Amperometric Determination of Cobalt as Tungstate

By V. D. ANAND*, G. S. DESHMUKH and A. JOSEPH

(Received November 29, 1960)

The use of sodium tungstate as a precipitant for the quantitative determination of cobalt was recently reported by Anand[1]. The method was based on the reaction studied by Smith and Bradbury[2]. A conductometric titration procedure for cobalt[3] based on the precipitation of cobalt as tungstate was also developed. Consequent upon the development of an amperometric titration method for the determination of cobalt as tellurite[4] it was considered worthwhile to examine the validity of the results of gravimetric and conductometric studies on the determination of cobalt as tungstate by the application of the amperometric technique to this precipitation reaction. A further confirmation of the composition of cobalt tungstate was also sought.

Experimental and Results

Solutions.—Sodium tungstate: An approximately 0.1 M solution was prepared from B. D. H. reagent grade sample. It was standardized by precipitating tungsten as the benzidine complex[5] and final weighing as WO_3 after incineration above 1000°C.

Cobalt(II) chloride solution was about 0.1 M and was standardized by the anthranillate procedure[6] and checked by the α-nitroso β-naphtol method[7].

Gelatin solution was prepared according to the details given by Meites[8] and was 0.1%. Fresh solutions of gelatin were prepared every day. B. D. H. Analar salt was used for preparing a stock 1.0 M solution of potassium chloride.

Apparatus. — A Fisher elecdropode (catalog No. 9-317) was used for recording the current potential characteristics during the amperometric determination of cobalt as tungstate. The instrument has a built in galvanometer and works on 115 V. A. C. supply. It is used in conjunction with the dropping mercury electrode. The working of the instrument involves the increment method which makes it necessary merely to obtain current values at a limited number of points both before and after equivalence point in order to carry out an analysis.

Determinations of Cobalt as Tungstate. — In a supporting electrolyte consisting of 0.1 M potassium chloride, having 0.01% gelatin and enough alcohol to give an overall concentration

of 50% was taken an aliquot of the cobalt-(II) solution. The mixture was thoroughly deaerated by a slow stream of purified nitrogen. Necessary connections were made and the drop time adjusted to a drop of mercury every three seconds. A potential of −1.5 V. vs. S. C. E. was applied to the dropping mercury cathode and the mean galvanometer deflection noted.

The process was repeated after every addition of the tungstate solution from a microburette. The mixture was thoroughly mixed and deaerated by a rapid stream of nitrogen and the precipitate allowed to settle for one minute before observing the current reading. The strength of the tungstate solution was maintained at approximately 10 times stronger than that of cobalt to eliminate the dilution effects. Correction factor for volume error $i_{obs}\{(V+v)/V\}$ was however, applied for greater accuracy. Point of intersection of the graph obtained by plotting the current against the volume of the titrant was read at the volume axis to get the equivalence point. Results of the titrations of cobalt solutions varying in concentration from 0.2∼10 mM are given in Table I.

The effect of addition of alcohol on the equivalence point of the precipitation of cobalt as tungstate was also studied. Alcohol concentrations were varied from 30∼90%. The results are presented in Table II and shown in Fig. 1, which also represents the mode of the titration curves obtained in the amperometric determination of cobalt as tungstate.

Discussion

Von Stackelberg et al.[9] studied the polarography of tungsten(VI) in conentrated hydrochloric acid and reported only a single reduction wave. In neutral or alkaline media tungsten does not produce any reduction wave[10]. Cobalt, however, is not reducible in hydrochloric acid[11]. There were accordingly two possibilities for the choice of a suitable supporting electrolyte in the amperometric titration of cobalt as tungstate. Either concentrated hydrochloric acid could be employed as the supporting medium, in which case the reducible ion would be tungsten(VI) ; or a supporting electrolyte in which cobalt ion is reduced at the dropping mercury electrode. The WO_4^{2-} ion was, however, reported to exist only alkaline media[12]. As such hydrochloric acid could not be used as the supporting electrolyte, because the precipitation of cobalt tungstate would be inhibited. Potassium chloride was, therefore, chosen as the medium, in view of its earlier use in the amperometric titrations of cobalt as tellurite[4], and also because earlier work on cobalt tungstate had been done in normal aqueous solutions[1,3].

In potassium chloride the $E_{1/2}$ vs. S. C. E. for cobalt was −1.2 V. and though the wave was reportedly irreversible, the magnitude of the current was found to be proportional to cobalt concentration over a considerable range[13] (up to 15 mM). For actual titrations a potential of −1.5 V. was applied during the amperometric titrations of cobalt as tungstate.

The diffusion current due to cobalt fell as more and more of the precipitant was added

and this continued till the whole of the cobalt in the test solution had been precipitated. Beyond the equivalence point, the current approached the residual current value due to the titration medium.

At low concentrations of cobalt encountered in these studies, the solubility of cobalt tungstate was significant. To overcome this effect, the addition of some non-aqueous medium was necessary. Alcohol up to 50% overall concentration was used in the conductometric studies reported earlier[3]. The effect of varying alcohol concentrations ranging from 30~90% was studied (cf. Table II, Fig. 1) to determine alcohol concentration required in these studies for getting reproducible results. Best results were obtained with alcohol concentrations above 50%. This concentration of alcohol was, therefore, used in the amperometric titration of cobalt.

The titrations for cobalt as tungstate were performed for different cobalt concentrations. In a series of 12 determination involving 0.2~10 mM Co, precision was better than 1%; with very dilute samples, however, it was poorer. The concentration limits for cobalt determination by the present technique were found to lie between 0.1~50 mM. Stronger solutions could be handled after proper dilutions. The method was not applicable in the presence of other cations giving insoluble tungstates.

Amounts of tungstate required during the amperometric titrations agreed with the molar ratio Co : W of unity and agreed with the observations of Smith and Bradbury[2] and Anthon[14], and also of the present author's[1,3] earlier reports. This confirms the composition of the precipitate formed to be $CoWO_4$ i. e. the normal tungstate.

Grateful thanks of the authors are due to Professor S. S. Joshi for keen interest and to Professor G. B. Singh, Head of the Chemistry Department for necessary facilities. The award of a Senior Scholarship to one of us (V. D. A.) from the Ministry of Scientific Research and Cultural Affairs is also acknowledged.

Infrared and Raman Spectra of Ethylidene Dialkyl Ethers

By Kenkichi NUKADA

(Received April 21, 1961)

The author has investigated the infrared and Raman spectra of dialkoxymethanes such as $CH_3OCH_2OCH_3$, $CH_3OCH_2OC_2H_5$, $C_2H_5OCH_2 \cdot OC_2H_5$ and $(CH_3)_2CHOCH_2OCH(CH_3)_2$ in various phases. He has concluded that dimethoxy methane ($CH_3OCH_2OCH_3$) takes one forms in both its vapor and liquid phases, at least near room temperature, and that the different figures of the vapor and liquid spectra are not due to the existence of rotational isomerism but to different intermolecular forces in the two phases. It was not clear whether or not in the other dialkoxy methanes such a conclusion is also reasonable, but from the similarity of behavior of spectra in various conditions he assumed that in the other dialkoxy methanes the molecule exists as one form in both the vapor and liquid phases[1]. With this assumption, the assignment of spectra of these compounds has been undertaken[1-3].

It is now interesting to study the rotational isomerism in ethylidene dialkyl ethers ($R_1OCH(CH_3)OR_2$), in which one hydrogen atom of the central OCH_2O group of dialkoxy methanes is replaced by a methyl group. In this paper, he presents the infrared spectra of ethylidene dimethyl ether ($CH_3OCH(CH_3)OCH_3$), ethlidene methyl ethyl ether ($CH_3OCH(CH_3)OC_2H_5$), and ethylidene diethyl ether ($C_2H_5OCH(CH_3)OC_2H_5$) in vapor at various temperatures, and in carbon tetrachloride and acetonitrile solutions. They are abbreviated as EDM, EME and EDE, respectively.

From a comparison of the spectra obtained, he has found that ethylidene dialkyl ethers

1) K. Nukada, This Bulletin, **34**, 1615 (1961).

2) K. Nukada, *Spectrochim. Acta*, to be published.

3) K. Nukada, This Bulletin, **34**, 1624 (1961).

have a possibility of having two or more rotational isomers in their vapor and liquid phases.

Raman spectra of these compounds were also obtained, and the assignment of spectra is presented with the observation that rotational isomerism could exist in these molecules.

Experimental

EDM and EDE were prepared from methanol and acetoaldehyde, and from ethanol and acetoaldehyde, respectively. EME was prepared from a mixture of methanol and ethanol and acetoaldehyde[4]. A detailed description of the preparation of EME will be given elsewhere. The purity of samples was checked by a gas-chromatograph.

Infrared spectra of vapor and liquid phases were taken by using a Perkin Elmer 21 spectrophotometer equipped with a sodium chloride prism. Vapor spectra at elevated temperatures were obtained by means of a high temperature gas cell designed and constructed by Tomita of the author's laboratory[5]. It must be noticed that ethylidene dialkyl ethers are decomposed very quickly at the vapor phase in the presence of oxygen at elevated temperatures, so the high temperature cell should be completely deoxygenized before using.

Raman spectra of pure liquid were taken by using a Cary 81 spectrophotometer. The degree of depolarization was obtained by wrapping two types of silver chloride polarizers around a Raman tube alternately.

Results and Discussion

Infrared Spectra of Ethylidene Dialkyl Ethers. — *Ethylidene Dimethyl Ether.* — The relative

intensity of the bands at 1121 and 1052 cm^{-1} decreases in the vapor phase, and that of the band at 1087 cm^{-1} in acetonitrile solution decreases slightly, as compared with that of the corresponding band in carbon tetrachloride solution (Figs. 1 and 2). The vapor spectra at elevated temperatures, however, show no appreciable change. Therefore, in EDE, there is no definite evidence that this molecule has two or more rotational isomers in its vapor and liquid phases.

Ethylidene Methyl Ethyl Ether.—The relative intensity of the bands at 1083, 1050 and 942 cm^{-1} decreases in the vapor phase, and that of the corresponding bands in acetonitrile solution definitely increases, as compared with that of the carbon tetrachloride solution bands (Figs. 4 and 5). In vapor spectra at elevated temperatures, the positions of maximum absorption are shifted from 1111 to 1098 cm^{-1} and from 935 cm^{-1} to a higher frequcncy, respectively (Fig. 6).

To interpret these results, the following theory is reasonable.

In this molecule, there are two rotational isomers, one with a less and the other with a more polar configuration both in the vapor and liquid phases. The bands at 1083, 1050 and at 942 cm^{-1} are due to the more polar form, while the band at 1105 cm^{-1} is due to the less polar form. From Figs. 4 and 5, it is clear that the abundance ratio of the more polar form to the less in acetonitrile solution is greater than that in carbon tetrachloride solution. In the vapor phase at low temperatures, the less polar form is predominant, but at higher temperature the number of molecules having the more polar form increases. In carbon tetrachloride solution, both forms exist almost equally.

Ethylidene Diethyl Ether.—The relative intensity of the band at 1095 cm^{-1} decreases in the

—— 24°C ---- 85°C ····· 145°C

vapor phase, and that of the corresponding band in acetonitrile solution increases (Figs. 8 and 9) as compared with that of the carbon tetrachloride solution band. In vapor spectra at elevated temperatures, the position of maximum absorption is shifted from 1109 to 1095 cm^{-1} (Fig. 10).

Hence, as in the case of EME, it is reasonable to assume that in EDE there also exists rotational isomerism. The bands at 1080 and 1060 cm^{-1} are due to a more polar form, and the band at 1099 cm^{-1} is due to a less polar form. The more polar form is predominant in acetonitrile solution and in vapor at higher temperatures. In carbon tetrachloride solution, both forms are mixed almost equally.

Next the author will consider the molecular configuration of these compounds by assuming the existence of rotational isomerism. As one can easily understand from the actual molecular model, a planar zigzag form and a gauche-gauche form, in which terminal alkoxy groups rotate counterclockwise about 120° from the

central OCO plane, could not exist, since the repulsion between central methyl ($OCH(CH_3)O$) and terminal alkyl groups is fairly large. Kubo has produced a diagram showing the relation between the dipole moment of a R_1–O–C–O–R_2 type molecule and the azimuthal angles φ and ϕ of terminal alkoxy groups from the central OCO plane. From the observed value of the dipole moment of EDE in the vapor phase, Kubo has suggested that the molecule has a configuration in which $\varphi=120°$ and $\phi=240°$ (A form), or one in which $\varphi=180°$ and $\phi=240°$ (B form)[6]. From the diagram given by Kubo, it is concluded that the more polar form is the A form and the less polar one is the B form, if rotational isomerism exists in EME and EDE.

6) M. Kubo, *Sci. Papers Inst. Phys. Chem. Research*, **30**, 169 (1936).

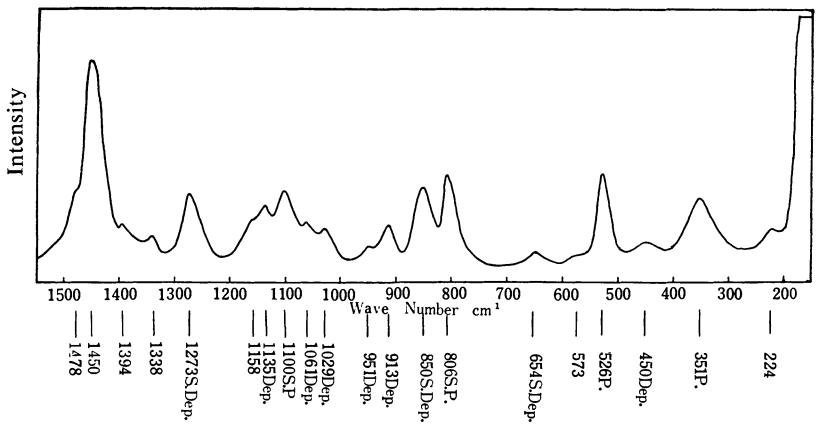

Fig. 11. Raman spectrum of ethylidene diethyl ether ($C_2H_5OCH(CH_3)OC_2H_5$).

As in the case of dialkoxy methanes, however, the difference in intermolecular interaction could produce some changes in the appearance of spectra in various phases[1]. Hence, a rigorous conclusion regarding the existence of rotational isomerism in EME and EDE in not obtained only from the present observation. To examine the reliability of the present interpretation of infrared spectra, the accurate measurement of the dipole moment in both the vapor and liquid phases at various temperatures is necessary, as in the case of dimethoxy methanes[1].

Assignment of Spectra of Ethylidene Dialkyl Ethers.—In this section, the assignment of the spectra of EDM, EME and EDE will be described by referring to that of dialkoxy methanes and related compounds. As discussed in detail in the preceding section, there is a possibility of the existence of rotational isomerism in EME and EDE. But in the assignment of these two compounds it is very difficult to decide one by one which band is due to which configuration, except for the few bands mentioned in the preceding section. So in the following description, an assignment to a definite molecular configuration is not presented except for a few cases. Raman spectra are shown in Figs. 3, 7 and 11.

A very weak infrared and medium Raman band appears at 1478~11479 cm^{-1} in EME and EDE, but no band appears at this frequency in EDM. As was discussed in detail in another paper[3], this band is assigned to the methylene scissoring of the ethoxy group.

From the study of the spectra of diethoxy methane[3] and dimethoxy methane[2], an asymmetrical methyl deformation of the ethoxy and methoxy groups is expected to appear at 1460 and 1455 cm^{-1} respectively. A symmetrical methyl deformation of methoxy group should exist at 1460 cm^{-1}, according to Nakagawa[7], Sheppard[8] and Nukada[3]. The position of the asymmetrical methyl deformation of central $OCH(CH_3)O$ group is not clear, but presumably it exists near 1460 cm^{-1}. Therefore, at least four kinds of vibrations could exist around 1460 cm^{-1}, and it is not possible to assign the spectra of EDM, EME and EDE in this region definitely. If spectra of deuterated compounds were obtained, one could assign the bands in this region clearly.

The strong infrared band at 1377 cm^{-1} (having no corresponding Raman band) in EDM completely disappears in dimethoxy methane[3]. Therefore, this band is due to the $OCH(CH_3)O$ group. Since the CH deformation is expected to appear at a much lower frequency, this band is assigned to the symmetrical methyl deformation of $OCH(CH_3)O$ group. In EME and EDE, strong infrared bands are observed also at 1382 and 1379 cm^{-1} respectively which have no corresponding Raman bands. The medium Raman bands appear at 1362, 1369 and 1394 cm^{-1} in EDM, EME and EDE respectively; they have corresponding very weak infrared bands. As there is no other appropriate mode at this frequency, these bands are also assigned to the symmetrical methyl deformation of $OCH(CH_3)O$ group. To interpret these results reasonably, it is better to conclude that these two types of bands correspond to two different types of rotational isomers. Since the more polar form (A form as defined in the preceding section) and the less polar form (B form) belong to the Cs and C_1 point groups (ignoring the species of terminal alkyl groups), the former band (strong in infrared and no Raman) is assigned to the

more polar form and the latter one (strong in Raman and very weak in infrared) to the less polar form.

The medium infrared band at 1338~1335 cm^{-1} in EME and EDE is assigned to the methylene wagging of ethoxy group by analogy with diethoxy methane[4]. The origin of the very weak band at 1340 cm^{-1} in EDM is not clear at present.

The very weak infrared bands at 1295~1296 (with no corresponding Raman band) and 1271~1272 cm^{-1} (the corresponding Raman band being strong and depolarized) both in EME and EDE are assigned to the methylene rocking and twisting of the ethoxy group respectively, because no band appears in this region in EDM and the appearance of the spectra is similar to that of diethoxy methane and diethoxy methane-d_2[4].

The bands at 1215 and 1203 cm^{-1} and one at 1206 cm^{-1} in EDM and EME are assigned to the methyl rocking of the methoxy group, as will be explained in detail in another paper[2].

polarized, strongly polarized, depolarized and strongly depolarized.

Skeletal stretchings are expected to appear between 1150 and 700 cm^{-1} as in the case of dialkoxy methanes[1,2].

The strong infrared band (with a corresponding medium or strong and depolarized Raman band) around 1135 cm^{-1} in EDM, EME and EDE is assigned to an asymmetrical COCOC skeletal stretching. Since the intensity of this band does not change in vapor, and in carbon tetrachloride and acetonitrile solutions, it is not clear to which molecular configuration this band belongs.

The bands at 1105 cm^{-1} in EDM and one at 1099 cm^{-1} in EDE (strong in infrared and medium or strong and polarized in Raman) are due to the less polar configuration, as described in the last section. Since the Raman band is strongly polarized, these bands are assigned to a symmetrical COCOC skeletal stretching.

The band at 1083 cm^{-1} in EME and that at 1080 cm^{-1} in EDE (strong in infrared and very weak in Raman) are due to the more polar configuration, as described in the last

section. Since the Raman band is depolarized (in EDE), these bands are assigned to an asymmetrical COCOC skeletal stretching.

Within the above-mentioned frequency region, the observed infrared and Raman bands of EDM do not correlate with those of EME and EDE. The band at 1121 cm^{-1} (strong both in liquid infrared and Raman and depolarized in Raman) in EDM is assigned to a symmetrical COCOC skeletal stretching, since the intensity of the vapor infrared band is very weak and that of the Raman band is strong. Although the definite assignment of the bands at 1085 and 1052 cm^{-1} in EDM is difficult, they have been assigned to asymmetrical stretchings since the intensity of the vapor and liquid infrared bands is very strong and that of the Raman bands is weak. It is not clear either that these bands are branches of doublet being caused by Fermi resonance, or that they are due to different molecular forms.

The weak or medium infrared bands around 1030 cm^{-1} (with depolarized Raman bands) in EDM, EME and EDE are assigned to a CC stretching of the $OCH(CH_3)O$ group.

The medium infrared bands around 990 cm^{-1} (with corresponding medium or strong and depolarized Raman bands) in EDM and EME are assigned to the methyl rocking of the methoxyl group.

There are three infrared bands between 960 and 910 cm^{-1} in EME and EDE. As no band appears in EDM and a few bands appear in diethoxy methane and diethoxy methane-d_2 in this region[3], they are assigned to vibrations due to the ethoxy group. More detailed assignment is quite hard, but they are presumably CC stretching or methyl rocking.

Between 870 and 850 cm^{-1}, strong and strongly depolarized Raman bands appear in EDM, EME and EDE. These bands have corresponding strong or medium infrared bands. As Raman bands are strongly depolarized. they are assigned to an asymmetrical COCOC skeletal stretching.

The Raman bands around 815 cm^{-1} are the strongest ones below 1300 cm^{-1} in EDM, EME and EDE. They are strongly polarized and have cerresponding medium or weak infrared bands. These bands are therefore definitely assigned to a symmetrical COCOC skeletal stretching.

In EDM, the number of bands assigned to the asymmetrical skeletal stretching exceeds two, so 1) at least two of them are the branches of doublet being caused by Fermi resonance, or 2) they are due to two rotational isomers.

The appearance of Raman spectra below 700 cm^{-1} is quite similar among EDM, EME and EDE; that is, the strongest and polarized bands appear around 530 cm^{-1}, while two medium or strong bands appear around 640 cm^{-1} (depolarized) and at 400~290 cm^{-1} (polarized). The position and the degree of depolarization of the bands are similar to those of dimethoxy methane, diethoxy methane and the deuterated compounds[2,3]. In accordance with the assignment of the spectra of dialkoxy methanes and the degree of depolarization observed, the following assignment has been obtained.

The bands around 640 cm^{-1} are assigned to the asymmetrical COCOC skeletal deformation because they are strongly depolarized. The strongest bands around 530 cm^{-1} and the next strongest bands between 400 and 280 cm^{-1} are assigned to the symmetrical COCOC deformations. In EDM, two bands having almost equal intensities appear, and it is not possible to give a more definite assignment for them at present.

Many weak bands appear below 600 cm^{-1} in EME and EDE; they should be 1) CH_3–C skeletal deformation, 2) overtone and/or combination of torsional vibrations, and 3) the skeletal deformations of the rotational isomers which are less predominant in the liquid phase.

Torsional vibrations are expected to exist below 250 cm^{-1}, but only one band was observed at this region in EDE.

The assignments thus obtained are tabulated in Table I.

Summary

Infrared spectra of three kinds of ethylidene dialkyl ethers ($CH_3OCH(CH_3)OCH_3$; EDM, $CH_3OCH(CH_3)OC_2H_5$; EME and $C_2H_5OCH\cdot(CH_3)OC_2H_5$; EDE), of vapor at various temperatures, and of carbon tetrachloride and acetonitrile solutions are presented.

From a comparison of the spectra obtained, it has been concluded that rotational isomerism could at least exist in EME and EDE.

Raman spectra of pure liquid have been obtained, together with the degree of depolarization.

The assignment of these spectra is given by referring to those of the homologues, such as dialkoxy methanes.

The author wishes to express his sincere thanks to Dr. Y. Mashiko for his valuable discussion, and to Mr. T. Suzuki for his help in the laboratory work.

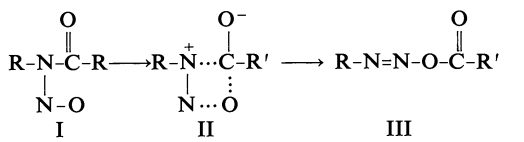
Effect of Hyperconjugation on the Decomposition of N-Alkyl-N-nitrosoacetamide

By Masuo MURAKAMI, Katsuhiko AKAGI and Yonosuke MORI

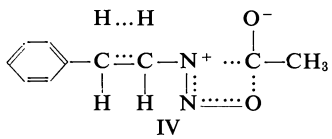
(Received April 4, 1961)



In the decomposition of *N*-alkyl-*N*-nitrosoacetamide, the β-phenyl group has been found, in an earlier paper, to decrease the heat of activation. This decrease in the heat of activation was explained by the stabilization of the transition state, involving second order hyperconjugation.

The effect of the β-phenyl group on the decomposition of *N-sec*-alkyl-*N*-nitrosoacetamide was found to be more pronounced when the alkyl group was cyclohexyl than when it was isopropyl, and the heat of activation of *N*-cyclohexyl-*N*-nitrosoacetamide was smaller than that of *N*-isopropyl-*N*-nitrosoacetamide. Hence the second order hyperconjugation was suggested as more probable for the cycloalkyl group. This hypothesis was supported by a hydrogen deuterium isotope effect experiment in which the rates of decomposition of *N*-cyclohexyl-*N*-nitrosoamides were found to be 1.1 ~2.8 times higher than those of corresponding deuterated homologues.

The thermal decomposition of *N*-alkyl-*N*-nitrosoamide has been known to result either in the formation of nitrogen and ester or in that of nitrogen, carboxylic acid and olefin as in the following equation (1).



$$\mathrm{RN(NO)COR'} \begin{cases} \rightarrow \mathrm{N_2 + ROCOR'} \\ \rightarrow \mathrm{N_2 + R'CO_2H + olefins\ (corresponding\ to\ R)} \end{cases} \quad (1)$$

This decomposition has been considered to proceed through an intermediate, III, diazoester, while the rate-determining step was suggested to involve a four-membered ring, II[1].

(2)

In an earlier work[2] we have shown that the rate and the heat of activation of decomposition of *N*-ω-phenyl-*n*-alkyl-*N*-nitrosoacetamide varied with the increase of methylene linkages, and that the heat of activation of *N*-2-phenylethyl-*N*-nitrosoacetamide was smaller than those of *N*-benzyl- and *N*-3-phenyl-*n*-propyl-*N*-nitrosoacetamides. The heat of activation of *N*-2-phenylethyl-*N*-nitrosoacetamide was found to be 3 kcal. smaller than that of *N-n*-propyl-*N*-nitrosoacetamide. We suggested that the transition state IV of the decomposition of *N*-2-phenylethyl-*N*-nitrosoacetamide is

IV

more stable than those of the others because the double bonds in the phenyl group can conjugate with the π-electrons in the four-membered ring by means of the second-order hyperconjugation[3].

In this paper, the decompositions of several *N*-alkyl-*N*-nitrosoacetamides are examined in order to confirm our hypothesis and to find the nature of the hyperconjugation which occurs in the alkyl group, especially in the cyclic alkyl group.

Results and Discussion

The rates of decomposition of the *N-n*-alkyl-*N*-nitrosoacetamides were measured in xylene, while those of the *N-sec*-alkyl-*N*-nitrosoacetamides were done in benzene. All the nitrosoamides examined decomposed following first order kinetics. At the same temperature duplicate rate measurements were carried out. The maximum deviation of rate constants obtained in each experiment fell within $\pm 1\%$. Thus, the error of the heat of activation was calculated to be ± 0.2 kcal. per mol.[4]

The Effect of β-Phenyl Group of *N*-2-Phenyl-*sec*-alkyl-*N*-nitrosoacetamide.—A similar effect by the β-phenyl group was observed in the decompositions of both *N*-2-phenyl-isopropyl- and *trans*-*N*-2-phenylcyclohexyl-*N*-nitrosoacetamides in benzene. The results obtained are shown in Table I.

	44.7	1.34		
	54.9	3.24		

As will be shown in the latter part of this paper, the rate of reaction was found to increase, decreasing the heat of activation by the steric effect of a α-substituent of *N*-alkyl group in the decomposition of nitrosoamide[5].

However, a β-alkyl substituent does not seem to have a steric effect; the heats of activation of *N*-2-cyclohexyl-isopropyl-*N*-nitrosoacetamide and *N*-*sec*-butyl-*N*-nitrosoacetamide were the same as that of *N*-isopropyl-*N*-nitrosoacetamide (23.7 kcal./mol.).

The phenyl group at the β-position apparently decreased the heat of activation of the decomposition. The decrease by the β-phenyl group, which can not be explained by steric effect, is probably caused by the greater stability at the transition state, which involves second order hyperconjugation between the phenyl group and four membered ring.

It is very interesting to note that the effect of β-phenyl on the heat of activation is greater in a cyclohexyl system than in an open chain system. The difference in the heat of activation between *N*-2-cyclohexyl-isopropyl- and *N*-2-phenyl-isopropyl-*N*-nitrosoacetamide was 3 kcal. per mol., while the difference in the heat of activation between *trans*-*N*-2-cyclohexylcyclohexyl- and *trans*-*N*-2-phenylcyclohexyl-*N*-nitrosoacetamides was 4 kcal. per mol.

5) R. Huisgen, *Ann.*, **595**, 55 (1955).

Although all these compounds have one hydrogen atom at the α-carbon atom of the *N*-alkyl group, the β-carbon atom of *N*-2-phenyl-isopropyl-*N*-nitrosoacetamide has two hydrogen atoms which are available for hyperconjugation with the benzene ring in the transition state, while *N*-2-phenylcyclohexyl-*N*-nitrosoacetamide has only one. Therefore, if the magnitude of second order hyperconjugation is dependent on the number of available hydrogen atoms, the effect of β-phenyl could be expected to be larger in the *N*-isopropyl compound than in the *N*-cyclohexyl compound. However, the observed result was contrary to our expection.

We would like to suggest that the magnitude of second order hyperconjugation is not determined by the number of available hydrogen atoms but rather by the structure of the ethylene linkage which is involved. In other words, hyperconjugation would be larger in cyclic alkane than in open chain alkane.

Decomposition of *N*-*n*-Alkyl-, *N*-*sec*-Alkyl- and *N*-Cycloalkyl-*N*-nitrosoacetamides.—There were large differences in the rate and the heat of activation in decompositions of *N*-*n*-propyl-, *N*-*sec*-butyl- and *N*-cyclohexyl-*N*-nitrosoacetamides. The decompositions of some *N*-*n*-alkyl-, *sec*-alkyl- and cycloalkyl-*N*-nitrosoacetamides were also examined in order to find if the reactivity of the nitrosoamide is affected by hyperconjugation which is caused by π-electrons in the four-membered ring at the transition state. The results obtained are shown in Tables II, III and IV.

The heats of activation on *N*-*n*-alkyl-*N*-nitrosoacetamides, as shown in Table II, had no correlation with the number of hydrogen atoms available for hyperconjugation, all

substances giving almost the same value (within the bounds of experimental error) except for the *N*-*n*-propyl compound. In the decomposition of *N*-*sec*-alkyl-*N*-nitrosoacetamides (Table III), the differences in heats of activation were very small, although there seems to be a trend for the heat of activation to increase with the decrease in the number of the available hydrogen atoms for the second order hyperconjugation. (All these compounds have one hydrogen atom for the first order hyperconjugation.) Therefore, in the decomposition of *N*-normal and *sec*-alkyl-*N*-nitrosoacetamides, the effect of hypercojugation is not large enough to effect the heat of activation. However, the situation was different when the *N*-alkyl group was cyclic. The heat of activation of *N*-cycloalkyl-*N*-nitrosoacetamides changed with the change in the ring size, the *N*-cyclohexyl compound being the most reactive.

Now let us look at the differences in the heat of activation (Table V) which appeared clearly in three alkyl series, *n*-alkyls, *sec*-alkyls, and cycloalkyls that are smaller than the seven-membered ring.

Table V. Heat of activation of *n*-alkyl-, *sec*-alkyl- and cycloalkyl-nitrosoacetamide

$RN(NO)COCH_3$ R	$\Delta H^{\neq}$ kcal. mol^{-1}
n-Alkyl	27.0～28.5
sec-Alkyl	23.7～24.3
Cycloalkyl	20.8～22.6

Huisgen[5] explained the difference between *N*-*n*-alkyl- and *N*-*sec*-alkyl-*N*-nitrosoamides as follows: the energy level of the ground state of *N*-*sec*-alkyl-*N*-nitrosoamide is higher than that of *N*-*n*-alkyl-*N*-nitrosoamide because the former has some steric strain as a result of the interaction of the branched alkyl group and the nitroso group, but the latter has not, while the energy levels of the transition states of the two compounds are the same.

While the difference in heat of activation between *N*-*n*-alkyl- and *N*-*sec*-alkylnitrosoamides can be accounted for by such a steric strain of the ground state, the difference between the heat of activation of *N*-*sec*-alkylnitrosoamide and that of *N*-cyclic alkyl nitrosoamide is hard to explain by a similar steric strain, because the acetamide group of the cyclic compound is at the equatrial position, thus causing no change in the steric strain.

Here again the second order hyperconjugation seems to offer a better explanation, because quasi-π-bond formation would be more favored in puckered cycloalkyl groups than in open chain compounds.

Decomposition of *N*-1- or 2-Deuterated Cyclohexyl-*N*-nitrosoacetamides.—If the assumption dercribed above is correct, it can be expected that the decomposition rate of *N*-cyclohexyl-*N*-nitrosoacetamide will decrease when 1- or 2-hydrogen atoms of cyclohexyl are replaced by deuterium atoms. The results obtained are exactly as expected and are presented in Table VI:

Table VI. Decomposition rates of *N*-cyclohexyl- and *N*-1- or 2-deuterated cyclohexyl-*N*-nitrosoacetamide in benzene

$RN(NO)COCH_3$ R	$10^4 \times k$ sec^{-1}	D atoms per molecule
Cyclohexyl	6.76	
1-Deuterated cyclohexyl	6.08	0.297
2-Deuterated cyclohexyl	2.43	2.54

The rate of acetolysis of cyclopentyl tosylate is known to be retarded[6] by the sustitution

6) A. Streitwieser, Jr., R. H. Jagow and S. Suzuki, *J. Am. Chem. Soc.*, 77, 6713 (1955).

of deuterium at the 2-position. The difference in free energy of activation per a deuterium atom was found to be ca. 100 cal. From this value it would be adequate to assume that the second order hyperconjugation can explain the decreased reactivities of *N*-deuterated cyclohexyl-*N*-nitrosoacetamides, because the second order hyperconjugation might be of the same order of magnitude as the first order hyperconjugation[7].

Experimental

Preparation of Amines.—Methyl-, ethyl-, *n*-propyl-, *n*-butyl-, isobutyl-, and cyclohexyl-amines were all commercially available products. *trans*-2-Phenylcyclohexylamine[8] (b. p. 116~118°C/6 mmHg., hydrochloride m. p. 247°C), *trans*-2-cyclohexyl-cyclohexylamine[8] (b. p. 110~110.5°C/4 mmHg), *sec*-butylamine[9] (b. p. 63°C), cyclopentylamine (b. p. 104~106°C) and cycloheptylamine (b. p. 85°C/75 mmHg, hydrochloride m. p. 245~246°C) were prepared from the corresponding oximes by reduction, using sodium and absolute ethanol[8]. Cyclooctylamine[9] (b. p. 72°C/12 mmHg, picrate m. p. 191~192°C), and 2-cyclohexyl-isopropylamine[10] (b. p. 85~87°C/21 mmHg, n_D^{20} 1.4615) were prepared by catalytic reduction from cyclooctanoneoxime and 2-phenylisopropylamine respectively. 1-Ethyl-*n*-propylamine (b. p. 90°C, picrate m. p. 167~168°C) and cyclobutylamine (b. p. 80~81°C) were prepared by the Schmidt reaction from α-ethylbutyric acid and cyclobutanecarboxylic acid respectively.

1-Deuterated Cyclohexylamine.—It has been reported that only 1-hydrogen atoms were exchanged by deuterium in the treatment of carboxylic acid with D_2SO_4. A mixture of 12 g. of cyclohexanecarboxylic acid (b. p. 113°C/6 mmHg, m. p. 29~30°C) and 18 g. of ice-cooled D_2SO_4 in a sealed tube was kept at 50°C for 300 hr. The resultant dark-brown mixture was poured into ice-water. The acid was extracted with ether and then was dissolved in a diluted aqueous sodium hydroxide solution. This solution was acidified with sulfuric acid and extracted with ether again. After drying the extract and removing the ether, the residue was distilled under reduced pressure, and 10.6 g. of 1-deuterated cyclohexanecarboxylic acid (b.p. 135°C/25 mmHg) was obtained. This substance has an absorption at 2195 cm^{-1} for carbon-deuterium bond. From 7.5 g. of this acid, 5 g. of 1-deuterated cyclohexylamine (b. p. 134°C) was obtained by the Schmidt reaction, using sulfuric acid. This amine has an absorption at 2170 cm^{-1} for carbon-deuterium bond.

2-Deuterated Cyclohexylamine.—2-Deuterated cyclohexanone was prepared by the method described in a previous work[12]. Twenty grams of cyclohexanone was added to ice-cooled D_2SO_4 (40 g.), and the mixture was kept at 20°C for 90 min. The resultant mixture was poured into ice-water and then extracted with ether. From the extract 5.2 g. of 2-deuterated cyclohexanone was obtained. This substance has an absorption at 2190 cm^{-1} for carbon-deuterium bond. From this ketone 2.2 g. of 2-deuterated cyclohexylamine (b. p. 133~134°C) was obtained by the usual oximation method, using

hydroxylamine hydrochloride, and reduction of the resultant oxime, using sodium and absolute ethanol. This amine has a strong absorption at 2175 cm^{-1} for carbon-deuterium bond.

Preparation of Acetamides.—Acetamides were prepared by acetylating the amines with acetic anhydride in ether. After washing with water, aqueous potassium carbonate solution, and water successively the mixture was dried over magnesium sulfate. Removal of the ether and distillation under reduced pressure gave the expected products. Recrystallization from a mixture of ligroin and chloroform gave the products in a pure form. Table VII lists the boiling points or the melting points and analytical data of the acetamides.

Water obtained from the combustion of 1- or 2-deuterated cyclohexyl acetamides contained 1.96 atom % and 16.5 atom % of deuterium respectively.

Nitrosation[13] of Amides.—Into an ice-cooled mixture of 0.01 mol. of acetamide and 0.03 mol. of anhydrous sodium acetate in carbon tetrachloride, a solution of 0.015 mol. of nitrogen tetraoxide in carbon tetrachloride, cooled to $-10\sim-15$°C, was stirred. After 30~60 min. at 0°C, the mixture was poured into ice-water. The carbon tetrachloride layer was washed with water, 5% aqueous solution of potassium carbonate, and water successively and dried over anhydrous sodium sulfate. The solvent was removed under reduced pressure at 0°C to give nitrosoacetamide, as yellow or reddish-yellow oil. Since nitrosoamide decomposes very easily, it was used immediately, without further purification, for the measurement of the rate.

Kinetic Studies.—The decomposition rates were measured volumetrically. A 50 cc. azotometer and 50% aqueous solution of potassium hydroxide were used for the measurement of the volume of nitrogen evolved from a solution of 0.004~0.007 mol. of nitrosoacetamide in 100 cc. of benzene or xylene. The thermostat was adjusted so as to maintain the temperature within ±0.01°C. The first order rate constant was calculated according to the following equation;

$$k = 2.303/t \cdot \log\{V_\infty/(V_\infty - V_t)\}$$

in which V_t and V_∞ are the volumes having evolved at time t and at the time when the decomposition ceased, usually ten-fold half the life of the reaction. The energy and entropy of activation were calculated by the least square method. Rate data for typical determination are shown in Tables VIII and IX.

The authors wish to thank Mr. Sotoo Yamamoto for his analysis of heavy water and Miss Kayo Kabazawa for her infrared spectral measurements. They are also grateful to the Ministry of Education for the grant-in-aid for the scientific research.

Photosensitized Oxidation of Leuco-uranine and the Identification of the Photobleached Product of Uranine in Ethanol Solution

By Kengo UCHIDA, Shunji KATO and Masao KOIZUMI

(Received April 24, 1961)

According to Imamura and Koizumi[1,2], the reductive photobleaching of xanthene dyes such as eosine and uranine takes place when the degassed solutions of such dyes in ethanol are irradiated by visible light. They studied the primary processes of this reaction to some extent, but did not undertake the identification of the final product, suspecting that the dye structure might be completely destroyed since the dye is not restored by the introduction of air after the reaction. There remains, however, a possibility that the leuco dye itself is stable and exists as such in the presence of air, and even in case the above speculation be true, it seems at least possible that the decomposition would take place after the formation of leuco dye; the transient existence of a rather stable semiquinone has been established by the flash technique[3], and this makes more plausible the ultimate formation of leuco dye through disproportionation reaction.

With regard to leuco-uranine, Kul'berg and Matveev[4] had reported that this compound, being rather stable in the presence of air, can be conveniently utilized for the quantitative analysis of a minute quantity of oxidant. The present authors have now found that this leuco compound is easily converted photochemically to uranine by the use of some dyes and acridine as photosensitizers. Moreover, this reaction, contrary to our expectation, has proved to take place more rapidly under the deaerated condition. A similar reaction was found to occur with the photobleached product in question; this and some other facts have now unambiguously confirmed that most of the photobleached product exists as leuco dye.

Preparation of Leuco-uranine and Some of its Physico-chemical Properties

Preparation.—*Reagents.* — 1) Sodium amalgam: Prepared from Merck's sodium and distilled mercury.

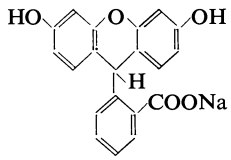
2) Sodium hydroxide solution: Saturated solution was prepared by dissolving Wako Pure Chemical Industries' G. R. grade sodium hydroxide. To minimize the contamination of sodium carbonate, the supernatant liquid was used.

3) Fluorescein: For the preparation of leuco-uranine, Hikotaro Shudzui & Co. G. R. grade fluorescein was used without further purification. For chromatography, polarography and sensitized reaction, the above sample was neutralized and then twice recrystallized from ethanol by evaporating the solvent without heating. The uranine crystal thus obtained was desiccated in a high vacuum. This sample has an extinction coefficient of 8.2×10^4 at 490 mμ, the highest value ever obtained[5]; this assures its high purity.

Procedure. — Fluorescein was dissolved in water, neutralizing it with a small excess of sodium hydroxide, and then reduced by sodium amalgam. When the dye color became quite faint, the amalgam was removed from the solution and the precipitate of leuco-fluorescein was obtained by adding dilute hydrochloric acid. The precipitate had a tint of yellow at first but gradually turned brown. It is a sticky resin-like material but solidifies by slight cooling.

This substance, after being dissolved in 99% ethanol, was neutralized with an equimolar sodium hydroxide pellet; evaporation of the solvent under reduced pressure gave a crystalline substance.

Further purification was performed to remove the sodum carbonate and the small amount remaining of the oxidized form of uranine. The latter substance, being more soluble in ethanol than leuco dye, can be washed out by a small quantity of ethanol. Then the substance is dissolved in a large quantity of ethanol; sodium carbonate which is insoluble in ethanol can be eliminated by this procedure. The solvent was distilled off in a high vacuum, and the crystal deposited was treated further in the above way several times. The final evacuation was continued for more than ten hours to remove any trace of ethanol; this was continued until the ethanol vapor could not be detected by Geissler's tube.



It is, of course, necessary to perform all the above procedures under a safety lamp. Heating in the course of dissolution and precipitation is undesirable since it tends to promote the decomposition of the sample. Only at the last stage of desiccation was the sample heated up to 40°C.

The final substance obtained with a slight tint of brown is very deliquescent; hence, it was preserved in a sealed ampoule and was kept in the dark.

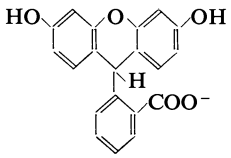
5) M. Imamura, This Bulletin. **31**, 962 (1958).

The crystal does not melt up to 210°C.

Analysis of Leuco-uranine. — The sample is considered to be practically pure (I) from the results of acid and base titration.

I



II

The sample was transformed into II by adding hydrochloric acid and, after washing with water and after desiccation through pumping in a high vacuum, was submitted to elementary analysis. The result is as follows:

Found: C, 68.06; H, 4.89. (a) Calcd. for II: C, 71.85; H, 4.22. (b) Calcd. for II with one mole of water (as crystalline water): C, 68.18; H, 4.58%.

The experimental value closely approximates the one for b.

Some Physico-chemical Properties of Leuco-uranine.—*Polarographic Studies.*—According to Delahay[6], who studied the polarogram of fluorescein in the pH range 2.00~10.83, two-stage waves appear only in the alkaline region; this indicates a two-steps reduction involving the formation of stable semiquinone. He considered the ultimate form of leuco dye to be III.

III

To ascertain that the same III is obtained by treating our sample of fluorescein with sodium amalgam, our starting substance, fluorescein was re-examined polarographically in the alkaline region. The result gave two-stage waves, the half-wave potentials being −1.12 and −1.36 V. at pH 10.5, and −1.16 and −1.60 V. in a 1.2 N sodium hydroxide solution (referred to as S. C. E.). Delahay's value at pH 10.5 (interpolated value) is −1.18 V.

It is most plausible from the above results that the treatment of fluorescein with sodium amalgam in the alkaline solution gives I as a final product.

Absorption Spectra.—As shown in Fig. 1, the absorption spectra of leuco-uranine have two peaks, at 280 mμ ($\varepsilon \sim 5\times10^3$) and at 210 mμ. The extinction in the visible region is different

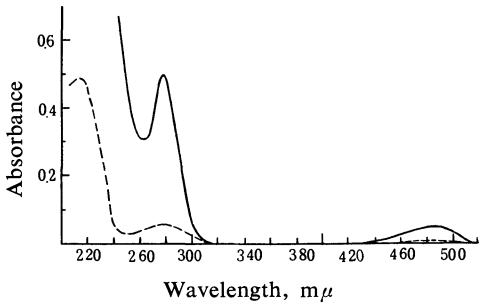


Fig. 1. Absorption spectra of leuco-uranine.
—— 1.0×10^{-4} M; ---- 1.0×10^{-5} M

from sample to sample, probably because of being contaminated with a different quantity of uranine, which has a large absorption maximum at 490 mμ. The second peak of leuco-uranine at 210 mμ is not so clear-cut, since it is superposed by the absorption of coexisting uranine.

Measurement of pK of Leuco-uranine. — For the measurement of pH, a Hitachi pH-meter E. H. P-1 was used. Acid and alkaline titration of leuco-uranine gave the two-step curves as shown in Fig. 2.

The two pK values obtained were $pK_1=3.8$ and $pK_2=9.6$ at 30°C. The first of these surely corresponds to the dissociation of the carboxyl group, II $\rightleftarrows$ III, in view of the fact that the pK values of benzoic acid, 2-ethylbenzoic acid

and 2-*tert*-butylbenzoic aid are respectively 4.2, 3.8[7] and 3.5[8].

The second value is most certainly an average of the two p*K* values corresponding to the following two dissociation processes:

Strong evidence for this is the fact that about two equivalents of sodium hydroxide are needed for neutralization. The value is reasonable in view of the p*K* value of phenol, 10.0. Table I gives a comparison of the above values with those of fluorescein. It seems worth while to note that leuco dye has somewhat different values.

Divalent~Tervalent			

Photosensitized Oxidation of Leuco-uranine

It was found that leuco-uranine in the aqueous solution is photochemically oxidized to uranine by adding some substances as sensitizers. Quite unexpectedly, the reaction was further found to take place more promptly in the deaerated condition. Acridine, xanthene dyes such as uranine, eosine, erythrosine and thiazine dyes such as methylene blue and thionine are more or less effective sensitizers. Some azo dyes and rhodamine were found to be not effective.

Detailed studies were made using acridine, uranine and methylene blue.

Materials.—*Acridine.*—Tokyo Kasei G. R. grade acridine was submitted to repeated crystallization using a water-ethanol mixture. The concentration of acridine employed as a sensitizer was usually 1.5×10^{-4} M.

Methylene Blue.—Grübler's sample was twice recrystallized from *n*-butanol.

Other Dyes. — Commercial reagents were used without further purification.

Water.—Twice distilled.

Ethanol.—Wako Pure Chemical Industries' G. R. grade ethanol was used without further purification.

The concentration of leuco-uranine was usually 1×10^{-5} M.

The solution for each experiment was prepared by diluting the stock solution of 1.0×10^{-4} M. The stock solution when kept in the dark scarcely showed any change.

Apparatus.—In the case of acridine being employed as a sensitizer, the irradiating light was 365 mμ from a high pressure mercury lamp, passed through a ultraviolet filter (D-2). When the sensitizer was uranine or methylene blue, a 75 V.-500 W tungsten lamp was used at 45.0 V., the light $<$360 mμ being cut off in the former case with a ultraviolet-cut off-filter, and the light $<$600 mμ in the latter case with a Walz R-2 filter. The degree of coloration was measured by a Hitachi spectrophotometer EPU-2A, using a $1\times1\times4$ cm. Terex cell which was designed for evacuation. Degassing of the sample was done by use of a mercury diffusion pump, melting and freezing (in a dry-ice bath) being repeated five or six times.

The aqueous solution of acridine has an absorption maximum at 355 mμ, at which there exists no absorption of leuco-uranine or uranine; hence, 365 mμ of mercury lamp is very convenient for studying this system. This is the reason that acridine was chiefly used as a sensitizer.

Results

When the aerated solution containing leuco-uranine and acridine was irradiated with 365 mμ light, the coloration due to the restoration of uranine took place, but it did not go over 40%; further irradiation after evacuation never induced any more coloration. Examination of this material by paper chromatography proved the absence of leuco-uranine. Thus, it seems plausible that the decomposition of the dye took place, perhaps photochemically, following the formation of uranine.

The absorption spectra of the irradiated solution completely coincide with those of uranine in the visible region, with a maximum at 490 mμ and a shoulder near 460 mμ.

7) "International Critical Table", VI, McGraw-Hill, New York (1929), p. 291.
8) J. B. Shoesmith and A. Mackie, *J. Chem. Soc.*, **1936**, 300.
9) V. Zanker and W. Peter, *Chem, Ber.*, **91**, 572 (1958).
10) L. Lindqvist, *Arkiv. Kemi.*, **16**, 79 (1960).

Scarcely any change was perceived in the spectra of acridine (in the ultraviolet region).

The unexpected coloration which takes place in the highly degassed system proceeds with a much greater speed, and, moreover, it is almost quantitative.

In Fig. 3 the absorption spectra before and

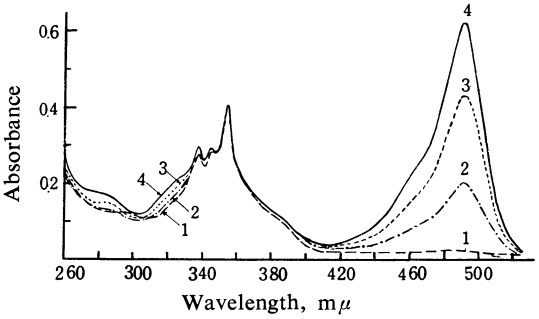

Fig. 3. Absorption spectra of leuco-uranine +acridine (sensitizer) at various irradiation times.

1 ——— Before irradiation
2 —·—· 1 min. irradiation
3 ------ 4 min. irradiation
4 ——— 30 min. irradiation

after the irradiation are shown. It is remarkable that there is no change in the absorption spectra of acridine, which precludes the hydrogenation of acridine taking place. There is no evolution of hydrogen*, but the exact nature of this reaction is quite unknown at the present time.

In the case of uranine as a sensitizer (with light $>360\,m\mu$), the reaction was also accele-

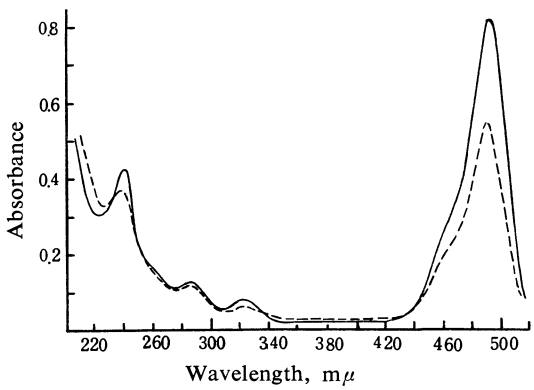

Fig. 4. Comparison between the absorption spectra of uranine and those of the irradiated product of leuco-uranine (a small quantity of uranine having been added previously as a sensitizer).

—— Uranine
---- The irradiated product of leucc-uranine

rated, so to speak in this case, autocatalytically. In this case also, degassing promotes the coloration and makes it more complete. The absorption spectra of the irradiated solution, as shown in Fig. 4, are quite similar to those of uranine. In the aerated solution, the coloration did not exceed 50%, whence the optical density at $490\,m\mu$ gradually declined, perhaps due to the irreversible photoöxidation.

When methylene blue was used as a sensitizer under the irradiation with light $>600\,m\mu$, the absorption spectra of uranine with a maximum at $490\,m\mu$ also grew with a moderate speed. In the presence of air, no appreciable change was observed in the absorption spectra of methylene blue, with only a slight decrease of optical dentity, probable due to photoöxidation[11].

In case of the evacuated solution, methylene blue is photoreduced to leuco, dye accompanied by the change of leuco-uranine to uranine. Its rate is very large, as is seen from Fig. 5A, which shows the absorption spectra of the solution at various irradiation times. The maximum of methylene blue at $665\,m\mu$ gradually declines even when the solution is kept in the dark, but the decline is very rapid when the solution is irradiated, and it is restored up to about 96% when air is introduced after the reaction. The maximum at $490\,m\mu$, which is due to uranine, grows gradually when the solution is kept in the dark. For example, the decrease of methylene blue and the increase of uranine when the solution is kept in the dark for four hours after evacuation, are respectively 0.33×10^{-8} mol. and 0.17×10^{-8} mol. The excess of the former over the latter is perhaps due to the adsorption of methylene blue to the cell wall. Irradiation accelerates the rate very much. The introduction of air causes a slight increase of absorbance at $490\,m\mu$, which is probably due to the absorption of methylene blue restored having a small extinction in this region.

In the ultraviolet region, the absorption spectra of methylene blue, leuco methylene blue, uranine and leuco-uranine overlap each other, complicating the change of the entire absorption spectra. Subtracting the absorption spectra due to uranine and leuco-uranine from the entire spectra, one gets the resultant spectra shown in Fig. 5B.

Although some degree of error is unavoidable in this treatment, it is clear that the absorption maxima at 293 and $248\,m\mu$ of methylene blue existent prior to irradiation disappear and that in their place a new maximum appears at $256\,m\mu$ in the irradiated solution.

* The experiment concerning this will be published shortly.

1′ ——— Before irradiation
4′ ------ After irradiation
5′ —·—· After introduction of air

This is exactly equal to that of leuco methylene blue[12]. When the air is introduced after the reaction, the latter disappears and the two maxima due to methylene blue again come to exist.

The oxidation of leuco-uranine proceeds quite rapidly as long as methylene blue exists, but it becomes very slow when almost all the methylene blue turns into leuco form.

The quantity of methylene blue and leuco-uranine having reacted can be evaluated separately by the use of the extinction coefficients of methylene blue (6.0×10^4 at 665 mμ) and of uranine (8.2×10^4 at 490 mμ). Calculation showed that during the irradiation for 1.5 min., 1.4×10^{-8} mol. of methylene blue has disappeared and 1.2×10^{-8} mol. of uranine has been produced. The two values coincide well within the range of experimental error.

The reactions with the use of methylene blue are quite reasonable, since the oxidation-reduction potential of methylene blue and uranine are respectively ca. 0 and <-1 V.

Identification of the Photobleached Product of Imamura and Koizumi with Leuco-uranine

As to the photobleached product when the ethanol solution of uranine or eosine is irradiated by a visible light, Imamura and Koizumi suggested that the structure of the dye might be decomposed[1,2]. Now it is evident, however, from the results described above that the leuco dye is not so reactive, and hence there is ample possibility for the final product to be nothing but leuco dye. Therefore, the comparison between the chemically prepared leuco dye and the photobleached compound was undertaken spectroscopically and especially in respect to the photosensitized oxidation, which is highly specific.

Besides, paper-chromatographic comparison between them was tried.

Photosensitized Oxidation of the Photobleached Product.—The absorption spectra of the photobleached product, as shown in Fig. 6, resemble those of leuco-uranine, with maxima at 285 mμ and <220 mμ.

The photobleached product was prepared by irradiating the ethanol solution of uranine in the usual way. It was then separated from ethanol by distilling the latter in vacuo; to its alkaline solution was added acridine, and then the solution was irradiated by a 365 mμ

12) Y. Usui, H. Obata and M. Koizumi, ibid., 34, 1049 (1961).

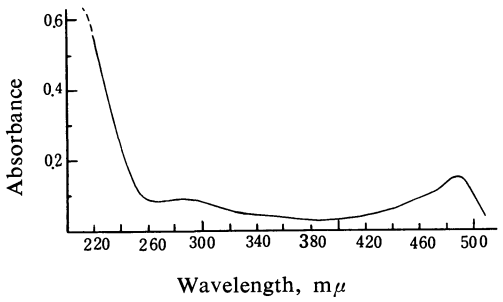

Fig. 6. Absorption spectra of the photobleached product of uranine as dissolved in a weak alkaline aqueous solution.

light. The formation of uranine was observed up to about 25% of the original quantity. In contrast to this result obtained for the aerated solution, degassing of the system accelerated the reaction, and the recovery attained about 60%. This indicates that at least more than 60% of the photobleached product exists as leuco dye.

It is to be added, however, that the restoration of color is slower than that of the chemically prepared leuco dye, the rate in the aerated and deaerated solution being respectively about half and one-fifth of that of the latter. This might be due to the inhibiting action of a certain substance produced during the photobleaching.

An analogous comparison was made with eosine.

The photosensitized coloration of the chemically prepared leuco-eosine in the deaerated alkaline solution was only about 70% of the total quantity. For the photobleached product it was about 35%. From these results it can be said that about half of the photobleached product exists as leuco dye.

In the aerated solution the result is not so clear-cut, the coloration in both the photobleached and chemically prepared samples being only 15~20%.

It is to be added that, in these cases, the shift of the maximum is accompanied by the oxidation of the leuco dye. Thus, the absorption peak of the recovered dye is 506~505 mμ compared with 514 mμ of eosine in the alkaline solution. This is due to the debromination reaction occurring in the alkaline solution[13]; this reaction would take place during the photosensitized oxidation and, moreover, might occur in the course of the preparation of leuco dye, which was done in a 1.3 N alkaline solution to make easy its reduction by sodium amalgam. According to Oster[14], dibromofluorescein has a peak at 506 mμ, which is exactly the same as the above value.

Analysis by Means of Paper Chromatography. —Taylor's method[15] was employed except that the composition of the developer was somewhat modified. Our composition was 28% ammonia water 10 vol.%, ethanol 15 vol.%, water 75 vol.%. Since the concentration of both uranine and leuco-uranine was low, the position after the development was decided by the fluorescence emitted by ultraviolet irradiation.

The ascending method was employed, and the filter papers used were Toyo Roshi (filter paper) No. 50. All the procedures were done in the dark room.

The results obtained for uranine are shown in Table II. It is clear that the result for the photobleached product is quite the same as that of leuco-uranine except for the existence of a certain substance with $R_f=0.935$. This unknown substance emits fluorescence with a white tint. 0.79 of leuco-uranine and the photobleached product, without doubt, is due to contaminated uranine. The R_f of leuco compound (0.86) is easily ascertained, since it is oxidized to uranine when irradiated (after development) and emits the fluorescence characteristic to uranine. Samples c and d usually give only $R_f=0.78$, but in addition they sometimes give $R_f=0.86$ of leuco-uranine, though its quantity is always very small.

Table II. The results of paper chromatography for uranine and related compounds

	R_f	
a) Uranine	0.78	
b) Leuco-uranine	0.79	0.86
c) The material obtained from leuco dye by oxidation in air	0.78	
d) The material obtained from leuco dye by oxidation in vacuo	0.79	0.86 (very little)
e) The photobleached product from uranine	0.79	0.85 0.935(?)

In case of eosine the results are more complicated and the reproducibility of the R_f-values is not so good. It can be said, however, from the results of more than ten tests, that the photobleached product contains an appreciable quantity of leuco-eosine. The material obtained by the photosensitized oxidation of leuco-eosine gives spots other than those of eosine, which may perhaps be attributed to dibromofluorescein.

13) M. Imamura and M. Koizumi, ibid., **29**, 913 (1956). Eosine, when, irradiated in the alkaline water-ethanol mixture, undergoes a rapid debromination.

Summary

Leuco-uranine was prepared by reducing uranine with sodium amalgam, and some of its properties were investigated. The aqueous solution of leuco-uranine is stable in the presence of air irrespective of its low oxidation-reduction potential.

It was found that leuco-uranine is photo-oxidized to uranine by the use of acridine and some dyes as sensitizers. The reaction may be attributed to the dissolved oxygen and is very reasonable. A quite unexpected result was, however, that a similar reaction takes place more rapidly and more quantitatively in the degassed solution than in the aerated solution. The uranine and acridine employed as sensitizers in this case were ascertained not to sustain any change. The nature of the reaction is not known at the present time.

It was further established that the photo-bleached product obtained by irradiating the deaerated ethanol solution of xanthene dyes, consists mainly of leuco dye. This was ascertained by comparing their absorption spectra, by the photosensitized coloration, acridine being used as a sensitizer, and, in addition, by means of paper chromatography.

The authors wish to thank Miss Chieko Iwanaga for her assistance.

Electrometric Study on Thorium-Arsenite System as a Function of the pH

By Ram Sahai SAXENA and G. P. SAXENA

(Received February 22, 1961)

The reaction between thorium nitrate and sodium(meta)arsenite solutions at different pH values has been studied by E.M.F. measurements reactants, using bright platinum as indicator involving potentiometric titrations between the electrode. The electrometric experiments give definite evidence of the formation of three arsenite compounds having the molecular formulae, $ThO_2 \cdot 2As_2O_3$; $ThO_2 \cdot As_2O_3$ and $3ThO_2 \cdot 2As_2O_3$ at pH 9.85, 11.25 and 12.28 respectively. The proportion of ThO_2 increases with the concentration of alkali used in the preparation of alkali arsenites and the formation of thorium arsenites is thus a function of the hydrogen ion concentration. The potentiometric titration curves are regular in form ; a pronounced maxima in dE/dV occurs at the end point, with either of the reagents used as the titrant and the results are accurate and reproducible. The effect of alcohol and electrolytes on the end point has been studied. The behavior of the indicator electrode and the mechanism of the electrode reaction have been discussed.

The precipitation of sodium arsenite solutions with heavy metal salts causes the formation of complex arsenites whose composition is mainly governed by the pH. The investigations of these compoundis made difficult by the adsoption of arsenic oxide by the metallic hydroxide; the conversion of ortho arsenite to pyro and meta arsenite takes place with great ease and these dissolve in excess of alkali or acid[1]. consequently analytical methods have failed to give a correct view of their composition. A survey of literature reveals that there are very few references to rare-metals arsenites and the earlier workers[2-4] mainly confined themselves to the analytical investigations of the precipitates formed by mixing metal salts and alkali arsenites under different conditions. Besides, it appears that the formation of arsenites has not been studied at different hydrogen ion concentration of the medium which plays an important role in their precipitation. Moreover, there is hardly any reference in literature to the study of this system by electrometric techniques which have provided more conclusive evidences on the composition of such metal complexes (Saxena et al.)[5] and hence the present investigation has been initiated.

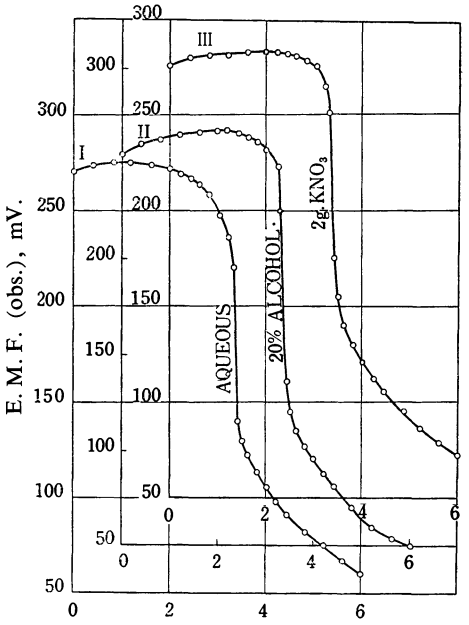
Experimental

Merck's guarateed extra-pure reagents thorium nitrate and $NaAsO_2$ were used. Thorium was estimated as thorium oxalate and its subsequent ignition to thorium oxide[6]. The strength of sodium arsenite solutions was checked by titrating against standardized iodine solution. The pH of $NaAsO_2$ solutions was measured using a glass electrode of the range (1~13 pH) with the help of buffer solution. Calculated amounts of sodium hydroxide were added to sodium arsenite solutions in definite molecular proportions to vary the pH.

Using differnt concentrations of thorium nitrate and alkali arsenite solution at pH levels 9.85, 11.25 and 12.28, potentiometric titrations were carried out both by the direct and the inverse methods, i. e. when the alkalized arsenite solutions from the micro-burette were add to thorium salt in the electrode vessel and vice versa. A bright platinum foil was dipped in the solution to be titrated and used as an indicator electrode in conjunction with saturated calomel electrode through potassium nitrate salt-bridge. The titration cell was kept in an electrically maintained thermostat. The E. M. F. was measured on a Cambridge (null deflection type) pH-meter. The titer solution was continuously stirred by a magnetic stirrer. Curves were plotted between the E(obs.) and the volume of the titrant added in ml. and from the sharp break in potential indicated by the titration curves, the equivalence point was obtained. This was further checked by calculating the maximum value of dE/dV in each case. The titrations were also performed in presence of varying concentrations of ethanol and electrolytes as potassium nitrate. Twenty milliliters of the reagent was taken in the cell each time (see Table I).

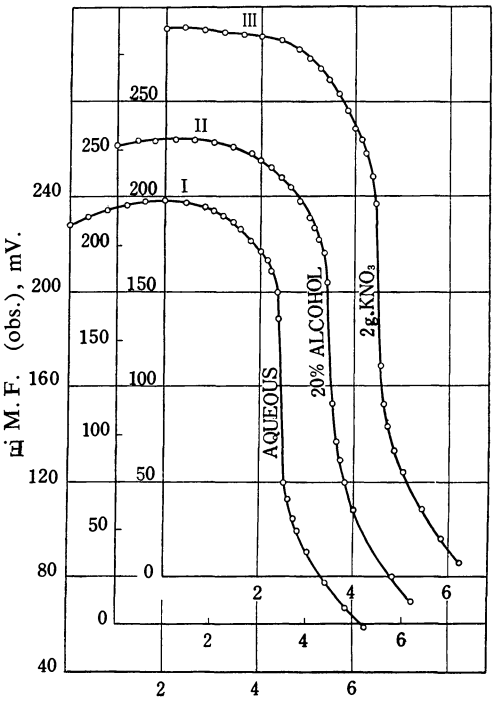
Discussion



The pH of stock solution of sodium arsenite was measured by glass electrode and found to be 9.85. The variations of the latter were obtained by the progressive additions of calculated

6) A. I. Vogel, "Quantitative Inorganic Analysis", p. 472.

quantities of sodium hydroxide solution to sodium arsenite. When sodium hydroxide is mixed with sodium arsenite in the molecular ratio 1 : 1 and 2 : 1, the corresponding compounds formed are $Na_4As_2O_5$ (sodium pyroarsenite) and Na_3AsO_3 (sodium orthoarsenite) and the pH of their solutions were found to be 11.25 and 12.28 respectively.



It is clear from Figs. 1 and 4 and from the summary of observations in Table I that when sodium arsenite solution at pH 9.85 is added to thorium nitrate solution and vice versa and the potential between a platinum indicator electrode and the calomel half-cell, measured and plotted against the volume of the titrant added in ml., a sharp deflection in curve occurs at a point where the molecular ratio of sodium arsenite and thorium nitrate is 4 : 1, corresponding to the formation of thick gelatinous precipitate of thorium metaarsenite $Th(AsO_2)_4$ or $ThO_2 \cdot 2As_2O_3$. At pH 11.25, the potentiometric titrations between $Th(NO_3)_4$ and $Na_4As_2O_5$ suggest the formation of thorium orthoarsenite having the molecular formula $ThAs_2O_5$ or $ThO_2 \cdot As_2O_3$ (Figs. 2 and 5). The titrations of thorium salt and Na_3AsO_3 ($2NaOH + NaAsO_2$) pH 12.28 show a sharp break in potential at the point of equivalence and the compound formed corresponds very closely to the normal compound $Th_3(AsO_3)_4$ or $3ThO_2 \cdot 2As_2O_3$ (vide Figs. 3 and 6).

In these titrations, the behavior of indicator electrode with bright platinum as electrodic metal in contact with thorium ions and

slightly soluble thorium oxide, could be interpreted as that of metal-metal oxide electrode (in this case Th-ThO_2), whose potential depends to a great extent upon the concentration of thorium ions which is groverned by its hydrogen ion concentration. The mechanism of the electrode reaction may be visualized as follows:

$$Th + 4AsO_2^- = ThO_2 \cdot 2As_2O_3 + 4e$$

$$ThO_2 + 4H + 4e \rightleftarrows Th^{4+} + 2H_2O$$

from which

$$\frac{[Th^{4+}]}{[ThO_2][H^+]^4} = K$$

and as $[ThO_2]$ (being slightly soluble) is a constant,

$$[Th^{4+}] = K'[H^+]^4$$

The potential of the electrode can therefore be represented by the Nernst equation

$$E = E_0 + 0.059/2 \log [Th^{4+}]$$

In the direct titrations, the electrode dipped in acidic thorium nitrate solution (pH 5.6), is positive. When alkalized arsenite solutions at different pH values are added from the microburette to thorium nitrate solutions, the concentration of thorium ions gradually decreases owing to their removal from solution by precipitation as thorium arsenites and consequently the E. M. F. slightly decreases after each addition of

the reagent. At the point of equivalence when all the thorium ions are removed, a sharp downward jump in potential is observed which is indicated by the steep portion of the titration curves (Figs. 1—3). In the case of inverse titrations, an equilibrium is established after the additon of a few drops of thorium nitrate solution to the titration cell containing arsenite solutions. The E. M. F. shows a gradual rise from the beginning of the reaction, till in the vicinity of the end point when the last traces of arsenite have been removed by precipitation, the first excess of thorium ions added causes a sudden leap in potential indicating the end point, after which the E. M. F. assumes more or less a constant value (Figs. 4—6).

It is noted that after each addition of the reagent, the E. M. F. readily becomes steady. A thorough stirring in the neighborhood of the end point has a favorable effect. Each titration takes about half an hour for completion. The addition of alcohol in varying concentrations improves the end point as the presence of alcohol reduces the adsorption of AsO_2^- ions and also the solubility of thorium arsenite precipitates and hence a closer approach to the theoretical values is envisaged in the experimental results in aqueous-alcoholic solutions (see Table I). The presence of electrolytes such as potassium nitrate has also a favorable effect on the end point as it curtails the time for titration by coagulating the arsenite sol formed in the reaction mixture and thus increasing the sensitiveness of the titration.

Potentiometric titration curves are symmetrical on both sides of the point of equivalence; a pronounced maxima in dE/dV is obtained at the end point and the results are accurate and reproducible. The reaction between alkali arsenites and thorium salts can be successfully studied potentiometrically. There is, however, no appreciable affect of alcohol or electrolytes on the nature of the curves or the magnitude of the break in potential.

It is observed that on mixing thorium nitrate and alkalized arsenite solutions different arsenites of thorium are formed, the composition of which depends on the conditions of precipitation, particularly the concentration of sodium hydroxide in sodium arsenite. Further, the arsenite precipitates dissolve in excess of alkali and also in acids and hence the precipitation of one or the other compound is a function of the hydrogen ion concentration of the medium. The disagreement between the views of previous workers on the molecular composition of thiorum arsenite compounds as reported earlier in literature (loc. cit.) seems to be due to the fact that the experiments were not performed at definite pH values of arsenite solutions.

The reactions between thorium nitrate and thorium arsenite at different pH levels can be represented as follows:

$$4NaAsO_2(2Na_2O+2As_2O_3)+Th(NO_3)_4 = Th(AsO_2)_4[ThO_2\cdot 2As_2O_3]+4NaNO_3$$

pH 9.85

$$2Na_4As_2O_5(4Na_2O+2As_2O_3)+2Th(NO_3)_4 = 2ThAs_2O_5[ThO_2\cdot 2As_2O_3]+NaNO_3$$

pH 11.25

$$4Na_3AsO_3(6Na_2O+2As_2O_3+3Th(NO_3)_4 = Th_3(AsO_3)_4[3ThO_2\cdot 2As_2O_3]+12NaNO_3$$

pH 12.28

The composition of thorium arsenites can thus be represented by the general formula $xThO_2\cdot As_2O_3$ and the amount of thorium oxide is proportional to the quantity of sodium oxide in sodium arsenite and its proportion increases with the concentration of alkali used in the preparation of arsenite solutions or, in other words, with the pH of the medium.

Spectroscopic Studies on Molecular Configurations of Some Aliphatic Dinitriles. III. Infrared Spectra of Adiponitrile and Bis-(adiponitrilo)copper(I) Nitrate

By Ikuo MATSUBARA

(Received April 24, 1961)

Recently the author has studied the infrared spectra of some copper(I) complexes of aliphatic dinitriles and showed that they are quite useful in understanding the spectra and molecular configurations of free dinitriles[1,2]. In the course of the spectroscopic studies on the molecular configurations of the series of aliphatic dinitriles, the infrared spectra of adiponitrile and bis(adiponitrilo)copper(I) nitrate, $[Cu\{NC-(CH_2)_4-CN\}_2]NO_3$, have been investigated. Because adiponitrile has three internal axes of rotation, the number of possible staggered rotational isomers becomes large[3], and the complexity of the liquid-state spectrum of this compound may be explained as due to the coexistence of these rotational isomers. X-Ray analysis of bis(adiponitrilo)-copper(I) nitrate[4] has revealed that the ligand adiponitrile takes the planar all-trans(TTT*) configuration in the crystals of this complex. The infrared spectrum of bis(adiponitrilo)-copper(I) nitrate has been explained satisfactorily on the basis of this result, and interpretation of the spectra of adiponitrile both in the liquid and in the crystalline solid states has been made possible by comparing them with that of the complex. The results of the previous spectroscopic studies on other molecules of the type $X-(CH_2)_4-X$ such as *n*-hexane[5-7], tetramethylene halides[8] and adipic acid[9] were also useful in the assignment of the vibrational frequencies of adiponitrile.

Experimental

Bis(adiponitrilo)copper(I) nitrate was prepared in the same way as described in the previous paper[4].

The infrared spectra in the 4000~400 cm^{-1} region of adiponitrile and the complex were obtained by using a Perkin-Elmer Model 21 and a Perkin-Elmer Model 13 spectrophotometer (with sodium chloride and potassium bromide optics respectively). The spectrum of adiponitrile in the liquid state is shown in Fig. 1a. The spectral simplification

which occurred when the liquid was cooled down to −20°C is shown in Fig. 1b. The solid-state spectrum of adiponitrile undergoes a reversible change depending on the temperature, although the main features of the spectrum remain the same and no discrete change of the spectrum as observed in the case of glutaronitrile[2] takes place. In Fig. 2 is shown the spectral change in the 830~720 cm^{-1} region which occurred when the temperature was lowered from −20°C to −150°C. The behavior of adiponitrile is anomalous in that the liquid, if it contains a trace of water, forms a transparent solid phase when rapidly cooled. This has the spectrum shown in Fig. 3. When the solid was warmed up to ca. −20°C, a transition occurred, giving the normal crystalline solid phase which has the spectrum shown in Fig. 1b. The spectrum of bis(adiponitrilo)copper(I) nitrate was obtained using both Nujol mull and potassium bromide disk techniques. Nujol mulls of the complex gave different spectra depending on the type of alkali halide cell windows used as supporting plates. The use of KRS-5 plates and sodium chloride plates resulted in spectra which were at first identical with each other, but the one obtained by using sodium chloride plates soon began to change gradually. When potassium bromide plates were used, the change took place more quickly than in the case of sodium chloride plates. These changes must be attributed to the reaction of the complex with sodium chloride and potassium bromide plates. In Fig. 4a is shown the spectrum obtained by using KRS-5 plates. The spectra in Figs. 4b and 4c are those obtained respectively by the use of sodium chloride and potassium bromide plates. (These two spectra were recorded after the specimens had been placed in the laboratory for one day.) The spectrum obtained from a potassium bromide disk of the complex is shown in Fig. 5. This spectrum agrees quite well with that obtained from Nujol mull by the use of potassium bromide supporting plates (Fig. 4c), showing that the type of reaction which occurs between the complex and potassium bromide is the same in both cases. The absorption frequencies of adiponitrile and bis-(adiponitrilo)copper(I) nitrate are listed in Table I, together with the assignment.

Results and Discussion

The symmetry types and the selection rules for the fundamental vibrations of adiponitrile in the 1400~400 cm^{-1} region are given in Table II[10,11]. Only the rotational isomers with the planar $C\diagdown C\diagup C\diagdown C$ skeleton are included here, because these are considered the most important among all the isomers of adiponitrile. For the TTT(C_{2h}) and the GTG′(C_1) isomers the existence of a center of symmetry makes the Raman and infrared active fundamentals mutually exclusive, and only nine infrared active modes are expected in this region. For the other isomers, all the fundamentals are expected to be active in both the Raman and infrared spectra. The spectrum of bis(adiponitrilo)-copper(I) nitrate can be explained on the basis of the result of X-ray analysis; the ligand

adiponitrile molecule takes the TTT configuration[4]. The Nujol mull spectrum of bis(adiponitrilo)copper(I) nitrate (Fig. 4a) shows quite simple features in good agreement with the selection rules for the centrosymmetric structure. The appearance of an intense band at 737 cm^{-1} is strong evidence for the TTT configuration of adiponitrile, because this band must correspond to the CH_2 rocking vibration of the methylene chain of the planar all-trans configuration[7,10]. Vibrational assignment of the individual bands is made with reference to the spectra of like molecules such as *n*-hexane[5-7]. Thus the strong bands at 1333 and 1290 cm^{-1} are assigned to the CH_2 wagging modes, and those at 1229 and 1155 cm^{-1} to the CH_2 twisting modes. The bands of medium intensity at 1006 and 921 cm^{-1} may correspond to the C–C stretching modes. As mentioned above, the strong band at 737 cm^{-1} is assigned with confidence to one of the CH_2 rocking modes, and the weak band at 895 cm^{-1} may be assigned to another CH_2 rocking mode. The relatively strong band at 581 cm^{-1} should be ascribed to the C–C–C bending mode. A broad weak band at 797 cm^{-1} may be an overtone or combination of some skeletal deformation modes, as has been suggested by Fujiyama and Shimanouchi[12], but no conclusive evidence in support of this view can be found at this stage of investigation.

The strong bands at 1364/57 and 830 cm^{-1} are assigned to the infrared active fundamentals of the nitrate ion, and the weak band at 1751 cm^{-1} must also be correlated with some nitrate vibration. When sodium chloride plates were used to support the mull, new bands appeared at 1795, 1362 and 836 cm^{-1}, as is shown in Fig. 4b. These frequencies correspond well to those of sodium nitrate[13]. In the Nujol mull spectrum obtained by the use

a) KRS-5 supporting plates were used to obtain the spectrum.

of potassium bromide plates and in the potassium bromide disk spectrum, new bands appear at 1770, 1383 and 824 cm^{-1}, as is shown in Figs. 4c and 5 respectively. These frequencies agree well with those of potassium nitrate[13]. It can be concluded from the above results that the mechanism of reaction of the complex and alkali halides should be ascribed largely to an ion interchange between the two phases. The spectra in Figs. 4c and 5 show absorptions which correspond to those of the liquid adiponitrile (Fig. 1a). This suggests that interaction between the complex and alkali halides results in the isolation of free adiponitrile.

The sharp band observed at 2273 cm^{-1} in the Nujol mull spectrum (Fig. 4a) corresponds to the C≡N stretching mode of the complex. The C≡N vibrational shift of 26 cm^{-1} towards higher frequencies by complex formation may be explained in the same way as in the cases of the lower homologues of this complex series[1,2]. Namely, X-ray analysis of this complex has revealed that the C–N bond distance is 1.13 Å and that the Cu–N–C–CH_2 group is close to linear, from which it is to be expected that the C–N bond is essentially of a triple-bond character, the contributions of polar resonance structures such as $-C^+=N^-$ being decreased and the C≡N stretching frequency being thereby increased. The effect of the interaction with the Cu-N stretching vibration, though small, may also contribute to the increase in the C≡N stretching frequency. As is evident from Figs. 4b, 4c and 5, reaction with alkali halides results in the appearance of the band at 2252 cm^{-1} which is attributed to the C≡N stretching frequency of free adiponitrile. The band observed at 2381 cm^{-1} may correspond to a vibration characteristic of the tetrahedral configuration of the complex[1,2].

Adiponitrile shows a marked spectral simplification on passing from the liquid to the crystalline solid state, as is shown in Fig. 1b.

TABLE II. THE SYMMETRY TYPES AND SELECTION RULES FOR THE FUNDAMENTAL VIBRATIONS OF ADIPONITRILE IN THE 1400～400 cm^{-1} region[a]

Types of symmetry coordinates	TTT(C_{2h})				GTG′ (C_i)		GTG(C_2)		TTG(C_1)
	A_g	B_g	A_u	B_u	A_g	A_u	A	B	
CH_2 wagging	2	0	0	2	2	2	2	2	4
CH_2 twisting	0	2	2	0	2	2	2	2	4
C–C stretching	3	0	0	2	3	2	3	2	5
CH_2 rocking	0	2	2	0	2	2	2	2	4
C–C–C bending	1	0	0	1	1	1	1	1	2
Selection rules IR	−	−	+	+	−	+	+	+	+
Selection rules Raman	+	+	−	−	+	−	+	+	+

a) Only the isomers with the planar C\C/C\C skeleton are included.

The isomer of adiponitrile stable in the crystalline solid state is considered to have a center of symmetry, as the number of prominent absorption peaks is close to that expected for such a configuration and much smaller than that required for a less symmetrical form (see Table II). Consideration of the selection rules for the skeletal deformation vibrations is particularly useful for the confirmation of this view. The fact that no strong band other than that at 556cm^{-1} is observed in the 600～450cm^{-1} region gives strong support to this conclusion, because only one vibration corresponding to the C–C–C bending mode is to be expected to appear in this region in a centrosymmetric structure. Determination of the isomeric form of adiponitrile in the crystalline solid state can then be made by comparing its spectrum (Fig. 1b) with that of bis(adiponitrilo)copper-(I) nitrate (Fig. 4a). The two spectra are evidently very different from each other. For example, the C–C–C bending frequency of 556 cm^{-1} in the crystalline adiponitrile is much lower than the corresponding value of 581 cm^{-1} in the complex. The band observed at 757/51 cm^{-1} in the spectrum of the crystalline adiponitrile must be assigned to the CH_2 rocking mode, while the absorption corresponding to this mode appears at 737 cm^{-1} in the case of the complex. As the frequencies of these two types of vibration are known to change conspicuously with the azimuthal angle of internal rotation[1,2], such differences in the observed values will serve to exclude the possibility that adiponitrile takes the TTT form in the crystalline solid state. Therefore, it can be concluded that the isomer of adiponitrile stable in the crystalline solid state is another centrosymmetric one, the GTG′ form. The vibrational assignment of the crystalline adiponitrile may be carried out with reference to the work of Brown and Sheppard[8] on tetramethylene halides, which are known to take the GTG′ configuration in the crystalline solid state. The fact that the spectral features of the crystalline adiponitrile are quite similar to those of tetramethylene halides may give additional support for the GTG′ configuration of the former. Thus, the bands observed at 1468 and 1431 cm^{-1} in the solid-state spectrum (Fig. 1b) are assigned to the CH_2 bending modes. The bands at 1328 and 1314 cm^{-1} may be ascribed to the CH_2 wagging modes, and those at 1217 and 1167 cm^{-1} to the CH_2 twisting modes. The bands at 1007 and 888 cm^{-1} may correspond to the C–C stretching modes. The band at 757/51 cm^{-1} must be assigned to one of the CH_2 rocking modes, and that at 900 cm^{-1} may correspond to another CH_2 rocking mode. As mentioned above, the band at 556 cm^{-1} should be ascribed to the C–C–C bending mode. By analogy with the cases of the lower homologues of the dinitrile series[1,2], the energetical contributions of both the C–C–C bending and C–C≡N bending motions are considered to be important in this vibration. The bands observed at 818 and 775 cm^{-1} may be explained as overtones or combinations of some skeletal deformation vibrations. Although the 775 cm^{-1} band seems too intense to be interpreted as such vibrations, this assignment is nevertheless not unreasonable, because the overtone or combination bands of this type are expected to become remarkably intense at low temperatures, as has been observed in the case of succinonitrile[1].

As shown in Fig. 2, the solid-state spectrum of adiponitrile undergoes a reversible change depending on the temperature, which suggests the occurrence of a change in the crystal structure. However, as the change is not discrete and the overall spectral features are essentially the same at all temperatures, it may not be attributed to a transition to different isomeric forms, as in the case of glutaronitrile[2].

The anomalous spectrum in Fig. 3 which is obtained when adiponitrile containing a trace of water is rapidly cooled may correspond to some metastable crystalline solid phase. Although this spectrum seems at first sight to

be very different from that of the normal crystalline solid phase (Fig. 1b), the one to one correspondence of the individual bands in the two spectra is quite good, showing that adiponitrile also takes the GTG′ form in this metastable solid state.

Many of the bands in the liquid-state spectrum of adiponitrile can be explained as due to the vibrations of the TTT and the GTG′ isomers, as is shown in Table I. Considering the number of the unassigned bands, at least one more isomer can be expected to exist in the liquid state. Determination of the configuration of this isomer will not be attempted here, however, as it would require much more detailed analysis of the spectrum based on a normal coordinate treatment.

Summary

The infrared spectra of adiponitrile and bis-(adiponitrilo)copper(I) nitrate, $[Cu\{NC-(CH_2)_4-CN\}_2]NO_3$, have been studied. The spectrum of the complex has been analyzed on the basis of the result of X-ray analysis which disclosed that the ligand adiponitrile takes the TTT(C_{2h}) configuration in the crystals of this compound. This complex reacts with alkali halides such as sodium chloride and potassium bromide, resulting in the isolation of free adiponitrile. Considering the frequency shifts of the nitrate vibrations, the reaction of the complex with alkali halides should be ascribed largely to an ion interchange between the two phases. The increase of 26 cm^{-1} in the C≡N stretching frequency by complex formation may be understood by considering the linear structure of the Cu–N–C–CH_2 group, which suggests that the carbon-nitrogen bond is essentially of a triple-bond character, the contributions of polar resonance structures such as $-C^+=N^-$ being decreased. Adiponitrile shows a marked spectral simplification on passing from the liquid to the crystalline solid state. From a comparison of the solid-state spectrum with that of the complex, and from a consideration of the vibrational selection rules, it has been concluded that adiponitrile takes the GTG′(C_i) configuration in the crystalline solid state. The fact that the solid-state spectrum of adiponitrile is subject to a reversible change depending on the temperature may be explained as due to a slight change in the crystal structure. Many of the bands in the liquid-state spectrum of adiponitrile have been assigned to the vibrations of the TTT and the GTG′ isomers, and the number of the remaining bands suggests the existence of at least one more isomer in the liquid state.

The author wishes to express his sincere thanks to Professor S. Imanishi of Kyushu University for his kind encouragement throughout the course of this study. He also wishes to thank Dr. T. Yoshino of Toyo Rayon Co., Ltd. for many valuable suggestions, and to Messrs. T. Ito, H. Kataoka and K. Shirasaki of Toyo Rayon Co., Ltd. for their assistance in the experiments.

A Theoretical Treatment of Molecular Complexes. II. Iodine-Aromatic Hydrocarbon Complexes

By Kenichi FUKUI, Akira IMAMURA, Teijiro YONEZAWA and Chikayoshi NAGATA

(Received April 28, 1961)

Theoretical and experimental research into the benzene-iodine complex has derived many welcome conclusions. With regard to the configuration of benzene-iodine complex for instance, Mulliken[1] had considered the symmetries of the molecular orbitals of electron donor and acceptor and predicted the resting model in which the iodine molecule is situated above the benzene molecule, with its axis parallel to the benzene plane and its center on the sixfold axis of the benzene molecule. This model, however, was contradictory to the

1) R. S. Mulliken, *J. Am. Chem. Soc.*, **74**, 811 (1952).

results of the study of X-ray diffraction[2] and of infrared spectra[3]. Both of these results supported the axial model in which the axis of iodine molecule was coincident with the sixfold axis of benzene. The reason for this discrepancy was pointed out by Aono[4], who calculated the magnitude of the overlap integral between a benzene molecule and an iodine molecule and made it clear that the error in the estimation of the overlap integral in Mulliken's treatment might be the reason for this discrepancy. Further, a numerical calculation for the benzene-iodine complex was made with respect to the axial model by using experimental data such as the ionization potential, so that a considerable agreement was found between the theoretical values and the experimental data of dipole moment, charge transfer spectra, and so on.

Another discrepancy between the theoretical and experimental data was found concering the intensity of the charge transfer spectra for the complex of iodine-benzene derivatives. From a theoretical point of view, the intensity of the charge transfer spectra would be expected to increase in proportion to the basicity of the aromatic molecule. On the other hand, experimental data showed the opposite[5]. In order to elucidate this experimental result the concept of the contact charge transfer spectra was introduced by Mulliken[6]. On the other hand, a statistical consideration of the configuration of aromatic compound-iodine complexs was made by Murakami, and numerical calculations of the intensity of the charge transfer spectra which were carried out on the basis of the statistical consideration showed a clear correlation with the experimental result[7].

It has recently been pointed out by many authors that the ease of complex formation depends not only on the charge transfer spectra, but also on the magnitude of other intermolecular interactions, such as dispersion force, exchange repulsion energy, and electrostatic force[6,7]. In many cases, the discussions of molecular complex formation in which these factors were taken into account seemed to be rather qualitative than quantitative. A more detailed discussion is in order.

In this paper we intend to apply aromatic hydrocarbon-iodine complex to the delocalization method that has already been used for aromatic compound-silver complexes[8], and to compare the results of numerical calculation with the experimental results, bearing the effects of the dispersion force in mind.

Model and Formulation

The procedure used in this paper is the same as has been described in a previous paper[8], that is, the delocalization method. In order to execute the theoretical treatment for aromatic compound-iodine complexes, the model adopted is the axial one in which the axis of the iodine molecule is coincident with the sixfold axis of one of the benzene rings in an aromatic compound; this model was supported by X-ray diffraction[3] as well as by infrared spectra[4] for benzene-iodine or benzene-bromine complexes.

In this model the stabilization energy due to the delocalization of π electrons from the aromatic compound to the iodine molecule is obtained by the perturbation method, in the same way as has been described in the previous paper.

Prior to the formulation, the electronic configuration of the iodine molecule should be discussed. The six outer-shell molecular orbitals of iodine molecule may approximately be written as a linear combination of two $5p_x$, $5p_y$ and $5p_z$ orbitals, as is shown in Eq. 1 (normalized factors are omitted).

$$\left.\begin{array}{ll} \phi_1 \approx 5p_x + 5p_x' & \phi_4 \approx 5p_y - 5p_y' \\ \phi_2 \approx 5p_y + 5p'_y & \phi_5 \approx 5p_z - 5p_z' \\ \phi_3 \approx 5p_z + 5p_z' & \phi_6 \approx 5p_x - 5p_x' \end{array}\right\} \quad (1)$$

In which $5p_x$, $5p_y$ and $5p_z$ are the atomic orbitals of iodine atoms and the x axis is taken to be the molecular axis of the iodine molecule. Therefore, the orbital ϕ_1 is nothing but the σ-bonding orbital, and ϕ_6, the σ-antibonding orbital.

At the stage of the first approximation, only ϕ_1 and ϕ_6 are involved in the linear combination of the atomic orbital for the total system of the complex, and the conjugations between the aromatic compound and one of ϕ_2, ϕ_3, ϕ_4 and ϕ_5 are neglected since the magnitude of overlap integrals between the $5p_y$ as well as the $5p_z$ and $2p\pi$ atomic orbital in aromatic compounds may reasonably be expected to be much smaller than that between $5p_x$ and $2p\pi$ in the axial model.

The secular equation for this model is written in a simple LCAO MO treatment (overlap neglected) in the following form:

$$D(\lambda)=\begin{vmatrix} h-\lambda & l & 0\cdots\cdots & 0 \\ l & h-\lambda & \gamma\cdots\cdots\ \gamma & 0\cdots\cdots\ 0 \\ 0 & \gamma & a_{11}-\lambda\ \ a_{12}\cdots\cdots\ a_{16}\cdots\cdots & a_{1n} \\ \vdots & \vdots & a_{21}\ \ a_{22}-\lambda\cdots a_{26}\cdots\cdots & a_{2n} \\ \vdots & \vdots & \vdots\ \ \vdots\ \ \vdots & \vdots \\ \vdots & \gamma & a_{61}\ \ a_{62}\cdots\cdots\ a_{66}-\lambda\cdots & a_{6n} \\ \vdots & 0 & \vdots\ \ \vdots\ \ \vdots & \vdots \\ 0 & 0 & a_{n1}\ \ a_{n2}\cdots\cdots a_{n6}\cdots\cdots & a_{nn}-\gamma \end{vmatrix}$$

$$=\{(h-\lambda)^2-l^2\}\Delta(\lambda)+(h-\lambda)\gamma^2\sum_{r,s=1}^{6}(-1)^{r+s+1}\Delta_{rs}(\lambda) \qquad (2)$$

in which

$$\Delta(\lambda)=\begin{vmatrix} a_{11}-\lambda & a_{12}\cdots\cdots a_{1n} \\ a_{21} & a_{22}-\lambda\cdots\cdots a_{2n} \\ \cdots\cdots & \cdots\cdots \\ a_{n1} & a_{n2}\cdots\cdots a_{nn}-\lambda \end{vmatrix} \qquad (3)$$

is the secular determinant for the isolated aromatic molecule and $\Delta_{rs}(\lambda)$ denotes the secular determinant with row r and column s struck out, and a_{ii} and $a_{ij}(i\neq j)$ are the Coulomb and the resonance integrals respectively; h and l are the Coulomb and the resonance integrals of 5p orbital in iodine molecule respectively, and γ is the resonance integral between the $2p\pi$ orbital of carbon atom in the aromatic compound and the $5p_x$ orbital of the iodine atom, which is the one of two iodine atoms nearer to the aromatic molecule. The suffixes $1, 2, 3\cdots\cdots, 6$ of the Coulomb and the resonance integrals in Eq. 2 correspond to the numbers of the constituent atoms of the benzene ring above which the iodine molecule is located.

Since the magnitude of γ is small, the perturbation method can be applied in this treatment, as has been shown in the previous paper.

Case 1: When neither $h+l$ nor $h-l$ is equal to any λ_j, the roots of Eq. 2, $\lambda^{(1)}, \lambda^{(2)}\cdots\cdots, \lambda^{(n)}$; $\lambda'^{(1)}$ and $\lambda'^{(2)}$ are represented by:

$$\lambda^{(j)}=\lambda_j+\frac{(\lambda_j-h)}{(\lambda_j-h)^2-l^2}\times(c_1{}^j+c_2{}^j+\cdots+c_6{}^j)^2\gamma^2+[\gamma^4]\quad(j=1, 2, \cdots, n) \qquad (4)$$

$$\lambda'^{(k)}=\lambda'_k+\frac{1}{2}\sum_{j=1}^{n}\frac{(c_1{}^j+c_2{}^j+\cdots\cdots+c_6{}^j)^2}{\lambda'_k-\lambda_j}\times\gamma^2+[\gamma^4]\quad(k=1, 2)$$

in which λ_j is the root of $\Delta(\lambda)=0$, and λ_1' λ_2' are equal to $h+l$ and $h-l$ respectively; $c_r{}^j$ is the coefficient of the rth atomic orbital in the jth molecular orbital; and $[\gamma^4]$ denotes the higher term. The delocalization energy for complex formation that was defined for silver-aromatic hydrocarbon complexes in the previous paper[8] may be described for the iodine-aromatic molecular complex as follows:

$$\Delta E=\left\{\sum_{j=1}^{m}\frac{2(\lambda_j-h)}{(\lambda_j-h)^2-l^2}(c_1{}^j+c_2{}^j+\cdots\cdots+c_6{}^j)^2+\sum_{j=1}^{n}\frac{(c_1{}^j+c_2{}^j+\cdots\cdots+c_6{}^j)^2}{h+l-\lambda_j}\right\}\gamma^2+[\gamma^4] \qquad (5)$$

in which $\lambda_1, \lambda_2, \cdots\cdots, \lambda_m$ correspond to the occupied orbitals.

Case 2: When $h-l$ is equal to the highest occupied orbital, λ_m, of the isolated aromatic molecule, the roots of Eq. 2 are represented by:

$$\left.\begin{matrix}\lambda^{(m)} \\ \lambda'^{(2)}\end{matrix}\right\}=\lambda_m\pm\frac{1}{\sqrt{2}}|c_1{}^j+c_2{}^j+\cdots\cdots+c_6{}^j|\gamma+[\gamma^2]$$

$$\lambda^{(j)}=\lambda_j+\frac{(\lambda_j-h)}{(\lambda_j-h)^2-l^2}(c_1{}^j+c_2{}^j+\cdots\cdots+c_6{}^j)^2\gamma^2+[\gamma_4]\quad(j=1, 2, \cdots\cdots, n;\ j\neq m) \qquad (6)$$

$$\lambda'^{(1)}=\lambda_1'+\frac{1}{2}\sum_{j=1}^{n}\frac{(c_1{}^j+c_2{}^j+\cdots\cdots+c_6{}^j)^2}{\lambda_1'-\lambda_j}\gamma^2+[\gamma^4]$$

In presenting the value of energies, we make the zero point equal to the Coulomb integral of the benzene carbon atom and express them in units of $(-\beta)$, which is the resonance integral of the benzene C–C bond.

In both cases, 1 and 2, the formulas for the delocalization energy indicate that the magnitude of delocalization energy depends upon the symmetry of the benzene ring combined with the iodine molecule; this conclusion is quite coincident with that of Mulliken's theory. This circumstance is similar to the case of silver-aromatic hydrocarbon complexes, as has been pointed out in the previous paper[8].

Result and Discussion

Benzene-Iodine Complex.—With regard to the benzene-iodine complex, many theoretical and experimental studies had been carried out as has been described in the introduction. In this paper we carry out the numerical calculation for the comparison with the experimental data of benzene-iodine complex, making use of the delocalization method. For the charge transfer spectrum, the transition of the π electron may occur from the lowest occupied π orbital of benzene to the lowest vacant orbital of the iodine molecule, and the transition from the highest occupied π orbital of benzene to the lowest vacant orbital of iodine is forbidden for the sake of the symmetry of complex of the axial model. Accordingly, the frequency of the charge transfer spectrum is given by:

$$h\nu = \left\{2 + \frac{6(2-h)}{(2-h+l)(2-h-l)}\gamma^2\right\} - \left\{(h-l) + \frac{3}{h-l-2}\gamma^2\right\} + [\gamma^4] \qquad (7)$$

in which h is Planck's constant and ν is the charge transfer frequency, and the first term and the second term correspond to the energy of the lowest occupied π orbital of benzene and that of the lowest vacant orbital of iodine molecule respectively. The energy is represented in units of $(-\beta)$ in Eq. 7.

In order to determine the value of h, l and γ, we adopt the semi-empirical treatment, that is, the value of l and γ are obtained on the assumption that the resonance integral is proportional to the corresponding overlap integral, and h is determined bearing in mind the fact that the value of $h-l$ is nothing but the electron affinity of the iodine molecule. The values used in the calculation have been taken as follows after a consideration of many experimental data:

The resonance integral of the benzene C–C bond: 2.39 eV.[9]
The electron affinity of the iodine molecule: 7.0 eV.[10]
The distance of the iodine-iodine bond in iodine molecule: 2.67 Å
The distance between the nearer iodine atom and a carbon atom of the benzene ring in the axial model; 3.7 Å*

Adopting these parameters in calculation, we can get the values of h, l and γ as follows:

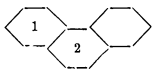
$$h=1.45 \qquad l=1.39 \qquad \gamma^2=0.021 \qquad (8)$$

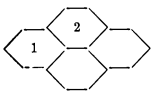
The frequency of the charge transfer spectrum and the magnitude of dipole moment of this complex are calculated and listed in Table I in comparison with the experimental results.

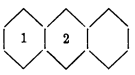
TABLE I. FREQUENCY OF THE CHARGE TRANSFER SPECTRUM AND THE DIPOLE MOMENT OF BENZENE-IODINE COMPLEX

	Calcd.	Obs.
Dipole moment (Debye unit)	1.31	0.72
Charge transfer spectrum, cm^{-1}	37.1×10^3	36.5×10^3

The solvent effect is taken into account to compare the observed value of charge transfer spectrum with that calculated in Table I, that is, $36.5\times10^3\,cm^{-1}$ in Table I is obtained by adding $2\times10^3\,cm^{-1}$ to the experimental value**.







The good agreement between experimental and calculated values is rather striking, since in this approximation the electron-electron repulsion is entirely neglected and the calculation is carried out by a method which is not more accurate than simple LCAO MO. Such a result may probably be attributed to the fact that the estimation of the Coulomb and resonance integrals is semi-empirically made so as to involve the effect of electron-electron repulsion implicitly.

As to the dipole moment, on the other hand, the agreement between experimental and calculated values is not good. This discrepancy is probably caused by two main factors. The first is the fact that the electron transfer from the occupied orbital of the iodine molecule to the vacant orbitals of the benzene is neglected in the calculation. The second is the ambiguity engendered in the process of determining the magnitude of many integrals in such a semi-empirical treatment. As is well known, the parameters used for the discussion of chemical reactivity in the simple LCAO MO treatment are often found not suitable for estimating the value of dipole moment, and in this case the reason of this discrepancy may perhaps be that parameters determined semi-empirically are not appropriate for the calculation of dipole moment.

Polycondensed Aromatic Hydrocarbon-Iodine Complexes.—Many experimental studies for polycondensed aromatic hydrocarbon-iodine complexes have been performed. The electric conductivity of these complexes was measured especially, and it was found that a remarkable increase in conductivity was caused by the molecular complex formation. In this paper we calculate the delocalization energy, making use of Eq. 5, in order to get a clue to elucidate the physical properties of these complexes. The delocalization energies obtained are listed in Table II, together with the equilibrium constant[11] of the complex formation and the energy of the highest occupied orbital of aromatic hydrocarbons. The parallelism between the magnitude of the theoretical index and the equilibrium constant is not complete. This discrepancy is owing to many factors pointed out in the previous paper. The most important factor among these seems to be the dispersion force. To estimate roughly the magnitude of the dispersion force, we calculate the potential due to the dispersion force for the benzene-iodine complex by making use of London's formula. London's formula is represented as:

9) R. Pariser and R. G. Parr, *J. Chem. Phys.*, **21**, 767 (1953).
10) S. Nagakura and J. Tanaka, ibid., **22**, 563 (1954).
* The value of the carbon-iodine distance is estimated by considering the results of X-ray analysis of the bromine-benzene complex[3].
** N. S. Bayliss, *J. Chem. Phys.*, **18**, 292 (1950).
11) R. Bhattacharya and S. Basu, *Trans. Faraday Soc.*, **54**, 1286 (1958).

TABLE II. THE VALUES OF THE THEORETICAL INDEX AND THE EQUILIBRIUM CONSTANT FOR THE COMPLEX FORMATION BETWEEN AROMATIC HYDROCARBON AND IODINE

Aromatic compound	Ring number*	K[11]	Delocalization energy**	Energy of the highest occupied orbital
		0.34	1.615	0.504
		0.37	1.579	0.705
		0.62	1.511	0.618
	1	1.06	1.547	0.605
	2	1.06	1.479	0.605
	1	36.49	1.517	0.445
	2	36.49	1.547	0.445
	1	52.35	1.505	0.414
	2	52.35	1.457	0.414

* Ring number indicates the ring that is assumed to associate with the iodine molecule in axial model.

** The value of localization energy listed in Table II is the coefficient of the second order perturbation term in Eq. 5.

$$E_{\text{disp}} = -\frac{3}{2R^6}\frac{I_1 \cdot I_2}{I_1 + I_2}\alpha_1^0\alpha_2^0 \qquad (9)$$

in which I and α^0 are the ionization potential and the static polarizability respectively, and the suffixes 1 and 2 denote the molecules 1 and 2 respectively, and R is the distance between the two molecules. For the benzene-iodine complex, the values of the ionization potential, static polarizability and distance used in calculation are listed in Table III. The dispersion energy is discovered to be 1.48 kcal.

TABLE III. THE IONIZATION POTENTIAL AND STATIC POLARIZABILITY AND ATOMIC DISTANCE FOR BENZENE AND IODINE MOLECULE AND THEIR COMPLEX

	Benzene	Iodine molecule
Ionization potential, eV.	9.24	9.41
Static polarizability*, cm^3	107×10^{-25}	105×10^{-25}
Distance between benzene and iodine molecule, Å	4.8	

* The static polarizability of iodine molecule is estimated from the value of atomic refraction of iodine atom.

Taking the magnitude of the dispersion force of the benzene-iodine complex into account, we may attain to the following conclusion. It is probably not only the delocalization energy but also the dispersion force and other factors that decides the case of complex formation for the iodine-aromatic hydrocarbon complexes. A detailed discussion of this point will be made in the future.

The Relation between the Delocalization Method and Mulliken's Theory

In both the previous and the present papers, we have proposed the delocalization method and applied this method to the problem of aromatic compound-silver and aromatic hydrocarbon-iodine complexes. The formulas of delocalization energy obtained for both complexes were coincident with Mulliken's theory in its symmetry character, as was earlier pointed out.

In Mulliken's theory the magnitude of charge transfer force was not given in an explicit form, and the symmetry consideration characteristic of his theory is substantially limited to the compound which has some symmetry.

Mulliken's theory was developed by Brown in order to apply to electrophilic aromatic substitutions[12]. The mathematical interrelation between the chemical reactivity indexes of the frontier theory and Brown's theory was pointed out by some of the present authors[13]. An analogous relation may be expected between the delocalization method and Mulliken's

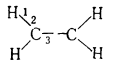
σ-Electronic Structure in Conjugated Systems

By Kenichi FUKUI, Hiroshi KATO, Teijiro YONEZAWA, Keiji MOROKUMA, Akira IMAMURA and Chikayoshi NAGATA

(Received May 18, 1961)

In the last quarter of a century, the electronic structures of numerous unsaturated compounds have been calculated quantum-mechanically by either a non-empirical or a semi-empirical method; electronic spectra, chemical reactivities and other physical properties of these compounds have also been interpreted with sufficient accuracy in terms of their electronic behavior.



In those calculations, however, except for some simpler compounds such as carbon dioxide, formaldehyde, ethylene and benzene, σ electrons have not been treated explicitly but, rather, have been looked upon as constructing a framework of potential in which π electrons move.

Some physico-chemical properties of unsaturated compounds, however, for example, the proton shift in the high resolution nuclear magnetic resonance spectroscopy, the frequency shift in the pure quadrupole resonance, the dipole moment, the polarographic reduction potential, the reactivity in the halogen substitution reaction, and inductive and hyperconjugative effects of substituents, can not be interpreted without an explicit consideration of the σ electrons in the system. Consequently, the appearance of a simple method of calculating the σ electronic structures of large unsaturated molecules has been loked for.

Recently Sandorfy[1] and the present authors[2] have computed the electronic states of saturated hydrocarbons and halides by a simple LCAO MO method where the molecular orbitals (MO's) are written as a linear combination of the atomic orbitals (LCAO) of the carbon, halogen and hydrogen atoms.

At this time, by extending the simple method stated above, the present authors have calculated the σ electronic structures in large

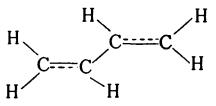
substituted as well as non-substituted unsaturated compounds. In the present paper, as in the first of the series, the σ electronic structures of ethylene, butadiene, propylene, benzene, naphthalene and toluene will be discussed and some characteristics of the σ MO's in these compounds will be given.



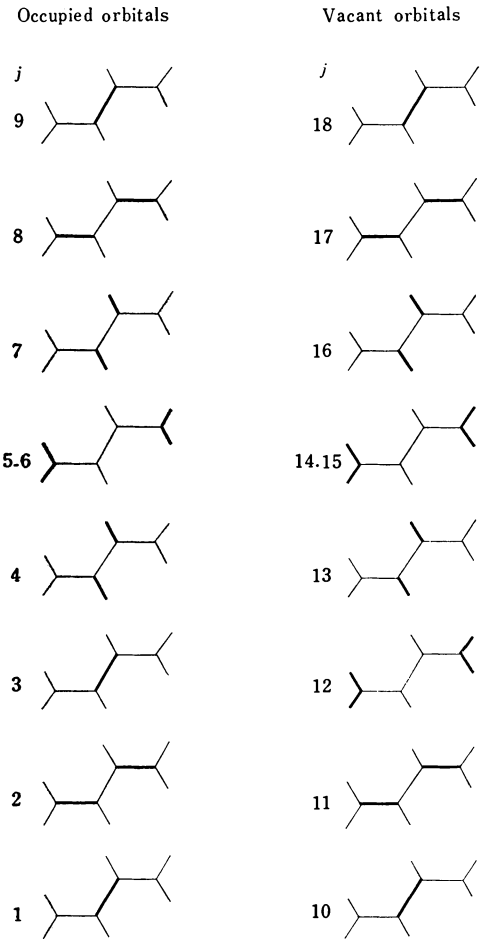
Method of Calculation

The method of calculation is similar to the one that has been employed in previous papers where the electronic structures of saturated compounds have been discussed[2].

The σ molecular orbitals in a conjugated hydrocarbon are represented by the linear combinations of atomic orbitals, the sp^2 hybridized orbitals of the carbon atoms and the 1s atomic orbitals of the hydrogen atoms. Thus, the jth σ MO is written as follows:

$$\psi_j=\sum_r^n C_{rj}\phi_{C,r}+\sum_l^m C_{lj}\phi_{H,l} \qquad (1)$$

in which C_{rj} denotes the coefficient of the



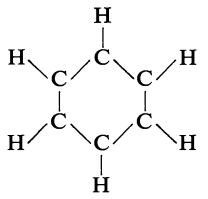


Fig. 1a. The σ electron distributions in butadiene. (Thick lines denote the most densely populated bonds.)

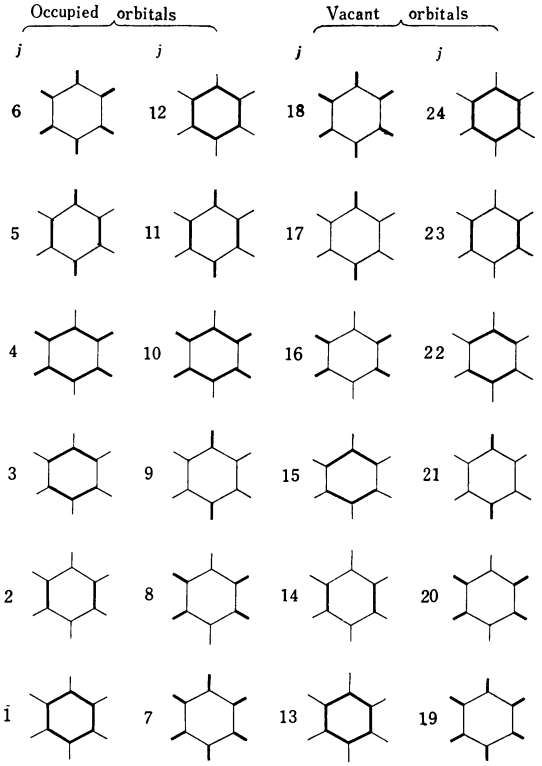

Fig. 1b. The σ electron distributions in benzene. (Thick lines denote the most densely populated bonds.)

rth sp^2 hybridized orbital of carbon in the jth MO, and C_{lj} denoted that of the 1s orbital of the lth hydrogen atom.

Referring to the simple LCAO MO approximation (the Hückel approximation) in the treatment of π electrons, the electronic interaction is not also explicitly considered in this σ problem. The overlap integrals between σ atomic orbitals are also neglected.

Furthermore, the σ electrons are assumed to be independent of the electronic distribution of π electrons. This neglect of so-called σ-π interaction is permissible in the present "simple" LCAO MO treatment.

The Coulomb and the resonance integrals are taken as follows:

The Coulomb integrals:

$$\int \phi_{C,r} H \phi_{C,r}\, d\tau = \alpha$$

$$\int \phi_{H,l} H \phi_{H,l}\, d\tau = \alpha - 0.2\beta$$

The resonance integrals:

$$\int \phi_{C,r} H \phi_{C,r+1}\, d\tau = \beta$$

(r and $r+1$ belonging to neighboring carbons)

$$\int \phi_{C,r} H \phi_{C,r+1}\, d\tau = m\beta = 0.38\beta$$

(r and $r+1$ belonging to the same carbon)

$$\int \phi_{C,r} H \phi_{H,r+1}\, d\tau = \beta_{sp^2-H} = 0.94\beta \qquad (2)$$

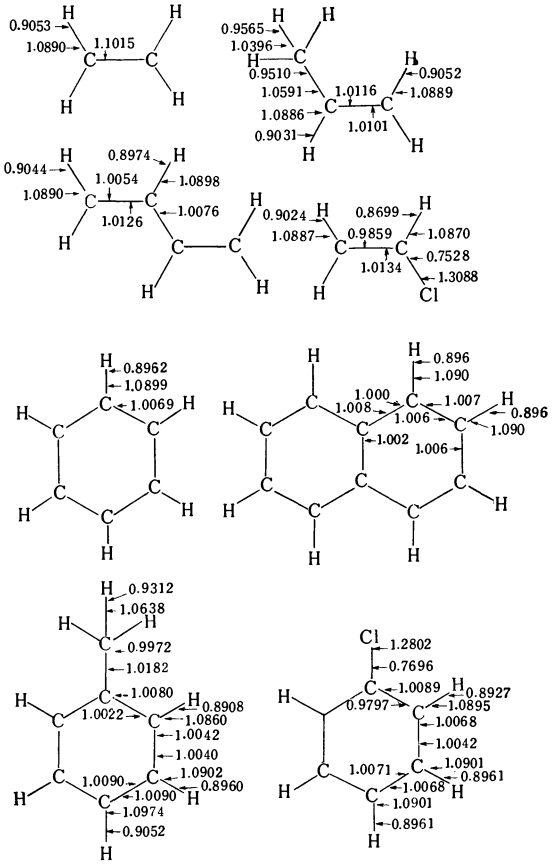

Fig. 2. The values of total σ electron densities of bonding orbitals (q_r^O) in some conjugated compounds.

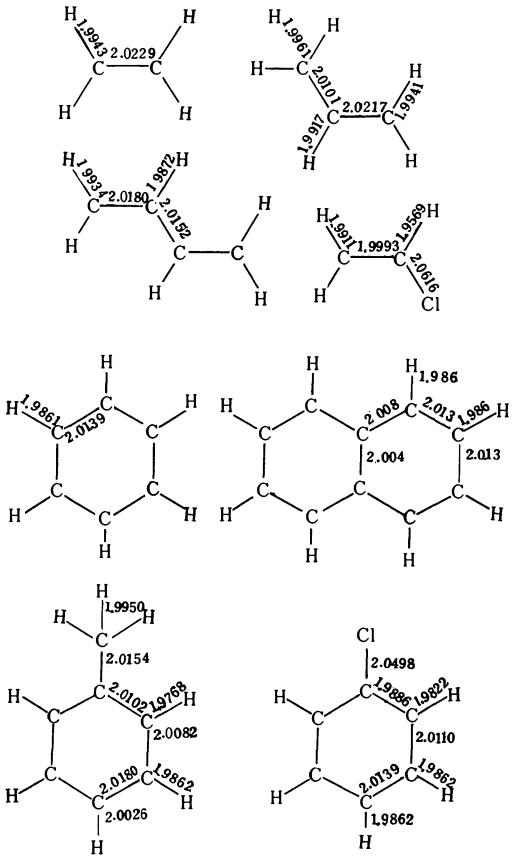

Fig. 3. The values of total σ electron densities of bonds (q_r^B) in some conjugated compounds.

in which H is the one electron hamiltonian of a σ electron. The value of m is determined by considering the degree of hybridization from the similar value of saturated hydrocarbons in previous papers[2,3]. The value of β_{sp^2-H} is estimated from the overlap integrals of a C–C and a C–H bond as calculated by Mulliken[4]. Further, α_H is determined so as to explain the C–H bond moment.

In treating propylene and toluene, the integrals containing the sp^3 hybridized orbital of carbon are needed. They are estimated from the electron affinity and the ionization potential of valence states and also from overlap integrals, resulting in

$$\left.\begin{aligned}
&\int \phi_{sp^3,r} H \phi_{sp^3,r}\, d\tau = \alpha - 0.1\beta \\
&\int \phi_{sp^3,r} H \phi_{sp^2,r+1}\, d\tau = 0.92\beta \\
&\int \phi_{sp^3,r} H \phi_{sp^3,r+1}\, d\tau = m(sp^3)\beta = 0.29\beta \\
&\int \phi_{sp^3,r} H \phi_{H,r+1}\, d\tau = \beta_{sp^3-H} = 0.93\beta
\end{aligned}\right\} \quad (3)$$

in which α and β are the integrals of the sp^2 orbitals defined in Eq. 2.

Electronic Structure of the σ-Skeleton in a Conjugated System

The calculated values of the energy level and the charge distribution of each orbital are listed in Table I for ethylene, butadiene and benzene. The characteristics of the σ-electronic structure of the polyene are found to be similar to those of the normal aliphatic hydrocarbons discussed in a previous paper[2].

On investigating Table I and Figs. 1—4, the following conclusions may be derived.

a) The bonding electrons belonging to each orbital tend to localize in certain particular bonds. For instance, the charge distribution of each orbital for butadiene, benzene, and so on, shows the above-mentioned characteristics, as is

3) H. Yoshizumi, *Trans. Faraday Soc.*, 53, 125 (1957).
4) R. S. Mulliken, C. A. Rieke, D. Orloff and H. Orloff, *J. Chem. Phys.*, 17, 1248 (1949); R. S. Mulliken, *J. Am. Chem. Soc.*, 72, 4493 (1950).

clearly seen in Fig. 1. Namely, the electron densities in the highest occupied orbital as well as in the lowest vacant orbital are largest in the carbon-carbon σ bond. Such general trend is also seen in benzene, naphthalene and chlorobenzene, where electrons belonging to the highest occupied orbital localize completely in carbon-carbon σ bonds.

b) The energy gap between the highest occupied orbital and the lowest vacant one is much greater than that of the π-orbitals. This point is discussed in detail in the following section.

c) Generally speaking, the charge distribution is not uniform. The values of the total electron density of the carbon hybridized orbital or hydrogen 1s orbital (q_r^{O}), the electron density of each bond (q_r^{B}), and the net charge of each atom (Q_r) for some compounds are indicated in Figs. 2, 3 and 4. The quantities of q_r^{O}, q_r^{B} and Q_r are given in the following formulas:

$$\left.\begin{aligned} q_r^{O} &= 2\sum_{i}^{occ} C_{ir}^{2} \\ q_r^{B} &= q_s^{O} + q_{s+1}^{O} \\ Q_r &= (\text{valence number of the } r\text{th atom}) \\ &\quad - \sum{}' q_s^{O} \end{aligned}\right\} \quad (4)$$

in which $\sum'$ denotes the summation carried out over all valence orbitals belonging to the rth atom.

It is worthy of notice that the magnitudes of the total electron densities of hydrogen atoms of benzene and naphthalene are smaller than those of ethylene and butadiene. The following interesting conclusion may accordingly be derived. In σ electron systems the benzene ring exerts an electron-attracting effect. Further, the hydrogen atoms belonging to the methyl group of propylene and toluene have larger electron densities than those of the hydrogen atoms attached to the sp^2 hybridized carbon orbital.

d) The order of magnitude of I-effect for many substituents can be indicated by referring to the values of Q_r listed in Fig. 4 for toluene, chlorobenzene* and so on. The more electronegative the substituent is, the larger the electron density of the substituent. The effect of the substituent, however, becomes smaller in the distant atom from the substituent, and the magnitude of the change in electron density effected by a substituent is approximately proportional to m^{2n}, where n is the number of atoms along the carbon chain from the substituent to the atom in question**. In this case the remarkable effect of the bond alteration is not revealed.

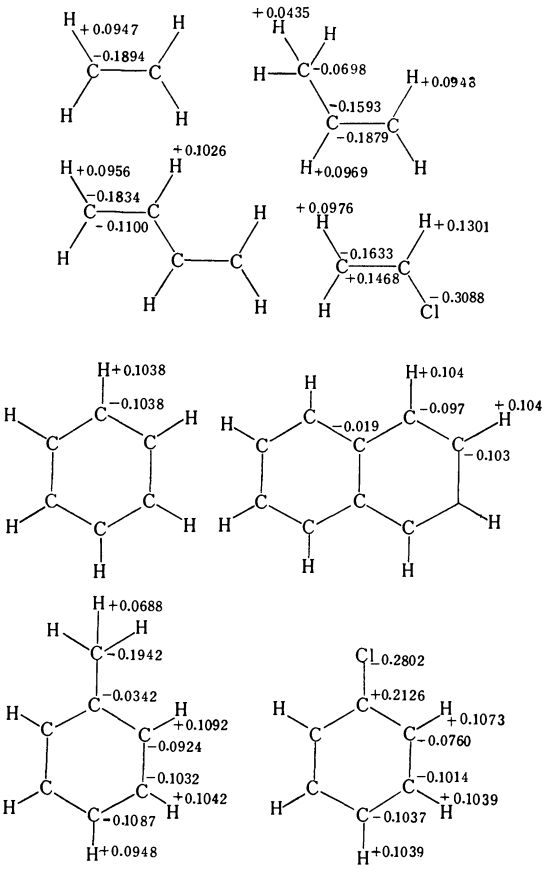

Fig. 4. The values of net charges of atoms (Q_r) in some conjugated compounds.

Comparative Discussion on σ- and π-Electronic Structures

Energy of σ-MO's

It has been believed that the energies of σ- and π-molecular orbitals increase in the following order:

$$\sigma\text{-occupied} < \pi\text{-occupied} < \pi\text{-unoccupied} < \sigma\text{-unoccupied orbitals}$$

Hence, it is required that the energy gap between the lowest vacant and the highest occupied σ-orbitals be large enough to include all the π-orbitals within it. The calculated energies of these σ-orbitals in some compounds

* The values of the Coulomb and the resonance integrals of a chlorine atom are put tentatively at $\alpha_{Cl}=\alpha+0.3\beta$ and $\beta_{C\text{-}Cl}=0.6\beta$ respectively.

** In the case of a simple LCAO MO treatment of the π electron systems, the I-effect upon the Coulomb integral is taken as $(1/3)^n$ by Dewar[5]. This approximation seems to be reasonable on the basis of the result obtained in the present paper.

5) M. J. S. Dewar, *J. Chem. Soc.*, **1949**, 463.

TABLE II. THE CALCULATED VALUES OF ENERGIES OF HIGHEST OCCUPIED (ho) AND LOWEST VACANT (lv) ORBITALS OF σ, AND OF ENERGIES OF LOWEST OCCUPIED (lo) AND HIGHEST VACANT (hv) ORBITALS OF π ELECTRONS OF SOME CONJUGATED COMPOUNDS

	σ (in unit of β_{sp^2})		π (in unit of β_p)	
	λ_{ho}	λ_{lv}	λ_{lo}	λ_{hv}
Ethylene	0.6377	−0.6641	1.000	−1.000
Butadiene	0.6258	−0.5758	1.618	−1.618
Propylene	0.5853	−0.6031	1.414	−1.414*
Benzene	0.6200	−0.5013	2.000	−2.000
Naphthalene	0.6200	−0.4428	2.300	−2.300
Toluene	0.6057	−0.4805	2.000	−2.000*

* These values were obtained by neglecting hyperconjugation of methyl group.

which are summarized in Table II show that the energy gap amounts to 1.1∼1.4 in units of $-\beta_{sp^2}$ or 11∼14 eV., which is sufficiently large to include all the π-MO's of ordinary conjugated compounds since in these the energies of the π-MO's lie in the range of $\alpha_p+2.5\beta_p$ to $\alpha_p-2.5\beta_p$*.

In some exceptional cases, however, the lowest vacant σ-orbital, whose energy is $\alpha_{sp^2}-0.2\beta_{sp^2}$ lies in proximity to the nonbonding π-MO of zero energy. Thus the lowest vacant σ-MO may be situated below the lowest vacant π-orbital in these compounds. This fact may have an important bearing on the chemical reaction and the polarographic reduction. The details of these facts will be published in the future.

σ-Electron Density

In the alternant hydrocarbon, the total π-electron density at the carbon atom is always equal to unity, whereas the σ-electron density at the carbon atom (Eq. 4), in the σ-skeleton of conjugated molecules is not necessarily uniform, as has been pointed out by the present authors[2].

It may be reasonable, therefore, to consider that this σ-electron distribution modifies the Coulomb integral of the π-electron system and causes an alteration of the π-electron density. In this connection a comprehensive SCF treatment, including both σ-electrons and π electrons, should be carried out.

One should bear in mind that the position of attack in the reaction is never determined by the magnitude of the σ-electron density, even when the π-electron distribution is uniform. Thus, in butadiene, the σ-electron densities, at positions 1 and 4, are larger than those at positions 2 and 3, as is shown in Fig. 4. This distribution appears to indicate that positions 1 and 4 are more susceptible to electro philic attack than positions 2 and 3, in agreement with experience. However, this distribution is incompatible with the fact that nucleophilic attack also takes place at positions 1 and 4. According to the self-consistency consideration, this σ-electron distribution may bring about a decrease in π-electron densities at positions 1 and 4 and an increase of those at 2 and 3. This result leads us again to a contradiction to the experimental facts in electrophilic substitutions. Also, in naphthalene, the σ-electron density increases in the order

$$9\text{-} < 1\text{-} < 2\text{-position}$$

which is reverse to the order of reactivity in electrophilic substitutions. In toluene, the calculated σ-electron density increases in the order

$$\text{ortho} < \text{meta} < \text{para}$$

which is not consistent with the *o*, *p*-directing property of this compound. All of these facts show that the σ-electron density has no direct concern with the chemical reaction and that the electron which plays an important role is not the σ-electron but the π-electron.

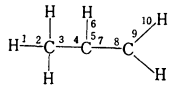
The σ-electron distribution stated above may be provide us with an indirect support of the validity of the π approximation in discussing the reactivity of conjugated molecules.

With respect to propylene and toluene, the σ-electron distribution of some σ occupied orbitals is shown in Table III. The molecular orbitals localized in the methyl group are closely similar to a normal π-type orbital and are orthogonal to each other. The mode of this distribution suggests that hyperconjugation may take place in these compounds, as has been pointed out by Mulliken[6] and Coulson[7].

Other Problems

Many other facts are successfully explained by the present results. Some of these will be described here. Full details of each topic will be published in the future.

Proton Shift



The calculated density of σ-electrons at the hydrogen atom will provide us with information about the local diamagnetic shielding of the proton in nuclear magnetic resonance spectra.

In the case of benzene and naphthalene (Fig. 2), the σ-electron densities at each hydrogen atom do not vary much according to the position attached. Therefore, it is considered that the difference in the chemical shift between α- and β-hydrogen atoms in naphthalene is ascribable to the unequal contribution of the induced π-ring current.

The σ-electron densities and values of chemical shifts in propylene and toluene are indicated in Table IV. In both cases, σ-electron densities at methyl hydrogen atoms are greater than those at other hydrogen atoms. These results coincide with the experimental fact that the resonance fields for methyl protons is higher than those for other protons.

In conclusion, a more quantitative explanation of the proton chemical shift is possible by the present procedure. The results will be published in the future.

TABLE IV. CHEMICAL SHIFTS AND σ ELECTRON DENSITIES OF HYDROGEN ATOMS IN SOME COMPOUNDS

(a) 

		Shift[1]*	Density

Dipole Moment

The dipole moment of conjugated molecules has hitherto been calculated as the sum of π moment obtained theoretically and the σ moment estimated empirically. The present treatment enables us to calculate the σ moment theoretically. According to our results, the σ dipole moments of toluene and propylene become 0.57 D and 0.05 D respectively*. Though it needs further investigation to decide whether these values are reasonable or not, the calculated result clearly indicates that conjugated compounds containing both sp^2 and sp^3 hybridized carbon atoms may have a σ moment of an appreciable magnitude. At least the usual procedure for explaining the dipole moment of these compounds only by hyperconjugation must be re-examined.

Summary

The σ-electronic structures and σ-electron densities of σ skeletons in some conjugated compounds are calculated by a simple LCAO MO method developed by the present authors. The inductive and hyperconjugative effects, dipole moment, proton shift, and so on, are briefly discussed. Agreements of the results with experiments seem to be almost entirely satisfactory.

A part of the calculation has been carried out with the KDC-I digital computer of Kyoto University.

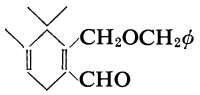
* The values of the Coulomb integral of the H atom in the CH_3 group in toluene and propylene are tentatively put $\alpha_H=\alpha-0.25\beta$ and $\alpha-0.2\beta$ respectively. Thus, the difference of σ-electron densities at these atoms is partially dependent on the difference of the values of parameters. In calculating the values of σ dipole moments in these compounds, the center of gravity of sp^3 and sp^2 hybridzed orbital is located at the positions of 0.44 Å and 0.41 Å apart from the carbon nucleus respectively.

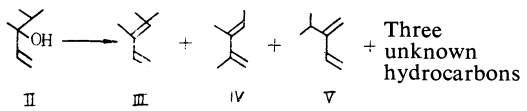
Syntheses of γ-Ionone Analogues. III. Diels-Alder Reaction Involving a Mixture of 3, 4-Dimethyl-1, 3-pentadiene and 2, 3-Dimethyl-1, 3-pentadiene, and Some Derivatives from 2-Benzyloxymethyl-4, 5, 6-trimethylcyclohexa-1, 4-dienylmethanal



By Atsuaki ARAI and Iwao ICHIKIZAKI

(Received April 13, 1961)

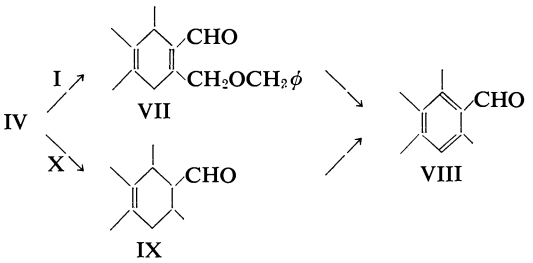
As described in a previous paper[1], 2-methylene-4, 5-dimethylcyclohexylmethanol, an analogue of γ-cyclogeraniol, can be conveniently synthesized, in five steps, from a Diels-Alder adduct prepared by the condensation of 2, 3-dimethyl-1, 3-butadiene with 4-benzyloxy-2-butyn-1-al (I), $C_6H_5CH_2OCH_2C{\equiv}CCHO$. It is to be expected, therefore, that a similar condensation of 3, 4-dimethyl-1, 3-pentadiene (III) with I will yield 2-benzyloxymethyl - 3, 3, 4 - trimethylcyclohexa - 1, 4 - dienyl methanal (VI) and contribute an easy approach



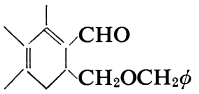
1) A. Arai and I. Ichikizaki, This Bulletin, **34**, 1571 (1961).

to either 6-methyl-γ-cyclogeraniol or, further, to γ-irone itself.

VI



The studies under various conditions to prepare III revealed that the dehydration of 3, 4-dimethyl-1-penten-3-ol (II)[2,3] with potassium hydrogen sulfate afforded totally, in a 75% yield, a diene mixture containing III, 2, 3-dimethyl-1, 3-pentadiene (IV) and 2-isopropyl-1, 3-butadiene (V) in a ratio of approximately 18 : 21 : 53, with unkown three hydrocarbons of minor quantities.



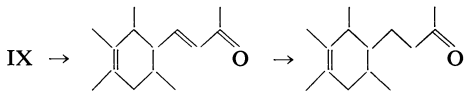
II III IV V

The composition of these hydrocarbons scarcely changed during many dehydrations at 140~180°C. Since the effective separation of III from IV was particularly difficult even by careful fractionations through an efficient column, a mixture consisting of 37.5% III and 62.5% IV, b. p. 107.5~108°C/753 mmHg, n_D^{20} 1.4664, was employed for the Diels-Alder reaction in the early stage of this research.

When a benzene solution of the mixed diene in the presence of a little amount of hydroquinone was heated for 10 hr. at 155°C with I, a doubly unsaturated aldehyde, $C_{18}H_{22}O_2$, ν_{max}^{film} 2750 and 1670 cm^{-1}, was obtained in a 64% yield. The light absorption band (in ethanol) at 236 mμ (ε 5900) revealed that the unsaturated aldehyde contains an α, β- and an isolated unsaturated linkage. The quantitatively yielded phenylsemicarbazone was readily hydrolyzed by super heated steam in the presence of both phthalic and sulfric acids to be converted with the elimination of benzyl alcohol into 2, 3, 4, 6-tetramethylbenzaldehyde (VIII). The aldehyde VIII was also prepared from the sulfur dehydrogenation of 2, 3, 4, 6-tetramethyl-3-cyclohexenylmethanal (IX), which had been obtained in a 52% yield by a similar treatment of the same mixed diene with crotonaldehyde (X). Consequently, the structure of the adduct was reasonably concluded to be 2-benzyloxymethyl-4, 5, 6-trimethylcyclohexa-1, 4-dienylmethanal (VII). The aldehyde VII was readily converted by the action of diluted sulfuric acid into an isomer which

was presumed to be 6-benzyloxymethyl-2, 3, 4-trimethylcyclohexa-1, 3-dienylmethanal (XI).

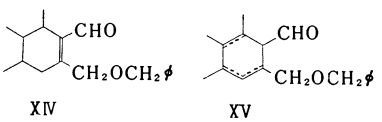
XI



All the results obtained above clearly indicated that only IV could participate in this reaction, that III could not practically react with the dienophiles, and, moreover, that a high degree of specificity was exhibited in the direction of the addition of IV to either I or X. And from the higher yield of VII than that expected, it was considered that III was partly isomerized to IV under the given conditions. In order to fully test the ability of III as a Diels-Alder diene, the authors employed for the reaction with X a specially enriched sample, b. p. 109.2~110°C/758 mmHg, n_D^{20} 1.4722, which had been confirmed to consist of 94.7% III, 5.3% IV and no other dienes; they then found that III was partly polymerized and mostly recovered after isomerizing to IV, whereas the addition product obtained in a slight yield was proved to consist largely of IX. On the other hand, a similar reaction at 125°C with a mixture, b. p. 106.3~106.6°C/760 mmHg, n_D^{20} 1.4634, containing 91.4% IV and 8.6% III, afforded IX in a 42% yield.

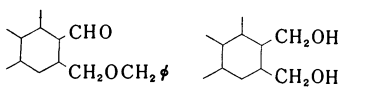
Naves[2], Nazarov[3] and their associates claimed that the Diels-Alder reaction between so-called 3, 4-dimethyl-1, 3-pentadiene and X gave an adduct which resulted directly from III itself as a main product, although as to the direction of the addition their conclusions were contradictory. It is still obscure, for the present, why the opinions about the Diels-Alder reaction involving III do not agree with one another; however, it should be emphasized that both the diene samples used by the European investigators, showing n_D^{20} 1.4560 and 1.4691 respectively, might be more heterogeneous and clearly more deficient in III than the one employed by the authors for the above test. Several problems concerning the diene III will be discussed in detail in a following paper.

2) Y. R. Naves and P. Ardizio, *Helv. Chim. Acta*, **31**, 2256 (1948).
3) I. N. Nazarov and M. V. Mavrov, *Zhur. Obshchei Khim.*, **29**, 1158 (1959).



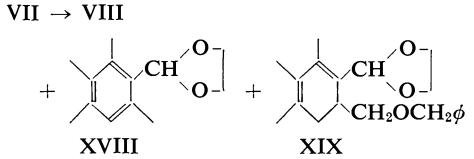
The Diels-Alder adducts, VII and IX, gave several derivatives, some of which were proved to have an odor.

The aldehyde IX freshly regenerated from its phenylsemicarbazone afforded, on condensation with acetone, 4-(2′, 3′, 4′, 6′-tetramethyl-3′-cyclohexenyl)-but-3-en-2-one (XII) in an 82.2% yield. The catalytic hydrogenation of XII over platinum oxide catalyst gave, in an 81% yield, 4-(2′, 3′, 4′, 6′-tetramethyl-3′-cyclohexenyl)-butan-2-one (XIII). Both XII and XIII have a pleasant odor.



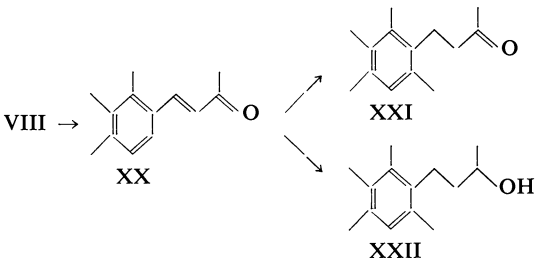
XII XIII

On the partial hydrogenation of VII in the presence of a palladium-calcium carbonate catalyst, when one mole of hydrogen was consumed, an α, β-unsaturated aldehyde XIV and appreciable amounts of an unconjugated unsaturated aldehyde XV were obtained, although the location of the double bond in the latter has not been confirmed. With a palladium-barium carbonate catalyst, after absorbing two moles of hydrogen, VII afforded 6-benzyl-oxymethyl-2, 3, 4-trimethylcyclohexylmethanal (XVI). In the meanwhile, when hydrogenation was carried out under pressure in the presence of a Raney nickel catalyst, it afforded the saturated diol XVII in a yield of 73%.



XIV XV

XVI XVII



Treatment of VII with ethylene glycol[4] in the presence of *p*-toluenesulfonic acid gave VIII, the ethylene acetal XVIII and, in only a 3% yield, an acetal which was presumed to be XIX, an isomer of the desired acetal.

XVIII XIX

4) E. I. Salmi, *Ber.*, **71**, 1803 (1938).

Finally, when VIII was condensed with acetone in the usual way 4-(2′, 3′, 4′, 6′-tetramethylphenyl)-but-3-en-2-one (XX), with a weak violet-like odor, was obtained in a 92% yield. On partial hydrogenation over platinum oxide catalyst XX afforded, in an excellent yield, 4-(2′, 3′, 4′, 6′-tetramethylphenyl)-butan-2-one (XXI), and, on further hydrogenation with a Raney nickel catalyst under pressure, it gave 4-(2′, 3′, 4′, 6′-tetramethylphenyl)-butan-2-ol (XXII).

XX XXI XXII

Experimental[5]

3, 4-Dimethyl-1-penten-3-ol (II).—3, 4-Dimethyl-1-penten-3-ol (II) was prepared in an 85~89% yield by hydrogenation of 3, 4-dimethyl-1-pentyn-3-ol, b. p. 134.5°C/760 mmHg, n_D^{20} 1.4362 (lit.[3] b. p. 134~134.5°C/752 mmHg, n_D^{20} 1.4370), with a palladium-on-calcium carbonate catalyst. The carbinol II had b. p. 134.7~135°C/760 mmHg and n_D^{20} 1.4335 (lit.[3] b. p. 130.7~131°C/748 mmHg, n_D^{20} 1.4361).

Dehydration of 3, 4-Dimethyl-1-penten-3-ol (II) with Potassium Hydrogen Sulfate.—The carbinol II (77 g.) was stirred, drop by drop, into potassium hydrogen sulfate (fused, 20 g.) over a period of 7 hr. at 175~180°C under a nitrogen atmosphere and simultaneous distillation of the dehydration products through a 25 cm. Vigreux column. After separating the aqueous layer, the distillate was dried over calcium chloride, then simply redistilled through a 30 cm. column, and a fraction boiled at 82 to 108°C was collected. The yield was 43.7 g. (75%). There remained a brown tarry oil (ca. 10 g.) containing unchanged II in a distilling flask. Vapor phase chromatography at 90°C showed that the above fraction consists of six components containing 3, 4-dimethyl-1, 3-pentadiene (III), 2, 3-dimethyl-1, 3-pentadiene (IV) and 2-isopropyl-1, 3-butadiene (V) in a ratio of approximately 18 : 21 : 53, with three unknown hydrocarbons of minor quantities (Fig. 1).

The above fraction was carefully fractionated through a 100 cm. modified Todd fractionating column to give the following representatitive fractions :

5) All m. p.'s were determined on the Kofleir hot-stage and are uncorrected. The ultraviolet absorption spectra were determined with a Hitachi spectrophotometer model EPU-2A, while the infrared absorption spectra were obtained with a Perkin-Elmer model 112, a Kōken model DS-301 and a Nippon Bunkō model IR-S recording spectrophotometer using sodium chloride optics. Vapor phase chromatographic analyses were carried out with a Kotaki Super Fractioner model GU-21 using a 200 mm. × 8 mm. φ copper tube packed with Celite DM-13 A which was coated with Carbowax-4000.

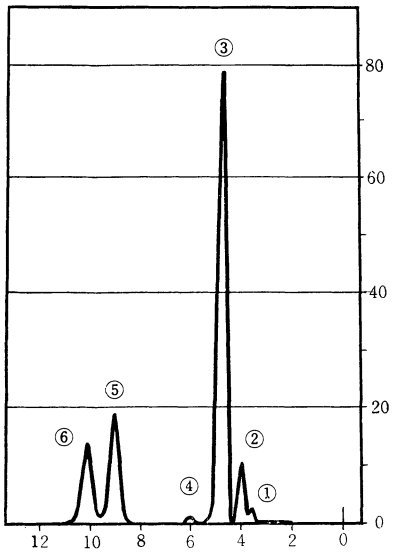


Fig. 1. Vapor phase chromatogram of the dehydration products of 3,4-dimethyl-1-penten-3-ol (II) with potassium hydrogen sulfate at 175~180°C.
①, ② and ④: Unknown hydrocarbons
③: 2-Isopropyl-1,3-butadiene (V)
⑤: 2,3-Dimethyl-1,3-pentadiene (IV)
⑥: 3,4-Dimethyl-1,3-pentadiene (III)

F. No.	B. p. °C/760 mmHg	n_D^{20}	Yield g.	Composition, % III : IV : V		
3	86~87	1.4326	16.0			98
7	104~106	1.4552~1.4617	1.8	6	72	15
8	106~106.5	1.4635	2.9	7.5	85	4.5
9	106.5~107.5	1.4635~1.4660	2.5	17	82	
10	107.5~108.5	1.4664~1.4671	5.3	42	58	
11	108.5	1.4680	1.4	52	48	

The diene V was easily isolated from the other components after two redistillations through the same column, whereas III and IV could not be separated from each other even by the repeated redistillations. The enriched sample of III which was thus obtained had b. p. 109.2~110°C/758 mmHg and n_D^{20} 1.4722 and consisted of 94.7% III and 5.3% IV; that of IV had b. p. 106.3~106.6°C/760mmHg and n_D^{20} 1.4634 and was composed of 91.4% IV and 8.6% III.

Many dehydrations of II with potassium hydrogen sulfate carried out in the range at 140 to 180°C showed that the composition of the hydrocarbons was practically constant and did not change with the temperature.

A mixed diene consisting of 37.5% III and 62.5% IV, b. p. 107.5~108°C/753 mmHg, n_D^{20} 1.4664, which was easily obtained, was employed for the next Diels-Alder reactions.

2-Benzyloxymethyl-4,5,6-trimethylcyclohexa-1,4-dienylmethanal (VII).—A mixture of 4-benzyloxy-2-butyn-1-al (I) (34.8 g.), the mixed diene (20.2 g.) and benzene (30 ml.) was heated with a little hydroquinone for 10 hr. at 155°C under nitrogen in a glass bomb. Concentration of the reaction mixture under reduced pressure, followed by distillation, gave a small amount of unchanged I and a pale yellow oil (36.0 g.), b. p. 133~135°C/2.2×10^{-3} mmHg, n_D^{20} 1.5496. There remained a considerable amount of a dark-red resinous matter. In order to investigate the homogeneity of the above fraction, the 2,4-dinitrophenylhydrazone was directly prepared from the above fraction (0.34 g.), and the excess of water was added to the reaction mixture to precipitate any methanol-soluble materials. When the precipitate (0.36 g.) was dissolved in chloroform (1.5 ml.) and chromatographed on alumina (200 mm.×18 mm. ϕ) from benzene, a weak red-orange band at the top of the column and then a strong yellow-orange band were obtained. The lower zone afforded orange silk-like needles (270 mg.), m. p. 155~156°C, after being crystallized from ethanol-ethyl acetate.

Found: N, 12.42. Calcd. for $C_{24}H_{27}O_5N_4$: N, 12.44%.

The upper band gave red-orange needles (10 mg.), m. p. 128~129.8°C, after crystallization from methanol.

Found: N, 12.60%.

The phenylsemicarbazone was prepared from the above fraction (1.0 g.) in the usual manner, and an excess of water was added and allowed to stand overnight. The crystalline solid was collected and crystallized from ethanol to give colorless needles (1.27 g.) melting at 163~164°C, λ_{max}^{EtOH} 235 mμ (ε, 17700), 285 (32100), which could be converted into the 2,4-dinitrophenylhydrazone, m. p. 155~156°C, described above.

Found: N, 10.46. Calcd. for $C_{25}H_{29}O_2N_3$: N, 10.41%.

From the mother liquor, colorless needles (60 mg.) melting at 139 to 141°C were isolated.

Found: N, 10.38%.

The crude pale yellow oil mentioned above was twice redistilled carefully under nitrogen to afford VII as a pale yellow viscous liquid, b. p. 133~134°C/2×10^{-3} mmHg, n_D^{20} 1.5494. ν_{max}^{film} 2750, 1670 (CHO, conju.), 1640 (C=C, conju.), 1070 (C-O-C), 3025, 1502, 742 and 705 cm^{-1} (phenyl group). λ_{max}^{EtOH} 236 mμ (ε 5900).

Found: C, 79.80; H, 8.27. Calcd. for $C_{18}H_{22}O_2$: C, 79.96; H, 8.20%.

From the above fraction, only the 2,4-dinitrophenylhydrazone, m. p. 155~156°C, was obtained.

Treatment of the Aldehyde VII with Diluted Sulfuric Acid.—The aldehyde VII (0.3 g.), dissolved in a solution of concentrated sulfuric acid (0.2 ml.) in 80% aqueous methanol (2 ml.), was warmed at 60°C for 5 min. A saturated solution of potassium acetate in methanol was added dropwise to the cooled reaction mixture until the precipitation of potassium sulfate was completed. The mixture was filtered, and the filtrate was then concentrated and treated with a solution of phenylsemicarbazide (0.4 g.) in methanol (5 ml.). After

this was kept overnight at room temperature, a solid derivative was collected and crystallized from 50% aqueous ethanol to yield what is believed to be the phenylsemicarbazone of 6-benzyloxymethyl-2, 3, 4 - trimethylcyclohexa - 1, 3 - dienylmethanal (XI) (0.26 g.) as long needles, m. p. 167~169°C; this showed a marked depression in melting point on admixture with that of VII, m. p. 163~164°C.

Found: N, 10.37. Calcd. for $C_{25}H_{29}O_2N_3$: N, 10.41%.

2, 3, 4, 6 - Tetramethyl - 3 - cyclohexenylmethanal (IX).—*a) From the Mixed Diene (b. p. 107.5~108°C/753 mmHg) and Crotonaldehyde (X).*—A mixture of mixed diene (16.2 g.), X (10.5 g.) and benzene (10 ml.) were heated with a small amount of hydroquinone for 7 hr. at 155°C in a 50 ml. glass bomb. After removal of the solvent, the residue was distilled to afford a colorless liquid (13.0 g.), b. p. 72~74.5°C/3.5 mmHg, n_D^{20} 1.4778.

Found: C, 79.16; H, 11.15. Calcd. for $C_{11}H_{18}O$: C, 79.46; H, 10.92%.

Treatment of the above fraction with the Brady reagent gave a yellow 2, 4-dinitrophenylhydrazone, m. p. 181~182°C, after crystallization from methanol.

Found: N, 16.16. Calcd. for $C_{17}H_{22}O_4N_4$: N, 16.18%.

From the mother liquor a small number of orange-yellow needles, m. p. 128.5~136°C, which have not been further investigated, were separated.

The phenylsemicarbazone obtained from the above fraction was crystallized from aqueous ethanol to give needles, m. p. 133~135°C, in a 62% yield.

Found: N, 14.23. Calcd. for $C_{18}H_{25}ON_3$: N, 14.04%.

From the mother liquor an appreciable amount of a crystalline solid melted at 115 to 121°C was separated.

The phenylsemicarbazone (6.7 g.) obtained above as the main product was mixed with *o*-phthalic acid (14 g.), ethylene glycol (6 ml.) and water (100 ml.), and distilled in steam. The distillate was extracted with ether, and the ether extract was then washed with a 10% aqueous sodium carbonate solution and with water, dried and evaporated. Distillation of the residue afforded the aldehyde IX (2.6 g., 68%), b. p. 61~63.5°C/1.5 mmHg, n_D^{20} 1.4795, which gave only 2, 4-dinitrophenylhydrazone melting at 181~182°C.

Found: C, 79.34; H, 11.08. Calcd. for $C_{11}H_{18}O$: C, 79.46; H, 10.92%.

b) From the Mixed Diene (b. p. 109.2~110°C/758 mmHg) and X.—A mixture of the mixed diene (2.5 g.), X (1.9 g.) and benzene (10 ml.) was heated with a small amount of hydroquinone for 30 hr. at 125°C in a 50 ml. glass bomb. After removal of the solvent, the residual oil was distilled through a 10 cm. Vigreux column to afford a considerable amount of fore-run consisting of the unchanged starting materials and an oil (0.3 g.), b. p. 71~73°C/3 mmHg, n_D^{20} 1.4796, whose vapor phase chromatogram showed that this fraction consisted mainly of IX and of an appreciable amount of some unknown components.

Found: C, 79.78; H, 11.12. Calcd. for $C_{11}H_{18}O$: C, 79.46; H, 10.92%.

From the vapor phase chromatography, it was shown that the fore-run obtained above contains the diene III and IV in the proportion of 1 : 5, besides unchanged crotonaldehyde (X).

When the same reaction mixture as above was heated for 6 hr. at 200°C, the compositions of product became more complicated. In all cases, a gummy matter, which on cooling solidified gradually to give a white amorphous polymer, softened at ca. 130°C.

c) From the Mixed Diene (b.p. 106.3~106.6°C/760 mmHg) and X.—A mixture of the mixed diene (2.5 g.), X (1.9 g.) and benzene (10 ml.) was heated with a small amount of hydroquinone for 12 hr. at 125°C in a 50 ml. glass bomb. After removal of the solvent, the residue was distilled through an 8 cm. Vigreux column under nitrogen to afford a fore-run consisting largely of the unchanged starting materials and a colorless oil (1.8 g.), b. p. 76~78°C/4 mmHg, n_D^{20} 1.4791. Redistillation gave pure IX (1.52 g.), b. p. 75.5°C/4 mmHg, n_D^{21} 1.4791. ν_{max}^{film} 2740, 1721 (CHO), 1468 (CH_2) and 1387 cm^{-1} (CH_3).

Found: C, 79.42; H, 11.12. Calcd. for $C_{11}H_{18}O$: C, 79.46; H, 10.92%.

Upon treatment with the Brady reagent, IX gave a yellow 2, 4 - dinitrophenylhydrazone, m. p. 181~182°C, which showed no melting point depression on admixture with that prepared in a).

2, 3, 4, 6-Tetramethylbenzaldehyde (VIII).—*a) Acid Hydrolysis of the Phenylsemicarbazone of VII Melted at 163~164°C.*—A mixture of this derivative (7.0 g.), *o*-phthalic acid (7.0 g.), ethylene glycol (50 g.), concentrated sulfuric acid (15 g.) and water (50 ml.) was distilled in steam until no more organic materials passed over (7 hr. were required for this). The distillate (1300 ml.) was extracted with ether, and the ether extract was washed with water, dried over sodium sulfate and concentrated. Fractional distillation of the residual oil afforded a fore-run (0.6 g.), b. p. 49~55°C/1.2 mmHg, and 2, 3, 4, 6-tetramethylbenzaldehyde (VIII) (2.0 g., 69%) as a colorless oil, b. p. 92~94°C/1.2 mmHg, n_D^{20} 1.5482. ν_{max}^{film} 1709 (C=O), 867 cm^{-1} (penta-substituted phenyl group). λ_{max}^{EtOH} 268.5 and 306 mμ (lit.[6] λ_{max}^{EtOH} 267 mμ (log ε, 4.00), 306 (3.32)).

Found: C, 80.75; H, 8.89. Calcd. for $C_{11}H_{14}O$: C, 81.44; H, 8.70%.

The semicarbazone crystallized from 50% aqueous methanol in the form of needles, melted at 189°C to a liquid which quickly solidified and then remelted at 259~260°C with partial decomposition. λ_{max}^{EtOH} 219 mμ (ε, 19200), 275 (12000).

Found: C, 65.72; H, 7.64; N, 19.12. Calcd. for $C_{12}H_{17}ON_3$: C, 65.72; H, 7.81; N, 19.16%.

The 2, 4-dinitrophenylhydrazone crystallized from ethanol-ethyl acetate in the form of orange-yellow needles, m. p. 222~223°C.

Found: C, 59.57; H, 5.15; N, 16.35. Calcd. for $C_{17}H_{18}O_4N_4$: C, 59.64; H, 5.30; N, 16.37%.

b) Sulfur Dehydrogenation of 2, 3, 4, 6-Tetramethyl-3-cyclohexenylmethanal (IX).—The aldehyde IX (3.3

6) N. J. Leonard and E. R. Blout, *J. Am. Chem. Soc.*, 72, 486 (1950).

g.) prepared in the method of c) was heated under reflux with sulfur (1.6 g.) at 220~230°C under a nitrogen atmosphere until the evolution of hydrogen sulfide ceased (40 min. were required). The volatile materials were distilled under reduced pressure. The yellow distillate, b. p. 120~130°C/8.2 mmHg, thus obtained, on further distillation under nitrogen through a 7 cm. Vigreux column, yielded 2,3,4,6-tetramethylbenzaldehyde (VIII) (1.0 g., 31%) which had b. p. 127°C/8.2 mmHg and n_D^{20} 1.5740. There remained black tarry materials (ca. 1.3 g.) in the distilling flask.

The semicarbazone crystallized from aqueous methanol in prisms melted at 187~188°C to a liquid which rapidly solidified and then remelted at 259°C with partial decomposition; it gave no melting point depression on admixture with that prepared in a).

The 2, 4-dinitrophenylhydrazone prepared in the usual manner was chromatographed on alumina from benzene and crystallized twice from methanol-ethyl acetate to yield orange-yellow needles, m. p. 221~222°C, which showed no melting point depression on admixture with that obtained in a).

4-(2′,3′,4′,6′-Tetramethyl-3′-cyclohexenyl)-but-3-en-2-one (XII).—The aldehyde IX (2.3 g.) regenerated from the phenylsemicarbazone described above in acetone (7.0 ml.) was added dropwise to a boiled solution of barium hydroxide (0.4 g.) in 80% aqueous acetone (20 ml.) and refluxed for 19 hr. After the bulk of the solvent had been removed, the residue was dissolved in ether. The ethereal solution was washed successively with 10% hydrochloric acid and water, dried over magnesium sulfate and evaporated. Distillation afforded the unsaturated ketone XII (2.35 g., 82.2%) as a colorless liquid with a pleasant odor, b. p. 98~100°C/1.2 mmHg, n_D^{20} 1.4979. ν_{max}^{film} 1680 (C=O), 1622 (C=C), 1257 (CH_3CO) and 984 cm^{-1} (-CH=CH-, *trans*).

Found: C, 81.63; H, 10.86. Calcd. for $C_{14}H_{22}O$: C, 81.50; H, 10.75%.

The phenylsemicarbazone crystallized from ethanol in the form of feather-like needles, m. p. 149~151°C.

Found: N, 12.33. Calcd. for $C_{21}H_{29}ON_3$: N, 12.38%.

The 2, 4-dinitrophenylhydrazone crystallized from ethanol-ethyl acetate in the form of ruby-red needles, m. p. 141~142°C.

Found: N, 14.51. Calcd. for $C_{20}H_{26}O_4N_4$: N, 14.50%.

4-(2′,3′,4′,6′-Tetramethyl-3′-cyclohexenyl)-butan-2-one (XIII).—The ketone XII (1.45 g.) in ethyl acetate (40 ml.) was hydrogenated at ordinary pressure in the presence of a platinum oxide catalyst (50 mg.) until one molar equivalent (170 ml. at 20°C) of hydrogen had been absorbed. Removal of the catalyst and solvent, followed by distillation of the residue, afforded XIII (1.18 g., 80.5%) as a colorless liquid with a pleasant odor, b. p. 97~99°C/1.5 mmHg, n_D^{20} 1.4769.

Found: C, 80.50; H, 11.77. Calcd. for $C_{14}H_{24}O$: C, 80.71; H, 11.61%.

The semicarbazone crystallized from 40% aqueous methanol in the form of needles, m. p. 152.5~153.5°C.

Found: C, 68.00; H, 10.09; N, 15.76. Calcd. for $C_{15}H_{27}ON_3$: C, 67.88; H, 10.26; N, 15.83%.

The 2,4-dinitrophenylhydrazone crystallized from ethanol-ethyl acetate in the form of bright yellow prisms, m. p. 150~150.5°C.

Found: C, 61.57; H, 7.11; N, 14.60. Calcd. for $C_{20}H_{28}O_4N_4$: C, 61.84; H, 7.27; N, 14.42%.

2-Benzyloxymethyl-4, 5, 6-trimethyl-1-cyclohexenylmethanal (XIV).—The aldehyde VII (5.4 g.) in ethanol (10 ml.) was hydrogenated in the presence of a palladium-on-calcium carbonate catalyst (2.5% Pd, 2.0 g.) until 1.1 mol. equivalents (508 ml. at 8°C and 754 mmHg) of hydrogen had been absorbed. Removal of the catalyst and solvent, followed by distillation of the residue, afforded a pale yellow liquid (3.6 g.), b. p. 124~126°C/9×10^{-3} mmHg, n_D^{20} 1.5388.

Found: C, 78.71; H, 8.72. Calcd. for $C_{18}H_{24}O_2$: C, 79.37; H, 8.88%.

The phenylsemicarbazone crystallized from ethanol in the form of needles, m. p. 173.5~174.5°C. λ_{max}^{EtOH} 232 mμ (ε 29400), 292 (22200).

Found: N, 10.46. Calcd. for $C_{25}H_{31}O_2N_3$: N, 10.36%.

The crude 2,4-dinitrophenylhydrazone prepared directly from the above hydrogenation product (0.4 g.) in the usual manner was chromatographed on alumina from benzene. The lower, main red-orange zone gave the 2,4-dinitrophenylhydrazone of XIV as orange-red needles, m. p. 164~165°C (0.33 g.), after recrystallization from ethanol-ethyl acetate.

Found: N, 12.52. Calcd. for $C_{24}H_{28}O_5N_4$: N, 12.38%.

The upper, slight yellow band yielded, after being crystallized from ethanol-ethyl acetate, a 2,4-dinitrophenylhydrazone (10 mg.), m. p. 193~194°C, which is believed to be that of 6-benzyloxymethyl-2,3,4-trimethylcyclohexenylmethanal (XV), although the location of the double bond has not been determined.

Found: N, 12.38%.

6-Benzyloxymethyl-2, 3, 4-trimethylcyclohexylmethanal (XVI).—The aldehyde VII (2.70 g.) in ethanol (20 ml.) was hydrogenated at one atmosphere in the presence of a palladium-on-barium carbonate catalyst (2.5% Pd, 1.0 g.) until 2.05 mol. equivalents (470 ml. at 9.5°C) of hydrogen had been absorbed. Removal of the catalyst and solvent, followed by distillation of the residue, afforded the saturated aldehyde XVI (2.10 g., 76.6%) as a colorless liquid, b. p. 115~117°C/5×10^{-3} mmHg, n_D^{20} 1.5290. ν_{max}^{film} 2710, 1724 (CHO), 1099 (C-O-C), 741 and 703 cm^{-1} (mono-substituted phenyl group).

Found: C, 78.74; H, 9.29. Calcd. for $C_{18}H_{26}O_2$: C, 78.79; H, 9.55%.

The phenylsemicarbazone crystallized from ethanol in the form of fine needles, m. p. 134~135°C. λ_{max}^{EtOH} 248 mμ (ε 28400).

Found: N, 10.47. Calcd. for $C_{25}H_{33}O_2N_3$: N, 10.31%.

The 2,4-dinitrophenylhydrazone crystallized from ethyl acetate in the form of orange-yellow needles, m. p. 105°C.

Found: N, 12.54. Calcd. for $C_{24}H_{30}O_5N_4$: N, 12.33%.

1, 2 - Bishydroxymethyl - 3, 4, 5 - trimethylcyclohexane (XVII).—The aldehyde VII (2.7 g.) in ethanol (30 ml.) was hydrogenated in the presence of a Raney nickel catalyst (1.0 g.) for 4 hr. at 150°C and 195 kg./cm². After the catalyst had been removed, the filtrate was again hydrogenated with a palladium-on-charcoal catalyst (5% Pd, 1.0 g.) for 2 hr. at 130°C and 150 kg./cm². Removal of the catalyst and solvent, followed by distillation of the residue, gave the diol XVII (1.36 g., 73%), b. p. 113~115°C/4×10^{-3} mmHg, n_D^{25} 1.4860. ν_{max}^{film} 3333 and 1054 cm^{-1} (OH).

Found: C, 71.32; H, 11.75. Calcd. for $C_{11}H_{22}O_2$: C, 70.29; H, 11.90%.

The bisphenylurethane crystallized from benzene-ethyl acetate in the form of needles, m. p. 173°C.

Found: C, 67.88; H, 7.59; N, 6.42. Calcd. for $C_{25}H_{32}O_4N_2\cdot H_2O$: C, 67.85; H, 7.75; N, 6.33%.

Attempted Acetalation of 2-Benzyloxymethyl-4, 5, 6-trimethylcyclohexa-1, 4-dienylmethanal (VII) with Ethylene Glycol.—A mixture of the aldehyde VII (13.5 g.), ethylene glycol (15 g.), *p*-toluenesulfonic acid (0.25 g.) and benzene (60 ml.) was heated under reflux in an oil bath at a temperature of 120°C for 4 hr. with an azeotroper. The reaction mixture was cooled and the benzene layer separated. The ethylene glycol layer was extracted with benzene. The combined benzene solution was washed with a 10% aqueous sodium carbonate solution and with water, dried over sodium sulfate and evaporated. The residue was fractionated through a 7 cm. Vigreux column to give three representative fractions: i) 2, 3, 4, 6-Tetramethylbenzaldehyde (VIII) (3.3 g., 40.0%), b. p. 106~107°C/2.2 mmHg, n_D^{20} 1.5482, whose infrared spectrum was identical with that of the authentic VIII described above.

Found: C, 81.34; H, 8.77%.

ii) 2, 3, 4, 6 - Tetramethylbenzaldehyde ethylene acetal (XVIII) (1.0 g., 17%), a colorless oil, b. p. 123~125°C/2.2 mmHg, which solidified quickly to give prisms melting at 58°C after being crystallized from petroleum ether.

Found: C, 75.32; H, 8.69. Calcd. for $C_{13}H_{18}O_2$: C, 75.69; H, 8.80%.

Treated with the Brady reagent, XVIII gave 2, 4-dinitrophenylhydrazone, m. p. 221°C, which showed no melting point depression on admixture with that of VIII.

iii) 6-Benzyloxymethyl-2, 3, 4-trimethylcyclohexa-1, 3-dienylmethanal ethylene acetal (XIX) (0.5 g., 3%), a pale yellow viscous oil, b. p. 147~150°C/2 $\times10^{-2}$ mmHg, n_D^{20} 1.5630.

Found: C, 76.20; H, 8.30. Calcd. for $C_{20}H_{26}O_3$: C, 76.40; H, 8.34%.

4-(2', 3', 4', 6' - Tetramethylphenyl)-but-3-en-2-one (XX).—The aldehyde VIII (1.0 g.) in acetone (5 ml.) was added dropwise to a boiled 80% aqueous acetone (10 ml.) containing barium hydroxide (0.2 g.), and the resultant mixture was refluxed for 21 hr. The cooled reaction mixture was neutrallized with 1 N hydrochloric acid and concentrated under reduced pressure. The pale yellow crystalline residue (1.25 g.) was crystallized from 80% aqueous methanol to give the unsaturated ketone XX (1.15 g., 92.2%) as colorless fine long needles with a weak violet-like odor, m. p. 80°C. ν_{max}^{KBr} 1658 (C=O, conju.), 1611 (C=C, conju.), 1255 (CH_3CO), 1004 (-CH=CH-, *trans*) and 878 cm^{-1} (penta-substituted phenyl group). λ_{max}^{EtOH} 218 mμ (ε 20500), 295 (11700).

Found: C, 82.88; H, 9.08. Calcd. for $C_{14}H_{18}O$: C, 83.12; H, 8.97%.

The semicarbazone crystallized from ethanol-ethyl acetate in leaflets, m. p. 225~226°C (partly decomp.). λ_{max}^{EtOH} 286 mμ (ε 31000).

Found: C, 69.27; H, 8.25; N, 16.05. Calcd. for $C_{15}H_{21}ON_3$: C, 69.46; H, 8.16; N, 16.21%.

The 2, 4-dinitrophenylhydrazone crystallized from ethanol-ethyl acetate in the form of dark-red prisms, m. p. 174~175°C.

Found: N, 14.58. Calcd. for $C_{20}H_{22}O_4N_4$: N, 14.65%.

4-(2', 3', 4', 6' - Tetramethylphenyl) - butan - 2 - one (XXI).—The ketone XX (50.6 mg.) in ethanol (20 ml.) was hydrogenated in the presence of a platinum oxide catalyst (30 mg.) until 1.05 mol. equivalents (5.9 ml. at 10°C and 754 mmHg) of hydrogen had been absorbed. Removal of the catalyst and solvent, followed by recrystallization of the residual solid from petroleum ether, gave the ketone XXI (47.0 mg., 93%) as colorless needles, m. p. 62.5~63.5°C.

Found: C, 82.54; H, 9.90. Calcd. for $C_{14}H_{20}O$: C, 82.30; H, 9.87%.

The 2, 4-dinitrophenylhydrazone crystallized from ethanol-ethyl acetate in the form of yellow needles, m. p. 166~167°C.

Found: C, 62.12; H, 6.26. Calcd. for $C_{20}H_{24}O_4N_4$: C, 62.48; H, 6.29%.

4 - (2', 3', 4', 6' - Tetramethylphenyl) - butan - 2 - ol (XXII).—The ketone XX (0.7 g.) in ethanol (50 ml.) was hydrogenated in the presence of a Raney nickel catalyst (1.2 g.) for 1.5 hr. at 120~130°C and 110 kg./cm² in a 100 ml. autoclave. Removal of the catalyst and solvent, followed by crystallization of the residue from methanol, yielded the carbinol XXII (0.66 g., 92.6%) as colorless needles, m. p. 79°C. ν_{max}^{KBr} 3356, 1089 (OH), 867 and 857 cm^{-1} (penta-substituted phenyl group).

Found: C, 80.75; H, 10.74. Calcd. for $C_{14}H_{22}O$; C, 81.50; H, 10.75%.

We wish to thank Dr. Asaji Kondo of the Tokyo Institute of Technology for his elementary analyses, and Dr. Tadashi Sato of Waseda University and Dr. Kenji Kuratani of the Aeronautical Research Institute, the University of Tokyo, for their infrared spectral measurements.

Complexing Behavior of Kojic Acid with Metal Ions. I. Mg(II) and Mn(II) Chelates[*1,*2]

By Yukito MURAKAMI

(Received May 4, 1961)

In recent years, the investigation of the metal complexes of tropolone and its derivatives has been in much progress and has brought about the information that these organic compounds form metal complexes of much greater stability than those of β-diketones of comparable acidity. Since kojic acid (I) forms a

I

five-membered chelate ring with hydrogen or metal ion, which is the same as tropolone, it was expected that kojic acid would react with metal ions to produce metal chelates or relatively high stability. Thus, Fernelius and his coworker[1] have carried out an investigation on this subject and found out that kojic acid forms metal chelates whose stabilities were greater than, or at least equal to, those of β-diketones of the same acidity.

To avoid such an ambiguity brought about by their use of non-aqueous solvent[1] (50% dioxane) for the determination of the stability constants, it was intended in this work to employ an aqueous system to clarify the interaction between kojic acid and metal ions.

Experimental

Reagents.—Kojic acid was purchased from the Tokyo Kasei Kogyo Co., Ltd., and was purified by sublimation in vacuo: m. p. 156~156.6°C; reported 154~156°C[1], 154°C[2].

This purified substance was used to prepare an aqueous stock solution which was standardized by potentiometric titration with standard base. Analytical grade $Mg(NO_3)_2 \cdot 6H_2O$ and $MnSO_4 \cdot nH_2O$, purchased from the Wako Pure Chemical Industries, Ltd., were used to make up stock solutions and standardized by the usual technique of chelatometric titration[3].

Potentiometric Measurements.—An HRL Model P pH meter (made by the Horiba Instruments Inc., Kyoto) with extension glass and calomel electrodes was used to measure hydrogen ion concentration after being calibrated with acetic acid buffer as well as standard hydrochloric acid and sodium hydroxide. Measurements were carried out at 25.0 $\pm$0.1°C, and the ionic strength was maintained at approximately 0.10 M with potassium nitrate. Solutions under investigation were kept in a nitrogen atmosphere by circulation of purified nitrogen through the jacketed titration cell.

Mathematical Treatment

In this investigation, metal species were found to exist in three forms: $M(H_2O)_4^{2+}$, $MA(H_2O)_2^{+}$, and MA_2. Therefore, the solution equilibria may be expressed in terms of the following equations:

$$HA \rightleftarrows H^+ + A^- \qquad K_D = \frac{[H^+]\,[A^-]}{[HA]} \tag{1}$$

$$M(H_2O)_4^{2+} + A^- \rightleftarrows MA(H_2O)_2^{+} + 2H_2O$$

$$K_1 = \frac{[MA^+]}{[M^{2+}]\,[A^-]} \tag{2}$$

$$MA(H_2O)_4^{+} + A^- \rightleftarrows MA_2 + 2H_2O$$

$$K_2 = \frac{[MA_2]}{[MA^+]\,[A^-]} \tag{3}$$

in which M represents a metal ion and HA indicates an undissociated form of a ligand.

The amount and distributing ratio of these chelate species may be calculated from the equilibrium relationships and the stoichiometric relations shown in the following paragraph.

If T_A and T_M represent the total concentration of the ligand species and of the metal species respectively, then

$$T_A = [HA] + [A^-] + [MA^+] + 2[MA_2] \tag{4}$$

$$T_M = [M^{2+}] + [MA^+] + [MA_2] \tag{5}$$

T_{OH}, the hydroxide added to a solution during the titration, introduces the relationship:

$$[H^+] - [OH^-] + T_{OH} = [A^-] + [MA^+] + 2[MA_2] \tag{6}$$

From Eq. 5 in combination with equilibrium relations 2 and 3, it results in

$$\frac{T_M}{[M^{2+}]} = 1 + K_1[A^-] + K_1K_2[A^-]^2 \tag{7}$$

---

*1 Contribution No. 19 from Department of Organic Synthesis, Faculty of Engineering, Kyushu University.

*2 Presented at the 14th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1961.

2) F. Challenger, T. Klein and T. K. Walker, *J. Chem. Soc.*, **1929**, 1498.

3) K. Ueno, "Chelatometric Titration" (in Japanese), Nankodo, Ltd., Tokyo (1960), pp. 274, 278.

The combination of Eqs. 1, 4 and 6 gives

$$[A^-] = \frac{K_D}{[H^+]}\left\{T_A - [H^+] + [OH^-] - T_{OH}\right\} \quad (8)$$

The quantity of free metal ion M^{2+} may be shown in terms of T_A, [HA], $[A^-]$, K_1 and K_2 from Eqs. 2, 3 and 4:

$$[M^{2+}] = \frac{T_A - [HA] - [A^-]}{K_1[A^-] + 2K_1K_2[A^-]^2} \quad (9)$$

Thus, substitution of the relationship 9 into Eq. 7 results in the final equation:

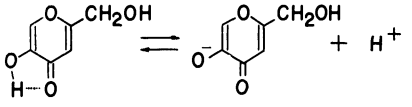
$$(F-1)[A^-]K_1 + (2F-1)[A^-]^2K_1K_2 = 1 \quad (10)$$

where

$$F = \frac{T_M}{T_A - [HA] - [A^-]}$$

Equation 10 means that K_1 may be plotted as a function of K_1K_2 corresponding to each experimental point on the titration curve. The intercept on the vertical axis is $1/(F-1)[A^-]$ and that on the horizontal axis is $1/(2F-1)[A^-]^2$. Straight lines obtained from a number of experimental points are to intersect at one point, which represents the solution of the simultaneous equations. The ordinate at this point is equal to K_1 and the abscissa is equal to K_1K_2. This method was employed for the determination of stability constants of the magnesium chelates. There is another graphical method for the evaluation of K_1 and K_2 employing Eq. 10. Equation 10 may be rewritten as

$$\alpha = K_1 + K_1K_2\beta \quad (11)$$



where

$$\alpha = 1/(F-1)[A^-];\ \beta = (2F-1)[A^-]/(F-1)$$

Thus if chelate formation reactions shown by Eqs. 2 and 3 occur, when α is plotted against β, a straight line is obtained the slope of which is equal to K_1K_2 and in which the intercept at $\beta = 0$ is equal to K_1. This alternate method was used for the evaluation of the stability constants of the manganese chelates.

Results and Discussion

Kojic Acid.—Potentiometric titration of kojic acid provides only one sharp inflection which corresponds to the following dissocciation:

The pK value of 7.68 is much smaller than the value of 9.40 obtained by Bryant and Fernelius[1] in 50% aqueous dioxane. This difference in pK value is to be expected because an acidic proton of an organic compound is more labile in aqueous system than in mixed aqueous systems.

Interaction of Mg(II) Ion with Kojic Acid.—Titration curves are illustrated in Fig. 1 for the kojate chelates of Mg(II) at 1 : 1 and 2 : 1 ratios of ligand to metal ion. In both titrations the total concentration of kojic acid was maintained constant.

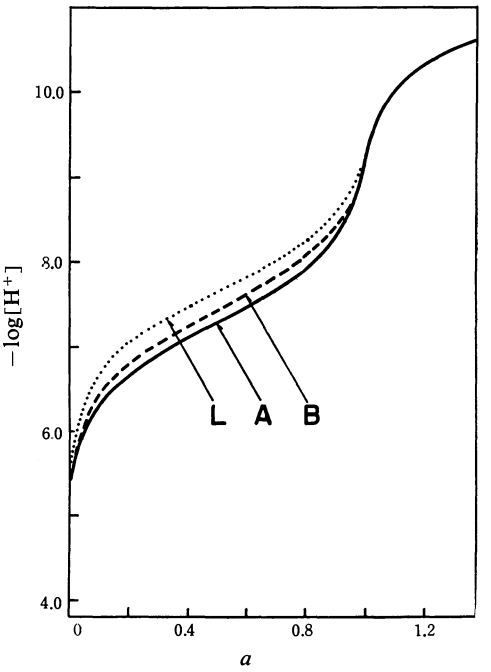


Fig. 1. Potentiometric titration of Mg(II)-kojate chelates at the total ligand concentration of 2.20×10^{-3} M, with these molar ratios of ligand to metal ion: A, 1 : 1; B, 2 : 1; L, ligand (kojic acid) alone; a = moles of base added per mole of ligand; t=25°C; μ=0.1 (KNO_3).

The apparent depression of the titration curves in the buffer region indicates the formation of the metal chelate species. The titration curve for the 2 : 1 ratio behaves similarly to that for the 1 : 1 ratio, thus suggesting the simultaneous formation of MgA and MgA_2. No precipitates were found throughout the titrations. Mg(II) ion undergoes hydrolysis in accordance with the equation:

$$Mg^{2+} + H_2O \rightleftarrows Mg(OH)^+ + H^+$$

However, the contribution of such a reaction is expected to be negligible in the buffer region where the two chelate formation reactions take place, for the K value is as much as $10^{-12.8}$ at 30°C and μ=0.1[4].

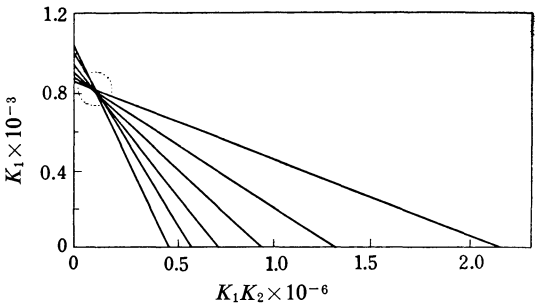
TABLE I. STABILITY CONSTANTS OF THE METAL CHELATES

Metal ion	Ligand	Temp., °C	μ	pK_D	log K_1	log K_2
Mg(II)	Kojic acid (HA)	25	0.10	7.68	2.92	2.19
	Acetylacetone[a] (HA)	30	→0	8.95	3.63	2.54
	Tiron[b] (H_2A)	20	0.1	7.66	1.98	
Mn(II)	Kojic acid (HA)	25	0.10	7.68	3.95	2.83
	Acetylacetone[a] (HA)	30	→0	8.95	4.18	3.07

K_D=first dissociation constant; $K_1=\frac{[MA]}{[M][A]}$; $K_2=\frac{[MA_2]}{[MA][A]}$

K_1 value for the Tiron chelate is shown for equilibrium: $\frac{[MHA]}{[M][HA]}$

a) See Ref. 5; b) See Ref. 6



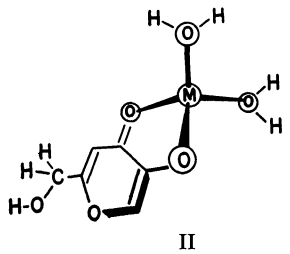


Fig. 2. Graphical determination of the formation constants for Mg(II)-kojate system.

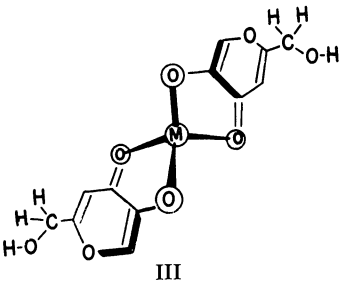
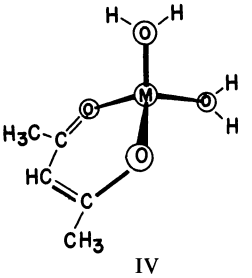
In order to evaluate the formation constants of the chelates, Eq. 10 was employed and K_1 and K_2 values were obtained graphically in Fig. 2. All the straight lines intersect satisfactorily at one point which verifies the formation of the two chelate species, MgA^+ and MgA_2.



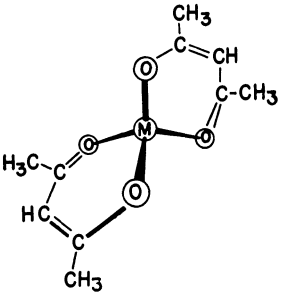
Although such differences were not critical, very slight deviations in K_1 and K_2 values, which depended upon the ligand to metal ratio, were noticed. Nevertheless, K_1 and K_2 values with reasonable accuracy may be obtained from 1 : 1 and 2 : 1 titration curves respectively. The values thus estimated are shown in Table I.

Formation of a tetracoördinated Mg(II) complex with tetrahedral configuration utilizing its $3s3p^3$ orbitals has been widely accepted. The 1 : 1 and 2 : 1 chelates probably have the structures indicated by II and III respectively.

The stability of the kojate chelate of Mg(II) may be compared with those of other Mg(II)



II

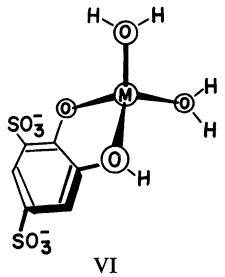


III

chelates having a similar configuration of the chelate ring.

Acetylacetone forms chelates with Mg(II)[5] the structure of which are shown by IV and V. These formation constants for IV and V are slightly greater than those for the corresponding kojate chelates. These formation constants of slightly greater values for the acetylacetonate complexes may be considered

IV



V

5) R. M. Izatt, W. C. Fernelius and B. P. Block, *J. Phys. Chem.*, **59**, 80 (1955).

due to the higher basicity of the enol group and the resonance stabilization of the heterocyclic chelate ring, while such resonance stabilization is prohibited for the kojate complexes.

Meanwhile, the Tiron chelate[6] indicated by VI is obtained with smaller stability in com-

VI

parison with the kojate chelate in spite of the fact that both kojic acid and the first phenol group of Tiron have almost the same magnitude of dissociation constants. Thus, this difference in stability is solely due to the difference in donor property of alcoholic oxygen and carbonyl oxygen toward Mg(II) ion.

Interaction of Mn(II) Ion with Kojic Acid.— A family of titration curves for solutions containing various amounts of kojic acid per mole of Mn(II) ion are shown in Fig. 3. Distinctive inflections were observed at m values corresponding to the complete neutralization of protons liberated from kojic acid.

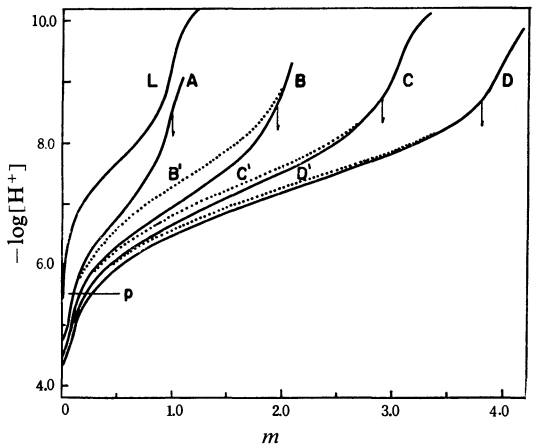


Fig. 3. Potentiometric titration of Mn(II)-kojate chelate system at the total metal concentration of 1.14×10^{-3} M, with these molar ratios of ligand to metal ion: A, 1 : 1; B, 2 : 1; C, 3 : 1; D, 4 : 1; L, ligand (kojic acid) alone; m=moles of base added per mole of metal ion; t=25°C; μ=0.1(KNO_3). Dotted curves represent superimposition of two titration curves: B', A+L; C', B+L; D', C+L. Arrows indicate points where pH drifting became noticeable, while titration curves below p represent non-equilibrated data.

The color of the titrating solutions was pale yellow and slightly deepened as pH went up. Precipitation was observed at very high pH beyond inflection regions. In all cases, the solutions did not come to equilibrium immediately in the pH($-\log[H^+]$) region below 5.5 and above 8.5. Thus, experimental titration curves lying between these pH values were actually used in pursuing the chelating behavior of kojic acid with the metal ion.

Curves obtained by superimposition of the titration curve of free kojic acid on adequate experimental titration curves are shown, together with experimental titration curves for solutions containing the same total concentrations of metal ion and ligand. The depression of pH is significant for the 2 : 1 ratio, and such depression decreases as the molar ratio of the ligand increases. However, such phenomena are not adequate enough to verify the chelate species formed at different molar ratios of kojic acid to Mn(II) ion.

As a first step in determining the Mn(II)-kojate chelate species, 1 : 1 titration curves were obtained over a four-fold concentration range as shown in Fig. 4.

The hydrolytic tendency of manganese(II) ion indicated by the equation:

$$Mn^{2+}+H_2O \rightleftarrows Mn(OH)^+ + H^+$$

does not seem to influence the complexing behavior of this metal ion with the ligand under

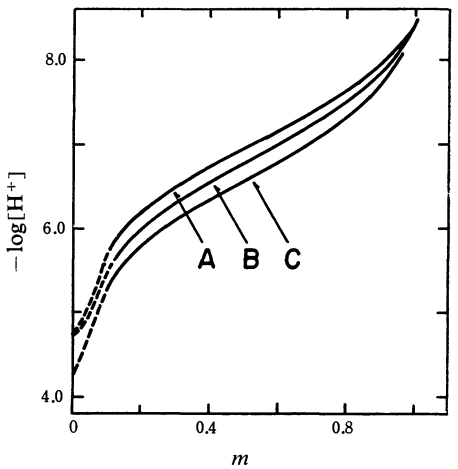

Fig. 4. Potentiometric titration of 1 : 1 Mn(II)-kojate chelate system: A, 5.68×10^{-4} M; B, 1.14×10^{-3} M; C, 2.28×10^{-3} M; m=moles of base added per mole of metal ion; t=25°C; μ=0.1(KNO_3). Dotted lines indicate non-equilibrated data.

experimental conditions of the present investigation since the K value is as small as $10^{-10.6}$ at 30°C and $\mu=0.1$[4]).

Mathematical treatment of the data employing Eq. 11 yielded the plots shown in Fig. 5. Good conformity with a straight line was obtained, and the slight fluctuation from the straight line for the data of lower concentration does not seem to disturb the evaluation of the formation constants. The same mathematical treatment performed for the titration curves of solutions containing 2 : 1 and 3 : 1 molar ratios of ligand to metal ion results in a satisfactory linear relationship as indicated

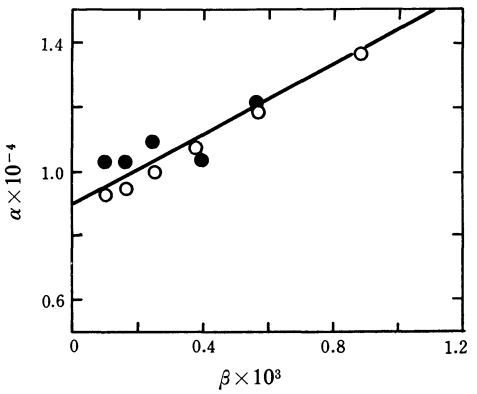

Fig. 5. Graphical determination of the formation constants for Mn(II)-kojate chelate system from titration data obtained for Mn(II)/kojic acid=1 in connection with Eq. 11. Concentrations of metal ion : ○, 2.28×10^{-3} M ; ●, 1.14×10^{-3} M.

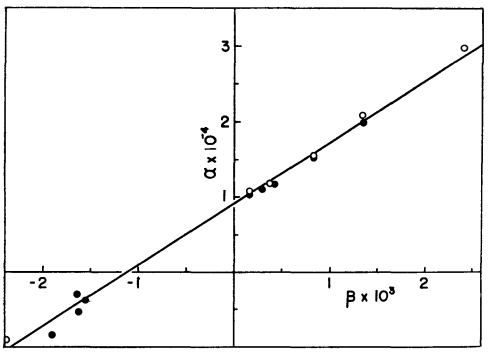

Fig. 6. Graphical determination of the formation constants for Mn(II)-kojate chelate system from titration data obtained for ligand to metal ratios : ○, 2 : 1 ; ●, 3 : 1.

in Fig. 6. With the same reason as mentioned above for the interaction of Mg(II) ion with the ligand, K_1 value was evaluated from the calculated data shown in Fig. 5 while K_2 value was determined from the data in Fig. 6. The results are summarized in Table I.

Satisfactory linear relationship in Fig. 6 provides the conclusive support for the formation of a chelate species containing two moles of ligand per mole of metal ion and not more than two moles of ligand. Manganese(II) ion could be expected to form a hexacoördinated chelate compound having octahedral configuration. In the case of hexacoördinated manganese(II) ion, the metal ion should utilize its $3d^24s4p^3$ atomic orbitals for the coördinate bond formation. Such a five-membered chelate ring formation that takes up two oxygens as donor atoms toward manganese(II) ion does not seem to supply enough energy to transfer the five 3d electrons into three degenerate t_{2g} orbitals. Instead, $4s4p^3$ atomic orbitals of manganese(II) ion could be utilized for the formation of four chelate bonds in the atmosphere of weak ligand field produced by kojate ion. The structures of Mn(II)-kojate chelates may be represented by II and III having tetrahedral configuration.

Mn(II)-kojate chelates possess slighly greater values of formation constant than Mg(II)-kojate chelates as observed in other Mn(II) chelates involving oxygen atoms as donor atoms[7]).

In conclusion, manganese(II) ion frequently behaves like magnesium(II) ion with a similar magnitude of chelate formation constants in aqueous system in spite of the fact that manganese(II) ion is a member of the first transition series.

Summary

Chelating tendencies of kojic acid toward divalent magnesium and manganese ions have been investigated in aqueous media at 25.0 ±0.1°C and 0.10 M of ionic strength. In spite of the difference in their electronic configurations, both metal ions formed similar chelate compounds and indicated an optimum coördination number of four. Both metal ions formed kojate chelates whose stabilities are nearly equal to the corresponding metal chelates of β-diketones of the same acidity.

Vinyl Copolymerization. I. Copolymerization of Acrylonitrile with Methyl Methacrylate

By Momotaro SUZUKI, Hajime MIYAMA and Shiro FUJIMOTO

(Received April 28, 1961)

In previous papers[1,2], investigations on the rate of copolymerization of VA (vinyl acetate)-MM (methyl methacrylate), St (styrene)-VA and MM-St by the thermistor method[3] were reported. Usually the rate of copolymerization is measured by weighing the copolymer's weight in the copolymerization system after a difinite time of reaction, but this method is not accurate because the concentration of each monomer changes during this definite period. On the other hand, the thermistor method can measure accurately the initial rate of copolymerization within ten seconds. In the VA-MM and St-VA systems, the large difference between the reactivity ratios of the two monomers caused a large error limit of ϕ, the ratio of the rate constant for "crossed" termination to the geometric mean of the rate constants of the chain termination of each monomer alone, so that we could not find any essential regularities in the variation of ϕ with successive mixing ratios. In the MM-St system, however, where the difference of the two reactivity ratios is not so large, we could determine the value of ϕ more precisely and obtain a concrete confirmation of Arlman's theory[4].

In this experiment, an AN (acrylonitrile)-MM pair was chosen for the rate measurement.

Experimental

The procedure and the treatment of the experimental results are almost the same as those described in detail in previous papers[1-3]. The temperature was 30.5°C and the fluctuation of the thermostat temperature was controlled within ±0.001°C. The sensitizer for photopolymerization was 1,1'-azobiscyclohexanecarbonitrile at a concentration of 7.56×10^{-3} mol./l.

The rate of polymerization was found by multiplication of the rate of temperature increase by the factor $1/\Delta t$ as follows[1,2]:

$$1/\Delta t=(S\times H)/(\Delta H_c\times M) \qquad (1)$$

Here, M, H, S and ΔH_c are molecular weight, specific heat, specific gravity and heat of polymerization, respectively, of the copolymerization system. The quantities M, H and S are related by:

$$M=(M_1f_1+M_2f_2)/(f_1+f_2) \qquad (2)$$

$$H=(H_1f_1+H_2f_2)/(f_1+f_2) \qquad (3)$$

$$S=(M_1f_1+M_2f_2)S_1S_2/(S_2M_1f_1+S_1M_2f_2) \qquad (4)$$

in which f's are the mole fractions of each monomer. According to Alfrey[4], ΔH_c is given by the following equation:

$$\Delta H_c=\frac{1-[1-F_2(1-F_2)(1-r_1r_2)]^{1/2}}{2(1-r_1r_2)}\times(\Delta H_{12}+\Delta H_{21}-\Delta H_{11}-\Delta H_{22})+F_1\Delta H_{11}+F_2\Delta H_{22} \qquad (5)$$

in which F's are the mole frations of each monomer in copolymer, r's are the reactivity ratios of each monomer, and the suffixes 1 and 2 denote the values of each monomer. ΔH_{11}, ΔH_{12}, ΔH_{21} and ΔH_{22} are heats of copolymerization corresponding to the following four different chain-propagation processes between monomers (M_1 or M_2) and radicals (M_1* or M_2*).

$$-M_1^* + M_1 \rightarrow -M_1-M_1^* \qquad \Delta H_{11}$$

$$-M_1^* + M_2 \rightarrow -M_1-M_2^* \qquad \Delta H_{12}$$

$$-M_2^* + M_1 \rightarrow -M_2-M_1^* \qquad \Delta H_{21}$$

$$-M_2^* + M_2 \rightarrow -M_2-M_2^* \qquad \Delta H_{22}$$

Although the values of ΔH_{11} and ΔH_{22} can be measured for the polymerization of each monomer alone, nothing is known about the values of ΔH_{12} and ΔH_{21}. As described in previous papers[5,6], the values of $\Delta H_{12}+\Delta H_{21}$, and also ΔH_c, can be obtained by comparing the rate of temperature rise with the rate of copolymerization. The rate of the temperature rise was measured every minute for 15 min. by the thermistor method, and the rate of copolymerization was obtained from the results of

analysis in which the copolymerization system was dissolved in a mixture of acetone and dimethylformamide after the photocopolymerization had proceeded 15 min.

In Table I, the necessary data for the calculation of $1/\Delta t$ are shown.

Results and Discussion

Heat of Copolymerization. — The values of the rate of temperature rise, the rate of copolymerization, ΔH_c and $\Delta H_{12}+\Delta H_{21}$ are shown in Table II. Details of the calculation of ΔH_c and $\Delta H_{12}+\Delta H_{21}$ have been described in previous papers[5,6].

From the fact that the values of $\Delta H_{12}+\Delta H_{21}$ are almost constant in Table II, the application of Eq. 5 in this system seems reasonable. By substituting the average value 28.40 kcal./mol. of $\Delta H_{12}+\Delta H_{21}$, the values of ΔH_{11} and ΔH_{22} of Table II and the values of r_1 and r_2 of Table I in Eq. 5, ΔH_c can be expressed as follows:

$$\Delta H_c = -1.32\,[1-(1-3.03F_1F_2)^{1/2}] + 16.75F_1 + 13.65F_2 \qquad (6)$$

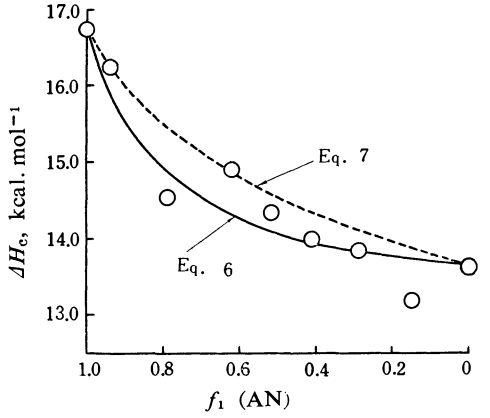

Fig. 1. Variation of ΔH_c with f_1.

○ Experimental values

Note: f_1 is a mole fraction of AN in the feed.

As shown in Fig. 1, the values of ΔH_c in Table II agree with the full line expressing Eq. 6. The dashed line in this figure is drawn by using the following equation:

$$\Delta H_c = F_1\Delta H_{11} + F_2\Delta H_{22} \qquad (7)$$

The results of calculation by using 6 and 7 give almost the same curve as shown in Fig. 1. Therefore, the application of 7 instead of 6 in this systems seem approximately correct.

Rate of Copolymerization. — In Fig. 2, the values of $1/\Delta t$ calculated from Eq. 1 are plotted against f_1, where Eq. 6 is used to obtain the value of ΔH_c. The values of the rate of polymerization as shown in Table III were calculated by a multiplication of the rate of temperature increase by this factor, $1/\Delta t$, where the rate of temperature increase was measured within 10 sec. of the instant polymerization starts by the thermistor method.

As shown in Fig. 3, the rate is minimum at the molar fraction of about 0.7 of AN. The

1.00	4.94	
		Av. 15

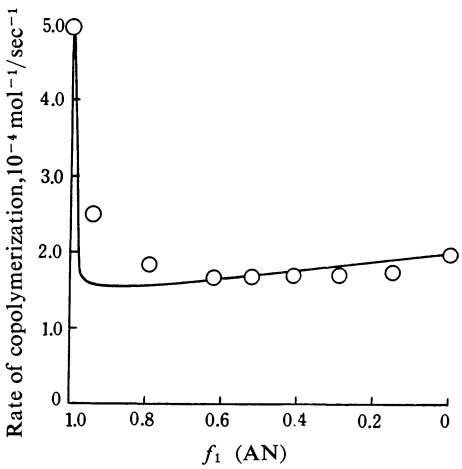

Fig. 3. Variation of rate of copolymerization with f_1.
○ Experimental values
— Walling's equation with $\phi=15$

rate of copolymerization is given by the following equation of Walling[11]:

$$V=\frac{(r_1[M_1]^2+2[M_1][M_2]+r_2[M_2]^2)I^{1/2}}{\left\{\begin{array}{c}((\delta_1^2r_1^2[M_1]^2+2\phi\delta_1\delta_2r_1r_2[M_1][M_2]\\+\delta_2^2r_2^2[M_2]^2)^{1/2}\end{array}\right\}} \quad (8)$$

The nomenclature of which is described in detail in Walling's paper[11] or in our previous papers[1,2]. Although ϕ in this equation should be constant, the values of ϕ calculated from Walling's equation (expressed as ϕ_{exp} in Table III) vary with the mole fraction of AN. The theoretical curve obtained by substituting $\phi=15$ (the average value of ϕ_{exp} in Table III) into Eq. 8 agrees with the experimental values as shown in Fig. 3. However, in order to explain the nonconstancy of ϕ, the application of Arlman's equation[12] to these data must be considered[2]. Arlman considered in his theory the following two cross-termination reactions:

(I) ~~~ BB· + ·A ~~~ k_{tbba}

(II) ~~~ AB· + ·A ~~~ k_{taba}

Reaction I is a usual cross-termination reaction, but in reaction II the existence of the penultimate unit A in the first free radical somewhat retards the termination reaction. Postulating these reactions, Arlman derived the equation:

$$(f_1\chi+r_2f_2)/(f_1+r_2f_2)=\phi_{exp}/\phi_n \quad (9)$$

χ and ϕ_n are related by:

$$\chi=k_{taba}/k_{tbba}<1 \quad (10)$$

$$1/\phi_n=(k_{taa}k_{tbb})^{1/2}/k_{tbba} \quad (11)$$

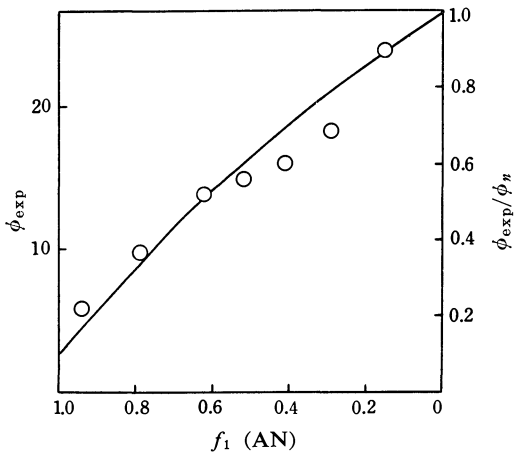

Fig. 4. Variation of ϕ_{exp} and ϕ_{exp}/ϕ_n with f_1.
○ Experimental values
— Arlman's equation with $\chi=0.1$ and $r_2=1.35$.

Here, k_{taa} and k_{tbb} are the termination constants of each monomer, and ϕ_{exp} is obtained from experimental data by a calculation according to Wallings' equation. Using Eq. 9, the curve shown in Fig. 4 was constructed; a χ with which the experimental and theoretical value in this figure agreed most satisfactorily was chosen. This value of χ is 0.1, and the corresponding value of ϕ_n is 27. Since k_{taa} and k_{tbb}, the termination constants of AN and MM, are known, k_{tbba} can be calculated by the substitution of these values and $\phi_n=27$ in Eq. 11. We took k_{taa} as 1.22×10^7 [13] and k_{tbb} as 2.32×10^7 [9] respectively at 25°C because no activation energy is available for the termination constant of AN, and, therefore, correction to the values for our polymerization temperature 30.5°C is impossible. The resulting value was $k_{tbba}=4.55\times10^8$. From

11) F. M. Lewis and C. Walling, ibid., **71**, 747 (1949).
12) J. Arlman and H. W. Melville, *Proc. Roy. Soc.*, **A203**, 301 (1950).
13) W. I. Bengough, *J. Polymer Sci.*, **28**, 476 (1958).

Eq. 10, using $\chi=0.1$, $k_{taba}=4.55\times10^7$ was obtained. Therefore, the termination constants for mixed radicals are larger than those for homogeneous radicals, and furthermore, the rate constant of reaction I is about ten times as large as that of reaction II.

Summary

Rates of copolymerization, of AN-MM for various mixing ratios of the two monomers were measured by the thermistor method. The heat of copolymerization, which was obtained by comparing the results of the thermistor method with those of the usual analytical method, agrees very well with Alfrey's equation. Also, the non-constancy of ϕ can be explained by Arlman's theory. It is concluded that the termination constants for mixed radicals are larger than those homogenous radicals and, furthermore, that the rate constant for a normal cross-termination reaction is about ten times as large as that of the cross-termination reaction having a penultimate unit.

The authors wish to thanks Mr. Shinichi Taira of Tokyo Metropolitan University for the preparation of 1,1′-azobiscyclohexanecarbonitrile.

Vinyl Copolymerization. II. Copolymerization of Acrylonitrile with Styrene and Vinyl Acetate

By Momotaro SUZUKI, Hajime MIYAMA and Shiro FUJIMOTO

(Received April 28, 1961)

In the previous paper[1], an investigation of the rate of copolymerization of AN(acrylonitrile)-MM(methyl methacrylate) by the thermistor method[2] was reported. In this experiment, two pairs, i. e., AN-St (styrene) and VA (vinyl acetate)-AN have been chosen for rate measurement.

The procedure and the treatment of the experimental results are the same as those in previous paper[1]. For both of the copolymerization systems, the temperature was 20.0°C and the sensitizer for photopolymerization was 1, 1'-azobiscyclohexanecarbonitrile at a concentration of 7.56×10^{-3} mol./l. The necessary data for the calculation of the factor $1/\Delta t$, which is used for converting the rate of temperature increase into the rate of copolymerization, are shown in Table I.

TABLE I. VALUES OF CONSTANTS OF EACH MONOMER IN THE AN-St AND VA-AN SYSTEMS AT 20.0°C

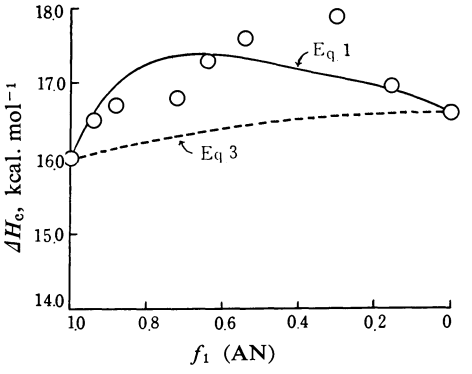

Fig. 1. Variation of ΔH_c with f_1 in the AN-St system.
○ experimental values
Note: f_1 is a mole fraction of AN in the feed.

By using these results and Alfrey's equation[10], the heat of copolymerization ΔH_c can be expressed as follows:

$$\Delta H_c = 1.02\,[1-(1-3.93F_1F_2)^{1/2}] + 16.03F_1 + 16.73F_2 \quad \text{for AN-St} \quad (1)$$

10) T. Alfrey, *J. Polymer Sci.*, 4, 222 (1949).

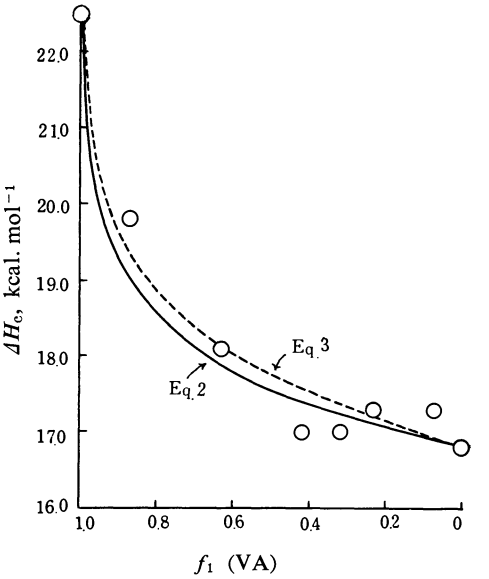

Fig. 2. Variation of ΔH_c with f_1 in the VA-AN system.
○ experimental values
Note: f_1 is a mole fraction of VA in the feed.

$$\Delta H_c = -0.76\,[1-(1-3.03F_1F_2)^{1/2}] + 22.49F_1 + 16.80F_2 \quad \text{for VA-AN} \quad (2)$$

As shown in Figs. 1 and 2, the values of ΔH_c in Tables II and III agree with the full lines expressing Eqs. 1 and 2. The dashed lines in these figures are drawn according to the following equation:

$$\Delta H_c = F_1\Delta H_{11} + F_2\Delta H_{22} \quad (3)$$

Rate of Copolymerization.—In Tables IV and V, the values of $1/\Delta t$, the rate of copolymerization and ϕ are shown, the details of calculation of which were shown in the previous paper[1].

As shown in Figs. 3 and 4, the theoretical curves obtained by substituting $\phi=80$ and $\phi=53$ (average values of ϕ_{exp}) into Walling's equation[11] agree with the experimental values. However, in order to explain the non-constancy of ϕ, the application of Arlman's[12] equation to these data must be considered. In the AN-St system, the curve shown in Fig. 5 was constructed by using Arlman's equation. The value of χ[1,12] is 0.05, and the corresponding value of ϕ_n[1,12] is 266. By using termination constants k_{taa} and k_{tbb} of each monomer alone, normal cross-termination constant k_{tbba} and constant k_{taba} of the cross-termination reaction having a penultimate unit are calculated[1]. These values are shown in Table VI.

Here, we took the values of k_{taa} and k_{tbb} at 25°C because the termination constant of AN is known only at 25°C and no activation energy

TABLE VI. VALUES OF k_{taa}, k_{tbb}, k_{tbba} AND k_{taba} FOR AN-St SYSTEM AT 25°C

$k_{taa}=1.22\times10^{7}$ [13] $k_{tbb}=2.79\times10^{6}$ [14]
$k_{tbba}=1.55\times10^{9}$ $k_{taba}=7.75\times10^{7}$

is available. From the results of Table VI, it is obvious that in the AN-St system, termination constants for mixed radicals are larger than those for homogeneous radicals and that the ratio of the normal cross-termination constant to the constant of the cross-termination having a penultimate unit is 20.

On the other hand, in the VA-AN system, the application of Arlman's equation was impossible. As explained in the case of the St-VA system[15], this seems to be due to the large difference between the reactivity ratios of the two monomers, which difference causes a large error limit in the calculated values of ϕ.

Summary

Rates of copolymerization of AN-St and VA-AN for various mixing ratios of the two monomers were measured by the thermistor method. The heat of copolymerization, which was obtained by comparing the results of the thermistor method with those of the usual analytical method, agrees very well with Alfrey's equation. Also, the non-constancy of ϕ in the AN-St system can be explained by Arlman's theory; it is concluded that the termination constants for mixed radicals are larger than those for homogeneous radicals and, furthermore, that the ratio of a normal cross-termintion constant to a constant of the cross-termination having a penultimate unit is 20.

However, in the VA-NA system, the application of Arlman's equation was impossible because the large difference between the reactivity ratios of the two monomers causes a large error limit in the calculated values of ϕ.

Hot-Atom Chemistry of Halogens in Cobaltammine Complex Salts. II. Hot-Atom Chemistry of Radiobromine in Pentammine Cobalt(III) Bromides and Bisethylenediamine Cobalt(III) Bromides

By Nobufusa SAITO, Takeshi TOMINAGA and Hirotoshi SANO

(Received May 2, 1961)

Among a number of studies of the hot-atom chemistry of complex compounds, only a few have contributed to elucidate the recoil reactions of ligand atoms or outer anions[1-6].

In the first paper of this series[2], the present authors reported on the behavior of radiobromine recoils in some neutron-irradiated bromopentammine cobalt(III) complex salts. They

found that radiobromine recoil atoms arising from thermal-neutron capture in outer anions of cobaltammine bromides could substitute in the cobalt co-ordination sphere to produce radiobromine-labeled complex cations[3].

In order to investigate the mechanism of such substitution of ligands by radiobromine recoil atoms, the present authors irradiated, with slow neutrons, solid complex salts of the formulas $[Co(NH_3)_5X]Br_{2,3}$ and $[Co(en)_2X_2]\cdot Br_{1,3}$, all of which contained different kinds of ligand (X), and bromine atoms outside the co-ordination sphere. It was found that the fraction of total radiobromine produced finally retained in ligands varied with the kind of ligand group, X, in each complex. A model has been proposed by the present authors to explain the experimental results.

Experimental

Sample.—Seventeen cobaltammine complex salts were prepared by well-known methods described in the literature:

1) $[Co(NH_3)_6]Br_3$[7]
2) $[Co(NH_3)_5NCS]Br_2$[8]
3) $[Co(NH_3)_5NO_2]Br_2$[9]
4) $[Co(NH_3)_5OH_2]Br_3$[10]
5) $[Co(NH_3)_5ONO]Br_2$[11]
6) $[Co(NH_3)_5ONO_2]Br_2$[12]
7) $[Co(NH_3)_5F]Br_2$[13]
8) $[Co(NH_3)_5Cl]Br_2$[14]
9) $[Co(NH_3)_5I]Br_2$[15]
10) $[Co(NH_3)_5Br]Br_2$[16]
11) $[Co(en)_3]Br_3\cdot 3H_2O$[17]
12) *trans*-$[Co(en)_2(NH_3)_2]Br_3\cdot H_2O$[18]
13) *trans*-$[Co(en)_2(NCS)_2]Br\cdot 1^1/_2\ H_2O$[19]
14) *cis*-$[Co(en)_2(NCS)_2]Br\cdot H_2O$[20]
15) *trans*-$[Co(en)_2Cl_2]Br$[21]
16) *cis*-$[Co(en)_2Cl_2]Br\cdot H_2O$[22]
17) *trans*-$[Co(en)_2Br_2]Br$[23]

Their composition and purity were checked by the spectrophotometric method and by the determination of halogen contents.

Irradiation.—Bombardments were made under conditions previously described[2].

Procedures of Separation.—The procedures of separation were similar to those employed for solid samples in the previous paper[2]. Two fractions were separated by means of a procedure involving a cation-exchange resin after dissolution of the activated salt. The first fraction contained bromide ions in the sample solution and anionic radiobromine. The second fraction contained ligand bromine, including its radioisotopes, which had been aquotized through digestion on a warm-bath and then extracted with water.

Measurements were made on each fraction with respect to the gross activity of ^{80m}Br (actually, of its daughter, ^{80}Br, in equilibrium) and ^{82}Br, and to the bromine content. The methods of determination have all been described previouly[2]. Although the hot-atom effects of ^{80m}Br and ^{82}Br, both arising from (n, γ) reactions, were observed at the same time, the contribution of ^{82}Br to the gross activity was, practically, small.

For convenience of discussion, the authors have defined the quantity "ligand yield", which indicates the fraction of the total activity produced retained in ligands of complex ions. "Ligand yield" was calculated as follows:

$$\text{Ligand yield} = \frac{\left(\begin{array}{c}\text{the activity of the}\\ \text{2nd fraction}\end{array}\right)}{\left(\begin{array}{c}\text{sum of the activtiy of the}\\ \text{1st and the 2nd fraction}\end{array}\right)} \times 100$$

Results and Discussion

Ligand Yield.—It was found by the present authors that energetic radiobromine atoms arising from the outside of the co-ordination sphere could substitute for ligands in these cobaltammine complex salts. The fraction of the radiobromine atoms retained in the ligands, or the ligand yield, is shown in Tables I and II.

As various complexes labeled with radiobromine (Br*) might be produced through reactions of hot radiobromine atoms with the target complex, the observed ligand yield was expected to be the sum of the fractions of radiobromine retained in ligands of such labeled complexes. Thus, on the irradiation of the complex salts of the formula $[Co(NH_3)_5\cdot X]Br_{2,3}$, some unstable radiobromine-labeled complexes ($[Co(NH_3)_4XBr^*]^{1,2+}$, etc.) of which the present authors have not yet confirmed the existence, might possibly be formed at first as

Table I. Ligand yield of irradiated complex salts, $[Co(NH_3)_5X]Br_{2,3}$

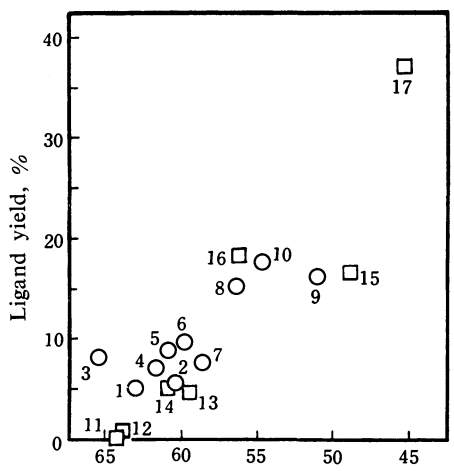
No.	Irradiated salt	Ligand yield[a], %	Enrichment factor
1	$[Co(NH_3)_6]Br_3$	4.8±0.2	4×10^2
2	$[Co(NH_3)_5NCS]Br_2$	5.7±0.3	1.2×10^2
3	$[Co(NH_3)_5NO_2]Br_2$	8.0±0.3	4×10^2
4	$[Co(NH_3)_5OH_2]Br_3$	7.1±0.7	0.2×10^2
5	$[Co(NH_3)_5ONO]Br_2$	8.8±0.1	9×10^2
6	$[Co(NH_3)_5ONO_2]Br_2$	9.0±0.3	0.3×10^2
7	$[Co(NH_3)_5F]Br_2$	7.3±0.6	6×10^2
8	$[Co(NH_3)_5Cl]Br_2$	15.2±0.4	3×10^2
9	$[Co(NH_3)_5I]Br_2$	15.8±0.4	5×10^2
10	$[Co(NH_3)_5Br]Br_2$	17.3±0.6	—

a) The ligand yield is nearly identical with the fraction (%) of radiobromine in the form of $[Co(NH_3)_5Br^*]^{2+}$.

Table II. Ligand yield of irradiated complex salts, $[Co(en)_2X_2]Br_{1,3}$

No.	Irradiated salt	Ligand yield[b], %	Enrichment factor
11	$[Co(en)_3]Br_3 \cdot 3H_2O$	0.0±0.1	—
12	*trans*-$[Co(en)_2(NH_3)_2] \cdot Br_3 \cdot H_2O$	0.8±0.1	0.8×10^2
13	*trans*-$[Co(en)_2(NCS)_2] \cdot Br \cdot 1^1/_2H_2O$	4.5±0.2	6×10^2
14	*cis*-$[Co(en)_2(NCS)_2]Br \cdot H_2O$	5.0±0.1	4×10^2
15	*trans*-$[Co(en)_2Cl_2]Br$	16.6±0.3	5×10^3
16	*cis*-$[Co(en)_2Cl_2]Br \cdot H_2O$	17.9±0.3	4×10^3
17	*trans*-$[Co(en)_2Br_2]Br$	37 ±2	—

b) The ligand yield denotes the fraction (%) of radiobromine in the form of $[Co(en)_2XBr^*]^{1,2+}$



well as the complex $[Co(NH_3)_5Br^*]^{2+}$. However, almost all radiobromine-labeled complexes other than $[Co(NH_3)_5Br^*]^{2+}$ were extremely unstable in aquotization, and adequate procedures of separation made it possible to determine the ligand yield as nearly entirely due to the stable complex $[Co(NH_3)_5Br^*]^{2+}$, without any appreciable contribution from unstable complexes.

In this investigation, the irradiated complex salts had been kept standing in aqueous solutions at room temperature for a sufficiently long time before the completion of the separation of the first fraction. By this treatment, most of the unstable radiobromine-labeled complexes, if they did exist at all, were aquotized and the labile radiobromine atoms extracted as anions into the first fraction, whereas the complex $[Co(NH_3)_5Br^*]^{2+}$ was not aquotized practically, keeping the radiobromine in ligands (i. e., in the second fraction). Therefore, the ligand yield shown in Table I may be considered to be nearly identical with the fraction of radiobromine in the form of $[Co(NH_3)_5Br^*]^{2+}$, which might be synthesized through replacement of X in $[Co(NH_3)_5X]^{2,3+}$ by Br*.

On the irradiation of the salts of the formula $[Co(en)_2X_2]Br_{1,3}$, the probability of the replacement of ethylenediamine molecules with radiobromine seemed to be very small (Table II). Thus, the ligand yield shown in Table II may be taken as indicating the fraction of radiobromine in the form of $[Co(en)_2XBr^*]^{1,2+}$.

Mechanism of Substitution of Ligands by Hot Radiobromine Atoms.—For both groups of complex salts shown in Tables I and II, the ligand yield was found to vary with the kind of ligand, X. Attempts to find the relationship between the ligand yield and the chemical or physical properties of the ligand X, might contribute to clarifying the mechanism by which radiobromine atoms substitute for ligands of the complex salts.

If radioactive complexes, $[Co(NH_3)_5Br^*]^{2+}$ and $[Co(en)_2XBr^*]^{1,2+}$, were produced through substitution of X in the target complex by a hot radiobromine atom (Br*), the ligand yields in the forms of such labeled complexes might be related to the stability of the ligand, X. With the cobalt complex salts studied in the present work, the relationship between their stability and the wavelength of the maximum in their optical absorption bands has been known as the spectrochemical series. In Fig. 1, the ligand yield was plotted against the frequency

Frequency of the maximum in the first absorption band, 10^{13}/sec.

Fig. 1. The relationship between the ligand yield and the frequency of the maximum in the first absorption band.
○ $[Co(NH_3)_5X]Br_{2,3}$
□ $[Co(en)_2X_2]Br_{1,3}$
Numbers in Figs. 1 and 2 correspond to those in Tables I and II.

of the maximum in the first absorption band of the target complex. Fig. 1 shows that the ligand yield roughly tends to increase with the decrease in the frequency of the maximum in the first absorption band or with the decrease in the stability of the ligand, X: the less stable the ligand X is, the more easily it is substituted for by hot radiobromine. However, the ligand yield in some complex salts was incompatible with the general tendency. For example, the ligand yield in $[Co(NH_3)_5 \cdot NO_2]Br_2$, which contained a very stable ligand NO_2, was considerably high, and the ligand yield in $[Co(NH_3)_5F]Br_2$, $[Co(NH_3)_5Cl]Br_2$, $[Co(NH_3)_5Br]Br_2$ and $[Co(NH_3)_5I]Br_2$, all of which contained halogen atoms (F, Cl, Br, I), did not increase in the order of the spectrochemical series.

As the maximum recoil energy of radiobromine resulting from slow neutron capture was calculated to be 174 eV.[24], most radiobromine atoms would recoil with energies larger than those which were involved in ordinary thermal reactions. Therefore, the present authors assumed a model in which collisions of a hot bromine atom with the donor atom in ligand X played an important role. When the masses of the donor atom in ligand X and of a bromine atom are M and M′ respectively, the fraction of the maximum possible loss in the recoiling energy of a hot bromine atom in an elastic collision with the donor atom is given as:

$$\gamma = 4MM'/(M+M')^2. \quad (1)$$

The calculated values of γ for donor atoms in different ligands, X, are shown in Table III. Fig. 2 shows the relationship between the ligand yield and the γ value for the complex salts listed in Tables I and II. As each complex molecule of the salts of the formula $[Co(en)_2X_2]Br_{1,3}$ contains more X's in ligands than that of $[Co(NH_3)_5X]Br_{2,3}$, the probability of the collision of a hot radiobromine atom with X may be somewhat larger for the salts

TABLE III. CALCULATED VALUES OF γ FOR THE DONOR ATOM IN LIGAND X IN A COLLISION WITH A HOT BROMINE ATOM

X	Donor atom	$\gamma=4MM'/(M+M')^2$

OH_2, ONO, ONO_2	O	0.56
F	F	0.64
Cl	Cl	0.85
I	I	0.95
Br	Br	1.00

24) A. C. Wahl and N. A. Bonner, "Radioactivity Applied to Chemistry", John Wiley & Sons, Inc., New York (1951), p. 247.

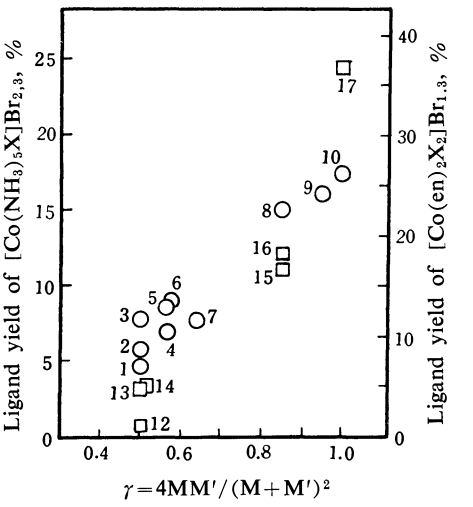

Fig. 2. The relationship between the ligand yield and the value of γ.
○ $[Co(NH_3)_5X]Br_{2,3}$
□ $[Co(en)_2X_2]Br_{1,3}$

of the former series*. Based on the available crystallochemical data, the ratio of relative collision cross sections of a bromine atom with X in ligands was estimated as about 1.5 : 1 for $[Co(en)_2X_2]Br$ and $[Co(NH_3)_5X]Br_2$. For convenience of comparison, these two series of complex salts, which did not seem much alike in crystal structure, are both shown in Fig. 2. Different ligand yield scales were used in Fig. 2 for the two series, considering the ratio of collision cross sections shown above. It is seen in Fig. 2 that the ligand yield tends to increase as the value of γ of the donor atom in ligands increases: the efficiency of replacement of X by a hot radiobromine atom depends mainly on γ.

It can be predicted on the collision model that a ligand group with the donor atom of a larger γ-value is more readily replaced by a hot radiobromine atom. As the experimental results are well explained by this model, the present authors presume that the kinetic processes might play an important role in determining the fate of hot radiobromine atoms, at least in the above solid complex salts. In addition to the kinetic processes, some chemical processes might contribute to determine the ligand yield at some stages in recoil reactions. However, it has not been unequivocally shown in the present work how much contribution such chemical processes make to the recoil reaction.

* Though the presence of crystalline water in some of the salts of the $[Co(en)_2X_2]Br_{1,2}$ series might possibly have more or less influence upon recoil reactions, the effect is not fully investigated in the present work.

Summary

The fate of energetic radiobromine atoms arising from the (n, γ) reaction on bromine in solid complex salts of the formulas $[Co(NH_3)_5X]Br_{2,3}$ and $[Co(en)_2X_2]Br_{1,3}$, was investigated. The fraction of the total radiobromine produced finally retained in ligands (ligand yield) was found to increase with a function of the mass of the donor atom in ligand X. Therefore, it was suggested that the kinetic processes might play an important role in recoil reaction in the solid complex salts.

*Diazo Reactions of 4-Aminotropolones**

By Kozo Doi

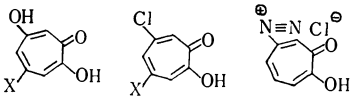
(Received May 9, 1961)

Recently the author[1] has synthesized 4-aminotropolone (I), 4-amino-6-methyltropolone (II) and 4-amino-6-isopropyltropolone (III) by an application of the elimination-addition mechanism[2] involving benzyne-type intermediate to the corresponding 3-iodotropolone. The author has also reported further synthetic methods of the aminotropolones, which include applications of the Curtius reaction to 4-carboxytropolones[1] and of the Schmidt reaction to acetyl, formyl and isopropenyl derivatives of tropolones[3], and the reaction of 4-bromotropolone and ammonia[4].

I: X=H II: X=Me
III: X=*iso*-Pr

On the other hand, there have been rare observations of the reactivities of 4-aminotropolones, except in the case of the diazotization of a methyl analogue II, in which instance the corresponding hydroxytropolone (V) was obtained without detecting the intermediate diazonium salt[5]. In the previous papers the author stated in brief some synthetic applications of the aminotropolone (I), involving preparations of some pyridotropolones[6] and of 4-aminotropone[7]. Furthermore, the author has very recently reported that the aminotropolone (I), differing from the isomeric 3- and 5-aminotropolones, undergoes some electrophilic substitutions to give normal nuclear substitution products[8].

It is well-known that diazotization of 5-aminotropolones results in formation of diazonium salts, which undergo the Sandmeyer reaction in the presence of cuprous salt to replace the amino group by halogen, nitrile and alkoxyl groups[9]. On the other hand, the diazotization of 3-aminotropolones is also known to undergo the Sandmeyer reaction[10], although accompanied by aromatization into the corresponding salicylic acid[11], forming 3-halogenotropolones and 3-hydroxytropolones under a certain reaction condition[12].



In this communication the author wishes to describe the diazotizations of the above three 4-aminotropolones in comparison with those of the 3- and 5-isomers.

On diazotization in a sulfuric acid solution the aminotropolones afford the corresponding hydroxytropolones, in neither case of which the addition of alkaline β-naphthol to the diazotized solution causes red coloration, as observed by Haworth and his co-workers[5]. The melting points and ultraviolet absorptions

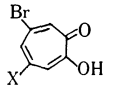
of 4-hydroxytropolone[13] (IV) and 4-hydroxy-6-methyltropolone[5] (V) respectively are in essentially good agreement with those reported. 4-Hydroxy-6-isopropyltropolone (VI) was also ascertained to agree with reaction product[14], obtained by high temperature alkaline hydrolysis of 3-bromo-6-isopropyltropolone.



IV: X=H VII: X=H
V: X=Me VIII: X=Me X
VI: X=*iso*-Pr IX: X=*iso*-Pr

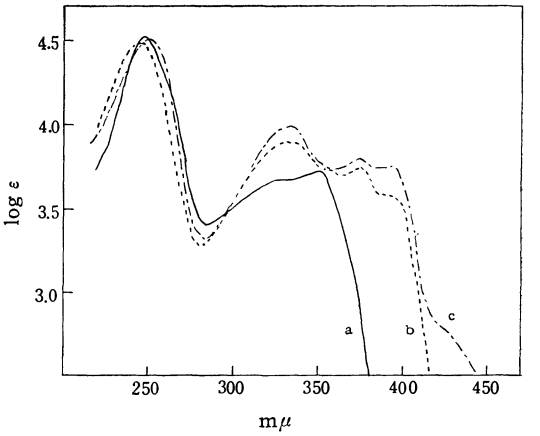
On diazotization in a dilute hydrochloric acid solution in place of sulfuric acid, the aminotropolones form corresponding 4-chlorotropolones in a good yield, even without any catalyst such as cuprous chloride or copper. 4-Chlorotropolone (VII) is in good agreement with an authentic sample[15] in both its melting point and ultraviolet absorption spectrum. The structures of 4-chloro-6-methyl-VIII and 4-chloro-6-isopropyltropolones (IX) are reasonably understood from the comparison of their ultraviolet absorptions with that of VII.

An isolation of a stable diazonium salt was possible in some cases. For instance, in a concentrated hydrochloric acid solution, 4-aminotropolone (I) results in facile diazotization, even in a state of suspension, and converts into yellow tropolone-4-diazonium chloride (X), which undergoes red coloration with alkaline β-naphthol. This diazonium salt gives the chloro derivative VII on being heated with copper powder under the vigorous evolution of nitrogen, 4-methoxytropolone on being heated with methanol, and 4-cyanotropolone on reaction with cuprous cyanide. From alkyl derivatives II and III, the corresponding diazonium salt has not been isolated in a solid state, but it seems to be formed as an intermediate in the above reactions.

In a similar manner, the use of hydrobromic acid in place of hydrochloric acid in the diazotization results also in the formation of corresponding bromotropolones without any catalyst. 4-Bromotropolone (XI) was identified with an authentic specimen[4] by the determination of the mixed melting point and by a comparison of the ultraviolet absorption. The structures of the other reaction products XII and XIII are assumed from the similarity of their ultraviolet absorptions to that of XI.

XI: X=H XII: X=Me
XIII: X=*iso*-Pr

Fig. 1 indicates the ultraviolet absorption spectra of hydroxyl (IV), chloro (VII), and bromo (XI) derivatives obtained from 4-aminotropolone (I). The ultraviolet spectra of the alkyl derivatives of the above three products resemble essentially that of the respective product from I.



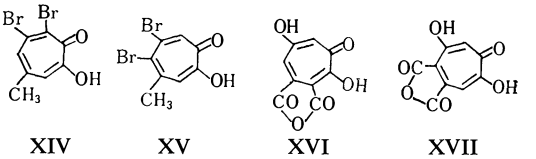


Fig. 1. The ultraviolet absorption spectra.
a: 4-Hydroxytropolone (IV)
b: 4-Chlorotropolone (VII)
c: 4-Bromotropolone (XI)

When diazotized in an concentrated hydrobromic acid solution, 4-amino-6-methyltropolone (II) has been found to yield not only 4-bromo-6-methyltropolone (XI) but also an unexpected

XIV XV XVI XVII

product, dibromo-methyltropolone. The ultraviolet absorption spectrum of this anomalously produced dibromotropolone resembles not so much that of 3,6-dibromotropolone as that of the 4-bromo derivative XI, although indicating a bathochromic shift by the introduction of one bromine atom (Fig. 2). For the above reason, the dibromo-methyltropolone is probably a nuclear substitution product, namely XIV or XV.

Whether the dibromotropolone is XIV or XV is reasonably suggested by its infrared absorption spectra. Table I indicates the absorption bands in the CH out-of-plane vibration regions

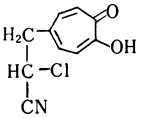
c: 5-(β-Chloro-β-cyanoethyl)tropolone (XVIII)

TABLE I. FREQUENCIES IN THE CH OUT-OF-PLANE VIBRATION REGION OF THE INFRARED SPECTRA OF SOME TRISUBSTITUTED TROPOLONES (cm^{-1})



XIV	896	867	823	795	735
XVI	896	865	806	774	730
XVII	—	—	814	763, 782	740

of the infrared spectra of the dibromotropolone, 6-hydroxytropolone-3, 4-dicarboxylic anhydride[16] (XVI) (3, 4, 6-trisubstituted tropolone), and stipitatonic acid[16] (XVII) (4, 5, 6-trisubstituted tropolone). Undoubtedly these absorptions of the dibromo-methyltropolone resemble not so much those of XVII as of XVI, and therefore, the dibromotropolone seems to be 3, 4-dibromo-6-methyltropolone (XIV) rather than 4, 5-dibromo-6-methyltropolone (XV).

The formation of this dibromotropolone (XIV) is probably interpreted to be due to further bromination of XI, which has been produced normally in the diazotization, with free bromine formed by an oxidation of hydrobromic acid with nitrous acid. A similar example was reported in the formation of 3, 5-dibromotropolone from 3- and 5-nitrotropolone when heated with hydrobromic acid[17].

The above description has demonstrated that the diazotizations of 4-aminotropolones result in the formation of diazonium salt, which reacts immediately with anions of the acid used to give the halogeno- or hydroxytropolones without any catalyst such as cuprous salt or copper. Such a fact has not been found in the other isomeric aminotropolones. This is probably to be understood as a competitive action of an electron-withdrawing effect of the diazonium group and a conjugate acid-forming effect of the tropolone ring with the acid used, resulting in promotion of the formation of a carbonium ion, which combines immediately with anions from the acid used to form substitution product.

In relation to the diazotization of the 4-aminotropolones, the author has investigated the reaction of 5-diazotized aminotropolone and acrylonitrile under the Meerwein condition to obtain 5-(β-chloro-β-cyanoethyl)tropolone (XVIII), although in a poor yield. The structure of this product XVIII is probably supported by the resemblance of the ultraviolet absorption (Fig. 2) to those of 5-alkyltropolones and by the result obtained in the reaction of diazotized aniline and acrylonitrile[18].

XVIII

Experimental

All of the ultraviolet absorption spectra were measured in methanol solution with a Beckman model DU quartz spectrophotometer. The infrared spectra were measured on potassium bromide disks with a Perkin-Elmer model 21 infrared spectrometer, using a rock salt prism.

4-Hydroxytropolone (IV).—A solution of sodium nitrite (70 mg.) and water (1 ml.) was added, drop by drop, for 5 min. into a cold suspension of 4-aminotropolone (I, 140 mg.), concentrated sulfuric acid (0.5 ml.) and water (5 ml.). After 30 min., the reaction mixture was gradually warmed up to 50°C, by which means a complete solution was effected. Then the mixture was diluted with water (20 ml.) and extracted continuously with ether for 8 hr. The residue obtained by the evaporation of the ether extract, after sublimation in vacuo and subsequent crystallization from acetic acid, afforded IV (60 mg.) as colorless needles, m. p. 230~231°C, undepressed on admixture with an authentic sample[13].

4-Hydroxy-6-methyltropolone (V).—A solution of sodium nitrite (70 mg.) and water (1 ml.) was added dropwise into a cold, stirred solution of 4-amino-6-methyltropolone (II, 150 mg.), concentrated sulfuric acid (0.5 ml.) and water (10 ml.). The reaction mixture was then treated as in the above case, and V (60 mg.) was obtained as colorless prisms, m. p. 241~242°C, undepressed on admixture with an authentic specimen[5].

4-Hydroxy-6-isopropyltropolone (VI).—A solution of sodium nitrite (70 mg.) and water (1 ml.) was added dropwise into a cold, stirred solution of 4-amino-6-isopropyltropolone (III, 180 mg.), concentrated sulfuric acid (0.5 ml.), and water (10 ml.) for 5 min. After 30 min., the reaction mixture was

16) K. Doi and Y. Kitahara, This Bulletin, 31, 788 (1958).
17) T. Nozoe, Y. Kitahara, K. Doi and T. Arai, *Bull. Chem. Res. Inst. Non-Aqueous Solutions, Tohoku Univ.*, 7, 13 (1957).

extracted with three 20-ml. portions of chloroform, and the residue obtained by evaporation of the chloroform extract was sublimed in vacuo. Recrystallization of the sublimate from dilute methanol gave VI (100 mg.) as colorless prisms, m.p. 178~179°C, undepressed on admixture with an authentic sample[14].

4-Chlorotropolone (VIII).—To a cold, stirred mixture of 4-aminotropolone (I, 70 mg.), concentrated hydrochloric acid (1 ml.) and water (2 ml.) was added dropwise for 5 min. a solution of sodium nitrite (40 mg.) and water (0.5 ml). Then the mixture was warmed gradually to 40°C, by which the suspended solid dissolved with evolution of gas to form a clear solution. This solution was extracted with three 3-ml. portions of chloroform, and the residue therefrom was recrystallized from cyclohexane. VII (50 mg.) was obtained as pale yellow needles, m. p. 78~79°C, undepressed on admixture with an authentic sample[15].

4-Chloro-6-methyltropolone (VIII).—A solution of sodium nitrite (70 mg.) and water (1 ml.) was added dropwise into a cold, stirred solution of 4-amino-6-methyltropolone (II, 150 mg.), concentrated hydrochloric acid (5 ml.), and water (2 ml.). With the progress of the diazotization, the colorless solid separated out from the reaction mixture. After stirring for 2 hr., the reaction mixture was diluted with water (10 ml.) and extracted with three 20-ml. portions of chloroform. The residue obtained by evaporation of the extract, after sublimation in vacuo and subsequent crystallization from cyclohexane, yielded VIII (120 mg.) as colorless needles, m. p. 117°C.

Found: C, 56.19; H, 4.62. Calcd. for $C_8H_7O_2Cl$: C, 56.30; H, 4.16%. λ_{max} mμ (log ε): 246 (4.49), 334 (3.90), 373 (3.78).

4-Chloro-6-isopropyltropolone (IX).—To a cold, stirred solution of 4-amino-6-isopropyltropolone (III, 180 mg.), concentrated hydrochloric acid (2 ml.) and water (2 ml.), was added dropwise a solution of sodium nitrite (70 mg.) and water (1 ml.). With the progress of the diazotization, the colorless solid precipitated out. The reaction mixture was treated as above and recrystallization of the final sublimate from petroleum ether (b. p. 40~60°C) afforded IX (110 mg.) as pale yellow needles, m. p. 42~43°C.

Found: C, 60.23; H, 5.86. Calcd. for $C_{10}H_{11}O_2Cl$: C, 60.46; H, 5.59%. λ_{max} mμ (log ε): 248 (4.51), 334 (3.94), 373 (3.78).

Tropolone-4-diazonium Chloride (X).—A solution of sodium nitrite (280 mg.) and water (1 ml.) was added dropwise into a cold, stirred mixture of 4-aminotropolone (I, 550 mg.), concentrated hydrochloric acid (20 ml.) and water (6 ml.), and then the reaction mixture was stirred for an hour at 0°C. The colorless solid turned gradually into a yellow solid with the progress of the diazotization. The residual yellow solid was collected by filtration to give X (0.31 g.), m. p. 100~103°C (decomp.). From the filtrate 4-chlorotropolone (120 mg.) was obtained.

The diazonium salt X showed red coloration on being added into an alkaline solution of β-naphthol, and yielded 4-chlorotropolone on being heated with copper bronze in benzene.

4-Methoxytropolone from X.—To a cold, stirred mixture of the diazonium salt (X, 100 mg.) and methanol (5 ml.) was added copper bronze (10 mg.). The reaction mixture turned into a deep red solution with the evolution of nitrogen, and then it was stirred for an hour at room temperature. The filtrate, after removal of copper, evaporation of the solvent, sublimation in vacuo and subsequent crystallization from methamol, gave 4-methoxytropolone (20 mg.) as colorless leaflets, m. p. 95°C, undepressed on admixture with an authentic sample[13].

4-Cyanotropolone from X.—To a stirred mixture of potassium cyanide (700 mg.), cuprous cyanide (450 mg.) and water (2 ml.), was added the diazonium salt (X, 400 mg.) at room temperature. The mixture was stirred for another hour and then warmed gradually to 50°C. Hydrogen sulfide was passed through the mixture, chloroform (10 ml.) was added, and some insoluble matter was removed by filtration. The chlorform solution, after evaporation of the solvent in vacuo, gave 4-cyanotropolone (40 mg.) as yellow needles, m. p. 194°C, undepressed on admixture with an authentic sample[4].

4-Bromotropolone (XI).—A solution of sodium nitrite (70 mg.) and water (1 ml.) was added dropwise under cooling into a stirred mixture of the aminotropolone (I, 140 mg.), concentrated hydrobromic acid (4 ml.) and water (2 ml.). With the progress of the diazotization, the reaction mixture became a clear solution under evolution of nitrogen. After 2 hr., the reaction mixture was diluted with water (40 ml.) and extracted with three 30-ml. portions of chloroform. The residue obtained by evaporation of the solvent of the extract, after sublimation in vacuo and subsquent crystallization from cyclohexane, afforded XI (100 mg.) as pale yellow needles, m. p. 85~86°C, undepressed on admixture with an authentic specimen[4].

4-Bromo-6-methyltropolone (XII).—A mixture of the aminotropolone (II, 150 mg.), concentrated hydrobromic acid (2 ml.) and water (4 ml.) was diazotized with a solution of sodium nitrite (70 mg.) and water (1 ml.). As treated similarly to the above case, the reaction mixture afforded XII (120 mg.) as pale yellow needles (cyclohexane), m. p. 116~117°C.

Found: C, 44.50; H, 3.34. Calcd. for $C_8H_7O_2Br$: C, 44.68; H, 3.28%. λ_{max} mμ (log ε): 253 (4.50), 336 (3.87), 370 (3.76), 395 (3.49).

4-Bromo-6-isopropyltropolone (XIII).—A solution of the aminotropolone (III, 90 mg.), concentrated hydrobromic acid (1 ml.) and water (2 ml.) was diazotized with a solution of sodium nitrite (40 mg.) and water (1 ml.). The procedure followed for isolating the product was essentially the same as above, and the reaction product XIII (20 mg.) was obtained. Analytical sample was crystallized from petroleum ether (b. p. 40~60°C) as pale yellow needles, m. p. 52~53°C.

Found: C, 49.19; H, 4.32. Calcd. for $C_{10}H_{11}O_2Br$: C, 49.38; H, 4.52%. λ_{max} mμ (log ε): 255 (4.49), 335 (3.38), 370 (3.74), 393 (3.48).

3, 4-Dibromo-6-methyltropolone (XIV).—A solution of sodium nitrite (70 mg.) and water (1 ml.) was added dropwise into a cold, stirred mixture of the aminotropolone (II, 150 mg.), concentrated hydrobromic acid (8 ml.) and water (2 ml.). After

being stirred for 3 hr. further, the reaction mixture was diluted with water (20 ml.), extracted with three 20-ml. portions of chloroform, and the solvent of the extract was evaporated in vacuo. The residual solid, m. p. 104~110°C, was dissolved in cyclohexane (50 ml.) and chromatographed on a column of silica gel (1.5×20 cm.). From the more soluble eluate, the monobromotropolone (XII, 40 mg., m. p. and mixed m. p. 116~117°C), was obtained, and from the less soluble eluate the dibromotropolone (XIV, 60 mg.) was obtained as pale yellow prisms (from ligroin), m. p. 127°C.

Found: C, 32.41; H, 2.31. Calcd. for $C_8H_6O_2Br_2$: C, 32.69; H, 2.06%. λ_{max} mμ (log ε): 264 (4.47), 345 (3.83), 383 (3.74), 410 (3.74).

5-(β-Chloro-β-cyanoethyl)tropolone (XVIII).—A cold solution of 5-aminotropolone (4.1 g.), concentrated hydrochloric acid (6 ml.), water (12 ml.), and dioxane (10 ml.) was diazotized with a solution of sodium nitrite (2.2 g.) and water (4 ml.). This diazonium salt solution was added dropwise under cooling to a stirred mixture of acrylonitrile (1.6 g.), sodium acetate trihydrate (4.1 g), cupric chloride (4 g.), water (6 ml.), and acetone (50 ml.), and the reaction mixture was stirred overnight at room temperature. Then the mixture was separated by filtration into the solid and the filtrate. The former afforded, after treatment with hydrogen sulfide, 5-chlorotropolone, m. p. and mixed[9] m. p. 180~181°C.

The filtrate was diluted with water (50 ml.), extracted with three 50-ml. portions of chloroform, and hydrogen sulfide was introduced into this extract. The chloroform solution, from which copper sulfide was removed, was evaporated in vacuo and the residual resinous matter was re-extracted with hot cyclohexane (100 ml.). The residue obtained on evaporation of the cyclohexane extract was separated by fractional sublimation into the two parts, A, which sublimed up to 120°C/2 mmHg (bath temp.), and B, which sublimed up to 170°C. The fraction. A was crystallized from cyclohexane to afford XVIII (20 mg.) as colorless leaflets, m. p. 119~120°C.

Found: C, 57.40; H, 3.72; N, 6.73. Calcd. for $C_{10}H_8O_2NCl$: C, 57.29; H, 3.80; N, 6.67%. λ_{max} mμ (log ε): 235 (4.36), 325 (2.92).

From the fraction B, 5-chlorotropolone (0.7 g.) was obtained.

The author wishes to express his deep gratitude to Professor Yoshio Kitahara for his kind guidance, to Professor Sekio Mitsui for supplying acrylonitrile, to Mr. Hideji Aono for infrared spectral measurements, and to Messrs. Shin-ichi Ohyama, Kuni Kato and Ayako Iwanaga for microanalyses.

Dehydration Reaction of Hydroxamic Acids with Unsaturated Ethers

By Teruaki MUKAIYAMA, Hiroyuki NOHIRA and Siro ASANO

(Received May 18, 1961)

In a preceding paper[1] a successful method for the conversion of hydroxamic acids into isocyanates by means of a ketene dimer has been described. It is one of the improved methods of Lossen rearrangement. In the present study, the dehydration of hydroxamic acids with organic reagents is extended to some unsaturated ethers. The dehydration by means of acetylenic ether was tried first, since acetylenic ether is hydrated to give carboxylic ester, which is unreactive with isocyanate and is known to be an effective reagent for the dehydrations of carboxylic acids, phosphoric acids[2], primary nitroparaffins[3,4] and aldoximes[4,5] into carboxylic acid anhydrides, pyrophosphoric acids, nitrile oxides and nitriles, respectively. It has also been confirmed that initially-formed addition compounds of acetylenic ether with the above-mentioned compounds are the necessary intermediate for these reactions.

It has been now established that without a catalyst benzhydroxamic acid does not react with ethoxyacetylene, but the reaction is carried out easily at about 40~50°C in the presence of a catalytic amount of boron trifluoride in tetrahydrofuran to give an addition compound. After removal of the solvent, the

* EA = Ethoxyacetylene

adduct is obtained as a viscous liquid which decomposes at about 90°C. When it was decomposed in a Claisen flask at a temperature between 90~110°C under reduced pressure, phenyl isocyanate was obtained in a 65% yield along with ethyl acetate.

$$CH{\equiv}COC_2H_5 + R{-}\overset{\overset{O}{\|}}{C}NHOH \longrightarrow$$

$$\left(CH_2{=}C\begin{matrix}OC_2H_5\\ ONHC{-}R\\ \quad\|\\ \quad O\end{matrix}\right) \longrightarrow CH_3{-}\overset{\overset{O}{\|}}{C}{-}OC_2H_5 + R{-}NCO$$

I

In order to obtain a variety of isocyanates by this process, the reactions of hydroxamic acids with acetylenic ether were examined, and successful results were obtained. The results of the experiments are summarized in Table I.

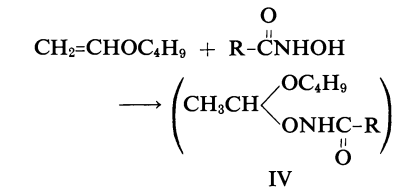
In the next place, dehydration with methylketone diethylacetal, a compound which possesses a similar dehydrating ability, was tried. In this connection, the dehydration of aldoximes with methylketone diethylacetal has been already examined, and an interesting reaction, to give isonitriles, rearranged products, has been reported[4,6]. It was found that a variety of hydroxamic acids react with methylketene diethylacetal at 30~50°C without a catalyst to give addition compounds. These adducts II are unstable, viscous liquids and could not be isolated as pure liquids or crystaline substances. However, by their decomposition at 80~100°C under reduced pressure, the corresponding isocyanates are obtained in good yields along with ethyl propionate and ethanol.

In the course of attempts to isolate the adducts II, a crystalline substance (m. p. 86~86.5°C decomp.) was obtained from the reaction mixture of p-nitrobenzhydroxamic acid and methylketene diethylacetal. From the results of the elementary analyses, the infrared spectra and some other examinations, the structure of this substance was concluded to be III, 1-ethoxypropenyl-1-p-nitrobenzhydroxamate. It decomposes into p-nitrophenyl isocyanate and ethyl propionate almost quantitatively. In addition, the same substance is obtained by the reaction of p-nitrobenzhydroxamic acid and ethyl orthopropionate; this reaction is also considered to proceed through the same intermediate II, as is shown in the following equations:

$$CH_3CH{=}C\begin{matrix}OC_2H_5\\ OC_2H_5\end{matrix} + R{-}\overset{\overset{O}{\|}}{C}NHOH \longrightarrow \left(CH_3CH_2C\begin{matrix}OC_2H_2\\ OC_2H_5\\ ONHC{-}R\\ \quad\|\\ \quad O\end{matrix}\right)$$

or

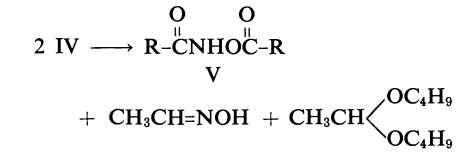
$$CH_3CH_2{-}C\begin{matrix}OC_2H_5\\ OC_2H_5\\ OC_2H_5\end{matrix}$$



II

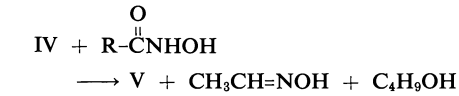
$$CH_3CH{=}C\begin{matrix}OC_2H_5\\ ONHC{-}R\\ \quad\|\\ \quad O\end{matrix} \longrightarrow CH_3CH_2\overset{\overset{O}{\|}}{C}OC_2H_5 + R{-}NCO + C_2H_5OH$$

III



Finally, the dehydration of hydroxamic acids with vinyl ether, which has been confirmed to be an effective reagent for the dehydration of benzaldoxime into benzonitrile[5], was examined. Analogous to the reaction described above, benzhydroxamic acid reacts with n-butylvinyl ether in the presence of a catalytic amount of phosphoric acid to give an adduct as a viscous liquid.

6) T. Mukaiyama, K. Tonooka and K. Inoue, *J. Org. Chem.*, **26**, 2202 (1961).



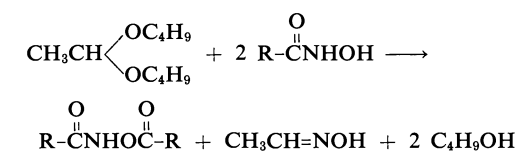
IV

This adduct could not be isolated pure, but it was confirmed to possess the structure of IV from its infrared spectrum. It decomposes, against expectation, however, at a relatively low temperature (50~70°C) into dibenzhydroxamic acid (or benzoyl benzhydroxamate) (V), acetaldoxime, acetaldehyde dibutylacetal and butanol. The formation of these products may be explained by the following two equations:

V

and

Dibenzhydroxamic acid (m. p. 163~164°C) is identified with an authentic sample, showing no depression in mixed melting points. The presence of acetaldoxime, acetaldehyde dibutylacetal and butanol is confirmed by fractional distillation and gas-chromatographic analysis.



This type of reaction, to produce dihydroxamic acids from hydroxamic acids by the action of ethyl acetoacetate or potassium cyanide, has been reported by Moissan[7], wherein it was suggested that this reaction is equivalent to 1 mol. dehydroxylamination from 2 mol. of hydroxamic acids. But some points concerning the mechanism of the reaction have remained unclarified.

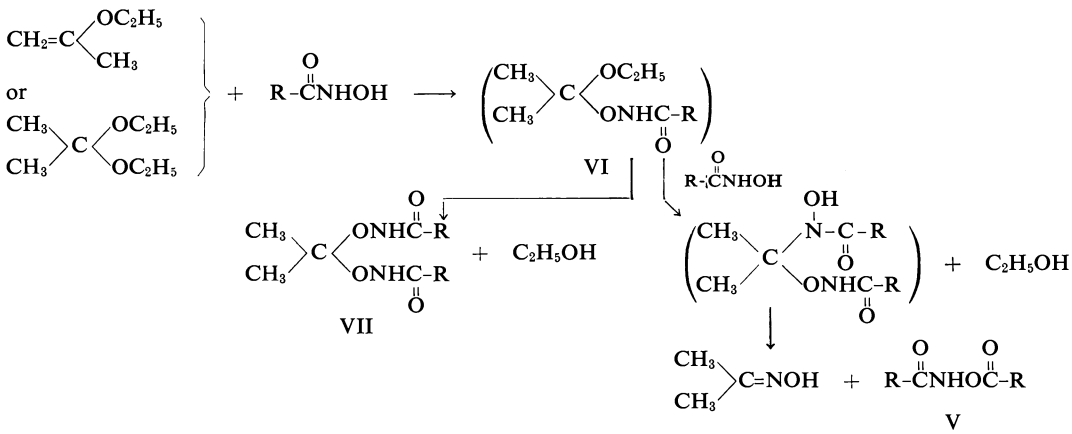


Table II. Reactions to give dihydroxamic acids

Hydroxamic acid R-CNHOH (R=)	Dehydroxylaminating reagent	Dihydroxamic acid R-CNHOC-R Yield %	M. p. °C
$C_6H_5CH_2$-	*n*-Butyl vinyl ether	37	150~151
p-$CH_3OC_6H_4$-	*n*-Butyl vinyl ether	47	143~143.5
p-$CH_3C_6H_4$-	*n*-Butyl vinyl ether	52	156~157
p-$NO_2C_6H_4$-	*n*-Butyl vinyl ether	27	174.5
C_6H_5-	*o*-Nitrobenzaldehyde	38	163~164
C_6H_5-	Acetaldehyde di-*n*-butylacetal	77	163~164

It is now established that a variety of hydroxamic acids react with *n*-butyl vinyl ether under the same condition as has been mentioned in the case of benzhydroxamic acid to give corresponding dihydroxamic acids (Table II). Further experiments were tried in order to ascertain whether or not carbonyl compounds or their derivatives, which are able to react with hydroxylamine to give oximes, are effective in this type of reaction. Analogous to the reaction of vinyl ether, dibenzhydroxamic acid has been obtained by the reaction of benzhydroxamic acid with acetaldehyde dibutylacetal, *o*-nitrobenzaldehyde, ethylpropenyl ether or acetone diethylketal. When acetaldehyde dibutylacetal is used, for example, the reaction is shown by the following equation.

7) M. U. Moissan, *Compt. rend.*, **140**, 1398 (1905).

In this case, the reaction is thought to proceed through the intermediate IV, and this result, together with the formation of III from ethyl orthopropionate, suggests that the ethoxyl group in orthoester or acetal is easily replaced by the -ONHCO-R group. This has been further confirmed by the following evidence.

When ethyl propenyl ether or acetone diethylketal was used, a crystalline product which melts at 160~161°C was isolated along with dibenzhydroxamic acid and identified as isopropylidene bis-benzhydroxamic acid, VII. Therefore these reactions are thought to proceed via the intermediate VI, which in turn changes into V or VII.

Experimental

Reaction of Benzhydroxamic Acid with Ethoxyacetylene.—A solution of ethoxyacetylene (1.1 g., 0.016 mol.) in 7 ml. of dry tetrahydrofuran was added dropwise with stirring over a period of 10 min. into a suspension of benzhydroxamic acid (2.0 g., 0.015 mol.) and 3 drops of boron trifluoride etherate in 8 ml. of tetrahydrofuran at 40°C. After the addition was completed, the mixture was stirred for an additional hour. The solvent was subsequently removed under reduced pressure, and an adduct I ($R = C_6H_5-$) was obtained as a viscous liquid which decomposed at about 100°C. By the decomposition of this adduct in a Claisen flask at 90~100°C under reduced pressure (12~15 mmHg), 1.1 g. (65%) of phenyl isocyanate was obtained, along with 0.8 g. (60%) of ethyl acetate.

Similarly, benzyl-, *p*-anisyl-, *p*-tolyl-, *p*-chlorophenyl-, *p*-nitrophenyl and *m*-nitrophenyl isocyanate were obtained from corresponding hydroxamic acids. Their experimental conditions and yields are listed in Table I.

Reaction of Benzhydroxamic Acid with Methylketene Diethylacetal.—A mixture of benzhydroxamic acid (4.11 g., 0.03 mol.) and methylketene diethylacetal (7.8 g., 0.06 mol.) in 30 ml. of dry ether was stirred for 3 hr. at 30°C. After the mixture became homogeneous, the solvent was removed under reduced pressure, and an adduct II ($R = C_6H_5-$) was obtained as a colorless, viscous liquid. By a similar pyrolytic process, it decomposed into ethyl propionate, phenyl isocyanate and ethanol in a high yield. Phenyl isocyanate was converted into diphenylurea by the addition of aniline (2.81 g., 0.03 mol.) to the pyrolyzate, which was collected in a cooled trap; 5.28 g. (83%, m. p. 238~239°C) of sym-diphenylurea was obtained.

Similarly, benzyl- and *p*-anisyl isocyanate were obtained from corresponding hydroxamic acids in yields ranging from 50 to 85%.

Formation of 1-Ethoxyprophenyl-1-*p*-nitrobenzhydroxamate (III).—A mixture of *p*-nitrobenzhydroxamic acid (6.6 g., 0.036 mol.) and methylketene diethylacetal (8.0 g., 0.062 mol.) in 70 ml. of dry ether was stirred for 4 hr. at 30°C. After the mixture became homogeneous, the solvent was removed under reduced pressure, and 8.9 g. (92%) of III ($R = NO_2-C_6H_4-$), was obtained as pale yellow crystalline. It was recrystallized from ether, m. p. 86~86.5°C, decomp.

Found: C, 54.41; H, 5.39; N, 10.62. Calcd. for $C_{12}H_{14}N_2O_5$; C, 54.13; H, 5.30; N, 10.52%.

It was readily soluble in ether, ethanol and sparingly in benzene and carbon tetrachloride. Its hydrolysis in dilute hydrochloric acid and ethanol gave *p*-nitrobenzhydroxamic acid, which was confirmed by its characteristic color reaction with ferric chloride. The infrared absorption bands are 3060~3125 cm^{-1} m (broad), 2986m, 2930m, 1635w (shoulder), 1600s, 1520w (shoulder), 1435m, 1310m, 1235s, 1155s, 1109w, 1075s, 1030w, 972s, 943m, 870m, 857m, 810m, (Nujol or carbon tetrachloride solution, s=strong, m=medium, w=weak).

Similarly, the same substance III was obtained from the reaction of *p*-nitrobenzhydroxamic acid with ethyl orthopropionate in an 82% yield.

Decomposition of III.—The above-mentioned III (5.32 g., 0.02 mol.) was decomposed under reduced pressure (17~18 mmHg) in a 50 ml. Claisen flask heated in an oil bath (150°C). The low boiling part of the pyrolyzate was collected in a cooled trap, from which 1.54 g. (75%, b. p. 98~99°C) of ethyl propionate was obtained by distillation. Separately, 2.73 g. (91%, m. p. 53~55°C) of *p*-nitrophenyl isocyanate was obtained from the pyrolysate which remained in the flask (recrystallization from chloroform).

Reaction of Benzhydroxamic Acid with *n*-Butyl Vinyl Ether.—A mixture of benzhydroxamic acid (2.75 g., 0.02 mol.), *n*-butyl vinyl ether (2.0 g., 0.02 mol.) and 2 drops of phosphoric acid (85%) in 11 ml. of ethyl acetate was refluxed for 3 hr., cooled and filtered. The precipitate of dibenzhydroxamic acid was washed with warm water and recrystallized from ethyl acetate (yield, 1.35 g. 56%, m. p. 163~164°C). By fractional distillation of the filtrate, two fractions of A (37~42°C/12.5 mmHg, 0.62 g.) and B (65~75°C/12.5 mmHg, 0.45 g.) were obtained. The fraction A was identified as a mixture of acetaldoxime and *n*-butanol by gas-chromatographic analysis, while the B was acetaldehyde di-*n*-butylacetal.

Similarly, a variety of dibenzhydroxamic acids were obtained from the reaction of corresponding hydroxamic acids with *n*-butyl vinyl ether or some other reagents. The results of all the experiments are summarized in Table II.

Formation of the Intermediate IV.—A mixture of benzhydroxamic acid (2.75 g. 0.02 mol.), *n*-butyl vinyl ether (2.0 g., 0.02 mol.) and 2 drops of phosphoric acid was warmed without a solvent at 50°C for an hour, and an adduct IV ($R = C_6H_5-$) was obtained as a viscous liquid. The infrared absorption bands of a carbon tetrachloride solution are at 3404 cm^{-1}(w) attributed to the free N-H group and at 3225 cm^{-1}(m) (broad) to the associated N-H group. Bands due either to the O-H group of hydroxamic acid or to the $C{=}CH_2$ group of vinyl ether were not observed. This intermediate IV decomposed to give dihydroxamic acid on heating, and even at room temperature it changed slowly to give dihydroxamic acid.

Formation of Isopropylidene-bis-benzhydroxamic Acid VII.—A mixture of benzhydroxamic acid

(2.75 g., 0.02 mol.) and isopropenyl ether (1.72 g., 0.02 mol.) in 10 ml. of ethyl acetate was refluxed for an hour in the presence of *p*-toluenesulfonic acid (0.03 g.). The solvent was removed under reduced pressure, and the residue was washed with ether and subsequently with warm water. It was then dried and weighed (1.1 g., m. p. 140~146°C). By fractional crystallization from ethyl acetate, 0.5 g. of VII (R = C_6H_5-, m. p. 160~161°C) and 0.1 g. of dibenzhydroxamic acid (m. p. 163~164°C) were obtained.

Found (for VII): C, 65.02; H, 5.89; N, 9.17. Calcd. for $C_{17}H_{18}N_2O_4$: C, 64.95; H, 5.77; N, 8.91%.

The infrared absorption bands are 3175 cm^{-1} m (broad), 2955s, 2890m, 1658s, 1592m, 1326m, 1205w, 1159m (Nujol or carbon tetrachloride solution).

Similarly, the same substance VII was obtained from the reaction of benzhydroxamic acid with acetone diethylketal in a good yield (75%), along with a trace of dibenzhydroxamic acid.

Summary

Dehydration reactions of hydroxamic acids with unsaturated ethers have been studied. The reaction of hydroxamic acids with ethoxyacetylene or methylketene diethylacetal led to the formation of corresponding isocyanates, along with ethyl acetate or ethyl propionate and ethanol, through the intermediate of addition compounds of hydroxamic acids and the dehydrating reagents.

The reaction of hydroxamic acids with *n*-butyl vinyl ether, on the other hand, led to the formation of dihydroxamic acids, along with acetaldoxime and acetaldehyde dibutylacetal. This type of reaction was further extended to the reactions of hydroxamic acids with propenyl ether, acetals and aldehydes, and the formation of dihydroxamic acids was confirmed.

The Cobalt(III) Complexes of Ethylenediaminediacetic and Ammoniadiacetic Acids[1]

By Motoshichi MORI, Muraji SHIBATA, Eishin KYUNO and Fukun MARUYAMA

(Received March 3, 1961)

In previous papers[2] of this series, some methods of preparation of the cobalt(III) complexes of ethylenediaminetetracetic acid and ammoniatriacetic acid were reported. The present paper is to report preparation of the cobalt(III) complexes of ethylenediaminediacetic and ammoniadiacetic acids. Since ethylenediaminediacetate ion commonly acts as a quadridentate ligand, the participation of its one molecule in the bonding to a cobalt(III) ion would be expected to be most regular. On the other hand, ammoniadiacetate ion usually acts as a tridentate ligand, and consequently the participation of the two molecules would seem most possible. Both of these possibilities are realized in this research.

2) M. Mori, M. Shibata, E. Kyuno and H. Nakajima, This Bulletin, **29**, 887 (1956); M. Mori, M. Shibata, E. Kyuno and Y. Okubo, ibid., **31**, 940 (1958).

Experimental

Chelating Agent. — Ethylenediaminediacetic acid (EDDA) was prepared by the action of monochloracetic acid on ethylenediamine. A solution of 10 g. monochloracetic acid in 10 ml. water was carefully neutralized with 17 g. of sodium bicarbonate, and then 7.5 g. of ethylenediamine (85%) was added to the solution. This was allowed to warm at about 50°C and a solution of 8 g. sodium hydroxide in 10 ml. water was added to it. After standing for few minutes, the solution was acidified with 6 N hydrochloric acid and then evaporated in vacuo, whereby some sodium chloride separated out. After the removal of the salt by filtration, two or three volumes of ethanol were added to the filtrate and the mixture kept in a refrigerator until white precipitates appeared. These were recrystallized from water. The nitrogen analysis and the potentiometric titration of this material gave satisfactory results for the desired ethylenediaminediacetic acid. Ammoniadiacetic acid (ADA) was provided by the Dojin Institute of Pharmaceutical Chemistry through the courtesy of Dr. K. Ueno.

Preparation. — *1) Potassium Bisammoniadiacetatocobaltate(III), $K[Co(ada)_2]\cdot 4H_2O$*.* — About 2 g. of ADA was suspended in 5 ml. of water, and the solution was neutralized with 2 g. of potassium bicarbonate. To this solution were added a solution of 2 g. $CoCl_2\cdot 6H_2O$ in a little water and 2 ml. of hydrogen peroxide (10%), and the mixture was warmed on a water bath to nearly 40°C, whereupon the color of the solution became red-violet. By cooling this solution in a refrigerator, red-violet crystals of the desired complex were obtained. Yield, about 0.5 g.

Found: Co, 14.7; N, 6.5. Calcd. for $K[Co(ada)_2]\cdot 4H_2O$: Co, 14.6; N, 6.49%.

*2) Potassium Carbonatoethylenediaminediacetatocobaltate(III), $K[Co(edda)(CO_3)]\cdot H_2O$***. — To a solution of the potassium tricarbonatocobaltate prepared by the method of a previous paper[3] were added equimoles of EDDA, and the mixture was warmed on a waterbath of 50°C for a few minutes. The resulting solution was evaporated in vacuo, whereby some salts were deposited. After the removal of these salts by filtration, about three volumes of ethanol were added to the filtrate, and it was kept in a refrigerator until red-violet crystals separated out.

Found: Co, 17.4. Calcd. for $K[Co(edda)(CO_3)]\cdot H_2O$: Co, 17.7%.

3) Ethylenediamminediacetatodiaquocobalt(III) perchlorate, $[Co(edda)(OH_2)_2]ClO_4$.—A solution of the carbonato-complex obtained in 2) was acidified with dilute hydrochloric acid, and then a certain amount of perchloric acid was added to it. After the removal of insoluble materials by filtration, the filtrate was treated in the same manner as mentioned in 2). In this case, some violet precipitates which may be regarded as the diaquo-complex were obtained, but the purity of the complex was not satisfactory.

Found: Co, 15.0. Calcd. for $[Co(edda)(OH_2)_2]\cdot ClO_4$: Co, 16.0%.

4) Potassium Dinitroethylenediaminediacetatocobaltate(III) $K[Co(edda)(NO_2)_2]\cdot H_2O$. — This was prepared by using the above-mentioned diaquo-complex. To a solution of the diaquo-complex was added the necessary amount of potassium nitrite, and the mixture was warmed to 50°C for some time until the color of the solution changed to yellow-brown. The solution was filtered once and the filtrate treated with ethanol in the same manner as mentioned in 2). The product was recrystallized from water in the form of red-brown prisms.

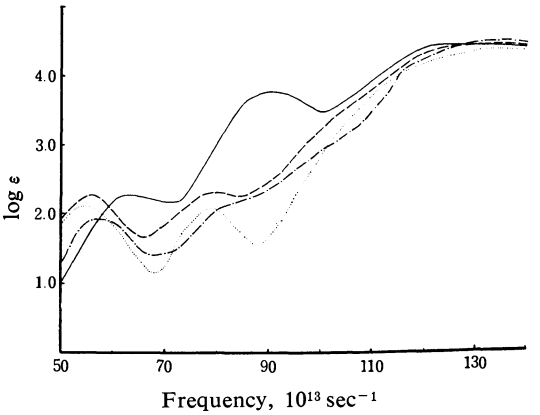
Found: Co, 15.2; N, 7.81. Calcd. for $K[Co(edda)(NO_2)_2]\cdot H_2O$: Co, 15.4; N, 7.36%.

For the determination of the chemical formulae of these complexes, chemical and thermal analyses, coagulation of ferric oxide sol and spectroscopic measurements were used in the same manner as described in previous papers[3,4].

Results and Discussion

Coagulation Value.—The values obtained in the present experiment were 4.1 mF for the $[Co(ada)_2]^-$, 3.4 mF for the $[Co(edda)(CO_3)]^-$, and 4.2 mF for the $[Co(edda)(NO_2)_2]^-$. These values were somewhat lower than the average value, 6.6 mF, for univalent complex anions, but far too high for that of bivalent anions (0.48 mF)[5]. Therefore, these complex anions may be regarded as univalent.

Absorption Spectra. — The visible and ultraviolet absorption spectra of these complexes are shown in Fig. 1 and the numerical data are given in Table I. Based upon these data, some discussion is possible about the geometrical structures of the complexes. In the case of the $[Co(ada)_2]^-$, two geometrically different structures, cis and trans in respect to the coordinated nitrogen atoms, are possible,



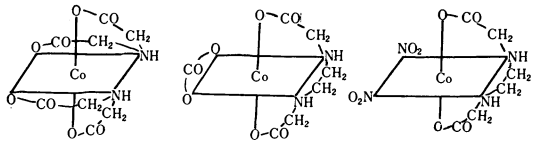


Fig. 1. Absorption spectra of:
·····: $K[Co(ada)_2]\cdot 4H_2O$
—·—·: $K[Co(edda)CO_3]\cdot H_2O$
– – –: $[Co(edda)(OH_2)_2]ClO_4$
———: $K[Co(edda)(NO_2)_2]\cdot H_2O$

TABLE I. ABSORPTION MAXIMA AND log ε (10^{13}/sec.)

	ν_1	log ε_1	ν_2 or ν_{sp}	log(ε_2 or ε_{sp})	ν_3	log ε_3
$K[Co(ada)_2]\cdot 4H_2O$	53.8	2.13	79.4	2.08	134.5	4.40
$K[Co(edda)(CO_3)]\cdot H_2O$	57.0	1.94	79.0	2.08	136.4	4.38
$[Co(edda)(OH_2)_2]ClO_4$	55.4	2.27	79.8	2.30	132.1	4.49
$K[Co(edda)(NO_2)_2]\cdot H_2O$	62.8	2.29	90.4	3.74	122.5	4.47

* "ada" stands for ammoniadiacetate ion.
** "edda" stands for ethylenediaminediacetate ion.

a b c

Fig. 2. Probable structures.

but the cis structure illustrated by a in Fig. 2 must be adopted for the present complex ion because the absorption maxima of this complex ion are similar to those of the α-$[Co(NH_3)_2 \cdot (C_2O_4)_2]^-$ regarded as cis isomer in the previous paper[4]. As the most probable structure, formula b in the figure may be assigned to the $[Co(edda)(CO_3)]^-$, because ethylenediaminediacetate ion usually acts as a quadridentate ligand and carbonate ion as a bidentate ligand. The dinitro-complex ion $[Co(edda)(NO_2)_2]^-$ which can be derived from the corresponding carbonatocomplex, probably has a structure illustrated by c. Evidence for the validity of this assignment lies in the fact that the absorption maxima of this complex ion are more similar to those of the cis isomer of the [Co en ox$(NO_2)_2]^-$ [6]. For *cis*-[Co en ox$(NO_2)_2]^-$: ν_1, 63.3; ν_{sp}, 90.9; ν_3, 121.0. For *trans*-[Co en ox$(NO_2)_2]^-$: ν_1, 63.3; ν_{sp}, 85.7; ν_3, 116.3.

In order to check the coordination of the carboxylate ions, the infrared spectra of the $K[Co(ada)_2] \cdot 4H_2O$ and the $K[Co(edda)(NO_2)_2] \cdot H_2O$ as well as the free acids of the chelating agents were measured. For the ammoniadiacetic acid, strong split bands were observed at 1718 and 1585 cm^{-1}, and for the ethylenediaminediacetic acid, at 1721 and 1605 cm^{-1}. On the other hand, the ammoniadiacetato- and the ethylenediaminediacetato-complex showed strong absorption arising from the coordinated carboxylate ions at 1623 and 1619 cm^{-1} respectively.

Table II is a summary of the absorption maxima of the first bands for several complexes which belong to the $[CoN_2 \cdot O_4]$-type and which are also regarded as cis form with respect to the coordinated nitrogen atoms. Among these complexes, the tetraaquo-complexes $[Co(NH_3)_2(OH_2)_4](ClO_4)_3$ and [Co en $(OH_2)_4](ClO_4)_3$ were prepared from the corresponding dichlorodiaquo-complexes[7] by treating with glacial acetic acid. Both of these were quite hygroscopic and difficult to be isolated as crystals, but the complex ions were completely held on a cation exchanger from the solutions. If the maximum value ν_1^0 for the $[Co(NH_3)_2(OH_2)_4]^{3+}$ is chosen as a standard absorption for the $[CoN_2 \cdot O_4]$-type complexes, the deviations of the maximum values for the other complexes from this standard value, $\alpha = \nu_1^0 - \nu_1$, may be regarded as a measure for the chelation effect.

Table II. Absorption maxima of $[CoN_2 \cdot O_4]$-type complexes

		ν_1	α
1	$[Co(NH_3)_2(CO_3)_2]^-$	52.2	1.3
2	$[Co\ en(CO_3)_2]^-$	53.2	0.3
3	$[Co(NH_3)_2\ ox\ CO_3]^-$	53.4	0.1
4	$[Co(NH_3)_2(OH_2)_4]^{3+}$	53.5	0
5	$[Co(ada)_2]^-$	53.8	−0.3
6	$[Co(NH_3)_2\ ox_2]^-$	54.4	−0.9
7	$[Co\ en(OH_2)_4]^{3+}$	54.8	−1.2
8	$[Co\ en\ ox_2]^-$	55.6	−2.1
9	$[Co(edta)]^-$	55.9	−2.4
10	$[Co(edda)(CO_3)]^-$	57.0	−3.5

Summary

The cobalt(III) complexes containing ammoniadiacetate group (ada) and ethylene diaminediacetate group (edda) have been prepared:

1) $K[Co(ada)_2] \cdot 4H_2O$ Red-violet
2) $K[Co(edda)(CO_3)] \cdot H_2O$ Red-violet
3) $[Co(edda)(OH_2)_2]ClO_4$ Violet
4) $K[Co(edda)(NO_2)_2] \cdot H_2O$ Yellow-brown

The visible and the ultraviolet absorption spectra as well as the infrared spectra of these complexes have been measured and discussed in relation to the structures of these complex ions.

Physicochemical Studies on Cobalt Salts of Higher Fatty Acids. V. Appearances, Densities, and X-Ray Analysis of Crystal Structures of Cobalt Soaps

By Hirotaro KAMBE*

(Received March 15, 1961)

In the previous papers of this study[1], three species of cobalt soap with different colors were investigated. They differ so much from each other to the eye and also, more especially, to the touch, that their crystallinities must be distinguishable. In the present parer, microphotographs of their appearances are shown, and apparent densities in air and in acetone, and true densities are measured. Moreover, X-ray analysis of these soaps is carried out.

X-Ray analysis of cobalt stearate and palmitate was executed by Vold and Hattiangdi[2]. However, as they had dried their soaps in an oven, their samples perhaps took a melted form which showed only an amorphous halo in the X-ray pattern. Our soaps, prepared in cold, are truly crystalline. But unfortunately, no adequate solvent was found for them, so single crystals of cobalt soaps have not yet been obtained. Complete X-ray analysis of their crystal structures must be reserved for the future.

Experimental

Materials. — The same cobalt stearates in three typical colors were used, as in the previous papers[1].

Microphotography.—Soap powder, passed through a sieve of 100 meshes per inch, was scattered on a glass plate in the field of a microscope. Microphotographs of 300 magnifications were taken with transmitted light.

Density Measurement. — The apparent packing densities of cobalt soap powders in air were measured in a graduated glass tube. Apparent volume was measured directly after the settling of the powder and after a gentle tapping of about 300 times. Finally the tube was inverted and the packing of the powder was observed. The sedimentation volume of soap powder in acetone was measured with the lapse of time in the same tube. Apparent densities in acetone were calculated. True densities of powder were measured with a substitution method in acetone. Acetone was chosen because the color of soaps did not change at all in it.

Powder X-Ray Analysis. — Debye-Scherrer's method was applied to soap powders*2. Powder was pushed into a glass capillary and extruded by a wire. A cylinder formed by soap with a length of 1~2 mm. and a diameter of about 0.5 mm. was barely attached to a sample holder at the center of a cylindrical camera. The camera radius, R, was 57.44 mm. The radiation used was CuKα with a nickel filter.

X-Ray diffraction patterns were analyzed with a microphotometer, and the diffraction angle θ was calculated by the formula:

$$L=2\theta\cdot R \qquad (1)$$

in which L is the distance of a diffraction line from the center of the film. Lattice spacing d was calculated by Bragg's formula:

$$2d\sin\theta=n\lambda \qquad (2)$$

in which n is an order of diffraction, λ is a wavelength of incident X-rays; in this case $\lambda(\mathrm{CuK}\alpha)=1.539$ Å.

Results and Discussion

Appearances.—Blue cobalt stearate was clearly crystalline and easily removable from filter paper in a dry state, but it was hard to pulverize it. Pink soap was rather plastic to the touch, like fatty acid, and adhered to filter paper after drying. Often it was charged electrically when it was removed from filter paper. When pulverized, it became a fluffy powder. Red soap was most easily pulverized, did not stick together, and freely flowed.

Crystal forms of powdered red and blue cobalt stearates are shown in microphotographs in Fig. 1. In blue soap powder some prismatic crystals are found, but in red soap only plate-like crystals exist in the field. Crystal forms of red soap are very similar to that of stearic acid.

Densities.—The apparent densities of cobalt stearates with different colors were distinguishable from each other. Packing densities in air are shown in Table I. In this state blue soap is much denser than red soap, and pink soap is between them. This is because of the difference in their crystalline forms.

2) R. D. Vold and G. S. Hattiangdi, *Ind. Eng. Chem.*, **41**, 2311 (1949).

*2 X-Ray measurements were carried out at Physics Department, Inst. Sci. Techn., following the advice of Mr. T. Sakurai.

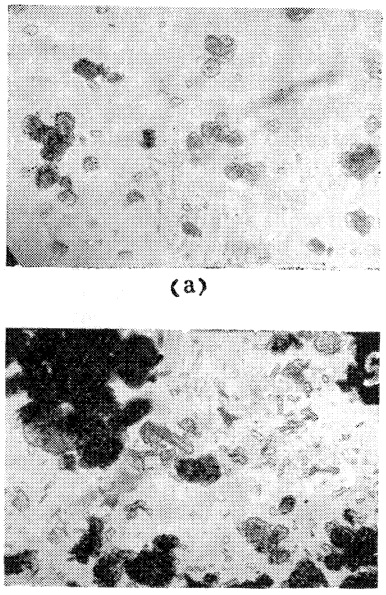

Fig. 1. Appearances of cobalt stearate crystals.
(a) Red dihydrate; (b) Blue anhydrate

TABLE I. APPARENT DENSITIES OF COBALT STEARATE POWDERS IN AIR (g./ml.)

Color of cobalt soap	After settling	After tapping 300 times	After inversion
Blue	0.195	0.333	0.221
Red	0.150	0.246	0.149
Pink	0.173	0.278	0.179

The apparent densities in acetone are shown in Table II. Sedimentation volumes of cobalt soaps in acetone gradually become smaller. In this case, the density of the blue form is also the highest, as in air. But red and pink soaps reverse their densities in acetone and air. Red form was apparently much denser in acetone.

True densities, measured with a substitution method in acetone at 25°C, are tabulated in Table III. It is found that the density of red soap is slightly larger than that of blue soap, in contrast with the apparent densities. This may be due to the difference in their crystalline structure.

				w 0.274	2.81	s 0.208	3.70

*1 s: strong; vs: very strong; m: medium; w: weak.
*2 Without nickel filter.
*3 Higher order of long spacing.
*4 The values in parentheses were calculated as CuKβ (λ=1.389 Å) diffraction. These lines were weakened by a nickel filter.

similar to that of stearic acid. It is characteristic of this pattern that a strong line exists between two medium lines, the inner one of which was weakened by the attachment of a nickel filter. Blue soap shows a quite different pattern, in which two groups of strong lines are characteristic.

Fatty acid and its derivatives usually exhibit crystals of a monoclinic system. Their crystal structure is composed alternately of ionic layers and hydrocarbon layers, stacked on one another. The resemblance of the X-ray pattern of red soap to that of fatty acid means that this species also has such a layer structure. Pink soap also shows such a layer structure pattern, and so it is evident that there is a similarity of structure between these soaps. The water molecules contained in red dihydrate must be attached directly to cobalt ion. The coordination number of six, which has been found by magnetic measurement on red soap[1], must be fulfilled by joining two cobalt ions together by carboxylate ions. Such a structure has been proposed by Stanley[3] for calcium stearate monohydrate.

It is certain, because of the difference in coordination numbers and X-ray patterns, that blue soap has a different structure from pink and red soaps, but X-ray analysis of crystals has not yet been executed on single crystals. The confirmation of the exact crystal structure must therefore be postponed.

Purple soaps, which were obtained from red or pink soaps immersed in absolute ethanol, showed a diffraction pattern from the blue type, but violet soap, which was half turning red from blue, showed a red-type pattern. Melted soap always showed a diffuse halo, as shown by Vold and Hattiangdi[2].

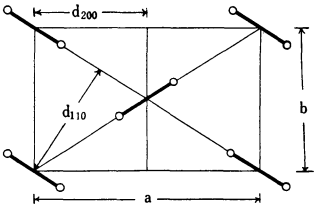

Fig. 4. Schematic diagram of a besal plane of unit cell in red cobalt stearate dihydrate. Dumbbells show orientations of paraffinic chains in crystal lattice.

The diffraction pattern of red soap was analyzed in the same way as Müller[4] had done on normal paraffins. A basal plane of paraffinic lattice may be described as Fig. 4. A lattice spacing obtained from the most intense diffraction line in an X-ray pattern of this type was identified as d_{110}; the outer medium line was d_{200}, and the inner medium CuKβ-diffraction of d_{110}, which was weakened line was by a nickel filter.

From the observed values of diffraction angles in red soap, d_{110}=4.05 Å and d_{200}=3.75 Å. From these, the lattice constants of red cobalt stearate were calculated as $a=2d_{200}$=7.50 Å, and b=4.81 Å. In the same way, stearic acid shows d_{110}=4.12 and d_{200}=3.70 Å. Therefore, in stearic acid, a=7.40 and b=4.96 Å. The lattice of red soap is broadened a little along the b axis and shortened along the a axis compared with acid.

Summary

Crystallinities of cobalt stearates with different colors have been compared. Blue soap

3) E. Stanley, *Nature*, **175**, 165 (1955).

4) A. Müller, *Proc. Roy. Soc.*, **A138**, 514 (1932).

shows a prismatic crystal form, but red soap a plate-like form. The apparent density of blue soap in air is much denser than other soaps. Red soap shows a larger density in acetone than in air. True densities measured in acetone show that the density of red soap is higher than that of blue soap.

X-Ray diffraction patterns show the difference between red or pink soap and blue soap. Red soap has a lamellar structure like that of fatty acid, while blue soap shows a quite different structure. Exact X-ray analysis was not executed, however, because single crystals of cobalt soaps have not yet been obtained.

The author wishes to express his thanks to Professor Bunnosuke Yamaguchi for his kind advice throughout this work, and to Mr. Toshio Sakurai for his cooperation in X-ray measurements. He is also indebted to Mr. Masami Ozaki for microphotography.

Physicochemical Studies on Cobalt Salts of Higher Fatty Acids. VI. Some Observations on Thermal Transitions of Cobalt Soaps, by Differential Thermal Analysis, Thermogravimetry, and Magnetic Measurement

By Hirotaro KAMBE*1, Takeo OZAWA*2, Masao ONOUE*3 and Shoichi IGARASHI*1

(Received March 29, 1961)

Cobalt soaps with different colors, obtained and examined in previous papers[1], are crystalline at room temperatures, but they melt at higher temperatures. In the present paper, their melting behaviors are investigated by differential thermal analysis, thermogravimetry, and the measurement of magnetic susceptibility at various temperatures.

Cobalt soap decomposes at extremely high temperatures. Thermogravimetric analysis is applied also to this process.

Soap which has been cooled from a molten state takes the form of a glassy mass. The characteristics of once-melted soap are examined by reflection spectroscopy, X-ray analysis, and the measurement of magnetic moment.

Experimental

Materials.—Cobalt stearate with different colors were used as in the previous papers[1].

Differential Thermal Analysis.—Soap sample and liquid paraffin, as a reference, were heated simultaneously in coaxial cylinder cells of stainless steel, as Vold has described[2]. Cells were put into holes of a copper block placed at the center of a vertical electric furnace, within an atmosphere of nitrogen. The difference of temperature between sample and reference was measured by a thermocouple of chromel-constantan with two pairs in series. Differential thermo-electric motive force was recorded on the chart of an electric recorder through a D. C. amplifier.

The temperature of the electric furnace was elevated continuously by a program controller at a constant heating rate of 2/3°C/min. The furnace temperature was measured by another thermocouple of chromel-alumel and directly recorded on the same chart as the record of differential temperature. Cooling curves were taken on free cooling.

Thermogravimetry. — An automatic recording thermobalance, with a differential transformer as a detector of the elongation of a spring balance, which will be described elsewhere, was used to record the weight changes during the elevation of the sample temperature at a constant rate of heating of 1°C/min. within an atmosphere of nitrogen. The weight changes by dehydration and by decomposition of cobalt soaps were observed. The sample weight was about 90 mg.

Magnetic Measurement.—Magnetic susceptibilities at various temperatures were measured with Gouy's method*4. Magnetic moments were calculated as in Part IV[1].

Results and Discussion

Differential Thermal Analysis.—Differential thermograms of cobalt stearates are shown in Figs. 1—3. Heating curves at a constant rate of heating and cooling curves at free cooling are shown on opposite sides of the base lines.

Blue anhydrous cobalt stearate (Fig. 1) showed two peaks at 99 and 108°C in the first heating curve, while on cooling two peaks appeared at 89 and 47°C. When cooled soap was heated again, it showed a low-temperature peak at 54C° and two high-temperature peaks at 90 and 100°C. The former of the high-temperature peaks was smaller than in the first heating curve, and the low-temperature peak appeared as a substitute for it.

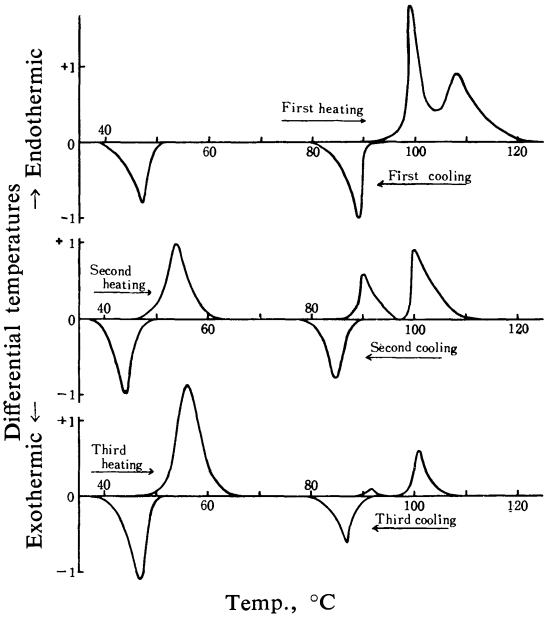

Fig. 1 Differential thermograms of blue cobalt stearate anhydrate. Heating rate: 2/3°C/min.

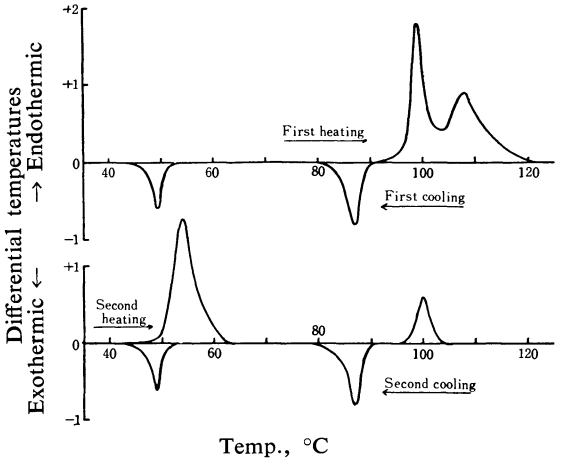

Fig. 2. Differential thermograms of blue cobalt stearate anhydrate. First cooling was done after heating at 120°C for one hour.

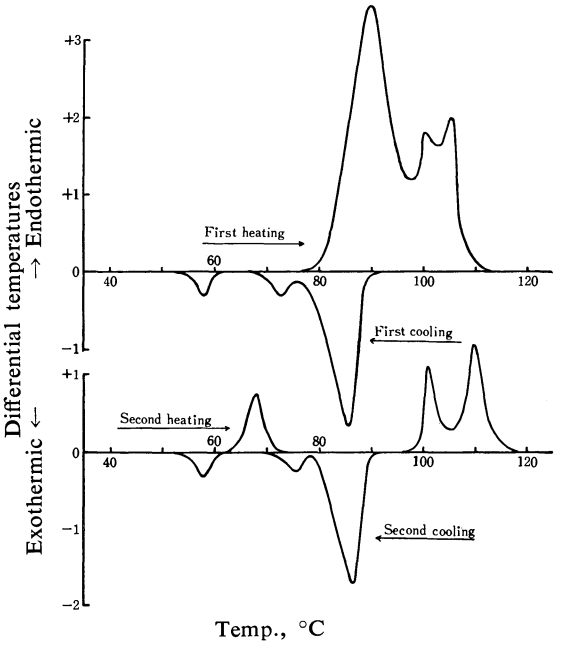

Fig. 3. Differential thermograms of red cobalt stearate dihydrate.

When the twice melted soap was cooled again, two peaks appeared at 85 and 44°C in the cooling curve. The soap generally showed a tendency to be supercooled in cooling curves, and peaks appeared at considerably lower temperatures than in heating curves. The high-temperature peak was not divided into two peaks, as in heating curves.

At the third heating, the low-temperature peak at 46°C was magnified, while the first high-temperature peak almost disappeared. On cooling two peaks appeared at 87 and 47°C.

From these facts, it is concluded that heating has the effect of reducing the high-temperature peaks, especially the lower of them, and extending the low-temperature peak. During heating, the mechanism of the first high-temperature transition might be replaced by that of a low-temperature transition.

When blue cobalt soap was held at 120°C for one hour, this process was advanced considerably, as shown in Fig. 2. In Fig. 2, the first heating and subsequent cooling curves were similar to that in Fig. 1, but in the second heating the low-temperature peak was much

intensified, while the first high-temperature peak disappeared completely, as had been expected.

In the first heating curve, red cobalt stearate dihydrate (Fig. 3) showed a very large peak at 90°C and two high-temperature peaks at 100 and 110°C, as did blue soap. On cooling, a low-temperature peak appeared at 58°C and the high-temperature peaks were displaced to 86°C and 76°C. In the cooling curve of red soap, the high-temperature peak was also divided into two peaks as in heating, in contrast with blue soap. In the second heating curve, a low-temperature peak clearly appeared, while high temperature peaks became smaller although they remained as they were.

In red soap the large peak at 90°C in the first heating curve must correspond to dehydration. This was confirmed by thermogravimetry, as will be discussed below.

Koenig[3] measured visually the melting point of cobalt stearate as 73~75°C. Hattiangdi, Vold and Vold[4] carried out a differential thermal analysis of cobalt soaps by heating at rate of 1.5°C/min. until 150°C, above which decomposition of the soap was feared. They found transition points at 59°C(ΔH=13440 cal./mol.) and at 92°C(probably second-order transition) in cobalt stearate. They also described the visual melting point of cobalt stearate as 80°C. In a free cooling curve, they found only a transition at 57°C. Their sample was perhaps a melted amorphous form, as Vold and Hattiangdi[5] observed only an amorphous halo in a powder X-ray pattern of this soap, as stated in Part V[1]. The peaks obtained by them might correspond to our low-temperatue peak and second high-temperature peak.

Hattiangdi, Vold and Vold[4] have concluded that cobalt soaps are in a mesomorphic state at room temperatures. A revised mechanism of the phase transitions of cobalt soap is proposed as follows:

Crystalline blue anhydrous soap melts at first heating in two stages. The first transition, which may be called premelting, is a phase transition from a crystalline to a plastic mesomorphic state, while the second transition corresponds to true melting. When blue soap is cooled from a melted state, it transforms to an (upper) mesomorphic state with some supercooling, but at a lower temperature a second transition occurs and the soap phase changes to a lower mesomorphic state.

At the second heating, soap transforms from a lower mesomorphic state to an upper mesomorphic state at low temperature transition, as described before. At a higher temperature region, the same two peaks appear as in the first heating. The first of them becomes smaller, however.

It is concluded, therefore, that although the upper transition peak was not apparently divided into two peaks in the first cooling curve, some of soap was transformed from an upper mesomorphic state to a true crystalline form, and it appeared in the second heating curve as a smaller first high-temperature peak. Repeated or prolonged melting suppressed this transition so much that the first high-temperature peak was faded markedly, while the low-temperature peak became eminent.

Crystalline red cobalt stearate shows a large dehydration peak, but thereafter it behaves as an anhydrous soap. The following processes are completely similar to those in the anhydrous blue soap. However, it shows high-temperature peak in the cooling curve, in contrast to blue soap.

Thermogravimetry.—Thermogravimetric curves of blue cobalt stearate anhydrate and red dihydrate are shown in Figs. 4 and 5. In these curves the weight loss (%) observed is plotted

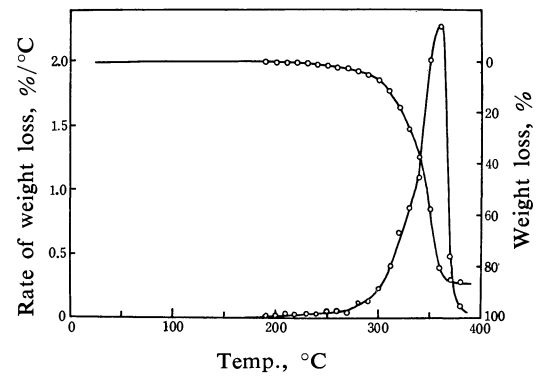

Fig. 4. Thermogravimetric curve of blue cobalt stearate anhydrate.

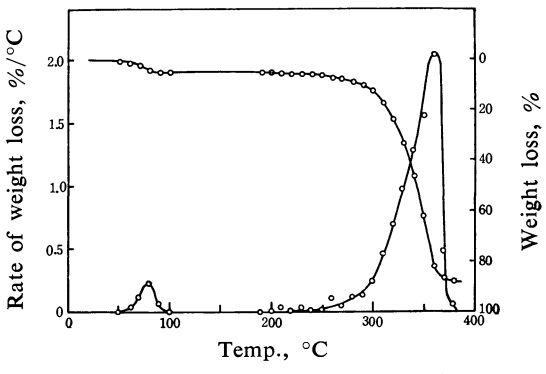

Fig. 5. Thermogravimetric curve of red cobalt stearate dihydrate.

against temperature. The rate of weight loss (%/°C) was obtained by a graphical differentiation of weight loss curve and is also plotted in the same figure.

Blue soap (Fig. 4) did not show any weight loss at the melting point, but red soap (Fig. 5) showed a weight loss of about 4.4% at about 80°C. Even if somewhat smaller, this is correspondent with the loss of hydrate water from cobalt stearate dihydrate (calcd. 5.46%). This process is also correspondent with the first large peak of differential thermogram of red soap.

Differential thermogravimetric curves of both soaps showed a significant weight loss, which commenced at about 200°C and reached a maximum rate of weight loss at about 360°C. This weight loss is evidently caused by the decomposition of soap. In this process some white crystalline powder was condensed at the cold part of a glass tube, which enveloped an inert atmosphere around the sample. This powder melts at 87.5~88.5°C. This was identified with stearone $(C_{17}H_{35})_2CO$, the melting point of which is 88.5°C. In the sample cell remained a black mass, which was identified as cobalt oxide.

Magnetic Measurement. — The reciprocal molar susceptibility of red cobalt soap was plotted against temperature, as shown in Fig. 6. It was found that the magnetic susceptibility of cobalt soap changed abruptly at the melting point. Below this temperature, Curie's law

$$\chi_M = \frac{C}{T} \qquad (1)$$

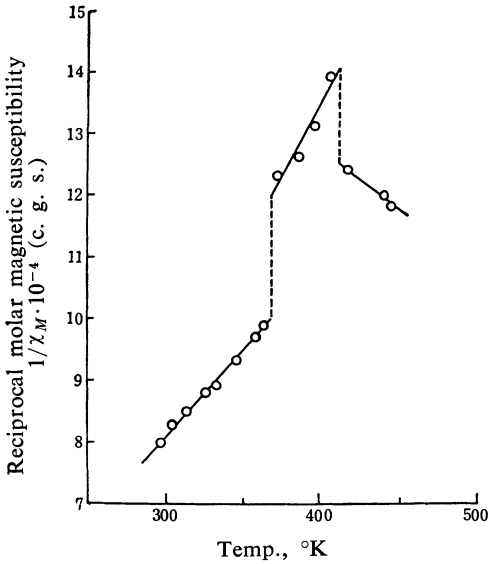

Fig. 6. Temperature dependence of magnetic susceptibility of red cobalt stearate dihydrate.

where C is a constant, held.

Herron and Pink[6] measured the thermal change of the magnetic susceptibility of cobalt soaps and found that Curie-Weiss' law

$$\chi_M = \frac{C}{T-\theta} \qquad (2)$$

where C and θ are constants, held below 320°K. They obtained Weiss' temperature $-\theta$ as 18.5°K in cobalt stearate. It is difficult to estimate Weiss' temperature from our experiments, which were conducted only above room temperatures.

Properties of Melted Soap.—When cobalt soap was cooled from its melted state, it took a mesomorphic state, as stated above. An X-ray diffraction pattern of melted soap is shown in Fig. 7. It is evident that there is only an amorphous halo, as Vold and Hattiangdi[5] pointed out. The color of melted soap is dark red. Its reflection curve is shown in Fig. 8, where its dominant wavelength is 546c mμ, its purity is 18%, and its brightness is 34.95% (cf. Part III[1]). The color is like that of red soap rather than blue soap. This is because the ground state of the spectral terms is seriously affected by the change of the crystal field on melting. The magnetic moment of melted cobalt stearate, calculated as in Part IV[1], was

4.86 B. M., in which there is a considerable orbital contribution.

Summary

The thermal transitions of red dihydrate and blue anhydrate of cobalt stearate have been measured by differential thermal analysis, thermogravimetry, and magnetic measurement.

Differential thermograms of anhydrous blue soap showed two peaks at high temperatures (about 100°C). When it was heated repeatedly, a new peak appeared at a lower temperature (about 50°C). A low temperature transition is considered to be a transition between mesomorphic phases. The first high-temperature transition corresponds to a transition from a crystalline to an upper mesomorphic state, which disappeared on repeated heating. Red dihydrate soap showed a large peak at 90°C owing to the removal of hydration water. Thereafter it appeared in an anhydrous state.

Thermogravimetric analysis showed the dehydration process in red soap, but not in blue anhydrate. The decomposition of cobalt stearates to stearone and cobalt oxide was found in thermogravimetric curves.

The magnetic susceptibility of cobalt soap obeys Curie-Weiss' law below the melting temperature, but above it the susceptibility decreases abruptly and anomalous behavior is observed.

Melted soap is in an amorphous state, which was certified by X-ray measurement. Its color and magnetic moment show that melted soap is different in nature from red and blue soaps.

The authors wish to express their gratitude to Professor Bunnosuke Yamaguchi for his advice throughout this work, and to Dr. Hidemasa Honda and Dr. Yoshio Matsunaga for their accomplishments in magnetic measurement.

Molecular Association and the Dielectric Constant of a Solution

By Ko KIMURA and Ryoichi FUJISHIRO

(Received May 12, 1961)

It may be expected that much useful information about the intermolecular force is obtained by an examination of the dielectric behavior of solutions. Only a few studies based on this point of view have been carried out because of the difficulty of taking into account the contributions of both the long- and short-range intermolecular forces to the dielectric constant of a solution. Buckingham and Raas[1] tried to examine the short-range intermolecular force between solutes by the help of the dielectric virial coefficients of solutions. They showed that, to some extent, the dielectric virial coefficients gave valuable information about the intermolecular configuration as well as the intermolecular force. The results obtained by them agree fairly well with spectroscopic data, but some questions still remain about the application of the virial expansion method[2] of the total dielectric polarization of a gas to solutions.

In this report, the dimerization of a nitrocompound in carbon tetrachloride will be discussed in detail, because De Maine et al.[3] suggested from spectroscopic measurements the dimerization of nitromethane due to the charge transfer force in solutions. Unfortunately, the dielectric constants of the concentrated solutions, as well as the pure liquid of nitromethane, varied with time during the measurements. This was probably due to the isomerization of nitromethane to methylnitrite[4]. Hence, this article describes the dimerization of nitrobenzene (instead of nitromethane) in carbon tetrachloride, which dimerization is estimated on the basis of some assumptions from the observed dielectric constant of the solution.

Experimental

The apparatus for the dielectric measurement has already been described elsewhere[5]. The dielectric cell used in this work was of a Sayce-Briscoe type, the electric capacity of which was about 5 pF. All material were purified according to standard methods[6].

Experimental Results

The dielectric constant of the mixture of nitrobenzene and carbon tetrachloride has already been measured by some authors[7], but we repeated the measurement in order to examine the temperature dependence of the dielectric constant of the solution. The observed results are shown in Table I.

Discussion

Determination of the Formation Constant of the Nitrobenzene Dimer in the Solution from the Observed Dielectric Data.—We can roughly estimate the formation constant K of the nitrobenzene dimer in the solution from the observed dielectric constant on the assumption that the difference between the observed dielectric constant and the calculated one obtained by the use of Scholte's model[8] is due to molecular association. We regard the monomer and the dimer of nitrobenzene as spheroidal in form and consider the spheroidal cavity of the molecular dimension in the dielectric. The surroundings of the spheroidal cavity are replaced as usual by the continuum of the macroscopic dielectric constant. The point dipole is located along the long axis. The dipole moment of the dimer is zero or twice the monomer moment according to the antiparallel or the parallel orientation of two dipoles. The long and short axes of the spheroids for the monomer and for the dimer are determined by the atomic distances and van der Waals radii of constituent atoms of a nitrobenzene molecule. Those for the monomer are easily obtained, whereas those for the dimer can not be obtained without assuming a tentative configuration for the dimer. In order to make the observed dielectric constant agree with the calculated one, only the parallel orientation of two dipoles is allowed for the configuration of the dimer. Therefore, we calculated the formation constant in each concentration by assuming some plausible configuration for the dimer with the parallel orientation of two dipoles. The most probable configuration of the dimer would indicate a small dependence of K on concentrations. Formulas required for this calculation are derived in quite the same way as in a paper already published[9].

When we use 0, 1 and 2 as suffixes expressing the nonpolar solvent, the monomer and the dimer, respectively, we obtain the following formula:

$$\varepsilon-1=4\pi\left[\sum_{i=1}^{2}N_i\frac{\varepsilon}{\varepsilon+(1-\varepsilon)A_i}\left\{\frac{\mu_i^2}{(1-\alpha_i g_i)^2 3\boldsymbol{k}T}+\frac{\alpha_i}{1-\alpha_i g_i}\right\}+N_0\frac{\varepsilon(n_0^2-1)}{2\varepsilon+n_0^2}a_0^3\right] \quad (1)$$

in which the notations are the same as those used in the previous paper[9]. In calculating N_1 and N_2 from Eq. 1, polarizability α_2 was assumed to be twice α_1, both α_1 and α_2 being isotropic, and volume change on mixing was ignored. When N_1 and N_2 are calculated from Eq. 1 by means of the observed dielectric constant, the formation constant is easily obtained,

$$K=\frac{N_2}{N_1^2}\cdot\frac{\boldsymbol{N}}{10^3}\ (\text{l./mol.}) \quad (2)$$

in which $\boldsymbol{N}$ is the Avogadro number. Table II shows some of the calculated results of K for the two plausible configurations of the dimer at different temperatures. When the ratio a_2/b_2 for the dimer is equal to 1, the variation of K with concentrations is comparatively small. This ratio a_2/b_2 for the dimer corresponds to a configuration such as that in which constituent dipoles of the dimer take a parallel orientation and in which one of them lies upon another one. The value of K is very small compared with that for hydrogen bonding and is kept almost constant at

any temperature between 25°C and 60°C. The latter result means that the heat of the formation of the dimer is of the same order of magnitude as kT. These results may probably be attributable to the electrostatic force by considering the large dipole moment of the solute molecule. In the next two sections, discussion will be given over mainly to electrostatic force.

Intermolecular Electrostatic Energy and the Sign of $\langle\cos\varphi_{12}\rangle$.—Let it be supposed that two dipoles form an angle φ_{12} in vacuo. The average value of $\langle\cos\varphi_{12}\rangle$ is given by

$$\langle\cos\varphi_{12}\rangle=\frac{\int\cos\varphi_{12}\,e^{-U/kT}\,d\omega}{\int e^{-U/kT}\,d\omega} \qquad (3)$$

where ω is a solid angle and U is the electrostatic potential energy. If the coordinate systems depicted in Fig. 1 are used, and coordinates of a charge e_i and those of a charge e_λ are r_i (x_i, y_i, z_i) in the O-coordinate system and ρ_λ $(\xi_\lambda, \eta_\lambda, \zeta_\lambda)$ in the Ω-coordinate system, respectively, U is given by the following formula[10],

$$U=-\frac{1}{R^3}\sum_{i,\lambda}e_ie_\lambda(2z_i\zeta_\lambda-x_i\xi_\lambda-y_i\eta_\lambda)+\frac{1}{2R^4}\sum_{i,\lambda}e_ie_\lambda\{r_i^2\zeta_\lambda-\rho_\lambda^2z_i+(2x_i\xi_\lambda+2y_i\eta_\lambda-3z_i\zeta_\lambda)(z_i-\zeta_\lambda)\}+\cdots \qquad (4)$$

The first term of the above formula corresponds to the dipole-dipole interaction energy, the second term to the dipole-quadrupole interaction, and so on. Generally speaking, non-electrostatic forces such as dispersion and repulsive forces must be included in the function U. However, if these non-electrostatic forces are assumed to have spherical symmetry, they have no effect on the averaging process over ω. In calculating the right hand side of Eq. 3, it is convenient to introduce rotating coordinate systems $\overline{X}$, $\overline{Y}$, $\overline{Z}$ of the origin O and $\overline{\Xi}$, $\overline{H}$, $\overline{Z}$ of the origin Ω. The direction of a dipole located at the origin O and that of another dipole located at the origin Ω are taken along the axes $\overline{Z}$ and $\overline{Z}$, respectively. Angles (α, β, γ) or $(\alpha', \beta', \gamma')$ express Eulerian angles of the axes $\overline{X}$, $\overline{Y}$, $\overline{Z}$ to X, Y, Z or those of the axes $\overline{\Xi}$, $\overline{H}$, $\overline{Z}$ to Ξ, H, Z. When we express the coordinates of e_i and e_λ by the rotating coordinate systems, coordinates of e_i $(\bar{x}_i, \bar{y}_i, \bar{z}_i)$ and e_λ $(\bar{\xi}_\lambda, \bar{\eta}_\lambda, \bar{\zeta}_\lambda)$ do not vary with the averaging process. Hence, the average value is obtained by carrying out integration over Eulerian angles only. If we introduce the following transformation matrix,

$$T=\begin{pmatrix}\cos\alpha\cos\gamma-\sin\alpha\sin\gamma\cos\beta, & -\cos\alpha\sin\gamma-\sin\alpha\cos\gamma\cos\beta, & \sin\alpha\sin\beta\\ \sin\alpha\cos\gamma+\cos\alpha\sin\gamma\cos\beta, & -\sin\alpha\sin\gamma+\cos\alpha\cos\gamma\cos\beta, & -\cos\alpha\sin\beta\\ \sin\gamma\sin\beta & \cos\gamma\sin\beta & \cos\beta\end{pmatrix} \qquad (5)$$

10) H. Margenau and V. W. Myers, *Phys. Rev.*, **66**, 307 (1944).

TABLE III. THE STABILIZATION ENERGY DUE TO THE SURROUNDING DIELECTRIC

[A] → →, [B] ⇄, [C] ⇉, [D] → ←

	$x=1$, $\varepsilon=34.16$, $\Delta G_1=-2.44$ kcal./mol.		$x=0.6995$, $\varepsilon=22.45$, $\Delta G_1=-2.38$		$x=0.2712$, $\varepsilon=8.82$, $\Delta G_1=-2.12$	
	ΔG_2	$1/2(\Delta W+\Delta G_2)-\Delta G_1$	ΔG_2	$1/2(\Delta W+\Delta G_2)-\Delta G_1$	ΔG_2	$1/2(\Delta W+\Delta G_2)-\Delta G_1$
[A]	−3.01	+0.65	−2.95	+0.62	−2.07	+0.80
[B]	0	+1.69	0	+1.62	0	+1.37
[C]	−9.46	−1.65	−9.16	−1.56	−7.81	−1.14
[D]	0	+2.70	0	+2.65	0	+2.39

we can transform the coordinate systems X, Y, Z and Ξ, H, Z to the new coordinate systems $\overline{X}$, $\overline{Y}$, $\overline{Z}$ and $\overline{\Xi}$, $\overline{H}$, $\overline{Z}$, respectively. The function $\cos\varphi_{12}$ is expressed by the use of Eulerian angles as follows:

$$\cos\varphi_{12}=\sin\alpha\sin\beta\sin\alpha'\sin\beta'+\cos\alpha\sin\beta\cos\alpha'\sin\beta'+\cos\beta\cos\beta' \quad (6)$$

Substituting Eqs. 4 and 6 into Eq. 3, integration is carried out over ω. Because the denominator of Eq. 3 is always positive, the numerator decides the sign of $\langle\cos\varphi_{12}\rangle$. If we expand the numerator of Eq. 3 in power series and retain only the dipole-dipole term of U, we have

$$\int\cos\varphi_{12}\,e^{-U/kT}\,d\omega=\frac{\pi^4}{3!}\cdot\frac{1024}{25}\cdot\left(\frac{\mu^2}{R^3kT}\right)^3+\frac{\pi^4}{5!}\cdot\frac{196608}{49}\cdot\left(\frac{\mu^2}{R^3kT}\right)^5+\cdots=452+204+\cdots>0 \quad (7)$$

where R is determined by the density of nitrobenzene at 25°C and μ is taken to be 4.27 D. The positive sign of $\langle\cos\varphi_{12}\rangle$ agrees with the experimental results. In order to confirm the minor effect of higher multipoles, the dipole-quadrupole term was included in Eq. 7. The result is as follows:

$$\int\cos\varphi_{12}\,e^{-U/kT}\,d\omega=-\frac{\pi^4}{2!}\cdot\frac{512}{75}\left(\frac{3\mu\Theta_{zz}}{2R^4kT}\right)^2+\frac{\pi^4}{3!}\cdot\frac{1024}{25}\left(\frac{\mu^2}{R^3kT}\right)^3+\frac{\pi^4}{5!}\cdot\frac{196608}{49}\left(\frac{\mu^2}{R^3kT}\right)^5+\cdots=-80+452+204+\cdots>0 \quad (8)$$

The above equation is derived on the assumption that the charge distribution of a molecule and that of another one are symmetrical about the axes $\overline{Z}$ and $\overline{Z}$, respectively and Θ_{zz} is presumed to be of the order of 10^{-25}. The series in Eq. 8 will converge gradually and be positive, even if the polarizability of molecules and the interaction energy between higher multipoles are taken into account. The result obtained experimentally in the previous section was confirmed theoretically.

The Dipole-Dipole Interaction Energy and the Stabilization Energy due to the Surrounding Dielectric—When two dipoles with polarizability α_1 are at distance R from each other in vacuo, the dipole-dipole interaction energy with respect to each of the four simple cases depicted in the upper part of Table III, is given by,

$$[A]\quad \Delta W_A=-\frac{2\mu_1^2}{R^3_A(1-2\alpha_1/R^3_A)}=-0.56 \text{ kcal./mol.}$$

$$[B]\quad \Delta W_B=-\frac{\mu_1^2}{R^3_B(1-\alpha_1/R^3_B)}=-1.51$$

$$[C]\quad \Delta W_C=\frac{\mu_1^2}{R^3_C(1+\alpha_1/R^3_C)}=1.29$$

$$[D]\quad \Delta W_D=\frac{2\mu_1^2}{R^3_D(1+2\alpha_1/R^3_D)}=0.53$$

If these dimers are introduced into the continuum of dielectric, there is the free energy of stabilization due to the reaction field. This energy ΔG_i (ΔG_1 for the monomer and ΔG_2 for the dimer), is

$$\Delta G_i=-\frac{1}{2}\cdot\frac{g_i\mu_i^2}{1-\alpha_i g_i} \quad (9)$$

The values of ΔG_2 for the four simple cases and those of ΔG_1 are shown in Table III in respective concentrations at 25°C. Apart from including dispersion energy, the values of $1/2(\Delta W+\Delta G_2)-\Delta G_1$ are considered as a measure of the stability of the dimer in solutions about the four configurations, although the stabilization energy ΔG_i is overestimated owing to the rough model. The most probable configuration of the dimer in solutions corresponds to the case [C]. This result of the semi-quantitative calculation thus agrees with the experimentally determined configuration of the dimer. Strictly speaking, the association of n-molecules ($n\geqq3$) will occur especially in concentrated solutions, but the dielectric behavior of solutions is, as a first approximation, interpreted in terms of dimerization.

Summary

The formation constant of the nitrobenzene dimer in carbon tetrachloride was estimated as of the order of 0.01 from the dielectric constant of the solution by the use of Scholte's model. The configuration of the dimer is probably such that one of the constituent molecules lies upon the other. The small formation constant and the configuration of the dimer suggest that there is no need to consider some special forces between molecules such as the charge transfer force. The results deduced experimentally are interpreted satisfactorily in terms of the electrostatic force.

The expenses for this work have been partly defrayed by a grant from the Ministry of Education.

Analysis of the Variation in Coil Character by Carbonized Coal with Q-Meter

By Sadaharu TOYODA

(Received April 27, 1961)

It is well known that the variation of character of a circuit, containing a coil or a condenser-type electrode, can be utilized to find a neutralization point on high frequency titration, though many other applications of the coil have been reported in several papers[1-11]. Many significant results[12,13] have been obtained by considering the variation of coil character, which is caused by inserting an aqueous solution into the coil. Recently, the calculation[14] of the relation between the variable resistance of platinum wire and the resistance of an aqueous solution has been extended on the basis of Ref. 12. However, some of the calculated values have not agreed with the experimental values in the case of a coil-type instrument. As a result of calculation, it has also been shown that the consideration of the dielectric constant of a sample solution would help to solve this problem.

The Q-change of the coil with aqueous solution has been explained in another paper[15]. The variation of coil character when a substance is inserted into the coil is visualized in Fig. 1. According to the experimental result, the value of Q/Q_1 for an aqueous solution ($\varepsilon'=80$) changes with the resistance of the solution, as is shown by the full-line in Fig. 2. This variation seems to be explained by the equivalent circuit (Fig. 4 in Ref. 15) and the following relation (Eq. 15 in Ref. 15), which are based on Refs. 13, 16 and 14:

$$\frac{Q}{Q_1} \fallingdotseq \frac{1}{1+\alpha\left(\frac{px}{1+x^2}+\frac{1}{pMx}\right)\frac{\omega L}{R_1}} \tag{1}$$

where

$$x \equiv \omega(\varepsilon' C_1 + C_0)R, \quad R \equiv kr, \quad p \equiv \frac{C_0}{\varepsilon' C_1 + C_0}$$

$$\alpha \equiv \omega^2 L C_0$$

After some calculation using the above relation, the dotted line in Fig. 2 is obtained in the case of a low dielectric constant (for example, $\varepsilon'=1$). Comparing these two curves, the minimum value of Q/Q_1 in the dotted line is smaller than the value in the full-line, while the maximum value of Q/Q_1 does not depend

on the dielectric constant. The present paper is concerned with the variation in coil character caused by carbonized coal. The experimental results seem to be understandable by taking account of the above-described difference between the full-line and the dotted line.

Experimental Equipment and Method

Fig. 3 shows an experimental apparatus. The explanation of the parts except a furnace (a) and its accessories are omitted, since they have been reported in Ref. 15. Although a long quartz pipe (b) shown in Fig. 3 has not been illustrated in Ref. 15, it had been attached to a quartz vessel of a sample solution. The length of the quartz pipe is about 45 cm., and the outside diameter, 2.5 cm. A three-way cock (c), suspended by a

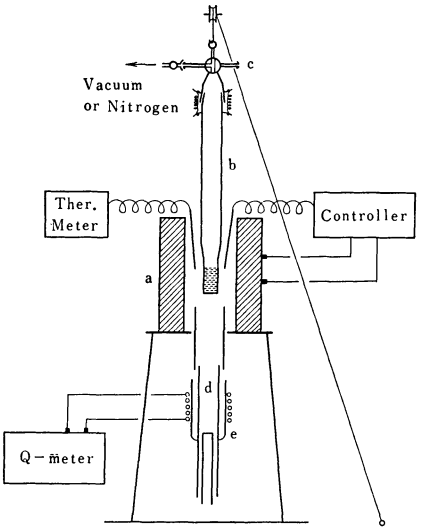

Fig. 3. Apparatus for experiment.
a Furnace b Quartz pipe
c Three-way cock
d Quartz pipe serving as a guide
e Quartz pipe for coil

string and a pulley as shown in Fig. 3, is connected to another end of the quartz pipe with a spring, and so the coal sample in the quartz vessel is located in the center of the furnace, which is regulated at the heating rate of 2°C per minute. When the temperature of the coal sample is raised to an appointed temperature, the connection to a vacuum or a nitrogen system is set off, and the heated quartz vessel containing the coal is inserted into a coil by using the string and the pulley. After measuring the Q-value of the coil as fast as possible, the quartz vessel is pulled up to the original position, the three-way cock is connected again to the vacuum or the nitrogen system, and the quartz vessel with the coal is heated to the next desired temperature.

When the heated quartz vessel is inserted into the coil, the Q of the coil is apt to decrease due to the heat conduction and the radiation from the vessel, in addition to the Q-change caused by the character of carbonized coal. The following method

TABLE I. ANALYSIS OF VARIOUS COALS

* Dry basis

was employed in order to suppress this tendency caused by the heat conduction and the radiation. Taking account of the heat conduction, the quartz tube (d) serving as a guide for the vessel containing the sample as shown in Fig. 3, is attached inside the quartz tube (e) on which the coil is wound; moreover, because of the radiation, the outside surface of the transparent quartz tube (d) is frosted. In spite of these attentions, the Q-change of the coil still remains somewhat, so that the coil must be cooled by a fan after the heated quartz vessel with coal is drawn up.

The coal specimens were pulverized to pass through a 30- and stand on a 60-Tyler mesh sieve. The vitrain of coals of specific gravity less than 1.30, except for Yatake coal, was isolated by the float-or-sink method using mixtures of benzene and carbon tetrachloride. Shikamachi and Yatake coals were pulverized to pass through a 200-Tyler mesh sieve. All samples were dried in air for several days. The characteristics[17] of the various coals are listed in Table I. Taking account of the loss in weight of coal by carbonization as shown in Fig. 4, the initial coal sample length in the quartz vessel was made longer than 6.5 cm. (refer to Table III and Ref. 15).

In the previous experiment (Ref. 15), the Q-value did not change when the quartz vessel without a sample solution was inserted into the coil. This seems to be attributable to the high resistance or low loss of the quartz vessel at 3×10^6 cycle. On the contrary, it can be imagined that the properties of the quartz vessel will change in the present case because the vessel is heated to about 1000°C. Therefore, it is necessary to investigate the variation in coil character due to the property change of the heated quartz vessel without a sample. The Q of the coil is measured when the heated quartz vessel without a sample is put into the coil; the results obtained are shown in Table II.

The notation Q_1 means the Q-value of the coil without a quartz vessel, just before measuring the Q-value of the heated quartz vessel with or without coal. In order to measure the Q-value correctly, the capacity of the condenser in the Q-meter most be adjusted at the tuning point, but it is not changed when measuring the heated quartz vessel without coal, after adjusting it without the vessel. It may be considered that the Q/Q_1-value of the heated quartz vessel, at least, would not be smaller than the one in Table II, because the V/V_0-value of coil has a tendency to decrease when the capacity of condenser is not tuned. According to the experimental result, the decrease of the Q-value is so small that it can not be detected up to 750°C, while the value of Q/Q_1 decreases slightly with the increase of temperature in the range from 800 to 900°C. Therefore, it may be concluded that the variation in Q-value caused by carbonized coal is hardly affected by the heated quartz vessel, because the variation due to the carbonized coal is much larger than that due to the heated quartz vessel at a high temperature.

When the Q-value is measured, as mentioned above, the capacity of the condenser must be adjusted again after the heated quartz vessel with coal sample is inserted into the coil. It is not unreasonable to assume that the tuning capacity of the condenser has a tendency to decrease when carbonized coal is inserted into the coil, because an aqueous solution has the same tendency. Thus, the capacity of the condenser decreases at a suitable rate from the tuning capacity without the heated vessel, and the maximum value of V/V_0, that is to say, the Q of the coil, is measured after the heated vessel with coal is put into the coil.

The time required for each measurement of Q-value is usually less than five seconds. The temperature at which the Q-value is measured is selected according to the quantity of variation of Q. As the temperature of the heated coal decreases when the coal is inserted into the coil, the next measurement of Q-value must be carried out after enough time to recover the decline in temperature and keep the heating rate of 2°C per minute on an average. Therefore, the narrowest interval of temperature for measurement has been decided as 20°C. The reading of the thermometer goes down about 5°C to 20°C over the range from 500°C to 900°C after the quartz vessel containing the coal is withdrawn into the furnace, but this decrease is recovered and the reading of the thermometer becomes the desired value after 2 to 5 min. In the measurement at higher temperatures, there is still a small decrease of Q_1, in spite of cooling the coil with the fan after the Q-value is measured and withdrawing the heated quartz vessel as fast as possible. It must be remembered, however, that this decay of Q_1 does not interfere with the following experiment, since the ratio, Q/Q_1, is discussed instead of the Q-value, and the variation in the Q-value due to the coal sample is rather large in the higher temperature range.

Experimental Results

The measurements were made of the samples under vacuum, and the results are shown by the dotted lines in Figs. 5a—5d. There is a slight danger under a vacuum condition that some of the coal samples may suddenly expand and lose packing uniformity by the gas given off on thermal decomposition. In order to avoid these errors, the variation of the Q-value was also measured for the sample in a nitrogen atmosphere (1 atm.) substituted for the air around the coal before the start of heating. In this case, the initial coal sample in the quartz vessel has a length of 10 cm., as is shown in Table III. The experimental results in the nitrogen atmosphere are shown by the full-lines in Figs. 5a—5d. Minimum and maximum values of the full-line and the dotted line in Figs. 5a—5d are listed in Table III, together with the temperature at which they were measured. These values are classified into first and second values by depth of minimum value. The shape of the curves which have one minimum is similar to that of aqueous solution, as shown in Ref. 13 and Fig. 2. As the length of coal in the quartz vessel changes with heating, the variation of Q/Q_1 and tuning capacity ($\Delta C'$) must be measured for an aqueous solution with the corresponding length in order to compare the results of coal with those of aqueous solution. They are listed in Table IV. It can be concluded from Table IV that the concentration of an aqueous solution which shows a minimum or a maximum has nothing to do with the change of length. However, the minimum value of Q/Q_1 slightly changes with the length, while the maximum value is

approximately constant. The value of the tuning capacity decreases with the increase of the concentration of the aqueous solution, although it becomes slightly smaller with the increase in the length of solution.

It seems impossible to neglect the change of length in a discussion of the experimental results of coal obtained under heating. Therefore, the following experiments were made. The powder of Shikamachi or Yatake coals was moulded like brick[18] under a pressure of 1000 kg./cm^2, and it was cut into the proper size for blocks. They were buried in other coal powder, and their temperatures were raised at a suitable rate so as to prevent oxidation and expansion by the gas evolved. In order to keep the heating uniform, they are kept in the last-desired temperature for one hour. After cooling, a cylindrical bar of carbonized coal was made by lathe. The length and the diameter are 6.5 cm. and 1.70 cm. respectively. The results made by measuring these samples at room temperature, are shown by the full-lines in Fig. 6 (refer to Table II, except 640

and 690°C). There exists at least one minimum value near 675°C (Shikamachi) or 625°C (Yatake). To make sure of the depth of the minimum, the bar of Shikamachi or Yatake coal, which had already been heated up to 550°C, was put into the quartz vessel and heated again from room temperature at the rate of 1°C per minute in vacuo. The results obtained are also shown by the dotted lines in Fig. 6.

Discussion

There exist several papers[19-25] on the subject of the dielectric sonstant of coal. According to Ref. 19, the dielectric constant and loss factor of various coals were measured at room temperature. Each of the test pieces was cut from the vitreous portion of a large block of coal and then carefully made into the form of a circular plate about 4 cm. in diameter. The test pieces thus prepared were kept in the desiccator over phosphoric anhydride for three or four months. The present writer measured the dielectric constant and the dielectric loss factor of various coals by using the above-mentioned method, as shown in Fig. 7. There have been few papers[26-28] concerning the

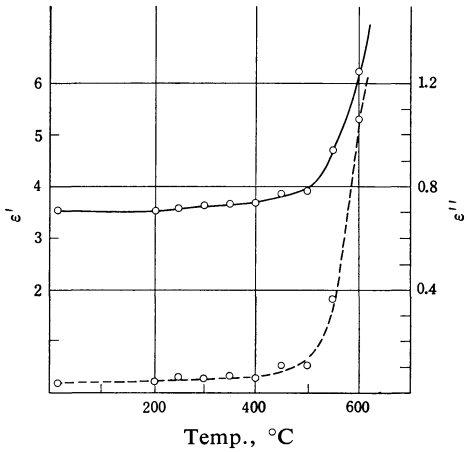

Fig. 8. Relation between dielectric constant (full-line), loss factor (dotted line) and carbonization temperature of Shikamachi coal (circular plate) at 3×10^6 cycle.

dielectric constant of carbonized coal. According to Ref. 26, a method using the powder of carbonized coal and paraffin was adopted for measuring the dielectric constant of carbonized bituminous coal. It has been described how the dielectric constant of the mixture increases beyond 600°C, while the dielectric loss factor increases with the temperature to a maximum at about 650°C, above which it decreases with the temperature, reaching a minimum at about 700°C; there is then a sudden increase above about 700°C. According to Ref. 28, a sudden increase in the dielectric constant of the original coals was observed at 600°C. Therefore, the present writer prepared many test pieces of circular plates (5.1 cm. in diameter, about 0.6 cm. in thickness) by pressing the powder of Shikamachi coal under 1400 kg./cm^2. These samples were carbonized up to the desired temperature at the heating rate of 1°C per minute. The dielectric constant and the loss factor of the sample were measured at room temperature by the method in Ref. 19, but the measurement was rather difficult for the sample beyond 550°C. The results are illustrated in Fig. 8.

It has been implied in Ref. 19 that Japanese coals are constituted mainly of non-polar substances. Furthermore, in Ref. 23, brown coals are found to have a moment near to that of one O–H group and that the polarity of bituminous coal is in general too small to be distinguishable from zero. According to Ref. 20, the ε' values of coals were found to rise very rapidly above 88% carbon content, and the rise was ascribed to a progressive increase in electrical conductance. The dielectric constant of coals used in the present experiment is less than ten, as is shown in Fig. 7. In Ref. 28, the sudden increase in the dielectric constant at 600°C has been attributed to an increase in the electrical conductivity of coals in the region of this temperature. Taking the above-mentioned results into account, it is unlikely that the ε' value of carbonized coal or coal being heated increases to a large value due to the mechanism shown by such polar molecules as water or methyl alcohol.

The specific resistance, r, at 3×10^6 cycle of carbonized Shikamachi and Yatake coal bars was obtained by the following method. The coal bar, of which a tin-foil with a short wire is attached to each side, was connected parallel to the variable condenser of Q-meter to measure the Q-value, so that the next relation (Eq. 18 in Ref. 15) can be used:

$$r=\frac{1}{\omega C}\cdot\frac{QQ_1}{Q_1-Q}\cdot\frac{\sigma}{h} \qquad (2)$$

in which σ is the section area of the coal bar and h its length. There is no sample having the value of $10^2\sim10^4\ \Omega\cdot$cm., so that the coal bars, S-675°C and Y-625 shown in Table II, are heated again up to 690 and 640°C respectively in vacuo. These results are listed in Table V, and the relation between the value of Q/Q_1 and the specific resistance is shown in Fig. 9 together with that of aqueous solution. The value of specific resistance at direct current

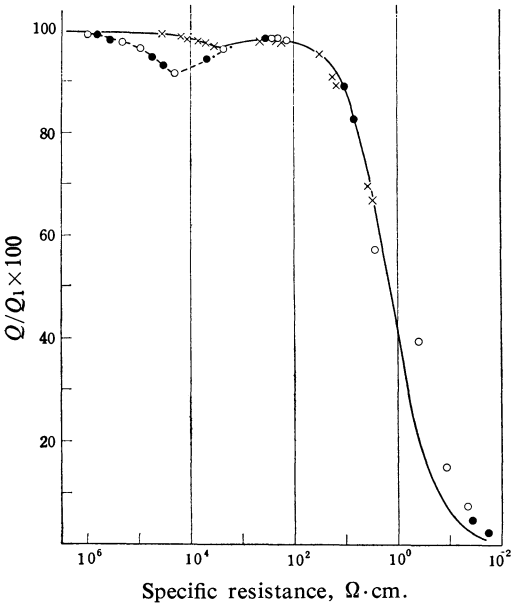

Fig. 9. Relation between $Q/Q_1\times100$ and specific resistance of carbonized coal or aqueous solution at 3×10^6 cycle.

○ Shikamachi ● Yatake
× Aqueous solution

for some coals carbonized at a higher temperature is used instead of that at 3×10^6 cycle since the latter can not be obtained by using the Q-meter. This manipulation results in several points in Fig. 9 not being located on the curve obtained by Eq. 1 over the range of lower specific resistance. The minimum value of carbonized coals in Fig. 9 is smaller than that of the aqueous solution. The description as shown in Ref. 15, "the minimum value of Q/Q_1 depends on the dielectric constant", is very helpful in understanding this difference in minimum value, because the original coal sample used in the present experiment has a dielectric constant value of less than ten. Therefore, this fact may support the view that there must be the dotted line as shown in Fig. 2 obtained by calculation. The dielectric constant of some of the carbonized coals is calculated by using the value of r at 3×10^6 cycle in Table V and Eq. 1. Above about 2×10^4 Ω·cm., in Table V, the values of ε' of the carbonized Shikamachi and Yatake coals are less than ten, but at the specific resistance lower than this value, they increase rapidly.

The calculation of the dielectric loss factor was done for the carbonized Shikamachi coal bar using the following relation from Ref. 15 and the value of $r(=\rho)$ as shown in Table V:

$$\frac{1}{\rho}=\frac{f(\varepsilon'/\varepsilon_0)\tan\delta}{1.8\times10^{12}}$$

or

$$(\varepsilon'/\varepsilon_0)\tan\delta=\frac{1.8\times10^{12}}{\rho f} \qquad (3)$$

From these values, ε' in Table V and Fig. 8, the variation in the dielectric property of the circular plate and the cylindrical bar of Shikamachi coal for carbonization temperature are visualized in Fig. 10, although the value of ε'' of the circular plate and the cylindrical bar at 600°C is slightly different since the value of

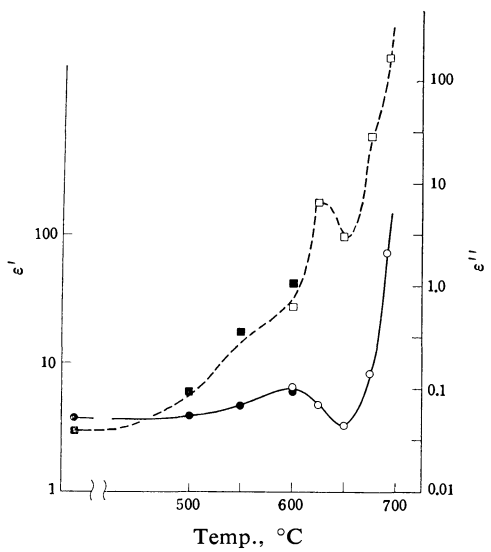

Fig. 10. Relation between dielectric constant (full-line), loss factor (dotted line) and carbonization temperature of Shikamachi coal at 3×10^6-cycle.

● ■ Circular plate
○ □ Cylindrical bar

ε'' of Shikamachi coal increases greatly in the vicinity of this temperature. The dielectric constant not only slightly increases from room temperature to 400°C, but also increases substantially beyond 400°C (refer to Fig. 8), shows a maximum and minimum at 600 and 650°C respectively, and then increases again rapidly. There is a similar tendency in the variation of the dielectric loss factor. However, the dielectric constant decreases in the neighboring range of 625°C, at which the dielectric loss factor shows a maximum value. It seems that this relation has something to do with the anomalous dispersion of carbonized coal shown at about 700°C in Refs. 26 and 27.

Returning to Fig. 6, the Q/Q_1 value of the full-line of the Shikamachi coal bar hardly changes over the range from room temperature to 500°C, since it may be considered that the values of ε' and r do not change greatly over this temperature range. Moreover, the Q/Q_1 value of the full-line has only a little change at the interval of 500~600°C, although the values of ε' and r changes substantially in this range. The variation of Q/Q_1 due to the effect of r appears beyond 600°C. In this case, the value of r, at which the dotted line in Fig. 9 begins to show the decrease of Q/Q_1, is larger than that of the aqueous solution, owing to the difference of dielectric constant between the carbonized coal and the aqueous solution. The Q/Q_1 value of the full-line of the Shikamachi coal bar in Fig. 6 increases in the range of 625~650°C, because the value of r increases greatly in spite of the decrease of ε', and then decreases to the minimum value. Under the conditions of the increase of ε' and the decrease of r, the value of Q/Q_1 increases from this minimum value to the maximum value determined by the effect of the eddy current in the coal sample. Furthermore, the eddy current causes a sudden decrease in the value of Q/Q_1 at a higher temperature, as deduced from the descriptions in Refs. 12—15, because the powders in the coal sample connect with each other owing to the strong caking property of coal. The first minimum of the full-line of the Yatake coal bar is not found in Fig. 6, although it might exist near 600°C. The dotted lines in Fig. 6 have not the first minimum. This result may be considered as due to the fact that the specific resistance in the sample is not uniform because of the low heat conductivity of this sample. It is reasonable that the temperature at the minimum value of Q/Q_1 shifts to the lower temperature side, comparing the dotted line with the full-line since the measurement was done at a high temperature with lower heating rate. The second minimum of the dotted lines in Fig. 6 seems to correspond to the minimum of the dotted line in Fig. 9. According to Table IV in Ref. 15, it is likely that the ε' values of S-550°C at 590°C and Y-550°C at 570°C are the order of 9~10.

The results of the coals in Figs. 5a—5d under the carbonization process show many different curves depending on the grade of coal. They may be caused by the different chemical structures of coal, as deduced from the result of analysis in Table I and the above-mentioned dielectric character. All the curves in Fig. 5a have the first and the second minima except Nakagō's full-line which has no second minimum, the reason for which is difficult to ascertain. These first minimums may be understood by considering the increase of r-value near 500°C, although the length of the samples changes during the carbonization process. Takamatsu coal does not show the first minimum on the full-line in Fig. 5b. It may be considered that the value of ε' would be less than about twenty over the range from room temperature to the second minimum temperature. The sudden decrease of Q/Q_1 in the full-line appears in the range of higher temperatures, whereas the one in the dotted line can not be located. The Yūbari coal lines in Fig. 5c are similar to those of Takamatsu coal as far as the first minimum is concerned. The value of Q/Q_1 of both the lines at higher temperatures sharply decreases to near zero, as do those of Shikamachi and Yatake coals

in Figs. 5c and 6. It may be considered that these decreases have shown the effect of eddy current due to the strong caking property of the coals. The ε' value of the carbonized Yūbari coal may be less than twenty till near 560°C. In Fig. 5c, the ε' value of the carbonized Shikamachi coal may be as small as the one of the original coal till the second minimum temperature. The value of Q/Q_1 of Uonuki coal in Fig. 5d decreases quite a bit at higher temperatures, although Uonuki coal is not a strong caking coal. The second minimum value is small, as is that on the full-line of Shikamachi coal in Fig. 5c. It seems that the value of ε' is less than ten at the second minimum temperature. The temperature, at which the first minimum value is shown, is below 600°C except that of Shikamachi coal. Above all, the first minimum value of Hongei (anthracite) under vacuum is located at rather a lower temperature. Both lines for Hongei coal in Fig. 5d begin to change the value of Q/Q_1 from a lower temperature than do those of other coals. These phenomena seem to be attributable to the special chemical structure Hongei coal, as imagined from the frequency dependence of the dielectric constant and the loss factor shown in Fig. 7. Although the coal samples change their length by thermal decomposition, the second minimum values are less than 93.8 per cent, which corresponds to the minimum value of aqueous solution having the length of 10 cm. This fact seems to support the deduction about the dotted line in Fig. 9, by taking it into account that the dielectric constant of the coals under carbonization would be quite a bit less than eighty over the range from room temperature to the respective temperature of the minimum.

Finally, the value of the variation in tuning capacity of carbonized Shikamachi and Yatake coals in Table II decreases with the increase of carbonization temperature over 600°C. It can be considered that these value seems to decrease monotonously with the increase of the dielectric loss factor, because the aqueous solution shows the same relation in Table IV. Comparing the carbonized coal and the distilled water, the variation in the tuning capacity of carbonized Shikamachi and Yatake coals, having a specific resistance of the same order or larger than that of distilled water, is less than that of distilled water, owing to the difference in the dielectric constant between the coal and the distilled water, as expected by Eq. 14 in Ref. 15.

Summary

The relation between the value of Q/Q_1 and the carbonization temperature of coal has been studied for various coals. The shape of the curve depends on the grade of coal. It is significant that the Q/Q_1 value of both the full-line and the dotted line in strongly caking coal suddenly decreases at higher temperatures. Most of the curves have a second minimum value which is smaller than that of the curve for the aqueous solution. This can be understood by taking account of the difference in dielectric constant between the coal and the aqueous solution. This result seems to support the existence of the dotted line in Fig. 2, as well as the opinion in Ref. 14 that the factor, p, would be very important.

The Crystal Structure of Nickel Dialpha-amino Isobutyrate Tetrahydrate

By Teruo NOGUCHI*

(Received May 16, 1961)

Recently the present author succeeded in constructing an electronic device[1] to compute the minimum-functions[1] proposed by Buerger[2]. The present paper will give a structure analysis of nickel(II) α-amino isobutyrate tetrahydrate, which seemed to present a suitable problem for applying this device.

A good deal of the structures of amino acids has been elucidated in the past several years, but not so much has been done for the amino acid salts. The differences in the configuration of acid groups between the free acid and salt might be one of the most interesting problems from the chemical point of view. This paper will present its findings by reviewing the X-ray analysis of nickel α-amino isobutyrate tetrahydrate.

Experimental

The crystals used in this investigation were prepared by adding an excess of freshly prepared nickel(II) hydroxide to a warm aqueous solution of α-amino isobutyric acid. The solution was then filtered and allowed to evaporate slowly. This procedure made it possible to obtain blue needle-like crystals, the direction of elongation being along the a-axis.

Crystallographic Data

Laue, oscillation and Weissenberg photographs taken with copper K_α radiation (λ= 1.542 Å) confirmed the unit cell dimensions of the crystal reported by Hirokawa et al.[3,4]:

$a=9.92\pm0.02$ Å $\quad c=11.42\pm0.02$ Å

$b=14.24\pm0.05$ Å $\quad \beta=107.5\pm0.5°$

The space group of the crystal was concluded to be $P2_1/a$ from the systematic absences of the following spectra: $(h\,k\,l)$ for all, $(0\,k\,0)$ for $k=2n+1$, and $(h\,0\,l)$ for $h=2n+1$.

The density of the crystal, measured by the floatation method, was found to be 1.48 g./cc., corresponding to four formula units, $4Ni(NH_2\cdot(CH_3)_2C\cdot COO)_2\cdot 4H_2O$, in the unit cell. There are two kinds of amino acid groups and four kinds of water molecules which are crystallographically non-equivalent.

Determination of the Structure

The intensities of the $(0\,k\,l)$, $(h\,0\,l)$ and $(h\,k\,0)$ reflections were estimated visually from Weissenberg photographs. The intensities of the reflections on different films were put on the same scale by comparing the intensities of the same reflections appearing on successive photographs.

No correction were made for absorption, because the crystals used were cut into suitable sizes and shapes, having dimensions less than 0.2 mm.×0.4 mm. in cross section.

After a correction for the Lorentz and polarization factors, the measured intensities were converted to an absolute scale by using Wilson's statistical method (Wilson, 1949)[5].

Using the F^2 values thus obtained, three sets of Patterson syntheses were computed along the a-, b- and c-axis. The minimum-function method (Buerger, 1951) was applied first to $P(v, w)$, using the image seeker described in a preceding paper[1]. The obtained minimum function (M_2) is given in Fig. 1. It gives a clue to the structure, giving approximate

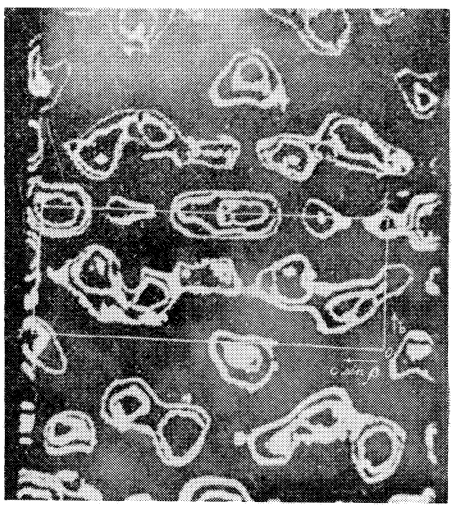

Fig. 1. M_2-Map from $P(v, w)$ obtained by the application of the newly designed image-seeker.

values of the y- and z-coordinates not only for the nickel atom but also for several light atoms. The same procedures were applied to $P(u,v)$ and $P(u,w)$. Though the obtained maps were rather poor to resolve the location of each atom, a rough lay-out of the structure was obtained from the interpretation of these three minimum function maps.

Structure factors for $(0\,k\,l)$, $(h0l)$ and $(hk0)$ were calculated using the parameters found from the three sets of M_2-maps. These parameter-values were first refined by the Fourier syntheses. The locations of some atoms on the projected electron-density maps were obscured on account of overlappings. The coordinates of these atoms were obtained by successive refinement, using the trial-and-error method.

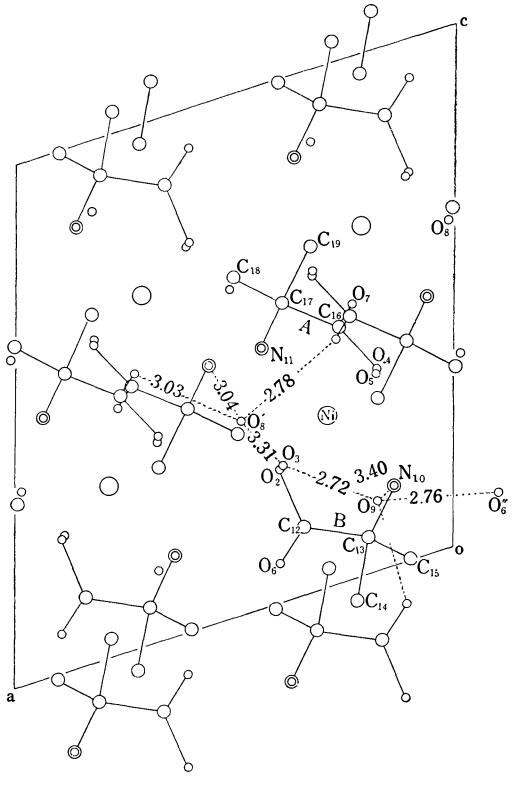

Fig. 6. The structure of nickel dialpha-amino isobutyrate tetrahydrate viewed along the b-axis.

○ Ni ∘ O ◎ N ○ C

Comparison of F_o are tabulated in Table II, where the F_c-values include the overall temperature factor ($-3.15 \sin^2\theta/\lambda^2$).

The reliability index, neglecting unobserved reflections, is 16.8, 15.7 and 18.1% respectively for the ($0kl$), ($h0l$) and ($hk0$) reflections.

Discussion of the Structure

The Amino Acid Radicals.—The interatomic distances and the bond angles for the two kinds of acid groups are given in Table III. Standard deviations were estimated to be ±0.05 Å for distances and ±5° for angles. For comparison, the reported values for the free acid (Hirokawa, 1952) are given in the last column of Table III.

In the structure of α-amino isobutyric acid (Hirokawa et al., 1952), the carboxyl group, C_α and N, is almost coplanar. The most characteristic feature of the structure of the nickel salt is that the nitrogen atoms are definitely out of the plane, the angles of twist around the C_α–C_o bonds being 17.8° and 24.1° respectively for groups A and B. It is interesting to note that the configurations and the dimensions of the two kinds of the amino acid groups are almost the same. The twist around the C_α–C_o bond may be caused by the coordination of amino groups around the nickel ion.

The nearest neighbors surrounding the nickel ion are two carboxylic oxygen atoms, two nitrogen atoms and two water molecules. They form a distorted octahedron, having the structural dimensions which are given in Table IV and Fig. 4 (a).

The two kinds of the amino acid groups form chelate rings with the nickel ion by the nitrogen atoms in the amino groups and by the carboxylic oxygen atoms, assuming a cis-configuration (Fig. 4 (b)).

TABLE III. MOLECULAR DIMENSIONS OF THE α-AMINO ACIDS

	Group A	Group B	Free molecule
(a) Interatomic distances, Å			
O_c-C_c	1.32	1.30	1.26
	1.29	1.22	1.20
C_c-C_α	1.48	1.58	1.52
C_α-N	1.47	1.48	1.49
C_α-C_β	1.50	1.57	1.53
	1.55	1.60	1.54
(b) Bond angles, °			
O_c-C_c-O_c	115	119	125
O_c-C_c-C_α	122	121	118
	119	119	118
C_c-C_α-N	113	112	109
C_c-C_α-C_β	114	105	114
	98	104	109
N-C_α-C_β	114	122	108
	118	109	105
C_β-C_α-C_β	100	104	112

TABLE IV. INTERATOMIC DISTANCES AROUND THE NICKEL ION, Å

Ni-O_2	2.11	N_{10}-O_5	3.01
Ni-O_3	2.14	N_{11}-O_2	2.97
Ni-O_4	2.24	N_{11}-O_3	3.14
Ni-O_5	2.01	N_{11}-O_4	2.88
Ni-N_{10}	2.11	N_{11}-O_5	3.01
Ni-N_{11}	2.10	O_2-O_3	3.02
N_{10}-O_2	2.79	O_2-O_4	3.07
N_{10}-O_3	3.03	O_3-O_5	2.82
N_{10}-O_4	2.99	O_4-O_5	2.99

Thus, two of the four water molecules are coordinated to the nickel ion, and the remaining two are found between these octahedra, playing the role of binding them. Each of the latter two water molecules has three carboxylic oxygen atoms and one nitrogen atom as its nearest neighbors. The interatomic distances and angles around these water molecules are shown in Fig. 5. It is rather difficult to say which of these contacts are hydrogen bonds, though the interatomic distances suggest they are O_7—$H_2O(O_8)$, O_3—$H_2O(O_9)$ and O'_6—$H_2O(O_9)$. These features may be compared to the hydrogen bonds in the structure of ice.

The structures viewed along the b-axis are shown in Fig. 6, where one can easily see the following structural features: the two amino acids and the two H_2O molecules are coordinated to the nickel ion, forming a complex. These groups are held together along the [101] and [100] directions by the other H_2O molecules, making short contacts between them.

Summary

The unit cell of nickel(II) dialpha-amino isobutyrate tetrahydrate has the follwing dimensions; a=9.92, b=14.24, c=11.42 Å, β=107.5°, and contains four chemical units. The space group is determined to be $P2_1/a$.

Buerger's minimum-function method was applied to the structure analysis, and the newly designed image-seeker was used. Two of the four water molecules are coordinated to the nickel ion, forming a distorted octahedron with the carboxylic oxygen and the amino nitrogen atoms. The other two water molecules play the role of binders for these octahedrons. The chelation of the amino acid molecules is of the cis-form. The structure of the skeleton of α-amino propionic acid in this complex is not planar, in contrast to that of its free acid.

The author is indebted to Professor Isamu Nitta, Professor Tokunosuke Watanabe and Professor Sakutaro Hirokawa, who encouraged him throughout this investigation. He also wishes to express his heartfelt thanks to Professor Masao Sawada, who showed a deep interest in this structure analysis.

*Biochemical Studies on Oils and Fats. X. Toxicity of Thermally Denatured Ethyl Linolenate**

By Noboru MATSUO

(Received May 19, 1961)

In previous papers the author has reported that thermally denatured fish oil (cuttle fish oil)[1,2], rape-seed oil[3], and the ethyl esters of highly unsaturated fatty acids[4] show toxicity due to monomeric cyclization products formed as a result of heating.

For the purpose of elucidating the properties and structure of the cyclic products, experiments were conducted to investigate whether or not ethyl linolenate shows a similar toxicity when thermally denatured. The present paper describes the results of the experiments.

Experimental and Results

Separation of Linolenic Acid from Linseed Oil.—Refined linseed oil, whose properties are shown in Table I, was saponified by the ordinary method, and the separated fatty acids were dissolved in ether. Bromine was dropped into the ether solution with cooling. The precipitated bromide was collected by filtration, washed with cold ether, and then dried. For purification, the bromide was dissolved in a large quantity of benzene, and the solution was boiled on a hot water bath. The hexabromide of linolenic acid was then obtained as white precipitate on cooling. The precipitate was collected, washed with cold ether and dried. The hexabromide thus obtained was treated with zinc, ethanol and hydrochloric acid to effect debromination and esterification simultaneously. The ester mixture was distilled in vacuo (1.5 mmHg), and the fraction boiling at 167~170°C was used in the experiment. The properties of this fraction are shown in Table I.

Thermal Denaturation of Ethyl Linolenate and Separation of Cyclic Monomer.—Thermal denaturation of ethyl linolenate was carried out by heating it for 40 hr. at 250°C in a carbon dioxide stream. During this process the iodine value decreased from 242.5 to 157.5, as is shown in Fig. 1. Straight chain ester and cyclic ester were separated from the denatured ethyl linolenate by the urea adduct method[1]. The yields of the straight chain ester and the cyclic ester were 21.2 and 63.3% respectively. By vacuum distillation, the latter was separated into distillate (153~175°C/1.8~2.0 mmHg) and residue. The distillate is a transparent light yellow, and its yield was 24.7% of the total cyclic ester. The residue is somewhat viscous, transparent, and reddish brown, and its yield was 70.8%.

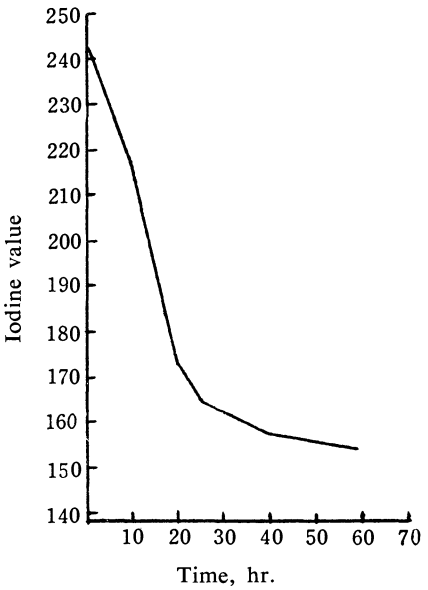

Fig. 1. Change in iodine value of ethyl linolenate due to thermal denaturation.

TABLE I. PROPERTIES OF LINSEED OIL AND ETHYL LINOLENATE

	n_D^{20}	Iodine value (Wijs)	Sap. value	Acid value	Molecular weight (Rast)
Linseed oil	1.4833	191.8	186.9	0	—
Ethyl linolenate	1.4688	242.5	183.1	1.0	302

Animal Experiments with Various Esters.— An animal experiment was conducted in which rats, each weighing about 60 g., were fed on the basal diet containing 20% of a sample ester, as shown in Table II.

TABLE II. COMPOSITION OF DIET (%)

Starch (rice powder):	65
Casein (ether extracted):	9
McCollum salt mixture:	3
Yeast	3
Liver oil:	One drop a day
Ester	20

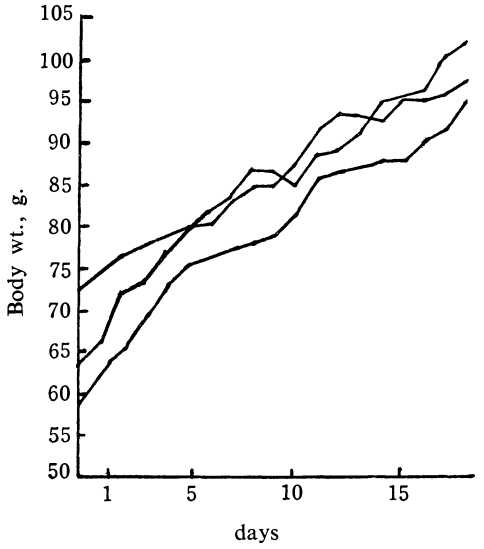

Fig. 2. Growth of rats fed on basal diet containing 20% ethyl linolenate.

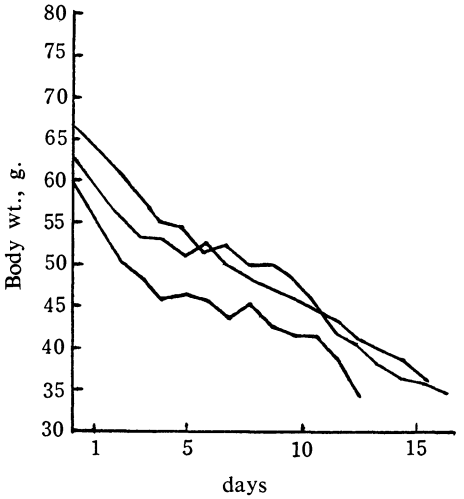

Fig. 3. Growth of rats fed on basal diet containing 20% denatured ethyl linolenate. (All rats died at the ends of the curves.)

Ethyl Linolenate. — The rats fed on a diet containing ethyl linolenate showed a healthy growth, as is seen in Fig. 2.

Denatured Ethyl Linolenate. — As shown in Fig. 3, these rats gradually became thinner and died in 15 days or so.

Distilled Cyclic Ester and Residual Cyclic Ester. — When rats were fed on a basal diet containing 20% distilled cyclic ester, extremely acute toxicity was shown, and all rats died in three or four days. However, no particular change was noticed in the appearance of the rats. In the case of feeding on a basal diet containing 20% residual cyclic ester, toxicity was considerably weaker, and there were some increases in the weight of the rats, although they excreted soft feces (Fig. 4).

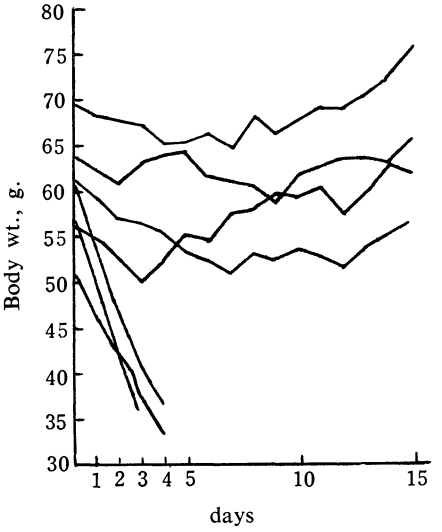

Fig. 4. Growth of rats fed on basal diet containing 20% of distilled cyclic ester (A) and residual cyclic ester (B). (A: all rats died at the ends of the curves.)

From these observations, it was apparent that distilled cyclic ester was severely toxic.

Properties of Various Esters.—The properties of these esters are shown in Table III.

From the iodine value 242.5 of ethyl linolenate (theoretical value: 247.4), it is assumed that the linolenate contained about 6% ethyl linoleate if the contaminant was only ethyl linoleate. The saponification value of this ethyl linolenate was 183.1 (theoretical value: 183.0) and its molecular weight 302 (theoretical value: 306).

The molecular weight of the distilled cyclic ester was 293. From its boiling point, the main component of this cyclic ester is considered a cyclic monomer. Since its iodine value was 159.4, it seems that the original

TABLE III. PROPERTIES OF ESTERS

	n_D^{20}	Iodine value (Wijs)	Sap. value	Acid value	Molecular weight (rast)
Ethyl linolenate	1.4688	242.5	183.1	1.0	302
Denatured ethyl linolenate	1.4838	157.5	170.1	6.5	
Straight chain ester	1.4692	201.5	177.4	0.4	
Cyclic ester	1.4891	142.5	168.6	7.3	
Distilled ester	1.4751	159.4	171.0	7.4	293
Residual ester	1.4948	135.8	168.5	8.2	

linolenate with three double bonds lost one on cyclization. The iodine value of ethyl linoleate, with two double bonds, is 166.0.

Infrared Absorption Spectra of Ethyl Linolenate and Distilled Cyclic Ester.—The infrared absorption spectra of ethyl linolenate and distilled cyclic ester are shown in Fig. 5, I and II, respectively, measured with the Baird B type. The absorption band at about 14 μ for ethyl linolenate is considerably intense and is attributable to cis double bonds.

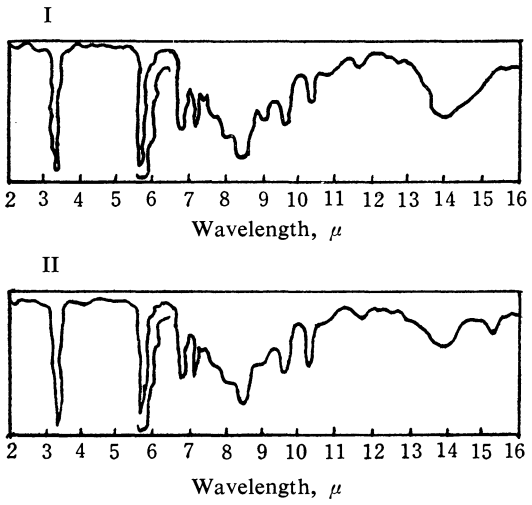

Fig. 5. Infrared absorption spectrum of ethyl linolenate (I) and distilled cyclic ester (II).

Linolenic acid has cis double bonds naturally. When it is separated by the bromination method, however, isomerization takes place to some extent, and an absorption band of 10.3 μ (970 cm^{-1}) attributable to trans double bonds appears. When the absorption band near 6 μ was examined with an increased concentration of the sample, a small absorption was noticed. This absorption is also considered to be attributable to cis double bonds.

When the infrared absorption spectrum (Fig. 5-II) of the distilled cyclic ester is compared with that (Fig. 5-I) of ethyl linolenate, it is found that the absorption attributed to cis double bonds is considerably weaker. This seems to be due to the disappearance of some double bonds. A new absorption band at 15.2 μ (660 cm^{-1}) was observed. Cyclohexene shows a band at 670 cm^{-1} (14.97 μ)[5]. Bands at 663 and 671 cm^{-1} (15.1 and 14.9 μ) are characteristic of Δ^2- and Δ^3-steroids respectively[6], *cis*-α-Ionone[7] also absorbs in this region. So this absorption band is considered to be attributable to the formation of a cyclohexene ring as a result of cyclization. This absorption band was also ascertained by MacDonald[5] in the monomeric, non-urea-adduct-forming material resulting from the ethanolysis of heated linseed oil.

Absorption due to trans double bonds became somewhat greater, but no significant change was observed. Examination of the absorption near 6 μ observed with the higher concentration of the sample showed the existence of two small bands. It seems that the new absorption band at about 6.1 μ (1650 cm^{-1}) originates from the cyclic compound.

Discussion

Acute toxicity is shown by the distilled cyclic ester separated from the denatured product obtained by heating ethyl linolenate for 40 hr. at 250°C. From its molecular weight and infrared absorption spectrum, this distilled ester is considered to be a cyclic monomer with a cyclohexene ring.

Paschke, Wheeler[8] and Rivett[9] have reported the possibility of the formation of intermolecular cyclic compounds. Apparent toxicity was shown also in an experiment feeding animals on a certain synthesized compound containing a cyclohexene ring and one double bond outside the ring[10,11].

Cyclic compounds showed toxicity also in an experiment[4] on highly unsaturated fatty acid

from fish oil; a monomeric cyclization product, separated by vacuum distillation, was the main origin of the toxicity.

From the result of the experiment on ethyl linolenate, it can be concluded that the origin of toxicity is a monomeric cyclization product, and that the main component of this product is a compound having a cyclohexene ring.

Summary

When ethyl linolenate is thermally denatured at 250°C for 40 hr. in a carbon dioxide stream, the product is toxic to rats. The origin of the toxicity of thermally denatured ethyl linolenate is a monomeric cyclization product, which is mainly a compound having a cyclohexene ring.

The author expresses his deep appreciation to Dr. Keizo Kodama, President of Tokushima University, for his guidance during this work.

Thanks are also due to Dr. Seishi Tanaka, instructor at the Engineering Research Institute, Faculty of Engineering, The University of Tokyo, to whom the author is greatly indebted for the infrared absorption spectra.

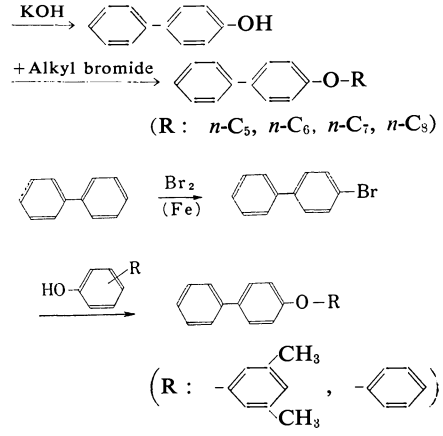
Synthesis of n-Alkyl p-Diphenyl Ethers and Aryl p-Diphenyl Ethers



By Hajime SUZUMURA

(Received May 4, 1961)

n-Alkyl *p*-diphenyl ethers[1] whose alkyl group consists of either C_1, C_2, C_3, C_4 and C_5, and aryl *p*-diphenyl ethers whose aryl group includes phenyl[2], *p*-tolyl[3] and benzyl[1] have hitherto been reported on in the literature. Their melting points are shown in Tables I and II.

The melting points, except for those of allyl, benzyl and *p*-tolyl ether, are within a relatively narrow range. In order to examine the physical properties of the ethers which have a longer alkyl chain or a methylated benzene ring, the author newly synthesized *n*-alkyl ethers (*n*-C_6, *n*-C_7 and *n*-C_8) and an aryl ether (3, 5-dimethylphenyl) along with the known *n*-amyl and *p*-phenyl ethers by the scheme shown below.

Diphenyl was first sulfonated in nitrobenzene[4], and the resulting sulfonic acid was

fused with potassium hydroxide to give *p*-phenylphenol, which was condensed with *n*-alkyl bromide in ethanol in the presence of sodium hydroxide.

In the case of aryl ethers, diphenyl dissolved in carbon tetrachloride was treated with bromine in the presence of iron powder, and the resulting *p*-bromodiphenyl was condensed with phenols in the presence of copper powder.

The properties of the purified specimens are shown in Table III.

Experimental

Materials.—*Diphenyl*[5].—A sample supplied by Yawata Chemical Industry Co. was recrystallized from ethanol in the form of white leaflets, m. p. 68～69.2°C.

n-Octanol[6].—A commercial reagent was redistilled, b. p. 194～196°C, n_D^{25} 1.4266.

n-Amyl Bromide[7].—A commercial reagent was redistilled, b. p. 126.5～128°C (757 mmHg) (uncorr.).

n-Hexyl Bromide[8].—A commercial reagent was redistilled, b. p. 155～157°C (757 mmHg), n_D^{20} 1.4469.

n-Heptyl Bromide[9].—A mixture of *n*-heptyl alcohol (20 g.), 72 g. of hydrobromic acid and 18.2 g. of concentrated sulfuric acid was refluxed for 6 hr., then washed with water and dilute sodium carbonate solution and finally dried over calcium chloride; yield 22.87 g., 75%, n_D^{25} 1.4482.

n-Octyl Bromide[10].—It was prepared in the same manner as above. From a mixture of *n*-octanol (18.6 g.), 65 g. of hydrobromic acid, 17.0 g. of concentrated sulfuric acid, and 9.6 g. of a fraction boiling at 195～203°C were obtained; $n_D^{19.5}$ 1.454.

1, 3, 5-Xylenol[11].—Commercial reagent; m. p. 61°C.

Bromine, Potassium Hydroxide, Sulfuric Acid.—Commercial reagent.

Synthesis of *n*-Alkyl *p*-Diphenyl Ether.—*Sulfonation of Biphenyl.*—Biphenyl (30 g.), 40 cc. of nitrobenzene and 19 g. of concentrated sulfuric acid were kept at 80～90°C while being stirred for 6.5 hr. Unreacted diphenyl and nitrobenzene were steam distilled, and sodium salt of diphenyl-*p*-sulfonic acid (20.7 g.) was obtained by the addition of a sodium hydroxide solution to the residue. 8.1 g. of diphenyl was recovered. The yield of the sulfonic acid based on the consumed diphenyl was about 57%.

Alkali Fusion of the Sulfonate.—Into potassium hydroxide melted in an nickel crucible at 290～300°C the sodium sulfonate was gradually stirred, and the heating was continued for a while. The mixture was then allowed to cool and dissolved in water. Upon the addition of hydrochloric acid to this solution, a precipitate of crude *p*-phenylphenol was obtained. The results of the potassium hydroxide fusion are shown in Table IV.

TABLE IV

Na-sulfonate g.	KOH g.	Time of fusion min. at 290～300°C	Time of fusion min. at 320～330°C	*p*-Phenylphenol Amount g.	*p*-Phenylphenol Yield %
7.7	25.0	10	15	4.15	81
12.0	46.5	15	5	6.80	85
9.6	32.0	10	5	5.60	88

The crude phenylphenol was distilled in vacuo to give a distillate which boiled at 184～190°C (18 mmHg) and melted at 159～162°C (uncorr.).

Condensation.—It was carried out by the Williamson reaction. A mixture of *p*-phenylphenol, ethanol, sodium hydroxide and *n*-alkyl bromide was refluxed, and the mixture was poured into water. On the addition of an aqueous solution of sodium hydroxide, the crude ether was separated from the phenylphenol which had been recovered by the acidification of the filtrate. The crude ether was purified by recrystallization from ethanol. The results are shown in Table V.

Synthesis of Aryl *p*-Diphenyl Ether.—*Synthesis of p-Bromodiphenyl*[12].—Bromine (90 g.) was gradually stirred into a mixture of diphenyl (86 g.), 260 cc. of carbon tetrachloride and 2 g. of iron powder, and heating was continued at 45～55°C for 11 hr. The solvent was then distilled off and the

residue distilled in vacuo, the distillate was recrystallized to give 66.7 g. of *p*-bromodiphenyl; yield 51%, m. p. 86~88.5°C.

p-Diphenylphenyl Ether.—A mixture of *p*-bromodiphenyl (47 g.), 27 g. of phenol, 12 g. of potassium hydroxide and 2 g. of copper powder was heated at 184~240°C for 6 hr. The mixture was extracted with benzene, and the benzene extract was concentrated and distilled in vacuo. Recrystallization of the distillate yielded 37.5 g. (76%) of the crude ether, m. p. 60~68°C which was further recrystallized from ethanol to give a purified specimen, m. p. 67~68°C.

Synthesis of 3, 5-Dimethylphenyl p-Diphenyl Ether.—A mixture of *p*-bromodiphenyl (8.7 g.), 2.2 g. of potassium hydroxide, 4.78 g. of 1, 3, 5-xylenol and 0.05 g. of copper powder was heated at 160~200°C for 2.5 hr. The mixture, when treated in the usual manner, gave 3.33 g. of colorless flakes; yield 33%, m. p. 65.5~66.5°C.

Found: C, 87.74; H, 6.49. Mol. wt., 273. Calcd. for $C_{20}H_{18}O$: C, 87.56; H, 6.61%. Mol. wt., 274.

Infrared Spectra of the p-Diphenyl Ethers.—The spectra of *n*-alkyl (C_5, C_6, C_7, C_8) and aryl (C_8) ethers are shown in Figs. 1, 2, 3, 4 and 5. The absorption bands common to these ethers are as follows: a band at 8 μ (1250 cm^{-1}) is assigned to the C-O stretching of the ether linkage, and an appearance of a band in the vicinity of 12.05 μ which corresponds to two adjacent hydrogen atoms in the benzene ring shows that the ethers are all substituted at the para position of diphenyl. Also,

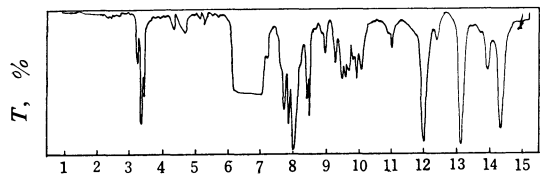

Fig. 1. *n*-Amyl *p*-diphenyl ether.

an absorption band due to the rocking motion of a methylene group in the *n*-alkyl chain appears at the same wavelength in all the *n*-alkyl ethers, as is shown below.

No. of C atoms of *n*-alkyl ether	5	6	7	8
Absorption, μ	13.94	13.95	13.93	13.95

A strong band near 1250 cm^{-1} of the *n*-alkyl ethers is shifted to a slightly shorter wavelength compared with that of the aryl ethers.

	n-Alkyl ether			
The ethers	*n*-C_5	*n*-C_6	*n*-C_7	*n*-C_8
Absorption, μ	8.05	8.07	8.06	8.07

	Aryl ether		
The ethers	Phenyl	3,5-Dimethyl-phenyl	*p*,*p*'-Diphenyl
Absorption, μ	8.15	8.20	8.15

Ultraviolet Spectra.—The spectra in cyclohexane are shown in Fig. 6. Showing almost the same pattern, bands appearing at 248, 254, 260 and 264 mμ are common to these ethers, except for *n*-octyl ether, and the maximum absorption is at a longer wavelength than that of *p*-diphenyl methyl ether, which has been reported to be 259 mμ in cyclohexane. The absorption maximum of *p*-terphenyl, which may be regarded as a phenyl derivative of diphenyl, is at 276 mμ in hexane. Thus the introduction of a phenoxyl group, i. e. an ether linkage, to diphenyl is less bathochromic than a phenyl.

Solubility.—The new alkyl ethers (C_6, C_7, C_8) are only with difficulty soluble in cold ethanol but are readily soluble in benzene. 3,5-Dimethylphenyl ether is with more difficulty soluble in ethanol than *n*-alkyl ethers but is readily soluble in benzene.

The author is indebted to Professor Ryozo Goto of Kyoto University for his helpful discussion and criticisms of this work, and to Professor Sakujiro Kimura for his advice and encouragement.

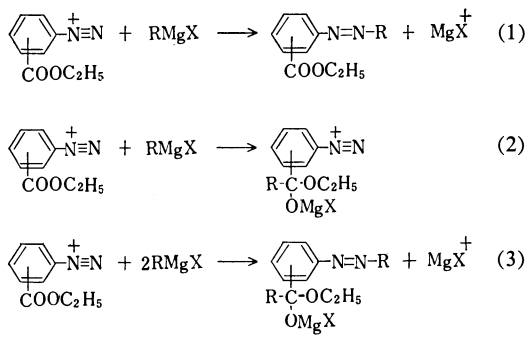
Syntheses and Ultraviolet Spectra of Aromatic Azo Compounds. II. Azobenzenecarboxylic Acids, Methylazobenzenecarboxylic Acids and their Ethyl Esters

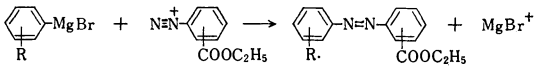


By Yujiro NOMURA and Hiroyuki ANZAI

(Received May 30, 1961)

In the preceding paper of this series[1] the syntheses of twelve bromomethylazobenzenes involving ten new substances by reactions of Grignard reagents with the zinc chloride double salts of diazonium chlorides were reported. We would now like to report our extension of this investigations with the aim of preparing a number of new azobenzene derivatives carrying an ethoxycarbonyl or carboxyl group.

In the reaction of Grignard reagent with ethoxycarbonylbenzenediazonium ion, it was considered that not only the reaction 1 but also the reaction 2 or/and 3 might occur simultaneously in whichever ethoxycarbonyl group was attacked by a Grignard reagent.



Fortunately, however, the azo compound formed by 1 could be readily isolated from the ether solution of the reaction mixture, since the reaction products by 2 and 3 are insoluble in the ether employed as a solvent in this reaction.

General Procedure.—The suspension of 1.25 mol. of the zinc chloride double salt of ethoxycarbonylbenzenediazonium chloride in ether was vigorously stirred and the ethereal solution of phenyl- or tolylmagnesium bromide prepared from 1 mol. of bromobenzene or bromotoluene and the excess of magnesium was added slowly to it at a rate necessary to maintain reflux. The mixture was stirred for an additional 60 min. at room temperature,

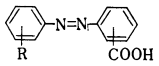
c Based on bromobenzene or bromotoluene used to prepare Grignard reagent.
d The yield was poor, and an analytically pure sample could not be obtained even after repeated distillation in vacuo. Its structure was confirmed, however, by converting it to the known free acid (XIII).
e The reported[2] b. p. of II is 248°C/38 mmHg; it was prepared by the esterification of azobenzene-3-carboxylic acid.
f The reported[3] m. p. of III is 85~86°C; it was prepared from silver azobenzene-4-carboxylate and ethyl iodide.

and the dark red ether solution was then separated by filtration with suction from the unreacted diazonium salt and solid products, which were washed several times with ether. The ether filtrate and washings were combined and washed with dilute hydrochloric acid and then with water, dried and evaporated to get azo compounds as red crystals or oil, which were purified either by recrystallization from alcohol and then from ligroin or by distillation under reduced pressure, depending on their nature.

The ethyl azobenzenecarboxylates prepared by this method are shown in Table I. They are all new compounds except ethyl azobenzene-3-carboxylate (II) and 4-carboxylate (III).

Azobenzenecarboxylic acids and methylazobenzenecarboxylic acids, which were prepared by the hydrolysis of the corresponding ethyl esters in almost quantitative yields, are listed in Table II.

An attempt to prepare azobenzenecarboxylic acid from diazotized aminobenzoic acid and Grignard reagent in ether was fruitless. The ether layer remained almost colorless when the Grignard reagent was added to the suspension of diazonium salt in ether, while diazonium salt turned red brown and from it only a trace amount of azobenzenecarboxylic acid was isolated. The formation of ether-insoluble magnesium salt of azobenzenecarboxylic acid according to reaction 4 and the covering of the surface of solid diazonium salt by it was considered to be responsible for such a poor yield of azo compound.



(4)

The wavelength and the molecular extinction coefficients, ε, of the absorption maxima of ethyl azobenzenecarboxylates and their free acids are listed in Table III.

Experimental

Zinc Chloride Double Salt of Ethoxycarbonylbenzenediazonium Chloride. — Following the procedure described in the previous paper[1], the mixture of ethyl aminobenzoate (1 mol.) and 6 N hydrochloric acid (3 mol.) was diazotized at 0°C with aqueous sodium nitrite, and zinc chloride double salt was precipitated by adding solid zinc chloride (0.65 mol.) to the diazotized solution. Thus, from 16.5 g. of ethyl *p*-aminobenzoate, 67 ml. of 6 N hydrochloric acid and 7 g. of zinc chloride 21.8 g. of the double salt in the form of colorless crystals was obtained. In the same way, from 13.2 g. of ethyl *m*-aminobenzoate and 18.2 g. of ethyl *o*-aminobenzoate 22.0 and 24.0 g. of the respective double salt were obtained.

* Wavelength of shoulder. Methylazobenzenecarboxylic acids and their ethyl esters, in which methyl and carboxyl or ethoxycarbonyl groups are not situated in the para position with respect to the azo group, have no maximum but do have a shoulder at the 220~250 mμ region.

Ethyl Azobenzenecarboxylates. — Twelve ethyl azobenzenecarboxylates were prepared following the general procedure described above. They have been summarized in Table I.

Azobenzenecarboxylic Acids. — A solution of ethyl azobenzenecarboxylate (1 mol.) in alcohol containing sodium hydroxide (1.5 mol.) was warmed on the water bath for an hour, diluted with four times its volume of water and acidified with dilute hydrochloric acid to precipitate azobenzenecarboxylic acid. The products obtained in this manner were almost pure in most cases, and analytically pure samples could be obtained by recrystallization from alcohol. They have been summarized in

Table II. Yields were almost theoretical in all cases.

Measurement of Spectra.—The absorption spectra were measured in an alcoholic solution with a Hitachi EPU 2 type spectrophotometer using a 1 cm. quartz cell.

Summary

1) The zinc chloride double salts of ethoxycarbonylbenzenediazonium chlorides reacted with aryl Grignard reagents to give ethyl azobenzenecarboxylates. This provides a new method for the preparation of these compounds, as has been demonstrated by the preparation of twelve azo compounds, including ten substances not hitherto known.

2) A group of azobenzenecarboxylic acids was prepared by the hydrolysis of the corresponding ethyl esters obtained above; seven of them are new compounds.

3) The ultraviolet absorption spectra of these esters and free acids were measured.

*3, 4-Benzotropolone and Related Compounds. I. Bromo Derivatives of 3, 4-Benzotropolone**

By Seiji EBINE

(Received April 24, 1961)

3, 4-Benzotropolone (I) was synthesized first by Cook et al.[1], later by Moroe et al.[2], and some of its substitution products were reported on by Nozoe et al.[3] Some other benzologs of tropolone and hydroxytropones, such as 4, 5-benzotropolone[4], 4-hydroxy-2, 3-benzotropone[5], and hydroxydibenzotropone[6,7], have recently been reported on. Of these compounds, I is most closely related to the parent tropolone. It seems, therefore, of interest to compare the chemical behavior of I with that of monocyclic tropolone and thereby to examine how the condensed benzene ring influences the character of the tropolone nucleus of I. From this point of view, the present author has undertaken a more detailed study of I and its derivatives. As a part of this work, this paper deals with bromo-3, 4-benzotropolones and their brominated products.

I and its monobromo- and dibromo-derivatives, II and III, the materials for this study, were prepared according to Cook's method[1] starting with 3, 4-benzocycloheptene-1, 2-dione. I, II and III gave ultraviolet spectra characteristic of troponoid compounds (Fig. 1)[8] and exhibited infrared absorption bands of their carbonyl groups within the same region as other troponoid carbonyl groups (as given in the experimental section).

Concerning the position of the bromine atoms in bromo-3, 4-benzotropolones, Cook et al.[1] have reasonably suggested, though without any experimental evidence, that II is 7-substituted and that III is 5, 7-disubstituted. Their prediction is now proved to be true by studies of the oxidation of II and III with alkaline

8) The ultraviolet spectrum of I was given previously. J. W. Cook et al., loc. cit.

hydrogen peroxide to *o*-carboxycinnamic acid and phthalic acid respectively. An attempt was made to obtain 5-bromo-3,4-benzotropolone by catalytic hydrogenolysis of III with one mole of hydrogen. However, this resulted only in the formation of one-half an equivalent of I, the remainder being recovered unchanged and no monobromo derivative being obtained.

I, II and III are less acidic than monocyclic tropolone and bromotropolones. I formed an unstable amine salt which was decomposed readily to its components on recrystallization from solvents. II and III formed stable salts with aliphatic amines but did not with aromatic amines, whereas monocyclic bromotropolones were known to combine firmly with both aliphatic and aromatic amines[9]. The lesser acidity of benzotropolones may be ascribed to the fact that the condensed benzene ring restricts the resonance of the tropolone nucleus. On the other hand, I, II and III behaved as weak bases and dissolved in concentrated sulfuric acid, from which they were recovered unchanged on dilution with water. Such an amphoteric property is characteristic of troponoid compounds.

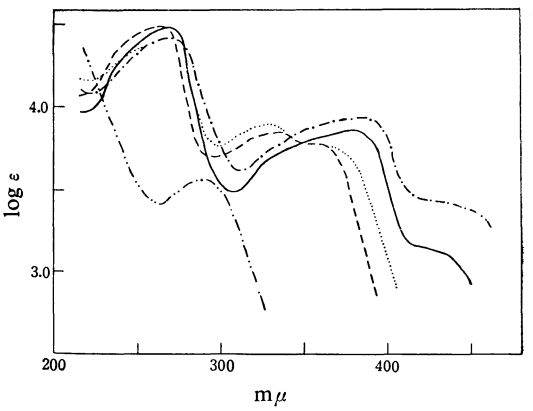
As reported by Nozoe et al.[10], 3-bromotropolone exists as a tautomeric mixture with 7-bromotropolone, and is methylated to produce the two corresponding isomeric methyl ethers. However, II, a benzolog of 3-bromotropolone, was methylated to give only one methyl ether, 6-bromo-7-methoxy-2,3-benzotropone, indicating that II exists in only one form, unlike the monocyclic bromotropolones. A tautomeric form (II′) of II could not exist because its benzene ring is not aromatic but quinonoid.

II′

III was similarly methylated, affording 4,6-dibromo-7-methoxy-2,3-benzotropone as the sole product. These methyl ethers, like II and III, exhibited ultraviolet spectra characteristic of troponoid compounds (Fig. 1). As compared with monocyclic bromotropolone methyl ethers, bromobenzotropolone methyl ethers were more stable towards hydrolysis and were not affected when heated with hydrobromic acid in a methanolic solution for an hour, but hydrolyzed when heated with 47% hydrobromic acid without methanol for two hours. The methyl ether of II was debrominated by catalytic hydrogenolysis to give an oily methyl ether of I, which failed to crystallize[11]. The methyl ether of I afforded a picrate and a 2,4-dinitrophenylhydrazone. II and III gave acetates which were readily hydrolyzed when their methanolic solutions containing a little hydrochloric acid, were refluxed for 5 min.

II was brominated in acetic acid solution to yield III as previously described[1]. In contrast, II was brominated in chloroform solution to yield an addition product assumed to be tetrabromo-3,4-benzocycloheptene-1,2-dione (IV) based upon its spectrum (Fig. 1), which was crystallized unchanged from petroleum ether but was decomposed to yield III on crystallization from acetic acid. III and bromine in chloroform gave an unstable addition product, from which III was regenerated on crystallization from solvents.

III was subjected to exhaustive bromination by heating its acetic acid solution with excess bromine on a water bath for fifteen hours, 2,3-dibromo-1,4-naphthoquinone (V) being unexpectedly produced. V was identified by mixed melting point determination and by agreement in ultraviolet and infrared spectra with an authentic sample. An anilino derivative of V also showed no melting point depression on admixture with an authentic 2-bromo-3-anilino-1,4-naphthoquinone. The structure of V was further elucidated by converting it to 2-bromo-3-*p*-toluidino-1,4-naphthoquinone, 2-bromo-3-hydroxy-1,4-naphthoquinone, 2-bromo- and 2,



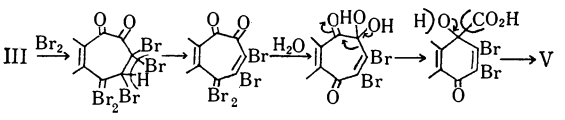


Fig. 1. Ultraviolet spectra of 7-bromo-3,4-benzotropolone (II) (——), 5,7-dibromo-3,4-benzotropolone (III) (-·-·), the methyl ether of II (----), the methyl ether of III (·····) in methanol and tetrabromo-3,4-benzocycloheptene-1,2-dione (IV) (-···) in cyclohexane.

11) Nozoe et al. (Ref. 3) have obtained the methyl ether of I, m.p. 82.5~83.5°C, by the action of ethereal diazomethane on I, while Cook et al. (Ref. 1) have reported that I reacts very sluggishly with diazomethane and smoothly with methyl *p*-toluenesulfonate to yield an oily methyl ether of I.

3-dibromo-1, 4-diacetoxynaphthalenes. The tentative mechanism of this transformation may be represented by the following scheme:

Closely related ring contractions of hydroxytropones into quinones have been reported: 5, 7-dibromo-4-hydroxy-2, 3-benzotropone is transformed on heating with alkali to 2-hydroxy-1, 4-naphthoquinone[5b], and 4-hydroxy-2, 3:6, 7-dibenzotropone in alkaline solution is oxidized by air to anthraquinone[7b].

Experimental

7-Bromo- and 5, 7-Dibromo-3, 4-benzotropolones (II and III). — Prepared according to Cook and others' method[1]. 7-Bromo-3, 4-benzotropolone (II), yellow prisms from ethanol, m. p. 149°C (reported m. p.'s 143~144[1] and 148~149°C[3]), (Found: C, 52.72; H, 3.02. Calcd. for $C_{11}H_7O_2Br$: C, 52.61; H, 2.81%), infrared ν(KBr): 1612, 1600, 1547 cm^{-1}.

5, 7-Dibromo-3, 4-benzotropolone (III), yellow needles, m. p. 127°C (reported m. p. 119~121°C[1]), (Found: C, 40.31; H, 2.08. Calcd. for $C_{11}H_6O_2Br_2$: C, 40.03; H, 1.83%), infrared ν(KBr): 1612, 1585, 1550 cm^{-1}.

The Amine Salts.—A solution of a 50-mg. sample and 0.2 g. of an amine in 1 ml. of ethanol was warmed on a water bath for 5 min. The solution was concentrated, and the product which separated on cooling was collected and recrystallized from ethanol. The amine salts thus obtained were decomposed to regenerate bromobenzotropolones when dissolved in ethanol containing a little hydrochloric acid.

Amine Salts of II. — Diethylamine salt, yellow scales, m. p. 130.5~131.5°C.

Found: C, 55.30; H, 5.57; N, 4.53. Calcd. for $C_{11}H_7O_2Br \cdot C_4H_{11}N$: C, 55.57; H, 5.60; N, 4.32%.

Ethylenediamine salt, yellow scales decomposing at 157°C.

Found: C, 50.86; H, 3.95; N, 5.03. Calcd. for $(C_{11}H_7O_2Br)_2 \cdot C_2H_8N_2$: C, 51.26; H, 3.94; N, 4.98%.

Benzylamine salt, yellow, silky needles, m. p. 143°C.

Found: C, 60.36; H, 4.32; N, 4.29. Calcd. for $C_{11}H_7O_2Br \cdot C_7H_9N$: C, 60.36; H, 4.50; N, 3.91%.

Amine Salts of III. — Diethylamine salt, yellow needles, m. p. 146~147°C.

Found: C, 44.58; H, 4.25; N, 3.71. Calcd. for $C_{11}H_6O_2Br_2 \cdot C_4H_{11}N$: C, 44.69; H, 4.25; N, 3.48%.

Ethylenediamine salt, a yellow crystalline powder, m. p. above 300°C.

Benzylamine salt, yellow, silky needles, m. p. 142°C (decomp.).

Found: C, 49.65; H, 3.40; N, 3.41. Calcd. for $C_{11}H_6O_2Br_2 \cdot C_7H_9N$: C, 49.46; H, 3.46; N, 3.21%.

The Methyl Ethers.—Prepared by methylation of II and III with ethereal diazomethane in the usual manner. Methyl ether of II, colorless needles from dilute methanol, m. p. 86~87°C (reported m. p. 84~85°C[1]), infrared $\nu(CCl_4)$: 1635, 1598, 1565 cm^{-1}.

Found: C, 54.54; H, 3.56. Calcd. for $C_{12}H_9O_2Br$: C, 54.36; H, 3.42%.

Methyl ether of III, pale yellow needles, m. p. 120°C, infrared $\nu(CCl_4)$: 1650, 1589, 1565 cm^{-1}.

Found: C, 42.19; H, 2.56. Calcd. for $C_{12}H_8O_2Br_2$: C, 41.89; H, 2.34%.

The Acetates.—A solution of a 50-mg. sample in 1 ml. of acetic anhydride containing a trace of concentrated sulfuric acid was heated on a water bath for 5 min., the excess acetic anhydride was decomposed with ice, and the product was crystallized from methanol. Acetate of II, colorless crystals, m. p. 91°C.

Found: C, 52.96; H, 3.13. Calcd. for $C_{13}H_8O_3Br$: C, 53.27; H, 3.10%.

Acetate of III, colorless crystals, m. p. 92°C.

Found: C, 41.90; H, 2.33. Calcd. for $C_{13}H_8O_3Br_2$: C, 41.97; H, 2.17%.

3, 4-Benzotropolone Methyl Ether. — A solution of 500 mg. of the methyl ether of II in 10 ml. of ethanol was shaken with hydrogen in the presence of 0.5 ml. of diethylamine and 50 mg. of 10% palladium-on-charcoal at ordinary temperature and pressure. After uptake of 1 mol. equivalent of hydrogen, the catalyst was removed and the solvent was evaporated. The crude product thus obtained was converted to its picrate, orange prismatic needles from carbon tetrachloride, m. p. 84~85°C.

Found: C, 52.24; H, 3.23; N, 9.97. Calcd. for $C_{12}H_{10}O_2 \cdot C_6H_3O_7N_3$: C, 52.05; H, 3.16; N, 10.12%.

The picrate was decomposed by passing its chloroform solution through an alumina column to yield 130 mg. (37%) of 3, 4-benzotropolone methyl ether, a pale yellow oil, which gave a 2, 4-dinitrophenylhydrazone[1], m. p. 238~240°C. In this experiment, there was produced a solid by-product, presumably a more hydrogenated product, which was not studied.

Attempted Monodebromination of III.—A solution of 500 mg. of III in 10 ml. of ethanol containing 0.3 ml. of 33% aqueous dimethylamine was shaken with hydrogen over 50 mg. of 10% palladium-on-charcoal until 1 mol. equivalent of hydrogen had been absorbed. The catalyst was removed, the solution was diluted with water, and the crystalline precipitate which separated was recrystallized from ethanol to yield 220 mg. (44%) of unchanged II, m. p. and mixed m. p. 125~126°C. The mother liquor from the above recrystallization was evaporated, and the residue was crystallized from petroleum ether to afford 80 mg. (30%) of I, pale yellow crystals, m. p. and mixed m. p. 84~85°C. No monobromo derivative could be obtained.

Oxidation of II and III.—To a stirred suspension of 200 mg. of II in 40 ml. of 0.2 N sodium hydroxide was added dropwise 2 ml. of 35% hydrogen peroxide, and the resulting mixture was set aside under continued stirring at room temperature. The suspension went into solution in 10 min. and the yellow color of the solution disappeared in an hour. Acidification with 6 N sulfuric acid produced a precipitate

which was collected and crystallized from dilute acetic acid to yield 70 mg. (46%) of colorless needles of *o*-carboxycinnamic acid. Found: C, 62.48; H, 4.33. Calcd. for $C_{10}H_8O_4$: C, 62.50; H, 4.20%), m. p. 187~189°C.

The melting point was undepressed on admixture with an authentic sample[12].

Oxidation under the same conditions was applied to 200 mg. of III, affording 74 mg. (74%) of phthalic acid, m. p. and mixed m. p. 199~201°C (decomp.).

Addition of Bromine to II and III.—A solution of 100 mg. of II and 0.1 ml. of bromine in 3 ml. of chloroform was left to stand for 10 min., the chloroform and excess bromine were evaporated, and the solid residue was crystallized from petroleum ether to give 140 mg. (72%) of tetrabromo-3,4-benzocycloheptene-1,2-dione (IV), a pale yellow, crystalline powder, decomposing at 115~118°C.

Found: C, 27.36; H, 1.45. Calcd. for $C_{11}H_6O_2 \cdot Br_4$: C, 26.98; H, 1.24%.

The product was insoluble in alkali, showed no ferric chloride coloration, and was decomposed to III, m. p. and mixed m. p. 126°C, on recrystallization from acetic acid.

A similar bromination of III gave an addition product, decomposing at 111°C, which could not be purified owing to its facile decomposition to regenerate III on crystallization from solvents.

Exhaustive Bromination of III.—A solution of 1 g. of III and 0.5 ml. of bromine in 15 ml. of acetic acid was heated on a water bath for 5 hr., and to this were added two additional 0.5-ml. portions of bromine at intervals of 5 hr. under continued heating. Dilution with water caused precipitation of the product, which was collected and crystallized from acetic acid, affording 775 mg. (81%) of yellow needles of 2,3-dibromo-1,4-naphthoquinone (V), melting at 218.5°C. (Found: C, 38.27; H, 1.38. Calcd. for $C_{10}H_4O_2Br_2$: C, 38.01; H, 1.28%). The melting point was not depressed on admixture with an authentic sample[13].

Derivatives of V. — 2-Bromo-3-anilino-1,4-naphthoquinone[13], 2-bromo-3-hydroxy-1,4-naphthoquinone[13] and 2,3-dibromo-1,4-diacetoxynaphthalene[14] derived from V showed no melting point depression on admixture with authentic samples. 2-Bromo-3-*p*-toluidino-1,4-naphthoquinone was prepared by warming 50 mg. of V and 170 mg. of *p*-toluidine in 2 ml. of ethanol for 5 min. Dark red plates from ethanol, m. p. 190.5°C.

Found: C, 59.83; H, 3.46; N, 4.35. Calcd. for $C_{17}H_{12}O_2NBr$: C, 59.66; H, 3.53; N, 4.09%.

2-Bromo-1,4-diacetoxynaphthalene was prepared by heating a mixture of 200 mg. of V, 600 mg. of zinc powder, 400 mg. of fused sodium acetate and 3 ml. of acetic anhydride on a water bath for 10 min. Colorless, granular crystals from ethanol, m. p. 146°C.

Found: C, 52.11; H, 3.62. Calcd. for $C_{14}H_{11} \cdot O_4Br$: C, 52.03; H, 3.43%.

The author wishes to express his sincere thanks to Professor Tetsuo Nozoe of Tohoku University for his guidance and encouragement throughout this work. The author is also indebted to Dr. Eishiro Tamate of the Nitto Institute of Chemical Research for infrared measurements, and to Mrs. Kuniko Kodaira and Miss Ayako Iwanaga of Tohoku University for microanalyses.

3,4-Benzotropolone and Related Compounds. II[1]. *Chloro and Iodo Derivatives of 3,4-Benzotropolone**

By Seiji EBINE

(Received April 24, 1961)

Nozoe and collaborators[2] have presented a short communication on the substitution of 3,4-benzotropolone (I) describing how I can be chlorinated to yield monochloro-3,4-benzotropolone. The chlorination and the iodination of I have now been studied in more detail and are described herein.

When treated with one molar equivalent of chlorine, I afforded 5,7-dichloro-3,4-benzotropolone (V) in a low yield besides the recovery of unchanged material, no monochloro derivative being isolated. Treatment of I with two molar equivalents of chlorine afforded V in a

TABLE I. M. P. AND MIXED M. P. OF CHLORO- AND BROMO-3,4-BENZOTROPOLONES

Chloro deriv.	M. p., °C	Bromo deriv.	M. p., °C	Mixed m. p., °C
7-Chloro-	151	7-Bromo-	148	148~149
methyl ether	97	methyl ether	87	87~ 89
acetate	101.5	acetate	91	90~ 91
5,7-Dichloro-	136	5,7-Dibromo-	126	122~126
methyl ether	106	methyl ether	120	104~109
5-Chloro-7-bromo-	111~114	5-Bromo-7-chloro-	122.5	116~119

fair yield. The monochlorination of 7-bromo-3,4-benzotropolone (II) gave 5-chloro-7-bromo-3,4-benzotropolone (VI). The passage of the excess chlorine into an acetic acid solution of II furnished 5,6,7-trichloro-7-bromo-3,4-benzocycloheptene-1,2-dione (VIII), which exhibited two infrared carbonyl absorption bands at 1753 and 1700 cm^{-1} and an ultraviolet spectrum closely similar to that of the parent 3,4-benzocycloheptene-1,2-dione (Fig. 2). When treated with a large excess of chlorine, 5,7-dibromo-3,4-benzotropolone (III) was transformed into 2,3-dichloro-1,4-naphthoquinone, identified by comparison with an authentic sample[3]. This ring contraction is analogous to that observed in the exhaustive bromination of III described in the preceding paper[1].

Heating II with concentrated hydrochloric acid gave 7-chloro-3,4-benzotropolone (IV) in a good yield which could not be obtained by the direct chlorination of I. A similar treatment of III gave V. The bromination of IV furnished 5-bromo-7-chloro-3,4-benzotropolone (VII). On slight warming with hydrochloric acid in methanol, 5-bromo- and 5,7-dibromo-3,4-benzotropolone methyl ethers, II′ and III′, easily underwent a halogen-exchange reaction to afford 5-chloro and 5,7-dichloro-3,4-benzotropolone methyl ethers, IV′ and V′, respectively. Under the same conditions, II and III remained unchanged and their acetates suffered hydrolysis their bromine atoms remaining intact. The ultraviolet spectra of IV, V, IV′ and V′ are analogous to those of general troponoid compounds as given in Fig. 1. II was allowed to react with thionyl chloride, producing an adduct which decomposed to give V on recrystallization from ethanol. The adduct, to which the structure IX was tentatively assigned, gave no coloration with ferric chloride and exhibited an ultraviolet spectrum entirly different from that of a troponoid compound (Fig. 2). III and thionyl chloride afforded the same V. It should be noted that, although monocyclic tropolones and their bromo derivatives react with thionyl chloride to form chlorotropones[4], II and III react with the same reagent to afford chlorobenzotropolones their hydroxyl groups remaining unreplaced[5]. The susceptibility of the bromine atoms at 5- and 7-positions and the inertness of hydroxyl and methoxyl groups at 1-position of bromobenzotropolones and their methyl ethers towards anionoid substitution may be ascribed to the resonance structures of these compounds to which formula A contributes mainly and formula B contributes only to a less extent because the benzene ring of formula A is aromatic, whereas that of formula B is quinonoid.

Bromo- and chloro-3,4-benzotropolones, like monocyclic halotropolones[6], possess melting points close to each other and show obscure mixed melting point depression, as is shown in Table I.

I was treated with sodium iodide and sodium iodate in an acetic acid solution to yield 7-iodo-3,4-benzotropolone (X). X was produced even when an excess of iodinating reagent was employed. Under the same conditions, II was not iodinated. II and III were heated with hydriodic acid to produce I and 5-bromo-3,4-benzotropolone (XII) respectively, instead of the expected iodobenzotropolones. The bromination of XII gave III. Analogously with the reaction of bromobenzotropolone methyl ethers with hydrochloric acid, II′ and III′ reacted with hydroiodic acid in methanol to give 7-iodo-3,4-benzotropolone methyl ether (X′) and 5-bromo-7-iodo-3,4-benzotropolone methyl ether (XI) respectively. XI was identified by converting it into methyl 1-hydroxy-4-bromo-2-naphthoate[7]. In these reactions, the 5-position of I and II was not iodinated, and 5-bromine atom of III and III′ remained unaffected, presumably because the action of an iodide ion on the 5-position was sterically hindered by the *peri* position of the condensed benzene ring.

It has been found that, as in the benzenoid compounds, the out-of-plane CH deformation

vibrations of troponoid compounds are correlated to the positions of their substituents[8]. A similar correlation is also found in halobenzotropolones, as is shown in Table II.

Experimental

7-Chloro-3, 4-benzotropolone (IV).—A mixture of 300 mg. of 7-bromo-3,4-benzotropolone (II), 3 ml. of concentrated hydrochloric acid and 9 ml. of acetic acid was heated in a sealed tube at 120~130°C for 5 hr. The product deposited on cooling. Concentration of the filtrate gave a further crop of the product. The combined products were recrystallized from ethanol to give yellow prisms of m. p. 151°C. Yield, 215 mg. (88%). IV gave a brown coloration with ferric chloride in amyl alcohol solution. ν(KBr): 1617, 1605, 1583 cm^{-1}. λ(MeOH), mμ (log ε): 245(4.40), 262(4.44), 345(3.80), 370(3.85).

Found: C, 63.84; H, 3.29. Calcd. for $C_{11}H_7O_2Cl$: C, 63.94; H, 3.42%.

IV was also obtained in an 84% yield by refluxing a mixture of 100 mg. of 7-bromo-3,4-benzotropolone methyl ether (II'), 3 ml. of acetic acid and 15 ml. of concentrated hydrochloric acid for 5 hr.

The Acetate of IV. — Colorless prisms from methanol, m. p. 101.5°C.

Found: C, 62.62; H, 3.54. Calcd. for $C_{13}H_9O_3Cl$: C, 62.79; H, 3.65%.

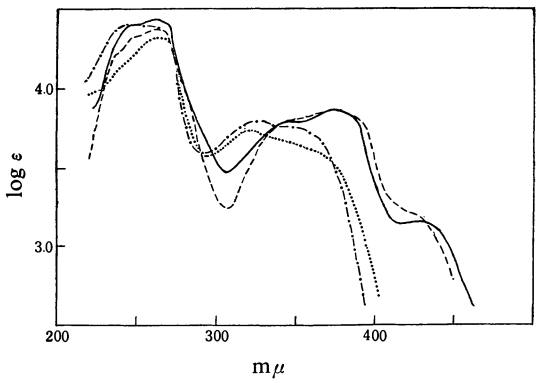

Fig. 1. Ultraviolet spectra of 7-chloro-3,4-benzotropolone (IV) (——), its methyl ether (IV') (-·-·), 5,7-dichloro-3,4-benzotropolone (V) (----) and its methyl ether (V') (·····) in methanol.

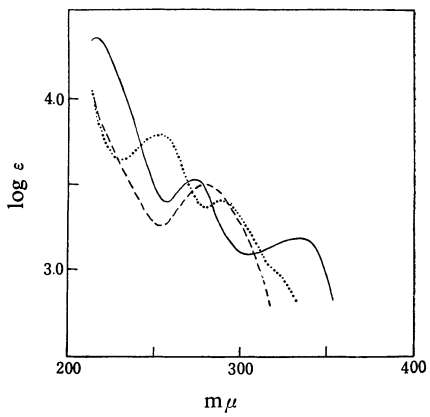

Fig. 2. Ultraviolet spectra of 3,4-benzocycloheptene-1,2-dione (·····), its 5,6,7-trichloro-7-bromo derivative (VIII) (——) in methanol and 7-bromo-3,4-benzotropolone-thionyl chloride adduct (IX) (----) in cyclohexane.

8) Y. Kitahara, *Sci. Repts. Tohoku Univ., I*, **39**, 275 (1956).

5, 7-Dichloro-3, 4-benzotropolone (V).—*From 3,4-Benzotropolone (I).* — To 100 mg. of I dissolved in 1.5 ml. of acetic acid was added an acetic acid solution of 82 mg. (2 mol. equiv.) of chlorine*. After standing for an hour at room temperature, the acetic acid was removed under reduced pressure below 30°C, leaving a crystalline residue which was washed with water and recrystallized from methanol to give 85 mg. (61%) of V, yellow needles, m. p. 135~136°C. V gave a brown coloration with ferric chloride in amyl alcohol solution. ν(Nujol): 1630, 1580 cm^{-1}. λ(MeOH), mμ(log ε): 266(4.40), 352 (3.85), 376(3.87).

Found: C, 54.85; H, 2.40. Calcd. for $C_{11}H_6O_2Cl_2$: C, 54.80; H, 2.51%.

Treatment of 100 mg. of I with 41 mg. (1 mol. equiv.) of chlorine in an acetic acid solution at room temperature gave 45 mg. (32%) of V and 30 mg. of an unidentified product with a m. p. 120~126°C, besides the recovery of 15 mg. of unchanged material.

From 7-Bromo-3, 4-benzotropolone (II).—A 300-mg. sample of II was dissolved in 3 ml. of thionyl chloride, and the solution was allowed to stand overnight at room temperature. Removal of the thionyl chloride under reduced pressure left an oily residue which solidified on trituration with ligroin. Recrystallization of the product from ligroin gave 320 mg. (73%) of yellow prisms of the addition product, m. p. 148°C (mixed m. p. with II, 107~111°C).

Found: C, 35.77; H, 1.80. Calcd. for $C_{11}H_7O_2Br \cdot SOCl_2$: C, 35.69; H, 1.91%.

On recrystallization from ethanol the adduct changed into V, m. p. 137°C. Yield, 190 mg. (66% based on II).

From 5,7-Dibromo-3,4-benzotropolone (III) and Hydrochloric Acid. — A mixture of 150 mg. of III, 1.5 ml. of concentrated hydrochloric acid and 6 ml. of acetic acid was heated in a sealed tube at 110~120°C for 5 hr. and worked up as described above for the preparation of IV, affording 100 mg. (90%) of V, m. p. 136°C.

V was also obtained by refluxing a mixture of 100 mg. of 5,7-dibromo-3,4-benzotropolone methyl ether (III'), 3 ml. of acetic acid and 15 ml. of concentrated hydrochloric acid for 5 hr., followed by recrystallization of the product from methanol.

From III and Thionyl Chloride. — A treatment of 300 mg. of III with 3 ml. of thionyl chloride similar to that described above afforded 140 mg. (64%) of V, m. p. 137°C.

7-Chloro-3, 4-benzotropolone Methyl Ether (IV') and 5, 7-Dichloro-3, 4-benzotropolone Methyl Ether (V').—*From IV and V.*—IV', colorless needles, m. p. 96~97°C. ν(Nujol): 1625, 1597, 1560 cm^{-1}. λ(MeOH), mμ(log ε): 243(4.40), 330(3.81).

Found: C, 65.30; H, 4.06. Calcd. for $C_{12}H_9O_2Cl$: C, 65.31; H, 4.11%.

V', pale yellow needles, m. p. 106°C. λ(MeOH), mμ(log ε): 262(4.34), 318(3.75).

Found: C, 56.46; H, 3.11. Calcd. for $C_{12}H_8O_2Cl_2$: C, 56.49; H, 3.16%.

* The content of chlorine in acetic acid solution was determined by iodometric titration.

From 7-Bromo- and 5,7-Dibromo-3,4-benzotropolone Methyl Ethers (II' and III').—A mixture of 50 mg. of II', 5 ml. of methanol and 2 ml. of concentrated hydrochloric acid was refluxed for 15 min. The product separated on dilution with water. This was then recrystallized from dilute methanol to yield 35 mg. (83%) of IV', m. p. 96°C. A similar treatment of III' with hydrochloric acid in methanol gave V', m. p. 106°C, in an 80% yield.

5-Chloro-7-bromo-3, 4-benzotropolone (VI). — II (200 mg.) dissolved in 15 ml. of acetic acid was treated with an acetic acid solution of 56 mg. (1 mol. equiv.) of chlorine at room temperature for an hour. The solution was then concentrated to 5 ml. in vacuo and diluted with an equal volume of water, forming a precipitate (190 mg.) of a crude product, which on recrystallization from methanol yielded 110 mg. (48%) of VI as yellow needles, m. p. 111~115°C, besides 25 mg. of unchanged material. VI gave a brown coloration with ferric chloride in amyl alcohol solution.

Found: C, 46.37; H, 2.27. Calcd. for $C_{11}H_6O_2 \cdot BrCl$: C, 46.27; H, 2.12%.

5-Bromo-7-chloro-3, 4-benzotropolone (VII). — A solution of 100 mg. of IV and 80 mg. (1 mol. equiv.) of bromine in 1 ml. of acetic acid was heated on a water bath for 2 hr. The crystalline product which separated on cooling was collected and recrystallized from methanol to give V as yellow needles, m. p. 122.5°C. Yield, 115 mg. (83%). VII gave a brown coloration with ferric chloride in amyl alcohol solution.

Found: C, 46.07; H, 2.08. Calcd. for $C_{11}H_6O_2 \cdot BrCl$: C, 46.27; H, 2.12%.

5, 6, 7-Trichloro-7-bromo-3, 4-benzocycloheptene-1, 2-dione (VIII).—Chlorine gas was bubbled into a solution of 400 mg. of II in 25 ml. of acetic acid at room temperature for an hour, the excess chlorine removed under reduced pressure, and 50 ml. of water added. A crude product (420 mg., m. p. 113~117°C) separated after standing overnight. This was collected and recrystallized from methanol to yield yellow prisms of VIII, m. p. 124~125°C. VIII gave no coloration with ferric chloride. ν ($CHCl_3$): 1753, 1700 cm^{-1}. λ(MeOH), mμ(log ε): 215(4.14), 275(3.32), 340(3.02).

Found: C, 37.12; H, 1.72. Calcd. for $C_{11}H_6O_2 \cdot BrCl_3$: C, 37.06; H, 1.70%.

2, 3-Dichloro-1, 4-naphthoquinone from III.—Into a solution of 250 mg. of III in 15 ml. of acetic acid was passed chlorine gas for 1.5 hr. at room temperature. After the removal of excess chlorine under diminished pressure, the solution was concentrated to 5 ml. and diluted with water to produce a precipitate. Sublimation at 110~120°C/7mmHg, followed by recrystallization from ethanol, gave yellow needles of 2,3-dichloro-1,4-naphthoquinone, m. p. 196~197°C, the melting point of which was undepressed on admixture with an authentic sample[3] prepared by chlorination of α-naphthoquinone. Yield, 60 mg. (35%).

3, 4-Benzotropolone (I) from 7-Bromo-3, 4-benzotropolone (II) and Hydriodic Acid. — A solution of 400 mg. of potassium iodide in 0.5 ml. of water was added to a suspension of 200 mg. of II in 5 ml. of acetic acid, and the mixture was heated in a

sealed tube at 120~130°C for 2 hr. Dilution of the reaction mixture with water gave a brown precipitate, which was collected and dissolved in ether. The ethereal solution was shaken with sodium thiosulfate solution, the ether removed, and the residue recrystallized from petroleum ether to give 100 mg. (73%) of I, m. p. and mixed m. p. 83.5~84°C.

5-Bromo-3, 4-benzotropolone (XII). — A solution of 300 mg. of potassium iodide in 0.5 ml. of water was added to a suspension of 200 mg. of 5,7-dibromo-3,4-benzotropolone (III) in 5 ml. of acetic acid, and the mixture was heated on a water bath for 5 hr. The product which separated on cooling was collected and recrystallized from methanol to yield 130 mg. (85%) of yellow needles, m. p. 140°C. ν(Nujol): 1635, 1588, 1558 cm^{-1}. λ(MeOH), mμ (log ε): 238(4.41), 263(4.33), 350(3.97), 375(3.99), 430(2.90).

Found: C, 52.86; H, 2.67. Calcd. for $C_{11}H_7O_2Br$: C, 52.61; H, 2.81%.

5-Bromo-3,4-benzotropolone Methyl Ether. — Colorless needles, m. p. 69~70°C. ν(Nujol): 1623, 1600, 1572 cm^{-1}. λ(MeOH), mμ(log ε): 240(4.18), 325 (3.82), 360~370(3.65).

Found: C, 54.02; H, 3.23. Calcd. for $C_{12}H_9O_2Br$: C, 54.36; H, 3.42%.

7-Iodo-3, 4-benzotropolone (X). — A mixture of 220 mg. of sodium iodide and 60 mg. of sodium iodate was added to a solution of 100 mg. of I in 5 ml. of acetic acid and 1.6 ml. of 2 N sulfuric acid. After standing for 10 min., the solution was diluted with water to produce a precipitate. An ethereal solution of the precipitate was shaken with sodium thiosulfate solution and the ether evaporated. The residue was recrystallized from methanol to give orange yellow crystals, m. p. 124~127°C. Yield, 70 mg. (40%). ν(Nujol): 1612, 1590, 1550 cm^{-1}. λ(MeOH), mμ(log ε): 268(4.32), 345(3.69), 360 (3.90), 380(3.75).

Found: C, 44.57; H, 2.50. Calcd. for $C_{11}H_7O_2I$: C, 44.31; H, 2.37%.

7-Iodo-3,4-benzotropolone Methyl Ether (X'). — A mixture of 100 mg. of 7-bromo-3,4-benzotropolone methyl ether (II'), 2 ml. of hydriodic acid and 2 ml. of methanol was heated for 10 min. on a water bath. Dilution with water gave a solid product. An ethereal solution of the product was shaken with sodium thiosulfate solution. The ether was evaporated and the residue recrystallized from dilute methanol. Yellow scales, m. p. 99~100°C. Yield, 100 mg. (85%). ν(Nujol): 1622, 1598, 1562 cm^{-1}. λ(MeOH), mμ(log ε): 268(4.32), 350~355 (3.66).

Found: C, 46.14; H, 3.18. Calcd. for $C_{12}H_9O_2I$: C, 46.17; H, 2.91%.

5-Bromo-7-iodo-3, 4-benzotropolone Methyl Ether (XI). — A mixture of 100 mg. of 5,7-dibromo-3,4-benzotropolone methyl ether (III'), 2 ml. of hydriodic acid and 10 ml. of methanol was refluxed for 5 hr., and then the resulting solution was worked up in the same way as above. Yellow scales, m. p. 130~131°C. Yield, 80 mg. (68%). ν(Nujol): 1631, 1602, 1582, 1560 cm^{-1}. λ(MeOH), mμ(log ε): 267(4.40), 320(3.88).

Found: C, 36.69; H, 2.07. Calcd. for $C_{12}H_8O_2BrI$: C, 36.86; H, 2.06%.

Methyl 1-Hydroxy-4-bromo-2-naphthoate from XI. —To a solution of 200 mg. of XI in 18 ml. of methanol was added a solution of 280 mg. of potassium hydroxide in 0.8 ml. of water; the resulting solution was heated for 5 hr. on a water bath. The solution was acidified with 6 N hydrochloric acid, the methanol evaporated and the residue recrystallized from methanol to yield 100 mg. (70%) of colorless needles, m. p. 119.5~120.5°C, the melting point of which was undepressed on admixture with an authentic sample[7].

The author gratefully acknowledges his indebtedness to Professor Tetsuo Nozoe of Tohoku University for his kind guidance throughout the course of this work. Thanks are also due to Dr. Eishiro Tamate of the Nitto Institute of Chemical Research for infrared spectra and to Mrs. Kuniko Kodaira and Miss Ayako Iwanaga of Tohoku University for microanalyses.

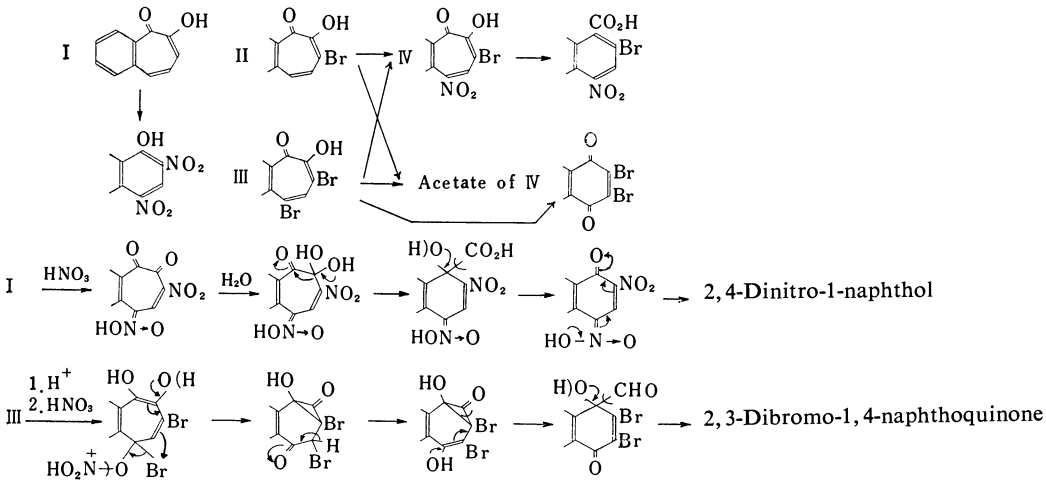
3, 4-Benzotropolone and Related Compounds. III[1]. *Nitration of 3, 4-Benzotropolone**



By Seiji EBINE

(Received April 24, 1961)

It has been reported that 3, 4-benzotropolone (I) can be nitrated to produce dinitro-3, 4-benzotropolone[2]. This nitration will now be re-examined.

Nitration of I with nitric acid in an acetic acid solution unexpectedly produced 2, 4-dinitro-1-naphthol, which was identified by mixed melting point determination and further by infrared-spectral agreement with an authentic sample[3]. No nitro derivative of I was isolated from the nitration product. I gave the same product in a lower yield even when one molar equivalent of nitric acid was employed. This transformation may be represented by the scheme described below. A similar type of ring contraction has been observed in the iodination of tropolone with sodium hypoiodite to produce 2, 4, 6-triiodophenol[4].

7-Bromo-3, 4-benzotropolone (II) was nitrated in an acetic acid solution to yield 5-nitro-7-bromo-3, 4-benzotropolone (IV). Since IV was highly susceptible to resinification during nitration, it was collected by filtration as soon as the reaction was completed. The yield of IV was somewhat improved when the reaction mixture was poured into a sodium bicarbonate solution before the filtration of the product. IV showed a brown coloration with ferric chloride, gave methyl ether and underwent rearrangement with alkali into 2-bromo-4-nitro-1-naphthoic acid. This behavior is characteristic of nitrotropolones. Nitration of II in acetic anhydride afforded the acetate of IV, which was hydrolyzed and then methylated to give the same methyl ether of IV as was obtained above. It has been known that monocyclic tropolones resist nitration in a concentrated sulfuric acid solution owing to the formation of a tropolonium (dihydroxytropylium) cation[5]. Nevertheless, II was successfully nitrated in concentrated sulfuric acid to afford IV. This fact indicates that II is less basic than monocyclic tropolones presumably because the condensed benzene ring restricts the resonance of the tropolone ring. III, although its tropolone ring is blocked by

bromo substituents, reacted with nitric acid in an acetic acid solution in such a manner that one of its two bromine atoms was replaced by a nitro group to yield IV. Similarly, nitration of III in acetic anhydride gave the acetate of IV. The nitration of III in concentrated sulfuric acid did not take place at room temperature, but was effected at 100°C, resulting in the unexpected formation of 2,3-dibromo-1,4-naphthoquinone, which showed no melting point depression on admixture with an authentic sample[6]. Under the same conditions, 5,7-dichloro-3,4-benzotropolone was also transformed into 2,3-dichloro-1,4-naphthoquinone which was identical with an authentic sample[7]. This reaction may include oxidation with nitric acid followed by migration of bromine atom, as described above. Treatment of II and III with nitric acid under more drastic conditions gave phthalic acid. In all nitrations mentioned above, the condensed benzene ring remained not nitrated.

Experimental

2,4-Dinitro-1-naphthol from 3,4-Benzotropolone (I).—To an ice-cooled solution of 200 mg. of I in 0.5 ml. of acetic acid was added 0.18 ml. (2 mol. equiv.) of concentrated nitric acid diluted with an equal volume of acetic acid. After standing for 10 min. with ice-cooling, the solution was diluted with 1 ml. of water to produce a precipitate. This was collected, washed with a small amount of cold methanol in order to remove a resinous material and then recrystallized from methanol to give 70 mg. (26%) of greenish yellow prisms of the dinitronaphthol, m. p. 137.5~138°C (decomposed at 140°C with effervescence), the melting point of which was undepressed on admixture with an authentic sample[8] prepared by the nitration of α-naphthol. (Found: C, 51.34; H, 2.60; N, 11.83. Calcd. for $C_{10}H_6O_5N_2$: C, 51.29; H, 2.58; N, 11.96%.)

5-Nitro-7-bromo-3,4-benzotropolone (IV).—*a) Nitration of 7-Bromo-3,4-benzotropolone (II).—In Acetic Acid:* To a mixture of 0.085 ml. (0.95 mol. equiv.) of concentrated nitric acid and 0.9 ml. of acetic acid was added 300 mg. of II. On stirring at room temperature, the suspension went into solution in a few minutes and then in an additional several minutes there separated out a crystalline powder (140 mg.), which was collected by filtration. On dilution with water, the filtrate gave a further crop of the product (10 mg.) which was also collected. The combined products were washed with a small amount of methanol to remove a resinous material and recrystallized from methanol to afford 110 mg. (30%) of IV as yellow scales decomposing at 161°C with effervescence. On rapid heating, the decomposition point was raised to 167°C. The mother liquor gave 30 mg. of unchanged material.

In another experiment, soon after the nitration had been completed, the reaction mixture was poured into a saturated sodium bicarbonate solution; the product was then collected and recrystallized from methanol to give 140 mg. (40%) of IV. λ(MeOH), mμ(log ε): 215(4.19), 268(3.92), 485 (4.20).

Found: C, 44.63; H, 2.33; N, 4.88. Calcd. for $C_{11}H_6O_4NBr$: C, 44.62; H, 2.04; N, 4.73%.

In Concentrated Sulfuric Acid: A mixture of 0.085 ml. (0.95 mol. equiv.) of concentrated nitric acid and an equal volume of concentrated sulfuric acid was added to 300 mg. of II dissolved in 1.5 ml. of concentrated sulfuric acid, and the solution was left aside for 10 min. at room temperature. On pouring it on crushed ice, a resinous product separated, which was collected and washed with 2 ml. of methanol, leaving a crystalline mass. Recrystallization from methanol afforded 105 mg. (29%) of IV decomposing at 160°C, as well as 65 mg. of unchanged material.

The nitration in concentrated sulfuric acid at 100°C resulted in resinification of a greater part of II besides the recovery of a minute amount of unchanged material.

b) Nitration of 5,7-Dibromo-3,4-benzotropolone (III).—A 300-mg. sample of III was treated with a mixture of 0.068 ml. (1 mol. equiv.) of concentrated nitric acid and 0.6 ml. of acetic acid in the same manner as above, affording IV in a lower yield (45 mg., 16%).

Attempted nitration of III in concentrated sulfuric acid at room temperature resulted in the recovery of unchanged material.

The nitration products of II and III obtained above proved to be the same from mixed melting point determination of their methyl ethers.

The Methyl Ether of IV.—Yellow prisms from dilute methanol, m. p. 146.5°C.

Found: C, 46.47; H, 2.81; N, 4.85. Calcd. for $C_{12}H_8O_4NBr$: C, 46.48; H, 2.60; N, 4.52%.

The p-Toluidine Salt of IV.—A red crystalline powder which darkened at 124°C and decomposed at 161°C with effervescence.

Found: C, 53.98; H, 3.98; N, 7.27. Calcd. for $C_{11}H_6O_4NBr \cdot C_7H_9N$: C, 53.62; H, 3.75; N, 6.95%.

The Acetate of IV.—*Nitration of II in Acetic Anhydride.*—A mixture of 0.085 ml. (0.95 mol. equiv.) of concentrated nitric acid and 0.34 ml. of acetic anhydride was added to 300 mg. of II suspended in 1.5 ml. of acetic anhydride. The suspension was warmed for a while until it went into solution. The acetic anhydride was decomposed with ice, and the product was then collected, washed with a small amount of methanol and recrystallized from methanol to afford 110 mg. (27%) of the acetate of IV as yellow prisms decomposing at 164°C with effervescence.

Found: C, 46.40; H, 2.22; N, 3.92. Calcd. for $C_{13}H_8O_5NBr$: C, 46.18; H, 2.39; N, 4.14%.

Nitration of III in Acetic Anhydride.—A suspension of 200 mg. of III in acetic anhydride was treated with a mixture of 0.046 ml. of concentrated nitric acid and 0.18 ml. of acetic anhydride in the same manner as above, affording 35 mg. (18%) of the acetate of IV.

6) C. Liebermann and S. Schlossberg, *Ber.*, **32**, 2097 (1899).
7) J. B. Conant and L. F. Fieser, *J. Am. Chem. Soc.*, **46**, 1873 (1924).

The acetate of IV obtained above was hydrolyzed by refluxing its methanolic solution in the presence of a few drops of concentrated hydrochloric acid, the product was treated with ethereal diazomethane to yield the methyl ether of IV.

2-Bromo-4-nitro-1-naphthoic Acid from IV.—A 100-mg. sample of IV was dissolved in 5 ml. of 2 N potassium hydroxide, and the solution was allowed to stand for 10 min. at room temperature. Acidification of the solution with hydrochloric acid and recrystallization of the product from methanol gave 80 mg. (80%) of yellow, granular crystals, m. p. 190°C. λ(MeOH), mμ(log ε): 220(4.76), 255(4.24), 285(3.67), 320(3.68), 340(3.80).

Found: C, 44.77; H, 2.01; N, 4.79. Calcd. for $C_{11}H_6O_4NBr$: C, 44.62; H, 2.04; N, 4.73%.

Formation of 2, 3-Dibromo-1, 4-naphthoquinone from 5, 7-Dibromo-3, 4-benzotropolone (III).—To a solution of 200 mg. of III in 1 ml. of concentrated sulfuric acid was added a mixture of 0.046 ml. (1 mol. equiv.) of concentrated nitric acid and 0.4 ml. of concentrated sulfuric acid. The solution was heated at 100°C for 10 min. and then poured on ice, producing a resinous product. Recrystallization of the product from methanol afforded 55 mg. (29%) of deep yellow needles of the dibromonaphthoquinone, m. p. 218°C, the melting point of which was undepressed on admixture with an authentic sample[6]. (Found: C, 37.77; H, 1.56%. Calcd. for $C_{10}H_4O_2Br_2$: C, 38.01; H, 1.28%.) Unchanged material (65 mg.) was also recovered.

2, 3-Dichloro-1, 4-naphthoquinone from 5, 7-Dichloro-3, 4-benzotropolone.—A similar treatment of 100 mg. of 5, 7-dichloro-3, 4-benzotropolone with 0.032 ml. (1 mol. equiv.) of concentrated nitric acid in concentrated sulfuric acid gave 15 mg. (16%) of yellow needles of the dichloronaphthoquinone, m. p. 195~196°C, identified by mixed melting point determination with an authentic sample[7], besides 25 mg. of unchanged material.

Oxidation of III with Nitric Acid.—A 200-mg. sample of III was heated with 0.5 ml. of concentrated nitric acid at 100°C for 10 hr. The product which separated on cooling was collected and recrystallized from water to yield 40 mg. of phthalic acid, m. p. and mixed m. p. 200~201°C (decomp.).

The author wishes to express his sincere gratitude to Professor Tetsuo Nozoe of Tohoku University for his kind guidance in carrying out this work. The author is also grateful to Mrs. Kuniko Kodaira and Miss Ayako Iwanaga of Tohoku University for microanalyses.

Potentiometric Determination of the Formation Constants of Thiocyanato Complexes of Mercury(II)

By Nobuyuki TANAKA, Kazuko EBATA and Teisuke MURAYAMA

(Received May 15, 1961)

Although a number of investigations have been carried out on the formation constant of the tetrathiocyanatomercurate(II) complex, the values reported are not in satisfactory agreement with each other[1]. As for the formation constants of the dithiocyanatomercury(II) and trithiocyanatomercurate(II) complexes, only a few papers have been published[1].

In the present communication, the potentiometric determination of the formation constants of the dithiocyanatomercury(II) and tri- and tetrathiocyanatomercurate(II) complexes and some thermodynamic data for the formation reactions of these complexes are presented. Although Nyman and Alberts[2] reported the formation constants of these complexes during the course of this study, the scope of their study was limited to the determination of the formation constants at 25°C.

Experimental

A stock solution of 0.05 M mercury(II) was prepared by dissolving mercury(II) nitrate of a guaranteed reagent grade in 0.3 N nitric acid. Its concentration was determined by titrating with the standard solution of sodium chloride, using sodium nitroprusside as indicator[3]. A solution of potassium thiocyanate was obtained by dissolving

an appropriate amount of potassium thiocyanate of a guaranteed reagent grade. The concentration of thiocyanate was determined by the Volhard method[4]. All other chemicals used were also of a guaranteed reagent grade.

A conventional manual apparatus similar to that of Kolthoff and Lingane[5] was used for the measurement of the current-potential curve. The dropping mercury electrode used had an m value of 2.109 mg./sec. and a drop time t_d of 4.22 sec., being measured in a de-aerated 0.2 M potassium nitrate solution at -0.5 V. vs. SCE at 59 cm. of the mercury height. A saturated calomel electrode (SCE) with a large surface area was used for the reference electrode; to this the electrolytic solution was connected with a Hume and Harris type salt bridge[6]. The measurements were carried out in the thermostat at 15, 25 and 35°C. The solutions prepared for the potentiometric determination contained 0.532 mM of mercury(II) and 0.016 to 0.03 M of thiocyanate, unless otherwise stated. The ionic strength of the solutions was adjusted to 0.2 with potassium nitrate. The residual current was obtained with a 0.2 M potassium nitrate solution. After the correction for the residual current and for the internal resistance (iR drop) across the electrolysis cell, the zero-current potential, i. e. the potential at which the current equals zero, was determined within the limits of ± 0.5 mV.

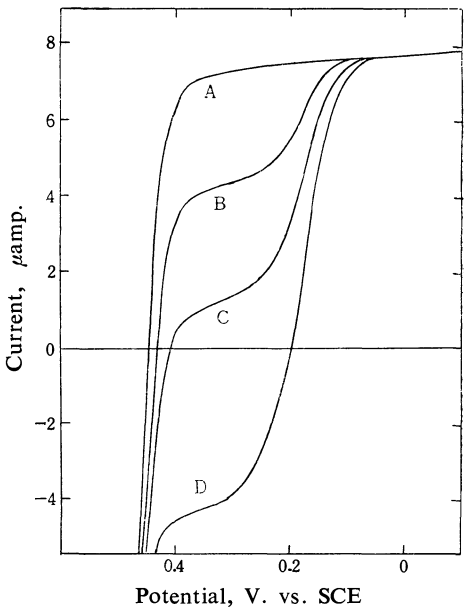

Fig. 1. Current-potential curves of 1.06_3 mM mercury(II) obtained at 25°C and $\mu=0.2$ without (curve A) and with 0.841 mM (B), 1.68 mM (C) and 2.94 mM (D) of thiocyanate. The residual current is not corrected.

Results

The current-potential curves of 1 mM mercury(II) obtained in the absence and in the presence of thiocyanate of various concentrations are reproduced in Fig. 1. The solution containing 1 mM of mercury(II) and less than 2 mM of thiocyanate gave a double wave. With the increasing concentration of thiocyanate at a constant concentration of mercury(II), the waves shifted to more negative potentials and the height of the first wave decreased, while the total height of both waves remained almost the same. The first wave was considered as due to the reduction of the free (hydrated) mercury(II) ion, and the second, to that of the thiocyanatomercury(II) complexes.

Since the limiting current of each wave was nearly completely dependent on the square root of the effective height of the mercury head, it was considered that the limiting currents are controlled by diffusion and are proportional to the concentrations of the hydrated and the complex mercury(II) ions in the bulk of solution respectively. The relation between the added concentration of the thiocyanate and the height of the wave showed that the complex which is formed under such conditions has two thiocyanate ions coordinating to the central metal ion. When the thiocyanate concentration exceeded 2 mM in the solution containing 1mM of mercury(II), the first wave became anodic, which is due to the dissolution of electrode mercury with the formation of thiocyanato complexes. These observations clearly showed that, in the concentration range employed in the present experiments, the presence of the mono-coordinated species $Hg(SCN)^+$ was negligible.

The relation between the zero-current potential ε and the thiocyanate concentration is given by the following equation:

$$\varepsilon = E^\circ + \frac{RT}{2F} \ln f_{Hg^{2+}} + \frac{RT}{2F} \ln \sum_j [Hg(SCN)_j^{2-j}] - \frac{RT}{2F} \ln \sum_j K_j^c [SCN^-]^j, \quad (0 \leqq j \leqq 4) \quad (1)$$

in which E° is the standard potential of the reaction,

$$Hg^{2+} + 2e = Hg$$

$f_{Hg^{2+}}$ the activity coefficient of the species Hg^{2+}, and K_j^c the formation constant of the complex $Hg(SCN)_j^{2-j}$ in terms of concentration. (When j equals zero, K_j^c is unity.) At the potential ε, the concentrations of the ions at the electrode surface are the same as those in the bulk of the solution.

4) I. M. Kolthoff and V. A. Stenger, ibid., Vol. II, p. 278.
5) I. M. Kolthoff and J. J. Lingane, "Polarography", Interscience Publishers, New York (1952), p. 297.
6) D. N. Hume and W. E. Harris, *Ind. Eng. Chem., Anal. Ed.*, 15, 465 (1943).

In the absence of thiocyanate, the potential ε° is expressed as

$$\varepsilon^\circ = E^\circ + \frac{RT}{2F} \ln f_{Hg^{2+}} + \frac{RT}{2F} \ln [Hg^{2+}]. \quad (2)$$

Since the value of ε° could not be obtained experimentally, it was calculated by means of Eq. 2. The standard oxidation-reduction potential of the system Hg(0)-Hg(II) at 25°C was taken as 0.850 V. vs. NHE, which had been obtained by Hietanen and Sillén[7] taking into account the complex formation between mercury(II) and nitrate ions. The standard potentials at 15° and 35° were calculated using the value at 25°C and the enthalpy change of the system at 25°C[8]. The ε° values calculated are given in Table I.

At the constant concentration of total mercury(II), Leden's F_0 function[9] was obtained from Eqs. 1 and 2 as:

$$F_0 \equiv \sum_j K_j^c [SCN^-]^j = \text{antilog}\left[0.435 \cdot \frac{2F}{RT} (\varepsilon^\circ - \varepsilon) \right] \quad (3)$$

Since the presence of hydrated mercury(II) and mono-coordinated thiocyanatocomplex ions was negligible compared to other species in the concentration range employed, the following F_2 function was obtained:

$$F_2 = \frac{F_0}{[SCN^-]^2} = K_2^c + K_3^c [SCN^-] + K_4^c [SCN^-]^2 \quad (4)$$

If the values of F_2 obtained experimentally are plotted against $[SCN^-]$, the value of K_2^c can be determined by extrapolation of the plot to a zero thiocyanate concentration. Using the K_2^c value thus obtained, the values of K_3^c and K_4^c can be determined by a similar graphical method with the aid of the following equation:

$$F_3 = \frac{F_2 - K_2^c}{[SCN^-]} = K_3^c + K_4^c [SCN^-] \quad (5)$$

In the above procedure the concentration of free (uncoordinated) thiocyanate $[SCN^-]$ must

be known. Since the concentration of the thiocyanate that is consumed by complexing cannot be ignored, the free thiocyanate concentration must be calculated from the added concentrations of the thiocyanate and mercury-(II) nitrate. At first, [SCN^-] was calculated with appropriate coordination numbers (2 or 3) assumed tentatively. When a set of approximate values of the formation constants were available, the concentration of free thiocyanate was computed again with those constants. Such a procedure of stepwise approximation was repeated until self-consistent values of the formation constants were obtained. As an example, the data at 25°C are presented in Table II. Similar sets of data are also obtained at 15 and 35°C, and the final values of K_2^c, K_3^c and K_4^c at 15, 25 and 35°C are given in Table III.

The plots of F_2 and F_3 versus [SCN^-] obtained at 25°C are given in Fig. 2. The

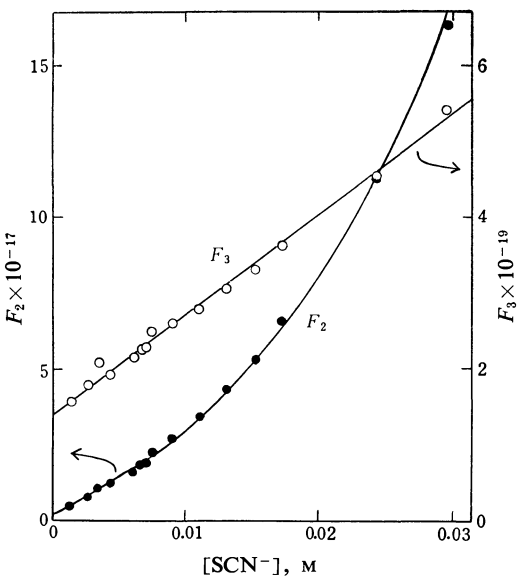

Fig. 2. F_2(Eq. 4) and F_3(Eq. 5) as functions of the thiocyanate ion concentration. (at 25°C). The solid line was calculated with the formation constants given in Table III.

solid line represents the theoretical curve which was calculated with the formation constants given in Table III. It is clearly seen that both F_2 and F_3 curves fit satisfactorily with the observed points plotted. This indicates that the formation constants obtained are proper ones.

Discussion

It is estimated from the experiments that, in a solution containing 0.532 mM of mercury-(II) and 0.03 M thiocyanate, the mean coordination number with respect to thiocyanate ion is approximately 3.7 and that some 70 per cent of the mercury(II) in the solution exists in the form of $Hg(SCN)_4^{2-}$. Hence, the range of the thiocyanate concentration chosen in the present investigation is considered sufficient for the determination of the formation constants of the three complex species, $Hg(SCN)_2$, $Hg(SCN)_3^-$ and $Hg(SCN)_4^{2-}$. The measurements at higher thiocyanate concentrations were not taken into account, because it seemed better, for the following reasons, to avoid varying the composition of the medium widely:

1. The residual current was measured with a solution containing 0.2 M potassium nitrate. With a solution containing thiocyanate, the oxidation of the electrode mercury occurs at almost the same potential as when mercury(II) nitrate is added to the solution.

2. The liquid junction potential will not stay constant with the increase of thiocyanate concentrations.

3. The activity coefficient will not be the same with the change in the composition of medium, even though the ionic strength of the medium is held constant at 0.2.

Using the activity coefficients of the ions, the formation constants given in Table III were reduced to thermodynamic formation constants, which are given in Table IV. The

Table IV. Thermodynamic formation constants of $Hg(SCN)_n^{2-n}$

Temperature °C	K_2	K_3	K_4
15	1.2×10^{18}	4.6×10^{20}	4.1×10^{22}
25	1.8×10^{17}	9.3×10^{19}	4.9×10^{21}
35	3.8×10^{16}	1.7×10^{19}	6.8×10^{20}

activity coefficients were evaluated with the equation[10],

$$\log f_i=\frac{-Az_i^2\sqrt{\Gamma}}{1+Ba_i\sqrt{\Gamma}}$$

in which A and B are constants at a given temperature[11], a_i is the mean distance of the nearest approach of the ions measured in Å, and Γ, the ionic concentration of the solution[11]. As for the mean distance of the nearest approach, the values given in Kielland's table[10] are used for the Hg^{2+} and SCN^- ions. For the $Hg(SCN)_3^-$ and $Hg(SCN)_4^{2-}$ ions, the a_i values were estimated from the data given in the same table[10].

From the thermodynamic formation constants, the free energy change ΔF, the enthalpy

11) G. Kortüm and J. O'M. Bockris, "Textbook of Electrochemistry", Vol. II, Elsvier Publishing Co., New York (1951), p. 645.

change ΔH and the entropy change ΔS for the reaction,

$$Hg^{2+}(aq.) + n\,SCN^{-}(aq.) \rightleftarrows Hg(SCN)_n^{2-n}(aq.) \quad (6)$$

were evaluated, as given in Table V.

TABLE V. THERMODYNAMIC DATA FOR REACTION 6 AT 25°C

	ΔH, kcal./mol.	ΔF, kcal./mol.	ΔS, cal./deg. mol.
$n=2$	−30	−23.6	−20
$n=3$	−29	−27.2	− 6
$n=4$	−36	−29.6	−20

In Table VI are presented the formation constants of thiocyanatomercury(II) complexes which are reported in the literature. Among them there are the formation constants K_2, K_3 and K_4 which were reported by Nyman and Alberts. They obtained those constants from the study of the polarographic anodic wave of mercury(II) which appeared in the presence of thiocyanate ions. Although the ionic strength of the solution in their study is not the same as that in our experiments, it is nevertheless reasonable to conclude that their values of the formation constants are in good agreement with ours. The values given by Korshunov and Shchennikova[13] and those by Yatsimirski and Tukhlov[16] are discussed by Nyman and Alberts in their paper[2]. Most of the formation constants given in Table VI were determined without taking into consideration the ionic strength of the medium. Therefore, those are not compared with the values obtained in this study. The constants k_3 and k_4 given by Gallais and Mounier[17] are the third and the fourth successive formation constants corresponding to the reactions

$$Hg(SCN)_2 + SCN^{-} \rightleftarrows Hg(SCN)_3^{-}$$
$$Hg(SCN)_3^{-} + SCN^{-} \rightleftarrows Hg(SCN)_4^{2-}$$

respectively. However, they are undoubtedly too small compared with the others.

Besides the values in Table VI, Toropova[12] reported the thermodynamic formation constant of $Hg(SCN)_4^{2-}$ at 25°C to be 7.8×10^{21}, which is greater than our value for K_4 by about 1.6 times. She also estimated the enthalpy change and the entropy change for reaction 6 to be −35 kcal./mol. and −20 cal./deg. mol. respectively for $n=4$ at 25°C; these figures are in good agreement with the values in Table V.

In the case of halo and pseudohalo complexes of mercury(II), it is known that the species with two anions coordinated, in general, are relatively more stable[19]. This tendency is clearly recognized in the formation constants of thiocyanato complexes of mercury(II) obtained in the present study.

Summary

The formation constants of dithiocyanatomercury(II) and tri- and tetrathiocyanatomercurate(II) complexes have been determined by the potentiometric method with a dropping

mercury electrode at ionic strength 0.2 and at 15, 25 and 35°C. The values obtained are:

at 15°C, $K^c_{Hg(SCN)_2}=1.8\times10^{17}$,
$K^c_{Hg(SCN)_3}=7.1\times10^{19}$,
$K^c_{Hg(SCN)_4}=1.11\times10^{22}$;

at 25°C, $K^c_{Hg(SCN)_2}=2.7\times10^{16}$,
$K^c_{Hg(SCN)_3}=1.39\times10^{19}$,
$K^c_{Hg(SCN)_4}=1.32\times10^{21}$;

at 35°C, $K^c_{Hg(SCN)_2}=5.5\times10^{15}$,
$K^c_{Hg(SCN)_3}=2.43\times10^{18}$,
$K^c_{Hg(SCN)_4}=1.68\times10^{20}$.

The thermodynamic formation constants of these complexes and the free energy change, the enthalpy change and the entropy change of the formation reactions of these complexes have been calculated.

The Decomposition of Methyl N-Nitroso-p-acetamidobenz[^{14}C]oate in Benzene. The Determination of the Products by the Isotopic Dilution Method

By Takashi INUKAI, Kenjiro KIMURA, Osamu SIMAMURA and Tadashi SUEHIRO

(Received May 23, 1961)

Nitrosoacylarylamines decompose in a liquid aromatic compound (Ar'H) to yield biaryls (Ar-Ar') as follows[1]:

$$ArN(NO)COR + Ar'H \longrightarrow Ar\text{-}Ar' + N_2 + RCOOH$$

The homolytic nature of this reaction is now widely accepted[2]; the biaryl is thought to be formed by substitution of Ar'H by aryl radicals (Ar·) homolytically produced from the nitroso compound. However, the yield of the biaryl is far from quantitative, and an appreciable quantity of tar is usually formed. In some cases a compound (ArH) resulting from abstraction of a hydrogen atom by the aryl radical was isolated[3]. Further, it was observed that about 3% of azobenzene was formed in the decomposition of *N*-nitrosoacetanilide in benzene[4]. In view of the complex nature of this reaction, it seemed of interest to determine the yields of various by-products from the decomposition of *N*-nitrosoacylarylamines. We report the results of isotopic dilution analysis of the products from decomposition of labelled methyl *N*-nitroso-*p*-acetamidobenzoate in benzene.

Methyl *N*-nitroso-*p*-acetamidobenz[^{14}C]oate (4.48 mmol.) was dissolved in benzene (405 mmol.) and left to stand for four days at 17~18°C; by the end of this period 76 cc. (0°, 1 atm., 76% of the theoretical amount) of nitrogen had been evolved. The reaction mixture was then worked up, and the yields of methyl benzoate, methyl *p*-acetoxybenzoate, methyl 4-biphenylcarboxylate etc. were determined by isotopic dilution analysis as will be described in the experimental part. The results are summarized in Table I.

Methyl 4-biphenylcarboxylate is obviously the product of the homolytic substitution of benzene by 4-methoxycarbonylphenyl radicals, although the detailed mechanism of this reaction is still obscure. Its yield, viz., 53.3%, definitely precludes the possibility, which has already come to be regarded as unlikely, that methyl 4-biphenylcarboxylate is formed exclusively by combination of 4-methoxycarbonylphenyl with phenyl radicals produced from benzene by hydrogen abstraction by the former radical. The low yield of methyl benzoate, which is formed by this abstraction, also supports this conclusion.

4) D. F. DeTar and H. J. Scheifele, *J. Am. Chem. Soc.*, **73**, 1442 (1951).

Dimethyl 4, 4′-biphenyldicarboxylate may have been produced by homolytic substitution of the methyl benzoate formed during the reaction by *p*-methoxycarbonylphenyl radicals. The extent of this substitution can be estimated as follows: The concentration of methyl benzoate may be assumed to be $0.013\times4.48\times0.5/405=7.2\times10^{-5}$ mol. per mole of benzene throughout the reaction, and as the partial rate factor of the para position of the methyl benzoate for the homolytic phenylation should be about 5[5] and the yield of methyl 4-biphenylcarboxylate was 53%, the yield of dimethyl 4, 4′-biphenyldicarboxylate by the substitution mechanism is expected to be of the order of $53\times7.2\times10^{-5}\times5/6=0.0032\%$. The experimentally found value of 0.024% therefore suggests that dimethyl 4, 4′-biphenyldicarboxylate must have been afforded largely by dimerization of *p*-methoxycarbonylphenyl radicals. But the possibility of induced decomposition by these radicals of the original *N*-nitroso-compound or of the rearranged diazoacetate could not be ruled out.

TABLE I. YIELDS OF VARIOUS PRODUCTS FROM THE DECOMPOSITION OF METHYL *N*-NITROSO-*p*-ACETAMIDOBENZ[^{14}C]OATE IN BENZENE

Product	yield, %
Methyl 4-biphenylcarboxylate	53.3
Methyl 4-acetoxybenzoate	0.046
Methyl benzoate	1.30
Dimethyl 4, 4′-biphenyldicarboxylate	0.024
Dimethyl 4, 4′-azobenzenedicarboxylate	0.46
Methyl 2-biphenylcarboxylate	<0.0074

The yields of dimethyl 4, 2′- and 4, 3′-biphenylcarboxylate, although no attempt was made at their determination, must have been small, since the homolytic arylation usually gives three isomerides in comparable amounts.

Methyl benzoate is thought to have been formed by hydrogen abstraction by *p*-methoxycarbonylphenyl radicals. Some of it must have reacted with *p*-methoxycarbonylphenyl radicals, giving three isomeric dimethyl biphenyldicarboxylates, but the extent of this reaction seems to have been exceedingly small, as is indicated by the low yield of dimethyl 4, 4′-biphenyldicarboxylate. The same is true of the substitution of methyl benzoate by any phenyl radicals to be generated from benzene by hydrogen abstraction by radicals, methyl 2-biphenylcarboxylate, one of the anticipated products of the phenylation, being formed in a negligible quantity, if at all. The yield of the meta isomeride would have been shown to be virtually nil, too. The conclusion is therefore drawn that the observed yield of methyl benzoate gives a practical estimate of the extent of the hydrogen abstraction by *p*-methoxycarbonylphenyl radicals.

5) A value estimated from the partial rate factors of ethyl benzoate for phenylation (unpublished work).

Experimental

Methyl *p*-Acetamidobenz[^{14}C]oate. — *p*-Aminobenz[^{14}C]oic acid was prepared according to the procedure described by Murry et al.[6] The labelled acid (0.357 g.) was dissolved in 37 cc. of anhydrous methanol and 1 cc. of acetyl chloride, the solution left to stand overnight, and the solvent removed on a water bath. The remaining methyl *p*-aminobenz-[^{14}C]oate hydrochloride was dissolved in water; the solution was treated with a little active charcoal, filtered, made slightly alkaline with sodium carbonate and stirred with acetic anhydride. The resulting precipitate was collected on a filter paper to give 0.352 g. of methyl *p*-acetamidobenz[^{14}C]oate, m. p. 129.7~130.5°C. A specimen of the non-labelled acid (Found: N, 7.25. Calcd. for $C_{10}H_{11}\cdot NO_3$: N, 7.25%) which was similarly prepared had the same melting point[7]. The labelled methyl ester was diluted with the inactive specimen and recrystallized from hot water containing 10% of methanol to give 990 mg. of methyl *p*-acetamidobenz-[^{14}C]oate (activity, 27.25 ± 0.545 mc./mol.), which was used for the preparation of the *N*-nitroso compound.

Methyl *N*-Nitroso-*p*-acetamidobenz[^{14}C]oate.— The above methyl *p*-acetamidobenz[^{14}C]oate (943.5 mg.) was dissolved in 6 cc. of a mixture (1 to 1 by volume) of acetic anhydride and acetic acid, containing 1.8 g. of potassium acetate and a little phosphorus pentoxide; this mixture was cooled with ice and water and nitrosated by adding dropwise 3 cc. of a solution of nitrosyl chloride (1 cc.) in acetic anhydride (4.3 cc.). The reaction mixture was stirred into 30 cc. of water, and the yellow precipitate was filtered off, washed with water and dried on a porous plate for 2 hr. and a half in an evacuated desiccator (3 mmHg) containing concentrated sulphuric acid, to give 1.004 g. of methyl *N*-nitroso-*p*-acetamidobenz[^{14}C]oate, m. p. 73~74°C with decomposition. This was immediately assayed for purity and subjected to decomposition in benzene. The purity of this specimen was estimated at $94.8\pm2.5\%$, as is described below. On the addition of 8.59 mg. of the labelled nitroso compound to a solution of 14 mg. of β-naphthol in 5 cc. of methanol, labelled 1-(*p*-methoxycarbonylphenylazo)-2-naphthol began to precipitate. The reaction mixture was allowed to stand for two days, 102.15 mg. of inactive 1-(*p*-methoxycarbonylphenylazo)-2-naphthol and 150 cc. of methanol were added, and the mixture was heated on a water bath to effect dissolution and then cooled. The precipitated azo compound was filtered off and repeatedly crystallized from methanol to a constant

7) N. W. Hirwe and P. Y. Kulkarni (*Proc. Indian Acad. Sci.*, **16A**, 294 (1942); *Chem. Abstr.*, **37**, 4061 (1943)) reported a m. p. of 114°C, but G. W. K. Cavill and J. M. Vincent (*J. Soc. Chem. Ind.* (London), **67**, 25 (1948); *Chem. Abstr.*, **42**, 4701b (1948)) reported a m.p. of 128°C.

activity of 2.70±0.043 mc./mol. The non-radioactive azo compound used as a carrier for the dilution analysis was prepared by coupling methyl *N*-nitroso-*p*-acetamidobenzoate with β-naphthol in methanol, m. p. 185.3~186.8°C (from methanol) (Found: N, 9.37. Calcd. for $C_{18}H_{14}N_2O_3$: N, 9.15%).

Decomposition of Methyl *N*-Nitroso-*p*-acetamidobenz[^{14}C]oate in Benzene.—The labelled nitroso compound (994.5 mg., 4.48 mmol.) was dissolved in 36 cc. of benzene (405 mmol.) containing a little anhydrous sodium sulphate and allowed to decompose at 17~18°C; at the end of four days the nitrogen evolved had amounted to 76 cc. (0°C, 1 atmosphere).

The solution was decanted from the sodium sulphate, which was then washed with benzene. To the combined benzene solutions, 753.35 mg. of methyl benzoate was added, and the benzene was removed on a water bath. The residue, after addition of 496.20 mg. of methyl *p*-acetoxybenzoate, m. p. 82.9~83.9°C, (lit.[8] m. p. 85°C), and 941.73 mg. of methyl 4-biphenylcarboxylate, m. p. 117~118°C, (lit.[9] m. p. 116~117°C), was subjected to distillation under diminished pressure. The following fractions were obtained: Methyl benzoate, b. p. 90.6~90.9°C at 21 mmHg, methyl *p*-acetoxybenzoate, b. p. 144~160°C at 9 mmHg, and methyl 4-biphenylcarboxylate, b. p. 179~180°C at 9 mmHg.

The methyl benzoate was hydrolyzed with alkali, and the resulting benzoic acid was repeatedly crystallized from hot water to a constant activity of 0.283±0.0099 mc./mol. The yield of methyl benzoate from the decomposition of the nitroso compound in benzene was therefore 7.91 mg., or 1.30% based on the nitroso compound.

The methyl 4-biphenylcarboxylate was purified by repeated crystallizations from methanol; the activity was found to be 9.55±0.191 mc./mol., corresponding to a yield of 53.3%.

It was found difficult to purify the methyl *p*-acetoxybenzoate by recrystallization from methanol on account of the contamination with methyl 4-biphenylcarboxylate. Accordingly, the fraction containing methyl *p*-acetoxybenzoate was dissolved in benzene, and the solution was washed with dilute aqueous alkali to remove any phenolic substance which might have been formed owing to unknown causes, washed with water, dried with anhydrous sodium sulphate and filtered through a column of alumina. Methyl 4-biphenylcarboxylate passed through, and on elution with ether 0.2 g. of methyl *p*-hydroxybenzoate was recovered. It was ascertained by a separate experiment that methyl *p*-acetoxybenzoate is deacetylated on alumina under those experimental conditions. The eluted methyl *p*-hydroxybenzoate was dissolved in benzene and extracted with dilute aqueous alkali, and the extract was washed with benzene and acidified with dilute sulfuric acid to precipitate methyl *p*-hydroxybenzoate, m. p. 131°C, (lit.[8] m. p. 131°C). Two crystallizations from water afforded a specimen with an activity of 0.0223 mc./mol. We were unable to pursue the purification to a constant activity on account of the dearth of the material. The activity of 0.0223 mc./mol. corresponds to a yield of 0.046%.

The mother liquors from the purification of methyl 4-biphenylcarboxylate were combined, and methanol was removed. The residue was combined with that from evaporation of the fraction containing 4-biphenylcarboxylate from the above chromatographic separation, and 750.15 mg. of methyl 2-biphenylcarboxylate, b. p. 173.5°C (18 mmHg), was added. The whole was dissolved in benzene and the solution washed with 0.05 N sodium hydroxide solution and then with water, dried with calcium chloride and filtered through a column of alumina to remove most of the methyl 4-biphenylcarboxylate. Benzene was removed from the filtrate, the remaining ester hydrolyzed by boiling for about five hours with sodium hydroxide in dilute alcohol, and hydrochloric acid added. The precipitated 2-biphenylcarboxylic acid was filtered off, dried (706 mg.), and heated for ten minutes with 4 cc. of concentrated sulphuric acid on a water bath. The reaction mixture was added to water, the precipitate filtered off and dissolved in ether, the solution washed thoroughly with dilute sodium carbonate and dried with anhydrous calcium chloride, and the ether removed on a water bath to give 0.50 g. of fluorenone. Repeated crystallizations from petroleum ether gave a specimen, m. p. 84°C (lit.[10] m. p. 84~86°C), with an activity of 1.1 μc./mol. with a reliable error of ±1.6 μc./mol. Therefore, the yield of methyl 2-biphenylcarboxylate is estimated to be less than 0.0074%.

The upper part of the chromatographic column for the separation of methyl 4-biphenylcarboxylate and methyl *p*-acetoxybenzoate showed an orange color. This part was extracted three times with hot 94% alcohol, and the combined extracts were evaporated. The residue was added, together with 175.5 mg. of dimethyl 4, 4'-azobenzenedicarboxylate, m.p. 242~242°C (lit.[11] m.p. 242°C), 365.1 mg. of methyl 4-azobenzencarboxylate, m.p. 123~124°C (lit.[12] m.p. 123~124°C), and 115.1 mg. of dimethyl 4,4'-biphenyldicarboxylate, m.p. 213~214°C (lit.[13] m.p. 212~213°C), to a benzene solution of the residue from the fractional distillation. The benzene solution was heated, and, on concentration to about 40 cc., dimethyl 4, 4'-azobenzenedicarboxylate crystallized out in small scales. This was filtered off and recrystallized from benzene to a constant activity of 0.947±0.018 mc./mol., corresponding to a yield of 0.46%. The mother liquor was chromatographed on alumina in order to effect a further separation. But, as no substances were eluted owing to strong adsorption, the alumina was boiled with methanol and 17.0 mg. of dimethyl 4, 4'-biphenyldicarboxylate recovered. This was diluted with 176 mg. of inactive ester and recrystallized from benzene to a constant activity of 0.0060±0.0006 mc./mol., corresponding to a yield of 0.024%. Purification of methyl 4-azobenzenecarboxylate failed owing to its greater

solubility than those of the other compounds added as carriers.

Radioactivity Determination.—Radiocarbon assays were carried out by oxidizing samples according to the method of Van Slyke and Folch[14] and by converting the resulting carbon dioxide into barium carbonate, the activity of which was counted with an end-window Geiger-Müller counter on an "infinitely thick" layer with a surface area of 4.9 cm^2, the counts being all corrected for background and compared with the count of a standard barium carbonate with a known activity.

Dimer-Monomer Equilibrium Constants for Acetic Acid and the Three Chloroacetic Acids in Benzene

By Yoichiro NAGAI and Osamu SIMAMURA

(Received May 23, 1961)

An accurate value of the equilibrium constant for the association of monomeric dichloroacetic acid to the dimeric form in benzene was required for a kinetic study being carried out in this laboratory. A search of the literature showed that a number of workers[1-5] had already been concerned with the problem of determining the association constants of acetic acid and the three chloroacetic acids in various non-polar solvents. In view of the lack of a reliable value for our present purpose, however, we have now determined, by infrared absorption measurement, the dimer-monomer equilibrium constant for dichloroacetic acid in benzene at 20°C, together with those for acetic, monochloroacetic, and trichloroacetic acid.

Experimental

Materials.—Benzene was shaken with concentrated sulphuric acid and with water, dried with calcium chloride and fractionated over sodium. Acetic acid was refluxed with potassium permanganate, distilled, and subjected to fractional crystallizations until a product with a constant freezing point, 16.5°C, was obtained; this material was distilled before use, b. p. 117°C. Monochloroacetic acid was recrystallized three times from benzene, dried over phosphorus pentoxide in an Abderhalden apparatus, m. p. 63.0°C, and distilled, b. p. 186°C. Dichloroacetic acid was prepared by Cope, Clark, and Connor's procedure[6] and fractionated three times under reduced pressure, b. p. 86.6~87.0°C/13mmHg. Trichloroacetic acid was distilled four times, b. p. 195.5~195.8°C.

Absorption Measurement.—The measurements were carried out at 20°C on benzene solutions of the acids in concentrations ranging from 0.01 to 1 mol./l., a Perkin-Elmer grating spectrophotometer Model 112G being used. A 1 mm. measuring cell was used for solutions of acetic, monochloroacetic, and dichloroacetic acid and an 0.1 mm. cell for solutions of trichloroacetic acid. The absorption spectra were measured in the region between 3250 and 3550 cm^{-1}, in which the peak of a band due to a free OH stretching vibration usually appears, with a spectral slit width of 1.0 cm^{-1} being used.

Results and Discussion

The absorption frequencies observed in benzene corresponding to the stretching mode of the free OH group of acetic acid and the three chloroacetic acids are listed in Table I, together with the values in carbon tetrachloride reported in the literature.

TABLE I. ABSORPTION FREQUENCIES (cm^{-1})

Acid	Present work in C_6H_6	Ref. 1 in CCl_4	Ref. 7 in CCl_4	pK_a[8] in H_2O
CH_3COOH	3472	3548	3533	4.76
$CH_2ClCOOH$	3438	3539	3522	2.86
$CHCl_2COOH$	3410	3529	3511	1.29
CCl_3COOH	3389	3526	3505	0.3

Table I shows that the free OH vibration frequency of the stronger acid is lower than that of the weaker one both in benzene and in carbon tetrachloride. There is a linear relation between the OH vibration frequencies in benzene and the pK_a values[8], as is shown in Fig. 1. A similar relation has also been observed in carbon tetrachloride solution[7].

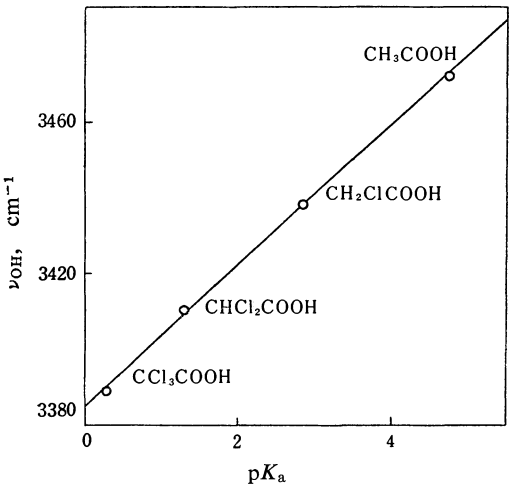

Fig. 1. Relation between the OH vibration frequency of the monomeric acid in benzene and the pK_a value.

Further, the observed frequencies are considerably lower in benzene than in carbon tetrachloride. This shift in the OH frequency is obviously attributable to an interaction, similar to hydrogen bond formation, between the hydroxyl of a carboxyl group and the π-electron system of a benzene nucleus. Since the relative affinity of the acid for benzene is considered to be parallel to the acid strength, it is expected that the more highly chlorinated acids interact more strongly with benzene, resulting in a larger shift in frequency; this has been borne out, as is shown in Fig. 1. Such a shift has also been observed for methanol-d[9] and phenols[10], and a similar one has been observed in the NH frequency for *N*-methylacetamide[11].

The dimer-monomer equilibrium constants were calculated from the change in the apparent molar extinction coefficient of the OH absorption band with the acid concentration by using the equations,

$$d = l\varepsilon C = lEM$$

$$K = 2M^2/(C-M)$$

In these equations d is the optical density, l the absorption path length, ε the apparent molar extinction coefficient, E the molar extinction coefficient of the monomeric acid, C the concentration of the acid taken, M the concentration of the acid monomer, and K the equilibrium constant. Combination of the above equations and rearrangement gives

$$\varepsilon C = (KE^2/2)(1/\varepsilon) - KE/2$$

It follows from this equation that a graph of εC at the particular OH absorption frequency against $1/\varepsilon$ should give a straight line of slope $KE^2/2$ and intercept $KE/2$. The experimental data are shown numerically in Table II and graphically in Fig. 2. The apparent molar extinction coefficient ε increases with a decreasing concentration of the acid, showing that the frequencies which have been measured are due to the OH vibration of the monomeric acids. Since there are satisfactory linear relations between εC and $1/\varepsilon$, as is shown in Fig. 2, it is evident that the assumption of a dimer-monomer equilibrium is well-founded.

The values of E and K calculated from the slopes and intercepts of the lines in Fig. 2 determined by the method of least squares are given in Table III. Harris and Hobbs[1] have estimated, by means of infrared absorption measurement, the equilibrium constants in carbon tetrachloride at 25°C at 2.5×10^{-4}, 6.2×10^{-4}, 9.3×10^{-4}, and 19×10^{-4} mol./l. for acetic, monochloroacetic, dichloroacetic, and trichloroacetic acid, respectively. Comparison with the present values indicates that these acids are very much more associated in carbon tetrachloride than in benzene. The larger dissociation in the latter solvent is evidently attributable to the same cause that has been adduced above to account for the shift in the hydroxyl frequency in benzene from that in carbon tetrachloride; the stabilizing interaction of a hydroxyl group with a molecule of benzene tends to bring about the dissociation of the dimeric form.

TABLE III. MOLAR EXTINCTION COEFFICIENTS AND DIMER-MONOMER EQUILIBRIUM CONSTANTS IN BENZENE AT 20°C

Acid	E l.mol^{-1} cm^{-1}	K mol./l.
CH_3COOH	50.8	0.036
$CH_2ClCOOH$	87.7	0.041
$CHCl_2COOH$	110.9	0.092
CCl_3COOH	92.2	0.91

Summary

Acetic, monochloroacetic, dichloroacetic, and trichloroacetic acid in benzene show an infrared absorption band due to the OH stretching vibration of the monomeric form at 3472, 3438, 3410, and 3389 cm^{-1}, respectively. The dimer-monomer equilibrium constants for these acids in benzene at 20°C have been evaluated, from the change in intensity of these bands with the acid concentration, to be 0.036, 0.041, 0.092, and 0.91 mol./l., respectively.

The observed shift in frequency indicates that there is an interaction, similar to hydrogen bond formation, between the hydroxyl of a carboxyl group and the π-electron system of a benzene nucleus and that the stronger acid interacts more strongly with benzene, resulting in a larger shift in frequency.

The authors are indebted to Professor Takehiko Shimanouchi for valuable suggestions.

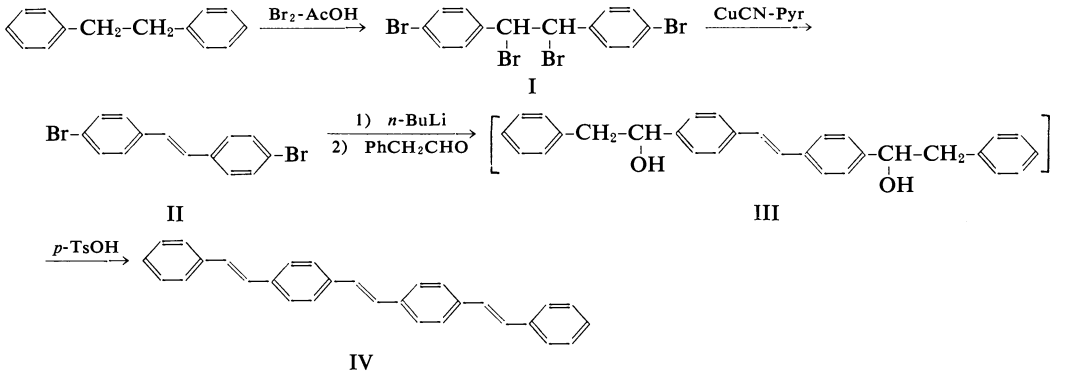
Alternant Conjugate Systems. III. Syntheses of Stereoisomeric p, p'-Distyrylstilbenes and Related Compounds

By Sōichi MISUMI, Motoyuki KUWANA and Masazumi NAKAGAWA

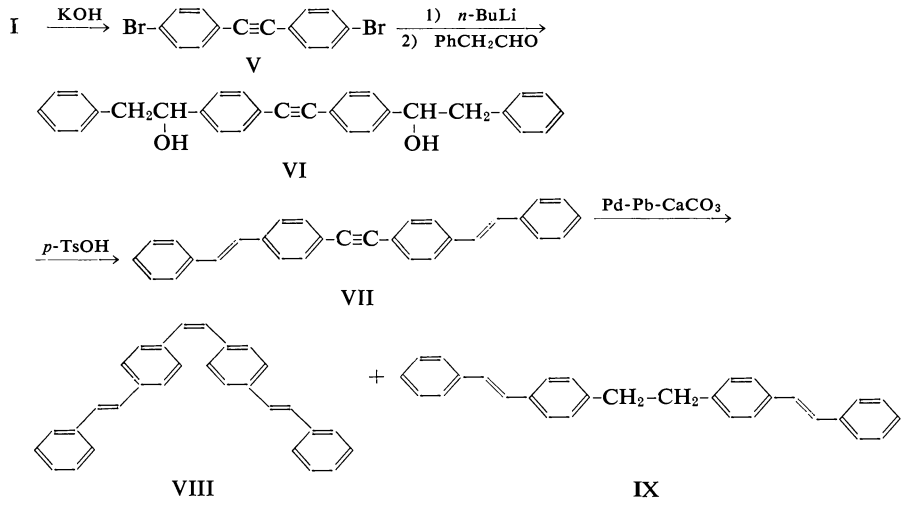
(Received March 7, 1961)

In Part II[1] of this series, the present authors reported the syntheses of alternatively conjugated compounds containing three benzene rings in the conjugate system. The appearance of absorption maxima at ca. 270 mμ in the ultraviolet spectra of these compounds could be attributed either to the so-called "cis-peak"[2] or to the partial chromophore[3] which became operative at the presence of steric hindrance. As it seems to be possible to distinguish the two possibilities stated above by an examination of the ultraviolet spectra of the longer alternant conjugate system, the authors have carried out the syntheses of stereoisomeric *p, p'*-distyrylstilbenes and the related compounds containing four benzene nuclei in the system.



Theoretically, eighteen stereoisomers are possible in the alternant conjugate system containing four benzene nuclei which are linked with each other by double or triple bonds in their para-positions. The present paper deals with the syntheses of ten of the eighteen stereoisomers of this series.

The all-trans isomers has been synthesized by Dale[4] through the Meerwein reaction of *p, p'*-diaminostilbene and by Drefahl and his co-worker[5] through the Grignard reaction of *p, p'*-stilbenedialdehyde. The present authors have synthesized the all-trans isomer according to the following scheme[6].



p, p'-Dibromostilbene (II) was derived from the tetrabromide (I) by treatment with cuprous cyanide[7]. The crude glycol (III) which was obtained by the metalation of the stilbene (II) and the subsequent reaction with phenylacetaldehyde was dehydrated without further purification, yielding trans, trans, trans-*p, p'*-distyrylstilbene (IV) as yellow crystals with green fluorescence.

Two different methods, a half-reduction of the corresponding acetylenic analogues and the Wittig reaction of the appropriate aldehyde with a phosphonium halide, were employed for the syntheses of trans, cis, trans- and trans, trans, cis-isomers of *p, p'*-distyrylstilbene (abbreviated as t-c-t and t-t-c).

The t-c-t isomer was synthesized according to the following scheme: *p, p'*-Dibromotolan (V) was obtained in an almost quantitative yield by the dehydrobromination[8] of the tetrabromide (I). Successive reactions of *n*-butyllithium with dibromotolan (V) and then with phenylacetaldehyde yielded the glycol (VI). The glycol (V) was dehydrated in boiling toluene in the presence of *p*-toluenesulfonic acid to yield *trans, trans-p, p'*-distyryltolan

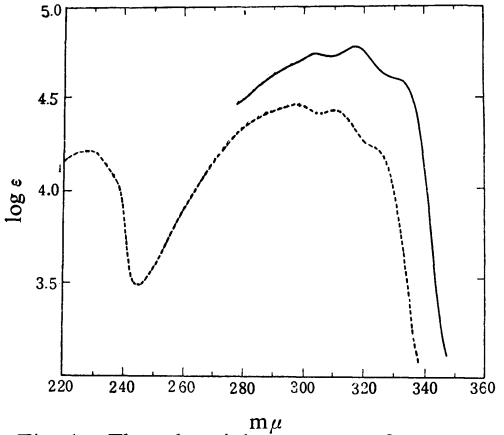
(VII)[6] (abbreviated as t-A-t).

t-A-t (VII) was found to be sparingly soluble in common solvents for catalytic hydrogenation. Therefore, VII was dissolved in a large amount of tetrahydrofuran (solubility: 3 mg. in 43 ml.) and hydrogenated in a dark place over a large amount of Lindlar's catalyst[9] (about the same weight as VII). The progress of hydrogenation was followed, measuring the change of the ultraviolet absorption at a certain time interval. The hydrogenation product from several runs was combined (300 mg.) and recrystallized from benzene. This substance yielded almost pure t-c-t isomer by chromatographic purification over alumina. The configuration of this material was inferred from the following evidence: (1) Analytical data, (2) definite and sharp melting point, (3) thermal isomerization to all-trans isomer, and (4) photoisomerization to all-trans isomer.



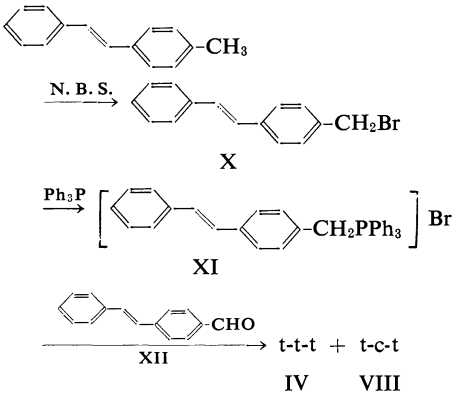


Fig. 1. The ultraviolet spectra of IX (——) (in benzene) and *p*-methylstilbene (·····) (in *n*-hexane).

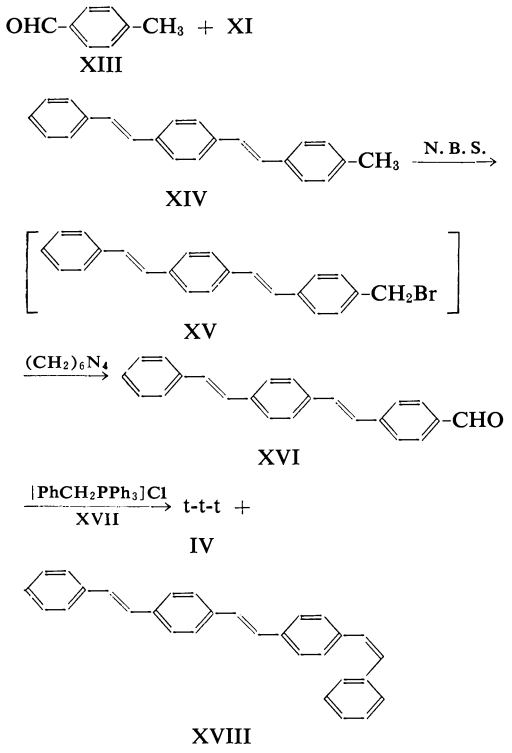
9) H. Lindlar, *Helv. Chim. Acta*, 35, 446 (1952).

Pale yellow needles with green fluorescence (m. p. 262°C.) were obtained from the first mother liquor of the recrystallization of t-c-t isomer. The solubility in organic solvents and the closely related ultraviolet spectrum of this compound with that of *p*-methylstilbene (maxima at almost the same positions with two-fold intensities) suggest that the substance with the melting point of 262°C is *p*,*p*'-distyryldibenzyl (IX) (Fig. 1 and Table I).

The t-t-t and t-c-t isomers were also prepared by the Wittig reaction. The reaction of the phosphonium salt XI, derived quantitatively from *p*-bromomethylstilbene (X), with *p*-stilbenealdehyde (XII)[10] resulted in a mixture of

t-t-t (IV) and t-c-t isomer VIII. Recrystallization and chromatography over alumina of the mixture afforded pure t-t-t and t-c-t isomer.



The synthesis of the third isomer, t-t-c (XVIII), was performed starting from *p*-tolualdehyde (XIII)[11]. *p*-Methyldistyrylbenzene (XIV)[5] was prepared by the Wittig reaction

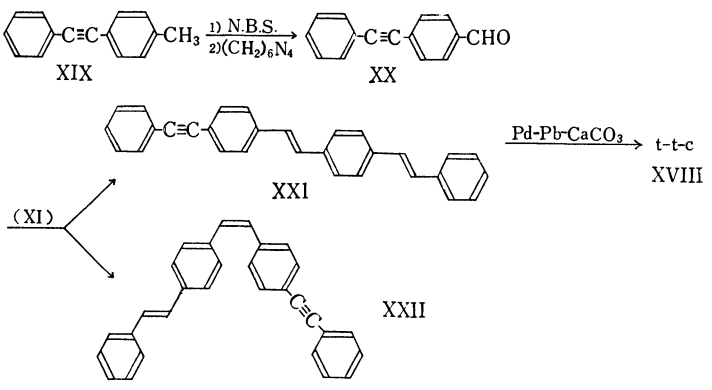
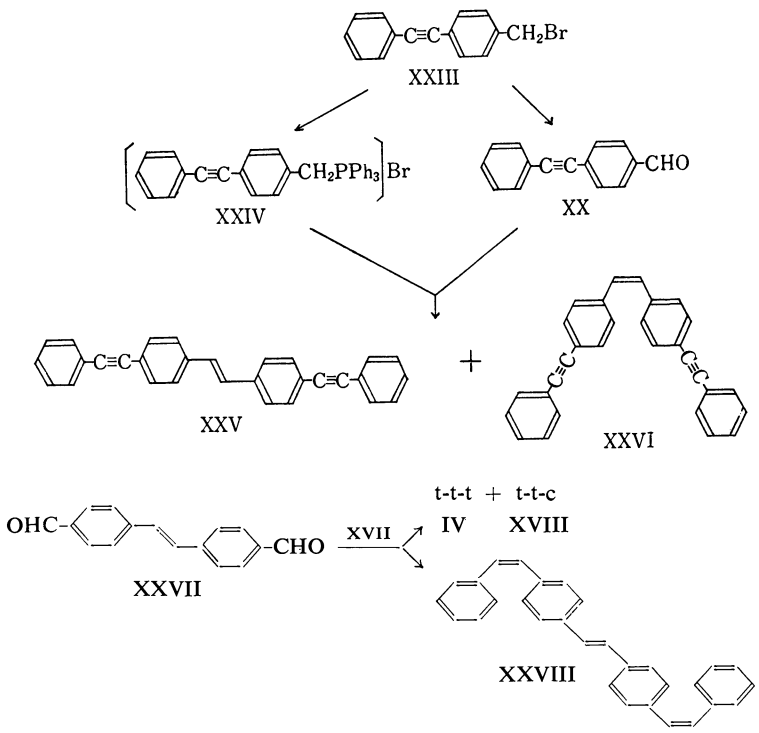
Table I. The ultraviolet spectra of IX and *p*-methylstilbene

	λ_{max}, mμ (ε_{max})				
IX		303 (55100)	317 (60900)	(benzene)	
p-Methylstilbene	229 (16100)	298 (29400)	310 (28000)	(*n*-hexane)	



of *p*-tolualdehyde (XIII) with the phosphonium bromide (XI) and converted to *p*-bromomethyl derivative XV by the reaction with *N*-bromosuccinimide. Distyrylbenzenealdehyde (XVI) was prepared according to Drefahl's procedure[5] with the slight modification of employing the crude bromide XV. The Wittig reaction of the aldehyde XVI with benzyltriphenylphosphonium chloride (XVII) was carried out in a dark place. Recrystallization and chromatography of the reaction product resulted in the separation of t-t-t (IV) and t-t-c isomer XVIII.



The t-t-c isomer XVIII showed a characteristic behavior which could not be observed in the other cis-isomer. When the temperature of a heating bath was gradually raised, a gradual sintering of the crystals was observed at ca. 227°C and the crystals melted at the melting point of the t-t-t isomer. On the other hand, when the bath temperature was rapidly elevated, the crystals melted at 227~230°C and the molten substance immediately resolidified. This solid showed an identical melting point with the all-trans isomer. Therefore, the definite melting point of the t-t-c isomer could not be determined owing to the above-mentioned thermal instability.

The t-t-c isomer XVIII was also prepared by the half-reduction of the corresponding acetylenic compound. *p*-Tolanaldehyde (XX)[1,12] obtained from *p*-methyltolan (XIX) was treated with *p*-styrylbenzyltriphenylphosphonium bromide (XI). A chromatographic purification of the reaction product afforded *p*-phenylethynyl-*p'*-styryl-*trans*-stilbene (XXI) (t-t-A) and *p*-phenylethynyl-*p'*-styryl-*cis*-stilbene (XXII) (t-c-A) in a yield of 40% and 30% respectively.

The structure of the t-c-A isomer was inferred from the analytical data and from the thermal- and photo-isomerizations to the t-t-A isomer. Owing to the poor solubility in common organic solvents, the catalytic half-hydrogenation of the t-t-A compound to the t-t-c isomer was performed in tetrahydrofuran as for the reduction of the t-A-t isomer. The t-t-c compound (XVIII) obtained by this method was proved to be identical with the specimen,

12) G. Drefahl and G. Plötner, *Chem. Ber.*, 93, 990 (1960).

which was prepared by the above-mentioned Wittig reaction, by the mixed melting point determination and by a comparison of the ultraviolet spectra.

With the purpose of comparing the ultraviolet spectroscopic properties with those of analogous alternant triene or alternant dienyne compounds, *cis*- and *trans*-*p*,*p*'-bisphenylethynylstilbenes (XXVI, A-c-A and XXV, A-t-A[12]) were synthesized by the reaction of phosphonium salt XXIV with tolanaldehyde (XX), both of which are derived from *p*-bromomethyltolan (XXIII). The structure of the cis-isomer was determined by the analytical data and the thermal- and photo-isomerizations to the A-t-A isomer.

The fourth isomer of *p*,*p*'-distyrylstilbene, c-t-c (XXVIII), was obtained by a double Wittig reaction of *p*,*p*'-stilbenedialdehyde (XXVII) together with t-t-t (IV) and t-t-c (XVIII). The structure of this isomer was confirmed by elementary analysis and the thermal- and photo-isomerizations to the t-t-t isomer. It is interesting to note that this isomer is thermally more stable than t-c-t (VIII) and t-t-c (XVIII).

Generally, a slightly larger or almost the same amount of cis-isomer as compared with that of trans-isomer could be isolated from the products of the Wittig reactions of these types of compound. This fact seems to be attributable to the difficult isolation and purification of the sparingly soluble trans-isomer from the unreacted phosphonium salt in contrast with the case of the more soluble cis-isomer.

The ultraviolet spectra of the above-mentioned ten compounds, t-t-t, t-t-c, t-c-t, c-t-c, t-t-A, t-A-t, A-t-A, A-c-A, t-c-A and A-A-A, are illustrated in Figs. 2, 3 and 4. The physical properties of these compounds are presented in Table II. A detailed discussion on the ultraviolet spectra and the photoisomerizations of these compounds will be presented in a following paper.

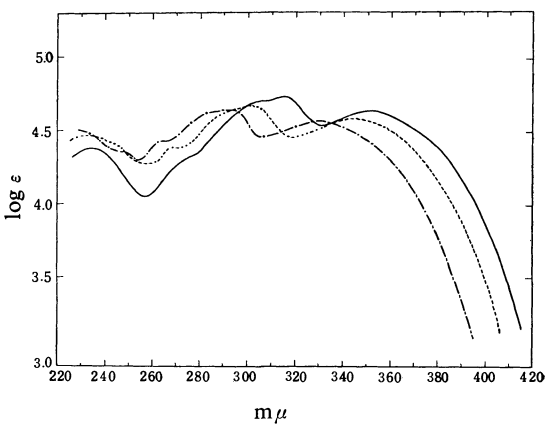


Fig. 2. The ultraviolet spectra of t-c-t (VIII, ——), t-c-A (XXII, ·····) and A-c-A (XXVI, —·—·) in tetrahydrofuran.

TABLE II. PROPERTIES OF STEREOISOMERIC *p,p'*-DISTYRYLSTILBENES AND RELATED COMPOUNDS

	M. p., °C	Color	Fluorescence in solution	Ultraviolet spectrum λ_{max} in mμ ($\varepsilon_{max} \times 10^{-3}$) in tetrahydrofuran			
t-t-t	334~336	Green yellow	Intense blueviolet	238 (35.9)	270 (18.6)		384 (89.3)
t-t-A	308~309	Light green yellow	Intense blueviolet	237 (32.1)	266 (20.8)		374 (78.7)
t-A-t	305~308	Light green yellow	Intense blueviolet	243 (43.2)			361 (84.3)

c, t and A denote cis-ethylenic, trans-ethylenic and acetylenic linkage respectively.

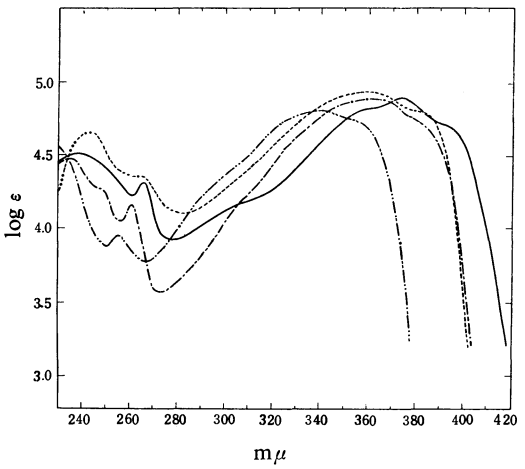

Fig. 3. The ultraviolet spectra of t-t-A (XXI, ——), t-A-t (VII, ·····), A-t-A (XXV —·—·) (in tetrahydrofuran) and A-A-A (—··—··) (in chloroform).

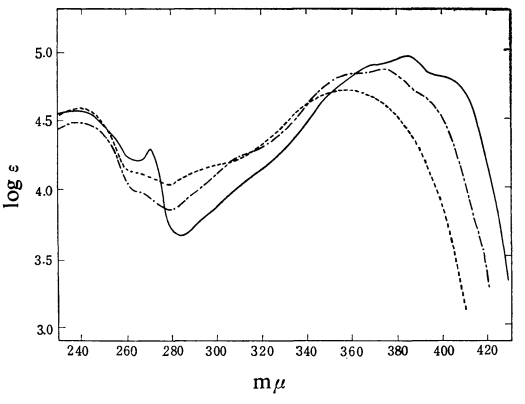

Fig. 4. The ultraviolet spectra of *p,p'*-distyrylstilbenes (t-t-t, IV, ——; t-t-c, XVIII, —·—·; c-t-c, XXVIII, ·····) in tetrahydrofuran.

Experimental*

***trans, trans, trans-p, p'*-Distyrylstilbene (t-t-t) (IV).** — *a) From p,p'-Dibromostilbene (II).* — The debromination of *p,p',α,α'*-tetrabromodibenzyl (I) according to the method of Bance et al. yielded *p,p'*-dibromostilbene (II), in the form of lustrous colorless plates, m. p. 207.5~209°C (81.7%) (lit., m. p. 206~210°C, 72%)[7]. A small excess of *n*-butyllithium in dry ether was slowly stirred into a suspension of dibromostilbene (II, 16.6 g., 0.049 mol.) in dry ether (170 ml.) in an atmosphere of pure nitrogen. The reaction mixture was kept overnight at room temperature, and then freshly distilled phenylacetaldehyde (15.0 g., 0.125 mol.) in dry ether (170 ml.) was slowly stirred into the mixture over a period of 1 hr. The stirring was continued for a further 10 hr., and then the mixture was refluxed for 4 hr. A slow stream of pure nitrogen was introduced continuously into the reaction flask throughout these operations. A saturated aqueous solution of ammonium chloride (10.7 g.) was added to the cooled reaction mixture. The crystals accumulated on the intersurface of organic and aqueous layers were collected by filtration (16.4 g.). The aqueous layer was extracted with ether. The extract was combined with the ethereal layer and washed with water. The solvent was removed from the dried ethereal solution, yielding crude glycol III (19.4 g.). The crude material was combined (35.8 g.) and dissolved in toluene (450 ml.). The toluene solution was refluxed for 7 hr. in the presence of a small amount of *p*-toluenesulfonic acid, and the water formed was removed continuously by means of a water-separator. Deposition of yellow crystals was observed during the course of dehydration. The mixture was cooled, and the crystals deposited were filtered. The crude crystals were recrystallized from chlorobenzene to give IV, on greenish yellow plates, m. p. 295~305°C,

* All melting points were measured on a Kofler block and were not corrected.

6.7 g. (35.6%). This material was recrystallized twice from the same solvent to yield pure IV, m. p. 334~336°C.

Found: C, 93.38; H, 5.99. Calcd. for $C_{30}H_{24}$: C, 93.71; H, 6.29%.

b) By the Wittig Reaction.—IV was also obtained as a by-product of the syntheses of *trans, cis, trans-*, *trans, trans, cis-*, *cis, trans, cis-p, p'*-distyrylstilbenes according to the Wittig reaction. The experimental details will be described in section b) on the syntheses of VIII and XVIII and the synthesis of XXVIII.

***trans, trans-p, p'*-Distyryltolan (t-A-t) (VII.)**—*p, p'-Dibromotolan (V).*—Finely powdered tetrabromide (I, 40 g., 0.08 mol.) was added to a solution of sodium ethoxide in absolute ethanol (sodium, 38 g., 1.65 mol. in absolute ethanol, 600 ml.), and the mixture was refluxed for 1 hr. The reaction mixture was poured into water (1.5 l.) and the precipitate formed filtered. The dried precipitate was recrystallized from chloroform to yield dibromotolan (V), on lustrous plates, m. p. 182~183°C, 25.6 g. (95.2%) (lit., m. p. 182~184°C, 74%[8]). Further recrystallization gave the analytically pure sample, m. p. 184.5~185°C.

Found: Br, 47.84. Calcd. for $C_{14}H_8Br_2$: Br, 47.57%.

p, p'-Bis(α-hydroxy-β-phenylethyl)tolan (VI).—The glycol (VI) was obtained through the metalation of the dibromotolan (V, 13.5 g., 0.04 mol.) and the subsequent reaction with phenylacetaldehyde (11.5 g., 0.096 mol.) as for the synthesis of t-t-t (IV). The crude glycol (20.7 g.) was twice recrystallized from benzene-light petroleum (1 : 3) to give pure VI, in the form of colorless fine crystals, m. p. 155.5~157.5°C, 4.6 g. (27.2%).

Found: C, 85.90; H, 6.32. Calcd. for $C_{30}H_{26}O_2$: C, 86.09; H, 6.26%.

$IR_{max}(cm^{-1})$ 3350 (νOH), 1052 (δOH).

t-A-t (VII).—A solution of the acetylenic glycol (VI, 2.5 g.) and *p*-toluenesulfonic acid (1.0 g.) in dry toluene (150 ml.) was refluxed for 2 hr., with a continuous removal of water. The crystals separated on cooling were filtered and recrystallized twice from chlorobenzene, yielding VII, in the form of pale greenish yellow leaflets, m. p. 305~308°C, 1.6 g. (70%).

Found: C, 94.19; H, 5.72. Calcd. for $C_{30}H_{22}$: C, 94.20; H, 5.80%.

***trans, cis, trans-p, p'*-Distyrylstilbene (t-c-t) (VIII).**—*a) From t-A-t (VII) by Partial Reduction.*—t-A-t (VII) in a large amount of tetrahydrofuran was hydrogenated over Lindlar's catalyst (about the same amount as VII) by shaking a dark brown flask in a dark place. The progress of hydrogenation was followed by measuring the change of the ultraviolet spectrum at 30 min. intervals instead of by observing the change of the absorption curve of hydrogen. It required about 2.5 hr. to complete the half-reduction. The reduction products from several runs were combined (ca. 300 mg.) and digested with hot benzene. The hot solution was filtered to remove the insoluble material (a mixture of t-A-t and t-t-t). Pale yellow crystals, m. p. 210~220°C, were obtained on cooling the filtrate. The crystals were dissolved in benzene and chromatographed on alumina in a dark place. The column was eluted first with benzene, then with benzene-alcohol and finally with alcohol. Fractions 1 and 2, eluted with benzene gave crystals of m. p. 225~227°C, whereas fractions 3—6, eluted with benzene, gave crystals of m. p. 261~262°C. Fraction 8, eluted with benzene-alcohol, furnished crystals of m. p. ca. 300°C. (sublime). The crystals obtained from the fractions 1 and 2 were recrystallized from benzene, resulting in t-c-t (VIII), in the form of pale yellow plates with a pale green fluorescence, m. p. 227~228°C.

Found: C, 93.50; H, 6.30. Calcd. for $C_{30}H_{24}$: C, 93.71; H, 6.29%.

Resolidification was observed when VIII was kept in a molten state for several minutes. The resolidified material began to sublime near 300°C and melted ca. 320°C, indicating the thermal isomerization to all-trans isomer (m. p. 334~336°C). Also an identical ultraviolet absorption curve with that of t-t-t isomer was obtained after the insolation of a solution of VIII in *n*-hexane.

The crystals obtained from fractions 3—6 were recrystallized from chlorobenzene, yielding IX, in the form of pale yellow needles, m. p. 262°C. An analysis could not be performed, however, because of the small amount.

b) From p-Stilbenealdehyde by the Wittig Reaction.—*p-Styrylbenzyltriphenylphosphonium Bromide (XI).*—A mixture of *p*-methylstilbene (15 g., 0.077 mol.), *N*-bromosuccinimide (15 g., 0.084 mol.)[13] and benzoyl peroxide (200 mg.) in carbon tetrachloride (150 ml.) was stirred for 8 hr. under reflux. The cooled reaction mixture was filtered to remove the succinimide. The imide was washed repeatedly with carbon tetrachloride. The combined filtrate and washing were concentrated under reduced pressure. The crystals thus obtained were washed with ethanol, resulting in colorless crystals, m. p. 119~121°C, 12.5 g. (57%). Finely powdered triphenylphosphine (20 g., 0.076 mol.) was added to a solution of the crude bromide (8 g., 0.029 mol.) in xylene (150 ml.), and the mixture was stirred for 4 hr. with gentle refluxing. The crystals deposited on cooling the reaction mixture were filtered and washed with ethanol, resulting in phosphonium bromide, XI, in the form of colorless fine needless, m. p. 286~288°C, 14.5 g. (92%).

trans, cis, trans-p, p'-Distyrylstilbene (t-c-t) (VIII) and trans, trans, trans-p, p'-Distyrylstilbene (t-t-t) (IV).—To a stirred suspension of *p*-stilbenealdehyde (XII, 2.0 g., 9.6 mmol.) and the phosphonium bromide (XI, 6.0 g., 11.2 mmol.) in absolute ethanol (120 ml.) was added a solution of lithium ethoxide in absolute ethanol (from 0.15 g. of lithium and 70 ml. of absolute ethanol). Fine yellow crystals were gradually deposited as the phosphonium salt disappeared. The crystals were filtered without suction and digested with hot benzene. The insoluble portion was recrystallized from chlorobenzene, yielding t-t-t isomer, IV, in the form of greenish yellow plates, m. p. 328~330°C, 0.08 g. A melting point depression was not observed on admixture with the authentic t-t-t isomer.

The benzene soluble portion was chromatographed

13) Y. Yukawa and U. Suzuki, *Mem. Inst. of Sci. Ind. Research, Osaka*, **10**, 190 (1952).

over alumina in a dark place, and the column was eluted with benzene. The column was exposed occasionally to ultraviolet light for a short time, and the shift of the absorption band was located by observing the fluorescence which is characteristic of the t-c-t isomer. Fractions 1 and 2, eluted with benzene, afforded VIII, in the form of light yellow plates, m. p. 227~228°C. The mixed melting point showed no depression on admixture with an authentic specimen obtained by the partial reduction of the t-A-t isomer VII. Also, the ultraviolet spectra of these two samples were found to be identical.

***trans, trans*-p-Phenylethynyl-*p'*-styrylstilbene (t-t-A) (XXI) and *trans, cis*-*p*-Phenylethynyl-*p'*-styrylstilbene (t-c-A) (XXII).**—To a mixture of *p*-tolanaldehyde (XX, 1.0 g., 4.9 mmol.) and finely powdered phosphonium salt (XI, 3.0 g., 5.6 mmol.) was added an excess of lithium ethoxide in absolute ethanol. After 30 min., the mixture was heated to 50~60°C for 2 hr. The solid deposited on cooling the reaction mixture was filtered and washed with ethanol. This was crystallized from chlorobenzene, yielding t-t-A (XXI), in the form of light greenish yellow plates, m. p. 308~309°C, 0.76 g. (40.6%).

Found: C, 94.25; H, 5.95. Calcd. for $C_{30}H_{22}$: C, 94.20; H, 5.80%.

The filtrate was concentrated to dryness under reduced pressure. The residual solid was dissolved in benzene and chromatographed over alumina in a dark place. The first fraction, eluted with benzene, gave t-c-A (XXII), in the form of light yellow plates, m. p. 198~199°C, 0.56 g. (29.9%). An analytical sample, melted at the same temperature, was obtained on recrystallization from benzene.

Found: C, 94.38; H, 5.91. Calcd. for $C_{30}H_{20}$: C, 94.20; H, 5.80%.

This substance isomerized to the t-t-A isomer XXI at its melting point. Also, the photoisomerization of XXII to XXI was confirmed by the observation of the ultraviolet spectrum of XXII on an insolation of the solution.

***trans, trans, cis-p, p'*-Distyrylstilbene (t-t-c) (XVIII).**—*a) From t-t-A (XXI) by Partial Reduction.*—The solubility of XXI in tetrahydrofuran was found to be 1 mg./9 ml. The hydrogenation was carried out in the same manner as described in the case of t-A-t isomer VII. The benzene solution of the reduction product was chromatographed over alumina and eluted with the same solvent. The crystals of m. p. ca. 227°C obtained from the eluate was recrystallized from benzene, resulting in XVIII, in the form of light yellow prisms, m. p. 226~229°C. The mixed melting point determination proved the identity of this substance with the specimen obtained by method b).

b) From p-Styryl-[p'-formylstyryl]benzene (XVI) by the Wittig Reaction.—p-Styryl-[p'-methylstyryl]-benzene (XIV).—An excess of lithium ethoxide in ethanol (0.2 g. of lithium and 130 ml. of absolute ethanol) was stirred into a mixture of *p*-tolualdehyde[11] (XIII, 2.8 g., 0.022 mol.), powdered phosphonium salt (XI, 11 g., 0.021 mol.) and absolute ethanol (130 ml.), and the mixture was refluxed gently for 5 hr. The crystals deposited from the cooled reaction mixture were filtered, yielding crude XIV. The second crop of XIV was obtained from the filtrate on exposure to sunlight to convert the cis-isomer to the trans compound. The combined crude XIV was washed with ethanol and recrystallized from chlorobenzene, yielding light yellow plates with a green fluorescence, m. p. 264~265°C, 1.8 g. (29.6%).

p-Styryl-[p'-formylstyryl]benzene (XVI).—A mixture of XIV (2 g., 6.7 mmol.) and *N*-bromosuccinimide (1.4 g., 7.8 mmol.) in chloroform (200 ml.) was refluxed for 8 hr. in the presence of benzoyl peroxide (200 mg.). After cooling the reaction mixture (a deposition of crystalline mass was observed), hexamethylenetetramine (3.5 g., 0.025 mol.) in chloroform (35 ml.) was added and the mixture was refluxed for 4 hr. The amine complex deposited on cooling the reaction mixture was filtered and mixed with aqueous acetic acid (160 ml.). The mixture was refluxed for 2 hr. to hydrolyze the complex. The crystals deposited from the cooled reaction mixture were washed with a small amount of ethanol and recrystallized from chlorobenzene, resulting in XVI, in the form of yellow thin plates, m. p. 250~253°C.

Found: C, 88.63; H, 5.84. Calcd. for $C_{23}H_{18}O$: C, 88.99; H, 5.84%.

UV_{max} ($m\mu$) 242 (ε=20000), 273 (61400) (in dioxane).

IR_{max} (cm^{-1}) 1702, 1166 (-CHO).

t-t-c (XVIII) and t-t-t (IV).—A solution of the above-mentioned aldehyde (XVI, 370 mg.) in dry tetrahydrofuran (250 ml.) was mixed with benzyltriphenylphosphonium chloride (XVII, 650 mg.) in ethanol (40 ml.). A small excess of lithium ethoxide in ethanol (15 ml.) was stirred drop by drop into the mixture at room temperature. Then, the mixture was heated at 40~50°C for 8 hr. while continually being stirred. The crystals deposited from the cooled reaction mixture were filtered and identified as all-trans isomer IV by means of a mixed melting point determination. The residue obtained on concentrating the filtrate under reduced pressure was dissolved in benzene and chromatographed over alumina. The fractions 3—5, eluted with benzene, gave crystals of m. p. 224~226°C*. The fractions 3—7, eluted with benzene, resulted in crystals of m. p. 224~228°C*. This was recrystallized carefully from benzene to give XVIII, in the form of light yellow prisms, m. p. 227~230°C*.

Found: C, 93.57; H, 6.46. Calcd. for $C_{30}H_{24}$: C, 93.71; H, 6.29%.

***trans*- and *cis*-Bis(*p*-phenylethynyl)stilbenes (A-t-A, XXV and A-c-A, XXVI).**—*p-Phenylethynylbenzyl-triphenylphosphonium Bromide (XXIV).*—A mixture of *p*-methyltolan[14] (7 g., 0.031 mol.), *N*-bromosuccinimide (7 g., 0.039 mol.) and benzoyl peroxide (200 mg.) in carbon tetrachloride (80 ml.) was stirred under reflux for 6~7 hr. The succinimide deposited on cooling was removed. The oily material admixed with crystals was obtained by

* The t-t-c isomer was found to be thermally unstable. The melting point was determined by a rapid elevation of the temperature of the heating bath to avoid a rearrangement to all-trans isomer; otherwise the t-t-c isomer showed the melting point of the t-t-t isomer.

14) G. Drefahl and G. Plötner, *Chem. Ber.*, **93**, 990 (1960).

concentration of the filtrate and dissolved in benzene. The solution was passed through a short column of alumina and the solvent removed in vacuo. To a toluene solution of the residue was added triphenylphosphine (8 g., 0.031 mol.). The mixture was refluxed for 7 hr. under stirring. The solid deposited from the cooled reaction mixture was washed three times with ethanol, yielding XXIV, a colorless amorphous solid, m. p. 286~288°C, 7.0 g. (36%).

A-t-A (XXV) and A-c-A (XXVI).—A small excess of lithium ethoxide in absolute ethanol (80 ml.) was added dropwise to a suspension of the phosphonium salt (XXIV, 3.0 g., 5.6 mmol.) and tolanaldehyde[1,12] (XX, 1.0 g., 4.8 mmol.) in absolute ethanol (150 ml.) at room temperature, and the mixture was stirred for 20 hr. The crude crystals deposited from the reaction mixture were digested with hot benzene and filtered (Filtrate A). The insoluble crystalline mass was recrystallized twice from chlorobenzene, yielding XXV, in the form of light yellow needles with a green fluorescence, m. p. 278~279°C, 0.30 g. (16.5%).

Found: C, 94.25; H, 5.32. Calcd. for $C_{30}H_{20}$: C, 94.70; H, 5.30%.

The filtrate A was chromatographed oved alumina. The fractions 1 and 2, eluted with benzene, gave crystals of m. p. 149~151°C. This was recrystallized from ethanol-benzene (9 : 1) to give XXVI, in the form of colorless plates, m. p. 151~152°C, 0.34 g. (18.7%).

Found: C, 94.61; H, 5.31. Calcd. for $C_{30}H_{20}$: C, 94.70; H, 5.30%.

The ultraviolet spectrum of XXVI changed to that of XXV on the insolation of the solution.

The total yield of the Wittig reaction was found to be 0.46 g. (35%).

***cis, trans, cis-*, *trans, trans, trans-* and *trans, trans, cis-p, p'*-Distyrylstilbenes (XXVIII, IV and XVIII).** — *p, p'-Stilbenedialdehyde (XXVII).* — The dialdehyde (XXVII) was prepared according to the usual method. The crude dibromide obtained by the reaction of *p,p'*-dimethylstilbene with *N*-bromosuccinimide was converted without purification to XXIX by the Sommelet reaction. The product was recrystallized from acetic acid to give pure XXVII, in the form of long yellow needles, m. p. 170~171°C, 3.5 g. (19.3%) (lit. value[14], 169~170°C, 8% yield).

Found: C, 80.95; H, 5.16. Calcd. for $C_{16}H_{12}O_2$: C, 81.34; H, 5.12%.

c-t-c (XXVIII), t-t-t (IV) and t-t-c (XVIII).—To the stirred suspension of benzyltriphenylphosphonium chloride (XVII, 3.6 g., 9.3 mmol.) in absolute alcohol (30 ml.) was added excess of lithium ethoxide (from 0.2 g. of lithium) in absolute alcohol (40 ml.). After stirring for 1 hr., tetrahydrofuran (30 ml.) was added and stirred for 30 min. To the stirred mixture was added dropwise stilbenedialdehyde (XXVII, 1.0 g., 4.2 mmol.) in tetrahydrofuran (80 ml.) and absolute alcohol (10 ml.). The mixture was stirred for 2 hr. at room temperature and 8 hr. at 40~50°C. After cooling, the crystals deposited were filtered, and the filtrate was diluted with water (ca. 1 l.), precipitating the crystals. The combined crystals were dried, extracted with hot benzene and filtered. The cooled filtrate was filtered to remove the crystals A deposited and chromatographed over alumina in a dark place. Fractions 2 and 3, eluted with benzene, afforded XXVIII, m. p. 109~111°C, which was recrystallized from alcohol to give greenish yellow plates with a green fluorescence, m. p. 111~112°C, 0.18 g. (11%).

Found: C, 93.71; H, 6.27. Calcd. for $C_{30}H_{24}$: C, 93.71; H, 6.29%.

This substance, thermally more stable than t-c-t and t-t-c, isomerized to t-t-t isomer at 170°C and photoisomerized to t-t-t on the insolation of the solution.

Fractions 4—6, m. p. 224~228°C, were recrystallized from benzene, yielding light yellow prisms with a green fluorescence 2.0 g. (12%), and were found to be identical with t-t-c (XVIII) by the determination of the ultraviolet spectrum and the mixed melting point.

The insoluble crystals, m. p. 310~320°C, 0.15 g. (9%), in hot benzene, showed an identical ultraviolet spectrum with t-t-t (IV) and the crystals A were found to be a mixture of t-t-c and the recovered aldehyde (XXVII).

The cost of this research was partly defrayed by the Scientific Research Expenditure Fund of the Ministry of Education, to which authors' thanks are due.

Alternant Conjugate Systems. IV. Ultraviolet Spectroscopic Properties and Photoisomerization of Geometrical Isomers of p-Distyrylbenzenes, p, p'-Distyrylstilbenes and Related Compounds

By Sōichi MISUMI, Motoyuki KUWANA and Masazumi NAKAGAWA

(Received March 23, 1961)

Zechmeister and his co-workers have observed the appearance of a new absorption maximum in the near ultraviolet region when various kinds of all trans isoprenic conjugated polyolefins were irradiated[1]. They have attributed the new absorption band to the presence of unhindered cis ethylenic linkage formed by a photochemical stereomutation of trans linkage. The so-called " cis-peak rule " was proposed by them to correlate the wavelength and the intensity of the new absorption maximum with the geometry of the cis-isomer. It has been proved that this rule is valid for a wide variety of carotenoids, such as central cis-β-carotene, central cis-bixin methyl ester, monocis- and dicis-homo-β-carotenes (I)[2] and the straight conjugated system, i. e., diphenylpolyenes[1].

Homo-β-carotene (I)

Recently Dale has shown that the wavelength of minor bands, (λ_s), including the so-called cis-peak in the spectrum of a polyene with n conjugated double bonds, lies very close to the wavelength of the main band of a corresponding polyene with n/s conjugated double bonds (where n/s does not need to be an integral)[3]. He has also shown that this simple relationship holds also in the conjugated system containing benzene nuclei such as diphenylbutadiene, stilbene, etc. From these results, he has concluded that the appearance of minor bands in a conjugated polyene can not be attributed to the operation of independent partial chromophores, but is ascribable to the higher order transition of the total chromophore system. According to this argument, Zechmeister's cis-peak can be regarded as the first overtone band of the full chromophore system.

On the other hand, it has been found that isoprenic diphenylpolyenes containing sterically hindered cis ethylenic linkage exhibit no distinct cis-peak[4]. Oroshnik and his coworkers[5] have attributed the absorption band at a shorter wavelength in the spectra of hindered retrovitamin A methyl ether and related compounds to an overlap of the cis-peak with an absorption arising from the partial chromophore systems. He has pointed out that the contribution of the cis-peak and the partial chromophore can not be distinguished in these cases and that Zechmeister's cis-peak rule seems to be inapplicable in its original form to a conjugated system with sterically hindered cis olefinic linkage.

As reported in the preceding papers of this series[6], the present authors have synthesized several geometrical isomers of stilbene homologues and the acetylenic analogues, including sterically hindered cis-isomers (Fig. 1). The

present paper deals with the ultraviolet spectroscopic properties and the photoisomerization of these geometrical isomers.

Spectroscopic Properties. — In the series of *p*-distyrylbenzene, the t-t isomer* showed a main maximum at the longest wavelength as compared with other geometrical isomers and the acetylenic analogues, as illustrated in Figs. 1 and 2 in Part II of this series. (The numerical data are summarized in Table I of Part II.) Substitution of the trans-linkage with cis- or acetylenic bonds caused a shift of the absorption maximum to shorter wavelength and a decrease of the absorption intensity. The decrease of absorption intensity was found to be much larger in the case of the insertion of cis-linkage than that of acetylenic bond, in spite of the same degree of hypsochromic shift in both cases. This fact is quite understandable from the fact that the coplanarity of the cis-molecule is broken as the result of the steric hindrance of hydrogen atoms in the *o*- and *o'*-positions of the benzene rings adjacent to the cis-linkage (Fig. 1). On the contrary, the absorption intensity of the band near 230 mμ is larger in the case of the cis-isomer than in that of the trans-isomer. The sequence of intensity of this absorption peak was found to be c-c>t-c>t-t and A-c>A-t. The ultraviolet spectra of the three compounds containing no cis-linkage, i. e., t-t, t-A and A-A, each exhibit a distinct absorption minimum in the region of 250~290 mμ. But an absorption maximum at about 270 mμ was observed in the spectra of the corresponding cis-isomers, i. e., t-c, c-c and A-c. An examination of the spectra of reference substances which can be regarded as the possible partial chromophores of the above-mentioned *p*-distyrylbenzenes and *p*-styryltolan indicates that the absorption maximum at ca. 270 mμ can not be attributed to a contribution of any partial chromophores (Table I). For instance, styrene, stilbene and vinylstilbene may be the possible partial chromophores for the t-c isomer, but it seems to be quite difficult to find out the contribution of the ultraviolet absorption of these compounds from the spectrum of the t-c isomer. Tolan, styrene and vinyltolan may be the possible partial chromophores of A-c isomer. Also, the shape of the absorption curve of the A-c isomer indicates that the participation of the partial chromophores is negligible.

The same situation was found in the spectra of the higher homologues; the isomeric *p,p'*-distyrylstilbenes and the related compounds (t-c-t, t-c-A and A-c-A) exhibit broad and most intense absorption maxima at the wavelength region of 280~320 mμ (cf. Fig. 2 in Part III of this series). An examination of the spectra of the reference substances corresponding to the partial chromophores also

* a=tetrahydrofuran, b=*n*-hexane, c=chloroform

reveals that the operation of partial chromophores is not reflected in the spectra of the distyrylstilbenes and their analogues. The absorption maximum at 312 mμ and the inflection at ca. 300 mμ in the spectrum of the t-c-t isomer seem to be attributable to the participation of the absorption of stilbene, an possible partial chromophore, which has a strong maxima at 297 and 310 mμ, while the presence of an absorption minimum at 326 mμ in the spectrum of t-c-t isomer excludes the possible operation of another partial chromophore, vinylstilbene, which has a strong maximum at the same wavelength (323 mμ). Also, the attribution of the λ_{max} at 293 mμ and the $\lambda_{infl.}$ at ca. 283 mμ in the spectrum of the A-c-A isomer to the contribution of a partial chromophore, tolan (λ_{max} 281 and 298 mμ), is inconsistent with the fact that the spectrum of this isomer shows a distinct λ_{min} at 307 mμ, while the spectrum of vinyltolan, another possible partial chromophore, exhibits a strong λ_{max} at about the same wavelength (301 mμ). Similarly, the absorption of the t-c-A isomer (λ_{max} 298 mμ, $\lambda_{infl.}$ ca. 290 mμ) could not be explained by the participation of either pair of the partial chromophores, stilbene-vinyltolan or tolan-vinylstilbene. Furthermore, the close resemblance of the shape of the absorption curve of the unsymmetrical t-c-A isomer to those of the symmetrical isomers (t-c-t and A-c-A) in this wavelength region seems to indicate the negligible participation of the partial chromophores. It may be reasonable to conclude from these observed results that the absorption maxima at ca. 270 mμ and at 280~320 mμ in the spectra of the three benzene and the four benzene systems do not arise from the participation of partial chromophores, but arise from the second order electronic transitions of the total chromophore.

The absorption curves of the t-c and A-c each form a distinct peak at 270 mμ, while the spectrum of the c-c isomer forms a plateau at the same wavelength (Fig. 1 in Part II). Also, the t-c-t, t-c-A and A-c-A isomers each showed a very strong absorption at 280~320 mμ (Fig. 2 in Part III). On the other hand, the t-t-c and c-t-c isomers did not exhibit a marked absorption peak at this region (Fig. 4 in Part III). These facts indicate that the probability of the second order transition is strongly affected by the geometry of the molecule. As illustrated in Fig. 2, the A-c and t-c isomers may have a dipolemoment perpendicular to the long axis of the conjugated system, whereas the most probable configuration of c-c isomer (a) has no dipolemoment perpendicular to the long axis, and the contribution of a configuration such as (b) which has the

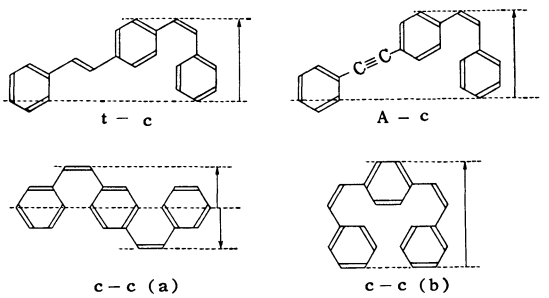

Fig. 2

above-mentioned dipolemoment seems to be highly improbable owing to its great steric hindrance. Similarly, the t-c-t, t-c-A and A-c-A isomers which may have large dipolemoment perpendicular to the long axis exhibit a distinct second order absorption maximum, and the t-t-c and c-t-c isomers having minor dipolemoment show only a weak shoulder at the corresponding wavelength position. The same trend has been pointed out by Zechmeister[1] in carotenoid series containing unhindered cis-linkage or cis-linkages.

If the appearance of the second absorption maximum in the spectra of cis-compounds could be attributed to the second order transition of the total chromophore, the all-trans isomer and the acetylene-trans compounds would also have an absorption in the same wavelength, even if it is extremely weak in its intensity. In fact, the spectra of t-t, t-A and A-A compounds exhibit a weak inflection at ca. 270 mμ (Figs. 1 and 2 in Part II). In the same way, a weak inflection at 290~310 mμ was observed in the spectra of t-t-t, t-A-t, t-t-A, A-t-A and A-A-A compounds (Figs. 3 and 4 in Part III). The existence of these inflections at the wavelength corresponding to the second absorption maximum of the cis-compound clearly indicates that the second order transition contributes to the spectra of the alternant conjugate systems lacking cis-linkage.

All compounds belonging to the four benzene system showed an absorption maximum at the wavelength of 260~280 mμ. This maximum was observed as a weak inflection in the cis-series. On the other hand, a fairly distinct peak was observed in the spectra of the trans- and acetylene-series. This absorption and the absorption at a shorter wavelength (235~245 mμ) can also be satisfactorily explained in terms of a third and of still higher order transitions of the total chromophore. It is to be noted that the probability of the xth order transition is larger in trans and/or acetylenic series than the corresponding cis-compounds when x is an even number. Conversely, when

x is an odd number, cis-compounds have larger xth order absorption maxima than the corresponding trans and/or acetylenic compounds (Figs. 3 and 4 in Part III).

As illustrated in Fig. 3, a smooth curve was obtained by plotting the position of the absorption maxima of the longest wavelength (λ_{max}) against the number of chromophore units (n), where an ethylenic bond is taken as an unit, and each benzene ring and acetylenic bond is set equal to the 1.6 and 0.6 ethylenic bond respectively, and the effect of the blue shift caused by the presence of cis- and acetylenic bonds is corrected by introducing cis- ($f_C=0.33$) and acetylenic ($f_A=0.66$) factors. The calculated chromophore units of this series of compounds are summarized in Table III. The relationship between λ_{max} and n is well represented by the following empirical Eq. 1.

$$\lambda=60\sqrt{n-2.15}+220 \qquad (1)$$

A fairly good agreement of the calculated values with the observed values was obtained for almost all compounds of this series, as shown in Table III. The minor deviation of the calculated values in the four benzene series seems to be attributable to a solvent effect, since the spectra were measured using tetrahydrofuran or benzene as the solvent. *n*-Hexane and ethanol could not be used owing to the poor solubility of the compounds to these solvents. A red shift of about 2~5 mμ was generally observed in the case of a solution in tetrahydrofuran or benzene as compared with those in aliphatic hydrocarbons. A slightly larger deviation between the predicted and observed values was observed in the cases of polytolans.

Photoisomerization. — In order to determine the relative rates of photoisomerization and to know the isomer ratios in the equilibrated mixtures, dilute solutions of each pair of the above-mentioned alternant conjugate systems

were exposed to the light of a fluorescent tube under controlled conditions and the course of photoisomerization was followed, measuring the change of the spectra. It was observed that some kind of photocyclization presumably accompanied with photodegradation occurs on a prolonged irradiation. As a result of these side-reactions, it was found to be impossible to determine the composition of the equilibrium mixture.

The changes of ultraviolet spectra on irradiation of the three geometrical isomers of *p*-distyrylbenzene (t-t, t-c and c-c) are illustrated in Figs. 4, 5 and 6, and those of absorption intensities at 350 and 270 mμ of each isomer are shown in Fig. 7. The bands at the longest wavelength in the t-c and c-c isomer shifted to the red side, increasing their intensities in accord with the period of irradiation. It was observed that the t-c isomer is converted to an approximate equilibrium with the t-t isomer after 1 hr. of irradiation. On the other hand, in the case of the c-c isomer, an approximate equilibrium with the t-t isomer was attained only after 13 hr. irradiation. It is to be noted that the rate of photoisomerization is much slower in the case of the more hindered c-c isomer than the case of the less hindered t-c isomer.

Further change of the spectra were observed on prolonged irradiation. A slow decrease of the intensity at 350 mμ was accompanied with a gradual increase of the intensity at 232 mμ, and the latter maximum was buried in the

strong absorption which appeared in the shorter wavelength region. The appearance of new inflections at 250 and 297 mμ was observed after exposure for ca. 54 hr. These inflections grew to the intense absorption maxima after exposure for 100 hr.

Also, the A-c and A-t isomers showed a distinct fine structure in their spectra after irradiation for a long time, suggesting the formation of phenanthrene nucleus by photochemical cyclization[12] (Figs. 8 and 9).

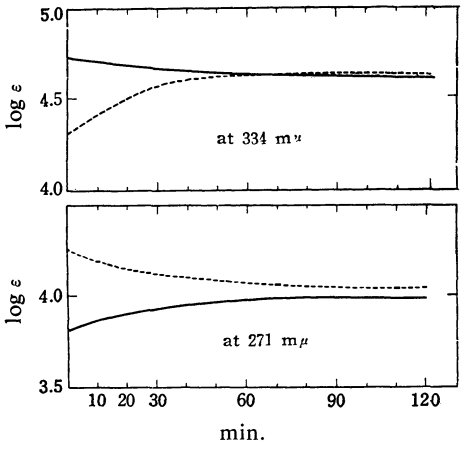

Fig. 8. The change of the extinction values of the ultraviolet spectra of stereoisomeric *p*-styryltolans in *n*-hexane by exposure to light at 10 cm. (A-t, ——; A-c, ------).

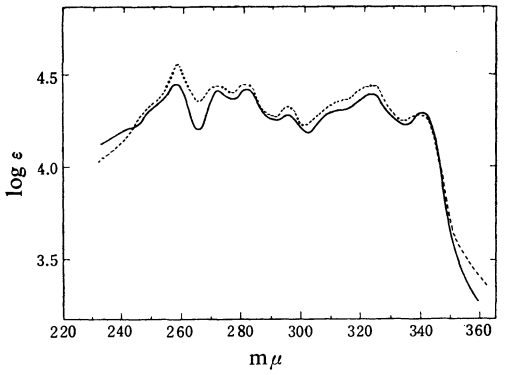

Fig. 9. The ultraviolet spectra of stereoisomeric *p*-styryltolans after irradiation for 213 hr. at 10 cm. (A-t, ——; A-c, ------).

The change of absorption intensities at three points of wavelength according to the progress of photoisomerization of the four geometrical isomers of *p,p'*-distyrylstilbene is illustrated in Fig. 10. The sequence of the rate of photochemical stereomutation was found to be

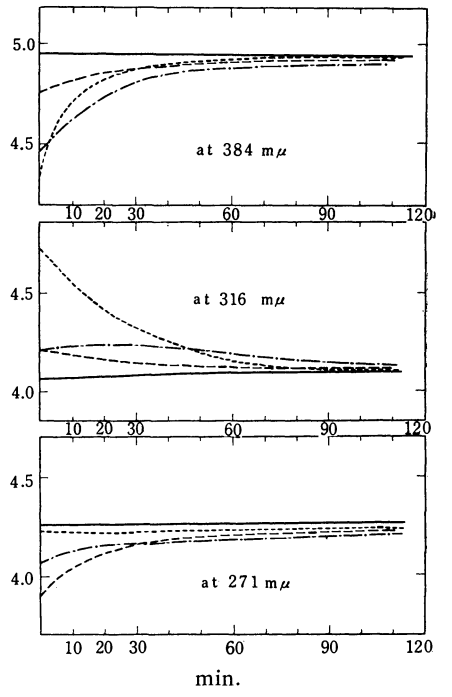

Fig. 10. The change of the extinction values of the ultraviolet spectra of four isomeric *p,p'*-distyrylstilbenes in tetrahydrofuran by exposure to light at 20 cm. (t-t-t, ——; t-c-t, ----; t-t-c, ------; c-t-c, —·—·).

t-c-t>t-t-c>c-t-c. The fact that the most hindered c-t-c isomer is most stable is consistent with the case of the c-c isomer. Also, it is an interesting fact that the isomer having a more intense cis-peak (in another word, absorption due to the second order transition of total chromophore) shows a larger rate of photoisomerization.

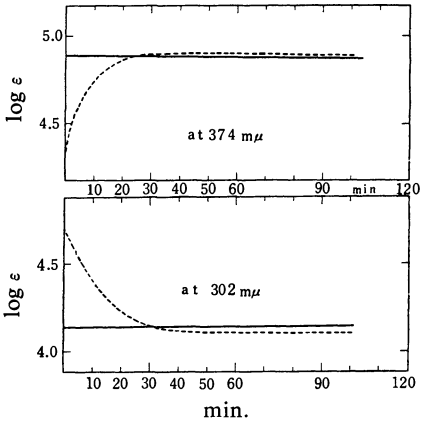

Fig. 11. The change of the extinction values of the ultraviolet spectra of isomeric *p*-styryl-*p'*-phenylethynyl-stilbenes in tetrahydrofuran by exposure to light at 10 cm. (t-t-A, ——; t-c-A, ------).

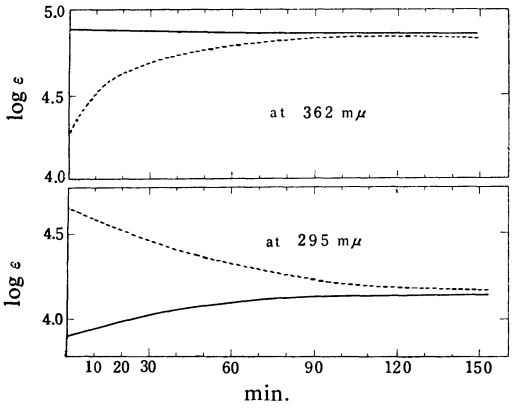

Fig. 12. The change of the extinction values of the ultraviolet spectra of isomeric *p*-bis-(phenylethynyl)stilbenes in tetrahydrofuran by exposure to light at 20 cm. (A-t-A, ——; A-c-A, ------).

The changes of the spectra by irradiation of other pairs of isomers of the four benzene series, t-t-A : t-c-A and A-c-A : A-t-A, are presented in Figs. 11 and 12. After prolonged irradiation, the spectra of these compounds showed distinct fine structures, indicating the formation of a condensed aromatic system.

The present authors are continuing the photochemical cyclization of these series of compounds.

Experimental

General Method of Photoisomerization. — The spectrum was measured in a sealed fused silica cell of 1.0 cm. thickness using a dilute solution (ca. 1 mg. of substance in 1000 ml. of solvent). Spectral grade *n*-hexane was used in the case of the compounds of the three benzene series. The compound of the four benzene series were dissolved in purified tetrahydrofuran. Two cells containing the solutions of the pair of isomers were irradiated with a fluorescent tube (10 W. daylight type). The change of spectrum and the change of intensities at particular wavelength were measured at an appropriate interval.

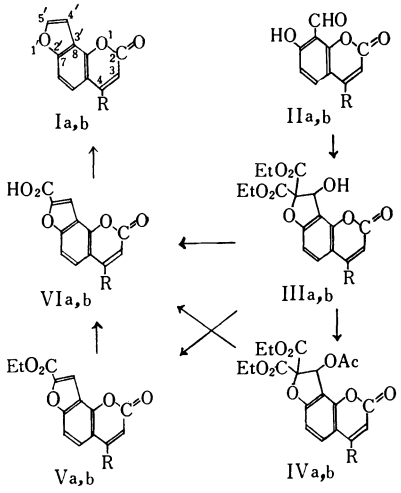
Synthetic Studies on the Benzofuran Derivatives. VII. A New Synthesis of Angelicin and 4-Methylangelicin

By Yoshiyuki KAWASE, Mitsuru NAKAYAMA* and Hiroko TAMATSUKURI



(Received June 1, 1961)

Angelicin, a furocoumarin isolated from *Angelica archangelica*[1-4] and *Psoralea corylifolia*[5], is an interesting compound because of its fluorescence and biological activity. Its chemical structure was established by Späth and Pesta[4] to be represented by the formula Ia. For the synthesis of Ia, several methods were reported by Späth and Pailer[6], Limaye[7], Naik and Thakor[8] and Seshadri et al.[9], and recently the synthesis of 4-methylangelicin (Ib) also has been reported by Antonello[10].

The present paper describes a new synthesis of Ia and Ib accomplished with more ease and furnishing higher yields following Tanaka's method[11] for benzofuran synthesis, as shown in the chart.

For I—VI; a) R=H, b) R=Me

The starting material is 8-formyl-7-hydroxycoumarin[6] (IIa) and 8-formyl-7-hydroxy-4-methylcoumarin[7] (IIb) as in the syntheses of Späth and Pailer, Naik and Thakor and Antonello. As the aldehydes were obtained only in poor yields by the formylation of coumarins following the hexamine method[6,12] attempts were made to improve the formylation by the glyceroboric acid-hexamine method[13] and by the dimethylformamide method[14], but they resulted only in failure.

The aldehyde, IIa or IIb, was made to react with ethyl bromomalonate and potassium carbonate in ethyl methyl ketone. Procedures of very little difference, namely, refluxing either with or without stirring, gave two different products: a higher melting ester (Va, m. p. 212~213°C or Vb, m. p. 194~195°C) with stirring and a lower melting ester (IIIa, m. p. 178~180°C or IIIb, m. p. 175~176°C) without stirring. Analysis and infrared spectroscopy proved that the latter is a hydroxy-diester IIIa or IIIb because it showed a sharp OH band (IIIa, 3226 cm^{-1}; IIIb, 3185 cm^{-1}) and ester CO bands (IIIa, 1767, 1727 cm^{-1}; IIIb, 1773, 1730 cm^{-1}), and that the former is an ester Va or Vb without a hydroxy-group because it showed the ester CO band (Va, 1718 cm^{-1}; Vb, 1724 cm^{-1}) and no OH band. As hydroxy-ester IIIa (or IIIb) was converted into ester Va (or Vb) by further action of potassium carbonate in ethyl methyl ketone under reflux with stirring, IIIa (or IIIb) seems to be the intermediate compound to Va (or Vb); the compound of this type has been reported in some cases[15]. Ester IIIa (or IIIb) was converted into Va (or Vb) also by the action of phosphoric acid, but was not affected by 10% hydrochloric acid and by *p*-toluenesulfonyl chloride, and was converted only into its acetate IVa or IVb by acetic anhydride with or without sodium acetate.

Alkaline hydrolysis of the esters IIIa, IVa, and Va or IIIb, IVb, and Vb furnished the same corresponding acid VIa or VIb, which was decarboxylated in quinoline into compound Ia, m. p. 137~138°C, or Ib, m. p. 190~192°C, in a good yield.

Experimental[16]

5', 5'-Diethoxycarbonyl-4'-hydroxy-4', 5'-dihydroangelicin (IIIa). — To a solution of 8-formyl-7-hydroxycoumarin[6] (IIa, m. p. 184~185°C, 0.5 g.) and ethyl bromomalonate (1 g.) in anhydrous ethyl methyl ketone (60 ml.) was added anhydrous potassium carbonate (1.5 g.); the mixture was refluxed for 8 hr. in a steam bath. The resulting mixture was freed from precipitates, and the solvent was distilled off. The residual product was recrystallized from ethanol to give IIIa in the form of colorless microcrystals, m. p. 178~180°C, giving a negative ferric reaction; yield 0.5 g. (54.9%).

Found: C, 58.83; H, 4.67. Calcd. for $C_{17}H_{16}O_8$: C, 58.62; H, 4.63%.

Acetate IVa was prepared quantitatively by refluxing IIIa (0.1 g.) and acetic anhydride (10 ml.) with or without anhydrous sodium acetate (0.1 g.), m. p. 140~141°C (from ethanol).

Found: C, 58.62; H, 4.65. Calcd. for $C_{19}H_{18}O_9$: C, 58.46; H, 4.69%.

5', 5'-Diethoxycarbonyl-4'-hydroxy-4', 5'-dihydro-4-methylangelicin (IIIb).—By a method similar to that described for IIIa, IIIb was obtained from 8-formyl-7-hydroxy-4-methylcoumarin[7] (IIb, m. p. 176~177°C, 2 g.), ethyl bromomalonate (2.3 g.), anhydrous potassium carbonate (4.8 g.) and anhydrous ethyl methyl ketone (150 ml.); colorless microcrystals, m. p. 175~176°C (from ethanol), giving a negative ferric reaction; yield 2 g. (56.5%).

Found: C, 59.84; H, 5.14. Calcd. for $C_{18}H_{18}O_8$: C, 59.66; H, 5.01%.

Acetate IVb: M. p. 189~190°C (from ethanol).

Found: C, 59.57; H, 4.97. Calcd. for $C_{20}H_{20}O_9$: C, 59.40; H, 4.99%.

5'-Ethoxycarbonyl-angelicin (Va).—*From Aldehyde IIa.*—A mixture of IIa (0.3 g.), ethyl bromomalonate (0.6 g.), potassium carbonate (0.8 g.) and ethyl methyl ketone (60 ml.) was refluxed with stirring for 8 hr. in a steam bath. The resulting mixture was treated similarly to IIIa; colorless needles, m. p. 212~213°C (from ethanol); yield 0.2 g. (50%).

16) Melting points are uncorrected, and IR spectra were taken by the Nujol method.

Found: C, 65.06; H, 4.07. Calcd. for $C_{14}H_{10}O_5$: C, 65.12; H, 3.90%.

From Hydroxy-ester IIIa.—1) By the Action of Potassium Carbonate.—A solution of IIIa (0.1 g.) in ethyl methyl ketone (20 ml.) was refluxed for 8 hr. while anhydrous potassium carbonate (0.5 g.) was stirred in and then treated as before to give Va, m. p. 210~211°C. *2) By the Action of Phosphoric Acid.*—A mixture of IIIa (0.1 g.) and phosphoric acid (40 ml.) was heated for 30 min. in a steam bath. The cooled mixture was poured into water, and the solid product was recrystallized from ethanol to give Va, m. p. 210~212°C.

5'-Ethoxycarbonyl-4-methylangelicin (Vb).—*From Aldehyde IIb.*—By a method similar to that described for Va, Vb was obtained from IIb (1 g.), ethyl bromomalonate (1.2 g.), potassium carbonate (2.4 g.) and ethyl methyl ketone (70 ml.); colorless needles, m. p. 194~195°C (from ethanol); yield 0.65 g. (48.9%). Reported m. p. is 192°C[10].

Found: C, 65.86; H, 4.48. Calcd. for $C_{15}H_{12}O_5$: C, 66.15; H, 4.45%.

From Hydroxy-ester IIIb.—1) By the Action of Potassium Carbonate.—Vb was obtained similarly to Va; m. p. 193~194°C. *2) By the Action of Phosphoric Acid.*—Vb was obtained similarly to Va; m. p. 193~194°C.

5'-Carboxy-angelicin (VIa).—*a) From Ester Va.*—A mixture of Va (0.4 g.) and a 5% potassium hydroxide solution in 50% aqueous methanol (20 ml.) was refluxed for 30 min. in a steam bath. The resulting mixture was filtered and acidified with dilute hydrochloric acid, and the precipitates were collected and recrystallized from ethanol to give VIa in the form of colorless needles, m. p. 320~325°C (decomp.); yield 0.35 g. (98.3%). Reported m. p. is 315°C[8].

Found: C, 62.30; H, 2.73. Calcd. for $C_{12}H_6O_5$: C, 62.66; H, 2.63%.

b) From Hydroxy-ester IIIa.—By a treatment similar to a), VIa was obtained from IIIa (0.1 g.); m. p. 315~320°C (decomp.).

c) From Acetoxy-ester IVa.—By a similar treatment, VIa was obtained from IVa (0.1 g.); m. p. 320°C (decomp.).

5'-Carboxy-4-methylangelicin (VIb).—*From Ester Vb.*—By a method similar to that described for VIa, VIb was obtained from Vb (0.6 g.) and a 5% potassium hydroxide solution in 50% aqueous methanol (25 ml.); colorless needles, m. p. 295~299°C (decomp.) (from ethanol); yield 0.5 g. (92.6%).

Found: C, 63.85; H, 3.45. Calcd. for $C_{13}H_8O_5$: C, 63.94; H, 3.30%.

From Hydroxy-ester IIIb.—VIb was obtained similarly; m. p. 290~295°C (decomp.).

From Acetoxy-ester IVb.—VIb was obtained similarly; m. p. 290~295°C (decomp.).

Angelicin (Ia).—A mixture of acid Va (0.3 g.), copper powder (0.5 g.) and quinoline (40 ml.) was heated while being stirred in an atmosphere of nitrogen at 200~220° until evolution of carbon dioxide ceased. The quinoline was distilled off by steam-distillation from the resulting mixture, the copper was filtered off while hot, and the precipitates obtained on cooling were collected and recrystallized from dilute ethanol to give Ia in the form of colorless needles, m. p. 137~138°C; this was not depressed on admixture with a natural specimen; yield 0.1 g. (41.7%).

Found: C, 70.84; H, 3.33. Calcd. for $C_{11}H_6O_3$: C, 70.95; H, 3.25%.

4-Methylangelicin (Ib).—By a method similar to that described for Ia, Ib was obtained from Vb (0.5 g.), copper powder (0.8 g.) and quinoline (40 ml.); colorless needles, m. p. 190~192°C (from petroleum benzine or methanol); yield 0.2 g. (50%). Reported m. p. is 194°C[10].

Found: C, 71.88; H, 4.08. Calcd. for $C_{12}H_8O_3$: C, 71.99; H, 4.03%.

On the Structures of p-tert-Butylphenol Resin and α-Naphthol Resin. III. Infrared Absorption Spectra of Resins of p-tert-Butylphenol and α-Naphthol

By Reisuke SODA

(Received March 8, 1961)

Polymer synthesized from *p-tert*-butylphenol and formaldehyde with ammonia was used as a suitable material for coating the fiber of a dust respirator to raise its efficiency; it showed an anomalous behavior in benzene solution[1]. Infrared spectra of the polymer in solid and in various solutions have been observed and its structure discussed[1], but there

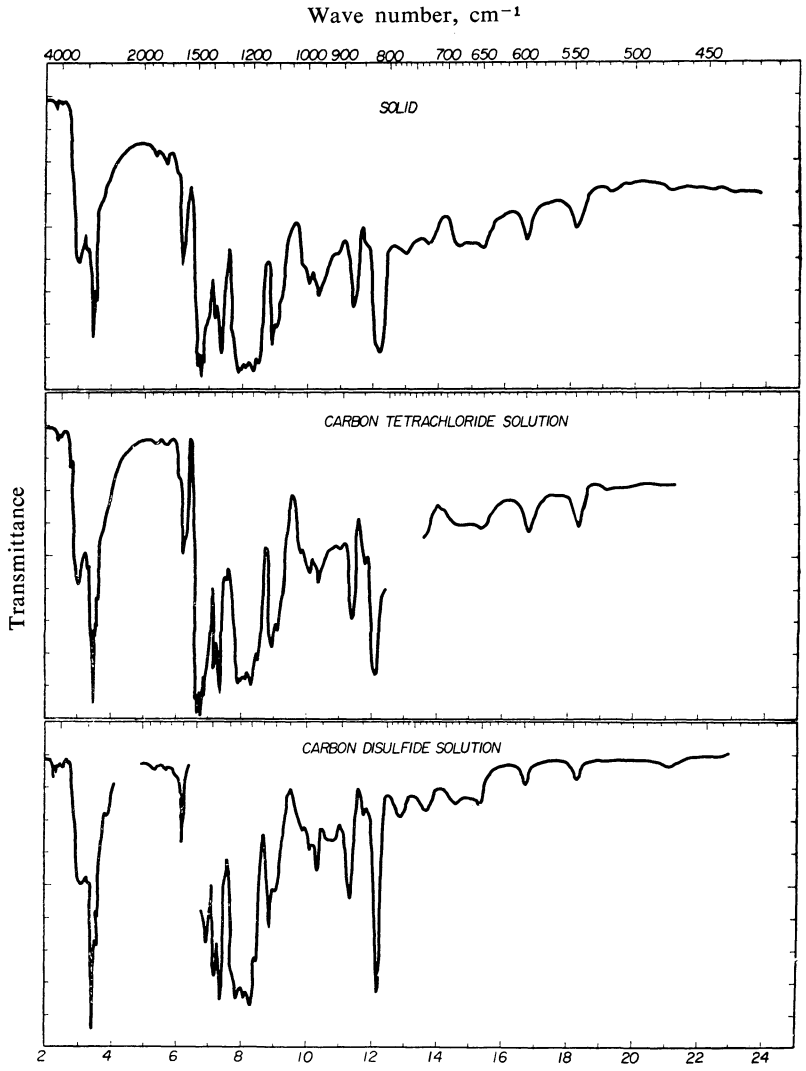

Fig. 1. Spectra of *p-tert*-butylphenol resin in solid and solutions. Spectrum is cut off in the region of interference due to solvents. Concentration of solution is about 15% in carbon tetrachloride and 10% in carbon disulfide.

1) R. Soda, *Bull. Nat. Inst. Ind. Health*, No. 3, 40 (1960).

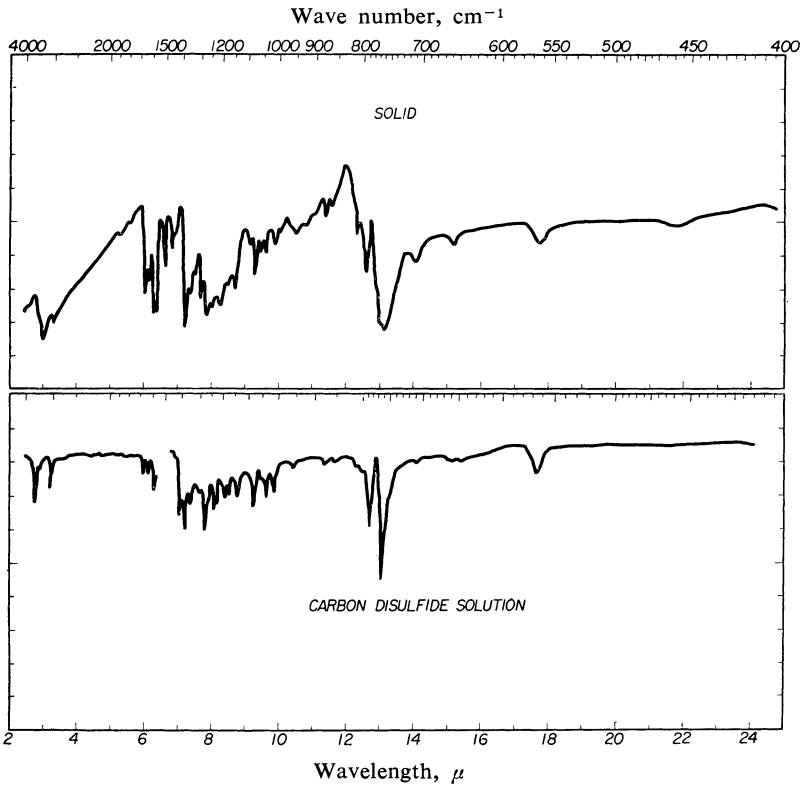

Fig. 2. Spectra of α-naphthol resin in solid and solution. Spectrum is cut off in the region of interference due to solvent. Concentration of solution is about 2%.

still remain some ambiguities in the assignment of those spectral bands. In order to eliminate the doubtfulness in the previous paper, infrared spectra of phenol, *p-tert*-butylphenol and α-naphthol were observed in more detail, and the band assignment and their structures were discussed more precisely[2]. The present paper deals with the band assignment of the spectra of the polymers of *p-tert*-butylphenol and α-naphthol, comparing them with information obtained already[2], particularly about the O–H deformation vibrations of those polymers.

Experimental

p-tert-Butylphenol formaldehyde resin and α-naphthol formaldehyde resin were supplied from S. Koshi. The former was synthesized from *p-tert*-butylphenol and formaline with ammonia as catalyst, and the latter, from α-naphthol and formaline. These polymers were purified from their benzene solutions. The color of *p-tert*-butylphenol polymer was yellowish brown, while that of α-naphthol polymer was dark brown or black.

The solvents used were benzene, acetone, carbon tetrachloride and carbon disulfide, each being distilled once. Only benzene and acetone were used as solvents for *p-tert*-butylphenol polymer. Spectra of the solvents were the same as those reported in the literature.

Solid spectrum of *p-tert*-butylphenol polymer was observed by sandwiched film which was resolidified between two window plates. α-Naphthol polymer did not fuse without decomposition; therefore, its solid spectrum was observed by potassium bromide disk alone. Some spectra of *p-tert*-butylphenol polymer were also obtained with this potassium bromide disk.

A Perkin-Elmer Model 137 infracord spectrophotometer, a Perkin-Elmer Model 21 spectrophotometer (cesium bromide region), and a Perkin-Elmer Model 221 spectrophotometer were used in the present experiment.

Results

***p-tert*-Butylphenol Polymer.**—Spectra of *p-tert*-butylphenol polymer in solid and in solutions of carbon tetrachloride and carbon disulfide are shown in Fig. 1. Solid spectrum of the polymer in cesium bromide region is shown in Fig. 3. The solution spectrum of *p-tert*-butylphenol polymer is almost the same as its solid spectrum, and no significant change in the bands is found when the concentration is altered, except a little change in the 3 and 8 μ regions, as is shown in Figs. 5 and 6. In solid the polymer gives rise to a broad

2) R. Soda, This Bulletin, **34**, 1842 (1961).

band near 3300 cm^{-1} which shows no appreciable change even if the polymer is dissolved in several solvents and the concentration of the solution varies. Only in the cases of carbon tetrachloride and benzene solutions is a weak but sharp band observed near 3600 cm^{-1} as a shoulder of the broad 3300 cm^{-1} band. In other solvents, such as acetone and carbon disulfide, it does not give rise to any band at 3600 cm^{-1}. The intensity of the band at 3600 cm^{-1} increases slightly as the concentration decreases, but the increment is so small that the quantitative relation with the concentration cannot be confirmed.

In the 8 μ region, this polymer gives rise to the bands at 1425, near 1232 and 1205 cm^{-1} in solid and in solution. Those bands in the 3 and 8 μ regions may be concerned in O–H vibration modes, but as far as the present experiment shows, a solvent cannot be found in which all O–H bonds are set free by dilution.

In the region of 600 to 400 cm^{-1}, and some

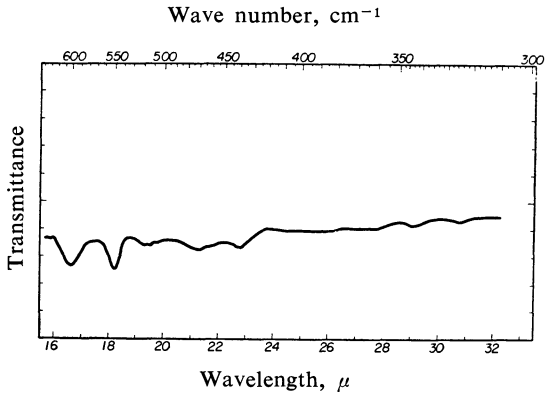

Fig. 3. Spectrum of *p-tert*-butylphenol resin in CsBr region (fused film).

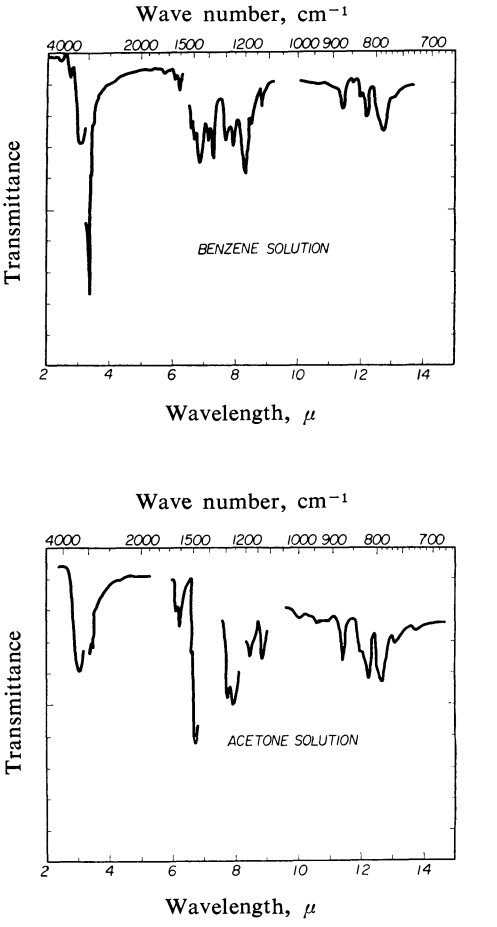

Fig. 4. Spectra of *p-tert*-butylphenol resin in benzene and acetone. Spectrum is cut off in the region of interference due to solvents. Concentration of solution is about 5% in benzene and 5% in acetone.

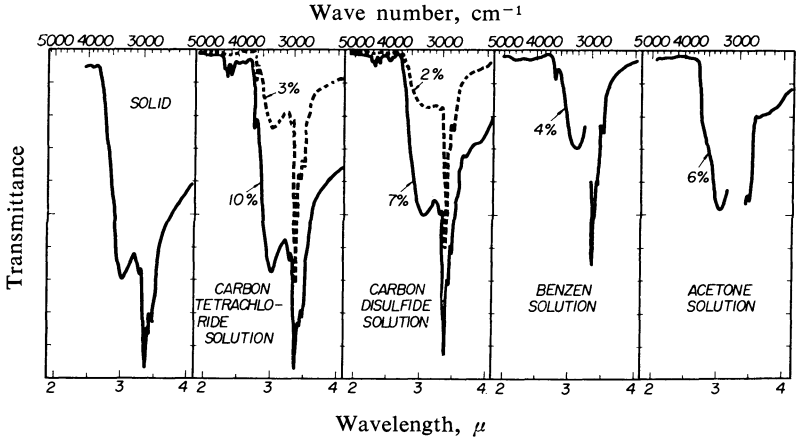

Fig. 5. Spectra of *p-tert*-butylphenol resin in 3 μ region. Spectrum is cut off in the region of interference due to solvents.

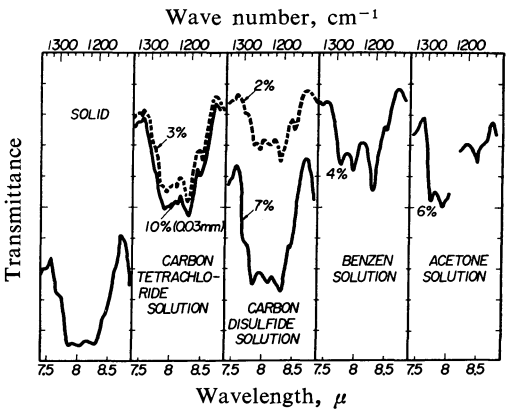

Fig. 6. Spectra of *p-tert*-butylphenol resin in the region near 1200 cm^{-1}. Spectrum is cut off in the region of interference due to solvents.

other regions, such a change of spectra with phase cannot be observed. The observed bands and their assignments are summarized in Table I.

α-Naphthol Polymer. — α-Naphthol polymer is insoluble or scarcely soluble in a non-polar solvent such as carbon tetrachloride; therefore, only a spectrum of a dilute solution of carbon disulfide was observed, as is shown in Fig. 2. The solution spectrum is considerably different from that of solid. This difference is so large that it cannot be explained as an impurity effect due to insufficient purification. In the region of the bands concerned with the C–H out-of-plane vibration mode, the strong bands occur at 765 and 755 cm^{-1}. In 3 μ, the solid gives rise to a very broad band near 3380 cm^{-1}, but the solution gives rise to a sharp (strong) band at 3600 cm^{-1} and a broader (weak) band at 3450 cm^{-1}. In the 8 μ region, several bands are observed, and the bands at 1441 and 1240 cm^{-1} in solid are considered to shift to 1385 or 1370 and 1176 cm^{-1} in solution respectively. In the lower wave number regions, no significant shift or chang is observed between solid and solution.

Discussion

***p-tert*-Butylphenol Polymer.** — *p-tert*-Butylphenol polymer is composed of *p-tert*-butylphenol and a methylene bridge at the ortho positions of phenol ring, and both sides of the linear polymer chain are probably *p-tert*-butylphenol residues[1,3-5]. The polymer has in it a methylene group, 1, 2, 3, 5-tetra- and 1, 2, 4-tri-substituted benzene rings, aromatic O–H and a *tert*-butyl group. *p-tert*-Butylphenol has in it a 1, 4-di-substituted benzene ring, aromatic O–H and a *tert*-butyl group. The polymer gives rise to the bands concerned with those group vibration modes, and the spectral difference between the polymer and *p-tert*-butylphenol may be attributed to the difference between groups or ring structures in these compounds.

The change of the bands concerned in the

Table I. Band positions and assignment of spectrum of *p-tert*-butylphenol resin

O–H vibration modes in the polymer with the phase or the concentration of solution is different from that of *p-tert*-butylphenol. The spectrum of the polymer shows no obvious difference between solution and solid. Solid and acetone solutions give rise to a broad band at 3300 cm^{-1} but carbon tetrachloride and benzene solutions give rise to a weak band at 3600 cm^{-1} near the 3300 cm^{-1} band. *p-tert*-Butylphenol gives rise to the broad band at 3300 cm^{-1} in solid and a sharp band at 3600 cm^{-1} besides the broader band at 3400 cm^{-1}. These bands are assigned to the O–H stretching vibration mode, the band at 3600 cm^{-1} is assigned to the vibration of free O–H, and the band at 3400 to 3300 cm^{-1}, to that of bonded O–H. Therefore, the O–H bond in the polymer is considered to be bound by very strong intramolecular H-bonding; this H-bonding cannot be easily broken into a free O–H bond in the solution. Only in a non-polar solvent, with interaction between the non-polar group of the polymer and the solvent, can the polymer chain extend to some extent and some O–H bond perhaps exist in a free state. The hydrogen bonded O–H bond of the polymer cannot be loosened by a hydrogen acceptor solvent such as acetone. Accordingly, in the case of the *p-tert*-butylphenol polymer, an appreciable change by the phase change cannot be expected in the bands concerned with O–H vibration modes.

The bands are assigned by comparing them with spectral data of various aromatic O–H compounds[4-6], particularly that of *p-tert*-butylphenol[2]. The assignment in Table I is carried out in such a way.

p-tert-Butylphenol in solid gives rise to the bands at 1389 and 1222 cm^{-1}, and those are assigned to the O–H in-plane deformation vibration, coupled with a C–O stretching vibration. Therefore, the bands at 1425 and 1232 cm^{-1} in the polymer are assumed to be assigned to those vibration modes. In a similar way, the bands at 548 and 520 cm^{-1} are assumed to be concerned with O–H out-of-plane deformation vibration.

The other bands at 600 to 400 cm^{-1} may be attributed to characteristics of 1, 2, 4, 6-tetra- and 1, 2, 4-tri-substitutions.

α-Naphthol Polymer.—Polymerization of α-naphthol and formaldehyde may take place at various positions of the α-naphthol nucleus. Position 1 of naphthalene ring is occupied by the O–H group, and there are two types of adjacent free hydrogen atom groups in α-naphthol. The methylene bridge can occupy several positions of the α-naphthol ring, for example, 2, 4, 6 and 8. The type of adjacent free hydrogen atom group is assumed to be as shown in Fig. 7.

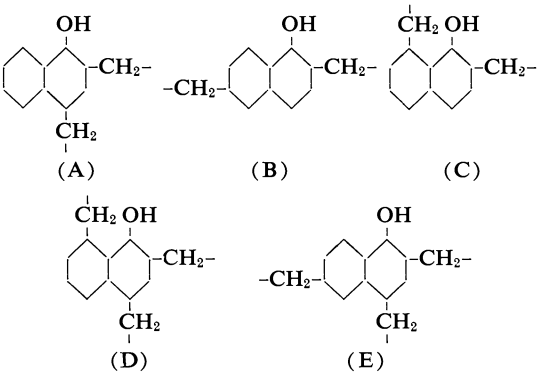

Fig. 7. Diagram regards to several types of methylene bridge in α-naphthol resin.

Out-of-plane bending vibration and some in-plane bending of aromatic C–H bond give rise to bands in the region of 950 to 650 cm^{-1}, and the band positions obey an empirical rule of the spectrum of substituted aromatic derivatives[7-11]. With several substituted naphthalene derivatives in which two sorts of adjacent free hydrogen atom groups exist, the intense band arise in the region of 860 to 800 cm^{-1} and 750 to 700 cm^{-1}. In the case of four adjacent free hydrogen atoms, the compound also gives rise to the bands in the region of 770 to 735 cm^{-1} and 730 to 710 cm^{-1}. With three adjacent aromatic hydrogen atoms, the characteristic bands appear at 810 to 750 cm^{-1} and 730 to 680 cm^{-1}. One isolated hydrogen atom attached to aromatic ring gives rise to the band at 900 to 850 cm^{-1}. From those rules of spectral bands concerned with out-of-plane C–H bending, the polymer may be considered to have a linear but a partly cross-linked chain structure in which the methylene bridge group mainly occupies the 2 and 4 or 6 positions of the naphthalene ring. The main structures may be drawn as shown by I and II in Fig. 8. Bands 850 and 870 cm^{-1} are assigned to out-of-plane bending of the isolated C–H group, bands 810 and 760 or 710 cm^{-1} to that of two adjacent free hydrogen atoms, and bands 770 and 760 or 710 cm^{-1} to that of four adjacent free hydrogen atoms. The band at 790 cm^{-1} is weak, and if the polymer has

structure I in Fig. 8, this band can be assigned to the vibration of three adjacent free hydrogen atoms in the end of the polymer chain.

In the region of 3 μ, the band at 3380 cm^{-1} is assigned to H-bonded O-H stretching vibration, that at 3450 cm^{-1} to that of weakly H-bonded O-H bond, and that at 3600 cm^{-1} to free O-H stretching vibration. The O-H bonds in the solid polymer may all be bound with each other by intermolecular hydrogen bonding, and in carbon disulfide solution, the polymer has a large number of free O-H bonds and a very small number of H-bonded O-H bonds. It may be assumed that the O-H bonds in the molecule of the α-naphthol polymer find it difficult to approach near enough to each other to build up a strong intramolecular hydrogen bonding.

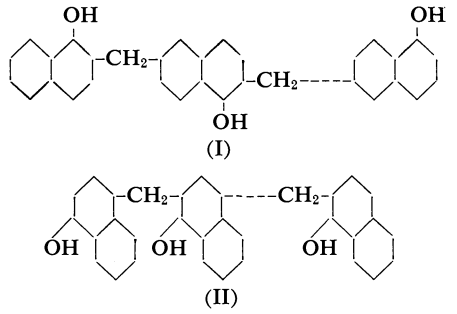

Fig. 8. Possible structures of α-naphthol resin prepared in this work.

From the comparison of the spectra of *p-tert*-butylphenol and its polymer, the bands at 1460, 1385 or 1353, 1335, 1300 and 750 cm^{-1} are assigned to the methylene group vibration[6,7]. O-H deformation vibration may be coupled with C-O stretching vibration. The bands 1385 or 1353 and 1176 cm^{-1} are assigned to the vibration of the free O-H bond, and the bands at 1441 and 1240 cm^{-1}, to those of H-bonded O-H. The bands at 568 cm^{-1} may be concerned with O-H out-of-plane bending. The other bands are attributed to the vibration of the condensed aromatic ring. The band positions and assignments are summarized in Table II.

Summary

Polymers of *p-tert*-butylphenol with formaldehyde and α-naphthol with formaldehyde have been synthesized, and infrared spectra have been observed in solid and in solutions. The following conclusions have been obtained concerning band assignments and the polymer structures.

(1) *p-tert*-Butylphenol polymer is a linear chain polymer connected with the methylene bridge, and O-H bonds restrict each other by a strong intramolecular hydrogen bonding. This hydrogen bonding is partly loosened in a benzene and carbon tetrachloride solution, but not in an acetone solution.

(2) With *p-tert*-butylphenol polymer the bands at 1425 and 1205 cm^{-1} are assigned to the deformation vibration of the O-H bond coupled with the C-O stretching vibration. Out-of-plane O-H bending is considered to give rise to the bands in the 550 to 500 cm^{-1} region, and the bands at 548 and 520 cm^{-1} are

assumed to be concerned with those vibrations.

(3) The O–H bond in α-naphthol polymer is bound by an intramolecular hydrogen bonding in solid, but in solution almost all the O–H bonds are liberated from the H-bonding. The polymer is considered to be a linear chain molecule whose O–H bonds can only with difficulty interact with each other to make an intramolecular hydrogen bonding.

(4) In-plane O–H deformation vibration coupled with C–O stretching vibration of α-naphthol polymer gives rise to the bands at 1385 or 1357 and 1176 cm^{-1}. The bands at 560 cm^{-1} may be concerned in out-of-plane O–H bending vibration.

The author wishes to express his hearty thanks to Assistant Professor Tatsuo Miyazawa and his collaborators at the Institute for Protein Research, Osaka University, for their kind permission to use their Perkin-Elmer Model 221 spectrophotometer. He also wishes to thank Mr. Michio Kawano, at the Railway Technical Research Institute, for the measurement of the spectrum in the cesium bromide region.

Dehydration of Bile Acids and their Derivatives. IX. Oxidation of Methyl 3α-Acetoxy-Δ⁷-cholenate with Selenium Dioxide

By Ryuzaburo OSAWA

(Received February 27, 1961)

Previously Fieser et al.[1] reported that the selenium dioxide oxidation of Δ^7-cholestene-3β-ol acetate in benzene-ether or ether-acetic acid affords, along with allylic rearrangement and acetylation, $\Delta^{8(14)}$-cholestene-3β, 7α-diol diacetate. Saucy et al.[2] found later that the same oxidation of $\Delta^{7,22}$-ergostadiene-3β-ol acetate in boiling ether containing a little acetic acid gives, as expected, not only $\Delta^{8(14),22}$-ergostadiene-3β, 7α-diol diacetate, but also $\Delta^{7,22}$-ergostadiene-3β, 9ξ-diol monoacetate. In his preceding paper, Fieser[3] had concluded that among the various steroids tested, 5α- or Δ^5-steroids having a double bond adjacent to the C-14 hydrogen atom give positive results in his selenium dioxide test, while none of the 5β-isomers does. Accidentally Professor Yamasaki has noticed that, contrary to Fieser's conclusion, some of the unsaturated bile acids (5β) give apparently positive results in the selenium dioxide test reported by Fieser[3]. These results are summarized in Table I.

It is interesting to note that not only the bile acids with a double bond adjacent to the C-14 hydrogen atom, but also those having a $\Delta^{8(14)}$ double bond afforded positive results in the selenium dioxide test.

The present author has sought to isolate the selenium dioxide oxidation products of methyl 3α-acetoxy-Δ^7-cholenate. The crude crystalline oxidation product was dissolved in benzene and chromatographed to give three crystalline substances. The substance eluted first proved to be the recovered starting material (melting point; mixed melting point; the infrared spectrum).

Substance A, eluted immediately after the starting material, was in the form of colorless needles (m. p. 174°C), the infrared spectrum of which indicated that the acetyl group and the double bond of the starting material were eliminated. No further evidence on the structure of this product has yet been obtained, since the amount of the product is too small for further study.

Substance B (II), in the form of colorless prisms (m. p. 114°C), eluted with a mixture of ether-methanol (4 : 1) showed a high absorption maximum at 214 mμ (ε_{max}^{EtOH} 7804). This characteristic absorption seems to indicate the presence of a tetra-substituted, exocyclic

(CHART)

ethylenic linkage in the molecule, as has been shown by Bladon et al.[4] and Osawa et al.[5,6]; indeed, the ultraviolet absorption spectrum of this substance was found to be quite similar to that of methyl 3α-acetoxy-$\Delta^{8(14)}$-cholenate[6] (IX) derived from apocholic acid (Fig. 1). From these observations and the structure of the starting material, it is highly probable that substance B has a double bond shifted to the position between C-8 and C-14, just like apocholic acid.

The infrared spectrum of substance B showed a distinct band at 3400 cm^{-1}, indicative of the presence of a hydroxyl group or groups (Fig. 2, II). This band disappeared when substance B was acetylated in the usual way, which indicates that the hydroxyl group or groups are not of tertiary, but probably of secondary nature. Analytical data of this acetylated substance correspond well to a tri-acetate, $C_{25}H_{37}O_5 \cdot (CH_3CO)_3$ (III). From these results it has been concluded that substance B contains no tertiary hydroxyl group unlike the oxidation product of $\Delta^{7,22}$-ergostadiene-3β-ol acetate[2], and that it probably has two acylable hydroxyl groups newly introduced at the positions adjacent to the double bond ($\Delta^{8(14)}$) as formulated as II.

The secondary nature of these hydroxyl groups was confirmed by the fact that chromic acid oxidation gave a diketone IV, which afforded a dioxime.

This unsaturated diketone IV showed an absorption maximum at 259 mμ with a characteristic extinction coefficient (ε_{max}^{EtOH} 10224)

TABLE II

Substance	M. p., °C	α_D	Absorption maximum, λ	Ref.
Methyl 3α-acetoxy-7,11-diketo-Δ^8-cholenate (IV′)	147~149	+ 32° (chf.)	272 mμ* ε_{max}^{EtOH} 5012	10
The oxidation product of substance B (IV)	154~155	+120.4°(chf.)	259 mμ ε_{max}^{EtOH} 10224	—
7,15-Dioxoergosta-$\Delta^{8(14),22}$-diene-3β-ol acetate	180~181	+ 36° (chf.)	259 mμ ε_{max}^{EtOH} 11300	7

* A sample of m. p. 136~143°C showed an absorption maximum ε_{max}^{EtOH} 8139 at 272 mμ[10].

quite similar to that shown by 7,15-dioxo-ergosta-$\Delta^{8(14),22}$-diene-3β-ol acetate[7].

On the basis of these results, it appears highly probable that the resulting diketone IV is methyl 3β-acetoxy-7,15-diketo-$\Delta^{8(14)}$-cholenate. Furthermore, the presence of an ene-1,4-dione system in the diketone was substantiated by the fact that the diketone not only gave a pyridazine derivative, characterized by the absorption maximum at 262 mμ (ε_{max}^{EtOH} 2440)[7,8], but also was reduced at room temperature by zinc and acetic acid like the dioxo-ergostadiene derivative[7]. This reduction product no longer showed such a characteristic absorption at 259 mμ (Fig. 3), and two kinds of crystalls

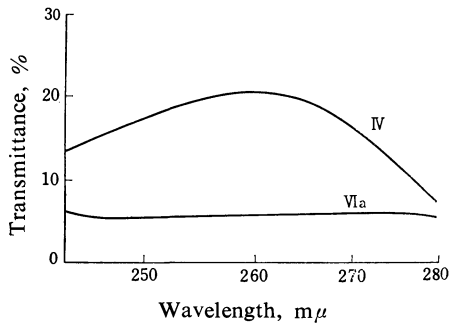

Fig. 3. Absorption spectra of: The oxidation product of substance B (IV) (1/1000% w/v MeOH) and its zinc dust-reduction product (VIa) (1/100% w/v MeOH).

were obtained, the one melting at 184°C and the other at 111°C. The former saturated diketone VIa, the major product, remained unchanged by treatment with alkali followed by esterification and acetylation, and it gave a bisthioketal (VII)[9] which in turn, by desulfuration with Raney nickel, was converted into methyl 3α-acetoxycholanate (VIII) (Identification: melting point; mixed melting point; infrared spectrum). These findings strongly indicate that the C/D ring fusion in this diketone is trans (14α-hydrogen), just like the usual bile acid. The other product of m. p. 111°C had been expected to have the structure of cis C/D fusion, as formulated as VIb, but the amount of the product was too small to elucidate the structure.

Furthermore, not only the unsaturated diketone IV but also the saturated diketone VIa showed characteristic infrared spectra, indicative of α,β-unsaturated (1692 cm^{-1}, 1634 cm^{-1}) and saturated (1732 cm^{-1}, 1717 cm^{-1}) ketonic groups in a five- and a six-membered ring respectively (Fig. 2).

From these experimental results the major product (substance B) of the selenium dioxide oxidation of methyl 3α-acetoxy-Δ^7-cholenate has been proved to be methyl 3α-acetoxy-7,15-dihydroxy-$\Delta^{8(14)}$-cholenate (II).

The fact that substance B (II) and its oxidation product IV showed great absorptions in the ultraviolet region, as indicated above, is consistent with Formulae II and IV, and not with Formulae II′[4] and IV′[10] respectively. The other physical constants of the oxidation product of substance B are also quite different from those of methyl 3α-acetoxy-7,11-diketo-Δ^8-cholenate[10] (IV′) (Table II).

The configurations of the newly introduced hydroxyl groups at C-7 and C-15 of substance B have not yet been established. Since the rear attack of selenium dioxide will be a very probable mode of action, as was the case in the oxidation of Δ^7-cholestene-3β-ol acetate[1], the C-7 hydroxyl group of substance B might be α-oriented (M_D contribution −79). If this were so, the M_D contributions of the hydroxyl and acetyl groups at C-15 could be calculated to be −162 and +30 respectively, indicating that the C-15 OH is α-oriented. Methyl 3α-acetoxy-$\Delta^{8(14)}$-cholenate (M_D +250)[6] has here been taken as a point of reference.

Experimental

Oxidation of Methyl 3α-Acetoxy-Δ^7-cholenate.—To a solution of methyl 3α-acetoxy-Δ^7-cholenate (I) (m. p. 126°C; 2 g.) in 50 ml. of absolute ether was added 92 ml. of a solution of 0.1 M selenium dioxide in acetic acid[1], and the mixture was kept at room temperature (18~25°C) overnight. Then the reaction mixture was poured carefully into 1 l. of water and extracted thoroughly with ether. The ethereal extract was washed with water, with sodium carbonate solution and again with water successively, and dried over sodium sulfate. Removal of the solvent gave a crystalline residue, which, dissolved in 4~5 ml. of benzene, was allowed to pass through a Brockmann-alumina column and eluted with petroleum ether, benzene, ether and methanol successively. The first portions (Fraction 1—4) of the eluate contained the starting material (yield: 55% as an average) and substance A of a higher melting point, while substance B of a lower melting point (yield: 15% as an average) was obtained from the fractions eluted with ether-methanol (4:1, v/v). Substance A and B were separately treated and refluxed in acetone with precipitated silver for about 3 hr. to remove colloidal selenium. Removal of the solvent of these solutions gave crystalline residues.

Methyl 3α-Acetoxy-7ξ, 15ξ-dihyroxy-$\Delta^{8(14)}$-cholenate (II).—Substance B was recrystallized repeatedly from methanol. Yield, 230 mg., m. p. 114~117°C, $\alpha_D^{29}=+2.0°$ (chf.); λ_{max} 214 mμ (ε_{max}^{EtOH} 7804). The infrared spectrum of this substance had a distinct hydroxyl absorption band at 3400 cm^{-1}. Substance B showed a melting point depression on admixture with the starting material and no more positive result in the selenium dioxide test.

Found: C, 69.78; H, 9.02. Calcd. for $C_{27}H_{42}O_6$ (462.61): C, 70.10; H, 9.15%.

Methyl 3α, 7ξ, 15ξ-Triacetoxy-$\Delta^{8(14)}$-cholenate (III).—Substance B (200 mg.) dissolved in 2 ml. of pyridine with 1 ml. of acetic anhydride was allowed to stand at room temperature. After 24 hr. the reaction mixture was warmed for 20 min. on a water bath and some concentrated hydrochloric acid was added. The separated solid was then collected. Recrystallized once from methanol, the product was obtained as colorless needles of m. p. 120~121°C, $\alpha_D^{28}=+25.0°$ (chf.); λ_{max} 214 mμ (ε_{max}^{EtOH} 8610). Yield, 188 mg. The hydroxyl absorption at 3400 cm^{-1} was not observed in the infrared spectrum of III.

Found: C, 68.16; H, 8.58. Calcd. for $C_{31}H_{46}O_8$ (546.68): C, 68.10; H, 8.48%.

Methyl 3α-Acetoxy-7, 15-diketo-$\Delta^{8(14)}$-cholenate (IV).—Substance B (400 mg.) in 40 ml. of acetone was oxidized with the chromium trioxide-sulfuric acid mixture (3.2 ml.) according to the method of Bladon et al.[4] After completion of the oxidation (3~4 min.), the excess of the oxidant was reduced with a small amount of methanol. The reaction mixture was diluted with water and extracted thoroughly with ether. The ethereal extract was washed with water, with sodium carbonate solution and again with water successively, dried over sodium sulfate and evaporated. Recrystallization from methanol and then aqueous methanol afforded yellowish crystals of m. p. 154~155°C; $\alpha_D^{28}=+120.4°$ (chf.); λ_{max} 259 mμ (ε_{max}^{EtOH} 10224). The infrared spectrum showed four carbonyl absorption bands, two of which indicated α, β-unsaturated 5- and 6-membered rings (1692, 1634 cm^{-1}).

Found: C, 70.77; H, 8.31. Calcd. for $C_{27}H_{38}O_6$ (458.57): C, 70.71; H, 8.35%.

Oxime of IV.—The diketone (100 mg.) in 20 ml. of methanol was treated with an aqueous solution of hydroxylamine (a mixture of 5 M sodium acetate, 4 ml. and 5 M hydroxylamine hydrochloride, 4 ml.). The mixture was refluxed for 2 hr. and then poured into 100 ml. of water, and the product was collected. The product failed to be crystallized, but repeated precipitations from aqueous methanol afforded a satisfactorily pure sample (87 mg.).

Found: N, 5.46. Calcd. for $C_{27}H_{40}O_6N_2$ (488.33): N, 5.73%.

Pyridazine Derivative of IV.—The diketone IV (200 mg.) in 33 ml. of methanol was refluxed for 6 hr. with 0.6 ml. of hydrazine hydrate (42%). Removal of the solvent left a residue which became crystalline when treated with a small amount of ether. The crystalline material dissolved in benzene was chromatographed (Florisil). M. p. 158°C; yield, 76 mg. λ_{max} 262 mμ (ε_{max}^{EtOH} 2440).

The infrared spectrum of the resulting product indicated that the acetyl group of the diketone IV was removed by the above treatment.

Found: C, 72.20; H, 8.88; N, 6.46. Calcd. for $C_{25}H_{38}O_3N_2$ (414.30): C, 72.42; H, 9.24; N, 6.76%.

Zinc Dust Reduction of IV.—*Methyl 3α-Acetoxy-7, 15-diketo-cholanate (VIa).*—A solution of the $\Delta^{8(14)}$-diketone (IV) (200 mg.) in 20 ml. of acetic acid was stirred with 1 g. of zinc dust for 5 hr. at room temperature. After removal of zinc dust the solution was diluted with water and extracted with ether. The ethereal extract was washed with water, with sodium carbonate and again with water successively and then evaporated to dryness. Recrystallized from methanol, the product was obtained as platelets of m. p. 184°C, $\alpha_D^{16}=+36.4°$ (chf.). Yield, 122 mg.

Found: C, 70.26, 70.40; H, 8.84, 8.73. Calcd. for $C_{27}H_{40}O_6$ (460.59): C, 70.40; H, 8.75%.

The infrared spectrum of the product showed characteristic bands of a saturated ketone: ν_{max}^{Nujol} 1750 cm^{-1} (ester), 1732 cm^{-1} (5-membered ring ketone), 1717 cm^{-1} (6-membered ring ketone); 1254, 1225 cm^{-1} (acetate).

Chromatography of the filtrate gave a further crop (35 mg.) of m. p. 182°C. Total yield, 157 mg. A small amount of another kind of crystals (m. p. 110°C) was also obtained; this yield, however, was not enough for its identification.

A solution of the ketone (50 mg., m. p. 184°C) in 2 ml. of 5% methanolic potassium hydroxide was refluxed for 1 hr. in an atmosphere of nitrogen, and then the solution was neutralized with dilute acetic acid. The precipitate was collected and esterified with diazomethane, followed by the usual acetylation (acetic anhydride and pyridine). Recrystallized from methanol, the product melted at 182°C, showing no melting point depression on admixture with the starting material.

Bisthioketal (VII) of VIa. — The saturated diketone (m. p. 184°C) (200 mg.) was allowed to react with 1 ml. each of ethanedithiol and borofluoride etherate at room temperature. After 72 hr. the reaction mixture was poured into 20 ml. of ice-cold water and extracted with ether. The ethereal extract was washed, dried and evaporated to dryness. After removal of residual ethanedithiol by steam distillation, the product was extracted with ethyl acetate and the solvent removed. Recrystallization from methanol gave needles of m. p. 178°C. Yield, 110 mg.

Found: S, 20.92. Calcd. for $C_{51}H_{48}O_4S_4$ (612.95): S, 21.32%.

Desulfuration of the Bisthioketal (VII).—*Methyl 3α-Acetoxycholanate (VIII).* — A solution of the thioketal VII (100 mg.) in 4 ml. of methanol was refluxed with Raney nickel (1 g.) for 8 hr. on a water bath. Chromatography of the product gave needles of m. p. 132°C (32 mg.). No melting point depression was observed on admixture with an authentic sample of methyl 3α-acetoxycholanate (m. p. 133°C).

Found: C, 75.02; H, 10.03. Calcd. for $C_{27}H_{44}O_4$ (432.626): C, 74.95; H, 10.25%.

Substance A. — Substance A was recrystallized from methanol or acetone-water and melted at 174°C; $\alpha_D^{29.5} = +136°$ (EtOH); λ_{max} 273 mμ; 240 mμ (ε_{max}^{EtOH} 11492, 7681). The substance in acetic acid absorbed bromine to turn dark brown in color. It was found to be resistant to catalytical hydrogenation as well as to chromic acid oxidation at room temperature. (Found: C, 65.04; H, 7.13%).

Summary

Carefully repeated experiments have shown that, contrary to Fieser's report[3], methyl 3α-acetoxy-Δ^7-cholenate and some other unsaturated bile acids (5β) listed in Table I give positive results in the selenium dioxide test. This finding was substantiated by the fact that two oxidation products of methyl 3α-acetoxy-Δ^7-cholenate were isolated, one of which was proved to be methyl 3α-acetoxy-7ξ, 15ξ-dihydroxy-$\Delta^{8(14)}$-cholenate.

It is very interesting to note that, unlike the Δ^7-steroids of the 5α-series, not only C_7-H, but C_{15}-H of the unsaturated bile acid mentioned above was oxidized with selenium dioxide to give hydroxyl groups, both of which remained without being acetylated under the experimental conditions described.

Dielectric Properties of Monohalogenobenzenes in the Microwave Region

By Hideo OKABAYASHI

(Received June 6, 1961)

The assumption of the local field plays an important rôle in the theory of the anomalous dispersion of a dielectric constant and the absorption of electric waves by a polar liquid.

Debye was the first to succeed in explaining theoretically the phenomena concerning the dielectric relaxation of polar liquids[1]. Debye's assumption for the local field explains inadequately the experimental results of dielectric constants, however. Nevertheless, the assumption of a single relaxation time seems to be at least approximately valid in the cases of many polar liquids from the experimental point of view[2].

Recently Yasumi and Komooka have derived a formula of the local field in liquids[3]. Applying the formula, they have shown that the validity of the assumption of a single relaxation time is justified in the case of polar liquids, which consist of molecules with a spherical shape and isotropic polarizability, and that the critical frequency ν_c is related to the relaxation time τ as follows:

$$2\pi\nu_c\tau=1$$

Thereafter, the formula for the local field has been extended to the case of liquids which consist of molecules with a ellipsoidal shape and anisotropic polarizability, and the formula for the static dielectric constant[4] and that for the Kerr constant of pure liquid[5] have been

derived. In the cases of liquid chloro-, bromo- and iodo-benzene, these formulae explain the experimental facts fairly well.

In the present work, the complex dielectric constants of liquid monohalogenobenzenes are measured in the microwave region; the paper's results are discussed on the basis of the formula of the local field derived by Yasumi and Komooka. The free wave method developed by Yasumi[6] and the waveguide method of Surber[7] are used.

Materials

Chloro- and bromo-benzene were fractionally distilled.

Iodobenzene was three times vacuum distilled.

	B. p., °C
Chlorobenzene	130.9
Bromobenzene	155.3
Iodobenzene	42.8 under the pressure of 3 mmHg.

Experimental

Free Wave Method. — This method has been theoretically developed in detail by Yasumi[6], and in his laboratory the dielectric properties of various liquids have been investigated in the microwave region[8-11].

In this work, the dielectric constant and the loss factor of halogenobenzenes were measured by the free wave method at the wavelength of 1.38 cm. The apparatus has been reported on in detail in a previous paper[11].

If R^2 is denoted as the reflection coefficient of a system consisting of a liquid layer of the thickness d on mercury, and λ is the wavelength of an electric wave in vacuo, the reflection coefficient is represented as follows:

$$R_2=\frac{\sinh^2\left(2\pi k\frac{d}{\lambda}+\frac{1}{2}\ln R_{12}\right)+\cos^2\left(2\pi n\frac{d}{\lambda}-\frac{\gamma}{2}\right)}{\sinh^2\left(2\pi k\frac{d}{\lambda}-\frac{1}{2}\ln R_{12}\right)+\cos^2\left(2\pi n\frac{d}{\lambda}+\frac{\gamma}{2}\right)} \tag{1}$$

in which n and k are the refractive index and the absorption coefficient of the liquid respectively, and, further, R_{12} and γ are expressed as

$$R_{12}^2=\frac{(n-1)^2+k^2}{(n+1)^2+k^2},\qquad \tan\gamma=\frac{2k}{n^2-1+k^2} \tag{2}$$

The real part ε' and the imaginary part ε'' of the complex dielectric constant are related to n and k in the following manner:

$$\varepsilon'=n^2-k^2,\qquad \varepsilon''=2nk \tag{3}$$

The values of ε' and ε'' can be determined from the observed curve of R versus d/λ by the same way as described in the previous paper[11].

The observed values of R at different thicknesses of the liquid layer of chlorobenzene (at $t=13$°C and $\lambda=1.38$ cm.) are shown in Fig. 1, together with the calculated curve for the determined values of n and k.

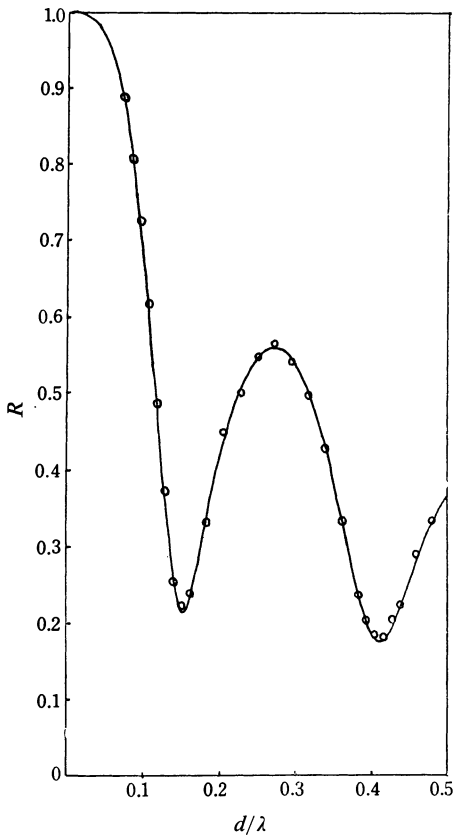

Fig. 1. The square root of the reflection coefficient of the chlorobenzene layer of the thickness d/λ measured at 13°C and the wavelength of 1.38 cm. and the calculated curve corresponding to $n=1.86$ and $k=0.36$.

The errors of ε' and ε'' are probably within ±1.5 and ±2.5% respectively.

Waveguide Method.—The dielectric constant and the loss factor at the wavelengths of 3.30 and 4.35 cm. were measured by means of the waveguide method. Each apparatus was similar to the one used by Crouch[12], by Smyth[13], or by Koizumi[14]. A block diagram of the apparatus is shown in Fig. 2.

The directional coupler picks up the reflected wave from the liquid-filled waveguide cell. The reflected power P corresponding to a liquid layer of the thickness d can be known by the detector

wavelength in the teflon-filled waveguide. The mica sheet of the thickness of about 3/100 mm. is inserted between the liquid cell and the waveguide connected to it in order to separate them. Two attenuators decrease the power level of the wave, which propagates towards the sample, about 30 db in order to loose the coupling between the klystron oscillator and the waveguide cell, because the reflection coefficient of the liquid-filled cell varies from unity to zoro.

The temperature of the liquid sample was controlled by water which circulated in the jacket surrounding the waveguide system and the thermostat, the fluctuation of the temperature was within ±0.1°C.

Before the liquid sample was poured into the

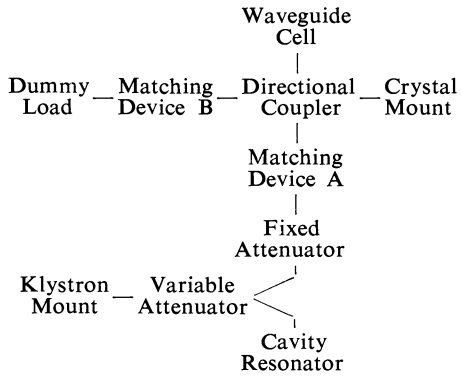

Fig. 2. The block diagram of the apparatus by the waveguide method.

waveguide cell, the following adjustments were made: After the movable dummy load of about 1.01 V. S. W. R. was inserted instead of the plunger in the waveguide cell, the matching device B (see Fig. 2) was adjusted so as to minimize the variation in the reading of the detector when the position of the dummy load was changed. After the plunger was set up in the waveguide cell, the matching device A (see Fig. 2) was adjusted so as to minimize the variation in the reading of the detector when the position of the plunger was changed.

If the effect of the mica sheet can be ignored, the reflection coefficient R_w^2 of the liquid layer in the waveguide cell has the following expression*1:

$$R_w^2=\frac{\sinh^2\left(2\pi k_w\frac{d}{\lambda}+\frac{1}{2}\ln R_{w12}\right)+\sin^2\left(2\pi n_w\frac{d}{\lambda}-\frac{\gamma_w}{2}\right)}{\sinh^2\left(2\pi k_w\frac{d}{\lambda}-\frac{1}{2}\ln R_{w12}\right)+\sin^2\left(2\pi n_w\frac{d}{\lambda}+\frac{\gamma_w}{2}\right)} \quad (4)$$

In this case R_{w12} and γ_w are related to n_w and k_w as follows:

$$R_{w12}^2=\frac{(n_w-n_{w1})^2+k_w^2}{(n_w+n_{w1})^2+k_w^2}$$

$$\tan\gamma_w=\frac{2n_{w1}k_w}{n_w^2-n_{w1}^2+k_w^2}$$

$$n_{w1}=\left\{1-\left(\frac{\lambda}{\lambda_c}\right)^2\right\}^{1/2} \quad (5)$$

in which λ_c is the cut-off wavelength characteristic of the waveguide. ε' and ε'' have the following relationship to n_w and k_w:

$$\varepsilon'=n_w^2-k_w^2+(\lambda/\lambda_c)^2,\quad \varepsilon''=2n_wk_w \quad (6)$$

If the reading of the detector system of the apparatus is proportional to the square of the field strength, it is also proportional to the reflection coefficient of the liquid layer in the waveguide. As the standard of the power, the power P_∞ for the liquid layer of infinite thickness is taken.

In this work, the values of n_w and k_w, and therefore ε' and ε'', were determined in the following way: Near the maximum and minimum points of the curve, P/P_∞ versus d/λ, the values of the power P were measured at short intervals. In Tables I and II some examples of the observed values of P/P_∞ are shown. The value of n_w was determined roughly from the separations of the maximum points. Next, the value of k_w was roughly determined from the values of P/P_∞ at the maximum points. Finally, the values of n_w and k_w were chosen in order to fit the observed values of P/P_∞ at different thicknesses of the liquid layer in the waveguide.

Various factors may contribute to the experimental error. One of the sources of error may be the disturbance of the wave by the mica sheet. This sheet forms a multiple layer with the liquid layer and the teflon-block in the waveguide*2. The effect can be checked by the theoretical calculation of the reflection coefficient of a multiple layer placed on a metal. The theoretical calculation shows that the effect of the mica sheet is negligible at the present stage of the accuracy.

When the values of n_w and k_w were determined, the value of P/P_∞ at the first minimum point was not taken into account*3.

* The values of λ_c for the apparatus at the wavelengths of 3.295 and 4.347 cm. are 4.58_0 and 6.97_0 cm. respectively.

*1 Yasumi's theoretical treatment concerning the free wave method can be conveniently applied to the waveguide method with a few modifications. For example, n_w and k_w in this case correspond to n and k, and the refractive index of vacuum (which is unity) should be replaced by $n_{w1}(\neq 1)$. ε'' is related to n_w and k_w by Eq. 6.

*2 The length of the teflon block is a quarter of the wavelength in the teflon-filled waveguide. In this work the samples with high absorption coefficients were tested. Therefore, the error due to the teflon block seems to be negligible.

*3 The details will be reported on elsewhere.

The errors of ε' and ε'' were within $\pm 1\%$.

The obtained values of ε' and ε'' of liquid monohalogenobenzenes are tabulated in Tables III and IV. On the other hand, Yasumi and Shirai have measured the complex dielectric constant of liquid chlorobenzene by the free wave method at the wavelength of 3.24 cm. These values are shown in Table III for comparison. The results by the waveguide method shows an fair agreement with those obtained by the free wave method.

Theoretical Discussion

A molecule of monohalogenobenzene is rigid, and each principal axis of its polarizability ellipsoid coincides with each of the principal axes of the molecular ellipsoid. In such a case, the component of the local field $\vec{F}$ has the following expression[4]:

$$\left.\begin{aligned} F_i &= \left(1-\frac{\varphi_i\alpha_i}{v}\right)^{-1}\left(E_i e^{i\omega t}+\frac{\varphi_i\mu_{0i}}{v}\right) \\ &= \gamma_i\left(E_i e^{i\omega t}+\frac{\varphi_i\mu_{0i}}{v}\right) \\ \varphi_i &= 2\pi a_1 a_2 a_3 \\ &\quad \times\int_0^\infty \frac{du}{(a_i^2+u)\sqrt{(a_1^2+u)(a_2^2+u)(a_3^2+u)}} \end{aligned}\right\} \quad (7)$$

in which $\vec{E}e^{i\omega t}$ is the field strength in the medium, ω is the angular frequency of an applied field, $\vec{\mu}_0$ is the permanent dipole moment. α_i is the principal component of the polarizability tensor along the principal axis of the molecular ellipsoid, v is molecular volume, and $2a_i$ is the length of the principal axis of the molecular ellipsoid.

Perrin[15] treated the dielectric relaxation of a polar liquid consisting of ellipsoidal molecules from the point of view of hydrodynamics, and derived a partial differential equation which determines the distribution function of dipole orientation. The equation of Perrin will be applied to Eq. 7.

If the potential energy of a dipole under the influence of the electric field is denoted by U, we have

$$U=-\left(\frac{1}{2}\sum \alpha_i F_i^2+\sum \mu_{0i}F_i\right) \quad (8)$$

If only the term proportional to E is retained, the torques L_i about each principal axis of the molecular ellipsoid have the following expressions:

$$\left.\begin{aligned} L_1 &= Ee^{i\omega t}(\mu_{02}\gamma_2^2\zeta_3-\mu_{03}\gamma_3^2\zeta_2) \\ L_2 &= Ee^{i\omega t}(\mu_{03}\gamma_3^2\zeta_1-\mu_{01}\gamma_1^2\zeta_3) \\ L_3 &= Ee^{i\omega t}(\mu_{01}\gamma_1^2\zeta_2-\mu_{02}\gamma_2^2\zeta_1) \end{aligned}\right\} \quad (9)$$

15) F. Perrin, *J. phys.*, 5, 497 (1934).

in which ζ_1, ζ_2 and ζ_3 are the direction cosines of the electric field $\vec{E}$ with respect to the principal axes of molecular ellipsoid respectively.

Inserting Eqs. 9 into Perrin's equation, we have the following expression of the probability function f as the approximate solution of the differential equation:

$$f=f_0+f_0\frac{Ee^{i\omega t}}{kT}\sum\frac{\mu_{0i}\gamma_i^2}{1+i\omega\tau_i}\zeta_i \quad (10)$$

f_0 denotes the distribution function when no electric field is applied. τ_i is the relaxation time and is related to the viscosity coefficient of liquid η as follows:

$$\left.\begin{aligned} \tau_i &= \frac{C_{jk}}{2kT} \\ \frac{2}{C_{jk}} &= \frac{1}{C_j}+\frac{1}{C_k} \\ C_i &= \frac{32\pi^2}{3}a_1a_2a_3\frac{\left(\frac{a_j}{a_1}\right)^2+\left(\frac{a_k}{a_1}\right)^2}{\left(\frac{a_j}{a_1}\right)^2\varphi_j+\left(\frac{a_k}{a_1}\right)^2\varphi_k}\eta \end{aligned}\right\} \quad (11)$$

The total electric moment of the molecule $\vec{\mu}$ is the sum of the permanent dipole moment and the induced dipole moment.

$$\mu_i=\mu_{0i}+\alpha_i F_i \quad (12)$$

If the component of $\vec{\mu}$ along the direction $\vec{E}$ is denoted by μ_E, and the statistical mean value of μ_E is denoted by $\langle\mu_E\rangle$, we have

$$\mu_E=\sum\mu_i\frac{E_i}{E}=\sum\gamma_i(\alpha_i Ee^{i\omega t}+\mu_{0i})\frac{E_i}{E} \quad (13)$$

and

$$\langle\mu_E\rangle=\frac{\int f\mu_E\,d\Omega}{\int f\,d\Omega} \quad (14)$$

in which $d\Omega$ is an elementary solid angle.

Inserting Eqs. 10 and 13 into Eq. 14, we have

$$\langle\mu_E\rangle=\left(\frac{\sum\alpha_i\gamma_i}{3}+\frac{1}{3kT}\sum\frac{\mu_{0i}\gamma_i^3}{1+i\omega\tau_i}\right)Ee^{i\omega t} \quad (15)$$

The complex dielectric constant ε is related to $\langle\mu_E\rangle$ by the following equation:

$$(\varepsilon-1)Ee^{i\omega t}=4\pi N_c\langle\mu_E\rangle \quad (16)$$

in which N_c is the number of molecules in a unit volume.

Accordingly, the dielectric constant ε' and the loss factor ε'' have the following expressions:

$$\left.\begin{aligned}\varepsilon' &= \varepsilon_\infty + \frac{4\pi N_c}{3kT}\sum \frac{\mu_{0i}^2\gamma_i^3}{1+\omega^2\tau_i^2}\\ \varepsilon'' &= \frac{4\pi N_c}{3kT}\sum \frac{\mu_{0i}^2\gamma_i^3}{1+\omega^2\tau_i^2}\omega\tau_i\\ \varepsilon_\infty &= 1+4\pi N_c\sum\frac{\alpha_i\gamma_i}{3}\end{aligned}\right\} \quad (17)$$

Equations 17 show that generally there are three relaxation times.

If the direction of the permanent dipole moment coincides with one of the principal axes of the molecular ellipsoid, the Eqs. 17 are simplified as follows:

$$\left.\begin{aligned}\varepsilon' &= \varepsilon_\infty + \frac{\varepsilon_0-\varepsilon_\infty}{1+\omega^2\tau^2}\\ \varepsilon'' &= \frac{\varepsilon_0-\varepsilon_\infty}{1+\omega^2\tau^2}\omega\tau\end{aligned}\right\} \quad (18)$$

in which ε_0 is the static dielectric constant of a polar liquid. It is assumed that the polarizability is independent of frequency.

In Tables V and VI the values of ε_∞ and τ obtained from the experimental values of the complex dielectric constant are tabulated, together with the value of the static dielectric constant ε_0 and that of the square of the refractive index n_D^2.

In Table VII the values of ε_∞ evaluated from the sum of the electronic polarization P_E and the atomic polarization P_A are tabulated. It is assumed that the Lorentz-Lorenz law is valid.

The values of ε_∞ evaluated from the experimental values of ε' and ε'' at different wavelengths coincide with each other within the limits of experimental error.

Yasumi, Shirai and Mizushima[10] hava measured the dielectric constant and the loss factor of liquid aliphatic alcohols at the wavelength of 3.24 cm. and have shown that the value of ε_∞ evaluated according to Eqs. 18 is considerably larger than the square of the refractive index for the sodium D line (n_D^2). This interesting result has been confirmed by the measurements at the wavelength of 1.38 cm.[11]

However, in the case of liquid monohalogenobenzene the value of ε_∞ is much closer to the value of n_D^2 and, moreover, is almost equal to the value ε_∞ evaluated from the value of (P_E+P_A).

From Tables V and VI the validity of Eqs. 18 seems to be justified in the cases of liquid monohalogenobenzenes; i. e. the dielectric relaxation is explained by the single relaxation time, and ε_∞ in Eqs. 18 has a value almost the same as the value of n_D^2.

According to Fqs. 11, the effective volume of a molecule v_e for the molecular rotation can be evaluated from the observed relaxation time if the ratios of the lengths of the principal axes of the molecular ellipsoid are known. In Table VIII the values of the effective volume v_e of the molecules at 25°C are shown, together with those of the volume $v_{(van\ der\ Waals)}$ of the molecular ellipsoid (the model which is assumed in order to determine the axial ratios). Also, the values of the molecular volume v

evaluated from the molar volume are shown for reference.

The value of v_e is only about 13% of the value of $v_{(van\ der\ Waals)}$. The reason why the value of v_e is so small is obscure as yet.

Summary

The dielectric constants and the loss factors of liquid monohalogenobenzenes were measured in the microwave region by the free wave method and the waveguide method. The experimental results were discussed on the basis of the formula of the local field previously proposed. In the cases of liquid monohalogenobenzenes, the experimental facts can be explained by a single relaxation time.

The author is grateful to Professor Masasi Yasumi for his kind guidance and encouragement throughout this work, and to Dr. Naokazu Koizumi, Dr. Michiro Shirai and Mr. Hitoshi Komooka for their advice. The author also wishes to thank Mr. Taketoshi Kato, who assisted the author in the experiment at the wavelength of 3.30 cm., and Mr. Yasuhiro Kawanishi, who prepared the samples used in these experiments.

SHORT COMMUNICATIONS

Polycondensation of Tripeptide with Bis-o-phenylene Pyrophosphite

By Toshiyuki FURUYAMA[1], Shumpei SAKAKIBARA and Shiro AKABORI

(Received November 20, 1961)

Many attempts to prepare high molecular polypeptides, in which amino acid residues were arranged in a regular order, have been made thus far[2-10]. These methods will be divided into two types. The one is the use of peptide derivative, e. g. peptide ester, *N*-carbothiophenylpeptide, as a monomer[2-7,9], and the other is the use of free peptide in the presence of the reagents which form peptide linkage, such as dicyclohexyl carbodiimide[8], tetraethyl pyrophosphite[9], or phosphorus pentoxide[10]. Among them, the carbothiophenyl method[7] and the tetraethyl pyrophosphite method[9] gave rather favorable results.

The present authors found a very handy procedure for the polycondensation of oligopeptides by the aid of bis-*o*-phenylene pyrophosphite. The present reagent was used previously for the peptide bond formation between acylamino acids and amino acid esters by Crofts et al.[11] In the present communication, polycondensation of L-leucylglycylglycine is described. Bis-*o*-phenylene pyrophosphite[12] resembles tetraethyl pyrophosphite[13] in the chemical nature, but the synthesis of the former reagent was much easier than that of the latter.

L-Leucylglycylglycine (m. p. 215~216°C with decomp. Found: C, 49.08; H, 7.96; N, 17.06. Calcd. for $C_{10}H_{19}O_4N_3$: C, 48.96; H, 7.81; N, 17.13%.) was synthesized from carbobenzoxy-L-leucine and glycylglycine ethyl ester by the use of isobutyl chloroformate, subsequent saponification and catalytic hydrogenation. Bis-*o*-phenylene pyrophosphite was synthesized according to the method of Crofts et al.[12]

A mixture of 1 g. of L-leucylglycylglycine, 1.2 g. of bis-*o*-phenylene pyrophosphite (an equimolar ratio) and 6 ml. of dry pyridine was heated at 100°C for 6 hr. in a sealed tube. During the reaction, the solution gradually gelled and became pale yellow. After the reaction completed, the product was poured into a flask containing 30 ml. of water. Then pyridine and water were removed in vacuo. The residues were dissolved in a small amount of ethanol, and an equal volume of water was added to the solution to decompose the terminal activated groups and the solvents were removed in vacuo. These procedures were repeated. An oily material remained was suspended in ethanol. Dry ether was added to the suspension and the syrupy material resulted was centrifuged off, washed several times with ethanol and ether*1, and finally dried. The weight of the dried material was 770 mg. The crude polypeptide was partly dissolved in hot dimethylformamide and precipitated by the addition of ether. In order to decompose the activated end groups completely, the precipitate was dissolved in 80% aqueous phenol*2 (5 ml.) and 1% aqueous ammonia (15 ml.) was added to the solution. The above solution was dialyzed against deionized water for 50 hr. in a cellophane tube. The precipitate obtained during dialysis was centrifuged off (fraction 1, which amounted to approximately 9% for L-leucylglycylglycine in weight) and the supernatant was lyophilized (fraction 2, which amounted to about 8%).

The polypeptide (fraction 1) was soluble in 80% aqueous phenol and 85% aqueous formic acid, and insoluble in glacial acetic acid,

*1 By these procedures the syrupy material changed gradually into powder.
*2 Sometimes the precipitate can dissolve in hot dimethylformamide.

pyridine, dimethylformamide, hot ethanol, water, benzene, chloroform and ethyl acetate. Found: C, 49.30; H, 7.41; N, 16.56. Calcd. for $(C_{13}H_{17}O_3N_3 \cdot H_2O)_n$: C, 48.96; H, 7.81; N, 17.13%*3. The phosphorus content of this material was determined by the method of Allen[14], and the value of 0.99% was obtained*4.

The average molecular weight of the polypeptides, fraction 1 and fraction 2 of poly-(L-leucylglycylglycine), was determined by titrating the end carboxyl groups with sodium methoxide in dimethylformamide[15], and the values of 3220 and 1730 were obtained for the fractions 1 and 2 respectively.

The infrared absoption bands which were characteristic for polypeptides could be observed at 3290, 1660, 1540 and 1250 cm^{-1}, especially in the fraction 1.

Further investigations on this condensation reaction are now in progress and details will be presented elsewhere.

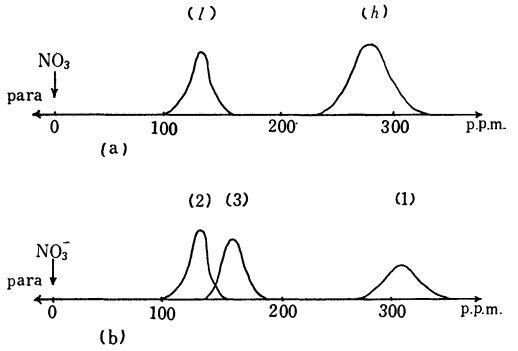

Fig. 1. NMR spectra of NaN_3 in aq. sol. (a) and $C_2H_5N_3$ (b).

Nuclear Magnetic Resonance of Azides

By Teinosuke KANDA, Yushiro SAITO and Kazutami KAWAMURA

(Received December 9, 1961)

We have measured, in a field of 16250 gauss, the chemical shift σ and the spin-lattice relaxation time T_1 of the N^{14} nuclear magnetic resonance (NMR) of the sodium azide in aqueous solution and of the ethyl azide.

As shown in Fig. 1 (a), NaN_3 gives two resonance lines. σ of the line of lower field side (*l*) is 130 p. p. m. and that of higher field side (*h*) is 280 p. p. m. where the origin of σ is resonance point of NO_3^-. The line width of *l* is narrower than that of *h* and the ratio of the absorption areas of *l* and *h* is equal to 1 : 2. As the atomic groups containing nitrogens which present in aqueous solution of NaN_3 we can cite three kinds, N_3^-, HN_3 and NaN_3, but the first is overwhelming in its quantity. The structure of the N_3^- is known to be linear[1] and so *l* must be the line of central nitrogen and *h* that of the both ends of the N_3^-. The origin of the line widths is mainly the spin-lattice relaxation and the T_1 values measured by the saturation method are 5.8 and 3.6 m. sec. for *l* and *h*, respectively.

Ethyl azide gives three lines, as shown in Fig. 1 (b), of equal intensity of which the σ's are 130, 160 and 310 p. p. m. respectively. The line widths increase in order from lower field one to higher one and their T_1 values are measured to be 4.5, 2.2 and 1.1 m. sec., respectively.

In methyl azide three nitrogen atoms are colinear and the angle CNN is 120° [1]. We expect that the ethyl azide might have the same structure as the methyl azide and we number the three nitrogen atoms 1, 2 and 3 from the carbon atom side.

The spectral position of the lowest line is just the same as the line *l* of the N_3^- and so this line is considered to arise from the central nitrogen (2). For the assignment of the other two lines, consider the electronic structures A and C given by Pauling[1],

A: $R-\ddot{N}=N^+=\ddot{N}^-:$

C: $R-\ddot{N}-N^+\equiv N:$

and calculate the number of unbalanced p-electron U_p by the method analogous to Townes and Dailey's[2]. As the atomic wave function of σ bonds we use the sp^2 hybridized orbital for nitrogen atom 1 and sp hybridized orbitals for 2 and 3.

1) L. Pauling, "The Nature of the Chemical Bond", 3rd Ed., Cornell University Press, p. 271.

In the Table I, the first and the second row show the U_p's of three N-atoms for the structure A and C respectively, and the last for the structure in which A and C are equally mixed.

TABLE I. NUMBER OF UNBALANCED p-ELECTRON OF NITROGEN ATOMS 1, 2 AND 3 OF AZIDE FOR THE STRUCTURES A AND C AND ALSO FOR THEIR EQUALLY MIXED STRUCTURE

	1	2	3
A	−2/3	0	0
C	−1/6	0	−1/2
	−5/12	0	−1/4

Since the spin-lattice relaxation is originated from the intramolecular quadrupole coupling, the inverse T_1 should be proportional to (e^2qQ^2) and hence to U_p^2. Therefore, we conclude that the line having the shortest T_1 is caused by the nitrogen atom 1 and the line having the medium T_1 by the atom 3. The assignment of three lines is indicated in Fig. 1 (b).

Several authors[3] have discussed on the NMR spectra of nitrogen. The spectra are separated into two groups; the first is the ammonia group distributing around the position $\sigma=300$ p. p. m. and the second is the nitro and CN-group around the position $\sigma=0$. It is remarkable that the azides have the lines belonging to each group. The diamagnetic shift due to *one* 1s electron or *one* 2s electron is calculated to be +120 and +17 p. p. m. respectively, and the paramagnetic shift due to *one* 2p electron to be −460 p. p. m. assuming the mean excitation energy of 5 eV. The chemical shift beyond 200 p. p. m. as displayed by the azides should be attributed to the paramagnetic shift of the 2p electron and so be proportional to U_p. But the experimental results are just in opposite direction; the line of the N-atom (1) having the largest U_p is the most diamagnetic. Such a contradiction was already found by Masuda[4] in the case of molecular chlorine compounds and the azides give the second example.

On the Mechanism of Pulp Bleaching. II[1]. *On the Residual Lignosulfonic Acid Existing Undissolved in Unbleached Sulfite Pulp*

By Koichiro SATO and Hiroshi MIKAWA

(Received December 19, 1960)

In order to make clear the mechanism of pulp bleaching, it is most important to know the chemical and physical nature of the residual lignin in unbleached pulp, in so far as it is the main material to be bleached. Knowledge about this residual lignin can be expected also to contribute to better understanding of the cooking mechanism of wood inasmuch as it will give information why some amount of lignin always remain undissolved in the pulp after the cooking.

Although there exist a few investigations into this lignin, not much is known as yet. Kawamura[2] prepared acetylated thiolignin from acetylated beech kraft pulp and showed that the thiolignin is chemically combined with xylose. Kratzl[3] compared the acid lignin obtained from unbleached pulp with that obtained from wood, concluding that they are at least partly identical. By nitrobenzene oxidation Bland[4] showed that there exists not much difference between the nuclear structures of the lignins in wood, in waste liquor and in unbleached pulp. Kullgren[5] extracted lignosulfonic acid from unbleached sulfite pulp by prolonged washing of the pulp and showed that the lignin thus obtained contained one carboxyl group per sulfonic acid group.

As for the reasons for the difficulty of dissolution of the total amount of lignin in the case of the sulfite process, one or several of the following reasons is conceivable.

1) Residual lignin is not sulfonated sufficiently, 2) it is firmly combined to carbohydrate, 3) it goes into solution with difficulty because of the morphological structure of its fiber, and 4) it is condensed to other lignin units during the digestion. As has been reported preliminarily before[6], we have succeeded in dissolving residual lignosulfonic acid from unbleached sulfite pulp by a drastic beating in water, which causes the fibrillation of the fiber. By this treatment any morphological hindrance to the dissolution of the lignin can be expected to be diminished. As is well known, the primary wall and the other layer of the secondary wall are said to be distructed successively by beating, while the fibrillation proceeds gradually into the middle layer of the secondary wall[7], thus enabling the dissolution of the low sulfonated residual lignosulfonic acid.

Residual lignosulfonic acid was isolated from the unbleached sulfite pulp prepared from a mixture of *Picea jezoensis* (spruce) and *Abies mariana* (fir), and the chemical nature of the isolated residual lignosulfonic acid was investigated. The isolable yield of the residual lignosulfonic acid thus obtained from the unbleached pulp is about one fifth of the total amount of lignin present in the pulp.

Experimental

Extraction of the Residual Lignosulfonic Acid.—540 g. of unbleached sulfite pulp from the mixture of *Picea jezoensis* and *Abies mariana* (Sieber Zahl 52, cuproammonium disperse viscosity (Japan Industrial Standard) 18.0 were suspended in water (21 l.) and beaten with a Niagara type 1 to 1/2 pound beater (TAPPI-Standard T200 m-45) for up to 20 hr. During the course of the beating, the SR-value, chlorine absorption[8], permanganate number (TAPPI-Standard T214m-50), specific surface area and degree of polymerization of the beaten pulp were measured and are shown by curves I, II, III, IV and V respectively in Fig. 1. The relative viscosity of the pulp was measured according to the Japan Industrial Standard, the specific outer surface area, by immersing the pulp in a solution of benzo fast scarlet 4BS and measuring the decrease of the absorption at 506 mμ[9], and the degree of polymerization, according to Okada's method[10].

Curve I shows that the SR-value approaches 100 after 10~12 hr., while the chlorine absorption (curve II) and the permanganate number (curve III) decrease monotonously. Although the SR-value reaches its maximum after 10~12 hr., the specific surface area of the fiber (curve IV) continues to increase, showing the progress of fibrillation. The degree of polymerization of the beaten pulp decreases along curve V.

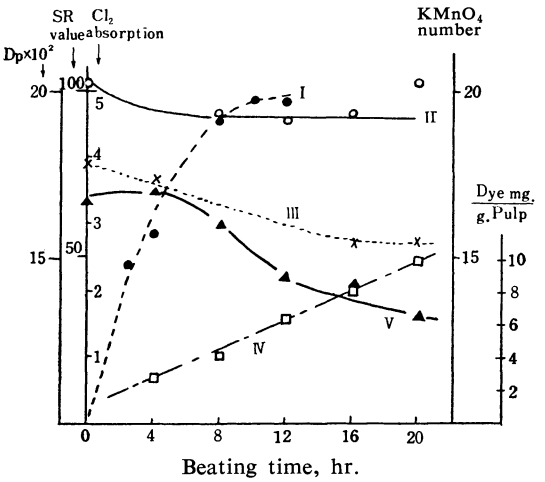

Fig. 1. Properties of the beaten unbleached sulfite pulp versus beating time. I, SR-value; II, Chlorine absorption; III, Permanganate number, IV, Specific surface; V, Degree of polymerization

The dissolution of the residual lignosulfonic acid was measured by the ultraviolet absorption spectra of the filtrate of the beaten pulp, which was diluted three times with water. Curve II in Fig. 2 shows the optical density at 280 mμ thus obtained, and curve III, the total amount of the dissolved lignosulfonic acid calculated from the optical density, assuming the molar extinction and methoxyl content of the lignosulfonic acid as 3000 and 11% respectively. As shown by curve II, the dissolved amount of lignosulfonic acid reaches its maximum at about 10~12 hr., although as stated previously the fibrillation continues to proceed even after this period of time. Curve I here is the same curve as curve I in Fig. 1.

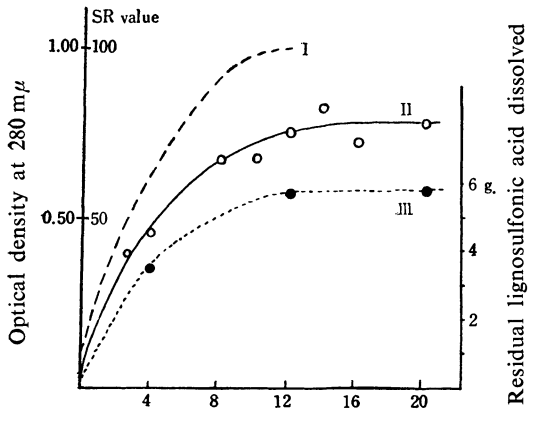

Fig. 2. Properties of beating water versus beating time. I, SR-value; II, Optical density of the beating water after being diluted three times with water; III, Calculated amount of the dissolved residual lignosulfonic acid.

After having been beaten for 20 hr., the pulp was separated by a centrifuge and washed with water, and the combined mother liquor and the washings (ca. 40 l.) were concentrated to 2 l. under 40°C in vacuo, centrifuged again in order to remove fine flocculating pulp fibers, and passed through ion exchange resin IR-120 in hydrogen form, after which the lignosulfonic acid was precipitated by adding 1-(*N*-piperidinoacetylamino)-naphthalene sulphate[11]. The precipitate was washed well with water, to which was added dilute sodium hydroxide solution until pH 8~9. After about one hour the separated free base was filtered and the filtrate passed through ion exchange resin IR-120 in hydrogen form, neutralized with barium carbonate until pH 6, centrifuged and poured into alcohol. The precipitated barium lignosulfonate was separated by centrifuge and then washed twice with alcohol, ether and petroleum ether successively. The yield was 5.5 g., which is not much less than the dissolved amount estimated from the optical density of the beating water (curve II, Fig. 2). As the total amount of the residual lignosulfonic acid contained in the pulp used is estimated as about 27.5 g., the isolated amount corresponds to about 20% of the total. The existence of no carbohydrate components in the sample was confirmed by paper chromatography after hydrolyzing the sample with 2% sulfuric acid at 100°C for 5 hr.[12] Anal. C, 45.36; H, 5.09; S, 3.73; Ba, 12.80; CH_3O, 11.12%.

Functional Groups of the Residual Lignosulfonic Acid.—As is well known, the conductometric titration curve of the lignosulfonic acid has two "breaks", the first being the completion of the neutralization of the sulfonic acid group. Richtzenhain proved[13] that lignin contains at least two types of phenolic hydroxyl groups; one is the phenolic hydroxyl group of the simple guaiacyl type (type I), and the other is that having a C–C side chain at the ortho position to the phenolic hydroxyl group of the guaiacyl type (type II). As was found by some of the present authors[14], the type I phenolic hydroxyl group was conductometrically titratable, while type II was untitratable; the second break represents the complete neutralization of the carboxyl group plus the type I phenolic hydroxyl group. It is possible to estimate the amount of both the types I and II phenolic hydroxyl groups separately by measuring the change in the $\Delta\varepsilon$-value[15] of the solution during the conductometric titration.

Barium salt of the residual lignosulfonic acid (500 mg.) was passed through ion exchange resin IR-120 in hydrogen form. The eluate was made up to 50 ml. and was titrated conductometrically with sodium hydroxide as usual (curve I, Fig. 3). The amount of sodium hydroxide consumed until the first break gives the amount of the sulfonic acid group, and that consumed between the first and the second break the amount of the carboxyl group

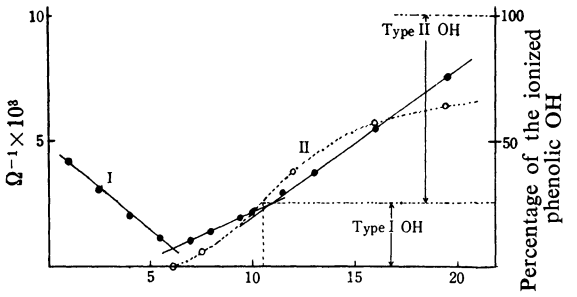

Fig. 3. Conductometric titration of the residual lignosulfonic acid. I, Conductivity; II, Ionization of phenolic hydroxyl group

plus the type I phenolic hydroxyl group. During the course of the titration the ultraviolet absorption spectra of the solution were measured by using a quartz cell 0.07 mm. thick. Curve II of Fig. 3 represents the percentage of the ionized phenolic hydroxyl group thus obtained. About 25% of the total phenolic hydroxyl group is ionized at the second break.

The amount of the type I phenolic hydroxyl group and the amount of the type II phenolic hydroxyl group were calculated separately, as was stated in a previous report[14]. Because, according to the $\Delta\varepsilon$-method of Erdtman[15], the amount of the total phenolic hydroxyl group is estimated as 0.23~0.19/CH_3O, the amount of the type I phenolic hydroxyl group is 0.06~0.05/CH_3O, that of type II, 0.17~0.14/CH_3O, and that of carboxyl group, 0.21/CH_3O. The amount of the sulfonic acid group is 0.32/CH_3O. The molecular formula of the residual lignosulfonic acid is thus expressed as follows:

$$C_9H_{10.55}O_{3.57}(CH_3O)_{0.95}(SO_3Ba/2)_{0.30}S^{neut}_{0.00}Ba^{excess}_{0.09}$$

in which $S^{neut}_{0.00}$ means non-acidic sulfur and $Ba^{excess}_{0.09}$, the amount of barium which is not combined with the sulfonic acid group.

Further Sulfonation of the Residual Lignosulfonic Acid.—As has been stated above, the degree of sulfonation of the residual lignosulfonic acid was only 0.32/CH_3O, much lower than the 0.6 of the ordinary lignosulfonic acid separated from the waste liquor. In order to know whether the residual lignosulfonic acid no longer has any sulfonatable group or if it has but remained unsulfonated during the sulfite cooking by, say, morphological reasons, further sulfonation of the residual lignosulfonic acid was attempted in a homogeneous solution.

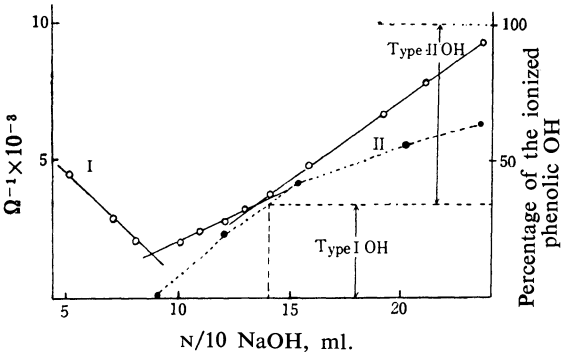

Fig. 4. Conductometric titration of the further sulfonated residual lignosulfonic acid. I, Conductivity; II, Ionization of phenolic OH

Residual lignosulfonic acid (2 g.) was dissolved in a cooking liquor of pH 1.8 (60 ml.) prepared from 5% sodium hydroxide solution and sulfur dioxide and heated at 135°C for 9 hr. The sulfonic acid was separated with 1-(*N*-piperidinoacetylamino)-naphthalene as usual and was obtained as barium salt. Anal. C, 39.92; H, 4.80; S, 5.28; Ba, 15.14; CH_3O, 10.30%. Total phenolic hydroxyl group, 0.24~0.19/CH_3O; type I phenolic hydroxyl group, 0.08~0.07/CH_3O; type II phenolic hydroxyl group, 0.16~0.12/CH_3O; carboxyl group, 0.26~0.25/CH_3O; SO_3H, 0.49/CH_3O. The molecular formula is as follows:

$$C_9H_{11.4}O_{4.08}(CH_3O)_{1.00}(SO_3Ba/2)_{0.49}S^{neut}_{0.01}Ba^{excess}_{0.08}$$

Discussion

The fact that the residual lignosulfonic acid in the unbleached sulfite pulp was at least partly dissolved out by drastic beating of the fiber in water seems to support strongly the thesis that this part of residual lignosulfonic acid remained undissolved in the fiber during the cooking because of morphological reasons. It is said that the residual lignin in the unbleached sulfite pulp is distributed across the whole section of the fiber, but the amount is larger near the outer surface[16] and near the inner surface around the lumen. As has been made evident in the present report, the dissolution of the residual lignosulfonic acid reaches its maximum when the SR-value of the beaten pulp reaches its maximum value of 100. Even though the outer specific surface of the fiber estimated by dye absorption continues to increase by prolonged beating, dissolution of any significant amount of the residual lignosulfonic acid was not observed any more. This fact will be well understood from the fact that during the beating process fibrillation proceeds from the surface of the fiber and that the amount of the residual lignin is comparatively larger near the outer surface of the fiber. As is shown in Table I, the residual lignosulfonic acid prepared carefully in the present paper contained no carbohydrates, although that prepared previously contained some. It seems, therefore, to be certain that there exists no chemical linkage between carbohydrates and the residual lignosulfonic acid obtained by beating.

*** $C_9H_{10.55}O_{3.57}(CH_3O)_{0.95}(SO_3Ba/2)_{0.30}S^{neut}_{0.00}Ba^{excess}_{0.09}$

**** $C_9H_{10.5}O_{3.31}(CH_3O)_{0.96}(SO_3Ba/2)_{0.66}S^{neut}_{0.02}Ba^{excess}_{0.04}$

***** $C_9H_{11.4}O_{4.08}(CH_3O)_{1.00}(SO_3Ba/2)_{0.49}S^{neut}_{0.01}Ba^{excess}_{0.08}$

Functional groups of the residual lignosulfonic acid and of the further sulfonated products obtained therefrom are summarized in Table I. The amount of the sulfonic acid group of the residual lignosulfonic acid, ca. 0.3 per C_9-unit, is low, of the same order of magnitude with that of the so-called low sulfonated lignosulfonic acid prepared from sulfonated wood by the Kullgren procedure, and also approximately half the amount of the sulfonic acid group of the ordinary lignosulfonic acid separated from waste liquor. 0.3 sulfonic acid groups per C_9-unit will be the lower limit of the degree of sulfonation which renders the lignin soluble. The degree of sulfonation could doubled by sulfonating further in the homogenous phase. Nearly half of the sulfonatable groups in lignin seems, therefore, to remain intact in the residual lignosulfonic acid.

The amount of the carboxyl group, 0.11～0.16, of the residual lignosulfonic acid is higher than that of low sulfonated lignosulfonic acid (0.08～0.1) and somewhat lower than that of ordinary lignosulfonic acid (0.16～0.17). The comparatively low degree of sulfonation and the low content of the carboxyl group in residual lignosulfonic acid seem to suggest that the action of the cooking acid is somewhat milder on the lignin in the fiber. The fact that the rather drastic condition of 135°C, for 9 hr., which nearly doubles the content of the carbonyl group in lignin, was required to elevate the degree of sulfonation to 0.5～0.6 seems to suggest that the sulfonatable group remaining in residual lignosulfonic acid is rather difficult to sulfonate in nature.

The ratio of the type I phenolic hydroxyl group to type II is about 1/3, being approximately the same as gymnosperm[17] α-lignosulfonic acid. The value is distinctly lower than that of low sulfonated lignosulfonic acid and of birch α-lignosulfonic acid. The total amount of the phenolic hydroxyl group is about the same as that of the ordinary α-lignosulfonic acid. Although the ratio of the type I phenolic hydroxyl group to type II, I/II, decreases somewhat with the further sulfonation of the low sulfonated lignosulfonic acid, the ratio increases from 1/3 to 1/2 with the further sulfonation of the residual lignosulfonic acid.

The authors wish to express their sincere thanks to Professor Yoshikazu Hachihama of Osaka University, for his unfailing kindness

Fundamentals of Statistical Thermodynamics

By Noboru NAGASAKO

(Received June 15, 1961)

Physico-chemical phenomena in stationary states obey not only thermodynamics, but also the theoretical probability distributions of mathematical statistics. These two branches of science can be connected more closely by a new definition of entropy.

1. Probability of Microscopic States. — We confine our attention to a homogeneous system in a stationary state which has been placed for a long period of time in a thermostat of temperature T. Let $\varepsilon_i (i=0, 1, \cdots\cdots, r)$ denote the energy level of a single particle, and n_i the number of particles in state ε_i. If the particles are independent, the probability of the microscopic states assigned by $n_0, n_1, \cdots\cdots, n_r$ will be given by

$$p(n_0, n_1, \cdots\cdots, n_r) = W \cdot {p_0}^{n_0} {p_1}^{n_1} \cdots\cdots {p_r}^{n_r} / \Xi \quad (1.1)$$

in which p_i denotes the relative probability of finding a particle in state ε_i, W a statistical weight or the number of complexions, and Ξ a normalizing factor.

For example, if we set $p_0+p_1+\cdots\cdots+p_r=1$, we have

$$1=(\sum_i p_i)^N=\sum \frac{N!}{n_0!\, n_1! \cdots n_r!} {p_0}^{n_0} {p_1}^{n_1} \cdots {p_r}^{n_r}$$

We have, therefore, as the multinomial distribution for N independent events, $(0<p_i<1)$,

$$p(n_0, n_1, \cdots\cdots, n_r) = \frac{N!}{n_0!\, n_1! \cdots\cdots n_r!} {p_0}^{n_0} {p_1}^{n_1} \cdots\cdots {p_r}^{n_r} \quad (1.2)$$

in which $N=\sum_i n_i=\sum_i \bar{n}_i$ and $\Xi=1$.

If every state ε_i is g_i-fold degenerate, and if we set $\sum_i g_i p_i=1$, in place of $\sum_i p_i=1$, we have

$$p(n_0, n_1, \cdots\cdots, n_r) = N! \frac{{g_0}^{n_0} {g_1}^{n_1} \cdots\cdots {g_r}^{n_r}}{n_0!\, n_1! \cdots\cdots n_r!} {p_0}^{n_0} {p_1}^{n_1} \cdots\cdots {p_r}^{n_r} \quad (1.3)$$

On the other hand, we have by binomial expansions

$$1=(1+p)^g/(1+p)^g=\sum \binom{g}{n} p^n/(1+p)^g$$

and $$1=(1-p)^{-g}/(1-p)^{-g} = \sum \binom{g+n-1}{n} p^n/(1-p)^{-g}$$

We have, therefore, as the product of binomial distributions

$$p(n_0, n_1, \cdots\cdots, n_r) = \prod_i \binom{g_i}{n_i} {p_i}^{n_i}/(1+p_i)^{g_i} \quad (0<p_i) \quad (1.4)$$

and $$p(n_0, n_1, \cdots\cdots, n_r) = \prod_i \binom{g_i+n_i-1}{n_i} {p_i}^{n_i}/(1-p_i)^{-g_i} \quad (0<p_i<1) \quad (1.5)$$

For (1.4) and (1.5) we have $\bar{N}=\sum_i \bar{n}_i$

and $$\Xi=\prod_i (1 \pm p_i)^{\pm g_i} \quad (1.6)$$

When $p_i \ll 1$, both (1.4) and (1.5) lead to the multiple Poisson distribution given by

$$p(n_0, n_1 \cdots\cdots n_r) = \exp[-\bar{N}] \times \frac{{g_0}^{n_0} {g_1}^{n_1} \cdots\cdots {g_r}^{n_r}}{n_0!\, n_1! \cdots\cdots n_r!} {p_0}^{n_0} {p_1}^{n_1} \cdots\cdots {p_r}^{n_r} \quad (1.7)$$

It is evident that these theoretical probability distributions may be reduced to (1.1). In place of the ergodic hypothesis by Boltzmann, the equal a priori probability of finding a particle in each energy level of a single particle has been postulated by ${p_i}^{n_i}$ of (1.1).

When a probability distribution is given, we can obtain the mean value and the other moments by a moment-generating function[1] defined by $\Phi=\sum p(x)\exp[xt]$, where $p(x)$ denotes the probability of a random variable x. Hence, we have

1) P. G. Hoel, "Introduction to Mathematical Statistics", John Wiley and Sons, Inc., New York (1951).

$$\Phi=\sum_x p(x)(1+xt+\cdots\cdots+x^m t^m/m!+\cdots\cdots)$$

$$=1+\bar{x}t+\cdots\cdots+\overline{x^m}t^m/m!+\cdots\cdots$$

Differentiating Φ with respect to t, and putting $t=0$,

$$\overline{x^m}=\left.\frac{\partial^m\Phi}{\partial t^m}\right|_{t=0} \tag{1.8}$$

The moment-generating function for the multinomial distribution will be given by

$$\Phi=(p_0+p_1+\cdots\cdots+e^t p_i+\cdots\cdots+p_r)^N \tag{1.9}$$

Hence, $$\bar{n}_i=\left.\frac{\partial\Phi}{\partial t}\right|_{t=0}=Np_i \tag{1.10}$$

The moment-generating function for the binomial distributions will be given by

$$\Phi=(1\pm e^t p_i)^{\pm g_i}(1\pm p_i)^{\mp g_i} \tag{1.11}$$

Hence, $$\bar{n}_i=\left.\frac{\partial\Phi}{\partial t}\right|_{t=0}=g_i p_i/(1\pm p_i) \tag{1.12}$$

2. Probability and Entropy. — The probability (1.1) is given in a form $W\times P$, where

$$P=p_0^{n_0}p_1^{n_1}\cdots\cdots p_r^{n_r}/\Xi$$

denotes the probability of a set of microscopic states. Taking the logarithm of P, we have

$$\ln P=\sum_i n_i\ln p_i-\ln\Xi$$

The mean value of $\ln P$ is given by

$$\overline{\ln P}=\sum_i \bar{n}_i\ln p_i-\ln\Xi$$

We define the entropy not by $S=k\ln W$, but by

$$S=-k\overline{\ln P}$$

i. e., $$S=-k\sum_i \bar{n}_i\ln p_i+k\ln\Xi \tag{2.1}$$

in which k denotes Boltzmann's constant.

We have, therefore, by (1.2)

$$S=-k\sum_i \bar{n}_i\ln p_i \tag{2.2}$$

and then we have by (1.10)

$$S=-kN\sum_i p_i\ln p_i$$

or $$S=-k\sum_i \bar{n}_i\ln\bar{n}_i+k\sum_i \bar{n}_i\ln N \tag{2.3}$$

We have by (1.6) and (2.1)

$$S=-k\sum_i \bar{n}_i\ln p_i\pm k\sum_i g_i\ln(1\pm p_i) \tag{2.4}$$

and then we have by (1.12)

$$S=-k\sum_i \bar{n}_i\ln\bar{n}_i\pm k\sum_i g_i\ln g_i$$

$$\mp k\sum_i(g_i\mp\bar{n}_i)\ln(g_i\mp\bar{n}_i) \tag{2.5}$$

Thus we obtain the entropies, nearly identical with the familiar expressions, without the aid of Stirling's approximation formula.

By differentiation of (2.2) we have

$$dS=-k\sum_i \ln p_i d\bar{n}_i$$

Since every g_i is maintained constant at constant volume, we have by differentiation of (2.4) at constant volume V

$$(dS)_V=-k\sum_i \ln p_i(d\bar{n}_i)_V$$

We may generalize the above results by differentiation of (2.1), which gives

$$dS=-k\sum_i \ln p_i d\bar{n}_i-k\sum_i \bar{n}_i d\ln p_i+k d\ln\Xi$$

We have, therefore,

$$dS=-k\sum_i \ln p_i d\bar{n}_i \tag{2.6}$$

if we may write

$$\sum_i \bar{n}_i d\ln p_i=0 \quad\text{and}\quad d\ln\Xi=0 \tag{2.7}$$

which is fulfilled to obtain (2.6) form (2.2). We have also

$$(dS)_V=-k\sum_i \ln p_i(d\bar{n}_i)_V \tag{2.8}$$

if we may write

$$\sum_i \bar{n}_i(d\ln p_i)_V=(d\ln\Xi)_V$$

i. e., $$\bar{n}_i=(\partial\ln\Xi/\partial\ln p_i)_V \tag{2.9}$$

which is fulfilled to obtain (2.8) from (2.4).

Now let us assume that a system obeys the thermodynamic equation

$$dU=TdS-pdV+\mu dN_t \tag{2.10}$$

in which U denotes the energy, p the pressure, μ the chemical potential, and N_t the total number of particles of the system. We have, therefore, at constant volume

$$(dU)_V=T(dS)_V+\mu(dN_t)_V \tag{2.11}$$

When the particles are independent, we may write

$$E=\varepsilon_0 n_0+\varepsilon_1 n_1+\cdots\cdots+\varepsilon_r n_r \tag{2.12}$$

and $$\bar{E}=\varepsilon_0\bar{n}_0+\varepsilon_1\bar{n}_1+\cdots\cdots+\varepsilon_r\bar{n}_r \tag{2.13}$$

in which E denotes the total energy of the system and $\bar{E}$ its mean value. Writing $U=\bar{E}$, we have

$$dU=\sum_i \varepsilon_i d\bar{n}_i+\sum_i \bar{n}_i d\varepsilon_i$$

Since we may write, in general, $d\varepsilon_i=0$ for $dV=0$, it follows that

$$(dU)_V=\sum_i \varepsilon_i(d\bar{n}_i)_V \tag{2.14}$$

Moreover, we may write

$$dN_t=\sum_i d\bar{n}_i \tag{2.15}$$

Substituting (2.8), (2.14) and (2.15) into (2.11), we have

$$\sum_i(\varepsilon_i+kT\ln p_i-\mu)(d\bar{n}_i)_V=0$$

Since we may write, in general, $(d\bar{n}_i) \neq 0$, it follows that

$$\varepsilon_i + \boldsymbol{kT} \ln p_i - \mu = 0$$

or
$$p_i = \exp[(\mu - \varepsilon_i)/\boldsymbol{kT}] \qquad (2.16)$$

which enormously simplifies the discussions.

Substituting (2.16) into (2.1), we obtain as the general equation of statistical-thermodynamic entropy

$$\boldsymbol{S} = \bar{E}/T - \mu \sum_i \bar{n}_i/T + \boldsymbol{k} \ln \Xi \qquad (2.17)$$

Since the Gibbs free energy of a homogeneous system will be given by $G = \mu \sum_i \bar{n}_i$, it follows that

$$pV = \boldsymbol{kT} \ln \Xi \qquad (2.18)$$

3. Fermi-Dirac and Bose-Einstein Statistics. —Dividing the $2f$-dimensional μ-space into many cells with the volume $\boldsymbol{h}^f$, where $\boldsymbol{h}$ denotes Planck's constant and f the degrees of freedom for a single particle, we shall find g_i cells for the same energy ε_i, when a state ε_i is g_i-fold degenerate. We now try to discover the law of probability by which these cells will be occupied by the particles.

If there are n_i particles in a g_i-fold degenerate energy level ε_i, and if the particles obey the Fermi-Dirac statistics, it is known that the number of complexions will be given by[2]

$$W(\text{Fermi-Dirac}) = \prod_i \binom{g_i}{n_i} \qquad (3.1)$$

and for the Bose-Einstein statistics

$$W(\text{Bose-Einstein}) = \prod_i \binom{g_i + n_i - 1}{n_i} \qquad (3.2)$$

We may consider by (1.1) and (3.1) that the probability distribution for the Fermi-Dirac statistics will be given by (1.4), the product of positive binomial distributions. Similarly, by (3.2) we obtain (1.5), the product of negative binomial distributions, for the Bose-Einstein statistics. Moreover, it is assumed by (1.4) and by (1.5) that the particles occupy each energy level independently.

The translational energy of an independent material particle of mass m in a state described by the three quantum numbers, k_x, k_y, k_z, is given by $\varepsilon_i = \boldsymbol{h}^2(k^2_x + k^2_y + k^2_z)/8mV^{2/3}$, which gives $d\varepsilon_i = 0$ for $dV = 0$. The energy of a photon in given by $\varepsilon_i = \boldsymbol{h}\nu$, i. e., $d\varepsilon_i = 0$. We may use (2.14), therefore, to obtain (2.16).

We may write for material particles $g_i = 4\pi V q^2 dq/\boldsymbol{h}^3$, in which q denotes the momentum of a single particle, and for photons, $g_i = (8\pi V/c^3)\nu^2 d\nu$. At constant volume, therefore, every g_i remains constant. Taking the logarithm of (1.6) for the probability distributions (1.4) and (1.5), we have

$$\ln \Xi = \pm \sum_i g_i \ln(1 \pm p_i)$$

Hence, $$(d \ln \Xi)_V = \sum_i g_i dp_i/(1 \pm p_i)$$

Since we have by (1.12)

$$\bar{n}_i = g_i p_i/(1 \pm p_i)$$

it follows that

$$\bar{n}_i = (\partial \ln \Xi/\partial \ln p_i)_V$$

which is the condition (2.9) to obtain (2.8).

Having examined the derivation of (2.16), and substituting (2.16) into (1.6), we have

$$\Xi = \prod_i (1 \pm \exp[(\mu - \varepsilon_i)/\boldsymbol{kT}])^{\pm g_i} \qquad (3.3)$$

Substituting (3.3) into (2.17), we obtain as the statistical-thermodynamic entropy of the Fermi-Dirac and the Bose-Einstein system

$$\boldsymbol{S} = \bar{E}/T - \mu \bar{N}/T \pm \boldsymbol{k} \sum_i g_i \ln(1 \pm \exp[(\mu - \varepsilon_i)/\boldsymbol{kT}]) \qquad (3.4)$$

Substituting (3.3) into (2.18), we obtain

$$pV = \pm \boldsymbol{kT} \sum_i g_i \ln(1 \pm \exp[(\mu - \varepsilon_i)/\boldsymbol{kT}]) \qquad (3.5)$$

Substituting (2.16) into (1.12), we obtain as the distribution law

$$\bar{n}_i = g_i \exp[(\mu - \varepsilon_i)/\boldsymbol{kT}] / (1 \pm \exp[(\mu - \varepsilon_i)/\boldsymbol{kT}]) \qquad (3.6)$$

Although a different method has been used to obtain (3.4), (3.5) and (3.6), these equations are identical with those proposed by Fowler and Guggenheim[3].

When $p_i \ll 1$, we have by (1.6)

$$\Xi = \exp[\sum_i g_i p_i]$$

and by (1.12)

$$\bar{n}_i = g_i p_i \qquad (3.7)$$

Hence, $$\Xi = \exp[\sum \bar{n}_i]_i = \exp[\bar{N}] \qquad (3.8)$$

The probability distribution for this case is given, therefore, by the multiple Poisson distribution (1.7), in which

$$W = \prod_i g_i^{n_i}/n_i ! \qquad (3.9)$$

Substituting (3.8) into (2.17), we have

$$\boldsymbol{S} = \bar{E}/T - \mu \bar{N}/T + \boldsymbol{k}\bar{N} \qquad (3.10)$$

Substituting (3.8) into (2.18), we obtain the equation of the state of an ideal gas given by $pV = \boldsymbol{kT}\bar{N}$.

Substituting (2.16) into (3.7), we obtain the Boltzmann distribution law for an ideal gas given by

2) J. E. Mayer and M. G. Mayer, "Statistical Mechanics", John Wiley & Sons, Inc., New York (1940), p. 111.

3) R. H. Fowler and E. A. Guggenheim, "Statistical Thermodynamics", Cambridge University Press (1939). pp. 50-67, 234.

$$\bar{n}_i = g_i \exp[(\mu - \varepsilon_i)/\boldsymbol{k}T] \quad (3.11)$$

Hence, $$\bar{N} = \sum_i \bar{n}_i = (p.f.)\exp[\mu/\boldsymbol{k}T] \quad (3.12)$$

where $(p.f.)$ denotes the partition function. We can eliminate, therefore, μ from (3.10) by (3.12) to obtain

$$S = \bar{E}/T + \boldsymbol{k}\bar{N}\ln[(p.f.)/\bar{N}] + \boldsymbol{k}\bar{N} \quad (3.13)$$

which is identical with the Sackur-Tetrode equation for the entropy of an ideal gas.

4. Multinomial Distributions.—In statistical mechanics the number of complexions was given first by

$$W = N!/n_0!\ n_1!\cdots\cdots n_r! \quad (4.1)$$

which may be interpreted as the number of ways that $n_0, n_1, \cdots\cdots, n_r$ identical particles with energies $\varepsilon_0, \varepsilon_1, \cdots\cdots, \varepsilon_r$ will be placed in N numbered, i. e., physically distinguishable, cells, one particle to each cell. The particles may or may not be localized, although the application of (4.1) has been restricted to the localized particles by Fowler and Guggenheim[4].

When W is given by (4.1), we obtain the multinomial distribution (1.2), with $\Xi = 1$. It may be noticed that we have $\Xi = (\sum_i p_i)^N$ for (4.1), if we set $\sum_i p_i \neq 1$. However, we can reduce this probability distribution to (1.2), if W is given by (4.1). When every state ε_i is g_i-fold degenerate, we have the probability distribution (1.3)

and $$W = N! \prod_i g_i^{n_i}/n_i! \quad (4.2)$$

Substituting $\Xi = 1$ into (3.18), we obtain $pV = 0$. We may apply the probability distributions (1.2) and (1.3), therefore, to the vibrational and rotational motions of gas molecules, since these motions have nothing to do with pV. In these cases we may omit the term $p\mathrm{d}V$ in (2.10) and may write $\mathrm{d}\varepsilon_i = 0$, i. e.,

$$\mathrm{d}U = \sum_i \varepsilon_i \mathrm{d}\bar{n}_i \quad (4.3)$$

We have, therefore, by (2.10), (4.3), (2.6) and (2.15)

$$\sum_i (\varepsilon_i + \boldsymbol{k}T \ln p_i - \mu_0)\mathrm{d}\bar{n}_i = 0$$

or $$p_i = \exp[(\mu_0 - \varepsilon_i)/\boldsymbol{k}T] \quad (4.4)$$

Substituting $\Xi = 1$ and (4.4) into (2.1), we have

$$S = \bar{E}/T - \mu_0 N/T \quad (4.5)$$

which is also obtained by substituting $\Xi = 1$ into (2.17). Denoting by A the Helmholtz free energy, we have, therefore, $\mu_0 = A/N$ which holds for the systems with $pV = 0$ and which has been distinguished from $\mu = G/N$.

Substituting (4.4) into $\sum_i p_i = 1$ of (1.2) and into $\sum_i g_i p_i = 1$ of (1.3), we have

$$1 = (p.f.)\exp[\mu_0/\boldsymbol{k}T] \quad (4.6)$$

We can eliminate, therefore, μ_0 from (4.5) by (4.6) to obtain

$$S = \bar{E}/T + \boldsymbol{k}\ln[(p.f.)^N] \quad (4.7)$$

For the non-localized gas molecules, the entropy due to vibrations of atoms and that due to rotations can be calculated by (4.7); these results have been verified by experiments.

Substituting (4.4) into (1.10), we have again the Boltzmann distribution law given by

$$\bar{n}_i = N \exp[(\mu_0 - \varepsilon_i)/\boldsymbol{k}T] \quad (4.8)$$

For the probability distribution (1.3), we have

$$\bar{n}_i = N g_i \exp[(\mu_0 - \varepsilon_i)/\boldsymbol{k}T] \quad (4.9)$$

We could also apply the probability distribution (1.2) and (1.3) to the localized oscillators in a crystal at low pressures.

If the number of complexions is given by (3.9), we can construct another probability distribution, i. e., the multinomial distribution for the translational motions of an ideal gas. If we set $N = \sum_i g_i p_i$, we have

$$1 = (\sum_i g_i p_i/N)^N = (N!/N^N)\sum \prod_i g_i^{n_i} p_i^{n_i}/n_i! \quad (4.10)$$

Hence,

$$p(n_0, n_1, \cdots\cdots, n_r) = (N!/N^N)\prod_i g_i^{n_i} p_i^{n_i}/n_i! \quad (4.11)$$

and $\bar{n}_i = g_i p_i$ which is identical with (3.7).

Substituting $\Xi = N^N/N!$ and (3.7) into (2.1), we have

$$S = -\boldsymbol{k}\sum_i g_i p_i \ln p_i + \boldsymbol{k}\ln(N^N/N!) \quad (4.12)$$

Differentiating (4.12) at constant V and N, we have

$$(\mathrm{d}S)_{N,V} = -\boldsymbol{k}\sum_i \ln p_i (\mathrm{d}\bar{n}_i)_{N,V} \quad (4.13)$$

Substituting (2.14) and (4.13) into the thermodynamic equation $(\mathrm{d}U)_{N,V} = T(\mathrm{d}S)_{N,V}$, we have

$$\sum_i (\varepsilon_i + \boldsymbol{k}T \ln p_i)(\mathrm{d}\bar{n}_i)_{N,V} = 0$$

Since $\sum_i (\mathrm{d}\bar{n}_i)_{N,V} = 0$, we may write

$$\varepsilon_i + \boldsymbol{k}T \ln p_i = \mu' \text{ (constant)}$$

or $$p_i = \exp[(\mu' - \varepsilon_i)/\boldsymbol{k}T] \quad (4.14)$$

Substituting (4.14) into (4.12), we have

$$S = \bar{E}/T - \mu' N/T + \boldsymbol{k}\ln(N^N/N!) \quad (4.15)$$

Since $N = \sum_i g_i p_i$, it follows that

$$N = (p.f.)\exp[\mu'/\boldsymbol{k}T] \quad (4.16)$$

Now we can eliminate μ' from (4.15) by (4.16) to obtain

4) R. H. Fowler and E. A. Guggenheim, loc. cit., pp. 20-29.

$$S=\bar{E}/T+\boldsymbol{k}\ln[(p.f.)^N/N!] \qquad (4.17)$$

which is identical with (3.13), when $\bar{N}=N\gg 1$.

Comparing (4.7) with (4.17), we find the well known difference, $N!$, in the divisor, which is often introduced ambiguously to obtain (4.17) from (4.7). It is evident that the number of complexions ((4.1) or (4.2)) and the entropy (4.7) can be applied solely to the system with $pV=0$. It is not legitimate, therefore, to try to obtain (4.17) for $pV=\boldsymbol{k}TN$ from (4.7) for $pV=0$, although the difference between these equations is apparently simple.

5. Grand-canonical and Canonical Distributions. — Substituting (2.16) into (1.1) and considering (2.12) and (2.18), we have

$$p(n_0, n_1, \cdots\cdots, n_r) = W\exp[(\mu N-E-pV)/\boldsymbol{k}T] \qquad (5.1)$$

Denoting by Ω the total number of complexions for the given N, E, and by $\sum_c$ the conditioned sum of W of which $n_0, n_1, \cdots\cdots, n_r$ satisfy the given N, E, we may write

$$\Omega(N, E)=\sum_c W(n_0, n_1, \cdots\cdots, n_r) \qquad (5.2)$$

The probability that the system contains N particles and is in state E is given, therefore, by

$$p(N, E)=\Omega(N, E)\exp[(\mu N-E-pV)/\boldsymbol{k}T] \qquad (5.3)$$

which corresponds to the Gibbs grand ensemble canonically distributed[5], i. e., the grand-canonical distribution. The probability distributions ((1.4), (1.5) for the Fermi-Dirac and Bose-Einstein statistics and (1.7) for an ideal gas) lead, therefore, to the grand-canonical distributions.

Substituting $\Xi=1$ and (4.4) into (1.1), we have

$$p(n_0, n_1, \cdots\cdots, n_r)=W\exp[(\mu_0 N-E)/\boldsymbol{k}T] \qquad (5.4)$$

The probability that the system is in state E is given, therefore, by

$$p(E)=\Omega(N, E)\exp[(A-E)/\boldsymbol{k}T] \qquad (5.5)$$

which corresponds to the Gibbs canonical distribution. The multinomial distributions ((1.2) and (1.3)) lead, therefore, to the canonical distributions.

Substituting (4.14) into (1.1), we have

$$p(n_0, n_1, \cdots\cdots, n_r) = W\exp[(\mu' N-E-\boldsymbol{k}T\ln\Xi)/\boldsymbol{k}T] \qquad (5.6)$$

Since we may write by (4.15) $A=\mu' N-\boldsymbol{k}T\ln\Xi$, we have again (5.5) for $p(E)$. The probability distribution (4.11) for an ideal gas leads, therefore, to the canonical distribution. It may be mentioned that it is difficult to treat the Fermi-Dirac and the Bose-Einstein statistics canonically, since, for these statistics, there is no simple probability distribution in which the total number of particles is maintained constant, while the total energy is variable.

For the linear harmonic oscillators with frequency ν, i. e., $\varepsilon_i=\boldsymbol{h}\nu/2+i\boldsymbol{h}\nu (i=0, 1, \cdots\cdots, \infty)$, we have by (4.4)

$$\begin{aligned} 1&=(\sum_i p_i)^N \\ &=(1-\exp[-\boldsymbol{h}\nu/\boldsymbol{k}T])^{-N}\cdot \\ &\quad \exp[\mu_0 N/\boldsymbol{k}T-N\boldsymbol{h}\nu/2\boldsymbol{k}T] \\ &=\sum_{J=0}^{\infty}\binom{N+J-1}{J}\exp[(A-E)/\boldsymbol{k}T] \end{aligned}$$

in which $E=N\boldsymbol{h}\nu/2+J\boldsymbol{h}\nu (J=0, 1, \cdots\cdots, \infty)$. We have, therefore the canonical distribution in a compact form

$$p(E)=\binom{N+J-1}{J}\exp[(A-E)/\boldsymbol{k}T] \qquad (5.7)$$

for which we may write by (5.2) and (5.5)

$$\Omega(N, E)=\binom{N+J-1}{J}=\sum_c N!/n_0!\ n_1!\cdots\cdots n_r!$$

Thus we obtain, in general, either the canonical or the grand-canonical distribution by the probability distribution (1.1).

6. Fluctuations. — By means of a moment-generating function we can calculate fluctuations. We have by (1.8) as the variance

$$\sigma^2=(\overline{x^2})-(\bar{x})^2=\frac{\partial^2\Phi}{\partial t^2}\bigg|_{t=0}-\left(\frac{\partial\Phi}{\partial t}\right)^2\bigg|_{t=0}$$

Calculations will be performed more simply by the following relations:

$$\frac{\partial\ln\Phi}{\partial t}=\frac{1}{\Phi}\frac{\partial\Phi}{\partial t}$$

and

$$\frac{\partial^2\ln\Phi}{\partial t^2}=\frac{1}{\Phi}\frac{\partial^2\Phi}{\partial t^2}-\frac{1}{\Phi^2}\left(\frac{\partial\Phi}{\partial t}\right)^2$$

Since $\Phi(t=0)=1$, it follows that

$$\bar{x}=\frac{\partial\ln\Phi}{\partial t}\bigg|_{t=0}$$

and

$$\sigma^2=\frac{\partial^2\ln\Phi}{\partial t^2}\bigg|_{t=0} \qquad (6.1)$$

For the binomial distributions (1.4) and (1.5), we have by (6.1) and the moment-generating function (1.11)

$$\sigma^2=(\overline{n_i^2})-(\bar{n}_i)^2=g_i p_i/(1\pm p_i)^2 \qquad (6.2)$$

Since the particles occupy each energy level independently, we have for $N=\sum_i n_i$

5) J. W. Gibbs, "Elementary Rrinciples in Statistical Mechanics", Yale University Press (1902).

$$\sigma^2{}_N=\overline{(N^2)}-(\overline{N})^2=\sum_i g_i p_i/(1\pm p_i)^2 \quad (6.3)$$

and for $E=\sum_i \varepsilon_i n_i$

$$\sigma^2{}_E=\overline{(E^2)}-(\overline{E})^2=\sum_i \varepsilon^2{}_i g_i p_i/(1\pm p_i)^2 \quad (6.4)$$

For the multiple Poisson distribution (1.7), in which $p_i \ll 1$, we have

$$\sigma^2{}_N=\sum_i g_i p_i=\overline{N}$$

and

$$\sigma^2{}_E=\sum_i \varepsilon^2{}_i g_i p_i=\sum_i \varepsilon^2{}_i \bar{n}_i \quad (6.5)$$

Applying (1.7) to an ideal gas, and setting $g_i=4\pi V\, q^2 \mathrm{d}q/\boldsymbol{h}^3$, we have by (2.13) and (3.11)

$$\overline{E}=\exp[\mu/\boldsymbol{kT}]\cdot(2\pi V/m\boldsymbol{h}^3)$$
$$\times\int_0^\infty q^2\exp[-q^2/2m\boldsymbol{kT}]\cdot \mathrm{d}q$$
$$=\exp[\mu/\boldsymbol{kT}]\cdot(3/2)\boldsymbol{kT}\cdot V(2\pi m\boldsymbol{kT})^{3/2}/\boldsymbol{h}^3$$

Since $(p.f.)=V(2\pi m\boldsymbol{kT})^{3/2}/\boldsymbol{h}^3$, we have by (3.12)

$$\overline{E}=\overline{N}(3/2)\boldsymbol{kT} \quad (6.6)$$

We have by (3.11) and (6.5)

$$\sigma^2{}_E=\overline{N}(15/4)(\boldsymbol{kT})^2$$

i. e.,

$$\sigma_E=\sqrt{\overline{N}}(\sqrt{15}/2)\boldsymbol{kT} \quad (6.7)$$

On the other hand, we have, in general, with respect to the variance

$$\sigma^2=\int_{-\infty}^{\infty}(x-\bar{x})^2 p(x)\mathrm{d}x=\int_{|x-\bar{x}|\geqq\xi\sigma}+\int_{|x-\bar{x}|<\xi\sigma}$$

Since

$$\int_{|x-\bar{x}|\geqq\xi\sigma}\geqq\xi^2\sigma^2 p(|x-\bar{x}|\geqq\xi\sigma)$$

we obtain Tchebychev's theorem given by

$$p(|x-\bar{x}|\geqq\xi\sigma)\leqq 1/\xi^2$$

where $p(|x-\bar{x}|\geqq\xi\sigma)$ denotes the probability that the deviation from the mean value $x-\bar{x}$ is greater than $\xi\sigma$.

We have, therefore, as the estimations for the grand ensemble

$$p(|N-\overline{N}|\geqq 100\sigma_N)\leqq 0.0001$$

and

$$p(|E-\overline{E}|\geqq 100\sigma_E)\leqq 0.0001 \quad (6.8)$$

For an ideal gas obeying (1.7), we may write $\overline{N}=2.7\times10^{19}$/cc. at N. T. P and by (6.5) $\sigma_N=\sqrt{\overline{N}}=5.2\times10^9$. $\overline{E}$ is given by (6.6) proportional to $\overline{N}$. σ_E is given by (6.7) proportional to $\sqrt{\overline{N}}$. It is evident, therefore, that we may neglect the probability of finding a system with N, E deviated from the physically observable mean values $\overline{N}, \overline{E}$. In other words, there is no significant difference between the grand ensemble from (1.7) for an ideal gas and the micro-canonical ensemble in which the total number of particles is fixed and the total energy falls within the narrow limits between E and $E+\Delta E$.

This is also the case with the Fermi-Dirac statistics. Comparing (6.3) and (6.4) with (6.5), it is seen that the probability distribution (1.4) for the Fermi-Dirac statistics is more sharply concentrated near the mean values than the distribution (1.7).

The probability distribution (1.5) for the Bose-Einstein statistics is more broadly distributed than the distribution (1.7). Applying the distribution (1.5) to the temperature radiation, and setting $g_i=(8\pi V/c^3)\,\nu^2\mathrm{d}\nu$, $\mu=0$ and $x=\boldsymbol{h}\nu/\boldsymbol{kT}$, we have by (3.6)

$$\overline{N}=(8\pi V/c^3)\int_0^\infty \nu^2 \mathrm{e}^{-x}(1-\mathrm{e}^{-x})^{-1}\mathrm{d}\nu$$
$$=16\pi^4(\boldsymbol{kT})^3 V/(25.8)c^3\boldsymbol{h}^3 \quad (6.9)$$

Hence, we obtain $\overline{N}=2.03\times10^{13}$/cc. at $T=1000°$K. We have also by (6.3)

$$\sigma^2{}_N=8\pi^3(\boldsymbol{kT})^3 V/3c^3\boldsymbol{h}^3=1.37\overline{N}$$

i. e.,

$$\sigma_N=1.17\sqrt{\overline{N}}$$

by (2.13) and (6.9)

$$\overline{E}=8\pi^5(\boldsymbol{kT})^4 V/15c^3\boldsymbol{h}^3=2.70\overline{N}\boldsymbol{kT}$$

and by (6.4)

$$\sigma^2{}_E=32\pi^5(\boldsymbol{kT})^5 V/15c^3\boldsymbol{h}^3=10.8\overline{N}(\boldsymbol{kT})^2$$

i. e.,

$$\sigma_E=3.29\sqrt{\overline{N}}\boldsymbol{kT}$$

Combining the above results with the estimations (6.8), we may consider that there is, in general, no significant difference between the grand ensemble from (1.5) for the temperature radiation and the micro-canonical.

Analytically the canonical and the grand-canonical distributions are much more manageable than the micro-canonical. It is especially simple and exact when we employ the theoretical probability distribution of mathematical statistics reducible to Eq. 1.1 to describe the probability of microscopic states and we define the entropy by Eq. 2.1.

It is possible to extend the present method to more complicated physico-chemical phenomena, such as chemical equilibria, adsorption and cooperative phenomena.

Some Spectral Studies of the Aqueous Solution of Pyronine G

By Kōnosuke FUJIKI, Chieko IWANAGA and Masao KOIZUMI

(Received April 13, 1961)

Pyronine G is a xanthene dye with a positive charge, as againt anionic eosine and uranine, and it has a simpler structure than the latter dye ions, as is shown below:

We have studied some of its optical properties in an aqueous solution as a preparatory step for studying its photochemical behavior; this paper concerns the following three phenomena: I) dimerization, II) formation of carbinol as studied from the absorption spectra (pH dependence of the absorption spectra), and III) pH dependence of the fluorescent behavior.

I. Dimerization

Not long ago, one of the present authors studied the dimerization of this dye in relation to metachromasy[1] and observed a typical spectral change due to the dimerization. In this paper, special attention has been paid to the interaction between the dye cation and inorganic anion.

Dimer bands, when observed, usually lie on the shorter wavelength side of monomer bands; this phenomenon has been interpreted on the basis of Förster's model[2]. Thus, when the dimer is formed from two monomeric ions lying close together, with their molecular planes opposite each other, the excited level is split into two, of which two only the higher level has an appreciable transition moment, causing the blue shift of the dimer-band. But it is not quite certain how, if at all, the anion takes part in the dimerization. Simpson et al.[3] observed that in the case of 1, 1'-diethyl-2, 2'-pyriodocyanine, iodide and perchlorate have different association constants and that, moreover, the position of the dimer band is different in the two cases; from these facts they concluded that anions are involved in the dimerization. They further inferred that the ionic pair is formed in both monomer- and dimer- forms, but in the former case, it can only occur at the expense of the resonance energy of dye ion (due to the electrical charge), while in the latter, the univalent anion is sandwiched between two dye ions, each with half a unit charge; this partly contributes to the stability of the dimer. Ramette[4] studied the association of rhodamine B, and from the finding that the dimerization constant is different for chloride, bromide and perchlorate (they studied in particular the variation of an orange-band which is due to a two-protonated species), they also surmised the participation of the ionic pair in the dimerization.

It may now be possible in principle to decide whether the molecular species involved in the dimerization are an ionic pair or free ions and what their ionic values are, if the effect of the ionic strength on the association constant is carefully investigated. Denoting monomer and dimer as M (or M' if in a different state) and MM', the thermodynamic dimerization constant for

$$M + M' \rightleftharpoons MM'$$

would be given as follows:

$$K_a = K\frac{f_{MM'}}{f_M f_{M'}}$$

$$\log K = \log K_a + \log f_M + \log f_{M'} - \log f_{MM'} \qquad (1)$$

in which K is the apparent association constant and f's, the activity coefficients.

If Debye-Hückel's theory in its simple form is applied to f's as an approximation, then

$$\log f_i = -aZ_i^2\sqrt{J} \qquad (2)$$

The combination of 1 and 2 would enable us to predict how the apparent dimerization constant is affected by the ionic strength. Some of the conceivable cases will be cited below:

a) Participation of no anion

$$\log K = \log K_a + 2a\sqrt{J}$$

or approximately

$$\log K = \log K_a + \sqrt{J}$$

b) Participation of a univalent anion (X^-)

i) if M=DX M'=DX

$$\log K = \log K_a$$

4) R.W. Ramette and E. B. Sandell, ibid., **78**, 4872 (1956).

ii) if $M=DX$ $M'=D^+$

$$\log K=\log K_a$$

c) Participation of a bivalent anion (Y^{2-})

i) if $M=M'=DY^-$

$$\log K=\log K_a+\sqrt{J}$$

ii) if $M=DY^-$, $M'=D^+$

$$\log K=\log K_a-\sqrt{J}$$

In the above classification, case b ii) and case c ii) will perhaps correspond to the sandwich-model of Simpson, while b i) and c i) will be cases in which a 1 : 1 ion pair is formed between the dye and the anion, those perhaps occupying lateral position in both monomer and dimer.

From such a view, the effects of the addition of some salts such as potassium chloride, potassium nitrate, magnesium sulfate, potassium iodide, potassium perchlorate and sodim perchlorate were investigated. As a supplement, the effect of pH on the dimerization was also examined.

Experimental.—*Sample.*—Merck's reagent was used without further purification. $\varepsilon\approx1.2\times10^4$. Later, for the sample in parts II and III, purification was made by repeated crystallization, giving an appreicable increase of ε; this indicated the crudeness of above sample. Hence, the absolute value of the dimerization constant is not very reliable, but discussion on the salt effect will nevertheless be permissible since it is essentially based on the relative rather than the absolute quantity.

The Method of Determining the Association Constant.—The absorption spectra are measured by a Hitachi spectrophotometer EPU-2, using cells 1, 0.3 or 0.1 cm. in thickness according to the concentration of dye (from ca. 10^{-5} to 10^{-3} M). Putting the analytical concentration of dye as C_0 and the molar fraction of dimer as x in a monomer unit, the apparent association constant is given by;

$$K=\frac{x}{2C_0(1-x)^2}$$

If one measures the apparent molar absorbance ε and determines in a suitable way the molar absorbance of monomer and dimer, ε_m and ε_d, then K can be evaluated from the following equation[5]:

$$\log C_0(\varepsilon_m-\varepsilon)=\log\frac{2K}{(\varepsilon_m-\varepsilon_d/2)}+2\log C_0(\varepsilon-\varepsilon_d/2) \quad (3)$$

In the case where further polymerization as well as dimerization occurs among three monomers and four monomers and so on, the following formula may hold if the absorbance of all the polymers can be disregarded:

$$C_0(\varepsilon_m-\varepsilon)=\frac{2K_1}{\varepsilon_m}(C_0\varepsilon)^2+\frac{3K_1K_2}{\varepsilon_m^2}(C_0\varepsilon)^3+\frac{4K_1K_2K_3}{\varepsilon_m^3}(C_0\varepsilon)^4+\cdots\cdots \quad (4)$$

5) N. Mataga, This Bulletin, **30**, 375 (1957).

in which K_1, K_2, K_3,…… are respectively the equilibrium constants for each successive polymerization.

For most of the experimental results a linear relation holds between $C_0(\varepsilon_0-\varepsilon)$ and $(C_0\varepsilon)^2$, whence it can be concluded that $K_2=K_2=\cdots\cdots=0$, and, further, that $\varepsilon_d\approx0$.

This method, which is satisfactory for the majority of cases, gives $2K_1/\varepsilon_m$ as a solpe of the plot.

Results and Discussion.—The dependence of the absorption spectra of pyronine G on pH is shown in Fig. 1. It is evident that in the

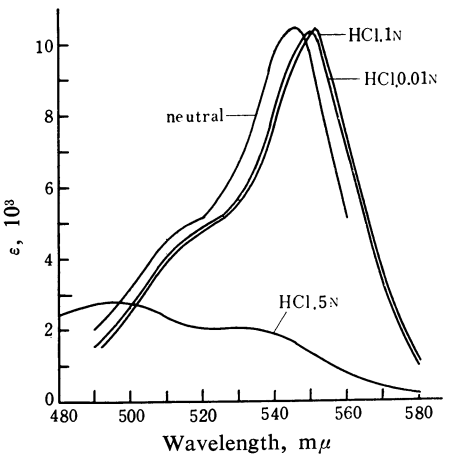

Fig. 1. pH dependence of the absorption spectra of pyronine G (2.12×10^{-5} M).

region $0<pH<3$, the maximum shifts several mμ towards red without any appreciable change in the entire feature. This would perhaps be due to the attachment of one proton to the $N(CH_3)_2$ group. A remarkable change was found to occur in the 5 N hydrochloric acid solution, the absorption spectra turning into a broad band with a maximum at 495 mμ. The exact assignment of this band was not undertaken, but in view of a large blue shift this would probably be due to the attachment of another proton to the C- or O- atom of the central ring. The case for $pH>7$ will be described in Part II. No particular attention was paid to the pH of the solution in studying the salt effect on the dimerization.

i) Potassium Chloride, Potassium Nitrate, Magnesium Sulfate.—In order to determine the salt effect on the dimerization constant, the absorption spectra of pyronine G in the aqueous solution were measured, adding various amounts of these salts and changing the dye concentration from ca. 2×10^{-5} to 9×10^{-4} M. Fig. 2 shows the case of 0.3 M potassium nitrate as an example. The position of the dimer band is practically the same for magnesium nitrate, potassium chloride or without any salt. The K-values evaluated from 3 or 4 (disregarding ε_d) are shown in Table I. In Fig. 3 the cases

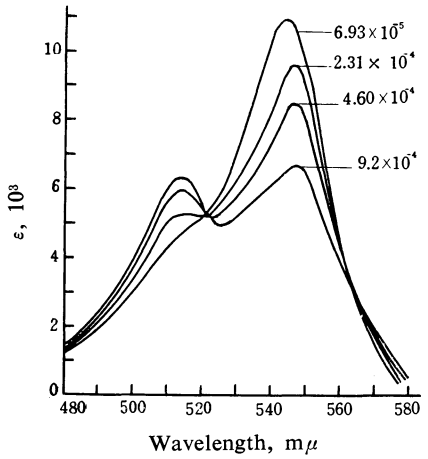

Fig. 2. The absorption spectra of pyronine G in the aqueous solution containing 0.3M KNO_3.

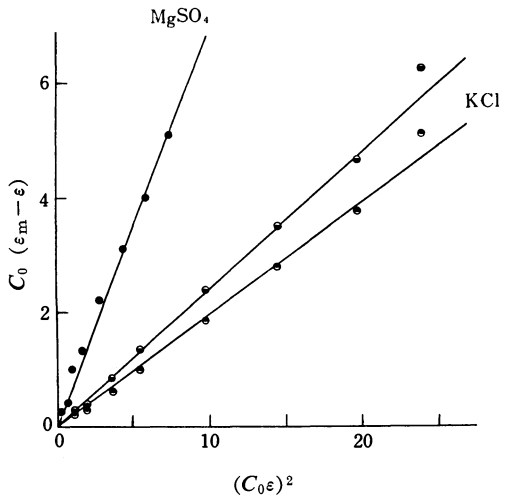

Fig. 3. Plot of $C_0(\varepsilon_m-\varepsilon)$ against $(C_0\varepsilon)^2$.
◒ $\varepsilon_m=12.0\times10^3$, ◓ $\varepsilon_m=10.9\times10^3$

of potassium chloride and magnesium sulfate are shown. These results are not satisfactorily accurate, the main cause of error perhaps lying in the fluctuation of ε_m. The K-value for the simple aqueous solution is quite smaller than that reported before[1] (1.6×10^3 at 27°C). This is probably due to the circumstance that in the previous case, the ε_d-value evaluated from the extrapolation of the ε-value in the higher concentration region was used for calculating the K-value. The present results are considered more reliable in view of the fact that a disregard of ε_d can give a satisfactory analysis in most cases.

Figs. 4a and 4b give plots of the log K-value at 20°C against the ionic strength and the molarity of the solution respectively. These

TABLE I

Temp.	Salt	Concn., M	K	log K

	$MgSO_3$	1	1560～1700	3.19～3.23

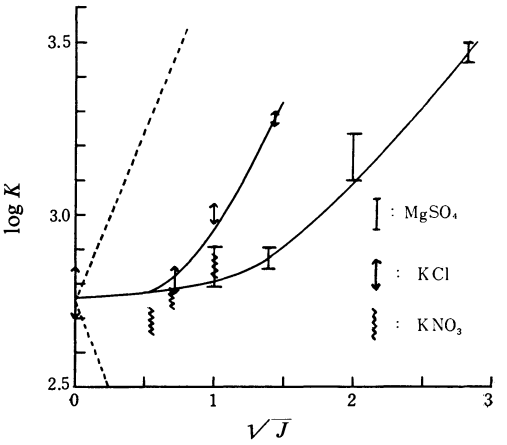

Fig. 4a. The dependence of log K on $\sqrt{J}$.

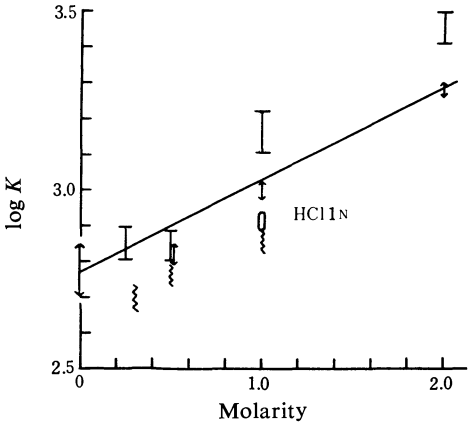

Fig. 4b. The dependence of log K on molarity.

figures show clearly the specificity in the effect of anions. Apart from the region of great ionic strength where Debye-Hückel's formula does

not hold, $\log K$ is almost independent of J (in the region $\sqrt{J} \ll 1$). The dotted lines in Fig. 4a are written with an inclination of ± 1.

Thus, the results obtained obviate the possibility of a reaction between free ions (case a) in the case of a univalent anion, while in the case of bivalent anions both case c i) and case c ii) do not match the experimental results, not to speak of the case of free ions. If the sandwich-model is generally to be adopted, case c ii) should hold for the bivalent anion, but this proved not to be the case. Hence, by analogy this model may also be rejected for the univalent anion (case b ii). This conclusion is also supported by the constancy of the position of the dimer band irrespective of the various anions.

Taking all this into consideration, it is most plausible that the dimerization in this case takes place as shown in Fig. 5.

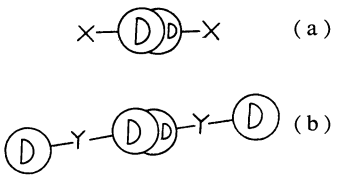

Fig. 5. Plausible models of a dimer.

Fig. 5a corresponds to the aforementioned case b i) of a univalent anion, but Fig. 5b for a bivalent anion Y^{2-} corresponds to neither c i) nor c ii).

ii) Potassium Iodide, Potassium Perchlorate, Sodium Perchlorate.—The specificity of the anion mentioned above is particularly prominent in the case of I^- and of ClO_4^-.

The measurements were made for 0.05, 0.1, 0.3, 0.5 and 1 M solutions of potassium iodide.

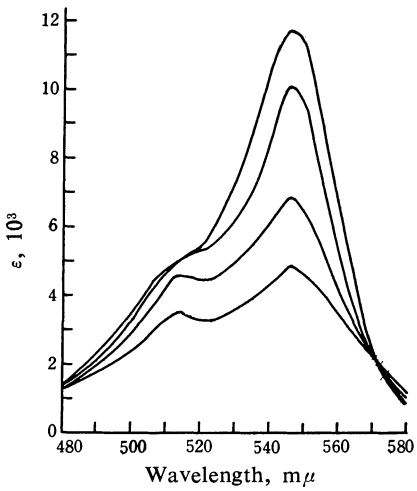

Fig. 6. The absorption spectra of pyronine G in the aqueous solution containing 0.1 M KI.

In all cases the dimer band somewhat increases up to $(2.3 \sim 3.0) \times 10^{-4}$ M in the dye concentration, but beyond this the entire absorption curve declines noticeably, accompaied by a slight red-shift of the maximum. No new band appears, at least in the region 400~780 mμ. The increase of the salt concentration does not essentially affect the above behavior. Fig. 6 shows the result for 0.1 M potassium iodide.

As for ClO_4^-, the measurements were made in 0.5 and 1 M. In both cases, the absorption band declines monotonously with the increase of the dye concentration from 2.11×10^{-5} to 9.2×10^{-4} M. Even a slight growth of the dimer band is not observable (Fig. 7). A similar change is observed when the dye concentration is kept constant and the quantity of sodium perchlorate is varied.

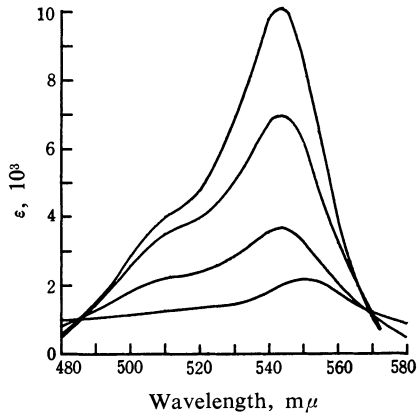

Fig. 7. The absorption spectra of pyronine G in the aqueous solution containing 0.5 M $NaClO_4$.

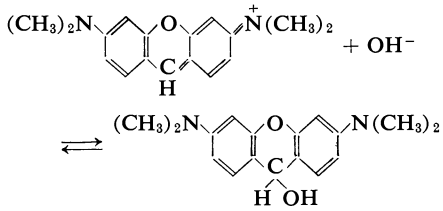
For the above two cases, perhaps polymers of higher association would be produced in view of the weak and broad absorption band.

The reason that only dimerization occurs in the case of Cl^- and of SO_4^{2-} may lie in the bulky size of such ions due to the high degree of hydration, these ions laterally attached to the dimer cation probably prohibiting the further approach of other dye ions. In the case of I^- and of ClO_4^-, for which the hydration is small at most, the lateral attachment of these ions close to the dye cation might not inhibit the alignment of many dye ions face to face and thus allow the high polymer to be formed.



iii) Hydrochloric Acid.—Similar experiments were made using 5 N hydrochloric acid, 1 N hydrochloric acid (potassium chloride 1 M) and 0.001 N hydrochloric acid (potassium chloride 0.1 M) solutions. Qualitatively the dimer formation is quite the same in the case of 0.001 N and of 0.1 N hydrochloric acid as for the neutral solution. One notable fact is that in spite of a shift of the monomer band (toward red),

the position of the dimer band completely coincides with that in the neutral solution. The K-values were found to be 785 and 1300 for 1 N (20°C) and 0.001 N respectively. Taking into account the somewhat larger error of these experiments, it may be said that the above values do not differ much from those in the neutral solution.

The result is quite different in the case of 5 N hydrochloric acid. The absorption spectra, which are shown in Fig. 1, never change through the variation of dye concentration from 2.8×10^{-5} to 9.2×10^{-4} M. The cause for this different behavior is not known at present.

II. The Equilibrium Constant of Carbinol Formation Evaluated from the pH Effect on the Absorption Spectra

The color of the acidic or neutral solution of pyronine G is red, while the alkaline solution is colorless; this change is reversible. As described below, the maximum absorption at 546 mμ in the neutral solution turns into a broader one with a new maximum at 390 mμ. A shift as large as 156 mμ clearly suggests the disappearance of the conjugation in the pyronine cation and may be inferred to be due to the formation of carbinol.

In xanthene dyes there seems to exist no detailed study about the formation of carbinol, but it is well known that triphenylmethane dyes easily form carbinols such as, the carbinol of phenolphthalein[6] crystal violet[7].

The reason for the easy formation of carbinol in the case of pyronine G and the rapid establishment of its equilibrium may perhaps be that it is a positive ion and has no steric hindrance, as judged from its rather simple structure.

In this paper, the equilibrium constant of the carbinol formation is determined at several temperatures from the variation of the absorption spectra due to pH change. From the results, some thermodynamic constants are estimated.

Experimental.—Pyronine G of Merck was dissolved in ethanol and recrystallised by evaporating the solution spontaneously. The crystal obtained was dried in a descicator. $\varepsilon_{max}\approx70000$. Sodium hydroxide, G. R. was used without further purification. Borate and Na_2HPO_4, both G. R., were recrystallized. The buffer solutions employed were the $NaOH\text{-}Na_2B_4O_7$ system and the $NaOH\text{-}Na_2HPO_4$ system. The former was used for the preliminary experiment in the range pH 9.24~12.25 and the latter, for more accurate measurements between pH 11.0 and 12.0. The pH of the solution was measured by a Hitachi pH meter prior to the measurement of the absorption spectra. The glass electrode used was GL-13 for the alkaline solution. Quartz cells were used for spectral measusement in order to minimize the adsorption of dye on the cell wall. The spectrophotometer used was a Hitachi EPU-2. The wavelength width was always maintained at 0.5 mμ. The temperature was controlled by circulating the water from the constant temperature bath.

Results and Discussion.—The pH change of absorption spectra is shown in Fig. 8. As seen from the figure, the peak at 546 mμ in the neutral solution declines with the increase of pH, and a broad band with a peak at 390 mμ gradually rises ($\varepsilon\approx10000$) with an isosbestic point at 445 mμ, which supports the existence of the equilibrium.

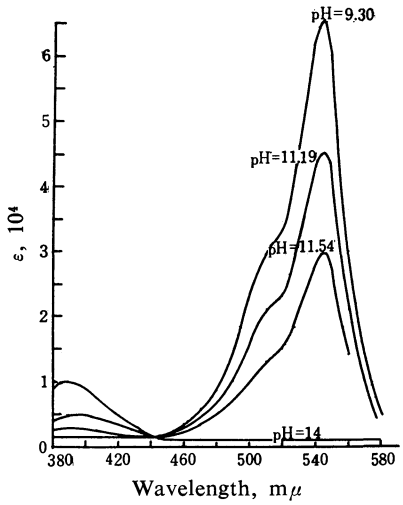


Fig. 8. pH change of absorption spectra of pyronine G.

From the data the equilibrium constant was determined by the following procedure[8]. Writing pyronine G cation as A^+ and carbinol as B, the reaction is represented by

$$A^+ + OH^- \rightleftharpoons B \qquad (5)$$

From a mass action law

$$K=\frac{[B]}{[A^+][OH^-]}=\frac{[B][H^+]}{[A^+]K_w} \qquad (6)$$

where K_w is the ionic product of water.

TABLE III. pK VALUES AT VARIOUS TEMPERATURES

Temp., °C.,	20	22.5	25	27.5	30
pK	-2.52 ± 0.02	-2.47 ± 0.02	-2.45 ± 0.02	-2.37 ± 0.02	-2.06 ± 0.04 -2.48 ± 0.02

Of course, K in 6 is not a rigorous equilibrium constant in the thermodynamical sense but only an apparent one in the phosphate buffer solution in the pH range 11~12.

Taking logarithm of Eq. 6

$$\log K=\log[H^+]-\log K_w+\log([B]/[A^+])$$

or

$$pK=pH+\log K_w-\log([B]/[A^+]) \qquad (7)$$

the application of Beer's law for each molecular species leads to Eq. 8 in which ε_{A^+}, ε_B and ε are respectively, the molar absorbancy of A^+ and of B and the apparent molar absorbancy at the corresponding pH.

$$pK=pH+\log K_w-\log\frac{\varepsilon_{A^+}-\varepsilon}{\varepsilon-\varepsilon_B} \qquad (8)$$

For ε_{A^+} and ε_B, one can use respectively the molar absorbancy in the neutral solution and in the strong alkaline solution. Plotting $\log(\varepsilon_{A^+}-\varepsilon)/(\varepsilon-\varepsilon_B)$ against pH, one obtains a straight line with a slope of 45°, and the pH-value at intercept, combined with $\log K_w$[9], gives the pK-value.

The experimental results in the phosphate buffer solution are given in Table II.

Using the above data and putting ε_B as 0.02, pK was calculated from 8. An example of the plot is shown in Fig. 9, and the results are given in Table III.

From these (the values at 30°C were omitted because they are less reliable), ΔG^0, ΔS^0 and ΔH^0 were calculated using the relations,

$$\Delta G=2.303\,RT\,pK,\quad \Delta S=-(\partial\Delta G/\partial T)$$
$$\Delta H=4.56\{\partial pK/\partial(1/T)\}$$

The results are

ΔG(kcal.): -3.38(20°C) -3.35(22.5°C)
-3.34(25°C) -3.30(27.5°C)

ΔS=ca. -12 cal./deg.mol.

$\Delta H=-8\pm3$ kcal./mol.

These values are not very accurate, but it is certain that the formation of carbinol in the phosphate buffer is an exothermic reaction with a small decrease of entropy.

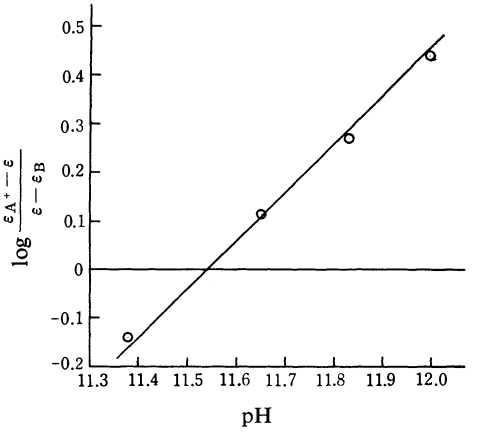

Fig. 9. Plot of $\log\frac{\varepsilon_{A^+}-\varepsilon}{\varepsilon-\varepsilon_B}$ against pH (20°C).

9) Beilstein, International Critial Table, Vol. VI, (1929), p. 152.

III. The Fluorescent Behaviors of the Aqueous Solution of Pyronine G

The formation of cabinol, which was established by the pH variation of the absorption spectra would not occur so promptly as does the proton addition or its detachment. Hence, the same equilibrium constant is to be expected from the pH variation of fluorescence if it can be measured. This was confirmed by the present investigation; in addition, the excitation spectra were measured.

Experimental.—*Sample.*—Same as the absorption experiment. The concentration is 2×10^{-5} M unless otherwise described.

Procedure.—The fluorescence spectra were measured with the fluorescence accessory of a Hitachi spectrophotometer EPU-2; hence, they are not genuine fluorescence spectra. The measurements were made at room temperature. The exciting light is 365 mμ from a high pressure mercury lamp (100 W). In order to obtain the pK-value of the carbinol formation from the pH variation of the fluorescence intensity, a newly constructed fluorometer was used which had been designed on the principle of the optical zero-method and which enables one to measure the action spectra of the fluorescence[10]. As the light source, a 200W tungsten filament lamp (projection lamp) was used. Its intensity distribution was calculated by the use of Planck's formula for black body radiation[11], in

$$N_\lambda = \frac{2\pi c}{\lambda^4}\left\{\exp\left(\frac{hc}{k\lambda T}\right)-1\right\}^{-1}$$

which c, λ and T are light velocity, wavelength (μ), and absolute temperature respectivery; the dimension of N_λ is photons/cm^2 sec. μ. The color temperature of the tungsten lamp (100 V.) was determined in such a way as to make the action spectra of eosine and uranine, of which the quantum yield is known to be independent of wavelength, as similar to the absorption spectra as possible. It was found that $T=2800$°K gives a satisfactory result, as is shown in Fig. 10.

The wavelength width was taken into account.

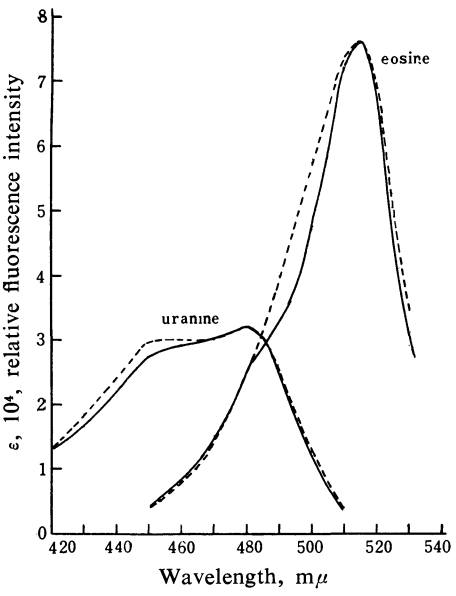

Fig. 10. Action spectra (------) and absorption spectra (——) of eosine and uranine.

Results.—*pH Variation of the Fluorescence Spectra.*—An example is shown in Fig. 11. The

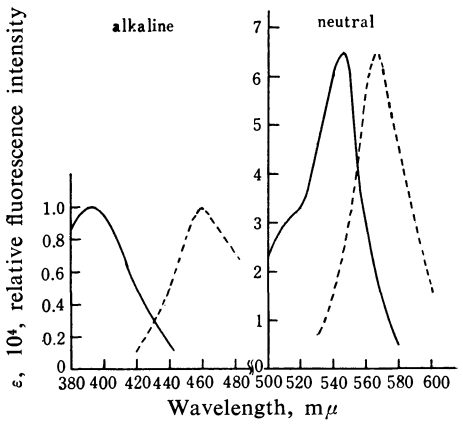

Fig. 11. Fluorescence spectra of pyronine G.

maximum of the fluorescence spectra in the neutral solution lies at 566 mμ, which is displaced about 20 mμ from the absorption maximum. The result that there exists no shoulder corresponding to a dimer is naturally to be expected, since the dimer in most dyes has no power of emission. The alkaline solution, on the other hand, gives a fluorescence spectra with a maximum at 460 mμ corresponding to 390 mμ of the absorption spectra. Stokes' shift of 70 mμ is much larger than the 20 mμ of the

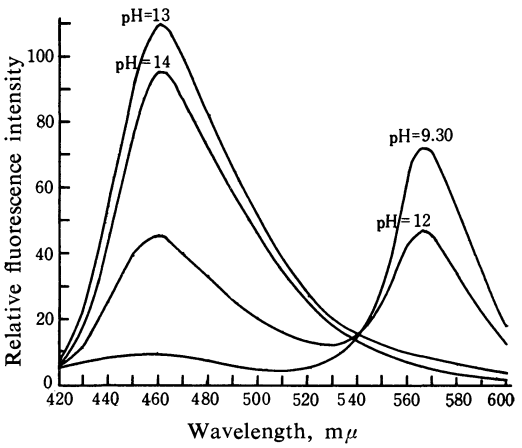

Fig. 12. The pH dependence of the flourescence spectra of pyronine G.

TABLE IV. pH CHANGE OF THE FRUORESCENCE INTENSITY

20°C	pH	9.30	10.95	11.37	11.51	11.87	12.00	14
	I	563	380	355	251	174	112	1.00
25°C	pH	9.30	11.12	11.35	11.45	11.60	12.06	14
	I	38	25.12	17.8	16.6	7.58	6.45	1.00
30°C	pH	9.30	11.0	11.19	11.37	11.54	11.76	14
	I	44.7	30.2	24.0	17.4	10.5	7.08	1.00

neutral solution. The spectra at various pH cross at a point near 540 mμ, which indicates, analogous to the isosbestic point in the case of absorption spectra, that two molecular species existent in equilibrium give rise to an independent fluorescence. This is shown in Fig. 12. The fluorescence of carbinol declines somewhat at pH 13 ; this may perhaps be due to the quenching by the OH^- ion.

The Determination of pK from the pH Change of Fluorescence Intensity.—Since pyronine G cation and carbinol each emit a separate fluorescence, the quantitative investigation of the pH change of the fluorescence intensity of one component will make it possible to determine the equilibrium constant of the carbinol formation. To make the calculation feasible, λ of the exciting light was chosen at 445 mμ, which is an isosbestic point. A photographic filter (0-2) which cuts $\lambda<560$ mμ was used to remove the exciting light.

The calculation was made as follows, taking into account the fact that the fluorescence of the two molecular species slightly overlap. Putting the molar fraction of the cation and carbinol as X_{A^+} and X_B respectively, and denoting the relative intensity as I_{A^+} and I_B, the measured intensity can be expressed by

$$I=I_{A^+}X_{A^+}+I_BX_B$$
$$=I_{A^+}\frac{[A^+]}{[A^+]+[B]}+I_B\frac{[B]}{[A^+]+[B]}$$

Combining this with

$$K=\frac{[B]}{[A^+][OH^-]}$$

one gets

$$pK=-\log\frac{I_{A^+}-I}{I-I_B}+pH+\log K_w$$

This is quite analogous to the formula for the absorption spectra. The results are given in Table IV. An example is shown in Fig. 13. From the above data, pK and the related thermodynamic quantities were calculated as follows:

pK: -2.66 ± 0.03(20°C), -2.59 ± 0.05(25°C), -2.50 ± 0.02(30°C)

ΔG: -3.60(20°C), -3.52(25°C), -3.45(30°C)

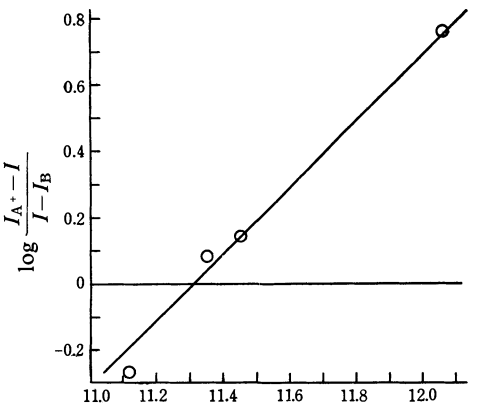

Fig. 13. Plot of $\log\frac{I_{A^+}-I}{I-I_B}$ against pH (25°C).

$\Delta H=-6.5\pm1.5$ kcal./mol.
$\Delta S=-14\pm3$ kcal./mol.

All the above data are nearly equal to those obtained from the absorption spectra. Above pH=13 the fluorescence intensity shows a decrease with the increase of $[OH^-]$, but in the above pH region this effect may perhaps be so small that it can be disregarded.

Action Spectra.—Excitation spectra of fluorsecence in the aqueous solution of pyronine G were measured by a newly constructed fluorometer. The result, as shown in Fig. 14, largely

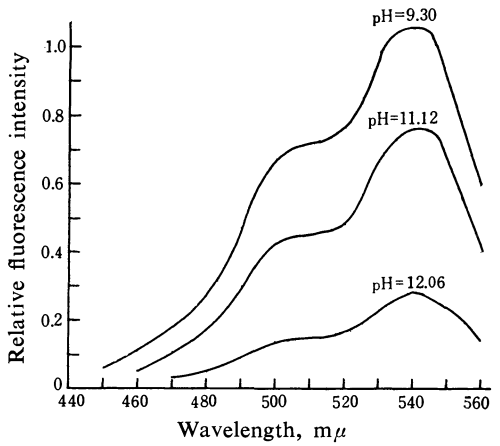

Fig. 14. Excitation spectra of fluorescence in the aqueous solution of pyronine G.

coincides with the absorption spectra, indicating that the quantum yield of fluorescence is independent of the wavelength. It is, however, worth while to note that a shoulder similar to that of the absorption is existent in the action spectra. This is somewhat curious in view of the fact that a dimer, which is the source of this shoulder, is commonly considered to be non-fluorescent, and there is indeed no shoulder in the fluorescence spectra. The reason for this is not yet certain ; it might be that the exciting energy is transferred to a neighboring monomer or that the excited dimer rapidly dissociates into monomers (in an excited and ground state) and then the emission takes place. Further studies are required.

Summary

Th effect of inorganic anions on the dimerization constant of pyronine G in an aqueous solution was examined. It was found that the effect is very specific and can not be explained simply by the effect of the ionic strength. The analysis led to the conclusion that a dimer exists as an ion-pair with the anions attached laterally to dye ions instead of being sandwiched between two dye ions.

The change of absorption spectra in the alkaline solution was interpreted to be due to the formation of carbinol, and from its analysis the formation constant of carbinol was determined.

Carbinol was found to have also its proper fluorescence, and from the pH change of fluorescence spectra the formation constant of carbinol was again decided, the value of which coincided well with that obtained from the absorption spectra.

Anionic Polymerization of Vinylidene Chloride. I. Susceptibilities of Vinyl Monomers to Initiation by Ionic Catalysis

By Akio KONISHI

(Received May 10, 1961)

The reactivity of the vinyl monomers in the radical polymerization have been theoretically discussed in a number of publications which have dealt with the problem using the molecular orbital method[1,2], the frontier electron theory[3-5], a Q-e or q-ε scheme[6-8], or a polarity parameter[9]. It is considered in ionic polymerization that monomers form an intermediate ionic complex with the catalyst; the mutual relationship between the monomer and the catalyst seems to be more important in ionic polymerization than in free radical polymerization. This paper is intended to make a survey of the susceptibility of vinyl monomers to ionic catalysis.

Theoretical

Susceptibility and Q-e or q-ε Map. — Alfrey and Price have presented polarity (e) and resonance (Q) factors for vinyl monomers derived from copolymerization data to explain the monomer reactivity ratios; they have reported Q and e values on thirty one monomers[6,7]. This concept has been theoretically extended and generalized, and a new set of parameter q for resonance and ε for polarity has been proposed for one hundred and ten monomers[8]. Walling[10] and Furukawa[11] pointed out that there is a linear relationship between relative reactivities or polarity factor

e and Hammett sigma constants of ionic reaction, and Price[8] has also shown a good linear relation between ε values of styrene derivatives and Hammett sigma constants. Although such a good linearity as this has not been obtained in the case of ethylene derivatives, the effect caused by a substituent of the phenyl group on the double bond of styrene is assumed to correspond to the effect caused by the substituent of ethylene derivatives on their double bond, and the polarity parameter *e* or ε should reasonably be applied for indicating the ionic reactivity of vinyl monomers in ionic polymerization as well as in radical polymerization.

Although numerous experimental data have been reported on the susceptibilities of various monomers to homopolymerization under anionic, free radical, and cationic conditions, Schildknecht's table[12] is taken here as a reliable reference; here he has classified the susceptibilities of fifty four monomers.

The relationship between the susceptibility and the *Q-e* values of fourteen monomers obtained from the original *Q-e* table[7] is illustrated in Fig. 1. Furukawa[11] has presumed that monomers having a large plus *e* value ($e>1.5$) are likely to be polymerized in an anionic condition; on the contrary, monomers having large negative *e* values ($e>-1.0$) are likely to be polymerized in a cationic condition. However, it seems rather difficult to explain the behavior of monomers (such as styrene, butadiene and methyl vinyl ketone) which can be polymerized in both radical and ionic conditions. The susceptibility arranged according to Price's new parameter *q*-ε for twenty two monomers is illustrated in Fig. 2.

In general, cationic polymerization takes place with monomers whose double bond is negatively polarized and has an affinity to electrophillic reagents, whereas the double bond of anionic polymerizable monomers is positively polarized and reacts with nucleophillic reagents. As a first approximation, the magnitude of polarization in an ionic condition seems to correspond to the polarity expressed by the polarity factor *e* or ε. With the resonance factor *Q* or *q*, such a good relationship as ε vs. sigma has not yet been obtained, but the *Q* or *q* factor is closely connected with the reactive pi electrons of the vinyl bond, namely, with the electron donating or accepting characters of the vinyl bond, and if the electronic field is so large as to induce the polarization of pi electrons, the magnitude of such electrodynamic polarity here induced may serve to form an ionic complex with an ionic catalyst. Accordingly, the *Q* or *q* factor may also be regarded as a reactivity determining factor in ionic reactions, and both the *e*(ε) and *Q*(*q*) factors may be helpful in explaining

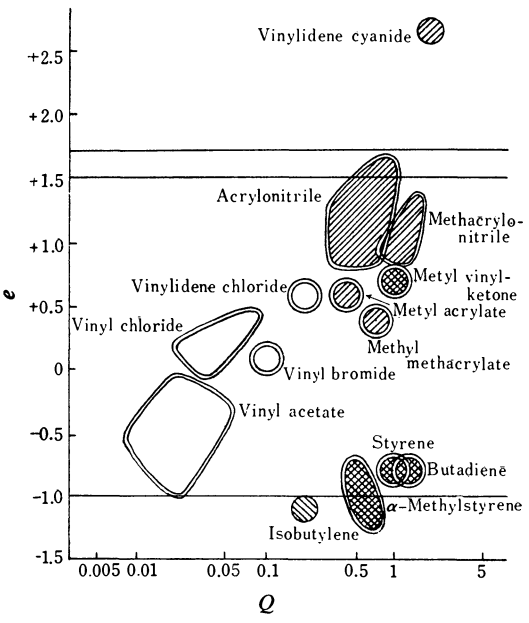

Fig. 1. Relationship between susceptibility and *Q-e* map. Susceptible to radical ◎, anion ▨ and cation ▩.

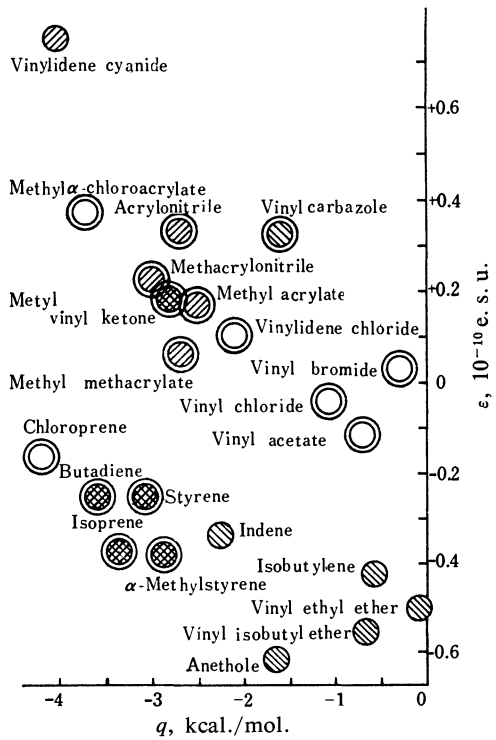

Fig. 2. Relationship between susceptibility and *q*-ε map. Susceptible to radical ◎, anion ▨ and cation ▩.

12) C. E. Schildknecht, *Ind. Eng. Chem.*, **50**, 107 (1958).

the susceptibility of a monomer in an ionic polymerization reaction. Hence, Q-e or q-ε maps can be related to the susceptibilities of vinyl monomers to initiation by an ionic catalyst. Monomers like styrene or butadiene, which has a conjugated double bond, are polymerized by either a cationic or anionic catalyst.

Another factor affecting polymerizability may be steric effect, but the order of its magnitude is difficult to estimate quantitatively. As the matter of fact, the steric factor should be involved implicity in the Q-e or q-ε factors, because the latter factors are experimentally determined.

The propagating macro anions seem to be relatively stable because the living polymer has been obtained in the anionic polymerization of styrene[13]. It is deduced that the larger the value of e (or ε) and Q (or q) of the monomers, the greater the susceptibilities of the monomers toward the ionic catalyst.

The relative susceptibilities can be shown as in Fig. 3 (q-ε map) and Fig. 4 (Q-e map), in which the Q-e values of vinyl ethyl ether[14], vinyl chloride[15], vinylidene chloride[15], acrylonitrile[15], chlorotrifluoroethylene[16] and vinylidene cyanide[17] are added, besides the values listed in Refs. 7 and 8. The values were converted by the following equations,

$$q = -2\times10^{-3}\,T\ln Q - 3.1$$

$$\varepsilon = 1.66\times10^{-12}\,T^{1/2}\,e$$

in which T=323°K. The area of the map is determined from the following monomers: vinylidene cyanide, anethole, 2, 3-dichloro-1, 3-butadiene and diphenylacetylene (Ref. 8).

In the map, the diagonal line along which the monomers are distributed shows the relative susceptibilities of monomers to catalysts: at first vinylidene cyanide is located at the upper left corner, followed by acrylonitrile, methacrylonitrile, methyl acrylate, methyl methacrylate (in the order of decreasing susceptibility to anion); styrene, butadiene, isoprene (susceptible to anion, radical and cation and located near the center parallel to the diagonal line); vinylidene chloride, vinyl chloride, vinyl acetate (susceptible to radical); isobutylene, indene, and finally vinyl ether (in the order of decreasing susceptibility to cation). The susceptibility of methyl vinyl ketone (to either cation, radical or anion) and vinylcarbazole (to both radical and cation) are understandable considering that they are located in the central part of the map.

Application of *Q-e* or *q-ε* Map. — It is considered that all monomers can be polymerized by either a anionic, radical or cationic catalyst under proper ionic conditions where undesired side reactions between the initiating ion (or its counter ion) and the polar substituents of the monomer can be eliminated as much as possible.

New Polymerization Reaction.—There are a considerable number of monomers which have not been polymerized by ionic reagents. Some of these which are not classified in Ref. 12 are shown in the map, Fig. 5. It can be predicted from the map that cationic polymerization should be possible for such monomers as hexene-1, hexyne-1, *N*-vinylpyrrolidone and stilbene, and for isostilbene, vinyl formate and vinyl acetate with some difficulty. Anionic polymerization will be possible for acrylamide, acrolein, vinylcarbazole, and vinylidene chloride, and either anionic or cationic polymerization of 1,1-diphenylethylene, methyl isopropenyl ketone, methacrolein, acrolein, and 2- and 4-vinylpyridines will be possible. The author has succeeded in the polymerization of vinylidene chloride in anionic mechanism; the details will be reported on in Parts II and III of this report.

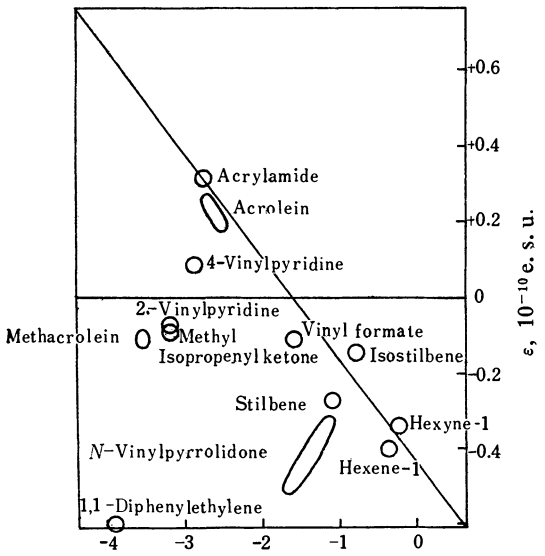

Fig. 5. Locations of several monomers in *q-ε* map.

Ionic Copolymerization.—Data of the monomer reactivity ratios in ionic polymerization[18,19] are very interesting since the relative reactivity of monomers in the ionic reaction can be estimated from them. Although data are less available and are more uncertain than in the case of radical copolymerization, it can be seen qualitatively that in cationic copolymerization the monomer reactivity ratios of the monomer seated near the lower right corner are larger than the comonomer, and in anionic copolymerization the monomer reactivity ratios of the monomer located near the upper left corner are larger than the comonomer; the arrow in Figs. 6 and 7 shows the monomers whose monomer reactivity ratios are larger in the pair. The case of styrene-vinyl acetate is

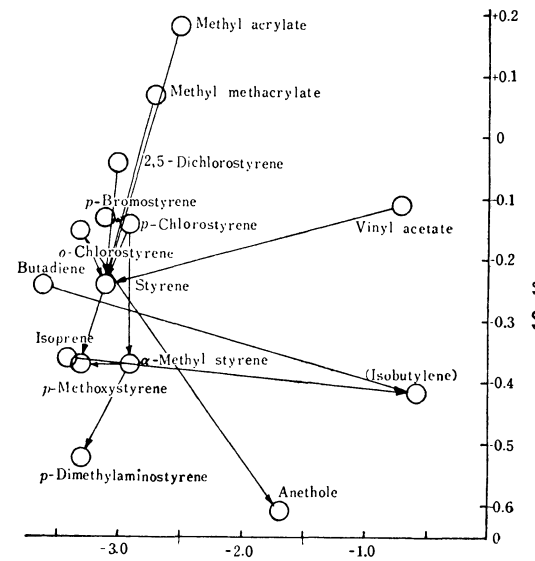

Fig. 6. Relative reactivities of monomers in cationic copolymerization.

somewhat abnormal, for in this case both r_1 and r_2 are far smaller than unity. It is possible to predict the relative tendency between two monomers which enter into copolymerization under an ionic condition, and the results on the anionic copolymerization of vinylidene chloride, which will be reported on in Part III, will present an experimental evidence of this scheme.

Summary

The relative reactivities of vinyl monomers under ionic conditions have been discussed using a Q-e or q-ε map. It has been deduced that the larger the value of the polarity factor e (or ε) and the resonance factor Q (or q) of the monomer, the greater the susceptibility of the monomers to ionic catalysis. The possibility of new ionic polymerization reaction and the relative reactivity of monomers in ionic copolymerization have been discussed. As the result of this scheme, it seems that the anionic polymerization of vinylidene chloride is possible.

Anionic Polymerization of Vinylidene Chloride. II. Homopolymerization Initiated by n-Butyllithium

By Akio KONISHI

(Received May 10, 1961)

A number of attempts to polymerize various vinyl monomers by *n*-butyllithium have recently been reported on such monomers as butadiene[2-4], isoprene[5-9], styrene[10-16], methyl methacrylate[12,13], acrylonitrile[12,13], vinyl chloride[13,17], methyl and butyl acrylates[12], dimethyl maleate[12], vinyl acetate[12,13], allyl acetate[12] and vinyl *n*-butyl ether[13], though successful results have not yet been obtained in the last five monomers. From the copolymerization data it has been proposed that the polymerization initiated by this catalyst is of anionic mechanism[18,19].

An attempt to polymerize vinylidene chloride under anionic conditions by *n*-butyllithium has been made because the monomer is considered to be susceptible to anionic catalysis, as has been discussed in a previous paper[1].

Experimental

A vinylidene chloride monomer produced by the Kureha Kasei Co. was repurified by drying it over calcium hydride and then distilling it under an argon atmosphere in the presence of copper stearate immediately before use. *n*-Hexane and *n*-butyl bromide were dried over calcium hydride and distilled immediately before use. Argon was freed from the oxygen by passing it through an alkaline solution of pyrogallol and drying it with concentrated sulfuric acid.

n-Butyllithium, prepared in *n*-hexane by the reaction of *n*-butyl bromide with lithium metal by a method similar to that of Gilman[20], was kept standing in the Schlenk apparatus and its concentration checked by titration[21] before use.

From half to one mole of monomer was used in every run. The addition of the reagents and the polymerizations were carried out under argon. Into

a four-necked flask fitted with a stirrer, thermometer, and a gas inlet as well as an outlet for the argon, the required amounts of monomer and solvent were added. At above 30°C the polymerizations were carried out in a 150 cc. glass ampoule as a polymerization apparatus, and the reagents used were all added at −70°C under argon. The polymerization was stopped after the required time interval by adding methanol, followed by the pouring in of excess methanol. The polymer precipitated was filtered off with a glass filter, washed with methanol and water successively, and then dried to a constant weight in a vacuum-desiccator at 40°C. The rate of polymerization was determined gravimetrically.

Intrinsic viscosities were measured in cyclohexanone at 30°C, using an Ubbelohde dilution viscometer. The chlorine content of the polymer was measured by the combustion method with a Shimadzu universal micro determination apparatus type UM-2. The infrared spectra of the pressed potassium bromide disk containing the above samples were measured by a Perkin-Elmer model 13 infrared spectrophotometer.

Results

Polymerizations were carried out with *n*-hexane as a solvent, and the influences of monomer concentration (M), catalyst concentration (BuLi) and polymerization temperature on the rate of polymerization (R_p), intrinsic viscosity [η] and chlorine content were investigated. The initial slope of conversion vs. time curve was taken as the rate of polymerization. The rate was markedly influenced by the method of the addition of the catalyst, as is illustrated in Fig. 1. In this paper, however, the author will report on the rate of polymerization induced by adding all the catalyst at the beginning of the reaction.

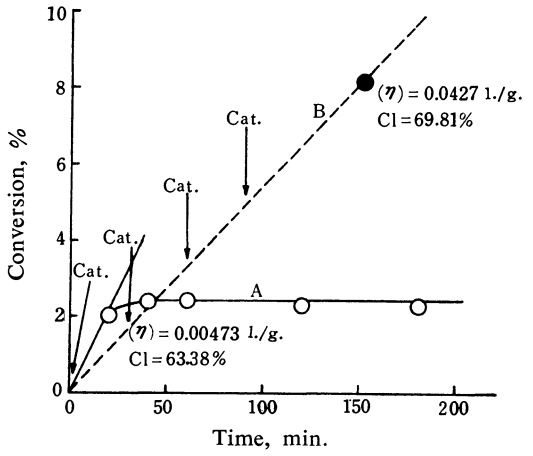

Fig. 1. Conversion vs. time curve.
Temp., 25°C ; A : (M) = 11.13 mol./l., (BuLi) = 0.111 mol./l., whole amount of the catalyst was added initially; B : (M) = 11.44 mol./l., (BuLi) (final) = 0.0917 mol./l., each quarter of the whole amount of the catalyst was successfully added in every 30 min.

As listed in Table I, hydroquinone, a typical radical scavenger, showed little effect on the rate of polymerization, whereas dibenzoyl peroxide, a typical peroxide, reacted immediately with the catalyst and showed an inhibiting effect. This is thought to be an experimental evidence of the ionic character of the polymerization.

In Fig. 2 it is shown that, for a given monomer concentration, the rate is independent of the catalyst concentration above the critical

TABLE I. EFFECT OF INGREDIENTS

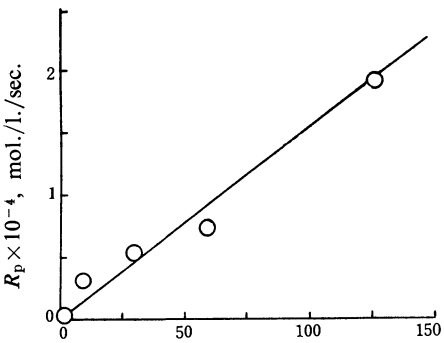
value (0.03 mol./l. in the case). The decrease in viscosity and chlorine content are inversely proportional to the increment of the concentration of the catalyst, as is shown in Figs. 3 and 4 respectively. Figure 4 also suggests that the polar chlorine atom reacted with the catalyst.



The rate of polymerization is proportional to the square of the monomer concentration, as in Fig. 5. Intrinsic viscosity decreases with the increasing monomer concentration, as in Fig. 6.

The effect of temperature on the rate was investigated in a range between −30 and +50°C, and the activation energy of the overall rate of polymerization was calculated to be 10.7 kcal./mol. from the Arrhenius plot, as is shown in Fig. 7. This relatively small value agrees with the activation energy found in methyl methacrylate (7.6 kcal./mol.)[13] and vinyl chloride (8.8 kcal./mol.)[13]. Intrinsic viscosity passed through a maximum at +10°C, as in Fig. 8. Chlorine content is almost independent of the temperature.

Discussion

The kinetics of anionic polymerization of some other monomers initiated by *n*-butyllithium have been presented by O'Driscoll[14], Welch[15], Furukawa[13] and Korotkov[9], though they have not coincided with one another at

several points. The following mechanism is suggested:

$$(BuLi)_n \rightleftarrows BuLi + (BuLi)_{n-1} \quad (1)$$

$$BuLi + M \xrightarrow{k_I} BuM^- + Li^+ \quad (2)$$

$$BuM^- + M + Li^+ \xrightarrow{k_p} \cdots \xrightarrow{k_p} Bu(M)_n^- + Li^+ \quad (3)$$

In a propagating step, the structure of the growing polymer chain seems to be not so simple as that expressed in an ion-pair form like 4, but it is assumed to be a complex one like cyclic structure 5 or like ionic quadrapole 6, as suggested by Cram[22] or Mark[23] in the stereospecific polymerization of methyl methacrylate or diene:

$$Bu\text{-}(\text{-}CH_2\text{-}CCl_2\text{-})_m\text{-}CH_2\text{-}\underset{\displaystyle Cl}{\overset{\displaystyle Cl}{\overset{|}{\underset{|}{C}}}}{}^{-} : Li^+ \quad (4)$$

$$Bu\text{-}(\text{-}CH_2\text{-}CCl_2\text{-})_m\text{-}CH_2\text{-}\underset{\displaystyle Cl}{\overset{\displaystyle Cl}{\overset{|}{\underset{|}{C}}}}{}^{-} \cdots Li^+ \quad (5)$$

$$Bu\text{-}(\text{-}CH_2\text{-}CCl_2\text{-})_m\text{-}CH_2\text{-}\underset{\displaystyle Li^+}{\overset{\displaystyle Li^+}{\overset{|}{\underset{|}{C}}}}{}^{-} : Bu^- \quad (6)$$

Since poly(vinylidene chloride) has no assymmetric centers, the problem of the tacticity of the polymer will not arise, the crystallinity of the polymer here obtained being similar to the polymer obtained by radical polymerization from X-ray study. It seems that structure 5 or 6 serves to stabilize the growing polymer anion. The termination probably occur by association reaction as follows:

$$Bu(M)_n^- + Li^+ + (BuLi) \xrightarrow{k_{t_1}} Bu(M)_nLi(BuLi) \quad (7)$$

or, less probably,

$$Bu(M)_n^-Li^+ \xrightarrow{k_{t_2}} Bu(M)_nLi \quad (8)$$

Since the elimination of chlorine is very remarkable, the following termination reactions are also suggested:

$$Bu\text{-}(\text{-}CH_2\text{-}CCl_2\text{-})_m\text{-}CH_2\text{-}\underset{\displaystyle Cl}{\overset{\displaystyle Cl^{\delta-}}{\overset{|}{\underset{|}{C}}}}{}^{-} : Li^+ \xrightarrow{k_{t_3}} Bu\text{-}(\text{-}CH_2\text{-}CCl_2\text{-})_m\text{-}CH_2\text{-}\underset{\displaystyle Cl}{\overset{\displaystyle Cl}{\overset{|}{\underset{|}{C}}}}{}^{-} + LiCl \quad (9)$$

then

$$\xrightarrow{H\text{-}R} Bu\text{-}(\text{-}CH_2\text{-}CCl_2\text{-})_m\text{-}CH_2\text{-}CHCl \quad (10)$$

or

$$\longrightarrow Bu\text{-}(\text{-}CH_2\text{-}CCl_2\text{-})_m\text{-}CH\text{=}CHCl \quad (11)$$

Other side reactions which induce the abstraction of chlorine from the polymer chain may be:

$$\text{-}CH_2\text{-}\underset{\displaystyle Cl}{\overset{\displaystyle Cl^{-\delta}}{\overset{|}{\underset{|}{C}}}}\text{-} + Li^+ \longrightarrow \text{-}CH_2\text{-}\underset{\displaystyle Cl}{\overset{\displaystyle Cl}{\overset{|}{\underset{|}{C}}}}{}^{+}\text{-} + LiCl \quad (12)$$

$$\xrightarrow{Bu} \text{-}CH_2\text{-}\underset{\displaystyle Cl}{\overset{\displaystyle Bu}{\overset{|}{\underset{|}{C}}}}\text{-} \quad (13)$$

$$\xrightarrow{H\text{-}R} \text{-}CH_2\text{-}CHCl\text{-} \quad (14)$$

The decrease in the chlorine content of the polymer can probably be attributed to reactions 9 and 12, in which the chlorine atom is eliminated as lithium chloride from the polymer chain.

Making the steady state assumption for the chain reaction:

$$k_i(M)(BuLi) = k_{t_1}(BuLi)(Bu(M)_n^-Li^+) + k_{t_2}(Bu(M)_n^-Li^+) + k_{t_3}(Bu(M)_n^-Li^+)$$
$$= (Bu(M)_n^-Li^+)\{k_{t_1}(BuLi) + k_{t_2} + k_{t_3}\} \quad (15)$$

$$(Bu(M)_n^-Li^+) = k_i(M)(BuLi)/\{k_{t_1}(BuLi) + k_{t_2} + k_{t_3}\} \quad (16)$$

$$R_p = k_p(Bu(M)_n^-Li^+)(M) = k_ik_p(M)^2(BuLi)/\{k_{t_1}(BuLi) + k_{t_2} + k_{t_3}\} \quad (17)$$

Supposing $k_{t_2}, k_{t_2} \ll k_{t_1}(BuLi)$ (18)

$$R_p \propto (M)^2 \quad (19)$$

Kinetic chain length $\overline{X}_n$ is written as

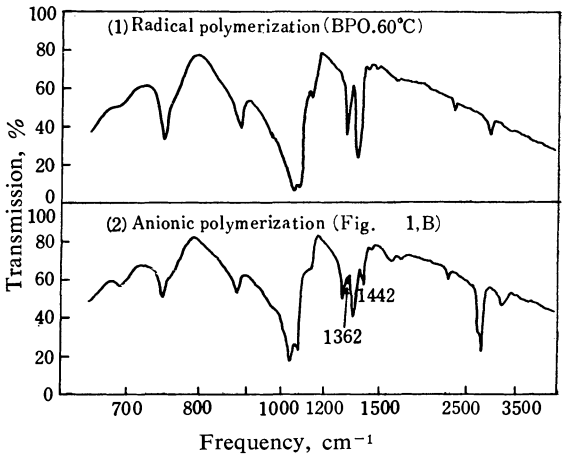

Fig. 9. Infrared spectrum of poly(vinylidene chloride).

23) S. Krim, *Fortschr. Hochpolym.-Forsch.*, **2**, 51 (1960).
22) D. J. Cram and K. R. Kopecky, *J. Am. Chem. Soc.*, **81**, 2748 (1959).

$$\overline{X}_n = R_p/R_t = k_p(\mathrm{Bu}(M)_n{}^-\mathrm{Li}^+)(M)/$$
$$(\mathrm{Bu}(M)_n{}^-\mathrm{Li}^+)\{k_{t_1}(\mathrm{BuLi}) + k_{t_2} + k_{t_3}\}$$
$$= k_p(M)/\{k_{t_1}(\mathrm{BuLi}) + k_{t_2} + k_{t_3}\} \quad (20)$$
$$\log[\eta] \propto \overline{X}_n \propto (M)/(\mathrm{BuLi}) \quad (21)$$

Namely, 19 and 21 accord with the experimental results qualitatively.

Infrared spectra of the polymer are compared with that of the polymer polymerized by dibenzoyl peroxide at 60°C, as is shown in Fig. 9. Characteristic differences observed at 1362 and 1442 cm^{-1}, are attributed to the methyl group in the terminal and pendant butyl groups of the polymer. These absorptions are thought to have been shifted by chlorine from the 1375 and 1457 cm^{-1} which were observed in polyethylene[23].

Summary

The polymerization of vinylidene chloride initiated by *n*-butyllithium in *n*-hexane has been investigated. It has been found that the initial rate of polymerization is independent of the catalyst concentration above a critical value and is proportional to the square of the monomer concentration. The activation energy of the over-all rate was 10.7 kcal./mol. The chlorine content of the polymer decreased inversely with the increase of catalyst concentration. An anionic mechanism is suggested for the polymerization kinetics.

Some Addition Compounds of Salicylaldehyde-ethylenediimine-copper. VI[1]. *The Absorption Spectra of 5,5'-Disubstituted Salicylaldehyde-ethylenediimine-coppers*

By Tsuguo TANAKA

(Received April 15, 1961)

It had been reported previously that the positions of the absorption maxima of the spectra of salicylaldehyde-ethylenediimine-copper were shifted in regular ways according to the nature of the solvents in which the absorption spectra were measured[2]. Now the absorption spectra of 5,5'-dichloro-[2], 5,5'-dibromo-, 5,5'-diiodo-salicylaldehyde-ethylenediimine-coppers[3] have been measured in various solvents, and some close relations have been observed between the position of the absorption maxima of band I and band II[4] of these chelates and their tendencies to form addition compounds with the solvents.

Measurement and Results

The absorption spectra were measured with a Hitachi EPU 2A spectrophotometer (cell depth 1.0 cm.). All solvents were purified according to the method of Weissberger[5]. The results are listed in Table I.

Discussion

Band I.—Although many discussions[6] have been presented by different authors about the origin of the visible band of the metal chelates, satisfactory experimental evidence for them have not yet been obtained. It is now frequently assumed, however, that the greatest factor leading to this absorption is the vibration of the non-bonding electron of the metal ion.

Martell and Ueno[7] measured the absorption spectra of the metal chelates of bisacetylacetone-ethylenediimine and its derivatives and found that the band I of copper chelates which appeared between 540~575 mμ is the characteristic absorption of the copper ion. Analogous observations had previously been reported by Sone[8] about the absorption spectra of the bidentate chelates.

TABLE II. ADDITION COMPOUNDS OF SALICYLALDEHYDE-ETHYLENEDIIMINE-COPPER DERIVATIVES[2,3]

Substituent	Addition compound			
	Pyridine	Propionic acid	Chloroform	Phenol
5,5'-H	—	Stable	—	Stable
5,5'-Cl	—	—	Least stable	Less stable
5,5'-Br	—	—	Less stable	Stable
5,5'-I	—	Stable	Stable	Stable

Calvin et al.[9] reported that band I of the copper chelates of bisacetylacetone and its 3-ethyl variant is composed of a set of three Gaussian components whose positions and intensities were shown to depend primarily upon solvent basicity; these component bands were identified with the transitions of the 3d electrons of the copper ion predicted from the crystal field and molecular orbital theories.

In this report, it is examined whether there are any relations between the tendencies of 5, 5'-dichloro-, 5, 5'-dibromo- and 5, 5'-diiodo-salicylaldehyde-ethylenediimine-coppers to form addition compounds with propionic acid, phenol and chloroform and the positions of band I of these chelates observed in these solvents.

The wavelengths of the absorption maxima of band I of these chelates in benzene solutions, as listed in Table I, increase in the order

$$5,5'\text{-I} < 5,5'\text{-Br} < 5,5'\text{-Cl}$$

which is the order of decreasing basicity[10];

9) R. L. Belford, M. Calvin and G. Belford, *J. Chem. Phys.*, **26**, 1165 (1957).

10) R. L. Belford, A. E. Martell and M. Calvin, *J. Inorg. & Nuclear Chem.*, **2**, 11 (1956).

that of the unsubstituted one lies between those of 5, 5'-dichloro- and 5, 5'-dibromo-derivatives, the order is

$$5,5'\text{-I} < 5,5'\text{-Br} < 5,5'\text{-H} < 5,5'\text{-Cl}$$

The extinction coefficients of band I as well as those of band II and band III of these chelates observed in the same solvent decrease in the order

$$5,5'\text{-I} > 5,5'\text{-Br} > 5,5'\text{-Cl}$$

The shifts listed in Table I were calculated as the deviations of the wavelengths of the absorption maxima measured in various solvents from those measured in benzene solutions.

In the pyridine solutions, red shifts of the absorption maxima of the band I were observed of these chelates. The magnitudes of the red shifts decrease in the order

$$5,5'\text{-I} > 5,5'\text{-H} > 5,5'\text{-Br} > 5,5'\text{-Cl}$$

On the other hand, in chloroform and propionic acid solutions, blue shifts were observed. The magnitudes of the blue shifts increase in the order

$$5,5'\text{-I} < 5,5'\text{-H} < 5,5'\text{-Br} < 5,5'\text{-Cl}$$

that is, the chelates which are characterized by the larger red shifts in pyridine solutions are those characterized by the smaller blue shifts in chloroform and propionic acid solutions.

It can be seen that these orders are the same as that of the tendency of the formation of the addition compounds which was reported previously[3].

In the cases of the propionic acid-benzene and of the phenol-benzene solutions, the order of the shifts is somewhat different from those discussed above; it is the same as that of the wavelengths of these chelates in benzene solutions. The blue shifts increase in the order

$$5,5'\text{-I} < 5,5'\text{-Br} < 5,5'\text{-H} < 5,5'\text{-Cl}$$

It is remarkable that a red shift is observed in the case of 5, 5'-diiodo-chelate in the propionic acid-benzene solution in contrast with the blue shifts of 5, 5'-dichloro- and 5, 5'-dibromo-chelates.

These results indicate that the energy changes of the 3d electrons which may be induced both by the ligands and the solvents are closely related to the tendency of the formation of the addition compounds. The circumstances are, however, somewhat more complicated in the case of the mixed solvents containing benzene and require further examination. It is also important to inquire whether there are any relations between the stabilities of the addition compounds of these chelates with solvents and the wavelengths of the absorption maxima of band I of the chelates in the respective solvents.

In the chloroform solutions, the absorption maxima are 544 mμ for 5, 5'-diiodo-chelate and 553 and 552 mμ for 5, 5'-dibromo, 5, 5'-dichloro-chelates, corresponding to the formation of stable and less stable addition compounds respectively, and 564 mμ for the unsubstituted chelate of which the addition compound cannot be isolated.

On the other hand, band III of the unsubstituted chelate in a chloroform solution consists of two maxima, i. e., a band at 245 mμ which seems to originate from the unstable addition compound of the chelate with chloroform and a band at 276 mμ which seems to originate from the original chelate; the former is analogous to band III of the substituted chelates in chloroform, while the latter is analogous to the absorption maxima of the unsubstituted chelate in a benzene solution. Therefore, the chelate is considered to exist in the chloroform solution as an equilibrium mixture of the original chelate with the unstable addition compound with chloroform.

In the phenol-benzene solutions, the maxima are 542 mμ for 5, 5'-diiodo-chelate corresponding to the formation of a stable addition compound with phenol, 550 mμ for an unsubstituted one, and 553 and 552 mμ for 5, 5'-dibromo- and 5, 5'-dichloro-chelates corresponding to less stable addition compounds.

These results seem to indicate that the shorter the wavelength of the absorption maximum of a chelate observed in a solvent, the greater the stability of the addition compound of the chelate with the solvent.

Band II.—In contrast with those of band I and band III, the wavelengths of the absorption maxima of band II in the spectra of 5, 5'-dichloro-, 5,5'-dibromo- and 5,5'-diiodo-chelates were found at 379 mμ in both benzene and pyridine solutions.

The flat maximum of 5, 5'-diiodo-chelate in benzene from 379 to 381 mμ was an abnormal case of which no appropriate explanation can be made at present.

The blue shifts of 2 mμ for 5, 5'-diiodo-chelate, 0$\sim$5 mμ for 5, 5'-dibromo-chelate and 2$\sim$4 mμ for 5, 5'-dichloro-chelate in the chloroform solutions, corresponding to stable, less stable and least stable addition compounds of these chelates with chloroform respectively, represent a series. Analogous series of the blue shifts of the wavelength of the absorption maxima of band II were observed in the propionic acid solutions as well as in the propionic acid-benzene solutions. The shifts in propionic acid solutions are, respectively, 18 mμ for 5, 5'-diiodo-chelate which can form

an addition compound with propionic acid, and 18~22 and 20 mμ for 5, 5'-dibromo- and 5, 5'-dichloro-chelates which can not form addition compounds with propionic acid; those in propionic acid-benzene solutions are 9 mμ for 5, 5'-diiodo-, 9~14 mμ for 5, 5'-dibromo- and 11 mμ for 5, 5'-dichloro-chelates. In the phenol-benzene solutions, the blue shifts are 10 mμ for 5, 5'-diiodo- and 5, 5'-dibromo-chelates and 11 mμ for 5, 5'-dichloro-chelates, all of which can form addition compounds with phenol.

From these results, it is assumed that the smallest shifts for 5, 5'-diiodo-chelate observed in chloroform as well as in propionic acid and in propionic acid-benzene solutions are related to the formation of the stable addition compounds of this chelate with these solvents, and the larger shifts for 5, 5'-dichloro-chelate correspond to the formation of unstable associated structures. The flat maxima of band II of 5, 5'-dibromo-chelate in these solvents, which are characterized by blue shifts ranging from the largest to the smallest values may be due to the properties of this chelate which are intermediate between those of 5, 5'-diiodo- and 5, 5'-dichloro-chelates.

It is also important to notice that 5, 5'-halogen substituents in comparison with that of the unsubstituted chelate, produce a marked influence on the wavelengths of band II.

Band III.—Some different orders are observed of the absorption maxima of band III of these chelates. Larger shifts of the wavelengths of the absorption maxima of 5, 5'-dibromo-chelate than those of the others were observed in the pyridine as well as in the phenol-benzene solutions. A smaller blue shift of 5, 5'-dibromo-chelate than those of the others was also observed in the propionic acid solution, while a flat maximum of 5, 5'-dibromo-chelate, with a blue shift ranging from 29 to 33 mμ in chloroform solution, was contrasted with those of the blue shifts of 31 mμ of 5, 5'-dichloro-chelate and 31.5 mμ of 5, 5'-diiodo-chelate in the same solvent. No shifts of the band III of these three chelates were observed in the propionic acid-benzene solutions.

It is important to notice that band III of the unsubstituted chelate in the chloroform solution consists of two maxima (cf. the discussions for band I).

From these results, it is supposed that 5, 5'-halogen substituents do not exert a marked influence on the origin of band III[7,11].

The Chemical Reaction in Silent Electric Discharge. II. The Frequency Effect on Ozone Formation

By Kihei MORINAGA and Momotaro SUZUKI

(Received May 16, 1961)

Numerous accounts have been published on silent discharge[1-11], the majority dealing with the electric characteristics of the ozonizer[1-6]. In the oscillographic study of the discharge[1-4] that was originated by Klemenc et al.[1], the rapid impulse with a "fringe"[2] structure was noticed, and the relation between the pulse and the discharge spot that appeared on the photographic plate in the gap space was investigated[3]. Fillipov et al. derived a equation[5,6] for the effective current in an ozonizer from a knowledge of the static and dynamic characteristics of discharge, and recently[7] they have combined this equation

with the intensity of the formation and decomposition of ozone in an ozonizer. Lunt has pointed out[10] the gaps in knowledge which hinder the identification of the reaction mechanism.

In the previous paper the ozone formation through silent discharge (50 c/sec.) was studied with its relation to the pulse current, the gap length and the discharge electrode area. The results showed that the ozone yield is proportional to the pulse current and that the ozone formation rate per unit pulse current has a linear relationship with A/d, where A is the effective discharge area and d, the discharge gap distance.

In the case of the 50 c/sec. electric source of the previous work[11], the pulse current was restricted up to 200 μamp. on account of possible damage to the discharge tube due to electrical breakdown. Furthermore, upon increasing the pulse current beyond the above value, the wave form of the secondary current became more irregular, making rather ambiguous the measurement of the pulse current by means of pulse heights.

In the present work, a relatively high and variable frequency electric source is applied. Accordingly, the pulse current range, upon applying a relatively high frequency current, could be extended up to 0~1300 μamp. The frequency dependence of the ozone formation that clarifies the effect of the pulse current on ozone formation was also pursued.

Experimental

All experiments were performed in an atmospheric flow system. The equipment and procedure were similar in principle to those described in the previous work. The glass discharge tubes had a discharge area of 50~200 cm^2 and a gap of 1~3 mm. respectively. The variable frequency electric source was supplied by a high frequency generator of 32 poles. The number of cycles could be adjusted from 500 to 2000 c/sec. by changing the number of revolutions of the armature. The output voltage could be regulated between 50 and 100 V. The applied high tension to the discharge tube was obtained from a core type transformer which had been designed in order to diminish the core loss of the current. The wave form of the output current remained steady, even with frequencies up to 2000 c/sec.

The frequency measurement of the source current was performed by both the tachometer and oscillographic methods. The frequency deviation in each run was controlled within a limit of ±3% by regulating the field current of the driving D. C. motor. The procedure for taking measurements of the pulse current was the same as in the previous work. The time constant of the leakage resistance and the integral condenser of the oscillogram circuit was 2.7×10^{-6} sec.

The ozone, after leaving the discharge tube, was led into a neutral potassium iodide solution and then analyzed in the usual method.

Results

The Effect of the Frequency.—In the course of the research for the frequency effect on ozone formation, the experiments were carried out with the value of variables as follows: the pulse current covering 0~1300 μamp., resident time 0.3~10 sec., and the total discharge current 0~16 mamp. using a discharge tube with an effective discharge area of 100 cm^2 (in one electrode side) and a gap length of 1 mm. This resulted in almost identical curves of ozone concentration vs. resident time τ in the various frequencies. The asymptotes on the curves of ozone concentration vs. resident time at $\tau=0$ give the value of the initial ozone formation rate. In Fig. 1, the ozone formation rates at

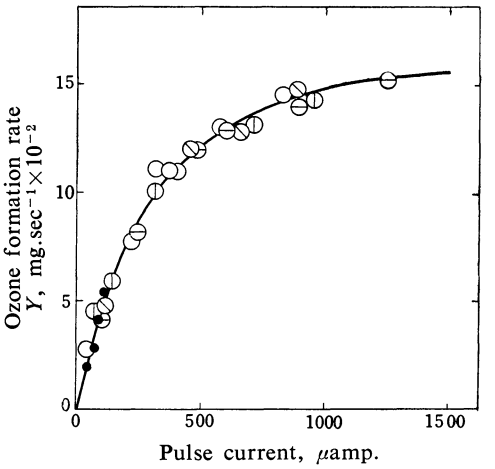

Fig. 1. Ozone formation rates at various frequencies electric source against pulse current. Discharge are a 100 cm^2, Discharge gap length 1 mm.

⊖ 2000, ○ 1000, ● 50, ① 1500, ⊘ 500 sec.

various frequencies against pulse current are given. The ozone formation rate is expressed in one diagram independent of the frequencies of the current. If the above rates are plotted against other parameters, such as total discharge current, secondary voltage etc., then the diagram does not show any unified form but rather appears as separate curves according to the frequency used.

In the previous report[11] the same ozone formation rate at 50 c/sec. current, under otherwise identical conditions, varied linearly with the pulse current, whereas in the present case the diagram starts at first linearly, then with the increase of the pulse current, bends

gradually downwards until it approaches a certain definite value. It should be noted that in the former case a high value of pulse current was precluded because of the reasons described elsewhere above, while in the present case the high frequency current enables a more intense flow of the pulse current.

In a discharge of a low pulse current the linear relationship will validly hold no matter how the frequency alters, but in the region of a high discharge current the rate value will be smaller than is anticipated from a linear relationship unaffected by a change of the frequency.

The Effect of Discharge Area and Gap Length.—Figures. 2, 3 and 4 show a relationship similar to that given in Fig. 1 for a certain current frequency (1000 c/sec.) and for various electrode areas, in which each diagram corresponds to values of a certain gap length. The operational specifications are the same as for the foregoing series, but the areas are changed 50, 100 and 200 cm^2 and the gap lengths are changed 1, 2, 3 mm. respectively. The whole aspect of the diagrams somewhat resembles that of Fig. 1.

The region where the curves leave the linear property depends upon the discharge area, and the values of the corresponding pulse current are around or less than 200 μamp.

To compare these results with those in the previous work, the authors denoted as before the ozone formation rates per unit pulse

current at a low pulse current region as Y_i. The relation between Y_i and A/d is shown in Fig. 5. The linear feature, independent of the value of frequency, appears here again as in the previous case of a 50 c/sec. current discharge. This linear relationship seemed to be valid for the frequency up to 200 c/sec. The slope was found to be 7.5×10^{-7} mg. sec^{-1} μamp^{-1} cm^{-1} whereas the corresponding value in the previous paper is 7.0×10^{-7} mg. sec^{-1} μamp^{-1} cm^{-1}; they therefore seem essentially equal.

Discussion

In the high frequency silent discharge, pulses were not noticeable up to a certain value of the total discharge current, and as long as the pulses were not observed, there was no gain of ozone. The above discharge region of missing pulses had hardly been noticed in the previous work of 50 c/sec. electric source frequency.

It seems that the electric source frequencies of the present studies would not be concerned with the ozone formation or with appropriate representation of the extent of silent discharge by the pulse current. Thus, as shown in Fig. 1, the ozone formation rates are solely dependent on the value of the pulse current and independent of the electric source frequencies used here.

The relationship between pulse current and initial ozone formation rate, which was reported in the previous paper[11], was revealed to be essentially consistent even in the high frequency discharge area studied here, i. e. 500~2000 c/sec., and with the pulse current up to 200 μamp. The ozone formation rate per unit pulse current Y_i at a low pulse current region changes along with the value of A/d linearly.

There have been observed, nevertheless, some discrepancies from the previous work. As is shown in Fig. 1, the linear relationship between the initial ozone formation rate Y and pulse current I_p holds up to a certain value of I_p independent of the frequency value. As is shown in Figs. 2, 3 and 4, however, the linear relationship is not valid from a certain current value upwards. The values where this linearity does not hold remain appreciably unaffected by the change of value of the discharge area. With an increasing discharge area, the pulse current region at which the curve departs from the linear relationship between Y and I_p, comes to assume a higher value.

Concerning the spot number, it was seemingly conceivable, as was discussed in the previous work[11], that the increase of discharge area led to the increase in spot number, because the increase of the discharge area implies that the spots are distributed more sporadically, thus offering more chance for the generation of new spot sites. As long as the number of the electrons ejected from a spot does not exceed the number of molecules just in front of the spot and as for as the more the generation of spots with an increasing pulse current is permitted, the formation of ozone may possibly be proportional to the number of electrons or, further, to the pulse current. The larger the area of the discharge electrodes is, the larger the region of the pulse current where are fulfilled the above conditions. Consequently, with an increase in the discharge area, the deviation from the linear relations tends to appear in a higher pulse current region than is the case in a smaller discharge area.

Concerning a lower pulse current region than the above discussion, the ozone formation rates per unit pulse current in high frequency discharge showed the same behavior as in the previous work, and the dependence on A/d was explainable in the same manner as in the previous paper.

The results which have been obtained in the present work are explainable by the above discussion, and the discussion also evidently supports the discussion of the previous paper.

Summary

1. The ozone formation in the silent electric discharge was investigated with a current of higher frequency. The rate is independent of the electric source frequency but dependent solely upon the value of the pulse current, and the rate per pulse current is linear in relation to the electrode area divided by the gap length. The above findings are similar to those in the case of 50 c/sec.

2. At a higher value of pulse current, the ozone formation rate is no longer linear to the pulse current and shows a type of saturation curve.

3. Some relations at a high frequency discharge among pulse current, electrode area and gap length have been discussed.

The Synthesis of Alkyltin Halides by Direct Reaction between Tin and Alkyl Halides[1)]

By Sumio MATSUDA and Haruo MATSUDA

(Received April 24, 1961)

Organotin compounds are widely used as stabilizers for polyvinylchloride or as antifungicides, and many patents or reports have been published about the synthesis of alkyltin halides, R_nSnX_{4-n}, which are the most important intermediates of these organotin compounds.

To obtain dialkyltin or trialkyltin halides, the redistribution reaction between tetraalkyltin and stannic chloride or the halogenation of tetraalkyltin has conveniently been employed. There have been, however, a few studies attempting to prepare these compounds from tin and alkyl halides by direct methods; with these, however, a considerable yield could be obtained only in the limited case where an alloy of tin was used.

In this report a modified direct synthesis of alkyltin halides will be described in which the reaction is carried out by adding a trace of magnesium or zinc and a small amount of alcohol, ester or an ether such as tetrahydrofuran. For its ease and the high yield of alkyltin halides, this method can be considered the most excellent one among the direct methods reported thus far.

For example, tin foil and butyl iodide were reacted at ordinary pressure in the presence of magnesium (0.2~0.3% to tin) and *n*-butanol (3% to butyl iodide); then almost all the tin foil was converted to dibutyltin diiodide.

By a similar reaction, alkyl bromide could convert tin almost completely to R_nSnBr_{4-n} (n=1—3) in an autoclave, but in this case it was found neccessary to add alkyl iodide (ca. 5% to alkyl bromide) besides magnesium and *n*-butanol.

The reaction of an alkyl chloride, for example, methyl chloride, with tin foil in the presence of magnesium, *n*-butanol or tetrahydrofuran and butyl iodide gave dimethyltin dichloride in a high yield of ca. 92%.

When aryl halides were used instead of alkyl halides, no reaction product was obtained.

1) This paper is a summarized report of four articles published in Japanese: S. Matsuda and H. Matsuda, *J. Chem. Soc. Japan, Ind. Chem. Sec.* (*Kogyo Kagaku Zasshi*), **63**, 114 (1960); H. Matsuda and S. Matsuda, ibid., **63**, 1958, 1965 (1960); H. Matsuda, H. Taniguchi and S. Matsuda, idid., **64**, 541 (1961).

Experimental

Materials.—The tin foil and the metals used as additives were 99.99 and 99.9% pure respectively. The alkyl halides and solvents used were purified by distillation.

Typical examples of the precedures are as follows.

Reaction of Tin and Butyl Iodide.—In a three-necked flask of 1 l. were placed 100 g. (0.843 mol.) of tin foil, 372 g. (0.843×2.4 mol.) of butyl iodide, 0.3 g. (0.3% to tin) of magnesium, and 11.2 g. (3% to butyl iodide) of *n*-butanol; then the mixture was heated to 130~135°C for three hours with being stirred. After the reaction, a small amount of solid was filtered off (98% of the tin was consumed). The fractionation of the remaining liquid gave unreacted butyl iodide and dibutyltin diiodide (b. p. 143~145°C/3 mmHg; yield 381 g., 95% to the reacted tin).

Reaction of Tin and Butyl Bromide.—A mixture of tin foil (30 g.: 0.253 mol.), butyl bromide (83~104 g.: 0.253×(2.4~3.0)mol.) and a catalytic amount of magnesium, butyl iodide and *n*-butanol was heated at 135~170°C in a stainless autoclave of 500 ml. After the reaction, the solid, which mainly consisted of unreacted tin, was filtered off. Fractionations through a helices-packed column of about thirty theoretical plates gave three fractions: unreacted butyl bromide, fraction I (95~100°C/2 mmHg) and fraction II (120~125°C/2 mmHg). Fraction I consisted of butyltin tribromide, while fraction II was a mixture of dibutyltin dibromide and tributyltin bromide.

The added butyl iodide was considered to have been converted to higher boiling substances.

Under optimum conditions (tin 30 g., butyl bromide 104 g., butyl iodide 5 g., *n*-butanol 2.5 g., and magnesium 0.12 g. were allowed to react at 160°C for 8 hr.), the tin was consumed completely and 27 g. of butyltin tribromide, 60 g. of dibutyltin dibromide and 6 g. of tributyltin bromide were obtained (yields: 26, 60 and 7% respectively).

Reaction of Tin and Methyl Chloride.—Methyl chloride 50~60 g. (ca. 1.0~1.2 mol.) was introduced into a stainless autoclave of 100 ml. in which 20 g. (0.169 mol.) of tin foil, magnesium, butyl iodide and *n*-butanol or tetrahydrofuran were charged. The temperature was kept at 190°C for six hours; then the reaction product was separated from the unreacted tin by filtration or sublimation under reduced pressure. The white crystal thus obtained was found to be dimethyltin dichloride. M. p. 105~106.5°C.

Found: Sn, 54.35; Cl, 32.32. Calcd. for $C_2H_6SnCl_2$: Sn, 54.03; Cl, 32.28%.

Analyses.—Halogen was determined by high frequency titration[2] with an aqueous silver nitrate solution. Gas chromatography was also applied[3] for identification of some of the products.

Results

Alkyltin Iodides.—In the reaction of tin and butyl iodide, the effect of the amount of magnesium and *n*-butanol vs. the tin conversion (see A and B), as well as the amount of the tin conversions by using various kinds of metal additives and solvents, are shown in Fig. 1. Usually 90~95% of dibutyltin diiodide was found in the reaction product.

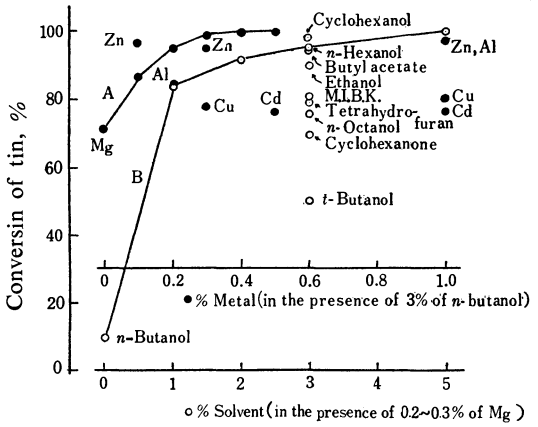

Fig. 1. The effect of the additives for the conversion of tin.

Figure 1 also shows that magnesium and zinc are two of the most effective additives in cooperation with alcohols such as *n*-butanol or cyclohexanol. The preferable amount of the metal seemed to be 0.1~0.3% to tin; an excessive addition caused an unfavourable discoloring of the product.

Methyl iodide and tin could be reacted completely in an autoclave within two hours in the presence of magnesium and methanol or *n*-butanol. Vacuum distillation gave a mixture of trimethyltin iodide, dimethyltin diiodide and methyltin triiodide in yields of 25~30, 40~46 and 20~27% respectively, and no appreciable change in composition was observed after changing the ratios of the reaction components, the amount of the additives, the reaction temperature or the reaction time.

Similarly, from tin and ethyl iodide, triethyltin iodide, diethyltin diiodide and ethyltin triiodide were obtained in yields of 14~18, 63~67 and 3~6% respectively.

Other alkyl iodides could be used as well as butyl iodide. In these reactions almost the same conversions were obtained as in the case

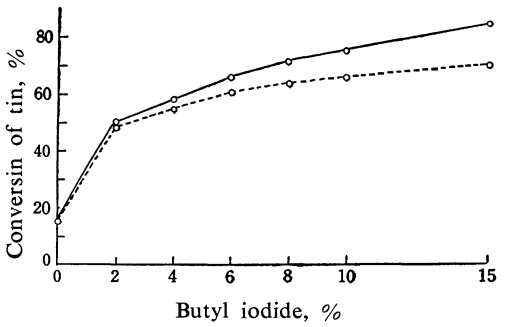

Fig. 2. The effect of butyl iodide for the reaction of tin and butyl bromide.
Butyl bromide (mol.)/tin (mol.) = 2.4, magnesium 0.06 g. (0.2% to tin), *n*-butanol 2.5 g. (6% to butyl bromide), reaction temperature 170°C, reaction time 4 hr.

of adding *n*-butanol by adding the alcohol with the same alkyl group as the iodide.

However, the rate of conversion of tin and the yield of dialkyltin diiodides decreased with the increasing size of the alkyl group. For example, *n*-dodecyl iodide converted 49% of tin and yielded di(*n*-dodecyl)tin diiodide corresponding to 59% of the tin consumed.

Alkyltin Bromides.—The reaction of tin with butyl bromide in the presence of magnesium and

n-butanol can be carried out by adding alkyl iodide. The effect of butyl iodide is shown in Fig. 2.

The reactions shown in Fig. 2 were carried out at 170°C for four hours, but the highest conversion of tin was observed in the experiment at 160°C for eight hours. It was also found that in this reaction the metal additives were not as effective as in the reaction of tin and butyl iodide; the amount of magnesium neccessary increased slightly, and zinc was found to be practically ineffective.

The reaction product from tin and butyl bromide, in contrast that of butyl iodide, was a mixture of three alkyltin bromides.

Ethyl bromide could react with tin under similar conditions; thus, from 30 g. of tin were obtained 34 g. of diethyltin dibromide and 32 g. of a mixture of triethyltin bromide (ca. 30%) and ethyltin tribromide (ca. 70%).

Long chain alkyl bromides such as *n*-octyl bromide could be reacted under ordinary pressure as well as in an autoclave, but the amount of conversion decreased with the increasing size of the alkyl group.

Alkyltin Chlorides.—The effect ot additives in the reaction between tin and methyl chloride is shown in Table I.

It can easily be seen from Table I that the three additives, magnesium, alkyl iodide and *n*-butanol or tetrahydrofuran, are indispensable for this reaction to proceed.

The high yield of dimethyltin dichloride obtained by this method is of special note.

Butyl chloride was treated with tin by a similar procedure, but the reaction was found to be unsuccessful because of side reactions.

The physical properties of the alkyltin halides obtained in these experiments are listed in Table II, together with the data which appeared also in a recent article[4].

Spark Ionization of Semi-metallic and Metallic Elements and of Ionic-crystals

By Toshiyoshi YUASA

(Received April 21, 1961)

Inghram et al.[1-3] and Honig[4] have observed polyatomic molecular ions of carbon, silicon, and germanium by means of a mass spectrometer with a high-temperature effusion cell. These molecular ions have also been observed by Dörnenburg and Hintenberger[5] and by Sasaki et al.[6] using a double-focusing Mattauch-type mass spectrometer with a high frequency spark ionization source. However, the mechanism of the production of the molecular ion is still not clear. Therefore, primarily to find out qualitatively what kinds of electrode elements are capable of producing such molecular ions, experiments on the electrodes of semi-metallic and metallic elements and on ionic-crystals were performed by the author. In addition, some measurements for thermal ionization were also made in connection with the spark ionization.

Experimental

A double-focusing Mattauch-type mass spectrometer with a high frequency spark ionization source, which had been constructed by Sasaki et al.[6-8], was used. The sample to be examined was prepared in the form of rods. Two such rods for each sample were mounted in the spark ionization source with their tips approximately 1 mm. apart. The source was evacuated and, when the pressure had fallen to about 10^{-6} mmHg, spark voltage of 20 kV. was applied to the sample rods. The mass spectrum

Thermal ion

$W(Al_2O_3)$

was recorded, at the ion-accelerating voltage of 16 kV., on an Ilford Q-2 photographic plate. The time of exposure required for taking mass spectrographs clearly for the samples of elements and of ionic-crystals were 1~5 min. and 10 min. respectively. Typical results obtained for samples of germanium, tin (white tin), and platinum are given in Fig. 1. Gaseous species for each sample were examined on the mass spectrograph; those results are summarized in Table I, in which the sample Pt(Cu) is a platinium rod plated with copper. The results obtained in the spark between the electrodes of the different kinds of sample rods are also given in Table I.

Furthermore, mass spectra of positive ions emitted by electrical heating from a filament which has been mounted at both ends of the sample holder of the electrodes were investigated.

The thermal ionization source $W(Al_2O_3)$ shown in Fig. 1 is an alumina-coated tungsten filament, 0.055 mm. in diameter.

Results and Discussion

Thermal Ionization.—The mass spectrographs (Nos. 1—5) of the thermal ion given in Fig. 1 were taken during the gradual rise of temperature in one filament. The observed color of the filament and the time of exposure at each

temperature were as follows: 1) dark red, 10 min.; 2) red, 10 min.; 3) yellowish red, 10 min.; 4) yellow, 5 min.; 5) yellowish white, 5 min. The experimental results can be summarized as follows.

The positive ions emitted from the filament are Na^+ and K^+ (39) at somewhat low tempertures, and K^+(41) and Al^+ in addition to Na^+ and K^+(39) at still higher temperatures, perhaps above 1000° C. At still higher temperatures these impure ions of alkali disappear and the emission of the only Al^+ ion is rich. Thus, the variation in positive ion emission caused by the gradual rise in temperature of the filament was successfully tracked out by taking a mass spectrograph of the ion emitted.

For the ion source of the platinum filament, 0.06 mm. in diameter, only alkali ions such as Na^+ and K^+ were observed.

Spark between Different Kinds of Electrode Elements.—Species found in the spark between the electrodes of different kind were found in just the same mixture as had been produced in the sparks of each electrode. For instance, in the spark between the electrodes of carbon and silicon elements no molecular ion such as silicon carbide was observed (cf. Table I).

Spark between the Same Kind of Electrode Elements.—Multiply-charged monatomic ions are given for all samples, whereas polyatomic ions are given only for several kinds of samples, and these are only singly charged ones (cf. Table I). This seems to show that monatomic molecules in the gas phase can be readily ionized to multiply-charged ions, whereas polyatomic molecules are too unstable to form doubly-charged ions without decomposition of the molecules.

Polyatomic ions are produced only for the semi-metallic elements (cf. Table I). (This result was obtained in a significant concentration of mass spectra under experimental conditions concerning spark voltage, the time of exposure, etc., such as has been described in the experimental section. No experiments under other conditions were carried out.)

Spark between the Electrodes of Ionic-crystal.—When the spark voltage was applied to the electrodes of an alkali halide single crystal, the crystals were brightly colored in the run, violet for sodium chloride, yellow for lithium fluoride, and cobalt blue for potassium bromide.

As shown in Table I, the gaseous species for each crystal are positive ions of alkali and halogen, including their isotopes, and the concentration of the spectral line of halogen ions is, in general, less then that of the corresponding alkali ions. For alkalis, their multiply-charged monatomic ions are given, whereas for halogens, only singly-charged monatomic ions are given. Molecular ions such as $NaCl^+$ and Na_2^+, for instance, were not observed.

When the crystals were taken out from the spark source after sparking, it was observed that the crystals still held their original shape and, moreover, that color centers had been formed finely, yellow for sodium chloride, yellowish brown for lithium fluoride, and cobalt blue for potassium bromide. These color centers seem to have been formed by electron impact on the crystals.

The species found in the spark between electrodes of different kinds (e. g., sodium chloride and potassium bromide) were in just the same mixture as what had been produced in the sparks of each electrode (cf. Table I). Similar results to the case of the same kind of electrodes were also obtained in the matters of the brightness of crystals during sparking and of the color centers after sparking.

Concentration of Mass Spectral Line of Spark Ion.—The results obtained from an examination of the mass spectral line in the significant concentration are as follows:

For all elements, as shown in Fig. 1, for instance, their isotopes are simultaneously given in the spark, and the relative intensity in the lines of an isotope corresponds approximately to their abundance ratio.

For each sample element (X), the relative intensity of multiply-charged monatomic ions is $X^+ > X^{2+} > X^{3+} \cdots\cdots$. In the case of polyatomic molecular ions, the relative intensity is $X^+ > X_2^+ > X_3^+ \cdots\cdots$ for silicon, germanium, and selenium, $X^+ > X_2^+$ for tellurium and antimony, and $X^+ > X_3^+ > X_2^+ > X_5^+ > X_4^+$ for carbon. Furthermore, the intensity of polyatomic ions is, in general, less than that of multiply-charged monatomic ions of the same element.

Discussion.—Gaseous species observed in the thermal ionization were usually singly-charged monatomic ions for the ion sources of alumina-coated tungsten filament, bare platinum filament, etc.[9-11], whereas, in the spark, multiply-charged monatomic ions were always observed. In addition, an estimation of quite a high temperature can be given for the tips of element rods during sparking, for, the tips have been observed in a melting state after sparking. These results seem to show a difference between the mechanism of ion formation by sparking and that by thermal ionization[9-11]. In the case of a spark, as is well known, electrons are produced through a kind of chain reaction, and most of the experimental results obtained here can well be understood as an effect of the

9) T. Yuasa, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **79**, 996 (1958).

11) T. Yuasa, ibid., **80**, 1117 (1959).

electron impact on the electrodes or gaseous particles.

In the condition of such an electron impact on gaseous particles, the ionization (or decomposition) process for the atom, ion, or molecule seems to overcome other processes such as the recombination of atom and ion.

Therefore, one of the two alternative mechanisms considered—the formation of polyatomic ions by recombining the atom with the ion in the gas phase—seems to be unlikely, and another formation process appears probable. That is, first, large gaseous molecules are emitted from the rods, then the substances are decomposed in the gas phase; thus a series of molecular ions as given in Table I are produced, or such a series of ions may be sublimated simultaneously from the first. (These two processes may take place simultaneously.) If this process, in which no polyatomic ions can be formed as long as polymerized substances are not sublimated from the solid, is applied to the experimental results, the conclusion can be drawn that the sublimation products from the metallic crystal are only a group of free monoatomic molecules, whereas for the semi-metallic crystal with a covalent bond some gaseous polymer must exist in the sublimation products.

Summary

Using a mass spectrometer, the nature of the mass spectrum produced by the spark ionization source of semi-metallic and metallic elements and of ionic-crystals was studied, and it was found that only semi-metallic elements are capable of producing their polyatomic ions in a significant concentration.

When the samples of alkali halide single crystals were taken out from the spark source after sparking, it was observed that the crystals held their shape and, moreover, that color centers had been formed finely.

In the light of the experimental results, the mechanism of the ion formation in the spark was discussed, and it was pointed out that some relation might exist between the crystal structure of the solid sample and the formation of the gaseous molecular ion.

The author wishes to express his thanks to Mr. S. Nas for his cooperation in the experiments.

Separation of Uranium from Fission Products using Cellulose

By Noboru Oi

(Received May 20, 1961)

Cellulose column chromatography has been extensively used for the separation of uranium from other metals[1], thorium from rare earths[2], uranium from thorium[3], uranium from plutonium[4] and so on.

This method has the advantage that minor components or impurities are adsorbed and collected onto cellulose. This is the opposite of the ion exchange or solvent extraction method, which extracts the main component, such as uranium or thorium.

The applicability of this method to the separation of uranium from fission products has been briefly mentioned by the author[5]. Because the amounts of fission products in irradiated uranium are very small, this method seems especially suitable for this separation. In this paper a detailed treatment of this program is presented.

Experimental

Reagents.—*Cellulose.*—Cellulose powder, 100~200 meshes for chromatography, was obtained from Toyo Roshi Co., Ltd., and was used after treatment with dilute nitric acid according to the method of Burstall[1].

The irradiation of the uranium was performed in a JRR-1 reactor. A uranium(IV) oxide pellet was irradiated for one week, and after a coling period of 30 to 100 days it was dissolved in nitric acid; then the excess nitric acid and water were evaporated off, leaving the uranyl nitrate hexahydrate.

Separation by Column Method.—One gram of cellulose was packed in a glass tube 18 mm. in

diameter. Uranyl nitrate containing fission products was dissolved in an organic solvent keeping the concentration of uraniun about 0.2 M, and this solution was passed through the column. Then the column was washed with ten milliliters of the organic solvent, and then 30 ml. of one molar nitric acid was passed to elute the adsorbed fission products. The fractions of the organic solution, nitric acid and remaining cellulose were analyzed by a single-channel γ-scintillation spectrometer.

Separation by Batch Methed.—To obtain the distribution ratios of individual fission products at various uranium concentrations in an organic solvent, the following method was employed. About one microcurie of nuclides in nitric acid was evaporated to dryness in a beaker under an infrared lamp. Then, various concentrations of uranyl nitrate in organic solution were added, and the nuclide was dissolved by stirring. This solution was then transferred to a graduated glass cylinder with a stopper, and 100~200 mg. of cellulose was added. The activities of the solution before and after the equilibration (one hour was enough) were measured by a scintillation counter, and the K_d value was calculated by the following equation:

$$K_d = \frac{\text{Activity adsorbed per g. of cellulose (c.p.m./g.)}}{\left(\begin{array}{c}\text{Activity per ml. in solution at equilibrium} \\ \text{(c.p.m./ml.)}\end{array}\right)}$$

Results

Selection of the Solvent. — Almost all the works ever published on cellulose column separation have used as an organic solvent, either ethyl ether, isopropyl ether, or, in some cases, ethyl methyl ketone. In order to establish a rule for the selection of the organic solvent, about forty solvents which can dissolve uranyl nitrate were tested (Table I). In this experiment, one gram of uranyl nitrate hexahydrate was dissolved in 30 ml. of organic solvent together with cerium-144 and was passed through the column. The eluted organic fraction was counted to calculate the percentage of the eluted cerium. The K_d values obtained for cesium-137 proved more clearly the rule for the selection of the organic solvent, as shown in Fig. 1. These two results agreed well in that the solubility of water in the solvent here plays a main role in the separation. A water-insoluble ether or an acetate, such as ethylether, *n*-butylacetate or isoamylacetate, showed good results. On the other hand, alcohols, acetone and tri-*n*-butylphosphate did not give good results.

Influence of Nitric Acid and Water.—All of the published works have used a mixture of inorganic acid and an organic solvent, such as nitric acid and ether, hydrofluoric acid and ethyl methyl ketone. As to the influence of nitric acid, Burstall and Wells[1] pointed out that nitric acid was necessary for the quantitative recovery of uranium or thorium, while large amounts of nitric acid caused an increase in the solubility of other metals.

In this work we used only organic solvent. For the separation of uranium from fission products, free nitric acid must be eliminated. In this case, however, the complete recovery

of uranium becomes difficult. From Table II, it is clear that the adsorption of fission products, especially ruthenium, decreased rapidly with the addition of nitric acid. The adsorption of uranium and its daughter nuclides also decreased, while adsorptions of cerium[6] and zirconium were little influenced. The increase in the elution of ruthenium is perhaps due to the formation of a trinitrato nitrosyl complex.

On the contrary, the presence of water is necessary for this separation, as is shown in Table III. This indicates also that water, namely partition, is a key factor for the adsorption. But the addition of water in excess must be avoided because the loss of uranium will increase.

Distribution Ratios for Individual Nuclides. — Irradiated uranyl nitrate cooled for four weeks was dissolved in *n*-butyl acetate and was passed through the cellulose column. Eluted fractions were collected and analyzed for uranium and fission products. The results are shown in Fig. 2. This pattern indicates that the adsorption of fission products onto cellulose is influenced by the concentration of uranium in the organic solvent. This phenomenon becomes clear with the determination of the K_d values of the fission products. Figure

6) Ce-144 was completely retained on the cellulose when 20% of HNO_3 in ethylether was used.

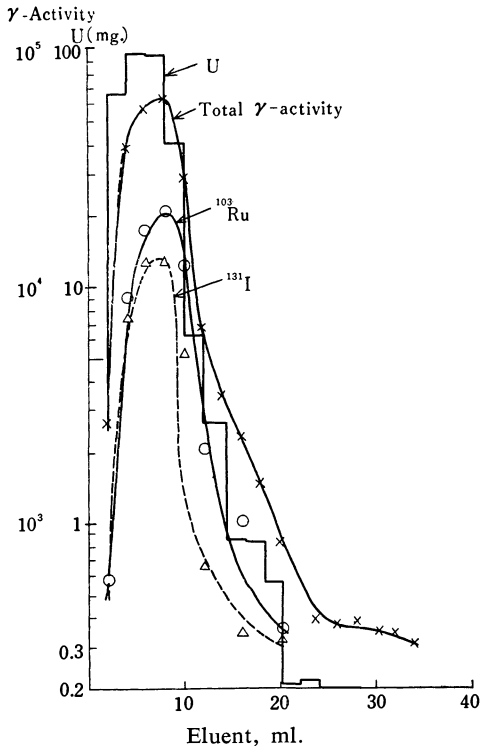

Fig. 2. Elution of uranium and fission products using *n*-butyl acetate.

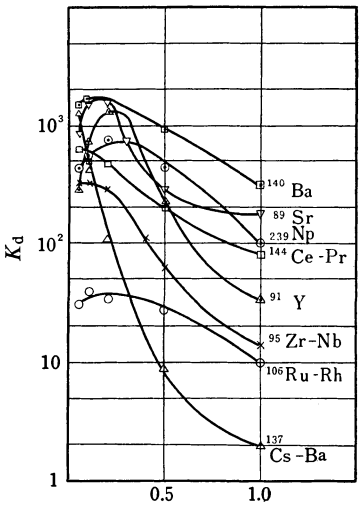

Fig. 3. Distribution ratios of fission products and neptunium as a function of uranium concentration in *n*-butyl acetate.

3 shows the K_d values for comparatively long-lived fission products and neptunium at various concentrations of uranium in *n*-butyl acetate. Here, the adsorption of fission products decreased rapidly with an increase in the uranium concentration. These values correspond well to the behavior of the nuclides in the column. Ruthenium is the most troublesome nuclide, and its degree of adsorption always determines the decontamination factor for total gamma activity. Cesium was found to elute when the uranium concentration was high. Consequently, uranium concentrations which passed through the column were limited to below 0.2 M.

Treatment of Irradiated Uranium. — As an example, the treatment of one-week-irradiated and 100 day-cooled uranium was conducted. The results are shown in Table IV. It must be noted that these results are valid only for this amount of uranium. Figure 4 shows the γ-spectrographs for the sample of uranium, the eluted organic solution and the activity remaining on the cellulose after the passage of one molar nitric acid. About 20~40% of zirconium was found to remain on cellulose without its being eluted by nitric acid.

Discussion

As has been mentioned, for the separation of uranium from fission products by cellulose,

we can not use nitric acid to keep off the elution of ruthenium. For this reason, large amounts of organic solvent are necessary for the complete recovery of uranium. But when one to two grams of uranium are to be treated, 99% or more of uranium recovery and 99% or more of fission products removal can be accomplished easily by using less than 40 ml. of organic solvent and one gram of cellulose.

As to the treatment of large amounts of irradiated uranium, it requires much further investigation. Because the K_d values for fission products nuclides are of the order of 10^2 to 10^3, even at a uranium concentration of 0.2 M the amount of uranium to be treated by one gram of cellulose seems to be limited.

This method has the advantage that the fission products are collected onto cellulose. This makes easier further treatment such as waste disposal or the recovery of potential radioisotopes. The selective elution of fission products nuclides from cellulose will be made possible by the use of a combination of complexing agents. This remains for further investigation.

The mechanism of this separation is not yet known. As has been mentioned, partition will be a large factor, while adsorption by ion exchange seems to be a factor, too.

Summary

The separation of uranium from fission products by using cellulose has been demonstrated. Uranyl nitrate hexahydrate containing fission products was dissolved in an organic solvent that had low solubility of water, and this solution was passed through the column of cellulose. Almost all the fission products were retained on the cellulose, while uranium passed almost unadsorbed. The most labile nuclides were found to be ruthenium and cesium. Free nitric acid must be eliminated to prevent the elution of ruthenium.

The distribution ratios of individual fission products and neptunium between cellulose and an uranyl nitrate solution in *n*-butyl acetate were determined, and it was found that the adsorption of fission products decreased with the increase in the uranium concentration of the organic solvent. Therefore, the concentration of uranium that passed through the column was limited to below 0.2 M.

It was also found that water was necessary. This indicated partition as one of the mechanisms of this separation.

In this method the mass transfer of uranium between two different phases is not performed, so the contamination of fission products is rather small. Moreover, uranium can be easily recovered and fission products are condensed on a small amount of cellulose.

Energy Distribution of Secondary Electrons from Copper-Beryllium Alloy by Bombardment of Positive Ions of Inert Gases. II. Activated Copper-Beryllium

By Toshio SUGIURA

(Received April 1, 1961)

In a previous communication[1], study of the electron ejection from the electro-polished copper-beryllium by the bombardment of the positive ions of inert gases has been reported on. In that work, the energy distribution of secondary electrons was measured, and the mechanism of the secondary electron ejection from the electro-polished copper-beryllium surface was discussed. It was found that the general features of the distribution curves show the kinetic ejection, and that the energy distribution of secondary electrons has a correlation with the ionization potential of the impacted ions. These results indicate that the mechanism of the secondary ejection in that study is not satisfactorily explained by the

1) T. Sugiura, This Bulletin, **34**, 1475 (1961).

simple kinetic ejections; the contribution of the potential ejection must also be taken into consideration. In an earlier communication[2], it has been reported that the secondary electron yield from the copper-beryllium surface impacted by positive ions is markedly increased by the activation treatment of the copper-beryllium surface, and that quite a thick layer of beryllium oxide is newly formed by the activation in the neighborhood of the surface.

It is, therefore, of interest to the present author to investigate the energy distribution of the secondary electrons emitted from the activated copper-beryllium surface, since such an investigation would make possible a comparison with the results reported in the previous communication[1] and with the information on the mechanism of the secondary electron ejection from the activated copper-beryllium surface.

Experimental

Apparatus and Procedure. — The apparatus and the procedure have already been described in the previous communication[1].

Preparation of Ion Target. — The activation treatment of the ion target was carried out in a quartz tube (45 mm. in inner diameter and 500 mm. in length) connected by a water-cooled taper joint to the vacuum system, the reservoir of purified oxygen, and a McLeod gauge. The quartz tube was heated in an electrical furnace, and the temperature was measured with an alumel-chromel thermocouple enclosed in this quartz tube. The shaped and electro-polished ion target was put into the quartz tube and evacuated to lower than 5×10^{-6} mmHg at about 800°C for about three hours. After the evacuation, the temperature in the quartz tube was lowered to the required temperature (400°C in this study), then a known quantity of oxygen was introduced into the quartz tube. The initial pressure of oxygen was about 5×10^{-2} mmHg.

Materials. — The inert gases were the same as those described in the previous communication[1]. Oxygen used for the activation of the ion target was prepared by the thermal decomposition of potassium permanganate and was purified by passing it through a trap cooled by liquid nitrogen.

Results

Contact Potential between Gold and Activated Copper-Beryllium. — The contact potential between gold and activated copper-beryllium was determined for the purpose of the correction of the energy scale for the secondary electrons. Typical results on the retarding potential measured in a manner similar to that described in the previous communication[1] are shown in Fig. 1, in which the circular points indicate the retarding potential curve between the tungsten filament and the gold surface, while the square points show the retarding potential curve between the tungsten filament and the activated copper-beryllium surface. As seen in Fig. 1, the retarding potential portion had been observed to be linear from 0.75 to 1.25 V. for the tungsten~copper-beryllium system, and the value of the retarding potential for the tungsten~gold system well coincides with that obtained in the previous communication. As shown by arrows in each curve in Fig. 1, the point of zero field has beeen determined by the intersection of each extrapolated straight lines with the saturated current and the retarding portion. The observed value of the contact potential difference between gold and activated copper-beryllium is 0.25 eV; namely, the surface potential of activated copper-beryllium is 0.25 eV. more positive than that of gold.

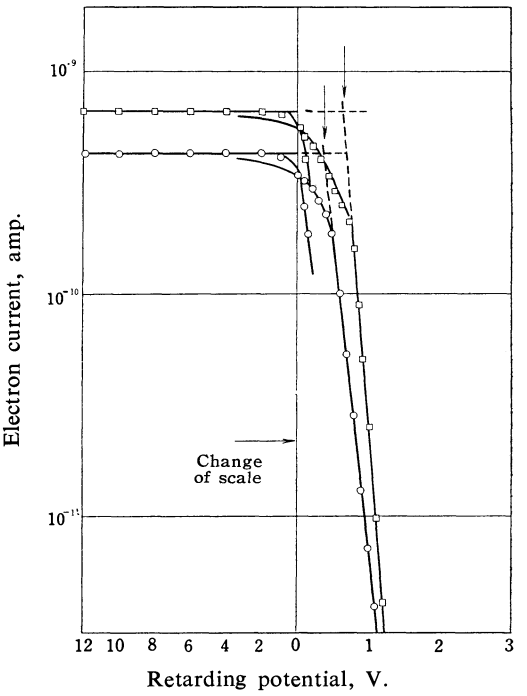

Fig. 1. Retarding potential curves of thermoionic electron from the heated tungsten used to determine the contact potential difference between gold and activated Cu-Be. The circular devices show the Au~W system, the square devices show the activated Cu-Be~W system. The vertical arrows on each curve indicate the values for the zero field in each systems.

Energy Distribution of Secondary Electrons. — The distribution curves of the kinetic energy of secondary electrons by singly-charged argon ions are shown in Fig. 2. In this figure, the results obtained for the incident ion energy of 1240, 840 and 540 V. are indicated by circular,

2) T. Sugiura and T. Hayakawa, ibid., 34, 58 (1961).

square and triangular devices respectively. The electron energy scale (V_r) in this figure was corrected to the contact potential difference between the ion target and the electron collector, as described above. The distribution curves of the kinetic energy of secondary electrons by doubly-charged argon ions, singly- and doubly-charged neon ions and singly charged helium ions have been also obtained; these distribution curves, which have been abbreviated in this paper, have a shape similar to and have the same tendency as the curves in Fig. 2. The distribution of the kinetic energy of the secondary electrons obtained in this study represented by half the width of each distribution curve and the yield of secondary electrons are summarized in Table I. As seen in Fig. 2, these distribution curves show no low energy tail, the fringing field of the analyzing magnet of the mass spectrometer having no observable influence on low energy electrons.

Discussion

General Features of Energy Distribution Curves. — As seen Fig. 2, the general features of the distribution curves of the secondary

electrons from the activated copper-beryllium surface are similar to those obtained for those of non-activated copper-beryllium surface already reported on in the previous paper[1]. But, as seen in Table I, the half-widths of the distribution curves increased about 10 to 50% by the activation of the copper-beryllium in each case, together with the increase in the secondary electron yield

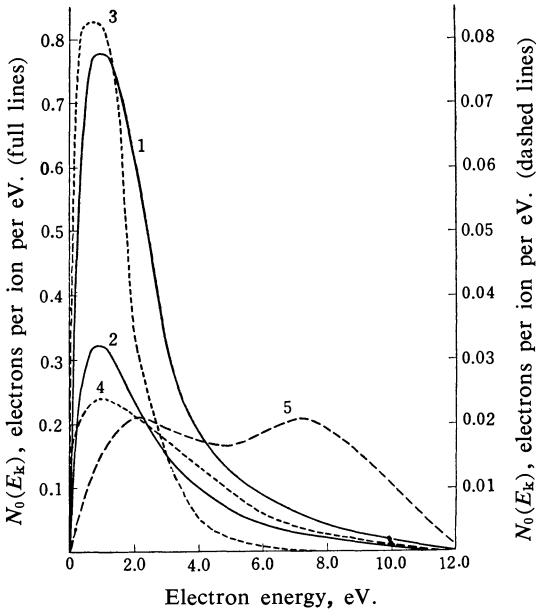

Fig. 3. Energy distributions of electrons ejected from activated Cu-Be by singly-charged helium ions of 1240 (curve 1) and 540 eV. (curve 2), and energy distributions of electrons ejected by 10 eV. helium ions from germanium (111) surface in various cleaning conditions obtained by Hagstrum[3] (curves 3, 4 and 5), the cleaning conditions of germanium surface described in the text.

3) H. D. Hagstrum, *J. Phys. Chem. Solid*, **14**, 33 (1960).

Recently, Hagstrum et al. have reported investigations into the interaction between the slowly moving helium ion and the germanium[3] and the silicon[4]; he was interested to find the procedures necessary for the preparation of clean semiconductor surfaces. In Fig. 3, the energy distribution curves 1 and 2 of secondary electrons ejected from activated copper-beryllium by 1240 and 540 eV. helium ions obtained in the present study are compared with the results of Hagstrum (curves 3, 4 and 5) with 10 eV. helium ions from the (111) face of germanium. Curve 3 in Fig. 3 was obtained for the face of etched germanium, and curve 4 was obtained for the germanium surface treated in the following manner: after being heated to 1125°K for 4 hr., the target was exposed with dry nitrogen at atmospheric pressure and successively repumped for about 100 hr. without any target heating. As seen in Fig. 3, the energy distribution curves of the secondary electrons are gradually broadened from curve 3 to curve 4 by target heating, but the area of the distribution curve is markedly decreased by the heat treatment i. e., the electron yield decreases as a result of target heating. Curve 5 in Fig. 3 was obtained for the germanium surface after heating at 940~1170°K for about 180 hr. and subsequent sputtering of about 100 layers of germanium at a 4 mA/cm^2 current intensity for 90 min.; Hagstrum has considered that curve 5 is the distribution curve of a secondary electron emitted from the atomically clean germanium surface. Hagstrum has obtained similar results for a silicon surface[4].

Figure 3 indicates that distribution curves 1 and 2 show a great similarity to distribution curves 3 and 4 rather than to the distribution curve of the kinetic ejection obtained by Waters[5]. These results imply that the emission of secondary electrons from activated copper-beryllium is followed by the Auger ejection in spite of the fact that the surface is not atomically clean. Further comparison reveals that the yields of secondary electrons in the present experiments are about one order greater than the results of Hagstrum, and distribution curves 1 and 2 are both broader than curve 3, though narrower than curve 4. These results suggest that the cleanliness of the target in the present study may correspond to that about the middle of curve 3 and of curve 4 in Fig. 3. In the present study, the ion target was heated to about 800°C by electron bombardment of the background pressure of 1×10^{-6} mmHg for about 10 min. It is clear that this treatment did not result in an atomically clean surface, but some adsorped layers of residual or foreign gases were removed. Allen[4] has studied the nature of the silicon surface by means of the field emission microscope connected with the investigations of Hagstrum; he has observed that the high intensity random spots from the unheated surface and the secondary electrons emitted by ions from this surface have an energy similar to that shown on curve 3 in Fig. 3. These high intensity spots were eliminated by heating of the silicon, and this surface then emitted secondary electrons having an energy similar to that shown on curve 4 in Fig. 3. Allen has described how these high intensity spots are emitted from the cluster of adsorption layers. From this study, the difference between curves 3 and 4 in Fig. 3 is considered to arise from the fact that the respective surface have and do not have the cluster of adsorption layers. In a comparison of the curves shown in Fig. 3, the energy of each secondary electron shown by curves 3 and 4 is considered to shift to a low energy compared with the energy of the secondary electrons shown by curve 5, and it is supposed that secondary electrons emitted from the ion target lose their kinetic energy in collisions with the adsorbed molecules or atoms. In these surfaces, it is supposed that the influence of the surface characteristics on the energy of the secondary electrons emitted by ions is obscured by the action of the adsorption layers. From the consideration described above, it may be considered that the cluster on the ion target in the present study is removed by the heating of the electron bombardment.

The influence of the ion kinetic energy, the ion species and the ionic charge on the distribution curves of the electron energy has a tendency similar to the results on the electro-polished surface reported on in the previous paper[1].

Influence of Target Activation of the Energy Distribution Curves. — By the activation of copper-beryllium, the yield of secondary electrons was greatly increased. For the purpose of obtaining information about the emission characteristics of the secondary electrons emitted from activated copper-beryllium, the energy distribution curves of the secondary electrons increased by target activation were plotted from the results both of the present study and of the previous communication[1].

Figures 4, 5 and 6 show the plot of the difference in the energy distribution $\Delta N_0(E_k)$ of secondary electrons at each electron energy E_k obtained for the activated and electro-polished

Circular, square and triangular devices indicate the kinetic energy of incident ions of 1240, 840 and 540 eV., respectively. The dashed curve shows the distribution of Auger electron ejected by singly neon ions of 10 eV. from atomically clean W surface obtained by Hagstrum[6].

copper-beryllium target impacted by the singly-charged argon, neon and helium ions respectively. In these figures, circular, square and triangular devices indicate the energy distributions by the incident ions of 1240, 840 and 540 eV. kinetic energy respectively. For comparison, the energy distribution curves of secondary electrons from an atomically clean tungsten surface impacted by 10 eV. inert gas ions obtained by Hagstrum[6] are shown by dashed lines in Figs. 4, 5 and 6.

The distribution curves of $\Delta N_0(E_k)$ were very different from that obtained from activated copper-beryllium. The distribution curves of the singly-charged ions, especially in the case of the slow ions shown in the figures, have two maxima, and the peak of the lower energy side is very narrow, while the distribution of the higher energy side is relatively broad and has a high energy tail. The emission processes of secondary electrons shown in these distributions must thus be considered separately in three parts.

The distribution curves higher than about 4 eV. in electron energy show a great similarity to the distribution curves of Hagstrum indicated by dashed line in each figure, and this distribution is independent of the kinetic energy of the incident ions. From this similarity, the distribution curve under the dashed line may be considered that of the secondary electrons emitted by the Auger

The dashed curve shows the distribution of Auger electron ejected by 200 eV. doubly-charged argon ions from atomically clean W surface obtained by Hagstrum[7].

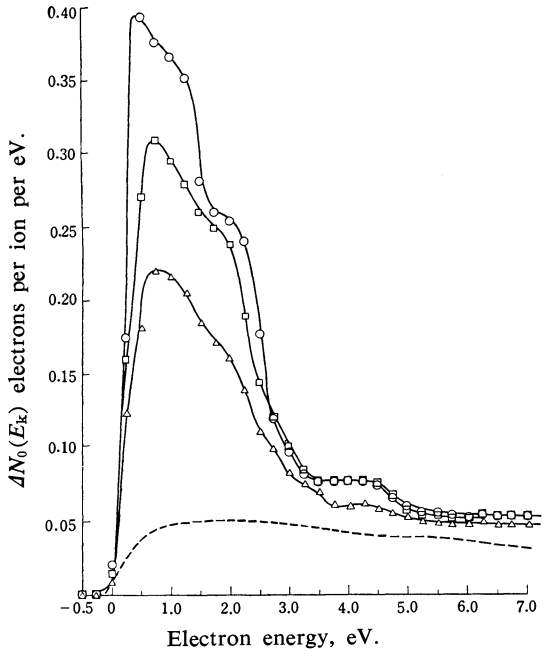

Fig. 8. Plots of the differences between energy distribution ejected from activated and electro-polished Cu-Be impacted by doubly-charged neon ions. Circular, square and triangular devices indicate the kinetic energy of incident ions of 1240, 840 and 540 eV., respectively. The dashed curve shows the distribution of Auger electron ejected by 200 eV. doubly-charged argon ions from atomically clean W surface obtained by Hagstrum[7].

process described by Hagstrum[7]. According to the earlier study by electron diffraction analysis of the activated and electro-polished copper-beryllium surface[2], the quite thick layers of the beryllium oxide were formed on the surface, replacing the copper oxide, by the activation treatment, and the results of the surface configuration suggested that the Auger ejection from activated copper-berillium might be contributed by the beryllium oxide layers mentioned above.

As seen in Figs. 4, 5 and 6, electron distributions exist above the dashed curve in each figure, and these distributions have relatively high energy as compared with distributions obtained from activated surface; the quantity of $\Delta N_0(E_k)$ depends on the kinetic energy of the incident ions. These phenomena show that secondary electrons emitted from activated copper-beryllium have a relatively a higher energy than those emitted from an electro-polished surface. Consequently, higher energy electrons markedly increased by the target activation may be formed relatively near the surface of the ion target. It is also supposed that the stopping cross-section of beryllium oxide for low speed ions in the present study may be greater than that of cupric oxide, although it is difficult to evaluate the values of the stopping cross-section of low energy ions.

The lower energy side of the distribution curves of $\Delta N_0(E_k)$ greatly depends on the kinetic energy of the incident ions, as seen in Figs. 4, 5 and 6; the low energy part of these distribution curves may imply the following interpretation. Part of the secondary electrons are produced in the deeper layer of the ion target by penetrated ions, and these secondary electrons thus produced pass through the considerable length of beryllium oxide produced near the surface of the ion target by target activation, and that part of these secondary electrons with sufficient energy may be ejected from the ion target. Assuming that the stopping power for the electrons of the beryllium oxide is greater than that of the copper oxide, the ejected electrons from the activated copper-beryllium may lose their energy more than those from the electro-polished copper-beryllium surface, as has been suggested by Sternglass[8]. A part of the ejected electrons from activated copper-beryllium may be shifted to the low energy side, in contrast to those from the electro-polished surface.

The distribution curves of $\Delta N_0(E_k)$ for doubly-charged argon and neon ions are shown in Figs. 7 and 8 respectively. As seen in Fig.

7) H. D. Hagstrum, ibid., **96**, 336 (1954).

8) E. J. Sternglass, ibid., **108**, 1 (1957).

7, for the doubly-charged argon ions the high energy tail in the present distribution curve is smaller than that of Hagstrum indicated by the dashed line in Fig. 7, and the separation of the distribution curve is not clear. In the case of the doubly-charged neon ions as seen in Fig. 8, the separation of the distribution curve is not clear for any incident ion energy. As seen from the results of Hagstrum[9] on the 200 eV. doubly-charged argon and neon ions shown by the dashed line in Figs. 7 and 8 respectively, the distribution curve by the Auger ejection processes of the doubly-charged inert gas ions has shifted to the lower energy side as compared with the distribution curves of singly-charged ions. Hagstrum has considered that the faster electrons may be ejected by highly charged ions in the Auger process and that the mean energy of the ejected electrons is practically independent of the ionic charges; he has explained his results by saying that the Auger neutralization of the highly charged ions by the metal surface occurs in steps. From the fact that this explanation may also be fitted to apply to the present result of the doubly-charged ions, it is considered that the distribution of $\Delta N_0(E_k)$ results from the shift of electron energy to the low energy side.

The phenomena in this study can not be attributed to the surface of the ion target not being atomically clean, but it is not unreasonable to consider that the secondary electron emission from activated copper-beryllium includes the contribution of the Auger ejection together with the kinetic ejection.

Summary

The distribution curves of the kinetic energis of secondary electrons from the activated copper-beryllium surface impacted by inert gas ions were together with the yield of the secondary electrons, measured by the retarding potential method. The contact potential difference between the ion target (activated copper-beryllium) and the electron collector (gold) was also measured by the retarding potential method for the thermal electrons from tungsten, and the correction to the kinetic energies of secondary electrons by this contact potential difference was made. For the purpose of obtaining information about the emission characteristics of the increase in the yield of secondary electrons by target activation, the distribution of $\Delta N_0(E_k)$, which is the difference in the secondary electrons emitted from activated and from electro-polished copper-beryllium, was plotted by electron energies. The main results obtained are as follows:

(1) The contact potential difference between activated copper-beryllium and gold is 0.25 eV. (gold, negative).

(2) The general features of the distribution curves of the secondary electrons emitted from activated copper-beryllium show a tendency similar to that of the secondary electrons emitted from electro-polished copper-beryllium, and they also show a great similarity to the distribution curves obtained from the not atomically clean semiconductor surface (germanium or silicon) by Hagstrum.

(3) The distribution of $\Delta N_0(E_k)$ show a remarkable difference from the distribution curves for activated copper-beryllium. Distribution curves of $\Delta N_0(E_k)$ higher than about 4 eV. in electron energies showed a great similarity to the distribution curves of the Auger electron obtained by Hagstrum. Moreover, the distribution of $\Delta N_0(E_k)$ for singly-charged ions shows clearly a separation in the electron energy scale; this result was explained by the fact that the stopping cross-section of the beryllium oxide is greater than that of the cupric oxide.

(4) From the explanation of the distribution of $\Delta N_0(E_k)$, it is considered that the increase in the yield of secondary electrons by target activation depends on the stopping cross-section of beryllium oxide and on the Auger process of electron emission.

The author wishes to acknowledge his indebtedness to Professor Shoji Shida of Tokyo Institute of Technology, and to Professor Teruo Hayakawa and Professor Osamu Toyama of University of Osaka Prefecture; under their direction and guidance this work was carried out. The expense has been defrayed in part from a grant given by the Ministry of Education, to which the author's thanks are also due.

*A New Method of Decomposition for Refractory Minerals and its Application to the Determination of Ferrous Iron and Alkalies**

By Jun Ito

(Received May 18, 1961)

The common ferrous minerals noted for their resistance to attack by a boiling mixture of hydrofluoric and sulfuric acids[1] are staurolite, tourmaline, axinite, kornerupine, sapphirine, ilmenite, chromite, spinels, columbite-tantalite and chrysoberyl. The determination of the ferrous oxide content in these minerals has long been a difficult problem in mineralogy as well as in analytical chemistry.

Among many attempts by analysts and mineralogists to solve this problem, the Mitscherlich method[2], involving decomposition with sulfuric acid in a heated sealed glass tube, and the Rowledge method[3], employing fusion with sodium metafluoborate in a sealed pyrex glass tube or a Vycor tube (Juulinen's modification)[4] or in a stream of carbon dioxide in a platinum boat[5] (Groves's modification), have been considered to be the best. None of these methods however, is simple. The sealing of the glass tubing, fusion under special conditions, continuous boiling of the titrant, etc. are all very time-consuming and are very likely sources of error unless done by well qualified analysts.

The writer noticed the strong resistivity of Teflon against hydrofluoric acid and sulfuric acid as well as its durability at a high temperature (260°C) and pressure and used it as a liner in a high temperature-pressure steel bomb. In this way, a new method of the decomposition of minerals in hydrofluoric acid and sulfuric acid at elevated temperatures and under fairly high pressures was established. This is very simple, less subject to error, and suprisingly efficient method for refractory minerals.

On the other hand, the recent developement of flame photometry has changed entirely the method of determination of alkalies, and the classical Laurence Smith decomposition has been largely replaced by simple acid decomposition, because the complete separation of the other elements has become unnecessary. For refractory minerals such as mentioned above, however, the Laurence Smith method has still been believed to be superior and indispensable. The writer's method offers a much simpler and more suitable way of decomposition with minimum contamination; also the results of an analysis of the alkalies in refractory materials should be more accurate than before. Using many pure minerals and standards available at Harvard Mineralogical Musem, the writer obtained the results given in the following section.

Experimental

Apparatus.—The electric furnace employed was of a vertical type, with chromel-alumel winding. It was operated at 110 V. AC, with Variac control.

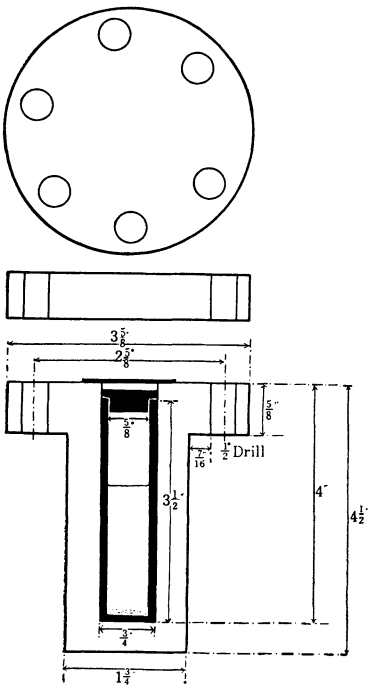

Fig. 1. Steel bomb and teflon liner.

Table I. Results of ferrous iron determination by both new and conventional methods in silicates

Sample	mg.	Heating time	FeO	Fe_2O_3	FeO, conventional
Tourmaline Newry, Maine	200	2	11.70	nil	Insoluble
	300	3	11.73		
Axinite, H. M. 86113 Roseberry, Tasmania	200	2	9.65	nil	Insoluble
	300	3	9.72		
W-1 Diabase	300	3	8.92 (mean of 3 determinations)	—	8.97 (Recommended value 8.72)
Staurolite Fanning Co., Georgia, U. S. A.	300	3	12.56	1.20	Incomplete decomposition
Staurolite, Kootenay Lake, British Columbia	300	3	10.81	1.73	9.92
Kornerupine, H. M. 46934 Itrongahy, Madagascar	200	4	2.39	nil	1.47
Chrysoberyl, H. M. 96545 Tokowaja Lake, Urals	100	3	2.1	—	—
Garnet (Almandite), Davis, New Hampshire, U. S. A.	300	3	31.70	nil	31.37
Garnet (Almandite), North County, N. H., U. S. A.	300	3	21.42	nil	20.65

The temperature was measured with a thermometer.

The steel bomb (Fig. 1) was machined by Arthur and Harold Ames (Dunbar Lab., Harvard) from 316 stainless steel. The bomb was roasted in air for 24 hr. at 450°C to provide a protective oxide coating.

The Teflon liner (tetrafluoethylene) (Fig. 1) was machined by Dr. I. Barnes from 3/4 inch round Teflon stock. The rod was turned to 5/8 inch O. D. and bored with a 19/32 inch drill. The Teflon cap was turned to 5/8 inch O. D. on the upper end and 9/15 inch on the lower end. The Teflon gasket was cut from a 1/32 inch sheet of teflon. The length of the Teflon cup with cap in place was 3 1/2 inches. The bolts were Allen caps the screws 1/2 inch and 3 inch.

Reagents.

H_2SO_4	1 : 1
HF	48%
H_3BO_3	Saturated aqueous solution
$KMnO_4$	0.1 N Standard solution

Procedure.—1) Transfer 0.300 g. of the fine powdered sample to a Teflon liner. 2) Add 5 ml. sulfuric acid (1 : 1), 5 ml. hydrofuoric acid. 3) Stir well with a thin platinum spatula and then wash it with a few drops of pure water. 4) Cover the liner and place in the bomb. 5) Place the gasket and cover on the bomb. 6) Tighten the cover with bolts, using a vise and a rachet wrench. 7) Place the bomb in a preheated furnace at 240°C and leave for 3~4 hr. 8) Take out, cool and open the bomb. 9) Pull out the teflon liner from the bomb using a thin needle. 10) a) For ferrous oxide determination, transfer the acid solution into a 500 ml. beaker filled with 300 ml. of distilled water and 10 ml. of saturated boric acid, then titarte with potassium permanganate standard solution. b) For alkali determination, transfer the acid solution into a platinum basin and heat until all the hydrofluoric acid is driven off, then follow the regular procedure for flame photometric determination.

Results

Diabase standard W-1[6] was analyzed for ferrous oxide (Table I) to check on the accuracy of the method. The results seem to be a little higher (0.1%) than the average analysis. The average value is not necessarily the true value, especially in terms of ferrous oxide determination with conventional methods, but a slight reduction of ferric iron to ferrous iron by pyrite ferrous sulfide could be suspected. Pyrite partly decomposed with this procedure.

Tourmaline from Newry, Maine, U. S. A., Axinite from Tasmania and Kornerupine from Madagascar were analyzed totally using the new method. The calculated formulae from the chemical analysis indicates that the iron present in these minerals is divalent, replacing magnesium manganese in the structure. Axinite definitely does not contain alkalies.

The iron in kornerupine and chrysoberyl is divalent; this explains their bluish color.

Fig. 2. shows that contamination of the iron by the steel of the bomb is remarkably low. Aparently the hydro fluoric acid and sulfuric acid were kept inside of Teflon liner well.

The blank consumption of potassium permanganate solution increases with the time of heating. For ferrous oxide determination, therefore, the heating should be limited to 4 hr. (Fig. 3) if possible.

Among the refractory minerals mentioned above, only tourmaline and kornerupine contain appreciable amounts of alkalies. The

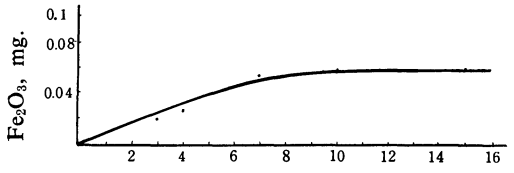

Fig. 2. Iron contamination during the decomposition with new method.

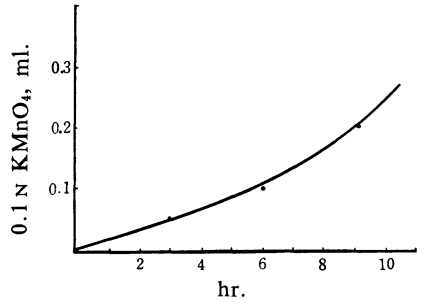

Fig. 3. Blank consumption of 0.1 N $KMnO_4$ after the heating of solution of H_2SO_4+HF with 1 ml of 5 N $Fe_2(SO_4)_3$ solution.

results of the alkali determination are shown in Table II. Blank values of contamination from the new procedure did not exceed the values obtained by the conventional procedure. Actually, the new method decomposed minerals more completely than the other method, and subsequent flame photometric determination was very easily carried out. Although none of the refractory oxide minerals which will be mentioned in the following section contain appreciable amount of alkalies, this method should be very suitable when their alkali content is in question.

Discussion

The principle of the method is somewhat similar to that of the Mitscherlich method, but the use of hydrofluoric acid inside a sealed vessel at an elevated temperature and pressure has never been attempted before for lack of a suitable liner such as Teflon.

As the results show, the reaction between minerals and acids under the stated conditions were carried out completely, and the difficulty of the ferrous ion and alkali determination of the refractory minerals was reduced.

The acid solution in a Teflon-lined bomb can be heated safely as long as the sample requires. Iron and alkali contamination are not detected, although consumption of the potassium permanganate standard solution gradually increases due to the very slight decomposition of the Teflon container. Also, there is no chance for any other contamination of the cation from outside.

Neither appreciable oxidation nor reduction occurred during the heating within a limited time, and the oxygen (air) contained in the partly-filled bomb does not significantly affect the results. The air can be replaced by nitrogen gas if desired.

The apparatus can be designed on a large industrial scale as well as on a microchemical scale, and there is no danger of breakage during the entire procedure because no glassware is involved.

In addition, the writer has extended these

Table II. Results of alkali determination

Mineral	Element	Number of analyses	%
Tourmaline Newry, Maine	Na_2O	3	1.78
	K_2O	3	0.09
Axinite, Roseberry, Tasmania	Na_2O	2	nil
	K_2O	2	nil
Kornerupine, Madagascar	Na_2O	3	0.30
	K_2O	3	0.12
Blank alkalies	Na_2O	3	0.5 ppm in final 100 ml test solution
	K_2O	3	0.5 ppm in final 100 ml test solution

Table III. Decomposition of non-silicates

Mineral	Heating time, hr.	FeO	Grade of decomposition
Magnetite, $FeOFe_2O_3$	4	29.9	Complete, Fe^3 hydrolyzed
Pyrite, FeS_2	5	—	Very incomplete
Ilmenite, $FeOTiO_2$	6	45.1	Complete, Ti^4 hydrolyzed
Chromite, $FeOCr_2O_3$	6	32.9	Complete, clean solution
Tantalite, $(FeMn)(TaCb)_2O_6$	8	7.9	Complete, Fe^3 hydrolyzed
Columbite	8	12.2	Complete, Fe^3 hydrolyzed
Baddeleyite, ZrO_2	12	—	Complete, clean solution
Rutile, TiO_2	16	—	Complete, clean solution
Corundum, Al_2O_3	4	—	Complete, small amount of Al salt precipitated
Zircon, $ZrSiO_4$	10	—	Only HF was used. Complete

experiments toward non-silicate minerals that are mostly oxides and the most difficult materials to dissolve in acids.

Chromite, ilmenite, baddeleyite, columbite-tantalite, rutile and corundum were readily decomposed by the same treatment, although pyrite and zircon were only partly decomposed.

Recently the writer has tried to decompose zircon ($ZrSiO_4$) in various ways and has finally found that it decomposes in the same vessel after 10 hr. of heating at 240°C, using hydrofluoric acid alone instead of a mixture of sulfuric acid and hydrofluoric acid.

The method is good not only for chemical analysis, but also various industrial uses may be found for it.

Finally, the use of strong alkalies instead of acids (Teflon is stable in alkalies too) should be studied.

The writer is indebted to Professor Clifford Frondel, Department of Mineralogy, Harvard University, for his kind advice and encouragement, to Dr. Ivan Barnes, now of the U. S. Geological Survey, for his help in supplying the bomb and furnace, and to Mr. A. Carpenter for his assistance in preparing many specimens used for this experiment.

Also, thanks are due to Dr. J. Frondel and Dr. K. Fuwa for their critical reading of the manuscript.

Differences in the Catalytic Activity of Nickel, Platinum and Palladium as Observed in the Isotopic Exchange Reaction of Paraxylene with Deuterium Oxide

By Kozo HIROTA and Tomiko UEDA

(Received May 23, 1961)

In our former reports on the isotopic exchange reaction of paraxylene with deuterium oxide, it was established that nickel powder exchanges the hydrogen of the methyl groups of paraxylene at 55~100°C with a much higher velocity than it does the hydrogen attached to the benzene ring[1], while platinum black can exchange both hydrogens under similar experimental conditions, as was reported preliminarily[2]. These results are interesting, because such a reaction would serve as an example wherein the difference in catalytic nature between nickel and platinum is shown definitely. Therefore, research has been extended to other metals and to nickel supported on several oxide carriers, using the NMR method for the analysis of products in addition to the infrared and mass-spectrometric methods hitherto adopted. The aims of the present paper are to confirm the above-mentioned difference in the catalytic activity of platinum and nickel and and further to investigate that of the palladium catalyst and the effects of carriers on the activity.

Experimental

Materials.—Deuterium oxide obtained from the Norsk Hydro Co. (99.7% D_2O) was used without any further purification.

Paraxylene (technical grade) was shaken with mercury to make it free from sulfur compounds and was separated from *o*- and *m*-xylene by recrystallization which was repeated five times. The paraxylene thus purified was dried over metallic sodium and distilled into a store vessel.

Raney nickel was developed from Ni-Al alloy consisting of 50% nickel by the method of W-2.

Ni-kieselguhr catalyst, K. S. Y.-6-FC, which had been prepared by the Nikko Co. (Tokyo) was used without any further treatment.

Nickel-alumina and nickel-silica were prepared by decomposing nickel formate supported on alumina and on silica at 270°C, according to the method already reported[1]. The preparation of the nickel-formate-alumina was as follows: 80% formic acid was added to a nickel carbonate solution in which alumina was suspended. In order to complete the

* These numerals denote the estimated values of the produced catalyst after the decomposition of $Ni(HCO_2)_2$-Al_2O_3.

precipitation of nickel formate on alumina, acetone was added to the solution. Two kinds of alumina were used as the carrier: (a) Al_2O_3[a]: commercial activated γ-alumina (Wako Co. (Osaka)); (b) Al_2O_3[b]: pure alumina obtained by dehydration of alumina gel, which was made by adding ammonia solution to aluminium nitrate and letting dry air flow over it for 10 hr. at 500°C. Nickelformate-silica was prepared by the same method as in the case of nickelformate-alumina, by the use of commercial silica gel (Mallinckrodt Chemical Works) in this case instead of alumina.

Platinum black was prepared by reducing chloroplatinic acid made from platinum with formaldehyde and potassium hydroxide.

Commercial palladium black was used (Mitsuwa Kagaku Yakuhin Co.).

Procedure. — Since the procedure has been described in detail in previous reports[1], only the essential points will be mentioned. The catalyst was always prepared in a reaction tube, in which *p*-xylene and deuterium oxide were charged by distillation from their store vessels. The tube was kept at the reaction temperature in a thermostat. After the reaction both *p*-xylene and deuterium oxide were separated from the catalyst by distillation. Paraxylene was pipetted out from the upper part of the distillate, which formed two liquid layers; the paraxylene was then dehydrated with calcium chloride and distillated into another vessel. By infrared spectrometry the deuterated positions of the *p*-xylene molecules were determined, but quantitative analysis of the degree of deuteration was made by resorting to the NMR method. The mass-spectrometric method was also adopted for the same purpose.

The experimental conditions of all the runs are summarized in Table I, where the ratios in parentheses denote those in weight. Infrared spectra were obtained by using Hilger H 800 and Hitachi EPI-2 spectrophotometers equipped with sodium chloride or lithium fluoride prism. The NMR analysis was made by resorting to a high resolution spectrometer (Varian 4300 B; 40 Mc/sec.). The mass-spectrometric analysis was conducted with a Hitachi RMU-5 mass-spectrometer.

Results and Discussion

Difference of Activity among Nickel Catalysts, Platinum Black and Palladium Black.— Before the particular discussion on all the runs, it will be convenient to explain the general tendency of the differences in catalytic activity, taking the runs of Raney nickel (No. 1) and platinum black (Nos. 10 and 11) as examples.

The infrared spectra of the reaction products of Nos. 1 and 11 are shown in Figs. 1 and 2 respectively. The former is quite similar to the one shown in Fig. 3, which was the spectrum of the product when a nickel catalyst prepared from nickel formate was used[1]. It will be evident from a comparison of Figs. 1 and 3 that only hydrogen molecules of the methyl group were catalytically exchanged by nickel, while a new band appeared at 2252 cm^{-1} in the spectrum (Fig. 2) of the sample after the exchange reaction in the presence of platinum at 80°C (No. 11*). The same band was observed in the spectrum of No. 10 when the reaction was carried out at 100°C. It perfectly coincides with that of the deuterated product[3] of *p*-xylene with deuterosulfuric acid D_2SO_4, as is shown in Fig. 4. Since it is a well-known fact that only ring hydrogen can be exchanged with deuterium oxide by an acid catalyst[4], this new band must be due to the stretching vibration of the C–D bond in the

* A similar conclusion has been obtained recently by A. Ozaki et al., (Abstr. Papers of the 14th Annual Meeting of Chem. Soc. Japan, p. 185 (1961)) in the system of toluene and deuterium oxide.

3) T. Ueda, *Catalyst (Tokyo)*, **1**, 1 (1959).

4) C. K. Ingold et al., *J. Chem. Soc.*, **1946**, 222.

ring. Two other bands, which appear at 2192 and 2124 cm^{-1} by deuteration, seem to coincide with those appearing at 2187 and 2118 cm^{-1} in Figs. 1 and 3, i. e., in the samples catalyzed by nickel. (When a lithium fluoride prism was used, the 2187 and 2118 cm^{-1} bands were found to be at 2183 and 2128 cm^{-1} respectively (Fig. 5).) These bands therefore can be ascribed to those of the stretching vibrations of the methyl C–D bond.

The characteristics of the activities of all the catalysts investigated in this research are summarized in Table II, with No. 0 indicating the previous data on nickel prepared by the decomposition of nickel-formate. It will be noted that the activity of palladium black (No. 12) is similar qualitatively to that of platinum, but lies between those of nickel and platinum. The above conclusion can be derived quantitatively from the data of the mass-spectrometric method shown in Table III, where deuterium distribution in the reacted samples was tabulated as d_i (=% of *p*-xylene molecules containing *i* deuterium atoms). The existence of highly deuterated xylene in the cases of platinum and palladium catalysts indicates that all the hydrogen molecules in *p*-xylene are exchangeable, and especially so in the case of platinum.

* Both fractions were determined by allotting ϕ proportionally to the height of NMR signals of methyl and ring hydrogens.

Another point to be mentioned here is the fact that nickel has no activity with the hydrogen atoms of benzene ring. This is apparently in contradiction to the finding of Horiuti and Polanyi[5] that benzene can exchange hydrogen with heavy water in the presence of nickel powder. According to our experiment[2], where nickel powder was prepared by the procedure adopted in the case of xylene, a similar degree of exchange could be found in the case of benzene under the same experimental conditions. Therefore, it must be considered that the activity of ring hydrogen is decreased by the introduction of methyl groups. Such a decrease may be explained by the "geometric" factor rather than by the "electronic" factor, because if it is assumed that the exchange of methyl hydrogen can be realized by dissociative chemisorption of the methyl group ($-CH_3 \rightarrow -CH_2 + H$) on a nickel surface, it will be difficult from the structural reason that a part of the benzene ring is chemisorbed simultaneously. However, the reason why platinum and palladium have the catalytic activity with both hydrogen atoms cannot be answered at the present state of investigation.

Effect of Carriers on Nickel.—As shown in Table II, in the presence of Ni-kieselgulr (No. 2) or Ni–SiO_2 (No. 3) the catalytic exchange of methyl hydrogen occurred in a way similar to the case when no carrier was used (Nos. 0 and 1); i.e., no qualitative effect of these carriers could be found in the infrared spectrum. On the other hand, the results obtained on the Ni-Al_2O_3catalysts (Nos. 4~7) were the same in nature as those obtained on the platinum and palladium catalysts (Nos. 10~12); i.e., both kinds of hydrogen atoms were exchanged, though no exchange could be observed in two runs of the alumina catalyst (Nos. 8 and 9). It is interesting that the catalytic activities of Ni-$Al_2O_3{}^a$ (No. 4) and Ni–$Al_2O_3{}^b$ (No. 7) were nearly the same, irrespective of the differences in their methods of preparation. In order to confirm quantitatively the above results obtained by the IR method, both mass-spectrometric and NMR methods were utilized, the results being shown in Tables IV A and B.

It must also be mentioned regarding Table IV B that the activity of the nickel-alumina catalysts obviously changes according to the ratio of the two components. From a comparison of Nos. 4, 5 and 6, it can be noted that No. 5, the catalyst of the least nickel content, shows the largest activity with ring hydrogen and that the degree of activity is similar to that of platinum black.

Such peculiar effects of alumina as a carrier make it difficult to classify this oxide in the same category as silica and kieselguhr, because it cannot be explained by the difference in surface area between these catalysts. According to Rubinishtein et al. and Morikawa et al.[6], when alumina coexists with nickel, it interacts with nickel more strongly than silica gel[6] does. If so, it is not surprising that nickel catalyst can change its activity when supported on alumina. Another explanation is the change in the valency state of nickel, as proposed by Selwood et al.[7] in the case of nickel oxide-alumina. From their magnetic susceptibility measurement, they concluded that the valency of some nickel atoms changes into +3 in the presence of alumina. Considering the infrared measurement of Eischens[8] that the chemisorbed state of carbon monoxide on platinum-alumina differs from that on platinum-silica, a valency change due to carriers may be possible. Such being the situation, it will be required hereafter to investigate the change in activity from the standpoint of the electronic factor.

Summary

It has been confirmed that nickel can exchange catalytically only hydrogen atoms of methyl groups of paraxylene with deuterium oxide, irrespective of the method of preparation, while platinum and palladium can exchange hydrogen atoms of both methyl groups and benzene ring under similar experimental conditions.

It has been found that the catalytic activity of nickel becomes similar to that of platinum and palladium if nickel is supported on alumina, but remains unchanged if it is supported on silica or kieselguhr.

It has been shown to be difficult to explain these two findings perfectly.

The authors wish to express their sincere thanks to Mr. Motoyoshi Hatada and Mr. Shiro Sato for the mass-spectrometric and NMR measurements of this research project.

Studies on Solvent Extraction using Radioactive Isotopes. VIII[1]. *Solvent Extraction of Cerium with Acetylacetone*

By Nobuo SUZUKI and Shohachiro OKI

(Received March 23, 1961)

The separation of cerium by solvent extraction with ethyl ether or methyl isobutyl ketone from a nitric acid medium has been studied by Imre[1] and by others[3-5], but their methods are tedious in order to avoid the hazard of an explosion of the solvent by concentrated nitric acid. Recently, however, an extraction with di(2-ethylhexyl) orthophosphoric acid and thenoyltrifluoroacetone has been reported[6,7].

It has been known that acetylacetone forms with cerium a chelate compound such as $Ce(C_5H_7O_2)_4$ which dissolves in organic solvents[8,9]. There is no report, however, on the extraction behavior of cerium with acetylacetone. The authors have therefore investigated the various conditions such as acetylacetonate, having an effect on the extraction of cerium.

Experimental

Reagents.—Acetylacetone on the market usually contains considerable amounts of acetic acid; therefore, it was purified as follows: One liter of acetylacetone was washed with 100 ml. of ammonia water (1 : 10), then washed twice with 100 ml. portions of water, and distilled. The distillation fraction of 138°C was collected and used. Carrier-free cerium-144 ($^{144}CeCl_3$) used as a tracer was imported from England; a part of this was diluted to 1 M nitric acid with an activity of about 10^6 c. p. m./ml.

Cerium stock solutions (10^{-2} M) of cerium(III) and cerium(IV) were prepared by dissolving the guaranteed-grade reagents of cerous nitrate and ceric sulfate in 1 M nitric acid respectively; the concentrations of the stock solutions were determined by titration with ferrous sulfate potentiometrically. More dilute solutions were prepared fresh before use from the stock solutions.

Sodium bromate, sodium acetate and other reagents were all guaranteed-grade reagents.

Redistilled water was used.

Apparatus.—For measurements of radioactivity, a well-type scintillation counter, Model RSP-1, made by Kobe Kogyo Co., Japan, was employed. For measurements of the pH of the aqueous phase, a glass electrode pH meter, Model GU-1, made by Shimadzu Co., Japan, was used.

General Procedure.—The general procedure is, unless otherwise stated, as follows: To a stoppered Erlynmeyer flask containing cerium (5×10^{-6} M) and ^{144}Ce, add sodium bromate, acetylacetone, and acetate buffer (20 ml.), and make up the volume to a constant (40 ml.) with water. Mix well for two minutes and let it stand. Every suitable period take out an aliquot (5 ml.) into a separatory funnel and extract the cerium acetylacetonate with 2 ml. of benzene by shaking for one minute. After the phases have separated, transfer the organic and the aqueous phases into two test tubes and let them stand for more than four hours till the radioactive equilibrium of ^{144}Ce and ^{144}Pr has been established; then measure the radioactivity of both phases and the pH of the aqueous phase.

Results and Discussion

Concentration of Acetylacetone.—As will be shown in the later part of this paper, cerous cerium is not extracted with acetylacetone by shaking for 40 min. Accordingly, it is necessary to oxidize cerium to the ceric state. The

authors used sodium bromate as an oxidizing agent.

The relation between the amounts of the chelate extracted and the reaction time is shown in Fig. 1. The reaction rate of cerium with acetylacetone is quite slow at room temperature. Even though the large excess of acetylacetone, such as 0.6 M acetylacetone, is used, complete extraction is not obtained.

Concentration of Bromate.—The concentration of bromate has a great influence on the oxidation of cerium, viz., on the extraction from cerous state, as is shown in Fig. 2. It is conceivable from the results in Figs. 1 and 2 that the rate of increase in the extraction

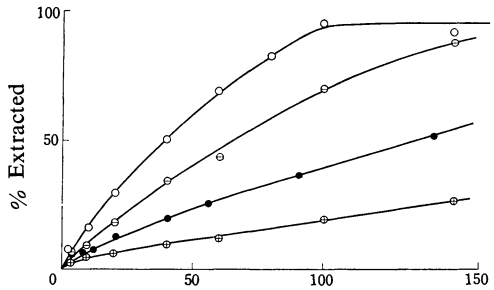

Fig. 2. Effect of concentration of $NaBrO_3$.

[HA] : 0.61 M

percentage against the time elapsed is approximately proportional to the concentration of acetylacetone and bromate, but the discrepancy from the linear proportionality in the case of bromate of a higher concentration can be presumed to be due to the formation of complexes of ceric ion with bromate ion or bromide ion.

Direct Extraction with Acetylacetone in Benzene.—A comparison was made between the following two cases:

(1) Acetylacetone was added to the aqueous solution and left to standing for 2.5 hr. Every suitable period, the chelate was extracted with benzene as described in the general procedure.

(2) Acetylacetone was added as benzene solution, and direct extraction of the chelate was carried out by shaking for a suitable period.

The amounts of acetylacetone used in the two cases were equal. As is shown in Fig. 3, the results of the two cases are, however, considerably different; the results in the latter case are lower. This may be expected from Fig. 1; i. e., the concentration of the acetylacetone distributed in the aqueous phase is decreased by the presence of benzene.

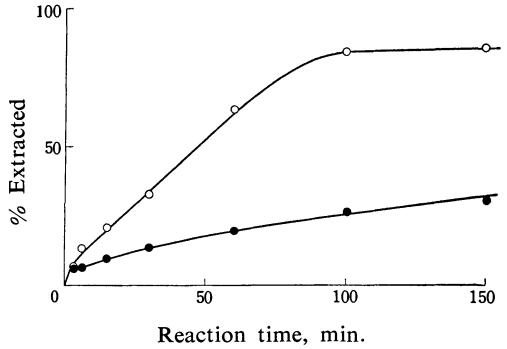

Fig. 3. Comparison of two types of extraction.

○: Extraction by benzene after acetylacetone was added to aqueous solution

●: Direct extraction with acetylacetone in benzene

Oxidation State.—In order to confirm the effects of the oxidation state and the oxidation process, the authors carried out some experiments on various combinations of carrier cerium and ^{144}Ce.

(1) Cerium(III) and ^{144}Ce with 0.61 M acetylacetone.

(2) Cerium(IV) and ^{144}Ce with 0.61 M acetylacetone.

(3) Cerium(IV) and ^{144}Ce with 0.61 M acetylacetone, but in this case ^{144}Ce was pretreated by being left standing overnight in a solution of 0.17 M bromate at pH 2.2.

(4) Cerium(IV) and ^{144}Ce with 0.61 M acetylacetone, but in this case ^{144}Ce was pretreated by being left standing overnight in a solution of 0.17 M bromate and 1 M nitric acid.

(5) Cerium(IV) and ^{144}Ce the same as Exp. 3, except that the concentration of acetylacetone was 1.2 M.

In all cases the concentration of cerium(III) and cerium(IV) was 1.0×10^{-6} M. The results are presented in Fig. 4. It can be observed that cerium in a cerous state can not be extracted with acetylacetone without an oxidizing agent. When cerium(IV) and pretreated ^{144}Ce are used, 50% extraction is obtained as a maximum. This is probably owing to the hydrolysis of cerium(IV). Therefore, though ceric cerium is extracted with acetylacetone, it is not desirable to oxidize cerium before the addition of acetylacetone.

The result of Exp. 2 shows that the exchange reaction is fairly slow. Consequently, in spite of the long reaction time, the apparent extraction remains low.

When an aqueous solution containing carrier-free ^{144}Ce is shaken with acetylacetone in

benzene, ^{144}Ce is rapidly extracted[10]. On the basis of the results in Exp. 1, cerous cerium in ordinary concentration can not be extracted.

This is one of the most characteristic features of the carrier-free ^{144}Ce. The details of this problem are now being examined.

Effect of Heating. — As described in the previous part, a fairly long time is necessary for complete extraction, but the reaction is accelerated by heating. After cooling to room temperature, the extraction with benzene was carried out. The effect of the concentration of reagents at 40°C is shown in Fig. 5.

The results with various concentrations of cerium at 40°C are shown in Fig. 6. Though heating is effective, the yield is low at about 5×10^{-5} M cerium. In every case in Figs. 5 and 6, the effect of heating is accompanied by the

simultaneous disadvantage of the destruction of the chelate compound by hydrolysis. Care should be taken not to heat too long. Ten minutes heating is the best. At room temperature, however, the chelate is found to be fairly stable in the organic phase.

The authors arranged the standard procedure for extraction as follows: A mixture containing 1 ml. of cerium(III)[11], 1 ml. of 2 M sodium bromate, 0.5 ml. of acetylacetone, and 2.5 ml. of the acetate buffer solution is heated at 40°C for the minutes. After cooling to room temperature, the chelate is extracted with 2 ml. of benzene by shaking for one minute.

Extraction and Back-extraction. — The extraction curve of cerium by the standard procedure is shown in Fig. 7. In comparison with the extraction curve of carrier-free ^{144}Ce[10], the optimum pH range is quite narrow, but it is not difficult to adjust the pH of the aqueous phase to about 5~6 with an acetate buffer solution.

In order to investigate the distribution of cerium between benzene and the aqueous phase, and in order to find the suitable conditions for the back-extraction of cerium, an aliquot (2 ml.) of the benzene solution containing chelate prepared by the standard procedure was shaken for 1 min.[12] with each 5 ml.

10) This is shown in Part IX of this series, This Bulletin, 35, 237 (1961).

11) In the final aqueous solution the concentration of Ce(III) is 5×10^{-6} M.

12) One minute was found to be enough for the extraction.

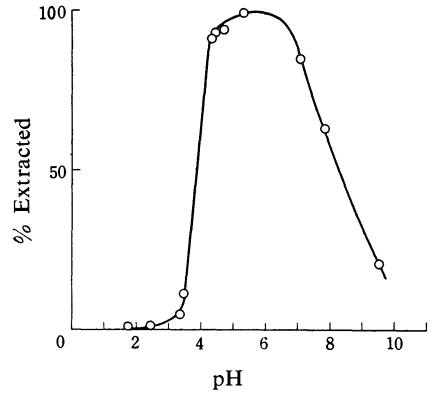

Fig. 7. Extraction curve of cerium. [HA] ; 0.81 M, [$NaBrO_3$] ; 0.33 M

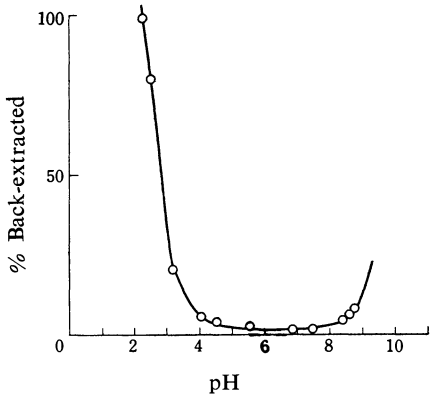

Fig. 8. Back-extraction of cerium from organic phase.

of the buffer solution or with dilute nitric acid.

As shown in Fig. 8, cerium extracted in benzene is easily stripped with a dilute acid, e. g., 0.1 M nitric acid. The chelate in the organic phase is not appreciably influenced by washing with the buffer solution of pH 4~8. The pH range is considerably wider than that of the extraction (cf. Fig. 7), but it is almost the same as the extraction curve of carrier-free ^{144}Ce[10]. Consequently, it is proper to consider that cerium was hydrolyzed in the region of pH 7~8.

Coexisting Substances. — Table I shows the effects of inorganic salts and organic acids. Of the substances tried phosphate, oxalic acid, citric acid, tartaric acid, and EDTA (disodium salt) cause severe interference, even with such a low concentration as ca. 10^{-2} M. A little

interference is observed with nitrate and sulfate. Chloride shows a more complicated interference. This is perhaps owing to the reduction effect of chloride ion in the case of cerium.

Summary

The extraction of cerium with acetylacetone was studied, using ^{144}Ce as a tracer. Cerous cerium can not be extracted without an oxidizing agent. After the mixture of 0.61 M acetylacetone, 0.65 M sodium bromate and 5×10^{-6} M cerium had been left standing for 100 min. at pH 5~6, 95% of the cerium was extracted in benzene. The reaction was accelerated by heating, e. g., at 40°C, or by increasing the concentration of acetylacetone and bromate. Care should be taken not to heat too long, thus avoiding the decomposition of the chelate by hydrolysis. The presence of phosphate, oxalic acid, citric acid, tartaric acid and EDTA caused severe interference.

The authors wish to express their hearty thanks to Professor Shin'ichiro Hakomori and Professor Kunio Seto for their kind suggestions in the course of this work.

Studies on Solvent Extraction using Radioactive Isotopes. IX[1]. *Solvent Extraction of Carrier-free Cerium-144 with Acetylacetone*

By Nobuo SUZUKI and Shohachiro OKI

(Received March 23, 1961)

Several methods for the extraction of cerium have been developed[2,3]. A few applications have also been made to the separation of carrier-free ^{144}Ce from fission products[4]. The separation of a daughter nuclide of a short half-life such as ^{144}Pr from her parent is a very difficult problem on account of the requirement of rapidity. For this purpose, solvent extraction is one of the most proper methods.

In a previous paper[1] the solvent extraction of cerium with acetylacetone was studied. In the course of the work, the carrier-free ^{144}Ce was found to show peculiar features. The authors intend not only to investigate the solvent extraction of ^{144}Ce from fission products, but also to visualize the outlines of the peculiar behaviors of the carrier-free ^{144}Ce compared with cerium of the ordinary concentration reported on in the previous paper.

In addition, because of the rapidity and the simplicity of the method, the separation of ^{144}Pr was found to be possible with acetylacetone.

Experimental

Reagents and Apparatus.—Reagents and apparatus were the same as those of the previous paper. The hydrogen ion concentration of the aqueous phase was adjusted with an acetate buffer solution (ca. 0.1 M for sodium acetate), sodium hydroxide (1 M), and/or nitric acid (1 M). The washing solution for the organic phase consisted of an 0.1 M acetate buffer solution with or without sodium bromate (ca. 0.3 M); this solution was pre-saturated with 20% acetylacetone in carbon tetrachloride or in benzene.

General Procedure.—Unless otherwise stated, the general procedure was as follows: To 5 ml. of an acetate solution containing ^{144}Ce in a separatory funnel, 1 ml. of a 1 M sodium bromate solution was added, and the pH of the aqueous phase was adjusted to 5~6, after which 3 ml. of 20% acetylacetone in carbon tetrachloride or in benzene solution was added. Equilibration was achieved by shaking. After the phases had disengaged the phases were transferred into two test tubes. If necessary, the organic phase was washed with the washing solution.

Results and Discussion

Shaking Time.—^{144}Ce is completely extracted by shaking for about 3 min., especially in the presence of bromate (Table I). It is strange that carrier-free ^{144}Ce is extracted without an oxidizing agent such as bromate. Smith and Pitzer have noticed that tracer amounts of cerium were oxidized by dichromate, but this phenomenon is not expected from the oxidation potential data of a cerous-ceric couple. Cerous cerium can not be extracted with acetylacetone[1], so it may be considered that ^{144}Ce is oxidized to a ceric state without an oxidizing agent and is extracted as acetylacetonate. This is very characteristic behavior of tracer amounts of cerium. This problem is now being examined. It may be noticed in Table I that it takes a longer shaking time for complete extraction without bromate.

TABLE I. THE EFFECT OF SHAKING TIME

Shaking time min.	% Extracted With $NaBrO_3$	% Extracted Without $NaBrO_3$

Isopropyl ether	78.6

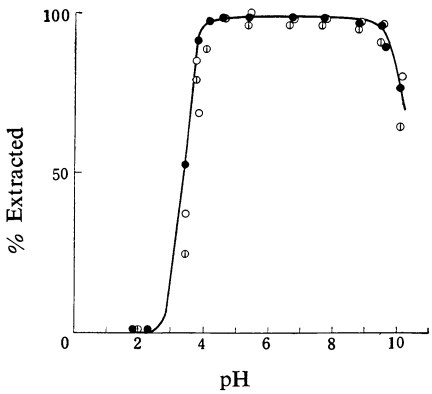

Fig. 1. Extraction curve of ^{144}Ce.
○ Benzene
● Carbon tetrachloride
◑ Xylene

The results of the extraction with 20% acetylacetone in various solvents are summarized in Table III. Carbon tetrachloride and benzene are found to be more effective for extraction.

Extraction and Back-extraction.—The extraction curves of ^{144}Ce by the general procedure with carbon tetrachloride, benzene and xylene are shown in Fig. 1. ^{144}Ce is completely extracted in the range of pH 4~9, and the range is wider than the case of the extraction of carrier cerium[1], but the pH range in the back extraction curve in the latter case is similar to that of the extraction curve of carrier-free ^{144}Ce.

In order to investigate the suitable conditions for the stripping of ^{144}Ce, an aliquot of the organic solution containing the chelate prepared by the general procedure was shaken with mineral acid or a hydrogen peroxide solution for one minute. After the aqueous phase had been removed, the remaining organic phase was shaken again with fresh mineral acid (second stripping). The results are summarized in Tables IV and V. ^{144}Ce in organic phase is readily stripped by dilute acid or hydrogen peroxide solution of about 10%.

Table IV. Back-extraction with mineral acids

Concn. of H_2O_2, %	Back-extracted, %
2	20.1
4	36.9
6	76.9
8	96.6
10	95.0

Decontamination from Fission Products.—The elements found in fission products were tested for their degree of separation from ^{144}Ce. Each pure nuclide was examined individually by the general procedure, and after the completion of this procedure the organic phase was washed with an equal volume of acetate buffer solution (pH 5.6) containing bromate, then the organic phase was shaken with 2 ml. of 0.1 M nitric acid. The results are summarized in Table VI. Decontamination from ^{90}Sr (^{90}Y), ^{106}Ru, ^{137}Cs and rare earth nuclides (e. g., $^{152,154}Eu$), except ^{95}Zr (^{95}Nb), is complete. ^{95}Zr (^{95}Nb) is extracted in the range of pH 2~7[5]; therefore, it is unavoidable that some ^{95}Zr (^{95}Nb) is joined with ^{144}Ce.

For the separation of ^{144}Ce from ^{95}Zr (^{95}Nb), the authors devised two tentative schemes;

Table VI. Behavior of other nuclides (expressed as percentage found in 0.1 M HNO_3 phase)

Nuclide	CCl_4 as solvent	Benzene as solvent

Zr-Nb-95	1	70.5
	2	82.1

5) N. Suzuki and T. Omori, This Bulletin, unpublished.

(a) and (b). Scheme (a) was designed on the basis of the following experimental results: ^{95}Zr (^{95}Nb) extracted in the organic phase is not practically stripped with the mixed solution of 0.01 M nitric acid and 2 M sodium nitrate; on the other hand, ^{144}Ce is stripped quantitatively with the same solution (cf. Table VII). ^{95}Zr (^{95}Nb) stripped in the aqueous phase is extracted again less than 60%, while ^{144}Ce is re-extracted more than 90%. By repeating the extraction-washing cycle twice, the radiochemically pure ^{144}Ce can be prepared from fission products.

In scheme (b), thiocyanate ion serves as a complete masking agent for cerium in the case of acetylacetone extraction[6], while ^{95}Zr (^{95}Nb) is not affected by the presence of thiocyanate[5]. Thiocyanate ions are easily destroyed with nitric acid. Then ^{144}Ce is extracted from the aqueous phase by adjusting the pH with an acetate buffer solution.

By either of the methods nearly 90% of the ^{144}Ce was recovered, while ^{95}Zr (^{95}Nb) was present less than 1% of the initial amount. Fortunately, fission products aged for two years or so have a smaller content of ^{95}Zr (^{95}Nb) than ^{144}Ce; therefore, the contamination by ^{95}Zr (^{95}Nb) is practically negligible. The purity of the ^{144}Ce obtained from such fission products by these methods is expected to be higher than that of ^{144}Ce separated from the mixture (ca. 1 : 1) of ^{144}Ce and ^{95}Zr (^{95}Nb). ^{144}Ce of a radiochemical purity of over 99% was obtained from the fission products with a high yield.

Separation of ^{144}Pr from ^{144}Ce. — As praseodymium is not extractable, the effective separation of a short-life daughter ^{144}Pr from its parent ^{144}Ce is possible. After the radioactive equilibrium of ^{144}Ce (^{144}Pr) in the organic phase has been established, an aliquot of the organic phase is shaken with 3 ml. of the washing solution with or without bromate, and then ^{144}Pr is brought into the aqueous phase. The aqueous phase is washed with carbon tetrachloride; then the radioactivity is measured by a well-type scintillation counter. The radiochemical purity of ^{144}Pr is measured at more than 99.5%. The separation takes only 3 min. or so. The results are summarized in Table VIII, together with the elapsed time after the preparation of the organic phase containing ^{144}Ce. As is shown in Table VIII, bromate is not always necessary to avoid the contamination of ^{144}Ce, and, for practical purposes, it is better not to add bromate to the washing solution. Milking of ^{144}Pr is possible succesively, and the results of the half life of ^{144}Pr show a good agreement with the literature's value (17.5 min), as shown in Fig. 2.

TABLE VIII. RADIOCHEMICAL PURITY OF Pr-144 OBTAINED BY WASHING

	33	99.8*
	50	99.6*

* The washing solution contains $NaBrO_3$.

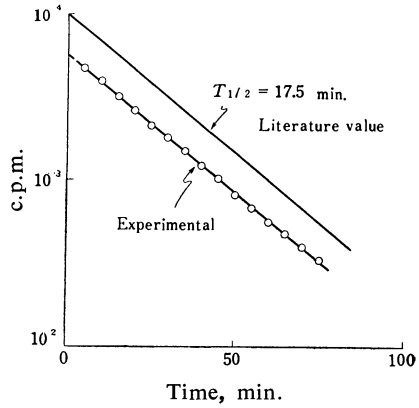

Fig. 2. Decay of ^{144}Pr.

Summary

^{144}Ce was extracted with acetylacetone in a benzene or in a carbon tetrachloride solution by shaking for 3 min. at a pH range of 4~9. Though an oxidizing agent such as bromate was not always necessary, the presence of bromate makes the time for extraction shorter. Decontamination from other fission products, ^{90}Sr (^{90}Y), ^{106}Ru, ^{137}Cs, and rare earths (e.g., $^{152,154}Eu$), except ^{95}Zr (^{95}Nb), was found to be negligible. The contamination of ^{95}Zr (^{95}Nb) was reduced to a negligible amount by repeating the cycle of extraction and stripping or by masking ^{144}Ce with thiocyanate. The separation of ^{144}Ce from fission products with acetylacetone was attempted. ^{144}Pr with a radiochemical purity of more than 99% was easily obtained by washing the organic phase with an acetate buffer solution of pH 5~8.

The authors wish to express their hearty thanks to Professor Shin'ichiro Hakomori and Professor Kunio Seto for their kind suggestions in the course of this work.

6) At the concentrations of 1 and 2 M KSCN, ^{144}Ce is extracted at only 3 and 2% respectively.

On the Mode of Interaction of Surface Active Agents with Gelatin

By Toshizo ISEMURA, Fumikatsu TOKIWA* and Shoichi IKEDA

(Received May 23, 1961)

There are a number of studies on the interaction of surface active agents with high polymers and proteins. It is well known that proteins exhibit a markedly strong affinity for both cationic and anionic detergents. Among various proteins, gelatin is suitable for investigating the nature of the affinity of polypeptide chains with detergents and the mechanism of their mutual interaction. It is readily available. It has no organized conformation as globular proteins have, and it behaves as a random coil, at least, at elevated temperatures (higher than about 30°C).

Pankhurst and his coworkers[1-4] have extensively investigated the interaction of gelatin with various detergents, particularly with sodium dodecyl sulfate, by examining the precipitation of a complex as a function of mixing ratio. They have pointed out that gelatin binds with detergents to form a complex and that the binding ratio of detergent to gelatin is of importance in elucidating the mode of interaction. Tamaki and Tamamushi[5] have also obtained the same conclusion from the determination of two detergents, sodium dodecyl sulfate and dodecylamine hydrochloride, bound to precipitated gelatin on the acidic and alkaline sides of the isoionic point of gelatin respectively.

However, the mode of binding of detergents by gelatin before precipitate formation can not be known by means of such a solubility determination. Detergents should interact and combine with gelatin even without precipitation, since the formation of precipitates would arise from the enhanced hydrophobicity of the gelatin-detergent complex with an increasing amount of detergent bound to gelatin. Evidence for the combination of detergents with other proteins in a region wherein precipitation does not occur has been obtained from studies by electrophoresis[6-8], equilibrium dialysis[6,9], ultracentrifugation[10], viscosity[5,9], solubilization[11], etc.

For solutions of low detergent-gelatin ratios in which no precipitation occurred, studies by electrophoresis and equilibrium dialysis were attempted in order to find quantitatively the amount of detergent bound to gelatin. With the experiment by electophoresis, however, two peaks appeared in the electrophoretic pattern for gelatin alone. It is supposed that the pattern would be more complicated in a gelatin solution mixed with detergent and that its interpretation will be more difficult. Thus electrophoretic investigation was abandoned. In this work, therefore, the mode of binding of detergent by gelatin has been studied by means of equilibrium dialysis in the range of low detergent concentrations at various values of pH. This paper concerns the interaction of gelatin with an anionic detergent, sodium dodecylbenzene sulfonate, and two cationic detergents, dodecyl pyridinium bromide and cetyl pyridinium chloride.

Experimental

Materials.—Commercial photographic gelatin was purified according to the method of James et al.[12] A gelatin solution (2%) was passed through a column of mixed resins (5 parts of Amberlite IRA-400 to 2 parts of Amberlite IR-120) at 30~35°C. The pH of the gelatin solution thus purified was 4.9. The concentration of the stock solution was determined by dry weight.

Sodium dodecylbenzene sulfonate (SDBS), which was prepared by the sulfonation of dodecylbenzene (Oronite Chemical Co., U. S. A.), was obtained from the Japan Surfactant Association. To remove the lower homologues and inorganic salts, it was extracted with distilled water and then with ethyl alcohol. The pH of a 1% solution of the purified SDBS was 7.0. Dodecyl pyridinium bromide (DPB)

supplied by the Kao Soap Co. was recrystallized twice from acetone. Cetyl pyridinium chloride (CPC) was prepared from cetyl alcohol of high purity and recrystallized several times from acetone.

Equilibrium Dialysis. — A dialysis cell consists of two compartments of equal volume, separated by a membrane. As a membrane, Vising cellulose casings (diameter of a pore: ca. 24 Å) were used after rinsing them with warm distilled water. A 10 ml. portion of a detergent solution was placed in one compartment of the cell and equilibrated against an equal volume of gelatin solution in the other compartment. Dialysis was carried out at 30 or 43°C for 3 to 4 days, with an occasional shaking of the cell. The concentration of gelatin was kept constant, 0.2%, and the pH of solution was adjusted by hydrochloric acid or sodium hydroxide. It was confirmed by a Horiba model M3 pH-meter that no change in the pH of the solutions was observed before and after dialysis, except for a slight difference of pH in the case of the binding of SDBS at the isoionic point of gelatin. After the attainment of equilibrium, the detergent concentration in the compartment containing no-gelatin was determined spectrophotometrically, because the molar extinction coefficient of detergent was greatly affected by the presence of gelatin. Since 0.1 M sodium chloride was added to all solutions to eliminate the correction for Donnan's effect, the amount of bound detergent was directly calculable from an analytical value. A control experiment with detergent alone was always carried out to minimize analytical errors. This dialysis method is applicable only to dilute solutions of detergent, since the detergent formed micelles at some high concentrations and was difficult to permeat through membrane[13].

Determination of Concentration of Detergents. —A spectrophotometric method has been developed to determine the concentration of detergents having benzene or pyridinium rings as low as 10^{-5} M[14]. Measurements of the ultraviolet absorption were made by means of a Hitachi type EPU-2A spectrophotometer at a wavelength of 230 mμ with SDBS (molar extinction coefficient, $\varepsilon_{SDBS}=8.75\times10^3$) or at a wavelength of 259 mμ with DPB and CPC ($\varepsilon_{DPB}=4.48\times10^3$ and $\varepsilon_{CPC}=4.59\times10^3$).

Results

The Binding of an Anionic Detergent, SDBS, by Gelatin.—The permeability of SDBS through dialysis membrane decreased with increasing concentration on account of the micelle formation and further decreased with the addition of neutral salts such as sodium chloride because of the lowering of the critical micelle concentration[15]. SDBS was permeable to membrane with difficulty at concentrations above 1.3×10^{-3} when 0.1 M sodium chloride was added. In addition, on the acidic side of the isoionic point of gelatin, precipitation occurred when gelatin was added to a relatively concentrated solution of SDBS. Accordingly, all the experiments were carried out at concentrations of SDBS lower than 1.0×10^{-3} M.

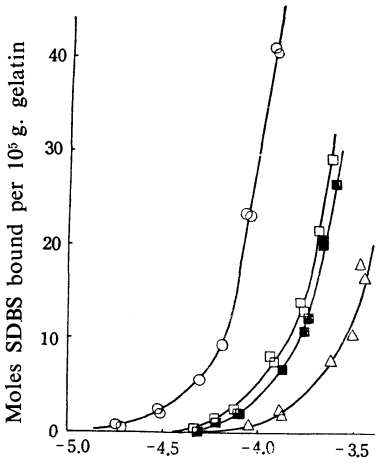

Fig. 1. Binding curves of SDBS by gelatin. ○, pH 2.7, 30°C; □, pH 5.0, 30°C; ■, pH 5.0, 43°C; △, pH 8.0, 30°C

Figure 1 illustrates the binding curves in which the number of moles bound SDBS per 10^5 g. of gelatin, r is plotted against the logarithm of the concentration of free SDBS, $\log c$. The amount of binding of SDBS increases acceleratively with increasing concentration. As the pH of the solution is lowered, the binding of SDBS is enhanced, but even on the alkaline side of the isoionic point of gelatin, SDBS combines with gelatin to a considerable extent. This indicates that gelatin has a strong affinity for SDBS, as other proteins have for long chain alkyl sulfate and alkylaryl sulfonate[4,6,7,11].

The Binding of Cationic Detergents, DPB and CPC, with Gelatin. — Since the critical micelle concentration of DPB lies in such a high concentration as 10.5×10^{-3} M[16], dialysis experiments were possible up to relatively high concentrations. However, experiments with CPC were carried out only at a low concentration region because of its low critical micelle concentration, i. e., 0.9×10^{-3} M[17].

Figure 2 shows the curves for the binding of DPB and CPC by gelatin. CPC combines with gelatin at the isoionic point as well as on the alkaline side of it, but not on the acidic side. DPB is, however, less bound with gelatin

even on the alkaline side. Both cationic detergents can bind with gelatin only to a less extent than the anionic detergent, SDBS. It has been observed[9] that proteins other than gelatin also have a weaker affinity for cationic detergents than for anionic detergents.

Discussion

Binding Isotherm. — If detergent ions bound with protein have no interaction with one another, the equation for the binding is written as

$$r=\frac{kmc}{1+kc} \qquad (1)$$

where k is a binding constant and m is the maximum amount of binding[18]. Eq. 1 implies that r approaches to a saturated value, m, when c is increased and that a plot of $1/r$ vs. c or r/c vs. r should be linear. It was found, however, that the binding data of detergents, SDBS and CPC, with gelatin could not fit Eq. 1. Since detergent ions can combine acceleratively with increasing concentration, detergent ions already bound seem to promote the succeeding binding; that is, the bound detergent ions interact with one another.

When the binding takes place cooperatively, Eq. 1 should be modified to[19-21]

$$r=\frac{kmc^n}{1+kc^n} \quad (n>1) \qquad (2)$$

where n is a constant characteristic of the kind of binding, and is greater than unity if the interaction is operative towards stabilization. Eq. 2 can be rewritten as

$$\frac{r}{m-r}=kc^n \qquad (3)$$

21) M. Kubo, *Proc. Japan Acad.*, **29**, 156 (1953).

The present experiments are concerned with the low detergent-gelatin ratios at which no precipitation occurs. Since the phase separation or precipitation occurs only at relatively high detergent-gelatin ratios, the amount of bound detergent in the present experiment is expected to be far less than the maximum amount of binding. The increasing steepness of the binding curves also suggests that the saturated amount of binding or the number of the binding sites is very large, if it exists at all. Based on these experimental facts, it may be assumed that r is small compared with m. Then Eq. 3 reduces to

$$r=Kc^n \quad (K=km) \qquad (4)$$

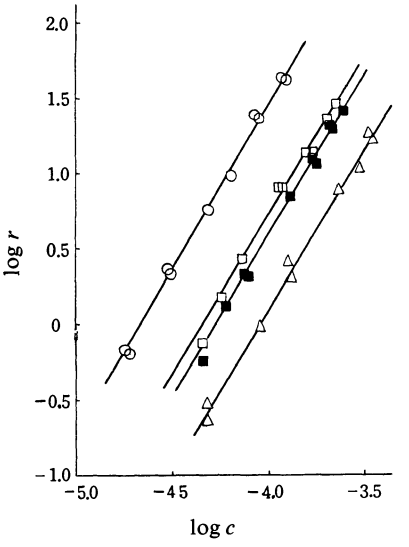

Fig. 3. The log r vs. log c diagram for the binding of SDBS by gelatin. ○, pH 2.7, 30°C; □, pH 5.0, 30°C; ■, pH 5.0, 43°C; △, pH 8.0, 30°C

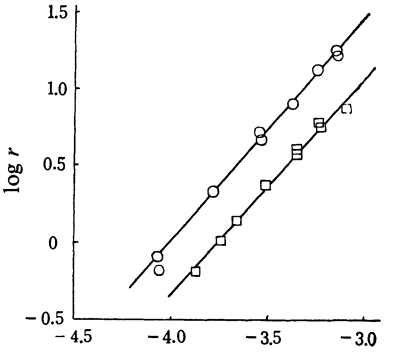

Fig. 4. The log r vs. log c diagram for the binding of CPC by gelatin at 30°C. ○, pH 7.0; □, pH 4.9

which is formally identical with the Freundlich adsorption isotherm, although n is greater than unity. Then a plot of $\log r$ vs. $\log c$ should be linear.

If the data of the binding of detergents, SDBS and CPC, with gelatin are replotted in a logarithmic scale, straight lines are obtained for all cases, as is shown in Figs. 3 and 4. Thus cooperative stabilization is effective for the binding of these detergents by gelatin. The values of the constants, K and n, which can be estimated from the intercept and slope of the straight line, are listed in Table I.

TABLE I. DEPENDENCE OF n AND K ON pH

Detergent	Temp. °C	pH	n	K	$\log K$
SDBS	30	2.7	2.13	8.71×10^{9}	9.94
	30	5.0	2.13	1.74×10^{9}	9.24
	30	8.0	2.10	2.95×10^{8}	8.47
	43	5.0	2.12	1.15×10^{9}	9.06
CPC	30	4.9	1.40	1.82×10^{5}	5.26
	30	7.0	1.44	6.03×10^{5}	5.78

Significance of the Constants, K and n. — Equation 2 can be expressed by an alternate form[21]

$$\frac{r}{m}=\frac{1}{2}\left\{1+\tanh\left(\frac{n}{2}\ln\frac{c}{c_{1/2}}\right)\right\} \qquad (5)$$

in which $c_{1/2}$ represents the concentration of free detergent ions at half saturation ($r=m/2$). Equation 5 can be identified with Eq. 2, if

$$k=c_{1/2}{}^{-n} \qquad (6)$$

Hence, in Eq. 4 for $m\gg r$,

$$K=mc_{1/2}{}^{-n} \qquad (7)$$

In this respect, K is regarded as a measure of the ability of binding or the extent of affinity.

On the other hand, the physical meaning of n is not explicit; the value of n depends on the strength of mutual interaction between bound detergent ions. If n is greater than unity, there occurs a cooperative interaction stabilizing the protein bound with detergent, so that the uptake of one ion makes another ion bind easier[20,21].

Dependence of K and n on pH and the Nature of the Binding. — As is shown in Table I, the value of K increases with the lowering of pH in the case of the binding of SDBS by gelatin. A linear relationship is found between $\log K$ and pH, as is shown in Fig. 5, which is represented by

$$\log K=10.7-0.27\,\mathrm{pH} \qquad \text{at } 30°\mathrm{C}$$

Thus the magnitude of K is related to the interaction of DBS anions with gelatin. This suggests that an electrostatic attraction between

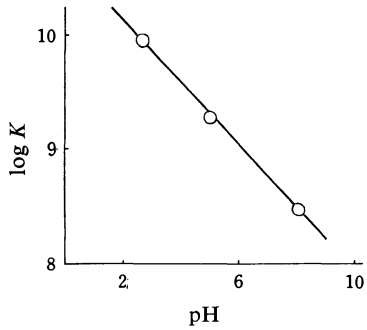

Fig. 5. Relationship between $\log K$ and pH for the binding of SDBS by gelatin.

DBS anions and positively charged groups of gelatin is partly responsible for the binding. Even on the alkaline side gelatin has positively charged sites and binds a finite number of DBS anions.

The value of n is about 2.1 and is independent of pH. This means that the uptake of DBS anions by gelatin favors further binding of other DBS anions in the vicinity of the binding site on gelatin, probably because of the hydrophobic cohesion between DBS anions. Thus, DBS anions form aggregates like micelles on a gelatin molecule. This might have some relation with the increase in the solubilizing power of sodium dodecyl sulfate in the presence of gelatin[22]. Generally, the binding of detergents on synthetic polymers is also interpreted as essentially due to the formation of this kind of micelles on a polymer molecule[23].

It may be concluded that a DBS anion combines with a positively charged group of gelatin and that its binding promotes the further binding of DBS anions around this site due to hydrophobic cohesion. Bound DBS anions form micelle-like aggregates on a gelatin molecule. The former binding will be mostly related to pH's while the latter will be influenced by the length of the alkyl chain of detergent. The effect of the length of alkyl chain has been investigated for anionic detergent-protein systems[4,7], and it is known[4] that the increase in chain length makes the detergent-gelatin ratio lower above which a precipitate separates out. This would also support the concept of the micelle formation on gelatin.

The binding isotherm of SDBS by gelatin can be expressed by

$$\log r=10.7-0.27\,\mathrm{pH}+2.13\log c \qquad \text{at } 30°\mathrm{C}$$

Temperature elevation scarcely influences the

23) S. Saito, ibid., **154**, 19 (1957).

value of n, but it does decrease the value of K by a small amount.

On the other hand, the value of K for CPC is considerably smaller than that for SDBS, and it increases with pH. Further, the value of n for CPC, 1.4, is independent of pH and smaller than that for SDBS, 2.1. These are an indication of the lower affinity of CPC for gelatin; that is, CPC and DPB are less bound to gelatin than SDBS. Generally, a cationic detergent exhibits less affinity for proteins and polymers than an anionic detergent[9,22].

The dependence of the value of K upon pH suggests that the binding of CPC by gelatin is of electrostatic nature. According to Pankhurst[2], an ion-ion binding is responsible for the combination between gelatin and CPC, but an ion-dipole binding can not occur at the peptide bonds of gelatin owing to a steric effect. However, the difference in the binding behavior of DPB from that of CPC, i. e., the insignificant binding of DPB as compared with CPC, implies that the length of the alkyl chain, i. e., the hydrophobic cohesion, is of primary importance even with the sufficiently long alkyl chain in the case of cationic detergents.

Summary

The mode of the binding of detergents, SDBS, CPC and DPB, by gelatin in the region of low detergent-gelatin ratios, where solutions are stable without precipitation, was investigated by determining the bound detergents by means of equilibrium dialysis.

Detergents bind with gelatin in accordance with the isotherm $r=Kc^n$, where K and n (>1) are constants which measure an affinity for the binding and an extent of cooperative interaction respectively. The value of K, which is dependent on pH and temperature, decreases with increasing pH for the binding of SDBS and vice versa for CPC. The value of n is characteristic of a given detergent. The value of n for SDBS is significantly greater than that for CPC. Thus the extent of the cooperative stabilization of a bound detergent is higher for SDBS than for CPC.

Both anionic SDBS and cationic CPC combine with gelatin, but cationic DPB scarcely combines with it. Further, it was inferred that a detergent, especially SDBS, binds with gelatin, forming aggregates on it in such a manner as the micelle formation.

The sign of charge of the detergent is of essential importance for the binding of the detergent by gelatin, and the length of the alkyl chain of detergent also has additional effects on the binding. The effect of chain length was examined with cationic detergents.

The Structural Assignments for the Geometrical Isomers of α, α'-Dimethylstilbene

By Yoichiro NAGAI, Osamu SIMAMURA* and Leo EHARA

(Received May 23, 1961)

Wessely and Welleba[1] assigned to α, α'-dimethylstilbene of m. p. 107°C the trans- and to the isomer of m. p. 67°C the cis-configuration on the basis of their dipole moment measurement, although without giving any experimental details. Some ambiguity, however, yet exists in the application of this method to the present case, because the substances examined are hydrocarbons probably with a small dipole moment value at most, even for the cis-compound. Suzuki[2] reached the same assignments by a theoretical consideration of their ultraviolet absorption spectra in relation to the shift of the absorption maximum due to the change in conjugation caused by the steric requirement of the substituent groups. It seemed desirable to confirm these conclusions by an unambiguous method. We now report the synthesis of *cis*- and *trans*-4, 4'-dinitro-α, α'-

* To whom inquiries regarding this paper should be directed.

2) H. Suzuki, This Bulletin, **25**, 145 (1952).

dimethylstilbene, whose geometrical configurations have been determined unequivocally by dipole moment measurement, and their conversion into *cis*- and *trans*-α,α'-dimethylstilbene. This constitutes chemical evidence in favor of the already assumed configuration of isomeric α,α'-dimethylstilbenes.

4, 4'-Dinitro-α,α'-dimethylstilbene was prepared from *p*-nitroacetophenone hydrazone with a method similar to that of Vargha and Kovacs's synthesis[3] of some substituted diethylstilbenes. The product was fractionated by recrystallization into the trans-, m. p. 222.4°C, and the cis-isomer, m. p. 151.8°C. The geometrical configurations were derived from dipole moment measurement in benzene[4], the former having a dipole moment of 0.68D and the latter a dipole moment of 6.88D. For the oxidation of the hydrazone to *p*-nitrophenyldiazoethane, one of the intermediates, we found that lead dioxide was much more efficient than mercuric oxide originally[3] used.

Catalytic reduction of *trans*-4, 4'-dinitro-α,α'-dimethylstilbene in the presence of a Raney nickel catalyst yielded 58% of 4, 4'-diamino-α,α'-dimethylstilbene (I), m. p. 157.5°C, and an oily mixture, which gave, on treatment with salicylaldehyde, two isomeric *N*, *N'*-disalicylidene derivatives (III and IV) in 6 and 13% yield, respectively, based on the dinitro compound used. In a separate experiment, pure diamine I gave disalicylidene derivative III in a nearly quantitative yield, but never gave the isomeric derivative IV; therefore, the latter was presumed to be formed only from the geometrically isomeric diamine II, which could not be isolated as such in this study.

$$(p\text{-}O_2NC_6H_4CMe:)_2 \downarrow$$
$$(p\text{-}H_2NC_6H_4CMe:)_2 \rightarrow (o\text{-}HOC_6H_4CH:NC_6H_4CMe:)_2$$
I (trans) | or II (cis) III (trans) or IV (cis)
$$\downarrow$$
$$(C_6H_5CMe:)_2$$

Although the assignment of configuration to the salicylidene derivatives is irrelevant to the main theme of the present report, it is obvious that the geometrical configurations of these compounds (III and IV) correspond with those of diamines I and II, respectively, since it is impossible for the complete inversion to the other configuration to take place in both cis- and trans-isomer.

Similarly reduced, *cis*-4, 4'-dinitro-α,α'-dimethylstilbene gave an oily mixture, which afforded *N*, *N'*-disalicylidene derivatives III and IV in yields of 12 and 61%, respectively, indicating the formation of diamine II in a yield of over 61%.

Although the catalytic reduction of 4, 4'-dinitro-α,α'-dimethylstilbene was thus accompanied by cis-trans isomerization, it follows from the above results that diamine I corresponds to the trans- and diamine II to the cis-configuration. If diamine I which was isolated from the reduction product of the trans-dinitro compound in a yield of at least 58% had had the cis-configuration, the equilibrium mixture of the isomeric diamines after stereomutation under the obtaining experimental conditions would have contained 58% or more of the cis-form, and, consequently, this compound (diamine I) should have been formed from the cis-dinitro compound in a yield of at least 58%, which is impossible because the other isomer (diamine II) was formed in 61% yield.

trans-Diamine I was diazotized and reduced with hypophosphorous acid, giving (67.4% of) α,α'-dimethylstilbene, m. p. 107°C, as the sole isolable product. This result shows that little, if any, stereomutation took place in the course of the deamination; extensive stereomutation would have given a mixture which melted much lower and, finally, an equilibrium mixture containing about 45%[5] of the lower melting isomer. Similarly, the diamine mixture (containing at least 61% of the cis form) from the catalytic reduction of *cis*-dinitrodimethylstilbene gave (58% of) a mixture of isomeric α,α'-dimethylstilbenes consisting of 78% (or 70%) of the form, m. p. 67°C, and 22% (or 30%) of the form, m. p. 107°C. These results establish that dimethylstilbene, m.p. 107°C, has the trans- and the isomer, m. p. 67°C, the cis-configuration.

Experimental

Melting points are corrected.

***cis*- and *trans*-4,4'-Dinitro-α,α'-dimethylstilbene.** —*p*-Nitroacetophenone hydrazone (10 g.) and lead dioxide (100 g.) were stirred in benzene (500 ml.) for 5 hr. at room temperature, the mixture was filtered, and sulphur dioxide was passed into the red filtrate until the solution turned light yellow. Removal of the benzene on a water-bath gave a solid product, which, recrystallized from acetic acid, afforded *trans*-4, 4'-dinitro-α,α'-dimethylstilbene (5.0 g., 60.1%) in colorless crystals, m. p. 221.6~222.4°C (Found: N, 9.71. $C_{16}H_{14}N_2O_4$ requires N, 9.40%). On slow evaporation at room temperature, the mother liquor deposited a mixture of the trans- and the cis-dinitro compound in large crystalline forms; the cis-isomer was picked out and recrystallized from acetone, giving *cis*-4, 4'-dinitro-α,α'-dimethylstilbene in pale yellow prisms (1.9 g., 22.8%), m.p. 150.8~151.8°C (Found: N, 9.56. $C_{16}H_{14}N_2O_4$ requires N, 9.40%). When light

petroleum was used instead of benzene in the above preparation and the solvent was allowed to evaporate at room temperature from the filtered reaction mixture, 1-*p*-nitrophenyldiazoethane was obtained in red needles, m. p. 84.5~87.5°C (decomp.) (Found: N, 23.69. $C_8H_7O_2N_3$ requires N, 23.73%). Passage of sulphur dioxide into a solution of 1-*p*-nitrophenyldiazoethane in light petroleum gave a white precipitate of 1, 2-bis-(*p*-nitrophenyl)-1, 2-dimethylethylene sulphone which was difficult to purify, decomposition at 130~200°C (Found: N, 8.31. $C_{16}H_{14}N_2O_6S$ requires N, 7.73%).

Reduction of *trans*-4, 4'-Dinitro-α, α'-dimethylstilbene.—*With Stannous Chloride.*—Powdered *trans*-4, 4'-dinitro-α, α'-dimethylstilbene (1.43 g.) was allowed to stand overnight with anhydrous stannous chloride (18 g.) in acetic acid (80 ml.) saturated with hydrogen chloride. The mixture was heated for 1 hr. on a water-bath and cooled. The precipitate was filtered off and dissolved in hot water, and the solution made alkaline with sodium hydroxide. The white precipitate was filtered off and recrystallized from benzene, affording *trans*-4, 4'-diamino-α, α'-dimethylstilbene (I) (1.149 g., 98%) in needles, m. p. 156.6~157.6°C (recrystallized from ethanol) (lit[6]., m. p. 146°C) (Found: N, 12.1. Calcd. for $C_{16}H_{18}N_2$: N, 11.8%).

This diamine and excess of salicylaldehyde in ethanol gave a nearly quantitative yield of *N, N'*-disalicylidene-4, 4'-diamino-α, α'-dimethylstilbene (III) (0.74 g.), m. p. 222.5~226.1°C (from benzene) (Found: N, 6.52. $C_{30}H_{26}N_2O_2$ requires N, 6.28%).

Catalytic Reduction.—The catalyst was a Raney nickel prepared according to the directions for W6 catalyst[7], washed with acetone and stored in it. The nitro compound (1.373 g.) was reduced with hydrogen in the presence of the nickel catalyst (from 4 g. of Raney alloy) in ethanol (20 ml.) under cooling with water. After the catalyst was filtered off, concentration of the filtrate gave *trans*-4, 4'-diamino-α, α'-dimethylstilbene (I) (0.635 g., 57.8%), m. p. 157.6°C. Removal of the ethanol from the mother liquor gave an oil which, on treatment with salicylaldehyde and fractional crystallization of the product from ethanol-benzene, yielded *trans-N, N'*-disalicylidene-4, 4'-diamino-α, α'-dimethylstilbene (III) (0.130 g., 6.3%) and the cis-isomer (IV) (0.282 g., 13.2%), m. p. 150.0~153.5°C (Found: N, 6.53%. $C_{30}H_{26}N_2O_2$ requires N, 6.28%).

Catalytic Reduction of *cis*-4, 4'-Dinitro-α, α'-dimethylstilbene.—Catalytic reduction of the *cis*-dinitro compound (1.12 g.) gave only an oil (0.8 g., 87%), which was converted into a mixture of *N, N'*-disalicylidene derivatives (1.57 g., m. p. 145~171°C). Fractional crystallization from ethanol-benzene gave the *cis*-disalicylidene derivative IV (1.06 g., 61% based on the dinitro compound subjected to the reduction) and the trans-isomer III (0.21 g., 12%).

Deamination of 4, 4'-Diamino-α, α'-dimethylstilbenes.—The *trans*-diamino compound I (0.474 g.) was diazotized with sodium nitrite (0.4 g.) in diluted hydrochloric acid (H_2O 40 ml. and concd. HCl 5 ml.) at 0°C. The solution was added to aqueous sodium hypophosphite (10 g. in H_2O 10 ml. and concd. HCl 10 ml.) and the mixture left overnight in a refrigerator. The solution was extracted with ether, the extract washed and dried ($CaCl_2$), and the ether removed. The residue was chromatographed in light petroleum on alumina, giving α, α'-dimethylstilbene (0.277 g., 67.4%), m. p. and mixed m. p. 104.5~.107°C

The product (0.484 g.) from the catalytic reduction of *cis*-4, 4'-dinitro-α, α'-dimethylstilbene was subjected to deamination as described above, yielding α, α'-dimethylstilbene (0.246 g., 58%), m. p. 52~60°C. This melting behavior indicates that the dimethylstilbene formed contained about 78% (or 70%) of the low melting isomer (see the accompanying figure).

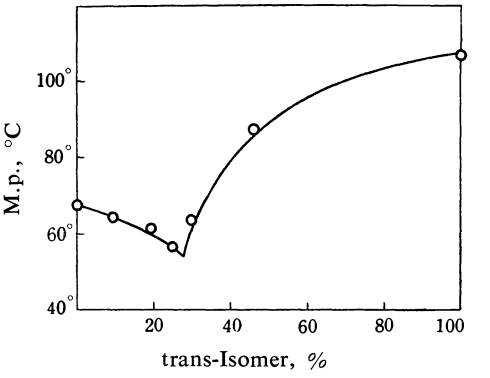

Fig. 1. Melting point—composition curve for a mixture of *cis*- and *trans*-α, α'-dimethylstilbene.

Summary

cis- and *trans*-4, 4'-Dinitro-α, α'-dimethylstilbene were prepared by oxidation of *p*-nitroacetophenone hydrazone with lead dioxide in benzene, followed by treatment with sulphur dioxide. Catalytic reduction of the *trans*-dinitro compound gave at least 64% of *trans*-4, 4'-diamino-α, α'-dimethylstilbene, m. p. 157.6°C, and a similar reduction of the cis-dinitro compound afforded a mixture of the cis- and trans-diamino compound which was shown to contain at least 61% of the cis-isomer. On deamination, the trans-diamino compound yielded α, α'-dimethylstilbene melting at 107°C, and the above mixture of the cis- and trans-isomer, a mixture of the isomeric α, α'-dimethylstilbenes in which the lower melting form predominated (at least 70%). These findings establish that α, α'-dimethylstilbene, m.p. 107°C, has the trans- and the isomer, m. p. 67°C, the cis-configuration.

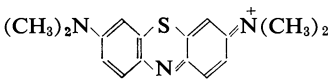
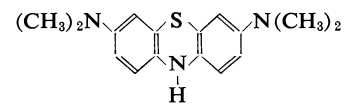
The Micro and Rapid Determination of Cobalt Carbonyl Anion in Organic Solvents by Titration with Methylene Blue



By Ryoji IWANAGA

(Received May 30, 1961)



In the course of an investigation of catalysts for oxo reactions, the rate of which seems to be dependent to a large extent on the rate of regeneration of cobalt hydrocarbonyl during the reaction, it was desired to measure rapidly a small amount of cobalt hydrocarbonyl or of cobalt carbonyl anion in various organic solvents. For a quantitative determination of cobalt carbonyl anion, the gasometric method of Sternberg et al.[1] and the gravimetric method of Hieber et al.[2] have been proposed. Neither of these methods, however, is suitable for a determination of the micrograms of the anion in Lewis-base solutions such as methanol and acetone, owing to the difficulty of a quantitative precipitation of the complex salt of the anion in Lewis-base solutions.

Reppe[3] mentioned briefly that "the acidimetric value of cobalt hydrocarbonyl with sodium hydroxide shows practical agreement with the reduction value titrated with methylene blue in the acid pH range", but quantitative results were not presented. The present author has, therefore, investigated on the conditions for titrimetric determination of the micrograms of the cobalt carbonyl anion in various organic solvents, especially in Lewis bases such as alcohols, ketones or aldehydes with methylene blue.

The cobalt carbonyl anion in the aqueous solution was primarily oxidized to dicobalt octacarbonyl by weak oxidizing reagents such as air, methyl orange, methyl red, ferric chloride or cupric sulfate[4]. Methylene blue also may oxidize the anion, and then a leuco-compound may be produced as follows:

$$+ H^+ + 2[Co(CO)_4]^-$$

$$+ Co_2(CO)_8 \qquad (1)$$

In the preliminary test it was observed that the above reaction did not take place quantitatively in a strong acid or in an alkaline medium.

The author has first investigated the effect of the pH of the titration medium on the stoichiometry of the titration of the anion with methylene blue. The end point of this titration was easily detected at the point where the blue color of the methylene blue added to the solution does not disappear for several minutes. By the titration of the anion in aqueous solutions of various pH, it was found that the stoichiometric reaction given by Eq. 1 can be held only at the pH range from 1.9 to 5.2 of titration solutions; at a higher pH range than 5.2 the molar ratio of the added methylene blue to the anion decreases below 1:2 with the increasing pH, and at a lower pH range than 1.9 it increases over 1:2 with the decreasing pH. From these results it was found that the quantitative titration of the anion with methylene blue according to Eq. 1 can be performed only in the pH range from 1.9 to 5.2.

Examining further a titration in a nonaqueous medium by using glacial acetic acid as a solvent for methylene blue titrant and for the titration medium, it was found that the titration could also be performed in good agreement with the reaction given by Eq. 1.

When a titration of the anion in Lewis bases such as methanol and acetone is carried out, methylene blue may be consumed excessively in more than the above ratio, in which case the end point becomes indistinguishable. This may be due to the occurrence of "the base reaction"[5], i.e., the reaction between dicobalt octacarbonyl formed from the anion according to Eq. 1 and a Lewis base, during the titration.

2) W. Hieber and H. Frankel, *Ber.*, **86**, 710 (1953).
3) W. Reppe, "Neue Entwicklung auf dem Gebiet der Chemie des Acetylens und Kohlenoxyds", Springer-Verlag (1949), p. 120; W. Reppe, *Ann.*, **582**, 122 (1953).
4) W. Hieber and W. Hübel, *Z. Elektrochem.*, **57**, 331 (1953).
5) W. Hieber et al., *Ber.*, **86**, 700 (1953); **87**, 25, 789 (1954); **91**, 1146, 1156 (1958). Alcohols, ketones, cyclic ethers, nitriles and isonitriles, as well as amines, react with dicobalt octacarbonyl and produce cobalt carbonyl anion as follows:
$3Co_2(CO)_8 + 2x\,\text{Base} \rightarrow 2[Co(\text{Base})_x][Co(CO)_4]_2 + 8CO$

The author has thus then investigated the conditions needed to decrease "the base reaction" with methanol, because methanol is one of the Lewis bases which reacts rapidly with dicobalt octacarbonyl, and has found that the influence of "the base reaction" on the analysis of the anion could be decreased effectively by diminishing the rate of the base reaction, by diluting the sample solution with a 1 : 1 mixture of glacial acetic acid and toluene, and by lowering the treating temperature as low as possible, about 0°C being satisfactory (see Fig. 4). On the basis of the above results, the author proposes a rapid and simplified method for determining a small amount of the anion in organic solvents, especially in Lewis bases. The author examined the proposed method for the titration of samples of a known concentration of the anion in the presence of water, methanol, acetone, dicobalt octacarbonyl and acetoaldehyde, and could determine the anion in all within a percentage of error of only about one percent.

Experimental and Results

Titration of Cobalt Hydrocarbonyl and Cobalt Carbonyl Anion

Reagents.—A test solution of a known concentration of cobalt hydrocarbonyl was prepared as follows: about 1 g. of dicobalt octacarbonyl was dissolved in 5 ml. of pyridine; after the solution turned clear pink, 1 : 1 aqueous sulfuric acid was dropped into the solution at about −5°C, and the cobalt hydrocarbonyl gas evolved was introduced, together with oxygen-free nitrogen, into an oxygen-free water or methanol through a U-tube filled with phosphorus pentaoxide and a trap cooled at −20°C. The concentration of cobalt hydrocarbonyl in the solution was determined by total cobalt analysis, and this value showed quite a good agreement with a value obtained from the titration with sodium hydroxide[6]. The test solution of cobalt carbonyl anion was also prepared by introducing the cobalt hydrocarbonyl gas evolved as described above into an oxygen-free aqueous or methanol solution of sodium hydroxide, until the solution was neutralized with phenolphthalein as an indicator; the concentration of this was also determined from the total cobalt content.

Standard methylene blue titrant of 1 meq./l. was prepared by dissolving 374 mg. of the special grade crystals of $C_{16}H_{18}N_3SCl \cdot 3\,H_2O$ (Junsei Pure Chemicals Co., Ltd.) into 500 ml. of oxygen-free glacial acetic acid and then filling the container with oxygen-free toluene to 1 l.

All of the above-mentioned oxygen-free solvents were prepared by being refluxed for 1 hr., cooled to room temperature and reserved under a slightly more positive pressure of nitrogen than the atmosphere.

6) This titration was made according to the procedure reported by W. Hieber and W. Hübel, *Z. Elektrochem.*, **57**, 235 (1953).

Apparatus.—Figure 1 illustrates a titration apparatus. Titration is carried out in a 100 ml. Erlenmeyer flask with two holes on each side, one of which holes is for inserting a thermometer and another for introducing the samples and the solvent. To the stopper of the flask, a 25 ml. buret and two glass tubes are attached, one of which is an inlet for nitrogen and another an outlet, the outer end of which is closed by a mercury valve.

B Buret
C Titration flask
D Inlet of sample
E Thermometer
F Inlet tube of N_2
G Outlet tube of gas
H Mercury valve
I Ice-water bath
J Magnetic stirrer

Procedures.—Because cobalt carbonyl anion in solutions is very sensitive and easily oxidized with air, a sample to be analyzed, as well as the titration solvents and the methylene blue titrant, must be strictly protected from the air. After all the system has been flushed with nitrogen, the standard methylene blue titrant is introduced into a holder A under a counter-current flow of nitrogen and poured into a buret B. Twenty milliliters of a mixture of glacial acetic acid and toluene are then introduced into the titration flask, which is placed in an ice-water bath, through a side hole D under a counter-current flow of nitrogen; this is cooled to about 0°C by stirring. After the solvent has been cooled, a suitable aliquot of the solution to be analyzed is pipetted into the solvent through D and titrated immediately with the methylene blue titrant while being stirred. While the blue color of methlene blue dropped disappears immediately, the solution titrated becomes light brown due to the formation of dicobalt octacarbonyl, and as soon as its color changes to light green, the titration is

TABLE I. TITRATIONS OF $HCo(CO)_4$ AND $Na[Co(CO)_4]$ IN TOLUENE-ACETIC ACID SOLVENT WITH 1 meq./l. METHYLENE BLUE TITRANT

Sample	ml.	Compound added	$[Co(CO)_4]^-$ obtained from total amount of Co	(μ.eq.) found	Std. dev. %
$HCo(CO)_4$ in water	1	—	7.29	7.26	−0.4
$Na[Co(CO)_4]$ in water	1	—	20.75	20.58	−0.8
$HCo(CO)_4$ in methanol	1	—	21.40	21.40	0
$HCo(CO)_4$ in methanol	2	Methanol 10 ml.	42.80	42.80	0
$Na[Co(CO)_4]$ in methanol	1	—	26.70	26.60	−0.4
$HCo(CO)_4$ in methanol	1	Acetone 10 ml.	21.40	21.40	0

Oxo product*1	3		34.56*2	36.78	+6.4

*1 This product was obtained as follows: a solution containing 2 eq./l. of methylacrylate and 9.11 meq./l. of $Co_2(CO)_8$ in toluene was treated with 1 : 1 CO and H_2 under 200 kg./cm^2 at 120°C.

*2 The amount of $[Co(CO)_4]^-$ was measured by *o*-phenanthroline method.

stopped. Weights of the anion in the sample are calculated as follows:

mg. of $[Co(CO)_4]^- =$

ml. of methylene blue titrant added $\times 0.342$

Results.—In order to examine the present method, aliquots of a solution of a known concentration of $HCo(CO)_4$ or $Na[Co(CO)_4]$ were pipetted and titrated, alone or in the presence of a large amount of methanol, acetone or dicobalt octacarbonyl. In addition, a titration in the presence of acetoaldehyde was tested. The results of these analyses, listed in Table I, are shown to be in good agreement with the values obtained from the total cobalt contents within a deviation of 1%. The larger deviation on the practical oxo reaction product (in Table I) was presumably due to the inaccuracy of the value obtained from the precipitate of Co-*o*-phenanthroline complex salt with the anion.

Effect of Hydrogen Ion

A pH determination was made by means of a glass electrode which was inserted into a 200 ml. titration flask. After all the system had been flushed with nitrogen, 50 ml. of oxygen-free distilled water were first introduced into the flask, and to this solution was added sulfuric acid, acetic acid or sodium hydroxide under a counter-current flow of nitrogen to give various pH values. Then, 1 ml. aqueous solution of $Na[Co(CO)_4]$ was added and titrated with 1 meq./l. aqueous methylene blue titrant at 20°C. At the end point of titration, the pH of the solution was measured. Figure 2 shows the curve of the molar ratio of methylene blue reacting with the anion at various pH values at the end point.

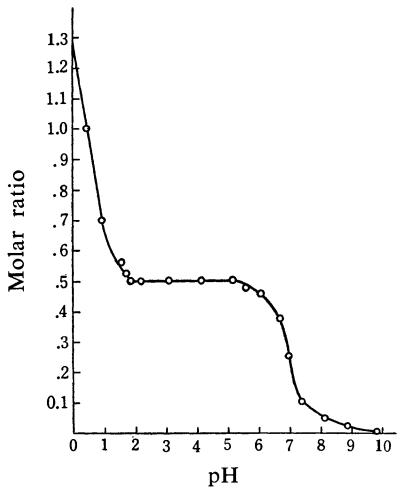

Fig. 2. Variations of molar ratio of methylene blue reacted with $[Co(CO)_4]^-$ at the end point of a titration as a function of pH.

Rates of Base Reaction of Dicobalt Octacarbonyl with Methanol in Various Solvents

Dicobalt octacarbonyl was recrystallized from oxygen-free toluene before use. Reactions of dicobalt octacarbonyl with methanol were carried out in a 100 ml. Erlenmeyer flask, as is shown in Fig. 1, at 20 and 0°C. After the flask had been thoroughly flushed with oxygen-free nitrogen, 25 ml. of oxygen-free methanol and 25 ml. of the oxygen-free solvent to be tested were introduced into the flask and kept at the temperature to be tested. Then a solid of about 0.5 g. of dicobalt octacarbonyl was vigorously stirred in at the controlled temperature. After various periods of reaction

time, 1 ml. of the solution was pipetted out, and the amount of the anion formed in it was determined by the titration described above. Figure 3 shows the rates of formation of the anion in various solvents at 20 and 0°C. In Fig. 3, $[Co]_0$ gives the concentration of the total cobalt in the solution, and $[[Co(CO)_4]^-]_t$ is of the anion formed after the reaction had proceeded for t minutes.

Discussion

This titration is based upon the reduction of one-valenced methylene blue cation into a no-valenced leuco-compound with cobalt carbonyl anion in an acid pH range. However, Fig. 2 shows that the stoichiometry of the reaction of titration as given by Eq. 1 does not always exist in the whole pH range. It may be due to other types of reactions of methylene blue in addition to the above reaction, the possibility of the former being postulated from the different redox-potentials of methylene blue at various pH's[7]. Therefore, it is convenient to use a mixture of acetic acid and toluene as the solvent, because the pH of the solution to be titrated does not have to be adjusted to 1.9~5.2. Furthermore, this solvent has the advantages over aqueous acetic acid or glacial acetic acid not only of its miscibility with the anion dissolved in organic solvents, but also of its lower freezing point.

It was found from Fig. 3 that the base reaction of dicobalt octacarbonyl with methanol is of the first order with respect to a concentration of dicobalt octacarbonyl, that the rate of the reaction is most effectively decreased by lowering the reaction temperature, and that in the base reaction at 0°C by using a 1 : 1 mixture of glacial acetic acid and toluene as solvent, the amount of the anion formed by the base reaction in a minute can be decreased by less than 0.1 mol. % of the cobalt of dicobalt octacarbonyl.

If a base reaction thoroughly proceeds during the titration, the amount of methylene blue which may be consumed may be triple that corresponding to the initial amount of cobalt carbonyl anion. The author could really observe such a result when a methanol solution of $Na[Co(CO)_4]$ was titrated for a long time at an atmospheric temperature. Therefore, for determining the anion in Lewis-base solutions, it is important to cool the sample and titrate it as rapidly as possible.

If substances easily oxidized with methylene blue are presented in the sample to be analyzed, it is impossible to determine the anion in the sample by this method. However, from the fact as is shown in Table I that no significant interference of aldehydes was observed under the conditions in this method, it seems to be possible to determine the anion in an oxo reaction product. Furthermore, this method may be especially suitable for the determination of the anion in solutions during oxo, base or other reactions, as it requires only a small amount of the anion (less than 1 mg. as a sample) and takes only about 0.5 to 1 min. for one titration.

Summary

An accurate and rapid method is described for the direct titration of cobalt carbonyl anion in organic solvents. This method is based upon the oxidation reaction of the anion with methylene blue in acid media. The stoichiometry of the reaction of 2 mol. of the anion with 1 mol. of methylene blue is found only at the pH range from 1.9 to 5.2 or in the acetic acid medium. By using a 1 : 1 acetic acid-toluene mixture as solvent, and by carrying out the titration at about 0°C, the anion in Lewis bases such as methanol and acetone is titrated successively without any interference by the base reaction. This method is very suitable for the

Estimation of Micellar Charge from Conductivity Data of Aqueous Detergent Solutions

By Hideo KIMIZUKA and Iwao SATAKE

(Received July 20, 1961)

The micellar molecular weight and the critical micelle concentration (CMC) are essential quantities in the study of the physicochemical properties of detergents. There are a number of methods for determining the CMC, while only a few methods are available for estimating the micellar molecular weight. This is true because of the complex nature of detergent solution, which contains the single detergent ion and the gegen ion in addition to the micellar aggregate in the concentration above the CMC.

The light scattering method is the most profitable one and is widely employed for the measurement of the micellar molecular weight. It is of interest, however, to estimate the micellar molecular weight from a measurement other than that of light scattering. Some authors have attempted the estimation of micellar size from the measurement of the diffusion coefficient[1], and attempts to determine the micellar charge have also been made by using the data of conductivity[2] and cataphoresis[3].

Since the measurement of conductivity has widely been employed for study of the solutions of ionic detergent, it is advantageous to estimate the micellar charge or the micellar aggregation number by using the conductivity data if possible. Therefore, we have started to obtain a method for determining the micellar charge based on assumptions somewhat different from those of the early studies[2,3].

For simplicity we assume, as did, e.g., Hutchinson[2], that above the CMC there is only one kind of micelle, containing a n unit of detergent ion and possessing a charge Z_m, and assume that the concentration of detergent ion in the micellar form is $C-C_m$, where C is the concentration in the gram formula weight per liter and C_m, the critical micelle concentration. It is well known that below the CMC the equivalent conductivity, Λ, of the ionic detergent solution is linear against the ionic strength, I, of the solution:

$$\Lambda=\Lambda_o-\alpha\sqrt{I} \tag{1}$$

$$I=\frac{1}{2}\sum_i C_i Z_i^2 \tag{2}$$

where Λ_o is the equivalent conductivity at infinite dilution, α, a constant for a given detergent, and C_i and Z_i, the concentration and valency of ith ion respectively. Here we assume that in dilute solutions Eq. 1 holds, even in concentrations above the CMC. This involves believing that an abrupt change in conductivity just above the CMC is to be attributed to the presence of the high valent micellar ion, which increases the ionic strength of the detergent solution.

Let us consider an ionic detergent $D_{\nu_d}^{z_d}G_{\nu_g}^{z_g}\rightleftarrows \nu_d D^{z_d\pm}+\nu_g G^{z_g\mp}$, where D and G denote the detergent ion and the gegen ion respectively.

At the CMC,

$$\Lambda_m=\Lambda_o-\alpha\sqrt{I_m} \tag{3}$$

where m refers to the CMC. By comparing Eq. 1 with Eq. 3 we obtain

$$(\Lambda_o-\Lambda/\Lambda_o-\Lambda_m)^2=I/I_m \tag{4}$$

In the concentration above the CMC,

1) D. Stigter, R. J. Williams and K. J. Mysels, *J. Phys. Chem.*, **59**, 330 (1955); G. S. Hartley and D. F. Runnicles, *Proc. Roy. Soc.*, **A168**, 420 (1938); M. E. L. McBain, *J. Phys. Chem.*, **48**, 237 (1944), etc.

2) P. van Rysselberghe, *J. Phys. Chem.*, **48**, 62 (1944); E. Hutchinson, *J. Colloid Sci.*, **9**, 191 (1954).

3) D. Stigter and K. J. Mysels, *J. Phys. Chem.*, **59**, 45 (1955).

the concentration of micelle $=\nu_d(C-C_m)/n$ (5a)

the concentration of the single detergent ion
$=\nu_d C_m$ (5b)

the concentration of the gegen ion
$=\nu_g C-(C-C_m)(Z_d-Z_m/n)\times(\nu_d/Z_g)$ (5c)

The ratio of the fixed gegen ion to micelle was taken into account in Eq. 5c.

The ionic strengths of the solutions above and at the CMC are therefore given as follows:

$$2I=\{C(Z_g+Z_c)+C_m(Z_d-Z_c)\}\nu_d Z_d \quad (6)$$

$$Z_c=\{Z_m^2-Z_g(nZ_d-Z_m)\}/nZ_d \quad (7)$$

$$2I_m=(Z_g+Z_d)\nu_d Z_d C_m \quad (8)$$

Substituting Eqs. 6 and 8 into Eq. 4,

$$(\Lambda_o-\Lambda/\Lambda_o-\Lambda_m)^2=\{(Z_d-Z_c)+(Z_d+Z_c)C/C_m\}/(Z_g+Z_d) \quad (9)$$

The last term on the right hand side of Eq. 7,

$$r=(nZ_d-Z_m)/nZ_d \quad (10)$$

expresses the ratio of the charge of the fixed gegen ion to that of the micelle. If r is zero and, consequently, Z_m is nZ_d, Z_c becomes nZ_d, which is the charge of the micelle having no fixed gegen ions. It may be pointed out here that we shall be able to obtain a similar expression with Eq. 4 for other properties of a detergent solution, e.g.,

$$(\ln f_g/\ln f_{gm})^2=I/I_m \quad (11)$$

where f_g denotes an activity coefficient of the gegen ion. But, unfortunately, we have no exact data on f_g.

Check of the Theory and Discussion

The conductivity data employed in the estimation of the micellar charge were taken from those reports which gave numerical data[4-7], although a number of studies have already been carried out for the conductivities of ionic detergent solutions.

In Figs. 1, 2 and 3, the calculated values of $(\Lambda_o-\Lambda/\Lambda_o-\Lambda_m)^2$ are plotted against C/C_m. The linearity of these lines is satisfactory to some extent above the CMC. The deviation from linearity appearing in higher concentrations probably comes from the assumption of the limiting law as expressed in Eq. 1. This

agrees well with the result that the reduced concentration, C/C_m at which the deviations are observed to begin becomes lower as the CMC of the detergent solution increases. The value of Z_c may be obtained from the slope of each linear portion according to Eq. 9.

Table I shows the value of Z_c and r, together with the value of n_l, the micellar aggregation number observed by means of the light scattering technique[8-10]. r was calculated from Eqs. 7 and 10 by using the value of n_l in place of n in these equations. As is seen in this table, the values of the Z_c of anionic detergent are almost the same as those of n_l. This would suggest that the micellar aggregate of the anionic detergent ion behaves as if it were *a* polyvalent ion with few fixed gegen ions.

Thus, Z_c gives approximately the micellar aggregation number; we can therefore estimate the micellar aggregation number from the conductivity data as described in the present study. We were unable to obtain a linear portion near the CMC in the plot, $(\Lambda_o-\Lambda/\Lambda_o-\Lambda_m)^2$ vs. C/C_m, for sodium decyl sulfonate. This probably comes from the fact that the CMC of sodium decyl sulfonate is relatively high, 6.25×10^{-2} mol./1., where the limiting law does not hold any more. The values of r for cationic detergents are somewhat higher than those for anionic detergents. This agrees with the conclusion obtained by Hartley[11].

Summary

An equation relating the micellar charge to the conductivity data was derived for the ionic detergent solutions. It was found that the calculated values of the micellar charge were approximately the same as the micellar aggregation number observed by means of the light scattering technique. The ratio of the fixed gegen ion to the micelle was also estimated.

ESR Study of the Radiation Chemical Process in Polyethylene

By Shun-ichi OHNISHI

(Received July 17, 1961)

Several works[1-10] have already been published on the ESR spectrum of irradiated polyethylene (PE). The results of these works have revealed that at least three kinds of radicals are produced in irradiated PE. The short-living component of the radicals (decay: 1 day) gives a sextet spectrum of ΔH_{hfs} (hyperfine separation) = 30 gauss and is assigned to the $-CH_2-\dot{C}H-CH_2-$ radical (FR_{VI})[1,3,4,7,9,10]. The radical of a longer life-time (decay: months) shows a septet spectrum ($\Delta H_{hfs}=18$ gauss) with further complex splittings, probably a doublet structure ($\Delta H_{hfs}=7$ gauss) and is identified with the $-CH_2-\dot{C}H-CH=CH-CH_2-$ radical (FR_{VII})[3,9,10]. The interpretation of the septet spectrum is, admittedly, not as well established as the sextet, about which there is no doubt in its identification. Lawton et al.[4] have expressed their view that the spectrum is a quintet with very "fine" struture and perhaps corresponds to the $-CH_2\cdot : \cdot CH_2-$ radical. Their view, however, does not seem to be well supported. The third component of the radicals has a very long life-time (half-life: 30 min. at 150°C) and gives only a singlet spectrum of ΔH_{msl} (line width at maximum slope) = 25 gauss. This is assigned to the polyenyl radical $-CH_2-\dot{C}H-(-CH=CH-)_n-CH_2-$[5,8]. The spectra of these radicals are summarized in Fig. 1.

In the present investigation PE was irradiated in vacuo at −196°C with a variety of doses, and the change in the obtained ESR spectrum with the rising temperature was followed. The results are discussed from the standpoint of the mechanism of the radiation-chemical changes in the irradiated PE.

Experimental

Material. — Marlex 50 inflation film ~30 μ in thickness was used. The inflation film had some internal strain; therefore, it expanded by about 5% in the extruded direction when put into boiling water.

Irradiations.—Electron irradiation by a 2 MeV. Van de Graaff accelerator was carried out in vacuo at −196°C as follows: Samples were sealed in a glass ampoule ~4 mm. in diameter under a high vacuum (~10^{-5} mmHg). The glass ampoule was adjusted to float about 1 mm. under the surface of liquid nitrogen so as to be located within the range of the 2 MeV. beam.

In some experiments samples were 'reirradiated'. Samples, preirradiated at a variety of doses, were heated at some high temperature (125°C for FR_{VII} and 250°C for FR_{I}) so that the free radicals produced by the irradiation could decay almost entirely. After the heat-treatment, the samples were irradiated again at −196°C.

The irradiation dose was calculated by referring to the calorimetry experiment. Hydrogen gas evolved by irradiation from PE was removed by evacuation at −196°C.

ESR Measurement.—ESR signal was recorded at −196°C on a Varian V-4500 spectrometer with Liquid Nitrogen Accessory. All spectra were recorded at a small power level (~1 mW) to avoid the power saturation effect[11]. The decay curve at room temperature was determined by storing the sample at room temperature for a certain time and then recording the spectrum at −196°C. The concentration of the free radicals was determined by comparing the ESR signal intensity at room temperature with that from a DPPH benzene solution (~1×10^{-5} mol./g.). Sufficient attention was paid to those fractors[12] which often lead to an erroneous estimation.

Results and Discussion

Spectrum of Irradiated PE at −196°C.—PE, irradiated at various doses at −196°C, has shown a broad sextet spectrum, as is shown in Fig. 2 (1). Comparing this sextet with that obtained from PE irradiated at room temperature (Fig. 1 (1)), the broadness of the former spectrum can be clearly seen. This arises from the spin-spin interaction and might correspond to the circumstance that such radicals are closely spaced[4]. It is to be added that, in the irradiated methane, both a broad and a narrow quartet spectrum were obtained and that the interpretation of such differences might be the same[13] as has been indicated above.

On warming to room temperature, the broad sextet decayed quickly, and the spectrum remaining after 2.5 hr. was a narrow sextet (see Fig. 2 (2)). After 7 days (Fig. 2 (5)), the sextet spectrum had decayed almost entirely and there only remained the septet spectrum, which hardly decays at all at room temperature.

Comparing the spectral change at room temperature of samples irradiated at higher doses with those irradiated at lower doses (cf. Fig. 2A with 2B), it can be concluded that FR_{VI} decays faster in those samples irradiated at larger doses. This result might be due to the existence of more 'defects', such as a cross-linked point or a double bond, caused by irradiation in the polymer, defects somewhat facilitating the motion of free radicals in the crystalline region[14]. It should be remembered in this connection that the ESR spectrum observed on γ-irradiation at room temperature was sextet at small doses <~1 Mrad and septet only in the intermediate dose range (10 ~100 Mrad)[10]. At higher doses (~3000 Mrad), only a singlet spectrum was observed. The phenomenon might be interpreted, at least in part, on the basis of the increased mobility of the free radicals with increasing doses. In the intermediate doses, for example, FR_{VI} as well as FR_{VII} were produced, but, owing to the increased rate of decay in PE irradiated with larger doses, the sextet spectrum was not observed on ESR recording.

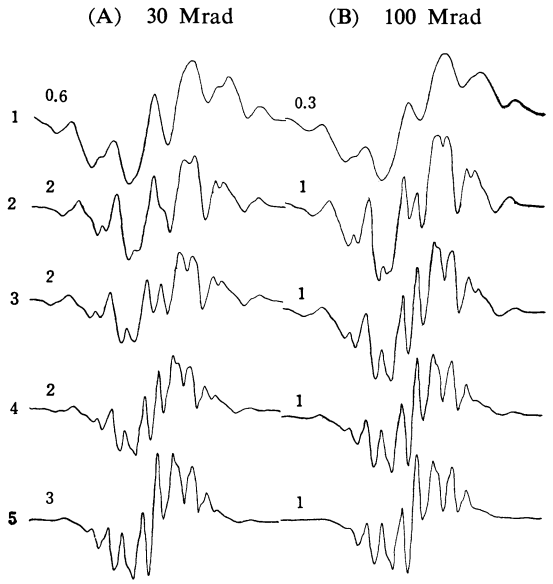

Fig. 2. Change of ESR spectrum of irradiated polyethylene on storage at room temperature. Spectra were recorded at −196°C. Irradiation was carried out in vacuo at −196°C with doses of (A) 30 Mrad and (B) 100 Mrad. The evolved H_2 gas was removed by evacuation. 1) Immediately after irradiation. 2) After 2.5 hr. at room temperature. 3) After 16 hr. 4) After 1 day, 15 hr. 5) After 7 days, 10 hr. Figures show the magnification factor of the amplifier.

Free Radical Formation Curve. — The concentration of free radicals produced by irradiation at −196°C was plotted against the dosage (see Fig. 3 curve A). The curve does not make a straight line, in contrast with the expectation based on a complete trapping of the primary radical at −196°C. This deviation from linearity might suggest that one part of the primary radicals, FR_{VI} showing the broad sextet in our case, reacts during irradiation even at −196°C. This component of FR_{VI} will be referred to as FR^{I}_{VI} (FR_{VI} reacting instantaneously at −196°C) in this paper. The occurrence of the reaction of FR^{I}_{VI} at −196°C might not be unreasonable in view of the fact that most FR_{VI}'s were produced by irradiation in close proximity and also that probably most of them were in 'hot' states.

The decay curve at room temperature is shown in Fig. 4 for samples irradiated with various doses at −196°C (cf. Fig. 2). It shows a quick decay of FR_{VI} and long life-time for the remaining FR_{VII}. This result can be interpreted to show that the free radicals in irradiated PE at −196°C consisted of about 90% FR_{VI} and 10% FR_{VII}. The concentration of the remaining FR_{VII} was plotted against the dosage in Fig. 3 (curve B). It should be noted that the decay curve given in Fig. 4 was for that in vacuo; the evolved hydrogen gas had been removed by reevacuation at −196°C. If the evolved gas was not removed, the decay of FR_{VI} and also of FR_{VII} were accelerated to a small but definite extent, showing a possibility of the backreaction of H_2 with the radicals.

The G_R values were estimated from the initial slope of the formation curve. G_R(total) was found to be 6.4 from curve A, and $G_R(FR_{VII})$ was 0.31 from curve B. It is assumed that $G_R(FR_{VI}) = G_R(\text{total}) - G_R(FR_{VII}) = 6.1$. Lawton et al.[4] obtained $G_R = 3.6$ at −196°C calculated at a dose of 40 Mrad. If we calculate the value at the dose of 40 Mrad, where the formation curve deviates from the straight line of slope $G_R = 6.4$, our result gives a value of 4.6. Voevodsky et al.[3] gave a value of 2.9±0.6 for FR_{VI} at 178°K and 0.16 for FR_{VII} at 323°K. The G_R value, estimated by the scavenger method for the lower aliphatic hydrocarbons[15], ranged from 6 to 8. This range is very close to that for irradiated PE at −196°C and shows that the yield of primary radicals in low and high molecular hydrocarbons is nearly the same.

In Fig. 3 the formation curve in the case of γ-irradiation at room temperatures[12] is shown for comparison (curve C). The G_R value 1.6 estimated from the initial slope corresponds almost exactly to that for FR_{VI}, and the value 0.09 determined from the slope of the curve in the intermediate dose ranges (10∼100 Mrad), to that for FR_{VII}.

The difference between the straight line with the slope $G_R = 6.4$ and the experimentally obtained curve A will correspond to the FR^{I}_{VI} disappearing during irradiation at −196°C. The G_R value for FR^{I}_{VI} was calculated from the amount of deviation to be 2.2 at a dose of 50 Mrad. Therefore, the G_R value for FR_{VI} reacting on being warmed to room temperature should be $G_R(FR_{VI}) - G_R(FR^{I}_{VI}) = 4$. The G_R

100	1.1×10^{-4}	1.1×10^{-5}
3000	1.2×10^{-4}	3.5×10^{-5}***

* $-CH_2-\dot{C}H-CH_2-$ + $-CH_2-\dot{C}H-CH=CH-CH_2-$. Corresponds nearly to $-CH_2-\dot{C}H-CH_2-$ except in the case of 3000 Mrad.

** Remaining component on storage of the samples at room temperature for a week or more.

*** Corresponds to polyenyl radical. Concentration of the $-CH_2-\dot{C}H-CH_2-$ radical 8.8×10^{-5} mol./g.

values obtained in the present investigation are summarized in Table I.

Formation of $-CH_2-\dot{C}H-CH=CH-CH_2-$ Radical.—The $G_R(FR_{VII})$ was found to be 0.31 for electron irradiation at −196°C and 0.09 for γ-irradiation at room temperature. The difference in the values might be due to the decay of FR_{VII} in the presence of evolved H_2 during irradiation, since γ-irradiation takes more time than electron irradiation. On the other hand, it is a well-known fact that irradiation produces a transvinylene group in PE. The G value was estimated to be 2.2 by Dole et al.[16] Comparing the values, it may be concluded that FR_{VII} is produced to a lesser extent, about 0.31/2.2=0.14, than the unsaturated group.

As for the mechanism of FR_{VII} formation, we do not yet have any definite picture. Several possible mechanisms will now be discussed, however,

1) Free radical migration such as

$$-CH_2-\dot{C}H-CH_2- \cdots\cdots -CH_2-CH=CH-$$
$$\rightarrow -CH_2-CH_2-CH_2- \cdots\cdots -\dot{C}H-CH=CH-$$

This mechanism might be essentially the same as that suggested by Voevodsky et al.[3], who had some experimental evidence that 'reirradiation' increased the $G_R(FR_{VII})$ to 3.2. Our result does not seem to support this mechanism strongly. First, FR_{VII} is produced in only 14% of the unsaturated group, as is stated above. Secondly, our results of the reirradiation experiment, summarized in Table II, cannot be interpreted to show that free radical migration is a predominant mechanism for FR_{VII} formation. As the preirradiation dose increased, more unsaturated groups existed in the irradiated polymer. Therefore, on reirradiation at the same dose (30 Mrad), samples preirradiated at higher doses should have a higher FR_{VII} concentration if the migration mechanism prevailed. The results given in Table II show a tendency toward a slightly increasing concentration of FR_{VII}, but it is not certain that the data provide strong evidence for mechanism 1. The

16) M. Dole, D. C. Milner and T. F. Williams, *J. Am. Chem. Soc.*, **80**, 1580 (1958).

spectrum obtained from the reirradiated samples was more or less the same as that from the virgin sample except one preirradiated with 3000 Mrad (see Fig. 5). PE irradiated with 3000 Mrad had shown a singlet spectrum. On reirradiation at −196°C with 30 Mrad, the sample (Sample I) gave the spectrum as shown in Fig. 5 (2A), with somewhat different features from those preirradiated with 0 to 100 Mrad. Immediately after being warmed to room temperature, Sample I gave only singlet spectrum (Fig. 5 (2B)). The subtracted curve (A–B) was almost a sextet. That conjugated double bond which exists in Sample I might have something to do with the different features observed.

2) Hydrogen abstraction; $-CH_2-CH=CH- + H \longrightarrow -\dot{C}H-CH=CH- + H_2$. This reaction requires an activation energy of the order of 5 kcal./mol.[17] and hence does not seem to occur easily at −196°C or at room temperature. Hot H atoms could abstract combined H to form FR_{VII} and H_2 even at −196°C, but the probability of H atoms finding double bonds before they cooled or before other reactions, such as the abstraction of H from the neighboring $-CH_2-CH_2-CH_2-$ chain, had occurred, would seem to be very small. Mechanism 3 may also be mentioned as possible:

$$-CH_2-CH_2-CH_2-CH_2- \rightsquigarrow (-CH_2-\dot{C}H-CH_2-CH_2-)_{hot} \longrightarrow -CH_2-\dot{C}H-CH=CH- + H_2$$

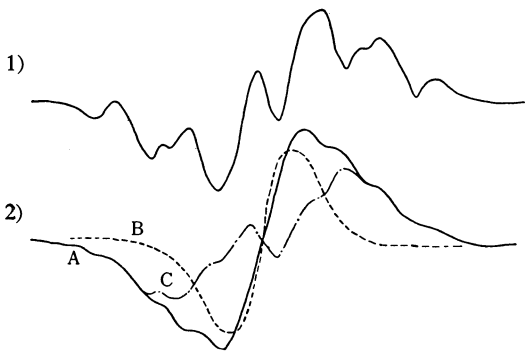

Fig. 5. Spectrum of polyethylene 'reirradiated' with 30 Mrad at −196°C. 1) For sample preirradiated with 100 Mrad. 2) For sample preirradiated with 3000 Mrad. A: Immediately after irradiation. B: After storage at room temperature for 25 min., spectrum being recorded at −196°C. C: Subtracted curve A–B, showing the decayed component to be nearly a sextet spectrum.

17) See, for example, E. W. R. Steacie, "Atomic and Free Radical Reactions", 2nd Ed. Vol. 1, Reinhold Publishing Corporation, New York (1954).

or

$$-CH_2-CH_2-CH_2-CH_2- \rightsquigarrow -CH_2-\overset{+}{C}H-CH_2-CH_2- + H + e$$

$$-CH_2-\overset{+}{C}H-CH_2-CH_2- \longrightarrow -CH_2-\overset{+}{C}H-CH=CH- + H_2$$

$$-CH_2-\overset{+}{C}H-CH=CH- + e \longrightarrow -CH_2-\dot{C}H-CH=CH-$$

The molecular elimination reaction of H_2 from the thermal $-CH_2-\dot{C}H-CH_2-CH_2-$ radical requires an activation energy of about 30 kcal./mol.[18] Some hot radicals could overcome the barrier and could produce FR_{VII} even at −196°C.

Other mechanisms than these three could be thought of, but as yet we have no experimental background available for further discussion.

Radiation Chemical Process in Polyethylene; a Concluding Remark.—The present ESR result could be interpreted to suggest the following features of the radiation chemical process in PE. Primarily irradiation produces the $-CH_2-\dot{C}H-CH-$ radicals (FR_{VI}) clustered in a spur with a G value of 6.4; it also produces the trans-vinylene unsaturated group by the molecular H_2 detatchment process with a G value of 2.2. The $-CH_2-\dot{C}H-CH_2-$ radicals are 'hot', and the excess energy might distribute over a certain range. Most of the $-CH_2-\dot{C}H-CH_2-$ radicals are produced in close proximity, giving the broad sextet spectrum, and the distance distribution among the radicals might be given by a certain function. The excess energy of the hot radicals would cool very rapidly ($\sim 10^{-12}$ sec.). Some hot radicals with sufficient excess energy decompose before cooling to give $-CH_2-\dot{C}H-CH=CH-$ and H_2, with a G value of 0.31. Other hot radicals located very closely within a certain range can react with each other during irradiation even at −196°C and form crosslinks. The rest of the hot radicals will only cool without reacting and so be trapped. They will, however, react to form crosslinks as the temperature is raised. Thus the reaction process can be represented as:

$$-CH_2-CH_2-CH_2-CH_2- \overset{1)}{\underset{G=6.4}{\rightsquigarrow}} (-CH_2-\dot{C}H-CH_2-CH_2-)_{hot} + H$$

$$\overset{2)}{\underset{G=2.2}{\rightsquigarrow}} -CH_2-CH=CH-CH_2- + H_2$$

$$(-CH_2-\dot{C}H-CH_2-CH_2-)_{hot}$$

18) A. S. Gordon and S. R. Smith, *J. Chem. Phys.*, **34**, 331 (1961).

$$\xrightarrow[G=0.31]{\text{3) sufficiently hot}} -CH_2-\dot{C}H-CH=CH- + H_2$$

$$\xrightarrow[\text{at } -196°C]{\text{4) located close together}} 1/2$$

$$-CH_2-CH-CH_2-CH_2-$$
$$|$$
$$-CH_2-\dot{C}H-CH_2-CH_2-$$

$$\xrightarrow[\text{cool at } -196°C]{\text{5) located apart}} -CH_2-\dot{C}H-CH_2-CH_2-$$

$$\downarrow \text{as temp. is raised}$$

$$1/2 \quad \begin{matrix} -CH_2-CH-CH_2-CH_2- \\ | \\ -CH_2-CH-CH_2-CH_2- \end{matrix}$$

The G value for the instantaneous crosslinking at $-196°C$ (Eq. 4) can be calculated from $G_R(FR^{I}_{VI})$ divided by 2 and so becomes 1.1. The G value for crosslinking ($G(X)$) resulted from being warmed to room temperature (Eq. 5) is calculated to $1/2(G_R(FR_{VI})-G_R(FR^{I}_{VI}))=2$. On irradiation at room temperature the $G(X)$ will then become $2+1.1=3.1$.

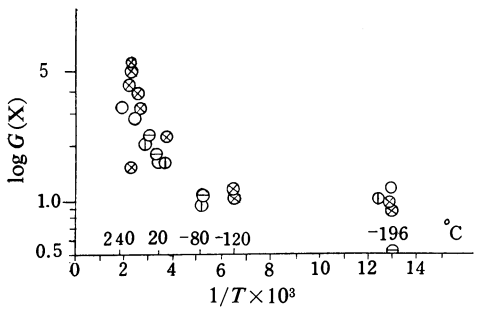

Fig. 6. An Arrhenius plot of the crosslinking yields obtained by various authors, compiled by A. Chapiro[19].

- ⊖ Black 1956
- ⊗ Charlesby Davison 1957
- ⊕ Pravednikov Medvedev 1958
- ○ Lawton et al. 1958

Comparing the crosslinking G value expected from the present ESR result with those obtained experimentally by several other authors, the agreement is found to be satisfactory. Chapiro[19] has summarized the $G(X)$ values by several authors as in Fig. 6. The data show the $G(X)$ at $-196°C$ to be nearly 1 and the value at 40°C to be 3, in agreement with the present suggestion. Such agreement may well show the reasonableness of the present picture of the radiation chemistry of PE. As Fig. 6 suggests, the crosslinking reaction below $-40°C$ proceeds with an activation energy of nearly zero. In order to explain this particular nature of the crosslinking reaction, some authors have suggested an 'ionic' mechanism[19,20]. Pravednikov et al.[21], on the other hand, proposed a 'hot' radical mechanism. Our result is in favor of the latter opinion. Production of the 'hot' $-CH_2-\dot{C}H-CH_2-$ radicals in close proximity is a characteristic of chemical reaction caused by ionizing radiation. They cannot react with oxygen, as has been revealed by us[22], and cannot react with radical scavengers such as DPPH, because, before the arrival of such scavengers, they react with each other almost instantaneously. The $-CH_2-\dot{C}H-CH_2-$ radicals produced apart from each other or diffused out of the spur, thus making 'background' radicals in Magee's sense[23], behave in a way similar to the so-called free radical reaction or photochemical reaction. They may react with oxygen or radical scavengers.

In irradiated poly(vinyl chloride)[24], poly(vinyl alchohol)[12], and nylon[12], the free radical formation curves deviated from straight line in a way quite similar to that of PE. This might suggest, as in the case of PE, the occurrence of the reaction of some hot radicals at $-196°C$. The G_R values were estimated from the initial slope to be 7.1, 8.0 and 10 respectively, Irradiated polypropylene[25] was an exceptional case where the free radical formation curve at $-196°C$ was nearly a straight line ($G_R=6.2$) up to 100 Mrad, showing an almost complete trapping of the primary radicals. This rather exceptional behavior might have something to do with the shrinkage of the spiral main chain on scission.

The author would like to express his sincere thanks to Professor Isamu Nitta for his discussions and also to Professor Shuzo Seki for his encouragement. Thanks are also due to Mr. Yohta Nakai of this Association for his determination of the irradiation dose.

*Electron Spin Resonance Hyperfine Spectra of Diphenyl Nitric Oxide**

By Yasuo DEGUCHI**

(Received June 30, 1961)

Many electron spin resonance spectra of organic free radicals have been reported by many investigators[1]. Hoskins[2], for instance, has reported that he could observe the proton hyperfine spectra of diphenyl nitric oxide (DPNO) during the oxidation of diphenylamine. The spectrum showed that it was composed of three groups, each of which consisted of more than thirteen sharp lines. His explanation of this result was that the separation into three groups was caused by the interaction of the nuclear magnetic moment of nitrogen (^{14}N) with that of electron and that each sharp line in any of the three groups occurred from the proton-electron hyperfine interaction. Thus, he obtained 10.3 gauss as the isotropic hyperfine interaction coefficient of ^{14}N and $g=2.0062$. However, he did not explain the proton hyperfine spectra in detail.

We have synthesized DPNO and studied the exchange narrowing effect and the crystal anisotropy effect on the spectra in crystalline states[3]. In this paper we shall report on the results of electron spin resonance measurements in liquid solutions of DPNO.

Experimental

The synthetic method of DPNO has already been described in a previous paper[3],***. The same compounds, in which either the para- or the meta-position in the two benzene rings was deuterized, were also synthesized.

The ESR spectrometer employed here is the new high-resolution apparatus constructed by Professor J. Townsend, of the Department of Physics of Washington University. The microwave length is 3 cm., and the cavity is a reflex cylindrical type. The static magnetic field is generated by a Varian electro-magnet with 12 pole faces. The magnetic field modulation frequency is 100 kc. An aqueous solution of peroxylamine disulfonate[4] was used as a standard of the g-value and the magnetic field. Especially for the precise measurement of the nitrogen and proton isotropic hyperfine splittings, a glass capillary filled with an aqueous solution of peroxylamine disulfonate was attached to a sample tube, a 2.5 mm. (I. D.) $\times$ 200 mm. pyrex glass tube sealed at one end.

Solutions of DPNO were made with various kinds of organic solvents, i. e., cyclohexane, ethyl ether, ethyl alcohol, dimethoxyethane, tetrahydrofurane and mixtures of ethyl alcohol and glycerol[5], either in vacuum-sealed glass tubes[6] or under ordinary pressure atmosphere conditions.

Results and Discussion

The Case of Samples Prepared under the Normal Pressure Atmosphere.—We determined the suitable concentration for obtaining well-resolved hyperfine spectra. Of the different concentrations of cyclohexane solutions, a 0.1 mol./l. solution showed a single absorption line, a 0.01 mol./l. solution began to reveal hyperfine spectra slightly, a 0.001 mol./l. solution had three broad absorption lines due to ^{14}N and a 0.0001 mol./l. solution also had three broad lines but never revealed further splittings due to protons. The measured g-values are 2.0078 for the 0.1 mol./l. solution, 2.0069 for the 0.01 mol./l. solution, 2.0106 for the 0.001 mol./l. solution, and 2.0100 for the 0.0001 mol./l. solution. The isotropic hyperfine splitting coefficient of ^{14}N is 9.55 gauss. In the 0.00001 mol./l. solution, no absorption spectra could be obtained, since at this concentration the noise level of the apparatus was much higher than the signal level. Solutions of ethyl ether, ethyl alcohol, dimethoxyethane and tetrahydrofurane behaved just the same as did the cyclohexane solution. In the case of a mixed solution of ethyl alcohol and glycerol, however, we obtained proton hyperfine spectra similar to those of Hoskins[2]. The remarkable difference between our spectra and Hoskins' is that our spectrum is asymmetric with respect to the center group lines, while Hoskins' is not, as is shown in Fig. 1. In Fig. 1, the absorption lines in the central group

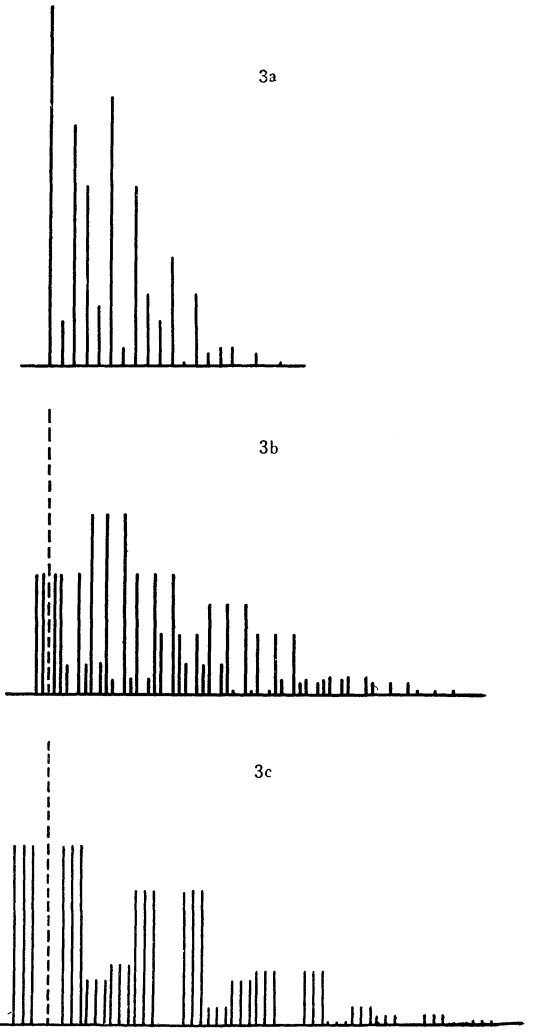
Fig. 1. ESR proton hyperfine spectrum of DPNO in a mixed solvent of ethyl alcohol and glycerol with a mixed ratio 3 : 2.

are the sharpest compared with the groups in both sides. Also, each line in the lower field side is sharper than the one in the higher field side. Each group overlaps at the tail of the other.

This phenomenon can be explained according to McConnel[7], as the effect of anisotropic hyperfine interaction on the paramagnetic relaxation in liquid. Further experiments will be made and discussed elsewhere in the near future.

The Case of Samples Prepared in Vacuum.— As reported before[6], diphenylpicrylhydrazyl (DPPH) revealed a well-resolved proton hyperfine structure in the ESR spectrum when its sample was prepared in vaccum. DPNO also shows a more detailed proton hyperfine structure when prepared in vacuo, as is shown in Fig. 2.

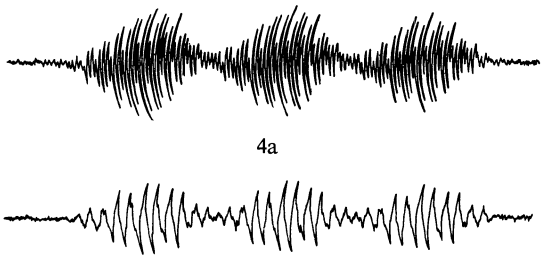


2a 2b

Figs. 2a and 2b. ESR protone hyperfine spectra of DPNO in degassed ethyl alcohol. Fig. 2b. is a half spectrum of the lower magnetic field side group where the concentration of the sample is a little more concentrated than the one in Fig. 2a.

From Fig. 2a, we can not determine exactly the total numbers of lines in each group, because the concentration of the sample is rather small for obtaining the weaker lines in the ends far from the center. Thus, by making a little more concentrated sample, Fig. 2b was obtained. From Figs. 2a and 2b, one could finally find that each group consisted of seventeen lines due to the proton hyperfine interaction.

In other solvents, such as dimethoxyethane, tetrahydrofuran cyclohexane, methylcyclohexane, carbon disulfide, toluene, etc., the same spectra as that of the ethyl alcohol solution have been obtained, except that small variations in the nitrogen and proton isotropic splitting coefficients appear from one solvent to another.



In order to explain these spectra, we assume

Figs. 3a, 3b and 3c. One halves of calculated intensities of the proton hyperfine spectra of DPNO in one of the three groups: (a) Non-deuterized DPNO; (b) Para-deuterized DPNO; (c) Meta-deuterized DPNO.

that the odd electron spin densities at the para- and ortho-position carbon adjacent to the proton in the benzene ring are equal to one another and nearly twice as large as the one at the meta-position. The relative intensities thus calculated are shown in Fig. 3a. The measured isotropic splitting coefficients due to the para- or ortho-position spin density and that of the meta-position are 1.89 gauss ($\Delta H_{p,o}$) and 0.83 gauss (ΔH_m) respectively, i. e., $\Delta H_{p,o} \gtrsim 2\Delta H_m$. To verify further the validity of our assumption, we observed the ESR spectra of deuterized DPNO, in which one of the para- or meta-protons of the benzene rings was substituted for by a deuterium, as is shown in

7) H. M. McConnell, ibid., 25, 709 (1956).

4a

4b

Figs. 4a and 4b. ESR spectra of para- or meta-deuterized DPNO in ethyl alcohol. Fig. 4a is the spectrum of the para-deuterized DPNO and Fig. 4b is the one of the meta-deuterized DPNO.

Figs. 4a and 4b. While each hyperfine line splits further into three lines by the substitution for the proton at the para-position of the deuteron ($I=1$) (cf. Fig. 4a), the appearance of the triple splitting in each line is very weak in the case of meta-deuterized DPNO. These results confirm that the aforementioned assumption about spin density is valid. Figures 3b and 3c are the calculated relative intensity diagrams for para- and meta-deuterized DPNO based upon the aforementioned assumption.

Hereafter we shall apply Kivelson's theory[8] to calculate the line width of each hyperfine line in the spectrum of DPNO. As has been described in the preceding paper[3], we will have

$$\omega=\omega_0-\Delta$$

$$\omega_0=\gamma B_0+\sum_\lambda a_\lambda M_\lambda-\frac{S(S+1)K'}{3}$$

where K' is the same as K as defined in the preceding paper[3] although $A_\lambda=a_\lambda$, a_λ is an isotropic hyperfine splitting factor for the λth nucleus and Δ is a nonsecular shift.

The integrated intensity of each line (I) is

$$I=\frac{NS(S+1)\gamma g_M}{3}$$

where N and g_M are defined as in the preceding paper[3].

Assuming $\tau_c^2 a_\lambda^2 \ll 1$ and $\gamma B_0 \gg a_\lambda$, $T_1'(IS)$ and $T_2'(IS)$ are given by

$$\begin{aligned}T_2'^{-1}(IS)=&\frac{3\tau_c}{20}\sum_\lambda(2S^2+2S+1)\sigma_{\lambda\lambda'}^2\\&\times[\ll J_\lambda(J_\lambda+1)\gg_{M_\lambda}-M_\lambda^2]\\&+\tau_c\sum_\lambda\sum_{\lambda'}\{\sigma_{\lambda\lambda'}^2M_\lambda M_{\lambda'}\}\\&+\frac{4\tau_c}{15}\left\{\frac{(\Delta\gamma B_0)^2}{3}+(\delta\gamma B_0)^2\right\}\\&-\frac{4\tau_c}{15}\sum_\lambda\{\Delta\gamma B_0 b_\lambda M_\lambda+2\delta\gamma B_0(c_\lambda+c_\lambda^*)M_\lambda\}\end{aligned}$$

$$\begin{aligned}T_1'^{-1}(IS)=&\tau_c[1+\omega_0^2\tau_c^2]^{-1}\left\{\frac{1}{15}(\Delta\gamma B_0)^2\right.\\&+\frac{1}{5}(\delta\gamma B_0)^2-\sum_\lambda\left[\frac{1}{5}\Delta\gamma B_0 b_\lambda M_\lambda\right.\\&+\frac{2}{5}\delta\gamma B_0(c_\lambda+c_\lambda^*)M_\lambda\\&+\frac{7}{40}(8S^2+8S-1)\sigma_{\lambda\lambda'}^2[\ll J_\lambda(J_\lambda+1)\gg_{M_\lambda}\\&\left.-M_\lambda^2]\right]+\sum_\lambda\sum_{\lambda'}\frac{3}{4}\sigma_{\lambda\lambda'}^2M_\lambda M_{\lambda'}\left.\right\}\end{aligned}$$

where

$$\sigma_{\lambda\lambda'}=\frac{1}{5}\left[b_\lambda b_{\lambda'}+\frac{8}{3}(c_\lambda^*c_{\lambda'}+c_\lambda c_{\lambda'}^*+d_\lambda^*d_{\lambda'}+d_\lambda d_{\lambda'}^*)\right]$$

If $\delta\gamma=c=d=0$, then

$$\begin{aligned}T_2'^{-1}(IS)=&\frac{3\tau_c}{20}\sum_\lambda(2S^2+2S+1)\\&\times\frac{b_\lambda^2}{5}[\ll J_\lambda(J_\lambda+1)\gg_{M_\lambda}-M_\lambda^2]\\&+\tau_c\sum_\lambda\sum_{\lambda'}\left(\frac{b_\lambda b_{\lambda'}}{5}M_\lambda M_{\lambda'}\right)\\&+\frac{4\tau_c}{45}(\Delta\gamma B_0)^2-\frac{4\tau_c}{15}\sum_\lambda(\Delta\gamma B_0 b_\lambda M_\lambda)\end{aligned}$$

$$\begin{aligned}T_1'^{-1}(IS)=&\tau_c[1+\omega_0^2\tau_c^2]^{-1}\left\{\frac{(\Delta\gamma B_0)^2}{15}\right.\\&-\sum_\lambda\left[\frac{1}{5}\Delta\gamma B_0 b_\lambda M_\lambda\right.\\&+\frac{7}{40}(8S^2+8S-1)\frac{b_\lambda^2}{25}\\&\left.\times[\ll J_\lambda(J_\lambda+1)\gg_{M_\lambda}-M_\lambda^2]\right]\\&\left.+\sum_\lambda\sum_{\lambda'}\frac{3b_\lambda b_{\lambda'}}{100}M_\lambda M_{\lambda'}\right\}\end{aligned}$$

where

$$\ll J_\lambda(J_\lambda+1)\gg_{M_\lambda}=\sum_{I_\lambda=M_\lambda}^{n_\lambda I_\lambda}J_\lambda(J_\lambda+1)\frac{g'_{J_\lambda}-g'_{J_\lambda+1})}{g_M}$$

$$g'_{J_\lambda}=[W(n_\lambda,J_\lambda,I_\lambda)]\prod_\lambda(2I_\lambda+1)^{-n_\lambda}$$

$$g_M=\prod_\lambda W(n_\lambda,J_\lambda,I_\lambda)(2I_\lambda+1)^{-n_\lambda}$$

In the case of diphenyl nitric oxide, we have one nitrogen atom and 6 para- and ortho-protons and 4 meta-protons; i. e.,

$$n_N=1,\quad I_N=1;\quad S=\frac{1}{2}$$

$$n_{p,o}=6,\quad I_{p,o}=\frac{1}{2}$$

$$n_m=4,\quad I_m=\frac{1}{2}$$

8) D. Kivelson, ibid., 33, 1094 (1960).

Also, as assumed in the preceding section, the electron spin density at the para- or ortho-position is about twice as large as that at the meta-position.

In the formula for ω_o, the term $\sum_\lambda a_\lambda M_\lambda$ gives the hyperfine structure in spectra. In our case, we have three different equivalent groups of niclei, i.e., one nitrogen, 6 para- and ortho-protons, and 4 meta-protons. One nitrogen has I_{zN}: $1, 0, -1$; 6 para- and ortho-protons, $I_{zp,o}$: $\pm3, \pm2, \pm1, 0$; 4 meta-protons, I_{zm}: $\pm2, \pm1, 0$. One thus obtains 105 absorption lines, but some of them will be so weak that one can not observe them in the spectra.

It is tedious to calculate the $\ll J_\lambda(J_\lambda+1)\gg_{M_\lambda}$ of all the component lines. Thus we shall calculate only those referred to the three center lines of each group. These lines are given as follows:

1. For $M_N=1$, there exist three different combination of $M_{p,o}$ and M_m, i.e.,

$$\begin{cases} M_{p,o}=0 \\ M_m=2 \end{cases} \quad \begin{cases} M_{p,o}=1 \\ M_m=-2 \end{cases} \quad \begin{cases} M_{p,o}=-1 \\ M_m=2 \end{cases}$$

2. For $M_N=0$ (this corresponds to the center group),

$$\begin{cases} M_{p,o}=0 \\ M_m=0 \end{cases} \quad \begin{cases} M_{p,o}=1 \\ M_m=-2 \end{cases} \quad \begin{cases} M_{p,o}=-1 \\ M_m=2 \end{cases}$$

3. For $M_N=-1$,

$$\begin{cases} M_{p,o}=0 \\ M_m=0 \end{cases} \quad \begin{cases} M_{p,o}=1 \\ M_m=-2 \end{cases} \quad \begin{cases} M_{p,o}=-1 \\ M_m=2 \end{cases}$$

Each combination has its own T_1', T_2' and integrated intensity I, which are given above. In order to evaluate a correlation time (τ_c) for the molecular tumbling, evidently we cannot assume the DPNO molecule as a sphere, but rather must regard it as a prolate ellipsoid. The dimensions thus determined are

$$a=4.84\,\text{Å}$$
$$b=2.10\,\text{Å}$$

where a and b are the longer and the shorter axes. According to Perrin's theory[9],

$$\frac{\tau_a}{\tau_o}=\frac{2(1-q^4)}{\dfrac{3q^2(2-q^2)}{\sqrt{1-q^2}}\ln\left\{\dfrac{1+\sqrt{1-q^2}}{q}\right\}-3q^2}$$

$$\frac{\tau_b}{\tau_o}=\frac{4(1-q^4)}{\dfrac{3q^2(2q^2-1)}{\sqrt{1-q^2}}\ln\left\{\dfrac{1+\sqrt{1-q^2}}{q}\right\}+3}$$

where τ_a: the correlation time for the molecular tumbling around the b-axis. τ_b: the correlation time for the molecular tumbling around the a-axis. τ_o: the correlation time for a hypothetical sphere with a volume equivalent to that of the actual ellipsoid.

$$\tau_o=\frac{4\pi\eta ab^2}{3KT}$$

q: an axial ratio given by

$$b/a$$

η: the viscosity of a solvent in poise, T: absolute temperature (°K).

In the case of ethyl alcohol at $T=293$°K,

$$\eta=1.20\times10^{-2}\ \text{poise}^{10)}$$

Thus we get

$$\tau_a=4.608\times10^{-11}\ \text{sec.}$$
$$\tau_b=4.256\times10^{-11}\ \text{sec.}$$

The numerical values of a_N, $a_{p,o}$, a_m, b_N, $b_{p,o}$, b_m, $\Delta\gamma$ and H_o have been given in the preceding paper[3]. The results thus obtained are tabulated in Table I. As can be seen in Table I, the angular quantum number dependency of the spectra for the center line in each group can be explained by this theory, but the two outside lines next to the center line in each group are one-eighth the intensity of the center lines, while their calculated widths are about five times broader than the center lines. Thus we

Table I

		Half-width at max. slope gauss	
		Calcd.	Obs.

10) "Handbook of Phys. & Chem.", 39th Ed., Chem. Rubber Publishing Co.

can not expect well-resolved absorption lines. This is the case in the actual spectra.

Effect of a Methyl Group Attached to the Benzene Ring either at the para-, meta- or ortho-Position. — Using bromo-toluene instead of bromo-benzene, these radicals were synthesized by the same procedure as has been described above. Among three methylized radicals, the ESR spectra of the para- or meta-methylized ones show that an attached methyl group adds extra proton hyperfine lines to the original spectra of DPNO, while the ortho-methylized one exhibits a drastic modification in the spectra, as is shown in Fig. 5. Only four broad lines instead of seventeen sharp lines appear in each group. From this spectra, one can conclude that the electron spin densities at the nitrogen and methyl groups are much greater than those at the other ring carbons.

Fig. 5. ESR spectrum of the ortho-methylized DPNO in ethyl alcohol.

In order to clarify this remarkable effect, further investigations, such as optical measurements and ESR measurement of its crystalline state, are now being undertaken.

Effect of Solvents on the Widths of Nitrogen and Proton Hyperfine Splittings. — During the course of the present study, it was found that the widths of nitrogen and proton hyperfine splittings vary from one solvent to other. These results are shown in Fig. 6. In this figure, the magnitudes of the dielectric constants of the solvents were conveniently taken as an abscissa scale. From this diagram, it can be seen that nitrogen and proton isotropic splittings are approximately linearly proportional to the dielectric constants of the solvents. This result can be qualitatively understood if one considers as follows:

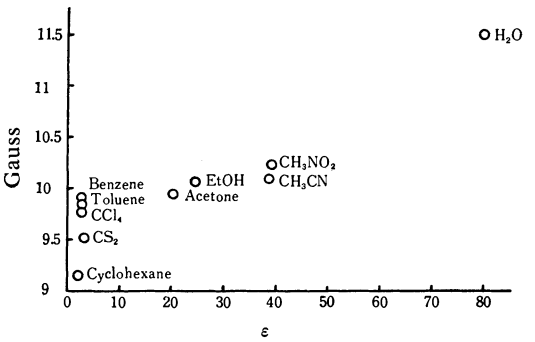

Fig. 6. Dependence of the nitrogen isotropic hyperfine splittings on dielectric constants of various kinds of solvent.

According to the valence bond theory, one will have various kinds of ionic structure besides the covalent bond structure, as is shown in Fig. 7.

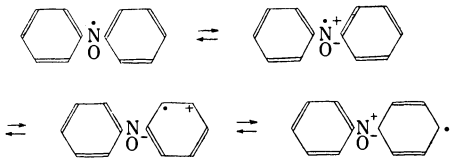

Fig. 7. Various resonance structures of DPNO.

The second structure gives the nitrogen splitting, and the third and fourth structures, the proton splitting. Thus, by the presence of polar solvents, the ionic structures among the above resonant ones will be favored.

In order to put this consideration on a rigorous theoretical basis, a further investigation is now under way.

Summary

Liquid solutions of diphenyl nitric oxide reveal well-resolved proton hyperfine spectra either in mixed solvents of glycerine and ethyl alcohol in a suitable mixed ratio or in vacuum-sealed, degassed solvents.

Assuming odd electron spin densities at the ring carbon atoms and applying Kivelson's theory, one can explain the experimental results. Moreover, the effect on the ESR spectra of the addition of a methyl group to a benzene ring has been reported on.

Finally, the solvent effect on the ESR spectra has been discussed.

The author is much obliged to Professor S. I. Weissman for his helpful discussions and encouragement during the course of this work. He is also indebted to Professor J. Townsend for offering him a chance to use the ESR apparatus. He also appreciates Dr. A. Holtzer's suggestion of the molecular tumbling-correlation time estimation method.

Physicochemical Studies on Cobalt Salts of Higher Fatty Acids. VII. Effects of Solvents on Cobalt Soaps. Solubilities and Color Changes of Cobalt Soaps in Solvents, and Adsorption of Water Vapor on Cobalt Soaps

By Hirotaro KAMBE*

(Received March 29, 1961)

Cobalt stearates with red and blue colors have been prepared and investigated in the previous papers[1]. Cobalt soaps do not readily dissolve in common solvents when cold, as has been stated in Part V. Boner[2] dissolved cobalt stearate in hot paraffinic oils and observed gelatinization after cooling. He described how cobalt stearate, dissolved in pyridine, made a red complex with the pyridine which decomposed in air on being heated. Lawrence[3] used this complex as a means of the purification of cobalt soaps. Koenig[4] described how cobalt stearate showed solubilities over 1% in chloroform, carbon tetrachloride, liquid paraffin, *n*-heptane, benzene, toluene, amyl alcohol and pyridine, and of about 0.01% in ethyl ether and carbon disulfide. It was stated to be insoluble in methanol, acetone and ethyl acetate.

In preliminary observation, some typical solubility characteristics were observed. Cobalt soaps did not dissolve in water. Because water did not wet them, they floated on its surface. Ethanol did wet them, but they did not show any solubility in it, even if it was hot. If cobalt soaps were immersed in cold ethanol for a long time, they changed purple, as stated in Part III. In benzene, cobalt soaps did not dissolve at room temperatures, but in hot benzene, a blue solution was obtained which appeared silky when it was stirred. A purple jelly was obtained after cooling. In hot toluene, cobalt soaps dissolved considerably, but the colors of the solutions changed to a dirty yellow.

In the present paper, the solubility characteristics and color changes of cobalt soaps in various solvents will be observed. Additionally, the adsorption of water vapor on cobalt soaps will be measured.

Experimental

Materials.—The same cobalt stearates were used as in previous papers[1]. Solvents (cf. Table I) were chemically pure reagents. They were used without special purifications.

Observations on Solubilities and Color Changes.—An amount (usually 10 mg.) of cobalt soap was sealed and shaken with various solvents (usually 5 ml.) in glass tubes. The changes in appearance and color were observed at cold temperatures. Then the solutions were heated in an air bath at 90~100°C for 3~4 hr. and cooled again. They were observed occasionally during these processes.

Adsorption of Water Vapor.—The same quartz spring balance was used as in determining the amount of hydrate water in Part II. The relative humidity (RH) in the atmosphere of the sample was controlled by aqueous solutions of sulfuric acid. Measurements of the amount of adsorbed water, x(g.), were carried out at room temperatures at about 25 and 30°C. The saturated vapor pressure, p_s, was obtained from International Critical Tables. The weight of the sample, m(g.), was 40~100 mg. Specific adsorption, x/m, was calculated and plotted against relative humidity to get an adsorption isotherm.

Results and Discussion

Solubilities.—The solubility characteristics of red dihydrate and blue anhydrate of cobalt stearate were almost identical. Although, in a cold solution, the red soap swelled and suspended more easily in many solvents than blue soap, at higher temperatures the difference of color did not significantly affect the appearance of the soaps. The results of observations on the changes in appearance of red cobalt soaps were tabulated in Table I. Much the same data were obtained for blue soap. The differences in characteristics between these tables were so minor that the latter table was eliminated.

There were several solvents in which cobalt soaps showed considerable solubilities. Among the solvents investigated, pyridine and bromoform were the most effective solvents for cobalt soaps, followed by benzyl alcohol, nitrobenzene, chlorobenzene and aniline.

Water showed absolutely no influences on cobalt soaps. Acetone was also a relatively indifferent solvent to them. In a hot state, halogen compounds and aromatic hydrocarbons were fairly good solvents for cobalt soaps. Glycols were poor.

When hot solutions in some comparatively good solvents were cooled, jellies were obtained. These solvents were carbon tetrachloride, trichloroethylene, benzene, toluene and chlorobenzene. Sometimes solutions became a dirty yellow or brown in which dark precipitates appeared.

As cobalt soaps did not readily dissolve in common solvents, it was difficult to get a single crystal from these solvents, as has been stated in Part V.

Color Change.—Several types of color change were observed. (i) No change of color was observed in water or in acetone. (ii) The color of red soap turned blue or gained a tinge of blue in ethanol, and violet in benzene. The color of blue soap in these solvents approaches to the color of changed red soap. (iii) The color of blue soap turned pale pink in methanol, and red in pyridine. Red soap also approached these colors in them. (iv) The color changed to a dirty yellow, brown, or green in *n*-butanol, toluene, *p*-xylene, *n*-heptane, dioxane (at first, red), cyclohexane (at first, blue), and in ethyl ether. The absorption spectra of solutions of cobalt stearates in dioxane and in xylene are shown in Fig. 1. Absorption maxima appeared

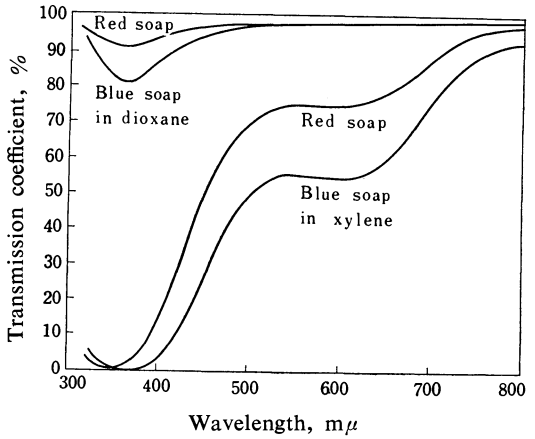

Fig. 1. Absorption spectra of cobalt stearate solutions in xylene and in dioxane.

at 360 mμ. In these systems, the addition of water did not recover soaps of the original color. It is suggested that some change in the electronic configuration of cobalt ion occurred in these solutions. (v) The solution gelatinized after cooling. Purple jelly was obtained in benzene, but dirty yellow or brown jellies grew in toluene, *n*-hexane, *p*-xylene and cyclohexane. These jellies were thixotropic and syneretic and gradually recovered their fluidities for a long time. (vi) In hot pyridine, cobalt stearates dissolved easily, but they soon turned red. Red crystals precipitated on cooling. These were complexes of cobalt soaps with pyridine[2].

In aqueous ethanol the color of blue cobalt soap gradually turned red. The effects of the addition of electrolytes to these systems were examined. Suspensions of red and blue cobalt stearate in mixtures of ethanol with water in 80, 50 and 40 wt.%, with the addition of potassium chloride, potassium nitrate, cobalt chloride and cobalt nitrate, were shaken with a machine at room temperatures. Cobalt stearates in all systems turned completely red after two or three days. Some bluish tint remained in red soaps in systems to which potassium salts had been added without regard to concentrations of ethanol. In other systems red soap did not change its color. In absolute ethanol, red and blue soaps became pale purple in systems with potassium salts, but with cobalt salts the color turned violet.

In benzene, hot solutions of cobalt soaps gelatinized after cooling. Red or blue cobalt soap was sealed in glass tubes with benzene, at various concentrations of 0.05~5.00 wt.%. When they were heated at 100°C for one hour, pale blue solutions were obtained in which some gelatinized mass floated. After subsequent cooling, they gelatinized soon. These processes were repeated three or four times. The appearances of jellies were observed. Below concentration of 0.12 wt.%, the jelly showed a considerable fluidity at 20°C, but above this concentration the system solidified as purple jelly. Red soap in benzene systems with concentrations above 0.28% were heterogeneous and turbid. Blue soap systems were clear and transparent.

When ethanol was added to benzene, the gelatinization was much suppressed. When various amounts of ethanol above 2 vol.% were added, solutions of cobalt stearates in benzene, with a concentration of 0.3%, did not solidify. Purple flocculates grew within the solution. Long after, the color of soap remained a reddish violet in pure benzene, but in other systems soap turned blue completely.

In pyridine red and blue soap dissolved above 10% and reddish violet solutions were obtained. Red crystals of complex precipitated from the solution.

Adsorption of Water Vapor.—The amounts of water adsorbed on red and blue cobalt stearates are shown in Table II and in Fig. 2. Red soap adsorbed much more water than blue soap, but the difference of temperature at

measurement must also be considered. The forms of the adsorption isotherm are apparently different from each other. The mechanisms of adsorption seem also to be different. Since the accuracy of measurement is insufficient, however, particularly in blue soap, the significance of these results must be minimized.

Summary

The effects of various solvents on cobalt soaps were investigated. The solubility of cobalt soap was low in general. In pyridine and bromoform, it showed a considerable value. In a hot state, several solvents dissolved cobalt soaps fairly well. In some solvents, jellies were obtained on cooling. In other solvents, the color changed to a dirty yellow. Absorption spectra showed that the absorption maxima in these solutions were displaced for a shorter wavelength. This means that a change of the electronic configuration occurred.

Adsorption of water vapor on cobalt soaps was measured. Red dihydrate seemed to adsorb much more water vapor than blue anhydrate.

Physicochemical Studies on Cobalt Salts of Higher Fatty Acids. VIII. Some Rheological Properties of Solutions of Cobalt Soaps. Specific Viscosities and Non-Newtonian Flow

By Hirotaro KAMBE*

(Received March 29, 1961)

It has been shown in the preceding part of this series[1] that cobalt is hard to dissolve in common solvents at room temperatures. It shows relatively higher solubilities in hot aromatic hydrocarbons, but these solutions gelatintize after cooling. The flow properties of these gelatinous solutions are investigated in the present paper. Intrinsic viscosities of red and blue cobalt stearates were obtained from specific viscosities of dilute benzene solutions. Jellies, formed by solutions in benzene, were peptized by adding a small amount of ethanol. It was observed in specific viscosities.

The non-Newtonian flow of concentrated solutions of cobalt soaps in benzene, toluene, xylene and *n*-heptane were measured with capillary viscometers. These solutions, particularly with higher concentrations, were gelatinized, and the capillary was often blocked by a slump of jelly. The jelly was so thixotropic and syneretic that the reproducibility of measurement was poor.

Experimental

Materials.—Cobalt stearates were used as in previous papers. Benzene, toluene, xylene and *n*-heptane, used as solvents, were purified as usual. Soap was mixed with an appropriate amount of solvent and dissolved by shaking while hot. Jellies or viscoelastic solutions were obtained after cooling in the viscometer.

Viscometry. — Specific viscosities of the dilute solution, η_{sp}, at several concentrations, were measured with an Ubbelohde suspended-level viscometer[2]. Intrinsic viscosity, $[\eta]$, was obtained by an extrapolation of the linear plots of reciprocal reduced viscosity, c/η_{sp}, against concentration, c, as applied by Gray and Alexander[3] to solutions of aluminum soap in benzene, using the following formula:

$$\frac{c}{\eta_{sp}}=\frac{1}{[\eta]}-k'c \qquad (1)$$

The non-Newtonian flow of solutions was measured by using a Tsuda[4] or Philippoff[5] viscometer of horizontal capillary with a manostat. Shearing stress $P_R=R\Delta P/2L$ and nominal rate of shear $\dot{e}_R=4Q/\pi R^3 t$ at wall were calculated and plotted as a flow curve; where R and L are radius and length of the capillary respectively, Δp is a pressure difference at both ends of the capillary, and Q is a volume of liquid flowing through the capillary during time t. Kinetic energy corrections are negligible. The dimensions of the capillaries are shown in Table I.

○ Red soap △ Blue soap

shown in Table II and are plotted in Fig. 1. Intrinsic viscosity was obtained by applying Eq. 1 to Fig. 1. The coefficients of Eq. 1 were determined by the least-square method. The following formulas were obtained for each soap:

$$c/\eta_{sp}=(0.32\pm0.02)-(0.005\pm0.005)c$$

for red soap.

$$c/\eta_{sp}=(0.55\pm0.10)-(0.18\pm0.07)c$$

for blue soap.

The values of $[\eta]$ are 3.13 for red soap and 1.81 for blue soap. They were larger than the value obtained for aluminum stearate in benzene by Gray and Alexander[3]. This discrepancy is because of the gelatinous character of cobalt soap in benzene.

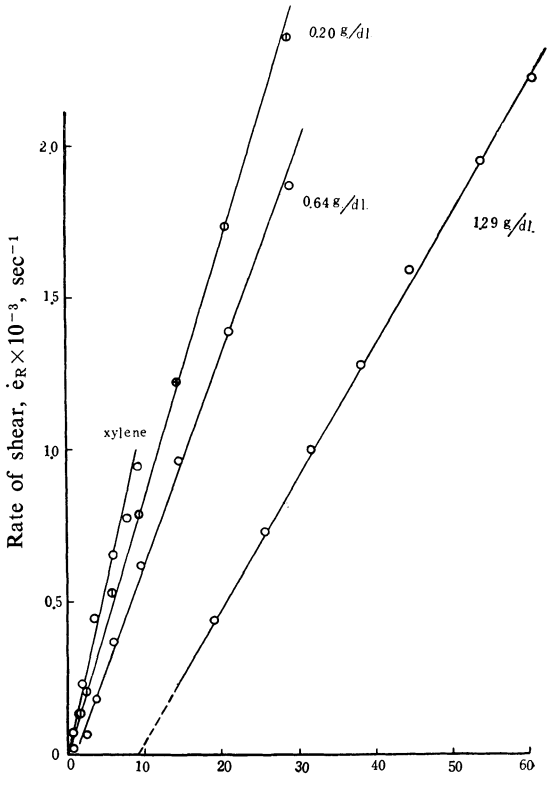

Fig. 2. Flow curves of solutions of red cobalt stearate in xylene, at 20°C.

Specific viscosities of cobalt stearates in mixtures of benzene and ethanol are shown in Table III. At a concentration of 0.045 g./dl. for red soap and 0.036 g./dl. for blue soap, the viscosity of the solution is markedly lowered by the addition of a little ethanol. The viscosity of a solution in a mixed solvent containing ethanol above 2% by volume is essentially the same as that of the mixed solvent itself. Additions of ethanol prevent the gelatinization of the system, and the solubility of soap is so much suppressed that the cobalt soap is almost removed from the solution by being deposited on the wall of the vessel.

Non-Newtonian Flow. — Solutions of cobalt stearate in xylene are dark violet at boiling, but solidify to jellies after cooling. Below concentrations of 2.0 g./dl., the solution is slightly fluid, and below 1.0 g./dl., it is so thixotropic that it increases its fluidity when it was shaken.

The viscosities of these solutions at concentrations of 1.29, 0.62 and 0.20 g./dl. were measured with a Tsuda viscometer at a range of rate of shear, as shown in Fig. 2, and the apparent viscosities, calculated from $\eta_{app}=p_R/\dot{e}_R$, are plotted in Fig. 3 against rate of shear. In Fig. 2, a flow curve of the solution at 1.29

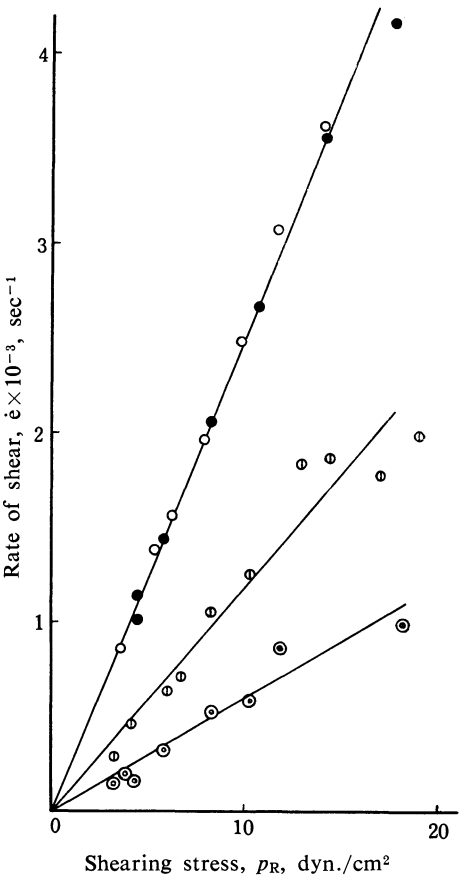

Fig. 5. Flow curves of solutions of cobalt stearate in *n*-heptane and in toluene.
In *n*-heptane ○ 0.057 g./dl. ● 0.17 g./dl.
In toluene ⦶ 0.08 g./dl. ◎ 0.12 g./dl.

g./dl. shows a typical form of the Bingham plastic flow, with a yield value of about 8.5 dyn./cm^2. At other concentrations, there appears no yield value. But in Fig. 3, it is evident that they also show structural viscosity at a low rate of shear range, which does not appear clearly in Fig. 2.

Non-Newtonian behaviors of benzene solutions, with concentrations of 0.097, 0.043 and 0.02 g./dl. at 30°C, were measured with Philippoff viscometers and are shown in Fig. 4. These solutions are blue when hot, but solidify after cooling to pink jellies. These jellies are viscoelastic, thixotropic and highly syneretic. Owing to their insufficient strength, they are easily crushed to pieces and their flow properties are poorly reproducible.

The flow curves of these systems are consistent with each other in this range of concentrations. It is apparently a Newtonian flow. The value of its apparent viscosity is obtained from Fig. 4 as 0.82 cp., which is not markedly different from that of pure benzene. In this case it is the viscosity of a saturated solution of a small concentration that is being measured.

Flow curves in *n*-heptane, shown in Fig. 5 at concentrations of 0.057 and 0.17 g./dl., are almost consistent with each other, as are benzene solutions. However, the flow curves of solutions in toluene, shown in the same figure at 0.08 and 0.12 g./dl., are considerably separated from each other. The apparent viscosity of the toluene solution at 0.12 g./dl. is considerably htgher than the other. Since this solution is most easily gelatinized, the capillary tube of viscometer was often blocked by a piece of gel in the solution. The low fluidity of xylene solution at a high concentration may be caused by such blockage.

The flow curves of benzene solutions at 0.152 g./dl. were measured with different capillaries in which R is 0.25 and 0.52 mm., as shown in Fig. 6. The flow curve must be principally unique to a material. The inconsistency of flow curves obtained with different bores might be caused by the slippage of the solution. In this case, the curve obtained with a large bore would be expected to show a large viscosity[6], and this holds true in Fig. 6.

Thixotropic effects often appeared in these systems. However, sometimes an antithixotropic hysteresis also appeared, as shown in Fig. 7. In this system, the viscosily becomes larger in the down-curve than in the up-curve. The origin of this behavior was not clarified, but blockage by gel is a conceivable cause.

Summary

The specific viscosity of dilute solution of cobalt stearate in benzene has been measured. Intrinsic viscosities are 3.13 for red soap and 1.81 for blue soap. The specific viscosity of benzene solution is decreased markedly by the addition of a small amount of ethanol, owing to the subsequent decrease of solubility.

The non-Newtonian flow behavior of solutions in xylene, benzene, *n*-heptane and toluene are shown. At higher concentrations, in particular in xylene, these solutions are Bingham plastic. In benzene and *n*-heptane,

flow curves with different concentrations are consistent with a flow curve of Newtonian behavior, which corresponds to that of a saturated solution in benzene. In toluene, flow curves are scattered, possibly due to the blockage of the capillary by a piece of gel.

Different flow curves are sometimes obtained with capillaries of different bores, owing to slippage at the wall. An antithixotropic flow curve was obtained in some solutions.

The author expresses his gratitude to Professor Bunnosuke Yamaguchi for his advice throughout this work, and to Messrs. Minoru Kawano and Masamichi Sato for their help in the experiments.

The Systematic Analysis of Silicate Rocks using Ion Exchange Resin

By Yasue Ôki*, Shôhachirô Ôki** and Hidekata Shibata

(Received June 5, 1961)

The many varieties of rock-forming-elements have necessitated the repetition of cycles of absorption and elution, which requires much time and effots for the analysis of silicate rocks using ion exchange resin[1,2]. In order to analyze many samples of ordinary silicate rocks, the present authors have developed a rapid and simple method of analysis using an ion exchange column and a solvent extraction technique. A complete analysis of an ordinary rock or silicate mineral can be carried out in only 3 days by this method.

Experimental

Chemicals and Ion Exchange Resin.—Amberlite IR-120 in 100~150 mesh was employed. The column was 18 cm. long and 1 cm. in diameter. The flow rate was 1 ml. per minute. Fractions were collected every 20 ml.

Constant boiling hydrochloric acid was used as 6 N acid.

Guaranteed-grade chemicals and distilled water were used.

Procedure.—*Decomposition.*—The analytical procedure is schematically illustrated in Fig. 1.

Weigh 100 mg. of the fine powder of the rock sample into a platinum dish, then add a few milliliter of water and dilute hydrofluoric acid. Mix and heat the dish on a sand bath, carefully at first, then more strongly, until fumes of sulfuric acid are given off. Cool, wash the side of the dish with a little water, and add 2 ml. of 1 : 1 sulfuric acid and 5 ml. of hydrofluoric acid. Evaporate again to dryness. Add 20 ml. of 6 N hydrochloric acid and warm until all soluble materials have been taken into solution. Remove the solution into a quartz dish. Cover with a watch glass, add 3 ml. of 3% hydrogen peroxide, and boil gently for a minute or two. After washing the watch glass with a little water, evaporate the solution to less than 10 ml.

Extraction Separation of Iron.—Cool the solution and transfer it to a 50 ml. separatory funnel. Make the solution less than 20 ml. and adjust the concentration of hydrochloric acid to 6 N hydrochloric acid. Shake thoroughly for two minutes. Allow the layers to settle and then separate the two layers. Repeat the extraction twice, and collect the ether layer containing iron in another separatory funnel. Strip the ferric iron into 10 ml. of water. Repeat stripping with 5 ml. of water. Transfer the aqueous layer into a 200 ml. Erlenmeyer flask and add 3 ml. of 6 N hydrochloric acid and 50 ml. of water. After gently boiling the aqueous solution to expel the ether, determine the total iron by the Zimmermann-Reinhard method.

Chromatographic Separation of Elements.—Evaporate the sample solution from which iron had been removed by extraction nearly to dryness (1~2 ml.). Care should be taken not to evaporate the contents; otherwise, titanium will be lost as insoluble materials to water. Add 20 ml. of water and pass through the column.

Pass 160 and 150 ml. of 0.4 N hydrochloric acid through the column to elute the sodium and potassium successively. Pass another 10 ml. of 8 N sulfuric acid for the detection of titanium by the hydrogen peroxide-sulfuric acid method. When no titanium is present, add the fraction to the effluent containing potassium and determine the sodium and potassium by flame photometry.

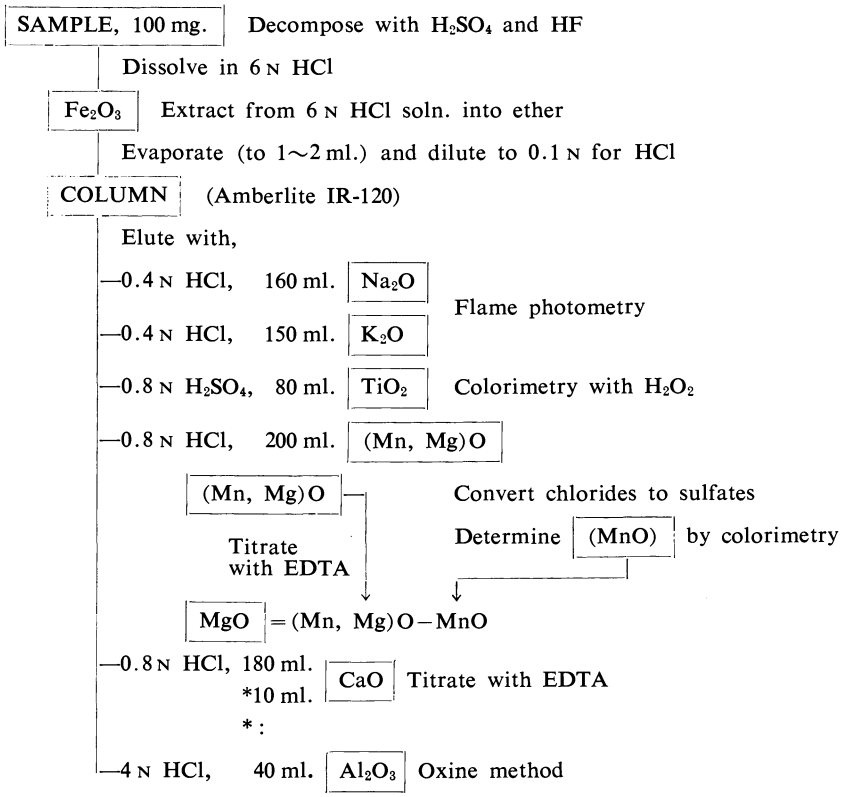

Fig. 1. The scheme of the analytical procedure.

* Detect Al with alizaline-S.

Table I. Ionic radius of rock forming elements

Element	Na	K	Ti(IV)	Mg	Fe(II)	Mn(II)	Ca	Fe(III)	Al
Ionic radius, Å[4].	0.98	1.33	0.68	0.78	0.83	0.91	1.06	0.67	0.57

Liberate the titanium with 70 ml. of 0.8 N sulfuric acid. Add 10 ml. of 1 : 1 sulfuric acid and 5 ml. of 3% hydrogen peroxide to the effluent and dilute the solution to 100 ml. in a volumetric flask. Determine the titanium by measuring the transmittancy of the solution at 420~430 mμ.

Pass 200 ml. of 0.8 N hydrochloric acid to elute the magnesium and manganese. Divide this effluent into two parts, and with the one part titrate the mixture of magnesium and manganese by the EDTA method. To the other part of the effluent, adding a few drops of dilute sulfuric acid to convert the chlorides into sulfates, evaporate it nearly to dryness. Determine the manganese colorimetrically by the permanganate method.

Elute the calcium by the 0.8 N hydrochloric acid. Test the absence of calcium in the first 40 ml. fraction. To make sure, pass fractionally 80, 40 and 20 ml. of 0.8 N hydrochloric acid. Determine the calcium for each fraction by the EDTA (Mg-EDTA) method. Ditect the aluminum with alizaline-S in each following 10 ml. fraction. When no aluminum is present, titrate the calcium.

Elute the aluminum with 40 ml. of 4 N hydrochloric acid. Evaporate the effluent nearly to dryness, and add 30 ml. of water. Warm at 70°C and add an excess of 8-hydroxyquinoline, and determine the aluminum by gravimetry.

Determination of Silica and Phosphorus.—Determine the silica by the ordinary gravimetric method by sodium carbonate fusion.

To determine phosphorus, take out one portion of the filtrate. The solution will conveniently contain less than 10 p. p. m. of phosphorus. Dilute with water, and pass through the column. Pass 50 ml. of 0.1 N hydrochloric acid to liberate the phosphorus completely. Evaporate the effluent nearly to dryness, and determine the phosphorus colorimetrically by the heteropoly-blue-method.

Discussion

Until recently, for the total analysis of a silicate rock, a long column or a set of columns consisting of two or more of them has been required. Aiming at simplicity and rapidity, the present authors adopted a short column (18 cm. long and 1 cm. in diameter) and constant-boiling hydrochloric acid as 6 N acid.

Titanium which is eluted with 0.8 N sulfuric acid as in Fig. 2 could also be eluted with 0.8 N hydrochloric acid. In this case, 0.8 N sulfuric acid is preferable for the colorimetric determination of titanium with hydrogen peroxide.

Following Sweet et al., a long column was used for the separation of the sodium and potassium with 0.7 N hydrochloric acid[3]. The present authors obtained good results with 0.4 N hydrochloric acid as shown in Fig. 2 with

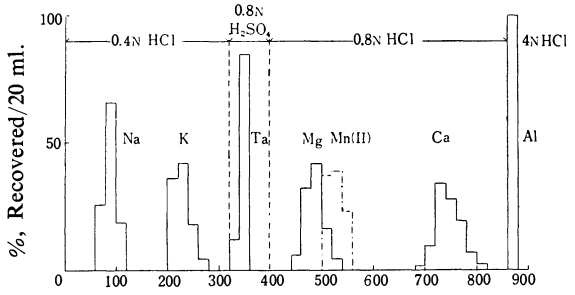

Fig. 2. Chromatographic separation of rock forming elements.

such a short column. Hydrochloric acid over 0.6 N causes the cross contamination of sodium (not shown).

Except for titanium, the order of elution is proved to be the order of increase in valence, and at constant valence, the order of increase in ionic radious (Table I).

Magnesium(II) and iron(II) and manganese-(II) are eluted with 0.8 N hydrochloric acid in almost the same position, as is shown in Fig. 2. The ionic radii of these ions are 0.78 for magnesium(II), 0.83 for manganese(II), and 0.91 Å for iron(II) respectively[4]. The similar size of the ionic radii of these ions inevitably causes the cross contamination of them with

such a short column. This disadvantage was overcome by the extraction of iron with ether before the chromatographic separation and by the respective determination of magnesium and manganese, as is shown in Fig. 1.

Aluminum and iron(III) are also eluted at the same time with 0.8 N hydrochloric acid (Fig. 3). This problem, however can be overcome by the extraction of the iron beforehand.

Titanium(IV) is hydrolyzed in dilute mineral acids to the titanyl ion. Accordingly, titanium should be ranked among the divalent ions.

Applicaton of this procedure was justified with the standard solution containing similar amounts of sodium, potassium, calcium, magnesium, manganese, iron, titanium and aluminum in 100~150 mg. of the ordinary igneous rocks (Table II). The practical applications of this method gave satisfactory results, which are summarized in Table III. A complete analysis of an ordinary rock sample can be carried out in only 3 days.

Summary

An accurate and rapid systematic analysis of ordinary silicate rocks was studied with a column of an ion exchange resin (Amberlite IR-120). A powdered rock sample was decomposed by the usual method of Berzelius. Iron was extracted from 6 N hydrochloric acid solution into ether before chromatographic separation Metal ions absorbed on the column are eluted as follows: With 0.4 N HCl Na and K, with 0.8 N H_2SO_4 Ti(IV), with 0.8 N HCl Mg, Mn(II), and Ca, and with 4 N HCl Al are eluted successively. A complete analysis of an ordinary rock sample can be carried out in only 3 days by this method.

The authors wish to express their gratitude to Dr. Shôhei Tamura of the Institute for Solid State Physics, the University of Tokyo, for his helpful suggestions. Thanks are also due to Mr. Yutaro Sakakibara of Tokyo University of Education and Assistant Professor Kazue Horikoshi of Ehime University, for their great help. A part of the expense of the study was defrayed by a grant-in-aid for science research of the Ministry of Education.

Infrared Spectra of Succinimide and Maleimide in the Crystalline State

By Toyozo UNO and Katsunosuke MACHIDA

(Received July 18, 1961)

Although the infrared spectra of succinimide[1-4] and maleimide[5,6] have been discussed in many papers, no investigation concerning the spectral change on deuteration has been made for these compounds. In a series of studies on the infrared spectra of acyclic imides[7-10], we have given assignments to the characteristic frequencies of the trans-trans -CONHCO- group. In contrast with the case of acyclic imides, the -CONHCO- group in cyclic imides is expected to be nearly in the cis-cis configuration. Under these circumstances, the present paper deals with succinimide and maleimide with a view of discussing the characteristic frequencies of the cis-cis -CONH·CO- group. The infrared spectra of both the undeuterated and the *N*-deuterated species of these compounds in the crystalline state have been measured in the region 4000 to 400 cm^{-1}, and several bands have been found to result from the vibrations of the -CONHCO- group. The spectral change on the addition of potassium iodide has also been examined for succinimide and succinimide-*d*.

Results and Discussion

Molecular Structure and Infrared Spectra.— By X-ray diffraction study, the molecular structure of succinimide in the crystalline state has been established to be planar except for the positions of the hydrogen atoms[11]. Furthermore, the sum of the three interbond angles around the nitrogen atom has been calculated to be 358°. Thus, in the following discussions, the cis-cis configuration of the -CONHCO- group will be adopted as a good approximation for succinimide. Although the molecular structure of maleimide has not been determined crystallographically, it may be reasonable to assume that the -CONHCO- group of this molecule in the crystalline state is also nearly in the cis-cis configuration.

Thus, the most symmetric arrangement of atoms in the molecule affords the point group C_{2v}, although the actual molecules may be of a somewhat lower symmetry. In fact, according to Mason[11] and Mirone[5], the crystals of succinimide and of maleimide consist of cyclic dimers, each of which involves two equivalent hydrogen bonds, so a molecule contains botb

bonded and free C=O bonds. This means both that the two C=O bonds in the –CONHCO– group are not equivalent to each other in the crystalline state and that the molecular symmetry of these compounds deviates appreciably from C_{2v}. This deviation from C_{2v} may or may not affect the feature of an absorption band according to the nature of vibration related to the band under consideration. The infrared spectra of succinimide and succinimide-*d* are shown in Fig. 1, while those of maleimide and maleimide-*d* are shown in Fig. 2. Table I shows the characteristic frequencies of succinimide and succinimide-*d*, together with their assignments. Similarly, Table II is concerned with maleimide and maleimide-*d*. The non-characteristic frequencies of these compounds are listed in Tables IV and V. In the region below 1100 cm^{-1}, the infrared spectrum of maleimide in the crystalline state measured in

the present study is somewhat different from that reported by Chiorboli and Mirone[5]. Thus, their interpretation of the absorption bands below 1100 cm^{-1} is not consistent with the results discussed below.

The In-plane Characteristic Frequencies Below 2000 cm^{-1}. — For both succinimide[1,2] and maleimide[5], the strongest band near 1700 cm^{-1} and the medium band near 1770 cm^{-1} have been assigned to the bonded and the free C=O stretching vibration respectively. Although there remains a question regarding how far the vibrational coupling contributes to the separation (ca. 70 cm^{-1}) between the two C=O stretching frequencies, no attempt will be made to discuss this problem further. The following discussion will be focussed on the absorption frequencies sensitive to the azimutal angles around the C–N bonds of the –CONHCO– group. In this respect, it is interesting to compare the infrared spectra of these cyclic imides with those of the acyclic imides reported in preceding papers[7,8]. A similarity in the characteristic bands between the trans-trans –CONHCO– and the trans –CONH– group has already been pointed out[8]. Thus, the spectral changes on deuteration for the cis-cis –CONH–CO– group may be expected to be analogous with those for the cis –CONH– group. The normal coordinate analysis for the cis *N*-methylacetamide[12] has shown that the coupling between the N–H in-plane deformation and the C–N stretching vibration is less significant for the cis –CONH– group than for the trans –CONH– group. This difference in the coupling results in the characteristic frequencies of the cis –CONH– group being markedly different from those of the trans –CONH– group. The most important difference is that the former does not show the amide II band which has been well established for the latter in the region near 1550 cm^{-1}. That a similar situation holds also for the –CONHCO– group is confirmed by the fact that neither succinimide nor maleimide shows any band in the region 1600 to 1450 cm^{-1}, whereas the trans-trans and the trans-cis –CONHCO– group show the strong imide II band which disappears on deuteration[7,8]. Instead, succinimide and maleimide show a band in the region 1380 to 1340 cm^{-1} which undergoes a low-frequency shift by 8~16 cm^{-1} on deuteration. A similar spectral change on deuteration has been reported for monosubstituted amides containing the cis –CONH– group[12]. As a consequence of these spectral features, the cis-cis –CONHCO– group is expected to show two fundamentals due to the C–N–C stretching vibrations in the region 1500 to 1000 cm^{-1}. Since it is quite probable that a marked coupling occurs among the stretching vibrations of adjacent bonds with similar bond orders, one of these vibrations may be more symmetric or less antisymmetric in nature than the other vibration. Analogy with the cis –CONH– group suggests that the band in the region 1380 to 1340 cm^{-1} observed for both the undeuterated and the *N*-deuterated species of succinimide and maleimide results essentially from the symmetric C–N–C stretching vibration. On the other hand, the antisymmetric C–N–C stretching vibration of the undeuterated species seems to be involved in an appreciable coupling with the N–H in-plane deformation vibration. This is suggested from the fact that two absorptions, which disappear on deuteration, are observed in the region 1450 to 1100 cm^{-1} for both of these cyclic imides. With respect to succinimide, these are the medium but well-resolved band at 1418 cm^{-1} and the strong and broad band near 1200 cm^{-1}. The high- and low-frequency counterparts of maleimide are observed at 1375 cm^{-1} as a shoulder of the broad symmetric C–N–C stretching band and near 1150 cm^{-1} as a strong doublet (1154 and 1141 cm^{-1}), respectively. These bands are considered to result from coupling between the N–H in-plane deformation and the antisymmetric C–N–C stretching vibration. Although the high-frequency bands are not so strong, the assignment to an in-plane vibration within the –CONHCO– group is confirmed, as will be discussed later, by an examination of the combination tone near the N–H stretching frequency. It is expected that the *N*-deuterated species will show a band contributed mainly from the antisymmetric C–N–C stretching vibration which is involved in the coupling for the undeuterated species. The bands at 1277 and 1205 cm^{-1} observed for succinimide-*d* and maleimide-*d* respectively are assigned to this vibration, so the product rule holds well. The other bands appearing on deuteration in this region may be considered not to be fundamentals.

The N–D in-plane deformation vibration has been reported to couple with other vibrations for the cis –CONH– group[12]. This situation seems to hold also for cyclic imides. The strong band at 1102 cm^{-1} for succinimide-*d* and the weak band at 1086 cm^{-1} for maleimide-*d* are undoubtedly contributed from the N–D in-plane deformation vibration. These frequencies, however, in comparison with the N–D in-plane deformation (imide III′) frequencies of the trans-trans –CONDCO– group (ca. 960 cm^{-1}), seem to be so high that they can only with difficulty be assigned to the pure N–D

12) T. Miyazawa, *J. Mol. Spectroscopy*, 4, 155 (1960).

in-plane deformation vibration. Thus, an appreciable coupling with other vibrations is expected to be the case with these frequencies. This is confirmed by the fact that the band near 936 cm^{-1} (medium for succinimide and strong for maleimide) of the undeuterated species disappears on deuteration. The alternative frequencies which satisfy the product rule can be found at 820 and 832 cm^{-1} for succinimide-*d* and maleimide-*d* respectively. These bands may also be contributed from the N–D in-plane deformation vibration. The marked difference in intensity in the corresponding bands between succinimide-*d* and maleimide-*d* may be due to the structural difference in the hydrocarbon residues of these two compounds.

The band near 640 cm^{-1} observed for both succinimide and maleimide remains unchanged on deuteration. Comparison with the other related compounds leads to the assigment of this band to the C=O in-plane deformation (the imide IV) vibration. Thus, nearly complete assignments have been made for the characteristic in-plane vibrations of succinimide, maleimide and their *N*-deuterated compounds. It is seen that succinimide and maleimide show quite analogous frequencies as far as the characteristic vibrations are concerned.

The Out-of-plane Characteristic Frequencies.—The broad bands at 849 and 725 bm^{-1}, observed respectively for succinimide and maleimide, disappear on deuteration, suggesting that they are due mainly to the N–H out-of-plane deformation (imide V) vibration. As alternative N–D out-of-plane deformation (imide V′) frequencies, the band at 636 cm^{-1} of succinimide-*d* and the band at 536 cm^{-1} of maleimide-*d* are quite probable. The sharp medium band at 556 cm^{-1} observed for succinimide shifts to 548 cm^{-1} on deuteration. These bands may be due to the C=O out-of-plane deformation (imide VI and VI′) vibration. The corresponding band for maleimide may be that observed at 550 cm^{-1}. However, this band's shift on deuteration is not obvious owing to the overlapping of the broad imide V′ band at 536 cm^{-1}. The marked differences in the imide V and V′ frequencies between succinimide and maleimide suggest that there is an appreciable difference in the strength of the hydrogen bond between the crystals of these compounds. This is consistent with the information from the N–H and N–D stretching frequencies, which will be discussed later. It is to be noticed here that similar differences in the N–H and N–D out-of-plane deformation frequencies have been pointed out also for monosubstituted amides[13] and acyclic imides[10].

The Product Rule.—The theoretical product rule ratios for species A′ and A″ are calculated from the principal moments of inertia, which, in turn, may be calculated for succinimide from Mason's data on the molecular structure[11]. On the other hand, the theoretical ratio for the frequencies above 2000 cm^{-1} may be given by $(\mu_N+\mu_H)^{1/2}/(\mu_N+\mu_D)^{1/2}$, since in this case only the N–H and the N–D stretching frequencies are involved. This ratio, together with the above-obtained ratio for all A′ frequencies, leads to the evaluation of the theoretical ratio for the A′ frequencies of succinimide below 2000 cm^{-1}. Table III shows these three theoretical ratios, together with the experimental ratios obtained from the frequencies which undergo an appreciable shift on deuteration. The theoretical ratios for maleimide are expected to be not far from the corresponding ratios for succinimide. It is seen that the observed ratios agree well with the theoretical ones. This result gives support to the assignment of the characteristic frequencies proposed in the present paper.

TABLE III. THE PRODUCT RULE RATIOS
(Undeut. compd./*N*-Deut. compd.)

		Succinimide		Maleimide	
		Theor.	Obs.*	Theor.	Obs.*
A′	(ν_{N-H}/ν_{N-D})	1.37	1.38	1.37	1.35
A′	($<2000\ cm^{-1}$)	1.44	1.40	—	1.38
A″		1.38	1.35	—	1.38

* The frequencies used are as follows: succinimide (A′) 3190, 1418, 1378, 1198, 936, (A″) 849, 556; succinimide-*d* (A′) 2325, 1362, 1277, 1102, 820, (A″) 636, 548; maleimide (A′) 3221, 1375, 1350, 1148 (the mean value of 1154 and 1141), 938, 899, (A″) 725, 678; maleimide-*d* (A′) 2380, 1342, 1205, 1086, 888, 832, (A″) 665, 536.

The N–H and N–D Stretching Frequencies.—As seen from Figs. 1 and 2, the N–H and the N–D stretching bands show quite different features from each other for these two cyclic imides. Similar phenomena have been observed for several acyclic imides and interpreted in terms of the Fermi resonance[9]. As shown in Tables I and II, the features of the N–H and the N–D stretching bands of cyclic imides in the present study can also be well elucidated from analogous points of view. The broad doublet (3190 and 3080 cm^{-1}) of succinimide is considered to result from the Fermi resonance between the the N–H stretching vibration and the combination tone of the lower characteristic fundamentals (1700 and 1418 cm^{-1}). The sum of these fundamental frequencies

13) T. Miyazawa, T. Shimanouchi and S. Mizushima. *J. Chem. Phys.*, 24, 408 (1956).

($3118\,cm^{-1}$) exceeds the frequency of the lower peak ($3080\,cm^{-1}$) by about $40\,cm^{-1}$, suggesting that the resonance is considerable. This is consistent with the fact that the peaks at 3190 and $3080\,cm^{-1}$ show almost the same intensity. The difference between the unperturbed and the perturbed frequency is expected to be the same for the N–H stretching frequency as for the combination frequency involved in the Fermi resonance[14]. Thus, the unperturbed N–H stretching frequency of succinimide may be estimated to be near $3150\,cm^{-1}$, that is, $40\,cm^{-1}$ lower than the frequency of the higher peak ($3190\,cm^{-1}$). Nakamoto et al. have pointed out the linear dependence of the N–H stretching frequencies on the N···O distances in the N–H···O hydrogen bond[15]. In this connection, the present result is nearly consistent with the crystallographic data, according to which the N···O distance is 2.85 Å for succinimide[11].

On the other hand, the weakness of the band at $3070\,cm^{-1}$ of maleimide, as well as the small difference between the observed ($3070\,cm^{-1}$) and the combined ($1700+1375=3075\,cm^{-1}$) frequencies, indicates that the Fermi resonance is less significant for this molecule. This means that the unperturbed N–H stretching frequency of maleimide is not far from the observed frequency ($3221\,cm^{-1}$). From these results it is seen that there is an appreciable difference (ca. $70\,cm^{-1}$) in the unperturbed N–H stretching frequencies between succinimide and maleimide. Thus, it may be suggested that the hydrogen bond involved in succinimide is stronger than that involved in maleimide. This results is consistent with the information from the spectral differences between these compounds in the potassium bromide region.

The weak peaks associated with the N–D stretching band can be interpreted as overtone or combination bands related to the characteristic frequencies in the region 1400 to 1000 cm^{-1}. This means that these characteristic frequencies of the –CONHCO– group are distinguished from the non-characteristic frequencies not only by their sensitivity to deuteration but also by their tendency to give rise to overtone or combination bands.

Frequencies Due to the Hydrocarbon Residues. —It is observed that the ring strain raises the C–H strecthing frequencies of these compounds by 60 to $100\,cm^{-1}$ from the ordinary positions for the structures $-CH_2-$ and $=CH-$[16]. However, the effect of the ring strain on the C–H deformation frequencies of these compounds is not so obvious as that on the stretching frequencies. If the symmetry C_{2v} is assumed, succinimide is expected to show six C–H deformation frequencies, since in this case the A_2 CH_2 twisting and the A_2 CH_2 rocking vibration are infrared inactive. Furthermore, the B_1 CH_2 bending and the A_1 CH_2 wagging frequencies may not be observed owing to the small transition moments for the corresponding vibrations. In fact, succinimide shows four bands, at 1431, 1298, 1241 and $1002\,cm^{-1}$, which remain unshifted on deuteration. These bands are assigned to the C–H deformation vibrations, as shown in Table IV. Thus, in contrast with the case of the vibrations related to the –CONHCO– group, the deviation from C_{2v} seems to be negligible with respect to the C–H deformation vibrations. Similarly, the three C–H deformation frequencies of maleimide may be assigned as shown in Table V. It should be noticed here that the C–H out-of-plane deformation frequency undergoes an appreciable shift on deuteration. The bands left unassigned so far in the region 1000 to $800\,cm^{-1}$ may be due to the in-plane ring skeletal vibrations, to which the contribution of the stretching of the C–C bonds is significant.

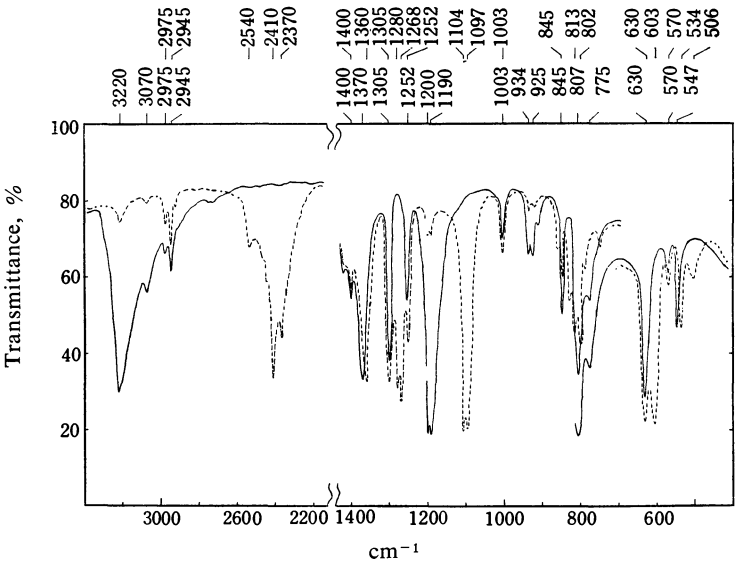

Fig. 3. Infrared spectra of succinimide (solid line) and succinimide-*d* (broken line) mixed with potassium iodide.

Interaction with Potassium Iodide.—Baker has reported that succinimide undergoes a marked spectral change on the change of matrix in the disk technique from potassium bromide to potassium iodide[4]. The anomalous infrared spectrum of succinimide measured with potassium iodide disks has been given for the region 1400 to 750 cm^{-1}. We have obtained an anomalous spectrum identical with that shown in Baker's paper by using a sample obtained by removing water from an aqueous solution of succinimide and potassium iodide. This procedure can be used to obtain the anomalous spectrum of the *N*-deuterated compounds corresponding to that of the undeuterated species. These anomalous spectra are shown in Fig. 3. From this spectral change due to potassium iodide, the several interesting results following concerning the characteristic frequencies have been obtained:

(1) The high-frequency shift of the N–H (N–D) stretching band and the low-frequency shift of the imide V (V′) band are observed on the spectral change due to potassium iodide. This suggests that the N–H hydrogen atom is involved in the interaction with the iodide anion, as in the case of diacetamide[10]. (2) The weak overtone or combination bands near the N–D stretching band also undergo a frequency shift according to the change in the lower characteristic fundamentals. (3) The overlapping of the imide IV and V′ bands at 634 cm^{-1} of the *N*-deuterated species is removed by the low-frequency shift of the latter band. Thus, it is explicitly observed that the former band remains unshifted on deuteration. (4) The band near 830 cm^{-1} observed for the *N*-deuterated species splits according to the splitting of the band at 936 cm^{-1} of the undeuterated species. This may be taken as indicating that the band at 936 cm^{-1} of the undeuterated species actually shifts to 820 cm^{-1} on deuteration. This frequency shift is not obvious in the ordinary spectra owing to the presence of the band at 820 cm^{-1} for both the undeuterated and the *N*-deuterated species. (5) The band at 1198 cm^{-1} of the undeuterated species and the band at 1102 cm^{-1} of the *N*-deuterated species split in a similar way, suggesting that these bands are contributed from vibrations of a similar nature. These results are consistent with the interpretation of the absorption bands given in the present paper, thus giving supports to the assignments made in Tables I, II, IV and V.

Experimental

Materials and Measurement.—G. P. grade succinimide was recrystallized from ethylmethylketone, m. p. 125°C. Maleimide was prepared from dimethyl maleate through maleindiamide, according to Rinkes' method[17], and purified by sublimation under reduced pressure, m. p. 93°C. No spectral change was observed for either of these compounds on crystallization from water. Thus, succinimide-*d* and maleimide-*d* were prepared by the usual exchange reaction with deuterium oxide. A Koken DS-301 infrared spectrophotometer equipped with rock salt or potassium bromide prisms was used. The measurements were carried out on pastes in

17) I. J. Rinkes, *Rec. trav. chim.*, **46**, 272 (1927); **48**, 961 (1929).

Nujol or hexachlorobutadiene under the same conditions as those reported previously[7].

Interaction with Potassium Iodide.—A small amount of an aqueous solution of succinimide and potassium iodide was evaporated to dryness under reduced pressure (ca. 5 mmHg) at 80~90°C. The samples thus obtained were measured immediately as pastes. The anomalous spectrum for the *N*-deuterated species was obtained by the same procedure, using deuterium oxide instead of water.

The authors wish to express their thanks to Dr. Tatsuo Miyazawa of Osaka University and to Dr. Kiyoshi Nakamura of the Research Laboratory, Dainippon & Co., Ltd., for their kind advice throughout this work.

Carboxyl Group as a Proton Donor in the Interaction between Hydroxyl Group and π-Electrons[1]

By Michinori Ōki and Hiizu Iwamura

(Received June 19, 1961)

Since carboxylic acids form stable dimers due to the strong hydrogen bonding and are generally considered to be stronger proton donors than alcohols and phenols, it is natural to expect that the carboxyl group will also be a proton donor in the interaction with the π-electrons. As to the intramolecular interaction, no example seems to be available in this class, but the report by Suzuki et al.[2] which reveals that *N*-methylphenylacetamide possesses this kind of interaction may be taken as an analogous phenomenon.

In this respect, the authors measured the O–H stretching absorptions (ν_{O-H}) of carboxylic acids which might exhibit the intramolecular interaction due to proximity of the carboxyl group to the aromatic nucleus. The carbonyl stretching absorptions ($\nu_{C=O}$) of the carboxylic acids were also measured, since it was found in this laboratory that the $\nu_{C=O}$ of the free carbonyl group in the " trans " carboxyl group[3] appears at as high as 1790 cm^{-1} [4].

Experimental

The materials used in this work were all known compounds and prepared or purified according to the literature. The physical constants were checked prior to the measurement.

The spectral measurements were carried out with a Perkin Elmer 112G grating infrared spectrometer, the samples being dissolved in carbon tetrachloride unless otherwise specified. The concentration of the solution was made up ca. 0.5 mmol./l. as a compromise between the convenient absorption and the minimum effect of the dimer. A quartz cell of 5 cm. optical length and a sodium chloride cell of 2.45 cm. length were used for the ν_{O-H} region, and the latter and another sodium chloride cell of 0.10 cm. length for the $\nu_{C=O}$ region.

Results and Discussion

The results of the measurements with a series of compounds are listed in Table I.

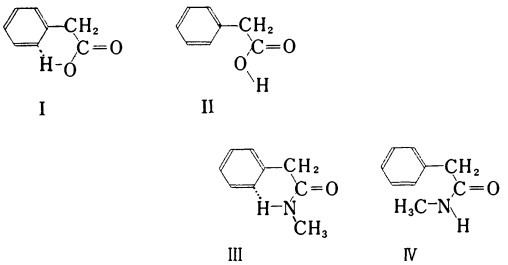

TABLE I. THE ν_{O-H} AND $\nu_{C=O}$ DATA OF SOME CARBOXYLIC ACIDS

Carboxylic acid	ν_{O-H} cm^{-1}	ε^{a}	$\nu_{C=O}$ cm^{-1}
$PhCH_2CO_2H$	3531.5	61.7	1762.7
Ph_2CHCO_2H	3526.7	68.3	1757.5
Ph_3CCO_2H	3520.9	79.4	1752.2

3) The nomenclature, " cis " and " trans " of a carboxyl group, is according to C. P. Smyth, " Dielectric Behavior and Structure ", McGraw-Hill Book Co., Inc., New York (1955), p. 306.

4) M. Ōki and M. Hirota, This Bulletin, **34**, 374 (1961).

In the first place, phenylacetic acid has been considered to be a carboxylic acid which should possess the intramolecular interaction from the structural analogy between the acid I and the methylamide III[2]. Contrary to the expectation, no intramolecular interaction between the carboxyl group and π-electrons is observed. Phenylacetic acid shows single ν_{O-H} and single $\nu_{C=O}$ at the ordinary regions assigned to the monomeric carboxylic acids.

It has been shown that the statistical factors obtained by considering the rotational isomerism about the single bonds play an important role in the intramolecular interaction. For example tribenzylcarbinol has no free hydroxyl group[5], whereas benzyldimethylcarbinol includes ca. 57% free form, provided that the absorption intensities per molecule due to O–H stretching are the same in both free and interacting forms. Triphenylacetic acid must favor the intramolecular interaction as far as the statistical factor is concerned. The results indicate, however, even diphenyl- and triphenylacetic acids possess a single peak for the ν_{O-H} and the $\nu_{C=O}$, respectively. The absorption maxima are in good agreement with those assigned to the monomeric "cis" forms.

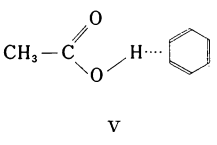
Hydrocinnamic acid and *o*-carboxybiphenyl show free carboxyl group only, indicating that the absence of the interaction in phenylacetic acid is not due to the unfavorable ring member. Otherwise, sterically advantageous *o*-carboxybiphenyl should possess the interaction. The doublet $\nu_{C=O}$ of *o*-carboxybiphenyl can not be ascribed to the interaction, but is common for the *o*-substituted benzoic acids[6].

The carboxyl group is known to assume "cis" and "trans" structures[3], examples of which are illustrated by I and II, respectively. Establishment of the intramolecular interaction requires the "trans" form of the carboxyl group and this requirement may be the reason why phenylacetic acid does not show the interaction. Namely no matter what configuration is taken, the "cis" structure is disadvantageous.

The "cis" configuration is known to be more stable than the "trans" by several kcal./mol.[7] On the other hand, it is found in this laboratory that a lone pair electrons of a rather highly basic atom is needed to convert the "cis" structure into the "trans"[4], the phenomenon being suggestive of the comparable energies in O–H···O hydrogen bond and in the "cis" structure. π-Electron system, acting as a proton acceptor, is a weak base and can not compensate the required stabilization energy as is suggested by the energy measurement of the O–H···π interactions[8]. The energy of the intramolecular interaction between hydroxyl group and π-electrons has never been higher than 2.5 kcal./mol.[9] and is too low to compete with the stabilization energy of the "cis" structure. In this manner, it is also possible to account for the presence of the intramolecular interaction in *N*-methylphenylacetamide, since the "trans" structure III is more stable than the "cis" IV in the secondary amides[10].

Recently, Nagai and Simamura[11] reported that acetic acid and its halogenated derivatives in carbon tetrachloride show a second ν_{O-H} on addition of benzene and attributed the phenomenon to the intermolecular association between the carboxyl group and the π-electrons of the benzene nucleus. Since the entropy requirement is rather severe in the intermolecular hydrogen bonding[12], it seems unreasonable from this standpoint that the interaction which has not been observed intramolecularly is taking place intermolecularly. The acetic acid-benzene system has therefore been reinvestigated and the results are summarized in Table II together with those of the other aromatic solvents.

TABLE II. ν_{O-H} AND $\nu_{C=O}$ OF THE MONOMERIC ACETIC ACID IN SEVERAL SOLVENTS



Solvent	ν_{O-H}, cm^{-1}	$\nu_{C=O}$, cm^{-1}
Carbon tetrachloride	3538.2	1769.3
Bromobenzene	3484.8	—
Benzene	3463.1	1763.2
Toluene	3458.8	1762.3
p-Xylene	3447.5	—
Mesitylene	3433.4	—

On dissolution of benzene, monomeric ν_{O-H} of acetic acid in carbon tetrachloride diminishes in its intensity and instead a second ν_{O-H} at ca. 3465 cm^{-1} arises. The intensity of the latter band grows as the concentration of benzene increases and the former disappears when the spectrum was measured in benzene. It can be seen from Table II that ν_{O-H} depends upon the basicity of the benzenoid π-electrons. Thus when the π-electron density in the benzene ring of the solvent molecule is decreased

by halogen substitution, ν_{O-H} of acetic acid appears at higher frequency than in benzene, indicating the weakening of the interaction. On the other hand, when the π-electron density in the benzene ring is raised by substituting with the alkyl group, ν_{O-H} shifts to the lower frequency corresponding to the stronger interaction. The phenomenon is in parallel with those of ν_{N-H} of *N*-methylacetamide[13] and ν_{O-H} of phenol[14] in aromatic solvents, and adds strong support to the notion of the intermolecular interaction between the carboxyl group and π-electrons.

In spite of a rather large shift in ν_{O-H}, $\nu_{C=O}$ shifts little. The wave number (1763 cm^{-1}) is the place where the ordinary monomeric $\nu_{C=O}$ of "cis" configuration appears and too low to be assigned to the "trans" configuration which has the $\nu_{C=O}$ at around 1790 cm^{-1}[14]. Therefore it is tentatively concluded that in the intermolecular interaction between carboxyl group and π-electrons the "cis" configuration is maintained (V and not VI).

Physicochemical Studies of Stearic Acid Monolayer-Aluminum Ion Interaction. I. The Surface Pressure

By Kinsi MOTOMURA and Ryohei MATUURA

(Received May 22, 1961)

There exist a number of reports on the interaction of the monolayers of fatty acid with aluminum ion[1-12], but no work has succeeded in establishing a complete picture of the structure and constitution of the monolayers resulting from the interaction. Schulman et al.[5-7], studying the effect of the presence of aluminum ion in underlying solutions on monolayers, suggested that the solidification of monolayers could be brought about by hydrogen bonding between the monolayer soaps produced through the dissociated monolayers-basic aluminum ion interaction. Spink and Sanders[8] could not arrive at any conclusion as to the interaction of the stearic acid monolayer with aluminum ion, reporting that the interaction was obviously complicated and further work was required. It was shown by Ekwall and Bruun[9-12] that the final product of the interaction was dibasic aluminum soaps. On the other hand, Sasaki and Matuura[2,3] ascribed the rigid expanded monolayer resulting from the interaction to a complicated polymeric structure in which the backbone of -Al-O- would lie flat on the surface. We think it reasonable that the interaction should be considered from the standpoint of the adoption of aluminum ion on the monolayer as well as

of the formation of aluminum soaps in the monolayers.

In the following series of investigations, our object is to determine, with the aid of surface pressure and viscoelasticity measurements, the structure and constitution of the stearic acid monolayers which have interacted with aluminum ion in the underlying solution. For this purpose the monolayers of aluminum distearate on water and aluminum salt solutions have also been investigated. It is also attempted in this paper to report the results of the surface pressure measurement and to find how they can be accounted for.

Experimental

The monolayers of stearic acid and aluminum distearate were prepared from benzene solutions on substrate solutions, and their surface pressures were measured by the modified Wilhelmy type surface balance described elsewhere[13]. The stearic acid was purified by repeated recrystallization from ethanol. The aluminum distearate was prepared by the addition of an excess of aluminum chloride solution to a solution of potassium soap. This was washed with water until the filtrate was free from chloride, thoroughly extracted free or loosely bound stearic acid with dried acetone and dried over phosphorus pentoxide for a few days. It was found by analyzing the aluminum content that the aluminum distearate thus obtained was almost in accord with the theoretical composition.

Redistilled water was used for preparing the substrate solution. The concentration of aluminum chloride was kept at 10^{-4} mol./l. The pH was adjusted with hydrochloric acid or sodium hydroxide over a wide range. The use of buffer salts was avoided so that they might not lead to an anomalous result due to their interaction with the monolayers. As the pH value of the solution, a mean value before and after the experiment was taken, but the deviation did not exceed 0.1 pH unit.

In order to maintain the experimental temperature constant, a constant temperature box was used. All the experiments were carried out in this box, kept at 25 ± 0.5°C.

The monolayers were left to stand for thirty minutes after spreading, and then their compression was started. The monolayers of stearic acid and aluminum distearate on aluminum chloride solutions were almost stable over the whole range of areas studied. On the contrary, the surface pressure of the aluminum distearate monolayer on distilled water varied distinguishably with time. As the surface pressure of this monolayer, therefore, we, for convenience's sake, read the value which the monolayer exhibited when left to stand for one minute.

Results

Stearic Acid Monolayer on Aluminum Chloride Solution.—The variation of surface pressure of the stearic acid monolayer on aluminum chloride solutions with the area occupied by a stearic acid molecule was measured over a range of pH values of the solution. Typical surface pressure-area curves are shown in Fig. 1, in which the numerals represent the pH

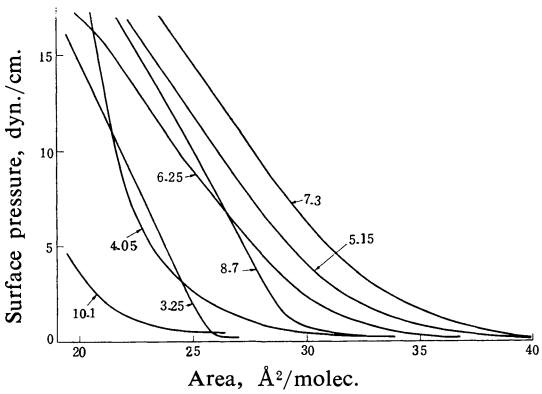

Fig. 1. Effect of pH on the pressure-area curves of stearic acid monolayer spread on 10^{-4} mol./l. aluminum chloride solution at 25°C.

values. It was found that the folds of the film were visibly detected at smaller areas than the inflection point of the pressure-area curves. It is obvious from this figure that the influence of aluminum ion is extremely characteristic for the pH, which suggests that it depends on the state of aluminum ion in the solution. This may be more clearly elucidated by plotting a limiting area, which we define as the area at which an appreciable rise in surface pressure occurs when the monolayer is compressed, against the pH of the solution. This relation is given by the curve 1 in Fig. 4. It is seen that the curve has two maxima and one minimum. In the previous work[2] only one maximum was found; another maximum and a minimum were overlooked since the intervals of pH were so coarse there. The shape of the curve characterizing the interaction between the stearic acid monolayer and aluminum ion is very similar to that already shown by Spink and Sanders[8], although in the magnitude of limiting areas there is a great difference, which might arise from the use of different aluminum salts or from other artificial causes. There is, however, no obtaining of further information on the reaction in the monolayer with only this finding. To gain a deeper insight into the problem, we investigated the monolayer of aluminum distearate which had been known to have a polymeric structure in the hydrocarbon solution as well as in the solid state.

Aluminum Distearate Monolayer on Distilled

13) R. Matuura and I. Hayasi, *Memoirs Fac. Sci., Kyushu Univ., Ser. C*, **1**, 31 (1948).

Water.—The monolayer of aluminum distearate on distilled water at various pH values was unstable, as has been previously stated, but it was revealed by the talc method that the monolayer was solid expanded at pH values between about 4.5 and 9.0. Figure 2 illustrates

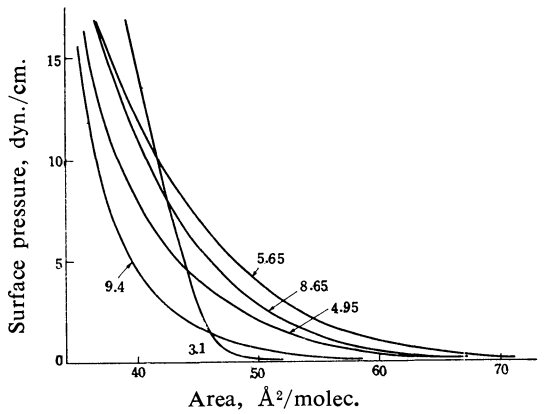

Fig. 2. Effect of pH on the pressure-area curves of aluminum distearate monolayer on distilled water at 25°C.

some pressure-area curves of the monolayer. These curves are less expanded than that of stearic acid on aluminum chloride solution when the area per chain of aluminum distearate is compared with that occupied by a stearic acid. In the same way as in the case of the stearic acid monolayer, the limiting area-pH curve is depicted in the Fig. 4 curve 2. This curve resembles curve 1 in shape; this might be considered to suggest that the reaction of the stearic acid monolayer with aluminum ion in the underlying solution forms aluminum distearate in the monolayer. However, there are considerable differences in the value of the

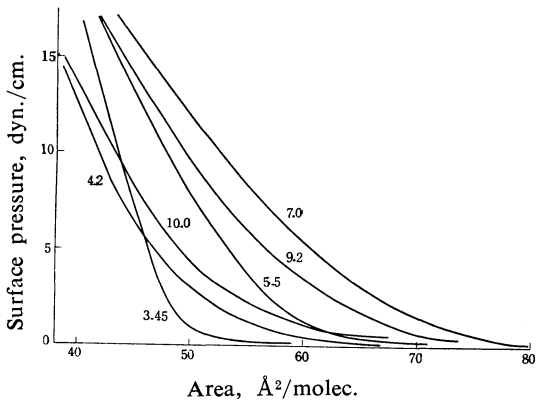

Fig. 3. Effect of pH on the pressure-area curves of aluminum distearate monolayer on 10^{-4} mol./l. aluminum chloride solution at 25°C.

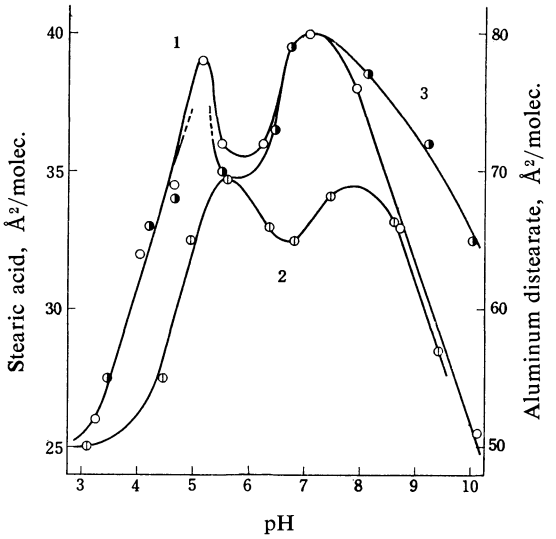

Fig. 4. Comparison among limiting area-pH curves of the monolayers of stearic acid and aluminum distearate on underlying solutions at 25°C: (1) Stearic acid on aluminum ion (○); (2) Aluminum distearate on water (◐); (3) Aluminum distearate on aluminum ion (◑).

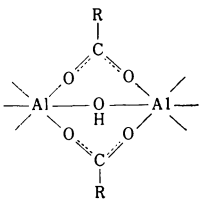
areas between the two curves. In order to interpret this difference, it seems necessary to study the interaction of the aluminum distearate monolayer with the aluminum ion in the solution.



Aluminum Distearate Monolayer on Aluminum Chloride Solution.—The results obtained for the influence of aluminum ion at various pH values on the pressure-area curve of the aluminum distearate monolayer are shown in Fig. 3. The behavior of these pressure-area curves is typically solid-expanded and is extremely similar, not to that of the aluminum distearate monolayer on water, but to that of the stearic acid monolayer on aluminum ion. The limiting area-pH curve produced from Fig. 3 is curve 3 in Fig. 4. This curve is partially a little different from curve 1, but there seems to be essentially no difference between them.

Discussion

The interaction of the monolayers of fatty acids with various metal ions has been discussed from the standpoint of the formation of metallic soaps in the monolayers ever since Langmuir and Schaefer[1], and many investigators have tried to shed light on the compositions of the interacted monolayers from only the results of chemical analysis carried out on

the matter collected after the monolayers were compressed to collapse. Through the investigation of tanning by chromium ion of various monolayers, e. g., the myristic acid monolayer, practicing at the same time the chemical analysis of them, Schulman and Dogan[14] thought it likely that the structure of solid monolayers can be brought about by the interlinking between chromium monosoap molecules by hydrogen bonding between two hydroxyl groups attached to the chromium ion or between hydroxyl and carbonyl in the carboxyl group. A similar investigation was made by Ekwall and Bruun[11,12] of the interaction of the myristic acid monolayer with aluminum ion; they concluded that the final product of the interaction seemed to be a dibasic aluminum monomyristate with regard to the composition of the interacted monolayer. The matter used by these authors for the analysis was, however, that which had been removed with a scoop at the very small area where the monolayers might be collapsed and, moreover, perhaps included physically adsorbed metal ions. Therefore, it seems doubtful whether the monolayer compositions thus estimated will express the true ones even if the physically adsorbed metal ions are taken into account experimentally. It is a well-known fact that the reaction of alkali salts of a fatty acid such as stearic acid with aluminum ion in an aqueous medium always results in aluminum disoap. It is conceivable, therefore, that when the stearic acid monolayer is spread on the solution containing aluminum ion at certain pH values, the former will combine with the latter to form aluminum distearate in the monolayer.

With aluminum disoap investigated by many workers from various viewpoints, it has been made clear that the structure of aluminum disoap is polymeric in its hydrocarbon solutions as well as in the solid state. Bauer et al.[15,16] elucidated by means of the technique of the infrared absorption spectra that the polymeric structure of aluminum disoaps is constituted not through hydrogen bonding between hydroxyl groups but through a coordinate bond between aluminum and oxygen in the hydroxyl group. Taking account of experimental results of various kinds, a reliable polymeric structure of aluminum disoap may be that of Leger et al.[17], similar to that of Bauer et al., i. e.,

in which R represents the hydrocarbon part. When aluminum distearate is spread on the substrate from the benzene solution, it is natural that the aluminum distearate will, in the monolayer state, hold the polymeric structure, the backbone chain of which will attach to or be immersed in the underlying solution. It was found that the pressure-area curve of a aluminum distearate monolayer spread on a sodium fluoride solution became less expanded with an increasing sodium fluoride concentration and finally coincided with that of stearic acid on water (i. e., it contained no aluminum ion) at about 10^{-3} mol./l. sodium fluoride solution. This is considered to show that the coordinate bond was cut by the fluorine ion which preferentially coordinates on aluminum ion[18]. Further discussions from the rheological aspect of the aluminum distearate monolayer will appear in part II of this series.

If the two-dimensional polymeric structure of aluminum distearate monolayer on distilled water is valid, its unstable behavior on compression can be ascribed to the fact that the rearrangement of aluminum distearate into the true equilibrium state takes a long time. Therefore, the pressure-area curves in Fig. 2 and the limiting area-pH curve illustrated by curve 2 in Fig. 4 may not be referable to those of the equilibrium, but some properties characteristic of the aluminum distearate monolayer would be disclosed in these curves. In this stage it is not easy to say what monolayer structures are corresponding to these pressure-area curves at respective pH values. However, the depression of the limiting area of the monolayer at the acidic side may be explained by its decomposition into stearic acid and aluminum ion, and at the alkaline side by its dissolution into water as sodium stearate.

Comparing the findings concerning the stearic acid monolayer on aluminum ion with those concerning the aluminum distearate monolayer on distilled water, we find a not negligible difference, even though they resemble each other in shape, as is clearly shown in Fig. 4. If only aluminum distearate was formed in the monolayer of stearic acid on aluminum ion and no other effects were exerted, the film 1 should agree with the film 2. In fact, the film

1 is very much analogous to film 3 in various properties. This suggests that the interacted stearic acid monolayer may be that in which aluminum ion is adsorbed on the aluminum distearate monolayer. In the limiting area-pH curves, however, there seems to be a little partial disagreement between curves 1 and 3 in Fig. 4. Perhaps this disagreement may be not essential. It is accordingly conceivable that these two curves would fall into agreement with each other if all the measurements of surface pressure were carried out on the monolayers which attained to a state of complete equilibrium after very long times.

In view of the above discussion, it may be concluded that the interaction of the stearic acid monolayer with aluminum ion in the underlying solution occurs only over a characteristic pH range, below which the acid monolayer does not dissociate enough to interact appreciably and above which the monolayer tends to dissolve in the underlying solution; the solid expanded film brought about through the interaction is quite similar to the polymeric aluminum distearate monolayer adsorbing aluminum ion.

In part II of this series we present a further discussion on the interaction by making use of the results of surface rheological measurements.

Summary

In order to throw light on the interaction of the stearic acid monolayer with aluminum ion in underlying solutions, surface pressure measurements were carried out on (1) the stearic acid monolayer spread on 10^{-4} mol./l. aluminum chloride solution, (2) the aluminum distearate monolayer spread on distilled water, and (3) the aluminum distearate monolayer spread on 10^{-4} mol./l. aluminum chloride. It was found that their pressure-area curves were all solid expanded films over characteristic pH ranges, with the curve of 1 especially analogous to that of 3. In the limiting area-pH curves, there seemed to be a little partial disagreement between them which would not be essential. From these results it was concluded that the monolayer of stearic acid interacting with aluminum ion might be analogous to the two-dimensional polymeric aluminum distearate adsorbing aluminum ion.

Physicochemical Studies of Stearic Acid Monolayer-Aluminum Ion Interaction. II. The Surface Viscoelasticity

By Kinsi MOTOMURA and Ryohei MATUURA

(Received May 22, 1961)

In the preceding paper[1] we investigated the interaction of the stearic acid monolayer with aluminum ion in underlying solutions by means of surface pressure measurement and concluded that the interacted monolayer had an analogous structure to the polymeric aluminum distearate monolayer adsorbed by aluminum ion. In order to confirm and further to develop this conclusion, it is most desirable to measure the surface rheological property of the monolayer, because a two-dimensional polymeric structure is most clearly revealed by surface viscoelasticity. Qualitative investigations have alcready been performed[2,3], but no quantitative study has been done with this system. Many investigators have tried to shed light on the rheological behavior of the monolayers of synthetic high polymers and proteins by making use of the aperiodic torsion pendulum[4-7] or the oscillating torsion pendulum[8,9], and it has been shown that these methods indeed give useful information about the structure of the monolayer. However, since the methods used by

these authors are either instrumentally unsatisfactory or mathematically only approximate in analysis, a new and more exact treatment seems to be required in order to obtain more detailed information about the molecular structure of the monolayer. Here we employed a ring torsion pendulum method similar to that used by Kimizuka[3] and performed an exact mathematical analysis based on Oka and Sato's equation[10]. The object of this paper is to show, from the results of rheological measurements, the structure and constitution of the stearic acid monolayer formed on the substrate solution containing aluminum ion.

Theoretical

The viscoelasticity of a monolayer is usefully expressed by a mechanical model made up of various combinations of springs indicating elasticity and dashpots indicating viscosity. Two examples of models are shown in Fig. 2. In order to evaluate the viscoelasticity, it is necessary to obtain the deformation-time curve of the monolayer under surface shearing stress and to analyze it through a given mechanical model.

Let us now imagine a system in which the monolayer is spread between the ring of radius R_1, suspended with a very fine wire of phosphorus bronze just so its lower edge touches the underlying solution, and that of radius R_2, as shown in Fig. 1. When the head of the suspending wire is twisted at a given angle ϕ,

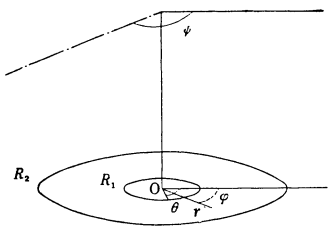

Fig. 1. Schematic diagram of the apparatus.

the ring R_1 will turn round by θ after the time t, and at the same time the monolayer being distant r from the origin O will also be displaced at an angle φ. Suppose, moreover, that the monolayer gets surface shear strain γ under the surface shearing stress S, which is brought about by the restoring torque of the suspending wire. If the monolayer is expressed by a certain mechanical model, we can obtain

$$L\gamma = MS \tag{1}$$

in which L and M are the operators characteristic of the mechanical model. The shear strain γ is subject to the relation

$$\gamma = -r\frac{\partial\varphi}{\partial r} \tag{2}$$

And then the shearing stress is expressed by

$$\sigma\frac{\partial^2\varphi}{\partial t^2} = -\frac{1}{r^3}\frac{\partial}{\partial r}(Sr^2) \tag{3}$$

in which σ is the surface density of the monolayer which is often neglected because of its small value. Using Eqs. 1, 2 and 3, φ can be given in the form of the function of r and t. From this φ and Eqs. 1 and 2, the relation between S and θ becomes

$$2\pi R_1^2 MS = CL\theta \tag{4}$$

by making use of the expression

$$\theta(t) = \varphi(R_1, t) \tag{5}$$

In Eq. 4 C is given by

$$C = 4\pi\Big/\left(\frac{1}{R_1^2} - \frac{1}{R_2^2}\right) \tag{6}$$

On the other hand, if I is the moment of inertia of the ring R_1 and κ the torsion constant of the suspending wire, the equation of motion with regard to the ring R_1 is given by

$$I\frac{d^2\theta}{dt^2} = \kappa(\phi - \theta) - 2\pi R_1^2 S \tag{7}$$

By substituting from 4 into 7, this becomes

$$IM\frac{d^2\theta}{dt^2} = \kappa M(\phi - \theta) - CL\theta^{10)} \tag{8}$$

When the monolayer is very rigid, then $d^2\theta/dt^2$ becomes negligibly small. Hence, Eq. 8 reduces to a simple form

$$\kappa M(\phi - \theta) - CL\theta = 0 \tag{9}$$

with sufficient accuracy. The approximate formula 9 is to be used throughout this paper, since the monolayer studied in the present experiment is so rigid that the condition for Eq. 9 is almost completely fulfilled. The general equation 8 will be used in another paper

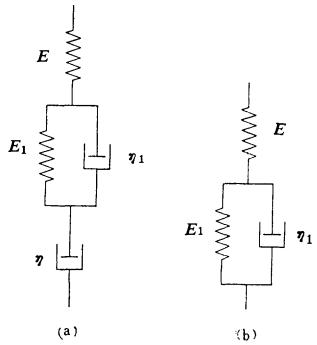

Fig. 2. Mechanical models: (a) four-parameter model; (b) three-parameter model (elasticity+Voigt element).

10) S. Oka and Y. Sato, *Bull. Kobayashi Inst. Phys. Res.*, 5, 96 (1955).

for the study of the rheological behavior of high polymer monolayers (which are not so rigid as in the present case).

In the first place let us consider the general mechanical model, i. e., the four-parameter model illustrated by a in Fig. 2. The relation between γ and S for the model is given by

$$\eta_1\frac{d^2\gamma}{dt^2}+E_1\frac{d\gamma}{dt}=\frac{\eta_1}{E}\frac{d^2S}{dt^2}+\left(1+\frac{E_1}{E}+\frac{\eta_1}{\eta}\right)\frac{dS}{dt}+\frac{E_1}{\eta}S \tag{10}$$

It follows thus that the operators $\boldsymbol{L}$ and $\boldsymbol{M}$ are expressed dy

$$\boldsymbol{L}=\eta_1\frac{d^2}{dt^2}+E_1\frac{d}{dt} \tag{11}$$

and

$$\boldsymbol{M}=\frac{\eta_1}{E}\frac{d^2}{dt^2}+\left(1+\frac{E_1}{E}+\frac{\eta_1}{\eta}\right)\frac{d}{dt}+\frac{E_1}{\eta} \tag{12}$$

when Eq. 10 is compared with Eq. 1. Inserting the operators into Eq. 9 and arranging, we can obtain a differential equation

$$\frac{d^2\theta}{dt^2}+b\frac{d\theta}{dt}+d\theta=d\phi \tag{13}$$

where

$$b=\frac{\kappa}{\kappa+CE}\left(\frac{E}{\eta_1}+\frac{E_1}{\eta_1}+\frac{E}{\eta}+\frac{C}{\kappa}\frac{EE_1}{\eta_1}\right) \tag{14}$$

and

$$d=\frac{\kappa}{\kappa+CE}\frac{EE_1}{\eta\eta_1} \tag{15}$$

It can easily be found that the solution of Eq. 13 is

$$\theta=\phi-Ae^{-\alpha t}-Be^{-\beta t} \tag{16}$$

in which A and B are arbitrary constants, and α and β are expressed by

$$\alpha=\frac{b-\sqrt{b^2-4d}}{2} \tag{17}$$

and

$$\beta=\frac{b+\sqrt{b^2-4d}}{2} \tag{18}$$

When α is much smaller than unity, Eq. 16 can be written in the form of

$$\theta=\phi-A+A\alpha t-Be^{-\beta t} \tag{19}$$

for small values of t. If the θ-t curve obtained experimentally of a certain monolayer coincides with the expression 16 or 19, it is thought natural that the rheological behavior of this monolayer can be analyzed by the four-parameter model. It is possible, therefore, to estimate the values of A, B, α and β, and, further, of b and d by making use of

$$b=\alpha+\beta \quad \text{and} \quad d=\alpha\beta \tag{20}$$

Thus using the values of A, B, b and d, we can evaluate the viscoelasticity by means of equations

$$E=\frac{\kappa}{C}\cdot\frac{A+B}{\phi-A-B} \tag{21}$$

$$E_1=1\Big/\left(\frac{C}{\kappa}\frac{\phi-A}{A}-\frac{1}{E}\right) \tag{22}$$

$$\eta_1=\frac{\kappa}{\kappa+CE}\cdot\frac{E+E_1+(C/\kappa)EE_1}{b} \tag{23}$$

and

$$\eta=\frac{\kappa}{\kappa+CE}\cdot\frac{EE_1}{d\eta_1} \tag{24}$$

Let us next consider the three-parameter model, the elasticity being accompanied by the Voigt model, as shown by b in Fig. 2. In a way similar as to that of the four-parameter model, it is readily found that for the three-parameter model

$$\boldsymbol{L}=\eta_1\frac{d}{dt}+E_1 \tag{25}$$

and

$$\boldsymbol{M}=\frac{\eta_1}{E}\frac{d}{dt}+\left(1+\frac{E_1}{E}\right) \tag{26}$$

By substituting the operators into Eq. 9, the expression for this model corresponding to Eq. 13 for the four-parameter model is given by

$$\frac{d\theta}{dt}+b\theta=d\phi \tag{27}$$

in which

$$b=\frac{\kappa}{\kappa+CE}\left(\frac{E}{\eta_1}+\frac{E_1}{\eta_1}+\frac{C}{\kappa}\frac{EE_1}{\eta_1}\right) \tag{28}$$

and

$$d=\frac{\kappa}{\kappa+CE}\left(\frac{E}{\eta_1}+\frac{E_1}{\eta_1}\right) \tag{29}$$

Then we, by solving Eq. 27, obtain

$$\theta=\frac{d}{b}\phi-Ae^{-bt} \tag{30}$$

A being an arbitrary constant. In the same way as the four-parameter model, from a comparison of the θ-t curve obtained experimentally with the expression 30 the evaluation of A, b and d is made easily. And hence the viscoelasticity can be evaluated by relations

$$E=\frac{\kappa}{C}\cdot\frac{(1-d/b)\phi+A}{(d/b)\phi-A} \tag{31}$$

$$E_1=(b-d)E\Big/\left(\frac{\kappa+CE}{\kappa}d-b\right) \tag{32}$$

and

$$\eta_1=\frac{\kappa}{\kappa+CE}\cdot\frac{E+E_1}{d} \tag{33}$$

This treatment for the three-parameter model leads to the same result as that which has been used to investigate the rheological properties of adsorbed films by Sasaki and Kimizuka[11].

In the third place, let us consider the monolayer having elasticity only. The operators as a matter of course are given by

$$\boldsymbol{L}=1 \tag{34}$$

and

$$\boldsymbol{M}=1/E \tag{35}$$

Therefore, we directly obtain the expression

$$E=\frac{\kappa}{C}\cdot\frac{\psi-\theta}{\theta} \tag{36}$$

from Eq. 9, where θ is independent of t.

Experimental

The measurement of surface viscoelasticity was carried out with the aid of the ring torsion pendulum apparatus used by Kimizuka[2] as shown schematically in Fig. 1. The ring R_1 was a platinum ring 2 cm. in diameter suspended with a phosphorus bronze wire, the torsion constant of which was 1.23 dyn. cm. As for the ring R_2, it was assumed that the radius was replaced by the distance from the origin 0 to the brim of the trough, i. e., 7.5 cm., with sufficient accuracy. The deflection angle θ of the ring R_1 was read by means of the lamp scale method and expressed by the moving distance on the scale.

The experiment was made on the stearic acid monolayer on a 10^{-4} mol./l. aluminum chloride solution and the aluminum distearate monolayer on both water and a 10^{-4} mol./l. aluminum chloride solution as described in the preceding paper[1]. All experimental conditions were entirely the same as in the preceding paper, except that the pH of the underlying solutions was kept constant at 5.5, which is in the region of maximum expansion of the monolayers.

After being spread on the substrate solutions, the monolayers were left to stand for 60 min. before the ring R_1 was deposited and then allowed to stand for another 30 min. because it was found that the values of viscoelasticity depended on the time of film aging.

Results and Discussion

It was found that the monolayer of aluminum distearate shows remarkable viscoelastic behavior even at considerably large areas. Fig. 3 illustrates an example of the θ-t relation obtained at 81.8 Å^2/molec. of the aluminum distearate monolayer on water. This relation

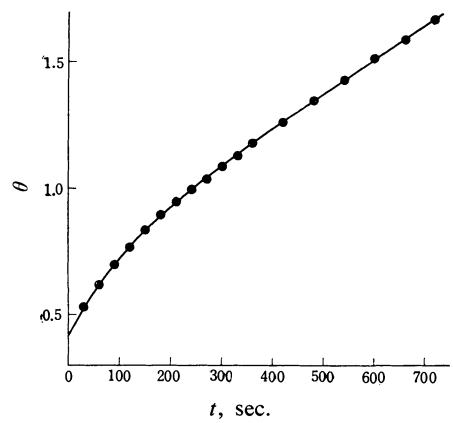

Fig. 3. θ-t curve of the aluminum distearate monolayer on water. Area 81.8 Å^2/molec.; Temperature 25°C.

is well expressed by the equation

$$\theta=0.714+0.00133\,t-0.297\,e^{-0.00882t} \tag{37}$$

which is shown as a full line in Fig. 3. Eq. 37 is in the same form as Eq. 19. We can say, therefore, that the surface rheological behavior of aluminum distearate can be explained in terms of the four-parameter model. From this result the values of viscoelasticity can be easily evaluated by applying Eqs. 21, 22, 23 and 24 in the manner described previously. We thus obtain 18.1 dyn./cm., 25.3 dyn./cm., 2.87×10^3 dyn. sec./cm. and 5.65×10^3 dyn. sec./cm. for E, E_1, η_1 and η respectively. These values are large enough to be compared with those of nylon 6 film at an area smaller than the limiting area as studied by Inokuchi[5]. Therefore, it is evident that the aluminum distearate spread on water holds the polymeric structure in the monolayer as well as in bulk and that its surface rheological behavior is due to a two-dimensional network brought about by its linear polymeric structure. Another proof comes from the studies on the aluminum distearate monolayer spread on sodium fluoride solution[12]. The viscoelasticity decreases with increase in the concentration of sodium fluoride, and at 10^{-3} mol./l. no rheological behavior is found anywhere over the area by means of this method. This may be explained by the destruction of the polymer chain through the bonding of fluorine with the aluminum atom in the chain, as stated in the preceding paper. The measured θ-t curves of the aluminum distearate monolayer on water at other areas than 81.8 Å^2/molec. are in shape quite similar to that illustrated in Fig. 3. By the same procedure as above, the values

11) T. Sasaki and H. Kimizuka, This Bulletin, 25, 318 (1952).

12) K. Motomura and R. Matuura, to be published soon.

of viscoelasticity were calculated for various areas of the monolayer. The results are shown in Fig. 4, where these values are plotted against the area per aluminum distearate molecule. It is seen that the viscoelasticity increases first gradually and then a little steeply as the area decreases.

If we accept the view that aluminum distearate is formed in the monolayer when the stearic acid monolayer was spread on aluminum ion, as discussed in the preceding paper, the interacted monolayer will show a rheological behavior. It was really found that the viscoelasticity of the stearic acid monolayer was so large as to be measured by the apparatus described here. Fig. 5 illustrates a typical θ-t curve for the monolayer of stearic acid on aluminum ion of 10^{-4} mol./l. at the area 38.9 Å^2/molec. The curve is essentially similar to that of the aluminum distearate monolayer on water. Furthermore, the curve is represented by

$$\theta = 0.552 + 0.00302\,t - 0.143\,e^{-0.0103t} \qquad (38)$$

bearing a resemblance to Eq. 37. Hence, this monolayer can also be analyzed in terms of the four-parameter model. We, in a like manner, obtained the similar θ-t curves at various areas. In Fig. 6, the values of E, E_1, η_1 and η evaluated from these curves are plotted against the area. It will be seen from Fig. 6

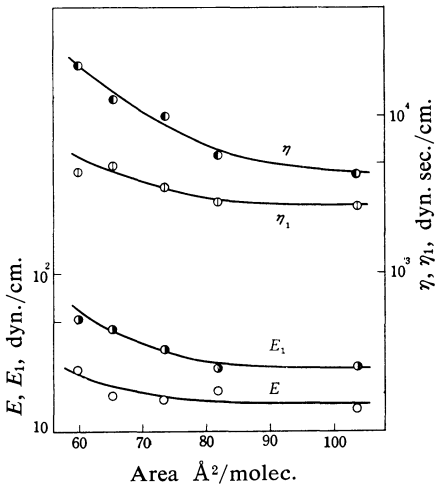

Fig. 4. Viscoelasticity-area curve of the aluminum distearate monolayer on water at 25°C.

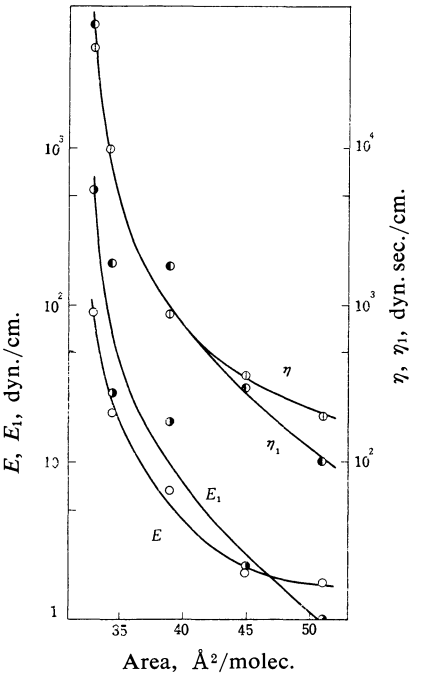

Fig. 6. Viscoelasticity-area curve of the stearic acid monolayer on 10^{-4} mol./l. aluminum chloride solution at 25°C.

(3) Aluminum distearate on aluminum ion (⊕).

that the curves, in contrast with those of aluminum distearate monolayer, rise steeply with a decrease in the area. In addition, it is to be noticed, when Fig. 6 is compared with Fig. 4, that the curves are lower than the latter at larger areas whereas higher at smaller areas. This fact may be more clearly revealed by the comparison between curves 1 and 2 in Fig. 9, which are the E-area curves for the aluminum distearate monolayer on water and the stearic acid monlayer on aluminum ion respectively. This difference leads us to the conclusion that, although the polymeric soaps are probably formed on water between stearic acid and aluminum ion, the structure of the monolayer thus formed is not just the same as that of aluminum distearate.

Now it is necessary to know the action of aluminum ion in the underlying solutions on the aluminum distearate monolayer. As an example of the viscoelastic behavior of the aluminum distearate monolayer on aluminum ion of 10^{-4} mol./l. over larger areas, the θ-t curve at the area 98.9 Å²/molec. is given in Fig. 7. It will be at once recognized that the curve behaves unlike those of Figs. 3 and 5. Since the curve can be represented in the form of the equation

$$\theta = 1.89 - 1.47\, e^{-0.00320t} \qquad (39)$$

which has just the same form as Eq. 30, the behavior of the monolayer must be expressed with the three-parameter model, the values E, E_1 and η_1 of which are calculated according to Eqs. 31, 32 and 33. In a smaller area, e. g., 75.6 Å²/molec., on the other hand, it was found that the value of θ kept constant throughout the measuring time within experimental errors. This means pure elasticity. Hence, the value is evaluated by use of Eq. 36. The values of elasticity at much smaller areas were too large to be measured by making use of this apparatus. In Fig. 8, the values of viscoelasticity in this system are plotted against the area. In comparing the curves in Fig. 8 with the corresponding curves in Fig. 4, it will be found that the former curves are incomparably higher than the latter at small areas, while equal to or rather a little less than the latter at large areas. It may be possible to say, therefore, that the aluminum ion in underlying solutions acts on the aluminum distearate monolayer through changing the four-parameter model into the three-parameter model, or pure elasticity, and making its values extremely large at smaller areas. In other words, we may be able to conclude that the aluminum ion is adsorbed on the monolayer of polymeric aluminum distearate, probably in a form of basic ion, and strengthens its two-dimensional network structure.

In the preceding paper, in which the interaction of stearic acid monolayer with aluminum ion was discussed from the viewpoint of surface pressure, it was suggested that the interacted monolayer might have the structure of the polymeric aluminum distearate adsorbing aluminum ion. According to this theory, the rheological behavior of both the stearic acid and aluminum distearate monolayers on

aluminum ion can be expected to agree. An appreciable difference exists, however, between them, e. g., curves 2 and 3 in Fig. 9, although aluminum distearate seems undoubtedly to be formed in the stearic acid monolayer. In Fig. 9 it is clear that the E of film 2 gets greater than that of film 1 and approaches to that of film 3 as the area decreases, while the former is lower than the latter two at large areas. It is quite possible that at much smaller areas the viscoelastic behavior of stearic acid monolayer on aluminum ion finally turns into the elastic one and that films 2 and 3 perfectly agree with each other. Therefore, this difference may be ascribed to the fact that the polymeric aluminum distearate formed in the interacted stearic acid monolayer is of a chain length shorter than that prepared in bulk. As elucidated by Singer's[13] or our[14] equation of state for high polymer, the effect of the chain length on surface pressure is very little when the high polymer has a fairly long one. The above result is not thought, therefore, to conflict with the well agreed results of surface pressure measurement between them. It thus may be concluded that the interacted monolayer of stearic acid with aluminum ion in underlying solution is constructed from the monolayer of polymeric aluminum distearate of a short chain length adsorbing basic aluminum ion.

Summary

By using the ring torsion pendulum method and applying the correct mathematical analysis, surface viscoelasticity measurements were carried out on the monolayers of (1) stearic acid on a 10^{-4} mol./l. aluminum chloride solution, (2) aluminum distearate on distilled water, and (3) aluminum distearate on a 10^{-4} mol./l. aluminum chloride solution. It was found that the rheological behavior of 1 and 2 could be analyzed in terms of the four-parameter model and of 3 by the three-parameter model or elasticity. Also, with regard to the values of viscoelasticity, it was shown that at large areas 1 was smaller than both 2 and 3, and at small areas 1 approaches to 3. From the viewpoint of these results, it was concluded that the interacted monolyer of stearic acid with aluminum ion in an underlying solution might be analogous to the monolayer of aluminum distearate with a short chain length adsorbing basic aluminum ion.

The Very Weak Visible Absorption Band of p-Benzoquinone

By Akira KUBOYAMA

(Received July 10, 1961)

Recently, in various carbonyl compounds[1-7] and azines[8], very weak absorption bands at the long wavelength sides of the $n\rightarrow\pi^*$ singlet-singlet absorption bands have been found and safely assigned as $n\rightarrow\pi^*$ singlet-triplet absorption bands from the phosphorescence spectra, the temperature-independency, the solvent effect and the substitution effect. Previously, Sidman[9], in his study of the low temperature crystalline spectrum of *p*-benzoquinone, found a very weak absorption band at the long wavelength side of the $n\rightarrow\pi^*$ singlet-singlet absorption band and tentatively assigned it to the $n\rightarrow\pi^*$ singlet-triplet absorption band. Apart from his study, the $n\rightarrow\pi^*$ singlet-triplet absorption bands of quinones have not been studied. Thus, we have studied this very weak visible absorption band of *p*-benzoquinone in solution. Our results are now reported on.

Experimental

Measurements. — The absorption spectra were measured with a Cary recording spectrophotometer 14 M with 1, 5, 10 cm. path quartz cells. For the measurements of the very weak absorption bands, the slidewire for the scale expansion, the accessory, was used. A thermostated cell jacket was used for measurements at 5 and 42°C.

Materials.—The solvents were purified according to the methods described in our previous work[10]. Ethyl iodide (a commercial product) was washed with a 1N aqueous solution of potassium hyroxide and repeatedly with water, and distilled after being dried over calcium chloride. *p*-Benzoquinone, toluquinone and *p*-xylo-*p*-quinone (commercial products) were purified by cautious sublimation. *o*-[11] and *m*-xylo-*p*-quinones[12] were prepared according to the methods described in the literature and were purified by cautious sublimation. α-Naphthoquinone was prepared according to Fieser's method[13] and purified by charcoal treatment in an ether solution. 2,5- and 2,6-dichlor-*p*-benzoquinones (commercial products) were recrystallized from ethanol and *n*-heptane, successively*1.

Melting Points (corr.) — *p*-ebnzoquinone 115~116°C, toluquinone 69°C, *o*-xylo-*p*-quinone 56.5~57.5°C, *m*-xylo-*p*-quinone 72.5~73°C, *p*-xylo-*p*-quinone 125°C, α-naphthoquinone 124°C, 2,5-dichloro-*p*-benzoquinone 121.5~122.5°C, 2,6-dichloro-*p*-benzoquinone 162~163°C.

Results

The absorption spectra obtained are given in Figs. 1—6. In these figures ε represents the molecular extinction coefficient.

Discussion

As seen in Figs. 1, 2, 3, 4, 5 and 6, *p*-benzoquinone and its derivatives have very weak adsorption bands (ε_{max} ~0.2) at the long wavelength sides of the $n\rightarrow\pi^*$ singlet-singlet absorption bands. In the following remarks, this band is called the α-band. In many carbonyl compounds (formaldehyde[2], acetaldehyde[3], benzophenone[4], glyoxal[5], diacetyl[6] and camphorquinone[7], very weak absorption bands similar to the α-band, at the long wavelength sides of the $n\rightarrow\pi^*$ singlet-singlet absorption bands, have been found and safely assigned to the $n\rightarrow\pi^*$ singlet-triplet absorption bands by many people on the basis of the phosphorescence spectra, the temperature-independency, the solvent effect and the substitution effect. The maximum molecular extinction coefficient of the α-band (ca. 0.2) is of the same order of magnitude as those of comphorquinone (ca. 0.1) and diacetyl (ca. 0.05), but it is far larger

than that of acetaldehyde (ca. 0.0001). For *p*-benzoquinone, the distance*2 (wave number) between the peak (at 539 mμ) of the α-band and the longest wavelength peak (at 479 mμ) of the $n\rightarrow\pi^*$ singlet-singlet band in *n*-heptane is 2330 cm^{-1}. If this value is regarded as the separation between the $n\rightarrow\pi^*$ singlet and triplet excited states, it is of the same order of magnitude as the reported values (2000~3000 cm^{-1}) for the above carbonyl compounds. As seen in Fig. 1, the α-band of *p*-benzoquinone is partly masked by the tail of the $n\rightarrow\pi^*$ singlet-singlet absorption band, and, especially in ethyl iodide, the α-band is so almost entirely masked that the spin-orbit interaction effect of iodine atom on the α-band cannot be examined. In *n*-heptane one peak and one shoulder are observed at 539 mμ and ca. 527.5 mμ respectively. The distance between the peak and the shoulder is ca. 410 cm^{-1}; this vibrational sequence probably corresponds to that in the crystalline spectrum assigned to the totally symmetric ring deformation vibration of the *p*-benzoquinone molecule by Sidman[9]. The α-band shifts toward shorter wavelengths in the order of *n*-heptane, carbon tetrachloride, and benzene, like the $n\rightarrow\pi^*$ singlet-singlet absorption band of *p*-benzoquinone. On the other hand, the $\pi\rightarrow\pi^*$ adsorption bands of the quinones are at shorter wavelengths in *n*-heptane than in carbon tetrachloride and in benzene. As for the methyl group substitution effect, in Fig. 2 the peak of the α-band shifts towards shorter wavelengths as the number of methyl groups increases, in the same manner as in the $n\rightarrow\pi^*$ singlet-singlet bands in Fig. 3. This fact is characteristic of the $n\rightarrow\pi^*$ absorption band[14]. The peaks of the α-band of toluquinone and *p*-xylo-*p*-quinone in *n*-heptane are at 528 and 519 mμ respectively*3. From the solvent effect and the methyl group substitution effect, the α-band is safely assigned to the $n\rightarrow\pi^*$ absorption band. As seen in Fig. 2, toluquinone alone has a shoulder at the long wavelength side of the peak. In the $n\rightarrow\pi^*$ singlet-singlet bands in Fig. 3, such an abnormality of toluquinone as the above cannot be observed. Therefore, this abnormality of toluquinone seems to be intrinsic to the α-band. In Fig. 4, the α-band of *o*-xylo-*p*-quinone is similar to that of *p*-xylo-*p*-quinone, while the band of *m*-xylo-*p*-quinone has a shoulder similar to that of toluquinone. Therefore, it is concluded that

*2 The corresponding one in the crystalline state, studied by Sidman[9], was 2060 cm^{-1}.

14) H. Baba, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **72**, 341 (1951); S. Nagakura, This Bulletin, **25**, 164 (1952); A. Kuboyama, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **77**, 1062 (1956).

*3 α-Naphthoquinone has a peak at 491 mμ in *n*-heptane, similar to that of *p*-xylo-*p*-quinone.

these shoulders are characteristic of the structure where two carbonyl groups of *p*-benzoquinone are not equivalent. As seen in Fig. 2, *p*-benzoquinone has a tail which extends over the long wavelength side of the peak. This tail may be enhanced to become the shoulders in toluquinone and *m*-xylo-*p*-quinone mentioned above. It is uncertain whether this tail and the α-band are due to the same electronic transition or not. As seen in Fig. 5, in dichloro-*p*-benzoquinones the intensities of the α-band are considerably enhanced in comparison with those of dimethyl-*p*-benzoquinones. This enhancement of the intensity of the α-band is surely to be attributed to the spin-orbit interaction effect of chlorine atoms. Therefore, this fact is indicative of the α-band being the singlet-triplet absorption band. Further, we have examined the temperature-dependency of the α-band of *p*-benzoquinone and toluquinone. Though, as seen in Fig. 6, owing to the tails of the $n\rightarrow\pi^*$ singlet-singlet bands the temperature-dependency cannot be fully examined, it seems that no noticeable temperature-dependency can be observed in the temperature range 4~42°C. In conclusion, from the results obtained in this work, the α-band is reasonably assigned to the $n\rightarrow\pi^*$ singlet-triplet absorption band.

Summary

The very weak absorption bands at the long wavelength sides of the $n\rightarrow\pi^*$ singlet-singlet absorption bands of *p*-benzoquinone and its derivatives were examined with regard to the solvent effect, the substitution effect and the temperature-dependency. From the obtained results, this absorption band is reasonably assigned to the $n\rightarrow\pi^*$ singlet-triplet absorption band. As for its absorption curve, a distinct difference between the structure where the two carbonyl groups of *p*-benzoquinone are equivalent and that where the two carbonyl groups are not equivalent is observed.

The author wishes to express his sincere thanks to Professor Saburo Nagakura and Dr. Hiroshi Tsubomura of The University of Tokyo for their helpful advices and to Dr. Yoichiro Mashiko of this Institute for his kind offices. Absorption Spectra and Catalytic Behavior of the Copper(II) Chelates of Some Alkylated Ethylenediamines

By Heijirô OJIMA and Kôzô SONE

(Received July 12, 1961)

The copper chelates of various alkylated ethylenediamines were studied first by Pfeiffer and Glaser[1], and then by Irving and Griffiths[2], and especially by Basolo and his collaborators[3]. Comparative studies of the absorption spectra of some of these chelates have been carried out recently by the present authors, together with some experiments on their activities to catalyze the chemiluminescent reaction of luminol with hydrogen peroxide in alkaline solution. The results of these experiments will be described and discussed in the present paper.

Experimental

Materials. — The samples of $[Cu\,en_2](ClO_4)_2$, $[Cu\,pn_2](ClO_4)_2$ and $[Cu(N,N\text{-diethyl-en})_2](ClO_4)_2$ were prepared and purified according to the methods of the literature[1], while those of $[Cu(\text{tetramethyl-en})_2]I_2$, $[Cu(N\text{-propyl-en})_2]Br_2$ and $[Cu(N,N'\text{-dipropyl-en})_2](NO_3)_2$ were kindly presented by Prof. Fred Basolo of Northwestern University (Evanston, Ill., U. S. A.) to one of the authors (K. S.). The spectrum of $[Cu(N\text{-hydroxyethyl-en})_2]^{2+}$ was measured with a solution containing $CuSO_4$ (5×10^{-3} M) and purified ligand amine in the molar ratio of 1 : 2 (ionic strength : 0.5 with KNO_3).

Absorption Spectra.—A Shimadzu QR-50 quartz spectrophotometer with cells 10 mm. in thickness

was used throughout this study. 5×10^{-3} M solutions of the chelates were used in the spectral measurements; their ionic strength was kept at 0.5 by adding potassium nitrate. The measurements were mostly carried out at approx. 27°C.

Paper Electrophoresis.—Filter paper strips (6× 22 cm²) were dipped in electrolyte solutions containing various amounts of NaOH up to 5×10^{-2} M (ionic strength: 5×10^{-2} with potassium nitrate for 10 hr., and small amounts of aqueous solutions of the chelates (approx. 10^{-7} mol.) were spotted at their centers. Electrophoresis experiments with these strips were then carried out by means of the horizontal open strip method, with a potential of 10 V./cm. and at 25°C for 30 min. The migration distances of the spots were measured, and corrections were made of the flow of the liquid phase caused by electroösmosis and evaporation effects, by comparing the data with those of *o*-nitroaniline obtained under the same conditions. The corrected data were plotted against the alkali concentration (cf. Fig. 5).

Catalytic Activity for the Chemiluminescence of Luminol. — Seven milliliters portions of various sodium hydroxide solutions ($0\sim5\times10^{-2}$ M; ionic strength: 0.1 with potassium nitrate) containing luminol (10^{-5} mol.) and each one of the chelates (5×10^{-6} mol.) were kept in a thermostat at 25°C, and 0.5 ml. portion of a hydrogen peroxide solution (containing 1.6×10^{-4} mol.) was poured rapidly into each of them. The intensities of the chemiluminescence emitted by these mixtures were measured by means of a selenium photocell-galvanometer circuit, and the maxima of the galvanometer readings, which were obtained several seconds after the addition of the hydrogen peroxide solution, were plotted against the alkali concentration (cf. Fig. 6).

Results and Discussion

Visible Absorption Spectra.—The visible absorption spectra of the chelates in their aqueous solutions are shown in Fig. 1, and the maximum frequencies and molar extinction coefficients (ν_{max} and ε_{max}) calculated from these curves are shown in Table I, together with the values of their stability constants taken from the literature[2,3]. It can be seen that there is an approximately linear relationship between ν_{max} and log k_1k_2 (or log k_2), so that the more stable a chelate is, the larger is its ν_{max} value, in accord with the general trend observed in many Co(III) and Cr(III) complexes as well as in certain complexes of

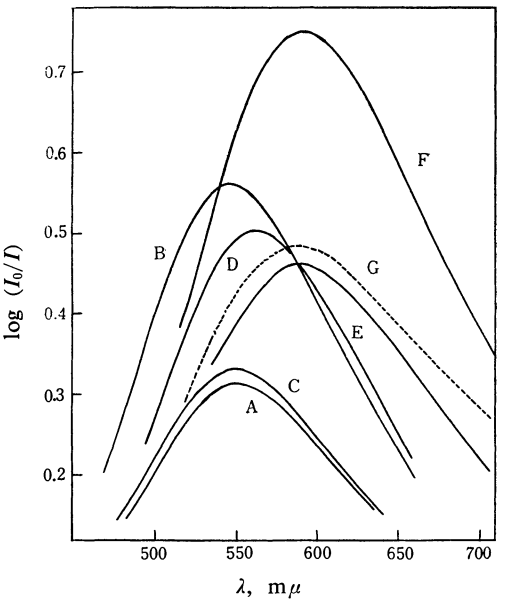

Fig. 1. Absorption spectra of the chelates. A, B,....., G: cf. Table I. Concn.: 5×10^{-3} M.

Table I

	Chelates	ν_{max} (10^{13} sec^{-1}) in H_2O ( ): ε_{max}*	in EtOH	log k_1	log k_2**

(D)	$[Cu(N\text{-}propyl\text{-}en)_2]^{2+}$	53.2 (101)	50.0	9.98	8.16[3]
(E)	$[Cu(N, N'\text{-}dipropyl\text{-}en\text{-}_2]^{2+}$	50.8 (93)	51.8	8.79	5.55[3]
(F)	$[Cu(N, N\text{-}diethyl\text{-}en)_2]^{2+}$	50.6 (150)	53.0	8.17	5.55[2]
(G)	$[Cu(N\text{-}hydroxyethyl\text{-}en)_2]^{2+}$	50.9 (97)	—	—	—

* The ε_{max} values in this table are those calculated from the curves of Fig. 1; the exact values of the more unstable chelates may be somewhat higher than these. In fact, while the addition of an excess of ethylenediamine (Cu: en=approx. 1:10) to a solution of $[Cu\,en_2]^{2+}$ has almost no effect on its spectra, the addition of *N*, *N*-diethyl-ethylenediamine to a solution of $[Cu(N, N\text{-diethyl-en})_2]^{2+}$ causes a small but noticeable increase in the intensity (up to approx. 15% when Cu: amine=1:8) of its absorption band, indicating the partial dissociation of the latter chelate in its solution.

** The log *k* values are all those at 25°C and at an ionic strength of 0.5, except in (F), where the ionic strength is 0.1. The log *k* values of $[Cu(N, N'\text{-dimethyl-en})_2]^{2+}$ in Fig. 2 are those of Basolo et al.[3], which were obtained under the same conditions.

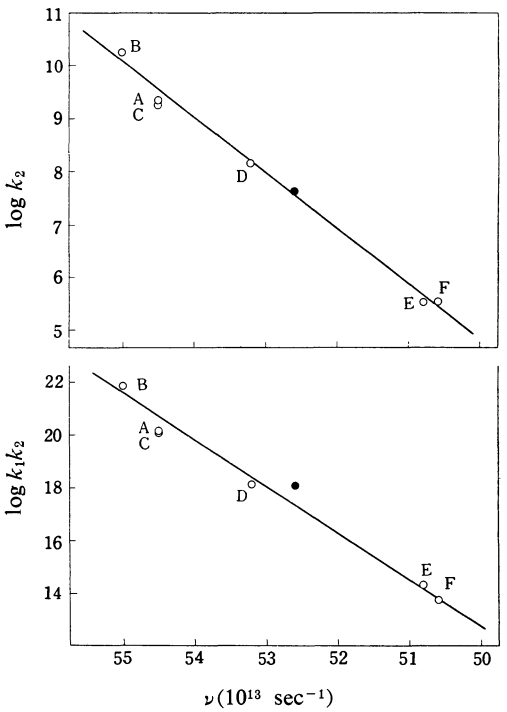

Fig. 2. Relation between ν_{max} and log k values of the chelates. A, B,···, F: cf. Table I. Black circles correspond to $[Cu(N,N'\text{-dimethyl-en})_2]^{2+}$, the value of which were taken from the literature[2,3] (cf. Footnote of Table I).

Ni(II) and Cu(II)[4] (cf. Fig. 2). It can also be seen that the absorption intensities of the alkylated chelates are generally much higher than that of $[Cu\,en_2]^{2+}$.

It was formerly observed by Sone and Kato[5] that a striking color change from blue-violet to yellow took place when the alcoholic solutions (or aqueous solutions containing sodium perchlorate) of $[Ni\,en_2]^{2+}$ and $[Ni\cdot pn_2]^{2+}$ were heated, and this change was ascribed to the existence of the equilibrium

$$[Ni\,en_2A_2]^{2+} \rightleftarrows \underset{\text{blue-violet}}{} [Ni\,en_2]^{2+} + 2A \quad (A: H_2O \text{ or EtOH})$$
yellow

in these media[5]. On the other hand, no such drastic spectral change was observed when the copper chelates studied here were treated in the same manner; only small shifts and intensity changes in their absorption curve occurred. Some data on the absorption bands in alcoholic solutions are given in Table I. It may be of interest that the bands of the two unstable chelates shift to shorter wavelengths in alcohol, while the bands of the other chelates generally shift in the opposite direction. The natures of these shifts were not studied in greater detail, however, partly because some of these chelates were sparingly soluble in such media, and also because of the lack of sufficient quantities for such a study.

It is also of some interest to compare the absorption curve of the chelate $[Cu(N\text{-propyl-en})_2]^{2+}$ with that of $[Cu(N\text{-hydroxyethyl-en})_2]^{2+}$, the ligand of which contains an -OH group instead of $-CH_3$ at the end of the *N*-substituent radical. It has already been shown by Harvey, Hall et al.[6,7] that the latter complex is formed predominantly in a solution containing Cu^{2+} and *N*-hydroxyethyl-ethylenediamine in the ratio of 1:2; the absorption curve of such a mixture measured by the present authors (curve G, Fig. 1) agreed well with the data of these earlier investigators, showing a band at 590 mμ which lies at a much longer wavelength than the band of the *N*-propyl chelate, This difference is very probably due to the 5- (or possibly 6-) coordinated structure of the *N*-hydroxyethyl chelate, in which also the -OH group is taking part in coordination, since a number of instances showing that the formation of a 5- or 6-coordinated structure in a copper complex is generally accompanied by a shift of its absorption band to a longer wavelength is already known in the literature[8-11]. For example, Rosenblatt[8] found that the addition of a large quantity of NH_3 to a solution of $[Cu\cdot en_2]^{2+}$ produced a shift of its band at 550 mμ to ~610 mμ, owing to the formation of the complex $[Cu\,en_2NH_3]^{2+}$, and Jonassen et al.[9] observed a similar shift in solutions containing $[Cu\,en_2]^{2+}$ and NaOH, owing to the formation of $[Cu\,en_2OH]^{+}$ in such media.

Effect of Added Alkali on the Spectra.—In their study of copper complexes of *N*-alkylated ethanolamines, the present authors found that the spectral data indicate the presence of at least two types of complexes, a chelate and a non-chelate, in their solutions containing various amounts of ligand and sodium hydroxide[12].

The effect of added alkali on the spectra of the alkylated ethylenediamine chelates, which were studied in a manner similar to that of Jonassen et al. cited above, is now shown in Figs. 3 and 4; it can be seen that the situation is quite different here from that in ethanolamine complexes, owing to the increased stability of the chelate rings formed by the diamine molecules[13].

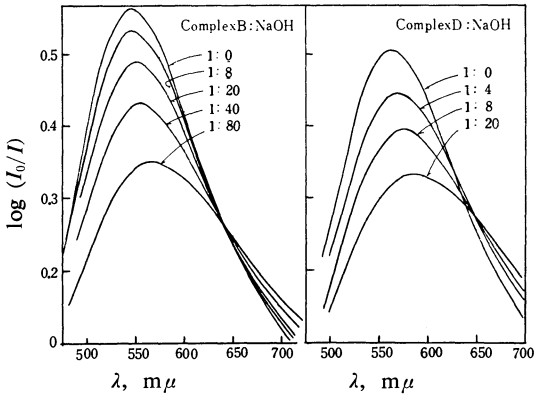

Fig. 3. Effect of added alkali on the spectra of $[Cu(tetramethyl\text{-}en)_2]^{2+}$ (B) and $[Cu\cdot(N\text{-}propyl\text{-}en)_2]^{2+}$ (D).

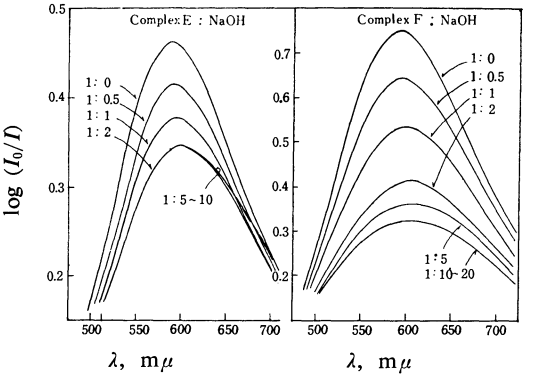

Fig. 4. Effect of added alkali on the spectra of $[Cu(N, N'\text{-}dipropyl\text{-}en)_2]^{2+}$ (E) and $[Cu(N, N\text{-}diethyl\text{-}en)_2]^{2+}$ (F).

In the case of tetramethyl and *N*-propyl chelates (Fig. 3), it can be seen that the appearance of the spectral changes is very similar to that of $[Cu\,en_2]^{2+}$ described by Jonassen et al.; this indicates the gradual formation of the complexes of the type $[Cu\,en_2\cdot OH]^{+}$ with an increasing OH^- concentration. Approximate values of their formation constants can be estimated at ~2 and 15 respectively from analysis of the curves in Fig. 3.

13) The precipitation of $Cu(OH)_2$, which frequently occurs in mixtures containing OH^- ions and *N*-alkylated ethanolamine complexes (cf. Ref. 12), is not observed in the solutions of the compositions shown in Figs. 3 and 4.

On the other hand, the situation is somewhat different in the case of *N, N'*-dipropyl and *N, N*-diethyl chelates. The curves in Fig. 4 show that even relatively small amounts of sodium hydroxide can cause a great decrease in their absorption intensities; as soon as only two moles of OH^- ions are added to one mole of the chelate, the change seems to become more or less complete.

Now the drastic spectral changes of these chelates can be explained in the following manner: because there are so many and such large alkyl groups around the coordination center, it is to be expected that the formation of the $[Cu\,en_2OH]^{+}$-type complexes would be strongly hindered in these chelates; however, the steric interactions of these groups make these chelates themselves unstable (cf. $\log k$ values in Table 1), so that they are easily decomposed by relatively small amounts of OH^- ions, probaly through the following successive steps:

$$[Cu(R_2\text{-}en)_2]^{2+} + OH^- + H_2O \longrightarrow \left[(R_2\text{-}en)Cu\begin{matrix}OH\\ \cdot\cdot OH_2\end{matrix}\right]^{+} + R_2\text{-}en$$

I

$$2\,I \longrightarrow \left[(R_2\text{-}en)Cu\begin{matrix}OH\cdot\cdot\\ \cdot\cdot OH\end{matrix}Cu(R_2\text{-}en)\right]^{2+}$$

II

$$+2H_2O$$

$$\left.\begin{matrix}I & +OH^-\\ II/2 & +OH^-\end{matrix}\right\} \longrightarrow [(R_2\text{-}en)Cu(OH)_2]^0$$

III

In fact, Pfeiffer and Glaser[1] obtained binuclear complexes like II by using *N, N'*-trialkylated ethylenediamines as ligands, and Martell et al.[14] recently studied the equilibria involving chelates of types I, II and III by using ligands which are very similar to those in this study.

Therefore, it seems probable that the spectral changes in Fig. 4 are due to these decomposition reactions, which lead eventually to the complexes of the type $[Cu\,en(OH)_2]$ with no electric charge. Experimental data supporting this point of view are also obtained from the studies of the behaviors of these chelates in paper electrophoresis.

Paper Electrophoresis Studies.—It was found by Maki[15] and also Ojima[16] that there is a marked parallel between the migration velocities

of ionic complexes in paper electrophoresis experiments and the magnitudes of their electric charges, if complexes with similar structures are used for comparison. The results of such experiments on the chelates studied here, carried out in solutions containing various amounts of sodium hydroxide, are shown in Fig. 5. In solutions containing no sodium

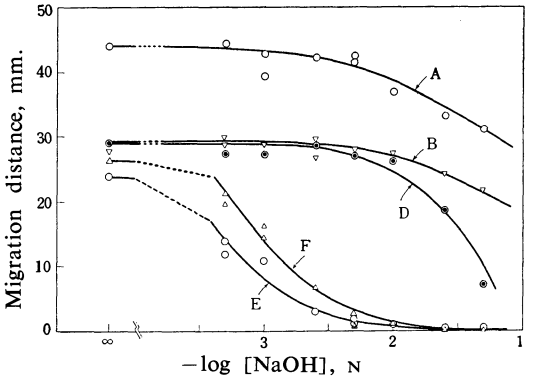

Fig. 5. Relation between migration distance and alkali concentration. A, B, ···, F: cf. Table I.

hydroxide, the mobilities of the alkylated chelates are all smaller than that of $[Cu\cdot en_2]^{2+}$ and are not very different from one another, although it seems that the mobility becomes smaller with the increase in substituted alkyl groups. The mobilities of the more stable chelates of ethylenediamine and tetramethyl- and *N*-propyl-ethylenediamines do not change very much with the addition of OH^- ions, and they gradually decrease when the alkali concentration becomes large, probably owing to the formation of $[Cu\,en_2OH]^+$-type complexes. On the other hand, the mobilities of the two other chelates begin to drop quickly and approach zero with an increasing alkali concentration, indicating the final formation of uncharged complexes. The color of the spots indicates, however, that there is no precipitation of $Cu(OH)_2$, and the tailing of the spots observed when the alkali concentration is $5\sim25\times10^{-4}$ N suggests the coexistence of two or more complex species in solution. All these findings are in accord with the foregoing considerations based on the spectral changes of these chelates.

Catalytic Behavior in the Chemiluminescence of Luminol.—It was shown earlier by Ojima[17,18] that the chemiluminescence emitted in the reaction between luminol (5-aminophthalaz-1, 4-dione) and hydrogen peroxide in alkaline solution is remarkably intensified by various amine complexes of copper. The mode of this catalytic action depends strongly on the nature of the amine used; NH_3, pyridine, and primary aliphatic amines are all effective, but complex solutions containing these ligands in a great excess (Cu: amine=1: several hundreds when the concentration of Cu^{2+} is 5×10^{-6} g. ion/7 ml.) must be used to obtain the maximum effect. On the other hand, only a small quantity of ethylenediamine (Cu: en=approx. 1:2) is sufficient to create an effect of similar magnitude, and the luminescence is markedly hindered when ethylenediamine is added in excess.

On the basis of these and other results, Ojima postulated the formation of an intermediate complex $[Cu\cdot en\cdot(\text{luminolate anion})]^+$ in such media, which reacts more easily with hydrogen peroxide than free luminol, emitting a stronger luminescence than that of the latter.

It was found that all the chelates studied here show the same catalytic effect; the relation between the observed luminescent intensities and alkali concentrations are shown in Fig. 6, and the relation between the maximum intensities in this figure and the chelate stabilities is shown in Fig. 7. It is clear from these data that the catalytic activity increases with the decreasing chelate stability; this fact is also in conformity with the mechanism postulated above, since the formation of the complex $[Cu\cdot en\cdot(\text{luminolate anion})]^+$ will be facilitated by the instability of the original chelate.

It is certain that many further studies are

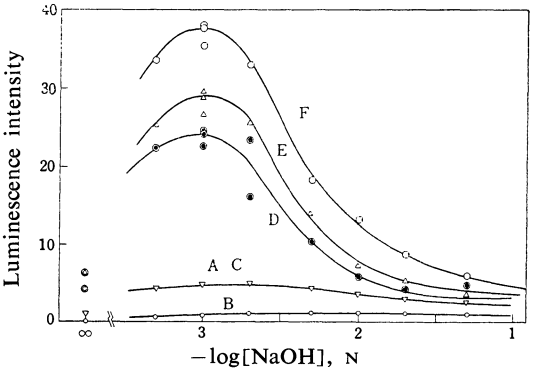

Fig. 6. Relation between chemiluminescence intensity and alkali concentration in the reaction mixture. A, B, ···, F: cf. Table I.

17) H. Ojima, ibid., **79**, 1076 (1958); **80**, 965, 1371 (1959); **81**, 1785 (1960).

18) Recently, the authors found that the data of B. Kirson (*Bull. soc. chim. France*, **1956**, 1793; **1957**, 257) on the catalytic decomposition of H_2O_2 by copper complexes are of special interest in connection with this problem. Some data on the absorption spectra of Cu-ammine complexes are also given in his papers. However, the possible relation of his results to those of the authors will be discussed more fully elsewhere.

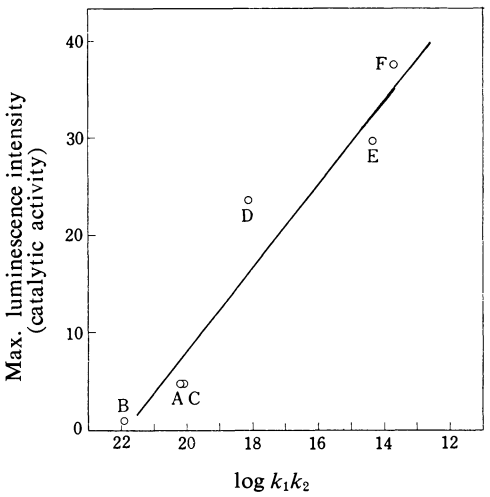

Fig. 7. Relation between catalytic activity and chelate stability. A, B,···, F: cf. Table I.

needed to get a clear understanding of this complicated reaction; however, even apart from the discussions of the reaction mechanism, the data in Figs. 6 and 7 are of practical interest, because they suggest a new method of estimating chelate stabilities with the aid of chemiluminescence measurements, although its application will be limited to certain favorable cases like the present ones.

Summary

The absorption spectra of the copper chelates of ethylenediamine and several alkylated ethylenediamines were studied in their aqueous solutions, and an approximately linear relationship was found between the frequencies of their absorption maxima and the logarithms of their stability constants. The spectral changes caused by the addition of a strong base (sodium hydroxide) to these solutions, and the activities of these chelates to catalyze the chemiluminescent reaction of luminol with sodium peroxide in an alkaline solution, were also studied; it was shown that the chelates with smaller stabilities show, in general, more drastic spectral changes and higher catalytic activities than those with larger stabilities.

The authors are grateful to Professor Fred Basolo of Northwestern University, Evanston, Ill., U. S. A., for his invaluable gift of chelate samples, and also to Professor Hatsusaka Kato of their University for his encouragement throughout this study.

*Polymerization of Olefines by Ziegler Catalyst. II. Polymerization of Ethylene by $AlEt_3$-$TiCl_4$ Catalyst**

By Kenichi FUKUI, Tsutomu KAGIYA, Sueo MACHI, Takeo SHIMIDZU and Sachio YUASA

(Received June 13, 1961)

Since polymerization of ethylene at low pressure and temperature in the presence of the catalyst obtained from the interaction of titanium tetrachloride with aluminum trialkyl has been discovered by Ziegler[1], several studies on this type of polymerization have been reported.

The present paper concerns a study on ethylene polymerization with $AlEt_3$-$TiCl_4$ catalyst as an extension of the investigation previously reported[2] for propylene polymerization with the same catalyst. The reaction conditions are correlated with the polymerization rate as well as with the properties of polymers.

Experimental

Ethylene was produced by dehydrating ethanol over activated alumina at 350°C and then liquefied under pressure and distilled. The purity of the gas is more than 99.9%. Other materials and the apparatus were exactly the same as those described

* Presented at the 11th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1958.

1) K. Ziegler, Belg. Pat. 533362 (1954).

in the previous paper[2]. Introduction of catalyst into the reaction vessel was made in a nitrogen stream by pipetting a definite amount of titanium tetrachloride solution (0.15 M. solution in *n*-heptane) followed by adding triethyl aluminum solution (0.9 or 3.0 M solution in *n*-heptane) at room temperature (15~20°C). Immediately after the addition of the catalyst, the inner nitrogen was purged under reduced pressure. After the temperature was raised to the desired one, the pressure was then raised to a definite one by introducing compressed ethylene gas. The polymerization then started. It always took 20 min. from the addition of the catalyst to the introduction of ethylene gas. The pressure decreased during the reaction, and was recorded to estimate the reaction rate. In addition, some experiments were carried out under constant pressure.

The number average molecular weight, $\overline{M}_n$, was estimated by the intrinsic viscosity measurement in tetralin at 130°C, using Tung's formula[3],

$$[\eta] = 5.10 \times 10^{-4} \overline{M}_n^{0.725}$$

Results and Discussion

The experimental results obtained are shown in the following several figures. The discussions will be made in regard to two items; namely, the molecular weight and the polymerization rate.

Molecular Weight.—The dependence of the molecular weight on the various factors is shown in Figs. 1, 2 and 3, which make it clear that the important factors affecting the molecular weight are the ratio of triethylaluminum to titanum tetrachloride. The increase in the reaction temperature and the amount of catalyst makes the molecular weight decreased to some extent, as shown in Fig. 1, where the ratio of triethylaluminum to titanium tetrachloride is kept constant. As shown in Fig. 2, the molecular weight also increases sharply with the ratio of triethylaluminum to titanium

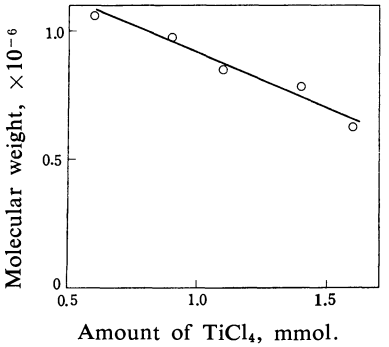

Fig. 1. Molecular weight vs. amount of $TiCl_4$. ($AlEt_3/TiCl_4$, 6.7; Solvent, 16 ml.; Temperature, 50°C; Initial pressure, 43 kg./cm²; Reaction time, 120 min.)

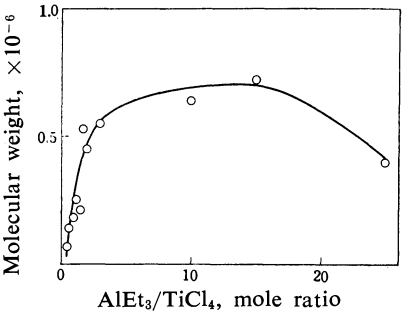

Fig. 2. Molecular weight vs. $AlEt_3/TiCl_4$ ratio. ($TiCl_4$, 1.2 mmol.; Solvent, 16 ml.; Temperature, 50°C; Initial pressure, 43 kg./cm²; Reaction time, 120 min.)

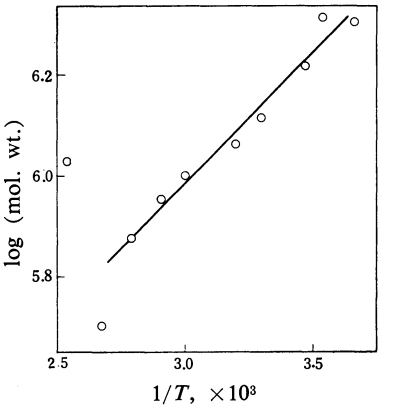

Fig. 3. Molecular weight vs. reaction temperature.
($TiCl_4$, 1.2 mmol.; $AlEt_3$, 8.0 mmol.; Solvent, 16 ml.; Initial pressure, 43 kg./cm².; Reaction time, 120 min.)

tetrachloride in the range from 0 to 3, but it is only slightly affected with more addition of trithylaluminum, where the amount of titanium tetrachloride is kept constant. The molecular weight decreases nearly exponentially with temperature rise. As shown in Fig. 3, the plot of the logarithm of molecular weight versus the reciprocal of absolute temperature gives a straight line. The dependences of the molecular weight on the temperature and the ratio of two components of catalyst are almost the same as the case of polypropylene produced by the same catalyst[2].

Recently, Badin[4] reported that the molecular weight of polyethylene produced by $TiCl_4$-Al·(i-C_4H_9)$_3$ catalyst, was decreased with raising reaction temperature, with increased ratio of $TiCl_4$ to Al(i-C_4H_9)$_3$, and with increasing amount of catalyst. These are coincident with our present results.

Rate of Polymerization. — Several pressure-reaction time curves are shown in Fig. 4. This

3) L. H. Tung, *J. Polymer Sci.*, **24**, 333 (1957).

4) E. J. Badin, *J. Am. Chem. Soc.*, **80**, 6545 (1958).

experiment is carried out in a batch type reaction vessel. These curves, of course, represent the diminishing ethylene pressure which causes the fall of polymerization rate. But, as was previously observed in the polymerization of propylene with the same catalyst, the polymerization rate falls even at a constant ethylene pressure. An experiment is carried out at a constant ethylene pressure, and the result is shown in Fig. 5.

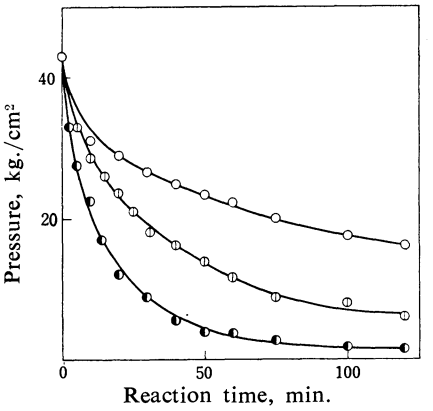

Fig. 4. Pressure vs. reaction time.
○ $TiCl_4$, 1.2 mmol.; $AlEt_3$, 0.96 mmol.;
◐ $TiCl_4$, 1.1 mmol.; $AlEt_3$, 7.4 mmol.;
◑ $TiCl_4$, 1.6 mmol.; $AlEt_3$, 10.7 mmol.;
Solvent, 16 ml; Temperature, 50°C.

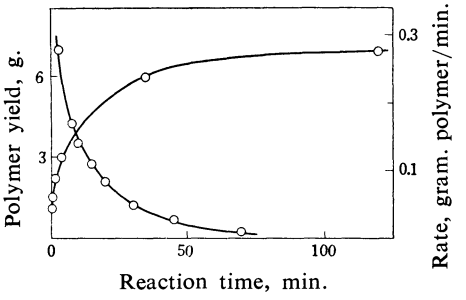

Fig. 5. Polymer yield vs. reaction time.
($TiCl_4$, 0.68 mmol.; $AlEt_3$, 4.65 mmol.; Solvent, 16 ml.; Temperature, 30°C; Pressure, 11 kg./cm².)

In order to decide the dependence of the rate on ethylene pressure, the initial rate is analyzed. Figure 6 shows that the initial rate is almost proportional to the ethylene pressure over the range of 0~30 kg./cm² (Ludlum et al.[5] reported that the rate of ethylene polymerization with $TiCl_4$-$LiAlR_4$ catalyst was also proportional to ethylene pressure). Thus the "specific" rate should be defined by the rate divided by ethylene pressure. The estimation

5) D. B. Ludlum, A. W. Anderson and C. E. Ashby, ibid., **80**, 1380 (1958).

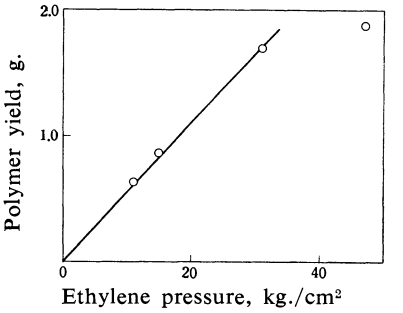

Fig. 6. Polymer yield during initial 90 sec. vs. reaction pressure.
($TiCl_4$, 0.6 mmol.; $AlEt_3$, 3.6 mmol.; Solvent, 16 ml.; Temperature, 30°C; Reaction time, 90 sec.)

of the rate of polymerization from the curves of Fig. 4 is made in the same manner as described in the previous paper. Namely, the pressure drop during the first 30 min. divided by the mean pressure times the duration of reaction (30 min.) is used as a measure of the rate. This value is indicated in Figs. 7, 8 and 9 as the "mean specific rate".

Dependence of Rate on the Amount of Catalyst. —Figure 7 indicates that the mean specific rate is almost proportional to the amount of titanium tetrachloride, where the ratio of triethylaluminum to titanium is kept constant. This result is the same as that obtained in the polymerization of propylene. That this curve does not pass through the origin might be due to the impurities.

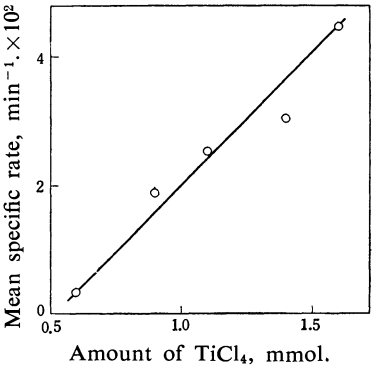

Fig. 7. Mean specific rate vs. amount of $TiCl_4$.
($AlEt_3/TiCl_4$, 6.7; Solvent, 16 ml.; Temperature, 50°C; Initial pressure, 43 kg./cm².)

Dependence of Rate on Catalyst Composition. —With a definite amount of titanium tetrachloride, the rate varies with the amount of triethylaluminum added as shown in Fig. 8. The rate increases rapidly with the increase in the amount of triethylaluminum and then maintains an almost constant value over the range of which the ratio of triethylaluminum

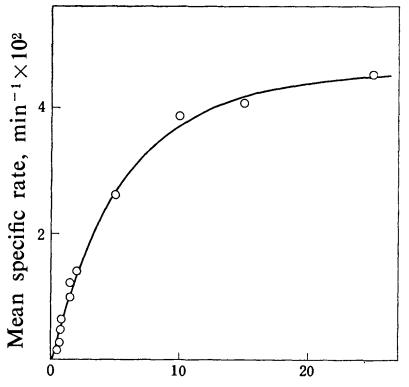

Fig. 8. Mean specific rate vs. $AlEt_3/TiCl_4$ ratio.
($TiCl_4$, 1.2 mmol.; Solvent, 16 ml.; Temperature, 50°C; Initial pressure, 43 kg./cm^2)

to titanium tetrachloride is from 10 to 25.

Temperature Dependence of Rate.—The plot of the logarithm of the rate against the reciprocal of absolute temperature is shown in Fig. 9. The rate first increases with temperature rise and then falls off at higher temperatures. The temperature to give the maximum rate is 85°C. The straight line in the range from 0 to 85°C gives an "apparent" activation energy of 1.0 kcal./mol. To estimate the value of activation energy corresponding to the pure polymerization step in the liquid phase, the heat of solution of ethylene in *n*-heptane is calculated from known data[6], which amounts to −1.7 kcal./mol. Consequently, 2.7 kcal./mol. for the activation energy of polymerization in the liquid phase is obtained.

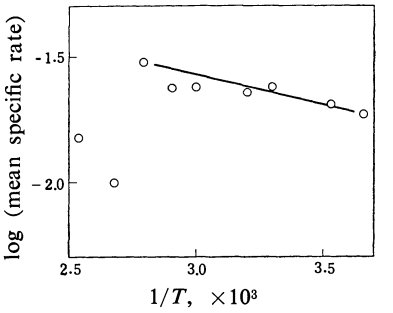

Fig. 9. Mean specific rate vs. reaction temperature.
($TiCl_4$, 1.2 mmol.; $AlEt_3$, 8.0 mmol.; Solvent, 16 ml.; Initial pressure, 43 kg./cm^2)

The decrease of the rate at higher temperatures may be due to the deterioration of the catalyst as has been observed in the propylene polymerization by $AlEt_3$-$TiCl_4$ catalyst[2].

*Polymerization of Olefines by Ziegler Catalyst. III. Polymerization of Ethylene by $AlEt_3$-$TiCl_3$ Catalyst**

By Kenichi FUKUI, Tsutomu KAGIYA, Sueo MACHI, Takeo SHIMIDZU and Sachio YUASA

(Received June 13, 1961)

As an extension of the investigation previously reported for ethylene[1] and propylene[2] polymerization with $AlEt_3$-$TiCl_4$ catalyst, a study on the polymerization of ethylene by means of $AlEt_3$-$TiCl_3$ catalyst is described in the present paper. No report of the study on the ethylene polymerization with $AlEt_3$-$TiCl_3$ catalyst is found, while the polymerization of propylene with the same catalyst has been studied by Natta et al.[3]

Experimental

The apparatus and the procedure adopted was utterly the same as those described in the previous paper[1,2]. Titanium trichloride was due to the Sumitomo Chemical Co., Ltd. Introduction of the catalyst components into the autoclave was made by pipetting an amount of a dispersion of titanium trichloride in *n*-heptane (78 g. titanium trichloride

* Presented at the 7th Annual Meeting of the High Polymer Chemical Society, Tokyo, May, 1958.

in 1000 ml. *n*-heptane) followed by addition of triethylaluminum solution (0.9 mol. solution in *n*-heptane), and then a suitable amount of *n*-heptane), was added to make the total volume of solvent 16 ml. The number average molecular weight, $\bar{M}_n$, is estimated by the intrinsic viscosity at 130°C in tetralin solution, using Tung's formula[4],

$$[\eta] = 5.10 \times 10^{-4} \times \bar{M}_n^{0.725}$$

Result and Discussion

Molecular Weight.—Figures 1, 2 and 3 indicate that important factors affecting the molecular weight of polyethylene are the reaction temperature and the amount of catalyst. Figure 1 shows that the melecular weight decreases with the increase in the amount of titanium trichloride where the ratio of triethylaluminum to titanium trichloride is kept constant. The dependence of the molecular weight on the amount of catalyst is almost the same as in the case of ethylene polymerization using $AlEt_3$-$TiCl_4$ catalyst. It may be a characteristic feature of the Ziegler type catalysts that the molecular weight decreases with the amount of the catalyst. As shown in Fig. 2, the molecular weight is but little affected by the quantity of triethylaluminium with a constant amount of titanium trichloride. But, in the range of 6~25 of $AlEt_3/TiCl_3$ ratio a tendency is observed that the molecular weight decreases slightly with the increase in the amount of triethylaluminum. The plot of the logarithm of the molecular weight versus the reciprocal of reaction temperature in an absolute scale is shown in Fig. 3. A decrease in the molecular weight with the increase in temperature has also been observed in the present case, as in the preceding two papers[1,2].

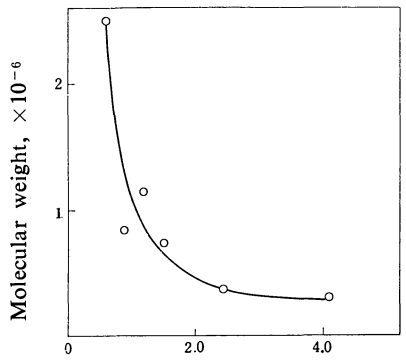

Fig. 1. Molecular weight vs. amount of $TiCl_3$. ($AlEt_3/TiCl_3$, 6.7; Temperature, 50°C; Initial pressure, 42 kg./cm²: Reaction time, 120 min.)

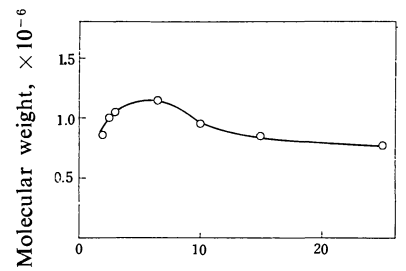

Fig. 2. Molecular weight vs. $AlEt_3/TiCl_3$ ratio. ($TiCl_3$, 1.2 mmol.; Temperature, 50°C; Initial pressure, 42 kg./cm²; Reaction time 120 min.)

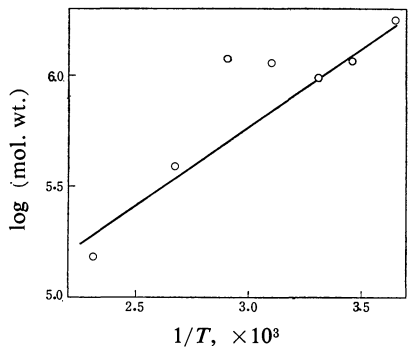

Fig. 3. Molecular weight vs. reaction temperature.
($TiCl_3$, 1.2 mmol.; $AlEt_3$, 8.0 mmol.; Temperature, 50°C; Initial pressure, 42 kg./cm²; Reaction time, 120 min.)

Rate of Polymerization.—The pressure drop was observed at every moment with regard to each run of an experiment. As shown in Fig. 4, the plot of $\log(P_0/P)$ versus reaction time

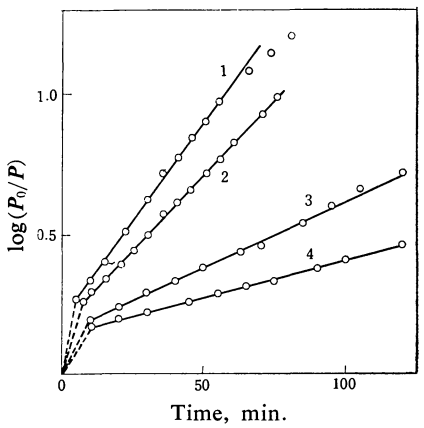

Fig. 4. $\log(P_0/P)$ vs. reaction time.

	$TiCl_3$ mmol.	$AlEt_3$ mmol.	Temperature °C
(1)	1.2	12.0	50
(2)	1.2	8.0	50
(3)	1.2	3.6	50
(4)	1.2	8.0	50

P_0, 42 kg./cm²

4) L. H. Tung, *J. Polymer Sci.*, **24**, 333 (1957).

gives almost a straight line. This means that the rate is approximately proportional to the pressure except an initial short interval of reaction time.

In regard to all runs of an experiment, the specific rate is calculated and is related to the various factors as follows.

Dependence of Rate on the Amount of Catalyst. —Figure 5 indicates that the relation between the specific rate and the amount of catalyst is almost linear, where the ratio of triethylaluminum to titanium trichloride is kept constant.

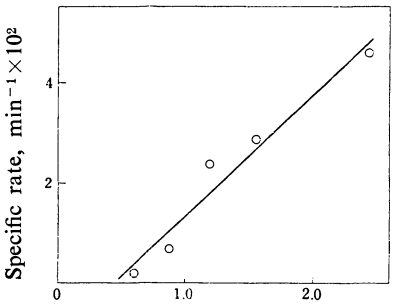

Fig. 5. Specific rate vs. amount of $TiCl_3$. ($AlEt_3/TiCl_3$, 6.7; Temperature, 50°C; Initial pressure, 42 kg./cm^2)

Dependence of Rate on Catalyst Composition. —With a constant amount of titanium trichloride, the rate grows with the increasing amount of triethylaluminum used, as shown in Fig. 6. The curve is very simple in comparison with that of the polymerization by means of $AlEt_3$-$TiCl_4$ catalyst. Natta et al.[3] already reported that the ratio of triethylaluminum to titanium trichloride did not affect the rate in the polymerization of propylene.

Temperature Dependence of Rate.—The logarithm of the rate is plotted against the reciprocal of absolute temperatue in Fig. 7. The straight line, obtained at 0~100°C, gives an apparent activation energy of 1.6 kcal./mol.

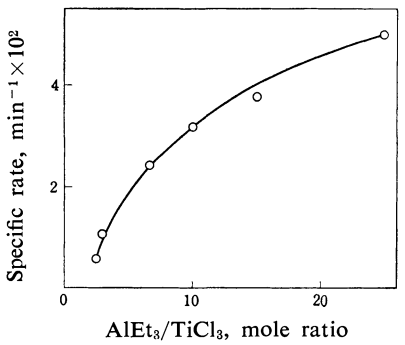

Fig. 6. Specific rate vs. $AlEt_3/TiCl_3$ ratio. ($TiCl_3$, 1.2 mmol.; Temperature, 50°C; Initial pressure, 42 kg./cm^2)

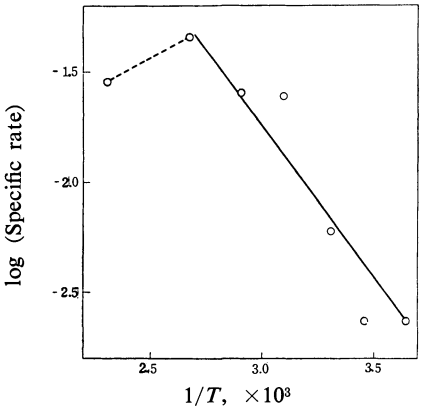

Fig. 7. Specific rate vs. reaction temperature. ($TiCl_3$, 1.2 mmol.; $AlEt_3$, 8.0 mmol.; Initial pressure, 42 kg./cm^2)

If the heat of solution of ethylene in the solvent, *n*-heptane, is added to the above value, 7.8 kcal./mol. is obtained as the activation energy of polymerization. Optimum temperature is 100°C and at higher temperatures a fouling up of the catalyst arises as has been observed in $AlEt_3$-$TiCl_4$ catalyst[2].

Rheological Properties of Thermo-reversible Gels

By Kiyoshi ARAKAWA

(Received June, 23, 1961)

In the preceding papers[1-3] the results of stress relaxation studies made on various kinds of thermo-reversible gels (for example, the gels of polyvinyl alcohol-glycerin-water system[1], the gels of polyvinyl alcohol-Congo red-water system[2], and the hydrogels of agar-agar[3]), were reported on.

In the present paper the author reports on the results of a more comprehensive study on the rheological properties of the thermo-reversible gels above described, including the results of a stress relaxation experiment on hydrogels of gelatin.

Experimental

A chainomatic balance relaxometer was used to measure the relaxation Young's modulus of hydrogels of gelatin, which was the same one as was used previously[1-3]. The intrinsic viscosity $[\eta]_{55°C}$ of a powder sample of gelatin in the presence of 0.15 M sodium chloride and at pH 7 was determined to be 0.21 (100 cc./g.) by means of a capillary viscometer of the Ostwald type, and the molecular weight M_n was estimated from the value to be about 2×10^4, according to the relation between M_n and $[\eta]_{55°C}$ which had been reported previously by Scatchard et al.[4] Cylindrical specimens of 17.5 wt.% were prepared and aged at about 0°C in liquid paraffin for more than two weeks. Before the experiment each specimen gel was brought to and kept at the temperature of measurement for five hours[5], and then the observation of the relaxation Young's modulus was started.

Results and Discussion

Stress Relaxation Data of Gelatin Gels.—The data of the relaxation Young's modulus of 17.5% gelatin gel under a constant compressional strain are given in Fig. 1. The amount of strain was 15% for all specimens. The mechanical behavior of the gel may be represented by a six-parameter model as shown in Fig. 2, and the relaxation Young's modulus $E_r(t)$ under constant strain is expressed by the following Eq. 1:

$$E_r(t)=E_1e^{-t/\tau_1}+E_2e^{-t/\tau_2}+E_3e^{-t/\tau_3} \quad (1)$$

in which

$$\tau_1 > \tau_2 > \tau_3$$

The values of the parameters obtained are given in Table I.

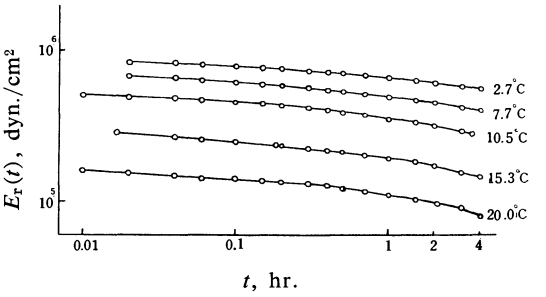

Fig. 1. Relaxation Young's modulus of 17.5% gelatin gel.

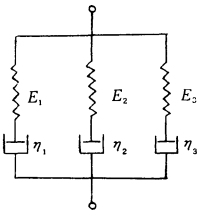

Fig. 2. Mechanical model.
$E_1/\eta_1=\tau_1$, $E_2/\eta_2=\tau_2$, $E_3/\eta_3=\tau_3$

Applcation of the Modified Time-Temperature Superposition Principle. — For the gels of the polyvinyl alcohol-glycerin-water system and those of the polyvinyl alcohol-Congo red-water system, the time temperature superposition principle[6] was applied successfully as has been reported previously[1,2] but the circumstances were found to be different in the hydrogels of agar-agar[3,7]; they were also found to be so in the hydrogels of gelatin, as is seen in Fig. 1.

Recently Nagamatsu, Takemura et al. have proposed the modified time-temperature superposition principle for crystalline polymers which include the vertical shift $\log b_T$ along

the log E_r axis as well as the usual horizontal shift log a_T along the log time axis[8].

The composite relaxation curve of 17.5% gelatin gels which has been obtained from the relaxation curves shown in Fig. 1 by the application of the modified superposition principle described above is shown in Fig. 3(a). Those of hydrogels of agar-agar which have been obtained according to the same procedure from the data previously reported[3,7] are also shown in Fig. 3(b). The values of the two kinds of shift factors log a_T and log b_T, are tabulated in Table II.

Structure of Thermo-reversible Gels.—Concerning those thermo-reversible gels which make the sol-gel transition reversibly, it may be generally said that the junctions supporting the network structure in the gels are of a secondary nature, rather than of a primary nature (covalent bond) as in swollen gels, for example, the swollen gels of vulcanized rubber. Therefore, it may be also said that in the stress relaxation experiment of thermo-reversible gels, scission of network chains occurs at the junctions rather than along the network stands.

In a rubber network with N_0 moles of effective network chains, the relaxation Young's modulus $E_r(t)$ under constant strain is proportional to the moles of effective network chains $N(t)$ at the time t as follows:

$$\frac{E_r(t)}{E_r(0)}=\frac{N(t)}{N_0} \tag{2}$$

and with the assumption that the rate of bond cleavage at network junctions is of a first order:

$$-\frac{dN(t)}{dt}=kN(t) \tag{3}$$

in which k is the rate constant of the bond cleavage reaction. Then we obtain from Eqs. 2 and 3:

$$E_r(t)=E_r(0)e^{-kt} \tag{4}$$

Therefore, the reciprocal of k is found to be

8) K. Nagamatsu, T. Yoshitomi and T. Takemoto, *Memoirs Fac. Eng. Kyushu Univ.*, **30**, 259 (1958); K. Nagamatsu, T. Takemura, T. Yoshitomi and T. Takemoto, *J. Polymer Sci.*, **33**, 515 (1958); T. Takemura, ibid., **38**, 471 (1959).

equal to τ_1, which is obtained graphically[3] from the experimental curve according to Eq. 1, and then the activation energy $\Delta\bar{H}$ as an average, which is obtained from the the $\log \tau_1$ vs. $1/T$ relation, may be regarded as the activation energy of the bond cleavage reaction at the junctions. An example[2] the $\log \tau_1$ vs. $1/T$ relation is shown in Fig. 4.

$$\Delta\bar{H}=R\frac{\partial \ln \tau_1}{\partial(1/T)} \qquad (5)$$

Mol. wt. of agar-agar	Concn. of agar-agar, %	$\Delta\bar{H}$ kcal./mol.
8×10^3	1.0	4.8
	2.6	5.8
	4.1	4.5
4×10^4	2.6	6.6

Gelatin gel

Mol. wt. of gelatin	Concn. of gelatin, %	$\Delta\bar{H}$ kcal./mol.
2×10^4	17.5	5.8

The values of $\Delta\bar{H}$ thus obtained for various kinds of thermo-reversible gels are tabulated in Table III. Those for the gels of the polyvinyl alcohol-glycerin-water system[1,9] and the gels of the polyvinyl alcohol-Congo red-water system[2] are calculated from the data previously reported[1,2,9] by the six-parameter model analysis and Eq. 5, while those for the agar-agar gels are quoted from a previous paper[7]. The value for the gelation gel is calculated from the values of τ_1 given in Table I.

It is clearly seen in Table III that the values of $\Delta\bar{H}$ for the gels of the polyvinyl alcohol-glycerin-water system, those for the hydrogels of agar-agar, and the value for the gelatin gel are all substantially equal with each other irrespective of the difference in chemical species and, of course, of the differencce in molecular weight. It is also seen that the values of $\Delta\bar{H}$ of the gels above described are substantially equal to the activation energy for the hydrogen bond between water molecules, 4.5 kcal./mol.[10], and to the one for the hydrogen bond between ethyl alcohol molecules, 6.2 kcal./mol.[10] The values $\Delta\bar{H}$ for the gels of the polyvinyl alcohol-Congo red-water system are found in Table III to be a little larger than those values for the hydrogen bonds described above, and to be nearly equal to the value for the hydrogen bond in the micelle of neutral cellulose[11], for example.

Therefore, in the gels of the polyvinyl alcohol-glycerin-water system in which no ions or ionic groups are present, it may be said that the hydrogen bonds play the principal part as the linkages between chain molecules.

In the hydrogels of agar-agar and those of gelatin, considering that the relaxation curves behave like those of other crystalline polymers concerning the application of the modified superposition principle as described above, and that the values of $\Delta\bar{H}$ are substantially equal to those of polyvinyl alcohol-glycerin-water gels, it may be also tentatively said that the hydrogen bonds in the micelles play a more important part as the linkages in the network than ionic groups do.

In the gels of the polyvinyl alcohol-Congo red-water system, Congo red molecules are supposed to play an important role in the formation of the network structure[12]. Probably in this case the hydrogen bond is also important.

Summary

From the stress relaxation data of various kinds of thermo-reversible gels obtained by means of a chainomatic balance relaxometer, it has been found that:

1) The modified time-temperature superposition principle which includes the vertical shift along the $\log E_r(t)$ axis as well as along the log time axis can be successfully applied to the hydrogels of agar-agar and gelatin, and composite relaxation curves are obtained with good coincidence;

2) The activation energy $\Delta\overline{H}$ which is obtained from the τ_1 vs. $1/T$ relation and which is regarded as the activation energy of the bond cleavage process at the junctions in the network is substantially equal to the value of the hydrogen bond in water and ethyl alcohol for the gels of the polyvinyl alcohol-glycerin-water system and for the hydrogels of agar-agar and gelatin; the value of $\Delta\overline{H}$ is, however, a little larger for the gels of the polyvinyl alcohol-Congo red-water system.

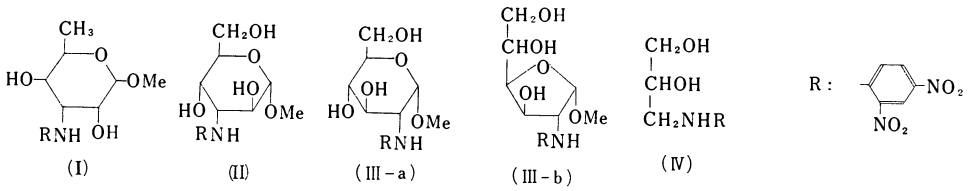
Periodic Acid Oxidation on N-Arylamino Alcohols

By Kiyoshi HATTORI, Hirokiti HARADA and Yoshimasa HIRATA

(Received June 28, 1961)



It has been known that the primary and secondary α-amino alcohols[1] are cleft by periodic acid like the vicinal glycols, whereas the tertiary α-amino alcohols are not, excepting a few examples[2]. Upon the periodic acid oxidation, the side reactions take place depending on the quantity of oxidant, temperature, pH, and even light. Some examples of such reactions have also been reported with phenols[3] and aromaitc amines[4] not containing the α-glycol or α-amino alcohol group.

The preparation of the *N*-2, 4-dinitrophenyl derivative of amine is widely used for the purpose of the isolation of amine from its mixture. We have also obtained an amino sugar in the form of *N*-2, 4-dinitrophenyl derivative from the antibiotic trichomycin. Investigations showed that this dinitrophenylamino sugar was not attacked by periodic acid[5] and was identical with the *N*-2, 4-dinitrophenyl derivative of mycosamine methyl glycoside obtained from pimaricin[6].

The cleavage reaction of the *N*-alkylamino alcohol group by periodic acid is well known[7], but that of the *N*-arylamino alcohol group is hardly known. In order to check the unreactivity of the above mentioned *N*-2, 4-dinitrophenyl derivative of mycosamine methyl glycoside (I), other *N*-2, 4-dinitrophenyl derivatives of amino alcohols have been examined.

Since it has been known that the *trans*-glycol group is difficultly attacked by periodic acid, methyl *N*-2, 4-dinitrophenyl-3-amino-3-deoxy-altroside (I) containing both cis and trans amino alcohol groups was studied. This compound was not attacked and the same applies for the *N*-2, 4-dinitrophenyl derivatives of D, L-serine and ethanolamine. These results indicated that the unreactivity of these compounds do not depend on the difference of the configuration of the amino and hydroxyl groups. Therefore, it can be said that the substitution of the *N*-2, 4-dinitrophenyl group on an amino alcohol almost protects the compound from the periodate oxidation. In general, the presence of an hydrogen atom on the amino nitrogen atom is important for the cleavage reaction of an amino alcohol by periodic acid, and in the case of the *N*-acetylated amino alcohol the reactivity is also reduced and no reaction occurs. Therefore, it might be inferred that one reason for the unreactivity of the *N*-2, 4-dinitrophenyl derivative is very similar to that

of the *N*-acyl substituent and lies in the strongly electron attracting property of the nitro group.

Jeanloz and Forchielli[8] reported that about six and two mole equivalents of periodic acid were consumed by one mole each of *N*-acetyl glucosamine and methyl *N*-acetyl glucosamide, respectively at 25°C. Similarly, as shown in Fig. 1, we observed that *N*-2, 4-dinitrophenyl-

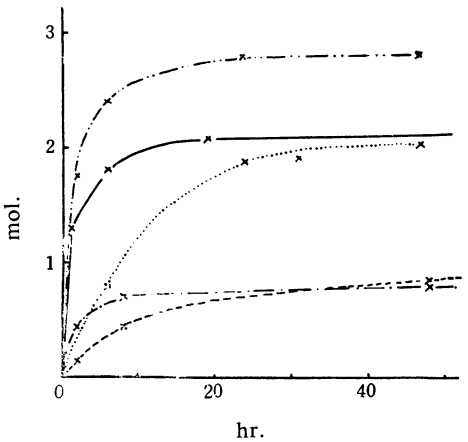

Fig. 1. Periodate consumption curves.
—··— *N*-2,4-Dinitrophenyl glucosamine
------ (III-a) mole ratio, 1 : 2
..... (III-a) mole ratio, 1 : 5
·—·— (III-b) mole ratio, 1 : 5
——— (IV)

D-α-methyl-glucopyranosamide (III-a) consumed one mole equivalent of the oxidant at 4°C, when the mole ratio of the reagent and sample was two. But anomalously when the mole ratio was increased to five, another one mole was consumed.

Another unusual example has been reported by Neuberger[9]; namely, *N*-benzoyl glucosamine was observed to be overoxidized by lead tetra-acetate. Since we had assumed the *N*-2, 4-dinitrophenyl substitution of α-amino alcohols had a masking effect towards periodic acid oxidation, the reactivity of compound III-a consuming two moles of the oxidant was unexpected. Further, the above-mentioned examples appeared to be very analogous, too. Besides, it was shown that 2, 4-dinitroanilino-1-propane-2, 3-diol (IV) consumed two mole equivalents of periodic acid, and that formaldeyde and formic acid were detected as the reaction products. The formation of formaldehyde was due to the normal cleavage of the α-glycol group. In order to avoid the side reaction, all experiments were run under the selected condition[10] in which the oxidation from aldehyde to acid did not occur. Therefore, the additional one mole consumption of periodic acid was caused by the cleavage reaction of the newly produced α-amino aldehyde group. With methyl *N*-2, 4-dinitrophenyl glucofuranosamide (III-b) having no possibility to produce the α-amino aldehyde group, the consumption of periodic acid was only one mole. From these results it might be said that the *N*-2, 4-dinitrophenyl derivative of the α-amino aldehyde group can be attacked by periodic acid, but that of the α-amino alcohol group can not be cleft under this condition even when the quantity of the oxidant is increased.

The unreactivity of the *N*-2, 4-dinitrophenyl-α-amino alcohol group towards periodate oxidation might suggest that the electron density of the amino nitrogen atom which is reduced by the nitro substitution has an important role in this reaction. In order to examine this effect of the nitro group, two mono-substituted aryl-amino alcohols were investigated as shown in Fig. 2. Since *N*-*p*-nitrophenylethanolamine consumed one mole equivalent of the oxidant, while *N*-*o*-nitrophenylethanolamine consumed only a small amount, it was presumed that the ortho substituted phenyl group might have a much greater masking effect against the attack

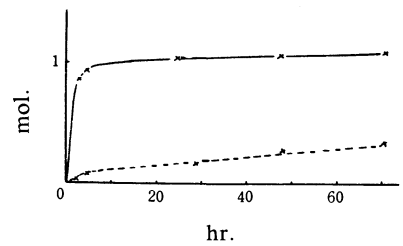

Fig. 2. Periodate consumption curves of *N*-*p*-nitrophenylethanolamine (——) and *N*-*o*-nitrophenylethanolamine (----).

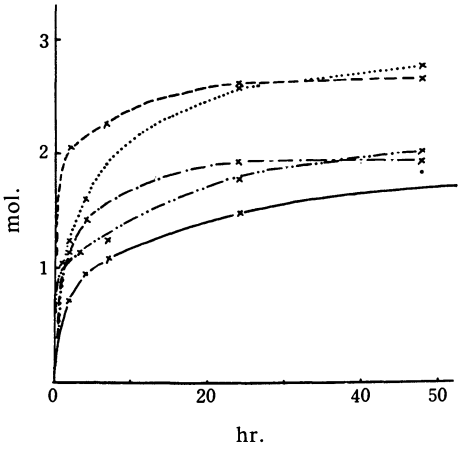
8) R. W. Jeanloz and E. Forchielli, *J. Biol. Chem.*, **188**, 361 (1951).
9) A. Neuberger, *J. Chem. Soc.*, **1941**, 47.
10) C. F. Huebner, S. R. Ames and E. C. Bubl, *J. Am. Chem. Soc.*, **68**, 1621 (1946); L. Hough, T. J. Taylor, C. H. S. Thomas and B. M. Woods, *J. Chem. Soc.*, **1958**, 1212.

of periodic acid than the para substituted isomer. Accordingly, the influence of various ortho substituents were investigated.

As shown in Fig. 3, all substituents excepting the nitro group showed no masking effect and gave the abnormally high consumption value



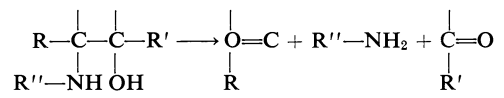


Fig. 3. Periodate cosumption curves.

X; OMe ·····, NH_2 ------,
Cl —·—, CH_3 ·—·—
H ———

of the oxidant. This tendency to afford the high consumption value was more apparent for the introduction of an amino or a methoxy group. As the pH of the reaction medium had some influence on the reaction curve as shown in Fig. 4, these measurements were all carried out in a constant buffer solution of pH 4.5. One of the factors giving such abnormally high consumption values might be considered to be the difference in electron negativity of the amino nitrogen atom, but other factors should be also considered, since the order of consumption and electron negativity was not parallelled, and the order was reversed for *N*-phenylethanolamine and *N*-*o*-chlorophenylethanolamine. The p*K* value of each amines was as follows; *N*-phenylethanolamine (3.8), *N*-*o*-nitrophenylethanolamine and *N*-*p*-nitrophenylethanolamine (below 2.5), *N*-*o*-methoxyphenylethanolamine (4.8), *N*-*o*-aminophenylethanolamine (4.6), *N*-*o*-chlorophenylethanolamine(2.6) in aqueous methanol (33%).

From the reaction scheme of α-amino alcohol[11] the abnormal consumption of periodic acid upon the *N*-arylamino alcohols might be caused by the oxidation of the newly produced aromatic amines. Tanabe has already investigated the periodate oxidation of aromatic amines in detail[4]. Thus we have examined the periodate oxidation of the aromatic amines which were expected to be produced by the oxidation of the *N*-arylamino alcohols, and straightforward results were obtained. An example shown in Fig. 5 indicated that the difference in the oxidation curves of *N*-*o*-chlorophenylethanolamine and *o*-chloroaniline gave the normal consumption value. The normal consumption curve of *N*-*o*-nitrophenylethanolamine was probably due to the property of *o*-nitroaniline which was not oxidized by periodic acid. Thus it was proved that the over-oxidation of *N*-arylaminoalcohols by periodic acid is due to the oxidation of the newly produced aromatic amine.

We are also investigating the masking property of other substituents including steric requirements, and will report on this subsequently.

Experimental

Preparation of Amino alcohols. — *N-2, 4-Dinitrophenyl Derivatives.*—Those were prepared by the usual condensation method of a primary amine and 2, 4-dinitrofluorobenzene in an alkaline medium. *N*-2, 4-Dinitrophenyl-D, L-serine[12], pale yellow crystals from aqueous ethanol, m. p. 198~201°C : *N*-2, 4-dinitrophenylethanolamine[13], yellow crystals from ether-methanol, m. p. 89~91°C : *N*-2, 4-dinitrophenyl glucosamine[14], pale yellow needle from benzene-methanol, m. p. 194~197°C : methyl *N*-2, 4-dinitrophenyl glucopyranosamide[14], yellow needle from acetone-ether, m. p. 212~214°C : methyl *N*-2, 4-dinitrophenyl glucofuranosamide[14], pale yellow needle from aqueous ethanol, m. p. 164~166°C : methyl *N*-2, 4-dinitrophenyl-3-amino-3-deoxy-D-altroside, yellow needle from aqueous methanol, m. p. 176~179°C : *N*-2, 4-dinitrophenyl-1-aminopropane-2, 3-diol, yellow crystals from aqueous ethanol, m. p. 82~83°C.

Found : N, 16.21. Calcd. for $C_9H_{11}N_3O_6$: N, 16.34%.

N-Phenylethanolamine.—This was prepared from aniline and ethylene chlorohydrin by the method of Knorr[15]. Pale yellowish viscid liquid of b. p. 151~156°C (16 mmHg). Benzoyl derivative, m. p. 90~92°C.

N-Nitrophenylethanolamine. — This was prepared from nitrochlorobenzene and ethanolamine as described by Kremer[16]. *N-o*-Nitrophenylethanolamine; deep orange needle from ethanol, m. p. 74~76°C.

Found : N, 15.44. Calcd. for $C_8H_{10}N_2O_3$: N, 15.38%.

N-p-Nitrophenylethanolamine ; golden yellow plate from ethyl acetate, m. p. 109~111°C.

Found : N, 15.51. Calcd. for $C_8H_{10}N_2O_3$: N, 15.38%.

N-o-Aminophenylethanolamine : By reduction of *o*-nitrophenylethanolamine with zinc and dilute acetic acid at 40°C, colorless plate crystals were obtained from benzene extraction and were recrystallized from benzene-ethanol, m. p. 105~107°C[17]. By the method of reductive acetylation, this compound was converted into *N, N'*-diacetyl-*o*-aminophenylethanolamine ; colorless needle, m. p. 128~130°C.

Found : C, 60.98 ; H, 6.71 ; N, 11.92. Calcd. for $C_{12}H_{16}N_2O_3$: C, 61.00 ; H, 6.83 ; N, 11.86%.

Further acetylation of this derivative changed to be *N, N', O*-triacetyl derivative ; colorless needle, m. p. 137~138°C.

Found : C, 60.23 ; H, 6.67 ; N, 10.28. Calcd. for $C_{14}H_{18}N_2O_4$: C, 60.42 ; H, 6.52 ; N, 10.02%.

N-o-Methoxyphenylethanolamine. — This was prepared by the method of Knorr[15] as pale yellowish liquid of b. p. 210~225°C (18 mmHg). This hydrochloride ; colorless crystals from ethanol, m. p. 149~153°C.

Found : N, 7.11. Calcd. for $C_9H_{13}O_2N \cdot HCl$: N, 6.91%.

N-o-Chlorophenylethanolamine.—This was prepared by the method of Dashen[18]. A fraction of b. p. 180~190°C (18 mmHg) was collected and converted into its hydrochloride ; colorless crystals from ethanol, m. p. 116~117°C.

Found : C, 45.99 ; H, 5.32 ; N, 6.88. Calcd. for $C_8H_{10}NOCl \cdot HCl$: C, 46.15 ; H, 5.33 ; N, 6.77%.

N-o-Tolylethanolamine.—After heating of a mixture of *o*-toluidine and ethylene chlorohydrin at 120°C for 6 hr., the fraction of b. p. 140~170°C (17 mmHg) was collected and dissolved in ethanol.

The insoluble fraction was *N, N'*-bistolylpiperazine ; sublimate at 166~168°C.

Found : C, 81.43 ; H, 8.49 ; N, 10.20. Calcd. for $C_{18}H_{22}N_2$: C, 81.16 ; H, 8.33 ; N, 10.52%.

The ethanol soluble fraction gave colorless crystals by treating with hydrochloric acid and ether. This was *N-o*-tolylethanolamine hydrochloride, recrystallized from ethanol, m. p. 134~135°C.

Found : C, 57.63 ; H, 7.46 ; N, 7.57. Calcd. for $C_9H_{13}NO \cdot HCl$: C, 57.59 ; H, 7.51 ; N, 7.46%.

Benzoyl derivative, m. p. 141~142°C.

Oxydation by Periodic Acid.—A quantity (about 0.02~0.03 mmol.) sample was dissolved in 2 cc. of methanol and added with about 3 equiv. of periodic acid, then the volume made up to 10 cc. with addition of pH 4.5 acetate buffer. The oxidation was carried out in a dark place at 4°C. A blank test was carried out similarly with the same concentration of periodic acid and no sample, and titration was practiced every times during the course of the oxidation. For the measurement of periodate consumption, 1 cc. of aliquot was pipetted into 3 cc. of saturated aqueous sodium bicarbonate solution, added with 2 cc. of N/100 arsenious acid solution and 1 cc. of potassium iodide (10%), and titrated with N/100 iodine solution.

N-2, 4-Dinitrophenyl derivatives of serine, ethanolamine, methylamine and methyl 3-amino-3-deoxy-altroside did not consume periodic acid after 72 hr., whenever the reaction temperature changed to 9°C or room temperature (about 20°C), and the quantity of oxidant changed to about six mole equivalents.

Production of formaldehyde was identified by making its 2, 4-dinitrophenylhydrazone and dimedone derivatives, and paper chromatographic analysis and mercuric chloride method[19] was applied for the detection of formic acid.

Summary

The authors have examined the cleavage reaction with periodic acid of the *N*-aryl-α-amino alcohols. It has been seen that the α-amino alcohols do not react with the oxidant when substituted by the *N*-2, 4-dinitrophenyl or *o*-nitrophenyl group. When *N*-aryl-α-amino aldehyde groups were produced during the course of oxidation, the normal cleavage reaction took place even if the substituent was a *N*-2, 4-dinitrophenyl group. An over-oxidation was observed in the periodate oxidation of other *N*-aryl-α-amino alcohols, and it was proved that the cause of such high consumption of periodic acid was due to the oxidation of the aromatic amine that was produced by the normal cleavage of the *N*-aryl-α-amino alcohol group.

The authors are indebted to Mr. S. Ohta for microanalyses, and to Dr. G. Huber for a sample of methyl 3-amino-3-deoxy-altroside, and we also wish to thank Dr. M. Ohara for his encouragement.

The Ignition of Methane-Oxygen Mixture by Reflected Shock Wave

By Momotaro SUZUKI, Hajime MIYAMA, Shiro FUJIMOTO and Tsuneo KASE

(Received June 26, 1961)

In a previous paper[1], measurements about the shock ignition of methane-oxygen mixture with a shock tube of 2.5 cm. internal diameter were reported. This time, measurements of the ignition of CH_4+2O_2 by reflected shock wave have been carried out with a shock tube which has a square cross section with an inside lateral of 5 cm. The tube is divided into three portions, a reservoir chamber 60 cm. in length, a buffer chamber 60 cm. in length and a test chamber 120 cm. in length. The buffer chamber was used to eliminate the effect of puncturing the membrane and was separated from a reservoir chamber by sheets of cellophane films and from a test chamber by a shutter. Details of the experimental procedure have been described elswhere[1-3]. The driver gas was air, the buffer gas a mixture of 88.8%

methane and 11.2% nitrogen, and the test gas a mixture of CH_4+2O_2. It was confirmed, as a result of piezo-electric measurements that almost all of ignitions were caused by the reflected shock waves[2] only the case of ignitions by reflected shock wave will be considered here, however.

The minimum pressures of the reservoir chamber necessary for igniting the detonable gas of the definite initial pressure were measured. By using the results of these measurements, the temperature T_r and pressure P_r behind the reflected shock wave were calculated[4]. In this calculation, a constant value of heat capacity of detonable gas was assumed because the variation of heat capacity caused a temperature decrease of less than 4% under our experimental conditions. In Fig. 1,

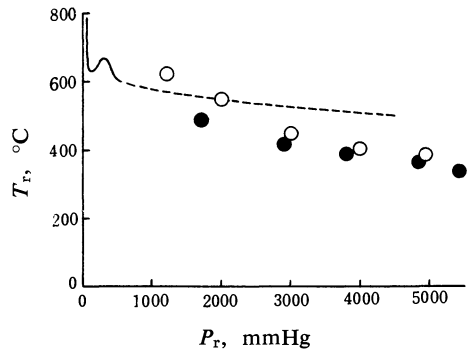

Fig. 1. Shock ignition limit expressed by T_r and P_r, where T_r and P_r are temperature and pressure behind reflected shock wave.
- ○ Shock ignition limit with a shock tube of 5 cm. inside lateral,
- ● Shock ignition limit with a shock tube of 2.5 cm. diameter[1],
- —— Thermal ignition limit by Neumann and Serbinoff[5],
- ------ Thermal ignition limit by Sagulin[6]

the explosion boundary is shown in terms of T_r and P_r. In the previous paper[1], it was shown that the shock ignition temperature is remarkably lower than the thermal ignition temperature. However, there was a mistake because the initial pressure of detonable gas was used instead of P_r. Corrected values from the previous data are shown in Fig. 1 for comparison. From this figure, it is obvious that the difference between the shock ignition and thermal temperatures[5,6] is not remarkable.

Sagulin[6] found that there is the following relationship in the reaction between aliphatic hydrocarbon and oxygen:

$$\log (P/T) = A/T + B$$

in which P is pressure (cmHg), T, ignition temperature (°K), and A and B are constants. Yamazaki and Kato[7] also found that this relationship can be applied to the cases of the ignitions of a propane-oxygen mixture by incident shock waves with a shock tube 2.6 cm. in diameter. In the present case, this relationship can be also observed, as is shown in Fig. 2, where Sagulin and Yamazaki's data are

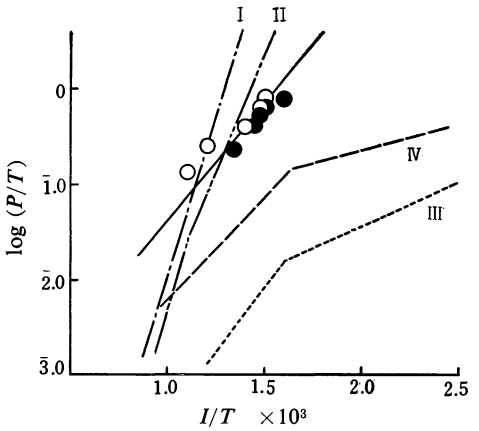

Fig. 2. Variation of log (P/T) with $1/T$ for the reaction of aliphatic hydrocarbon and oxygen.

shown for comparison. The slope of our line is very different from that of Sagulin's but similar to the slope of the initial part of Yamazaki's line III, although the position of our line is very far from that of line III. Although Yamazaki et al. used the initial pressure in their calculation, the pressure behind the incident shock wave should have been used. Therefore, we recalculated those values by using the pressure behind the incident shock wave and obtained line IV of Fig. 2. This corrected line is much closer to

our line, and the slope of the initial part of this line is almost the same as that of our line about methane-oxygen. This result seems to confirm their conclusion that the mechanism of the breaking C–H bond is predominant at the lower pressure of a propane-oxygen mixture*.

Department of Chemistry
Defense Academy
Yokosuka

* Sagulin found that the above-described linear relationship for ethane, propane and pentane consists of two parts, one at the lower pressure (i. e., at the lower value of P/T) and another at the higher pressure (i. e., at the higher value of P/T). Although the slope of the line at the higher pressure is different for the different hydrocarbons, the slope at the lower pressure is the same for ethane, propane and pentane; it is also as same as the slope for methane. From this result, Sagulin (and also Yamazaki et al.) concluded that the mechanism of the breaking C–H bond is predominant at the lower pressure and that of the breaking C–C bond at the higher pressure. Details are described in Refs. 6 and 7.

Electronic Spectra of Polynitrophenols and their Anions

By Takehiro ABE

(Received June 26, 1961)

In previous papers[1] it has been reported that, for *m*-dinitro- and 1, 3, 5-trinitro-benzene, a 260 mμ band of nitrobenzene shifted toward blue in the order of the increasing numbers of the nitro group, although substitution had been considered to shift in general the absorption of a parent molecule to longer wavelengths. High-intensity absorption bands of mono- and di-substituted benzenes, each containing only a strongly electron-attracting substituent, have been interpreted by Nagakura and Tanaka[2-5] in terms of the intramolecular charge transfer spectra. In the present paper, an attempt has been made to expand Nagakura and Tanaka's theory into high-intensity absorption bands of polynitrophenols and their anions, which contain two or three electron-attracting substituents. The absorption spectra of the polynitrophenols and their anions have been indicated in the Landolt-Börnstein table[6]. However, the spectra are not complete. In this work, the absorption spectra of *p*-nitrophenol, 2, 4-dinitrophenol and picric acid, all in water, were measured, if necessary, in the presence of either hydrochloric acid or sodium hydroxide in order to obtain the spectra of these polynitrophenols and their anions.

Experimental

Commercial grade polynitrophenols were recrystallized several times from water. Commercial grade hydrochloric acid and sodium hydroxide were used without further purification. The spectra of solutions were measured using a Hitachi EPU-2 spectrophotometer at room temperature. The length of absorption cells was 1 cm.

Results

The results of the measurements of the absorption spectra are shown in Fig. 1 and Table I. The spectrum of an aqueous picric acid solution (2.69×10^{-5} M) containing hydrochloric acid at a concentration 4.8 N is considered to be due almost entirely to the undissociated picric acid, because the spectrum is nearly identical with that of a hydrochloric acid concentration of 7.2 N. Therefore, *p*-nitrophenol and 2, 4-dinitrophenol, whose dissociation constants are smaller than that of picric acid, are not dissociated in water containing 4.8 N hydrochloric acid. Aqueous solutions both of 4.8 N hydrochloric acid and of 4.2×10^{-2} N sodium hydroxide scarcely absorb in wavelength regions above 230 mμ. An absorption at 31300 cm^{-1} for *p*-nitrophenol is only slightly more intense in the aqueous hydrochloric acid solution (4.8 N) than in pure water, so that it is known that *p*-nitrophenol is mostly undissociated in water at room temperature (ca. 25°C). 2, 4-Dinitrophenol absorbs somewhat more strongly at 27600 cm^{-1} and slightly more weakly at

TABLE I. ULTRAVIOLET ABSORPTION BANDS OF THE POLYNITROPHENOLS AND THEIR ANIONS (IN cm^{-1})

p-Nitrophenol	31300*	44300			
p-Nitrophenolate anion	24900*	38000^s	41000^s		
2,4-Dinitrophenol	33000^s	37900*			
2,4-Dinitrophenolate anion	25000^s	27600*	38600 ?	45000	
Picric acid	29100	35000^s	42000*		
Picrate anion		25000^s	28300*	41000^s	45000^s

The marks of * and ^{s} denote the long wavelength absorption maxima (except for the case of picric acid) and the absorption shoulders, respectively.

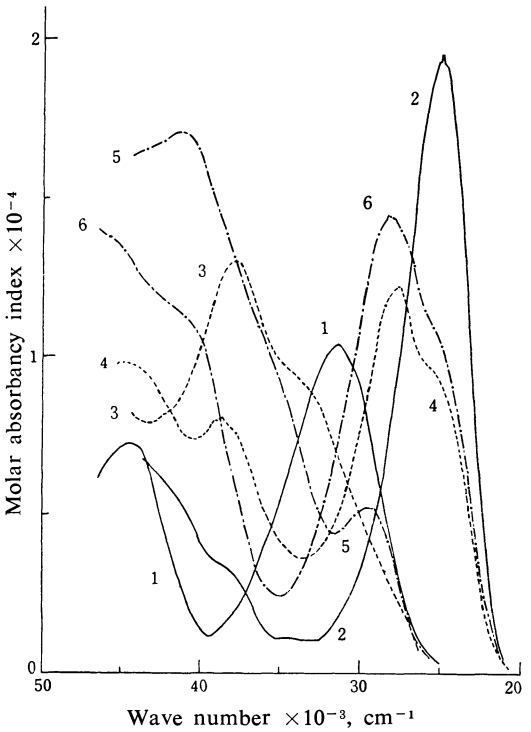

Fig. 1. Absorption spectra of aqueous solutions of the polynitrophenols.

1 An aqueous solution of *p*-nitrophenol (*p*-nitrophenol)
2 An aqueous 4.2×10^{-2} N sodium hydroxide solution of *p*-nitrophenol (*p*-nitrophenolate anion)
3 An aqueous 4.8 N hydrochloric acid solution of 2,4-dinitrophenol (2,4-dinitrophenol)
4 An aqueous solution of 2,4-dinitrophenol (2,4-dinitrophenolate anion)
5 An aqueous 4.8 N hydrochloric acid solution of picric acid (picric acid)
6 An aqueous solution of picric acid (picrate anion)

38600 cm^{-1} in the aqueous sodium hydroxide solution (4.2×10^{-2} N) than in water. From this it follows that 2,4-dinitrophenol (2.77×10^{-5} M) is dissociated to a large extent in water at room temperature, giving the 27600 cm^{-1} band, although it is not so distinct that the 2,4-dinitrophenolate anion also gives a band at 38600 cm^{-1}. A 28300 cm^{-1} band of picric acid has almost the same intensity in water as in an aqueous sodium hydroxide solution (4.2×10^{-2} N). This means that picric acid (2.69×10^{-5} M) is almost dissociated in water at room temperature. From the above results one can conclude that the absorption curves 1—6 in Fig. 1 are due to *p*-nitrophenol, *p*-nitrophenolate anion, 2,4-dinitrophenol, 2,4-dinitrophenolate anion, picric acid and picrate anion respectively, except for the 38600 cm^{-1} band in absorption curve 4.

In the present work, the absorption spectra of both 2,4-dinitrophenol and picric acid may probably be affected both by intramolecular hydrogen bonds and by intermolecular ones, since it is well known that the formation of a hydrogen bond has an effect on the near ultraviolet absorption spectra of many aromatic compounds*.

In addition to the hydrogen bonds, it is to be expected that, in both 2,4-dinitrophenol and picric acid, steric hindrances between the hydroxyl groups and the adjacent nitro groups will occur, affecting their spectra.

According to the Landolt-Börnstein table[6], *p*-nitrophenol and its anion show absorption shoulders near 36000 and 28000 cm^{-1} respectivery. These shoulders, although they seem to appear, can not be perceived distinctly in absorption curves 1 and 2 in Fig. 1.

From Fig. 1 and Table I one can see that the long wavelength absorption maxima of the polynitrophenols shift toward blue in the order of *p*-nitrophenol, 2,4-dinitrophenol and picric acid, all having increasing molar absorbancy indexes in the same order, and that the absorption maxima of these polynitrophenolate anions similarly shift toward blue with the increasing number of the nitro groups. The absorption maximum of each anion lies at a longer wavelength than does that of the corresponding polynitrophenol. This red shift is greater with the increasing number of the nitro group.

* For example: a) S. Nagakura and H. Baba, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), 71, 527, 560, 610 (1950); 72, 3 (1951); *J. Am. Chem. Soc.*, 74, 5693 (1952). b) N. D. Coggeshall and E. M. Lang, ibid., 70, 3233 (1948).

Discussion

The longer wavelength absorption maximum of *p*-nitrophenol has been interpreted by Nagakura and Tanaka[3,4] in terms of the intramolecular charge transfer involving an excitation of a bonding π-electron of the highest occupied energy-level of phenol to a vacant energy-level of the nitro group, as illustrated in Fig. 2. According to Nagakura and Tanaka's theory[2-5], all high intensity absorption bands of the polynitrophenols and their anions may be similarly interpreted as due to intramolecular charge transfers. From the viewpoint of the theory, these bands will be briefly discussed below.

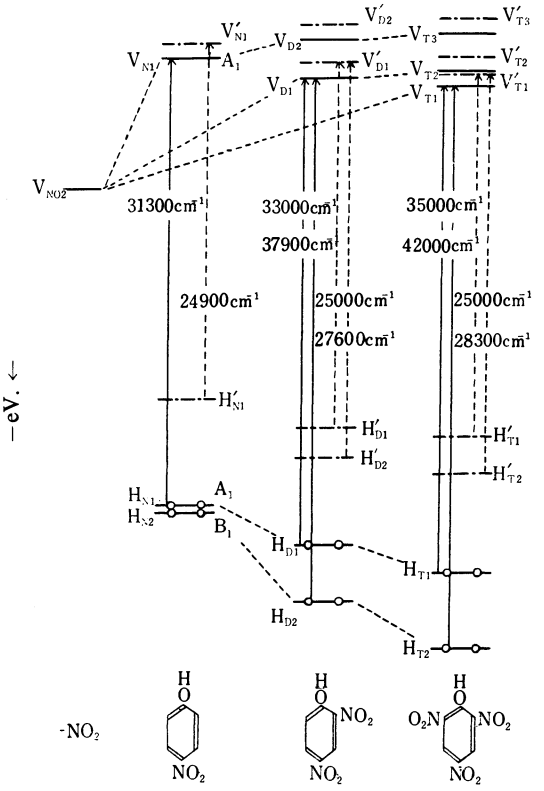

Fig. 2. The highest occupied and lowest vacant energy-levels for the polynitrophenols (——) and their anions (—·—).

When one more nitro group is substituted for hydrogen in a 2-carbon atom of *p*-nitrophenol, the highest occupied π-levels (H_{N1} and H_{N2}) of *p*-nitrophenol can be expected to interact mainly with the vacant energy-level V_{NO2} of the second entering nitro group, because both H_{N1} and H_{N2} are widely separated from the occupied energy-levels of the nitro group or have no interaction with them. H_{N1} lies close to H_{N2}. According to Nagakura and Tanaka, as the result of the interaction with V_{NO2}, the highest occupied energy-level H_N ($=H_{N1}$ or H_{N2}) is shifted by the following amount:

$$\Delta E_N = 1/2 \cdot [(V_{NO2} - H_N) - \{(H_N - V_{NO2})^2 + 4C_N^2 C_{NO2}^2 \beta^2\}^{1/2}] \quad (1)$$

Here C_N is a coefficient of an atomic orbital of the 2-carbon atom in a molecular orbital of H_N, C_{NO2}, a coefficient of an atomic orbital of a nitrogen atom in a molecular orbital of V_{NO2}, and β, a resonance integral between the two atomic orbitals of the carbon atom and the nitrogen. Similarly, V_{NO2} may interact mainly with H_{N1}, H_{N2} and V_{N1}, which are relatively near V_{NO2}. V_{N1} is the lowest vacant energy-level in *p*-nitrophenol. In 2, 4-dinitrophenol, therefore, V_{NO2} of the second nitro group may be sifted as follows:

$$\begin{aligned}\Delta E_{NO2} = {} & 1/2 \cdot [(H_{N1} - V_{NO2}) \\ & + \{(H_{N1} - V_{NO2})^2 + 4C_{N1}^2 C_{NO2}^2 \beta^2\}^{1/2}] \\ & + 1/2 \cdot [(H_{N2} - V_{NO2}) \\ & + \{(H_{N2} - V_{NO2})^2 + 4C_{N2}^2 C_{NO2}^2 \beta^2\}^{1/2}] \\ & + 1/2 \cdot [(V_{N1} - V_{NO2}) \\ & - \{(V_{N1} - V_{NO2})^2 + 4C_{VN1}^2 C_{NO2}^2 \beta^2\}^{1/2}]\end{aligned} \quad (2)$$

in which formula C_{VN1} is a coefficient of an atomic orbital of the 2-carbon atom in a molecular orbital of V_{N1}. By the simple LCAO MO method Nagakura[3] calculated the square values of the coefficients for *p*-nitrophenol as $C_{N1}^2 = 0.100$, $C_{N2}^2 = 0.250$ and $C_{VN1}^2 = 0.009$. By putting these values in Eq. (1), one knows that H_{N2} interacts more strongly with V_{NO2} than does H_{N1}. This suggests that an intramolecular charge transfer band due to an $H_{N2} \rightarrow V_{NO2}$ ($H_{D2} \rightarrow V_{D1}$) transition appears at a shorter wavelength than that for an $H_{N1} \rightarrow V_{NO2}$ ($H_{D1} \rightarrow V_{D1}$) transition. The two bands at 33000 and 379000 cm^{-1} for 2, 4-dinitrophenol may be associated with the transitions, $H_{D1} \rightarrow V_{D1}$ and $H_{D2} \rightarrow V_{D1}$, respectively. According to Eq. 2, the main interactions of V_{NO2} with H_{N1} and H_{N2} can be expected to raise V_{NO2} considerably, since C_{VN1}^2 is negligibly smaller than either C_{N1}^2 or C_{N2}^2. The support for this expectation comes from the fact that the band due to the $H_{D1} \rightarrow V_{D1}$ transition in dinitrophenol is at a shorter wavelength than for the $H_{N1} \rightarrow V_{N1}$ transition in nitrophenol; from this blue shift it follows that $(H_{N1} - H_{D1}) > (V_{N1} - V_{D2})$. From the above discussion, the observed 33000 and 37900 cm^{-1} bands of 2, 4-dinitrophenol may be interpreted as indicated in Fig. 2.

Next, the substitution of the third nitro group in a 6-carbon atom of 2, 4-dinitrophenol can be roughly thought to move H_{D1}, H_{D2} and

V_{D1} of dinitrophenol and V_{NO2} of the third nitro group in the same directions by the same mechanism as for the substitution of the second nitro group in *p*-nitrophenol, since picric acid belongs to the symmetry group C_{2v}. It is, however, to be expected that the square values of the coefficients of the 6-carbon atom in the molecular orbitals of H_{D1} and H_{D2} in 2, 4-dinitrophenol are smaller than C_{N1}^2 and C_{N2}^2 respectively, owing to the strong electron-attracting nature of the second entering nitro group. Moreover, interactions of V_{NO2} of the third nitro group with V_{D1} and V_{D2}, although weak, may lower the V_{NO2}. Accordingly, it may be expected that H_{D1} and H_{D2} of dinitrophenol and V_{NO2} of the third nitro group are shifted to a lesser extent in picric acid than H_{N1} and H_{N2} of *p*-nitrophenol and V_{NO2} of the second nitro group in 2, 4-dinitrophenol respectively. Consequently, one may predict that the intramolecular charge transfer bands due to the $H_{T1}\rightarrow V_{T1}$ and $H_{T2}\rightarrow V_{T1}$ transitions in picric acid will appear at shorter wavelengths than do those for the $H_{D1}\rightarrow V_{D1}$ and $H_{D2}\rightarrow V_{D1}$ transitions respectively, although the respective blue shifts are smaller than the corresponding shifts of *p*-nitrophenol for 2, 4-dinitrophenol. The $H_{T1}\rightarrow V_{T1}$ and $H_{T2}\rightarrow V_{T1}$ transitions are most likely to produce high-intensity bands at 35000 and 42000 cm^{-1} respectively. The above expectation is in agreement with the experimental result.

In addition to the above intramolecular charge transfer bands, absorption bands due to the transitions $H_{D1}\rightarrow V_{D2}$ and $H_{D2}\rightarrow V_{D2}$ in 2, 4-dinitrophenol and those due to the transitions $H_{T1}\rightarrow V_{T2}$, $H_{T2}\rightarrow V_{T2}$, $H_{T1}\rightarrow V_{T3}$ and $H_{T2}\rightarrow V_{T3}$ in picric acid would be expected to appear, although they are not distinguished in Fig. 1.

A predominating difference in π-electron structure between each polynitrophenol and its anion can be ascribed to the fact that the electronegativity of an oxygen atom belonging to the hydroxyl group in the polynitrophenol is greater than that for the polynitrophenolate anion. It may, therefore, be approximately assumed that the dissociation of each polynitrophenol reduces only the coulomb term for the oxygen atom by $\Delta\alpha_0$ through the decrease in electronegatively. Then, according to Coulson and Longuet-Higgins[7], if an inductive effect is disregarded, each orbital of the polynitrophenol is raised by the following amount in the polynitrophenolate anion:

$$\Delta E = C_0^2 \cdot \Delta\alpha_0 \qquad (3)$$

Here C_0 is a coefficient of an atomic orbital of the oxygen atom belonging to the hydroxyl group in the molecular orbital of each level.

The calculation[3] for *p*-nitrophenol gave values of C_0^2 for H_{N1}, H_{N2} and V_{N1} of 0.127, 0 and 0.012 respectively. Putting these values in Eq. 3, it follows that in *p*-nitrophenolate anion H_{N1} is raised more greatly than V_{N1}. It is, therefore, to be expected that an intramolecular charge transfer band of *p*-nitrophenolate anion appears at a longer wavelength than that of *p*-nitrophenol. This agrees with the experimental data.

The great red shifts of the high-intensity absorptions of 2, 4-dinitrophenol on dissociation lead to the suggestion that, in 2, 4-dinitrophenolate anion, H_{D1} and H_{D2} are raised more greatly to H'_{D1} and H'_{D2} respectively than V_{D1} and V_{D2}, as is shown in Fig. 2. The 25000 and 27600 cm^{-1} bands are possibly asssigned to the transitions $H'_{D1}\rightarrow V'_{D1}$ and $H'_{D2}\rightarrow V'_{D1}$ respectively.

When picric acid is dissociated, the energy-levels of picric acid may be raised in the same way as in the case of 2, 4-dinitrophenol. The transitions indicated by the dotted lines in Fig. 2 may produce the observed 25000 and 28300 cm^{-1} bands.

The red shifts of the intramolecular charge transfer bands of each polynitrophenol for its anion are greater with the increasing number of the nitro group. This means that the two highest occupied orbitals of each polynitrophenol are more greatly raised in its anion as the number of the nitro group increases. This, with Eq. 3, suggests that the values of C_0^2 in the molecular orbitals of these occupied levels in each polynitrophenol are greater with the increasing number of the nitro group.

Summary

The absorption spectra of *p*-nitrophenol, 2, 4-dinitrophenol, picric acid and their anions, all in water, were measured in the presence or absence of either hydrochloric acid or sodium hydroxide. The long wavelength absorption maxima of these polynitrophenols shift toward blue in the order of *p*-nitrophenol, 2, 4-dinitrophenol and picric acid, with increasing molar absorbancy indexes in the same order. The absorption maxima of the anions similarly shift toward blue. The absorption maxima of each anion lie at longer wavelengths than do those of the corresponding polynitrophenol. These red shifts are greater with the increasing number of the nitro group. The high-intensity bands of these nitro compounds containing two or three electron-attracting substituents are interpreted from the viewpoint of Nagakura and Tanaka's theory of the intramolecular charge transfer spectra.

The Assignment of the Molecular Vibrations of Hexachlorobenzene

By Shinnosuke SAËKI

(Received June 3, 1961)

The Raman spectrum of hexachlorobenzene has been studied by Dadieu and his colleagues[1] and by Murray and Andrews[2], and the infrared absorption spectrum of the same substance, by Plyler and his collaborators[3]. But, in all of these papers, only the results of observations (vibrational frequencies, intensities, depolarization ratios of Raman lines, etc.) have been presented, and no discussion has been given concerning the assignment of the observed lines or bands. In this paper, the Raman spectra of hexachlorobenzene in various solutions, the qualitative depolarization ratio of each Raman line, and infrared absorption spectra in gaseous state are reported on, and an assignment of these observed lines and bands is proposed.

Experimental and Results

Hexachlorobenzene of extra pure grade on the market was recrystallized from ethanol three times and used for the measurement of the spectra.

The Raman spectra were measured using a Cary model 81 Raman spectrophotometer. The qualitative depolarization ratios were observed by the two-exposure method, using polaroid cylinders. As the solubility of this substance is not enough to obtain an adequately clear spectrum, not only benzene and carbon tetrachloride, but also carbon disulfide were used as the solvents in order to make the measurements as accurate as possible. To prepare the

sample solutions, 0.2~0.25 g. solute was dissolved in 5 ml. solvent in all cases. The obtained Raman spectra are shown in Figs. 1—3, and the frequencies of the observed lines are shown in Table I. The small arrows in the figures point out the Raman lines of the solvent and the mercury lines from the source lamp.

The infrared absorption specta were measured using a Perkin-Elmer model 21 spectrophotometer equipped with sodium chloride or a cesium bromide prism over the region of 4000~300 cm^{-1}. The far infrared spectrum was measured in the region of 300~100 cm^{-1} using the grating spectrophotometer installed at the laboratory of Professor Yoshinaga of Osaka University[4].

As the vapor pressure of hexachlorobenzene is quite low, a high temperature and long path length cell was necessary to measure the spectrum in a gaseous state. The spectra in the sodium chloride region were measured using a long path and high temperature cell of the multiple reflection type. This cell has an optical system quite similar to that of the Perkin-Elmer long path gas cell, but all its mirrors are spattered with gold to prevent corrosion. The path length used in the measurements was 720 cm. The cell can be used at any desired temperature below 120°C by the aid of a transformer and the heaters which are coiled over the outside surface of the cell body. In the measurement, the specimen was put in the cell, and the air in the cell was replaced by nitrogen from the bomb in order to make the absorption by the atmospheric water vapor as weak as possible*. Then, after keeping the cell at a desired temperature for two or three hours in order to saturate the vapor pressure of the sample substance, the spectrum was measured.

The spectrum in the cesium bromide region was measured using the 85 mm. high temperature cell with cesium bromide windows 50 mm. in diameter. The design of this cell is almost the same as that described previously[5].

In the far infrared region, since a high temperature cell could not be used because of the complete difference in the type of spectrometer, the spectrum was taken as the Nujol mull sandwiched between two thick sheets of polyethylene. However, no absorption band was observed in this region. Since this molecule certainly has some vibrations of low frequency which are active to the infrared

		ν_{17}	Ring in-plane deformation	340
		ν_{18}	C–Cl in-plane bending	322

absorption, this fact might be because the intensity of these vibrations is too low to be observed.

The infrared absorption spectra in the sodium chloride and cesium bromide regions are shown in Fig. 4, and the frequencies of the observed bands are listed in Table II.

Assignment

Assuming the symmetry D_{6h} for the molecule of hexachlorobenzene, the normal vibrations are classified as:

$$\text{In-plane vibrations}: 2A_{1g}+A_{2g}+2B_{1u}+2B_{2u}+3E_{1u}+4E_{2g}$$

$$\text{Out-of-plane vibrations}: A_{2u}+2B_{2g}+E_{1g}+2E_{2u}$$

Among these vibrations, those belonging to the species A_{1g}, E_{1g} and E_{2g} are active in the Raman effect, and those belonging to the species A_{2u} and E_{1u} are active in the infrared absorption spectrum. Consequently, seven Raman lines and four infrared absorption bands are expected for this molecule. These are listed in Table III.

Raman Spectrum.—*Species A_{1g}.*—Two vibrations belong to this species. One is the breathing vibration of the molecule as a whole, and the other is the symmetric stretching vibration of the C–Cl bands. Though the former would empirically be expected to have a frequency about 1000 cm^{-1} and the latter about 600 cm^{-1}, this expectation is not realized in this case. As is shown in Table I, two strong and polarized lines were observed at 372 and 1225 cm^{-1}. The third polarized line at 1195 cm^{-1} was much weaker than the first two and should be considered as an overtone or a combination. The observed frequencies of both ν_1 and ν_2 are completely different from the above, expected values. Since the two totally symmetric vibrations can be regarded as linear combinations of the breathing vibrations of two rings, that is, the rings consisting of six carbon atoms and six chlorine atoms respectively, the line at 1225 cm^{-1} can be assigned to the antiphase linear combination of these breathings, namely, the symmetric stretching vibration of the C–Cl bonds (ν_1), while the line at 372 cm^{-1} can be assigned to the same-phase linear combination of these breathings, namely, the breathing vibration of the molecule as a whole.

Species E_{1g}.—Only one vibration, ν_{11}, belongs to this species. As this is the out-of-plane bending vibration of the C–Cl bonds, the line observed at 213 cm^{-1} was assigned to it.

Species E_{2g}.—The line at 1522 cm^{-1} was apparently assigned to the stretching vibration of the benzene ring, ν_{15}. Though this line was not very clearly observed in the carbon tetrachloride and carbon disulfide solutions because of the overlapping with lines of solvents, it was clearly observed in benzene solution and its depolarization ratio could be confirmed to be large.

The C–Cl stretching vibration, ν_{16}, was expected to appear near 700 cm^{-1}, but no line was observed around there. In the carbon tetrachloride solution a weak line was observed at 572 cm^{-1}, but this line was found to be polarized and could not be regarded as a fundamental. Though no fundamental line was found which might give an overtone at 572 cm^{-1}, it might possibly still be an overtone since there are many fundamentals inactive in both Raman and infrared spectra.

The weak line at 340 cm^{-1} was assigned to the deformation vibration of the ring, ν_{17}. This line probably corresponds to a fundamental vibration irrespective of its extremely low intensity, for its frequency is too low to be considered as an overtone or a combination.

The remarkable line at 322 cm^{-1} was assigned to the in-plane bending vibration of the C–Cl bonds, ν_{18}.

Overtones and Combinations.—The five lines at 3042, 2452, 1248, 1195 and 572 cm^{-1} which were not assigned to fundamentals are all polarized and were considered to be overtones. The first two are apparently the overtones of ν_{15} (1522 cm^{-1}) and ν_1 (1225 cm^{-1}). The other three are not overtones of observed fundamentals, but they might be the overtones of inactive fundamentals of the frequencies about 624, 598 and 286 cm^{-1}. However, of course, the above-mentioned observed bands can by no means be adequate evidence for the existence of these fundamental frequencies.

Infrared Absorption Specta.—*Species* A_{2u}.—Only the out-of-plane bending vibration of C–Cl bonds, ν_4, belongs to this species. Though this vibration was expected to appear near 200 cm^{-1}, no absorption band was observed in the far infrared region, as has already been mentioned. This might be due to the difficulty in the measuring technics* and to the low intensity of this band.

Species E_{1u}.—Three vibrations, ν_{12}, ν_{13} and ν_{14}, belong to this species. The modes of these vibrations might be rather complicated in this case, and it is difficult to visualize these modes because of extreme mixing of the stretching and deformation vibrations of the ring and the C–Cl bonds. Though the simple modes are given for these vibrations in Table III, this is simply for the sake of convenience; actually such simple notations might by no means describe the true modes faithfully. On account of such complexity in the vibrational mode, the empirical estimation of the normal frequencies might be very difficult for this species. However, one can find an analogy in the case of the species E_{1u} of benzene. The mode of ν_{12} of benzene is nearly the stretching vibration of C–H bonds, that of ν_{13} is nearly the stretching vibration of the carbon ring, and that of ν_{14} is the vibration between the carbon ring and the ring consisting of six hydrogen atoms[6]. The observed frequencies for these vibrations are 3099, 1485 and 1037 cm^{-1} respectively. The first two are just the frequencies to be expected from the modes, but it is interesting that the third is the frequency empirically expected for a C–H in-plane bending vibration. Provided that the analogy can be applied to the case of hexachlorobenzene, irrespective of the large difference between the masses of hydrogen and chlorine atom, the vibration ν_{12}, ν_{13} and ν_{14} might have the frequencies of the ring stretching vibration, of C–Cl stretching vibration and of C–Cl in-plane bending vibration respectively. In the infrared absorption spectrum, two strong absorption bands were really observed at 1350 and 696.2 cm^{-1}. Consequently, the former can be assigned to ν_{12} and the latter to ν_{13}. However, though ν_{14} could be expected to appear at 200~300 cm^{-1} according to the above-mentioned analogy, no band was observed in the far infrared region, as has already been mentioned. This is probably because ν_{14} has a very low intensity.

Combination Bands.—A considerable number of combination bands were observed in the infrared absorption spectra, as is shown in Table II. As this molecule has a center of symmetry, only the vibrations belonging to the ungerade species are active to the infrared absorption. Since the first overtone of a fundamental of any species belongs to a gerade species, and since second overtones and higher might not have observable intensities, the observed absorption bands not corresponding to fundamentals should be regarded as combination bands between a gerade fundamental and an ungerade fundamental. However, the clear explanation of these combination bands is not easy in this case. The molecule of hexachlorobenzene has ten fundamental frequencies belonging to the ungerade species, but only two of them were observed; the others were inactive or unobserved. Also, of the vibrations belonging to the gerade species, only a few were observed. Under such conditions, it is not possible to explain all of the combination bands, and it seems to be rather insignificant to present the explanations for only a few combination bands. Thus, discussion of the combination bands has been entirely omitted.

The above-mentioned assignment for the normal vibrations is shown in the last column of Table III.

Summary

The infrared absorption spectra of hexachlorobenzene were measured in a gaseous state from 4000 to 300 cm^{-1}, and in solid state from 300 to 100 cm^{-1}. The Raman spectra of the same substance were measured in solutions in benzene, carbon tetrachloride and carbon disulfide. The depolarization ratio of each Raman line was also observed qualitatively. The assignment of the observed absorption bands and Raman lines was determined, partly by referring to that of benzene.

The author wishes to express his appreciation to Professor H. Yoshinaga and Dr.

* The measurement had to be carried out in vacuo in order to avoid the extreme masking effect of the strong absorption of water vapor in the atmosphere. However, as the window material of the sample holder was polyethylene, it was not certain that the proper thickness and homogeneity of the Nujol paste layer was preserved even in vacuo.

The Infrared Absorption Spectra of p-Dichlorobenzene and p-Dichlorobenzene-d_4

By Shinnosuke SAËKI

(Received June 26, 1961)

A report has previously been published by the author[1] concerning the infrared absorption spectra of *p*-dichlorobenzene and *p*-dichlorobenzene-d_4 in the regions of the lithium fluoride, sodium chloride and potassium bromide prisms. Recently the author carried out the measurement of the infrared spectra in the farther region, that is, from 400 to 300 cm^{-1} which a cesium bromide prism and from 300 to 100 cm^{-1} with gratings. In addition, the shape of each absorption band observed between 1700 and 700 cm^{-1} was also measured by the aid of a high-temperature long-path cell. The results of these measurements and the new assignment determined on the basis of these experimental results are reported in this paper. The assignment proposed in the previous paper was revised in several points in the new assignment proposed here.

Experimental

Far Infrared Absorption Spectra.—The measurement in the cesium bromide prism region was carried out from 670 to 300 cm^{-1} using a Perkin-Elmer model 21 spectrophotometer and a 85 mm. high temperature gas cell almost identical with that described in the previous paper[1], except that the window material was cesium bromide. The method of measurement need not be mentioned, since it was quite similar to the previous case[1]. The measurement was done at about 210°C. As a number of intense bands of atmospheric water vapor made the 100% line uneven, especially beyond 330 cm^{-1}, and as the infrared radiation from the cell and the hot sample vapor itself made the base line also uneven, it was necessary to measure the 100% and base lines, as well as the absorption curve for each measurement, in order to obtain a correct spectrum.

The spectra between 300 and 100 cm^{-1} were measured using the grating spectrophotometer installed in the laboratory of Professor Yoshinaga of Osaka University[2]. As the construction of the spectrometer did not allow the measurement in a gaseous state, the spectra were taken in the state of Nujol mull sandwiched between two polyethylene sheets (1 mm. thick)*. As the specimen, on measurement, was placed in a vaccum in order to avoid disturbance by the strong absorption of atmospheric water, some extent of inhomogenity of thickness might occur in the layer of Nujol mull due to the insufficient rigidity of the polyethylene sheet. However, this inhomogenity, if any, gave rise to no obstacle to simple, accurate observation of the frequencies of absorption bands.

Observation of Band Shapes.—It is very desirable for the determination of the assignment to observe the correct shapes of the band envelopes. However, using the 85 mm. high temperature cell, it proved to be impossible to observe the clear band envelopes. This failure might be attributed to the high temperature at which the measurements were carried out more than to the poor resolution of the spectrometer. If the 85 mm. high temperature cell was used, it was necessary to raise the temperature over the boiling points of these sample substances, that is, at 200 or 300°C, to obtain an enough strong absorption curve. But at high temperatures the width of an absorption band becomes large**, and a clear envelope can not be observed, even if a small slit width is used. Also, because of the extremely low vapor pressures of the sample substances, the use of an ordinary long path cell of the multiple reflection type (for example, a ten-meter gas cell) at room temperature was not sufficient to obtain a strong enough absorption curve. Thus it proved necessary, in order to obtain a sufficiently clear spectrum, to carry out a measurement at a temperature not extremely high, using a high temperature long path cell.

The high temperature long path cell constructed in our laboratory has the same optical alignment as that of the Perkin-Elmer ten-meter cell, but all its mirrors were spattered with gold to secure them from corrosion by the heat and by the sample

2) H. Yoshinaga, S. Fujita, S. Minami, A. Mitsuishi, R. A. Oetjen and Y. Yamada, *J. Opt. Soc. Am.*, **48**, 315 (1958).

* To prepare the specimen, the method of compounding the substance with hot polyethylene was not available in this case because of the high volatility of the sample substance. The method of making the solid solution in paraffin was also found to be impossible.

** This might be due to the increasing collision between molecules and to the increasing population at the levels of higher *J* values.

gases. The cell was coiled with heaters on the whole outside surface and then covered with several layers of asbestors for the sake of heat insulation. The entrance and exit openings were doubly closed by potassium bromide plates in order to prevent the condensing of the sample gas on the inner surfaces of the windows. The temperature of the cell could be raised up to about 110°C without any risk of decomposing the binding and sealing materials. A slight leakage at the stopcock, however, did not allow the maintenance of the vacuum over the whole period of scanning the spectrum. The 720 cm. path length was used for the measurements, and the sufficiently clear spectra were obtained at 60~80°C for *p*-dichlorobenzene. Although the large amount of energy loss due to multiple reflections in the cell obliged the use of considerably wide slits, the obtained spectra were much clearer than those obtained using the 85 mm. high temperature cell, and many absorption bands which could not be resolved previously were newly observed by the aid of this 720 cm. cell. The absorption curves for the bands at 1417 and 1393 cm^{-1} of *p*-dichlorobenzene obtained using these two cells of different types are shown in Fig. 1 for comparison.

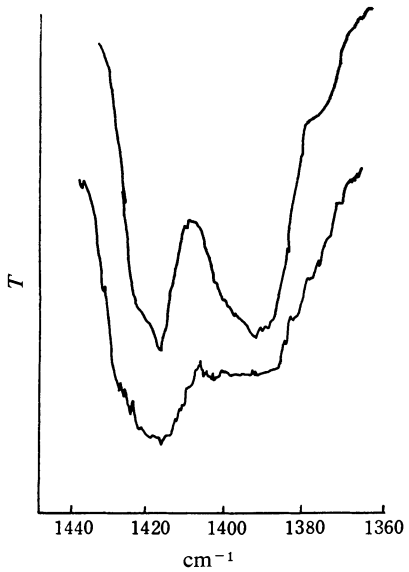

Fig. 1. The infrared absorption spectra of *p*-dichlorobenzene near 1400 cm^{-1} measured using the long path and short path gas cells.
The upper curve: spectrum measured using the 720 cm. cell (slit width: 70 μ)
The lower curve: spectrum measured using the 85 mm. cell (slit width: 40 μ)

Although every effort was made to reduce the absorption due to atmospheric water vapor, a remarkable amount of absorption, which necessarily remained because of the design of the long-path cell, made difficult the observation of band envelopes in the 6 μ region. The adsorption of the sample gas on the inner surface of the cell required the paying of a good deal of attention to the washing of the cell after measurements. It proved to be necessary in the case of *p*-dichlorobenzene, when measurement was over, to drive the sample gas out by nitrogen as completely as possible; then the cell was demounted and kept open for forty hours at a high temperature. Even after such a drastic washing, on the next use, the absorption bands of desorbed gas were often observed with considerable intensities when the measurement was carried out over a long period of time. Accordingly, on the analysis of the spectra taken under such conditions, much attention was required to rule out the undesired band.

Results

The observed spectra of *p*-dichlorobenzene and *p*-dichlorobenzene-d_4 are shown in Fig. 2. The curves beyond 300 cm^{-1} are fragmental because of the necessity of frequent exchanges of the gratings and filters with the decreasing frequency during the measurement.

The observation of band envelopes was successful for some of the bands observed in the region of cesium bromide prism, while it is impossible in principle in the region of the gratings, where the spectra were observed in the solid state.

The spectra of *p*-dichlorobenzene-d_4 observed using the 720 cm. high temperature cell are shown in Fig. 3 for the region where the principal bands appeared.

The frequencies, intensities and types of the observed bands are shown in Table I. However, it should be mentioned here that the strong band at 1170 cm^{-1} of *p*-dichlorobenzene-d_4 proved to originate in a substance other than *p*-dichlorobenzenes. A comparison with the spectrum of the solutions and an examination of the time dependent change of the spectrum revealed this. Accordingly, no further consideration should be given to this band.

Discussion and Assignment

Band Envelopes.—In the case of *p*-dichlorobenzene, the three principal axes of the moment of inertia coincide with the three symmetry axes of the molecule because of the high symmetry. Taking the x-axis perpendicular to the molecular plane, the z-axis along the line combining two chlorine atoms, and the y-axis perpendicular to these two, the moments of inertia are calculated to be:

	$C_6H_4Cl_2$	$C_6D_4Cl_2$	
I_x	823	848	
I_y	735	741	
I_z	88	106	(in physical atomic weight·Å^2)

Therefore, vibrations belonging to species B_{1u}, B_{2u} an B_{3u} give absorption bands of type A, B and C respectively. In the actual spectrum,

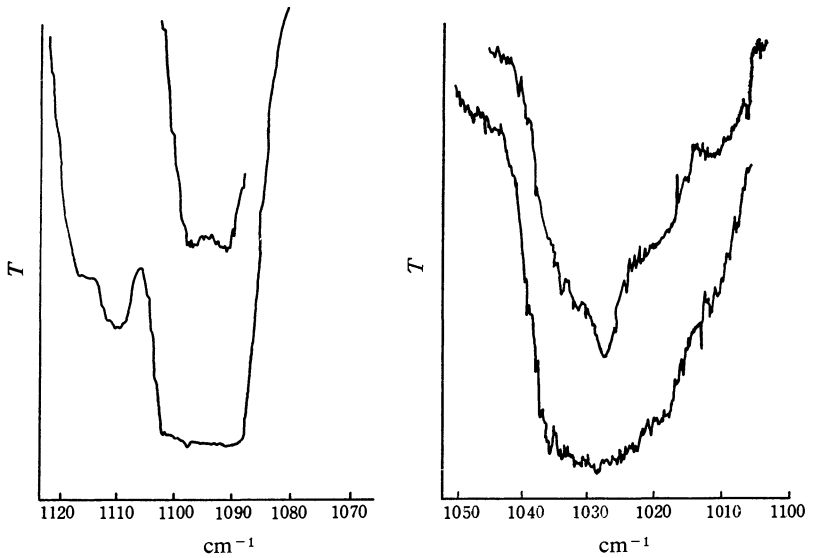

Fig. 4. The shapes of the bands at 1094 cm^{-1} of ordinary *p*-dichlorobenzene and at 1028 cm^{-1} of deuterated *p*-dichlorobenzene.

relatively clear band envelopes were observed for type C bands, for, as was expected from their vibrational modes, all of them appeared in a lower frequency region, where the resolution of the spectrometer is relatively high. However, for the bands of the other species, when they appeared in the higher frequency region, the observed envelopes were not adequately clear to distinguish them as type A or B. In Table I, bands having somewhat pointed peaks are descibed as type A bands, and bands having somewhat round peaks, as type B bands. On the contrary, envelopes were clearly observed for the bands which appeared in the region below 1100 cm^{-1}, except for a few bands. Examples will be shown below.

The band of $C_6H_4Cl_2$ at 1094 cm^{-1}, which certainly corresponds to 1028 cm^{-1} of $C_6D_4Cl_2$*, is shown in Fig. 4. This appeared to be a type B band showing a clear absorption minimum at the center, while the band of $C_6D_4Cl_2$ at 1028 cm^{-1} could be explained only as a type A band because of its clear Q branch, as is seen in the figure. This fact suggests that too much significance should not be attached to the observed band envelopes on determining the assignment, at least when their apparent shapes are considered.

In the observed spectra, there were many asymmetrical absorption bands consisting of two branches of unequal intensity. The band of *p*-dichlorobenzene observed at 1217 cm^{-1} is shown in Fig. 5 as a typical example. Considering the existence of two branches, they might be regarded as type B bands, but if the stronger branch is regarded as an overlap of the Q and R branches, such a band should be considered as a type A or C band. As will be mentioned later, the band of $C_6D_4Cl_2$ at 414 cm^{-1} also showed such an envelope and appeared to be a type B band, but it was revealed to be a type C band by a consideration of the product rule and of the correspondence with a band of $C_6H_4Cl_2$. There were many other bands like this, of which the type could not be determined clearly.

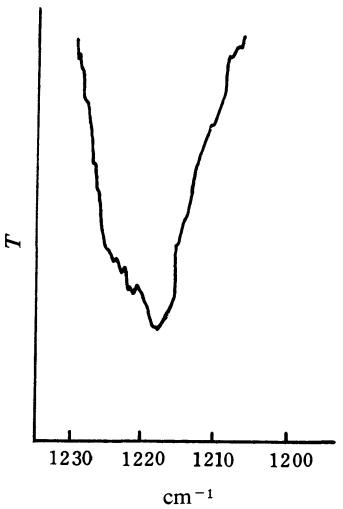

Fig. 5. The shape of the band at 1217 cm^{-1} of *p*-dichlorobenzene.

* This correspondence between bands satisfied the product rule, as will be shown later.

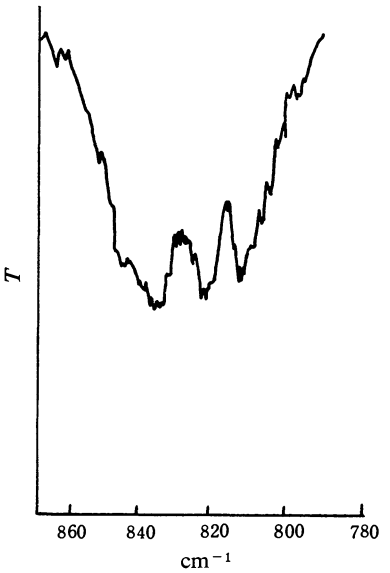

Fig. 6. The shape of the band at 820 cm^{-1} of *p*-dichlorobenzene-d_4.

Another difficult band was observed in the spectrum of deuterated *p*-dichlorobenzene. In Fig. 6 is shown a band observed around 820 cm^{-1}. The large spacing between the three absorption maxima (see the figure) could be explained neither as three branches of a single band, nor as three separate absorption bands, because of the resultant absence of the branches of each band. However, in the spectra of solutions, three closely positioned weak bands were observed in this frequency region; these may be separate bands, the branches of which overlap, one with the others.

Assignment.—Taking account of the product rule, and on the basis of the above-mentioned results concerning the envelopes of principal bands, the assignment of the observed bands was determined as is shown in Table II.

Some revisions of the previous assignment were required to be consistent with the above-mentioned new experimental results. In our previous paper[1], the band at 483 cm^{-1} of $C_6H_4Cl_2$ (414 cm^{-1} for $C_6D_4Cl_2$) was assigned

TABLE II. ASSIGNMENT OF THE INFRARED ABSORPTION BANDS OF *p*-DICHLOROBENZENE AND *p*-DICHLOROBENZENE-d_4

Wave number		Assignment	Mode
$C_6H_4Cl_2$	$C_6D_4Cl_2$		
3098	2301	$\nu_{10}(b_{1u})$	C-H or C-D stretching
3098	2289	$\nu_{18}(b_{2u})$	C-H or C-D stretching
1888	1622	$\nu_7(a_u)+\nu_{15}(b_{2g})$	
1758		$\nu_2(a_g)+\nu_{30}(b_{3u})$	
1656		$\nu_4(a_g)+\nu_{14}(b_{1u})$

	1568	$\nu_3(a_g)+\nu_{28}(b_{3u})$	
1509		$\nu_{12}(b_{1u})+\nu_{16}(b_{2g})$	
	1434	$\nu_{13}(b_{1u})+\nu_{26}(b_{3g})$	
1478	1370	$\nu_{11}(b_{1u})$	Ring stretching
1417	1405	$\nu_{19}(b_{2u})$	Ring stretching
1393	1334	$\nu_{20}(b_{2u})$	Ring stretching
	1315	$\nu_{13}(b_{1u})+\nu_{17}(b_{2g})$	
1297		$\nu_9(b_{1g})+\nu_{29}(b_{3u})$	
1253		$\nu_7(a_u)+\nu_{17}(b_{2g})$	
1217		$\nu_4(a_g)+\nu_{29}(b_{3u})$	
	1205	$\nu_{13}(b_{1u})+\nu_{16}(b_{2g})$	
1173		$\nu_{14}(b_{1u})+\nu_{26}(b_{3g})$	
	1127	$\nu_4(a_g)+\nu_{29}(b_{3u})$	
1112	811.7	$\nu_{21}(b_{2u})$	C-H or C-D in-plane bending
	1096	$\nu_3(a_g)+\nu_{30}(b_{3u})$	
1094	1028	$\nu_{12}(b_{1u})$	Ring in-plane deformation
1017	821.8	$\nu_{13}(b_{1u})$	C-H or C-D in-plane bending
819.2	694.8	$\nu_{28}(b_{3u})$	C-H or C-D out-of-plane bending
774.2		$\nu_{17}(b_{2g})+\nu_{29}(b_{3u})$	
588	581.7	$\nu_6(a_g)+\nu_{22}(b_{2u})$ or $\nu_{22}(b_{2u})+\nu_{27}(b_{3g})$	
545.2	527.4	$\nu_{14}(b_{1u})$	C-Cl stretching
480.7	418.4	$\nu_{29}(b_{3u})$	Ring out-of-plane deformation
225.2	221.2	$\nu_{30}(b_{3u})$	C-Cl out-of-plane bending

to ν_{14} of the species B_{1u}, and the band at 544 cm^{-1} of $C_6H_4Cl_2$ (526 cm^{-1} for $C_6D_4Cl_2$) was assigned to ν_{29} of species B_{3u}. However, as the bands at 481 cm^{-1} of $C_6H_4Cl_2$ and at 418 cm^{-1} of $C_6D_4Cl_2$ proved to be type C bands in this study, it became clear that the 481 cm^{-1} and the 418 cm^{-1} should be assigned to ν_{29} and the 545 cm^{-1} and 527 cm^{-1} should be assigned to ν_{14}, inverting the previous assignment.

Furthermore, in our previous assignment, the pair of bands at 1014 and 800 cm^{-1} was assigned to the ring deformation vibration ν_{20} of species B_{2u}. However, as is clear from a consideration of the vibrational mode, this vibration is necessarily accompanied with the ring stretching one, and, consequently, the frequency of this vibration must be relatively high. From this viewpoint, the bands at 1393 cm^{-1} of $C_6H_4Cl_2$ and at 1334 cm^{-1} of $C_6D_4Cl_2$ were assigned to this vibration, ν_{20}.

As the large frequency shifts observed for the bands at 1017 and 1112 cm^{-1} of $C_6H_4Cl_2$ on the deuteration (to 821.8 and 811.7 cm^{-1} of $C_6D_4Cl_2$ respectively) suggest that these vibrations mainly concern the motions of the C–H bonds, they are assigned to the C–H in-plane bending vibrations.

The assignment of the combination bands is also shown in Table II. Of these combination bands, a brief discussion should be given about the assignment of the band at 588 cm^{-1} of $C_6H_4Cl_2$ which appearently corresponds to the band at 581.7 cm^{-1} of $C_6D_4Cl_2$. This pair of bands is difficult to explain as any combination of the observed fundamentals. The unobserved low frequency fundamental of the gerade species is ν_{27} of $C_6D_4Cl_2$* (b_{3g}, Raman active), and those of ungerade species are $\nu_8(a_u)$ and $\nu_{22}(b_{2u})$ of each substance. Therefore, the possible assignments for 588 and 581.7 cm^{-1} are as follows:

$$\nu_6(a_g)+\nu_{22}(b_{2u})$$
$$\nu_{22}(b_{2u})+\nu_{27}(b_{3g})$$
$$\nu_8(a_u)+\nu_{17}(b_{2g})$$
$$\nu_8(a_u)+\nu_{27}(b_{3g})$$

However, as $\nu_8(a_u)$, being the out-of-plane deformation vibration of the ring, may have a frequency higher than 300 cm^{-1} at the lowest, the last two assignments appear to be impossible. The remaining two assignments seem to have similar possibilities. If the first assignment is taken up, the frequencies of ν_{22}'s are calculated from the frequencies of ν_6's to be 259 and 258 cm^{-1} for $C_6H_4Cl_2$ and $C_6D_4Cl_2$ respectively. If the second assignment is taken up, 239 cm^{-1} is obtained as the frequencies of ν_{22} for $C_6H_4Cl_2$, while the frequency of ν_{22} for $C_6D_4Cl_2$, can not be calculated, for the frequency of ν_{27} was not observed for $C_6D_4Cl_2$. However, if the above-mentioned frequency of 340 cm^{-1} for the ν_{27} of $C_6D_4Cl_2$ (see the last footnote) is used, ν_{22} can be calculated to be 242 cm^{-1} for $C_6D_4Cl_2$. Since, from a theoretical viewpoint, the frequency must be lower for $C_6D_4Cl_2$ than for $C_6H_4Cl_2$, the frequencies of ν_{22} and ν_{27} for $C_6D_4Cl_2$ should be determined to be 239 and 343 cm^{-1}. After all, two possible pairs of ν_{22} for each substance are obtained, that is, 259 and 258 cm^{-1}, and 239 and 239 cm^{-1}. As both of these two pairs are plausible for the C–Cl in-plane bending vibrations, it is very difficult to distinguish which pair is the true one, while one of these two pairs is certainly true. Since the influence of these two assignments on the ratio of the products of the frequencies is very small, even the product rule sheds little light on the determination of this question.

Product Rule.—The ratios of products of the frequency required by the theorem of Teller and Redlich are as follows:

1.972 for species B_{1u}

1.972 for species B_{2u}

1.395 for species B_{3u}

The ratios calculated from the observed frequencies are 1.977 for species B_{1u} and 1.379 for species B_{3u}, showing good accordances with the above theoretical values. As for species B_{2u}, since ν_{22} was observed for neither $C_6H_4Cl_2$ nor $C_6D_4Cl_2$, the perfect application of the product rule was impossible. However, taking account of the fact that a low frequency vibration such as ν_{22} is little influenced by deuteration, the ratio of ν_{22}'s for both substance could be estimated to be little larger than 1. This estimation seems to be justified by the calculated pairs of frequencies for ν_{22}'s in the previous paragraphs. With this assumption, the ratio of the products of the frequencies can be calculated to be 1.953 for species B_{2u}; the accordance with the theoretical value is also very good in this case. From such considerations, the assignment proposed here proves to have much reliability.

Summary

The infrared absorption spectra of *p*-dichlorobenzene and *p*-dichlorobenzene-d_4 were measured from 300 to 700 cm^{-1} in a gaseous state with cesium bromide prism, from 300 to 100 cm^{-1} in a solid state with gratings, and, using a newly constructed long path (720 cm.) high

* ν_{27} of $C_6H_4Cl_2$ was observed at 349 cm^{-1}. Applying the product rule using this frequency, the frequency of ν_{27} of $C_6D_4Cl_2$ is calculated to be about 340 cm^{-1}.

temperature cell, from 1700 to 700 cm^{-1} in a gaseous state with a sodium chloride prism. The frequencies and band envelopes of observed absorption bands were reported.

On the basis of these results, the assignment of the infrared active normal vibrations of these molecules was determined. The assignment was checked by means of the application of the product rule, and the correctness was verified by the good agreement between the theoretical and experimental values.

The assignment was also determined for the observed combination bands, using the Raman fundamental frequencies presented in the previous paper as well as infrared frequencies.

The author wishes to express his indebtedness to Professor H. Yoshinaga and Dr. A. Mitzuishi for the use of the far infrared grating spectrometer, and to Dr. Y. Mashiko for his advice and encouragement.

Infrared Absorption Spectra of Hydrazides. I. Hydrazides of Aromatic Acids

By Mitsuo MASHIMA

(Received June 8, 1961)

The infrared absorption spectra of a number of mono-substituted amides and their related compounds have been studied[1], and the characteristic bands of mono-substituted amides have been reported on in detail[2]. Bands amide I, amide II and amide III in the rock salt region have been associated with CONH group of non-cyclic secondary amides. Amide frequencies of difomylhydrozine[2,3] and diacetylhydrazine[2,4] have recently been studied, and amide I and amide II bands have been observed to shift abnormally to the lower frequencies in the spectra of these hydrazides. However, the number of the hydrazides examined has been rather limited. The aim ot the present study is to examine in detail the amide bands of various aromatic hydrazides containing a CONHNHCO group.

Experimental

Acetylbenzoylhydrazine was synthesized with acetic anhydride and benzoylhydrazine[5] and purified by recrystallization from ethanol, m. p. 171°C. Benzoylhydrazine was prepared with ethylbenzoate and hydrazine hydrate[6] and purified by recrystallization from benzene, m. p. 111°C. Trichloroacetylbenzoylhydrazine was synthesized with trichloroacetylchloride and benzoylhydrazine[7] and purified by recrystallization from benzene, m. p. 164°C. Dibenzoylhydrazine was synthesized with benzoylchloride and hydrazine hydrate[8] and purified by recrystallization from ethanol, m. p. 238°C. Benzamide was prepared by recrystallization of the material of G. R. grade from ethanol, m. p. 130°C. *N*-Deuterated derivatives examined were prepared in sealed tubes in the presence of heavy water (99.8%). The excess of heavy water was evaporated in vacuo.

The spectra of hydrazides which were insoluble in non-polar solvents, such as carbon disulfide and carbon tetrachloride, were obtained with acetonitrile as a solvent and cells of 0.1 mm. in the optical path. The solid spectra of all compounds were studied with potassium bromide disk. A double-beam Hitachi infrared spectrophotometer Type EPI-2 was used in the rock salt region.

Results and Discussion

Acetylbenzoylhydrazine (ABH).—The infrared absorption spectra of ABH are given in Fig. 1, in which a solid curve shows the solid spectrum, a dotted curve, the solution spectrum and a dashed curve, the spectrum of *N*-deuterated ABH (ABH-d_2) in the solid state. The solution spectrum of ABH was obtained with a saturated solution (ca. 0.1 mol./l.) in acetonitrile.

The 3000 cm^{-1} Region. — Two strong bands were found at 3180 and 3000 cm^{-1} in the spectrum of solid ABH. Probably an ABH molecule is planar in the solid state, and the two

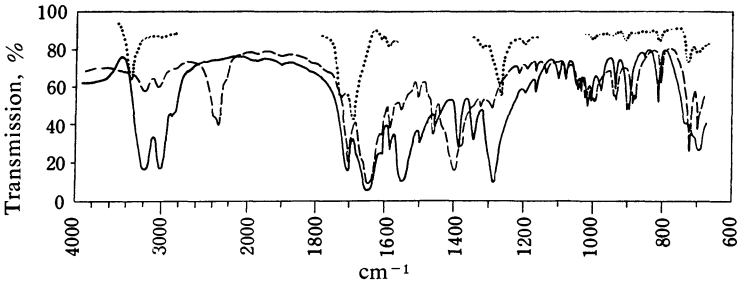

Fig. 1. Infrared absorption spectra of ABH in the rock salt region. The solid curve indicates the solid spectrum, the dotted curve partly represented is the solution spectrum of ABH (0.1 mol./l., 0.1 mm. cell), and the dashed curve shows the spectrum of ABH-d_2 in the solid state.

frequencies can be ascribed to the N–H stretching vibration. The abnormally low frequencies for the N–H vibration may be attributed to the coupling between two N–H vibrations in the CONHNHCO group of point group C_{2h}. On the other hand, only one band at 3320 cm^{-1} was found in this region for the solution spectrum. Probably the molecule is nonplanar in the solution, and the increase in frequency in the solution spectrum may be due to a decrease in the interaction between the two N–H vibrations. A band corresponding to them in the spectrum of *N*-deuterated ABH was found at 2310 cm^{-1}, which band was accompanied by two shoulder bands near 2340 and 2380 cm^{-1}. They are assigned to ν(N–D). ABH also has two weak bands at 2860 and 2830 cm^{-1} which are assigned to ν(C–H). Bands corresponding to them are found at 2830 and 2800 cm^{-1} for ABH-d_2.

The 1700~1450 cm^{-1} Region.—ABH has two bands which must be ascribed to the C=O stretching vibration. They are 1707 and 1644 cm^{-1} in the solid spectrum and 1720 and 1683 cm^{-1} in the solution spectrum. ABH-d_2 has bands at 1697 and 1645 cm^{-1} corresponding to them. The splitting of ν(C=O) may be due to the interaction of two vibrations which are two related C=O groups. However, the frequencies are rather higher than those of the hydrazides studied already, i. e., at 1610 cm^{-1} for diformylhydrazine[3] and 1597 cm^{-1} for diacetylhydrazine[4] in the solid state. The bands of those frequencies are called amide I.

There was also a strong band at 1527 cm^{-1} in the solid spectrum of ABH ascribed to the amide II band. A band corresponding to it is found at 1393 cm^{-1} in the spectrum of ABH-d_2 and called amide II′ according to Miyazawa et al.[2], the ratio ν_H/ν_D being 1.096. It was impossible to check this band in the solution spectrum because of interference by solvent absorption.

In this region two comparatively strong bands are also found at 1607 and 1582 cm^{-1} in the solid spectrum and at 1603 and 1583 cm^{-1} in the solution spectrum. Bands corresponding to them are found at 1607 and 1581 cm^{-1} in the solid ABH-d_2 spectrum. These bands can be assigned to aromatic ring vibrations. Two other bands are found at 1493 and 1450 cm^{-1} in the spectrum of ABH and are also ascribed to aromatic ring vibrations. In the spectrum of ABH-d_2 bands corresponding to them are found at 1497 and 1453 cm^{-1} respectively.

The 1450~1200 cm^{-1} Region. — Deformation frequencies of a CH_3 group are expected to concern two bands in this region. In the spectrum of ABH a band at 1381 cm^{-1} may be taken as the symmetric vibration $\delta_s(CH_3)$ and a shoulder at 1442 cm^{-1} of the band at 1450 cm^{-1}, ν(aromatic C–C), is probably due to the asymmetric $\delta_{as}(CH_3)$. In the spectrum of ABH-d_2 the corresponding bands are found at 1372 and near 1430 cm^{-1}, which are both observed as shoulders on the low- and high-frequency sides of the 1393 cm^{-1} band, amide II′.

The most intense band at 1281 cm^{-1} in this region of the solid spectrum is assigned to the amide III band. A relatively weak band at 1337 cm^{-1} is also probably an amide III. Two bands corresponding to them are found at 1256 and 1313 cm^{-1} in the solution spectrum. The splitting of amide III may be due to coupling between two N–H vibrations; this finding is in accordance with that discussed already in connection with the N–H stretching frequencies.

The 1200~690 cm^{-1} Region. — Owing to the complexity of the spectral pattern in this region, the observed bands will be assigned through a comparison of the spectrum with those of related compounds. Strong and relatively weak bands have been found in this region in the spectra of aromatic compounds; the strong bands may generally be ascribed to the out-of-plane C–H deformation vibrations. In the solid ABH spectrum the most intense

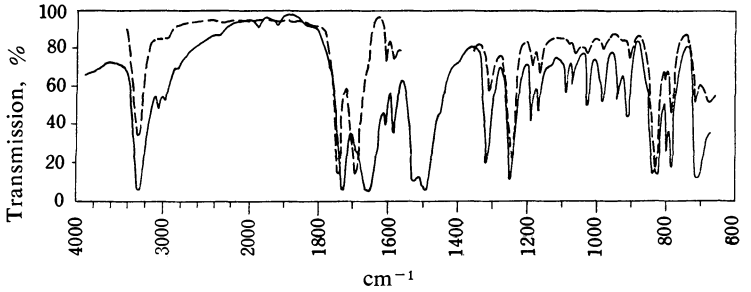

Fig. 2. Infrared absorption spectra of TCABH in the solid state (solid curve) and in a 0.2 mol./l. solution (dashed curve).

band in this region is found at 687 cm^{-1}, which band is accompanied by two well-defined shoulders at 702 and 724 cm^{-1}. ABH in solution has two bands at 691 and 717 cm^{-1}, while ABH-d_2 has them at 691 and 715 cm^{-1}. Since these frequencies are, in general, within or near the range of 700±10 cm^{-1} [1], the two bands can be attributed to the out-of-plane C–H deformation vibrations.

The out-of-plane C–H deformation vibrations of the mono-substituted benzene ring give rise to another band generally within the range 770~730 cm^{-1} [1]. Kross et al.[9] studied the influence of substituents of mono-substituted benzene on the positions of the C–H deformation bands and pointed out that the introduction of electrophilic substituents tends to increase the C–H band in frequency. A band at 803 cm^{-1} of the ABH spectrum can, therefore, be attributed to the C–H out-of-plane vibration. A band corresponding to it is found at 794 cm^{-1} in the ABH-d_2 spectrum.

Other relatively weak bands in this region can not be interpreted with confidence because of the complexity of the spectrum.

Trichloroacetylbenzoylhydrazine (TCABH). —The infrared absorption spectrum of TCABH was studied in the rock salt region in the solid state and in a solution in acetonitrile (0.2 mol./l.). The spectra obtained are illustrated in Fig. 2.

In the solid spectrum TCABH has a band 3280 cm^{-1} which lies in the range 3320~3270 cm^{-1} characteristic to ν(N–H) of many secondary amides[1], and the band can surely be ascribed to ν(N–H). Its appearence as a single band might depend on a decrease in the interaction between two N–H stretching vibrations. However, it must be pointed out that the ν(N–H) frequency does not change in value in the solution spectrum. That is one of the characteristics of the TCABH spectrum different from the ABH spectrum shown in Fig. 1.

TCABH has its amide I bands at 1731 and 1658 cm^{-1} in the solid spectrum and at 1742 and 1694 cm^{-1} in the solution spectrum. This suggests that there is a coupling between two C=O stretching vibrations. It is very interesting to compare the amide I frequencies with those of ABH. The amide I frequencies are collected in Table II. An increase of ν(C=O) due to α-halogen substitution of organic acids has been found to be of the order of 20 cm^{-1} [1]. Such an increase in ν(C=O) is also observed here, e.g., for the higher frequency band of amide I an increase by 24 cm^{-1} is seen between the solid spectra of TCABH and ABH and an increase by 22 cm^{-1} between their solution spectra.

Let us consider next the effect of solvent on the splitting of the amide I band. In the case of ABH the spacing of the splitting is 63 cm^{-1} in the solid and 37 cm^{-1} in solution, and that for TCABH is found to be 73 cm^{-1} in the solid and 48 cm^{-1} in solution. The differences between the values of the splitting in the solid state and solution are, accordingly, relatively very close, i.e., about 25 cm^{-1}. Although obtaining nearly the same values in the splitting of the amide I bands of ABH and TCABH may be accidental because of the different environments of the molecules in the crystalline state and in solution, the phenomenon seems to be worth describing here.

Two bands corresponding to the amide II bands are observed at 1524 and 1492 cm^{-1} in the solid spectrum, and, accordingly, the coupling between two C–N stretching frequencies must be taken into account, although the doublet splitting of amide II was not seen in the ABH spectrum. In solution no amide II band was observed because of interference by the absorption of solvent.

Furthermore, the splitting of the amide III band is also observed; i.e., two bands appear at 1317 and 1248 cm^{-1} in the solid spectrum and at 1305 and 1241 cm^{-1} in the solution spectrum. Thus, it can easily be concluded

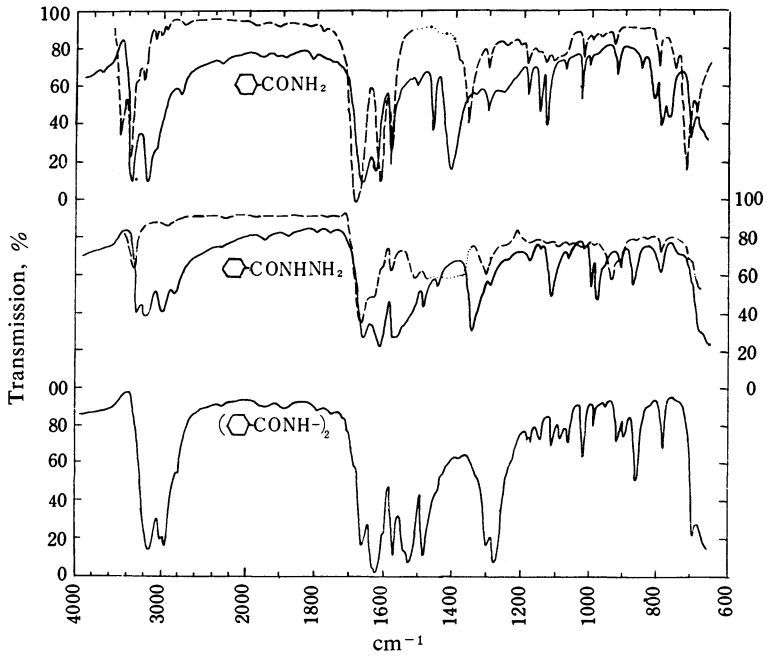

Fig. 3. Infrared absorption spectra of hydrazides and benzamide. The solid curves indicate the solid spectra in KBr disk, and the dashed curves show the solution spectra in acetonitrile.

that there is also a coupling between the two amide III frequencies of the CONHNHCO group.

In the solid spectrum TCABH has a very intense band with two peaks at 835 and 824 cm^{-1}, and a band corresponding to it is found at 827 cm^{-1} in the solution spectrum. This band may be due to the C–Cl stretching frequencies since no corresponding band is observed in the ABH spectrum, as is indicated in Fig. 1.

Other bands, especially due to vibrations of the aromatic ring, will be considered in the next section.

Dibenzoylhydrazine (DBH) and Relating Compounds. — The infrared absorption spectra of DBH and its related compounds are shown in Fig. 3, in which solid curves show the solid spectra and dashed curves indicate the solution spectra. The solution spectrum of DBH could not be observed because no appropriate solvent was found.

The 3000 cm^{-1} Region.—DBH has two intense bands at 3170 and 2980 cm^{-1} which may be assigned to N–H vibrations analogous to the bands at 3180 and 3000 cm^{-1} of ABH mentioned already. In the solid state benzamide also has two absorption bands of an NH_2 group at 3330 and 3140 cm^{-1}, to which correspond two bands at 3460 and 3350 cm^{-1} in the solution spectrum. These bands are naturally due to the asymmetric and symmetric N–H stretching frequencies. On the other hand, benzoylhydrazine (BH) has three bands at 3280, 3180 and 3010 cm^{-1}, of which the latter two bands have nearly the same frequencies as those of DBH and ABH. Moreover, it is interesting to see that only one band, at 3350 cm^{-1}, in the solution spectrum of BH corresponds to those three NH bands. The primary amides having an NH_2 group indicate generally two bands in the solid state and in solution[1]. They are also found in the benzamide absorption, while BH containing an NH_2 group adjacent to the CONH group has the three bands as mentioned above. It is impossible to give a reasonable interpretation for such a feature of ν(N–H) of BH without further observations, but the following explanation may tentatively be presented. In the solid state at least two of the three NH vibrations of BH may interact with each other, and hence bands similar to those of DBH and ABH may appear. The coupling between the two N–H vibrations decreases in solution, and hence BH has only one N–H band. The N–H stretching frequencies of the hydrazides and their related compounds are collhcted in Table I.

Other relatively weak bands in this region probably are due to C–H stretching frequencies, but their full assignment can not yet be completely given.

TABLE I. ν(N-H) VALUES IN cm^{-1}

Molecule	Solid	In CH_3CN
	3280, 3050	3280
	3180, 3000	3320
	3170, 2980	—
	3280, 3180, 3010	3350
	3340, 3140	3460, 3350

The Amide Frequencies. — DBH has bands at 1669 and 1636 cm^{-1}. Although DBH is examined only in the solid state, these two bands may be ascribed to C=O stretching frequencies (amide I) by comparison of the solid spectrum with those of TCABH and ABH.

Benzamide also has two bands at 1656 and 1623 cm^{-1} in the solid spectrum, while in the solution spectrum, bands corresponding to them are seen at 1682 and 1608 cm^{-1}. The 1656 cm^{-1} band is assigned to an amide I, and the 1623 cm^{-1} band to NH_2 deformation vibration.

In this region BH also has two bands at 1664 and 1618 cm^{-1} in the solid state, of which the latter is more intense, while in the solution spectrum a band at 1672 cm^{-1} is stronger than that at 1634 cm^{-1}. BH has an NH_2 group, and an NH_2 deformation vibration will give rise to a band near 1590 cm^{-1} as sustituted hydrazines[10]. In addition to it, an amide I band should also be found in this region. The 1664 cm^{-1} band of solid BH may correspond to the 1672 cm^{-1} band in solution, and, accordingly, it is probably due to the C=O vibration. On the other hand, the 1618 cm^{-1} band of solid BH probably corresponds to the 1634 cm^{-1} band in solution, but it is difficult to discuss its assignment from the present observation only. For instance, three absorption bands characteristic to mono-acid hydrazides in this region were reported by Jensen[11], and one of them was seen to appear at 1620 cm^{-1}. Moreover, a band of the same frequency was seen in solution.

DBH has a band at 1535 cm^{-1} which can undoubtedly be assigned to an amide II band since the frequency is very close to that of the corresponding band of ABH. This region of the spectrum of BH is complicated by bands due to the vibrations of the aromatic ring. Nevertheless, it is not difficult to find bands due to the ring vibrations by comparison of the spectrum with those of relating compounds. The ring absorption bands will soon be discussed. BH has an intense band at 1568 cm^{-1} which is accompanied by a band at 1527 cm^{-1}. In the solution spectrum a corresponding band may appear in the lower frequencies, but it would be impossible to observe it because of interference by solvent absorption.

DBH has bands at 1305 and 1285 cm^{-1} of which the latter is stronger, and they are both ascribed to amide III bands by comparison of frequencies and their relative intensities with those of the corresponding bands of ABH. This suggests that there also is the coupling of two identical vibrations of the CONHNHCO group. In the solid state BH has an intense band isolated at 1349 cm^{-1} which is higher than the amide III frequencies of secondary amides. The frequency value decreases to 1311 cm^{-1} in the solution spectrum. Benzamide has an intense absorption at 1403 cm^{-1}, while a band at 1356 cm^{-1} is considered to correspond to it in the solution spectrum. This frequency is within the range of 1420~1400 cm^{-1} in which many primary amides have bands of frequencies characteristic to them[1]. The amide frequencies shown by the hydrazides examined are collected in Table II. Frequencies of BH and benzamide similar in value to them are also indicated in the lower part on the table.

In order to ascertain the assignment of characteristic bands of these hydrazides, absorption bands due to the ring vibrations will be discussed. The identification of these bands was made by a comparison of the spectra of all materials examined.

Four bands produced by skeletal stretching vibrations are easily found in spite of the superposition of other strong absorption bands. They lie near 1600, 1580, 1500 and 1450 cm^{-1}, as usually found in ordinary aromatic compounds[1]. The intensity of the 1580 cm^{-1} band is seen to be enhanced in the spectra of the compounds examined. This fact is regarded as a positive indication[1] of the conjugation of the C=O bond with the aromatic ring.

Strong bands assigned to the out-of-plane C–H deformation vibrations are little difficult to detect if shifts of the bands to higher frequencies are taken into account. A band near

a) The values in the solid state. b) ν; stretching, π; out-of-plane deformation.

800 cm^{-1} is commonly found for all materials with a C=O group directly attached to the ring, as has been pointed out by Kross et al.[9]

The C-H in-plane deformation vibrations will concern bands in the range 1225~950 cm^{-1}, but they are not always found because of the superposion of many relatively weak bands in this region.

Characteristic Bands. — The features of the amide frequencies of the hydrazides of aromatic acids are summarized as follows: (1) The splitting of the C=O stretching vibration (amide I) is observed in both solid and solution spectra. The spacing of the splitting of these two frequencies depends on radicals attached to the CONHNHCO group. (2) The amide II absorption band is found on the lower frequency side of the normal range of the corresponding band of secondary amides. The splitting of the amide II frequency was observed for TCABH, but not for ABH and DBH. It is noteworthy that TCABH has a single N-H stretching absorption band, while ABH and DBH have two N-H bands each. (3) The splitting of the amide III absorption band is seen for all of the hydrazides examined in both solid and solution, as it is for amide I. The frequencies of these two bands are in the normal range 1305~1200 cm^{-1}, in which many secondary amides have their characteristic frequencies of vibrations[1].

Summary

The infrared absorption spectra of acetylbenzoylhydrazine, trichloroacetylbenzoylhydrazine and dibenzoylhydrazine have been studied in the rock salt region. The assignment of the amide frequencies characteristic to the hydrazides RCONHNHCOR′ and the coupling between vibrations due to two CONH groups have been discussed.

The author is grateful to Professor Sunao Imanishi of Kyushu University for his generous permission to use the spectrophotometer, and to Dr. Yoshiya Kanda of Kyushu University for his encouragement throughout the work. He is also indebted to the Ministry of Education for financial support.

Infrared Absorption Spectra of Hydrazides. II. Sodium Hydrazides

By Mitsuo MASHIMA

(Received June 17, 1961)

In a previous paper[1] amide frequencies of aromatic hydrazides have been studied. In the present study, the influence on the amide frequencies of the ionized group of $CONHNCO^-$ of the substitution for a hydrogen atom of a sodium ion will be discussed.

Experimental

Diformylhydrazine was synthesized with sodium formate and hydrazine sulfate[2] and purified by recrystallization from ethanol, m. p. 155°C. Diacetylhydrazine was prepared with acetic anhydride and hydrazine hydrate[3] and purified by recrystallization from ethanol, m. p. 137°C. The syntheses of acetylbenzoylhydrazine and dibenzoylhydrazine have been described previously[1]. Sodium salts of these hydrazides were obtained by heating their ethanol solutions with sodium ethoxide and repeatedly washing them with a large quantity of ethanol. The salts obtained were examined analytically*1. Calcd. for $HCONHNCOH \cdot Na$: C, 21.8; H, 2.75; N, 25.5; Na, 20.9%. Found: C, 22.4; H, 3.16; N, 22.6; Na, 22.0%. Calcd. for $CH_3 \cdot CONHNCOCH_3 \cdot Na$: C, 34.8; H, 5.1; N, 20.3; Na, 16.7%. Found: C, 34.6; H, 5.4; N, 20.0; Na, 17.3%. Calcd. for $CH_3CONHNCOC_6H_5 \cdot Na$: C, 54.0; H, 4.53; N, 14.0; Na, 11.5%. Found: C, 54.0; H, 4.68; N, 13.8; Na, 12.1%. Calcd. for $C_6H_5CONHNCOC_6H_5 \cdot Na$: C, 64.1; H, 4.23; N, 10.7; Na, 8.77%. Found: C, 61.8; H, 4.23; N, 10.3; Na, 8.44%. Deuterium-containing salts were prepared in sealed tubes in the presence of heavy water (99.8%), of which the excess was evaporated in vacuo after the exchange reaction. A Hitachi infrared spectrophotometer type EPI-2 with a rock salt prism was used throughout the work.

Results and Discussion

Sodium Diformylhydrazine (SDFH).—The infrared absorption spectrum of diformylhydrazine[4] was reasonably explaned with a model of a transplanar configuration. It may be assumed that an ion $(HCONHNCOH)^-$ also has a planar configuration. It has only one plane of symmetry of point group C_s, and all twenty-one $(3N-6)$ fundamental modes will be active in the infrared. Of these, fifteen modes are of species A′ and six of species A″. Five of those will give rise to bands outside of the rock salt region. They may be torsional, τ(N–N), $\tau(C_1\text{–}N)$*2 and $\tau(C_2\text{–}N)$ (species A″), and deformation vibrations, $\delta(C_1\text{–}N\text{–}N)$ and $\delta(C_2\text{–}N\text{–}N)$ (species A′), because the τ(N–N) frequency of NH_2NH_2 is 377 cm^{-1} [5], and the δ(C–N–N) frequency of CH_3NHNH_2 is 433 $^{-1}$ [6]. In consequence, sixteen bands are expected to appear in the rock salt region.

The infrared absorption spectra of SDFH and SDFH-d are illustrated in Fig. 1. Let us first consider the frequencies related to the C–H bond, such as bond stretching ν(C–H), in-plane bending δ(C–H) and out-of-plane bending π(C–H). For diformylhydrazine Miyazawa[4] obtained a ν(C–H) frequency of 2900 cm^{-1} and a δ(C–H) frequency of 1368 cm^{-1}, while no π(C–H) frequency was found. SDFH has bands at 2870 and 1357 cm^{-1} and, accordingly, they are ascribed to ν(C–H) and δ(C–H) respectively. Bands corresponding to them are found at 2870 and 1354 cm^{-1} in the SDFH-d spectrum, respectively. For the ion $(HCONHNCOH)^-$ twe bands may be expected to appear as ν(C–H) or δ(C–H). However, only a single band due to ν(C–H) was observed on the background of absorption. On the other hand, a band appears at 1380 cm^{-1} in the SDFH spectrum which may be assigned to δ(C–H), while a band corresponding to it is seen at 1378 cm^{-1} for SDFH-d. SDFH has two bands at 1026 and 974 cm^{-1} which are easily ascribed to π(C–H), because bands corresponding to them were obtained at 1050 cm^{-1} for formamide[7], 1037 cm^{-1} for formamidoxime[8] and 1015 cm^{-1} for *N*-methyl formamide[9].

Other vibrational modes involving a hydrogen atom will be ν(N–H), δ(N–H) and π(N–H).

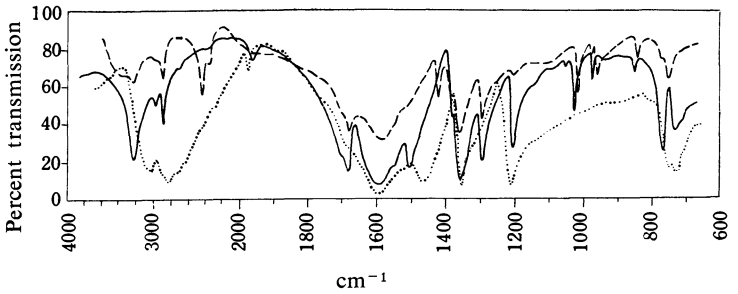

Fig. 1. Infrared absorption spectra of sodium diformylhydrazine (the solid curve), its *N*-deuterated derivative (the dashed curve) and diformylhydrazine (the dotted curve) in the solid state (KBr disk).

SDFH has a band at 3210 cm^{-1}, while a band at 2410 cm^{-1} corresponds to it in the spectrum of SDFH-d, the ratio ν_H/ν_D being 1.33. The band of 3210 cm^{-1} can, therefore, be easily assigned to ν(N-H). The identification of δ(N-H) will be considered later. The 785 cm^{-1} band of SDFH is not very different in frequency from the 770 cm^{-1} band of π(N-H) of diformylhydrazine[4], and, further no band corresponding to it is seen in the SDFH-d spectrum. It may, therefore, be taken as π(N-H).

Next the amide bands will be considered. In the range 1700~1200 cm^{-1} SDFH has bands at 1683, 1592, 1507, 1295, and 1202 cm^{-1} (except for the bands at 1380 and 1357 cm^{-1} which have already been ascribed to δ(C-H)). Three of the five bands scarcely change in frequency on *N*-deuteration; i. e., bands at 1676, 1588, and 1288 cm^{-1} in the spectrum of SDFH-d correspond to the bands at 1683, 1592, and 1295 cm^{-1} of SDFH respectively. On the other hand, two bands at 1417 and 955 cm^{-1} of SDFH-d correspond to the two remaining bands at 1507 and 1202 cm^{-1} respectively. Therefore, these two bands can be assigned without difficulty. The 1507 cm^{-1} band can be taken as an amide II band, because it is close in frequency to the corresponding bands of secondary amides, which generally show frequencies within 1570~1515 cm^{-1} [10]. Moreover, the wave number ratio is 1.063. This is close in value to 1.106 for diformylhydrazine[4]. The 1202 cm^{-1} band can be ascribed to an amide III band, the ratio ν_H/ν_D being 1.258, which is close to 1.248 for diformylhydrazine[4]. In addition to the amide II and amide III bands due to the CONH group of the ionized group $CONHNCO^-$, an amide I band will be expected to appear. It can be identified with the 1683 cm^{-1} band because the value of frequency is very close to the upper limit of the range 1680~1630 cm^{-1} in which many secondary amides have amide I frequencies. In consequence, the amide bands I, II, and III due to the CONH group are located in their own characteristic regions. It may, therefore, be concluded that the vibrations relating to the CONH group are not much influenced by an electronic charge stored in another part of the $CONHNCO^-$ group, and hence the NCO^- group probably has its own absorption frequencies. It is reasonable to expect that in the ion $(RCONHNCOR')^-$ there is a resonance between the two structures as indicated in Fig. 2. Therefore, absorptions due to the NCO^- group will be somewhat similar to those of the ionized group COO^-. The antisymmetrical and symmetrical vibrations of the COO^- structure concern two bands within the ranges 1610~1550 cm^{-1} and 1420~1300 cm^{-1} respectively[10]. In the range 1700~1200 cm^{-1} of SDFH two bands at 1592 and 1295 cm^{-1} remain to be assigned. We may ascribe the bands at 1592 and 1295 cm^{-1} to $\nu'(NCO^-)$ and $\nu''(NCO^-)$ respectively. The modes of vibrations of $\nu'(NCO^-)$ and $\nu''(NCO^-)$ may be assumed to be similar to those of ν_{as} and ν_s of a COO^- group respectively.

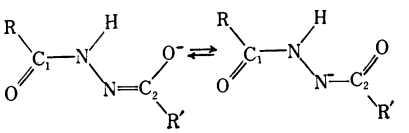

Fig. 2.

There remain three fundamentals unaccounted for, i. e., δ(O-C_1-N), δ(O-C_2-N), and ν(N-N). SDFH has a band at 731 cm^{-1} which can possibly be assigned to δ(O-C_1-N), because a band corresponding to it is observed at 753 cm^{-1} in the diformylhydrazine spectrum[4] and 746 cm^{-1} for SDFH-d. A ν(N-N) band was observed at 1100 cm^{-1} for HCONDNHCOH[4] and at 1165 cm^{-1} for $(CH_3CONH-)_2 \cdot H_2O$[11].

A''	τ(C_1-N)			
	τ(C_2-N)			
	τ(N-N)			

ν: stretching, δ: in-plane bending, π: out-of-plane bending, τ: torsional.
Values in parentheses are no exact ones.

SDFH and SDFH-d also have a band near 1100 cm^{-1}, but the definite frequency can not be determined because of its broad absorption pattern. Now, only one fundamental, δ(O-C_2-N), remains to be located. The 843 cm^{-1} band not yet interpreted may be ascribed to δ(O-C_2-N), a corresponding band being at 837 cm^{-1} for SDFH-d. The observed frequencies and their assignments are summarized in Table I.

In order to check the validity of these assignments, the Teller-Redlich product rule[12] is applied to the frequencies of species A'. The structure of $(HCONHNCOH)^-$ is not definitely determined, but the dimensions used in calculating moments of inertia are assumed as follows; for the HCONH-N part[4] N-H 1.00 Å, C-N 1.32 Å, C-O 1.21 Å, C-H 1.07 Å, N-N 1.38 Å, ∠C-N-N- 116°, ∠H-N-C 122°, ∠N-N-H 122°, ∠O-C-N 124°, ∠H-C-O 118°, ∠N-C-H 118°, for the HCON-N part C-N 1.21 Å, C-O 1.27 Å, C-H 1.07 Å, ∠N-N-C 118°, ∠H-C-O 118°, ∠N-C-O 124°. For the HCON the C-O distance and N-C-O angle are assumed to be equal to the C-O distance and O-C-O angle of sodium formate[13], and the C-N distance and N-N-C angle are chosen as equal to the C-N distance and H-N-C angle of HNCO[14]. In applying the product rule, it is assumed that the ratio ν_H/ν_D is 1.024*3 for δ(C-N-N) due to the HCONH-N part and that the values of δ(C-N-N) related to the HCONH-N part and ν(N-N) of SDFH-d are the same as those of SDFH. The observed product ratio is 0.530, while the calculated ratio is 0.509. Although the agreement is not very good, a much better value could be calculated if more reasonable estimates of the ratios of δ(C-N-N) and ν(N-N) could be made.

Sodium Diacetylhydrazine (SDAH). — The infrared absorption spectra of SDAH and SDAH-d in the solid state are shown in Fig. 3, in which the spectrum of diacetylhydrazine is also given for comparison. Let us chiefly consider the location of bands due to vibrations relating to the ionized group $CONHNCO^-$. SDAH has a band at 3290 cm^{-1} which is easily assigned to ν(N-H), while a band corresponding to it is at 2390 cm^{-1} for SDAH-d, the ratio ν_H/ν_D being 1.34.

A complicated spectral pattern is seen in the region of 1650~1250 cm^{-1}, and bands in that region will reflect vibrations relating to the $CONHNCO^-$ and CH_3 groups. There are bands at 1656, 1552*4, 1513, 1428, 1392, 1339,

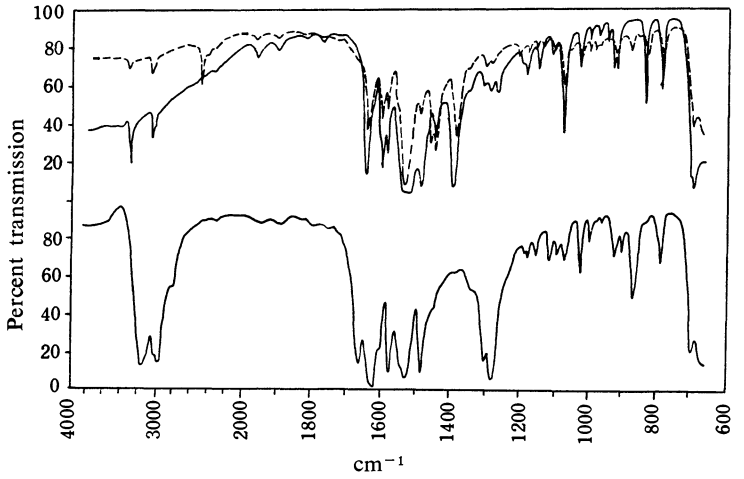

Fig. 4. Infrared absorption spectra of sodium dibenzoylhydrazine (the upper solid curve), its *N*-deuterated derivative (the dashed curve) and dibenzoylhydrazine (the lower solid curve) in KBr disk.

and 1249 cm^{-1} for SDAH. Of these seven bands the 1513 cm^{-1} band seems to correspond to a band at 1473 cm^{-1} of the SDAH-d spectrum, while the 1249 cm^{-1} band has no counterpart in the SDAH-d spectrum. The former is very close in frequency to the amide II band at 1506 cm^{-1} for diacetylhydrazine[11], and hence it may be taken as the amide II band relating to the CONH group of the ion $(CH_3CONHNCOCH_3)^-$. The latter may be taken as the amide III band of the CONH group because a band corresponding to it was found at 1260 cm^{-1} for diacetylhydrazine[11].

On the other hand, the five remaining bands of SDAH have respective counterparts of nearly the same frequencies in the SDAH-d spectrum. Their assignments can be made by comparison of the SDAH spectrum with that of SDFH. The rather weak band at 1656 cm^{-1} corresponds to the 1683 cm^{-1} band of SDFH and, accordingly, may be ascribed to the C=O vibration relating to the CONH group. Although the occurrence of two peaks as indicated in the footnote is not reasonably explained the 1552 cm^{-1} band corresponds in frequency and especially in intensity to the 1592 cm^{-1} band of SDFH. In consequence, it is probably ascribed to ν' as mentioned in the previous section. Further, two bands at 1428 and 1392 cm^{-1} can be assigned to the asymmetrical and symmetrical CH_3 deformation vibrations respectively; a detailed assignment will be given in a later section. Only the 1339 cm^{-1} band is not yet accounted for in the region 1650~1250 cm^{-1}. It can probably be ascribed to ν'' of the NCO^- group like the 1295 cm^{-1} band of SDFH. This assignment is corroborated by the fact that no corresponding band has been observed for diacetylhydrazine[11].

Sodium Dibenzoylhydrazine (SDBH).—The infrared absorption spectra of SDBH and SDBH-d are shown in Fig. 4, the solid spectrum of dibenzoylhydrazine (DBH) is also given for comparison.

In the 3000 cm^{-1} region, SDBH has a band at 3290 cm^{-1} and a relatively weak band at

3030 cm^{-1}. The former is within the normal range 3320~3270 cm^{-1} of secondary amides[10], and a band corresponding to it is found at 2480 cm^{-1} in the SDBH-d spectrum. Therefore, the 3290 cm^{-1} and 2480 cm^{-1} bands are ascribed to ν(N-H) and ν(N-D) respectively, the ratio ν_H/ν_D being 1.326. The 3030 cm^{-1} band can be attributed to the aromatic C-H stretching vibrations, because its corresponding band is seen at 3040 cm^{-1} in the SDBH-d spectrum. Since the ionized group $CONHNCO^-$ has one N-H group, only a single N-H band is expected to appear. In fact, it is observed at 3290 cm^{-1}, as indicated above.

Next we will consider amide bands. As pointed out previously[1], DBH has amide I bands at 1669 and 1636 cm^{-1}, while SDBH has a band at 1637 cm^{-1} and a band of the same frequency is found in the SDBH-d spectrum. All the bands lie within the normal range (1680~1630 cm^{-1}) of the amide I band of the secondary amides. In consequence, the 1637 cm^{-1} band should be taken as the amide I band due to the CONH group of $CONHNCO^-$.

The amide III absorption has also been found as two bands at 1302 cm^{-1} and 1285 cm^{-1} in the DBH spectrum[1], while SDBH has a band at 1264 cm^{-1} (very weak) and no corresponding band is seen in the SDBH-d spectrum. Therefore, the 1264 cm^{-1} band is taken as the amide III band of the CONH part of the $CONHNCO^-$ group.

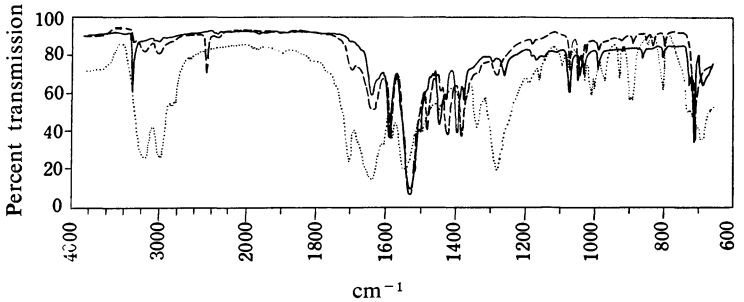

Fig. 5. Infrared absorption spectra of sodium acetylbenzoylhydrazine, its (solid curve), its *N*-deuterated derivative (dashed curve), and acetylbenzoylhydrazine (dotted curve) in KBr disk.

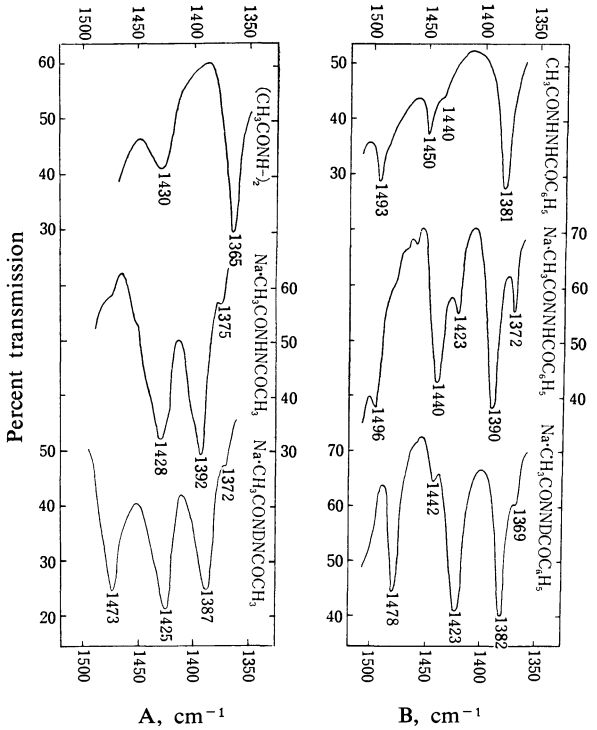

Fig. 6. Infrared spectra in the region of methyl bending vibrations.

The presence of the aromatic ring absorption in the 1600～1450 cm^{-1} region makes the spectrum much more complicated, but the amide bands in that region can be located without difficulty by comparison of the spectral patterns in Fig. 4 with each other. The 1535 cm^{-1} band of DBH[1] has been assigned to the amide II band. SDBH has a very strong absorption band at 1528 cm^{-1} and, further, a band at 1390 cm^{-1}, while SDBH-d has corresponding bands at 1527 and 1383 cm^{-1}. Moreover, a band at 1485 cm^{-1} of SDBH is too intense to be ascribed to an aromatic ring vibration of about 1500 cm^{-1} [10]. In the SDBH-d spectrum a relatively weak band at 1487 cm^{-1} may correspond to it, and in addition a band of 1442 cm^{-1} appears. Therefore, the 1485 cm^{-1} band of SDBH is ascribed to the amide II band of the CONH group. In consequence, both bands, at 1528 and 1390 cm^{-1} of SDBH, are ascribed to vibrations of the NCO^- group. They can probably be attributed to ν' and ν'', as indicated in the previous sections.

Sodium Acetylbenzoylhydrazine (SABH).— The infrared absorption spectra of SABH and SABH-d are illustrated in Fig. 5. The spectrum of acetylbenzoylhydrazine is also shown for comparison.

SABH has an isolated absorption band at 3300 cm^{-1} which can easily be assigned to ν(N–H). A corresponding band is located at 2460 cm^{-1} for *N*-deuterated SABH, the ratio ν_H/ν_D being 1.34.

The 1637 cm^{-1} band of SABH is in good accordance in frequency and in relative intensity with the 1637 cm^{-1} of SDBH assigned to the amide I. A corresponding band is found at 1638 cm^{-1} for SABH-d. Therefore, both bands are ascribed to the amide I band.

Acetylbenzoylhydrazine[1] has an amide III band at 1281 cm^{-1}. A corresponding band is seen at 1256 cm^{-1} in the spectrum of SABH, but it is very weak in intensity. In the SABH-d spectrum a band at 1046 cm^{-1} may correspond to it. Therefore, the 1256 cm^{-1} band of SABH is taken as the amide III absorption.

SABH shows the most intense band at 1527 cm^{-1} among its spectral bands. It is in good accordance with the 1528 cm^{-1} band of SDBH in frequency, and a band of the same frequency is seen for SABH-d similar to that of SDBH-d. Hence, it is ascribed to $\nu'(NCO^-)$ like the 1528 cm^{-1} band of SDBH. On the other hand, it is difficult to fix a band due to $\nu''(NCO^-)$. Since SABH has a methyl group, deformation vibrations of the methyl group give rise to bands generally in the region of 1500～1350 cm^{-1}, and, moreover, SABH may also have bands of $\nu''(NCO^-)$ and aromatic ring frequencies in that region. The infrared spectra in the region of methyl bending vibrations of diacetylhydrazine, SDAH, and SDAH-d are illustrated in Fig. 6A, while those of acetylbenzoylhydrazine, SABH, and SABH-d are given in Fig. 6B. Acetylbenzoylhydrazine[1] has a band at 1381 cm^{-1} which is undoubtedly due to $\delta_s(CH_3)$. However, SABH has bands corresponding to it at 1390 and 1372 cm^{-1}, and SABH-d has them at 1382 and 1369 cm^{-1}. Similar bands are also observed in the spectra of diacetylhydrazine and its sodium salt, as is shown in Fig. 6A. Diacetylhydrazine shows a band due to $\delta_s(CH_3)$ at 1365 cm^{-1}. Bands corresponding to it are observed at 1392 and 1375 cm^{-1} in the spectrum of SDAH and at 1387 and 1372 cm^{-1} of SDAH-d. In general, the bands due to $\delta_s(CH_3)$ appear at nearly the same position. In the spectrum of SABH appearances of two bands due to $\delta_s(CH_3)$ can not be interpreted with confidence. However, these two bands can probably be ascribed to $\delta_s(CH_3)$, since they are in good agreement in frequency and relative intensity with those of the spectra SABH, SABH-d, SDAH, and SDAH-d. The compounds containing a methyl group generally show another absorption band near 1460 cm^{-1} arising from the asymmetrical deformation $\delta_{as}(CH_3)$. Diacetylhydrazine shows a corresponding band at 1430 cm^{-1}. SDAH also has an absorption band at 1428 cm^{-1}, and SDAH-d, at 1425 cm^{-1}. On the other hand, it is difficult to locate a band of $\delta_{as}(CH_3)$ in the spectra of SABH and of SABH-d, because aromatic ring vibrations also give rise to bands near 1450 cm^{-1}. In the spectrum of acetylbenzoylhydrazine, a band which appeared as a shoulder of the 1450 cm^{-1} band was ascribed to $\delta_{as}(CH_3)$ in the previous paper[1]. However, SABH shows two bands at 1423 and 1440 cm^{-1} (relatively strong), and, also, SABH-d has bands at 1423 (more intense) and 1442 cm^{-1}. These two bands of SABH are in good agreement with the corresponding bands of SABH-d in frequency but in an inverse intensity ratio. As mentioned above, diacetylhydrazine and its salt show a single band each assigned to $\delta_{as}(CH_3)$, i. e., 1430 and 1428 cm^{-1} respectively, while acetylbenzoylhydrazine has a single band at 1440 cm^{-1}. On the other hand, it can be expected that in SABH and SABH-d the absorption due to $\delta_{as}(CH_3)$ is overlapped by the absorption due to the aromatic ring vibrations and further $\nu''(NCO^-)$ vibrations. In consequence, it is impossible to locate these three vibrations definitely. The 1478 cm^{-1} band of SABH-d is not yet accounted for. No corresponding band is observed in the spectrum of SABH and also of acetylbenzoylhydrazine.

TABLE II. OBSERVED FREQUENCIES AND THEIR ASSIGNMENTS (in cm^{-1})

Group	Assignment	DFH	SDF	DAFH	SDAH	DBH	SDBH	ABH	SABH
	Amide I	1610	1683	1598	1656	1669 1636	1637	1707 1646	1637
CONH	Amide II	1480	1507	1506	1513	1535	1485	1527	1510
	Amide III	1229	1202	1260	1249	1285 1305	1264	1281 1337	1256
NCO^-	ν'		1592		1552		1528		1528
	ν''		1295		1339		1390		—

Furthermore, its frequency value is too low to be ascribed to aromatic ring vibrations whose bands generally appear near 1500 cm^{-1}. The ring vibrations were observed at 1493 cm^{-1} and 1497 cm^{-1} for acetylbenzoylhydrazine and its *N*-deuterated derivative respectively. SABH also shows a band at 1496 cm^{-1}. Thus, the 1478 cm^{-1} band of SABH-d can be ascribed to the amide II′ absorption relating to the COND part of the ionized group $CONDNCO^-$. A corresponding band for SABH can be taken as a poorly defined shoulder (near 1510 cm^{-1}) which is accompanied by the 1528 cm^{-1} band.

Characteristic Frequencies.—In the solid state the sodium hydrazides can be expected to exist in a form $Na^+RCONHNCOR'^-$. The amide bands will, therefore, be shown by the group CONH in their infrared spectra. In addition to them, absorption bands due to the ionized group NCO^- will also be observed.

The observed frequencies and their assignments are summarized in Table II. For comparison the amide frequencies of the hydrazides are also represented in that table.

Secondary amides[10] in the solid state have the amide I and amide II bands in the ranges 1680～1630 cm^{-1} and 1570～1515 cm^{-1} respectively, and the amide III band near 1290 cm^{-1}. The hydrazides of aliphatic acids[15] have bands shifted towards lower frequencies. However, SDFH and SDAH show amide frequencies somewhat different from those of the corresponding hydrazides, i. e., the amide I band increased distinctly in frequency but decreased a little in intensity, the amide II band increased a little in frequency, and the amide III band decreased in frequency.

On the other hand, the hydrazides of aromatic acids[1] in the solid state showed the amide I band within the range of secondary amides but split into two bands, which bands are attributable to coupling between two C=O vibrations. Further, the amide II and amide III bands are seen within the normal ranges of secondary amides, but the latter splits into two bands. As for SDBH and SABH, their amide I bands are in good agreement in frequency each other, and they can be ascribed to the C=O group adjacent to the benzene ring. Further, these salts show that the amide II band has decreased in frequency, while the amide III bands of SDBH and SABH are nearly equal in frequency. Therefore, it may be understood that the amide bands due to the CONH group of the ions $(RCONHNCOR')^-$ appear generally in the normal range of secondary amides, so that the vibrations relating to CONH group are little affected by an electronic charge stored in the NCO^- group. In the NCO^- group resonance will be possible between the C–N and C–O bonds. In consequence, the NCO^- structure gives rise to two bands similar to those of the COO^- group as represented in Table II.

Furthermore, it is noteworthy that an N–H stretching vibration concerns a band near 3300 cm^{-1} in the spectra of the sodium hydrazides. The value of frequency lies in the normal range 3320～3270 cm^{-1} of the secondary amides[10].

Summary

The infrared absorption spectra of $HCONH \cdot NCOH \cdot Na$, $CH_3CONHNCOCH_3 \cdot Na$, $CH_3CONHNCOC_6H_5 \cdot Na$, and $C_6H_5CONHNCOC_6H_5 \cdot Na$ and their *N*-deuterated derivatives have been examined in the rock salt region. The characteristic frequencies of the ions $(RCONHNCOR')^-$ have been obtained, and the influence of an electronic charge on the amide frequencies has been discussed.

The author is grateful to Professor Sunao Imanishi of Kyushu University for his generous permission to use the spectrophotometer, and to Dr. Yoshiya Kanda of Kyushu University for his encouragement throughout the work. The Reaction of Hydrogen and Oxygen through a Silent Electric Discharge. I. The Formation of Hydrogen Peroxide

By Kihei MORINAGA

(Received June 26, 1961)

The formation of hydrogen peroxide from a hydrogen-oxygen gas mixture through a high frequency silent discharge has been investigated with the intention of obtaining a reaction pattern in connection with an accompanying pulse current. The features of the peroxide formation more resembles that of ozone formation in a silent discharge[1,2] than that of both gases in a low pressure glow discharge.

Experimental

All the measurements were carried out under atmospheric pressure using the flow method.

The reaction mixture of hydrogen and oxygen gas (4.5% vol. O_2) was held in a gas holder of ca. 1 m^3. The gas mixture was dried by passing it through a 4 m. glass tube filled with calcium chloride and silica gel and then was served for use. The humidity of the gas on the final issue was about $-20°C$.

The electric circuit was similar to that which had been used in the previous work[2]. The high frequency electric current was provided by a 32 pole generator with the R. P. M. selected so as to obtain an output frequency of from 500 c./sec. to 2000 c./sec.

The discharge tubes were of the Siemens type, made of Telex glass, with a length and diameter of 40 and 4 cm. respectively. The gap length was varied between 1, 2 and 3 mm., and the discharge area could be varied by applying an adequate expansion of a tin foil patch on the outside of the glass tube.

After being exposed to the electric discharge, the reactant gas was cooled in a condensation trap where the hydrogen peroxide and water were caught by freezing. The cooling agents of the condensation trap were a salt-ice mixture or liquid air. The former was used mainly for the constant flow system, and the latter for the variable rapid flow system. The condensate was weighed and analyzed by iodometry, using ammonium molybdate as a decomposition catalyst for the hydrogen peroxide.

Results

1) The effect of the change of frequencies of the discharge current on the formation of peroxide is shown in Fig. 1, where the pulse current is scaled on the abscissa and the rate of conversion of reactant oxygen gas to hydrogen peroxide, on the ordinate. The flow rate, or the time (τ) of the residence in the discharge tube, is the same throughout the runs — 5.0 sec. for each run. The measurements were conducted up to the high frequency pulse current value of 600 μamp., this being the safety limit to prevent damage to the discharge tube. The area of the electrode and the gap length have values of 233 cm^2 and 3 mm. respectively.

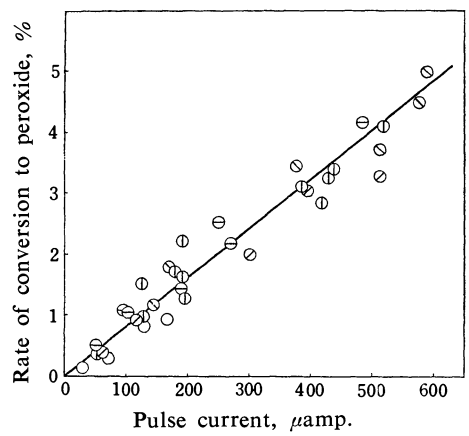

Fig. 1. The rate of conversion to the peroxide under the discharge of various frequencies against pulse current.
$A=233$ cm^2; $d=3$ mm.
○ 50 c./sec. ⊖ 500 c./sec. ◐ 1000 c./sec.
⊘ 1500 c./sec. ⊗ 2000 c./sec.

As shown in Fig. 1, the above rate, plotted against the pulse current, shows as a straight line and is independent of the frequency of the discharge current. The exclusive products of the reaction were water and hydrogen peroxide. The concentration of the hydrogen peroxide in the product solution was about 60% by wt., which percentage does not vary extensively in accordance with the different values of frequencies.

2) The rate of peroxide formation in various shaped discharge tubes was measured with respect to the pulse current. The values of the time of residence ($\tau=5.0$ sec.) and the frequency of discharge current (1000 c./sec.) were kept constant.

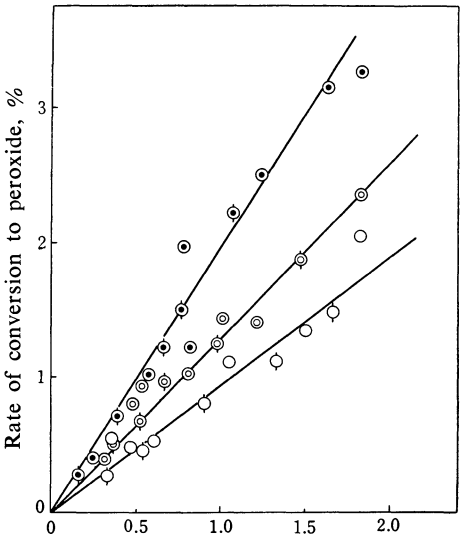

Fig. 3. The rate of conversion to the peroxide against the pulse current per unit discharge area. A and d are varied. Each of the plots represents such the discharge tube as is noted in Fig. 2.

In Fig. 2, the concentration of the hydrogen peroxide in the condensate is plotted against the pulse current per unit electrode area. The concentration does not depend on the pulse current, or on the electrode area, but rather depends on the gap length of the discharge tube. In Figs. 3, 4 and 5, the pulse current per unit electrode area is plotted on the abscissa. The conversion rate of the peroxide and water are increased linearly with respect to the pulse current per unit electrode area but does not depend on the electrode area. In these figures, one gap length corresponds to

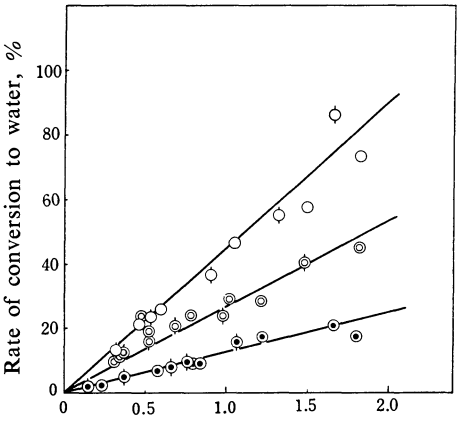

Fig. 4. The rate of conversion to water against pulse current per unit discharge area. A and d are varied. Each of the plots represents such the discharge tube as is noted in Fig. 2.

one straight line. The rate of conversion of the peroxide is larger with the larger gap length, while, on the other hand, that of water is larger in the shorter gap length. In Fig. 5, the overall conversion rate is summarized. So far as the constant resident time (ca. 5 sec.) is concerned, the results obtained using both liquid air or salt-ice coolants were entirely identical.

3) In the following experiments, the results of which are shown in Figs. 6, 7 and 8, the gap length of the discharge tubes were 1, 2 and 3 mm. and the discharge area was 250 cm^2. In these figures, the peroxide concentration

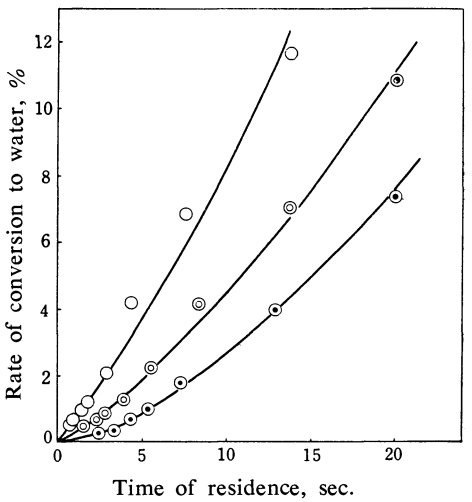

Fig. 8. Rate of conversion to water against time of residence. d is varied. Each of the plots represents such the discharge tube as is noted in Fig. 6.

and the rate of conversion of peroxide and water are plotted against the time of residence, the pulse current per area being ca. 0.85 μamp./cm^2. For each case, a run corresponding to a certain gap length is represented by a curve. In the runs where the flow velocities vary, that is, when the time of residence is occasionally very short, the condensate product was trapped by liquid air freezing. The peroxide concentration in the condensate decreases with increasing resident time, as is shown in Fig. 6, and the conversion rate to the peroxide plotted in Fig. 7, showed a kind of saturation-like behavior against the resident time. On the other hand, the conversion rate to water shows a different behavior than Fig. 7.

Discussion

From Fig. 1, one may conclude that the mechanism of the rate of formation of hydrogen peroxide is the same for all reactions, regardless of the output frequency (between 50 c./sec. and 2000 c./sec.). The same applies to the formation of water under identical conditions, for the rate of water formation versus pulse current has about the same characteristics as those of peroxide formation.

The whole pattern which is apparent in the above-mentioned figures is very much like those of ozone formation. In the reaction between hydrogen and oxygen, the elementary processes which govern the rate of formation of the entire series would be, then, the one wherein an electron participates.

According to the generally accepted mechanism[3-8], the simplest reaction scheme to explain these essential features may be written as follows:

$$H_2+e=2H+e \quad (1)$$

$$O_2+e=2O+e \quad (2)$$

$$H+O_2=OH+O \quad (3)$$

$$O+H_2=OH+H \quad (4)$$

$$OH+H_2=H_2O+H \quad (5)$$

$$OH+OH=H_2O_2 \quad (6)$$

$$H_2O_2+H=H_2O+OH \quad (7)$$

The reaction involving H atoms and the OH radical may be of importance here. If the pressure under which the reaction proceeds is rather high, then the concentration of the H atom is not likely to be high; on the other hand, if the amount of oxygen in the starting mixture is small, then the number of oxygen atoms will also be small. Because reactions 3 and 4 are fast, an equilibrium concentration for the OH radical may be established which will govern the overall reaction rate and, simultaneously, be governed by the molecular entities of the collision product with electrons.

It seems to be irrelevant to go into more detail in each of these elementary processes; it will suffice to explore the obtained results from the postulate concerning the behavior of issued electrons and their first-step elementary act. Therefore, in this pattern of reaction mechanism, the overall rate of formation should keep a linear relationship with the quantity of electrons carried through the discharge zone or the pulse current which is in accord with Figs. 3, 4 and 5.

The fact that, in Fig. 2, the concentration of the produced hydrogen peroxide remains constant, independent of the value of the pulse current, agrees with the features of the diagrams in Figs. 3, 4 and 5. The reaction rate at a certain flow velocity ($\tau=5.0$ sec.), and under a certain frequency of discharge current, is again proportional to the pulse current. In conclusion, the ratio of produced hydrogen peroxide to the whole reaction product should remain constant regardless of the pulse current per unit area.

Each straight line in Figs. 3, 4 and 5 is assigned to a certain value of gap length because the rate of reaction should receive considerable influence from the gap length between the electrodes.

The curves for the relationship between concentration and flow velocities (Figs. 6, 7 and 8) are those usually known for such cases. As the flow rate becomes smaller, the composition of the product tends to approach a limiting value which is expected to be an equilibrium value between formation and destruction at an approximately static state.

As has been pointed out in the ozone formation process[1], the initiation of the reaction is started in a small column by an individual discharge lasting half the period of every discharge frequency. The remaining space in the whole discharge zone serves partly as a destruction area for the hydrogen peroxide which is the result of the sequence of processes in the discharge column. The larger the gap length is, then, the more the small discharge column will be expanded; in other words, the field of formation is relatively larger than that of destruction. The postulate is then concordant with the results.

The elucidation of the detailed behavior of the reacting molecular species in connection with the accepted elementary processes is not yet fully feasible because of the lack of detailed knowledge of the discharge phenomena which accompany chemical reactions.

Summary

1) The reaction between hydrogen and oxygen in a silent electric discharge of high frequency was investigated. The product, in the course of reaction, is solely hydrogen peroxide and water.

2) The linear relationship, independent of the frequency of the current, between the rate of formation of hydrogen peroxide or of water and the pulse current was established.

3) The composition of the hydrogen peroxide-water solution is constant so long as the gap length is constant.

4) The flow rate and the said composition relation were measured.

5) The reaction pattern in the discharge zone was briefly discussed.

The author would like to express his deep appreciation to Professor Momotaro Suzuki of the Defense Academy for his encouragement, helpful advice and guidance throughout this investigation.

The Reaction of Tropoids and Quinone Derivatives. II. Reaction of Several Tropolones and p-Benzoquinone

By Shuichi SETO and Humio SATO

(Received June 13, 1961)

Preceding paper of this series[1] reported the reaction of several kinds of tropolones and *p*-benzoquinone dibenzenesulfonimide. The use of *p*-benzoquinone in place of *p*-benzoquinone dibenzenesulfonimide results in rather complicated reactions but under certain reaction conditions, products having a tropolone ring were found to be formed. The present paper reports on the structure of products obtained by the reaction of tropolone and its bromo derivatives with *p*-benzoquinone.

A solution of tropolone and *p*-benzoquinone dissolved in methanol containing a small amount of acetic acid afforded at room temperature, orange crystals (A) and colorless crystals (B). Analytical values of B corresponded to the molecular formula of $C_{13}H_{10}O_4$ and, from its coloration to ferric chloride and ultraviolet absorption spectrum, it was found to retain the tropolone ring. Methylation of B with diazomethane afforded a monomethyl ether (C) and dimethyl ether (D). Hydrolysis of C reverted it to B, but that of D afforded a monomethyl ether (E) different from C. C and D do not show the characteristic coloration to ferric chloride but E does so. Methylation of B with dimethyl sulfate, in the presence of potassium hydroxide afforded monomethyl ether (E), whose further methylation with diazomethane gave D. These facts show that B possesses two hydroxyl groups, one of which is phenolic and the other is the hydroxyl in the tropolone ring. In order to determine the structure of B, the tropolone ring was made to undergo rearrangement to form a benzoic acid derivative. D was led to the 2-bromotropone derivative through the hydrazino derivative[2] and treated with alkali to form a benzoic acid derivative which showed no depression of the melting point on admixture with 4-(4′-methoxyphenoxy)benzoic acid (VII)[3] and ultraviolet absorption spectra of these two substances were in good agreement. Consequently, the foregoing 2-bromotropone and hydrazino derivatives would respectively be 2-bromo-5-(4′-methoxyphenoxy) tropone (VI) and 2-hydrazino-5-(4′-methoxyphenoxy)tropone (V). The methyl ethers, C, D and E would then be 2-methoxy-5-(4′-hydroxyphenoxy)tropone (II), and 2-methoxy-5-(4′-methoxyphenoxy)-tropone (III), and 5-(4′-methoxyphenoxy)-tropolone (IV). It has therefore been proved that B is 5-(4′-hydroxyphenoxy)tropolone (I).

The analytical values of the orange crystals (A) agreed with the formula of $C_{13}H_8O_4$ and this substance was also found to retain the tropolone ring from its coloration to ferric chloride and ultraviolet absorption spectrum. Its infrared spectrum exhibited absorption of $\nu_{C=O}$ of *p*-benzoquinone at 1657 and 1651 cm^{-1}. These facts suggest that A is a compound formed by carbon-carbon bonding of tropolone and *p*-benzoquinone. As for the position of its bonding, there is only one possible position in *p*-benzoquinone but three positions, 3, 4 and 5, are possible in the tropolone ring. It was proved, by the experiments to be iterated below, that the bonding position in the tropolone ring is at 3 and that A is 3-(*p*-benzoquinonyl)tropolone (VIII).

Catalytic reduction of A over palladium-carbon or treatment with sodium dithionite affords a dihydroxyphenyltropolone (IX), whose methylation with dimethyl sulfate gives dimethoxyphenyltropolone (X). X forms two kinds of 2-methoxytropone derivative (XI and XII) by treatment with diazomethane which indicates that the aryl group is bonded to a position other than 5 in the tropolone ring. Similar to the foregoing case, 2-methoxytropone (XI) was led to 2-chlorotropone (XIV) via 2-hydrazinotropone (XIII) and alkali treatment of XIV gave a benzoic acid derivative (F). F was identified with 2-(2′, 5′-dimethoxyphenyl)-benzoic acid (XV), synthesized by the following route, by mixed fusion and comparison of infrared and ultraviolet absorption spectra.

In accordance with the preparation of 4-(2′,-5′-dihydroxyphenyl)acetophenone from 4-aminoacetophenone and *p*-benzoquinone[4], the diazonium salt obtained from methyl anthranilate was reacted with *p*-benzoquinone, in the

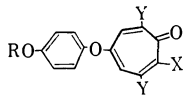
3) C. R. Harrington, *Biochem. J.*, 20, 300 (1926).
4) G. A. Reynolds and J. A. VanAllen, "Organic Syntheses", 34, 1 (1954).

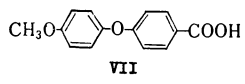
presence of sodium hydrogencarbonate and reduction of its product with sodium dithionite afforded colorless crystals (G), whose analytical values corresponded to the formula of $C_{13}H_8O_3$ and which formed phthalic acid by oxidation with potassium permanganate. Methylation of G with dimethyl sulfate in the presence of potassium carbonate gave a monomethyl ether. Therefore G would be 2-hydroxybenzo[c]coumarin (XVI) and its monomethyl ether, 2-methoxybenzo[c]coumarin (XVII). Methylation of XVI with dimethyl sulfate with heating in the presence of potassium hydroxide, resulted in opening of the lactone ring to form 2-(2′, 5′-dimethoxyphenyl)benzoic acid (XV).

Since the structure of F is 2-(2′, 5′-dimethoxyphenyl)benzoic acid, the structure of A would be 3-(*p*-benzoquinonyl)tropolone (VIII).

The reduction product of A, 3-(2′, 5′-dihydroxyphenyl)tropolone (IX), easily undergoes dehydration when warmed with *p*-toluenesulfonic acid and changes into 2-hydroxybenzofuro[2, 3-b]tropone (XVIII). This reaction also supports the above structure. Methylation of XVIII with dimethyl sulfate in the presence of potassium carbonate, affords 2-methoxybenzofuro[2, 3-b]tropone (XIX).



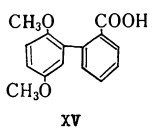
3-Bromotropolone also undergoes reaction with *p*-benzoquinone to form *p*-benzoquinonyl-3-bromotropolone (XX) whose catalytic reduction over palladium-carbon or treatment with sodium dithionite affords a dihydroxyphenyl derivative (XXI). Hydrogenolysis of XXI in ethanol containing diethanolamine, with palladium-carbon catalyst, gives 3-(2′, 5′-dihydroxyphenyl)tropolone (IX). Consequently, XX is proved to be 3-bromo-7-(*p*-benzoquinonyl)tropolone.



Methylation of XXI with dimethyl sulfate in acetone, in the presence of potassium carbonate, results in rearrangement of the tropolone ring to benzoic acid and 2-methoxy-7-bromobenzo[c]coumarin (XXIV) is obtained. Treatment of XXI with *p*-toluensulfonic acid affords 2-hydroxy-7-bromobenzofuro[2, 3-b]tropone (XXII) and its methylation as above produces 2-mehoxy-7-bromobenzofuro[2, 3-b]tropone (XXIII) and dimethyl ether (XXV) of 3-bromo-7-(2′, 5′-dihydroxyphenyl)tropolone (XXI) without such a rearrangement.

The ultraviolet absorption spectra of benzocoumarin derivatives and benzofuro-tropone derivatives are similar in the wavelength of absorption maxima but there is a distinct difference in the infrared spectra of these two series. The infrared spectra of benzocoumarin derivatives show strong absorptions in the range of 1690~1720 cm^{-1} (at 1696 cm^{-1} in XVI, at 1709 cm^{-1} in XVII, and at 1721 cm^{-1} in XXIV) while that of benzofuro-tropone derivatives does not show any absorption in this region.

Reaction of 3, 7-dibromotropolone with *p*-benzoquinone first precipitated crystals of 3, 7-dibromotropolone and methylation of its mother liquor, without purification, with dimethyl sulfate in the presence of potassium hydroxide and fractional crystallization of the potassium salt of its product afforded 3, 7-dibromo-5,(4′-methoxyphenoxy)tropolone (XXVII). The structure of XXVII is clear from its analytical values and formation of 5-(4′-methoxyphenoxy)-tropolone (IV) by its hydrogenolysis. Consequently, the product obtained by the reaction of 3, 7-dibromotropolone and *p*-benzoquinone would be 3, 7-dibromo-5-(4′-hydroxyphenoxy)-tropolone (XXVI).



Reaction of *p*-benzoquinone and tropolones in the presence of a weak base affords a product corresponding to 1 : 1 molar compound of *p*-benzoquinone and tropolone. This compound does not show the properties of a tropolone

derivative. Examinations are now under way on its structure.

Experimental[5]

3-(*p*-Benzoquinonyl)tropolone (VIII) and 5-(4'-Hydroxyphenoxy)tropolone (I).—A solution of 5 g. of tropolone, 2.1 g. of *p*-benzoquinone, and 2 ml. of acetic acid dissolved in 10 ml. of methanol was allowed to stand in a room temperature. After several hours, orange crystals precipitated out. After standing for 4 days, the orange crystals (A) (1.58 g.), m. p. 160~165°C, were collected, washed with methanol, and recrystallized from ethyl acetate to 1.3 g. of 3-(*p*-benzoquinonyl)tropolone (VIII), m. p. 169~170°C.

Found: C, 68.24; H, 3.52. Calcd. for $C_{13}H_8O_4$: C, 68.42; H, 3.57%. λ_{max}^{MeOH} mμ (log ε): 242 (4.45), 328(3.87), 335(3.88), 361(3.66), 376(3.71).

The filtrate left after separation of A was allowed to stand and 0.52 g. of colorless crystals (B), m. p. 195~197°C, precipitated out. Recrystallization of B from methanol afforded 5-(4'-hydroxyphenoxy)-tropolone (I) as colorless crystals, m. p. 196~197°C.

Found: C, 67.82; H, 4.38. Calcd. for $C_{13}H_{10}O_4$: C, 67.91; H, 4.49%. λ_{max}^{MeOH} mμ (log ε): 238 (4.54), 340 (4.24), 390 (3.91), 410 (3.83).

The filtrate left after separation of B was evaporated and sublimation of its residue at 80°C (bath temperature) at 2 mmHg, afforded 2.5 g. of recovered tropolone.

Reaction of I and Diazomethane.—Ether solution of diazomethane was added to 0.1 g. of I suspended in methanol and the mixture was allowed to stand over night. The crystals that precipitated out were collected and recrystallized from a mixture of benzene and acetone to give 2-methoxy-5-(4'-hydroxyphenoxy)tropone (II) as pale yellow prisms, m. p. 164~166°C. Yield, 60 mg.

Found: C, 68.82; H, 5.30. Calcd. for $C_{14}H_{12}O_4$: C, 68.84; H, 4.95%. λ_{max}^{MeOH} mμ (log ε): 231 (4.48), 330 (4.10).

II did not show any coloration with ferric chloride.

The filtrate left after separation of II was evaporated to dryness, the residue was dissolved in benzene, and the solution was purified by passing through an alumina column. From its effluent, 2-methoxy-5-(4'-methoxyphenoxy)tropone (III) was obtained as pale yellow crystals, m. p. 89~91°C. Yield, 30 mg.

Found: C, 70.20; H, 5.21. Calcd. for $C_{15}H_{14}O_4$: C, 69.75; H, 5.46%. λ_{max}^{MeOH} mμ (log ε): 234 (4.53), 330 (4.16).

III also did not undergo coloration with ferric chloride.

Hydrolysis of II.—A mixture of 10 mg. of II in 0.1 ml. of 2 N sodium hydroxide and 0.1 ml. of methanol was heated on a water bath for 1 hr., methanol was evaporated, and residual solution was acidified with dilute hydrochloric acid. The precipitate that formed was collected and sublimed at 200°C (bath temperature) at 1.5 mmHg, from which 5 mg. of colorless crystals, m. p. 192~193°C, was obtained. This showed no melting point depression on admixture with I.

Hydrolysis of III.—The same treatment as above of 20 mg. of III afforded 15 mg. of 5-(4'-methoxyphenoxy)tropolone (IV), m. p. 129~130°C.

Found: C, 68.62; H, 4.83. Calcd. for $C_{14}H_{12}O_4$: C, 68.84; H, 4.95%. λ_{max}^{MeOH} mμ (log ε): 235 (4.50), 345(4.23), 390 (3.82).

Methylation of I with Dimethyl Sulfate.—A mixture of 0.2 g. of I, 0.6 g. of potassium hydroxide, and 5 ml. of water was heated on a water bath and 0.2 g. of dimethyl sulfate was added while stirring. After 30 min., the reaction mixture was cooled, acidified with dilute hydrochloric acid, and the precipitate thereby formed was collected. The proddct was sublimed at 200°C (bath temperature) and 1.5 mmHg, and the sublimate was recrystallized from benzene-petroleum ether mixture to give 150 mg. of colorless crystals, m. p. 128~129°C, undepressed on admixture with IV obtained by hydrolysis of III.

Reaction of IV and Diazomethane.—Ether solution of diazomethane was added to a solution of 0.1 g. of IV dissolved in 15 ml. of ether and the solution was allowed to stand over night. The solvent was evaporated and the residue was sublimed at 200°C (bath temperature) and 1.5 mmHg. The sublimate was recrystallized from ether to give 75 mg. of pale yellow crystals, m. p. 89~90°C, undepressed on admixture with III.

2-Hydrazino-5-(4'-methoxyphenoxy)tropone (V).—A mixture of 80 mg. of III and 30 mg. of hydrazine hydrate (80%) in 0.4 ml. of methanol was warmed on a water bath for 30 min., methanol was evaporated, and the residue was diluted with a small amount of water. The precipitate that formed was collected and recrystallized from methanol to 55 mg. of yellow crystals, m. p. 123~124°C.

Found: C, 64.92; H, 5.48; N, 11.19. Calcd. for $C_{14}H_{14}O_3N_2$: C, 65.10; H, 5.46; N, 10.85%. λ_{max}^{MeOH} mμ (log ε): 231 (4.22), 250 (4.30), 348 (4.12), 424 (3.89).

2-Bromo-5-(4'-methoxyphenoxy)tropone (VI).—A solution of 0.5 g. of copper sulfate dissolved in 0.8 ml. of water with heating was maintained at 120°C and a mixture of 50 mg. of V and 0.5 ml. of concentrated hydrobromic acid was added to it while

5) All melting points are not corrected. Microanalyses were carried out by Misses Yôko Endô and Yukiko Endô of this Institute. Measurements of ultraviolet and infrared spectra were made respectively by a Hitachi EPU-2A type spectrophotometer and by a Perkin-Elmer Model 21 infrared spectrophotometer in potassium bromide disk.

stirring. A vigorous evolution of nitrogen occurred and the liquid turned black. After maintaining the mixture at 120°C for 5 min., it was cooled, 5 ml. of water and 30 ml. of chloroform were added, and the whole was shaken thoroughly. The mixture was filtered, chloroform layer was separated from the filtrate, and dried over anhydrous sodium sulfate. The dried chloroform solution was purified by passage through an alumina column and the product obtained from its effluent was recrystallized from petroleum ether, affording 30 mg. of pale yellow crystals, m. p. 95~97°C.

Found: C, 55.15; H, 3.99. Calcd. for $C_{14}H_{11}O_3Br$: C, 54.72; H, 3.61%. λ_{max}^{MeOH} mμ (log ε): 225 (4.48), 247 (4.30), 341 (4.19).

Rearrangement Reaction of VI with Alkali.—A mixture of 10 mg. of VI in 0.5 ml. of dioxane and 0.5 ml. of 0.2 N sodium hydroxide was heated on a water bath for 1 hr., the solvent was evaporated in reduced pressure, and the residue was treated with activated carbon after dilution with 0.2 ml. of water. The pale yellow aqueous solution so obtained was acidified with dilute sulfuric acid and this was allowed to stand over night in an ice chamber. The crystals that separated out were collected and sublimed at 160°C (bath temperature) and 2 mmHg, affording 5 mg. of colorless crystals, m. p. 173~174°C, underpressed on admixture with 4-(4'-methoxyphenoxy)benzoic acid (VII), m. p. 176~176.5°C, prepared through a known process[3]. The ultraviolet absorption spectra of these two compounds were also in good agreement.

λ_{max}^{MeOH} mμ (log ε): 252 (4.22).

3-(2', 5'-Dihydroxyphenyl)tropolone (IX).—a) A solution of 0.4 g. of sodium dithionite dissolved in 2 ml. of water was added while stirring into 0.2 g. of VIII, reduced to a powder in a mortar, suspended in 5 ml. of water and the mixture was warmed to 40°C. The color of the suspension changed from orange to yellow. After stirring for 10 min., the mixture was cooled, the precipitation was collected by filtration, and washed with water to 0.2 g. of a yellow substance, m. p. 285°C. Recrystallization from methanol afforded 0.18 g. of pale yellow microcrystals, m. p. 289~290°C.

Found: C, 67.29; H, 4.14. Calcd. for $C_{13}H_{10}O_4$: C, 67.82; H, 4.38%. λ_{max}^{MeOH} mμ (log ε): 227 (4.34), 330 (4.00), 375 (3.88)

b) A solution of 0.1 g. of VIII dissolved in 50 ml. of ethanol in the presence of 40 mg. of palladium-carbon was shaken in hydrogen atmosphere at room temperature. When the absorption of hydrogen ceased, the catalyst was filtered off and the filtrate was concentrated, affording 95 mg. of pale yellow crystals, m. p. 288~290°C, undepressed on admixture with the product obtained in a).

3-(2', 5'-Dimethoxyphenyl)tropolone (X).—A solution of 0.6 g. of sodium hydroxide in 5 ml. of water was added to a mixture of 0.1 g. of IX and 0.5 g. of dimethyl sulfate while stirring. After stirring the mixture for 30 min. at room temperature and for 1 hr. on a water bath, the reaction mixture was cooled and shaken with 5 ml. of ether. The yellow crystals that separated out were collected, dissolved in 2 ml. of water, and the solution was acidified with dilute hydrochloric acid. The oil that separated solidified into crystals, when allowed to stand in an ice box. The crystals were collected, sublimed at 200°C (bath temperature) and 2 mmHg, and the sublimate was recrystallized from ether-petroleum ether mixture to 60 mg. of pale yellow needles, m. p. 82~84°C.

Found: C, 69.56; H, 5.16. Calcd. for $C_{15}H_{14}O_4$: C, 69.75; H, 5.46%. λ_{max}^{MeOH} mμ (log ε): 225 (4.41), 325 (3.96), 350 (3.86), 372 (3.84).

Reaction of X and Diazomethane.—Ether solution of diazomethane was added to 0.26 g. of X dissolved in 10 ml. of ether and the mixture was allowed to stand over night. The crystals that separated out were collected and recrystallized from acetone to 140 mg. of pale yellow needles, m. p. 145~146°C.

Found: C, 70.39; H, 5.73. Calcd. for $C_{16}H_{16}O_4$: C, 70.57; H, 5.92%. λ_{max}^{MeOH} mμ (log ε): 223 (4.26), 320 (3.83), 350(3.79).

The ether solution left after separation of foregoing crystals was evaporated to remove excess of diazomethane, passed through a column of alumina, and the column was eluted with ether. From the initial effluent, 70 mg. of colorless crystals, m. p. 116~117°C, was obtained and later fraction afforded 20 mg. of crystals, m. p. 145°C.

Crystals of m. p. 116~117°C.

Found: C, 70.24; H, 5.90. Calcd. for $C_{16}H_{16}O_4$: C, 70.57; H, 5.92%. λ_{max}^{MeOH} mμ (log ε): 223 (4.44), 325 (4.05).

Neither of these two kinds of crystals colored with ferric chloride. Assuming from their solubility, shape of their ultraviolet absorption spectra, and ease or difficulty of elution in chromatography, the structure of these products was assumed to be 2-methoxy-7-(2', 5'-dimethoxyphenyl)tropone (XI) for the product of m. p. 145~146°C and 2-methoxy-3-(2', 5'-dimethoxyphenyl)tropone (XII) for that of m. p. 116~117°C.

2-Hydrazino-7-(2', 5'-dimethoxyphenyl)tropone (XIII).—A mixture of 70 mg. of methoxytropone (XI) of m. p. 145~146°C, 1 ml. of methanol, and 80 mg. of hydrazine hydrate (80%) was warmed on a water bath for 30 min., cooled, and crystals that separated out were collected. Recrystallization from methanol gave 55 mg. of yellow prisms, m. p. 194~195°C.

Found: C, 65.74; H, 5.50; N, 10.66. Calcd. for $C_{14}H_{16}O_3N_2$: C, 66.16; H, 5.92; N, 10.29%. λ_{max}^{MeOH} mμ (log ε): 223 (4.24), 252 (4.19), 345 (3.93), 412 (4.01).

2-Chloro-7-(2', 5'-dimethoxyphenyl)tropone (XIV).—To a solution of 0.4 g. of crystalline copper sulfate in 1 ml. of water and maintained at 120°C, a mixture of 50 mg. of XIII in 0.5 ml. of concentrated hydrochloric acid was added while stirring, the mixture was cooled after 5 min., and 10 ml. of water and 20 ml. of chloroform were added. This mixture was shaken thoroughly, filtered, and the chloroform layer was separated from the filtrate. After drying over anhydrous sodium sulfate, the chloroform layer was passed through an alumina column and the solvent was evaporated from effluents. The crystalline residue was recrystallized from petroleum ether to 45 mg. of pale yellow prisms, m. p. 114~115°C.

Found : C, 65.25 ; H, 4.72. Calcd. for $C_{15}H_{13}O_3Cl$: C, 65.08 ; H, 4.74%. λ_{max}^{MeOH} mμ (log ε) : 265 (3.92), 320 (3.95).

Rearrangement Reaction of XIV with Alkali.—A mixture of 40 mg. of XIV, 2 ml. of water, 0.2 g. of sodium hydroxide, and 1 ml. of ethanol was heated on a water bath for 2 hr., ethanol was evaporated, and the residual solution was extracted with ether to remove neutral substance. The aqueous layer was acidified with dilute hydrochloric acid, extracted with ether to collect an acid substance, and the ether extract was esterified by addithon of ether solution of diazomethane. The product therefrom was purified through an alumina column, the column was eluted with ether, and the initial eluate afforded 30 mg. of colorless oil.

A mixture of this oily product with 0.1 g. of sodium hydroxide, 5 ml. of water, and 2 ml. of methanol was refluxed on a water bath for 3 hr., methanol was evaporated, and the residue was treated with activated carbon. The solution so obtained was acidified with dilute hydrochloric acid and the crystals that separated out were recrystallized from 50% methanol to 15 mg. of colorless needles, m. p. 152~153°C, undepressed on admixture with 2-(2′, 5′-dimethoxyphenyl)benzoic acid (XV) prepared in a different way. Infrared spectra of these two were in good agreement.

2-Hydroxybenzo[c]coumarin (XVI).—A solution of 1.38 g. of sodium nitrite in 6.6 ml. of water was added to a mixture of 3.8 g. of methyl anthranilate hydrochloride, 4 ml. of concentrated hydrochloric acid, and 2 g. of ice, while stirring under cooling, to effect diazotization and the pale yellow solution so obtained was added dropwise into a suspension of 2 g. of *p*-benzoquinone in a mixture of 3.4 g. of sodium hydrogencarbonate, 5 ml. of water, and 5 g. of ice, while stirring under ice-cooling. Vigorous evolution of carbon dioxide and nitrogen was noticed. The dropwise addition was made during about 1 hr., the mixture was stirred at room temperature for a further 1 hr., and the yellow solid that separated was collected by filtration. This yellow solid was difficult to purify, so that it was dissolved in 20 ml. of chloroform, a solution of 5 g. of sodium dithionite in 50 ml. of water was added to it while stirring, the mixture was stirred for 1 hr., and allowed to stand over night. The colorless crystals that separated out were collected and washed with a small amount of chloroform and water to give 2.5 g. of colorless crystals, m. p. 195~198°C. Recrystallization from methanol-benzene mixture raised the melting point to 218~220°C.

Found : C, 72.45 ; H, 3.79. Calcd. for $C_{13}H_8O_3$: C, 73.58 ; H, 3.80%. λ_{max}^{MeOH} mμ (log ε) : 230 (4.54), 263 (4.11), 317 (3.81), 325 (3.82).

Oxidation of XVI with Potassium Permanganate.—A solution of 1 g. of XVI dissolved in 4 ml. of pyridine with 12 ml. of 5% aqueous solution of potassium permanganate added was warmed on a water bath for 2 hr., and evaporated to dryness in a reduced pressure. The residue was diluted with 5 ml. of water, filtered, and the filtrate was acidified with dilute hydrochloric acid. This was extracted with ethyl acetate, the solvent was evaporated from this extract, and 0.1 ml. of acetic anhydride was added to its residue. After warming this mixture on a water bath the product was sublimed at 60°C (bath temperature) and 20 mmHg, and 60 mg. of colorless prisms, m. p. 129~131°C, was obtained, showing no depression of the melting point on admixture with phthalic anhydride.

2-Methoxybenzo[c]coumarin (XVII).—A mixture of 0.8 g. of XVI, 25 ml. of acetone, 1.7 g. of dimethyl sulfate, and 4.5 g. of potassium carbonate was refluxed for 2 hr. while stirring, acetone was evaporated in a reduced pressure, and 10 ml. of water was added to the residue. The crystals were collected by filtration, dissolved in methanol, and treated with activated carbon. Evaporation of methanol afforded 0.7 g. of colorless needles, m. p. 118~119°C.

Found : C, 74.20 ; H, 4.41. Calcd. for $C_{14}H_{10}O_3$: C, 74.33 ; H, 4.46%. λ_{max}^{MeOH} mμ (log ε) : 231 (4.62), 260 (4.14), 270 (4.06), 316 (3.88), 326 (3.88).

2-(2′, 5′-Dimethoxyphenyl)benzoic Acid (XV).—To 1.2 g. of XVI being stirred on a water bath, a solution of 2.24 g. of potassium hydroxide in 10 ml. of water and 1.26 g. of dimethyl sulfate were added in four portions at an interval of 30 min. The mixture was heated for 1 hr. after the final addition, cooled, and extracted with ether to remove neutral substane. The aqueous layer was acidified with dilute hydrochloric acid, the solid (0.73 g.) that separated was collected, and dissolved in ether. Ether solution of diazomethane was added to it to effect esterification and the product was purified by passage through an alumina column.

The oily product (0.5 g.) so obtained was hydrolyzed with 0.75 g. of sodium hydroxide in 5 ml. each of methanol and water by heating on a water bath for 1 hr., methanol was evaporated from the reaction mixture, and the aqueous solution was extracted with benzene to remove neutral substance. This aqueous solution was treated with activated carbon, acidified with dilute hydrochloric acid, and 0.32 g. of colorless crystals that separated out was recrystallized from 50% methanol to colorless needles, m. p. 152~154°C.

Found : C, 69.92 ; H, 4.85. Calcd. for $C_{15}H_{14}O_4$: C, 69.75 ; H, 5.46%. λ_{max}^{MeOH} mμ (log ε) : 305 (3.65).

2-Hydroxybenzofuro[2, 3-b]tropone (XVIII).—A mixture of 70 mg. of IX and 0.2 g. of *p*-toluenesulfonic acid was heated in an oil bath at 110~120°C, by which the solution turned red, heated for 20 min., and cooled. The reaction mixture solidified into a pale yellow mass, 2 ml. of water was added to it, and the solid was collected by filtration. Recrystallization from acetone-methanol mixture afforded 60 mg. of pale yellow prisms, m. p. 287~290°C.

Found : C, 72.76 ; H, 3.63. Calcd. for $C_{13}H_8O_3$: C, 73.58 ; H, 3.80. λ_{max}^{MeOH} mμ (log ε) : 275 (4.61), 325 (4.40).

2-Methoxybenzofuro[2, 3-b]tropone (XIX).—A mixture of 0.17 g. of XVIII in 10 ml. of acetone, 0.4 g. of dimethyl sulfate, and 2 g. of potassium carbonate was refluxed for 1 hr. with stirring. Acetone was evaporated from this mixture, 10 ml. of water was added to the residue, and 0.12 g. of insoluble substance so obtained was recrystallized

from methanol to 80 mg. of colorless needles, m. p. 179~180°C.

Found: C, 73.80; H, 4.46. Calcd. for $C_{14}H_{10}O_3$: C, 74.33; H, 4.46%. λ_{max}^{MeOH} mμ (log ε): 267 (4.38), 325 (4.22).

3-Bromo-7-(*p*-benzoquinonyl)tropolone (XX).—A mixture of 3 g. of 3-bromotropolone, 1 g. of *p*-benzoquinone, 10 ml. of methanol, and 1 ml. of acetic acid was warmed slightly to effect solution and allowed to stand over night, by which orange plate crystals separated out. After standing the mixture for 2 days, 0.82 g. of crystals were collected and recrystallized from a mixture of methanol and ethyl acetate to give orange scales (XX), m. p. 175~181°C.

Found: C, 50.82; H, 2.63. Calcd. for $C_{13}H_7O_4Br$: C, 50.82; H, 2.30%. λ_{max}^{MeOH} mμ (log ε): 255 (4.51), 338 (3.99), 408 (3.91).

The mother liquor left after removal of the orange plate was evaporated and the residue was sublimed at 120°C (bath temperature) and 1 mmHg, from which 2 g. of 3-bromotropolone was recovered.

3-Bromo-7-(2', 5'-dihydroxyphenyl)tropolone (XXI).—a) To a suspension of 0.2 g. of XX, reduced to a powder in a mortar, in 5 ml. of water, a solution of sodium dithionite in 2 ml. of water was added while stirring at 40°C, by which color of the suspension changed from orange to yellow. After stirring for 20 min., the mixture was cooled, and filtered to collect a pale yellow powder, which was washed with water. Recrystallization from methanol afforded 0.18 g. of pale yellow crystals, m. p. 237~240°C.

Found: C, 50.21; H, 2.95. Calcd. for $C_{13}H_9O_4Br$: C, 50.48; H, 2.93%. λ_{max}^{MeOH} mμ (log ε): 260 (4.34), 330 (3.98), 385 (3.80), 408 (3.77).

b) A suspension of 0.1 g. of XX in 100 ml. of ethanol and added with 50 mg. of palladium-carbon was shaken in hydrogen atmosphere. Absorption of hydrogen ceased after 2 hr. The catalyst was filtered off and evaporation of the filtrate afforded 90 mg. of pale yellow crystals, m. p. 240~242°C, undepressed on admixture with the product obtained by the method a).

Hydrogenolysis of XX.—A mixture of 0.1 g. of XX, 0.1 ml. of diethanolamine, and 50 mg. of palladium-carbon in 100 ml. of ethanol was shaken in hydrogen atmosphere. The catalyst was filtered off, when absorption of hydrogen ceased, 0.2 ml. of acetic acid was added to the filtrate, and the solution was evaporated to dryness. To its residue, 5 ml. of water was added, insoluble matter was collected, and recrystallized from a mixture of methanol and ethyl acetate to give 60 mg. of pale yellow crystals, m. p. 288~289°C, undepressed on admixture with IX.

2-Hydroxy-7-bromobenzofuro [2, 3-b] tropone (XXII).—A mixture of 0.27 g. of XX and 0.81 g. of *p*-toluenesulfonic acid was heated at 125°C while stirring for 20 min., by which the solution turned red. This was cooled, 5 ml. of water was added, and insoluble matter was collected by filtration. This was washed with water and 0.26 g. of crude crystals melting at 288~290°C so obtained was recrystallized from methanol to give crystals of m. p. 300~303°C.

Found: C, 53.44; H, 2.50. Calcd. for $C_{13}H_7O_3Br$: C, 53.61; H, 2.42%. λ_{max}^{MeOH} mμ (log ε): 280 (4.54), 334 (4.23).

2-Methoxy-7-bromobenzofuro [2, 3-b] tropone (XXIII).—a) Ether solution of diazomethane was added to 0.12 g. of XXII suspended in 10 ml. of methanol and the mixture was allowed to stand for 2 days. The mixture was evaporated and the residue was fractionally crystallized from methanol. From the sparingly soluble portion, 65 mg. of XXII was recovered. An easily soluble portion afforded 40 mg. of pale yellow needles (XXIII), m. p. 222~224°C.

Found: C, 55.06; H, 2.95. Calcd. for $C_{14}H_9O_3Br$: C, 55.09; H, 2.97%. λ_{max}^{MeOH} mμ (log ε): 278 (4.52), 330 (4.18).

b) A mixture of 0.37 g. of XXII in 20 ml. of acetone, 0.8 g. of dimethyl sulfate, and 4 g. of potassium carbonate was refluxed for 1 hr. while stirring, acetone was evaporated from the reaction mixture, and the residue was diluted with 10 ml. of water, separating 0.34 g. of insoluble matter, m. p. 150~190°C. This was dissolved in methanol, treated with activated carbon, and fractional recrystallization afforded 80 mg. of pale yellow needles, m. p. 223~225°C, undepressed on admixture with XXIII prepared by the method a).

Easily soluble portion afforded 50 mg. of pale yellow crystals, m. p. 118~120°C, which was assumed to be XXV from the shape of its ultraviolet absorption spectrum, its analytical values and no coloration with ferric chloride.

Found: C, 53.32; H, 3.87. Calcd. for $C_{15}H_{13}O_4Br$: C, 53.41; H, 3.88%. λ_{max}^{MeOH} mμ (log ε): 220 (4.26), 256 (4.37), 334 (4.08), 380 (3.84).

2-Methoxy-7-bromobenzo[c]coumarin (XXIV).—A mixture of 170 mg. of XXI, 12 ml. of acetone, 0.6 g. of dimethyl sulfate, and 1.1 g. of potassium carbonate was refluxed for 2 hr. while stirring, acetone was evaporated from the reaction mixture, and 5 ml. of water was added to the residue. The insoluble matter was collected, dissolved in methanol, and treated with activated carbon. Evaporation of the filtrate afforded 80 mg. of colorless crystals, m. p. 176~177°C.

Found: C, 54.91; H, 3.08. Calcd. for $C_{14}H_9O_3Br$: C, 55.09; H, 2.97%. λ_{max}^{MeOH} mμ (log ε): 238 (4.51), 268 (4.06), 330 (3.93).

Hydrogenolysis of XXIII.—A solution of 30 mg. of XXIII dissolved in 100 ml. of ethanol, added with 30 mg. of sodium acetate and 20 mg. of palladium-carbon, was shaken in hydrogen atmosphere, the catalyst was filtered off when absorption of hydrogen ceased, and the filtrate was evaporated in a reduced pressure. To its residue, 2 ml. of water was added, insoluble matter was collected, and recrystallized from methanol to 10 mg. of crystals melting at 175~178°C, alone and in admixture with XIX.

Hydrogenolysis of XXIV.—XXIV (20 mg.) was treated in the same manner as in hydrogenolysis of XXIII and 10 mg. of crystals, m. p. 113~117°C, was obtained. It showed no depression of the melting point on admixture with XVII.

Reaction of 3, 7-Dibromotropolone and *p*-Benzoquinone.—A mixture of 3 g. of 3, 7-dibromotropolone, 1 g. of *p*-benzoquinone. 30 ml. of methanol, and

2 ml. of acetic acid was heated at 60°C for 5 hr., cooled to the room temperature, and 1.14 g. of crystals, m. p. 146~152°C, was obtained. This was found by admixture to be the starting tropolone. Concentration of the filtrate left after separation of these crystals afforded 1.27 g. of recovered 3, 7-dibromotropolone.

This filtrate was evaporated to dryness, 13 ml. of 5 N potassium hydroxide and 7 g. of dimethyl sulfate were added to its residue, and the mixture was heated on a water bath for 8 hr. while stirring. When cooled, 1.25 g. of yellow potassium salt separated which was dissolved in 100 ml. of water, dark insoluble matter was filtered off, and the filtrate was concentrated to 50 ml. On cooling this solution, 0.4 g. of the salt was obtained. This salt was suspended in water, acidified with dilute hydrochloric acid, and the separated crystals were collected. Recrystallization from methanol gave 0.15 g. of pale yellow crystals, m. p. 130~135°C. This is 3, 7-dibromo-5-(4'-methoxyphenoxy)tropolone (XXVII).

Found : C, 41.47 ; H, 2.79. Calcd. for $C_{14}H_{10}O_4Br_2$: C, 41.80 ; H, 2.51%. λ_{max}^{MeOH} mμ (log ε) : 268 (4.49), 348 (4.10), 446 (3.90).

Hydrogenolysis of XXVII.—A mixture of 30 mg. of XXVII, 30 mg. of potassium hydroxide, and 40 ml. of water, with 30 mg. of palladium-carbon added, was shaken in hydrogen atmosphere until absorption of hydrogen had ceased. The catalyst was filtered off, the filtrate was acidified, and the crystals that separated out were collected to 10 mg. of crystals melting at 125~127°C, alone and on admixture with 5-(4'-methoxyphenoxy)tropolone (IV).

Summary

Reaction of tropolone and *p*-benzoquinone was carried out in methanol containing acetic acid and the structure of products so obtained was determined. Tropolone gave 5-(4'-hydroxyphenoxy)tropolone and 3-(*p*-benzoquinonyl)-tropolone, 3-bromotropolone gave 3-bromo-7-(*p*-benzoquinonyl)tropolone, and 3, 7-dibromotropolone gave 3, 7-dibromo-5-(4'-hydroxyphenoxy)tropolone by this reaction. Benzofurotropones were derived from benzoquinonyltropolones.

In order to prove the structure of the product by admixture, benzocoumarin derivative was prepared by the reaction of the diazonium salt of anthranilate and *p*-benzoquinone.

The present work was aided by financial assistance from the Sankyo Co., Ltd. The authors are indebted to Mr. Yusaku Ikegami for infrared spectral analyses.

De-localization of Bond Eigenfunctions in π-Electronic Systems. I. Proposal of an Approximate Method for the Calculation of the π-Electronic States of Molecules

By Shozaburo TAKEKIYO

(Received October 21, 1960)

If in complex π-electronic systems all kinds of linearly independent resonance structures were taken as a set of canonical structures, the calculation of the various physical quantities (for example, energy levels, π-electron densities, or bond orders) would be extremely laborious. For the sake of diminishing such difficulties, various approximate treatments have been proposed. In most of them, however, only a small number of resonance structures, which are expected to be comparatively important, have almost intuitively been taken as a set of canonical structures[1-3].

One of these treatments is the Heitler-London method, where only the covalent structures are considered. One of the greatest defects of this method is that by this method it is impossible to explain the migration effects of the π-electrons from the substituents of mono-substituted benzenes (phenol, aniline, chlorobenzene, etc.) to the benzene nuclei[4].

Importance of the ionic structures has been emphasized by Daudel and Daudel[5], and a few calculations including them have been carried out[6]. But these attempts are very qualitative,

1) L. Pauling and G. W. Wheland, *J. Chem. Phys.*, **1**, 362 (1933).
2) A. L. Sklar, ibid., **5**, 669 (1937).
3) D. P. Craig, *Proc. Roy. Soc.*, **A200**, 401 (1950).
4) L. Pauling and G. W. Wheland, *J. Am. Chem. Soc.*, **57**, 2086 (1935).
5) P. Daudel and R. Daudel, *J. Chem. Phys.*, **16**, 639 (1948).
6) J. A. A. Ketelaar, *Rec. trav. chim.*, **58**, 266 (1939); See also Refs. 2 and 3.

and the number of ionic structures considered is also extremely small.

Now, it is well known that the molecular orbital method and the Heitler-London method are the two extreme approximations, in which the contributions of the ionic structures are too much emphasized and too much neglected respectively. Therefore, a new approximate method is desirable one, which corresponds to the middle point of view of the two methods.

The approximate method which is proposed by us stands on this middle ground and is as follows: all the resonance structures under consideration are sorted out into a few classes, suitable functions which are the linear combinations of the bond eigenfunctions for the structures in each class are found, and the wave functions for the molecule are represented by linear combinations of them.

By this method the degree of the energy determinants is more diminished than in the straightforward method. Hence, the problem can be simplified in cases when a great number of resonance structures are included.

Since there are various manners for the classification of the resonance structures, one particular manner must be selected. The appraisal of multiple exchange integrals is however, made prior to this, since it directly relates to our manner of classification.

Appraisal of Multiple Exchange Integrals

Multiple exchange integrals, which appear by way of the computation of the π-electronic energy levels of polyatomic molecules based on the valence bond method, have hitherto been neglected[2,3]. It does not seem, moreover, that satisfactory appraisals of them have been made, in spite of the emphasis on their importance[7].

Accordingly, in this paragraph the influence of the multiple exchange integrals upon the energy matrix with respect to the bond eigenfunctions is discussed by means of illustrations

TABLE I. COMPARISON OF RESONANCE INTEGRALS*

of *trans*-butadiene and cyclobutadiene molecules.

When the numerical values of the molecular integrals are taken from Parr and Mulliken[8] for *trans*-butadiene and from Craig[9] for cyclobutadiene, the results of Table I for the resonance integrals are obtained. In the table *a*, *b*, *c* and *d* are carbon atoms and are marked in order from one end of the molecule to the other for *trans*-butadiene and clockwise beginning with the left upper atom for cyclobutadiene. $ij : kl$ $(i \neq j, k \neq l)$ is the resonance structure in which there are π-electronic covalent bonds between atoms i and j, k and l. $ii : kl$ is that in which an atom i possesses a lone pair of π-electrons. $(ij : kl - pq : rs)$ means the interaction between structures $ij : kl$ and $pq : rs$.

$$(ij : kl - pq : rs) = \int \Psi_{ij:kl} H \Psi_{pq:rs} \mathrm{d}v_1 \mathrm{d}v_2 \mathrm{d}v_3 \mathrm{d}v_4$$

were $\Psi ij : kl$ is the normalized bond eigenfunction corresponding to the structure $ij : kl$, $\mathrm{d}v_i$ is the volume element for electron i, and H is the Hamiltonian operator commonly employed in considerations of π-electronic system

$$H = \sum_i H_{\mathrm{core}}(i) + (1/2) \sum_{\substack{i,j \\ i \neq j}} (e^2/r_{ij})$$

where

$$H_{\mathrm{core}}(i) = T(i) + U_{\mathrm{core}}(i)$$

$T(i)$ is the kinetic energy operator for electron i, and $U_{\mathrm{core}}(i)$ is the potential energy operator for this electron in the field of the core.

Numerical values in column 3 in Table I are results obtained by neglecting the multiple exchange integrals*. The integrals taken into account are of the following type:

$$Q_0 = \int \cdots\cdots a(1)b(2)c(3)d(4)e(5)f(6) \cdots\cdots H \cdots\cdots a(1)b(2)c(3)d(4)e(5)f(6) \cdots\cdots \mathrm{d}\tau$$

$$Q_1 = \int \cdots\cdots a(1)b(2)c(3)c(4)e(5)f(6) \cdots\cdots H \cdots\cdots a(1)b(2)c(3)c(4)e(5)f(6) \cdots\cdots \mathrm{d}\tau$$

$$Q_2 = \int \cdots\cdots a(1)b(2)b(3)d(4)d(5)f(6) \cdots\cdots H \cdots\cdots a(1)b(2)b(3)d(4)d(5)f(6) \cdots\cdots \mathrm{d}\tau$$

and the coulomb integrals Q_i's for the other higher polar structures:

$$K = \int \cdots\cdots a(1)b(2)c(3)d(4)e(5)f(6) \cdots\cdots H \cdots\cdots a(1)b(2)c(3)c(4)e(5)f(6) \cdots\cdots \mathrm{d}\tau$$

$$J_0 = \int \cdots\cdots a(1)b(2)c(3)d(4)e(5)f(6) \cdots\cdots H \cdots\cdots a(1)b(2)d(3)c(4)e(5)f(6) \cdots\cdots \mathrm{d}\tau$$

$$J_1 = \int \cdots\cdots a(1)b(2)c(3)d(4)e(5)f(6) \cdots\cdots H \cdots\cdots a(1)b(2)b(3)d(4)d(5)f(6) \cdots\cdots \mathrm{d}\tau$$

$$J_2 = \int \cdots\cdots a(1)b(2)b(3)d(4)e(5)f(6) \cdots\cdots H \cdots\cdots a(1)b(2)c(3)d(4)d(5)f(6) \cdots\cdots \mathrm{d}\tau$$

where $k(i)$ is the atomic orbital of the i-th electron on atom k and $\mathrm{d}\tau$ is the product of the volume elements for all the π-electrons.

Values in column 4 in the same table are results in which all types of integrals have been taken into account in the calculations.

In this table, only the results for the interactions of the resonance structures are shown in which the differences in the results for the approximate treatment from those for the exact one are the largest or the smallest for each kind.

Numerical values of the last column in Table I are of the same order as the penetration and coulomb-exchange integrals over atomic orbitals[8,9]. Particularly, in interactions between ionic structures and covalent structures or ionic structures, the lowest order of multiple exchange integrals L_i's appear, namely:

$$L_1 = \int \cdots a(1)b(2)c(3)d(4)e(5)f(6)g(7)h(8) \cdots H \cdots a(1)b(2)d(3)c(4)e(5)e(6)g(7)h(8) \cdots \mathrm{d}\tau$$

$$L_2 = \int \cdots a(1)b(2)c(3)d(4)e(5)f(6)g(7)h(8) \cdots H \cdots a(1)b(2)b(3)d(4)d(5)f(6)f(7)h(8) \cdots \mathrm{d}\tau$$

$$L_3 = \int \cdots a(1)b(2)c(3)c(4)e(5)f(6)g(7)h(8) \cdots H \cdots a(1)b(2)d(3)d(4)e(5)e(6)g(7)h(8) \cdots \mathrm{d}\tau$$

In the computations in which this kind of integral appears frequently, the influence of the multiple exchange integrals will be larger than that in the Heitler-London method because in the Heitler-London method the J_i' type of integrals,

$$J_0' = \int \cdots a(1)b(2)c(3)d(4)e(5)f(6)g(7)h(8) \cdots H \cdots a(1)b(2)d(3)c(4)f(5)e(6)g(7)h(8) \cdots \mathrm{d}\tau$$

$$J_1' = \int \cdots a(1)b(2)d(3)c(4)e(5)f(6)g(7)h(8) \cdots H \cdots a(1)b(2)c(3)d(4)f(5)e(6)g(7)h(8) \cdots \mathrm{d}\tau$$

appear as the lowest order multiple exchange integrals and are approximately equal to L_iS, where S is the overlap integral**.

8) R. G. Parr and R. S. Mulliken, *J. Chem. Phys.*, **18**, 1338 (1950).

9) D. P. Craig, *Proc. Roy. Soc.*, **A202**, 498 (1950).

* The use here of the term "multiple exchange integral" is not strictly correct. It is used conveniently for the higher orders of integrals, whose corresponding integrals, When the Hamiltonian operator is substituted for the unit operator, are more than the three order of overlap integrals.

** It will go without saying that the multiple exchange integrals which appear among atoms with nearer distances are more important than the non-multiple exchange integrals in the farther ones.

Use of the Orthogonalized Atomic Orbitals and Classification of Resonance Structures

From these considerations it seems that for quantitative or at least semi-quantitative computations of the π-electronic states of molecules, including the ionic structures besides the covalent ones, multiple exchange integrals must be taken into consideration.

One of the manners of classification of resonance structures which may easily be thought of is that in which covalent structures, monopolar structures, and di-polar structures, etc., are assigned to respective classes. It is, however, entirely inadequate to apply this manner to the quantitative calculations of polyatomic molecules, because in complex molecules the explicit evaluations of the multiple exchange integrals are extremely troublesome. Orthogonalized atomic orbitals[10] are, therefore, generally used to avoid this difficulty.

Actually, when only the covalent structures are assigned to a class, the integral types appearing in calculations are Q_0, J_0 and the other higher order ones. In cases when orthogonalized atomic orbitals are used, Q_0 is a mere additive term in each energy level and J_0 is generally repulsive, as can be inferred from the following expanded expression:

$$\overline{J_0}=\sum_{\substack{k\\ k\neq c,d}}\overline{\alpha}_k\overline{S}^2_{cd}+2\overline{\beta}_{cd}\overline{S}_{cd}+(1/2)\sum_{\substack{k,l\\ k\neq c,d\\ l\neq c,d,k}}(\overline{k}\overline{k}\mid\overline{l}\overline{l})\overline{S}^2_{cd}$$
$$+2\sum_{\substack{l\\ l\neq c,d}}(\overline{c}\overline{d}\mid\overline{l}\overline{l})\overline{S}_{cd}+(\overline{c}\overline{d}\mid\overline{c}\overline{d}),$$

where

$$\overline{\alpha}_k=\int\overline{k}(i)H_{\mathrm{core}}(i)\overline{k}(i)\mathrm{d}v_i$$

$$\overline{\beta}_{kl}=\int\overline{k}(i)H_{\mathrm{core}}(i)\overline{l}(i)\mathrm{d}v_i$$

$$\overline{S}_{kl}=\int\overline{k}(i)\overline{l}(i)\mathrm{d}v_i$$

$$(\overline{k}\overline{l}\mid\overline{p}\overline{q})=e^2\int(1/r_{ij})\overline{k}(i)\overline{l}(i)\overline{p}(j)\overline{q}(j)\mathrm{d}v_i\mathrm{d}v_j$$

where $\overline{k}(i)$ is the orthogonalized atomic orbital for the atomic orbital $k(i)$.

It will be understood by a procedure similar to that for $\overline{J_0}$ that the other higher order multiple exchange integrals lead to zeros.

It is ultimately deduced that, when the orthogonalized atomic orbitals are employed, the integral type, playing the most important role for the resonance effect of a molecule, is type $\overline{K}$, whose expanded expression is

$$\overline{K}=\sum_{\substack{k\\ k\neq d}}\overline{\alpha}_k\overline{S}_{cd}+\overline{\beta}_{cd}+(1/2)\sum_{\substack{k,l\\ k\neq d\\ l\neq d,k}}(\overline{k}\overline{k}\mid\overline{l}\overline{l})S_{cd}$$
$$+\sum_{\substack{l\\ l\neq d}}(\overline{c}\overline{d}\mid\overline{l}\overline{l})$$

It can be understood from the integral form of type K that, when including this type of integral in calculations, the ionic structures must always be included in each class of the classification.

From these considerations, the following manner of classification of resonance structures is proposed.

A covalent structure K and all the ionic structures, in which the two π-electrons on a certain bond in the structure K occupy the same atomic orbital on either side of the atom for the bond, are assigned to class K. Then the normalized bond eigenfunctions Ψ_L's corresponding to all the resonance structures I's belonging to this class are combined linearly, viz.,

$$\phi_i^K=\sum_L C_L^K\Psi_L$$

C_L^K is the coefficient of the bond eigenfunction Ψ_L and is determined by the variational method together with the normalization condition. ϕ_i^K is the function associated with class K, and the corresponding energy is E_i^K.

The function ϕ_i^K may be derived from the other covalent structures. Wave functions Φ_j's for the electronic states of the molecule are assumed to be linear combinations of the linearly independent ϕ_i^K's,

$$\Phi_j=\sum_K C_i^K\Phi_i^K$$

The values of the coefficients C_i^K's are, again, determined by the use of the variational method and the normalization condition. The resulting energies are denoted by E_j's.

Probabilities of Resonance Structures, π-Electron Densities and Bond Orders

Electron density and bond order have been discussed and have also been defined variously from the points of view of the molecular orbital method and the valence bond method[11]. Since, however, analyses of these definitions are not our principal purpose, in this paper the contributive probabilities of resonance structures, π-electron densities, and bond orders are first defined for the straightforward HLSP valence bond method by the most conventional

10) P. O. Löwdin, *J. Chem. Phys.*, **18**, 365 (1950); **21**, 496 (1953).

11) L. Pauling, L. O. Brockway and J. Y. Beach, *J. Am. Chem. Soc.*, **57**, 2705 (1935); C. A. Coulson and H. C. Longuet-Higgins, *Proc. Roy. Soc.*, **A191**, 39 (1947); W. G. Penny, ibid., **A158**, 306 (1937); R. McWeeny, ibid., **A223**, 63 (1954).

expressions, and then a definition of them on the basis of our approximate method is made on that basis.

The Straightforward HLSP Method.—When the wave function Φ_G for the ground state of a molecule is represented by

$$\Phi_G=\sum_L C_L\Psi_L$$

where Ψ_L is the normalized bond eigenfunction for structure L and C_L is the coefficient, the probability P_L for structure L is

$$P_L=C_L\sum_J C_J\int\Psi_L\Psi_J\mathrm{d}\tau$$

and the π-electron density D_i in atom i is

$$D_i=\sum_L P_L m(i)_L$$

where $m(i)_L$ is the number of π-electrons in atom i in structure L. The bond order B_{ij} between atoms i and j is

$$B_{ij}=\sum_L P_L\,[n(ij)_L+1]$$

where $n(ij)_L$ is the number of π-electronic covalent bonds between atoms i and j in structure L.

The approximate method.—1) The probability P_L^K of structure L in class K is

$$P_L^K=C_L^K\sum_J C_J^K\int\Psi_L\Psi_J\mathrm{d}\tau$$

where C_L^K is the coefficient of the bond eigenfunction Ψ_L in the wave function ϕ_1^K for the ground state of this class.

The π-electron density D_i^K in atom i in the ground state of class K is

$$\mathrm{D}_i^K=\sum_J P_J^K m(i)_J^K$$

where $m(i)_J^K$ is the number of π-electrons in atom i in structure J in class K. The bond order B_{ij}^K between atoms i and j in this state of class K is

$$B_{ij}^K=\sum_J P_J^K\,[n(ij)_J^K+1]$$

where $n(ij)_J^K$ is the number of π-electronic covalent bonds between atoms i and j in structure J in class K.

2) The probability P^K of the class K in the ground state of the molecule under consideration is represented by

$$P^K=C_1^K\sum_J C_1^J\int\phi_1^K\phi_1^J\mathrm{d}\tau$$

Therefore, the probability P_L of structure L is

$$P_L=\sum_J P^J P_L^J$$

the π-electron density D_i of atom i is

$$D_i=\sum_J P^J D_i^J$$

and the bond order B_{ij} between atoms i and j is

$$B_{ij}=\sum_J P^J B_{ij}^J$$

Survey of the Approximate Method and the Excited States

It must now be explained to what kind approach our method belongs. When a conjugated molecule is interpreted to be due to the σ-bond between parts, each of which contains a double bond, the wave functions representing the π-electronic states of this hypothetical molecule K are ϕ_i^K's in our approximation, and the energy values E_i^K's are obtained by solving the following equation:

$$H\phi_i^K=E_i^K\phi_i^K$$

Since, from the point of view of the valence bond method, the parts due to the π-bond between two non-neighboring atoms may be supposed, such hypothetical molecules K's can be found by the same number as all the π-type covalent structures conceivable for the molecule under consideration. The corresponding wave functions are ϕ_i^K's for all the class K's in our approximation. Wave functions Φ_i's for the electronic states of the entire molecule may, therefore, be represented by linear combinations of these linearly independent functions ϕ_i^K's.

Our approximate method is based on a hypothetical interpretation of the structures of molecules rather than on a mathematical approximation. In the Heitler-London method the basic functions Ψ_K's correspond to covalent structures. On the other hand, the functions ϕ_i^K's in our method mean that the π-bond between the two atoms is not the so-called "covalent bond", but is partly ionic.

For obtaining wave functions corresponding to the excited states of a molecule, number of wave functions in each class should be considered as a step in calculating the interaction of classes. It is not easy to find such wave functions however. In the practical calculations given in a later paper, therefore, an assumption will be made that the wave functions ϕ_i^K's for the lowest energies belonging to the respective symmetries in class K are employed as the wave functions associated with this class.

Our method may now also be applied successfully to computations using non-orthogonal atomic orbitals and Slater functions, as well as the orthogonalized atomic orbitals. An example based on the non-orthogonal atomic orbitals will be shown in Part II, where the energy levels evaluated by our approximaxe method are lower than the corresponding ones obtained by the Heitler-London method.

In the examples of Parts II–IV, the orthogonalization of the atomic orbitals is not made,

except in cases where it is especially required. This is because, since the approximate procedure is generally made for the orthogonalization, the accuracy of the results is lower than that for calculations based on the non-orthogonal atomic orbitals, considering all the overlap and exchange integrals. Particularly for a molecule with a lower symmetry, matrix S does not commute with matrix H[10], and the procedure for the orthogonalization is more troublesome than expected.

Summary

The influence of the multiple exchange integrals in the HLSP method for the π-electronic systems has been investigated by means of the illustrations of *trans*-butadiene and cyclobutadiene molecules. Their importance for the theory, including ionic structures, has been emphasized. For avoiding difficulties in calculations due to the presence of many resonance structures in complex compounds, an approximate method has been proposed. In that method, the degree of energy determinants is diminished.

The author wishes to express his sincere thanks to Professor Kyosuke Omori, Kyushu University, for his continual encouragement and helpful, discussions on the subjects. Thanks are also due to Professor Saburo Nagakura, The University of Tokyo, suggestions and criticisms, and to Professor Eiichi Ishiguro, Ochanomizu University, for his extremely helpful discussions and readings of the manuscripts.

De-localization of Bond Eigenfunctions in π-Electronic Systems. II. Non-Empirical Calculation of the π-Electronic States of the trans-Butadiene Molecule

By Shozaburo TAKEKIYO

(Received October 21, 1960)

trans-Butadiene is a simple molecule, suitable for considering the π-electronic states of conjugated chain compounds consisting of homonuclear atoms.

Non-empirical treatment of *trans*-butadiene molecule was first undertaken by Parr and Mulliken[1], using the ASMO SCF method, and the wave function for the ground state and the energy levels were calculated. The method of molecular orbitals with configuration interaction has been applied to the study of the π-electronic structure of the molecule by Coulson and Jacobs[2]. Then the influences of the configuration interaction procedure upon the LCAO SCF treatment was investigated by Pullman and Baudet[3].

It does not appear that treatments by the valence bond method have been undertaken. In this paper, the approximate method proposed by us in part I[4] is applied to the calculation of the π-electronic states of the *trans*-butadiene molecule. The wave functions, energy levels, electron densities, and bond orders are evaluated. These results are compared with those, obtained by the molecular orbital method.

Classification of Resonance Structures

The skeleton of the *trans*-butadiene molecule is shown in Fig. 1. Slater $2p_\pi$-orbitals with the effective nuclear charge $Z_C=3.18$ have been

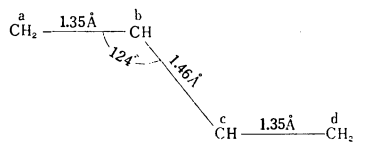

Fig. 1. Skeleton of *trans*-butadiene molecule.

assumed for the atomic orbitals of the carbon atoms. Integrals over atomic orbitals have been taken from Parr and Mulliken[1]. Calculations have been carried out, considering all kinds of overlap, single exchange, and multiple exchange integrals.

Three classes of the canonical structures,

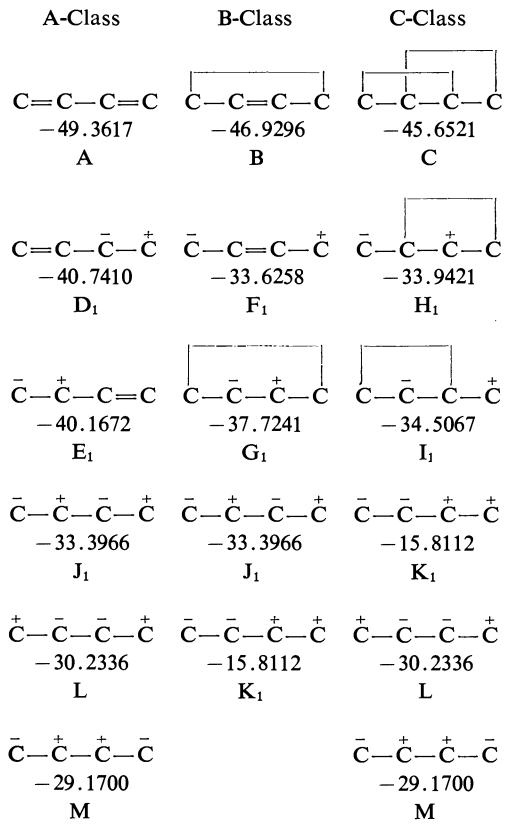

Fig. 2. Classification of resonance structures and the energy values for the structures.

K_2's are given by inversion with respect to the center of molecule from K_1's. Values are in electron volts and are relative to $4W_{2p}$, where W_{2p} is the energy of a $2p_\pi$-electron of a carbon atom in its valence state.

derived from the three covalent structures, and the corresponding energy values are shown in Fig. 2.

Wave functions ϕ_i^K's, associated with class K, and the corresponding energy values E_i^K's are shown in Table I, where Ψ_L is the normalized bond eigenfunction for structure L.

Then, the probability P_L^K of structure L, the π-electrons densities, and the bond orders in class K have been evaluated. Results are shown in Table II and Fig. 3.

From these values, the probabilities P_L's of structure L's, the π-electron densities, and the bond orders in the molecule have been computed. Results are shown in Table IV and Fig. 4.

$$\underset{0.9882}{H_2C} \overset{1.6884}{\text{———}} \underset{1.0118}{CH} \overset{1.1063}{\text{———}} \underset{1.0118}{CH} \overset{1.6884}{\text{———}} \underset{0.9882}{CH_2}$$

Fig. 4. π-Electron densities and bond orders.

Comparison with Other Methods

Calculations have also been performed by the Heitler-London method, including all kinds of overlap, single exchange, and multiple exchange, integrals. The results are as follows:

$$\Phi_1(^1A_g) = 0.90568\Psi_A + 0.15086\Psi_B$$
$$E_1 = -49.4312 \text{ eV}.$$
$$\Phi_2(^1A_g) = 0.81991\Psi_A - 1.21233\Psi_B$$
$$E_2 = -44.8795 \text{ eV}.$$

The probabilities of the two covalent structures are

$$P_A = 0.89875 \qquad P_B = 0.10125$$

and the π-electron densities and the bond orders are given in Fig. 5.

In Fig. 6, the energy levels, obtained above, are shown, together with the results found by the molecular orbital method.

From this figure, it can be seen that the values obtained by our approximate method agree quantitatively with those obtained by the ASMO SCF CI method[5]. The energy value for the ground state computed for the class, derived from the most stable covalent structure, is more satisfactory than that by the Heitler-London method. In the calculation due to that single class. however, it is impossible to obtain the correct order of the levels of the molecule*.

$$\underset{1}{H_2C} \overset{1.89875}{\text{———}} \underset{1}{CH} \overset{1.10125}{\text{———}} \underset{1}{CH} \overset{1.89875}{\text{———}} \underset{1}{CH_2}$$

The π-electron densities obtained by the ASMO SCF CI method are:

$$D_a = D_d = 0.978 \qquad D_b = D_c = 1.022^{3)}$$

and are in good agreement with our results (Fig. 4).

One of the causes of the success of our method is that the ionic structures are always considered; this point is a difference between our method and the conventional approximate methods.

Summary

An approximate method, proposed in Part I, has been applied to the non-empirical calculation of the π-electronic states of the *trans*-butadiene molecule. All the higher orders of overlap and exchange integrals have been considered. Slater $2p_\pi$-orbitals have been used through out. The values of the energy levels obtained are −51.099 eV. (^1A_g), −45.237 eV. (^1A_g), and −41.429 eV. (^1B_u). The π-electron densities for the ground state are $D_a = D_d = 0.988$, and $D_b = D_c = 1.012$. These results agree quantitatively with those evaluated by the ASMO SCF CI method.

The author wishes to express his sincere gratitude to Professor Kyosuke Omori, Kyushu University, for his helpful criticisms and suggestions. Thanks are also due to Professor Saburo Nagakura, The University of Tokyo for his advice and valuable assistance, and to Professor Eiichi Ishiguro, Ochanomizu University, who has read the manuscript and helped the author to remove obscurities.

5) Y. Mori, ibid., **28**, 291 (1956).

* In Fig. 6, some of the levels obtained by our mothod are lower than the corresponding levels found by the ASMO SCF CI method. The cause of this appearance seems to be due to intermediate approximations in numerical calculations.

SHORT COMMUNICATIONS

*Presence of a New Species of Titanium-Titanochloroform**

By Isao SHIIHARA, Jun IYODA and Kazuko SUGITA

(Received December 6, 1961)

Titanochloroform or titanium hydrotrichloride[1], $HTiCl_3$, is one of the supposed intermediates in the olefine polymerization by Ziegler and Natta catalysts. Recently Cooper[2] proposed the possibility of the occurrence of titanochloroform as Eq. 1.

$$\text{R-ti} \rightleftarrows \text{Olefine} + \text{H-ti} \quad (\text{ti} = 1/4\ \text{Ti}) \qquad (1)$$

But the actual existence of this compound has not been proved so far. Recently we obtained titanochloroform as a solution and the presence was evidenced by the chemical analysis and the infrared spectrum. Moreover, we could find considerable amount of H-Ti bond remaining in the solid phase of some species of titanium trichloride, especially in the so-called active form prepared by aluminum reduction of titanium tetrachloride in benzene.

Previously, we found that propylene was polymerized by the methylhydropolysiloxane modified Ziegler catalyst system, and gave silicon containing polypropylene[3]. To clarify the process, the reaction of titanium tetrachloride with triethylsilane, triphenylsilane, triethoxysilane, methylhydropolysiloxane, or methylhydrodichlorosilane, were studied and the reaction mechanism was disclosed as Eq. 2.

$$TiCl_4 + R_3SiH \longrightarrow \left[Cl_3Ti \begin{matrix} H \\ \diagup\diagdown \\ Cl \end{matrix} SiR_3 \right] \longrightarrow HTiCl_3 + R_3SiCl \downarrow TiCl_3 + 1/2H_2 \qquad (2)$$

In these experiments, the volatile fraction consisting of titanochloroform and the recovered titanium tetrachloride was obtained in a dry-ice-acetone trap by vacuum distillation of the products at room temperature. In most cases the fraction liberates hydrogen by alcoholic potash which was measured by volume. One typical example, the analysis of the condensate obtained from the reaction of titanium

* Presented at the Symposium on Organosilicon and Organometallic Compounds at Osaka, October, 1961.

1) The name was used in J. W. Melllor, "A Comprehensive Treatise on Inorganic and Theoretical Chemistry", Vol. VII, Longmans, Green and Co., Ltd., London (1927), p. 80.

2) D. Cooper and H. L. Finkbeiner, *Chem. & Eng. News*, 39, No. 37, p. 60 (1961).

3) I. Shiihara, W. Kawai and T. Ichihashi, International Symposium on Macromolecular Chemistry, Montreal, August, 1961.

tetrachloride and triphenylsilane as a benzene solution showed; Ti(total) 4.54, Cl 12.8, H(OH^- active) 0.029, Si 0.10%, and thus Cl/Ti=3.82, H/Ti=0.37. The amount of hydrogen does exist twice as much as that of the amount required from the silicon content, even if the all silicon was assumed to compose silane. This fact affords one evidence that some part of the hydrogen is originated from the volatile H-Ti containing compounds, i. e. titanochloroform in this case.

Moreover, this condensate showed a characteristic infrared absorption at 1610 cm^{-1} (m). It is plausible to consider the absorption is due to H-Ti bond stretching vibration, because the product obtained from the other route by reacting commercial titanium hydride TiH and titanium tetrachloride as Eq. 3 showed the same absorption at about 1600 cm^{-1}. These data are given in Table I.

$$TiH+3TiCl_4 \rightarrow HTiCl_3+3TiCl_3 \qquad (3)$$

The H-Ti bond was also observed in the solid phase of titanium trichloride. Analytical value and infrared data (in Nujol) of some examples are: Titanium trichloride originated from $TiCl_4+Et_3SiH$, Ti^{III} 24.8, Ti 28.7, Cl 64.6, H(OH^- active) 0.092, Si 0.70%, H-Ti absorption, at 1595 cm^{-1} (w); from $TiCl_4+(MeHSiO)_n$, Ti^{III} 10.1, Ti 14.8, H(OH^-) (about the acid extract) 0.038%, H-Ti absorption, at 1602 cm^{-1} (vs); from $TiCl_4$+Al (in benzene)[4], Ti^{III}/Ti> 95%, H-Ti absorption, at 1605 cm^{-1} (m).

This compound in high concentration is unstable liquid, and the blackening, precipitation and then gelation occurred after a few days. The studies on the isolation of titanochloroform and the catalytic action are now undertaken.

Effects of Outer Anions on the Recoil Reactions in the Irradiated Hexammine-cobalt(III) Complex Compounds

By Nobufusa SAITO, Takeshi TOMINAGA and Hirotoshi SANO

(Received January 9, 1962)

It was previously reported by the present authors that various ^{60}Co-labeled species were formed through recoil reactions in the irradiated cobalt complex compounds and that among these labeled species were found such substituted products as might be produced by incorporation of outer anions of the target complex into ligands[1]. Though the mechanism of formation of these recoil species has not been fully clarified, such outer anions of the target complex must no doubt play an impotant role during the recoil reactions. In the present work, they have investigated the distribution of recoil species in various hexamminecobalt-(III) complex salts containing different kinds of outer anions in order to elucidate the role of the outer anions in recoil reactions.

Nine kinds of hexamminecobalt(III) complex salts listed in Table I were irradiated in an experimental hole in JRR-1 reactor for one or five hours at ambient temperature. Thermal neutron flux was approximately 3×10^{11} n/cm^2 sec. After bombardments, the ^{60}Co-labeled species present in aqueous solutions of the

target salt were separated by procedures involving paper electrophoresis, ion exchange, precipitation, or recrystallization. The results are summarized in Table I.

For the salts shown in Table I, the distribution of ^{60}Co-labeled recoil species was found to vary with the kind of outer anion in the target. The retention (or the percentage of activity as CoA_6^{3+}) tends to increase with the decrease in frequency of the maximum in the first absorption band of CoA_5X (X denotes the outer anion in CoA_6X_3), or the decrease in stability of the outer anion X complexed with cobalt. This relationship is shown in Fig. 1.

For the convenience of discussion on the relative yield of substituted recoil products, a factor, S, was calculated as in the following:

$$S = \frac{\left(\begin{array}{c}\text{Sum of percentages of } ^{60}\text{Co-labeled complexes containing more anionic ligands than the target complex}\end{array}\right)}{\left(\begin{array}{c}\text{Sum of percentages of all } ^{60}\text{Co-labeled complexes}\end{array}\right)}$$

As seen in Fig. 2, the relative yield of substituted products (S) seems to decrease with the decrease in frequency of the maximum in the first absorption band of CoA_5X, or the decrease in stability of the outer anion X complexed with cobalt.

The above relationships indicate together that the facility of incorporation of outer anions into ligands around the hot cobalt atom might mainly depend on the stability of such anions as ligands in cobalt(III) complexes.

It was presumed from these results that chemical processes might mainly contribute to determine the fate of hot cobalt atoms at such stages in recoil reactions as involved energies low enough to distinguish the difference in stabilities of these anions as ligands.

A Kinetic Study of the Isotopic Exchange of Indium between the Indium Ion and its N-2-Hydroxyethylethylenediamine-N, N', N'-triacetate Complex in an Acid Solution

By Kazuo SAITO and Michiko TSUCHIMOTO (nee TAMURA)

(Received January 24, 1961)

Since tervalent gallium, indium and thallium give co-ordination compounds of a typical d^{10} structure, a kinetic study of the isotopic exchange of these elements, which has been left unchallenged, will provide useful information on the nature of the so-called outer co-ordination compounds. With the aid of a tracer study with indium-114 m, the present authors previously found[1] that exchange of indium proceeds with a measurably slow rate between the indium ion and its *N*-2-hydroxyethylethylenediamine-*N*, *N'*, *N'*-triacetate (written as EDTA-OH henceforth) complex in an acid solution and that the rate depends on the hydrogen ion concentration. The rate is immeasurably small in a neutral solution. It appears to increase in a basic solution of a pH more than 10, where indium remains in the aqueous phase only in the presence of a large amount of a masking agent such as citrate and tartrate. This paper deals with the kinetics of this exchange reaction, especially in a pH range from 2 to 3.5, where the exchange rate is proportional to the hydrogen ion concentration.

Results

According to McKay[2], the exchange constant is expressed by

$$R = -2.303 \cdot \frac{ab}{(a+b)} \cdot \frac{\log (1-F)}{t}$$

where a and b stand for the molar concentration of the indium ion and its EDTA-OH complex respectively, t is the lapse of time, and F the fraction of the reaction. First, the relationship between R, and a and b was examined, the results being shown in Figs. 1 and 2 respectively. It is clearly seen that R is proportional to the concentration of the complex (b), regardless of the presence of a buffer, whereas it is independent of the concentration of the indium ion (a). Hence, the reaction constant k is given by R/b and has a dimension T^{-1}. The pH dependence was tabulated in Table I

at 25°C; acetate buffer 0.042 M

in Ref. 1 and is also shown in Fig. 3, in which a linear relationship is seen in a pH range from 2.5 to 3.2. In a more acid solution, the exchange proceeds too fast to permit a precise kinetic study, but there appears to be an appreciable deviation from the linear relationship.

It is rather noticeable that the exchange constant R increased by the use of a buffering agent such as citrate and acetate. Especially in the presence of citrate, R increased linearly with an increase in the concentration of the dihydrogen citrate ion, as is shown in Fig. 4. On the other hand, acetate affected the R value to a much less extent.

The temperature dependence of R is shown in Fig. 5, in which $\log k/[H^+]$ is plotted against $1/T$ (T, absolute temperature). The Arrhenius

to be very small. When potassium chloride was used in place of nitrate, the exchange rate significantly increased, as is seen in Table II.

Discussion

Only a little information is available concerning the mechanism of the isotopic exchange of the co-ordination compounds of EDTA and its analogues, especially of those with tervalent metal ions. Jones and Long[3] reported that the isotopic exchange of iron between the ferric ion and its EDTA complex was dependent on the pH value in a complexed manner in the range from 1 to 2.5 and that at least three separate kinetic terms participated in the exchange. In the case of indium, the kinetic

3) S. S. Jones and F. A. Long, *J. Phys. Chem.*, **56**, 251 (1952).

term appears to be much simpler under the given conditions. The dissociation of the indium EDTA-OH complex must play an important role in determining the exchange rate, because the concentration of the uncomplexed indium does not affect the rate in either the presence or the absence of a buffering agent which is capable of forming complex ions with indium. The pH dependence of the k value suggests that the indium EDTA-OH complex is in a protonated form in the given pH range, and its dissociation appears to be the rate-determining step. (Z, EDTA-OH radical)

$$[{}^*InZ\cdot OH_2] + H^+ \rightleftarrows [{}^*InHZ\cdot OH_2]^+ \quad \text{(Equil.)}$$

$$[{}^*InHZ\cdot OH_2]^+ + In^{3+}\cdot OH_2 \rightleftarrows [InHZ\cdot OH_2]^+ + {}^*In^{3+}\cdot OH_2$$

$$[InHZ\cdot OH_2]^+ \rightleftarrows [InZ\cdot OH_2] + H^+ \quad \text{(Equil.)}$$

The second step can also be written as follows:

$$[{}^*InHZ\cdot OH_2]^+ \xrightarrow{\text{slow}} {}^*In^{3+}\cdot OH_2 + HZ^{2-}$$

$$HZ^{2-} + In^{3+}\cdot OH_2 \xrightarrow{\text{fast}} [InHZ\cdot OH_2]^+$$

The dissociation of the complex $[InHZ\cdot OH_2]^+$ may presumably involve the rupture of one or two of the In-O linkage as the first step, which eventually results in the release of the radioactive indium ion. The free protonated EDTA-OH radical HZ^{2-} could combine with the hydrated indium ion at a greater rate than that of the dissociation. Since neither the equilibrium constant of the protonation nor the rate constant of the rate-determining step is known, further quantitative elucidation must be abundoned. Nevertheless, it is a rather marked fact that the rate is independent of the concentration of one of the components to be exchanged.

When the hydrogen ion concentration is higher, protonation could occur on two acetate radicals of the complex side by side,

$$[{}^*InHZ\cdot OH_2]^+ + H^+ \rightleftarrows [{}^*InH_2Z\cdot OH_2]^{2+} \quad \text{(Equil.)}$$

the diprotonated complex undergoing a similar dissociation at a comparable or a greater rate. Deviation from the linear relationship seen in Fig. 3 could be thus accounted for by taking the participation of the diprotonated complex into consideration. If such a dissociation were regarded as the rate-determining step, it would be rather reasonable to assume that the Arrhenius activation energy is as low as 11 kcal. per mole and that the change in ionic strength affects the rate to a less extent.

Nothing decisive can be stated concerning the role of an acidic radical such as citrate and acetate. It has already been established that the co-ordinated water in an indium EDTA complex can be replaced by an acidic component such as chloride and bromide[4]. It would not be unusual if a similar replacement occurred in an aqueous solution of an indium EDTA-OH complex.

$$[InZ\cdot OH_2] + H_2cit^- \rightleftarrows [InZ\cdot H_2cit]^- + H_2O$$

When it is assumed that the dissociation of the protonated acido complex proceeds faster than that of the aquo complex, the relationship shown in Fig. 4 will be accounted for. Such an explanation expresses, with a little different shade of meaning, the idea that the dissociation of the protonated complex is accelerated in the presence of an organic oxy-acid, which can pull the indium ion to form a complex. The extent to which the dissociation is facilitated depends on the nature and the concentration of the organic compound, citrate exerting a greater influence than acetate. Such an effect must be reflected in the change in Arrhenius activation energy and in the influence of the ionic strength. The accuracy of an isotopic tracer study, however, is not high enough to make such a change clear. The influence of the chloride ion indicated in Table II can be similarly understood. Although the chloride ion forms chloro complexes with indium ions in an acid solution, the formation constant is so small that its effect is appreciable only in the presence of a large amount of the chloride ion.

A gallium complex of EDTA-OH also undergoes isotopic exchange of gallium with the gallium ion in a more acid region[5]. The rate depends on the hydrogen ion concentration to a more marked extent and will be compared with the present result elsewhere.

Experimental

Preparation and Properties of the Complex.— Since this complex is a new compound, its preparation and properties will be described briefly. Indium was dissolved in dilute nitric acid, the hydroxide precipitated with aqueous ammonia solution, centrifuged, washed and boiled with EDTA-OH, slightly less in amount to the equivalent. When the mixture became almost transparent, the solution was filtered to remove the excessive indium hydroxide, evaporated, and treated with ethanol to give prismatic crystals of aquo *N*-2-hydroxyethylethylenediamine-*N*, *N'*, *N'*-triacetato indium monohydrate which lost 8.78% of water at 110°C, corresponding to two moles per mole of the complex (calcd., 8.46%).

Found: N, 6.43; In, 26.78. Calcd. for $C_{10}H_{15}O_7N_2In\cdot 2H_2O$: N, 6.62; In, 26.94%.

When titrated with a sodium hydroxide solution, an aqueous solution of this complex gave a titration curve as shown in Fig. 6, from which the apparent

4) K. Saito and H. Terrey, *J. Chem. Soc.*, **1956**, 4701.
5) K. Saito and M. Tsuchimoto, *J. Inorg. Nucl. Chem.* in press (appear in early issue, 1962).

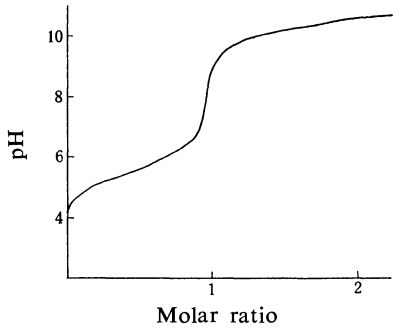

Fig. 6. Titration of $[In \cdot EDTA\text{-}OH \cdot H_2O] \cdot H_2O$ with sodium hydroxyde.
$[InZ \cdot OH_2]H_2O$, 0.2×10^{-4} M; $\mu = 0.05$ (KNO_3); 25°C

dissociation constant was calculated to be approximately 1.5×10^{-6} at 25°C in an ionic strength $\mu = 0.05$. This value is significantly greater than that of the indium EDTA complex (1.6×10^{-9})[4], indicating that the co-ordinated water is bound to indium more firmly than in the latter complex. In an acid solution as used in the present study, the dissociation of the co-ordinated water can be ignored. By the use of an irradiated unit In-114 m, a radioactive indium EDTA-OH comlex of a due specific activity was obtained crystalline.

Procedure for Kinetic Runs.—An aqueous solution (200 ml.) of indium nitrate of a known pH value, containing potassium nitrate and the buffer, was mixed in a thermostat with a radioactive indium EDTA-OH solution (100 ml.) of the same pH value. A 25 ml. portion was taken out at certain intervals and treated with 8-quinolinol in ethanol (0.5%, 1 ml., less than the equivalent amount of indium nitrate), and the pH was adjusted to about 3.2 with brom phenol blue as indicator. The precipitate was filtered off through a sintered glass filter plate No. 4, washed with water, dried at 110°C, weighed and submitted to radioactivity measurement. The molar ratio of 8-quinolinol to indium remained unchanged when the precipitate was formed in the presence of an excess of indium. The separation was satisfactorily effected within 2 min., and no appreciable heterogeneous isotopic exchange was observed between the precipitate and the solute under the given conditions. The zero time exchange was negligible.

Measurement of Radioactivity.—A scintillation spectrometer with a sodium iodide crystal (diameter, 4.8 cm.; thickness, 4.8 cm.) was used with due accessories. The weighed filter plate was covered with cellotape and fixed on a methylmethacryllate plate (thickness, 1 cm.) which absorbed 1.98 MeV. β-rays of ^{114}In. The plate was placed upon the scintillator crystal, and the photo- and the Compton electrons coming from γ-rays of In-114 m were counted, the less distinctive back-scattering peak being biased by a pulse-height analyzer. The overall counting efficiency was about 20%. The integrated counting rate increased linearly with the increase in the amount of radioactive indium, and the specific counting rate of the precipitate was calculated from the weighed amount of the indium 8-oxyquinolinol complex.

All the chemicals were of reagent grade. Indium nitrate was prepared from metallic indum of a purity more than 99.99%. The pH value was measured with a glass electrode, the error being less than 0.02 pH.

Summary

1) The isotopic exchange of indium between the indium ion and its EDTA-OH complex was kinetically studied in an acid solution, indium-114 m being used as tracer.

2) Separation of the indium ion from its EDTA-OH complex was satisfactorily carried out with 8-quinolinol (oxin) at a pH about 3, and no appreciable heterogeneous exchange was observed between the precipitate and the solute.

3) The exchange constant R was proportional to the concentration of the complex, the hydrogen ion and the ions such as dihydrogen citrate, but was independent of the concentration of the indium ion. It was affected by the ionic strength to a less extent, and the Arrhenius activation energy was 11 kcal. per mole.

4) A plausible reaction mechanism was postulated on the basis of the kinetic data. The dissociation of the protonated indium EDTA-OH complex appears to be the rate-determining step.

The authors wish to express their thanks for a grant-in-aid given by the Ministry of Education.

Cationic Polymerization of Isobutene in Liquid Sulfur Dioxide. Role of Water of Cocatalyst[1]

By Niichiro TOKURA, Minoru MATSUDA and Isoo SHIRAI

(Received October 4, 1960)

Cationic polymerization of isobutene in liquid sulfur dioxide has already been proposed by Elwell and Meier[2a], and has been examined by Furuya and Honda[2b], who reported on the formation of high molecular weight polyisobutene when it was polymerized with alminum chloride at low temperature, but no suggestion has been made on the mechanism of the polymerization.

It is widely recognized that when a Friedel-Crafts catalyst was used in a cationic polymerization, a cocatalyst was necessary to initiate the polymerization[3-5]. Among such cocatalysts, water has lately been known as important proton releasing substance[3,4,6].

On the other hand, the solvents used for the polymerization such as alkyl halides or alkylene dihalides[6-8] have often been regarded as useful cocatalysts in cationic polymerization. However, a recent publication[9] is opposing the proposal.

Dainton[10] has carried out polymerization of isobutene in a gas phase at room temperature using boron trifluoride as a catalyst together with D_2O as a cocatalyst. The polymer obtained (DP, 10) was investigated by infrared spectral analysis in order to elucidate the mechanism of the initiation as well as the termination of the polymerization, though no decisive result was obtained concerning the mechanism of the initiation of the polymerization.

Liquid sulfur dioxide has been found to be a peculiar solvent by us and by others[11] in some organic reactions involving polymerization and a small amount of water in it is very difficult to eliminate within the order of 100 p. p. m. by ordinary method[12]. Therefore, water remaining in liquid sulfur dioxide will often act as a cocatalyst. On the other hand, liquid sulfur dioxide is reported to be able to dissociate as follows[13],

$$2SO_2 = SO^{2+} + SO_3^{2-}$$

Thus sulfur dioxide seems likely to play a part as a cocatalyst via the sulfite cation.

This paper aims at the elucidation of the role of water, when the comparable amount of water is present in the cationic polymerization of isobutene in liquid sulfur dioxide by using stannic chloride.

The liquid sulfur dioxide used for the present investigation was dehydrated according to Hata and Asano's method[14] of this Institute, whereby water content in liquid sulfur dioxide was reduced to as low as 30 mg./l., that is calculated from the infrared absorption in 3675 cm^{-1} of the vibration of OH.

The participation of heavy water was examined by adding it to this dried sulfur dioxide in the polymerization of isobutene with stannic chloride as the catalyst.

To obtain polymers having the degree of polymerization (DP) of 2 to 4, an experimental condition has been chosen so as to polymerize the monomer at 35°C and stop at the conversion of 2~3%. The products were examined by their infrared spectral absorptions to determine the possibility of the participation of D_2O or sulfur dioxide as the catalyst in the polymerization reaction.

Experimental

Materials.—Isobutene was prepared by dehydration of *tert*-butyl alcohol with acetic acid anhydride containing a small amount of concentrated sulfuric acid. The purity of the isobutene was analyzed by gas chromatography, no contaminant being found in this material. Commercial stannic chloride was dehydrated with phosphoric acid anhydride

and distilled in dry nitrogen atomosphere. Heavy water of 99.8 mol. per cent, $d_4^{25}=1.1043$, made at the Asahi Kasei Industries Ltd. (Nobeoka) was used.

Sulfur dioxide was dehydrated according to the procedure of Hata and Asano[14]. In a glass pressure vessel, predehydrated sulfur dioxide[12] (200 ml. of liquid sulfur dioxide, which was treated with 30 g. of phosphoric acid anhydride for 24 hr.) was mixed with purified iodine (0.5 g.) and pure pyridine (10 ml.). The mixture was then distilled carefully through a tube packed with copper powders. The water content of the sulfur dioxide thus dehydrated was reported as 30 mg./l.[14]

Polymerization. — A weighed amount of stannic chloride sealed in an ampoule was added to a definite amount of sulfur dioxide in a pressure vessel by breaking the ampoule. This solution after filtration was diluted with a requisite amount of sulfur dioxide to the catalyst of a definite concentration.

The preparation of the normalized D_2O solution of sulfur dioxide was also prepared by a similar manipulation.

The DP of polyisobutene has been reported to be dependent on the temperature of polymerization. If the DP was large, the weak band of C–D stretching vibration derived from the cocatalyst fragment would become difficult to identify by an infrared spectral analysis. The optimum condition to realize the purpose of this project was searched in the ranges, 1.6×10^{-1} to 4.0×10^{-4} mol. per liter for tin(IV) chloride and 1.0×10^{-1} to 9.0×10^{-3} mol. per liter for D_2O respectively and decided as,

$SnCl_4$	3.0×10^{-2} mol./l.
D_2O	6.0×10^{-2} mol./l.

the concentrations being calculated by volume of sulfur dioxide at −10°C. The samples in Figs. 3 and 4 were prepared with catalysts in such concentrations. The specimens in Figs. 1 and 2 were prepared by another recipe, i. e. $SnCl_4$ 7.4×10^{-3} and D_2O 3.3×10^{-2} mol./l., respectively. The polymerization was carried out at 35°C, and the mole ratio of isobutene to liquid sulfur dioxide was 1 to 2. The time for 2∼3% conversion required about 20 min.

To stop the polymerization, liquid sulfur dioxide and isobutene unreacted were evaporated as fast as possible, the temperature of the residue being sustained at −10°C. The polymer produced during this period was so scarce that it should be treated cautiously during the water washing and the separation. The liquid polymer thus obtained, about 1 to 2 g. for each run, was dried with sodium sulfate and fractionated into the respective fractions, dimer (b. p. 104∼105°C)[15], (yield about 50% of the total polymer), trimer (b. p. 181∼183°C)[15] and tetramer (b. p. 120∼121°C/20 mmHg)[15].

The average molecular weight of the liquid polymer obtained was in the range of 138 (DP, 2.5) to 209 (DP, 3.7) which were measured by the cryoscopic method in benzene.

Infrared Spectra. — Infrared spectra were taken by a Perkin-Elmer double beam model 21 spectrometer, the cells being made of sodium chloride of the width, ca. 0.05 to 0.5 mm., respectively.

Results and Discussion

We have obtained a clear evidence to support the participation of water molecule as a cocatalyst in the polymerization. The polymerization in the extremely dried sulfur dioxide did not proceed to an appreciable extent.

As has been pointed out very recently by Kennedy[16], the monomer transfer should be as minimized as possible. So the polymerization was conducted at a higher reaction temperature (35°C) and the reaction was stopped at 2∼3% conversion, thus obtaining the polymer of a lower DP and of a lesser monomer transfer. Another reason for stopping the polymerization at low conversion was to inhibit the further polymerization of the low polymer produced, where the formation of head to head type polymer was expectable.

The C–D bonding of the polymer was observed distinctly by the infrared spectroscopy. The molecular weight of the polymer thus obtained was in the range of 138 (DP, 2.5) to 209 (DP, 3.7) according to the result of cryoscopic measurements in benzene. Figure 1 shows the spectrum of polyisobutene (unfractionated) of DP 2.5.

The solid line 1 in Fig. 2 shows the spectrum of the dimer fraction (cell width, 0.0496 mm.). If sulfur dioxide reacted as the cocatalyst, there should be absorptions corresponding to SO, SO_2H or SO_2 group in the polymer chain. We could not identify SO group absorption (1060∼1040 cm^{-1})[17] in Figs. 1 and 2. Since the polymer obtained was so low in its DP that the presence of any sulfur atom clinging

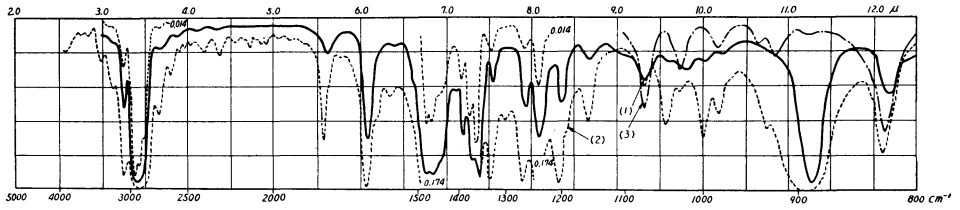

Fig. 2. Infrared spectra of isobutene dimer.

(1) ——— Sample (dimer) (cell, 0.0496 mm.)
(2) ------ 2,4,4-Trimethyl-1-pentene (cell, 0.174 and 0.014 mm.)
(3) —·—· 2,4,4-Trimethyl-2-pentene (cell, 0.013 mm.)

to the polymer chain may be ruled out. The dotted line 2 in Fig. 2 is the infrared spectrum of authentic 2, 4, 4-trimethyl-1-pentene (one of diisobutenes) cited from the Infrared Spectral Data of A. P. I.[18], which is consistent with that of our dimer except only by a small discrepancy in 1100~950 cm^{-1}.

In Fig. 3, line 1 shows a spectrum of the dimer in the range between 3000~1800 cm^{-1}, polymerized with D_2O in liquid sulfur dioxide. Line 2 in Fig. 3 is that of the dimer obtained with water. If water was playing a role as a cocatalyst, the polymer obtained from the polymerization with heavy water added should have a C–D bond at the end of the chain as shown in the following equations:

$$SnCl_4 \cdot D_2O + (CH_3)_2C{=}CH_2 \rightarrow CH_2D{-}\overset{+}{C}(CH_3)_2 + SnCl_4DO^-$$

$$CH_2D{-}\overset{+}{C}(CH_3)_2 + (CH_3)_2 \cdot C{=}CH_2 \rightarrow CH_2D{-}C(CH_3)_2{-}CH_2{-}\overset{+}{C}(CH_3)_2$$

Comparing lines 1 and 2 in Fig. 3, we can recognize a sharp band at 2183 cm^{-1} (C–D stretching frequency) in 1, which evidently proves the participation of water molecule in the polymerization.

The line 3 in Fig. 3 is the spectrum of the dimer fraction obtained at a nearly 100% conversion of the polymerization in the same condition with heavy water. In this spectrum, we can recognize the dilution of the C–D band as the result of transfer reaction during the polymerization.

Figure 4 shows the infrared spectrum of the fraction of trimer and the higher polymer of the same product polymerized with D_2O (line 1). Other lines 2 and 3 are those of trimer and tetramer, respectively, which were derived by polymerization with water. However, the absorptions in the line 1 are overlapping and those at 2130 to 1820 cm^{-1} indicate a slight

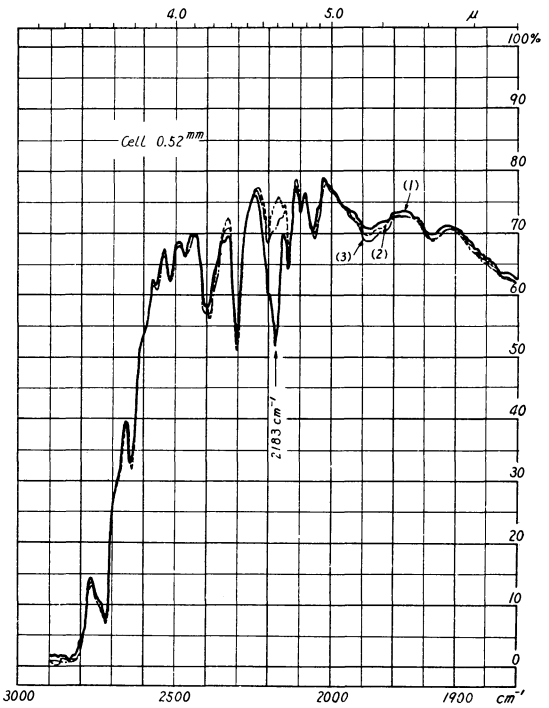

Fig. 3. Infrared spectra of isobutene dimer (3000~1800 cm^{-1}).

(1) ——— with D_2O
(2) ------ with H_2O
(3) —·—· with D_2O (near 100% conversion)

shift, the presence of C–D band is evidenced by a clear peak at 2183 cm^{-1}. From the result above described, it can be concluded that in the cationic polymerization of isobutene with stannic chloride as catalyst in liquid sulfur dioxide, added water may take part in the polymerization as the cocatalyst.

Next, we have to discuss again the spectra in Fig. 3, in which the line 3 is that of authentic 2, 4, 4-trimethyl-2-pentene of A. P. I.[18] The dimer prepared by us had strong absorptions at 1642 and 888 cm^{-1} of terminal double

18) A. P. I., Infrared Spectral Data, I (Pittburgh), No. 276 and 277 (1943—1945).

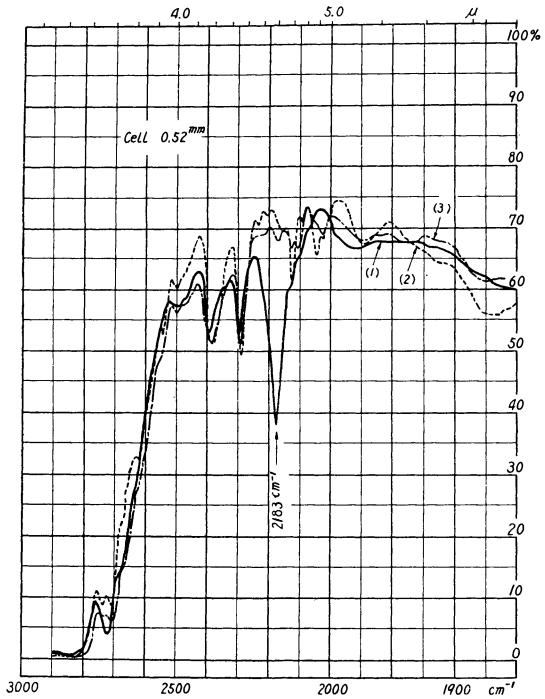

Fig. 4. Infrared spectra of isobutene polymers.
(1) ——— Trimer and higher fraction (with D_2O)
(2) ------ Trimer (with H_2O)
(3) —·—· Tetramer (with H_2O)

bond[19,20] and at 1200 and 1237 cm^{-1} of terminal *tert*-butyl group, respectively, which are almost consistent with 3. But there seem some inaccordances in the range of 1100 to 950 cm^{-1} between the two. The authentic 2, 4, 4-trimethyl-pentene has strong absorptions in its spectrum at 1074, 1034 and 983 cm^{-1}, whereas our dimer has weak bands at 1074 and 1030 cm^{-1}, which may be attributed to the presence of a small amount of 2, 4, 4-trimethyl-2-pentene (cf. line 3 in Fig. 2). Accordingly, in the termination step of the polymerization, reaction 1 may be preferred but reaction 2 may also occur in lower frequency.

$$(CH_3)_3C{-}CH_2{-}\overset{+}{C}(CH_3)_2 + SnCl_4OH^- \rightarrow (CH_3)_3C{-}CH_2{-}\overset{CH_3}{\overset{|}{C}}{=}CH_2 + SnCl_4H_2O \quad (1)$$

$$(CH_3)_3{\cdot}C{-}CH_2{-}\overset{+}{C}{\cdot}(CH_3)_2 + SnCl_4OH^- \rightarrow (CH_3)_3{\cdot}C{-}CH{=}\overset{CH_3}{\overset{|}{C}}{-}CH_3 + SnCl_4H_2O \quad (2)$$

Finally, some comment should be added on the deuterium-hydrogen exchange during the polymerization. If the deuterium hydrogen exchange was proceeding competitively in the polymerization reaction, above conclusion could not be drawn. However, the possible deuterium hydrogen exchange during the polymerization would be rured out by the following reason. The line 3 in Fig. 3, which is the spectrum of the dimer fraction obtained at a nearly 100% conversion of the polymerization with D_2O, shows no strengthening of C–D band absorption as compared with that of 2~3% conversion. On the contrary, there is marked decrease of C–D absorption in 3. Thus, no deuterium hydrogen exchange is conceivable.

This view may be supported by the experiment of Price and Berti[21], who observed no inclusion of deuterium in the polymerization of *cis*-stilben with boron fluoride and heavy water. The discussions on the same subject associated with the reacting species in the cationic reactions with Lewis acid as catalyst will be found abundantly, among which the works of Levy, Taft, Jr. and Hammett[22], Tauber and Eastham[23], and Hart and Levitt[24] are suggestive.

Water can thus be a cocatalyst in a cationic poymerization in liquid sulfur dioxide. However, the conclusion that sulfur dioxide cannot always be a catalyst or a cocatalyst is premature and should be reserved, because the polymerizations described above were undertaken only in a limited condition. The monomers such as vinyl ethers[25] and formaldehyde[26] can be polymerized cationically in liquid and gaseous sulfur dioxide without an acid catalyst.

Summary

Polymerization of isobutene was carried out in liquid sulfur dioxide with stannic chloride as catalyst containing water or heavy water. It was confirmed with the aid of infrared spectrometry that in liquid sulfur dioxide water was playing a part as a cocatalyst when water was present in a comparable amount.

The authors are indebted to Professor Susumu Kinumaki and his associates for carrying out this project, to Messrs. Takeshi Asano and Syuji Aono for infrared spectrometry and to the Befu Chemical Industries for donation of sulfur dioxide.

Studies on the Micro-paraffins. V. X-Ray Investigation of Various Paraffin Waxes

By Kazuo Negoro

(Received February 20, 1961)

Fundamental studies of micro-paraffins performed previously by the present author have revealed that the formation of fine crystal grains of micro-paraffin is not an essential character of micro-paraffin itself[1-3]. It has been found that the existence of a small amount of a certain compound seems to be the cause of the formation of fine crystal grains. In order to verify this point, an X-ray investigation of various paraffins seems to be necessary.

There have been many reports on X-ray diffraction of *n*-paraffin. Müller reported[4] that the cell dimensions of *n*-paraffin (carbon number 29) are $a=7.45$ Å, $b=4.97$ Å, and $c=79.2$ Å. Bunn[5] studied the crystal structure of long-chain normal paraffin hydrocarbons and, in particular, examined the "shape" of $>CH_2$ groups. Furthermore, many data on the X-ray diffraction of *n*-paraffin were introduced by Francis and Piper[6].

The present paper deals with the X-ray diffraction of *n*-dotriacontane (carbon number 32), various paraffin waxes (commercial products), micro-paraffins (commercial products), the micro-paraffin obtained from the tank residue of Aramco crude oil in Saudi-Arabia, and each fraction of micro-paraffin separated by the urea method and chromatography. The chain length, the lengths of a- and b-axes, the cross-sectional area occupied by one paraffin molecule, molecular volume, etc. were determined from the peak in the X-ray diffraction curve. There were a few interesting phenomena and observations on X-ray diffraction when some agents with a O-H group and a benzene ring were added to *n*-dotriacontane.

Experimental

Sample of Paraffin.—The following samples were used as described in the former reports: various paraffin waxes (commercial products), micro-paraffins (commercial products), refined *n*-dotriacontane, the micro-paraffin obtained from the tank residue of Arabian crude oil, and each fraction of micro-paraffin separated by the urea method and chromatography.

Measurement of X-Ray Diffraction.—An X-ray diffractometer (Geiger Flex, manufactured by Rigaku Denki Co.) was used for the measurement of the X-ray diffraction. The sample was placed on a glass plate, melted by heating to 70~75°C (a little higher than its melting point), and kept standing at room temperature (15~20°C), then the solidified sample was placed in the apparatus for the measuremen of the X-ray diffraction. When *n*-dotriacontane, to which substances such as "Santopour", picric acid, *p*-hydroxydiphenyl, asphalt components, etc. had been added, was taken as a sample, it was dissolved in ethyl alcohol and the crystals, formed by cooling gradually to room temperature, were filtered and measured after drying, as in the above operation.

At first, preliminary measurements were made in the range of 0~90° (2θ), in order to fix the range of the diffraction angle where (100) and (200) peaks appeared. Then the diffraction curves were carefully recorded for the range where the main peaks appeared.

The scale of the diffraction angle (2θ) was calibrated by using a standard sample (quartz)[7] and was measured under the conditions shown in Table I.

It was found by preliminary measurement that the peak due to (001) appeared at an angle less than

5°; the measurement of this peak was made under the conditions shown in Table II (Almost all of these experiments were made by using CuK_α radiation). In this case, various paraffin samples, the surfaces of which were cut smooth with a microtome and cut to suitable thickness with a knife, were placed on the glass by means of Scotch tape.

Results and Discussion

The Spacings d_{110} and d_{200}.—From the peak of each X-ray diffraction curve of the various paraffins obtained by FeK_α or CuK_α radiation, the spacings d_{110} and d_{200} were computed by Bragg's equation. The results are shown in Table III.

The results obtained by FeK_α and CuK_α radiation were markedly similar, as is shown in Table III repeatability.

n-Dotriacontane or pure *n*-hydrocarbon (carbon number 32) has the value of 4.15 Å for d_{110} and of 3.77 Å for d_{200}. The crystalline paraffin (m. p. 53.5°C), a mixture of various hydrocarbons, has the value of 4.19 Å for d_{110}; in other words the spacing is increased. Moreover, in the case of micro-paraffin, the product obtained from the tank residue of Aramco crude oil and the commercial one both have the value of 4.16 Å for d_{110}, which is slightly larger than that of *n*-dotriacontane.

*** — does not show any peak in the X-ray diffraction curve.

It was noticed that the values for d_{110} and d_{200} of the paraffin, about 62% of which formed urea adducts, were vary similar to those of *n*-paraffin when obtained from micro-paraffin by the urea method.

Consequently, though it has been stated that micro-paraffin consists of side-chain paraffins[8] it may be certain from the above results that some straight-chain hydrocarbons are possibly also contained in it.

The value for d_{110} of the remainder of the paraffin forming usea rejects in micro-paraffin was as large as 4.21 Å, and the value for d_{200} increased to 3.80 Å. It seems likely that these parts of micro-paraffin were rich in side-chain hydrocarbons.

When micro-paraffin was directly separated by chromatography, no great difference was observed between the pentane and benzene fractions, and its alcohol fraction was amorphous, for the peak on the X-ray diffraction curve was not observed. However, when micro-paraffin was separated into urea adducts and rejects by the urea method, the fractions of pentane, benzene and alcohol, separated by chromatography, showed remarkable differences.

When substances such as "Santopour", picric acid, *p*-hydroxydiphenyl, asphalt components, etc., were added to *n*-dotriacontane, the peaks (110) and (200) were not clearly observed. Therefore, it appeared that the product became amorphous.

Chain Lengths of Various Paraffins.—From the peak of (001), the chain lengths of carbon of various paraffin samples were computed by Bragg's equation. The results are listed in Table IV. The relation between the chain length and the carbon number of *n*-paraffin is given by the following Eq. 1 obtained by Kurtz and Lipkin[9].

$$\text{Å} = 1.27\, N_1 + 2.0 \qquad (1)$$

where Å is chain lengh in Å and N_1 is carbon number.

Column "a" in Table IV shows the values of N_1 computed by the values of chain length in Eq. 1. If N_1 were calculated by Eq. 1 from the results of the X-ray diffraction of refined *n*-dotriacontane (carbon number 32), its value would be

$$31.7 \fallingdotseq 32$$

Accordingly, it was recognized that the above value nearly agreed with the theoretical one.

In fact, the constant (2.0) in the above equation was in the range of 2.0~3.5 according to the preparation methods of samples as reported by Piper et al.[10] and Müller[11].

It was reported[12] that the lowest value (approximately 2) was obtained when *n*-paraffin, crystallized on a glass plate, was measured by X-ray diffraction. The constant was computed by Eq. 1 at 1.7 from the chain length of *n*-dotriacontane (42.3 Å) and the theoretical value of carbon number (32). Thus, Eq. 1 can be written as follows:

$$\text{Å} = 1.27\, N_1 + 1.7 \qquad (2)$$

TABLE IV. CHAIN LENGTHS OF VARIOUS PARAFFINS

Name	2θ(°)	Chain length Å	Carbon number of chain a	Carbon number of chain b
n-Dotriacontane	2.09	42.3	31.7	32.0
Crystalline paraffin (m. p. 53.5°C)	2.38	37.1	27.7	27.9
Crystalline paraffin (m. p. 60.0°C)	2.08	42.0	31.4	31.7
Crystalline paraffin urea adducts (m. p. 53.5°C)	2.42	36.8	27.4	27.6
Crystalline paraffin urea rejects (m. p. 53.5°C)	2.36	37.8	28.2	28.5
Micro-paraffin	1.20	50.8	38.4	38.6
Micro-paraffin (de-asphalted)	1.48	48.5	36.6	36.8

Table V. Values of constant (k), when those substances which were considered to have micro-crystallization effects were added to n-dotriacontane

Name	2θ(°)	Chain length Å	Constant number k
Base (n-dotriacontane)	2.09	42.3	1.7
n-Dotriacontane (picric acid added)	2.05	43.1	2.5
n-Dotriacontane (" Santopour " added)	2.01	44.0	3.4
n-Dotriacontane (p-hydroxydiphenyl added)	2.05	43.1	2.5
n-Dotriacontane (asphalts added)	2.06	42.9	2.3

Column " b " in Table IV shows the values of the carbon numbers of various paraffins computed by Eq. 2.

As shown in Table IV, it was recognized that the micro-paraffin consisted of long carbon chain hydrocarbons and that the chain length was in the range 47～53 Å, while the value for crystalline paraffin was 36～42 Å.

As for the carbon number of the chain, it was found that the value for micro-paraffin was considerably larger, 37～40, assuming that it was in the fully extended chain state, while the value for crystalline paraffin was 27～32. The straight paraffin obtained from the micro-paraffin by the urea method was C_{35}; therefore, its carbon chain was shorter than that of the base paraffin.

On the contrary, it was recognized that the carbon number of the urea non-adducts was slightly larger than that of the base paraffin, when the value was computed assuming that the paraffin was in the fully extended chain state even though it was actually rich in side chain hydrocarbons.

As reported in the previous paper,[3] when " Santopour ", picric acid, p-hydroxydiphenyl and asphalt components, nemely those compounds which were considered to have micro-crystallization effects, were added to n-dotriacontane, (110) the peak shifted to the smaller angle of 2θ, indicating that the chain length increased compared only with the case of n-dotriacontane of the base paraffin. In this case, the constant (2.0) of Eq. 1 was replaced by k:

$$\text{Å} = 1.27\, N_1 + k \qquad (3)$$

The value of k was computed by replacing $N_1 = 32$ and the observed value of the chain length (Å), the results being shown in Table V.

The larger values of k in Table V suggest that the crystal lattice has a certain disorder, and it was noticed that " Santopour " had the largest effect on the crystal of n-dotriacontane with the largest value of k.

X-Ray Diffraction Pattern of d_{001} and Crystallinity.—The X-ray diffraction curves of typical paraffins are shown in Fig. 1, in which intensity is in ordinate and the diffraction angle (2θ) is in abscissa. As for the crystalline paraffin or n-dotriacontane, various orders of reflections of (001) were observed, but for the micro-paraffin, it was noticed that only the first order appeared. If " Santopour ", picric acid, p-hydroxydiphenyl, etc., or those substances having micro-crystallization effects, were added to n-dotriacontane, it was found that all the higher order reflections disappeared.

Table VI. Length of a and b axes, cross-sectional area of one molecule (S), and ϕ of various paraffins

Name	a, Å	b, Å	S, cm^2	ϕ
n-Dotriacontane	7.54	5.03	19.0×10^{-16}	67°24′
Crystalline wax (m. p. 53.5°C)	7.56	5.04	19.1×10^{-16}	67°22′
Micro-paraffin	7.50	5.00	18.8×10^{-16}	67°30′
Micro-paraffin (de-asphalted)	7.52	5.00	18.8×10^{-16}	67°14′
Micro-paraffin (Shell)	7.50	5.01	18.8×10^{-16}	67°30′
Micro-paraffin (commercial)	7.50	5.01	18.8×10^{-16}	67°30′
Micro-paraffin urea adducts	7.52	5.00	18.8×10^{-16}	67°14′
Micro-paraffin urea rejects	7.60	5.05	19.2×10^{-16}	67°12′
Micro-paraffin pentane fraction	7.56	5.04	19.0×10^{-16}	67°22′
Micro-paraffin adducts pentane fraction	7.50	5.01	18.8×10^{-16}	67°30′
Micro-paraffin rejects pentane fraction	7.56	5.04	19.0×10^{-16}	67°22′
Ar wax	7.52	5.01	18.8×10^{-16}	67°20′
Amber wax	7.50	5.01	18.8×10^{-16}	67°30′

When micro-paraffin was reacted with urea, the straight paraffin (urea adducts paraffin) thus obtained showed (001) and a very weak (002). However, the pentane fraction, obtained from the urea adducts by chromatography, showed higher order reflections clearly, and it was found that the crystalline state gradually had a resemblance to that of n-paraffin. On the contrary, in the case of urea rejects of paraffin, such peaks did not appear at all. As mentioned above, the appearance of the peaks on X-ray diffraction curves has some relation with the crystallinity of paraffins in actuality, and it is interesting that the details of the X-ray dffraction pattern of micro-paraffin have been made clear, and that the effects of "Santopour" etc., or those compounds with an O–H group and benzene ring, have been observed on the change which occurred in the peaks on the X-ray diffraction curve.

Length of a- and b-Axes and Cross-sectional Area of Various Paraffin Crystals.—Müller[13] studied the X-ray diffraction of n-paraffin, and the cross-section of the unit cell is shown in Fig. 2. It was confirmed that one paraffin chain was in the center of unit cell and that a paraffin chain with a different azimuthal orientation was at each of the four corners of the unit cell.

For the packing of paraffin molecules, no experimental evidence was obtained for any kind of paraffins; however, according to Müller, it would be proper to consider that each crystal had a cross-section as shown in Fig. 2 and a c-axis perpendicular to it. The length of the a- and b-axes, the cross-sectional area occupied by one molecule (S), and ϕ were computed from the values for d_{110} and d_{200} by the following Eqs. 4—7. The calculated values are shown in Table VI, and part of the values which Müller reported on n-paraffins of various carbon numbers are reproduced in Table VII.

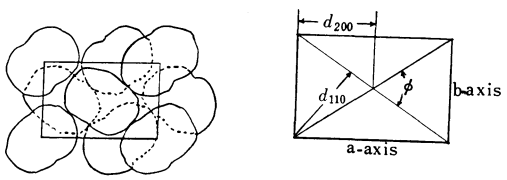

Fig. 2. Cross-section of unit cell.

$$a=2\cdot d_{200} \tag{4}$$

$$b=a\cdot d_{110}/\sqrt{a^2-(d_{110})^2} \tag{5}$$

$$c=a\cdot b/2 \tag{6}$$

$$\tan\phi/2=b/a \tag{7}$$

Table VII. Length of a and b axes, cross-sectional area of one molecule (S), and ϕ of various n-paraffins (Müller)

Number of carbon atoms	a, Å	b, Å	S, cm^2	ϕ
19	7.55	5.01	18.9×10^{-16}	67°10′
24	7.41	4.94	18.3×10^{-16}	67°20′
29	7.42	4.94	18.3×10^{-16}	67°16′
30	7.33	4.92	18.2×10^{-16}	67°44′
31	7.40	4.93	18.2×10^{-16}	67°15′
34	7.40	4.95	18.3×10^{-16}	67°30′
44	7.33	4.93	18.1×10^{-16}	67°52′

The length of the a- and b-axes of n-dotriacontane (n-paraffin of carbon number 32) had slight differences of 0.14 Å and 0.10 Å compared with the values for n-paraffin (carbon number 31) of Müller; it was also recognized that the values for various paraffins were almost similar. As for the cross-sectional area occupied by one molecule, the values for various paraffins were in the range of $(18.8\sim19.2)\times10^{-16}$ cm^2, and it was recognized that no great differences were to be seen among various paraffins, assuming that they were in normal crystal form, though

13) A. Müller, *Proc. Roy. Soc.*, **A128**, 514 (1932).

the urea adducts of paraffins showed somewhat larger values than those of the other paraffins.

Molecular Volume of Various Paraffins. — When the chain length and the cross-sectional area occupied by one molecule have been computed, the molecular volume of various paraffins may be calculated by the following equation, assuming that they are *n*-paraffins:

$$V = d_{001} \cdot ab/2 \qquad (8)$$

Table VIII shows the molecular volume (Å^3/mol.) of various paraffins calculated from Eq. 8.

TABLD VIII. MOLECULAR VOLUME OF VARIOUS PARAFFINS

Name	Molecular volume, Å^3
n-Dotriacontane	804
Crystalline wax (m. p. 53.5°C)	708
Micro-paraffin	955
Micro-paraffin (de-asphalted)	911
Micro-paraffin (Shell)	928
Micro-paraffin (commercial)	998
Micro-paraffin urea adducts	872
Micro-paraffin urea rejects	974
Micro-paraffin pentane fraction	900
Micro-paraffin adducts pentane fraction	867
Micro-paraffin rejects pentane fraction	909
Ar wax	695
Amber wax	923

The molecular volume of *n*-paraffin was computed from carbon number (N_1) by the following equation:

$$V = 23.50\, N_1 + 37.0 \qquad (9)$$

For *n*-dotriacontane the molecular volume, calculated by putting $N_1 = 32$ in Eq. 9, was 789, while that computed from X-ray diffraction data by Eq. 8, was 804. The difference between these two is 15, that is, approximately 2%. As for the micro-paraffin, a mixture of various hydrocarbons, the value of the molecular volume is not accurate, but this might give some clue as to the molecular volume.

Summary

From the X-ray diffraction of *n*-dotriacontane, various paraffin waxes, micro-paraffin, and each fraction of micro-paraffin separated by the urea method and chromatography, the chain length and the spacings (110) and (200) of each crystal have been computed. Furthermore, the carbon number of the chain, the lengths of the a- and b-axes, the cross-sectional area occupied by one molecule, and the molecular volume have been calculated. They have been calculated on the assumption that thay were in normal crystal form, but in order to make it exact, it is necessary to work with a single crystal. The author would like to try further experiments.

The author wishes to express his sincere appreciation to Professor Ryozo Goto and Professor Saburo Yagi, Kyoto University, for their cordial guidance and discussion throughout this research. He is also grateful to Dr. Kenziro Asai and Dr. Tsuneo Seto, Kyoto University, for their cordial guidance in these analyses.

He also thanks Mr. Takashi Matsuoka et al., the personnel of the Central Research Laboratory of Nippon Mining Co., for their cooperation in the measurement of X-ray diffraction.

Dehydration of Bile Acids and their Derivatives. X. A Study of the Physical Properties of Various 3α-Hydroxycholenates and their Derivatives, with Special Reference to their Optical Rotatory Dispersions

By Ryuzaburo OSAWA

(Received March 13, 1961)

In the previous papers[1,2], the synthesis of methyl 3α-hydroxy-$\Delta^{8(14)}$-cholenate and 3α-hydroxy-Δ^{14}-cholenate was reported. Besides these unsaturated bile acids, various 3α-hydroxycholenic acids of known structure have already been reported. The present paper deals with the study of the correlation of the physical properties with the positions of the double bonds of these 3α-hydroxycholenates and their derivatives, above all, the optical rotatory dispersions of these bile acids are discussed in detail because Djerassi[3] has shown that the rotatory dispersion curve (the RD curve) is an excellent tool for elucidating the structure of steroids.

The ultraviolet absorption spectra of the unsaturated bile acids of various types were studied; their ε values are shown in Table I. The bile acids with exocyclic, tetrasubstituted double bonds ($\Delta^{8(14)}$) give much higher ε values than do unsaturated bile acids of the other types. On the other hand, bile acids with a disubstituted ethylenic linkage, such as 3-keto-Δ^{6}-cholenate, give much lower ε values than those with trisubstituted (Δ^{7}, $\Delta^{9(11)}$, Δ^{14}) or endocyclic, tetrasubstituted (Δ^{8}) double bonds. These results agree fairly well with those reported by Bladon et al.[4]

As Barton[5] has reported, the position of a double bond in the steroid molecule can be deduced by calculating the molecular rotation increment due to the introduction of the double bond. As a supplement to the data in this field, the molecular rotations of various available unsaturated and corresponding saturated bile acids were measured; the calculated M_D contributions of the double bonds are summarized in Table II. It was an interesting finding that the positive sign of the M_D contributions due to the double bonds in ring B or C is strongly inverted when the C_{12}-carbonyl group is simultaneously introduced; e. g., the

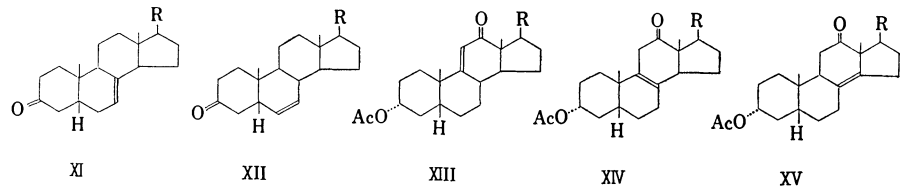
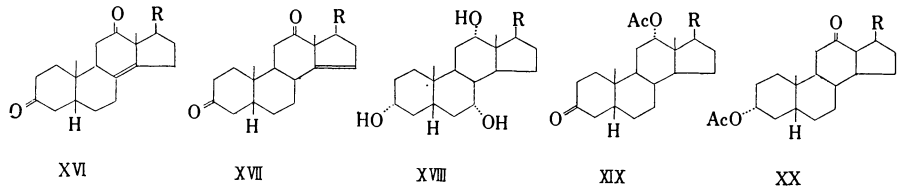
bile acids have not yet been covered in the literature. Following Djerassi's report[9], the background rotations of some unsaturated bile acids were measured and compared with that of a saturated bile acid, cholic acid (as methyl ester). As shown in Fig. 1, the unsaturated bile acids (Δ^7, $\Delta^{8(14)}$ and Δ^{14}) (I—IV) give positive plain curves similar to that of cholic acid (XVIII). The background rotations of the above acids, therefore, are not affected by the introduction of these double bonds.



Some kinds of unsaturated keto bile acids with carbonyl groups at C_3 and/or C_{12} were prepared; by measuring their RD curves, the effect of the positions of the double bonds on the RD curves of the parent saturated keto bile acids was studied.

A) Unsaturated 3-Keto Bile Acids.—*A—1) Compounds with Double Bonds in Ring A.*—Methyl 3-keto-Δ^4-cholenate (V) has the same nuclear structure as Δ^4-cholestene-3-one, and, as expected, it gives a multiple negative Cotton-effect RD curve, similar to that of Δ^4-cholestene-3-one[8], as is shown in Fig. 2.



A—2) Compounds with Isolated Double Bonds in Ring C or D.—The unsaturated bile acids VII—X show negative Cotton-effect curves which are not only similar to one another, but also resemble that of methyl 3-keto-12-acetoxycholanate (XIX) (Fig. 3). The result clearly indicates that the introduction of double bonds at positions remote from the carbonyl groups of these bile acids does not exert remarkable effects on the RD curves, though the intensity of the trough in the curves is more or less increased.

A—3) Compounds with Double Bonds in Ring B.—Figure 4 illustrates the RD curves of methyl 3-keto-Δ^7-cholenate (XI) and methyl 3-keto-Δ^6-cholenate (XII). Though the RD curve of

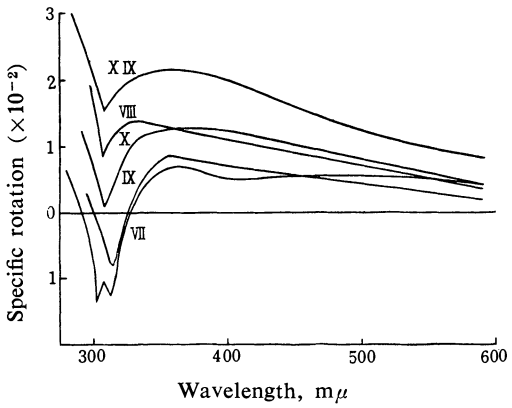

Fig. 3. Rotatory dispersion curves of: methyl 3-keto-Δ^8-cholenate (VII), methyl 3-keto-$\Delta^{8(14)}$-cholenate (VIII), methyl 3-keto-$\Delta^{9(11)}$-cholenate (IX), methyl 3-keto-Δ^{14}-cholenate (X) and methyl 3-keto-12-acetoxycholanate (XIX).

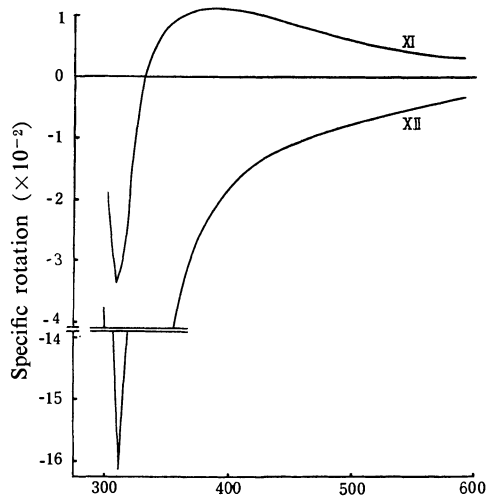

Fig. 4. Rotatory dispersion curves of: methyl 3-keto-Δ^7-cholenate (**XI**) and methyl 3-keto-Δ^6-cholenate (**XII**).

the former XI shows a negative drift greater than those of the above-mentioned compounds with double bonds in ring C or D (A—2), it must be noted that all of these curves are of the same shape. The RD curve of the Δ^6-compound XII is likewise a negative Cotton-effect curve of the same type and, indeed, of a strikingly high intensity (α_{312} −1615°). Since the RD curve of the 3-keto-steroid of the 5α-series with an isolated double bond in ring B hardly differs from that of the corresponding saturated ketone, as Djerassi[9] has pointed out, such a characteristic phenomenon as is given by the above Δ^6-compound XII might be attributable to the cis A/B fusion of this compound and will serve for the diagnosis of the position of the double bond in the unsaturated 3-keto-5β-steroids.

Djerassi et al.[10] reported that the introduction of a second double bond ($\Delta^{9(11)}$) in Δ^7-lanostene-3-one results in a strong positive

10) C. Djerassi and O. Halpern, *J. Am. Chem. Soc.*, **80**, 4001 (1958).

shift of the RD curve. Methyl 3-keto-$\Delta^{7,9(11)}$-choladienate (Fig. 2, VI), which has a structure similar to the lanostadiene derivative, likewise shows a positive, but irregularly shaped, shift of the RD curve of the Δ^{7}-bile acid (XI).

B) Unsaturated 12-Keto Bile Acids. — As reported by Djerassi et al.[8], a series of saturated 12-keto bile acids give positive Cotton-effect curves with peaks on the positive side. The effect of the introduction of double bonds in ring C or D on the RD curves of some 12-keto bile acids was found to be as follows:

B—1) Compounds with α,β-Unsaturated 12-Keto Groups.—The RD curve of methyl 3α-acetoxy-12-keto-$\Delta^{9(11)}$-cholenate (XIII) (Fig. 5) shows a multiple negative Cotton-effect curve quite similar in shape to those of cholestene-3-one and methyl 3-keto-Δ^{4}-cholenate (V) mentioned above (A—1); i. e., the introduction of a double bond conjugated to the keto group resulted in the strong negative shift of the RD curve displayed by the saturated 12-keto bile acid[8]. This phenomenon can be well explained by the fact that the B/C bicyclic system including the $\Delta^{9(11)}$-12-ketone group XIII has quite the same configuration as the A/B bicyclic system with the Δ^{4}-3-ketone group V.

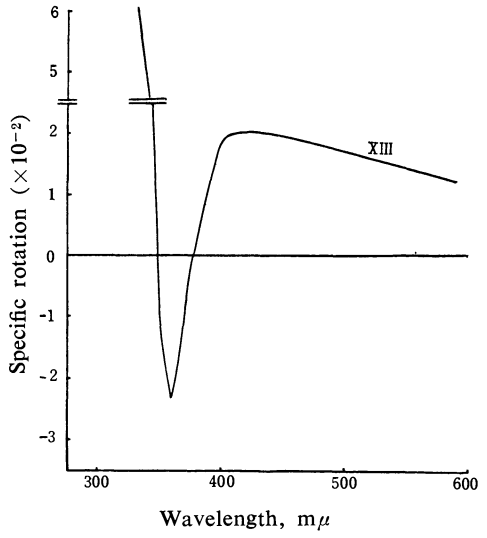

Fig. 5. Rotatory dispersion curves of methyl 3α-acetoxy-12-keto-$\Delta^{9(11)}$-cholenate (XIII).

B—2) Compounds with Isolated Double Bonds in Ring C.—It is very interesting to note that, while the RD curve of methyl 3α-acetoxy-Δ^{8}-cholenate (XIV) gives a positive Cotton-effect curve similar to that of the saturated 12-keto-cholanic acid derivative XX, methyl 3α-acetoxy-12-keto-$\Delta^{8(14)}$-cholenate (XV) shows a very strong negative shift of the RD curve, as is illustrated in Fig. 6. Since methyl 3α-acetoxy-

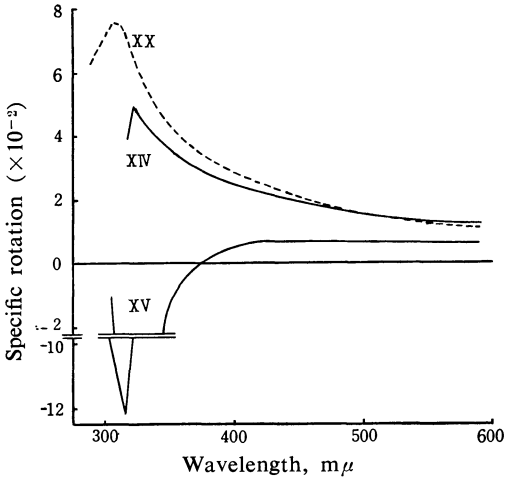

Fig. 6. Rotatory dispersion curves of: methyl 3α-acetoxy-12-keto-Δ^{8}-cholenate (XIV), methyl 3α-acetoxy-12-keto-$\Delta^{8(14)}$-cholenate (XV) and methyl 3α-acetoxy-12-keto-cholanate (XX).

$\Delta^{8(14)}$-cholenate (III) shows a positive background rotation just like the saturated bile acids (Fig. 1), such an inversion of the Cotton-effect as is shown by the $\Delta^{8(14)}$-12-keto bile acid XV might be attributed to a possible fact that the environment surrounding the C_{12}-carbonyl group of the bile acid XX is altered by the introduction of the $\Delta^{8(14)}$-bond so as to result in a strong inversion of the Cotton-effect.

B—3) 3,12-Diketo Bile Acids with Double Bonds in Ring C or D.—Previously Djerassi et al.[8]

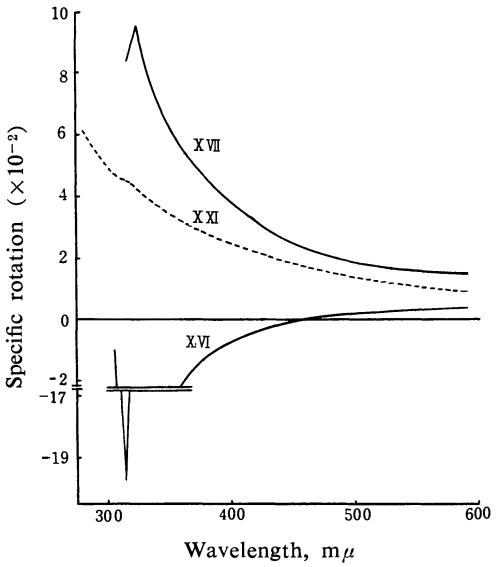

Fig. 7. Rotatory dispersion curves of: methyl 3, 12-dikoto-$\Delta^{8(14)}$-cholenate (XVI), methyl 3, 12-diketo-Δ^{14}-cholenate (XVII) and methyl 3, 12-diketocholanate (XXI).

reported that the RD curves of saturated diketo bile acids, such as 3, 12-diketocholanic acid (XXI), can be calculated by superimposing the RD curve of 3-ketocholanic acid on that of 12-ketocholanic acid. As samples of unsaturated diketo bile acid, methyl 3, 12-diketo-$\Delta^{8(14)}$-cholenate (XVI) and methyl 3, 12-diketo-Δ^{14}-cholenate (XVII) were prepared and their RD curves were determined. The curves are shown in Fig. 7. Such an inversion of the Cotton-effect as is shown above (B—2) is also observed in the RD curve of the $\Delta^{8(14)}$-diketo bile acid (XVI), and the negative Cotton-effect given by methyl 3α-acetoxy-12-keto-$\Delta^{8(14)}$-cholenate (XV) is increased by the introduction of the 3-keto group. The RD curve of the Δ^{14}-diketo bile acid (XVII) shows that the positive Cotton-effect RD curve of the saturated 12-ketocholanic acid XX is superimposed by the curve of methyl 3-keto-Δ^{14}-cholenate (X).

Methyl 3-Keto-Δ^{8}-cholenate (VII).—3α-Acetoxy-12-keto-Δ^{8}-cholenic acid (m. p. 148°C) (200 mg.), synthesized by the method reported by Fieser et al.[13], was reduced by the Huang-Minlon procedure (hydrazine hydrate, 5 ml. and potassium hydroxide, 5 g.). The resulting free acid (m. p. 173°C) was methylated with diazomethane, and the product was oxidized according to the method of Bladon et al.[3] The oxidation product was chromatographed and recrystallized from methanol. Yield, 68 mg., m.p. 122°C, $[\alpha]_D^{20}$ +22° (chf.). IR ν_{max}^{Nujol}; 1715 cm^{-1}, 1740 cm^{-1} (C=O). RD (Fig. 3); $[\alpha]_{589}^{28.3}$ +18°, $[\alpha]_{400}$ +66°, $[\alpha]_{310}$ −125°, $[\alpha]_{302.5}$ −134° (trough), $[\alpha]_{300}$ −73° (Xe).

Found: C, 77.50; H, 9.84. Calcd. for $C_{25}H_{38}O_3$ (386.55): C, 77.65; H, 9.91%.

Methyl 3-Keto-$\Delta^{8(14)}$-cholenate (VIII).—3α-Hydroxy-$\Delta^{8(14)}$-cholenic acid (m. p. 168°C) (100 mg.), derived from apocholic acid[2], was methylated with diazomethane, and the ester was oxidized according to the method of Bladon et al.[3] Yield, 56 mg., m. p. 104°C, $[\alpha]_D^{19}$ +68° (chf.). IR ν_{max}^{Nujol}; 1710 cm^{-1}, 1730 cm^{-1} (C=O). RD (Fig. 3); $[\alpha]_{589}^{16.4}$ +39°, $[\alpha]_{400}$ +112°, $[\alpha]_{310}$ +105°, $[\alpha]_{307.5}$ +87° (trough), $[\alpha]_{305}$ +115° (Zr.)

Found: C, 77.19; H, 9.80. Calcd. for $C_{25}H_{38}O_3$ (386.55): C, 77.65; H, 9.91%.

Methyl 3-Keto-$\Delta^{9(11)}$-cholenate (IX).—Methyl 3α-acetoxy-12-keto-$\Delta^{9(11)}$-cholenate (200 mg.) obtained by the method reported by Fieser et al.[13], was reduced by the Huang-Minlon method as mentioned above, and the product (its methyl ester) was purified by chromatography. Methyl 3α-hydroxy-$\Delta^{9(11)}$-cholenate (m. p. 103°C) thus obtained was oxidized with a chromic acid-sulfuric acid mixture[3]. The oxidation product was recrystallized from methanol. M. p. 106°C, $[\alpha]_D^{21}$ +33° (chf.). IR ν_{max}^{Nujol}; 825 cm^{-1} (=C-H), 1720 cm^{-1}, 1738 cm^{-1} (C=O); RD (Fig. 3): $[\alpha]_{589}^{21}$ +41°, $[\alpha]_{400}$ +102°, $[\alpha]_{317.5}$ −66°, $[\alpha]_{315}$ −81° (broad trough), $[\alpha]_{312.5}$ −76°.

Found: C, 77.01; H, 9.83. Calcd. for $C_{25}H_{38}O_3$ (386.55): C, 77.67; H, 9.91%.

Methyl 3-Keto-Δ^{14}-cholenate (X)[1].—M. p. 89°C, $[\alpha]_D^{24}$ +38° (chf.). IR ν_{max}^{Nujol}; 777 cm^{-1} (=C-H), 1715 cm^{-1}, 1742 cm^{-1} (C=O). RD (Fig. 3); $[\alpha]_{589}^{19}$ +42°, $[\alpha]_{400}$ +122°, $[\alpha]_{310}$ +14°, $[\alpha]_{307.5}$ +10° (trough), $[\alpha]_{305}$ +24 (Zr).

Methyl 3-Keto-Δ^{7}-cholenate[1] **(XI).**—M. p. 125°C, $[\alpha]_D^{23}$ +62° (chf.). IR ν_{max}^{Nujol}; 795 cm^{-1} (=C-H), 1712 cm^{-1}, 1740 cm^{-1} (C=O). RD (Fig. 4); $[\alpha]_{589}^{20.8}$ +29°, $[\alpha]_{400}$ +110°, $[\alpha]_{310}$ −322°, $[\alpha]_{307.5}$ −334° (trough), $[\alpha]_{305}$ −186° (Zr).

Methyl-3-Keto-Δ^{6}-cholenate (XII).—3α-Hydroxy-Δ^{6}-cholenic acid (m. p. 214°C) prepared according to the method of Schubert et al.[14] was methylated with diazomethane, and the product was oxidized with a chromic acid-sulfuric acid mixture[3]. M. p. 125°C, $[\alpha]_D^{22}$ −52° (chf.). IR ν_{max}^{Nujol}: 740 cm^{-1} (=C-H), 1717 cm^{-1}, 1743 cm^{-1} (C=O). RD (Fig. 4);

* Ultraviolet absorption spectra were measured in ethanol solutions with a Beckman spectrophoto-densitometer (Model DU); rotatory dispersion, in methanol solutions (concentration: 0.1%), with a Rudolph high precision photoelectric polarimeter (Model 200S-80Q) (light source: zirconium lamp (Zr) or xenon arclamp (Xe)).

Summary

Not only ultraviolet and infrared absorption spectra but also optical rotatory dispersions of various unsaturated bile acids were studied, and most of the data were found to be in good agreement with those hitherto obtained concerning the other steroids. The determination of the rotatory dispersion gave the following results:

1) The background rotation of the saturated bile acid is not affected by the introduction of a double bond in ring B, C or D.

2) The introduction of a double bond in ring C or D does not remarkably affect the RD curve of the saturated 3-keto bile acids, while the negative drift of the RD curve given by 3-keto-Δ^{6}-cholenic acid is so very striking that this phenomenon could be utilized for the diagnosis of Δ^{6}-3-keto bile acids (5β).

3) The positive Cotton-effect RD curve given by a saturated 12-keto bile acid is strongly inverted by the introduction of the $\Delta^{8(14)}$-bond, but not by that of the Δ^{8}-bond.

The author is greatly indebted to Professor Dr. K. Yamasaki, Department of Biochemistry, Tottori University School of Medicine, Yonago, and to Professor Dr. K. Tsuda, Pharmaceutical Institute, the University of Tokyo, for their valuable suggestions and encouragement. He is also heartily thankful to Drs. T. Okuda and S. Susuki, Laboratory of the Tanabe Seiyaku Co., Tokyo; to Mr. F. Nakada, Department of Biochemistry, Tottori University School of Medicine, Yonago; to Miss. F. Tomura and Mr. T. Murata, Laboratory of the Nippon Eiyô Kagaku Co., Tokyo, and to the doctors of the Laboratory for the Applied Microbiology, the University of Tokyo, for their technical assistance.

Physicochemical Studies on Cobalt Salts of Higher Fatty Acids. IX. Cobalt Complex Soap

By Hirotaro KAMBE*

(Received March 29, 1961)

It has been certified the cobalt soap is a salt between cobalt ion and fatty acid ion, in Part IV of these studies[1]. In the present paper, the preparation of soaps of cobalt complex ions is presented and some of their properties are investigated.

The reflection spectrum of cobalt complex soap shows that it certainly has color characteristics similar to those of the parent cobalt complex ion. In the infrared absorption spectrum, the existence of carboxylate ion is confirmed, as in simple cobalt soap. The magnetic susceptibility of complex soap verifies that cobalt(III) ion is in a state of an electronic configuration of d^2sp^3 six covalent complex ion. Decomposition at heating was followed by thermogravimetric analysis.

Experimental

Cobalt complex soaps were prepared by metathesis between inorganic cobalt complex salts and potassium soap, as was the simple cobalt soap described in Part I. Luteo-salt, $[Co(III)(NH_3)_6]Cl_3$, and purpureo-salt, $[Co(III)(NH_3)_5Cl]Cl_2$, were used as inorganic salts. Hereafter, these salts are called I and II respectively. Stearates of these complex ions are called I-S and II-S respectively.

Reflection spectrophotometry, infrared absorption spectrophotometry, and the measurement of magnetic susceptibility were carried out as in Parts III and IV. Thermogravimetry was conducted as in Part VI.

Results and Discussion

The reflection spectra of cobalt complex soaps are shown in Fig. 1, with that of inorganic complexes. Their trichromaticity constants were calculated as in Part III and are shown in Table I.

The similarity of the trichromaticity constants, in particular those of the dominant wavelength, of complex soaps to that of the inorganic complex ion suggests the ionic nature of these soaps.

The infrared absorption spectra of these soaps and the parent complexes are shown in Figs. 2 and 3 and in Table II. Since carboxylate absorptions at 1400 and 1540 cm^{-1} are clearly found in them, it is evident that they are truly ionic. Absorptions of ammonia bending appeared as several bands around 1320 cm^{-1}, and as a broad band 1550~1600 cm^{-1}.

The specific magnetic susceptibility of cobalt

complex soap I-S was measured as -0.58×10^{-6} c. g. s. Its molar susceptibility was calculated as -587.54×10^{-6} c. g. s. As the diamagnetic susceptibility of stearate ion is -209×10^{-6}, and that of cobalt(III) complex ion is -38×10^{-6}, the calculated value of the diamagnetic susceptibility of cobalt complex soap is -665×10^{-6} c. g. s., which is consistent with the observed value. In consequence, cobalt ion in cobalt complex soap is in the octahedral six-covalent electronic configuration, $(3d)^2(4s)(4p)^3$.

The decomposition curves of the cobalt complex soaps are shown in Fig. 4, and that of their parent inorganic complexes in Fig. 5. Inorganic complexes decompose at two stages. The first decomposition begins at 150°C and, through a maximum rate at 230°C for I and at

260°C for II, ends at 280°C. The second decomposition begins at 280°C and ends at 350~360°C, through a maximum rate at 350°C for I and 340°C for II. These peaks correspond to the liberation of ammonia at the first peak and of chlorine at the second peak. The residue is cobalt chloride.

The decomposition curves of cobalt complex soaps show three peaks. At the first peak ammonia is liberated, which is certified by an insertion of litmus paper in it. At the second peak, the white crystal deposits on the inner wall of the glass tube surrounding the reaction chamber, as was also observed in the decomposition of simple cobalt soaps (Part VI). At this stage, about one molecule of stearic acid is liberated as stearone from each soap. The last peak differs greatly between the two soaps. The remainder of stearic acid in the soap must be liberated, but stearone is not observed in this stage. The intermediate reaction products were not confirmed. The residue contains cobalt oxide in both cases.

Summary

Soaps of cobalt complex ions and fatty acid have been prepared and investigated. Reflection spectra and infrared spectra show that these soaps are ionic in nature, as is simple cobalt soap. The magnetic susceptibility of complex soap shows that cobalt ion is in the electronic configuration of octahedral six-covalent cobalt-(III) ion. Thermogravimetric analysis of these soaps shows that they decompose at three stages, but the precise mechanism of these reactions has not yet been determined.

The author expresses his gratitude to Professor Bunnosuke Yamaguchi for his advice throughout these studies, and to Messrs. Itaru Mita and Shoichi Igarashi for their help in the experiments.

Electronic Structures of Naphthalenediols. II. β, β′-Naphthalenediols

By Kichisuke NISHIMOTO and Ryoichi FUJISHIRO

(Received April 21, 1961)

To elucidate the molecular properties of naphthalene derivatives with auxochromic substituents, such as methoxy, amino, halogen etc., we have been studying the electronic structures of naphthalenediols. In the previous paper[1], we studied the electronic structures of α, α'-naphthalenediols and pointed out that their molecular properties, such as charge distribution and electronic spectra, depend remarkably upon the type of substitution. These are as follows:

(1) A, A-derivative, in which two hydroxy groups link to the same ring, (A ring in Fig. 1)

(2) A, B-derivatives, in which each hydroxy group bonds with a different ring.

Namely, in the case of 1, 4-diol it is found from the molecular diagram[1] that the substituents have no significant influence upon the B ring, which remains nearly the same as naphthalene, but do produce rather a large effect on the A ring. This fact seems to suggest that the 9—10 bond plays an important role in the conjugation interaction between the ring and the substituents. In the present paper, we will examine this point by calculations based on the perimeter models. It is a well-known fact to organic chemists[2] that the reactivities of naphthalene derivatives with substituents in β-position are peculiar. In the present paper, the theoretical treatment based on the simple MO theory will be applied to the electronic structures of β, β'-naphthalenediols, such as 2, 3-, 2, 6- and 2, 7-diols and

we will try to explain the peculiarities in the reactivities of those molecules.

Method of Calculation

The calculation is carried out by means of the simple LCAO MO theory, with only $2p\pi$-electrons considered explicitly. The Coulomb and the resonance integrals used are the same as those in the previous paper[1]. The numbering of the atoms and the symmetry orbitals for the molecules are shown in Fig. 2. The notations of irreducible representations are also the same as those in the previous paper.

Results and Discussion

Vacant MO's and Molecular Diagrams.— The π-MO's of each naphthalenediol are expressed by linear combinations of the twelve $2p\pi$ atomic orbitals. Consequently, there are twelve π-MO's in each diol. According to Pauli's principle, the lowest seven are occupied by fourteen electrons. In the ordinary method

it is necessary to use these seven occupied MO's in constructing the molecular diagram. The other five are called "vacant MO's". As we have pointed out in a previous paper[3], the molecular diagram of a diol is obtained from only the five vacant MO's; namely, the π-electron density on the μ-th atom, q_μ, the π-bond order for the μ-ν bond, $p_{\mu\nu}$, and the free valency of the μ-th atom, f_μ, are given by the following relations respectively:

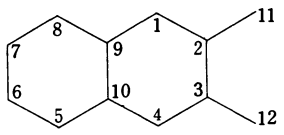
i) $q_\mu=2-2\sum_i^{\text{vac}} C_{\mu i}^2$

ii) $p_{\mu\nu}=-2\sum_i^{\text{vac}} C_{\mu i}C_{\nu i}$

iii) $f_\mu=\sqrt{3}-\sum_\nu p_{\mu\nu}$

(μ and ν are nearest neighbors)

in which $\sum_i^{\text{vac}}$ means the summation over the vacant orbitals and $C_{\mu i}$ is the coefficient of the μ-th $2p\pi$ atomic orbital, ϕ_μ, in the i-th MO, ϕ_i.



The calculated vacant MO's, ϕ_i^v, are given in Table I, and the molecular diagrams are indicated in Fig. 3. A comparison of these diagrams with those of α,α'-diols[1] makes it possible to say that the introduction of substituents into the α-position leads to increases in the bond orders of the 2—3 and 9—10 bonds and to decreases in those of the 1—2, 1—9 and 3—4 bonds. That is, α-substitutions have a tendency to unify the bond orders along the direction of the short molecular axis. Contrary to this, substitutions in the β-positions cause decreases in the bond orders of the 1—2, 2—3 and 9—10 bonds and an increase in that of the 1—9 bond. The same result is reported in the case of α- and β-naphthylamines[4]. In other words, the substitutions in α-positions cause an increase in the mobilities of π-electrons in the direction of the short molecular axis, whereas those in β-positions lead to decreased π-electron mobilities in this direction and to an increase of mobilities in the direction of the long molecular axis. This is an important difference between the α- and β-derivatives, and this remarkable circumstance may be responsible for the distinction between the α- and β-derivatives in their molecular properties, such as reactivities, etc.

Reactivity.—It is a well-known fact[2a] that in all naphthalene derivatives with substituents in β-positions the 1-position is found to be reactive and the 3-position to be inert, or nearly so in the case of electrophilic substitution reactions.

In the electrophilic substitution reaction, π-electron density at the positions which are attacked by the reagent is a measure of reactivity. From the standpoint of this situation, it may be expected that their 1-positions in any β-substituted naphthalene derivatives are the first point to be attacked by any reagent. In a similar way, the 3-positions in α-derivatives may become less active. It is a well-known fact that the frontier electron

theory proposed by Fukui et al.[5] provides powerful information for chemical reactions, such as electrophilic, nucleophilic and radical reactions. Frontier electron densities in occupied highest orbitals, which are responsible for electrophilic substitutions, are collected in Table II. As is seen from this table, the 3-positions in any naphthalene derivatives with auxochromic substituents should be inactive for this type of reaction. This expectation is consistent with the experimental facts[2b]. For example, 2, 7-diol couples at positions 1 and 8, but if these positions are blocked by alkyl groups, no coupling occurs. The molecular diagrams of A, A-derivatives show that their A rings are

reactive and their B rings less reactive than the A rings. By a simple extension of this result, it would be expected that even in the ecas of α- and β-naphthol the A ring would be more active than the B ring. This expectation has been supported by many experiments in connection with substitution reactions. For example, in α-naphthol the 4-position is the first point of attack, and also in β-naphthol the point of first attack is the activated 1-position. Of course, in the case of A, B-derivatives, the reactivities of the two rings are not different from each other.

Molecular Diagrams based on Perimeter Model.—As mentioned above, the B rings in A, A-derivatives are scarcely influenced by the substitution. This result seems to suggest that the 9—10 bond in the derivatives may play an important role in the motion of the $2p\pi$ electrons in the molecules. When the 9—10 bond in the naphthalene is absent, the reactivity at any position and the bond order of any bond in the molecule may be nearly equivalent. Therefore, the presence of the 9—10 bond may be the main reason for the appreciable difference in the reactivity from one position to another. In order to examine the effect of the 9—10 bond on the electronic structures of the diols, we carried out calculations based on the perimeter model. In this model it is assumed that the π-electrons are moving in the perimeter potential field. Our method of calculation is based on the simple LCAO MO theory. The parameters used were the same as in the above calculation, except

that the 9—10 bond was neglected, that is, the value of resonance integral $\int\phi_9 H\phi_{10}d\tau$ was put at zero. The molecular diagrams obtained on the basis of this model are shown in Fig. 3. We can see from the diagrams that the 9—10 bond has the following effects on the electronic structures of these molecules:

1) It breaks the uniformity of the bond order in the case of naphthalene, which means a decrease in the mobilities of the π-electrons.

2) It suppresses the effect of substituents on the B ring in the case of A, A-derivatives. This circumstance may probably be expected in the cases of mono- and polysubstitution.

3) It restrains the conjugation interactions among the ring and substituents to some extent. We will consider this point in the next section.

4) It makes the distinction of positions, i. e., the α-position or β-position, in naphthalene necessary.

From the above results, the differences among the molecular properties of α-, β-, α, α'-, β, β'-, α, β-, A, A- and A, B-naphthalene derivatives should be attributable to the presence of the 9—10 bond in these molecules.

Extradelocalization Energies.—Extradelocalization energy is defined as the stabilization energy of the molecule due to substitution. By using the VO method[3], the extradelocalization energy, $\Delta\varepsilon$, of a naphthalene derivative with auxochromic substituents can be obtained from five vacant orbital energies, ε_i, using the following equation:

$$\Delta\varepsilon = -2(\sum_i^{\text{vac}}\varepsilon_i - \sum_i^{\text{vac}}\varepsilon_i^\circ)$$

In this equation, the ε_i°'s are those of naphthalene. They are -2.3028, -1.6180, -1.3028, -1.0000 and -0.6180 in β respectively. Therefore, $\sum_i^{\text{vac}}\varepsilon_i^\circ$ amounts to $-6.8416\ \beta$. In the case of the perimeter model, $\sum_i^{\text{vac}}\varepsilon_i^\circ = -6.4720\ \beta$. The calculated $\Delta\varepsilon$'s are given in Table III. The table also contains those values of α- and β-naphthol calculated by using the same parameters as those of the diols.

Table III. Extradelocalization energies of naphthalene hydroxy derivatives

	$\Delta\varepsilon$ in β	
	With 9—10 bond	Without 9—10 bond
α-Naphthol	0.1862	0.1888
β-Naphthol	0.1792	0.1888
1,4-Naphthalenediol	0.3618	0.3720
1,5-Naphthalenediol	0.3700	0.3722
1,8-Naphthalenediol	0.3730	0.3790
2,3-Naphthalenediol	0.3544	0.3706
2,6-Naphthalenediol	0.3560	0.3722
2,7-Naphthalenediol	0.3586	0.3780

From this table we obtain the following results;

1) The α-derivatives are more stable than the β-derivatives.

2) The effect of the insertion of the 9—10 bond in the perimeter model is to decrease the extradelocalization energies. This effect is remarkable in the case of β-, β, β'- and A, A-derivatives, but rather small in that of α-derivatives.

3) The $\Delta\varepsilon$'s of diols are nearly equal to double that of the corresponding naphthol; for example, those of α, α'-diols are nearly equal to twice that of α-naphthol.

Summary

The molecular diagrams and extradelocalization energies of the 2, 3-, 2, 6- and 2, 7-naphthalenediols were calculated by using the LCAO MO method. To elucidate the effect of the 9—10 bond on the molecular properties of naphthalene derivatives, we carried out calculations of the electronic structures of naphthalene hydroxy derivatives based on the perimeter model. These calculations proved that:

1) The 3-position in the naphthalene derivatives in less reative than the other positions.

2) The α-derivatives are more stable than the β-derivatives.

3) The insertion of the 9—10 bond in the perimeter model causes a decrease in the degree of conjugation interactions among the ring and the substituents.

4) In the cases of A, A-derivatives, the substituents have no significant influence on the unsubstituted ring, but produce rather a large effect on the substituted rings.

5) α-Substitutions cause an increase in the mobilities of π-electrons in the direction of the short molecular axis, but the β-substitutions lead to an increase in the direction of the long molecular axis.

The authors wish to express their gratitude to Dr. Noboru Mataga for his helpful discussions.

Anionic Polymerization of Vinylidene Chloride. III. Copolymerization Initiated by n-Butyllithium

By Akio KONISHI

(Received May 10, 1961)

Although plans for the cationic coplymerizations of vinylidene chloride with styrene and with vinyl *n*-butyl ether have been announced by Florin[1] and by Walling[2], reports of their success have yet to be published.

The mechanism of the polymerization of vinyl monomers initiated by *n*-butyllithium has been generally recognized as anionic polymerization. However, there are some questions concerning the mechanism of the polymerization of a monomer such a vinylidene chloride, with a relatively low susceptibility to anionic catalysis.

In order to elucidate the mechanism of the vinylidene chloride polymerization initiated by *n*-butyllithium, a copolymerization study was undertaken because the proof of ionic mechanism can best be accomplished by the relative reactivity ratios in the copolymerization data[3]. Methyl acrylate, styrene and vinyl chloride were chosen as the comonomer for this study because vinylidene chloride is surrounded by the above three monomers in q-ε map[4].

Experimental

The details of the preparation of *n*-butyllithium and of the purification of *n*-hexane and vinylidene chloride were given in a previous report[5]. Methyl acrylate and styrene were dried over calcium hydride and distilled under argon before use. Vinyl chloride produced by the Kureha Kasei Co. was repurified by drying over phosphorus pentoxide, followed by distillation under argon into a polymerization vessel in a closed system.

The polymerization apparatus and procedure were the same as before[5]. The catalyst was added to monomers in the polymerization vessel cooled at -70°C with dry ice-methanol, sealed, and then gradually warmed to the desired polymerization temperature. The polymerization was stopped by adding methanol and the mixture was poured into excess methanol or petroleum ether, and then the polymer was successively filtered, washed and dried to a constant weight in vacuo at 40°C.

All copolymerizations were stopped within a ten per cent conversion. The copolymers formed were repurified as follows: poly(vinylidene chloride *co* methyl acrylate)* was dissolved in acetone, filtered, precipitated by petrolum ether, washed, and dried in vacuo. Poly(vinylidene chloride *co* styrene) is only with difficulty soluble in common solvents and was therefore thoroughly allowed to swell in cyclohexanone and was then reprecipitated by methanol. Poly(vinylidene chloride *co* vinyl chloride) was successively redissolved in tetrahydrofuran, filtered and precipitated by methanol. The compositions of the copolymers were determined by chlorine analysis and some infrared spectroscopic data were added to qualify the copolymer, as is discussed below.

Results

Tables I—III and Figs. 1—6 show details of experiments which were employed to determine the monomer reactivity ratios. The monomer reactivity ratios for the three monomer pairs have been calculated using the intersection

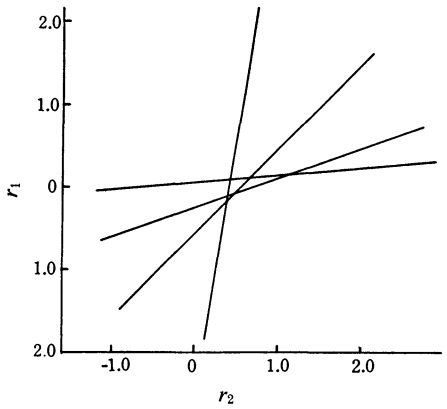

Fig. 6. Reactivity ratio diagram. Vinylidene chloride (M_1)-vinyl chloride (M_2)

The difficulties in determining accurate copolymer compositions arise from the side reaction which is thought to take place during the polymerization reaction and which causes the elimination of chlorine from the copolymer, as has been reported before[5].

In order to confirm the copolymerization and to estimate the copolymer compositions of the copolymers, the infrared spectra given in Figs. 7 and 8 were studied.

The spectra of poly(vinylidene chloride *co* styrene) shown in Fig. 7-a (initiated by *n*-BuLi) and Fig. 7-b (initiated by dibenzoyl peroxide) have common bands at 906 and 842 cm^{-1} whose absorptions increase with an

increase in the styrene content; this is thought to be a proof of the copolymerization.

In the spectra of poly(vinylidene chloride *co* vinyl chloride), the shift of the strong CH_2-bending frequency from 1407 to 1428 cm^{-1} and optical density ratio of 1206 to 1355 cm^{-1} have been used for the characterization of the copolymer by Narita[14]. Although the determination of the vinyl chloride fraction in the copolymer is rather difficult in the case of a high vinyl chloride content, the spectra agreed qualitatively with the results obtained from chlorine analysis.

Discussion

The monomer reactivity ratios of all the three monomer pairs initiated by *n*-butyllithium are distinctly different from those initiated by a radical initiator and present a proof of the anionic mechanism of the polymerization of vinylidene chloride initiated by *n*-butyllithium.

The poly(vinylidene chloride *co* styrene) here obtained are only with difficulty soluble, are only partly soluble or are nearly swollen in the common organic solvents, i. e., benzene, acetone, ethyl methyl ketone, tetrahydrofuran and cyclohexanone. On the contrary, the copolymers obtained by radical polymerization are easily soluble in benzene; this suggests that some structural differences may exist between these copolymers.

In Fig. 9 the known copolymer composition curves[15,16] of anionic copolymerizations are shown together with their known radical[7] and cationic copolymerization[15] curves. Comparing them with the curves shown in Figs. 1, 3 and 5, the mutual relationships between the curves obtained in the anionic and in the radical copolymerization of vinylidene chloride-methyl acrylate and vinylidene chloride-styrene pairs can be seen to be similar to the relationships in (2) methyl methacrylate-acrylonitrile, (3) methacrylonitrile-methyl methacrylate and (5) methyl methacrylate-styrene pairs. The curves of vinylidene chloride-vinyl chloride are

similar to those of (4) methyl methacrylate-vinyl acetate and (6) styrene-vinyl acetate pairs.

The experimental results show that the susceptibility of methyl acrylate to anion is larger than that of vinylidene chloride. The copolymer composition curve of styrene-vinyl acetate resembles that of vinylidene chloride-vinyl chloride.

Summary

The copolymerization reaction of vinylidene chloride with methyl acrylate, styrene and vinyl chloride initiated by *n*-butyllithium has been studied. The monomer reactivity ratios have been found to be distinctly different from those of the radical copolymerizations. The results clearly showed that the nature of the polymerization of vinylidene chloride initiated by *n*-butyllithium is anionic, in accordance with the prediction from the q-ε or the Q-e map.

The author wishes to express his sincere thanks to Professor Hiroshi Azumi, Professor Tetuo Nozoe and Professor Shinichiro Fujise of Tohoku University for their kind guidance and encouragement throughout this work. The author is also indebted to Dr. Kanji Mayumi and Dr. Keiichi Numbu of this laboratory for their helpful advice and to the assistance given by Mr. Akira Izuka in conducting these experiments.

Rates of Solvolysis of Substituted 4-Biphenylyldimethylcarbinyl Chlorides. A Test of the Free-energy Relationship

By Takashi INUKAI

(Received May 17, 1961)

The general applicability of Hammett Eq. 1 to the correlation of a large number, and a variety of, side-chain reactions and equilibria of aromatic derivatives is well established[1,2]. On the other hand, it has become progressively evident that electrophilic aromatic substitution reactions and some side-chain reactions, involving presumably stronger interactions between the substituent and the electron-deficient reaction center in the transition state do deviate from this equation[3,4].

$$\log k/k_0 = \rho\sigma \qquad (1)$$

Several sets of new substituent constants have thus been proposed by the workers[5-12] to reconcile their own results with the linear free-energy relationship of the type of Eq. 2.

$$\log k/k_0 = \rho\sigma^+ \qquad (2)$$

The fact that the new sets of substituent constants are more or less similar to each other might suggest that those reactions of the type which requires enhanced substituent constants constitute a distinct group on the one hand, as contrasted with the prevailing group of normal reactions on the other hand.

This view was encouraged by the considerable success in correlating a number of appropriate reaction rates by means of the modified substituent constants, σ^+, proposed by Brown and Okamoto[10-12]. There are a few cases of difficulties[13,14], however, which may likely escape the serious attention of proponents of the new treatments. Although the general success of σ^+ is apparent, it is still reasonable to state that the electronic contribution of a substituent could not be represented by a single constant as in Eq. 2, since the resonance contribution by a substituent can vary markedly from reaction to reaction, the very existence of different sets of substituent "constants" showing the non-reality of the "constants"[4,14,15].

In view of the utility of such equations over a wide variety of reactions it is not surprising that Eqs. 1 and 2 have been accepted with tolerance. This situation makes, however, proper evaluation of the linear free-energy relationship considerably complicated: in one case the deviation of a particular series of data may be attributed to a special interaction between the substituent and the solvent molecules or to anything which is convenient for rationalization of the result, in another case the deviation as detected may be thought to be due to experimental errors.

Therefore, it is desired to reexamine the linear free-energy relationship with due care, rather than to explore its utility. The study of the Hammett type relation should be done with the following things in mind; 1) Small deviations from the equation may be neglected in the first approximation. 2) Those deviations or agreements which are observed in the course of a study of a reaction of unknown or ambiguous mechanism do not argue against or for the validity of the relation. 3) The reaction series to be compared in relation to the equation should preferably be closely similar to each other so as to minimize unnecessary complications which may arise otherwise, although this would limit the virtue of the equation as far as its utilities are concerned.

Furthermore, it is anticipated that there will remain some uncertainty or arbitrariness in interpreting the results even if the study

was made under ideal conditions. So far as we remain in the study of simple benzene derivatives, strictly following the original definition of the Hammett equation, such uncertainty always accompanies our interpretation since we have, at present, no basis of estimating how the resonance contribution of a substituent varies depending on the kind of reaction. Therefore it is desirable to find out an obvious case of deviation from the linearity by purposely providing selected conditions for a possible deviation.

In this paper we report the study on the rates of solvolysis of substituted 4-biphenylyldimethylcarbinyl chlorides in 90% acetone and compare them with that of substituted phenyldimethylcarbinyl chlorides[16] under the identical conditions. It is reasonably hoped that the effects of various possible factors on the rate such as solvent interactions with the substituents and/or the reaction center are mostly compensated by comparison of the two series. The only difference is structural, i. e. the effect of the substituent in biphenyl derivatives is transmitted to the reaction center through the biphenyl ring system and that in benzene derivatives through the benzene ring. The two modes of transmission of the substituent effect, inductive and resonance, will play their roles in the biphenyl derivatives in a ratio different from that in the benzenes. Consequently, if these two series deviate from the linear relationship of free-energy of activation we will get an experimental foundation to believe that the deviations can be real and are understandable on the basis of the variance of the relative importance of the resonance and inductive contributions of the substituents.

Results

The substituted 4-biphenylyldimethylcarbinyl chlorides required were synthesized by treating the corresponding tertiary carbinols with dry hydrogen chloride in methylene chloride at 0°C and removing the solvent. Since the tertiary chlorides are unstable and difficult to purify, we were content with preparing pure samples of the tertiary carbinols and using the crude tertiary chloride directly, without further treatment[17].

The tertiary chlorides were dissolved in 90% aqueous acetone and the first order rate constants of solvolysis determined at 0 and 25°C. Since the rates are to be compared with those of the substituted phenyldimethylcarbinyl chlorides by Brown and collaborators[16], the water content of the solvent was adjusted to reproduce the original rate constant for phenyldimethylcarbinyl chloride. The rate constant for 4-biphenylyldimethylcarbinyl chloride was also reproduced quite well in this batch of solvent as it should be. Consequently there is no doubt about the identity of both the expermental conditions. Because of the fast rate exhibited by the 4'-methoxy compound, it was found difficult to obtain its precise rate constant at 25°C. Therefore, the more reliable value was calculated by using the thermodynamical quantities for activation obtained by

Table I. Rate constants for the solvolysis of the aryldimethylcarbinyl chlorides in 90% acetone

Discussion

The electrophilic subsituent constants, σ^+, for the substituted phenyl groups studied in this investigation, after the definition by Brown and Okamoto[10,12], are presented in Table III. They were calculated by the formula, $\log k/k_H = \rho\sigma^+$, where k_H is the rate constant for the solvolysis of phenyldimethylcarbinyl chloride in 90% acetone at 25°C and ρ is the reaction constant (−4.54)[12]. Hammett's σ values for these groups are also included in the table for ready comparison.

That the σ^+'s are consistently lower (more negative) than σ's is clearly due to the larger resonance contribution of the aryl groups in the solvolysis than the resonance contribution in the dissociation of benzoic acids (such tendency has been remarked in ortho-para directing groups already studied)[12].

TABLE III. SUBSTITUENT CONSTANTS FOR ARYL GROUPS

Group (para)	$\log k/k_H$	σ^+	σ[a]
C_6H_5-	0.819	−0.180	−0.0455
4-MeO-C_6H_4-	1.595	−0.351	−0.114

m-Cl	0.311	−0.508	0.0156	−1.807

In Table IV the effect of substituents on the rate of solvolysis of 4-biphenylyldimethylcarbinyl chlorides are compared with that found for the solvolysis of phenyldimethylcarbinyl chlorides[16]. Figure 1 shows the plot of $\log k/k_H$ for the solvolysis of 4-biphenylyldimethylcarbinyl chlorides versus σ^+, which is numerically equal to $-\log k/k_H \times 1/4.54$, as determined by using the data for the solvolysis of phenyldimethylcarbinyl chlorides.

It is clear in Fig. 1 that there is no simple relation between these two series of reactions. Since the size of the circles shown represents an experimental uncertainty of 3%, the "deviations" from a straight line, if any, are too large to be treated as experimental errors. Therefore, rather than draw a median line through these points, a line was drawn through H and *m*-Cl points in Fig. 1. Since the resonance contribution of the meta substituent is known to be negligible in the benzene series, it should be likewise negligible in biphenyl. This justifies the use of *m*-Cl point to fix an approximate reference line on which

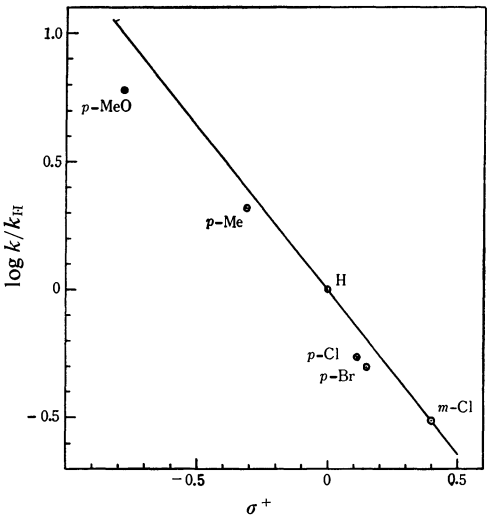

Fig. 1. Plot of $\log k/k_H$ for solvolysis of substituted 4-biphenylyldimethylcarbinyl chlorides versus σ^+.

the para points would lie if the linear free-energy relationship held between these closely related reaction series. Thus the downward displacements from this line exhibited by the four para-substituted compounds correpond to the depression of the resonance contribution by these groups in biphenyl series, compared with the hypothetical resonance contributions expected from the linear free-energy relationship. The depression thus demonstrated agrees with the widely accepted view of the restricted conjugation through the pivot bond of biphenyl.

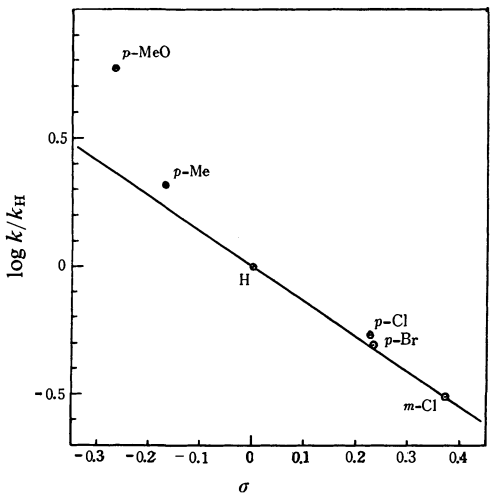

Fig. 2. Plot of $\log k/k_H$ for solvolysis of substituted 4-biphenylyldimethylcarbinyl chlorides versus Hammett's σ.

Figure 2 shows the plot of $\log k/k_H$ for biphenyl series versus the Hammett σ. The plot does not define any straight line either, but a straight line has been drawn through H and *m*-Cl points for the same purpose as above. This line approximately shows the hypothetical rates of reaction for biphenyl derivatives if the effect of the substituent on the rate were such that the linear free-energy relationship holds between the rates of the solvolysis of substituted biphenylyldimethylcarbinyl chlorides on the one hand and the equilibria of substituted benzoic acids on the other hand. The upward displacements of the points for the para substituted compounds from the line shown undoubtedly indicate the incorporation of additional resonance contribution in the solvolysis compared with that in the acid dissociation.

It is clear, from these discussions, that the features of the substituent effects in this solvolysis reactions are intermediate between those which characterize the solvolysis of phenyldimethylcarbinyl chlorides (σ^+-type) and dissociation of benzoic acids (σ-tye).

In searching for some criterion for the applicability of σ^+-values, the following view seems to be fundamentally correct. A resonance interaction or charge delocalization takes place powerfully between the substituent and the electron-deficient reaction center, in the transition state, a view which has been discussed by a number of workers[5-15] in this field and needs no elaboration.

On the basis of this view, the fact that the substituent effects in this solvolysis reactions are intermediate between σ^+-type and σ-type shows that the resonance interaction or charge delocalization which occurs in solvolysis of biphenylyldimethylcarbinyl chlorides is shared by the substituent in lesser degree than in the solvolysis of phenyldimethylcarbinyl chlorides. All chemical data can be explained satisfactorily on the basis of a restricted resonance of the two benzene rings in biphenyl. Thus the orientation in the electrophilic substitution of substiuted biphenyls conforms to the idea that the two rings act independently[19]. For example, Mizuno and Simamura[20] determined the partial rate factors for nitraticn of *o*-, *m*- and *p*-nitrobiphenyl with the results that the resonance formula like I, as would be reasonably suggested by simple application of

I

the electronic theory of organic reaction, is not a predominant factor in determining the reactivity of these compounds. A relative ineffectiveness of the substituent effect in the biphenyl system is also found in a nucleophilic displacement of 2, 4′-dinitro-4-bromobiphenyl[21]. From these chemical evidences it would be concluded that the resonance interactions extending over the biphenyl ring system is in general not influential in determining its chemical reactivities.

This situation only must be responsible for the break-down of the linear free-energy relationship, bipenyl derivatives versus phenyl derivatives, reported in this paper.

Consequently, the deviations from a linear free-energy relationship that have been observed in studies of benzene derivatives[13,14] can be ascribed, in some case and partly at least, to the variance of weight of the resonance contribution from reaction to reaction.

Modified Treatments.—Although the above arguments indicate that it is fundamentally

a) Ref. 12, b) Ref. 24

incorrect to assign a single substituent constant to a substituent, it may be still possible to correlate rates by means of a combination of two types of substituent constant, one for the inductive mode and the other for the resonance mode of electronic displacement. Such attempts have been made by Taft[22] (for shielding constants δ^F for fluorine NMR spectra of substituted fluorobenzenes), Corio and Dailey[23] (for proton NMR spectra of substituted benzenes) using σ_I and σ_R[24] and by Yukawa and Tsuno[26,27] for several reaction rate data proposing a formula, $\log k/k_H = \rho \cdot (\sigma + r\Delta\sigma_R^+)$. The substituent constants used for the following computations are tabulated in Table V.

1) Taft's Treatment.—This method in effect treats the substituent effect as a composite of the inductive polar effect (σ_I) and the resonance polar effect (σ_R). Thus the actual formula is,

$$\log k/k_H = \alpha\sigma_I + \beta\sigma_R \qquad (3)$$

Least squares treatment of the present data by means of Eq. 3 leads to expression 4.

$$\log k/k_H = -2.282\sigma_I - 1.650\sigma_R - 0.014 \qquad (4)$$

The plot is shown in Fig. 3. Although this exhibits a satisfactory linearity, the apparent agreement does not prove that this procedure is a correct approach to reality since the introduction of one additional parameter affords a better opportunity of getting a better fit for no other reason but mathematical. The author believes that the success of this procedure suggests rather that the evaluation of σ_I and σ_R by Taft was fairly good.

2) Yukawa's Treatment. — Yukawa and Tsuno[25,26] recently proposed a modified Hammett type Eq. 5 for electrophilic reactions,

27) W. E. Bachmann and R. A. Hoffman, "Organic Reaction", Vol. II, John Wiley and Sons, Inc., New York (1944), p. 224.

$$\log k/k_H = \rho(\sigma + r\Delta\sigma_R^+) \quad (5)$$

where r is a reaction constant describing the degree of resonance stabilization in the transition state, and $\Delta\sigma_R^+$ is a substituent constant suggesting the resonating capacity of the substituent and is defined as $\Delta\sigma_R^+ \equiv \sigma^+ - \sigma$. They demonstrated that Eq. 5 correlates the rate data more satisfactorily than Eq. 2 does, presenting the results of application of Eq. 5 to 35 different reactions. This method, applied to our present rate data, leads to Eq. 6.

$$\log k/k_H = -1.363(\sigma + 0.606\Delta\sigma_R^+) - 0.019 \quad (6)$$

The plot of $\log k/k_H$ versus $\sigma + 0.606\Delta_R^+$, Fig. 4, appears satisfactory.

3) Limitations of Eq. 5.—In view of the success of Eq. 5 in correlating a number of reaction series, it is interesting to see if it can successfully correlate the rates of solvolysis of the benzyl tosylates in 55.6 vol. % aqueous acetone at 25°C[14], which has given the greatest trouble to Brown-Okamoto's treatment[12] (Eq.2). The result of the least squares treatment of the rate data by means of Eq. 5 is expressed by Eq. 7 and has been shown in Fig. 5,

$$\log k/k_H = -2.949\ (\sigma + 2.175\Delta\sigma_R^+) + 0.057 \quad (7)$$

The correlation thus obtained, Fig. 5, is no better than the σ^+-plot shown in Fig. 6. *m*-MeO and *p*-Cl compounds should react faster than the unsubstituted compound according to the correlation line in Fig. 5 or Eq. 7, which is of course contrary to the experimental observations. Such contradiction is also found in correlating the rate data of brominolysis of benzeneboronic acids[13] (see Fig. 9. of Ref. 27).

It is seen that although all the points have been brought closer to a straight line by introduction of a parameter, r, the *m*-MeO and *p*-Cl points thereby moved too far to the left-hand side (in Fig. 5). Consequently, it is difficult to take the r in Eq. 5 for a constant of reaction.

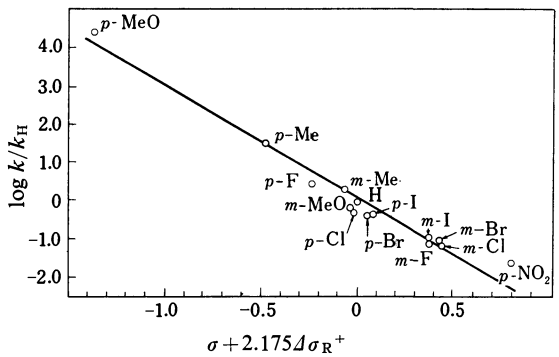

Fig. 5. Plot of $\log k/k_H$ for solvolysis of the benzyl tosylates (Hammond's data) versus $\sigma + 2.175\Delta\sigma_R^+$.

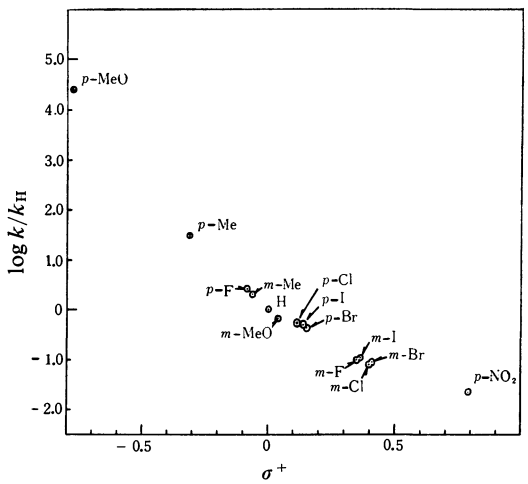

Fig. 6. Plot of $\log k/k_H$ for solvolysis of the benzyl tosylates (Hammond's data) versus σ^+.

Experimental

The following monosubstituted biphenyls were prepared by the Gomberg-Bachmann reaction[27]: *p*-Me, m. p. 48.5~49.5°C (lit.[28] 47.7°C); *p*-Cl, m. p. 78.5~79.5°C (lit.[29] 77.5°C); *p*-Br, m. p. 89.5~90°C (lit.[30] 89.5~90°C); *m*-Cl, b. p. 141~143°/10 mmHg (lit.[31] 150~160°C/6 mmHg). *p*-Methoxybiphenyl was prepared by methylation of commercial *p*-hydroxybiphenyl; m. p. 90~91°C (lit.[32] 90°C).

All the 4-acetylbiphenyls used were prepared by the Friedel-Crafts acetylation of the corresponding biphenyls: 4'-H, m. p. 121~122°C (lit.[33] 121°C); 4'-MeO, m. p. 153~154°C (lit. 153~154°C[34,35], 154.6~155.5°C[36]); 4'-Me, m. p. 122~123°C (lit.[37] 122°C); 4'-Cl, m. p. 102~103°C (lit.[38] 102~103°C); 4'-Br, m. p. 129°C (lit.[39] 131°C).

3'-Chloro-4-acetylbiphenyl.—To a mixture of *m*-chlorobiphenyl (22.5 g., 0.119 mol.), acetyl chloride (12 g., 0.153 mol.) and 100 ml. of dry carbon disulfide was added powdered anhydrous aluminum chloride (21 g., 0.158 mol.) in five portions over a

period of 20 min. without external heating. The mixture was stirred for 10 min. longer and was refluxed for 1/2 hr. Cooled in an iced water bath the complex was decomposed with dilute hydrochloric acid. The carbon disulfide was removed by distillation and the residue recrystallized twice from ethanol; yield 10 g. (36%). Colorless needles, m. p. 57.5~58.5°C. (Found: C, 73.09; H, 4.73. Calcd. for $C_{14}H_{11}OCl$: C, 72.89, H, 4.81%). This material was a sole isolable product from the reaction above. The position of the acetylation is most probably 4' by analogy with the similar acetylation of 3-bromobiphenyl[36].

All the 4-biphenylyldimethylcarbinols used were prepared by the action of methylmagnesium iodide on the corresponding ketones: 4'-H, m. p. 91.5~92.5°C (lit. 92~93°C[40], 91.5~92.5°C[16b]); 4'-MeO, m. p. 137~137.5°C, recrystallized from benzene (Found: C, 79.39; H, 7.31. Calcd. for $C_{16}H_{18}O_2$: C, 79.31; H, 7.49%); 4'-Me, m. p. 116~116.5°C, recrystallized from benzene (Found: C, 84.89; H, 8.09. Calcd. for $C_{16}H_{18}O$: C, 84.91; H, 8.02%); 4'-Cl, m. p. 143.2~144.2°C, recrystallized from benzene (Found: C, 73.16; H, 6.29; Cl, 14.36. Calcd. for $C_{15}H_{15}OCl$: C, 73.02; H, 6.13, Cl, 14.37%); 4'-Br, m. p. 143~145°C, recrystallized from benzene (Found: C, 61.61; H, 5.21; Br, 27.47. Calcd. for $C_{15}H_{15}OBr$: C, 61.87; H, 5.19; Br, 27.45%); 3'-Cl, m. p. 74~75°C, recrystallized from petroleum ether (Found: C, 73.20; H, 6.14; Cl, 14.36. Calcd. for $C_{15}H_{15}OCl$; C, 73.02; H, 6.13; Cl, 14.37%).

Kinetic Measurement.—The solvent, 100 ml., was placed in a long-necked flask and brought to reaction temperature. Approximately 1 g. of the tertiary chloride was dissolved in the solvent and 5 ml. aliquots were removed at appropriate intervals of time. The aliquots were run into 100 ml. of ice-cold dry acetone to stop the reaction and hydrogen chloride was titrated with 0.03 N sodium ethoxide/ethanol using a solution of 3 parts of bromocresol green and 1 part of methyl red in ethanol as an indicator. The reaction mixture was allowed to stand overnight to obtain the aliquots for the "infinity" titer. The first-order rate constants, k_1, were calculated by the formula, $k_1 = [\ln(a_\infty - a_0) - \ln(a_\infty - a_t)]/t$, where a_0, a_t and a_∞ stand for the titer at time 0, t and "infinity", respectively.

Some of the rate data for the solvolysis of 4-biphenylyldimethylcarbinyl chlorides and phenyldimethylcarbinyl chloride in 90% acetone are presented in Table VI.

40) D. T. Mowry, J. Dazzi, M. Renoll and R. W. Shortridge, *J. Am. Chem. Soc.*, **70**, 1916 (1948).

Summary

The rates of solvolysis of 4'-MeO-, 4'-Me-, 4'-H-, 4'-Cl-, 4'-Br- and 3'-Cl-4-biphenylyldimethylcarbinyl chlorides in 90% aqueous acetone have been determined and compared with those of the correspondingly substituted phenyldimethylcarbinyl chlorides. The effect of substituents is very much depressed in biphenyl derivatives as compared with that in phenyl derivatives, and a remarkable deviation from the linear free-enegy relationship was observed between these systems. This is attributed to the difference in the relative importance of the resonance effect and inductive effect of substituents between these two different systems.

Studies on Fluorene Derivatives. XIII[1]. *The Formation of Tribiphenylenepropane by Self-condensation of Dibiphenyleneethylene*

By Kazuo SUZUKI and Shōji KAJIGAESHI

(Received May 29, 1961)

Certain halides possessing a relatively reactive α-hydrogen such as 9-halogenofluorenes or its derivatives are converted to dimeric olefines by the action of methanolic potassium hydroxide in acetone at room temperature. Thus, 9-bromo-(or chloro)-fluorene[2] gave dibiphenyleneethylene (I). The corresponding substituted I are obtained in good yields from 2-nitro-9-bromofluorene[3], 1-chloro-9-bromofluorene[4], 2,9-dibromofluorene[5], 3,9-dibromofluorene[6a] and 4,9-dibromofluorene[6b].

9-Chlorofluorene[7] and liquid ammonia also interact at room temperature to form I and fluorene.

In regard to the mechanisms[8] involved in the first reaction it has been postulated that a self-alkylation of the halides forms the corresponding dimeric halides which in turn give the dimeric olefines by a β-elimination.

In the present investigation different products were observed when 9-bromofluorene was refluxed for longer periods in methanolic potassium hydroxide-acetone. These were two isomers of tribiphenylenepropane (II)[9,10], m. p. 293°C and m. p. 257°C, dibiphenyleneethane (III)[11], fluorenone, a trace of fluorene, and a small amount of unidentified material, m. p. 90~92°C which analyzed correctly for 9-acetonylfluorene (Chart I).

Under the same conditions 3,9-dibromofluorene and 4,9-dibromofluorene furnished the corresponding 3,3′,3″-tribromotribiphenylenepropane(IV) and 4,4′,4″-tribromotribiphenylenepropane(V), respectively. Both propanes were identical with those obtained previously by the Michael condensation of 3,3′-dibromodibiphenyleneethylene and 3-bromofluorene[5], or 4,4′-dibromodibiphenyleneethylene and 4-bromofluorene[6b], respectively.

However, with 1,9-dibromofluorene and with 2,9-dibromofluorene the methanolic alkali in acetone yielded 1,1′-dibibromodiphenyleneethan (XI) and 2,2′-dibromodibiphenyleneethane (VI)[12], respectively, as reduction products, rather than the substituted tribromotribiphenylenepropanes. With the former compound this could be the result of steric hindrance due to the bromine at the 1-position. The Micheal condensation did not occur either between 1,1′-dibromodibiphenyleneethylene and

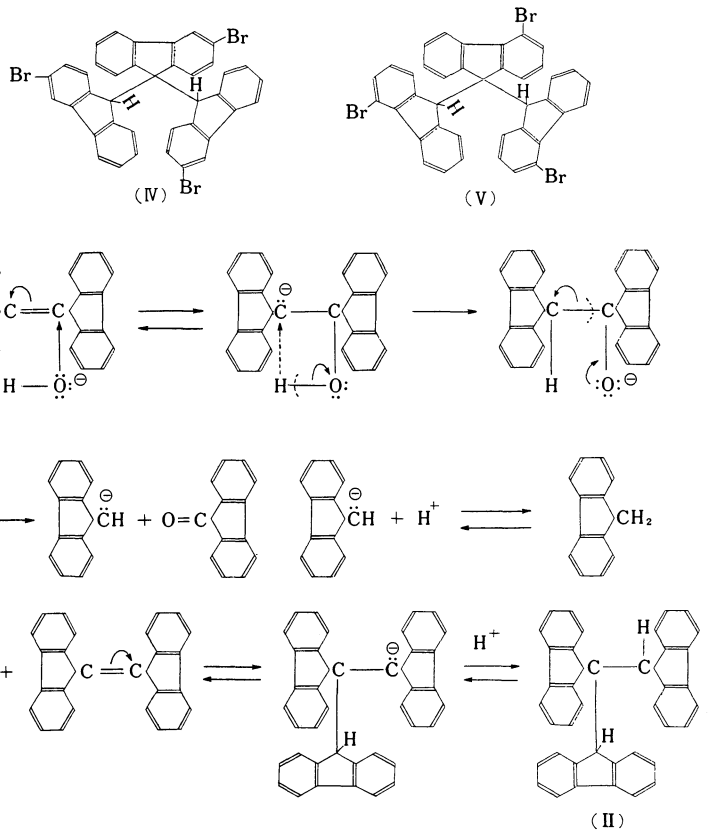

Chart 2.

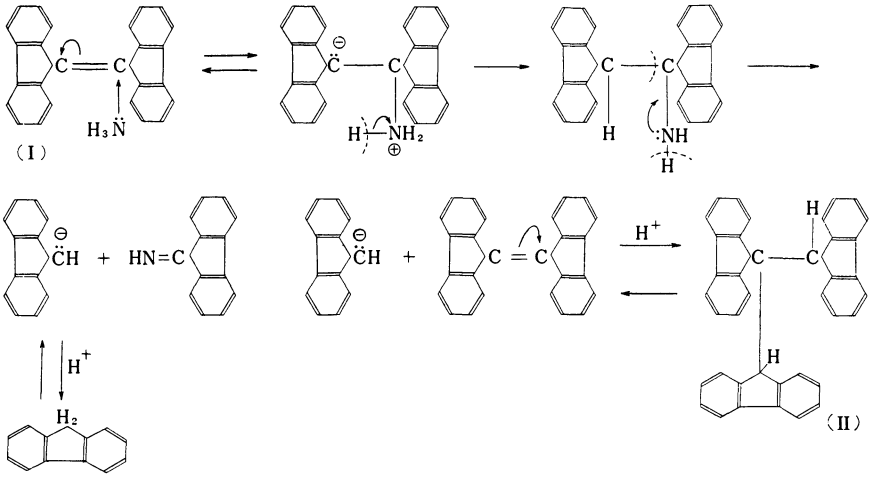

Chart 3.

1-bromofluorene. 2, 9-Dibromofluorene do not give rise to 2, 2′, 2″-tribromotribiphenylenepropane by methanolic alkali in acetone. This reason is not clear; it might be, however, that the formation of VI is the faster rather than the other leading to the 2-substituted propane from 2-substituted ethylene in the two competitive reaction sequences.

In any case, the conversion of 9-bromofluorene to II by the action of methanolic alkali and acetone probably proceeds via the intermediate formation of I. This concept is supported by the fact that practically the same products were obtained (Tables I and II) when the analogous reactions were performed using substituted I as the starting material. Here also,

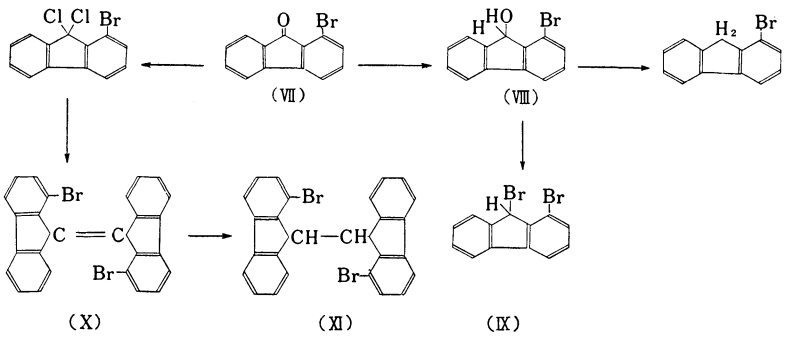

Chart 4.

both isomers of II, III, fluorene and fluorenone were the products.

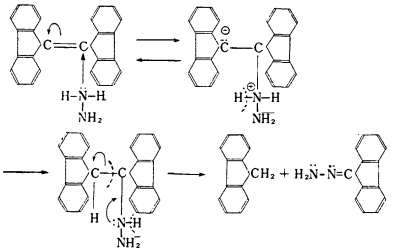
Central π-electron pairs in I is less firmly held between the two carbon nuclei, and the approach of a negatively charged hydroxyl ion induces a charge separation. This high polarizability is greatly responsible for the reactivity of I for addition reaction.

The reactions accounting for the observed products is illustrated in Chart 2. It may be noted that they are analogous to the production of II from I and liquid ammonia (Chart 3).

The negatively charged fluorenyl ion and fluorenone were formed by addition of hydroxyl ion to I in methanolic alkali in acetone as a preliminary step. I is also reduced to III in the same solution as two competitive reactions. The required proton is obtained by interaction of acetone with alkali; thus these reactions do not proceed in the absence of acetone and alkali.

Moreover, in this case, the fluorenyl ion can not be formed by dissociation of III which is reduced from I in the same alkaline media as suggested by the observations of Weisburger and Grantham[13]. They could not isolate fluorene in any amount when subjecting III to a Wolff-Kischner reduction. On the other hand, they obtained 70% yields of fluorene (and 19% of III) which I as starting material[14].

In another analogous case, Pinck et al.[9a] isolated the γ-form of II, 9-fluorenylidene imine, and fluorene upon treating I with liquid ammonia for 21 days at 60°C. This is a direct addition of ammonia to the unsaturated grouping of I and is also an analogous behavior to that described above. And the mechanism of formation may be proposed as illustrated in Chart 3.



New intermediates required for these studies were prepared by conventional reactions. 1-Bromofluorenone (VII)[15] was obtained from 1-aminofluorenone by a Sandmeyer reaction, a method different from that used by Montagne[16]. The ketone was reduced to 1-bromo-9-fluorenol (VIII) by zinc dust and ammonium hydroxide. VIII was converted to 1, 9-dibromofluorene (IX) by the action of hydrogen bromide in acetic acid, or it was reduced to 1-bromofluorene by hydrogen iodide and red phosphorus. The reaction of phosphorus pentachloride on VII afforded 1-bromofluorene-9, 9-dichloride, which was dehalogenated by powdered copper to 1,1′-dibromodibiphenyleneethylene (X). This compound in turn was reduced to the ethane, XI as illustrated in Chart 4.

Experimental

Formation of Tribiphenylenepropanes.—*Reaction of 9-Bromofluorene and its Bromo-derivatives with Methanolic Potassium Hydroxide in Acetone.*—To a stirred solution of 2.9 g. of potassium hydroxide in 12 cc. of methanol 5 g. of 9-bromofluorene in 23 cc. of acetone was added in small portions at room temperature, and stirring was continued for 20 min. The red I precipitated immediately with heat evolution. The mixture was refluxed gently for 15 hr. during which the color changed from dark red to dark green, and small colorless crystals were deposited after 1/2 hr. The solids were filtered off, washed with water, and extracted with a large volume of ethanol. Colorless needles of III (0.13 g., m.p. and mixed m.p. 243°C) were isolated from the solution.

13) J. H. Weisburger et al., *J. Org. Chem.*, **21**, 1160 (1956).

14) The formation mechanisms of fluorene and hydrazone at the first stage of reaction between I and hydrazine hydrate may be presented as follows.

TABLE II. CONDITIONS AND PRODUCTS WHEN THE SAME REACTIONS WERE PERFORMED ON SUBSTITUTED DIBIPHENYLENEETHYLENES

Dibromodibi-phenylene-ethylene, g.	Acetone cc.	KOH g.	CH_3OH cc.	Time hr.	Product	Yield, g. (m. p., °C)
1,1'-, 0.24	4	0.28	1	7	XI	0.04 (242)
2,2'-, 3.4	400	3.9	30	2	VI	0.3 (283)
3,3'-, 0.73	10	0.84	3	7	IV	0.1 (275)
4,4'-, 0.6	10	0.7	3	1	V	0.05 (256)

The ethanol-insoluble residue was fractionally crystallized from benzene to give two isomers of II, colorless tetragonal crystals, m. p. 293°C (decomp.), 0.2 g., and m. p. 257°C (decomp.), 0.25 g.

M. p. 293°C, Found: C, 94.69; H, 5.31; mol. wt., 490; m. p. 257°C, Found: C, 94.70; H, 5.30; mol. wt., 475. Calcd. for $C_{39}H_{26}$: C, 94.69; H, 5.31%; mol. wt., 494.

The mother liquor of the acetone-methanol reaction mixture, above, was steam-distilled. I (0.5 g., m. p. 187°C) was recovered from the brown residual product by crystallization from ethanol. Sublimation of this residue gave 0.01 g. of fluorene and 0.11 g. of fluorenone, m. p. 81°C. Colorless needless, m. p. 90~91°C, 0.1 g., which could be 9-acetonylfluorene were isolated from the mother liquor after removal of I. (Found: C, 86.46; H, 6.14%).

Reaction of I and its Bromoderivatives with Methanolic Potassium Hydroxide in Acetone. — To a solution of 1.8 g. of potassium hydroxide in 7.8 cc. of methanol 3 g. of I in 20 cc. of acetone was added and refluxed gently for 10 hr. The brown color noted during the addition turned dark brown after 1 hr. and dark green after 3 hr. The water-washed precipitate (1.6 g.) was extracted with 300 cc. of boiling ethanol. Colorless needles of III, m. p. 244°C, 0.01 g., crystallized from the solution. The insoluble residue was fractionally crystallized from benzene to yield 0.35 g. of colorless tetragonal II, m. p. 257°C. A further 0.25 g. of II, m. p. 257°C, 0.4 g. of the isomeric II, m. p. 293°C and 0.15 g. of fluorenone, m. p. 81°C were isolated from the mother liquor by chromatography in benzene on alumina.

The mother liquor from the reaction mixture was steam-distilled. The distillate contained 0.15 g. of fluorene, m. p. 113°C. In addition, 0.35 g. of I was recovered from the residue by chromatography in benzene on alumina.

Preparation of Intermediate Products.—*1-Bromofluorenone (VII).*—1-Aminofluorenone (8 g.) in 40 cc. of 40% hydrobromic acid was diazotized with 3 g. of sodium nitrite in 3 cc. of water below 10°C. The diazonium solution was added to a boiling mixture of 10 g. of cuprous bromide in 250 cc. of 40% hydrobromic acid and refluxing continued for 30 min. Upon cooling the product was filtered, washed with sodium hydroxide solution, and recrystallized from ethyl acetate 3 g. (28%), m. p. 132~134°C.

1-Bromo-9-fluorenol (VIII).—A mixture of 2 g. of VII, 6 g. of zinc dust, ammonium hydroxide and 60 cc. of ethanol was refluxed for 1 hr. and filtered hot. VIII (1.5 g., 75%, m. p. 140~141°C, colorless needles from benzene) was isolated upon concentration.

Found: C, 59.56; H, 3.41; Br, 30.38. Calcd. for $C_{13}H_9OBr$: C, 59.79; H, 3.47; Br, 30.61%.

1-Bromofluorene.—A mixture of 0.05 g. VIII, 0.4 g. red phosphorus, 2 cc. of hydroiodic acid (d=1.7) and 10 cc. of acetic acid was refluxed for 9 hr., cooled, filtered and poured into water: Colorless plates (0.39 g., 64%, m. p. 59~60°C from ethanol).

Found: C, 63.73; H, 3.83; Br, 32.76. Calcd. for $C_{13}H_9Br$: C, 63.70; H, 3.70; Br, 32.60%.

1,9-Dibromofluorene (IX).—VIII (2 g.) in 40 cc. of acetic acid and 3 cc. of hydrobromic acid (47%) was heated on a water bath for 3 hr. The crystals isolated upon cooling weighed 1.5 g. (60%), m. p. 137~138°C, from ethanol.

Found: C, 48.13; H, 2.72; Br, 49.51. Calcd. for $C_{13}H_8Br_2$: C, 48.18; H, 2.49; Br, 49.33%.

1,1'-Dibromodibiphenyleneethylene (X).—A mixture of 5 g. of VII and 25 g. of phosphorus pentachloride in a 100 cc. flask was placed in an oil bath preheated to 160°C. The temperature was raised to 185~190°C, and maintained for 1/2 hr. The cool mixture was added to water and the gradually solidifying 9,9-dichloro-1-bromofluorene was filtered: 4.5 g., 74%, m. p. 132~135°C, from benzene.

This material in 70 cc. of absolute xylene was refluxed for 15 hr. with 10 g. of powdered copper. After filtration and concentration, 2 g. (58%) of X (m. p. 230~231°C, dark red from acetone) was obtained.

Found: Br, 32.63; mol. wt., 490. Calcd. for $C_{26}H_{14}Br_2$: Br, 32.87%; mol. wt., 486.

1,1'-Dibromodibiphenyleneethane (XI).—A mixture of 0.5 g. of X in 30 cc. of benzene, 2 g. of zinc dust, and 12 cc. of concentrated ammonium hydroxide was refluxed for 3 hr. After filtration and concentration 0.2 g. (40%) of colorless needles, m. p. 240~242°C from benzene, were isolated.

Found: C, 64.06; H, 3.52; Br, 32.88. Calcd. for $C_{26}H_{16}Br_2$: C, 63.96; H, 3.30; Br, 32.74%.

The authors wish to express their gratitude to Drs. John and Elizabeth Weisburger of National Institutes of Health, U. S. A., for their helpful suggestions.

Studies on Metal Complex Species using an Anion Exchange Resin. III. Uranium(VI)-Nitrate Complex and Zinc-Chloride Complex

By Jun YOSHIMURA, Hirohiko WAKI and Shingo TASHIRO

(Received May 31, 1961)

Kraus and Nelson[1] reported a method to identify the principal metal complex species in the aqueous phase by using an anion exchange resin. This may be applicable when the complex is very stable and when its form in the resin phase is the same as that in the aqueous phase. However, it is also often observed that the complexes in these two phases have different forms. Recently, Marcus and Coryell[2-4] have developed a method for the evaluation of stability constants by taking into consideration an invasion of electrolytes into the resin phase and by using the available data on activity coefficients in equations.

On the other hand, in the previous papers[5-7] of this series two new methods for the determination of the complex form have been derived which are particularly suitable for a study of the relatively unstable complexes.

It is known that uranium(VI) is adsorbed on an anion exchange resin from nitric acid or nitrate solutions[1], but no investigation of its anionic nitrate complex has be undertaken. It is also known that zinc is strongly adsorbed on the same resin from hydrochloric acid or chloride solutions, and thorough studies of its chloride complex have been made by Horne et al.[8,9] by means of anion exchange.

In the present study, the "indifferent electrolyte-adding" method described in the first papers[5,6] of this series was applied to the uranium(VI)-sodium nitrate system and also to the zinc-sodium chloride system in order to examine the applicability of the method to complex species in the aqueous phase. Sodium perchlorate was selected as an additional electrolyte in the uranium(VI)-nitrate system and sodium nitrate in the zinc-chloride system,

because they have no direct effect on the complex formation in each system.

Experimental

a) Uranium-Nitrate System.—The sodium nitrate solution was prepared from a guaranteed reagent, and the sodium perchlorate solution from a first class reagent. The uranyl nitrate solution was prepared by dissolving the guaranteed reagent $UO_2(NO_3)_2 \cdot 6H_2O$ in dilute nitric acid. Each mixture of these solutions added to the resin had a volume of 10 ml. and contained 0.0347 mmol. of uranium and a series of sodim nitrate and sodium perchlorate mixed in various ratios, although the total concentration was constant within the individual series.

An anion exchanger "Dowex 1-X8" of a nitrate form (100~200 mesh) was swollen in water and then fitered under suction, after which the adhering water was removed with filter paper. Two grams of this resin was promptly put in a stoppered glass vessel. In order to estimate the exchange capacity of this amount of resin, at the same time another 0.5 g. of the resin was converted to chloride form in a small column. Its exchange capacity was then determined by the desorption of the chloride ions with a sodium nitrate solution and by Mohr's titration of them in the effluent. Resin set in this way tends to have a relatively constant value with respect to the exchange capacity and does not suffer an appreciable change in volume when it comes in contact with a nitrate solution.

The batch experiment was carried out with total concentrations of the solutions at 2, 3.2, 3.5, 4 and 6 M, and each series consisted of 4—6 batches of various nitrate concentrations. The resin and the solution were equilibrated at room temperature by being allowed to stand for an hour, with frequent shaking. It was recognized in the preliminary test that a sufficient equilibrium state was attained in about forty minutes. After the equilibrium mixture was filtered through a glass filter under suction without any further washing of the resin, 5 ml. of the filtrate was taken out, and the uranium concentration in the solution phase was determined colorimetrically at 372 mμ by the hydrogen peroxide method, using a Hirama photoelectric colorimeter. The amount of uranium in the resin was estimated from the difference between the total amount given and the amount in the solution phase at equilibrium. The distribution coefficient was calculated as

$$D=\frac{\text{mmol. of U per mequiv. of the resin}}{\text{mmol. of U per ml. of the soln.}}$$

This representation of the ion concentration in the resin phase is suitable in such a system because the density of resin varies with the nitrate-perchlorate exchange. On the other hand, nitrate concentrations were estimated in the following manner: the resin separated from the solution was wrapped in filter paper and pressed in order to remove the solution attached to the surface. About 1 g. of this resin was transferred to a short column, and then the nitrate ions were desorbed by 25 ml. of 2 M perchloric acid. The effluent was diluted to 50 ml., and its absorbance was measured at 300 mμ, using a Shimadzu spectrophotometer QB-50. A correction was made for uranyl ion, which had a little absorption at this wavelength, after the exchange capacity of resin in the column had been determined in the same way as before. The nitrate concentration in the resin phase was represented as millimole of the ion per milliequivalent of the resin.

b) Zinc-Chloride System.—The solutions of sodium chloride, sodium nitrate and zinc chloride were prepared from guaranteed reagents. To the zinc chloride solution a small quantity of hydrochloric acid was added to prevent the hydrolysis of the zinc. "Dowex 1-X8" chloride form (100~200 mesh) of 0.5 g. was set, and at the same time the exchange capacity was determined in the same way as described in a). Each mixture of the solutions added to the resin had a volume of 50 ml. and contained 0.0970 mmol. of zinc and a series of sodium chloride+sodium nitrate mixed in various ratios, although the total concentration was always 0.4 M or 3 M.

The resin and the solution were equilibrated at 25°C for an hour and the zinc and the chloride concentrations in the resin determined by EDTA and Mohr's titration respectively, after the two phases had been separated by a procedure similar to that used in a). The concentrations of these ions in the solution were estimated by subtraction. The distribution coefficient was calculated as:

$$D=\frac{\text{mmol. of Zn per mequiv. of the resin}}{\text{mmol. of Zn per ml. of the soln.}}$$

Results and Discussion

Uranium-Nitrate System. — By the same treatment as in the previous papers, the following equation obtained for the uranyl-nitrate complex:

$$\log D=(n-2)\log[NO_3^-]-(m-2)\log(NO_3^-)+K+G \qquad (1)$$

where (NO_3^-) and $[NO_3^-]$ represent the concentrations of nitrate ion not bound to uranyl ion, and m and n are the numbers of nitrate ions bound to each metal ion of the complex, in the solution and the resin phases respectively. K and G indicate the terms containing equilibrium constants and activity coefficients.

Assuming that a uranyl ion does not form any nitrate complex in the solution ($m=0$) and that at a constant ionic strength the activity coefficient term is kept constant, the following equations may be derived from Eq. 1:

$$\log D-2\log(NO_3^-)=(n-2)\log\{[NO_3]^*-n[U]\}+K+G \qquad (2)$$

and

$$\frac{d\{\log D-2\log(NO_3^-)\}}{d\log\{[NO_3]^*-n[U]\}}=n-2 \qquad (3)$$

where $[NO_3]^*$ is the stoichiometric concentration of all the nitrate ions in the resin, obtained directly by spectrophotometric measurement, and [U] is the concentration of the uranyl-nitrate complex in the resin.

Using the approximate n-value obtained from the gradient of the $\log D-2\log(NO_3^-)$ vs. $\log[NO_3]^*$ curve, $\log D-2\log(NO_3^-)$ was plotted against $\log\{[NO_3]^*-n[U]\}$, i. e., $\log[NO_3^-]$. As shown in Fig. 1, the gradient in the nitrate-rich range was 1.1, 1.4, 1.4, 1.9 and 2.0 for the external concentrations of 2, 3.2, 3.5, 4 and 6 M respectively. The n-values obtained from Eq. 3 in this way are plotted against the external nitrate concentration in Fig. 2. It may be recognized that uranium(VI) exists as $UO_2(NO_3)_3^-$ for the external nitrate concentration of 2 M, as $UO_2(NO_3)_4^{2-}$ for 4~6 M, and as a mixture of $UO_2(NO_3)_3^-$ and $UO_2(NO_3)_4^{2-}$ for the range between 2 M and 4 M.

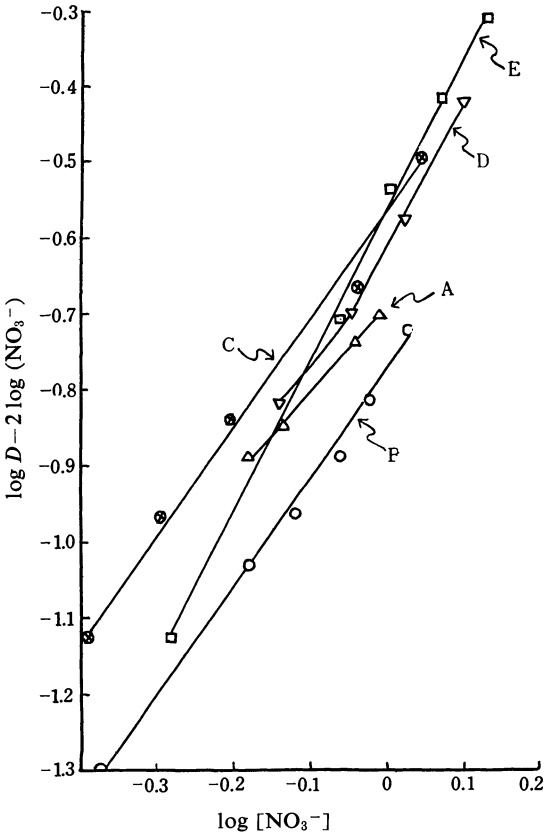

Fig. 1. Determination of n at various total concentration of the external solution in the nitrate-rich range. The rightest point in each curve is one in the absence of perchlorate.

Total external concentration is about; A 2 M, B 3.2 M, C 3.5 M, D 4 M, and E 6 M.

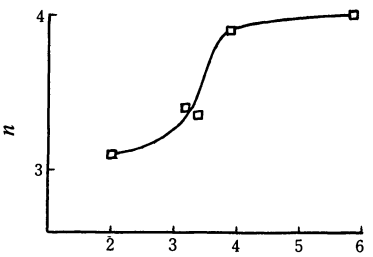

Fig. 2. n-Value of the uranyl-nitrate complex adsorbed from sodium nitrate solutions of various concentrations.

Zinc-Chloride System.—In the same way, the following equation was applied to the zinc-chloride complex:

$$\log D=(n-2)\log[Cl^-]-(m-2)\log(Cl^-)+K+G \qquad (4)$$

where the denotations are the same as those in the uranium-nitrate system. As it is known[9] that zinc is adsorbed as $ZnCl_4^{2-}$ at a 2~7 M chloride concentration, Eq. 4 becomes as follows by substituting $n=4$:

$$\log D-2\log\{[Cl]^*-4[Zn]\}=-(m-2)\log(Cl^-)+K+G \qquad (5)$$

where $[Cl]^*$ and [Zn] are the stoichiometric concentrations of all the chloride ions and zinc ions in the resin, obtained directly by measurement. (Cl^-) has been estimated, without regard to the chloride ions bound to the zinc ions in the solution. When K and G are constant, the following equation is applicable:

$$\frac{d[\log D-2\log\{[Cl]^*-4[Zn]\}]}{d\log(Cl^-)}=-(\bar{m}-2) \qquad (6)$$

where $\bar{m}$ is the mean number of ligands as defined by Bjerrum for the aqueous phase. The $\log D-2\log\{[Cl]^*-4[Zn]\}$ vs. $\log(Cl^-)$ plot at the external ionic strength $\mu=3$ is shown in Fig. 3. As can be seen from the curve, no appreciable change in the composition of complex species took place up to the external chloride concentration of 2 M, and from the gradient $ZnCl^+$ and $ZnCl_2^0$ were presumed to be the predominant species in this region. At a concentration of more than 2 M, anionic complex species were produced, and at the concentration of 3 M where only chloride ion is present, the coexistence of $ZnCl_3^-$ and $ZnCl_4^{2-}$ was presumed from the gradient of about −1.4, i. e., $m=3.4$.

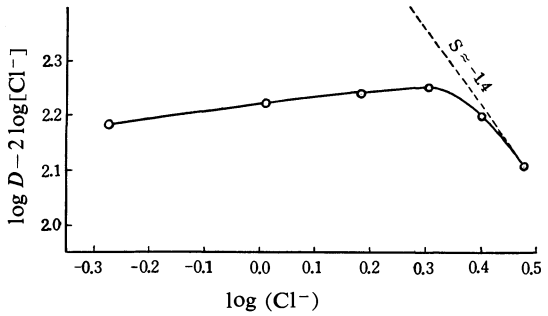

Fig. 3. Variation of distribution coefficient with external chloride concentration at constant ionic strength $\mu=3$.

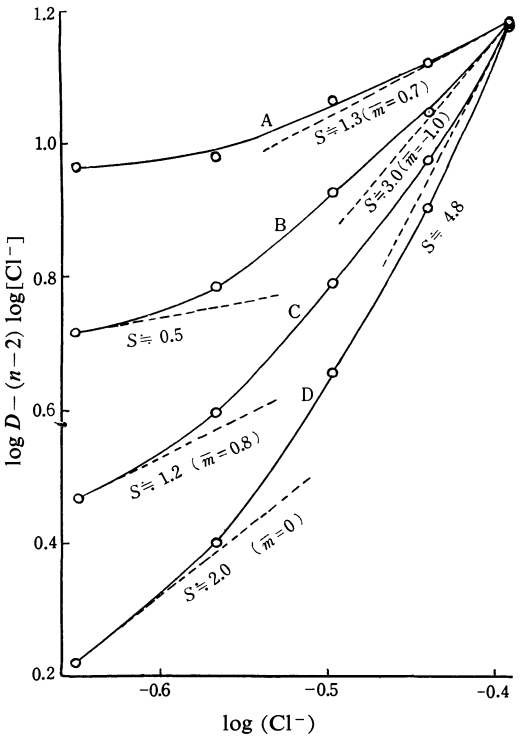

Fig. 4. Distribution coefficient curves when n is arbitrary assumed.

A, $n=4$; B, $n=3.5$; C, $n=3$; D, $n=2.5$

On the other hand, at the ionic strength $\mu=0.4$, the complex in the resin phase does not seem to be limited to one species, this being understood from the fact that the gradient of each curve in Fig. 4 increases with the chloride concentration. Even in such a complicated system, the principal species in the two phases can be identified graphically by introducing a condition $\bar{m}\geqq 0$ and $\bar{n}\leqq 4$. Curves were drawn in Fig. 4 on the assumption that $n=4$, 3.5, 3 and 2.5. At the point designating only the presence of 0.4 M chloride (at the right end of curve), the gradient of the curve was about 1.3 for $n=4$, which corresponded to $\bar{m}=0.7$, and 3.0 for $n=3.5$, which corresponded to $\bar{m}=-1.0$, since the gradient is $-(m-2)$ in Eq. 6. $m=0$ corresponds to $n=3.8$ by interpolation between $n=4.0$ and $n=3.5$. From the fact that $3.8\leqq\bar{n}\leqq 4.0$ corresponds to $0\leqq\bar{m}\leqq 0.7$, it may be considered that $ZnCl_4^{2-}$ is present as a predominant complex in the resin and that Zn^{2+} and $ZnCl^+$ are present in the solution when the aqueous phase is near the 0.4 M chloride solution. For a lower chloride concentration at the same ionic strength, $\bar{m}$ should be less than 0.7. At the chloride concentration of about 0.2 M (at the left end of the curve in Fig. 4), $\bar{m}=0$ corresponded closely to the gradient of the curve D for $n=2.5$ and $\bar{m}=0.7$, nearly to the gradient of the curve C for $n=3.0$ in Fig. 4. Consequently, $ZnCl_3^-$ (more than half) and $ZnCl_2^0$ seemed to be present as principal complexes in the resin phase at this concentration.

Further quantitative relations among the steps of the step-by-step formation of complex species may be estimated only with difficulty unless the stability constants are obtained. The evaluation of these constants requires not only many strict measurements but an extensive knowledge of activity coefficients.

Summary

1) The "indifferent electrolyte-adding" method described in previous papers was applied to the uranyl-nitrate and to the zinc-chloride complexes. A sodium nitrate-sodium perchlorate mixed medium was employed in the former, and a sodium chloride-sodium nitrate mixed medium in the latter.

2) The predominant species of the uranyl-nitrate complex adsorbed from sodium nitrate solutions was $UO_2(NO_3)_3^-$ at the external nitrate concentration of about 2 M and $UO_2(NO_3)_4^{2-}$ at the 4~6 M concentration. The coexistence of the two species may be presumed at 2~4 M.

3) The principal zinc-chloride complex adsorbed on the resin from the chloride solution of 0.4~3 M was simply $ZnCl_4^{2-}$, accompanied by a small quantity of $ZnCl_3^-$ in a low ionic strength. On the other hand, the predominant species in the aqueous phase were $ZnCl_3^-$ and $ZnCl_4^{2-}$ for a sodium chloride concentration of 3 M, and Zn^{2+} and $ZnCl^+$ for a 0.4 M concentration. These results were approximately consistent with those obtained in a hydrochloric acid medium by other investigators.

A Systematic Ion Exchange Separation of Metallic Elements. I. Group Separation of Metallic Elements by Anion Exchange with Hydrochloric Acid

By Jun YOSHIMURA and Hirohiko WAKI

(Received July 13, 1961)

A number of systematic separation methods of metallic elements using an ion exchange resin have been reported. Tompkins, Khym and Cohn[1], and Kimura, Minami and Honda[2] have reported systematic procedures for the separation of fission products by means of cation exchange. Minami, Fujimoto and Kakihana proposed a method[3,4] for the analysis of major ionic species in natural water using a cation exchange resin. Takiyama and Suito[5] reported a group separation of cations using anion exchange resins of various forms as precipitants, according to the principle of the usual qualitative analysis. Kraus and his co-workers[6] separated transition metals from each other by anion exchange in a hydrochloric acid medium. They have also carried out an extensive study[7] of the anion exchange adsorption of a number of elements from the same acid and other media. Jentsch and Pawlik[8] have also studied the adsorption from hydrochloric acid. A few years ago, the present authors reported an ion exchange method for silicate analysis[9]. The present authors are now interested in a systematic method for the isolation of all metallic elements in the usual quantity by ion exchange, without any other separatory operation. In systematic separation procedures, it is usual first to separate these elements into several groups, instead of isolating them one by one from the start. For an eluant employed in a group separation as the first stage of systematic procedure by ion exchange, it is necessary that it not produce an insoluble compound with most metals, and that it can be easily removed by heating or other simple operations after elution, since a large excess of eluant may make the subsequent separation troublesome. From this point of view, hydrochloric acid may be considered to be one of the most suitable eluants. In this experiment, the group separation was carried out by elution with various concentrations of hydrochloric acid through an anion exchange column, based on the Kraus' method. Some of the metallic elements which form insoluble or volatile compounds with hydrochloric acid, or which occur rarely in nature, and which form complicated compounds of various oxidation states, were excepted.

Experimental

Resin.—The anion exchanger used in this work was a "Dowex 1-X8". The commercial chloride resin (100~200 mesh) was previously washed with water by means of suspension. The water, together with the resin of the finest mesh, was removed several times by decantation. Ten and forty milliliters columns of this chloride resin were used in the preliminary test and the separation experiment respectively. Each column was washed in turn with concentrated and dilute hydrochloric acids and water, and just before the addition of a sample solution it was treated with 10.5~11 M hydrochloric acid.

Solutions.—Hydrochloric acid as an eluant was of special grade and was used without further purification. Solutions of metal elements were prepared by dissolving their chlorides or oxides in water or hydrochloric acid except in the following cases: solutions of lead, bismuth and uranium were the acidified aqueous solutions of their nitrates: the solution of thallium(III) was prepared by treating thallous nitrate with a mixture of hydrochloric acid and nitric acid and then dissolving it in hydrochloric acid after the volatilization of nitric acid; the solution of arsenic(III) was prepared from arsenous acid, and the solution of arsenic(V) was obtained by oxidizing arseneous acid.

Procedure for Separation Experiments.—Each solution, usually containing about 5~10 mg. of an element, was evaporated to small volume, and concentrated hydrochloric acid was added so that the sample

solution might be adjusted to a volume of 10 ml. and to a hydrochloric acid concentration of 10.5~11 M. This solution was immediately added on the top of the column (Dowex 1, 40 ml., ϕ 1.2 cm.), and at the same time the effluent began to collect. When the sample solution was passed through the resin bed and no liquor was found on the top of the bed, a small volume of 11 M hydrochloric acid was added after washing the inside wall of the vessel used and the glass column, and the elution by 11 M hydrochloric acid was kept continuously by a connection with a separating funnel. When 40 ml. of the effluent was obtained, the elutriant was altered by 6.5 M hydrochloric acid, and the effluent was collected in another vessel. When 80 ml. of the effluent for 6.5 M was obtained, the elutriant was altered by 3 M hydrochloric acid. One hundred milliliters of the effluent for 3 M was collected. The metal elements still remaining in the resin bed after elution with 3 M hydrochloric acid were desorbed with extremely dilute hydrochloric acid below 0.5 M or with other elutriants appropriate for individual cases. The flow rate was 0.5 ml./min. for 11 M and 3 M hydrochloric acids, and 0.8 ml./min. for 6.5 M. All elutions were done at room temperature. In each elution the metal element in each fraction of the effluent was detected or determined, mostly by a usual method. Also, in the preliminary test, a similar procedure was employed, though a smaller column and smaller volumes of sample solution and of elutriant were used.

Results and Discussion

In the preliminary test in which a 10 ml. column was used, results* were obtained as expected from Kraus' experiments. Most metallic elements seemed to be classified experimentally into four groups from their behavior in elution with hydrochloric acid using an anion exchange resin, though each group was not enough separated from the others. The four groups were those not adsorbed even from concentrated hydrochloric acid, those adsorbed from the concentrated hydrochloric acid and desorbed with the 6 M acid, those desorbed by the acid below 6 M to 3 M, and those eluted with difficulty by 3 M hydrochloric acid. Besides, there were also some elements which have behavior intermediate between the first two groups.

The use of a longer column leads to the possibility of the more quantitative separation for these elements, and this may be required when considerable amounts of sample are treated. From this point of view, the column of 40 ml. was employed as well as in the silicate analysis[9]. The second elution was done by preferance with 6.5 M hydrochloric acid, since the use of hydrochloric acid less than 6 M might cause a partial effluence of cobalt into the part of the second group.

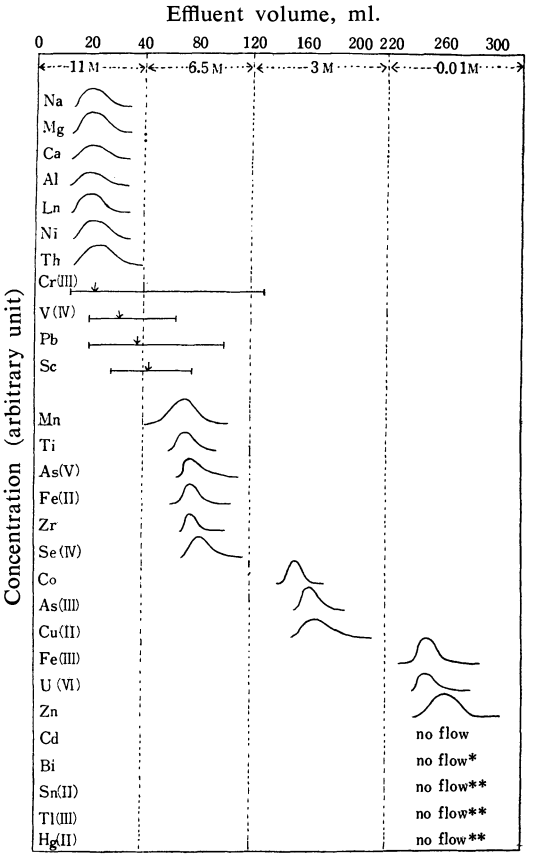

Fig. 1. Elution curves of metallic elements from the 40 ml. column of "Dowex 1-X8" with hydrochloric acid solutions of various concentrations.

|—| : Range where an metal element was detected
↓ : Point of maximum metal concentration in the effluent
* Test by 0.1 M HCl
** Test by 0.5 M HCl

As shown in Fig. 1 which gives an individual elution curve obtained by quantitative or semi-quantitative analysis of the effluent, the metallic elements investigated, except scandium, lead, vanadium(IV) and chromium(III), were quantitatively separated into four groups using the column of 40 ml. Scandium was found in the second section of effluent for the most part, although also in the first section of effluent in some portions. In order to separate it perfectly from non-adsorbed elements, 13 M hydrochloric acid must be employed[10]. But this may be of no practical use as an elutriant. Chromium(III)

* Elution curves have not been shown in this paper to avoid duplication, since they were like in tendency to those in the separation experiment where a 40 ml. column was used.

TABLE I. CLASSIFICATION OF METALLIC ELEMENTS

Group I			Group II			Group III		Group IV	
Li	Be	Al	Th	Mn	Fe(II)	Se	Co	As(III)	Fe(III)	Zn
Na	Mg	Y			As(V)			Cu(II)	U(VI)	Cd
K	Ca	La–Lu			Ti					Sn(II)
Rb	Sr				Zr					Tl(III)
Cs	Ba				Hf					Hg(II)
	Ni									Bi(III)
	Cr(III)		V(IV)	Sc	Pb					

Group I is eluted by 1 column volume of 11 M HCl.
Group II is eluted by 2 column volume of 6.5 M HCl.
Group III is eluted by 2.5 column volume of 3 M HCl.
Group IV is still held by the resin column after elutions by 11 M, 6.5 M and 3 M HCl.

and vanadium(IV) were found for the most part in the first section of effluent, but some portions of them were in the second one. Chromium can not be concentrated in a small volume of the effluent by hydrochloric acid because, it is considered, chromium has variously stable complex forms in the chloride solution. Lead extended half-and-half over the two sections. The elution favorable for only these elements may, conversely, be unsuitable for the group separation of most other metallic elements.

The classification of metallic elements based on the preliminary test and the separation experiment are tabulated in Table I. Some elements not described in this paper will be added to this table later in further studies. Especially, the assignment of more elements to group IV may be expected from Kraus' distribution data[7].

The use of a longer column and the careful selection of eluting conditions employing more kinds of chloride concentration might permit a further separation of the moderately adsorbable elements (groups II and III). However, much more time and a delicate technique may be required for them. Consequently, other eluants may be preferable for isolation inside these groups. Among the elements in group IV, the separation of Fe, U–Zn–Cd can be done easily using hydrochloric acid of extremely low concentration. However, such an dilute acid must be used prudently, since a number of strongly adsorbable elements tend to be hydrolyzed in dilute acid. The subdividing of this group by more dilute hydrochloric acid can be formalized only with difficulty unless the elution behaviors of these elements are known extensively. For the desorption of group IV in this experiment, hydrochloric acid of an arbitrary concentration below 0.5 M, water, perchloric acid, nitric acid and other elutriants were selected according to individual cases. The use of a smaller column leads to a poor separation between group I and manganese, and at least a near-40 ml. column is needed for a quantitative separation. If a sample contains no manganese, a somewhat smaller column may be used.

These classifications can not be interpreted in terms of the stability constant[11] of a chloro-complex in the solution phase. To explain the adsorbability of a metal ion on an anion exchange resin, the form and the stability of the complex in the resin phase must also be taken into account. Although these are not clear in general at present, the features of the four groups may be given an outline as described below.

Group I contains alkali metals, alkaline earth metals, aluminum, yttrium, lanthanide elements, thorium and nickel. These elements do not form any anionic complex species in either hydrochloric acid solution or resin, and pass through the resin column even with concentrated hydrochloric acid. They are collected in only one column volume of the effluent by 10.5~11 M.

Group II contains manganese, titanium, iron(II), zirconium, arsenic(V), selenium(IV) and also probably hafnium*, which are collected in the next two column volumes of the effluent by 6.5 M. These elements form anionic chloro-complexes in the resin phase for the concentrated hydrochloric acid medium, while they do not form presumably anionic chloro-complexes in any appreciable amount in the solution phase over the whole range of chloride concentration. An exception is arsenic(V), which appears to exist not as a chloro-complex anion but as an arsenate ion. Among non-metallic ions, sulfate and phosphate fall into both groups I and II.

11) J. Bjerrum, G. Schwarzenbach and L. G. Sillén, "Stability Constants, Part II—Inorganic Ligands", London (1958).

* It was confirmed that the adsorption of hafnium was not stronger than that of zirconium, although hafnium was not eluted by 10 M hydrochloric acid.

TABLE II. ANALYSES OF MIXED SOLUTIONS

Sample No.	Element	Taken	Found I	Found II	Found III	Found IV
1	Ni	5.97 mg.	5.94 mg.			
	Mn	2.00 mg.		2.02 mg.		
	Co	0.0840 mmol.			0.1591 mmol.	
	Cu(II)	0.0771 mmol.				
	Fe(III)	9.92 mg.				9.80 mg.
2	Th	7.42 mg.	7.08 mg.			
	Zr	3.97 mg.		3.90 mg.		
	U(VI)	89.4 mg.				89.3 mg.
3	Ni	59.7 mg.	59.5 mg.			
	Cu(II)	49.0 mg.			49.4 mg.	
	Zn	0.0708 mmol.				0.1120 mmol.
	Cd	0.0419 mmol.				

I : Effluent by 11 M HCl
II : Effluent by 6.5 M HCl
III : Effluent by 3 M HCl
IV : Effluent by extremely dilute HCl

Group III contains cobalt, arsenic(III) and copper(II), which are collected in the next two and a half column volumes of the effluent by 3 M. These elements form anionic chloro-complexes not only in the resin phase, but also in the solution phase for the concentrated hydrochloric acid medium.

Group IV contains iron(III), uranium(VI), zinc, cadmium, bismuth, tin(II), mercury(II), thallium, etc., which remain in the column after the elution with 3 M. Most elements in group IV form stable anionic chloro-complexes in both phases, even in a dilute hydrochloric acid medium. Iron(III) and uranium(VI) may be rather like the elements in group III in this point. However, they are conveniently classified in group IV, since their concentration regions of adsorption are as wide as those of other elements in this group.

The separation data on mixed solutions which consist of a few elements are shown in Table II. Sample 1 contains the elements situated in one end of each group with respect to the effluence. Samples 2 and 3 are those which contain a large quantity of special elements. Furthermore, a successful quantitative group separation can be expected in a mixed solution containing more elements in ordinary combination except in the following cases: 1) when an element undergoes a change in valency during the separatory process by reaction with other elements or with hydrochloric acid, 2) when a sample solution contains an element which is apt to produce a volatile compound in hydrochloric acid, 3) when the quantity of metal elements included is beyond a limit permissible from the column exchange capacity, and 4) when a sample solution of 10 ml. of concentrated hydrochloric acid can not be prepared in the case where a metal element of small solubility in the acid is treated in a relatively large amount.

For case 3 or 4, an increase in the resin bed volume and the volume of sample solution may be required.

Summary

1) As the first stage in the systematic separation of metallic elements by ion exchange, a group separation on an ordinary scale was tried using an anion exchanger "Dowex 1-X8", with hydrochloric acid, a method based on Kraus' method.

2) Most metallic elements usually treated in the chemical analysis can be separated into four groups by the elution through a 40 ml. column using 11 M, 6.5 M and 3 M hydrochloric acid as elutriant. Satisfactory results were obtained on analysis for a mixed solution.

3) These classifications may be explained in terms of the formation of a chloro-complex of a metal, not only in the solution phase but also in the resin phase.

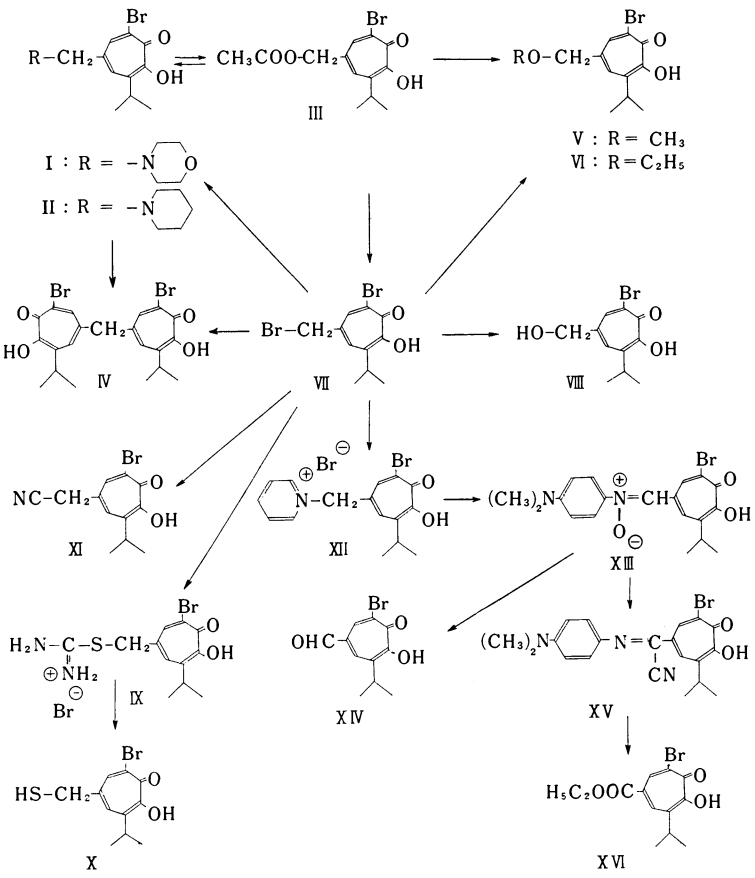
The Mannich Base of Troponoid and its Application. VII. The Synthesis of 5-Formyl Derivative of 3-Isopropyltropolone

By Kyozo OGURA

(Received May 30, 1961)

The present author has reported the synthesis of some Mannich bases of 3-isopropyltropolone (α-thujaplicin) and their properties[1]. The present paper describes the synthesis of 5-bromomethyl and 5-formyl derivatives of 3-isopropyltropolone from the Mannich base.

X = OAc , Br



Treatment of 3-isopropyl-5-morpholinomethyl-7-bromotropolone (I) or 3-isopropyl-5-piperidinomethyl-7-bromotropolone (II) with acetic anhydride resulted in cleavage of the C–N bond to give 3-isopropyl-5-acetoxymethyl-7-bromotropolone (III). As in the case of 3, 7-dibromo-5-acetoxymethyltropolone[2], glacial acetic acid could also be used in place of acetic anhydride for the preparation of the acetoxymethyl derivative III, but the yield was lower. In the preparation of 3,7-dibromo-5-acetoxymethyltropolone from 5-morpholinomethyl derivative, bis(3, 7-dibromotropolon-5-yl)methane was produced as a by-product[2], while the reaction of I or II with glacial acetic acid did not give such a by-product; instead the corresponding bis(3-isopropyl-7-bromotropolon-5-yl)methane (IV) was obtained by refluxing II in toluene in the presence of sodium hydroxide. The compound IV forms a ferric complex which is insoluble in both water and organic solvents.

Alcoholysis of III by methanol and ethanol gave 3-isopropyl-5-methoxymethyl-7-bromo- (V) and 3-isopropyl-5-ethoxymethyl-7-bromotropolone (VI) respectively. Treatment of III with morpholine and piperidine, respectively, gave I and II. When III was treated with diluted sodium hydroxide solution, a transitory red color appeared and a resinous substance was formed. When III was heated in hydrobromic acid, 3-isopropyl-5-bromomethyl-7-bromotropolone (VII) was obtained in a good yield. The bromomethyl derivative VII is also very unstable to alkali. The unstability of III and VII to alkali may be due to their tendency to form such a quinonoid structure as follows.

The bromine in the bromomethyl group of VII is very reactive, and it is easily replaced by various anionoid reagents, so that C–O, C–N, C–S and C–C bond can be formed at the end of the methylene in the 5-position of the tropolone ring. Treatment of VII with dimethysulfoxide afforded 3-isopropyl-5-hydroxymethyl-7-bromotropolone (VIII). Alcoholysis of VII gave 5-alkoxymethyl derivatives, V and VI, and aminolysis of VII by morpholine and piperidine gave I and II respectively. The reaction of VII with thiourea gave *S*-(3-isopropyl-7-bromotropolon-5-ylmethyl)isothiouronium bromide (IX), which was converted into 3-isopropyl-5-mercaptomethyl-7-bromotropolone (X) by alkaline hydrolysis. The reaction of VII and potassium cyanide afforded 3-isopropyl-5-cyanomethyl-7-bromotropolone (XI). The reaction of VII with pyridine also easily proceeded in dry benzene at room temperature forming (3-isopropyl-7-bromotropolon-5-ylmethyl)pyridinium bromide (XII) quantitatively, which was soluble in water and formed a water-soluble ferric complex; on the other hand, the reaction of VII with triethylamine resulted in dehydrobromination to give triethylamine hydrobromide and a deep greenish blue substance which was too unstable to be obtained as pure crystals. This substance was decolorized by the action of hydrochloric acid to give IV. The reaction of the pyridinium salt XII with piperidine gave II, and that with sodium acetate afforded III.

Kröhnke's method[3] was applied to XII in order to obtain the 5-formyl derivative. Reaction of XII with *p*-nitroso-*N*, *N*-dimethylaniline

1) K. Ogura, This Bulletin, **34**, 839 (1961).
2) S. Seto and K. Ogura, ibid., **32**, 493 (1959).
3) F. Kröhnke, *Angew. Chem.*, **65**, 605 (1953).

in the presence of sodium hydroxide gave brilliant red crystals of (3-isopropyl-7-bromotropolon-5-yl)-*N*-(*p*-dimethylaminophenyl)nitrone (XIII), which when hydrolyzed with hydrochloric acid afforded 3-isopropyl-5-formyl-7-bromotropolone (XIV). The aldehyde XIV reacts with ordinary ketonic reagents, and its infrared spectrum shows an absorption maxima at 1680 and 2880 cm^{-1} due to its formyl group. When nitrone XIII was treated with potassium cyanide, (3-isopropyl-7-bromotropolon-5-yl)-*N*-(*p*-dimethylaminophenyl)cyanoanile (XV) was obtained as deep wine red prisms, and treating this with alcoholic hydrochloric aicd gave 3-isopropyl-5-ethoxycarbonyl-7-bromotropolone (XVI).

The reaction of the aldehyde will be reported in the near future.

Experimental*

3-Isopropyl-5-acetoxymethyl-7-bromotropolone (III).—a) When II (1 g.) was warmed in acetic anhydride (10 ml.) at 95°C with occasional stirring, the solution turned black in a few minutes, and it was decolorized gradually. After being kept at the same temperature for 1 hr., the solution was filtered to remove a small amount of precipitate, and the filtrate was concentrated under reduced pressure. Colorless needles which separated on being cooled were collected and recrystallized from methanol, m. p. 124~125°C. Yield, 0.6 g.

Found: C, 49.86; H, 4.86. Calcd. for $C_{13}H_{15}O_4Br$: C, 49.52; H, 4.76%.

λ_{max}^{MeOH} mμ(log ε): 262(4.14), 344(3.82), 386(3.65).

b) The solution of I (300 mg.) in glacial acetic acid (3 ml.) was heated at 110~120°C for 3 hr., and colorless needles which separated on being cooled were collected. Evaporation of the filtrate under reduced pressure gave a syrup residue, from which the starting material (100 mg.) was recovered as its hydrochloride by addition of a few drops of 6 N hydrochloric acid.

Bis(3-isopropyl-7-bromotropolon-5-yl)methane (IV).—A suspension of II (150 mg.) and powdered sodium hydroxide (30 mg.) in toluene (1 ml.) was refluxed for 3 hr., and yellow crystals were collected and acidified by 6 N hydrochloric acid to yield colorless powder, which was recrystallized from methanol to afford colorless scales, m. p. 157~158°C. Yield, 50 mg.

Found: C, 50.50; H, 4.46. Calcd. for $C_{21}H_{22}O_4 \cdot Br_2$: C, 50.60; H, 4.42%.

* All melting points are uncorrected. The microanalyses were carried out by Misses Yoko Endo and Yukiko Endo of this Institute, to whom the author is indebted.

λ_{max}^{MeOH} mμ(log ε) : 260(4.74), 340(4.24), 420(3.70).

3-Isopropyl-5-methoxymethyl-7-bromotropolone (V).—A solution of III (50 mg.) in methanol (0.5 ml.) was refluxed for 1 hr., and the removal of methanol left an oily residue, which solidified by addition of a few drops of water. The solid was collected and recrystallized from petroleum ether to give colorless needles, m. p. 60~61°C. Yield, 10 mg.

Found: C, 50.34; H, 5.33. Calcd. for $C_{12}H_{15}O_3 \cdot Br$: C, 50.17; H, 5.22%.

3-Isopropyl-5-ethoxymethyl-7-bromotropolone (VI).—A solution of III (50 mg.) in ethanol (0.5 ml.) was refluxed for 1 hr., and colorless needles of VI were obtained in the same manner as in the case of V. The ethoxymethyl derivative VI was also obtained by refluxing 5-bromomethyl derivative Vll in ethanol, m. p. 60~61°C. Yield ca. 10 mg.

Found: C, 51.89; H, 5.71. Calcd. for $C_{13}H_{17}O_3 \cdot Br$: C, 51.83; H, 5.65%.

3-Isopropyl-5-bromomethyl-7-bromotropolone (VII).—When III (1 g.) was heated in 4 ml. of hydrobromic acid (*d*, 1.4) at 95~100°C with occasional swirling for 40 min., yellow oil separated which was solidified on being cooled. The solid was collected, washed with water and dried well. Recrystallization from petroleum ether gave colorless prisms, m. p. 87~90°C. Yield, 0.95 g.

Found: C, 39.66; H, 3.55. Calcd. for $C_{11}H_{12}O_2 \cdot Br$: C, 39.29; H, 3.67%.

$\lambda_{max}^{isooctane}$ mμ(log ε) : 258(4.48), 330(3.94), 375(3.74).

3-Isopropyl-5-hydroxymethyl-7-bromotropolone (VIII).—After a solution of VII (50 mg.) in dimethylsulfoxide (0.2 ml.) was kept at room temperature for 14 hr., cracked ice (ca. 2 g.) was added to the solution. The solid, which was formed by scratching the wall of the vessel, was collected and recrystallized from benzene-petroleum ether, affording colorless needles, m. p. 84~87°C. Yield, 20 mg.

Found: C, 48.88; H, 5.13. Calcd. for $C_{11}H_{13}O_3 \cdot Br$: C, 48.35; H, 4.76%.

λ_{max}^{MeOH} mμ(log ε) : 260(4.42), 338(3.73), 380(3.65).

***S*-(3-Isopropyl-7-bromotropolon-5-ylmethyl)isothiouronium Bromide (IX).**—When a solution of VII (100 mg.) and thiourea (40 mg.) was warmed in *tert*-butanol (0.7 ml.) on a water bath for 5 min., the colorless crystals separated, which were collected and washed with ethanol, m. p. 217°C (decomp.). Yield, 80 mg.

Found: C, 35.07; H, 3.88; N, 6.08. Calcd. for $C_{12}H_{16}O_2N_2SBr$: C, 35.05; H, 3.97; N, 6.45%.

λ_{max}^{MeOH} mμ(log ε) : 259(4.52), 340(3.96), 395(3.70), 410(3.69).

3-Isopropyl-5-mercaptomethyl-7-bromotropolone (X).—After IX (80 mg.) was warmed in 45% sodium hydroxide (0.7 ml.) on a water bath for a few minutes, the solution was acidified with 6 N hydrochloric acid containing cracked ice (ca. 1 g.). The precipitate was collected, washed with water and recrystallized from methanol, affording 50 mg. of pale yellow needles, m. p. 80~81°C.

Found: C, 46.13; H, 4.73. Calcd. for $C_{11}H_{13}O_2 \cdot SBr$: C, 45.67; H, 4.50%.

λ_{max}^{MeOH} mμ(log ε) : 258(4.49), 333(3.91), 375(3.73).

3-Isopropyl-5-cyanomethyl-7-bromotropolone (XI).—A solution of VII (100 mg.) in dioxane (2 ml.) was added dropwise into a solution of potassium cyanide (100 mg.) in dioxane (3 ml.) and water (0.5 ml.), while being stirred under ice cooling, the drop causing a transitory red color to appear. After completion of addition the mixture was stirred for 1 hr., and the solvent was removed under reduced pressure at room temperature, and the residue was acidified with diluted hydrochloric acid. The precipitate was collected and recrystallized from petroleum ether to colorless needles, m. p. 102~103°C. Yield, 20 mg.

Found: C, 51.27; H, 4.14; N, 5.03. Calcd. for $C_{12}H_{12}O_2NBr$: C, 51.06; H, 4.26; N, 4.97%.

λ_{max}^{MeOH} mμ(log ε) : 260(4.56), 330(3.91), 375(3.79).

(3-Isopropyl-7-bromotropolon-5-ylmethyl)pyridinium Bromide (XII).—When pyridine (350 mg.) was added dropwise into a solution of VII (1.5 g,) dissolved in dry benzene (10 ml.), colorless precipitate appeared immediately. After being allowed to stand for 30 min. with occasional stirring, the precipitate was collected and washed with benzene, m. p. 214~215°C (decomp.). Yield, 1.8 g.

Found: C, 46.70; H, 4.25; N, 3.70. Calcd. for $C_{16}H_{17}O_2NBr$: C, 46.51; H, 4.00; N.3.37%.

λ_{max}^{MeOH} mμ(log ε) : 260(4.53), 340(3.93), 380(3.80).

(3-Isopropyl-7-bromotropolon-5-yl)-*N*-(*p*-dimethylaminophenyl)nitrone (XIII).—To a mixture of XII (1.5 g.), *p*-nitrosodimethylaniline (0.6 g.) and ethanol (14 ml.), 3.9 ml. of sodium hydroxide solution (3.8%) was added, while being stirred under ice cooling. After completion of addition the mixture was stirred at room temperature, and red crystals began to appear in a few minutes. After being stirred for 30 min., the mixture was diluted with water (5 ml.), and the crystals were collected, washed well with water and recrystallized from ethanol, affording brilliant red needles, m. p. 142~143°C (decomp.). Yield, 1.45 g.

Found: C, 55.79; H, 5.55; N, 6.61. Calcd. for $C_{19}H_{21}O_3N_2Br$: C, 55.30; H, 5.18; N, 6.92%.

λ_{max}^{MeOH} mμ(log ε) : 264(4.60), 355(4.17), 427(4.00).

3-Isopropyl-5-formyl-7-bromotropolone (XIV).—When 6 N hydrochloric acid was added to XIII (1 g.), the mixture turned yellow. After being warmed on a water bath for a few minutes, the mixture was allowed to stand at room temperature for 1 hr. with occasional stirring. The precipitate was collected, washed well with water and recrystallized from petroleum ether to give colorless scales, m. p. 102~103°C. Yield, 0.67 g.

Found: C, 48.85; H, 4.22: Calcd. for $C_{11}H_{11}O_3 \cdot Br$: C, 48.81; H, 4.06%.

$\lambda_{max}^{isooctane}$ mμ (log ε) : 277(4.40), 345(4.02).

Oxime.—Yellow prisms, m. p. 143~144°C.

Found: C, 46.80; H, 4.25; N, 4.89. Calcd. for $C_{11}H_{12}O_3NBr$: C, 46.15; H, 3.85; N, 4.90%.

Phenylhydrazone.—Red needles, m. p. 186~191°C.

Found: C, 56.87; H, 4.71; N, 7.74. Calcd. for $C_{17}H_{17}O_2N_2Br$: C, 56.53; H, 4.74; N, 7.76%.

2,4-Dinitrophenylhydrazone.—Red prisms, m. p. 236~237°C.

Found: C, 44.80; H, 3.46; N, 11.99. Calcd. for $C_{17}H_{15}O_6N_4Br$: C, 45.25; H, 3.32; N, 12.41%.

Thiosemicarbazone.—Orange prisms, m. p. 210°C (decomp.).

Found: C, 42.39; H, 3.68; N, 11.12. Calcd. for $C_{12}H_{14}O_2N_3SBr$: C, 41.83; H, 4.07; N, 12.21%.

(3-Isopropyl-7-bromotropolon-5-yl)-*N*-(*p*-dimethylaminophenyl)cyanoanile (XV).—When a mixture of XIII (100 mg.), potassium cyanide (60 mg.) and ethanol (1 ml.) was stirred at room temperature, a yellow precipitate appeared. Addition of a few drops of water to the mixture effected a clear solution, and red crystals separated in a few minutes, which were collected, acidified with 6 N hydrochloric acid and recrystallized from petroleum ether to wine red prisms, m. p. 195~196°C. Yield, 20 mg.

Found: C, 57.22; H, 4.18; N, 9.41. Calcd. for $C_{20}H_{20}O_2N_3Br$: C, 57.97; H, 4.83; N, 10.14%.

λ_{max}^{MeOH} mμ(log ε): 265(4.24), 423(4.22), 500(4.35).

3-Isopropyl-5-ethoxycarbonyl-7-bromotropolone (XVI).—When XV (100 mg.) was heated in 6 N hydrochloric acid (1 ml.) and ethanol (1 ml.) on a water bath, yellow crystals separated, which were collected and recrystallized from petroleum ether to pale yellow needles, m. p. 123~128°C. Yield, 50 mg.

Found: C, 49.48; H, 4.55. Calcd. for $C_{13}H_{15}O_4 \cdot Br$: C, 49.52; H, 4.76%.

λ_{max}^{MeOH} mμ(log ε): 256(4.27), 271(4.21), 370(3.99), 386(4.20).

Summary

3-Isopropyl-5-bromomethyl-7-bromotropolone and 3-isopropyl-5-formyl-7-bromotropolone were synthesized from 3-isopropyl-5-piperidinomethyl-7-bromotropolone, and some 5-substituted 3-isopropyl-7-bromotropolones were derived from the bromomethyl derivative.

The author wishes to express his deep gratitude to Professor Shuichi Seto for his kind guidance and encouragement throughout this work, to Mr. Shuji Aono for infrared spectral measurements and to Mr. Fumio Sato for ultraviolet spectral measurements. A part of the expense for the present work was defrayed by Sankyo Co., Ltd., to whom the author wishes to express his sincere gratitude.

Infrared Absorption Spectra of Hydrazides. III. Hydrazides of Aliphatic Acids

By Mitsuo MASHIMA

(Received June 23, 1961)

In a previous paper[1] the amide frequencies characteristic of the hydrazides of aromatic acids were discussed, and for the ion $(RCONHNCOR')^{-}$ [2] amide I, II and III bands were observed within the normal frequency ranges for secondary amides. The present investigation was undertaken to determine the characteristic frequencies of the hydrazides of aliphatic acids. Solid spectra of diformylhydrazine and its *N*-deuterated derivative[3] of diacetylhydrazine, its mono-hydrate, and of their deuterated derivatives[4] have already been published. For the present study, the spectra of dipropionylhydrazine, dibutyrylhydrazine, diisovalerylhydrazine, formyl-acetylhydrazine, and cyanoacetyl-acetylhydrazine were examined in the solid state and in solution. The solution spectrum of diacetylhydrazine was also observed, diformylhydrazine in solution could not, however, be examined because of its sparing solubilities in solvents suitable to observation in infrared spectra.

Experimental

Dipropionylhydrazine was prepared with propionic anhydride and hydrazine hydrate[5] and was purified by recrystallization from benzene, m. p. 136°C. Dibutyrylhydrazine was synthesized by the reaction of butyrylhydrazine with iodine in ethanol[6] and was purified by recrystallization from benzene, m. p. 163°C. Diisovalerylhydrazine was synthesized with isovalerylhydrazine and iodine in ethanol[7] and was purified by recrystallization from benzene, m. p. 180°C. Formyl-acetylhydrazine was synthesized with formylhydrazine and acetic anhydride[8]

and was purified by recrystallization from ethanol, m. p. 96°C. Cyanoacetyl-acetylhydrazine was synthesized with cyanoacetylhydrazine and acetic anhydride[9] and was purified by recrystallization from ethanol, m. p. 171°C. The synthesis of diacetylhydrazine has been described previously[2]. The method of preparation of compounds containing deuterium was similar to that described previously[1]. Solution spectra were obtained in acetonitrile with cells of 0.1 mm. in optical path, and solid spectra were studied in potassium bromide disk with a Hitachi infrared spectrophotometer EPI-2 in the rock salt region.

Results and Discussion

Solid Spectra.—*Symmetric Hydrazides.*—The solid spectra of dipropionylhydrazine (DPH), dibutyrylhydrazine (DBuH), and diisovalerylhydrazine (DIVH) are shown in Fig. 1, in which the solid spectrum of diacetylhydrazine (DAH) is also represented for purposes of comparison. Let us consider mainly the N–H stretching band and the amide I, amide II and amide III bands because they may be characteristic of the hydrazides.

By comparison of the spectra with those of diformylhydrazine (DFH)[3] and DAH[4], the following assignments are possible:

All of these hydrazides have a very intense band near 3200 cm^{-1} which is easily assigned to the N–H stretching vibration ν(N–H) and a rather weak band near 3030 cm^{-1} which is also attributed to ν(N–H). The assignment of the former was confirmed by *N*-deuteration; e. g., *N*-deuterated DPH has a band at 2380 cm^{-1} which corresponds to the 3200 cm^{-1} band of DPH, the ratio ν_H/ν_D being 1.34. The latter disappears from the solution spectra, as is indicated in a following section. Therefore, it is probably also associated with ν(N–H).

The symmetric hydrazides have the most intense band among their absorption bands near 1600 cm^{-1}. The amide I band was found at 1610 cm^{-1} for DFH[3] and at 1598 cm^{-1} for

DAH*. Thus, the band near 1600 cm^{-1} is assigned to the amide I band.

The amide II band is observed near 1500 cm^{-1} for these hydrazides. A corresponding band was found at 1414 cm^{-1} for *N*-deuterated DPH, the ratio ν_H/ν_D being 1492/1414 (1.055). The value is close to 1.106 for DFH[3] and to 1.065 for DAH[4].

For hydrazides of aromatic acids[1] the amide III band was found in the normal range of secondary amides, and it split into two bands. However, no such splitting can be observed for the symmetric hydrazides of aliphatic acids; only a single amide III band is found near 1200 cm^{-1}. For *N*-deuterated DPH a corresponding band is found at 928 cm^{-1}, the ratio ν_H/ν_D being 1217/928 (1.311). The value of ν_H/ν_D is close to 1.248 for DFH[3] and to 1.333 for DAH[4].

Formyl-acetylhydrazine (FAH) and Cyano-acetyl-acetylhydrazine (CAH).—The solid spectra of FAH, CAH, and their *N*-deuterated derivatives are illustrated in Fig. 2. In the 3000 cm^{-1} region a strong band is found at 3200 cm^{-1} for FAH and at 3190 cm^{-1} for CAH. A corresponding band is found at 2380 cm^{-1} for *N*-deuterated FAH and at 2370 cm^{-1} for *N*-deuterated CAH, the values of ν_H/ν_D being 1.344 and 1.346 respectively. These bands are easily assigned to ν(N–H) by comparison of the values of frepuency and ν_H/ν_D with those of the symmetric hydrazides indicated in the foregoing section. The main band near 3200 cm^{-1} is accompanied by several shoulder bands in the spectra of FAH and CAH indicated in Fig. 2 and of DAH indicated in Fig. 1. A well-defined shoulder is found at 3020 cm^{-1} for FAH, at 3050 cm^{-1} for CAH, and at 3060 cm^{-1} for DAH. No corresponding band is found in the solution spectra, as is indicated in a following section. In consequence, the shoulder band near 3050 cm^{-1} is probably due to ν(N–H). Other shoulder bands can probably be ascribed to the C–H stretching vibrations, but we can not assign the individual shoulder band with confidence because of the complexity and the rather weak intensity of the absorption bands.

We will next consider the amide bands. DAH has a very strong band at 1598 cm^{-1} which has been ascribed to the amide I band by Yamaguchi[4], while two corresponding bands are found at 1613 and 1580 cm^{-1} for FAH and at 1623 and 1593 cm^{-1} for CAH. Both bands can undoubtedly be assigned to the amide I because they are in good agreement with the band of DAH in frequency. Yamaguchi[4] observed the solid spectra of diacetylhydrazine monohydrate and ascribed a single band at 1661 cm^{-1} to an amide I band. On the other hand, similar doublets have been observed for hydrazides of aromatic acids[1], and a further consideration will be represented later on. *N*-Deuterated FAH and *N*-deuterated CAH have only a single band at 1604 cm^{-1} and 1607 cm^{-1} respectively, both of which bands correspond to the amide I band.

FAH and CAH have amide II bands at 1483 cm^{-1} and at 1497 cm^{-1} respectively. The values of these frequencies are very close to the 1506 cm^{-1} of DAH and the 1480 cm^{-1} of DFH[3]. The assignments of these bands were confirmed by *N*-deuteration; i. e., *N*-deuterated FAH has a corresponding band at 1383 cm^{-1},

* Yamaguchi (Ref. 4) obtained the band at 1597 cm^{-1} for DAH in Nujol.

the ratio of ν_H/ν_D being 1.072, and *N*-deuterated CAH has a band at 1413 cm^{-1}, the ratio being 1.059. These values of ν_H/ν_D are very close to those of the symmetric hydrazides indicated in the previous section, i. e., 1.106 for DFH, 1.065 for DAH, and 1.055 for DPH.

DAH has only a single amide III band at 1260 cm^{-1}, but FAH has two corresponding bands at 1279 and 1232 cm^{-1} and CAH has two bands at 1281 and 1235 cm^{-1}. The assignment of these two bands is confirmed by the finding of corresponding bands at 946 and 924 cm^{-1} for *N*-deuterated FAH and at 962 and 918 cm^{-1} for *N*-deuterated CAH. The values of the ratio ν_H/ν_D are 1.352, 1.333 for the two bands of FAH and 1.345, 1.342 for CAH.

Vibrations relating to the CH_3, CH_2 and CH groups are also to be associated with bands in the rock salt region. The C–H stretching bands have been discussed already. Bands due to CH_3, CH_2 and CH deformation vibrations are expected to appear in the region 1450~1350 cm^{-1}. DAH has a $\delta_a(CH_3)$ band at 1430 cm^{-1} and a $\delta_s(CH_3)$ band at 1365 cm^{-1}, and DFH[3] has a δ(CH) band at 1368 cm^{-1}. CAH has bands at 1448, 1392, and 1331 cm^{-1}, of which the first band is assigned to $\delta_a(CH_3)$ or $\delta(CH_2)$; the second one can be ascribed to $\delta_a(CH_3)$, while the last band might possibly be due to CH_3 or CH_2 deformation vibration. In this region FAH has three bands at 1441, 1390 and 1372 cm^{-1}, of which the 1441 cm^{-1} band is easily assigned to $\delta_a(CH_3)$, while the other two bands are probably due to either $\delta_s(CH_3)$ or δ(CH). These deformation bands can not be determined in the spectra of *N*-deuterated derivatives of CAH and FAH because of the overlap of the amide II band.

Rocking vibrations of the CH_3 and CH_2 groups can also concern bands which are ordinarily shown in the range of 1200~800 cm^{-1}. DAH has rocking CH_3 bands at 1027 and 1016 cm^{-1} **. CAH has two bands at 1041 and 996 cm^{-1} which can probably be ascribed to the rocking CH_3 or CH_2 vibrations. For *N*-deuterated CAH, corresponding bands are found at 1103 and 1030 cm^{-1}. In this region FAH has a relatively intense band at 1093 cm^{-1} and three weaker bands at 1038, 1018 and 995 cm^{-1}. *N*-Deuterated FAH has six rather weak corresponding bands. C–H out-of-plane deformation vibrations are also to be related to one of them. For sodium diformylhydrazine[2], two bands due to the out-of-plane deformation vibrations have been obtained at 1026 and 974 cm^{-1}. In consequence, the four bands of FAH can not definitely be assigned, but it is sure that they are due to either the CH_3 rocking or the CH out-of-plane deformation vibrations.

An in-plane bending O=C–N band has been obtained at 753 cm^{-1} for DFH[3]. The 784 cm^{-1} band of FAH is also probably due to δ(O=C–N). The corresponding band of *N*-deuterated FAH is observed at 769 cm^{-1}. Further, DFH[3] has the out-of-plane bending N–H band at 770 cm^{-1}, while no band corresponding to it is observed for FAH. In the region examined, neither the δ(O=C–N) nor the π(N–H) is observed for CAH.

On the other hand, DAH has the 921 cm^{-1} band which is to be ascribed to the C–CH_3 stretching vibration[4]. No corresponding band for FAH is observed, while CAH has the 914 cm^{-1} band which is assigned to ν(C–CH_3),

and the corresponding band of *N*-deuterated CAH is found at 881 cm^{-1}.

CAH has a further band at 2270 cm^{-1} which can possibly be assigned to the stretching C≡N vibration because the frequency hardly changes on *N*-deuteration.

DAH has four bands at 1695, 1538, 1195 and 1112 cm^{-1}, none of which was interpreted by Yamaguchi[4]. The corresponding bands of CAH are found at 1710, 1538, 1200 and 1143 cm^{-1} respectively. Of these four bands, the one near 1700 cm^{-1} is also found for FAH; it may, therefore, be a combination band involving low frequency fundamentals. The 1538, 1195 and 1112 cm^{-1} bands of DAH might also be similar combination bands. However, FAH has a weak band at 1133 cm^{-1} which corresponds to the 1143 cm^{-1} band of CAH. A band at 1100 cm^{-1} of $HCONDNHCOCH_3$[3] and the one at 1165 cm^{-1} of $(CH_3CONH-)_2 \cdot H_2O$[4] were ascribed to the N-N stretching vibration. In consequence, the 1143 cm^{-1} band of CAH and the 1133 cm^{-1} band of FAH may possibly be ν(N-N). A corresponding band of *N*-deuterated CAH is not observed, while for *N*-deuterated FAH a band is found at 1143 cm^{-1}.

The observed frequencies of FAH and CAH and their assignments are summarized, with those of DFH[3] and DAH[10], in Table I.

10) For this compound the values of frequencies are obtained in the present study although their assignments depend on the work by Yamaguchi (see Ref. 2).

Solution Spectra.—The solution spectra of DPH, DAH and FAH are illustrated in Fig. 3 because they are typical.

All the hydrazides examined have a band near 3300 cm^{-1} which is probably due to a monomeric ν(N-H). Further, the hydrazides generally have the amide I band near 1690 cm^{-1} and a well-defined shoulder band on the high-frequency side. However, only FAH has two bands of nearly the same intensity. In spite of this, they are easily assigned to the amide I band, but further consideration will be given to the problem in a following section. The amide II band may not be observed in the solution spectra because of interference by solvent absorption. A band near 1200 cm^{-1} can be assigned to the amide III band because the frequencies are very close to the amide III band of the hydrazides in the solid state.

Characteristic Bands.—The N-H stretching and amide frequencies of the hydrazides of aliphatic acids and *N*-methyl acetamide are summarized in Table II.

In the solid state, simple *N*-mono-substituted amides show a very strong band (amide I) in the range 1680~1630 cm^{-1}, a strong band (amide II) in the range 1570~1515 cm^{-1} and a relatively weaker band (amide III) in the range 1305~1200 cm^{-1} [11]. Sodium hydrazides[2] with only one CONH group showed the amide I band in the normal range of secondary amides. The decrease in the

frequency of the amide I band may be characteristic of the hydrazides of aliphatic acids since all the hydrazides have this near 1600 cm^{-1} in the solid state. In a dilute solution the secondary amides show the amide I absorption in the range 1700~1670 cm^{-1} [11]. The hydrazides examined here have two amide I bands in acetonitrile. Thus, it may be expected that these two bands come from the coupling of two vibrations which are localized mainly on the C=O groups, as was pointed out for the hydrazides of aromatic acids in a previous paper[1]. Moreover, it is noteworthy that in the solution spectra the amide I band is shown at frequencies higher by ca. 100 cm^{-1} than that in the solid spectra. This fact was not seen for the secondary amides; e. g., *N*-methyl acetamide in an acetonitrile solution has an amide I band higher in frequency by ca. 20 cm^{-1} than that in the solid state.

The amide II band of the hydrazides examined here may also be characteristic. In the solid state the hydrazides have their amide II bands at ca. 1500 cm^{-1}, somewhat lower in frequency than those of secondary amides.

The amide III frequency of the hydrazides in the solid state lies near the lower limit of the normal range of 1305~1200 cm^{-1} for bands of the secondary amides. In the solution spectra the amide III frequency decreases by ca. 20 cm^{-1}. A similar decrease is found with *N*-methyl acetamide, as is indicated in Table II.

All the hydrazides examined in the solid state have N-H stretching bands near 3200 cm^{-1} which are also lower than those of many secondary amides. Miyazawa[3] postulated that the markedly decreased ν(N-H) frequency of diformylhydrazine was due to strong hydrogen bonding in the solid state. The strength of the hydrogen bond will be different from molecule to molecule. However, the hydrazides, with the exception of DFH, have a N-H band the frequency of which is very close to 3200 cm^{-1}. On the other hand, Davies et al.[12] examined the infrared absorption of *N*-methyl acetamide in acetonitrile and obtained a single monomeric ν(N-H) at 3398 cm^{-1}, 80 cm^{-1} lower than that in carbon tetrachloride. Therefore, they concluded that the N-H group was markedly solvated in acetonitrile. The hydrazides in acetonitrile also have an N-H band, the frequency of which is higher by ca. 110 cm^{-1} than that of a main N-H band in the solid spectra of the hydrazides. Further, the ν(N-H) frequency of the hydrazides in acetonitrile is still lower by ca. 90 cm^{-1} than that of *N*-methyl acetamide in the same solvent. The lower value of the ν(N-H) frequency is, therefore, found in both solid spectra and solution spectra of the hydrazides examined here. Such a decrease of the ν(N-H) frequency can not reasonably be explained as the effect of strong hydrogen bonding or solvation only. Thus, the decrease of ν(N-H) in frequency can also be taken as one of the characteristics of the hydrazides examined; namely, there is a coupling between

11) L. J. Bellamy, "The Infrared Spectra of Complex Molecules", Methuen & Co. Ltd., London (1954).

12) M. Davies, J. C. Evans and R. L. Jones, *Trans. Faraday Soc.*, **51**, 761 (1955).

two CONH groups of each hydrazide molecule in the solid state. Probably hydrazide molecules are nonplanar in solution, and the increase of the ν(N–H) frequency in the solution spectra may come from a decrease in the coupling between two CONH groups. In addition to the main 3200 cm^{-1} absorption, the hydrazides have a weak band near 3030 cm^{-1}. Its occurrence is in accordance with that of the band near 3080 cm^{-1} for the secondary amides.

Summary

The infrared absorption spectra of the hydrazides of aliphatic acids have been examined in the rock salt region. The N–H stretching frequencies are found near 3200 and 3030 cm^{-1} in the solid state and near 3320 cm^{-1} in dilute solution. The amide I band is seen near 1600 cm^{-1} in the solid state, while in solution there are two bands, near 1720 and 1690 cm^{-1}. In the solid state the amide II band appears near 1490 cm^{-1}. The amide III band is found near the lower limit of the normal range of 1305$\sim$1200 cm^{-1} for the secondary amides.

*The Chemical Reaction in Silent Electric Discharge. III. The Effect of the Packings on Ozone Formation**

By Kihei MORINAGA and Momotaro SUZUKI

(Received June 26, 1961)

In the previous reports on ozone formation in a silent electric discharge, the relation between the gap length, the electrode area and the pulse current was studied[1,2].

For the present paper, an investigation of the ozone formation from oxygen has been carried out using a special type discharge tube with some adequate fillings to serve as dielectrics.

Experimental

The apparatus and the procedure, except for the packings, are essentially the same as in the previous report[1]. The space between the electrodes was filled with a granular packing of titanous oxide ceramics whose dielectric constant varied in accordance with the percentage composition of the ingredients, such as barium oxide, or tin(IV) oxide. Ordinary soda glass packings with the same geometry were used as a check standard. The packings were made by "one time baking" to an amorphous mass, then by crushing the granules to 0.75~1.00 mm. size mesh, which is an adequate size for filling. The ozonizer was again of a Siemens type, which has a gap length of 2.6 mm. and an effective electrode area of 250 cm^2. The voidage of gap space with the packing was 47% of the total gap volume in each case.

The stoichiometric composition of the ceramics and their dielectric constant, at room temperature and at 1 kc, are given in Table I.

TABLE I

Number of runs	Composition of the packings	Dielectric constant
I	Blank	1
II	Soda glass	6
III	$2MgO/TiO_2$	20
IV	TiO_2	100
V	$BaTiO_3$	1200
VI	$95BaTiO_3/5SnO_2$	5500~6000

The frequency of the electric source for silent discharge was 50 c/sec. The electric circuit that provided a high tension to the discharge tube and the whole flow system with its detecting device for ozone were similar to those described in the previous work[1,2]. Through a packed tube a discharge current can be raised to such a value that eventually damage will occur to the usual ozonizer. For example, in the case of titanous oxide packing, a stable discharge will be established up to around 8 mamp. current, while the maximum ozone concentration will be somewhat over 6.5%. The pulse current

* Presented at the 11th Annual Meeting of the Chemical Society of Japan, Tokyo, April 1958.

2) K. Morinaga and M. Suzuki, ibid., **35**, 204 (1962).

was measured by the device of the oscillogram with an integral circuit that inserted a series to the earth line of discharge tube. The pulse current will be less than that of an ozonizer of the same type without any packing.

Results

All measurements were carried out with a residence time of the reactant gas of 1.5~80 sec. in the ozonizer.

Figure 1 represents the saturated state ozone concentration under a certain constant total discharge current, and Fig. 2 represents the saturated state ozone concentration under a certain constant pulse current. In both figures, the results are plotted against the value of the dielectric constant of the packing materials, and the location at the value of 1 on the abscissa represents the results that were obtained in a blank discharge tube without any packing fill. Under a constant discharge current, the maximum value of the saturation ozone concentration appears at the packing of titanium(IV)

oxide, whose dielectric constant is around 100. In the case of a constant pulse current, the maximum saturation ozone concentration occurs at the dielectric constant value of about 1200 of $BaTiO_3$.

Under the same conditions as in Figs. 1 and 2, the rate (mg./sec.) of ozone formation is plotted in Figs. 3 and 4 against the same abscissa as before. The curves in Fig. 3, where the parameter of each diagram is the discharge current, do not show any regular feature, whereas in Fig. 4, where the parameter is pulse current, the rate of ozone formation at a higher value of dielectric constant is nearly independent of the dielectric constant value of the packing materials. In Fig. 5, the ozone formation rates for various ceramics fillings of different dielectric constants against the pulse current are shown. The rates for each packings, independent of the dielectric constant values, are represented by a straight line whose inclination has a value of 3.3×10^{-3} mg. sec^{-1} μamp^{-1}.

The observed number of hairs of the packing fill ozonizer is more than that of the usual ozonizer without packings where all other conditions are the same.

Discussion

It is highly conceivable that the surface of the dielectric packing is partly electrically conductive. The conductivity will increase in accordance with the higher value of the dielectric constants. At the application of some electric tension between the electrodes, the current will be carried in two ways, one by the discharge current through the gas phase, and the other along the surface leakage. In the oscillogram pattern, the discharge current will manifest itself as pulse current or hair on the base current pattern, where the leakage current is implied together with the basic current.

The presence of the packing is equivalent to the larger value of the electrode area and the small value of gap length, which leads to the conclusion that rate of ozone formation should be higher with a packing-filled ozonizer.

The mean value of the ozone formation rates per unit pulse current for discharge tubes with a filling whose dielectric constant in each case has a different value, was 3.3×10^{-3} mg. sec^{-1} μ amp^{-1}.

In the case of 50 c/sec. discharge and for unit A/d, the corresponding rate is 7.0×10^{-7} mg. sec^{-1} μ amp^{-1} [1], were A is the electrode area and d is the gap length.

The experimental conditions are about the same for both cases, the exception being the packing fill. The rate value should be proportional to the A/d value in both cases. The assumed A/d value for the packed discharge tube is 4.7×10^{3} cm., which means a very large electrode area and/or a very small gap length. In the above pattern of discharge in packed ozonizers, the discharge potential, then, will be appreciably smaller than in the usual ozonizer, which fact accounts for the larger number of hairs and the larger value of the formation rate. The discharge current involves two contributions, the gas discharge and the surface leakage. For a certain fixed value of discharge current, the discharge contribution will increase at first with the increase of ozone formation, because in an ozonizer, absorbed electric energy which is to be proportional to the ozone formation is proportional to the total capacity C, where C is given by

$$1/C=1/C_g+1/C_a$$

in which C_g is the capacity of glass or dielectrics, which is proportional to the value of the dielectric constant, and C_a the capacity of the air gap. On the other hand, the surface leakage effect will increase in company with the increase of the dielectric constant of the fillings, and above a certain value of the ozone formation rate it will begin to decrease according to the increasing leakage current under a certain fixed discharge current, because the leakage current does not benefit the ozone yield. These patterns explain the features of the diagrams in Figs. 1 and 3.

The pulse currents represents only the quantity of discharge electricity through the air gap space, while the base current, in an oscillogram, implies the leakage electricity. For a certain

amount of discharge electricity, or pulse current, the ozone formation should be the same no matter what the value of the dielectric constant of the filled packing, because the rate is referred to the value at zero time of residence and is, therefore, governed solely by the discharge quantity of electricity.

The ozone concentration is the complicated results of reaction under which the gas is exposed for a certain period of residence. It is, therefore, no wonder that the diagram in Fig. 2 does not show any regularity. However, it arouses rather a practical interest that the packing of titanium(IV) oxide under a certain constant total discharge current shows the maximum value. Rummel also uses in his patent** layers of ceramic substances containing titanium(IV) oxide with a dielectric constant of 80 for the preparation of ozone.

In conclusion, the application of the packing in an ozonizer makes two contributions to ozone formation, the one due to the shortening of the gap distance, which is equivalent to the expansion of the electrode area, and the other corresponding to the enhancement of the dielectric constant on the wattage absorbed in the ozonizer and on the leakage current along the surface of the packing. These effects benefit the ozone formation by exempting the adverse effect of leakage current, which will increase according to the increasing value of the dielectric constant.

** T. Rummel, German Pat. 1028544 (April 24, 1958).

Summary

1. The ozone formation rate was increased in a packed discharge tube more than in the same type of ozonizer without packing.

2. The linear relationship, which has been proved before, between the pulse current and the ozone formation rate was also obtained in this case, independent of the dielectric constant value of the packing materials.

3. The ozone concentration shows a maximum value at a certain value of the dielectric constant.

4. The rate of ozone formation is independent of the dielectric constant at the higher values of the dielectric constant.

5. A tentative mechanism which is plausible for the elucidation of the results has been discussed.

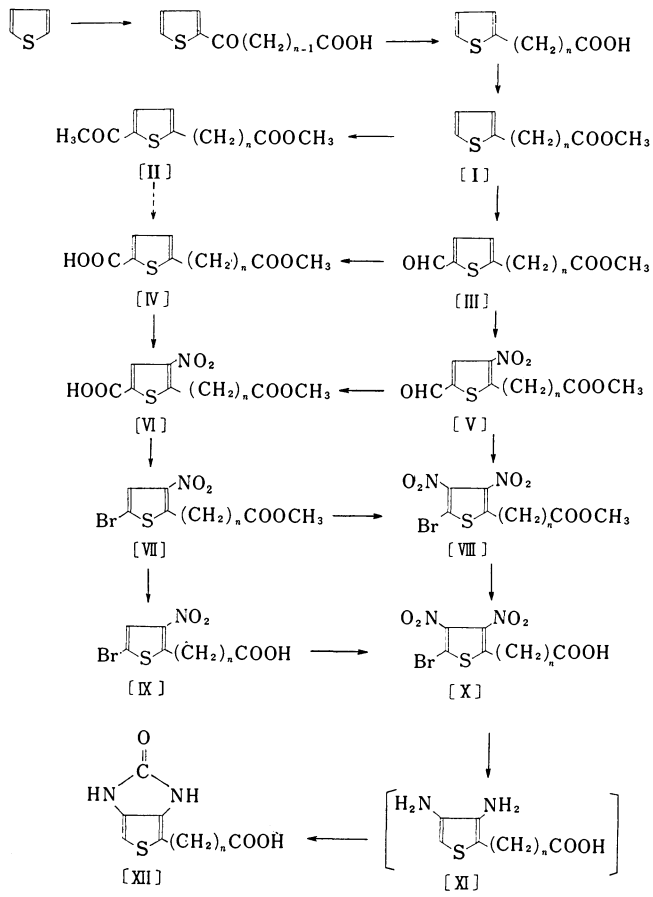
Studies on Thiophene Compounds. XIX. Syntheses of 2, 3, 4, 5-Tetradehydrobiotin and 2, 3, 4, 5-Tetradehydronorbiotin[1]

By Shoji NISHIMURA and Eiji IMOTO



(Received June 30, 1961)

Biotin is a very important growth-promoting factor for yeast and other micro-organisms. Since Harris[2] and his co-workers first synthesized biotin, various methods have been reported by many authors. However, all of the methods proposed required many steps for the synthesis, and consequently the over-all yield was low. According to the patent[3], biotin can be prepared with the hydrogenation of 2, 3, 4, 5-tetradehydrobiotin (or so-called aromatic biotin). In the present paper are reported the syntheses of aromatic biotin and of aromatic norbiotin, which has one less methylene group in the side chain than does aromatic biotin. Both of the compounds were synthesized by starting with thiophene. The following procedures were followed.

Results and Discussion

In the preparation of the aromatic biotin and the aromatic norbiotin, it was most difficult to introduce two amino groups into the 3- and 4-positions of the thiophene nucleus. It has been known that the nitration of 2, 5-dibromo-, 2, 5-dichloro- and 2, 5-dimethyl-thiophene gives the 3, 4-dinitro-derivatives of the respective starting compounds[4-6]. An attempt was thus made to introduce a nitro group into

(n=3 or 4)

the vacant 4-position of the thiophene nucleus of 4-(5-bromo-2-thienyl)-butyric acid, but the result was unsuccessful. Nitration under severe conditions caused an oxidative decomposition and gave merely tarry material. No nitrated product was obtained from 5-bromo-2-methylthiophene either. As has been mentioned in another paper[7] of this series, ω-(5-bromo-2-thenoyl)-fatty acid can be nitrated at the 4-position. It must, therefore, be easier to introduce a nitro group into the 4-position if an electron-releasing amino group is placed in the neighboring 3-position. However, the nitration of 3-(3-acetylamino-5-bromo-2-thenoyl)-propionic acid unexpectedly gave 3-acetylamino-5-bromo-2nitro-thiophene, which was produced as the result of the replacement of the succinoyl group by the nitro group in the 2-position. From this experimental result, it could be deduced that the 3-acetylamino group can not promote an electrophilic substitution at the 4-position. As the third method to introduce an amino group into a β-position of the thiophene nucleus, there is the amination of β-halogenothiophenes, in which method the halogene atom is activated by a nitro or a carboxyl group. According to this scheme, an amination of 3-bromo-4-nitro-2-thiophenecarboxylic acid was carried out by the method mentioned in an earlier paper[8] of this series, but no aminated product was obtained. In general, a nitro group can be introduced into the 3-position of the thiophene nucleus when the thiophene nucleus has an electron-releasing group such as chloro or alkyl group in the 2-position and an electron-withdrawing group such as formyl or acetyl group in the 5-position. It is, however, impossible to introduce an additional nitro group to the 4-position after the first nitration has been carried out. As reported in a previous paper[9] of this series, it is necessary to put an electron-releasing group in the 5-position in order to introduce the second nitro group, which has to be

neighbored by the first nitro group at the 3-position. The formyl or acetyl group in the 5-position, which is necessary for the introduction of the first nitro group, can be converted to a bromo group by Hunsdiecker's reaction after its oxidation to the carboxylic acid. As the aromatic biotin and the aromatic norbiotin have a ω-caboxybutyl and a ω-carboxypropyl group respectively, the free terminal carboxyl group may simultaneously be replaced by a bromo group by Hunsdiecker's reaction. To avoid this complication, it is necessary to protect the carboxyl group by a method such as esterification. According to this scheme, methyl 4-(5-acety-2-thienyl)-butyrate was oxidized with sodium hypochlorite with the intention of preparing methyl 4-(5-carboxy-2-thienyl)-butyrate, but the oxidation yielded dicarboxylic acid, which was produced by the simultaneous saponification of the terminal methyl ester. Even isopropyl 4-(5-acetyl-2-thienyl)-butyrate, which is expected to resist saponification, was useless for the purpose of oxidation without saponification. This means that alkaline oxidation can not prevent simultaneous saponification. As an alternative method, methyl 4-(5-formy-2-thienyl)-butyrate, prepared by the formylation of methyl 4-(2-thienyl)-butyrate, was oxidized by chromic acid in acetic acid, and thus methyl 4-(5-carboxy-2-thienyl)-butyrate was obtained. Although methyl 4-(5-carboxy-3-nitro-2-thienyl)-butyrate was prepared with the nitration of methyl 4-(5-carboxy-2-thienyl)-butyrate, the oxidation of methyl 4-(5-acetyl-3-nitro-2-thienyl)-butyrate prepared by the nitration of methyl 4-(5-acetyl-2-thienyl)-butyrate gave a more favorable result. Similarly, methyl 5-(5-carboxy-3-nitro-2-thienyl)-valerate was obtained by the oxidation of methyl 5-(5-formyl-3-nitro-2-thienyl)-valerate in acetic acid. The carboxyl group thus obtained was converted to the bromine atom by Hunsdiecker's reaction. Then, 4-(5-bromo-3, 4-dinitro-2-thienyl)-butyric and -valeric acids were derived through the nitration of methyl ω-(5-bromo-3-nitro-2-thienyl)-butyrate and -valerate respectively, followed by the saponification of the terminal methyl ester. When ω-(5-bromo-3, 4-dinitro-2-thienyl)-butyric and -valeric acids were treated with tin and hydrochloric acid, 3, 4-dinitro groups were reduced to 3, 4-diamino groups and the 5-bromo atom was eliminated by reduction. As 3, 4-diaminothiophenes are unstable in an atmosphere of air, the reduced products were not isolated, and the double salts of the diamino-compounds with tin chloride were treated with phosgene after decomposition with an alkaline solution to obtain the aromatic biotin and the aromatic norbiotin respectively. The aromatic biotin obtained here was identical to that obtained by Cheney[10] and his co-workers by another method.

Experimental

4-(5-Bromo-2-thienyl)-butyric Acid.—Into a solution of 4-(2-thienyl)-butyric acid[11] (6 g.) in 50% aqueous acetic acid (65 ml.) was slowly stirred, drop by drop, a solution of bromine (1.85 ml.) in 50% aqueous acetic acid (47 ml.) at $-8\sim-10$°C over a period of 2 hr. After the addition was completed, the reaction mixture was stirred at the same temperature. The crystals which were precipitated from the reaction mixture by the addition of water (100 ml.) were collected by filtration, washed with water and recrystallized from methanol-water. The yield of 4-(5-bromo-2-thienyl)-butyric acid (m. p. 58$\sim$59.5°C) was 56% after recrystallization.

Found: Br, 31.45; Neut. equiv., 250. Calcd. for $C_8H_9O_2BrS$: Br, 32.08%; Neut. equiv., 249.

Nitration of 4-(5-Bromo-2-thienyl)-butyric Acid. — Into a solution of 4-(5-bromo-2-thienyl)-butyric acid (2.5 g.) in acetic anhydride (10 ml.) was slowly stirred mixture of concentrated nitric acid (2 ml.), acetic anhydride (10 ml.) and acetic acid (10 ml.) at $-5\sim-10$°C. The reaction mixture was stirred for 30 min. at the same temperature after the additon and then poured into ice-water. An oily product was separated and solidified after the mixture had been left to stand for several days. The solid collected, m. p. 56$\sim$58°C after recrystallization from methanol-water, did not show a depression of the melting point on mixing with the starting compound. A nitration of 4-(5-bromo-2-thienyl)-butyric acid with a mixed acid consisting of sulfuric acid and nitric acid at 0$\sim$5°C also gave merely a brown tarry matter.

Nitration of 2-Bromo-5-methylthiophene. — A nitration of 2-bromo-5-methylthiophene[12] with a mixed acid consisting of concentrated nitric acid and concentrated sulfuric acid merely gave a brown tarry matter; no crystalline products were separated.

Nitration of 4-Acetylamino-2-bromo-5-thenoyl-propionic Acid.—4-Acetylamino-2-bromo-5-thenoyl-propionic acid[13] (0.32 g.) was stirred into sulfuric acid (2 ml.) which had been greatly cooled by the addition of pieces of dry ice. Into the above viscous solution was stirred dropwise a mixed acid consisting of concentrated nitric acid (0.17 ml.) and concentrated sulfuric acid (0.1 ml.) at a temperature below -20°C. The reaction temperature was kept constant by the frequent addition of small pieces of dry-ice. After adding the mixed acid, the reaction mixture was stirred for one hour and then diluted with iced water. The precipitates were collected by filtration, washed with water and recrystallized from methanol. The pale yellow needles obtained melted at 174$\sim$175°C, produced no 2, 4-dinitrophenylhydrazone, and must be 4-acetylamino-2-bromo-5-nitrothiophene.

Found: C, 26.65; H, 2.09; N, 10.11. Calcd. for $C_6H_5O_3BrN_2S$: C, 27.1; H, 1.89; N, 10.05%.

Oxidation of Methyl 4-(5-Acetyl-2-thienyl)-butyrate with Sodium Hypobromite. — A solution of sodium hypobromite was prepared by stirring 5 ml. of bromine into a solution of sodium hydroxide (10 g.) in water (15 ml.) and ice (40 g.) below 0°C. Methyl 4-(5-acetyl-2-thienyl)-butyrate (4 g.) was added to the solution of sodium hypobromite prepaped above and stirred for 5 hr. at 5~10°C. An aqueous solution of sodium bisulfite was added under ice-cooling to the reaction mixture to decompose an excess of sodium hypobromite. After removing the bromoform and carbon tetrabromide by an extraction with ether, the alkaline aqueous layer was acidified. The colorlesss precipitates (1.6 g.) were collected by filtration, washed with water and recrystallized from water, m. p. 192~194°C. The neutralization equivalent of the crystals was 110, which coincided with the calculated value (107) for 4-(5-carboxy-2-thienyl-butyric acid. The mixed melting of the crystals with the authentic sample, which had been synthesized by the oxidation of 4-(5-acetyl-2-thienyl)-butyric acid (m. p. 193~194.5°C), showed no depression.

Isopropyl 4-(2-Thienyl)-butyrate.—A solution of 50 g. of 4-(2-thienyl)-butyric acid in 80 ml. of ether was refluxed, together with 30 ml. of thionyl chloride and few drops of pyridine, for 4 hr. Ether and an excess of thionyl chloride were distilled off in vacuo. The residue was dissolved in a solution of dimethylaniline (40 g.) and isopropyl alcohol (20 g.) and refluxed for 4 hr. After cooling, the reaction mixture was poured into diluted hydrochloric acid and extracted with ether. The ethereal extract was washed successively once each with diluted hydrochloric acid and with an aqueous solution of sodium bicarbonate, and then dried over anhydrous sodium sulfate. After distilling off the ether, the distillation under reduced pressure gave 52 g. of isopropyl 4-(2-thienyl)-butyrate, b. p. 140~149°C.

Found: C, 61.88; H, 7.38. Calcd. for $C_{11}H_{16}O_2S$: C, 62.26; H, 7.55%.

Isopropyl 4-(2-Acetyl-5-thienyl)-butyrate.—Twenty grams of isopropyl 4-(2-thienyl)-butyrate were heated and stirred with acetic anhydride (11 ml.) and phosphoric acid (0.8 ml.) for 4 hr. at 100~110°C. After cooling, the reaction mixture was poured into water, neutralized with powdered sodium carbonate, and extracted with ether. The ether portion was washed with water and dried over anhydrous sodium sulfate. After distilling off the ether, the distillation under reduced pressure gave 20.5 g. of isopropyl 4-(2-acetyl-5-thienyl)-butyrate (b. p. 185~188°C/3.5 mmHg), which solidified after cooling with dry-ice. After the recrystallization from petroleum ether, crystals of m. p. 15~16.5°C were obtained.

Found: C, 61.38; H, 7.10. Calcd. for $C_{13}H_{18}O_3S$: C, 61.42; H, 7.08%.

Oxidation of Isopropyl 4-(2-Acetyl-5-thienyl)-butyrate with Sodium Hypobromite.—To a solution of sodium hypobromite, which had been prepared from sodium hdydroxide (20 g.), water (7 ml.) and bromine (2.4 ml.) by the method similar to that mentioned in the case of (II (n=3)), a solution of isopropyl 4-(2-acetyl-5-thienyl)-butyrate (4 g.) in dioxane (6 ml.) was added and stirred below 10°C for 3 hr. After treating the reaction mixture by a usual method, 1.7 g. of crude acid (m. p. 186~193°C) were obtained and recrystallized from water, m. p. 192~194°C. The mixed melting point with an authentic sample of 4-(2-carboxy-5-thienyl)-butyric acid showed no depression.

Methyl 4-(5-Formyl-2-thienyl)-butyrate (III (n=3)). — A solution of methyl 4-(2-thienyl)-butyrate (4.3 g.) in dimethylformamide (2.5 g.) was slowly combined with oxyphosphorus chloride (2.5 g.) and kept for 2 hr. at 110°C while frequency being shaken. The reaction mixture was poured into water, neutralized with sodium carbonate and extracted with ether. The ethereal extract was washed with water and dried over anhydrous sodium sulfate. After distilling off the ether, the residue was distilled under reduced pressure to obtain methyl 4-(5-formyl-2-thienyl)-butyrate in a yield of 67.5% (3.5 g.), b. p. 172~175°C.

Found: C, 62.18; H, 7.50. Calcd. for $C_{10}H_{12}O_3S$: C, 62.26; H, 7.55%.

Methyl 4-(5-Carboxy-2-thienyl)-butyrate (IV (n=3)).—A mixture of methyl 4-(5-formyl-2-thienyl)-butyrate (III (n=3)) (1.2 g.), acetic acid (10 ml.) and sodium bichromate (1.5 g.) was stirred at 60~70°C for 7 hr. After cooling, cold water and 5 g. of sodium carbonate were added to the reaction mixture to precipitate green crystals. The crystals were extracted with ether. The ether extract was was washed with water and treated with a saturated aqueous solution of sodium bicarbonate. The aqueous portion was acidified with hydrochloric acid, and the colorless precipitates obtained were colleted by filtration and washed with water, m. p. 79.5~81°C. This acid was methyl 4-(5-carboxy-2-thienyl)-butyrate, as is shown in the following analytical results.

Found: Neut. equiv., 226; Sapon. equiv., 112. Calcd. for $C_{10}H_{12}O_4S$: Neut. equiv., 228; Sapon. equiv., 114.

Methyl 4-(5-Formyl-3-nitro-2-thienyl)-butyrate (V(n=3)).—Methyl 4-(5-formyl-2-thienyl)-butyrate (6 g.) was dissolved in ice-cooled concentrated sulfuric acid (30 ml.). Into this solution was slowly stirred the mixed acid consisting of concentrated nitric acid (8.7 ml.) and concentrated sulfuric acid (30 ml.), while the reaction temperature was kept below −5°C by means of the frequent addition of small pieces of dry ice. After this addition, the reaction mixture was stirred for 15 min. at the same temperature and then poured into ice water to afford the precipitations of crude methyl 4-(5-formyl-3-nitro-2-thienyl)-butyrate (7.2 g.). The precipitates obtained were recrystallized from ligroin, m. p. 70.5~72.5°C. Yield, 82%.

Found: N, 5.48. Calcd. for $C_{10}H_{11}O_5NS$: N, 5.44%.

2,4-Dinitrophenylhydrazone: m. p. 202~203.5°C (recrystallized from methanol).

Found: N, 10.49. Calcd. for $C_{16}H_{15}O_8N_3S$: N, 10.27%.

Methyl 4-(5-Carboxy-3-nitro-2-thienyl)-butyrate (VI (n=3)).—A mixture of methyl 4-(5-formyl-3-nitro-2-thienyl)-butyrate (7.5 g.), acetic acid (60 ml.) and sodium bichromate (10 g.) was stirred at 60~

70°C for 6.5 hr. and then poured into iced water to precipitate pale green crystals. After adding 30 g. of sodium carbonate slowly under ice-cooling, the reaction mixture was extracted with ether, and the ether portion was washed with water and shaken with a cold aqueous saturated solution of sodium bicarbonate. Acidification of the alkaline solution afforded a precipitation of methyl 4-(5-carboxy-3-nitro-2-thienyl)-butyrate, m. p. 95~96.5°C. Yield, 4.45 g. (56%).

Found: N, 5.23; Neut. equiv., 276. Calcd. for $C_{10}H_{11}O_6NS$: N, 5.13%; Neut. equiv., 273.

Other Method. — 1) Into a solution of methyl 4-(5-formyl-3-nitro-2-thieny)-butyrate (4 g.) in acetone (200 ml.) was stirred potassium permanganate (4.5 g.) in small portions at 0~5°C. After the addition was completed, stirring was continued at the same temperature for two hours. To the reaction mixture was added 10 ml. of methanol, and it was again stirred for ten minutes. Acetone and methanol were distilled off under reduced pressure, and to the residue was added a cold aqueous saturated solution of sodium bicarbonate. The precipitates were removed by filtration, and the filtrate was acidified with hydrochloric acid under ice-cooling to afford precipitation of crystal (m. p. 92~94°C). The mixed melting point of the crystals with the 4-(5-carboxy-3-nitro-2-thienyl)-butyrate obtained above showed no depresssion. The yield was 55%.

2) A mixed acid consisting of 1.4 ml. of concentrated nitric acid and 5 ml. of concentrated sulfuric acid was slowly stirred at −5~0°C into a soluion of methyl 4-(5-carboxy-2-thienyl)-butyrate (1 g.) in concentrated sulfuric acid (200 ml.). After this addition, the reaction mixture was stirred for 15 min. at the same temperature and then poured into iced water to cause the precipitation of viscous matter. The viscous matter which solidified after standing was dissolved in ether. The ethereal solution was extracted with a cold aqueous saturated solution of sodium bicarbonate; then the alkaline solution was acidified with hydrochloric acid to precipitate crystals of m. p. 92~95°C. The precipitates showed no depression of the melting point on mixing the methyl 4-(5-carboxy-3-nitro-2-thienyl)-butyrate obtained above. The yield was 33%.

Methyl 5-(2-Thienyl)-valerate (I (*n*=4)). — A solution of 5-(2-thienyl)-valeric acid[14] (100 g.) in 500 ml. of methanol was saturated with dry hydrochloric acid and refluxed for 7 hr. After distilling off the methanol, the residue was poured into iced water and then extracted with ether. The ether extract was washed with water and dried over anhydrous sodium sulfate. After distilling off the ether, the residue was distilled under reduced pressure to give methyl 5-(2-thienyl)-valerate in a yield of 85.5% (92 g.), b. p. 139~143°C/13 mmHg.

Found: C, 66.02; H, 7.81. Calcd. for $C_{10}H_{14}O_2S$: C, 66.66; H, 7.77%.

Methyl 5-(5-Formyl-2-thienyl)-valerate (III (*n*=4)).—A formylation of methyl 5-(2-thienyl)-valerate similar to that of methyl 4-(2-thienyl)-butyrate gave methyl 5-(5-formyl-2-thienyl)-valerate in a yield of 79%, b. p. 182~186°C/6 mmHg, m. p. 63~64°C.

Found: C, 58.16; H, 6.15. Calcd. for $C_{11}H_{14}O_3S$: C, 58.41; H, 6.19%.

Methyl 5-(5-Formyl-3-nitro-2-thienyl)-valerate (V (*n*=4)).—A nitration of methyl 5-(5-formyl-2-thienyl)-valerate similar to that of methyl 5-(5-formyl-2-thienyl)-butyrate gave methyl 5-(5-formyl-3-nitro-2-thienyl)-valerate as an oily product in a yield of 91.7%.

Methyl 5-(5-Carboxy-3-nitro-2-thienyl)-valerate (VI (*n*=4)).—This compound was obtained with an oxidation of methyl 5-(5-formyl-3-nitro-2-thienyl)-valerate with sodium bichromate in a yield of 59%, or with potassium permanganate in a yield of 76%, when the treatment was similar to that of methyl 4-(5-formyl-3-nitro-2-thienyl)-butyrate. The melting point of the crystals obtained was 37~38.5°C.

Found: N, 4.84; Neut. equiv., 288. Calcd. for $C_{11}H_{13}O_6NS$: N, 4.88%; Neut. equiv., 287.

Methyl 4-(5-Bromo-3-nitro-2-thienyl)-butyrate (VII (*n*=3)).—To an exactly neutralized solution of methyl 4-(5-carboxy-3-nitro-2-thienyl)-butyrate (2.5 g.) with a 1% aqueous solution of sodium hydroxide was added 1 N silver nitrate to precipitate colorless silver salt. The silver salt was collected by filtration, washed with water, dried at 100~110°C, powdered and then completely dried again over phosphorus pentoxide in a vacuum desiccator. To a refluxing suspension of the silver salt in dry carbon tetrachloride (25 ml.) was slowly added bromine (0.46 g.) in carbon tetrachloride (5 ml.). The addition required 30 min. After the addition, refluxing was continued for 1 hr. The reaction mixtue was filtered while it is hot and the solid obtained was washed twice with 140 ml. of hot carbon tetrachloride. The combined filtrate and washed liquor was washed successively with a solution of sodium bisulfite and a cold solution of sodium bicarbonate and then with water and dried over anhydrous sodium sulfate. Distilling off the carbon tetrachloride yielded a solid material, which was purified by washing with petroleum ether. The yield of methyl 4-(5-bromo-3-nitro-2-thienyl)-butyrate was 82% (2.32 g.). After recrystallization from petroleum ether, the melting point of the crystals was 49~51°C.

Found: N, 4.52. Calcd. for $C_9H_{10}O_4BrNS$: N, 4.54%.

Methyl 5-(5-Bromo-3-nitro-2-thienyl)-valerate (VII (*n*=4)). — Methyl 5-(5-carboxy-3-nitro-2-thienyl)-valerate (5 g.) was treated by the same procedure as described above to prepare methyl 5-(5-bromo-3-nitro-2-thienyl)-valerate (3 g.) in a yield of 53.5%. The product was an oily matter.

5-(5-Bromo-3-nitro-2-thienyl)-valeric Acid (IX (*n*=4)). — A solution of methyl 5-(5-bromo-3-nitro-2-thienyl)-valerate (5 g.) in acetic acid (80 ml.) and concentrated hydrochloric acid 50 ml.) was refluxed for one hour, filtered while hot by adding active charcoal, then diluted with water to precipitate crystals of 5-(5-bromo-3-nitro-2-thienyl)-valeric acid in a yield of 94% (4.5 g.), m. p. 99~102°C. The crystals were recrystallized from acetic acid-water, m. p. 102~103.5°C.

Found: N, 4.56; Neut. equiv., 307. Calcd. for $C_9H_{10}O_4BrNS$: N, 4.54%; Neut. equiv., 308.

14) P. Cagniant and A. Deluzarche, *Compt. rend.*, 222, 1301 (1946).

Methyl 4-(5-Bromo-3, 4-dinitro-2-thienyl)-butyrate (VIII (n=3)).—A mixed acid consisting of concentrated nitric acid (0.21 ml.) and concentrated sulfuric acid (1 ml.) was added slowly to a solution of methyl 4-(5-bromo-3-nitro-2-thienyl)-butyrate (1 g.) in concentrated sulfuric acid (3 ml.) at 5~10°C. After this addition, the reaction mixture was stirred for 30 min., then poured into iced water to precipitate crystals of methyl 5-(5-bromo-3,4-dinitro-2-thienyl)-butyrate. The crystals were collected by filtration and washed with water. The melting point of the crude product was 54~56.5°C, and the yield was 96% (1.1 g.). Recrystallization from ligroin raised the m. p. to 56.5~58°C.

Found: N, 7.96. Calcd. for $C_9H_9O_6BrN_2S$: N, 7.93%.

Methyl 5-(5-Bromo-3, 4-dinitro-2-thienyl)-valerate (VIII (n=4)). — Methyl 5-(5-bromo-3-nitro-2-thienyl)-valerate (5 g.) was treated similarly to the above compound to prepare methyl 5-(5-bromo-3,4-dinitro-2-thienyl)-valerate in a yield of 88% (6 g.) as a crude product, m. p. 57~60.5°C. After recrystallizing from ligroin-benzene, the melting point was 59.5~61.5°C.

Found: N, 7.59. Calcd. for $C_{10}H_{11}O_6BrN_2S$: N, 7.63%.

4-(5-Bromo-3, 4-dinitro-2-thienyl)-butyric Acid (X (n=3)).—A solution of methyl 4-(5-bromo-3,4-dinitro-2-trienyl)-butyrate (0.5 g.) in concentrated hydrochloric acid (15 ml.) was refluxed for 4 hr., then diluted with water after cooling to afford precipitation of crude 4-(5-bromo-3,4-dinitro-2-thienyl)-butyric acid (m. p. 134~136°C) in a yield of 87.5%. After recrystallization from 6 N-AcOH, the m. p. was 135~136.5°C.

Found: N, 8.18; Neut. equiv., 342. Calcd. for $C_8H_7O_6BrN_2S$: N, 8.26%; Neut. equiv., 339.

5-(5-Bromo-3, 4-dinitro-2-thienyl)-valeric Acid (X (n=4)).—A solution of methyl 5-(5-bromo-3,4-dinitro-2-thienyl)-valerate (2.4 g.) in acetic acid (50 ml.) and concentrated hydrochloric acid (50 ml.) was refluxed for one hour, then diluted with water after cooling to afford a precipitate of crude 5-(5-bromo-3,4-dinitro-2-thienyl)-valeric acid in a crude yield of 91% (2.1 g.). After recrystallization from 6 N-AcOH, the m. p. was 132~133°C.

Found: N, 7.90; Neut. equiv., 356. Calcd. for $C_9H_9O_6BrN_2S$: N, 7.93%; Neut. equiv., 353.

When acetic acid was not used as the solvent, tarry matter was produced as a by-product and the yield of the acid was lowered to 35%.

Another Method. — A mixed acid consisting of 0.2 ml. of concentrated nitric acid and 2 ml. of concentrated sulfuric acid was slowly stirred into a solution of 5-(5-bromo-3-nitro-2-thienyl)-valeric acid (0.9 g.) in concentrated sulfuric acid (8 ml.) at 0~5°C. After this addition, the reaction mixture was stirred for 15 min., and the reaction temperature was gradually raised to 10°C while being stirred. The reaction mixture was poured into ice-water. The crystals precipitated were collected by filtration, then washed with water. The yield of crude 5-(5-bromo-3,4-dinitro-2-thienyl)-valeric acid (m. p. 128~132°C) was 87% (0.9 g.). After recrystallization from acetic acid-water, the melting point of the crystals was 132~133°C. No depression of the melting point on mixing them with the compound prepared by the alternative method was observed.

Aromatic-Norbiotin (XII (n=3)).—A suspension of 0.4 g. 4-(5-bromo-3,4-dinitro-2-thienyl)-butyric acid in 10 ml. of concentrated hydrochloric acid was stirred, together with 0.8 g. tin in small pieces, at 25~30°C untill the tin disappeared, then evaporated to dryness in vacuo to obtain colorless tin double salt. The tin double salt was dissolved in 20 ml. of water and a solution of potassium hydroxide while bing cooled by ice; then immediately phosgen was introduced into the solution. The introduction phosgen was continued until the solution became acidic to Congo red paper. The crystals precipitated during the introduction of the phosgen were collected by filtration, washed with water and recrystallized from methanol-water to obtain curde product (m. p. 228~230°C decomp.) in a yield of 0.12 g. (45%). The melting point of the crystals was 244~245°C decomp. after recrystallization from water.

Found: N, 12.46. Calcd. for $C_9H_{10}O_3N_2S$: N, 12.93%.

The absorption maximum (λ_{max}) in a ultraviolet spectrum (solvent: ethanol): 260 mμ.

Aromatic-Biotin (XII (n=4)).—5-(5-Bromo-3,4-dinitro-2-thienyl)-valeric acid (0.4 g.) was similarly treated to obtain crude aromatic-biotin (m. p. 236~238°C decomp.) in a yield of 70% (0.2 g.). After recrystallizing them from water, the melting point of the crystals was 253~254°C decomp. (The meltint point given in the literature was 254~254.5°C decomp.). The λ_{max} (in ethanol as solvent) in ultraviolet spectrum was 260 mμ (coinciding with the value, 260 mμ given in the literature).

Found: N, 11.49. Calcd. for $C_{10}H_{12}O_3N_2S$: N, 11.67%.

O→*N*-Acetyl Shift of *O*-Acetylserine and *O*-Acetylthreonine. An Approach to the Separation of Serine and Threonine Fraction from Amino Acid Mixture

By Sadao FUJIWARA, Shigeru MORINAGA and Kozo NARITA

(Received June 30, 1961)

In relation to the modification of proteins, the *N*→*O*-peptidyl shift of serine and threonine residues in proteins through the influence of concentrated sulfuric acid was intensively investigated by Elliott[1-3]. This technique was applied to silk fibroin[1,4], lysozyme[2], wheat proteins[5,6] and clupein[7] in order to split *N*-seryl and *N*-threonyl bonds. Anhydrous formic acid was also shown to be useful as the same purpose of the modification of proteins by Josefsson and Edman[8], but a main reaction of anhydrous formic acid with proteins was demonstrated to be *O*-formylation of serine and threonine residues[9-11].

It was reported that of the β-hydroxy-α-amino acid residues in proteins *N*→*O*-peptidyl shift which resulted with concentrated sulfuric acid or concentrated phosphoric acid, mainly occurred at the serine residues[3,4]. However no experiment on the *N*→*O*-acyl shift has been performed with synthetic *N*-acylthreonine. The kinetic studies on the reverse reaction, *O*→*N*-acyl shift, have been reported for *O*-acetylserine and *O*-acetylserylleucine[8], but that for *O*-acylthreonine or its peptide has not been investigated. In the present communication, the rate of *O*→*N*-acetyl shift of *O*-acetylserine measured by the ninhydrin reaction was compared with that of *O*-acetylthreonine at several pH's, at several temperatures and in the presence and absence of inorganic salts. The present results show that *O*-acetylthreonine is more labile than *O*-acetylserine and that it shifts to the *N*-acetyl derivative even at neutral pH. In addition, an approach to the separation of β-hydroxy-α-amino acids, serine and threonine, from the hydrolyzate of casein is described. The principle of the present method is based on the facts that only serine and threonine react with acetic acid and hydrogen chloride to give their *O*-acetyl derivatives, and that the *N*-acetyl derivatives which were derived from the *O*-acetyl derivatives by the *O*→*N*-acetyl shift can be easily separated from free amino acids by the aid of ion exchange resin.

Experimentals

***O*-Acetyl-L-serine.**—This compound was synthesized by the method of Sheehan and his coworkers[12]. M. p. 167~168°C (with decomp.). Found: C, 40.5; H, 6.22; N, 9.40. Calcd. for $C_5H_9O_4N$: C, 40.8; H, 6.17; N, 9.52%.

***O*-Acetyl-DL-threonine and *O*-Acetyl-D-threonine.**—A solution of 10 g. of DL-threonine in 100 ml. of acetic acid was saturated with hydrogen chloride at 0°C and it was kept overnight at room temperature. The solvent was removed in vacuo and the above procedures were repeated. The residues were crystallized by the addition of ether under scratching the wall of the flask. Upon recrystallization from ethanol-ether, 15 g. of *O*-acetyl-DL-threonine hydrochloride were obtained (78.4%). M. p. 155~157°C (with decomp.). On addition of 3.3 g. of triethylamine into a solution of 6.5 g. of the hydrochloride in 150 ml. of ethanol, *O*-acetyl-DL-threonine was crystallized. It war recrystallized twice from water-ethanol. Yield, 4.7 g. (87.4%). M. p. 144~145°C (with decomp.) (reported m. p.[13] 146~149°C). Found: C, 44.66; H, 6.98; N, 8.59. Calcd. for $C_6H_{11}O_4N$: C, 44.71; H, 6.88; N, 8.69%.

Similarly *O*-acetyl-D-threonine was prepared from D-threonine through its hydrochloride (m. p. 155~156°C, with decomp.) with over-all yield of 68.3%. M. p. 145~146°C (with decomp.). Found; C, 44.68; H, 7.08; N, 8.68%. $[\alpha]_D^{20} = -21.25$ (*c* 2, in 2 N HCl).

***N*-Acetyl-DL-threonine and *N*-Acetyl-D-threonine.**—Both the compounds were prepared by similar

methods for the preparation of *N*-acetylserine reported previously[9]. 2.7 g. of *O*-acetyl-DL-threonine were dissolved in 50 ml. of 0.5 N ammonium hydroxide and the solution was kept at room temperature for 3 hr. It was concentrated in vacuo at 60°C and the ammonium salt of *N*-acetyl-DL-threonine was obtained as crystals. The above salt was dissolved in 100 ml. of water. The solution was placed on an acid form of Amberlite IR-120 column (7 $cm^2 \times 10$ cm.) and the column was washed with 150 ml. of water until the effluent became neutral. On concentration of the effluent to a syrup and on addition of ethyl acetate, 2.5 g. of *N*-acetyl-DL-threonine were obtained. 100 ml. of ethyl acetate were added to a solution of the crude material in 4 ml. of ethanol and 2.2 g. (81.5%) of the purified material were obtained as needles. M. p. 130~132°C (reported m. p.[14] 131~133°C). Found: C, 44.62; H, 6.91; N, 8.60. Calcd. for $C_6H_{11}O_4N$: C, 44.71; H, 6.88; N, 8.69%.

N-Acetyl-D-threonine was similarly prepared. M. p. 103~104°C. $[\alpha]_D^{18} = +1.5$ (*c* 2, in water). Found: C, 43.89; H, 6.87; N, 8.34%.

Measurement of the Rate of *O*→*N*-Acetyl Shift. —The *O*-acetyl compound was dissolved in a desired buffer solution with the concentration of 0.1%. One milliliter of the solution was pipetted at scheduled intervals into a 100 ml. of volumetric flask containing 1 ml. of 1 N hydrochloric acid to stop the reaction and filled with water to the mark. The amount of the *O*-acetyl compound that remained was analyzed by the ninhydrin method of Moore and Stein[15] using 1 ml. of the diluted solution.

Isolation of Serine and Threonine from the Acid Hydrolyzate of Casein. — Twenty-five grams of casein (commercial preparation) were hydrolyzed with 250 ml. of 20% hydrochloric acid at 100°C for 24 hr. and it was concentrated to a syrup. The residue was dissolved in 300 ml. of hot water and treated with 5 g. of charcoal. The filtrate was applied to a column of Amberlite IR-120 (acid form, 9 $cm^2 \times 35$ cm.) and the column was washed with 700 ml. of water to remove hydrochloric acid. The adsorbed amino acids were eluted with 500 ml. of 1.5 N ammonium hydroxide from the column and the column was washed with 300 ml. of water. The eluate was evaporated in vacuo and was dried in an evacuated desiccator. Twenty-three grams of acid free hydrolyzate were obtained. The results of amino acid analysis of the hydrolyzate by the Levy's dinitrophenyl technique[16] are listed in Table I. The hydrolyzate was suspended in 250 ml. of acetic acid and saturated with hydrogen chloride at room temperature for 48 hr., acetic acid was removed in vacuo and the above *O*-esterification procedures were repeated. The residues were dried in a desiccator over sodium hydroxide pellet for 24 hr. in vacuo and then it was dissolved in 200 ml. of water. The pH of the solution was adjusted to 8.0 with about 175 ml. of 2 N sodium hydroxide and it was diluted to 500 ml. with water. The solution was kept at room temperature for 4 hr. with an occasional addition of 2 N sodium hydroxide to keep the pH at above 8. Then the reaction mixture was treated with a column of Amberlite IR-120 (acid form, 20 $cm^2 \times$ 32 cm.) and the column was washed with 1.5 l. of water to separate *N*-acetylserine and *N*-acetylthreonine from the other amino acids. The effluent and washings which contained the *N*-acetylamino acids were combined and concentrated to a syrup. It was hydrolyzed with 200 ml. of the boiling 20% hydrochloric acid for 10 hr. The concentrated hydrolyzate was dissolved in 100 ml. of water and treated with a column of Amberlite IR-120 (acid from, 7 $cm^2 \times 15$ cm.) to remove hydrochloric acid as was described previously. The adsorbed amino acids were eluted with 200 ml. of 2 N ammonium hydroxide and the column was washed with 200 ml. of water. The eluate and washings were combined and it was concentrated in vacuo and decolorized with 300 mg. of charcoal. Amino acid analysis of the dried residues which amounted to 2.08 g. (9.0% of the original hydrolyzate) by the Levy's method showed that they contained 0.105 g. of aspartic acid, 0.925 g. of serine (4.0% of the original hydrolyzate), 0.836 g. of threonine (3.6%) and no other amino acids. The recoveries of serine and threonine were 80.5 and 88.8%, respectively. Aspartic acid might have been eluted with the *N*-acetylhydroxyamino acids from the second column, but could be easily removed by the treatment of a weakly basic ion exchange

TABLE I. AMINO ACID ANALYSIS OF THE HYDROLYZATE OF CASEIN

Amino acid	g. amino acid per 100 g. of hydrolyzate
Glycine	1.52
Alanine	2.77
Valine	6.57

resin. In another experiment, a mixture of serine and threonine was isolated with the yield of 12.8%. Amino acid analysis of the isolated material showed 83.0% and 88.3% recoveries of serine and threonine, respectively.

Results and Discussion

Stein et al.[20] reported a simple isolation method of serine from the acid hydrolyzate of proteins by the specific precipitating reagent, *p* - hydroxyazobenzene-*p'* - sulfonate. However this reagent also forms sparingly soluble salts with the other amino acids, especially basic ones. Therefore when an attempt is made to isolate serine from usual protein hydrolyzates by the above technique, interfering amino acids have to be removed previously. For this purpose the oxazoline method reported by Elliott[21] is useful. The esters of serine and threonine form the oxazoline derivatives by the action of benziminoethyl ether. However the other amino acids give the aminoether derivatives and the former can be separated from the latter materials by vaccum distillation.

The present method seemed to be simpler than the oxazoline method and was applied to the acid hydrolyzate of casein. Eighty to ninety per cent of serine and threonine were recovered as was described in the experimental part. Sometimes β-hydroxy-α-amino acid fractions thus obtained were contaminated with small amounts of aspartic acid, but the latter amino acid was easily removed by a weak basic ion exchanger such as Amberlite IR-4B.

It is believed that the $O \rightarrow N$-acyl shift of *O*-acetyl - β - hydroxy - α - amino acids proceeds

TABLE II. OPTICAL ROTATION OF SERINE AND THREONINE OBTAINED BY THE $O \rightarrow N$-ACETYL SHIFT OF THE *O*-ACETYL DERIVATIVES*

	Before the reaction	After the reaction	Literature[22]
L-Serine	+15.5	+15.5	+15.1
D-Threonine	+16.5	+16.5	+15.0

* The specific rotation was measured in 2% solution in 2 N HCl at 25°C.

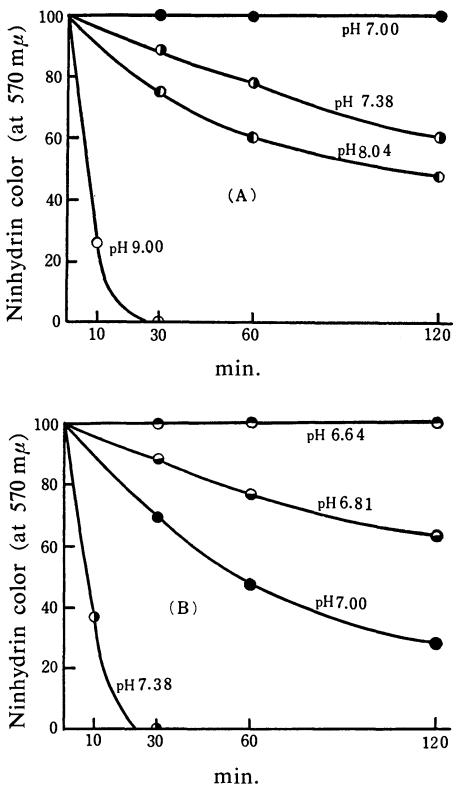

Fig. 3. *O*→*N*-Acetyl shift of *O*-acetyl-L-serine (A) and -DL-threonine (B) in 0.05 M phosphate buffer at 20°C.

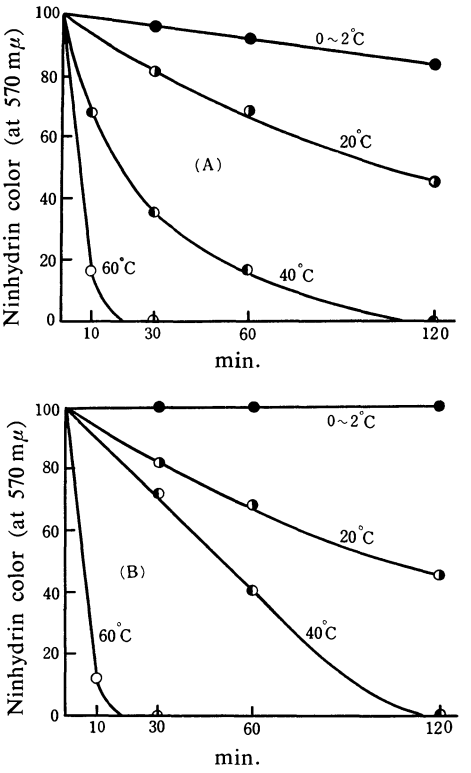

Fig. 4. Effect of temperature on the *O*→*N*-acetyl shift. 0.2 M phosphate buffers of pH 7.38 and 6.81 were used for *O*-acetyl-L-serine (A) and -DL-threonine (B) respectively.

through oxazoline derivatives as intermediates[1,3]. Consequently a possibility of racemization during the reaction must be considered. Synthetic *O*-acetyl-L-serine and -D-threonine were converted to their *N*-acetyl derivatives by incubating them at pH 8 or above, respectively, and then the acetyl group was removed by acid hydrolysis. It is clear from Table II, that no racemization occurred during *O*→*N*-acetyl shift reaction.

If the difference between the rate of the *O*→*N*-acetyl shift of *O*-acetylserine and that of *O*-acetylthreonine were remarkable, both the amino acids might be separable from each other. The rates of *O*→*N*-acetyl shift of *O*-acetylserine and *O*-acetylthreonine at various pH's were measured. As is shown in Fig. 1, the rate of the reaction of *O*-acetylthreonine is greater than that of the serine derivative under the conditions used. The above results seemed to indicate that the mutual separation of serine and threonine would be possible. Therefore a mixture of serine and threonine was treated with acetic acid and hydrogen chloride in order to convert them to their *O*-acetyl derivatives. The hydrochlorides of the *O*-acetyl derivatives thus obtained were incubated at room temperature keeping the pH at 7.0 with sodium hydroxide solution. In this case it was observed that the reaction was quite slow. The difference between the conditions of this reaction and those of model reaction shown in Fig. 1 is the presence of sodium chloride which was formed by the neutralization of the hydrochloride of the *O*-acetylamino acids with sodium hydroxide in the former experiment. Thus the effect of sodium chloride on the shift reaction was examined. As is shown in Fig. 2, sodium chloride inhibits the *O*→*N*-acetyl shift. When Fig. 3, which records the reaction rate of the shift in a low ionic strength of the buffer, 0.05 M phosphate, is compared with Fig. 1, it is clear that the increase of the ionic strength of the buffer has the accelerating effect on the reaction rate contrary to sodium chloride. Temperature increase accelerates the reaction rate and the temperature dependence is remarkable as is shown in Fig. 4. Therefore the mutual separation of serine and threonine from the mixture by the above reaction is affected by the many factors described above. The best conditions could not be found thus far.

In any rate the present experiments demonstrated that *O*-acetylthreonine was more labile than *O*-acetylserine, and even at pH 7 acetyl group of *O*-acetylthreonine migrated to its amino group. Therefore, if the shift reaction occurred at threonine bonds in proteins by the influence of concentrated sulfuric acid, it is difficult to estimate the number of the migrated threonine bond quantitatively, and precautions have to be taken to discuss the results for the modified proteins by this technique.

Summary

The reaction rate of *O*→*N*-acetyl shift of *O*-acetylserine was compared with that of *O*-acetylthreonine, and it was found that the latter was greater than the former. By utilizing the difference of the rates of the reaction of these amino acid derivatives, an attempt to separate serine and threonine from their mixture was unsuccessful owing to the fact that the shift reaction was affected by many factors, i.e., the ionic strength of inorganic salts present, pH of the reaction medium and the reaction temperature. Serine and threonine were isolated from the acid hydrolyzate of casein through their *O*-acetylation and subsequent *O*→*N*-acetyl migration with 80～90% yield.

The Infrared Absorption Spectra of 1,3,5-Trichlorobenzene, 1,2,4,5-Tetrachlorobenzene and their Deuterated Derivatives

By Shinnosuke SAËKI

(Received July 19, 1961)

The infrared absorption spectra of 1, 3, 5-trichlorobenzene[1], 1, 3, 5-trichlorobenzene-d_3[1], 1, 2, 4, 5-tetrachlorobenzene[2] and 1, 2, 4, 5-tetrachlorobenzene-d_2[2] have been studied from 4000 to 400 cm^{-1}, and the assignments of the observed bands have previously been proposed by the author. Also, recently the spectra of these substances have been measured in the far infrared region between 400 and 100 cm^{-1} using the cesium bromide prism and the gratings, and the spectra in the sodium chloride region have been reexamined with the aid of the high temperature long path cell described in a previous paper[3]. In this paper, the results of these measurements are reported, and, on the basis of this information, revised assignments for the infrared active normal vibrations of these molecules are proposed.

Experimental

As the method of the measurements was quite identical to that for *p*-dichlorobenzene and *p*-dichlorobenzene-d_4 which has been previously reported[3], any description of the measuring techniques is entirely omitted in this paper. The spectra obtained in the sodium chloride region using the high temperature long path cell were measured at different temperatures below 70°C for trichlorobenzenes and below 90°C for tetrachlorobenzenes, in order to observe the shapes of the bands of various intensities as accurately as possible. When the 85 mm. high temperature cell was used, the measurements were carried out at 240°C for trichlorobenzene and at 280°C for tetrachlorobenzene. The spectra in the far infrared region were measured in a solid state (Nujol mull) at room temperature using the grating spectrophotometer installed at the laboratory of Professor Yoshinaga of Osaka University.

Results

The far infrared absorption spectra of 1, 3, 5-trichlorobenzene and 1, 3, 5-trichlorobenzene-d_3 are shown in Fig. 1. The absorption curves are fragmental below 300 cm^{-1} because of the frequent exchanges of filters and gratings with the decreasing wave number. The spectra in the sodium chloride region measured by using the high temperature long path cell are shown in Fig. 2 for the range where the principal absorption bands appeared. In Figs. 3 and 4 the similar spectra for 1, 2, 4, 5-tetrachlorobenzene

and tetrachlorobenzene-d_2 are shown. The frequencies, the intensities and the types of the observed bands are listed in Tables I and II, in which the intensities are described by a rough visual estimation, and the types are presented only for the bands whose envelopes showed the typical features of any band type.

Comparing the absorption curves shown in Figs. 2 and 4 with those presented in the previous papers[1,2], one can easily see that the absorption bands are separated from each other

much more distinctly by the use of the high temperature long path cell, and also that the shape of each band can be much more clearly observed by means of this cell.

Band Shapes and Assignment

1, 3, 5-Trichlorobenzene and 1, 3, 5-Trichlorobenzene-d_3. — The vibrations of these molecules, which are active in infrared absorption, belong to species A_2'' or E' because of the high symmetry of the molecule, D_{3h}. Three of the ten infrared active normal vibrations are out-of-plane vibrations belonging to species A_2'', and the other seven are in-plane vibrations belonging to species E'. Furthermore, as the molecule is a symmetric top, the out-of-plane vibrations give parallel bands which show remarkable Q branches under proper resolution of the spectrometer, and the in-plane vibrations are perpendicular, showing less remarkable Q branches.

The bands which actually showed a clear Q branch in the observed spectra were those at 660.9 and 855.4 cm^{-1} of $C_6H_3Cl_3$ and those at 535.3, 583.4 and 767.0 cm^{-1} of $C_6D_3Cl_3$. Of these five bands, the last two were less intense than the first three. The three normal vibrations of species A_2'' are the out-of-plane vibrations of C–H (or C–D), C–Cl and the ring. Therefore, the pair of bands with the highest frequencies, that is, the bands observed at 855.4 and 767.0 cm^{-1}, were assigned to the out-of-plane bending vibrations of C–H and C–D bonds respectively, and the second highest pair of bands, at 660.9 and 535.3 cm^{-1}, were assigned to the ring deformation vibration. To the C–Cl out-of-plane bending vibrations, the pair of bands at 194.3 and 193.5 cm^{-1} which were observed in the grating region were quite confidently assigned. In the above correspondences between the bands of each species of the substance, the bands at 767.0 cm^{-1} of the deuterated substance seems to be too weak to correspond to the band at 855.4 cm^{-1} of the ordinary substance, even if the difference in the concentrations of the sample solutions is taken into account. The explanation for this fact will be seen later. The band at 583 cm^{-1} of the deuterated substance was ruled out from the fundamental bands because it has a relatively low intensity and did not satisfy the product rule.

There is a very noticeable fact in the above-mentioned assignment of the parallel vibrations. According to the above assignment, the band at 855.4 cm^{-1} of the ordinary substance (the out-of-plane bending vibration of the C–H bonds) should show a large frequency shift on the deuteration, and the frequency shift of the band at 660.9 cm^{-1} (the out-of-plane deformation vibration of the ring) should be much smaller than that. But, in practice, the behavior of these bands on the deuteration was quite contrary. While the band at 855.4 cm^{-1} of the ordinary substance shifted to 767.0 cm^{-1} on the deuteration, showing only a 10% decrease in frequency, the band at 660.9 cm^{-1} shifted to the band at 535.3 cm^{-1} on the deuteration, showing a 19% decrease in frequency. However, these experimental results, which appeared to be inconsistent with the assignment, can be explained as follows. As the out-of-plane C–H bending vibration of this molecule has been observed at 855 cm^{-1}, that

* Note in proof: This band may be more confidently assigned to the second overtone of the fundamental at 193.5 cm^{-1} (a_2'', C–Cl out-of-plane bending) which borrows the intensity from the foundamental at 535.3 cm^{-1} of species A_2''. In the case of ordinary trichlorobenzene, this overtone is not observed, because it has no fundamental of the same species in its vicinity.

of the C–D bands can be expected to appear in the vicinity of 650 cm^{-1}. Consequently, in the case of the deuterated molecule, an extreme coupling must be expected between the C–D bending vibration and the ring deformation vibration, and, provided that the proper frequency of the ring deformation vibration exists a little higher than that of a C–D bending vibration, the coupling might push up the former and push down the latter by many wave numbers. The apparently contradictory phenomenon mentioned above is probably brought about in such a way. One can easily see from this consideration that the mode of these vibrations of the deuterated molecule are not simple but an almost fifty-fifty mixture of the C–D bending and the ring deformation modes, and, from the consideration of the intensity shown below, it might be better to assign the band of higher frequency to the ring deformation vibration and the lower to the C–D bending vibration.

This supposition for the vibrational modes appeared to be justified by the inversion of the relative intensities of these bands on the deuteration, that is, the fact that while the band at 855.4 cm^{-1} is stronger than the band at 660.9 cm^{-1} in the case of an ordinary molecule, the band at 767.0 cm^{-1} is weaker than the band at 535.3 cm^{-1} in the case of a deuterated molecule.

Among the seven vibrations belonging to species E′, the C–H (or C–D) stretching vibration (ν_{11}) was not observed, being beyond the high frequency limit of the region of this investigation*, and the C–Cl in-plane bending vibration (ν_{17}) was not found in the observed spectra, in spite of being expected to appear between 200 and 300 cm^{-1}**.

* It has already been reported in our previous paper[1] that this vibration was found at 3089 and 2310 cm^{-1} for the ordinary and deuterated 1,3,5-trichlorobenzene respectively.

** In the grating region, only one absorption band was found and was assigned to ν_{10} of the species A_2'', as has already been mentioned.

The other five vibrations are two stretching vibrations of the ring (ν_{12}, ν_{13}), an in-plane bending vibration of the C–H (or C–D) bonds (ν_{14}), a stretching vibration of the C–Cl bonds (ν_{15}) and an in-plane deformation vibration of the ring (ν_{16}). The observed remarkable absorption bands were unambiguously assigned to these vibrations by taking account of the observed frequencies and intensities, as shown in Table III.

The next step to be done is the applying of the product rule to the assignment determined above. In species E′, although the C–Cl bending vibration (ν_{17}) was observed for neither species of the substance, the ratio of the frequencies of such a low frequency vibration as ν_{17} can well be assumed to be nearly 1. With this assumption, the ratio of the products of the frequencies for each species of the substace was calculated to be 1.956 for species E′. The ratio calculated for species A_2'' was 1.383. As the theoretical values are 1.972 and 1.402 for species E′ and A_2'' respectively, the agreement between the observed and theoretical values are quite satisfactory, verifying the correctness of the proposed assignment.

On the basis of the assignment previously determined for the Raman active normal vibrations[4] and the above-mentioned assignment for the infrared active normal vibrations, the assignment of overtone and combination bands observed in the infrared absorption spectra could be determined. However, since there are three normal vibrations belonging to species A_2' for which there is no way of knowing the frequencies because of the inactivity in both of the Raman effect and infrared absorption, there might unavoidably be some overtone and combination bands for which the determination of assignment is impossible.

Among the observed overtone and combination bands, the three bands of ordinary trichlorobenzene at 1384, 1059 and 795.1 cm^{-1} have unusually high intensities. As an explanation of this fact could be found only in the Fermi resonances with the fundamental bands at 1412, 1103 and 813.7 cm^{-1} respectively, and as all of these fundamental bands belong to species E′, the species of these overtone or combination vibrations should also be E′. On the contrary, the fact that the combination band at 1543 cm^{-1} of the deuterated substance has a relatively low intensity in spite of the close existence of the fundamental band at 1560 cm^{-1} (E′), indicated that the species of this combination band should be A_2''. By taking into account such facts, as well as the frequencies and activities, the assignment of overtone and combination bands was determined as shown in Table III.

1, 2, 4, 5-Tetrachlorobenzene and 1, 2, 4, 5-Tetrachlorobenzene-d_2. — As the symmetry of these molecules is V_h, as in the case of *p*-dichlorobenzene, thirteen of thirty normal vibrations are active in infrared absorption; five of them belong to species B_{1u} (in-plane), five belong to species B_{2u} (in-plane), and three belong to species B_{3u} (out-of-plane)*.

This molecule is an asymmetric top, three moments of the inertia of which are as follows (in physical atomic weight·A^2):

	$C_6H_2Cl_4$	$C_6D_2Cl_4$
I_x:	1470	1482
I_y:	412	423
I_z:	1059	1059

Accordingly, the vibrations belonging to species B_{1u}, B_{2u} and B_{3u} give type B, A and C bands respectively.

The three out-of-plane normal vibrations belonging to species B_{3u} are the C–H (or C–D) and C–Cl bending vibrations and the deformation vibration of the ring. The C–Cl bending vibration appeared at 140.4 cm^{-1} in the grating region. However, since the spectra were measured in a solid state in this region, observation of the band envelope of this vibration was impossible. For the other two vibrations, the observation of the band envelopes was as had been expected. But, in practice, only one band of each substance, that is, the band at 882.4 cm^{-1} of $C_6H_2Cl_4$ and the band at 726.6 cm^{-1} of $C_6D_2Cl_4$, showed the remarkable Q branch which is the feature of the type C band. This pair of bands was assigned to the out-of-plane C–H (or C–D) bending vibration by considering their frequencies. The out-of-plane deformation vibration of the ring was expected to appear between 400 and 600 cm^{-1}. In this region of frequency, three remarkable bands were observed for each substance, that is, the bands at 643.1, 506 and 441 cm^{-1} of ordinary tetrachlorobenzene, and at 623.1, 505.9 and 384 cm^{-1} of the deuterated substance. All of these three pairs of bands have remarkable intensities, but their band envelopes were not clearly observed. Therefore, it was impossible to determine which of these three pairs of bands is to be assigned to the out-of-plane deformation vibration of the ring. However, as the assignment of the other two pairs of normal vibrations of species B_{3u} had already been

4) S. Saëki, This Bulletin, **34**, 1851 (1961).

* In the case of the point group V_h, the notation of the species depends on which of the three principal axes is taken for the x axis, which for the y, and which for the z. In this case, the axis perpendicular to the molecular plane is taken as the x axis, the axis combining two hydrogen (or deuterium) atoms as the z, and the third axis perpendicular to the first two as the y axis.

TABLE IV. THE ASSIGNMENT OF INFRARED ABSORPTION BANDS OF 1,2,4,5-TETRACHLOROBENZENE

Wave number		Assignment	Mode
$C_6H_2Cl_4$	$C_6D_2Cl_4$		
	1425	?

1069	1057	$\nu_{12}(b_{1u})$	C-Cl stretching
882.4	726.6	$\nu_{28}(b_{3u})$	C-H or C-D out-of-plane bending
820.7		$\nu_{13}(b_{1u})+\nu_{16}(b_{2g})$	
767.2		?	
	743.6	?	
	738.9	?	
643.1	623.1	$\nu_{21}(b_{2u})$	C-Cl stretching
507.2	505.9	$\nu_{13}(b_{1u})$	Ring in-plane deformation
441.2	384.3	$\nu_{29}(b_{3u})$	Ring out-of-plane deformation
140.4	140.4	$\nu_{30}(b_{3u})$	C-Cl out-of-plane bending

determined, the assignment of the third pair could be determined by applying the product rule. Among the observed three pairs of bands, the pair of 441.2 cm^{-1} (of $C_6H_2Cl_4$) and 384.3 cm^{-1} (of $C_6D_2Cl_4$) proved best to satisfy the product rule, and so was assigned to the ring deformation normal vibration, ν_{29}.

The in-plane vibrations of these molecules belong to species B_{1u} or B_{2u}, as was mentioned above. There exist three stretching vibrations of the benzene ring, one of which belongs to species B_{1u}, while the other two belong to species B_{2u}. In the observed spectra, three intense bands were actually found between 1300 and 1500 cm^{-1} for each substance (see Fig. 4 and Table II). Accordingly, these three pairs could apparently be assigned to $\nu_{11}(b_{1u})$, $\nu_{18}(b_{2u})$ and $\nu_{19}(b_{2u})$, and, by analogy to the case of *p*-dichlorobenzene[3], the pair of bands at 1473 and 1396 cm^{-1} was assigned to ν_{11} (b_{1u}) and the other two pairs were assigned to $\nu_{18}(b_{2u})$ and $\nu_{19}(b_{2u})$.

To the C-H and C-D in-plane bending vibration (ν_{20}'s), the bands at 1120 and 873.5 cm^{-1} were assigned respectively. Although, considering the frequency only, the band observed at 1069 cm^{-1} appears to correspond to the C-H in-plane bending vibration better than the band at 1120 cm^{-1}, this pairing must be ruled out, for the band at 1069 cm^{-1} was found to be a type B band showing two clear absorption maxima, as has been shown in Fig. 4 and Table II. As the spectrum of the deuterated substance also shows a type B band at 1057 cm^{-1} which apparently corresponds to the band in question at 1069 cm^{-1} of the ordinary substance, this pair of bands must be considered to originate in vibrations belonging to species B_{1u}. Furthermore, apart from the band envelope, this pair of bands could not be taken for ν_{20} because of the small frequency shift (12 cm^{-1}) on duteration. Thus it was determined that the pair of bands at 1120 and 873.5 cm^{-1} was to be assigned to the C-H (or C-D) in-plane bending vibration, ν_{20}.

The above-mentioned pair of bands at 1069 and 1057 cm^{-1} was assigned to the C-Cl stretching vibrations of species B_{1u}, ν_{13}'s. To the C-Cl stretching vibrations of species B_{2u} (ν_{21}'s), the pair of bands observed at 643.1 623.1 cm^{-1} was assigned. Though the frequency difference between these two pairs of C-Cl stretching vibrations appears to be too large, it is really quite probable considering that the C-Cl stretching vibration has a strong tendency to couple with other vibrations, that is, for example, with a ring deformation vibration or a C-H (or C-D) bending vibration.

The last pair of the observed strong bands, at 507.2 and 505.9 cm^{-1}, was assigned to the deformation vibration of the ring belonging to species B_{1u}.

The remaining two normal vibrations are C-Cl in-plane bending vibrations belonging to species B_{1u} and B_{2u} respectively. Although they were expected to appear around 200 cm^{-1}, no absorption band except the above-mentioned one at 140.4 cm^{-1} was observed in the grating region.

The next step is to prove the assignment determined above by making use of the product rule. The theoretical values of the ratios of the products of frequencies for both species of substance are 1.407 for all three vibrational

species (B_{1u}, B_{2u} and B_{3u}). In the proposed assignment, the frequencies of two C–Cl in-plane bending vibrations of species B_{1u} and B_{2u} are wanted. However, as the ratios of these frequencies could be assumed to be 1 without any serious error, the ratio of the products of the observed frequencies could be calculated based on the proposed assignment as follows:

Species B_{1u}:	1.439
Species B_{2u}:	1.436
Species B_{3u}:	1.394

The calculated values for species B_{1u} and B_{2u} exceeds the theoretical values by about 2%, while that for species B_{3u} is lower than the theoretical value by 1%. The accordances can be said to be satisfactory enough to show the correctness of the assignment.

On the basis of the assignment of the infrared active normal vibrations determined above and the assignment of the Raman active normal vibrations reported previously[5], some of the combination bands observed in the infrared absorption spectra could well be explained. However, since this molecule has two normal vibrations (the out-of-plane vibrations of the C–Cl bonds and the ring) belonging to species A_u which are inactive in both the Raman effect and infrared absorption, and since, even among active normal vibrations, some had not been observed, there were necessarily some combination bands which could not be explained. The assignment of the combination bands is shown in Table IV, together with the assignment of the fundamental bands.

5) S. Sački, This Bulletin, **34**, 1858 (1961).

Summary

The infrared absorption spectra of 1, 3, 5-trichlorobenzene, 1,3,5-trichlorobenzene-d_3, 1,2,4,5-tetrachlorobenzene and 1, 2, 4, 5-tetrachlorobenzene-d_2 were observed in a gaseous state from 700 to 300 cm^{-1} with a cesium bromide prism and in a solid state from 300 to 100 cm^{-1} using a grating spectrometer. Furthermore, the spectra in the sodium chloride region were carefully observed in the ranges where the main absorption bands appear, using a long path (720 cm.) high temperature cell. The obtained accurate frequencies and envelopes of the absorption bands have been reported on.

On the basis of these results, the assignments of the infrared active normal vibrations of these substances have been determined and checked by the product rule.

The assignments of the overtone and combination bands have also been determined using the assigned frequencies and species of infrared active and Raman active fundamental vibrations.

The author wishes to express his appreciation to Professor Hiroshi Yoshinaga and Dr. Akiyoshi Mitzuishi for the use of the far infrared spectrometer, and to Dr. Yoichiro Mashiko for his helpful suggestions.

Geochemical Investigations of the Volcanoes in Japan. LI. Titanomagnetites in Volcanic Rocks of Nekodake, Aso Volcano***

By Iwaji IWASAKI, Takashi KATSURA and Minoru YOSHIDA

(Received February 8, 1961)

There have been many reports on the magnetochemical or mineralogical properties of titanomagnetites in volcanic rocks[1-4]. Also, many investigations have been made of the titanomagnetites in relation to the chemical or petrological properties of their host rocks. Iwasaki and Katsura[5] have studied the relation between the chemical composition of titanomagnetites in various Japanese volcanic rocks and the stage of magmatic differentiation of their host rocks. Buddington, Fahey, and

Vlisidis[6] have reported that the titanium content of magnetite is largely a function of the temperature of its formation. Vincent and Phillips[7] investigated titanomagnetites from the Skaergaard gabbroic intrusion and discussed the variation in content of major and minor constituents in a suite of differentiated gabbros. Recently, Marmo[8] has reported on the correlation of the titanium content of magnetite with certain geological facts. The problems discussed in these papers have, however, been mostly restricted to the variation in the titanium content of titanomagnetite, that is, the changes along the ulvöspinel-magnetite join in the FeO–Fe_2O_3–TiO_2 system.

Recent study by Akimoto and Katsura[9] has shown that the chemical composition of titanomagnetite in volcanic rocks does not always accord with ulvöspinel-magnetite join, but in most cases deviates from this join towards the ilmenite-hematite join side. In other words, some natural titanomagnetites have a more oxidized composition than the solid solutions between ulvöspinel and magnetite. The existence of such an oxidized titanomagnetite is also supported by synthetic investigation[10]. The state of oxidation of that natural titanomagnetite which is represented by the deviation of its chemical composition from ulvöspinel-magnetite join in the FeO–Fe_2O_3–TiO_2 system should be intimately related to the physicochemical history of its host rock.

Vincent and Phillips[7] concluded that the compositions of the magnetite are largely determined by the oxidation-reduction equilibria between ferrous and ferric oxides and oxygen in the crystalizing magma. However, the variation in the degree of oxidation of titanomagnetite dealt with in their report is rather small as compared with those of volcanic rocks. This paper is concerned chiefly with the relation between the state of oxidation of titanomagnetites (free from the ilmenite-hematite series minerals) in volcanic rocks and the chemical and petrological properties of their host rocks.

Materials and Methods

The volcanic rocks of Nekodake, Aso Volcano, from which titanomagnetites were extracted came in through the courtesy of Mr. H. Matsumoto, Institute of Geology, Kumamoto University, who has made geological studies and chemical analyses of these rocks[11]. The localities where these rocks were collected are shown in Table I*. They all belong to andesite (SiO_2 content 52~57%). It is considered that the volcanic activity of Nekodake has been in three stages: that is, the first was an activity of the Old Nekodake, which was followed by the second one forming the chief part of it (Nekodake lava), and then a number of dykes were injected as the last phase of the volcanic activity[11].

motor in the presence of water. The suspension thus prepared was poured into about 100 ml. of water, and the ferromagnetic fraction was attracted by a magnet, the suspension of silicate minerals being abandoned. These procedures were repeated until the purity could hardly be improved by the repetition of these procedures. Titanomagnetites in volcanic rocks are so finely grained that a small amount of silicate, such as olivine, pyroxene, etc., still remained as an impurity in spite of our efforts. As will be seen in Table II, the purity of these specimens mostly exceeds 90% and is sufficient for the present discussion.

X-Ray analysis was carried out for all specimens by means of a wide range X-ray spectrometer "Norelco" with Fe-K radiation. In all these specimens (with only the one exception of No. 13), the amount of the minerals which belonged to the ilmenite-hematite series was less than five percent. The lattice constant of each sample was also measured. In most cases, titanomagnetite lines in the X-ray diffraction diagram showed considerable broadening. This broadening can be attributed to the specimens being not strictly of a single phase which has a definite composition, but rather mixtures of phases with a spinel structure whose chemical composition differ continuously (probably along the oxidation-reduction lines in the FeO-Fe_2O_3-TiO_2 system[9]). Therefore, the chemical and physical properties of these titanomagnetites obtained by several methods will show the average values of such phases and so will involve some ambiguity.

Chemical analyses of titanomagnetite (FeO, Fe_2O_3, TiO_2, V_2O_3 and MnO) have been made by the method devised by Iwasaki et al.[12] The cobalt contents of several specimens were determined by colorimetric methods, using nitroso-R salt[13].

Results and Discussion

The results of the chemical analysis, together with the formular proportions of three oxides (FeO, Fe_2O_3, TiO_2), are given in Table II and are represented in the diagram of the FeO-Fe_2O_3-TiO_2 ternary system (Fig. 1).

The quantity of specimen No. 7 was insufficient for chemical analysis. The atomic ratio Fe/(Fe+Ti) and the atomic proportions of the metals to oxygen calculated on the basis of 32 oxygen atoms $32\times(Fe+Ti)/O$ are also given in Table II. They are used in the report by Akimoto and Katsura[9] in the form of a parameter where the former shows the change along the ulvöspinel-magnetite join, while the latter shows the change along the oxidation-reduction lines in the FeO-Fe_2O_3-TiO_2 system.

As will be seen in Fig. 1, the chemical composition of these titanomagnetites generally

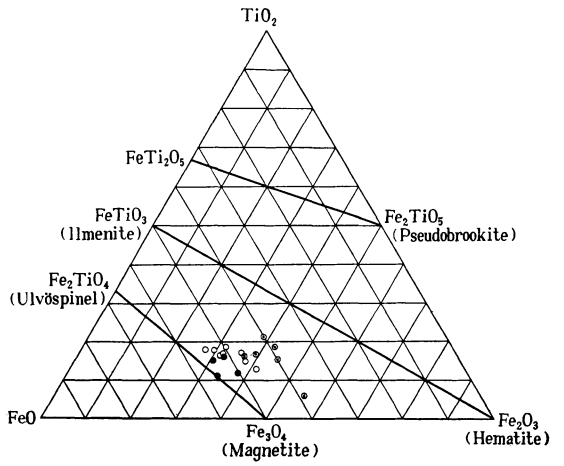

Fig. 1. Chemical composition of analysed titanomagnetites represented on a FeO-Fe_2O_3-TiO_2 system. (Formula %)
● dike rock ○ Nekodake lava
⊙ Old-Nekodake lava

does not accord with the Fe_2TiO_4-Fe_3O_4 solid solution line, but deviates considerably from this join towards the $FeTiO_3$-Fe_2O_3 join side. The TiO_2 contents of these titanomagnetites are confined to a relatively narrow range (Fe/(Fe+Ti)=0.83~0.91), except for No. 13, which contains a fairly large amount of hematite, as has already been mentioned. According to the previous studies[5,9], the titanium content of the titanomagnetite increases (or, Fe/(Fe+Ti) decreases) gradually in the order of the decreasing SiO_2 content of the host rock: rhyolite, dacite, andesite, basalt. The host rocks in this study belong to andesite, and the result agrees satisfactorily with previous reports. It is very convenient for a discussion of the relation between the degree of oxidation of titanomagnetites and other properties that the variation in the TiO_2 contents of these titanomagnetites is small.

Akimoto and Katsura[9] have referred to the titanomagnetite that lies almost precisely on the line of the Fe_3O_4-Fe_2TiO_4 join as "the normal titanomagnetite", to that which lies in the Fe_3O_4-Fe_2TiO_4-$FeTiO_3$ compositional field as "the abnormal titanomagnetite", and to that which lies in the Fe_3O_4-$FeTiO_3$-Fe_2O_3 field as "the very abnormal titanomagnetite". In accordance with this classification, only one specimen (No. 6) of titanomagnetite, can be referred to normal titanomagnetite, eight specimens (including No. 14) to abnormal titanomagnetite, and nine specimens to very abnormal titanomagnetite. As compared with the chemical composition of the already reported titanomagnetites in volcanic rocks[5,9], titanomagnetites in Nekodake volcanic rocks

13) E. B. Sandell, "Colorimetric Determination of Traces of Metals", 3rd. Ed., Interscience Publishers, New York, London (1959), pp. 415, 429.

have a very oxidized composition (especially those in Old Nekodake lavas). It is also seen in Fig. 1 that titanomagnetites in Old Nekodake lava have the most oxidized composition and that those in dike rocks have the least oxidized composition. The chemical composition of titanomagnetite in Nekodake volcanic rock varies with the periods of volcanic activity.

In order to see the relation between the state of oxidation of titanomagnetite and that of the host rock, the FeO/Fe_2O_3 (by weight) of the titanomagnetites is plotted against the FeO/Fe_2O_3 of their host rocks (Fig. 2). A clear correlation is seen in this figure. It is also seen from the figure that the points which represent the Old Nekodake lavas take positions nearer to the axis of abscissa than do the others. This implies that titanomagnetite in Old Nekodake lava has a more oxidized composition than others in relation to the host rock. No difference seen is between Nekodake lava and dike rock. When the $32\times(Fe+Ti)/O$ value of titanomagnetite is taken in place of the FeO/Fe_2O_3 of titanomagnetite, the result is almost the same as the results obtained by Fig. 2. Some investigators[7,14] have emphasized the importance of the role of the volatile constituent (mainly water) on the state of the oxidation of iron in the rock. The $H_2O(+)$ content of the host rock is plotted against the FeO/Fe_2O_3 ratio of titanomagnetite in Fig. 3. As will be seen in the figure, Old Nekodake lava behaves in a different manner from others.

Apart from the results obtained by the study of titanomagnetites, the properties of Old Nekodake lava are almost same as those

● dike rock ○ Nekodake lava
⊙ Old Nekodake lava

of Nekodake lava. The former can be distinguished from the latter only by the information of the geological field survey[11]. On the other hand, dike rocks are readily distinguished from others by the fact that dike rocks alone bear hornblende as a constituent. Differences between Old Nekodake lava and Nekodake lava in the degree of the oxidation of titanomagnetite might be explained in two ways. First, the Old Nekodake lava may have originally been different from the Nekodake lava in its volatile constituent and the difference may have had an effect on the state of the oxidation of iron ore minerals. Second, the Old Nekodake lava may have been almost the same as the Nekodake lava, but the Old

Nekodake lava may have suffered strong oxidative actions for some reason (for example, because of secondary heating in the atmospheric conditions). Most of the rocks which contain very abnormal titanomagnetite bear hematite. This fact seems to support the second of these possibilities.

The MnO contents of these titanomagnetites are 0.25~0.53%, and there is no correlation with the oxidation parameter $32\times(Fe+Ti)/O$. Manganese is somewhat concentrated in titanomagnetite. (Mn in titanomagnetite)/(Mn in host rock) are between 1.9 and 4.7 (Table III). The V_2O_3 contents of titanomagnetites are plotted against the oxidation parameter $32\times(Fe+Ti)/O$ in Fig. 4. Generally speaking, the vanadium content increases as the oxidation parameter decreases. Vanadium is considerably concentrated in titanomagnetite, as is shown in Table IV, and this result agrees well with those of previous investigators[5,9,15].

Cobalt is also fairly concentrated in titanomagnetite (Table V). These results agree well with the results of Wager and Mitchell[15].

The lattice constants of these titanomagnetites are plotted against the oxidation parameter. An almost linear relation, in which the lattice constant becomes smaller according as the oxidation proceeds, will be clearly found in Fig. 5. This result is in good accordance with the results obtained by the synthetic experiments[10] and the study on the natural titanomagnetites[9].

Conclusion

The study of the titanomagnetite in volcanic rocks of Nekodake, Aso Volcano, has given the following results:

1. The natural occurrence of titanomagnetite the chemical composition of which lies in the Fe_3O_4–Fe_2O_3–$FeTiO_3$ compositional field, far beyond the Fe_2TiO_4–Fe_3O_4 and $FeTiO_3$–Fe_3O_4 line in the FeO–Fe_2O_3–TiO_2 diagram (" very abnormal titanomagnetite "), is confirmed in these volcanic rocks. About a half of the specimens in this paper are " very abnormal titanomagnetite ", and it may be supposed that " very abnormal titanomagnetite " exists rather commonly in volcanic rocks.

2. The state of the oxidation of titanomagnetite must have an important relation to the physico-chemical history of the host rock.

From the study of the correlation between the state of the oxidation of titanomagnetites and some chemical properties of their host rocks, it becomes possible to distinguish the rock belonging to Old Nekodake lava from that belonging to Nekodake lava or dike rock. However, for the present, the method must be considered valid only for the rocks of Nekodake.

3. Vanadium and cobalt in volcanic rock are considerably concentrated in titanomagnetite, and the vanadium content in titanomagnetite has a correlation to the oxidation parameter $32\times(Fe+Ti)/O$ which represents the state of the oxidation of titanomagnetite.

The authors are much obliged to Mr. Hatao Matsumoto, the Institute of Geology, Kumamoto University, for kindly supplying the specimens of Nekodake volcanic rocks and for many valuable suggestions and discussions from the petrological point of view. They also wish to express their hearty thanks to Dr. Syun-iti Akimoto, Geophysical Institute, the University of Tokyo, both for his great help and valuable advice in X-ray study and for his fruitful discussions throughout the study.

Geochemical Investigations of Volcanoes in Japan. LII. Vanadium Content of the Lava Flow in 1950—1951 from Volcano Ō-sima, Izu, Japan***

By Iwaji IWASAKI and Bunji IWASAKI

(Received July 24, 1961)

Since the beginning of the twentieth century, the contents of various elements in volcanic rocks have been determined and these data have been compared with one another. A comparison of these data depends on the assumption that the contents of these elements in one volcanic body, such as one lava flow, are uniform[1]. An experimental approach to these uniformities has not yet been made systematically, but Grout[2] studied the method of selection and preparation of granite and other rock samples without consideration of the error in chemical analysis. Brown et al.[3] found the uniformity of Moune granite G-2 without regard to the selection and preparation of rock samples.

As a part of the geochemical study at our laboratory, an attempt has been made to show whether the contents of various elements in one lava flow are uniform or not, to determine the relation between the contents of these elements and the external appearance of rocks, and to examine the method of selection and preparation of rock samples from a large volcanic body for chemiacl analysis.

In the previous work, Volcano Ō-sima, one of the representative active volcanoes in Japan, was selected for the reasons described below. Volcano Ō-sima has been well studied in the fields of geophysics, geology and geochemistry and is covered with several lava flows, from one of which we can collect rock samples systematically. A systematic collection of the rock samples in the lava flow which erupted in 1950—1951 from Volcano Ō-sima was therefore carried out. From the results of chemical analysis, the major components such as iron[4], titanium[5], manganese[6], sodium[6] and potassium[6] were found to be very uniform in content in spite of the different appearances of the samples. On the other hand, the ratio of ferric

oxide to ferrous oxide varied markedly with the degree of oxidation during cooling of the lava flow. This ratio is larger in the samples of red color, porus structure and scoria, or stalactitic structure than in normal compact samples. The vanadium contents of some of the volcanic rocks from Volcano Ō-sima had already been determined by Iwasaki et al.[7]

In this paper, a minor component, vanadium, one of metallic elements, was selected for the determination. A discussion is made of its uniformity, and a comparison of its value with those of volcanic rocks erupted in other ages is made. The relation between the vanadium content and the contents of other elements is also discussed.

Experimental

Selection and Preparation of Rock Samples.— The lava flow, which erupted in 1950—1951, is about 6 m. thick, covers an area of 2.6 km^2, and totals 2×10^{10} kg. in weight. Figure 1 shows the original location of the rock samples collected.

The collection of the rock specimens was carried out as follows. Along the traverse line from Kakō-chaya to Gosinka-chaya, many parallel lines about 150 m. apart were set up. Along these lines, about 2 kg. of single hand specimen or aggregate sample were taken from each place at intervals of about 100 m. Furthermore, three samples were taken from the top, center and base at the particular place where the lave flow was about 13 m. thick. These collected samples were generally normal compact fragments and were often rock specimens of various appearances, such as red color, porus structure, scoria, etc. A total of 171 samples involving 9 samples of Anei lava erupted in 1778 and 3 samples of Meiji-Taisho volcanic rocks erupted in 1912 was collected; in all, 169 samples were analyzed.

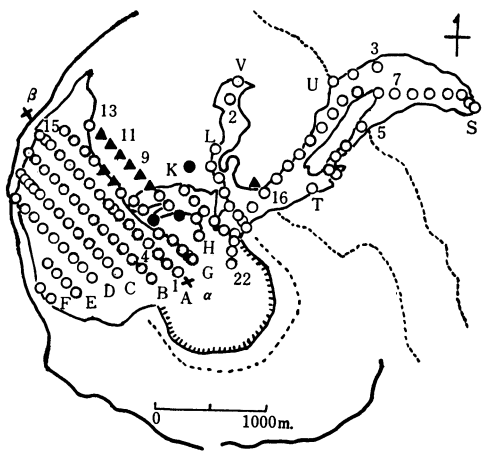

Fig. 1. The location of rock samples.
○ The lava in 1950—1951
● Meiji-Taisho volcanic rock
△ Anei lava
×α Kakō-chaya
×β Gosinka-chaya

About 4 g. of rock specimens, which was found in the previous paper[4] to be sufficient for the determination of the total iron, was crushed in a steel mortar and ground to fineness with an agate mortar and a pestle.

The Colorimetric Method. — About 200 mg. of rock powder was fused with anhydrous sodium carbonate in a platinum crucible, and vanadium was completely extracted with hot water. The colorimetric determination of vanadium in the extract was made directly by the phosphotungstic acid method modified by Katsura[8]. As a test of the reproducibility of this method, the determinations on the samples A-1 were repeated six times. These analyses were carried out on six separate fragments from a single had specimen. The results obtained are presented in Table I.

Table I. The results of repeated determinations

Sample (A-1)	V, %
1	0.046
2	0.046
3	0.047
4	0.047
5	0.048
6	0.046
Mean value	0.0467
Standard deviation	0.00055

By this method, it is possible to ascertain the vanadium contents of rocks with an precision of ±2% when they fall in a range of 0.04 to 0.05%.

Results and Discussion

Vanadium Contents. — Table II shows the contents of vanadium, total iron and ferric iron of 169 rock specimens from Volcano Ō-sima.

The Vanadium contents of 159 rock specimens from the lava flow erupted in 1950—1951 range from 0.043 to 0.048% and average 0.0455% (standard deviation 0.0014%). Even in view of possible error in chemical analysis, these ranges clearly show the differences among them, although they are small.

As a result, the vanadium contents of the lava flow stated above are considered to show a high degree of uniformity.

Figure 2 shows the frequency curve drawn on normal probability paper to test whether this distribution is normal or not.

Fe*: Total iron content; Fe**: Ferric iron content
Anei lava: G-10, G-9, H-7, H-8, H-9, H-10, H-11, H-12
Meiji-Taisho volcanic rock: G-5, H-4
Base: A-12-1, D-9-1, Center: A-12-2; Top: A-12-3, D-9-2
X: Normal compact sample; Y: Scoria-like sample
Z: Sample of porus structure; W: Sample of stalactitic structure
R: Sample of red color

This shows almost a normal distribution, although Ahrens[9] has reported that the concentration of a minor element is lognormally distributed in any specific igneous rock.

The vanadium contents of 8 specimens from Anei lava range from 0.050 to 0.052% and average 0.051% (standard deviation 0.0009%), while those of 2 specimens from Meiji-Taisho volcanic rocks average at 0.040%. Consequently, the distinction between the vanadium contents of Anei lava and of Meiji-Taisho volcanic rock is comparatively easy, but it is difficult to distinguish the lava in 1950—1951 from the volcanic rocks of the other ages on the basis of their vanadium contents.

When the vanadium content of Anei lava, the highest value of the three, is compared with those of volcanic rocks in Japan and in the world respectively, it was found to be the highest value of volcanic rocks in Japan, higher than the values (0.015~0.030%) found in gabbroic and basaltic rocks by Goldschmidt[10] which had already been observed by Katsura[11].

As already stated in connection with the total iron content, the vanadium contents of the lava in 1950—1951 are also independent of their appearances as rock specimens.

The Relation between the Vanadium and Ferric Iron Content of the Lava Flow in 1950—1951. —As stated above, the quantities of various elements, such as total iron, titanium, etc., in the lava in 1950—1951 are very uniform. They, therefore, can not be considered to show

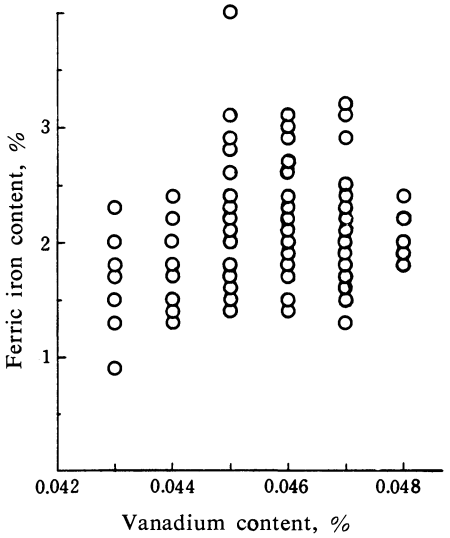

Fig. 3. The relation between vanadium and ferric iron content.

the relationship to the vanadium contents clearly. However, the ferrous iron and ferric iron contents vary markedly. As vanadium is believed to replace ferric iron, the relation between vanadium and ferric iron contents is shown in Fig. 3.

As shown in Fig. 3, there is no distinct, regular relation, although the contents of vanadium appear to become higher with increasing ferric iron contents. This seems to be attributable to the fact that vanadium had no time to replace the ferric iron, which increased rapidly by the oxidation of air and water vapor during the cooling of the lava flow at atmospheric temperature and pressure. In other words, it seems that the distribution of vanadium remains unchanged, but that ferric iron contents vary during the course of solidification and cooling. This consideration also agrees with that of the previous paper[4].

The Relation between the Contents of Vanadium and Other Elements in Volcanic Rocks in Different Ages.—The quantities of various elements[7,12] such as total iron, aluminum, titanium, magnesium and vanadium in volcanic rocks erupted in different ages are shown in Table III.

The number of rock specimens is too small to show the general relation definitely, but the relation may be discussed qualitatively. The positive correlation between the total iron and the vanadium content is shown in Fig. 4.

Table III. The contents of various elements in volcanic rocks from Volcano Ō-sima

Sample	Fe*, %	Al, %	Mg, %	Ti, %	V, %
Okata volcanic rock	7.0	10.9	3.5	0.47	0.027
Okata volcanic rock	10.6	7.8	3.3	0.49	0.054
Outer Somma lava	9.9	8.1	2.9	0.50	0.051
Anei lava	10.7	7.7	3.0	0.77	0.051
Meiji-Taisho volcanic rock	9.0	8.9	2.7	0.61	0.040
The lava in 1950—1951	10.0	8.0	3.0	0.70	0.046

Fe*: Total iron content.

Vanadium is found to be most concentrated in magnetite among the common rock-forming minerals[7]. Anei lava is 6% magnetite (according to a microscopic analysis by Kuno[13]), with about 0.7% vanadium[14]. This magnetite is not pure magnetite, but involves the glassy ground mass and pyroxene. Thus, the vanadium content in the magnetite corresponds to about 80% ($6\times0.007\times100/0.051$) in rock. If the amounts of magnetite are proportional to the total iron content, the relation under consideration may be understood completely[7].

The negative correlation to aluminum content is presented in Fig. 5.

The main rock-forming mineral involving aluminum in Anei lava is plagioclase (contained in 50% of rock), which generally contains little vanadium. If the amounts of plagioclase decrease along with an increase in the amount of magnetite, this seems to explain this relation.

The contents of vanadium are independent of the titanium and magnesium contents, but the correlation to the contents of total iron plus titanium is shown in Fig. 6.

The magnetite in Anei lava contains 38% total iron plus titanium[14]. If the titanium plus total iron contents are proportional to the amounts of magnetite, this relation seems to be explained well. This relation has also been shown in ultrabasic potassic rocks by Higazy[15].

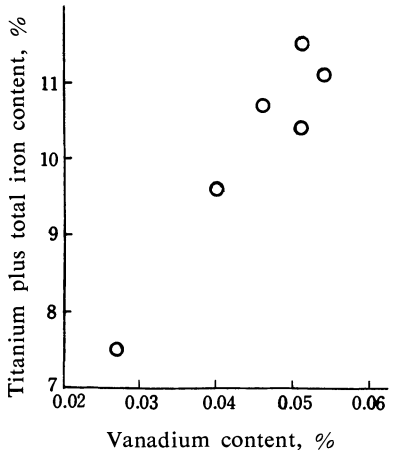

Fig. 6. The relation between vanadium and titanium plus total iron content.
Regress coefficient, $\gamma=0.90$

Conclusion

1) The vanadium contents of the lava flow erupted in 1950—1951 show a high degree of uniformity.

2) The frequency diagram shows an almost normal distribution.

3) It is difficult to distinguish between the lava of 1950—1951 and the volcanic rocks of the other ages in the basis of their vanadium contents.

4) A relation between the vanadium and ferric iron contents of the lava flow in 1950—1951 could not be found.

The expenses of this research were defrayed by a Scientific Research Encouragement Grant from the Ministry of Education, to which the authors wish to express their thanks.

De-localization of Bond Eigenfunctions in π-Electronic Systems. III. Non-Empirical Calculation of the π-Electronic States of the Vinyl Chloride Molecule

By Shozaburo TAKEKIYO

(Received October 21, 1961)

In previous papers[1] an approximate method, in which all the ionic structures are taken into consideration, was applied to the calculation of the π-electronic states of a conjugated homo-nuclear chain compound, and the quantitative agreement of the results with those obtained by the ASMO SCF CI method was achieved.

On the other hand, if that approximate method is applied, in the same way as in part II, to a consideration of the π-electronic states of monosubstituted benzenes, such as chlorobenzene or phenol molecules, almost meaningless results will be obtained. This is because by that method the ionic structures in such molecules, which are obtained by moving one or both of the lone pair of π-electrons in the atom adjacent to the benzene ring in the covalent structure into the ring, are not derived from any covalent structure conceivable at all with respect to those molecules.

In order to apply the approximate method to such molecules, therefore, special treatment will be required.

In this paper, the method is developed in order to be applied to the vinyl chloride molecule, from which chlorobenzene is derived by substituting the benzene nucleus for the vinyl radical. Electronic states of the molecule are calculated, and the results are compared with those obtained by the HLSP standard method.

Derivation of Three Classes of Canonical Structures

A conjugated double bond molecule, having the same number (four) of π-electrons as the vinyl chloride molecule, is supposed, and all the covalent structures conceivable with respect to this molecule are set up (Ref. Fig. 1.).

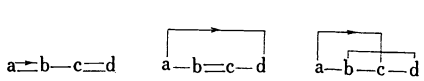

Fig. 1. Resonance structures of the conjugated molecule, consisting of four π-electrons and four atoms.

Then the π-electron, belonging to atom a in each structure, is made to move towards the atom in the direction of the arrow head, and ion a^+ is made to shift to an infinite distance (Ref. Fig. 2.).

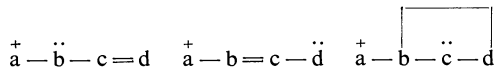

Fig. 2

Atoms b, c and d being substituted for chlorine, carbon and carbon atoms respectively, the resultant structures are the basic forms for the three classes of canonical structures; each class is obtained as in Fig. 3.

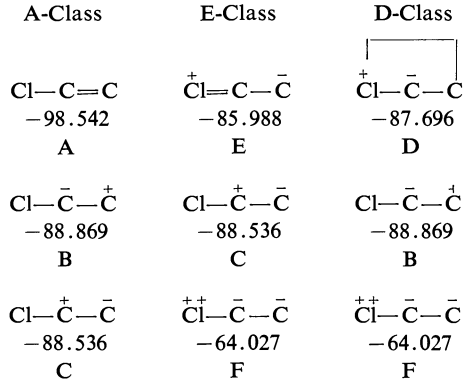

Fig. 3. Three classes of canonical structures and the energy values for the structures. Values are in electron volts.

The skeleton of the molecule is shown in Fig. 4. Slater $2p_\pi$- and $3p_\pi$-orbitals, with $Z_C=3.18$, $Z_{Cl}=6.099$ respectively, have been assumed for the carbon and the chlorine atoms. Numerical values of integrals over the atomic orbitals have been taken from Simonetta et al.[2]

TABLE I. WAVE FUNCTIONS ASSOCIATED WITH CLASSES AND THE CORRESPONDING ENERGY VALUES

A-Class

$\phi_1^A = 0.78468\Psi_A + 0.23865\Psi_B + 0.22923\Psi_C$ $E_1^A = -100.304$ eV.
$\phi_2^A = 0.026821\Psi_A - 0.75119\Psi_B + 0.71540\Psi_C$ $E_2^A = -86.005$ eV.
$\phi_3^A = 0.84357\Psi_A - 0.73278\Psi_B - 0.77065\Psi_C$ $E_3^A = -80.335$ eV.

E-Class

$\phi_1^E = 0.73693\Psi_C + 0.51843\Psi_E + 0.034910\Psi_F$ $E_1^E = -91.061$ eV.
$\phi_2^E = 0.71522\Psi_C - 0.85513\Psi_E - 0.099032\Psi_F$ $E_2^E = -81.517$ eV.
$\phi_3^E = 0.072333\Psi_C - 0.34638\Psi_E + 1.0230\Psi_F$ $E_3^E = -61.593$ eV.

D-Class

$\phi_1^D = 0.81035\Psi_B + 0.55853\Psi_D + 0.024643\Psi_F$ $E_1^D = -89.891$ eV.
$\phi_2^D = 0.58685\Psi_B - 0.82679\Psi_D - 0.041893\Psi_F$ $E_2^D = -86.628$ eV.
$\phi_3^D = 0.0^2 51618\Psi_B - 0.081459\Psi_D + 0.99936\Psi_F$ $E_3^D = -63.870$ eV.

All kinds of overlap, single exchange, and multiple exchange integrals have been considered.

Wave functions ϕ_i^K's for class K's and the corresponding energy values E_i^K's are given in Table I, where Ψ_L is the normalized bond eigenfunction for structure L.

Probabilities of the structures, π-electron densities, and bond orders for each class are shown in Table II and Fig. 5 respectively.

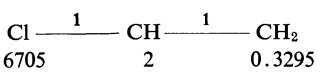

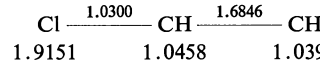

Fig. 5. π-Electron densities and bond orders in each class.

Electronic States of the Molecule

Wave functions for the lowest energy values in the respective classes have been combined linearly, and the wave functions Φ_i's for the molecule and the corresponding enery values E_i's have been calculated. The results are shown in Table III.

Then the probabilities of the structures, the π-electron densities, and the bond orders in the ground state of the molecule have been calculated from the results of Table II and Fig. 5. The results are shown in Table IV and Fig. 6, together with those obtained by the exact method.

HLSP method

Approximate method

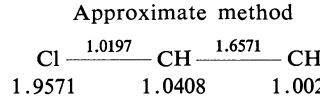

Fig. 6. Comparison of π-electron densities and bond orders.

Discussion

The value of the energy level for the ground state of the molecule, obtained by the exact HLSP method[3], is −100.91 eV. The difference of this value from the one obtained by the approximate method (Table III) is 0.35 eV., so the approximate method constitutes a good approach.

On the other hand, the excitation energy from the ground state to the first excited state is 11.41 eV. in the HLSP method. The approximate method, in which 12.98 eV. is obtained as in Table III, does not show a good agreement.

Finally, the wave function for the ground state has been transformed to represent the bond eigenfunctions explicitly. The result is:

$$\Phi_1 = 0.6939\Psi_A + 0.3046\Psi_B + 0.2801\Psi_C + 0.0644\Psi_D + 0.0544\Psi_E + 0.0065\Psi_F$$

while the result obtained by the HLSP method is

$$\Phi_G = 0.7359\Psi_A + 0.2184\Psi_B + 0.2213\Psi_C + 0.1616\Psi_D + 0.1152\Psi_E + 0.0067\Psi_F$$

From these results, it can be noticed that the migration percentage of the π-electrons in the chlorine atom to the vinyl radical in the approximate method is smaller than that in the other method.

One of the causes for such unsatisfactory results seems to be the neglect of the lower excited states in each class, which are at energy states close to the corresponding ground state, in the interaction of the classes (Ref. Table I).

Summary

The π-electronic energy levels, wave functions, π-electron densities, and bond orders of the vinyl chloride molecule have been calculated by the approximate method proposed in part I. Slater orbitals have been employed for the atomic orbitals of the carbon and chlorine atoms. All kinds of overlap, single exchange, and multiple exchange integrals have been considered. The calculated values of the energies for the ground state and the first excited state are -100.56 and -87.58 eV. The values obtained by the HLSP method are -100.91 and -89.50 eV. π-Electron densities are Cl $=1.957$, C (in the center of the molecule) $=1.041$, and C (in the edge of the molecule) $=1.002$. These values, based on the HLSP method, are 1.915, 1.046 and 1.039 respectively. Bond orders between the neighboring carbon and chlorine atoms are 1.02 and 1.03 in the respective methods.

The author wishes to express his sincere gratitude to Professor Kyosuke Omori, Kyushu University, for his helpful criticisms and suggestions. Thanks are also due to Professor Saburo Nagakura, the University of Tokyo, for his advice and valuable assistance, and to Professor Eiichi Ishiguro, Ochanomizu University, who has read the manuscript and helped the author to remove obscurities.

De-localization of Bond Eigenfunctions in π-Electronic Systems. IV. Non-Empirical Calculation of the π-Electronic States of the Cyclobutadiene Molecule

By Shozaburo TAKEKIYO

(Received October 21, 1960)

In part I[1] of this series an approximate method for the calculation of the π-electronic states of molecules was proposed, and in part II[2], where the method was applied to the consideration of a conjugated homo-nuclear chain compound, *trans*-butadiene molecule, the quantitative agreement of the results with those obtained by the ASMO SCF CI method was obtained. Then, in part III[3], that method was extended to the treatment of a hetero-nuclear system, the vinyl chloride molecule, in which a special atom possesses a lone pair of π-electrons; good results were obtained.

In this paper, the theory is applied to the calculation of the π-electronic states of a molecule, the cyclobutadiene molecule, belonging to the conjugated cyclic systems. Calculations of the probabilities of the resonance structures, the wave functions and the corresponding energy levels are made non-empirically, using the non-orthogonal atomic orbitals. The higher orders of overlap and exchange integrals are taken into account. These results are compared with the values obtained by the HLSP method.

The orthogonalized rather than the non-orthogonal (cf. Ref., part I) atomic orbitals[4] are usually employed for the quantitative considerations of polyatomic molecules, since it is very difficult to consider fully the higher order permutations of the electrons[5]. Therefore, calculations based on the orthogonalized atomic orbitals are also attempted, and the adaptability of the approximate method in this scheme is investigated.

Classification of the Resonance Structures

Cyclobutadiene has been assumed to be a square molecule, with the neighboring carbon nuclear distance $R_{C-C}=1.40$ Å.

Core integrals have been evaluated by the method of Parr and Mulliken[6], and the numerical values of the electron repulsion integrals have been taken from Craig[7].

The three classes of canonical structures are given in Fig. 1, in which energies are relative to $4W_{2p}$, where W_{2p} is the energy of a $2p_\pi$-electron of a carbon atom in its valence state.

Relations between bond eigenfunctions Ψ_L's and functions Ψ_i's which are the bases for

$\overline{\Phi}_3(^1B_{1g}) = 0.75721\overline{\Psi}_6 + 0.49877\overline{\Psi}_7 + 0.42174\overline{\Psi}_8$ $\overline{E}_3 = 4\overline{\alpha} + 46.939$ eV.

the irreducible representations of the D_{4h} group, are shown in the Appendix.

A- and B-classes are incorporated to form one class, AB-class, due to the symmetry of the molecule. Wave functions for each class and the corresponding energy values are given in Table I.

Interaction of the Classes

Wave functions for the lowest energies, belonging to the same symmetry, have been picked up from the two classes, AB- and C-classes, and have been linearly combined.

The resulting wave functions for the molecule and the corresponding energy values are given in Table II.

TABLE IV. WAVE FUNCTIONS FOR THE MOLECULE AND THE CORRESPONDING ENERGY VALUES (the Heitler-London method)

Based on non-orthogonal atomic orbitals

$\Phi_1(^1B_{2g}) = \Psi_A - \Psi_B$ $E_1 = 4W_{2p} - 57.653$ eV.
$\Phi_2(^1A_{1g}) = \Psi_A + \Psi_B$ $E_2 = 4W_{2p} - 54.949$ eV.

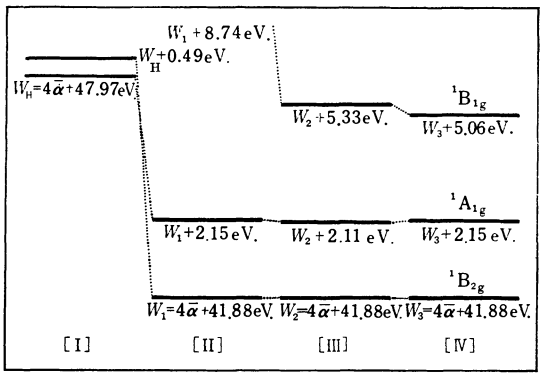
Discussion

In Fig. 2, the energy levels of the cyclobutadiene molecule, which have been found by the various methods, are shown.



From the figure, it can be noticed that the approximate method gives successful results to the calculations of the electronic states of a conjugated cyclic system, as it did to that of a conjugated chain system investigated in part II.

Good agreements of the energy levels are also seen in the case of the evaluation for only the AB-class, which originates from the most stable covalent structures. From such agreements we can expect that, for molecules with high symmetry, the quantitative calculations of the energy levels may be performed

* For the ground $^1B_{2g}$-state, the approximate and the usual method are theoretically identical.

Based on non-orthogonal atomic orbitals

Based on orthogonalized atomic orbitals

Fig. 2. Comparison of energy levels.

with a good result by a simplified process in the valence bond method.

It is recognized that, for the calculations of the energy levels, the approximate method gives quantitative agreements with the usual method, even if we use the orthogonalized instead of the non-orthogonal atomic orbitals.

Good agreements of the approximate method with the usual method are also seen for the values of the probabilities of the resonance structures (Tables V and VI).

In the cases of complex molecules, the valence bond method has, hitherto, been used only for the object of the qualitative considerations. But in view of the success in trials over parts I–IV, such deadlocks can probably be overcome to some extent by the application of our approximate method.

Summary

Calculations of the π-electronic energy levels, the wave functions, and the probabilities of the resonance structures of cyclobutadiene molecule have been made by an approximate method, proposed in part I, using the non-orthogonal Slater orbitals. Results have agreed quantitatively with the values calculated by the usual HLSP method.

Calculations have also been made using the orthogonalized atomic orbitals. Agreement of the results with those obtained by the usual method has been recognized.

The author wishes to express his sincere gratitude to Professor Kyosuke Omori, Kyushu University, for his helpful criticisms and suggestions. Studien über D-Glucosamin-derivaten. VII[1]. *Darstellung von 3,4; 5,6-Di-O-isopropyliden-N-acetyl-D-glucosaminsäure über das entsprechende D-Glucosaminol-derivat*

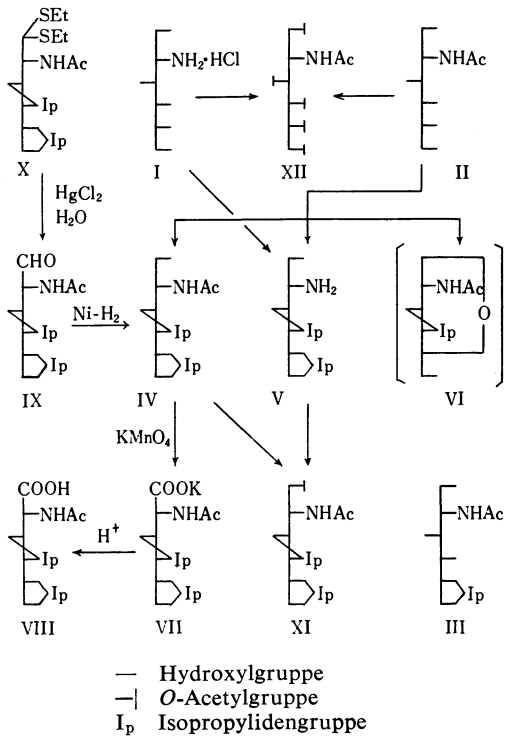
Von Juji YOSHIMURA, Toshio NAKAGAWA und Tetsuo SATO

(Eingegangen am 27. Juli 1961)



Nach allgemeinen Methoden wird D-Glucosaminsäure nicht acetalisiert, weil die Säure in den organischen Lösungsmitteln schwer löslich ist. Bei Behandlung mit Acetanhydrid und Natriumacetat[2] oder mit Acetanhydrid in Pyridin[3] gibt die Säure nicht das entsprechende Pentaacetat, sondern 2-Acetamino-5-acetoxymethyl-α-pyron. Es ist unerwartet schwer[4], das an den allen Hydroxyl-gruppen blockierten D-Glucosaminsäure-derivat zu erhalten.

Wir haben daher über die Oxydation vom D-Glucosaminol-derivat, in dem nur die Hydroxyl-gruppe am C-1-Stellung frei ist, in das entsprechende D-Glucosaminsäure-derivat versucht. Um die allen andern Hydroxyl-gruppen außer der am C-1-Stellung des D-Glucosaminols oder *N*-Acetyl-D-glucosaminols zu blockieren, muß man eine selektive Reaktion benutzen.

Die Behandlung von Polyhydroxyalkohol mit Aldehyd oder Keton gibt das entsprechende Ringacetal. Dabei ist es bekannt, daß Keton vorzüglich einen α-Ring (5-Ring) gibt und Aldehyd einen β-Ring (6-Ring) gibt[5]. Bei der Acetonisierung von *N*-Acetyl-D-glucosaminol kann man daher die Bildung vom 3,4; 5,6-Di-*O*-isopropyliden-derivat mit einer freien Hydroxyl-gruppe am C-1-Stellung erwarten.

Karrer und Meyer[6] berichteten über die Darstellung von D-Glucosaminol-hydrochlorid (I) und *N*-Acetyl-D-glucosaminol (II) durch katalytische Hydrierung von D-Glucosaminhydrochlorid und *N*-Acetyl-D-glucosamin. Turumi und Yamada[7] stellten 5,6-*O*-Isopropyliden-*N*-acetyl-D-glucosaminol (III) aus II in Aceton in Gegenwart von Kupfersulfat her. Aber andere Derivate des D-Glucosaminols sind noch kaum bekannt.

Nach Behandlung von II in Aceton in Gegenwart von Kupfersulfat und einer kleinen Menge konzentrierter Schwefelsäure, Neutralisierung der Reaktionslösung mit eisgekühlter Alkalilauge, Ausziehung mit Chloroform und Vertreiben des Lösungsmittels haben wir 3,4; 5,6-Di-*O*-isopropyliden-*N*-acetyl-D-glucosaminol (IV) vom Schmp. 158~160°C und $[\alpha]_D^{22}$ −7.8° (in Methanol) gewonnen. Der aus der wäßrigen Schicht beim Eindampfen erhaltene Sirup wurde durch Hochvakuumdestillation in zwei Fraktionen geteilt, d. h. eine kleine Menge Erstdestillates vom Sdp.$_{0.005}$ 105~106°C und eine große Menge Hauptdestillates vom Sdp.$_{0.02}$ 190~192°C. Aus dem Erstdestillat haben wir 3,4; 5,6-Di-*O*-isopropyliden-D-glucosaminol (V) vom Schmp. 65~68°C und $[\alpha]_D^{22}$ +8.5° (in Methanol) erhalten und aus dem Hauptdestillat IV und eine kristalline Verbindung (VI) mit der Formel $C_{11}H_{19}O_5N$ vom Schmp. 170~172°C und $[\alpha]_D^{22}$ −164.1° (in Methanol) erhalten. Die Struktur von VI ist

noch nicht ganz klar, aber weil Zuckeralkohole überhaupt sich mit Hilfe von Säure leicht in die entsprechenden Anhydriden überführen lassen[8], ist die oben gezeigte Konstitutionsformel wahrscheinlich.

Die Oxydation von IV mit alkalischer Kaliumpermanganat-lösung gab das Kaliumsalz (VII) der 3, 4; 5, 6-Di-*O*-isopropyliden-*N*-acetyl-D-glucosaminsäure. Diese Tatsache zeigt, daß es in IV eine freie, primare Hydroxylgruppe gibt. Unter der Wirkung eines kleinen Überschüsses Mineralsäure ließen sich VII in die entsprechende freie Säure (VIII) vom Schmp. 195~196°C und $[\alpha]_D^{22}$ −14.9° (in Methanol) überführen.

3, 4; 5, 6-Di-*O*-isopropyliden-*N*-acetyl-*al*-D-glucosamin (IX), aus dem entsprechenden Diäthylmercaptal[9] (X) dargestellt, konnte unter katalytischer Hydrierung zu IV geführt werden. Die Acetonisierung von I in Gegenwart von konzentrierter Schwefelsäure gab IV, und die Acetylierung von V und IV mit Acetanhydrid in Pyridin dasselbe Diacetat (XI). Daraus folgt, daß die Verknüpfungsstellen von der Isopropylidenresten in IV, V, VII und VIII den in X gleich sind.

Die Acetylierung von I und II mit Acetanhydrid in Pyridin gab auch dasselbe Hexaacetat (XII).

Bescheibung der Versuche

Acetonisierung von *N*-Acetyl-D-glucosaminol (II).—Mit einer Lösung von 260 ccm trocknem Aceton und 4 ccm konz. Schwefelsäure wurden 20 g II und 50 g wasserfreies Kupfersulfat versetzt. Nach 70 stdg. Rühren bei 30~40°C sog man das Unlösliche ab und goß das Filtrat unter kräftigem Rühren tropfenweise ins Eiswasser, das 25 g Natriumhydrogencarbonat enthielt. Nach Vertreiben des Acetons i. Vak. bei 35°C wurde wenig Natriumsulfit zugesetzt und der Niederschlag wurde abgesogen. Dann schüttelte man das Filtrat dreimal mit je 50 ccm Chloroform aus, wusch die Extraktbrühe zweimal mit Wasser, und verdampfte das Lösungsmittel i. Vak. bei 40°C nach Trocknen über Natriumsulfat. Der rückständige Sirup wurde aus Äthanol-Petroläther umkristallisiert. Man erhielt farblose Kristalle des 3, 4; 5, 6-Di-*O*-isopropyliden-*N*-acetyl-D-glucosaminols (IV) vom Schmp. 158~160°C und $[\alpha]_D^{22}$ −7.8° (*c* 0.97, Methanol). Ausb. 6.2 g (23% d. Th.).

$C_{14}H_{25}O_6N$ (303.4) Gef.: C, 55.16; H, 8.48; N, 4.58; Ber.: C, 55.43; H, 8.31; N, 4.62%.

Nach Eindampfen der wäßrigen Schicht i. Vak., Extrahierung des Rückstand mit etwa 100 ccm heißem Äthanol und Vertreiben des Lösungsmittels i. Vak., erhielt man 16.8 g Sirup, welcher durch Hochvakuumdestillation in zwei Fraktionen geteilt wird, d. h. 2.1 g Erstdestillat vom Sdp.$_{0.005}$ 105~106°C und 13.4 g Hauptdestillat vom Sdp.$_{0.02}$ 190~192°C. Das Erstdestillat kristallisierte sich nach einigen Tagen. Nach Umkristallisierung aus Äther-Petroläther erhielt man farblose Kristalle des 3, 4; 5, 6-Di-*O*-isopropyliden-D-glucosaminols (V) vom Schmp. 65~68°C und $[\alpha]_D^{22}$ +8.5° (*c* 0.97, Methanol). Ausb. 1.8 g (7.7% d. Th.).

$C_{12}H_{23}O_5N$ (261.3) Gef.: C, 55.10; H, 8.63; N, 5.33; Ber.: C, 55.15; H, 8.87; N, 5.36%.

Nach Umkristallisierung des Hauptdestillates aus Äther-Petroläther und dann aus Äthylacetat wurden die Kristalle von IV isoliert. Schmp. und Misch-Schmp. 158~160°C. Ausb. 9.5 g (34.9% d. Th.).

Aus der Mutterlauge wurde die zweite Substanz isoliert. Nach Umkristallisierung aus Äthylacetat erhielt man 2.9 g farblose Kristalle (VI), deren Struktur noch nicht ganz klar ist. Schmp. 170~172°C und $[\alpha]_D^{22}$ −164.1° (*c* 0.66, Methanol).

$C_{11}H_{19}O_5N$ (245.3) Gef.: C, 54.52; H, 8.00; N, 6.08; Ber.: C, 53.86; H, 7.81; N, 5.71%.

Acetonisierung von D-Glucosaminol-hydrochlorid (I).—In eine Lösung von 340 ccm trocknem Aceton und 4 ccm konz. Schwefelsäure wurden 15 g I versetzt und etwa 100 Std bei 30~45°C aufgerührt. Nach Abfiltrierung des unreagierten Materials, Neutralisierung des Filtrates mit eiskalter wäßrg. Natriumhydrogencarbonat-lösung und Vertreiben des Acetons i. Vak., schüttelte man den Rückstand dreimal mit je 50 ccm Chloroform aus, aber kein Produkt wurde extraktiert. Aus der wäßrigen Schicht erhielt man 2.2 g Sirup durch die gleiche Behandlung wie in 1) beschrieben. Aus dem Sirup wurden 1.5 g Destillat (105~106°C/0.005 Torr) erhalten und das Destillat kristallisierte sich sofort. Schmp. und Misch-Schmp. mit V aus II 65~68°C und $[\alpha]_D^{22}$ +8.5° (*c* 0.94, Methanol).

Kalium-3, 4; 5, 6-di-*O*-isopropyliden-*N*-acetyl-D-glucosaminat (VII).—Zu einer Lösung von 7 g IV in 50 ccm Wasser ließ man unter Kühlung und Rühren eine wäßrg. Lösung von 6.3 g Kaliumpermanganat und 2.5 g Kaliumhydroxyd langsam zutropfen. Nach 24 stdg. Stehenlassen bei Zimmertemperatur wurde der Niederschlag abgesogt, das Filtrat mit verd. Salzsäure bis auf pH 9.5 neutralisiert und i. Vak. bei 40°C eingedampft. Der Rückstand ließ sich dreimal in je 20 ccm heißem Äthanol aufnehmen. Daraus wurden 7.8 g (95% d. Th.) farblose Nadeln vom Schmp. 203~204°C und $[\alpha]_D^{22}$ −21.7° (*c* 0.69, Methanol) erhalten.

$C_{14}H_{22}O_7NK$ (355.4) Gef. N, 3.73; Ber.: N, 3.94%.

3, 4; 5, 6-Di-*O*-isopropyliden-*N*-acetyl-D-glucosaminsäure (VIII).—Zu einer Lösung von 2 g VII in 20 ccm Wasser ließ man unter Kühlung eine Lösung von 0.6 g konz. Schwefelsäure in 5 ccm Wasser zutropfen und sofort mit 100 ccm Chloroform ausziehen. Nach zweimaligem Waschen mit Wasser und Vertreiben des Lösungsmittls wurden 1.5 g (84% d. Th.) farblose Nadeln erhalten. Schmp. 195~196°C, $[\alpha]_D^{22}$ −14.9° (*c* 0.77, Methanol).

$C_{14}H_{23}O$-N (317.3) Gef.: C, 53.23; H, 7.25; N, 4.61; Ber.: C, 52.99; H, 7.31; N, 4.41%.

Darstellung von IV aus 3, 4; 5, 6-Di-*O*-isopropyliden-*N*-acetyl-D-glucosamindiäthylmercaptal (X).—In eine Lösung von 6 g X[9] in 20 ccm Aceton versetzte man 40 g feuchtes Kadmiumcarbonat

8) L. F. Wiggins, "Advances in Carbohydrate Chemistry", Vol. 5, Academic Press Inc., New York (1950), S. 191.
9) J. Yoshimura und T. Sato, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **80**, 1479 (1959).

und dazu ließ unter kräftigem Rühren eine Lösung von 17 g Quecksilberchlorid in 20 ccm Aceton innerhalb einer Stunde bei Zimmertemperatur zutropfen. Nach 24 stdg. Rühren wurde der Niederschlag abgesogen und zweimal mit je 20 ccm Aceton gewaschen. Man vereinigte das Filtrat und die Waschlauge, vertrieb das Aceton i. Vak. bei 40°C und zog den Rückstand dreimal mit je 50 ccm Chloroform aus. Nach Vertreiben des Lösungsmittels i. Vak. wurde der zurückständige Sirup in 50 ccm Äthanol gelöst und im Autoklaven mit Hilfe von Raney-Nickel bei 40°C unter 20 Atm hydriert. Man filtrierte den Katalysatoren ab, vertrieb das Lösungsmittel i. Vak., löste den Rückstand in wenigem Äthanol, versetzte mit Petroläther bis zur Trübung und nach Einimpfen ließ im Eisschrank stehen. Daraus wurden 0.8 g farblose Kristalle erhalten. Schmp. und Misch-Schmp. mit dem früher dargestellten Produkt 158 ~160°C und $[\alpha]_D^{22}$ −7.5° (*c* 0.85, Methanol).

3,4; 5,6-Di-*O*-isopropyliden-di-*N*,*O*-acetyl-D-glucosaminol (XI).—Zwei Gramme V wurden mit 15 ccm Acetanhydrid in 15 ccm Pyridin behandelt und nach 24 Std. in Eiswasser gegossen. Das Gemisch wurde mit Chloroform ausgezogen und das Filtrat mehrmals mit Wasser, dann dreimal mit wäßrg. Natriumhydrogencarbonat-lösung und nochmal mit Wasser ausgeschüttelt. Nach Trocknen über Natrium sulfat verdampfte man das Lösungsmittel i. Vak. und nahm den gelben, öligen Rückstand auf. Das Produkt wurde i. Hochvak. destilliert. Bei 135~136°C unter 0.002 Torr ging hellgelber, viskoser Sirup über, welcher sich nach einigen Tagen kristallisierte. Nach Umkristallisierung aus Äther-Petroläther erhielt man 1.7 g (64% d. Th.) farblose Nadeln vom Schmp. 61~62°C und $[\alpha]_D^{22}$ +6.7° (*c* 1.04, Methanol).

$C_{16}H_{27}O_7N$ (345.4) Gef.: C, 55.85; H, 7.74; N, 4.22; Ber.: C, 55.64; H, 7.88; N, 4.06%.

Nach der gleichen Behandlung, wie oben beschrieben, wurden 1.4 g IV mit 12 ccm Acetanhydrid in 12 ccm Pyridin behandelt. Man erhielt 0.9 g (54% d. Th.) XI von Schmp. und Misch-Schmp. 61~62°C und $[\alpha]_D^{22}$ +6.5° (*c* 0.95, Methanol).

Hexa-*N*,*O*-acetyl-D-glucosaminol (XII). — Nach der gleichen Behandlung wie oben ließ man 3 g I mit 30 ccm Acetanhydrid in 30 ccm Pyridin acetylieren und erhielt 3.6 g hellbraunen Sirup von Sdp.$_{0.02}$ 190~195°C. Nach Umkristallisierung aus Äthanol-Äther erhielt man 3.1 g (52% d. Th.) farblose Nadeln von Schmp. 95~96°C und $[\alpha]_D^{22}$ −3.7° (*c* 1.07, Methanol).

$C_{18}H_{27}O_{11}N$ (433.4) Gef.: C, 49.27; H, 6.61; N, 3.39; Ber.: C, 49.88; H, 6.28; N, 3.23%.

Nach der gleichen Methode wie oben ließen 3 g II sich in die farblose Nadeln von XII von Schmp. und Misch-Schmp. 95~96°C überführen. Ausb. 3.5 g (60% d. Th.).

Zusammenfassung

Nach der Acetonisierung von *N*-Acetyl-D-glucosaminol in Gegenwart von wasserfreiem Kupfersulfat und konzentrierter Schwefelsäure wurden drei kristallisierende Substanzen isoliert: 3,4; 5,6-Di-*O*-isopropyliden-*N*-acetyl-D-glucosaminol (IV), 3,4; 5,6-Di-*O*-isopropyliden-D-glucosaminol (V) und eine kristalline Verbindung (VI) mit der Formel $C_{11}H_{19}O_5N$. Bei der Acetonisierung von D-Glucosaminol-hydrochlorid in Gegenwart von konzentrierter Schwefelsäure wurde nur V erhalten.

Um die Verknüpfungsstellen von der Isopropylidenresten in IV und V zu bestimmen, wurde IV aus 3,4; 5,6-Di-*O*-isopropyliden-*N*-acetyl-D-glucosamindiäthylmercaptal geleitet und wurden IV und V acetyliert.

Die Oxydation von IV mit Kaliumpermanganat gab Kalium-3,4; 5,6-di-*O*-isopropyliden-*N*-acetyl-D-glucosaminat, welches mit der Wirkung eines kleinen Überschüsses Mineralsäure sich zu der entsprechenden freien Säure geführt wurde.

Wir danken Herrn Dr. Asaji Kondo für die Elementaranalysen und auch Herrn Chikao Kikuchi und Herrn Hirokichi Ono für die Mithilfe bei der vorliegenden Versuchung.

Studies on the Reduction of Phosphorus Trichloride with Copper Powder in Non or Less Polar Solvents

By Masanao NAKAGAWA

(Received June 20, 1961)

It has been reported in former papers[1-3] that chlorides and oxychlorides of arsenic, vanadium and phosphorus can be partially reduced with copper, and that this reduction leads to the formation of compounds of the chlorides with copper, the chlorides or their lower chlorides with cuprous chloride, and of these elements with copper. Recently, arsenic trichloride[4] and vanadium tetrachloride and oxychloride dissolved in titanium tetrachloride[5] have been studied for their reduction with copper. Little knowledge, however, has been obtained on the reduction of the chlorides of the group V element with copper; the behavior of phosphorus trichloride is particularly unclear,

In the present work the reduction of phosphorus trichloride with copper is studied in non or less polar solvents such as carbon tetrachloride, cyclohexane, silicon tetrachloride, chloroform and tetrachloroethane.

Experimental

Materials.—The solvents and the phosphorus trichloride were purified by normal procedure and stored in a desiccator. The water contents of these solvents was less than 1 mg. per 50 ml. Electrolytic copper powder used, of a purity more than 99.5%, was stored in another desiccator. It passed through a standard sieve of 250 mesh.

Procedure.—In a 100 ml. flask, 0.5 ml. of the trichloride was dissolved in 50 ml. of each solvent or dissolved in a mixture of 5 ml. of silicon tetrachloride and 50 ml. of carbon tetrachloride. The solution of the trichloride was refluxed with 10 or 20 g. of copper powder while being stirred. In another case, 10 ml. of the solution was heated with 4 g. of copper powder in an autoclave with a 20 ml. inner tube of "Teflon", while being shaken. After being cooled, a portion of the supernatant, 2 or 5 ml., was pipeted from the resulting solution and hydrolyzed in a conical flask containing 100 ml. of distilled water by cooling with ice water. The aqueous solution thus obtained, without removing the small amount of the organic phase, was half-saturated with sodium chloride and then titrated with a N/10 sodium hydroxide solution, in the presence of methyl orange and phenolphthalein as indicators, to determine the phosphorous acid and hydrochloric acid derived from the phosphorus chlorides. The procedure of the titration is almost the same as that used for the determination of phosphoric acid in the presence of hydrochloric acid. Another analytical method for chlorine, including chloride other than phosphorus chloride, and phosphorus was also used: An aqueous, hydrolyzed solution was treated with an excess of N/10 silver nitrate, the silver chloride precipitated was filtered off, and the filtrate obtained was titrated with N/10 ammonium thiocyanate after the addition of ferric alum solution as an indicator. Another aqueous, hydrolyzed solution was evaporated to nearly dryness in the presence of nitric acid on a water bath, and the residue obtained was dissolved in water and titrated with a N/10 sodium hydroxide solution as described above. In this method the aqueous solution also was subjected to analyses without removing the small amount of the organic phase. The silicon tetrachloride solution also was hydrolyzed, and the resulting solution was heated with hydrofluoric acid in the presence of perchloric acid and evaporated to nearly dryness; then the residue obtained was analyzed for phosphorus by titration with sodium hydroxide solution.

In these experiments the sampling of the trichloride, solvent, etc., was made in a dry box, and precaution was taken to exclude any effect of water vapor.

Results

Figures 1—4 represent the results of the reflux treatment at 20~140°C, where analyses were made only by the titration with sodium hydroxide. The treatment leads to a decrease in the phosphorus content of the solution and of the ratio of Cl/P, which represents the atomic ratio of chlorine to phosphorus in the solution. This reaction is rather rapid even at a lower temperature, as is shown in Figs. 2 and 3, from which it can be observed that the reaction reaches an equilibrium state within one hour. The percentage of decrease in the phosphorus content depended slightly on the preperty of the solvents and on the temperature of the treatment, although its value in every solution was about 40~50%

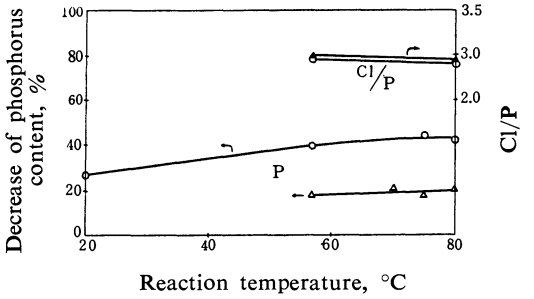

Fig. 1. Temperature dependence of the decrease of the phosphorus content and the value of Cl/P in CCl_4 soln. by the reflux treatment for 1 hr. Reaction temperature represents the temperature of a water bath in which reaction flask is heated.
○ Cu, 20 g. △ Cu, 10 g.

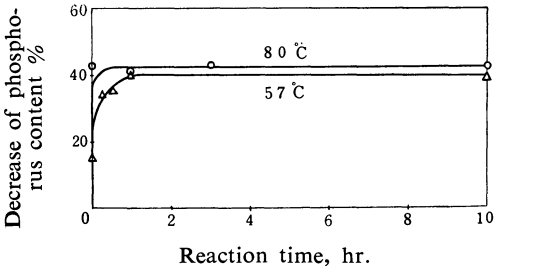

Fig. 2. Reaction time dependence of the decrease of the phosphorus content of CCl_4 soln. by the reflux treatment. Cu, 20 g.

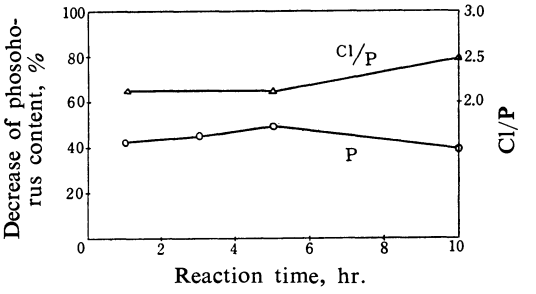

Fig. 3. Reaction time dependence of the decrease of the phosphorus content and the value of Cl/P of $CHCl_3$ soln. by the reflux treatment at 57°C. Cu, 20 g.

under these experimental conditions, whereas the value of Cl/P depended on the property of the solvent, and the values for carbon tetrachloride, chloroform and tetrachloroethane were about 3, 2.2~2.5 and 1.2~1.4 respectively. Cyclohexane, whose graphical representation is omitted, behaved like carbon tetrachloride regarding the percentage of decrease in the phosphorus content and the value of Cl/P, which were 39.6% and 2.96 respectively at 57°C.

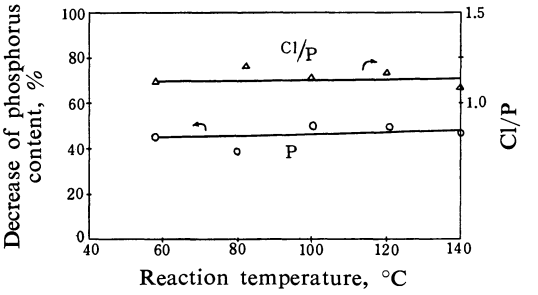

Fig. 4. Temperature dependence of the decrease of phosphorus content and the value of Cl/P of $C_2H_2Cl_4$ soln. by the reflux for 1 hr. Cu, 20 g.

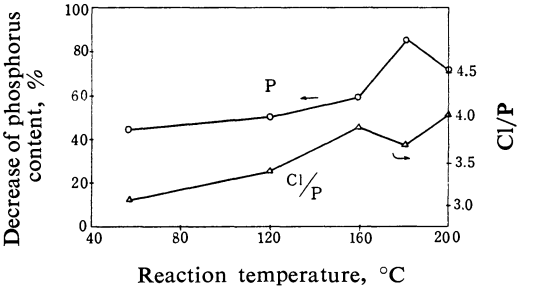

Fig. 5. Temperature dependence of the decrease of the phosphorus content and the ratio of Cl/P of CCl_4 soln. by the autoclave treatment for 1 hr.

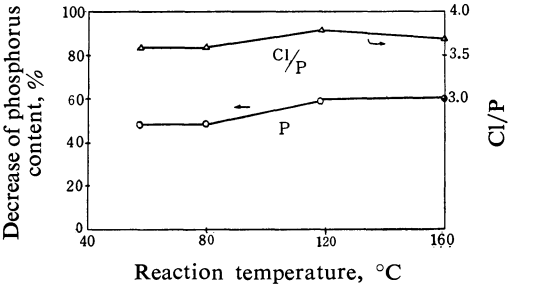

Fig. 6. Temperature dependence of the decrease of the phosphorus content and the ratio of Cl/P of $CHCl_3$ soln. by the autoclave treatment for 1 hr.

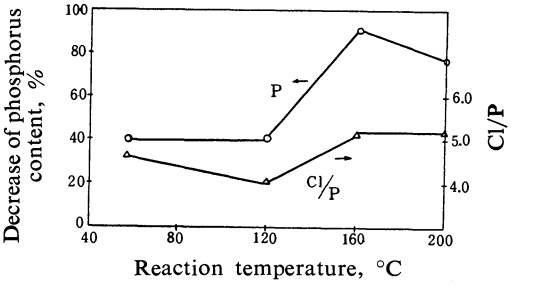

Fig. 7. Temperature dependence of the decrease of the phosphorus content and the ratio of Cl/P of $C_2H_2Cl_4$ soln. by the autoclave treatment for 1 hr.

Figures 5—7 represent the results of the treatment in the autoclave, where analyses were made by titrations with silver nitrate and sodium hydroxide. Although the phosphorus contents of the solutions treated at 56～120°C were comparable to those obtained by the reflux treatment, the ratios of Cl/P of the solution differed from those obtained by the reflux treatment and were more than 3. With an increase in the temperature of the treatment above 160°C, the phosphorus contents decreased and the ratios of Cl/P presented a particular change in every solvent. In the chloroform solutions, the treatment above 160°C gave rise to an obvious change in the quality of the solvent; the copper powder became voluminous and the volume of the liquid phase decreased. Because of this change, the treatment for the chloroform solution was not carried out above 160°C. Some darkening of the surface of copper powder was seen in the treatment at 200°C for the carbon tetrachloride solution and the tetrachloroethane solution. In Fig. 5 or 7, the irregular change in the phosphorus content and the ratio of Cl/P can be observed at 160～200°C, and this change was consistent with the change in the quality of the copper surface at that temperature range. In Figs. 1—7, it can be observed that the percentage of decrease in the phosphorus content in every solution treated by the reflux amounted to nearly the same, 40～50%, whereas the percentage of decrease in the phosphorus content in the carbon tetrachloride solution and the tetrachloroethane solution treated by autoclave at 160 or 180°C amounted to about 85 and 90% respectively, while those treated at 200°C amounted to about 70 and 80% respectively. The value of Cl/P in the former solution treated at 200°C was about 4, and that of the latter solution was about 5.

TABLE I. Cl/P RATIO OF SOLUTION TREATED WITH COPPER FOR ONE HOUR

	Refluxed at 57°C Analyzed by		Autoclaved at 200°C Analyzed by	
Solvent	NaOH	$AgNO_3$, NaOH	NaOH	$AgNO_2$, NaOH
CCl_4	2.97	ca. 3.0	3.30	4.02
$CHCl_3$	.142	3.26	—	3.68[6]
$C_2H_2Cl_4$	1.18	4.75	—	5.15

Table I represents the values of Cl/P in the solutions subjected to the treatments. In Table I it is clear that the values of Cl/P, obtained only by titrations with sodium hydroxide, of the solutions subjected to the reflux treatment were less than 3; this difference afforded a measure of the degree of the reduction, which was higher in more polar solvent. When the estimation of the value of the same solution was made by titration with silver nitrate and sodium hydroxide, the value of every solution became more than 3 and the solution of a more polar solvent took a larger value. The silver nitrate herein used reacts not only with the chloride ion produced by the hydrolysis of phosphorus chloride, but also with cuprous chloride in a solid state and with some others. The Cl/P ratio larger than 3 obtained by this analytical method, therefore, presumably implies the presence of cuprous chloride in the solvent and, in consequence, the reduction of phosphorus trichloride. Such facts were observed for the value of Cl/P in the solutions subjected to the autoclave treatment at 200°C, where the value was larger than 3 even in the case of titration with only sodium hydroxide. In connection with the action of silver nitrate, it also was found qualitatively that the solutions of a more polar solvent subjected to these treatments contained a greater amount of copper compound.

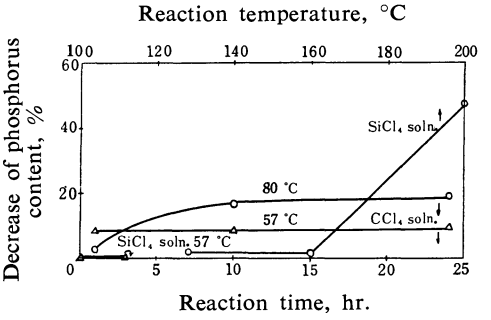

Fig. 8. Effect of $SiCl_4$ on the decrease of phosphorus content. CCl_4 soln. and $SiCl_4$ soln. represents a soln. of PCl_3: $SiCl_4$: CCl_4=1 : 10 : 100 in volume and PCl_3: $SiCl_4$=1 : 100 respectively, Cu, 20 g. in reflux; 4 g. in autoclave.

Figure 8 represents the effect of silicon tetrachloride. A slight decrease in the phosphorus content by the treatment was obtained with the mixed solution of phosphorus trichloride and silicon tetrachloride in carbon tetrachloride. Such facts were observed in the silicon tetrachloride solutions of the trichloride at lower temperatures. Although the phosphorus content presented a marked decrease as a result of the treatment at 200°C, the percentage of decrease was only about 50%, smaller than that in the case of other solvents.

Discussion

From the above results it was considered that the phosphorus trichloride in the solution

6) Representation of the treatment at 160°C.

is primarily decreased by its adsorption on the surface of copper powder; then the trichloride on the surface and in the solution is reduced by another reaction, in which the solvents themselves are dechlorinated[7] with copper and then such dechlorinated products are chlorinated with phosphorus trichloride and with its lower chloride produced by the reduction. This reaction of copper powder yields cuprous chloride, which is insoluble in water and many solvents. The values of Cl/P smaller than 3 were obtained by titration with sodium hydroxide. The values greater than 3, however, were obtained by titration with silver nitrate and sodium hydroxide. These facts suggest that a certain part of the cuprous chloride has been dissolved in the solvents and that this cuprous chloride reacts with silver nitrate. This suggestion contradicts the expectation derived from the solubility of cuprous chloride described above. Thus, it was assumed that cuprous chloride partly reacts with solvents and forms certain complexes, which are soluble in the solvents but only with difficulty soluble in water; such complexes then react with silver nitrate in the aqueous phase in contact with the solvent during analytical procedure. With an increase in the treatment temperature by the autoclave, the compounds of phosphorus trichloride with copper powder are probably transformed into a more reduced form, ultimately into copper phosphides, and this change of the compounds is followed by the darkening of the surface of copper above 140~160°C. Thus, a greater amount of cuprous chloride is produced above this temperature range. The cuprous chloride herein produced is not necessarily in the form of a complex with a solvent, but a part of it may be in the form of another complex which has an ionic property. Such a complex is possibly hydrolyzed during the analytical procedure, thereby leading to the formation of chloride ion and, in consequence, to a greater value of Cl/P, as is shown in the carbon tetrachloride solution at 200°C, in which the value is larger than 3 even in the case of titration only with sodium hydroxide.

Silicon tetrachloride inhibits the reaction of phosphorus trichloride with copper powder. This inhibiting action may be due either to the adsorption of the tetrachloride on the surface of copper powder or to the solvation of phosphorus trichloride with silicon tetrachloride, or it may be due to both the effect of the adsorption and the solvation.

Summary

A phosphorus trichloride solution in non or less plar solvents was subjected to reaction with copper powder in a flask equipped with a reflux condenser or in an autoclave with an inner tube of "Teflon", and the resulting solution was examined with respect to the phosphorus content and the ratio of Cl/P. By these treatments the phosphorus trichloride was partially reduced with copper powder, and the phosphorus content decreased by the formation of a certain compound of phosphorus trichloride or its lower chloride or phosphorus with copper or cuprous chloride. The degree of the reduction depends on the property of the solvent and on the temperature of the treatment, whereas the decrease in the phosphorus content slightly depends on the property of the solvent. Silicon tetrachloride inhibits the reaction even at 200°C. This action may be due either to the adsorption of silicon tetrachloride on the surface of copper powder or to the solvation of phosphorus trichloride with silicon tetrachloride, or it may be due to the effects of both the adsorption and the solvation.

The author wishes to express his sincere thanks to Mr. Seiichi Ujiie for his helpful co-operation.

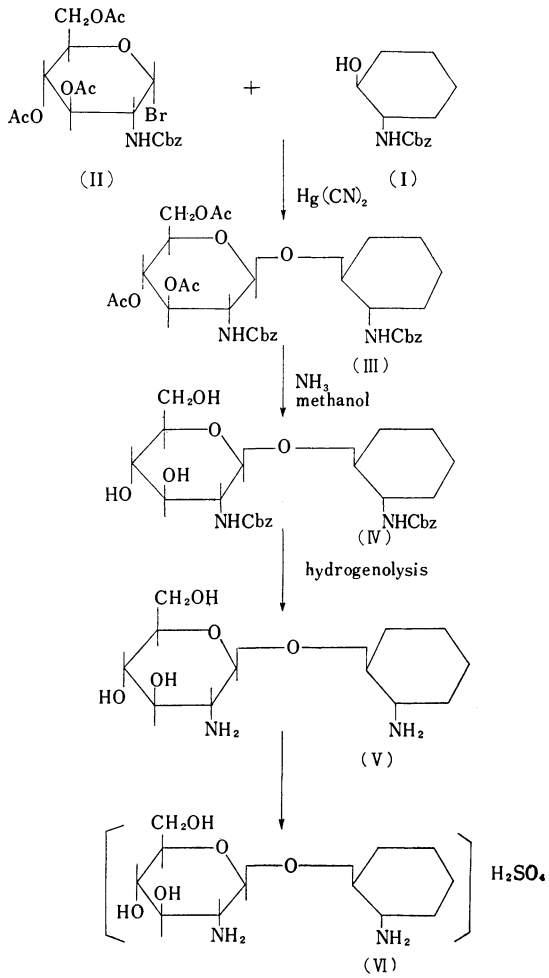
*Studies on Antibiotics and Related Substances. XIV. Synthesis of trans-2-Aminocyclohexyl-D-glucosaminide**



By Tetsuo SUAMI, Seiichiro OGAWA and Sumio UMEZAWA

(Received July 24, 1961)

The interest in inosadiamines and inosamines and inosamines was stimulated by their occurrence in certain antibiotics. Scylloinosadiamine was isolated from streptomycin[1]. Another antibiotics, neomycin[2] and paromomycin[3] contained all-*trans*-2-deoxystreptamine. Pseudoneamine was a glucosaminide of 2-deoxystreptamine[4]. This occurred again in kanamycin[5] in which it linked at C-4 and C-6, respectively, to kanosamine and 6-amino-6-deoxy-D-glucose. Also neosamine-2 was isolated from hygromycin A[6]. So it is desirable to study the relationships between chemical structures and antibiotic activities with model compounds of simpler structure. Besides our interest in this problem has been prompted by the recent development of the structural studies of kanamycin in our laboratory[7].

For this purpose 2-aminocyclohexy-D-glucosaminide is selected. Both cis and trans forms of 2-aminocyclohexanol have been thoroughly characterized[8]. Since the stereochemical studies on streptamine indicate that natural streptamine is the all-trans meso-form[9], *trans*-2-aminocyclohexanol derivatives have been adopted for the present studies.

N-Carbobenzoxy-*d, l-trans*-2-aminocyclohexanol (I) was prepared by carbobenzoxylation

of *d, l-trans*-2-aminocyclohexanol[10] obtained by ammonolysis of 2-chlorocyclohexanol. α-1-Bromo-3, 4, 6-triacetyl-*N*-carbobenzoxy-D-glucosamine (II) was prepared by the method of Irvine et al.[11] and Zervas et al.[12]

The condensation of I and II catalyzed by mercuric cyanide gave β-[*N*-carbobenzoxy-*d, l-trans*-2-aminocyclohexyl]-3, 4, 6-triacetyl-*N*-carbobenzoxy-D-glucosaminide (III) in 19.9% yield.

* This work was reported at the 14th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1961.

The partial hydrolysis of III with absolute methanol saturated with ammonia gave β-[*N*-carbobenzoxy-*d*, *l*-*trans*-2-aminocyclohexyl]-*N*-carbobenzoxy-D-glucosaminide (IV) in 63.1% yield. By the catalytic hydrogenolysis of IV, β-[*d*, *l*-*trans*-2-aminocyclohexyl]-D-glucosaminide (V) was obtained. V was then converted into its sulfate VI by neutralization with dilute sulfuric acid.

Designation of the condensation products as β-anomers is based on their optical rotation and infrared spectra. The optical rotation of V and VI is $[\alpha]_D^{13}$ −71.1° (*c* 1.7, water) and −44.4° (*c* 2, water) respectively. Compared with the optical rotation of kanamycin free base $[\alpha]_D^{13}$ +140° (*c* 1, water)[13] and paromamine free base $[\alpha]_D^{26}$ +114° (*c* 1.35, water)[14] both having α-configurations, that of V and VI are less dextrorotatory and since glucosamine is in D-series, the assignment to V and VI of β-configurations appears to be reasonable. The infrared spectra of III, IV, V and VI show absorption bands at 900, 893, 890 and 891 cm^{-1} respectively, indicating a characteristic absorption band for β-glucoside[15] while kanamycin free base shows absorption bands at 838 and 823 cm^{-1} corresponding to two α-anomeric configurations[16]. So the assignment of β-configuration to III, IV, V and VI will be reasonable.

On the other hand, from the mother liquor of III, a small amount of a crystalline product VII was recovered. Its elemental analysis was identical with that of III, but it showed a sharp and considerably lower melting point. VII was then treated with methanolic ammonia to yield a deacetylated compound VIII. The catalytic hydrogenolysis of VIII gave *d*, *l*-*trans*-2-aminocyclohexyl-D-glucosaminide (IX) but this material was not obtained analytically pure. The optical rotation of IX was $[\alpha]_D^{13}$ +1.8 (*c* 3.9, water).

Considering from the fact that kanamycin and paromamine have strong dextrorotation α-anomer of *d*, *l*-*trans*-2-aminocyclohexyl-D-glucosaminide should have considerably high dextrorotation. Estimating from the molecular rotation of paromamine free base[3], the contribution of the anomeric center to the molecular rotation of *trans*-2-aminocyclohexyl-D-glucosaminide is approximately +30000, and the contribution of the remaining portion is generally about +10000. Thus assuming the β-D-configuration, the molecular rotation of *trans*-2-aminocyclohexyl-D-glucosaminide should be in the order of −20000 and that of α-D-anomer in the order of +40000. So the observed molecular rotation of V (−19600) is in good agreement with the theoretical value for β-D-configuration, but that IX is far below the theoretical value for α-D-configuration. The attempt to obtain pure α-anomer of *trans*-2-aminocyclohexyl-D-glucosaminide by different methods is under way.

Experimental

α-1-Bromo-3, 4, 6-triacetyl-*N*-carbobenzoxy-D-glucosamine (II).—Starting from commercially available glucosamine hydrochloride, α-1-bromo-3, 4, 6-triacetyl-D-glucosamine hydrobromide was prepared by the method of Irvine et al.[11] in a yield of 20~30%. α-1-Bromo-3, 4, 6-triacetyl-D-glucosamine hydrobromide was introduced with the carbobenzoxyl group by the method of Zervas et al.[12] to give II melting at 97~99°C in a yield of 30% (Found: C, 48.18; H, 4.99; N, 2.89; Br, 15.14%).

***N*-Carbobenzoxy-*d*, *l*-*trans*-2-aminocylohexanol (I).**—A 11.5 g. (0.1 mol.) portion of *d*, *l*-*trans*-2-aminocyclohexanol[9] was dissolved in 50 ml. of water and added with 8.4 g. of sodium bicarbonate. 17.1 g. (0.1 mol.) of carbobenzoxy chloride was added portionwise into the mixture with mechanical agitation. After two hours' agitation at room temperature, the reaction mixture was put in a refrigerator overnight. The precipitate was collected by filtration, washed well with water and dried in vacuo. The colorless crystalline solid weighed 20.5 g. and melted at 94~101°C. The crude product was recrystallized from water-methanol (3:2) to yield 15.8 g. (63.6%) of colorless needles melting at 103~104°C.

Found: C, 67.72; H, 7.67; N, 5.50. Calcd. for $C_{14}H_{19}NO_3$ (249.3): C, 67.44; H, 7.68; N, 5.62%.

β-[*N*-Carbobenzoxy-*d*, *l*-*trans*-2-aminocyclohexyl]-3, 4, 6-triacetyl-*N*-carbobenzoxy-D-glucosaminide (III).—II (2.2 g.), I (1.1 g.) and mercuric cyanide (1.9 g.) were added in 70 ml. of anhydrous benzene and the mixture was refluxed on a boiling water bath for two hours. The reaction mixture was cooled and filtered to remove an insoluble matter. The filtrate was diluted with 180 ml. of chloroform and the solution was washed twice with 100 ml. of 10% sodium chloride solution and three times with cold water. After drying over anhydrous sodium sulfate, the solvent was removed under reduced pressure yielding a pale yellow residue. The residual product was washed with ether to yield 1.55 g. (52.8%) of colorless solid melting at 160~180°C (decomp.).

The product was recrystallized repeatedly from absolute ethanol to yield 0.68 g. (23.2%) of fine needles melting at 201~205°C. $[\alpha]_D^{10}$ +9.6 (*c* 2.7, chloroform).

Found: C, 61.15; H, 6.53; N, 4.35. Calcd. for $C_{34}H_{42}N_2O_{16}$ (670.7): C, 60.88; H, 6.31; N, 4.18%.

β-[*N*-Carbobenzoxy-*d*, *l*-*trans*-2-aminocyclohexyl]-*N*-carbobenzoxy-D-glucosaminide (IV).—Two grams of III was suspended in 100 ml. of absolute methanol saturated with ammonia. After

leaving overnight at room temperature, a clear solution was obtained and evaporated under reduced pressure to yield a colorless residue. The product was washed with warm ethyl acetate to remove acetamide and then recrystallized from isopropanol to yield 1.02 g. (63.0%) of colorless needles melting at 219~221°C (decomp.). A sample further recrystallized for analysis twice from isopropanol melted at 224.5~225°C (decomp.). $[\alpha]_D^{10}$ −31.5° (*c* 2.9, pyridine).

Found: C, 61.94; H, 6.52; N, 4.97. Calcd. for $C_{28}H_{36}N_2O_9$ (544.6): C. 61.75; H, 6.66; N, 5.14%.

β-[*d, l-trans*-2-Aminocyclohexyl]-D-glucosaminide (V).—IV (800 mg.) was suspended in 45 ml. of dioxane-water mixture (1 : 1) and added to a prehydrogenated suspension of 200 mg. of palladium black in 10 ml. of dioxane-water mixture (1 : 1). The reaction mixture was hydrogenated under mechanical shaking at 36~38°C. After four hours, 50 ml. of hydrogen had been absorbed. The reaction mixture was filtered to remove palladium black and the filtrate was evaporated under reduced pressure to yield a colorless syrup. Th product was dissolved in absolute ethanol and added with an hydrous petroleum ether to yield 100 mg. (24.7%) of fine needles melting at 160~161°C (decomp.). $[\alpha]_D^{13}$ −71.1° (*c* 1.7, water).

Found: C, 51.76; H, 8.56; N, 9.99. Calcd. for $C_{12}H_{24}N_2O_5$ (276.3): C, 52.16; H, 8.75; N, 10.14%.

β-[*d, l-trans*-2-Aminocyclohexyl]-D-glucosaminide Sulfate (VI).—The crude free base (470 mg.) was neutralized with 0.1 N sulfuric acid to pH 7 and the solution was filtered to remove a small amount of insoluble matter. Then the filtrate was evaporated under reduced pressure to yield 1 ml. of a residual solution. Addition of absolute ethanol to the residue resulted in precipitation of colorless crystals. After standing for two hours in a refrigerator, the crystals were collected by filtration and washed with absolute ethanol to yield 300 mg. (47.5%) of fine crystals melting at 270~271°C (decomp.). $[\alpha]_D^{13}$ −44.4° (*c* 2, water).

Found: C, 38.07; H, 6.79; N, 7.30. Calcd. for $C_{12}H_{24}N_2O_5 \cdot H_2SO_4$ (374.4): C, 38.49; H, 7.00; N, 7.48%.

***d, l-trans*-2-Aminocyclohexyl-D-glucosaminide (IX).**—After standing the mother liquor of III for five days at room temperature, crystals appeared again and were collected by filtration. The product was recrystallized twice from absolute ethanol to yield 0.15 g. (5.1%) of crystals of *N*-carbobenzoxy-*d, l-trans*-2-aminocyclohexyl-3, 4, 6-triacetyl-*N*-carbobenzoxy-D-glucosaminide (VII) melting at 186~189°C. $[\alpha]_D^{10}$ +16° (*c* 2.6, chloroform). Further recrystallization from absolute ethanol did not raise its optical rotation.

Found: C, 61.01; H, 6.17; N, 4.33. Calcd. for $C_{34}H_{42}N_2O_{12}$ (670.7): C, 60.88; H, 6.31; N, 4.18%.

VII (477 mg.) was suspended in 25 ml. of absolute methanol saturated with ammonia. After standing overnight at room temperature, the solution was evaporated under reduced pressure to dryness. The product was washed with warm ethyl acetate and recrystallized from isopropanol to yield 262 mg. (67.5%) of crystals of *N*-carbobenzoxy-*d, l-trans*-2-aminocyclohexyl-*N*-carbobenzoxy-D-glucosaminide (VIII) melting at 198~199°C. The recrystallization of the product from isopropanol raised the m. p. to 199~200°C. $[\alpha]_D^{15}$ +6.3° (*c* 1.9, pyridine).

Found: C, 61.52; H, 6.55; N, 5.35. Calcd. for $C_{28}H_{36}N_2O_9$ (544.6): C, 61.75; H, 6.66; N, 5.14%.

VIII (189 mg.) was suspended in 10 ml. of dioxane-water mixture (1 : 1) and added to a prehydrogenated suspension of 50 mg. of palladium black in 3 ml. of dioxane-water mixture (1 : 1). After four hours' hydrogenation at 37~39°C, the reaction mixture was filtered to remove palladium black and the filtrate was evaporated under reduced pressure to yield 92 mg. (90.2%) of amorphous solid of IX melting at 190~193°C (decomp.). $[\alpha]_D^{13}$ +1.8° (*c* 3.9, water). The attempt to obtain the product in a crystalline form failed.

Found: C, 49.52; H, 9.01; N, 9.29. Calcd. for $C_{12}H_{24}N_2O_5 \cdot H_2O$ (294.3): C, 48.96; H, 8.90; N, 9.52%.

Chromatography. — No satisfactory chromatographic separation of α- and β-anomer could be accomplished by ascending paper chromatography. Glucosamine hydrochloride, V and IX showed R_f values 0.12, 0.28 and 0.30 respectively in 1-butanol-ethanol-water system (5 : 1 : 4) and 0.12, 0.28 and 0.26 in 1-butanol-acetic acid-water system (4 : 1 : 5). These spots were developed by ninhydrin in pyridine.

Bioassays.—V and IX did not show antimicrobial activity against *E. coli* in a dilution ratio 1 : 1000 by a dilution assay method.

The authors were indebted to Mr. S. Nakada for microanalysis and to Miss S. Fukuyama for bioassays.

On the Mechanism of Pulp Bleaching. III. Some Properties of Lignosulfonic Acid Treated with Chlorine Water*

By Koichiro SATO and Hiroshi MIKAWA

(Received February 20, 1961)

In part I of this series[1], the present authors reported that when lignosulfonic acid is brought into reaction with chlorine water at 0°C, at least 50% of the sulfonic acid group is split off as sulfuric acid, while the methoxyl group is cleaved as methanol in a yield ca. 80% of the theoretical, when about 4 mol. of chlorine are consumed per methoxyl. As that paper was published in Japanese, the main results of the chlorination of spruce (*Picea jezoensis*) and birch (*Betula Platyphylla*) lignosulfonic acids are cited here again in Figs. 1, 2 and 3. As shown in Figs. 1 and 2, the yield of methanol reaches a maximum at the consumption of about 4 mol. of chlorine and thereafter decreases, probably because of the decomposition of methanol from excess chlorine. The methoxyl content of the residue obtained by evaporation of the solution to dryness after the distillation of methanol decreases very rapidly, as expected, until the yield of methanol reaches a maximum. As is evident from Fig. 2, in which the formation of methanol from birch lignosulfonic acid is shown, the yield of methanol based on the total methoxyl of the lignosulfonic acid is very high, suggesting the formation of methanol not only from guaiacyl but also from syringyl type structural units in a high yield. The amount of sulfuric acid formed during the chlorination is shown in Fig. 3. When about 4 mol. of chlorine are consumed, about 0.5 mol. of SO_4^{2-} are formed per sulfonic acid group in lignin.

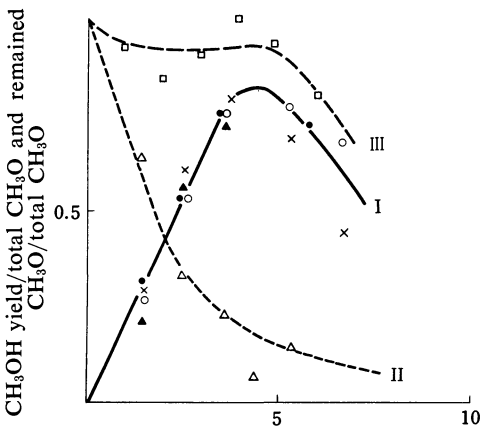

Fig. 1. Formation of methanol from spruce lignosulfonic acid by chlorination. I, mol. ratio of methanol formed to total methoxyl in lignin. II, mol. ratio of methoxyl remaining in the residue after distillation of methanol to total methoxyl in lignin. III, II+I.
[4 g. of Ba-lignosulfonate prepared from spruce (Anal. CH_3O, 11.95%; S in SO_3H form, 4.73%) were dissolved in water, passed through ion exchanger, made up to 100 ml., 20 ml. of this solution were mixed with an appropriate amount of saturated chlorine water at 0°C and analyzed after 16 hr.]

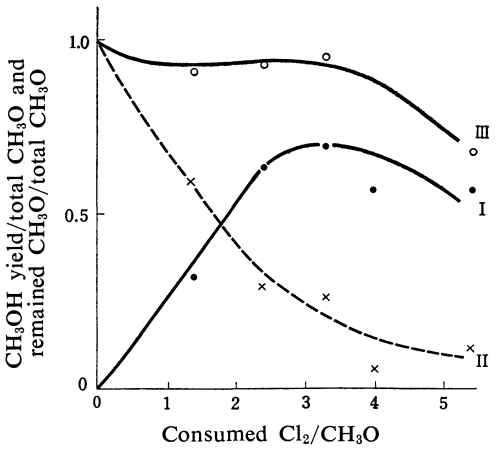

Fig. 2. Formation of methanol from birch lignosulfonic acid by chlorination. I, II and III, same as in Fig. 1. (Experimental conditions are also the same as the case of spruce lignosulfonic acid. Birch lignosulfonic acid, $C_9H_{9.65}O_{2.87}(CH_3O)_{1.40}(SO_3Ba/2)_{0.53}S^{neut}_{0.36}\cdot Ba^{excess}_{0.04}$).

Hibbert[2] assumed that when lignin was treated with chlorine, chlorine atoms were introduced at positions 5 or 6 of the benzene nucleus, the methoxyl group became unstable and the orthoquinone structure was perhaps formed after the cleavage of the methoxyl

* Presented in part at the Second Lignin Symposium of Japan, Tokyo, November, 1957.

group. Giertz[3] reports that substitution and oxidation reactions may occur when lignin is treated with chlorine water. During the first fifteen minutes the former reaction predominates almost exclusively, while thereafter the latter reaction increases, both reactions being about the same after one hour; after four hours, more than half of the consumed chlorine had been used for the oxidation reaction. Adler[4] has reported recently that the methoxyl groups of the lignin model compounds of the guaiacyl type cleave to give methanol in a good yield when treated with periodate and that guaiacol gives orthobenzoquinone by the same reaction.

It may therefore be expected that carboxyl, carbonyl and/or orthoquinone structures would be formed in the residual lignosulfonic acid in unbleached sulfite pulp when it is treated with chlorine water during the bleaching process. In the present paper, some properties of lignosulfonic acid treated with chlorine water at 0°C were investigated: — 1) the amount of sodium borohydride consumed by the chlorinated lignosulfonic acid, 2) the nature of the weakly acidic group formed by the chlorination, and 3) the change in the ultraviolet and infrared absorption spectra during the chlorination. The main object in the present investigation is, therefore, to see preliminarily the mode of the chemical change of the lignosulfonic acid during its chlorination in aqueous solution at 0°C.

Chlorination of Lignosulfonic Acid

The results obtained when 70, 100, 130 and 160% (by weight) of chlorine were reacted with lignosulfonic acid are shown in Figs. 4, 5, 6 and 7, in which curve I represents the amount of chlorine added, curve II, the chlorine reacted with the lignin, curve III, the amount of carbonyl group estimated from the sodium

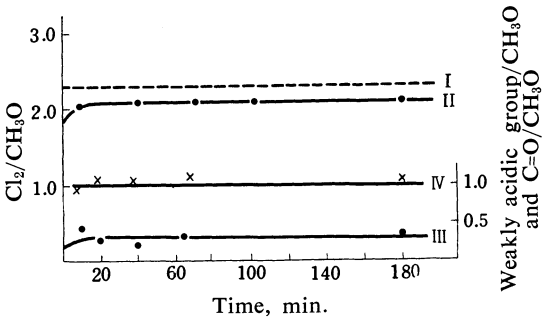

Fig. 4. Chlorination of lignosulfonic acid. 70% of chlorine was added.
I, Chlorine added II Chlorine consumed

4) E. Adler, S. Hernestam and I. Walldén, *Svensk Papperstidn.*, **61**, 641 (1958); E. Adler and R. Magnusson, *Acta, Chem. Scand.*, **13**, 505 (1959).

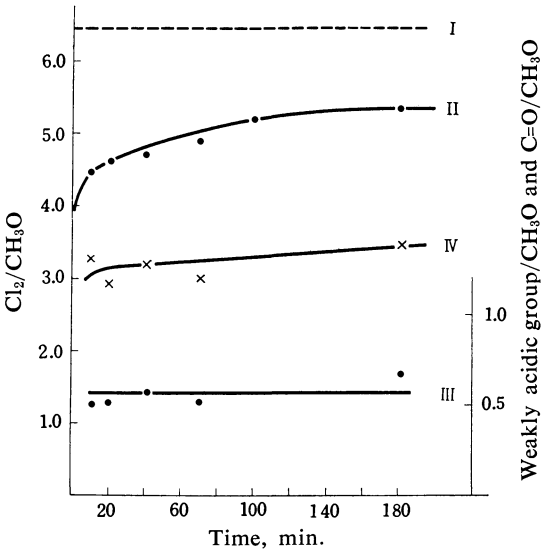

Fig. 7. Chlorination of lignosulfonic acid. 160% of chlorine was added (I, II, III and IV are the same as in Fig. 4).

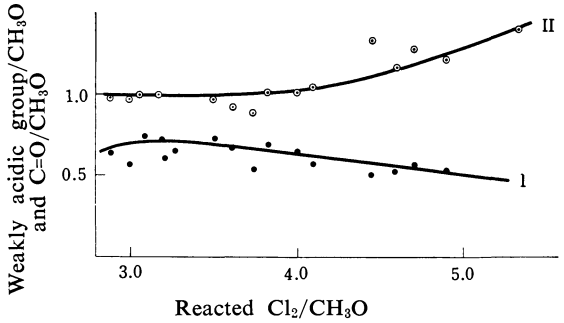

Fig. 8. Formation of weakly acidic groups and carbonyl groups during chlorination.
Curve I, Carbonyl group
Curve II, Weakly acidic group

borohydride consumption, and curve IV, the amount of the weakly acidic group estimated by conductometric titration.

When 70 and 100% of chlorine were used, the amounts of chlorine consumed after twenty minutes were 90 and 85% of the chlorine added respectively. The amount of the consumed chlorine did not exceed 90%, however, even after completion of the reaction.

Curve III in Figs. 4, 5, 6 and 7 shows the amounts of sodium borohydride consumed in the reduction of the reaction mixture with sodium borohydride for various lengths of time, the amounts being expressed for the sake of simplicity as mol. of carbonyl groups equivalent to the sodium borohydride consumed per methoxyl. It must, therefore, be remarked that the carbonyl groups of quinoidal structure, if any, are not calculated as two, because an ordinary carbonyl group consumes two atoms of hydrogen, but quinoidal structure with two carbonyl groups consumes the same amount. Curve IV indicates the amounts of the weakly acidic group. When the amounts of the carbonyl group and of the weakly acidic group of all these figures are plotted against the amount of chlorine consumed, Fig. 8 is obtained. It clearly shows that when the consumed chlorine is lower than 4 mol. per methoxyl, the amount of the weakly acidic group is about 1 equiv./CH_3O, which is distinctly higher than the value of ca. 0.3 equiv./CH_3O of ordinary lignosulfonic acid. After the consumption of about 4 ml. Cl_2/CH_3O, the amount of the weakly acidic group begins to increase, and at the same time the amount of the carbonyl group decreases. This fact might suggest that carbonyl groups, once formed, are oxidized further to give carboxyl groups after the consumption of about 4 mol. of Cl_2/CH_3O.

It must be remarked here that, if no carboxyl groups were formed, the amount of the conductometrically estimated weakly acidic group existing in the solution of chlorination would not exceed one per methoxyl group, insofar as no C_9-building units with more than one phenolic hydroxyl group in a unit—eq. pyrocatechol structure—are formed by chlorination, and only one of the two phenolic hydroxyl groups of the pyrocatechol type structure thus formed is conductometrically titratable.

As shown in Fig. 9, the introduction of chlorine atoms into the nucleus seems to have no influence on the titratability of the carboxyl and phenolic hydroxyl groups (cf. 6-chlorovanillic acid and 5,6-dichlorovanillin), and only one phenolic hydroxyl group of the two phenolic hydroxyl groups of the pyrocatechol structure is conductometrically titratable (cf. protocatechualdehyde and propiocatechon). Moreover, as is evident from Fig. 10, where some hydrochloric acid is added first to the solution of the model compounds almost all of the excess hydrochloric acid was neutralized by adding 3~4 ml. of a 0.1 N sodium hydroxide solution and the remaining excess hydrochloric acid and the phenolic hydroxyl groups were titrated conductometrically, although only one of the two phenolic hydroxyl groups of the pyrocatechol structure is conductometrically titratable, even in the presence of a salt of a strong acid and a base in excess.

The authors will report in a forthcoming paper that some of the pyrocatechol structure may be formed in the chlorination of lignin. As stated above, the maximum amount of the conductometrically estimated weakly acidic group existing in the reaction mixture of chlorination can not exceed one per methoxyl

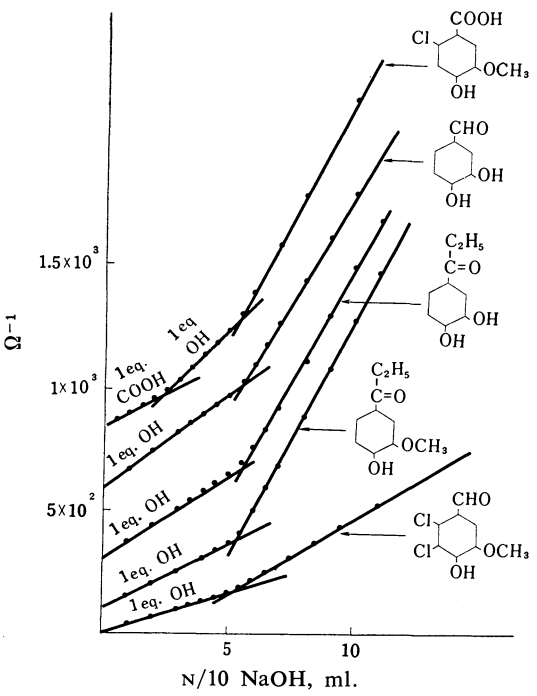

Fig. 9. Conductometric titration curves of some model compounds related to the chlorination of lignosulfonic acid.

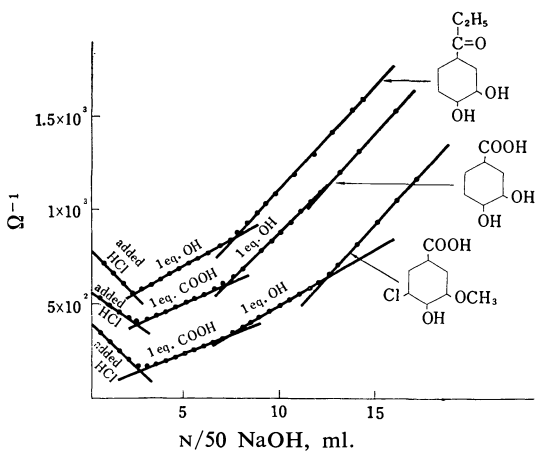

Fig. 10. Conductometric titration curves of some model compounds, titration being performed in the presence of excess hydrochloric acid.

group if no carboxyl group is formed, since it has been proved that only one phenolic hydroxyl of the pyrocatechol structure is conductometrically titratable. Hence it may safely be concluded that at least that part of the weakly acidic group of Fig. 8 exceeding the one-per-methoxyl level may be due to the newly-formed carboxyl group.

The infrared absorption spectra of isolated

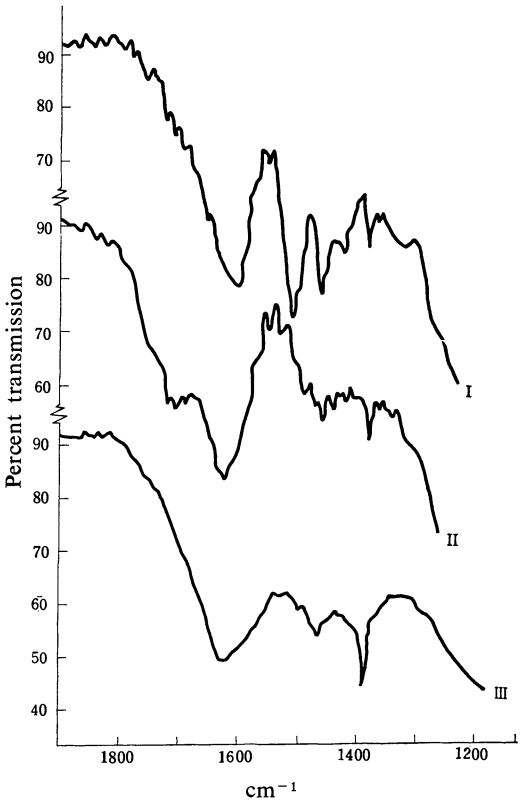

Fig. 11. Infrared absorption spectra of various barium-lignosulfonates. Curve I, Original sulfonate, Curve II, Chlorinated sulfonate; Curve III, Chlorinated sulfonate reduced with $NaBH_4$.

chlorinated barium lignosulfonate also seem to support the theory of the presence of carboxyl groups in it. Figure 11 shows the infrared absorption spectra of ordinary α-lignosulfonic acid (curve I), chlorinated α-lignosulfonic acid (curve II), and chlorinated lignosulfonic acid reduced with sodium borohydride (curve III). Curve II, the absorption spectrum of chlorinated α-lignosulfonic acid, has two absorptions, at 1700 and 1750 cm^{-1}, which do not exist in the case of ordinary α-lignosulfonic acid (curve I). The absorption band at 1700 cm^{-1} disappears after reduction with sodium borohydride, suggesting that this band is due to the carbonyl group. The wave number of this band is somewhat higher than that of the ordinary carbonyl absorption of usual lignin, 1660 cm^{-1} [5]. The wave number of the carbonyl group of lignosulfonic acid seems therefore to shift to the vicinity of 1700 cm^{-1} when chlorine is introduced; similarly, it is known that carbonyl groups of aldehyde, ketone and orthoquinone generally have absorption near 1660 cm^{-1} and

5) H. Sofuye and S. Fukuhara, *J. Chem. Soc. Japan, Ind. Chem. Soc.* (*Kogyo Kagaku Zasshi*), **61**, 1070 (1958).

that this absorption shifts to the 1690 cm^{-1} region when chlorine is introduced into the molecule[6,7].

The absorption at 1751 cm^{-1} seems to be due to the carboxyl group influenced by chlorine, which group is, however, not clear in curve III. There exists, however, anothor, broad absorption at the vicinity of 2610 cm^{-1} which seems to be due to the carboxyl group[7]. It can, therefore, safely be concluded that there exist carbonyl groups and carboxyl groups in chlorinated lignosulfonic acid.

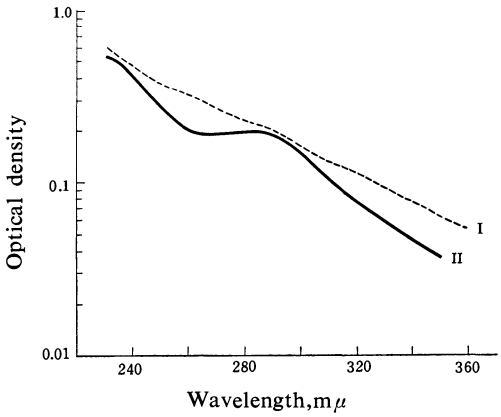

Fig. 12. Ultraviolet absorption curves of the solution of lignosulfonic acid after treatment with chlorine water. Curve I, Reaction mixture not reduced; Curve II, Reaction mixture reduced with sodium borohydride.

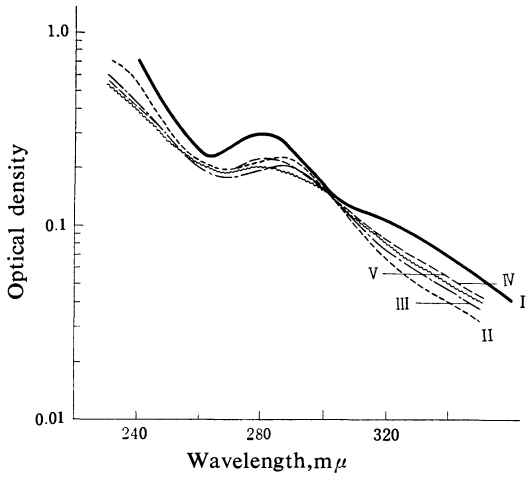

Fig. 13. Ultraviolet absorption curves of lignosulfonic acid at various stages of chlorination. (Spectra were taken after reduction with sodium borohydride.) Curve I, Original; Curve II, $Cl_2/CH_3O=2.09$; Curve III, 3.25; Curve IV, 4.1; Curve V, 5.35.

Figure 12 shows an example of the ultraviolet absorption spectra of lignosulfonic acid both immediately after chlorination and when reduced with sodium borohydride after the chlorination. The former has no minimum and maximum; these reappear only after the reduction. Figure 13 shows the ultraviolet absorption spectra of lignosulfonic acid reduced with sodium borohydride after chlorination to various stages. The minimum and maximum at 263 and 280 mμ in the spectrum of the original lignosulfonic acid shift to 270 and 285 mμ respectively. The fact that the optical density at 285 mμ maximum remains approximately constant might suggest that not very profound structural changes occur when 2 to 5 mol. of chlorine are consumed; i.e., the main part of the benzene ring structure seems not to be destroyed by the chlorination.

Experimental

Barium Lignosulfonate.—Barium lignosulfonate was prepared as usual from spruce (*Picea jezoensis*) sulfite waste liquor by 1-(*N*-piperidinoacetylamino)-naphthalene (PAN)[8], and was analyzed as follows: CH_3O, 11.95; S, 8.07%.

Chlorinated Barium Lignosulfonate.—Barium lignosulfonate (20 g.) was dissolved in a small portion of water and passed through ion-exchange resin in hydrogen form, and an aqueous chlorine solution was added ($Cl_2/CH_3=2.48$). After having been kept at 0°C for 5 min., this was diluted with water, and the chlorinated barium lignosulfonate was precipitated as usual from the above solution by PAN. As it is well known that the chlorine atoms in chlorinated lignin are at least partly unstable to alkali, the separation of the chlorinated lignosulfonic acid from the PAN salt thus obtained was performed as follows: The PAN salt of the chlorinated lignosulfonic acid was suspended in a small amount of water, mixed with ion exchange resin Amberlite IR-120 in hydrogen form, and shaken for about one hour, and then the solution of the chlorinated lignosulfonic acid thus obtained was again passed through ion-exchange resin Amberlite IR-120 in hydrogen form. The solution thus obtained was neutralized with barium carbonate, and the barium salt of the chlorinated lignosulfonic acid was isolated as usual.

Anal. CH_3O, 2.82; Cl, 12.45; Ba, 24.21%.

Chlorination.—Barium lignosulfonate containing 5 mmol. of the methoxyl group was dissolved in a small amount of water, passed through ion exchange resin in hydrogen form, and increased to 30 ml. To the lignin solution thus obtained were added, at 0°C, 190 ml. of an aqueous chlorine solution containing 23.2 mmol. of chlorine (the weight of chlorine is approximately 130% of that of lignin), and the whole was maintained at 0°C while being stirred. At definite periods, 1 ml. of the solution

6) Marie-Louise Josién, N. Fuson and Jeanne-Marie Lebas, *J. Chem. Phys.*, **21**, 331 (1953).

7) L. J. Bellamy, "The Infra-red Spectra of Complex Molecules", Methuen & Co., London (1954).

8) B. Leopold, *Acta Chem. Scand.*, **6**, 64 (1952).

was sucked out and the amount of the chlorine consumed was measured iodometrically as usual. Another 30 ml. of the reaction solution was also sucked out into a graduated flask of 40 ml. capacity, several drops of allyl alcohol were added, the pH adjusted by alkali to 7, and increased to just 40 ml. Half of this solution was used for the sodium borohydride reduction, and the other half for conductometric titration.

Amount of Chlorine Consumed. — The amount was determined iodometrically as usual. No correction is applied for the orthoquinone structure which might be formed during the chlorination and thus exist in the solution. As is known, the orthoquinone structure is able to isolate iodine[9] from the iodide solution.

Reduction with Sodium Borohydride.—The above-mentioned solution (20 ml.) from the chlorination was reduced with sodium borohydride for one hour according to the method of Lindberg[10]. As a control experiment, vanillin, 5-chlorovanillin, acetoguaiacon, propioguaiacon, camphorquinone and β-naphthoquinone were reduced by this method. The amount of the consumed borohydride were 100, 102, 97, 104, 96.6 and 104% of the theoreticals

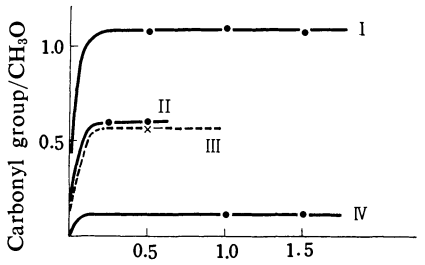

Fig. 14. $NaBH_4$ reduction of several lignin samples. Curve I, Chlorinated thiolignin ($Cl_2/CH_3O=4.58$); Curve II, Chlorinated hydrochloric acid lignin ($Cl_2/CHO_3=2.26$); Curve III, Chlorinated barium lignosulfonate; Curve IV, Thiolignin.

respectively. The chlorinated lignosulfonic acid isolated from the chlorination solution was also reduced. As is evident from Fig. 14, one hour is sufficient for complete reduction.

Conductometric Titration.—Four milliliters of the above-mentioned neutral solution (40 ml.) prepared from the chlorination solution were eluted through ion exchange resin in hydrogen form and were neutralized with 4~5 ml. of a 0.1 N sodium hydroxide solution in order to neutralize a part of the hydrochloric acid. The solution thus obtained was titrated conductometrically with a 0.02 N sodium hydroxide solution. The amount of the weakly acidic group and/or weakly acidic substances were determined from the difference in the titers of the second and the first "breaks".

Ultraviolet Absorption Spectra. — The solution obtained after the above-mentioned reduction with sodium borohydride contains reaction products in reduced form. One milliliter of this solution was diluted to 50 ml. with water, and the ultraviolet absorption spectra were measured and shown directly as the optical density of the solution.

Infrared Absorption Spectra. — The infrared absorption spectra of barium lignosulfonate and chlorinated barium lignosulfonate were measured by the potassium bromide method using a Koken D 101 type infrared spectrophotometer (Japan).

Syntheses of the Model Compounds for the Conductometric Titration. — 5-Chlorovanillic acid was obtained by the oxidation of 5-chlorovanillin with silver oxide[11]; propiocatechon and propioguaiacon, by the condensation of propionic acid with catechol and guaiacol, according to the method of Nakazawa[12], and 5,6-dichlorovanillin, according to the method of Laiford[13].

The authors wish to express their sincere thanks to Professor Yoshikazu Hachihama of Osaka University, for his unfailing kindness in encouraging this work and to Kokusaku Pulp Co. for its permission to publish this paper.

On the Mechanism of Pulp Bleaching. IV. Extracts from Unbleached Sulfite Pulp with Dimethyl Sulfoxide*

By Koichiro SATO, Akio KOBAYASHI and Hiroshi MIKAWA

(Received February 20, 1961)

As already reported, a part of the residual lignosulfonic acid in unbleached sulfite pulp can be dissolved by beating the pulp in water violently[1]. This lignin seems to have existed between fibrils. The chemical nature of this residual lignosulfonic acid was also investigated briefly. About 75~80% of the residual lignosulfonic acid remained, however, undissolved in the beaten pulp. It is therefore attempted, in the present communication, to isolate and investigate this residual lignosulfonic acid remaining in the beaten pulp.

Recently Björkman succeeded in extracting the so-called lignin-carbohydrate complex (LCC) with a solvent like acetic acid, dimethyl formamide or dimethyl sulfoxide, after having extracted the so-called milled wood lignin (MWL) from the finely milled wood powder with aqueous dioxane[2].

Lindgren[3] separated this LCC into a pure carbohydrate component consisting of carbohydrate and lignin chemically combined in a one to one ratio by using the technique of electrophoresis on glass fiber paper. Kawamura and Higuchi[4] isolated lignin preparation from beech wood by several different methods and recognized paper-chromatographically that a part of the lignin is chemically combined with xylose and xylobiose. In his investigation of the biosynthesis of lignin, Freudenberg obtained a compound consisting of both carbohydrate and coniferyl alcohol chemically combined[5]. A recent accumulation of experimental results seems to have confirmed almost definitely, the existence of a chemical combination of both the components in wood, although the mode of the combination remains to be investigated as yet.

It has, therefore, been attempted to dissolve the lignin, carbohydrate and lignin-carbohydrate complex, if any, from the unbleached sulfite pulp, which has already been beaten in water and extracted exhaustively with water, with dimethyl sulfoxide, to see if such materials can be extracted with this solvent and, if so, to investigate the chemical nature of the extracted materials.

Already extracted beaten pulp was repeatedly extracted further with dimethyl sulfoxide, and a grayish white powder was obtained. The yield was of the order of 10% of the pulp. The material contains about 6% methoxyl group, has ultraviolet absorption spectra characteristic of lignin, and gives a sugar mixture on hydrolyzation of the material. It is therefore evident that the materials contains both lignin and carbohydrate. In order to know whether the carbohydrate component and the lignin component exist independently or whether they are combined chemically in the material, the material was separated electrophoretically on a filter paper; it was found that there exists no chemical combination between the two components. The carbohydrate component and the lignin component were next separated by zone electrophoresis on cellulose powder, and both the components were investigated separately.

Preparation of the Dimethyl Sulfoxide (DMSO) Extract.—Unbleached sulfite paper pulp from spruce (*Picea jezoensis*, 1615 g.) was beaten in water until no more water-soluble residual lignosulfonic acid dissolved out, and then the beaten pulp was dried, crushed with a disk refiner, and respectively extracted with absolute dimethyl sulfoxide at room temperature (total amount of dimethyl sulfoxide: 50 l.). Figure 1 shows the ultraviolet absorption curves of DMSO extracts from spruce pulp. The dimethyl sulfoxide solution thus obtained was concentrated in vacuo and poured into alcohol, and the precipitate was dissolved in water and reprecipitated with alcohol. The yield of the water-soluble grayish-white "dimethyl sulfoxide extract" thus obtained was 18 g.

Dimethyl Sulfoxide Extract.—As no sugars are found in the extract by paper chromatography, the carbohydrate portion of the extract must be water soluble hemicellulose. The amount of hemicellulose in the extract and the component sugars were determined by hydrolyzing the extract (50 mg.) with 4% sulfuric acid (4 ml.) in an ampoule at 100°C for 8 hr.

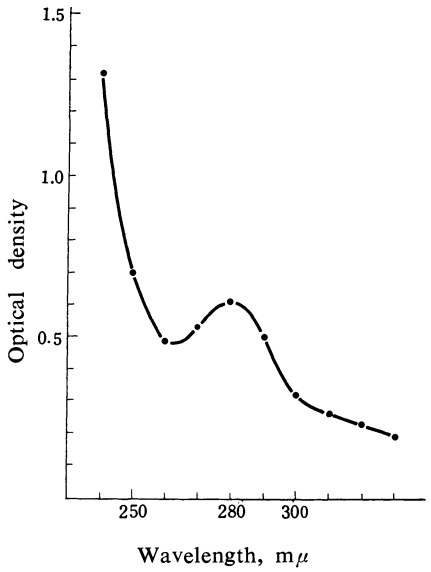

Fig. 1. Ultraviolet absorption curve of the "dimethyl sulfoxide extract" obtained by extracting the beaten unbleached sulfite pulp by dimethyl sulfoxide (52.0 mg. in 300 ml. water).

The total amount of the sugars was determined by Somogyi's method, and the component sugars, by paper chromatography[6]. The amount of the lignin in the extract was estimated from the ultraviolet absorption, the methoxyl content of lignin being assumed as 10.83% and the molar extinction at 280 mμ, as 2870 per CH_3O. The values obtained for the residual lignosulfonic acid in the previous paper[1] were used. The results are shown in Table I. It will be seen from the table that the carbohydrate component consists almost exclusively of xylose.

In order to know the nature of the lignosulfonic acid existing in the dimethyl sulfoxide extract, the extract was titrated conductometrically (Fig. 2). Assuming that all of the strong acid is attached to lignin as a sulfonic acid group, SO_3H/CH_3O was calculated as 0.32, which is considerably lower than that (0.5～0.6) of the ordinary lignosulfonic acid, and the presence of a weakly acidic group is not clear. To make clearer the nature of the residual lignosulfonic acid in the dimethyl sulfoxide extract, the isolation of it free from carbohydrate was attempted.

TABLE I. ANALYSES OF THE "DIMETHYL SULFOXIDE EXTRACT"

Lignin		35.1%	96.9%
carbohydrate		61.8%	
Component sugars	Xylose	94.6%	
	Arabinose*	1.6%	
	Mannose		
	Glucose	2.4%	
	Galactose	1.4%	
CH_3O		5.33%	

* As arabinose shows the same R_f as that of mannose by paper chromatography, it was calculated as mannose.

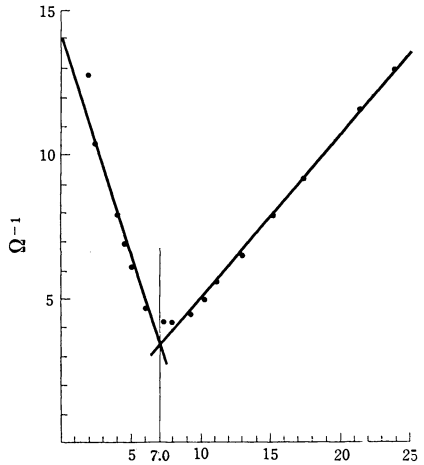

Fig. 2. Conductometric titration of the "dimethyl sulfoxide extract" obtained from the beaten pulp.

The simplest way to isolate the lignin in its sulfonated form, free from carbohydrate, is to sulfonate "the extract" in an acidic condition in order to hydrolyze the linkage between lignin and carbohydrate, if any, and to isolate the lignin in the form of lignosulfonic acid. The extract (4.73 g.) was dissolved in an ampoule in a cooking acid (100 ml. pH 4.2) prepared from 5% sodium hydroxide and sulfur dioxide and cooked at 135°C for 5 hr. The lignosulfonic acid was separated with 1-(*N*-piperidinoacetylamino)-naphthalene as usual. The analytical values of the lignosulfonic acid

TABLE II. ANALYSES OF THE DIMETHYL SULFOXIDE EXTRACT AND THE LIGNOSULFONIC ACID PREPARED FROM THE EXTRACT BY SULFONATION

	Dimethyl sulfoxide extract	Lignosulfonic acid prepared from the extract
CH_3O	5.33%	11.84%
S in SO_3H form	1.77%	4.54%
SO_3H/CH_3O	0.32	0.37
Phenolic OH/CH_3O	—	0.21～0.26
Type I OH/ Type II OH		1 : 4

thus prepared and that of the dimethyl sulfoxide extract are shown in Table II.

From the conductometric titration and the spectrum change during the titration[7], the ratio between the type I and the type II phenolic hydroxyl group was found to be ca. 1/4, which is a little lower than that between residual lignosulfonic acid dissolved by beating (1/3～1/4) and ordinary soft wood α-lignosulfonic acid (1/3).

On the Non-existence of the Linkage between Lignosulfonic Acid and Carbohydrate in the Dimethyl Sulfoxide Extract.—As it was thought to be highly possible that the lignin and carbohydrate in the dimethyl sulfoxide extract are chemically combined, the possibility of any linkage between the components was investigated by paper electrophoresis.

An aqueous solution of dimethyl sulfoxide extract was applied quantitatively (1.1 mg. in 0.05 ml.) on the cathodic side of a paper strip (Toyo Roshi Co., No. 50., 2×40 cm.) soaked with a 0.05 N sodium hydroxide solution and developed electrophoretically for 2.5～3 hr., the current density being maintained at 3 mA per paper strip. The paper strip was cut into pieces 2 cm. in length, and every piece was separately eluted with definite amount of water. The eluates were examined spectroscopically. As shown in Fig. 3, the absorption curves are characteristic of lignin. The lignin content of the eluates was therefore calculated from optical density at 280 mμ. For the carbohydrate assay, another paper strip developed similarly at the same time was eluted in just the same manner as in the case of lignin with 1 N sodium hydroxide. Carbohydrate was difficult to elute with water, but with sodium hydroxide it could be eluted very easily. Although the elution was repeated three times, the first elution was almost enough to extract all of the carbohydrate. The carbohydrate thus obtained was estimated as xylose by Somogyi's method.

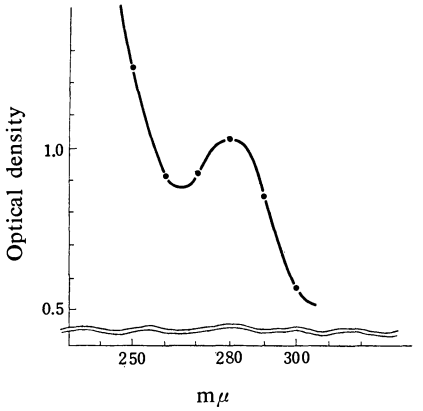

Fig. 3. Ultraviolet absorption curve of the solution of residual lignosulfonic acid obtained by developing electrophoretically the dimethyl sulfoxide extract on a paper strip and eluting the lignosulfonic acid from the strip.

7) H. Mikawa, K. Sato, C. Takasaki and K. Ebisawa This Bulletin, **28**, 653 (1955).

The distribution of the lignin and the carbohydrate over the paper strip thus discovered is shown in Fig. 4. The values are corrected for the blank values due to the impurities coming from the paper, which were not very large. The total amount of the lignin and the carbohydrate thus recovered from the developed paper strip was nearly 100%, as is shown in Table III.

As is evident from the figure, carbohydrate and lignin migrate almost independently. As it does not seem very probable that some linkage between the components existed before the electrophoresis and that this linkage was ruptured during the electrophoresis, the existence of any chemical linkage may not be expected between lignin and carbohydrate in dimethyl sulfoxide extract, just as in the case

Table III.

Carbohydrate eluted	64.4%*
Lignin eluted	40.2%
Total	104.6%

* % based on the materials applied.

The ordinate means the weight percent of the substances obtained by eluting pieces of paper strip cut into 2 cm. length against the total amount of lignin or carbohydrate in the material applied to the origin.

of the residual lignosulfonic acid isolated by beating.

Lignosulfonic Acid in Dimethyl Sulfoxide Extract Separated by Zone Electrophoresis.— In order to investigate the lignin in the extract in detail, the isolation of it free from carbohydrate was attempted. As it was found that electrophoresis is suited for this purpose, zone electrophoresis was applied to the extract. Cellulose powder (Schleicher u. Schüll), which had been exhaustively extracted with 0.05 N sodium hydroxide until the washings no longer showed any absorption at 280 mμ, was used together with 0.05 N sodium hydroxide as the carrier. Five hundred milligrams of DMSO extract was dissolved in a small portion of water, mixed with warm dilute agar-agar solution, and poured into a hole made in the slurry of cellulose powder at the origin of the cathodic side. After the agar-agar solution solidified, the extract was developed with a constant current density of 80 mA per 10 cm^2. This procedure was repeated six times, and then all the carbohydrate-free lignin portions were mixed and eluted with water, and the lignin was separated as barium salt using 1-(*N*-piperidinoacetylamino)-naphthalene as usual. The total yield was 0.557 g. The ultraviolet absorption curve of the lignosulfonic acid thus obtained is characteristic of lignin; the analytical values are listed in Table IV. It may be seen that the degree of sulfonation is low and that the ratio of type II phenolic hydroxyl group to the total phenolic hydroxyl groups is high. This lignosulfonic acid prepared by zone electrophoresis is otherwise not very different from the lignosulfonic acid reported previously, which had been obtained by a drastic beating of pulp.

Table IV. Analyses of the barium salt of the residual lignosulfonic acid extracted from beaten unbleached sulfite pulp by dimethyl sulfoxide and purified by electrophoresis

CH_3O	11.01%
SO_3H/CH_3O	0.34

carbons produced, but much remains unexplored.

In this report, we are presenting the physical properties of carbons produced by the pyrolysis of hydrocarbons, which have been studied by means of electron microscopy, X-ray diffraction the B. E. T. method and the Kelvin method.

Experimental

Materials.—The applied hydrocarbons, benzene, toluene naphthalene and *n*-hexane were "extra pure grade" reagents supplied by the Wako Junyaku Co., Ltd. Ethylene was prepared by dehydrating ethyl alcohol with concentrated sulfuric acid; it was then purified by vacuum distillation. Methane was provided by the Nihon Kei Kinzoku Co., Ltd. and was passed through a concentrated potassium hydroxide aqueous solution and a calcium chloride tube. Further, this was distilled in vacuo for purification.

Apparatus and Procedure.—The apparatus used for the reaction, constructed of soda-glass except for the reaction tube, is shown in Fig. 1. In this figure, A_1 is a graduated sample vessel which was used for benzene, toluene or *n*-hexane. A_2 is a gas reservoir for methane or ethylene, and A_3 is a side tube of the reservoir. B is a reaction tube made of transparent quartz 2.5 cm. in diameter and 100 cm. long. In the reaction tube, porcelain insulators 0.5 cm. in diameter and 2.5 cm. long are packed to facilitate the pyrolysis of hydrocarbons.

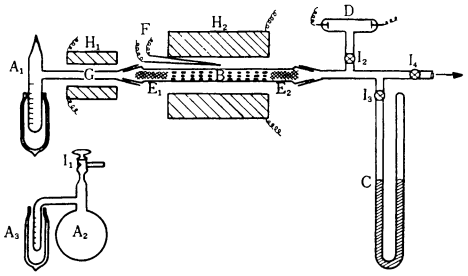

Fig. 1. Apparatus for pyrolysis.

Inside both ends of the tube, glass wool (E_1, E_2) was loosely packed to avoid contamination by the tarry materials produced during the pyrolysis. The tube was connected by a ground glass joint to a vacuum system. H_1 is a pre-heating heater, and H_2 is an electric furnace about 50 cm. long. The temperature of the furnace was controlled (± 1°C) automatically.

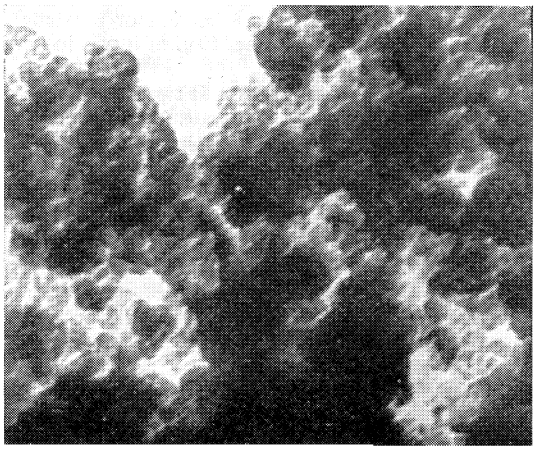
In the case of liquid materials, a certain amount (5 cc.) of each material in A_1, kept at the temperature of liquid oxygen (−183°C), was evacuated. The liquid oxygen bath was then removed to melt the frozen material and to draw off any gas involved in it. In order to remove the gas completely, such treatments were repeated three times.

In the cases of methane and ethylene, A_2 was used instead of A_1. The materials (10 cc. of liquid state) were introduced to A_3 by cooling with a liquid oxygen bath (for methane) or with a conical aluminum powder bath, the top of which was immersed in liquid oxygen to maintain the temperature of the bath at −135°C (for ethylene).

In the case of naphthalene, 10 g. of it was loosely packed in an inlet, G.

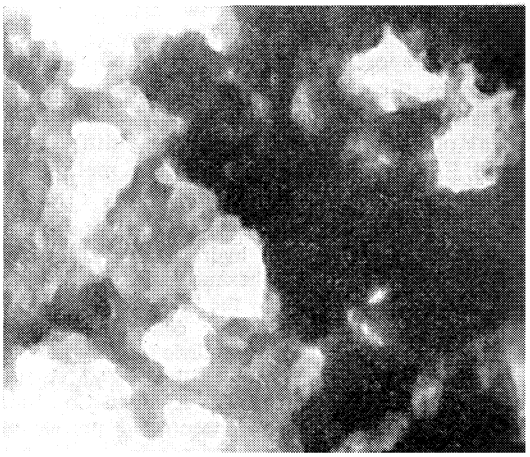
The pyrolysis was carried out at two temperatures, 800 and 1100°C, and the flow rate of the materials was kept constant at 2.5 cc. per hour, by controlling the opening of tap I_4 and also the temperature of the sample vessel, A_1, A_3 or G. For benzene, toluene and *n*-hexane, the temperatures of the sample vessel were 23, 47 and 12°C respectively, while for methane and ethylene, they were −183 and −135°C respectively. That of naphthalene was 140°C. At these temperatures, the same vapor pressure (83 mmHg) held for all materials. The rates of the consumption of materials were measured with the graduations of the sample vessel. During the pyrolysis, part G was always heated at 200°C (except in the case of naphthalene) to prevent condensation of the materials. After a certain amount of the liquid material had been consumed, A_1 was cooled with a liquid oxygen bath to stop the reaction. In the cases of ethylene and methane, tap I_1 was closed to the stop position. Then tap I_4 was opened completely, and the reaction system was evacuated to remove the tarry substances formed during the reaction; the reaction tube was cooled, it was cut off, and the insulators which had been covered with the carbon produced were taken out. The impurities contained in all the carbon were removed by treating them with aceton and carbone tetrachloride.

The surface areas and the micro-pore size distributions of the carbons were obtained from the adsorption and the desorption of methane gas at the temperature of liquid oxygen (−183°C). The B. E. T. method was applied on the results of the adsorption isotherms to determine the surface areas of the carbons by assuming 18.1 Å^2 as the cross-sectional area of methane; Kelvin's equation was applied to the desorption isotherms to determine the micro-pore size distributions.



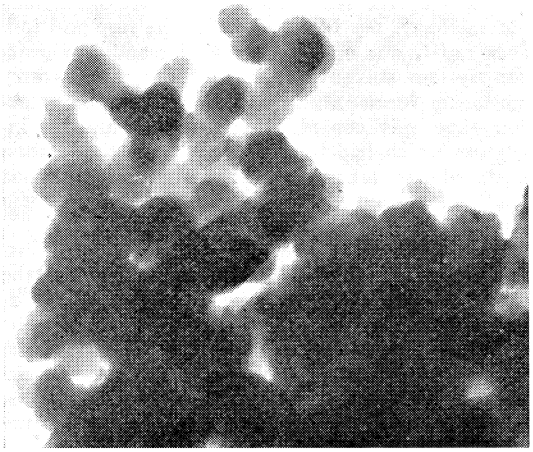
The particle shapes of the carbons were observed with an electron microscope (Type JEM-5G) made by the Japanese Electron Optics Laboratory Co., Ltd. The specimens were prepared by dispersing the carbons in alcohol by an ultrasonic waves apparatus and by scooping them on collodion film supported on a copper mesh.

The degrees of crystallization by X-ray diffraction were measured with a "Geigerflex" made by the Rigaku Denki Co., using Cu(Ni)K_α radiation after the carbons had been pulverized with a mortar.



Results and Discussion

The electron micrographs of the carbons are shown in Figs. 2 and 3. The nomenclatures 800BC, 800TC, 800HC, 800EC and 800MC denote the carbons obtained by the pyrolysis of benzene, toluene, *n*-hexane, ethylene and methane respectively at 800°C. Similarly, 1100BC, 1100TC, 1100NC, 1100EC and 1100MC denote those obtained at 1100°C.



800HC is composed of aggregates of very small particles, the shape of which can not be

TABLE I. SURFACE CHARACTERISTICS OF THE CARBONS

Surface character	Carbon produced					
	800HC	800TC	800MC	1100HC	1100TC	1100MC
B.E.T. surface area, $m^2/g.$	49.0	44.0	11.5	4.7	2.9	1.9
Electron microscopic surface area, $m^2/g.$	176.0	40.0	—	—	—	—
Particle diameter, $m\mu$	17.0	75.0	–	–	–	–
Peak micro-pore radius, Å	9	12	18	9	12	18
Micro-pore volume, cc./g.	0.06	0.07	0.03	0.01	0.01	0.01

determined exactly. From the photograph, however, we can estimate their diameters to be about 17 $m\mu$. The samples, 800BC and 800TC, are composed of an aggregation of spherical particles with average diameters of 40 and 75 $m\mu$ respectively. The particle sizes of 800TC are almost equal, but those of 800BC are not equal to one another. 800EC is composed of irregular and thin particles. 800MC has a fiber-like shape; the intensity of its photograph is greater than that of the others, since their state is apparently more compact in the aggregation of the crystallites. The rate of the pyrolysis of naphthalene was very slow at 800°C, and no detectable amounts of carbon could be obtained. When the temperature was raised to 1100°C, the rate increased markedly. This fact accords with the findings of Kinney and DelBel[3].

In the cases of 1100BC, 1100TC and 1100HC, most of the boundaries of the particles become obscure or disappear, causing the formation of uniform plates. However, the diameters of the spherical particles which are found therein do not differ so from those of 800°C. On the other hand, the shape of 1100NC, 1100EC and 1100MC is plate-like, and its uniformity is greater than that of the others. Among them, that of 1100NC is the greatest*.

The results of the surface area measurement are shown in Table I. In the table, the area of 800HC is nearly the same as that of 800TC, while that of 800MC is one-fourth of these carbons; all of them decrease remarkably when the temperature is raised to 1100°C. The electron microscopic area of 800TC calculated by assuming 2.0 as their density (40 $m^2/g.$) coincides with the B.E.T. area (44 $m^2/g.$); however, a great difference was found in 800HC, i. e., 49 $m^2/g.$ for the B.E.T. method and 176 $m^2/g.$ for the electron microscopic method.

X-Ray diffraction patterns of produced carbons are shown in Fig. 4. The results show that the degree of crystallization depends

greatly upon the reaction temperature, but not upon the starting materials, and that the crystallization advances markedly when the temperature is raised from 800 to 1100°C.

The micro-pore size distribution is shown in Fig. 5, and the peak radii and the micro-pore volumes, which were calculated from the figures, are shown in Table I. It should be noted that each carbon kept its inherent peak radii according to the kind of starting material and that their radii did not vary with the change in the reaction temperature. This interesting result is similar to that of the study by Kipling and Wilson[16], who found that the

* To know whether the particle shapes of the carbons produced are affected by the flow rate, an experiment was carried out by changing the flow rate in the range of 0.3 cc./hr. and 10 cc./hr. No obvious change was found in the shape as long as the reaction temperatures were the same.

16) J. J. Kipling and R. B. Wilson, *Trans. Faraday Soc.*, 56, 557 (1960).

pore structure of polymer carbon was controlled by the starting material. However, further studies are required to interpret this phenomena. The micro-pore volume of 800HC was almost the same as that of 800TC, but greater than that of 800MC, and when the reaction temperature was raised to 1100°C, the volume decreased remarkably in every sample and came to be the same as the others.

The significant feature of the electron microscopic observation is as follows: in the cases of benzene, toluene and *n*-hexane, the carbons produced are composed of spherically shape particles, but not, in the cases of ethylene, methane and naphthalene. Those are composed of irregular plate-like or fiber-like shape particles. From this fact, it can be said that the shape of carbons depends upon the starting material; i. e., when the material is liquid (benzene, toluene and *n*-hexane), the shape of the carbons produced is spherical, when it is gas (ethylene and methane) or solid (naphthalene), the sharp is irregular. It can thus be assumed that the liquid material will be pyrolyzed not in the state of gas but in the state of droplets, while the solid material will be pyrolyzed in the state of gas formed by the sublimation.

A great difference in the surface area of 800HC was found between the B.E.T. area and the electron microscopic area. The occurrence of this difference would seem to be due to something about the aggregation of the minute particles; i. e., observation with the electron microscope showed that the aggregation is recognizably very tight. Therefore, it can be considered that the gas used in the observation of the B.E.T. area was not permitted to penetrate the interstices of the minute particles. A very small peak radius was found in the micro-pore size distribution curve of 800HC (see Table I). This result might be ascribed to the fact that this carbon is composed of minute particles aggregated very tightly. Such a supposition agrees well with the observation made about the discrepancy found in both areas. When the reaction temperature was raised to 1100°C, remarkable decreases in the B.E.T. area and in the micro-pore volume of the carbons and a change in the carbon particle shape were observed. This result would be due to the development of the crystallization.

Quantative interpretation of the mechanism of carbon formation will be made in further studies.

Summary

The pyrolysis of six different pure organic compounds (benzene, toluene, naphthalene, ethylene, *n*-hexane and methane) has been studied to discover the relation between the starting materials and the carbon produced. The B.E.T. area, micro-pore size distribution, particle shape, and degree of crystallization have been measured in the carbon produced. The carbonization has been carried out by pyrolyzing the material by means of the flow method at the two temperatures of 800 and 1100°C, keeping the flow rate constant at 2.5 cc./hr. and the vapor pressure at 83 mmHg.

The order of the B.E.T. areas, A, of the carbons produced by pyrolysis is as follows: at 800°C, A(hexane), $49.0 > A$(toluene), $44.0 > A$(methane), 11.5, and at 1100°C, A(hexane), $4.7 > A$(toluene), $2.9 > A$ (methane), 1.9 respectively.

The peak radii, R, of the micro-pore size distribution curves are not changed by the raising of the reaction temperature (800, 1100°C); the order of the radii is R(methane), $18 > R$(toluene), $12 > R$(hexane), 9. Notwithstanding the fact that the peak radii are not changed by the reaction temperature, the micro-pore volumes diminish remarkably.

Electron microscope observation has shown that the shape of the particle is affected by the physical state of the starting material during pyrolysis. If the material is gaseous, plate-like carbon is obtained. If the material is liquid, spherical carbon is obtained.

X-Ray diffraction has shown that the degree of crystallization is not affected by the kind of material. When the temperature of pyrolysis is raised from 800 to 1100°C, the crystallization advances markedly.

The author wishes to express his gratitude to Professor Toyosaburo Takeuchi for his cordial guidance and discussion during this study.

*Studies on Solid Carbons. II. The Gas-phase Oxidation of Solid Carbons**

By Masakazu SAKAGUCHI**

(Received June 20, 1961)

The heterogeneous reaction between solid carbon and oxidizing gas is important from both the theoretical and industrial standpoints. In the past, several studies[1-7] have been made of this problem, but there still remain many points unresolved.

It is well known, regarding the oxidation of carbon, that the reactivity diminishes in accordance with the degree of graphitization[8]. The reactivity would be expected to depend primarily upon the physical fine structure (i. e., surface area, micro-pore volume and micro-pore radius) in a case of the same order of graphitization. It appears to be of interest, therefore, to find some correlation between the reaction rate and the surface properties of carbon.

The present work was carried out in order to investigate the gas-phase oxidation with nitrogen dioxide, using five typical carbons which differ in material and in manufacturing method, and also to investigate the characteristics of the rate of reaction under various conditions. The particle shapes and the degrees of the graphitization of carbon samples were observed with an electron microscope and X-ray diffraction. The physical fine surface structure of the composing particles was determined by means of the adsorption and desorption of gas at a low temperature.

Experimental

Apparatus and Procedure. — The reaction apparatus is illustrated in Fig. 1. The reaction vessel H was a modification of that of Takeuchi[9]. The volume of the vessel H up to tap K_4 and K_5 is 123 cc. The carbon sample (2.0 g.) was kept in the vessel H. After it was evacuated under about

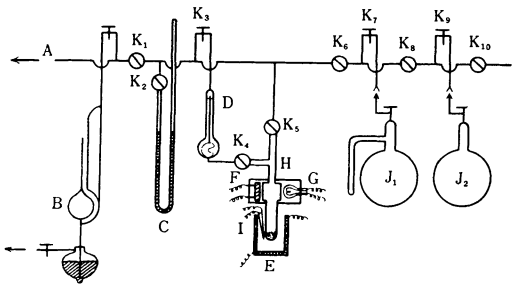

Fig. 1. Apparatus for the reaction between carbons and NO_2.

10^{-5} mmHg at 200°C for several hours, the temperature was lowered to 150°C (reaction temperature). The temperature of the electric furnace E, which contains H, was controlled (±1°C) automatically. A MacLeod gauge B was used for the measurement of the low pressure. J_2 is a reservoir of hydrogen gas used for the "H_2-treatment" of the carbon sample. NO_2 gas was taken from the gas reservoir J_1 into the space between the taps K_1, K_2, K_3, K_5, K_7 and K_8, space with a volume of 277 cc. (not including the volume of the manometer C). The gas was introduced in H by opening K_5 to start the reaction. F is a photo-cell attached closely to H and connected to a micro-ammeter. The intensity of incident light from lamp G was kept constant. The variations of transmittance accompanying the reaction were followed by the photo-cell. The relation between the transmittance and the NO_2 concentration at the temperature range of 120 to 170°C is shown by a curve in Fig. 2. The reaction rate was obtained from this curve. A Bourdon gauge D was used to follow the changes in total pressure.

The surface areas, the micro-pore volumes and the mean micro-pore radii were obtained from

Mean micro-pore radius (Å)	13.5	12.1	26.8	32.8	133.4	26.0	33.8	—

adsorption and desorption-isotherms of nitrogen at the temperature of liquid nitrogen (−195°C). The B. E. T. method was applied to the adsorption isotherms to determine the surface areas of the carbon samples assuming 16.1 $Å^2$ as the cross-sectional area of nitrogen, and Kelvin's equation was adopted for the desorption isotherms to determine the micro-pore volumes and the mean micro-pore radii.

The particle shapes of the carbons were observed with an electron microscope (Type JEM-5G, made by the Japan Electron Optics Laboratory Co., Ltd.). The specimens were prepared by dispersing the carbons in alcohol by an ultrasonic wave apparatus (cycle: 7000 kc.; time: 2 min.) and by scooping them on collodion film supported on a copper mesh.

The degrees of crystallization by X-ray diffraction were measured with a "Geigerflex" made by the Rigaku Denki Co., using Cu(Ni)K_α radiation on the specimens packed in an aluminum case after the carbons had been pulverized with a merter.

Materials.—Five carbons produced commercially (Philblack-I (C_1), Miike carbon (C_2), artificial graphite (C_3), petroleum coke-A (C_4) and petroleum coke-B (C_5)) were used, whereas sample C_4 was powder of 200-mesh which had been prepared by the pulverization of sample C_5. The physical properties of these carbons are listed in Table I. Before use, these carbons were washed in boiling water for about one hour and were then dried in the atmosphere.

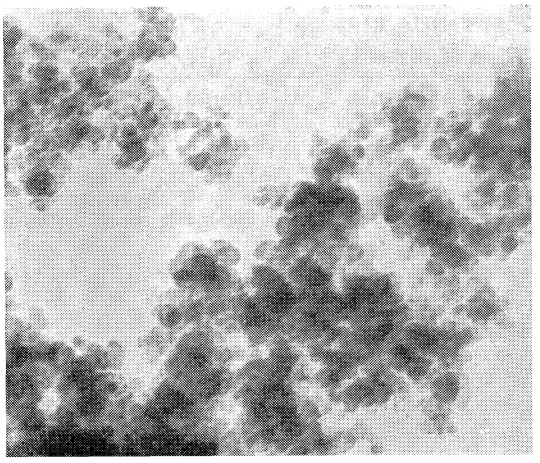
The "H_2-treatment" of carbon was performed under about 50 cmHg of hydrogen at 500°C for about 30 min. after it had been washed by boiling water. Before use, the temperature of the reaction vessel was lowered to 200°C; the procedure subsequently followed was as mentioned above*.

The treatment of carbon by benzoyl peroxide was performed by Ōkita's method[10].

The following procedure was adopted to regenerate the sample: after the reaction had stopped, the oxidized sample was washed with boiling water for about one hour**.

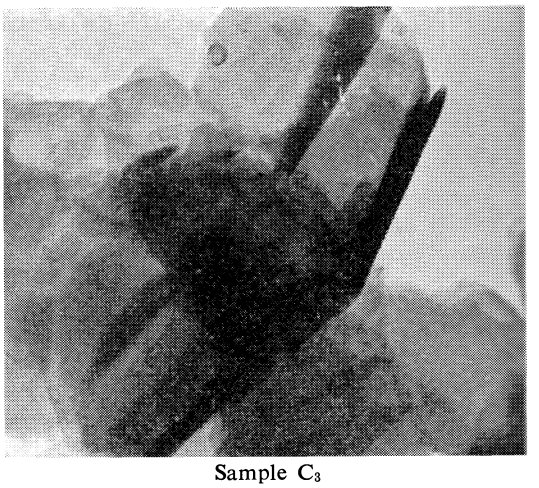
The nitrogen dioxide gas was prepared by heating of "extra pure grade" lead nitrate (supplied by Wako Junyaku Co., Ltd.) at 470°C. It was purified by vacuum distillation and stored in reservoir J_1.

The nitrogen gas used in the adsorption experiment was of a high purity (99.98%), having been supplied by Nissan Kagaku Co., Ltd.



Results

The values of the surface area and of the physical fine structure are shown in Table I, and the results of observation with the electron microscope are shown in Table I and Fig. 3. The sign "C_{orig}" in line 8 of the table denotes the sample washed in boiling water, and the "C_{re}" denotes the sample regenerated by



* The hydrogen contents found by elementary analysis of the sample were 0.56% after the "H_2-treatment" and 0.30% for the original sample.

washing with boiling water after it had been used for the reaction with nitrogen dioxide. The electron microscopic areas of samples C_1 and C_2, calculated by assuming 2.0 as their density, are shown in line 7 of the table. The area of sample C_1 coincides with that given by the B. E. T. method, but the area of sample C_2 is smaller by about 40% than the B. E. T. area. From this fact, it can be surmised that the surface of the particles composing C_1 is comparatively smooth. On the other hand, the discrepancy in the areas of sample C_2 found in the two methods can be attributed to the existence of a roughness which could not be recognized with the electron microscope. In Fig. 3, it is also clear that both the samples, C_1 and C_2, are composed of spherical particles of inherent diameters, and that the diameter of C_2 is about 10 times larger than that of sample C_1. The particles of sample C_2 are more dispersed than those of sample C_1, which agglomerate to form secondary particles. Consequently, the physical fine structure of sample C_1 (Table I, lines 10 and 11) is formed of particles which have a smooth surface, while that of C_2 exists on the surface of a composing particle itself. Sample C_3 is composed of irregular thin films, while C_4 is composed of irregular thin films and small spherical particles. Therefore, the roughness in the surfaces can not be estimated as it was in the cases of C_1 and C_2. The electron micrographs suggest also that the degree of graphitization of sample C_3 is higher than those of C_1 and C_2, and that that of sample C_4 is between C_3 and C_1 or C_2, because it is composed of films similar to those found in C_3 and of particles similar to those found in C_1 or C_2.

X-ray diffraction patterns of sample carbons are shown in Fig. 4. The results show that the degrees of graphitization of samples C_1 and C_2 are quite low and indicate the characteristics of typical carbon black. The patterns of both samples, C_3 and C_4, indicate that their degrees

of graphitization are quite high compared with C_1 and C_2 and that that of C_3 is higher than that of C_4. These facts support the conclusion obtained from the results of the electron microscopic observation.

The results of oxidation, which was carried out at 150°C with 4.2 cmHg of initial pressure of nitrogen dioxide, are shown in Fig. 5. The figure shows that the relation of the logarithm of pressure against time can be expressed by bent straight lines which are steep in the the initial stage. The rates of the consumption of nitrogen dioxide obtained from the lines are shown in Table II, where K_1 and K_2 denote the rate constants per unit gram and area respectively. It is noteworthy that the ratio of the rate in the initial stage (k_1) to that in the second stage (k_s) can be given in the range 2.0 to 3.0 for every carbon.

Figure 6 shows the results of the experiments carried out to ascertain the reaction order of

* Sign $C_{no\text{-}re}$ denotes the sample which was outgassed for several hours at 200°C after sample C_{orig} had been oxidized by nitrogen dioxide.

nitrogen dioxide by using sample C_2 under various initial pressures. From the results shown in Figs. 5 and 6, reaction order could be determined to be first. Unexpectedly, in spite of the change of the pressure of nitrogen dioxide in the reaction, no change at all in total pressure was recognized. Figure 5 shows that either the sample C_3 of the highest degree of graphitization or C_5 of a little higher degree did not react with a measurable rate.

It is of particular interest that the pulverization of carbon markedly increased the reaction rate. By pulverization, the rate of C_5 (i. e., that of C_4) became as fast as that of C_2. In the cases of C_1 and C_2, no remarkable difference in the rate K_1 could be found, though a difference exists in their surface areas. Accordingly, the rate K_2 of sample C_2 becomes greater than that of C_1.

The exeriment on sample C_2 at the higher temperature, i. e., 170°C, was carried out to learn the activation energies at the initial and second stages of the reaction. However, no detectable change in the rate could be found. This fact indicates that the activation energies in both stages are very small (< 3 kcal.*), giving thus no difference between the two.

When pre-treated with hydrogen and benzoyl peroxide, the reaction rate of nitrogen dioxide the B. E. T. areas and the electron micrographs showed no detectable change in any sample.

Tables I, II and Fig. 7 show the results of the reaction carried out to observe the effect

of the regeneration upon the surface structure and the reaction rate of the carbons. In Table II, it can be found that the rate K_1 of the regenerated sample C_1 became markedly greater than that of the not regenerated sample and that it is almost the same as that of fresh carbon. In the cases of C_2 and C_4, the rates also became greater than that of not regenerated samples, while their rates in the initial and second stages of the reaction are about half of those of the fresh carbons. In Table I, it can be found that the change in fine structure of the regenerated sample C_1 is very small, but both samples C_2 and C_4 indicate a decrease in B. E. T. areas and an increase in mean micropore radii. Those facts suggest that the roughness of the composing particles of C_2 and C_4 were diminished to some extent by the regeneration. However, these hypotheses could not be verified by the electron micrographs.

Discussion

The rate of oxidation of carbons can be considered simply to be controlled by the following factors: the degree of graphitization, the physical fine and/or the chemical structures of the surface, though these factors can not be discussed separately.

The well-graphitized carbons, C_3 and C_5, possessed different X-ray diffraction patterns, as is shown in Fig. 4. However, no difference was found in the oxidizing reaction with nitrogen dioxide. This indicates that the progress of graphitization prevents the oxidation by nitrogen dioxide. The samples which are composed from amorphous carbon, i. e., C_1 and C_2 reacted with nitrogen dioxide quickly, but their K_2 rates differed markedly from each other. It can be noticed that the micro-pore volume of sample C_2, which reacted with nitrogen dioxide more rapidly than C_1, is smaller than that of C_1, and that the mean micro-pore radius is greater than that of C_1. If the micropore radius is small, the wall of the capillary will be a much more difficult location for the reaction than a free surface. Therefore, the difference in rates found in the two samples (C_1, C_2) can be attributed to a defference in their physical fine structures. Whether or not the rate of oxidation is affected by the diffusion of gas can be confirmed by plotting the concentration of nitrogen dioxide against square root of time[11]. Figure 8 shows that the relationships are represented by convex curves in the initial stage of the reaction, but, by straight lines in the second stage. This indicates that the rate of the reaction was controlled by the

11) R. M. Barrer and D. W. Riley, *J. Chem. Soc.*, **1948**, 133.

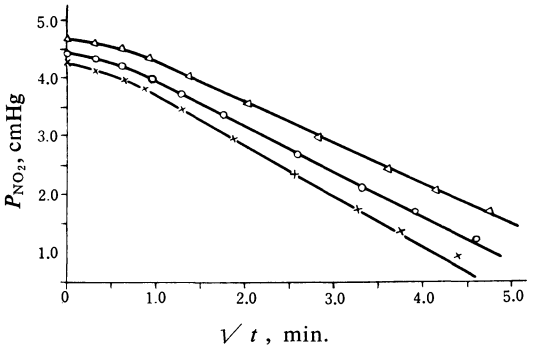

Fig. 8. Changes of NO_2 pressure with square root of time on carbons (per 2 g.) at 150°C. ×: C_1; ○: C_2; △: C_4.

diffusion of gas except in the short initial stage. We can conclude by referring Fig. 5 to Fig. 8 that rate k_1 in Table II concerns only the chemical reaction and that it is the rate of the reaction on the free surface of carbons.

The sites of different reactivities can be considered to exist on the surface of carbon as has been believed in the field of physico-chemical studies on solid surfaces.

To explain exactly the differences in rates k_1 which were not controlled by diffusion, more information about the physical and chemical properties of the free surface, e. g., geometrical arrangement and functional group on the surface, will be required. It is very difficult, however, to make clear the properties mentioned above because of the complexity and the instability of the carbon surface. However, the adaptation of the results in the following two studies can be ascribed to the relation between the rate of reaction and the nature of the surface.

The number of edge atoms in C_5 must be increased by pulverization. The increase in the reaction rate in C_4 should correlate with the increase in edge atoms because the edge atoms of microcrystalline of carbons may be considered to be more susceptible to chemical attack than the atoms in the center of the basal plane. Such a view accords with that of Long and Sykes[12], who studied the oxidation of carbon with steam.

Recently, Smith and his co-workers[7] have reported that the oxidation of carbon by nitrogen monoxide was greatly retarded by pretreatment with hydrogen at 1000°C for 15 min. In this study, the oxidation of carbon was not affected by hydrogen. In both reactions, the adsorption of oxidizer (nitrogen dioxide or nitrogen monoxide) occurs on carbon prior to oxidation. In this case, the number of sites to be occupied by the oxidizer would be decreased by the occupation of pre-treated hydrogen. Accordingly, the rate of oxidation is expected to decrease. The result of the reaction with nitrogen monoxide reveals either that the hydrogen on carbons is not readily attacked by the adsorbed nitrogen monoxide or that the reaction products (or groups) of hydrogen and oxygen given by nitrogen monoxide have a nature which is hard to distinguish from the carbon. However, in the case of nitrogen dioxide the result indicated that because of the nature of the strong oxidizer, the hydrogen was readily released into the gas-phase after it had been attacked by nitrogen dioxide.

In short, the oxidation of carbon by nitrogen dioxide is greatly affected by the physical fine structure but not by the chemical structure of the carbon surface.

12) F. J. Long and K. W. Sykes, *Proc. Roy. Soc.*, A 193, 377 (1948).

Summary

The gas-phase oxidation of five sorts of carbons with nitrogen dioxide has been measured under a pressure range from 2.4 to 9.0 cmHg at 150°C by a static method, in order to determine, primarily, the relation between the reaction rate and the physical properties of carbons (B. E. T. area, degree of graphitization, particle shape, micro-pore volume and mean micro-pore radius).

The rate of consumption of nitrogen dioxide has been determined photometrically.

The well-graphitized carbons did not react with nitrogen dioxide, while the rate curves obtained on the amorphous carbons showed as bent straight lines, the inclination of which is steep at the initial stage, followed by a slow second stage. The activation energy in the reaction is very small (< 3 kcal.).

The explanation of the results is as follows: the consumption of nitrogen dioxide in the initial stage relates mainly to chemical reaction on the free surface of the carbon, and the rate is controlled by the free surface area and the concentration of the edge atoms of the surface. The rate of the second stage relates to the diffusion process the micro-pore of carbon particles, and it is controlled by the physical fine structure of the surface.

The author wishes to express his gratitude to Professor Toyosaburo Takeuchi for his cordial guidance and discussion on this study.

Long-chain Phosphates. II. Reactions of Crystalline Sodium Metaphosphates with Solutions of Various Metal Salts

By Shigeru OHASHI and Takashi NAKAMURA

(Received July 17, 1961)

Four modifications of crystalline sodium metaphosphate are known. They are designated as $NaPO_3$-I, $NaPO_3$-II, $NaPO_3$-III and $NaPO_3$-IV. As $NaPO_3$-I is sodium trimetaphosphate, $(NaPO_3)_3$, it is out of the scope of this investigation. $NaPO_3$-II, $NaPO_3$-III and $NaPO_3$-IV are long-chain phosphates. $NaPO_3$-II is called sodium Maddrell salt of high temperature form, $NaPO_3$-III, sodium Maddrell salt of low temperature form, and $NaPO_3$-IV, sodium Kurrol salt.

In the previous paper[1] it was found by Ohashi and Yamagishi that the reaction of crystalline potassium Kurrol salt with a solution of nickel sulfate is a kind of cation-exchange reaction. They investigated also the cation-exchange reactions of crystalline potassium Kurrol salt with various metal ions other than the nickel ion. The present authors have investigated the cation-exchange reactions of the crystalline sodium metaphosphates having long-chain structures with aqueous solutions of various metal salts.

Experimental

Preparation of $NaPO_3$-II.—$NaPO_3$-II is usually prepared by dehydrating sodium dihydrogen orthophoshate at a relatively high temperature in a humid atmosphere[2]. In a platinum dish 100~150 g. of sodium dihydrogen orthophosphate dihydrate was dehydrated by the use of an electric furnace. After the temperature of the furnace reached about 160°C, aqueous steam was introduced over the sample. Then the temperature of the furnace was gradually raised to 400°C. After being kept at 400°C for 3 hr., the sample was removed from the furnace and chilled by holding the lower part of the dish in water. A white powdery product was obtained. The small amount of soluble phosphate remaining in the product was removed by washing it with distilled water. An X-ray diffraction pattern of the sample was identical with that of the ASTM cards.

Preparation of $NaPO_3$-III.—It is very difficult to prepare $NaPO_3$-III in a pure state and in a high yield. The dehydration of sodium dihydrogen orthophosphate should be carried out at a relatively low temperature in a dry atmosphere[3]. When the temperature is too high, $NaPO_3$-II is also produced. When the temperature is too low, a large amount of disodium dihydrogen pyrophosphate remains and the yield of $NaPO_3$-III becomes very low. In a porcelain dish 20~40 g. of sodium dihydrogen orthophosphate dihydrate was gradually dehydrated. The temperature of the furnace was raised from room temperature to 260°C in 5~6 hr. and kept at 260°C for 2.5 hr. A white powdery product was obtained. The product was washed with distilled water to remove the pyrophosphate. Although the X-ray diffraction pattern of the sample was identical with that of the ASTM cards, the yield was only 0.3%. $NaPO_3$-III supplied by Dr. T. P. Kickline of the Monsanto Chemical Co. was used in the present investigation on the cation-exchange reactions. 82% of the sample was composed of $NaPO_3$-III and 18% of $NaPO_3$-II.

Preparation of $NaPO_3$-IV.—$NaPO_3$-IV was prepared by Griffith's method[4]. In a platinum dish about 150 g. of sodium dihydrogen orthophosphate dihydrate was dehydrated at a relatively low temperature and melted at 800°C for 2~3 hr. in an electric furnace. Then the platinum dish was removed from the furnace and transferred to another furnace, which had been previously controlled at 550°C. The temperature of the second furnace was raised to 580°C by introducing the hot dish but fell back to 550°C within 15 min. Seed crystals of $NaPO_3$-IV, supplied by Dr. E. J. Griffith of the Monsanto Chemical Co., were then added to the sample. After being kept at 550°C for 2 hr., the sample was removed from the furnace and chilled by holding the lower part of the dish in water. In order to remove Graham salt and sodium trimetaphosphate, the sample was crushed and washed with distilled water. Although there is no available data on the X-ray diffraction pattern of $NaPO_3$-IV, the pattern of the sample obtained was quite different from those of $NaPO_3$-II and $NaPO_3$-III. Moreover, the appearance of the sample was asbestos-like and quite similar to that of potassium Kurrol salt. The sample was doubtless $NaPO_3$-IV.

The experimental conditions for the cation-exchange reactions and the analytical methods for the determination of phosphate and metal ions were essentially the same as those used in the previous investigation[1].

Results and Discussion

When any one of the sodium metaphosphates was added to a solution of nickel sulfate, the white crystalline sodium metaphosphate was gradually converted into a green gummy substance. The adsorption of the nickel ion was investigated in the following manner. At the bottom of an Erlenmeyer flask of 300 ml., 1 g. of the ground sodium metaphosphate was placed flat, and then 200 ml. of a 0.1 M solution of nickel sulfate was added to it. The mixture was kept at 20°C without agitation. The variation in the amount of the nickel ion adsorbed as time went on was determined by measuring the decrease in the nickel ion concentration in the solution. As shown in Fig. 1, after about 24 hr. the reaction reached equilibrium in every case of the three sodium metaphosphates. The reaction of $NaPO_3$-IV with a solution of cobalt sulfate also reached equilibrium after about 24 hr., as is shown in Fig. 2.

The cation exchange reactions between the sodium ions in the solid sodium metaphosphates and various metal ions in their solutions were investigated as follows. In an Erlenmeyer flask of 100 ml., about 250 mg. of each crystalline sodium metaphosphate was placed, and then 50 ml. of an about 0.1 M solution of a metal salt was added to it. After being kept at 20°C for 24 hr. without agitation, an aliquot of the solution was taken and analyzed for the metal ion remaining in the solution and for the phosphate dissolved into the solution. From these data a percentage of the sample dissolved, an amount of the sample remaining as a solid phase, and a percentage

	IV	2.50	26.4	1.84	34.8	3.20

of the sodium ion exchanged by the metal ion at the end of the reaction were calculated. Before and after the reaction, the pH values of the solution were measured. The results are summarized in Table I.

The percentages of the cation exchange in the cases of magnesium, calcium, iron(II), cobalt(II) and nickel(II) ions were in the range of 14 to 41 for $NaPO_3$-II, 70 to 83 for $NaPO_3$-III, and 81 to 98 for $NaPO_3$-IV. The tendency of the cation exchange of the sodium metaphosphates for these metal ions decreases in the order:

$$NaPO_3\text{-IV} \gtrsim NaPO_3\text{-III} > NaPO_3\text{-II}$$

In the case of potassium Kurrol salt, the percentages of the cation exchange for these cations were in the range of 82 to 94, as mentioned in the previous paper[1].

The following facts in regard to the dissolution of the sodium metaphophates in water were described by Van Wazer[2]. $NaPO_3$-II is dissolved in water at a very slow rate, 1.8×10^{-2} %/hr., and $NaPO_3$-III is also dissolved in water at a slow rate, 0.34%/hr. $NaPO_3$-IV appears to be dissolved more rapid; it forms a gel-like substance when it is kept in water for a long time. These facts may indicate that the tendency toward hydration of the sodium metaphosphates decreases in the following order:

$$NaPO_3\text{-IV} > NaPO_3\text{-III} > NaPO_3\text{-II}$$

which coincides with the order of the tendency of the cation exchange of the sodium metaphosphates. Therefore, in the course of the cation exchange of the sodium metaphosphates, the process of the hydration may play an important role.

The percentages of the phosphates dissolved during the cation exchange reactions were in the range of 0.4 to 4 for almost all of the bivalent metal ions tested in the present investigation. However, only in the case of copper(II) ion were large amounts of the phosphates, which ranged from 26 to 58%, dissolved in the course of the reactions. In the reaction of potassium Kurrol salt with the copper(II) ion, 32% of the phosphate was dissolved. It is a well-known fact that potassium Kurrol salt is not easily soluble in pure water, but it is soluble in dilute solutions of salts of alkali metals other than potassium; furthermore, crystalline sodium metaphosphates with long-chain structures are also not easily soluble in pure water, but they are soluble in dilute solutions of salts of alkali metals other than sodium. In regard to the reactions with the long-chain phosphates, the copper(II) ion has an intermediate property between alkali metals and bivalent metals such as magnesium, calcium and so on.

In all cases the pH of the solutions of the metal salts decreased in the course of the reactions. The decrease in pH may be due to the dissolution and the hydrolysis of the sodium metaphosphates. Actually, in the case of $NaPO_3$-III, both the percentages of the phosphate dissolved and of the decrease in pH were larger than in the case of the other metaphosphates. As indicated by Wieker and Thilo[5], the hydrolysis of the metaphosphates may be accelerated by the catalytic actions of the metal ions.

Summary

Three kinds of crystalline sodium metaphosphates with a long-chain structure, $NaPO_3$-II, $NaPO_3$-III and $NaPO_3$-IV, were prepared, and the cation exchange reactions of the solid sodium metaphosphates with aqueous solutions of bivalent metal salts, calcium, magnesium, iron(II), cobalt(II), nickel(II) and copper(II), were investigated. The tendency of the cation exchange of the sodium metaphosphates for these metal ions, except for copper(II), decreases in the order:

$$NaPO_3\text{-IV} \gtrsim NaPO_3\text{-III} > NaPO_3\text{-II}$$

which coincides with the order of the tendency of the hydration of the sodium metaphosphates. Only in the case of copper(II) ion were large amounts of the sodium metaphosphates dissolved in the course of the reactions.

The authors are indebted to Dr. Thomas P. Kickline and Dr. Edward J. Griffith for sending them samples of $NaPO_3$-III and $NaPO_3$-IV and for giving them information on the preparation of $NaPO_3$-III and $NaPO_3$-IV.

Condensed Vanadate-Phosphates

By Shigeru OHASHI and Tadashi MATSUMURA

(Received July 24, 1961)

It is well known that the structural frameworks of condensed phosphates are composed of P–O–P linkages. Some attempts to prepare condensed phosphates containing anions other than phosphate have been made. Thilo and his coworkers[1] have succeeded in making glasses and crystals of sodium or potassium arsenate-phosphates, which are composed of P–O–P and P–O–As linkages. Some experiments have been made on glasses of sulfate-phosphates[2] and silicate-phosphates[3]. The purpose of the present investigation is to prepare glasses and crystals of sodium vanadate-phosphates, which have P–O–V linkages.

Both the glasses and the crystals of alkali arsenate-phosphates, when dissolved in water, decompose by the scission of P–O–As linkages to give arsenate and mixtures of condensed phosphates[1]. As is the case with alkali arsenate-phosphates, sodium vanadate-phosphates, it is assumed, decompose by the scission of P–O–V linkages, when dissolved in water, to give vanadate and mixtures of condensed phosphates.

The present authors have made glasses and crystals of sodium vanadate-phosphates with various P/V ratios and have also obtained some information on the structures of the glasses and the crystals from paper chromatographic analyses of their aqueous solutions.

In the course of the present investigation it was found that vanadium(V) is partially reduced to vanadium(IV) when the starting materials, i.e., sodium metaphosphate, vanadium(V) oxide and sodium carbonate, are melted together to form the glasses or the crystals. Munakata et al.[4] found that a considerable amount of low valency vanadium, probably vanadium(IV), is produced when glasses of the V_2O_5-P_2O_5-BaO system are prepared.

Experimental

Vanadium(V) Oxide.—Ammonium metavanadate was recrystallized at least twice from its hot aqueous solution by adding ammonium chloride. The purified ammonium metavanadate was converted to vanadium(V) oxide by heating it at 350°C in a porcelain dish. The lower oxides of vanadium produced, together with vanadium(V) oxide, were oxidized by heating them with a small amount of nitric acid. The vanadium(V) oxide thus obtained was melted in a platinum crucible and crystallized by pouring out the melt on a copper plate.

Glasses of Sodium Vanadate-Phosphates.—Glasses of sodium vanadate-phosphates with various P/V ratios were prepared by melting mixtures of sodium metaphosphate (Graham salt), vanadium(V) oxide and sodium carbonate.

$$2x\mathrm{NaPO_3}+y\mathrm{V_2O_5}+y\mathrm{Na_2CO_3} = 2x\mathrm{NaPO_3}\cdot 2y\mathrm{NaVO_3}+y\mathrm{CO_2} \quad (1)$$

or

$$= (x+y)\mathrm{Na_2O}\cdot x\mathrm{P_2O_5}\cdot y\mathrm{V_2O_5}+y\mathrm{CO_2} \quad (2)$$

However, a part of the vanadium(V) oxide was reduced to vanadium(IV) oxide formally.

$$y\mathrm{V_2O_5} = (y-z)\mathrm{V_2O_5}+z\mathrm{V_2O_4}+z/2\mathrm{O_2} \quad (3)$$

In a platinum crucible a certain amount (15~30 g.) of monosodium dihydrogen orthophosphate dihydrate was dehydrated and melted by heating and converted into a glass of sodium metaphosphate by cooling the melt in the platinum crucible. After the weight of the glass was measured, calculated amounts of vanadium(V) oxide and sodium carbonate were taken on the glass in the crucible. Then the mixture of these three materials was melted at 900°C for 1 hr. The melt was quenched by pouring it on a copper plate and by pressing it with another copper plate. By this procedure glasses of sodium vanadate-phosphates with P/V ratios (x/y in Eq. 1) of 1, 2, 3, 4, 7, 10, 50, 100 and 200 were prepared. The glasses had colors ranging from dark brown toward yellow with the increasing P/V ratio.

Crystals of Sodium Vanadate-Phosphates.—A melt obtained from a mixture of sodium metaphosphate, vanadium(V) oxide and sodium carbonate was crystallized by keeping it at 450~500°C for 24 hr. By this treatment crystals of sodium vanadate-phosphates with P/V ratios of 7, 10 and 50 were prepared. All of the crystals are yellowish-green. By a similar treatment, the melts with P/V ratios of 3 and 4 were only partially crystallized.

Determination of Percentages of Vanadium(IV) in Relation to Total Vanadium.—An appropriate amount of sodium vanadate-phosphate was dissolved in 2 N sulfuric acid and titrated with 0.03 N potassium permanganate while being warmed on a water bath. After the titration with permanganate, the sample solution was titrated with 0.03 N ammonium iron(II) sulfate by the use of a few

drops of a diphenylamine solution as an indicator, which solution was made by dissolving about 0.5 g. of diphenylamine in 50 ml. of 85% phosphoric acid. Before the second titration, 3 ml. of 85% phosphoric acid should be added to each 100 ml. of the sample solution in order to mask the iron(III). The first titration corresponds to the amount of vanadium-(IV), and the second, to the total amount of vanadium. From these titrations the percentages of vanadium(IV) in relation to the total vanadium ($z/y \cdot 100$ in Eq. 3) were calculated.

Paper Chromatography.—The paper chromatographic method of Karl-Kroupa[5] was used for samples containing short-chain phosphates and trimetaphosphate, while that of Smith[6] was used for samples containing relatively long-chain phosphates. The acid solvent was made by mixing 735 ml. of isopropyl alcohol, a solution of 50 g. of trichloroacetic acid in 265 ml. of water, and 2.5 ml. of concentrated aqueous ammonia. The basic solvent was made by mixing 387 ml. of isopropyl alcohol, 200 ml. of isobutyl alcohol, 408 ml. of water, and 5 ml. of concentrated aqueous ammonia. Toyo No. 51A filter papers were used. The colorimetric determination of orthophosphate was done by Nakamura's method[7].

A paper area for each phosphate species was cut into pieces and transferred to a small glass-filter connected to a suction bottle. Then 3~4 ml. of 1 N aqueous ammonia was added to the glass filter; after a few minutes it was filtered into a volumetric flask of 25 ml. by the use of a suction pump. This procedure was repeated four times, and a total of 15 ml. of 1 N aqueous ammonia was used. To the solution in the flask, 3.88 ml. of 8 N sulfuric acid was added, and the flask was placed in a boiling water bath for 20 min. in order to hydrolyze all the condensed phosphates to orthophosphate. After the flask was cooled, 3.3 ml. of amidol reagent[7] and 1.7 ml. of molybdate reagent[7] were added. Then the volume was brought up to the 25 ml. mark with distilled water. After the flask had been kept at 20°C for 10 min., the absorbance of blue color was measured against a reagent blank at 750 mμ.

Results and Discussion

When a mixture of sodium metaphosphate, vanadium(V) oxide and sodium carbonate is melted, carbon dioxide and then another kind of gas are evolved. It was qualitatively confirmed that the gas is oxygen. On the other hand, solutions of the glasses or the crystals of vanadate-phosphates are green and discolor a dilute solution of potassium permanganate acidified with sulfuric acid. These facts indicate that a part of the vanadium(V) in the melt is reduced to vanadium(IV) by the evolution of oxygen.

When a melt of vanadate-phosphates with a P/V ratio of 3 is heated at 900°C for 1, 2, 3 or 4 hr., the resulting glasses contain about 19% of vanadium(IV) in relation to the total vanadium in all cases, as is shown in Table I. This fact means that a heating of 1 hr. is sufficient to achieve an equilibrium between vanadium(V) and vanadium(IV) at 900°C.

Table I. Percentages of vanadium(IV) in relation to the total vanadium in the glasses with P/V ratio of 3, prepared by heating for 1~4 hr. at 900°C

Heating time, hr.	V(IV), %
1	18.9
2	18.7
3	18.8
4	18.9

The percentages of vanadium(IV) in relation to the total vanadium in the glasses of vanadate-phosphates with various P/V ratios are shown in Table II. With an increasing P/V ratio, i. e., with a decrease in the absolute amount of vanadium, the percentages of vanadium(IV) increase and reach an almost nearly constant value, 37~38%, when the P/V ratio is larger than 50.

Table II. Percentages of vanadium(IV) in relation to the total vanadium in the glasses having various P/V ratios

P/V ratio	V(IV), %
1	4.5
2	11.4
3	18.9
4	22.8
7	30.1
10	33.8
50	37.4
100	38.0
200	37.8

The percentages of vanadium(IV) in relation to the total vanadium in the crystals of vanadate-phosphates with P/V ratios of 7, 10 and 50, which are shown in Table III, are always a little smaller than those of vanadium-(IV) in the glasses with the same P/V ratios.

Table III. Percentages of vanadium(IV) in relation to the total vanadium in the crystals having various P/V ratios

P/V ratio	V(IV), %
7	27.1
10	32.0
50	34.1

The results of the paper chromatography for the determination of phosphate species in the aqueous solutions of the glasses and the crystals of vanadate-phosphates are summarized in Table IV. Almost all of these data were obtained by the paper chromatography with an acid solvent. Although by the use of the acid solvent trimetaphosphate can not be completely separated from tetrapoly- or pentapolyphosphate, two-dimensional paper chromatograms for the aqueous solutions of the glasses with P/V ratios of 1~10 did not indicate the presence of ring phosphates such as trimeta- or tetrametaphosphate. Since the aqueous solutions of the crystals, on the contrary, contained trimetaphosphate, the total amount of tetrapoly-, pentapoly- and trimetaphosphate was determined by the use of the acid solvent, and the amount of trimetaphosphate was separately determined by the use of the basic solvent. The sum of tetrapoly- and pentapolyphosphate was calculated as the difference between these two figures.

The data for the glasses in Table IV indicate that the contents of the longer chain phosphates increase with an increasing P/V ratio. If it is assumed that P–O–V linkages in the solid substances are hydrolyzed as soon as dissolved in water, it may be presumed that the glasses are composed of chain structures such as

where vanadium(V) atoms are inserted into the phosphate chain.

Since a melt having a composition of sodium metaphosphate is crystallized as sodium trimetaphosphate under the same conditions as those used for the preparation of the crystals of sodium vanadate-phosphates, it is easy to surmise that crystals with P/V ratios of 7, 10 and 50 are mainly composed of trimetaphosphate, as is shown in Table IV. With an decreasing P/V ratio, i.e., with an increase in the absolute amount of vanadium, the amounts of trimetaphosphate decrease and those of pyrophosphate increase. Moreover, the pyrophosphate found in the solutions of the crystals are predominant in comparison with the other chain phosphates. These facts indicate that the pyrophosphate is probably derived from the hydrolysis of the following vanadate-phosphate ring:

At the present stage of investigation, it is not possible to determine, however, whether the chain phosphates other than the pyrophosphate are derived from amorphous substances mixed in the crystals.

The data in Table IV show that the main component in the case of the glass with a P/V ratio of 1 is orthophosphate. This fact may indicate that the glass is composed of a chain structure of alternate P–O and V–O linkages. The aqueous solutions of the glasses with P/V ratios of 2~10 contain predominant amounts of pyrophosphate in comparison with the other short-chain phosphates. From the fact it seems probable that the trimeta-vanadate-phosphate ring described in the case of the crystals is present also in the glasses.

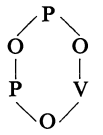
In the aqueous solutions of the glasses, the number of chain phosphates longer than octapolyphosphate increases with an increasing P/V ratio. Although the aqueous solutions of the glasses with P/V ratios of 50, 100 and 200

could not be analyzed quantitatively by paper chromatography, almost all of the phosphorus were found as non-moving spots in their paper chromatograms developed with the acid solvent.

The role of vanadium(IV) in the glasses and the crystals has not been clear. However, from the fact that vanadyl ions VO^{2+} are most stable in crystals and solutions of vanadium(IV) salts, the vanadium(IV) in the vanadate-phosphates may also be present as vanadyl ions and may play a role as a cation like sodium ions.

An X-ray diffraction pattern of the crystal with a P/V ratio of 50 is identical with that of sodium trimetaphosphate. This means that the presence of the vanadate, which is a minor constituent in this case, has not a great effect on the pattern of sodium trimetaphosphate. On the contary, X-ray patterns of crystals with P/V ratios of 7 and 10 are quite different from those of both sodium trimetaphosphate and sodium metavanadate.

Summary



Glasses of sodium vanadate-phosphates with P/V ratios of 1∼200 were prepared from mixtures of sodium metaphosphate, vanadium(V) oxide and sodium carbonate. Crystals of sodium vanadate-phosphates with P/V ratios of 7, 10 and 50 were also prepared.

During the preparation of the glasses and the crystals, a part of the vanadium(V) is reduced to vanadium(IV). The percentages of vanadium(IV) in relation to the total vanadium increase with an increasing P/V ratio.

From the paper chromatographic analyses of the aqueous solutions of the glasses and the crystals, it may be presumed that the glasses are mainly composed of chain structures such as

and that the crystals contain considerable amounts of a vanadate-phosphate ring as follows:

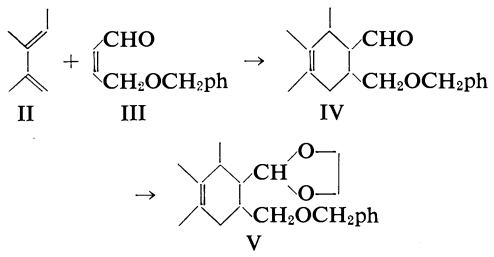
*Syntheses of γ-Ionone Analogues. IV. An Attempted Approach to 4-(2′-Methylene-3′, 4′, 5′-trimethylcyclohexyl)-but-3-en-2-one from 6-Benzyloxymethyl-2, 3, 4-trimethyl-3-cyclohexenylmethanal, and Investigation on Some Derivatives Thereby**

By Atsuaki ARAI and Iwao ICHIKIZAKI

(Received May 15, 1961)



In the present work we have researched a synthetical route for the preparation of 4-(2′-methylene-3′, 4′, 5′-trimethylcyclohexyl)-but-3-en-2-one, an analogue of γ-ionone, from 6-benzyloxymethyl-2, 3, 4-trimethyl-3-cyclohexenylmethanal (IV). During the course of investigation we have studied on the hydrogenolysis products of 6-benzyloxymethyl-2, 3, 4-trimethyl-3-cyclohexenylmethanal ethylene acetal (V), and, moreover, investigated *p*-benzyloxybenzaldehyde as a new hydrogen acceptor for the modified Oppenauer oxidation.

A diene mixture[1] containing 37.5% 3, 4-dimethyl-1, 3-pentadiene (I) and 62.5% 2, 3-dimethyl-1, 3-pentadiene (II) underwent the Diels-Alder reaction with 4-benzyloxy-2-buten-1-al (III). This resulted in the selective addition of III to II in the presence of a small amount of hydroquinone at 140 to 150°C to produce a pale yellow adduct, $C_{18}H_{24}O_2$, which was proved extremely homogeneous after careful redistillation. From the experimental result[1] with regard to the direction of addition of 4-benzyloxy-2-butyn-1-al, $C_6H_5CH_2OCH_2C{\equiv}CCHO$, or of crotonaldehyde to II, the structure IV was assigned for the adduct obtained above. This

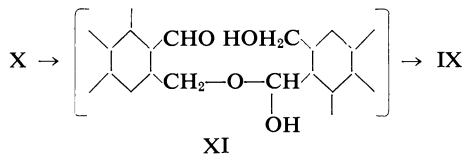
1) A. Arai and I. Ichikizaki, This Bulletin, **35**, 45 (1962).

compound readily reacted with ethylene glycol in the presence of *p*-toluenesulfonic acid in benzene to afford its ethylene acetal V in an 80% yield. No elimination of benzyl alcohol was then observed, although in the analogous treatment of 2-benzyloxymethyl-4,5,6-trimethylcyclohexa-1, 4-dienylmethanal, a doubly unsaturated analogue of IV, a remarkable aromaticization with removal of benzyl alcohol had been observed[1].



Hydrogenation of V in the presence of a palladium-on-charcoal catalyst in ethanol afforded in a 90% yield 6-benzyloxymethyl-2, 3, 4-trimethylcyclohexylmethanal ethylene acetal (VI), after a little more than one mole of hydrogen had been absorbed. In the presence of a more active catalyst, V afforded on hydrogenation a low-boiling oil, $C_{11}H_{20}O$, and a high-boiling liquid, $C_{13}H_{24}O_2$, in a 25.4 and 69% yield respectively, while ethylene glycol was then also obtained in a 86.5% yield. The low-boiling oil had a strong menthol-like odor, and has been proved to be 8, 9-*cis*-4, 5, 6-trimethyloctahydroisobenzofuran (VII), a full description on whose structure and some reactions will be given in a following paper. The infrared spectrum of the higher boiling oil clearly indicated the presence of a C–O–C–O–C group[2], while, the presence of neither carbonyl nor hydroxyl group was shown. On treatment with the Brady reagent, the oil gave a yellow 2,4-dinitrophenylhydrazone. This crystalline derivative was also obtained from the compound, $C_{11}H_{20}O_2$, which had been given by treating the oil with diluted sulfuric acid and showed a weak absorption band at 1721 cm^{-1} indicative of a carbonyl group in addition to marked absorption band characteristic of a hydroxyl and a C–O–C–O group in the infrared spectrum. From considering the fact[3,4] that α-alkoxytetrahydrofurans are readily converted with aqueous mineral acid into the corresponding γ-hydroxyaldehydes, which generally exist in an equilibrium between an acyclic and a cyclic form, we assigned 3-ethoxy-4, 5, 6-trimethyloctahydroisobenzofuran (VIII) and a tautomeric mixture of 6-hydroxymethyl-2, 3, 4-trimethylcyclohexylmethanal (IXb) and the cyclic hemiacetal IXa for the higher boiling oil and its hydrolyzed product respectively. By comparing the intensity at the carbonyl maximum in the infrared region of the equilibrium mixture with that of 4, 5-dimethyl-2-methoxymethylcyclohexylmethanal[5] which was adopted as a standard compound, it was suggested that the cyclic form IXa exists predominantly and the open free hydroxyaldehyde IXb in only 8.3%.
