in trifluoroethanol —pentafluoropropanol. Exaltation in the latter is the due consequence of the longer C–F bond length and the larger van der Waals radius of fluorine atom.

It may be concluded that, by introducing fluorine atom in R of primary alcohols,

*Metal Ketyls of Benzophenone Derivatives. I**

By Ryozo GOTO, Kazuhiro MARUYAMA, Rikuhei TANIKAGA and Yasuo DEGUCHI

(Received June 28, 1962)

The metal ketyls of benzophenone (I), *p*-methylbenzophenone (II), *p,p'*-dimethylbenzophenone (III), *p-tert*-butylbenzophenone (IV), *p,p'*-di-*tert*-butylbenzophenone (V), and dimesityl ketone (VI) were studied by electron spin resonance spectroscopy**. Metalic potassium was used as the alkali metal, and tetrahydrofuran as the solvent. A hyperfine structure was obtained for each spectrum of these ketyls (Fig. 1 (I)—Fig. 6 (VI)).

* The present work was presented at the 15th Annual Meeting of the Chemical Society of Japan, Kyoto, April, 1962.

** A spectrometer, 3B-type. Japan Electron Optics Laboratory Co., Ltd. (Tokyo, Japan) was used.

The present authors found that the molecular symmetry of ketyls has a considerable influence on the total shape of the spectra. Although there has as yet been no explanation for these experimental facts, the present writers are rather inclined to consider that the cause of the poor resolution of the spectra of the ketyls (II, IV) which have different phenyl groups seems to be due to the different contributions of the two phenyl groups to the free electron.

We have not yet been able to assign their hyperfine structures, but there seems to be a relation between the number of hydrogen atoms and the overall proton hyperfine splitting of the spectra, as can be seen from Table I.

Factor F was calculated assuming that the weight of the ortho- and para-hydrogen atoms was 2, and that of meta- and α-hydrogen atoms, 1. For example, in the case of compound I, $F=4\times2+4\times1+2\times2=16$.

The authors wish to thank the Ministry of Education for its grant.

SHORT COMMUNICATIONS

Complex of Boron Fluoride with Olefin on the Low-temperature

By Ryohei NAKANE, Tsunao WATANABE and Osamu KURIHARA

(Received July 2, 1962)

In our recent paper[1] we showed by the measurements of isotopes effect that boron trifluoride can form the complexes with chloro- and chlorodifluoromethane only at the low-temperature. In the present work the possibility of the presence of complexes of boron trifluoride with olefins was examined by the same method and the relation of them with the mechanism of the boron trifluoride catalyzed polymerization reaction is discussed. Propylene was chosen as an olefin, being suitable for our purpose, because it was found against Booth's claim[2] that a well-purified boron trifluoride - propylene mixture is condensed together at $-112°C$ (m. p. of carbon disulfide) without polymerization, but only the passage of moist air through its mixture can initiate polymerization.

We measured the equilibrium constants for isotopic exchange between boron trifluoride gas and boron trifluoride in propylene solution at $-112°C$ and $-96.5°C$ (m. p. of cumen) in a shaking type gas-liquid contactor, used in a previous work[1]. The two phases of boron trifluoride gas and propylene solution of boron trifluoride were kept in a glass flask, which was vigorously shaken in the low-temperature bath

for several hours. The equilibrium constant could be determined by measuring the $^{10}B/^{11}B$ ratio in the gas phase before and after equilibrations on a mass spectrometer, since a large excess of boron trifluoride was used in the liquid phase and hence the isotopic composition in the liquid phase remained practically unchanged throughout the experiments. On warming to room temperature after the experiments, the mixture, when evaporated, leaving only a trace amount of polymer on the vessel wall.

Results are shown in Table I. The equilibrium constant at $-112°C$ on no propylene in the liquid phase was also secured. In this case, isotopic exchange occurs between gaseous boron trifluoride and liquid boron trifluoride as follows;

$$^{10}BF_3(gas) + {}^{11}BF_3(liq) \overset{K}{\rightleftharpoons} {}^{11}BF_3(gas) + {}^{10}BF_3(liq)$$

$$K=\frac{[^{10}BF_3(liq)]}{[^{11}BF_3(liq)]} \Big/ \frac{[^{10}BF_3(gas)]}{[^{11}BF_3(gas)]}$$

$$=1.011\pm0.002 \quad (-112°C)$$

Thus, this constant is identical with the vapor pressure ratio of isotopic molecules, $^{11}BF_3$ and $^{10}BF_3$.

We found that the values of the equilibrium constants were much larger when there was propylene in the liquid, than the value when there was no liquid propylene, as in the case of boron trifluoride-chloromethane and boron trifluoride-chlorodifluoromethane systems. These results show that isotopic exchange occurs between gaseous boron trifluoride and a new liquid compound, being quite different from liquid boron trifluoride, because the equilibrium constant for isotopic exchange is well correlated with the translational, rotational and vibrational energy states of molecules. Boron trifluoride is known to coordinate with many compounds and the equilibrium constants for isotopic exchange between these liquid complexes and gaseous boron trifluoride are always larger than the vapor pressure ratio of isotopic molecules. Therefore, we consider that its new liquid compound is the complex of boron trifluoride with propylene, and isotopic exchange is shown by following equation;

$$^{10}BF_3(gas) + {}^{11}BF_3\cdot CH_2CHCH_3(liq) \overset{K}{\rightleftharpoons} {}^{11}BF_3(gas) + {}^{10}BF_3\cdot CH_2CHCH_3(liq)$$

$$K=\frac{[^{10}BF_3\cdot CH_2CHCH_3(liq)]}{[^{11}BF_3\cdot CH_2CHCH_3(liq)]} \Big/ \frac{[^{10}BF_3(gas)]}{[^{11}BF_3(gas)]}$$

$$=1.021\pm0.003 \quad (-112°C)$$

Although Evans et al.[3] claimed in their investigation on the mechanism of the polymerization that boron trifluoride did not form a stable complex with isobutylene, our result suggests that Evans' conclusion is wrong and the complex, $BF_3\cdot CH_2C(CH_3)_2$, can also exist at low-temperature.

However, these liquid complexes are stable only at low-temperature, because it was found that the solubility of boron trifluoride in propylene solution decreased markedly with the increase in temperature and, for example, boron trifluoride could scarcely be dissolved into liquid propylene even at $-78°C$.

For comparison, the system of boron trifluoride and paraffin such as propane was also investigated and it was found that the two liquids are practically immiscible at $-96.5°C$ or $-112°C$. Therefore the formation of any complex can not be considered.

Thus, we could detect the formation of the stable liquid complexes of boron trifluoride with an unsaturated hydrocarbon such as propylene at the low-temperature, and would like to conclude that these stable complexes have no concern with the mechanism of the polymerization and are not the intermediate products for polymerization, because the polymerization of both propylene and isobutylene can not proceed as long as there is no co-catalyst such as water, albeit the complexes can exist always at the low-temperature.

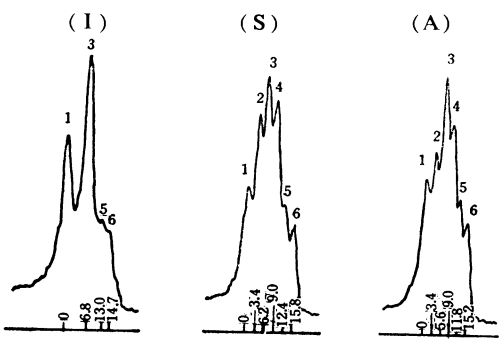
High Resolution NMR Spectra of Stereoregulated Polyvinyl Alcohol

By Akibumi DANNO and
Naohiro HAYAKAWA



(Received July 19, 1962)

In order to study the stereoregulated structure of polyvinyl alcohol (PVA), the high resolution NMR spectra of PVA dissolved in heavy water (about 3% PVA in weight) were examined. The samples used in the present work were isotactic rich (I), syndiotactic rich (S) and atactic PVA (A). The sample I obtained from poly-*tert*-butyl ether, and S from polyvinyl formate which was polymerized from vinyl formate at $-78°C$. The sample A was prepared from thermally polymerized polyvinyl

acetate. NMR measurements were made with a Varian V-4300-C spectrometer operating at 56.4 Mc.

The spectra of PVA consist of three signals corresponding to the three nonequivallent proton groups, namely, methylene, methine and hydroxyl groups. Among them, the hydroxyl proton signal appears in the lowest magnetic field at room temperature, shifts remarkably to higher magnetic field with increasing sample temperature (about 0.6 p. p. m. over the temperature range from 24 to 110°C). This shift is believed to be assigned to breaking of hydrogen bond[1]. The methine signal is seen in the magnetic field higher than that for hydroxyl signal at room temperature. However, its structure can not be resolved separately from hydroxyl signal in higher temperature, as the shift of hydroxyl signal results an overlapping on the methine signal. Finally, methylene signal appears in the highest magnetic field. Raising the temperature of sample makes the methylene signal narrower, and gives a hyperfine structure above 70°C. It is clear that the above narrowing is due to the more free segmental motion of PVA molecule at higher temperature.

The methylene signals obtained at 110°C show different patterns depending on the structures of the stereoregulated PVA molecules as shwon in Fig. 1. In this figure, the spectrum I, S and A stand for isotactic rich, syndiotactic rich and atactic PVA, respectively. In the isotactic rich PVA the peaks 1 and 3 are predominant, while in the syndiotactic rich PVA other peaks 2, 4 and 6 are also observed. The syndiotactic rich PVA used in the present work was so abundant in isotactic structure that the difference between the spectrum S and A was not so markedly.

Relative line positions measured from the lowest peak, c./sec.

Fig. 1. Spectra of methylene group of stereoregulated PVA at 110°C. The spectrum I, S and A stand for isotactic rich, syndiotactic rich and atactic PVA, respectively.

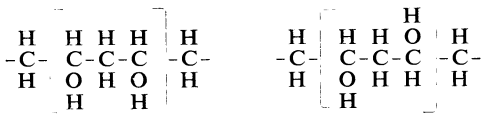


Fig. 2. Structure of the ideal isotactic and syndiotactic PVA.

As shown in Fig. 2, cis- and trans-configurations of a proton and a hydroxyl group around –C–C– chain are most remarkable difference between the isotactic and the syndiotactic PVA molecule as far as ideal structures concern. In a PVA molecule, two protons of a given methylene group are affected both by the spin-spin interaction with the proton of the methine and by the magnetic anisotropic effect of the hydroxyl group[2]. Therefore, it is explained that the differences in both effects mentioned above bring about the difference in hyperfine structures observed. Details of the work will be published in the near future in this journal.

The authours wish to express their heartly thanks to Dr. Hiroyuki Tadokoro and Dr. Masakazu Matsumoto for kind preparation of the stereoregulated PVA samples and also for their helpful discussions.

Structure of Isojervine[1]

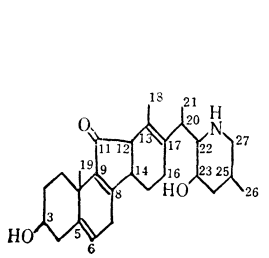
By Tadashi MASAMUNE, Mitsuo TAKASUGI, Hiroshi SUZUKI, Shozo KAWAHARA, Masatoshi GOHDA and Toshi IRIE

(Received July 18, 1962)

Isojervine[2], $C_{27}H_{39}O_3N$, an unexpected product obtained on acid treatment of pseudojervine or jervine[3] (I), has received no generally accepted structural assignment. We

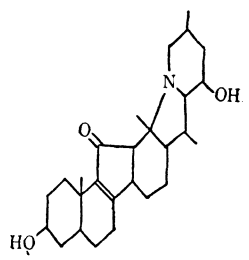
1) When we have completed this work, Dr. O. Wintersteiner, the Squibb Inst., and Prof. W. G. Dauben, California Univ., kindly informed us that they have arrived at the same structure as ours.

2) W. A. Jacobs and L. C. Craig, *J. Biol. Chem.*, 155, 565 (1944).



3) J. Fried, O. Wintersteiner, M. Moore, B. M. Iselin

wish to report that the structure II is consonant with all chemical and spectral data for isojervine[4], which is a secondary base with two acylable hydroxyl groups and one $\alpha\beta$-unsaturated keto group. IR[5], 1684, 1630 and 1063 cm^{-1}, UV[4], 330 mμ (ε, 250), 252 mμ (inflexion, ε, 2900) and end absorption (ε, 9000 at 211 mμ).



Reduction of II with lithium and methanol in liquid ammonia at $-70°C$ has now afforded α-dihydrojervinol[4], thus establishing the skeleton and the position of all oxygen-containing functional groups of II.

The location of a double bond at C_5–C_6 was confirmed by the Oppenauer oxidation of II with cyclohexanone and aluminum isopropoxide to isojervone[6], m. p. 112~114°C, $[\alpha]_D$ +140° (ethanol), IR, 1682, 1642 and 1620 cm^{-1}, UV, 234 mμ (ε, 22000). Hydrogenation of II over platinum in acetic acid resulted in preferential reduction of the C_5–C_6 double bond to yield dihydroisojervine (III), m. p. 153~155°C (as hydrate) and 171.5~172.5°C (after drying), IR, 1679, 1625 and 1040 cm^{-1}, UV, 238 mμ (ε, 9400); that is, the Oppenauer oxidation of III produced dihydroisojervone, m. p. 108~110°C, IR, 1712, 1687 and 1629 cm^{-1}, UV, 238 mμ (ε, 9900), only in a low yield. Hydride reduction of II yielded isojervinol (IV), m. p. 210~211°C, which exhibited only a weak end absorption (ε, 6400 at 212 mμ). The spectroscopic behavior of II, III and IV completely paralleled that of 1-acetyl-1, 4-cyclohexadiene[7], suggesting that another double bond would exist at C_8–C_9. The NMR spectral data (deuterochloroform, 60 Mc.) supported this view; the C_{19}-methyl signal of triacetate (IIa) of II appeared at the lower field (8.68 τ) as compared with that (8.97 τ) of diacetate (Ia) of I. The observed shift would be explained by assuming the field due to magnetic anisotropy not only of the C_8–C_9 double bond itself[8,9] but also associated with interaction[7] between the C_5–C_6 and C_8–C_9 double bonds. The C_{19}-methyl signals of triacetate, m. p. 203~205°C, of III and of diacetyl-Δ^{13}-jervine[5] appeared at the normal positions (8.98 and 8.87 τ) and the ultraviolet absorptions of these compounds were devoid of anomalies as observed with II.

The NMR spectrum of IIa showed a broad multiplet centered at 4.53 τ due to *one* olefinic proton (C_6-hydrogen) and a sharp singlet of methyl group attached to olefinic carbon at 8.06 τ instead of that at 7.77 τ due to C_{18}-methyl of Ia. The Birch reduction of III led to reduction of the C_8–C_9 double bond to yield two crystalline substances, α-tetrahydroisojervine (V), m. p. 147~149°C, IR, 1731 cm^{-1}, and β-isomer (VI), m. p. 138~142°C (chloroform addition compound), IR, 1741 cm^{-1}. However, neither triacetate, m. p. 179~182°C, of V, nor the corresponding β-isomer, m. p. 168~168.5°C, was found to be identical with 22, 27-imino-Δ^{17-20}-jervene-3, 23-diol-11-one triacetate prepared by Wintersteiner et al.[10] Treatment of III with 1 N potassium *t*-butoxide in refluxing *t*-butanol[11] under nitrogen for an hour yielded a crystalline compound (VII), m. p. 142~144°C, IR, 1670, 1621 and 1036 cm^{-1}, chloroform, 1678 and 1630 cm^{-1}, UV 239 mμ (ε, 8600). It was a *weak* tertiary base; (1) the pK_a value of VII, II and III were 6.12, 6.92 and 7.08 in 50% ethanol. (2) Acetylation of VII with acetic anhydride and pyridine on steam bath for 3 hr. gave exclusively an amorphous *O,O*-diacetate, IR, chloroform, 1725, 1685 and 1632 cm^{-1}, pK_a, 4.47. In view of the analogous examples[12], the formula VII was assigned to the m. p. 144°C compound. Similar reactions were observed with V and VI. Apparently these reactions involve migration of C_{13}-C_{17} double bond to $\alpha\beta$-position of the carbonyl group followed by cyclization. Thus, the formula II is the most favorable structure of isojervine.

Electrolytically Regenerated Ceric Sulfate for the Oxidation of Organic Compounds. I. Oxidation of p-Xylene to p-Tolualdehyde

By R. RAMASWAMY, M. S. VENKATACHALAPATHY and H. V. K. UDUPA

(Received April 15, 1961)

The use of ceric sulfate as "oxygen carrier" is described in many electro-organic oxidation processes[1-3]. These carriers act as depolarizers and ceric sulfate belongs to the group of ionic oxidizing agents which act only as electron-abstracting agents[21]. The reaction of the oxidized reagent with the organic compound to give the desired product is also expected to take place. If the latter is true, it would be a most convenient and economical procedure[4] to carry out the oxidation reaction in two stages, the first stage of electrolytically oxidizing cerous sulfate into ceric sulfate and the second stage of reacting the ceric sulfate with the organic compound to obtain the desired product. The oxidation of trivalent to tetravalent ceric sulfate[5-7] at a lead dioxide anode for the use of oxidation of xylenes and the electrolytic regeneration of ceric sulfate for further use have therefore been studied. Such a two-stage process has recently been developed in this laboratory, using manganous sulfate for the oxidation of aromatic hydrocarbons[11,12].

Kinetic studies of the oxidation of organic compounds by ceric sulfate have been described in literature[8-10,20]. A kinetic study of the oxidation of *p*-xylene by manganic sulfate was reported[11], but no kinetic study of the reaction between *p*-xylene and ceric sulfate appears to have been carried out. Ceric sulfate brings about controlled oxidation of *p*-xylene to *p*-tolualdehyde and a kinetic study of this oxidation using Ce^{4+} cation in sulfuric acid is described in the present article.

Experimental

Electrolytic Cell.—A glass trough of diameter of 12 cm. and height of 6.5 cm. with a suitable perspex lid carrying four holes for the electrodes, diaphragms, and thermometer respectively was used as electrolytic cell. Cylindrical lead anode with an effective area of 40 cm^2 was used as rotating anode. In the case of divided cells, two ceramic diaphragms of outer diameter of 2.5 cm. and height of 10 cm. and two narrow lead strips of 2 cm. wide and 14 cm. long were used as cathodes. In the case of investigating the use of stationary electrode with the same cylindrical lead anode, a glass stirrer was used for effective agitation in the cell. The anode potential was measured by Crompton potentiometer against a saturated calomel electrode. The other experimental conditions employed are given in the tables.

Analysis.—When electrolysis was over, 5 cc. of the oxidized solution was added to a known volume (20 cc.) of N/10 ferrous sulfate solution and then the excess of ferrous sulfate was titrated with a standard permanganate solution. In the case of electrolysis in the state of suspension, a known weight of the paste was added to excess ferrous sulfate solution and titrated in the same way and the current efficiency was calculated from the titre values knowing the total weight of the paste.

Kinetic Study of the Oxidation of *p*-Xylene with Ceric Sulfate

Materials.—Distilled *p*-xylene (b. p. 138°C) was used in the study. Cerous sulfate and all other chemicals were of A. R. quality. The ceric sulfate was prepared by the anodic oxidation of cerous sulfate in sulfuric acid as described before.

Measurement of Reaction Kinetics.—Ceric sulfate solution (350 cc.) in 5% sulfuric acid was taken in a three-necked flask and maintained at a desired temperature in a thermostat. Forty cc. of *p*-xylene was added to the flask containing ceric sulfate. A blade-type stirrer with a constant r.p.m. of 200 was employed to ensure identical agitation conditions. No attempt has been made to study the reaction in the absence of air. After five minutes of starting the reaction, stirring was stopped and the emulsion allowed to clear (30 sec.)

and an aliquot part (2 cc.) was pipetted out almost from the bottom of the flask and added to excess ferrous sulfate and then back titrated against standard potassium permanganate. Determinations were carried out at 90, 85, 80 and 75°C in the manner just described and with the experimental data curves were drawn for log C vs. time where C indicates the concentration of ceric sulfate. The slopes of all these straight lines in Fig. 1 are within experimental error. A blank was run at 90°C to make suitable corrections, but it was found that there was no appreciable decomposition of ceric sulfate during 25 min.

Reaction of *p*-Xylene with Ceric Sulfate.—Ceric sulfate solution or paste was taken in a three necked flask fitted with a mercury seal and stirrer, reflux condenser and thermometer. Required volume of *p*-xylene was added and the flask kept in the thermostat so that the oxidation could be carried out at 80°C. The contents of the flask were well agitated until the reaction was over.

Isolation of Aldehyde. — After cooling, the *p*-xylene layer was separated from the paste or solution and washed well with water to remove any sulfuric acid. Then the layer was treated with a saturated solution of sodium bisulfite to get *p*-tolualdehyde addition compound which on decomposition with soda ash and steam distillation, gave *p*-tolualdehyde.

Purification of used Electrolyte.—The used electrolyte was well extracted with xylene to remove all organic materials and after separation of xylene-layer the electrolyte was distilled under reduced pressure. The distillation was continued until a few cc. of water (5~15 cc.) was collected and the electrolyte after being made up to the original strength was recycled to the cell for regeneration of ceric sulfate, thereby making the process continuous and cyclic.

Results

The relationship between current efficiency and current density using stationary anode is shown in Fig. 2. Figure 3. shows the variation of anode potential with current density. The current efficiency obtained varying the concentration of sulfuric acid is given in Table I. Table II gives the current efficiency obtained using a divided or undivided cell. Table III gives the current efficiency obtained using a suspension of cerous sulfate in the electrolyte. The influence of anode material on current efficiency and yield is given in Table IV.

Values of the rate constants obtained in the kinetic study of the oxidation of *p*-xylene are given in Table V. Similarly the results of chemical oxidation of *p*-xylene by ceric sulfate are given in Table VI. Table VII includes the

results of the effect of cathodic reduction of ceric sulfate.

Discussion

The results indicate that the anodic oxidation of cerous sulfate in sulfuric acid is dependent upon a number of factors. Figure 2 shows that high current efficiencies are obtained at low current density values. The anode potential rapidly increases with current density as seen from Fig. 3. The decrease of current efficiency with increase of current density is therefore to be attributed to simultaneous oxygen evolution taking place at higher anode potentials. Results in Table I indicate that the concentration of sulfuric acid exerts a marked influence on the current efficiency because of the above reason. The difference in current efficiency obtained with divided and undivided cells is shown in Table II. The application of the rotating anode technique gave improved current efficiency due to the decrease of polarization. In subsequent experiments only stationary anodes were employed as the results obtained were satisfactory for the present purpose. The difference in current efficiency between divided and undivided cell is not large and the use of diaphragm can therefore be avoided by employing high cathodic current density.

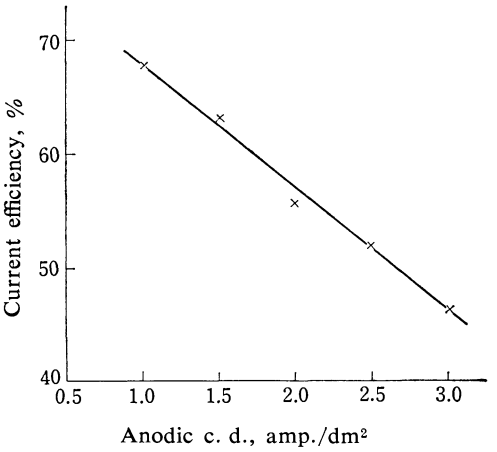

Fig. 2. Current efficiency against current density.

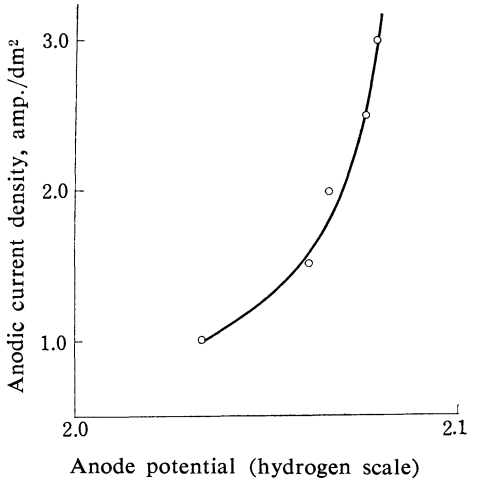

Fig. 3. Current density against anode potential (hydrogen scale).

Technique of avoiding the use of diaphragms in electrolytic cells is an important aspect to be considered on a practical scale and should lead to energy economics in addition to making cell design simple. Although this fact is known in developing practical scale production techniques, it is necessary to examine various aspects of the reaction itself. In the oxidation of manganous to manganic sulfate, evidence has been found for the existence of trivalent manganese in the complex form $H_2[Mn_2(So_4)_4]$. The reduction of the trivalent manganese in the anion $[Mn_2(So_4)_4]^{2-}$ at the cathode may be prevented especially at high current densities so that an undivided[12,13] cell can be advantageously employed. The direct reduction of the Mn^{+3} to Mn^{+2} at the cathode has thus been found to be negligible, especially when

the ratio of anode area to cathode area is sufficiently high. In a similar manner, ceric sulfate is also known to exist as the complex[6,14] sulfato-ceric acid, $H_4[Ce(So_4)_4]$ so that the reduction of Ce^{4+} in this anion should be prevented. The effect of cathodic reduction of ceric sulfate can be seen from Table VII and it is clear that the efficiency of reduction is very much affected, especially when the cathodic current density is above 15 amp./dm².

The results given in Table III are quite interesting and reveal the fact that the current efficiency remains more or less the same even when a cerous sulfate suspension in sulfuric acid is used for the oxidation. The portion of cerous sulfate in solution gets oxidized to ceric sulfate and a corresponding amount of the former dissolves in the electrolyte from the suspended state. However, when the solution becomes saturated with ceric sulfate, further formation of the same leads to a separation of the salt giving finally a suspension of ceric sulfate in the electrolyte. The effect of anode material on the current efficiency is shown in Table IV and it indicates that either lead dioxide electrodeposited on graphite[15] or lead dioxide on lead electrode can be used. By passing excess current, the yields obtained are almost theoretical even though the current efficiency bared on the ceric sulfate is somewhat lowered.

The electrochemical oxidation of *p*-xylene[16-19] in a single stage process using ceric sulfate as oxygen carrier has been reported to give very poor current efficiency. The oxidation carried out in two stages gives overall current efficiency of 23 to 30% as seen from Table VI, even though the efficiency of the oxidation of *p*-xylene with reference to ceric sulfate is more than 50%.

Energy of Activation for the Oxidation of *p*-Xylene by Ceric Sulfate

The reaction appears to be essentially homogenous, the dissolved *p*-xylene mainly taking part in the reaction. The efficient agitation was helpful in maintaining the solution saturated with *p*-xylene.

Figure 4 shows plot of log k against $1/T$ (°K). From the slope, the calculated apparent energy of activation is 23840 cal./mol., which would be inclusive of the effect of change of solubility of *p*-xylene in the medium with temperature.

Oxidation of hydrocarbons generally requires severe conditions and is usually retarded by bases, but is catalyzed by acids. The mechanism appears to be a single electron transfer reaction

and by the action of tetravalent ceric ion, exclusive oxidation of one of the methyl groups takes place and the initial attack may occur by hydrogen abstraction according to the reaction 1 given below:

The reaction of the substituted benzyl radical then takes place to yield tolylcarbinol which again reacts with Ce^{4+} to give the radical A which immediately reacts to give *p*-tolualdehyde as in Eq. 2.

Summary

1. The current efficiency for the oxidation of cerous sulfate in sulfuric acid at a lead dioxide in an undivided cell was generally found to be 70%.

2. By using a paste of cerous sulfate in sulfuric acid, ceric sulfate reagent is obtained in a concentrated form.

3. A kinetic study of the oxidation of *p*-xylene by ceric sulfate is described and apparent energy of activation is calculated.

4. The process of oxidation of *p*-xylene to *p*-tolualdehyde is made cyclic and continuous by regeneration of ceric sulfate at a lead dioxide anode.

The authors thank Professor K. S. G. Doss, Director of the Institute for his keen interest in this investigation. They also thank Shri K. C. Narasimham of this Institute for preparing graphite substrate lead dioxide anode.

Conformational Analysis of Isomeric 4-Substituted Cyclohexylcarbinyl p-Tosylates

By Nobuo Mori

(Received May 22, 1961)

In a previous work[1] which was carried out to investigate the difference in reactivity between the axial and the equatorial *p*-toluenesulfoxymethyl group in a cyclohexane system, it was found that *cis*-4-methylcyclohexylcarbinyl *p*-tosylate was solvolyzed more rapidly in acetic acid and more slowly in ethanol than the trans-isomer. From the observed rates and the consideration for their possible conformations, it was suggested that conformation Ia rather than IIa should be favorable for the axial *p*-toluenesulfoxymethyl group and conformation Ie rather than IIe for the equatorial one.

However, the above tosylates are unsuitable to provide a precise solution for the above problem, since each of them may exist in two interconvertible chair-conformations, the conformations and their relative rates of reaction must be taken into account estimating reactivity. Consequently, it is desirable to study a pair of diastereoisomeric compounds whose chair conformations are entirely pure.

Ia More stable — IIa Less stable

Ie More stable — IIe Less stable

Fig. 1

1) N. Mori, This Bulletin, **34**, 1299 (1961).

A detailed study has now been made of solvolysis of *cis*- and *trans*-4-*t*-butylcyclohexylcarbinyl *p*-tosylate under the assumption that the *t*-butyl group is more bulky than the *p*-toluenesulfoxymethyl group so that it is entirely restricted in the equatorial orientation and exerts no direct polar or steric effect across the cyclohexane ring, as in the case of *t*-butylcyclohexyl *p*-tosylates[2,3].

The results obtained show that the *cis*-*t*-butylcyclohexyl compound with an axial toluenesulfoxymethyl group is solvolyzed more rapidly by a factor of 4 in acetic acid and more slowly by a factor of 0.5 in ethanol than the trans-form with an equatorial toluenesulfoxymethyl group and the free energy difference ($e-a$) is $-1.7\sim-1.8$ kcal./mol., which is surprisingly almost equal to $-1.6\sim-1.8$ kcal./mol.[4] for the methyl group and which supports the assumption that the *t*-butyl group is entirely restricted in the equatorial orientation.

Experimental

Samples. — *cis*- and *trans*-4-*t*-Butylcyclohexylcarbinyl *p*-tosylate were prepared from the corresponding *cis*- and *trans*-4-*t*-butylcyclohexylcarbinols according to the method[5] previously reported by the author. The former melted at 95~95.5°C and the latter at 84°C.

Acetolysis of Cyclohexylcarbinyl *p*-Tosylate.— Cyclohexylcarbinyl *p*-tosylate[1] (6 g.) and an approximately equivalent amount of anhydrous sodium acetate in acetic acid (50 cc.) in a sealed ampoule were heated at 110°C for 60 hr. The reaction mixture was neutralized with sodium carbonate and extracted with ether. After drying, the ether solution was concentrated and the residue was heated with a methanolic sodium hydroxide solution for a short period. The mixture was evaporated and extracted with ether, and the ether extract was washed with water, dried and distilled. The distillation gave only one fraction (2 g., 80% yield) boiling at 89~90°C/19 mmHg and having $n_D^{21}=1.4638$, which was identical with cyclohexylcarbinol having b. p. 91°C/18 mmHg and $n_D^{20}=1.4649$. The above methanol distilled out, on addition of a salt solution, deposited an oily product (ca. 40 mg., 1.5% yield), which absorbed bromine and was therefore probably methylenecyclohexane boiling at 103°C.

Procedure for Rate Measurements. — Solvolysis was followed in ethanol (98.5% by weight) and in acetic acid containing a slight excess of acetic anhydride to 20~50% completion at 99.8±0.1°C or to 40~60% completion at 110±0.1°C by the usual ampoule technique[6] and first order rate constants calculated were steady to ±3% in the acetolysis and to ±5% in the ethanolysis. Table I lists the data for a typical run with *cis*-4-*t*-butylcyclohexylcarbinyl *p*-tosylate at 99.8°C in acetic acid.

Table I. Acetolysis of *cis*-4-*t*-butylcyclohexylcarbinyl *p*-tosylate at 99.8°C

Time sec.	Tosylate 10^2 mol./l.	$k_1\times10^5$/sec.
0	1.550	
5400	1.450	1.23
9000	1.385	1.28
12600	1.326	1.23
16200	1.279	1.24
19800	1.219	1.21
22200	1.180	1.23
25200	1.144	1.20
28800	1.100	1.20
	Mean	1.23

Unsubstituted and 4-methyl substituted cyclohexylcarbinyl tosylates[1] previously used were also solvolyzed at 110°C. Heats and entropies of activation were calculated by means of the equation given by Eyring[7].

The rate constants obtained are summarized in Table II, along with those of some other primary alkyl *p*-tosylates for comparison.

Discussion

Behavior in Solvolysis.—Since unsubstituted and substituted cyclohexylcarbinyl *p*-tosylates are regarded as members of a β-branched primary alkyl series, a similarity of behavior in solvolysis would be expected between these *p*-tosylates and, for example, isobutyl *p*-tosylate. In fact, Table II shows that the rates and $\Delta H^{\neq}$ and $\Delta S^{\neq}$ values of acetolysis of all cyclohexylcarbinyl *p*-tosylates used in the present work agree substantially with those of primary alkyl *p*-tosylates such as ethyl and isobutyl *p*-tosylate[8]. Further, an upward trend in rate as going from acetic acid to ethanol is not only observed for the former tosylates except *cis*-*t*-butylcyclohexycarbinyl tosylate, but also similarly for the latter tosylates, as shown in Table III. Such an upward trend in the rate attending the solvent change has not been found for secondary alkyl *p*-tosylates in general as well as cyclohexyl *p*-tosylates, while for these tosylates a downward trend in rate is observed which probably arises from the electron repelling inductive effect of α-alkyl substituents. Additionally, the absence of such α-substituents would be expected to result in lower acetolysis rates (10^{-5}/sec. at 100°C) of the primary alkyl and the cyclohexylcarbinyl *p*-tosylates, as compared

to those (10^{-3}/sec. at 100°C) of the secondary alkyl and the cyclohexyl *p*-tosylates.

In view of the result to be published in a subsequent paper that rates of acetolysis of isomeric 1, 2-bis-*p*-toluenesulfoxymethylcyclohexanes are not influenced by the presence of sodium acetate, the acetolysis of the cyclohexylcarbinyl *p*-tosylates is essentially of the unimolecular type involving a carbonium ion. Further, the acetolysis of cyclohexylcarbinyl *p*-tosylate gave predominantly one substituted product with a very small amount of olefin (see Experimental). This fact means that the acetolysis of the isomeric cyclohexylcarbinyl tosylates probably consists substantially of a substitution reaction while an elimination reaction is practically of unimportance. The ethanolysis of these compounds also may mainly consist of a substitution reaction. This expection is also supported by the fact[9] that bimolecular reaction of dimethanesulfonates of *cis*- and *trans*-1, 3-dihydroxymethylcyclohexanes with sodium iodide in acetone gives the corresponding *cis*- and *trans*-diiodide in 41 and 94% yield, respectively, and hydrolysis of the above two dimethanesulfonates in aqueous potassium hydroxide solution gives the corresponding *cis*- and *trans*-dicarbinol in a major yield (70% or more) and 4-methylenecyclohexylcarbinol in a minor yield (ca. 7%).

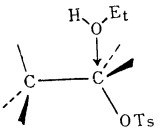
9) G. A. Haggis and L. N. Owen, *J. Chem. Soc.*, **1953**, 404.

Table IV. Relative rates of cis/trans

4-Substituent	99.8°C		110°C	
	EtOH	AcOH	EtOH	AcOH
t-Bu	0.51	4.2	0.55	4.3
Me	0.69	2.4	—	2.4

From Tables III and IV in which relative rates are shown, it will be seen that behavior in solvolysis of *cis-t*-butylcyclohexylcarbinyl tosylate in different solvents is essentially different from that of the trans-isomer. That is to say, the cis-form is acetolyzed more rapidly than the trans-form and on the contrary the former is ethanolyzed more slowly than the latter. The rate ratios of cis/trans in the acetolysis and in the ethanolysis are respectively 4.2 and 0.51 at 99.8°C which are almost the same as the values at 110°C, and these values agree essentially with 2.4 and 0.69 for 4-methylcyclohexylcarbinyl tosylates.

Further, the tables show that *trans*-4-*t*-butylcyclohexylcarbinyl tosylate is solvolyzed more rapidly in ethanol than in acetic acid and the ratio of EtOH/AcOH is 6.4. This value agrees substantially with 6.1 for *trans*-4-methylcyclohexylcarbinyl tosylate and also with similar values for primary alkyl tosylates, especially with a value of 6.2 for isobutyl tosylate at 75°C. This increase in rate attending the solvent change suggests that participation of the solvent, as shown in Fig. 2, which is a part of a driving force for ionization is more important in the ethanolysis of these compounds than in the acetolysis, since ethanol is of more nucleophilic nature than acetic acid.



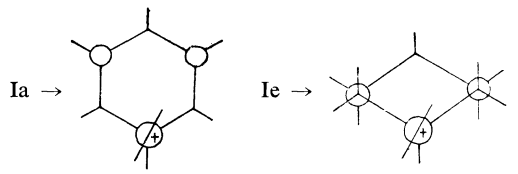


Fig. 2

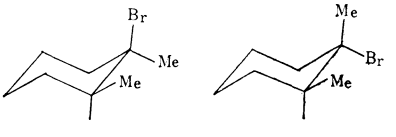
On the contrary, *cis*-4-*t*-butylcyclohexylcarbinyl tosylate was solvolyzed more slowly in ethanol than in acetic acid and the rate ratio of EtOH/AcOH averages 0.75. The corresponding ratio for unsubstituted and *cis*-4-methyl substituted cyclohexylcarbinyl tosylates, however, are respectively 3.7 and 1.8 which are lower than 6.1 for *trans*-4-methylcyclohexylcarbinyl tosylate. The lowest value of 0.75 for the *cis*-4-*t*-butyl-compound would be due to the cause that the ethanolysis of this compound does not substantially involve participation of the solvent such as shown in Fig. 2 for the case of the corresponding trans-form, as will be detailed later. The relatively high ratios of EtOH/AcOH for the unsubstituted and *cis*-4-methyl substituted compounds arise from their interconvertible chair conformations.

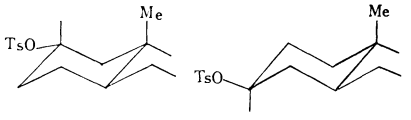
Conformational Analysis.—In Fig. 1, the possible conformations for the axial and the equatorial toluenesulfoxymethyl group which were proposed in the previous paper[1] are projected along the C_7–C_1 axis. Conformation Ie is more stable than IIe, since the former is free from the two 1, 3-diaxial interactions which are present in the latter. On the other hand, conformation Ia is more stable than IIa, since the bulky toluenesulfoxy group in the former is separated far from the two axial hydrogens on C_3 and C_5.



According to the consideration in the previous paper[1], in the conformation Ia there is very high crowding between the two axial hydrogens on C_3 and C_5 and the inside hydrogen on C_7. In the course of formation of the carbonium ion IIIa from the ground state Ia in Fig. 3, a large strain originally exerted on the inside hydrogen on C_7 decreases to a considerable extent. If the decrease in strain is much

IIIa IIIe

Fig. 3



larger than that in the case of formation of the carbonium ion IIIe from the ground state Ie, that is to say, the difference in energy between Ia and IIIa is lower than that between Ie and IIIe, this would provide a convenient explanation for the high rate ratio (higher than 1) of cis/trans observed in the acetolysis of isomeric 4-*t*-butylcyclohexylcarbinyl tosylates. Such a consideration may be supported by the experimental fact[10] that *trans*- and *cis*-1, 2-dimethylcyclohexyl bromides I and II are solvolyzed at an equal rate, and therefore steric interaction affecting the axial methyl group on C_1 in the cis-form II accelerates ionization of the equatorial bromine atom, to an almost equal extent with that of the so called 1, 3-diaxial interaction-accelerate-ionization of the axial bromine atom in the trans-form.

I II

10) T. D. Nevitt and G. S. Hammond, *J. Am. Chem. Soc.*, 76, 4124 (1954).

Further, it is supported also by the fact[11] that cholestan-2α-yl tosylate (III) is solvolyzed more rapidly by a fact of 3 than cholestan-3β-yl tosylate (IV), owing to relatively high interaction between the axial hydrogen on C_2 and the methyl group in the former tosylate.

III IV

On the other hand, as described above, the ethanolysis of the 4-*t*-butylcyclohexylcarbinyl tosylate would involve a solvent participation, but in the case of the cis-isomer such a participation would not be involved. Examination of the molecular models shows that in the conformation Ia a back-side entry of nucleophilic molecules, as shown in Fig. 2, is hindered by the axial hydrogen on C_3 or C_5, but in the conformation Ie such a steric hindrance is absent. This examination can give a convenient reason for the observed lower rate ratio of of EtOH/AcOH for the cis-form containing an axial toluenesulfoxymethyl group, as compared to that for the trans-form containing an equatorial one.

Summarizing the above consideration, in the acetolysis of the compound containing a toluenesulfoxymethyl group in an axial or an equatorial position, the decrease in steric strain controls the rate. On the other hand, in the ethanolysis of the compound containing an equatorial toluenesulfoxymethyl group, a driving force for ionization consists of the decrease in strain and the high solvent participation effecting to push the toluenesulfoxy radical, where the former being less important than the latter, while in the case of the compound containing an axial toluenesulfoxymethyl group the steric hindrance results in less importance of the solvent participation and only the decrease in strain effects a substantial driving force for ionization.

Although the conformations Ia and Ie may be respectively more stable than the corresponding IIa and IIe, this does not mean that these tosylates must react only in these stable conformations, since the energy barriers for their interconversion are probably less than the activation energies involved in the solvolysis.

Further, from the above conformations, it is easily understood that steric strain for the toluenesulfoxy group and for the inside hydrogen in the respective *trans*- and *cis*-4-*t*-butylcyclohexylcarbinyl tosylates is much higher by considerable factors than in cyclohexyl tosylates in general, and such high strain would result in a high rate of solvolysis. However, α-alkyl substituents or their electron-donating inductive effect can give much higher rate-increasing effects than steric strain does, and this has been borne out by the lower acetolysis rates of the former tosylates than that of the latter tosylates.

Free Energy Difference between Axial and Equatorial Toluenesulfoxymethyl Group. — Winstein and Holness[2] proposed a very useful relationship between the specific reaction rate k for any reaction of a molecule which exists in the two interconvertible chair conformations and has a departing group directly bound to the ring, the mole fractions N_a and N_e of the two conformations at equilibrium and the respective individual rate constants k_a and k_e, as follows:

$$k = N_a \cdot k_a + N_e \cdot k_e \quad (1)$$

On the other hand, Eliel and Lukach[3] gave an equivalent relationship, as follows:

$$k = (k_e \cdot K + k_a)/(K+1) \quad (2)$$

where K is the equilibrium constant N_e/N_a between the two conformations. From this equation Eq. 3 may be derived.

$$K = (k_a - k)/(k - k_e) \quad (3)$$

If the proportions of Ia and IIa and of Ie and IIe are affected by any substituent present in the tosylates, the above equations are applicable to solvolysis of the tosylates. In Table V are listed the conformational equilibrium constants derived from the rate constants in Table II by Eq. 3 in which k is the rate constant for the compound indicated, k_a is the rate constant for the purely axial isomer *cis*-4-*t*-butylcyclohexylcarbinyl tosylate and k_e is the rate constant for the purely equatorial isomer *trans*-4-*t*-butylcyclohexylcarbinyl tosylate. $\Delta F°$ in the table is the free energy difference between the chair-conformational isomers derived from the K value by Eq. 4.

$$\Delta F° = -2.3RT \log K \quad (4)$$

The $\Delta F°$ values require comment. It must be realized that these values no more than indicate orders of magnitude, since K in Eq. 3 is obtained as a quotient of two differences, one of which is usually small and therefore affected by a large relative error. Therefore, the values for the ethanolysis, in which measurement errors have been relatively high, are unsatisfactory (not shown in the table).

The conformational equilibrium constant for cyclohexylcarbinyl tosylate in acetolysis listed in Table V indicates that about 90% of the molecules exists with the toluenesulfoxymethyl

11) S. Nishida, ibid., 82, 4290 (1960).

Table V. Summary of K and ΔF° values in acetic acid

4-Substituent	99.8°C			110°C		
	K	ΔF° kcal./mol.	N_a %	K	ΔF° kcal./mol.	N_a %
cis-t-Bu	0	—	100	0	—	100
cis-Me	1.17	−0.12	46	1.3	−0.20	44
H	9.6	−1.7	10	8.7	−1.8	9.0

trans-t-Bu	∞*	—	0.0	∞*	—	0.0

* Assumed

group equatorial in equilibrium with 10% whose toluenesulfoxymethyl group is axial. The ΔF° value of −1.7∼1.8 kcal./mol. for the cyclohexylcarbinyl tosylate seems to be reasonable for the difference ΔF°_{TsOMe} in free energy between the equatorial and axial toluenesulfoxymethyl group.

The conformational free energy differences ΔF°_{cis} and ΔF°_{trans} for *cis*- and *trans*-4-methylcyclohexylcarbinyl tosylates should be related to that of cyclohexylcarbinyl tosylate by the equations:

$$\Delta F^\circ_{cis} = -\Delta F^\circ_{Me} + \Delta F^\circ_{TsOMe}$$

and

$$\Delta F^\circ_{trans} = \Delta F^\circ_{Me} + \Delta F^\circ_{TsOMe}$$

The ΔF°_{Me} is the difference in free energy between an equatorial and an axial methyl group or the energy required for moving a methyl group from an equatorial to an axial position and may be taken as −1.6 kcal./mol.[4] Since the corresponding value ΔF°_{TsOMe} for toluenesulfoxymethyl group is −1.7 kcal./mol. at 99.8°C, the calculated free energy difference ΔF°_{cis} for *cis*-4-methylcyclohexylcarbinyl tosylate with an equatorial toluenesulfoxymethyl group and its conformational isomer with an axial one is 1.6−1.7 or −0.1 kcal./mol.

Similarly, from the values of −1.8 kcal./mol. at 110°C for the toluenesulfoxymethyl group, the corresponding value is −0.2 kcal./mol. The calculated values of −0.1 and −0.2 kcal./mol. are in good agreement with the observed −0.12 and −0.2 kcal./mol.

For *trans*-4-methylcyclohexylcarbinyl tosylate, the value for moving a methyl and a toluenesulfoxymethyl group from axial to equatorial positions is −1.6 −1.7 or −3.3 kcal./mol. at both temperatures, which is in good agreement with the experimental values of −5.1 and −3.5 kcal./mol.

The value of 1.7∼1.8 kcal./mol. for the difference in free energy between the conformations with a toluenesulfoxymethyl group in an equatorial and an axial position respectively is almost equal to 1.6∼1.8 kcal./mol. for the methyl group[4] and 0.7∼1.7 kcal./mol. for the toluenesulfoxy group[2,3] but lower than 2.1 kcal./mol. for the ethyl and the *n*-propyl group[2]. The relatively low value of 1.7∼1.8 kcal./mol. appears quite reasonable, however, since in view of varying experimental conditions such as difference in solvents and temperatures, complete agreement of the ΔF° values should perhaps not be expected and the value of 1.7∼1.8 kcal./mol. would not be expected to be very different, as compared to that for the other groups.

The author wishes to express his sincere thanks to Professor Yojiro Tsuzuki for his advice.

Rates of Solvolysis of Bis-p-toluenesulfoxymethylcyclohexanes

By Nobuo Mori

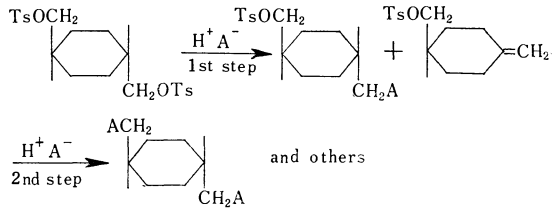
(Received June 17, 1961)

According to the previous work[1] dealing with solvolytic reactivity of a departing group such as a toluenesulfoxy group bound through a methylene linkage to a cyclohexane ring, the compound with a toluenesulfoxy group in an axial position is solvolyzed at a rate 4.2 times as fast and one half as fast as the corresponding isomer with that group in an equatorial position in acetic acid and in ethanol, respectively.

In the present work, the investigation has been extended to similar solvolysis of *cis*- and *trans*-1, 2- and 1, 4-bis-*p*-toluenesulfoxymethylcyclohexanes (described as ditosylates herein).

Experimental and Results

Samples. — All samples were prepared according to the methods by Haggis and Owen[2,3] with some modifications. The four ditosylates so obtained had the following melting points, respectively:



Position of $TsOCH_2$	M. p., °C	M. p. (reported)
cis-1,2	88	84 ~85[2]
cis-1,4	94.5~ 95	95[3]
trans-1,2	107.5~108	108[2]
trans-1,4	163 ~163.5	162~163[3]

Procedure for Rate Measurements. — Rate measurements were carried out in a similar manner to the previously employed method[4]. Rate constants were calculated from the formula

$$k=2.3/t\cdot\log 2a/(2a-x) \qquad (1)$$

in which a was the initial molar concentration of a ditosylate and x was the molar concentration of sulfonic acid liberated at time t.

Solvolysis was followed to 30~50% completion at 99.8±0.1°C in neutral ethanol (98.5% by weight) and in dry acetic acid containing a slight excess of sodium acetate. Concentrations were 0.01~0.015 mol./l. for the 1, 2-ditosylates and 0.002 mol./l. for the 1, 4-ditosylates, since especially the latter were difficulty soluble in these solvents. The solvolysis proceeds substantially in two steps with different rates where in the first step monotosylates are predominantly produced which in the second step are converted into final products, for example, as illustrated in the case of the *trans*-1, 4-ditosylate by the following formula:

where H^+A^- is the solvent and TsO is the toluenesulfoxy group. In all cases, however, the rate constants derived by Eq. 1 were nearly of the first order with a maximum error of 6%. Table I shows the data of a typical run with the *cis*-1, 2-ditosylate in ethanol at 99.8°C.

The acetolysis rates of the isomeric 1, 2-ditosylates were not substantially influenced by

	trans	6.4		

the absence of sodium acetate. The rate constants and the relative rates are summarized in Tables II and III.

Discussion

In the isomeric 1, 4-ditosylates, the trans-form may substantially exist in a diequatorial conformation while a diaxial conformation is negligible, since the energy required for moving the toluenesulfoxymethyl group from an equatorial to an axial position is 1.7 kcal./mol.[1] and therefore the free energy difference between the two conformations may be 3.4 kcal./mol. which indicates the proportion of the former conformation in the ground state to be more than 99%. On the other hand, especially in the *trans*-1, 2-ditosylate there are probably some interactions such as the steric and the electrostatic repulsion between the two bulky and polar toluenesulfoxymethyl groups, and therefore for this ditosylate a diaxial conformation may be preferable, as shown in various *trans*-1,2-disubstituted cyclohexanes[5] containing dipolar groupings such as halogen and others, which are mainly in a diaxial conformation. Accordingly, from the considerations based on the conformational preference at the ground state and the previous results described above, it is expected that the *cis*-1, 4-ditosylate is acetolyzed more rapidly than the trans-isomer with a relatively low ratio of k_{cis}/k_{trans}, as compared with the value of 4.2 for 4-*t*-butylcyclohexylmethyl tosylate, because in the cis-form one of the two toluenesulfoxymethyl groups is always axial. On the other hand, in the 1, 2-ditosylates it may be difficult to expect their solvolysis behavior.

According to the experiments, the rate ratio in acetolysis is 2.3 for the 1, 4-ditosylate and also 1.2 for the 1, 2-ditosylate.

Further, the *cis*-1, 4-ditosylate and also the *cis*-1, 2-ditosylate are ethanolyzed more slowly than the corresponding trans-isomers with a similar trend in rate ratio to that (0.51) for the 4-*t*-butyl compound, as seen in Table III.

Further, a ratio of k_{EtOH}/k_{AcOH} is 0.76 for the *cis*-4-*t*-butyl compound and 6.4 for the trans-isomer. The high ratios of 5.1 and 2.6 for the *cis*-1, 2 and 1, 4-ditosylates should be due to one equatorial toluenesulfoxymethyl group present in them.

The Radiation-Induced Exchange Reaction of Oxygen Atoms in Carbon Dioxide

By Kozo Hirota, Hideo Terasaki and Motoyoshi Hatada

(Received July 12, 1962)

There have been several reports on the radiation-induced reactions of carbon dioxide since the classical paper of Lind[1]. Recently Harteck and Dondes[2] obtained a small G value on the decomposition of carbon dioxide in relation to the study on the production of carbon suboxide and its polymers. However, they concluded[3] that this is due to the presence of the backward reaction, because the G-value became higher by the inhibition of the backward reaction with nitrogen dioxide. In relation to the above conclusion on the decomposition of carbon dioxide by Harteck

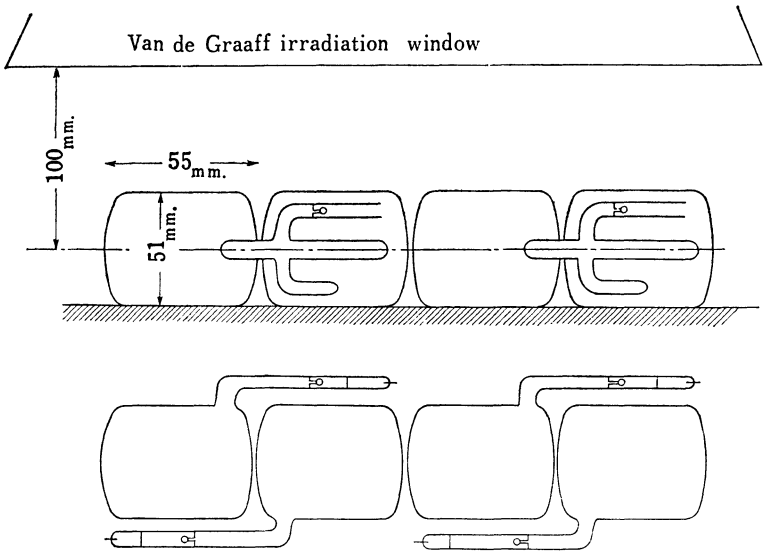

Fig. 1. Arrangement of the irradiation ampoules.

et al., it will be interesting to study the radiation-induced oxygen exchange between normal and labeled carbon dioxide: $C^{18}O_2 + C^{16}O_2 \rightarrow 2C^{16}O^{18}O$. Our purpose in the present paper is to report the investigation actually carried out on this line.

Experimental

Labeled Carbon Dioxide $C^{18}O_2$. — The enriched carbon dioxide $C^{18}O_2$ used in this experiment was prepared by the thermal diffusion method at the Faculty of Science, Osaka University[4]. The ^{18}O content was ca. 29 atom % and the ratio $C^{16}O_2$: $C^{16}O^{18}O$: $C^{18}O_2$ was 51.1 : 39.9 : 8.5*.

Normal Carbon Dioxide. — Commercial carbon dioxide was used after vacuum distillation.

Irradiation. — Definite amounts of the normal and the labeled carbon dioxide were taken and introduced into a cylindrical glass ampoule (80 cc.) with a break-off-tip by using liquid nitrogen cold trap. A set of such ampoules were arranged as shown in Fig. 1 and was irradiated simultaneously with 1.5 MeV. electron beam from the Van de Graaff accelerator (High Voltage Eng. Co., Model AKS).

Analysis. — After the irradiation, the samples were taken out from the ampoules and were analyzed by use of a mass-spectrometer (Hitachi, RMU-5 type).

Results and Discussion

The results in addition to the conditions of the irradiation are described in Table I. In the case of No. 4, glass wool was inserted into the ampoule.

Effect of the Irradiation Time. — The logarithm of the excess amount of heavy carbon dioxide in mole from the equilibrium value is plotted against the irradiation time t. The rate constant k was estimated to be $1.5_2\ hr^{-1}$, assuming that this exchange reaction proceeds according to 1st order, i. e.,

$$\ln\frac{[CO_2^*] - [CO_2^*]_\infty}{[CO_2^*]_0 - [CO_2^*]_\infty} = -kt$$

and reaches the equilibrium, the thermal equilibrium constant of which is as follows.

$$[COO^*]^2/[CO_2^*]\,[CO_2] = 4.0$$

where $[COO^*]$, $[CO_2^*]$ and $[CO_2]$ are the amounts of COO^*, CO_2^* and CO_2 in mol./unit volume, respectively.

Determination of the Apparent G Value. — The G^{exc}-value of the exchange reaction is given by the decrease of CO_2^* as follows:

$$G(-CO_2^*) = \frac{\text{Number of the } CO_2^* \text{ exchanged} \times 100}{\text{Energy absorbed in eV.}} \quad (1)$$

This value will be called an apparent one of G^{exc}, because only the value of the labeled CO_2 is determined.

In order to evaluate the energy absorbed by carbon dioxide in Eq. 1, effective thickness of the ampoules was calculated to be 2.1 mm. in No. 1—3, while it was estimated to be 2.2 mm. in No. 4 by considering the thickness corresponding to a half amount of the glass wool besides. The dose rate I thus calculated in

Before the irradiation	Labeled carbon[a] dioxide, $\times 10^{-5}$ mol.	5.23	5.41	5.50	5.48	4.02
	Normal carbon dioxide, $\times 10^{-5}$ mol.	16.24	16.11	16.08	16.16	12.38
	Total CO_2, $\times 10^{-5}$ mol.	21.48	21.52	21.58	21.64	16.41
	Normal CO_2 : Labeled CO_2	3.10	2.98	2.93	2.95	3.08
After the irradiation	CO_2 (%)	(88.6)[c]	86.6	86.3	86.6	86.7
	COO* (%)	(9.5)	12.7	12.4	13.0	12.4
	CO_2* (%)	(1.90)	0.11	0.84	0.45	0.94

N. B. a) Isotopic composition of the carbon dioxide used (CO_2 : COO* : CO_2* = 51.1 : 39.9 : 8.5)
b) The value corrected for the energy absorption by glass wool in the reaction vessels.
c) Percentages in parentheses are those of the blank.

both cases was 0.88×10^5 rad/sec. and 0.55×10^5 rad/sec., respectively.

First, mean $G(-CO_2^*)$ value was estimated to be 0.3_7 from No. 1, 2 and 3. In the case where glass wool was contained in the ampoule, the $G(-CO_2^*)$ value was calculated to be 0.3_5 using the dose rate corrected for the energy absorbed by the glass wool. Since $G(-CO_2^*)$ was not altered by the addition of the glass wool, it may be reasonable to regard the effect of the wall of the vessel negligible to the reaction.

However, the result observed after 3 hr. irradiation (No. 3) should be eliminated from the data for discussion, because the isotopic equilibrium may have been completed at that time and the isotopic composition of this system was not changed by further irradiation. Therefore, it is more reasonable to calculate the G-value of the exchange reaction of oxygen atoms between carbon dioxide molecules by the following equation,

$$G_{corr}(-CO_2^*)=\frac{([CO_2^*]_0-[CO_2^*]_\infty)k\times N_A}{I\cdot W\cdot 6.25\times10^{11}}$$

where I is the dose rate in rads/hr., and W is the amount of carbon dioxide in grams. The G value calculated by this equation was 1.7_2. In the discussion $G_{corr}(-CO_2^*)$ will be used hereafter.

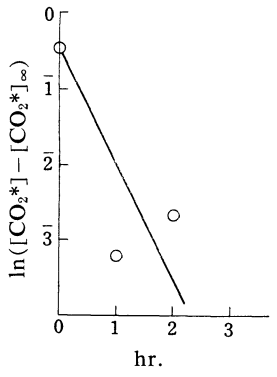

Fig. 2. Irradiation time vs. $\ln([CO_2^*]-[CO_2^*]_\infty)$. $k=1.5\ hr^{-1}$

Total G Value of the Exchange Reaction. — The apparent G values calculated above correspond to the exchange reaction a between CO_2* and CO_2. However, there are several similar reactions b—f in this system, which are not observed because of the situation that the species of the reactant and the product are the same.

$$CO_2^*+CO_2 \rightarrow COO^*+COO^* \quad (a)$$
$$CO_2^*+COO^* \rightarrow COO^*+CO_2^* \quad (b)$$
$$CO_2^*+CO_2^* \rightarrow CO_2^*+CO_2^* \quad (c)$$
$$COO^*+CO_2 \rightarrow COO^*+CO_2 \quad (d)$$
$$COO^*+COO^* \rightarrow COO^*+COO^* \quad (e)$$
$$CO_2+CO_2 \rightarrow CO_2+CO_2 \quad (f)$$

Fraction of the reaction a to all the reactions is calculated by

$$\frac{l\cdot n}{l\cdot n+l\cdot m+m\cdot n+\frac{l^2}{2}+\frac{m^2}{2}+\frac{n^2}{2}}=\frac{l\cdot n}{\frac{1}{2}(l+m+n)^2}$$

where l, m and n are the initial molar fractions of CO_2*, COO* and CO_2, respectively. Thus, the total G value of carbon dioxide G_{total}^{exc} in such a kind of exchange reaction is given by

$$G_{total}^{exc}=G_{corr}(-CO_2^*)\cdot\frac{1}{2\cdot l\cdot n} \quad (2)$$

Since $2\cdot l\cdot n$ equals to 0.033_7, G_{total}^{exc} was calculated to be 51 using the $G_{corr}(-CO_2^*)$ value of 1.7_2.

Comparison of the G Value of the Radiation-Induced Exchange Reaction with That of Radiolysis.—Harteck et al.[3] reported a rather small G^{dec} value (0.005) for the radiolysis of carbon dioxide at 1 atm. and concluded that

this small value was resulted from the simultaneous backward reaction induced by radiation. This conclusion was based on the fact that the G^{dec} value increased to 8.5 ± 1 when nitrogen dioxide (NO_2) was added as inhibitor to the backward reaction[3]. In our experiment, the forward and backward reactions under irradiation may give rise to exchange reaction of oxygen atoms between carbon dioxide molecules as actually shown by the present experiment. Therefore the G^{exc}_{total} must correspond to Harteck's G^{dec} in which the contribution of the backward reaction was eliminated. However, since the G^{exc}_{total} is determined to be 51, it is larger to some extent than G^{dec} of Harteck (8.5). This discrepancy may be attributed to the fact that the nitrogen dioxide added in Harteck's experiment may have some roles other than as an inhibitor of the backward reaction, whereas the samples in our experiment did not contain any impurities.

Summary

Oxygen exchange of carbon dioxide induced by β-ray irradiation has been investigated by use of oxygen isotope O*. From the decrease of O* amount, the apparent and total values of the exchange reaction, $G_{corr}(-CO_2^*)$ and G^{exc}_{total}, have been calculated to be 1.7_2 and 51, respectively. The latter value 51 would be equivalent to the forward reaction, but has been shown to be larger than the corresponding value (8.5) in Harteck's experiment.

Appreciation is expressed to Mr. Yohta Nakai for his collaborations in operation of the Van de Graaff accelerator and also to Dr. Yasushi Kobayashi and Mr. Masashi Takahashi for their preparation of heavy carbon dioxide.

Action des Ions du Fer Trivalent sur la Chalcopyrite

Par Masami ICHIKUNI

(Reçu le 15 Novembre 1961)

Comme la désagrégation qui a lieu dans la nature est composée de plusieurs processus: mécaniques, chimiques et microbiologiques, l'interprétation des descriptions faites aux mines offre une difficulté considérable. On trouve dans la littérature de nombreux travaux, soit géologiques, soit minéralogiques. Cependant on ne rencontre que très rarement des études géochimiques, qui présentent un grand intérêt aux géologues et géochimistes. Dans un travail antérieur[1], le présent auteur signalait la décomposition de la chalcopyrite en solution par de l'oxygène libre. Les décompositions oxydatives des minéraux sulfurés peuvent être provoquées principalement par l'oxygène et les ions du fer trivalent. Avec les expériences effectuées au laboratoire, on est capable de poursuivre uniquement l'action des ions du fer trivalent sans intervention de l'oxygène, ainsi on peut estimer avec facilité l'importance des facteurs géochimiques participant à ce phénomène. Le but de ce rapport est d'examiner par voie expérimentale la décomposition de la chalcopyrite en solution acide contenant des ions du fer trivalent.

1) M. Ichikuni, Ce Bulletin, 33, 1052 (1960).

Expérience

Les échantillons utilisés dans ce rapport sont un grand monocristal de pyrite, produit à la mine de Kanaborizawa, département d'Aomori et une masse de cristaux de chalcopyrite, produite à la mine d'Ani, département d'Akita, dont la description détaillée a été donnée ailleurs[1]. L'examen à l'aide des rayons X a montré que cettre chalcopyrite ne présente pas de phase cristalline étrangère. Ces minéraux ont été broyés, et passés au tamis de 200 mesh. Des sulfures mixtes de composition connue ont été préparés par mélange soigneux des deux minéraux pesés.

Comme la chalcopyrite est facilement attaquée par l'oxygène en milieu fortement acide, la réaction entre ce minéral et les ions du fer trivalent doit être effectuée à l'abri de l'oxygène atmosphérique. Dans une solution acide chlorhydrique, contenant

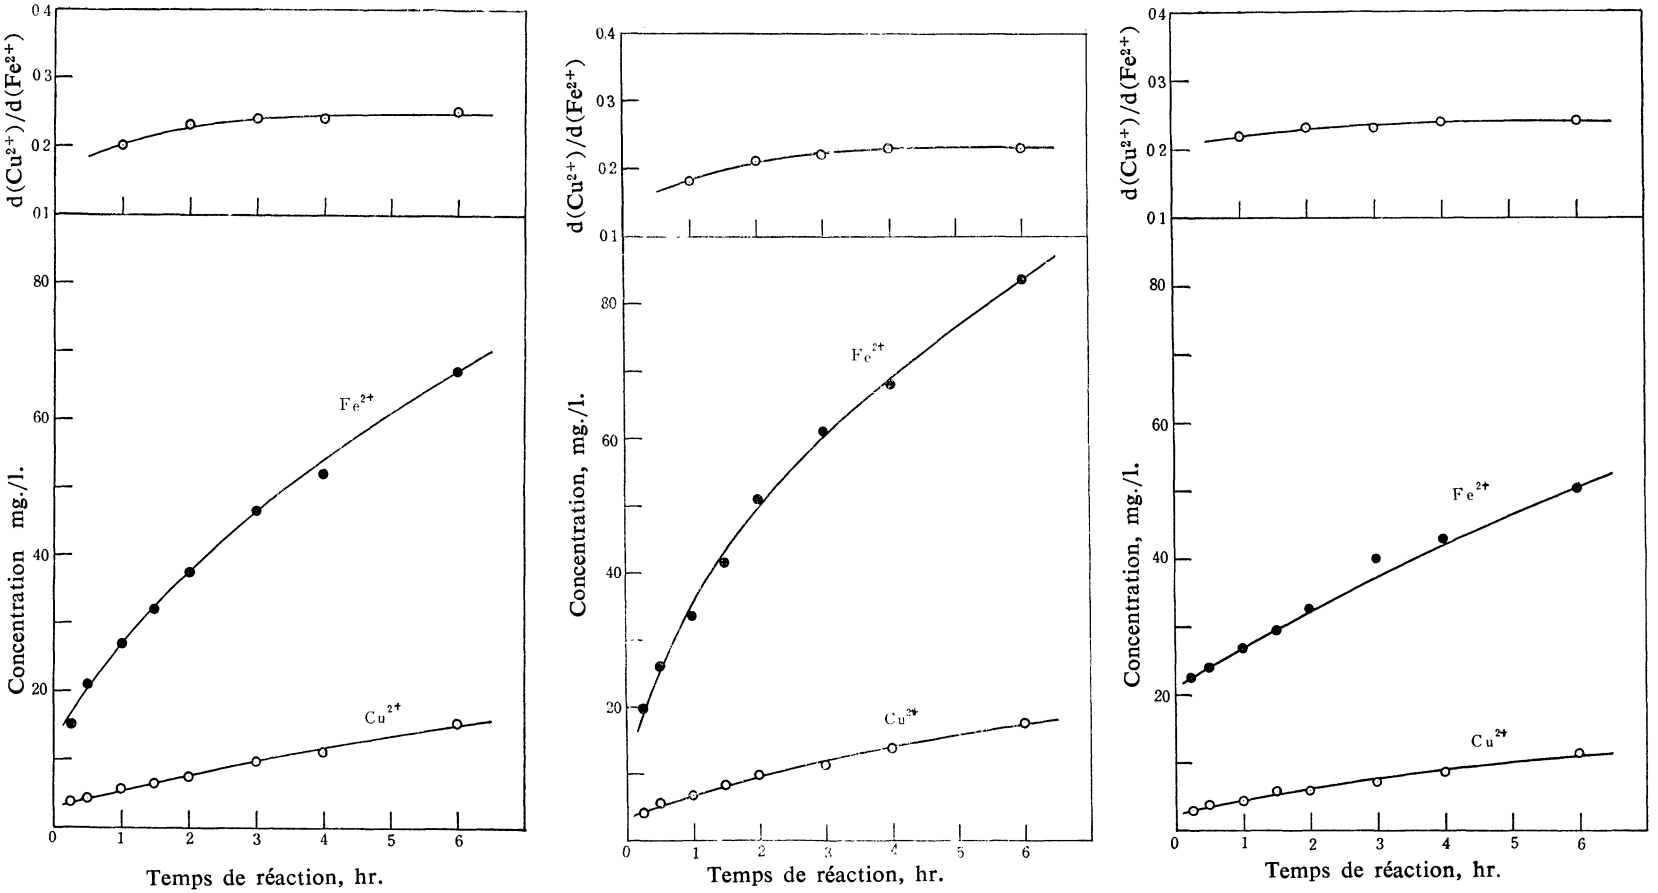

Fig. 1. Variation des concentrations de Cu^{2+} et de Fe^{2+} ainsi que du rapport $d(Cu^{2+})/d(Fe^{2+})$ en fonction du temps.

des ions du fer trivalent en concentration de 100 mg./l., préalablement chauffée à 50°C, on introduit un courant de dioxyde de carbone pour entraîner l'oxygène dissous. On ajoute ensuite 500 mg. de chalcopyrite ou de sulfures mixtes. De la solution agitée vigoureusement à l'aide d'un agitateur magnétique, on effectue plusieurs prélèvements de 5 ml. de liqueur avec des intervals appropriés. Ces liqueurs, immédiatement filtrées, sont diluées à 50 ml., d'où on prend 5 ou 10 ml. pour doser le cuivre, le fer divalent, le sulfate et le soufre libre. L'analyse du premier s'effectue par la colorimétrie avec le cupférazone[2], et celle du dernier, avec l'*o*-phénanthroline.

Résultats et Discussion

La décomposition de la chalcopyrite, causée par l'action des ions du fer trivalent, donne des ions du cuivre et du fer divalent, et du soufre libre, mais pas d'ions sulfate, d'où on déduit l'équation suivante:

$$CuFeS_2 + 4Fe^{3+} \rightarrow Cu^{2+} + 5Fe^{2+} + 2S \qquad (1)$$

L'analyse des résultats d'expériences révèle que le rapport de la vitesse de formation d'ions du cuivre sur celle d'ions du fer divalent $d(Cu^{2+})/d(Fe^{2+})$ varie avec le temps de réaction. Si la réaction avait lieu exactement comme indiquée par l'équation 1, le rapport serait de Cu/5Fe, soit de 0.23, indépendamment du temps de réaction. On voit sur la Fig. 1 que le rapport est légèrement inférieur à 0.23 au départ de la réaction, augmente lentement et s'approche de 0.23 environs.

Le présent auteur propose un mécanisme de réaction pour expliquer ces résultats: les atomes du fer contenus dans la chalcopyrite sont plus facilement libérés par l'attaque des ions du fer trivalent que ceux du cuivre, ce qui aboutit à un enrichissement en cuivre à la surface du minéral. Cette fois, les ions du fer trivalent peuvent réagir plus aisément sur les atomes du cuivre et le rapport $d(Cu^{2+})/d(Fe^{2+})$ augmente. L'enrichissement en cuivre ne peut donc être très imporant, et le minéral se décomposera entièrement en présence d'un excès d'ions du fer trivalent.

Il semble que la réaction ralentisse avec l'augmentation de l'acidité de solution et que la variation du rapport $d(Cu^{2+})/d(Fe^{2+})$ en fonction du temps soit influencée par le pH, mais il peut y avoir d'autres facteurs qui jouent un rôle important dans ce processus.

Une autre série d'expériences a été effectuée sur des sulfures mixtes, dont la proportion pondérale, chalcopyrite/pyrite+chalcopyrite, a varié de 5 à 100%. L'acidité de solution a été constamment de 0.01 N en acide chlorhydrique. Au terme de la réaction, où les ions du fer se trouvent tous à l'état divalent, on a fait le dosage des ions du cuivre et du fer. On peut trouver facilement les quantités augmentées de cuivre et de fer en solution, en sachant la concentration initiale en ions du fer.

Tableau I. Quantités de cuivre et de fer dissous a partir de 500 mg. de sulfures mixtes sous l'action de 20 mg. d'ions du fer trivalent

Composition de sulfures mixtes		Cu dissous mg.	Fe dissous mg.	Fe provenant de la pyrite mg.
Chalcopyrite %	Pyrite %			
5	95	0.38	2.2	1.9
10	90	0.66	2.4	1.8
20	80	1.2	2.6	1.5
40	60	2.1	2.8	1.0
100	0	5.4	4.8	0

Le Tableau I montre les quantités de cuivre et de fer dissous par la décomposition de sulfures mixtes. En admettant que la chalcopyrite donne 1 mol. de fer pour 1 mol. de cuivre en se décomposant sous les conditions d'expériences, on a calculé la quantité de fer libéré à partir de la pyrite. La Fig. 2 indique que la quantité de cuivre est proportionnelle à la teneur en chalcopyrite des sulfures mixtes, et que celle de fer provenant de la pyrite l'est à la teneur en pyrite.

Ces résultats mènent à une conclusion importante que les ions du fer trivalent réagissent sur des sulfures mixtes d'une façon peu sélective par rapport à l'oxygène. Notons que l'oxygène favorise une forte dissolution de la chalcopyrite associée à une quantité considérable de pyrite[3]. On a souvent remarqué que les minéraux sulfurés associés se

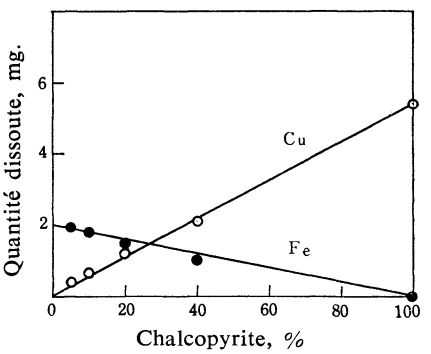

Fig. 2 Quantités de cuivre dissous de la chalcopyrite et de fer dissous de la pyrite en fonction de la teneur en chalcopyrite des sulfures mixtes.

3) M. Ichikuni, Ce Bulletin, **33**, 1156 (1960).

dissolvent chacun avec une vitesse différente lors de la désagrégation. Ce phénomène peut être expliqué par la différence du potentiel de contact existant entre de différents minéraux. Cette explication ne semble pas toujours s'appliquer à la désagrégation simultanée de minéraux associés, provoquée par les ions du fer trivalent. Toutefois des expériences répétées sur d'autres minéraux associés seront encore exigées pour faire la preuve de cette conclusion hardie.

Résumé

Sous l'action des ions du fer trivalent, la chalcopyrite libère tout d'abord plus de fer que du cuivre, ce qui aboutit à un enrichissement en cuivre à la couche superficielle du minéral. Cette couche est attaquée à son tour par les ions du fer trivalent, ainsi la décomposition avance en tout comme l'équation 1 l'indique. Pour la chalcopyrite associée à la pyrite, l'action des mêmes ions ne favorise pas de dissolution sélective d'un des deux minéraux. Répétons que l'action de l'oxygène accélère la dissolution de la chalcopyrite en milieu acide, si elle est associée à la pyrite. On trouve ici les caractéristiques des actions de l'oxygène et des ions du fer trivalent sur les minéraux sulfurés associés.

L'auteur se permet d'adresser ses remerciements sincères à Monsieur le professeue Kimio Noguchi et à Monsieur le professeur Takahisa Hanya qui lui ont donné des conseils utiles au cours de l'exécution de ce travail, et à Monsieur le professeur Takeo Watanabé, à l'Université de Tokyo, qui a bien voulu lire le manuscrit de ce rapport.

Physico-chemical Studies on the Composition of Thiosulfates of Metals. I. Thermometric Studies of Bismuth Thiosulfate Complexes

By Mahendra Singh BHADRAVER

(Received April 11, 1962)

The composition of bismuth thiosulfate has been studied by the method of thermometric titrations between bismuth nitrate and sodium thiosulfate in aqueous and alcoholic medium. The direct titrations curve suggest the formation of $Na_3Bi(S_2O_3)_3$ in which the ratio of $Bi : S_2O_3$ is 1 : 3. In the reverse titrations also the formation of $Na_3Bi(S_2O_3)_3$ is indicated.

There is a meager amount of literature on the study of the composition of bismuth thiosulfate. Carnot and Hauser[1] suggested the formula $R_3Bi(S_2O_3)_3 \cdot nH_2O$ and he pointed out that the solutions of these salts contain $Bi(S_2O_3)^{3-}$ which breaks up readily. There is however hardly any reference in literature on the study of bismuth thionsulfate by physicochemical methods. Hence the present investigation by applying thermometric method was considered worthwhile.

In view of the difficulties associated with analytical work and to throw further light on the composition of bismuth thiosulfate, attempts have been made in this paper to study the composition of these complexes by thermometric method. With the results of potentiometric, conductometric and amperometric measurements in progress, the results of thermometric method have been incorporated and discussed in this paper.

Experimental

The Reagents used were of E. Merck quality. Standard solutions were prepared by weighing. In case of sodium thiosulfate few drops of chloroform were added during the preparation of the solution so that the solution may be serviceable for a longer time. The strength of the sodium thiosulfate solution was further checked by standard KIO_3 solution[2]. Bismuth nitrate $Bi(NO_3)_3 \cdot 5H_2O$ was prepared by direct weighing and the solution was estimated as bismuth oxy-iodide[3].

The arrangement for thermometric titrations was the same as has been described by Naldar[4]. Using different concentrations of the two salts in solution,

Curve 1, 2, 3 M/5 sodium thiosulfate and M/80 $Bi(NO_3)_3$
Curve 4, 5, 6 M/10 sodium thiosulfate and M/125 $Bi(NO_3)_3$

the titrations were followed by the direct and reverse methods (i. e. when $Bi(NO_3)_3$) was added from burette to sodium thiosulfate solution in thermos flask and vice versa).

Titrations were also carried out in presence of alcohol up to 20% by volume. The total rise in temperature was then plotted against the titre in cc.

Discussion

It is evident from the summary of the observations of thermometric titrations that in the direct titrations the theoretical titre values required for the formation of $[Na_3Bi(S_2O_3)_3]$ would be (Table Nos. 1 to 6) 5.0, 4.5, 4.0, 2.0, 1.8 and 1.6 respectively in the ratio of 1 : 3. In the direct titrations one break occurs at the point of equivalence in the ratio 1 : 3. The theoretical values calculated for the reverse titrations accordingly for the ratio 1 : 1 are (Table Nos. 7 to 12) 1.25, 1.125, 1.00, 1.6, 1.44 and 1.28 respectively and therefore the theoretical titre values required for the ratio 3 : 1 would be 3.75, 3.375, 3.00, 4.80, 4.32 and 3.84 respectively. The observed values in the reverse titrations are in agreement with the values for the ratio 3 : 1. Thus the formation of the same compound $Na_3Bi(S_2O_3)_3$ is supported.

With a view to show the discrepancy between the observed and calculated titre values, a summary of observations in aqueous and alcoholic solutions is given above for comparison.

The results of our thermometric method are accurate and fairly support the views of Hauser[5].

Grateful thanks are due to Dr. J. N. Gaur, Maharaja College, Jaipur for his kind guidance in this piece of investigation.

Physico-chemical Studies on the Composition of Complex Arsenites of Metals. I. Conductometric and Thermometric Studies on the Composition of Copper Arsenite (Scheele's Green) Complexes

By Mahendra Singh BHADRAVER

(Received April 11, 1962)

The formation and composition of copper arsenite (Scheele's Green) has been investigated by conductometric and thermometric titrations between copper sulfate and sodium arsenite at several dilutions of the reactants by direct and reverse methods. The composition arrived at both by conductometric and thermometric titrations is $Cu(AsO_2)_2$.

There are variable formulae suggested in literature for the composition of copper arsenite: $CuHAsO_3$ or $Cu_3(AsO_3)_2 \cdot 2H_2O$ (Bornemann 1922; Inorganic Chemistry Partington p. 628). There is hardly any reference in literature on the composition of copper arsenite by applying physico-chemical methods. In order to arrive at decisive conclusions and to throw light on the composition of copper arsenite it was considered worthy of interest to study its composition by conductometry and thermometry.

A. R. (B. D. H.) reagents were used. Standard sodium arsenite solution was prepared and estimated as described (Vogel; Text Book of Quantitative Inorganic Analysis, p. 342). Copper sulfate solution was standardized against standard sodium thiosulfate solution.

Using different concentrations of the solutions of copper sulfate and sodium arsenite, conductometric and thermometric titrations were carried out by direct and reverse methods, i. e., when copper sulfate solution was added from micro-burette to sodium arsenite solution taken in conductivity cell or thermos flask and vice versa. The titrations were performed both in aqueous and aqueous alcoholic medium, the maximum alcoholic concentration in the latter case being 20% by volume. The results are shown in Figs. 1, 2 and 3.

Considering the strength of solutions of copper sulfate (M/10, M/20) and sodium arsenite (M/40, M/80), the observed titre values in conductometric titrations are 2.6, 2.2, 2.1, 2.6, 2.3

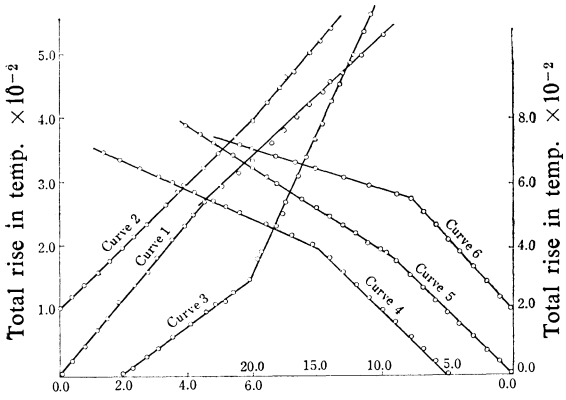

Fig. 1. Direct-titrations.
Curves 1, 2, 3 M/5 $CuSO_4$ and M/20 $NaAsO_2$
Curves 4, 5, 6 M/5 $CuSO_4$ and M/10 $NaAsO_2$

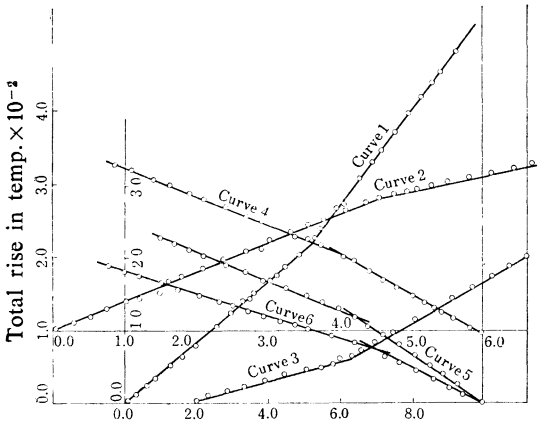

Fig. 2. Direct-titrations.
Curves 1, 2, 3 M/5 $NaAsO_2$ and M/20 $CuSO_4$
Curves 4, 5, 6 M/5 $NaAsO_2$ and M/10 $CuSO_4$

and 2.1 which are in agreement with the theoretical values 2.5, 2.25, 2.0, 2.5, 2.25, and 2.0 for 20.18 cc. and 16 cc. of sodium arsenite in case of direct titrations. The observed values in reverse titrations show a fair agreement

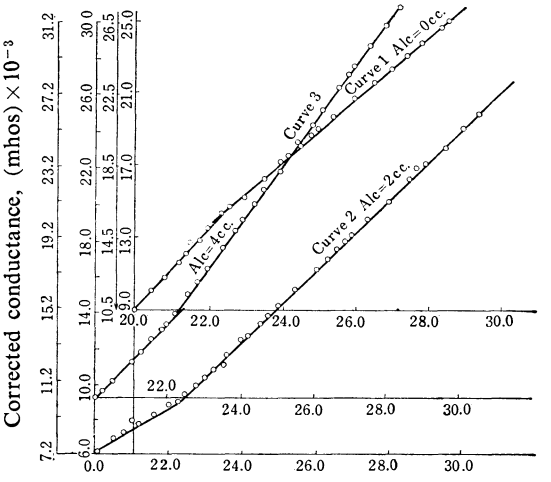

Fig. 3. Reverse-titrations.
Curves 1, 2, 3 M/5 $NaAsO_2$ and M/40 $CuSO_4$
Curves 1, 2, 3 M/10 $NaAsO_2$ and M/80 $CuSO_4$

with the theoretical values. Similarly in thermometric titrations the theoretical titre values calculated for 20.18 cc. and 16 cc. of solution in thermos flask show a notable agreement with the observed values, both in direct and reverse titrations. The details have not been given for the sake of brevity.

Thermometric and conductometric titration curves, both in direct and reverse methods, show one break corresponding to the point of equivalence in the ratio of 1 : 2 ($CuSO_4$: $NaAsO_2$) suggesting the formation of $Cu(AsO_2)_2$ which can be explained on the basis of the following equation:

$$CuSO_4 + 2NaAsO_2 = Cu(AsO_2)_2 + Na_2SO_4 \quad (1)$$

Studies on the complex by potentiometric titrations and Job's method of continued variation are in progress and the results will be communicated shortly.

Further Studies on Kinetics of Reaction of Malachite Green with Acids. Influence of Temperature

By Sarvagya S. KATIYAR

(Received April 16, 1962)

Lapin and Gein[1] suggested the use of malachite green (MG) as an analytical reagent especially for the colorimetric estimation of Sb^{3+}, Au^{3+} and Tl^{+}. For these estimation the interaction between metal ions and malachite green has been found sensitive to acidity. In acid medium, however, malachite green reacts with acid[2-4], resulting in the loss of characteristic color which sets a limitation to its usefulness in acid medium. This instability of malachite green in acid medium was hitherto uninvestigated in detail and therefore, warranted investigations for the elucidation of the mechanism involved therein. The variation of velocity constant with temperature could be utilized for the computation of energy, heat and entropy of activation, which are of immense value for the elucidation of reaction mechanism. In the present paper are reported the investigations on the reaction of MG with hydrochloric acid at different temperatures in aqueous medium as well as in media containing varying percentages of organic solvents.

Experimental

Malachite green of B. D. H. quality was purified in the manner described by Lewis and coworkers[5]. The purified product used for kinetic study was obtained as sulfate. The hydrochloric acid used was Merck GR sample.

Acetone of B. D. H. Analar Grade was purified by refluxing over calcium oxide and distilling[6].

Dioxane, the extra pure product of E. Merck was purified by refluxing with acid and then over sodium and finally distilling according to procedure of Hess and Frahm[7].

The organic solvent water mixtures containing varying amounts of dioxane and acetone were made by volume percent. The reaction mixtures were so prepared that the final volume was the same containing fixed quantities of MG and acid but varying amounts of dioxane or acetone.

The progress of the reaction of MG with hydrochloric acid was investigated with the help of Beckman DU spectrophotometer by making optical density measurements at the wavelength of maximum absorption at different intervals of time. Corex cells of 10 mm. width were employed. The temperature in the cell compartment was maintained at the desired value by circulating water in the dual thermospacer set fixed in the spectrophotometer, from an external thermostat controlled by an electronic micro relay. By this arrangement temperature could be controlled with a precision of ± 0.05°C.

Results and Discussion

Malachite green is known[4,5] to exhibit absorption maximum at $\lambda = 617.5$ mμ in aqueous medium. This absorption maximum is, however, affected by the presence of organic solvents such as dioxane or acetone which shift it to 620.0 and 622.5 mμ respectively. The kinetic studies at different temperatures were therefore carried out at $\lambda = 617.5$ mμ in water, 620 mμ in acetone and at 622.5 mμ in dioxane water mixtures. At these wavelengths MG obeys Beer's law and the reaction products do not show any absorption.

Time Variant Nature of the Reaction: First Order Nature.—In presence of acids the characteristic green color of MG decreases continuously and progressively with time. The data given in Fig. 1 illustrate the variation with time of optical density in presence of 60 mM hydrochloric acid. Here curves 1 to 6 refer to different initial concentration of MG employed, in the range 0.006~0.014 mM. Thus the concentration of hydrochloric acid is in very great excess over that of MG. Under this experimental condition the reaction obeyed first order law, when analyzed by differential method. The average value of n, the order of reaction corresponded to 1.11. The first order nature of the reaction is further substantiated by what follows.

For establishing the order of a reaction and to calculate velocity constant k from the values

of C at time t, a number of methods[8] have been proposed from time to time. The following is the familiar equation for obtaining the first order rate constants

$$\ln C = \ln C_0 - kt$$

where C_0 is the initial concentration and C the concentration at time t. According to this equation the plot of log C vs. t would yield a straight line for a first order reaction. It is of interest to note from Fig. 2 that the plots of log C vs. t are sensibly linear confirming thereby the first order nature of the reaction. As mentioned above that $C_{MG} \ll C_{H^+}$ therefore the real velocity constant k' was obtained as follows:

$$k' = \frac{(\Delta \log C_{MG})}{\Delta t\ (C_{H^+})}\ \text{l. mol}^{-1}\,\text{sec}^{-1} \qquad (2)$$

Dependence of k' on Temperature in Aqueous Medium.—The data given in Fig. 2 show the variation of log (OD) with time of malachite green solutions at different temperatures in the range 298~313°K. For these experiments the

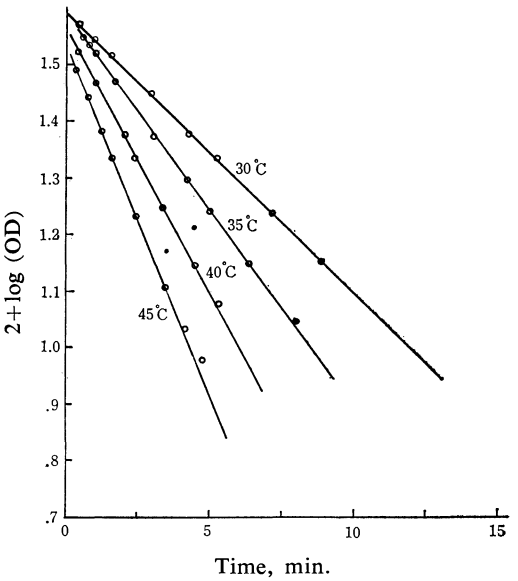

Fig. 2. Variation of log (OD) with time at different temperatures in aqueous medium.

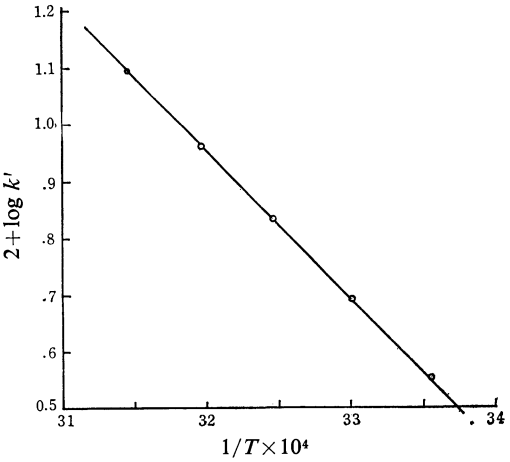

Fig. 3. Linear variation of log k' with $1/T$ in aqueous medium.

initial concentrations of MG and hydrochloric acid were 0.008 and 40 mM respectively. From the slope of these plots and the known initial concentration of hydrochloric acid k' was computed and the values obtained are reported in Table I; k' were 3.56×10^{-2} and 6.77×10^{-2} l. mol^{-1} sec^{-1} at 298 and 308°K respectively. The data of Table I were analyzed by the Arrhenius equation

$$\ln k' = \ln A - \frac{RT}{E^*} \qquad (3)$$

and the results are given in Fig. 3. It is interesting to note that sensibly linear plot of log k' vs. $1/T$ was obtained in accord with the

TABLE I. VELOCITY CONSTANT FOR THE REACTION OF MG AND HCl AT DIFFERENT TEMPERATURES IN AQUEOUS MEDIUM

Temp. °K	$k' \times 10^2$ l./mol. sec.
298	3.56
303	4.91
308	6.77
313	9.12
318	12.40

TABLE II. THERMODYNAMIC QUANTITIES OF ACTIVATION IN AQUEOUS MEDIUM AT 25°C

E^*	11.91	kcal.
A	1.92×10^7	l./mol.sec.
ΔF^*	19.42	kcal./deg.mol.
ΔS^*	−27.20	cal./deg.mol.
ΔH^*	11.32	kcal.

above equation. The slope of this plot yielded a value of 11.91 kcal. for E^*, the energy of activation. This value of E^* together with k' (given in Table I) gave a value of 1.92×10^7 l. mol^{-1} sec^{-1} for A, the frequency factor. Further, these data were also utilized for the computation of other thermodynamic quantities of activation such as free energy (ΔF^*), entropy (ΔS^*) and heat (ΔH^*) of activation with the aid of following equations[9]

$$\Delta F^* = 2.303\, RT\left(\log \frac{RT}{Nh} - \log k'\right) \qquad (4)$$

$$\Delta S^* = 2.303\, R\left(\log A - \log e\frac{RT}{Nh}\right) \qquad (5)$$

The values of themodynamic quantities are summarized in Table II. It is seen from this table that ΔS^* corresponded to −27.2 cal./deg. mol. This negative value of ΔS^* indicates that the reaction is occurring between ionic species[10,11].

Dependence of Velocity Constant on Temperature in Dioxane and Acetone - Water Medium.— A typical set ot kinetic data obtained in 10% dioxane - water and 10% acetone-water is shown in Figs. 4 and 5 respectively. Similar type of data were obtained in 5 and 15% composition of these solvents. For these experiments the initial concentration of MG and hydrochloric acid were 0.008 and 80 mM respectively. The values of rate constants k' obtained from these data are listed in Table III. It may be noted from this table that k' decreased with

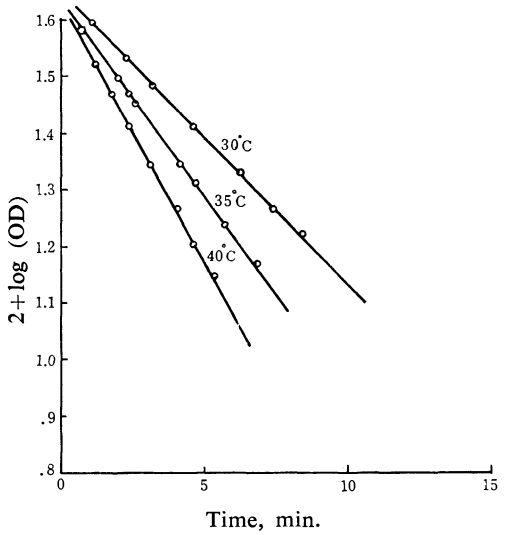

Fig. 4. Typical kinetic data for the reaction of MG and HCl in 10% dioxane.

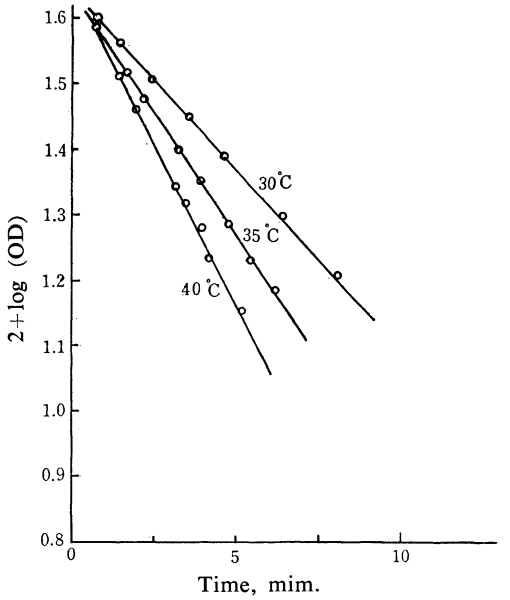

Fig. 5. Typical kinetic data for the reaction of MG and HCl in 10% acetone.

the increase in percentage of organic solvent at a particular temperature. This lowering of k' with decrease of dielectric constant of the medium when examined from Bronsted, Christiansen and Scatchard[12] equation points out towards the like charged nature of reactants involved in the reaction. This aspect has already been discussed in detail in a separate communication[2,3]. Further, at a fixed composition of solvent, however, rate constant

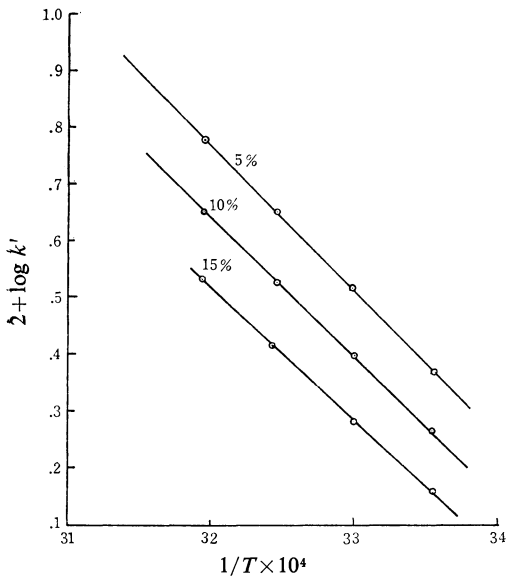

Fig. 6. Variation of log k' with $1/T$ in dioxane-water.

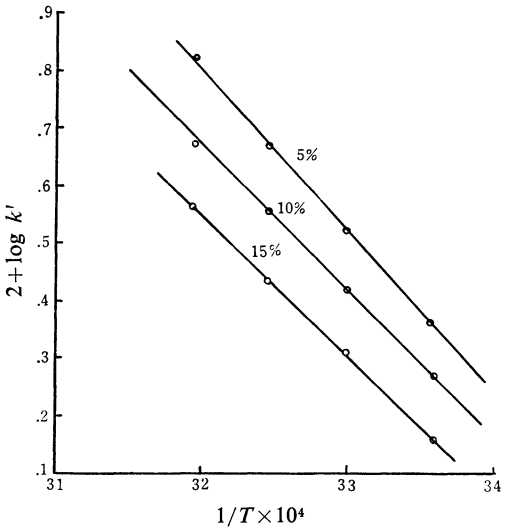

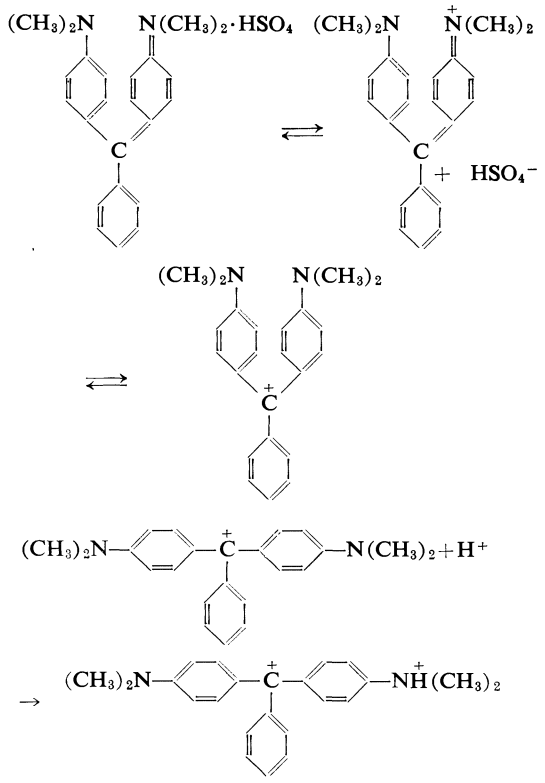

Fig. 7. Variation of log k' with $1/T$ in acetone-water.

k' was found to increase with increasing temperature. Thus, e. g. in 5% dioxane k' was 2.32×10^{-2} and 4.47×10^{-2} l. mol^{-1} sec^{-1} at temperatures 298 and 308°K respectively. This gave a value of 1.92 for temperature coefficient which is of the same order as observed in case of a numder of other reactions[13].

The data of Table III were also employed for the calculation of E^* in different composition of organic solvent. The plots of log k' vs. $1/T$ are shown in Figs. 6 and 7, for dioxane and acetone water mixtures. These plots as required by Eq. 3 are straight lines and the values of E^* obtained from the slopes are returned in Table IV. It is instructive to note that E^* decreases slightly with increasing percentage of organic solvent. Further the data of Table IV were also employed for the computation of thermodynamic quantities of activation such as ΔS^*, ΔH^* and ΔF^*. The values of these in different solvent compositions are summarized in Table IV. It is instructive to observe that ΔS^* becomes more negative with increasing percentage of organic solvents. This is probably due to solvated nature of intermediate complex. This observation also suggests that the species involved in the reaction responsible for the fading of color of MG in acid media are similarly charged[14] and this is in accord with the earlier findings.

Reaction Mechanism.—The results obtained by the kinetic studies on the reaction of malachite green and hydrogen ions led the author to suggest the following mechanism

13) S. Glasstone, "A Text Book of Physical Chemistry", MacMillan and Co., Ltd., London (1956), p. 1087.
14) Cf. Ref. 9, p. 122.

It is suggested that the first step represented by an equilibrium between the HSO_4^- and MG^+ ion does not contribute to the kinetic studies as the ionic recombination processes are known to be very fast[15,16]. Therefore, the second step involving the formation of acid salt is the rate determining step. It is instructive to note here that the second step points out towards reaction between positively charged ions, which is in complete agreement with the kinetic data obtained and presented in this paper and other communications[2,3]. It will be of interest to refer in this connection the observation of Branch and Tolbert[17] and Newman and Deno[18] who have also suggested the formation of acid salt for the reaction of malachite green with acids at pH 1.

Author's thanks are due to Professor P. K. Kelkar, Director of Indian Institute of Technology, Kanpur, for encouragement and kind interest in the work and to Director of N. S. I. Kanpur for the facilities of a spectrophotometer.

*Thortveitite from Kobe, Omiya, Kyoto, Japan**

By Kin-ichi SAKURAI**, Kozo NAGASHIMA and Akira KATO***

(Received May 12, 1962)

In 1960, T. Hisano, an amateur mineral collector in Kyoto, presented several mineral specimens gathered from Shiroishi pegmatite at Kobe, Omiya, Naka-gun, Kyoto, to the first author for identification. Of these, a small greenish gray crystal, after being subjected to X-ray diffraction, X-ray fluorescent and emission spectrochemical studies, turned out to be the first thortveitite fonnd in Japan.

Thortveitite, a soro-silicate of the scandium and yttrium group rare earths, was first described by Schetelig[1] in 1911 as gathered from a pegmatite at Iveland, Saetersdalen, Norway. Since then, only one locality, Befanamo, Madagascar, has been added, by Lacroix[2]. The material from this locality, containing more zirconium and less yttrium than that from Iveland material, was called by the variety name of befanamite.

In 1924, Goldschmidt and Thomassen showed the selective assemblage of rare earth elements in this mineral, the surprisingly high content of ytterbium, and the higher contents of scandium and yttrium[3]. Also, Goldschmidt alone has demonstrated an average of as much

as 20 p. p. m. scandium in the gabbro-amphibolite of Iveland and has suggested that the scandium in the thortveitite did not originate from granitic residual material but from the surrounding gabbro-amphibolite penetrated by the pegmatite dikes[4].

The peculiarity of this rare silicate is also found in its unusually high HfO_2/ZrO_2 ratio[5,6], which reaches 0.5 in the Norwegian thortveitite associated with zircons, with $HfO_2/ZrO_2=0.02$ as an average. Furthermore, as is frequently mentioned in textbooks of crystal chemistry, this mineral is one of the most representative species among soro-silicates[7,8].

Occurrence

The Shiroishi pegmatite is enclosed by a late Cretaceous biotite granite overlain by Miocene volcanic sediments about 10 km. north of the pegmatite[10]. The granite body contains many pegmatites, as at Oro, Mie, Morimoto, Ushio Mine, and also this Shiroishi pegmatite.

The pegmatite from which this mineral was derived is called Shiroishi pegmatite and is composed chiefly of perthite, quartz, biotite, muscovite and many such rare accessory minerals as kobeite[10,11], perrierite[12,13], euxenite, monazite, radioactive zircon, allanite, tourmaline, magnetite and ilmenite.

There are only two specimens that have been identified as thortveitite. One is a prismatic crystal $10\times4\times3.5$ mm. in size, while the other is much smaller, $9\times2\times2$ mm. Minute crystals of zircon are attached to the surface of the latter. Because both of them were found in the waste of the quarry, the minerals in the paragenetic relation are uncertain except for the zircon. The fresh surface is greenish gray in color with a glassy luster, but when altered it turns somewhat brownish. The streak color is white.

Emission Spectrochemical Analysis

As the amount of the sample available was so small, the emission spectrochemical technique was applied for the estimation of the scandium, yttrium, ytterbium, zirconium and hafnium. Sodium chloride contaminated by 0.01% palladium as the internal standard was used as the spectrochemical buffer to depress the intensities of the cyanogen bands, which may interefere with many sensitive lines of rare earth elements.

A graduated standard series covering the 0.002~2.0% range as the oxide of each element was prepared by diluting a mixture of scandium oxide, yttrium oxide, ytterbium oxide, zirconium oxide and hafnium oxide with a buffer. Samples were mixed according to one of the following ratios: (a) one part of sample to 9 parts of buffer, or (b) one part of sample to 99 parts of buffer. The wall of the cavity of the graphite electrode was cut as thin as possible so as to aid the quick burning of the sample, and higher amperage was applied to reduce the volatility differences between the elements.

Working conditions were as follows:

Instrument: Shimadzu Littrow type spectrograph.
Spectral region: 4400~2700 Å.
Electrode: National Carbon's special-grade 1/8 inch graphite electrode.
Loaded sample: About 10 mg.
Analytical gap: 3 mm.
Voltage: 230 V. D. C.
Current: 9 amp. anode excitation.
Exposure: 0~50 sec.
Photographic plate: Fuji Spectroscopic Process.

In the sample with 1:9 dilution, such elements as aluminum, calcium, dysprosium, erbium, iron, hafnium, lutetium, magnesium, manganese, scandium, silicon, yttrium, ytterbium and zirconium were detected. Of these, except for silicon, scandium, yttrium and ytterbium the main components of this mineral, the lines of only iron and manganese were strong enough to be estimated as much as the order of 1%. Beryllium, often reported in this mineral, was not found.

Adopting the line pairs of Sc 3365/Pd 3481, Y 3242/Pd 3481, Yb 3298/Pd 3481, and Zr 3391/Pd 3481, smooth calibration curves were drawn for each element except hafnium at lower concentrations. Taking account of the previous lack of study of error for actual analysis, the range of values for each oxide is shown in Table I.

Table I. Spectrochemical analysis

Sc_2O_3	10 %
Y_2O_3	3~10 %
Yb_2O_3	3~10 %
ZrO_2	0.1~0.3 %

Such other minerals as kobeite, monazite, zircon, ilmenite, and feldpars were analyzed in the same way; only in kobeite 0.1~0.3 % scandium oxide was determined.

X-Ray Powder Studies

A very small fraction of the thortveitite was examined by X-ray powder study using a Norelco X-ray diffractometer. These powder data were compared with those of the thortveitite from Befanamo, Madagascar,[14] as given in Table II.

As may easily be seen, there are consistent discrepancies in the respective corresponding diffractions; that is, their *d*-values are always smaller in the Befanamo material. The discrepancies are to be ascribed to the increase of lattice constants due to the substitution for the smaller ion (Zr^{4+}=0.86Å) of the larger ion (Y^{3+}=1.00Å), both of which replace scandium.

Distribution of Lanthanum Series Elements

The distribution of lanthanum series elements was determined by the X-ray fluorescent method. The results are graphically configured in Fig. 1 and compared with those of Goldschmidt and Thomassen. The figure indicates the prevailing dominance of ytterbium among the lanthanide elements and how the elements belonging to the cerium-, gadolinium- and terbium-groups are quite deficient (detection limit: 0.01 % as R_2O_3). Although there are slight discrepancies between the present results and those of Goldschmidt and Thomassen in point of the distribution of the lighter lanthanides, a good coincidence was attained for those of the heavier lanthanides according to Oddo-Harkin's law.

Discussion

From the results of X-ray powder study, X-ray fluorescent and emission spectrochemical analyses, it is quite certain that the mineral in question is thortveitite.

As for the contents of the yttrium group of rare earths, that is, a summation of yttrium oxide and the oxides of the yttrium group

lanthanide elements, values by older analyses fall in the range between 8.89~17.7 % which range includes the present value.

The zirconium contents in thortveitites vary considerably. For example, Schetelig found 5 % zirconium oxide from the Iveland material[15], but a newer analysis[16] shows the absence of zirconium in other thortveitite from the same locality, suggesting a fluctuation in zirconium content even in samples from the same locality. Therefore, the rather low zirconium content of the present material is not particularly unusual; moreover, as may easily be seen from Table I, the extraordinary concentration of hafnium with respect to zirconium is in good harmony with the results of Hevesy and Jantzen[5].

Our discovery of thortveitite and detection of scandium in kobeite from the Shiroishi pegmatite indicates a notable accumulation of scandium in the magmatic residue of the granitic rock in this area in which no vestige of basic rock is found. In this respect, Goldschmidt's opinion is not applicable to the genesis of the thortveitite from the Shiroishi pegmatite.

Very recently, Neumann[17] has suggested the origin of scandium in several kinds of minerals in pegmatites of the Iveland district, where some thortveitite-bearing pegmatite dikes are developed.

The writers wish to express their hearty thanks to Mr. Takeshi Hisano for his kind presentation of the material used in this study. Our study was aided by a grant from the Scientific Research Fund of the Ministry of Education.

*Isomerization of Cyclohexyl Phenyl Ketoxime in Liquid Sulfur Dioxide**

By Niichiro TOKURA and Katsuo SHIINA

(Received May 16, 1962)

It has been shown by Waterman et al.[1] that the cis-trans isomerization of olefins is carried out by sulfur dioxide at 100~140°C. As to the elaidination of oleic acid by sulfur dioxide, many papers have been published[2] since the first paper on this subject appeared in 1894 by Saytzeff[3]. The carbon-carbon double bonds of steroids are also rearranged by liquid sulfur dioxide or by sulfur dioxide vapor[4]. Recent works by Cunneen et al.[5] are concerned with the cis-trans isomerization of polybutadiene and polyisoprene by sulfur dioxide at high temperatures.

The isomerization of a ketoxime in liquid sulfur dioxide was first found by Tada, Masubuchi and Tokura[6], the isomerization taking place even at low temperatures. According to their view[6], the rate of the Beckmann rearrangement of a ketoxime in liquid sulfur dioxide is so fast that the isomerization of the ketoxime is not competitive with the Beckmann rearrangement in liquid sulfur dioxide, the product of the reaction being a pure and single acidamide.

On the other hand, Brown et al.[7a] have reported on an ordinary case of Beckmann rearrangement in which the isomerization was predominant over the rearrangement, the product being a mixtue of the acidamides.

derived from both the initial and the isomerized oximes. Yukawa et al. have tried the Beckmann rearrangement of cyclohexyl phenyl ketoxime in order to obtain various mixtures of the two acidamides, the proportions of which were dependent upon the reagents used for the rearrangement[7b].

Chart 1

In the present paper, the present authors should like to submit their findings on the kinetics of the liquid sulfur dioxide-catalyzed isomerization of β-cyclohexyl phenyl ketoxime ($R=C_6H_{11}$, $R'=C_6H_5$) to the α-isomer.

Experimental

Liquid Sulfur Dioxide.—Sulfur dioxide was dehydrated by phosphoric acid anhydride[6].

Preparation and Separation of Cyclohexyl Phenyl Ketoxime.—The method used in the preparation and separation of the α and β-oximes was that described in a preceding paper[6].

Experimental Procedure.—In a 200 ml. glass pressure vessel about 250 mg. of the β-oxime(m. p., 114.5°C) was dissolved into liquid sulfur dioxide to make up a 40 ml. solution of the reaction mixture, the temperature of which was kept constant throughout the preparation[8] and the runs by means of a thermostat. At definite time intervals 8 ml. portions of the solution were withdrawn from the mixture. The aliquot was mixed with ice water and neutralyzed with an ammonia solution, and the precipitate was filtered, dried and analyzed for the oxime content. The run in dark was also carried out to compare the photochemical effect on the isomerization.

Analysis of the Isomeric Oximes.—The infrared spectrophotometric method was employed for this analysis. A Perkin-Elmer double-beam model 21 type spectrometer was used. As may be seen in Fig. 1, the characteristic absorption curves of α and β-oximes in carbon disulfide (curves II and III respectively) offer absorption maxima at 762 and 957 cm^{-1} for use as key bands for the analysis of the oximes. The simultaneous Eqs. 1 and 2 were used to calculate the content of the oximes.

$$E_m^{762}=C_\alpha\cdot E_\alpha^{762}+C_\beta\cdot E_\beta^{762} \quad (1)$$

$$E_m^{957}=C_\alpha\cdot E_\alpha^{957}+C_\beta\cdot E_\beta^{957} \quad (2)$$

where, E_α^{762}, E_β^{762}, E_α^{957}, and E_β^{957} are the molecular extinction coefficients of α-oxime and of β-oxime at 762 and 957 cm^{-1} respectively, the upper suffixes corresponding to the wave numbers and the lower suffixes to the α- and β-oximes, E_m^{762} and E_m^{957} are the extinction coefficients of the sample at the respective wave numbers, and C_α and C_β are the contents of the oximes in the sample. Beer's law was obeyed throughout the experimental conditions, and the experimental error of this analytical method was within three percent.

Results and Discussion

The isomerization of the β-oxime to the α-oxime is a slow reaction, as was expected. The conversions, in percentages, were 27 at 48 hr. and 20 at 12 hr., the initial concentrations of the oxime being, 2.46×10^{-2} mol./l. and 4.31×10^{-2} mol./l. at 0°C in diffused-room daylight. The reaction was accelerated by light and retarded by the addition of hydroquinone (H.Q.) (Fig. 2). In Fig. 3 the effects of the degree of dehydration of the liquid sulfur dioxide and of the addition of

8) N. Tokura, M. Matsuda and F. Yazaki, *Makromol. Chem.*, **42**, 108 (1960).

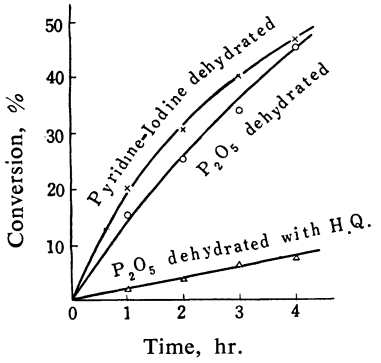

Fig. 3. Effect of degree of dehydration of liquid sulfur dioxide.
[β-oxime] 4.31×10^{-2} mol./l., Temp. 30°C

hydroquinone at 30°C in diffused daylight are visualized together. Liquid sulfur dioxide dried with phosphorus pentoxide (assuming the water content to be 100~50 p. p. m.)[9] or liquid sulfur dioxide dried with pyridine and iodine (estimating the water content as 30 p. p. m.)[10] has produced little difference in the rate of isomerization, whereas the addition of hydroquinone produced a marked depression of the rate at this temperature also.

These results are consistent with the radical nature of the isomerization reaction, as was shown in the cases of the cis-trans isomerization of olefins at higher temperatures[1-5]. However, acid catalysis by sulfur dioxide in part may not completely be ruled out since Tokura et al.[11] have found that a cationic polymerization by sulfur dioxide itself can be carried out in preference to a radical reaction in liquid sulfur dioxide.

To avoid the effect of light, all of the following kinetic runs were performed in the dark. The extent of the isomerization for the kinetical analysis was confined to a low conversion as much as possible. The reactions were carried out at 0, 10 and 20°C, the initial concentration of the β-oxime being 4.31×10^{-2} mol./l. The $\ln\{a/(a-x)\}$ vs. time plots are shown in Fig. 4. The results fit well with a first-order rate expression with respect to the concentration of the β-oxime. The rate constants, k, for the respective temperatures are listed in Table I.

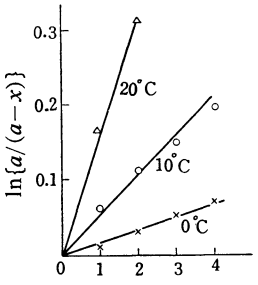

Fig. 4

Table I. The rate constants of the isomerization
Rate=k·[oxime]

Temp., °C	Rate constant, k $\times10^5$ sec^{-1}
0 (dark)	0.41
10 (dark)	1.58
20 (dark)	4.66
0 (diffused daylight)	0.65

Table II. The Arrhenius parameters

Activation energy:	E_a	19.1 kcal./mol.
Frequency factor:	A	6.3×10^{11} sec^{-1}
Rate constant:	k	$=6.3\times10^{11}\times\exp[-19.1/RT]$ sec^{-1}

Table III. Attempted isomerization in various solvents
(In the dark at 0°C and over a 12-hr. period)

Solvent	Isomerization
Ethanol	None
Acetone	None
Benzene*	None
CCl_4	None
Acetic acid*	None
Dimethyl sulfoxide*	None
Dimethylformamide	None

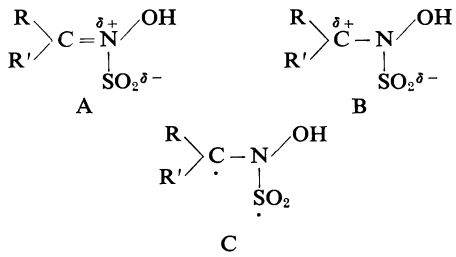
* At room temperature

The Arrhenius parameters are obtained from the linear plot, $\log k$ vs. $1/T$, and are listed in Table II.

To compare these results with the catalytic action of the ordinary solvents with the syn-anti isomerization of the oxime, the β-oxime

9) D. Murakami and N. Tokura, This Bulletin, 31, 431 (1958).
10) T. Hata and T. Asano, *Bull. of Res. Inst. of Non-Aqueous. Solns.* (*Hisuiken Hokoku*), 9, 79 (1960).
11) N. Tokura, M. Matsuda, I. Shirai, K. Shiina, Y. Ogawa and Y. Kondo, This Bulletin, 35, 1043 (1962).

was dissolved in a number of solvents and the mixtures were allowed to stand for 12 hr. at 0°C in the dark. As is shown in Table III, no isomerization was observed.



Tada, Shoji and Tokura[12] have shown that oxime is liable to form a 1 : 1 complex with sulfur dioxide:

$$\text{Oxime} + SO_2 \rightleftharpoons \text{Oxime}\cdot SO_2 \text{ (complex)} \quad (3)$$

The postulated dual (radical and ionic) nature of sulfur dioxide catalysis upon isomerization may well be elucidated by such a complex formation as an intermediate, as such is often the case in sulfur dioxide catalyses[1-5].

In the absence of light, the isomerization may be subject to acid catalysis via form B in Chart 2 through a rotating of the C–N axis conducted by a carbonium ion mechanism.

Chart 2

On the other hand, in the presence of light complex A may be excited to make easy the formation of the carbon radical, as is seen in form C in Chart 2, the rotation of the C–N axis being carried out through this radical form. That sulfur dioxide is an excellent radical acceptor by using the expanded orbital (3d orbital) of the sulfur atom has already been recognized in many instances.

For the early stage of the oxime conversion and in the case of a large excess of liquid sulfur dioxide, the rate of the isomerization, R, may be expressed as Eq. 4, the rate-determining step being assumed as the isomerization of the complex.

$$R = k_o[\text{complex}] = k_o K[\beta\text{-oxime}][SO_2] = k[\beta\text{-oxime}] \quad (4)$$

where K is an equilibrium constant for Eq. 3, k_o and k are the rate constants of the isomerization for the second order and the pseudo-first order reactions respectively, and the brackets indicate the concentrations of the respective components.

As has been described above, the isomerization of the oxime in liquid sulfur dioxide is a very slow reaction in comparison with the fast Beckmann rearrangement, the latter reaction being much too fast to be measured accurately and the rearrangement being completed within 5 min. at 0°C[6].

However, the conclusion that liquid sulfur dioxide is an excellent solvent for such a Beckmann rearrangement should be taken with many reservations, since there remains another possibility of the isomerization during the Beckmann rearrangement, viz., an acid-catalyzed isomerization accompanied by this rearrangement. The acid may be either the acid (Lewis acid) itself used as the reagent for the Beckmann rearrangement or a Brønsted acid derived from Lewis acid. Experiments on an acid-catalyzed isomerization in liquid sulfur dioxide are now in progress; and the results will be published in a following article.

Summary

1. The syn-anti isomerization of β-cyclohexyl phenyl ketoxime is carried out in liquid sulfur dioxide.

2. The isomerization is accerelated by light and retarded by hydroquinone. The degree of the dehydration of liquid sulfur dioxide has little effect on the rate of isomerization.

3. The kinetic result has shown that the reaction is of the first order with respect to the concentration of the oxime and that the rate constant, k for $R = k[\beta\text{-oxime}]$, may be expressed as:

$$k = 6.3 \times 10^{11} \exp\ [-19.1/RT]$$

4. A complex between the oxime and sulfur dioxide is assumed as the intermediate step, the isomerization of the complex being the rate-determining step. The dual (radical and ionic) nature of the isomerization in liquid sulfur dioxide may well be elucidated by such an assumption.

Synthesis of Mononitro-, Monoamino- and Monohalo-p-terphenyls, and their Solubility and Specific Gravity

By Tadashi NOZAKI and Yûhei HARADA

(Received May 21, 1962)

Many physical properties of monosubstituted *p*-terphenyls should vary greatly according to the variety in the nature and the position of the substituent. This is because, since *p*-terphenyl (in general, a para-polyphenyl) is a long planar molecule having many π-electrons, the change in its energy levels caused by a substituent should usually be large, with the mode and degree of the change depending more strongly on the nature and the position of the substituent than in the case of an aliphatic or a condensed aromatic compound. Therefore, various kinds of isomeric monosubstituted *p*-terphenyls seem to be an interesting example regarding the influence of a substituent on physical properties of organic compounds. Studies on their synthesis and physical properties would also be useful for further development in the basic study of organic scintillator and organic semiconductor.

Various synthetic methods for mononitro-, monoamino-, monochloro-, monobromo- and monoiodo-*p*-terphenyls were examined and compared with one another, and suitable methods of preparation are presented in this paper. All isomers of these compounds, including several new compounds, were synthesized and purified. Their solubility and specific gravity were measured, and other physical properties including absorption spectra are now under measurement.

Synthesis.—Ames reviewed the synthesis of substituted terphenyls in 1958[1]. We reported a suitable condition for the mononitration of *p*-terphenyl[2]. In general, the following processes seem to be available for the synthesis of the compounds in question: (1) direct nitration or halogenation of *p*-terphenyl, (2) reaction of 4-(*N*-nitrosoacetamido)-biphenyl (abbreviated as NAB) or *p*-phenylbenzenediazonium oxide (abbreviated as PBDO) with nitrobenzene or halobenzene, (3) reaction of monosubstituted NAB or monosubstituted PBDO with benzene, (4) conversion of another monosubstituted *p*-terphenyl into the desired compound, (5) dehydrogenation of monosubstituted 4-cyclohexylbiphenyl, (6) reaction of monosubstituted *N*-nitrosoacetanilide with biphenyl. The process 1, 2 and in some cases 4 offer a mixture of isomeric monosubstituted *p*-terphenyls. For the separation, column chromatography followed by recrystallization is usually suitable.

The mono-nitration of *p*-terphenyl[2] gave a mixture of 2-nitro-*p*-terphenyl (15~25%), 4-nitro-*p*-terphenyl (ca. 60%) and 2'-nitro-*p*-terphenyl (15~20%). This reaction is suitable for preparing 4-nitro-*p*-terphenyl, since it is easily separated from the mixture owing to its low solubility. But, separation of other two isomers required very tedious processes because of their marked similarity in many physical properties. Earlier workers obtained[3] 2-nitro-*p*-terphenyl and 4-nitro-*p*-terphenyl by treating NAB with nitrobenzene and separating the product by fractional recrystallization. According to our experimental result, PBDO could be used in place of NAB to give almost the same yield of the product, and PBDO was prepared much more easily than NAB. Further, 3-nitro-*p*-terphenyl, a new compound, was obtained by column-chromatographic separation of the reaction products, though the yield was poor. 3-nitro-*p*-terphenyl was more conveniently prepared by deacetamidating a nitration product of 4-acetamido-*p*-terphenyl (overall yield, 40% based on 4-amino-*p*-terphenyl). 2'-Nitro-*p*-terphenyl had been obtained by dehydrogenating 3-nitro-4-cyclohexylbiphenyl[4]. This compound was synthesized more conveniently, contrary to the description in a literature[3], by the reaction of nitrosated 3-nitro-4-acetamidobiphenyl with benzene. Although pure 3-nitro-NAB was not obtained, the yield of purified 2'-nitro-*p*-terphenyl was satisfactory (30~40% based on 3-nitro-4-acetamidobiphenyl).

Nitro-*p*-terphenyl was reduced to amine hydrochloride with tin(II) chloride almost quantitatively, and iodo-*p*-terphenyl was obtained by the Sandmeyer reaction of the diazotized amine with a good yield (50~60%). The

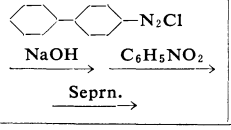
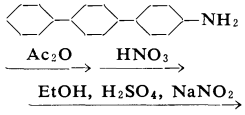
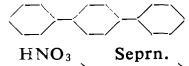
yield of chloro- and bromo-*p*-terphenyls except 4-chloro- and 4-bromo-*p*-terphenyls by this method, however, was poor. Several new compounds, i. e. 2'-chloro-, 2'-bromo-, 2-, 3- and 2'-iodo-*p*-terphenyls, were thus obtained.

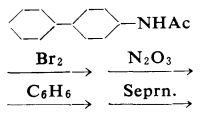
The earlier workers[3] also prepared 2-, 3-, 4-chloro-, 2-, 3- and 4-bromo-*p*-terphenyls by similar processes as they used for preparing 2- and 4-nitro-*p*-terphenyls. In these cases, too, PBDO was found to be used preferably to NAB. Separation of isomeric halo-*p*-terphenyls was more tedious than in the case of the nitro-compounds, requiring repeated chromatographic separation and recrystallization. Hence, for preparing a definite quantity of 2- and 3-chloro (or 2- and 3-bromo), it is preferable to separate a part of 2- and 3-chloro (or 2- and 3-bromo) in pure state from a larger quantity of the mixture. Some of the compounds have considerably higher melting points than the values in the literature[5]. The reaction of PBDO or NAB with iodobenzene, however, gave only traces of iodo-*p*-terphenyls with a much larger quantity of 4-iodobiphenyl.

3-Chloro-4-acetamidobiphenyl had been prepared[6] by chlorinating 4-acetamidobiphenyl with sodium hypochlorite and treating the product with hot acetic acid. Crude 3-bromo-4-acetamidobiphenyl had also been prepared[7] by treating 4-acetamido-biphenyl with bromine in acetic acid and removing less soluble by-products. The two halo-acetamidobiphenyls were nitrosated and converted into 2'- (30~40% yield based on 4-acetamidobiphenyl) and crude 2'-bromo compounds, the latter being purified chromatographically. These processes compare favorably with the syntheses from 2'-nitro-*p*-terphenyl.









Direct bromination and iodination of *p*-terphenyl under a suitable condition offer 4- and 4-iodo respectively, but the products are contaminated by 4, 4''-dihalo-*p*-terphenyl, which is removed with great difficulty on recrystallization and vacuum sublimation. Column-chromatographic separation with the aid of the absorption technique of a soft γ-ray, however, was very useful for obtaining a small quantity (less than a few grams) of 4-bromo or 4-iodo in pure state, as reported previously[8].

Efforts were made to obtain some kinds of monosubstituted *p*-terphenyl by the reaction of substituted *N*-nitrosoacetanilide with biphenyl in a suitable solvent. The yield of the desired compound, however, was always poor, and by-products were removed with great difficulty.

Suitable processes for preparing the monosubstituted *p*-terphenyls are listed in Table I, and melting points summarized in Table II.

Solubility and Specific Gravity.—Tables III and IV show the solubility, and Fig. 1 shows the relationship between the melting point and the solubility in *n*-hexane at 25°C. Both values are more strongly influenced by the position of the substituent than by its nature. Among 2-halo-*p*-terphenyls, the melting point becomes lower in the order of chloro- iodo-

and bromo-*p*-terphenyl. The same order is seen for 2'-halo-*p*-terphenyls, though the differences are small. For 3- or 4-halo-*p*-terphenyls, on the other hand, the order is iodo-, bromo- and chloro-*p*-terphenyl. The 2- and 2'-halo-*p*-terphenyls are apt to form supersaturate solutions. Table V indicates the specific gravity at 25°C. It is, of course, quite sensitive to the nature of the substituent. The influence of the position of the substituent, on the other hand, is less clear and less systematic on the specific gravity than on the melting point and the solubility.

Figure 2 shows the dependence of the solubility on the temperature. The heat of solution is calculated by the use of the Clapeyron's equation (Eq. 1) with the assumption (Eq. 2):

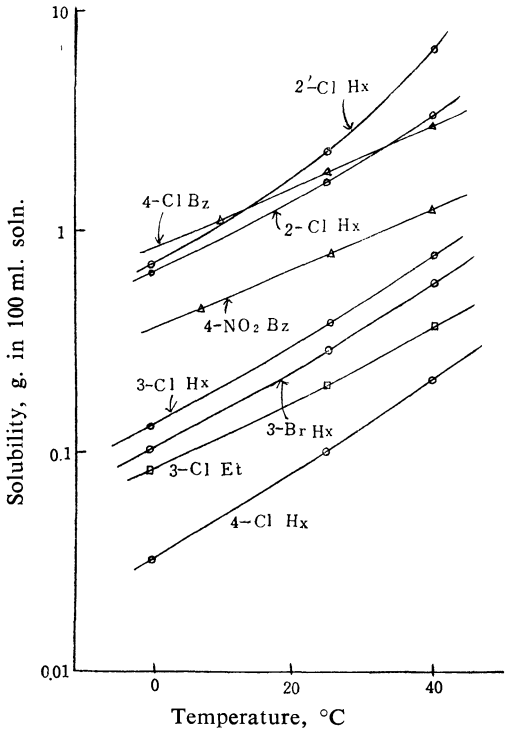

Fig. 2. Temperature dependence of the solubility.

$$\frac{dP}{dT}=\frac{\Delta H}{T(V_L-V_S)} \quad (1)$$

$$P=kC,\ V_L \gg V_S,\ kCV=RT \quad (2)$$

where ΔH is the molar heat of the solution, V_L the molar dilution, V_S the molar volume of solid solute, C the concentration and k a coefficient independent of temperature.

Since

$$\Delta H=\frac{RT^2}{C}\cdot\frac{dC}{dT} \quad (3)$$

and dC/dT is known from Fig. 2, ΔH can be calculated. The result is shown in Table VI.

Table VI. Partial molar heat and entropy of solution at 25°C for the saturation concentration (kcal./mol.)

Solute	Solvent	ΔH	TS_m	$\Delta H-TS_m$
2-Cl	Hx	4.0	2.9	1.1
3-Cl	Hx	4.1	3.8	0.4
4-Cl	Hx	4.1	4.5	−0.4
2'-Cl	Hx	5.1	2.7	2.4
3-Cl	Et	3.5	4.6	−1.1
4-Cl	Bz	3.3	3.0	0.3
3-Br	Hx	3.9	4.0	−0.1
4-NO_2	Bz	3.0	3.6	−0.5

Hx: *n*-Hexane; Et: Ethanol; Bz: Benzene
ΔH: Partial molar heat of solution
S_m: Entropy of mixing for perfect gases (cratic quantity)
T: Absolute temperature

Since this ΔH is the partial molar heat of solution at the saturation concentration, the value with the opposite sign is the product of partial molar entropy of solution and the temperature. The partial molar entropy of solution for a dilute solution consists of two terms[9]: (1) a term depending only on the concentration (cratic term or entropy of mixing of perfect gases), (2) terms independent of concentration (unitary quantity). The term 1, S_m, is expressed by

$$S_m=-R\ln\{x/(1-x)\} \quad (4)$$

where x is the molar fraction of the solute to the solution. Table VI also shows the value of TS_m and that of $H-TS_m$. The term 2, on the other hand, is dependendent on the various quantities: the degree of symmetry and flexibility of the solute molecule, the shape and size of the solute and of the solvent molecule, the translation and rotation of the solute molecule in solution, the lattice vibration of the solute substance in a solid state and the intramolecular motion of the solute substance both in solution and in solid state. A higher degree of symmetry of 4-substituted compounds is one reason for low solubility. Since the translational and the rotational entropy should not differ largely from compound to compound in question, the difference in the term $H-TS_m$ in Table VI should be due mainly to the degree of flexibility and to a different mode of intramolecular motions. These two are intercorelated.

Studies on absorption spectra, specific heat, X-ray crystallography etc. are necessary for quantitative treatment of such phenomena.

Experimental

Preparation of Nitro-, Chloro- and Bromo-*p*-terphenyls by the Reaction of PBDO with Nitrobenzene, Chlorobenzene and Bromobenzene.—The procedure for the synthesis of 4-bromobiphenyl described in the "Organic Syntheses"[10] was successfully applied to the synthesis of the present compounds with a slight modification: 4-aminobiphenyl was diazotized in a mortar under grinding with a pestle at 8~10°C with occasional addition of ice. When the reaction of PBDO with nitrobenzene, chlorobenzene or bromobenzene was completed, the remaining monosubstituted benzene was removed by distillation. The residue was distilled under reduced pressure, and the distillate subjected to column-chromatographic separation, the solvent and eluant being benzene for nitrocompounds or a mixture of petroleum benzine (b. p., 70~90°C) and benzene for halo-compounds (the molar fraction of benzene being increased with progress of elution). Complete separation was not attained, but the following three fractions were obtained: (1) pure 2-nitro (or 2-chloro or 2-bromo), (2) 3-nitro (or 3-chloro or 3-bromo) containing 2-nitro (or 2-chloro or 2-bromo), (3) 4-nitro (or 4-chloro or 4-bromo) containing the other two isomers. From fractions 2 and 3, 3-nitro (3-chloro or 3-bromo) and 4-nitro (4-chloro or 4-bromo)-*p*-terphenyls were obtained respectively by recrystallization from a mixture of ethanol and ethyl acetate. The compounds in the mother-liquor of the recrystallization were separated by repeating column chromatography and recrystallization. From each 21 g. portion of 4-aminobiphenyl the following products were obtained: 2-nitro, 3.7 g.; 3-nitro, 1.3 g. and 4-nitro, 5.2 g.; 2-chloro, 5 g.; 3-chloro, 2.5 g. and 4-chloro, 4.5 g; 2-bromo, 4 g.; 3-bromo, 2.5 g. and 4-bromo, 5 g.

3-Nitro-*p*-terphenyl was identified as follows: (1) analysis (Found: C, 78.70; H, 4.72; N, 5.00. Calcd. for $C_{18}H_{13}NO_2$: C, 78.53; H, 4.76; N, 5.09%); (2) it gave an amine on reduction, which was converted into 3-chloro by the Sandmeyer reaction.

Synthesis of 3-Nitro from 4-Nitro-*p*-terphenyl.—4-Nitro was reduced to 4-amino (see below). To a warm solution of 4-amino (5 g.) in acetic acid (250 ml.) was added acetic anhydride (30 ml.) to give a fine suspension. This was treated with nitric acid (d=1.38, 20 ml.), gradually warmed to

10) R. Adams, "Organic Syntheses", Vol. 8 (1928), p. 42.

60°C and poured into water. The precipitate was filtered off, boiled in a mixture of ethanol (300 ml.) and sulfuric acid (200 ml.) for 1 hr. Sodium nitrite (20 g.) was added in small portions to the hot mixture, which was then diluted with water. The precipitate was filtered off, distilled in vacuo and purified by column-chromatography. Pure 3-nitro compound (2.3 g.) was obtained in pale yellow plates (from a mixture of ethanol and ethyl acetate).

Synthesis of 2'-Nitro-*p*-terphenyl from 3-Nitro-4-acetamidophenyl. — 3-Nitro-4-acetamidobiphenyl (30 g.) in a mixture of acetic acid (700 ml.) and acetic anhydride (300 ml.) was nitrosated at 10~15°C by passing nitrous fumes for 4 hr. and adding simultaneously solid sodium nitrite (10 g.). When the green solution was poured into water with stirring, an orange oil separated, which gradually solidified into a hard yellow mass. This material contained slightly less nitrogen than the theoretical value for 3-nitro-NAB. The solid was dried, dissolved in dry benzene (1.5 l.), warmed with care and eventually refluxed for 5 hr. until the evolution of nitrogen ceased. After benzene was removed from the solution, the residue was under reduced pressure, and the distillate subjected to column-chromatography. 2'-Nitro-*p*-terphenyl (12 g.) was obtained as almost colorless plates (from ethanol). A considerable quantity of 3-nitro-4-acetamidobiphenyl was recovered.

Reduction of Nitro-*p*-terphenyls.—Hot solution of 2-nitro, 3-nitro or 2'-nitro compound (3 g.) in ethanol (30 ml.) or in a mixture of ethanol and ethyl acetate was added to a warm solution of tin(II) chloride ($SnCl_2 \cdot 2H_2O$ 15 g.) in hydrochloric acid (11 N, 20 ml.), and boiled for 20 min. On cooling, the amino-*p*-terphenyl hydrochloride precipitated as colorless small crystals in a nearly quantitiative yield. In some cases, the precipitate contained some tin salt, which, however, was easily removed by treatment with dilute hydrochloric acid. Free amine (2-, 3- or 2'-amino compound) was obtained by treating the amine hydrochloride with an aqueous solution of sodium hydroxide. For the reduction of 4-nitro-*p*-terphenyl other solvents were preferably used[2] owing to its low solubility in ethanol, and 4-amino-*p*-terphenyl was obtained by treating the hydrochloride with hot solution of sodium ethylate in a mixture of ethanol and toluene.

The Sandmeyer Reaction.—The amine hydrochloride (2 g.) was dissolved in a mixture of acetic (70 ml.) and sulfuric acid (30 ml.) or suspended in water, diazotized at 5~10°C and converted into the iodo-*p*-terphenyl with 40~60% yield. 2'-Chloro and 2'-bromo were also prepared by the Sandmeyer reaction, but the yield was lower. On the other hand, 4-chloro and 4-bromo were synthesized with 40~60% yield. 2-Iodo: colorless needles from ethanol (Found: C, 60.61; H, 3.80; I, 35.79. Calcd. for $C_{18}H_{13}I$: C, 60.69; H, 3.68; I, 35.63%). 3-Iodo; colorless plates from ethanol (Found: C, 60.54; H, 3.51; I, 35.45%. Calcd.: the same with 2-iodo). 2'-Iodo: colorless plates from ethanol (Found: C, 60.62; H, 3.91; I, 35.76%. Calcd: the same with 2-iodo). 2'-Chloro: colorless needles or plates from ethanol (Found: C, 81.80; H, 5.13; Cl, 13.46. Calcd. for $C_{18}H_{13}Cl$: C, 81.65; H, 4.95; Cl, 13.39%). 2'-Bromo: colorless plates from ethanol (Found: C, 69.84; H, 4.38; Br, 26.06. Calcd. for $C_{18}H_{13}Br$: C, 69.92; H, 4.24; Br, 25.84%).

Synthesis of 2'-Chloro-*p*-terphenyl from 3-Chloro-4-acetamidobiphenyl.—3-Chloro-4-acetamidobiphenyl (20 g.) dissolved in a mixture of acetic acid (150 ml.) and acetic anhydride (50 ml.) was nitrosated by passing nitrous fumes for 2 hr. at 10~15°C. Stirring the solution into ice water resulted in formation of a milky suspension, from which yellowish hydrophobic powder gradually precipitated. The precipitate was dried and allowed to react with benzene (300 ml.) at 35°C overnight. After benzene was removed from the solution, the residue was distilled under reduced pressure, and the distillate recrystallized from ethanol to give 2'-chloro compound (9 g.).

Preparation of 2'-Bromo-*p*-terphenyl from 4-Acetamidobiphenyl.—4-Acetamidobiphenyl (20 g.) in acetic acid (200 ml.) was treated with bromine (30 g.) at 30~35°C and poured into water. The separated solid was digested with a mixture of ethanol (100 ml.) and water (100 ml.), the insoluble solid removed, and the solution poured into a large quantity of water. From the precipitate (10 g.), 2'-bromo compound (3 g.) was obtained by a similar process to that for 2'-chloro followed by column-chromatographic separation.

Measurement of the Physical Constants.—Melting point was measured in a capillary tube dipped in a sulfuric acid bath, and the value was corrected with reference to several standard substances. The solubility in a given solvent was measured by weighing the solid that was obtained by drying up a definite volume of the saturated solution. For the measurement of the specific gravity, a small crystal of the compound was prepared using a Bridgeman-type furnace. A portion of the crystal was immersed in water, to which a concentrated aqueous solution of a heavy metal salt was added until the specific gravity of the liquid became equal to that of the crystal.

We acknowledge with thanks the aid given to us during the course of the synthesis by Mr. Jun-ichi Shimada, Mr. Takashi Yamamoto and Mr. Kunio Sakai.

Synthesis and Purification of Quinquiphenyl for Scintillator

By Tadashi NOZAKI

(Received May 21, 1962)

It has been pointed out that quinquiphenyl and sexiphenyl are interesting organic semiconductors and promissing scintillators for charged particles[1]. Previously, we reported on the synthesis and purification of sexiphenyl[2]. Preparation of a large crystal of high-purity quinquiphenyl, however, has not been substantiated owing to the difficulty in the synthesis by older methods and in the purification. A convenient process for preparing quinquiphenyl of high purity is presented in this paper.

Mayer and Schiffner[3] briefly reported that *p*-terphenyl was formed when a reaction product of cyclohexanedione-1, 4 with phenylmagnesium bromide was sublimed under reduced pressure. A similar process has been found to be convenient for the synthesis of quinquiphenyl:

Cyclohexanedione-1, 4 is highly soluble in benzene, which keeps the compound mostly in keto-form. When the reaction product of cyclohexanedione-1, 4 in benzene with the etherial Grignard reagent is treated with a mineral acid, pale yellow powder containing quinquiphenyl precipitates gradually from the solution. None of the intermediates such as 1, 4-bisbiphenylylcyclohexanediol-1, 4 and 1, 4-bisbiphenylylcyclohexadiene has separated in pure state. They must be quite unstable and convert themselves into quinquiphenyl. The conversion is very slow at an ordinary temperature, but much faster at a higher temperature or in the presence of a mineral acid. Therefore, a rapid synthesis of quinquiphenyl can be substantiated by heating the Grignard reaction product to 400~450°C afterteatmeat with a boiling mixture of sulfuric acid and ethanol.

This heat treatment serves also for the purification, since most of the impurity by-products suffer thermal decomposition more easily than quinquiphenyl to give products which are easily removed. Too high a temperature or a prolonged heating, however, causes considerable decomposition of quinquiphenyl itself. Three other processes are also useful for the purification: i. e. vacuum sublimation, recrystallization and segregation. Slow sublimation at about 300°C (ca. 10^{-3} mmHg) is much more effective than rapid sublimation at a higher temperature. Since quinquiphenyl is quite sparingly soluble in any solvent under 100°C, a large quantity of a solvent having a high boiling point, such as nitrobenzene, tetraline or diethyl succinate should be used for recrystallization. Segregation with a Bridgeman-type furnace is especially effective for further purification of the sample already purified by other methods. The same process is also useful for single-crystal preparation. Yield of the purified quinquiphenyl was about 20% based on cyclohexanedione-1, 4 or 15% based on 4-iodobiphenyl.

A large crystal of purified quinquiphenyl is completely colorless, transparent, hard and tough, and gives an intense violet fluorescence. It has no marked habit to cleave into thin plates. It melts at 388°C into liquid crystal, which becomes transparent at 423°C. (These constants in literature[4] are 401°C (observed, 375°C) and 445°C (observed, 413°C) respectively, while in another literature[5] the melting point is 388.5°C). Specific gravity of quinquiphenyl at 25°C is 1.284 (terphenyl, 1.236; quarterphenyl, 1.262; sexiphenyl, 1.287).

Physical properties of pure quinquiphenyl, such as infrared, ultraviolet and fluorescence spectrum and scintillator efficiency are now under measurement. The results will be reported with those of quarterphenyl and sexiphenyl.

Experimental

Synthesis.—To a warm solution of 4-iodobiphenyl (40 g.) in diethyl ether (250 ml.) containing magnesium ribon (ca. 10 g.) was added a crystal or two of iodine, and the mixture refluxed for 3 hr. and filtered through asbestos fibers.

5) O. Gerngross et al., *Ber.*, **57**, 745 (1924).

Cyclohexanedione-1, 4 (5 g.) in benzene (100 ml.) was slowly stirred into the Grignard solution during 10 min., and the mixture refluxed for 20 min. and treated with hydrochloric acid. Most part of the solvent being removed, the residue was boiled in a mixture of sulfuric acid (50 ml.) and ethanol (50 ml.) for 30 min., cooled, collected by filtration and sublimed in vacuo to give two kinds of sublimate: (1) yellowish powder (7 g.) melting at ca. 300°C, (2) colorless material of a higher vapor pressure, melting at 180~185°C, which seemed to be a derivative of biphenylylcyclohexane. Sublimate 1 was placed in a narrow-necked glass tube and heated to 400°C in a furnace. Gas evolved vigorously form the molten product. When the evolution became feeble, the temperature was gradually raised to 450°C during 20 min. The dark grey massive product was sublimed (10^{-3} mmHg, 300°C) to give yellowish powder with black residue. The heat treatment and the vacuum sublimation of this sublimate were repeated once again to give crude quinquiphenyl (4 g.) in almost colorless powder, which melted at 350~360°C into liquid crystal.

Purification.—The crude quinquiphenyl (ca. 4g.) was recrystallized from diethyl succinate (800 ml.) into thin plates, which were sealed in an evacuated Telex-glass tube (9 mm. diameter) and purified by segregation with a Bridgeman-type furnace as in the case of sexiphenyl[2] (maximum temperature, 405°C; rate of downward movement, 8 mm. per hr.). The brownish segregate was removed, and the yellowish mass slowly sublimed in vacuo (10^{-3}~10^{-4} mmHg, 290~300°C) into colorless fluorescent powder, which was again subjected to the segregation and sublimation. The sublimate was recrystallized from tetralin, sublimed in vacuo and submitted to single-crystal formation by the same technique used for the segregation. Large colorless crystals were obtained (10×5×2 mm.) with a small amount of faintly yellowish segregate. Found: C, 94.26; H, 5.90. Calcd. for $C_{30}H_{22}$: C, 94.20; H, 5.85%.

Measurement of Melting Point and Specific Gravity.—The sample in a glass capillary was placed along the central axis of a transparent quartz tube (3.5 cm. diameter) together with an Almel-Chromel thermocouple. The tube was heated from outside with nichrome wire, and the temperature was read with a calibrated millivoltmeter. Melting point was measured with the sample obtained as mentioned above and also after further purification; no difference was observed. For the measurement of specific gravity, the crystal was immersed in water, to which a concentrated solution of a heavy metal salt was added until specific gravity of the liquid became equal to that of the crystal, and the former was measured.

*On the Solubility and the Velocity of Dissolution of Corundum under Hydrothermal Conditions**

By Goro YAMAGUCHI, Hiroaki YANAGIDA and Shigeo SOEJIMA**

(Received May 23, 1962)

The fact that the dehydration of boehmite under hydrothermal conditions gives corundum directly has been noted by Laubengayer and Weisz[1], Ervin and Osborn[2] and Kennedy[3]. Using this reaction, the present authors obtained grains consisting of separated single crystals of corundum of a uniform size and habits[4]. The grains showed excellent qualities as abrasives for germanium, silicon and glass materials[5]. The uniformity in the grain size and habits may be attributed to a proper reaction mechanism under hydrothermal conditions. The mechanism, however, has not been clarified yet. In order to obtain some basic and important data for a discussion of the mechanism, the present authors have measured the solubilitiy of corundum under hydrothermal conditions.

The solubilities of aluminum hydroxides and aluminas as measured by Russell, Edwards and Taylor[6] have been widely accepted. It is, however, almost impossible to extrapolate these values to the temperature at which boehmite may be transformed into corundum. Yalman, Shaw and Corwin have presented

some data about the solubility of corundum[7], but they are insufficient to discuss the transformation of boehmite into corundum without the seed crystal, which has been observed practically only above 440°C[4]. The data above 420°C have not been included in their paper[7]. In the present work, the solubility of corundum has been measured up to 500°C under different conditions of hydrothermal pressure, alkaline solution and reaction period.

Experiments

Procedure.—Fused corundum grains of a uniform size, over 99 per cent pure and weighing 0.40 mg. on the average, were weighed and laid in a Morey-type reactor with an aqueous solution of sodium hydroxide or sodium carbonate. They were heated from room temperature to an appointed temperature within 15 min. and then kept at that temperature for some hours in an electric furnace. The hydrothermal pressure at that temperature was calculated from Kennedy's table showing the relations among pressure, density and temperature of water[8]. They were also quenched to room temperature within 15 min. The quenched contents, the solution and the residue were washed out completely with distilled water into a glass beaker. The residue was then washed with hot hydrochloric acid, and the gelatinous precipitate of aluminum hydroxide was eliminated by decantation, leaving only the corundum residue in the beaker.

Analysis.—Aluminum dissolved in a solution is usually analyzed by the EDTA titration method, with an indicator such as chromazurol S[9]. This method, however, cannot applied when an aluminum hydroxide is precipitated. A hydrothermal solution may become supersaturated through cooling it to room temperature, and aluminum hydroxide may be newly precipitated. In this case, the solubility obtained by the titration method may show a lower value. Actually, the gelatinous precipitate was observed in some runs in the present work. The true corundum residue was separated from the gelatinous precipitate by the above-mentioned procedure, and the difference in the weight of corundum between that placed in the reactor and that which remained after hydrothermal treatment was considered to indicate the dissolved alumina in the solution.

Results and Discussion

Effects of the Sample Quantity on the Solubility and Velocity of Dissolution.—0.5 or 1.0 g. of the corundum grain was treated with 3 normal sodium carbonate aqueous solutions at 450°C under a 1000 atmospheric pressure; the results of this experiment are shown in Table I and Fig. 1. It can be seen there that the time derivative of dissolved corundum has

a term proportional to the surface area of the sample. This may mean that the rate-determinant process of the dissolution is an elementary process occurring on or near the surface of the grain and that the diffusion velocity in space is sufficiently large. After being supersaturated, the dissolved alumina recrystallizes into corundum and the concentration of dissolved alumina approaches 0.024 g. per 1 cc. of the solution regardless of the sample quantity. This value corresponds to a 0.47 g. equiv. of dissolved alumina per 1 g. equiv. of sodium carbonate in the solution and can be considered as an equilibrium solubility. Here, the 1 g. equiv. of corundum 1/6 Al_2O_3, is 17 g. and that of sodium carbonate 1/2 Na_2CO_3, is 53 g.

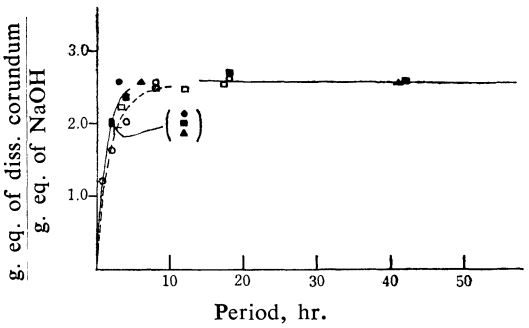
Effects of Pressure, Alkaline Concentration and Temperature on the Solubility and Velocity of Dissolution.—The solubility of corundum at 400°C and at 450°C were measured under atmospheric pressures of 100, 500, 1000 and 1500 with 0.005, 0.010 and 0.020 g. equiv. of sodium hydroxide in an aqueous solution for various reaction periods. Table II and Fig. 2 show the results at 400°C, and Table III and Fig. 3 those at 450°C. The supersaturation which was found in the sodium carbonate solution could not be observed here in this sodium hydroxide solution. The total gram equivalent of alumina in a saturated solution may be expressed in terms of temperature, total gram equivalent of sodium hydroxide in the solution, and hydrothermal pressure as follows:

$$x_{\infty}^{\mathrm{cor}} = f(T) \cdot g(x_{\mathrm{OH}}) \cdot h(P_{\mathrm{H_2O}}) \qquad (1)$$

where, $x_{\infty}^{\mathrm{cor}}$ is the total gram equivalent of dissolved alumina in the saturated solution, $f(T)$, the temperature term, $g(x_{\mathrm{OH}})$, a function of



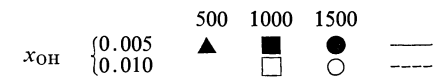


Fig. 2. Dissolution curve of corundum in sodium hydroxide aqueous solution at 400°C.

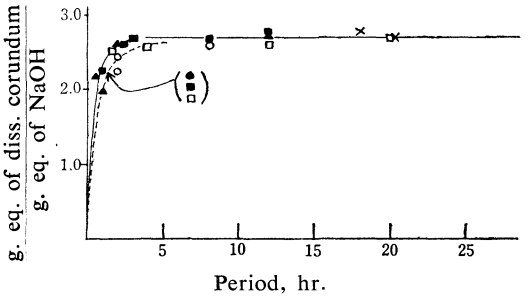

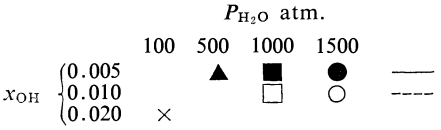

Fig. 3. Dissolution curve of corundum in sodium hydroxide aqueous solution at 450°C.

the total gram equivalent of sodium hydroxide in the solution, and $h(P_{H_2O})$, the pressure factor. In the present work, x_∞^{cor} appeared nearly proportional to x_{OH} independently of pressure. This means that

$$g(x_{OH}) \simeq x_{OH} \tag{2}$$

$$h(P_{H_2O}) \simeq 1 \tag{3}$$

Substituting 2 and 3 into 1, the present authors obtained the temperature term as:

$$f(T) = \begin{cases} 2.58_8 \pm 0.02 & \text{at } 400°C \quad (4) \\ 2.70_0 \pm 0.05 & \text{at } 450°C \quad (5) \end{cases}$$

From the fact that the velocity of dissolution appeared proportional to the total gram equivalent of sodium hydroxide in the solution independently of the hydrothermal pressure, it can be considered that the rate-determinant process of dissolution is an elementary process occurring on or near the sample surface and that the diffusion velocity in space is sufficiently large, as the sodium carbonate solution.

$$\frac{d(x_{cor}/x_{OH})}{dt} = kS(x_\infty^{cor}/x_{OH} - x_{cor}/x_{OH}) \tag{6}$$

may be proposed as a general equation of dissolution in the present case; here k is a velocity constant dependent on the temperature, S, the total surface area of corundum grains at t, and x_{cor} the total gram equivalent of dissolved alumina in the solution, also at t. In Eq. 6, $d(x_{cor}/x_{OH})/dt$ indicates the relative velocity of dissolution and $(x_\infty^{cor}/x_{OH} - x_\infty^{cor}/x_{OH})$, a driving force to a saturated solution instead of a term of the concentration gradient. Two variables, S and x_{cor}, are included in 6. The total surface area of the initial corundum grains before hydrothermal treatment is expressed as

$$S_0 = N_0\theta_0\left(\frac{17}{4}a_0\right)^{2/3} \tag{7}$$

where S_0 indicates the initial surface area in cm^2, N_0, the numbers of corundum grains, θ_0, a factor depending on the shape, and a_0, the gram equivalent of corundum per each initial grain. It is assumed that N_0 and θ_0 are invariants throughout the hydrothermal dissolution treatment. Therefore, it may be also expressed as

$$S = N_0\theta_0\left(\frac{17}{4}a\right)^{2/3} \tag{8}$$

where S is the total surface area of corundum grains during dissolution at t and a, the gram equivalent of corundum per each grain during dissolution, also at t. A_0, the total gram equivalent of the initial corundum grains, can be expressed as:

$$A_0 = N_0a_0 \tag{9}$$

and A, that of the corundum residue during dissolution at t, as:

$$A = N_0a \tag{10}$$

From the mass balance in the corundum,

$$A_0 \equiv A + x_{cor} \tag{11}$$

Substituting 7, 8, 9, 10 and 11 into 6, an equation including only one variable, x_{cor}/x_{OH}, is obtained:

$$\frac{d(x_{cor}/x_{OH})}{dt} = kS_0\left(\frac{A_0}{x_{OH}}\right)^{-2/3}\left(\frac{A_0}{x_{OH}} - \frac{x_{cor}}{x_{OH}}\right)^{2/3} \times\left(\frac{x_\infty^{cor}}{x_{OH}} - \frac{x_{cor}}{x_{OH}}\right) \tag{12}$$

This can be solved as follows;

$$\frac{2}{3}\ln\left\{\frac{\left(\frac{A_0}{x_{OH}}\right)^{1/3}-\left(\frac{A_0}{x_{OH}}-\frac{x_\infty^{cor}}{x_{OH}}\right)^{1/3}}{\left(\frac{A_0}{x_{OH}}-\frac{x_{cor}}{x_{OH}}\right)^{1/3}-\left(\frac{A_0}{x_{OH}}-\frac{x_\infty^{cor}}{x_{OH}}\right)^{1/3}}\right\}$$

$$+\frac{1}{3}\ln\left\{\frac{\left(\frac{x_\infty^{cor}}{x_{OH}}\right)-\left(\frac{x_{cor}}{x_{OH}}\right)}{\left(\frac{x_\infty^{cor}}{x_{OH}}\right)}\right\}$$

$$+\sqrt{3}\left\{\left(\frac{A_0}{x_{OH}}\right)-\left(\frac{x_\infty^{cor}}{x_{OH}}\right)\right\}^{1/3}$$

$$\times\left\{\tan^{-1}\frac{\left(\frac{A_0}{x_{OH}}-\frac{x_{cor}}{x_{OH}}\right)^{1/3}+\frac{1}{2}\left(\frac{A_0}{x_{OH}}-\frac{x_\infty^{cor}}{x_{OH}}\right)^{1/3}}{\frac{\sqrt{3}}{2}}\right.$$

$$\left.-\tan^{-1}\frac{\left(\frac{A_0}{x_{OH}}\right)^{1/3}+\frac{1}{2}\left(\frac{A_0}{x_{OH}}-\frac{x_\infty^{cor}}{x_{OH}}\right)^{1/3}}{\frac{\sqrt{3}}{2}}\right\}$$

$$=k(T)S_0\left(\frac{A_0}{x_{OH}}\right)^{-2/3}\left(\frac{A_0}{x_{OH}}-\frac{x_\infty^{cor}}{x_{OH}}\right)^{2/3}t \qquad (13)$$

The velocity constant, $k(T)S_0$, can be calculated according to 13 by comparison with the experimental results as follows;

$$k(T)S_0=\begin{cases}0.80/\text{hr.} & \text{at } 400^\circ\text{C} \quad (14)\\ 1.90/\text{hr.} & \text{at } 450^\circ\text{C} \quad (15)\end{cases}$$

The surface area of the initial corundum grains is estimated to be 33 cm^2/g. assuming the shape of corundum grain to be a tetragonal prism 1 : 1 : 2 in edge length. Putting this value into S_0 of 14 and 15, the present authors calculated the general velocity constant, not including the S_0 term, to be:

$$k(T)=\begin{cases}0.024/\text{cm}^2\,\text{hr.} & \text{at } 400^\circ\text{C} \quad (16)\\ 0.056/\text{cm}^2\,\text{hr.} & \text{at } 450^\circ\text{C} \quad (17)\end{cases}$$

From the velocity constant ratio, 0.056/0.024, with the temperature difference between 400°C and 450°C, the activation energy for the rate-determinant process is considered to be of the order of 3.8 kcal.

Effect of Temperature on the Equilibrium Solubility.—From 2 and 3, the equilibrium solubility can be considered in the term of $f(T)$ independently of pressure. The $f(T)$ term was obtained at 350°C and at 500°C in addition as at 400°C and 450°C. The $f(T)$ value at 350°C was measured for more than 70 hr. under an atmospheric pressure at 500 and that at 500°C for more than 12 hr. under an atmospheric pressure of from 500 to 1500. These are summarized in Table IV and are illustrated in Fig. 4.

TABLE IV. TEMPERATURE DEPENDENCE OF THE SOLUBILITY OF CORUNDUM

Temp. °C	g. eq. of diss. corundum / g. eq. of NaOH
350	2.46 ±0.09
400	2.58_8±0.02
450	2.70_0±0.05
500	2.85 ±0.10

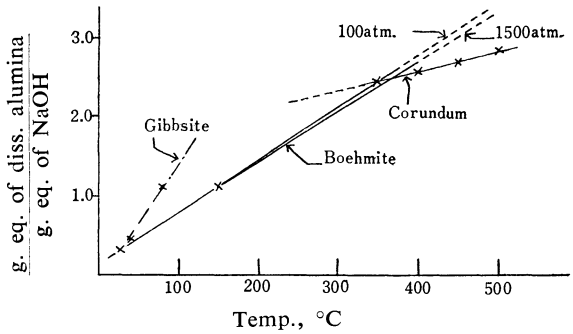

Fig. 4. Solubility curves of aluminas in sodium hydroxide aqueous solution ($Na_2O < 100$ g./l.).

Russell et al.[6] showed boehmite to be dissolved by 5.6% as alumina in 90 g. of sodium oxide per 1 l. aqueous solution at 150°C. This corresponds to a 1.14 g. equivalent of boehmite to be dissolved in a 1 g. equiv. of a sodium hydroxide aqueous solution. Here, the 1 g. equiv. of boehmite, 1/3 AlOOH, is 20 g. Russell et al. proposed that the equilibrium point between boehmite and gibbsite should be 27°C with extrapolation of the solubility. Near this temperature of 30°C, gibbsite is dissolved by 1.82% as alumina in 96.8 g. of sodium oxide per 1 l. of an aqueous solution[10]. This corresponds to a 0.34 g. equiv. of gibbsite to be dissolved in a 1 g. equivalent of a sodium hydroxide aqueous solution. Here, the 1 g. equiv. of gibbsite, 1/3 $Al(OH)_3$, is 26 g. In these alkaline concentrations lower than 100 g. of sodium oxide per 1 l., the ratio of the gram equivalent of dissolved alumina to that of sodium hydroxide in the solution may be considered to be invariant with the concentrations at the same temperature[11]. The solubility of gibbsite at 40°C is 0.45, and that at 80°C is 1.11 in the ratio.

The equilibrium point between boehmite and corundum varies with the pressure[3]; 355°C under 100 atm., 360°C under 500 atm., 365°C under 1000 atm. and 370°C under 1500 atm. The solubility curves of boehmite and corundum may intersect each other at these points. This indicates that the supersaturation

10) "Kagaku-Binran," Ed. by the Chemical Society of Japan, Maruzen Co., Tokyo (1958), p. 610.
11) J. Shimozato, Ph. D. Thesis, Tokyo Univ. (1961).

factor seems to be about 0.12 at the temperature where boehmite can be transformed into corundum without seed.

The curves illustrated in Fig. 4 give the basic information for a discussion about the transformation mechanism and for the growth of a single crystal of corundum under hydrothermal conditions. The present authors will discuss the mechanism in a later paper.

Summary

The solubility of corundum was measured under hydrothermal conditions. The equilibrium solubility seems independent of the pressure. The temperature term, $f(T)$, the ratio of the gram equivalent of dissolved corundum to that of sodium hydroxide in the solution, was as follows:

$$f(T)=\begin{cases} 2.46 \pm 0.09 & \text{at } 350^\circ\text{C} \\ 2.58_8 \pm 0.02 & \text{at } 400^\circ\text{C} \\ 2.70_0 \pm 0.05 & \text{at } 450^\circ\text{C} \\ 2.85 \pm 0.10 & \text{at } 500^\circ\text{C} \end{cases}$$

The velocity of dissolution was proportional to the surface area of the corundum crystal and the total gram equivalent of sodium hydroxide in the solution. This is shown as

$$\frac{\mathrm{d}(x_{\mathrm{cor}}/x_{\mathrm{OH}})}{\mathrm{d}t}=kS(x_{\infty}^{\mathrm{cor}}/x_{\mathrm{OH}}-x_{\mathrm{cor}}/x_{\mathrm{OH}})$$

The velocity constant was as follows:

$$k(T)=\begin{cases} 0.024/\mathrm{cm}^2\,\mathrm{hr.} & \text{at } 400^\circ\text{C} \\ 0.056/\mathrm{cm}^2\,\mathrm{hr.} & \text{at } 450^\circ\text{C} \end{cases}$$

The nucleation of corundum may be initiated at the supersaturation ratio of 0.12 without seed.

Statistical Thermodynamics of Solutions of Optically Active Substances. III. Influence of an Optically Active Substance on the Equilibrium between Interconvertible d- and l-Optical Isomers

By Kazuo AMAYA

(Received June 1, 1962)

If an optically active substance is added to a mixture of d- and l-optical isomers which are interconvertible to each other, the original equilibrium between d- and l-isomers is expected to change. This seems to cause a new type of solvent effect on the optical rotation, the feature of which is that the solvent molecules themselves contribute to the optical rotation. Before the addition of an optically active substance there exist an equal number of the molecules of d- and l-isomers in the mixture, so it shows no optical rotation, but after that addition, the number of molecules of d- and l-isomers in equilibrium is expected to become unequal; this unbalanced number of molecules of either d- or l-isomer contribute to the total optical rotation.

This problem also seems to be important for studying asymmetric synthesis in an optically active solvent, because it is intimately related to the optical purity of the product.

In order to clarify the fundamental features of these problems, the statistical mechanics of such systems have been developed and the influence of the addition of optically active substances on the equilibrium between interconvertible d- and l-optical isomers has been examined.

Theory

Consider a system consisting of N_A molecules of either d- or l-isomer of an optically active substance of species A and of N_B molecules of a mixture of interconvertible d- and l-isomers of species B, namely, $N_B = N_{B_d} + N_{B_l}$ where N_{B_d} and N_{B_l} denote the number of molecules of d- and l-isomers respectively.

For the sake of simplicity, assumptions similar to those described in previous papers[1] are made. These are briefly summarized here again:

1) K. Amaya, This Bulletin, **34**, 1689, 1803 (1961).

1) The molecules of species A and B are covered by z planes. One of them consists of 3 different subelements; the arrangement of these three subelements for d- and l-isomers are mirror images of one another (this plane will be called the optically active plane). The remaining z-1 planes, composed of one uniform element and the pair of optically active planes in contact, can take three sets of configuration of a different energies.

2) The molecules of A and B have the same molecular volume; these molecules occupy the lattice points of the quasi-crystalline lattice of the nearest neighbors of z, and the molecule at a given site posseses $3z$ orientational freedom.

3) The configurational energy of the system is the sum of the potential energy of the $1/2 \cdot z(N_A+N_B)$ pairs of the surface plane of the molecules in contact.

To make the fundamental features of the problem as clear as possible, mathematical rigorousness is abandoned and we now introduce a concept of effective potential energy for a pair of optically active planes and attribute any difference between two optical isomers to it. Here "effective" means that we take the weighted mean of the potential energy of a given pair of planes in contact by averaging three different configurations by multiplying each Boltzmann factor.

Following the above assumptions, it can easily be expected that the non-zero value of the effective interchange energy of B_d and B_l molecules, w_{dl}, arises only from the pair of optically active planes, and that the differences in the effective interchange energy of A and B_d molecules, w_{AB_d}, and that of A and B_l, w_{AB_l}, also arise from the difference in the potential energy of the pairs of optically active planes of the A and B_d molecules and those of the A and B_l molecules.

Following the model described above, $w_{AB_d} - w_{AB_l}$ and w_{dl} will be estimated. If the potential energy of the i-th configuration of a pair of optically active planes from the pairs of molecules A–A, B_d–B_d, B_l–B_l, A–B_d, A–B_l and B_d–B_l are denoted by $U^{aa}_{AA_i}$, $U^{dd}_{BB_i}$, $U^{ll}_{BB_i}$, $U^{ad}_{AB_i}$, $U^{al}_{AB_i}$ and $U^{ld}_{BB_i}$ respectively, the weighted mean potential energy of each pair over three different configurations may be represented as:

$$\bar{U}^{aa}_{AA} = \sum_{i=1}^{3} U^{aa}_{AA_i} e^{-U^{aa}_{AA_i}/kT} \Big/ \sum_{i=1}^{3} e^{-U^{aa}_{AA_i}/kT}$$

$$\bar{U}^{dd}_{BB} = \sum_{i=1}^{3} U^{dd}_{BB_i} e^{-U^{dd}_{BB_i}/kT} \Big/ \sum_{i=1}^{3} e^{-U^{dd}_{BB_i}/kT}$$

$$\bar{U}^{ll}_{BB} = \sum_{i=1}^{3} U^{ll}_{BB_i} e^{-U^{ll}_{BB_i}/kT} \Big/ \sum_{i=1}^{3} e^{-U^{ll}_{BB_i}/kT}$$

$$\bar{U}^{ab}_{AB} = \sum_{i=1}^{3} U^{ad}_{AB_i} e^{-U^{ad}_{AB_i}/kT} \Big/ \sum_{i=1}^{3} e^{-U^{ad}_{AB_i}/kT}$$

$$\bar{U}^{al}_{AB} = \sum_{i=1}^{3} U^{al}_{AB_i} e^{-U^{al}_{AB_i}/kT} \Big/ \sum_{i=1}^{3} e^{-U^{al}_{AB_i}/kT}$$

$$\bar{U}^{dl}_{AB} = \sum_{i=1}^{3} U^{dl}_{AB_i} e^{-U^{dl}_{AB_i}/kT} \Big/ \sum_{i=1}^{3} e^{-U^{dl}_{AB_i}/kT}$$

Since each term of $U^{ad}_{AB_i}$ has a different value, from the corresponding term in $U^{al}_{AB_i}$, the effective potential energies, $\bar{U}^{ad}_{AB}$ and $\bar{U}^{al}_{AB}$, have different values. In a similar way, it is deduced that $\bar{U}^{dl}_{BB}$ and U^{dd}_{BB} or $\bar{U}^{dl}_{BB}$ and U^{ll}_{BB} have different values. In this way, d and l optical isomers in the system can be made distinguishable energetically.

Further, we define the following quantity:

$$\chi_A = \frac{1}{2z}\left\{(z-1)^2 U^{bb}_{AA} + 2(z-1)\bar{U}^{ab}_{AA} + U^{aa}_{AA}\right\}$$

$$\chi_{B_d} = \frac{1}{2z}\left\{(z-1)^2 U^{bb}_{BB} + 2(z-1)\bar{U}^{ab}_{BB} + \bar{U}^{dd}_{BB}\right\}$$

and

$$\chi_{B_l} = \frac{1}{2z}\left\{(z-1)^2 U^{bb}_{BB} + 2(z-1)\bar{U}^{ab}_{BB} + U^{ll}_{BB}\right\}$$

where χ_A, χ_{B_d}* and χ_{B_l}* indicate the mean potential energy per molecule of the A, B_d and B_l molecules respectively; U^{bb}_{AA} and U^{bb}_{BB} are the potential energies of a pair of planes which are not optically active of the A and B molecules respectively, and U^{ab}_{AA} and U^{ab}_{BB} are those of a pair of** planes, one of which is optically active and the other of which is optically inactive for A and B molecules respectively.

The interchange energy of A and B_d, w_{AB_d}, that of A and B_l, w_{AB_l}, and that of B_d and B_l, w_{dl}, molecules are, by definition, expressed as follows:

$$2\bar{w}_{AB_d} = \frac{2}{z}\left\{(z-1)^2 U^{bb}_{AB} + (z-1) \times (\bar{U}^{ab}_{AB} + U^{ba}_{AB}) + \bar{U}^{ad}_{AB}\right\} - 2\chi_A - 2\chi_{B_d}$$

$$2\bar{w}_{AB_l} = \frac{2}{z}\left\{(z-1)^2 U^{bb}_{AB} + (z-1) \times (\bar{U}^{ab}_{AB} + U^{ba}_{AB}) + \bar{U}^{al}_{AB}\right\} - 2\chi_A - 2\chi_{B_l}$$

$$2w_{dl} = \frac{2}{z}\left\{(z-1)^2 U^{bb}_{AB} + 2(z-1) + U^{ab}_{BB} + \bar{U}^{dl}_{BB}\right\} - 2\chi_{B_d} - 2\chi_{B_l}$$

---

* χ_{B_d} and χ_{B_l} are imaginary because B_d and B_l are interconvertible and an assembly of pure B_d or B_l molecule cannot exist.

** The suffix "a" denotes optically active and "b" denotes optically inactive.

Since $\bar{\bar{U}}_{BB}^{dd}=\bar{\bar{U}}_{BB}^{ll}$ $(=\bar{\bar{U}}_{BB}^{aa})$ and, hence, $\chi_{B_d}=\chi_{B_l}$ $(=\chi_B)$, it follows that

$$\Delta\bar{\bar{w}}=\bar{\bar{w}}_{AB_d}-\bar{\bar{w}}_{AB_l}=\frac{1}{z}(\bar{U}_{AB}^{ad}-\bar{U}_{AB}^{al})$$

$$\bar{w}_{dl}=\frac{1}{z}(U_{BB}^{dl}-\bar{U}_{BB}^{aa})$$

Having thus defined these quantities, we can proceed to the next step.

Before considering the ternary system, we must first consider the pure solvent system, a binary system composed of N_{B_d} molecules of B_d and N_{B_l} molecules of B_l.

The configurational free energy of the system F_C^B is represented as:

$$F_C^B=-kT\ln\frac{(N_{B_d}+N_{B_l})!}{N_{B_d}!\,N_{B_l}!}+\frac{N_{B_d}N_{B_l}}{N_B^2}\bar{\bar{w}}_{dl}-\chi_B N_B-kT N_B\ln 3z$$

In the equilibrium state, F_C^B must be the minimum.

Then, the first derivative of F_C^B with respect to N_{B_d} under the condition that $N_B=N_{B_d}+N_{B_l}$ =constant must be zero, we have

$$\left(\frac{\delta F_C^B}{\delta N_{B_d}}\right)_{N_B}=kT\ln N_{B_d}/(N_B-N_{B_d})+(N_B-2N_{B_d})w_{dl}=0$$

Since the B_d and B_l molecules are equivalent, the same relation must hold for N_{B_l}. Therefore, we obtain, by using the relation $N_{B_l}=N_B-N_{B_d}$;

$$\left(\frac{\delta F_C^B}{\delta N_{B_l}}\right)_{N_B}=kT\ln(N_B-N_{B_d})/N_{B_d}+(2N_{B_d}-N_B)\bar{\bar{w}}_{dl}=0$$

For the simultaneous satisfaction of these two relations both terms must always be zero; it follows that

$$N_{B_d}=N_{B_l}=\frac{1}{2}N_B$$

Next, we consider the solution, a ternary system composed of A, B_d and B_l molecules.

The configurational free energy of the system F_C is represented by

$$F_C=-N_A\chi_A-N_B\chi_B-kT\ln\frac{(N_A+N_B)!}{N_A!\,N_{B_d}!\,N_{B_l}!}+\frac{N_A N_{B_d}}{N_A+N_B}\bar{\bar{w}}_{AB_d}+\frac{N_A N_{B_l}}{N_A+N_B}(\bar{\bar{w}}_{AB_d}-\Delta\bar{\bar{w}})+\frac{N_{B_d}N_{B_l}}{(N_A+N_B)}\bar{\bar{w}}_{dl}-(N_A+N_B)kT\ln 3z$$

The equilibrium concentration of B_d or B_l molecules is the one that minimizes F_C. This can be obtained by differentiating F_C with respect to N_{B_d} or N_{B_l}, under the condition that $N_B=N_{B_d}+N_{B_l}$ is constant, and by then equating it with zero. Thus, we obtain

$$\delta F_C/\delta N_{B_d}=Tk\ln\frac{N_{B_d}}{N_B-N_{B_d}}+N_A/(N_A+N_B)\Delta w+(N_B-2N_{B_d})/(N_A+N_B)w_{dl}=0$$

By introducing the notations y and x_A defined by the following equations:

$$y=\frac{N_{B_d}}{N_B},\qquad x_A=N_A/(N_A+N_B)$$

the above equation may be rewritten as:

$$kT\ln y/(1-y)+x_A\Delta w-(1-x_A)(1-2y)w_{dl}=0$$

When y is close to 0.5, y can be replaced by $0.5+\Delta$. The logarithmic term is expanded in the power series in Δ and, by neglecting terms higher than the second, we can obtain the following approximate solution for Δ:

$$\Delta=-\frac{x_A\cdot\Delta w}{4kT-(1-x_A)w_{dl}}$$

Discussion

Since the value of Δ is usually different from zero, the equilibrium is shifted in either direction. If the sign of Δ is positive, the D isomers increase, and vice versa.

The absolute value of Δ increases as x_A increases, and the maximum value of $|\Delta|$ is $|\Delta w/4kT|$. Usually $w_{dl}\ll kT$, and w_{dl} can be neglected as too small, and the $|\Delta|$ is approximated to $\Delta w/4kT\cdot x_A$. Since Δw is nearly proportional to $1/T$, $|\Delta|$ is nearly proportional to $1/T^2$. The extent of the shift from the original equilibrium state become greater as the temperature decreases. This indicates that, in order to get optically active polymers of a large optical rotatory power by the polymerization of monomers in an optically active solvent, it is desirable to perform polymerization at as low temperatures and as low concentrations (large value of x_A) as possible.

In order to get direct evidence of this predicted phenomena, it seems to be most suitable to measure the optical rotatory dispersion of these mixtures, since, by the measurement of optical rotation with the light of a single wavelength, it is difficult to distinguish the contributions of the solute from that of the solvent in the observed optical rotation.

However, if the optical rotatory dispersion is measured, the contributions from each species can easily be distinguished, for usually the dispersion curve is different and the maxima of optical rotation appear at different wavelengths. Humps may be observed on the optical rotatory dispersion curve of the solute. (No such hump is expected for optically inactive solvents.) Another indirect evidence

may be obtained by the study of polymerization in an optically active medium. This kind of study has already been done[2], but the effect of the temperature of polymerization is not apparent.

Effects of Nonelectrolytes on the Temperature of the Maximum Density of Water. II. Organic Compounds with Polar Groups

By Goro WADA and Saburo UMEDA*

(Received June 4, 1962)

Water normally shows its maximum density at 3.98°C under atmospheric pressure, although "the temperature of the maximum density" (abbreviated as T. M. D.) is altered by foreign substances dissolved in it. In the preceding paper[1], the T. M. D.'s of dilute aqueous solutions of various alcohols were determined and several monovalent alkyl alcohols were found to elevate the T. M. D. of water when present in a low concentration. The effects of these substances on the T. M. D. of water were ascribed to the mutual interaction between the solute and water, such as the hydration and the hydrogen bondings formed between dipolar molecules. In this paper, some polar substances other than alcohols, i. e., amines, nitriles, ketones and cyclic ethers, are mainly examined in order to elucidate their influence upon the T. M. D. of water and to compare the results with those concerning alcohols already reported on[1].

Experimental

The experiments were carried out by means of dilatometry in a manner quite similar to that described in the previous report[1]. Fourteen species were used, all of which were thoroughly purified enough for the present purpose. Pure water was prepared by distillation and by the ion-exchange method.

The elevation of the T. M. D., ΔT, is defined by the following equation, in which T_m indicates the T. M. D. of a solution of mole fraction x of a solute and T_{m_0} is that of water, namely 3.98°C.

$$\Delta T = T_m - T_{m_0} \tag{1}$$

The observed values of ΔT at various concentrations are listed in Table I. The experimental errors are within ±0.02°C.

Discussion

Generally surveying Table I, the ΔT's are all negative, in contrast with the case of the alcohols previously observed[1]. Particularly, urea, pyridine, acetonitrile, propionitrile and 1, 4-dioxane are seen to exhibit superior abilities in lowering the T. M. D. of water.

The Excessive Elevation of the T. M. D. of an Aqueous Solution Caused by Mutual Interaction.—If there occur no change in volume and no interaction between a solute and water on mixing the two, the T. M. D. of water should be elevated as high as ΔT_n shown by the next equation[1]. As a matter of course, judging from the equation, ΔT_n should always be negative.

$$\Delta T_n = -\frac{x}{1-x} \cdot \frac{\alpha}{2\beta} \cdot \frac{V_{s_0}}{V_{w_m}} \tag{2}$$

Here, V_{s_0} and V_{w_m} are the molar volumes of the solute at 0°C and of water at T_{m_0} respectively, and α and β are the respective coefficients of thermal expansion. The molar volumes at θ°C are, therefore, expressed as:

$$V_s = V_{s_0}(1+\alpha\theta) \tag{3}$$

$$V_w = V_{w_m}\{1+\beta(\theta-T_{m_0})^2\} \tag{4}$$

Therefore, the excessive elevation of the T. M. D. of an aqueous solution, $\Delta T'$, is defined as follows:

$$\Delta T' = \Delta T - \Delta T_n \tag{5}$$

The necessary data on α and V_{s_0} for calculating the ΔT_n for each substance are collected in Table II. For water, the following values are adopted[1,2]: $\beta = 7.80\times10^{-6}$ deg^{-2}, and $V_{w_m} = 18.016$ cc. mol^{-1}. The values of $\Delta T'$ derived from Eq. 5 are also shown in Table I, together

with those of ΔT for comparison, and the relationships between $\Delta T'$ and x are pictured separately for three groups of substances in Figs. 1—3. Since $\Delta T'/x$ holds an approximate linearity with x in any solute substance, $\Delta T'$ may be expressed as a second order equation with respect to x, both the a and b parameters being shown in Table II as well.

$$\Delta T' = ax + bx^2 \qquad (6)$$

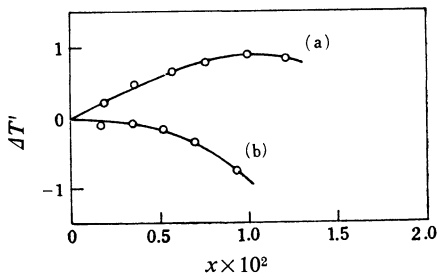

Fig. 3. Variation of $\Delta T'$ with the concentration of (a) tetrahydrofuran and (b) 1,4-dioxane.

In the cases of urea, formaldehyde and tetraethylammonium bromide, a and b are not known because of the lack of appropriate data for α and V_{so} in the liquid state.

The Nature of *a*.—Since, as was mentioned in the previous paper[1], $\Delta T'$ is caused by an appreciable change in the molar volume and in the coefficient of the thermal expansion of the solute (ΔV_{so} and $\Delta\alpha$) on mixing a solute and water, a has a nature expressed as follows:

$$a\equiv\lim_{x\to0}\left(\frac{\mathrm{d}\Delta T'}{\mathrm{d}x}\right)=-k(\alpha\Delta V_{so}+V_{so}\Delta\alpha) \tag{7}$$

As $k=(1/2)\,\beta V_{wm}$ is taken to be constant, any changes in the volume or the coefficient of the thermal expansion of water accompanied by a transition of states in the sheaths of the hydration layer attached to the solute molecules are entirely included in ΔV_{so} or $\Delta\alpha$ respectively.

A polar substance in question may overcome the association between the molecules themselves and may newly establish the hydration sphere around the individual molecules when it is dissolved in water. Since water is as much compressed in the hydration sphere as in "the packed state" of pure water, the coefficient of

the thermal expansion of water in this state is larger than that in the free state[1,2]. Consequently, the second term in the parenthesis on the right-hand side of Eq. 7, $V_{s_0}\Delta\alpha$, may be reasonably regarded as positive in most cases. On the other hand, ΔV_{s_0} may be either positive or negative according to whether or not the degree of the contraction of volume caused by the association of the solute due to its cohesive force in the separated state is superior to that resulting from the formation of the hydration sphere in the dissolved system. Thus, the magnitudes of a are dependent upon the signs and the absolute values of $\alpha\Delta V_{s_0}$ and $V_{s_0}\Delta\alpha$ in Eq. 7.

As is illustrated in Fig. 1, the a values for monomethylamine, dimethylamine and *n*-butylamine are all positive; the a for dimethylamine especially is as high as that for *t*-butyl alcohol*. In the case of dimethylamine, the $|\alpha\Delta V_{s_0}| \gg |V_{s_0}\Delta\alpha|$ relation may hold because it would be least associative with a very small dipole moment (Table II); consequently, $\Delta V_{s_0}<0$ and $\Delta\alpha$ would be nearly equal to zero, as it has an extraordinarily large α.

On the other hand, a becomes negative for acetamide; this is because both α and V_{s_0} are essentially small due to the strong formation of the intermolecular hydrogen bondings. Since this tendency occurs more severely in urea than in acetamide on account of its molecular structure, the ΔT of urea appears far lower than that of acetamide at the same mole fraction**. Unfortunately, the a value for urea can not be known, for it is not liquidous. Pyridine also exhibits an excellent ability to lower the T. M. D. of water, probably due to its good hydrophilic nature.

In Fig. 2, acetonitrile and propionitrile show large negative a values because of their large dipole moments. In Fig. 3, on the contrary, tetrahydrofuran and 1, 4-dioxane, which are both cyclic ethers, have positive a's as in the cases of amines and acetone; this is because they have comparatively many alkyl radicals in the molecule which are of rather a hydrophobic nature and are likely to diminish the degree of hydration.

In the case of benzene, $\Delta T'$ is zero within the range of experimental error; therefore, $a=b=0$. This fact shows that benzene is a perfect non-polar liquid and that it behaves quite independently in its aqueous solution with no mutual interaction with water.

Since tetraethylammonium bromide is a kind of electrolyte, its ability to lower the T. M. D. of water is much greater than that of any polar nonelectrolyte. The relation between ΔT and x shows a features similar to those of ammonium bromide[4]. Generally speaking, the lowering of the T. M. D. of water by 1-1 type electrolytes, composed of monatomic ions, seems to become greater as the size of the ion grows larger; moreover, this trend appears more effective in anions than in cations. In spite of such a tendency, it is quite strange that $N(C_2H_5)_4^+$ ion exhibits behavior similar to that of the simple NH_4^+ ion.

Additivity of a.—When an assumption is made that the total effect of a substance to lower the T. M. D. of water is approximately the additive sum of the nature of its individual component radicals according to their polarity, the a values assigned to several radicals can be obtained by the least square method based on the observed data of relatively simple compounds, including alcohols[1], such as are taken up in Table IV. Table III shows the a values thus calculated for various radicals and, as well, their radical dipole moments, between which a good parallelism is easily recognized; namely, the more polar a radical, the more negative a becomes. By using the a values for radicals in Table III, the a values for compounds are calculated in Table IV, the agreement with the observed a values being satisfactory, with errors of less than ± 0.3.

TABLE III. a AND DIPOLE MOMENT FOR RADICALS

Radical	$a\times10^{-1}$	μ, D. U.
$-CH_3$	27.8	0.3
$-CH_2-$	3.4	0
$-O-$	− 4.3	—
$>NH$ (or $-NH_2$)	− 4.4	1.31
$-OH$	− 7.6	1.53
$>CO$	−37.7	2.5
$-CN$	−40.0	3.6

The Nature of b.—In dilute solutions of some electrolytes, an approximate linearity is established between ΔT and x (Despretz's rule), but in the case of nonelectrolytes, the deviation from this linearity is considerable, from which fact the b parameter in Eq. 6 originates and always exhibits a negative value. As b is the coefficient of the second-order term with respect to the mole fraction, it may be related to some solute-solute interaction. When b values for various substances are

* In the case of *t*-butyl alcohol, $a=60.5$ and $\alpha=1.295$, both of which are the largest values among the observed alcohols[1].

** Urea and acetamde are far more likely to form hydrogen bondings than alcohol and acetone; the dielectric constants of their aqueous solutions are larger than that of water itself[3].

Acetonitrile	CH_3CN	−12.2	− 9.4
Propionitrile	C_2H_5CN	− 8.8	−11.7
Tetrahydrofuran	CH_2-CH_2 | CH_2-CH_2 >O	9.3	15.4
1, 4-Dioxane	O<CH_2-CH_2 CH_2-CH_2>O	5.0	1.8

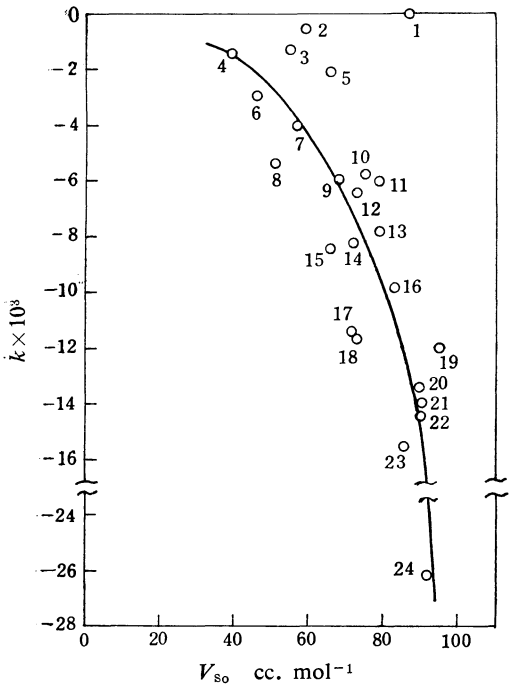

Fig. 4. Relation of b against V_{so}. 1: Benzene, 2: Acetamide, 3: Ethylene glycol, 4: Methyl alcohol, 5: Ethylene chlorohydrin, 6: Monomethylamine, 7: Ethyl alcohol, 8: Acetonitrile, 9: Propionitrile, 10: Isopropyl alcohol, 11: Tetrahydrofuran, 12: *n*-Propyl alcohol, 13: Pyridine, 14: Glycerin, 15: Dimethylamine, 16: 1,4-Dioxane, 17: Acetone, 18: Propylene glycol, 19: *n*-Butylamine, 20: *n*-Butyl alcohol, 21: Isobutyl alcohol, 22: *sec*-butyl alcohol, 23: Phenol, 24: *t*-Butyl alcohol.

plotted against their molar volumes, as in Fig. 4, the explicit correlation is indicated, with the exception of benzene, that the larger the molar volume, the greater negative value b has. Nevertheless, the mechanism of the solute-solute interaction can not be made clear at present.

Summary

The temperature of the maximum density (T. M. D.) of aqueous solutions of various organic polar substances at various concentrations were measured dilatometrically, and the degrees of elevating the T. M. D., ΔT, were estimated. The information derived from the experimental results includes:

1) At any concentration, the values of ΔT for all substances used in the present study are inevitably negative, in contrast with the cases of alkyl monovalent alcohols, reported on in the preceding paper[1].

2) $\Delta T'$, defined as the difference between the actual elevation of T. M. D. and that when the solution is assumed to be an ideal mixture, is given by an empirical formula, $\Delta T' = ax + bx^2$, where a is a characteristic constant of the solute, indicating the degree of the interaction between the solute and water; it generally has a more negative value as the substance is more polar.

3) Benzene does not interact with water; therefore, $\Delta T' = 0$ and $a = b = 0$ in so far as it is soluble in water.

4) An additivity correlation concerning a is realized from the composing radicals, and the a values assigned to respective radicals show a simple parallelism with their own polarities.

5) The b parameter is negative for all substances; the absolute value of this is greater as the molar volume becomes larger.

Polarographic Study of the Rate of the Dissociation Reaction of the Zinc(II)-Nitrilotriacetate Complex in Ammonia-Ammonium Nitrate Buffer Solutions

By Mutsuo KODAMA and Mitsuo HASHIMOTO

(Received June 8, 1962)

It has been known that the cadmium-nitrilotriacetate complex in ammonia-ammonium nitrate buffer solutions gives a reversible kinetic wave due to the dissociation of the complex and that the height of the limiting current of the kinetic wave increases with the concentration of ammonia[1,2]. A similar phenomena can also be observed in the case of zinc(II)-nitrilotriacetate[3]. In this study, the nature of the kinetic wave due to the dissociation of zinc(II)-nitrilotriacetate complex ions has been investigated more thoroughly from both theoretical and experimental viewpoints.

Experimental

Apparatus.—Direct current (D. C.) polarograms were measured by a manual polarograph similar to that of Kolthoff and Lingane[4]. The current was calculated from the ohmic potential drop, measured by a potentiometer, across a 10000-ohm resistance which was in series with the polarographic cell. A Yanagimoto Model GA-103 galvarecorder equipped with an automatically-scanning potentiometer was employed for the measurements of all alternating current (A. C.) polarograms.

A dropping mercury electrode, which has an m value of 1.23_7 mg./sec. and a drop time of 4.02 sec./drop in air-free 0.1 M potassium chloride solutions with an open circuit at 70 cm. of mercury column at 25.0 ± 0.1°C, was used for all measurements. A saturated calomel electrode (S. C. E.) of a large area was used as the reference electrode and was connected to the cell solution through a Hume and Harris-type[5] salt bridge.

The dissolved oxygen in the solution was removed by bubbling pure nitrogen gas through the solution. All D. C. polarograms given in this paper were measured at 25.0 ± 0.1°C unless otherwise stated and are corrected for residual currents. The pH value of the solution was measured with a glass electrode pH meter (Toyoroshi Kaisha Model G).

Reagent.—A standard solution of zinc(II) was prepared by dissolving pure zinc sulfate crystals in redistilled water. The concentration of zinc(II) was determined accurately by titrating it with standard nitrilotriacetate volumetrically[6]. Nitrilotriacetic acid (NTA) of an analytical reagent grade (Wako Pure Chemical Industries, Ltd.) was used without further purification. The stock solution of NTA was standardized with a standard nickel(II) solution[7]. The ammonia-ammonium nitrate buffer solutions were prepared by the method described in a previous paper[6]. All other chemicals were of an analytical reagent grade and were used without further purification. The ionic strength of the solution was adjusted to 0.4 by adding appropriate amounts of potassium nitrate.

Results and Discussion

In order to simplify the theoretical treatment, it is desirable to keep the concentration of NTA ions at the electrode surface constant during the reaction. This is ordinarily attained by adding a large excess of NTA ions. In the present case, however, it is advantegeous to keep the concentration of NTA ions fairly low, because the kinetic wave decreases with the increase in the concentration of free NTA ions. As an alternative, the above condition may be satisfied by adding a large excess of calcium ions to the solution; these ions react with free NTA ions to form stable complex ions. Therefore, all experiments were carried out in a solution containing a large excess of calcium ions, in other words, in a solution well-buffered with respect to free NTA ions.

The zinc(II)-nitrilotriacetate complex ion in a 0.1 M potassium nitrate medium does not show a reduction wave at less negative potentials than those where the supporting electrolyte is reduced. The system containing $2.11_6\times10^{-3}$ M NTA, $9.15_2\times10^{-4}$ M zinc(II) and 0.1 M calcium nitrate, however, exhibits a reduction wave in the ammonia buffer medium of a pH value of 8.25 (ionic strength 0.4), which corresponds to the reduction of zinc(II)-ammine complex

ions (see Fig. 1). The limiting current of the polarogram is much larger than that which would be expected from the calculated concentration of the free ions which are in equilibrium with the zinc(II)-nitrilotriacetate complex at a pH value of 8.25. The numerical values for the equilibrium constants of NTA, ammonia, and their complexes, which were used for the calculation of the concentration of zinc(II)-ammine complex ions, the ZnX^-, NH_3 and X^{3-} listed in Table III, are given in Table II. These values were also used for the various calculations discussed below.

The relation between the limiting current of the reduction wave, i_t, and the effective pressure, H_c, was examined. The limiting current was found to be independent of H_c within the range of experimental error (Table I).

C: 0.1 M KNO_3 medium containing $2.11_6\times10^{-3}$ M NTA

TABLE I. RELATION BETWEEN THE LIMITING CURRENT AND THE EFFECTIVE PRESSURE OF MERCURY ON THE DME

($9.15_2\times10^{-4}$ M Zn(II), $2.11_6\times10^{-3}$ M NTA, 0.1 M $Ca(NO_3)_2$, ionic strength 0.4, 25°C)

Height of mercury column, H cm.	Limiting current i_l, μA	$i_l/H_c^{1/2}\times10$
55	0.74_5	1.02_1
70	0.75_1	0.91_0
90	0.75_5	0.80_5

H_c: Effective pressure in cm.

The effect of the pH value of the solution on i_l was studied over the pH range of 8.26 to 9.36 in ammonia buffer solutions containing $2.11_6\times10^{-3}$ M NTA, $9.15_2\times10^{-4}$ M zinc(II) and 0.1 M or 0.05 M calcium(II), the ionic strength of which was adjusted to 0.4. The total concentration of ammonia in the solution was 0.1 M or 0.05 M. The expeimental results show that the limiting current increases with the pH value of the solution, provided the other conditions are kept constant (Table III). The concentration of ammonia was calculated by successive approximation. Similar results were also obtained at 15 and 33°C.

TABLE II

i) Dissociation constants of NTA (hybrid constants; ionic strength: 0.4)[8]
$pK_1=1.82_1$ $pK_2=2.30_6$ $pK_3=9.44_5$
ii) Dissociation constants of zinc-ammine complex (ionic strength: 0.4)[9]
$pK_1=2.18$ $pK_2=2.25$ $pK_3=2.31$ $pK_4=1.96$
iii) Formation constant of Zn(II)-NTA (ionic strength: 0.4)[10]
$K_{ZnX}=C_{ZnX}/C_{Zn}\cdot C_X=10^{10.09}$
iv) Formation constant of Ca(II)-NTA (ionic strength: 0.4)[8]
$K_{CaX}=C_{CaX}/C_{Ca}\cdot C_X=10^{5.83_4}$
v) Dissociation constant of ammonia (hybrid constant; ionic strength: 0.4)[11]
$pK=9.30$

In this table, the C's, represent the concentration of the corresponding ionic species.

As these values had not been determined experimentally, they were calculated from the related formation constants in the solution of an ionic strength of 0.1 at 20°C. The activity coefficients of the ions were calculated by means of the Debye-Hückel equation, using the proper values of ionic radii given in Kielland's table[12]. The temperature coefficients of these formation constants were assumed to be zero between 15° and 33°C in these calculations.

The relation between $\log(i/(i_l-i))$ and E, where i_l indicates the limiting current, and i, the current at a potential of E, was analyzed with some typical examples. This relation gave a straight line with a slope of 57 mV. (Fig. 2), which is greater than the value of 45 mV. obtained for the zinc(II) ion in the ammonia buffer solution[13].

The value for the degree of reversibility, K, defined by Eq. 1, was 0.03 for the reduction of the zinc(II) ions in the ammonia buffer solution. This value is much smaller than that for the reduction of cadmium(II) in a potassium nitrate medium.

$$K=I/n\cdot t_d^{1/2}\cdot i_d \qquad (1)$$

a) Total concentration of Ca(II), 0.1 M
b) Total concentration of NH_3, 0.1 M
c) Total concentration of Ca(II), 0.05 M
d) Total concentration of NH_3, 0.05 M

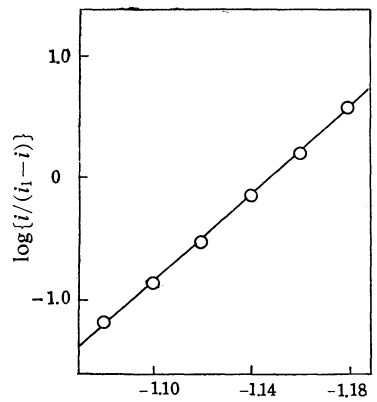

Fig. 2. Log-plot analysis of the reduction wave of Zn(II)-NTA complex in an ammonia buffer of pH 8.2_6 containing 0.1 M $Ca(NO_3)_2$ (Zn(II), $9.15_2\times10^{-4}$ M; NTA, $2.11_6\times10^{-3}$ M; $\mu=0.4$).

In Eq. 1, I indicates the A.C. peak current and t_d, the drop time.

In view of the experimental facts that K for the reduction of zinc(II) ions in the ammonia buffer solution corresponds to the value of the irreversible electrode reaction and that the slope of the log-plots for the reduction wave of the zinc(II)-NTA system is greater than that of the zinc(II) ions in the ammonia buffer solution, we can conclude that the electrode reaction of the zinc(II)-NTA system proceeds irreversibly in a usual polarographic sense.

The effect of temperature on the limiting current was also examined. The results show that the i_l increases in an appreciable degree with the temperature and that the value of the temperature coefficient was 5%, which is larger than that expected for the diffusion-controlled case (Table IV).

TABLE IV. THE RELATION BETWEEN THE LIMITING CURRENT AND THE TEMPERATURE OF THE SOLUTION

($9.15_2\times10^{-4}$ M Zn(II), $2.11_6\times10^{-3}$ M NTA
0.1 M $Ca(NO_3)_2$, ionic strength 0.4)

Temp. T, °C	Limiting current i_l, μA	$\Delta i_l/\Delta T$ %
15	0.38_2	4.8
25	0.75_1	5.8
33	1.10_1	

The experimental results on the relation between the limiting current and the effective pressure of mercury on the DME clearly indicate that the limiting current is kinetic in nature. This explanation is also supported by the experimental finding on the relation between the limiting current and the temperature of the solution.

Under the experimental conditions employed, ZnX^-, zinc ammine complex ions and zinc(II) ions coexist in the bulk of the solution; their concentrations are determined according to the following chemical equilibria:

$$ZnX^- + m\,NH_3 \rightleftharpoons Zn(NH_3)_m^{2+} + X^{3-} \quad (2)$$

$$Zn(NH_3)^{2+} \rightleftharpoons Zn^{2+} + NH_3 \quad (3)$$

$$Zn(NH_3)_2^{2+} \rightleftharpoons Zn(NH_3)^{2+} + NH_3 \quad (4)$$

$$Zn(NH_3)_3^{2+} \rightleftharpoons Zn(NH_3)_2^{2+} + NH_3 \quad (5)$$

$$Zn(NH_3)_4^{2+} \rightleftharpoons Zn(NH_3)_3^{2+} + NH_3 \quad (6)$$

In an ammonia buffer of a value from pH 8.3 to 9.5 and containing a large excess of calcium(II) ions with respect to the total concentration of NTA, the equilibrium between ZnX^- and zinc ammine-complex ions is greatly in favor of ZnX^-; i.e., the concentration of

ZnX^- is virtually equal to the total concentration of zinc in the bulk of the solution.

It is a well-known fact that the electrode reaction of zinc ions at mercury electrodes in ammonia buffer solutions corresponds to the direct reduction of zinc ammine complex ions[14]. From the above consideration, and from the fact that the limiting current increases with the concentration of ammonia in the solution provided that the other conditions are kept constant (Table III), it is very reasonable to conclude that the reaction at the electrode surface proceeds according to the following equations:

$$(I_a)\quad \begin{cases} ZnX^- + m\,NH_3 \rightleftharpoons Zn(NH_3)_m{}^{2+} + X^{3-} \text{ (slow)} & (2) \\ Zn(NH_3)_m{}^{2+} + 2\,e^- + Hg \rightleftharpoons Zn(Hg) + m\,NH_3 & (7) \end{cases}$$

where the forward reaction rate of process 2 is assumed to be nearly equal to or smaller than the rate of the diffusion process of the ordinary ionic species and where the electron transfer reaction 7 proceeds irreversibly.

The theoretical equation of the kinetic current derived for the simple electrode reaction by Delahay[15] can not be applied without modification to the kinetic current obtained in the electrode reaction, where the complicated chemical reaction precedes the irreversible electron-transfer process. Therefore, we tried to derive a theoretical equation of the current-voltage curve obtained under such a mechanism as Ia by using the concept of the reaction layer[17], as in the case of cadmium(II)-EDTA complex ions[16].

When the concentrations of hydrogen ions, ammonia and X^{3-} ions at the electrode surface are kept constant by using buffer solutions containing a large excess of calcium ions which readily react with X^{3-} ions and form stable complex ions, reaction (I_a) can be written in a simpler form:

$$(II)\quad \begin{cases} Y \underset{\vec{k_8}}{\overset{\vec{k_8}}{\rightleftharpoons}} O & \text{slow} \quad (8) \\ O + 2\,e \underset{\vec{\kappa}}{\overset{\vec{\kappa}}{\rightleftharpoons}} R & (9) \end{cases}$$

where the $(m+1)$-th order reaction 2 is replaced by the pseudo-first order reaction 8. O represents the oxidized form, and R, the reduced form, both of which concern the electron-transfer process. The terms k and κ are the reaction rate constants corresponding to each process, the former of which is a usual rate constant of the first order homogeneous reaction expressed in sec^{-1}, while the latter is a rate constant of an electron-transfer process expressed in cm. sec^{-1}. In the present case, $\vec{\kappa}$ and $\overleftarrow{\kappa}$ are represented by the following relations:

$$\vec{\kappa} = \vec{\kappa}_0 \exp\left(\frac{-2\,\alpha EF}{RT}\right)$$

$$\overleftarrow{\kappa} = \overleftarrow{\kappa}_0 \exp\left(\frac{+2(1-\alpha)EF}{RT}\right) \qquad (10)$$

where E is the electrode potential, α, the transfer coefficient, F, the Faraday constant, R, the gas constant, T, the absolute temperature, and κ_0, the value of κ at $E=0$.

Taking into consideration the diffusion process of Y from the bulk of the solution to the electrode surface and assuming the condition of the stationary state with respect to the concentrations of Y, O and R at the electrode surface, the following equations are obtained:

$$dC_Y/dt = K^D{}_Y(C^\circ{}_Y - C_Y) - (\vec{k_8}'C_Y - \overleftarrow{k_8}'C_O) = 0 \qquad (11)$$

$$dC_O/dt = (\vec{k_8}'C_Y - \overleftarrow{k_8}'C_O) - (\vec{\kappa}C_O - \overleftarrow{\kappa}C_R) = 0 \qquad (12)$$

$$dC_R/dt = (\vec{\kappa}C_O - \overleftarrow{\kappa}C_R) - K^D{}_R C_R = 0 \qquad (13)$$

$$\vec{k_8}' = \mu_8 \vec{k_8}$$

$$\overleftarrow{k_8}' = \mu_8 \overleftarrow{k_8}$$

where the C°'s represent the concentrations in the bulk of the solution, the C's, the concentrations at the electrode surface, the K's, the rate constants corresponding to the diffusion processes, and the μ's, the thicknesses of the reaction layer of the corresponding chemical reactions expressed in cm^{-1}. In the above equations, the diffusion process of O is neglected, because, in the present case, the concentration of O in the bulk of the solution can be assumed to be negligibly small.

The average current, i, can be represented by the equation:

$$i = 2\,AF(\vec{\kappa}C_O - \overleftarrow{\kappa}C_R) \qquad (14)$$

where A is the mean surface area of DME. From Eqs. 11, 12, 13 and 14, we can obtain the following equation for the limiting current, i_l:

$$i_l = 2\,AF\left\{\frac{\vec{k_8}' \cdot C^\circ{}_Y}{1 + \vec{k_8}'/K^D}\right\} \qquad (15)$$

15) p. Delahay, "New Instrumental Methods in Electrochemistry", Interscience Publishers, New York (1954), p. 87.
16) N. Tanaka, R. Tamamushi and M. Kodama, *Z. physik. Chem. N. F.*, **14**, 141 (1958).
17) For example, see Ref. 15, p. 94.

under the assumption that K_Y^D and K_R^D are the same ($=K^D$).

By introducing the relation $\mu_8=K_8^{1/2}\cdot D^{1/2}\cdot(\vec{k_8})^{-1/2}$ [17], Eq. 15 can be rearranged to:

$$\frac{1}{i_l}=\frac{1}{2AFK_8^{1/2}D^{1/2}\vec{k_8}^{1/2}C^\circ}+\frac{1}{2AFK^D C^\circ_Y} \tag{16}$$

where D is the diffusion coefficient of Y and O, and $K_8=C^\circ_O/C^\circ_Y$. On the right-hand side of Eq. 16, the first and the second terms represent the contribution of the kinetic and the diffusion currents respectively to the limiting current. If $K^{1/2}D^{1/2}\vec{k_8}^{1/2}C^\circ_Y$ is much larger than $K^D C^\circ_Y$, the limiting current comes to be completely diffusion-controlled, which state is represented by the well-known Ilkovic equation.

If the electron-transfer process is assumed to be irreversible, i. e., $\vec{\kappa}\gg\overleftarrow{\kappa}$, as in the present case of the zinc(II)-NTA system, we can obtain the following equation, which represents the current-voltage relation of the so-called irreversible reduction wave corresponding to reaction II by combining Eqs. 11, 12, 13 and 14.

$$i=\frac{\vec{\kappa}}{\overleftarrow{k_8}}(i_l-i)\left(1+\frac{\vec{k_8}'}{K^D}\right) \tag{17}$$

When the limiting current is kinetic in nature, as in the case of the zinc(II)-NTA system, $\vec{k_8}'$ is assumed to be much smaller than K^D. For this reason, the term $\vec{k_8}'/K^D$ is negligibly small in comparison with 1 and Eq. 17 can be simplified as follows at 25°C:

$$E=\frac{0.0591}{2}\left\{\log\vec{\kappa}_0-\log\left(\frac{i}{i_l-i}\right)-\log\overleftarrow{k_8}'\right\} \tag{18}$$

The experimental results on the zinc(II)-NTA system were analyzed with the aid of Eqs. 16 and 18. When these equations are applied to the electrode Eq. Ia, Y and O correspond to ZnX^- and $Zn(NH_3)_m^{2+}$ respectively, and the rate constants and equilibrium constants in these equations must be replaced by the corresponding terms, as in the following way:

$$\vec{k_8}=\vec{k_2}(C^\circ_{NH_3})^m$$

$$\overleftarrow{k_8}=\overleftarrow{k_2}C^\circ_X$$

$$K_8=\frac{C^\circ_{Zn(NH_3)_m}}{C^\circ_{ZnX}}=K\times\frac{(C^\circ_{NH_3})^m}{C^\circ_X}$$

$$K=K_{Zn(NH_3)_m}/K_{ZnX}$$

$$K_{Zn(NH_3)m}=\frac{C^\circ_{Zn(NH_3)_m}}{(C^\circ_{NH_3})^m C^\circ_X}$$

$$K_{ZnX}=\frac{C^\circ_{ZnX}}{C^\circ_{Zn}\cdot C^\circ_X}$$

Therefore, Eq. 16 can be written as

$$\frac{1}{i_l}=\frac{1}{2AFD^{1/2}K^{1/2}\vec{k_2}^{1/2}}\cdot\frac{(C^\circ_X)^{1/2}}{C^\circ_{ZnX}\cdot(C^\circ_{NH_3})^m}+\frac{1}{2AFK^D\cdot C^\circ_{ZnX}} \tag{19}$$

This equation indicates that, if the electrode reaction proceeds according to the Ia mechanism, the relation between $1/i_l$ and $(C^\circ_X)^{1/2}/C^\circ_{ZnX}\cdot(C^\circ_{NN_3})^m$ must be linear. The above relations were examined in connection with the experimental data in Table III. Linear relations were found between $1/i_l$ and $(C^\circ_X)^{1/2}/C^\circ_{ZnX}\cdot(C^\circ_{NN_3})^2$, but not between $1/i_l$ and $(C^\circ_X)^{1/2}/C^\circ_{ZnX}$, $(C^\circ_X)^{1/2}/C^\circ_{ZnX}\cdot C^\circ_{NN_3}$ or $(C^\circ_X)^{1/2}/C^\circ_{ZnX}\cdot(C^\circ_{NN_3})^3$ (Figs. 3, 4, 5 and 6). Similar results were also obtained at 15 and 33°C. Therefore, it can be concluded that the electrode reaction

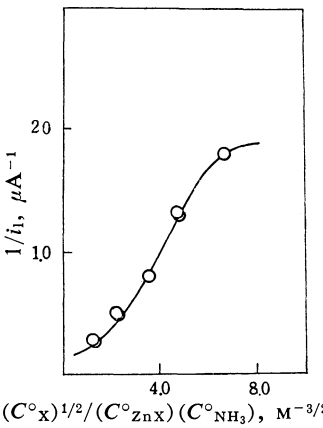

Fig. 4. Relation between $1/i_l$ and $(C^\circ_X)^{1/2}/(C^\circ_{ZnX}\cdot C^\circ_{NH_3})$.

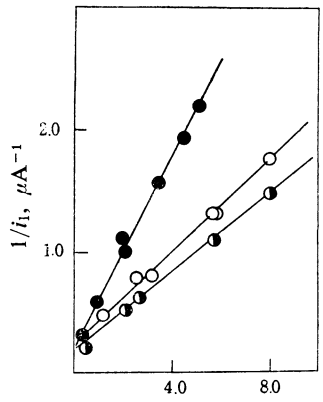

Fig. 5. Relation between $1/i_l$ and $(C^\circ_X)^{1/2}/(C^\circ_{Zn^X})(C^\circ_{NH_3})^2$.

● 15°C ○ 25°C
◐ 33°C

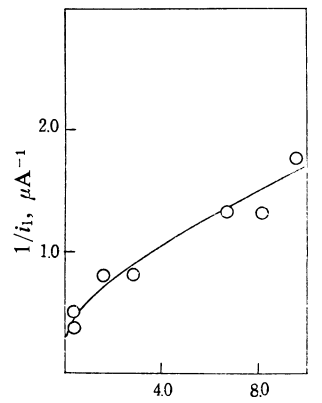

Fig. 6. Relation between $1/i_l$ and $(C^\circ_X)^{1/2}/(C^\circ_{ZnX})(C^\circ_{NH_3})^3$.

of the zinc(II)-NTA system proceeds according to the following mechanism:

$$\text{(Ib)}\begin{cases} ZnX^- + 2\,NH_3 \\ \quad \rightleftharpoons Zn(NH_3)_2^{2+} + X^{3-} & (2) \\ Zn(NH_3)_2^{2+} + 2\,e + Hg \\ \quad \rightleftharpoons Zn(Hg) + 2NH_3 & (7) \end{cases}$$

By remembering the fact, mentioned by Matsuda and Ayabe[14], that the reduction wave of zinc-ammine complex ions at the dropping mercury electrode is due to the direct reduction of $Zn(NH_3)_2^{2+}$, it is very plausible to propose the I_b electrode reaction mechanism, where the dissociation reaction of ZnX^- precedes the electron transfer process.

The fact that linear relations between $1/i_l$ and $(C^\circ_X)^{1/2}/C^\circ_{ZnX}(C^\circ_{NN_3})^2$ were found at 15, 25 and 33°C clearly show that the concentration of calcium(II) employed was high enough to keep the concentration of X^{3-} constant at the electrode surface.

Figure 5 clearly shows the existence of a small contribution of the diffusion-controlled current to the total limiting current, which must be equal to $(2\,AFK^DC^\circ_{ZnX})^{-1}$, according to Eq. 19. Theretically, this term must be equal to $(2\times6.07\times10^4\times m^{2/3}\,t^{1/6}\,D^{1/2}\,C^\circ)^{-1}$ in comparison with the Ilkovic equation, where m is expressed in g./sec. and t_d, in sec., and where D is the deffusion coefficient of Zn^{2+}, ZnX^- or $Zn(NH_3)_m^{2+}$ expressed in cm. sec^{-2} [18]. The current is expressed in ampere and the concentration, in mol./cc. The observed value of $(2\,AFK^DC^\circ_{ZnX})^{-1}$ was 1.8×10^3 amp^{-1}, whereas the calculated value is 2×10^3 amp^{-1}. It could be said that the observed value agrees with the calculated value.

The tangent of the relation of $1/i_l$ vs. $(C^\circ_X)^{1/2}/C^\circ_{ZnX}(C^\circ_{NN_3})^2$ was found to be 2.4×10^{-3}. According to Eq. 22, this value must be equal to $(2\,AFK^{1/2}\,D^{1/2}\,\vec{k}_2^{1/2})^{-1}$, which can be written as $(2.51+10^5\,m^{2/3}\,t^{2/3}\,D^{1/2}\,K^{1/2}\,k_2^{1/2})^{-1}$. If we use the values of $10^{10.09}$ for K_{ZnX} and $10^{4.43}$ for $K_{Zn(NH_3)_2}$, $\vec{k}_2$ in Eq. 22 is calculated to be 0.85_0 $(mol./l.)^{-2}\,sec^{-1}$, which corresponds to the rate constant of the forward reaction of $ZnX^- + 2\,NH_3 = Zn(NH_3)_2^{2+} + X^{3-}$ at 25°C in the medium with the ionic strength of 0.4 containing a large excess of calcium(II) ions. The rate constant of the backward reaction, $\overleftarrow{k}_2$, is also found to be equal to 2.42×10^5 $(mol./l.)^{-1}\,sec^{-1}$ from the $K=\vec{k}_2/\overleftarrow{k}_2$ relation.

The experimental data on the limiting current obtained at 15 and 33°C at various pH values were analyzed by using Eq. 22. The linearity between $1/i_l$ and $(C^\circ_X)^{1/2}/C^\circ_{ZnX}(C^\circ_{NH_3})^2$ was satisfied also in these cases. If we assume that the value of the equilibrium constant, K, is independent of the temperature, the values of $\vec{k}_2$ are calculated as 0.22 $(mol./l.)^{-2}\,sec^{-1}$ and 5.52 $(mol./l.)^{-2}\,sec^{-1}$ for 15 and 33°C respectively. From the values of $\vec{k}_2$ at 15, 25 and 33°C, the heat of activation, ΔH^*, and the entropy of activation, ΔS^*, of the forward reaction of $ZnX^- + 2NH_3 = Zn(NH_3)_2^{2+} + X^{3-}$, are obtained as 31.1 kcal. and -25.4 e. u. respectively. These thermodynamic values, however, are not so accurate partly because of the approximate estimation of the equilibrium constants, K_{ZnX} and $K_{Zn(NH_3)_2}$.

When the mechanism of the electrode reaction is represented by Ib, the natures of the current-voltage curve must satisfy Eq. 18. This equation predicts that the log-plot analysis will give a straight line with a slope of 57 mV. at

18) In this calculation, the diffusion coefficients of Zn^{2+}, ZnX^- and $Zn(NH_3)_2^{2+}$ were assumed to be the same, 8.40×10^{-6} cm. sec^{-2}.

25°C; this is in agreement with the experimental results when we employ the value of 0.53_0 for (see Fig. 2).

The expression of the half-wave potential, $E_{1/2}$, is obtained from Eqs. 10 and 18 as:

$$E_{1/2}=\frac{0.0591}{2\alpha}\left\{\log\vec{\kappa}_0-\log\overleftarrow{k_2}'\right\} \quad (20)$$

By remembering the nature of $\overleftarrow{k_2}'$, Eq. 20 can be written as

$$E_{1/2}=\text{const}-\frac{0.0591}{4\alpha}\log C^\circ \quad (21)$$

This relation was examined by using some typical data from Table III, the results of which are shown in Fig. 6. The tangent of the relation between $E_{1/2}$ and C°_X is 35 mV. and is in agreement with the theoretical prediction of 29 mV.

It can be concluded from the results of the theoretical analysis of the experimental data that the reduction wave of the zinc(II)-NTA system under the presence of an excess of calcium ions is of a kinetic nature, the mechanism of which is represented by the I_b reaction.

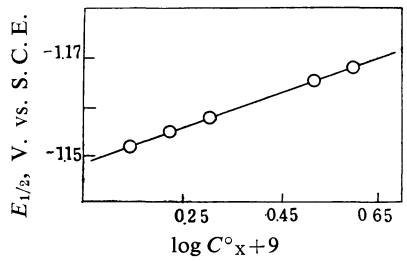

Fig. 7. Relation between $E_{1/2}$ ang $\log C^\circ_X$.

Summary

The kinetic current due to the dissociation of zinc-nitrilotriacetate complexes has been investigated in buffers with pH values from 8.3 to 9.5 and containing a large excess of calcium ions with respect to the total concentration of nitrilotriacetate. The ionic strength was kept at 0.4.

It was confirmed that the electrode reaction at the surface of the dropping mercury electrode proceeds according to the mechanism:

$$ZnX^- + 2\,NH_3 \rightleftarrows Zn(NH_3)_2^{2+} + X^{3-} \quad \text{(slow)}$$

$$Zn(NH_3)_2^{2+} + 2\,e + Hg \rightleftarrows Zn(Hg) + 2\,NH_3 \quad \text{(fast)}$$

The rate constants were calculated as 0.85_0 $(\text{mol./l.})^{-2}\,\text{sec}^{-1}$ for the dissociation reaction of $ZnX^- + 2\,NH_3 = Zn(NH_3)_2^{2+} + X^{3-}$ and $2.42\times 10^5(\text{mol./l.})^{-1}\,\text{sec}^{-1}$ for the association reaction at 25°C. in buffer solutions of pH values from 8.3 to 9.5 with an ionic strength of 0.4 and containg 0.1 M calcium nitrate. The heat of activation and the entropy of activation of the dissociation reaction were calculated as 31.1 kcal. and −25.4 e. u. respectively.

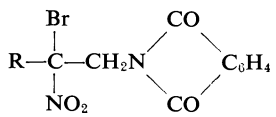
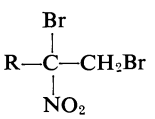
Die Darstellung und Charakterisierung von 2-Brom-2-nitroalkylaminen

Von Mitsuo MASAKI und Masaki OHTA

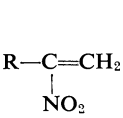


(Eingegangen am 14 Juni, 1962)

Kürzlich berichteten wir[1], dass durch neue Darstellungsmethode der Umsetzung von 1, 2-Dibrom-2-nitropentan (III-a) mit Phthalimidkalium und nachfolgender Behandlung der entstandenen Phthalimid-Körper (II-a) mit Hydrazinhydrat 2-Brom-nitropentylamin (I-a) dargestellt werden kann.



Zur Prüfung auf die Anwendungsfähigkeit



(I)

(II)

(III)

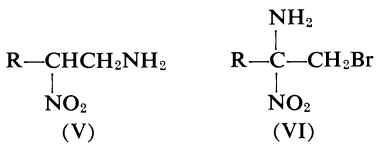
iso-C_4H_9 (c)

1) M. Masaki und M. Ohta, Dieses Bulletin, 35, 1418 (1962).

dieser Methode versuchten wir weiter auch andere Nitroolefine (IV) in 2-Brom-2-nitroalkylamine (I) überzuführen, weil diese Verbindungsklasse in der erst wenigen Literatur beschrieben worden ist[2].



In analoger Weise wie bei I-a konnten wir 2-Brom-2-nitrohexylamin (I-b) und 2-Brom-2-nitro-4-methylpentylamin (I-c) mit befriedigender Ausbeute herstellen.

Nitroolefine lassen sich gewöhnlich nach der von Hass und Mitarbb.[3] angegebenen Methode, die in Erhitzen von 2-Nitroalkylacetat mit Alkalicarbonat besteht, darstellen. Bei unserem Fall jedoch konnte in der Ausbeute kein befriedigenes Resultat erhalten werden. Die direkte Dehydratisierung von Nitroalkohol mittels Phthalsäureanhydrid zu Olefin ist schon von Buckley und Scaife[4] sowie von Khannanov und Mitarbb.[5] berichtet worden. Nach dieser Methode erhielten wir[1] auch 2-Nitropenten (IV-a) in guter Ausbeute und ferner konnten wir durch Erhitzen von 2-Nitrohexanol und 2-Nitro-4-methylpentanol mit Phthalsäureanhydrid die entsprechenden Nitroolefine (IV) darstellen.

Die auf diese Weise erhaltenen Nitroolefine (IV) liessen sich in 1,2-Dibrom-Körper (III) überführen, welche bei 30 stdg. Erhitzen mit Phthalimidkalium in Aceton 1-Phthalimid-2-brom-2-nitroalkane (II) lieferten, die sich mit Hydrazinhydrat zu der Aminen I zersetzen liessen.

Die so erhaltenen 2-Brom-2-nitroalkylamine (I) wurden durch Infrarot-Spektren und Elementaranalysen von den Hydrochloriden und den Pikraten, sowie durch Umsetzung mit Phenylisocyanat charakterisiert.

In Infrarot Absorptionsspektrum des Hydrochlorids von I tritt die für aktive Methylengruppe, d. h. an NH_3^+ benachbartes CH_2 charakteristische Bande[6] bei 1440 cm^{-1} intensiv auf, welche in demjenigen des freien Amins I verschwindet. Vergleicht man ferner die Absorptionsbanden der Nitrogruppe in I mit denjenigen in 2-Nitroalkylamine (V) (s. Tabelle I), so kann man einen Effekt des α-Substituent finden, welcher mit dem Bericht Haszeldines[7] übereinstimmt und darauf hinweist, dass Bromatom in I an α-Kohlenstoff der Nitrogruppe gebunden ist. Somit lässt sich beweisen, dass I nicht das alternative Nitroamin, d. h. 1-Brom-2-amino-2-nitro-Körper (VI) ist.

(V) (VI)

Durch Umsetzung mit Phenylisocyanat lieferten die Amine I die entsprechenden Derivate des Harnstoffes und mit Benzoylchlorid konnte die Benzoylierung erreicht werden. Dagegen ist uns die Umsetzung von I mit Chlor- bzw. Brom-essigester nicht gelungen. Auch bei der Reaktion mit verschiedenen Carbonylverbindungen konnte kein definiertes Produkt erhalten werden.

Im Infrarot-Spektrum von I-a beobachtet man zwei schwache Banden bei 3420 und 3345 cm^{-1}, welche man zu den asymmetrischen und symmetrischen NH_2-Valenzschwingungen zurückführen kann, weil die Wellenzahl-Beziehung dieser zwei Banden in guter Übereinstimmung mit der Gleichung von Bellamy-Williams[8] ist. Doch ist die Lage dieser Banden einigermassen in niedriger Wellenzahl verschoben als diejenige eines freien primären Amins[9]. Diese Verschiebung

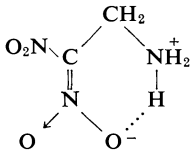
9) L. J. Bellamy, "The Infra-red Spectra of Complex Molecules", 2nd Ed., Methuen, London; Wiley, New York (1958), s. 250.



mag möglicherweise auf Wasserstoffbindung beruhen.

Ferner weist es auf die Bildung der intramolekularen Wasserstoffbindung in diesem Nitro-amin I-a hin, dass die Lage der NH_2-Valenzschwingungsbanden von Konzentration unabhängig ist und die Bande von der symmetrischen NO_2-Valenzschwingung in I-a um 10 cm^{-1} in niedriger Wellenzahl verschoben wird als diejenige in Hydrochlorid von I-a.

Vor einiger Zeit stellten Kamlet und Dacons[10] 2, 2-Dinitroethylamin (V, R=NO_2) her und beobachteten, dass Formylierung, Mannich-Reaktion oder Michael-Kondensation des Dintro-amins nicht auftrat und dies auf die Bildung der intramolekularen Wasserstoffbindung VIII, die Zwitterion enthält, zurückzuführen ist.

(VII)

(VIII)

Im Infrarot-Spektrum von 2-Nitropentylamin (V, R=C_3H_7), das durch die Anlagerung von Ammoniak an 2-Nitropenten hergestellt wurde, erscheinen auch die zwei Banden bei 3410 und 3330 cm^{-1}, die zur NH_2-Valenzschwingung gehören, und dafür kann man die analogen Verhältnisse wie bei I-a beobachten.

Aus den oben erwähnten Tatsachen wird es klar, dass die 2-Nitroalkylamine auf jeden Fall die intramolekulare Wasserstoffbindung auszubilden scheinen.

Jedoch kann man es nicht durch Wasserstoffbindung erklären, dass die Aminogruppe in 2-Brom-2-nitroalkylamin (I) reaktionsträge ist, was vielmehr auf sterische Grüde zurückzuführen sein dürfte.

Beschreibung der Versuche

2-Nitro-1-hexen (IV-b).—Ein Gemisch von 42 g 2-Nitro-1-hexanol und 41 g Phthalsäureanhydrid wurde im Destillierkolben unter vermindertem Druch von ca. 45 mmHg bei 160～170°C erhitzt und das erzeugte Olefin kam durch 15 cm Kolonne mit wenigem Wasser sehr langsam über. Nach 5～6 Stdn. war das Destillieren beendet, das Destillat wurde mit Äther versetzt und nach der Befreiung von der Wasserschicht mit Calciumchlorid getrocknet. Nach dem Abdampfen des Äther wurde der Rückstand unter vermindertem Druck destilliert. Ein gelbliches, Augen stechendes Öl vom Sdp. 93.5～94.5°C/47.5 mmHg. Ausb. 24 g.

Gef.: N, 10.45. Ber. für $C_6H_{11}O_2N$: N, 10.85%.

1, 2-Dibrom-2-nitrohexan (III-b).—Eine Lösung von 60 g IV-b in 80 ccm Chloroform wurde mit 24.8 g Brom in 45 ccm Chloroform langsam versetzt. Die Reaktion verlief langsam unter mässiger Wärmeerzeugung. Nach 3 stdg. Stehenlassen bei Raumtemperatur wurde das Lösungsmittel entfernt und der Rückstand unter vermindertem Druck destilliert. Sdp. 108～109°C/7 mmHg. Ausb. 41 g.

Gef.: C, 25.05; H, 3.91; N, 4.56. Ber. für $C_6H_{11}O_2NBr_2$: C, 24.91; H, 3.86; N, 4.84%.

1-Phthalimid-2-brom-2-nitrohexan (II-b).—Ein Gemisch von 28.9 g III-b und 18.5 g Phthalimidkalium in 100 ccm des mit Kupfersulfat getrockneten Acetons wurde 30 Stdn. unter Rühren und Rückfluss erhitzt. Nach dem Abkühlen filtrierte man Kaliumbromid ab, dampfte das Filtrat unter vermindertem Druck ein und versetzte das verbliebene Öl mit 30 ccm Äthanol, woraus sich beim Stehenlassen der Phthalimid-Körper (II-b) auskristallisierte. Dieser wurde mit verdüunnter Natronlauge, dann mit Wasser gewaschen und aus Äthanol umkristallisiert. Farblose Prismen vom Schmp. 88°C. Ausb. 24 g.

Gef.: C, 47.29; H, 4.33; N, 8.03. Ber. für $C_{14}H_{15}O_4N_2Br$: C, 47.32; H, 4.23; N, 7.89%.

1-Amino-2-brom-2-nitrohexan-hydrochlorid. — In 50 ccm Äthanol wurden 5 g II-b mit 1 g Hydrazinhydrat (80%) versetzt, 6 Stdn auf dem Wasserbad auf 40～50°C erwärmt und dann über Nacht stehengelassen. Am nächsten Tag wurde das Reaktionsgemisch mit 2.5 ccm konz. Salzsäure versetzt und noch 2 Stdn. bei 30°C stehengelassen. Das ausgeschiedene Phthalsäureanhydrid wurde abfiltriert und das Filtrat nach Einengen auf ca. 5 ccm mit 50 ccm Wasser versetzt, wobei weiteres Phthalsäurehydrazid ausfiel, das abfiltriert wurde. Das Filtrat wurde weiter unter vermindertem Druck eingedampft. Der Rückstand wurde aus Äthanol-Äther in Nadelchen vom Schmp. 134～138°C umkristallisiert. Ausb. 2.3 g. Zur Analyse wurden diese noch zweimal umkristallisiert. Farblose Nadelchen vom Schmp. 147～148°C.

Gef.: C, 27.14; H, 5.17; N, 10.31. Ber. für $C_6H_{13}O_2N_2Br \cdot HCl$: C, 27.55; H, 5.19; N, 10.71%.

Pikrat.—Gelbe Nadeln vom Schmp. 147°C.

Gef.: C, 31.70; H, 3.68; N, 15.58. Ber. für $C_{12}H_{16}O_9N_5Br$: C, 31.72; H, 3.52; N, 15.42%.

Zur Aufnahme des Infrarot-Spektrum liess sich die Lösung des freien Amins I-b in Chloroform dadurch erhalten, dass man eine Lösung von 0.5 g Hydrochlorid von I-b in 20 ccm Wasser in einem Scheidetrichter mit 20 ccm Chloroform und 0.16 g Natrium Hydrogencarbonat versetzte und die nach dem Durchschütteln abgetrennte Chloroformschicht dreimal mit Wasser wäscht, und anschliessend mit Natriumsulfat trocknet.

***N*-(2-Brom-2-nitrohexyl-1)-*N'*-phenylharnstoff.** — Die Lösung von I-b in Chloroform (aus 1 g Hydrochlorid von I-b und 30 ccm Chloroform dargestellt) wurde mit 0.45 g Phenylisocyanat versetzt, 2 Stdn. unter Rückfluss erwärmt und unter vermindertem Druck eingeengt. Beim Versetzen mit Ligroin und Stehenlassen kristallisierte sich der Rückstand. Ausb. 0.9 g. Aus Ligroin umkristallisiert, farblose Nadelchen vom Schmp. 110～112°C.

Gef.: N, 12.21. Ber. für $C_{13}H_{18}O_3N_3Br$.: N, 12.21%.

10) M. J. Kamlet und J. C. Dacons, *J. Org. Chem.*, **26**, 3005 (1961).

2-Nitro-4-methyl-1-penten (IV-c).—Ein Gemisch von 26 g 2-Nitro-isohexanol (aus 1-Nitro-isopentan nach der Methode von Vanderbilt und Hass[11] dargestellt) und 25.5 g. Phthalsäureanhydrid wurde analog wie bei IV-b aufgearbeitet. Ein gelbliches, Augen stechendes Öl vom Sdp. 82~83°C/42 mmHg. Ausb. 17.5 g (77%).

Gef.: N, 10.99. Ber. für $C_6H_{11}O_2N$: N, 10.85%.

1,2-Dibrom-2-nitro-4-methylpentan (III-c).—Eine Lösung von 15 g IV-c in 60 ccm Chloroform wurde mit 18.6 g Brom in 35 ccm Chloroform langsam versetzt. Dann wude das Gemisch analog wie bei III-b aufgearbeitet. Sdp. 106~108°C/7 mmHg. Ausb. 31 g (92%).

Gef.: N, 4.94. Ber. für $C_6H_{11}O_2NBr_2$: N, 4.84%:

1-Phthalimid-2-brom-2-nitro-4-methylpentan (II-c).—Ein Gemisch von 29 g III-c und 20 g Phthalimidkalium in 120 ccm des mit Kupfersulfat getrocknetens Acetons wurde 30 Stdn. unter Rühren und Rückfluss erhitzt, und dann wurde das Reaktionsgemisch analog wie bei II-b aufgearbeitet. Ausb. 22 g. Farblose Prismen vom Schmp. 111°C (aus Äthanol).

Gef.: N, 7.74. Ber. für $C_{14}H_{15}O_4N_4Br$: N, 7.89%.

1-Amino-2-brom-2-nitro-4-methylpentan-hydrochlorid.—Ein Gemisch von 5 g II-c und 1 g Hydrazinhydrat (80%) in 50 ccm Äthanol wurde 5~6 Stdn. auf 40~50°C erwärmt und dann über Nacht bei Raumtemperatur stehengelassen. Am nächsten Tag wurde das Reaktionsgemisch aufgearbeitet, wie bei Hydrochlorid von I-b beschrieben. Farblose Nadelchen vom Schmp. 150~153°C (aus Äthanol-Äther).

Gef.: C, 27.74; H, 5.49; N, 10.51. Ber für $C_6H_{13}O_2N_2Br \cdot HCl$: C, 27.55; H, 5.19; N, 10.71%.

***N*-(2-Brom-2-nitro-4-methylpentyl-1)-*N'*-phenylharnstoff.**—Analog wie bei *N*-(2-Brom-2-nitrohexyl-1)-*N'*-phenylharnstoff wurde eine Lösung von I-c und Phenylisocyanat in Chloroform aufgearbeitet. Farblose Nadelchen vom Schmp. 106°C.

Gef.: N, 12.43. Ber. für $C_{13}H_{18}O_3N_3Br$: N, 12.21%.

1-Benzoylamino-2-brom-2-nitro-4-methylpentan.—Bei Umsetzung von I-c mit Benzoylchlorid erhielt man farblose Nadeln, die aus Ligroin umkristallisiert wurden. Schmp. 110°C.

Gef.: N, 8.64. Ber für $C_{13}H_{17}O_3N_2Br$: N, 8.51%.

1-Amino-2-nitropentan (V, R=C_3H_7).—Eine Lösung von 9 g 2-Nitro-1-penten[1] in 30 ccm Methanol liess sich unter Rühren und Kühlung im Eis/Kochsalz-Bad zu 70 ccm des mit Ammoniak gesättigten Methanols hinzutropfen. Nach der zugabe der Olefin-Lösung wurde die Mischung 2 Stdn. bei 0°C und noch 1 Std bei Raumtemperatur weitergerührt, und dann unter vermindertem Druck eingeengt. Nach der vollständigen Entfernung von Ammoniak wurde das verbliebene Öl mit Äther versetzt und mit verd. Salzsäure durchgeschüttelt, dabei scheidet ein Kristallbrei ab. Die abgetrennte Wasserschicht wurde unter vermindertem Druck zur Trockenheit eingedampft. Durch Umkristallisieren des festen Rück standes aus Äthanol-Äther erhielt man 2.5 g 1-Amino-2-nitropentan-hydrochlorid. Schmp. 143~145°C.

Gef.: N, 16.69. Ber. für $C_5H_{12}O_2N_2 \cdot HCl$: N, 16.62%.

Der oben erwähnte, beim Durchschütteln des Reaktionsgemisches mit verd. Salzsäure erhaltene Kristallbrei wiegt 2.5 g und wird aus Äthanol umkristallisiert. Farblose Nadeln vom Schmp. 160°C scheinen uns nach Elementaranalyse bis(2-Nitropentyl)amin-hydrochlorid zu sein.

Gef.: C, 42.62; H, 7.56; N, 15.21. Ber. für $C_{10}H_{21}O_4N_3 \cdot HCl$: C, 42.33; H, 7.66; N, 14.82%.

Carbon-14 in a Biological Environment. I. Annual Variation of Carbon-14 Concentration in Thymol

By Yosihiko KASIDA, Mikio YAMAZAKI, Tetsuo IWAKURA, Naoko MAGINU and Joju HAGINIWA*

(Received June 15, 1962)

Since 1954, the concentration level of C-14 in the atmosphere has remarkably increased as a result of the artificial production of C-14 by the successive nuclear testings; this tendency was confirmed by many investigators[1].

Recently, two excellent methods have become available for the measurement of the concentration level of C-14, i. e., gas sample counting with a proportional counter and liquid scintillation counting. Although the latter is very useful for the measurement of

* Pharmaceutical Faculty, Chiba University, Yahagi-cho, Chiba-shi.

1) Scientific Committee on the Effect of Atomic Radiation, A/AC. 82/R. 105; K. Kigoshi, This Bulletin, 33, 1576 (1960).

the radioactivity of many liquid samples, it has the characteristic weakness that the counting efficiency is strongly influence by the quenching of the sample. Unfortunately, many organic compounds act as quenching agents. Therefore, the solvent system which is used for this method can only measure the radioactivity of a limited number of organic compounds[2].

In the present work, the concentration of C-14 in thymol was measured by the liquid scintillation counting method; its annual variation was observed from 1954 to 1961.

Althouth thymol and other phenolic compounds could not be measured directly by this method because of the strong quenching effect arising from their phenolic nature, it was found that the quenching effect of phenols could be masked by the methylation of their phenolic hydroxyl group. Moreover, the methylation of thymol was carried out with a good yield.

Experimental

Sample Materials.—Thymol was obtained by the usual method[3] from the essential oil of *Orthodon japonicum* Benth (Labiatae). The plant, cultivated every year from 1954 to 1961, was harvested in October in the Experimental Field of Chiba University, located in Chiba city (35°35'N, 140°08'E). The methylation of the thymol was carried out according to the method used in the preparation of anisol[4]. Table I shows the yields of thymol from the essential oil and the yields arising from the methylation of the thymol thus obtained.

TABLE I. THE YIELDS OF THYMOL FROM ESSENTIAL OIL AND OF METHYLATION OF THE THYMOL THUS OBTAINED

Year	Oil	Thymol		Thymol methyl ether	
	g.	g.	(%)	g.	(%)
Pre-war[a]	84	41.4	(49.2)	24.0	(58.0)
1954	100	53.2	(53.2)	27.7	(75.6)
1955	—	—	—	—	—
1956	100	44.3	(44.3)	25.0	(71.4)
1957	90	49.2	(54.7)	25.2	(78.2)
1958	100	52.4	(52.4)	27.3	(81.4)
1959	100	46	(46.0)	28.9	(82.5)
1960	100	52	(52.0)	26.5	(75.7)
1961	150	80	(53.3)	30.3	(37.9)[b]

a) This was probably harvested during 1930—1940.

b) Raw product was used for methylation.

Preparation of Counting Samples. — 2,5-Diphenyloxazol (PPO) and 1,4-bis-(5-phenyl-2-oxazolyl)-benzene (POPOP) were dissolved in the thymol methyl ether obtained in concentrations of 0.4 and 0.01% respectively. Eighteen grams of these solutions were then put in low potassium glass vials (obtained from the Wheaton Glass Co., N. J., U. S. A).

Preparation of "Dead Carbon" Standard Samples. — *p*-Cymene and thymol methyl ether, consisting of the so-called "dead carbons" from petroleum products, were synthesized as standard samples in order to estimate the background counting rate. *p*-Cymene was prepared by the Friedel-Crafts reaction of toluene and isopropyl alcohol. Thymol synthesized from *m*-cresol and isopropyl chloride was obtained from the Koso Chemical Co., Tokyo, Japan, while its methyl ether was prepared in this laboratory.

Counting Procedure.—The measurement of radioactivity was carried out using a scintillation spectrometer Tri-Carb Model 314 A (Packard Instrument Co. Inc., Ill., U. S. A.) which incorporated a coincidence circuit and a two-channel pulse height analyzer. Each sample was counted 4 times for every 100 min. at a balance point operation with a 10~100 V. window setting. The counting efficiency of C-14 was calibrated by an internal standard of 5 mg. of benzoic acid (1-C-14). The specific activity is 5080 d. p. m. per mg. (Standard Source Compound, Packard).

Results and Discussion

Hayes et al.[5] recently reported the measurement of C-14 in *p*-cymene obtained from lemongrass oil with the aid of liquid scintillation counting, thereby proving that *p*-cymene could be used as an excellent liquid scintillation solvent. It is possible to synthesize *p*-cymene from thymol by elimination of its phenolic group[6], but the chemical yield of this dehydroxylation is poor (Chart 1).

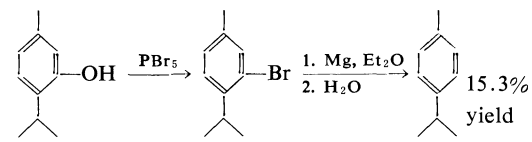

Chart 1. Synthesis of *p*-cymene from thymol.

On the other hand, the methylation of thymol is possible, giving a 70~80% yield (Table I); the strong quenching effect of thymol is almost masked by the methylation (Fig. 1). The counting efficiency of thymol methyl ether was found to be about 86% of that of toluene when it was used as a scintillation solvent.

TABLE II. ANNUAL VARIATION OF C-14 CONCENTRATION IN THYMOL

Year	n_s	d. p. m./g. of carbon
Pre-war	123.47	13.62±0.14
1954	126.90	14.05±0.16
1955	—	—
1956	120.85	13.28±0.17
1957	140.85	15.84±0.17
1958	135.67	15.16±0.17
1959	148.89	16.82±0.17
1960	151.60	17.21±0.17
1961	154.29	17.49±0.17

$$\text{d. p. m./g. carbon} = \frac{n_s - n_b \pm 2sd}{C_g \times E}$$

$$sd = \sqrt{\frac{n_s + n_b}{t}}$$

n_s=Counts of samples, c. p. m.
n_b=Counts of natural background, 16.96 c. p. m.
$t = t_s = t_b$=Counting time, 400 min.
C_g=Carbon weight in thymol, 18 g. 13.16 g.
E=Counting efficiency, 59.4%

standard were 120~150 c. p. m. and 17 c .p. m. respectively.

The data of measurement are listed in Table II. All the values of radioactivity are indicated in d. p. m./g. of carbon.

As is shown in this table, it was observed that the concentration of C-14 in thymol increased 18.4% from 1954 to 1961. This values was rather lower than the 26.8% which was reported by Hayes for the northern hemisphere[5]. This difference suggests that the dilution effect by the "dead carbon" from fossil fuels probably contributes somewhat to the depression of the C-14 concentration. In fact, steel-manufacturing and other heavy industrial plants have gone into operation in the suburbs of Chiba city, and the consumption of coal in one of the big steel factories last year was about eight times that in 1953. Therefore, a considerable amount of "dead carbon" has been added to the atmosphere by the combustion of coal or oil; the C-14 concentration level might have been thereby reduced.

The pre-war sample shown in Table II was supplied from the Kasukabe Experimental Field of the National Institute of Hygienic Sciences, in Saitama prefecture (35°59'N, 139°45'E). This was harvested during the 1930—1940 period, but no definite harvesting data are known. The sample is used in the data as a supplemental reference to the level before the beginning of World War II.

The authors wish to thank Dr. Toyohiko Kawatani of the Kasukabe Experimental Field of the National Institute of Hygienic Sciences, for his kind assistance in obtaining the pre-war sample, and Professor Eizo Tajima, a Scientific Consultant of this Institute, for his kind advice.

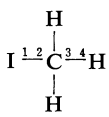
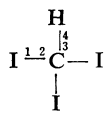
MO Interpretation of Some Physico-chemical Properties of Alkyl Compound



By Teijiro YONEZAWA, Hiroshi KATO, Hazime SAITO and Kenichi FUKUI

(Received July 2, 1962)



A few quantum-mechanical investigations of the electronic structure of halomethane molecules have been made by the VB method, discussing the ionic character of carbon-halogen bonds in these compounds[1], and also by a simple two-center LCAO MO treatment[2].

In a previous paper[3], we discussed the electronic structures and reactivities of some halomethane molecules using the simple LCAO MO treatment for saturated compounds we had previously reported. In this treatment, the molecular orbitals of halomethanes are given by the linear combinations of the atomic (or of hybridized) orbitals of the composite atoms in a molecule. It has been made clear by the microwave spectral data that the bond lengths, especially that of the C–X bond, and also the valence angles vary remarkably among CH_3X, CH_2X_2, CHX_3 and CX_4. Also, the double bond character, which has been particularly recognized in CX_4 molecules, has been disregarded, since the main purpose of our paper is to a verification of the validity of our simple LCAO MO treatment. For the sake of simplicity, overlap integrals are neglected and the same values as in the previous paper[3] are adopted in the present paper for Coulomb and resonance integrals. These values

are summarized as follows:

$\alpha_C=\alpha$	$\beta_{CC}=\beta$
$\alpha_H=\alpha-0.2\beta$	$\beta_{-C-}=0.34\beta$
$\alpha_F=\alpha+0.9\beta$	$\beta_{CH}=1.1\beta$
$\alpha_{Cl}=\alpha+0.5\beta$	$\beta_{CF}=0.5\beta$
$\alpha_{Br}=\alpha+0.45\beta$	$\beta_{CCl}=0.65\beta$
$\alpha_I=\alpha+0.4\beta$	$\beta_{CBr}=0.58\beta$
	$\beta_{CI}=0.53\beta$

Since the lone pair electrons at halogen atoms are not explicitly taken into account in the present treatment, the energy of this non-bonding orbital is estimated from the experimental values of the ionization potentials assigned by McDowell[4]. The estimated energies of non-bonding orbitals at fluorine, chlorine, bromine and iodine atoms are represented in terms of α and β, which are the standard Coulomb and resonance integrals respectively in σ-electronic systems*.

Electronic Structure of Halomethanes

The calculated energy levels and electronic distributions for iodine derivatives of methane are listed in Table I, while a diagram indicating the change in the energy levels is given in Fig. 1. As was mentioned in our previous paper[3], the bonding electrons tend to be

$\varepsilon_{Cl}=\alpha+0.5\beta$
$\varepsilon_{Br}=\alpha+0.4\beta$
$\varepsilon_I=\alpha+0.2\beta$

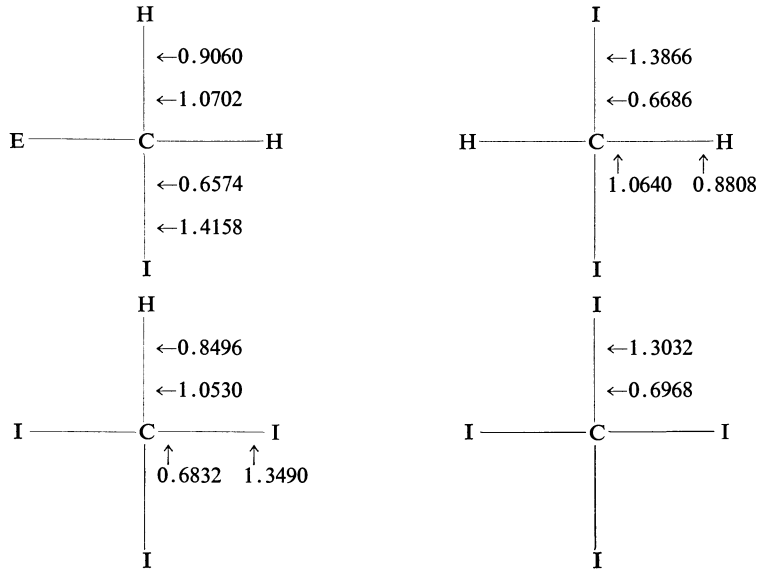

Fig. 2. The σ electronic densities of iodomethanes.

localized in the particular bonds in each molecular orbital; the bonding electrons in the highest occupied and the lowest vacant orbital are localized mainly in the C–I bond, and those in the next highest occupied orbital, in the C–H bond.

As to the orbital energies, it is seen that the larger the number of substituted halogen atoms, the lower the lowest vacant orbital energy, as is shown in Fig. 1.

In Fig. 2, the calculated total σ-electron densities in iodomethanes are presented.

As a general tendency, the ionic character interpreted from the present molecular orbital treatment decreases in the order: $CH_3X > CH_2X_2 > CHX_3 > CX_4$. This order agree with that indicated by the experimental results of pure quadrupole coupling constants.

Based upon these findings, a molecular orbital interpretation of such physico-chemical properties of halomethane molecules as n-σ^* absorption, PQR coupling constants, and proton chemical shifts are presented.

***n*-σ^* Absorption.**—The theoretical interpretation of the n-σ^* absorption of halomethane molecules, especially of iodine and chlorine compounds, has been argued by Mulliken[5], Walsh[6], and Nagakura et al.[7] The longest-wavelength absorption in halomethanes is due to the excitation of an electron from the lone pair electron orbital to the lowest vacant orbital. The calculated energy differences between the lone pair electron orbital and the vacant orbital in these compounds are listed in Table II, together with the observed wavelengths[8]. In the series of halomethanes substituted for by a certain number of halogen atoms of the same kind, a parallelism is found between experimental and calculated values; the calculated values show a tendency for the wavelength of the absorption spectrum to increase with the number of halogen atoms in halomethanes, all in accordance with experimental findings. When a comparison is made among the molecules with different halogen atoms, however, a discrepancy between the observed and the calculated results is found. This discrepancy may

TABLE III. OSCILLATOR STRENGTH

Compound	Calcd. by Nagakura et al.		Present	Obs.[7]
	AO	non polar		
CH_3Br	0.0262	0.0422	0.0276	0.0106
CH_3I	0.0105	0.0264	0.0169	0.0087
CH_3Cl	—	—	0.0346	—

partly be ascribed to the values of the parameters adopted.

The oscillator strengths of n-σ^* transitions in bromo-methane and iodo-methane have been calculated by Kimura and Nagakura both by the VB method and by a localized molecular orbital method in which the molecular orbital is constructed in terms of two AO's of the C–X bond[7]. Their results are listed in Table III for the sake of comparison. In the table, one can see that the results obtained by the VB method are much better than those by the localized molecular orbital method. In the present treatment, where the molecular orbital is delocalized, we can see that a considerable improvement in the value of oscillator strength is achieved, as is shown in the same table.

The $CH_3I \rightarrow CH_3 + I$[6] bond dissociation and the continuous absorption spectrum are observed after the light absorption takes place in these compounds.

These results might well be explained by our calculated results; that is, in the lowest vacant orbital in these compounds, electrons are localized mainly in the carbon-halogen bonds, and this orbital is strongly anti-bonding. This result is recognized in terms of the partial σ bond order* (p_{rs}) between the r-th atoms and the s-th atom in the lowest vacant orbitals of these compounds; that is, the p_{rs} values of methyl iodide are the largest among the methyl halides. These calculated values are listed in Table IV.

TABLE IV. THE CALCULATED VALUES OF PARTIAL BOND ORDER IN THE LOWEST VACANT ORBITAL OF HALOMETHANES

X	p_{C-H}	p_{C-X}
I	−0.0160	−0.7616
Br	−0.0202	−0.7504
Cl	−0.0264	−0.7370

PQR Coupling Constant.—PQR coupling constants of some halomethanes have been discussed theoretically by Hamano[1]. He calculated the ionic character of C–X bond by VB method. A satisfactory parallelism was observed between experimental coupling constants and his results. In the present paper, a molecular orbital procedure to discuss coupling constants is presented. We estimate the magnitude of the coupling constant by the total σ density (q_X) of halogen atoms in these compounds. Neglecting the s-character of the bonding orbital of halogen atoms, the equation connecting the coupling constant, eQq, with the total electron density, q_X, is given as[9]:

$$|eQq| = (2 - q_X)|eQq_{atm}|$$

The calculated values of $|eQq|$ of some halomethanes are listed, together with the observed values[10], in Table V, which shows that the results obtained by our present procedure seem almost satisfactory. Hence, it may be stressed that the observed coupling constants in halomethane molecules are explained well by the magnitude of the total σ electron density.

Proton Nuclear Magnetic Shielding in Halomethanes.—It has been pointed out that the proton chemical shift depends upon the local diamagnetic shielding, due to the electron cloud around the nucleus, and to long-range shielding due to the magnetic anisotropies of halogen and carbon atoms which are remote from the nucleus[11]. The proportion of the contribution of these two effects in propane was discussed by Narasimhan et al.[12] In the present paper, we indicate that a qualitative interpretation of the chemical shifts in halomethanes may be possible on the basis of the local diamagnetic shielding. This nuclear magnetic shielding constant in a molecule can be represented by the equation

$$\sigma_{dia} = -Aq_r \quad \text{(in units of p. p. m.)}$$

* This indicates the product of the molecular orbital coefficients $2C_rjC_sj$.

where A is the constant and q_r is the total σ-electron density at the r-th hydrogen atom.

Hence, the resonance magnetic field of a proton is expected to increase with the total σ density. In fact, in Table VI, there exists a parallelism between the magnitude of chemical shifts and the values of the total σ density. Some further experimental investigation has been carried out on iodo-methanes and so forth. The observed chemical shifts in these molecules (written in parenthesis in Table VI) support our interpretation based upon the total σ electron density. The apparent discrepancies found in methyl fluoride, methyl chloride, methyl bromide and methyl iodide are shown to be in a reasonable order according to the values, −3.99, −2.71, −2.32 and −1.85 p.p.m. respectively, observed by Spieseck and Schneider[13]. Hence, it may be concluded that the parallelism between the observed shift and the total electron density is rather satisfactory. Regarding the quantitative interpretation, the following points should be remarked:

1. The deformation of the valence angle in these compounds is not considered.
2. The magnetic anisotropy of the neighboring atom is omitted in the present consideration.
3. The lone pair electron is considered to be thoroughly isolated in a molecule.

A further interpretation of the fluorine chemical shifts in fluoromethanes has been successfully made by the present authors; it will be published in the near future.

In the present paper, we have investigated some physico-chemical properties of halomethanes by the simple LCAO MO treatment. In spite of the extreme simplicity of our method, the calculated results are almost parallel with the observed values. If one may further adopt the modified Coulomb integrals of halogen atoms, a more comprehensive explanation of the physico-chemical properties of saturated and unsaturated σ-electron systems may be possible in the future.

The Gelation of Lead Aldose-cysteinate. The Properties of Gel and the Structure of Lead Aldose-cysteinate

By Fujio TAKAHASHI and Jun MIZUGUCHI

(Received July 6, 1962)

The authors have studied the preparation and utilization of cysteine and have already reported on the electrolytic preparation of cysteine[1], and on the preparation and properties of glucose-cysteine[2]. The organo- and physicochemical properties of the metal salts of

1) J. Mizuguchi, S. Suzuki, F. Takahashi and Y. Kawasaki, Annual Meeting of the Electrochemical Society of Japan, 1958.

2) J. Mizuguchi, S. Suzuki and F. Takahashi, 13th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1960.

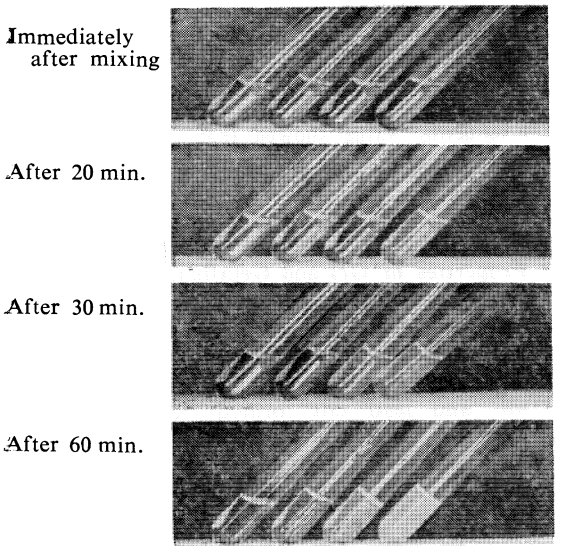

Photo. 1. The solution containing equimolar NaGC and lead acetate.
Concn.; distilled water, 0.01, 0.03, 0.05 M from left to right of test tubes. Temp. 16.5°C

HGC* have now been studied. When a solution containing HGC and lead salt was allowed to stand for some time, it was found to form gel[3], as is shown in photographs attached. This gel is stable, and no syneresis is observed. This gel has a heat-reversible property.

It has been known that the gelation of a solution containing such high molecular substance as agar-agar, gelatin, silicic acid occurs because of the formation of an infinite three-dimentional network in the solution by means of intermolecular cross-linking[4]. Most of the gels of such inorganic substances as hydrous oxides of iron and aluminum have been found to expel liquids.

The gel composed of HGC and lead salt was different from the other gels because of its stability. Furthermore, high molecular compounds were unexpectedly found in this gel.

This investigation was carried out to elucidate the mechanism and kinetics of the gelation of a solution containing HGC and lead salt. In this paper, we report on an extensive study of the properties of the gel and gelation and on the structure of lead aldose-cysteinate.

Experimental

Materials.—HSCs were prepared by the condensation reaction of cysteine hydrochloride and an aldose such as glucose, galactose, mannose, arabinose and xylose in a methanol or aqueous solution after the addition of pyridine[5]. The products precipitated were washed with methanol after filtration.

Apparatus and Procedure. — The turbidity was measured by a Coleman spectrophotometer, universal model. The turbidity was measured from the time a solution of lead salt was added to a solution of HSC. On the basis of these measurements, we got the relative values of turbidity based on the definition that the turbidity of distilled water is 0%. The turbidity measured 3 hr. after the time a solution containing 40 mM of NaGC and 40 mM of lead acetate formed a gel is 100%.

The rigidity of the gel was determined by an apparatus** measuring gel rigidity. The amount of weight which sank into the gel with a velocity of 2 cm./20~40 sec. was adopted as the rigidity of the gel. Each 100 ml. of a solution containing HGC and lead salt was poured into several 100 ml. beakers and allowed to stand at 25°C. The rigidity of the gel was measured at intervals from the time when a solution of lead salt was added to a solution of HGC.

Preparation of Lead Aldose-cysteinates. — *$PbGCNO_3$*—a) 2.83 g. of HGC and 0.84 g. sodium bicarbonate were dissolved in 20 ml. of water; 10 ml. of 1 M lead nitrate was then added. On the addition of 60 ml. of methanol or ethanol before the gelation of the mixture, sticky precipitates soon separated. The precipitates were crystallized in alcohol after an hour or so. The product was filtered and washed with methanol; yield, 5.3 g. (96%).

Found: C, 19.6; H, 3.0; N, 5.1; Pb, 37.3; NO_3, 9.9. Calcd. for $C_9H_{16}NO_7SPbNO_3$: C, 19.6; H, 2.9: N, 5.1; Pb, 37.5; NO_3, 11.3%.

b) 10 ml. of 1 M NaGC was added to 10 ml. of 1 M lead nitrate. The mixture formed at gel after a few minutes at room temperature; then fine crystals separated from this gel. After two days, the product was filtered and washed with 50% aqueous ethanol, and then with ethanol; yield, 5.0 g. The crystalline product melted at 193.5°C with decomposition.

Found: C, 19.7; H, 2.6; Pb, 37.2. Calcd. for $C_9H_{16}NO_7SPbNO_3$: C, 19.6; H, 2.9; Pb, 37.5%.

$PbGCNO_3$ is soluble in water (1.2~1.3 g./dl.) The solution of $PbGCNO_3$ formed a gel when it was allowed to stand at room temperature for a while. $PbGCNO_3$ is insoluble in methanol, ethanol,

* All the aldose-cysteines and their sodium salts are abbreviated as follows:

Aldose-cysteine	HSC
Glucose-cysteine	HGC

** A Nikkansui-shiki apparatus measuring agar-agar gel rigidity.

benzene, acetic acid, pyridine, acetone and chloroform.

$PbGaCNO_3$.—A mixture of NaGaC and lead nitrate was prepared in the same manner as has been described in the preparation of $PbGCNO_3$. On the addition of 200 ml. of ethanol, sticky precipitates separated. When it was allowed to stand overnight at room temperature, sticky precipitates were crystallized in alcohol. The product was filtered and washed with ethanol; yield, 4.5 g. (76%).

Found: C, 19.0; H, 3.6; N, 4.6; Pb, 36.4; NO_3, 9.8; H_2O, 3.3. Calcd. for $C_9H_{16}NO_7SPbNO_3 \cdot 2H_2O$: C, 19.0; H, 3.2; N, 4.9; Pb, 36.4; NO_3, 10.9; H_2O, 3.2%.

PbGCOH.—2.83 g. of HGC and 0.84 g. of sodium bicarbonate were dissolved in 20 ml. of water; 10 ml. of 1 M lead acetate was added. On the addition of 300 ml. of ethanol, fine precipitates soon separated. The product was filtered and washed with ethanol; yield, 4.2 g. (75%). The product was dried on phosphorus pentoxide at 100°C under reduced pressure.

Found: C, 21.9; H, 3.3; N, 2.7; Pb, 40.7. Calcd. for $C_9H_{17}NO_8SPb$: C, 21.3; H, 3.4; N, 2.8; Pb, 40.9%.

It was found, from the result of alkaline titration, that the filtrate contained 8.5 mmol. (85%) of acetic acid. PbGCOH is slightly soluble in water. When it was allowed to stand at room temperature for a while, the suspension of PbGCOH formed a gel.

$PbGC \cdot CH_3COO \cdot PbGCOH$.—To a solution in which 2.83 g. of HGC and 0.84 g. of sodium bicarbonate were dissolved in 20 ml. of water, 5 ml. of acetic acid and 10 ml. of 1 M lead acetate were added. A hundred mililiters of methanol and 100 ml. of acetic acid were added before the gelation of the mixture. After a week, precipitates were filtered and washed with methanol; yield, 1.78 g.

Found: C, 22.5; H, 3.0; N, 2.6; Pb, 39.0. Calcd. for $C_{18}H_{36}N_2O_{17}S_2Pb_2$: C, 22.8; H, 3.4; N, 2.7; Pb, 39.3%.

$PbMCNO_3$ and $PbACNO_3$.—It was difficult to obtain pure $PbMCNO_3$ and $PbACNO_3$ prepared in the same manner as $PbGCNO_3$. When the solution containing lead nitrate or acetate and NaMC or NaAC was allowed to stand for a few days, white precipitates separated. The precipitates were found to be crude lead cysteinate from the following results: 1.41 g. of HMC and 0.42 g. of sodium bicarbonate were dissolved in 10 ml. of water; 5 ml. of 1 M lead acetate was added. The mixture was allowed to stand at room temperature for a few days. The precipitates were filtered and washed with distilled water; yield, 1.5 g.

Found: Pb, 61.6; N, 4.1. Calcd. for $PbC_3H_5NO_2S$: Pb, 63.3; N, 4.3%.

The determination of the reducing value showed that the filtrate contained 4.4 mM (97%) of mannose.

The Preparation of Lead Cysteinate from Gel.—Fifty milliliters of 0.2 M NaGC was added to 50 ml. of 0.2 M lead acetate. The mixtue formed a gel. An hour after the beginning of the gelation, the gel was heated at 100°C for 6 hr. The gel melted, and then gray precipitates separated. The precipitates were filtered and washed with water; yield 3.1 g. (94%).

Found: C, 11.3; H, 1.6; N, 4.3; Pb, 62.2. Calcd. for $PbC_3H_5NO_2S$: C, 11.0; H, 1.5; N, 4.3; Pb, 63.3%.

The alkaline titration and the determination of the reducting value showed that the filtrate contained 9.7 mM (97%) of acetic acid and 9.5 mM. of glucose.

Results and Discussion

Properties of Gel and Gelation.—*Gel-forming HSC*.—A solution containing HGaC and lead salt also yielded gel in the same manner as HGC. However, in the case of HXC and HAC, flocculation occured. A solution containing HMC and lead salt formed neither gel nor fluocculent precipitates.

Turbidity.—The transparent solution containing HGC and lead salt became turbid gel rapidly upon gelation. The turbidity of the gel increased with the lapse of time for a few hours, and then the turbidity approached to almost constant values. The turbidity of this gel was greater than that of agar-agar gel. The results are shown in Fig. 1.

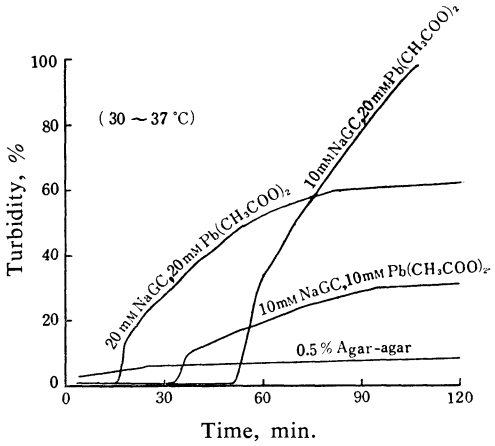

Fig. 1. Development of turbidity.

Rigidity.—The rigidity of the gel increased rapidly with gelation. The rigidity of gel depends on the pH value and the concentration. The rigidity of this gel was smaller than that of agar-agar gel (Figs. 2, 3 and 4).

The Range of pH Values and Concentrations.—The lowest concentration of a solution which was able to yield gel was the 5 mM (0.3%) of a lead glucose-cysteinate solution (Fig. 3). The pH range of the formation of gel was between 3.8 and 11 (Fig. 4). When a solution of NaGC was added to a solution of lead salt in the pH range of 8～11, precipitation occured immediately. The precipitates redissolved gradually, and then the solution set to gel after a certain time, whether precipitates redissolved perfectly or not.

Measuring after 3 hr. from the gelation time

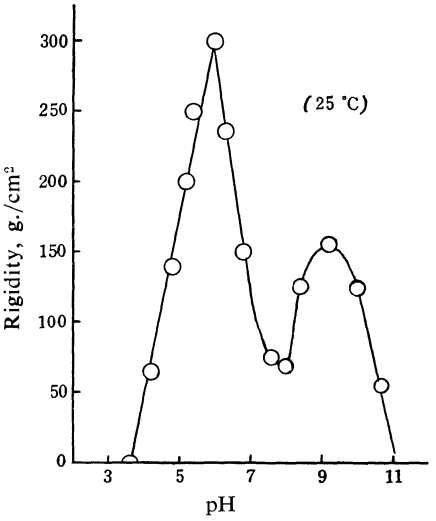

Fig. 4. Rigidity and pH of gel.
0.06 M NaGC, 0.03 M lead nitrate or acetate measuring after 3 hr. from the gelation time.

Heat-reversible Property.—As it was warmed, this gel melted above 70°C. The liquified gel yielded gel containing a small amount of white precipitates when it was allowed to stand at room temperature. The amount of precipitates increased with the lapse of the time of heating. Re-gelation could not occur when the heating of the gel was continued further.

Properties of the Solution before Gelation.—*Chemical Reactions of Lead Ion in Solution.*—Insoluble lead salt was precipitated by the addition of hydrogen sulfide, phosphoric acid, or potassium chromate or iodide into the HGC-lead acetate solution. Lead sulfate, however, was not found to precipitate when sodium sulfate was added.

Stability of Lead Glucose-cysteinate.—The stability constant, $\log k = 4.5$, was given from the method of pH titration, as is shown in Table I.

TABLE I. STABILITY CONSTANT

To 50.0 ml. of the solution (4.00×10^{-3} M HGC, 3.79×10^{-3} M $Pb(NO_3)_2$) 0.973 N NaOH solution was titrated. 30°C. Ionic strength 0.1 (KNO_3) $K_{COOH}=6.6_1\times10^{-3}$, $K_{NH_2}=8.3_2\times10^{-6}$ (reference value[5]: $K_{COOH}=7.24\times10^{-3}$, $K_{NH_2}=4.27\times10^{-6}$)

pH	NaOH, ml.	$\bar{n}$	pA
3.00	0.000	0.41	4.8_5
3.13	0.030	0.45	4.7_3
3.31	0.060	0.50	4.5_7
3.50	0.100	0.63	4.4_8
3.75	0.130	0.72	4.3_4
4.11	0.160	0.83	4.1_6

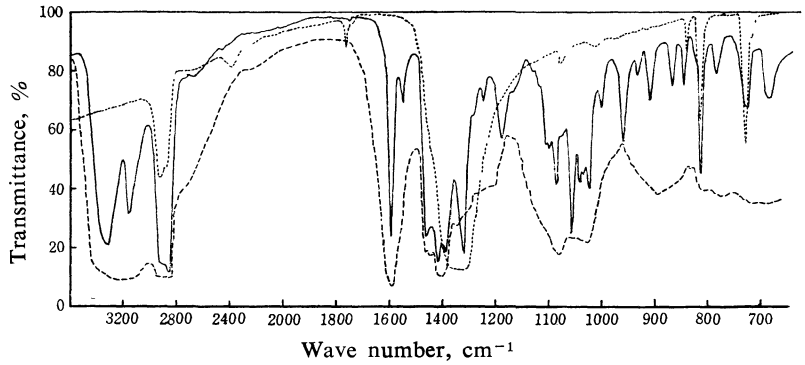
$pA_{\bar{n}=0.5}=4.5$

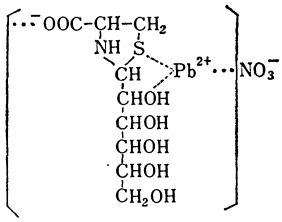
Structure and Properties of the Lead Aldose-cysteinate.—*Structure of Lead Aldose-cysteinate.* It was found that the lead aldose-cysteinates isolated ($PbGCNO_3$, PbGCOH and $PbGaCNO_3$), which are the essential materials for gelation, are composed of one atom of lead, one molecule of HSC, and one univalent anion (e. g., NO_3^-, OH^-, etc.).

The infrared spectra of NaGC and $PbGCNO_3$ show peaks at 1600 and 1400 cm^{-1} which arise from the antisymmetric and symmetric carbon-oxygen stretching vibration in the carboxylate ion[6]. The $PbGCNO_3$ bands and lead nitrate bands observed at about 820 and 730 cm^{-1} arise from the deforming vibrations of the nitrate ion, which does not coordinate with the lead atom (Fig. 5).

It was found, from the study of ultraviolet absorption spectra[7], that the sulfur atom and

6) D. N. Sen, S. Mizushima, C. Curran and J. V. Quagliano, *J. Am. Chem. Soc.*, **77**, 211 (1955).
7) The results of ultraviolet spectra will be described in the next paper. F. Takahashi and J. Mizuguchi, This Bulletin, **35**, 1823 (1962).





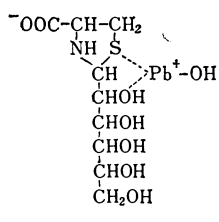


Fig. 5. Infrared spectra (Nujol method). —— $PbGCNO_3$, --- NaGC, ····· $Pb(NO_3)_2$

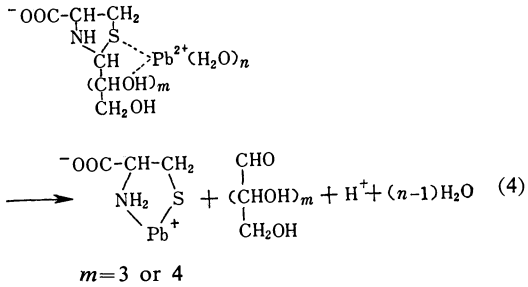
one hydroxyl group of HGC coordinate with the lead atom in solution.

Based on the infrared and ultraviolet absorption spectra, structural formulae (I, II) were suggested for lead aldose-cysteinate:

(I)

(II)



Properties of Lead Aldose-cysteinate. — Pure $PbGC \cdot CH_3COO$ could not be prepared from the solution of NaGC and lead acetate. Judging from this fact, it is presumed that the following reactions occur in solution.

$$NaGC + Pb(CH_3COO)_2 \rightarrow PbGC \cdot CH_3COO + CH_3COONa \quad (1)$$

$$PbGC \cdot CH_3COO + nH_2O \rightarrow [PbGC(H_2O)_n]^+ + CH_3COO^- \quad (2)$$

$$[PbGC(H_2O)_n]^+ \rightarrow PbGCOH(H_2O)_{n-1} + H^+ \quad (3)$$

It is suggested that the lead complex ion of HSC in solution converts to lead cysteinate and aldose as shown in Eq. 4:

$$m=3 \text{ or } 4$$

Summary

When a solution containing HGC or HGaC and lead acetate on nitrate was allowed to stand for sometime, it was found to form a stable gel like agar-agar in the pH range between 3.8 and 11 and with a concentration over 0.3%. The turbidity and rigidity of the gel began to increase rapidly with gelation. A solution containing HMC and lead salt did not form a gel, but precipitated lead cysteinate with the liberation of mannose.

It was found that the lead aldose-cysteinates isolated, which are the essentials materials for gelation, are composed of one atom of lead, one molecule of HSC, and one univalent anion, and that the sulfur atom and one hydroxyl group HGC coordinate with the lead atom, but that the carboxyl group of HGC does not coordinate to the lead atom.

*Ultraviolet Absorption Spectra of Lead Aldose-cysteinate**

By Fujio TAKAHASHI and Jun MIZUGUCHI

(Received July 6, 1962)

When the present authors studied metal complexes of HGC**, lead glucose-cysteinates in solution were found to form a gel like agar-agar and to have an ultraviolet absorption maximum at 270 mμ[1]. The other HSCs** with lead acetate in solution also show the same absorption spectra as HGC. These absorption spectra have not been known thus far. Moreover, no absorption spectrum of lead cysteinate has been reported.

In the study of the mechanism of gelation, one of the most important projects is to clarify the structure of lead aldose-cysteinate in solution.

In this paper, the results of spectrophotometric study related to the structure of lead aldose-cysteinates are described.

Experimental

HSCs were prepared in the same manner as was described in the previous paper[1]. Cysteine was prepared by the addition of pyridine to cysteine hydrochloride (monohydrate) in hot ethanol, filtration, and washing with ethanol until the pyridine odor had vanished; d. p., 218°C. The cysteine methyl ester was prepared by the electrolytic reduction of the cystine dimethyl ester which had been obtained by the usual method. Thiazolidine carboxylic acid-4 was prepared by the treatment of cysteine hydrochloride in an aqueous solution with formalin.

The spectrophotometric measurements were carried out in an aqueous solution with a Hitachi spectrophotometer, model EPU-2.

The pH value of the solution was adjusted by the addition of an appropriate amount of nitric acid or sodium hydroxide.

Results and Discussion

The absorption spectra in the solution containing different HSCs and lead acetate, and HGC and different metal salts are shown in Figs. 1 and 2 respectively. Only the lead complex of HSC in solution shows an absorption maximum at 270 mμ. Neither HSCs nor metal salts in solution show an absorption in the range between 250 and 600 mμ.

The lead complexes of different amino acids, except cysteine, show no absorption in the range between 250 and 300 mμ (Fig. 3). On the other hand, the lead complexes of various thiol-containing compounds have an absorption maximum at about 270 mμ (Fig. 4). From

0.5 mM $Pb(CH_3COO)_2$, 0.5 mM thiol-containing compounds

these results, it can be concluded that lead is coordinated through the sulfur atom of thiol-containing compounds.

The lead complexes of HSCs, which have a thiazolidine ring and no thiol group, show the same absorption spectra as that of thiol-containing compounds. In the beginning of this

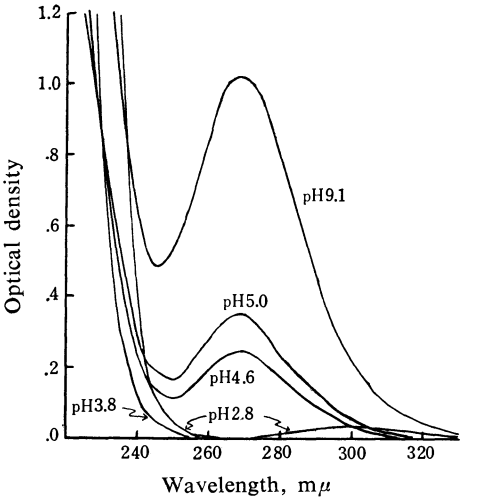

Fig. 5. HGC-lead salt in various pH.

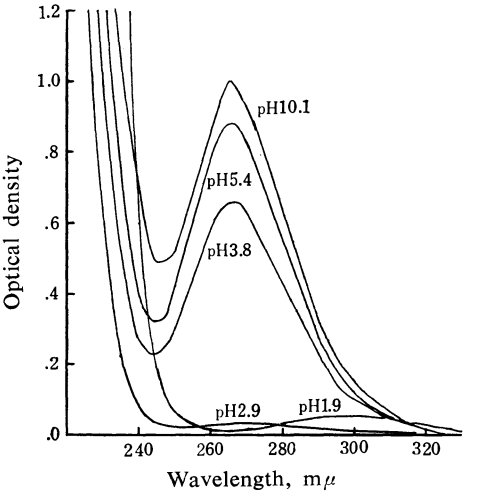

Fig. 6. Cysteine-lead salt in various pH.
0.5 mM cysteine, 0.25 mM lead salt

work, it was thought that the material which shows an absorption maximum was not the lead complexes of HSC but lead cysteinate, because HSC can be hydrolized to form cysteine in an aqueous solution. However, from the results of iodide-iodate determination[2], it was found to show no cysteine in the solution prepared for the determination of absorption spectra. Therefore, it is suggested that lead is doubtless coordinated through the sulfur atom of HSC and that the absorption maximum appears by means of this Pb–S bond.

Lead aldose-cysteinate, which has hydroxyl groups, shows the absorption maximum, but thiazolidine carboxylic acid, which has no

Total concn. 0.5 mM

hydroxyl group, does not show it, as is shown in Fig. 3. It is suggested that an absorption maximum appears when lead is coordinated through not only the sulfur atom but also hydroxyl groups of HSC.

It seems that these coordinations exist in the pH range between 3 and 10. In this pH range, the curves exhibit the same general contour and the same peak, as is shown in Fig. 5. The characteristic absorption spectra could not be observed in the pH range of 6 to 8 because the solution became turbid. In the lower pH range below 3, an absorption maximum was found to shift from 270 to 300 mμ. This fact presumably means that the complex is transformed.

Lead cysteinate was found to show the same absorption spectra as lead glucose-cysteinate (Fig. 6).

The absorption spectra of lead glucose-cysteinate was found to obey Beer's law in the range of 250 to 300 mμ (Fig. 7). When the absorption spectra were measured according to Job's method[3], the optical density at 270 mμ was found to be at a maximum at the molar ratio of about 1 : 1 (Fig. 8). It can be concluded that the highest order lead aldose-cysteinates and lead cysteinate are 1 : 1. These results can be supported by the suggestion obtained from the potentiometric study of Li and Manning[4].

Summary

Lead Aldose-cysteinates in solution were found to show an ultraviolet absorption maximum at 270 mμ. Moreover, lead complexes of various thiol-containing compounds were found to show the same absorption spectra as aldose-cysteine. From these results, it has been suggested that the absorption maximum appears when lead is coordinated through the sulfur atom.

Cyclic Acetylenes. VIII. Synthesis of 1, 1'-Dianthryltetraacetylene. A Model Substance of a Cyclic Octaacetylene Containing Anthracene Nuclei*

By Shuzo AKIYAMA, Soichi MISUMI and Masazumi NAKAGAWA

(Received July 10, 1962)

The synthesis of the macrocyclic tetraacetylene (I) in which two anthracene nuclei constitute a part of the fully conjugated planar macroring has been reported by the present authors[1]. It is of interest to prepare the higher homologue of I in view of the unusual stability and

I (n=2)
II (n=4)

III (n=2)
IV (n=4)

the characteristic spectroscopic properties of I. The present paper concerns with the synthesis of 1, 1'-dianthryltetraacetylene (IV) which is a model substance of the cyclic octaacetylene (II), a higher homologue of I. The structural units of IV can be regarded as the same with that of II. Also a lower homologue of IV, 1 1'-dianthryldiacetylene (III) has been synthesized by the present authors[2]. Therefore, the comparison of the physical and chemical properties of these compounds with those of IV is also of interest.

Benzanthrone was converted into 1-carboxyanthracene via two steps[2] and the carboxylic acid was esterified yielding the methyl ester (V). Reduction of the ester V by means of lithium aluminum hydride afforded 1-hydroxymethylanthracene (VI) in a good yield. 1-Bromomethylanthracene (VII) derived from VI was converted to 1-formylanthracene (VIII) by the Sommelet's method[3]. The aldehyde VIII was also prepared directly by the oxidation of the alcohol VI with chromium trioxide-pyridine[4] in a yield of 88%. The reaction of the aldehyde VIII with the Grignard derivative of tetrahydropyranyl ether of propargyl alcohol yielded the acetylenic glycol (IX). The glycol IX was treated with thionyl chloride and pyridine, and the dichloride X thus obtained was dehydrochlorinated without further purification with sodium amide in liquid ammonia. 1-Butadiynylanthracene (XI) was obtained in yellow needles. The diacetylene XI was found to be fairly stable substance and could be kept without decomposition for periods of days in a refrigerator. A dilute solution of XI in an organic solvent exhibits an intense lilac fluorescence. XI gave orange cuprous and orange-yellow silver salts indicating the presence of terminal acetylene. Also the infrared spectrum of XI exhibits strong bands at 3250 and 2210 cm^{-1} indicating the presence of ethynyl group and disubstituted carbon-carbon triple bond (Fig. 1). The electronic spectrum of XI was illustrated in Fig. 2.

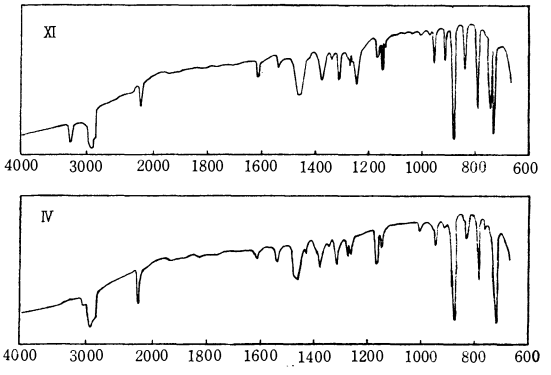

Fig. 1. The infrared spectra of 1-butadiynylanthracene (XI) and 1, 1'-dianthryltetraacetylene (IV) (Nujol mull).

The oxidative coupling of XI according to the procedure of Eglinton[5] yielded golden-yellow leaflets or needles. The structure of

* Although the present paper is concerned with acyclic acetylenes, it has been included in this series since the compounds and the reaction described here served as models for the synthesis of analogous cyclic derivative.

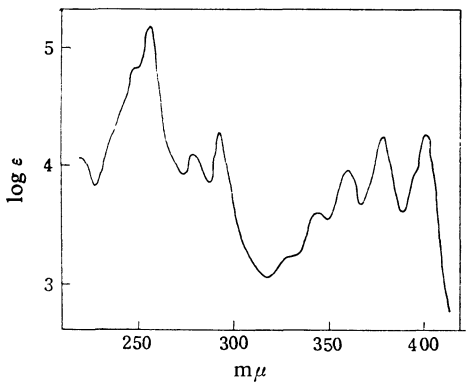

Fig. 2. The electronic spectrum of 1-butadiynylanthracene (XI).

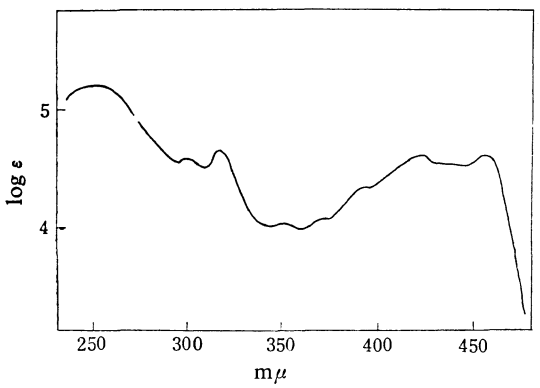

Fig. 3. The electronic spectrum of 1, 1'-dianthryltetraacetylene (IV).

1, 1'-dianthryltetraacetylene (IV) was given to the substance on the bases of its analytical data and the infrared spectroscopic evidences (the absence of free ethynyl absorption and the presence of acetylenic absorption at 2205 cm^{-1} (Fig. 1)). IV was found to be a very stable substance. IV showed no melting point, it decomposed on heating to ca. 245°C forming a black substance without the change of its crystal form. Like I and III, the tetraacetylene (IV) is slightly soluble or almost insoluble in common organic solvents. The electronic spectrum of IV was shown in Fig. 3. The electronic spectral properties of XI, IV and related compounds will be discussed in the following paper[6].

Experimental*

1-Methoxycarbonylanthracene (V).—1-Carboxyanthracene was refluxed with methanol in the presence of sulfuric acid yielding V, m. p. 104°C, (lit., m. p. 108°C[7]; m. p. 104°C[8]).

1-Hydroxymethylanthracene (VI).—The methyl ester (V, 30.6 g., 0.13 mol.) was reduced with lithium aluminum hydride (4.8 g.) in boiling ether (1.2 l.) using a Soxhlet type extractor. The refluxing of the reaction mixture was continued for further 1 hr. to complete the reduction after all of the ester V had been extracted (3 hr.). Ethyl acetate (6 ml.) and 5% aqueous sodium hydroxide (100 ml.) were added successively to the ice-cooled reaction mixture under vigorous stirring. The ether layer was separated and the residue obtained by the removal of the solvent was stirred with 10% aqueous sodium hydroxide (100 ml.) for 1 hr. The insoluble material was collected by filtration,

Found: C, 68.27; H, 4.64; N, 3.92. Calcd. for $C_{20}H_{16}NBr$: C, 68.53; H, 4.60; N, 4.00%.

The Pyridinium Perchlorate.—Pale yellow leaflets, m. p. 235~237°C (decomp.).

Found: C, 64.94; H, 4.43; N, 3.93, Cl, 9.07. Calcd. for $C_{20}H_{16}O_4NCl$: C, 64.96; H, 4.36; N, 3.79, Cl, 9.59%.

An accurate analysis of chlorine could not be performed owing to an explosive decomposition of the salt in the combustion tube.

1-Formylanthracene (VIII).—*a) By the Sommelet Method.*—The hydroxymethyl derivative (VI, 2.2 g., 0.01 mol.) was treated with phosphorus tribromide according to the above-mentioned procedure and the chloroform solution was washed with water and dried (sodium sulfate). A solution of hexamethylenetetramine (1.7 g., 0.012 mol.) in chloroform (15 ml.) was added to the dried solution and the mixture was refluxed for 3 hr. About half of the solvent was removed and the concentrated solution was chilled with ice. The hexamine-adduct deposited was filtered and washed with a small amount of chloroform affording pale yellow crystalline solid (3.3 g.). Water (30 ml.) was added to a solution of the adduct (3.3 g.) in acetic acid (30 ml.) and the mixture was refluxed for 1 hr., then 12 N hydrochloric acid (0.7 ml.) was added and refluxed for 5 min. The mixture was poured into water (200 ml.), extracted with benzene (100 ml.), and the extract washed with water and dried (sodium sulfate). Evaporation of the solvent under reduced pressure afforded yellow leaflets, m. p. 126~130°C (from ethanol), (1.1 g., 53%). Further recrystallization from the same solvent gave pure VIII, m. p. 131~132°C, (lit., m. p. 131~133°C[9], m. p. 126.5~127.5°C[10]).

Found: C, 87.16; H, 4.97. Calcd. for $C_{15}H_{10}O$: C, 87.35; H, 4.89%.

b) By the Oxidation of VI with Chromium Trioxide-pyridine.—A solution of VI (4.2 g., 0.02 mol.) in dry pyridine (30 ml.) was added in one portion to an ice-cooled mixture of chromium trioxide (3.8 g., 0.08 mol.) and dry pyridine (80 ml.). The mixture was shaken for 30 min. in the cooling bath, then for 2 hr. at room temperature and then poured into water (1.5 l.); leaflets precipitated. The crystals were extracted with benzene (100 ml.) employing a Soxhlet type extractor. Evaporation of the solvent afforded VIII, yellow leaflets, m. p. 123~129°C, (3.6 g., 88%). Analytical specimen (m. p. 131~132°C) was prepared by one recrystallization from benzene.

Found: C, 87.36; H, 4.93. Calcd. for $C_{15}H_{10}O$: C, 87.35; H, 4.89%.

IR: 2710 (-CHO), 1690 cm^{-1} (C=O), (KBr-disk).

UV λ_{max}^{MeOH} mμ (log ε): 241.5 (4.80), 259.5 (4.63), 334† (3.16), 348 (3.48), 366 (3.69), 392 (3.76), 405† (3.71).

1-(1', 4'-Dihydroxybut-2'-ynyl)-anthracene (IX).—To a solution of ethylmagnesium bromide (prepared from magnesium, 9.7 g., 0.4 g. atom and ethyl bromide, 49 g., 0.45 mol.) in tetrahydrofuran (150 ml.) was added a solution of tetrahydropyranyl ether of propargyl alcohol[11] (56 g., 0.4 mol.) in tetrahydrofuran (50 ml.) over a period of 30 min. under cooling with water and then the mixture was refluxed for 1.5 hr. A solution of the aldehyde (VIII, 20.6 g., 0.1 mol.) in the same solvent (460 ml.) was introduced during 1 hr. under cooling with water. After stirring for 10 hr. at 10°C, 4 N sulfuric acid (800 ml.) was added into the reaction mixture under cooling with water and stirred for 1.5 hr. The mixture was extracted with benzene (300 ml.). The extract was washed with 4 N sulfuric acid (100 ml.) and water, successively and dried (sodium sulfate). The most part of the solvent was removed under reduced pressure. The crystals deposited were filtered and washed with a small amount of benzene yielding crude IX, pale yellow fine crystals, m. p. 192~196°C, (18.4 g., 70%). This material was recrystallized from ethanol-benzene (4:1) to give pure IX, yellowish white leaflets, m. p. 204~205°C.

Found: C, 82.20; H, 5.50. Calcd. for $C_{15}H_{14}O_2$: C, 82.42; H, 5.38%.

IR: 3220 (O-H), 1015, 1030 cm^{-1} (C-O), (KBr-disk).

UV $\lambda_{max}^{95\%EtOH}$ mμ (log ε): 254 (5.13), 302† (2.76), 312 (3.15), 327 (3.51), 342 (3.78), 359 (3.95), 378 (3.87).

1-Butadiynylanthracene (XI).—To an ice-cooled mixture of the acetylene glycol (IX, 3.15 g., 0.012 mol.) in dry pyridine (4 g., 0.05 mol.) and tetrahydrofuran (100 ml.) was added under stirring a solution of thionyl chloride (6 g., 0.05 mol.) in tetrahydrofuran (10 ml.) over a period of 1 hr. The mixture was stirred for 0.5 hr. at 40°C and then refluxed for 1.5 hr. resulting in a dark red solution.

Crushed ice was added to the solution and extracted with benzene (100 ml.). The extract was washed with aqueous sodium hydrogen carbonate and dried (sodium sulfate). The solvent was removed under reduced pressure in an atmosphere of nitrogen yielding the crude dichloride X as tarry viscous oil. A solution of the crude dichloride in tetrahydrofuran (25 ml.) was added dropwise into a solution of sodium amide (prepared from sodium, 5.8 g., 0.25 g. atom) in liquid ammonia (250 ml.) in the course of 1 hr. After stirring for 3 hr., ammonium chloride (10 g.) was introduced to the mixture and the ammonia was allowed to evaporate. The residue was repeatedly extracted with petroleum benzine (b. p. 60~80°C, total 1000 ml.). The extract was condensed, after being washed with water and dried (sodium sulfate), to ca. 300 ml. under reduced pressure in nitrogen atmosphere. The condensed extract was filtered through a thin layer of alumina (10 g.). The filtrate was again condensed under reduced pressure in nitrogen atmosphere to yield XI, yellow needles, (0.89 g., 33%) which decomposed at ca. 130°C forming a black solid without fusion.

Found: C, 95.38; H, 4.44. Calcd. for $C_{18}H_{10}$: C, 95.54; H, 4.46%.

IR: 3250 (≡C-H), 2210 cm^{-1} (-C≡C-), (Nujol mull).

UV $\lambda_{max}^{n\text{-Hexane}}$ $m\mu$ (log ε): 249.5 (4.85), 257.5 (5.19), 279 (4.10), 294.5 (4.27), 330 (3.23), 345 (3.60), 361 (3.97), 380 (4.22), 402 (4.25).

Formation of IV by the Oxidative Coupling of XI.—Cupric acetate monohydrate (15 g.) was added to a solution of the diacetylene (XI, 0.79 g., 0.0035 mol.) in pyridine (100 ml.) and the mixture was stirred for 4 hr. at 45°C. The solid obtained by filtrating the reaction mixture was washed thoroughly with water affording tiny yellow crystals, 0.65 g. (82%). The crystals were found to be free from inorganic substance. The residue obtained by the concentration of the filtrate under reduced pressure was dissolved in benzene (80 ml.) and passed through a thin layer of alumina. Benzene was removed by evaporation yielding crude orange-yellow crystals, 0.05 g. (6%). The combined crystals were recrystallized thrice from benzene to give pure IV, golden yellow leaflets or needles. The crystals decomposed at ca. 245°C without fusion forming a black solid.

Found: C, 95.90; H, 4.10. Calcd. for $C_{36}H_{18}$: C, 95.97; H, 4.03%.

IR: 2205 cm^{-1} (-C≡C-), (Nujol mull).

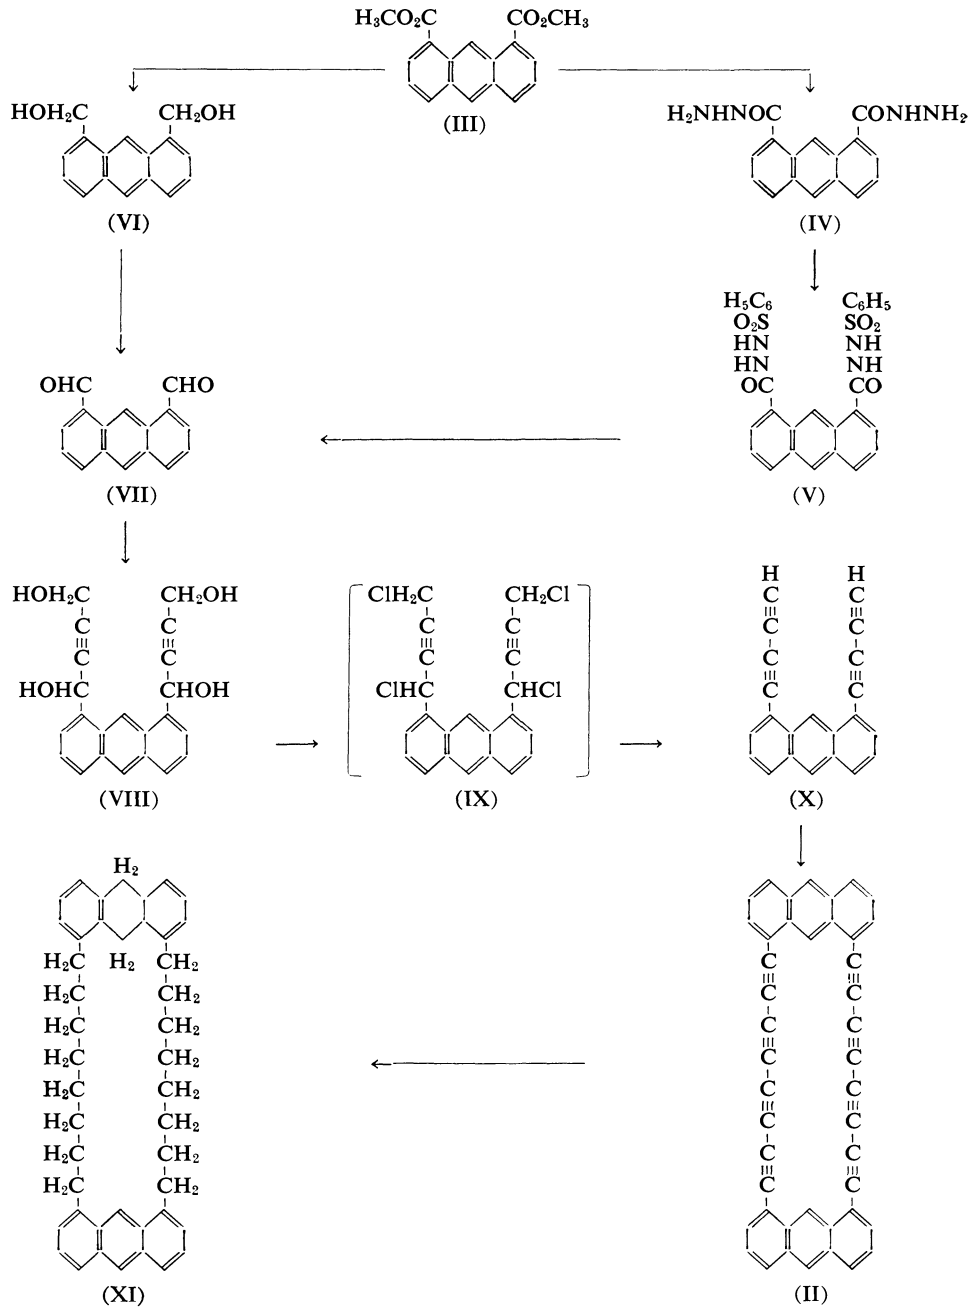
Cyclic Acetylenes. IX. Synthesis of a Cyclic Octaacetylene Containing Anthracene Nuclei

By Shuzo AKIYAMA, Soichi MISUMI and Masazumi NAKAGAWA

(Received July 10, 1962)



As reported in a previous paper[1] of this series, we have synthesized a fully conjugated cyclic tetraacetylene containing anthracene nuclei. The extremely stable nature of the cyclic acetylene (I) urged the present authors to the synthesis of a higher homologue of I. The present paper deals with the synthesis of the same type cyclic octaacetylene (II).

1, 8-Dicarboxyanthracene which was derived from 1, 8-dichloroanthraquinone[1] was converted to the corresponding dimethyl ester (III). The ester III was treated with hydrazine hydrate yielding the bishydrazide (IV). The decomposition of the benzenesulfonyl derivative of IV (V) in ethylene glycol in the presence

I ($n=2$)
II ($n=4$)

of sodium carbonate afforded 1, 8-diformylanthracene (VII)[2]. But the procedure was found to be scarcely feasible for the preparation of VII owing to its highly sensitive nature to reaction conditions which makes impossible to improve the low yield and the poor reproducibility. The reduction of the dimethyl ester III with lithium aluminum hydride yilded 1, 8-bis-hydroxymethylanthracene (VI). The attempts to convert VI into 1, 8-bis-bromomethyl derivative which is the potential starting material of the preparation of the dialdehyde VII according to the Sommelet[3] or the Kröhnke method[4], were prevented due to the poor solubility of VI in chloroform or carbon tetrachloride. Finally we have found

that the oxidation of VI by means of chromium trioxide in pyridine[5] results in the formation of VII in a reasonable yield.

The reaction of the lithium derivative of the tetrahydropyranyl ether of propargyl alcohol, 2-(prop-2'-yn-1'-yloxy)-tetrahydropyran with the dialdehyde VII was studied to obtain the tetraol VIII. The lithium derivative obtained by the action of lithium on the mercuric acetylide of the tetrahydropyranyl ether gave the tetraol VIII in a low yield. According to this result, the tetrahydropyranyl ether in tetrahydrofuran was treated with phenyllithium to attain a complete metalation. The reaction of the resulting lithium salt with the aldehyde VII at low temperature followed by the hydrolysis of the tetrahydropyranyl ether yielded the tetraol VIII in a reasonable yield. The tetrachloro-compound IX which was obtained by the treatment of VIII in tetrahydrofuran with thionyl chloride and pyridine was dehydrochlorinated without purification by the action of sodium amide in liquid ammonia yielding 1, 8-bis-butadiynylanthracene (X) as bright yellow fine needles in a reasonable yield. The terminal bis-diacetylene X was found to be fairly unstable substance. The crystals lose their bright surface lustre on exposure to air and form a brown material insoluble in common organic solvents. A dilute solution of X exhibits an intense, beautiful lilac fluorescence. The infrared spectrum of X showed absorptions at 2280 and 3200 cm^{-1} indicating the presence of ethynyl group and disubstituted carbon-carbon triple bond (Fig. 1). X forms red cuprous and orange-yellow silver acetylides.

In the course of the oxidative coupling of X to the cyclic octaacetylene II according to the method of Eglinton[6], we have encountered

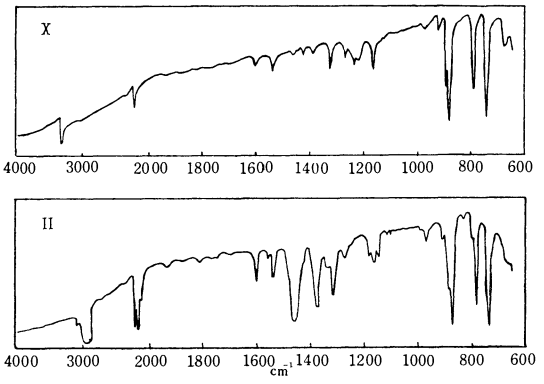

Fig. 1. The infrared spectra of 1, 8-bis-butadiynylanthracene (X) (KBr-disk) and cyclic-octaacetylene (II) (Nujol mull).

5) Cf., G. I. Poos, G. E. Arth, R. E. Beyler and L. H. Sarett, *J. Am. Chem. Soc.*, **75**, 422 (1953).

unexpected difficulty. A large amount of a decomposition product soluble in pyridine was formed when the oxidative coupling was carried out under ordinary conditions for several ten minutes at a slightly elevated temperature. In these cases, the isolation of the cyclic dimer II was practically impossible. Finally it was found that the oxidation had to be carried out at a temperature of ca. 20°C and be interrupted within 1 min. The cyclic octaacetylene II thus obtained was deep red fine needles which decomposed at ca. 160°C into brown solid keeping the shape of the crystals. The octaacetylene II was found to be a stable substance and could be kept without decomposition for a long time. No change of the electronic spectrum was observed after a benzene or a tetrahydrofuran solution of II was exposed to a direct sunlight or a mercury are lamp for some several hours. The analytical data and the infrared spectrum are consistent with the structure of II. The infrared spectrum of II exhibits strong absorptions at 2190, 2140 and 2110 cm^{-1} indicating the presence of polyacetylenic linkage and lacks the absorption arising from the C–H streching of ethynyl group (Fig. 1). Also a solution of II gave a negative test against alcoholic silver nitrate solution. The molecular weight of II could not be determined owing to its poor solubility in organic solvents. The Rast method also gave unsatisfactory result as a result of decomposition of II at the elevated temperature. The catalytic reduction of II in benzene over a large amount of palladium-on-charcoal afforded stable pale yellow crystals. The empirical formula of this substance was determined to be $(C_{22}H_{25})_n$. The molecular weight determination of this substance by Rast's method in camphor (found, 613) revealed that the molecular formula should be $(C_{22}H_{25})_2$, (calcd., 579). The dimeric nature of the coupling product II was unequivocally confirmed by this result.

The infrared spectroscopy of the hydrogenated product revealed the presence of 1, 2, 4, 5-tetrasubstituted benzene nucleus. Also the presence of anthracene nucleus was inferred from the characteristic ultraviolet absorption. The structure of XI was tentatively assigned to the reduction product on the bases of the above-mentioned evidences.

As stated above, the oxidative coupling of X gave II in a poor yield under the restricted conditions. This fact makes a sharp contrast with fact that the oxidative coupling of 1, 8-diethynylanthracene[1] yields the cyclic tetraacetylene I in a quantitative yield. This difference seems to be rather surprising in view of their similar molecular geometry which

is most favorable to the cyclic dimerization. It was confirmed that II was stable in the reagent of Eglinton's oxidative coupling. A solution of II in the reagent was diluted with a large amount of water and extracted with benzene. After treatment according to the usual manner, the benzene solution was subjected to a spectroscopic examination. An identical electronic spectrum was obtained. On the other hand, the cuprous salt of X readily decomposed in pyridine forming a decomposition product. This behavior makes a contrast with the stable nature of the cuprous salt of 1,8-diethynylanthracene in the same solvent. The details of the oxidative coupling of X is not clear, but it seemed to be related with the enhanced flexibility of the diacetylenic groups in X as compared with the rigid ethynyl groups in 1, 8-diethynylanthracene.

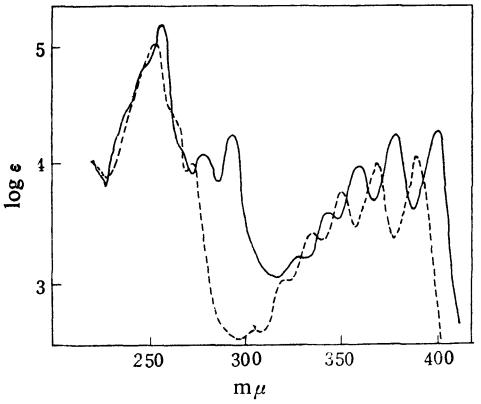

Fig. 2. The electronic spectra of 1-ethynylanthracene (------) and 1-butadiynylanthracene (XI, ——).

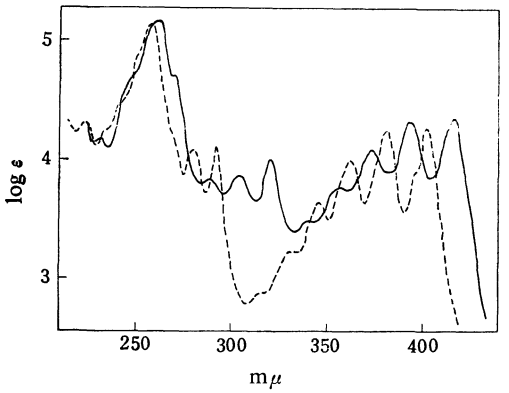

Fig. 3. The electronic spectra of 1, 8-diethynylanthracene (------) and 1, 8-bis-butadiynylanthracene (X, ——).

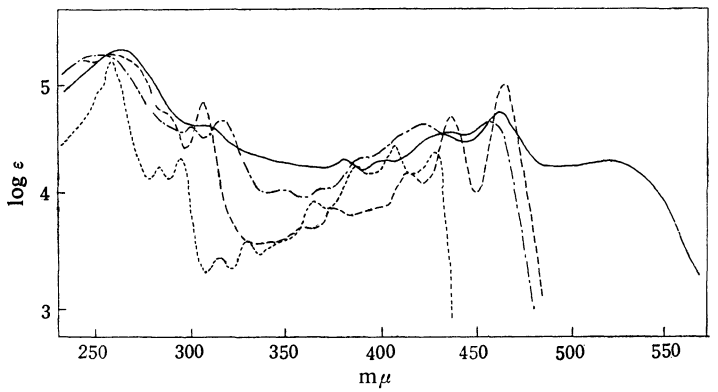
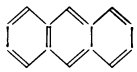
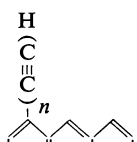
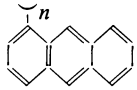
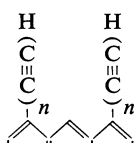
As illustrated in Figs. 2 and 3, the electronic spectra of 1-ethynyl-[7], 1-butadiynyl-[8], 1, 8-diethynyl-[1] and 1, 8-bis-butadiynylanthracene exhibit absorption curves characteristic to anthracene nucleus excepting the wavelength region of 270~320 mμ. The characteristic feature of the electronic spectra of these acetylenic compounds appears in this wavelength. 1-Ethynylanthracene has an absorption peak in this region. 1-Butadiynyl- and 1, 8-diethynylanthracene exhibit two absorption peaks. Whereas three absorption maxima appeared in the case of 1, 8-bis-butadiynylanthracene (X). The spectra of 1, 1'-dianthryldiacetylene[6], 1, 1'-dianthryltetraacetylene[7], the cyclic tetraacetylene I[1] and the cyclic octaacetylene II were summarized in Fig. 4. The fine structures in the spectra of 1, 1'-dianthryltetraacetylene and II are much more indistinct as compared with those of 1, 1'-dianthryldiacetylene and the cyclic tetraacetylene I. It is of interest to note that the fine structure in the spectra of α, ω-diphenyl- or α, ω-dialkylpolyynes become more and more distinct with the increasing number

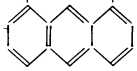


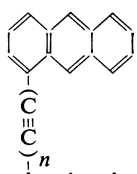


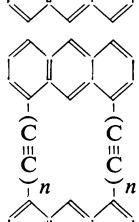












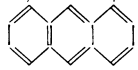


Fig. 4. The electronic spectra of 1, 1'-dianthryldiacetylene (------), 1, 1'-dianthryltetraacetylene (—·—·—·) cyclictetraacetylene (I, ------) and cyclicoctaacetylene (II, ——).

of the acetylenic linkage making a contrast with the case of the acetylenic derivatives of anthracene[9].

The position of absorption maxima, their ε-values and the relative shifts of the maxima of the above-mentioned acetylenic derivatives as compared with anthracene are tabulated in Table I. The comparison of the spectra of 1, 1'-dianthryltetraacetylene and the cyclic tetraacetylene I indicates that the red-shift of the maximum at the longest wavelength of I from the acyclic analogue is only 8 mμ, but the ε-value of I is over twice as large as that of the acyclic tetraacetylene. The large difference in the ε-values is remarkable, because these two compounds have the same structural units. The five absorption peaks at the longer wavelength region in the spectrum of II correspond well with those of the spectrum of the cyclic tetraacetylene I*, but the magnitude of red-shifts of the corresponding absorption peaks increases with the increasing wavelength of the maxima (4, 11, 17, 25 and 55 mμ). The characteristic of the spectrum of the cyclic octaacetylene II is the relatively low absorption intensity at the maximum of the longest wavelength, but the absorption intensities of other peaks are found to be higher than those of the corresponding peaks of I. Another remarkable feature of the spectrum of II is its high absorption intensity over a wide range of wavelength. It was found that the log ε-value was over 4.0 from 230 to 550 mμ.

* The absorption peaks of I are as follows: λ_{max} 258 mμ (logε, 5.22) (in *n*-hexane), 307 (4.82), 340 (3.66), 358 (3.79), 376 (3.93), 392 (3.90, shoulder), 413 (4.22), 437 (4.67), 465 (4.96) (in benzene).

Experimental*

1, 8-Dimethoxycarbonylanthracene (III). — A stirred mixture of 1, 8-dicarboxyanthracene[1] (50 g., 0.188 mol.), (methanol 1000 ml.) and concentrated sulfuric acid (20 g.) was refluxed for 8 hr. The reaction mixture was chilled with ice precipitating crystalline solid. The solid was washed with a small amount of methanol and water, successively, yielding yellow needles, m. p. 104~105°C (34 g.). The filtrate was concentrated under reduced pressure. The residue was poured into water (100 ml.) and extracted with benzene (60 ml.). Further crop of yellow needles, m. p. 104~105°C (10.5 g.) was obtained from the benzene extract. The combined yield was found to be 81%. Crystallization from methanol gave pure III, long yellow needles, m. p. 104~105°C.

Found: C, 73.41; H, 4.68. Calcd. for $C_{18}H_{14}O_4$: C, 73.46; H, 4.80%.

Anthracene-1, 8-bis-carbohydrazide (IV.). — A solution of the methyl ester (III, 85 g., 0.28 mol.) in 99% ethanol (430 ml.) containing 80% hydrazine hydrate (170 ml.) was refluxed for 4 hr. Deposition of crystals was observed after 30 min. The reaction mixture was cooled in an ice-bath, and the crystals deposited were filtered, washed with ethanol (100 ml.) and water (300 ml.), successively, yielding crude IV, yellow needles, m. p. 279~288°C (decomp.), 75 g., (92%). The crude material was recrystallized twice from ethanol to give pure IV, yellow needles, m. p. 292~293°C (decomp.).

Found: C, 64.86; H, 4.87; N, 18.97. Calcd. for $C_{16}H_{14}O_2N_4$: C, 65.29; H, 4.80; N, 19.04%.

Bis-benzenesulfonyl Derivative of IV (V). — The hydrazide (IV, 73 g., 0.25 mol.) and benzenesulfonyl chloride (146 g.) were dissolved in dry pyridine (365 ml.) and the mixture was stirred at 0°C. Gradual deposition of light yellow crystals was observed. After 3 hr., the reaction mixture was allowed to warm up to room temperature and the stirring was continued for further 5 hr. The solid deposited was filtered, washed successively with a small amount of pyridine, diluted hydrochloric acid and water yielding light yellow crystalline powder, m. p. 260~264°C (decomp.), 133 g. (92%). This substance was recrystallized 3 times from pyridine yielding pure V, light yellow fine crystals, m. p. 263~264°C (decomp.).

Found: N, 9.71. Calcd. for $C_{28}H_{22}N_4O_6S_2$: N, 9.75%.

1, 8-Bis-hydroxymethylanthracene (VI). — The methyl este (III, 29.4 g., 0.10 mol.) was placed in a Soxhlet type extractor and extracted with ether (1.4 l.) containing lithium aluminum hydride (3.8 g., 0.10 mol.). The ester III was completely extracted during 4 hr. The reflux was continued for further 3 hr. to complete the reduction. Ethyl acetate (9 ml.) was added to the ice-cooled reduction mixture and the solvent was distilled out. 6 N-Hydrochloric acid (250 ml.) was added to the residue and the insoluble substance was collected, washed successively with diluted hydrochloric acid and water yielding crude VI, light yellow fine needles, m. p. 215~217°C, 23.0 g. (97%). Crystallization from ethanol gave pure VI, light yellow cubes, m. p. 217~218°C.

Found: C, 80.31; H, 5.93. Calcd. for $C_{16}H_{14}O_2$: C, 80.64; H, 5.92%.

IR: 3260 (-OH), 1010 cm^{-1} (C-O), (KBr-disk).

1, 8-Diformylanthracene (VII). — *a) By the Alkaline Decomposition of V.* — A solution of the bis-benzenesulfonyl derivative (V, 11.5 g., 0.02 mol.) in anhydrous ethylene glycol (240 ml.) was heated to 165°C. Finely powdered anhydrous sodium carbonate (25 g.) was added in one portion to the solution accompanying vigorous frothing. After 10 sec., the solution was poured into water (600 ml.) and the precipitate formed was filtered, washed with water yielding yellowish brown solid (1.8 g.). The solid was digested with hot benzene. Concentration of the benzene solution resulted in the crude dialdehyde (VII), yellow needles, m. p. 181~185°C, 0.7 g. (15%). Recrystallization from benzene gave pure VII, m. p. 189~191°C.

Found: C, 81.83; H, 4.29. Calcd. for $C_{16}H_{10}O_2$: C, 82.04; H, 4.30%.

b) By the Oxidation of the Bis-hydroxymethyl Derivative VI. — A solution of VI (4.8 g., 0.02 mol.) in dry pyridine (120 ml.) was added in one portion to an ice-cooled solution of chromium trioxide (16 g., 0.16 mol.) in dry pyridine (160 ml.) and the mixture was shaken. The cooling-bath was removed after 20 min. The mixture was shaken for 2 hr. at room temperature and poured into water. The precipitate formed was filtered, washed with water affording a brown powder (4.4 g.). The powder thus obtained was extracted with benzene (100 ml.) employing Soxhlet type extractor. Evaporation of the solvent gave yellow leaflets, m. p. 187~190°C, 3.5 g. (75%). Recrystallization from benzene yielded pure VII, yellow cubes, m. p. 189~191°C.

Found: C, 82.06; H, 4.29. Calcd. for $C_{16}H_{10}O_2$: C, 82.04; H, 4.30%.

IR: 2710 (-CHO), 1675 cm^{-1} (-C=O), (KBr-disk).

1, 8-Bis (1', 4'-dihydroxybut-2'-ynyl)-anthracene (VIII). — *a) Via 2-(Prop-2'-yn-1'-yloxy)-tetrahydropyran Mercuric Salt.* — The mercuric acetylide of tetrahydropyranyl ether of propargyl alcohol (11.5 g., 0.024 mol.) was prepared according to the method of Johnson[10] was refluxed for 1.5 hr. with an excess of lithium in dry dioxane (120 ml.) in an atmosphere of nitrogen. The solution of the lithium acetylide thus prepared was transferred into another reaction vessel, and was mixed with a solution of the dialdehyde (VII, 0.94 g., 0.004 mol.) in dioxane (50 ml.) and tetrahydrofuran (120 ml.). The mixture was stirred for 4 hr. at 10°C and then 4 N sulfuric acid (100 ml.) was added under ice-cooling. After stirring for 1 hr., the mixture was extracted with benzene (200 ml.), washed successively with saturated solutions of sodium chloride, sodium hydrogen carbonate and sodium chloride, and dried (sodium sulfate). Removal of the solvent under reduced pressure resulted in a dark red oil. Light brown

amorphous solid, m. p. ca. 170°C, 0.26 g. (19%) was obtained on addition of benzene (20 ml.) to the dark red oil. This substance was recrystallized 3 times from benzene-methanol to give pure VIII, light yellow leaflets. This material decomposed at ca. 210°C.

Found: C, 75.89; H, 5.24. Calcd. for $C_{22}H_{18}O_4$: C, 76.28; H, 5.24%.

b) By the Method of Metalation with Phenyllithium.—An ethereal solution of phenyllithium (1.66 N, 90 ml.) was added during 20 min. to an ice-cooled solution of tetrahydropyranyl ether of propargyl alcohol (21.0 g., 0.15 mol.) in ether (20 ml.) under nitrogen atmosphere. The mixture was stirred for 30 min. at room temperature, then for 1 hr. under reflux. A solution of the dialdehyde (VII, 7.0 g., 0.03 mol.) in tetrahydrofuran (750 ml.) was added to the ice-cooled mixture and stirred for 4.5 hr. resulting in a dark red solution. At this stage, an aliquot of the reaction mixture gave negative test against carbonyl reagents. 4 N Sulfuric acid (300 ml.) was introduced to the reaction mixture under ice-cooling and the mixture was stirred for 3 hr. at 10°C. The organic layer separated was washed with saturated solutions of sodium chloride, sodium hydrogen carbonate and sodium chloride, successively, and dried over sodium sulfate. Evaporation of the solvent under reduced pressure gave a dark red viscous oil. Benzene (100 ml.) was added to the oil precipitating a light brown amorphous solid, 4.4 g. (42%). The solid was recrystallized twice from tetrahydrofuran-benzene to give pure VIII, m. p. ca. 210°C (decomp.), light yellow leaflets.

Found: C, 76.31; H, 5.24. Calcd. for $C_{22}H_{18}O_4$: C, 76.28; H, 5.24%.

The infrared and ultraviolet spectra were proved to be entirely identical with those of the specimen prepared by the above-mentioned method a).

IR: 3260 (O-H), 1055, 1020 cm^{-1} (C-O) (KBr-disk).

UV $\lambda_{max}^{90\%EtOH}$ mμ (log ε): 254 (5.10), 300† (2.54), 315† (3.05), 329 (3.42), 345 (3.70), 362 (3.88), 381.5 (3.80).

1, 8-Bis-butadiynylanthracene (X).—A mixture of thionyl chloride (5.0 g., 0.042 mol.), dry pyridine (0.5 g., 6 mmol.) and tetrahydrofuran (10 ml.) was added dropwise during 1 hr. to an ice-cooled solution of the tetraol (VIII, 2.10 g., 6 mmol.) in tetrahydrofuran (100 ml.) under stirring. Stirring was continued for 30 min. at the same temperature, for 1.5 hr. at 20°C and finally for 10 min. under reflux. The dark red reaction mixture was concentrated to ca. 20 ml. under reduced pressure in an atmosphere of nitrogen. The solution of the crude tetrachloride thus obtained was added dropwise during 30 min. into a solution of sodium amide (prepared from sodium, 7 g., 0.3 g. atom) in liquid ammonia (250 ml.) at −70°C. After stirring for 2 hr., ammonium chloride (15 g.) was added and the ammonia was allowed to evaporate. The residual solid was repeatedly digested with petroleum benzine (b. p. 60~80°C, total 1.8 l.). The extract was washed with water and dried (sodium sulfate). The solvent was removed under reduced pressure in nitrogen atmosphere resulting in crude crystals, which were dissolved in benzene (40 ml.). The solution was passed through a thin layer of alumina (20 g.). Concentration of the filtrate afforded X, bright yellow fine needles, m. p. ca. 110°C (decomp.), 0.38 g. (23%). Crystallization from benzene-petroleum benzine gave the analytical sample with m. p. ca. 110°C (decomp.).

Found: C, 96.54; H, 3.79. Calcd. for $C_{22}H_{10}$: C, 96.33; H, 3.67%.

The Oxidative Coupling of X.—To a mixture of finely powdered cupric acetate monohydrate (9 g.) and dry pyridine (30 ml.) was added a solution of the tetraacetylene (X, 0.35 g., 0.0013 mol.) in pyridine (10 ml.) and methanol (10 ml.) in one portion at 20°C. The color of the reaction mixture changed immediately to brownish black. The mixture was vigorously shaken for 1 min., and petroleum ether (100 ml.) was added to quench the reaction. The solid formed was filtered, washed with a small amount of petroleum ether and ethanol, and then thororoughly with water. The solid thus obtained was triturated successively with a minor amount of ethanol and benzene yielding reddish black powder (0.18 g.). The substance was digested with chlorobenzene (1.2 l.). The chlorobenzene solution was passed twice through a short column of alumina (15 g.) resulting in deep orange-red filtrate with fluorescence. Concentration of the solution under reduced pressure in an atmosphere of nitrogen resulted in deep red crystals. This was filtered, washed with a small amount of benzene yielding II, deep red fine needles, 0.06 g., (17%). II changed to a brownish black solid at ca. 160°C without fusion.

Found: C, 96.73; H, 3.31. Calcd. for $C_{44}H_{16}$: C, 97.04; H, 2.96%.

IR: 2190, 2140, 2110 cm^{-1} (-C≡C-), (Nujol mull).

Electronic spectrum $\lambda_{max}^{Tetrahydrofuran}$ mμ (log ε): 262 (5.26), 330† (4.41), 380 (4.33), 403† (4.30), 430 (4.53), 462 (4.71), 520 (4.31).

Catalytic Reduction of the Octaacetylene (II).—A suspension of II (0.04 g.) in pure benzene (500 ml.) was shaken in an atmosphere of hydrogen in the presence of 10% palladium-on-charcoal (0.1 g.). The progress of hydrogenation was followed by the change of the electronic spectrum. After 72 hr., no more change in the spectrum was observed. The catalyst was removed by filtration, and washed with benzene (250 ml.). The combined benzene solution was concentrated to 150 ml. and hydrogenated for 24 hr. in the presence of the fresh catalyst (0.05 g.). Further change of the spectrum could not be detected. The catalyst was removed and washed with the same solvent. The solvent was removed under reduced pressure giving light yellow solid. The solid was dissolved in petroleum benzine (10 ml.) and chromatographed on alumina (2.0 g.). Elution with petroleum benzine-benzene (3:1) afforded a light yellow

† Dagger on the figure of the electronic spectral data denotes shoulder.

solution. After concentration of the eluate, a small amout of ethanol was added yielding a faint yellow amorphous substance. A benzene solution (2 ml.) of this substance was passed through a thin layer of alumina (1 g.) and eluted with benzene resulting in a light yellow eluate with blue fluorescence. The most part of the solvent was removed under reduced pressure and a minor quantity of ethanol was added yielding light yellow crystals. Recrystallization from benzene-ethanol gave XI, light yellow fine crystals, m. p. 122~125°C (0.01 g.).

Polarographic and Chronopotentiometric Studies on the Dissociation Reaction of Nitrilotriacetatocadmate(II) Complexes

By Nobuyuki TANAKA, Kazuko EBATA, Tomoo TAKAHARI* and Tsutomi KUMAGAI**

(Received July 17, 1962)

The kinetic current due to the dissociation of nitrilotriacetatocadmate(II) complexes has been investigated by several researchers[1-4]. In early works, however, the effect of acetate ion on the kinetic current was not taken into consideration, though the measurements were made in acetic acid - sodium acetate buffer solutions. Koryta[4] was the first to consider this effect and to assume the kinetic current as due to the reduction of the free (hydrated) ions and acetato complexes of cadmium. Similar treatments of the effect of acetate and/or other coexisting ions have been approved when applied to the equilibrium and kinetic studies on the substitution or complex-forming reactions in solutions.

Since the application of the treatment to the kinetic current has not been proved, it seems worth while to investigate the dissociation reaction of nitrilotriacetatocadmate(II) in the presence and absence of acetate ions. Because of the limitations of polarographic and chronopotentiometric methods, the reaction rate was determined polarographically in the presence of acetate and chronopotentiometrically in the absence of acetate.

Experimental

Reagents. — A standard solution of cadmium nitrate was obtained by the same procedure as reported previously[5]. A stock solution of disodium nitrilotriacetate (NTA) was prepared from the commercial nitrilotriacetic acid, the concentration of which was determined against the standardized copper(II) nitrate solution by amperometric titration with a dropping mercury electrode. All chemicals used were of analytical reagent grade and all solutions were prepared with redistilled water.

Apparatus and Procedure. — Polarographic current-voltage curves were obtained with a Yanagimoto pen-recording polarograph (Polarorecorder Model PR-2 with an automatic potential scanner) and a dropping mercury electrode. The measurements were carried out in solutions containing 0.4 mM of cadmium nitrate, 0.01 M of NTA and 0.05 M of sodium acetate - acetic acid buffers. The

ionic strength was adjusted to be 0.2 with potassium nitrate. The pH of the solution was measured, immediately after the measurement of the current-voltage curve, with a Hitachi EHP-1 pH meter with a glass electrode.

For chronopotentiometric study, an apparatus similar to that reported in the previous paper[6] was used. The hanging mercury drop electrode served as a cathode and a saturated calomel electrode with a large surface area (SCE) as an anode. Controlled electrolysis current was supplied by five 90 V. dry cells connected in series and resistors of 0.1 to 100 megohms. The electrolysis current was measured by means of a standard resistance and potentiometer. The potential difference between the working electrode and the SCE was fed to the Y-axis of a cathode-ray oscillograph (Toshiba ST-1747A) through a direct-current preamplifier. The alternating voltage of 100 to 1000 cycles/sec. from an oscillator (Yokogawa OV 21 A) was supplied for the beam modulation. Thus, chronopotentiograms were obtained as dotted curves as shown in Fig. 1, of which the transition

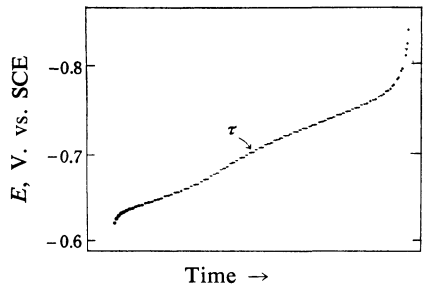

Fig. 1. Chronopotentiogram of Cd(II)-NTA complex. $[Cd^{2+}]_t$, 1.04 mM; $[NTA]_t$, 0.0202 M; pH, 3.19; μ, 0.2 (KNO_3); current density, 5.25 μamp./mm^2; surface area, 3.65 mm^2. The interval of every two dots corresponds to 1/140 sec.

time was determined by counting the number of dots. The measurements of chronopotentiograms were made with the solutions containing 1.04 mM of cadmium nitrate and 0.0202 M of NTA. The ionic strength was adjusted to be 0.2 with potassium nitarte and the pH, to be of an appropriate value between 2.8 and 3.4 with nitric acid. In this range of pH's, nitrilotriacetate itself served as a buffer. All chronopotentiometric measurements were carried out at 25°C.

Results

a) Polarographic Study. — In acetate buffer solution of an appropriate pH containing NTA in excess, cadmium(II) gave a doublet wave. As has been reported previously[1-4], the first wave is kinetic in nature and considered as due to the reduction of cadmium(II) which is dissociated from Cd(II)-NTA complex. The over-all electrode reaction at the dropping mercury electrode is written as

$$CdX^- + jH^+ \overset{k_j}{\rightleftharpoons} Cd^{2+} + H_jX^{(3-j)-} \quad (j=0, 1, \cdots\cdots, n) \tag{1}$$

$$Cd^{2+} + OAc^- \rightleftharpoons CdOAc^+ \tag{2}$$

$$\left\{\begin{matrix} Cd^{2+} \\ \uparrow\downarrow \\ CdOAc^+ \end{matrix}\right\} + 2e + Hg \rightleftharpoons \left\{\begin{matrix} Cd(Hg) \\ Cd(Hg) + OAc^- \end{matrix}\right\} \tag{3}$$

where X^{3-} denotes a tervalent NTA anion and k_j the rate constant of the dissociation reaction given by Eq. 1. Assuming that reactions 2 and 3 are rapid enough to attain the equilibria and that the hydrated ions and the acetato complex ions of cadmium are both reduced at the potentials under consideration where the Cd(II)-NTA complexes are not reduced, the following equation is derived according to Koryta[4],

$$\frac{\bar{i}_l}{\bar{i}_d - \bar{i}_l} = 0.886\sqrt{\frac{kK_{CdX}[X^{3-}]t_d}{1+K_{CdOAc}[OAc^-]}} \tag{4}$$

$$k = \sum_{j=0}^{n} k_j [H^+]^j$$

where $\bar{i}_l$ and $\bar{i}_d$ mean the kinetic current and the hypothetical diffusion current of total electro-inactive species respectively, K_{CdOAc} and K_{CdX} the formation constants of $CdOAc^+$ and CdX^- respectively, and t_d the drop time. Equation 4 holds only when NTA exists in a large excess over cadmium(II) in the solution.

The rate constants were calculated with the observed values of $\bar{i}_l$ at various pH's using Eq. 4. The concentration of X^{3-} at the given hydrogen ion concentration was calculated with the total concentration ($[NTA]_t$) and the dissociation constants of NTA. The values of $10^{-1.89}$, $10^{-2.49}$ and $10^{-9.73}$ were used for the first, second and third dissociation constants, respectively, which were determined by Schwarzenbach et al.[7] at 20°C and 0.1 ionic strength. For the formation constants of CdX^- and $CdOAc^+$, $10^{9.83}$(K_{CdX}) obtained by Schwarzenbach et al.[7] and 16(K_{CdOAc}) determined in this laboratory[5] were used, respectively.

In Fig. 2, the rate constants at 5, 15 and 25°C are plotted against hydrogen ion concentration. Those linear plots clearly indicate that the rate constants can be expressed as linear functions of hydrogen ion concentration as shown in Table I, where the rate constants obtained by other researchers are also given. Our values at 25°C may be compared with those by Koryta, though the experimental

conditions and the values of various constants used in the calculation are not the same.

b) Chronopotentiometric Study. — Chronopotentiometric potential-time curves were obtained with the solutions of pH 2.8 to 3.4 in the absence of acetate. An example of those curves is given in Fig. 1, which shows the separation of two steps to be ambiguous. Therefore, the transition time was determined by measuring the time that was required for the given change in potential from the beginning of electrolysis. Such a potential change was not the same at different pH's and, consequently, was determined preliminarily at every pH with the chronopotentiogram which is relatively well-defined. Examples of the transition times obtained at varied current densities are given in Table II.

TABLE II. EXAMPLES OF CHRONOPOTENTIOMETRIC MEASUREMENTS

$Cd(NO_3)_2$ 1.04 mM; NTA 0.0202 M; pH 3.12; ionic strength 0.2; 25°C

i_0, μamp./mm²	τ, sec.	$i_0\tau^{1/2}$
4.06	0.68_0	3.3_5
5.23	0.36_5	3.1_6
5.74	0.25_5	2.9_0
7.02	0.15_2	2.7_4
8.65	0.09_0	2.6_0
9.30	0.07_3	2.5_1

The relation between the transition time and the current density for the electrochemical reaction which is preceded by a first order chemical reaction was derived first by Delahay and Berzins[8] for a linear diffusion and later by Murayama[6] for a spherical diffusion. Although the measurements were made with the hanging mercury drop electrode, the observed values of transition time were not accurate enough for the Murayama's rigorous treatment. In this study, therefore, the equation derived by Delahay and Berzins for a linear diffusion was employed.

When NTA is present in the solution in a large excess over cadmium(II), the relation,

$$i_0\tau^{1/2}=\pi^{1/2}FD^{1/2}[Cd^{2+}]_t - \frac{\pi^{1/2}K_{CdX}[X^{3-}]}{2k^{1/2}(1+K_{CdX}[X^{3-}])^{1/2}}i_0 \qquad (5)$$

holds, where i_0 is the current density, τ the transition time for the reduction of free cadmium ion, F the Faraday, D the common value of the diffusion coefficients of various species which are assumed to be equal, and $[Cd^{2+}]_t$ the total concentration of cadmium. Equation 5 indicates that the plot of $i_0\tau^{1/2}$ against i_0 should give a straight line with a negative slope. In Fig. 3, the values of $i_0\tau^{1/2}$ calculated with the observed transition times at pH 2.99 and 3.35 are plotted against current

8) P. Delahay and T. Berzins, *J. Am. Chem. Soc.*, 75, 2486 (1953).

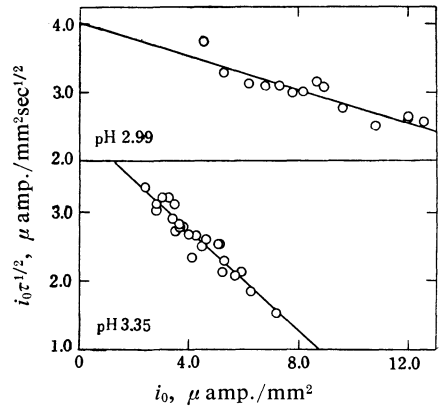

Fig. 3. $i_0\tau^{1/2}$ as a function of i_0 at various pH's.

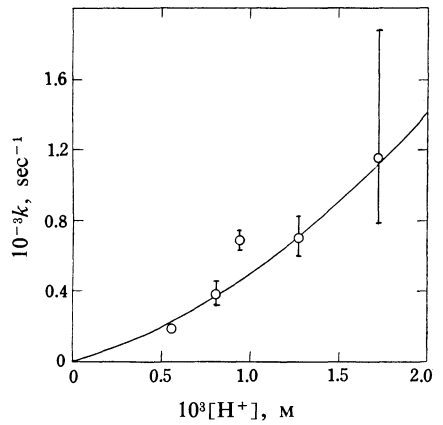

Fig. 4. Dependence of the dissociation rate constant on the hydrogen ion concentration. The solid curve represents the relation, $k=3\times10^5[H^+]+2\times10^8[H^+]^2$.

density. The negative slopes of those plots clearly indicate that the electrode processes are kinetic in nature. The rate constants at various pH's were calculated from the slopes, and are plotted against hydrogen ion concentration with the standard deviation (Fig. 4). The solid curve in Fig. 4 represents a relation given by the equation,

$$k=3\times10^5[H^+]+2\times10^8[H^+]^2 \qquad (6)$$

At lower pH's the contribution of the term independent of the hydrogen ion concentration is so small compared to other terms that it can be hardly determined.

Discussions

Inaccuracy of the present chronopotentiometric measurement is due to mainly the fact that the reduction potentials for hydrated ion and NTA complex of cadmium are not sufficiently separated. In addition, the chronopotentiogram of cadmium is considerably affected by the presence of surface-active substance, and this may be another cause of the inaccuracy of the measurement. Murayama[6] reported that the presence of 0.001% gelatin decreased the transition time and deteriorated the shape of the chronopotentiogram of hydrated cadmium ion. In the present experiment, redistilled water was used and no surface-active substance was added, but an effect of aging of the hanging mercury drop electrode was clearly observed. Transition time was measured as a function of time after the formation of a mercury drop (θ) and the values of $i_0\tau^{1/2}$ were plotted against θ (Fig. 5). Those linear plots in Fig. 5 suggest that an abrupt decrease in $i_0\tau^{1/2}$ in the region of small values of θ would be most unlikely.

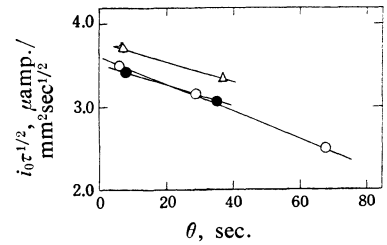

Fig. 5. Variations of $i_0\tau^{1/2}$ with θ.
-△-△-, pH 3.19 and i_0 3.64 μamp./mm^2;
-○-○-, pH 3.12 and i_0 4.06 μamp./mm^2;
-●-●-, pH 2.86 and i_0 5.87 μamp./mm^2.

The over-all rate constant k obtained from the kinetic current was a linear function of the hydrogen ion concentration. The chronopotentiometric study, on the other hand, showed that at lower pH's the over-all rate involves a second-order term with respect to the hydrogen ion concentration. The first-term of Eq. 6 obtained by the chronopotentiometric method, $3\times10^{-5}[H^+]$, is in good agreement with the values obtained polarographically by the authors and by Koryta (see Table I). This proves clearly that the Koryta's treatment of the effect of acetate ion on the kinetic current is appropriate.

In conclusion, the rate constant of the dissociation of Cd(II)-NTA complex is a function of hydrogen ion concentration, and expressed as

$$k=3.4+2.5\times10^5[H^+]+2\times10^8[H^+]^2$$

at 25°C, from the results obtained polarographically and those obtained chronopotentiometrically. The dissociation reaction, therefore, is considered to proceed through three simultaneous reaction paths,

$$CdX^- \rightarrow Cd^{2+}+X^{3-}$$
$$CdX^-+H^+ \rightarrow Cd^{2+}+HX^{2-}$$
$$CdX^-+2H^+ \rightarrow Cd^{2+}+H_2X^-$$

Summary

The dissociation reaction of nitrilotriacetatocadmate(II) complexes has been investigated polarographically and chronopotentiometrically in the presence and the absence of acetate ions. The results indicate that the treatment reported by Koryta for the effect of acetate ion on the kinetic current is appropriate.

The rate constant of the dissociation reaction of nitrilotriacetatocadmate(II) complexes is a function of hydrogen ion concentration and expressed as

$$k = 3.4 + 2.5 \times 10^5 [H^+] + 2 \times 10^8 [H^+]^2$$

at 25°C.

*Preparation of Some Tricyclohexylsilyl Derivatives**

By Motonori KANAZASHI and Michio TAKAKURA

(Received July 25, 1962)

Preparation of organosilicon compounds containing cyclohexyl groups has been studied by several workers[1-5] from a viewpoint of steric effect. Nebergall and Johnson[3] synthesized a wide variety of tricyclohexylsilyl compounds through the reaction of cyclohexyllithium with silicon tetrachloride. Lately it was reported by Eaborn[4] and Petrov[5] that the use of silicon tetrafluoride or fluorosilanes was more effective than that of silicon tetrachloride in the reaction. However, substitution or condensation reaction of a compound carrying two or three bulky cyclohexyl groups has an unavoidable difficulty in approaching of a reagent. We overcame the difficulty and prepared tetracyclohexylsilane and three cyclohexylmethylsilanes by hydrogenation of the corresponding phenyl-silicon compounds[1].

Hexacyclohexyldisilane was not obtained by the reaction of tricyclohexylchlorosilane with metallic sodium[3], whereas the corresponding digermane was obtained by a similar treatment[6]. It has been also reported by Nebergall and Johnson[3] that the hydrolysis product of chlorosilane was tricyclohexylsilanol, m. p. 177°C. The compound reported by Jenkins and Post[7] as "probably hexacyclohexyldisiloxane", m. p. 178°C, seems to be the same compound.

In the present paper hydrogenations of hexaphenyldisilane, hexaphenyldisiloxane and triphenylsilanol are reported.

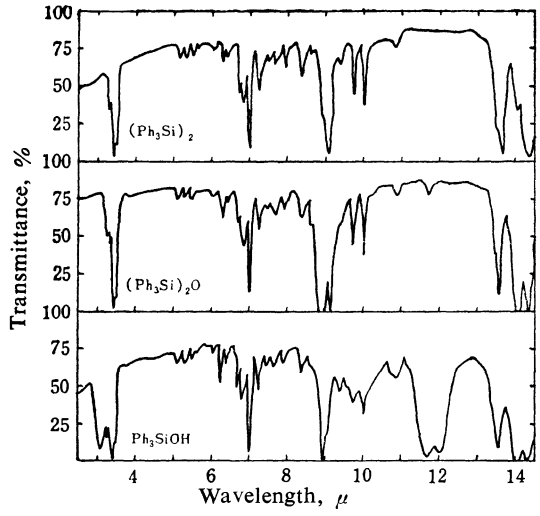

Fig. 1 (B). Infrared spectra of phenyl-silicon compounds measured in Nujol mull.

Each compound absorbed the calculated amount of hydrogen, and hexacyclohexyldisilane, m. p. 351°C, hexacyclohexyldisiloxane, m. p. 308°C, and tricyclohexylsilanol, m. p. 177°C, were obtained. As was expected, hydrogenation of triphenylsilanol proceeded more smoothly than those of tetraphenylsilane, hexaphenyldisilane and hexaphenyldisiloxane.

The infrared spectra of the hydrogenation products show none of the absorption bands associated with the phenyl group or phenyl-silicon bond but, instead, clearly show the strong bands characteristic to the cyclohexyl group at 10.0, 11.2 and 11.8 μ[8].

Experimental

All melting points and boiling points are uncorrected.

Hexaphenyldisilane. —Triphenylchlorosilane was treated with sodium in xylene solution at reflux temperature. The precipitate was washed with benzene, treated with methanol, and then washed with hot water and methanol, to give hexaphenyldisilane, m. p. 342~350°C.

Hexaphenyldisiloxane. — Triphenylchlorosilane was hydrolyzed in aqueous ethanol by refluxing for thirty hours with a small amount of hydrochloric acid. The precipitate of hexaphenyldisiloxane was washed with benzene repeatedly and recrystallized. M. p. 221~222.5°C.

Triphenylsilanol.—Hydrolysis of triphenylchlorosilane was carried out in neutral acetone solution. Recrystallization from petroleum ether (50~70°) of triphenylsilanol thus obtained gave white crystals melting at 152°C.

Methylcyclohexane. — Methylcyclohexane was dried over calcium chloride and fractionated through a 30 cm. column packed with single turn helices. B. p. 98~98.5°C.

Raney Nickel Catalyst.—The catalyst was prepared from Raney nickel alloy (Ni content, 42%) in the same way as reported in a previous paper[1]. It was kept under absolute alcohol in a refrigerator, and the alcohol was substituted by methylcyclohexane before use.

Hydrogenation. — A sample in about 50 cc. of methylcyclohexane was hydrogenated in a stainless steel autoclave (capacity, 100 cc.) equipped with a magnetic inner agitator. The initial hydrogen pressure was 100~110 atm., and the conditions are listed in Table I.

Separation of Products. Disilane (Table I, No. 1).—A solid part was separated from the reaction mixture, and the solid was extracted with about 500 cc. of cyclohexane. Recrystallization of a white material, 1.7 g., obtained from the extract gave 0.8 g. of hexacyclohexyldisilane, m. p. 339~343°C. The melting point of hexacyclohexyldisilane was raised to 349~351.5°C by recrystallization from cyclohexane-petroleum ether (9 : 1).

Found: C, 78.04, 78.09; H, 11.86, 11.75; mol. wt. (Rast), 539~559. Calcd. for $C_{36}H_{66}Si_2$: C, 77.90; H, 11.99%; mol. wt., 555.

From the liquid part of the reaction mixture an additional 2.4 g. of hexacyclohexyldisilane was obtained. The solvent recovered was carefully fractionated, but cyclohexane was not detected; the fact shows that silicon-carbon cleavage did not occur during the course of hydrogenation. Another run carried out under forced conditions gave also hexacyclohexyldisilane as a sole product.

TABLE I. HYDROGENATION CONDITIONS

Exp. No.	Material	g.	Catalyst[a] g.	Reaction temp. °C	Hydrogen[c] absorbed l.	Hydrogen[c] calcd. l.
1	Ph_6Si_2	9.35	12~15	110~200	7.7	7.3
2	Ph_6Si_2O	8.0	4	110~160	6.0	6.1
3	Ph_3SiOH	6.9	5	100~130[b]	4.9	5.0

a) The catalyst was added in 3~5 portions.
b) The reaction started at 70~80°C.
c) The initial pressure of hydrogen was 100~110 atm.

8) A study on the infrared spectra of organosilicon compounds containing cyclohexyl groups was presented at the Fall Meeting of the Chemical Society of Japan in 1956 by T. Yoshimoto and M. Takakusa; the paper will be published shortly.

Disiloxane (Table I, No. 2). — From the solid part of the reaction mixture, there was obtained 3.1 g. of crude material melting at 300～308°C. Recrystallizations from cyclohexane-ethanol and from petroleum ether gave 0.95 g. of hexacyclohexyldisiloxane, m. p. 305～308°C. Further recrystallization from petroleum ether, carbon tetrachloride or benzene did not raise the melting point.

Found: C, 76.22, 76.41, 76.44; H, 11.65, 11.75, 11.69; mol. wt. (Rast), 558～592, 575. Calcd. for $C_{36}H_{66}OSi_2$: C, 75.71; H, 11.65%; mol. wt., 571.

From the liquid part, 1.6 g. of hexacyclohexyldisiloxane was separated. Cyclohexane was not detected in the recovered reaction solvent.

Silanol (Table I, No. 3). — By a similar treatment, 6.2 g. of tricyclohexylsilanol was obtained from the reaction mixture. M. p. 174～176°C. Duplicated recrystallization from petroleum ether raised the melting point to 176～177°C (Reported[3], 177°C).

Found: C, 73.50, 73.57; H, 11.81, 11.78. Calcd. for $C_{18}H_{34}OSi$: C, 73.40; H, 11.64%.

Infrared Spectra.—The absorption spectra were measured in Nujol mull and in carbon tetrachloride solution with a Shimadzu AR-275-I infrared spectrophotometer equipped with a sodium chloride prism. Solubility in carbon tetrachloride of hexacyclohexyldisilane (less than 1%) or hexacyclohexyldisiloxane (ca. 2%) was not sufficient to give good spectra.

Summary

Hydrogenations of hexaphenyldisilane, hexaphenyldisiloxane and triphenylsilanol were carried out in the presence of Raney nickel catalyst (W-6), and hexacyclohexyldisilane**, hexacyclohexyldisiloxane** and tricyclohexylsilanol were obtained (41, 56, 84%, respectively). Infrared spectra of the products and the starting materials were measured.

The authors are grateful to Dr. Toshio Yoshimoto for valuable suggestions in the analysis of the infrared spectra of the compounds.

Studies on trans-Dicyanodiethoxycarbonylethylene. III. Diels-Alder Reaction

By Ken-ichi KUDO

(Received July 31, 1962)

Knowledge in various addition reactions of tetracyanoethylene[1] and the properties of *trans*-dicyanodiethoxycarbonylethylene (I) described in the previous papers[2] suggest that I might also undergo Diels-Alder additions with conjugated dienes with unusual ease. However, such vigorous and exothermic reactions as expected were not observed in the additions of I with conjugated dienes. Namely, the addition of I with cyclopentadiene proceeded in tetrahydrofuran slowly at room temperature. Furthermore, to obtain a condensation product of I with butadiene or isoprene, it was necessary to heat them in an autoclave under pressure at 180~190°C for several hours.

In the reaction with cyclopentadiene, the reaction mixture showed a transient yellow color, which would be attributed to the formation of a π-complex between I and cyclopentadiene.

The proposed structures of the adducts were supported by the infrared absorption spectra and the elemental analyses.

Experimental

Adduct with Isoprene. — A mixture of 4 g. (0.06 mol.) of isoprene and 13 g. (0.06 mol.) of I in

1) W. J. Middleton et al., *J. Am. Chem. Soc.*, **80**, 2783 (1958).
2) Parts I and II: K Kudo, This Bulletin, **35**, 1490, 1730 (1962).

100 ml. of benzene was heated in an autoclave at 180～188°C for 5 hr. After cooling, benzene was removed by vacuum distillation to obtain the syrupy residue which changed to crystals. The crystals were collected by filtration, washed with benzene-petroleum benzine, and recrystallized to give 17 g. (100%) of 1-methyl-4,5-dicyano-4,5-diethoxycarbonylcyclohexene, m. p. 77～79°C, as colorless crystals.

Found: C, 62.30; H, 6.36; N, 9.73. Calcd. for $C_{15}H_{18}O_4N_2$: C, 62.05; H, 6.25; N, 9.65%.

Its infrared absorption spectrum had bands at 2252 cm^{-1} (C≡N) and at 1761 cm^{-1} (C=O).

Adduct with Butadiene. — A mixture of 13 g. (0.06 mol.) of I and 100 ml. of benzene in a flask was chilled to −40°C. The flask was tarred, charged with 3.2 g. (0.06 mol.) of butadiene by distillation, and placed in an autoclave. The mixture was heated at 170～190°C for 5 hr. After cooling, benzene was removed by distillation and the residue solidified. After recrystallization from benzene-petroleum benzine, there was obtained 11 g. (70%) of 4,5-dicyano-4,5-diethoxycarbonylcyclohexene, m. p. 109～110°C, as colorless crystals.

Found: C, 61.11; H, 5.76; N, 10.15. Calcd. for $C_{14}H_{16}O_4N_2$: C, 60.86; H, 5.84; N, 10.14%.

Its infrared absorption spectrum had a C≡N band at 2247 cm^{-1} and a C=O band at 1757 cm^{-1}.

Adduct with Cyclopentadiene. — A mixture of 6.5 g. (0.03 mol.) of I and 20 ml. of tetrahydrofuran in a flask was chilled to 0°C. The flask was tarred, charged with 2.3 g. (0.03 mol.) of cyclopentadiene by distillation, capped, and allowed to stand at room temperature for 24 hr. The mixture was evaporated to expel benzene at room temperature and the residue crystallized to give 8 g. (90%) of the adduct, m. p. 70～71°C, as colorless crystals.

Found: C, 62.40; H, 5.34; N, 9.52. Calcd. for $C_{15}H_{16}O_4N_2$: C, 62.49; H, 5.59; N, 9.72%.

Its infrared absorption spectrum had a C≡N band at 2247 cm^{-1} and a C=O band at 1761 cm^{-1}.

Adduct with Anthracene. — A mixture of 13 g. (0.06 mol.) of I and 8 g. (0.06 mol.) of anthracene was heated at 130～150°C for 5 min. After cooling, the mixture was crystallized by trituration with acetone to give 12 g. (57%) of the adduct, m. p. 168～169°C, as colorless crystals.

Found: C, 72.20; H, 5.01; N, 7.37. Calcd. for $C_{24}H_{20}O_4N_2$: C, 71.98; H, 5.03; N, 7.00%.

Its infrared absorption spectrum had a C≡N band at 2242 cm^{-1} and a C=O band at 1764 cm^{-1}.

The author wishes to express profound gratitude to Professor Risaburo Nakai of the Institute for Chemical Research of Kyoto University for his cordial encouragement and direction throughout this work. He also desires to give sincere thanks to Professor Ryozo Goto of Kyoto University for his invaluable advice and criticism throughout the investigation.

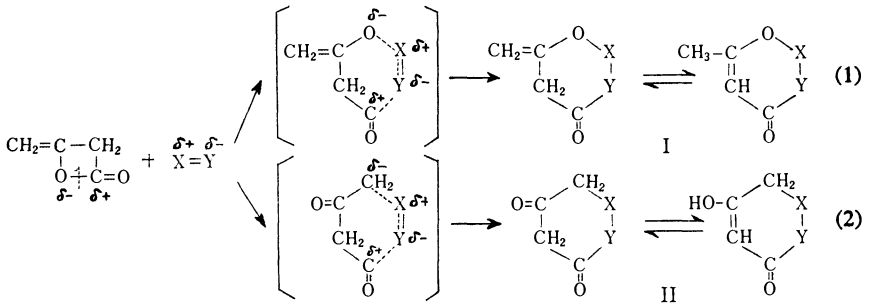
New Addition Reactions. IV. The Addition of Schiff Bases to Diketene

By Ryohei ODA, Shunichi TAKASHIMA and Masaya OKANO



(Received August 13, 1962)

For the cyclic addition of unsaturated components to diketene, two possible paths may be considered.

The type 1 reaction including the reaction of diketene with ketones[1], carbodiimides[2] and enamines[3], and the formation of dimeric dehydroacetic acid[4] are already known, but examples of the type 2 addition have not been reported. We wish to report the formation of type II adduct by the reaction of diketene with some Schiff bases.

Treatment of diketene with *N*-benzylidene-*t*-butylamine in chloroform gave a cyclic adduct, 1-*t*-butyl-6-phenyl-2, 4-piperidinedione (III), in an excellent yield. The structural assignment was made on the basis of its elementary analysis, infrared spectrum, dinitrophenylhydrazone formation, and a positive ferric chloride test. No evidence for the formation of a type I adduct was observed. Similar reactions with *N*-methylene-*t*-butylamine and *N*-methylenecyclohexylamine also gave the corresponding piperidinediones, but the yields were very low. In the spectra (Nujol) of all adducts obtained, two sharp bands at 1700～1725 cm^{-1} (keto CO) and 1633～1650 cm^{-1} (lactam CO) regions, along with two other bands (conjugated C=C, 1550 cm^{-1} and OH,

2) R. N. Lacey and W. R. Ward, *J. Chem. Soc.*, **1958**, 2134.
3) B. B. Millward, *J. Chem., Soc.*. **1960**, 26; S. Hünig, E. Benzing and K. Hübner, *Chem. Ber.*, **94**, 486 (1961).
4) A. B. Boese, Jr., *Ind. Eng. Chem.*, **32**, 21 (1940); T. Isozima, *J. Chem. Soc. Japan, Ind. Chem. Sec.* (*Kogyo Kagaku Zassi*), **57**, 773 (1954).

3290～3300 cm^{-1}) assigned to the enolic structure of II, were observed.

In cases where *N*-benzylideneaniline and *N*-benzylidenecyclohexylamine were used as Schiff bases, the desired adduct could not be isolated from the resinous reaction mixtures. On the other hand, when diketene was treated with *N*-isopropylidenecyclohexylamine, the formation of a polymer of diketene was observed. Its melting point and infrared spectrum were essentially in accord with those of a polyester obtained by the aluminum isopropoxide-[5] or potassium *t*-butoxide-[6]catalyzed polymerizations of diketene.

The failure of the desired cyclization appears to depend largely on the nature of the Schiff base used, especially its degree of dimerization or trimerization[7], its basicity and its bulkiness; but a detailed explanation is not possible at the present time.

Experimental[8]

1-*t*-Butyl-6-phenyl-2, 4-piperidinedione (III).—A mixture of 30 g. (0.19 mol.) of *N*-benzylidene-*t*-butylamine (prepared by the procedure of Emmons[9]) and 17 g. (0.19 mol.) of diketene in 100 ml. of chloroform was refluxed for 5 hr. After removal of the solvent, there was obtained 37 g. (80%) of crude 1-*t*-butyl-6-phenyl-2,4-piperidinedione. Recrystallization from benzene gave the pure product which melted at 108～109°C. This adduct gave a dark-red color with ethanolic ferric chloride on standing for several hours.

Found: C, 73.68; H, 7.85; N, 5.53. Calcd. for $C_{15}H_{19}NO_2$: C, 73.34; H, 7.81; N, 5.71%.

The 2,4-dinitrophenylhydrazone after recrystallization from ethanol melted at 230°C with decomposition.

Found: C, 59.23; H, 5.61; N, 16.24. Calcd. for $C_{21}H_{24}N_5O_5$: C, 59.14; H, 5.67; N, 16.42%.

1-*t*-Butyl-2, 4-piperidinedione.—To a stirred solution of 6 g. (0.07 mol.) of freshly distilled *N*-methylene *t*-butylamine[9] in 100 ml. of ether was added slowly 6.7 g. (0.08 mol.) of diketene at room temperature. After completion of the addition, the mixture was heated at 30°C for 3 hr. The resultant precipitate was collected, and weighed 1 g. (8%). An analytical sample was obtained by recrystallization from benzene, m. p. 159～160°C.

Found: C, 63.87; H, 9.23; N, 8.52. Calcd. for $C_9H_{15}NO_2$: C, 63.88; H, 8.94; N, 8.28%.

1-Cyclohexyl-2, 4-piperidinedione.—A mixture of 11 g. (0.10 mol.) of *N*-methylenecyclohexylamine[10] and 300 ml. of ether was stirred and cooled to −15°C, 25 g. (0.30 mol.) of diketene was added dropwise to this solution at such a rate so as to maintain that temperature. After the addition of diketene, the stirring was continued at the same temperature for 1 hr. and at 0°C for 5 hr. The tar-like product that separated was extracted with petroleum ether. Removal of the solvent by distillation gave 0.5 g. (3%) of the crude adduct. After one recrystallization from toluene, the adduct melted at 182～186°C. The analysis was somewhat unsatisfactory, but the infrared spectrum was quite similar to that of III.

Found: C, 66.75; H, 9.04; N, 7.14. Calcd. for $C_{11}H_{17}NO_2$: C, 67.66; H, 8.78; N, 7.17%.

The authors wish to express their gratitude to Dainippon Celluloid Co., Ltd., for the gift of diketene.

Study on Unimolecular Decomposition of Excited Olefin Ions

By Itiro OMURA

(Received June 29, 1962)

Since Eyring and his co-workers[1] first used statistical theory in the interpretation of the mass spectra of polyatomic molecules, several authors[2-5] have reported applications of the theory. They have adopted some alkanes, esters as well as aliphatic alcohols, and discussed mass spectra, appearance potentials, yields of fragment ions, frequency factors, decomposition processes and such other things. The present author reported in a previous paper[6] on his experimental results concerning the mass spectra of some paraffins and olefins and discussed the bond dissociation of molecular ions.

In this paper, frequency factors, rate constants and decomposition probabilities are estimated from the mass spectra of olefins by the quasi-equilibrium theory, and the decomposition processes of olefins are briefly discussed in comparison with those of paraffins.

Theory

According to the quasi-equilibrium theory[1], the rate constant for the unimolecular dissociation of a polyatomic ion with the excitation energy of E is given by:

$$K(E)=\int_{\circ}^{E-\varepsilon_{\circ}} \frac{1}{h}\cdot\frac{\rho^{+}(E,\varepsilon_{\circ},\varepsilon_t)}{\rho(E)}\mathrm{d}\varepsilon_t \qquad (1)$$

where $\rho(E)$ is the density of the states of the ion with an energy of E, $\rho^{+}(E,\varepsilon_{\circ},\varepsilon_t)$ is the density of the states of the ion in the activated complex configuration with the potential energy of $\varepsilon_{\circ}$ and the translational energy of ε_t, and h is Planck's constant. The internal energy of the transition complex is, then, $E-\varepsilon_{\circ}$. Neglecting the contribution of the electronic state to the state density function, and assuming the oscillations in normal and activated complex configurations of the molecular ion to be harmonic, Eq. 1 can be rewritten as:

$$K(E)=z\left(1-\frac{\varepsilon_{\circ}}{E}\right)^{p}(E-\varepsilon_{\circ})^{q} \qquad (2)$$

Here, z is the frequency factor; the exponents p and q are defined by the following equations:

$$p=(3N'-6)-L/2-1$$
$$q=(L-L^{*})/2$$

where N' is the number of atoms in the parent ion, L is the number of internal rotational degree of freedom, and the symbol* indicates the quantities relating to the activated complex.

In such a system of unimolecular reaction, the amount of parent ions left at time t is given by:

$$n_t=n_{\circ}\exp(-\sum_{i}^{n}K_i t) \qquad (3)$$

Here, $n_{\circ}$ is the amount of parent ions at the beginning. In practical calculation, the time, t, is usually assumed to be a certain constant value of the order of 10^{-5} sec. according to the dimension of the ion source as well as of the ion-accelerating voltage. The relative abundance of fragment ions is given by:

$$(I_i)_j=\frac{K_j}{\sum_{i}K_i(E)} \qquad (4)$$

It is very difficult to calculate theoretically the frequecy factor. In general, the frequency factor is estimated from the experimental data concerning the reactant and activated complex states in spectroscopy. In other cases, the frequency factor is determined inversely from the relative yields of the principal ions in mass spectrometry. Thus, low-energy reaction paths for the unimolecular decomposition of the polyatomic ion have been studied through mass spectrometry[1,4-8].

Experimental

The instrument used was a Hitachi mass spectrometer, RMS-3, of a single focusing, 60°-sector type with a radius of 100 mm. Ionization is carried out by electron impact. The appearance potentials and the relative yields of the principal ions produced from some paraffins and olefins were measured and reported on in the previous paper[6].

For the case of propylene, a block diagram for the unimolecular decomposition is shown in Fig. 1.

TABLE I. LOW VOLTAGE PATTERNS AND APPEARANCE POTENTIALS FOR OLEFINS

Mass	Propylene ion yield	Propylene A. P., eV.	1-Butene ion yield	1-Butene A. P., eV.	*cis*-2-Butene ion yield	*cis*-2-Butene A. P., eV.
$C_4H_8^+$			34.5	9.72	42.5	9.25
$C_4H_7^+$			9.5	12.01	6.3	11.20
$C_3H_6^+$	57.4	9.74				
$C_3H_5^+$	30	12.11	34.5	11.73	29.5	11.60
$C_3H_4^+$	8.5	12.52				
$C_3H_3^+$	4.5	14.21	2.5		3.0	
$C_2H_5^+$					1.5	12.25
$C_2H_4^+$		12.85	9.0	12.38	6.8	12.19
$C_2H_3^+$	2.6	13.80		13.6		

V_e—I: 4 eV.

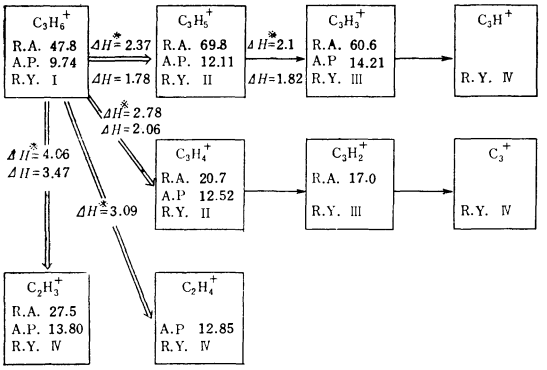

Fig. 1. Unimolecular decomposition scheme for propylene ion by electron impact.
R.A. Relative abundance (%)
A.P. Appearance potential (eV.)
R.Y. Type of relative yield curve[6]
ΔH^* Heat of activation (eV.)
ΔH Heat of reaction (eV.)

In each block are shown the chemical formula of the ion, the relative abundance (R. A.), and the type of relative yield curve (R. Y.)[6]. The bold lines connecting two blocks show primary reaction paths, fine lines, secondary or higher reaction paths, and broken lines, energetically impossible paths. Over and along the arrow are shown the heat of activation (ΔH^*) and the heat of reaction (ΔH). Table I shows the appearance potentials of principal fragment ions from propylene, 1-butene and *cis*-2-butene, and also the relative abundances at the ionizing voltage four volts higher than the ionization potantial of the parent molecule.

Figure 2 shows the decomposition probability of the parent ion calculated from the following equation:

$$F_p = \frac{\sum_j (I_f)_j}{I_p + \sum_j (I_f)_j} \qquad (5)$$

where I_p is the intensity of the undecomposed parent ions and $\sum_j (I_f)_j$ is the total sum of all the other fragment ions in the mass spectrum. Abscissa, V_e-I, is the excess energy of the ionizing electron over the ionization potential of the parent

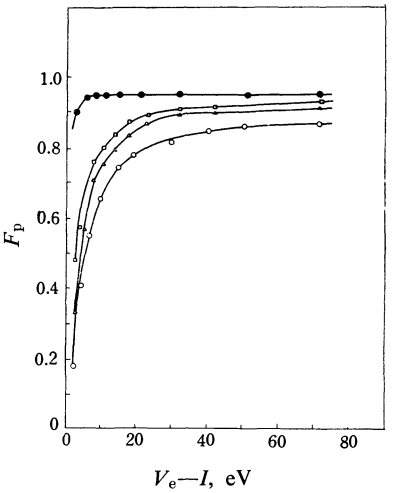

Fig. 2. Decomposition probability of parent ions.
○ Propylene
△ 1-Butene
□ *cis*-2-Butene
● *n*-Butane.

molecule. The curve for *n*-butane is taken as an example of paraffins.

Similarly, the probability of the secondary decomposition of $C_3H_5^+$ ions is shown in Fig. 3. In this case, the $C_3H_5^+$ ion intensity corresponds to I_p in Eq. 6, while the total sum of fragment ions expected from the decomposition of $C_3H_5^+$ ions corresponds to $\sum (I_f)$. The ratio of the intensity of the $C_3H_5^+$ ion to that of the parent ion, as well as the ratio of the intensity of the $C_3H_3^+$ ion produced from the $C_3H_5^+$ ion by secondary decomposition to that of the $C_3H_5^+$ ion, are shown in Fig. 4.

The rate constants for the $C_3H_6^+$, $C_3H_5^+$ and $C_3H_3^+$ ions from propylene are calculated from the mass spectrometric data and are shown in Fig. 5, where the time is assumed to be 1×10^{-5} sec. In Table II are listed the rate constants of the parent ions of some olefins at an ionizing voltage four volts higher than the ionization potential. The frequency factors are also calculated and listed in Table III.

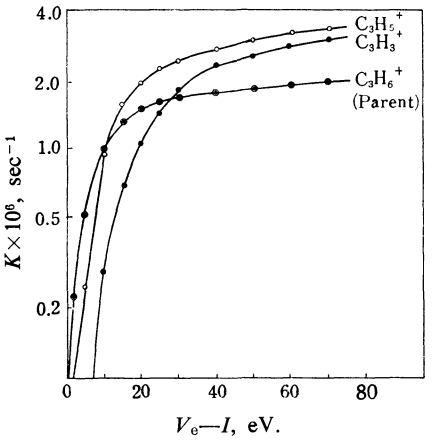

Fig. 5. Unimolecular decomposition rate constant — propylene —.

Discussion

In the estimation of the rate constant, the time, t, in Eq. 3 is assumed to be 1×10^{-5} sec. because the time between the formation of the ions and their entering the focusing system is presumed to be of the order of 10^{-5} sec. The absolute value of the rate constant obtained depends greatly on this assumption and is not very important. It should be discussed in relation with the assumption as well as with the value obtained from theory or other kinds of experiment. The frequency factor is of the same type.

The frequency factor obtained for the hydrogen atom abstraction from propane ion and that obtained for the methyl radical abstraction are in the ratio of about $1:10^3$, as has been reported by Friedman[5]. It seem there are no gross mistakes in the present experiment.

The rate constant of the parent ion in a homologous series seems to increase with the size of the ion, as is shown in Table II. This may be due to the increase in possible reaction paths.

It might be simply considered that the character of the fragment ion, $C_3H_5^+$, is independent of the parent ion. Contrary to this simple expectation, the secondary decomposition probabilities of the $C_3H_5^+$ ion in the cases of propylene, 1-butene, and *cis*-2-butene are slightly different from each other,

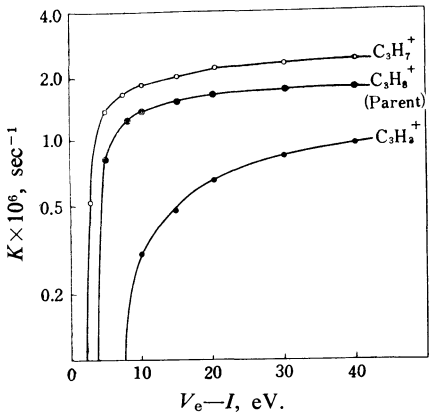

Fig. 6. Unimolecular decomposition rate constant — propane —.

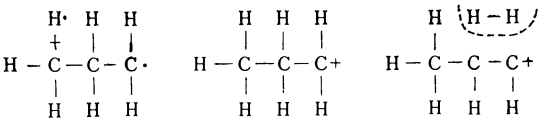
as is shown in Fig. 3. The $C_3H_3^+/C_3H_5^+$ ratio for the ions from propylene considerably differs from those for the ions from 1-butene and *cis*-2-butene, as is shown in Fig. 4. The cause remains to be further investigated.

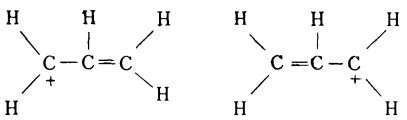
The rate constants of the principal ions from propane are shown in Fig. 6 in comparison with those of propylene, as in Fig. 5. The decomposition paths of the propane ion are as follows:



$$C_3H_8^+ \xrightarrow[\text{primary}]{\text{H abstraction}} C_3H_7^+ \begin{cases} \xrightarrow[\text{secondary}]{H_2\text{ abstraction}} C_3H_5^+ \\ \longrightarrow C_2H_3^+ \\ \longrightarrow CH_3^+ \end{cases}$$

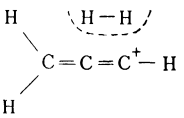
Here, bold lines indicate principal paths and fine lines, reaction paths energetically possible but of secondary importance. The secondary decomposition path from $C_3H_7^+$ to $C_3H_5^+$ in the case of propane corresponds to the path from $C_3H_5^+$ to $C_3H_3^+$ in the case of propylene. Comparing Fig. 5 with Fig. 6, we can see that the rate constant for the secondary decomposition probability is larger in the case of propylene than in the case of propane. This may be caused by the fact that the probability of the abstraction of the hydrogen molecule is closely related with the distribution of the positive charge or the ionic structure of the activated complex. According to the quasi-equilibrium theory, the density of the positive charge associated with the bonds has an effect on the bond rupture, and the relative yield of ions is related with the distribution of the positive charge[6]. Inversely, the effect of positive charge distribution may be presumed from the rate constant or the activation energy.

The decomposition paths to the $C_3H_3^+$ ion from the propylene ion are as follows:



$$C_3H_6^+ \xrightarrow[\text{primary}]{\text{H abstraction}} C_3H_5^+ \xrightarrow[\text{secondary}]{H_2\text{ abstraction}} C_3H_3^+$$

The ionic structure of the $C_3H_7^+$ ion from propane is presumed to be of the last type of the follwing three structures;



I II III

Similarly, the ionic structure of the $C_3H_5^+$ ion from propylene is presumed to be of the last type of the following three structures:

I' II'

III'

In the case of propylene, the activation energy for the secondary reaction (hydrogen molecule abstraction) is smaller than twice the activation energy for the primary reaction (hydrogen atom abstraction), as is shown in Table IV. In the case of propane, on the other hand, the energy for the secondary reaction (hydrogen molecule abstraction) is larger than twice the energy for the primary reaction (hydrogen atom abstraction). These interesting results seem to be very important for the study of the dissociation of these molecular ions.

TABIE IV. ENERGY FOR THE ABSTRACTION OF A HYDROGEN ATOM AND A HYDOGEN MOLECULE

Parent ion	Primary H, eV.	Secondary H_2, eV.	H_2-2H eV.
$C_3H_6^+$	2.37	2.10	−2.64
1-$C_4H_8^+$	2.29	2.09	−2.49
cis-2-$C_4H_8^+$	1.95	2.15	−1.75
$C_3H_8^+$	0.56	3.2	+2.08
n-$C_4H_{10}^+$	0.78	2.54	+0.98
iso-$C_4H_{10}^+$	1.37	3.39	+0.65

Summary

The decomposition probabilities, rate constants, and frequency factors for some olefins have been calculated on the basis of mass spectrometric data and the quasi-equilibrium theory.

The rate constant of the parent ion in a homologous series increases with the size of the ion. Fragment ions of the same form but from different parent ions sometimes reveal different rate constants.

The scheme of hydrogen molecule abstraction in the secondary decomposition processes of propane is analogous to that of propylene, and reasonable ionic structures of primary ions can be presumed.

For a more quantitative discussion, however, there remain some indistinct points in the application of the quasi-equilibrium theory. For instance, the time of reaction along with the rate constant is assumed to be 1×10^{-5} sec. and to be constant for all ions. Further studies should be carried out both in theory and experiments.

The author wishes to thank Dr. Nozomu Morito and the members of the mass spectrometry section of Hitachi Central Research Laboratory for their helpful discussions throughout this work.

Thanks are also due to Professor Keniti Higasi of Hokkaido University, as well as Professor Itiro Kanomata of Tokyo Metropolitan University, for their discussions regarding the broader of the problems treated.

The cis-trans Photoisomerization of Azobenzene

By Shigeru YAMASHITA, Hiroshi ONO and Osamu TOYAMA

(Received July 7, 1962)

The cis-trans photoisomerization of azobenzene in solution has been investigated by a number of workers[1-3]. For both of the isomers of azobenzene, n-π^* bands have been observed in the visible wavelength region and π-π^* bands in the near-ultraviolet region. However, the quantum yield values reported by the previous workers show some inconsistency concenrning the relative efficiencies of n-π^* and π-π^* absorption for the isomerization.

The present paper reports on a reinvestigation of these quantum yield values as well as on a kinetic study of the isomerization reaction. All the experiments have been carried out with *n*-hexane as the solvent.

Experimental

Materials.—*cis-Azobenzene.*—The method of preparation described by Hartley[4] was followed.

trans-Azobenzene.—A commercial reagent was used after repeated recrystallization. The absorption curves of the two azobenzene isomers were in good agreement with those in the literature.

n-Hexane.—A commercial reagent of a chemically pure grade was treated with fuming sulfuric acid, concentrated sulfuric acid, and an aqueous solution of potassium permanganate successively. After having been dried over anhydrous calcium chloride, the product was fractionally distilled.

Apparatus and Procedure.—In Fig. 1 are shown the absorption curves of *cis*- and *trans*-azobenzene in *n*-hexane at 15°C. The light source for the photoisomerization was a Mazda SHL-100 mercury lamp. A combined filter consisting of Mazda UV-D2 and a potassium chromate solution was used to isolate the 313 mμ line, which gives rise to π-π^* transitions in both the isomers of azobenzene. To study the effect of the n-π^* absorption of *cis*-azobenzene, a combintation of Mazda V-P 1.5 and Walz UV was used; the 405 mμ line was thereby isolated. To study the effect of the n-π^* absorption of *trans*-azobenzene, a Walz Y-1 filter was used; this allowed mercury lines of longer wavelengths

than about 420 mμ to enter the reaction cell, although the only strongly absorbed lines of these, in view of the absorption curve in Fig. 1, was 436 mμ. Through the collimating quartz lens and the filters, a parallel light beam of a desired wavelength was projected upon a quartz reaction cell 4 cm. in diameter and 2 cm. thick immersed in a thermostat which had a window for the exciting light beam. For experiments at −78°C, the thermostat was replaced by a Dewar vessel containing dry ice-ethanol.

In the present study the rate of isomerization reaction was measured only in the initial stage of reaction so that the reverse reaction could be neglected. The change in concentration of *cis*- and *trans*-azobenzene caused by isomerization was determined by a Hitachi EPB-U type spectrophotometer.

For determination of the exciting light intensity, a potassium ferrioxalate actinometer was used[5]. Taking the actinometric result and transmittancy of the reaction mixture into account, quantum yields for the isomerization reaction under various conditions were obtained. Other details of the procedure have been described in a previous paper on the photochemical cis-trans isomerization of stilbene[6].

Results and Discussion

The results obtained are shown in Tables I—V. The kinetic results obtained with dilute solutions approximately conform to the rate expression:

$$-\mathrm{d(A)}/\mathrm{d}t=\phi I_a=kI_0(\mathrm{A})$$

where A represents *cis*- or *trans*-azobenzene, and I_0, the incident light intensity. This rate equation implies that the rate of isomerization is simply proportional to the light quanta absorbed per unit time, I_a, since I_a is proportional

to the product, $I_0(A)$, for dilute solutions. The constancy of the quantum yield values, the ϕ's, given in each table proves the validity of such an interpretation.

Fischer[3], on the basis of measurements of photoequilibrium at varied temperatures, argues that the trans→cis photoisomerization of azobenzene and its derivatives is dependent on temperature. In the present work, such a temperature dependence has really been found, as

is shown in Table II, for the trans → cis conversion of azobenzene caused by n-π^* absorption. The effect of the temperature, however, is rather small, the activation energy being as low as 0.7 kcal./mol. For the trans → cis conversion caused by π-π^* absorption and for the conversion in the reverse direction caused by either n-π^* or π-π^* absorption, similar rate measurements have shown that these are all independent of temperature within the range of experimental error.

TABLE VI. SUMMARY OF QUANTUM YIELDS

Reaction	Temp. °C	Light wave-length mμ	Absorption	Quantum yield
cis→trans	3∼4	313	π-π^*	0.44
				0.42[a]
				0.69[b]
	0	405	n-π^*	0.68
				0.55[a]
				0.45[b]
trans→cis	3∼4	313	π-π^*	0.10
				0.10[a]
				0.22[b]
	0	436	n-π^*	0.20
				0.25[a]
				0.36[b]

a) Values obtained by Zimmerman et al. (Ref. 2) at 25°C.
b) Values obtained by Birnbaum and Style (Ref. 1) at room temperature.

The quantum yield values obtained in this work are summarized in Table IV, together with those reported by previous workers. As may be seen in the table, Zimmerman et al. report that n-π^* absorption is more efficient than π-π^* in both directions of conversion, while according to Birnbaum and Style π-π^* absorption is more efficient in the cis→trans conversion. The results obtained in the present work confirm the observations of the former workers.

The sum of the quantum yields for the cis→trans and trans → cis isomerization reactions is frequently found to be approximately unity; the mechanism of isomerization in such a case is usually supposed to be:

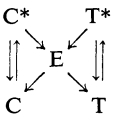
$$C \rightleftarrows E \rightleftarrows T \qquad (1)$$

where C and T denote normal molecules of cis and trans-forms respectively, and E is the excited state reached by light absorption, where the two isomeric forms are assumed to be indistinguishable. The assumption of such an excited state may not be improbable, since there are theoretical grounds for supposing the potential barrier separating the two isomeric forms in the excited state to be much lower than that in the ground state[7]. The sum of quantum yields obtained in the present work, with n-π^* absorption at 0°C, is about 0.9; the mechanism in this case may be supposed to be approximately as described above.

However, the conversion due to π-π^* absorption cannot be interpreted in the same way, since the sum of the quantum yields is here distinctly lower than unity. Zimmerman et al. have proposed the following mechanism as an interpretation:

$$C \underset{k_1}{\overset{h\nu}{\rightleftarrows}} C^* \underset{k_4}{\overset{k_3}{\rightleftarrows}} T^* \underset{h\nu}{\overset{k_2}{\rightleftarrows}} T \qquad (2)$$

Here the two isomeric forms in the exited state, C* and T*, are assumed to be separated by a potential barrier of an appreciable magnitude —say, 5 kcal./mol. Scheme 2 explains the sum of quantum yields lower than unity, since they are represented by:



$$1/\phi_{C\to T} = 1 + (k_1/k_3)\,[1 + (k_4/k_2)]$$

and

$$1/\phi_{T\to C} = 1 + (k_2/k_4)\,[1 + (k_3/k_1)]$$

where the k's are the respective rate constants given in the scheme. These expressions for the quantum yields are, however, incompatible with the experimental findings in the present work, for the quantum yields obtained with 313 mμ are $\phi_{C\to T} = 0.44$ and $\phi_{T\to C} = 0.10$, both being independent of temperature; it follows from these figures that neither k_3 nor k_4 can have an appreciable activation energy.

An alternative interpretation reconcilable with the experimental results may be presented as follows:

(3)

Here E denotes an excited state similar to the one assumed in scheme 1, which lies lower than either state C* or T*. Scheme 3 leads to a sum of quantum yields, $\phi_{C\to T} + \phi_{T\to C}$, less than unity, where neither $\phi_{C\to T}$ nor $\phi_{T\to C}$ now needs to be dependent on temperature.

Summary

The photoisomerization of *cis*- and *trans*-azobenzene in an *n*-hexane solution has been studied in the n-π^* and π-π^* absorption wavelength regions. The rate of isomerization has always been found to be proportional to the

7) For example, the bond order of the ethylenic double bond in stilben, calculated for the first excited state, is markedly lower than that for the ground state. (C. A. Coulson and J. Jacobs, *J. Chem. Soc.*, **1949**, 1983)

product of the incident light intensity and the concentration of *cis*- or *trans*-azobenzene. This simply means that the rate of isomerization is proportional to that of light absorption. Quantum yields of isomerization are independent of the temperature except for the trans → cis conversion caused by n-π^* absorption, where the quantum yield is slightly dependent on temperature. The sum of quantum yields for cis → trans and trans → cis conversions caused by n-π^* absorption is approximately unity, while the sum obtained with π-π^* absorption is much smaller than unity. The mechanism of photoisomerization has been discussed with reference to these results.

Relations between the Electronic Absorption Spectra and the Spatial Configurations of Conjugated Systems. XIII. Phenyl-carbonyl and Vinyl-carbonyl Systems

By Hiroshi SUZUKI

(Received July 7, 1962)

As is well known, Braude[1] classified the steric effects in the ultraviolet absorption spectra of conjugated compounds into two types. Type 1, exemplified by the substituted phenyl- and vinyl-carbonyl compounds, is characterized by a decrease in the absorption intensity alone, with no appreciable accompanying change in the position of the absorption maximum. Type 2, exemplified by the *o*-alkylated biphenyls, is characterized by a hypsochromic shift as well as by a decrease in the absorption intensity.

Braude ascribed the difference between the two types to the difference in the underlying mechanism. According to him, while the type 2 effect occurs when the steric hindrance to the planarity of the conjugated system is relatively strong, the type 1 effect occurs when the steric hindrance is relatively weak, and while in the former case the maximum absorption originates in electronic transitions in those molecules with the most probable non-planer configuration in the electronic ground state, in the latter case it originates in transitions in those molecules with the less probable planar or near-planar configuration in the ground state. He therefore ascribed the decrease in the intensity of the absorption maximum in the case of type 1 to the decrease in the population ratio, r, of the planar or near-planar configuration in the electronic ground state (i.e., the probability in which molecules in the electronic ground state assume the planar or near-planar configuration); further, he assumed that the population ratio, r, and hence the molar extinction coefficient of the absorption maximum, ε, would be proportional to $\cos\theta$, where θ is the interplanar angle between moieties of the conjugated system linked to each other by a formally single bond, i.e., the angle of twist of the bond, in the most probable configuration[2,3]. Afterwards[4,5], he replaced the cosine of θ in the above assumption by the cosine-square of θ; that is, he assumed the following relation:

$$\varepsilon/\varepsilon_0=\cos^2\theta \qquad (1)$$

where ε_0 is the molar extinction coefficient of the absorption maximum of the sterically unhindered reference compound.

As has been mentioned in Parts XI[6] and XII[7] of this series, Braude's interpretation of steric effects is unacceptable. Although the border line between the two types of steric effect is not distinct in practice, the classification may be provisionally admitted. However, the difference between the two types is due neither to a difference in the underlying mechanism nor to a difference in the magnitude of steric hindrance. The sensibility of the transition energy to a change in the spatial configuration of the conjugated system depends on the nature of the electronic upper state to which the transition leads. According to Murrell[8], the energy of the transition to a perturbed, locally-excited state is relatively sensitive to a change in the configuration, while, on the other hand, that of the transition to a perturbed, intramolecular electron-transfer state is relatively insensitive. Roughly, it may be said that the steric effect in the former case corresponds to type 2, and that in the latter case to type 1. At any rate, in both cases, the maximum absorption is considered to originate in transitions in those molecules with the most probable configuration in the electronic ground state, contrary to the theory of Braude.

In this way, the untenability of the theory of Braude may be said to have been established. However, Eq. 1 itself, assumed by Braude on the wrong grounds, seems to have some plausibility. Thus, the values of θ calculated by the use of this relation for some benzaldehydes and acetophenones are generally in quite good agreement with the values deduced from the dipole moment data, although the latter values themselves seem also to be unreliable, because their deduction was based on a rather arbitrary assumption bearing a certain similarity to Eq. 1. Furthermore, a relation similar to Eq. 1 was found by Klevens and Platt[9] to hold in the case of *o*-substituted dimethylanilines. Thus, according to them, the oscillator strength, f, of each band varies with the cosine-square of the minimum angle of twist of the dimethylamino group with respect to the benzene ring estimated from the van der Waals radius of the ortho substituent.

It may, therefore, be of some interest to examine to what extent the relation assumed by Braude can be validated by theoretical considerations. In the present paper, with special emphasis on this problem, it is attempted, on the same ground as in the previous papers of this series, to clarify the relation between the conjugation band and the spatial configuration of the conjugated system in the cases of the phenyl-carbonyl (C_6–C=O) and vinyl-carbonyl (C=C–C=O) systems as representatives of systems exhibiting the so-called type 1 steric effect.

Transition Energy as a Function of the Angle of Twist

It has already been pointed out by Nagakura and Tanaka[10-12] that the intense band near 240 mμ, i. e., the conjugation band, of acetophenones as well as of benzaldehydes has the nature of an intramolecular electron-transfer band. According to them, the band is due to electronic transition between two π-orbitals, ψ_{-1} and ψ_{+1}, which arise primarily from the interaction of the lowest antibonding π-orbital of the carbonyl group, $\phi_{-1(C)}$, and the highest bonding π-orbital of the benzene ring, $\phi_{+1(B)}$. Since the interaction of two orbitals is always in the sense of a repulsion, the energy separation between ψ_{-1} and ψ_{+1} will become greater as the interaction between $\phi_{-1(C)}$ and $\phi_{+1(B)}$ becomes greater. Therefore, this theory leads to a surmise that the steric hindrance to coplanarity of the benzene nucleus and the carbonyl group would result in a bathochromic shift of the band. As was pointed out in Part X[13] of this series, this surmise is contrary to observed facts. Thus, with the acetophenone system, the steric effect should be considered to cause a hypsochromic shift of the band. It is evident that the omission of interactions among orbitals other than $\phi_{-1(C)}$ and $\phi_{+1(B)}$ is an over-simplification. Therefore, in the first place, the dependence of the transition energy on the angle of twist of the formally single bond is examined by the use of the perturbation theory, all the π-orbitals being taken into account.

Notation.—A conjugated system is represented by R–S and is regarded as being composed of two mesomeric systems, R and S, linked to each other by a formally single bond between the atoms r and s, which belong to R and S respectively. In the phenyl-carbonyl and vinyl-carbonyl systems, R represents the benzene nucleus or the ethylenic bond and S represents the carbonyl bond.

The following notation is used: ϕ_m: m-th MO of R. $\phi_{n'}$: n'-th MO of S. ϕ_k: k-th

MO of R–S. $F_m=\alpha-v_m\beta$: energy of ϕ_m. $F_{n'}=\alpha-v_{n'}\beta$: energy of $\phi_{n'}$. $E_k=\alpha-w_k\beta$: energy of ϕ_k. χ_i: AO of atom i. $b_{m,r}$: coefficient of χ_r in ϕ_m. $b_{n',s}$: coefficient of χ_s in $\phi_{n'}$. $c_{k,i}$: coefficient of χ_i in ϕ_k. $p_{k,i-j}=c_{k,i}c_{k,j}$: partial π-bond order of the i–j bond in ϕ_k, i.e., the contribution to the π-bond order of the bond by an electron occupying ϕ_k. $\alpha_i=\alpha+\delta_i\beta$: coulomb integral of χ_i. $\rho_{i-j}\beta$: resonance integral between χ_i and χ_j.

By the way, α is the coulomb integral of the 2 pπ atomic orbital of a carbon atom, and β is the resonance integral of the 2 pπ atomic orbitals of adjacent carbon atoms in the benzene ring. That is, v or w represents the energy of the orbital in a unit of $-\beta$ relative to the energy of the 2 pπ atomic orbital of a carbon atom.

In each of the mesomeric systems, the highest bonding π-orbital is designated as $+1$, and the lower orbitals in the order of decreasing energy are designated as $+2$, $+3$, and so on. Quite analogously, the lowest antibonding π-orbital is designated as -1, and the higher orbitals in the order of increasing energy are designated as -2, -3, and so on. Thus, for example, ϕ_{+1}, $\phi_{+1'}$, and ψ_{+1} refer to the highest bonding π-orbitals of R, S, and R–S respectively.

The parameter ρ_{i-j} can be expressed as follows, on the basis of the usual assumption of the proportionality of the resonance integral to the overlap integral:

$$\rho_{i-j}=\cos\theta_{ij}\cdot S(R_{i-j}, 0^\circ)/S(\text{benz.}) \qquad (2)$$

In this expression, θ_{ij} is the angle of twist of the bond (i.e., the angle by which the axes of χ_i and χ_j are twisted with respect to each other), R_{i-j} is the length of the bond, $S(R_{i-j}, 0^\circ)$ is the overlap integral of χ_i and χ_j when the interatomic distance is R_{i-j} and the angle of twist is 0°, and S(benz.) is the π–π overlap integral for adjacent carbon atoms in the benzene nucleus.

Classification of Conjugated Systems.—With respect to the heights of the energies of $\phi_{-1'}$ and $\phi_{+1'}$ relative to the energies of ϕ_{-1} and ϕ_{+1}, the following three typical cases are distinguished:

(A) $v_{-1}=v_{-1'}$; $v_{+1}=v_{+1'}$

(B) $v_{-1}<v_{-1'}$; $v_{+1}>v_{+1'}$

(C) $v_{-1}>v_{-1'}$; $v_{+1}>v_{+1'}$

These cases are exemplified by the following conjugated systems: (A), butadiene and biphenyl; (B), styrene; and (C), phenyl-carbonyl and vinyl-carbonyl.

In the case of A, ψ_{-1} and ψ_{+1} are regarded as orbitals arising from the perturbation of $1/\sqrt{2}\cdot(\phi_{-1}+\phi_{-1'})$ and of $1/\sqrt{2}\cdot(\phi_{+1}-\phi_{+1'})$ respectively, and the transition from ψ_{+1} to ψ_{-1} corresponds to the transition to a so-called charge-resonance state[14]. In the case of B, ψ_{-1} and ψ_{+1} are regarded as originating from ϕ_{-1} and ϕ_{+1} respectively, and the transition from ψ_{+1} to ψ_{-1} is the transition to a so-called perturbed, locally-excited state.

In general, the π-orbitals in any even-alternant hydrocarbon system occur in pairs. Thus, for such a system, $v_{+m}=-v_{-m}$, and $|b_{+m,i}|=|b_{-m,i}|$. Therefore, any system in which both fragments, R and S, are even-alternant hydrocarbon systems belongs to either case A or case B; moreover, in such a system, not only in case A but also in case B, the interaction of ϕ_{-1} with $\phi_{-1'}$ and that of ϕ_{+1} with $\phi_{+1'}$ make predominant contributions to the formation of ψ_{-1} and of ψ_{+1} respectively. Accordingly, as the value of ρ_{r-s} becomes larger, the energies of ψ_{-1} and ψ_{+1} become lower and higher respectively, and, consequently, the energy separation between them becomes smaller. This means that a deviation from coplanarity of R and S by a twist of the formally single r–s bond in any even-alternant hydrocarbon system, R–S, results in a hypsochromic shift of the conjugation band. In particular, in case A, the interaction of ϕ_{-1} with ϕ_{-1}, as well as that of ϕ_{+1} with $\phi_{+1'}$, depends on the ρ_{r-s} in the first order. Therefore, in this case, the transition energy increases to a first approximation linearly with the decreasing value of ρ_{r-s}. Representative alternant hydrocarbon systems have been discussed in some detail in the preceding parts of this series.

In case C, the transition from ψ_{+1} to ψ_{-1} corresponds to the transition to a perturbed electron-transfer state. The present paper is concerned chiefly with this case.

Treatment of Case C by Means of the Perturbation Theory.—In case C, ψ_{-1} and ψ_{+1} are regarded as orbitals arising from the perturbation of $\phi_{-1'}$ and ϕ_{+1} respectively, interaction between ϕ_m's and $\phi_{n'}$'s being regarded as a pertubation. Thus, if the $|A_{m,n}\rho_{r-s}|\ll 1$ relation holds for each pair of orbitals of R and S, where $A_{m,n'}=b_{m,r}b_{n',s}/(v_m-v_{n'})$, the first order perturbation theory gives the following expressions for ψ_{-1} and ψ_{+1}:

$$\psi_{-1}=N_{-1}(\phi_{-1'}-\sum_m A_{-1',m}\rho_{r-s}\phi_m) \qquad (3)$$

$$\psi_{+1}=N_{+1}(\phi_{+1}-\sum_{n'} A_{+1,n'}\rho_{r-s}\phi_{n'}) \qquad (4)$$

where N_{-1} and N_{+1} are normalization factors. The second order approximation to the energy of these orbitals is given by:

14) J. N. Murrell, *Quart. Revs.*, **15**, 191 (1961).

$$w_{-1}=v_{-1'}+\sum_{m} G_{-1',\,m}\,\rho^2_{r-s} \equiv v_{-1'}+g_{-1}\,\rho^2_{r-s} \quad (5)$$

$$w_{+1}=v_{+1}+\sum_{n'} G_{+1,\,n'}\,\rho^2_{r-s} \equiv v_{+1}+g_{+1}\,\rho^2_{r-s} \quad (6)$$

where $G_{m,n'}=b^2_{m,r}b^2_{n',s}/(v_m-v_{n'})$. Accordingly, the energy separation between ψ_{-1} and ψ_{+1}, $\Delta E_{-1,+1}$(in $-\beta$), is expressed as:

$$\Delta E_{-1,+1}=\Delta w_{-1,+1}=\Delta v_{-1',+1}+\Delta g_{-1,+1}\,\rho^2_{r-s}$$

where $\Delta v_{-1',+1}$ and $\Delta g_{-1,+1}$ represent $v_{-1'}-v_{+1}$ and $g_{-1}-g_{+1}$ respectively. (The subscript -1, $+1$, which refers to quantities concerning the transition from ψ_{+1} to ψ_{-1}, is subsequently omitted for the sake of brevity.) The partial π-bond orders are given by:

$$p_{-1,\,r-s}=-g_{-1}\,\rho_{r-s}\,N^2_{-1}$$

$$p_{+1,\,r-s}=-g_{+1}\,\rho_{r-s}\,N^2_{+1}$$

The change in the π-bond order of the r–s bond on the one-electron transition from ψ_{+1} to ψ_{-1}, ΔP_{r-s}, is $p_{-1,\,r-s}-p_{+1,\,r-s}$.

When R is an alternant hydrocarbon system, and when $v_{-1'}$ is positive, $-G_{-1',\,-m}$ is greater than $G_{-1',\,+m}$; that is, the contribution of the antibonding orbitals of R to ψ_{-1} is greater than that of the bonding orbitals of R. In this case, g_{-1} is negative, and $p_{-1,\,r-s}$ is positive.

S is taken to represent an unsaturated group, C=X, in which X may represent a hetero-atom such as oxygen or nitrogen. The coulomb integral of the pπ atomic orbital of atom X, α_X, is expressed as $\alpha+\delta_X\beta$. As may easily be proved, according as $\delta_X \lessgtr -v_{+1}$, $-G_{+1,\,-1'} \lessgtr G_{+1,\,+1'}$, and, consequently, $g_{+1} \gtrless 0$ and $p_{+1,\,r-s} \gtrless 0$. Thus, if δ_X is smaller than $-v_{+1}$, the contribution of ϕ_{+1} to $\psi_{+1'}$ as a perturbed orbital of ϕ_{+1} surpasses that of $\phi_{-1'}$. As δ_X becomes greater, the contribution of $\phi_{+1'}$ decreases owing to an increase in the energy separation of $v_{+1}-v_{+1'}$ as well as to a decrease of $b_{+1',\,s}$, and the contribution of $\phi_{-1'}$ increases owing to a decrease in the energy separation of $v_{-1'}-v_{+1}$ as well as to an increase of $b_{-1',\,s}$. This situation may be stated in terms of the resonance theory as follows: With the increasing value of δ_X, the contribution of the ionic structure, $R^+=S^-$, to the electronic ground state increases, resulting in an increase of the π-bond order of the r–s bond in the state.

Putting the above discussions together, the situation can be expressed as follows. If $\delta_X \leqslant -v_{+1}$, Δg is negative and ΔP_{r-s} is positive. In this case, a decrease in ρ_{r-s} results in an increase in Δw. This means that a twist of the r–s bond will cause a hypsochromic shift of the absorption band due to the transition from ψ_{+1} to ψ_{-1}. Of course, the smaller the value of δ_X, the larger the absolute value of Δg and, hence, the more effective the steric hypsochromic effect. The extreme case in which δ_X is zero reduces to case A or B. If δ_X has a moderately larger value than $-v_{+1}$, Δg may be nearly zero. In this case, a steric distortion will result in substantially no shift of the band. In the case where δ_X is much larger than $-v_{+1}$, Δg is positive and, accordingly, a twist of the bond will cause a bathochromic shift of the band.

Calculation and Discussion.—The length of the carbonyl bond in a number of compounds has an average value of 1.23±0.01 Å[15]. By the use of the value of 1.23 Å, the ρ-value for this bond is estimated at 0.844.

In the C_6–C=O and the C=C–C=O systems, the r–s bond is the 1–1′ bond linking the carbonyl group to the phenyl or the vinyl group. The length of this bond, $R_{1-1'}$, is assumed for the sake of convenience to be 1.48 Å when the angle of twist of the bond, $\theta_{1,\,1'}$, is 0°. Then the value of $\rho_{1-1'}$ is 0.858 when $\theta_{1,\,1'}$ is 0°, and the same relation among ρ, θ, and R as the one assumed tentatively for the cases of styrene[6] and biphenyl[16] can be used.

In application of the perturbation theory, the forms of ϕ's and the values of v's obtained by the simple LCAO MO method were used. When R is the benzene ring, for example, $v_{-1}=-v_{+1}=1$, and $b_{-1,\,1}=b_{+1,\,1}=1/\sqrt{3}$. By the way, in the C=C–C=O system, the δ-value for the ethylenic bond was taken to be 1.080, as in the cases of butadiene[7], styrene[6] and stilbene[17].

In Fig. 1, the following quantities as functions of δ_X for the C_6–C=X system, calculated by the use of th above parameter values, are

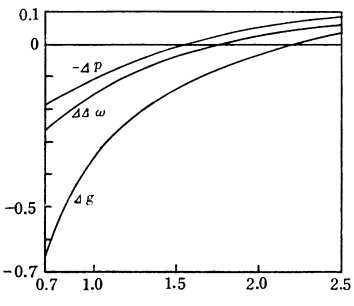

Fig. 1. ΔP_{r-s}, $\Delta\Delta w$, and Δg as functions of δ_X in the C_6–C=X system.

shown graphically: the value of Δg calculated from Eqs. 5 and 6; the difference between the value of Δw at $\theta_{rs}=0°$ and the value at $\theta_{rs}=90°$, $\Delta\Delta w$, and the value of ΔP_{r-s} at $\theta_{rs}=0°$, calculated by an application of the simple LCAO MO method to the whole conjugated system. The foregoing trends of the dependence of a change in the transition energy associated with a change in the angle of twist of the pivot bond, and of the change in the π-bond order of the bond, on the transition on the value of δ_X are clearly shown. In the case of C=C-C=X, the situation is quite similar.

After Matsen[18], the α/β ratio is assumed to be about 2.4. Then, on the basis of the assumption that the value of α_X should be proportional to the ionization energy of an electron occupying the pπ atomic orbital in the pertinent valence state of atom X, the value of δ for the 2pπ orbital of oxygen is estimated at 1.27, by the use of the ionization energy data collected by Pritchard and Skinner[19]. Of course, this numerical value is not conclusive, but approximately this value, probably 1.2~1.3, seems to be pertinent. (By the way, the value of δ for the 2pπ orbital of nitrogen is estimated at 0.60 by a similar procedure.)

When δ_X is 1.2~1.3, Δg, as well as $\Delta\Delta w$, has a small negative value. This means that a deviation from planarity of the conjugated system, of C_6-C=O as well as of C=C-C=O, will cause a small hypsochromic shift of the socalled conjugation band, in accordance with observations.

In Figs. 2 and 3, the Δw values for $\delta_X=1.3$, calculated by the simple LCAO MO method for the phenyl-carbonyl and vinyl-carbonyl systems, are plotted against θ_{rs} with broken lines. In these figures, the corresponding curves for the styrene and the butadiene system are also shown for the sake of comparison.

If X is N instead of O, the steric hypsochromic shift will be somewhat more effective, δ_N being smaller than δ_O. Experimental data pertinent to test this surmise is not available. However, for example, the fact that the steric hypsochromic effect in the case of the semicarbazones of acetophenones is appreciably more effective than in tha case of acetophenones[5] seems to suggest the validity of this surmise.

According to Heilbronner and Gerdil[20], the weak longest-wavelength band at 546 mμ ($\varepsilon_{max}=440$) (A-band) of 1-acetylazulene undergoes a bathochromic shift as well as a reduction of intensity by substitution of a methyl group

18) F. A. Matsen, *J. Am. Chem. Soc.*, **72**, 5243 (1950).
19) H. O. Pritchard and H. A. Skinner, *Chem. Revs.*, **55**, 745 (1955).
20) E. Heilbronner and R. Gerdil, *Helv. Chim. Acta*, **39**, 1996 (1956).

at the 2- or the 8-position of the azulene nucleus, which will prevent the coplanar arrangement of the azulene nucleus and the carbonyl group. This band has been considered to correspond to the α-band ($\lambda_{max}=580\,m\mu$; $\varepsilon_{max}=329$) of azulene, and the latter has been assigned as a band due to the $N \rightarrow V_1$ transition[21]. Thus, if R and S are taken to refer to the azulene nucleus and the carbonyl group respectively, the $v_{-1} < v_{-1'}$ and $v_{+1} > v_{+1'}$ relations probably exist, and the A-band of the 1-acetylazulenes may be regarded as a band due to the transition from ϕ_{+1} as a perturbed orbital of ϕ_{+1} to ψ_{-1} as a perturbed orbital of ϕ_{-1}. The transition may be said to be one to a perturbed locally-excited state, and the situation may be considered to belong to case B. Therefore, a bathochromic effect of a twist of the bond linking the azulene nucleus and the carbonyl group to each other would be rather surprising. Heilbronner and Gerdil correlated this effect to a possible decrease in the π-bond order of the bond upon excitation. This effect can be interpreted as below on the basis of the above considerations.

According to Pariser[22], the energies of the lowest vacant and the highest occupied orbital of azulene and the coefficients of the $2p\pi$ atomic orbital χ_1 in these orbitals in the simple LCAO MO approximation are as follows: $v_{-1}=+0.40039$, $v_{+1}=-0.47726$; $b_{-1,1}=0.06321$, $b_{+1,1}=0.54285$. On the other hand, if the values $\delta_0=1.3$ and $\rho=0.844$ are used for the carbonyl bond, the following values are obtained: $v_{-1'}=+0.415$, $v_{+1'}=-1.715$; $b_{-1',1'}=0.897$, $b_{+1',1'}=0.441$. Thus, since $-v_{+1}$ is smaller than δ_0, g_{+1} is negative. That is, of the effects of the two orbitals of the carbonyl group on ϕ_{+1}, the depressing effect of $\phi_{-1'}$ outweighs the raising effect of $\phi_{+1'}$. In addition, since $b_{+1,1}$ is much larger than $b_{-1,1}$, $|G_{+1,-1'}|$ is larger than $|G_{-1,-1'}|$, notwithstanding the fact that the energy separation of $v_{-1'}-v_{+1}$ is larger than that of $v_{-1'}-v_{-1}$. That is, the depression of the energy of ϕ_{+1} due to the interaction with $\phi_{-1'}$ is probably greater than that of ϕ_{-1}. Thus, the energy separation between ψ_{-1} as a perturbed orbital of ϕ_{-1} and ψ_{+1} as a perturbed orbital of ϕ_{+1} will become greater as the $\rho_{1-1'}$ parameter becomes greater.

Absorption Intensity as a Function of the Angle of Twist

The moment of the one-electron transition from ψ_{+1} to ψ_{-1} is denoted by $M_{-1,+1}$, which is subsequently abbreviated to M, the subscript being omitted. In the case of C, on the basis of Eqs. 3 and 4, the square of this transition moment, i.e., the dipole strength of the transition, can be expressed as follows:

$$M^2=2\left(\int \psi_{-1}\, q\, \psi_{+1}\, d\tau\right)^2$$
$$=2\,\rho^2_{r-s}\,N^2_{-1}\,N^2_{+1}\times\left(\sum_m A_{-1',m}\,I_{+1,m}+\sum_{n'} A_{+1,n'}\,I_{-1',n'}\right)^2$$

where $I_{m,n}$ represents the integral $\int \phi_m\, q\, \phi_n\, d\tau$, q being a general symbol for the position coordinate of the electron. To a first approximation, $I_{m,n'}=0$. Accordingly, when ρ_{r-s} is zero, M^2 is zero.

If the assumption is made that N_{-1}, N_{+1}, and I's do not vary in magnitude to any appreciable extent with changes in the value of ρ_{r-s}, the oscillator strength, f, can be considered to be approximately proportional to ρ^2_{r-s}, since Δw, and hence ν_{max}, are comparatively insensitive to a change in the value of ρ_{r-s}. Further, if it is assumed that the length of the pivot bond remains unchanged when the angle of twist of the bond, θ_{rs}, does vary, ρ_{r-s} can be taken to be proportional to $\cos\theta_{rs}$; hence, the oscillator strength can be considered to be proportional to $\cos^2\theta_{rs}$. Furthermore, if the molar extinction coefficient at the absorption maximum can be taken to be proportional to the oscillator strength of the band, its proportionality to the cosine-square of the angle of twist, i.e., the relation assumed by Braude, is reached.

It should be noted that many assumptions have been needed to reach this relation by the present approach. Above all, the assumption of the insensibility of $N_{-1}\,N_{+1}$ to ρ_{r-s} seems not to be permissible. Accordingly, insofar as it depends on the present approach based on the perturbation theory, the relation of Braude can be admitted only as a very rough approximation.

The dipole strength of the transition as a function of θ_{rs} has been calculated for the phenyl-carbonyl system, as well as for the vinyl-carbonyl system, by taking the value of δ_0 to be 1.3 and by applying the simple LCAO MO method to the whole conjugated system. In these calculations, all the valence angles at carbon atoms have been assumed to be 120°. In Figs. 2 and 3, the results of the calculation are shown graphically with solid lines, together with the analogous data for the styrene and butadiene systems for the sake of comparison.

21) C. A. Coulson, *Proc. Phys. Soc.*, **65**, 933 (1952).
22) R. Pariser, *J. Chem. Phys.*, **25**, 1112 (1956).

It is seen that the transition probability of the electron-transfer band of the phenyl-carbonyl system, as well as of the vinyl-carbonyl system, is slightly more sensitive to the steric hindrance than that of the conjugation band of the corresponding conjugated hydrocarbon system.

By the way, the calculated values (in Å^2) of M^2 at $\theta=0°$, i.e., $M^2(0°)$, are as follows: C_6–C=O, 1.984; C=C–C=O, s-trans, 1.794; s-cis, 1.140. The prefix s denotes that the steric arrangement is about the formally single bond between the ethylenic bond and the carbonyl bond. From the value of $M^2(0°)$, the oscillator strength (the f_{theor}-value) for the planar phenyl-carbonyl system, for example, is calculated to be 0.909. This value is to be compared with the f_{exp}-value of 0.310 for benzaldehyde estimated from the absorption curve reported in Part X[13] of this series. In this case, the ratio of f_{theor} to f_{exp} is 2.93, a value which is reasonable in view of the general trend of this ratio observed for some conjugated hydrocarbons in Part XII[7] of this series.

In Figs. 2 and 3, curves for $M^2(0°)\cdot\cos\theta$ and $M^2(0°)\cdot\cos^2\theta$ are also shown with dotted lines. It is seen that, for each system, the $M^2(\theta)$ curve lies between the cosine curve and the cosine-square curve, largely approaching the former.

As was mentioned in Part XII of this series, however, there seems to be a trend, the smaller the f-value, for the ratio of f_{theor} to f_{exp} to be slightly the greater, and also a trend, the greater the most probable angle of twist, for the ratio of f_{exp} to the molar extinction coefficient at the absorption maximum, ε_{max}, to be the greater. If these trends can be considered as holding in general, it may be expected that the value of ε_{max} decreases somewhat more rapidly with an increasing value of θ than would be anticipated from the calculated value of $M^2(\theta)$. Therefore, it is not imposible thet ε_{max} is approximately proportional to $\cos^2\theta$ rather than to $\cos\theta$.

Thus, it may be said that the relation, proposed by Braude on a quite unreasonable ground, has been given a theoretical support here to some extent. At any rate, such a relation should, of course, be considered to be a rough approximation, since it is an approximation to correlate the observed ε-value or the f_{exp}-value with the steric effect alone, neglecting the possible hyperchromic effect of an electronic origin of the substituent and the uncertainty of the values due to the probably poor resolvability of the band concerned from the neighboring bands.

Summary

It has been shown that the characteristic feature of the steric effect on the conjugation band in the case of the phenyl-carbonyl and vinyl-carbonyl systems, i.e., the relatively small hypsochromic shift and the relatively large decrease in the intensity of the band, as compared with that in the case of the conjugated hydrocarbon systems, can be adequately interpreted using the simple MO approach. From theoretical considerations it has especially been concluded that the proportionality of the intensity of the band to the cosine-square of the angle of twist of the formally single bond in these systems, formerly assumed by Braude, may be admitted as a rough approximation in spite of the invalidity of its original reasoning.

Photoreduction of Methylene Blue by Some Derivatives of N-Phenylglycine. Relation between the Structure and the Reactivity of the Electron Donors

By Shiro MATSUMOTO

(Received July 11, 1962)

It has been reported[1] that the photoreduction of methylene blue was effected in deaerated solutions by some chelating agents, including *N*-phenylglycine. To elucidate the mechanism of the photoreduction of dyestuffs and to understand, in general, the nature of the reactions of photo-excited species, it may be useful to investigate systematically the effects of changes in the structure of the reducing agent (the electron donor). *N*-Phenylglycine was chosen as a suitable starting material for this purpose, as its homologues and benzene ring-substituted derivatives are well characterized (loc. cit.) and are prepared easily in a fairly good crystalline state.

N-Phenylglycine becomes unstable to air-oxidation upon the introduction of electropositive substituents into the ortho- and para-positions of the benzene ring, while the introduction of electronegative substituents has the opposite effect. A solution of *N*-*p*-oxyphenylglycine soon assumes a brown color, especially when it is alkaline, while *N*-*p*-nitrophenylglycine can be heated in boiling water without any appreciable decomposition. It seems, therefore, that the rate of the photoreduction of the dyestuff in the presence of various benzene ring-substituted *N*-phenylglycines should increase in proportion to the order of the electron-repelling tendency of the substituents. The highest rate was observed, however, with unsubstituted *N*-phenylglycine. Both positive and negative substituents reduced the efficiency of the *N*-phenylglycine as a photoreductant.

This apparent contradiction can be explained by taking into account the possibility of the deactivation of the excited dye ions by the reductant ions. In fact, *N*-*p*-methoxyphenylglycine was found to have a remarkable retarding effect, comparable to that of *p*-phenylenediamine[1], upon the photoreduction of the dye by other reducing agents. It is shown in this paper that, if a customary reaction scheme is assumed, certain of its rate constants parallel Hammett's σ[2] value for the substituent.

Other kinds of derivatives of *N*-phenylglycine were also examined; it was found that the replacement of the hydrogen atom, either on the nitrogen or on the α-carbon atom of *N*-phenylglycine, by the methyl group did not deprive it of the ability to photoreduce the dye. These hydrogen atoms, therefore, do not take part in the photoreduction. On the other hand, the insertion of a methylene unit between the amino and the carboxyl group greatly reduced the ability.

Experimental

Benzene ring-substituted *N*-phenylglycines were prepared from the corresponding anilines either by the action of haloacetic acid or by Knoevenagel's[3] or Schwalbe's[4] method. *N*-Methyl-*N*-phenylglycine was prepared by the action of ethyl bromoacetate on dimethylaniline[5], followed by hydrolysis. It was separated as hydrochloride and purified in this form. α-Methyl-*N*-phenylalanine was prepared by the hydrolysis of the nitrile, which had been obtained by the action of potassium cyanide on the acetone in acetic acid[6]. *N*-Acetyl-*N*-phenylglycine was prepared by the acetylation of *N*-phenylglycine with acetic anhydride[7]. *N*-phenyl-β-alanine was prepared by the action of 3-bromopropanoic acid on aniline[8].

Methylene blue was a G. R. grade reagent from the Koso Chem. Co. and was used without further purification. Its molar extinction coefficient at 665 mμ was 8.16×10^4. *p*-Phenylenediamine hydrochloride was a G. R. grade reagent from the Kanto Chem. Co.

Photobleaching was followed, in an apparatus which was similar to that used by Pestemer[9], by some practical modification. The light source for the reaction was a 200 W./100 V. incandescent lamp operated at 78 V. This voltage was regulated to within 0.03 V. during a run. The light, filtered through a layer of water and an interference filter ($\lambda_{max.}$ 665 mμ, band width 12 mμ), fell on a reaction

cell in a thermostat kept to 40±0.1°C. The transmitted light was measured by a photocell to follow the change in the optical density. The thickness of the liquid layer was 15.5 mm., while the light intensity was estimated to be 2.2×10^{14} photons per cm^2 per sec. A metal net was inserted between the light source and the cell to reduce the light intensity if necessary. Deaeration was achieved by flushing with nitrogen as in Pestemer's[9] experiment.

Absorption spectra and total fluorescence intensity were measured by a Shimadzu Spectrophotometer QR 50.

Results and Discussion

A qualitative test showed that *N*-*p*-chlorophenylglycine (*p*-Cl-ϕ·G) would be more suitable than unsubstituted *N*-phenylglycine (ϕ·G) as a reference substance. The former was found to be more stable in air, though it caused the photobleaching nearly as effectively as the latter. Therefore, all the preliminary experiments to inspect various factors were performed with this substance as the electron donor.

1. Time Course of the Bleaching.—The change in the optical density, *D*, with time could be expressed quite well by the superposition of two exponential terms, as in the case of methylamines reported by Obata and Koizumi[10]. An example is shown in Fig. 1, in which the curve is drawn according to $D=0.1099\times10^{-0.00344t}+0.0220\times10^{-0.000787t}$. This fact may be explained most simply by assuming an intermediate that slowly accumulates during the course of the reaction[10]. However, to avoid complexity in treating the kinetic data and to minimize special assumptions, it may be convenient to consider, for the moment, only the early stage of the photoreduction.

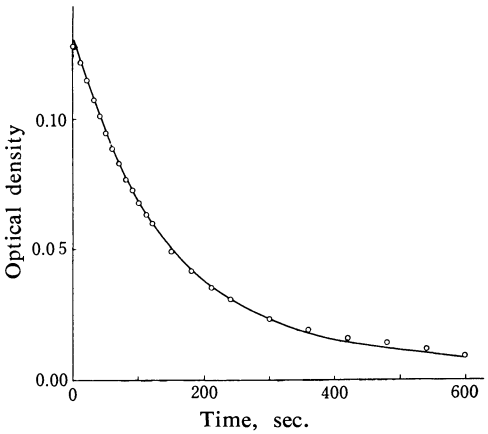

Fig. 1. Photobleaching of M.B.
M.B. 1.1×10^{-6} M, *p*-Cl-ϕ·G 1.0×10^{-4} M
pH 7.0 40°C

At this stage, such intermediates, if any, can safely be neglected. Therefore, Bodenstein's stationary state method may be used to derive the rate equation. Accordingly, tangents were drawn at time zero to the log *D* versus time curves, which were usually convex to an ordinate showing the deviations from the first order kinetics; the initial values of quautum yield Φ[11] were calculated from the slopes.

2. Effect of Light Intensity on Φ.—As is shown in Table I, a two-to three-fold variation in light intensity has little effect on Φ.

Table I. Effect of light intensity on ϕ
M.B. 1.5×10^{-6} M, *p*-Cl-ϕ·G 1.0×10^{4} M pH 7.0

Relative intens.*	1.00	0.55	0.34
Φ	0.150	0.157	0.147

* Stand. intens. 2.2×10^{14} photons/cm^2·sec.

3. Effect of Dye Concentration.—Table II shows that Φ is practically independent of the dye concentration in the $(1\sim5)\times10^{-6}$ mol./l. range.

Table II. Effect of dye concn. on Φ
p-Cl-ϕ·G 1.0×10^{-4} M. pH 7.0

Dye concn. $\times10^{6}$ M	0.92	1.53	3.13	5.47
Φ	0.141	0.150	0.150	0.130

4. Effect of the pH Value.—The points in Fig. 2 are taken from some preliminary experiments, where the concentrations of the methylene blue and *p*-Cl-ϕ·G were fixed arbitrarily at 1.5×10^{-6} and 1.0×10^{-4} mol./l. respectively. A maximum is observed at a pH value near 7.8. However, Φ depends also on the concentration of the electron donor. This matter will be described more fully in the next paper, together with the effect of buffer solutions.

11) Any inaccuracy in the determination of the absolute light intensity does affect the absolute values of Φ, but their relative values are of main interest here.

5. Dependence of Φ on the Concentration of the Electron Donor.—The dependence is expressed by the equation:

$$1/\Phi = 1/\Phi_0 + b/[E] \quad (1)$$

where Φ_0 and b are constants and [E] is the concentration of the electron donor. An example is shown in Fig. 3.

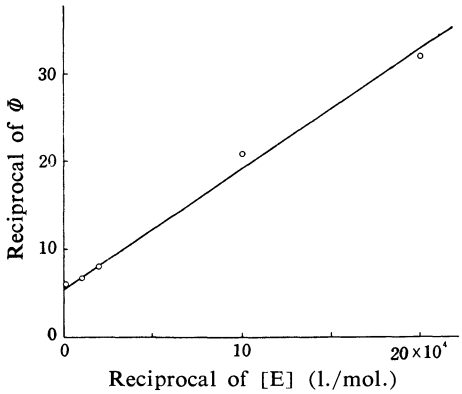

Fig. 3. Dependence of Φ on electron donor concn.
E: p-Cl-ϕ·G, pH 7.0 40°C

6. Dependence of Φ on the Structure of the Electron Donor.—In Table III are summarized the Φ's of the photoreduction by various *N*-phenylglycines and related compounds of the same molarity (10^{-4} mol./l. except for *N*-phenyl-β-alanine, for which 10^{-3} mol./l.). It is seen that the replacement of the hydrogen atom on the nitrogen or α-carbon atom of *N*-phenylglycine by a methyl group does not deprive it of its ability as a photoreductant. These hydrogen atoms are therefore, not included in photoreduction process; and reduction is probably initiated by electron transfer from the reducing ions to the excited dye cations. *N*-Acetylation reduces the ability, but this may be due either to steric effects or to the electron-attracting influence of the acetyl group (see below). The insertion of a methylene unit between the amino and the carboxyl group greatly reduces the ability as a photoreductant.

Table III also shows that both electropositive and electronegative substituents in the ortho- and para-positions reduce the effectiveness of the *N*-phenylglycine. Moreover, bromine-substitution in these positions has a much more pronounced effect than chlorine-substitution, though these two elements have nearly the same substituent effects in ordinary thermal reactions, as is seen in their similar Hammett σ[2] values. It may be added here that slow bleaching is observed even in the absence of any reducing agent (the quantum yield is of the order of 10^{-3} at a pH value of 7). Such slow bleaching is completely absent in the presence of *N*-*p*-methoxyphenylglycine (p-MeO-ϕ·G), while it is at least preserved in the case of *N*-*p*-nitrophenylglycine (p-NO_2-ϕ·G). These facts suggest the parallel occurrence of the retardation by the reductants themselves. It is also interesting that the effect of substituents is much smaller in meta-substitution than in ortho- and para-substitutions. It is especially ramarkable that *N*-*m*-methoxyphenylglycine (m-MeO-ϕ·G) normally photoreduces the dye.

In regard to the high efficiencies of *N*-phenylglycines in the photoreduction, a question arises whether any complex is formed between *N*-phenylglycines and the dye in its ground state, the complex being ready to undertake inner oxidation-reduction upon the absorption of light. To check this point, the absorption spectra of the reaction mixtures were examined, together with those of the components from the ultraviolet end to the red end of the

visible region. As may be seen in Figs. 4 and 5, a good additivity holds in the entire region. No sign of complex formation is observed.

The following scheme may tentatively be assumed as the simplest for describing the reaction sequences:

$$\begin{array}{ccccccc} & & \overset{k_2}{\longrightarrow} & & \overset{k_r[E]}{\longrightarrow} & & \\ D^{+*} & & & D^{+t} & & M & \longrightarrow \text{Red. Prod.} \\ h\nu \uparrow\downarrow k_1 & & & k_s+k_d[E] & & \gamma_E & \\ D^{+} & \longleftarrow & & \longleftarrow & & & \end{array}$$

where D^+ is the dye cation in the ground state, and D^{+*} is that in its first electronically-excited singlet state. A second metastable excited state, D^{+t}, is assumed for the same reason as in some other cases[9,12]. It was confirmed that the fluorescence intensity of methylene blue was little affected by the addition of *p*-Cl-ϕ·G or *p*-MeO-ϕ·G up to a concentration of 10^{-4} mol./l.

The rate constants of deactivation, k_1 and k_s, may contain terms that correspond to the deactivation by the emission of radiation, as well as terms corresponding to radiationless deactivation. The deactivation of D^{+t} must be enhanced by E (an electron donor), as is stated above, which is represented by the term, $k_d[E]$. Adding a term representing the deactivation of D^{+*} by E is not justifiable because that will lead to a rate equation that has not the simple form of Eq. 1. The reduction of D^{+t} may take place via intermediate, M, some fraction of which may foil to give the reduction product. The fraction of M's that succeeds in getting to the final product is denoted by γ_E.

Therefore, Φ may be expressed according to Bodenstein's approximation:

$$\Phi=\varphi\cdot\frac{k_r[E]}{k_s+(k_d+k_r)[E]}\cdot\gamma_E \qquad (2)$$

where $\varphi=k_2/(k_1+k_2)$ may be said to be the quantum yield of the first stage. Equation 2 is identical with Eq. 1, if $\Phi_\infty=\varphi\cdot\gamma_E\cdot k_r/(k_d+k_r)$ and $1/b=\varphi\gamma_E\cdot k_r/k_s$. Φ_∞ is the quantum yield extrapolated for infinite electron

donor concentration and is naturally the Φ when k_s is neglected compared with (k_d+k_r) [E]. In this kinetic scheme, $1/b$ represents the relative effectiveness of ϕ·G's as a photoreductant, if k_s is independent of the nature of the added substances. These quantities can be obtained from plots similar to those in Fig. 3.

The results are summarized in Table IV. As is seen in the table, *o*- and *p*-Br-ϕ·G, for which unexpectedly small Φ values were observed, have small Φ_∞ values, which implies large k_d values.

7. Direct Measurement of the Retardation by *N*-Phenylglycines.—The retarding action of *N*-phenylglycines is demonstrated in the plots of Fig. 6, where Φ is measured in a system containing 1.5×10^{-6} mol./l. of methylene blue and 1.0×10^{-4} mol./l. of *p*-Cl-ϕ·G, to which are added various concentrations [E'] of retarding ϕ·G's. When [E'] $=0$, the system bleaches with $\Phi=0.150$. Φ decreases, in general, by the addition of ϕ·G's, which were above suspected of retarding action. The effect of *p*-MeO-ϕ·G is most remarkable; it shows only a retarding action. The efficiency is comparable to that of the well-known retarder *p*-phenylenediamine (PPD)[1]. The retarding ratio $R_{ret}=\Phi_0/\Phi$ (Φ_0 and Φ are the quantum yields in the absence and in the presence of retarders respectively) with 10^{-5} mol./l. of PPD was 1.88, whereas that with *p*-MeO-ϕ·G was 1.79. It is interesting that *p*-MeO-ϕ·G is isoelectronic with PPD. Other ϕ·G's, e. g., *p*-Br-ϕ·G, cause photobleaching by themselves. If it is assumed that these ϕ·G's compete with *p*-Cl-ϕ·G in reacting with D^{+t}, the equation for Φ is modified as follows:

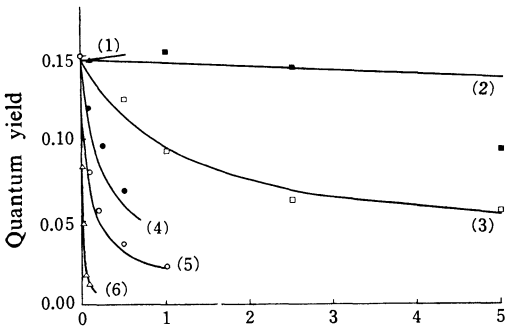

Fig. 6. Retardation by *N*-phenylglycines.
Test soln. contains: *p*-Cl-ϕ·G 1.0×10^{-4} M, retdg.
ϕ·G's [E'] M and M. B. 1.5×10^{-6} M pH 7.0
(1) *m*-NO_2-ϕ·G (2) *p*-NO_2-ϕ·G (3) *N*-ϕ-β-alanine (4) *o*-Br-ϕ·G (5) *p*-Br-ϕ·G (6) *p*-MeO-ϕ·G

$$\Phi=\varphi\cdot(\gamma_E\cdot k_r[E]+\gamma_E' k_r'[E'])/\{k_s+(k_d+k_r)[E]+(k_d'+k_r')[E']\}$$

where k_d', k_s' and γ_E' are the quantities corresponding to k_d, k_s and γ_E respectively for the second ϕ·G.

Or

$$\Phi=\varphi\cdot\frac{[E]/b+[E']/b'}{1+[E]/(b\cdot\Phi_\infty)+[E']/(b'\cdot\Phi_\infty')} \quad (3)$$

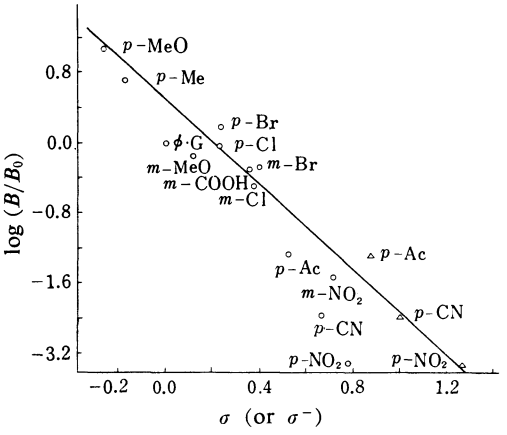
Again, b' and Φ_∞' correspond to b and Φ_∞ respectively. This relation could be checked by the insertion of the values of b, Φ_∞, b' and Φ_∞' given in Table IV. The curves in Fig. 6 are drawn to show this calculation. They coincide, at least qualitatively, with the experimental results. Φ_∞ and b could not be determined directly for *p*-MeO-ϕ·G and *N*-phenyl-β-alanine. In these cases, the insertion of the b and Φ_∞ values of *p*-Cl-ϕ·G into Eq. 3 gave:

$$\Phi=(0.739+A[E'])/(5.00+B[E'])$$

where $A=1/b'$ and $B=1/(b'\cdot\Phi_\infty')$. A and B were then determined, so that the best fit was obtained in Fig. 6. This required $B=5.29\times10^5$ and $A\fallingdotseq0$ for *p*-MeO-ϕ·G and $B=4.31\times10^3$ and $A=1.40\times10^2$ for *N*-phenyl-β-alanine respectively.

8. Reactivities of *N*-Phenylglycines and Hammett's σ Value.—The B quantity given above has a simpler kinetic meaning than either $1/b$ or Φ_∞ has; i. e., $B=1/(b\cdot\Phi_\infty)=(k_d+k_r)/k_s$. It is the sum of the rate constants for the reduction and deactivation of D^{+t} by the ϕ·G concerned, divided by the rate constant for the spontaneous deactivation. The value of k_s may be independent of the nature of the ϕ·G. Thus, B represents the relative total reactivity of the ϕ·G with D^{+t}.

Some relation might be sought between this value and Hammett's σ for the substituent in the benzene ring. The plots of $\log(B/B_0)$ versus σ are given in Fig. 7, where B_0 is the B



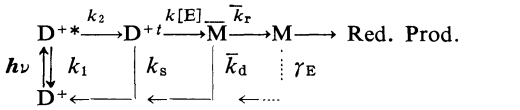


Fig. 7. Hammett's σ and the reactivity of *N*-phenylglycines.
○: σ △: σ^- pH 7.0 40°C

for the unsubstituted *N*-phenylglycine. It is seen that the points arrange near a straight line, the σ^- values giving better fits for the +E substituents. This might indicate the importance of the lone pair of electrons on the nitrogen atom of *N*-phenylglycine in the first stage of interaction with D^{+t} [13]. Although the detailed reason must be kept unspecified until other physico-chemical studies throw light from other angles on this problem, it is, nevertheless, interesting that a relation like Hammett's rule is found in a photochemical process.

The above considerations may be consistent with a kinetic scheme written in a more detailed form than the previous one:

where a step is imagined in which D^{+t} forms a loose complex, M, with E before it is either reduced or deactivated by E. Then,

$$\Phi=\varphi\{k[E]/(k_s+k[E])\}\times\{\bar{k}_r/(\bar{k}_d+\bar{k}_r)\}\ \gamma_E \quad (4)$$

and $k_d=k\cdot\bar{k}_d/(\bar{k}_d+\bar{k}_r)$ and $k_r=k\cdot\bar{k}_r/(\bar{k}_d+\bar{k}_r)$ correspond; i. e., Eq. 4 becomes identical with Eq. 2 with these substitutions. B becomes simply k/k_s, and the rate constant of the complex formation k bears a regular relation to δ irrespective of the $\bar{k}_r/\bar{k}_d$ ratio.

9. Evaluation of the Life-time of D^{+t}.— The retardation data with PPD may be used to estimate the lower limit of $1/k_s$, the life-time of the metastable state D^{+t}, using the method described by Oster and Adelman[12], in which it is assumed that the reaction is diffusion-controlled and that every collision of a PPD molecule with D^{+t} effectively deactivates the latter. It is easy to derive

$$R_{ret}=\Phi_0/\Phi=1+\frac{k_q/k_s}{1+\{(k_d+k_r)/k_s\}[E]}\cdot[X] \quad (5)$$

where X represents PPD or another quencher molecule and [X] is its concentration. The rate of the deactivation of D^{+t} is supposed to increase by a term of $k_q[X]$. Φ_0 is the Φ when $[X]=0$. As is stated above, $R_{ret}=1.88$ for $[X]=10^{-5}$ mol./l. and $[p\text{-Cl-}\phi\cdot G]=10^{-4}$ mol./l. As $(k_d+k_r)/k_s=1/(b\cdot\Phi_\infty)=4.00\times10^4$ l./mol. for p-Cl-$\phi\cdot$G (Table IV), Eq. 5 gives $k_q/k_s=4.4\times10^5$ l./mol. The number of collisions of a D^{+t} with X molecules in a unit of time is given as $(8RT/3\eta)\cdot[X]\times10^{-3}$ [12] by the use of Smoluchowski's theory of diffusional collisions and Einstein's theory of diffusion, together with the simplifying assumptions that the reacting species are spherical and equal in size, with encounter radii equal to their diffusional radii. R and η are the gas constant and the viscosity of the medium respectively. Hence, $k_q\leqq(8RT/3\eta)\times10^{-3}$. If $T=313$ and $\eta=6.56\times10^{-3}$ poise, this gives $k_q\leqq1.06\times10^{10}$ sec^{-1}, so that $\tau=1/k_s\geqq4.2\times10^{-5}$ sec., which is of a reasonable order of magnitude for a triplet of the dye in aqueous solutions at ordinary temperatures. If $1/k_s=4.2\times10^{-5}$ sec., then k_d+k_r is determined. For example, it is 9.6×10^8 l./mol. for p-Cl-$\phi\cdot$G.

Summary

The photobleaching of methylene blue in the presence of various derivatives of *N*-phenylglycine has been examined to investigate the relation between the structure and the reactivity of the electron donor and to get information about the nature of the photoreaction. The time course of the photobleaching is well expressed by the superposition of two terms decreasing exponentially with time.

The hydrogen atom on the nitrogen or α-carbon atom of the *N*-phenylglycine molecule seems to take no part in the photoreduction process, and the first stage is probably the electron transfer between the interacting species.

As judged from the initial quantum yield, Φ, of the photoreductions, the influence of substituents in the ortho- and para-positions of the benzene ring is much larger than that in the meta-position. Both electropositive and electronegative substituents reduce Φ. The small Φ in the former cases is attributed to the ability of such $\phi\cdot$G's to deactivate the excited dye ions. From spectral data, no sign of complex formation between $\phi\cdot$G's and unexcited dye molecules can be inferred. The fluorescence of methylene blue is not quenched by $\phi\cdot$G's in the range of concentrations used in the photochemical reaction. In view of these results, the kinetic data are treated by use of a current kinetic scheme, when a relation akin to Hammett's rule is found between a certain rate constant and the σ value of the substituent in the benzene ring of the *N*-phenylglycine.

Kinetic data are also used to estimate the life-time of the metastable excited state of the dye, which is calculated to be about 4.2×10^{-5} sec. or longer. This value is in a range reasonable to be interpreted as that of the lowest triplet state of the dye.

Effect of the pH Value on the Rate of the Photoreduction of Methylene Blue by N-Phenylglycines

By Shiro MATSUMOTO

(Received July 11, 1962)

In the preceding paper, a preliminary result was described as to the dependence of the initial quantum yield, Φ, of the photoreduction of methylene blue by *N*-phenylglycines on the pH value of the medium. As Φ does not vary linearly with the concentration of electron donors, it is not sufficient to investigate the problem only at a definite electron donor concentration. The ionization of the *N*-phenylglycines is another factor to be studied. Moreover, Φ will also depend on the nature and concentrations of the buffer solutions. It is the object of this paper to investigate these factors in some detail.

Experimental

The photobleaching apparatus and the experimental method were the same as those described in the preceding paper. A Shimadzu Glass Electrode Potentiometric Titrator PT-1 was used to measure the pH value of solutions. Reagents for the buffer solutions were obtained from the Kanto Chem. Co., Inc. The phosphates were of the G. R. grade "for pH determination," while the others were of E. P. grades. The borax was recrystallized once from water. Corrections for ionic strength were made with sodium chloride which was also a G. R. reagent from the Kanto Chem. Co., Inc.

Results and Discussion

1.—First, two orienting experiments were carried out.

a. Dissociation of N-Phenylglycines.—Figure 1 shows the titration curve of *N*-phenylglycine (10^{-2} mol./l.) with a 0.0553 N sodium hydroxide solution. The points agree fairly well with the calculated curve for monobasic acid of pK_a 4.3, except in alkaline regions, where the deviation is probably due to the effect of atmospheric carbon dioxide. It is evident, therefore, that *N*-phenylglycine exists only in a definite form, $C_6H_5NH\cdot CH_2\cdot COO^-$, in aqueous solutions with pH values within the 5.9~10.5 range, where the experiments were performed.

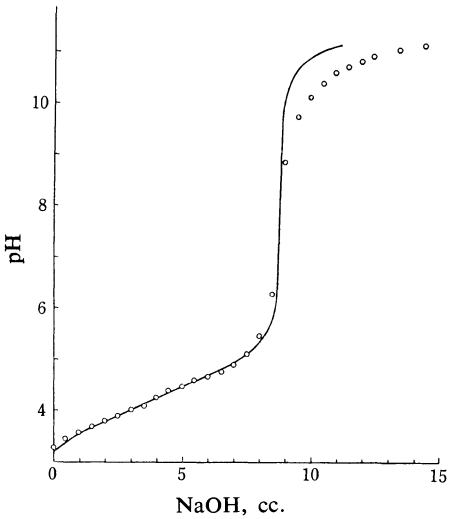

Fig. 1. Base titration of *N*-phenylglycine.

3.8	3.7	(3.7)*

* The pH of half titrated soln. Ionization of the two COOH-groups cannot be separated titrimetrically.

Such other forms as $C_6H_5NH\cdot CH_2\cdot COOH$ and $C_6H_5NH_2^+\cdot CH_2\cdot COO^-$ may be neglected in this study. Similar experiments gave the pK_a values of various *N*-phenylglycines; these are listed in Table I.

b. Effect of the Concentration of Buffer Solutions and Ionic Strength. — The quantum yield, Φ, of the photoreduction was measured in buffer solutions of three different concentrations at various pH values. The ionic strength, μ, was designed to be constant. The results are shown in Fig. 2, which clearly shows the effect of buffer concentration. It is

TABLE II. EFFECT OF IONIC STRENGTH ON Φ

μ (g. ion./l.)	0.049	0.074	0.149	0.449
Φ	0.159	0.162	0.144	0.139

especially marked at the lower end of the pH region. The effect of ionic strength at a constant buffer concentration is shown in Table II. It is seen that the effect is within the range of experimental error for $\mu<0.1$ g. ion/l.

To avoid the above complexity, it would be best, theoretically, to use the Φ's extraporated to those in infinitely dilute buffer solutions. However, this procedure would be too troublesome to be practicable, and the errors in the extrapolation might be appreciable. Accordingly, the following experiments were performed in buffer solutions in which the total phosphate, borate or carbonate concentration and the ionic strength were maintained at constant and minimum practical values.

2. Dependence of Φ_∞, $1/b$ and B on pH Value. —At every pH value the following relation[1] holds:

$$1/\Phi=1/\Phi_\infty+b/[\mathrm{E}]$$

where [E] is the concentration of the electron donor and Φ_∞ and b are constants for the particular conditions. Φ_∞ and b naturally

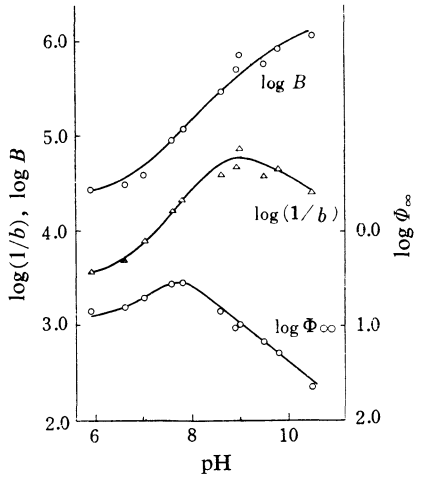

Fig. 3. Dependence of Φ_∞, $1/b$ and B on pH.
Electr. donor p-Cl-ϕ·G M. B. 2.5×10^{-6} M
40°C

depend on the pH value. In Fig. 3 their values and the $B=1/(\Phi_\infty\cdot b)$ value[1] for *N*-*p*-chlorophenylglycine are plotted on a logarithmic scale against the pH values. The dependence of Φ_∞ on the pH value is similar to that of Φ measured at a definite electron donor concentration. This is in contrast to Oster's[2] results with EDTA, where Φ_∞ was independent of the pH value. On the other hand, $\log(1/b)$ and $\log B$ increase markedly with an increase in the pH value. $\log B$ increases especially steadily and is linear with the pH value in the 7~9 range[3]. The slope is approximately 0.51. Figure 4 shows similar results with *N*-phenylglycine. In this case, the variation of Φ_∞ is smaller, but the slope of $\log B$ against the pH value is nearly the same. Figure 5 shows the results with *N*-*p*-acetylphenylglycine, which has a much smaller reactivity[1] than the above two *N*-phenylglycines. The slope of $\log B$ is approximately 0.45.

To see whether the linear dependence of $\log B$ on the pH value is a general occurrence, it is desirable to investigate also with other simple molecules. Methylamines are the simplest, but their dissociation constants are comparatively large, and for the study with uniform ionic species[4], the bleaching must be measured in a region of higher pH value,

1) Cf. (the preceding paper) S. Matsumoto, 35, 1860 (1962).

2) G. Oster and N. Wotherspoon, *J. Am. Chem. Soc.*, 79, 4836 (1957).

3) At higher pH values, the photobleaching of methylene blue occurs appreciably in the absence of any reductant, and rigorous treatment of the data is more difficult, unless the nature of such bleaching is definitely established, than at a low pH value where the photobleaching is negligible in the absence of a reductant. In the above calculation of Φ, such a bleaching rate was merely subtracted, for the moment, as 'blanck' from the total bleaching rate.

4) Cf. section 1, a of this paper.

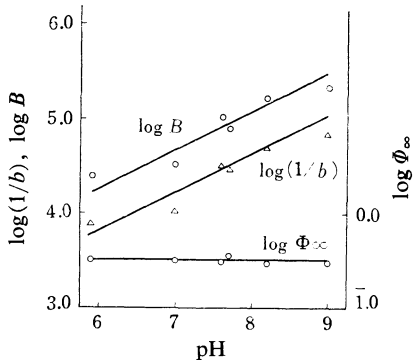

Fig. 4. Dependence of Φ_∞, $1/b$ and B on pH. Electr. donor ϕ·G M. B. 2.5×10^{-6} M 40°C

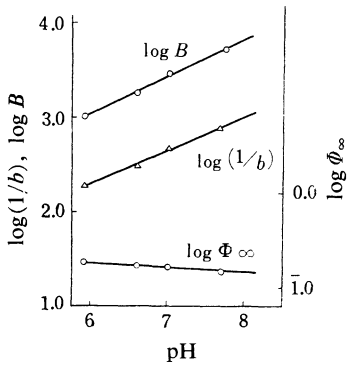

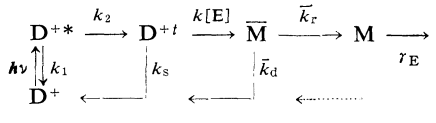

Fig. 5. Dependence of Φ_∞, $1/b$ and B on pH. Electr. donor *p*-Ac-ϕ·G M. B. 2.5×10^{-6} M 40°C

where another complexity arises[3]. Among the several substances tested, semicarbazide was found to have ability as a photoreductant and also to have a low ionization constant: $pK_b=10.6$[5]. Its effectiveness was, however, very much smaller than that of the *N*-phenylglycines. The results are shown in Fig. 6. It is interesting that the pH value dependences of Φ_∞, $1/b$ and B are similar for this different kind of substance. The slope of log B against the pH value is, however, much smaller (ca. 0.1) than those in the preceding cases.

Let the following scheme be assumed as in the preceding paper:

Then,

$$\Phi=\varphi\cdot\gamma_E\{k[E]/(k_s+k[E])\}\{\bar{k}_r/(\bar{k}_d+\bar{k}_r)\}$$

$$\Phi_\infty=\varphi\cdot\gamma_E\cdot\bar{k}_r/(\bar{k}_d+\bar{k}_r)$$

$$1/b=\varphi\cdot\gamma_E(k/k_s)\{\bar{k}_r/(\bar{k}_d+\bar{k}_r)\}$$

5) N. A. Lange, "Handbook of Chemistry", 8th Ed., Handbook Publishers, Inc., Sandusky, Ohio (1952), p. 1235.

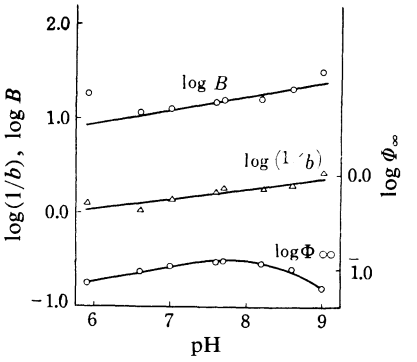

Fig. 6. Dependence of Φ_∞, $1/b$ and B on pH. Electr. donor $NH_2\cdot CO\cdot NH\cdot NH_2$ M. B. 2.5×10^{-6} M 40°C

and $$B=k/k_s$$

The simpler dependence of B is in accord with the simpler expression of B than those of Φ_∞ and $1/b$.

If k_s is independent of the pH value, then

$$\partial \log B/\partial pH=\partial \log k/\partial pH$$

In most of the cases described above, this slope is approximately 0.5, so that $k\propto\sqrt{[OH^-]}$. This may suggest the contribution of OH^- in the reaction: $D^{+t}+E\rightarrow\bar{M}$, though the true nature is uncertain as yet.

Summary

The effect of the pH value on the rate of the photoreduction of methylene blue by *N*-phenylglycines was studied in detail in the range between 5.9 and 10.5, attention being paid to the effects of buffer solutions and to a possible change in the ionic species of *N*-phenylglycines with the change in pH value. *N*-Phenylglycine behaved as a monobasic acid of pK_a 4.3 to base titration, so that it existed solely as a univalent anion $C_6H_5NH\cdot CH_2COO^-$ in this pH value range. The pK_a of several other *N*-phenylglycines was given also. The concentration and ionic strength of the buffer solutions had some effect; they must be kept constant and as small as possible.

With these precautions, the pH value dependences of Φ_∞, $1/b$ and $B=1/(\Phi_\infty\cdot b)$, which characterize the quantum yield of the photoreduction, were determined for several electron donors. They were similar in all cases. Semicarbazide was found to be effective as an electron donor for this photoreduction. Log B varied linearly with the pH value in the pH range between 7.0 and 9.0. The slopes were nearly 0.5 for all the *N*-phenylglycines studied. This means that, if the excited metastable state of the dye formed a complex before the oxidation-reduction reaction, the rate constant of

its formation must vary as the root of the hydroxide ion concentration.

The auther is indebted to Professor Ikuzo Tanaka of the Tokyo Institute of Technology and to Professor Masao Koizumi of Tohoku University for their helpful discussions and constant encouragement during this work.

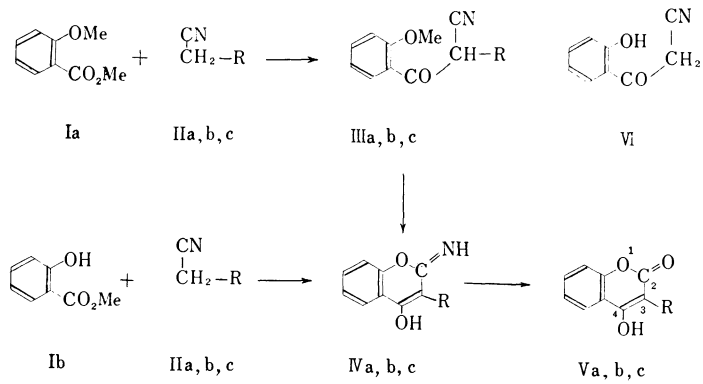
Reactions of Active Methylene Compounds. VIII. A New Route to 3-Alkyl-4-hydroxycoumarins



By Yoshiyuki KAWASE and Kazuko SAKASHITA

(Received July 16, 1962)

In previous papers[1], one of the present authors has reported the synthesis of 3-aryl-4-hydroxycoumarins by the ester condensation of methyl *o*-methoxy- or *o*-hydroxy-benzoate and phenylacetonitriles, followed by the ring closure of the condensation products. Now the method has been applied, with some modifications, to the synthesis of 3-alkyl-4-hydroxycoumarins (V).

For the preparation of 3-alkyl-4-hydroxycoumarins, several methods have hitherto been reported: (a) by the reaction of *o*-acetoxybenzoyl chlorides with ethyl alkylmalonates, alkylacetoacetates or alkylcyanoacetates, followed by hydrolysis[2], (b) by the ring closure of *o*-acyloxybenzoates[3], (c) by the reaction of alkyl *o*-hydroxyphenyl ketones with ethyl carbonate[4] or with carbon dioxide and potassium carbonate[5], and (d) by the reaction of phenols with ethyl alkylmalonates[6] or by the ring closure of phenyl alkylmalonates[7].

For the present paper the authors synthesized 3-alkyl-4-hydroxycoumarins (Va, b, c) by two similar routes. In one route, the ester condensation of methyl *o*-methoxybenzoate (Ia) and nitriles (IIa, b, c) gave α-(*o*-methoxybenzoyl)-nitriles (IIIa, b, c) in a good yield by a method analogous to that reported by Hauser et al.[8] for ester condensation; one mole of ester Ia was made to react with the sodio compound prepared from 2.5 mol. of sodium amide and 2 mol. of nitrile II in liquid ammonia. In this procedure, care was taken to prevent the formation of *o*-methoxybenzamide and the

self-condensation of the nitrile. On the other hand, only poorer yields were obtained by the method reported previously for phenylacetonitriles[1] in which sodium hydride was used in benzene. The nitriles III were then demethylated by anhydrous aluminum chloride in nitrobenzene to give 3-alkyl-4-hydroxycoumarin-2-imides (IVa, b, c), which were readily hydrolyzed by dilute hydrochloric acid to 3-alkyl-4-hydroxycoumarins (Va, b, c). The intermediate *o*-hydroxybenzoyl-acetonitrile (VI) was isolated in the case of *o*-methoxybenzoylacetonitrile (IIa).

By another route, the ester condensation of methyl salicylate (Ib) and nitriles IIa, b, c directly gave the imides IVa, b, c in a fairly good yield by means of sodium amide in liquid ammonia.

Attempted condensations of Ia or Ib and dinitriles (e. g., malono-, succino-, glutaro- and adipo-nitriles) failed, furnishing only the self-condensed products of nitriles.

Experimental*

o-Methoxybenzoylacetonitrile (IIIa). — *a) By Sodium Amide in Liquid Ammonia.*—A solution of acetonitrile IIa (3 g., 0.072 mol.) in an equal volume of anhydrous ether was stirred over a period of 5 min. into a solution of sodium amide in liquid ammonia (prepared from 2.1 g. (0.09 mol.) of sodium and 50 ml. of ammonia) and then cooled in dry ice-acetone. After 5 min., a solution of *o*-methoxybenzoate (Ia) (6 g., 0.036 mol.) in an equal volume of ether was added rapidly, and the stirring and cooling were continued for one hour The ammonia was then removed, and the residue was treated with ice water. The aqueous solution obtained was washed with ether, filtered and acidified with dilute hydrochloric acid. The crystalline product obtained was washed with aqueous sodium bicarbonate and then recrystallized from ethanol to give IIIa in the form of colorless needles; m. p., 86~87°C; yield, 5.3 g. (84%). The reported m. p. is 87°C[9].

Found: N, 8.28. Calcd. for $C_{10}H_9O_2N$: N, 8.00%.

b) By Sodium Hydride in Benzene.—A mixture of Ia (8.4 g., 0.05 mol.), sodium hydride (1.8 g., 0.075 mol.) and anhydrous benzene (100 ml.) was refluxed for 2 hr., and for a further 5 hr. after the addition of IIa (3.1 g., 0.075 mol.). The cooled mixture was treated with water, and the aqueous layer obtained was acidified with hydrochloric acid. The crystalline product formed was washed with aqueous sodium bicarbonate and recrystallized from ethanol; m. p., 84.5~85.5°C; yield, 2.4 g. (27.4%).

α-(o-Methoxybenzoyl)propionitrile (IIIb). —*a) By Sodium Amide.* — Ia (7.5 g., 0.045 mol.) was made to react in a manner similar to that described for IIIa, with the sodio compound prepared from 2.6 g. (0.11 mol.) of sodium and 5 g. (0.09 mol.) of propionitrile (IIb) in liquid ammonia; the oily product formed by acidifying the aqueous alkaline solution was taken up in ether. The ether solution was washed with aqueous sodium bicarbonate, the solvent was removed, and the residual product was distilled in a high vacuum to give IIIb as colorless oil; b. p., 100~150°C/0.003 mmHg; yield, 6.8 g. (80%). 2,4-Dinitrophenylhydrazone: yellow microcrystals; m. p., 167~168°C (from ethanol).

Found: C, 55.48; H, 4.20; N, 19.08. Calcd. for $C_{17}H_{15}O_5N_5$: C, 55.28; H, 4.09; N, 18.96%.

b) By Sodium Hydride.—By the same procedure, 4.5 g. (36.8%) of IIIb (b. p., 100~124°C/0.001 mmHg) were obtained from Ia (10.7 g., 0.065 mol.), sodium hydride (3.3 g., 0.13 mol.) and IIb (3.5 g., 0.065 mol.).

α-(o-Methoxybenzoyl)butyronitrile (IIIc). — *a) By Sodium Amide.*—By the same procedure, 1.4 g. (57%) of IIIc (a colorless oil; b. p., 150~160°C/0.0035 mmHg) were obtaind from sodium (0.7 g., 0.03 mol.), IIc (1.7 g., 0.024 mol.) and Ia (2 g., 0.012 mol.). 2,4-Dinitrophenylhydrazone: yellow microcrystals; m. p., 128~129°C (from ethanol).

Found: C, 56.41; H, 4.55; N, 18.56. Calcd. for $C_{18}H_{17}O_5N_5$: C, 56.39; H, 4.47; N, 18.27%.

b) By Sodium Hydride.—By the same procedure, 0.9 g. (35%) of IIIc was obtained from Ia (2.1 g., 0.0125 mol.), sodium hydride (0.6 g., 0.025 mol.) and IIc (0.9 g., 0.0125 mol.).

4-Hydroxycoumarin-2-imide (IVa). — *a) From Methyl Salicylate (Ib) and IIa.*—Ib (2.5 g., 0.0165 mol.) was made to react in a manner similar to that described for IIIa with the sodio compound prepared from 1.3 g. (0.058 mol.) of sodium and 1.4 g. (0.033 mol.) of IIa in liquid ammonia. The ammonia was removed, and the residue was treated with water; the aqueous solution was filtered, washed with ether, and warmed for a while. The crystalline product separated was collected and recrystallized from ethanol to give IVa as colorless needles (m. p. 275°C (decomp.)), which were soluble in dilute hydrochloric acid; yield, 1 g. (38%).

Found: C, 66.81; H, 4.43; N, 8.97. Calcd. for $C_9H_7O_2N$: C, 67.07; H, 4.38; N, 8.69%.

b) From IIIa.—Powdered anhydrous aluminum chloride (3 g.) was added to a solution of IIIa (1 g.) in nitrobenzene (10 ml.), and the mixture was heated on a steam-bath for 1.5 hr. The cooled solution was then treated with ice water, the nitrobenzene was removed by steam-distillation, and the residual product was dissolved in ethyl acetate. The ethyl acetate solution was washed with aqueous sodium bicarbonate and then extracted with aqueous sodium hydroxide. From the ethyl acetate solution, 0.2 g. (23%) of IVa was obtained (m. p., 272~273°C (decomp.), identical with the other sample). The crystals obtained by acidifying the sodium hydroxide solution were recrystallized from ethanol to give 0.1 g. of *o*-hydroxybenzoylacetonitrile (VI) as colorless microcrystals (m. p., 108~109°C), which gave a red ferric chloride reaction in ethanol.

Found: C, 66.90; H, 4.75; N, 8.32. Calcd. for $C_9H_7O_2N$: C, 67.07; H, 4.38; N, 8.69%.

This VI was readily converted into IVa by warming its sodium hydroxide solution for a while.

* Melting and boiling points are uncorrected.

9) R. S. Long, *Chem. Abstr.*, **40**, 2634 (1946).

3-Methyl-4-hydroxycoumarin-2-imide (IVb).—*a) From Ib and IIb.*—By the same procedure, 5.9 g. (74.4%) of IVb were obtained from Ib (7 g., 0.046 mol.) and the sodio compound prepared from 3.7 g. (0.161 mol.) of sodium and 5.1 g. (0.092 mol.) of IIb in liquid ammonia (colorless microcrystals; m. p., 238~241°C (from dilute ethanol)).

Found: C, 68.47; H, 5.37; N, 7.93. Calcd. for $C_{10}H_9O_2N$: C, 68.56; H, 5.18; N, 8.00%.

b) From IIIb.—By the same procedure, 0.3 g. (37.7%) of IVb (m. p., 235~239°C) was obtained from 1 g. of IIIb.

3-Ethyl-4-hydroxycoumarin-2-imide (IVc).—*a) From Ib and IIc.*—By the same procedure, 0.6 g. (16.5%) of IVc was obtained from Ib (2.9 g., 0.019 mol.) and the sodio compound prepared from 1.5 g. (0.065 mol.) of sodium and 2.6 g. (0.038 mol.) of IIc in liquid ammonia (colorless microcrystals; m. p., 192~193.5°C (from dilute ethanol)).

Found: C, 69.39; H, 5.77; N, 7.80. Calcd. for $C_{11}H_{11}O_2N$: C, 69.82; H, 5.86; N, 7.40%.

b) From IIIc.—By the same procedure, 0.1 g. (21.5%) of IVc (m. p., 185~186°C) was obtained from IIIc (0.5 g.) and aluminum chloride (1.5 g.).

4-Hydroxycoumarin (Va).—*a) From IVa.*—A solution of IVa (0.5 g.) in 2 N hydrochloric acid (20 ml.) was heated on a steam-bath for 2 hr. The crystalline product separated from the cooled solution was recrystallized from dilute ethanol to give Va in the form of colorless needles; m. p., 208.5~209.5°C, identical with the authentic sample; yield, 0.3 g. (60%). The reported m. p. is 204~206°C[2] or 214~216°C[3].

Found: C, 66.61; H, 3.84. Calcd. for $C_9H_6O_3$: C, 66.67; H, 3.73%.

b) From IIIa.—Powdered anhydrous aluminum chloride (3 g.) was added to a solution of IIIa (1 g.) in nitrobenzene (10 ml.), and the mixture was heated on a steam-bath for 1.5 hr. The cooled solution was treated with ice water and hydrochloric acid, and the nitrobenzene was removed by steam-distillation. The crystalline product obtained from the cooled residue was recrystallized from ethanol; m. p., 205~207°C; yield, 0.5 g. (54.3%).

3-Methyl-4-hydroxycoumarin (Vb).—*a) From IVb.*—By the same procedure, 0.35 g. (70%) of Vb was obtained from IVb (0.5 g.); colorless crystals; m. p., 225~227°C (from dilute ethanol). The reported m. p. is 227~228°C[3] or 230°C[6].

Found: C, 68.10; H, 4.53. Calcd. for $C_{10}H_8O_3$: C, 68.18; H, 4.58%.

b) From IIIb.—By the same procedure, 0.4 g. (43%) of Vb was obtained from 1 g. of IIIb.

3-Ethyl-4-hydroxycoumarin (Vc).—*a) From IVc.*—By the same procedure, 0.2 g. (66.7%) of Vc was obtained from IVc (0.3 g.); colorless crystals; m. p., 157~158°C (from benzene). The reported m. p. is 155~156°C[3].

Found: C, 69.52; H, 5.25. Calcd. for $C_{11}H_{10}O_3$: C, 69.46; H, 5.30%.

b) From IIIc.—By the same procedure, 0.2 g. (43%) of Vc (m. p., 156~157°C) was obtained from 0.5 g. of IIIc and 1.5 g. of aluminum chloride.

Photosensitized Oxidation of Leuco-uranine. I. Qualitative Studies of the Nature of the Reaction in the Deaerated Solution

By Kengo UCHIDA and Masao KOIZUMI

(Received March 12, 1962)

In a previous paper[1], the present authors joined in studying some properties of leuco-uranine prepared by reducing uranine with the use of sodium amalgam. It was found that the aqueous solution of it is rather stable in the presence of dissolved oxygen but that it is easily oxidized to the colored form by adding some suitable sensitizer to the solution and by then irradiating with the light appropriate to the sensitizer. A remarkable result then found was that the restoration of the color also takes place in the absence of oxygen and, moreover, faster and more completely. Besides, it has been established that the photoproduct obtained by the irradiation of the deaerated alcoholic solution of xanthene dyes[2] shows similar behavior; this affords definite evidence that it consists mostly of the reduced form of the dye.

The purpose of the present paper is to

1) K. Uchida, S. Kato and M. Koizumi, This Bulletin, 35, 16 (1962).

2) M. Imamura and M. Koizumi, ibid., 28, 117 (1955); 29, 899 (1956); M. Imamura, ibid., 30, 249 (1957).

clarify the nature of this sensitized oxidation in the deaerated condition; this oxidation is peculiar because the oxidation of the leuco dye may take place accompanied by no eventual reduction of the sensitizer. Thus no even slight change in the spectrum of acridine, used as a sensitizer, was perceived; a more definite fact was that uranine itself is efficient as a sensitizer. For the present research, acridine and uranine were chosen as sensitizers; the former, which absorbs light in the 400~330 mμ region where neither leuco-uranine nor uranine has any absorption, can afford an unequivocal interpretation of the results, while the latter has no possibility of promoting the reaction by being itself reduced to the leuco form. The nature of the reaction is studied rather qualitatively, the quantitative treatment being postponed to the next report.

Experimental

Materials.—*Leuco-uranine.*—Uranine was reduced by sodium amalgam and, after repeated recrystallization from an ethanol solution, was desiccated in a vacuum. The details of the procedure were the same as reported on in the previous paper. The solution is rather stable in the dark, but it gradually gets colored due to the formation of the oxidized form of uranine. For example, in several months the oxidation proceeds to the extent of more than half in the case of a 10^{-2} M solution. The coloration is less in the dilute solution, the magnitude being less than 20% for a 10^{-4} M solution.

Acridine.—Tokyo Kasei special-grade acridine was recrystallized twice from the water-ethanol mixture.

Uranine. — Commercial material was repeatedly recrystallized from ethanol.

Sodium Hydroxide.—The saturated solution was prepared from the G. R. reagent of the Wakojunyaku Co. The supernatant liquid was diluted to the desired concentration.

Disodium Hydrogen Phosphate and Potassium Dihydrogen Phosphate. — The G. R. Wakojunyaku reagents were recrystallized three times from the aqueous solution.

Sodium Carbonate, Barium Hydroxide, Ethanol and Sodium Thiosulfate.—Special grade reagents were used without further purification.

Procedure.—The stock solution of leuco-uranine 9.5×10^{-5} M was ordinarily diluted ten times. The evacuation of the solution was usually performed five to six times by the use of a mercury diffusion pump, melting and freezing being repeated each time.

When acridine was used as a sensitizer, 365 mμ light from a mercury lamp was used for exciting the acridine, which has an absorption maximum at 355 mμ. Neither uranine nor leuco-uranine has any absorption in this region. The concentration of acridine is usually 1.3×10^{-4} M. The apparatus specially designed for kinetic study was used; details will be described in the next paper. A high-pressure mercury lamp (Matsuda SHL-100UV) was used as the light source.

When uranine was used as a sensitizer, 1×10^{-6} M of uranine was added in some experiments, but in most experiments, especially in later ones, uranine was not added purposely, since the solution of leuco-uranine already had a small quantity of uranine produced during its storage. The apparatus for the photochemical reaction was similar to those used for other experiments in our laboratory. The reaction cell was the one for a spectrophotometer, $1\times1\times4$ cm., especially designed for evacuation. As a light source, a 75 V. 500 W. tungsten lamp was used at 55 V. The ultraviolet part was removed by a Waltz yellow filter Y1 (> 430 mμ).

Results and Discussion

I. Possibility of the Evolution of Hydrogen Gas. — On the basis of the results already reported, it seemed most natural to infer that molecular hydrogen is evolved accompanying the production of the oxidized dye; first this was examined.

One-hundred milliliters of the aqueous solution of leuco-uranine 6×10^{-5} M was irradiated using uranine or acridine as a sensitizer. When the oxidation of leuco dye had almost completely taken place, the water was distilled to another trap in vacuum and, at the same time, the gas non-condensable by liquid nitrogen was gathered by the use of a small mercury diffusion pump and a Toepler-pump. The quantity of the gas obtained was about 9.8 ml. at 1 mmHg, this quantity being about one-tenth of that expected stoichiometrically. The gas was examined spectroscopically by the use of a small Geissler tube. Faint hydrogen lines were detected in one experiment (sensitizer: acridine), but in the other two experiments no trace of hydrogen could be found.

The above tests do not seem conclusive, however, because the discharge rapidly declined in strength; it is suspected that a small quantity of hydrogen might be fixed in that metallic film which had been spattered from the molybden electrode on to the wall of the tube.

II. Scrutiny of Any Impurity which Might Act as an Oxidizing Agent.—Since the above results were not conclusive, all possibilities of the contamination of a small quantity of the oxidizing agent were examined.

a) Utmost Exclusion of Molecular Oxygen.— The following procedure was adopted for this purpose. First, nitrogen gas which had been purified by bubbling it through the aqueous solution of vanadous sulfate[3] was passed through for more than 30 min. After extensive evacuation, the water was sublimed into another ampoule and it was further evacuated, melting and freezing being repeated for five times. Finally, the water was distilled back to the

Table I. The effect of the addition of sodium carbonate

Concn. of Na_2CO_3	0	4.0×10^{-3} M	0	4.7×10^{-3} M
Initial rate (M. min^{-1})	0.55×10^{-5}	0.46×10^{-5}	0.63×10^{-5}	0.49×10^{-5}

reaction cell. The experiment using this sample showed that the reaction proceeded and with a rate not so much lower than that of the sample evacuated in the ordinary way.

b) The Effect of the Addition of Sodium Thiosulfate.—The results described above strongly establish the impossibility of molecular oxygen participating in the reaction.

However, oxygen might be loosely attached to leuco dye or some other compound in such a way that it can not be eliminated by mere evacuation. Furthermore, there might exist a trace of some other unknown oxidant which induces the reaction in question. In order to examine such a possibility, the effect of the addition of sodium thiosulfate was studied. If the reaction were due to some unknown oxidant, it would not proceed at all in the presence of sodium thiosulfate, or it would proceed at a much lower rate.

An amount of sodium thiosulfate about equal to that of leuco dye was added; the result was that the reaction took place at a rate about 75% of that for the solution to which no sodium thiosulfate was added.

III. Scrutiny of the Contamination of Any Small Quantity of a Reducible Substance.—From the results in a) and b), it can be said with confidence that no conceivable oxidant takes part in the present reaction.

Another possibility to be examined is that the reaction might be induced by some easily reducible substance contaminating the solution. Since the oxidation-reduction potential of uranine is quite low, the reduction of the carbonate ion may be possible, at least energetically, if the light energy absorbed by a sensitizer is utilized for the reaction. If this be the case, the effect of the addition to the solution or of the elimination of sodium carbonate from it ought to be carefully studied, since there is no doubt that a sample contains more or less sodium carbonate.

c) The Effect of the Addition or of the Elimination of Sodium Carbonate.—The addition of the salt up to 4×10^{-3} M did not essentially affect the rate, although the rate decreased somewhat, as may be seen from Table I.

There is, however, another possibility, that the original solution already contains an appreciable quantity of carbonate ions and, so, further addition of them scarcely affects the rate. Hence, the effect of an extensive elimination of carbonate ions was next examined. Barium hydroxide was added to the concentration of 0.1 M; this should decrease the concentration of carbonate ions down to one-hundredth that of leuco dye. The precipitate of barium carbonate was eliminated by passing the solution through a glass-filter and by repeated decantation, all procedures being done in vacuo. The experiment with the solution thus treated showed about the same rate as that of the solution not so treated.

If the carbonate ion were to be reduced, the formation of the formaldehyde would be expected. Hence, the solution was, after a long irradiation, tested by Tollens' reagent, by Schiff's reagent and by a method based on the catalytic action of aldehyde on the oxidation of *p*-phenylenediamine by means of hydrogen peroxide[4]. All the results proved to be negative. From the above results, it can be concluded that carbonate ions are indifferent to the reaction.

d) The Effect of Ethanol on the Rate.—The contamination of a small quantity of ethanol is inevitable, since it was used for repeated crystallization. Hence, the effect of the elimination or addition of ethanol was tested, though its reduction seems rather improbable. Leuco-uranine was prepared by treating an alkaline (0.5 N sodium hydroxide) solution of uranine 1×10^{-5} M with sodium amalgam. When the experiment was made utilizing the above solution, it was found that a similar reaction occurs and that the addition of 10 vol.% ethanol does not affect the rate at all.

Thus it is clear that ethanol does not participate in the reaction.

IV. Reaction in the Presence of Palladium Asbestos.—All these results, a)—d), led once more to the view that hydrogen is to be evolved as a reaction product in spite of a rather negative result of part I above. To test this from a different view-point, the experiment was undertaken in the presence of palladium asbestos suspended in the solution. If the reaction were to proceed under such conditions, the hydrogen which might be evolved would be arrested by the palladium. The oxidized dye, when kept in the dark, would be expected to be reduced, and this cycle would be repeated again and again. The above test would, in addition, completely eliminate the possibility of any oxidizing agent taking part in the reaction.

Uranine 1.0×10^{-5} M in the alkaline solution

4) F. Feigl, "Spot Tests", Vol. II, Elsevier, Amsterdam (1956), p. 208.

of 0.5 N sodium hydroxide was reduced by hydrogen in the presence of a small quantity of palladium asbestos to the extent that a small quantity of uranine was left behind to take the role of sensitizer. The sample was then evacuated and irradiated as usual. The recovery of color went on at about the same as in the case of the leuco dye prepared by the sodium amalgam method.

The sample when kept in the dark (in the presence of palladium asbestos) became almost colorless, but when irradiated once more it regained its color. This could be repeated more than three times.

An analogous experiment could be performed in the presence of sodium amalgam.

The above experiment definitely demonstrates that no impurity takes part in the oxidation of leuco-uranine and that the uranine $\rightleftharpoons$ leuco-uranine process is accompanied by no other side reaction of an appreciable magnitude.

Thus, the oxidation of leuco-uranine is most probably due to the detachment of hydrogen, although this had not yet been proved successfully by the experiment described in part I.

The evolution of the hydrogen gas is to be examined by a different method in the near future.

V. Semiquinone as an Intermediate of the Reaction.—During the course of the reaction in which uranine was used as a sensitizer, the existence of semiquinone was clearly observed spectroscopically. A typical result, which was obtained by a Hitachi recording spectrophotometer, is shown in Fig. 1.

The concentration of leuco-uranine in this case is 1×10^{-5} M, while that of sodium hydroxide is 0.10 N. About 1×10^{-6} M uranine was existent in the original solution. It is seen that, after 3 min. of irradiation, the absorption with a maximum ca. 393 mμ clearly appears. This maximum declines gradually, as is shown in the figure, when kept in the dark. There is no doubt, judging from the findings of some previous workers[5] that the absorption in the 350~420 mμ region is due to semiquinone. The molar extinction coefficient at the maximum was reported to be 6.5×10^{4}. Although the details of the reaction mechanism must await further examination, it seems certain that semiquinone is formed in the early stage of the reaction and that this changes into an oxidized form of uranine either by dismutation or by evolving hydrogen through the intermolecular reaction. If only the dismutation were to occur in the dark, the rise of the maximum at 490 mμ ought to be much smaller.

VI. Reexamination of the Spectral Change of Acridine During the Reaction. — In view of the results described in part V, there is the distinct possibility of the formation of semi-hydrogenated acridine when acridine is used as a sensitizer. If this were the case, more or less acridan would be produced according to the experimental conditions. From such a viewpoint, the spectra of acridine during the course of the reaction was reexamined more carefully under various conditions*. No definite evidence for the formation of either acridan or semi-hydrogenated acridine was obtained, but in some cases, especially at a low concentration of acridine, a clear drop of the maximum at 355 mμ was perceived. Its magnitude fluctuates from one experiment to another; the reason for this is not clear.

All the above facts suggest that, to some extent, acridine is partially hydrogenated at an earlier stage of the reaction and that some of it changes into acridine with the formation of molecular hydrogen while the remaining part dismutes into acridine and acridan.

Summary

The nature of the photosensitized oxidation of leuco-uranine (in the deaerated condition), using uranine or acridine as a sensitizer, was investigated from various viewpoints. The possibility of either an oxidizing or a reducing impurity taking part in the reaction was definitely ruled out. The uranine $\underset{\text{dark}}{\overset{\text{light}}{\rightleftharpoons}}$ leuco-

5) M. Imamura, This Bulletin, **31**, 962 (1958); L. Lindqvist, *Arkiv. Kemi.*, **16**, 79 (1960).

* Thus, the concentration of leuco was varied from 1×10^{-5} to 2×10^{-5}M and that of acridine from 1.8×10^{-5} to 13×10^{-5}M. The concentration of sodium hydroxide was always 0.122 N.

uranine reaction could be repeatedly carried out in the presence of palladium asbestos. When uranine was used as a sensitizer (alkaline solution), an appreciable quantity of semiquinone could be detected as an intermediate. Reexamination of the spectra of acridine (when acridine was used as a sensitizer) showed that in some cases acridine takes part in the eventual reaction.

It is concluded from various pieces of indirect evidence that the overall reaction is the evolution of hydrogen gas from the leuco dye, although the direct detection of hydrogen formation has not yet been successful.

The authors wish to thank Dr. Shunji Kato for his illuminating discussions.

Photosensitized Oxidation of Leuco-uranine. II. Kinetics of an Acridine-sensitized Photoöxidation in the Deaerated Solution

By Kengo UCHIDA and Masao KOIZUMI

(Received March 12, 1962)

As has been reported in a preceding paper[1], leuco-uranine is oxidized to the colored form when its deaerated aqueous solution is irradiated by 365 mμ in the presence of acridine. There was some ambiguity as to the role which acridine plays in this reaction, since, although its quantity remained almost constant in most cases, in a few experiments it decreased a little, as judged from its spectra. In spite of this finding, preliminary experiments showed that the rate of restoration of the dye is quite reproducible under given conditions, suggesting that the process in question does not essentially affect the overall rate of the reaction.

As described in the preceding paper, acridine is a suitable sensitizer for a quantitative study of the reaction; the objective of the present paper is to report on investigations into the influence of various factors upon this reaction. They may be summarized as follows. The triplet state of acridine reacts with leuco-uranine, producing perhaps the semi-hydrogenated form of both species. The various ionic forms of leuco-uranine (mono-, di- and tri-valent anions) have different reactivities towards the triplet state of acridine, which can be evaluated quantitatively from the pH dependence of the overall rate constant. The rate constants of various steps have been obtained with moderate accuracy.

Apparatus and Procedure

The apparatus is shown in Fig. 1.

The light source, L, is a high-pressure mercury lamp (Mazuda SHL 100 UV) operating at 100 V. The power was supplied through a voltage stabilizer, Volco H. T. A remarkable feature is that the same light source, L, was made use of in a specific manner both for inducing the reaction (excitation) and for tracing the reaction (measurement). This technique, which was suggested by Dr. Kato, is described below.

F_1 is an aqueous solution of copper sulfate designed to remove the thermal radiation. F_2 is a specially-designed interference filter (manufactured by the Shonan Komaku Co.), the second order interference of which is 727 mμ; accordingly, the

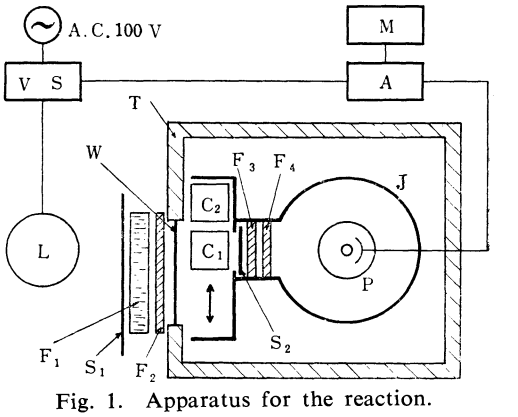

Fig. 1. Apparatus for the reaction.

M: Micro-ammeter W: Glass window

third and the fourth interference are, respectively, 490 and 375 mμ (half width 18 mμ), transmitted light being chiefly limited in the region near the above three wavelengths. The 365 mμ of the mercury lamp can pass through the above filter with a transmission of about 19%. 490 mμ corresponds just to the absorption maximum of the aqueous uranine solution and, since the present mercury lamp has a weak continuous emission, the light in the region of 490 mμ passing through F_2 can be utilized for measuring the quantity of uranine produced. The light of 490 mμ passing through the solution is received by a photocell, P (Mazuda No. 7211). The optical density of the solution at this wave length can easily be evaluated. The fact that its intensity is very weak does not affect the reaction. Between the sample-solution and the photocell are inserted an opaque glass, F_3, and a cut-off filter, F_4 (>450 mμ), in order to remove the light of 365 mμ.

C_1 and C_2 are, respectively, the reaction cell and the reference cell for optical density. Both are set tightly in a movable cell-holder. They are made from Terex, are 1×1×4 cm, and are fitted with a side tube for evacuation. The reading of the meter, M, was calibrated by the use of a Hitachi spectrophotometer (EPU-2A). J is a brass tube with an air-tight glass window, F_3; it contains a photocell and a part of circuit for multiplication, C_1, C_2 and J being immersed in a water-thermostat, T. S_1 and S_2 are shutters. The reaction temperature is 30°C unless otherwise denoted.

The intensity of the irradiating light was controlled by changing the distance between the light source and the cell, or by the use of neutral density filters (manufactured by the Hoya Co.), and it was measured each time by means of a potassium ferrioxalate actinometer.

Results

Rate Formula for a Run. — Under certain experimental conditions, i. e., when the intensity of light, I_0, the concentration of acridine, [A], the initial concentration of leuco-uranine, $[L]_0$, and the temperature, T, are in proper range, the reaction proceeds as of first order with regard to [L]:

$$\frac{d[U]}{dt}=k'[L] \qquad (1)$$

Hence,

$$\ln\frac{[L]_0}{[L]}=k't \qquad (2)$$

Equation 2 fits the experimental results quite satisfactorily, and the reproducibility is moderately good. Typical examples are shown in Fig. 2. The conditions of the reaction for these examples are $[A]=1.3\times10^{-4}$ M, $[L]_0=9.5\times10^{-6}$ M, $I_0\sim5.5\times10^{-8}$ mol. min^{-1} cm^{-2}, and temperature, 30°C. When [A] becomes less and $[L]_0$ larger than the above values, the applicability of the first order rate formula becomes gradually less satisfactory (see below).

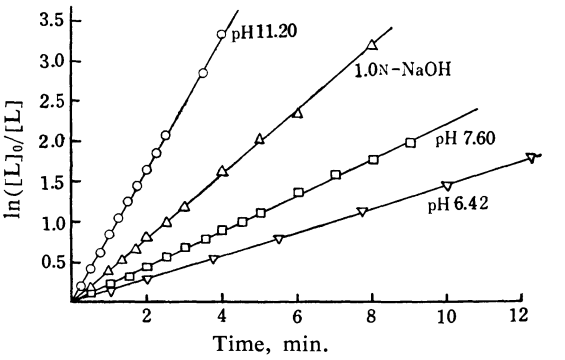

Fig. 2. Plots of $\ln([L]_0/[L])$ against time for typical examples.
$[L]_0=9.5\times10^{-6}$ M, $[A]=1.3\times10^{-4}$ M

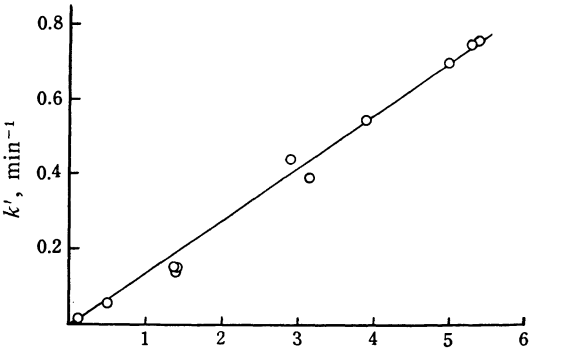

Fig. 3. Dependence of k' on the light intensity.
pH=11.1, $[A]=1.7\times10^{-4}$ M, $[L]_0=9.5\times10^{-6}$ M

In this paper, most of the experiments were performed under the above conditions.

The Effect of Light Intensity.—The results are shown in Fig. 3. k' increases proportionally to the light intensity.

The Effect of the Concentration of Acridine. —The values of k' for various [A]-values are listed in Table I.

In this table, D is the optical density at 365 mμ; hence, $1-10^{-D}$ is a fraction of the light absorbed by acridine. The concentration of acridine was calculated from the optical density of the solution at 365 mμ using the value of $\varepsilon_{365}=0.455\times10^4$.

If the rate is proportional to the absorbed light, Eq. 1 can be rewritten as follows with a new constant, k;

$$\frac{d[U]}{dt}=-\frac{d[L]}{dt}=k'[L]$$
$$=10^3\frac{k}{d}I_{abs}[L]$$
$$=10^3\frac{k}{d}I_0(1-10^{-D})[L] \qquad (3)$$

where I_{abs} is the number of photons (in the mole) absorbed ($cm^{-2}.min^{-1}$), d is the light path length (=1 cm.), and D is the optical density at 365 mμ. $k[L]_0$ gives the quantum yield at the initial stage.

As may be seen from Table I, $k'd/10^3I_0(1-10^{-D})=k$ begins to decrease beyond about 0.8×10^{-4} M of acridine. This is most plausibly due to the self-quenching of the singlet or triplet excited state of acridine.

It can be said from the above results that the rate is proportional to the absorbed light up to ca. 0.8×10^{-4} M, whence the self-deactivation of the excited acridine molecule becomes appreciable.

The Effect of the Initial Concentration of Leuco-uranine. — Equation 1—3 hold when $[L]_0\leqq10^{-5}$ M and $[A]\geqq10^{-4}$ M. To examine the general applicability of the first order rate formula, $[L]_0$ was increased from 0.475×10^{-5} to 2.38×10^{-4} M, keeping [A] constant (0.6×10^{-4} M, about half of the usual value). The results are listed in Table II.

As may be seen from Table II, the initial rate increases with the rise of $[L]_0$. Each run can be approximately treated as of the first order with respect to [L] up about 1×10^{-5} M. However, it is evident that k' decreases appreciably with the increase in $[L]_0$. For the highest concentrations of $[L]_0$ (6.89 and 23.8 $\times10^{-5}$ M), the zeroth order rate formula is rather better than that of the first order.

All these facts suggest that the order of the reaction is generally between zero and one, the first order rate formula holding only for the limited conditions under which most of the experiments happen to have been performed. The interpretation of this will be given in the discussion of the 7th column, $10^3 I_0(1-10^{-D})/$(initial rate), of the table.

The Effect of the pH Value.—When the pH value of the solution was changed from ca. 6.4 to 14 by the use, for example, of the phosphate buffer, $[L]_0$ and [A] being given the values of 9.5×10^{-6} M and 1.3×10^{-4} M respectively, it was found that the rate changes in a curious manner.

Figure 4 shows the plot of k against the pH value, where k is the constant introduced in Eq. 3. Equations 1 to 3 hold satisfactorily throughout the whole pH region. It is evident that the rate constant has a maximum near the pH value of 11~12. The full line represents the calculated values, which will be described in the discussion below.

It is to be noted that below a pH value of 6, the oxidized form of uranine exists as a neutral molecule, of which the absorption in the visible region at 490 mμ is quite small.

Under the present experimental conditions, no coloration could be perceived in situation below a pH value of 6.0, but preliminary experiments showed that the solution, after being irradiated, becomes colored when made alkaline. As to the higher alkaline solution, the solubility of acridine decreases with the

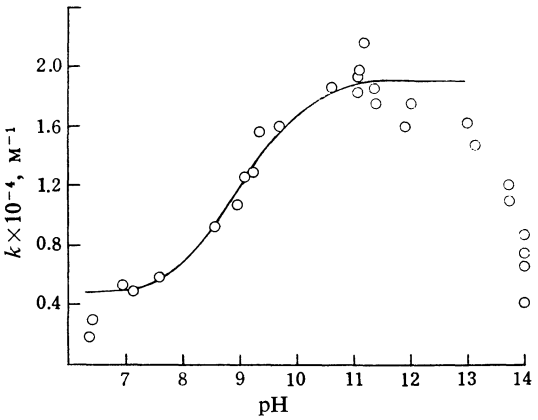

Fig. 4. Dependence of k on pH. The line corresponds to the calculated values.

$[A]=1.3\times10^{-4}$ M, $[L]_0=9.5\times10^{-6}$ M

alkalinity, and the experiments could not be carried out beyond 1.5 N.

The Effect of Temperature.—The rate was measured from 10° to 52°C. The results are listed in Table III.

These data are not very accurate, and the following Arrhenius formula only serves to show an approximate relation between k and T:

$$k=8.1\times109\exp(-8000/RT)$$

Discussion

The first problem to be solved is the exact determination of the excited species of acridine (singlet or triplet) which actually reacts with leuco-uranine. This can be judged from the experiment concerning the effect of leuco-uranine on the fluorescence of acridine. The fluorescence intensity of the aqueous solution of acridine (1.3×10^{-4} M) was measured by a fluorescence accessory attached to a Hitachi spectrophotometer. The addition of leuco-uranine (9.5×10^{-6} M) to the above solution scarcely affected the intensity of the fluorescence, showing that the quenching effect of the former is within the range of experimental error.

From this result, it can be inferred that leuco-uranine does not appreciably attack the singlet excited state, because the opposite assumption leads, as is shown below, to a relation contradicting the experimental result.

Let the quantum yield of the fluorescence be designated as η_E and η_E', in the absence and in the presence of leuco-uranine respectively. If leuco-uranine attacks the singlet excited state as the first step of the reaction, η_E and η_E' can be expressed as follows:

$$\eta_E=\frac{v_E}{v_E+v_Q} \qquad \eta_E'=\frac{v_E}{v_E+v_Q+v_R} \tag{4}$$

where v_E, v_Q and v_R are, respectively, the rate of emission, the inner quenching, and the process leading to the reaction.

The quantum yield of the reaction, on the other hand, can be written as follows:

$$\eta_R=\frac{v_R}{v_E+v_Q+v_R}\cdot\alpha \tag{5}$$

where $\alpha<1$. Equations 4 and 5 lead to the following relation:

$$\frac{\eta_E-\eta_E'}{\eta_E}=\frac{\eta_R}{\alpha} \tag{6}$$

Now, since the addition of leuco-uranine does not affect the intensity of fluorescence beyond the range of experimental error, the left side of the above equation can safely be said to be smaller than 1/10, perhaps, a few hundredths or so. Thus, $1/10>\eta_R/\alpha$ must hold. The quantum yield of the reaction being in favorable conditions, ~0.2, η_R must >0.2; hence, $\alpha>2$, which never holds in any case. Thus one can safely conclude that leuco-uranine does not appreciably react with the singlet state, its contribution to the entire reaction, even if it exists, being less than 10%.

In the following, we assume that the entire reaction proceeds via the triplet state of acridine, which attacks leuco-uranine.

In general, it must be taken into account that the triplet state returns to the ground state, dissipating its excess energy. Therefore, $k[L]$ in Eq. 3 must be represented as follows:

$$k[L]=\varphi\frac{k_r[L]}{k_d+k_r[L]}\ ^* \tag{7}$$

where φ gives the fraction of the singlet excited state that goes to the triplet, and k_d and k_r are, respectively, the rate constant of deactivation and the reaction with leuco-uranine. The rate formula should be of the first order or zeroth order according as $k_r[L]\ll k_d$ or $k_r[L]\gg k_d$. The general applicability of Eq.

* The mere deactivation by leuco-uranine in this case may be ignored.

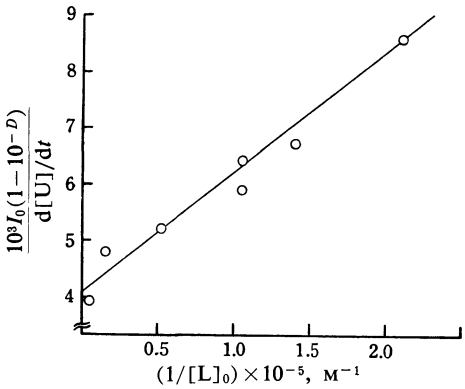

Fig. 5. Plot of $10^3 I_0(1-10^{-D})/(d[U]/dt)$ against $1/[L]_0$.

7 can be tested from the data in Table II. Based on Eqs. 3 and 7, the initial rate can be written as follows:

$$\frac{d[U]}{dt}=10^3 I_0(1-10^{-D})\varphi\frac{k_r[L]_0}{k_r[L]_0+k_d} \qquad (8)$$

whence

$$\frac{10^3 I_0(1-10^{-D})}{d[U]/dt}=\frac{1}{\varphi}+\frac{1}{\varphi}\times\frac{k_d}{k_r[L]_0}$$

As is shown in Fig. 5, the plot of $10^3 I_0(1-10^{-D})/(d[U]/dt)$ against $1/[L]_0$ gives a satisfactory straight line. From the slope and the intercept, the values of φ and k_d/k_r can be set at 0.24 and 0.51×10^{-5} mol./l. φ gives the intersystem crossing probability ($S'\rightarrow T$); this value reconfirms that the reaction involves the triplet state of acridine.

In most experiments the initial concentration of leuco-uranine is $\sim1\times10^{-5}$ M; hence, $k_d/k_r[L]_0\sim0.51$. Thus, the rate of deactivation is rather smaller than that of the reaction. Integrating Eq. 8, one gets an exact rate formula as follows:

$$\frac{k_r}{k_d}\{[L]_0-[L]\}+\ln\frac{[L]_0}{[L]}=10^3\frac{k_r}{k_d}I_0(1-10^{-D})\varphi t \qquad (9)$$

Equation 9 can reproduce quite satisfactorily most of the runs for which the first order rate formula fails. Examples are shown in Fig. 6.

In most of the experiments, [A] was chosen as $\geqq1.3\times10^{-4}$ M, where the deactivation of the triplet state is rather large (see Table I); hence, k_d becomes more than twice as large as the above value. Thus, the situation in this case is more favorable for the first order rate formula; yet it is unlikely that the $k_r[L]$ term is negligible in comparison with the k_d term. Therefore, the possibility of the quenching action of uranine (produced) on the triplet state of acridine was examined. Thus, if

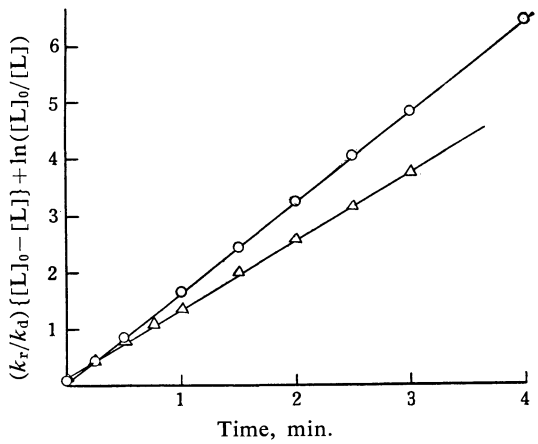

Fig. 6. Plots of $(k_r/k_d)\{[L]_0-[L]\}+\ln([L]_0/[L])$ against t.
○: [A]$=0.6\times10^{-4}$ M, [L]$=0.95\times10^{-5}$ M, [NaOH]$=0.01$ N
△: [A]$=0.6\times10^{-4}$ M, [L]$=1.9\times10^{-5}$ M, [NaOH]$=0.01$ N

uranine were to deactivate the triplet of acridine about a rate constant equal to that with which leuco-uranine attacks the triplet state of acridine, then the denominator of Eq. 7 would be expected to be approximately constant during the course of the reaction. In this case, Eq. 7 can be replaced by:

$$k[L]=\varphi\frac{k_r[L]}{k_d+k_r[L]_0} \qquad (7a)$$

and the run is to proceed as of the first order in [L]. However, it was found that the addition of uranine up to 8×10^{-6} M never affects the rate beyond the range of experimental error. Taking all the above facts into account, there still remains some question as to the reason why the first order rate formula fits most of the experimental results quite well.

We will next discuss the actual molecular species which participates in the reaction. First, acridine is a base, and in an acidic solution it exists as acridinium cation; it must be determined which species is really involved in the reaction. However, according to Jackson and Porter[2], the pK value of acridine in the triplet state is 5.6 and, in the present pH range, it can be said that acridine exists only as a neutral molecule.

On the other hand, due attention must be paid to the various ionic forms of leuco-uranine. Information as to the reactivity of various species can be obtained from an analysis of the pH effect. In other words, the results depicted in Fig. 4 can be satisfactorily

2) G. Jackson and G. Porter, *Proc. Roy. Soc.*, **A260**, 13 (1961).

interpreted on the basis of the four species of leuco-uranine, L, L^-, L^{2-} and L^{3-}, having different reactivities and, accordingly, different rate constants.

All the processes to be considered (taking the deactivation process into account) are:

$A + h\nu \rightarrow A^*$	$10^3\varphi I_{abs}$	(i)
$A^* + L^{3-} \rightarrow AH + UH^{3-}$	k_1	(ii)
$A^* + L^{2-} \rightarrow AH + UH^{2-}$	k_2	(iii)
$A^* + L^- \rightarrow AH + UH^-$	k_3	(iv)
$A^* + L \rightarrow AH + UH$	k_4	(v)
$A^* \rightarrow A$	k_q	(vi)
$A^* + OH^- \rightarrow A + OH^-$	k_{OH}	(vii)

In this scheme, A* is the triplet state of acridine. ii~v are tentatively expressed as formations of the semi-reduced forms of acridine and uranine. This is plausible, as has been described in the preceding paper, but it has not yet been decided definitely. vii was added for the sake of completeness (see below).

The application of the steady state method leads at once to the following equation:

$$\frac{d[U]}{dt}=10^3\varphi I_{abs}\times\frac{k_1[L^{3-}]+k_2[L^{2-}]+k_3[L^-]+k_4[L]}{k_1[L^{3-}]+k_2[L^{2-}]+k_3[L^-]+k_4[L]+k_q+k_{OH}[OH^-]} \quad (10)$$

As long as the first order rate formula holds, $k_1[L^{3-}]+k_2[L^{2-}]+k_3[L^-]+k_4[L]+k_q$ may be put approximately as

$$k_r[L]_m+k_q=k_t$$

in which $[L]_m$ is the mean value of [L] during the course of the reaction and k_r depends on the pH value. Furthermore, one may assume that:

$$k_t \gg k_{OH}[OH^-]$$

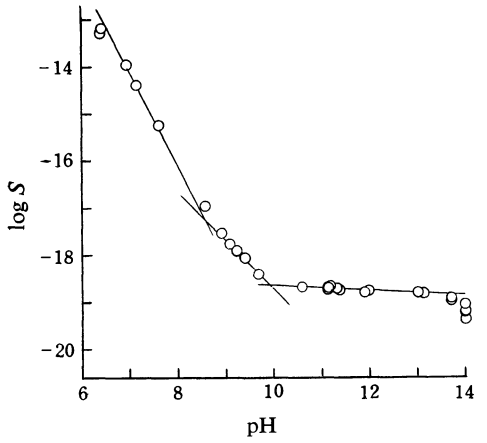

Fig. 7. Plot of log S against the pH value.

so long as $[OH^-]$ is not very great.

By the use of the successive dissociation constants of leuco-uranine (K_1, K_2 and K_3), Eq. 8 can be rewritten as follows:

$$\frac{d[U]}{dt}=10^3\frac{\varphi}{k_t}I_{abs}\times\frac{k_4[H^+]^3+k_3K_1[H^+]^2+k_2K_1K_2[H^+]+k_1K_1K_2K_3}{[H^+]^3+K_1[H^+]^2+K_1K_2[H^+]+K_1K_2K_3}[L]_s \quad (11)$$

where $[L]_s$ is the analytical concentration of leuco-uranine.

Thus, the experimentally-obtained k-value in Eq. 3 can be related to the rate constants of various species in the following way:

$$k\{[H^+]^3+K_1[H^+]^2+K_1K_2[H^+]+K_1K_2K_3\}(=S)=\frac{\varphi}{k_t}\{k_4[H^+]^3+k_3K_1[H^+]^2+k_2K_1K_2[H^+]+k_1K_1K_2K_3\} \quad (12)$$

The left side of this equation is experimentally determined, since K_1, K_2 and K_3 have already been evaluated as $pK_1=3.8$, $pK_2\approx$, and $pK_3=9.6$[3].

Plotting log S against the pH value, it is expected that in the region where the pH value is so small that the first term of the right side overwhelms the other terms, the curve should be a straight line with a slope of -3. As the pH value increases, the straight line gradually curves and connects with another straight part having a slope of -2, then further to a part with slopes of -1 and of 0.

The results obtained by the use of the above K-values and the experimentally determined k-values are shown in Fig. 7. It is seen that the curve really consists of three linear sections with slopes of -2, -1 and approximately 0, although the second range is very short and is not quite clear. The most plausible values of k_1 to reproduce the experimental curve are $\varphi k_1/k_t=1.9\times10^4$, $\varphi k_2/k_t=1.4\times10^4$ and $\varphi k_3/k_t=0.48\times10^4$ (l./mol.)*. The calculated values of k at various pH values are compared with the experimental values in Fig. 4. The line with a slope of -3 having not been obtained, $\varphi k_4/k_t$ can not be obtained under the present experimental conditions.

In the highest pH value region, the line has a little negative slope; this can be attributed to the quenching of the triplet state due to the hydroxyl ion.

Thus, one can write in this region:

3) K. Uchida, S. Kato and M. Koizumi, This Bulletin, 35, 16 (1962).

* As pK, the pH values at the points of intersection in Fig. 7 are employed: $pK_1=3.8$, $pK_2=8.6$ and $pK_3=9.9$.

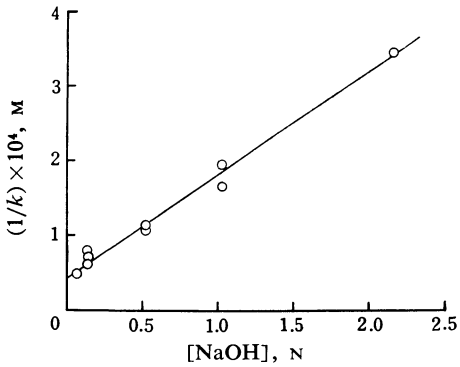

Fig. 8. Plot of $1/k$ against [NaOH].
$[L]_0=9.5\times10^{-6}$ M, $[A]=1.3\times10^{-4}$ M

$$k=\frac{\varphi k_1}{k_t+k_{OH}[OH^-]}$$

or

$$\frac{1}{k}=\frac{k_t}{\varphi k_1}+\frac{k_{OH}}{\varphi k_1}[OH^-] \qquad (13)$$

The plot of $1/k$ against $[OH^-]$ gives a straight line, as is shown in Fig. 8. From the slope and the intercept, one can evaluate k_{OH}/k_t at ~3 l./mol. Furthermore, the value of $\varphi k_1/k_t$ obtained from the intercept is 2.3×10^4 l./mol., with a fair agreement with that obtained from the analysis of Eq. 12.

At this point, it is to be noted that the fluorescence of acridine is also quenched by the hydroxyl ion. The quantitative investigation has shown that the effect is satisfactorily reproduced by Stern-Volmer's equation, the value of the quenching constant K being 0.50 ~0.69 l./mol. K is given by

$$K=\frac{k'_{OH}}{k'_q+k_f}$$

where k_f, k'_q and k'_{OH} are, respectively, the rate constant of emission, of self-quenching and of the reaction between the singlet excited state of acridine and the hydroxyl ion.

In view of the quenching action of the hydroxyl ion on the fluorescence, the above-mentioned value of k_{OH}/k_t ~3 is, of course, an apparent one, pertaining to the action on the singlet excited state as well as on the triplet state. However, the fact that k_{OH}/k_q is much larger than K shows that the latter predominates, reconfirming again that the reaction chiefly takes place via the triplet state of acridine.

In concluding the discussion, it must be added that the absolute value of each rate constant can be estimated with moderate accuracy for a high alkaline region. In this region one may take the value of φ as 0.24; then one can get the value of k_r/k_t as follows:

from the relation between the initial rate and $[L]_0$, 6.6×10^4

from the pH effect on k, 7.9×10^4

from the effect of $[OH^-]$ on k, 9.5×10^4

Perhaps the first value is the most accurate. From this, the value of k_d/k_1 can be evaluated as 0.51×10^{-5} (as has already been described). Although this is not very reliable, chiefly because of the assumption about k_t and φ, it is certain that the reaction between leuco-uranine and the triplet state of acridine occurs quite rapidly, the quantum yield in favorable conditions, being chiefly determined by φ. If one tentatively assumes $k_d=10^4$ sec^{-1}, then k_1 is ca. 2×10^9 sec^{-1} l. mol^{-1}.

Summary

The acridine-sensitized photoöxidation of leuco-uranine in the deareated aqueous solution was studied kinetically. It was established that about 0.24 of the excited acridine molecules goes to the triplet state and then reacts with leuco-uranine. In favorable conditions, the quantum yield is near 0.20, which shows that the genuine reaction rather predominates over the deactivation process of the triplet state.

The pH value dependence of the rate was successfully interpreted from the assumption that each of the different molecular species has a different rate constant.

Infrared Absorption Spectra of Hydrazides. IV Some Monoacid Hydrazides

By Mitsuo MASHIMA

(Received July 18, 1962)

Although Jensen[1] studied the infrared absorption spectra of some monoacid hydrazides, he examined the bands in the 6 and 3 μ regions only. The infrared spectrum of benzoylhydrazine was previously observed by the present author[2], but the absorption bands obtained could not be interpreted with confidence.

In the present study the spectra of some monoacid hydrazides in the solid state and in acetonitrile solutions are examined in the rock salt region and the frequencies characteristic of the $-CONHNH_2$ group are considered.

Experimental

Formyl-[3], acetyl-[4], cyanoacetyl-[5], propionyl-[6], butyryl-[7] and isovaleryl-hydrazine[8] were synthesized with ethyl esters of corresponding acids and hydrazinehydrate and were purified by recrystallization from ethanol or ether; m. p., 54, 67, 110, 40, 45, 68°C, respectively. *N*-Deuterated cyanoacetylhydrazine was prepared in sealed tubes in the presence of heavy water (99.8%), the excess of which was evaporated in vacuum.

The spectra were taken with a double-beam Hitachi infrared spectrophotometer, type EPI-2, with rock salt prisms. Potassium bromide disks were employed for taking the spectra of solids, and the solution spectra were examined in acetonitrile.

Results and Discussion

Cyanoacetylhydrazine (CAH). — The solid spectra of CAH and *N*-deuterated CAH (CAH-d_3) and the solution spectrum of CAH are illustrated in Fig. 1. The absorption bands of CAH are interpreted without much difficulty by comparing the spectrum with those of cyanoacetyl-acetylhydrazine (CAAH)[9], hydrazine[10] and its derivatives[11,12].

The 3000 cm^{-1} Region. — The most intense band among the bands in this region is found at 3180 cm^{-1} for solid CAH, while a corresponding band is observed at 2380 cm^{-1} for solid CAH-d_3, the value of ν_H/ν_D being 1.336. This is probably due to the N–H stretching vibration of the –CONH– group, because CAAH[9] has also a NH band at 3190 cm^{-1} which is displaced by a band at 2370 cm^{-1} on *N*-deuteration, the ν_H/ν_D ratio being 1.346. The NH_2 stretching vibrations ($\nu(NH_2)$) of the hydrazine residue will also give rise to bands in this region. Hydrazine[10] in the solid state has two bands, ascribed to $\nu_a(NH_2)$ at 3315 cm^{-1} and to $\nu_s(NH_2)$ at 3204 cm^{-1}. Monomethylhydrazine[11] in the liquid state shows three Raman lines, 3317, 3245 and 3177 cm^{-1}, which have been ascribed to NH or NH_2 stretching

vibrations, while 1,1-dimethylhydrazine[12] shows two Raman lines, 3330 and 3141 cm^{-1}, assigned to $\nu(NH_2)$. In this region, CAH has a band at 3320 cm^{-1} and CAH-d_3 has an isolated band at 2510 cm^{-1} and a shoulder band at 2430 cm^{-1}. The 3320 cm^{-1} band is very close in frequency to the 3315 cm^{-1} band ($\nu_a(NH_2)$) of solid hydrazine; its counterpart is found at 2510 cm^{-1} in the CAH-d_3 spectrum, the ν_H/ν_D ratio being 1.323. Therefore, the 3320 cm^{-1} band may be ascribed to $\nu_a(NH_2)$. On the other hand, the $\nu_s(NH_2)$ absorption is expected to appear near 3200 cm^{-1} because solid hydrazine has a corresponding band at 3204 cm^{-1}. However, we can not observe the corresponding band because of the overlap of the intense band at 3180 cm^{-1}, which was already ascribed to $\nu(NH)$. CAH-d_3 has, however, a band at 2430 cm^{-1} which is probably to be ascribed to $\nu_s(ND_2)$. For phenylacetic acid hydrazide, Jensen[1] obtained three bands, at 3300, 3175 and 3000 cm^{-1}, in the solid state, but he did not make detailed assignments of them. The former two bands are very close in frequency to the 3320 and 3180 cm^{-1} bands of CAH respectively. In the present study the assignment of the 3180 cm^{-1} band to the NH stretching vibration of the -CONH- group depends also on the fact that CAH in acetonitrile has a band at 3320 cm^{-1} which is very close in frequency to the $\nu(NH)$ band at 3310 cm^{-1} of CAAH[9] in the same solvent

In this region, CAH has several more weak bands. Of these, three bands are shifted to lower frequencies on *N*-deuteration, but a reasonable interpretation of them is not easy on the basis of the present observations only. On the other hand, a sharp band at 2925 cm^{-1} and a shoulder band at 2860 cm^{-1} are probably to be ascribed to the CH_2 stretching vibrations, because the corresponding bands are found at 2930 and 2870 cm^{-1} for CAH-d_3.

A band at 2265 cm^{-1} of CAH is easily assigned to $\nu(C\equiv N)$, because CAH-d_3 has a corresponding band at 2270 cm^{-1} and CAAH[9] absorbs at 2270 cm^{-1}.

The 1700~700 cm^{-1} Region. — The amide group, -CONH-, is contained in a CAH molecule, so CAH will show amide I, II, III and IV absorptions in this region[13]. CAH has a very strong and broad band with a center at 1698 cm^{-1} and CAH-d_3 has a corresponding band at 1680 cm^{-1}, the ν_H/ν_D ratio being 1.010. Therefore, the 1698 cm^{-1} band of solid CAH may surely be assigned to the amide I band. In the acetonitrile solution, CAH has the corresponding band at 1704 cm^{-1}.

CAH has a band at 1534 cm^{-1} which corresponds in intensity to the band of CAH-d_3 at 1451 cm^{-1}, the ν_H/ν_D ratio being 1.057. A corresponding band is also found at 1513 cm^{-1} for CAH in acetonitrile. CAAH[9] has an amide II band at 1497 cm^{-1}, and CAAH-d_2 has an amide II′ band at 1413 cm^{-1}, the ν_H/ν_D ratio being 1.059. Thus, the 1534 cm^{-1} band of CAH is undoubtedly to be ascribed to the amide II band.

Although the amide III band is expected to appear in the 1300~1250 cm^{-1} range, its identification will be considered with the assignments of the NH_2 deformation vibrations.

Let us now consider the location of the NH_2 deformation vibrations. Yamaguchi[14] has shown that the deformation vibrational modes of the non-planar $-NH_2$ group (e. g., of methylamine and hydrazine) are composed of bending, twisting and wagging vibrations and that the absorption bands due to them occur near 1600, 1300 and 800 cm^{-1} respectively. On the other hand, the deformation vibrations of the planar $-NH_2$ group are composed of bending, rocking, wagging and twisting vibrations. Urea[15] in the solid state has the bands at 1629 and 1603 cm^{-1} (bending), 1150 cm^{-1} (rocking), 719 cm^{-1} (wagging) and 500 cm^{-1} (twisting). Oxamide[16] in the solid state has these four bands at 1608, 1103, 792 and 678 cm^{-1} respectively. Therefore, the presence of the non-planar $-NH_2$ group may probably be detected by the presence of the NH_2 deformation band near 1300 cm^{-1}. Yamaguchi[14] has assigned the 1275 cm^{-1} band of hydrazine vapor to the NH_2 twisting vibration. For solid hydrazine Giguere and Liu[10] have obtained the 1320 cm^{-1} band, which corresponds to the 1275 cm^{-1} band of hydrazine vapor. Axford and others[11] obtained an absorption band at 1308 cm^{-1} for methylamine in the liquid state, but they could not reasonably assign the band. For liquid 1, 1-dimethylhydrazine, Shull and others[12] have observed a strong band at 1321 cm^{-1} which they ascribed to a CH_3 bending vibration. However, this assignment is doubtful because liquid trimethylhydrazine[12] has no band corresponding to it. The band of these hydrazine derivatives near 1300 cm^{-1} is probably due to the non-planar NH_2 deformation vibration.

In the region below 1650 cm^{-1}, CAH has five band which disappear on *N*-deuteration; they are the bands at 1625 (s), 1347 (s), 1258 (m), 1105 (s) and 1009 (s) cm^{-1}. On the other hand, CAH-d_3 has five new bands at 1192 (m), 1044 (m), 973 (m), 928 (s) and 842

(w) cm^{-1}. Of these, the 1625 cm^{-1} band of CAH will correspond to the 1192 cm^{-1} band of CAH-d_3, the ν_H/ν_D ratio being 1.363. This band is close in frequency to the band due to the NH_2 (planar or non-planar) bending vibration and, acoordingly, it is surely to be ascribed to the NH_2 bending vibration of the $-CONHNH_2$ group. The corresponding band is observed at 1636 cm^{-1} for CAH in acetonitrile.

The 1313 cm^{-1} band of CAH probably corresponds to the 1044 cm^{-1} band of CAH-d_3 ($\nu_H/\nu_D=1.257$). This is close in frequency to the 1320 cm^{-1} band of solid hydrazine[10]. As was mentioned above, the 1320 cm^{-1} band of solid hydrazine corresponds to the 1275 cm^{-1} band of hydrazine vapor[10], and the latter has been assigned to the NH_2 (non-planar) twisting vibration[14]. Therefore, the 1313 cm^{-1} band of CAH may probably be ascribed to the NH_2 twisting vibration of the $-CONHNH_2$ group. It is further concluded that the NH_2 group of CAH has the non-planar structure, because only such a group has the band near 1300 cm^{-1} indicated above.

Next, the 1258 cm^{-1} band of CAH is considered to correspond to the 973 cm^{-1} of CAH-d_3 ($\nu_H/\nu_D=1.293$). Its value of frequency lies in the normal 1250~1300 cm^{-1} range in which the amide III band is usually found for the secondary amides. CAAH[9] has also amide III bands at 1281 and 1235 cm^{-1}. Therefore, the 1258 cm^{-1} band of CAH is undoubtedly to be ascribed to the amide III band. CAH in acetonitrile has also a corresponding band at 1258 cm^{-1}.

The 1105 cm^{-1} band of CAH probably corresponds to the 928 cm^{-1} band of CAH-d_3, the ν_H/ν_D ratio being 1.190. CAH in acetonitrile has a corresponding band at 1122 cm^{-1}. Such a strong band as the 1105 cm^{-1} one may not be observed near 1100 cm^{-1} for CAAH[9] and cyanoacetate acid amide*1. It is, therefore, concluded that the 1105 cm^{-1} band is not due to a vibration of the $N\equiv C-CH_2-CO-$ group, which is the group contained in CAH, CAAH and cyanoacetic acid amide. In consequence, the 1105 cm^{-1} band has to be due to a vibration of the hydrazine residue. Hydrazine in the vapor state has the bands at 966, 933 cm^{-1} (doublet) and 780 cm^{-1} which have been ascribed[14] to the NH_2 wagging vibrations of different species (B and A) respectively. The bands corresponding to the former have been observed at 1078, 1072 cm^{-1} for solid hydrazine by Giguere and Liu[10]. The 1105 cm^{-1} band of CAH is close in frequency to the 1078, 1072 cm^{-1} bands of solid hydrazine. Therefore, it is probably to be ascribed to the NH_2 wagging vibration of the hydrazine residue.

The band at 1009 cm^{-1} of CAH probably corresponds to the 842 cm^{-1} band of CAH-d_3 ($\nu_H/\nu_D=1.198$); it is probably due to an NH_2 deformation vibration (perhaps rocking).

As was mentioned above, it is seen that CAH has four bands ascribed to the NH_2 deformation vibrations. This is not consistent with Yamaguchi's conclusion[14], that the deformation modes of the non-planar NH_2 group are composed of three fundamental vibrations. However, it is of interest to note that four NH_2 deformation frequencies are obtained for other monoacid hydrazides the absorption bands of which will be considered later. In spite of some doubtfulness in the assignments, we can regard these frequencies as characteristic of the $-CONHNH_2$ group.

The $CH_2<$ deformation vibrations are probably to be found in this region. For the $CH_2<$ deformation frequencies, Nakagawa[17] has proposed the following ranges: 1450~1350 cm^{-1} for bending, 1350~1100 cm^{-1} for wagging, 1250~1000 cm^{-1} for twisting, and 1000~700 cm^{-1} for rocking. CAH has 1396, 1347, 1205 and 1009*2 cm^{-1} bands, which are scarcely changed in frequency on *N*-deuteration. CAH-d_3 has corresponding bands at 1397, 1347, 1206 and 1000 cm^{-1}. These four bands lie in the four ranges indicated above; accordingly, they are ascribed to the CH_2 bending, wagging, twisting and rocking vibrations respectively. The bending and wagging frequencies are not observed for CAH in acetonitrile because of interference due to solvent absorption, but the bands due to the latter two vibrations are found at 1197 and 997 cm^{-1} respectively.

Bands ascribed to the skeletal (CH_2–CO, NC–CH_2 and N–N) stretching vibrations and the O=C–N deformation vibration (amide IV) are expected to appear in this region. The N–N stretching frequency of 1143 cm^{-1} has been obtained for CAAH[9], but no band corresponding to it is observed for CAH because of its location on the sloping back ground of the much more intense band at 1105 cm^{-1}. On the other hand, CAH-d_3 has a very weak band at 1112 cm^{-1} which is probably to be ascribed to the N–N stretching vibration. Hydrazine[10] absorbs at 1098 cm^{-1} (vapor) and 1124 cm^{-1} (solid). The 1098 cm^{-1} band has been ascribed to the N–N stretching vibration[14]. The corresponding band was observed at 1110 cm^{-1} for HCONDNHCOH[18], at 1165 cm^{-1} for

*1 Its infrared absorption spectrum will be published elsewhere.

17) I. Nakagawa, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zassi*), **76**, 540 (1955).

*2 It seems probable that this band arises from the NH_2 deformation band overlapping the CH_2 deformation band.

$(CH_3CONH-)_2 \cdot H_2O$[19] and at 1133 cm^{-1} for formyl-acetylhydrazine[9].

CAH has bands at 932 (w), 924 (s), 913 (s), 738 (s) and 723 (sh) cm^{-1} not yet accounted for. CAH-d_3 also has four bands at 912 (sh), 892 (sh), 772 (s) and 729 (sh) cm^{-1}. Of these, the bands near 900 cm^{-1} are probably due to the C–C stretching vibrations and a band near 750 cm^{-1} can be assigned to amide IV, although their detailed assignments are not easy.

The infrared frequencies of CAH and their tentative assignments are summarised in Table I.

Formylhydrazine (FH).—The infrared spectra of FH in the solid state and in acetonitrile are illustrated in Fig. 2. Although the spectrum of *N*-deuterated FH could not be observed*3, absorption bands of FH were interpreted without much difficulty by comparing the spectrum with those of diformylhydrazine (DFH)[18], formamide(FA)[20]and *N*-methylformamide (MFA)[21]. The infrared frequencies of DFH, FA and MFA have reasonably been explained with a model of a trans-planar configuration of the HCONH– group. Therefore, it will be assumed that an FH molecule also contains such a planar HCONH– group. This assumption is supported by the fact that FH has six bands very close in frequency to the bands of DFH; accordingly, these bands are immediately assigned to vibrational modes of the HCONH– group, as is indicated in Table II (upper part).

The amide I absorption will be shown near 1600 cm^{-1} because DFH has a band at 1610 cm^{-1}. FH in the solid state has a very strong band at 1674 cm^{-1} which corresponds to the band at 1689 cm^{-1} of FH in acetonitrile. The value of 1674 cm^{-1} is rather higher than that of the amide I band of DFH, but it is surely taken to be an amide I band because MFA in the solid state also has a band at 1672 cm^{-1} [21].

DFH[18] has a 3100 cm^{-1} band ascribed to the NH stretching vibration. In this region, FH in the solid state shows very intense and broad absorption with a maximum near 3210 cm^{-1}, while FH in acetonitrile has the band at 3330 cm^{-1}. FA[20] in the solide state also has a broad and strong band near 3250 cm^{-1}, which has been ascribed to the NH_2 assym. or sym. stretching vibration. The rock salt optics employed are not suitable for measurements in this region because of low resolution, but it is seen that the band near 3210 cm^{-1} of solid FH is really composed of three bands, i. e., it is accompanied by a shoulder band which could not be defined on both the high- and low-frequencies sides. Therefore, these bands are due to the NH_2 and NH stretching vibrations.

The out-of-plane CH deformation vibration may also be located in the region examined here. No band corresponding to it has been observed for DFH[18], but its sodium salt[22] has

a band at 1026 cm^{-1}. FA[20] and MFA[21] in the solid states have a CH band at 1060 cm^{-1} and 1015 cm^{-1} respectively. In this region FH has a weak band at 1050 cm^{-1} which is probably to be ascribed to the out-of-plane CH deformation vibration.

Let us now consider the location of the NH_2 deformation vibrations and the N–N stretching vibration of the hydrazine residue. Solid FH has a strong band at 1632 cm^{-1} which is very close in frequency to the 1625 cm^{-1} band (ascribed to the NH_2 bending vibration) of CAH. FH in acetonitrile has a corresponding band at 1635 cm^{-1}. Thus, the 1632 cm^{-1} band may be ascribed to the bending vibration.

The infrared frequencies of FA have been reasonably explained[20] by use of the model of the planar structure of the $-CONH_2$ group; the compound shows the NH_2 deformation frequencies as follows: 1610 cm^{-1} (bending), 1110 cm^{-1} (rocking), and 800 cm^{-1} (wagging). As has been indicated already, CAH has the end group $-NH_2$, being non-planar in structure, and it has four bands, 1625, 1347, 1105 and 1009 cm^{-1}, due to the NH_2 deformation vibrations. FH has several weak or shoulder bands not yet accounted for. Of these, the very weak band at 1262 cm^{-1} is expected to be due to a fundamental vibrational mode because the band corresponding to it is observed at 1305 cm^{-1} for FH in acetonitrile. This band probably corresponds to the 1347 cm^{-1} band of CAH; it will be ascribed to the NH_2 deformation vibration. Two further bands at 1104 and 927 cm^{-1} and the doublet band (826, 807 cm^{-1}) have their respective counterparts in the solution spectrum as represented in Table II. Of these three, the 1104 cm^{-1} band and the doublet

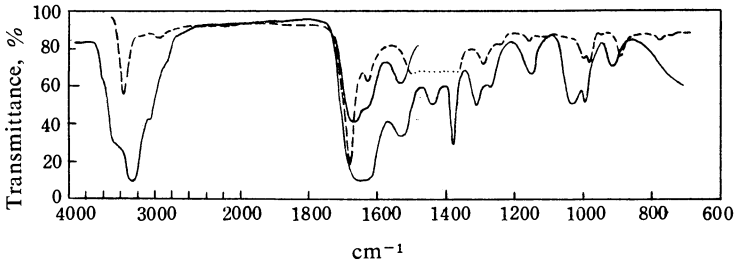

Fig. 3. Infrared spectra of acetylhydrazine in the solid state (solid curve) and in the CH_3CN solution (dashed curve).

band are very close in frequency to the 1110 cm^{-1} (NH_2 rocking) and 800 cm^{-1} (NH_2 wagging) bands of FH respectively. These two bands are probably to be ascribed to the NH_2 deformation vibratios and the band at 927 cm^{-1}, to the N–N stretching vibration, but these assignments, of course, are not certain.

The infrared frequencies of FH and their tentative assignments are summarized in Table II, in which the frequencies of DFH are also indicated for the sake of comparison.

Acetyl-, Propionyl-, *n*-Butyryl- and Isovaleryl-hydrazine. — The infrared spectra of acetylhydrazine (AH) in the solid state and in the acetonitrile solution are illustrated in Fig. 3. The spectrum of its *N*-deuterated species could not be observed*4, but the absortion bands of AH were interpreted by a comparison of the spectrum with those of diacetylhydrazine[19], *N*-methylacetamide[23] and cyanoacetylhydrazine. The infrared frequencies of AH and their tentative assignments are summarized in Table III.

In the solid state, AH has a very strong band at 3270 cm^{-1}, which is accompanied by two shoulder bands at 3420 and 3050 cm^{-1}. These bands are probably to be ascribed to the NH_2 or NH stretching vibrations. The band corresponding to them is found at 3360 cm^{-1} for AH in acetonitrile.

The very strong band at 1673 cm^{-1} of solid AH corresponds to the 1684 cm^{-1} band of AH in acetonitrile; it may surely be taken as an amide I band. The band at 1535 cm^{-1} is easily taken as an amide II band. Further, it is expected that an amide III band will appear near 1300 cm^{-1}. Solid AH has two bands at 1316 and 1276 cm^{-1}. They will correspond to the band at 1295 cm^{-1} of AH in acetonitrile. An amide III band has been obtained at 1261 cm^{-1} for diacetylhydrazine[19], 1258 cm^{-1} for cyanoacetylhydrazine and 1312 cm^{-1} for *N*-methylacetamide[23]. Therefore, one of the two bands, 1316 and 1276 cm^{-1}, is probably to be taken as an amide III band.

		780 (w)

ν, stretching; β, bending; δ, deformation; γ, rocking; a, asymmetric; s, symmetric

AH in the solid state has two bands at 1443 and 1382 cm^{-1}. They may surely be ascribed to the CH_3 asym. and sym. deformation vibrations, for the corresponding bands have been found at 1433 and 1368 cm^{-1} for solid diacetylhydrazine[19] and at 1413 and 1373 cm^{-1} for *N*-methylacetamide[23] in the carbon tetrachloride solution.

The CH_3 rocking and C–CH_3 stretching vibrations may be located without difficulty in the spectrum of AH. *N*-Methylacetamide[23] in carbon tetrachloride has two bands, at 1040 and 987 cm^{-1}, which have been ascribed to the CH_3 rocking vibrations. They correspond to the bands at 1050 and 1001 cm^{-1} for solid *N*-methylacetamide[23]. The compound has, further, a C–CH_3 stretching band at 881 cm^{-1} in carbon tetrachloride solution and at 892 cm^{-1} in the solid state[23]. Diacetylhydrazine[19] also has

*4 *N*-Deuterated acetylhydrazine could not be prepared by the usual exchange reaction.

23) T. Miyazawa, T. Shimanouchi and S. Mizushima, *J. Chem. Phys.*, **29**, 611 (1958); see also T. Miyazawa, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zassi*), **77**, 171, 321, 619 (1956).

CH_3 rocking bands at 1029 and 1019 cm^{-1} and a C–CH_3 stretching band at 921 cm^{-1}. In the region of 1100~800 cm^{-1}, solid AH has three bands at 1034, 994 and 909 cm^{-1}; bands corresponding to them are found at 998, 986 and 894 cm^{-1} respectively for AH in acetonitrile. The value of 909 cm^{-1} is considered to be basis enough for ascribing the band to the C–CH_3 stretching vibration, because in the solid state *N*-methylacetamide and diformylhydrazine have the C–CH_3 stretching band at 892 and 921 cm^{-1} respectively, as has been mentioned above. This assignment is also supported by the fact that a similar frequency shift in the change of states is seen between the 909 cm^{-1} band of AH and the C–CH_3 stretching band at 892 cm^{-1} of solid *N*-methylacetamide. Two other bands, 1034 and 994 cm^{-1}, may be interpreted as follows: if the 1034 cm^{-1} band of solid AH corresponds to the 998 cm^{-1} band of the compound in solution, the value of the frequency shift is 36 cm^{-1}, which value is relatively larger than that of the CH_3 rocking vibration of *N*-methylacetamide. On the other hand, the 994 cm^{-1} band of solid AH is, in the value of frequency, 8 cm^{-1} larger than its 986 cm^{-1} band in solution. This value of the frequency shift is in accordance with that of the CH_3 rocking bands of *N*-methylacetamide. In consequence, the 994 cm^{-1} band of AH is ascribed to the CH_3 rocking vibration and the 1034 cm^{-1} band is due to another vibrational mode.

Solid AH has four more bands, at 1633, 1316 (or 1276), 1154 and 1034 cm^{-1}, not yet acounted for. These four bands correspond, respectively, to the bands at 1625, 1347, 1105 and 1009 cm^{-1} of cyanoacetylhydrazine. The 1633 cm^{-1} band is surely to be ascribed to the NH_2 bending vibration, while the latter three bands are due to the NH_2 deformation vibrations.

Let us next consider the absorption spectra of propionyl-, *n*-butyryl- and isovaleryl-hydrazine. They are illustrated in Fig. 4, in which the spectra of corresponding symmetric diacid

hydrazides are represented for purposes of comparison; the infrared frequencies of these monoacid hydrazides are summarized in Table IV.

All of these hydrazides have a very strong band near 3250 cm^{-1}, which may be ascribed to the NH_2 or NH stretching vibrations. In the 1630~1680 cm^{-1} range, these hydrazides are expected to have an amide I band and a band due to the NH_2 bending vibration. These two bands are not separated from each other for propionyl- and *n*-butyrylhydrazine; i. e., they have a very broad and strong band with a center near 1640 cm^{-1}. On the other hand, isovalerylhydrazine has a very strong band at 1632 cm^{-1} which is accompanied with a shoulder band at 1682 cm^{-1}; these two bands are taken, respectively, as a band due to the NH_2 bending vibration and an amide I band. In the region below 1350 cm^{-1}, the spectral patterns of these hydrazides are rather complex, but we can find four bands corresponding to the 1316, 1276, 1154 and 1034 cm^{-1} bands of AH. They are summarized, with other frequencies characteristic of the $-CONHNH_2$ group, in Table V.

Characteristic Frequencies.—As may be seen from Table V, the frequencies characteristic of the $-CONHNH_2$ group were obtained as follows: 1) An amide I band is found near 1670 cm^{-1} for the monoacid hydrazides when examined in the solid state. 2) An amide II band is also shown near 1530 cm^{-1}. 3) All the monoacid hydrazides examined here have a band near 1630 cm^{-1} ascribed to the NH_2 bending vibration. 4) In the region below 1350 cm^{-1}, these hydrazides have four bands which may also be taken as bands characteristic of the $-CONHNH_2$ group. Of these four, one band near 1250 cm^{-1} is probably to be taken as an amide III band. However, the detailed assignment of these four bands is difficult on the basis of the present observations only. The present author plans to examine the infrared absorptions for other monoacid hydrazides and related compounds. 5) A strong band due to the NH_2 or NH stretching vibrations is found near 3250 cm^{-1}.

The author is grateful to Professor Sunao Imanishi of Kyushu University for his generous permission to use the University's spectrophotometer.

*The Reaction of cis-2-α-Carboxyethylcyclopentanol Lactone**

By Tsuguo TANAKA

(Received July 23, 1962)

It is of some interest to synthesize nor-nepetalactone and nor-nepetalic acid through the stereospecific route starting from a compound of an identified structure. The author attempting such a synthesis, has examined some reactions of *cis*-2-α-carboxyethylcyclopentanol lactone[1].

First, in order to obtain cyanoacid III, *cis*-2-α-carboxyethylcyclopentanol lactone (I) was heated with potassium cyanide[2] at 250~260°C for 24 hr., and the products were isolated and fractionally distilled. Two compounds were obtained as the main products. One was a lactone, $C_8H_{12}O_2$ (II), and the other, a cyanoacid, $C_9H_{13}O_2N$ (III). Many differences were observed between the infrared spectra as well as the ultraviolet spectra of lactone II and those of *cis*-2-α-carboxyethylcyclopentanol lactone I, although the molecular formulas of these two lactones are identical.

The 5.83 μ band of the carbonyl stretching vibration of II, as compared with the 5.70 μ band of that of I[1], seems to indicate that the five-membered γ-lactone ring of I is expanded to a six-membered δ-lactone ring[3] linked to the same cyclopentane unit, producing structure (II) of *cis*-3-α-carboxyethylcyclopentanol lactone as a result of the rearrangement[4] induced by potassium cyanide. Lactone II is easily hydrolysed by aqueous sodium hydroxide into the hydroxyacid, which is easily reconverted into the original lactone on acidification. We are dealing with *cis*-lactone in this case. In order to obtain further evidence for structure II, lactone II was hydrolysed with a 10% aqueous sodium hydroxide solution and the sodium salt of hydroxyacid was thoroughly oxidised with potassium permanganate. Two compounds were isolated from the reaction mixture. The one, a tricarboxylic acid, $C_8H_{12}O_6$ (IV), (m. p., 180°C), was identified as α-methyl-β-carboxyadipic acid[5] both by mixed melting point determination and by its infrared spectra, substantially supporting structure II for new lactone. The other, a tricarboxylic acid, $C_8H_{12}O_6$ (m. p., 140°C), was not identified. It might be the lower melting modification of α-methyl-β-carboxyadipic acid, but its identity was not examined because the author could not convert α-methyl-β-carboxyadipic acid (m. p., 180°C[5]) into an acid of m. p. 140°C, either by heating the aqueous solution at 200°C for 10 hr. or by heating it in acetyl chloride[6]. Another possibility is β-(α-carboxyethyl)glutaric acid[7]. But mixed melting of tricarboxylic acid V with it shows a melting point depression.

In order to see whether or not there exists another modification of β-(α-carboxyethyl)-glutaric acid, the synthesis of this acid was attempted.

The condensation of diethyl β-bromoglutarate with diethyl methylmalonate produced diethyl glutaconate (VI) and tetraethyl 2, 3-bis(carboxymethyl)adipate (VII) ; the latter on hydrolysis yielded tetracarboxylic acid (m. p., 203°C) which was proved to be 2, 3-bis(carboxymethyl)adipic acid (VIII), reported previously to have been obtained from diethyl β-bromoglutarate by a different procedure[8]. Another condensation of diethyl malonate with diethyl β-bromoglutarate resulted in the same products. The original aim was no attained. The hydrolysis of cyanoacid III with hydrochloric acid yielded a dicarboxylic acid, $C_9H_{14}O_4$ (IX) (m. p., 130°C).

Cyanoacid III was treated with oxalyl chloride and warmed on the water bath. The cyanoacid chloride X obtained was, very unstable. The distillation of the raw material was accompanied by extensive degradation and resinification and was not considered to be an convenient intermediate for further synthesis.

In the second scheme, attention was centered on the reduction of *cis*-lactone I into hydroxyaldehyde (XII).

The reduction of *cis*-lactone I with lithium

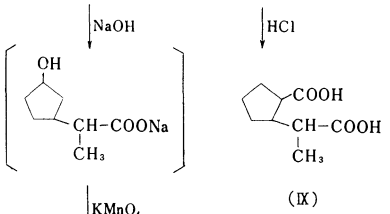
aluminum hydride at a low temperature[9] was not satisfactory. It is liable to produce diol (XIII) and unreacted recoveries. The reduction of methylanilide of hydroxyacid XI with lithium aluminum hydride[10] is also a possible route to a hydroxyaldehyde. It is realized in this case that the reduction of methylanilide XI proceeds in as much as a 50~55% yield. However, the yield of the methylanilide in the reaction of *cis*-lactone with methylanilinomagnesium bromide[11] as well as with methylanilinomagnesium iodide is not satisfactory. When the *cis*-lactone is treated with an equivalent amount of a fresh colorless reagent (immediately after methylaniline has been added), plates (m. p., 130°C (a)) are obtained in a low yield but in a very pure state. However, in the usual procedures using an excess amount of an aged (20 min.), purple-colored methylanilinomagnesium bromide solution, although the yield is improved the products are crystal needles (m. p., 110~120°C) from which, after repeated crystallization from ethyl acetate, a lower yield of crystals (m. p., 130°C (a)) is obtained. The chromatography of a tetrahydrofuran solution of crystals (m. p., 110~120°C) through alumina produced in a 64% yield, crystals (m. p., 130°C (b)), the 14.14 μ band of the infrared spectra of which differs from the corresponding 14.35 μ band of that of crystal with a m. p. of 130°C (a) although the mixed melting of these two methylanilides does not show any melting point depression.

The configuration of the carbon atom adjacent to the carbonyl group of *cis*-lactone I is considered to be that formulated by Ia, whereas for *trans*-2-α-carboxyethylcyclopentanol lactone, either XIVa or XIVb is possible. In accordance with this, the singlet infrared band (10.50; 11.13 μ) of *cis*-lactone appears as a doublet band (10.50, 10.64; 11.13, 11.25 μ) of *trans*-lactone[1]. However, whether or not modifications a and b correspond to XIa and XIb respectively has not been ascertained. It seems probable that the colorless methylanilinomagnesium bromide which is produced immediately by reacting the ethylmagnesium bromide with methylaniline is a covalented $C_6H_5(CH_3)$-N-MgBr and that the aged, purple-colored solution of the reagent is an ionic conjugate, $C_6H_5(CH_3)N^{\ominus}Mg^{\oplus}Br[O(C_2H_5)_2]_2$ which is an effective reagent for the aldol type condensation[12] and which can also act to induce the dissociation of the hydrogen attached to the carbon atom adjacent to the carbonyl group, resulting in the inversion or racemization at a carbon atom adjacent to the carbonyl. For methylanilinomagnesium iodide, however, no such ionic conjugate form seems possible.



By the reaction of hydroxyaldehyde XII with ethylene glycol a high yield to product is obtained, although it is not the ordinary form of the ethylenedioxy derivative but a cyclic acetal formulated in XV[9b].

Experimental

***cis*-3-α-Carboxyethylcyclopentanol Lactone (II) and 2-α-Carboxyethylcyclopentyl Cyanide (III).**—Eight grams of *cis*-2-α-carboxyethylcyclopentanol lactone (I) and 6.4 g. of potassium cyanide are sealed in a glass tube and heated at 250~260°C for 24 hr. The mass becomes a dark solid. After cooling, the tube is opened (a slight pressure is observed) and the reaction mass is dissolved in 60 ml. of water. When 10 ml. of 6 N hydrochloric acid is added to the solution, it becomes turbid and some tarry substance separates. The suspension is made alkaline by the addition of an excess of a saturated sodium bicarbonate solution, and a small amount of active charcoal is added and filtered. The tarry residue is further extracted with a sodium bicarbonate solution. The filtrates are joined and acidified with 30 ml. of concentrated hydrochloric acid and extracted with ether. The ether layer is separated and washed with water. Ethereal solutions obtained from six batches of such a reaction (treating 48 g. of *cis*-lactone) are joined and then dried with sodium sulfate. The ether is evaporated, and the residue is distilled in a vacuum. Two fractions are obtained as the main distillate.

Fraction 1: 15 g. of oil (b. p., 48~85°C/3 mmHg), the redistillation of which gives 13 g. of the fraction (b. p. 85~86°C/3.5 mmHg). Yield, 27.1%. λ_{max}^{EtOH} 211 mμ, IR 5.83 μ (C=O), 8.24 μ (C-O).

Found: C, 68.05; H, 8.80. Calcd. for $C_8H_{12}O_2$: C, 68.54; H, 8.63%.

Fraction 2: 11 g. of oil (b. p., 126~127°C/0.6 mmHg. Yield, 22.9%. λ_{max}^{EtOH} 212.5 mμ, IR 5.84 μ (C=O), 4.42 μ (C≡N).

Found: C, 64.12; H, 8.22; N, 6.99. Calcd. for $C_9H_{13}O_2N$: C, 64.65; H, 7.84; N, 8.38%.

Oxidation of *cis*-3-α-Carboxyethylcyclopentanol Lactone (II) with Potassium Permanganate.—To a stirred and ice-cooled solution of 3g. of lactone (II) dissolved in aqueous sodium hydroxide (1.1 g. sodium hydroxide in 9 ml. water), a saturated aqueous solution of 12 g. of potassium permanganate is added for 30 min.; the mixture is then left to stand overnight. Copious precipitates of manganese dioxide are filtered out, and the mother liquor is evaporated to a syrup, acidified with concentrated hydrochloric acid, and evaporated to dryness; the residue is then extracted with ether. Evaporation of the ether produces crystals (m. p., 120°C) which are dissolved in ethyl acetate and precipitated by adding petroleum ether. The procedure is repeated again, and the precipitate thus obtained is recrystallized twice from ethyl acetate. M. p., 140°C. 300 mg. Melting point depression was observed by mixed melting with authentic β-(α-carboxyethyl)-glutaric acid synthesized by the method of Skraup[7]. IR 5.86, 5.81 (shoulder) μ (C=O)[13].

Found: C, 47.26; H, 6.21. Calcd. for $C_8H_{12}O_6$: C, 47.06; H, 5.92%.

The filtered manganese dioxide is extracted three times with 100 ml. of a 3% aqueous sodium hydroxide solution. The combined filtrates are evaporated to a syrup, acidified with concentrated hydrochloric acid and evaporated to dryness. The residue is extracted with ether; the evaporation of ether from the ether extract produces crystals with a m. p. of 160°C which, after recrystallization twice from ethyl acetate, give crystals with a m. p. of 180°C, the mixed melting of which with authentic α-methyl-α-β-carboxyadipic acid does not show any melting point depression; also the infrared spectra of this acid is superimposable with that of α-methyl-β-carboxyadipic acid synthesized by Perkin's method. IR 5.89, 5.83 (shoulder) μ (C=O).

Found: C, 47.05; H, 6.28. Calcd. for $C_8H_{12}O_6$: C, 47.06; H, 5.92%.

2-α-Carboxyethylcyclopentanecarboxylic Acid (IX).—One gram of cyanoacid III is dissolved in 7 ml. of concentrated hydrochloric acid and refluxed for 8 hr. Hydrochloric acid is evaporated on the water bath, and from the concentrated hydrochloric acid solution crystals separate out on cooling. Recrystallized from ethyl acetate. M. p., 130°C. Yield, 150 mg.

Found: C, 57.77; H, 7.62. Calcd. for $C_9H_{14}O_4$: C, 58.05; H, 7.58%.

α-(2-Cyanocyclopentyl)propionic Acid Chloride (X).—Three grams of cyanoacid III, 3.5 g. of oxalyl chloride and 6 ml. of benzene are mixed and refluxed on the water bath for 2 hr. Benzene and excess oxalyl chloride are evaporated off, and the residue is distilled in vacuum. 2.1 g. of the fraction with a b. p. of 90~105°C/3 mmHg is obtained, from which on redistillation there emerges a fraction with a b. p. of 96.5~99.5°C/0.6 mmHg. IR 5.60, 5.91 μ (C=O); 4.44 μ (C≡N).

Found: C, 58.63; H, 6.49; N, 5.76. Calcd. for $C_9H_{12}ONCl$: C, 58.22; H, 6.52; N, 7.55%.

Tetraethyl 2,3-Bis(carboxymethyl)adipate (VII).—(1) 0.7 g. of sodium is dissolved in 25 ml. of absolute alcohol, to which after cooling is added 5.2 g. of diethyl methylmalonate. The solution is stirred and kept at 20°C, and 8 g. of diethyl-β-bromoglutarate is added to it over the period of

13) Those of synthetic β-(α-caboxyethyl)glutaric acid are 5.73, 5.87 and 5.95 (shoulder) μ. Many differences are observed between the infrared spectra of the acid (m. p., 140 C°) isolated and those of β-(α-carboxyethyl)glutaric acid and α-methyl-β-carboxyadipic acid.

an hour. Stirring is continued at 20°C for an hour more, and then the solution is refluxed on a water bath for an hour. The alcohol is distilled off, the reaction mixture is poured into ice-water, and the product is extracted with ether. The ether layer is washed with water and dried with sodium sulfate. The ether is distilled off, and the residue is distilled in vacuum. Three fractions are obtained. Fraction I. B. p., 60°C/2.5 mmHg (obtained by redistillation of the fraction with a b. p. of 63~120°C/4 mmHg). 3.6 g. Diethyl methylmalonate. By reaction with ammonia, it gives methylmalonamide (m. p., 206°C). Fraction II, B. p., 83~85°C/2.5 mmHg (obtained by redistillation of the fraction with a b. p. of 63~120°C/4 mmHg). Diethyl glutaconate. IR 5.8 μ (C=O), 6.05 μ (C=C), 2.90 μ (very weak, OH)[14].

Found: C, 57.74; H, 7.71. Calcd. for $C_9H_{14}O_4$: C, 58.05; H, 7.58%. Fraction III. B. p., 155~165°C/2.5 mmHg. 2.4 g. Tetraethyl 2,3-bis(carboxymethyl)adipate.

Found: C, 57.77; H, 7.83. Calcd. for $C_{18}H_{30}O_8$: C, 57.74; H, 8.08%.

(2) 0.6 g. of sodium is dissolved in 17 ml. of absolute alcohol, to which is added 4.2 g. of diethyl malonate. The solution is stirred and cooled in an ice bath, and 7 g. of diethyl β-bromoglutarate is added to it over a 30-min. period. After the addition is over, stirring is continued for 2.5 hr.; then the solution is refluxed on a water bath for 2 hr. more. After cooling, the reaction mixture is poured into ice-water and dried with sodium sulfate. The ether is distilled off, and the residue on distillation in vacuum yields three fractions. Fraction I. B. p., 60~65°C/2.5 mmHg. 4 g. Diethyl malonate. By reaction with ammonia it gives malonamide (m. p., 168°C). Fraction II. B. p., 82~85°C/2.5 mmHg. 2.3 g. Identified as diethyl glutaconate by comparison of infrared spectra. Fraction III. B. p., 153~155°C/2.5 mmHg. 1 g. Tetraethyl 2,3-bis(carboxymethyl)adipate.

Found: C, 57.87; H, 7.89. Calcd. for $C_{18}H_{30}O_8$: C, 57.74; H, 8.08%.

2,3-Bis(carboxymethyl)adipic Acid (VIII).—Two grams of tetraester VII is mixed with 18 ml. of concentrated hydrochloric acid and refluxed for 10 hr. After evaporation of the hydrochloric acid and cooling, crystals separate out which are three times recrystallized from ethyl acetate. M. p., 203°C. On further recrystallization from acetone, it shows a m. p. of 206°C. Yield, 200 mg.

Found: C, 45.92; H, 4.99. Calcd. for $C_{10}H_{14}O_8$; C, 45.80; H, 5.38%.

Diethyl β-Bromoglutarate.—7.2 g. of β-bromoglutaric acid[15], 36 ml. of absolute alcohol and 1.8 g. of concentrated sulfuric acid are mixed and refluxed for 5 hr. Thirty milliliters of benzene is added to it, the benzene and alcohol are distilled off, and the residue is poured into ice-water and extracted with ether. The ether layer is separated, washed with an aqueous sodium bicarbonate solution and water, dried with sodium sulfate, and distilled. B. p., 114~115°C/2.5 mmHg. 7.3 g.

Found: C, 40.67; H, 5.84. Calcd. for $C_9H_{15}O_4Br$: C, 40.46; H, 5.66%.

Reduction of *cis*-Lactone I with Lithium Aluminum Hydride.—Twenty-one grams of *cis*-lactone I is dissolved in 40 ml. of tetrahydrofuran and cooled to −15~−13.5°C, while 1.8 g. of lithium aluminum hydride dissolved in 60 ml. of tetrahydrofuran is efficiently stirred in at this temperature over a 40-min. period. Stirring is continued at that temperature for 30 min., and then the solution is left to stand to raise the temperature to 7°C. The reaction mixture is poured into ice-colled aqueous hydrochloric acid (concentrated hydrochloric acid 110 ml. in 200 ml. of water), and extracted with ether. The ether layer is separated, washed with water, and dried with sodium sulfate. The ether is distilled off and, on fractionation of the residue, the following fractions are obtained. Fraction I. B. p., 72~82°C/5.5 mmHg. 0.2 g. Fraction II. 82~89°C/5.5 mmHg. 3.8 g. The infrared spectra of these fractions show a band of 2.98 μ (OH stretching), but it lacks many of the characteristic bands of hydroxyaldehyde XII and is considered to be an unreacted lactone contaminated with some hydroxylic compounds. Fraction III. B. p., 89~93°C/5.5 mmHg. Recovered lactone. Fraction IV. B. p., 132~135°C/3 mmHg. 6 g. *cis*-Diol XIII.

Methylanilide of *cis*-2-α-Carboxyethylcyclopentanol (XI).—Into a solution of ethylmagnesium bromide (prepared by the reaction of 48 g. of magnesium with 24 g. of ethyl bromide in 200 ml. of ether) is efficiently stirred a solution of 18.2 g. of methylaniline in 50 ml. of ether (nitrogen atmosphere; moisture is avoided) over a 10-min. period in an ice bath. After stirring is continued for 25 min., a deep purple solution of methylanilinomagnesium bromide is produced, to which is added 11 g. of *cis*-lactone I in 50 ml. ether for 5 min. The ice bath is removed, and the reaction mixture is refluxed for one and a half hours with stirring. After the reaction is over, the mixture is cooled in an ice bath and decomposed by the addition of dilute hydrochloric acid (30 ml. of concentrated hydrochloric acid in 300 ml. of water). The products are thoroughly extracted with ether, and the ether layers are separated, washed with an aqueous sodium bicarbonate solution and water, and dried with sodium sulfate. The ether is distilled off, and the residue, which separates as a yellow solid, is washed with a small amount of ethyl acetate. Crystals with a m. p. of 110°C are obtained. Yield, 11 g. After recrystallization six times from ethyl acetate, 3.2 g. of plates (m. p., 130°C) are obtatined. IR 6.18 μ (C=O), 2.99 μ (OH).

Found: C, 72.75; H, 8.52; N, 5.66. Calcd. for $C_{15}H_{21}O_2N$: C, 72.84; H, 8.56; N, 5.66%.

From the mother liquor, needles with a m. p. of 110~118°C are obtained.

Found: C, 72.72; H, 8.48; N, 5.76. Calcd. for $C_{15}H_{21}O_2N$: C, 72.84; H, 8.56; N, 5.66%.

In an analogous procedure using 12 g. of *cis*-lactone I, 9.8 g. of methylaniline, 2.4 g. magnesium and 12 g. of ethylbromide, 9.8 g. of raw crystals with a m. p. of 110°C are obtained; from these, after repeated recrystallization from ethyl acetate, 4.6 g. of

14) F. Henrich, *Ber.*, **35**, 1663 (1902).
15) Obtained by the method of Semenow, *Chem. Zentr.*, **11**, 28 (1899).

plates (m. p., 130°C) are obtained. However, when the reaction is conducted in such a way as *cis*-lactone I is added to a fresh colorless methylanilinomagnesium bromide solution (immediately after methylaniline has been added), the yield of the raw methylanilide is 6.5 g.; from these, after one recrystallization from ethyl acetate, 4.8 g. of plates (m. p., 130°C) are obtained.

By the use of 6 g. of *cis*-lactone I, 11.5 g. of methylaniline, 2.5 g. of magnesium and 14.2 g. of methyl iodide, 4.4 g. of the raw methylanilide is obtained; after recrystallization from ethyl acetate this gives 2.8 g. of crystals with a m. p. of 130°C. Methylanilinomagnesium iodide consists of crystals insoluble in ether. A tetrahydrofuran solution of methylanilide with a m. p. of 110~118°C is chromatographed on alumina. From an tetrahydrofuran effluent plates with a m. p. of 130°C are obtained in a 64% yield after one recrystallization from ethyl acetate. However, the 14.14 μ band of the infrared spectra of these plates differs from the 14.35 μ band of that of crystals with a m. p. of 130°C obtained by direct crystallization of the reaction product.

***cis*-2-α-Formylethylcyclopentanol (XII).**—11.5 g. of methylanilide of *cis*-2-α-carboxyethylcyclopentanol is dissolved in 110 ml. of tetrahydrofuran and cooled in an ice-salt bath. 1.1 g. of powdered lithium aluminum hydride is efficiently stirred into it for 30 min. After the addition is over, the ice-salt bath is replaced by an ice bath and stirring is continued for 7.5 hr. 200 ml. of hydrochloric acid (1 : 4) is added, the mixture is left to stand overnight and then extracted with ether. The ether layer is separated, washed with water and dried with sodium sulfate. The ether is distilled off, and the residue is distilled in vacuum. 3.5 g. of an oil b. p. 89~90°C/5 mmHg are obtained. *cis*-2-α-Formyl ethylcyclopentanol. IR 2.93, 2.85 μ (OH), 5.70 μ (C=O).

Found: C, 68.00; H, 8.94. Calcd. for $C_8H_{14}O_2$: C, 67.57; H, 9.93%.

Ethylenedioxy Derivative XV.—Four grams of 2-α-formylethylcyclopentanol and 2.5 g. of ethyleneglycol, together with 20 mg. of *p*-toluenesulfonic acid, are dissolved in 15 ml. of benzene and refluxed for 3 hr. 50 ml. of benzene is gradually added while the amount of benzene and water formed in the reaction are distilled off over a 4-hr. period. After cooling, the reaction mixture is diluted with ether, washed with an aqueous sodium bicarbonate solution and water, dried with sodium sulfate, and distilled. 3.1 g. of an oil (b. p., 76~78°C/3 mmHg) are obtained.

Found: C, 68.65; H, 8.86. Calcd. for $C_{18}H_{30}O_4$: C, 69.64; H, 9.74%.

The author is grateful to Mr. H. Kotsuma*1 and Dr. Y. Kanda*2 for the determination of the infrared spectra and to Mr. M. Shito*2 for his microanalysis.

NOTES

A Supplementary Note on the Author's Equation of State

By Tetsuya ISHIKAWA

(Received June 4, 1962)

Bentley's mass spectral study at room temperature of carbon dioxide gas[1] seems to give a concrete meaning to the ε of the author's equation of state: $p+a/V^{2-\varepsilon}=RT/(V-b)$, where $a=3p_cV_c^2$, $b=V_c/3$, and ε is a parameter depending upon molecular association[2]. Since ε is presumably the concentration of associated molecules (cybotactic groups) as judged from the deduction of the equation from the kinetic theory of gases[3], the $(2-\varepsilon)$ parameter should be the concentration of unassociated molecules. If this is really so, $\varepsilon/(2-\varepsilon)$ may correspond to the total intensities of CO_2^+, $(CO_2)_2^+$, $(CO_2)_3^+$, ……, and $(CO_2)_{23}^+$ relative to CO_2^+, which is numerically equal to 0.0442 as estimated from the graph given by Bentley. In his graph the point for $(CO_2)_{23}^+$ is lacking, probably because experimental errors for polymers above $(CO_2)_{22}^+$ become too great for actual values to be decided.

For the test of this postulation, the author has quoted PVT measurements on carbon dioxide at the critical temperature (30.98°C) from the I. C. T.[4] and those at 32.075, 31.037, 25.053 and 0°C from Michels and Michels' data[5], using 44.011 for the molecular weight and 1.9768 g. cm^{-3} for the density at 0°C.

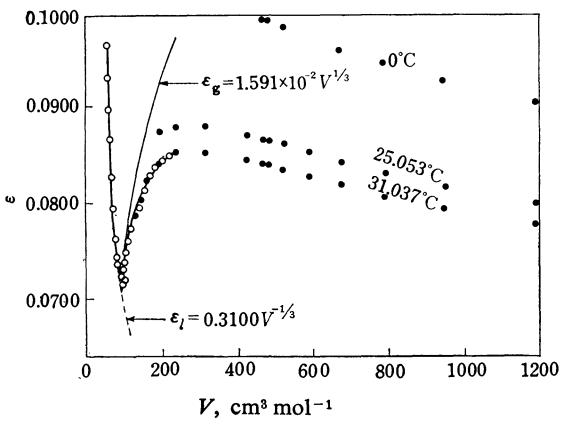

Fig. 1. ε-V Diagrams of carbon dioxide at 30.98, 31.037, 25.053 and 0°C.

ε-V relations are shown in Fig. 1, in which the values from the former data are denoted by white circles and those from the latter data by black circles. The analysis of ε at the critical temperature is quite similar to that already made in the case of isopentane[6].

We obtain for the liquid portion $\varepsilon=5.046\ V^{-1}$ ($V=52.59\sim63.72$) and $\varepsilon_l=0.3100\ V^{-1/3}$ ($V=67.93\sim73.38$); for the liquid and gaseous coexisting portion $\varepsilon_l+\varepsilon_g=0.1406$ ($V=81.40\sim106.36$) and $\varepsilon_g=1.591\times10^{-2}\ V^{1/3}$; and, for the gaseous portion, $\varepsilon=\varepsilon_g-cV^n$, $n=4$, $c=7.130\times10^{-12}$ ($V=113.59\sim139.71$), $n=3$, $c=1.116\times10^{-9}$ ($V=156.54\sim190.63$), and $n=2$, $c=2.284\times10^{-7}$ ($V=207.37\sim224.15$), the numbers in parentheses indicating volume ranges in $cm^3\ mol^{-1}$. The calculated pressures from these values have an average deviation of $\pm0.52\%$ from the observed pressures[7].

Granting that the ε values at the lowest pressure, 16.5~19.0 atm., listed in Michels and Michels' data are not so much different from those for 5 atm., at which the pressure of the beam of gas molecules passing through a small orifice and a series of larger orifices from a reservoir was maintained in Bentley's measurements, we can guess at what temperature his measurements were made: Bentley's value, 0.0442, will lie on a straight line passing through the four values of $\varepsilon/(2-\varepsilon)$ at 32.075, 31.037, 25.053 and 0°C, namely, 0.0403 at 19.0843 atm., 0.0405 at 19.0023 atm., 0.0417 at 18.5374 atm., and 0.0474 at 16.5488 atm., if his measurements were made at 14.2°C. However, as Bentley remarked, cooling of the bulk gas occurs as a result of the Joule-Thomson effect, which is less than 6°C for 5 atm.; his so-called room temperature seems, therefore, to have been about 20°C.

In Bentley's reply to the author's request, he

said the room temperature was indeed about 20°C; it is difficult to give a more precise figure as the work was done over a long period during which the temperature altered by several degrees.

The above consideration leads us to the following conclusion: $\varepsilon/(2-\varepsilon)$ corresponds to the ratio of the total sum of ion intensities of polymers to that of monomers, at least so far as the present data are concerned.

On the Relation among γ-, η- and δ-Al_2O_3 under Hydrothermal Condition

By Goro YAMAGUCHI and Hiroaki YANAGIDA

(Received June 19, 1962)

What was formerly called simply γ-Al_2O_3 may in truth consist of the three forms of γ-, η- and δ-Al_2O_3. The γ-Al_2O_3 is usually obtained by dehydration of good crystalline boehmite γ-$Al_2O_3 \cdot H_2O$ in air over 500°C[1]. The crystal structure is considered to be closely related to that of spinel $MgO \cdot Al_2O_3$[2,3] with a small amount of strongly bound water[4,5], but slightly deformed tetragonally with a lattice constant $a=b=7.96$ and $c=7.82$ Å[6,7]; the (400) peak in the spinel indice in the X-ray diffraction diagram is slightly split into a doublet. The η-Al_2O_3 has been proposed[8] as a product of the dehydration of bayerite α-$Al_2O_3 \cdot 3H_2O$. Its X-ray diffraction diagram seems extremely similar to that of γ-Al_2O_3 except for the (400) peak being hardly split at all[9]. The δ-Al_2O_3 has been proposed as a product of the further heating of γ-Al_2O_3[10]; the peaks in the X-ray diffraction diagram are somewhat sharp and have, except for the weak ones, mostly been attributed to the spinel indice. The existence of η- and of δ-Al_2O_3 as discrete forms independent of γ-Al_2O_3 has been doubted[11]. The present authors have therefore investigated the relation among γ-, η- and δ-Al_2O_3 under hydrothermal conditions.

The starting material was obtained by the dehydration of good crystalline boehmite at 700°C in air. The X-ray diffraction diagram is that of γ-Al_2O_3. This was treated hydrothermally under 20 to 100 atm. at 450 to 500°C. One of the X-ray diffraction diagrams of the products is shown in Fig. 1. There can easily be noticed a remarkable split about the peak (400) in the spinel indice. The diagram about the (400) peak was examined by slow-scanning X-ray diffraction (Geigerflex, Ni filtered Cu$K\alpha$ 30 kV. 10 mamp. irradiation; 1° 1° 0.2 mm. slit system; rate meter, 16; time constant, 4 sec.; scanning speed, 1°/2 min.). The results of the products under various hydrothermal conditions are as shown in Fig. 2 and as summarized in Table I. Under such condition, γ-Al_2O_3 was more deformed tetragonally. The degree of deformation increased as

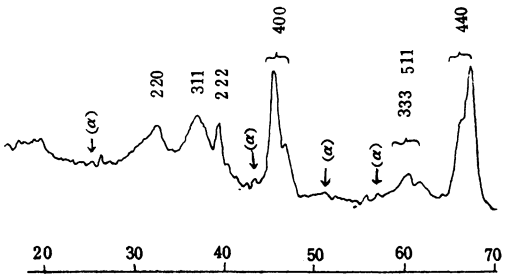

Fig. 1. (γ-Al_2O_3 treated under 50 atm. at 500°C for 15 hr.) No. 9 (α) indicates α-Al_2O_3.

the hydrothermal pressure became high and as the reaction period lengthened. Corundum α-Al_2O_3 was directly obtained from γ-Al_2O_3, while good crystalline γ-Al_2O_3 or δ-Al_2O_3 was not found in the present work.

The tetragonally-deformed γ-Al_2O_3 were re-heated in air at 800°C. The results are summarized in Table II. The degree of tetragonal deformation decreased with re-heating.

The present authors were able to prepare γ-Al_2O_3 with various degrees of tetragonal deformation. The lattice constant could not be determined precisely, for it varied with the conditions of formation. This led us to conclude that there may be η-Al_2O_3 as an extrapolated form of γ-Al_2O_3 with little tetragonal deformation. Good crystalline γ-Al_2O_3 or δ-Al_2O_3 was not found under the hydrothermal conditions.

Deformation Vibration of SiOH

By Reisuke SODA

(Received July 14, 1962)

When crystalline silica is ground into fine particles which have a particle size of about 1 μ, its surface is destroyed and its original structure is modified into an irregular one. On this layer, which is easily soluble in an aqueous alkaline solution, the silanol group is formed by the reaction between atmospheric water vapor and the Si–O$^-$ or Si$^-$ which is produced by the cleavage of the Si–O–Si bond. A parallel exists between the grinding process and the infrared absorption spectrum of the particle; i. e., the spectrum of the ground particle gives rise to a band at 950

cm^{-1} band, and the band group near 1100 cm^{-1} becomes more diffuse. The present author[1,2] has previously assigned the band near 1100 cm^{-1} to the SiO stretching vibration which appeared on the new surface layer and the band at 950 cm^{-1} to the SiOH deformation vibration. On the basis of the experimental finding that the band at 950 cm^{-1} diminishes or decreases in intensity by ethylation of the ground particle, his assignment has been considered to be correct[3]. Recently, however, Takamura et al.[4] assigned the band at 950 cm^{-1} to the SiO stretching vibration of the silicate structure which is produced on the new surface layer and the band near 1120 cm^{-1} to the SiOH deformation vibration on the basis of the results of the deuteration and other treatments of the particle. The experimental results described above can be explained according to the assignments made by Takamura et al. Ethylation of the SiOH of the silicate structure produces SiOEt, and then the SiO structure of the silicate decreases; therefore, the band at 950 cm^{-1} decreases in intensity. The fact that the ethylation is more difficult than the deuteration can be also explained, considering that the SiO in the silicate structure has an ionic bond character, while the SiO in SiOEt has a homopolar bond character and that the reaction from SiOH in the silicate structure to that in SiOEt must pass over a relatively high activated-energy level. Therefore, the present author wishes here to correct his assignment of the 950 cm^{-1} band to the SiO stretching vibration and the band near 1100 cm^{-1} to the SiOH deformation vibration.

Shimadzu[5] has found a resemblance between the infrared absorption bands near 1100 cm^{-1} of the leached particle, the size of which is less than 0.1 μ, and that of the ground particle, but he found no band at 950 cm^{-1} for the leached particle. The surface of the particle is a terminal structure of the SiO_2 frame, and, therefore, it normally consists of Si–O–H and Si–O–Si bonds, the former being particularly dominant. Fine particles have a larger surface area, and the SiOH group increases in proportion to the particle size. The leached particle apparently does not have a silicate structure which is easily soluble in an aqueous solution of sodium hydroxide. These facts are only explainable by the assignments made by Takamura et al. Though the structure of the surface layer of the particle which is considered to be silicate-like SiO by Takamura et al. should be further reexamined, their assignment of the SiOH deformation vibration is correct.

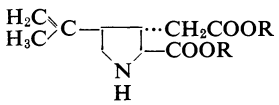
Nuclear Magnetic Resonance Spectra of Isopropenyl Groups

By Kazue KONDO, Yoshikazu KONDO, Tsunematsu TAKEMOTO and Tsuneo IKENOUE



(Received August 6, 1962)

Definition of structures on α-kainic acid and α-allokainic acid as anthelmintic agent of *Digenea simplex* has been presented by Takemoto et al.[1] and by Morimoto et al.[2] In this report nuclear magnetic resonance (NMR) spectra of these compounds were observed by a Varian V-4300B NMR spectrometer at a fixed frequency 40 Mc.

Since both α-kainic acid (I) and α-allokainic acid (III) did not have a sufficient solubility in organic solvents to measure their NMR spectra at 40 Mc., their dimethyl esters, dimethyl α-kainate (II) and dimethyl α-allokainate (IV), were employed for the measurement of their spectra.

(I) R=H
(II) R=CH_3

(III) R=H
(IV) R=CH_3

The interesting patterns of olefinic protons, doublet in the case of II and singlet in IV respectively, are illustrated in Fig. 1. It is considered that there is difference in degree of receiving steric hindrance dynamically when isopropenyl group makes rotation. In other words, H_b of olefinic protons and methyl group of isopropenyl receive a steric hindrance at

C_5 protons when they are rotated. Further, in the case of II they also receive steric hindrance from the protons of methylene group in C_3 side chain, so that the dynamic steric hindrance is greatly increased. Therefore, H_b shifts to low field considerably. H_a also shifts very slightly. The C_5 protons and methylene of C_3 side chain in II both shift to lower field in comparison with IV. These results may be also explained as follows; when isopropenyl group is rotated, the olefinic proton H_b is locating in high probability between C_5 protons and the methylene protons of C_3 side chain which are affected by the long-range shielding of double bond of isopropenyl group.

It is of interest that olefinic protons, methylene protons of C_3 side chain and C_5 protons are all broad compared with the spectrum of

other groups and fine splittings greater than 1 c. p. s. were not observed in each of them. It is considered that the broadening are due to the asymmetry of their electron cloud caused by the dynamic steric hindrance.

Doublet patterns of NMR spectra is also observed in olefinic protons of isopropenyl group of other compounds (Table I)[3-5]. When its adjacent group is polar group or aromatic ring[3,6] its patterns shows doublet. This is thought to be caused by different degree of inductive effect or long-range shielding one. On the contrary, when the effects of polar group and of imhomogeneous magnetic field are both weak, and the effect of dynamic steric hindrance is considered small, singlet structure is observed in olefinic protons (Table II)[3,5-7].

The authors wish to thank Dr. J. Wolinsky for his kindly supply of the NMR data of 1-acetyl-4-isopropenyl-1-cyclopentene and several other compounds.

The Geometric Factor of Catalysts in the Isotopic Exchange Reaction of Paraxylene with Deuterium Oxide

By Kozo HIROTA and Tomiko UEDA

(Received August 8, 1962)

Since two decades ago, the geometric factor of catalysts have been discussed by Horiuti[1], Beeck[2] and others as an interesting problem in catalysis. However, it is difficult to investigate this factor extensively for lack of such convenient reactions as to fulfill the requirement of investigation.

According to our former reports[3], it has been found promising to use the isotopic exchange reaction of *p*-xylene with deuterium oxide for such purpose, because some catalysts (nickel, nickel-silica, nickel-kieselguhr) can exchange only methyl hydrogen with deuterium while others (platinum, palladium and nickel-alumina) can exchange hydrogen of benzene ring as well as of methyl groups. Such a selectivity now observed can be determined without any knowledge of exchange activities per unit area of each metal. Moreover, the reaction suits the present purpose, by the reason that it is unnecessary to take the electronic factor of metals into consideration. Because even if work function has some connection with the mechanism of both exchange reactions, the selectivity above mentioned would be invariant, as far as their ratio of velocities is concerned.

The research has, therefore, been extended to other metals since the former papers, adopting the same method of research, and a relation was found between the selectivity and the geometric factor of catalysts; i. e., if the ratios of the exchanged degree* of ring hydrogen to that of methyl hydrogen are plotted against lattice constants** of the catalysts, a

* The exchanged degree was determined by the mass-spectrometric and NMR methods.

** R. W. G. Wykoff, "Crystal Structures", Vol. I, Interscience, New York (1948—1958).

monotonous curve is obtained between the two quantities, as shown by the curve in Fig. 1. For the sake of reference the ratios are plotted against Pauling's d-characters of the metals as triangles as shown in Fig. 1. As might be expected, it seems that no relation exists between them.

It will be mentioned here that this relation is perfectly different from the one found by Beeck[2] in the hydrogenation of ethylene with films of similar metals; i.e., he found a maximum in the curve of logarithms of velocity constant vs. lattice constants of these metals. The present result resembles, however, that of Balandin[4], who found a linear relation between interatomic distance and activation energy in the dehydrogenation of isopropanol.

Any explanation is not given here to the discrepancy found above, because such an attempt would not be so easy, considering the situation that the reactions to be discussed are not the same in the cases of Beeck, Balandin and the present authors.

We express our thanks to Professor Ryoiti Kiriyama, Osaka University, who kindly taught us the recent data of lattice constants.

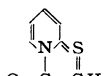
Preparation of Meso-ionic ψ-Pyrido[2,1-b]-3,4-dihydro-4-keto-(and imino)-thiazole[1] *by a New Mode of Formation**

By Hiroshi KATO, Kazuo TANAKA and Masaki OHTA

(Received August 29, 1962)

Duffin and Kendall[2] have prepared a meso-ionic compound I[3] by the reaction of (2-pyridylthio)-acetic acid and acetic anhydride. In an attempt to prepare meso-ionic compounds of the type II, in which the positions of CH and CO groups in the meso-ionic ring are reversed, the authors have carried out the reaction between *S*-acetyl-2-mercaptopyridine (yellow liquid, b.q. 96~99°C/3.5 mmHg; absence of band between 1600 and 1700 cm^{-1} due to non-benzenoid double bond system[4], ν_{CO} 1050, 952, 770 cm^{-1} [5]; Found: C, 54.56; H, 4.86; N, 9.30. Calcd. for C_7H_7NOS: C, 54.90; H, 4.61; N, 9.15%.) and chloroacetic acid. The reaction product was, quite unexpectedly, identical with I instead of the expected quaternary salt.

The same compound I was formed by the following reactions: i) *S*-benzoyl-2-mercaptopyridine (white needles, m.p. 44~45°C, b.p. 172°C/3 mmHg; Found: C, 66.76; H, 4.39; N, 6.48. Calcd. for $C_{12}H_9NOS$: C, 66.97; H, 4.22; N, 6.51%.) and chloroacetic acid (accompanied by benzoic acid); ii) *S*-acetyl- or *S*-benzoyl-2-mercaptopyridine and chloroacetamide; iii) (2-pyridylthio)-acetamide (white leaflets, m.p. 80°C; Found: C, 49.88; H, 4.88; N, 16.68. Calcd. for $C_7H_8N_2OS$: C, 50.00; H, 4.80; N, 16.66%.) and acetyl chloride (accompanied by acetamide)[6]; iv) sodium 2-pyridylmercaptide and chloroacetyl chloride, followed by acetic anhydride and sodium acetate.



This type of ring formation was further extended to the preparation of the unknown corresponding meso-ionic acyl-imino derivatives III by the reaction with chloroacetonitrile: the reaction of *S*-acetyl-2-mercaptopyridine with chloroacetonitrile in benzene gave III (R=Me yellow needles, m.p. 73~74°C; absence of ν_{CN} in 2200~2300 cm^{-1}; Found: C, 51.52; H, 5.06; N, 13.58. Calcd. for $C_9H_8N_2OS+H_2O$: C, 51.42; H, 4.80; N, 13.33%;

* Presented at the 15th Annual Meeting of The Chemical Society of Japan, Kyoto, April, 1962.

1) The authors have adopted the nomenclature and symbol proposed by Baker. (W. Baker, W. D. Ollis and V. D. Poole, *J. Chem. Soc.*, **1949**, 311; W. Baker and W. D. Ollis, *Chem. & Ind.*, **1955**, 910.)

2) G. F. Duffin and J. D. Kendall, *J. Chem. Soc.*, **1951**, 734.

3) Duffin and Kendall (*J. Chem. Soc.*, **1956**, 361) are now of the opinion that compounds of this type can be satisfactorily represented by the structural formula V, and that they should no longer be regarded as meso-ionic. The present authors belive that structure V certainly would contribute to some extent to resonance, but it is more probable that several dipolar canonical forms play important role in the resonance. Discussion on the structure of these types of compounds will be given in a detailed report.

6) Duffin et al.[2] reported that when (2-quinolythio)-acetamide was treated with acetic anhydride, the starting material was recovered unchanged.

hydrochloride: yellow prisms; m. p. 250°C; Found: N, 12.04. Calcd. for $C_9H_9N_2OSCl$: N, 12.25%), and the reaction of *S*-benzoyl-2-mercaptopyridine gave III (R=Ph; yellow needles, m. p. 206°C. Found: C, 66.14; H, 3.75; N, 10.76. Calcd. for $C_{14}H_{10}N_2OS$: C, 66.13; H, 3.96; N, 11.02%.). Compound III was also prepared by the reaction of (2-pyridylthio)-acetonitrile (unstable yellow liquid, b. p. 118 ~120°C/3 mmHg; Found: C, 55.03; H, 3.90; N, 18.26. Calcd. for $C_7H_6N_2S$: C, 56.00; H, 4.03; N, 18.66%.) and acetyl or benzoyl chloride. The corresponding acyl-imino derivative (IV, R=Me; yellow needles, m. p. 215°C, absence of ν_{CN}, Found: C, 64.25; H, 4.40; N, 11.59. Calcd. for $C_{13}H_{10}N_2OS$: C, 64.46; H, 4.16; N, 11.59%. R=PhCO; yellow leaflets, m. p. 273°C, no ν_{CN}, Found: C, 71.30; H, 3.81; N, 9.49. Calcd. for $C_{18}N_{12}N_2OS$: C, 71.04; H, 3.98; N, 9.21%.) was prepared by treatment of (1-isoquinolylthio)-acetonitrile (white plates, m. p. 95.5°C, ν_{CN} 2240 cm^{-1}, Found: C, 65.91; H, 3.84; N,14.27: Calcd. for $C_{11}H_8N_2S$: C, 65.99; H, 4.03; N, 13.99%.) with acetyl or benzoyl chloride, but when (4-lepidyl-2-thio)-acetonitrile (colorless needles, m. p. 65°C, Found: C, 67.28; H, 4.71; N, 13.09. Calcd. for $C_{12}H_{10}N_2S$: C, 67.28; H, 4.71; N, 13.08%.) was treated with acyl chloride by the same method, the starting material was recovered unchanged. The failure of ring formation in this case might be ascribed to the steric hindrance by the hydrogen at 8 position of quinoline nucleus.

The starting material, 1-mercaptoisoquinoline and 2-mercapto-4-lepidine were prepared in almost quantitative yield and in high purity by treatment of the corresponding chloro derivatives with thioacetic acid.

The preparation of intermediate compounds, discussions on the mechanism of formation and the structure, properties and reactions of III and IV and the extension of this type of ring formation to the syntheses of other new meso-ionic ring systems will be reported shortly.

The authors are indebted to the Kawakami Foundation for partial support of this study, and to Kyorin Pharmaceutical Co. for measurement of UV and IR spectra.

Polymerization of Styrene in Liquid Sulfur Dioxide Initiated by Alkyl or Aralkyl Chloride

By Niichiro TOKURA and Tetsuyo KAWAHARA

(Received September 4, 1962)

Alkyl chloride catalyzed polymerization has never hitherto been reported in the literature. Triphenylmethyl chloride has been shown to be a catalyst for a cationic polymerization of vinyl ether in cresol[1]; no detailed information, however, on the mechanism has been indicated. The role of alkyl chloride such as methyl chloride, ethyl chloride or ethyl bromide as a cocatalyst in a cationic polymerization with a Lewis acid catalyst has been the subject of controversy in recent years. While Plesch and his collaborators[2] have indicated in several experiments that alkyl halides are no more an effective cocatalyst for polymerization of isobutene with titanium(IV) chloride, Kennedy et al.[3] have suggested methyl chloride could be a cocatalyst in the same polymerization with aluminum chloride.

In this article, the present authors would like to report on the alkyl or aralkyl chloride catalyzed polymerization (without any Lewis acid) of styrene in liquid sulfur dioxide. It was found that ethyl, *n*-propyl, isopropyl, *n*-butyl, *t*-butyl, α-phenethyl, and benzyl chlorides are all effective catalysts for the cationic polymerization of styrene. No Lewis acid catalyst has been used with the alkyl chloride in the polymerization.

Initial over-all rates were estimated. The viscosity of the polymer was measured in ethyl methyl ketone and the number average molecular weight was calculated from the viscosity using Outer, Carr and Zimm's equation[4],

$$[\eta]_{\mathrm{dl./g.}} = 3.9 \times 10^{-4} \ [\mathrm{M}]^{0.58}$$

The polymerization may be of cationic nature, since (1), no styrene-polysulfone was found in the polymer and (2) any anionic polymerization may be inhibited in liquid sulfur dioxide

because of its acid nature. The elementary analysis and the infrared[5] spectrum of the polymer indicated that the polymer was a polystyrene.

As is listed in Table I, the initial rates of the polymerization initiated by various chlorides seem to follow neither the order of the inductive effect of the respective alkyl groups nor the order of the ionization tendency of the alkyl chloride in liquid sulfur dioxide. Triphenylmethyl chloride has been said to be a good electrolyte in the solvent[6], and an extensive ionization is to be expected in the solvent, but no reproducible result on the polymerization was obtained and the rate was approximately zero. A steric inhibition of the triphenylmethyl carbonium ion may perhaps be partly responsible for the restriction of polymerization. An alternative explanation for the failure of polymerization by triphenylmethyl carbonium ion may exist in the fact that this ion is too stable in liquid sulfur dioxide to initiate the cationic polymerization.

The attempted polymerization with hydrogen chloride as catalyst failed to suggest that the formation of α-phenethyl cation is impossible in liquid sulfur dioxide, since the addition of a proton to styrene, as the following,

$$C_6H_5CH{=}CH_2 + H^+ \rightarrow \underset{\alpha\text{-Phenethyl cation}}{C_6H_5\overset{+}{C}H{-}CH_3}$$

should yield an α-phenethyl cation which might be able to initiate the polymerization as is the case in α-phenethyl chloride. It should be also reminded that α-phenethyl cation[7] has been shown as an acting species for the initiation of the ordinary cationic polymerization of styrene. Inadequacy of hydrogen chloride as a catalyst may be verified by a few studies in our laboratory. The association of hydrogen chloride in liquid sulfur dioxide has already been suggested by one of the present authors[8]. No deuterium exchange in liquid sulfur dioxide between a growing polymer cation and heavy water has also been reported earlier[9]. These facts are well consistent with the protophobic nature of liquid sulfur dioxide.

The fastest rate is attained by benzyl chloride catalysis, however the authors have no appropriate explanation for such a phenomenon at present. As is seen in the table, the polymerization has also been conducted by ethyl, *n*-propyl or *n*-butyl chloride. The production of free carbonium ions of them is not conceivable in ordinary solvent, but a strong solvation of chloride anion with liquid sulfur dioxide may be operative during the polymerization in liquid sulfur dioxide. The ionized carbonium ion may initiate and conduct the polymerization, however, the mechanism of initiation needs a further study.

The authors wish to thank the Seitetsu Kagaku K. K. for the donation of liquid sulfur dioxide.

The Absolute Configuration of the Asymmetric Center at Position of 7 of α- and β-Desmotroposantonin

By Masao Nakazaki

(Received September 13, 1962)

Although the bulk of the evidence[1] mainly deduced from the stereochemistry of α-(II: X, OH) and β-desmotroposantonin strongly favors R-configuration at position 11 of (−)-α-santonin (I), recent publications[2,3] confirmed Abe's assignment[4] of the s-configuration at this center. To settle this discrepancy, the determination of the absolute configuration of α- and β-desmotroposantonin seemed necessary.

The methyl ester of (+)-α-desmotroposantonous acid methyl ether (III: R, CO_2Me) was reduced with lithium aluminum hydride to the alcohol (III: R, CH_2OH), b.p. 160~180°C/10^{-2} mmHg, $[\alpha]_D^{27}$ +60.8° (*c* 2.90 in ethanol), (phenylurethane: m.p. 125~126°C, $[\alpha]_D^{27}$ +47.3° (*c* 0.65 in ethanol)), which was converted with phosphorus tribromide/pyridine to the bromide (III: R, CH_2Br), b.p. 150~160°C/10^{-2}mmHg, $[\alpha]_D^{28}$ +66.4° (*c* 2.24 in ethanol). The bromide was refluxed with lithium aluminum hydride in tetrahydrofuran to afford the methyl ether (III: R, Me), b.p.

145~155°C/3 mmHg, n_D^{29} 1.5328, $[\alpha]_D^{25}$ +60.0° (*c* 2.52 in ethanol), (Found: C, 83.0; H, 10.4. Calcd. for $C_{16}H_{24}O$: C, 82.70; H, 10.41%). Exhaustive ozonolysis (30 hr.) of III (R, Me) followed by peracetic acid oxidation gave crude β-isopropyladipic acid (IV: R, H) which was purified via the dimethyl ester (IV: R, Me), b.p. 100~150°C (bath temp.)/5 mmHg. Heating IV (R, H) with barium hydroxide at 280~300°C gave 3-isopropylcyclopentan-1-one (V) which was directly converted into the semicarbazone, m.p. 181~183°C, $[\alpha]_D^{31}$ +43.8° (*c* 0.48 in ethanol), (Found: C, 59.2; H, 8.9: N, 22.7. Calcd. for $C_9H_{17}ON_3$: C, 58.98; H, 9.35; N, 22.93%). Its identity with R-(+)-3-isopropylcyclopentan-1-one semicarbazone[5,6], m.p. 186~187°C, $[\alpha]_D^{26}$ +65.2° (*c* 0.62 in ethanol) prepared from R-(+)-dihydrolimonene[7] was established by mixed melting point (181~183°C) and comparison of infrared absorption (in chloroform).

This correlation established the R-configuration of (−)-α-desmotroposantonin (II: X, OH) at position 7. Since (−)-α-desmotroposantonin may be derived from (−)-α-santonin via isohyposantonin (II: X, H) without affecting the configuration at C_7[8], the R-configuration of (−)-α-santonin at this center is also confirmed.

The fact that (+)-β-desmotroposantonin has the opposite configuration from (−)-α-desmotroposantonin at C_7 was established by the conversion of the former into the enantiomer of III (R, Me), b.p. 110~120°C/0.1 mmHg, n_D^{29} 1.5322, $[\alpha]_D^{28}$ −65.1° (*c* 1.51 in ethanol), (Found: C, 82.6; H, 10.3. Calcd. for $C_{16}H_{24}O$: C, 82.70; H, 10.41%), whose infrared absorption spectrum was found superimposable on that of III (R, Me).

High-resolution NMR Spectra of Crystalline Cyclohexanol

By Hiroshi SUGA and Syûzô SEKI

(Received September 22, 1962)

Usually, broad line NMR spectral study gives some important informations on the nature of molecular motion in the crystalline state by observing so-called motional narrowing. On the other hand, high-resolution NMR spectrometer has been generally applied to the study of chemical shift only when the samples are in their liquid or solution states.

We have been studying for a long time the behavior of molecular motion in the plastic crystals[1], mainly by use of X-ray and thermal methods[2]. This kind of crystals has been known to exhibit self-diffusion phenomenon even at the temperatures considerably below their melting points[3]. These things led us to expect strongly that the high-resolution NMR techniques would disclose their usefulness for investigating molecular motion in these crystals in more details and also for observing directly chemical shifts of the protons involved in the constituent molecule. We have chosen cyclohexanol crystal for the study of this purpose and found it was indeed the case.

Measurement were carried out with the Varian Associates Model V-4311 high-resolution NMR spectrometer. Comparison of the entropy of transition[4], $\Delta S_{tr}=7.44$ e. u. ($T_{tr}=263.5°K$), and entropy of fusion[4], $\Delta S_f=1.37$ e. u. ($T_f=297.0°K$) of the present material with the entropies of fusion of rare gases, such as argon: $\Delta S_f=3.4$ e. u.[5] and krypton: $\Delta S_f=3.38$ e. u.[6] and also broad line NMR study by Averbuch[7] below the transition point suggest strongly the possibility of occurrence of the self-diffusion above the transition point.

As we have expected, the line width is sufficiently narrow to give well-separated peaks originated from different protons even just above the transition point. The area under the peaks stand roughly in the ratio 1 : 1 : 10, as would be expected if each peak in the order

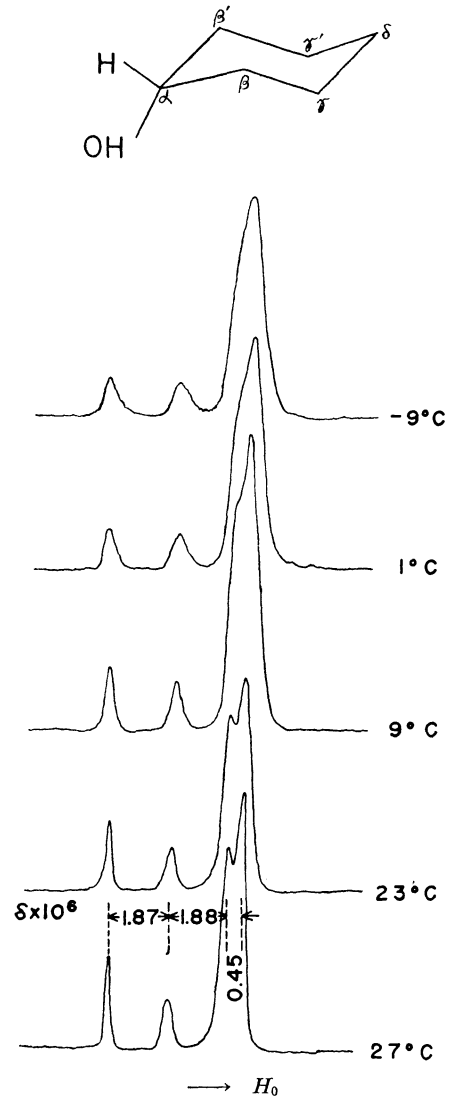

Fig. 1. Temperature variation of high-resolution NMR spectra of cyclohexanol.

of increasing field corresponded to the chemically different OH, H_α and the other ring protons (see figure). As the temperature rises and the line width of each peak narrows by the self-diffusion process, the main peak gives a further splitting in the approximate intensity ratio 2 : 3. These two peaks may not be due to chemical shifts between the axial and the equatorial ring protons, since there are equal number of protons in each species, and rather may be interpreted as the chemical shift between H_β (or $H_{\beta'}$) and H_γ (or $H_{\gamma'}$) plus H_δ. The rate at which the change from one conformation to the other of the cyclohexanol isomers will be faster[8] than the inverse of the chemical shift

difference between the axial and the equatorial protons attached to the same carbon atom. There is no discernible change in the line width at the melting point.

In conclusion, it was revealed that the high-resolution NMR spectrometers were also useful for investigating the molecular motions and also for detecting the chemical shifts in the plastic crystals. Similar results were also obtained for crystalline trimethylacetic acid[9]. A full discussion will be published elsewhere in near future.

We wish to express their sincere thanks to Dr. Eiichi Nagai and Mr. Shiro Satō of Kureha Bōseki Co. for their kindness of allowing the use of the Varian Associates spectrometer for our purposes and also for their collaboration in the measurements.

*Electrochemical Fluorination of Aldehydes**

By Shunji NAGASE, Hajime BABA and Rimpei KOJIMA

(Received January 16, 1962)

It has been shown in previous papers[1,2] that perfluorocarboxylic acids are prepared by electrochemical fluorination from alcohols and esters in a significant yield. A possible mechanism for the formation of perfluorocarboxylic acid fluorides from alcohols was suggested to involve the first attack by fluorine on the α-carbon atom of the alcohols, and dehydrofluorination followed by exhaustive fluorination of the acid fluorides formed into perfluorocarboxylic acid fluorides. In this process, it is possible to consider the formation of aldehydes as an intermediate, though not actually isolated, at the next step of the dehydrofluorination, before the formation of the acid fluorides.

With esters, the mechanism was assumed to start with the hydrofluorolysis of the esters in hydrogen fluoride to form acid fluorides and alcohols. The latter would then be converted into acid fluorides by the mechanism involving dehydrofluorination at the α-carbon atom. Perfluorocarboxylic acid fluorides would be formed by exhaustive fluorination of these two kinds of acid fluorides.

On the basis of these previous works and from the results of the fluorination of ketone[3], which gave perfluorocarboxylic acids in a reasonable yield, the electrochemical fluorination of aldehydes was attempted with the expectation that perfluorocarboxylic acids could be prepared from aldehydes.

So far, very little attention has been paid to the fluorination of aldehydes. Simons[4] carried out the electrochemical fluorination of butyraldehyde and obtained perfluoropropane. In the present work, acetaldehyde, propionaldehyde, butyraldehyde and aldol, as well as paraldehyde, were fluorinated under various anodic current densities (2.5~3.5 amp./dm^2). This treatment afforded trifluoroacetic acid, a mixture of trifluoroacetic acid and perfluoropropionic acid, or a mixture of trifluoroacetic acid, perfluoropropionic acid, and perfluorobutyric acid. Generally, however, the yield and current efficiency were relatively lower than those obtained in alcohols[1], esters[2], ketones[3] and some unsaturated compounds[5], because of considerable fragmentation or polymerization. No formation of a detectable amount of partially fluorinated aldehydes or perfluoroaldehydes could be confirmed throughout the reaction. Acid fluorides, unreacted aldehydes, and a tarry polymeric substance were found in the residue in the electrolytic cell.

The possible major route of the formation of perfluorocarboxylic acid fluorides from aldehydes may involve the fluorination-fragmentation of the ringed para-type polymer of the aldehyde which is in equilibrium with the aldehyde in hydrogen fluoride.

Experimental

Materials. — *Aldehydes.* — Special or first grade commercial reagents were used after distillation, but aldol (first grade) in a glass ampoule (25 g.) was used without further purification. Acetaldehyde was prepared in the usual manner from paraldehyde.

Hydrogen Fluoride.—Hydrogen fluoride of 99.4% purity was supplied from a commercial cylinder.

Apparatus.—The apparatus used for this work essentially consisted of an electrolytic cell provided with a reflux condenser at the top and a drain at the bottom, a sodium fluoride tube, and a pair of polyethylene bottle absorbers. The details have been described in previous papers[1,2].

Standard Procedure.—One liter of hydrogen fluoride was placed in the cell and, prior to the addition of the sample, in order to remove a trace of water in hydrogen fluoride, electrolysis was carried out in a nitrogen atmosphere, with an anodic current density of 2.7 amp./dm^2 until the cell voltage rose to 5.5 V. Twenty-five grams of the sample were then introduced into the cell, and electrolysis was carried out with an anodic current density of 3.3 amp./dm^2 at about 4.8~5.2 V. until the cell voltage again rose to 5.5 V.

The same amount of electricity as used under this current density was supplied for electrolysis under different current densities. The reaction temperature was kept at 4~6°C by the circulation of ice water through the copper tubing in the cell.

The gaseous product generated from the cell, containing perfluorocarboxylic acid fluorides, was passed through the reflux condenser and the sodium

fluoride tube and bubbled through water in then polyethylene absorber. The perfluorocarboxylic acid formed in the absorber was neutralised with sodium carbonate and filtered; the filtrate was the evaporated to dryness. The sodium perfluorocarboxylate thus formed was then extracted with absolute ethanol and dried. Quantitative analysis of the product thus prepared was made by means of the base line method of infrared absorption spectrum, as was previously described in detail[1].

A pair of glass traps, cooled by ice and by dry ice-acetone respectively, was connected with the absorber to collect the low-boiling fluorocarbons for the reaction under this current density.

Results and Discussion

Trifluoroacetic acid was obtained in a reasonable yield from acetaldehyde. The product from propionaldehyde was a mixture of trifluoroacetic acid and perfluoropropionic acid, while that from butyraldehyde and aldol consisted of trifluoroacetic acid, perfluoropropionic acid, and perfluorobutyric acid. However, the yield of these products was relatively low compared with those from alcohols[1], esters[2], ketones[3], or esters of unsaturated carboxylic acids[5], because of the great fragmentation or polymerization in the fluorination reaction. A considerable part of the perfluorocarboxylic acids obtained consisted of degraded acid, the number of whose carbon atoms was less than that of the starting aldehydes.

The results of the fluorination of acetaldehyde, propionaldehyde, butyraldehyde, and aldol are given in Tables I, II, III and IV. The calculation of the current efficiencies shown was based on the amount of electricity assumed to be required to form fluorine by discharging the fluoride ion which would substitute for hydrogen in the aldehyde and combine with it to form hydrogen fluoride.

This means that electricity enough to make 4, 6, 8 and 9 mol. of fluorine would be required for the fluorination of 1 mol. of acetaldehyde, propionaldehyde, butyraldehyde, and aldol respectively to yield perfluorocarboxylic acid fluorides the number of whose carbon atoms corresponds to those of the starting aldehydes.

In the case of the fluorination of alcohols[1] and in the majority of ketones[3], the highest yield of perfluorocarboxylic acids was found at the anodic current density of 3.3 amp./dm^2, irrespective of the kind of the sample used; with aldehydes, however, the yield appeared not to be much affected within the range of anodic current densities applied, although the highest yield was also found at 3.3 amp./dm^2 for most of the aldehydes.

It is interesting to note that the composition of the perfluorocarboxylic acids prepared was

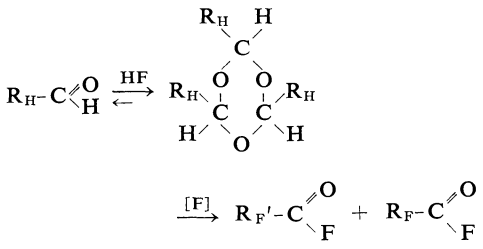
not changed and was almost independent of the anodic current densities within the range of experimental conditions used, as was seen in the fluorination of alcohols[1], esters[2], ketones[3], and unsaturated alcohols, esters and ketones[5].

In the cold trap, about 5, 3, 1 and 1 ml. of a solution were collected at the anodic current density of 3.3 amp./dm² by the fluorination of acetaldehyde, propionaldehyde, butyraldehyde and aldol respectively. These solutions were identified as a mixture of fluorocarbons by their infrared absorption spectra, but they were not separated into their individual components. In the case of acetaldehyde, a considerable amount of perfluorodiethyl ether was found in the mixture.

In about 50 ml. of the residue remaining in the bottom of the cell after the distillation of hydrogen fluoride, a tarry polymeric substance was found which was soluble in such organic solvents as acetone, ethanol, ether, and carbon tetrachloride, and in hydrogen fluoride, but which was insoluble in water. This was extracted by the method described previously[5]. In the fluorination of acetaldehyde, propionaldehyde, butyraldehyde, and aldol, 1.0, 4.3, 6.0, and 6.0 g. of the tarry substance were yielded, respectively, at the anodic current density of 3.3 amp./dm².

The presence of a carboxylic acid formed through acid fluoride in the residue was also identified by its formation of a sodium carboxylate (0.5~1 g.) in the same way as has been mentioned earlier[1], and a small amount of unreacted aldehyde was identified by its formation of a 2,4-dinitrophenylhydrazone with hydrazine in 1:4 hydrochloric acid solution. An examination of the formation of partially fluorinated aldehydes was attempted by the zirconium-alizarine test[6], which was carried out after combustion treatment of the hydrazones, obtained as described above, with fused metallic potassium, but the presence of fluoride could not be confirmed. No evidence could be obtained either for the formation of perfluoroaldehydes throughout the fluorination reactions. For example, in the case of acetaldehyde, the gaseous product generated from the cell was collected in the cold trap, without bubbling through water, and the condensate was examined by its infrared absorption spectrum; however, no perfluoroacetaldehyde was found.



As a polymeric aldehyde having a six-membered oxide ring, paraldehyde was fluorinated with anodic current densities of 3.0, 3.3 and 3.5 amp./dm². Trifluoroacetic acid was obtained. The results are shown in Table V.

Yield I and current efficiency I were calculated in the same way as for other aldehydes, while yield II and current efficiency II were calculated on the assumption that 1 mol. of paraldehyde would give 3 mol. of sodium trifluoroacetate. The amount of fluorocarbon mixture containing perfluorodiethyl ether obtained, as in the case of acetaldehyde, was 5 ml., and the tarry polymeric substance in the residue was 1.0 g. at an anodic current density of 3.3 amp./dm². Although the amount of electricity required for the fluorination of paraldehyde was a little more than that for required for acetaldehyde, the overall results appeared to be similar in these two cases.

The mechanism for the formation of perfluorocarboxylic acid fluorides from aldehydes may

6) F. Feigl (Translated by R. E. Oesper), "Spot Tests", Vol. I, Elsevier Pub. Co., New York (1954), p. 252.

be explained by the following representative scheme, although the reaction could, and probably did, follow different routes simultaneously:

where R_H is the hydrocarbon radical, and R_F and $R_{F'}$ are fluorocarbon radicals.

When aldehydes are dissolved into hydrogen fluoride, they undergo rapid polymerization into para-type ringed aldehydes to reach a condition of equilibrium. The perfluorocarboxylic acid fluorides are probably formed through the process of the fluorination-fragmentation of the para-type aldehydes. The postulated mechanism should explain the bulk of the experimental evidence described above involving a low yield and a greatly degraded product of perfluorocarboxylic acids (a considerable part of which consisted of acids having a smaller number of carbon atoms than those of the starting aldehydes), the presence of a carboxylic acid fluoride in the residue, and the very similar feature fluorination reactions between acetaldehyde and paraldehyde including the formation of perfluorodiethyl ether, etc.

If alcohol has been fluorinated through the route involving the formation of intermediate aldehyde, the aldehyde thus formed would be fluorinated into acid fluoride, immediately and successively, on the surface of the electrodes, without accumulation to any considerable extent in hydrogen fluoride.

Summary

Aldehydes were fluorinated electrochemically to prepare prefluorocarboxylic acids. The results were compared with those obtained from the fluorination of alcohols, esters, ketones and unsaturated compounds.

Generally, the yield of perfluorocarboxylic acids was considerably lower in aldehydes because of a great fragmentation or polymerization in the fluorination reaction. No evidence could be obtained for the formation of a detectable amount of partially fluorinated aldehydes or perfluoroaldehydes in the reaction. The mechanism for the formation of perfluorocarboxylic acid fluorides from aldehydes was discussed.

The authors are much indebted to Professor Ikumi Kagawa of Nagoya University for his invaluable advice and encouragement throughout this work. They wish to express their thanks also to the Osaka Metal Industries Co. for supplying the hydrogen fluoride used in this work.

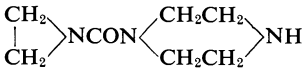
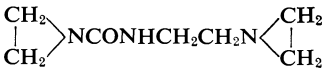
Studies of 2-Oxazolidinones. II. Products of the Pyrolysis of Some 2-Oxazolidinones



By Ryohei ODA, Masahiko MIYANOKI and Masaya OKANO

(Received February 2, 1962)



Among the various earlier studies of 2-oxazolidinones, some recent observations on the formation of ethylenimine and its polymer from 2-oxazolidinone[1-3] have been of great interest to us. Jones[3], studying the pyrolysis of 2-oxazolidinone at 210~235°C without a catalyst, isolated the following six products from ca. 42 g. of 2-oxazolidinone: ca. 11 g. of a polymer (A); 12.5 g. of a hygroscopic substance (B), b. p. 231~236°C/13 mmHg; 1.5 g. of a basic substance having the empirical formula of $C_7H_{13}N_3O$ (C), m. p. 244°C; 1 g. each of two distillates D and E, b. p. 86°C/13 mmHg and 136~160°C/13 mmHg respectively, and ca. 1 g. of ethanolamine. On the basis of infrared analysis, Jones suggested a poly(ethylenimine)

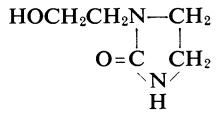
structure having a certain carbonyl group for A, and a tri- or tetrasubstituted urea structure such as I or II for C. However, there are some doubtful points in his assignments of A and C, and no information on the structure of B, one of the major products, has yet been obtained.

I

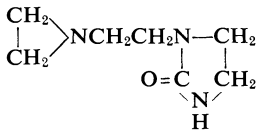
II



It is the purpose of this investigation to provide more detailed information on the structures of the pyrolysates from some 2-oxazolidinones and also to discuss a possible mechanism of the pyrolysis.

Results and Discussion

Products of the Pyrolysis of 2-Oxazolidinone.—2-Oxazolidinone was pyrolyzed at 230°C until the evolution of carbon dioxide ceased completely, this was done under the same conditions as Jones'[3], i. e., under the atmospheric pressure of dry nitrogen in the absence of a catalyst. Somewhat unexpectedly, the evolution of carbon dioxide ceased at ca. 61% of the theoretical amount. Moreover, in the infrared spectrum of the pyrolysate, the disappearance of the carbonyl band at 1760 cm^{-1}, which was found in 2-oxazolidinone, was accompanied by the formation of a new carbonyl band at the 1686 cm^{-1} position. These facts suggest that ca. 39 mol. % of 2-oxazolidinone was converted to another carbonyl compound which was thermally stable.



By careful fractionation, the pyrolysate (21 g.) could be separated into the following four fractions; probably ethanolamine (fraction 1), 1 g.; a hygroscopic product of b. p. 180~185°C/3.5 mmHg and m. p. 51.5°C, $C_5H_{10}N_2O_2$ (fraction 2), 11 g.; a basic powder of m. p. 234°C, $C_7H_{13}N_3O$ (fraction 3), 1 g.; and a semi-solid polymeric residue (fraction 4), 8 g. In comparison with Jones's results, our fractions 2 and 3 seem to correspond to his substances B and C respectively.

In the infrared spectrum of fraction 2 shown in Fig. 1A, three strong bands corresponding to amide I, II and III appeared at 1690, 1495 and 1279 cm^{-1} respectively; they are in nearly the same positions as in unsubstituted 2-imidazolidinone (1660, 1508 and 1270 cm^{-1})[4]. A characteristic hydroxyl band can also be found at 1067 cm^{-1}. Based on spectral and analytical data, formula III was proposed as the structure of fraction 2. This structure was further confirmed by a mixed melting point determination with an authentic sample prepared by an independent method.

III

As is shown in Fig. 1B, fraction 3 also has three bands, corresponding to amide I, II and III, at 1690, 1500 and 1279 cm^{-1}. Their positions and intensities are just the same as those in fraction 2; this suggests a 1-substituted 2-imidazolidinone structure for fraction 3[5]. Futhermore, an absorption which is probably due to the C–H stretching vibration of a strained ethylenimine ring[6] is found at 3080 cm^{-1}. These data suggest that the most probable structure of fraction 3 is represented by formula IV. If Jones' tentative structure I or II were correct, its carbonyl frequency (amide I) should be lower than that of normal tri- or tetrasubstituted urea (cf. footnote 5) under the influence of a strained, three-membered ring[7]. Therefore, it is obvious that Jones's structures for fraction 3, which shows an amide I absorption in such a higher frequency region (near 1690 cm^{-1}), are erroneous.

IV

In polymeric fraction 4, the infrared spectrum was measured after its low boiling portion had been distilled off as completely as possible; the absorption curve is shown in Fig. 1C. Three amide absorptions (1695, 1495 and 1275 cm^{-1}) agreed with those in fractions 2 and 3. This would imply that the 2-imidazolidinone

4) R. Mecke, Jr. and R. Mecke, Sr., *Chem. Ber.*, **89**, 343 (1956).

5) Judging from the position of the amide I of the product, the possibility of some other carbonyl structure may be excluded. The amide I absorption of acyclic urethanes usually occurs in the 1705~1722 cm^{-1} region, while in cyclic systems such as 2-oxazolidinone, the carbonyl frequency falls in the range 1745~1760 cm^{-1} [e. g., S. Pinchas and D. Ben-Ishai, *J. Am. Chem. Soc.*, **79**, 4099 (1957).]. In acyclic *N,N'*-disubstituted ureas, the amide I absorption appears at a lower frequency than 1660 cm^{-1} [e. g., H. J. Becher, *Chem. Ber.*, **89**, 1953 (1956).], and in tri- or tetrasubstituted ureas, a further decrease in the frequency would be expected. However, the amide I band of fraction 3 was observed in another region. This is equally true for fraction 4.

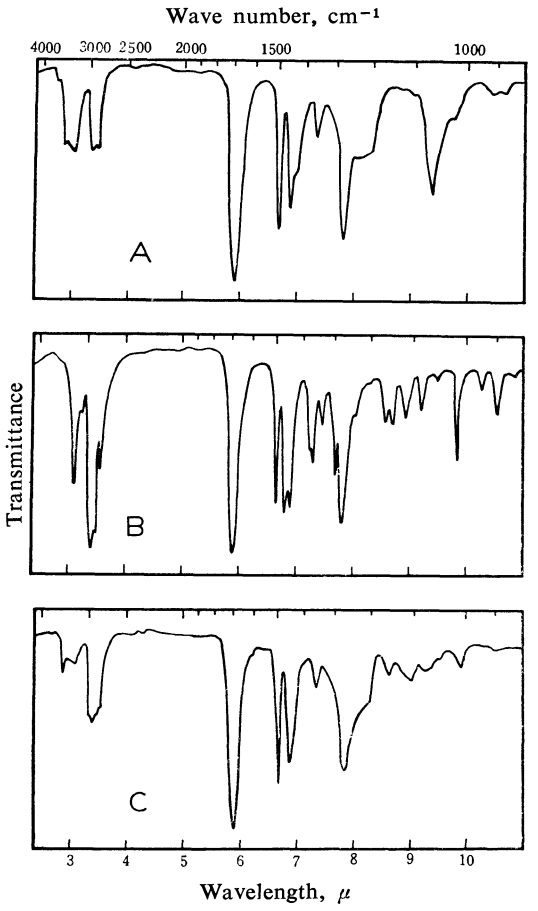

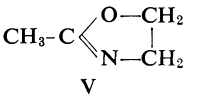

Fig. 1. Infrared spectra of each fraction of the pyrolysate from 2-oxazolidinone: A, fraction 2 (in $CHCl_3$ sol.); B, fraction 3 (in Nujol); C, fraction 4 (in $CHCl_3$ sol.).

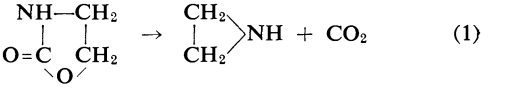
rings are joined at the 1-position with the chain ends of some part, if not all, of the poly(ethylenimine) molecules[8].

Products of the Pyrolysis of 3-Substituted 2-Oxazolidinones.—3-*p*-Chlorophenyl-2-oxazolidinone, which was less reactive than 2-oxazolidinone itself, was completely decarboxylated at 230°C. In the infrared spectrum of the pyrolysate, the carbonyl absorption which is found at 1740 cm^{-1} in the starting oxazolidinone completely disappears. This coincides with the fact that quantitative decarboxylation was observed. It therefore appears that the basic residue on the pyrolysis of this oxazolidinone is mainly composed of poly(*N*-*p*-chlorophenylethylenimine), in contrast with the polymeric product from unsubstituted 2-oxazolidinone. The pyrolysis of 3-*p*-nitrophenyl-2-oxazolidinone at 230°C gave essentially the same results. After half one of the theoretical amount of carbon dioxide had been evolved, the pyrolysis was stopped and the reaction mixture was examined by infrared analysis. The 1767 cm^{-1} absorption (in chloroform) due to the carbonyl group in 2-oxazolidinone was decreased to just half in transmittance, and no new carbonyl absorption was found.



As a particular case, the pyrolytic decarboxylation of 3-acetyl-2-oxazolidinone at 195°C afforded a basic distillate of b. p. 110°C in addition to a polymeric residue. The infrared spectrum suggested that the distillate was 2-methyl-2-oxazoline V[9]. The structural assignment was established by a mixed melting point determination of its picrate with an authentic sample prepared by an independent route. This substance probably results from the rearrangement of *N*-acetylethylenimine, which seems to be an intermediate in pyrolysis. The above

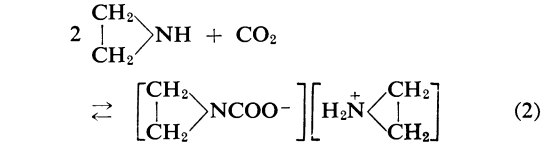
V

consideration appears reasonable in view of the fact that *N*-benzoylethylenimine thermally rearranged to 2-phenyl-2-oxazoline with ease[10].

Mechanism of the Pyrolysis of 2-Oxazolidinones.—All experimental results, including our data, seem to indicate that the pyrolysis proceeds through the intermediate formation of ethylenimine.

(1)

It is well known that ethylenimine is rather stable in strong alkaline media, but that in the presence of acids (including carbon dioxide) it easily polymerizes to give poly(ethylenimine) according to a step-wise mechanism[11,12] promoted by the ethylenimmonium cation. In connection with our work, an initiation by carbon dioxide is interesting; it seems to arise from the following equilibrium:



8) It is known that the shift of amide I frequency is of the order of 20 cm^{-1} to the lower side, with the structure varying from secondary to tertiary amide (Ref. 7, p. 211), from secondary to tertiary urethane [S. Pinchas and D. Ben-Ishai, *J. Am. Chem. Soc.*, **79**, 4099 (1957).], and from *N*-monosubstituted to *N*,*N*-disubtituted urea [H. J. Becher et al., *Chem. Ber.*, **89**, 1593 (1956); *Naturwiss.*, **43**, 467 (1956).]. If fraction 3 or 4 had any 1, 3-disubstituted 2-imidazolidinone structure, a similar frequency decrease would be expected. Therefore, there is no possibility that the 2-imidazolidinone ring is sandwiched in between two poly(ethylenimine) residues.

9) The same compound has been obtained as a by-product in the preparation of 3-acetyl-2-oxazolidinone from *N*-(2-hydroxyethyl)-acetamide and methyl trichloroacetate. [G. Y. Lesher and A. R. Surrey, *J. Am. Chem. Soc.*, **77**, 639 (1955)].

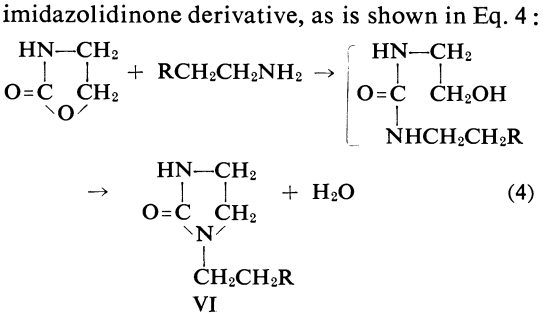
(2)



The same reaction path would be expected in the formation of ethylenimine polymer by pyrolysis. In default of equilibrium 2, however, the pyrolytic polymerization of 3-aryl- or 3-acyl-2-oxazolidinone seems to be initiated by some acidic impurity (e. g., traces of water).

Furthermore, the fact that, in the pyrolysis of unsubstituted 2-oxazolidinone, some 1-substituted 2-imidazolidinones including the polymer were isolated, as has been described above, is strikingly different from the result in other cases, so that some explanation seems to be necessary. First, the formation of 1-(β-hydroxyethyl)-2-imidazolidinone could be understood in terms of a nucleophilic attack of ethylenimine having active hydrogen on a cyclic

(3)

urethane, 2-oxazolidinone, followed by cyclization of the resulting adduct. However, in this mechanism, it is necessary for the reactants to be unsubstituted at the 3-position of 2-oxazolidinone and the 1-position of ethylenimine; this requirement is fulfilled in 2-oxazolidinone itself. Secondary, a similar attack of the terminal amino group of the polymer on 2-oxazolidinone, followed by dehydration of the adduct, may also lead to the formation of a 2-imidazolidinone derivative, as is shown in Eq. 4:

(4)

(R: Any group derived from ethylenimine)

Actually, a compound corresponding to R=$-\underset{|}{N}CH_2CH_2\underset{|}{-}$ in VI, as well as a polymer having a VI type structure, was isolated as described above. In this connection, Gabriel and Eschenbach[13] long ago investigated a similar reaction, which involved the formation of 1-phenyl-2-imidazolidinone from 2-oxazolidinone and aniline. Further, the water formed in Eq. 4 seems to be consumed by the ring-cleavage of ethylenimine itself and by the terminal ethylenimine ring of the polymer.

Under such severe conditions as bulk pyrolysis, the contribution of more complicated reactions may also be considered. However, the discussion above seems to be sufficient to explain all the products of the pyrolysis.

Finally, we wish to point out the difference in mechanism between this reaction and the formation of polypeptide from 2, 5-oxazolidinedione (Leuchs' anhydride), which involves a similar decarboxylative polymerization. On the formation of ethylenimine from 2-oxazolidinone, the ethylenimine and its polymer act only as a catalyst for the decarboxylation[14] and cannot directly initiate the polymerization, so the decarboxylation and the polymerization are two entirely independent steps. On the other hand, in the formation of polypeptide, the reaction proceeds by the repeated attack of the propagating chain on the monomer (Leuchs' anhydride); that is, the decarboxylation and the polymerization occur simultaneously.

Experimental

Materials.—2-Oxazolidinone was prepared by the condensation of ethanolamine with diethyl carbonate according to Homeyer's procedure[15]. The yield was 70%. It melted at 89~90°C after recrystallization from tetrahydrofuran.

3-Acetyl-2-oxazolidinone was prepared from acetylchloride and 2-oxazolidinone by the method of Close[16]. The yield was 70%. It melted at 69°C after recrystallization from benzene. 3-*p*-Chlorophenyl- and 3-*p*-nitrophenyl-2-oxazolidinone were prepared as previously desribed[17]. The *p*-chlorophenyl derivative, m. p. 121°C; the *p*-nitrophenyl derivative, m. p. 154.5°C.

General Procedure of Pyrolysis. — The material was placed in a small flask fitted with a nitrogen inlet and a delivery tube which was connected with a potash-bulb through a trap, and then heated under a stream of dry nitrogen in a silicone oil bath maintained at the descired temperature. The extent of pyrolysis was determined from the amount of absorbed carbon dioxide. After the evolution of carbon dioxide has ceased completely, the syrupy or resinous mass remaining in the flask was cooled and examined by infrared analysis. The amount

17) R. Oda, M. Miyanoki and M. Okano, This Bulletin, **35**, 1309 (1962).

of evolved carbon dioxide was 61.4% of the theoretical value in the case of 2-oxazolidinone and quantitative in the case of its 3-substituted derivative (e. g., *p*-chlorophenyl, 101%). The pyrolysate from 2-oxazolidinone was further fractionated (as described below). However, the fractionation of no other pyrolysate was undertaken. Their molecular weights were not very high, this may be due to the simultaneous depolymerization cited by Barb[12].

Fractionation of the Pyrolysate from 2-Oxazolidinone.—The pyrolysate (21 g.) obtained by the decomposition of 2-oxazolidinone (30.5 g.) at 230°C under the atmospheric pressure of nitrogen was distilled under reduced pressure to yield 1 g. of a water-soluble base boiling below 100°C at 4 mmHg, probably ethanolamine (fraction 1), and 11 g. of a viscous liquid, b. p. 185°C/3.5 mmHg (fraction 2). The addition of chloroform to the resulting residue gave 1 g. of a white powder, m. p. 234°C (fraction 3) which was removed by filtration; the filtrate was then evaporated to yield 8 g. of a polymeric residue (fraction 4). Treatment of this fraction at 240°C/3 mmHg for a short time to remove its low boiling portion gave a pale yellow mass which solidified on cooling.

Redistillation of fraction 2 gave hygroscopic crystals, m. p. 51.5°C, having an empirical formula of $C_5H_{10}N_2O_2$ (Found: C, 45.96; H, 8.51; N, 21.27. Calcd. C, 45.79; H, 8.45; N, 21.36%.). This compound was presumed to be 1-(β-hydroxyethyl)-2-imidazolidinone, and no depression in melting point was observed when it was mixed with an authentic sample, which had been prepared in a 68% yield according to Wilson's procedure[18] except that diethyl carbonate was used instead of urea as a carbonyl source.

In basic fraction 3, its empirical formula $C_7H_{13}N_3O$ (Found: C, 53.41; H, 8.57; N, 27.13. Calcd. C, 54.17; H, 8.44; N, 27.08%.) agreed with Jones' result, but its melting point was 10°C lower than that he reported. A higher value was not obtained by repeated recrystallizations from chloroform. This fraction is believed to be 1-(β-aziridinylethyl)-2-imidazolidinone.

Fraction 4 was strongly basic and hygroscopic. On the basis of infrared analysis, it was assumed to be a mixture of low molecular weight poly(ethylenimine) partially terminated with 2-imidazolidinone ring.

On the pyrolysis of 2-oxazolidinone under a reduced pressure of 20 mmHg at 170°C a similar result was obtained.

Distillate of the Pyrolysis of 3-Acetyl-2-oxazolidinone.—When 16.5 g. of 3-acetyl-2-oxazolidinone was thermally decarboxylated at 195°C, 4.4 g. of a basic oil having a pyridine-like odor was distilled out in addition to a polymeric residue. The redistilled liquid boiled at 110°C. Its picrate recrystallized from absolute ethanol melted at 151°C. The infrared spectrum of the free base is identical with that of 2-methyl-2-oxazoline. Furthermore, a mixed melting point of its picrate with an authentic sample prepared according to Wenker's procedure[19] showed no depression.

Summary

The products obtained by the pyrolytic decarboxylation of 2-oxazolidinones have been investigated, chiefly by infrared analysis. In the case of 2-oxazolidinone, the products are 1-(β-hydroxyethyl)-2-imidazolidinone, 1-[β-(1-azilidinyl)ethyl]-2-imidazolidinone (somewhat uncertain), and poly(ethylenimine) having a 2-imidazolidinone ring at the chain end. On the other hand, the only products from 3-*p*-chlorophenyl- and 3-*p*-nitrophenyl-2-oxazolidinone are believed to be low molecular weight polymers of the corresponding ethylenimines. From 3-acetyl-2-oxazolidinone, a considerable amount of 2-methyl-2-oxazoline, which seems to arise from the rearrangement of *N*-acetylethylenimine, is isolated, in addition to the corresponding poly(ethylenimine). On the basis of the products obtained, a possible mechanism for the pyrolysis has been proposed.

The authors wish to thank Dr. Tōru Takenaka and Mr. Shōzō Iida for their infrared measurements.

Studies of 2-Oxazolidinones. III. Kinetics of the Pyrolytic Decarboxylation of 2-Oxazolidinones

By Ryohei ODA, Masahiko MIYANOKI and Masaya OKANO

(Received February 2, 1962)

Studies of the thermal decomposition of 2-oxazolidinones are important not only in order to synthesize ethylenimines or their polymers, but also in order to consider the thermal stability in some applications of 2-oxazolidinone derivatives to polymer chemistry[1]. In the second paper of this series[2], the authors examined the pyrolysates from 3-substituted 2-oxazolidinones by means of infrared spectroscopy and discussed a two-step process, in which decarboxylation was followed polymerization. The present kinetic study has been undertaken to provide further insight into the mechanism of the decarboxylation step in this reaction. The effect of a 3-substituent on the decarboxylation rate and the rate-accelerating effect of various amines have been especially studied in detail.

Results and Discussion

Autocatalytic Nature of the Reaction. — The decarboxylation rates of some 2-oxazolidinones without either catalyst or solvent were measured. Figure 1 shows the results of plotting the decarboxylation rate, dx/dt, against the conversion x, for two representative 2-oxazolidinones. As is illustrated in this figure, the rate first increases as the reaction proceeds, but it comes to a maximum and then decreases[3]. The basic products of the reaction —the corresponding ethylenimines and/orth eir polymers—appear to at as an auto-catalyst; this will be proved experimentally below.

Effect of the 3-Substituent on the Decarboxylation Rate.—The decarboxylation rates of various 3-substituted 2-oxazolidinones are summarized in Table I. Each of these values indicates a relative rate at 25% conversion taking as a standard the rate of the 3-phenyl

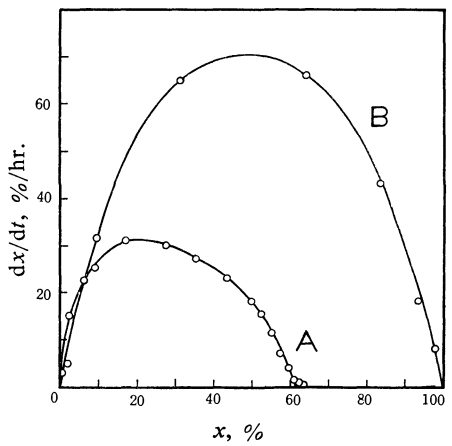

Fig. 1. Rate vs. conversion curves for the bulk decarboxylation of 2-oxazolidinones (0.02 mol.) without catalyst: A, 2-Oxazolidinone (at 200°C); B, 3-*o*-Nitrophenyl-2-oxazolidinone (at 230°C).

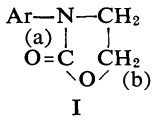
TABLE I. RELATIVE RATES FOR BULK DECARBOXYLATION OF 3-SUBSTITUTED 2-OXAZOLIDINONES WITHOUT CATALYST AT 230°C[a]

Run	Oxazolidinone[b]	Relative rate[c]
1	C_6H_5-Ox	1
2	*p*-CH_3-C_6H_4-Ox	0.7
3	*p*-C_2H_5OOC-C_6H_4-Ox	1.3
4	*p*-Cl-C_6H_4-Ox	1.9
5	*p*-NO_2-C_6H_4-Ox	130
6	*o*-NO_2-C_6H_4-Ox	140
7	$CH_3(CH_2)_3$-Ox	2.3
8	Ox-Ox	33[d]
9	Ox-$(CH_2)_2$-Ox	8.6[d]
10	Ox-$(CH_2)_4$-Ox	15[d]



a) In each run, 0.02 mol. of oxazolidinones was used.
b) The oxazolidinonyl group, -N-CH_2CH_2OCO-, abbreviated as Ox.
c) The volume of the compounds differs, but no correction for this is made, so that it is impossible to compare each rate value exactly.
d) This value has been divided by a statistical correction factor of two.

High Polymer Japan* (*Kōbunshi Kagaku*), 17, 72 (1960): G. P. Speranza and W. J. Peppel, *J. Org. Chem.*, 23, 1922 (1958); E. K. Drechsel, ibid., 22, 849 (1957).

2) R. Oda, M. Miyanoki and M. Okano, This Bulletin, 35, 1910 (1962).

3) In the decarboxylation of such 3-substituted 2-oxazolidinones as the 3-*o*-nitrophenyl or 3-*p*-chlorophenyl derivatives, the evolution of the theoretical amount of carbon dioxide was observed. In the case of unsubstituted 2-oxazolidinone, however, the evolution of carbon dioxide ceased at 61.4% of the theoretical amount; this is attributed to the fixation of the part corresponding to 38.6 mol.% as 1-substituted 2-imidazolidinones [see Ref. 2].

derivative. The results from runs 1—6 in Table I show that the reactivity of various 3-aryl derivatives depends on the electronic effect of the substitutent on the benzene ring; that is, an electron-attracting group such as *p*-nitro accelerates the decarboxylation, while an electron-releasing group such as *p*-methyl retards it. It may be inferred from this observation that the rate-determining step for this ring-cleavage is the fission of the N–C bond, (a) in I, rather than that of the O–C bond, (b) in I.

I

As is seen in runs 8–10, all bis-oxazolidinones showed high decomposition rates compared with that of *n*-butyl-2-oxazolidinone (run 7). This may be partially accounted for by the participation of the steric effect[4], but at present no complete solution is possible.

Aromatic Amine-Catalyzed Decarboxylation of 3-Aryl-2-oxazolidinone. — In both the presence and absence of *N*, *N*-diethyl-*p*-nitroaniline, the decarboxylation rates of 3-*p*-nitrophenyl-2-oxazolidinone in *o*-nitroanisole were measured. Rate vs. conversion curves are shown in Fig. 2[5]. Since the structure of the amine used is similar to that of *N*-*p*-nitrophenylethylenimine, which seems to be an initial product in this decomposition, and since the amount of the amine added is equivalent to that of the oxazolidinone, rate maximum would be expected to appear at the beginning of the reaction. As is shown in curve B, however, the rate increases gradually at first and comes to a maximum only after some conversion has occurred. This means that the pyrolysate formed, rather than the amine added, acts as the more effective catalyst.

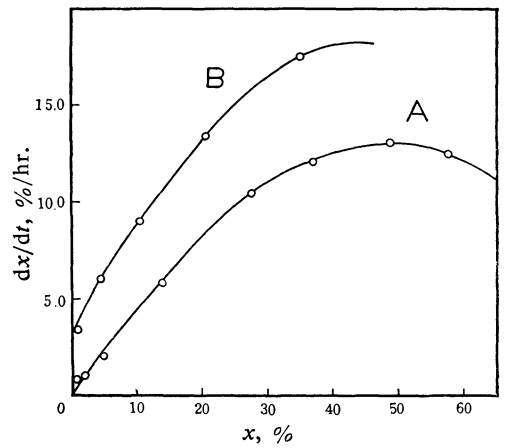


Fig. 2. Rate vs. conversion curves for the decarboxylation of 3-*p*-nitrophenyl-2-oxazolidinone (1 mol./l.) in the absence (A) and presence (B) of *N*, *N*-diethyl-*p*-nitroaniline in *o*-nitroanisole at 230°C. $[Ox]_0=[I]_0=1.00$ mol./l.

The rates of decarboxylation catalyzed by some *N*-ethylaniline derivatives for the same oxazolidinone were also measured. A comparison between the rates at 25% conversion are given in Table II. The order of the rates disagrees with that which would be expected judging from the basicities of the catalysts[6]. The larger accelerating effects of a polyamine (run 5) and of a small ring monoamine (run 4) as compared with an ordinary monoamine (run 2) suggest that the rates depend considerably on the steric requirements of amines.

TABLE II. RATE-ACCELERATING EFFECT OF ANILINE SERIES ON DECARBOXYLATION OF 3-*p*-NITROPHENYL-2-OXAZOLIDINONE IN *o*-NITROANISOLE AT 230°C[a]

Run	Catalyst added	Concn. mol./l.	Rate, dx/dt %/hr.
1	None	—	9.5
2	$C_6H_5N(C_2H_5)_2$	1.00	20
3	$C_6H_5NHCH_2CH_2NHC_6H_5$	0.50	30
4	$C_6H_5NCH_2CH_2$ (ring)	0.75	31
5	$(-NCH_2CH_2-)_n$ (C$_6$H$_5$ on N)	0.20/*n*	23

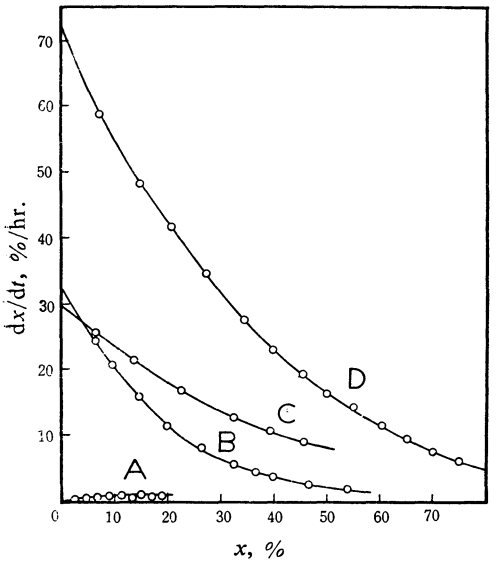
a) In each run, $[Ox]_0=1.00$ mol./l.

Aliphatic Amine-Catalyzed Decarboxylation of 3-Aryl-2-oxazolidinones.—Using high boiling aliphatic amines as catalysts for the decarboxylation of 3-*p*-nitrophenyl- and 3-*p*-chlorophenyl-2-oxazolidinone, the kinetic order with respect to the catalysts and the rate constants have been determined. In all cases, there was a rate maximum at the beginning of the reaction, as expected. Figure 3 shows the rate vs. conversion curves for the *n*-dodecylamine-catalyzed decarboxylation in dibenzyl ether. From this

4) In the contiguous existence of two rings (intermolecular or intramolecular), the imino group resulting from one oxazolidinone ring would lie in a suitable position for promoting the decomposition of the other ring, though it appears to depend on the number of carbons in the polymethylene linkage.

5) In this figure and hereafter, $[Ox]_0$ and $[I]_0$ represent the initial concentrations of oxazolidinone and amine respectively.

6) The basicity constants of $(C_2H_5)_2NH$, $NH_2CH_2CH_2NH_2$, and HN(CH$_2$CH$_2$) at 25°C are estimated to be 9.6×10^{-4}, 8.5×10^{-5}, 1.1×10^{-7} respectively. [a) "Handbook of Chemistry (Kagaku Binran)", New Ed., compiled by the Chemical Sociehy of Japan, Maruzen, Tokyo, (1958) p. 871; b) S. Searles et al., *J. Am. Chem. Soc.*, 78, 4918 (1959).] Presumably, those of $C_6H_5N(C_2H_5)_2$, $C_6H_5NHCH_2CH_2NHC_6H_5$, and C_6H_5N(CH$_2$CH$_2$) would decrease in this order.



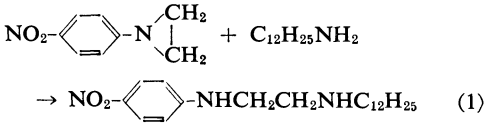


Fig. 3. Rate vs. conversion curves for the *n*-dodecylamine-catalyzed decarboxylation of 3-*p*-nitrophenyl- and 3-*p*-chlorophenyl-2-oxazolidinones in dibenzyl ether at 230°C: A, *p*-NO_2, non-catalyzed; B and D, *p*-NO_2, amine-catalyzed; C, *p*-Cl, amine-catalyzed. $[Ox]_0=1.00$ mol./l.; $[I]_0=1.00$ mol./l. in C and D, and 0.50 mol./l. in B.

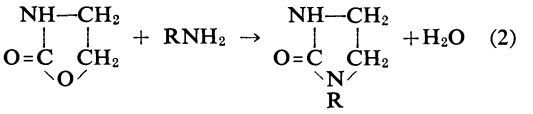


figure, it can be seen that the rate of the decarboxylation of the *p*-nitrophenyl compound in the absence of a catalyst is very slow in comparison with that in the presence of the amine; hence, the participation of the non-catalyzed term is possibly negligible for the latter case.

If the amine concentration remains constant during a run, the reaction will be in pseudo-first-order; hence, a plot of dx/dt vs. x should be linear. However, first-order plots with a downward curvature were obtained, as is shown in B, C and D of Fig. 3. This observation may be interpreted as follows: By the reaction with the *N*-arylethylenimines formes as reaction intermediates, *n*-dodecylamine is partially converted to the less effective *N*-aryl-*N'*-*n*-dodecylethylenediamines, and the low catalytic activity of these amines may lead to a slower rate. Judging from the experimental data (see below), it is appearent that a secondary aliphatic amine is less effective than a primary one as a catalyst. Additionally, no appreciable rate acceleration by the aromatic amine in dibenzyl ether was observed in a preliminary test.

(1)

Another consumption of the amine which is due to the condensation with oxazolidinone to afford 1-substituted 2-imidazolidinone may also be considered[7] (cf. our previous paper[2]). In

(2)

another experiment[8], however, it has been found that the existence of a 3-substituent on the oxazolidinone ring makes this condensation difficult. Therefore, such consumption would be negligible.

Since the rate did not fit the simple pseudo-first-order rate equation, as has been mentioned above, the initial second-order rate constants, k, were computed from the values of the initial rate, $(dx/dt)_{x=0}$, which were extrapolated graphically in Fig. 3, using the following equation:

$$(dx/dt)_{x=0}=k[Ox]_0[I]_0 \qquad (3)$$

In Table III-A, a little increase of k with an increase in the amine concentration is observed; this may be ascribed to a small contribution of the second-order term with respect to amine.

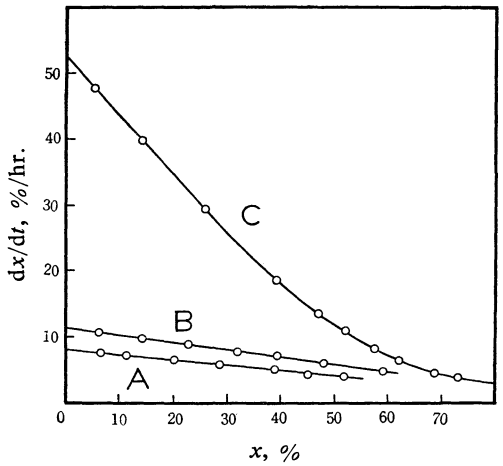
Table III. Rate constants of decarboxylation of 3-*p*-nitrophenyl-2-oxazolidinone catalyzed by various amines in dibenzyl ether at 230°C[a]

Amine added	Concn. of amine mol./l.	Initial second-order rate constant, l. mol^{-1} min^{-1} $k\times10^3$
A series		
n-Dodecylamine	0.50	10.7
n-Dodecylamine	1.00	12.0
N-Ethyl-*n*-dodecylamine	1.00	8.75
Bis(2-ethylhexyl)-amine	1.00	1.40
N,*N*-Diethyl-*n*-dodecylamine	1.00	1.90
B series		
Tetraethylenepentamine	0.125	73
Triethanolamine	0.20; 0.40	33[b]

a) In each run, $[Ox]_0=1.00$ mol./l.
b) Mean value for two different amine concentrations.

Rate vs. conversion curves for similar decarboxylations in the presence of aliphatic secondary or tertiary amines (e.g., *N*-ethyl-*n*-dodecylamine, bis(2-ethylhexyl)-amine and *N*,*N*-diethyl-*n*-dodecylamine) are shown in Fig. 4. In contrast with Fig. 3, the plots of A and B in Fig. 4 are very close to straight lines; hence, it appears that the concentration of the catalyst remains constant, at least in the range

7) S. Gabriel and G. Eschenbach, *Ber.*, 30, 2495 (1879).
8) R. Oda and K. Yamamoto, Unpublished data.



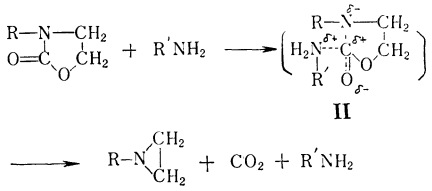


Fig. 4. Rate vs. conversion curves for the aliphatic amine-catalyzed decarboxylation of 3-*p*-nitrophenyl-2-oxazolidinone in dibenzyl ether at 230°C: A, Bis(2-ethylhexyl)-amine; B, *N*,*N*-Diethyl-*n*-dodecylamine; C, *N*-Ethyl-*n*-dodecylamine. $[Ox]_0=[I]_0=1.00$ mol./l.

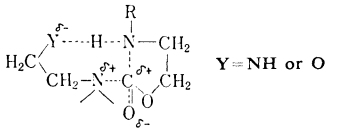
of ca. 50% conversion. Probably this means that these amines react only slowly with the intermediate *N*-aryl-ethylenimine. The initial second-order rate constants calculated from Eq. 3 are also listed in Table III-A. In a series of amines, a variation in structure from primary to secondary and from secondary to tertiary leads to a decrease in the catalytic effect; this order disagrees with that of their basicities[9]. Such behavior would be caused by steric hindrance to the approach of the oxazolidinone molecule. Actually, in the case of highly hindered bis(2-ethylhexyl)-amine, an unexpectedly low rate was observed.

It can be seen from Table III that a polyamine is more effective as a catalyst than a monoamine in the aliphatic as well as in the aromatic series (cf. Table II). In order to make the rate constant for the tetraethylenepentamine-catalyzed reaction comparable with the value obtained from monoamine-catalyzed decomposition, a statistical correction factor of 5 has to be applied. The calculated rate constant per amino group, 14.6×10^{-3} mol.$^{-1}$·min^{-1}, is somewhat larger than the observed values in other cases. Considering that this polyamine contains three secondary amino groups, which are less effective than primary groups, the larger value would be expected. Therefore it seems, clear that polyamine acts as a bi-functional (or polyfunctional) catalyst in this decarboxylation. This suggests a push-pull mechanism which involves the nucleophilic attack of one amino group on the positive carbon of the carbonyl group in oxazolidinone and the simultaneous electrophilic attack of the hydrogen of the other amino group on the nitrogen of the urethane group in the same molecule of oxazolidinone. Since the hydroxyl group is known to be more acidic than the amino group, triethanolamine, which has both groups, may be expected to be a more powerful catalyst[10]. As is shown in Table III-B, the decomposition rate in the presence of this amine is much larger than that for the ordinary tertiary amine-catalyzed reaction. Additionally, it was ascertained experimentally that just aliphatic alcohols such as *n*-dodecyl alcohol showed no accelerating effect on the rate. Therfore, the first-order dependence with respect to triethanolamine strongly supports a concerted mechanism, in which the hydroxyl group in the catalyst acts as electrophile and the amino group act as a nucleophile simultaneously.

The above considerations may also be applied to the problem of two amino groups in separate molecules; that is, the slight second-order dependence with respect to amine, which has been observed in the monoamine-catalyzed reaction, can be understood by a similar explanation.



In summary, it may be concluded that amine-catalyzed decarboxylations proceed by two different mechanisms depending on the structure of the amine. When simple monoamine is used as a catalyst, the reaction occurs mainly through transition state II, as is shown in Eq. 4. On the other hand, in the reaction catalyzed

II

(4)

by an amine having an active hydrogen group, such as NH_2 or OH, on the β-carbon, the activated complex may be approximated by structure III:

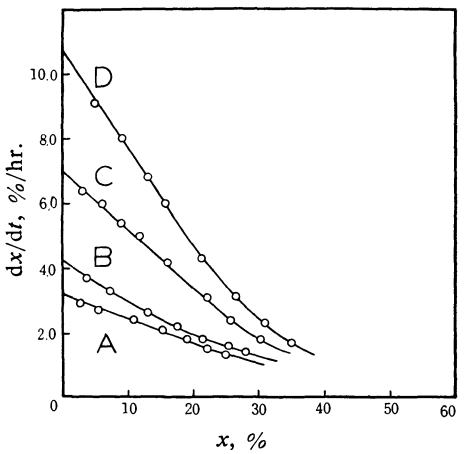
III

9) e.g., the basicity constants of $C_2H_5NH_2$, $(C_2H_5)_2$-NH, and $(C_2H_5)_3N$ at 25°C are estimated to be 3.4×10^{-4}, 9.6×10^{-4} and 5.65×10^{-4} respectively (Ref. 6a).

10) In fact, it has been reported in patent literature [O. Sunden, Swed. Pat. 148559; *Chem. Abstr.*, **50**, 2679 (1956)] that the use of triethanolamine on the decarboxylation of 2-oxazolidinone leads to a satisfactory yield of ethylenimine.

TABLE IV. RATE CONSTANTS OF DECARBOXYLATION OF 2-OXAZOLIDINONE CATALYZED BY *n*-DODECYLAMINE IN DIBENZYL ETHER AT 230°C

Initial concn. of oxazolidinone mol./l.	Initial concn. of amine mol./l.	Initial second-order rate constant l. mol^{-1} min^{-1} $k \times 10^3$	Initial third-order rate constant l. mol^{-1} min^{-1} $k' \times 10^3$
0.50	0.50	1.00	2.00
0.50	0.75	0.98	1.96
1.00	0.50	2.33	2.33
1.00	0.75	2.37	2.37



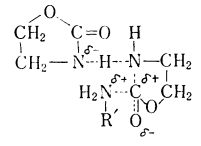


Fig. 5. Rate vs. conversion curves for the *n*-dodecylamine-catalyzed decarboxylation of 2-oxazolidinone in dibenzyl ether at 230°C. $[Ox]_0=1.00$ mol./l. in C and D, and 0.50 mol./l. in A and B. $[I]_0=0.75$ mol./l. in A and C, and 0.50 mol./l. in B and D.

Aliphatic Amine-Catalyzed Decarboxylation of 2-Oxazolidinone. — Finally, in the presence of an amine catalyst, the rate of the decarboxylation of 2-oxazolidinone itself was measured. As is shown in Fig. 5, rate vs. conversion curves for the *n*-dodecylamine-catalyzed reaction in dibenzyl ether tend to converge at a point near 60%-conversion; similar behavior has also been observed in the non-catalyzed reaction (cf. Fig. 1).

The initial second-order and third-order rate constants, k and k', for various concentrations of oxazolidinone and amine, were evaluated by using Eqs. 3 and 5 respectively. These values are listed in Table IV.

$$(dx/dt)_{x=0}=k'[Ox]_0^2[I]_0 \qquad (5)$$

In the table, the k value changes for the two initial concentrations of oxazolidinone, while the k' value becomes nearly constant, though one can not overlook a slight increase in k' with an increase in the oxazolidinone concentration. Therefore, the amine-catalyzed decarboxylation of 2-oxazolidinone would proceed mainly by a concerted mechanism, in which the added amine attacks oxazolidinone as a nucleophile and, simultaneously, another oxazolidinone molecule attacks it as an electrophile. The transition state may be represented as IV[11]:

IV

Experimental

Materials. — All 2-oxazolidinones used in this work were prepared by methods previously described[2,12]. The following constants were observed: 3-substituent, b. p. or m. p.; none, m. p. 90°C; *n*-butyl, b. p. 113°C/4.3 mmHg; phenyl, m. p. 49°C; *p*-tolyl, m. p. 61°C; *p*-nitrophenyl, m. p. 116°C; *o*-nitrophenyl, m. p. 70.5°C; *p*-carbethoxyphenyl, m. p. 145°C; *p*-chlorophenyl, m. p. 69°C; bis, m. p. 97°C; ethylene-bis, m. p. 136°C; tetramethylene-bis, m. p. 118°C. The solvents (*o*-nitroanisole and dibenzyl ether) and the aliphatic and aromatic amines, except those described below, were of the best grade commercially available and were used after sufficient purification.

N, N-Diethyl-p-nitroaniline. — The amine was prepared according to the procedure of Behr et al.[13] from *p*-chloronitrobenzene and diethylamine in a 94.5% yield. Recrystallization from ethanol afforded the pure product, m. p. 77°C.

N-Phenylethylenimine and its Polymer.—*N*-(β-Bromoethyl)-aniline was treated with aqueous sodium hydroxide according to the method of Heine et al.[14] The *N*-phenylethylenimine thus obtained boiled at 62~65°C/10 mmHg. The polymer was purified by reprecipitation using dimethylformide as a solvent and water as a precipitator.

N-Ethyl-n-dodecylamine. — A mixture of 25 g. of

11) Though the existence of an oxazolidione dimer has been known [Cf. S. Pinchas and D. Ben-Ishai, *J. Am. Chem. Soc.*, 79, 4102 (1956); E. Fischer, *J. Chem. Soc.*, **1952**, 4525], the dimer seems to be inferior in reactivity because of the lower reactivity of the carbon atoms of its carbonyl groups. Therefore, the possibility of the nucleophilic attack of amine on the dimer may be eliminated from the main route of the reaction. However, the appearance of a third order term with respect to oxazolidinone, though in a slight degree, seems to indicate the participation of such an attack.

12) R. Oda, M. Miyanoki and M. Okano, This Bulletin, 35, 1309 (1962).

13) L. C. Behr, E. J. Kirby, R. N. MacDonald and C. W. Todd, *J. Am. Chem. Soc.*, 68, 1296 (1946).

n-dodecylbromide and 25.8 g. of 70% aqueous ethylamine was allowed to stand in a sealed tube at 80°C for 24 hr. The resulting mixture was gradually made acidic with hydrochloric acid. After the extraction of the organic layer with ether, the aqueous layer was made strongly alkaline with aqueous potassium hydroxide, and the amine formed was extracted with ether. After the resulting ethereal solution had been dried over anhydrous potassium carbonate and the ether had then been evaporated, distillation in vacuo gave 19 g. (90%) of the fraction of *N*-ethyl-*n*-dodecylamine, b. p. 107~110°C/2 mmHg. The redistilled product boiled at 108°C/2 mmHg.

Found: C, 78.59; H, 14.43; N, 6.69. Calcd. for $C_{14}H_{31}N$: C, 78.79; H, 14.64; N, 6.56%.

N,N-Diethyl-n-dodecylamine.—The amine was prepared according to the method of Coan et al.[15] in an 87% yield by the reaction of *n*-dodecylbromide with diethylamine. The product boiled at 155°C/16.5 mmHg, and its hydrochloride melted at 116°C.

Kinetic Measurement.—Pyrolytic decarboxylation was carried out in glass tubes of ca. 5 or 10 ml. volume for bulk and solution experiments respectively; these tubes were immersed in a constant temperature bath of silicone oil. The evolved carbon dioxide was swept out by a stream of purified nitrogen and absorbed in a potash-bulb. Figure 6 shows an outline of the apparatus. After the immersion of the reaction vessel, a period of 10 min. was allowed for establishment of the temperature equilibrium, and then the rate was measured by weighing the potash-bulb at appropriate time intervals.

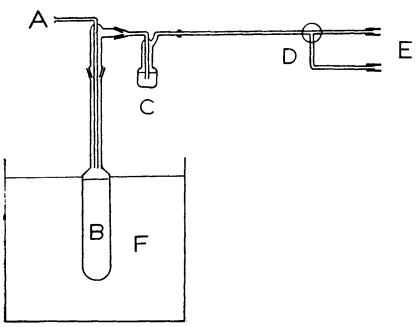

Fig. 6. Apparatus.
A: Dry nitrogen inlet
B: Reactor (Pyrex tube)
C: Trap containing concd. sulfuric acid
D: Switching cook
E: To potash-bulb
F: Thermo-regulated silicone oil bath

In the complete decarboxylation of 3-*p*-chlorophenyl- and 3-*o*-nitrophenyl-2-oxazolidinone, the amounts of evolved carbon dioxide were nearly quantitative (101 and 98% respectively). Therefore, it is believed that the above estimation method leads to responsible results.

Summary

The kinetics of the pyrolytic decarboxylation of 3-substituted 2-oxazolidinones have been studied and the following results obtained. (1) This decomposition is an autocatalytic reaction, in which the amine formed acts as a catalyst. (2) In the decarboxylation of 3-aryl-2-oxazolidinones, the electronic effect of the substituent on the benzene ring indicates that the fission of the N–C bond of the urethane group in the 2-oxazolidinone ring is rate-determining. (3) The initial rate of the aliphatic amine-catalyzed decarboxylation of 3-aryl-2-oxazolidinones is of the pseudo-first-order; it also depends on the concentration and structure of the amine. A mechanism has been proposed which involves a nucleophilic attack of amine on the carbonyl-carbon atom. An amine having an hydroxyl or amino group on the β-carbon shows a large rate-acceleration; this suggests the simultaneous electrophilic participation by the active hydrogen of these groups. (4) The initial rate of the decarboxylation of 2-oxazolidinone itself, catalyzed by aliphatic amine, is of the second-order in oxazolidinone and of the first-order in amine. From this a concerted mechanism has been inferred, in which the amine acts as a nucleophile and the other oxazolidinone acts as an electrophile.

The Behavior of Heat-treated Graphitizing Carbons in Wet Oxidation[1)]

By Hiroaki TAGAWA and Hitoshi NAKAJIMA

(Received April 17, 1962)

The chemical property of carbon may vary considerably according to the nature of the original carbonaceous material and the conditions under which it has been carbonized. Although the problem of the chemical reactivity of solid carbon is very complex, the reactivity of carbon which is free of ash and appreciable amounts of hydrogen and oxygen may be thought to depend mainly on such structural factors as the crystallinity and the state of the condensed system of aromatic carbon.

The wet oxidizability of carbon in a solution of potassium dichromate in phosphoric acid has been studied by Riley et al.[2-5)], Akamatu et al.[6)], Tamaru[7)], and Honda and Hirose[8)]. It has been reported by Riley et al.[2-5)] that differences in the oxidation rate for various cokes are due largely to differences in graphite content and give a semiquantitative measure of the degree of graphitization. Akamatu et al.[6)] have investigated the reactivity of various kinds of carbon in wet oxidation and have concluded that the rate of reaction depends on the type of carbon and on the modes of the aggregation of crystallites.

The relationship between the chemical reactivity of carbon and its structure has been studied only from the standpoint of carbon species of different degrees of graphitization. In order to obtain a general view of that relationship, the wet oxidation of three kinds of graphitizing carbon graphitized by heat treatment is here examined in the solution of potassium dichromate in phosphoric acid.

Experimental

Materials and Heat Treatments.—Petroleum coke (Union Oil Co., U. S. A.), coal coke used as the industrial raw material of calcium carbide (Kinki Cokes Co., Japan) and anthracite (Hongay, Vietnam). The proximate analysis of these substances and the chemical analysis of ashes are listed in Tables I and II respectively. The specimens were prepared by preheating these substances for 2 hr. at 900°C in a laboratory electric furnace in a nitrogen atmosphere and by then heating them, in vacuo, to the higher temperatures of 1100, 1380, 1660, 1950 and 2250°C. The maximum temperature for each preparation was maintained for 2 hr. Heat treatments at 2600 and 2800°C were also made in the industrial graphitizing furnace for about 15 min. This latter procedure was undertaken in the Nagoya Factory of the Tokai Electrode Manufacturing Company to which our thanks are due. The heat-treated specimens were pulverized and graded for wet oxidation between a 180~200 tyler mesh sieve. The ashes in the carbon decreased with the rise in temperature, showing 6.4 and 2.0% at 1660°C and 0.3 and 0.04% at 2250°C for coal coke and anthracite respectively.

TABLE I. PROXIMATE ANALYSIS OF CARBONS (%)

	Petroleum coke	Coal coke	Anthracite
Moisture	6.7	1.4	1.8
VM	11.5	2.3	6.6
Ash	0.7	7.9	6.9
Fixed carbon	81.7	88.4	84.7

maxima did not directly give the true interlayer spacing in the case of low graphitic carbon, the correction factors given by Ruston were used[9]. These factors were negligibly small for the specimens treated above 2250°C.

The crystallite size was obtained from the broadening of the X-ray diffraction lines according to the procedure described by Klug and Alexander[10]. The crystallite dimension was calculated according to the following equation;

$$L = K\lambda/\beta\cos\theta$$

where L is the average effective dimension of the crystallite in the direction perpendicular to the reflecting plane at the glancing angle θ, λ is the wavelength of the X-ray, K is a shape factor, and β is defined as the half-value breadth. The L_c-dimension, the thickness of the parallel packets of layers, was obtained from the (002) line using $K=0.9$, while the L_a-dimension, the width of the graphite-like layer, was obtained from the (10) band using $K=1.84$, as well as from the (110) lines using $K=0.9+(1.84-0.9)p$ for highly graphitizing specimens[11], where p as defined by Franklin[12] meant the fraction of the amorphous part in graphitic carbon and was given as the following equation; $d_{002}=3.44-0.086(1-p^2)$.

The diffration conditions employed were as follows: The target, copper, filtered by nickel; filament voltage and current, 40 kV. and 15 mamp. respectively; divergent slit 1°; receiving slit 1° and 0.1 mm.; time constant, 4 sec., and scanning speed, 1/4°/min.

Wet Oxidation Procedure. — Carbon is oxidized to carbon dioxide in the solution of potassium dichromate in phosphoric acid. The reactivity of carbon can be known from the quantity of carbon dioxide evolved per unit time or of the carbon decomposed, which is calculated from the quantity of carbon dioxide evolved. The author used the volumetric method, which gives reproducible results.

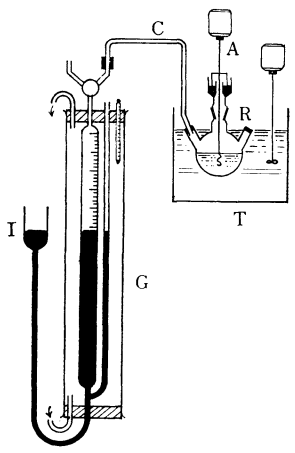

Fig. 1. Apparatus.

The apparatus used in these experiments is shown in Fig. 1. It consists of the temperature-controlled bath, T, a reaction vessel, R, and a gas burette, G. The reaction vessel was a 100 cc. three-necked flask with a mercury-sealed stirrer, S, of the constant speed. The gas burette, 80 cc. in volume, was kept at a constant temperature with flowing water in order to avoid the effect of any change in room temperature. The gas burette was connected to the levelling bulb I, filled with mercury, and to the reaction vessel with a glass capillary tube, C. The bath temperature was measured with a mercury thermometer and was maintained at a desired value within 0.1°C by the aid of an automatic temperature controller, although this is not shown in the figure.

The experimental procedure was as follows: 1 g. of the sample was added to the reaction flask already containing 10 g. of potassium dichromate (G. R. Grade, Wako Chemicals Co.) and 50 cc. of concentrated phosphoric acid (d 1.70 g./cc.; E. P. Grade, Wako Chemicals Co.). While the water bath was being heated to the desired temperature, the three-way cock of the gas burette was opened to the air. When the vessel was dipped in the bath, the meniscus was adjusted to the zero mark of the burette and the stopcock was closed. The volume of gas evolved was measured with the burette as a function of time. It was found, by means of gas chromatography analysis, that all the gas evolved was carbon dioxide. The volume of gas was converted to the value in the standard state. Fifty cubic centimeters of carbon dioxide (N. T. P.) is equivalent to 2.68% of consumed carbon. The reaction temperatures were 62, 67, 73, 79, 85 and 89°C.

Results and Discussion

Graphitization.—The graphitization states of the specimens heated at several temperatures from 1100 to 2800°C were determined by means of the X-ray diffractometer.

The interlayer spacings obtained from the (002) line are plotted against the temperature of heat treatment in Fig. 2. The crystallite sizes determined from the breadth of the diffraction patterns of the (002) line and the (10) band or the (110) line are given against the heating temperature in Figs. 3 and 4. It has been found that the developement of crystallinity by heat treatment varies among different carbon species. The growth of crystallite proceeds with the most facility in petroleum coke. No remarkable difference, however, could be found between these three materials in the general features of graphitization.

Wet Oxidation. — The results for petroleum coke and anthracite at 85°C are shown in Figs. 5 and 6 respectively, where the gas evolved is plotted as a function of time. In Fig. 5, all the curves of the gas evolved vs. time are

seemingly linear; however, the oxidation velocity for the petroleum cokes heat-treated below 1950°C decreased as the oxidation proceeded, while that for the specimens heat-treated above 2600°C increased with time.

These curves may be roughly classified into the following three types according to the heat treatment temperature:

(1) The oxidation rate decreases as the reaction proceeds for the specimens heat-treated below 1950°C.

(2) The rate is almost constant during the whole course of the reaction for the specimens heat-treated near 2250°C.

(3) The rate increases as the oxidation proceeds for the specimens heat-treated above 2600°C.

To examine whether these phenomena are expressed by a quantitative measure, all the curves in Fig. 5 are replotted in the logarithm

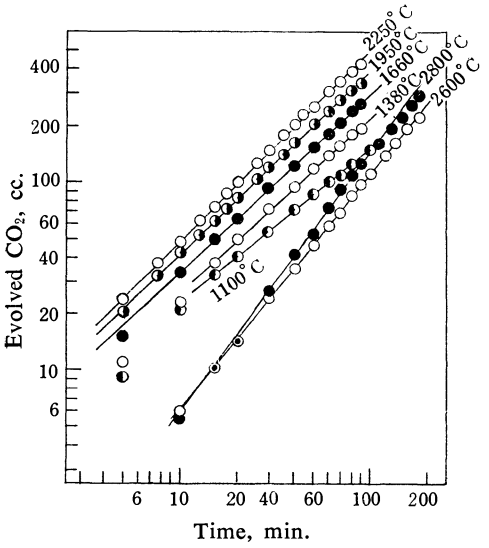

Fig. 7. Evolved carbon dioxide vs. reaction time.

scale in Fig. 7. The logarithm of the quantity of carbon dioxide evolved, V, becomes linear with that of time, t, and is expressed as the following equation at any reaction temperature:

$$V=at^b$$

where a and b are constant. The b-value depends on only the heat treatment temperature. Moreover, that value does not depend on the oxidation temperature; e. g., the values for petroleum coke treated at 2600°C were 1.49, 1.39, 1.43, 1.44 and 1.44 at the oxidation temperatures of 62, 67, 73, 79 and 85°C respectively.

As is shown in Fig. 6, the curves of carbon dioxide evolved vs. the time for anthracite were more linear than those for petroleum coke. The quantity of the gas evolved per unit time for anthracite and coal coke was much less than that for petroleum coke; therefore, the curve of three types. i. e., $b<1$, $b=1$ and $b>1$ in $V=at^b$, is not explicitly shown in Fig. 6 as in the case of petroleum coke in Fig. 5. Anthracite and coal coke heat-treated at 2250°C and below were oxidized at 100°C in order to obtain the b-value. The b-values for anthracite and coal coke heat-treated at 2600 and 2800°C were the average values at the reaction temperatures from 65 to 89°C.

The b-values for three kinds of carbon are plotted as a function of the interlayer spacing in Fig. 8. It is interesting that these b-values of all specimens compose one curve which increases monotonically as graphitization proceeds.

The oxidation velocity was obtained as follows: the reaction velocity for petroleum

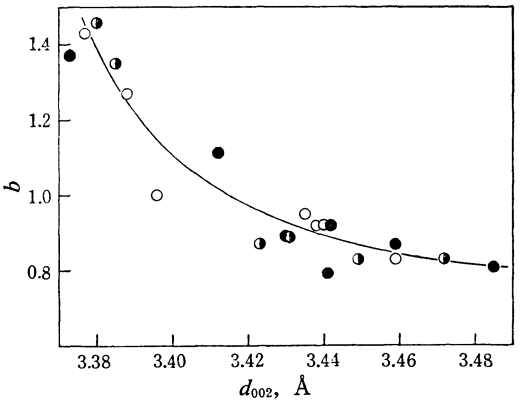

Fig. 8. b-Value vs. interlayer spacing.
○ Petroleum coke ● Coal coke
◑ Anthracite

coke was measured from the time which it took for initial 50 cc. of carbon dioxide to evolve; for anthracite and coal coke, this was decided from the slope of each straight line which related the carbon dioxide evolved and the reaction time. The curve of the gas evolved vs. the time was apparently linear when the less reactive carbons such as anthracite and coal coke were oxidized.

The reaction velocities at 85°C of three heat-treated carbon are plotted against the interlayer spacing in Fig. 9. Of the three, petroleum coke was oxidized with the highest rate; the reactivity of coal coke was of the same order as that of anthracite. The velocity for petroleum coke heat-treated at 2600 and 2800°C was smaller than that heat-treated below 2250°C, but the reason can not be

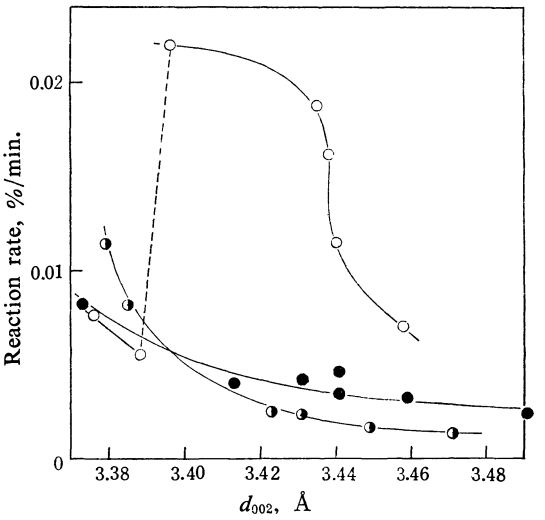

Fig. 9. Reaction velocity at 85°C vs. interlayer spacing.

◑ Anthracite

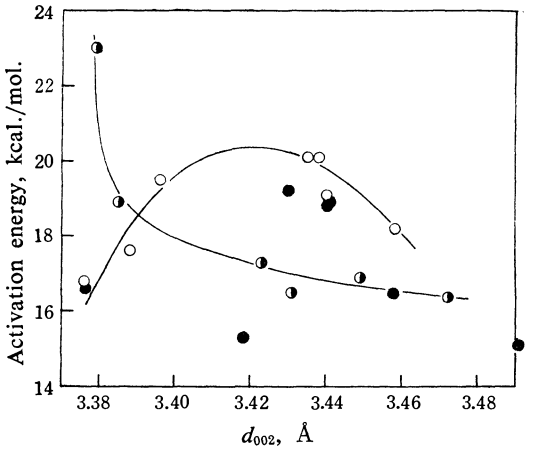

Fig. 10. Activation energy in wet oxidation vs. interlayer spacing.
○ Petroleum coke ● Coal coke
◑ Anthracite

understood from only the standpoint of the graphitization.

The activation energy obtained from the Arrhenius plot is shown as a function of the interlayer distance in Fig. 10. The standard deviation of activation energy for the three carbons obtained from the method of least squares was 0.7 kcal./mol. at most, although this is not shown in the figure. The activation energy for anthracite increased monotonically with the decrease of d_{002}, but for petroleum coke and coal coke there was a maximum at about 3.42Å of the interlayer spacing. The different behavior of the activation energy mentioned above seems to come from the nature of the original carbonaceous materials.

It has been reported that petroleum coke, anthracite and coal coke are non-graphitic graphitizing carbons. These carbons graphitize easily upon heat treatment. The difference of the graphitization between petroleum coke and anthracite and coal coke seems to be attributable to the original carbonaceous materials. As is shown in Fig. 2, of the three specimens, the graphitization of these carbons proceeds with the most facility in petroleum coke. The structure of anthracite is seemingly similar to that of coal coke, although anthracite has been carbonized naturally.

The difference in structure between petroleum coke and anthracite and coal coke appears in the wet oxidation, as is shown in Fig. 9. As far as our experiments show, the oxidation velocity of the carbon graphitized increases toward graphite. Of the three kinds of carbon, the dioxidation velocity of petroleum coke is five times as large as that of the other, and coal coke is of the same order as anthracite in oxidation velocity.

As has been mentioned above, the behavior of the oxidation velocity of three different types of carbon in accordance with the reaction time has been classified. For non-graphitizing carbon of d_{002} 3.44Å, the oxidation velocity decreases as the reaction proceeds.

As for the graphitic carbon of d_{002} 3.44Å, the oxidation velocity, which increases with the degree of graphitization, has a tendency to increase as the reaction proceeds. The reason for the increase in the reaction velocity may be thought to be that the carbon heat-treated disperses into the colloidal state in the process of the wet oxidation and that its surface area in contact with the oxidizing solution increases progressively. It seems that the increase in the surface area is closely connected with the rigidity of the cross-linkage bridged between crystallites. Moreover, the linkage between them weakens as the graphitization proceeds.

It is considered that the *b*-value, which is a unique function of the degree of graphitization, as is shown in Fig. 8, becomes one measure of the rigidity of the crystallite linkage. Akamatu et al.[6] have found that such carbons as carbon black and graphitic carbon disperse into the colloidal state during the wet oxidation, whereas no colloidal dispersion occurs in the case of charcoal and pitch coke. It is shown that their conclusion is in good agreement with our experimental results given in Fig. 8.

Summary

The wet oxidation of three kinds of heat-treated graphitizing carbons, petroleum coke, anthracite and coal coke, in a solution of potassium dichromate in phosphoric acid has been studied in order to clarify the relationship between the chemical reactivity and the carbon structure.

Changes in the interlayer spacing and crystallite size, which are used as a measure of graphitization, have been examined by X-ray diffraction method for each specimen over the range of heat treatment temperatures from 1100 to 2800°C.

The oxidation velocity increases with the degree of graphitization. The quantity of carbon dioxide evolved, V, is generally expressed by the following equation, $V=at^b$. The *b*-value depends on only the degree of graphitization and varies from 0.8 to 1.5 according to the increase of graphitization, but it does not depend on the oxidation temperatures.

*3-Aryl-2, 4-thiazolidindiones. New Local Anaesthetics. IV**

By Prithwi Nath BHARGAVA and Suresh Chandra SHARMA

(Received June 2, 1962)

In viw of close relationship between thiazolidones and thiazolidiones and reported uses of thiazolidone compounds as local anaesthetics*,[1,2], amoebacidal agents[3], and anticonvulsants[4], it was considered worthwhile to prepare 3-aryl-2, 4-thiazolidindiones under the conditions laid down by earlier workers[5-8]. The compounds having piperazino group connected to the heterocyclic nucleus as a lipophylic moiety confer greater activity and less toxicity than the benzene analogues[9-11].

3-Aryl-2, 4-thiazolidindiones have been obtained in good yields by interaction of *S*-diarylthiourea with monochloroacetic acid and glacial acetic acid. An amino group has been introduced at 5-position in the thiazolidindionyl nucleus at the reactive methylene group[12,13] through coupling[14] with benzenediazonium chloride and subsequent reduction[15,16] with sodium hydrosulfite. 5-Chloroacetyl-amino-3-aryl-2, 4-thiazolidindiones, prepared from the chloroacetyl chloride and respective 5-amino compounds, have been further condensed with piperazine to give the required piperazino-1, 4-bis(5-acetylamino-3-aryl-2, 4-thiazolidindiones). These bases have been converted into their hydrochlorides by the usual method.

These compounds have also been tested for the local anaesthetic activity by frog's sciatic plexus method[17] which has shown that the hydrochlorides of piperazino-1, 4-bis(5-chloroacetylamino-3-*p*-chlorophenyl-, -3-*m*-tolyl-, -3-*p*-tolyl-, -3-*p*-anisyl-, -3-*p*-phenetyl-2, 4-thiazolidindiones) have been found most effective local anaesthetics in this class of compounds.

Experimental

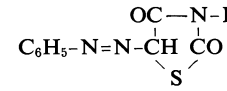
5-Phenylazo-3-phenyl-2, 4-thiazolidindione. — A solution of 5 g. of 3-phenyl-2, 4-thiazolidindione in 30 cc. of glacial acetic acid was slowly added to a solution of benzenediazonium chloride (prepared from 4 cc. of aniline), cooled with the freezing mixture at 0°C, with stirring and kept for an hour at 0~5°C. The precipitate formed was filtered, washed with water and dilute ethanol and crystallized from absolute ethanol, m. p. 122°C.

Similarly other thiazolidindiones were coupled with benzenediazonium chloride. Their properties and analytical data are recorded in Table I.

5-Amino-3-phenyl-2, 4-thiazolidindione. — A solution of 8 g. of sodium hydrosulfite in 20 cc. of water was added to the solution of 5 g. of azo compound dissolved in 20 cc. of ethanol. The product which separated, was filtered, washed with hot water and finally crystallized from absolute ethanol into a colorless form, m. p. 133°C.

Similarly, 5-amino derivatives of other 5-phenylazo-3-aryl-2, 4-thiazolidindiones were prepared. Their properties and analytical data are mentioned in Table II.

5-Chloroacetylamino-3-phenyl-2, 4-thiazolidindione.—Chloroacetyl chloride (0.5 cc.) and 5-amino compound (4 g.) were refluxed in 45 cc. of dry benzene for 2 hr. on a water bath at 70°C. Benzene and excess of chloroacetyl chloride were distilled off and the residue washed with the solution of sodium bicarbonate and water. The product was crystallized from absolute ethanol, m. p. 146°C.



Chloroacetylamino derivatives of other 5-amino-3-aryl-2, 4-thiazolidindiones were prepared similarly and their properties and analytical data are shown in Table III.

Piperazino-1, 4-bis(5-acetylamino-3-phenyl-2, 4-thiazolidindione).—A mixture of 5.6 g. of 5-chloroacetylamino-3-phenyl-2, 4-thiazolidindione and 0.84 g. of piperazine in 40 cc. of absolute ethanol was refluxed on a water bath at 60°C for 4 hr. Ethanol was recovered by distillation and the residue subsequently washed with sodium bicarbonate solution and water. The product was crystallized from ethanol and recrystallized from benzene, m. p. 304°C.

The hydrochloride of the base was prepared by dissolving in dry ether and passing into it dry hydrochloric acid gas. The mass was crystallized from absolute ethanol, m. p. 305°C.

The properties and analytical data of the piperazino derivatives and hydrochlorides of the bases prepared similarly from other 5-chloroacetylamino compounds are reported in Tables IV and V respectively.

Pharmacological Screening.—Adopting the procedure of Bülbring and Wajda[17], the local anaesthetic activity of these hydrochlorides was tested on frogs and the time of onset of anaesthesia i. e. the time for which a given concentration (0.1%) of the local anaesthetic failed to provoke withdrawal of feet is also recorded in Table V.

Pharmacological screening of these compounds

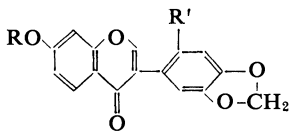
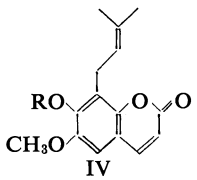
Synthesis of Maxima Substance B

By Kenji FUKUI, Mitsuru NAKAYAMA and Masayuki HATANAKA



(Received June 18, 1962)

In 1954 Rangaswami and Sastry reported the isolation of three colorless substances from the roots of *Tephrosia maxima* Aers[1]. The substances were called maxima substance A, B and C[1], and later were assigned as isoflavones[2-4]. Degradative work with three crystalline, which shows that they all have the same isoflavone skeletons including the methylenedioxy group, has led to the following structures being proposed for them, maxima substance A (I)[2], B (II)[3] and C (III)[4].



Maxima substance B was of interest as it is one of the naturally occuring γ,γ-dimethylallylethers of chromone derivatives. These ethers have been isolated and known as maxima substance C (III)[4], brayleyanin (IV)[5] and 5-hydroxy-4'-γ,γ-dimethylallyloxy-3',7-dimethoxyflavanone (V)[6]. None of these substances has so far been synthesized. We were led by our interest in the oxygen heterocyclics synthesis to attempt their synthesis and our initial aim was to prepare maxima substance B.

V

For II—V; R, $\begin{matrix}CH_3\\CH_3\end{matrix}\!\!>\!C{=}CH{-}CH_2$

In the present communication, we now record the synthesis of maxima substance B and related compounds. A key intermediate in our proposed synthesis was pseudobaptigenin (VI), an isoflavone which has been obtained by Späth and Schmidt[7] and synthesized by Späth[8], Venkataraman[9], Baker[10-11] and Farkas[12-13]. The reaction of pseudobaptigenin (VI), which was prepared by the Farkas' method[13], and γ,γ-dimethylallylbromide[14] with potassium carbonate gave an ether in good yield. It formed colorless needles, having an empirical formula of $C_{21}H_{18}O_5$, m. p. 134~135°C.

of the ether in the presence of platinum oxide catalyst in acetic acid afforded a dihydrocompound, m. p. 138~139°C, after one mole of hydrogen was absorbed. Pseudobaptigenin (VI) and isoamylbromide with potassium carbonate gave the 7-isoamyloxypseudobaptigenin (VII), m. p. 139~140°C, which was identical with the above dihydrocompound as shown by the infrared spectrum and the mixed melting point determination. It was shown to have structure II of the ether. The ether II was identical with the natural substance in the mixed melting point determination by Rangaswami. The structure assigned to maxima substance B has, therefore, been fully confirmed. The infrared and ultraviolet spectra of II and VII were shown in Figs. 1 and 2.

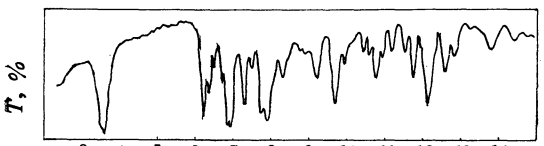

Fig. 1a. Infrared spectrum of maxima substancce B (II) (Nujol).

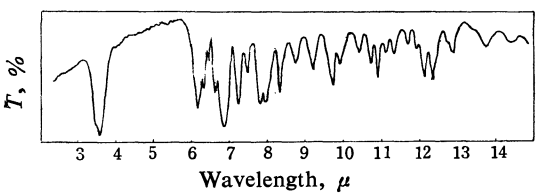

Fig. 1b. Infrared spectrum of 7-isoamyloxypseudobaptigenin (VII) (Nujol).

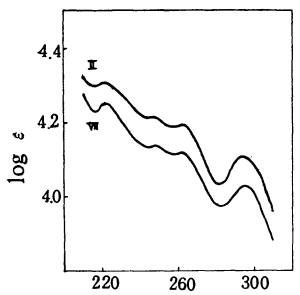

Fig. 2. Ultraviolet spectra of maxima substance B (II) and 7-isoamyloxypseudobaptigenin (VII).

By model experiment with a simple analogue, 7-γ, γ-dimethylallyloxyisoflavone (VIII) and 7-isoamyloxyisoflavone (IX), respectively m. p. 157~158°C and 149~150°C, were obtained from 7-hydroxyisoflavone (X)[15].

Experimental*

Maxima Substance B (7-γ, γ-Dimethylallyloxypseudobaptigenin) (II).—To a solution of pseudobaptigenin[13] (VI, m. p. 288~290°C, 1.0 g.) and γ, γ-dimethylallylbromide[14] (1.1 g.) in anhydrous acetone (250 ml.) was added anhydrous potassium carbonate (5.0 g.), and the mixture was refluxed for 20 hr. in a steam bath. The resulting mixture was filtered from precipitates and the solvent was distilled off. The residual product was recrystallized from ethanol to give II in the form of colorless needles, m. p. 134~135°C; yield 0.9 g. (75%). The natural substance is m. p. 126~128°C[1]. This substance showed no depression of the meltint point on admixture with the natural specimen by Rangaswami.

Found; C, 71.85; H, 5.23. Calcd. for $C_{21}H_{18}O_5$: C, 71.99; H, 5.18%.

UV λ_{max}^{EtOH} mμ (log ε): 222 (4.32), 249 (4.21), 264 (4.19), 295 (4.12).

7-Isoamyloxypseudobaptigenin (VII).—*a) From II.*—The mixture of maxima substance B (II) (300 mg.) and platinum oxide (50 mg.) in glacial acetic acid (80 ml.) was shaken in the atmosphere of hydrogen until 1.2 mol. of hydrogen was absorbed. After separation of the catalyst, the filtrate was evaporated under reduced pressure. The residual product was recystallized from ethanol to give VII in the form of colorless needles, m. p. 138~139°C; yield 150 mg. (50%).

b) From VI.—By a similar method as described for II, VII was obtained from VI (1.5 g), isoamylbromide (2.0 g.), anhydrous potassium carbonate (5.0 g.) and acetone (150 ml.); colorless needles, m. p. 139~140°C; yield 1.5 g. (76%). This substance showed no depression of the melting point on admixture with the specimen derived by the above-mentioned method a).

Found: C, 71.77; H, 5.76. Calcd. for $C_{21}H_{20}O_5$: C, 71.58; H, 5.72%.

UV λ_{max}^{EtOH} mμ (log ε): 223 (4.26), 249 (4.14), 261 (4.12), 295 (4.04).

Degradation of Maxima Substance B (II).—To maxima substance B (II) (2.0 g.) in acetic acid (100 ml.) was added concentrate sulfuric acid (1 ml.). After standing of the mixture for two days at room temperature, the solids appeared and were collected by filtration. The product was recrystallized from ethanol to give VI in the form of colorless microcrystals, m. p. 288~290°C; yield 1.4 g. (86%). Reported m. p. is 296°C[13].

Acetate of VI was prepared quantitatively by refluxing VI and acetic anhydride with anhydrous sodium acetate, m. p. 175~175.5°C. Reported m. p. is 176°C[13].

* All melting points are uncorrected.

These substances showed no depression of the melting point on admixture with the authentic specimens.

7-γ,γ-Dimethylallyloxyisoflavone (VIII).—By a similar method as described for II, VIII was obtained from 7-hydroxyisoflavone[15] (X, m. p. 211~212°C, 1.0 g.), γ,γ-dimethylallylbromide (1.3 g.), anhydrous potassium carbonate (2.5 g.) and acetone (100 ml.); colorless plates, m. p. 157~158°C; yield 0.9 g. (70%).

Found: C, 78.61; H, 5.95. Calcd. for $C_{20}H_{18}O_3$: C, 78.41; H, 5.92%.

7-Isoamyloxyisoflavone (IX).—By a similar method as described for II, IX was obtained from X (0.5 g.), isoamylbromide (0.7 g.), anhydrous potassium carbonate (2.0 g.) and acetone (50 ml.); colorless needles, m. p. 149~150°C; yield 0.6 g. (92%).

Found: C, 77.78; H, 6.62. Calcd. for $C_{20}H_{20}O_3$: C, 77.90; H, 6.54%.

We are grateful to Professor S. Rangaswami, Andhra University, India, for measurement of the mixed melting point with the natural substances and ours and to Professor Minoru Nakajima and Professor Tetsuo Mitsui, Kyoto University, for measurements of infrared spectroscopy and microanalysis. This work is being partially supported by the grant-in-aid for Scientific Research from the Ministry of Education.

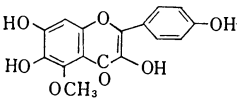
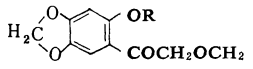
Synthetic Studies of the Flavone Derivatives. I. Syntheses of Some 3-Methoxy-6, 7-methylenedioxyflavones



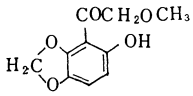
By Kenji FUKUI and Takashi MATSUMOTO

(Received July 6, 1962)

There have been only a few investigations of flavones which possess a methylenedioxy group in the chromone nucleus. Meliternatin (3, 5-dimethoxy-6, 7; 3', 4'-bismethylenedioxyflavone) (I) and wharangin have been isolated from the bark of *Melicope ternata*[1] and *M. mantelli*[2]. 3, 4'-Dihydroxy-5-methoxy-6, 7-methylenedioxyflavone have been obtained from naturally occurring vogoletin (3, 6, 7, 4'-tetrahydroxy-5-methoxyflavone) (II)[3]. 7, 8-Methylenedioxyflavone, 6, 7-methylenedioxyflavone and 3', 4'-dimethoxy-6,7-methylenedioxyflavone have been synthesized[4-5]. However, 3-methoxy-6, 7-methylenedioxyflavone derivatives and 3, 5-dimethoxy-6, 7-methylenedioxyflavone derivatives have not yet been synthesized.



(I)



(II)

In the present paper, the syntheses of 3-methoxy-6, 7-methylenedioxyflavone (VIII) and its analogues are described. The Hoesch reaction of sesamol (3, 4-methylenedioxyphenol) and methoxyacetonitrile yielded a ketone, $C_{10}H_{10}O_5$ (m. p., 136~138°C). At this stage, the reaction could give either 2-hydroxy-4, 5-methylenedioxy-ω-methoxyacetophenone (III) or 2-hydroxy-5, 6-methylenedioxy-ω-methoxyacetophenone (VI). The oxidation of the ω-methoxyacetophenone to a benzoic acid derivative was used to settle this question. The ketone was methylated to monomethyl ether (m. p., 99~100°C), which was then converted into 2-methoxy-4, 5-methylenedioxybenzoic acid (VII)[6-7] by potassium permanganate oxidation. The acid VII was identified by direct comparison with an authentic sample. From this fact, the structure of 2-hydroxy-4, 5-methylenedioxy-ω-methoxyacetophenone (III) was established for the ketone.

(VI)

(VII)

According to Allan and Robinson's flavone synthesis[8], the condensation of the ketone III with benzoic anhydride in the presence of potassium benzoate, followed by treatment with alcoholic potassium hydroxide, afforded 3-methoxy-6, 7-methylenedioxyflavone (VIII) (m. p., 180.5~182.5°C). By a similar reaction, 3, 4'-dimethoxy-6, 7-methylenedioxyflavone (IX) (m. p., 238.5~239°C), 3, 3', 4'-trimethoxy-6, 7-methylenedioxyflavone (X) (m. p., 171~172°C), 3-methoxy-6, 7; 3', 4'-bismethylenedioxyflavone (XI) (m. p., 247~248°C), 3, 3', 4', 5'-tetramethoxy-6,7-methylenedioxyflavone (XII) (m. p., 224~225°C) and 3-methoxy-3', 4'-dibenzyloxy-6, 7-methylenedioxyflavone (XIII) (m. p., 123.5~125°C) were obtained. These compounds gave a negative ferric reaction and were soluble in concentrated sulfuric acid to a yellow solution. The debenzylation of XIII with hydrogen afforded 3-methoxy-3', 4'-dihydroxy-6, 7-methylenedioxy-flavone (XIV) (m. p., 293~295°C) (decomp.), which was then converted into 3, 3', 4'-trimethoxy-6, 7-methylenedioxyflavone (X) by methylation. The ultraviolet spectra of these compounds are shown in Figs. 1 and 2. In most cases there are two peaks, ca. 245 and ca. 335 mμ, but the absorption maxima of VIII and IX is observed ca. 255 mμ in addition to these two peaks.

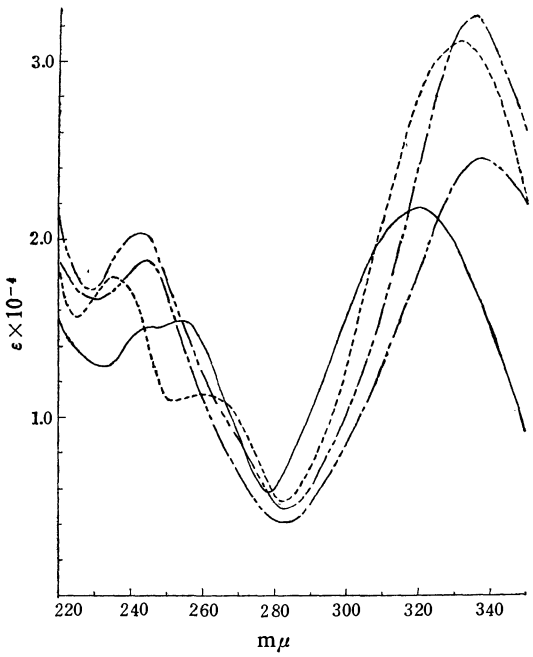

Fig. 1. Ultraviolet spectra of VIII (——), IX (----), X (– – –) and XI (–·–·–) in ethanol.

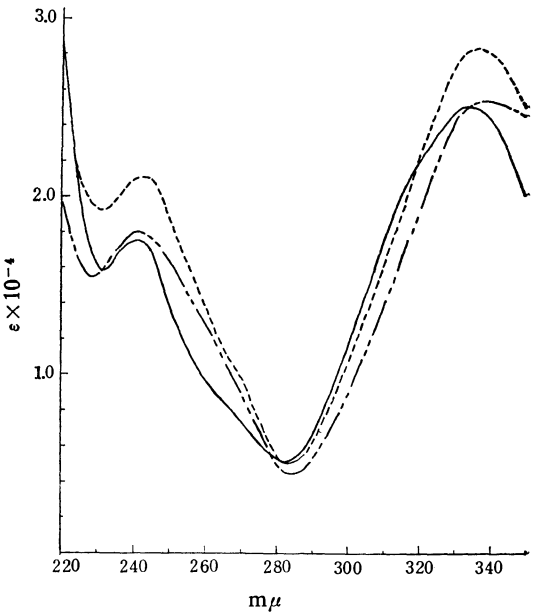

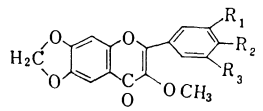

Fig. 2. Ultraviolet spectra of XII (——), XIII (----) and XIV (– – –) in ethanol.

Experimental*

2-Hydroxy-4, 5-methylenedioxy-ω-methoxyacetophenone (III).—A mixture of sesamol (3.1 g.),

8) J. Allan and R. Robinson, *J. Chem. Soc.*, **1924**, 2192.

* All melting points were uncorrected. The ultraviolet spectra were determined with a Shimadzu model SV-50A spectrophotometer, while the infrared spectra were determined with a Hilger model 800 spectrophotometer.

which had been obtained from piperonal by Baeyer-Villiger oxidation[9], methoxyacetonitrile (1.9 g.) and anhydrous zinc chloride (0.6 g.) in anhydrous ether (20 ml.) was saturated with dried hydrogen chloride in an ice-bath and allowed to stand overnight. The ether solution was decanted from the ketimine hydrochloride-zinc chloride complex which had separated. The residue was washed twice with dry ether and then heated on a steam bath with water (20 ml.) for 30 min. After this had cooled and stood, the precipitated ketone was collected. Recrystallization from ethanol gave colorless needles (m. p., 136~138°C) which gave a dark blue color with ferric chloride; yield, 1.2 g. (26%). IR 1636 (C=O), 1025 (=C-O-C), 915 cm^{-1} ($O-CH_2-O$) (Nujol).

Found: C, 57.17; H, 4.84. Calcd. for $C_{10}H_{10}O_5$: C, 57.14; H, 4.80%.

III was acetylated with acetic anhydride and pyridine. The acetate IV formed colorless needles from aqueous methanol (m. p., 87~89°C) which gave a negative ferric reaction. IR 1753, 1675 (C=O), 1028 (=C-O-C), 925 cm^{-1} ($O-CH_2-O$) (Nujol).

Found: C, 57.08; H, 4.79. Calcd. for $C_{12}H_{12}O_6$: C, 57.14; H, 4.80%.

2-Methoxy-4, 5-methylenedioxy-ω-methoxyacetophenone (V). — The ketone III (1.0 g.), dissolved in acetone (40 ml.), was heated under reflux with methyl iodide (1.0 g.) and anhydrous potassium carbonate (3.0 g.) for 6 hr. on a steam bath. The solution was then filtered and evaporated to dryness. The residue was collected, washed with a dilute alkaline solution and recrystallized from aqueous ethanol to give colorless needles (m. p., 99~100°C) which gave a negative ferric reaction; yield, 0.45 g. (42%). IR 1663 (C=O), 1030 (=C-O-C), 915 cm^{-1} ($O-CH_2-O$) (Nujol).

Found: C, 58.65; H, 5.36. Calcd. for $C_{11}H_{12}O_5$: C, 58.92; H, 5.40%.

2-Methoxy-4,5-methylenedioxybenzoic Acid (VII). —A suspension of 2-methoxy-4, 5-methylenedioxy-ω-methoxyacetophenone (V) (0.4 g.) in water (15 ml.) was treated under reflux with small portions of a 2% potassium permanganate solution until the consumption of the oxidant subsided. After the excess permanganate had been reduced with sodium bisulfite, the precipitate was separated by filtration and washed with hot water. The combined filtrates were acidified with dilute sulfuric acid and extracted with ethyl acetate. The organic layer was washed with water and dried over anhydrous sodium sulfate. The solvent was evaporated, and the residue was recrystallized from aqueous methanol to give pale yellow needles (m. p., 150~151°C) (reported 148~149°C[6] and 147~147.5°C[7]); yield, 0.1 g. Its identity with an authentic sample of 2-methoxy-4,5-methylenedioxybenzoic acid (VII) was established by mixed melting point determination and infrared spectral comparison. IR 1710, 1625 (C=O), 1026 (=C-O-C), 920 cm^{-1} ($O-CH_2-O$) (Nujol).

Found: C, 55.31; H, 4.10. Calcd. for $C_9H_8O_5$: C, 55.10; H, 4.11%.

3-Methoxy-6, 7-methylenedioxyflavone (VIII).— The ketone III (0.7 g.), benzoic anhydride (1.5 g.) and potassium benzoate (0.8 g.) were ground together and heated at 170~180°C under reduced pressure for 3 hr. The reaction mixture was ground and boiled with 8% aqueous alcoholic (1 : 4) potassium hydroxide (25 ml.) for 15 min. After the removal of the solvent in vacuo, water (60 ml.) was added to the pasty mass. The precipitated solid was collected, washed with water and recrystallized from ethanol to give colorless needles m. p., 180.5~182.5°C) which gave a negative ferric reaction and a yellow colored solution with concentrated sulfuric acid; yield, 0.35 g. (35%). IR 1618 (C=O), 1023 (=C-O-C), 928 cm^{-1} ($O-CH_2-O$) (Nujol). UV λ_{max}^{EtOH} mμ ($\varepsilon \times 10^{-4}$); 247** (1.51), 254 (1.55), 320 (2.18).

Found: C, 68.95; H, 4.07. Calcd. for $C_{17}H_{12}O_5$: C, 68.91; H, 4.08%.

3, 4'-Dimethoxy-6, 7-methylenedioxyflavone (IX). —A mixture of the ketone III (1.0 g.), anisic anhydride (2.8 g.) and potassium anisate (1.4 g.) was treated in a way similar to that used for VIII. Yield, 0.8 g. of colorless needles (m. p., 238.5~239°C) from acetic acid and then from ethyl acetate. This substance gave a negative ferric reaction and a yellow colored solution with concentrated sulfuric acid. IR 1629 (C=O), 1025 (=C-O-C), 928 cm^{-1} ($O-CH_2-O$) (Nujol). UV λ_{max}^{EtOH} mμ ($\varepsilon \times 10^{-4}$); 235 (1.80), 260 (1.14), 332 (3.12).

Found: C, 66.04; H, 4.15. Calcd. for $C_{18}H_{14}O_6$: C, 66.25; H, 4.32%.

3, 3', 4' - Trimethoxy - 6, 7 - methylenedioxyflavone (X).—From the ketone III (0.5 g.), veratric anhydride (1.7 g.) and potassium veratrate (0.8 g.), synthesis was carried out by a method similar to that used for VIII. Yield, 0.35 g. of pale yellow needles (m. p., 171~172°C) from ethanol. This substance gave a negative ferric reaction and showed a yellow color in a concentrated sulfuric acid solution. IR 1630 (C=O), 1020 (=C-O-C), 923 cm^{-1} ($O-CH_2-O$) (Nujol). UV λ_{max}^{EtOH} mμ ($\varepsilon \times 10^{-4}$); 243 (2.05), 336 (3.27).

Found: C, 64.31; H, 4.69. Calcd. for $C_{19}H_{16}O_7$: C, 64.04; H, 4.53%.

3-Methoxy-6, 7; 3', 4'-bismethylenedioxyflavone (XI). — From the ketone III (1.0 g.), piperonylic anhydride (3.9 g.) and potassium piperonylate (1.5 g.), synthesis was carried out by a method similar to that used for VIII. Yield, 0.56 g. of colorless needles (m. p., 247~248°C) from acetic acid. This substance gave a negative ferric reaction and showed a yellow color in a concentrated sulfuric acid solution. IR 1635 (C=O), 1025 (=C-O-C), 925 cm^{-1} ($O-CH_2-O$) (Nujol). UV λ_{max}^{EtOH} mμ ($\varepsilon \times 10^{-4}$); 244.5 (1.89), 337 (2.46).

Found: C, 63.54; H, 3.67. Calcd. for $C_{18}H_{12}O_7$: C, 63.53; H, 3.55%.

3, 3', 4', 5' - Tetramethoxy - 6, 7 - methylenedioxyflavone (XII). — From the ketone (III) (1.0 g.), trimethylgallic anhydride[10] (4.0 g.) and potassium trimethylgallate (1.9 g.), synthesis was carried out by a method similar to that used for VIII. Yield,

0.8 g. of pale yellow needles (m. p., 224~225°C) from acetone. This substance gave a negative ferric reaction and showed a yellow color in a concentrated sulfuric acid solution. IR 1628 (C=O), 1023 (=C-O-C), 930 cm^{-1} (O-CH_2-O) (Nujol). UV λ_{max}^{EtOH} mμ ($\varepsilon \times 10^{-4}$) ; 242 (1.76), 335 (2.50).

Found : C, 61.98 ; H, 4.61. Calcd. for $C_{20}H_{18}O_8$; C, 62.17 ; H, 4.70%.

3-Methoxy-3', 4'-dibenzyloxy-6,7-methylenedioxyflavone (XIII). — From the ketone III (1.0 g.), 3,4-dibenzyloxybenzoic anhydride[11] (6.5 g.) and potassium 3,4-dibenzyloxybenzoate (2.8 g.), synthesis was carried out by a method similar to that used for VIII. Yield, 1.0 g. of pale yellow needles (m. p., 123.5~125°C) from aqueous acetone and then from ethanol. This substance gave a negative ferric reaction and showed a yellow color in a concentrated sulfuric acid solution. IR 1610 (C=O), 1035 (=C-O-C), 943 cm^{-1} (O-CH_2-O) (Nujol). UV λ_{max}^{EtOH} mμ ($\varepsilon \times 10^{-4}$) ; 243 (2.11), 337 (2.83).

Found : C, 73.16 ; H, 4.83. Calcd. for $C_{31}H_{24}O_7$: C, 73.22 ; H, 4.76%.

3-Methoxy-3', 4'-dihydroxy-6, 7-methylenedioxyflavone (XIV). — A solution of 3-methoxy-3', 4'-dibenzyloxy-6,7-methylenedioxyflavone (XIII) (600 mg.) in acetic acid (30 ml.) was submitted to catalytic reduction in the presence of a 10% Pd-C catalyst (1.0 g.) at room temperature. The precipitate was collected and extracted with dilute aqueous sodium hydroxide. After the alkaline extract had been acidified with dilute sulfuric acid, the precipitate was collected, washed with water and recrystallized from ethanol to give yellow needles (m. p., 293~295°C) (decomp.) which gave a green color with ferric chloride ; yield, 170 mg. IR 1630 (C=O), 1028 (=C-O-C), 928 cm^{-1} (O-CH_2-O) (Nujol). UV λ_{max}^{EtOH} mμ ($\varepsilon \times 10^{-4}$) ; 242 (1.80), 338 (2.53).

Found : C, 61.99 ; H, 3.85. Calcd. for $C_{17}H_{12}O_7$: C, 62.20 ; H, 3.68%.

A solution of 3-methoxy-3', 4'-dihydroxy-6, 7-methylenedioxyflavone (XIV) (100 mg.) in acetone (50 ml.) was heated under reflux with methyl iodide (0.3 g.) and anhydrous potassium carbonate (0.5 g.) for 5 hr. The acetone solution was filtered and evaporated to dryness. The residue was washed with water and recrystallized from ethanol to give colorless needles (m. p., 171~172°C, undepressed on admixture with X).

Found : C, 64.00 ; H, 4.53. Calcd. for $C_{19}H_{16}O_7$: C, 64.04 ; H, 4.53%.

The authors wish to express their gratitude to the members of the Microanalytical Center of Kyoto University for their microanalyses. The cost of this research was partly defrayed by the Scientific Research Expenditure Fund of the Ministry of Education, to which the authors' thanks are due.

*The Mechanism of the Gelation of a Lead Aldose-cysteinate Solution**

By Fujio TAKAHASHI and Jun MIZUGUCHI

(Received July 6, 1962)

Previous papers have described studies of the properties of the gel and the structure of lead aldose-cysteinate[1]. On measuring the rigidity of the gel, the pH value of a lead glucose-cysteinate solution was found to vary with the lapse of time, as is shown in Table I. From this fact, it was suggested that the internal structure of a lead glucose-cysteinate solution, which appeared to be transparent initially, might also change with the lapse of time.

In this paper, the study of the mechanism of gelation deals with the measurement of such various developments as the pH value, the conductivity, the optical density, and the gelation time.

* Gelation of Lead Aldose-cysteinate: Part III.

1) F. Takahashi and J. Mizuguchi, This Bulletin 35, 1823 (1962).

Experimental

Materials.—All materials used are the same as have been described in the previous papers[1].

Apparatus.—The measurements of the pH value, the conductivity, and the optical density were carried out with a portable pH meter, a Yanagimoto conductometer, model MY-6, and an Erma Lippich Polarimeter respectively. The measurements of volume change were carried out with a 25 ml. pycnometer with an attached, graduated glass tube (0.0~0.1 ml.) shown in Fig. 1.

Procedure.—All the measurements were carried out from the time when a solution of lead salt was mixed with a solution of HSC at a constant temperature in the thermostats. The different pH value of the solution was adjusted by the addition of an appropriate amount of nitric acid or sodium hydroxide. Re-distilled water ($2.0\times10^5\ \Omega\cdot$cm.) was used for conductivity water measurements.

TABLE I. pH CHANGE

0.06 M NaGC, 0.03 M $Pb(CH_3COO)_2$ or $Pb(NO_3)_2$, appropriate amount of HNO_3 or NaOH. 25°C. Rigidity was measured after 3 hr. from the gelation time.

pH		The gelation time	Rigidity
Initial	Final (after gelation)	min.	g./cm²
3.6	3.3	Not form gel	—
4.2	3.3	5.5	65
4.8	3.5	4	140
5.2	3.7	5	200
5.5	4.4	8	260
6.0	5.3	9	300
6.8	6.6	8.5	150
7.6	7.5	10	75
8.0	8.5	5	70
8.4	8.7	3	125
9.2	9.9	4	155
10.0	10.3	10	125
10.7	10.6	1 day	55

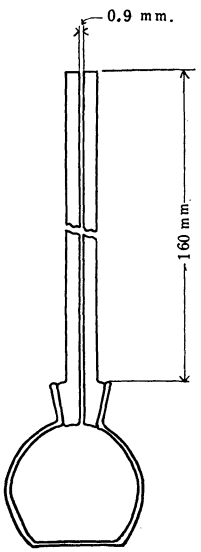

Fig. 1

All the measurements of the gelation time were carried out with test tubes in which a solution containing 0.15 to 2.5 ml. of 0.2 M NaGC** or 0.05 M NaGaC** and 0.15 to 2.5 ml. of 0.1 or 0.2 M lead acetate or nitrate was diluted to 5.0 ml. with distilled water. The mixtures were allowed to stand for a while. The time when a mixture lost fluidity was adopted as the gelation time.

Precipitates obtained in the pH Range between 8 and 10. — White precipitates were obtained when 10 ml. of 0.2 M lead acetate was added to a mixture of 10 ml. of 0.2 M NaGC and 30 ml. of 0.1 M sodium hydroxide. The precipitates were filtered and washed with a little amount of water and then with methanol as fast as possible for fear that precipitates might redissolved; yield, 0.40 g.

Found: C, 13.1; H, 2.1; N, 1.6; ash, 71.2%.

Results

pH Value. — In the pH range below 8, the lower the initial pH value, the more this pH

The sign ⋮ denotes the gelation time.
25°C.

** See This Bulletin 35, 1819 (1962).

value gradually decreased with the lapse of time. In the pH range between 8 and 10, white precipitates were obtained. These precipitates were gradually redissolved with the rise of the pH value. The results are shown in Fig. 2.

From the analytical results, the precipitates were found to be neither pure lead glucose-cysteinates, the lead content of which is less than 41%, nor pure lead hydroxide. It is seen that the precipitates presumably consist of lead hydroxide and lead glucose-cysteinate co-precipitated.

Conductivity and Optical Density.—The conductivity of the mixture of NaGC and lead acetate gradually. In the mixture of NaGC and lead nitrate, the conductivity increased initially and then stayed constant (Fig. 3).

The mutarotation toward dextrorotary occurred in every case. Optical rotation could not determined after gelation (Fig. 4).

A	0.50 M	0.50 M
B	0.33 M	0.33 M
C	0.20 M	0.20 M

Volume Change.—In the case of the mixture of NaGC and lead acetate, the volume of the mixture increased proportionally with the lapse of time before gelation. The rate of increase of the volume rose remarkably after gelation. After about an hour, however, the rate of increase slowed down. The results are shown in Fig. 5.

In the case of the mixture of NaGC and lead nitrate, the increase also occurs, but it was not proportional to the lapse of time.

The Gelation Time.—In every case, the gelation time was proportional to the reciprocal

of the concentration of lead salt (Fig. 6). Regarding temperatures between 20 to 50°C, straight lines are given in Fig. 7.

Discussion

In the previous paper[1], Eq. 1 was assumed from the fact that lead glucose-cysteinate hydroxide was isolated from the solution of NaGC and lead acetate.

The "ol" structure has been proposed by Hall and Eyring[2], who have studied the conductance of chromic salts in solution. It can be assumed that the "olation" of lead glucose-cysteinate occurs by the same mechanism as that of the hexaaquo chromic ion. Accordingly, the complex ion of hydrated lead glucose-cysteinate may be transformed into an "ol" structure with dehydration (Eq. 2). Perhaps the gelation occurs when an infinite three-dimensional structure is formed by olation.

The "olated" lead glucose-cysteinate so formed has to be removed from the system of an equilibrium state. Equation 1 may transfer to the right side in the pH value range between 3.8 and 8, and the concentration of protons may increase. In the pH value range between 8 and 10, the pH value of the solution may rise because of a reaction as is shown in the following equation:

$$Pb(OH)_2 + GC^- \rightarrow PbGCOH + OH^- \quad (3)$$

In the solution containing NaGC and lead acetate, the acetate ion shows the buffer action against the proton liberated by the olation:

$$CH_3COO^- + H^+ \rightleftharpoons CH_3COOH \quad (4)$$

In the solution containing NaGC and lead nitrate, the nitrate ion does not show any buffer action, so that the pH value of the solution may vary downward because of the liberation of the proton.

It is presumably seen that the optical rotation varies also because the olation occurs.

To verify the above assumptions, the kinetics of gelation was studied by determining the gelation time. The olation of the complex ion of hydrated lead glucose-cysteinate, accompanied with dehydration, was considered to be a process which follows the laws of ordinary chemical reaction. The reaction of the intermolecular combination is of the second order. Therefore, this reaction was expressed as follows:

$$-dC/dt = kC^2 \quad (5)$$

where C is the concentration against the time, t, of the complex ion of lead glucose-cysteinate not "olated"; k is the velocity constant. From 5 and Arrhenius' equation, $k = A \cdot e^{-\Delta E/RT}$, Eq. 6 was derived:

$$-(1/C_0)\cdot(C_0/C-1) = Kt\cdot e^{-\Delta E/RT} \quad (6)$$

where C_0 is the initial concentration of the complex ions of lead glucose-cysteinate and K is constant. This equation has already been

2) H. T. Hall and H. Eyring, *J. Am. Chem. Soc.*, 72, 782 (1950).

reported by Hurd and Letteron[3]. They permitted themselves to make an assumption in which C_0/C was constant. Therefore, the following equation was derived:

$$1/C_0 = K't \cdot e^{-\Delta E/RT} \quad (7)$$

where K' is constant. The experimental results were found to obey Eq. 7.

It has been known that the volume occupied by a molecule of free water is larger than that occupied by one of bound water[4]. Therefore, it can be suggested that the dehydration makes for a volume increase of the solution and that the rate of olation is parallel to the amount of volume increase. Regarding the gelation time, the concentration of olated lead glucose-cysteinate, C_0-C, is parallel to the ratio of the volume increase to the initial volume; that is,

$$C_0 - C = B(\Delta V_t/V_0) \quad (8)$$

where B is constant, ΔV_t is the amount of volume increase at the gelation time, and V_0 is the initial volume. Both sides of Eq. 8 may be divided by C_0. Therefore,

$$1 - C/C_0 = B(\Delta V_t/V_0)/C_0 \quad (9)$$

The $(\Delta V_t/V_0)/C_0$ calculated from the data of Fig. 5 shows almost constant values (Table II).

TABLE II. VOLUME CHANGE

Concn. of lead aldose-cysteinate C_0, M	$\frac{\Delta V_t}{V_0}$	$\frac{\Delta V_t}{V_0} \cdot \frac{1}{C_0}$
0.50	5.7×10^{-4}	$1.1_4\times10^{-3}$
0.33	3.4×10^{-4}	$1.0_3\times10^{-3}$
0.20	2.1×10^{-4}	$1.0_5\times10^{-3}$

3) C. B. Hurd and H. A. Letteron, *J. Phys. Chem.*, **36**, 604 (1932).
4) T. Yasunaga and T. Sasaki, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zassi*), **70**, 379 (1949).

The assumptions concerning the mechanism of gelation seem to have been verified by the determination of the gelation time.

Summary

The mechanism of the gelation of a solution containing aldose-cysteine and lead salt was studied by measuring various developments such as the pH value, the conductivity, the optical density, and the gelation time. From these results, it was suggested that the gelation occurred when the complex ion of hydrated lead glucose-cysteinate was transformed into an "ol" structure with dehydration. The process of this olation was found to follow the laws of ordinary chemical reaction. The reaction was of the second order.

The authors wish to express their sincere thanks to Professor Ikuzo Tanaka, Professor Kunio Kojima, Professor Koemon Funaki and Dr. Hiroshi Kobayashi of Tokyo Institute of Technology, and Director Kiyoshi Morikawa of the Research Laboratory of Resources Utilization, Tokyo Institute of Technology, for their invaluable advice on the structure of lead aldose-cysteinates and the mechnism of gelation. The authors are also indebted to Dr. Shoji Matsumoto of Tanabe Pharmaceutical Co., Ltd., who has provided facilities for elementary and infrared spectra analyses, and to Mr. Kaoru Matsuzaki and Miss Satoko Miyashita for their assistance in the experiments.

Thermometric Studies on the Reaction between Silver Nitrate and Sodium Thiosulfate

By Mahendra Singh BHADRAVER

(Received June 19, 1962)

Thermometric titrations between silver nitrate and sodium thiosulfate with varying concentrations of two salts in solution were performed. Reactions are indicated when Ag^+ and $S_2O_3^{2-}$ ions are present in solution in the molar ratio of 1 : 2, 1 : 1, 3 : 4 and 2 : 1 (in the direct method) and 1 : 2 and 1 : 1 (in the reverse method) respectively, indicating the formation of the complexes $Na_3Ag(S_2O_3)_2$, $NaAgS_2O_3$, $Na_5Ag_3(S_2O_3)_4$ and $Ag_2S_2O_3$ whereas in the reverse titrations $NaAgS_2O_3$ and $Ag_2S_2O_3$. The results support and throw more light on the reaction between silver nitrate and sodium thiosulfate.

There is meager amount of literatures on the study of this reaction. The possibility of formation of silver thiosulfate complexes was discovered by Herschel[1]. More recently Rosenheim and Steinhäuser[2] and Meyer and Eggeling[3] and lastly Rosenheim and Trewendt[4] carried out the study on the silver thiosulfate complexes. No attempt has so far been made by applying thermometric studies on this reaction. It was therefore considered worthy of interest to carry out study this reaction by thermometric method to throw more light on the nature of this reaction.

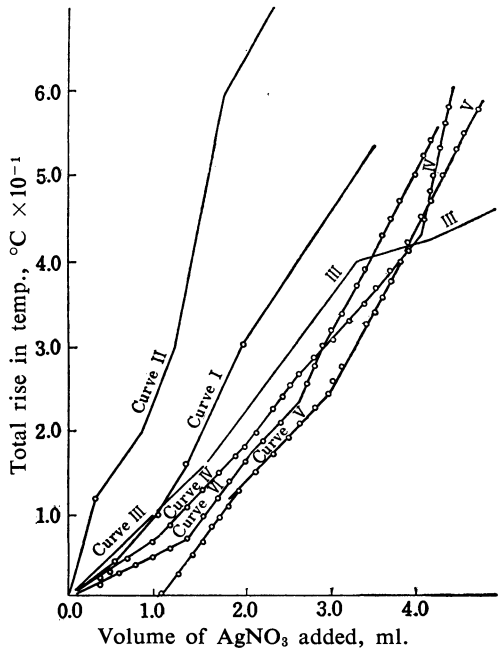

Fig. 1. Direct thermometric titrations curves for silver nitrate against sodium thiosulfate.
Curves I, II, III; M/5 $AgNO_3$ and M/100 $Na_2S_2O_3$
Curves IV, V, VI; M/10 $AgNO_3$ and M/100 $Na_2S_2O_3$ for curve IV, V, VI scale 1″=2 ml.

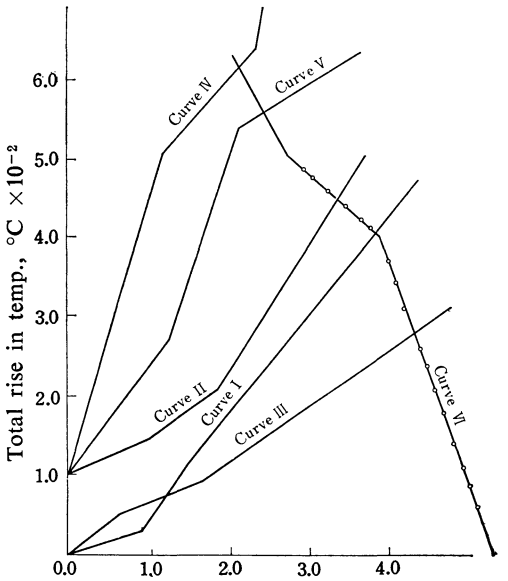

Fig. 2. Thermometric titrations curves for silver nitrate against sodium thiosulfate. (Reverse titrations) [Ag^+] conc. (molality or M)
Curve I, II, III; M/10 $Na_2S_2O_3$, M/200 $AgNO_3$
Curve IV, V, VI; M/40 $AgNO_3$; M/5 Na_2SO_3

Experimental

Silver nitrate and sodium thiosulfate employed for the preparation of solutions were of E. Merck quality. Thermometric titrations were carried out in the apparatus described by Dutoit[5]. Titrations

1) J. F. W. Herschel, *Edinb. Phil. Journal*, **26**, 2, 154 (1819).

2) A. Rosenheim and S. Steinhäuser, *Z. anorg. Chem.*, **25**, 72 (1900).

3) J. Meyer and H. Eggeling, *Ber.*, **40**, 1351 (1907).

4) A. Rosenheim and G. Trewendt, ibid., **61**, 1731 (1928).

5) P. Dutoit and E. Grobet, *J. Chim. Phys.*, **19**, 324 (1922).

were performed by the direct and reverse methods. Titrations were also carried out in varying percentage of alcohol upto a total concentration of 20% by volume. A correction was applied by carrying out 'blank' experiment using water instead of either reactants to account for the dilution effect.

Discussion

From the summary of observations in Table I it is clear that when silver nitrate is added to sodium thiosulfate, the reaction involves the formation of four different compounds $Na_3Ag(S_2O_3)_2$, $NaAgS_2O_3$, $Na_5Ag_3(S_2O_3)_4$ and $Ag_2S_2O_3$ respectively where the molar ratio of the reactants (silver nitrate and sodium thiosulfate) is 1 : 2, 1 : 1, 3 : 4 and 2 : 1 respectively. The reverse thermometric titration curves suggest that when the order of addition of reagents is reversed, the formation of the complexes $Ag_2S_2O_3$ and $NaAgS_2O_3$ takes place.

Rosenheim and Trewendt[4] have reported

TABLE I. SUMMARY OF THERMOMETRIC TITRATIONS

the formation of the complexes $NaAgS_2O_3 \cdot 1/2\ H_2O$, $Na_3Ag(S_2O_3)_2 \cdot H_2O$, and $Na_5Ag_3(S_2O_3)_4$. The formation of these complexes have been confirmed by our thermometric studies.

The possibility of the formation of the complexes $NaAg(S_2O_3)_2 \cdot H_2O$ as reported by Basset and Lemon[6] and $Ag_2S_2O_3 \cdot 4Na_2S_2O_3$ by Dey and Mushran[7] (by analysis) is ruled out by our thermometric studies.

Other physico-chemical methods are being tried for the study of this reaction and the results will be communicated in future.

Thanks of author are due to Professor Dr. J. N. Gaur, Head of Chemistry Department, Maharaja College, Jaipur, for his constant help and keen interest in this piece of investigation.

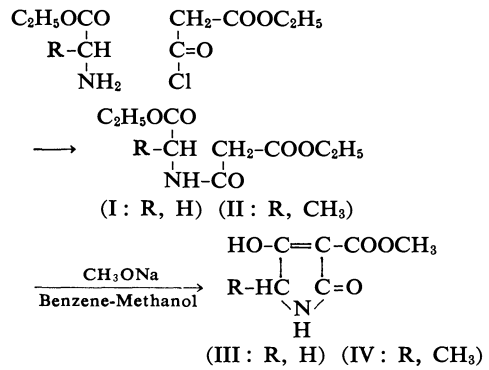
Synthesis of Tetramic Acids

By Yoshikazu Isowa and Masaki Ohta



(Received July 10, 1962)

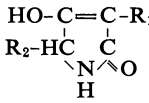
Recent interest has been shown in the study of acids concerning tetramic acid nucleus which was found to be a metabolic product obtained by micro-organisms[1].

There is only one report concerning the synthesis of tetramic acid in the case of α-acetyltetramic acids[2] which was prepared from α-amino acid esters and diketene. It was shown there that α-acetyltetramic acid is not a desirable intermediate for the preparation of tetramic acid itself because α-acetyl derivatives are resistant to alkaline hydrolysis.

In the present study, the synthesis of some tetramic acids was tried and the ultraviolet spectra of tetramic acid derivatives were measured.

In the first place, ethyl ethoxycarbonylacetaminoacetate (I) was prepared from ethyl α-aminoacetate and ethoxycarbonylacetyl chloride in the hope that the activation of the methylene group by the adjacent carboxyl group would facilitate the cyclisation to yield tetramic acid.

When the acetate I was refluxed in benzene-metanol solution in the presence of the sodium methoxide, α-methoxycarbonyltetramic acid (III) was obtained in a 80% yield by the self-ester condensation. The formation of methyl ester may be attributed to the ester exchange between the ester and solvent methanol.



When ethyl α-aminopropionate was treated with ethoxycarbonylacetyl chloride in a cold alkaline solution, ethyl α-(ethoxycarbonylacetamino)propionate (II) was obtained as an oil. The treatment of the crude oily product with sodium methoxide in benzene-methanol gave α-methoxycarbonyl-γ-methyltetramic acid (IV).

Tetramic acid (V) was prepared from III by hydrolysis with aqueous barium hydroxide, followed by neutralisation. Similarly hydrolysis of IV gave γ-methyltetramic acid (VI). Tetramic acid and γ-methyltetramic acid liberated carbon dioxide from sodium hydrogen carbonate and gave a red color with ferric chloride.

The light-absorption properties of tetramic acid derivatives resemble that of tetronic acids and the spectrum of α-methoxycarbonyl-γ-methyl tetramic acid in aqueous solution exhibits pH dependence.

* Lacey (1954)
** The details of this compound will be published in the near future.

The absorption maximum of tetramic acid displays two bands at 239 mμ and 320 mμ, and the introduction of an α-alkoxycarbonyl group displaces the maximum to shorter wavelength.

The introduction of α-acetyl group has little influence on the peak at 239 mμ, but the group causes a shift of the absorption maximum at 320 mμ to shorter wavelength.

Although the introduction of the γ-alkyl or aryl group has little influence on the absorption maximum and its intensity of the two bands, yet the presence of an γ-alkoxycarbonyl group shows an increase in intensity of the peak at 240 mμ.

In position and intensity of the absorption maximum α-methoxycarbonyl-γ-methyltetramic acid exhibits the two characteristic bands at 228 mμ and 263 mμ in aqueous solution at different pH value as follows.

Table II. The pH value effect on the light absorption of α-methoxycarbonyl-γ-methyltetramic acid in water

pH	Short wavelength		Long wavelength	
	λ_{max}, mμ	ε_{max}	λ_{max}, mμ	ε_{max}
	228	1.31×10^4	263	1.05×10^4
11	229	2.63×10^4	263	2.14×10^4
3	230	2.08×10^4	257.5	1.34×10^4

Experimental

Ethyl Ethoxycarbonylacetaminoacetate (I).—Ethoxycarbonylacetyl chloride (22.5 g.) was added during 2 hr. to a mixture of ethyl α-aminoacetate hydrochloride (21 g.) and 50% potassium carbonate (100 ml.) at 0°C, and the mixutre set aside overnight, then extracted with chloroform. The chloroform-extracts were washed with cold water, dried over anhydrous sodium sulfate, and the solvent was evaporated. The residue crystallized, m. p. 60~61°C, 27 g. (84%). Chromatography of this product on alumina afforded a pure crystalline substance, m. p. 64~65°C, on elution with benzene.

Found: C, 50.03; H, 7.21; N, 6.59. Calcd. for $C_9H_{15}O_5N$: C, 49.76; H, 6.96; N, 6.45%.

α-Methoxycarbonyltetramic Acid (III).—Ethyl ethoxycarbonylacetaminoacetate (21 g.) in benzene (100 ml.) was refluxed with agitation with a solution of sodium methoxide (from 2.3 g. of sodium and 40 ml. of methanol) for 3.5 hr. and set aside overnight. Water was added and the solvent layer extracted with water (2×60 ml.). The aqueous extracts were carefully acidified with concentrated sulfuric acid and then precipitated a crystalline product. This material was dissolved with aqueous sodium hydrogen carbonate, acidification of the solution with sulfuric acid precipitated α-methoxycarbonyltetramic acid. The white micro-crystals were washed with cold water, m. p. above 360°C (decomp.).

Found: C, 45.80; H, 4.46; N, 8.64. Calcd. for $C_6H_7O_4N$: C, 45.86; H, 4.49; N, 8.92%.

α-Methoxycarbonyl-γ-methyltetramic Acid (IV).—Ethoxycarbonylacetyl chloride (22.5 g.) was added during 2 hr. to a mixture of ethyl α-aminopropionate hydrochloride (23 g.) and 50% potassium carbonate (100 ml.) at 0°C, and the mixture set aside overnight, then extracted thoroughly with chloroform. The chloroform extracts were washed with cold water, dried on anhydrous sodium sulfate and the solvent evaporated at reduced pressure. The product was a pale yellow oil (28 g. 80%).

In order to remove traces of water from this product, it was dissolved in benzene, dried over anhydrous magnesium sulfate, filtered, and evaporated to yield 27.7 g. of the oil product which was used directly in the next step.

The above crude product (23 g.) in benzene (100 ml.) was refluxed with agitation with a solution of sodium methoxide (from 2.4 g. of sodium and 30 ml. of methanol) for 3 hr. and set aside overnight.

Water was added and the benzene layer was extracted with water.

The combined extracts were carefully neutralized with concentrated sulfuric acid and extracted thoroughly with chloroform. The organic extracts

were washed with water, dried over anhydrous sodium sulfate, filtered and evaporated to yield 15 g. of crude acidic product.

Recrystallization from ethyl acetate (or, better, methanol) yielded 13.5 g. (61%), m. p. 135~136°C.

Found: C, 49.64; H, 5.28; N, 8.11. Calcd. for $C_7H_9O_4N$: C, 49.12; H, 5.30; N, 8.18%.

Tetramic Acid (V).—α-Methoxycarbonyltetramic acid (1.5 g.) and 0.2 N barium hydroxide (50 ml.) were boiled under reflux for 3 hr., after cooling carefully concentrated hydrochloric acid was added to the mixture and then carbon dioxide was evolved.

The mixture was filtered and evaporated to a small volume at reduced pressure. After standing overnight tetramic acid separated as microcrystals from the solution. The product was washed with cold water, m. p. above 360°C. Yield, 0.65 g. (66%).

Found: C, 48.39; H, 5.15; N, 13.97. Calcd. for $C_4H_5O_2N$: C, 48.48; H, 5.09; N, 14.14%.

γ-Methyltetramic Acid (VI). — α-Methoxycarbonyl-γ-methyltetramic acid (1.7 g.) and 0.2 N barium hydroxide (50 ml.) were boiled under reflux for 2.5 hr. After cooling the mixture carefully neutralized with concentrated hydrochloric acid and then carbon dioxide evolution was observed. The solution was filtered, was concentrated in vacuo and microcrystals were obtained. Yield, about 0.67 g. (60%).

Found: N, 12.34: Calcd. for $C_5H_7O_2N$: N, 12.38%.

α-Acetyl-γ-phenyltetramic Acid. — Prepared by the use of Lacey's procedure from phenylglycine ester: m. p. 126°C.

Found: C, 66.36; H, 5.20; N, 6.38. Calcd. for $C_{12}H_{11}O_3N$: C, 66.35; H, 5.10; N, 6.45%.

2,4-dinitrophenylhydrazone, m. p. 246°C.

Found: C, 54.66; H, 4.06; N, 17.24. Calcd. for $C_{18}H_{15}O_6N_5$: C, 54.41; H, 3.81; N, 17.63%.

The authors wish to express their gratitude to Dainippon Celluloid Co., Ltd., for the gift of ketene dimer. Thanks are also due to Mr. Keiji Naruse for the microanalysis.

*Synthesis of Histidyl Peptides. II. Synthesis and Properties of Dicarbobenzyloxyhistidylamino Acid Esters**

By Fumio SAKIYAMA

(Received July 11, 1962)

In the previous paper[1], a report was made of the snythesis of some *N*-α-*N*-*Im*-dicarbobenzyloxy-L-histidyl-L-amino acid esters including neutral, acidic, hydroxyl and sulfur-containing amino acids from dicarbobenzyloxyhistidine and respective amino acid esters by the dicyclohexylcarbodiimide method and it was observed that this reagent was useful for the preparation of these peptide derivatives. However, other possible methods for the synthesis of the dicarbobenzyloxyhistidyl peptide ester have not yet been investigated. In the present communication, some recent studies on the application of the other peptide bond forming methods for the preparation of dicarbobenzyloxy peptide esters are described, and additional syntheses of some of dicarbobenzyloxyhistidyl-amino acid esters by the dicylohexylcarbodiimide method are also included.

In order to find the most suitable method to prepare dicarbobenzyloxyhistidylamino acid ester from its constituent, three different methods (the mixed anhydride, the *p*-nitrophenyl ester and the dicyclohexylcarbodiimide methods) were compared in points of easiness of purification, purity and yield of the product. Because of the relative ease in the preparation of crystalline material, dicarbobenzyloxy-L-histidyl-L-phenylalanine methyl ester was chosen as a model peptide in the present investigation.

In the first place, the mixed anhydride method using alkylchloroformate[2] was employed as a synthetic method.

When dicarbobenzyloxy derivative of L-histidine is recrystallized from methyl alcohol, this material is known to contain one molecule of methyl alcohol which is the essential factor in getting stable crystals[1]. Since methyl alcohol was known to react with alkylchloroformate, twice molar amounts of the reagent were brought to reaction with dicarbobenzyl-

* Part I; The previous report (Ref. 1) was Part I of this series. Preliminary study was presented at the 14th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1961.

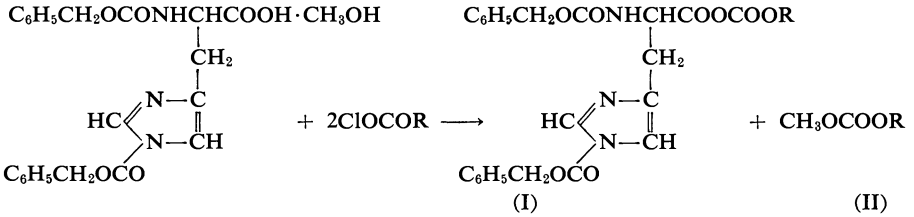

Fig. 1. Reaction of *N*-α-*N*-*Im*-dicarbobenzyloxyhistidine methanolate with alkyl chloroformate.

oxy-L-histidine methanolate[3] in dry tetrahydrofuran to prepare the mixed anhydride (I). Both the mixed anhydride (I) and alkyl-methyl carbonate (II) were formed in the reaction mixture (Fig. 1). By the coupling of the ester component with the mixed anhyride (I), the crystalline model peptide derivative was obtained in a 46% yield when isobutyl chloroformate was used. The same product was also obtained in a 35% yield by using ethyl chloroformate in place of the isobutyl derivative. When the reaction mixture was immediately warmed up to the refluxing point, after completion of the addition of L-phenylalanine methyl ester to the mixed anhydride (I), the yield increased significantly higher (50%).

After the first crop of the model peptide derivative was collected, no ninhydrin positive substances was detected in the mother liquor by paper chromatography.

It seems that no side reaction of alkyl methyl carbonate (II) with the methyl ester of L-phenylalanine occurs at this temperature. Therefore the absence of a free amino group might be due to the acylation of the amino group of phenylalanine ester with an excess of alkyl chloroformate. Next, the model peptide was prepared using a reduced amount of the reagent, one and a half equivalents of alkyl-chloroformate to a unit amount of disubstituted histidine, in stead of two, by a similar refluxed procedure. The yield of the model peptide derivative in this experiment was much higher than the previous. This fact suggested that the methyl alcohol was partly liberated from dicarbobenzyloxyhistidine methanolate[4] and the amount of the reagent was sufficient even under the above conditions, or that the reagent was preferably reacted with phenylalanine ester than alcohol.

In the second place, *p*-nitrophenyl ester of dicarbobenzyloxy-L-histidine was prepared in an 85% yield in chloroform by the Bodanszky's procedure[5] and also obtained by the procedure via the mixed anhydride[6]. This *p*-nitrophenyl ester could not be obtained in a crystalline state, in contrast to those of the other amino acid derivatives. Coupling of this ester with L-phenylalanine methyl ester afforded the model peptide derivative in a yield of 58%. This relatively low yield of the product might be attributed to the presence of another unsubstituted tertiary nitrogen in the imidazole nucleus and partly to the steric hindrance by the bulky substituent adjacent to the carboxyl group in the histidine residue.

Thirdly the model peptide derivative was prepared by the condensation using dicyclohexylcarbodiimide[7]. No difficulties were encountered in the procedure of the peptide synthesis by this reagent as mentioned in the previous paper. The most satisfactory result was given in the present case.

Some pysico-chemical properties of this model peptides obtained by the above described different methods were compared as is shown in Table I and Fig. 2.

It was concluded from the above results that the dicyclohexylcarbodiimide method was the most suitable for the formation of the peptide bond in which dicarbobenzyloxyhistidine was concerned. By this method additional dicarbobenzyloxy-L-histidyl-L-amino acid esters containing alanine, valine, aspartic acid, tyrosine, *S*-benzylcysteine, methionine and serine were synthesized. The author also describes the preparation of the benzyl ester of dicarbobenzyloxy-L-histidyl-L-threonine. The benzyl ester of the threonine was prepared by an esterification procedure similar to that of L-histidine benzyl ester[8]. The DL-isomer of threonine benzyl ester tosylate was obtained in fine crystals. Efforts to crystallize the L-isomer failed, but L-threonine benzyl ester could be obtained in fine needles[9]. *N*-α-Carbobenzyloxy-L-histidyl-L-threonine hydrazide from this benzl ester was identical with same compound obtained from the methyl ester.

3) Dicarbobenzyloxy-L-histidine methanolate represents crystalline dicarbobenzyloxy-L-histidine with one molecule of methyl alcohol.

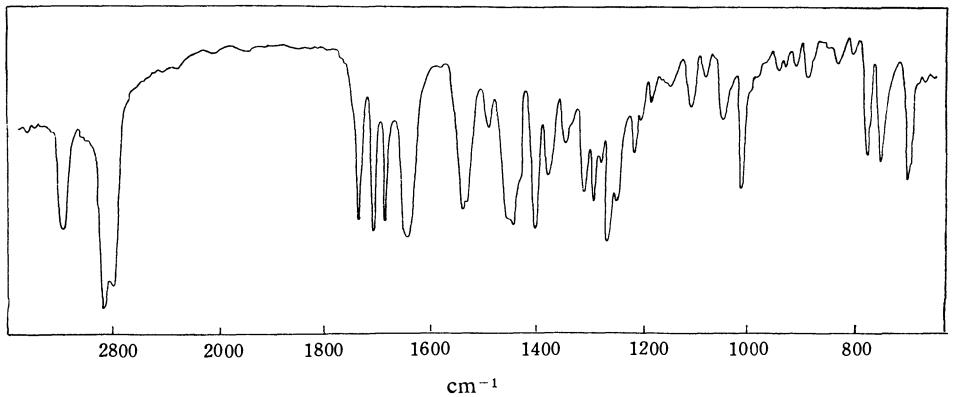

Fig. 2. IR-Spectrum of *N*-α-*N*-*Im*-dicarbobenzyloxy-L-histidyl-L-phenylalanine methyl ester obtained by the DCCD method.

It is interesting to note that the imidazole linked carbobenzyloxy group of dicarbobenzyloxyhistidine is relatively less stable than that of dicarbobenzyloxyhistidylamino acid ester, when the crystalline material is allowed to stand in the atmosphere for a long time.

When the dicarbobenzyloxyhistidine was exposed to alkaline media, the labile imidazole-linked carbobenzyloxy group was eliminated and *N*-α-carbobenzyloxyhistidine was produced. Therefore it was expected that some difficulties would be encountered during the alkaline hydrolysis of the disubstituted histidyl peptide ester owing to the presence of the labile carbobenzyloxy group. In the present paper, the problems concerning the alkaline hydrolysis of the dicarbobenzyloxy-L-histidylamino acid ester are also investigated.

As has been reported[10], *N*-α-carbobenzyloxyhistidylamino acid esters, which were prepared by means of the azide method, were thoroughly hydrolyzed by an equimolar amount of alkali in aqueous alcoholic solution. The alkaline hydrolysis of dicarbobenzyloxyhistidylamino acid esters was thus explored under similar conditions. But only low yield of the hydrolysis product was obtained. Since no detectable cleavage of the peptide bond and no destruction of the imidazole nucleus were found, it appears probable that the low yield was based on the incomplete hydrolysis.

It seems probable that the incompleteness of the hydrolysis reaction was due to the presence of the alkaline labile carbobenzyloxy group. For example, a hydrolysis product of dicarbobenzyloxy-L-histidyl-L-phenylalanine

10) R. Holley and E. Sondhemer, *J. Am. Chem. Soc.*, **76**, 1326 (1954).

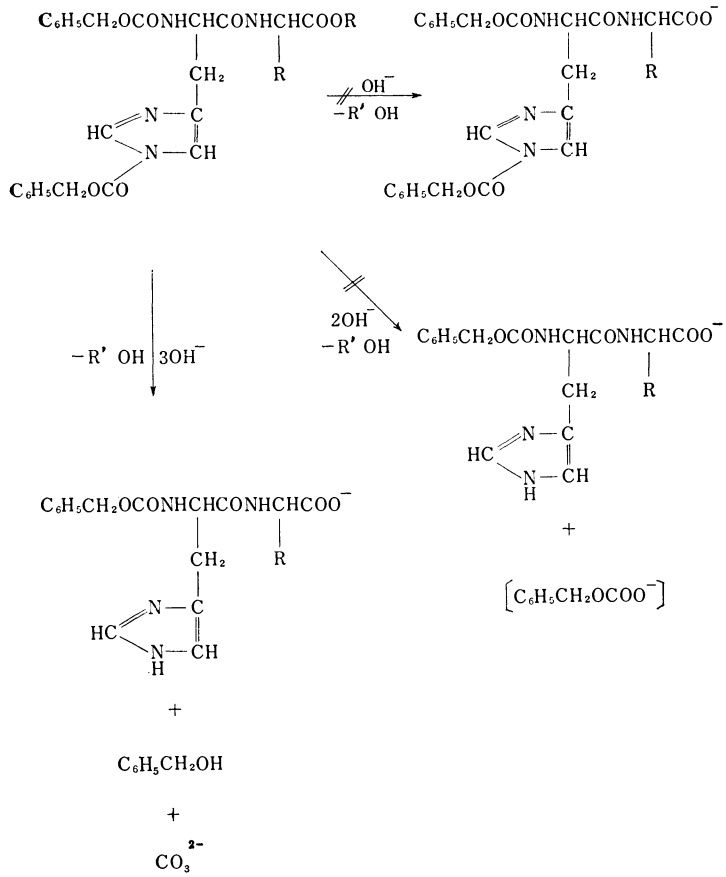

Fig. 3. Alkaline hydrolysis of the dicarbobenzyloxyhistidyl amino acid ester.

ethyl ester was identified to be *N*-α-carbobenzyloxy-L-histidyl-L-phenylalanine and not the dicarbobenzyloxy dipeptide. The carbobenzyloxy group linked to the nitrogen of the imidazole nucleus in the histidyl peptide derivative was quite stable comparing with that of dicarbobenzyloxy histidine in the crystalline state. However, in the alkaline or basic medium, this carbobenzyloxy group was also unstable. In alkaline media, hydroxide ions might simultaneously attack both the labile carbobenzyloxy group and the carboxyl ester group. Generally, the active acyl group linked to imidazole was readily convertible to the acyl anion and imidazole by hydroxdie ions. Thus the formation of the acyl anion might result in the consumption of hydroxide ions. If the acyl anion produced was stable in alkaline media, twice molar amounts of alkali would be sufficient for the hydrolysis reaction as is shown in Fig. 3. But the use of twice molar amounts of alkali also brought the incomplete hydrolysis of the ester group. For example, *N*-α-carbobenzyloxy-L-histidyl-L-leucine, which used to be readily obtained as crystals, was not crystallized merely by acidification of the reaction mixture but the isolation yield was 60%.

The complete hydrolysis was finally obtained by the use of three-fold molar equivalents of alkali in alcohol, dioxane or acetone. Thus the following mechanism for the hydrolysis of dicarbobenzyloxyhistidylamino acid ester with aqueous alkali would be considered: hydroxide ions attacked not only the –CO–N= bond in the imidazole-linked carbobenzyloxy group but also the –CO–O– bond in the carboxyl ester group, and the intermediate monobenzyl carbonate ions produced from the former might be converted into benzyl alcohol and carbonate ions by the action of hydroxide ions as is shown in Fig. 3. This carbonate forming reaction would prevent the complete hydrolysis of the ester group when equi- or twice molar amounts of alkali are used.

The infrared spectra of these *N*-α-carbobenzyloxy-L-histidylamino acids showed the absence of the absorption band at near 1750 cm^{-1}.

N-α-N-Im-Dicarbobenzyloxy-L-histidyl-L-phenylalanine prepared by the direct carbobenzyloxylation of the *N-α*-carbobenzyloxy dipeptide revealed the above characteristic absorption[11] owing to the presence of the imidazole-linked carbobenzyloxy group as is shown in Fig. 4.

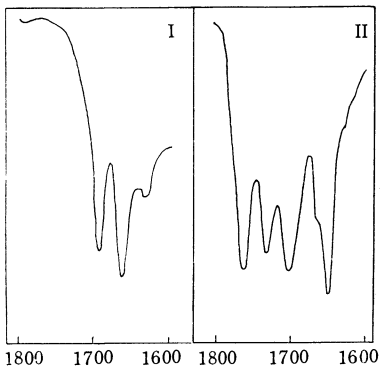

Fig. 4. Infrared spectra of *N-α*-monocarbobenzyloxy- and *N-α-N-Im*-dicarbobenzyloxy-L-histidyl-L-phenylalanine.

I *N-α*-Carbobenzyloxy-L-histidyl-L-phenylalanine.
II *N-α-N-Im*-Dicarbobenzyloxy-L-histidyl-L-phenylalanine.
(Nujol mull. Rock-salt optics. Hitachi infrared spectrophotometer)

A few of *N-α*-carbobenzyloxyl-L-histidylamino acids were obtained by this hydrolysis procedure. The threonine derivative was obtained in a poor yield in contrast to the *O*-benzylserine derivative. The fact seems to be due to the presence of a free hydroxyl group in threonine residue. It was observed that the carbobenzyloxyhistidylamino acids are generally hardly soluble in ordinary oranic solvents, as is expected from their dipolar properties.

Experiental

All melting points were uncorrected. The R_f values described were those by *n*-butanol-acetic acid-water (4 : 1 : 1, by volume) and the spot of *N-α*-carbobenzyloxyhistidylamino acid was detected by the use of Pauly's reagent.

***N-α-N-Im*-Dicarbobenzyloxy-L-histidyl-L-phenylalanine Methyl Ester.**—*A) By the Mixed Anhydride Method.* — i) The mixed anhydride method with isobutyl chloroformate:

Dicarbobenzyloxy-L-histidine methanolate (4.5 g., 0.01 M) was dissolved in anhydrous tetrahydrofuran (10 ml.) and triethylamine (3 ml.). Then isobutyl chloroformate (2.7 g., 0.02 M) was added dropwise to the above solution with vigorous stirring at −16 ∼−10°C and the temperature was maintained at −10°C for 15 min. L-Phenylalanine methyl ester was added to the above mixed anhydride solution at −15∼−20°C with vigorous stirring. After being kept overnight at room temperature, white precipitates were filtered off and the filtrate was evaporated to syrup, which was first dissolved in methyl alcohol and then gradually crystallized out. The fine needles were collected. Yield 2.5 g. The second crop (0.2 g.) was obtained from the mother liquor. Total yield was 2.7 g. (46%). Recrystallization was performed from methyl alcohol.

ii) The mixed anhydride method with isobutyl chloroformate under heating:

After the addition of the ester component to the anhydride solution was complete, the mixture was warmed to the refluxing point and then immediately cooled to room temperature. The filtrate, after triethylamine hydrochloride had been removed, was concentrated and treated with methyl alcohol. The yields were 50% (when dicarbobenzyloxy-L-histidine methanolate/isobutyl chloroformate=1/2), and 71% (when the above ratio=2/3), respectively.

iii) The mixed anhydride method with ethyl chloroformate:

The procedure of synthesis was similar to i).

B) By the p-Nitrophenyl Ester Method. — i) Dicarbobenzyloxy-L-histidine *p*-nitrophenyl ester: A solution of dicyclo hexylcarbodiimide (1.1 g.) in chloroform (6 ml.) was added into a chloroform solution (20 ml.) containing dicarbobenzyloxy-L-histidine methanolate (2.3 g.) and *p*-nitrophenol (0.83 g.). After being kept at room temperature for 5 hr., two drops of glacial acetic acid was added to the above mixture. After one hour, dicyclohexylurea was separated and filtered off. The filtrate was evaporated to syrup in vacuo. By the addition of ether, a gelatinous product was precipitated, filtered off and thoroughly washed with ether. The removal of ether gave a powder-like *p*-nitrophenyl ester with slight yellowish color. Yield 2.4 g. (85%). Sample for analysis was reprecipitated from ethyl alcohol but could not be obtained in fine crystals, m. p. 86∼90°C.

Found: C, 61.53; H, 4.55; N, 10.35. Calcd. for $C_{28}H_{24}O_8N_4$: C, 61.76; H, 4.44; N, 10.29%.

ii) Dicarbobenzyloxy-L-histidyl-L-phenylalanine methyl ester: Dicarbobenzyloxy-L-histidine *p*-nitrophenyl ester (2.2 g.) was dissolved in warm chloroform (7 ml.) and the chloroform solution was mixed with L-phenylalanine methyl ester which was prepared from its hydrochloride (1.1 g.) and triethylamine in chloroform. After being kept at room temperature overnight, the solvent was removed and resulting syrup was treated with methyl alcohol, and then chilled as was described in A i). Yield 1.35 g. (58%).

C) By the Dicyclohexylcarbodiimide Method.—Dicarbobenzyloxy-L-histidine methanolate (2.3 g.) was dissolved in chloroform (7 ml.). A solution of L-phenylalanine methyl ester, which was prepared from its hydrochloride (1.4 g.) and triethylamine, was added into the above solution. After the addition of dicyclohexylcarbodiimide (1.1 g.) in chloroform was complete, the reaction mixture was

11) In general, dicarbobenzyloxyhistidine and dicarbobenzyloxyhistidyl amino acid esters show strong absorption at 1750∼1760 cm⁻¹.

TABLE II. DICARBOBENZYLOXY-L-HISTIDYLAMINO ACID ESTERS OBTAINED BY THE DCCD METHOD

Dicarbobenzyloxy derivative of L-histidyl-	Yield %	M. p. °C	$[\alpha]_D^{20}$*	Solvent for recrystallization	Anal. Found C	Found H	Found N	Calcd. C	Calcd. H	Calcd. N

* *c* 2, in chloroform

allowed to stand overnight at room temperature. The cyclohexylurea precipitated was filtered off and the filtrate was evaporated. The syrupy material was dissolved in a small amount of methyl alcohol and chilled. The fine needles precipitated were collected and weighed. Yield, 2.7 g. (93%). By recrystallization from methyl alcohol 2.3 g. of pure materials were obtained (80%).

This peptide derivative has double melting points. The crystal melted at 123~124°C after softening at 117~119°C and meanwhile (within from thirty seconds to a few minutes) the molten materials solidified and melted again at 131~132°C.

Dicarbobenzyloxy-L-histidylamino acid esters described in Table II were synthesized by the carbodiimide method[1] from dicarbobenzyloxy-L-histidine methanolate and respective amino acid esters.

DL-Threonine Benzyl Ester *p*-Toluenesulfonate. —DL-Threonine (5 g.), *p*-toluenesulfonic acid monohydrate (10 g.) and benzyl alcohol (50 ml.) were dissolved in chloroform (100 ml.). The mixture was refluxed for thirty hours by using Wieland's esterification apparatus, in which silica gel was used as a desiccant. The solvent and excess benzyl alcohol were removed under reduced pressure and the oily product obtained was gradually crystallized by a minute trituration in ether (200 ml.) under cooling. After being kept in a refrigerator overnight, the crystals were filtered and washed thoroughly with ether until no smell of benzaldehyde was detected. Recrystallization of the crude product (12.5 g., 89%) from methyl alcohol-ether gave fine crystals. m. p. 113°C. R_f 0.72, yellow spot with ninhydrin.

Found: C, 57.46; H, 5.82; N, 3.59. Calcd. for $C_{18}H_{23}O_6NS$: C, 56.68; H, 6.08; N, 3.67%.

Since an attempt to crystallize the L-isomer by the same procedure failed, and a slightly brownish paperchromatographically pure L-threonine benzyl ester *p*-toluenesulfonate was used as a starting material for the peptide synthesis without further purification.

Dicarbobenzyloxy-L-histidyl-L-threonine Benzyl Ester. — Dicarbobenzyloxy-L-histidyl-L-threonine benzyl ester was prepared in a 71% yield. Recrystallization from ethyl alcohol or ethyl alcohol-petroleum ether gave fine crystals. M. p. 130~131°C. $[\alpha]_D^{20}$ +22.5° (*c* 2, in chloroform).

Found: C, 64.46; H, 5.66; N, 9.40. Calcd. for $C_{33}H_{34}O_8N_4$: C, 64.47; H, 5.57; N, 9.11%.

***N*-α-Carbobenzyloxy-L-histidyl-L-threonine Hydrazide.**—Warm methanolic solution of dicarbobenzyloxy-L-histidyl-L-threonine benzyl ester (600 mg.) was cooled to room temperature and 80% hydrazine hydrate (0.3 ml.) was added. After 42 hr. at room temperature, white crystals (350 mg., 82%) precipitated, and were collected, washed with water and recrystallized from ethyl alcohol. M. p. 185.5~186°C (decomp.).

Found: C, 51.20; H, 6.29; N, 19.72. Calcd. for $C_{18}H_{24}O_5N_6 \cdot H_2O$: C, 51.18; H, 6.20; N, 19.90%.

The same product was also obtained from the methyl ester of dicarbobenzyloxy-L-histidyl-L-threonine by a similar procedure.

***N*-α-Carbobenzyloxy-L-histidylglycine.**—Into dicarbobenzyloxy-L-histidylglycine methyl ester (478 mg.) suspended in methyl alcohol (4 ml.), N sodium

hydroxide (3 ml.) was portionwise added with shaking. By the addition of the first 2 ml. of alkali the suspension became clear. After being kept for half an hour at room temperature, the clear solution was diluted with water (5 ml.) and acidified with N hydrochloric acid to pH 4.8~5.0. Yield, 300 mg. (83%). Recrystallization from hot dimethylformamide-ether gave pure *N*-α-carbobenzyloxy-L-histidyl-glycine, m. p. 230°C (decomp.); lit.[12], 230~231°C (decomp.). $[\alpha]_D^{31.2}$ −20.5° (*c* 1.05, in 5% aqueous hydrogen carbonate), R_f, 0.78.

Found: C, 55.00; H, 5.34; N, 16.39. Calcd. for $C_{16}H_{18}O_6N_4$: C, 55.48; H, 5.24; N, 16.17%.

This procedure is referred to below as method-i-a.

***N*-α-Carbobenzyloxy-L-histidyl-L-alanine.**—Into a suspension of dicarbobenzyloxy-L-histidyl-L-alanine ethyl ester (600 mg.) in ethyl alcohol (3 ml.), N sodium hydroxide (3 ml.) was added. The resulting solution was allowed to stand for half an hour at room temperature and then acidified with N hydrochloric acid to pH 4.8~5.0. Fine white needles (285 mg.) were obtained by scratching and chilling, m. p. 214~216.5°C (decomp.). Additional crystals (30 mg.) were obtained from the mother liquor. Total yield, 87%. Pure materials recrystallized from water melted at 218~219°C with decomposition after sintering at 215°C. $[\alpha]_D^{31.2}$ −25.5° (*c* 1.00, in 5% sodium hydrogen carbonate).

Found: C, 56.36; H, 5.60; N, 15.81. Calcd. for $C_{17}H_{21}O_5N_4Cl$: C, 56.65; H, 5.59; N, 15.55%.

This procedure is referred to below as method-i-b.

***N*-α-Carbobenzyloxy-L-histidyl-L-valine.**—A solution of dicarbobenzyloxy-L-histidyl-L-valine methyl ester (536 mg.) in methyl alcohol (4 ml.) was treated with N sodium hydroxide (3 ml.) at room temperature for half an hour and then the resulting solution was acidified. In this case, contrary to the other dipeptide derivative no precipitates were produced. The solution then evaporated to dryness under reduced pressure. The residues were dissolved in ethyl alcohol and the insoluble material (probably sodium chloride) was filtered off. The filtrate was diluted with ether. Fine crystals were collected (385 mg., 95%), m. p. 196~197.5°C (decomp.). Recrystallization from ethyl alcohol-ether gave fine crystals after being kept in a refrigerator about three weeks, m. p. 187~187.5°C (decomp.) sintered at 175°C. $[\alpha]_D^{31.2}$ −20.0° (*c* 1.08, in water).

Found: C, 56.52; H, 6.23; N, 13.95. Calcd. for $C_{19}H_{25}O_5N_4 \cdot H_2O$: C, 56.17; H, 6.45; N, 13.79%.

This procedure is referred to below as method-ii.

***N*-α-Carbobenzyloxy-L-histidyl-L-leucine.**—By method-i-b *N*-α-carbobenzyloxy-L-histidyl-L-leucine was obtained from dicarbobenzyloxy dipeptide ester in a 90% yield. Recrystallization from ethyl alcohol-water gave pure materials, m. p. 188~189°C (decomp.) $[\alpha]_D^{31.2}$ −9.9° (*c* 1.00 in 5% aqueous sodium hydrogen carbonate).

Found: C, 57.09; H, 6.87; N, 13.42. Calcd. for $C_{20}H_{26}O_5N_4 \cdot H_2O$: C, 57.13; H, 6.87; N, 13.33%.

***N*-α-Carbobenzyloxyl-L-histidyl-L-phenylalanine.**—Dicarbobenzyloxy-L-histidyl-L-phenylalanine ethyl ester (600 mg.) was hydrolyzed by method-i-a and *N*-α-carbobenzyloxy-L-histidyl-L-phenylalanine (420 mg.) was obtained in an almost theoretical yield. Recrystallization from a large amount of 25% aqueous ethyl alcohol gave fine crystals, m. p. 231~232°C (decomp.) (lit., 227~228[13]).

Found: C, 63.28; H, 5.58; N, 13.15. Calcd. for $C_{24}H_{26}O_6N_4$: C, 63.29; H, 5.54; N, 12.84%.

The alkaline hydrolysis in aqueous dioxane solution also proceeded smoothly in a homogeneous solution but only colloidal precipitates resulted from acidification. The hydrolysis in the acetone solution was, at first, in a heterogeneous state and after a few minutes the solution became clear but the sodium carbonate was precipitated at the end of the reaction.

By method-i-a the dipeptide derivatives mentioned below were also prepared.

***N*-α-Carbobenzyloxy-L-histidyl-*O*-benzyl-L-serine.**—Yield, 80%. M. p. 210~211°C (decomp.). Recrystallization from dimethylformamide-ether.

Found: C, 61.51; H, 5.72; N, 12.04. Calcd. for $C_{24}H_{26}O_6N_4$: C, 61.79; H, 5.61; N, 12.01%.

***N*-α-Carbobenzyloxy-L-histidyl-L-tyrosine.**—Yield, 88%. M. p. 240°C (decomp.). Recrystallization from ethyl alcohol-water.

Found: C, 61.05; H, 5.35; N, 12.38. Calcd. for $C_{24}H_{26}O_7N_4$: C, 60.89; H, 5.52; N, 12.30%.

***N*-α-Carbobenzyloxy-L-histidyl-*S*-benzyl-L-cysteine.**—Yield, 94%. M. p. 197~199°C. (lit., 191~192°C[14]).

Found: C, 59.87; H, 5.35; N, 11.63. Calcd. for $S_{24}H_{26}O_5N_4S$: C, 59.58; H, 5.43; N, 12.09%.

***N*-α-Carbobenzyloxy-L-histidyl-L-aspartic Acid.**—By method-i-b, dicarbobenzyloxy-L-histidyl-L-aspartic acid dimethyl ester (2.3 g.) in methyl alcohol (8 ml.) was treated with four molar equivalents of alkali because of the presence of two carboxyl groups in the aspartic acid residue. Yield, 1.3 g. (75%). M. p. 222~222.5°C (decomp.). Recrystallization from dimethylformamide did not raise the melting point. $[\alpha]_D^{31.2}$ −16.9° (*c* 1.05, 5% aqueous sodium hydrogen carbonate) (lit., m. p. 222°C[14]).

Found: C, 53.15; H, 5.19; N, 13.83. Calcd. for $C_{18}H_{20}O_7N_4$: C, 53.47; H, 4.98; N, 13.86%.

Dicarbobenzyloxy-L-histidyl-L-phenylalanine.—*N*-α-Carbobenzyloxy-L-histidyl-Lphenylalanine (420 mg.) was dissolved in a mixture of sodium hydroxide (1 ml.), water (7 ml.) and solid sodium carbonate (100 mg.). Into the above solution, carbobenzyloxychloride (171 mg.) was portionwise added under cooling and stirring. An oily product was separated, then gradually solidified, and finally gelled. After half an hour, the solution was acidified to Congo red and the gel was filtered, washed with alcohol and dried. White powders (300 mg.) were obtained and reprecipitated from the mixture of ethyl alcohol and ethyl acetate-ether. M. p. 123°C.

Found: C, 63.84; H, 5.40; N, 9.31. Calcd. for $C_{31}H_{30}O_7N_4 \cdot H_2O$: C, 63.25; H, 5.48; N, 9.52%.

Summary

Three different methods for the synthesis of dicarbobenzyloxy-L-histidylamino acid esters were studied. The general procedure of the hydrolysis of dicarbobenzyloxyhistidylamino acid esters were reported and the mechanism of this hydrolysis reaction was also discussed.

The author wishes to express his sincere thanks to Professor Shiro Akabori, Professor Kozo Narita, Institute for Protein Research, Osaka University, and Dr. Kenji Okawa, Faculty of Science, Kwansei-Gakuin University, for their guidances, and he is also indebted to Mr. Tsuneo Sowa and Mr. Yasuhiro Murase for their assistance.

Molecular Rotations of Glucides in Relation to their Structures. X[1]. *On the ζ-Coefficient of the Hydroxyl Group in Pentose and Methylpentose*

By Shukichi YAMANA

(Received July 14, 1962)

In the analysis of the $[M]_D^{20}$(W) by using the PM-method reported on in previous papers[1,2], the following two facts became apparent:

(1) The product of the ζ-coefficients of the hydroxyl and methyl groups, $\zeta_{OH}\zeta_{CH_3}$, is nearly definite and constant, regardless either of the kind of ring or of the number of hydroxyl groups in the molecule in which they are contained.

(2) When there are only two hydroxyl groups in a molecule, the value of ζ_{OH}^2 is also nearly constant, regardless of the kind of ring in the molecule.

On the other hand, the value of ζ_{OH}^2 when there are more than three hydroxyl groups in a molecule does not seem to be so simple. That value was calculated as $3.6402\{3/(n^2+2)\}$ (for polyhydroxycyclohexane[3]) and $2.4897\{3/(n^2+2)\}$ (for pentose, etc.[4]).

These two values show that the value of ζ_{OH}^2 is not nearly constant in this case. Therefore, it is necessary in this article to examine the value of ζ_{OH}^2 in pentose, etc.

New Treatment Applied

The value of ζ_{OH}^2 in pentose, etc., $2.4897\cdot\{3/(n^2+2)\}$, was obtained in a previous paper[5] on the assumption that every one of the hydroxyl groups in a carbohydrate molecule has the same ζ_{OH} value. However, it is well-known that the chemical character of the hydroxyl group which combines with the C^1-atom of the aldopyranose-ring, $(OH)^1$[6], is quite different from that of the other hydroxyl groups in the carbohydrate molecule. Therefore, it may be appropriate to presume that the optical character of $(OH)^1$ may also be different from that of the other hydroxyl group[7]. In

β-D-Talose	[$(OH)^{1\beta}$, $(OH)^{2\beta}$, $(OH)^{3\beta}$, $(OH)^{4\beta}$, $(CH_2)^{5\beta}$, $(OH)^6$, Ring]	23.8°	10

Note: In order to simplify the calculations, all of these aldopyranoses may be assumed to be entirely of C1 conformation

this article, the ζ-coefficient of $(OH)^1$ is symbolized as $\zeta_{(OH)^1}$ and is distinguished from the general ζ_{OH}.

Molecular Model and Data Used

McGeachin and Beevers' molecular model[8] of C1 conformation, used in a previous paper[2], is again employed here. The unit groups in the molecules of several aldopyranoses and the corresponding values of molecular rotations are shown in Table I.

A part of Table I is a repetition of Table I of a previous paper[2]. The optical properties of the unit groups (except for the value of the ζ-coefficient) used in a previous paper[2] are adopted here without any correction. The optical center of a unit group is located at the center of the mass of its corresponding bond.

Method Proposed

$[\mu]^{20}_{D\,calcd}\{3/(n^2+2)\}$, caused by the dynamical coupling effect between any two members of the unit groups (except the ring) has already been calculated; it is given in Table III of a previous paper[2]. That table is applicable for this article without any correction.

Moreover, the equation which indicates the relation between ζ_{OH} and ζ_{CH_3} in pentose and methylpentose has already been obtained in a previous paper[2]:

$$\zeta_{OH}\zeta_{CH_3}=1.5440\{3/(n^2+2)\} \quad (1)^{12}$$

Now, some new equations concerning $\zeta_{(OH)^1}$ can be obtained as follows:

$$[\mu]^{20}_{D\,obs} \text{ of the An. Diff. of D-rhamnose}^{13}$$
$$=\{(1\alpha)-(1\beta)\}\,\text{Å}\,\{(2\beta)+(3\beta)+(4\alpha)+(CH_3)^{5\beta}+R\}^{15}=\{(1\alpha)\,\text{Å}\,(2\beta)+(1\alpha)\,\text{Å}\,(3\beta)+(1\alpha)\,\text{Å}\,(4\alpha)+(1\alpha)\,\text{Å}\,(CH_3)^{5\beta}+(1\alpha)\,\text{Å}R\}-\{(1\beta)\,\text{Å}\,(2\beta)+(1\beta)\,\text{Å}\,(3\beta)+(1\beta)\,\text{Å}\,(4\alpha)+(1\beta)\,\text{Å}\,(CH_3)^{5\beta}+(1\beta)\,\text{Å}R\}=[\{1.51\zeta_{(OH)^1}\zeta_{OH}+2.54\zeta_{(OH)^1}\zeta_{OH}+0.02\zeta_{(OH)^1}\zeta_{OH}-5.57\zeta_{(OH)^1}\zeta_{CH_3}\}-\{12.60\zeta_{(OH)^1}\zeta_{OH}-0.82\zeta_{(OH)^1}\zeta_{OH}+0.02\zeta_{(OH)^1}\zeta_{OH}+1.26\zeta_{(OH)^1}\zeta_{CH_3}\}]\{(n^2+2)/3\}+(1\alpha)\,\text{Å}R-(1\beta)\,\text{Å}R^{16}=(-7.73\zeta_{(OH)^1}\zeta_{OH}-6.83\zeta_{(OH)^1}\zeta_{CH_3})\{(n^2+2)/3\}+(1\alpha)\,\text{Å}R-(1\beta)\,\text{Å}R$$

TABLE II. $[\mu]^{20}_{D\,obs}$, CAUSED BY THE DYNAMICAL COUPLING EFFECT BETWEEN ANY TWO MEMBERS OF UNIT GROUPS (EXCEPT RING) IN McGEACHIN AND BEEVERS' MOLECULAR MODEL

	$(CH_3)^{5\beta}$	4β	4α	3β	3α	2β	2α
1α	− 5.6	0.1	0.0	6.0	− 4.5	3.6	28.6
1β	1.3	− 0.6	0.0	− 1.9	− 3.5	29.6	−28.7
2α	− 0.9	7.1	− 0.5	40.2	−40.5		
2β	2.0	− 2.4	− 6.6	−41.1	1.1		
3α	5.6	0.6	45.4				
3β	0.4	41.9	−43.7				
4α	37.9						
4β	−37.6						

The corresponding ovserved value is given by, $\{[M]^{20}_{D}(W)$ of α-D-rhamnose$\}$ minus $\{[M]^{20}_{D}(W)$ of β-D-rhamnose$\}$. This is $15.7-(-63.0)$[15] $=78.7$. As these two values should be equal to each other,

$$(-7.73\zeta_{(OH)^1}\zeta_{OH}-6.83\zeta_{(OH)^1}\zeta_{CH_3})\{(n^2+2)/3\}+(1\alpha)\text{Ä}R-(1\beta)\text{Ä}R\equiv 78.7 \quad (2)$$

By using a method similar to that mentioned above, another equation is obtained for $[\mu]^{20}_{D\,obs}$ of the An. Diff. of L-arabinose:

$$28.06\zeta_{(OH)^1}\zeta_{OH}\{(n^2+2)/3\}+(1\alpha)\text{Ä}R-(1\beta)\text{Ä}R\equiv 169.7 \quad (3)$$

From Eq. 3 minus Eq. 2[17]:

$$(35.79\zeta_{(OH)^1}\zeta_{OH}+6.83\zeta_{(OH)^1}\zeta_{CH_3})\times\{(n^2+2)/3\}=91.0 \quad (4)$$

Now, in order to calculate the values of ζ_{OH}, ζ_{CH_3}, and of $\zeta_{(OH)^1}$ in pentose and methylpentose, another new equation (besides Eqs. 1 and 4) is necessary.

On the other hand, it has already been pointed out that the values of ζ_{OH} in the carbohydrate which has only two hydroxyl groups in its molecule (i. e., hydro-D-xylal) is nearly equal to that in the polyhydroxycyclohexane which has only two hydroxyl groups in the molecule (i. e., (−)1/2-cyclohexanediol)[1]. Therefore, it may be presumed that the ζ_{OH} value of some hydroxyl groups in pentose or methylpentose may be nearly equal to that in the polyhydroxycyclohexane which has more than three hydroxyl groups in the molecule, $1.9079\{3/(n^2+2)\}^{1/2}$ [3]. Therefore, in order to simplify the calculations, the author assumes, in pentose and methylpentose, the next equation:

$$\zeta_{OH}=1.9079\{3/(n^2+2)\}^{1/2} \quad (5)$$

or

$$\zeta_{OH}^2=3.6402\{3/(n^2+2)\} \quad (6)$$

Combining Eqs. 1, 4 and 5, the following values of ζ-coefficients can be obtained:

$$\zeta_{CH_3}=0.8093\{3/(n^2+2)\}^{1/2} \quad (7)$$

$$\zeta_{(OH)^1}=1.2329\{3/(n^2+2)\}^{1/2} \quad (8)$$

$$\zeta_{(OH)^1}\zeta_{OH}=2.3522\{3/(n^2+2)\}$$[18] $\quad (9)$

$$\zeta_{(OH)^1}\zeta_{CH_3}=0.9978\{3/(n^2+2)\} \quad (10)$$

By combining Eqs. 1, 6, 9 and 10 with Table III of a previous paper[2], a table of $[\mu]^{20}_{D\,obs}$ in pentose and methylpentose can be produced[19]. This is Table II.

In order to test the correctness of Table II, the $[M]^{20}_{D}(W)$ values of some carbohydrates have been calculated by using it, and those calculated values have then been tested by using Hudson's methyl glycoside rule[20] or another new method, devised by the author.

Calculation of $[M]^{20}_{D}(W)$

Pentose[21].—At first, by using the experimental data of $[M]^{20}_{D}(W)$ of β- and α-L-arabinoses, the value of $\{(1\alpha)\text{Ä}R-(1\beta)\text{Ä}R\}$ can be calculated as below:

$$[\mu]^{20}_{Dob} \text{ of the An. Diff. of L-arabinose} = \{(1\alpha)-(1\beta)\}\text{Ä}\{(2\alpha)+(3\beta)+(4\beta)+R\}$$[13] $$=(1\alpha)\text{Ä}(2\alpha)+(1\alpha)\text{Ä}(3\beta)+(1\alpha)\text{Ä}(4\beta)+(1\alpha)\text{Ä}R-\{(1\beta)\text{Ä}(2\alpha)+(1\beta)\text{Ä}(3\beta)+(1\beta)\text{Ä}(4\beta)+(1\beta)\text{Ä}R\}$$

17) Eq. 3 is used for the purpose of cancelling the $\{(1\alpha)\text{Ä}R-(1\beta)\text{Ä}R\}$ term in Eq. 2.

18) According to the conception that $\zeta_{(OH)^1}$ is different from ζ_{OH}, Eq. 11 in a previous paper[5] is rewritten as follows: $\zeta_{(OH)^1}\ \zeta_{OH}=2.4897\{3/(n^2+2)\}$. Note: This value was calculated by using McDonald and Beevers' molecular model (T. R. R. McDonald and C. A. Beevers, *Acta Cryst.*, **5**, 654 (1952)) and the $[M]^{20}_{D}(W)$ value of four hexoses (i. e., α-D-glucose, β-D-glucose, α-D-mannose and β-D-mannose) on the assumption that the internal conformation of the C^6-O bond is definite and similar in those four hexoses.

19) Concerning the making of the table of $[\mu]^{20}_{D\,obs}$, cf. Eq. 3 in a previous paper[5].

20) Cf. Ref. 20 in a previous paper[2].

21) There are four kinds of pentose, arabinose, xylose, lyxose and ribose. However, the exact $[M]^{20}_{D}(W)$ value of ribose has never been observed, and lyxose is of C1 and 1C conformations in an aqueous solution (R.E.Reeves, *J. Am. Chem. Soc.*, **72**, 1499 (1950)). Ribose and lyxose will be discussed by the author in detail in a future paper. Therefore, these two pentoses are not discussed in this article.

$$=28.6+6.0+0.1+(1\alpha)\lambda R-\{-28.7-1.9-0.6+(1\beta)\lambda R\}=65.9+(1\alpha)\lambda R-(1\beta)\lambda R^{22)}\equiv 169.7^{23)}$$

or

$$(1\alpha)\lambda R-(1\beta)\lambda R=103.8 \qquad (11)$$

In a like manner, by using Table II and Eq. 11, the $[\mu]^{20}_{D\,obs}$ value of the An. Diff. of D-xylose can be calculated as 169.0. Therefore, if the $[M]^{20}_{D}$(W) of β-D-xylose is x, $\{[M]^{20}_{D}(W)$ of α-D-xylose$\}-\{[M]^{20}_{D}(W)$ of β-D-xylose$\}=140.5-x^{15)}\equiv 169.0$

$$\therefore \quad x=-28.5$$

This calculated value is approximately equal to Hudson's figure, $-30°$ [24].

Methylpentose. — When the H atom which is combined with the C^5-atom of pentose is replaced by $(CH_3)^{5\beta}$ [15], methyl pentose can be obtained. This process can be shown schematically by the following equation:

$$(\text{pentose})-H^{5\beta}+(CH_3)^{5\beta}=(\text{methylpentose})$$

Because of its small polarizability, the $[\mu]^{20}_{D\,obs}$ of $H^{5\beta}$ can be neglected. Then, concerning the molecular rotations, the next equation can be obtained:

$$\{[M]^{20}_{D}(W) \text{ of pentose}\}+\{[\mu]^{20}_{D\,obs} \text{ of } (CH_3)^{5\beta}\}\simeq\{[M]^{20}_{D}(W) \text{ of methylpentose}\} \qquad (12)$$

Next, the value of $(CH_3)^{5\beta}\lambda R$ is calculated quasi-empirically as follows: The unit groups which can couple with $(CH_3)^{5\beta}$ in α-D-fucose are $(OH)^{1\alpha}$, $(OH)^{2\alpha}$, $(OH)^{3\beta}$, $(OH)^{4\beta}$ and ring [15]. Then,

$$[\mu]^{20}_{D\,obs} \text{ of } (CH_3)^{5\beta} \text{ in } \alpha\text{-D-fucose}=(CH_3)^{5\beta}\lambda\{(1\alpha)+(2\alpha)+(3\beta)+(4\beta)+R\}=(CH_3)^{5\beta}\lambda(1\alpha)+(CH_3)^{5\beta}\lambda(2\alpha)+(CH_3)^{5\beta}\lambda(3\beta)+(CH_3)^{5\beta}\lambda(4\beta)+(CH_3)^{5\beta}\lambda R=-5.6-0.9+0.4-37.6+(CH_3)^{5\beta}\lambda R=-43.7+(CH_3)^{5\beta}\lambda R$$

The corresponding observed value is given by the following equation:

$$\{[M]^{20}_{D}(W) \text{ of } \alpha\text{-D-fucose}\} \text{ minus } \{[M]^{20}_{D}(W) \text{ of } \beta\text{-L-arabinose}\}=251.0-303.3^{15)}=-52.3$$

$$\therefore \quad -43.7+(CH_3)^{5\beta}\lambda R\equiv -52.3$$

or

$$(CH_3)^{5\beta}\lambda R=-8.6 \qquad (13)$$

Referring to Eq. 12 and the unit groups in the molecules of α-D-xylose and of α-D-isorhamnose, the next equation can be obtained:

$$\{[M]^{20}_{D} \text{ of } \alpha\text{-D-xylose}\}+\{[\mu]^{20}_{D\,obs} \text{ of } (CH_3)^{5\beta}\}\simeq\{[M]^{20}_{D}(W) \text{ of } \alpha\text{-D-isorhamnose}\}$$

In this equation, $[\mu]^{20}_{D\,obs}$ of $(CH_3)^{5\beta}$ can be given by the following equation:

$$(CH_3)^{5\beta}\lambda\{(1\alpha)+(2\alpha)+(3\beta)+(4\alpha)+R\}^{15)}=(CH_3)^{5\beta}\lambda(1\alpha)+(CH_3)^{5\beta}\lambda(2\alpha)+(CH_3)^{5\beta}\lambda(3\beta)+(CH_3)^{5\beta}\lambda(4\alpha)+(CH_3)^{5\beta}\lambda R=-5.6-0.9+0.4+37.9-8.6^{22,25)}=23.2$$

Combining this value with Eq. 14, the $[M]^{20}_{D}$ of α-D-isorhamnose is calculated as 163.7. This is just equal to the observed value, 163.7 [15]. By using a method similar to that mentioned above, the $[M]^{20}_{D}$(W) values of two methylpentoses (β-D-fucose and β-D-isorhamnose) which have never been observed are calculated as 88.2 and 1.6 respectively from the $[M]^{20}_{D}$(W) values of their corresponding pentoses. As the $[M]^{20}_{D}$(W) values of methyl-β-D-fucoside and of methyl-β-D-isorhamnoside are $-25.3^{26)}$ and $-97.3^{27)}$, their respective $[M]^{20}_{D}$(W)-Diff. < methyl glycoside − cor. al.[28] pyranose > [29] values become −113.5 and −98.9. Therefore, the above expected values of β-D-fucose and β-D-isorhamnose satisfy Hudson's methyl glycoside rule [20]; accordingly, these two expected values seem to be reliable.

Next, by using the experimental data of the $[M]^{20}_{D}$(W) values of α-D-xylose and β-L-arabinose, the value of $\{(4\alpha)\lambda R-(4\beta)\lambda R\}$ can be calculated as follows:

$$[\mu]^{20}_{D\,obs} \text{ of Yo. Diff.}^{30)} < \alpha\text{-D-xylose} - \beta\text{-L-arabinose} >^{29)}=\{(4\alpha)-(4\beta)\}\lambda\{(1\alpha)+(2\alpha)+(3\beta)+R\}^{31,15)}=(4\alpha)\lambda(1\alpha)+(4\alpha)\lambda(2\alpha)+(4\alpha)\lambda(3\beta)+(4\alpha)\lambda R-\{(4\beta)\lambda(1\alpha)+(4\beta)\lambda(2\alpha)+(4\beta)\lambda(3\beta)+(4\beta)\lambda\}^{22)}=-93.3+(4\alpha)\lambda R-(4\beta)\lambda R$$

The corresponding observed value is given by the next equation:

$$\{[M]^{20}_{D}(W) \text{ of } \alpha\text{-D-xylose}\}-\{[M]^{20}_{D}(W) \text{ of } \beta\text{-L-arabinose}\}=140.5-303.3^{15)}=-162.8$$

Then, $-93.3+(4\alpha)YR-(4\beta)\lambda R\equiv -162.8$

$$\therefore \quad (4\alpha)\lambda R-(4\beta)\lambda R=-69.5 \qquad (15)$$

22) Table II is used.
23) Cf. Eq. 3.

TABLE III. $[M]_D^{20}$(W)-DIFF. ⟨HEXOSE−COR. METHYLPENTOSE⟩

Series	$[M]_D^{20}$(W) of hexose[15]	$[M]_D^{20}$(W) of cor. methyl pentose[15]	$[M]_D^{20}$(W)-Diff.
I	α-D-Glucose (202.1)	α-D-Isorhamnose (163.7)	38.4
	α-D-Mannose (52.8)	α-D-Rhamnose (15.7)	37.1
II	β-D-Glucose (33.7)	β-D-Isorhamnose ((1.6))	32.1
	β-D-Mannose (−30.6)	β-D-Rhamnose (−63.0)	32.4
III	α-D-Galactose (271.5)	α-D-Fucose (251.0)	20.5
	α-D-Talose (122.5)	α-D-Talomethylose ((99.6))	22.9
IV	β-D-Galactose (95.1)	β-D-Fucose ((88.2))	6.9
	β-D-Talose (23.8)	β-D-Talomethylose ((20.2))	3.6

Note: The value in (( )) is the calculated value in this article.

By using Eq. 15, the $[M]_D^{20}$(W) of α-D-talomethylose can be calculated as follows:

$$[\mu]_{D\,obs}^{20} \text{ of Yo. Diff}\langle\alpha\text{-D-rhamnose} - \alpha\text{-D-talomethylose}\rangle = \{(4\alpha)-(4\beta)\}\lambda \{(1\alpha)+(2\beta)+(3\beta)+(CH_3)^{5\beta}+R\}^{15,31)} = -83.9^{22)}$$

If the $[M]_D^{20}$(W) value of α-D-talomethylose is y, the corresponding observed value is given by {$[M]_D^{20}$(W) of α-D-rhamnose} minus {$[M]_D^{20}$(W) of α-D-talomethylose} $= 15.7^{15)} - y$

$$-83.9 \equiv 15.7 - y$$

or

$$y = 99.6$$

By using a similar method, the $[M]_D^{20}$(W) value of β-D-talomethylose is calculated as 20.2. However, in these cases, as the $[M]_D^{20}$(W) values of their corresponding methyl glycosides have not yet been observed, examinations by using Hudson's methyl glycoside rule are impossible. Therefore, in order to test the validity of these presumed $[M]_D^{20}$(W) values of methylpentoses, a new method has been devised as follows:

When an $(H)^6$ [32] in $(CH_3)^{5\beta}$ of methylpentose is replaced by $(OH)^6$ [32], hexose can be obtained. This process can be shown schematically by the next equation:

$$(\text{methylpentose}) - (H)^6 + (OH)^6 = (\text{hexose})$$

Owing to its small polarizability, the $[\mu]_{D\,obs}^{20}$ value of $(H)^6$ can be neglected; the following equation on molecular rotations is obtained:

$$\{[M]_D^{20}(\text{W}) \text{ of methylpentose}\} + \{[\mu]_{D\,obs}^{20} \text{ of } (OH)^6\} \simeq \{[M]_D^{20}(\text{W}) \text{ of hexose}\}$$

or

$$[M]_D^{20}\text{(W)-Diff.}\langle\text{hexose} - \text{cor. methylpentose}\rangle \equiv \{[M]_D^{20}(\text{W}) \text{ of hexose}\} - \{[M]_D^{20}(\text{W}) \text{ of methylpentose}\} \simeq [\mu]_{D\,obs}^{20} \text{ of } (OH)^6 \quad (16)$$

On the other hand, $(OH)^2$ is situated at the opposite end of a diameter of the aldopyranose-ring in relation to the C^5-atom with which $(CH_2OH)^{5\beta}$ is combined, and the distance between $(OH)^2$ and $(OH)^6$ is fairly large[34]. Therefore, referring to Tschúgaeff's Entfernungssatz[35] and Freudenberg's Verschiebungssatz[36], the following anticipation is possible:

The value, expressed in Eq. 16, should be almost indifferent to the orientation-change of $(OH)^2$. In short, the $[M]_D^{20}$(W)-Diff.⟨hexose-cor. methylpentose⟩ of the epimer[37] should be nearly equal to each other. (Anticipation 3)

Therefore, if a $[M]_D^{20}$(W) value does not satisfy Anticipation 3, it should be doubtful. Thus, Anticipation 3 can be a new instrument to test the validity of any $[M]_D^{20}$(W) value of hexose or methylpentose.

The concrete values of $[M]_D^{20}$(W)-Diff. ⟨hexose−cor. methylpentose⟩ now available are shown in Table III.

It is apparent in Table III that $[M]_D^{20}$(W)-Diff.⟨hexose−cor. methylpentose⟩ can be classified into approximately four series and that, moreover, when considering the orientation of $(OH)^2$ [15], the hexoses (or methylpentoses) which belong to the same series are the empimers of each other. Therefore, the values of $[M]_D^{20}$(W) in Table III satisfy Anticipation 3. This fact indicates that the $[M]_D^{20}$(W) values in Table III are almost completely reliable.

Summary

As there are four hydroxyl groups in the pentose and methylpentose molecules, the ζ_{OH} values in some of them may be nearly equal to that in the polyhydroxycyclohexane which has four hydroxyl groups in the molecule. In order to satisfy this condition, the ζ-coefficient of $(H)^1$, $\zeta_{(OH)^1}$, was distinguished from that of the other (OH), ζ_{OH}. Next, by using the PM-method, the values of $\zeta_{(OH)}$, ζ_{OH} and ζ_{CH_3} were calculated. Making use of these ζ-coefficients, a table of $[\mu]^{20}_{D\,obs}$ values was made. By using this table, the $[M]^{20}_{D}(W)$ values of some carbohydrates, hitherto unknown, were calculated. The validity of the presumed values was then tested by applying Hudson's methyl glycoside rule and a new anticipation proposed by the author.

Decomposition of Peroxybenzoic Acid in Solution. III. Decomposition in Ethers

By Katsumi TOKUMARU and Osamu SIMAMURA

(Received July 24, 1962)

In previous papers[1,2], an account has been given of the decomposition of peroxybenzoic acid in alcohols and hydrocarbons and a radical chain mechanism has been proposed for the decomposition. This part deals with the decomposition of peroxybenzoic acid in diethyl, diisopropyl, and di-*n*-butyl ether.

Experimental

Materials.—Peroxybenzoic acid was prepared as previously described[1].

Diethyl ether was shaken with cold 50% sulphuric acid, followed by aqueous sodium hydroxide, dried with calcium chloride and then with sodium metal, and distilled under an atmosphere of nitrogen. Diisopropyl ether and di-*n*-butyl ether were similarly purified. Dioxan was refluxed with sodium metal in a stream of nitrogen and distilled.

Kinetic Measurements.—Rate of decomposition of peroxybenzoic acid was measured under an atmosphere of nitrogen by the same method as in Part I[1].

Product Study. — The general procedure was essentially the same as that described in Part II[2].

1) Decomposition in Diisopropyl Ether. — Peroxybenzoic acid (5.0 g., 36 mmol.) was decomposed in diisopropyl ether (150 ml.), in a stream of nitrogen at 65°C for 6 hr. Carbon dioxide (4 mmol.) was caught by absorption in a potash bulb. The reaction mixture was distilled, with occasional addition of fresh diisopropyl ether to the distilling flask to remove volatile matter completely. The distillate and the condensate in a trap cooled with solid carbon dioxide were combined and shown to contain isopropyl alcohol and acetone by gas chromatography. This mixture was extracted repeatedly with water, and the aqueous extract, on treatment with 2, 4-dinitrophenylhydrazine, gave 2, 4-dinitrophenylhydrazone of acetone (24 mmol.), melting point and mixed melting point with an authentic sample, 126°C. The residue from the distillation was extracted with water, and the aqueous extract, on treatment with 2, 4-dinitrophenylhydrazine, gave no appreciable precipitate; the organic layer was extracted with aqueous sodium hydrogen carbonate, and the extract gave benzoic acid (3.8 g., 31 mmol.), m. p. 121°C, on acidification.

In an experiment intended to investigate gaseous products, peroxybenzoic acid (2.8 g., 20 mmol.) was decomposed in diisopropyl ether (50 ml.) at 65°C in a closed system. Analysis of the gaseous products by absorption method showed formation of carbon dioxide (2 mmol.) and oxygen (3 mmol.).

2) Decomposition in Diethyl Ether.—Peroxybenzoic acid (2.8 g., 20 mmol.) was decomposed in boiling diethyl ether under an atmosphere of nitrogen. The reaction mixture was distilled. The distillate and the condensate in a trap chilled with solid carbon dioxide were combined and the mixture shown by gas chromatography to contain ethyl alcohol and acetaldehyde, on treatment with 2, 4-dinitrophenylhydrazine, gave 2, 4-dinitrophenylhydrazone of acetaldehyde (7 mmol.), melting point and mixed melting point with an authentic sample, 168°C. The distillation of the remaining reaction mixture at reduced pressure gave acetic acid (trace), which was identified by the infrared spectrum. The residue from the distillation consisted of almost pure benzoic acid (2.2 g., 18 mmol.), m. p. 121°C.

2) K. Tokumaru and O. Simamura, ibid., 35, 1678 (1962).

3) Decomposition in Di-n-butyl Ether. — Peroxybenzoic acid (2.1 g., 15 mmol.) was decomposed in di-*n*-butyl ether at 60°C in a stream of nitrogen. The reaction mixture was distilled, and the distillate, treated with 2, 4-dinitrophenylhydrazine, gave 2, 4-dinitrophenylhydrazone of *n*-butyraldehyde (3 mmol.), melting point (from ethyl alcohol) and mixed melting point with an authentic sample, 122°C. Gas chromatographic analysis of the distillate showed the presence of *n*-butyraldehyde and *n*-butyl alcohol. Benzoic acid (1.7 g., 14 mmol.), m. p. 121°C, was obtained from the residue of the distillation.

Results and Discussion

Peroxybenzoic acid decomposed rapidly in ethers. The initial rapid decomposition often was followed by decomposition with decreasing speed as shown in Fig. 1, and the rate of decomposition did not conform to a simple first-order kinetics. Therefore, only percentage decomposition of peroxybenzoic acid is shown in Table I. The results of the product study are summarized in Table II.

If peroxybenzoic acid decomposes in ethers by the radical chain mechanism postulated previously[1,2], the reaction paths in ethers will be represented as follows.

$$PhCO_3H \rightarrow PhCO_2\cdot + HO\cdot \quad (1)$$

$$PhCO_2\cdot \rightarrow Ph\cdot + CO_2 \quad (1')$$

$$ROCHR'R'' + \text{Radical} \rightarrow ROC\dot{R}'R'' + \text{Stable molecule} \quad (2)$$

$$PhCO_3H + ROC\dot{R}'R'' \rightarrow ROCR'R''OH + PhCO_2\cdot \quad (3)$$

$$ROC\dot{R}'R'' \rightarrow R\cdot + R'R''CO \quad (4)$$

$$ROCR'R''OH \rightarrow ROH + R'R''CO \quad (5)$$

In the above mechanism, the radicals formed from peroxybenzoic acid abstract a hydrogen atom α to the oxygen of ether (reaction 2). Solvent radicals thus formed, that is, 1-alkoxyalkyl radicals, attack peroxybenzoic acid, producing 1-hydroxyalkyl ether and the benzoyloxy radical (reaction 3), which in turn abstracts a hydrogen atom from ether, propagating the chain. 1-Hydroxyalkyl ether will be unstable, decomposing to an alcohol and a carbonyl compound (reaction 5). There exists the alternative possibility of thermal decomposition of the solvent radical (reaction 4), but it does not seem important, since, in the first place, in the decomposition of benzoyl peroxide in ethers, its induced decomposition by 1-alkoxyalkyl radicals is reported to take place to an appreciable extent[3-5], and, secondly, peroxybenzoic acid is more readily attacked by radicals than benzoyl peroxide is, as will be shown in a subsequent paper. The alcohols formed by reaction 5 may suffer further oxidation by peroxybenzoic acid as described in Part I of this series. In fact, the production of acetone and isopropyl alcohol from diisopropyl ether can be explained on the basis of the above reaction scheme, and some part of the acetone may have been formed by further oxidation of isopropyl alcohol. The products from diethyl and di-*n*-butyl ether listed in Table II are explained similarly.

The isolation of benzoic acid in a yield ranging from 80 to 93% indicates that the benzoyloxy radical underwent only a slight thermal decomposition and mainly abstracted an α-hydrogen of ethers. This conclusion is well in accord with the behaviour of the benzoyloxy radical in the decomposition of benzoyl peroxide in ethers [3-5].

TABLE II. PRODUCTS FORMED IN DECOMPOSITION OF PEROXYBENZOIC ACID IN ETHERS

Ether	Temp.	Product and yield (% based on peroxybenzoic acid)			
		Products from ether	Benzoic acid	Carbon dioxide	Oxygen
Diethyl	under reflux	Acetaldehyde, 35; Ethyl alcohol, Acetic acid	90		
Diisopropyl	65°C	Acetone, 67; Isopropyl alcohol	80	11	
Diisopropyl	65°C			10	15
Di-*n*-butyl	60°C	*n*-Butyraldehyde, 20; *n*-Butyl alcohol	93		

Peroxybenzoic acid has been thought[6,7] to exist in a monomeric form with an intramolecular hydrogen bond in a non-polar solvent, but in polar solvents like alcohols and ethers, it can form an intermolecular hydrogen bond with an oxygen atom of the solvent molecule. This view has been supported by a spectroscopic study of peroxybenzoic acid made in this laboratory[7]. Thus it is reasonable to suppose that the acidic dissociation of peroxybenzoic acid will be favoured in polar solvents like alcohols and ethers with a basic oxygen atom, producing peroxybenzoate anions. These anions will attack peroxybenzoic acid with electron transfer, giving radicals according to the mechanism suggested by Kirmse and Horner[8] as follows:

$$PhCO_3^- + PhCO_3H \rightarrow PhCO_3\cdot + PhCO_2^- + HO\cdot$$

This process will contribute, as an initial radical forming process, to the rapid decomposition of peroxybenzoic acid in ethers and alcohols. Some part of the benzoylperoxy radicals thus formed may give rise to molecular oxygen by some mechanism such as:

$$2PhCO_3\cdot \rightarrow 2PhCO_2\cdot + O_2$$

For the production of oxygen an alternative mechanism similar to that postulated by Kharasch and coworkers[9] in the case of α-cumyl hydroperoxide cannot be excluded, thus:

$$RO_2^- + ROOH \rightarrow RO^- + ROH + O_2$$

Summary

Decomposition of peroxybenzoic acid was studied in diethyl, diisopropyl and di-*n*-butyl ether and explained in terms of the same radical mechanism that was postulated previously. Besides ready induced decomposition of peroxybenzoic acid by solvent radicals and facile abstraction of a hydrogen atom from ether by radicals, attack of peroxybenzoate anions on peroxybenzoic acid was pointed out to be an important contributing factor for the relatively rapid decomposition in ethers.

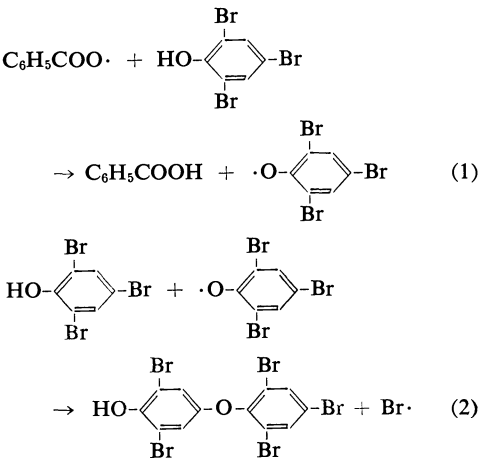
*Reaction of Benzoyl Peroxide with Phenols Substituted with Electron-Withdrawing Groups**

By Hakuai INOUE, Osamu SIMAMURA and Kanichiro TAKAMIZAWA

(Received September 4, 1962)

Ever since benzoyl peroxide was recognized as a typical radical generator in solution[1], a great many investigations have been made to elucidate the nature of the reactions which ensue from the homolytic rupture of benzoyl peroxide in various solvents[2]. The detailed reaction pattern depends on the nature of a substrate compound in which benzoyl peroxide is allowed to decompose. Among other substrates phenols are of particular interest, since they act as efficient inhibitor or retarder of free-radical reactions, especially of autoxidation. Studies[3-6] carried out on the reaction with phenols show that the reaction of benzoyl peroxide takes place quite differently in phenols than in other solvents; a marked feature in phenols is that carbon dioxide is evolved in very much smaller amounts than in other solvents, and that the yield of benzoic acid is correspondingly higher, thus:



$$(C_6H_5COO)_2 \rightarrow 2C_6H_5COO\cdot$$

$$C_6H_5COO\cdot + ArOH \rightarrow C_6H_5COOH + ArO\cdot$$

The aryloxy radical ArO· produced from phenols by abstraction of a hydrogen atom of the hydroxyl group is comparatively stable because of the conjugation of the odd electron on the oxygen atom with the π-electron system of the nucleus and consequently tends to dimerize giving dihydroxybiphenyls rather than to attack some other molecules. The aryloxy radical may also cause, according to its reactivity, the induced decomposition of benzoyl peroxide giving a benzoyloxy derivative of the phenol and a benzoyloxy radical. Recently, on the basis of kinetic evidence, Walling and Hodgdon[7] have put forward a simple bimolecular "four-center" mechanism without radical formation for the reaction between benzoyl peroxide and phenols at 30°C.

Except for Walling and Hodgdon's work which included *m*-chloro-, *p*-chloro-, and *p*-bromo-phenol, previous studies have been carried out on phenol and phenols substituted with electron-releasing groups. We now report the results of a study on the reaction of benzoyl peroxide with various phenols with electron-withdrawing groups such as halogens and nitro group.

The Reaction of Benzoyl Peroxide with 2,4,6-Tribromophenol. — Benzoyl peroxide was refluxed with 2, 4, 6-tribromophenol in carbon tetrachloride and there were isolated as major products benzoic acid and a polymeric material of an approximate molecular weight of 3600~4800, whose chemical constitution was shown to be polydibromophenylene oxide $H(OC_6H_2\cdot Br_2)_nBr$. Minor products are shown in Table I. In one experiment 2, 6-dibromo-4-(2, 4, 6-tribromophenoxy)-phenol ($n=2$ in the above formula) was isolated. The structure of this compound suggests the following mechanism in which a benzoyloxy radical generated by unimolecular decomposition of benzoyl peroxide abstracts a hydrogen atom from the hydroxy group of 2, 4, 6-tribromophenol and the resulting 2, 4, 6-tribromophenoxy radical then attacks 2, 4, 6-tribromophenol to give 2, 6-dibromo-4-(2, 4, 6-tribromophenoxy)phenol and a bromine atom.

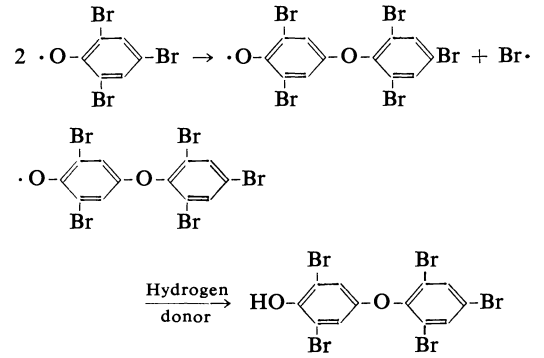
			Br_2	0.48
	Refluxed 17 hr. in CCl_4 (400 cc.)		C_6H_6	trace
			C_6H_5Br	0.1
			$(C_6H_5)_2$	trace
			C_6H_5COOH	1.89
			$C_6H_5COOC_6H_5$	0.002
			$H(C_6H_2Br_2O)_2Br$	0.14
			$H(C_6H_2Br_2O)_nBr$	(34 g.)
			$HOC_6H_2Br_3$ (recovered)	2.5

It may be plausible to suppose that in step 2 a 2,6-dibromo-4-(2,4,6-tribromophenoxy)-phenoxy radical and hydrogen bromide are produced without liberation of any bromine atoms:

(3)

This view is supported by the fact that no chlorine was formed at all in the reaction of benzoyl peroxide with 2,4,6-trichlorophenol under similar experimental conditions.

The bromine atoms produced in step 2 may combine to give molecular bromine or react with phenols (ArOH), affording aryloxy radicals including 2,4,6-tribromophenoxy-, 2,6-dibromo-4-(2,4,6-tribromophenoxy)phenoxy radicals etc.:

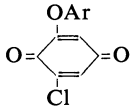


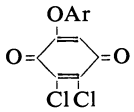
$$2Br\cdot \longrightarrow Br_2$$

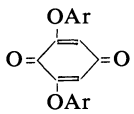
$$Br\cdot + ArOH \rightleftarrows HBr + ArO\cdot$$

Bromine can also be produced from hydrogen bromide by oxidation with benzoyl peroxide.

Obviously, successive attack by aryloxy radicals on phenols at a nuclear position carrying a bromine atom according to the above mechanism (step 2 or 3) leads to the formation of polymeric $H(OC_6H_2Br_2)_nBr$.







However, the possibility cannot be excluded that two of the tribromophenoxy radical react with each other with expulsion of a bromine atom giving a 2,6-dibromo-4-(2,4,6-tribromophenoxy)phenoxy radical, which then affords a molecule of the corresponding phenol by abstracting an atom of hydrogen from a hydrogen donor, that is, presumably from another molecule of phenols or from a molecule of hydrogen bromide, one of the reaction products:

Continuation of such a reaction between two aryloxy radicals may similarly result in the formation of the polydibromophenylene oxide $H(OC_6H_2Br_2)_nBr$.

As for the minor products there scarcely seems to be any need of comments, since these are the usual products in the decomposition of benzoyl peroxide in solvents. Carbon dioxide was evolved in much larger amount than in the decomposition in phenol itself and in phenols with an electron-releasing group. This fact seems to indicate that the benzoyloxy radical has a little more difficulty in abstracting a hydrogen atom from tribromophenol.

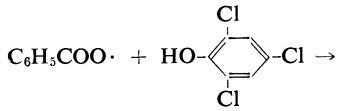


TABLE II. REACTION OF BENZOYL PEROXIDE WITH 2,4,6-TRICHLOROPHENOL

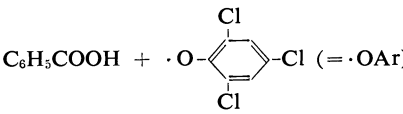

Reactant	mol.	Product	mol./mol. peroxide
$HOC_6H_2Cl_3$	0.426	C_6H_5COOH	0.60

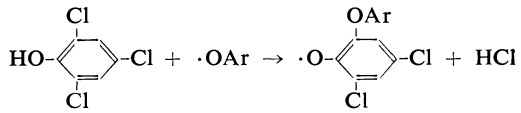
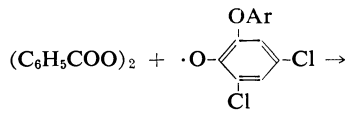
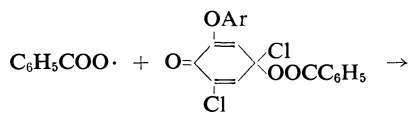
		C_6H_5COCl	0.113
		$HOC_6H_2Cl_3$ (recovered)	0.162



Ar=2,4,6-Trichlorophenyl



Hunter and his coworkers[8] had observed that in the presence of trace amount of bromine vapour potassium or silver 2,4,6-tribromophenoxide decomposes to give poly-dibromophenylene oxide. This fact indicates that bromine and tribromophenoxide can give tribromophenoxy radicals, which then start the chain reaction to give the polymeric material similarly to the case initiated by benzoyl peroxide. Recently Price[9] has reported the formation of polyphenylene oxides by oxidation of substituted *p*-bromophenols and proposed a mechanism involving the aryloxy radical.



The Reaction of Benzoyl Peroxide with 2, 4, 6-Trichlorophenol.—The results of the reaction of benzoyl peroxide with 2,4,6-trichlorophenol in boiling carbon tetrachloride are tabulated in Table II. Although a considerable amount of tar was formed, a polymeric material corresponding to polydibromophenylene oxide could not be isolated. Among other products, however, 2-chloro-6-(2,4,6-trichlorophenoxy)-, 2,3-dichloro-6-(2,4,6-trichlorophenoxy)-, and 2,6-bis-(2,4,6-trichlorophenoxy)-*p*-benzoquinone are worth mentioning. Obviously their isolation indicates the formation of 2,4,6-trichlorophenoxy radicals by attack of the benzoyloxy radical on 2,4,6-trichlorophenol. Further the formation of benzoyl chloride is remarkable, and a separate experiment showed that it is formed even in the absence of carbon tetrachloride as solvent. These findings immediately suggest the following steps for the mechanism of the formation of the quinones:

Similar steps will explain the formation of the other quinones. 2,3-Dichloro-6-(2,4,6-trichlorophenoxy)-*p*-benzoquinone seems to have been produced by chlorination of 2-chloro-6-(2,4,6-trichlorophenoxy)-*p*-benzoquinone, as is supported by an experiment described in the experimental part.

The isolation of methyl 3,5-dichloro-4-hydroxybenzoate suggests the involvement of trichloromethyl radicals derived from carbon tetrachloride, thus:

$$C_6H_5COO\cdot \rightarrow C_6H_5\cdot + CO_2$$

$$C_6H_5\cdot + CCl_4 \rightarrow C_6H_5Cl + CCl_3\cdot$$

Any substituted *o*-benzoquinones could not be isolated; such compounds would have decomposed under the present experimental conditions because of their instability. No chlorine was detected at all; since benzoyl peroxide does not oxidize hydrochloric acid to chlorine, this fact suggests that either the substitution of trichlorophenol by the trichlorophenoxy radical takes place without producing free chlorine atoms or these atoms, if produced at all, are very quick to abstract a hydroxyl hydrogen atom from the phenol.

Another mechanism for the production of aryloxyquinones from trichlorophenol is initial formation of 2,6-dichloro-*p*-benzoquinone followed by substitution of chlorine with 2,4,6-trichlorophenoxy radicals. The following findings, however, rule out this possibility. Since the same aryloxyquinones, viz., 2-chloro-6-(2,4,6-trichlorophenoxy)- and 2,6-bis-(2,4,6-trichlorophenoxy)-*p*-benzoquinone, are formed by oxidation of 2,4,6-trichlorophenol with lead dioxide at room temperature[10], it is reasonable to suppose that the same mechanism should be operative in the oxidation with lead dioxide as well as with benzoyl peroxide. In order to examine the effect of 2,6-dichloro-*p*-benzoquinone oxidation of 2,4,6-trichlorophenol with lead dioxide was carried out both in the presence and in absence of the dichloroquinone; the results tabulated in Table III show that the yield of aryloxyquinones were nearly equal in both experiments and that the dichloroquinone added beforehand was recovered unchanged, eliminating the formation of this compound as an intermediate.

The Reaction of Benzoyl Peroxide with 2,6-Dihalogenophenols.—The results of the reaction are summarized in Table IV. In the reaction with 2,6-dibromophenol bromine and 2,4,6-tribromophenol were formed, whereas hydrogen chloride and benzoyl chloride were detected in the reaction with 2,6-dichlorophenol. The formation of these products indicates that at

least part of the reaction mechanism is essentially similar to that in the case of tribromo- or trichloro-phenol, although any substances containing a diphenyl ether linkage could not be isolated. In contrast to the case with trihalogenophenols 2, 6-dibromophenol gave 3, 5, 3', 5'-tetrabromo - 4, 4' - dihydroxybiphenyl, and 2, 6-dichlorophenol, the corresponding tetrachloro-compound. Evidently dimerization of the dihalogenophenoxy radical gave the tetrahalogenodihydroxybiphenyl:

The Reaction of Benzoyl Peroxide with *p*-Halogenophenols. — Products from these reactions are listed in Table V.

The formation of benzoic acid and 2-benzoyloxy-4-halogenophenols is in line with the observations by Suehiro[6] and by Cosgrove and Waters[5] with phenol and its homologues.

The Reaction of Benzoyl Peroxide with *o*- and *p*-Nitrophenols. — The results are shown in Table VI.

When a mixture of benzoyl peroxide and *p*-nitrophenol was refluxed in carbon tetrachloride, benzoyl peroxide reacted only with carbon tetrachloride and the whole of the *p*-nitrophenol used was recovered. However, when both components were allowed to react at 100°C in the absence of any solvent, an appreciable amount of carbon dioxide was evolved in contrast to the reactions with other phenols. The isolated products were *p*-nitrophenyl benzoate and benzoic acid.

Similarly, *o*-nitrophenol gave at 100°C carbon dioxide, benzoic acid, 4-biphenylcarboxylic acid, phenyl-*o*-nitrophenol, and phenyl benzoate. In this case phenylation of *o*-nitrophenol occurred; no such reaction has ever been observed with phenols. These results show that the benzoyloxy radical abstracts a hydrogen atom from nitrophenols only with difficulty and therefore has to decompose into carbon dioxide and a phenyl radical.

Experimental

Materials.—Benzoyl peroxide was recrystallized twice from chloroform and methanol, m. p. 106°C

(decomp.), purity 99.8% as determined by iodometry. 2,4,6-Tribromophenol, prepared according to Vanino[11], had m. p. 96°C. 2,4,6-Trichlorophenol was prepared by chlorination of phenol with sodium hypochlorite solution[12], m. p. 66~67°C. 2,6-Dibromophenol was synthesized according to Huston and Neeley's method[13], m. p. 56°C. 2,6-Dichlorophenol was synthesized from *t*-butyl *p*-hydroxybenzoate by chlorination with sulphuryl chloride followed by hydrolysis and decarboxylation[14]. *p*-Chlorophenol was obtained from phenol and sulphuryl chloride[15], b. p. 99°C/11 mmHg, m. p. 44°C. *p*-Bromophenol was prepared by bromination of phenol in carbon disulphide[16], m. p. 64°C, b. p. 145~150°C/25 mmHg. *p*-Iodophenol was synthesized from *p*-aminophenol by diazotization followed by action of potassium iodide[17], m. p. 94°C. *o*- and *p*-Nitrophenols were prepared by nitration of phenol[18], m. p. 46.5~47.5° and 114°C, respectively.

Reaction of Benzoyl Peroxide with 2,4,6-Tribromophenol.—a) Benzoyl peroxide (3.63 g.) and 2,4,6-tribromophenol (8.00 g.) were heated in boiling carbon tetrachloride (40 cc.) for 22 hr., nitrogen being passed through the reaction mixture. The effluent nitrogen was passed through aqueous potassium hydroxide solution to determine the carbon dioxide formed. From the red-coloured reaction mixture carbon tetrachloride was distilled, and the bromine formed came over with it. The distillate, boiled with concentrated nitric acid and concentrated sulphuric acid, gave trace of *m*-dinitrobenzene indicating the formation of benzene. The residue from the distillation was extracted with aqueous sodium hydrogen carbonate solution, and the aqueous solution, on acidification, precipitated benzoic acid, which was then collected and weighed (2.23~2.36 g.). Then the residue was subjected to steam distillation to give tribromophenol. The resulting light brown residue was dissolved in chloroform, and addition of ethanol to the solution gave a precipitate. The precipitate was collected and dried to give white powder. This material is soluble in chloroform, ether, and benzene, but insoluble in methanol and petroleum ether, begins to soften at 240°C and melts at 260~285°C. It had molecular weight 3600~4800 (cryoscopy in bromoform or benzene) contained no benzoyloxy group, and strongly resisted hydrolysis in aqueous alkaline solution. The results of elemental analysis (Found: C, 26.75; H, 1.19; Br, 63.78, 64.05. Calcd. for $C_6H_2Br_2O$: C, 28.80; H, 0.80; Br, 64.00%) show that this compound must be a polymer consisting of many units of the dibromophenoxy group, $H(OC_6H_2Br_2)_nBr$. The same polymeric material was also obtained in the reaction in ligroin (b. p. 150°C).

b) Benzoyl peroxide (13.5 g.) was gradually added in small portions during 15 hr. to a boiling solution of 2,4,6-tribromophenol (91.5 g.) in carbon tetrachloride (400 cc.). After the addition of benzoyl peroxide was over, the solution was kept boiling for a further 15 hr. The gas evolved during the reaction was passed through a trap cooled with dry ice-ethanol, and then through acidic silver nitrate solution. The weight of the silver bromide precipitated gave the amount of hydrogen bromide formed (0.49 g.). The carbon tetrachloride was distilled from the reaction vessel and the bromine which came over with it was determined by the usual method (0.027 mol.). The carbon tetrachloride was treated with a mixture of nitric acid and sulphuric acid giving traces of dinitrobenzene. The residue was further distilled under reduced pressure (2 mmHg) and treatment of the distillate with a mixture of nitric acid and sulphuric acid gave 2,4-dinitrobromobenzene (1.14 g.). The residue was extracted with aqueous sodium carbonate and the extract acidified to pH 6 to give 2,4,6-tribromophenol (45.0 g.), which was filtered off. The filtrate, on acidification to Congo red, yielded benzoic acid (12.8 g.). The neutral residue was extracted with warm petroleum ether, giving polydibromophenylene oxide as insoluble part, and the extract was distilled in vacuo to yield phenyl benzoate (40 mg.) and a new compound (b. p. 200°C/5×10^{-4} mmHg) melting at 167~168°C (from methanol) (3.8 g.). This compound was identified with 2,4,6,3',5'-pentabromo-4'-hydroxydiphenyl ether on the basis of molecular weight measurement (Found: 583 (Rast). Calcd. for $H(OC_6H_2Br_2)_2Br$: 581) and the results of the following debromination: In the presence of palladium-calcium carbonate catalyst in ethanol the compound absorbed five moles of hydrogen, affording the corresponding amount of bromide ions and one mole of *p*-hydroxydiphenyl ether, melting point and mixed melting point with an authentic specimen, 85°C. Incidentally another debromination by Raney alloy in aqueous alkaline solution brought about splitting of the ether linkage as well as debromination, and produced two molecules of phenol.

The Reaction of Benzoyl Peroxide with 2,4,6-Trichlorophenol.—Benzoyl peroxide (36.4 g.) was allowed to react with 2,4,6-trichlorophenol (85.0 g.) in boiling carbon tetrachloride for 30 hr. with purified nitrogen being passed. Evolution of hydrogen chloride was observed during the reaction. After the reaction was over, the solvent was removed by distillation on a water bath. The distillate, boiled with a mixture of concentrated nitric acid and concentrated sulphuric acid gave *m*-dinitrobenzene. The residue was further distilled at 170 mmHg to afford benzoyl chloride, which on hydrolysis gave 0.2 g. of benzoic acid, and chlorobenzene, which on nitration gave 2.65 g. of 2,4-dinitrochlorobenzene. The residue was extracted with methanol and the extract was distilled in steam to give trichlorophenol (32 g.), benzoic acid (11 g.), and methyl benzoate (2 g.). Vacuum distillation

of the residue gave methyl 3,5-dichloro-4-hydroxybenzoate (0.6 g.), m. p. 122°C (from petroleum ether) (Found: mol. wt., 198 (Rast); Cl, 31.63. Calcd. for $C_8H_6Cl_2O_3$: mol. wt., 221; Cl, 32.12%). The identification was done by hydrolyzing it with alkali to 3,5-dichloro-4-hydroxybenzoic acid, melting point and mixed melting point with an authentic specimen 256°C, and by converting the ester into the known acetyl derivative, m. p. 70~71°C. When the residue from the vacuum distillation was dissolved in ether and the solution left to stand, 2,6-bis-(2,4,6-trichlorophenoxy)-*p*-benzoquinone (1.0 g.), m. p. 241~243°C, mixed m. p. 240°C with authentic specimen[10], was obtained. Ether was removed from the filtrate and vacuum distillation at 10^{-3} mmHg of the residue gave 2-chloro-6-(2,4,6-trichlorophenoxy)-*p*-benzoquinone (0.1 g.), melting point and mixed melting point with an authentic specimen[10] 120.5~121°C, and 2,3-dichloro-6-(2,4,6-trichlorophenoxy)-*p*-benzoquinone (2.79 g.), m. p. 155~156°C (Found: mol. wt., 387 (Rast); Cl, 47.85. Calcd. for $C_{18}H_3O_3Cl_5$: mol. wt., 372; Cl, 47.64%). The structure of the latter quinone was established both by its preparation by chlorination of the former quinone with hydrochloric acid and potassium bichromate on a boiling water bath and by its conversion into 2,5-dianilino-6-chloro-*p*-benzoquinone, melting point and mixed melting point with an authentic specimen 263°C, and trichlorophenol on treatment with aniline and aniline hydrochloride on a boiling water bath.

The residual tarry material (mol. wt., 650 by cryoscopy in benzene) contained 47.0% of chlorine and 3.5% of the benzoyloxy group.

Reaction of Benzoyl Peroxide with 2,4,6-Trichlorophenol in the Absence of Solvent.—Benzoyl peroxide (12.2 g.) and 2,4,6-trichlorophenol (39.0 g.) were allowed to react in the absence of solvent at 100°C on a water bath for 20 hr. After the reaction was over, vacuum distillation (2 mmHg) gave benzoyl chloride in a trap which was cooled in dry ice-ethanol mixture, and it was characterized by the formation of benzanilide, m. p. and mixed m. p. 162°C.

Reaction of 2,4,6-Trichlorophenol with Lead Dioxide.—2,4,6-Trichlorophenol (1.0 g.) was allowed to react with lead dioxide (7.0 g.) in the presence of anhydrous sodium sulphate in benzene (40 cc.) with and without 2,6-dichloro-*p*-benzoquinone (1.0 g.) at room temperature for 30 hr. The lead dioxide was filtered off and extracted with benzene, the filtrate and the benzene extract were combined and distilled, and the residue was subjected to sublimation on a boiling water bath to give 2,6-dichloro-*p*-benzoquinone (1.1 g. in the reaction in the presence of 2,6-dichloro-*p*-benzoquinone; 0.1 g. in the absence of the quinone). When the residue from the sublimation was dissolved in small amount of ether, 2,6-bis-(2,4,6-trichlorophenoxy)-*p*-benzoquinone precipitated (0.07 g. each in both experiments), and the filtered ether solution gave on condensation 2-chloro-6-(2,4,6-trichlorophenoxy)-*p*-benzoquinone (0.8 g. each in both experiments).

The Reaction of Benzoyl Peroxide with 2,6-Dibromophenol.—Benzoyl peroxide (5 g.) was allowed to react with 2,6-dibromophenol (20.0 g.) in boiling carbon tetrachloride (100 cc.) for 25 hr., with purified nitrogen being passed. As in the case of tribromophenol, bromine (0.14 g.) was produced during the reaction, and the amount of carbon dioxide evolved was 0.12 g. Benzoic acid (4.3 g.) was obtained from the reaction mixture by extracting with aqueous sodium hydrogen carbonate. On distillation of the residue, 2,6-dibromophenol (10.1 g.) was recovered, and 2,4,6-tribromophenol (0.3 g.) and 3,5,3',5'-tetrabromo-4,4'-dihydroxybiphenyl (0.2 g., m. p. and mixed m. p. 268°C) were isolated.

The Reaction of Benzoyl Peroxide with 2,6-Dichlorophenol.—Benzoyl peroxide (12.1 g.) was allowed to react with 2,6-dichlorophenol (16.3 g.) in boiling carbon tetrachloride (100 cc.) for 20 hr., during which period evolution of hydrogen chloride was observed. Extraction of the reaction mixture with aqueous sodium hydrogen carbonate followed by acidification gave benzoic acid (7.4 g.). The residue from distillation of the carbon tetrachloride solution was subjected to distillation in vacuo to give 2,6-dichlorophenol (6.0 g.). The distillation residue was dissolved in ether, and the solution extracted with dilute sodium hydroxide solution. On acidification of the extract 3,5,3',5'-tetrachloro-4,4'-dihydroxybiphenyl (0.2 g.) was isolated, m. p. and mixed m. p. 234°C.

The Reaction of Benzoyl Peroxide with *p*-Chlorophenol.—Benzoyl peroxide (16.2 g.) and *p*-chlorophenol (25.0 g.) in carbon tetrachloride solution were boiled on a water bath for 12.5 hr. with purified nitrogen being passed. The effluent gas was passed through a trap cooled with dry ice-ethanol and then through potassium hydroxide solution. Weight increase of the alkali solution was 0.256 g. This value and the amount of chloride ions (0.22 g.) in the solution determined by argentometry show that only hydrogen chloride evolved and evolution of carbon dioxide was very slight. Benzoic acid (11.5 g.) was separated from the reaction mixture by extraction with aqueous sodium hydrogen carbonate, and carbon tetrachloride was removed by distillation. The crystalline residue was recrystallized from benzene to give 2-benzoyloxy-4-chlorophenol, m. p. 147.5~149.5°C (Found: mol. wt., 253 (Rast); Cl, 14.05. Calcd. for $C_{13}H_9O_3Cl$: mol. wt., 249; Cl, 14.28%). Its structure was established by its preparation by chlorination of catechol monobenzoate with sulphuryl chloride.

The Reaction of Benzoyl Peroxide with *p*-Bromophenol.—Benzoyl peroxide (24.2 g.) and *p*-bromophenol (52.0 g.) in carbon tetrachloride were refluxed for 35.5 hr. with purified nitrogen being passed. No gas was evolved during the reaction. The solvent was distilled, and in the distillate no benzene could be detected. When benzoic acid (17.6 g.) and *p*-bromophenol (21.0 g.) were separated as before, the residue changed to crystalline solid, which recrystallized from benzene gave 2-benzoyloxy-4-bromophenol, m. p. 156~157°C (Found: mol. wt., 308, 284 (Rast); Br, 27.18, 27.36. Calcd. for $C_{13}H_9O_3Br$: mol. wt., 293; Br, 27.30%). The structure of this compound was proved by mixed

melting point determination with the bromocatechol monobenzoate which was prepared by bromination of catechol monobenzoate with bromine in glacial acetic acid.

The Reaction of Benzoyl Peroxide with *p*-Iodophenol.—Benzoyl peroxide (9.5 g.) and *p*-iodophenol (17.5 g.) were boiled in carbon tetrachloride for 13 hr. with purified nitrogen being passed. No gas was evolved, but iodine (2.38 g.) was liberated. Vacuum distillation of the reaction mixture gave benzoic acid (4.43 g.) and *p*-iodophenol (3.78 g.). The solid residue, recrystallized from methanol, gave a white crystalline compound, m. p. 165~169°C (Found: C, 45.86; H, 2.81. Calcd. for $C_{13}H_9O_3I$: C, 45.88; H, 2.65%), which was thought to be 2-benzoyloxy-4-iodophenol.

The Reaction of Benzoyl Peroxide with *p*-Nitrophenol.—Benzoyl peroxide (12.1 g.) and *p*-nitrophenol (13.8 g.) were refluxed in carbon tetrachloride solution (100 cc.) on a water bath for 15 hr. Vigorous evolution of hydrogen chloride was observed during the reaction. The solvent was removed and vacuum distillation of the residue gave benzoyl chloride and a crystalline residue, which, on recrystallization from water, gave almost all the original *p*-nitrophenol unchanged.

A mixture of powdered *p*-nitrophenol (13.8 g.) and powdered benzoyl peroxide (12.1 g.) was gently heated with stirring on a water bath with nitrogen being passed. At about 90°C, the mixture melted into a viscous fluid and the melt was kept at 100°C for 13 hr. with stirring. During that period 0.484 g. of carbon dioxide evolved. A small amount of carbon tetrachloride was added to the reaction mixture and the mixture was distilled. In the distillate benzene (25 mg.) was detected (as *m*-dinitrobenzene). Steam distillation of the residue gave benzoic acid (10 g.) and codistillation with purified ligroin (b. p. 100~165°/25 mmHg) yielded *p*-nitrophenol (10.1 g.). The residue was extracted with warm petroleum ether, the extract condensed and the residue recrystallized from benzene to give *p*-nitrophenyl benzoate (20 mg.).

The Reaction of Benzoyl Peroxide with *o*-Nitrophenol.—A mixture of *o*-nitrophenol (27.5 g.) and benzoyl peroxide (24.2 g.) was heated on a boiling water bath for 17 hr. with agitation with purified nitrogen being passed. Carbon dioxide (2.6 g.) was evolved. To the reaction mixture carbon tetrachloride was added and the mixture distilled. Nitration of the distillate gave *m*-dinitrobenzene (0.2 g.). Steam distillation of the residue yielded phenyl benzoate (0.66 g.), *o*-nitrophenol (17.3 g.), benzoic acid (11.2 g.) and a yellow crysalline compound (2.35 g.). This yellow compound, recrystallized from methanol, melted at 103~104.5°C (Found: C, 67.14; H, 4.63; N, 6.40. Calcd. for $C_{13}H_9NO_3$: C, 66.98; H, 4.19; N, 6.51%) and seems to be phenyl-*o*-nitrophenol. The residue, distilled in super-heated steam, gave 4-biphenylcarboxylic acid (0.37 g.), m. p. and mixed m. p. 219~221°C.

Summary

Benzoyl peroxide has been allowed to react with various halogenophenols in boiling carbon tetrachloride and the nature of the products has been examined.

2,4,6-Tribromophenol gave benzoic acid, polydibromophenylene oxide $H(OC_6H_2Br_2)_nBr$, 4-hydroxy-3,5,2',4',6'-pentabromodiphenyl ether, carbon dioxide and bromine, whereas in the case of 2, 4, 6-trichlorophenol the corresponding polymeric material could not be isolated, but *p*-benzoquinones substituted with chlorine and the 2, 4, 6-trichlorophenoxy group were formed. The reaction with 2, 6-dichloro- and 2, 6-dibromophenol gave a small amount of the corresponding 3, 5, 3', 5'-tetrahalogeno-4, 4'-dihydroxybiphenyls, a type of product which were not obtained in the other cases. *p*-Halogenophenols yielded an appreciable amount of halogenocatechol monobenzoates.

p-Nitrophenol did not react with benzoyl peroxide in boiling carbon tetrachloride, but at 100°C in the absence of any solvent this phenol as well as the ortho isomer underwent reaction with evolution of considerable amount of carbon dioxide. These observations are discussed in terms of mechanisms involving free radicals.

*Studies on the Synthesis of Peptides Containing Glutamine as the C-Terminal. I. Protection of Amide-nitrogen with Xanthyl Group during Peptide Synthesis**

By Yasutsugu SHIMONISHI, Shumpei SAKAKIBARA and Shiro AKABORI

(Received July 26, 1962)

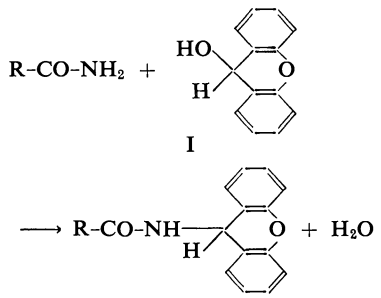
To date reports on the synthesis of glutaminyl peptides have been rare, because the chemically unstable amide group in glutamine makes preparation of these peptides difficult. Therefore the development of a practical method for synthesizing these peptides would be of particular interest in the study of the synthesis of peptides. The authors have attempted to find a new method especially for the synthesis of *C*-terminal glutaminyl peptides, as well as to improve earlier methods.

It is known that troublesome side reactions[1] occur during the synthesis of asparagine- and glutamine-peptides because of the instability of the β- and γ-amide groups respectively. For example, Sondheimer and Holley[2] synthesized peptides such as L-glutaminyl-L-leucine by the carbobenzoxy azide method, but their method could not be used to prepare peptides containing *C*-terminal glutamine. They reported also[3] that carbobenzoxyglutamine and its isomer, namely carbobenzoxyisoglutamine, could be obtained by normal alkaline saponification of carbobenzoxyglutamine methyl ester. During this treatment α-carbobenzoxyaminoglutarimide was found to be an intermediate; consequently the product was a mixture of α- and γ-amides. Similar reactions took place in the synthesis of asparagine series. It was also reported[4] that peptide derivatives, when treated in the same way, gave rise to a mixture of α- and γ-peptide derivatives.

Glutamine or glutaminyl peptides are labile even in neutral solution and are cyclized to pyrrolidonecarboxylic acid or to pyrroglutamyl peptides, respectively, merely by heating their aqueous solutions[5,6] or by passing them through a strongly acidic ion-exchange resin[7]. It has been found[8-10] that the application of tetraethylpyrrophosphite or *N,N'*-dicyclohexylcarbodiimide as a condensing reagent gave the cyano-compound as one of the products by intramolecular dehydration of the amide group during the formation of asparaginyl peptide bonds and, to a lesser extent, during the formation of glutaminyl peptide bonds.

Hofmann et al.[11] prepared L-methionyl-L-glutamine, intermediate for melanocite stimmulating hormone, from carbobenzoxy-L-methionine and L-glutamine by the mixed anhydride procedure. By the same method, Shiba et al.[5,12] and Rudinger et al.[13] synthesized L-pyrroglutamyl-L-glutaminyl-L-glutamine (fastigiatin) from carbobenzoxy-L-glutamic acid γ-methyl ester and L-glutaminyl-L-glutamine, and L-glutaminyl-L-glutamine (its intermediate) starting with carbobenzoxy-L-glutamic acid γ-methyl ester and L-glutamine. Vigneaud et al.[14] synthesized tosyl-L-isoleucyl-L-glutamine from tosyl-L-isoleucyl chloride and L-glutamine, but this procedure has not been used generally. These methods are limited to the reaction in which unprotected glutamine can be used.

In developing a method of preparation of these peptides which does not involve side reactions, the following considerations must be investigated. It is desirable to protect the amide nitrogen by a protective group which is easily removable after the formation of peptide bonds. This protective group should not be attacked by the reagents used for synthesis of the peptide. The optical activity of the amino acids or peptides should be maintained during the introduction and removal of the protective group.



The author first tried the benzyl group as a

protective group and prepared N^{α}-carbobenzoxy-N^{γ}-benzyl-L-glutamine from carbobenzoxy-L-glutamic acid γ-hydrazide, but the benzyl group could not be removed. Frankel et al.[15] also reported that they prepared poly-N^{β}-benzyl-asparagine in order to obtain poly-asparagine, but that the removal of the benzyl group was very difficult because of its unexpected stability.

Phillips et al.[16] reported that unsubstituted acyl amide reacted with xanthydrol (I) to give acyl xanthyl amide. The present authors applied the reaction to carbobenzoxy-L-glutamine (II) and N^{α}-carbobenzoxy-N^{γ}-xanthyl-L-glutamine (III) was obtained in a good yield.

The authors found that the N^{γ}-xanthyl group was comparatively stable in caustic alkalis, but very unstable in mineral acids. Both decarbobenzoxylation and dexanthylation took place, when III was treated with glacial acetic acid containing hydrogen bromide. From the reaction mixture, L-glutamine was recovered in a 55% yield by the usual procedures, and it had the same optical activity as glutamine which had been obtained directly from II. By catalytic reduction with Pd-charcoal only decarbobenzoxylation occurred, and N^{γ}-xanthyl-L-glutamine (IV) was obtained. Moreover, IV could not be prepared from glutamine and I in acetic acid. The xanthyl derivative III, obtained from carbobenzoxy-L-glutamine (II) with xanthydrol (I), was esterified to N^{α}-carbobenzoxy-N^{γ}-xanthyl-L-glutamine methyl ester (V) by means of diazomethane. After catalytic hydrogenation of V by Pd-charcoal in the presence of acetic acid, the acetate ester (VI) obtained was coupled with carbobenzoxy-glycine *p*-nitrophenyl ester[17] (VII, R=H) to form carbobenzoxy-glycyl-N^{γ}-xanthyl-L-glutamine methyl ester (VIII). Glycyl-L-glutamine

(Xa) was obtained by treatment of carbobenzoxy-glycyl-N^{γ}-xanthyl-L-glutamine (IX, R=H) with hydrogen bromide, which had been prepared by saponification of VIII (R=H). The yield at each step of these reactions was more than 70%. The above synthetic route is shown in Fig. 1. Carbobenzoxy-L-alanyl- (VIIIb), -L-phenylalanyl (VIIIc) N^{γ}-xanthyl-L-glutamine methyl ester were synthesized from N^{γ}-xanthyl-L-glutamine methyl ester acetate (VI) and the respective carbobenzoxyamino acid *p*-nitrophenyl esters (VII) prepared by the procedure of Bodanszky et al.[18] After saponification of VIII, followed by treatment with hydrogen bromide, L-alanyl-L-glutamine (Xb) and L-phenylalanyl-L-glutamine (Xc) were obtained. This method, using the xanthyl derivatives, was superior to the methods used in earlier work in that there was less possibility of the occurrence of side reactions. A weak point is that the solubility of xanthyl derivatives in organic solvents is low. Therefore, it was difficult to observe the rotation of the xanthyl derivatives of peptides. An attempt was made to apply the protection resulting from the xanthyl group to asparagine derivative; however, N^{β}-xanthyl-L-asparagine methyl ester acetate, a starting material in peptide synthesis, could not be obtained from the catalytic hydrogenation of carbobenzoxy-N^{β}-xanthyl-L-asparagine methyl ester, which had been previously obtained by the reaction of carbobenzoxy-N^{β}-xanthyl-L-asparagine with diazomethane.

Experimental*

N^{α}-Carbobenzoxy-N^{γ}-xanthyl-L-glutamine.—Xanthydrol[19] (9.8 g., 0.050 mol.) and carbobenzoxy-L-glutamine (13.9 g., 0.050 mol.) were dissolved in 200 ml. of glacial acetic acid and the solution was allowed to stand for 2 days at room temperature. The gelatinous solid product was drained, filtered and dried in an alkali desiccator. The resulting white powder was recrystallized from tetrahydrofran to give colorless needles with a melting point at 182~183°C. The yield was 18.5 g. (80% of the theoretical amount). $[\alpha]_D^{17}=-5.7°$ (*c* 5.7, dimethylformamide).

Found: C, 66.36; H, 5.55; N, 6.13. Calcd. for $C_{26}H_{24}O_6N_2 \cdot 1/2H_2O$ C, 66.52; H, 5.37; N, 5.97%.

N^{α}-Carbobenzoxy-N^{γ}-xanthyl-L-glutamine Methyl Ester.—*Preparation of an Ethereal Solution of Diazomethane*[20]. — In a 200 ml. round bottomed flask were placed 12 ml. of 50% aqueous potassium hydroxide solution and 35 ml. of ether. The mixture was cooled to 5°C in an ice-bath, and 4.0 g. of nitrosomethylurea was slowly added with shaking. The upper layer was colored yellow by diazomethane. After the complete decomposition of nitrosomethylurea by alkali to diazomethane, the upper layer was decanted and dried over pellets of potassium hydroxide for two hours. A measured portion of this solution was allowed to react at 0°C with a solution of an accurately weighed excess of pure benzoic acid dissolved in absolute ether. The unreacted benzoic acid was titrated with standard N alkali. The yield of diazomethane was found to be about 70 per cent.

Preparation of the Ester (V).—The dry ethereal solution of diazomethane was slowly dropped, with stirring, into a suspension of 6.0 g. (0.013 mol.) of N^{α}-carbobenzoxy-N^{γ}-xanthyl-L-glutamine in 100 ml. of dioxane at 0~10°C. With the evolution of nitrogen gas the reaction proceeded smoothly. The mixture was kept overnight at room temperature in a flask, to which was attached a tube of mercury seal. The precipitate was filtered by suction, washed with ether and dried on sodium hydroxide in a vacuum desiccator. After recrystallization of the crude product (5.2 g., m. p. 235°C) from 150 ml. of dioxane, colorless needles were obtained, m. p. 235~235.5°C. The yield was 81% of the theoretical (5 g.). Titration by sodium methoxide solution showed the absence of free carboxylic acid.

Found: C, 68.21; H, 5.50; N, 5.94. Calcd. for $C_{27}H_{26}O_6N_2$: C, 68.34; H, 5.52; N, 5.90%.

N^{γ}-Xanthyl-L-glutamine. — N^{α}-Carbobenzoxy-N^{γ}-xanthyl-L-glutamine (4.6 g., 0.01 mol.) was hydrogenated in 150 ml. of ethanol under 70~80 atm. of H_2 at 75~80°C in the presence of Pd-charcoal catalyst, which was prepared from 10% palladium chloride in dilute hydrochloric acid (15 ml.) and charcoal (3 g.). The hydrogenated product was deposited on the catalyst. After 3 hr. the reaction mixture was cooled to room temperature. The mixture was filtered and washed three times with 20 ml. of hot ethanol. The residue on the filter paper was suspended in 60 ml. of water containing 1.5 ml. of triethylamine to dissolve the product deposited on the charcoal. After filtration, the filtrate and aqueous washings were combined and brought to pH 4.5~5.0 with 2 N hydrochloric acid. The precipitate was separated by centrifugation and washed with methanol and then with ether. 2.2 g. of N^{γ}-xanthyl-L-glutamine was obtained after drying in a desiccator, and purified by reprecipitation from 2 N ammonium hydroxide and 2 N hydrochloric acid. This compound melted at 218~220°C (60% of the theoretical).

Found: C, 65.17; H, 5.60; N, 8.94. Calcd. for $C_{18}H_{18}O_4N_2$: C, 66.24; H, 5.56; N, 8.58%.

N^{γ}-Xanthyl-L-glutamine Methyl Ester Acetate.—Five grams (0.01 mol.) of N^{α}-carbobenzoxy-N^{γ}-xanthyl-L-glutamine methyl ester were suspended in 130 ml. of methanol and palladium-charcoal catalyst, prepared freshly from 25 ml. of 1% palladium chloride solution, and 5 g. of charcoal were added. Three milliliters of glacial acetic acid were dropped into the above mixture. Hydrogen gas was allowed to bubble through the mixture for

6 hr. at room temperature. The filtrate was concentrated under reduced pressure, at low temperature. The residue was dissolved in a small amount of methanol and the undissolved part was filtered off. Ether was added to the filtrate and a colorless crystalline product was obtained in a 67% yield (2.8 g.) which melted at 148~148.5°C. This material was ninhydrin positive and had an R_f value of 0.85 on paper chromatography in a solvent system of *n*-butanol : acetic acid : water (4 : 1 : 1).

Found: C, 62.72; H, 6.07; N, 6.90. Calcd. for $C_{21}H_{24}O_6N_2$: C, 62.99; H, 6.04; N, 7.00%.

Carbobenzoxy-glycyl-N^{γ}-xanthyl-L-glutamine Methyl Ester.—Carbobenzoxy-glycine *p*-nitrophenyl ester (3.5 g., 0.011 mol.) was added to an anhydrous solution of N^{γ}-xanthyl-L-glutamine methyl ester acetate (3.5 g., 0.0087 mol.) and triethylamine (1.2 ml., 0.0087 mol.) in chloroform according to the description of du Vigneaud[18]. The clear pale yellow solution was allowed to stand overnight at room temperature. The crystalline precipitate was filtered and washed with chloroform. After recrystallization of crude material (4.0 g.) from dioxane, fine colorless needles, which melted at 184°C, (3.5 g.) were obtained in a 76% yield.

Found: C, 65.49; H, 5.64; N, 7.89. Calcd. for $C_{29}H_{29}O_7N_3$: C, 65.52; H, 5.50; N, 7.91%.

Carbobenzoxy-L-alanyl-N^{γ}-xanthyl-L-glutamine Methyl Ester. — N^{γ}-Xanthyl-L-glutamine methyl ester, prepared from its acetate (2.0 g., 0.0050 mol.), was treated with carbobenzoxy-L-alanine *p*-nitrophenyl ester (2.4 g., 0.0070 mol.). Carbobenzoxy-L-alanyl-N^{γ}-xanthyl-L-glutamine methyl ester (2.4 g.) was obtained as a precipitate. Recrystallization from ethanol yielded colorless needles (1.4 g., 52% of the theoretical yield) with a melting point at 208°C (decomp.).

Found: C, 65.17; H, 5.69; N, 7.79. Calcd. for $C_{30}H_{31}O_7N_3$: C, 66.04; H, 5.73; N, 7.70%.

Carbobenzoxy-L-phenylalanyl-N^{γ}-xanthyl-L-glutamine Methyl Ester. — By the same treatment as above, crystalline precipitates (5.9 g.) were obtained in an 80% yield from N^{γ}-xanthyl-L-glutamine methyl ester acetate (4.8 g., 0.012 mol.) and carbobenzoxy-L-phenylalanine *p*-nitrophenyl ester (6.0 g., 0.014 mol.). M. p. 215~216°C.

Found: C, 69.60; H, 5.59; N, 6.59. Calcd. for $C_{36}H_{35}O_7N_3$: C, 69.55; H, 5.68; N, 6.76%

Carbobenzoxy-glycyl-N^{γ}-xanthyl-L-glutamine.— To a solution of 1.6 g. (0.003 mol.) of carbobenzoxy-glycyl-N^{γ}-xanthyl-L-glutamine methyl ester in 100 ml. of dioxane 30 ml. of 0.1 N sodium hydroxide was added (1.0 equiv.). After standing for an hour at room temperature (25°C), the solution was acidified to about pH 3.5 with N hydrochloric acid and concentrated under reduced pressure at low temperature. The residue was suspended in water and filtered. The resulting precipitate was dried in a desiccator and then dissolved in a warm mixture of methanol and toluene (4 : 1) and the insoluble material was filtered off. A small quantity of water was slowly added to the filtrate whereby IX (R=H) deposited in colorless needles. M. p. 198°C. The yield was 77% of the theoretical.

Found: C, 65.17; H, 5.39; N, 8.04. Neut. eq. 516. Calcd. for $C_{28}H_{27}O_7N_3$: C, 64.98; H, 5.26; N, 8.12%; mol. wt. 517.5.

Glycyl-L-glutamine. — Carbobenzoxyglycyl-N^{γ}-xanthyl-L-glutamine (1.5 g., 0.0029 mol.) was treated with 4.2 g. (5.0 equiv.) of 28.1 per cent glacial acetic acid containing hydrogen bromide. This solution was kept for about an hour at room temperature and dry ether was added where a colored material precipitated. Then the precipitate was washed with ether and the ether was decanted. The residue was dissolved in water and the undissolved material was filtered. The filtrate was passed through a weakly basic resin (Amberlite IR-4B) column, and the product was washed out of the column with a sufficient volume of water. The effluent was lyophilized, and the residue was dissolved in a small amount of water. On addition of ethanol to the solution, the final product was obtained as fine colorless crystals of the monohydrate (0.44 g., 70%), m. p. 260°C (decomp.). $[\alpha]_D^{15}=-1.8\pm0.5°$ (*c* 3.8, water). R_f value was 0.17 in solvent system (*n*-BuOH : AcOH : H_2O=4 : 1 : 1).

Found: C, 38.02; H, 7.02; N, 19.12. Calcd. for $C_7H_{13}O_4N_3\cdot H_2O$: C, 38.00; H, 6.84; N, 19.00%.

Thierfelder reported; m. p. 199~200°C. $[\alpha]_D^{15}=-2.47°$ (*c* 4.20, water).

L-Alanyl-L-glutamine. — One gram (1.83×10^{-3} mol.) of carbobenzoxy-L-alanyl-N^{γ}-xanthyl-L-glutamine methyl ester was saponified with 2.8 ml. (1.5 equiv.) of N sodium hydroxide in 100 ml. of dioxane for about 4 hr. at room temperature (15~20°C). The reaction mixture was concentrated to dryness after neutralization with dilute hydrochloric acid. The residue was crystallized from dioxane to yield a product (0.7 g.) having m. p. 138°C. This product was treated with 2.7 g. of 20% glacial acetic acid containing hydrogen bromide. This mixture was kept for 2 hr. at room temperature, and then dry ether (100 ml.) was added. A precipitate was obtained and the upper solution was decanted. The precipitate was dissolved in a small amount of water and the undissolved material was filtered. The filtrate was passed through an Amberlite IR-4B (OH-form) column. The effluent was lyophilized and the residue was recrystallized from water-ethanol as fine needles. One hundred milligrams of L-alanyl-L-glutamine were obtained as the monohydrate in about a 30% yield which melted at 214~215°C with decomposition. On paper chromatography it had an R_f value of 0.14 in the solvent system (*n*-BuOH : AcOH : H_2O=4 : 1 : 1). $[\alpha]_D^{14}=+11.4\pm0.5°$ (*c* 3.7, water).

Found: C, 40.42; H, 7.52; N, 17.82. Calcd. for $C_8H_{15}O_4N_3\cdot H_2O$: C, 40.84; H, 7.28; N, 17.86%.

Carbobenzoxy-L-phenylalanyl-N^{γ}-xanthyl-L-glutamine. — Carbobenzoxy-L-phenylalanyl-N^{γ}-xanthyl-L-glutamine methyl ester (2.6 g., 0.0042 mol.) was dissolved in 130 ml. of dimethylformamide and 6.3 ml. (1.5 equiv.) of N sodium hydroxide were added. After standing for 3 hr. at room temperature, the solution was neutralized with aqueous hydrochloric acid and then concentrated under reduced pressure. The residue was suspended in water, finely crushed with a rod, filtered by suction and dried in vacuo. Recrystallization of crude material (2.4 g., 188~

189.5° with decomposition) from methanol-water gave a crystalline product (1.7 g.) in a 68% yield. M. p. 188~189.5°C (decomp.). Neut. eq. 601, (mol. wt. 604).

L-Phenylalanyl-L-glutamine. — Carbobenzoxy-L-phenylalanyl-N^{γ}-xanthyl-L-glutamine (1.6 g., 0.0027 mol.) was treated with 5.0 g. (5 equiv.) of 21.4% glacial acetic acid solution containing hydrogen bromide. After the mixture was allowed to stand for 2 hr. at room temperature, a precipitate was obtained by adding 150 ml. of dry ether. The upper layer was decanted, and the residue was washed with dry ether and dissolved in a small amount of water. After filtration, the filtrate was passed through an Amberlite IR-4B (OH-form) column. The effluent was lyophilized and the residue was dissolved in water. Fine crystals were obtained in a 35% yield 0.26 g.) by adding ethanol. These melted at 209~210°C. $[\alpha]_D^{17} = +51.9 \pm 0.5°$ (c 4.0, in water).

Found: C, 57.55; H, 6.78; N, 14.45. Calcd. for $C_{14}H_{19}O_4N_3$: C, 57.32; H, 6.53; N, 14.33%.

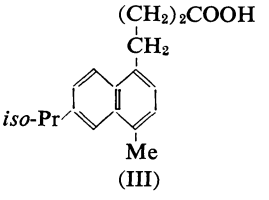
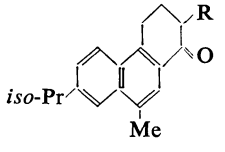
*7-Isopropyl-2, 9-dimethylphenanthrene and 2-Isopropyl-10-methylphenanthrene**

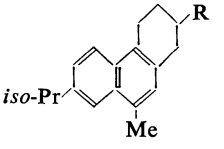


By Hiroshi KOBAYASHI

(Received August 2, 1962)



During degradative studies on the constitution of the conifer diterpene thunbergene[1], 7-isopropyl-2, 9-dimethylphenanthrene and 2-isopropyl-10-methylphenanthrene have been synthesized as reference compounds by standard methods.



(I)

The Friedel-Crafts succinoylation of 7-isopropyl-1-methylnaphthalene furnished 4-(6-isopropyl-4-methyl-1-naphthyl)-4-oxobutyric acid (I) along with a minor product, which was considered to be 4-(6-isopropyl-4-methyl-2-naphthyl)-4-oxobutyric acid (II) as mentioned below.

Reduction of the ketoacid (I) by the Wolff-Kishner method as modified by Huang-Minlon gave 4-(6-isopropyl-4-methyl-1-naphthyl)-butyric

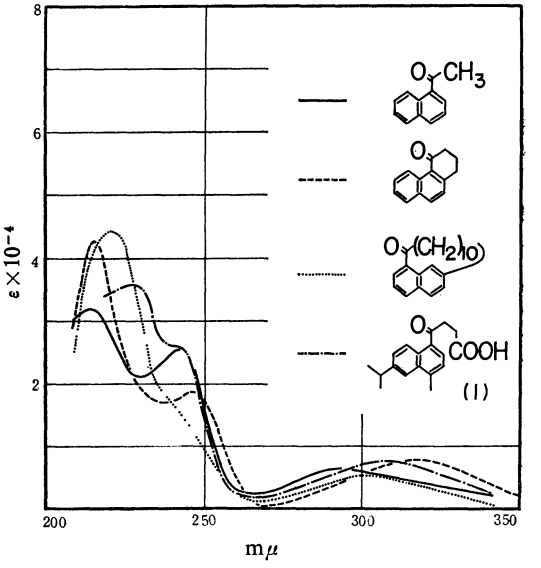

Fig. 1. UV Absorptions of α-naphthyl-keto systems in ethanol.

* Contribution No. 32 from the Deparment of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka.

1) H. Kobayashi and S. Akiyoshi, This Bulletin, 35, 1044 (1962).

acid (III), which was cyclized 1, 2, 3, 4-tetrahydro-7-isopropyl-9-methyl-1-oxophenanthrene (IV). Introduction of a methyl group at the 2-position of this cyclic ketone (IV) yielded 1, 2, 3, 4-tetrahydro-7-isopropyl-2, 9-dimethyl-1-oxophenanthrene (V). Wolf-Kishner reduction of the last ketone (V) yielded 1, 2, 3, 4-tetrahydro-7-isopropyl-2, 9-dimethylphenanthrene (VI) which furnished 7-isopropyl-2, 9-dimethylphenanthrene on dehydrogenation.

Similarly 2-isopropyl-10-methylphenanthrene was prepared from the cyclic ketone IV via VII.

In accordance with general principles[2], the succinoylation of 7-isopropyl-1-methylnaphthalene should occur at the 3- and 4-positions. This expectation was supported by the ultraviolet absorption spectra[3] which showed that one of the two isomeric naphthyl-oxobutyric acids I and II, had 1-naphthoyl chromophore (Fig. 1) while the other had 2-naphthoyl one (Fig. 3).

The structure of the 4-substituted product I was confirmed by obtaining 6-isopropyl-1, 4-dimethylnaphthalene (X)[4], via intermediates, VIII and IX. If the 5-substitution had occurred, instead, the reaction sequence should lead to 3-isopropyl-1, 5-dimethylnaphthalene[5].

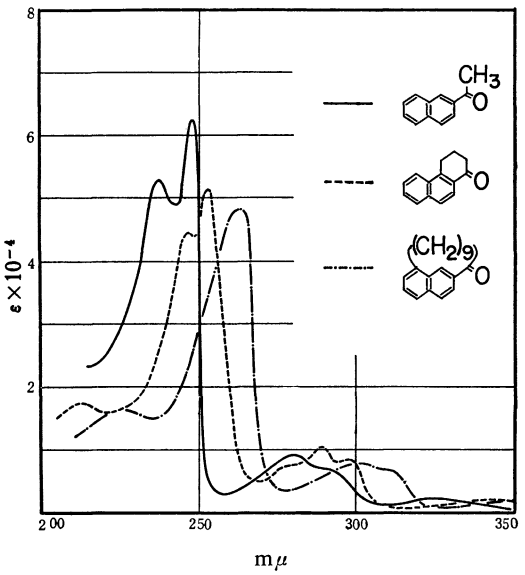

Fig. 2. UV Absorptions of 2-naphthoyl systems in ethanol.

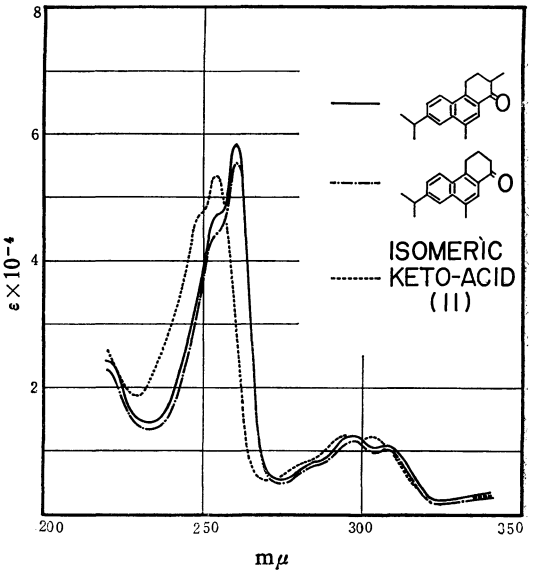

Fig. 3. UV Absorptions of the naphthoyl systems in this study.

Additional evidences for the assignments are that the cyclic ketones formulated as IV and V show similar ultraviolet spectra (Fig. 3) to those of the 2-naphthoyl system (Fig. 2)[3] and that final tricyclic hydrocarbons are phenanthrenes but not anthracenes. The 3-substituted naphthalene II has not been further investigated.

Experimental

Melting points are uncorrected and were measured on a Kofler micro hot stage. The ultraviolet spectra were recorded on a Hitachi EPS-2 type spectrophotometer. 7-Isopropyl-1-methylnaphthalene (eudalene) was synthesized according to the method of Ruzicka and Stoll[6] via 1,2,3,4-tetrahydro-7-isopropyl-1-oxonaphthalene[7]. The picrate, m. p. 92°C, was identical with that of eudalene prepared from eudesmol which occurred naturally. Pure eudalene was regenerated from the picrate by elution from alumina column.

7-Isopropyl-2, 9-dimethylphenanthrene. — Finely powdered aluminum chloride (28.0 g.) was added slowly to a stirred solution of eudalene (18.4 g.) and succinic anhydride (11.0 g.) in nitrobenzene (130 ml.) at 0°C, and after 30 hr. of a reaction period at room temperature the mixture was treated with ice (150 g.) and excess of hydrochloric acid (30 ml.). The removal of the nitrobenzene by steam-distillation furnished a resinous acid which was dissolved in 5% sodium carbonate and treated with activated charcoal. The resulting alkaline solution was acidified with dilute hydrochloric acid. A mixture of keto-acids (18.0 g.) was precipitated.

Repeated crystallization from ethanol gave 4-(6-isopropyl-4-methyl-1-naphthyl)-4-oxobutyric acid (I) (6.5 g.) as plates, m. p. 133.7~134.4°C.

Found: C, 75.85; H, 7.09. Calcd. for $C_{18}H_{20}O_3$: C, 76.03; H, 7.09%.

The mother liquor from this acid slowly deposited a crystalline acid (1.6 g.) which on repeated crystallization from ethanol gave the isomeric naphthyl-oxobutyric acid II (0.85 g.) m. p. 179.5~181.0°C.

Found: C, 75.77; H, 7.11. Calcd. for $C_{18}H_{20}O_3$: C, 76.03; H, 7.09%.

A mixture of 4-(6-isopropyl-4-methyl-1-naphthyl)-4-oxobutyric acid (I) (2.90 g.), 80% hydrazine hydrate (1.5 ml.), potassium hydroxide (2.0 g.) and diethylene glycol (15 ml.) was refluxed at 170~180°C for 2 hr., then excess of hydrazine and water were removed by distillation until the reaction temperature was 220°C and this temperature was maintained for an additional 3 hr. After acidification of the cooled reaction mixture, the product was purified by recrystallization from ethanol to give 4-(6-isopropyl-4-methyl-1-naphthyl)-butyric acid (III) as needles, m. p. 151.5~153.5°C (2.45 g.).

Found: C, 79.94; H, 8.18. Calcd. for $C_{18}H_{22}O_2$: C, 79.96; H, 8.20%.

4-(6-Isopropyl-4-methyl-1-naphthyl)-butyric acid (III) (950 mg.) was added with stirring to a cooled 80% sulfuric acid (6.5 ml.) and then heated to 100°C for 1.5 hr. with occasional swirling. The cooled reaction mixture was added to ice and water and extracted with ether. The extract was washed with aqueous sodium carbonate, dried and evaporated to yield a crystalline solid IV which was purified by recrystallization from ethanol, m. p. 125.5~127.0°C, (750 mg.).

Found: C, 85.53; H, 8.02. Calcd. for $C_{18}H_{20}O$: C, 85.67; H, 7.99%.

The semicarbazone formed white glittering plates decomposing at about 220°C. The crystals melted at 255°C with immediate decomposition upon rapid heating.

Found: C, 73.65; H, 7.59; N, 13.47, 13.45. Calcd. for $C_{18}H_{20}O \cdot CH_3N_3$: C, 73.75; H, 7.49; N, 13.58%.

Finely powdered sodium amide (250 mg.) suspended in dry benzene (10 ml.) was added to the cyclic ketone IV (1450 mg.) dissolved in dry benzene (5 ml.). After refluxing for 45 min., the evolution of ammonia ceased and a solid sodio-derivative separated. Addition of methyl iodide (1.0 g.) to the cooled solution resulted in an exothermic reaction, which was completed by refluxing for 30 min. The mixture was treated with dilute hydrochloric acid. Extraction with ether followed by crystallization from ethanol gave cycloketone V (650 mg.), m. p. 101~103°C.

Found: C, 85.69; H, 8.19. Calcd. for $C_{19}H_{22}O$: C, 85.67; H, 8.33%.

Semicarbazone could not be prepared in the usual way.

Reduction of the methylated cycloketone V (620 mg.) with 80% hydrazine hydrate (0.5 ml.), potassium hydroxide (500 mg.) and diethylene glycol (10 ml.) was carried out at 150°C for 2 hr., and then at 220°C for 4 hr. after removal of excess of hydrazine and water. The product VI was extracted with ether and then purified by elution with petroleum ether from an alumina column. A mixture of this tetrahydrophenanthrene VI (540 mg.) and 30% palladium on charcoal (50 mg.) was heated under reflux at 300°C for 2 hr. and then at 350°C for half an hour. The cooled mixture was extracted with petroleum ether and the crude product purified by chromatography from the same solvent on activated alumina, to give 7-isopropyl-1,9-dimethylphenanthrene which separated from ethanol in plates m. p. 77~79°C. λ_{max} (in hexane): 224, 250(shoulder), 257, 274, 281, 288, 299, 319, 328 and 355 mμ. log ε 4.44, 4.84, 5.00, 4.44, 4.37, 4.19, 4.08, 2.46, 2.40 and 2.45 respectively.

Found: C, 91.90; H, 8.19. Calcd. for $C_{19}H_{20}$: C, 91.88: H, 8.12%.

The picrate separated from ethanol in orange yellow needles melting at 133.5~134.5°C.

2-Isopropyl-10-methylphenanthrene.—The Wolff-Kishner reduction of 1,2,3,4-tetrahydro-7-isopropyl-9-methyl-1-oxophenanthrene (IV) (250 mg.) furnished 1,2,3,4-tetrahydro-7-isopropyl-9-methylphenanthrene (VII) (210 mg.), which could not be crystallized. Dehydrogenation of this tetrahydrophenanthrene with 30% palladium on charcoal as before furnished 2-isopropyl-10-methylphenanthrene, which separated from ethanol in white needles melting at 49.0~49.5°C. λ_{max} (in hexane): 223, 248(shoulder), 255, 272, 279, 285, 298, 318, 327 and 334 mμ.

log ε 4.37, 4.75, 4.88, 4.25, 4.21, 4.09, 4.01, 2.37, 2.35 and 2.38 respectively.

Found: C, 92.15; H, 7.75. Calcd. for $C_{18}H_{18}$: C, 92.26; H, 7.74%.

The picrate separated from ethanol as orange yellow needles melting at 123~124°C.

6-Isopropyl-1,4-dimethylnaphthalene via 6-Isopropyl-4-methyl-1-naphthoic Acid.—To a solution of sodium hypochlorite (30 ml. of 10% available chlorine) and sodium hydroxide (6 g.) in water (250 ml.) was dissolved 4-(6-isopropyl-4-methyl-1-naphthyl)-4-oxobutyric acid (I) in aqueous sodium hydroxide (20 ml. of 5%) and the mixture was heated at 65°C for 20 min. and then at 100°C under reflux for 20 min. The cooled solution was washed with ether and the aqueous solution was completely freed from ether by heating and then recooled. Acidification of this solution with sulfur dioxide furnished a solid which after recrystallization from benzene, gave 6-isopropyl-4-methyl-1-naphthoic acid (VIII) (470 mg.), m. p. 179.5~181.0°C.

Found: C, 79.05; H, 7.05. Calcd. for $C_{15}H_{16}O_2$: C, 78.92; H, 7.06%.

The naphthoic acid VIII (141 mg.) was methylated with diazomethane in ether. Excess of diazomethane was removed together with ether by evaporation. Residual oily methyl ester dissolved in dry ether was reduced with lithium alminum hydride (40 mg.). Excess of the hydride was decomposed by addition of dilute hydrochloric acid. Recrystallization from petroleum ether gave 1-hydroxymethyl-6-isopropyl-4-methylnaphthalene (IX) (129 mg.) m. p. 52.5~53.5°C.

Found: C, 83.99; H, 8.28. Calcd. for $C_{15}H_{18}O$: C, 84.07; H, 8.47%.

The carbinol IX (129 mg.) and ethanol (120 mg.)

were dissolved together in liquid ammonia (3.5 ml.) and sodium (70 mg.) was added in small pieces with stirring[8]. A deep blue-colored mixture was obtained. Further ethanol was then added, and after the blue color had disappeared most of the ammonia was allowed to evaporate. The residue was cautiously decomposed by addition of dilute hydrochloric acid, and then extracted with ether. The ether extract was washed with water, and dried. Removal of the solvent followed by chromatography on an alumina column yielded 6-isopropyl-1,4-dimethylnaphthalene (62 mg.) which gave a picrate melting at 103.5~105°C (from ethanol). The mixed melting point of the picrate with that of the authentic sample[9] was undepressed and the infrared spectrum was superimposable on that of the authentic picrate.

*The Behavior of Various Inorganic Ions in the Separation of Calcium Carbonate from a Bicarbonate Solution**

By Yasushi KITANO

(Received July 11, 1962)

Calcium carbonate has three different crystal forms: calcite, aragonite and vaterite. Many studies have been made of the conditions under which calcium carbonate is formed in various forms[1-14]. No definite conclusion has yet been reached, however, as to the exactness and the significance of the results.

The factors influencing the mineralogy of carbonate sediments include: (1) the presence of certain inorganic ions, including hydrogen ions, hydroxide ions and carbon dioxide, in the mother solution; (2) the influence of organic material; (3) enzymes (carbonic anhydrase) and bacteria; (4) the mechanical conditions; (5) the temperature, and (6) the transformation of the crystal type after calcium carbonate has been formed.

Experiments on the effects of the materials in the mother solution have been few and inconclusive compared with those on the other factors. The purpose of this study is to cover one phase of this problem: the influence of various inorganic ions on the polymorphic crystallization of calcium carbonate.

In the experiments, calcium carbonate was formed from a calcium bicarbonate solution as carbon dioxide gas escaped. This reaction was used, because it is typical for the formation of calcium carbonate by inorganic processes in the hydrosphere, because it is one of the "homogeneous precipitation" reactions and reproducible precipitation is easily achieved, because no ions other than the calcium, the bicarbonate, and the carbonate ions are present in the mother solution.

Experimental

Materials and Solutions.—The effects of the following alkali and alkaline earth salts (analytical grade reagents) were investigated, since most of them are expected to be found in nature: lithium chloride, sodium chloride, potassium chloride, ammonium chloride, rubidium chloride, cesium chloride, sodium nitrate, sodium sulfate, sodium

bicarbonate, sodium carbonate, sodium hydroxide, magnesium chloride, calcium chloride, strontium chloride, barium chloride, magnesium sulfate, magnesium bicarbonate, strontium bicarbonate and barium bicarbonate.

For the preparation of the bicarbonate solution of alkaline earth elements, the carbonate was pulverized and suspended in distilled water, and then carbon dioxide gas was bubbled through the suspension for approximately one day at room temperature. After having been allowed to stand for 30 min., the suspension was filtered. The filtrate was aerated for another hour with carbon dioxide.

Procedure.—Different amounts (0~6 g.) of the salts were placed in one liter flasks with a small amount of distilled water, and 300 ml. portions of a calcium bicarbonate solution (prepared according to the above procedure) were added to each. The flasks were left to stand at room temperature for two or three weeks, during which time carbon dioxide gas escaped from the solution and calcium carbonate crystals were separated. As the carbon dioxide gas escaped, portions of the supernatant solution were withdrawn to determine the change in the pH value and the decrease in the calcium content. The rate of calcium carbonate precipitation was estimated from these data. Eventually, the remaining precipitate of carbonate was filtered off and washed with distilled water until it was free from any trace of the mother solution. After having been dried in an air bath and ground in an agate mortar, a fraction of the crystals was used for the determination of the chemical composition, while another fraction was used for the identification of the crystal form by X-ray diffraction.

Calcium carbonate was formed at room temperature. The pH value and the calcium content in the mother solution changed during the process of calcium carbonate precipitation; therefore, it is considered that calcium carbonate precipitates were formed from solution of varying pH values and varying calcium concentrations. The author studied whether there was a difference in the polymorphic composition among the calcium carbonate crystals after different lapses of time. Under the given conditions, the difference was not significant.

Results and Discussion

The Effect of Alkali Chlorides.—Table I and Fig. 1 show that alkali chlorides in the mother

solution inhibited the formation of aragonite favored the formation of calcite. Furthermore, Table I shows that alkali chlorides had little influence on the pH value of the mother solution. The extent of the inhibition of the aragonite formation decreased in the sequence: ammonium chloride>lithium chloride, sodium chloride>potassium chloride>rubidium chloride, cesium chloride, (sodium nitrate).

Previous reports[4,8] showed that the presence of alkali chlorides favored aragonite formation. This report, covering a large number of samples in various amounts, shows, in every case, a definite decrease in the percentage of aragonite formation with an increase in the concentration of alkali chloride. The precipitate consisted only of calcium and carbonate.

The Effect of Anions.—Calcium carbonate was formed from the calcium bicarbonate solution containing sodium salt. The crystal form of the calcium carbonate was identified (Fig. 2), and the change in the pH value of the mother solution with time was measured (Fig. 3). The following results were obtained concerning the effect of anions on the crystallization of calcium carbonate:

Sodium Chloride and Nitrate.—The presence of both sodium chloride and sodium nitrate inhibited aragonite formation, although the effect of sodium chloride was stronger than that of sodium nitrate (Fig. 1).

Sodium Bicarbonate and Carbonate.—With a moderate increase in the amount of sodium bicarbonate (sodium carbonate) added to the mother bicarbonate solution, the percentage of aragonite formation increased. With a further increase in amount, however, the percentage began to decrease and reached zero (Fig. 2). The present author has previously joined to show[15] that calcium carbonate was not formed directly from a solution highly concentrated in calcium, bicarbonate or carbonate ions, but that a gelatinous, unstable compound having a

15) Y. Inoue, Y. Kitano and E. Yagyu, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zassi*), **96**, 19 (1955).

definite chemical composition was first formed. Furthermore, the present author[16-17] has reported that the unstable compound was then transformed into a calcium carbonate precipitate, and that with an increase in the concentrations of the calcium ions and the carbonate ions in the original, highly-concentrated solution, the stability of the unstable compound increased; consequently, the rate of calcium carbonate separation decreased. Therefore, one can say that the rate of calcium carbonate separation is moderate when the concentration of calcium ions or carbonate ions is either very high or very low. When calcium carbonate separation is moderate, the most stable form, calcite, is predominant. This finding helps qualitatively to explain the maximum percentage of aragonite formation for a certain value of the added carbonate salt.

Sodium Hydroxide.—When sodium hydroxide was added, only calcite was formed (Fig. 2). Aragonite was never formed from the solution which had been made alkaline (up to a pH value of 10) with sodium hydroxide. It has been reported by many researchers[3,4,8] that aragonite formation was favored in a solution having a pH value of more than 8. However, as can be seen from Figs. 2 and 3, aragonite was not always formed from an alkaline solution; the previous conclusion, therefore, is not always reliable.

The ease of aragonite formation does not seem always to depend upon the pH value, but upon the carbonate ion* content of the mother solution. Since the pH value and the total carbonate content changed with time in the mother solution, the estimation of the carbonate ion content in the mother solution was difficult. A more detailed study is under way on the effect of sodium bicarbonate, sodium carbonate and sodium hydroxide.

Sodium Sulfate.—The presence of sulfate ions favored aragonite formation.

The Effect of Alkaline Earth Salts.—*Magnesium Chloride, Bicarbonate and Sulfate.*—On the basis of the following facts, it can be supposed that the presence of magnesium bicarbonate or magnesium sulfate in the mother solution is more conducive to aragonite formation than is the presence of magnesium chloride. (1) Magnesium ions, bicarbonate ions and sulfate ions favored aragonite formation (Figs. 2 and 4), but chloride ions inhibited aragonite formation (Table I). (2) According to the previous conclusion[3,4], aragonite in general was formed

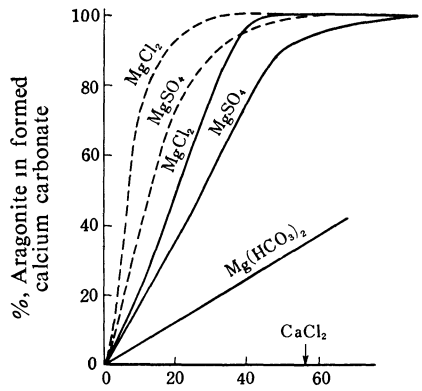

Fig. 4. Effect of calcium and magnesium salts in mother solution on crystal type of formed calcium carbonate.
—— 10±2°C
--- 28±3°C

when the rate of calcium carbonate precipitation was large, while calcite was formed when the rate was small, provided that the mechanism of calcium carbonate formation was similar. It must be noted that the rate was larger in a mother solution containing magnesium bicarbonate than in that containing magnesium chloride (Fig. 5). However, in the experiment, the presence of magnesium chloride in the mother solution was more favorable to aragonite formation than that of magnesium bicarbonate or magnesium sulfate (Fig. 4). The presence of the magnesium salts had little influence on the pH value of the solution. The result shows that the presence of magnesium ions in the mother solution seems to favor aragonite formation very strongly. Working with solutions of a low and a nearly constant ionic strength ($\mu=0.15$), Greenwald[18] concluded that following equilibria exist at 22°C:

$$\frac{M_{Ca^{2+}}\, M_{HCO_3^-}}{M_{CaHCO_3^+}} = K'_{CaHCO_3^+} = 1.6\times10^{-1}$$

$$\frac{M_{Mg^{2+}}\, M_{HCO_3^-}}{M_{MgHCO_3^+}} = K'_{MgHCO_3^+} = 1.7\times10^{-1}$$

$$\frac{M_{Ca^{2+}}\, M_{CO_3^{2-}}}{M_{CaCO_3^0}} = K'_{CaCO_3^0} = 1\times10^{-3}$$

$$\frac{M_{Mg^{2+}}\, M_{CO_3^{2-}}}{M_{MgCO_3^0}} = K'_{MgCO_3^0} = 4.3\times10^{-3}$$

and Garrels[19] concluded $K'_{MgCO_3^0}=4.0\times10^{-4}$.

The concentration of magnesium ions in the mother solution was calculated by the use of

** No vaterite was formed.

the dissociation constants of the complexes, $MgHCO_3^+$ and $CaHCO_3^+$, because the concentration of carbonate ions is very small compared with that of bicarbonate ions at the given pH value; even when the calculated concentration of magnesium ions was the same, aragonite formation was much more favored in the solution containing magnesium chloride than in the solution containing magnesium bicarbonate.

Figure 5 shows the rate constants* in the reaction of calcium carbonate separation from a calcium bicarbonate solution containing various amounts of salts. Magnesium and sodium were not co-precipitated with calcium carbonate (Table II). The presence of magnesium chloride (which aided aragonite formation) lowered the rate of calcium carbonate separation to a greater extent than did sodium chloride (which aided calcite formation).

It must be said that the percentage of aragonite (unstable crystal) formation does not always increase with an increase in the rate of calcium carbonate separation and that the mechanism of the effect of ions in the mother solution upon the polymorphic crystallization is probably be different from ion group to ion

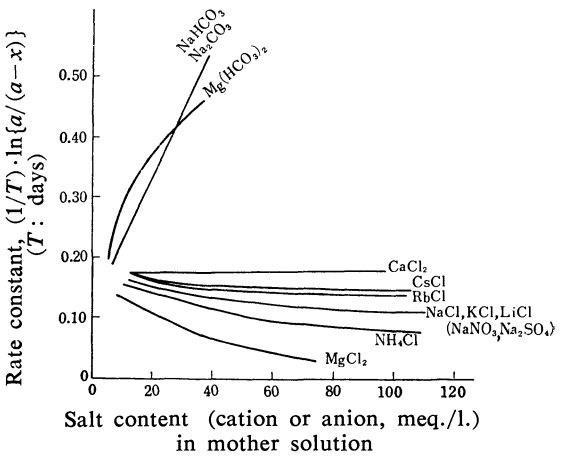

Fig. 5. Rate constant in reaction of calcium carbonate separation from calcium bicarbonate solution containing salt.

group. Work is under way to investigate the mechanisms whereby magnesium chloride favors aragonite formation more than magnesium bicarbonate or magnesium sulfate and whereby magnesium chloride favors aragonite formation while sodium chloride favors calcite formation at room temperature.

Calcium Chloride.—Calcium chloride was added to the mother solution to accelerate calcium carbonate precipitation; its addition did not aid aragonite formation (Fig. 4).

Strontium Chloride and Bicarbonate.—The significant behavior of strontium ions in the

* The decrease in the calcium content of the mother solution was measured during the process of calcium carbonate precipitation. On the basis of the measurements, the rate constant, $(1/T)\cdot\ln\{a/(a-x)\}$, of the first order reaction, and the constant, $[1/2T]\cdot[1/(a-x)^2-1/a^2]$, of the third order reaction were calculated. Judging from these calculations, the reaction seemed to be a first order reaction; therefore, in Fig. 5, the rate constants of the first order reaction are given.

separation of calcite or aragonite has been clarified previously[5]: (1) With an increase in the amount of strontium bicarbonate added to the original calcium bicarbonate solution, the percentage of aragonite formation increased to a maximum (optimum strontium content: approximately 2 mg./l.). The percentage began to decrease with a further increase in the strontium concentration (Fig. 6). When strontium chloride was added to the mother solution, aragonite formation was inhibited. (2) The strontium was always entrained in the calcium carbonate precipitate, even when the strontium concentration in the mother solution was very low.

Barium Chloride and Bicarbonate.—Calcium carbonate was formed from the calcium bicarbonate solution containing barium bicarbonate or barium chloride; it was also formed from the calcium bicarbonate solution containing magnesium chloride and barium bicarbonate or barium chloride (Table III and Fig. 7), judging from the fact that calcium carbonate consisting of increasing percentages of aragonite could be obtained from calcium bicarbonate solutions containing increasing amounts of magnesium chloride (Fig. 3). Table III shows the barium content in the carbonate prepared. The barium content was obtained by first adding different amounts of barium ions labeled with ^{140}Ba to the mother bicarbonate solutions. Measured volumes of the original solution, and of the residual solution from which the calcium carbonate crystals had been collected, were dried in planchets. The radioactivities of the two samples were measured at the same time, sixteen days after the residual solution had been dried. The ratio of the distribution of barium between the precipitate and the residual solution was calculated. From this ratio, the

original and the residual calcium content and the original barium content in the solution, the barium content of the precipitated carbonate was calculated.

The behavior of barium ions in the separation of calcium carbonate from a bicarbonate solution has been clarified. (1) Contrary to previous findings[4,9,14] that the presence of a small number of barium ions in the mother solution favored aragonite formation, the presence of barium ions favored calcite formation (Table III, and Fig. 7). (2) The presence of a large amount of barium ions favored vaterite formation[2] (Table III). (3) Even at a low concentration in the mother solution, barium was always entrapped in the precipitates (Table III). The behavior of barium ions did not follow the law of solubility. (4) With an increase in the barium concentration of the mother solution, the amount of barium entrapped in the calcium carbonate increased and the specific peak for calcite configuration became diffuse when measured with an X-ray diffractometer. Therefore, it can be expected that barium is present in calcium carbonate as a form of $(Ca, Ba)CO_3$. As can be seen from Table III, the amount of entrapped barium in calcium carbonate increased with an increase in the magnesium chloride concentration of the mother solution. The presence of the barium salts had little influence on the pH value of the solution.

Summary

The author has shown the effect of various inorganic ions on the polymorphic crystallization of calcium carbonate from a bicarbonate solution. No definite conclusion regarding the mechanism to give calcite, aragonite or vaterite can yet be made, but these data help to give a pattern of the influence of inorganic ionic species and the concentration of the mother solution on the polymorphic crystallization of calcium carbonate.

(1) Alkali chlorides in the mother solution inhibited aragonite formation and favored calcite formation. The extent of the inhibition of the aragonite formation decreases in the sequence: ammonium chloride>lithium chloride, sodium chloride>potassium chloride >rubidium chloride, >cesium chloride (sodium nitrate).

(2) (a) Sodium chloride and sodium nitrate in the mother solution inhibited aragonite formation, sodium chloride more strongly than sodium nitrate. (b) With a moderate increase in the amount of sodium bicarbonate (sodium carbonate) added to the mother solution, the percentage of aragonite formation increased to a maximum. With a further increase in the amount, however, the percentage began to decrease and reached zero. (c) When sodium hydroxide was added to the mother solution, only calcite was formed. Aragonite was never formed from the solution which had made alkaline with sodium hydroxide. (d) The presence of sulfate ions favored aragonite formation.

(3) (a) Magnesium ions in the mother solution favored aragonite formation very strongly. The presence of magnesium chloride in the mother solution was more favorable to aragonite formation than that of magnesium bicarbonate or magnesium sulfate. Magnesium was not co-precipitated with calcium carbonate. (b) The presence of calcium chloride in the mother solution had no effect on the crystallization. (c) With an increase in the strontium concentration in the original solution, the percentage of aragonite formation increased to a maximum (optimum strontium content: approximately 2 mg./l.). The percentage began to decrease with a further increase in strontium

concentration. The strontium was always entrained in calcium carbonate precipitates, even when the strontium concentration was very low. (d) The presence of a small number of barium ions in the mother solution favored calcite formation. The presence of a large number of barium ions favored vaterite formation. Even at a low concentration in the mother solution, barium was always entrapped in the precipitates.

The author wishes to express his deep appreciation to Mrs. Nobuko Kanamori of Nagoya University for her help in the experiment on the behavior of barium, and to Professor Donald W. Hood, Mr. Edward R. Ibert and Miss. Lela M. Jeffery of Texas A & M College and Professor Ken Sugawara of Nagoya University for their encouragement throughout this work.

A Study of the Polymorphic Formation of Calcium Carbonate in Thermal Springs with an Emphasis on the Effect of Temperature

By Yasushi KITANO

(Received July 16, 1962)

The conditions which determine the polymorphic crystallization of calcium carbonate have been discussed by many researchers[1-9]; however, many questions still remain unsolved. The temperature of the mother solution should be considered as one of the most important factors controlling the polymorphic formation. It has been reported that aragonite was formed easily from a solution at a temperature above 50°C, but this conclusion is not always reliable[3]. In the following discussion of the conditions of the polymorphic formation of calcium carbonate, the combined effect of the temperature and of the materials in the mother solution is examined. The author has attempted to show this combined effect on the formation of the various crystal forms of calcium carbonate in the thermal springs of Japan, such springs being typical areas of calcium carbonate deposition.

Crystal Forms of Calcium Carbonate Deposited in Thermal Springs of Japan.—Table I shows the chemical constituents of the thermal spring waters in Japan from which calcium carbonate deposits have been formed and the crystal forms of this calcium carbonate. Related articles have showen that the presence of sodium chloride, magnesium chloride and carbon dioxide in the mother solution greatly affects the polymorphic crystallization of calcium carbonate[10,11]. On the basis of their sodium, magnesium and chloride ion content, the spring waters are classified in two typical groups, A and B, as is shown in Table I.

Experimental and Results

When thermal waters come to the surface of the earth, they are subjected to a sudden environmental change, exposure to the air at an atmospheric pressure. Then, on the one hand, carbon dioxide gas escapes from the water to precipitate calcium carbonate, and on the other, some of the ferrous and manganous ions begin to be oxidized by the air.

Calcium carbonate is formed in thermal springs according to the following reaction : $Ca^{2+}+2HCO_3^- \rightarrow CaCO_3+CO_2+H_2O$. Therefore, the effect of temperature upon the polymorphic formation of calcium carbonate formed from a calcium bicarbonate solution has been studied in the laboratory. For the preparation of the calcium bicarbonate solution,

Group B: NaCl, 5 g./l.; $MgCl_2$, 0.07 g./l.

carbon dioxide gas was bubbled into a suspension of 40 g. of calcium carbonate in 20 l. of distilled water for 48 hr. at room temperature and filtered (Whatman No. 3 filter paper); and then carbon dioxide gas was bubbled again into the filtrate for 2 hr. The calcium content was 300 mg. per liter. The bicarbonate solution prepared at room temperature was used throughout the present experiments. When the solution was left to stand at various temperatures, carbon dioxide gas escaped from the solution and calcium carbonate crystals appeared; even when carbon dioxide gas was passed continuously through the bicarbonate solution at high temperatures, calcium carbonate was precipitated because of the decrease in the solubilities of carbon dioxide and calcium carbonate with the increase in the temperature of the solution.

Experiment A.—Calcium carbonate was precipitated from the calcium bicarbonate solution in order to examine the effect of temperature change.

1) A 300 ml. portion of the bicarbonate solution was allowed to stand (20 min. to 3 weeks) at varying temperatures, with occasional stirring so that carbon dioxide gas escaped from the solution and calcium carbonate crystals appeared. The crystals were filtered off and washed several times with distilled water. After the crystals had been dried in an air bath and ground in an agate mortar, their crystal forms were identified by the use of an X-ray diffractometer (Fig. 1). At temperatures below 25°C, only calcite was formed. At around 30°C, both calcite and aragonite were formed, but no vaterite was. Between 40 and 60°C, all three forms were formed, but the proportion of calcite was small. At around 40°C the proportion of vaterite was large. With a rise in the temperature, the proportion of aragonite increased, and at around 60°C aragonite predominated. Between 70 and 90°C, only aragonite was formed. At the boiling point, aragonite predominated, but a small amount of vaterite was formed.

2) Calcium carbonate was formed from 300 ml. of the calcium bicarbonate solution through which carbon dioxide gas was bubbled continuously at high temperatures. The carbon dioxide content controls the pH value of the solution, and the pH value is an important factor in determining the crystal form of the resulting calcium carbonate. The experiments were conducted at various temperatures above 70°C because at lower temperatures the formation of calcium carbonate was difficult from the solution bubbled with carbon dioxide gas. When calcium carbonate was formed from the solution bubbled with carbon dioxide gas, even at a high temperature, calcite and vaterite were formed with aragonite, as is shown in Fig. 2. With a rise in the temperature, the formation of aragonite increased.

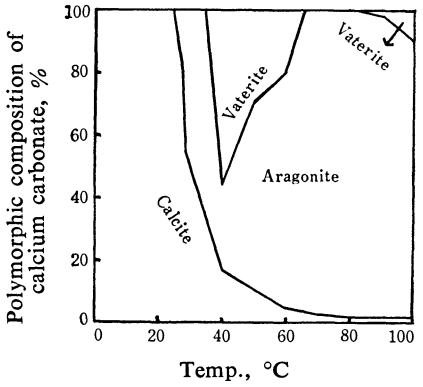

Fig. 1. Polymorphic composition of calcium carbonate formed from calcium bicarbonate solution at various temperatures.

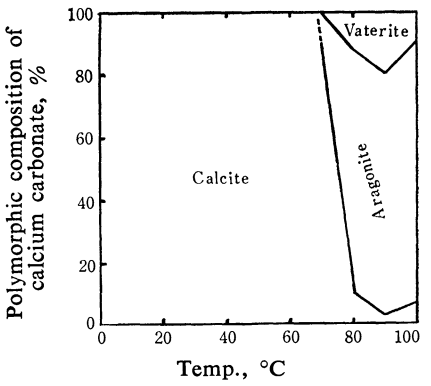

Fig. 2. Polymorphic composition of calcium carbonate formed from calcium bicarbonate solution bubbled with carbon dioxide gas at various temperatures.

Experiment B.—Calcium carbonate was precipitated from 300 ml. of the calcium bicarbonate solution containing sodium chloride and/or magnesium chloride, in order to investigate the effect of these salts on the polymorphic formation of calcium carbonate.

1) Sodium Chloride.—a) Calcium carbonate was formed as in Experiment A-1 from the calcium bicarbonate solution containing various amounts of sodium chloride (Table II). With an increase in the temperature and in the concentration of sodium chloride in the solution, the proportion of vaterite increased. At the boiling point, vaterite predominated. From Fig. 1 and Table II, it can be concluded that the presence of sodium chloride favors the formation of vaterite at a high temperature, while it favors calcite formation at a low temperature[10]. b) When calcium carbonate was formed from the solution containing sodium chloride and bubbled with carbon dioxide gas, only calcite was formed (Table II).

2) Magnesium Chloride.—a) Calcium carbonate was formed from the calcium bicarbonate solution containing various amounts of magnesium chloride according to the same procedure as in Experiment A-1 (Table III). Table III and Fig. 1 indicate that the presence of magnesium chloride in the solution favored aragonite formation and hindered vaterite formation. b) When calcium carbonate was formed from the solution containing magnesium chloride and bubbled with carbon dioxide gas continuously, only calcite was formed (Table III).

the crystal forms was dependent upon the magnesium chloride content (Fig. 3, Tables II and III). When calcium carbonate was formed from the calcium bicarbonate solution containing both sodium chloride (5 g./l.) and magnesium chloride (0.07 g./l.) (group B in Table I), vaterite was always

TABLE IV. CRYSTAL FORMS OF CALCIUM CARBONATE IN FUTAMATA THERMAL SPRINGS

Station No.	Distance from orifice to station, m.	Water		Crystal forms of $CaCO_3$		
		Temp. °C	pH	Vaterite %	Calcite %	Aragonite %
1	0	42	6.6	0	100	0
2	15	38	7.0	0	95~90	5~10
3	40	27	7.3	0	80~35	20~65

formed (Fig. 4). At a temperature above 50°C the proportion of calcite was very small, at below 70°C aragonite predominated, and at above 70°C vaterite predominated and its proportion increased with a rise in the temperature. Apparently the magnesium chloride content in the solution was too small to affect the polymorphic formation of calcium carbonate, so that the composition of the crystal forms of calcium carbonate was dependent upon the sodium chloride content (Fig. 4, Tables II and III).

b) When calcium carbonate was formed from the calcium bicarbonate solution containing sodium chloride and magnesium chloride and bubbled with carbon dioxide gas continuously during the formation of the calcium carbonate, only calcite was formed, even at a high temperature.

Discussion

Calcium carbonate formed in the laboratory from the calcium bicarbonate solution bubbled with carbon dioxide gas continuously during the formation of calcium carbonate is comparable to calcium carbonate deposited in the original orifice of thermal spring waters where carbon dioxide gas gushes forth, while calcium carbonate formed from the solution without aeration of carbon dioxide gas is comparable to calcium carbonate deposited with the escape of carbon dioxide gas from spring waters during the flow.

The following facts were observed in thermal springs:

1) When the temperature of thermal spring waters was very high, aragonite was usually formed (Table I). Futamata spring waters were made to flow through an open wooden conduit from the orifice to a bath[12,13]. As carbon dioxide gas escaped from the waters, calcium carbonate was deposited. The crystals of calcium carbonate formed at various locations in the flow were sampled and their crystal forms were identified (Table IV). The data indicate that calcite was formed readily at the original location of thermal springs despite a high temperature, where carbon dioxide gas was supplied to the water. Aragonite was formed at a location where carbon dioxide gas was not supplied, despite a low temperature. These observations were supported by the experimental results in the laboratory (Fig. 2, Tables II and III, Experiment B-3-b). The content of carbon dioxide controls the pH value of the solution. The solution bubbled with carbon dioxide gas is acid. It can be said that even at a high temperature calcite was formed from the solution containing carbon dioxide, sodium chloride and/or magnesium chloride, in other words, from an acid solution. This appears to be attributable to the facts that the solubility of calcium carbonate is very large in the acidic solution containing carbon dioxide, sodium chloride and/or magnesium chloride[14] and that the rate of the calcium carbonate formation is very small, because calcite (a stable crystal) is formed easily when the rate of calcium carbonate formation is very small. It can also be said that, even at a low temperature, aragonite is formed from the basic solution which does not contain a large amount of carbon dioxide.

2) Calcite was formed from Futamata spring waters running still, while aragonite was formed when the same waters struck a rock so strongly that carbon dioxide gas escaped rapidly; calcium carbonate was also formed rapidly. In the laboratory, calcite was formed from Futamata water which was kept still so that carbon dioxide gas could gradually escape from the water with a slow separation of calcium carbonate crystals, at 30 and 35°C; a mixture of calcite and aragonite was formed from the same Futamata water which was repeatedly stirred, whereby the escape of the carbon dioxide gas and calcium carbonate formation were accelerated, at the same temperatures, 30 and 35°C. The result makes it possible to conclude that, in waters with the same chemical constituents, pH value, and temperature, with an increase in the rate of carbon dioxide gas escape from the waters and in the rate of calcium carbonate formation, the proportion of aragonite (an unstable crystal) increases and that of calcite (a stable crystal) decreases.

3) Vaterite has not been found in thermal

springs. On the basis of the laboratory results, possible explanations for this are: a) The spring waters contain a rather large amount of magnesium chloride (Tables II and III, Fig. 3), or calcium carbonate is formed near the orifice where carbon dioxide gas is supplied (Fig. 2, Tables II and III, Experiment B-3-b). b) When vaterite is formed, it changes to calcite or aragonite because of its high instability in a solution. It seems probable, however, that vaterite can be found in thermal springs when calcium carbonate is formed at a high temperature from the waters of group B in Table I (NaCl 5 g./l., $MgCl_2$ 0.07 g./l.), at a location where carbon dioxide gas is not supplied to the waters (Fig. 4).

4) The mechanical and physical conditions and the minor elements in the waters have an influence on the polymorphic formation of calcium carbonate in thermal springs. Aragonite was found in precipitates which were floating on the surface of the waters, but it was not found in precipitates deposited on the wall or on the bottom in the same waters[3]. In addition, strontium ions[7,10,15] and barium ions[10] are minor elements affecting the polymorphic formation. The presence of strontium ions favored aragonite formation and that of barium ions favored calcite formation, but the effects of these factors are less significant than those of carbon dioxide (pH), sodium ions, magnesium ions, and chloride ions and the temperature of the mother solution.

Summary

1) When calcium carbonate was formed in the laboratory from the calcium bicarbonate solution through which carbon dioxide gas had not been bubbled during the process of the calcium carbonate formation: a) Only calcite was formed at a temperature below 25°C; aragonite was formed above 25°C, and vaterite was formed above 40°C. Between 40 and 60°C a large amount of vaterite was formed. With a rise in the temperature of the mother solution, the proportion of calcite decreased. b) Vaterite was easily formed from the calcium bicarbonate solution containing sodium chloride at a high temperature. With an increase in the temperature and in sodium chloride concentration, the proportion of vaterite increased. c) With an increase in both temperature and magnesium chloride concentration, the proportion of aragonite increased but that of calcite decreased. The presence of magnesium chloride in the mother solution hindered the formation of vaterite.

2) When calcium carbonate was formed in the laboratory from the calcium bicarbonate solution containing sodium chloride (or magnesium chloride) and bubbled with carbon dioxide gas continuously during the calcium carbonate formation, only calcite was formed despite a high temperature.

3) When calcium carbonate was deposited in thermal spring waters of a high temperature, aragonite was formed. However, from the waters into which carbon dioxide gas was supplied, in other words, from the acidic solution, calcite was formed despite a high temperature, and aragonite was formed from the waters to which carbon dioxide was not supplied, in other words, from the basic waters, despite a low temperature.

4) Up to the present time, vaterite has not been found in the deposits of thermal springs because: a) Calcium carbonate deposits of thermal springs were either formed at a location where carbon dioxide gas was supplied to the mother waters or where the concentration of magnesium ions in the waters was rather high, or b) even if vaterite had been formed, it would have changed to calcite or aragonite very quickly because of its low stability in solution.

5) In spring waters with the same chemical constituents, pH value, and temperature, the proportion of aragonite increased and that of calcite decreased with an increase in the rate of carbon dioxide gas escape from the waters and in the rate of calcium carbonate formation.

6) Aragonite was readily found in calcium carbonate precipitates formed floating on the surface of thermal spring waters, but it was not likely to be found in the precipitates deposited on the wall or bottom in the same waters.

The polymorphic formation of calcium carbonate formed in thermal springs depends mainly on the temperature, the concentrations of sodium ions, magnesium ions and carbon dioxide (pH) in the waters, and on the rate of calcium carbonate formation when calcium carbonate is formed from a similar water.

The author wishes to express his deep appreciation to Professor Ken Sugawara of Nagoya University and to Professor Donald W. Hood and Mr. Edward R. Ibert of Texas A & M College for their encouragement throughout this work.

The Acid-Catalyzed Isomerization of Cyclohexyl Phenyl Ketoxime in Liquid Sulfur Dioxide[1]

By Niichiro TOKURA, Katsuo SHIINA and Tetsuo TERASHIMA

(Received July 18, 1962)

It has been previously demonstrated that the Beckmann rearrangement of a geometrical isomer of a ketoxime in liquid sulfur dioxide at −70°C results in the trans-migrated products exclusively[2]. Although the slow syn-anti isomerization of the ketoxime in liquid sulfur dioxide has also been observed in the same medium, the rate of the Beckmann rearrangement has been too fast to be competitive against the rate of the isomerization[2]. According to Tokura and Shiina[3], the sulfur dioxide-catalyzed isomerization is accelerated by light and retarded by hydroquinone, and the rate is of the first order with respect to the concentration of the oxime.

Since the isomerization of the oxime may also be undertaken by an acid and since such an acid may often be present in the medium by the decomposition of the Lewis acid (the reagent of the Beckmann rearrngement) with a trace of water in liquid sulfur dioxide, the acid-catalyzed isomerization of β-cyclohexyl phenyl ketoxime has been carried out in order to obtain further information about the competition of the isomerization versus the Beckmann rearrangement. Such hydrohalogenic acids as hydrochloric acid, hydrobromic acid and hydroiodic acid have been used as the catalyst.

The acid-catalyzed isomerization experiment has been preceded by an NMR spectrometry to confirm the intrinsic structures of the respective geometrical isomers, the α- and the β-ketoxime, since the previous establishment of the structures of the ketoximes has only been proved by the results of the Beckmann rearrangement[2]. The experience of Lustig[4] has also prompted the present writers to this procedure.

Experimental

Materials. — β-Cyclohexyl phenyl ketoxime was prepared and separated as described in a preceding paper[2]. Commercial sulfur dioxide was dehydrated with phosphorus pentoxide and distilled. The hydrogen halogenide (Cl, Br or I) solution of liquid sulfur dioxide was prepared by passing a dry hydrogen halide gas into liquid sulfur dioxide cooled to −70°C. From the increase in the weight and by volumetric analysis, the strength of the acid was determined. An acid solution of liquid sulfur dioxide of a definite concentration was prepared by adding liquid sulfur dioxide to this parent mixture. The DCl solution of liquid sulfur dioxide was prepared by the following reaction in liquid sulfur dioxide:

$$SOCl_2 + D_2O \rightarrow 2DCl + SO_2$$

Method of Analysis. — The analysis of the α-oxime produced and of the unchanged β-oxime was made by infrared spectroscopy using a Perkin-Elmar model 21 doule-beam spectrophotometer[3]. The specimen in carbon disulfide was analyzed at the absorption maxima, with 762 and 957 cm^{-1} as key bands. The contents of the oximes were calculated by the following equations:

$$E_m^{762} = C_\alpha E_\alpha^{762} + C_\beta E_\beta^{762} \quad (1)$$

$$E_m^{957} = C_\alpha E_\alpha^{957} + C_\beta E_\beta^{957} \quad (2)$$

where E_α^{762}, E_β^{762}, E_α^{957} and E_β^{957} are the molar absorption coefficients of α- and β-oxime at 762 and 957 cm^{-1} respectively, E_m^{762} and E_m^{957} are those of the sample for analysis, and C_α and C_β are the content of the α- and β-oximes in the sample.

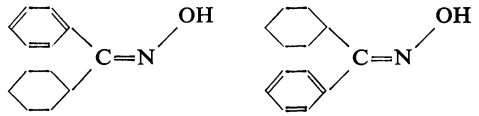
1) The Beckmann Rearrangement in Liquid Sulfur Dioxide. Part XI.
2) R. Tada, Y. Masubuchi and N. Tokura, This Bulletin 34, 209 (1961).
3) N. Tokura and K. Shiina, ibid.. 35, 1779 (1962).
4) E. Lustig, *J. Phys. Chem*, 65, 491 (1961).



Beer's law was obeyed throughout this experiment, and the range of experimental error was within three percent.

Kinetic Procedure. — The β-oxime was dissolved into a sulfur dioxide solution of an acid at −70°C to make a 50 ml. solution of the reaction mixture. The mixture was then placed in a thermostat. A 10 ml. aliquot was taken off after a definite time interval, and the mixture was mixed with ice water, neutralyzed with ammonia water, and filtered. The precipitate was well rinsed with water, dried in vacuo, and analyzed for the oxime content. A typical run is listed in Table I. No symptom of the Beckmann rearrangement was observed during the course of the isomerization experiment.

NMR Spectrometer.—A Varian Associates' type V-4300B (60 Mc.) was used.

Results and Discussion

NMR Spectrometry of the Geometrical Isomers.—The geometrical structures of the cyclohexyl phenyl ketoximes were assigned as below in a previous paper[2], the hydroxyl group in the α-oxime being syn-positioned to the phenyl groups. If the Beckmann rearrangement in liquid sulfur dioxide should take place in the migration of the group trans to the hydroxyl group, such a conclusion must be accepted. Moreover, no contamination by another acidamide which might be derivable by a competitive isomerization of the ketoxime was observed.

α-Oxime β-Oxime

However, Lustig[4] has recently disclosed that the assignments of the isomeric ketoximes by the Beckmann rearrangement are not always safe since the oximes considered as single materials were often found by the NMR spectrometry to be contaminated by another isomers. Since no contamination of acidamides other than the authentic trans-migrated product was seen after the rearrangement in liquid sulfur dioxide, and since the oximes afforded only the corresponding acidamides, which were proved to be the proper (trans-migrated) ones[2], further examination into the purity of the respective oximes may not be needed.

An NMR study of the α- and β-oximes was undertaken in order to confirm the previous assignments for the geometrical structures of the respective oximes; the results are listed in Table II.

As is seen in Table II, the Tau values assigned for the cyclohexyl and phenyl groups coincide well with the literature values[5] of cyclohexane and benzene, 8.564 and 2.734 respectively.

Table II. NMR chemical shift of α- and β-ketoximes

Assigned	Oxime α	Oxime β
in CCl_4 in Tau value (T.M.S. as reference)		
Cyclohexyl	8.76	8.76
	8.27	8.27
Phenyl	2.91	2.90
=N-O-H	1.04	1.37
in Dioxane in c. p. s.		
Cyclohexyl	−2.28	−2.26
	−2.21	−2.21
	−1.81	−1.91
Phenyl	+3.72	+3.70
=N-O-H	+5.48	+5.95

The NMR spectrum of the hydroxyl proton of the α-oxime always shifts to a lower field than that of the β-oxime. This may be interpreted as being caused by the interaction of the hydroxyl proton with the benzene ring. In addition, no anisotropic effect may be anticipated from the Fischer-Hilschfelder model of the oxime. Moreover, our calculation, by the method of Johnson and Bovey[6], of the difference in the shifts between the two ketoximes on the hydroxyl proton, the results of which will be published elswhere in the near future, supports the above explanation.

Effect of Temperature.—The reaction rate of the acid-catalyzed isomerization was a faster reaction than the isomerization by sulfur dioxide itself. The concentrations of the β-oxime and of hydrochloric acid were 0.05 M/l.

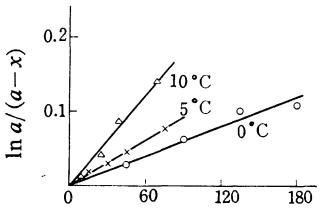


Fig. 1

Table III. Rate constant k, for $R=k$[oxime]

Temp., °C	$k\times10^5$ sec^{-1}
0	1.36
5	1.87
10	3.44

6) C. E. Johnston, Jr. and F. A. Bovey, *J. Chem. Phys.*, **29**, 1012 (1958).

and 0.15 M/l. respectively. The order of the reaction is of the first order with respect to the concentration of the oxime, as may be seen in the $\ln a/(a-x)$ vs. time plots at 0, 5 and 10°C in Fig. 1. The rate constant k and the Arrhenius parameters calculated are listed in Table III.

Effect of Light. — The isomerization of the ketoxime in liquid sulfur dioxide has been reported to be effected by diffused daylight in the room[2]. In the acid-catalyzed isomerization, the reaction in diffused daylight was compared with the reaction in the dark. (Table IV)

TABLE IV. EFFECT OE DIFFUSED DAYLIGHT ON ACID-CATALYZED ISOMERIZATION

[oxime] = 0.05 M/l. ; [HCl] = 0.15 M/l. Temp. 10°C

k(dark) $= 3.20 \times 10^{-5}$ sec^{-1}

k $= 3.44 \times 10^{-5}$ sec^{-1}

where, k (dark) and k are the constants in the dark and in diffused room daylight respectively.

The reaction was slightly accelerated by daylight, but the effect was not significant.

Effect of Salts and Deuteriochloric Acid. — Tetraethylammonium halides, $(C_2H_5)_4NX$, X = Cl, Br or I, were used as the salts. The salt, 0.005 M/l., was added to the reaction mixture. Table V lists the results. The results of Table V agree with the general trend of ionic catalysis. The depression of the rate by the addition of the chloride may be explained by a mass law effect, while the increase of the rate by the bromide and iodide may be due to the ionic strength effect[7].

TABLE V. THE EFFECT OF SALT ON THE HCl-CATALYZED ISOMERIZATION

[oxime] = 0.05 M/l., [HCl] = 0.15 M/l. Temp. 0°C

Salt, $(C_2H_5)_4NX$ salt	$k \times 10^5$ sec^{-1}
None	1.36
X=Cl	1.07
Br	1.95
I	2.04

The isomerization experiment using DCl as the catalyst resulted in the isotope effect;

$$k_{HCl}/k_{DCl} = 1.21 \quad (\text{at } 30°C)$$

Both the salt and isotope effect suggest the importance of the dissociation equilibrium of the acid catalyst in liquid sulfur dioxide.

Acid-Catalyzed Reaction with Hydrogen Bromide or Hydrogen Iodide. — Neither hydrogen bromide nor hydrogen iodide has had any reproducible effect on the isomerization. In both cases the color of the reaction mixture gradually changed to a yellowish red, suggesting the slow decomposition of the reagent in liquid sulfur dioxide. The gradual decomposition of hydrogen iodide to iodine in liquid sulfur dioxide has already been noticed by Steele and Bagster[8]. Moreover, the result may have been complicated also by an accompanying Beckmann rearrangement if the bromine or iodine produced was present[9].

The Effect of the Concentration of Hydrogen Chloride.—No symptom of the Beckmann rearrangement was observed by hydrogen chloride in liquid sulfur dioxide. The reason for this has been discussed in a preceding paper[10]. The isomerization reaction was carried out at various concentrations of [HCl], 0.05, 0.15 and 0.27 M/l., with [oxime], 0.05 M/l. at 0°C.

From the log-log plot of the initial rate, R, and the concentration of hydrogen chloride, [HCl], the order of the [HCl] is obtained as 1.43 (approximately 1.5) (Fig. 2). Because the linear plot of $\log R$ vs. log[HCl] does not pass through the origin and because the simultaneous catalysis by sulfur dioxide itself must be considered, the overall rate expression may be as follows:

$$R = A + k_{HCl}[\text{oxime}] \cdot [\text{HCl}]^{1.5} \qquad (3)$$

where k_{HCl} is the rate constant catalyzed by hydrogen chloride and A is the rate when [HCl] = 0, i. e., the rate of the isomerization by liquid sulfur dioxide itself, as has been reported in a previous paper[2]. Judging from previous results[2].

$$A = k_{SO_2}[\text{oxime}] \qquad (4)$$

Therefore,

$$R = k_{SO_2}[\text{oxime}] + k_{HCl}[\text{oxime}] \cdot [\text{HCl}]^{1.5} \qquad (5)$$

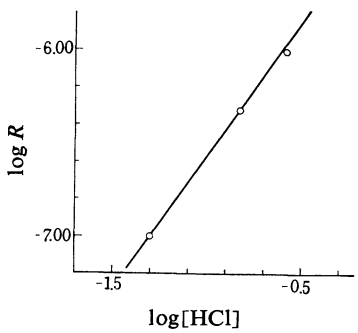

Fig. 2. Plot of $\log R$ vs. log[HCl].

8) B. D. Steele and L. S. Bagster, *J. Chem. Soc.*, **97**, 2607 (1910).

9) N. Tokura, R. Asami and R. Tada, *J. Am. Chem. Soc.*, **79**, 3135 (1957).

10) N. Tokura, R. Tada and K. Yokoyama, This Bulletin, **34**, 1812 (1961).

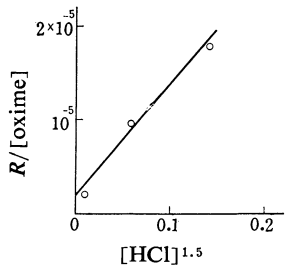

Fig. 3

Eq. 5 is transformed to 6 by dividing it with [oxime]:

$$R/[\text{oxime}] = k_{SO_2} + k_{HCl}[HCl]^{1.5} \quad (6)$$

From the linear plot of $R/[\text{oxime}]$ vs. $[HCl]^{1.5}$, as shown in Fig. 3, k_{SO_2} and k_{HCl} are obtained from the intercept and the slope of the plot as:

$$k_{SO_2} = 0.23 \times 10^{-5}\ \text{sec}^{-1}$$

$$k_{HCl} = 1.04 \times 10^{-4}\ \text{l}^{1.5}\,\text{mol}^{-1.5}\,\text{sec}^{-1}$$

The value of k_{SO_2} agrees well with the rate constant of the liquid sulfur dioxide-catalyzed isomerization (0.65×10^{-5})[2] in its order, when the accuracy of the treatment is considered. Although the rate as catalyzed by hydrogen chloride is over three times as fast as the rate by sulfur dioxide, yet the order of both rates is of $10^{-4}-10^{-5}$. When the β-oxime, [oxime] $=5.0 \times 10^{-2}$ M/l., was subject to the Beckmann rearrangement in liquid sulfur dioxide with thionyl chloride, $[SOCl_2] = 5.0 \times 10^{-2}$ M/l., the reaction was completed within 5 and 3 min. at 0 and -75°C respectively, the rate being so fast that no accurate kinetic measurement was possible[2].

A discussion should be added on the reason of the order of hydrogen chloride, 1.5, in rate expression 5. For the mechanism of the acid-catalyzed isomerization, the following scheme may be considered:

$$HCl \underset{K_{HCl}}{\rightleftharpoons} H^+ + Cl^- \quad (7)$$

$$\begin{matrix} R \\ R' \end{matrix}\!\!>\!C{=}N\!-\!OH + H^+ \xrightarrow[k_H]{} \left[\begin{matrix} R \\ R' \end{matrix}\!\!>\!C{=}\overset{+}{N}\!<\!\begin{matrix} OH \\ H \end{matrix}\right]$$

$$\longrightarrow \begin{matrix} R \\ R' \end{matrix}\!\!>\!\overset{+}{C}\!-\!N\!<\!\begin{matrix} OH \\ H \end{matrix} \quad (8)$$

$$\begin{matrix} R \\ R' \end{matrix}\!\!>\!\overset{+}{C}\!-\!N\!<\!\begin{matrix} OH \\ H \end{matrix} \xrightarrow[k]{\text{R.D.}} \begin{matrix} R' \\ R \end{matrix}\!\!>\!\overset{+}{C}\!-\!N\!<\!\begin{matrix} OH \\ H \end{matrix} \quad (9)$$

$$\begin{matrix} R' \\ R \end{matrix}\!\!>\!\overset{+}{C}\!-\!N\!<\!\begin{matrix} OH \\ H \end{matrix} \longrightarrow \begin{matrix} R' \\ R \end{matrix}\!\!>\!C{=}N\!-\!OH + H^+ \quad (10)$$

If Eq. 9 is selected as the rate-determining step, the rate expression is found to be:

$$R = k\left[\begin{matrix} R \\ R' \end{matrix}\!\!>\!\overset{+}{C}\!-\!N\!<\!\begin{matrix} OH \\ H \end{matrix}\right] = k \cdot k_H[\text{oxime}] \cdot [H^+]$$

$$= k \cdot k_H \cdot K_{HCl}^{0.5}[\text{oxime}] \cdot [HCl]^{0.5}$$

$$= k'[\text{oxime}][HCl]^{0.5} \quad (11)$$

when the value of K_{HCl} is very small. Thus, in the above scheme the order of hydrogen should be 0.5, whereas in reality the order is 1.5 in this experiment.

In such a non-aqueous solvent as sulfur dioxide, the association of ion pairs is a phenomenon of considerable importance. If the three associated molar hydrochloric acids could give one set of cations and anions, and if the cation could behave as the catalyst for the oxime isomerization, the order for hydrogen chloride, 1.5 may be derived; however, the kinetics can give no detailed information on the nature of the active species for the isomerization. The following dissociation equilibria may be considered as examples:

$$3\,HCl \rightleftharpoons H^+ + (HCl)_2 \cdot Cl^-$$

$$3\,HCl \rightleftharpoons HCl \cdot H^+ + Cl \cdot HCl^-$$

In conclusion, sulfur dioxide-catalyzed or acid catalyzed-isomerization is not competitive against the Beckmann rearrangement of the oxime in liquid sulfur dioxide.

Summary

1. The hydrochloric acid-catalyzed isomerization of β-cyclohexyl phenyl ketoxime has been carried out in liquid sulfur dioxide. The effects of temperature, light, deuterium chloride and the concentrations of hydrogen chloride have been examined.

2. The overall rate may be expressed as;

$$R = k_{SO_2}[\text{oxime}] + k_{HCl}[\text{oxime}] \cdot [HCl]^{1.5}$$

and the k_{SO_2} and the k_{HCl} have been estimated. The reason for the order of hydrogen chloride, 1.5 has also been discussed.

The present authors would like to express their appreciation to Professor G. Hazato and Mr. K. Takahashi for their NMR spectrometry. The authors are also indebted to the Seitetsu Kagaku K. K., Ltd., for its donation of liquid sulfur dioxide.

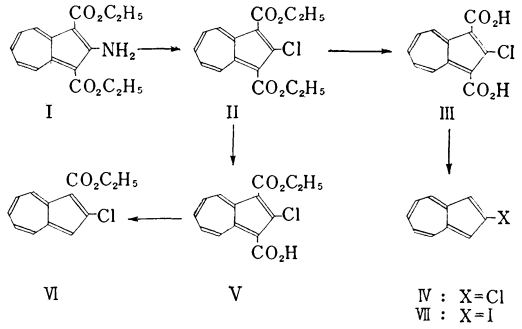
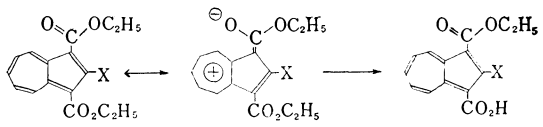
*Synthesis of 2-Substituted Azulenes by Nucleophilic Substitution Reactions of 2-Haloazulene Derivatives**



By Tetsuo NOZOE, Shuichi SETO** and Shingo MATSUMURA**

(Received March 3, 1962)



Quantum mechanical calculation as to the position of attack on azulenes by nucleophilic reagents, first made by Brown[1], showed that such reactions should result in substitution in the 4- (or 8-) and 6-positions. The susceptibility of the 4-position to nucleophilic attack was proved by an ether exchange reaction converting ethyl 4-methoxyazulenecarboxylate into 4-ethoxyazulenecarboxylate[2]. According to the result of the ground state electron density calculation made by Julg[3] using the SCF-method, it has been shown that the density in the 2-position has comparatively lower values.

In the preceding papers[4], we reported that the reaction of 2-halo- or 2-methoxytropone with ethyl cyanoacetate resulted in the novel condensation to form diethyl 2-aminoazulene-1, 3-dicarboxylate (I) and other related azulene derivatives. In the present series of experiments, we wish to report on nucleophilic substitution at 2-position in 2-haloazulene derivatives, obtained from the compound I by Sandmeyer reaction.

Passage of dry hydrogen chloride gas through the benzene solution of I precipitated reddish orange salt[4b], and addition of isoamyl nitrite to this suspension resulted in the color change from green, blue, violet, to red, and the reaction mixture afforded diethyl 2-chloroazulene-1, 3-dicarboxylate (II), m. p. 78°C, in over 90% yield. The use of hydrogen bromide in place of hydrogen chloride resulted in the formation of a small amount of deaminated product, diethyl azulene-1, 3-dicarboxylate, but not of the anticipated 2-bromo compound. Hydrolysis of II with an excess of 10% ethanol - water solution of potassium hydroxide afforded 2-chloroazulene-1, 3-dicarboxylic acid (III), very sparingly soluble in organic solvents, and its decarboxylation by heating at 265~270°C under a partially reduced pressure gave 2-chloroazulene (IV) as violet crystals of m. p. 92°C, in a fairly good yield. Hydrolysis of II with one molar equivalent of potassium hydroxide produced a crystalline monobasic acid (V), whose decarboxylation by heating at 250°C afforded ethyl 2-chloroazulene-1-carboxylate (VI) as reddish violet oil (picrate, m. p. 92°C). It is

interesting to note that one of two ethoxycarbonyl groups in II is somewhat more resistant to alkali, and monobasic acid (V) is obtained in a good yield. This probably means that one of two ethoxycarbonyl groups is stabilized by the resonance with the following ionic structure.

The halide interchange reaction was studied in connection with the preparation of 2-iodo- and 2-bromoazulene. 2-Iodoazulene (VII) as violet crystals of m. p. 126°C could be prepared conveniently form 2-chloro compound IV by treatment with potassium iodide in wet acetic acid. 2-Bromoazulene (VIII), however, could

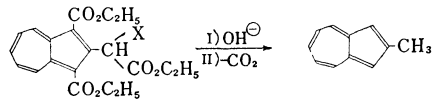
not be obtained by the action of potassium bromide in similar condition.

By the use of these compounds (II—VII), we had been able to synthesize various new azulene derivatives of the types A, B and C.

(A) (B) (C)

1, 2, 3,-Trisubstituted Azulene (A).—Reaction of II with sodium methoxide in methanol afforded dimethyl 2-methoxyazulene-1, 3-dicarboxylate (IX) and monomethyl ester of 2-methoxyazulene-1, 3-dicarboxylic acid (X). Ester group in azulene nucleus, in the presence of alkali or alcoholate, is easily exchanged by alcoholysis. Treatment of II with ammonia, methylamine, dimethylamine, aniline and *p*-bromoaniline, respectively afforded 2-amino- (I), 2-methylamino- (XI), dimethylamino- (XII), anilino- (XIII) and 2-(4'-bromoanilino)-azulene derivatives (XIV). Reaction of II with hydrazine hydrate afforded, besides diethyl 2-hydrazinoazulene-1, 3-dicarboxylate (XV), bis-1, 3-diethoxycarbonylazulen-2-yl) hydrazine (XVI).

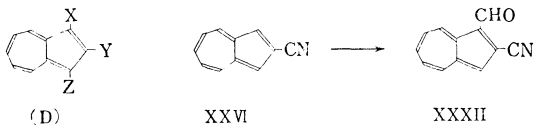


XVI

Treatment of II with sodiocompound of diethyl malonate, ethyl cyanoacetate, and ethyl acetoacetate respectively afforded the anticipated diethyl 2-diethoxycarbonylmethyl-(XVII), 2-(cyano-ethoycarbonylmethyl)- (XVIII), and 2-(acetyl-ethoxycabonylmethyl)-azulene-1,3-dicarboxylate (XIX).

1, 2-Disubstituted Azulenes (B).—Ethyl 2-chloroazulenl-1-carboxylate (VI) may be generally used to synthesize 1,2-disubstituted azulenes of the type (B). For example, reaction of VI with sodium ethoxide afforded ethyl 2-ethoxyazulene-1-carboxylate (XX), and reaction of VI with ethyl cyanoacetate, in the presence of sodium ethoxide, also afforded XX, besides a small amount of violet crystals (XXI) of unknown structure. Trisubstituted azulene (A) also could be converted to disubstituted derivatives (B) without difficulty. Thus, hydrolysis of XIII with one molar equivalent of potassium hydroxide afforded crystalline carboxylic acid, whose decarboxylation gave ethyl 2-anilinoazulene-1-carboxylate (XXII).

2-Substituted Azulenes (C).—2-Monosubstituted azulenes can be obtained as follows: 1) By saponification followed by decarboxylation of di- or trisubstituted derivatives, 2) by nucleophilic substitution of 2-iodoazulene (VII), or 3) more conveniently by nucleophilic substitution of 2-chloroazulene-1, 3-dicarboxylic acid (III) accompanied by simultaneous decarboxylation. Hydrolysis of IX, XX and XIII followed by decarboxylation respectively afforded 2-methoxy- (XXIII), 2-ethoxy- (XXIV) and 2-anilinoazulene (XXV). Heating of 2-chloroazulene (IV) with a methanolic solution of sodium methoxide in a sealed tube, however, gave only a trace of XXIII, while most of the original compound were recovered. Under the same condition, 2-iodoazulene (VII) afforded XXIII in a fairly good yield. Similarly, 2-cyanoazulene (XXVI) was obtained from VII by treatment with cuprous cyanide in pyridine over 85% yield. Heating of 2-chloroazulene-1, 3-dicarboxylic acid (III) with aniline, hydrazine and dimethylamine, respectively, resulted in facile substitution and simultaneous decarboxylation to form 2-anilino- (XXV), 2-hydrazino- (XXVII) and 2-dimethylaminoazulene (XXVIII). Hydrolysis of XVII and XVIII followed by decarboxylation produced 2-methylazulene (XXIX).



XVII : X=$CO_2C_2H_5$
XVIII : X=CN

XXIX

Cyano group in the 1- and 3-position is quite stable to attempted saponification with strong acid or alkali[4b], 2-cyanoazulene, however, are susceptible to such reagent, affording methyl azulene-2-carboxylate (XXX), on heating with absolute methanol containing hydrogen chloride. Hydrolysis of XXVI and XXX with alkali gave azulene-2-carboxylic acid (XXXI).

Further Substitution of Azulene Derivatives.—The fact that azulenes are liable to electrophilc substitution in the 1- and 3-positions is generally well known, and various azulene derivatives have been obtained by this method[5]. Combination of this electrophilic substitution and our nucleophilic substitution would give various azulene derivatives (D) having different substituents in the 1-, 2- and 3-positions. For example, application of Vilsmeier method to 2-cyanoazulene (XXVI) gave 2-cyano-1-formylazulene (2-cyanoazulene-1-carboxyaldehyde) (XXXII). This compound has been substituted further to give the compound of the type D[6].

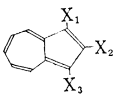
(D) XXVI XXXII

Julg[3] predicted that the elctron density of the 5-position of azulene nucleus has the next highest values after 1- and 3-positions. More recently Anderson et al.[7] have reported that the acetylation of 1, 3-dichloroazulene by means of acetyl chloride in carbon tetrachloride in the presence of stannic chloride gave 5-acetyl-1, 3-dichloroazulene.

In the case of 2-amino- substituted azulenes



(E) (F)

R=H, CH_3, Ph.

(I, XI—XIII), the 4- (or 8-) and 6-positions would have higher electron density than the 5-position by the electron releasing mesomeric effect of the amino group in the 2-position. Accordingly, the electrophilic substitution of these compounds is likely to occur in the 4- (or 8-) and 6-positions, because 1- and 3-positions are already blocked by ethoxycarbonyl groups. Furthermore, it may be presumed that the 4- or 8-position is sterically hindered by the ethoxycarbonyl groups in the 1- and 3-positions and is less easily attacked than the 6-position. The bromination of 2-amino- (I), 2-methylamino- (XI) and 2-anilinoazulene derivatives (XIII) respectively afforded monobromo derivatives, XXXIII, XXXIV and XXXV (type F), while 2-dimethylaminoazulene derivative XII was inert to bromine. Diethyl 2-(4'-bromoanilino)azulene-1, 3-dicarboxylate (XIV) and the brominated product XXXV showed the closs melting point, but

7) A. G. Anderson and L .L. Replogle, *J. Org. Chem.*, 25, 1275 (1960).

a distinct depression of the melting point occurred on their admixture. As the 2'- (or 6'-) position of benzene ring in XIII is sterically hindered by two ethoxycarbonyl groups in the 1- and 3-positions, the possibility of the substitution of benzene ring would be excluded. From these considerations, it was assumed that XXXIII, XXXIV and XXXV were likely to be 6-bromo derivatives of I, XI and XIII respectively. Resistance of dimethylamino compound XII in bromination reaction would be due to the steric interference between two ethoxycarbonyl groups and a dimethylamino group. More recently, one of us (Matsumura)[4e] established the structure of the compound (XXXIII) as diethyl 2-amino-6-bromoazulene-1, 3-dicarboxylate, by synthesizing this compound from 5-bromo-2-methoxytropone and ethyl cyanoacetate.

Visible Absorption Spectra.—The visible absorption spectra[8] of the compounds IV, VII, XXIII, XXVI, XXVIII, and XXX are shown in Fig. 1. It was found that substitution of *o, p*-directing group in the 2-position of azulene ring caused a shift toward shorter wavelengths and substitution of *m*-directing group in the same position, a shift toward longer wavelengths in the spectra.

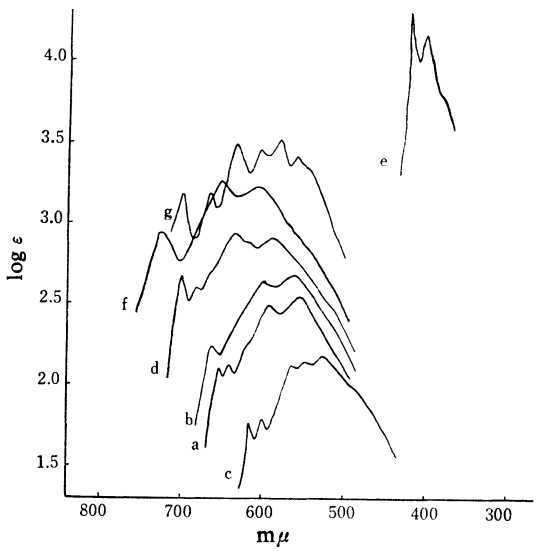

Fig. 1. Visible absorption spectra of IV, VII, XXIII, XXVI, XXVIII and XXX in cyclohexane.

IV(a) $Y = \log\varepsilon + 0$
VII(b) $Y = \log\varepsilon + 0.1$
XXIII(c) $Y = \log\varepsilon + 0$
XXVI(d) $Y = \log\varepsilon + 0.2$
XXVIII(e) $Y = \log\varepsilon + 0$
XXX(f) $Y = \log\varepsilon + 0.5$
Azulene(g) $Y = \log\varepsilon + 1.0$

8) Visible absorption spectra were measured with a Beckman DK spectrophotometer.

Experimental[9]

Diethyl 2-Chloroazulene-1, 3-dicarboxylate (II).—Dry hydrogen chloride gas passed through a solution of 6 g. of diethyl 2-aminoazulene-1, 3-dicarboxylate (I) dissolved in 200 ml. of dehydrated benzene under cooling and reddish orange precipitates began to separate out. Addition of 2.7 g. of isoamyl nitrite to this suspension resulted in the color change form green, blue, violet, to red gradually and the reaction mixture was allowed to stand overnight at room temperature. The solution was washed with water. After being dried over anhydrous sodium sulfate, the solvent was evaporated. The crystalline residue that formed was recrystallized from ethanol to afford 5.4 g. of II as red prisms, m. p. 77~78°C.

Found: C, 62.96; H, 4.91. Calcd. for $C_{16}H_{15}O_4Cl$: C, 62.54; H, 4.92%.

UV λ_{max}^{MeOH} mμ (logε): 237 (4.50), 272 (4.36), 296 (4.65), 306 (4.75), 310 (4.58), 344 (3.90), 349 (3.89), 357 (3.68).

Diethyl Azulene-1, 3-dicarboxylate.—To a solution of 600 mg. of I dissolved in 20 ml. of dehydrated benzene saturated with dry hydrogen bromide, 270 mg. of isoamyl nitrite was added at room temperature. The color of the mixture changed to reddish brown gradually. After allowing to stand overnight at room temperature, the solution was washed with water and dried over anhydrous sodium sulfate and the solvent was removed under a reduced pressure. The oily residue was dissolved in benzene and the solution was passed through a column of alumina. The column was eluted with benzene and the solvent was evaporated. The crystalline residue was recrystallized from ethanol to give 150 mg. of diethyl azulene-1, 3-dicarboxylate, m. p. 120~121°C

2-Chloroazulene-1, 3-dicarboxylic Acid (III).—A solution of 5 g. of II dissolved in 50 ml. of 10% ethanol-water (4 : 1) solution of potassium hydroxide was refluxed in a water bath for 15~30 min. The solution colored from red to reddish violet. After being cooled, the solution was acidified with 6 N nitric acid. The precipitate thereby formed was collected by filtration and repeatedly washed with water, by which 4 g. of sparingly soluble 2-chloroazulene-1, 3-dicarboxylic acid (III), m. p. 260 ~265°C (decomp.), was obtained.

2-Chloroazulene (IV).—Low-pressure (200 mmHg) sublimation of 1 g. of III by heating at 265~270°C produced violet crystals. The crystals were dissolved in petroleum ether (b. p. 50~60°C) and the solution was passed through a column of alumina. The column was eluted with petroleum ether and the solvent was cautiously removed. The crystalline residue was recrystallized from methanol to give 600 mg. of IV as violet needles, m. p. 91~92°C.

Found: C, 74.16; H, 4.13. Calcd. for $C_{10}H_7Cl$: C, 74.07; H, 4.32%.

9) All melting points are uncorrected. The microanalyses were carried out by Mr. S. Ohyama, Miss. A. Iwanaga and Mr. S. Azumi, to whom the authors are deeply indebted.

UV λ_{max}^{MeOH} mμ (logε): 226 (4.36), 275 (4.87), 284 (4.88), 290 (4.35), 328 (3.76), 343 (3.85), 350 (3.53); $\lambda_{max}^{Cyclohexane}$ mμ (logε): 552 (2.55), 593 (2.49), 619 (2.22), 638 (2.11), 653 (2.10).

Ethyl 2-Chloroazulene-1-carboxylate (VI).—To a solution of 200 mg. of potassium hydroxide dissolved in 10 ml. of ethanol-water (4 : 1) mixture, 1 g. of II was added and the mixture was refluxed in a water bath for 15 min., by which the color of solution turned clearly reddish violet. The solution was acidified with 6 N nitric acid. The precipitate was collected by filtration and repeatedly washed with water, by which 500 mg. of crude crystalline carboxylic acid (V), m. p. 193~195°C (decomp.), was obtained. Five hundred milligrams of V was decarboxylated by treatment as in the foregoing case. The oily substance thereby obtained was dissolved in petroleum ether (b. p. 50~60°C) and the solution was passed through a column of alumina, by which the product separated into violet and reddish violet bands. Elution of the violet band with petroleum ether afforded ca. 20 mg. of IV. Elution of the reddish violet band with benzene gave 300 mg. of reddish violet oil (VI).

Picrate of VI.—Red needles, m. p. 91~92°C, as recrystallized from ethanol. Found: C, 48.97; H, 3.15; N, 9.26. Calcd. for $C_{19}H_{14}O_9N_3Cl$: C, 49.20; H, 3.02; N, 9.07%.

2-Iodoazulene (VII).—A mixture of 10 g. of IV and 200 g. of potassium iodide in 600 ml. of acetic acid containing 50 ml. of water was refluxed at 130~140°C for 3.5 hr. and diluted with 1000 ml. of water. The violet crystals thet separated out were collected by filtration. The collected crystals were dissolved in benzene to separate from inorganic salt and the solution was passed through a column of alumina. The column was eluted with benzene and the solvent was removed. The violet crystals thereby obtained were recrystallized from a large quantity of methanol to afford 12 g. of violet needles (VII), m. p. 125~126°C.

Found: C, 47.08; H, 2.69. Calcd. for $C_{10}H_7I$: C, 47.24; H, 2.75%.

UV $\lambda_{max}^{Cyclohexane}$ mμ (logε): 558 (2.58), 601 (2.54), 660 (2.13).

Attempted Synthesis of 2-Bromoazulene (VIII).—A mixture of 100 mg. of IV and 1.5 g. of potassium bromide was refluxed with 6 ml. of glacial acetic acid and 0.5 ml. of water for 4 hr. The reaction mixture was diluted with 10 ml. of water. The black precipitates that separated out were collected by filtration. The precipitates were very sparingly soluble in organic solvents.

Action of Sodium Methoxide on II.—To a solution of 300 mg. of sodium methoxide dissolved in 3 ml. of absolute methanol, 200 mg. of II was added and the mixture was refluxed on a water bath for 2 hr. After evaporation of methanol, the residue was dissolved in water to separate into water-insoluble and soluble portions. The water-insoluble portion was recrystallized from methanol to give 120 mg. of orange needles (IX), m. p. 61~62°C.

Found: C, 65.53; H, 5.12. Calcd. for $C_{15}H_{14}O_5$: C, 65.69; H, 5.15%.

The water-soluble portion produced, upon neutralization with dilute nitric acid, 20 mg. of orange precipitates and recrystallization from methanol afforded micro scales (X), m. p. 143~145°C (decomp.).

Found: C, 64.82; H, 4.58. Calcd. for $C_{14}H_{12}O_5$: C, 64.61, H, 4.65%.

Diethyl 2-Aminoazulene-1, 3-dicarboxylate (I).—A mixture of 100 mg. of II, 1 ml. of ethanol and 1 ml. of 28% ammonia water was sealed in a tube and heated at 100°C for 1 hr. The mixture was allowed to cool and crystals that formed were collected by filtration. The recrystallization from ethanol afforded 60 mg. of orange prisms (I), m. p. 93~94°C.

Diethyl 2-Methylaminoazulene-1, 3-dicarboxylate (XI).—To a solution of 200 mg. of II dissolved in 3 ml. of ethanol, 3 ml. of 10% aqueous solution of methylamine was added and refluxed on a water bath for 2 hr. After removal of ethanol, the reaction mixture was diluted with water and extracted with benzene and the benzene extract was passed through a column of alumina, by which the product separated into red and orange bands. Elution of the red band with benzene recovered 40 mg. of II. Further elution of the orange band with benzene-ethyl acetate mixture afforded 160 mg. of orange oil (XI).

UV λ_{max}^{MeOH} mμ (logε): 230 (4.13), 253 (4.25), 275 (4.23), 325 (4.62), 405 (3.82).

1, 3, 5-Trinitrobenzene Compound of XI.—Orange needles, m. p. 100~102°C, as recrystallized from ethanol.

Found: C, 53.92; H, 4.56; N, 10.76. Calcd. for $C_{23}H_{22}O_{10}N_4$: C, 53.70; H, 4.31; N, 10.89%.

Diethyl 2-Dimethylaminoazulene-1, 3-dicarboxylate (XII).—A mixture of 200 mg. of II, 3 ml. of 40% aqueous solution of dimethylamine and 3 ml. of ethanol was refluxed on a water bath for 2 hr. and the reaction mixture was diluted with water. The orange crystals that separated out were collected by filtration. The collected crystals were recrystallized from petroleum ether (b. p. 80~90°C) to afford 160 mg. of orange leaflets (XII), m. p. 81~82°C.

Found: C, 68.77; H, 6.49; N, 4.83. Calcd. for $C_{18}H_{21}O_4N$: C, 68.55; H, 6.71; N, 4.44%.

UV λ_{max}^{MeOH} mμ (logε): 223 (4.20), 265 (4.30), 323 (4.58), 430 (4.04).

Diethyl 2-Anilinoazulene-1,3-dicarboxylate (XIII).—A mixture of 100 mg. of II dissolved in 2 ml. of ethanol and 60 mg. of aniline was heated in a water bath for 3 hr. and the reaction mixture was diluted with water and extracted with benzene. After removal of the solvent, the residue was recrystallized from ethanol to give 70 mg. of orange needles (XIII), m. p. 141~142°C.

Found: C, 72.81; H, 5.83; N, 3.69. Calcd. for $C_{22}H_{21}O_4N$: C, 72.71; H, 5.82; N, 3.85%.

UV λ_{max}^{MeOH} mμ (logε): 230 (4.25), 237 (4.25), 260 (4.28), 270 (4.40), 310 (4.62), 327 (4.68), 420 (4.09).

Diethyl 2-(4'-Bromoanilino)-azulene-1, 3-dicarboxylate (XIV).—A mixture of 100 mg. of II dissolved in 2 ml. of ethanol and 100 mg. of *p*-bromoaniline was treated as in the foregoing case, by which 60 mg. of orange needles (XIV), m. p. 166~168°C was obtained.

Found: C, 59.58; H, 4.77; N, 3.16. Calcd. for $C_{22}H_{20}O_4NBr$: C, 59.73; H, 4.52; N, 3.16%.

Diethyl 2-Hydrazinoazulene-1, 3-dicarboxylate (XV).—To a solution of 100 mg. of II dissolved in 3 ml. of ethanol, 100 mg. of 80% aqueous solution of hydrazine hydrate was added and the mixture was refluxed for 2 hr. When cooled, crystals formed, they were collected by filtration and recrystallized from ethanol to give 30 mg. of orange scales of bis-(1, 3-diethoxycarbonylazulen-2-yl)hydrazine (XVI), m. p. 163~164°C.

Found: C, 67.37; H, 5.59; N, 4.68. Calcd. for $C_{32}H_{32}O_5N_2$: C, 67.12; H, 5.63; N, 4.89%.

The mother liquor after separation of above product was evaporated. The oily residue thereby formed was dissolved in benzene and the solution was passed through a column of alumina, by which the product separated into red, yellow and orange bands. Elution of the red band with benzene recovered II. Further elution of the orange band with benzene afforded 30 mg. of orange oil (XV).

Isopropylidine Compound of XV.—A solution of 30 mg. of XV dissolved in 0.3 ml. of acetone was warmed on a water bath for 10 min. After removal of the solvent, the residue was dissolved in benzene and chromatographically purified through a column of alumina. Isopropylidine compound was obtained as orange leaflets, m. p. 133~134°C.

Found: C, 67.15; H, 6.34; N, 8.33. Calcd. for $C_{19}H_{22}O_4N_2$: C, 66.65; H, 6.48; N, 8.18%.

Acetate of XV.—A solution of 50 mg. of XV dissolved in 0.5 ml. of acetic anhydride was warmed on a water bath for 50 min. Evaporation of excess acetic anhydride left crystals which were recrystallized from ethanol and acetate of XV, m. p. 130~132°C, was obtained.

Found: C, 62.61; H, 5.83; N, 8.25. Calcd. for $C_{18}H_{20}O_5N_2$: C, 62.78; H, 5.85; N, 8.14%.

Diethyl 2-(Diethoxycarbonylmethyl)-azulene-1, 3-dicarboxylate (XVII).—To a suspension of diethyl sodiomalonate prepared from 30 mg. of metallic sodium, 250 mg. of diethyl malonate and 1 ml. of absolute ethanol, 100 mg. of II was added and the mixture was warmed on a water bath for 1 hr. The color of reaction mixture turned into dark reddish violet. After removal of the solvent, the residue was dissolved in water and the solution was acidified with acetic acid and the dark red oil that formed was extracted with benzene. The benzene extract was dried over anhydrous sodium sulfate and passed through a column of alumina, by which the product separated into red and dark red bands. Elution of the red band with benzene afforded ca. 10 mg. of II. Further elution of the dark red band with ethyl acetate gave 60 mg. of red oil (XVII).

Found: C, 64.57; H, 6.83. Calcd. for $C_{23}H_{26}O_8$: C, 64.17; H, 6.09%.

Diethyl 2-(Cyano-ethoxycarbonylmethyl)-azulene-1, 3-dicarboxylate (XVIII).—To a suspension of ethyl sodiocyanoacetate prepared from 75 mg. of metallic sodium, 370 mg. of ethyl cyanoacetate and 5 ml. of absolute ethanol, 500 mg. of II was added and the mixture was heated at 90°C for 1 hr. and small amount of precipitate separated gradually. Ethanol was evaporated from the mixture, the residue was dissolved in water and the solution was acidified with 6 N nitric acid by which red crystalline precipitate was produced. The precipitate was dissolved in benzene and chromatographically purified through an alumina column. The crystals thereby obtained were recrystallized from ethanol to give 470 mg. of XVIII as red prisms, m. p. 116~117°C.

Found: C, 65.63; H, 5.68; N, 3.92. Calcd. for $C_{21}H_{21}O_6N$: C, 65.78; H, 5.52; N, 3.65%.

UV λ_{max}^{MeOH} mμ (logε): 235 (4.50), 277 (4.51), 300 (4.72), 335 (3.87), 355 (3.86), 363 (3.97).

Diethyl 2-(Acetyl-ethoxycarbonylmethyl)-azulene-1, 3-dicarboxylate (XIX).—To a suspension of ethyl sodioacetoacetate prepared from 50 mg. of metallic sodium, 400 mg. of ethyl acetoacetate and 4 ml. of absolute ethanol, 200 mg. of II was added and the mixture was warmed in a water bath for 1 hr. The reaction mixture changed the color from reddish purple to dark purple and the precipitates began to separate out gradually. After removal of the solvent, the residue was dissolved in water and the aqueous solution was acidified with 6 N nitric acid. The red oil thereby produced was extracted with benzene and the benzene extract was dried over anhydrous sodium sulfate. The solution was passed through a column of alumina. The column was eluted with ethyl acetate and 120 mg. of red crystals was obtained. Recrystallization from cyclohexane afforded 100 mg. of red prisms (XIX), m. p. 53~54°C.

Found: C, 66.03; H, 5.25. Calcd. for $C_{22}H_{24}O_7$: C, 65.98; H, 6.04%.

UV λ_{max}^{MeOH} mμ (logε): 235 (4.55), 267 (4.41), 305 (4.80), 340 (3.90).

Ethyl 2-Ethoxyazulene-1-carboxylate (XX).—To a solution of 100 mg. of sodium ethoxide dissolved in 3 ml. of absolute ethanol, 200 mg. of VI was added and the mixture was refluxed for 3 hr. After evaporation of ethanol, the residue was dissolved in benzene and the solution was passed through a column of alumina, by which the product separated into red and pink bands. Elution of the red band with benzene recovered 60 mg. of VI. Further elution of the pink band with benzene afforded 90 mg. of pink crystals. Recrystallization from ethanol afforded pink prisms (XX), m. p. 84~85°C.

Found: C, 73.68; H, 6.49. Calcd. for $C_{15}H_{16}O_3$: C, 73.75; H, 6.60%.

UV $\lambda_{max}^{Cyclohexane}$ mμ (logε): 464 (2.09), 488 (2.11), 527 (1.92), 574 (1.17).

Reaction of VI with Ethyl Cyanoacetate.—To a suspension of ethyl sodiocyanoacetate prepared from 40 mg. of metallic sodium, 200 mg. of ethyl cyanoacetate and 4 ml. of absolute ethanol, 150 mg. of VI was added and the mixture was heated at 120~130°C for 1.5 hr. The reaction occurred gradually and dark violet precipitate began to separate out. After removal of ethanol, the residue was dissolved in water and the solution was acidified with 6 N nitric acid. The dark oil thereby formed was extracted with benzene. The benzene extract was dried over anhydrous sodium sulfate and the solution was passed through a column of alumina, by which the product separated into red, pink and dark violet bands. Elution of the red band with

benzene recovered 90 mg. of VI. Further elution of the pink band with benzene afforded crystalline substance. Recrystallization from ethanol gave ca. 20 mg. of XX, m. p. 84~85°C. Further elution of the dark violet band with ethyl acetate afforded a small amount of violet needles (XXI), m. p. 115~116°C. The yield of XXI was so poor that further examination of this product was not made.

Ethyl 2-Anilinoazulene-1-carboxylate (XXII).—To a solution of 15 mg. of potassium hydroxide dissolved in 1.5 ml. of ethanol, 100 ml. of XIII was added and the mixture was refluxed in a water bath for 3 hr. After being cooled, the solution was acidified with 6N hydrochloric acid. The crystalline carboxylic acid thereby formed was collected by filtration and washed with water and benzene. The thermal decomposition of the carboxylic acid by heating at 160°C produced orange oil and the oil was dissolved in petroleum ether (b. p. 70~80°C). The solution was passed through a column of alumina. The column was eluted with benzene and 50 mg. of orange oil (XXII) was obtained.

Trinitrobenzene Compound of XXII.—Brownish orange needles, m. p. 111~112°C, as recrystallized from ethanol.

Found: C, 60.41; H, 3.52; N, 10.86. Calcd. for $C_{25}H_{20}O_8N_4$: C, 59.52; H, 4.00; N, 11.11%.

2-Methoxyazulene (XXIII).—a) A mixture of 50 mg. of VII and 100 mg. of sodium methoxide dissolved in 1 ml. of absolute methanol was sealed in a tube and heated at 100°C for 30 hr. The reaction occurred gradually and the color changed from violet to reddish violet. Evaporation of methanol left crystalline residue. The residue was dissolved in petroleum ether (b. p. 50~60°C) and the solution was passed through a column of alumina. The column was eluted with petroleum ether and a small amount of VII was recovered. Further elution of the column with petroleum ether-benzene (1 : 1) mixture afforded 20 mg. of reddish violet crystals which were crystallized from methanol to give reddish violet needles (XXIII), m. p. 82~83°C, with an aroma.

Found: C, 83.46; H, 6.21. Calcd. for $C_{11}H_{10}O$: C, 83.51; H, 6.37%.

UV λ_{max}^{MeOH} mμ (logε): 237 (4.07), 275 (4.76), 300 (4.72), 335 (3.87), 355 (3.86), 363 (3.97). $\lambda_{max}^{Cyclohexane}$ mμ (logε): 524 (2.19), 544 (2.14), 550 (2.13), 561 (2.12), 592 (1.77), 613 (1.75).

b) A mixture of 100 mg. of IV and 200 mg. of sodium methoxide dissolved in 2 ml. of absolute methanol was treated as in the foregoing case. One-hundred and seventy milligrams of IV was recovered and a small amount of XXIII was obtained.

c) To a solution of 50 mg. of IX dissolved in 0.5 ml. of ethanol, 1 ml. of 10% aqueous solution of potassium hydroxide was added and the solution was refluxed in a water bath for 2 hr. The color of the solution changed from orange to reddish violet. After cooling, the solution was acidified with 6N sulfuric acid and the precipitate was washed with water and 30 mg. of crude acid substance sparingly soluble in organic solvents was obtained. Low-pressure (100 mmHg) sublimation of the acid substance by heating at 200°C produced red oily substance. Purification by chromatography over alumina gave 10 mg. of XXIII.

2-Ethoxyazulene (XXIV).—To a solution of 50 mg. of XX dissolved in 1 ml. of 10% aqueous solution of potassium hydroxide was added and the mixture was treated as in the case of above procedure c). The oil thereby obtained was chromatographically purified through an alumina column, by which 20 mg. of reddish violet oil (XXIV) was obtained.

UV λ_{max}^{MeOH} mμ (logε): 237 (3.99), 275 (4.69), 285 (4.81), 315 (3.65), 340 (3.45), 355 (3.59), 370 (3.48).

2-Anilinoazulene (XXV).—a) A solution of 100 mg. of XIII dissolved in 2 ml. of 10% ethanol-water (4 : 1) solution of potassium hydroxide was warmed in a water bath for 2.5 hr. After cooling, the solution was acidified with 6N hydrochloric acid. The acid substance thereby formed was collected by filtration, washed with water and completely dried in a desiccator. The acid substance was heated at 160°C under a reduced pressure (10 mmHg) to effect decarboxylation, by which reddish orange crystals were obtained. The crystals were recrystallized from petroleum ether (b. p. 50~60°C) to give 40 mg. of XXV as reddish orange scales, m. p. 144~145°C.

Found: C, 87.53; H, 6.07; N, 6.43. Calcd. for $C_{16}H_{13}N$: C, 87.64; H, 5.98; N, 6.39%.

UV λ_{max}^{MeOH} mμ (logε): 256 (4.14), 310 (4.75), 352(3.78), 420 (4.35).

b) To a solution of 50 mg. of III dissolved in 0.5 ml. of pyridine, 100 mg. of aniline was added and the mixture was heated at 120~130° for 1 hr. After removal of pyridine, the residue was dissolved in benzene and the solution was passed through a column of alumina, by which the product separated into yellow and brown bands. Elution of the yellow band with benzene recovered aniline. Further elution of the brown band with benzene afforded reddish orange crystals which were recrystallized from petroleum ether to give ca. 15 mg. of XXV, m. p. 144~145°C.

2-Cyanoazulene (XXVI).—a) A mixture of 5 g. of VII, 5 g. of cuprous cyanide and 50 ml. of pyridine, dried over solid potassium hydroxide, was heated at 140~150°C for 30 min. The color of the solution changed from violet to deep blue. Pyridine was distilled off under a reduced pressure and the residue was dissolved in benzene to separate from inorganic substance. Evaporation of benzene left deep blue crystalline solid. The crystalline solid was dissolved in a large quantity of cyclohexane and the solution was passed through a column of alumina, by which the product separated into violet and deep blue bands. Elution of the violet band with cyclohexane recovered 600 mg. of VII. Further elution of the deep blue band with benzene afforded 2 g. of blue crystals which were recrystallized from methanol to give deep blue leaflets (XXVI), m. p. 77~78°C.

Found: C, 86.31; H, 4.43; N, 9.36. Calcd. for $C_{11}H_7N$: C, 86.25; H, 4.61; N, 9.15%.

UV $\lambda_{max}^{Cyclohexane}$ mμ (logε): 586 (2.72), 621 (2.71), 635 (2.73), 660 (2.50), 679 (2.40), 697 (2.47).

b) A mixture of 500 mg. of IV, 500 mg. of cuprous cyanide and 5 ml. of pyridine was treated as in the foregoing case, by which 430 mg. of IV was recovered and 10 mg. of XXVI was obtained.

2-Hydrazinoazulene (XXVII).—A solution of 100 mg. of III dissolved in 3 ml. of 80% aqueous solution of hydrazine hydrate was heated in a water bath for 30 min. The leaflet crystals began to separate out. The crystals were collected by filtration and recrystallized from benzene to afford 30 mg. of reddish orange leaflets (XXVII), m. p. 127~128°C.

Found: C, 75.89; H, 6.54; N, 17.83. Calcd. for $C_{10}H_{10}N_2$: C, 75.92; H, 6.37; N, 17.71%.

UV λ_{max}^{MeOH} mμ (logε): 240 (4.12), 285 (4.82), 296 (4.92), 347 (3.76), 389 (3.94), 405 (3.86).

2-Dimethylaminoazulene (XXVIII).—A solution of 100 mg. of III dissolved in 3 ml. of 40% aqueous solution of dimethylamine was sealed in a tube and heated at 100°C for 3 hr. The leaflet crystals formed on cooling were collected by filtration and dissolved in benzene. The solution was passed through a column of alumina. The column was eluted with benzene and 50 mg. of orange crystals was obtained. Recrystallization from ethanol afforded 30 mg. of XXVIII as orange leaflets, m. p. 98~99°C.

Found: C, 84.21; H, 7.85; N, 8.43. Calcd. for $C_{12}H_{13}N$: C, 84.17; H, 7.65; N, 8.18%.

UV λ_{max}^{MeOH} mμ (logε): 247 (4.05), 292 (4.75); 302 (4.83), 335 (3.69), 355 (3.74), 400 (4.06), 424 (4.23).

2-Methylazulene (XXIX).—A solution of 200 mg. of XVII or XVIII dissolved in 30% ethanol-water (4:1) solution of potassium hydroxide was heated at 100°C for 6 hr. After cooling, the solution was acidified with 6 N hydrochloric acid. The precipitate thereby formed was collected by filtration and repeatedly washed with water. After being dried, low pressure sublimation (100 mmHg) of the precipitate by heating at 260~270°C produced violet oil with an odor of naphthalene. The oil was dissolved in petroleum ether (b. p. 50~60°C) and chromatographically purified through an alumina column, by which 70 mg. of the crystalline residue was obtained. Recrystallization from methanol-water mixture gave 50 mg. of violet needles (XXIX), m. p. 49~50°C. The ultraviolet and visible absorption spectra of XXIX and its melting point were in good agreement with those reported in the literature.

Methyl Azulene-2-carboxylate (XXX).—Hydrogen chloride gas was passed through the solution of 100 mg. of XXVI dissolved in 3 ml. of absolute methanol and the solution was heated on a water bath for 8 hr. Methanol was evaporated from the solution and residual crystals were dissolved in petroleum ether-benzene (1:1) mixture. The solution was passed through a column of alumina. The column was eluted with benzene-petroleum ether mixture and 60 mg. of blue crystals was obtained. Recrystallization from methanol afforded blue needles (XXX), m. p. 110~111°C.

Found: C, 77.19; H, 5.40. Calcd. for $C_{12}H_{10}O_2$: C, 77.40; H, 5.41%.

UV $\lambda_{max}^{Cyclohexane}$ mμ (logε): 604 (2.71), 656 (2.73), 713 (2.37), 728 (2.42).

Azulene-2-carboxylic Acid (XXXI).—a) A solution of 100 mg. of XXVI dissolved in 2 ml. of 10% ethanol-water (4:1) solution of potassium hydroxide was warmed in a water bath for 3 hr. Black substance began to precipitate out. The filtrate obtained after isolation of the black substance was concentrated and the residue was dissolved in water. The solution was neutralized with dilute sulfuric acid, from which green precipitate was obtained. Recrystallization of this precipitate from benzene afforded 20 mg. of XXXI as green needles, m. p. 200~203°C (decomp.).

Found: C, 76.67; H 5.00. Calcd. for $C_{11}H_8O_2$: C, 76.73; H, 4.68%.

UV λ_{max}^{MeOH} mμ (logε): 610 (2.62), 661 (2.65), 732 (2.35).

b) A solution of 100 mg. of XXX dissolved in 2 ml. of 10% ethanol-water (4:1) solution of potassium hydroxide was treated as the above procedure, by which 40 mg. of XXXI was obtained.

2-Cyano-1-formylazulene (XXXII).—To a solution of 100 mg. of XXVI dissolved in 0.3 ml. of dimethylformamide, 120 mg. of phosphorus oxychloride was added under ice-cooling. The reaction mixture was poured into ice-water, by which reddish violet crystals began to precipitate out. The crystals were recrystallized from methanol to afford 80 mg. of XXXII as reddish violet scales, m. p. 180~182°C.

Found: C, 79.46; H, 4.05; N, 7.62. Calcd. for $C_{12}H_7ON$: C, 79.55; H, 3.89; N. 7.73%.

UV $\lambda_{max}^{Cyclohexane}$ mμ (logε): 543 (2.88), 583 (2.90), 629 (2.57), 645 (2.51).

Bromination of Diethyl 2-Aminoazulene-1, 3-dicarboxylate (I).—To a solution of 100 mg. of I dissolved in 2 ml. of chloroform, 60 mg. of bromine was added and the mixture was allowed to stand at room temperature for 2 hr. A large amount of orange crystals began to precipitate out. The crystals were collected by filtration and repeatedly washed with water. Recrystallization from benzene afforded 130 mg. of orange prisms (XXXIII), m. p. 163~164°C.

Found: C, 52.65; H, 4.23; N, 3.72. Calcd. for $C_{16}H_{16}O_4NBr$: C, 52.35; H, 4.37; N, 3.87%.

UV λ_{max}^{MeOH} mμ (logε): 245 (4.33), 320 (4.55), 332 (4.66), 410 (3.38), 473 (3.50).

Bromination of Diethyl 2-Methylaminoazulene-1, 3-dicarboxylate (XI).—To a solution of 100 mg. of XI dissolved in 1.5 ml. of acetic acid, 60 mg. of bromine was added, by which brownish red oil separated out and later crystallized. The mixture was allowed to stand overnight at room temperature. Acetic acid removed and the residual oil was extracted with chloroform. The chloroform extract was washed with an aqueous solution of sodium hydrogencarbonate and water. After removal of chloroform, the residue was dissolved in benzene and the solution was passed through a column of alumina. The column was eluted with benzene and 120 mg. of brown oil which was crystallized from cyclohexane to crystals of melting point, 98~105°C.

Recrystallization from ethanol afforded 90 mg. of orange scales (XXXIV), m. p. 117~118°C.

Found: C, 53.79; H, 4.65; N, 3.46. Calcd. for $C_{17}H_{18}O_4NBr$: C, 53.54; H, 4.73; N, 3.67%.

Bromination of Diethyl 2-Anilinoazulene-1, 3-dicarboxylate (XIII).—To a solution of 100 mg. of XIII dissolved in 2 ml. of chloroform, 60 mg. of bromine was added and the mixture was allowed to stand at room temperature for 2 hr. The chloroform solution was washed with water and dried over anhydrous sodium sulfate. After removal of the solvent, the residue was dissolved in benzene and the solution was passed through a column of alumina. The column was eluted with benzene and 60 mg. of orange crystals was obtained. Recrystallization from ethanol afforded orange scales (XXXV), m. p. 173~174°C, which showed a distinct depression of the melting point on admixture with XIV.

Found: C, 59.64; H, 4.82; N, 3.27. Calcd. for $C_{22}H_{20}O_4NBr$: C, 59.73; H, 4.52; N, 3.16%.

The authors wish to take this opportunity to express their gratitude for the donation of the grant-in-aid for Scientific Research from the Ministry of Education and for financial assistance from the Sankyo Pharmaceutical Co., Ltd. The authors gratefully acknowledge their debts to Messrs Yasohiro Murase and Akira Sato for their co-operations in carrying out the experiments.

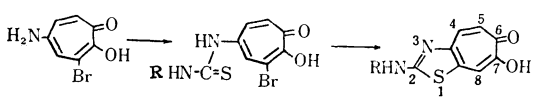
Cycloheptathiazole Derivatives. I. Synthesis of 7-Hydroxycyclohepta-[d]thiazol-6-one and its Derivatives

By Shuichi SETO, Yukio NISHIYAMA and Kyozo OGURA

(Received April 16, 1962)



Tropolone derivatives with fused thiazole ring would be interesting compounds from the point of biology and pharmacology, but none has been reported to date. One of the authors (K. O.) found a noteworthy phenomenon during studies on 5-formyltropolone derivatives[1] that the treatment of a condensation product I of 5-formyltropolone derivative and rhodanine with alkali resulted in facile cyclization with liberation of bromide ion to form a thiophene derivative II.

I : R=Br or *i*-Pr II

It was thought that this type of reaction might be utilizable for the synthesis of tropolone derivatives with a fused thiazole ring. Therefore, thiourea derivatives obtained from 3-bromo-5-aminotropolone (III) were treated with a base and structure of the products was examined. It was thereby found that the reaction had proceeded as expected and tropolone derivatives with a fused thiazole ring could certainly be obtained. The cyclization was effected in one step by the reaction of III and carbon disulfide, and a tropolone derivative with a fused thiazole ring was obtained. This cyclization reaction and structural determination of its products will be described herein.

Treatment of III with benzoyl isothiocyanate and ethoxycarbonyl isothiocyanate in methanol respectively affords *N*-(3-bromotropolon-5-yl)-*N'*-benzoylthiourea (IV) and *N*-(3-bromotropolon-5-yl)-*N'*-ethoxycarbonylthiourea (V). By stirring IV in aqueous alkali solution at room temperature, the substance dissolves once to form an orange-yellow solution and yellow alkali salt begins to precipitate out after a few hours. The filtrate left after removal of this salt contains one atom equivalent of bromide ion. Treatment of this salt with an acid gives pale yellow crystals (VI), whose analytical values correspond to the formula of $C_{15}H_{10}O_3N_2S$. The ultraviolet spectrum of VI (Fig. 1) suggests the presence of a tropolone ring in VI. Compound VI is also obtained on treatment of IV with pyridine.

III IV : R=COC_6H_5 VI : R=COC_6H_5
V : R=$COOC_2H_5$ VII : R=$COOC_2H_5$
VIII : R=H

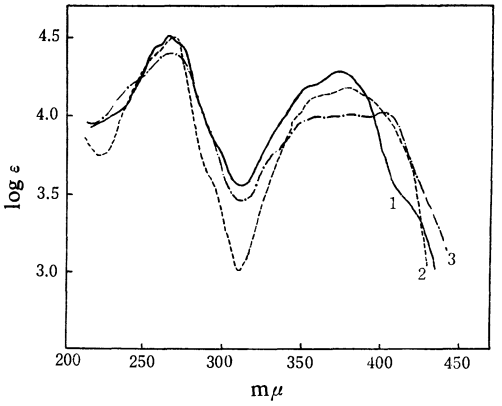

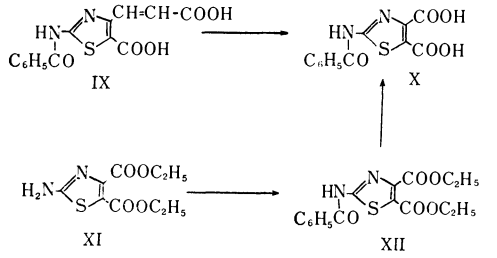

Fig. 1. The ultraviolet absorption spectra in methanol.
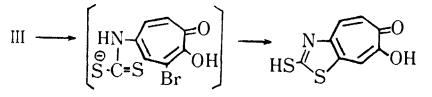
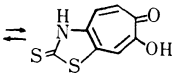
1 : VI 2 : VIII 3 : XIX

Thiourea derivative V undergoes similar reactions with alkali to form VII whose ultraviolet spectrum is similar to that of VI, indicating that VI and VII have a common skeleton. In fact, heating of VI and VII with concentrated sulfuric acid results in the formation of identical yellow crystals (VIII). While VI is stable to alkali and is recovered unchanged even when heated at 200°C, VII forms VIII on being heated with alkali.

In order to prove the presence of a thiazole ring in VI, its oxidative degradation was carried out. Oxidation of VI with alkaline hydrogen peroxide afforded a dicarboxylic acid (IX). If a cleavage had occurred in this case as in the oxidation of fused-ring tropolones with alkaline hydrogen peroxide[1,2], IX should be 2-benzamido-4-(β-carboxyvinyl)-5-carboxythiazole. Further oxidation of IX with alkaline potassium permanganate afforded a dicarboxylic acid (X), which was assumed to be 2-benzamido-4, 5-dicarboxythiazole.



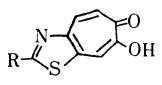


In order to confirm this assumption, the known 2-amino-4, 5-bis(ethoxycarbonyl)thiazole[3] was benzoylated to XII which was hydrolyzed to form the structurally reliable 2-benzamido-4, 5-dicarboxythiazole. The product (X) was found to be completely identical with this 2-benzamido-4, 5-dicarboxythiazole through mixed melting point and by comparison of infrared and ultraviolet spectra.

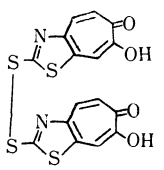
The foregoing facts have shown that VI has a thiazole ring, as anticipated, and VI, VII and VIII were proved respectively as the 2-benzamido, 2-ethoxycarbamido, and 2-amino derivatives of 7-hydroxycyclohepta[d]thiazol-6-one.

Reaction of III and carbon disulfide, in the presence of a tertiary amine, will now be described. In this case, as in the reaction of amines in general and carbon disulfide, formation of a dithiocarbamate XIII may be expected.

However, as was witnessed in the case of IV and V, formation of a thiazole ring by the liberation of hydrogen bromide is very facile and there is a possibility that the reaction would proceed on to XIV without stopping at XIII.



XIVb



Reaction of III and carbon disulfide in pyridine, evaporation of pyridine and excess carbon disulfide from the reaction mixture, and addition of dilute sulfuric acid to its residue precipitated yellow crystals (XIV). The filtrate left after removal of XIV contained one atom equivalent of bromide ion. The analytical values of XIV corresponded to the molecular formula of $C_8H_5O_2NS_2$. This fact supports the assumption that the reaction had progressed to cyclization and that XIV would be a 2-mercaptothiazole derivative. Ultraviolet spectrum of XIV is different from that of VI and exhibits absorption in a longer wavelength region. The ultraviolet spectrum of the *S*-methyl derivative XV, obtained by application of dimethyl sulfate to XIV in the presence of alkali, is similar to that of VI. Consequently, XIV may be assumed to have a thiazole ring. This assumption was found to be correct from following facts. Oxidation of XIV with hydrogen peroxide gives sparingly soluble substance (XVI) and easily soluble pale yellow crystals (XVII). Analytical values of XVII correspond to $C_8H_5O_2NS$ and the substance is assumed to be 7-hydroxycyclohepta[d]thiazol-6-one. It is known that application of hydroxylamine to

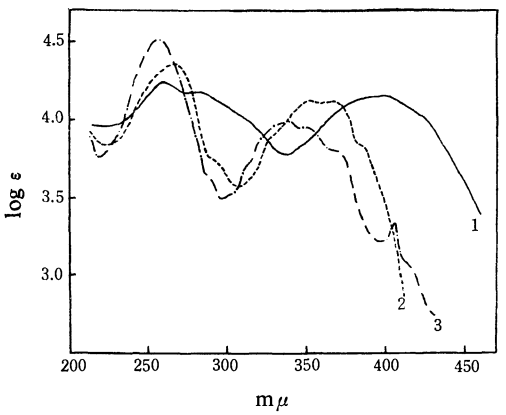
3) L. H. Conover and D. S. Tarbell, *J. Am. Chem. Soc.*, **72** 5222 (1950).

benzothiazole in the presence of alkali results in the formation of 2-aminobenzothiazole[4]. If XVII were a thiazole derivative as

XV: R=SCH_3
XVII: R=H
XVIII: R=SCH_2COOH

XVI

anticipated it should form a 2-aminothiazole derivative VIII by reaction with hydroxylamine, as in the case of benzothiazole. Experimental result showed that this assumption had been correct and the structure of XVII and XIV was therefore proved.



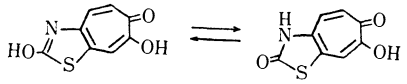


Fig. 2. The ultraviolet absorption spectra in methanol.
1: XIV 2: XV 3: XVII

Compound XVI is assumed to be a disulfide derivative from its analytical values, and ultraviolet and infrared spectra.

Application of chloroacetic acid to XIV in the presence of sodium hydrogencarbonate gives a 2-carboxymethylthio derivative XVIII, which remains unchanged on treatment with liquid ammonia at room temperature but forms a 2-hydroxyderivative XIX on being heated with an acid.

XIXa XIXb

Experimental[5]

***N*-(3-Bromotropolon-5-yl)-*N'*-benzoylthiourea (IV).**—A solution of 1.2 g. of benzoyl isothiocyanate dissolved in 10 ml. of methanol was added dropwise into 1.2 g. of 3-bromo-5-aminotropolone (III) suspended in 50 ml. of methanol, maintained at 50°C, while stirring, during ca. 1 hr. The mixture was stirred for subsequent 3 hr., cooled to room temperature, and crystals that precipitated out were collected by filtration. The crystals were washed with a small amount of methanol and was obtained as pale yellow needles, m. p. 340°C (decomp.). Yield, 1.5 g.

Found: C, 47.75; H, 3.02; N, 6.60. Calcd. for $C_{15}H_{11}O_3N_2BrS$: C, 47.48; H, 2.92; N, 7.39%.

UV λ_{max}^{MeOH} mμ(log ε): 258(4.54), 350(4.07).

***N'*-(3-Bromotropolon-5-yl)-*N*-ethoxycarbonylthiourea (V).**—To a suspension of 0.8 g. of III in 40 ml. of methanol, 1.5 g. of ethoxycarbonyl isothiocyanate was added dropwise during 30 min., while the suspension was stirred at 40°C, and the mixture was stirred at the same temperature for subsequent 1 hr. The mixture was cooled, precipitated crystals were collected, and washed a small amount of methanol to pale yellow scales (V), m. p. 280°C (decomp.). Yield, 1.1 g.

Found: C, 38.31; H, 3.23; N, 7.60. Calcd. for $C_{11}H_{11}O_4N_2BrS$: C, 38.03; H, 3.19; N, 8.07%.

UV λ_{max}^{MeOH} mμ (log ε): 254 (4.51), 350 (4.05).

2-Benzamido-7-hydroxycyclohepta[d]thiazole-6-one (VI).—a) A mixture of 0.1 g. of IV and 4 ml. of 2 N sodium hydroxide was stirred, by which the mixture went into solution, coloring orange yellow. After about 10 min., orange-yellow crystals began to separate out. The mixture was stirred for 1 hr. at room temperature and the orange-yellow crystals were collected by filtration. The crystals were suspended in 4 ml. of water, the solution was adjusted to pH 3 with 6 N sulfuric acid, by which the solid became pale yellow, and the mixture was stirred for about 20 min. The solid was collected and washed with water to VI as pale yellow microcrystals, m. p. 340°C (decomp.). Yield, 75 mg.

Found: C, 60.36; H, 3.20; N, 9.27; S, 10.51. Calcd. for $C_{15}H_{10}O_3N_2S$: C, 60.37; H, 3.38; N, 9.40; S, 10.79%.

UV λ_{max}^{MeOH} mμ (log ε): 264 (4.51), 375 (4.27).

b) A mixture of 0.1 g. of IV and 0.4 ml. of pyridine was warmed at 40°C for 2 hr., 3 ml. of water was added, and the solution was adjusted to pH 3 with 6 N sulfuric acid. The crystals of VI that separated out were collected and washed with water. Yield, 70 mg.

2-Ethoxycarbamido-7-hydroxycyclohepta[d]thiazol-6-one (VII).—A mixture of 0.8 g. of V in a solution of 1.2 g. of sodium hydroxide in 4 ml. of water was stirred for 1 hr. at room temperature and the orange yellow crystals sodium salt that separated out was collected by filtration. This sodium salt was suspended in 10 ml. of water, the solution was adjusted to pH 3 with 6 N sulfuric acid, and the mixture was stirred for 30 min. The solid that separated was collected by filtration and washed with water to give VII as pale yellow

4) S. Skraup, *Ann.*, **419**, 1 (1920).

5) All melting points are uncorrected. Microanalyses were carried out by Misses Yôko Endô and Yukiko Endô of this Institute, and microanalyses of sulfur were made in Takamine Research Laboratory of Sankyo Co., Ltd., to whom the present authors are indebted. Ultraviolet spectra were measured with a Hitachi EPU-2A type spectrophotometer.

microcrystals, m. p. 313°C (decomp.). Yield, 0.57 g.

Found: C, 49.89; H, 4.02; N, 10.32. Calcd. for $C_{11}H_{10}O_4N_2S$: C, 49.63; H, 3.79; N, 10.52%.

UV λ_{max}^{MeOH} mμ (log ε): 268 (4.45), 371 (4.11).

2-Amino-7-hydroxycyclohepta [d] thiazol-6-one (VIII).—a) A mixture of 40 mg. of VI in 0.2 g. of concentrated sulfuric acid was heated at 120°C for 5 hr. and 3 g. of ice was added to the mixture, by which the sulfate of VIII separated out as colorless crystals. Without collecting these crystals, the mixture was adjusted to pH 4 with ammonia water and cooled in ice. The yellow crystals that separated out were collected and washed with water to give VIII as yellow crystals, m. p. 280~285°C (decomp.). Yield, 20 mg.

Found: C, 49.65; H, 2.98; N, 13.85. Calcd. for $C_8H_5O_2N_2S$: C, 49.47; H, 3.12; N, 14.43%.

UV λ_{max}^{MeOH} mμ (log ε): 272 (4.52), 383 (4.17).

VIII colors brown with ferric chloride in methanol.

b) A mixture of 50 mg. of VII in 0.2 g. of concentrated sulfuric acid was heated at 110°C for 1 hr. and treated as in above method a), from which 30 mg. of VIII was obtained.

c) A mixture of 100 mg. of VII, 300 mg. of potassium hydroxide, and 1 ml. of water was heated at 130°C for 2 hr., diluted with 5 ml. of water, and adjusted to pH 4 with 6 N sulfuric acid. The crystals that separated out were collected and washed with water to 70 mg. of VIII.

d) A mixture of 20 mg. of XVII, 0.4 ml. of 2 N sodium hydroxide, 0.6 ml. of water, and 10 mg. of hydroxylamine hydrochloride was heated at 110°C for 1 hr., cooled, and yellow crystals (sodium salt of VIII) that separated out were collected by filtration. The crystals were suspended in water, the mixture was adjusted to pH 4 with acetic acid, and the free VIII that separated out were collected by filtration and washed with water. Yield, 18 mg.

This substance was found to be identical with VIII, obtained by the foregoing methods a), b) and c), through mixed melting point and by comparison of thier ultraviolet and infrared spectra.

Oxidation of VI with Hydrogen Peroxide.—A mixture of 100 mg. of VI, 200 mg. of potassium hydroxide, and 10 ml. of water, in which the potassium salt of VI is sparingly soluble in water and the majority remains as a solid in suspension, was stirred and 30% hydrogen peroxide was added in drops. One milliliter of hydrogen peroxide was added every 12 hr. until a total of 4 ml. was added, when the reaction mixture formed a pale yellow solution. 6 N Sulfuric acid was added to the mixture under ice-cooling to adjust the solution to pH 2 and 40 mg. of crystals, m. p. 220~223°C (decomp.), that separated out was collected. Recrystallization from methanol gave 2-benzamido-4-(β-carboxyvinyl)-5-carboxythiazole (IX) as colorless crystals, m. p. 229~230°C (decomp.) Yield, 20 mg.

Found: C, 50.48; H, 2.99; N, 8.53. Calcd. for $C_{14}H_{10}O_5N_2S$: C, 52.83; H, 3.17; N, 8.80%.

UV λ_{max}^{MeOH} mμ (log ε): 240 (4.23), 301 (4.24).

2-Benzamido-4, 5-dicarboxythiazole (X).—a) To a solution of 15 mg. of IX dissolved in 0.08 ml. of 2 N sodium hydroxide, 0.6 ml. of 5% aqueous solution of potassium permanganate was added and the mixture was allowed to stand at room temperature. After 1 hr., manganese dioxide that separated out was filtered off, the filtrate was adjusted to pH 2 with dilute sulfuric acid, and the mixture was allowed to stand overnight in an ice box. The colorless crystals that separated out were collected by filtration, washed with water, and recrystallized from hydrous methanol to X as colorless crystals, m. p. 283~285°C (decomp.). Yield, 5 mg. This substance was identical with X obtained by the following method b), through mixed melting point and by comparison of ultraviolet and infrared spectra.

b) To a solution of 60 mg. of 2-amino-4, 5-bis-(ethoxycarbonyl)thiazole (XI) dissolved in 0.35 ml. of pyridine, 0.15 ml. of benzoyl chloride was added dropwise with stirring at room temperature, the mixture was stirred for further 15 min., and allowed to stand at room temperature. Pyridine was evaporated in a reduced pressure, 2 g. of ice was added to the residue, and colorless crystals that separated out were recrystallized from 50% methanol to 2-benzamido-4, 5-bis(ethoxycarbonyl)thiazole (XII) as colorless crystals, m. p. 151~153°C. Yield, 60 mg.

Found: C, 55.42; H, 4.51; N, 7.67. Calcd. for $C_{16}H_{16}O_5N_2S$: C, 55.17; H, 4.63; N, 8.04%.

UV λ_{max}^{MeOH} mμ (log ε): 232 (4.18), 301 (4.25).

A mixture of 50 mg. of XII, 3 ml. of ethanol, and 230 mg. of potassium hydroxide was allowed to stand overnight at room temperature, ethanol was evaporated in reduced pressure, and the residue was dissolved in 3 ml. of water. The solution was adjusted to pH 2 with dilute sulfuric acid, the crystals that separated out were collected by filtration, and washed with water. Recrystallization from hydrous methanol gave X as colorless crystals, m. p. 285°C (decomp.). Yield, 35 mg.

Found: C, 49.47; H, 2.86; N, 9.29. Calcd. for $C_{12}H_6O_5N_2S$: C, 49.32; H, 2.76; N, 9.59%.

UV λ_{max}^{MeOH} mμ (log ε): 235 (4.25), 301 (4.17).

2-Mercapto-7-hydroxycyclohepta[d]thiazol-6-one (XIV).—a) A mixture of 1 g. of 3-bromo-5-aminotropolone (III), 8 ml. of pyridine, and 1.2 ml. of carbon disulfide was stirred at room temperature for 1 hr., and then maintained at 45°C for 1 hr., and pyridine and excess carbon disulfide were evaporated in a reduced pressure. Water was added to the residue, the solution was adjusted to pH 2 with 6 N sulfuric acid, and the yellowish brown solid (XIV), m. p. 305~310°C (decomp.), was collected by filtration and washed with water. Yield, 0.95 g.

Found: C, 44.34; H, 2.59; N, 6.24. Calcd. for $C_8H_5O_2NS_2$: C, 45.51; H, 2.39; N, 6.63%.

UV λ_{max}^{MeOH} mμ (log ε): 258 (4.23), 280 (4.17), 390 (4.14), 400 (4.14).

b) A mixture of 30 mg. of III, 1 ml. of triethylamine, and 0.1 ml. of carbon disulfide was maintained at 50°C for 2 hr. and excess of the reagents was evaporated in a reduced pressure. The residue was added with 2 ml. of water, adjusted to pH 2 with 6 N sulfuric acid, and the yellowish brown solid (XIV) that separated out was collected. Yield, 26 mg.

2-Methylthio-7-hydroxycyclohepta[d]thiazol-6-one (XV).—To a solution of 200 mg. of XIV dissolved in a mixture of 6 ml. of 2 N sodium hydroxide and 4 ml. of water, 380 mg. of dimethyl sulfate was added with stirring under ice-cooling and yellowish orange crystals began to separate out after 1 hr. The mixture was stirred for 2 hr., diluted with 15 ml. of water to dissolved the crystals and treated with activated carbon. The filtrate was adjusted to pH 2 with 6 N sulfuric acid by which yellow precipitate formed. After standing the mixture in an ice box over night, the precipitate was collected and washed with water. This precipitate was sublimed at 140°C (bath temp.)/2 mmHg and the sublimate was redrystallized from ether to XV as pale yellow crystals, m. p. 191~193°C. Yield, 190 mg.

Found: C, 47.76; H, 3.11; N, 6.35. Calcd. for $C_9H_7O_2NS_2$: C, 48.01; H, 3.13; N, 6.22%.

UV λ_{max}^{MeOH} mμ (log ε): 267 (4.35), 355 (4.10), 365 (4.11).

2-Carboxymethylthio-7-hydroxycyclohepta[d]thiazol-6-one (XVIII).—To a mixture of 200 mg. of XIV, 400 mg. of sodium hydrogen carbonate, and 5 ml. of water, 200 mg. of monochloroacetic acid was added with stirring, and the mixture was stirred for subsequent 3 hr. at room temperature. The reaction mixture remained a suspension at first but went completely into solution 2 hr. later. The solution was adjusted to pH 2 with 6 N sulfuric acid, by which a precipitate formed, and the mixture was allowed to stand in an ice box overnight. The precipitate was collected by filtration, washed with water, and XVIII was obtained as a pale yellow solid, m. p. 245~250°C (decomp.). Yield, 250 mg.

Found: C, 43.67; H, 2.56; N, 5.01. Calcd. for $C_{10}H_7O_4NS_2$: C, 44.62; H, 2.62; N, 5.20%:

UV λ_{max}^{MeOH} mμ (log ε): 268 (4.44), 370 (4.22).

Reaction of XIV and Hydrogen Peroxide.—A mixture of 80 mg. of XIV, 3 ml. of *t*-butanol, and 0.4 ml. of 30% hydrogen peroxide was heated at 90°C for 15 hr. When cooled, 40 mg. of yellow insoluble matter (XVI), m. p. 230°C (decomp.), was collected by filtration.

Found: C, 44.88; H, 2.48; N, 6.55. Calcd. for $C_{16}H_8O_4N_2S_4$: C, 45.51; H, 2.28; N, 6.63%.

t-Butanol was evaporated in a reduced pressure from the filtrate left after removal of XVI, a small amount of water was added to the residue, and the solution was adjusted to pH 3 with sodium hydrogen carbonate. This was extracted with ethyl acetate, the solvent was evaporated from the extract, and the residue was sublimed at 120°C (bath temp.)/1 mmHg. The sublimate was recrystallized from methanol to 7-hydroxycyclohepta[d]thiazol-6-one (XVII) as pale yellow needles, m. p. 162~163°C. Yield, 20 mg.

Found: C, 53.86; H, 2.76; N, 7.77; S, 17.68. Calcd. for $C_9H_5O_2NS$: C, 53.64; H, 2.81; N, 7.82; S, 17.90%.

UV λ_{max}^{MeOH} mμ (log ε): 258 (4.50), 340 (3.96).

The benzene solution of XVII colored brownish red in the organic layer with ferric chloride.

2,7-Dihydroxycyclohepta[d]thiazol-6-one (XIX).—a) A mixture of 30 mg. of XIV and 0.1 ml. of 85% phosphoric acid was heated at 160~170°C for 11 hr., cooled and diluted with a small amount of water. The mixture was adjusted to pH 4 with ammonia water under ice-cooling, the black precipitate that formed was collected, and washed with water. The precipitate was sublimed at 200°C (bath temp.)/1 mmHg and the yellow sublimate was recrystallized from ethyl acetate. m. p. 275~278°C (decomp). Yield, 10 mg.

Found: C, 49.20; H, 2.92; N, 7.12. Calcd. for $C_8H_5O_3NS$: C, 49.24; H, 2.58; N, 7.18%.

UV λ_{max}^{MeOH} mμ (log ε): 265.5 (4.43), 355 (3.99), 370 (3.99), 384 (4.00), 402 (4.01).

The ethyl acetate solution of XIX colors green in the aqueous layer by addition of aqueous solution of ferric chloride.

b) A mixture of 100 mg. of XVIII, 9 ml. of concentrated hydrochloric acid, and 3 ml. of water was heated at 120°C for 8 hr., cooled and insoluble matter was filtered off. The filtrate was evaporated to dryness in a reduced pressure, the residue was dissolved in water, and the solution was adjusted to pH 4 with ammonia water. The solid (A) that separated out was collected by filtration.

The filtrate left after removal of A was extracted with ethyl acetate and the solvent was evaporated from this extract. This residue was combined with A and sublimed at 200°C (bath temp.)/1 mmHg. The yellow crystalline sublimate was recrystallized from ethyl acetate. Yield, 40 mg.

Summary

It has been found that treatment of 3-bromotropolon-5-yl-thiourea derivatives with a base resulted in facile formation of 7-hydroxycyclohepta[d]thiazol-6-one derivatives, with liberation of hydrogen bromide. Out of such products, 2-benzamido derivative was submitted to oxidative degradation and its structure was confirmed.

Reaction of 3-bromo-5-aminotropolone and carbon disulfide, in the presence of a tertiary amine, was found to form a 2-mercapto derivative. Correlation of this product with the foregoing products proved the structure.

A part of the expenses for the present work was supported by a fund from the Sankyo Co., Ltd., which is gratefully acknowledged.

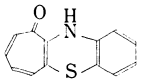
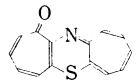
*2-Phenylthiazolo[4, 5-b]tropones**



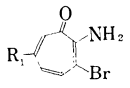
By Tetsuo NOZOE, Toyonobu ASAO and Kazuko TAKAHASHI

(Received August 8, 1962)



The authors have been reported[1] the synthesis of benzo-1,4-thiazino[3,2-b]tropone (cyclohepta[b]benzo-1,4-thiazin-10(11*H*)-one) (I) and its various derivatives by the reaction of 3-halotropolones and *o*-aminothiophenol. In anticipation of the sythesis of the similar compound II having 7–6–7 ring system, the reaction of 2-amino-3-bromotropones and 2-mercaptotropones was carried out, but in this reaction 2-phenylthiazolo[4,5-b]tropones, instead of II, were obtained by rearrangement of mercaptotropone nucleus, the results of which will be described herein.

When 2-amino-3-bromotropone (III)[2] and 2-mercaptotropone (2-hydroxytropothione[3]) (IV)[4] was refluxed in ethanol, the starting materials were recovered with a minute amout of disulfide V. However, heating of the mixture of III and IV in ethanol in the presence of sodium ethoxide in a sealed tube at 125°C for 10 hr., which is the same conditon as in the synthesis of 3-alkylthiotropolones from 3-bromotropolone[4], gave yellow prisms (VI), m.p. 183°C, with the correct analytical values for II. In a similar reaction of IV and 2-amino-3-bromo-6-isopropyltropone (VII), which was obtained from 3-bromo-6-isopropyl-2-methoxytropone[5] and liquid ammonia, yellow plates (VIII), m.p. 145°C, were obtained, analysis being agreed with isopropyl derivative of VI.



Reaction of III with 6-isopropyl-2-mercaptotropone (IX)[6] or 4-isopropyl-2-mercaptotropone (X)[6] were carried out. Although the reaction of III and IX at 125°C in the presence of sodium ethoxide gave no definite product except disulfide XI and some starting materials, the reaction at 110°C afforded yellow prisms (XII), m.p. 142°C, having the same molecular formula with VIII. X also gave yellow prisms by the reaction with III, but the product proved to be identical with XII. This fact clearly showed that the reactions in both cases underwent a quite different fashion from our anticipation and the product (XII) could not be the homologs of II. These unexpected reaction can be explained by assuming XII

is 2(3'-isopropylphenyl)-thiazolo[4,5-b]tropone produced by rearrangement of the mercaptotropone nucleus to the benzenoid one. Moreover, the similarity of ultraviolet spectra of VI and VIII with that of XII (Fig. 1), implies that VI and VIII, both formed under a similar reaction condition, are not II and its isopropyl derivative but 2-phenylthiazolo[4,5-b]tropone and its 6-isopropyl derivatives.

These hypotheses were confirmed by the formation of VI from the condensation reaction of thiobenzoic acid and III.

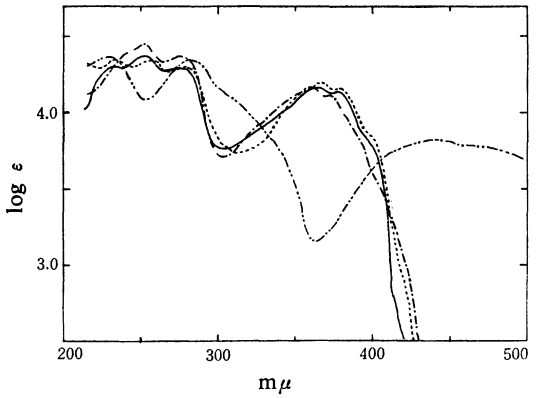

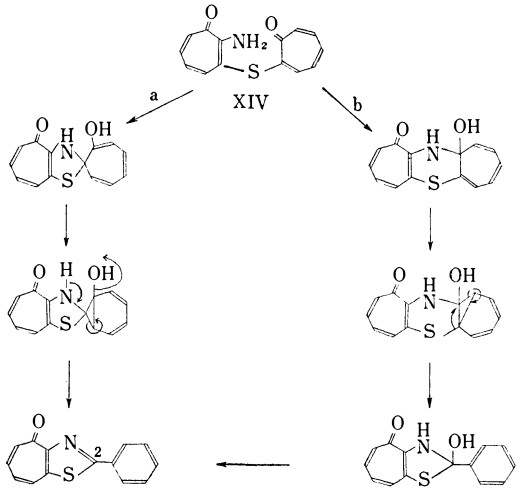

Fig. 1. Ultraviolet absorption spectra of I (—··—··), VI (———), VIII (—·—·) and XII (·····) in methanol.

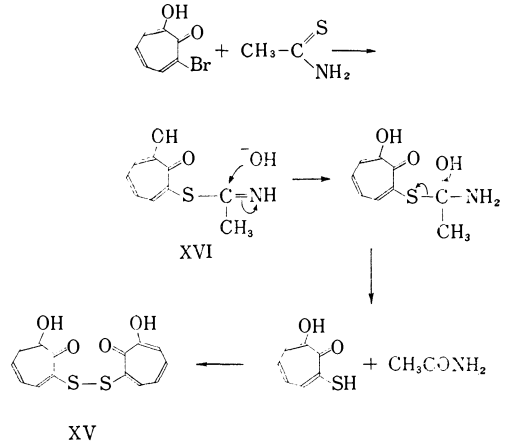
Ultraviolet spectra of these thiazolotropones show considerable hypsochromic shift compared with I and rather resemble that of 2-methyloxazolo[4,5-b]tropone (XIII)[7]. While, in their infrared spectra, absorption band of N–H or O–H do not appear and C=O stretching bands appear at 1627 cm^{-1} in VI and 1622 cm^{-1} in VIII, and these values seem to be reasonably corresponding to the C=O band of tropones[8] VI, VIII and XII are very stable toward heat, acid or alkali and do not give any molecular compound such as picrate. However, they give 2,4-dinitrophenylhydrazones, m. p. 251, 259 and 218°C, respectively.

Since it was found that 2-mercaptotropone was stable under the condition employed in these condensation reactions, the reaction path to these 2-phenylthiazolo[4,5-b]tropones involves the initial formation of thio ether XIV which undergoes rearrangement by one of the following routes.



In path a, carbon at 2-position in the product, thiazolotropone, is originated from carbon-2 of mercaptotropone, while the same carbon in the product is carbonyl carbon if path b has been followed. It is considered that b is the more favorable path than a, since the aromatization of 2-substituted tropones is accepted to be initiated by attack of bases on the carbonyl-carbon, a similar attack on carbon-2 resulting in the replacement of the substituent at the same carbon[9]. A more detailed examination would, however, be desirable before any difinite conclusion is drawn.

Attempted synthesis of other thiazolotropones will be described in the following. Attempted reaction of III and thioacetic acid gave an oily substance, whose ultraviolet spectrum is similar to that of VI. However, the closer investigation on the structure was interrupted by minuteness of the yield.

It has been known that the reaction of 3-bromotropolone and thioacetamide gave an undifined compound[10]. This reaction was duplicated in various condions. The compound, m. p. 236°C, was obtained which was identical with the one previously obtained. However, it became clear that this compound is, in fact, 3,3'-ditropolonyl disulfide (XV)[4]. It is considered that this reaction proceeds through the initial formation of thio ether XVI followed by its decomposition to acetamide and 3-mercaptotropolone, which is oxidized to XV as is depicted below[11].

The reaction of thiourea with isomeric methyl

11) 3-Mercaptotropolone has not been obtained due to its facile oxidation to give the corresponding disulfide under neutral or acidic conditions (cf. Ref. 4).

ethers obtained from 3-bromotropolone was attempted. Heating of 2-bromo-7-methoxytropone with thiourea in ethanol gave yellow needles (XVII), m. p. 152°C. By the same way, pale yellow needles (XVIII), m. p. 108°C, were obtained from 3-bromo-2-methoxytropone. From the fact that original bromomethoxytropones were obtained by treatment of these products with silver nitrate and their ultraviolet spectra resemble those of original tropones, together with their analyses, it is concluded that XVII is a molecular compound of 2-bromo-7-methoxytropone and thiourea with a ratio of 2 : 1, and XVIII is 1 : 1 molecular compound of 3-bromo-2-methoxytropone and thiourea. These molecular compounds are quite stable and always only products obtained from the above-menthioned reactions under more severe conditions.

Experimental*

2-Phenylthiazolo[4, 5-b]tropone (VI).—a) To a sodium ethoxide solution prepared from sodium (51.7 mg.) and anhydrous ethanol (15 ml.), 2-mercaptotropone (IV) (310 mg.) and 2-amino-3-bromotropone (III) (300 mg.) were added, and the mixture was heated in a sealed tube at 125°C for 10 hr. After cooling, the precipitate was filtered off, the solvent was removed from the filtrate in vacuo. To the dark oily residue, water (50 ml.) was added, adjusted to slightly alkaline and extracted with chloroform. Recrystallization from benzene of the crude crystals (159 mg.) obtained from the extract afforded yellow prisms (VI), m. p. 182~183°C.

Found: C, 70.02; H, 3.77; N, 5.56. Calcd. for $C_{14}H_9ONS$: C, 70.29; H, 3.79; N, 5.86%.

UV: λ_{max}^{MeOH} mμ (log ε): 233 (4.29), 252 (4.37), 273 (4.29), 363 (4.16), 380 (4.13).

2,4-Dinitrophenylhydrazone; violet needles, m. p. 251°C.

Found: C, 57.18; H, 2.87; N, 16.37. Calcd. for $C_{20}H_{13}O_4N_5S$: C, 57.28; H, 3.12; N, 16.70%.

b) To a solution of sodium (26 mg.) in anhydrous ethanol (10 ml.), III (150 mg.) and thiobenzoic acid (155 mg.) were added and the mixture was treated in the same way as in a). Sixty milligrams of yellow prisms obtained showed no depression of the melting point on admixture with VI obtained by method a) and their ultraviolet and infrared spectra were identical.

2 (3' - Isopropylphenyl) - thiazolo [4, 5 - b] tropone (XII).—a) Heating of a solution of III (300 mg.) and 6-isopropyl-2-mercaptotropone (IX) (405 mg.) in a sodium ethoxide solution prepared from 57 mg. of sodium and 15 ml. of ethanol in a sealed tube at 110°C for 10 hr., followed by the same procedure described in the preceeding section yielded 227 mg. of yellow prisms (XII) (from acetone), m. p. 141~142°C.

Found: C, 72.51; H, 5.09; N, 4.85. Calcd. for $C_{17}H_{15}ONS$: C, 72.58; H, 5.37; N, 4.98%.

UV: λ_{max}^{MeOH} mμ (log ε): 235 (4.35), 256 (4.35), 275 (4.29), 365 (4.19), 380 (4.15).

2,4-Dinitrophenylhydrazone; violet needles, m. p. 218°C.

Found: C, 60.15; H, 3.93; N, 15.02. Calcd. for $C_{23}H_{19}O_4N_5S$: C, 59.87; H, 4.15; N, 15.18%.

b) The reaction of III (300 mg.) and 4-isopropyl-2-mercaptotropone (X) (405 mg.) according to the above mentioned procedure afforded 265 mg. of yellow prisms, m. p. 142°C, which is identical with XII (mixed melting point, and ultraviolet and infrared spectra).

6-Isopropyl-2-phenylthiazolo[4,5-b]tropone (VIII).—The reaction of IV (857 mg.) and 2-amino-3-bromo-6-isopropyltropone (VII) (752 mg.) in ethanol contained 143 mg. of sodium followed by the above-mentioned procedure resulted in 300 mg. of yellow plates (XIII), m. p. 144~145°C.

Found: C, 72.89; H, 5.59; N, 4.82. Calcd. for $C_{17}H_{15}ONS$: C, 72.58; H, 5.37; N, 4.98%.

UV: λ_{max}^{MeOH} mμ (log ε): 253 (4.45), 275 (4.38), 359 (4.16), 375 (4.10).

2,4-Dinitrophenylhydrazone; violet needles, m. p. 259°C.

Found: C, 59.61; H, 3.95; N, 15.14. Calcd. for $C_{23}H_{19}O_4N_5S$: C, 59.87; H, 4.15; N, 15.18%.

2-Amino-3-bromo-6-isopropyltropone (VII).—After a solution of 3-bromo-6-isopropyl-2-methoxytropone (1.16 g.) in liquid ammonia (20 ml.) was allowed to stand at room temperature for 3 days, ammonia was evaporated, the residual yellow oil was dissolved in chloroform, washed with water, dried (sodium sulfate) and passed through an alumina column, and 812 mg. of yellow oil was obtained, which was crystallized by adding ethanol. Recrystallization from ethanol gave yellow crystals, m. p. about 35°C.

Found: C, 48.80; H, 4.69; N, 5.99. Calcd. for $C_{10}H_{12}ONBr$: C, 49.60; H, 4.99; N, 5.79%.

Reaction of 3-Bromotropolone with Thioacetamide.—a) A solution of 3-bromotropolone (600 mg.) and thioacetamide (600 mg.) in pyridine (12 ml.) was refluxed for 3.5 hr. To the residue left after removal of pyridine, water was added and the precipitate (484 mg.) was recrystallized from ethanol affording 3,3'-ditropolonyl disulfide, m. p. 235°C, which was identified by the mixed melting point with authentic sample[4].

b) A solution of sodium salt (300 mg.) of 3-bromotropolone and thioacetamide (250 mg.) in anhydrous pyridine (8 ml.) was heated in a sealed tube at 120°C for 3 hr., from which 127 mg. of 3, 3'-ditropolonyl disulfide was obtained.

Molecular Compounds (XVII and XVIII) of 3-Bromotropolone Methyl Ethers and Thiourea.—a) A solution of 2-bromo-7-methoxytropone (500 mg.) and thiourea (266 mg.) in ethanol (13 ml.) was refluxed for 1 hr. By cooling the mixture, yellow needles (432 mg.) were obtained and recrystallized from methanol giving yellow needles (XVII), m. p. 152°C.

Found: C, 40.27; H, 3.56; N, 5.58. Calcd. for $C_{17}H_{18}O_4N_2SBr_2$: C, 40.33; H, 3.66; N, 5.54%.

b) Heating of a solution of 3-bromo-2-methoxytropone (600 mg.) and thiourea (213 mg.) in ethanol

* All melting points were not corrected.

(15 ml.) afforded XVIII (213 mg.) pale yellow needles, m. p. 108°C.

Found: C, 36.69; H, 3.71; N, 9.56. Calcd. for $C_9H_{11}O_2N_2SBr$: C, 37.13; H, 3.81; N, 9.63%.

Syntheses of DL-Hydroxylysine and DL-Allohydroxylysine

By Nobuo IZUMIYA, Yoshimasa FUJITA and Motonori OHNO

(Received August 13, 1962)

Although the separation of normal and allo form of DL-hydroxylysine derivatives were performed by Fones[1] through fractional recrystallizations of two diastereomeric α-chloroacetyl-ε-carbobenzoxy lactones and by Zahn and Zürn[2] in the same way through α, ε-dicarbobenzoxy lactones, none of them were considered satisfactory because of their poor yields. This paper describes the separation of α, ε-dicarbobenzoxyhydroxylysine lactones into the two diastereomers with good yield by a new method which was based on the fact that the normal form of dicarbobenzoxy lactone is saponified by alkali faster than its allo form.

For the synthesis of diastereomeric mixture of hydroxylysine hydrochlorides, the methods of the literatures[2-3] were slightly modified. To reduce an intermediate diethyl (γ-hydroxy-δ-nitro-*n*-butyl)-acetamidomalonate (I) to the δ-amino derivative, Van Zyl et al.[3] used platinum black as a catalyst and Zahn et al.[2] employed Raney-nickel catalyst under high pressure of hydrogen. However, both procedures seemed not to be practical for a large scale experiment. We studied with palladium catalyst on the reduction of the δ-nitro group in I in several different solvents and found acetic acid to be an excellent solvent. Some results were shown in Fig. 1. In this way, 300 g. of I were reduced to diethyl (γ-hydroxy-δ-amino-*n*-butyl)-acetamidomalonate which was then hydrolyzed with acid giving 158 g. of hydroxylysine hydrochloride. Thus, the yield was improved and the procedure was remarkably simplified. Chromatographic analysis[4] revealed that the ratio of normal to allo form of this synthetic hydroxylysine hydrochloride was 46 : 54. In the next steps of carbobenzoxylation and lactonization, although Zahn and Zürn[2] reported the synthesis of diastereomeric dicarbobenzoxy lactones with the yield of 61%, we improved the yield until 91% applying an azeotropic distillation technique with benzene for the completion of lactonization. For the separation of the diastereomers, a solution of dicarbobenzoxy lactones in dioxane was first treated with sodium hydroxide equivalent to an amount of normal form which was estimated on free hydroxylysine by chromatographic analysis. Sodium salt of dicarbobenzoxyhydroxylysine thus obtained by partial saponification gave pure normal dicarbobenzoxy lactone while unsaponified lactone extracted into ethyl acetate was purified, giving the pure allo form. The two diastereomers of hydroxylysine hydrobromide were obtained from the corresponding dicarbobenzoxy lactones by the treatment of hydrogen bromide in acetic acid, and their purities were ascertained by the elution analysis from a column of Dowex 50[4] (see Figs. 5, 6 and 7).

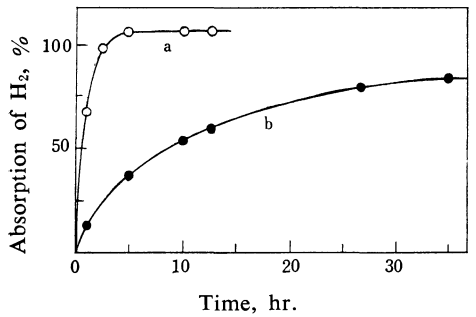

Fig. 1. Reduction of diethyl (γ-hydroxy-δ-nitro-*n*-butyl)-acetamidomalonate (I) : a, I (1 g.) and 10% Pd charcoal (0.2 g.) in acetic acid (10 ml.) ; b, I (1 g.) and 10% Pd charcoal (0.2 g.) in methanol (10 ml.) containing HCl equivalent to I.

The rates of saponification of the pure dicarbobenzoxy lactones were determined using a pH-Stat. As shown in Fig. 2, the normal

form was saponified about 10 times faster than the allo form. Recently Witkop reported that the normal hydroxylysine and its lactone have erythro and trans configuration, respectively[5]. Taking this view into consideration, it is concluded that the lactone with trans configuration is easily saponified as shown in Fig. 3. In this connection, it should be noted that Wisiger reported that dibenzoyl derivative of L-allohydroxylysine was obtained as the lactone, whereas that of D-hydroxylysine as free acid[6]. In a preliminary experiment in this laboratory in collaboration with Dr. Bernhard Witkop, diastereomeric dicarbobenzoxy-DL-hydroxyornithine lactones, unlike the case of dicarbobenzoxyhydroxylysine lactones, could not be separated with the use of sodium hydroxide equivalent to an amount of the trans form.

Experimental

Diethyl (γ-Hydroxy-δ-nitro-*n*-butyl)-acetamidomalonate (I).—Diethyl acetamidomalonate (760 g., 3.5 mol.) and acrolein (257 ml., 3.86 mol.) were condensed in ethanol (1.4 l.) containing metallic sodium (1.1 g.)[7]. The solution containing γ-acetamido-γ,γ-diethoxycarbonylbutyraldehyde was added during 30 min. under stirring to an ice-cooled solution of nitromethane (0.88 l.), dioxane (0.088 l.) and 5 N sodium hydroxide (0.088 l.). After being stirred for 16 hr. at room temperature, 5 N sodium hydroxide (0.025 l.) was added and the stirring was continued for another 24 hr. After being neutralized with acetic acid (0.039 l.), the solution was evaporated in vacuo and the residue was added to a mixture of benzene (1.5 l.) and petroleum ether (0.15 l.). The mixture was allowed to stand for several days in a refrigerator to cause the separation of crystals which were filtered and washed with water. After being dried well and recrystallized from benzene (2.5 l.), it was dissolved in ethanol (1.5 l.) and the solution was evaporated in vacuo. The addition of water (1.5 l.) and the shaking of mixture caused the formation of crystals, yield 620 g. (53%), m. p. 68~71°C. This was saved for the next step. Two recrystallizations from aqueous ethanol gave an analytical sample, m. p. 76°C (Found: C, 46.70; H, 6.52; N, 8.34%). The reported values are m. p. 95.2~96°C[8] and 77°C[8].

Hydroxylysine Monohydrochloride (Diastereomeric Mixture).—I (300 g., 0.9 mol.) in acetic acid (1.5 l.) containing 10% palladium charcoal (30 g.) was reduced for 6 hr. at room temperature under 1 atm. of hydrogen in a 5 l. three-neck flask, fitted with a sealed stirrer, an inlet tube for hydrogen, and an outlet tube which was in contact with a surface of mercury. The catalyst was removed by filtration, the filtrate was added to concentrated hydrochloric acid (1.5 l.), and the solution was refluxed for 10 hr. It was evaporated to dryness in vacuo and the excess of acids was removed by repeated addition of water and evaporation. The residue was taken up in water, treated with triethylamine (0.4 l.) and the solution was evaporated to dryness in vacuo. After being washed with a mixture of ethanol (1.5 l.) and acetone (0.3 l.) by the method of decantation, the residue was taken

up in water. The solution was decolorized with charcoal and concentrated in vacuo to a small volume. The addition of ethanol (1.8 l.) effected the precipitation of a powdery substance, yield 158 g. (88%). This was saved for the next step. The paper chromatography of this compound showed only one spot by means of the ninhydrin test with several solvent systems. As shown in Fig. 4, ion-exchange analysis of the compound gave a ratio, normal to allohydroxylysine, of 46 : 54. Two recrystallizations from water-ethanol gave a sample, m. p. 212~218°C (decomp.). (Found: C, 35.99; H, 7.72; N, 14.31%).

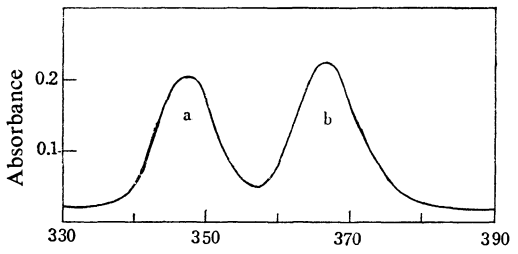

Fig. 4. Chromatography of diastereomeric hydroxylysine monohydrochloride: a, hydroxylysine; b, allohydroxylysine.

Chromatographic Assay of Normal and Allohydroxylysine. — The method of Stein and Moore as modified by Witkop and Beiler[4] was utilized to assay the composition of hydroxylysine. A 100× 0.9 cm. column of Dowex 50×8 (200~400 mesh) was treated with 0.1 M sodium citrate buffer of pH 3.4. An aqueous solution containing 1.0 mg. of hydroxylysine monohydrochloride was passed through the column and eluted with 0.1 M sodium phosphate buffer of pH 7.6. Slight pressure was applied to keep the flow rate at 4 ml. per hr. One-ml. samples were collected with an automatic fraction collector and analyzed by the ninhydrin method[9] at 570 mμ.

Dicarbobenzoxyhydroxylysine Lactone (Diastereomeric Mixture) (II).—The powdery hydroxylysine monohydrochloride (39.8 g., 0.2 mol.) obtained above was treated with carbobenzoxy chloride (89 ml., 0.52 mol.) and 2 N sodium hydroxide (0.52 l.) by Schotten-Baumann's procedure. An oil separated upon acidification with 5 N hydrochloric acid (0.21 l.) was extracted with chloroform. The chloroform solution was dried over sodium sulfate and evaporated in vacuo to an oil to which benzene (1 l.) was added. The mixture was heated under reflux for 3 hr., the liberated water being removed azeotropically using a Dean and Stark distilling apparatus[10]. After the filtration of some insoluble material, the filtrate was evaporated to an oil which was crystallized by the addition of petroleum ether. It was filtered and washed with petroleum ether, yield 75.4 g. (91%). This was used without further purification. We supposed that a ratio of normal to allo form in this compound should have been close to 46 : 54 because the yield of dicarbobenzoxy derivative from diastereomeric hydroxylysine, the ratio of which was 46 : 54, was excellent (91%).

Dicarbobenzoxy-DL-hydroxylysine Lactone (III). To a solution of II (41.2 g., 0.1 mol.) in dioxane (400 ml.) was added 1 N sodium hydroxide (46 ml.)* at room temperature. After standing for 1 hr., the solution was evaporated in vacuo to dryness. The residue was shaken with a mixture of ethyl acetate (600 ml.) and water (400 ml.) (the ethyl acetate layer was saved for the recovery of IV), the aqueous layer was acidified with 5 N hydrochloric acid (10 ml.) and an oil separated was extracted with ethyl acetate. The solution was dried over sodium sulfate and evaporated in vacuo to an oil to which benzene was added. The benzene solution was refluxed for 3 hr., the liberated water being removed azeotropically. Benzene was removed by evaporation in vacuo and the residue was recrystallized twice from ethyl acetate, yield 10.4 g. (55% based on the supposed amount (46%) of normal form in II), m. p. 135~136°C.

Found: C, 64.01; H, 5.97; N, 6.67. Calcd. for $C_{22}H_{24}O_6N_2$: C, 64.06; H, 5.87; N, 6.79%.

The reported value is m. p. 137~141°C[2].

Dicarbobenzoxy-DL-allohydroxylysine Lactone (IV).—After the ethyl acetate layer described above was kept in a refrigerator, crystals appearing were filtered and washed with cold ethyl acetate. The combined filtrate and washings were dried over sodium sulfate and evaporated in vacuo to dryness. The crystals and dried residue were recrystallized twice from ethanol, yield 17.8 g. (80% based on the supposed amount (54%) of allo form in II), m. p. 151°C.

Found: C, 63.96; H, 5.86; N, 6.74. Calcd. for $C_{22}H_{24}O_6N_2$: C, 64.06; H, 5.87; N, 6.79%.

The reported value is m. p. 154~155.5°C[2].

DL-Hydroxylysine Monohydrobromide (V). — A saturated solution of hydrogen bromide in acetic acid[11] (30 ml.) was added at room temperature to III (6.17 g., 0.015 mol.) which had been previously pulverized. III was dissolved within 2~3 min. and different crystals appeared after 5~6 min. The mixture was allowed to stand with occasional shakings for 1 hr., and then treated with ether (120 ml.) and petroleum ether (30 ml.). The crystals were filtered and washed with ether, but changed instantly to a gummy product because of its highly hygroscopic character. Second crop of the gummy product was obtained from the filtrate and washings by the addition of petroleum ether. The combined products were dissolved in water and triethylamine (9 ml.) was added**. The solution was evaporated in vacuo

* In another run of the same experiment, a half mole of 1 N sodium hydroxide (50 ml.) was used, III and IV being obtained with the yields of 9.5 g. and 17.1 g., respectively.

11) D. Ben-Ishai and A. Berger, *J. Org. Chem.*, **17**, 1564 (1952).

** In another run of the same experiment, silver carbonate was added to the aqueous solution until pH 6.5 and pure DL-hydroxylysine monohydrobromide was obtained from the filtrate with a similar yield in the case of the use of triethylamine.

to dryness and the residue was filtered with the aid of ethanol. It was recrystallized from water (7 ml.)-ethanol (20 ml.), yield 3.17 g. (87%), m. p. 230~231°C (decomp.).

Found: C, 29.66: H, 6.31; N, 11.39. Calcd. for $C_6H_{15}O_3N_2Br$: C, 29.64; H, 6.22; N, 11.52%.

The product (1.0 mg.) was analyzed by the method of ion-exchange chromatography, the procedure being described before. The curves of absorbance of V itself and a mixture of V and L-allohydroxylysine monhydrochloride[12] were shown in Figs. 5 and 6, respectively. These results indicate that V is a pure normal form.

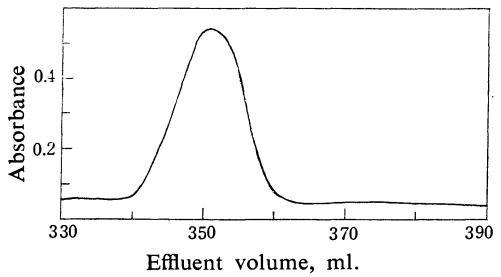

Fig. 5. Chromatography of DL-hydroxylysine monohydrobromide.

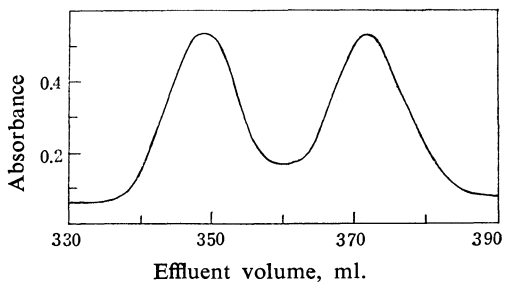

Fig. 6. Chromatography of a mixture of DL-hydroxylysine monohydrobromide and L-allohydroxylysine monohydrochloride.

DL-Allohydroxylysine Monohydrobromide (VI).—IV (6.17 g.) was treated with hydrogen bromide in acetic acid in the same way as described above. The yield of the recrystallized product was 2.61 g. (71%), m. p. 219°C (decomp.)

Found: C, 29.74; H, 6.26; N, 11.21. Calcd. for $C_6H_{15}O_3N_2Br$: C, 29.64; H, 6.22; N, 11.52%.

As shown in Fig. 7, the product is a pure allo form. Zahn and Zürn reported the preparation of DL-hydroxylysine and DL-allohydroxylysine monohydrochloride[2].

Saponification of Dicarbobenzoxy Derivatives, III and IV.—A solution of III or IV (4.12 mg., 0.01 mmol.) in a mixture of dimethylformamide (1.5 ml.) and water (1.5 ml.) was saponified at 40°C with 0.1 N sodium hydroxide using Radiometer's pH-Stat (type TTTl) which was set at a constant pH of 10.0. The curves recorded automatically were shown in Fig. 2, indicating that III was saponified completely within about 10 min., while IV needed about 100 min. for complete saponification.

Summary

A diastereomeric mixture of DL-hydroxylysine hydrochlorides was obtained with a good yield through hydrogenation of diethyl (γ-hydroxy-δ-nitro-*n*-butyl)-acetamidomalonate with palladium catalyst in a solvent of acetic acid, which was followed by hydrolysis of the reduced product. Dicarbobenzoxy lactone was prepared with a yield of 91% from hydroxylysine hydrochloride obtained above. A solution of diastereomeric dicarbobenzoxy lactones in dioxane was treated with sodium hydroxide equivalent to the amount of normal form. The salt obtained after saponification converted into a pure normal dicarbobenzoxy lactone, a pure allo compound being isolated from the unsaponified portion. The two lactones were converted into chromatographically pure normal and allohydroxylysine monohydrobromides by the action of hydrogen bromide in acetic acid.

Synthesis of DL-*Lysine from 1, 1, 1, 5-Tetrachloropentane*

By Kazuo SAOTOME and Yasuto KODAIRA

(Received August 23, 1962)

In a previous paper[1], the synthesis of DL-lysine from 1, 1, 1, 5-tetrachloropentane which was prepared by the telomerization of ethylene and carbontetrachloride via benzoylaminocaproic acid as the intermediate was reported.

The present work is concerned with another process for the synthesis of DL-lysine from 1, 1, 1, 5-tetrachloropentane involving seven steps as shown below.

$Cl(CH_2)_4CCl_3$ (I) $\longrightarrow$ $Cl(CH_2)_3CH{=}CCl_2$ (II) $\longrightarrow$ $CN(CH_2)_3CH{=}CCl_2$ (III) $\longrightarrow$ $H_2N(CH_2)_4CH{=}CCl_2$ (IV) $\longrightarrow$ $C_6H_4(CO)_2N(CH_2)_4CH{=}CCl_2$ (V) $\longrightarrow$ $C_6H_4(CO)_2N(CH_2)_4CHCl\text{-}COOH$ (VI) $\longrightarrow$ $C_6H_4(CO)_2N(CH_2)_4CHNH_2\text{-}COOH$ (VII) $\longrightarrow$ DL-Lysine·HCl

In the first step, I was dehydrochlorinated to 1, 1, 5-trichloropentene-1 (II) in the presence of anhydrous ferric chloride as the catalyst[2]. Since the dichlorovinyl group in II is inert towards nucleophilic reagents, II was treated with potassium cyanide in dimethylformamide (DMF) solution to prepare 1, 1-dichloro-5-cyanopentene-1 (III). In the hydrogenation of III under a high pressure of hydrogen, the Raney cobalt was found to be a favorable catalyst for attacking the nitrile group selectively. 1, 1-Dichloro-6-aminohexene-1 (IV) was acylated by heating with phthalic anhydride to give 1, 1-dichloro-6-phthaliminohexene-I (V).

Some examples of the reaction between the dichlorovinyl group and chlorine in a sulfuric acid solution to obtain α-chlorocarboxylic derivatives were reported by Russian authors[3]. The reaction mechanisms are explained as follows.

$$C_6H_4(CO)_2N(CH_2)_4CH{=}CCl_2 \xrightarrow[H_2SO_4]{Cl_2} C_6H_4(CO)_2N(CH_2)_4\underset{Cl}{CH}\text{—}\underset{OSO_3H}{CCl_2} \xrightarrow{H_2O} C_6H_4(CO)_2N(CH_2)_4\underset{Cl}{CH}\text{—}COOH$$

A chlorine atom and a sulfuric acid residue are added to the double bond of V, and the resulting adduct decomposes with water to give 2-chloro-6-phthaliminocaproic acid (VI). The resulting VI was aminated with aqueous ammonia. Since phthaliminolysine could not be crystallized, the reaction mixture was concentrated, and without further purification it was hydrolyzed by hydrochloric acid to give DL-lysine. DL-Lysine monohydrochloride was separated and purified as in the previous paper[1].

Experimental

1, 1, 5-Trichloropentene-1 (II).—Dehydrochlorination of I was investigated using several Friedel-Crafts type catalysts. After the evolution of hydrogen chloride had ceased, the reaction mixture was

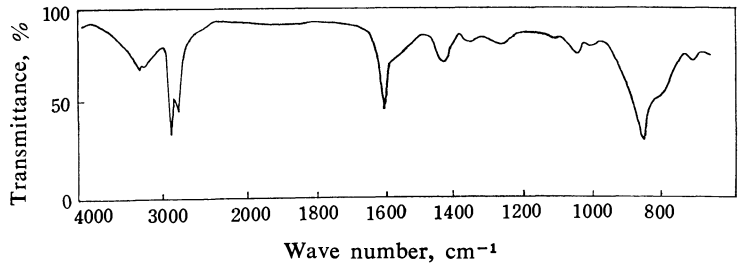

Fig. 2. Infrared spectrum of 1, 1-dichloro-6-aminohexene.

washed with water, then distilled under reduced pressure to afford II, b. p. 48~50°C/4 mmHg, n_D^{20} 1.4892 (lit. b. p. 68~69°C/7 mmHg, n_D^{20} 1.4892). The reaction conditions and the yields are shown in Table I.

When aluminum chloride which is a stronger catalyst than ferric chloride was used for the reaction, the reaction proceeded smoothly at a lower temperature. But the resinous by-product was observed to increase in the distillation residue.

However, in the case of a weaker catalyst such as zinc chloride or stannic chloride, the reaction proceeded only slowly even at an elevated temperature. The best result was obtained when ferric chloride was added in two portions. The infrared spectrum of II showed a strong absorption band at 1620 cm^{-1} due to C=C double bond.

1, 1-Dichloro-5-cyanopentene-1 (III).—Into a solution of 82 g. of potassium cyanide in 500 ml. of DMF maintained at 115°C was added dropwise 174 g. of II over one hour with stirring. The reaction was continued for additional two hours. Potassium chloride was filtered and the solvent was evaporated under reduced pressure. Distillation of the residue under reduced pressure afforded 142 g. of III (88% yield), b. p. 99~101°C/5 mmHg, n_D^{20} 1.4818 (lit.[4] b. p. 80~81°C/3 mmHg, n_D^{20} 1.4815).

1, 1-Dichloro-6-aminohexene-1 (IV).—Hydrogenation of III was carried out using the Raney cobalt and nickel (prepared according to the recipe W-7[4]) as a catalyst in an alcoholic solution containing ammonia. An autoclave (500 ml.) equipped with a magnetic stirrer was used for the reaction. After removal of the catalyst and the solvent, the reaction product was washed with water and extracted with ether. Distillation of the extract under reduced pressure afforded IV, b. p. 77~80°C/5 mmHg, n_D^{20} 1.4860. Details of the reaction are shown in Table II.

From Table II, the Raney cobalt is shown to be the preferable catalyst to the Raney nickel for the selective hydrogenation of III. On the other hand, the hydrogenation of 1, 1, 5-trichloropentene-1 was attempted under the same conditions, but no absorption of hydrogen was observed. An attempt to hydrogenate the nitrile group in III by metallic sodium in an alcoholic solution was also made. But the product was resinous, and no IV was obtained.

Infrared Spectra.—The spectra of III and IV are shown in Figs. 1 and 2. The characteristic band

4) A. N. Nesmeyanov, L. I. Zakharkin and R. Kh. Freidlina, *Izv. Akad. Nauk SSSR, Otd. Kim. Nauk*, **1954**, 34.
5) H. Adkins and H. R. Billica, *J. Am. Chem. Soc.*, **70**, 695 (1948).

at 2220 cm^{-1} due to cyano group in Fig. 1 disappears in Fig. 2, and a new band at 3250 cm^{-1} (NH) appears in Fig. 2. While the band at 1620 cm^{-1} assigned to carbon-carbon double bond is observed both in Fig. 1 and Fig. 2.

1, 1-Dichloro-6-phthaliminohexene-1 (V).—A mixture of IV (16.4 g.) and phthalic anhydride (29 g.) was heated under nitrogen atomosphere at 145~150°C in an oil bath for 4 hr. Aqueous solution of sodium hydroxide (5%, 120 ml.) was poured to the reaction mixture to dissolve the excess phthalic anhydride. The precipitate was separated, powdered and washed several times with water. Its recrystallization from ethanol afforded white crystals. Yield, 27.4 g. (96%); m. p., 56°C.

Found: C, 56.56; H, 4.70; N, 4.59. Calcd. for $C_{14}H_{13}O_2NCl_2$: C, 56.39; H, 4.39; N, 4.70%.

2-Chloro-6-phthaliminocaproic Acid (VI).—Into 70 ml. of sulfuric acid (96%) cooled with ice-water, V (15 g.) was added slowly to make a clear solution. Chlorine gas was passed through this solution at 5°C with stirring. The reaction was continued for 3 hr. until the evolution of hydrogen chloride had ceased. The reaction mixture was poured into ice-water, and the solidified product was washed with water. Recrystallization from benzene afforded white crystals. Yield, 14.1 g. (95%); m. p., 124~125°C.

Found: C, 56.83; H, 4.72; N, 5.01. Calcd. for $C_{14}H_{14}O_4NCl$: C, 56.82; H, 4.73; N, 4.73%.

DL-Lysine Monohydrochloride.—Into an autoclave (200 ml.) equipped with a magnetic stirrer, were taken VI (10 g.), ammonium carbonate (15 g.) and 100 ml. of 28% aqueous ammonia. The reaction was carried out at 60~65°C for 8 hr. The reaction mixture was concentrated to about 30 ml. to remove free ammonia. To this solution was added 80 ml. of 20% hydrochloric acid and the mixture was refluxed for 12 hr. Phthalic acid precipitated was filtered off and the solution was concentrated to dryness under reduced pressure. The solid product was dissolved in 200 ml. of water. The solution was treated with anion exchange resin (Amberlite IR-4B) to remove the excess hydrochloric acid. The solution was concentrated and cooled. DL-Lysine monohydrochloride was precipitated by adding acetone. The pure sample (3.3 g.) was obtained by recrystallization from an acetone-water mixture. The yield was 53.4% of the theoretical amount. This was identified by paper chromatography with the authentic sample and shown to be one-spot.

Found: C, 39.21; H, 8.06; N, 15.46. Calcd. for $C_6H_{15}O_2N_2Cl$: C, 39.45; H, 8.23; N, 15.34%.

Summary

DL-Lysine was synthesized from 1, 1, 1, 5-tetrachloropentane. The process involves seven steps; 1, 1, 5-trichloropentene-1 (92%), 1, 1-dichloro-5-cyanopetene-1 (88%), 1, 1-dichloro-6-aminohexene-1 (59%), 1, 1-dichloro-6-phthaliminohexene-1 (96%), 2-chloro-6-phthaliminocaproic acid (95%), DL-lysine monohydrochloride (53%). The over-all yield from 1, 1, 1, 5-tetrachloropentane to DL-lysine monohydrochloride was 23%.

In the hydrogenation of 1, 1-dichloro-5-cyanopentene-1 to 1, 1-dichloro-6-aminohexene-1; the Raney cobalt was found to be a favorable catalyst for attacking the nitrile group selectively.

Vinyl Polymerization. LXIV. Graft Copolymerization of Vinyl Monomers to Starch*

By Shoichi KIMURA**, Takehiro TAKITANI and Minoru IMOTO

(Received August 6, 1962)

Many authors have reported on the synthesis of graft copolymers of starch. The methods described were chain transfer reaction[1,2], high energy radiation[3], oxidation with ozone[4], oxidation with ceric salt[5], and polymer blend[6]. In order to obtain a graft copolymer of starch with high efficiency, we used the method of the polymerization of the monomer in the presence of oxidized starch. Kargin et al. peroxidized starch with ozone and initiated vinyl polymerization with it to obtain a graft

copolymer. They obtained grafted starch with polymethyl methacrylate or polystyrene. However, the efficiency of their reaction was not stated[4].

The present paper concerns the stability of ozone-oxidized starch, the graft copolymerization of methyl methacrylate, acrylonitrile or vinyl chloride with the oxidized starch, and the fractionations of the grafted copolymer and their properties.

Experimental

Oxidation of Starch.—Starch was purified by reprecipitation from an aqueous solution with ethanol. It was charged into a four-necked flask which contained water or carbon tetrachloride. Ozonized oxygen generated by an ozonizer of the Japan Ozonizer Co. (Type 03-5-2) was introduced at the velocity of 6 l./hr. at room temperature while the mixture was vigorously stirred. A stirrer, as shown in Fig. 1, was made from a glass-tube; it had two gas-outlets, of which one opened near the bottom in the liquid layer and the other just above the liquid surface. After a definite time, the reaction mixture was filtered in order to obtain oxidized starch.

Determination of the Content of the Peroxide Group in Oxidized Starch. — The content of the peroxide group in the oxidized starch was determined as follows. A definite quantity of the oxidized starch was immersed in a 10% aqueous solution of potassium iodide for 10 min. at room temperature (29°C) or for 3 min. at 70 and 100°C. The content of the peroxide group was expressed by the number of peroxide groups per anhydroglucose unit (AGU) of starch. The quantity of starch in the filtrate was estimated on the basis of the amount of glucose which was liberated by hydrolysis in 1.0 N hydrochloric acid at 95°C for 3 hr. The determination of the glucose was made by Somogyi's method.

Polymerization Procedure.—The polymerization of methyl methacrylate (MMA), acrylonitrile (AN), and vinyl chloride (VC) was carried out under the conditions described in Table I.

In Experiments I, III, V and VI, a mixture of a monomer, starch and solvent was charged in a test tube, cooled in a dry ice-methanol bath, and sealed in vacuum. The sealed tube was shaken at 90°C in a thermostat for a given time; the contents were then poured into methanol to precipitate the polymer mixtures. In Experiments II and IV, the mixture was charged into a three-necked flask, and nitrogen was then introduced into it at room temperature for 15 min. Then, the mixture was heated while being stirred. After a given time, the contents were poured into methanol to precipitate all the polymers.

Fractionation of Polymerization Products. — *Copolymerization Product with Methyl Methacrylate.*— Copolymerization product with MMA was extracted with benzene for 30 hr., using a Soxlhet extractor. The benzene solution was poured into methanol to precipitate polymer I. The residue of the extraction was dissolved or swelled in dimethyl sulfoxide. It was then poured into warm water (about 50°C) to precipitate polymer II. As will be discussed below, it was assumed that polymer I was pure PMMA and that polymer II was a starch-PMMA graft copolymer.

The grafting efficiency and grafting ratio were computed as follows:

$$\text{Grafting efficiency} = \frac{\text{Wt. of vinyl polymer in grafts}}{\text{Total wt. of vinyl polymer formed}} \times 100$$

$$\text{Grafting ratio} = \frac{\text{Wt. of vinyl polymer in grafts}}{\text{Wt. of starch in grafts}}$$

The intrinsic voiscosities of PMMA and hydrolyzed graft copolymer were measured in benzene at 30°C.

Copolymerization Product with Vinyl Chloride. — Copolymerization product with vinyl chloride was

extracted with tetrahydrofuran for 30 hr., using a Soxlhet extractor. The solution was poured into methanol to precipitate polymer III. The residue of the extraction was dissolved in dimethylsulfoxide and poured into warm water (about 50°C) to precipitate polymer IV. Polymers III and IV were assumed to be pure polyvinyl chloride and its graft copolymer respectively. The grafting efficiency and grafting ratio were computed according to the above equations. The intrinsic viscosities of polymer III and hydrolysed polymer IV were measured in a tetrahydrofuran solution at 30°C.

Acetylation of Graft Copolymer.—The acetylation of the graft copolymer of starch was carried out with acetic anhydride in pyridine, according to Pacsu's method[7]. The pyridine solution was poured into methanol to obtain the acetylated polymer. The infrared spectra of the resulting acetate no longer showed hydroxyl band.

Melting Points of Polymers.—An apparatus with a hot plate and a microscope (Shimadzu Seisakusho) was used for the measurement of the melting points of polymers.

Results and Discussion

Oxidation of Starch with Ozone.—During the oxidation with ozone in water, the oxidized starch was separated into water-soluble and water-insoluble parts. Figures 2 and 3 show the relationships between the contents of the peroxide group and the oxidation durations. The insoluble oxidized starch in water (abbr. as insoluble "oxi-starch-W") was used for syntheses of graft copolymers.

Oxi-starch-W was colored red purple with an iodine solution. Since the coloration of non-oxidized starch is blue, it was assumed that partial hydrolysis occured in the course of oxidation.

However, when ozonization was carried out in carbon tetrachloride, starch remained in-

soluble in the medium and was not hydrolyzed. This was abbreviated in "oxi-starch-C". Figure 4 shows the relationship between the contents of the peroxide group of oxi-starch-C and the oxidation time.

The figures for the contents of the peroxide group of oxi-starch-W, as determined by treating it at room temperature for 10 min., were higher than those determined by treating it at 70°C for 3 min. Conversely, the figures for the contents of the peroxide group of oxi-starch-C, as determined by treating it at room temperature for 10 min., were lower than those determined at 100°C for 3 min. During the oxidation, starch particles swelled in water but not in carbon tetrachloride. Accordingly, it was assumed that the swelled particles were oxidized more uniformly, and that the unswelled particles were oxidized only on the surface. The differences in the contents of peroxide group according to the temperature of determination may be explained by the consideration that the peroxide groups located within the strach particles were inactivated at a higher temperature, before potassium iodide molecules diffused to the reaction centers. The following determination of the peroxide group of oxi-starch was

Bulk Polymerization of MMA in the Presence of Oxi-Starch. — The results of the bulk copolymerization of MMA with oxi-starch, and of the fractionation of the products, are summarized in Table II. Polymer I was not colored by the iodine solution and was so assumed to be pure PMMA. Polymer II contained starch and was insoluble in most organic solvents. However, after hydrolysis in an acidic medium, the product dissolved in benzene. Polymer II was therefore assumed to be a starch-PMMA graft copolymer.

The polymerization of MMA initiated with oxi-starch gave a large amount of the homopolymer of PMMA and a small amount of grafted PMMA.

From this table, it can be seen that the intrinsic viscosities of grafted PMMA were slightly higher than those of free PMMA.

Emulsion Polymerization of MMA in the Presence of Oxi-Starch or Non-oxidized Starch. —The polymerization of MMA in the presence of oxi-starch was carried out in an aqueous emulsion. The results of the polymerization and of the fractionation of the products are summarized in Table III. At 90°C, the polymerization proceeded smoothly. The grafting efficiency and the grafting ratio were quite high. At 60°C, the graft copolymer was obtained.

The graft copolymer was insoluble in most organic solvents, but the acetylated graft copolymer dissolved in some solvents, as is shown in Table IV. It was also shown that its solubility lay between PMMA and starch triacetate. From this solubility, it was assumed that polymer II is a starch-PMMA graft copolymer.

The differences between the cases of oxi-starch-W and of oxi-starch-C were only with difficulty observed with regard to the conversion of MMA and the free starch content of the products. The degrees of polymerization of free PMMA and of grafted PMMA were the same. However, the grafting efficiency with oxi-starch-C was slightly higher than that with oxi-starch-W.

Unexpectedly, non-oxidized starch could initiate the polymerization of MMA to yield a graft copolymer in an aqueous emulsion state. It is clear from Table III that the initiation of polymerization is not due to the heat. However, in the absence of water, no initiation by starch itself as is shown in Table II, was observed. The results of the interesting

graft-copolymerizations are tabulated in Table V.

Even starch treated with a solution of potassium iodide could initiate the polymerization of MMA. In this case, it is clear that starch had no peroxide group.

Dialdehyde starch, which was prepared by the oxidization of starch with periodic acid, could initiate the polymerization of MMA at a greatly increased rate. When starch was preheated, the rate of polymerization decreased. Glucose and purified maltose had no abilities to initiate the polymerization. However, when impure maltose was used, the polymerization of MMA started. Accordingly, the polymerization was initiated by some impurities existing in starch. The exact process still remains unexplained.

The melting points of starch-PMMA graft copolymers are shown in Table VI. They are slightly higher than the values of the homopolymer.

Polymerization of AN in the Presence of Oxi-Starch. — The polymerization of AN in the presence of oxi-starch was carried out in an aqueous suspension at 90°C. The results are shown in Table VII. The polymerization product dissolved with difficulty in most organic solvents. After its hydrolysis with 1 N hydrochloric acid at 95°C for 3 hr., a polymer soluble in dimethyl formamide was obtained. It contained no free starch.

After the acetylation of the polymerization product, it was separable into two parts: soluble and insoluble polymers in pyridine. The former was 89.5% starch, and the latter, 20.3% starch. It was assumed that the former was a mixture of PAN and starch acetate-PAN graft copolymers and that the latter was a mixture of starch acetate and a small number of the graft copolymers. The isolation of the graft copolymer was too difficult to accomplish. The solubilities of these polymers are shown in Table VIII.

No polymerization of AN by non-oxidized starch in an aqueous suspension was observed.

Polymerization of Vinyl Chloride (VC) in the Presence of Oxi-Starch. — The polymerization of VC in the presence of oxi-starch was carried out in bulk or in an aqueous

emulsion, as is shown in Table IX. Only in aqueous emulsion was the polymerization observed. Polymer III did not contain starch and was assumed to be PVC. Polymer IV was 67.6% starch and was soluble in dimethyl sulfoxide. It was considered to be a starch-PVC graft copolymer. The degree of polymerization of PVC was lower. The grafting efficiency and the grafting ratio were lower than in the case of PMMA. The solubility of the graft copolymer is shown in Table X.

Summary

1) Starch was oxidized with ozone in a medium of water or carbon tetrachloride to yield per-oxidized starch (abbreviated as oxi-starch-W or oxi-starch-C).

2) The stabilities of the peroxide-group of oxi-starchs were measured.

3) In the present of oxi-starch, polymerizations of methyl methacrylate (MMA), acrylonitrile (AN) and vinyl chloride were carried out. Graft copolymers of starch with vinyl polymers were obtained. Their properties were described.

4) It was confirmed that commercial starch, dialdehyde starch oxidized with periodic acid, starch treated with potassium iodide, and commercial maltose could also initiate the polymerization of methyl acrylate, yielding graft copolymers and vinyl homo-polymers.

Infrared Absorption Spectra of Hydrazides. V. Oxal-, Malon- and Succin-Hydrazides

By Mitsuo MASHIMA

(Received August 11, 1962)

In a previous paper[1] the infrared frequencies characteristic of the $-CONHNH_2$ group have been reported on. The present investigation has aimed at obtaining further evidence about the characteristic frequencies of the $-CONHNH_2$ group. The infrared absorption spectra of oxal-, malon- and succin-hydrazides and their *N*-deuterated species in the solid state were examined in the rock salt region. For the sake of comparison, the infrared absorption spectra of hydrazioxlyl, hydrazimalonyl, hydrazisuccinyl and oxamide acide hydrazide were also examined. The results of these measurements are reported in this paper, and the frequencies characteristic of the $-CONHNH_2$ group are considered on the basis of these experimental results.

Experimental

Oxal-, malon- and succin-hydrazides were synthesized with ethyl esters of corresponding acids and hydrazine hydrate and were purified by recrystallization from ethanol (m. p., 236, 150, 167°C respectively). Oxamide acid hydrazide was synthesized by the reaction of oxalic acid ethylester amide and hydrazine hydrate and was purified by recrystallization from water (m. p., 220°C). Hydrazioxalyl and hydrazisuccinyl were synthesized by the reactions of oxal- and succin-hydrazides respectively, with sodium nitrite in the acetic acid solution. Hydrazimalonyl was prepared by heating malon-hydrazide with acetic acid. These compounds were purified by repeatedly washing the precipitates obtained with a quantity of ethanol; they were neither melted nor decomposed up to 280°C. The *N*-deuterated derivatives examined were prepared in sealed tubes in the presence of heavy water (99.8%), the excess of which was evaporated in a vacuum.

The infrared spectrophotometer used to obtaining the absorption spectra is an Hitachi infrared spectrophotometer Type EPI-2 with rock salt prisms. Potassium bromide disks were used to obtain the solid spectra.

Results and Discussion

Oxalhydrazide (OxH) and Oxamide Acid Hydrazide (OAH).—The infrared spectra of OxH, its *N*-deuterated species (OxH-d_6), and OAH are illustrated in Fig. 1. The absorption bands of these compounds were interpreted by comparison of the spectra with those of oxamide[2] and *NN'*-dimethyloxamide[3].

In the 3000 cm^{-1} region, oxamide* has two very strong bands, at 3363 and 3185 cm^{-1}, which have been ascribed to the asymmetric and symmetric NH_2 stretching vibrations. *NN'*-Dimethyloxamide[3] has a band at 3290 cm^{-1} which has been ascribed to the NH stretching vibration. OAH has three bands at 3340, 3250, and 3190 cm^{-1}. Of these three, the first and the third bands are very close in frequency to the two bands due to the NH_2 stretching vibrations for oxamide, while the second one is close in frequency to the ν(NH) band of *NN'*-dimethyloxamide. Therefore, the 3340 and 3190 cm^{-1} bands are probably to be ascribed to $\nu(NH_2)$, and the 3250 cm^{-1} band, to ν(NH).

OxH has a relatively sharp band at 3260 cm^{-1}, two broad bands at 3160 and 3000 cm^{-1}, and a shoulder band at 2780 cm^{-1}. These bands are probably due to $\nu(NH_2)$ and ν(NH), but further, detailed assignments of them are not easy. OxH-d_6 has two bands, at 2640 and 2300 cm^{-1}, which are due to $\nu(ND_2)$ or ν(ND).

The 1662 and 1606 cm^{-1} bands of OxH correspond in frequency, respectively, to the 1656 cm^{-1} band ascribed to the C=O stretching vibration and the 1608 cm^{-1} band ascribed to the NH_2 bending vibration for oxamide[2]. OxH-d_6 has a broad and intense absorption band with a centre near 1650 cm^{-1}; this band corresponds to the 1662 cm^{-1} band of OxH, the ratio of ν_H/ν_D being 1.01. The 1606 cm^{-1} band of OxH corresponds to the band at 1202 cm^{-1} for OxH-d_6, $\nu_H/\nu_D=1.336$. From these facts, the 1662 and 1606 cm^{-1} bands can surely be ascribed to the C=O stretching and the NH_2 bending vibrations respectively. These assignments are also supported by the fact that *NN'*-dimethyloxamide[3] has an amide I band at 1658 cm^{-1}, while the compound has

no band corresponding to the 1606 cm^{-1} band of OxH. On the other hand, OAH shows rather different absorptions in this region; i. e., it has two intense bands, at 1637 and 1583 cm^{-1}, both of which are associated with a shoulder band, at 1684 and 1532 cm^{-1} respectively. These bands are probably due to the C=O stretching and NH_2 bending vibrations, but detailed interpretations of them are not easy.

The 1522 cm^{-1} band of OxH has its counterpart at 1440 cm^{-1} in the OxH-d spectrum, the value of ν_H/ν_D being 1.057. These two bands are, respectively, very close in frequency to the amide II band at 1532 cm^{-1} for *NN'*-dimethyloxamide[3] and the amide II' band at 1445 cm^{-1} for its *N*-deuterated specy[3]. In consequence, the 1522 cm^{-1} and 1440 cm^{-1} bands can surely be taken as the amide II and amide II' bands respectively. In this region, oxamide[2] has no band corresponding to the amide II band, while the compound has a 1348 cm^{-1} band which has been ascribed to the C–N stretching vibration. For OAH, the 1417 and 1326 cm^{-1} bands can also be ascribed to the C–N stretching vibrations, but the assignments are not certain.

In the 1300~900 cm^{-1} range, OxH has three bands, at 1267, 1097 and 973 cm^{-1}, which correspond in frequency to the bands at 1261, 1107 and 991 cm^{-1} respectively for OAH. The three bands of OxH are apparently weakened on *N*-deuteration; they correspond, respectively, to the bands at 1067, 966 and 858 cm^{-1} for OxH-d_6. They are, therefore, due to the NH_2 or NH deformation vibrations. For OxH, the band at 1307 cm^{-1} corresponds to the band at 1108 cm^{-1} for OxH-d_6. OAH also has a band at 1296 cm^{-1}. For monoacid hydrazides, the present author has obtained three frequencies due to the NH_2 deformation vibrations, e. g., 1347, 1105 and 1009 cm^{-1} for cyanoacetylhydrazine[1]. Consequently, the bands at 1307, 1097 and 973 cm^{-1} for OxH and 1296, 1107 and 991 cm^{-1} for OAH are taken as characteristic of the $-CONHNH_2$ group. The 1267 cm^{-1} (for OxH) and 1261 cm^{-1} (for OAH) bands are close in frequency to the amide III band at 1239 cm^{-1} for *NN'*-dimethyloxamide[3]. They will, therefore, be taken as the amide III band.

OxH has a strong band at 792 cm^{-1} which has not yet been accounted for. This band shifts to 757 cm^{-1} on *N*-deuteration. OAH has a band with two peaks (713 and 702 cm^{-1}); this band corresponds to the 792 cm^{-1} band for OxH. *NN'*-Dimethyloxamide[3] has an amide IV band at 765 cm^{-1}, the frequency value of which is close to that of the 792 cm^{-1} band for OxH. Therefore, the 792 cm^{-1} band of OxH will be taken as an amide IV band. On the other hand, oxamide[2] has a 629 cm^{-1} band which has been ascribed to the in-plane N–C=O deformation vibration. For OAH the appearance of two peaks, 713 and 702 cm^{-1}, will depend on the reduced symmetry of the molecule.

The 1124 cm^{-1} band of OxH has its counterpart at 1146 cm^{-1} in the OxH-d_6 spectrum. OAH also has corresponding bands at 1159 and 1144 cm^{-1}. They are probably dut to the N–N stretching vibration, but the assignments are not sure. OxH has more two weak bands, at 834 and 815 cm^{-1}, while no band corresponding to them has been found for OxH-d_6 in the region examined here. These two bands correspond in frequency to the bands at 824 and 783 cm^{-1} of OAH, but these can

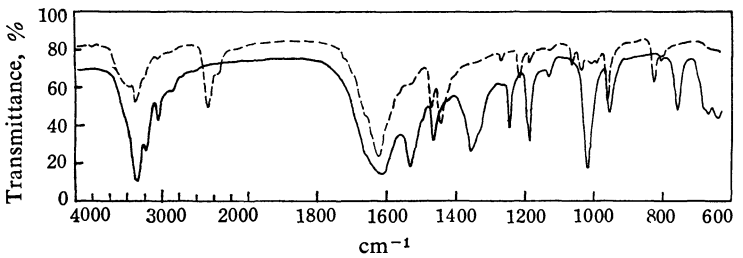

Fig. 2. Infrared absorption spectra of succinhydrazide (solid curve) and its *N*-deuterated specy (dashed curve).

not be interpreted with confidence. For OAH a weak band at 925 cm^{-1} is probably to be attributed to the C-C stretching vibration, which is infrared active because of the asymmetric character of the molecule.

The observed frequencies for OxH and OAH and their tentative assignments are summarized in Table I, in which the infrared frequencies of oxamide and *NN'*-dimethyloxamide are also represented for the sake of comparison.

Succinhydrazide (SH).—For this compound the frequencies characteristic of the $-CONHNH_2$ group were rather easily obtained. The solid spectra of SH and its *N*-deuterated specy (SH-d_6) are illustrated in Fig. 2, and the tentative assignments of the absorption bands are given in Table II.

In the 3000 cm^{-1} region, SH has three strong or moderately strong bands, at 3270, 3160 and 3030 cm^{-1}, all of which are apparently weakened on *N*-deuteration. Their counterparts are found at 2440 and 2340 cm^{-1} in the SH-d_6 spectrum. They can, therefore, be ascribed to NH_2 or NH stretching vibrations. Since an SH molecule has a hydrazine residue, it can reasonably be expected that three bands due to the N-H bond stretching vibrations appear in this region. However, detailed assignments of the observed bands are impossible on the basis of present observations only.

Next, we will concern ourselves with the location of the CH_2 deformation vibrations. For $X-XH_2-CH_2-X$ type molecules, Nakagawa[4]

ν; stretching, β; bending, ω; wagging, τ; twisting, γ; rocking

has obtained the following ranges for the CH_2 deformation frequencies; 1400~1450 cm^{-1} for bending, 1200~1350 cm^{-1} for wagging, 1050~1250 cm^{-1} for twisting, and 700~1000 cm^{-1} for rocking. For SH, the band at 1462 cm^{-1} is near the range for CH_2 bending vibrations, and its value of frequency is scarcely changed on *N*-deuteration. In consequence, it may be assigned to the CH_2 bending vibration. The band at 1258 cm^{-1} corresponds to the band at 1265 cm^{-1} of SH-d_6 and they both fall in the range for the CH_2 wagging vibrations; accordingly, they are assigned to the CH_2 wagging vibration. SH has a further weak band at 1126 cm^{-1} which is scarcely changed in frequency on *N*-deuteration and which falls in the range for the CH_2 twisting vibrations. Thus, the 1126 cm^{-1} band may be assigned to the CH_2 twisting vibration. The weak band at 800 cm^{-1}, which also is scarcely changed in frequency on *N*-deuteration, falls in the range for the CH_2 rocking vibration. Consequently, the 800 cm^{-1} band is assigned to the CH_2 rocking vibration. However, SH has a further band falling in the 700~1000 cm^{-1} range. This is the band at 948 cm^{-1}, which is also scarcely changed in frequency on *N*-deuteration. Although the 948 cm^{-1} band is tentatively assigned to the C–C stretching vibration, an alternative assignment (to the CH_2 rocking vibration) is also possible.

Let us now consider the location of vibrations relating to the $-CONHNH_2$ group. This group contains the –CONH– group, so the amide I, II, III and IV bands may be expected to appear in the region examined here. In fact, very strong band at 1624 cm^{-1} is surely assigned to amide I because it corresponds in frequency and intensity to the band at 1620 cm^{-1} of SH-d_6. SH has a band at 1528 cm^{-1} which can easily be assigned to the amide II band. This assignment is supported by the observation that SH-d_6 has a corresponding band (amide II') at 1441 cm^{-1}, the ratio of ν_H/ν_D being 1.060. The amide III band is expected to appear near 1300 cm^{-1}, but its identification will be considered with those of the bands due to the NH_2 deformation vibrations. SH apparently shows absorptions below 700 cm^{-1} and the amide IV band will apparently appear near 700 cm^{-1}, but no definite evidence can be observed in the spectra of SH-d_6 in the region examined here.

In the 700 to 1700 cm^{-1} region, five absorption bands (with the exception of the amide I and II bands) have been found for some monoacid hydrazides; these have been taken as characteristic of the $-CONHNH_2$ group[1]; e. g., for cyanoacetylhydrazine they have been observed at 1625, 1347, 1258, 1105 and 1009 cm^{-1}. Of these five the first band has been ascribed to the NH_2 bending vibration. For SH no band corresponding to it is observed because of its location near the amide I band at 1624 cm^{-1}, while SH-d_6 has a band at 1212 cm^{-1} which is probably due to the ND_2 bending vibration. SH has bands corresponding to the latter four at 1353, 1240, 1181 and 1012 cm^{-1}, all of which disappear on *N*-deuteration. The 1258 cm^{-1} band of cyanoacetylhydrazine has been taken as the amide III band; accordingly, the 1240 cm^{-1} band of SH can be assigned similarly. In the SH-d_6 spectrum, the counterpart of the 1012 cm^{-1} band is easily found at 820 cm^{-1} ($\nu_H/\nu_D=1.234$), but definite identifications of the counterparts of the other three are not easy. SH-d_6 has a further two bands at 1059 and 1032 cm^{-1} which are not present in the SH spectrum. These two bands probably correspond to two of the bands at 1353, 1240 and 1181 cm^{-1} for SH.

Malonhydrazide (MH). — The absorption spectra of MH and its *N*-deuterated specy (MH-d_6) are illustrated in Fig. 3. The obserevd frequencies of MH and MH-d_6 and their tentative assignments are summarized in Table III.

In the 3000 cm^{-1} region, a strong band at 3290 cm^{-1} and two moderately strong bands

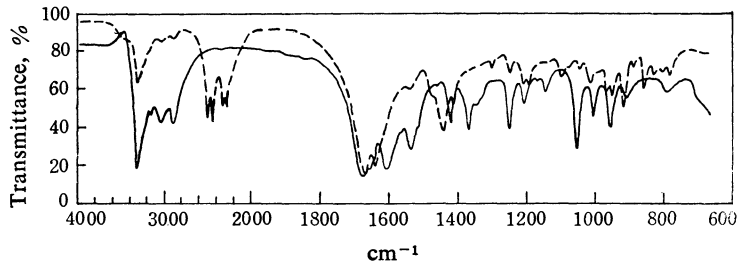

Fig. 3. Infrared absorption spectra of malonhydrazide (solid curve) and its *N*-deuterated specy (dashed curve) in the rock salt region.

at 3020 and 2870 cm^{-1} are found for MH. For MH-d_6 two doublet bands are found at 2480 and 2430 cm^{-1} and at 2310 and 2260 cm^{-1}. They are probably due to NH_2 (ND_2) or NH(ND) stretching vibrations; more detailed assignments are difficult on the basis of present observations only.

MH has two very strong bands at 1669 cm^{-1} (accompanied by two ill-defined shoulder bands on the lower frequency side) and 1602 cm^{-1}. The two bands correspond to the bands at 1664 and 1636 cm^{-1} for MH-d_6 and are taken as amide I bands. The appearance of two bands taken as amide I bands is due to coupling two vibrations which are localized mainly on two C=O bonds. Although the NH_2 bending vibration is also expected to give rise to bands near 1600 cm^{-1}, definite identification is impossible because of its location near the amide I band. For MH-d_6, the band at 1189 cm^{-1} is probably to be ascribed to the ND_2 bending vibration. The 1532 cm^{-1} band of MH shifts to 1435 cm^{-1} (ν_H/ν_D= 1.068) on *N*-deuteration; it may be taken as an amide II band. For monoacid hydrazides[1], an amide III band has been observed near 1250 cm^{-1}. MH has a band at 1247 cm^{-1} which shifts to 1036 cm^{-1} on *N*-deuteration (ν_H/ν_D=1.203) and which hence may be taken as an amide III band.

Let us next consider the locations of the NH_2 deformation vibrations other than the bending one already accounted for. For monoacid hydrazides[1] such vibrations have been observed near 1300, 1150 and 1000 cm^{-1}. MH has three bands, at 1365 (accompanied by a shoulder band on its lower frequency side), 1139 and 1051 cm^{-1}. All these three disappear on *N*-deuteration; their counterparts are found at 1093, 962 and 918 cm^{-1} in the MH-d_6 spectrum, the values of ν_H/ν_D being 1.249, 1.184 and 1.145 respectively. They may, therefore, be ascribed to the NH_2 deformation vibrations.

In the region examined here, the CH_2 deformation vibrations are also expected to give rise to bands. For them Nakagawa[5] has obtained the ranges of 1350~1450 cm^{-1} (bending), 1100~1350 cm^{-1} (wagging), 1000~1250 cm^{-1} (twisting) and 700~1000 cm^{-1} (rocking) for the molecules of the CH_2XY type. MH has corresponding bands at 1418, 1202, 1002 and 785 cm^{-1}. None of these four is greatly changed in frequency on *N*-deuteration; i.e., MH-d_6 has the four bands at 1408, 1203, 1008 and 775 cm^{-1}. In consequence, they may easily be ascribed to the CH_2 bending, wagging, twisting and rocking vibrations respectively.

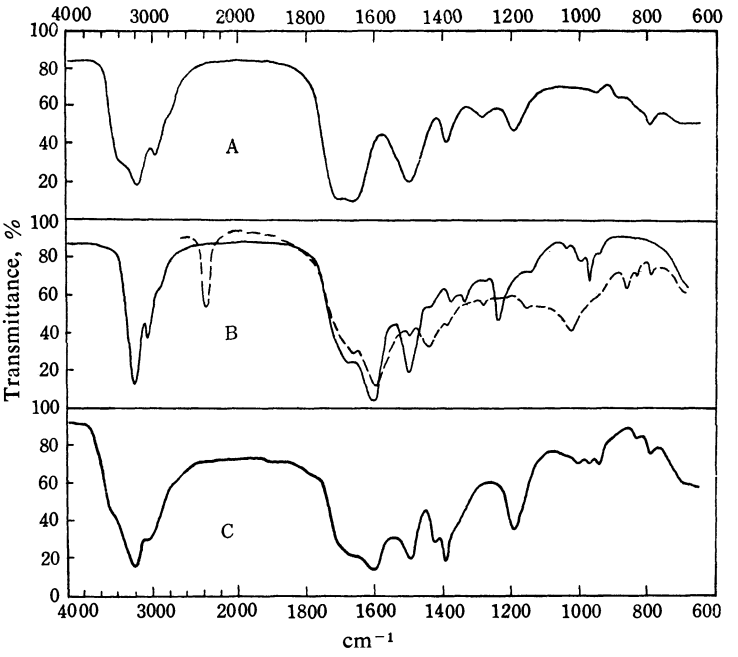

Fig. 4. Infrared absorption spectra of hydrazioxalyl (curve A), hydrazimalonyl (curves B's), and hydrazisuccinyl (curve C). Of the curves B's the dashed curve indicates the spectrum of *N*-deuterated specy of hydrazimalonyl.

For MH, two bands, at 952 and 903 cm^{-1}, are not yet accounted for. In the MH-d_6 spectrum, the former has its counterpart at 948 cm^{-1}, but the band corresponding to the latter can not be identified because of its location on the sloping background of the more intense band at 918 cm^{-1}. MH-d_6 has a rather stronger band at 850 cm^{-1}. These are probably due to the C–C stretching vibrations.

Hydrazioxalyl (HO), $(C_2H_2O_2N_2)_x$, Hydrazimalonyl (HM), $(C_3H_4O_2N_2)_x$ and Hydrazisuccinyl (HS), $(C_4H_6O_2N_2)_x$. — The solid spectra of these compounds are illustrated in Fig. 4. For HM the absorption spectrum of its *N*-deuterated specy (HM-d_2) was also examined. The so-called amide bands were identified without difficulty.

For HM, two, very strong bands are found at 1662 and 1593 cm^{-1} which correspond in intensity to the bands at 1655 and 1590 cm^{-1} for HM-d_2. The two bands, therefore, may easily be taken as amide I bands; corresponding bands are found at 1655 and 1590 cm^{-1} for HS and at 1705 and 1656 cm^{-1} for HO.

HM has a strong band at 1486 cm^{-1} which shifts to 1432 cm^{-1} on *N*-deuteration, ν_H/ν_D= 1.038. The corresponding band is found at 1492 cm^{-1} for HO and 1485 cm^{-1} for HS. In consequence, they may surely be taken as amide II bands.

The amide III band is also expected to appear in the region examined here. For HM, the band at 1230 cm^{-1} shifts to 1009 cm^{-1} on *N*-deuteration, ν_H/ν_D=1.219. This band corresponds to the 1185 cm^{-1} band for HO and the 1184 cm^{-1} band for HS; these are taken as amide III bands.

For all these compounds, a strong band is found near 3160 cm^{-1}; this band is probably due to the NH stretching vibration.

The present author[6] has obtained the frequencies characteristic of the –CONHNHCO– group of some diacid hydrazides; e. g., formylacetylhydrazine in the solid state absorbs at 3020 and 3200 cm^{-1} (NH stretching), 1580 and 1613 cm^{-1} (amide I), 1483 cm^{-1} (amide II), and 1232 and 1279 cm^{-1} (amide III). In the present study, bands similar to these were obtained for HO, HM and HS as is summarized in Table IV.

Characteristic Frequencies. — Oxal-, malon- and succin-hydrazide show the frequencies characteristic of the $-CONHNH_2$ group, as

6) M. Mashima, This Bulletin, 35, 423 (1962).

summarized in Table V. The characteristic frequencies of HO, HM and HS are represented in Table IV.

Amide Bands.—In the 600~1800 cm^{-1} region mono-substituted amides[7] usually show the following bands characteristic of the trans-planar –CONH– group; the amide I band ca. 1650 cm^{-1}, the amide II band ca. 1550 cm^{-1}, the amide III band in the 1200~1300 cm^{-1} range, and the amide IV band ca. 760 or 630 cm^{-1}. As may be seen from Table V*, the –CONH– group contained in the $-CONHNH_2$ group also exhibits the characteristic bands indicated above.

On the other hand, *NN'*-diacid hydrazides[6] show amide I, II and III bands having rather low frequency values. Further, two values of frequencies have been obtained for the amide I and III bands. In the present study also, amide bands of rather low frequencies were obtained for HO, HM and HS, while two frequency values were obtained for the amide I band, as may be seen from the Table IV. The spectroscopic evidence, therefore, suggests that the –CONHNHCO– group of HO, HM and HS has a structure similar to that of *NN'*-diacidhydrazides. The presence of two frequencies, taken as amide I bands, is probably due to the coupling of two vibrations which are localized mainly on the C=O group, as was postulated in an earlier paper[6].

NH_2 Deformation Absorptions. — For some aliphatic acid hydrazides[1], four frequencies characteristic of the $-CONHNH_2$ group have been obtained, in addition to the amide I, II, and III absorptions and the $\nu(HN_2)$ or $\nu(NH)$ absorptions. The highest one of the four was found ca. 1630 cm^{-1} and the second highest one in the 1260~1350 cm^{-1} range. The other two bands were observed ca. 1150 and ca. 1000 cm^{-1}. In the present study for dicarboxylic acid hydrazides, bands corresponding to them were obtained (cf. Table V), while HO, HM and HS have no band corresponding to them. Thus, they may surely be taken as the characteristic frequencies of the $-CONHNH_2$ group. They are probably due to the NH_2 deformation vibrations, but, of course, no definite assignments can be made without a theoretical investigation of the normal vibrations.

The author is grateful to Professor Sunao Imanishi of Kyushu University for his generous permission to use the University's spectrophotometer. He is also indebted to the Ministry of Education for its financial support.

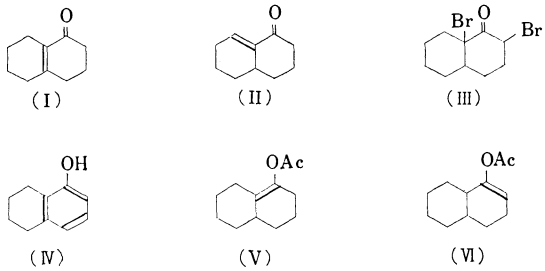
$\Delta^{9(10)}$-Octal-1-one and its Molecular Compound[1]



By Akira SUZUKI* and Takeshi MATSUMOTO

(Received August 16, 1962)

In the course of a study on the synthesis of a certain diterpenoid[2] the authors stood in need of the synthesis of $\Delta^{2(3)}$-octal-1-one from decal-1-one. It is well known that the bromination of 6-ketocholestanyl acetate[3] at low temperature gives a 5-bromo-derivative, which is converted into an isomeric 7-bromoketone on heating in acetic acid containing hydrogen bromide. Although there have been few papers[4] reporting the bromination of decal-1-one at the time this work was initiated, the authors attempted to synthesize $\Delta^{2(3)}$-octal-1-one through bromination of *trans*-decal-1-one, followed by conversion of thus obtained 9-bromo-derivative into 2-bromo-isomer, and then by dehydrobromination.

The reaction of *trans*-decal-1-one with an equivalent of bromine in chloroform at low temperature led to a mixture of bromoketones, from which a dibromodecalone, melting at 94~95°C and being designated as " dibromide ", was isolated. The yield of dibromoketone depended upon the rate of addition of bromine. The NMR spectrum (40 Mc.) of a mixture of bromoketones contained resonance lines centered at 5.41τ[5] attributable to the hydrogen atom at the C_2 position of 2-bromodecal-1-ones. It was, however, found that the quantity of 2-bromo-derivatives was several per cent by the estimation of the relative peak area. At the time such results were ascertained, Zimmerman and Mais[6] reported that the monobromination product of *trans*-decal-1-one in acetic acid containing hydrogen bromide at low temperature consists of ca. 80% of 9-bromodecalones (cis and trans) and ca. 20% of 2-bromo-isomers.

The crude bromination product, which appeared to be chiefly composed of 9-bromodecalones, was treated with hydrogen bromide in acetic acid solution, but the isomerization shown in 6-ketocholestanyl acetate[3] could not be effected. The first attempt to synthesize $\Delta^{2(3)}$-octal-1-one from *trans*-decal-1-one was thus unsuccessful. However, the dehydrobromination product of bromodecalones described above is expected to be either $\Delta^{8(9)}$-octal-1-one (II) or $\Delta^{9(10)}$-octal-1-one (I). The literature describes[7-23] a variety of reactions leading to an octal-1-one, to which usually the structure I is assigned.

Although the chemical properties of this substance were in accord with structure I, the observation[13] that the compound exhibited an ultraviolet absorption maximum at 243 mμ led Campbell and Harris to assign structure II to this octalone. The present authors therefore undertook the elucidation of the structure of the unsaturated ketone, which is also a

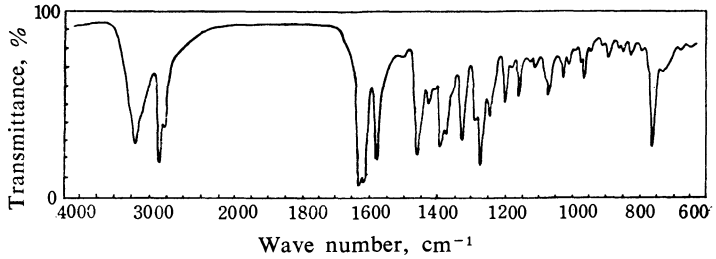

Fig. 1. Infrared spectrum of "solid octalone" (KBr Tablet).

possible intermediate for the synthesis of certain diterpenes. The crude 9-bromodecalones, previously described, could be converted into an octalone, b. p. 133~136°C/14 mmHg, by thermal dehydrobromination at 145°C; the octalone was tentatively named "liquid octalone". The identity of this product with that described in the literature was established by conversion to the 2, 4-dinitrophenylhydrazone, oxime, and semicarbazone. At the same time, there could be obtained a crystalline compound which had m. p. 58~59°C and was designated as "solid octalone". The latter compound afforded the same 2, 4-dinitrophenylhydrazone, oxime and semicarbazone as the those from "liquid octalone". The authors supposed at this stage that though the chemical and physical properties of "liquid octalone" are similar to the octalone which was previously reported[7-23], the "solid octalone" is a purer sample. Contrary to expectation, the elemental composition of the latter compound corresponded to $(C_{10}H_{13}O)_n$ rather than to that of the expected octalone, $C_{10}H_{14}O$ (see Experimental). Moreover, the infrared spectrum of the "solid octalone" (Fig. 1.) exhibited absorption bands at 3200, 1637, 1623, 1587 and 760 cm^{-1}. These bands suggest presence of a hydroxyl group and aromatic ring.

That the octal-1-one afforded the corresponding 2, 4-dinitrophenylhydrazone in a quantitative yield, was described by Campbell and Harris[13]. The "solid octalone", however, could only afford the same derivative in about a 50% yield.

From the above results, the authors next supposed that the "solid octalone" was a molecular compound of the octalone I or II, and a phenolic substance, perhaps, 5, 6, 7, 8-tetrahydronaphth-1-ol, because the presence of 2, 9-dibromodeca-1-one in the reaction mixture of the bromination of *trans*-decalone was indicated, as will be shown later. The obtained experimental data seem to support this assumption, which can be summarized as follows:

(1) The elemental composition completely agrees with that of the molecular complex $C_{20}H_{26}O_2 (=C_{10}H_{14}O+C_{10}H_{12}O)$.

(2) In the infrared spectrum, the bands at 1587 and 760 cm^{-1} correspond to aromatic ring, 1637 cm^{-1} to the conjugated carbonyl group, 1623 cm^{-1} to a conjugated double bond, and 3200 cm^{-1} to the bonded hydroxyl group.

(3) The "solid octalone" affords the same 2, 4-dinitrophenylhydrazone, oxime and semicarbazone obtained from the "liquid octalone" which is regarded as the octalone I or II.

(4) The yield of the 2, 4-dinitrophenylhydrazone is about 50%.

(5) Furthermore, through the aid of NMR spectroscopy, the "solid octalone" was suggested to be a molecular compound consisting of hydronaphthol V and octalone I rather than II. The absorption spectrum[24] (Fig. 2) is roughly divided into two parts, at a low and high applied magnetic field. The former, part A, is characteristic of proton resonance for aromatic, vinyl, and phenolic hydroxyl hydrogens[25], and the latter, part B, for other alicyclic hydrogens[25]. The intensity ratio between parts A and B, I_A/I_B which is given by the area ratio, is 5.3. The calculation value is 5.5 for the molecular compound made up of IV and I, while it is 4.2 for that composed of IV and II.

In hope confirming the structure, the authors next attempted the separation of components. After chromatography on alumina, there could

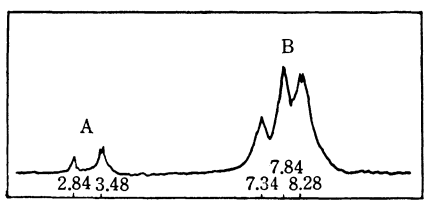

Fig. 2. The NMR spectrum of "solid octalone" in CCl_4.

24) The NMR spectra were taken on a Varian 40 Mc. instrument at Tohoku University through the courtesy of Prof. Genjiro Hazato, Drs. Tsuneo Ikenoue and Kensuke Takahashi, to whom the authors are pleased to express their sincere thanks.

25) H. S. Gutowsky, D. S. McCall, B. R. McGarvey and L. H. Meyer, *J. Am. Chem. Soc.*, **74**, 4809 (1952); L. M. Jackman, "Applications of Nuclear Magnetic Resonance Spectroscopy in Organic Chemistry", Pergamon Press, London (1959), pp. 50—71; see also Ref. 5.

be quantitatively isolated from the "solid octalone", a crystalline compound, m. p. 70~71°C and a liquid fraction. The former compound was characterized, as expected, as 5, 6, 7, 8-tetrahydronaphth-1-ol (V) and the latter compound as the "liquid octalone" by comparison with authentic sample. Conversely, the "solid octalone" could be obtained by mixing the two components in the proportion of one to one in mole.

Next, the authors discuss the structure of the "liquid octalone". The ultraviolet spectrum shows a maximum at 245 mμ (ε 12000) (lit., House and Thompson[29], 245.5 mμ (ε 12400); Campbell and Harris[13], 243 mμ (ε 11000)) characteristic of an α,β-unsaturated ketone. The basis on which Campbell and Harris[13] considered the structure to be octalone II, is that the maximum at 243 mμ falls within the range (234 to 244 mμ) which was shown by Woodward[26] to be characteristic of α,β-unsaturated ketones having one hydrogen on the doubly bound carbon atoms, and the only octal-1-one which meets this requirement is the $\Delta^{8(9)}$-derivative II. However, according to Woodward's calculation rule[26,27] for ultraviolet spectrum, the most probable maximum for $\Delta^{9(10)}$-octalone I ought to be situated at about 247 mμ[28]. Further evidence, therefore, is needed before a definite decision between the 8, 9 and 9, 10 positions of the double bond can be made. In the present work, the question was solved by the aid of NMR spectroscopic method. The NMR spectrum (40 Mc.) of the "liquid octalone" exhibited no absorption below 7 τ. It has been therefore confirmed that the structure of the "liquid octalone" is $\Delta^{9(10)}$-octal-1-one (I). Recently, the same result had been reported by House and Thompson[29]. Consequently the "solid octalone" is the molecular compound of I and 5, 6, 7, 8-tetrahydronaphth-1-ol (IV).

Moreover, the dibromodecalone, m. p. 94~95°C, which was previously named "dibromide", is probably 2, 9-dibromodecal-1-one (III) for the reason that the bromide, on heating with collidine, gives 5, 6, 7, 8-tetrahydronaphth-1-ol (IV). The "dibromide" appears to correspond to a dibromodecalone reported by Galinovsky[4] and by Zimmerman and Mais[6]. The infrared spectrum of III showed an absorption at 1726 cm^{-1} characteristic of carbonyl vibration, whereas that of parent decal-1-one at 1705 cm^{-1}. Considering Corey's observation[30] for α,α'-dibromocyclohexanone derivative, this wave number between the two ketones indicates that one bromine atom is axial and the other is equatorial in the dibromodecalone III. Further evidence, however, is necessary for determination of the complete stereochemistry.

In order to introduce a functional group only at the 2 position of decal-1-one, the authors next undertook to prepare the enol acetate VI. The reaction of *cis*-decal-1-one with acetic anhydride in the presence of *p*-toluenesulfonic acid was reported by Zimmerman and Mais[6] to yield an enol acetate. However, that the enol acetate prepared from *trans*-decal-1-one by tehir method has no absorption below 7τ in the NMR spectrum, has been ascertained in the course of the present work[31]. The product therefore may be regarded as practically pure $\Delta^{1(9)}$-enol acetate V.

Experimental[32]

By the procedure of Johnson[33], *trans*-decal-1-one was prepared. The infrared spectrum of the decalone differed markedly from that of the cis compound[6]. For example, at 950 cm^{-1}, where the former showed a minimum, the latter exhibited a maximum. Conversely, at 907 cm^{-1}, *cis*-decalone had a minimum while trans-isomer showed a maximum. It was found through the infrared analysis that the decalone prepared in the above manner is an almost pure trans compound.

Bromination of *trans*-Decal-1-one.—A solution of 30.0 g. (0.2 mol.) of *trans*-decalone in 100 ml. of chloroform was kept at −20 to −10°C while a solution of 32.0 g. (0.2 mol.) of bromine in 100 ml. of chloroform was added dropwise with stirring over a period of 3 hr. The resulting solution was further stirred for 2 hr. under cooling and then washed successively with water, aqueous sodium bicarbonate, and saturated aqueous sodium chloride. After the organic layer was dried over anhydrous sodium sulfate and concentrated under reduced pressure at room temperature, 45.0 g. of crude 9-bromodecalone was obtained.

In the case of rapid addition of bromine to chloroform, the "dibromide" III was obtained. For example, 10.4 g. (0.065 mol.) of bromine in 30 ml. of chloroform was added to the decalone, 10.0 g. (0.065 mol.) in 30 ml. of chloroform for 20 min. After the reaction mixture was treated by the procedure described above, removal of the solvent in vacuo left an oily residue from which

31) Independently, House and Thompson also obtained the same conclusion. See Ref. 29.
32) All melting and boiling points are uncorrected. Unless otherwise specified, infrared spectra were taken on a Koken model DS-301 infrared spectrophotometer with sodium chloride optics. Ultraviolet spectra were measured in 95% ethanol solution by means of a Beckman model DK-2 spectrophotometer. The authors are indebted to Mr. K. Narita for microanalysis.
33) W. S. Johnson, *J. Am. Chem. Soc.*, **65**, 1322 (1943).

on cooling 1.0 g. of crystalline material, m. p. 88～93°C, was obtained. The sample for analysis was prepared by recrystallization from petroleum ether (b. p. 30～60°C) ; it had m. p. 94～95°C, IR(KBr) 1726 cm^{-1} (ketone group).

Found: C, 38.96; H, 4.66. Calcd. for $C_{10}H_{14}OBr_2$: C, 38.73; H, 4.64%.

Thermal Dehydrobromination of 9-Bromodecal-1-one.—The crude 9-bromodecalone, 45.0 g., was heated at 145°C under slightly reduced pressure (ca. 85 mmHg) for 2 hr. and then cooled. Distillation of the residue gave 13.5 g. of "liquid octalone" and 2.0 g. of "solid octalone".

"Liquid Octalone", Namely $\Delta^{9(10)}$-Octal-1-one (I).—This ketone has the following physical properties; b. p. 133～136°C/14 mmHg (lit., ca. 140°C/9 mmHg[10]), 127～128°C/10 mmHg[13]), 134～136°C/13 mmHg[16]), 85～92°C/3 mmHg[17]), 60～70°C/0.3 mmHg[23]), n_D^{25} 1.5234 (lit., n_D^{14} 1.4996[10]), n_D 1.4931[23]), n_D^{25} 1.5267[29]). The material had infrared absorption bands at 1660 (conjugated C=O) and 1632 cm^{-1} (cojugated C=C). The NMR spectrum in carbon tetrachloride solution has a series of partially resolved bands in the region 7.5 to 8.6 τ with no absorption attributable to a vinyl hydrogen atom.

Found: C, 80.24; H. 9.45. Calcd. for $C_{10}H_{14}O$: C, 79.95; H 9.39%.

Reaction of a sample of the ketone with 2, 4-dinitrophenyl hydrazine yielded, after several recrystallizations from *n*-butyl alcohol dark red needles, m. p. 263°C decomp. (lit., m. p. 262°C[16]), 266.5～267.5°C[17]), 268°C[19]), 264～266°C[20]), 264.5～265.5°C[22]), 271～272°C[23]), 266～266.5°C[29]).

Found: C, 58.10; H, 5.31. Calcd. for $C_{16}H_{18}O_4N_4$: C, 58.17; H, 5.49%.

The melting point of the semicarbazone which was recrystallized from ethanol as colorless plates, was 240°C decomp. (lit., m. p. 242～243°C[11]), 241～242°C[13,17]), 246～247°C[23]).

Found: C, 63.64; H, 8.00. Calcd. for $C_{11}H_{17}ON_3$: C, 63.74; H, 8.27%.

The oxime of I, recrystallized from methanol, was colorless needles, melted at 147.5～128°C (lit., 144～145°C[10]), 146～147°C[13]), 148～149°C[23]).

Found: C, 72.37; H, 9.15. Calcd. for $C_{10}H_{15}ON$: C, 72.69; H, 9.15%.

"Solid Octalone", viz. Molecular Compound of 5, 6, 7, 8-Tetrahydronaphth-1-ol (IV) and $\Delta^{9(10)}$-Octal-1-one (I).—The complex, distilled at 145～147°C/14 mmHg, crystallized after standing at room temperature. Recrystallization from petroleum ether (b. p. 30～60°C) gave a pure sample as colorless needles, m. p. 58～59°C.

Found: C, 80.61, 80.72, 80.40, 80.57; H, 8.78, 8.88, 8.94, 9.01. Calcd. for $C_{20}H_{26}O$(=$C_{10}H_{12}O$+$C_{10}H_{14}O$) : C, 80.49; H, 8.78%.

Ultraviolet absorption bands (Fig. 3) were found at 246 mμ (ε 7160), and infrared absorption bands (Fig. 1) at 3200 (phenolic OH), 1637 (conjugated C=O), 1623 (conjugated C=C), and 1587 cm^{-1} (aromatic ring). The NMR spectrum was reproduced in Fig. 2.

Separation of Each Component from the Molecular Compound by Chromatography.—Two hundred milligrams of the molecular compound was chromatographed on alumina (10 g.) packed and washed with ether. Forty fractions were collected as in the following table.

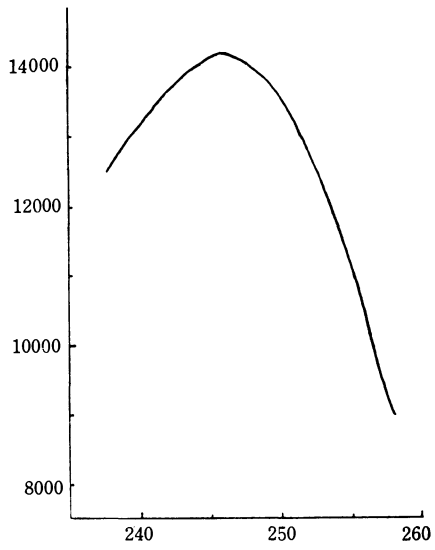

Fig. 3

Fraction No.	Eluant	Residue
1—10	Ether; 50 ml.	Colorless oil, 95 mg.
11—40	Ether; 150 ml.	Colorless crystal, 102 mg. m. p. 65～68°C

The colorless liquid, $n_D^{25.7}$ 1.5270, was identified by comparison of infrared spectra with $\Delta^{9(10)}$-octal-1-one (I). The colorless crystal afforded a pure sample by recrystallization from petroleum ether (b. p. 30～60°C), m. p. 70～71°C.

Found: C, 80.93; H, 8.02. Calcd. for $C_{10}H_{12}O$: C, 81.04; H, 8.16%.

The latter compound was characterized as 5, 6, 7, 8-tetrahydronaphth-1-ol (V) on the basis of mixed melting point determination with the authentic sample prepared by Papa's procedure[34]).

Conversely, the molecular compound was yielded by mixing an equivalent amount of the former component with the latter. The identity of these two complex compounds was proved by melting and mixed melting point determinations.

Dehydrobromination of 2, 9-Dibromodecal-1-one (III) with Collidine.—A mixture of 100 mg. of the dibromodecalone (III) and 5 ml. of collidine was heated at 150°C for 20 min. under a nitrogen atmosphere. The resulting mixture was diluted with 6 N hydrochloric acid and then extracted with ether. The ether extracts were washed successively with 2 N hydrochloric acid, 5% aqueous sodium bicarbonate and water, and dried over anhydrous sodium sulfate. The solution was concentrated in vacuo to leave a pale brown oil, which on trituration with petroleum ether completely crystallized. Upon recrystallization from petroleum ether, it

34) D. Papa, E. Schwenk and B. Whitman, *J. Org. Chem.* 7, 587 (1942).

formed colorless needles, m. p. 70~71°C. This compound was confirmed to be 5, 6, 7, 8-tetrahydronaphth-1-ol (IV) by the observation of mixed melting point with an authentic sample.

Preparation of the Enol acetate (V).—A mixture of 6.0 g. of *trans*-decal-1-one, 1.3 g. of *p*-toluenesulfonic acid and 150 ml. of acetic anhydride was heated under reflux in such a way that the acetic acid formed was allowed to distil from the reaction mixture. After 7 hr. 1.24 g. of anhydrous potassium acetate was added and the excess of acetic anhydride was almost completely evaporated under reduced pressure. The residue was cooled, diluted with benzene and washed successively with water, 5% aqueous sodium bicarbonate and water. The organic layer was concentrated and distilled to give 6.1 g. of enol acetate as a colorless liquid, b. p. 60~65°C/0.7 mmHg (lit., b. p. 63~66°C/0.75 mmHg[6], 68~79°C/0.6 mmHg[29]).

Found: C, 74.42; H, 9.30. Calcd. for $C_{12}H_{18}O_2$: C, 74.19; H, 9.34%.

IR (film) 1751 (C=O stretching) and 1217 cm^{-1} (C−O stretching).

According to the report by House and Thompson [29], the enol acetate fraction prepared by a similar method was a mixture of $\Delta^{1(9)}$-enol acetate (V) (90%), *trans*-$\Delta^{1(2)}$-enol acetate (VI) (5%), and a component believed to be the *cis*-$\Delta^{1(2)}$-enol acetate. The product in the present experiment, however, has no absorption below 7τ in the NMR spectrum and may be regarded as practically pure $\Delta^{1(9)}$-enol acetate (V).

Studies on the Chemical Decomposition of Simple Sugars. XIII. Separation of the So-called Glutose (a 3-Ketohexose)

By Akira SERA

(Received August 3, 1962)

In 1895 Lobry de Bruyn and Alberda van Ekenstein[1] found that glucose, when treated with a dilute alkaline solution, gave a equilibrium mixture containing original glucose, mannose, and fructose. This isomerization of reducing sugars is well known as the Lobry de Bruyn-Alberda van Ekenstein transformation[2,3]. Through this transformation, all of the known reducing sugars and some non-carbohydrate substances such as α-hydroxy-ketones and -aldehydes have been converted into their epimers or diastereomers through the action of inorganic or organic bases, or, in some cases, enzymes.

According to present thinking[2,3], this classical transformation is base-catalysed; it has usually been supposed to proceed through an enolization which gives rise to an 1, 2-enediol or enediolate anion intermediate. The 1, 2-enediol or enediolate anion so produced may either revert to the starting aldose (i. e., glucose), be converted into the epimeric aldose (i. e., mannose), or be further transformed to the corresponding ketose (i. e., fructose).

The transformation, however, may further proceed and, if so, the 2, 3-enediol or enediolate anion can be produced; this is probably converted into the corresponding 2-ketoses (i. e., fructose and allulose) or 3-ketohexoses. Lobry de Bruyn and Alberda van Ekenstein[1] could separate an unfermentable, reducing substance from the equilibrium mixture which was produced by the action of alkalis on glucose or fructose. They mistakenly considered allulose to be a fermentable sugar, so they described the unfermentable, reducing substance as a 3-ketose and named it "glutose", though they did not provide any supporting experimental evidence.

Their unfermentable, reducing substance was imagined to be the same as the unfermentable portion of cane molasses. Goto[4] prepared an osazone from the unfermentable, reducing substance obtained from invert sugar by the action of dibasic sodium phosphate. After repeated fractional recrystallization, he obtained; osazone A, m. p. 172~176°C* (163

* Further recrystallization gave osazones: A_1, m. p. 178~180°C and A_2, m. p., 185~186°C.

parts); osazone B, m. p. 190~194°C (325 parts; after recrystallization, m. p. 193~194°C); and others (about 170 parts). He also considered that the so-called "glutose" was not 3-keto-hexose but a more complex mixture which was produced from sugar by means of rearrangements, dehydrations, decompositions and polymerizations. Sattler and Zarban[5] observed that the "glutose" from fructose was a mixture of fructose anhydride and difructose dianhydride.

In accordance with the research program in our laboratory on the decomposition of simple sugars, the separation of "glutosazone" has been investigated. When D-glucose was treated with oxygen-free saturated lime-water, an unfermentable, reducing substance was obtained (about 11%); the osazone of this, prepared in the usual way, melted at 194°C. The "glutosazone" from cane molasses* also melted at 192~193°C. With liquid chromatography by silica-gel-Celite (5 : 1, wt./wt.), using petroleum ether (40~70°C) as a developer, the osazone of m. p. 194°C was separated into 3 parts. From the top zone D-glucosazone (m. p., 207~208°C) and from the lower zone methylglyoxal bisphenylhydrazone (m. p. and mixed m. p., 152°C) were isolated. The composition of these two was 37 : 1 in a typical run. The middle zone contained a trace of an unidentified substance. From these results, it is claimed that the so-called "glutosazone" is substantially glucosazone contaminated with among other things, methylglyoxal bisphenylhydrazone; this is consistent with the results of Sattler and Zarban[5].

Experimental

Preparation of the Unfermentable, Reducing Substance.—Thirty grams of D-glucose was dissolved in oxygen-free, saturated lime-water (100 ml.), and the solution (initial pH 10.0) was allowed to stand or to boil gently. After 22 hr. at room temperature, the solution turned yellow in color and the pH value of the solution fell to 9.2. The solution was neutralized with 0.1 N oxalic acid, and the precipitated calcium oxalate was filtered off with the aid of Celite**. Then the filtrate was diluted with distilled water to about 600 ml. To this aqueous solution (pH 7.15), 90 g. of baker's yeast*** was added, and the mixture was kept in an incubator at 30°C. After 72 hr. the yeast was removed by filtration, and the filtrate was neutralized with dilute sodium hydroxide and freed from protein by the addition of a slight exess of lead acetate solution. After filtration, the filtrate was bubbled with hydrogen sulfide gas to remove any dissolved lead salt. The precipitate was filtered and the filtrate was concentrated under reduced pressure at 40~50°C to about 100 ml. of syrup. To this syrup, an equal volume of alcohol was added, and the mixture was heated on a water bath for 15 min., whereupon the flocculent precipitate appeared. After filtration, the filtrate was concentrated as above. After this purification process with alcohol had been repeated three times, the resulting filtrate was decolorized with active carbon and concentrated under reduced pressure at 40~50°C to a syrup.

This syrup was freed from water by repeated azeotropic distillation by adding a benzene-alcohol mixture. The syrup obtained was slight yellow in color and was not fermented by baker's yeast; yield, 3.5 g. With repeated reprecipitations of this syrup from methanol-acetone, a light yellow, hygroscopic solid was obtained. The reducing power of this unfermentable substance was 10.3% of that of D-fructose (Fehling's solution).

Treatment of the unfermentable, reducing substance with phenylhydrazine hydrochloride and sodium acetate, under the usual conditions, produced a yellow osazone which melted at 148~152°C when crude. After three recrystallizations from aqueous alcohol, yellow crystals were obtained; m. p., 194°C.

Found: N, 15.8%. Calcd. for $C_{18}H_{22}O_4N_4$: N, 15.6%.

Many authors have reported on the melting points of the so-called "glutosazone": 194~195[5], 165[1,5], 207[6] and 163~166°C[7].

Chromatographic Separation of the So-called "Glutosazone".—A portion of "glutosazone" (720 mg.) was dissolved in a minimum volume of ethanol, and the solution was placed at the top of a chromatographic column (2.6×30 cm.) in which acid-washed silica gel-Celite (5 : 1, wt./wt.) had been packed. The development was carried on with petroleum ether (40~70°C) until the separation of the yellow zones was complete. The content was extruded, and each zone was cut and extracted with boiling ethanol. The solvent was distilled off, and the residual crystalline mass was weighed, and recrystallized from aqueous ethanol. The results obtained are shown in Table I.

Table I. Chromatographic separation of "glutosazone"

No.	Zone	Wt., mg.	Remark
1	Top	630	D-Glucosazone, m. p. 208~209°C*
2	Middle	trace	Orange yellow powder
3	Lower	17	Methylglyoxal bisphenylhydrazone, yellow crystal; m. p. and mixed m. p., 152°C*,**

*Studies on the Chemical Decomposition of Simple Sugars. XIV. 3-Xylulose (a 3-Ketopentose)**

By Akira SERA

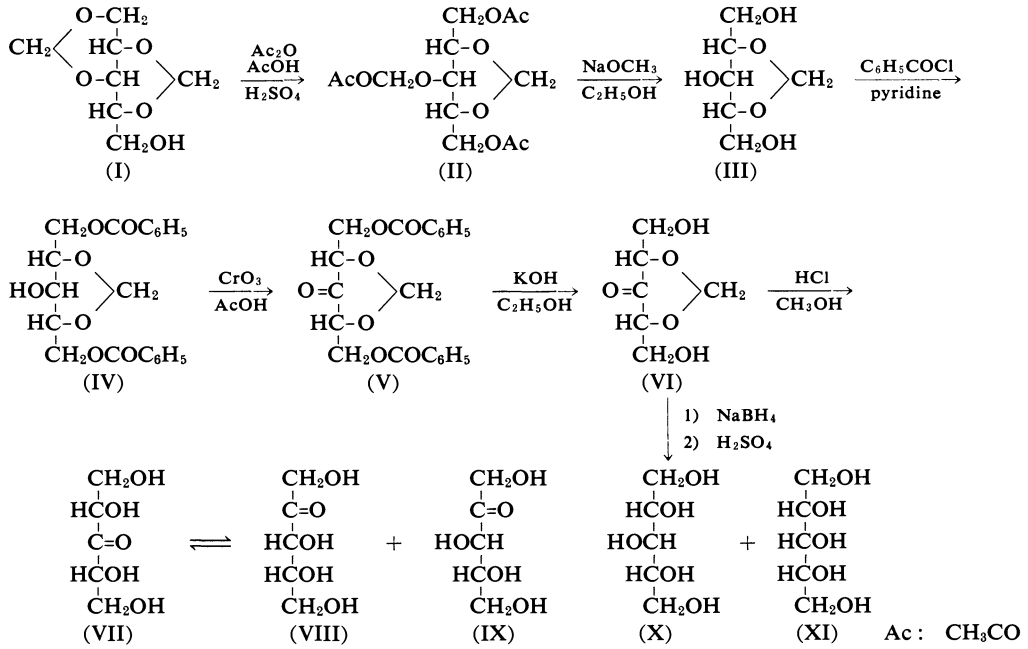
(Received August 24, 1962)

In a previous communication, the present author has shown that so-called "glutosazone" is not an osazone of 3-ketose but is substantially glucosazone contaminated by a small amount of methylglyoxal bisphenylhydrazone and other substances. On the other hand, D-allulose[1], DL- and D-sorbose[2,3] had been obtained from D-glucose (or from D-fructose) by the action of bases. Although the production of these sugars indicates that the transformation** of carbohydrates may proceed through 2, 3- or 3, 4-enediol intermediates under suitable conditions, no 3-ketose is isolated from any transformation mixture. The absence of a 3-ketose in a mixture obtained from hexose by means of this transformation suggests that a 3-ketose or its equivalents are unstable under the conditions employed and are converted into the corresponding 2-ketoses.

Recently, attempts to prepare a 3-ketose have been carried out by many authors. Jones[4] obtained 2-*O*-methyl-L-*xylo*-3-hexulose from an L-ascorbic acid derivative. Sugihara and Yuen[5,6] oxidized 3-*O*-benzoyl-1, 2; 5, 6-di-*O*-isopropylidene-D-mannitol and 6-*O*-benzoyl-1, 2; 4, 5-di-*O*-isopropylidene-DL-galactitol with chromium trioxide and obtained 4-*O*-benzoyl-1, 2; 5, 6-di-*O*-isopropylidene-D-*arabo*-3-hexulose and 6-*O*-benzoyl-1, 2; 4, 5-di-*O*-isopropylidene-DL-*xylo*-3-hexulose respectively. After the protecting substituents had been removed, the former gave a mixture of ketoses produced via an enediol intermediate during the debenzoylation procedure. The latter, however, gave a crystalline DL-*xylo*-3-hexulose after saponification of a benzoyl group followed by hydrolysis of isopropylidene groups. Schaffer[7] prepared D-manno-3-heptulose from 3-*O*-formyl-D-*glycero*-D-*talo*heptitol. From the products formed on the oxidation of ribitol with mercuric acetate, Stoodley[8] isolated *erythro*-3-pentulose in addition to D-*threo*- and D-*erythro*-2-pentulose.

In the biological field, some 3-ketoses are produced from suitable precursors. Thus, *Acetobacter suboxydans* transforms L-fucitol into 1-deoxy-D-*xylo*-3-hexulose[9]. D-Ribose-5-phosphate, when incubated with a mouse spleen extract, gave a mixture of phosphorylated pentoses. From the dephosphorylated pentose mixture, Ashwell and Hickman[10] isolated a small amount of *erythro*-3-pentulose besides D-*threo*- and D-*erythro*-2-pentulose.

In the present paper, a new synthesis of 3-xylulose and related preliminary examinations are described. The synthesis of 3-xylulose resulted in success in the following manners.



Results and Discussion

The oxidation of a secondary hydroxyl group to a carbonyl group may be realized by using a variety of agents. However, in the presence

of acid- and base-sensitive groups in the starting material, chromium trioxide in pyridine or acetic acid is the most suitable oxidant. For preparing 3-ketose from polyol, the hydroxyl groups attached at other carbons than carbon 3 in polyol must be protected by suitable substituents (i. e., isopropylidene, benzylidene, methylene, and/or ester groupings); then the remaining free hydroxyl group on carbon 3 may be oxidized with chromium trioxide. After the protecting groups have been removed, the oxidized polyol may give an unsubstituted 3-ketose. α-Ketol, however, when dissolved in an alkaline solution in the presence of oxygen, gives acidic products produced by autoxidation[11] and carbon chain fission. In the case of the synthesis of 3-ketoses, the products are easily transformed through an enediol intermediate (Lobry de Bruyn—Alberda van Ekenstein transformation) into a mixture of ketoses through the action of alkalis.

The behavior of some acetoxyketones as model compounds in a dilute alkaline solution are shown in Fig. 1. As is shown α-ketols were autoxidized easily, even in a dilute solution (such as 0.05 N) in the presence of oxygen. Furthermore, α, α'-diacetoxyketones gave the corresponding dicarbonyl derivatives in an alkaline solution in accordance with the β-hydroxy-carbonyl elimination mechanism[12,13].

ketones were oxidized with potassium permanganate. The α,β-dihydroxyketones produced through above-mentioned treatments seemed smoothly to eliminate their β-hydroxy groups under alkaline conditions in both cases.

When 2,4-diacetoxypentan-3-one (XII) and 2,6-diacetoxycyclohexanone (XIII) were treated with an ethanolic sodium hydroxide solution under a nitrogen atmosphere, pentan-2,3-dione (XIV) and cyclohexan-1,2-dione (XV) were produced respectively. In these reactions it is considered that the α,α'-dihydroxyketone produced by means of the saponification rearranges itself to an α,β-dihydroxyketone* which easily eliminates its β-hydroxyl group and gives rise to an enolic form of dicarbonyl compounds.

Sugihara and Yuen[5,6] failed to obtain crystalline products from 4-*O*-benzoyl-1,2;5,6-di-*O*-isopropylidene-D-*arabo*-3-hexulose after debenzoylation and deacetonation. They mentioned that the enediol produced by saponification of benzoyl group would provide a mixture of four isomeric ketoses. Consequently, in the final stage during the synthetic route of unsubstituted 3-ketose, alkaline treatment must be avoided, if possible.

In attempting to synthesize 3-xylulose, 1,3;2,4-di-*O*-methylene-xylitol (I) was used as a starting substance. The preparation of this compound was carried out by a modification of the procedure of Hann, Ness and Hudson[15]. The acetolysis of 1,3;2,4-di-*O*-methylene-xylitol gave crystalline 3-*O*-acetoxymethyl-1,5-di-*O*-acetyl-2,4-*O*-methylene-xylitol (II) in a good yield (96%). All attempts to obtain 1,5-di-*O*-acetyl-2,4-*O*-methylene-xylitol by the limited hydrolysis of the *O*-acetyl group on carbon 3 failed. The saponification of all ester linkages in 3-*O*-acetoxymethyl-1,5-di-*O*-acetyl-2,4-*O*-methylene-xylitol, followed by the benzoylation of the resulting 2,4-*O*-methylene-xylitol (III) with two molar equivalents of benzoyl chloride, gave 1,5-di-*O*-benzoyl-2,4-*O*-methylene-xylitol (IV) in a 79% yield. The infrared spectrum of IV shows the presence of benzoyl groups (conjugated carbonyl absorptions at 1685 and 1715 cm^{-1}, and phenyl group absorptions at 1580 and 1595 cm^{-1} respectively). The 1 and 5 positions for the benzoyl groups were assigned because of the well-known preferential benzoylation of primary hydroxyl groups under the conditions employed.

After being oxidized with chromium trioxide in anhydrous pyridine, 1,5-di-*O*-benzoyl-2,4-*O*-methylene-xylitol was recovered unchanged, but when pyridine was replaced with glacial acetic acid, the oxidation afforded crystalline 1,5-di-*O*-benzoyl-2,4-*O*-methylene-3-xylulose (V) in a 30% yield. In the infrared spectrum, V shows an absorption peak at 1725 cm^{-1}, indicating the presence of a carbonyl group. No absorption, however, is observed near 3420 cm^{-1}, where the parent compound IV had an absorption because of its free hydroxyl group.

The saponification of the substituted 3-xylulose (V) with an alcoholic potassium hydroxide solution gave crystalline 2,4-*O*-methylene-3-xylulose (VI) in a 64% yield. The sodium borohydride reduction of the product VI, followed by the hydrolysis of the methylene group with sulfuric acid, gave an excepted mixture containing xylitol (X) and ribitol (XI) (paper chromatographic separation), confirming that the parent compound VI is of a 3-ketose structure. 2,4-*O*-Methylene-3-xylulose (VI) has an absorption at 3317 cm^{-1} (hydroxyl groupings), but it has no peaks at 1580~1600 cm^{-1} (phenyl groupings), indicating the completeness of saponification. However, no absorption at 1700~1735 cm^{-1} is observed because of its carbonyl grouping. Hence, in 2,4-*O*-methylene-3-xylulose, the carbonyl group must be masked, presumably by a dimer formation, in which the carbonyl group of the ketose may be combined with the free hydroxyl groups of the other to form acetal linkage. Späth and his co-workers[16] established that β-hydroxy-aldehyde, in general, took a dimeric form containing a 1,3-dioxane ring structure. Schaffer and

Isbell[17] found that 5-aldo-1, 2-*O*-isopropylidene-D-*xylo*-pentofuranose existed in the form of a dimer, as has been mentioned above.

The demethylenation of 2, 4-*O*-methylene-3-xylulose (VI) with methanolic hydrogen chloride gave a syrup which did not crystallize. The acid hydrolysis of the syrup gave a viscous syrup which also did not give a crystalline product. Paper chromatographic investigations of this syrup showed that it was composed of 3-xylulose (VII), *erythro*-2-pentulose (VIII*), and of *threo*-2-pentulose (IX)* (R_f values: 0.369, 0.359 and 0.347 respectively). The R_f value of 3-xylulose (0.369) corresponds to 1.26 in R_{rib}** value. Stoodley[8] has recorded the R_{rib} of 1.23 for 3-xylulose obtained from ribitol. The observation that the syrup obtained by removing the methylene group was a mixture of 3-ketose and corresponding 2-ketoses suggests that isomerization plays a leading role during acid treatment. It is suggested also that the unsubstituted 3-ketose does, in general, not exist in a stable form but is transformed into its isomers according to the Lobry de Bruyn—Alberda van Ekenstein transformation.

Further investigations related to those described in this communication are in progress.

Experimental

All melting points and boiling points are corrected. All concentrations were carried out under reduced pressure at 30~40°C (bath temp.) unless otherwise stated. Paper chromatographic analyses were carried out on Toyo Roshi No. 50 filter paper by the descending method at 30°C, using a *n*-butanol—ethanol—acetic acid—water mixture (40 : 10 : 5 : 15, vol./vol.) as a developer. Spots were located on chromatograms by the following color reagents: a) silver nitrate in ammonium hydroxide, b) lead tetraacetate in anhydrous benzene, c) naphthoresorcinol in hydrochloric acid and d) aniline hydrogenphthalate in *n*-butanol saturated with water. Multiple developments were employed for the complete separation of spots, if necessary. Infrared spectra were determined by using an infrared recording spectrophotometer (Model D. S. 301, Nippon Bunko Co., Ltd.).

Acetoxyketones.—Acetoxyketones were prepared by the method of Cavill and Solomon[18]. The samples obtained were as follows: 2-acetoxycyclohexanone, b. p., 103~104°C/6 mmHg, n_D 1.4598 (Cavill and Solomon reported a b. p. of 123~126°C/16 mmHg); 2, 6-diacetoxycyclohexanone***, b. p., 140~142°C/1 mmHg, m. p., 147~148°C (leaflets, recrystallized from ethanol—petroleum ether) (Cavill and Solomon reported a b. p. of 158~160°C/10 mmHg and m. p. 145~146°C); 2-acetoxypentan-3-one, b. p., 58~60°C/3 mmHg, n_D 1.4181; and 2, 4-diacetoxypentan-3-one, b. p., 81~82°C/2 mmHg (Cavill and Solomon reported a b. p. of 80°C/1 mmHg).

Behavior of Acetoxyketones in a Dilute Alkaline Solution.—*In the Presence of Oxygen.*—In a 0.05 N sodium hydroxide solution (70% aqueous ethanol*), each acetoxyketone was dissolved and allowed to stand at room temperature. When the solution was aerated with a stream of gas, a dry ice—acetone condenser was fitted to the reaction flask to prevent the evaporation loss of the solvent. At suitable intervals, an aliquot of the reaction mixture was pipetted out and titrated with 0.05 N hydrochloric acid, using phenolphthalein as an indicator.

b) In the Absence of Oxygen. — The above-mentioned procedure was carried out using an oxygen-free alkaline solution. Nitrogen gas was passed through the mixture during the reaction period. The results obtained (a) and b)) are shown in Fig. 1.

c) Cyclohexan-1, 2-dione (XV) from 2, 6-Diacetoxycyclohexanone (XIII).— 2, 6-Diacetoxycyclohexanone was dissolved in a 0.28 N sodium hydroxide solution (70% aqueous ethanol) under nitrogen gas bubbling for 3 hr. at room temperature. After the solution had been neutralized with dilute hydrochloric acid to a slightly alkaline state, phenylhydrazine hydrochloride and sodium acetate were added and the mixture was allowed to stand overnight. The precipitate was then filtered and recrystallized from ethanol. Cyclohexane-1, 2-dione bisphenylhydrazone was obtained as golden yellow needles; m. p. 150.5~151.0°C.

Found: N, 19.08. Calcd. for $C_{18}H_{20}N_4$: N, 19.16%.

d) Pentan-2, 3-dione (XIV) from 2, 4-Diacetoxypentan-3-one (XII). — After the treatment of 2, 4-diacetoxypentan-3-one in a 0.048 N sodium hydroxide solution (70% aqueous ethanol), as mentioned above, bisphenylhydrazone of pentane-2, 3-dione was obtained in the form of yellow needles (recrystallized from benzene—ethanol); m. p., 170~171°C.

Found: N, 20.30. Calcd. for $C_{17}H_{20}N_4$: N, 19.99%.

e) Analysis of the Reaction Mixture.— From the reaction mixture (2-acetoxycyclohexanone in 0.5 N sodium hydroxide, under aeration), an aliquot was pipetted ont at suitable intervals, neutralized with dilute acetic acid, and deionized by Amberlite IR-120*. The resulting aqueous solution** was concentrated under reduced pressure. To the distillate, which was collected in a cold trap, a 2 N hydrochloric acid solution of 2, 4-dinitrophenylhydrazine was added. After the whole solution had been allowed to stand overnight, cyclohexane-1, 2-dione bisphenylhydrazone was obtained (m. p., 225~226.5°C), after recrystallization from ethyl acetate—ethanol. From the distillation residue, adipic

TABLE I. RESULTS OF THE ALKALI TREATMENT OF 2-ACETOXYCYCLOHEXANONE

Time hr.	Yield of products from 1 g. of ketone: Cyclohexane-1,2-dione mg.	Adipic acid mg.
6	660	85
10	210	125
15	140	325

acid was isolated, by recrystallizing from ethanol, in the form of crystals (m. p. and mixed m. p. 150~151°C). The results obtained are shown in Table I.

1,5-Di-*O*-acetyl-3-*O*-acetoxymethyl-2,4-*O*-methylene-xylitol (II).—Twenty grams of finely powdered 1,3; 2,4-di-*O*-methylene-xylitol (I) was added into an ice-cold acetylating mixture containing 140 ml. of acetic anhydride, 60 ml. of glacial acetic acid, and 4 ml. of sulfuric acid. The diacetal dissolved slowly, and, after standing 15 min. at 5°C, the reaction mixture was poured into 500 ml. of ice and water. The precipitate was filtered by suction and washed with a small amount of cold water (first crop). The filtrate and the washings were combined, and the whole solution was neutralized with aqueous sodium carbonate to a slightly alkaline state; then the produced precipitate was collected by filteration (second crop). The filtrate was extracted with chloroform (150 ml. ×3), and the chloroform layer was washed with water and dried over magnesium sulfate. After removal of the solvent, a yellow solid was obtained (third crop). After recrystallizing from water, the combined product (34.8 g., 95.6%) gave crystalline 1,5-di-*O*-acetyl-3-*O*-acetoxymethyl-2,4-*O*-methylene-xylitol (II); yield, 31.5 g., m. p., 136~137.5°C. After two recrystallizations from water, an analytical sample was obtained, m. p., 139.5~140.0°C.

Found: CH_3CO, 39.0. Calcd. for $C_{13}H_{20}O_9$: CH_3CO, 40.3%.

After being treated with boiling 70% acetic acid for 2 hr., or after being stirred with Amberlite IR-45 for 2 hr., II was recovered unchanged.

2,4-*O*-Methylene-xylitol (III). — In 25 ml. of chloroform (dried over phosphorous pentoxide), 5.9 g. of 1,5-di-*O*-acetyl-3-*O*-acetoxymethyl-2,4-*O*-methylene-xylitol (II) was dissolved and the solution was cooled with an ice-bath. Into the cold solution, 20 ml. of absolute ethanol and 20 ml. of 0.1 N sodium methoxide in methanol were added. The ice-bath was removed after 1 hr., and the solution was allowed to stand overnight at room temperature. The solvent was distilled off under reduced pressure, the residue obtained was dissolved in 5 ml. of water, and the solution was decolorized with active carbon. The resulting pale yellow solution was evaporated under reduced pressure to dryness. After being recrystallized from 5 ml. of ethanol, the residue gave a crystalline solid (2.1 g.). An additional 0.5 g. of the product was obtained from the mother liquor after it had been left standing for a few days. Yield, 2.6 g. (86.1%). After several recrystallizations from ethanol, 2,4-*O*-methylene-xylitol (III) was obtained as needles which melted at 110~110.5°C. The infrared spectrum is shown in Fig. 2.

1,5-Di-*O*-benzoyl-2,4-*O*-methylene-xylitol (IV).—Ten grams of 2,4-*O*-methylene-xylitol (III) was dissolved in 100 ml. of ice-cooled anhydrous pyridine (dried over barium oxide and stored over calcium hydride); 14 ml. (2 mol. equiv.) of benzoyl chloride was then added with agitation into the solution. The reaction mixture, which after being stirred for 2.5 hr. at room temperature became slushy, was poured into 700 ml. of ice and water. The amorphous precipitate was filtered by suction, washed with cold water, and dried. Yield, 18.0 g. (79.3%); recrystallizations from absolute ethanol gave pure 1,5-di-*O*-benzoyl-2,4-*O*-methylene-xylitol (IV) in the form of long needles (m. p., 140.5~141.0°C).

Found: C, 64.64; H, 5.59; C_6H_5CO, 55.9. Calcd. for $C_{20}H_{20}O_7$: C, 64.51; H, 5.41; C_6H_5CO, 56.4%.

The infrared spectrum is shown in Fig. 3.

A solution of 1,5-di-*O*-benzoyl-2,4-*O*-methylene-xylitol (1.0 g.) in 3 ml. of glacial acetic acid and 7 ml. of acetic anhydride was treated with the above-mentioned acetylating mixture (10 ml.) for 1 hr. at room temperature, and the resulting slushy mixture was poured into 250 ml. of ice and water. The resulting precipitate, after filtration, washing with water, and drying, weighed 850 mg. Two recrystallizations from absolute ethanol gave 1,5-di-*O*-benzoyl-3-*O*-acetyl-2,4-*O*-methylene-xylitol in the form of long needles (m. p., 174.5~175.0°C).

Found: C, 63.96; H, 5.49; acyl groups, 60.3.

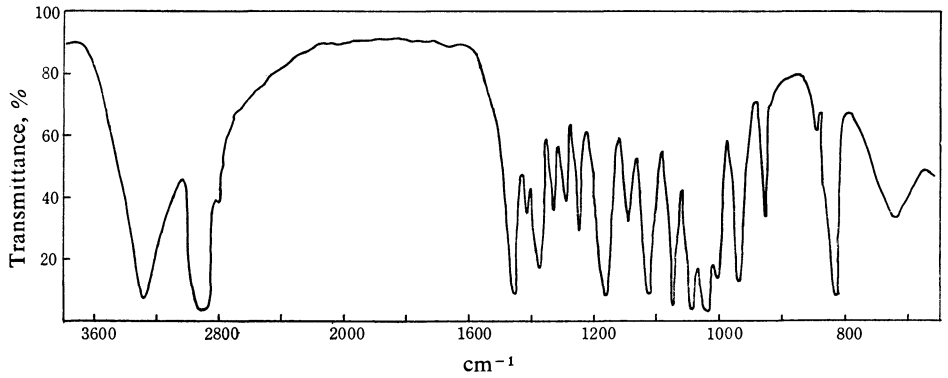

Fig. 2. Infrared spectrum of 2,4-*O*-methylene-xylitol (III), in Nujol.

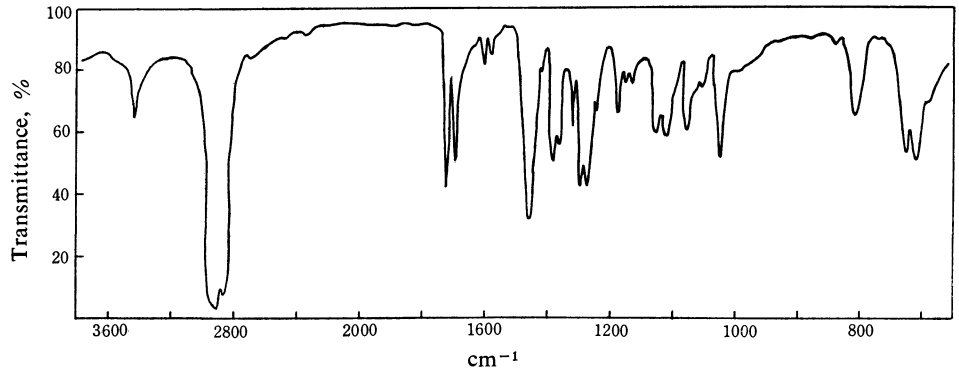

Fig. 3. Infrared spectrum of 1,5-di-*O*-benzoyl-2,4-*O*-methylene-xylitol (IV), in Nujol.

Calcd. for $C_{22}H_{22}O_8$: C, 63.76; H, 5.35; acyl groups, 61.1%.

1, 5-Di-*O*-benzoyl-2,4-*O*-methylene-3-xylulose (V). — A portion (4.4 g.) of 1,5-di-*O*-benzoyl-2,4-*O*-methylene-xylitol (IV) was dissolved in 200 ml. of glacial acetic acid (treated with chromium trioxide and distilled). To the resulting solution maintained at 15°C, 5.0 g. of chromium trioxide in 300 ml. of acetic acid was added with agitation. After this addition, the mixture was stirred for 1 hr. and then allowed to stand overnight at room temperature. The excess of the oxidant was decomposed by adding methanol, and the mixture was evaporated under reduced pressure to a black residue. The residue was extracted three times with warm diisopropyl ether (100 ml. portions). The combined ethereal solution was washed successively with water, 5% aqueous sodium bicarbonate, and again with water, and then dried over anhydrous magnesium sulfate. The solvent was distilled off under reduced pressure, and the resulting thick syrup was dissolved in 30 ml. of warm ethanol and decolorized with active carbon. When the solvent was evaporated under reduced pressure, a crystalline mass

3	0.347	Black	Light brown	Strong	*threo*-2-Pentulose
4	0.357	Black	Light brown	Strong	*erythro*-2-Pentulose
5	0.369	Black	Brown	Strong	3-Xylulose
6	0.54~0.56	Black	Faint	Variable	Unchanged substance

Spot 2 gave a blue color with reagent c).

To confirm spots 3 and 4 as *threo*- and *erythro*-2-pentulose, authentic specimens prepared by the pyridine epimerization of the corresponding aldoses, were dotted on the side of the paper and then developed.

Spot 6 was negative against reagent b).

was obtained (1.3 g. (29.3%); m. p., 111~112°C). After repeated recrystallizations from diisopropyl ether, an analytical sample of 1,5-di-*O*-benzoyl-2,4-*O*-methylene-3-xylulose (V) was obtained as long needles (m. p., 115.5~116.5°C).

Found: C, 64.44; H, 4.96; C_6H_5CO, 56.9. Calcd. for $C_{20}H_{18}O_7$: C, 64.86; H, 4.90; C_6H_5CO, 56.8%.

The infrared spectrum is shown in Fig. 4.

2,4-*O*-Methylene-3-xylulose (VI). — In 20 ml. of ethanol, 480 mg. of 1,5-di-*O*-benzoyl-2,4-*O*-methylene-xylulose (V) was dissolved, and to this solution, 30 ml. of 95% ethanol containing 0.5 g. of potassium hydroxide was then added. The solution was allowed to stand overnight, after which the solvent was evaporated by a jet of dry air. The residual syrup was dissolved in 10 ml. of water and deionized by passing it through a column containing ion exchange resins (5 ml. of Amberlite IR-45 and of IR-120). The effluent and the washings were decolorized with active carbon, concentrated under reduced pressure to dryness. After recrystallization from ethanol—diisopropyl ether (1 : 1, vol./vol.), the resulting white solid gave 2,4-*O*-methylene-3-xylulose (VI) as fine needles (80 mg.; m. p., 90~92°C). After further recrystallizations from the same solvent, an analytical sample was obtained (m. p., 95.5~97.5°C).

Found: C, 43.97; H, 6.10. Calcd. for $C_6H_{10}O_5$: C, 44.44; H, 6.22%.

The infrared spectrum is shown in Fig. 5.

Reduction of 2,4-*O*-Methylene-3-xylulose (VI). —In 5 ml. of water, 120 mg. of 2,4-*O*-methylene-3-xylulose was dissolved; this solution was then cooled and maintained at 5°C. Ten milliliters of a 1.5% sodium borohydride aqueous solution was added drop by drop under agitation. After being allowed to stand for 1.5 hr., the reaction mixture was acidified by dilute acetic acid to a slightly acid state and concentrated under reduced pressure to 5 ml. To the resulting solution, 0.5 ml. of concentrated sulfuric acid was added, and the solution was heated on a water bath for 4 hr. The hydrolysate was neutralized with barium carbonate and filtered through a layer of Celite*, and the filtrate and the washings were deionized by passing it through a column (Amberlite IR-45 and IR-120), decolorizing it by active carbon, and dried under reduced pressure to a thick syrup. Paper chromatographic separation of the syrup, using reagent a) and b) as detectors, showed the presence of xylitol (X) and ribitol (XI) (R_f 0.243 and 0.281 respectively).

Hydrolysis of 2,4-*O*-Methylene-3-xylulose (VI) into 3-Xylulose (VII). — In 10 ml. of a 9.3% methanolic hydrogen chloride solution was dissolved 620 mg. of 2,4-*O*-methylene-3-xylulose (VI); the solution was then allowed to stand for 48 hr. at room temperature (about 15°C). The resultant mixture was evaporated under reduced pressure to a thick syrup, which was then dissolved in 5 ml. of water, followed by deionizing (Amberlite IR-45) and by decolorizing by a small amount of active carbon. The clear solution obtained was concentrated under reduced pressure to a thick syrup which did not crystallize. When the methanolysis was carried out for 10, 24, and 72 hr., the resulting syrups also failed to yield a crystalline product. The syrup obtained was hydrolyzed in 0.1 N hydrochloric acid for 24 hr. at room temperature. After the removal of acid with Amberlite IR-45, the solution was concentrated under reduced pressure to a thick syrup, which reduced a warm Fehling's solution. Paper chromatographic investigations of this syrup gave the results shown in Table II.

The author wishes to express his thanks to Professor Ryozo Goto for his kind guidance and encouragement throughout the course of the present work.

Gouy Magnetic Balance for Use at Low Temperatures

By Yoshiaki SHIRAIWA*, Katsunari KIKUCHI**, Eichi KISHI, Hiroshi NAGANO and Keichi OSHIMA

(Received June 25, 1962)

A magnetic balance of the Gouy type has been constructed in our laboratory for making absolute measurements of the magnetic susceptibility of paramagnetic salts which are to be used as working substances in adiabatic demagnetization experiments; the construction of the balance was very simple, and its performance has proved to be very satisfactory. The paramagnetic susceptibility of potassium chromium alum was measured over the temperature range between room temperature and liquid nitrogen temperatures.

When a cylindrical specimen is suspended between the magnet poles so that the lower end of the specimen is at the center of the magnet, where the field strength, H, is strongest, and the other end in a weaker field, the specimen is influenced by a longitudinal force, f, with a magnitude[1] in which

$$f=1/2\,\chi A(H_1^2-H_2^2) \qquad (1)$$

χ is the volume susceptibility of the specimen, H_1, H_2 are the maximum and minimum values of the field strength respectively, and A is the cross sectional area of the specimen.

Construction of the Apparatus

A chemical balance of the standard type (as shown in Fig. 1) was used for measuring the body force, f. For the measurements in the low temperature region, the magnetic balance was set as a whole in a large, glass bell-jar so as to avoid the condensation of air and vapors on the surface of a quartz tube containing the specimen. The helium which filled the bell-jar served as a heat exchange gas. The balance was placed on the thick aluminum plate (600 mm.×600 mm.×20 mm.) with leveling screws.

The beam arrest of the balance was achieved by pushing an O-ring-sealed metal bar below the pillar of the balance. The compensation[2] of the body force being exerted upon the specimen was adjusted by the electromagnetic force between a needle-shaped permanent magnet suspended from an end of the beam and a solenoid with 2500 turns of copper wire wound on an ebonite pipe (30 mm.×8 mm.ϕ×5 mm.ϕ). A storage battery of 2 volts was used as the current source of the solenoid. A "Kovar seal" was used for electrical lead connections from the storage battery to the solenoid set on the aluminum plate.

Powdered potassium chromium alum was filled in a long quartz tube, which was suspended at one end of the beam by a nylon string. This tube was enclosed in a pyrex glass tube in a Dewar flask, as shown in Fig. 1. A number of compression nuts with O-ring seals were used so as to avoid leakage of the helium gas.

The magnet used was a highly homogeneous permanent magnet with a 30 mm. pole gap, a 150 mm. pole diameter and a 5820 gauss field intensity. The homogeneity of this magnet, which has previously been used in nuclear magnetic resonance studies in this laboratory, is very high to the degree that the fluctuation is less than 0.1 gauss in the 2.54 cm. square area at the center of the pole face.

The ball bearing used in the wheels of the truck on which the permanent magnet was mounted was satisfactory enough to free the balance system from vibrations when the permanent magnet slides on the rails. For the determination of the specimen temperature, a copper-constantan thermocouple was used. It was, however, necessary not to set the leads in the suspended specimen, because the leads may influence the smooth swinging of the beam. Three thermocouples, the upper, the middle, and the lower, were set quite near the specimen, as is shown in Fig. 1, so that the temperature gradient could be checked. From this measurement, it was proved that the temperature difference was within 0.3 degree centigrade over the specimen when the liquid nitrogen filled the Dewar flask. These copper-constantan thermocouples have been calibrated by the melting point of several pure liquids (water, carbon tetrachloride, and ethyl alcohol). The sample of potassium chromium alum was

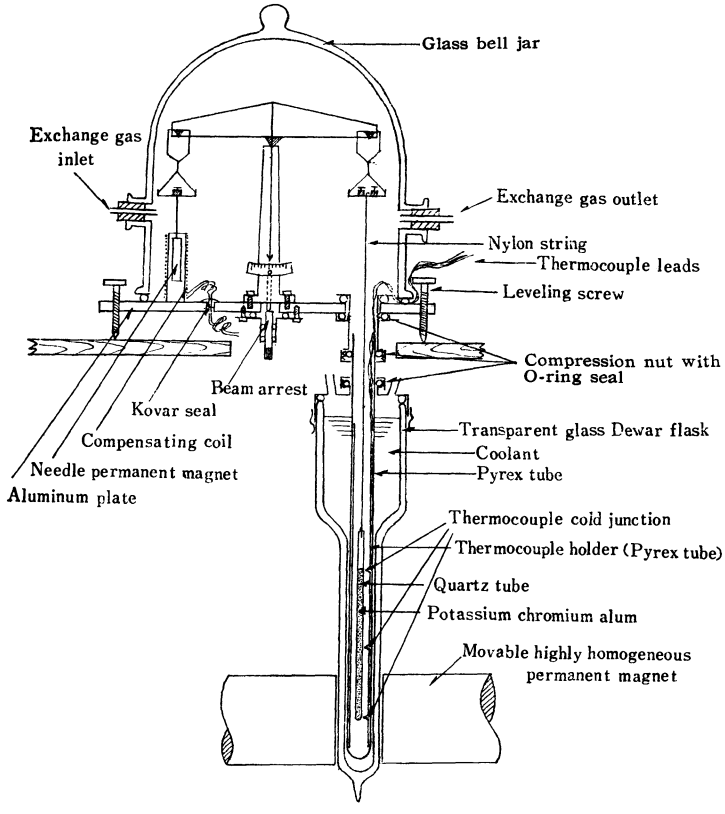

Fig. 1. Sketch of the Gouy magnetic balance.

the same as that which was previously used by us as a cooling substance in adiabatic demagnetization experiments*. The weight of the powdered specimen was approximately 2.77 g. in the present experiments.

Experimental

After filling the refrigerant into the Dewar flask, the temperature equilibrium of the whole system containing the specimen was attained in 10 min. Then, the pointer of the magnetic balance was adjusted to come to rest at the zero mark. Thereafter, the specimen was subjected to the magnetic field by setting the permanent magnet at the position of the specimen. The force acting on the specimen was measured by the compensating system explained above.

No linear relation was obtained between the force and the compensating current. Therefore, several approximate experimental expressions for the relation between the body force and compensating current were set up. The compensating current was read by a precise milliammeter. The magnetic field measurement was made using a magnetic fluxmeter of Yokogawa Electric Works which had been calibrated by the nuclear magnetic resonance frequency of protons. The field intensity at the lower end of the specimen tube was 5820 gauss, while that at the upper end was 25 gauss. H_2 (25 gauss) in Eq. 1, therefore, is negligible as compared with H_1 (5820 gauss), and Eq. 1 reduces to this relation:

$$f=1/2\,\chi AH_1^2 \qquad (2)$$

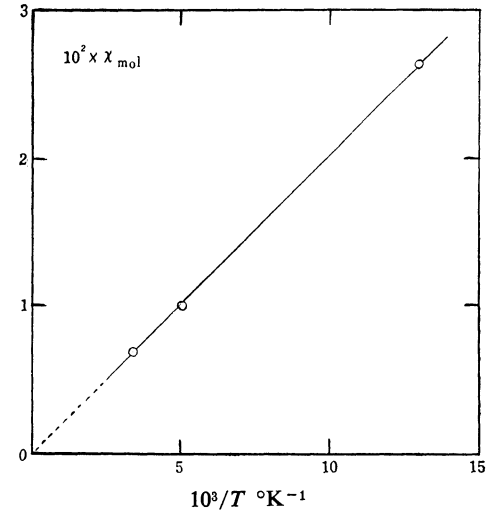

Fig. 2. Plot of susceptibility per mol. vs. reciprocal temperature for potassium chromium alum.

* To be published shortly.

TABLE I. THE MEASURED VALUES OF THE BODY FORCE AND MOLAR SUSCEPTIBILITY OF POTASSIUM CHROMIUM ALUM VS. ABSOLUTE TEMPERATURE

	T°K		
	285	195	77
f, dyne	21.7	31.6	85.0
$\chi_{mol} \times 10^3$	6.73	9.76	26.4

The cross-sectional area of the powdered specimen was determined gravimetrically by assuming that the powder is uniformly filled in the quartz tube. The diamagnetic susceptibility of a quartz tube was measured over the range from room temperature to liquid nitrogen temperature and was found to be suitable for the present work, because its variation with the temperature was very small. The observed susceptibility is the sum of the susceptibility of a quartz tube and the powdered specimen. The diamagnetic fraction of the quartz tube was about 1.5% of the total susceptibility at the liquid nitrogen temperature, and about 6% at room temperature. In Table I, the measured values of the body force and the molar susceptibility of potassium chromium alum are given. The Curie constant of potassium chromium alum, which was determined from the data in Fig. 2, was $C=1.86$. This value is comparable with the theoretical value, $C=1.84$, which is calculated by assuming the "spin only paramagnetism" for the Cr^{+3} ion[3].

Summary

This paper has reported on the performance, in the range between room and liquid nitrogen temperatures, of a Gouy-type magnetic balance, which had been constructed for absolute measurements of the magnetic susceptibility of paramagnetic salts. As a magnetic field, we used a highly homogeneous permanent magnet which was easily movable by hand. Therefore, precise measurement of the susceptibily is possible. With this balance, the susceptibility of 10^{-5} c. g. s. units was measurable within a range of error of 5%.

NOTES

Synthesis of Pseudoionone and its Homologues Using the Wittig Reaction

By Kazuyoshi FUJIWARA, Hidetaka TAKAHASHI and Masaki OHTA

(Received May 1, 1962)

Pseudoionone and its homologues are prepared by the condensation of citral with ketone in the presence of alkali; in the case of unsymmetrical alkyl ketones, however, a mixture of isomers is produced. For example, ethyl methyl ketone gives a mixture of *n*-methylpseudoionone and isomethylpseudoionone, and the separation of these isomers is very difficult. In order to obtain pure *n*-methylpseudoionone and isomethylpseudoionone separately, the

Wittig olefin synthesis[1], in which the olefinic double bond is to be located in a given position, was adopted. For this paper pseudoionone and three of its homologues were synthesized by means of the Wittig reaction, i. e., the reaction of citral with triphenylphosphine-acylmethylene. The products were identified as their 2, 4-dinitrophenylhydrazones.

Triphenylphosphineacylmethylenes were prepared by Ramirez's method[2] through the phosphonium salts obtained from triphenylphosphine with appropriated α-halogenoketones. Different structures have been suggested for the triphenylphosphineacylmethylenes by Michaelis[3], Wittig[4] and Ramirez[2]. The elementary analysis of carbon and hydrogen for the triphenylphosphineacylmethylenes obtained favored the formulae $(C_6H_5)_3P=CR^1 \cdot COR^2$) which Ramirez suggested.

Pseudoionone and its homologues were obtained by the reaction of citral with triphenylphosphineacylmethylenes in *n*-butyl ether at 100°C for 4~5 hr. and thereafter treated with 2, 4-dinitrophenylhydrazonium sulfate to give their hydrazones (see Table II). Moreover, the pseudoionone obtained above gave α-ionone by the usual method, heating with 85% phosphoric acid: this α-ionone was identified as its 2, 4-dinitrophenylhydrazone (m. p., 144~145°C, Found: N, 15.28; Calcd. for $C_{19}H_{24} \cdot N_4O_4$: N, 15.05%).

Experimental

Triphenylphosphineacylmethylenes. — Triphenylphosphineacylmethylenes were prepared according to the methods described in Ramirez's paper. A solution of triphenylphosphine and α-haloketone was allowed to stand at room temperature for 1 day; then triphenylphosphineacylmethylene was obtained as a crystal by shaking the obtained phosphonium salt with 10% aqueous sodium carbonate.

Pseudoionone and its Homologues.—A solution of citral (0.01 mol.) and triphenylphosphineacylmethylene (0.01 mol.) in *n*-butyl ether (10 cc.) was heated at 100°C for 4~5 hr. The solvent was removed in vacuo, ether was added to the residue, and then the crystallized triphenylphosphine oxide was filtered off. The oily residue obtained on the removal of the solvent from the ether solution was

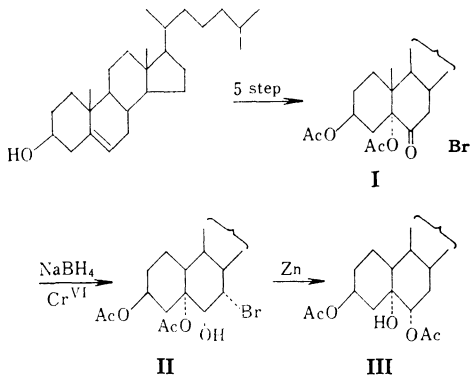
Steroid Studies. III. A New Route for the Preparation of Cholestane-3β, 5α, 6α-triol 3, 6-Diacetate from Cholesterol*



By Toshio GOTO and Yoshito KISHI

(Received May 30, 1962)

Several methods have been reported for the preparation of cholestane-3β, 5α, 6α-triol from cholesterol, but none of them are practicable for large-scale preparation because of their low yields[1,2] or because of the necessity for an expensive reagent[3]. Recently, Mori and Yoshida[4] reported a stereospecific synthesis of this triol in a 36.5% yield from cholesterol, the method involving a treatment of 6β-chlorocholestane-3β, 5α-diol diacetate with silver acetate.

Fieser and Rajagopalan have converted cholesterol in a good yield (52%) to 7α-bromocholestane-3β, 5α-diol-6-one diacetate (I)[5]. This procedure consists of no less than five steps, but each step is conducted without difficulty and is not time-consuming. We found that this bromodiolone diacetate I is convertible to cholestane-3β, 5α, 6α-triol 3, 6-diacetate (III) simply by borohydride reduction and by debromination with zinc. The over-all yield of triol diacetate III from cholesterol is about 32%.

Thus, the bromodiolone diacetate (I) obtained from cholesterol is reduced with sodium borohydride in methanol-dioxane to give exclusively a *cis*-bromohydrin[6], 7α-bromocholestane-3β, 5α, 6α-triol 3, 5-diacetate (II), the configuration of which will be discussed below. The solvents used in this reduction must be purified carefully to exclude a trace of heavy-metal impurities, especially those of lead, since its catalytic action alters the reaction course and produces cholestane-3β, 5α-diol-6-one diacetate[8].

The *cis*-bromohydrin II thus obtained was debrominated on refluxing with zinc dust in ethanol. During the reaction, the acetyl group at the C_5 position migrates to the C_6 position to produce cholestane-3β, 5α, 6α-triol 3, 6-diactate (III). Bromohydrins, both cis and trans, when refluxed with zinc dust in ethanol or in acetic acid, usually give monoenes[9]. However, not even in boiling acetic acid was bromohydrin II reduced to Δ^6-cholestene-3β, 5α-diol diacetate; on the contrary, it afforded, though in a lower yield, the same triol diacetate III.

The formation of the known 5, 6-cis compound III indicates that the hydroxyl group at the C_6 position in bromohydrin II must have α-configuration. Although an attempted acetylation with acetic anhydride and pyridine at room temperature was unsuccessful, bromohydrin II gave, by dichromate oxidation, bromodiolone diacetate I. This means that the acetyl

5) L. F. Fieser and S. Rajagopalan, *J. Am. Chem. Soc.*, **71**, 3938 (1949).

6) On borohydride reduction, 3β-acetoxycholestan-6-one gives exclusively the corresponding 6β-ol, whereas 5α-bromo- and 7α-bromo-3β-acetoxycholestan-6-one afford mixtures of *cis*- and *trans*-bromohydrins[7]. The greater the shielding of the α-side of 6-ketone, the more the corresponding 6α-ol is produced. Although, therefore, it is quite reasonable that the bromodiolone diacetate (I) gives the corresponding 6α-ol, it is curious that cholestane-3β, 5α-diol-6-one diacetate is not reduced under the same reaction conditions. The difference in those reactivities may be due to the inductive effect of the bromine atom.

7) D. R. James and C. W. Shoppee, *J. Chem. Soc.*, **1954**, 4224.

8) 4γ Lead acetate/200 mg. bromoketone (I) is still effective for debromination: T. Goto and Y. Kishi, *Tetrahedron Letters*, 513 (1961).

9) For example, 7α-bromo-3β-acetoxycholestane-6β-ol, 7α-bromo-6α-ol, and 6β-bromo-7α-ol all afford the same ethylenic compound, 3β-acetoxy-Δ^6-cholestene; D. R. James, R. W. Rees and C. W. Shoppee, *J. Chem. Soc.*, **1955**, 1370.

group migration occurred during the debromination reaction and not during the borohydride reduction.

Experimental

7α-Bromocholestane-3β, 5α-diol-6-one Diacetate (I) from Cholesterol. — Essentially according to Fieser and Rajagopalan's procedure[3]. Cholestane-3β, 5α, 6β-triol: m. p., 236~238°C (not recrystallized); 90% yield. Cholestane-3β, 5α-diol-6-one: m. p., 232~233°C (not recrystallized.); 95% yield. Cholestane-3β, 5α-diol-6-one 3-acetate: m. p., 233~234°C (not recrystallized); 95% yield. 7α-Bromocholestane-3β, 5α-diol-6-one 3-acetate: m. p., 160~165°C (recrystallized from methanol); 80% yield. 7α-Bromocholestane-3β, 5α-diol-6-one diacetate; m. p. 215~216°C (recrystallized from methanol); 80% yield. The overall yield from cholesterol is 52%. In the last step, the diolone monoacetate was brominated and then acetylated since in the alternate procedure the brominated product of the diolone 3, 5-diacetate was very difficult to purify.

7α-Bromocholestane-3β, 5α, 6α-triol 3, 5-Diacetate (II).—Two milliliters of EDTA solution (1 mol./l. in methanol) and 2.0 g. of sodium borohydride were added to a solution of 3.0 g. of the bromoketone I in 450 ml. of dioxane and 300 ml. of methanol. After having been allowed to stand at room temperature for 45 min., the mixture was acidified with acetic acid and diluted with 700 ml. of water. The precipitates obtained were crystallized from methanol to give plates melting at 148~149°C (2.4 g., 80%); IR 3380, 1740, 1720 cm^{-1} (in carbon disulfide).

Found: C, 63.72; H, 8.64. Calcd. for $C_{31}H_{51}O_5Br$: C, 63.79; H, 8.67%.

After having been treated with acetic anhydride and pyridine at room temperature overnight, the bromohydrin was recovered unchanged.

Dichromate Oxidation of Bromohydrin II.—To a solution of 110 mg. of bromohydrin II in 3 ml. of acetic acid was added a solution of 50 mg. of sodium dichromate in 1 ml. of acetic acid; the mixture was allowed to stand overnight at room temperature. The addition of water and extraction with ether in the usual way gave a crystalline solid which on several recrystallizations from methanol gave needles (m. p., 208~209°C), the mixed melting point of which with ketone I was 210~214°C and the infrared spectra of which are superimposable. From the mother liquor, a small quantity of starting material was recovered.

Cholestane-3β, 5α, 6α-triol 3, 6-Diacetate (III).—A solution of 3.0 g. of bromohydrin II in 70 ml. of ethanol was refluxed with 5.0 g. of zinc dust for 30 hr. and then filtered. The filtrate was diluted with water and extracted with ether in the usual way, and the ether solution was evaporated to dryness. The solid residue was crystallized from methanol to give prisms (2.0 g., 77%) (m. p., 186~187°C); no melting point depression was observed when this was admixed with an authentic sample.

Found: C, 73.74; H, 10.19. Calcd. for $C_{31}H_{52}O_5$: C, 73.76; H, 10.38%.

When treated with acetic anhydride and pyridine, diacetate III was recovered unchanged.

The authors are indebted to Professor Yoshimasa Hirata for his interest in this research. They are also grateful for a grant from the Ministry of Education.

Radioactivation Analysis of Bromine and Iodine in Organic Compounds Using a Low-level Neutron Source

By Haruo Tsuji, Yuzuru Kusaka and Yasuo Namikawa

(Received June 6, 1962)

This paper describes some experimental results on the activation analysis of bromine and iodine in various organic compounds using a 50 mg.-radium-plus-beryllium-neutron source.

The sample solution to be analyzed was put in a polyethylene capsule (length, 86 mm.; diameter, 16 mm.; thickness, 1 mm.) and irradiated with neutrons at the sample hole of the irradiation apparatus shown in Fig. 1. The thermal neutron flux at the sample position,

where the paraffin thickness between the neutron source and the sample hole was 7 mm., was approximately 1×10^3 neutrons/cm^2/sec. (The accuracy of this value will be estimated in another report). When the source was at position A in Fig. 1, the radiation dosage at position B, which was just in front of the lead shield, was about 2 mr./hr. When the source was set at the irradiation position, it was about 1 mr./hr.

A known amount of the sample to be analyzed was dissolved in an appropriate solvent, such as benzene, methyl alcohol or water, adjusted to 5.00 ml. in 30°C, and then irradiated. The irradiation times were 1.0 and 16.0 hr. in the bromine analysis and 1.0 hr. in the iodine analysis. After the end of the irradiation, the neutron source was pulled up to position A in Fig. 1 and the sample capsule was taken out rapidly. Then, after a 2.5 min. interval, the radioactivity induced in the sample was measured by a well-type NaI scintillation counter (1.75''$\phi\times$2''h. hole; 0.75''$\phi\times$1.5'' deep) for 30.0 min.

The induced radioactivities in the bromine analysis were due to ^{80}Br, ^{80m}Br and ^{82}Br, whose counting rate ratio at the beginning of the counting was 1000 : 80 : 66 in the 1.0 hr. irradiation. In the iodine analysis, the induced radioactivity was due only to ^{128}I.

Among the irradiation samples of a water, a methyl alcohol and a benzene solution of a compound to be analyzed, and even of a solid mixture of the compound and cane sugar, no appreciable difference in the induced radioactivity strength could be found.

Using the solution of *p*-dibromobenzene in benzene or hydrogen bromide in water as a standard substance in the bromine analysis, the bromine content in various organic compounds was determined. The analytical results obtained are shown in Tables I and II, along with the

theoretical values. Iodine analysis was done using a solution of iodobenzene in benzene as a standard. The results are shown in Table III.

As is shown in these tables, the results of the non-destructive activation analysis of bromine and iodine in various organic compounds were satisfactory. Although the sensitivities of both the analyses in this report were low, but it is expected that the use of a stronger neutron source will improve the sensitivities and will also make possible the use of smaller amounts of the sample.

A Kinetic Study of the Reaction from Tetramethyl-p-benzoquinone to Tetramethylhydroquinone

By Chie MIYAKE, Takasuke MORI and Tadao SANO

(Received June 25, 1962)

The semiquinone free radical which appears during course of the oxidation-reduction reaction between quinone and hydroquine has been widely studied to ascertain the relation between the formation of the free radical and the condition of the reacting solution[1], as well as its electronic structure. However, there is little conclusive information about the nature of these reactions because they are confused with fairly complicated side reactions.

The measurement of the magnetic susceptibility of the solution during the course of reaction was carried out with systems having duroquinone and various monosaccharides applied as reducing agents, considering that in these systems the side reactions need not be taken into account[2]. The results have already been reported but are now dealt with from the view-point of chemical kinetics. The rates of the formation and decomposition of the tetramethyl-*p*-benzosemiquinone radical are empirically found to follow such simultaneous differential equations as:

$$dx/dt = -(k_1 + k_2 y)x$$
$$dy/dt = (k_1 + k_2 y)x - k_3 y$$
$$dz/dt = k_3 y$$

where x, y and z are the concentrations of tetramethyl-*p*-benzoquinone, tetramethyl-*p*-benzosemiquinone and tetramethyl-*p*-hydroquinone, respectively, after time t. k_1, k_2 and k_3 are rate constants. Figure 1 shows the relation between the experimental and calculated values using the equation as representative. The dependency of the rate constants k_1, k_2 and k_3 on the temperature at which the measurement was performed is represented in Fig. 2, which shows a good linearity. k_1 and k_3 are found to be proportional to the concentrations of such monosaccharide used as glucose, mannose or fructose, while k_2 is in parabolic proportion to those of every monosaccharide. The activation energy necessary for the formation of the free radical by the reaction of tetramethyl-*p*-benzoquinone with monosaccharide, that for the formation of the free radical by a reaction like the auto-reduction reaction between the

*Some Reactions of Pentamethylenediaziridine**

By Hiroshi KATO and Masaki OHTA

(Received July 16, 1962)

Increasing attention has been attracted to diaziridines, and it would be worth while to report some preliminary results on the reactions of pentamethylenediaziridine (I).

Schmitz and Ohme[1] reported that diaziridines are readily dehydrogenated with silver oxide to give diazirines. The present authors have attempted the preparation of diazirines by the action of bromine on diaziridines, and have found that when pentamethylenediaziridine (I) was treated with bromine in the presence of triethylamine, bromination-dehydrobromination took place to afford pentamethylenediazirine (II), which was identified by addition of cyclohexylmagnesium bromide and conversion to urea derivative III by treatment with phenylisocyanate.

As to the reaction with acyl chloride, Abendroth et al.[2] reported that when 3,3-dimethyldiaziridine was treated with an excess of benzoyl chloride in an aqueous medium, acetone and *N*,*N'*-dibenzoylhydrazine were formed. The present authors have studied the reaction of I with an equivalent amount of benzoyl chloride in tetrahydrofuran in the presence of pyridine. In this case also, *N*,*N'*-dibenzoylhydrazine was obtained. When diaziridine I was treated with *p*-tosyl chloride in benzene in the presence of triethylamine, the reaction product was not a diaziridine derivative but an open ring isomer, *N*-cyclohexylidene-*N'*-*p*-tosylhydrazine (IV). The structure of IV was determined by comparison with a specimen of IV, prepared by the reaction between *p*-tosyl hydrazine and cyclohexanone.

Diaziridine I could neither be metalated with sodium amide, sodium hydride, or Grignard reagent, nor be alkylated directly with cyclohexyl bromide.

Experimental[3]

Pentamethylenediaziridine (I)[4]. — Finely powdered hydroxylamine-*O*-sulfonic acid (11.4 g.) was added portionwise under cooling, to a stirred mixture of concentrated ammonia (34 ml.), cyclohexanone (15 g.) and methanol (10 ml.). After two hours, the mixture was extracted with chloroform. The chloroform extracts were dried over potassium carbonate, concentrated and the residue was collected and washed with ether, to give white plates, m. p. 102°C (5.7 g.). Reported m. p.[6], 102~104°C.

Found: N, 25.20. Calcd. for $C_6H_{12}N_2$: N, 24.98%.

Reaction of Pentamethylenediaziridine with Bromine.—A solution of bromine (3.2 g.) in hexane (5 ml.) was added dropwise to a stirred suspension of pentamethylenediaziridine (2.24 g.) in a mixture of triethylamine (4.04 g.) and ether (20 ml.), while the mixture was maintained at 0~10°C. Stirring was continued for two hours after the addition of bromine was complete. The precipitate of triethylamine hydrobromide (6.6 g.) was filtered off;

2) H. J. Abendroth and G. Henrich, *Angew. Chem.*, **71**, 283 (1959).

3) All the melting points reported are micro-melting points corrected.

4) After the experiment had been performed, detailed descriptions of preparative method of I has appeared[1,5].

5) E. Schmitz and D. Habisch, *Chem. Ber.*, **95**, 680 (1962).

6) H. J. Abendroth, *Angew. Chem.*, **73**, 67 (1961).

the filtrate was washed with 1 N hydrochloric acid (5 ml.), and was dried over potassium carbonate. Distillation under reduced pressure gave colorless liquid (0.6 g.) which distilled at 28°C/35 mmHg[7].

To a solution of Grignard reagent prepared from cyclohexyl bromide (1.8 g.) and magnesium (0.27 g.) in ether, was added a solution of the above described distillate in ether (10 ml.) with stirring and cooling. After an hour, the mixture was decomposed with water and was extracted with ether (100 ml.). The ether layer was extracted with ice-cooled 2 N sulfuric acid (30 ml.); the acid extracts were neutralized with aqueous sodium hydroxide and again extracted with ether (50 ml.). The ether extracts were dried over potassium carbonate and was concentrated. Phenylisocyanate (0.3 ml.) was added to the residue and the crystals which separated out were collected. Recrystallization from *n*-hexane afforded white needles (0.4 g.), m. p. 146°C. Reported m. p.[1] for *N*-(1-cyclohexylaminocyclohexyl)-*N'*-phenylurea is 147~148°C.

Found: N, 13.24. Calcd. for $C_{19}H_{27}N_3O$: N, 13.42%.

Reaction of Pentamethylenediaziridine with Benzoyl Chloride. — Benzoyl chloride (0.7 g.) was added under cooling to a stirred solution of pentamethylenediaziridine (0.56 g.) and pyridine (0.4 ml.) in tetrahydrofuran (10 ml.). Stirring was continued for two hours; the precipitate of pyridine hydrochloride was filtered off and the filtrate was concentrated under reduced pressure. The oily residue which slowly solidified on cooling was recrystallized from ethanol to give white silky needles, m. p. 241°C. Its melting point was undepressed on admixture with an authentic specimen of *N,N'*-dibenzoylhydrazine.

Found: N, 11.68. Calcd. for $C_{14}H_{12}N_2O_2$: N, 11.66%.

Reaction of Pentamethylenediaziridine with *p*-Tosyl Chloride.—To a stirred solution of pentamethylenediaziridine (2.24 g.) and triethylamine (4.04 g.) in benzene (20 ml.), was added *p*-tosyl chloride (3.82 g.) under cooling, and the mixture was allowed to stand overnight. The crystals of triethylamine hydrochloride (1.8 g.) were filtered off and the filtrate was concentrated under reduced pressure. The colorless prisms which separated out were collected (4.7 g., m. p. 155~156°C) and recrystallized from ethanol to afford colorless prisms, m. p. 160°C. Its melting point was undepressed on admixture with a sample of *N*-cyclohexylidene-*N'*-*p*-tosylhydrazine, prepared by the following method.

Found: C, 58.33; H, 6.60; N, 10.52. Calcd. for $C_{13}H_{18}N_2O_2S$: C, 58.63; H, 6.81; N, 10.52%.

***N*-Cyclohexylidene-*N'*-*p*-tosylhydrazine (IV).** — A solution of *p*-tosylhydrazine (1.86 g.) and cyclohexanone (0.98 g.) in ethanol (30 ml.) was refluxed for an hour. The colorless prisms which separated out on cooling were collected (1.35 g.), m. p. 160°C.

Found: N, 10.79. Calcd. for $C_{13}H_{18}N_2O_2S$: N, 10.52%.

Attempted Metalation and Alkylation of Pentamethylenediaziridine. — When pentamethylenediaziridine was treated with ethylmagnesium iodide in ether at room temperature, or with sodium amide or sodium hydride in benzene at reflux temperature in an atmosphere of nitrogen, and then with cyclohexyl bromide, unchanged starting material was recovered.

*The Selective Adsorption of Optical Antipodes as Revealed by the Chromatographic Techniques**

By Masaaki CHARA, Isao FUJITA and Takao KWAN

(Received July 21, 1962)

A number of attempts for the optical resolution by adsorption have been so far made, using various optically active adsorbents such

* Presented at the 15th Annual Meeting of the Chemical Society of Japan, Kyoto, April, 1962.

as protein[1], starch[2], lactose[3], alumina coated with L-(+)-tartaric acid,[4] optically active quartz powder[5], ion exchange resins[6] and so on. Most of these observations, with the use of batch technique, appear to give too small a rotation to draw any definite conclusion while some using the chromatographic one seem to give a partial yet definite resolution[2,4]. Even for the latter case there are conflicting observations and uncertainties, suggesting that the phenomenon is extremely sensitive to the environment of the adsorbate-adsorbent system, particularly to the surface structure of the adsorbent.

We undertook this problem by utilizing both gas chromatographic and Tswett type column chromatographic techniques and by using starch, (−)-quartz, cellulose, alumina coated with various optically active substances as column packings.

Particular interest was first in the gas chromatographic separation of DL-*sec*-butanol on starch due to Karagounis et al.[7] We prepared *specific starch* according to the method kindly communicated by Karagounis and followed their work.

Helium was the carrier when the thermal conductivity cell was used as the detector, while nitrogen was the carrier when the hydrogen flame ionization gauge was employed as the detector*1. In both cases we had nothing but single peaks on the chart, however. Other optically active packings were investigated without success.

On the other hand the passage of DL-mandelic acid through Tswett column packed with starch—the one first studied by Krebs et al.[2]—was found to give a distinct resolution of the racemate: the initial fractions of the eluate as well as those close to the final stage gave rise to almost 100% optical purity differing in the direction of rotation.

Experiments were made as follows. A potato starch column 149×1.6 cm. was employed. Mandelic acid was chosen as the adsorbate because of its large specific rotation. Sample of 0.25~2.00 g. mandelic acid in a 5% aqueous methanol was adsorbed on top of the column and then eluted with water through the column kept at room temperature. The eluate from the column was fractionated with the automatic fraction collector. The rotation of each fraction amounting 2.2 cc. was determined by Zeiss-Kreis polarimeter. The amount of mandelic acid in each fraction was weighed out after evaporating the solvent up to dryness.

The specific rotation $[\alpha]_D$ was now calculated according to the expression:

$$[\alpha]_D = (100 \times \alpha)/(d \times c)$$

where c is the number of grams of mandelic acid in 100 cc. of the solution, α the observed angle of rotation and d the cell length (usually 1 dm.). In Fig. 1 $[\alpha]_D$ is shown against fraction numbers.

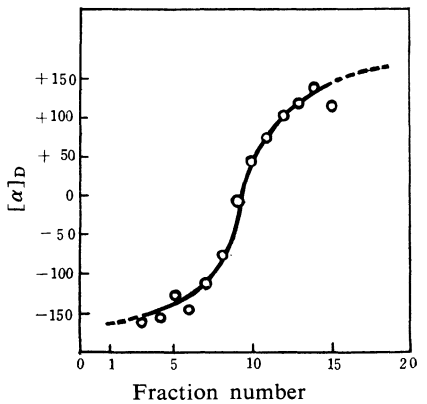

Fig. 1. The plot of the specific rotation $[\alpha]_D$ against fraction numbers.

Figure 1 shows that mandelic acid having a negative angle of rotation is eluted first, then followed by the one with the positive angle of rotation. It is apparent therefore that the latter, denoted by L-(+)-mandelic acid, is adsorbed on the starch more strongly than D-(−)-isomer. Now assuming that the additivity rule holds between the specific rotation and the composition of each optical isomer and that $[\alpha]_D$ of mandelic acid is independent of the concentration at ±157 at room temperature, the concentration of D- or L-isomer was calculated against each fraction. The chromatogram obtained in this way is shown in Fig. 2.

Figure 2 shows that the initial fractions as well as those close to the final stage are highly enriched or almost pure with regard to D- or L-mandelic acid respectively. None of the previous reports ever achieved such high resolution*2. The efficiency of resolution, judged

7) G. Karagounis and G. Lippold, ibid., **46**, 145 (1959).
*1 Karagounis used Scott type detector using hydrogen as the carrier.

*2 Using a starch column 45 cm. long, Krebs et al. were able to enrich D- or L-mandelic acid only partially. Our satisfactory results may perhaps be due partially to the comparatively long column length 149 cm., which has much more plate numbers effective in the resolution.

TABLE I. AMOUNT OF D-MANDELIC ACID (%) IN THE FIRST THREE FRACTIONS

Run	Amount of racemate g.	Recovery %	% D-Mandelic acid in fraction number			Ratio of V_R L/D
			1	2	3	
1	2.00	83	65	57	52	
2	2.00	97	96	90	87	1.04
3	1.00	99	100	99	89	1.04
4	0.50	100	93	94	100	1.04
5	0.25	96	100	100	79	1.04

a Total amount of mandelic acid
b L-(+)-Mandelic acid
c D-(−)-Mandelic acid

from the optical rotation of the initial fractions, was found unexpectedly to be little affected by preheating the starch in the air around 110°C or by the pretreatment with ether.

Table I shows the concentration of D-mandelic acid calculated for the first three fractions respectively.

It is noted from the third column of the table that fresh starch i. e. the one used in run 1 adsorbs mandelic acid irreversibly or results in an imperfect material balance. This was not the case with the subsequent runs: run 2—5 gave almost perfect material balance. Thus, a sample of starch pretreated with dilute mandelic acid solution was packed in the column and subjected to experiment which was found to give reasonable recovery of mandelic acid with high resolution similar to those of run 2—5 of the table. The resolution of racemate on the *pretreated* starch may perhaps be associated with some physical modification of the adsorbent due to the irreversibly occluded mandelic acid molecules.

To estimate the degree of resolution of the racemate, the ratio of the retention volume V_R*3 of each isomer was calculated except run 1 and compared in the last column of the table. The ratio was invariable at 1.04 with varying the amount of mandelic acid eluted.

Several homologues of mandelic acid were also subjected to experiment for resolution on the starch column and found to be resolved definitely but to a less extent. The details of the experiments will be presented and discussed in the near future.

*3 V_R was defined as the volume of the effluent that passed through the column until the highest concentration of L- or D-mandelic acid was collected in the fraction.

Hafnyl Ion - Sodium Alizarin 3-Sulfonate Chelate : A Spectrophotometric Study

By Samir K. BANERJI* and Arun K. DEY

(Received August 18, 1962)

Considerable work on metal chelates involving sodium alizarin-3-sulfonate (trivial name Alizarin Red S, abbr. ARS), and their analytical applications have been reported from these

* Present address: Chemistry Department, Birla Engineering College, Pilani, India.

laboratories[1-9]. From electrical conductance measurements[10] it has been concluded that the reagent behaves as a colloidal electrolyte and aqueous solutions of ARS show the characteristics of a true solution, only when very dilute.

Chelate formation of sodium alizarin-3-sulfonate with quadrivalent metals like zirconium and hafnium[11,12], and thorium[13] has been studied mainly with reference to the nature of lakes formed and position of the chelate ring in the structures. This paper describes the composition and stability of the hafnium chelate.

Experimental

Materials.—BDH reagent grade sodium alizarin-3-sulfonate (Alizarin Red S reagent) was used for the studies without any further purification. A solution of suitable concentration was prepared and standardized by determining the sulfur in the compound. Hafnyl chloride, obtained from M/S A. D. Mackay & Co. Inc., N. Y., was dissolved in water, hydrochloric acid being added to prevent hydrolysis and the hafnium in the solution was determined as hafnia. Freshly prepared solutions in redistilled water, free from carbon dioxide, were employed to avoid effects due to the hydrolysis of the metal salt.

Experimental Procedure. — A Unicam SP 500 spectrophotometer, operated by Doran mains unit on 220 V./50 cycl., single phase stabilized mains was used. Matched glass cells of 10 mm. thickness were used for absorbance measurements, which were noted against distilled water blanks.

pH measurements were made with a Leeds and Northrup pH meter with a glass-calomel electrode system. The experiments were performed in a room maintained at 25°C. The pH of all solutions were adjusted to 2.0±0.2, by the addition of hydrochloric acid.

Results

Nature of the Complex in Solution. — The method described by Vosburgh and Cooper[14] was adopted. Mixtures were prepared containing various proportions of hafnyl chloride and sodium alizarin-3-sulfonate and the absorbances were measured at different wavelengths. The λ_{max} of each mixture is found to lie at the same spectral region of 520 mμ, which shows that only one complex is formed, under the conditions of study, in the system investigated here.

Stoichiometry of the Components.—The ratio of the metal : reagent in the complex has been established by the method of continuous variations. The total volume in each case was 50 ml. The absorbances were measured at 500 and 520 mμ. Various concentrations of the reactants were used and the results are summarized in Table I and some are graphically represented in Fig. 1. In Fig. 1, the difference of the absorbance of the mixture and that which would be shown by the chelating agent alone, if no chelation occurred, is plotted against the composition of the mixture. In Table I and in the legends of Fig. 1, c represents the concentration of hafnyl chloride and

Fig.	Curve	$c \times 10^4$ M	p	Wavelength mμ	Vol. of $HfOCl_2$ ml. at peak	Composition of the chelate Hf : ARS
1	A	4.00	1.0	500	16.7	1 : 2
	B	3.33	1.0	500	16.7	1 : 2
	C	2.50	1.0	500	16.7	1 : 2
	D	2.00	1.0	500	16.7	1 : 2
Not	A	4.00	1.0	520	16.7	1 : 2
shown	B	3.33	1.0	520	16.7	1 : 2
	C	2.50	1.0	520	16.7	1 : 2
	D	2.00	1.0	520	16.7	1 : 2
Not	A	3.33	1.5	500	21.4	1 : 2
shown	B	2.00	2.0	500	25.0	1 : 2
Not	A	3.33	1.5	520	21.4	1 : 2
shown	B	2.00	2.0	520	25.0	1 : 2

$p = c'/c$, where c' is the concentration of sodium alizarin sulfonate.

From the above table it is evident that the composition of the chelate is $HfO(ARS)_2$.

Influence of pH on the Stability of the Chelate.—The absorbances of mixtures containing 0.00009 M of hafnyl chloride and 0.00018 M of the reagent at different pH were measured at different wavelengths and it is seen that the λ_{max} lies at 520 mμ in the case of solutions having pH of 1.0 to 4.0, showing thereby that the chelate is stable in this range of pH.

Evaluation of the Stability Constant. — The stability constant has been calculated by the modified method of Anderson et al.[15] as described earlier[7-9]. In this case the stability constant K is given by

$$K = \frac{x}{(a-x)(b-2x)^2} \qquad (1)$$

where x is the concentration of the complex at equilibrium and a and b are the initial concentration of the metal ion and the chelating agent, respectively. Taking two sets of concentrations with the same absorbance, i. e. the same value of x, we have:

$$K = \frac{x}{(a_1-x)(b_1-2x)^2} = \frac{x}{(a_2-x)(b_2-2x)^2} \qquad (2)$$

Hence, from a knowledge of two sets of initial concentrations of a and b, the value of x can be calculated and therefrom K may be evaluated.

The value of $\log K$ in the system hafnyl chloride-sodium alizarin-3-sulfonate works out to be 10.4 ± 0.3 at 25°C, and the corresponding free energy of formation ΔF° is -14.4 ± 0.4 kcal.

SHORT COMMUNICATIONS

On the ESR Study of Quinquevalent Chromium Complexes

By Hideo KON

(Received August 24, 1962)

The author has been interested in the four characteristic ESR lines observed at room temperature of the chromium(VI) oxide (or potassium bichromate) - concentrated sulfuric acid system. As is shown in Fig. 1, a very remarkable feature of the absorption is that all the four lines are very narrow (ca. 1~5 gauss), even narrower than the Cr^{3+} absorption lines which can be observed at room temperature. Observations of the same solution doped with Cr^{3+} show that the narrow lines in question are definitely different from that of Cr^{3+}. Also, careful purifications of concentrated sulfuric acid and potassium bichromate do not alter the signal intensity and the number of lines. It is suspected, therefore, that the paramagnetic species responsible for the narrow absorption lines be some chromium oxides of intermediate valence state, the best possiblity being chromium(V) oxide.

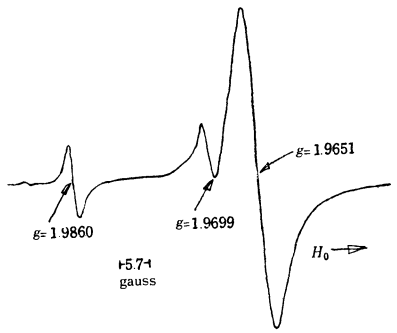

Fig. 1. ESR absorption of a CrO_3 - conc. H_2SO_4 solution. Observed g-value is accurate to ± 0.0005.

The transition metal ions with one 3d electron (for example, Cr^{5+}, Ti^{3+}, etc.) usually show the electron spin resonance absorption which is so broad that the observation is sometimes prohibitively difficult, particularly at ambient temperatures. In fact, Ti^{3+} absorption was observed only at 4 to 8°K with remarkably anisotropic g-value and with very short relaxation time[1]. This is explained as due to the fact that the combined effect of the microcrystalline field and the spin orbit coupling is not so great as to lift the degeneracy of the ground spin orbitals very much and so, there is always an excited state fairly close to the lowest Kramer's doublet. A quinquevalent chromium compound was shown to behave in a similar fashion; its electron spin resonance was observed in CrO_4^{3-} at 20°K with very broad and temperature dependent absorption lines. Thus the assumption of quinquevalent chromium in chromium oxide-concentrated sulfuric acid system seems to be in conflict with the above consideration on the line width.

However, if the crystalline field perturbation would be greater and the deviation from the cubic symmetry extreme, then, there could be further decrease in the spin-lattice relaxation, and so the reduction in the ESR line width. In order to see if such is the case actually, a few complexes of quinquevalent chromium, such as K_2CrOCl_5, $HCrOCl_4X$ (where X is the base; pyridine, quinoline tetramethylamine) were prepared and their ESR absorption observed in solution and in polycrystalline form. If the structural unit of these compounds would be CrO^{3+}, the microcrystalline field symmetry would have a strong axial component and the line width could be smaller than in, for example, CrO_4^{3-}. A

typical solution spectrum shown in Fig. 2 indicates that this is the case at least in solution, and the peak to peak line width there, is only 2.7 $\pm$0.2 gauss, a value much smaller than VO^{2+} which has an analogous structure. Though not conclusive, this result may lend a strong support to the assumption of chromium(V) existing in chromium(VI) oxide-concentrated sulfuric acid system. Several other ESR absorptions with even narrower line widths and with different *g*-values were also observed transiently during the course of the reaction of the chromium(VI) compounds with various acids (acetic, trifluroacetic, phosphoric, oxalic, lactic, citric, malonic acid and so on), and the paramagnetic species may be considered here again as some quinquevalent chromium oxyions.

Details of the result of these ESR observation will be published soon with the visible and infrared absorption data.

Continuous Isotope Enrichment by a Simultaneous Use of Ion Exchange and Electromigration

By Hidetake KAKIHANA, Yoshihiro MORI and Tadaya HOSHINO*

(Received October 8, 1962)

For a continuous isotope enrichment a new type of apparatus (Fig. 1) was devised on the basis of a simultaneous use of ion exchange and electromigration. The principle of the continuous enrichment is schematized in Fig. 2.

If an ion of isotope I moving down through an ion exchange bed with velocity of v_1 is placed under the horizontal supply of an electric field, the movement of the ion should be the addition of vectors v_1, the vertical velocity, and h_1, the horizontal velocity caused by the electric field. Similarly the movement of isotope II ion is the addition of vectors v_2, and h_2. If $v_1 > v_2$ and $h_1 < h_2$, the movement of the two ions can be expressed by the vectors R_1 and R_2. As R_1 and R_2 are different each other not only in their magnitude but also in their direction, the continuous enrichment of the isotopes should be possible by the continuous feed of the isotope solution from the top (Fig. 2).

After the compartments (1, 2, 3, 4, 5 and 6 in Fig. 1) had been filled with ion exchange resin, a lithium solution was introduced at the top and drawn from the bottom, and at the same time a electric current was horizontally passed through the apparatus. To the electrode compartments electrolyte solutions were circulated.

To find whether any isotopic enrichment can be experimentally detected, a number of runs were carried out. Data for a run are given in Table I. In 35 hr. the run reached the stationary state, where the potential gradient

was 2V./cm., the current density was 18 mamp./cm^2 and the thermal convection and gas evolution were effectively reduced. The samples of solution drawn off from each bottom of the six compartments were analyzed. Lithium concentration in the samples was determined by colorimetry with thoron[1]. Another portion of the sample solutions was evaporated to dryness, and sulfate ion was separated with anion exchange resin column in the hydroxide form. Then the lithium was converted to iodide by the addition of hydroiodic acid and evaporation to dryness, the lithium in the feed solution was also converted to lithium iodide in the similar manner. Isotopic ratios of the lithium iodide samples were determined with a Nier-type 60 degree mass spectrometer, Atlas CH-4 using the thermionic method[2].

The analytical results are given in Table II. The ratios $^7Li/^6Li$ were decreased in the solutions from the compartment 1 and the cathode, and increased in the solutions from the compartment 5 and 6. At the stationary state about 38.2 per cent of the lithium came out continuously from the compartment 1 to the cathode compartment and the bottom of the compartment, while 2.7 per cent of the lithium could be continuously collected in the outputs from the compartments 5 and 6. The values for the ratio of $^7Li/^6Li$ in both products are estimated 12.14 and 12.30 respectively.

Micro-wave Absorption in Benzene Solution of Cyclohexane-1, 4-dione

By Ariyuki AIHARA*, Kazuo CHITOKU and Ken-ichi HIGASI

(Received October 13, 1962)

With an aim of checking the polarity of cyclohexane-1, 4-dione molecule, dielectric absorption of this substance in micro-wave region (0.446 molar benzene solution) has been measured with use of a resonant cavity which was originally designed by Dr. Hatori of this Institute. The results obtained at a frequency of 9.4 Gc/sec. (3.2 cm.) are shown in the following table:

* On leave from the University of Electro-Communications, Chofu, Tokyo.

TABLE I. DIELECTRIC LOSS AND DIELECTRIC CONSTANT AT 3.2 cm. (20°C)

Substance	$\tan\delta\cdot10^4$	ε'
Benzene	5.8	2.282
Cyclohexane-1, 4-dione in benzene	22.3	2.383
Chlorobenzene in benzene	28.6	2.286

For the sake of comparison, the results obtained with the solution of chlorobenzene in benzene (0.049 molar) are also shown in Table I.

Considering the fact that a fairly large value of the dipole moment has been reported so far for cyclohexane-1, 4-dione (1.2~1.5 Debye)[1-5], the $\tan\delta$ value for this compound as listed in Table I is unexpectedly small, being less than that of chlorobenzene solution, the concentration of which is almost one tenth of the former, while the increment of dielectric constant with the former is much more appreciable. This seems to indicate that either the actual dipole moment of this compound should be much smaller than those so far obtained by other investigators or that we must seek for the mechanism of dielectric absorption which differs from that of usual Debye absorption.

If we assume the magnitude of relaxation time for cyclohexane-1, 4-dione as 7×10^{-12} sec.[6], we can calculate an apparent dipole moment of the compound with use of the following equation:

$$\mu^2=6750\,\varepsilon'\boldsymbol{k}T(1+\omega^2\tau^2)\tan\delta/(\varepsilon'+2)^2\pi c\boldsymbol{N}\omega\tau$$

where ε', $\boldsymbol{k}$, T, c, $\boldsymbol{N}$, ω, and τ are the dielectric constant of the solution, Boltzmann's constant, absolute temperature, molar concentration, Avogadro's number, angular frequency, and the relaxation time of the molecule, respectively. The value of dipole moment thus calculated is 0.43 Debye, suggesting that the molecule of cyclohexane-1, 4-dione exists almost in a non-polar conformation.

We may conclude, therefore, that 1) the larger values of dipole moment so far reported for this compound by a number of investigators are due to their underestimation of atom polarization or "vibration polarization" in calculating μ value from the observed molar polarization, and 2) the "libration" of two carbonyl groups attached at the opposite ends of flexible ring, or "puckering" should be responsible for such a high value of atom polarization (Chiba's estimation is ~33 cc.)[5], and 3) consequently, cyclohexane-1, 4-dione exists predominantly in the flexible form with two carbonyl groups directed almost in opposite sense: libration of the groups may give rise to a small apparent dipole moment.

Details will be published later in this Bulletin.

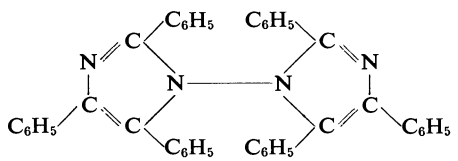
Mechanism of Chemiluminescence of 2, 4, 5-Triphenylimidazole

By Taro HAYASHI and Koko MAEDA

(Received October 12, 1962)

Radziszewsky[1] found that lophine exhibits a whitish greenish blue luminescence in an ethanolic solution of potassium hydroxide with molecular oxygen or several oxidizing agents. We have been studying the mechanism of the chemiluminescence of 2, 4, 5-triphenylimidazole (lophine) for several years[2,3], and have found that substitution of its imino-hydrogen[4] prevented luminescence. This fact suggests that the anion produced by the dissociation of the imino-hydrogen is the active agent of chemiluminescence.

The chemiluminescence of lophine with an ethanolic solution of bromine or an aqueous solution of potassium ferricyanide was inhibited by the removal of dissolved oxygen in the solutions and the luminescence was restored immediately upon passing oxygen into the reaction mixture. This indicates that molecular oxygen is necessary for chemiluminescence. When an ethanolic solution of bromine



1) B. Radziszewsky (*Ber.*, **10**, 70 (1877)) found that benzoic acid and ammonia were produced with the chemiluminescence of lophine.

2) T. Hayashi and K. Maeda, 1st Joint Meeting of the Societies of Chemistry in Japan, Tokyo, November, 1957; 11th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1958; T. Hayashi, K. Maeda and H. Ojima, Symosium on Mechanism of Organic Reactions, Chem. Soc. Japan, Tokyo, 1959; Shirahama, 1960; Sendai, 1961.

3) The spectrum of luminescence extending over the visible region with a maximum at about 540 mμ will be reported soon.

4) *N*-Methyllophine (m. p. 149~150°C), *N*-ethyllophine (m. p. 125~126°C) and *N*-*n*-butyllophine (m. p. 122~123°C were investigated.

was mixed with a solution of lophine in ethanolic potassium hydroxide, a reddish violet color was produced and soon faded. When an aqueous solution of potassium ferricyanide was mixed with the solution of lophine, a grayish white precipitate was produced[5]. The precipitate was recrystallized from benzene at a temperature below room temperature to give fine pale yellow prisms of $C_{42}H_{30}N_4$, m. p. 199~201°C (decomp.)[5]. Its benzene solution turned reddish violet with ultraviolet irradiation or heating. Electron spin resonance[6], formation of yellow nitroso compound, m. p. 110~113°C (decomp.)[5], molecular weight determination and spectroscopic investigation revealed that the color was due to the free radical 2, 4, 5-triphenylimidazyl $C_{21}H_{15}N_2$ produced by the dissociation of the N–N bond in the dimeric compound $C_{42}H_{30}N_4$[7] (I). The dissociation was increased with ultraviolet radiation or heating.

(I)

These findings suggest that the free radical is the essential intermediate in the process of chemiluminescence. The reddish violet benzene solution showed a luminescence, similar to that of lophine, with the addition of hot ethanolic potassium hydroxide, yielding benzoic acid and ammonia. When the solutions of lophine and potassium ferricyanide or bromine were mixed in the absence of oxygen, no luminescence was observed, although the reddish violet color did appear; and when oxygen was passed into the solution, a luminescence was immediately produced. This fact shows that molecular oxygen is necessary for the luminescence of the free radical. When the solution of the dimeric compound in carbon disulfide was exposed to air in direct sunlight, the reddish violet color, first produced, gradually faded to yellow, giving a yellow solid residue by evaporation of the solvent at room temperature. It melted at about 110~120°C with evolution of gas, presumably oxygen, and it oxidized potassium iodide in acetic acid to iodine. Thus it seems probable that the yellow solid contains the peroxide produced from the free radical and molecular oxygen[8]. The benzene solution of the yellow solid exhibited luminescence, similar to that of lophine, with hot ethanolic potassium hydroxide in the absence of oxygen.

From the facts mentioned above, the probable mechanism of the chemiluminescence of lophine is suggested[9] to be as follows: the anion of lophine formed in ethanolic potassium hydroxide yields the free radical 2, 4, 5-triphenylimidazyl by oxidation, from which the peroxide is produced with molecular oxygen and finally the peroxide emits light to yield benzoic acid and ammonia[10].

Chemiluminescence of 2, 3, 4, 5-Tetraphenylpyrrole

By Taro HAYASHI and Koko MAEDA

(Received October 13, 1962)

We have been studying[1] the mechanism of the chemiluminescence of 2, 4, 5-triphenylimidazole (lophine) and have already proposed a mechanism involving free radical and peroxide[2]. Recently an investigation of the electron spin resonance of the free radical 2, 3, 4, 5-tetraphenylpyrryl, a solution of which was prepared by oxidation of tetraphenylpyrrole, was reported[3].

Lophine and tetraphenylpyrrole resemble each other in several aspects. They are both nitrogen-containing, unsaturated, five-membered heterocyclic compounds in which each of the carbon atoms of the ring combines with a phenyl group; and they both produce a free

1) T. Hayashi and K. Maeda, This Bulletin, **33**, 566 (1960) : T. Hayashi, K. Maeda, S. Shida and K. Nakada, *J. Chem. Phys*, **32**, 1568 (1960).

2) T. Hayashi, *Chemistry and Industry* (*Kagaku to Kogyo*), **14**, 225 (1960); T. Hayashi and K. Maeda, This Bulletin, **35**, 2057 (1962).

3) S. M. Blinder. M. L. Peller, N. W. Lord, L. L. Aamodt and N. S. Ivanchukov, *J. Chem. Phys.*, **36**, 540 (1962).

radical by oxidation, which reacts with molecular oxygen to produce a peroxide. Tetraphenylpyrrole was therefore expected to exhibit chemiluminescence on oxidation as lophine does. As expected, a solution of tetraphenylpyrrole (0.1 g.) in 20 cc. of 2 N ethanolic solution of potassium hydroxide produced a weak greenish blue luminescence[4] at about 60°C upon addition of 3% aqueous hydrogen peroxide solution followed by 2% aqueous potassium ferricyanide solution, or 2% aqueous potassium ferricyanide solution only, or 2% ethanolic solution of bromine. When dissolved oxygen in the solutions in the latter two cases was removed by a stream of nitrogen, no luminescence was shown, and when oxygen was passed into the reaction mixture, a luminescence appeared immediately. Therefore it seems probable that molecular oxygen is necessary for the luminescence of tetraphenylpyrrole.

By oxidation of the benzene solution of tetraphenylpyrrole containing 2 N ethanolic potassium hydroxide with 2% aqueous solution of potassium ferricyanide in nitrogen, a pink benzene solution was obtained containing the free radical 2, 3, 4, 5-tetraphenylpyrryl, with optical absorption maxima at 524 mμ and 563 mμ[3]. The benzene solution containing the free radical produced a weak greenish blue luminescence when 2 N ethanolic potassium hydroxide was added with a stream of oxygen at about 60°C. Thus it appears probable that the free radical tetraphenylpyrryl is the intermediate stage of the chemiluminescence process of tetraphenylpyrrole.

The pink solution of the free radical tetraphenylpyrryl in benzene reacted with molecular oxygen to turn yellow. The reaction was promoted markedly by irradiation with ultraviolet light. The yellow solution was evaporated under reduced pressure to leave a yellow solid residue which melted at about 70~80°C with evolution of gas, presumably oxygen, and proved positive in the starch test for iodine when treated with potassium iodide. Hence the yellow residue seemed sure to contain the peroxide. When 2 N ethanolic potassium hydroxide was added to the benzene solution of this yellow residue at about 60°C in the absence of oxygen, a weak greenish blue luminescence was produced. This fact shows that the peroxide of tetraphenylpyrryl produces a luminescence in ethanolic potassium hydroxide in the absence of oxygen.

Accordingly, the mechanism of the chemiluminescence of tetraphenylpyrrole appears probable that tetraphenylpyrrole in the first step produces the free radical tetraphenylpyrryl with oxidizing agent, and then the free radical produces the peroxide with molecular oxygen and the peroxide exhibits a luminescence without molecular oxygen. This free radical-peroxide mechanism is analogous to that of lophine[2,5]. It is considered that this mechanism would be general for luminescence, at least for that of nitrogen-containing unsaturated heterocyclic compounds requiring molecular oxygen, and would be involved in the mechanism of bioluminescence.

When the solution of the peroxide in ethanolic potassium hydroxide was heated at about 60°C in nitrogen atmosphere for several hours, ammonia, benzoic acid and 2, 3, 4, 4-tetraphenyl-5-oxo-2-pyrroline were detected. The mechanism of the luminescence of the peroxide has not yet been determined.

Faraday Soc.*, 35, 491 (1939).

Polarographic Determination of Lignosulfonic Acid in Sulfite Spent Liquor

By Akira HAYASHI, Hiroko YAMAJO and Yoshikazu KOJIMA

(Received October 18, 1962)

Determination of lignosulfonic acid in sulfite spent liquor is very troublesome, because in sulfite spent liquor there are many impurities which behave very similarly to lignosulfonic acid in its physical and chemical behavior.

The present communication deals with the rapid and accurate determination of lignosulfonic acid in sulfite spent liquor with polarographic method. Lignosulfonic acid does not show any d. c. polarographic waves. It was found, however, that lignosulfonic acid combines quantitatively with polarographically active methylene blue to give polarographically inactive form, leaving excess methylene blue active.

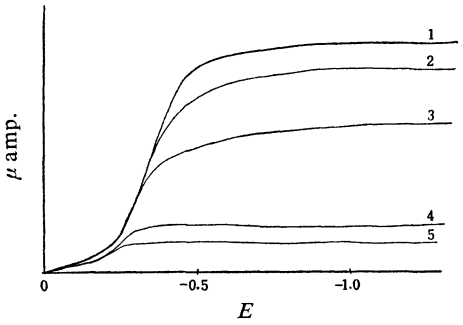

Fig. 1. Polarogram of methylene blue with lignosulfonate.
KCl : 0.5 N. Methylene blue : 0.00125 mol.
1 Lignosulfonate : 0%
2 Lignosulfonate : 0.01%
3 Lignosulfonate : 0.02%
4 Lignosulfonate : 0.05%
5 Lignosulfonate : 0.06%

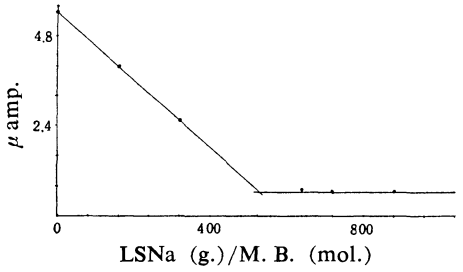

Fig. 2. The relation of wave-height to lignosulfonate concentration.
KCl : 0.5 N, Methylene blue : 0.00125 mol., Sodium lignosulfonate : 0~900 g./mol. M.B.

The polarograms of methylene blue and the combination of methylene blue and purified lignosulfonic acid are shown in Fig. 1. The wave height of methylene blue is depressed linearly by addition of lignosulfonic acid and after a certain point it becomes constant as shown in Fig. 2. This equivalent point was 530 g. of lignosulfonic acid per 1 mol. of methylene blue, being in good agreement with the sulfonic acid equivalence of lignosulfonic acid. Diluted and neutralized sulfite spent liquor, which contained 12.0% of lignosulfonic acid by β-naphthylamine method and 11.4% by methoxyl method, was analyzed by this method, and it was found that 11.6% of lignosulfonic acid was contained.

In order to simplify this method, the amperometric titration of methylene blue by sulfite spent liquor was carried out at −0.8 V. of mercury electrode potential. 11.6% of lignosulfonic acid was found again in the sulfite spent liquor.

These results show that in sulfite spent liquor only lignosulfonic acid combines quantitatively with methylene blue and is precipitated in polarographically inactive form. This method is very useful for the rapid and accurate determination of lignosulfonic acid in sulfite spent liquor.
