Catalyst Acidity.—The acidity was determined on a separate sample drawn from the same batch as the catalysts used in the activity test in the preceding paper[1]. The procedure of the determination is dependent on the chemisorption measurement of quinoline or ammonia. In this study, the quinoline chemisorption method was adopted, and the data were in some cases supplemented with the ammonia chemisorption method.

The quinoline chemisorption measurement was made by means of the technique developed by Mills et al.[2], using an apparatus of a more simplified design developed by Hara et al.[3] Prior to the chemisorption the catalyst sample was successively heated at 500°C in a stream of dry air for fifteen hours and a stream of purified nitrogen for three hours. The quinoline chemisorption and subsequent flushing of the sample with nitrogen at the flow rate of 300 cc./min. were made at 300°C.

The ammonia chemisorption was pointed out by Tamelle[4], Milliken et al.[5], Webb[6], and Voltz[7] as

serving as a measure for the catalyst acidity. In this study, the method of Voltz was followed, and the chemisorption measurement was conducted in a static system at a fixed ammonia pressure of 35 mmHg at 60°C (the polymerization temperature). Each molecule of quinoline or ammonia chemisorbed was considered to correspond to one acid site, and the acidity data were given in the form of mmole equivalent base (quinoline or ammonia)/g. catalyst.

Removal of Nickel Oxide from Catalyst.—It would be desirable to divide the observed acidity of the catalyst into the individual contributions of the catalyst components. This would be possible if nickel oxide could be removed without causing irreversible changes in the silica-alumina support. In this respect, Schuit et al.[8] developed a very convenient method for removing nickel at a comparatively low temperature. In their study on nickel-on-silica catalysts, nickel was converted to nickel carbonyl by treatment with carbon monoxide at atmospheric pressures to remove it from the catalysts, and then the changes in the specific surface area and average pore radius caused by the removal were investigated. This method of romoval has been followed in this study with some modifications: after having been thoroughly reduced at 450°C under high pressure (50~100 kg./cm^2) of hydrogen for a week, the catalyst was treated with flowing carbon monoxide at high pressure (150 kg./cm^2) at 150°C for a week. Schuit et al.[8] stated that the removal of nickel seldom proceeded quantitatively when the coprecipitated catalysts were treated. It has been proved in the present study, however, that by the treatment at the higher pressure and temperature, more than 99% of the nickel can be removed from the coprecipitated catalysts. The catalyst acidity and the activity as well as the specific surface area were determined, in the same manner as described previously[1], on the catalyst samples thus depleted of nickel oxide (hereafter denoted as catalyst A′).

Valence State of Nickel in Catalyst.—The valence state of nickel was evaluated by precise reduction of the nickel oxide with hydrogen. The reduction was conducted according to the method of Hill et al.[10] in a circulatory flow system similar in construction to that used for the catalyst activity test in the preceding paper[1]. The catalyst sample weighing about 5 g. was placed in a catalyst tube and was pretreated in the same way as for the activity test[1], followed by introduction of hydrogen from an attached gas burette into the system to a pressure of 500 mmHg. Two U-traps were placed in the circulating system and were cooled at −78°C to remove the water vapor formed by reduction. The reduction was made at 540°C in a circulating current of hydrogen maintained at about 500 mmHg by frequent introductions of hydrogen from the gas burette. It was continued until the hydrogen consumption diminished to such a small extent as 0.1 cc. (N. T. P.)/g. catalyst·day. The reduction durations ranged from 7 to 15 days according to the reducibility. After the reduction was completed, the volume of hydrogen necessary for keeping the final pressure of the entire system exactly at 500 mmHg was measured. The system was evacuated again at 540°C for 3 hr., followed by the immediate introduction of hydrogen to the pressure of 500 mmHg. The difference between the volumes of hydrogen introduced before and after the evacuation gave the hydrogen consumption for the reduction of the nickel oxide. The processings of evacuation and the subsequent introduction of hydrogen were done in such a way as to minimize the error of overestimating the hydrogen consumption, which error might result from a considerable amount of hydrogen chemisorption on the reduced catalysts.

Experimental Results

Catalyst Activity after Nickel Oxide Removal.—In the preceding paper[1], the catalyst activity for ethylene polymerization was expressed in terms of the rate constant per gram of catalysts A (k_g). For the sake of a convenient comparison between the k_g and the activity of corresponding catalysts A′ after the nickel oxide removal, the activity of the latter catalysts is given by a rate constant based on the amount of silica-alumina contained in 1 g. of the original catalysts A but not in 1 g. of catalysts A′. The rate constant defined in this manner will be conventionally denoted by k_g of catalysts A′[11]. The results are listed in Table I, which includes the k_g for catalysts A. The table shows that catalysts A′, the silica-alumina residues from catalysts A, give poor activities which are lower than several hundredths of the activities of the corresponding catalysts A, with the exception of catalyst A–6, with a large aluminum content[12]. The ethylene

polymerization seems to proceed on the active sites on which nickel oxide is acting effectively.

Changes in Specific Surface Area and Pore Volume by Nickel Oxide Removal.—The specific surface area and the pore volume of catalysts A′ are expressed in m^2 and cc. respectively of the silica-alumina contained in 1 g. of catalysts A. The area thus defined, in place of the surface area based on 1 g. of catalysts A′, may lead to an easier understanding of the effect of nickel oxide addition on the change in the catalyst surface area. Figure 1 presents the results as a plot against the Al/(Al+Si) ratio, together with the plot for a series of catalysts A. The former plot lies a little above the latter plot over the whole range of aluminum content examined in this study[14]. The result is the opposite of that of Schuit[8], who stated a decrease in the specific surface area of nickel-on-silica catalysts from which nickel had been driven out.

Definite tendencies in the change of the pore volume have scarcely been found between the catalysts A and corresponding catalysts A′ (refer to Fig. 2).

—○— Catalysts A
--●-- Catalysts A′
-·-□-·- Difference between acidities of catalysts A and A′

Catalyst Acidity.—Figure 3 shows the acidity (denoted by A_g) determined by the quinoline chemisorption method for the two series of catalysts A and A′, plotted against the Al/(Al+Si) ratio. Again, the acidity for the catalysts A′ for the sake of convenience, is expressed in mmole equivalent (meq.) quinoline chemisorbed on the silica-alumina contained in 1 g. of the original catalysts A. The plot for catalysts A (plot I) tends to rise rapidly, to pass through a maximum at a Al/(Al+Si) ratio of about 0.05, and to fall off gradually with the increasing aluminum content. The plot for catalysts A′ (plot II) lies below plot A, and the difference between the two plots (plot III), which is larger in the range of the higher acidity of catalysts A, is a measure of the acidity resulting from the nickel oxide. A small amount of nickel oxide can in some cases produce a large number of acid sites, besides those of silica-alumina alone[15]. It should be noted, further, that the numbers of acid sites thus produced are greatly dependent on the aluminum content.

Valence State of Nickel in Catalyst.—The result is shown in Fig. 4 as a plot of the atom ratio of hydrogen consumed for reduction to

14) Since the specific surface area of catalyst A-2 decreased by 2.5% of the original area after the catalyst underwent the hydrogen treatment at 450°C and subsequent oxidation at 500°C with air, the increase in the specific surface area can not be ascribed to the treatments other than the nickel oxide removal.

15) The increase in the acidity caused by an addition of metal oxides, such as chromium oxide, copper oxide, and other oxides of the transition metals, to silica-alumina over that of silica-alumina alone has already been pointed out by Clark[13] and Fisher et al.[16]

16) K. A. Fisher and G. Brandes, *Erdoel u. Kohle*, 9, 81 (1956).

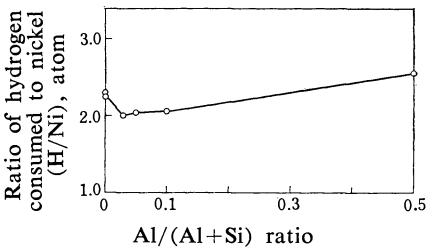

Fig. 4. Hydrogen consumption plotted against Al/(Al+Si) ratio.

nickel vs. the Al/(Al+Si) ratio. Nickel exhibits a normal valence of 2 in the Al/(Al+Si) range from 0.03 to 0.1, while on the sides both of decreasing and increasing aluminum contents valences a little higher than 2 are found. Concerning the valence of nickel in catalysts, Holm et al.[17] reported the normal valence of 2 for series of impregnated and coprecipitated nickel oxide-silica-alumina catalysts containing silica and alumina in the ratio of 9 : 1 with a wide range of nickel oxide contents. The present result is consistent with the result of Holm et al. in the sense that the valence is 2 for the catalysts with relatively small aluminum contents. On the other hand, Selwood[18] obtained a valence higher than 2 for nickel in nickel oxide-on-alumina catalysts. The slight valence increase in the range of higher aluminum content may be explainable in view of Selwood's result, since the larger the aluminum content, the larger the amount of nickel oxide which can be combined with alumina. However, no interpretation of the higher nickel valence for catalyst A-1 with no aluminum is possible.

Discussion

Relationship between Catalyst Activity and Acidity.—Previous papers dealing with the nickel oxide-silica-alumina catalysts indicated no direct relationship between the catalyst activity for olefin polymerization and the catalyst acidity[19,20]. As shown in Fig. 5[21], a simple plot of the activity (k_g) against the acidity (A_g) does not show such a relationship, either. Regarding dual-oxide catalysts, however, it was not infrequently possible to obtain

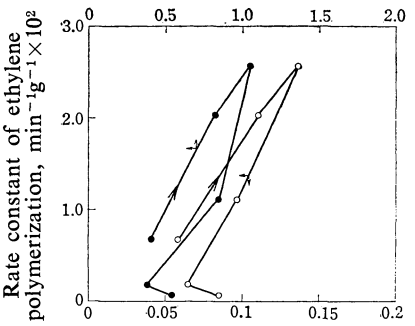

Fig. 5. Plots of catalyst activity vs. acidity.

--●-- Catalysts A'
--□-- Difference between acidities of catalysts A and A'

a definite relationship between them[4,22,23], and hence the present data will be treated in further detail.

The preceding paper[1] of this series established that the specific activity per unit surface area of the catalyst and the specific surface area are the major factors determining the catalyst activity for ethylene polymerization on the nickel oxide-silica-alumina catalysts. In the present work, it has been determined that the nickel oxide has no appreciable effect on the surface area of silica-alumina and, therefore, that the increased activity is not due to an increase in the specific surface area. In order

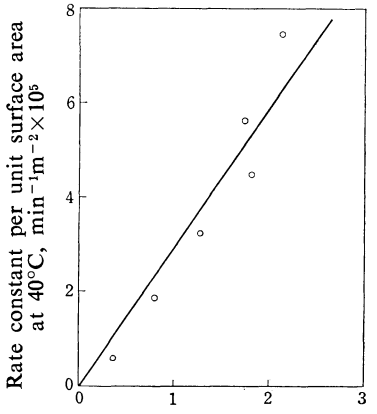

Fig. 8. Rate constant per unit surface area plotted against difference between acidities of catalysts A and A'.

to examine the possible relationship of the specific activity to the acidity, the acidity is likewise considered on the basis of unit surface area (denoted by A_s); namely, the A_g in Fig. 3 is divided by the surface area in Fig. 1 to result in the acidity based on the unit surface area of the catalysts. The A_ss are shown in Fig. 6 with separate plots of I and II for respective series of catalysts A and A' as a function of the Al/(Al+Si) ratio. Plot I rises rapidly in the range of the Al/(Al+Si) ratio from 0 to 0.05 and more slowly in the range of higher ratios with the increasing aluminum content. In contrast to this, plot II rises monotonously with the increasing content, as is usually the case with silica-alumina catalysts[24,25]. Further, the difference between the two plots, which indicates the acidity produced on the unit surface area of the catalysts with nickel oxide (denoted by A_{sNi} hereafter), is shown by plot III as a function of Al/(Al+Si) ratio. Plot III is quite different in tendency from plot I, showing a maximum at the Al/(Al+Si) ratio of 0.05.

The direct relationship of the catalyst activity to the acidity is to be given rather by the plot of k_s against A_s than by that of k_g against A_g. Of the two acidities, namely, A_s with catalysts A, and A_s with nickel oxide (A_{sNi}), only the latter acidity gives an approximate straight line when plotted against the k_s (refer to Figs. 7 and 8). In view of this fact, combined with the extremely low activity of catalysts A' as compared with that of catalysts A, it can be concluded that only the acid sites produced with nickel oxide act effectively for the ethylene polymerization and that the individual acid sites thus produced promote the polymerization to an equal extent, regardless of the aluminum contents.

Acid Site Produced with Nickel Oxide.—If an extension of Thomas' proposal[25] for silica and other binary oxide mixtures, in which he postulates the formation of protons from residual water to satisfy the valence deficiencies associated with the unit cell, is applied conventionally to the present three-component catalysts, two kinds of acid sites, as pictured respectively by models I and II in Fig. 9, may be formed. On the other hand, the preceding paper[1] suggested the existence of two kinds of acid sites, H^+X^- and H^+Y^-, on the catalysts, one of which acts effectively for the ethylene polymerization and the other one of which acts effectively for the isomerization between

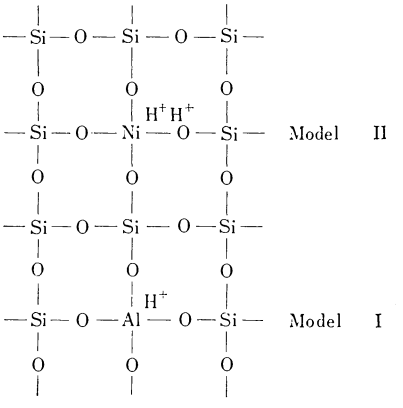

Fig. 9. Structures of acid sites.

25) C. L. Thomas, *Ind. Eng. Chem.*, **41**, 2564 (1949).

the product butene-isomers. Taking into account the linear relationship observed between the k_s for the polymerization and A_{sNi}, H^+X^- would correspond to the acid site given by the model II.

The model II proposed for the acid site H^+X^- can explain the observed relationship between the A_{sNi} and the aluminum content of the catalysts. The acid site represented by model II is brought about by the condensation of hydroxyls existing at the interface between silica and nickel oxide particles. This suggests that the acid sites could be increased in number according as the particles of nickel oxide and silica are more finely dispersed, consequently according to the increasing specific surface area of the catalyst granules. As for the present series of catalysts containing a fixed amount of nickel oxide with varying amounts of alumina, the specific surface area is greatly dependent on the alumina contents[26], and the plot of the specific surface area against the aluminum content is recognized as running approximately parallel with the same plot of A_{sNi} (compare Fig. 6 with Fig. 1). The fact that nickel in the catalysts of high A_{sNi} is divalent is another support for the model.

Moreover, the decreasing tendencies in the activity and the acidity with the increasing aluminum content in the Al/(Al+Si) range above 0.05 may be partially due to the more frequent formation of the nickel oxide-alumina compound, which gives neither the high activity[19] nor the acidity.

The fact that the initial rates of formation of three *n*-butene isomers and the A_s due to silica-alumina both depend on the aluminum content might lead to the assumption that the acid site H^+Y^- as pictured by model I acts as the site for the isomerization. However, nothing decisive can be established until further experimental data are available with respect to the catalysts with a wide range of the ratio between nickel and aluminum. The matter will be dealt with in one of the succeeding papers of this series.

26) Milligan et al.[27] stated that in the dual-oxide system (e. g. nickel oxide-alumina), one oxide (e. g. alumina) might exhibit a protective action against crystallization, resulting in finer particles of the other oxide.

27) W. O. Milligan and L. Merten, *J. Phys. Chem.*, **50**, 465 (1946); H. B. Weiser, W. O. Milligan and G. A. Mills, ibid., **52**, 942 (1948).

Summary

After nickel oxide is removed from the catalysts consisting of nickel oxide, silica, and alumina, the catalysts usually show a much lower activity than the original catalysts, with a slight increase in the specific surface area.

The acidity of the original catalysts indicates a maximum at the Al/(Al+Si) ratio of 0.05 and diminishes to some extent after the removal of the nickel oxide. The difference between the acidities before and after the removal of nickel oxide, which is a measure of the acidity originating from nickel oxide, is larger in the range of the higher acidity of the original catalysts. The valence state of nickel is found to be 2 in the Al/(Al+Si) range from 0.03 to 0.1, while it is a little higher than 2 with both decreasing and increasing aluminum contents.

Very few definite relationship have been found between the catalyst activity and acidity. However, when both the activity and the acidity originating from nickel oxide are considered on the basis of the unit surface area, an approximately linear relationship is found between them. The structure of the acid site produced by an addition of nickel oxide is discussed from the view point of an extension of Thomas' proposal for silica and other binary oxide mixtures.

Ultraviolet Spectrophotometric Determination of Vanadium in Silicate Rocks

By Jun YOSHIMURA and Yoshio MURAKAMI

(Received September 19, 1961)

The spectrophotometric determination of a metal using various mineral acids has the advantage of not requiring a special reagent such as organic reagents, besides having the merits of simplicity of operation and of giving comparative accuracy.

Several works have recently reported on the spectrophotometric determination of various metals, such as iron(III), lead and bismuth, in which sulfuric[1], perchloric[2,3], and hydrochloric acid[4-6] were used as reagents respectively. These methods are based on the absorbance measurement at maximum wavelength of the absorption band, which is considered to be due to the complexes formed between metallic ions and anions such as sulfate, hydroxy and chloride ions.

Regarding vanadium, there are a few articles on the spectrophotometric investigation of vanadium species in acidic media[7-9], but nothing on the spectrophotometric determination of vanadium with mineral acid.

Desesa and Rogers[4] have suggested, on the other hand, the possibility of the ultraviolet spectrophotometric determination of vanadium-(V) with hydrochloric acid in their investigation of interference in the spectrophotometric determination of iron with hydrochloric acid.

The present paper is concerned with the investigation of the absorption spectra of vanadium(V) in a hydrochloric acid medium and with the application of their results to the spectrophotometric determination of vanadium(V) in silicate rock.

Experimental

Apparatus.—All absorbance measurements were carried out with a Shimadzu photoelectric spectrophotometer QB-50, with 1 cm. silica cells.

Reagents.—A standard vanadium solution was prepared by dissolving 0.4595 g. of analytical reagent grade ammonium metavanadate in 500 ml. of distilled water. One milliliter of this solution contained 200 μg. of vanadium. The solutions for the absorption spectra measurements were prepared by drying up the aliquots of the stock solution on the water bath and then dissolving the residues in hydrochloric acid solutions of various concentrations. All the other reagents used were of analytical reagent grade.

General Procedure.—Transfer about 2 g. of the rock samples to a platinum crucible and mix with 10 g. of anhydrous sodium carbonate. Fuse the mixture and allow it to cool to room temperature. Transfer the crucible and contents to a 300 ml. beaker and add a few milliliters of distilled water. Heat to boiling in order to loosen the residue in the crucible, and crush any large particles with a flattened stirring rod. Remove the crucible, and wash it sufficiently with water. Add 3 ml. of methyl alcohol to reduce the manganate, warm in the boiling water for 10 min., and filter through filter paper (Toyo-roshi 5B) into a 100 ml. beaker while the solution is hot. Wash the residue 2~3 times with 10 ml. of hot water, and add the washing to the filtrate. After cooling the filtrate, transfer it to a 100 ml. volumetric flask and dilute to the volume with distilled water. Add 25 ml. of this solution to an ion-exchange column containing Dowex-50 Na-form and collect the effluent in a 50 ml. flask. Rinse the column with several portions of water. After neutralizing the effluent, adjust the pH to 4.5~5.2 with acetate buffer and add 0.2 ml. of a 2.5% oxine solution with 2 N acetic acid and 2 ml. chloroform[10]. Shake for 1 min. to extract the vanadium oxinate, transfer the organic phase into a platinum crucible, then repeat the extraction three times and evaporate up to dryness. Add 0.2 g. of anhydrous sodium carbonate to the crucible containing the residue, and fuse it again to convert the vanadium into sodium vanadate. Dissolve the melt in a few milliliters of water. Transfer this solution into a 25 ml. volumetric flask, add 5 ml. of 5 N hydrochloric acid, and dilute to the volume with water. Measure the ultraviolet absorbance at 222 mμ. and obtain the concentration of vanadium from a calibration curve.

Results and Discussion

Absorption Spectra.—A series of complete absorption spectra for vanadium(V) in hydrochloric acid solutions of various concentrations

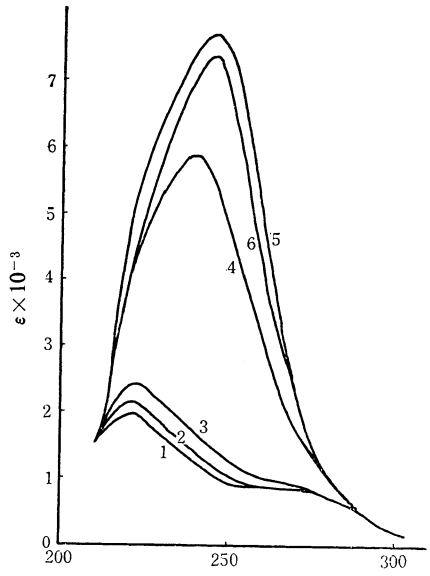

Fig. 1. Absorption spectra of vanadium in HCl.

1:	0.1~2 N HCl	4:	8 N HCl
2:	4 N HCl	5:	10 N HCl
3:	6 N HCl	6:	11.4 N HCl

is shown in Fig. 1. In a 0.1~2 N hydrochloric acid solution, the absorption spectra hardly changed with the acid concentration, but in an acid solution more concentrated than in 4 N, the absorption band shifted to a longer wave length with the increasing acid concentration. The position of the maximum was 222 mμ for a 0.1~2 N, but 246 mμ for an 11.4 N hydrochloric acid solution. In a 0.1~2 N hydrochloric acid solution, vanadium(V) exists in the form of pervanadyl ion, VO_2^+ [7,9]. Moreover, the bathochromic and hyperchromic effects with hydrochloric acid, mentioned above, are presumably due to the formation of the higher complex species. The decrease of absorbance in an 11.4 N hydrochloric acid solution compared with that in a 10 N acid solution is attributed to the reduction of a part of vanadium(V) to vanadium(IV) by hydrochloric acid, because concentrated hydrochloric acid has a reducing power and reduces vanadium(V) slowly to vanadyl(IV) ion, VO^{2+}, which is the sole species of vanadium(IV) in a hydrochloric acid medium[11], and the molar extinction coefficient of vanadium(IV) is smaller than that of vanadium(V) in the near ultraviolet region (Fig. 2). Moreover, it is well known that when vanadium(V) is dissolved in an 11.4 N hydrochloric acid solution, the solution becomes intense brown. The absorption spectra for a

series of solutions having a constant 10 N hydronium ion concentration but varying chloride concentrations, obtained by mixing hydrochloric acid and perchloric acid in various ratios are shown in Fig. 3. This red brown species, which has its absorption maximum at 450 mμ, was formed in a high hydronium ion concentration such as in 10 N, but it was not formed in a low concentration even if a solution of 8 N chloride concentration was used (Fig. 3). At a high hydronium ion concentration, with the increasing chloride concentration this species became unstable and was converted into vanadyl(IV) ion. From the facts that this species was formed at a high hydronium ion concentration, reduced to vanadyl ion easily, adsorbed by anion exchange resin[12], and extracted to tributyl phosphate, and that the species extracted to tributyl phosphate from the solution of low acid concentration was considered to be $VOCl_3$[13], this red brown complex seemed to be $VOCl_4^-$. The relation between the absorbance of the vanadium and the hydrochloric acid concentration of the solution

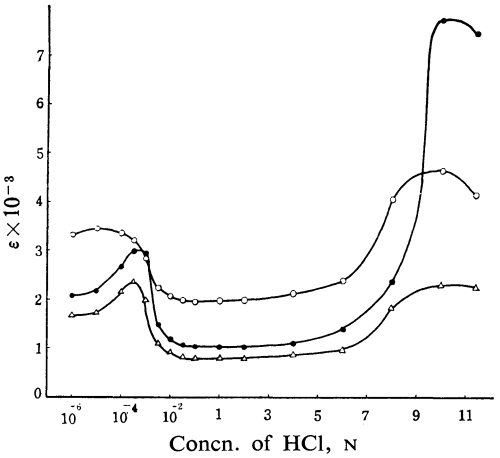

Fig. 4. Relation between the absorbance and the hydrochloric acid concentation.
-○- at 220 mμ -●- at 245 mμ
-△- at 270 mμ

at a specific wavelength is shown in Fig. 4; it is clear from this figure that in the range of hydrochloric acid concentrations from 0.1 to 2 N the effect of the acid concentration on the absorbance was very small and that the absorbance values are nearly equal.

Determination of Vanadium.—On the basis of the above results, a 1 N hydrochloric acid concentration and 222 mμ were chosen as the working conditions for the determination of vanadium making use of the absorption of pervanadyl ion.

Calibration Curve.—Using the standard solution, having the concentration of 200 p. p. m. of vanadium with 1 N hydrochloric acid, a series of 1 N hydrochloric acid solutions having various concentrations of vanadium from 0 to 25 p. p. m. was prepared; then the absorbance was measured at 222 mμ, using a 1N hydrochloric acid solution as reference. As shown in Fig. 5, Beer's law is obeyed up to 25 p. p. m. at 222 mμ.

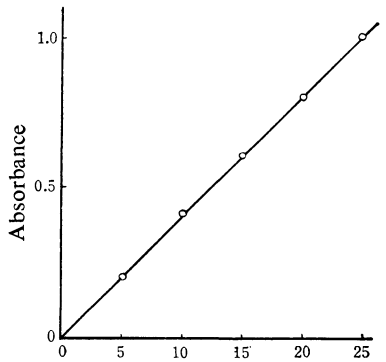

Fig. 5. Calibration curve at 222 mμ.
HCl : 1 N

Stability.—The stability of the system was then investigated for a week; it was found that the absorbance at 222 mμ did not change during this time, as is shown in Fig. 6.

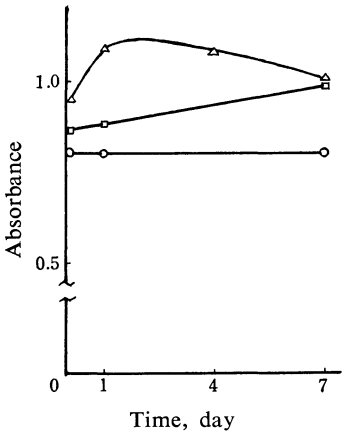

Fig. 6. Stability of absorbance at 222 mμ.

Application of This Method to Silicate Rock Analysis.—After fusion and extraction with water as in the usual method, the sample solution was passed through a column of Dowex-50 Na-form. In the sample solution vanadium existed in the form of vanadate and was not adsorbed by cation exchange resin. However, in this treatment, silicate, phosphate, arsenate, chromate, molybdate and tungstate passed through together with vanadate. Therefore, the absorption spectra of all these elements were observed and are shown in Fig. 7. It is evident from this figure that chromium, molybdenum and tungsten seriously interfered with the determination of vanadium at 222 mμ. Of these three elements, chromium

200	As(V)	Na_3AsO_4	2 mg.	202

could be separated from vanadium by oxine extraction, but the others could not be separated[14]. The results obtained by the general procedure are shown in Table I. Generally, however, these elements present in silicate rocks are very small quantities compared with vanadium, so the interference by these elements is negligible. The analyses of the Sekisonzan Lave of Asama and of the standard rock sample, diabase W-1, by this method gave the values of 0.024% and 0.043% respectively as V_2O_3; these values were consistent with the value of 0.021% obtained by the phosphotungstate method and with the average value of 0.038%[15].

Summary

1) The absorption spectra of vanadium(V) in the media of various concentrations of hydrochloric acid were studied.

2) A 1 N hydrochloric acid concentration was recommended as the working medium for the spectrophotometric determination of vanadium(V), because the change in the intensity of the absorbance with the change in the reagent concentration is slight.

3) Beer's law was obeyed up to 25 p. p. m. of the metal, measuring the absorbance at 222 mμ.

4) The analysis of the silicate rocks by this method was studied, and good results were obtained.

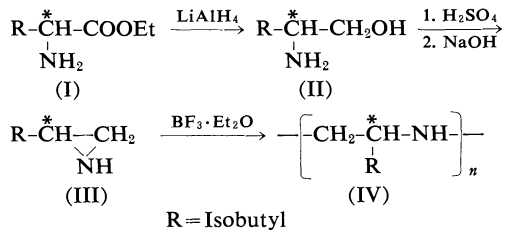
Catalytic Asymmetric Cyanohydrin Synthesis with Synthetic Optically Active Polymer. I. Synthesis of Benzaldehyde Cyanohydrin



By Sei TSUBOYAMA

(Received November 29, 1961)

Catalytic asymmetric synthesis with optically active substances has been studied by several investigators[1-6], however, no attempts with synthesized polymer. The present author used a synthesized optically active polymer with amino groups as functional group for asymmetric synthesis of benzaldehyde cyanohydrin. This study is of interest for the subject is an enzyme model of biological asymmetric synthesis.

Recently, Minoura et al.[7] reported that, in the polymerization of R- and S-propylenimine, asymmetry of the obtained polymer was well retained. This process was considered available for the synthesis of an optically active polymer with functional groups. In the present work, S-isobutyl-ethylenimine (III), synthesized from L-leucine, was polymerized to an optically active linear polymer IV with ring opening.

This polymer is solid, softening at about 56°C. Its molecular weight is 4000~6000, and the sign of optical rotation is opposite to that of the monomer, similar to poly-s-propylenimine. An insoluble polymer could not so far be obtained by common cross-linking reagents except tolylene-diisocyanate.

In carrying out the asymmetric cyanohydrin synthesis, styrene-divinylbenzene copolymer containing methyl-D-glucosamide, diethylaminoethyl cellulose, L-leucinol, quinine and Amberlite IR-4B were also employed as catalysts for reference. The results are listed in Table V.

Experimental

Preparation of s-Isobutyl-ethylenimine Polymer (IV, IEI-Polymer).—*L-Leucinol (II).* — The amino alcohol was prepared as described by Karrer[8]. L-Leucine ethyl ester[9] (I) (20 g., 0.125 mol.; b. p. 74°C/7 mmHg, n_D^{20} 1.4289) in ether (150 ml.) was added dropwise with stirring to lithium aluminum hydride (7.6 g., 0.2 mol.) in ether (170 ml.). After the mixture was stirred for 15 min., diluting with ether, water (10 ml.) was added with vigorous stirring. The ether solution was decanted from the precipitate, which was extracted with ether and then with alcohol. These extracts were combined with the first ether solution. The mixture was dried and fractionated under reduced pressure, this gave 10~12 g. (69~82%) of L-leucinol, 78.5°C/2 mmHg, 83°C/4 mmHg, n_D^{27} 1.4470.

S-Isobutyl-ethylenimine (III). — The imine was obtained by a modified procedure of Campbell[10]. A cold mixture of sulfuric acid (11 g., 0.11 mol.) and water (20 ml.) was added with shaking to a solution of L-leucinol (11.7 g., 0.1 mol.) and water (20 ml.). The mixture was distilled at atmospheric pressure until the temperature of the contents reached 115°C. The distillation was continued under reduced pressure while the bath temperature was gradually raised to 180°C. The contents, when solidified, were left as it was for one hour. A cold solution of 40% sodium hydroxide (25 g., 0.25 mol.) was added to the cooled solidified product. The mixture was distilled and the distillate at 94~101°C was collected and saturated with potassium hydroxide. The organic layer formed was separated and was dried with potassium hydroxide pellets and finally with sodium. Distillation gave 4.5 g. (45%) of colorless liquid of ammoniacal odor, b. p. 130~131°C, d_{28}^{28} 0.8123, n_D^{28} 1.4242, $[\alpha]_D^{28}$ −15.39° (original liquid), $[\alpha]_D^{32}$ −24.60° (*c* 1.828 in benzene).

Found: C, 72.58; H, 13.12; N, 13.72%; MR_D, 31.172. Calcd. for $C_6H_{13}N$: C, 72.66; H, 13.21; N, 14.12%; MR_D, 31.307.

The infrared spectrum of the imine III is shown in Fig. 1.

Polymerization of the Imine III.—The polymerization was carried out according to Minoura's procedure. s-Isobutyl-ethylenimine was placed in a dry nitrogen-filled hard glass tube which was

cooled in a dry ice-methanol bath, and when cooled, boron trifluoride-etherate was added to the imine. The tube, after flushed again with nitrogen and sealed, was placed in a constant temperature bath (see Table I). After the required reaction time, the reaction mixture was dissolved in benzene and washed with 10% sodium hydroxide solution to remove the catalyst. The pale yellow benzene solution of the polymer was then washed with deionized water until the washings became neutral and was dried with anhydrous sodium sulfate. The benzene was then removed from the solution in vacuo at room temperature (freez-dry technique was always unsuccessful with this polymer). The obtained polymer was tacky, it solidified when cooled in a dry ice bath. The pale yellow glassy polymer softened at about 56°C. The softened polymer did not vitrify at room temperature unless cooled again in a dry ice bath. The polymer was soluble in common organic solvents, slightly soluble in dimethyl formamide, and insoluble in water. Its molecular weight was measured by cryoscopic method in benzene. For the polymerization, hydrochloric acid and camphor-sulfonic acid were also used as catalysts in place of boron trifluoride as shown in Table I. The infrared spectrum of the linear polymer is given in Fig. 1. From the spectra, it is found that characteristic absorption of ethylenimine, 3070 cm^{-1}, disappeared in spectrum of the polymer.

Polymer Containing Methyl-D-glucosamide (GA-Resin). — Generally, methyl glucoside of amino sugar is said to be very resistant to acid hydrolysis on account of its positive charge of amino group or betain structure, especially, methyl-D-glucosamide is known to be extremely stable to alkali[11,12]. For that reason, methyl-D-glucosamide is available as a functional group for anion exchange resin. Moreover, the amine has many hydroxy groups and many asymmetric carbons. The amine was introduced into chloromethylated styrene-divinylbenzene copolymer.

3,4,6-Triacetyl-methyl-D-glucosamide (VIII). — The amine was prepared from D-glucosamine hydrochloride (V) via bromotriacetyl-D-glucosamine hydrobromide (VI) and triacetyl-methyl-D-glucosamide hydrobromide (VII)[11]. A methanol solution of glucosamide hydrobromide (VII) was passed through a column of free form of Amberlite IR-4B to remove bromine anion. In this procedure, α- and β-methyl-D-glucosamide mixture is supposed to be produced. Recrystallizations from methanol-ether gave free glucosamide (VIII) of m. p. 139～140°C, $[\alpha]_D^{14}$ −20° (*c* 1; methanol).

TABLE II. CAPACITIES OF AcO-GA-RESIN AND GA-RESIN

12) R. C. G. Moggridge and A. Neuberger, ibid., **1938**, 745.

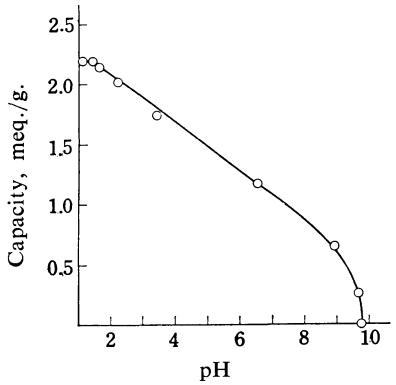

Fig. 2. Titration curve of methyl-D-glucosamide polymer (GA-resin).

Amination.—Styrene-divinylbenzene copolymer (2% crosslinked, 80~100 mesh) was chloromethylated for 48 hr. at 25°C by Pepper's procedure[13]. After the chloromethylated copolymer (10 g.; chlorine content, 16.5%) was allowed to stand overnight in dioxane, the acetylated glucosamide (VIII) (15 g.), dioxane (35 g.), and a trace of methanol were added and the mixture was placed in a bath at constant temperature for appropriate time listed in Table II. The product was washed by cycling with 1 N hydrochloric acid and 1 N sodium hydroxide to remove soluble materials.

The exchange capacity of the resin was fairly high in spite of a bulky group. The resin exhibited an abnormal behavior for adsorption to mandelic acid as shown in Table II. The polymer containing acetyl-glucosamide (VIII) (AcO-GA-resin) was then treated by a barium hydroxide solution for 45 min. to remove the acetyl group. The obtained deacetylated polymer (GA-resin) swelled in alcohol and shrank with acetone and acetic acid. In this respect, acetylated resin was opposite to GA-resin. A titration curve of the resin was typical of weak basic resin.

Diethylaminoethyl Cellulose (DEAE-Cellulose).—This ion-exchange cellulose was prepared from cotton or wood cellulose powder (Toyo Roshi Co., Ltd.) and 2-chlorotriethylamine hydrochloride as described by Peterson and Sober[14]. The exchange capacities of cotton cellulose (nitrogen content, 1.02%) and wood cellulose (nitrogen content, 0.79%) were 0.6 and 0.4 meq./g. respectively.

Asymmetric Synthesis and Analysis of Benzaldehyde Cyanohydrin.—The catalysts used in the cyanohydrin synthesis are very different from one another in chemical, physical and kinetic properties. Since it is essentially difficult to apply the same condition to those catalysts the reaction was carried out under similar conditions as for mole ratio of reagents, reaction time, reaction temperature and solvent.

To a solution of refined benzaldehyde (10.0 ml.) and anhydrous hydrogen cyanide (4.0 ml.), catalyst (0.1~1.0 mmol.) was added and the mixture was made up to 50 ml. with benzene. The solution of benzene was allowed to stand at 20°C for 20 hr. with stirring. The catalyst was filtered off and the filtrate was distilled under reduced pressure to remove unreacted hydrogen cyanide and again was made up to 50 ml. with benzene. Optical rotation of the solution was measured by a polarimeter (Hitachi Ltd.) in 2 dm. tube. A sample of given volume was pipetted from the benzene solution and, after dilution with water, it was treated with 0.1 N potassium hydroxide until pH ca. 11 and was titrated with 0.1 N silver nitrate by means of the potentiometric method[15]. As shown in Fig. 3, the titration curves of benzaldehyde cyanohydrin (fresh distilled, b. p. 118~119°C/0.25 mmHg, 124~126°C/1mmHg[16]), potassium cyanide and several samples from the reaction product mixture were almost of the same form and their end points were very sharp. The titration value of fresh distilled cyanohydrin in benzene

solution with benzaldehyde agreed throughly with that of equal quantity of the same cyanohydrin used alone. For the calculation of cyanohydrin concentration, the value of the first inflection point in the titration curve was doubled. IEI-polymer, dissolved in benzene solution, may be removed by shaking with sulfuric acid but this process gives rise to various troubles. Furthermore, Amberlite IR-120 or Dowex-50·X-1 (low crosslinked) did not adsorb the polymer even if it is low molecular weight. From Tables III and IV we see that the value of optical rotation of the product with catalyst still in it should be considered satisfactory with the accuracy of 1% or less in error if the correction is made for optical rotation of the polymer itself. Therefore, the optical rotation of cyanohydrin was measured regardless of the polymer content. The optical yield, "P%", expresses the ratio of specific rotation of the product to the absolute value of rotation of optically pure cyanohydrin in benzene, $[\alpha]_D^{25}$ 43.75 (2 dm., c 5.006)[17].

Results and Discussion

As regards P% in the last column of Table V, IEI-polymer gives considerably good results presumably because of steric hindrance of bulky isobutyl group adjacent to a functional group and large influences of structural regularity of optically active polymer on the asymmetric synthesis of cyanohydrin. In the regularity of the polymer, a helical conformation may be existent to some extent in dilute benzene or toluene solution. If we could make an IEI-polymer of higher molecular weight, we could expect a better result because of enhanced stereo-regularity.

With GA-resin, the yield and P% are both poor. The resin hardly swelled in benzene and, therefore, the reaction velocity was very slow. Even if satisfactorily swelled, the aldehyde group could not approach the amino group of the catalyst, for the functional amino group is sandwhiched between the polymer skeleton and the bulky glucoside ring. Furthermore, the resin has no asymmetric carbon in the polymer main chain. In spite of many optically active carbons that are in side chains, reagents may be receiving just a slight chance of steric control in transition state.

Concerning DEAE-celluloses, wood cellulose is inferior to cotton cellulose both in yield and in P%, for which lower crystallinity of original wood cellulose powder and intermingled impurities seem responsible. But, what is most unaccountable about wood cellulose is, that the signs of optical rotations of the two reaction produdts are reversed, notwithstanding the two celluloses, one obtained on the market, the other synthesized in the laboratory, being of the same structure (see Table V). It may have been due to differences of the synthetic methods of the DEAE-celluloses or of their

*1 $[\alpha]_D$ are the values corrected for the rotation of the polymer.
*2 Catalyst polymerized with camphor sulfonic acid was used; softening point, 53°C.
*3 Molecular weight of the catalyst, 1020. In other cases, molecular weight is 4000~6000.
*4 DEAE-Cellulose of Type 20 (Brown Co.) was used (nitrogen content, 1.10%; exchange capacity, 0.7 meq./g.).

fine structure of the cellulose part. Previously, Bredig et al.[2] found that when diethylamino cellulose was used in the studies of asymmetric cyanohydrin synthesis, the optical yield of the product was 22% as mandelic acid. In comparison with this, the results shown in Table V are too small, which is attributable to the difference between amination processes and the difference in distance between the cellulose part and the amino group.

L-Leucinol, regarded as monomer of IEI-polymer, did not catalize in the asymmetric cyanohydrin synthesis and the cyanohydrin was obtained in a poor yield.

The result with quinine is similar to the results obtained by other workers[2-4].

Amberlite IR-4B does not swell easily in solvent, hence, the reaction velocity is slow and, as expected, stereo-specific reaction did not occur.

Behavior of IEI-Polymer under Various Conditions.—Rate of cyanohydrin formation with IEI-polymer is shown in Fig. 4 (A mixture of 20 ml. of benzaldehyde, 8 ml. of hydrogen cyanide, and 200 mg. of polymer was made up to 100 ml. with benzene. Five milliliters of this reaction mixture was used for every analysis.). Variation of P% vs. reaction time is similar to that in Bredig's case[2] of diethylamino cellulose; it is accompanied with slow racemization. Specific rotation of the polymer is affected a little by the temperature of toluene solution (Fig. 5). Curve of P% vs. reaction temperature is shown in Fig. 5; it has a

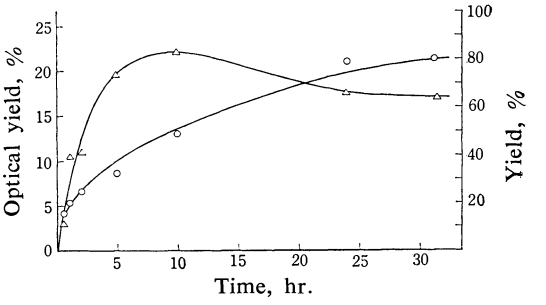

Fig. 4. Time dependence of yield (-○-) and optical yield (-△-) of benzaldehyde cyanohydrin with IEI-polymer.

maximum near −10°C at which temperature the ratio of (−)-cyanohydrin to (+)-isomer is 65:35. It is of interest to note that the existence P% maximum in the range of reaction temperature resembles the enzyme action which becomes powerful within limited ranges of temperature and pH.

In cyanohydrin synthesis, it is well known that carbonium ion of the carbonyl group is more unstable than negatively polarized oxygen, hence, the first step of the reaction is the nucleophilic attack. The reaction is therefore accelerated by the base.

In this asymmetric synthesis, we consider that either the conformation of the transition state is fixed by the steric effect of isobutyl group of the polymer when the carbonyl group approaches the nitrogen of the catalyst or cyanide ion weakly bonded with the amino

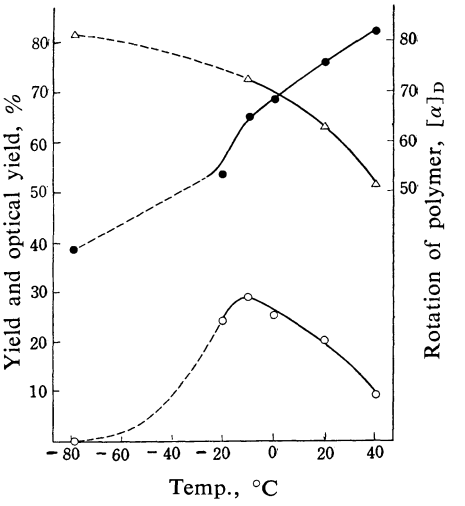

Fig. 5. Temperature dependence of yield (-●-) and optical yield (-○-) of benzaldehyde cyanohydrin and specific rotation (-△-) of IEI-polymer.

group of the polymer attacks the carbonyl group only from a definite direction on account of the isobutyl group. In any case, the spiral structure of the polymer, too, is presumed to give rise to a promoting effect on the asymmetric synthesis.

Summary

Poly-s-isobutyl-ethylenimine was synthesized and with it asymmetric synthesis of benzaldehyde cyanohydrin was carried out with good results: P% is 20%.

This is ascribable to (1) the steric effect of the isobutyl group adjacent to the amino group in the polymer, (2) the stereo-regularity of the polymer, and presence of an asymmetric center and functional group in the main chain of the polymer, and (3) the spiral structure, if it exists, of the polymer enhancing its stereo-regularity effect.

The author wishes to thank Dr. Masaya Yanagita for his many valuable suggestions and constant encouragement throughout the course of this study.

The Reaction of Tropoids and Quinone Derivatives. III. Reaction of Several Tropolones and o-Benzoquinone Dibenzimide

By Shuichi SETO and Yukio NISHIYAMA

(Received November 22, 1961)

In earlier papers of this series, reaction of several tropolones with *p*-benzoquinone-dibenzenesulfonimide[1] and *p*-benzoquinone[2] was reported. The present paper describes the structure of the reaction products of tropolone and its bromo derivatives with *o*-benzoquinone-dibenzimide (I)[3].

A solution of tropolone and I dissolved in a mixture of methanol and chloroform, added with a small quantity of triethylamine, affords colorless crystals (II) when allowed to stand at room temperature. Analytical values of II correspond to the formula $C_{27}H_{20}O_4N_2$ and the presence of a tropolone ring in II is certain from its ultraviolet absorption spectrum and coloration to ferric chloride. II is also obtained by the use of diethylamine in place of triethylamine in the foregoing reaction, and also by the same reaction carried out in an aqueous solution with addition of alkali, though in a poor yield. Heating of II in a sealed tube with concentrated hydrochloric acid gives 2-phenylbenzimidazole derivative III and phenylenediamine derivative IV. Although the latter was not isolated in a pure state, its formation seemed certain from the facile formation of a triazole derivative V by application of sodium nitrite to the mother liquor left after separation of III. III is also obtained on treatment of II with alcoholic potassium hydroxide. Oxidation of III with alkaline potassium permanganate affords 2-phenylbenzimidazole and

1) S. Seto, H. Yamazaki and Y. Nishiyama, This Bulletin, 33, 1081 (1960).
2) S. Seto and H. Sato, ibid., 35, 349 (1962).
3) R. Adams and J. W. Way, *J. Am. Chem. Soc.*, 76, 2763 (1954).

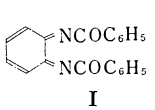
this fact suggests that 2-phenylbenzimidazole and tropolone are bonded through the nitrogen in the imidazole ring in III.

In order to make further confirmation of the structure of III, rearrangement of the tropolone ring in III into benzoic acid was attempted.

Application of diazomethane to III afforded only one kind of methyl ether VI, suggesting that 2-phenylbenzimidazole is bonded to 5-position of the tropolone ring in III. The methyl ether VI was converted into 2-chlorotropone derivative VIII through the hydrazino derivative VII[4].

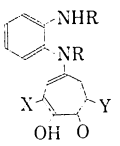
2-Chlorotropone derivative VIII easily underwent conversion to a benzoic acid derivative when heated with alkali and this derivative was changed to a methyl ester IX with diazomethane. According to the afore-mentioned assumption, this methyl ester IX should be 1-(4′-methoxycarbonylphenyl)-2-phenylbenzimidazole and structurally apparent IX was synthesized by the following route.

2-Amino-4′-methyldiphenylamine[5] was treated with benzoyl chloride in pyridine and the monobenzoyl derivative so formed was treated with acetic anhydride to effect cyclization to 1-(4′-methylphenyl)-2-phenylbenzimidazole, which was oxidized with potassium permanganate to form the benzoic acid derivative.

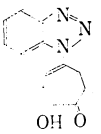


The methyl ester obtained from this acid derivative has the structure of 1-(4′-methoxycarbonylphenyl)-2-phenylbenzimidazole and this was found to be identical with the foregoing IX through mixed fusion test and by comparison of ultraviolet and infrared spectra. The foregoing facts have proved that III is 1-(tropolon-5′-yl)-2-phenylbenzimidazole and II is *N*-(tropolon-5-yl)-*N*, *N*′-dibenzoyl-*o*-phenylenediamine.

3-Bromotropolone also undergoes reaction with I to form a monobromo derivative X, whose structure was determined from its analytical values and formation of II by hydrogenolysis.



X is also obtained by monobromination of II.



3, 7-Dibromotropolone also affords a dibromo derivative XI by the reaction with I and the structure of XI was also determined from its analytical values and formation of II by hydrogenolysis.

From the similarity of tropolone and phenol, reaction of I with phenol is of interest and examination of this reaction revealed that the product in this case is *N*-(4-hydroxyphenyl)-

Experimental[7]

***N*-(Tropolon-5-yl)-*N*, *N*′-dibenzoyl-*o*-phenylenediamine (II).**—a) A solution of 1 g. of *o*-benzoquinone-dibenzimide (I) and 770 mg. of tropolone dissolved in 65 ml. of a mixture (3 : 1 by volume) of methanol and chloroform, added with 3 drops of triethylamine, was allowed to stand at room temperature for 4 days. Evaporation of the solvent in a reduced pressure precipitated crystals. The first crop of 470 mg. of crystals melted at 212～213°C. Its mother liquor was further concentrated, the residue was treated with dilute hydrochloric acid, and washed with petroleum ether, affording a second crop of 780 mg. of crystals melting at 199～203°C. The two crops of crystals were combined and recrystallized from a chloroform-ethanol mixture to give 970 mg. of colorless crystals (II), m. p. 220～221°C.

Found: C, 73.55; H, 4.74; N, 6.87. Calcd. for $C_{27}H_{20}O_4N_2$: C, 74.30; H, 4.62; N, 6.42%. λ_{max}^{MeOH} mμ (log ε): 230 (4.62), 352 (4.20).

The petroleum ether layer left after separation of the second crop of crystals was evaporated and the residue was sublimed at 60°C (bath temperature) at 1 mmHg, affording 200 mg. of the recovered tropolone.

Addition of an aqueous solution of ferric chloride to a solution of II in ethyl acetate resulted in coloration of the aqueous layer to green and organic layer, red.

b) A solution of 100 mg. of I and 100 mg. of tropolone dissolved in 16 ml. of a mixture (3 : 1 by volume) of methanol and benzene, added with 3 drops of diethylamine, was allowed to stand for

6) S. Seto and Y. Nishiyama, *J. Pharm. Soc. Japan* (*Yakugaku Zasshi*,) **82**, 590 (1962).

7) All melting points are uncorrected. Microanalyses were carried out by Misses Yôko Endô and Yukiko Endô of this Institute. Measurements of ultraviolet spectra were made by a Hitachi EPU-2A type spectrophotometer.

7 days at room temperature. Evaporation of the solvent in a reduced pressure left 40 mg. of crystals, m. p. 217~222°C, which were recrystallized from an ethanol-chloroform mixture to 35 mg. of colorless crystals, m. p. 225°C, undepressed on admixture with the product obtained by the foregoing method a).

c) A mixture of 100 mg. of I with 100 mg. of tropolone, 100 mg. of potassium hydroxide, and 5 ml. of water was stirred for 15 hr. under ice cooling, and *o*-phenylenedibenzamide (40 mg.) that separated from the reaction mixture was filtered off. The filtrate was acidified with dilute hydrochloric acid, the solid that precipitated, was collected, and recrystallized from an ethanol-chloroform mixture to 5 mg. of colorless crystals. This product was found to be identical with the product obtained by the foregoing methods a) and b). The filtrate left after separation of the solid was extracted with chloroform and the extract was sublimed on a water bath at 60°C 1 mmHg, affording 50 mg. of recovered tropolone.

Reaction of II and Concentrated Hydrochloric Acid.—A mixture of II (432 mg.) and concentrated hydrochloric acid (8.8 ml.) was heated in a sealed tube at 120°C for 3 hr. When cooled, the tube was opened and the reaction mixture was extracted with benzene. The benzene extract afforded benzoic acid. Concentration of the aqueous layer in a reduced pressure gave 100 mg. of colorless crystals, m. p. 248~250°C (decomp.), which is the hydrochloride of 1-(tropolone-5′-yl)-2-phenylbenzimidazole (III).

Found: C, 68.08; H, 4.38; N, 7.81. Calcd. for $C_{20}H_{15}O_2N_2Cl$: C, 68.45; H, 4.31; N, 7.99%.

A solution of sodium nitrite (50 mg.) in water (0.5 ml.) was added to the filtrate left after separation of the foregoing crystals and the crystals that separated immediately were recrystallized from an ethanol-chloroform mixture to 10 mg. of 1-(tropolon-5′-yl)-benztriazole (V) as crystals of m. p. 225°C.

Found: C, 64.91; H, 3.75; N, 18.13. Calcd. for $C_{13}H_9O_2N_3$: C, 65.26; H, 3.76; N, 17.57%. λ_{max}^{MeOH} mμ (log ε): 288 (4.41), 345 (4.25).

Reaction of II and Potassium Hydroxide. — A solution of II (1 g.), potassium hydroxide (3 g.), water (10 ml.), and ethanol (15 ml.) was heated at 120°C for 4 hr. and then evaporated to dryness. A small amount of water was added to the residue, insoluble matter was collected, and suspended in water. The mixture was adjusted to pH 4 with acetic acid, the solid (530 mg.) that remained was collected, and recrystallized from an ethanol-chloroform mixture to 340 mg. of 1-(tropolon-5′-yl)-2-phenylbenzimidazole (III) as colorless crystals, m. p. 247~248°C.

Found: C, 75.99; H, 4.03; N, 9.03. Calcd. for $C_{20}H_{14}O_2N_2$: C, 76.42; H, 4.49; N, 8.91%. λ_{max}^{MeOH} mμ (log ε): 227 (4.55), 289 (4.24), 341 (4.19), 405 (3.70).

Oxidation of III with Potassium Permanganate. — A solution of VII (100 mg.) dissolved in 2 N potassium hydroxide (2 ml.), added to 1 ml. of 5% aqueous solution of potassium permanganate and 2 ml. of pyridine, was heated on a water bath for 30 min., cooled, and filtered to remove manganese dioxide. Evaporation of the filtrate left 30 mg. of colorless crystals, m. p. 293°C, undepressed on admixture with an authentic specimen of 2-phenylbenzimidazole.

1-(2′-Methoxytropon-5′-yl)-2-phenylbenzimidazole (VI). — An ether solution of diazomethane was added to a suspension of III (50 mg.) in methanol (10 ml.) and the mixture was allowed to stand over night. The solvent was evaporated from the reaction mixture in a reduced pressure and the residue was recrystallized from ethanol to 20 mg. of colorless crystals, m. p. 161~162°C.

Found: C, 74.67; H, 4.51; N, 8.42. Calcd. for $C_{21}H_{16}O_2N_2$: C, 76.81; H, 4.91; N, 8.53%. λ_{max}^{MeOH} mμ (log ε): 289 (4.29), 325 (4.11).

1-(2′-Hydrazinotropon-5′-yl)-2-phenylbenzimidazole (VII). — A solution of the 2-methoxytropone derivative (VI) (100 mg.) dissolved in methanol (1 ml.), added with 80% hydrazine (20 mg.), was allowed to stand for one hour, during which yellow crystals began to precipitate after a few minutes. The crystals were collected by filtration and 90 mg. of yellow crystals, m. p. 233~235°C (decomp.), was obtained.

Found: C, 71.96; H, 4.26; N, 16.29. Calcd. for $C_{20}H_{16}ON_4$: C, 73.15; H, 4.91; N, 17.06%. λ_{max}^{MeOH} mμ (log ε): 230 (4.47), 255 (4.45), 352 (4.23), 415 (3.98).

1-(2′-Chlorotropon-5′-yl)-2-phenylbenzimidazole (VIII). — A solution of cupric sulfate crystals (1 g.) dissolved in water (1.6 ml.) with warming was maintained at 120°C and a mixture of VII (110 mg.) and concentrated hydrochloric acid (1 ml.) was added with stirring, by which a vigorous evolution of nitrogen was observed. After being maintained at 120°C, the solution was cooled, adjusted to pH 4 by addition of water (10 ml.) and sodium hydrogencarbonate, and shaken thoroughly with chloroform. The mixture was filtered, the chloroform layer was separated from the filtrate, and dried over anhydrous sodium sulfate. The solution was purified through an alumina column and evaporation of the solvent from its effluent afforded 95 mg. of colorless crystals, m. p. 185~186°C.

Found: C, 72.09; H, 3.86; N, 8.36. Calcd. for $C_{20}H_{13}ON_2Cl$: C, 72.18; H, 3.94; N, 8.42%. λ_{max}^{MeOH} mμ (log ε): 237 (4.50), 290 (4.29), 336 (3.97).

Rearrangement Reaction of VIII with Alkali.— A mixture of the chlorotropone derivative (VIII) (90 mg.), 50% methanol (4 ml.), and sodium hydroxide (200 mg.) was heated on a water bath for 30 min., methanol was evaporated, and the solid that separated was collected. This solid was suspended in water and acidified with acetic acid by which 1-(4′-carboxyphenyl)-2-phenylbenzimidazole separated as colorless crystals (50 mg.), m. p. 330°C (decomp.).

Found: C, 74.78; H, 4.00; N, 9.04. Calcd. for $C_{20}H_{14}O_2N_2$: C, 76.42; H, 4.49; N, 8.91%. λ_{max}^{MeOH} mμ (log ε): 272 (4.25).

The carboxylic acid (40 mg.) thereby obtained was suspended in methanol (3 ml.), ether solution of diazomethane was added, and the mixture was allowed to stand over night. The solvent was

evaporated to dryness, the residue was dissolved in ether, and the solution was passed through an alumina column for purification. Evaporation of the solvent from the effluent afforded 20 mg. of the methyl ester as colorless crystals, m. p. 115°C.

Found: C, 74.84; H, 4.61; N, 8.09. Calcd. for $C_{21}H_{16}O_2N_2 \cdot 1/2H_2O$: C, 74.76; H, 5.08; N, 8.30%. λ_{max}^{MeOH} mμ (log ε): 276 (4.31).

This methyl ester showed no depression of the melting point on admixture with 1-(4'-methoxycarbonylphenyl)-2-phenylbenzimidazole (IX), prepared by the method to be described below. The ultraviolet and infrared spectra of the two were also identical.

1-(4'-Methoxycarbonylphenyl)-2-phenylbenzimidazole (IX).—Benzoyl chloride (0.9 ml.) was added to a solution of 2-amino-4'-methyldiphenylamine (1 g.) dissolved in pyridine (5 ml.) while cooling with ice, the mixture was allowed to stand at room temperature for 30 min., and heated at 90°C for 30 min. Ice water was added to the reaction mixture, crystals that precipitated were collected, and recrystallized from ethanol to 1.2 g. of 2-benzamido-4'-methyldiphenylamine, m. p. 145~146°C.

Found: C, 79.63; H, 4.18; N, 9.18. Calcd. for $C_{20}H_{18}O_2N_2$: C, 79.44; H, 6.00; N, 9.27%. λ_{max}^{MeOH} mμ (log ε): 270 (4.23).

A mixture of the diphenylamine derivative (500 mg.) obtained as above and acetic anhydride (4 ml.) was heated at 140°C for 6 hr. Acetic anhydride was evaporated in a reduced pressure from the reaction mixture, water (2 ml.) was added to the residue, and the mixture was allowed to stand to over night. This was extracted with ether, the extract was dried over anhydrous sodium sulfate, and passed through a column of alumina.

Evaporation of ether from the effluent afforded 430 mg. of 1-(4'-methylphenyl)-2-phenylbenzimidazole, m. p. 91~92°C.

Found: C, 83.93; H, 5.34; N, 9.70. Calcd. for $C_{20}H_{16}N_2$: C, 84.48; H, 5.67; N, 9.85%. λ_{max}^{MeOH} mμ (log ε): 289 (4.22).

The benzimidazole derivative (400 mg.) so obtained was dissolved in pyridine (3 ml.), added to a solution of potassium permanganate (450 mg.) in water (6 ml.), and the mixture was heated on a water bath for 1 hr. After cooling, manganese dioxide that separated out was filtered off, a small amount of water was added to the filtrate, and extracted with ether to remove neutral substances. Acidification of the aqueous layer with acetic acid afforded 120 mg. of 1-(4'-carboxyphenyl)-2-phenylbenzimidazole as crystals of m. p. 340°C (decomp.).

The carboxylic acid (110 mg.) thereby obtained was suspended in methanol (6 ml.), ether solution of diazomethane was added to it to effect methylation, and the solvent was evaporated. The residue was dissolved in ether, the solution was passed through a column of alumina, and the solvent was evaporated from the effluent, affording 1-(4'-methoxycarbonylphenyl)-2-phenylbenzimidazole (IX) (60 mg.) as colorless crystals, m. p. 115°C.

***N*-(3-Bromotropolon-5-yl)-*N*, *N'*-dibenzoyl-*o*-phenylenediamine (X).** — A solution of 3-bromotropolone (35 mg.) and I dissolved in a mixture (3 : 1 by volume) of ethanol and chloroform, added with 1 drop of triethylamine, was allowed to stand at room temperature for 3 days. The crystals that separated were collected. Concentration of the filtrate in a reduced pressure afforded a second crop of crystals. The two crops of crystals were combined and recrystallized from an ethanol-chloroform mixture to give pale yellow crystals (30 mg.), m. p. 242~243°C (decomp.).

Found: C, 63.19; H, 3.83; N, 5.36. Calcd. for $C_{27}H_{19}O_4N_2Br$: C, 62.90; H, 3.72; N, 5.44%. λ_{max}^{MeOH} mμ (log ε): 230 (4.54), 240 (4.53), 250 (4.53), 355 (4.23), 420 (3.86).

***N*-(3, 7-Dibromotropolon-5-yl)-*N*, *N'*-dibenzoyl-*o*-phenylenediamine (XI).** — By the same procedure as above, 250 mg. of 3, 7-dibromotropolone and 150 mg. of I afforded 75 mg. of yellow crystals, m. p. 230~231°C (decomp.)

Found: C, 54.35; H, 3.19; N, 4.72. Calcd. for $C_{27}H_{18}O_4N_2Br_2$: C, 54.55; H, 3.05; N, 4.72%. λ_{max}^{MeOH} mμ (log ε): 265 (4.49), 275 (4.49), 360 (4.16), 430 (3.86), 440 (3.87).

Hydrogenolysis of X.—A solution of the monobromo derivative X (90 mg.) dissolved in a solution of potassium hydroxide (20 mg.) in water (1 ml.), to which was added palladium-carbon (50 mg.), was shaken in a hydrogen stream at room temperature. When the absorption of hydrogen had ceased, the catalyst was filtered off, the filtrate was acidified, and the precipitate that appeared was collected. Its recrystallization from an ethanol-chloroform mixture afforded 30 mg. of colorless crystals, m. p. 218~220°C, undepressed on admixture with II. The ultraviolet spectra of the two were identical.

Bromination of II.—A chloroform (1 ml.) solution of bromine (15 mg.) was added to the tropolonyl-*o*-phenylenediamine derivative II (20 mg.) suspended in chloroform (2 ml.) and the mixture was allowed to stand over night at room temperature, by which a resinous substance precipitated. The chloroform layer was separated by decantation, a small quantity of methanol was added to the resinous precipitate, and the crystallized solid was recrystallized from an ethanol-chloroform mixture to 5 mg. of crystals, m. p. 237~240°C undepressed on admixture with X. The ultraviolet spectra of these two substances were identical.

Hydrogenolysis of XI. — A solution of the dibromo derivative XI (200 mg.) in water (20 ml.) and ethanol (10 ml.) containing potassium hydroxide (600 mg.), added with palladium-carbon (400 mg.), was shaken in a hydrogen stream at room temperature. When the absorption of hydrogen had ceased, the catalyst was filtered off, the ethanol was evaporated from the filtrate at a reduced pressure, and the residual solution was acidified with 6 N sulfuric acid. This was extracted with ethyl acetate, the solvent was evaporated from the extract, and the residue was washed with benzene. The benzene-insoluble residue was recrystallized from an ethanol-chloroform mixture to 10 mg. of colorless crystals, m. p. 218~220°C, undepressed on admixture with II. The ultraviolet spectra of these two substances were identical.

Summary

Reaction of tropolone and *o*-benzoquinone dibenzimide was carried out and the structure of its product was determined by deriving it to a 2-phenylbenzimidazole derivative. This revealed that the product is *N*-(tropolon-5-yl)-*N*, *N'*-dibenzoyl-*o*-phenylenediamine. 3-Bromotropolone and 3, 7-dibromotropolone also underwent the same reaction to afford the corresponding bromo derivatives. For the sake of identification, 1-(4'-methoxycarbonylphenyl)-2-phenylbenzimidazole was synthesized from 2-amino-4'-methyldiphenylamine.

A part of the expenses for the present work was supported by a fund from the Sankyo Co., Ltd., which is gratefully acknowledged.

Krypton-85 in the Atmosphere

By Kunihiko KIGOSHI

(Received November 21, 1961)

Measurements of the krypton-85 in atmospheric krypton have been reported by deVries[1] and by Delibrias et al.[2] The atmospheric krypton-85 produced by the fission of uranium or plutonium may possibly serve as a tracer for geophysical circulation problems. This article presents a recent variation in the concentration of atmospheric krypton-85, together with some details on the experimental method.

Experimental

Collection of the Atmospheric Krypton.—The atmospheric krypton of 10~50 ml. was collected in Tokyo from the liquid oxygen obtained from a small-scale nitrogen-liquefier machine after it had run continuously for a day or two. About 5 l. of this liquid oxygen—which is supposed to have more krypton than usual liquid oxygen because the liquid oxygen had been used as a coolant in the nitrogen liquefier—was evaporated in a Dewar vessel until the volume was reduced to about 100 ml. The gas evaporated from the final 100 ml. of liquid oxygen was passed through a trap refrigenated with liquid oxygen. Nearly 50 ml. of the atmospheric krypton gas was obtained from the liquid condensate (20~30 ml.) in the trap by heating the evaporated gas with calcium. Further purifications of the krypton were made by condensation in a trap at 61~65°K and by evaporation at the temperature of liquid oxygen. The purity of the krypton was examined by gas density measurements and by static vapor pressure measurements at the liquid oxygen point.

Radioactivity Measurements.—The radioactivities of the purified krypton samples were measured by using the small-volume Geiger counter shown in Fig. 1. As shown in Fig. 2, the counter worked as an external quenching Geiger counter and had a good characteristic curve for the mixture of the purified krypton of 150~350 mmHg and propane of 2~5 mmHg. The effective volume of the counter was estimated from the geometrical dimensions, and the end effect was measured by the use of the movable teflon rod in the counter, as shown in Fig. 1.

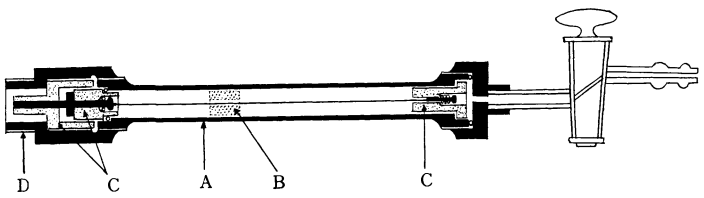

Fig. 1. Small volume counter tube.

2) G. Delibrias and C. Jehanno, *Bulletin d'informations scientifiques et technologiques*, **No. 30**, June, (1959).

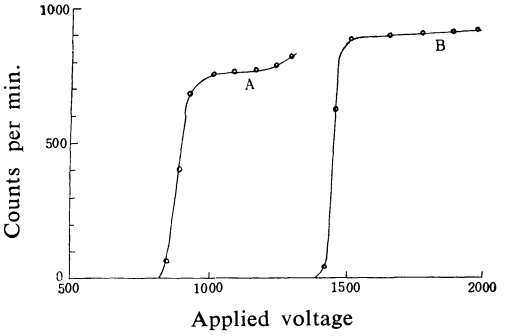

Fig. 2. Characteristic curve for Kr—Propane filled counter.
A: Kr 175 mmHg, C_3H_8 5.5 mmHg
B: Kr 386 mmHg, C_3H_8 5 mmHg

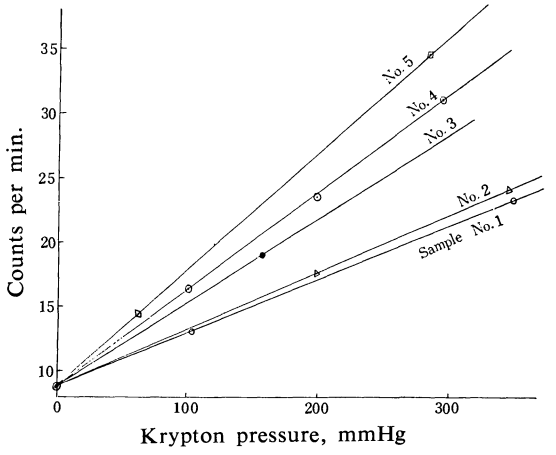

Fig. 3. Measured activities of the atmospheric krypton.

The measured counting rates showed a linear dependence on the amount of krypton in the counter. As shown in Fig. 3, the extrapolated counting rate of every sample at zero pressure met at a background counting rate, which was also checked with the counting with argon and propane. The number of disintegrations per minute was calculated by assuming a counting efficiency of 100% in the measured effective counter volume of 8.25 ml.

Results

The results of the measurements are shown in Table I. Sample 1 was collected from a large-volume liquid oxygen reservoir in an air liquefaction plant in Tokyo. Therefore the exact date of the collection of this sample is unknown. The data shown here and the data by Delibrias et al.[2] (1954; 1.160 d. p. m./ml. Kr; 1958: 4.200 d. p. m./ml. Kr) and by deVries[1] (March 1955: 26000 c.p.m./mol. Kr) show a steady increase in the concentration of atmospheric krypton-85 between 1954 and 1961. The increase in the atmospheric krypton-85 after the end of 1958 gives a maximum possible rate of supply of stratospheric krypton-85 to the troposphere, because the increase arose from the transfer of krypton-85 from the stratosphere to the troposphere and the direct supply to the troposphere by the atomic piles.

TABLE I. VARIATION OF KRYPTON-85 ACTIVITY IN THE ATMOSPHERIC KRYPTON

Sample No.	Collection date	Measured activity d.p.m./ml. Krypton (NTP)
1	Sept.—Nov. 1959	3.90±0.05
2	18—19 May 1960	4.14±0.04
3	9—11 July 1960	5.97±0.05
4	1— 2 Oct. 1960	6.86±0.09
5	10 Jan. 1961	8.32±0.09

The amount of man-made carbon-14 transported into the stratosphere from the troposphere after the biginning of 1959 can be estimated from the annual variation in mean atmospheric carbon-14 concentration. Using the measured variation of carbon-14 in tree rings[3,4] as the variation range of the atmospheric carbon-14, and assuming a mean residence time of 6 years for the carbon atoms in the troposphere before transfer to surface ocean water[5], the amount of injection of carbon-14 into the troposphere is estimated as follows:

$$1959: \quad 8\times10^{26} \text{ atoms/year}$$

$$1960: \quad 4\times10^{26} \text{ atoms/year}$$

The estimated total amount of man-made carbon-14 in the troposphere and ocean water is about 1.3×10^{28} atoms at the end of 1958[6]. Almost the same ratio of the amount injected into the troposphere from the stratosphere to the total amount in the troposphere and in ocean water may hold in the case of man-made carbon-14 and in the case of krypton-85 produced by nuclear tests.

The solubility of krypton in the sea water is so small that we can disregard sea water as a reservoir of krypton-85. When we assume that all the krypton-85 in the atmosphere in 1959 was produced by nuclear tests, the total atmospheric krypton-85 of 2.5×10^{26} atoms at that time corresponds to the carbon-14 of 1.3×10^{28} atoms in the troposphere and in sea water. Using these figures, the amount of krypton-85 injected from the stratosphere to the troposphere is estimated as 6×10^{24} atoms per year in 1959 and 3×10^{24} atoms per year

4) K. Kigoshi, *Journal of Radiation Research*, **1**—2, 111 (1960).
5) H. Craig, *Tellus*, **9**, 1 (1957).
6) F. Hagemann, J. Gray, L. Machta, Jr. and A. Turkevich, *Science*, **130**, 542 (1959).

in 1960. These figures correspond to the increase in atmospheric krypton activities of 0.24 d. p. m./ml. Kr/year in 1959 and 0.12 d. p. m./ml. Kr/year in 1960. The observed slow increase up to May, 1960, does not contradict the above estimate based on the parallelism between carbon-14 and krypton-85.

The increase after July, 1960, can not be attributed to the transfer of stratospheric krypton-85 to the troposphere. Even if the total fission energy released by nuclear tests between 1953 and 1958 were equivalent to the energy produced by 200 megatons of TNT, the total calculated amount of produced krypton-85 is about 7×10^{25} atoms. This amount is too small to explain the atmospheric krypton-85 after July, 1961, because the krypton activity of 8 d. p. m./ml. Kr corresponds to about 5×10^{26} atoms of krypton-85 in the whole atmosphere. The escape of krypton-85 from the atomic piles and from chemical processing plants for used fuel might be the main sources of the supply of atmospheric krypton-85 after July, 1960.

In the present situation, information on the mixing and movement of the air masses in the troposphere can be obtained when detailed measurements are made on the local distribution and variation in atmospheric krypton.

Summary

The activities of atmospheric krypton-85 were measured on the samples of krypton collected in Tokyo. The observed activities show a remarkable increase after May, 1960, which can not be explained by the production of krypton-85 by nuclear tests. The slow increase before May, 1960, does not contradict an assumed parallelism between the behavior of the man-made carbon-14 in the atmosphere and that of the krypton-85 produced by nuclear tests.

The author wishes to thank Dr. S. Horibe of Tokyo Metropolitan University and members of his laboratory for permission to operate their nitrogen-liquefier machine in order to sample atmospheric krypton.

Hydrophile-Lipophile Balance Values for O/W Emulsions Stabilized by Nonionic Surfactants. I. Hydrophile-Lipophile Balance Values of Nonionic Surfactants Determined by Emulsification

By Noriaki OHBA

(Received June 30, 1961)

Concerning the study of emulsifications or emulsions stabilized by any nonionic surfactants, there is the well-known concept of HLB (hydrophile-lipophile balance) suggested by Griffin[1].

Following this concept, Kawakami[2] has presented an equation to calculate the HLB value from the structure of the surfactant molecule, that is,

$$\mathrm{HLB}=7+11.7\log(M_w/M_o) \qquad (1)$$

In this equation, M_w is the molecular weight of the hydrophilic group in the molecule and M_o, that of the lipophilic group.

In 1954, Griffin[3] also proposed another equation for this purpose, which enabled one to calculate the HLB value from both analytical and composition data. His second equation was,

$$\mathrm{HLB}=20(1-S/A) \qquad (2)$$

where S is the saponification number of the ester and A, the acid number of fatty acid used for the preparation of the derivatives of polyhydric alcohols, such as sorbitan, glycerol, etc.* For the surfactants, which involve only the polyoxyethylene chain as a hydrophilic group, the following equation was said to be suitable:

1) W. C. Griffin, *J. Soc. Cosmetic Chemists*, **1**, 311 (1949).
2) Y. Kawakami, *Kagaku*, **23**, 546 (1953).
3) W. C. Griffin, *J. Soc. Cosmetic Chemists*, **5**, 249 (1954).

* The values calculated by Eq. 1 are not materially different from those calculated by Eq. 2; we used the latter equation, together with Eq. 3, in the present experiment.

$$HLB = E/5 \quad (3)$$

where E is the weight percentage of oxyethylene content.

Furtheremore, Griffin assumed that the HLB of the surfactant mixture can be calculated by the following equation:

$$[HLB]_m = [HLB]_a x/100 + [HLB]_b(100-x)/100 \quad (4)$$

where $[HLB]_m$, $[HLB]_a$ and $[HLB]_b$ are the HLB values for the mixture, surfactant "a" and surfactant "b" respectively, and x, the weight percentage of "a" in the mixture. By this equation, the HLB value of any mixture of two surfactants can be predicted.

The concept of HLB, though convenient in practice, still has some difficulties in its applications. Besides, Griffin did not give the details of his emulsification experiments which are required for the HLB calculation. To clarify these points, we took up those O/W emulsions stabilized by nonionic surfactants and studied the system in detail by a method of emulsification experiments similar as those proposed by Griffin.

Experimental

Materials.—*Nonionic Surfactants.*—Sorbitan fatty acid esters and their polyoxyethylene derivatives were selected as typical nonionic surfactants, polyethylene glycol stearates as the ester type, polyoxyethylene-lauryl ethers and -cetyl ethers as the ether type, and polyoxyethylene nonylphenyl ethers as the alkylphenyl ether type, as listed in Tables I to VI.

These were used without further purification, as we needed to know merely the exact HLB value of a given sample. The nonionic surfactants listed in Tables III, IV, V and VI were exclusively prepared in the author's laboratory.

Mineral Oil. — "Carnation white mineral oil", prepared by the Sonneborn Co., U.S.A., was used as the oil to be emulsified, its average viscosity being 70 cp.

Emulsification.—In the present series of experiments, an "Emulsification by Inversion"[4], which involves phase inversion as an important process, was utilized to prepare the emulsions.

The standard composition of the emulsion for this series of experiments is shown in Table VII.

TABLE VII. COMPOSITION OF EMULSION

Mineral oil	40.0%
Mixture of emulsifiers	4.0%
Distilled water	56.0%

The emulsifications were carried out by the following procedure. A mixture of mineral oil and mixed surfactants was heated up to about 90°C. Into this mixed oil phase, water which had also been heated to about 90°C was added slowly with stirred. After adding all of the water, stirring was continued until the temperature of the emulsion fell to about 40°C. The emulsions thus obtained were used for studying their properties.

Estimation of the "Required HLB Value" of O/W Emulsion

Griffin suggested the HLB system, but there is no nonionic surfactant to use as the standard of the HLB value.

In our series of experiments, however, Arlacel 60 (HLB=4.7) and Tween 60 (HLB=14.9), i. e., SMS and E-SMS-20 in our case, were used as the standards of the HLB value. These two samples were selected as standard because they are easy to prepare as a series of homologues, they emulsify a wide variety of oils, and they are situated in appropriate positions in the HLB region.

The HLB value of an emulsion or the HLB value for an oil in making an emulsion can be estimated by means of an emulsification test following the concept of HLB. Griffin proposed the term "required HLB" for the oil phase used to emulsify. This required HLB value is considered to be equal to $[HLB]_m$ in Eq. 4, calculated from the composition of a system when the mixture of two surfactants gives the most stable emulsion among a series of emulsions made with a given pair of agents under varying compositions, as is shown in Table VIII.

TABLE VIII. ESTIMATION OF THE HLB VALUE BY EMULSIFICATION TESTS

No.	Composition of emulsifier: SMS %	Composition of emulsifier: E-SMS-20 %	Stability of emulsion
1	52.5	47.5	+
2	50.0	50.0	++
3	47.5	52.5	+++
4	45.0	55.0	+++
5	42.5	57.5	++
6	40.0	60.0	++

We can see in Table VIII that the emulsions of Nos. 3 and 4 are the most stable, and the HLB, $[HLB]_m$, required for a mineral oil to be emulsified with a pair of SMS and E-SMS-20 is estimated as 10.2 by Eq. 4. In later sections, we adopt this value as the standard of the required HLB. Thus, by these experiments, the required HLB of mineral oil may be determined for every pair of emulsifiers. To make the comparison simple, one of the emulsifiers taken as the standard is always kept as a fixed component in any pair of surfactants in the emulsification tests.

Results and Discussion

Applicability of Eq. 4.—The results of sorbitan fatty acid esters and their polyoxyethylene derivatives are shown in Table IX. In this table, the required HLB values of mineral oil, $[HLB]_m$, which are shown in the 4th column, were calculated by Eq. 4, using the HLB value of the combined component surfactant, $[HLB]_{calcd}$, shown in the 2nd column, and the HLB value of the fixed component surfactant.

TABLE IX. HLB VALUES FOR SORBITAN DERIVATIVES

Combined emulsifier	$[HLB]_{calcd}$	Fixed emulsifier	$[HLB]_m$	$[HLB]_a$
SML	8.6	E-SMS-20	11.6	5.8
SMP	6.7	E-SMS-20	11.2	4.4
SMS	4.7	E-SMS-20	10.2	4.7
STS	2.1	E-SMS-20	(7.8)	(6.5)
SMO	4.3	E-SMS-20	9.8	5.1
SSO	3.7	E-SMS-20	9.4	5.2
STO	1.8	E-SMS-20	(4.4)	(9.0)
E-SML-20	16.7	SMS	9.9	17.3
E-SMP-20	15.6	SMS	10.2	15.6
E-SMS-6	9.6	E-SMS-20	10.4	9.4
E-SMS-20	14.9	SMS	10.2	14.9
E-SMO-6	10.0	E-SMS-20	11.0	9.0
E-SMO-20	15.0	SMS	10.2	15.0
E-STS-20	10.5	SMS	10.2	10.5
E-STO-20	11.0	E-SMS-20	11.6	9.3
			Average 10.5 ± 1.1	

The required HLB value of mineral oil is

$$[HLB]_m = 10.5 \pm 1.1 \quad (5)$$

excepting the values for STO and STS, which are not considered to fall into the category of O/W emulsifiers. Within the range of this error, it may be said that the concept of the HLB system is applicable in emulsion systems with nonionic surfactants.

4) Presented at the 12th Symposium of Colloid Chemistry, Hiroshima, 1959.

For the rest of the types of nonionic surfactants, the required HLB values of mineral oil were calculated by the same procedure as in Table IX; the results obtained are:

$$\text{PEGS}, \quad [\text{HLB}]_m = 10.2 \pm 0.3 \qquad (6)$$

$$\text{POEL}, \quad [\text{HLB}]_m = 9.7 \pm 1.6 \qquad (7)$$

$$\text{POEC}, \quad [\text{HLB}]_m = 9.0 \pm 0.6 \qquad (8)$$

$$\text{POENP}, [\text{HLB}]_m = 8.9 \pm 0.8 \qquad (9)$$

From these results, it may be concluded that the allowance of an obtained $[\text{HLB}]_m$ is in the range of ± 1, excepting the case of POEL. However, we must draw attention to the fact that the mean value of the HLB itself fluctuates according to the pair of surfactants used. This fact has a very important implication concerning the concept of the HLB, which becomes the starting point for the further study of these phenomena.

HLB Values of Nonionic Surfactants.—If the additivity expressed in Eq. 4 is assumed to be correct, we can calculate $[\text{HLB}]_a$ from the values of $[\text{HLB}]_m$ and $[\text{HLB}]_b$ according to the following equation:

$$[\text{HLB}]_a = \{[\text{HLB}]_m - [\text{HLB}]_b(100-x)/100\}100/x \qquad (10)$$

Thus, using these $[\text{HLB}]_m$ and $[\text{HLB}]_b$ values;
$[\text{HLB}]_m$: 10.2, determined with the standard emulsifiers, SMS and E-SMS-20,
$[\text{HLB}]_b$: 4.7 for SMS, and 14.9 for E-SMS-20,
x: percentage content of emulsifier "a" in the mixed emulsifier,
the HLB value of any nonionic surfactant can be estimated from the emulsification experiments. The results are shown in the last column of Table IX.

Of course, in this case, it is assumed as an important condition that the required HLB of mineral oil takes a fixed value.

$[\text{HLB}]_{calcd}$ and $[\text{HLB}]_a$. — To make a comparison between the values, $[\text{HLB}]_{calcd}$, calculated by Eq. 2 or 3 and $[\text{HLB}]_a$, those obtained experimentally, $[\text{HLB}]_{calcd}$ vs. $[\text{HLB}]_a$ diagrams are plotted in Figs. 1 and 2 for each type of nonionic surfactant. In these figures we should expect the plot to fall on the bisector of the angle between two coordinate axes.

In Fig. 1, for sorbitan derivatives, ○, an interesting curve is obtained. Their polyoxyethylene derivatives showed a coincidence between two values; however, sorbitan fatty acid esters deviated remarkably from the bisector, and this deviation seemed to follow a definite function of the HLB values. As a result, the values of $[\text{HLB}]_a$ for STO, STS, SSO and SMO are higher than the corresponding $[\text{HLB}]_{calcd}$ drawn from Eq. 2, while those for

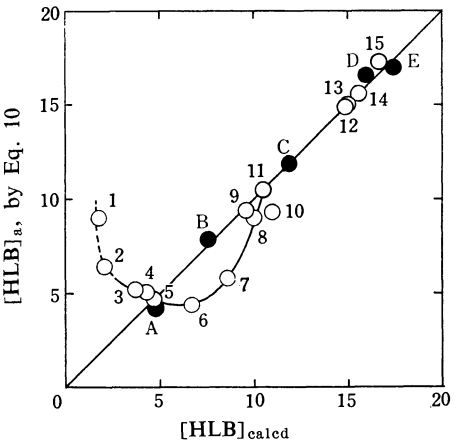

Fig. 1. $[\text{HLB}]_{calcd}$ vs. $[\text{HLB}]_a$ diagram for sorbitan derivatives: ○,

and for polyoxyethylene nonylphenyl ethers: ⊗,
I, POENP-2 II, POENP-7.5 III, POENP-9
IV, POENP-10 V, POENP-20

SMP and SML are lower than the corresponding $[HLB]_{calcd}$.

As the sorbitan group is a complicated hydrophilic group compared with those of polyoxyethylenes, there is some question as to the calculation of the HLB value according to Eq. 2 or 3, which merely involve the percentage content of the hydrophilic group in the molecule.

STS and STO, having little hydrophilic property, show too high a $[HLB]_a$ compared with their $[HLB]_{calcd}$. This means that the amount of emulsifiers, x, necessary for optimum emulsification is larger than that calculated from its $[HLB]_{calcd}$. Further, they do not produce fine emulsions. Thus, the behavior of a poorly hydrophilic emulsifier is quite different from the more hydrophilic one.

Polyethylene glycol stearates, as shown in Fig. 1, ●, showed only a slight deviation in plot from the bisector; i. e., Eqs. 2 and 10 give nearly equal results for this type of nonionic surfactants.

In this case, the emulsifiers used are all stearic acid esters, and an agreement is obtained between the values of $[HLB]_{calcd}$ and $[HLB]_a$. From this fact, together with the fact that the two components of the emulsifier have a stearate radical in common, we are inclined to the opinion that the mutual interaction between hydrophilic emulsifier and oleophilic one is due largely to this oleophilic stearate group in the molecule.

In Fig. 2, POELs, ○, POECs ●, and POENPs ⊗, show remarkable difference between their two values. POENP shows nearly the same deviation as POEL; that is, nonylphenol behaves quite similarly to lauryl alcohol in the emulsification of mineral oil, although the carbon number 15 for nonylphenol is different from the carbon number 12 for lauryl alcohol. As a whole, this difference between their two values is greater at a higher HLB and smaller at a lower HLB range. In other words, the difference between $[HLB]_a$ and $[HLB]_{calcd}$ for these types of nonionic surfactants becomes greater at a higher mole number of the ethylene oxide unit in the molecule, and the difference increases in the following order:

$$PEGS < POEC < POEL \leqslant POENP$$

The difference is due perhaps to the emulsifier having a different oleophilic group.

HLB Value by Emulsifications. — In HLB systems, the additivity of HLB values between two components was assumed as an important basis. Generally, in many cases of the two-component system their physicochemical properties show some deviation from an algebraic additivity as a result of their component properties.

To investigate the value of $[HLB]_m$ in Eq. 4 is merely to discuss its deviation from the value which is calculated by interpolation using two emulsifiers obtained by Eq. 2 or 3.

On the other hand, to examine the values of $[HLB]_a$ in Eq. 10 is to study its deviation, adopting the value calculated by extrapolation using the fixed $[HLB]_m$ and $[HLB]_b$ from $[HLB]_{calcd}$, which is calculated only by the percentage content of the hydrophilic group in the molecule. By this latter procedure, the difference between $[HLB]_{calcd}$ and $[HLB]_a$ naturally becomes larger, and this makes the discussion rather easy.

The above results and discussions lead us to the conclusion that it is possible to illustrate and study more details of the HLB systems or the HLB values for several nonionic surfactants in the emulsifications of mineral oil when we refer them to the properly assigned standards.

Summary

The HLB values of several types of nonionic surfactants were determined by experiments in emulsification according to the concept of HLB suggested by Griffin.

The HLB values required to emulsify the mineral oil do not show a consistent value, although the values are limited within a narrow range.

The HLB values calculated according to the law of the additivity for the surfactant mixture, $[HLB]_a$, and the values calculated by the equations proposed by Griffin, $[HLB]_{calcd}$, were compared. The differences between these two values were most remarkable in the case of sorbitan fatty acid esters and became greater at the higher mole numbers of the ethylene oxide in the molecule, excepting polyoxyethylene sorbitan esters and polyethylene glycol stearates.

Some explanations were attempted for such differences and for the deviations from the assumed additive properties of the HLB system, in connection with the role or behavior of nonionic surfactants in emulsification.

The author wishes to thank Professor Tsunetaka Sasaki of Tokyo Metropolitan University, for his encouragement and advice in this work.

Hydrophile-Lipophile Balance Values for O/W Emulsions Stabilized by Nonionic Surfactants. II. "Required Hydrophile-Lipophile Balance Values" of the Oil Mixture

By Noriaki OHBA

(Received June 6, 1961)

In a preceding paper[1], the HLB values of nonionic surfactants were determined by means of emulsification tests conducted according to the HLB concept presented by Griffin[2]. The HLB values thus obtained were compared with the values calculated from their structural data, and the additivities of these values were discussed in connection with the behaviors of these nonionic surfactants in the systems of O/W emulsions.

In the HLB concept, an algebraic additivity of the HLB values in the mixtures of two or more surfactants is assumed as an important basis, which is expressed as follows[3]:

$$[\mathrm{HLB}]_m = [\mathrm{HLB}]_a x/100 + [\mathrm{HLB}]_b(100-x)/100 \quad (1)$$

Here, $[\mathrm{HLB}]_m$, $[\mathrm{HLB}]_a$ and $[\mathrm{HLB}]_b$ are the HLB values of the mixed emulsifier and of the surfactants "a" and "b" respectively, and x, the percentage content of surfactant "a" in the mixture.

Furthermore, the HLB concept is extended to apply in the case of the oil phase of the emulsion, and the term "required HLB value" is adopted for the given oil in a sense similar to that of the HLB value for the emulsifier. It was shown by Griffin that this required HLB value can be determined by means of emulsification tests, and such values obtained for several oils and waxes were presented by him[3].

In a manner similer to that in the case of the HLB values for emulsifier mixtures, he also assumed that the required HLB value for the oil mixture is obtained as an algebraic additivity from those values for the component oils in the mixture; that is,

$$[\mathrm{HLB}]_o = \sum [\mathrm{HLB}]_i R_i/100 \quad (2)$$

where $[\mathrm{HLB}]_o$ is a required HLB value of the oil mixture, and $[\mathrm{HLB}]_i$ and R_i a required HLB value and the percentage content of the ith component oil in the oil mixture respectively.

In this paper, to study the additivity in the HLB system and the characteristics of oil mixtures, the required HLB values of several oil mixtures were determined by means of emulsification tests[1].

Experimental

Materials. — *Nonionic Surfactants.* — Commercial products of sorbitan monostearate, SMS, and polyoxyethylene sorbitan monostearate, E-SMS-20, which were used in a preceding report[1], were also adopted as the standards for nonionic emulsifiers. The HLB values for these materials are 4.7 for SMS and 14.9 for E-SMS-20. When the required HLB of an oil mixture exceeds 14.9, polyoxyethylene cetyl ether, POEC-20, with the HLB value of 18.4, was adopted instead of E-SMS-20.

Oils and Waxes.—"Carnation White Mineral Oil" produced by the Sonneborn Co. was adopted as the fixed component of the oil mxture to be emulsified, its HLB value being 10.2 and its average viscosity, 70 cp.

Several materials were used as the additive component of the oil mixture; these are listed in Tables II to VI.

These additives, which are usually employed in the emulsion technique, were used without further purification.

Emulsification.—Emulsification was carried out by the phase inversion method reported on in a preceding paper[1]. The composition of the emulsion tested in the present series of experiments is shown in Table VII.

In this table, the oil mixture consists of a mineral oil taken as the fixed component and an additive component, the content of which varies from 0 up to 30% in weight.

The required HLB values of the oil mixtures were determined as the value which was calculated by Eq. 1 for the composition of the mixed emulsifier giving the most stable emulsion in the series of emulsification tests, as described in a preceding paper[1].

Results

In Figs. 1—5, $[HLB]_o$ vs. R diagrams are shown. In Table VIII, which selects one example from many calculations, the content (R %) of the additive in the oil mixture is listed in the 2nd column, the required HLB value ($[HLB]_o$) in the 3rd, and the difference (Δ) between the required HLB value of the oil mixture and the required HLB value of mineral oil ($[HLB]_m$), in the 4th column. In the last column, the apparent HLB value of the additive,

$$[HLB]_i = \Delta(100/R) + [HLB]_m$$

calculated from Δ at each concentration, is shown; $[HLB]_m = 10.2$ in the present case. If the additivity in Eq. 2 is valid, $[HLB]_i$ should be constant.

TABLE VIII. REQUIRED HLB VALUES OF MIXTURES OF FATTY ACIDS AND MINERAL OIL

Discussion

Fatty Acids.—Among the three fatty acids, lauric acid is the nearest of all to the additivity rule expressed by Eq. 2; however, the observed required HLB values, $[HLB]_i$, 42~45, are remarkably large, even considering the required HLB value for stearic acid listed in Table I. We should like to draw attention to the fact that no HLB value exceeding 20 can be evaluated according to the equation presented by Griffin.

Stearic acid also shows a marked deviation from Griffin's value listed in Table I, and the additive property of the HLB value is not distinct.

In the case of oleic acid, the diagram obtained is complicated in the region of R near 10%, where this curve shows a minimum. In the rest of the region studied, the curve runs similar to the other two acids. The value of $[HLB]_i$ for an R larger than 10% is constant and is nearly the same as those for stearic acid.

The elucidation of the anomalous phenomena mentioned above for oleic acid must await further investigation.

Alcohols.—Lauryl alcohol and cetyl alcohol gave coincident results in the region of R examined, and the obtained values of $[HLB]_i$ were 15~17, which are slightly larger than the corresponding values in Table I.

Though the composition and chemical structure of lanolin alcohol is not so simple as those of lauryl alcohol and cetyl alcohol, the curves for these three alcohols run parallel to each other, excepting the curve for lanolin alcohol in the region of R exceeding 10%, where the $[HLB]_o$ is nearly independent of R. Precisely speaking, therefore, the curve for lanolin alcohol is somewhat different from the other two but is, on the other hand, rather similar to that of waxes, as is shown in Fig. 5.

TABLE IX. ANALYTICAL DATA AND THE VALUES OF $[HLB]_i$

1) Content of additives is 10% unless otherwise stated.
2) Negligible
3) COOH: acid value, COOR: ester value, OH: hydroxyl value, C=C: iodine value.

Acetylated Esters.—The molecules of this group contain a different number of free hydroxyl radicals, as the result of a varying degree of acetylation. This enables us to study the effects of the increase of the OH-radical on emulsification. Indeed, the results obtained show large differences in $[HLB]_o$ values according to the degree of acetylation, as is shown in Figs. 3 and 4.

The values of the $[HLB]_o$ of acetylated esters increases with the increase in the OH content of the molecules, as indicated in the following series:

AGMS-I<AGMS-II<AGMS-III<AGMS-IV

In the case of AGMS-I, which lacks an OH-radical in the molecule due to the nearly perfect acetylation, the curve is somewhat like that for waxes in Fig. 5. The large difference in the inclinations of curves between these esters and those for alcohols suggests the effect of other factors than the OH content, such as ester linkage and the alkyl chain length of their molecules.

Though the values of $[HLB]_i$ do not fluctuate so much with R, its values are too large in the cases of AGMS-III (33.7~37.2) and AGMS-IV (82.2~84.2).

Oils and Waxes.—Though the natural oils and waxes are of a complicated nature in composition, they behave rather simply, as is shown in Fig. 5. $[HLB]_i$ values are also listed in Table I.

The results obtained for esters are somewhat similar to those for oils and waxes, although their structures are more simple than those for oils and waxes, as is shown in Fig. 2.

Structural Effects.—As far as the present experiments are concerned, the additivity of the required HLB values of the oil mixture from its components, as shown by Eq. 2, if any, is recognized to hold to some extent in the cases of saturated fatty, acids, *n*-fatty alcohols and some acetylated esters.

For the rest of the materials examined, the additivity of the required HLB values is hardly valid. Generally, the required HLB values of oil mixtures varied to some extent with the increase of R up to 10%, and they level off with the further increase of R; in certain cases, as in the AGML in Fig. 4, even an inversion of the sign of Δ from positive to negative is observed with the increase of R.

As for the explanation of these results, it is worth while to list the analytical data of these additives in Table IX. They are arranged in

the decreasing order of $[HLB]_i$ at 10% R. From this table, it may be concluded as a whole that the intensity of the structural effects on the value of $[HLB]_i$ decreases in the following order:

$$COOH > OH > COOR$$

As seen from this order, the OH-radical by itself does not increase so markedly the values of $[HLB]_i$ as in the case of alcohols, although it increases the value of $[HLB]_i$ when ester-linkage coexists with the OH-radical in a molecule, as seen, for instance, in the case of AGMS-IV.

Summary

To study the additivity of the HLB values of an oil mixture from its component and the characteristics of the oil mixture forming a component of the emulsion, the required HLB values of several oil mixtures were determined by means of the emulsification tests proposed by Griffin.

The oil mixtures examined in this series of experiments consist of two oils, one being a mineral oil of fixed components and the other an oil to be studied as the additive, which is added in varying ratios to the fixed-component mineral oil.

The additivity of the required HLB values in oil mixtures was shown to hold to some extent for the case of saturated fatty acids, *n*-fatty alcohols, and some acetylated esters. For the rest of the additives, the additivity is not valid.

The required HLB values of these additive oils were remarkably large in the case of fatty acids, alcohols and some acetylated esters, excepting the anomalous value for oleic acid.

The structural effects on the increase of required HLB values seem to be in the following order:

$$COOH > OH > COOR$$

Gas Absorption by Cobalt Soaps

By Hideo FUNAKOSHI

(Received September 22, 1961)

Cobalt soaps are of wide industrial application as oxidizing calalysts in organic reactions, such as dryers of paints. It has been known that if the cobalt soaps of unsaturated acids, such as cobalt resinate, are left standing in the air, they change color from red to dark brown and sometimes ignite spontaneously. The mechanism of these characteristic oxidizing actions of cobalt soaps is not, however, known well. Ingle[1] has indeed presented a theory based on the oxidation of a substance by the oxygen carried by cobalt soaps, but direct evidence for this theory has not been offered. In this report the absorptive properties of cobalt oleate and stearate for a few gases are studied. Especially the absorption of oxygen by cobalt oleate is investigated from various points of view.

Experimental

Materials.—Cobalt soaps were prepared by metathesis from alkali soaps and cobaltous salts in ethanol-water solutions at about 50°C. It had previously been established that the composition of cobalt soaps depends perceptibly on the conditions of the preparation[2]. In this experiment the conditions were kept as constant as possible in order to obtain samples of a definite composition. The details are as follows.

Cobalt Oleate.—Oleic acid (15 g.) was dissolved in 95% ethanol (185 ml.) and neutralized by 1 N sodium hydroxide, using phenolphthalein as an indicator. This was diluted dy hot water (400 ml.) (solution A). Cobaltous nitrate (7.6 g.) was dissolved in water (230 ml.) (solution B). Both solutions were warmed at 50°C. Solution B was added to solution A drop by drop. The precipitated cobalt oleate was filtered and washed with ethanol and water. To avoid oxidation, all procedures were carried out in a stream of nitrogen gas. The sample was dried in vacuo at room temperatures and kept by sealing it in a glass bottle. Pink powder.

Found: Co, 12.70; C, 63.56; H, 10.13. Calcd. for $Co_3(C_{18}H_{33}O_2)_4(OH)_2 \cdot 2H_2O$: Co, 12.88; C, 63.00; H, 10.13%.

Cobalt Stearate.—Stearic acid (2 g.) was dissolved in 95% ethanol (100 ml.) and neutralized with 1 N

1) H. Ingle, *J. Soc. Chem. Ind.*, **36**, 319 (1917).

2) Y. Koga and R. Matuura, *Mem. Faculty Sci., Kyushu Univ.*, **C4**, 1 (1961).

sodium hydroxide as above. This mixture was then diluted with hot water (100 ml.) (solution A'). A solution of cobaltous chloride (1.2 g.) in water (50 ml.) (solution B') was added drop by drop at 50°C to solution A'. The precipitate was treated as in the case of cobalt oleate. Blue powder.

Found: Co, 10.26; C, 69.01; H, 11.59. Calcd. for $Co(C_{18}H_{35}O_2)_2$: Co, 9.42; C, 69.02; H, 11.28%.

Oleic acid was obtained from camellia oil by treating it with potassium hydroxide, lead acetate and lithium hydroxide and finally by distilling it at 228.5°C/13 mmHg. M. p. 12.6°C. Stearic acid was recrystallized from commercial samples. M. p. 68.8~69.3°C. Cobaltous nitrate, $Co(NO_3)_2 \cdot 6H_2O$, and chloride, $CoCl_2 \cdot 6H_2O$, were purified by recrystallization. As gases, oxygen, nitrogen and hydrogen were used. They were purified by the usual method.

Procedure.—The gas absorption was measured by using a Warburg manometer at 22~23°C under atmospheric pressure. The weight change accompanying the gas absorption was also measured. X-Ray diffraction patterns and ultraviolet and infrared absorption spectra of oxygenated cobalt oleate were investigated, too. The X-ray patterns were obtained by the Debye-Scherrer method. A Shimadzu QB-50 spectrophotometer was used for the ultraviolet absorption spectra, while for the infrared studies a Hitachi EPI-2 infrared spectrometer was used.

Results and Discussion

Gas Absorption by Cobalt Oleate.—In Fig. 1 the volume of gases (STP) absorbed by one gram of cobalt oleate is plotted against the time required. It is clear that oxygen is absorbed noticeably, while the absorption of nitrogen and hydrogen is very small. For the first hundred minutes the absorption of oxygen

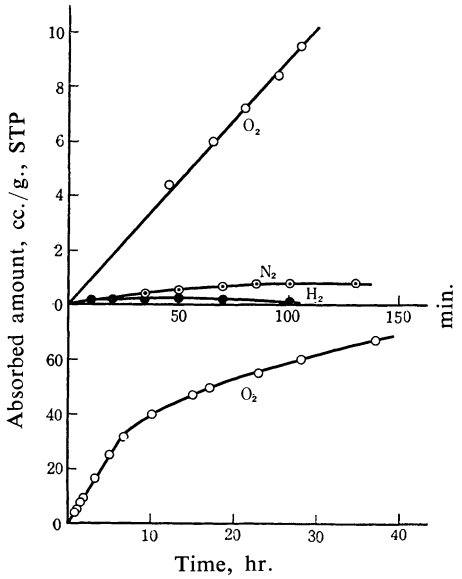

Fig. 1. Absorption of gases by cobalt oleate. 23°C, 1 atm.

by cobalt oleate is almost linear against time, and it was found that a few months are required to reach the absorption equilibrium. At the end of the linear part of the absorption rate curve, the composition of the sample corresponds to $Co_3(C_{18}H_{33}O_2)_4(OH)_2 \cdot 2H_2O \cdot 6O$. After the complete oxygenation of cobalt oleate, the composition was found to be $Co_3(C_{18}H_{33}O_2)_4 \cdot (OH)_2 \cdot 2H_2O \cdot 16O$. The color was changed from pink (original sample) to dark brown (completely oxygenated sample), and the solubility in organic solvents decreased considerably as a result of the absorption of oxygen. When cobalt oleate was in contact with dry air, the results were almost the same in quantity as in the case of oxygen absorption.

The Absorption of Oxygen by Cobalt Stearate and by the Mixture of Cobalt Stearate and Oleic Acid.—From Fig. 2 it is evident that the absorptive power of cobalt stearate for oxygen is negligible compared with that of cobalt oleate. However, the mixture of cobalt stearate and oleic acid absorbs oxygen fairly well compared with the absorption of oxygen by oleic acid alone. It may be said that cobalt

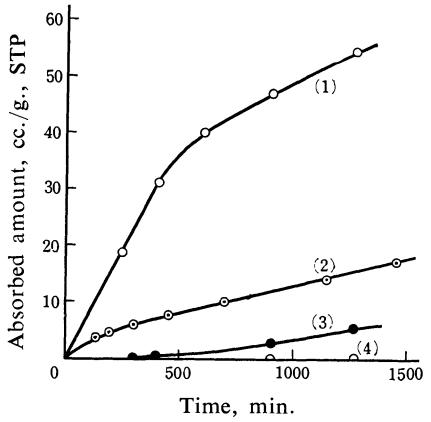

Fig. 2. Absorption of oxygen by (1) cobalt oleate, (2) cobalt stearate+oleic acid (1 : 70), (3) oleic acid, and (4) cobalt stearate.

stearate, although a poor oxygen absorber by itself, is a rather good catalyzer for the oxygenation of oleic acid. At any rate, the absorptive capacity of cobalt oleate for oxygen is by far the most remarkable. Probably the origin of absorption exists both in cobalt atoms and in double bonds, which will be examined below.

Ultraviolet Spectroscopic Investigation of Oxygen Absorption by Cobalt Oleate.—A thin film of cobalt oleate was prepared on the surface of the quartz cell from its benzene solution, and the cell was placed in contact with dry air. The ultraviolet spectra of this film were taken at various intervals of time. The results

are shown in Fig. 3. It is shown that the absorption at 350 mμ increases. It is evident that this increase reveals the absorption of oxygen by cobalt oleate. The relation of the absorption intensity at 350 mμ to time is represented in Fig. 4. The intensity becomes almost constant after about three days in contact with air. No doubt, the absorption at 350 mμ is not due to the oxydation of the double bond of oleate, since there is no absorption near 350 mμ in either the spectrum of oxygenated oleic acid as well or in that of non-oxygenated oleic acid. On the basis of various experimental results by many workers[3], it is concluded that

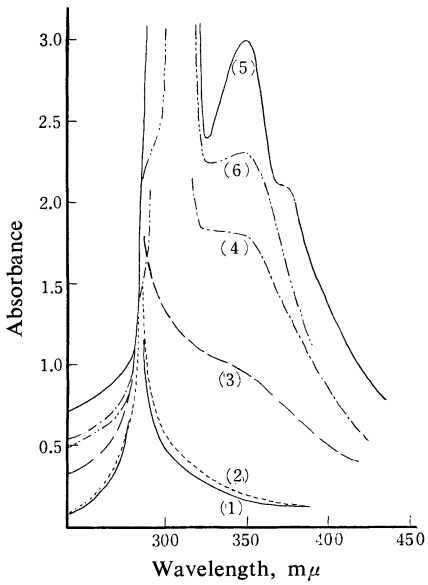

Fig. 3. Ultraviolet absorption spectra of oxygenated cobalt oleate. Oxygenation time: (1) 0, (2) 15, (3) 27, (4) 36, (5) 75 and (6) 175 hr.

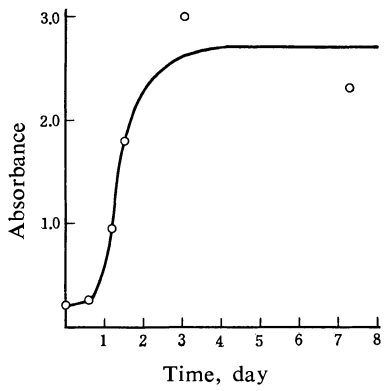

Fig. 4. Absorbance at 350 mμ against time of oxygenation.

3) E. g., R. Tsuchida, This Bulletin, 13, 388, 436 (1938); M. Linhard and M. Weigel, *Z. physik. Chem., N. F.*, 20 (1955).

the absorption at 350 mμ corresponds to the second absorption band, i. e., the absorption of shorter wavelength usually appearing in the spectrum of cobalt coordination compounds. In the process of oxygen absorption by cobalt oleate, therefore, it may be concluded that, at least in the initial stage, oxygen is coordinated to the cobalt atom.

The Infrared Spectra of Oxygenated Cobalt Oleate.—Infrared spectra of the original cobalt oleate and of a few oxygenated cobalt oleates, differing in their degree of oxygenation, were taken by the potassium bromide disk method. In Fig. 5 the infrared absorption spectrum of non-oxygenated cobalt oleate is shown together with a reference spectrum of oleic acid. The essential differences between these spectra are the disappearance of the bands of 2670, 1715 and 935 cm^{-1} and the appearance of the 1565 cm^{-1} band in the spectrum of cobalt oleate. The three bands, 2670, 1715 and 935 cm^{-1}, are ascribed respectively to the stretching vibration of hydroxyl, the stretching vibration of carbonyl and the out-of-plane deformation mode of hydroxyl, all in the carboxyl group of oleic acid. It is known that the bands at 2670 and 935 cm^{-1} vanish on the esterification of the acid. The band at 1565 cm^{-1} is ascribed to the characteristic frequency of carbonyl in the ionized carboxyl group, appearing as a shift of the 1715 cm^{-1} absorption of carbonyl in the unionized carboxyl group. The ionic structure of cobalt oleate is thus clearly indicated. The band at 3031 cm^{-1} is ascribed to the stretching vibration of the =CH- group in unsaturated hydrocarbons.

The infrared absorption spectra of oxygenated cobalt oleates are shown in Fig. 6. The three samples used were different in their oxygenating time, that is, 4 hr., 24 hr. and 150 days. The noticeable effect of the oxygen absorption is the appearance of bands near 1720 and 1178 cm^{-1}, which bands increase in intensity as the oxygenation proceeds, and of a band at 971 cm^{-1}, which again decreases its intensity and

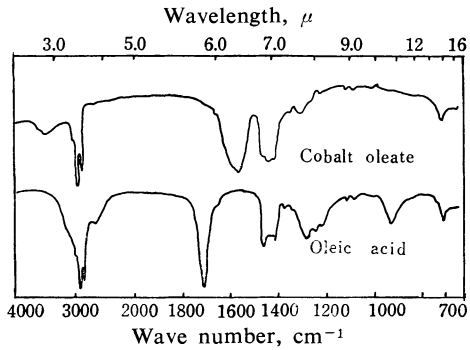

Fig. 5. Infrared absorption spectra of cobalt oleate and oleic acid.

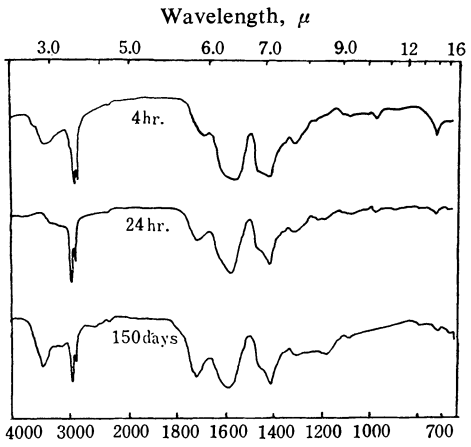

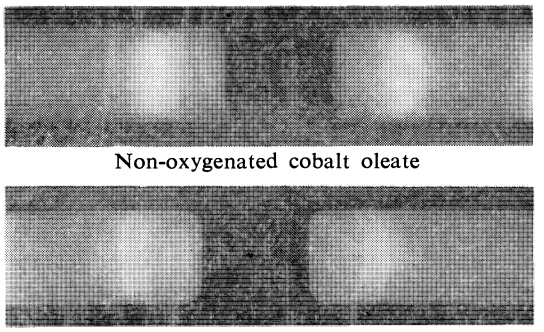

Fig. 6. Infrared absorption spectra of oxygenated cobalt oleates, for the oxygenating time, 4 hr., 24 hr. and 150 days.

finally disappears as a result of the strong oxygenation of cobalt oleate. A band at 3020 cm^{-1} of the original sample also vanishes when the sample is oxygenated strongly. The band at 1720 $^{-1}$ is ascribed to the stretching vibration of carbonyl in the carboxyl group of the acid, as has already been mentioned. The band at 971 cm^{-1} is originally the CH out-of-plane deformation vibration of the -CH=CH- group (trans) which is observed in the spectrum of elaidic acid, a geometrical isomer of oleic acid (cis). Swern et al.[4-5] have reported that the cis-trans isomerization of methyl oleate arises from the oxygenation of oleyl group and that the trans-type hydroperoxide is produced. It is reasonable to ascribe the absorption at 1178 cm^{-1} to the stretching vibration of the

—C—C— group of hydroperoxide produced by the oxygenation of cobalt oleate. The decrease in intensity of a band at 3020 cm^{-1} with oxygenation shows that the double bond structure is destroyed as the oxygenation proceeds. All these results would indicate that, in the oxygenating process of cobalt oleate, the oxygenation of the double bond takes place and that a hydroperoxide structure is formed, together with acid produced by the destruction of the double bond. It is probable that oxygen attacks double bonds as well, as it is coordinated to the cobalt atom, as is shown by the ultraviolet spectroscopy of the oxygenating process.

Non-oxygenated cobalt oleate

Oxygenated cobalt oleate
(about three-month contact with dry air)

Fig. 7. The X-ray diffraction patterns of cobalt oleate.

The X-Ray Diffraction Pattern of Oxygenated Cobalt Oleate.—As shown in Fig. 7, the X-ray diffraction pattern of non-oxygenated cobalt oleate consists of a "halo". This indicates that non-oxygenated cobalt oleate is an amorphous solid. When the sample is completely oxygenated (after about three months contact with air), it is seen that the crystallization is effected to some degree. We have proposed[6] a polymeric structure, loosely bonded through OH groups, for cobalt oleate, which gives rise to an amorphous pattern in an X-ray spectrum. The crystallization by oxygenation may results from the coordination of oxygen to cobalt and the formation of an oxidized product, which gives the rigid crystalline structure to the original cobalt oleate. However, the point must be investigated further.

The Probable Mechanism of the Catalytic Action of Cobalt Soaps.—It may be concluded from the experimental results obtained in the present study that oxygen is coordinated to the cobalt atom and attacks the double bond in the case of cobalt oleate. Cobalt stearate alone does not absorb oxygen, but in the presence of oleic acid considerable absorption of oxygen takes place. This suggests that the oxygen absorption by cobalt soaps takes place when the oxygen acceptor is present at the same time. Oxygen will be coordinated to the cobalt atom and activated, resulting in the oxidation of the unsaturated compounds existing with the soap. This is similar to Ingle's theory[1] on the mechanism of the drying action of metal soaps, but the present study gives a more direct explanation for the mechanism, based on various experimental facts.

Summary

The gas absorption by cobalt oleate and stearate has been studied. It was found that cobalt oleate absorbs oxygen very remarkably,

6) H. Funakoshi, *Bull. Fukuoka Gakugei Univ.*, Part III, **11**, 93 (1961).

but nitrogen and hydrogen, very little. Cobalt stearate absorbs oxygen negligibly, but in the presence of oleic acid the absorption becomes considerable. From the studies of ultraviolet and infrared spectra and X-ray analysis of the oxygen absorption by cobalt oleate, it was found that oxygen is coordinated by the cobalt atom and destroys the double bond structure. The probable mechanism of the catalytic action of cobalt soaps has also been presented.

The author wishes to thank Professor Ryohei Matuura for his kind guidance throughout this study. The author is also deeply grateful to Dr. Hideo Kimizuka for his helpful advice and encouragement, and to Dr. Shigeru Miyamoto for valuable discussions. The author wishes also to thank Professor Sunao Imanishi and Dr. Yoshiya Kanda for their valuable suggestions for using the spectrophotometers, and Dr. Ryoichi Shimada for his recording and for discussions of infrared and ultraviolet absorption spectra. The author is indebted to Professor Atsushi Okazaki for taking Debye-Scherrer photographs, and to Mr. Michio Shito for the elementary analysis of cobalt soaps.

Chemical Use of the Absorption of Soft γ-Rays, β-Ray-excited X-Rays and K-Capture X-Rays. II. Application to the Analysis of a Binary Alloy and the Determination of a Heavy Element in a Multi-component System

By Tadashi NOZAKI

(Received December 20, 1960)

The technique described in Part I[1] provides a method of chemical analysis by the use of the absorption phenomenon of the photon-beams. Determination of a heavier element in a given sample was tried by using a single source of a suitable energy and the exponential-absorption law[2]. In applying such a method, the use of a pair of sources appears to be suitable for a greater variety of samples. This is easily to be understood by analogy with the so-called absorption-edge method in X-ray absorptiometry.

The present author has intended to extend this technique by the use of radio-isotopes as the radiation source. Mono-energetic soft X-rays (less than 25 keV.) can be obtained, of course, by the use of an X-ray tube and a proper diffraction crystal. Almost mono-energetic photon-beams of a higher energy, however, are required or preferable when a certain kind of element is to be analyzed or when the absorbance due to the matrix elements is too large for a photon of a lower energy. Radio-isotopes giving soft γ-rays, β-ray-excited X-rays and K-capture X-rays are more useful, and the discussion[3] concerning the comparison of K-capture spectroscopy with ordinary X-ray absorptiometry for sulfur in petroleum appears to hold in other cases.

In this paper, the use of two photon-beam sources with suitable energies is generally discussed, and the application to the analysis of a binary alloy (solder) and of a heavy element in a multi-component system (glass) is proposed.

With a binary system, there are two alternative modes in the choice of the sources: (1) the K absorption edge of one of the two elements, usually of the higher atomic number, is to fall between the energies of the two sources, and (2) both sources are to have higher energies than any of the K absorption edges of the elements, but the absorption coefficients of the two elements for one of the photon-beams are to be markedly different from each other and those for the other photon-beams are to be narly equal (The latter demand is fulfilled by a γ- ray of more than 1 MeV. in energy, to which the photoelectric effect contributes only slightly.). Choice 1 is useful for a sample of this foil, while choice 2 is suitable when the sample is a thick plate or block. The composition of solders without appreciable impurity was determined by using two pairs of sources. (1) U-β and ^{204}Tl, (2) ^{203}Hg and ^{60}Co. (For convinience, M-β is used in this paper for the β-ray-excited X-ray of element M.)

1) T. Naoki, This Bulletin, **34**, 1769 (1961).
2) H. K. Hughes et al., *Anal. Chem.*, **26**, 1889 (1954).
3) W. R. Doughman et al., ibid., **30**, 1924 (1958).

For a plate (either a foil or a block) of a binary alloy consisting of x(g./cm^2) of element A and y(g./cm^2) of element B, there are the following relationships:

$$\left.\begin{aligned}\Phi(E_1\ \mathrm{A})x+\Phi(E_1\ \mathrm{B})y&=-\ln D(E_1)\\ \Phi(E_2\ \mathrm{A})x+\Phi(E_2\ \mathrm{B})y&=-\ln D(E_2)\end{aligned}\right\} \quad (1)$$

$$[\text{Thickness of the plate}]=x+y \quad (2)$$

where Φ (E M) is the total absorption coefficient of element M for a photon-beam of energy E, and $D(E)$ is the transmittance (denoted by a fraction) of a photon-beam of energy E through the plate. Thus, simultaneous determination of the composition and of the plate thickness is possible.

When the element to be determined is in a multi-component system, the situation is slightly more complicated. The use of a number of sources of suitable energies equal to the number of the component elements offers the necessary relationships for determining all the component elements and the plate thickness. Such an argument, however, is only theoretical and impracticable. In practice, the plate thickness must be measured by some other method. Therefore, the measurement of the transmittances of two photon-beams, between the energies of which lies the absorption edge of only the element to be determined, offers a relationship for calculating the content. This relationship (indicated by Eq. 5) is derived as follows:

Eq. 13 in Part I can also be written as

$$\frac{\phi(E_1\ \mathrm{M})}{\phi(E_2\ \mathrm{M})}=(E_1/E_2)^{-\lambda}\quad (8/3<\lambda<7/2) \quad (3)$$

where $\phi(E$ M) is the absorption coefficient (of an element or a material M for a photon-beam of energy E) excluding the contribution of the Compton scattering. When one gram of the sample contains x gram of the element A to be determined and y_m gram of a matrix element M_m, there are the following relationships, where G means the sample (glass):

$$\left.\begin{aligned}\phi(E_1\ \mathrm{A})x+\sum_m[\phi(E_1\ \mathrm{M}_m)y_m]&=\phi(E_1\ \mathrm{G})\\ \phi(E_2\ \mathrm{A})x+\sum_m[\phi(E_2\ \mathrm{M}_m)y_m]&=\phi(E_2\ \mathrm{G})\end{aligned}\right\} \quad (4)$$

On assuming that λ in Eq. 3 remains constant for all elements, Eq.s 3 and 4 offer this relationship for calculating x:

$$x=-\frac{\begin{vmatrix}\phi(E_1\ \mathrm{G}) & 1\\ \phi(E_2\ \mathrm{G}) & (E_1/E_2)^{-\lambda}\end{vmatrix}}{\begin{vmatrix}\phi(E_1\ \mathrm{A}) & 1\\ \phi(E_2\ \mathrm{A}) & (E_1/E_2)^{-\lambda}\end{vmatrix}} \quad (5)$$

For a β-ray-excited X-ray or a K-capture X-ray, the E_1 and E_2 should be the weighed means of the energies of K_{α_1} and K_{α_2}. A source pair consisting of RaD and Ce-β and that of U-β and ^{204}Tl were used for the determination of barium and lead respectively.

The error of results is discussed below.

Experimental

Sample.—Solder containing no appreciable ammount of any elements other than tin and lead was rolled to a plate or a foil. Plates of barium glass and lead glass of uniform thickness (about 2 mm.) were prepared. The barium glass contained sodium, boron, silicon, barium and oxygen, while the lead glass consisted of boron, sodium, aluminum, zinc, lead and oxygen. The thickness (g./cm^2) of the glass plates and of the solder foils was determined by measuring the weihgt and the area, while that of the solder plates was done by measuring the thickness and the specific gravity.

Counting.—In all cases a scintillation counter was used with the geometrical arrangement shown in Fig. 1, Chapter I.

The sources were chosen as described above. The measurement was done by using the techniques in Part I, tin foil and lead foil being used as the auxiliary absorbers for Ce-β and U-β respectively. With ^{60}Co as the source, only the γ-ray of the higher energy was counted. For the analysis of solder, the total count taken in each measurement was over 5×10^4, while for that of glass at least 3×10^3 (when the counting rate was smallest) or 3 minutes' counting (when it is largest) was taken.

Chemical Analysis.—Chemical analyses by ordinary methods were carried out for comparison. Solders were analyzed by determining tin gravimetrically as tin(IV) oxide and lead, electrochemically as lead(IV) oxide. A part of any of the glass samples was decomposed with hydrofluoric and sulfuric acid, and barium was determined gravimetrically as barium sulfate, while lead was converted into lead chromate and determined iodometrically by the standard technique.

Results and Discussion

In Tables I, II, III and IV are shown the results. The values with the sign ± indicate the error due to the standard error of counting. In general, all values are in good agreement with those obtained by ordinary chemical analysis. Moreover, the usefulness of Eq. 5 is proved.

Sample No.	Lead content, %			
	λ=3/8	λ=2/7	Mean	Chem. anal.
1	−0.4	−0.07	−0.2±0.3	0.00
2	1.78	2.04	1.9±0.3	1.77
3	3.30	3.48	3.4±0.4	3.15
4	8.15	8.43	8.3±0.5	8.2
5	17.7	17.9	17.8±0.6	17.5
6	35.4	35.6	35.5±1.0	34.0
7	54.7	54.9	54.8±1.1	54.6

The error in the final result due to the standard error of counting is calculated as follows: When $\Phi(E\,\mathrm{M})$ in Eq. 1 has been preliminarily determined accurately, the final error in x and y in the same equations depends on that of the determination of $D(E)$. When it is assumed that total counts C is taken during time t without the sample, and C', during t' with the sample, the fractional standard error in $\ln D(E)$, denoted by $\Delta \ln D(E)$, is the standard error in

$$\ln\left[\frac{(C'+\Delta C')/t'}{(C+\Delta C)/t}\right]-\ln\left[\frac{C'/t'}{C/t}\right]$$

where ΔC equals $\pm\sqrt{C}$ and $\Delta C'$, $\pm\sqrt{C'}$. For large values of C and C', for which the approximation

$$\ln\left(1\pm\sqrt{\frac{1}{C}+\frac{1}{C'}}\right)=\pm\sqrt{\frac{1}{C}+\frac{1}{C'}}$$

is valid,

$$\Delta \ln D(E)=\sqrt{\frac{1}{C}+\frac{1}{C'}} \qquad (6)$$

because, the fractional standard error in

$$\frac{C'+\Delta C'}{C'}\Big/\frac{C+\Delta C}{C} \quad \text{is equal to}$$

$$\sqrt{\left(\frac{\Delta C'}{C}\right)^2+\left(\frac{\Delta C}{C}\right)^2} \quad \text{or} \quad \sqrt{\frac{1}{C}+\frac{1}{C'}}$$

The errors in Tables I and II are calculated by Eq. 6. For a multi-component system, when $\phi(E\,\mathrm{A})$ in Eq. 4 and the thickness of the sample have been preliminarily determined with precision, the final error is derived either from the determination of $\phi(E\,\mathrm{G})$ or from the uncertainty of λ in Eqs. 3 and 5. The latter can be regarded as small, as is shown in Part I. By a calculation similar to that for the binary system, the standard error in the final result due to the error of counting for $\Phi(E\,\mathrm{G})$ is obtained and is shown in Tables III and IV. When the optimum determination accuracy within a given counting time is required, the time should be so divided that the determination of $\phi(E\,\mathrm{G})$ for the photon-beam of the higher energy may be done more precisely than for that of the lower energy, owing to the factor of $(E_1/E_2)^{-2}$ in Eq. 5. There are, of course, some uncertainties in $\Phi(E\,\mathrm{A})$, but they can be made insignificantly small when determined once with precision.

The value x in Eq. 5 varies with the value of λ for a given value of $\phi(E\,\mathrm{A})$ and ϕ $(E\,\mathrm{G})$. However, the mean value of x for λ=8/3 and λ=7/2 agrees well with the result of ordinary chemical analysis. This mean value is not significantly different from the value for λ=3.

The physical meaning of the denominator of Eq. 5 is the coefficient of the photoelectric absorption by only the K-shell for a photon-beam of energy E_2 (with a negative sign) with a small contribution of the coherent scatterings. There are several theoretical formulas for the photoelectric absorption cross section by the electrons in the K-shell, (σ_k). The formula obtained by the Born approximation[4] is:

$$\sigma_k=\phi_0\,4\sqrt{2}\,\frac{Z^5}{137^4}\,\frac{(mc^2)^{7/2}}{E} \qquad (7)$$

$$\phi=\frac{8\pi}{3}\,(e^2/mc^2)^2=6.651\times10^{-25}\,\mathrm{cm}^2$$

However, application of the correction factor from the chart[3] to the value of Eq. 7 usually offers a value higher than the experimental result by several per cent, in spite of the contribution of the coherent scatterings to the latter. Other, simpler formulas provide poorer results.

Summary

The absorption phenomenon of soft γ-rays, β-ray-exited X-rays and K-capture X-rays was applied to the following two kinds of analyses (1) Analysis of solder (simultaneous determination of the composition of a binary system and the sample thickness), and (2) Determination of barium or lead in glasses (determination of an element of high atomic number in a multi-component system). Two photon-beams of energies suitable for each purpose were chosen, and for the latter purpose the relationship between the absorption coefficient of an element and the photon-beam energy was used. The results were in good agreement with those obtained by usual chemical analysis.

Chemical Use of the Absorption of Soft γ-Rays, β-Ray-excited X-Rays and K-Capture X-Rays. III. Application to Column-chromatographic Separation of Halogen Compounds

By Tadashi NOZAKI

(Received December 20, 1960)

Column-chromatographic separation of colorless compounds always involves a tedious procedure or requires a special instrument[1]. With such a method, usually only frontal analysis is possible, and no information concerning the behavior of each compound in the column is offered. Even where colored compounds are concerned, a small overlap of two adsorption zones is often overlooked and the observation of their behavior in the column is ambiguous. In this paper, the author will indicate that utilization of the absorption phenomenon of soft γ-rays, β-ray-excited X-rays and K-capture X-rays offers a very useful technique for the column-chromatographic separation of iodine-, bromine- or chlorine-containing substances, which are mostly colorless. Frontal analysis is thus made always possible regardless of the use of the solvent consisting of lighter elements than oxygen. With iodine- or bromine-containing compounds, nondestructive determination of the location of each compound in the column is made possible. As shown in Table I, a photon-beam of a suitable energy is absorbed strongly by bromine or iodine, but only slightly by column-wall substances, adsorbents and solvents; these usually consist of elements of a low atomic number. Nondestructive determination of the location of the compounds at a given time is named "in-situ determination".

^{204}Tl	0.17	0.24	0.35	1.9	5.17

Outline of the Technique.—Figure 1 shows the measuring device. Useful sources are listed in Table II. (For convenience, the β-ray-excited X-rays of element M are written as M-β in this paper.)

As shown in Table II, the source for the in-situ determination of iodine or bromine must be chosen according to the diameter of the column or the concetration of the solution.

Table II. Useful photon-beam sources

	In-situ determination	Frontal analysis
Chlorine	Unsuccessful	^{55}Fe, Sr-β, Br-β
Bromine	Ce-β[a], Ba-β[a] RaD[b]	Ba-β, Sn-β, Mo-β
Iodine	RaD[c] ^{204}Tl[d] ^{203}Hg[e]	RaD, Ce-β

a) When a small amount of bromine is adsorbed.
b) When a large amount of bromine is adsorbed.
c) When the column diameter is small (less than 3 cm.).
d) When the column diameter is large (3 to 8 cm.).
e) When the column diameter is still larger.

For the in-situ determination of iodine, the following method is useful for a column of a larger diameter: a fine polyethylene tube is placed at a suitable position in the adsorbent along the direction of the tube, so that a point source can be moved in the tube and the absorption of the photon-beam by the material can be measured at a given location in the column. This method is one of the techniques that are made possible only by utilizing a radio-isotope rather than an X-ray generator. For the in-situ determination of bromine of a smaller concentration, Ba-β or Ce-β should be used in spite of the ease with which the photon-beam is absorbed by other materials than the compounds in question. Hence, the column should preferably be made of polyolefine, and, whenever possible, the adsorbent should be charcoal or carbohydrate. When a large amount of bromine compounds is to be separated, it is preferable to carry out, in the first place, both the in-situ determination and the frontal analysis by the use of a small column and of a minor portion of the compounds. The behavior of the compounds in the column, including the retention volumes and the relation between the results of both determinations, are thus made clear. The major portion is then separated on a large scale with the aid of only frontal analysis.

Unfortunately, the in-situ determination of chlorine is very difficult because of the more pronounced absorption of the soure photon-beam by other materials than the compounds in question.

Throughout these cases, the use of an exact exponential absorption curve is not essential, unless an accurate determination of the compound is to be made in the column.

Discussion on the Usefulness of the Technique. —By the use of the in-situ determination, the following important information for column-chromatographic separation can be obtained in the early stage of adsorption (when only a small quantity of the original solution has been treated): (1) the retention volume of each compound, (2) minimum recovery of most weakly adsorbed substance in a pure state without elution, and also without elution tailing, (3) maximum quantity of the original solution which can be treated in one lot for complete separation under the given conditions, (4) the necessary quantity of an eluent for eluting each of the compounds. An almost ideal case (without marked elution tailing) is exemplified by the separation of iodobenzene and 4-iodobiphenyl described below.

When a pronounced elution tailing is observed, complete separation is usually impossible. But a part of the most weakly adsorbed compound is obtained in a pure state, leaving a mixture in the column. For molecules having a similar functional group, it is generally true that the stronger the affinity with an adsorbent, the less the solubility in a given solvent. Thus, for the separation of a binary mixture, a method consisting of the following procedures is useful; (1) the mixture is dissolved in a suitable solvent of a quantity sufficient for complete dissolution of the more soluble compound I; (2) when the less soluble compound II remains undissolved, it is obtained in a pure state by filtration and, whenever necessary, by recrystallization; (3) a part of pure I is obtained chromatographically; (4) the mixture of I and II is completely eluted with a solvent with a strong eluting power; (5) the solvent is removed from this effluent to give a solid mixture, which is submitted to the same process again to give further I and II in a pure state. Step 3, the most important procedure, can be made easier by the use of the photon-beam absorption technique for colorless bromine and iodine compounds. Such a case is exemplified by the preparation of 4-iodobiphenyl and 4, 4′-diiodobiphenyl by direct iodination of biphenyl and their separation (see below).

Column chromatography is also useful for purifying some kinds of material. Crude halogen compounds prepared by the Sandmeyer reaction always contain impurities (e. g., phenols and oxidation products of the amines), which are much more easily adsorbed than the halogen compounds themselves. When the halogen compound is colorless, the photon-beam absorption provides a valuable tool in its chromatographic purification. Such a process is exemplified by the purification of 2-chloro-*p*-terphenyl (see below).

Separation of Iodobenzene and 4-Iodobiphenyl. —Figure 2 shows the behavior of iodobenzene

(A) (724 mg.) and 4-iodobiphenyl (B) (555 mg.) which have been dissolved in petroleum benzine (50 ml.). The column was 13.5 mm. in diameter and contained alumina (38 g.; apparent length: 30 cm.). The adsorption heads of the two substances move at a definite rate according to the volume of both the solution and the eluent (5.0 mm. per ml. for A, 2.0 mm. per ml. for B). Iodobenzene gives some elution tailing, though not pronounced, and 4-iodobiphenyl gives a marked tailing.

When the rate of migration of substance I, which is eluted easier, and that of substance II are denoted by R_I and R_{II} (in cm. per ml.) respectively, and the length of the adsorbent is L (cm.), the retention volumes of the substances V_I and V_{II} (ml.) are:

$$V_I = L/R_I \qquad V_{II} = L/R_{II} \tag{1}$$

In the absence of tailing, there are the following approximate relationships between the maximum treatable quantity of the original solution for complete separation, Q (ml.), and the minimum volume of the eluent necessary for complete elution of I under the given condition, S (ml.):

$$L = (Q+S)R_{II} = SR_I$$

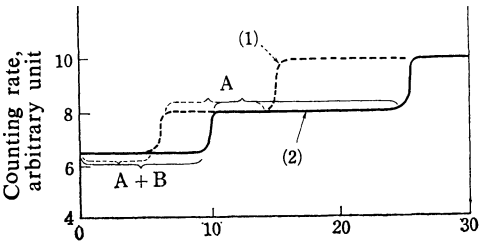
Thus,

$$Q = L/R_{II} - L/R_I = V_{II} - V_I \tag{2}$$

$$S = L/R_I = V_I \tag{3}$$

Since L, R_I and R_{II} are 30, 0.50 and 0.20 respectively, V_I and V_{II} are 60 and 150 respectively; without tailing of I, Q and S should be 90 and 60 respectively. When the elution tailing of I is as in Fig. 2, Q is 70 to 75 and S about 75.

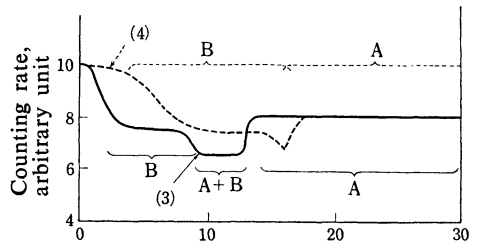
When only the original solution is passed through the column until the adsorption head of II reaches the lower end of the column with the aim of obtaining a part of I in a pure state, the yield, Y, is expressed by:



$$Y > (V_{II} - V_I)/V_{II} \tag{4}$$

This is because the concentration of I at the location where only I is adsorbed is higher than that at the location where both I and II are present, owing to the displacement of I by II. Moreover, this relation is always valid regardless of the presence of tailing. When this mixture is submitted to such a treatment,

$$(V_{II} - V_I)/V_{II} = 0.60$$



but the true value of Y, which is easily obtainable from Fig. 2 and the quantity of the substances present, should be about 0.75.

When elution is carried out to such a degree that an incomplete separation is caused, an approximate value of Y can be estimated by the use of the in-situ determination.

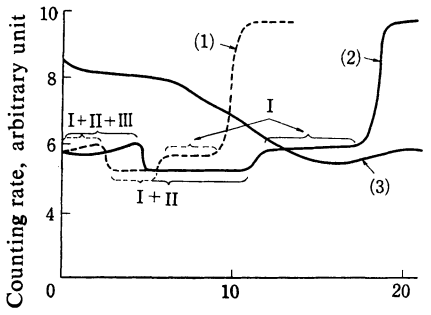
Fig. 3. Frontal analysis of iodine.

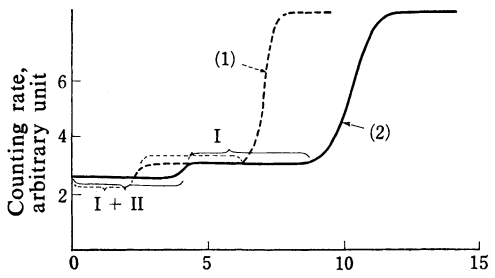
Frontal analysis was also carried out successfully, the results being shown in Fig. 3. When all of A came out, ether was caused to pass in order to elute B rapidly.



Similar results were obtained with bromobenzene and 4-bromobiphenyl.

Preparation of 4-Iodobiphenyl and Similar Compounds.—4-Iodobiphenyl and 4-bromobiphenyl are useful for the synthesis of polyphenyl compounds. Direct bromination of biphenyl offers 4-bromobiphenyl contaminated with 4, 4′-dibromobiphenyl, which can be only with difficulty removed. Thus, the standard method[2] for the synthesis of pure 4-bromobiphenyl is the reaction of the diazotization product of 4-bromoaniline with benzene in an alkaline medium. 4-Iodobiphenyl is prepared by the Sandmeyer reaction from 4-aminobiphenyl, which must be synthesized from biphenyl.

Direct iodination of biphenyl can be attained easily in acetic acid with the aid of nitric acid. Column-chromatographic separation offers both 4-iodobiphenyl and 4, 4′-diiodobiphenyl in a good yield and with a satisfactory purity.



For the bromine compounds, the separation method is less effective, because the adsorbing power of an adsorbent toward 4-bromobiphenyl and 4, 4′-dibromobiphenyl differs less than in the case of corresponding iodo-compounds, and because the in-situ determination of bromine is less easy than that of iodine. For most synthetic purposes, however, the use of 4-iodobiphenyl is preferable to that of 4-bromobiphenyl.

Figure 4 indicates the behavior of 4-iodobiphenyl (I) and 4, 4′-diiodobiphenyl (II) including by-product (III) of the iodination reaction of biphenyl. Both I and II are partly replaced by III, which forms a visible zone. The head of the zone of II becomes less clear with the progress of elution owing to the elution tailing of I. Frontal analysis is useless in such a case.

Location, cm. from the upper end

(1); 320 ml. adsorption
(2); 500 ml. adsorption

Figure 5 shows the behavior of the same iodine compounds, from which the by-product has been removed by a preliminary treatment. In this case, all the substances in the column are easily eluted with benzene or, preferably, with ethyl acetate, and the alumina can be reused after heat treatment at 200 to 250°C under a reduced pressure. The impurity in the eluted I appears to consist of a small quantity of remaining biphenyl or, more probably, 2-iodobiphenyl simultaneously formed. The impurity, however, can be removed, by recrystallization and pure I is obtained easily in a good yield. This synthesis of I is definitely superior to the Sandmeyer reaction with 4-aminobiphenyl with respect to the saving of time, labor and expense. The product will contain no trace of II.

Direct iodination of *p*-terphenyl is similarly attained by using a larger amount of the solvent. 4-Iodo-*p*-terphenyl is obtained from the product, by a similar, process, but with a disadvantage due to its lower solubility. Benzene must be used in place of benzine despite the much smaller retention volume, which always decreases the quantity of materials treated in one lot. This method, however, is preferable for preparing a small quantity (less than a few grams) of pure 4-iodo-*p*-terphenyl, which must otherwise be synthesized through many tedious steps[3].

Purification of Mono-halogeno-*p*-terphenyls.—Figure 6 shows the results of the frontal analysis of 2′-chloro-*p*-terphenyl prepared by the Sandmeyer reaction. The size, shape and mode of attachment of the adsorption cell are very important in determining the real concentration of chlorine in the effluent at a given instant. Some other mono-halogeno-*p*-terphenyls prepared by the same reaction were

3) T. Nozaki et al., This Bulletin, 33, 1329 (1960).

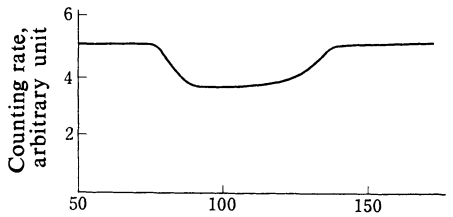

Fig. 6. Frontal analysis of chlorine.

similarly purified with the aid of the absorption technique, and their properities are now under investigation.

The technique was, however, unsatisfactory for the separation of a mixture of 2-, 3- and 4-chloro-*p*-terphenyl, prepared by the decomposition of 4-(*N*-nitrosoacetamido)-biphenyl in chlorobenzene because of the marked elution tailing.

Experimental

Adsorbent and Reagents.—Freshly purchased commercial alumina (Kantō Chem. Co. for chromatographic purpose) was used without further treatment. Too great an activity of alumina sometimes caused a slight decomposition of the iodine compounds. All solvents were of the first grade and were used after having been kept in contact with a small quantity of highly activated alumina for several days. In some cases, extremely purified solvents were also used, but no significant difference in the behavior of the compounds was observed. Other reagents were also of a commercial first grade.

Measurement Device.—For the in-situ determination, a collimated photon-beam was caused to pass along cross-section of the chromatographic column to enter the scintillation crystal or the counter tube (Fig. 1). For the frontal analysis of chlorine, the outlet of the tube was connected to a polypropylene absorption cell of a suitable dimension, while for that of iodine, the alumina near the outlet was replaced by cotton wool. The output pulse of the scintillation head or the counter tube was amplified by a linear amplifier, and the photo-peak was counted by the use of a single channel analyzer and a scaler or an automatic recorder.

For the analysis of chlorine Br-β was adopted and the photon-beam was measured by a xenon-filled proportional counter tube. For other sources a scintillation counter was used.

Preparation of 4-Iodobiphenyl and 4, 4'-Diiodobiphenyl.—A mixture of 20 g. of biphenyl and 20 g. of iodine in acetic acid (150 ml.) containing nitric acid (d=1.38, 25 ml.) was boiled gently under reflux (for about 1.5 hr.) until the color of iodine disappeared. After the mixture had been poured into water, the separated solid was filtered off, washed with an aqueous alkali solution and dried. About 40 g. of a faintly yellowish hydrophobic powder was obtained, which was recrystallized from 200 ml. benzene. On filtration and washing of the precipitate with ethanol, 8 g. of fairly pure 4,4'-diiodobipenyl (II) was obtained (m. p. and mixed m. p. 203~205°C). The mother liquor was caused to pass through a column of alumina (ca. 200 g.) to remove the yellow material, from which a small quantity of 4-nitrobiphenyl was isolated by further purification, including recrystallization. Benzene was then removed from the effluent, aud the colorless residual solid was digested with 600 ml. of petroleum benzine. The insoluble solid offered 2 g. of fairly pure II. Moreover, the mother liquor was submitted to column-chromatographic separation with the aid of the adsorption technique by using a column 6 cm. in diameter containing 300 g. of alumina.

Alter all the solution had been passed through, petroleum benzine was caused to pass through the column for elution until the adsorption head of II reached the lower end of the column. The effluent gave, on removal of the solvent, 20 g. of solid melting at 107~112°C. This gave, however, after a single recrystallization from a small quantity of ethanol, 15 g. of pure 4-iodobiphenyl (I) (m. p. and mixed m. p. 113~114°C). The column was eluted with ethylacetate to offer 6 g. of solid with ease after removal of the solvent. This solid gave, on a treatment similar to that above under a diminished scale, 1 g, of II, 3 g. of I and 2 g. of their mixture. The I obtained at this time was pure enough without recrystallization from ethanol. Thus, from 20 g. of biphenyl and 20 g. of iodine, 18 g. of I and 11 g. of II were obtained in a fairly pure state along with 2 g. of their mixture.

Another experiment which did not involve the removal of the yellow material (nitro-compounds) was also carried out. About 4 g. of the crude iodination mixture was treated with 80 ml. of petroleum benzine, and, after removal of the insoluble II, the solution was submitted to column chromatography. Both the in-situ determination and the frontal analysis were applied.

Purification of 2'-Chloro-*p*-terphenyl.—2'-Nitro-*p*-terphenyl (2 g.) prepared by the reaction of nitrosation product of 3-nitro-4-acetamidobiphenyl with benzene was reduced with tin(II) chloride, and the amine hydrochloride was diazotized and decomposed in concentrated hydrochloric acid with the aid or copper(I) chloride. The product was extracted with a mixture of petroleum benzine (40 ml.) and benzene (40 ml.), caused to pass through a column of alumina (40 g.), and eluted with the same solvent. The chlorine-containing part, which was recognized by frontal analysis, offered, on removal of the solvent, a colorless mass which was recrystallized from ethanol (25 ml.) into transparent square platelets (0.5 g.) [m. p. 101°C].

Summary

The absorption technique of soft γ-rays, β-ray-excited X-rays and K-capture X-rays was successfully applied to column-chromatographic separation and purification of halogen compounds. By this technique, the behavior of the iodine- and bromine-containing compounds

in the column was determined in situ, and important information for column chromatography, including the retention volume, was obtained at an early stage of adsorption. The technique was also satisfactorily applied to the frontal analysis of halogen compounds. An excellent method for the preparation of pure 4-iodobiphenyl by the use of the in-situ determination was provided.

Radiation-induced Polymerization of α-Methylstyrene. II. Reply to the Criticism of Bates et al.

By Kozo HIROTA and Fukuo TAKEMURA

(Received November 20, 1961)

In radiation-induced polymerization, there are now a number of examples which can be explained by ionic mechanisms. However, these experiments were carried out at much lower temperatures than 0°C, and the monomers irradiated were all, except isobutene, of a solid state[1]. On the other hand, α-methystyrene (αMS) is known to be hardly polymerizable by ordinary peroxide initiators. Therefore, it would be interesting from the point of view of the reaction mechanism to investigate the radiation-induced polymerization of liquid αMS at room temperature[2].

In former reports[3], we came to the conclusion that the mechanism would be a radical one by taking the following experimental facts into consideration: 1) Besides such radical inhibitors as oxygen and *p*-benzoquinone, the reaction was retarded or inhibited by the presence of naphthalene or nitrobenzene respectively, which would make it likely for the polymerization to occur by an ionic mechanism. 2) Radical initiators produced photochemically or by a redox-reagent[4] had the power to polymerize αMS at room temperature. 3) Though the amount of polymerized product increased in proportion to the dose rate, this could be explained if the degradative chain transfer were considered in the reaction scheme, taking the existence of a low ceiling temperature for this monomer (60~70°C) into consideration. 4) The activation energy was found to be 4.1 kcal., which was a reasonable value for radical polymerizations initiated photochemically or by irradiation.

However, Bates et al.[5] recently proposed a cationic mechanism for this reaction based on the fact that its *G* (-monomer) increased up to 10000 from 10 if the monomer was pretreated with silica gel. Their theory is slightly contradictory to ours, because the monomer used in our experiment was dehydrated more severely with evaporated sodium film, while our *G* (-monomer) was smaller (200~600) than that of the Bates experiment. Such being the situation, further experiments were carried out by the use of three different methods of research in order to decide the mechanism.

Experimental and Results

The method of preparation of the samples was quite similar to that used in a former report; i. e., the monomer was deaerated and sealed in a glass ampule. Dehydration was carried out with calcium hydride instead of metallic sodium.

Experiment 1. The Effect of Zinc Oxide.—In order to study the effect of dehydration on the polymerization, the effect of zinc oxide was investigated, according to the suggestion of Bates et al. For the sake of comparison, styrene was irradiated as well as αMS. All the samples in the systems to be compared were irradiated for 18 hr. under the same dose rate. The results are shown in Table I.

In the case of αMS without dehydration, the yield of polymer rather decreased in the presence of zinc oxide, but it increased twofold when αMS was deaerated and dehydrated with calcium hydride. It is noteworthy that no such accelerating effect was observed in the case of styrene, which is a well-known monomer polymerizable by the radical mechanism.

—— Product polymerized by irradiation
---- Product polymerized by ABIN
1728 cm^{-1} stretching vibration of C=O group
755 and 695 cm^{-1} out-of-plane bending vibrations of CH of C_6H_5 group

Experiment 2. Copolymerization with Methyl Methacrylate.— Six cc. of an equivolume mixture of αMS and MMA (methyl-methacrylate) which was sealed and deaerated in a glass ampule was irradiated with γ-rays for 376 hr. at room temperature. The dose rate was 0.73×10^4 r/hr., the total dose therefore amounting to 2.7×10^6 r. In the infrared spectrum of the polymer thus obtained, characteristic bands corresponding to the carbonyl group at 1728 cm^{-1} and to the phenyl group at 755 cm^{-1} and 695 cm^{-1} appeared, as is shown by the full curve in Fig. 1. Moreover, this spectrum was quite similar to the spectrum (dotted curve) of the product copolymerized from the same mixture of αMS and MMA with azo-bis-isobutylonitril. Therefore, the product obtained by irradiation may be a copolymer of both monomers.

Experiment 3. Turbidometry of the Copolymer. —Strictly speaking, there is yet a possibility in Exp. 2 that the product might be a mixture of poly-αMS and poly-MMA. In order to investigate this possibility, turbidometry was adopted on the product by use of a self-recording apparatus manufactured by Shimadzu. By dropping a mixture of methanol-water (50% : 50%) into the acetone solution (100 cc.) of the polymer, a turbidity-time curve was obtained, as is shown in Fig. 2. It was found by the shape of the curve that the product was composed of two polymers. The major part (90%) of the polymer is established as copolymer, while the remaining, more insoluble part (10%) as poly-αMS, in the following discussion.

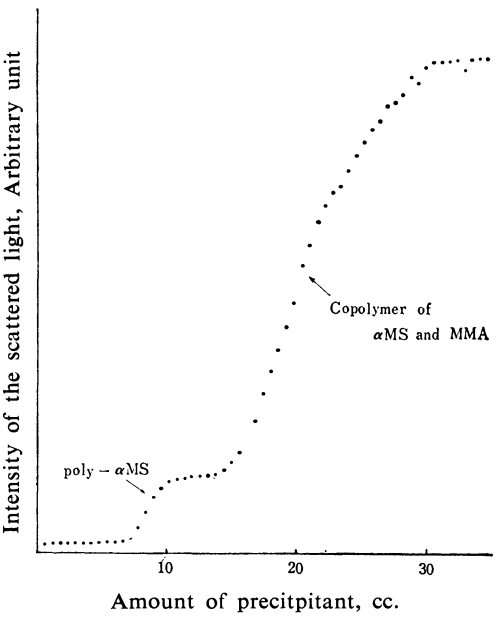

Fig. 2. Turbidity-time curve of the polymer obtained by irradiating the mixture of αMS and MMA.
Sample : 100 cc. of acetone solution (0.01%)
Precipitant : Water-methanol (50% : 50%)
Apparatus : Shimadzu PG-21.

Discussion

Generally, there exists no reliable report on radiation-induced polymerization which is explained by an anionic mechanism, in a case when no solvent is used and the polymerization is carried out at room temperature. The present polymerization, therefore, must be explained by radical or cationic mechanisms, or by both. According to Exp. 2, the polymerization may be explained at least by a radical mechanism for the following reasons. First, MMA is only with difficulty copolymerizable with αMS by a cationic catalyst, such as iodine[6]. Second, it is hardly conceivable that the radical ends of both poly-αMS and poly-MMA coexist in the solution. Therefore, the polymer here obtained must be a copolymer, produced by a radical mechanism.

However, according to Exp. 1, the presence of zinc oxide seems to accelerate the polymerization, though the effect was not so marked. This result can be explained by the cationic mechanism, if zinc oxide plays the role of an electrontrap, which would help the formation of cation, though Bates et al. attributed its dehydrating action to the origin of the accelerating effect. It may therefore be reasonable to conclude that the polymerization did not necessarily always occur according to one and the same mechanism. If this is so, the product of Exp. 2 will include not only the copolymer but also the homopolymer. Such a possibility is actually confirmed by Exp. 3. Now the minor part of the product confirmed by Exp. 3 must be the homopolymer of αMS, considering that it is less soluble than the major part and also that the homopolymer of MMA may not be produced under the present conditions.

In short, the above results teach us that γ-ray-induced polymerization of αMS occurs simultaneously as a result of both radical and cationic initiators produced by irradiation, the fraction of the polymer produced by the radical initiator, however, being much larger. By assuming such a coexistence of two mechanisms during the process of the present polymerization, the data of Bates et al. and those of present authors, regarding this reaction, can be explained without any contradiction.

Summary

Gamma-ray-induced polymerization of α-methylstyrene occurs mostly according to the radical mehanism, as had been concluded by one of the present authors, but simultaneously it occurs to some extent according to the cationic mechanism, as had been asserted by Bates et al.

In conclusion, we wish to express our deep thanks to Dr. Keiji Kuwata and Mr. Junichi Matuura of Osaka University for their discussions and help in the measurement of the turbidometry.

NOTES

The Electron Spin Resonance Absorption of the Complexes of Aromatic Sulfur Compounds with Lewis Acids

By Minoru KINOSHITA and Hideo AKAMATU

(Received December 14, 1961)

The origin of the unpaired electrons which are responsible for the electron spin resonance (ESR) absorption of the complexes of aromatic compounds with Lewis acids has not been clarified. The ESR absorption of aromatic hydrocarbons, such as tetracene and perylene, in a sulfuric acid solution has been observed. Also, the ESR absorption of the complexes of these hydrocarbons with antimony pentachloride[1,2] and aluminum chloride[3,4] has been investigated, both in solids and in solutions in phosphorus oxychloride or carbon disulfide. In solutions the complexes display hyperfine structures which are similar to those of the corresponding hydrocarbon solutions in sulfuric acid. Thus the same organic radicals are likely responsible for the ESR absorption of the complexes and the sulfuric acid solutions. On the other hand, it is known that the radicals produced from compounds containing sulfur atoms show absorption lines which are characterized by relatively large g-values, because of the localization of unpaired electrons on the sulfur atoms. The ESR absorption of aromatic sulfur compounds, such as thio-phenol, thio-β-naphthol and thianthrene, in a sulfuric acid solution has been reported[3,5,6]. The characteristic features in the absorption of these radicals are large g-values in comparison with those of other organic free radicals and the appearance of two absorption bands[5]. Hence, the similar characteristic features in the ESR absorption of the complexes of aromatic sulfur compounds with Lewis acids can be expected. This short report is concerned with these.

The solid complexes with antimony pentachloride were made by mixing the solutions of sulfur compound and antimony pentachloride in dried chloroform. The solutions of the complexes with aluminium chloride were prepared in the same way by the use of nitrobenzene as a solvent. The concentration of these solutions and of the sulfuric acid solutions of the compounds was about $10^{-2}\sim10^{-3}$ M.

The solid complexes are deeply colored; thio-β-naphthol and 2, 2′-dinaphthyl disulfide give dark green compounds, while thianthrene forms a brownish purple compound. These colorations are identical with the colors of the sulfuric acid solutions of the corresponding compounds. When once dried completely in vacuum, the complexes with antimony pentachloride are very stable even in exposure to the air, but the complex of dibenzothiophene seems to be rather unstable.

The ESR absorption was examined at a frequency of 9.4 kMc./sec. at room temperature with a Hitachi MPS-1 spectrometer. As shown in Table I, the g-values of these complexes, estimated by a comparison with DPPH ($g=2.0036$), were found to be large, coinciding with those of the sulfuric acid solutions of these compounds.

In the sulfuric acid solution, thio-β-naphthol and 2, 2′-dinaphthyl disulfide showed two absorption lines. The peak of the lower field side was very weak. This weak peak was not observed in the dried complexes, but when an excess of antimony pentachloride was added to the complexes, the weak line at the lower field could be detected; on removal of the exceses of the reagent, this peak disappeared.

In the solid complexes with antimony pentachloride, the ESR absorption lines were found to be very broad in contrast to those of the complexes of aromatic hydrocarbons[2]. In Table II, the line widths are shown by the distances between the points of maximum slope. The broadness and the large g-values of the ESR absorption of the radicals containing sulfur atoms can be interpreted by the localization of an unpaired electron on the sulfur atom[7]. In the powdered thianthrene complex with

Thianthrene	Three lines[b]	Five lines[c]	Five lines[c]
Dibenzothiophene	4.5	—	—

a) Distance between the points of maximum slope in gauss.
b) Over-all width of about 45 gauss.
c) Over-all width of about 10 gauss.

antimony pentachloride, the absorption was found to consist of three broad lines, which may be ascribed to the anisotropy of g-value. In other complexes studied here, no structure in the ESR absorption was observed, but thio-β-naphthol and 2, 2'-dinaphthyl disulfide seemed to form two kinds of complexes; one of them had a g-value of 2.0076 and 2.0074 respectively and the other 2.0051, for both compounds. When the antimony pentachloride solution was dilute, a complex with a higher g-value was resulted, but if a somewhat concentrated solution was used, a complex with $g=2.0051$ and a line width of 5.6 gauss, or the mixture of these two kinds of complexes, which gave an asymmetric or two absorption lines, was obtained. The presence of two kinds of complexes has been already found in the system of tetracene and antimony pentachloride[2].

The solutions of these compounds as well as of the complexes displayed sharp absorption lines compared with the solid complexes; however, no hyperfine structures were observed other than in the solutions of thianthrene and its complex. For dibenzothiophene we could not obtain any ESR absorption in the dissolved state, but in a fuming sulfuric acid solution it showed a weak and sharp absorption.

Since the thianthrene complex with antimony pentachloride was found to show an interesting behavior in the ESR absorption, we shall describe it in detail shortly.

Pure Quadrupole Spectra of Propargyl Chloride and its Related Compounds

By Takashi SHIMOZAWA*, Takehiko CHIBA** and Yonezo MORINO

(Received December 19, 1961)

In the preceding papers[1], the molecular structures of propargyl chloride and its related compounds were discussed on the basis of the observed dipole moments. The results obtained so far are listed in Table I. It can readily be seen that the C–Cl bond moment in these compounds is smaller than the average value of the usual C–Cl bond moment of the halogenated saturated hydrocarbons (1.86 D), except in the case of monochlorobutyne-2. The early investigation gave a considerably longer C–Cl distance for the bond which is adjacent to a triple bond[2]. Pauling explained

TABLE II. NUCLEAR QUADRUPOLE COUPLING CONSTANTS AND APPARENT DIPOLE MOMENT OF PROPARGYL CHLORIDE AND ITS RELATED COMPOUNDS

	at 77°K	(eqQ)	μ(app.)
Propargyl chloride	35.812,3 Mc.	71.6 Mc.	1.65 D
1-Chlorobutyne-2	35.361,8 Mc.	70.7 Mc.	2.17 D
1,4-Dichloro-2-butyne	36.372,8 Mc.	72.6 Mc.	1.47 D

this lengthening of the C-Cl bond in propargyl chloride by assuming that the resonance form II makes a large contribution to the structure. However, the experimental results on the bond moment stated above contradict this explanation. Rogers[3] attributed this small dipole moment to the presence of structure III.

$$\underset{\text{I}}{HC{\equiv}C\text{-}CH_2Cl}, \quad \underset{\text{II}}{HC^+{=}C{=}CH_2Cl^-}$$

$$\underset{\text{III}}{HC^-{=}C{=}CH_2Cl^+}$$

As is well known, the electric quadrupole coupling constant (eqQ) obtained from the pure quadrupole spectra provides us with information on the charge distribution of the chemical bond[4]. If the distribution of the electron is spherically symmetric, as it is in a free Cl-ion, the eqQ constant vanishes, whereas it must be quite large in the case of Cl^+, where two unbalanced p-electrons exist. Therefore, it seemed of interest to measure the pure quadrupole resonance spectra of propargyl chloride and its related compounds to obtain some information about the electronic structure of the C–Cl bond in these compounds. The experimental method used is the same as that reported previously[5]. The results are listed in Table II.

A linear relation was previously pointed out[5] between the nuclear quadrupole coupling constants and the apparent C–Cl bond moment of the halogen derivatives of saturated hydrocarbons, as is shown in Fig. 1. Using the bond moments, 1.65 D, 2.17 D and 1.47 D, derived from the observed dipole moments[1],

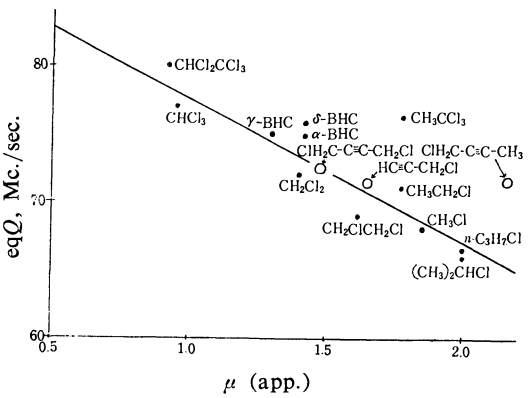

Fig. 1. Relation between eqQ and apparent C–Cl bond moment.

the eqQ constants of the three compounds are plotted on this diagram with white circles. They are in good agreement with the straight-line relation for the saturated hydrocarbons, though in the case of monochlorobutyne-2 a sight discrepancy from the line is apparent. It may be concluded, therefore, that the electronic states of the C–Cl bond in these molecules are nearly the same as those of the halogenated saturated hydrocarbons: the presence of a triple bond in the molecule has no great effect on the local C–Cl bond structure. It should be noted here that recent microwave study of propargyl chloride has confirmed the normal value, 1.78 A, of the C–Cl bond distance of this molecule[6].

SHORT COMMUNICATIONS

Liquid Sulfur Dioxide Catalyzed Polymerization of Styrene Derivatives and Formaldehyde

By Niichiro TOKURA, Minoru MATSUDA, Isoo SHIRAI, Katsuo SHIINA, Yasuo OGAWA and Yasuhiko KONDO

(Received March 27, 1962)

It has been recently shown that liquid sulfur dioxide is an excellent medium for cationic polymerization[1] with Lewis acid as catalyst. Moreover, there have been reported several cases where the polymerizations were carried out only by the medium (sulfur dioxide) without any catalyst[2,3]. Vinyl ethers are known as belonging to this class[3].

The present authors have found some additional monomers which are capable of carrying out such a liquid sulfur dioxide catalyzed polymerization. It has been found by the present authors that alkyl substituted styrenes are easily polymerized by liquid sulfur dioxide itself. Especially, *p*-methylstyrene will be mentioned here as an example. *p*-Methylstyrene, b. p. 58.5°C/12 mmHg, was dissolved in liquid sulfur dioxide with a trace of hydroquinone and allowed to stand at 50°C in a thermostat. The polymer obtained was separated and purified by the usual procedure (precipitation by methanol from benzene solution of the polymer). The product (5.67 wt.% conversion at 90 min.) was an amorphous powder and melted at 159~162°C (Found: C, 91.23; H, 8.58. Calcd. for poly-*p*-methylstyrene: C, 91.47; H, 8.35%, $[\eta]_{\text{dl./g.}}$ (in DMF), 0.04).

That the polymerization is of cationic mechanism is proved by the facts (a) the radical polymerization of the *p*-methylstyrene in liquid sulfur dioxide must result in the formation of of polysulfone[4], (b) the polymerization by sulfur dioxide was inhibited by electron-donors such as dimethylformamide (DMF), dioxane or amine into the mixture and (c) the reaction was not inhibited by hydroquinone or else which were recognized as radical inhibitor. When the monomer was subjected to a condition of a radical polymerization at 50°C with azobisisobutyronitrile (AIBN), as a catalyst, the product obtained was a mixture of poly-*p*-methylstyrene and *p*-methylstyrene polysulfone, the constitution of the latter being *p*-methylstyrene : SO_2 = 2 : 1 in its mole ratio. The polymer melted at 149~151°C. Analysis of the polysulfone, (Found: C, 71.30; H, 6.61; S, 10.23. Calcd. for 2 : 1 polysulfone; C, 72.00; H, 6.67; S, 10.67%, $[\eta]_{\text{dl./g.}}$, (DMF), 0.4).

Thus a cationic polymerization arose competitvely in liquid sulfur dioxide with an AIBN catalyzed radical polymerization. The product produced by the simultaneous cationic and radical polymerization could be separated by the extraction of poly-*p*-methylstyrene with cyclohexane in a Soxhlet apparatus, the yield of the poly-*p*-methylstyrene being 13~15% of the total.

α-Methylstyrene was polymerized readily by liquid sulfur dioxide. However, in contrast to the result of *p*-methylstyrene, an attempted radical polymerization with AIBN was not successful and gave only poly-α-methylstyrene as a result of a cationic polymerization. The detail of the simultaneous polymerization will be reported elesewhere in the near future.

The present authors have also observed that formaldehyde was polymerized by liquid sulfur dioxide or by sulfur dioxide vapor to yield polyoxymethylene. When liquid sulfur dioxide was maintained at a constant temperature between −70 to −10°C and formaldehyde vapor was streamed into this medium, semitransparent films were obtained on the surface of the solution or on the wall of the glass vessel. The films produced at −70°C were colorless and melted at 169~172°C, containing no sulfur atom (Found: C, 39.37; H, 6.37. Calcd. for $(-CH_2O-)_n$: C, 40.0; H, 6.67%). $[\eta]_{\text{dl./g.}}$ (acetylated polymer in *p*-chlorophenol with 2% α-pinene) was 0.6. The infrared spectrum of the specimen was in close resemblance to that of polyformaldehyde prepared by Novak et al.[5], at low temperature. IR, 2990

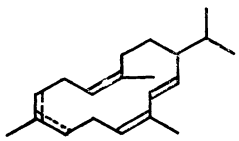
Thunbergene[1], *a Macrocyclic Diterpene**

By Hiroshi KOBAYASHI and Saburo AKIYOSHI



(Received March 29, 1962)

Thunbergene, $C_{20}H_{32}$, m. p. 61°C, $[\alpha]_D$ (benzene) +260°, is a monocyclic diterpene hydrocarbon obtained from several kinds of pine roots. Isolation and some properties of this compound were reported previously by one of the authors (S. A.)[2] and by some other investigators[3-5].

This communication comprises the results of the dehydrogenation and of the ozonolysis of thunbergene, the most probable structure of this interesting compound being proposed.

The dehydrogenation of thunbergene with selenium gave 7-isopropyl-2, 9-dimethylphenanthrene, m. p. 78°C, the picrate melting at 133°C[6] (Found: C, 91.90; H, 8.19. Calcd. for $C_{19}H_{20}$: C, 91.88; H, 8.12%). The structure of the dehydrogenation product was assigned on the basis of the spectroscopic data[7,8] UV λ_{max}^{hexane} 224, 249, 257, 274, 281, 288, 299, 319, 328 and 335 mμ, log ε 4.44, 4.84, 5.00, 4.41, 4.37, 4.19, 4.08, 2.46, 2.40 and 2.45. NMR (in carbon tetrachloride solution with water as an external reference) δ −3.5, −2.5, 3.0 and 4.0 p. p. m., relative intensities 2, 5, 6 and 6 respectively), and was confirmed by infrared spectra and mixed melting point test with an authentic sample synthesized by the standard method from eudalene.

The ozonization at low temperature followed by the oxidative decomposition gave levulinic acid (semicarbazone, m. p. 184°C) and 2-isopropyl-5-oxohexanoic acid, $[\alpha]_D$ ($CHCl_3$) −30° (semicarbazone, m. p. 138~140°C[9]. Found: C, 52.30; H, 8.55; N, 18.14. Calcd. for $C_{10}H_{19}O_3N_3$: C, 52.38; H, 8.35; N, 18.33%). The latter was identified by infrared spectral comparison with a racemic authentic sample. Other fragments on ozonolysis have not been determined yet. As known already, thunbergene has a conjugated diene system which does not undergo the Diels-Alder's addition (UV λ_{max}^{hexane} 240 and 246 mμ, log ε 4.15 both) and octahydrothunbergene is optically inactive. Therefore, the carbon skeleton of thunbergene together with the positions of four double bonds can be reconstructed as shown below with an assistance of the isoprene rule.

According to this formula, thunbergene is hydrogenated to a mixture of eight stereoisomers of octahydrothunbergene; four symmetric isomers and two pairs of enantiomers. The product should be optically inactive as a whole even if the asymmetric center** of thunbergene would be retained.

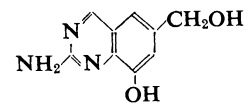
** *Added in proof.*

The absolute configuration at the asymmetric center: (−)-2-isopropyl-5-oxohexanoic acid was oxidized with hypobromite to 2-isopropylglutaric acid, m. p. 94°C, $[\alpha]_D$ −20°, the absolute configuration of which had been confirmed by Fredga (*Acta Chem. Scand.*, **1**, 371 (1947)).



Since the asymmetric center is not affected in the course of degradation, the isopropyl group of thunbergene seems to project up ward from the plane of paper when the ring framework being placed as shown above.

Thunbergene is a hydrocarbon with the fourteen membered macroring. This type of diterpene seems to be very rare. No example could be found in literature. Details will be presented elsewhere in the near future.

Structure of the C_9-Base, an Alkaline Degradation Product of Tetrodotoxin

By Toshio GOTO, Yoshito KISHI and Yoshimasa HIRATA

(Received March 29, 1962)

By alkaline degradation of tetrodotoxin, Kawamura[1] obtained a yellow compound (C_9-base), to which he assigned a molecular formula $C_9H_{11}N_3O_2$ and a partial structure (I). 2-Aminopyrimidine moiety of the structure was rigorously established by isolation of 2-aminopyrimidine-4, 5-dicarboxylic acid from the oxidation products of the C_9-base. Tsuda et al.[2] further assumed that the pyrimidine nucleus would be fused with a five-membered ring containing an enol group. From the results reported, however, an alternate possibility that the C_9-base might be a phenol derivative, instead of the enol, can not be excluded. We wish to present a new structure, 2-amino-6-hydroxymethyl-8-hydroxyquinazoline (II), to the C_9-base from the following evidences.

The analytical value of the C_9-base hydrochloride is rather consistent with the formula of $C_9H_9N_3O_2 \cdot HCl$ (Found: C, 47.86; H, 4.47; N, 18.33, 18.09. Calcd.: C, 47.48; H, 4.42; N, 18.46%)[3]. Since one of the two hydroxyl groups in the C_9-base is alcoholic[1], only possible structure having a phenolic hydroxyl group is 2-amino-x-hydroxymethyl-x'-hydroxyquinazoline. For alkyl substituents would not influence much on the ultraviolet spectra of aromatic compounds, 2-amino-4-methyl-8-hydroxyquinazoline (III) was synthesized to compare its ultraviolet spectrum with that of the C_9-base. The quinazoline III, m. p. over 270°C (in sealed tube), was obtained from 2-nitro-3-hydroxyacetophenone by catalytic hydrogenation to 2-amino derivative, m. p. 165~168°C, and then by condensation with cyanamide. Ultraviolet spectra of the synthetic quinazoline III in different pH's almost superimposable, except for slightly hypsochromic shifts of 2~5 mμ, with those of the

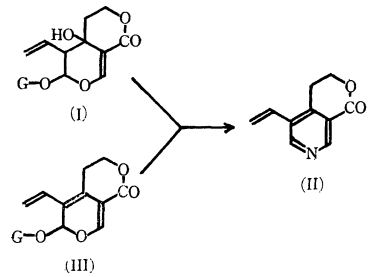
2) K. Tsuda, M. Kawamura and R. Hayatsu, 3rd Symposium of Natural Products, Japan, October, 1959.
3) Analyses of the all derivatives of the C_9-base reported[1] are consistent with this formula.

C_9-base (Fig. 1). It is, therefore, quite reasonable to assume that the C_9-base has a 2-amino-8-hydroxyquinazoline skeleton[4].

NMR spectrum of the C_9-base shows four signals (all singlet) at +26, −48, −65, −113 c. p. s.[5] (area ratio ca. 2 : 1 : 1 : 1), which are assigned to two protons in $-CH_2O-$, two in benzene ring (two signals), and one attached at C_4-position, respectively. Since no coupling is observed between their signals, two aromatic protons are not in adjacent position. Thus the hydroxymethyl group must be attached to the C_6-position. NMR spectrum of the triacetate[1] of C_9-base possesses the following signals which are also consistent with the structure assigned: (τ-values) 8.00 (NH); 7.80, 7.50, 7.30 (three acetyl groups); 4.70 ($-CH_2O-$); 2.40, 2.25 (arom.); 0.68 (proton at C_4); all signals are singlets[6].



The authors wish to thank Fujisawa Pharmaceutical Co., Ltd. for collecting ovaries of swellfish and to express appreciation to the Public Health Service, National Institutes of Health, for support of this work under Research Grant RG-7969.

4) 2-Amino-4-methyl-6-hydroxyquinazoline was also synthesized, but its UV spectrum ($\lambda_{max}^{H_2O}$ 233 mμ; $\lambda_{max}^{0.1N\ NaOH}$ 245 mμ) was quite different from that of the C_9-base.

5) Spectra were taken on a Nihondensi JM (40 Mc) spectrometer using D_2O containing NaOD as solvent, and a signal of DOH as an internal reference (0 c. p. s.).

6) Using $CDCl_3$ as solvent and tetramethylsilane as an internal reference (τ = 10).

G = glucose

reaction was applicable to gentiopicrin[3] (III) also. A solution of gentiopicrin (178 mg.) in ethanol was saturated with ammonia and allowed to stand overnight. The solvent was removed and 1 N hydrochloric acid (20 ml.) was added. The solution was then heated under reflux for 30 min. The acidic solution was made alkaline with ammonium hydroxide and extracted with chloroform. The resinous product (50 mg.) was adsorbed on a silica gel column and eluted with acetone-chloroform (1 : 9). Recrystallization from petroleum ether gave colorless needles (19 mg.), m. p. 83~84°C. This substance was found to be identical with gentianin (II) (mixed melting point and infrared absorption spectrum).

Isolation and Characterization of Lunamycin, an Antitumoric Substance from Lampteromyces japonicus

By Haruhisa SHIRAHAMA, Yohei FUKUOKA and Takeshi MATSUMOTO

(Received March 24, 1962)

Lampteromyces japonicus (tsukiyotake) has long been well known in Japan as a poisonous mushroom. However, untill recently, the nature of the active principle has attracted

only little attention. In 1958, Nakai[1] concentrated a toxic material from this fungus and studied its pharmacological action, but could not obtain the toxin in a pure state. More recently, the active constituent of the mushroom has come to attract growing interest, since Komatsu and his coworkers[2] demonstrated a remarkable effect of extracts of the mushroom antagonistic to Ehrlich ascites carcinoma.

The writers wish to report the isolation of an active principle which exhibits antitumoric as well as toxic action[3], $C_{15}H_{22}O_4$, for which the name "Lunamycin" is suggested. Lunamycin was obtained in about 10^{-4}% yield from fresh mushrooms by careful, repeated chromatography through alumina of the ethyl acetate soluble, neutral part of the mushroom as a prismatic crystal, m. p. 122~124°C (Found: C, 67.78; H, 8.20; mol. wt. (micro Rast), 280. Calcd. for $C_{15}H_{22}O_4$: C, 67.64; H, 8.33%; mol. wt. 266. UV spectrum; λ_{max}^{EtOH} 235 mμ (log ε; 4.1), 325 mμ (log ε; 3.5). IR bands at 3500, 3400, 3280, 1692, 1660, 1602, 1107, 1026 cm^{-1}). Treatment of lunamycin with acetic anhydride and pyridine gave a diacetate, m. p. 98~99°C (Found: C, 65.38; H, 7.09; Calcd. for $C_{19}H_{26}O_6$; C, 65.12; H, 7.48%. UV spectrum; λ_{max}^{EtOH} 227 mμ (log ε; 4.1), 317 mμ (log ε; 3.5). IR bands at 3480, 1730, 1695, 1650, 1605, 1230, 1110, 1035 cm^{-1}). Thus lunamycin seems to have one conjugated carbonyl, two acylable hydroxyl and one hindered or tertiary hydroxyl groups. In certain cases a crystal $C_{15}H_{20}O_4$, m. p. 179~181°C (Found: C, 67.84; H, 7.28; mol. wt. (micro Rast), 281. Calcd. for $C_{15}H_{20}O_4$; C, 68.16; H, 7.63%; mol. wt. 264. UV spectrum; λ_{max}^{EtOH} 248 mμ (log ε; 4.3). IR bands at 3430, 3330, 1685 cm^{-1}) was isolated from a fraction eluted just before the most toxic part. This crystal exhibited rather low toxicity; injection of 26 mg. of sample killed a mouse in three days. The compound gave a triacetate, m. p. 110~111°C (Found: C, 64.68; H, 6.76; Calcd. for $C_{21}H_{26}O_7$: C, 64.60; H, 6.71%. UV spectrum λ_{max}^{EtOH} 253 mμ (log ε; 4.3). IR bands at 1730, 1700, 1240 cm^{-1}) upon treatment with pyridine and acetic anhydride. The details of the procedure for isolation of lunamycin will be reported elsewhere.

2) N. Komatsu, Y. Ogata, S. Nakazawa, I. Yamamoto, M. Hamada, H. Terakawa and T. Yamamoto; Lecture at the 34th Annual Meeting of the Japan Bacteriological Society, April, 1961.

3) Lunamycin kills a mouse in a dosis of 0.6 mg. within 12 hr. Daily administration of 5 γ lunamycin for 4 days completly cures a mouse transplanted with 2.5×10^6 Ehrlich ascites carcinoma cells. The treatment was started one day after the transplantation (private communication from Dr. N. Komatsu).

The authors express their sincere thanks to Drs. Nobuhiko Komatsu, Takehiko Suzuki, Kengo Nakai and Professor Sajiro Makino for tests of biological activity, to Professor Yoshio Ohtani for botanical advice and to Messrs. Shoji Ueno, Hiroshi Yokoyama, Noboru Mikami and Akinori Sugiyama for their great help in collecting and extracting a huge amount of the mushroom.

Added in proof; Professor Koji Nakanishi of Tokyo University of Education also isolated a toxic material lampterol from the same mushroom. The two samples were proved to be identical by comparison of infrared spectra and m. p. s.

Intramolecular Hydrogen Bonding in o-Aryloxybenzoic Acids

By Michinori Ōki and Minoru Hirota

(Received March 7, 1962)

Although many investigators[1-4] reported the infrared spectra of benzoic acids, most of the measurements were restricted to the O–H stretching absorptions. A report by Brooks, Eglintion and Morman[2] is an exception which reports both ν_{O-H} and $\nu_{C=O}$ absorptions and the higher $\nu_{C=O}$ frequencies with the *ortho* substituted acids are mentioned. In the light of the recent observation[5] of the intramolecular hydrogen bonding in aryloxy- and alkoxyacetic acids, it will be interesting to interprete the data of the ν_{O-H} and $\nu_{C=O}$ absorptions with *o*-aryloxybenzoic acids from the stand point of the cis and trans isomerism (Ia, Ib and II) of the carboxyl group.

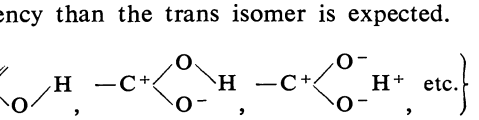
The infrared spectral data* are summarized in Tables I and II. It will be seen that the electronic effect of thes ubstituent is operative to the hydrogen bonding. An electron repelling group at the *para*-position enhances the hydrogen bond formation and causes a larger A_t/A_c ratio, where A_t and A_c represent the integrated intensities due to trans and cis isomers, respectively.



Ia Ib II

In the ν_{O-H} region, the band at the lower frequency (3411~3350 cm^{-1}) is undoubtedly assigned to the trans hydrogen-bonded isomer (II). On the other hand, the assignment of the $\nu_{C=O}$ absorption band is not clearly established and the lower $\nu_{C=O}$ band has been assigned to the trans isomer by several investigators. Quite contrary to the previous assignment, the present authors attribute the higher $\nu_{C=O}$ band (ca. 1752 cm^{-1}) for aryloxybenzoic acids) to the trans isomer from the following reasons.

i) The ratio A_t/A_c increases as the Hammett's σ-constant of the substituent decreases, and this tendency is consistent with the A_t/A_c ratio in the ν_{O-H} region.

ii) Through the intensity measurement at various temperatures with the ν_{O-H} and the $\nu_{C=O}$ bands of o-phenoxybenzoic acid, nearly equal energy difference (ΔH) values (1.90 kcal./mol. with the ν_{O-H} bands and 1.87 kcal./mol. with the $\nu_{C=O}$ bands) for the equilibrium between the cis and the trans isomers were obtained by assuming the assignment in Table II.

iii) Since the resonance forms of the cis isomer illustrated below are possible and the ionic character of the C=O bond may cause the lower C–O bond order, the lower $\nu_{C=O}$ frequency than the trans isomer is expected.

The ultraviolet spectra of these acids were

* The infrared measurement was carried out with a Perkin Elmer 112G spectrophotometer under the condition in which the spectral slit width was less than 1.0 cm^{-1} for the ν_{OH} region and less than 0.7 cm^{-1} for the $\nu_{C=O}$ region. (See Refs. 5 and 6) The samples were dissolved in carbon tetrachloride to make up ca. 0.001 mol./l. solution.

6) M. Ōki and M. Hirota, *Spectrochim. Acta*, **17**, 583 (1961).

also measured and an outstanding hypsochromic shift of B-band[7] was observed when the solvent was changed from heptane to ethanol. (For example, the bands at 287 and 293 mμ of *o*-phenoxybenzoic acid in heptane shift to 274 and 279 mμ.) This phenomenon can be interpreted as support for the existence of an intramolecular hydrogen bonding.

The pH Change with Concentration of Aqueous Solutions of Metal Dodecyl Sulfates

By Ryohei MATUURA, Iwao SATAKE
Ichiro IWAMATSU and Shizuko HOSOKAWA

(Received April 27, 1962)

Lawrence and McDonald[1] reported that the critical micelle concentration (CMC) of aqueous solutions of sodium dodecyl sulfate (SDS) could be determined by pH measurements, showing that the pH vs. concentration curve of SDS solution has a kink point at the CMC. We have made experiments on the concentration dependence of the pH of aqueous solutions of some metal dodecyl sulfates and obtained a result different from theirs for SDS. For some metal dodecyl sulfates, however, for example copper and nickel salts, we have found that the kink point appears in the pH vs. concentration curve at the CMC of each dodecyl sulfate solution.

SDS used in the present experiment was prepared from fractionally distilled pure dodecyl alcohol. It was recrystallized several times from butanol solution and washed with ether for 60 hr. Finally the sample was recrystallized from aqueous solution. Copper dodecyl sulfate tetrahydrate (CuDS) and nickel dodecyl sulfate hexahydrate (NiDS) were prepared from SDS by the method of Lottermoser and Püschel[2]. They were recrystallized several times from aqueous solution. The purity of these samples were confirmed by elementary analysis and surface tension measurements. The pH measurements were performed with a glass electrode pH meter at 25°C. Special precautions were not taken for eliminating carbon dioxide from the solution investigated in order to compare the result with that of Lawrence and McDonald. We suppose, in any way, that the effect of carbon dioxide is not so serious for the solution of anionic detergents as for cationic ones.

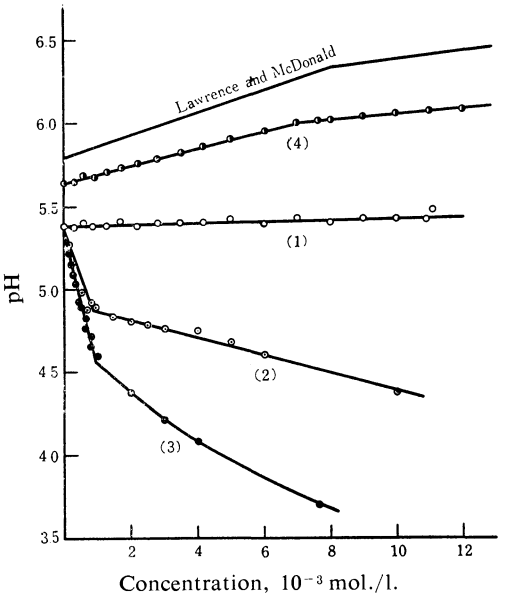

Fig. 1. The pH vs. concentration curves for aqueous solutions of metal dodecyl sulfates.
(1) SDS, (2) CuDS, (3) NiDS, (4) SDS+NaOH ($1:1\times10^{-4}$)

The result is shown in Fig. 1. It is evident that the pH vs. concentration curve for SDS (curve 1) shows no kink point at the CMC ($6\sim8\times10^{-3}$ mol./l.), while the curve for CuDS (curve 2) and for NiDS (curve 3) shows a clear kink at the CMC (both 1×10^{-3} mol./l.[3]). The Lawrence and McDonald's curve for SDS is shown in Fig. 1 for comparison with ours. The difference is remarkable. We do not completely understand the origin of this difference at the present stage, but one reason is supposed to exist in the purity of the sample. We investigated the effect of alkali added to the SDS solution on the pH vs. concentration curve and found that small amounts of alkali

2) A. Lottermoser and F. Püschel, *Kolloid-Z.*, **63**, 175 (1933).

3) S. Miyamoto, This Bulletin, **33**, 375 (1960); I. Satake and R. Matuura, to be published.

caused an appearance of a kink at the CMC of the SDS solution. The curve 4 in Fig. 1 represents this effect. In this case the mole ratio of SDS to sodium hydroxide in the solution was 1 to 1×10^{-4}. It may be inferred that SDS used by Lawrence and McDonald contained alkali as an impurity.

The kink at the CMC of CuDS and NiDS solutions comes undoubtedly from hydrolysis of these detergents. The details of the discussion will be reported in connection with the surface activity of metal dodecyl sulfates in a near future.

Potential vs. Hg/HgO (5 M KOH), V.

Fig. 1. Current-potential curves for a platinum electrode in 5 M KOH. A and B: oxidation curves of an electrochemically pre-reduced Pt electrode at the 1st and 3rd trials respectively from −0.9 to +0.6 V. C: reduction curve of a Pt electrode with some platinum oxides and/or hydroxides on it from +0.5 to −0.9 V.

Evidence for a Series of Redox Couples on the Surface of a Platinum Electrode and their Significance

By Akiya KOZAWA*

(Received March 20, 1962)

A series of redox couples on a platinum electrode was found by a voltammetric method as follows. A platinum electrode (approximately 0.6 cm^2 surface area) was placed in one arm of an H-cell containing 5 M potassium hydroxide solution from which air had been expelled by an inert gas. The counter electrode was Hg/HgO. The potential applied to the platinum electrode against the Hg/HgO electrode was scanned at a rate of 0.3 V. per 100 sec. from −0.9 to +0.6 V. or +0.5 to −0.9 V. and the current flow through the platinum electrode was recorded automatically. In Fig. 1 there are shown two oxidation curves for a pre-reduced platinum electrode and a reduction curve for the platinum electrode at which the oxidation curves had been taken. The presence of many peaks on these curves is evident. These peaks may not be attributed to adsorbed oxygen nor hydrogen as repeated experiments with the same electrode produced identical peaks. Peaks a, b, c, d and e on the oxidation curve may indicate the formation of five kinds of platinum oxides and/or hydroxides. The corresponding reduction peaks a', b', c' and d' can be seen on the reduction curve. The potentials (E_A, E_B, etc. in Fig. 1) between a pair of oxidation and reduction peaks can give approximate redox potentials for the redox couples. This has been verified of known redox couples such as $Ni \rightleftharpoons Ni(OH)_2$ and $Ni(OH)_2 \rightleftharpoons NiO_2$. The same experiments at a platinum electrode in 0.05 M potassium hydroxide showed also four to five peaks. The standard redox potentials in alkaline solution for the redox couples on the platinum surface were obtained from the values E_A, E_B, E_C, E_D and E_E in 5 M and 0.05 M potassium hydroxide by making correction for OH^- activity and were −0.67, −0.54, −0.25, +0.05 and (+0.3$_9$) V. vs. N. H. E. respectively.

A platinum electrode has been used to measure redox potential in solution. It is well known that the potential of a platinum electrode placed in a solution containing a redox system follows the Nernst equation. It was assumed that the platinum electrode was inert and served only as a means of transferring electrons. The present finding of a series of oxidation-reduction couples on the surface of a platinum electrode suggests a new interpretation for the behavior of a platinum electrode. When a platinum electrode is placed into a solution containing a redox system, the surface redox couples, which are probably composed of platinum oxides and/or hydroxides, are reduced or oxidized to the redox potential of the system, and the platinum electrode exhibits exactly the redox potential of the system in the solution. As the standard potentials of

* Present address: Department of Chemistry, Western Reserve University, Cleveland 6, Ohio, U. S. A.

the five redox couples on the platinum surface are well distributed between the potentials of hydrogen and oxygen evolution, the potential of the platinum electrode can be kept stable at any potential depending on the redox system involved. Platinum thus can not be considered as an inert electrode as has been traditionally assumed, but rather as an active metal. Recently, existence of oxide film[1] on platinum electrodes and their important role in various electrode reactions at platinum electrode have been reported[2-5] but the redox character of these oxide films was not made clear. In addition to the new interpretation which these redox couples on platinum can give to the behavior of so-called "inert platinum electrodes", these redox couples may play an important role in the explanation of the catalytic activity of platinum in various chemical reactions.

Physico-chemical Studies on the Complex of Metals. I. Thermometric Studies on the Composition of Manganese Arsenate Complexes

By Mahendra Singh BHADRAVER and Jifendra Nath GAUR

(Received June 10, 1960)

The composition of so-called manganese arsenate has been studied by the thermometric method involving the thermometric titrations between $MnCl_2 \cdot 4H_2O$ and disodium hydrogen arsenate in aqueous and alcoholic medium. The direct titration curves suggest the formation of $MnHAsO_4$, $MnNa_2(HAsO_4)_2$, and in reverse titrations the formation of $MnHAsO_4$ (ratio of Mn : As is 1 : 1) is indicated. The results of this investigation support the formation of $MnHAsO_4$.

Referance in literature about the elaborate study of the composition of manganese arsenate is scarcely available. Coloriano[1] prepared chestnut brown needles of manganese ortho-arsenate $Mn_3(AsO_4)_2 \cdot H_2O$ by heating sodium ortho-arsenate with an excess of manganese sulfate in a sealed tube at 175°C. Scheele[2] treated manganese salt with alkali-hydro-arsenate and obtained a white gelatinous precipitate, which according to J. H. Debray became crystals when digested for a long time in the mother liquor. Rose[3] said that the precipitate was a mixture of sodium-manganese-ortho-arsenate and manganese-hydro-arsenate $MnHAsO_4 \cdot H_2O$. The monohydrate of the hydro-arsenate, $MnHAsO_4 \cdot H_2O$ was obtained from solutions containing MnO and As_2O_5 in the ratio of 3 : 1 by precipitation with alcoholic solution of arseneous acid. The salt is stable in water at 25°C. Schiefer[4] reported that $Mn(H_2AsO_4)_2$ was obtained from a solution of $MnCO_3$ in theoretical quantity of arseneous acid. Amadori[5] found that $Mn(H_2AsO_4)_2 \cdot H_2O$ was deposited from a solution containing excess of arseneous acid. The composition of manganese arsenate should correspond to the formula $MnHAsO_4$ when manganese chloride is added to disodium hydrogen arsenate. Apart from the above study a number of variable and more complex formula have been reported in literature, e. g., $Mn(H_2AsO_4)_2H_3AsO_4$, $Mn_2As_2O_7$ (Otto), $Mn_5 \cdot As_4O_7 \cdot 2H_2O$ or $Mn_5H_2(AsO_4)_4 \cdot H_2O$ (Coloriano), $MnAsO_4 \cdot H_2O$ (Christensen[6]).

Takahasi and Sasaki[7] during the course of phase rule study of MnO-As_2O_5-H_2O system and heat of formation of $MnHAsO_4$ showed the existence of $Mn_3(AsO_4)_2 \cdot H_2O$, $MnHAsO_4 \cdot H_2O$, $Mn(H_2AsO_4)_2$ and $Mn(H_2AsO_4) \cdot 2H_3AsO_4$. Reference in literature about the study of these complexes by applying other physico-chemical methods i. e., conductometric, potentiometric and thermometric, etc. is scarcely available. In view of the difficulties associated with the analytical work and in the absence of any decisive views on the composition of manganese-arsenate complexes, it was considered worthwhile to undertake the study of these complexes by physico-chemical methods.

With the results of potentiometric, conductometric and amperometric measurements in progress, the results of thermometric titrations are incorporated and discussed in this paper.

Experimental

A.R.E.D.H reagents were used. Solutions of $MnCl_2 \cdot 4H_2O$ and Na_2HAsO_4 were prepared by weighing and the strength of $MnCl_2 \cdot 4H_2O$ was further cheked by estimating manganese as manganese pyrophosphate, Na_2HAsO_4 solution was standardized against sodium thiosulfate of known strength.

The arrangements for the thermometric titrations were the same described by Haldar[9]. Using different concentrations of the two salts in solution, the direct and reverse titrations (i. e., when manganese chloride solution from micro-burette was added to Na_2HAsO_4 solution in the thermos flask and vice versa) were done. Titrations were also carried out in presence of alcohol upto the total concentration of 20% by volume. The conditions for the experiments for the various titrations were maintained the same. The total rise in temperature was then plotted against the titre in cc.

Discussion

The possible reaction between manganese chloride and sodium hydrogen arsenate in reverse titrations i. e., when disodium hydrogen

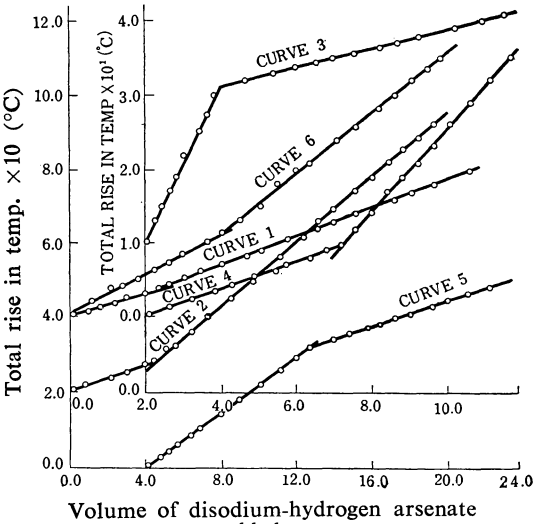

Fig. 2. Reverse thermometric-titrations. Curves 1,2 and 3; M/5 Na_2HAsO_4 and M/40 $MnCl_2$. Curves 4,5 and 3; M/5 Na_2HAO_4 and M/20 $MnCl_2$.

arsenate was added from microburette to manganese chloride contained in thermos flask, can be represented as follows:—

$$Na_2HAsO_4 + MnCl_2 = 2\,NaCl + MnHAsO_4$$

In case of direct titrations the mechanism may be explained as follows:—

$$MnCl_2 + 2\,Na_2HAsO_4 = 2NaCl + MnNa_2(HAsO_4)_2 \quad (1)$$

$$MnCl_2 + Na_2HAsO_4 = 2NaCl + MnHAsO_4 \quad (2)$$

Considering the strength of the solutions of manganese chloride (M/5) and disodium hydrogen arsenate (M/20 and M/40), the theoretical calculated titre values for 20, 18 and 16 cc. of disodium hydrogen arsenate solution for the direct thermometric titrations are 5.0, 2.5, 4.5, 2.25, 4.0, 2.0, 2.5, 1.25, 2.25, 1.125, 2.0 and 1.0 cc. respectively, which are in fair agreement with the observed values in each case respectively, for the formation of the compounds: $MnHAsO_4$ and $MnNa_2(HAsO_4)_2$ (in direct titrations). The formation of only $MnHAsO_4$ is supported in reverse titrations. The theoretical titre values required for the formation of $MnHAsO_4$ (ratio 1 : 1) in reverse titrations can be calculated accordingly. It is observed that the formation of $MnNa_2(HAsO_4)_2$ in the ratio of $Mn : AsO_4$ as 2 : 1 is not proved in the reverse titrations. It is observed from the curves obtained in direct titrations that only two breaks are observed corresponding to the formation of $MnHAsO_4$ and $MnNa_2 \cdot (HAsO_4)_2$ in the ratio of $Mn : AsO_4$ as 1 : 1 and 1 : 2. The reverse titration curves show only one break at the point of equivalence (the ratio of $Mn : AsO_4$ as 1 : 1).

Potentiometric and conductometric studies on the complexes are in progress and the results will shortly follow.

Infrared Absorption Spectra of Water of Crystallization in Aluminum Sulfate Octodecahydrate Crystals

By Itaru GAMO

(Received January 19, 1961)

The study of the vibrational spectra of hydrated aluminum salts seems to be more attractive than that of most of the hydrated salts of other metals, because the water bands of the former present some peculiar features that are not observable in those of the latter. We meet in particular several bands that are not found in other salts. Among aluminum salts, aluminum chloride hexahydrate has already been subject to several fairly detailed infrared[1,2] and Raman[3] studies.

In the present paper the infrared absorption spectra of aluminum sulfate octodecahydrate are compared with those of aluminum chloride hexahydrate, and their characteristic features are analyzed. Attention is mainly focused on the water bands.

Experimental

Preparation.—Commercial aluminum sulfate octodecahydrate of a guaranteed grade was recrystallized from water.

Measurement.—Spectra were obtained by means of a Perkin-Elmer Infracord spectrophotometer with a rock-salt prism. The potassium bromide disk technique was employed.

Results

The spectra are shown in Fig. 1. In the 3μ region, two strong bands are observed at 3330 and 2940 cm^{-1}. The former can be assigned to the antisymmetric, while the latter can be assigned to the symmetric, O–H stretching mode of a water molecule affected by the aluminum-water coördination and by the hydrogen bonding O–H···O[2]. It is interesting that in hydrated salts usually only one peak is observed in this region, while in the present case there are two clearly-separated bands. They seem to correspond to the one broad band which ranges from 3400 to 2900 cm^{-1} in aluminum chloride hexahydrate.

In the 4 μ region, one weak band is observed at 2460 cm^{-1}. This probably corresponds to the band at 2420 cm^{-1} in aluminum chloride hexahydrate and can be assigned to a combination of the bending and a restricted rotation mode of a ligand water molecule. In the 6μ region, the spectrum shows a band of medium intensity at 1640 cm^{-1}, attributable undoubtedly to the bending mode of water. In the 8$\sim$10μ

region, characteristic bands of inorganic sulfates[4] are observed at 1230, 1190, 1110 and 975 cm^{-1}, all attributable to the stretching vibrations of the sulfate ion and presumably resulting from a distortion of the tetrahedron of the ion caused by some perturbations from outside.

The weak broad band at 920 cm^{-1} can be assigned, from its position and shape, to a restricted rotation mode of water. It is probably due to the rotation of a water molecule about the axis of the smallest moment of inertia (wagging vibration). Similarly, the very broad band at 690 cm^{-1} can be assigned to another restricted rotation, that is, the twisting or the rocking vibration. Since the twisting band is too weak to be observed in ice and in other cases, it seems reasonable to attribute this band to the rocking vibration (rotation about the axis of the greatest moment of inertia). Of course, the difference between the binding states of the water molecules in aluminum salts and in ice must be taken into account; the latter is free from coördination. Judging from its very broad shape, one cannot assign this band to the bending vibration of the sulfate ion (613 cm^{-1} in solution[5]). The very weak band at 1390 cm^{-1} can be tentatively assigned to the first overtone of this band.

Table I summarizes these results.

TABLE I. OBSERVED FREQUENCIES OF $Al_2(SO_4)_3 \cdot 18H_2O$[a]

Wave number, cm^{-1}		Assignment
3330	s	$\nu_3(H_2O)$ antisym. stretch.
2940	s	$\nu_1(H_2O)$ sym. stretch.
2460	w	$\nu_2+\nu_{R'}(H_2O)$
1640	m	$\nu_2(H_2O)$ bend.
1390	vw	$2\nu_{R''}(H_2O)$
1230	w shoulder	$\nu_3(SO_4)$ triply degenerate stretch.
1190	w shoulder	$\nu_3(SO_4)$ triply degenerate stretch.
1100	vs	$\nu_3(SO_4)$ triply degenerate stretch.
975	w	$\nu_1(SO_4)$ totally sym. stretch.
920	w, b	$\nu_{R'}(H_2O)$ wag.
690	m, vb	$\nu_{R''}(H_2O)$ rock.

a) Abbreviations: s, strong; m, medium; w, weak; b, broad; v, very.

Discussion

The results obtained above supply some insight into the binding states of the water molecules in the crystal. As in the previous studies[6], the water frequencies will be assumed to be influenced by the coördination and the hydrogen bonding.

The deviations of the two stretching frequencies from the values of the vapor state (3755.8 and 3651.7 cm^{-1}) are reasonable as compared with the usual cases of hydrated salts. It suggests that at least some of the water molecules are coördinated with an aluminum atom, like the six water molecules in aluminum chloride hexahydrate, and that at the same time they form hydrogen bonds with oxygen atoms of other water molecules or sulfate ions. The clear separation of the symmetric stretching band from the antisymmetric one is probably due to its sharpness and strong intensity. The combination band at 2460 cm^{-1} is also much stronger than usual.

The position of the bending band is the same as in aluminum chloride hexahydrate within the range of experimental error. This indicates that in this mode the total effect of aluminum-water coördination and hydrogen

bonding O–H···O is of the same order as in aluminum chloride hexahydrate.

The 920 cm^{-1} wagging frequency is, on the contrary, about 80 cm^{-1} higher than the corresponding one in aluminum chloride hexahydrate. (In a previous paper[2] the bands in the 11~14 μ region were tentatively assigned to the rocking mode, but it seems better to assign them to the wagging vibration for reasons stated in the preceding section.) Therefore, the total effect mentioned above is somewhat greater in aluminum sulfate octodecahydrate. Furthermore, the value, 920 cm^{-1}, is much higher than in the usual cases of inorganic hydrated salts[2]. This leads one to expect a very high frequency also for the rocking mode, since the two modes are likely to be influenced in a similar manner by the two effects. This seems to provide another reason for the assignment which was proposed in the preceding section for the band at 690 cm^{-1}. The rocking frequency is usually under 650 cm^{-1}.

The discussion hitherto has been based on the assignments described in the preceding section. As an alternative, an assumption of the existence of two kinds of water molecules is possible if the bands at 920 and 690 cm^{-1} are assigned to wagging vibrations, and if the bands at 2940 and 3330 cm^{-1} are regarded as due to the corresponding stretching modes. However, the following discussion suggests the invalidity of such an assumption. First, it will be reasonable in this case to suppose that water molecules of the first kind are coördinated with the aluminum atom, while those of the second kind are almost free from such coördination, since coördination lowers the stretching and increases the wagging frequency. On these suppositions one may try to apply to the 3330 cm^{-1} band the relationship proposed by Glemser[7] between the O–H···O distance and the stretching frequency in inorganic hydrated salts. This relationship seems to be correctly applicable to cases where only the hydrogen bonding effect dominates the frequency. In the present case, the 3330 cm^{-1} band is supposed to be due to the stretching mode affected only by this effect. Hence, the application is suitable, giving 2.66 Å for the O–H···O distance. Then, from the band at 690 cm^{-1}, one may try to estimate this distance by applying the relationship obtained in a previous study[2]. It shows the dependence of the wagging frequency* upon the hydrogen bond distance and the metal-water distance[2]. The aluminum-water distance in the present case must be far greater than 1.88 Å (the value in aluminum chloride hexahydrate[8]), because the water molecules are supposed to be almost free from coördination and 1.88 Å is abnormally short, even for coördination distance. Correspondingly, a value far less than 2.66 Å is obtained for the O–H···O distance by the above-mentioned relationship. After all, the two values estimated from the stretching and from the wagging frequency conflict with each other, while in the original assignments they can be reconciled by proper adjustment. These circumstances seem to favor the original assignments.

Lastly, we have been able to observe an overtone and a very strong combination band of water, just as we observed several in the case of aluminum chloride hexahydrate, because of their great intensity. It may be that some connection exists between this fact and the aluminum-water coördination, because the coördination distance in aluminum chloride hexahydrate (1.88 Å) is anomalously shorter than usual.

Summary

The observed spectra of water of crystallization were compared with those of aluminum chloride hexahydrate and interpreted on the basis of the effects of aluminum-water coördination and hydrogen bonding O–H···O. The wagging and the rocking frequency were both much higher than is usual in water of crystallization. It was proposed that this result, together with other peculiarities, may have some connection with the coördination strength between aluminum and water.

Infrared Absorption Spectra of Water of Crystallization in Sodium Sulfate Decahydrate Crystals

By Itaru GAMO

(Received January 19, 1961)

Preceding papers[1] have examined the observed spectra of water of crystallization of various salts as they were affected by the coördination of the water molecule on the metal atom and by the hydrogen bonding between the water molecule and the anion.

For the present study, spectra of sodium sulfate decahydrate were investigated. Attempts were made to interpret the results by the effect of hydrogen bonding only, because no coördination exists between the water molecule and the sodium atom. The spectra suggest the existence of at least two kinds of water molecules in the unit cell of the crystal.

Experimental

Preparations.—Commercial sodium sulfate decahydrate of a guaranteed grade was recrystallized from water. Sodium sulfate, used for the reference spectra, was obtained by keeping this purified sodium sulfate decahydrate at 100°C for 30 min.[2]

Measurements.—Spectra were obtained by means of a Perkin-Elmer Infracord spectrophotometer with a rock-salt prism. For the hydrate, the use of the potassium bromide disk was unsuitable because a large amount of water escaped during the vacuum process, resulting in a considerable weakening of the water bands. Therefore, the Nujol and H.C.B. mull techniques were employed. For the anhydride, however, the potassium bromide disk technique was suitable.

Results

The spectra are given in Fig. 1. (For reference, the spectra of sodium sulfate are also given in the figure.) In the 3μ region, one strong band is observed at 3510 cm^{-1}. Is can be assigned to the O–H stretching mode of a water molecule affected by hydrogen bonding. A weak but relatively sharp band is observed at 2940 cm^{-1}. It disappears upon complete dehydration and therefore must be attributde to a water mode. Probably this is due to a stretching vibration much more strongly influenced by hydrogen bonding than that mentioned above. These two bands are too widely separated to be attributed to the antisymmetric and the symmetric O–H stretching mode respectively of one and the same water molecule. In the 5μ region a very weak but clear band is observed at 2170 cm^{-1}. It also disappears upon dehydration and can be assigned to a combination of the bending and the wagging (probably) vibration of a restricted water molecule. A similar band is observed at 2080 cm^{-1}. It does not disappear by the same treatment and therefore can be attributed to a

combination of the triply degenerate and the totally symmetric stretching mode of the sulfate ion. In the 6 μ region the spectrum shows a band of medium intensity at 1650 cm^{-1}, attributable undoubtedly to the bending mode of a water molecule. The band of medium intensity at 1290 cm^{-1} disappears upon dehydration. Therefore, it must be attributed to a water mode even though its origin cannot be decided at present. Probably it is due to an overtone of some deformation mode or to a combination of deformation modes. The bands at 1180, 1090 and 988 cm^{-1} can be assigned to the stretching vibrations of the sulfate ion, as in the usual cases of sulfates[3]. The band at 720 cm^{-1} overlaps a Nujol band to some extent. It can be assigned from its position to the wagging vibration[1] of that water molecule which is responsible for the 2940 cm^{-1} stretching band. (The reason is explained later).

Table I summarizes these results.

Table I. Observed frequencies of $Na_2SO_4 \cdot 10H_2O$[a]

Wave number, cm^{-1}		Assignment[b]

a) Abbreviations: s, strong; m, medium; w, weak; v, very; b, broad; sh, sharp.
b) H_2O (I) and H_2O (II) denote two different kinds of water molecules in the unit cell respectively.

Discussion

The results obtained in the preceding section supply some insight into the binding states of water molecules in the crystal. Since the water molecules in this crystal do not seem to be affected by the coördination, only the influence of hydrogen bonding will be considered. From this standpoint, at least some of the water molecules must form hydrogen bonds with the oxygen atoms of other water molecules or of sulfate ions. Otherwise, it is impossible to explain the observed deviations in the water stretching frequencies from the values of the vapor state.

The 3510 cm^{-1} stretching frequency, which is considerably higher than the values for the water of crystallization in the usual inorganic salts[1], must be due to water molecules which are relatively free. Water molecules which are much more strongly influenced by hydrogen bonding are probably responsible for the band at 2940 cm^{-1}, since, in general, hydrogen bonding lowers the stretching frequency. By an application of Glemser's relationship between the stretching frequency and the O–H···O distance[4], 3.01 and 2.58 Å are obtained for the first and the second water molecule respectively. These values are comparable with those for ice (2.76 Å[5]) and gypsum (2.82 Å[6]), in both of which the water molecules are also free from coördination.

By the aid of the values thus obtained, the origin of the wagging band at 720 cm^{-1} can be deduced as follows. To begin with, this band may tentatively be assumed to be due to that water molecule which is responsible for the stretching band at 3510 cm^{-1}, the corresponding O–H···O distance being 3.01 Å. A previous study[7] shows roughly the dependence of the wagging frequency upon the metal-water distance and the hydrogen bond distance. It follows from this relationship that in the present case the metal-water distance is far less than 1.80 Å. But the distance cannot be less than 2.27 Å, the sum of the ionic radii of sodium and oxygen, since no water molecule seems to be coördinated with the metal atom, the interaction between them being purely electrostatic. The distance is estimated to be about 2.80 Å when this band is correlated with the stretching band at 2940 cm^{-1}. These circumstances seem to favor the assignment of this band described in the preceding section.

Summary

The observed spectra of water of crystallization were interpreted on the basis of the effect of hydrogen bonding. It was proposed that at least two kinds of water molecules exist in the unit cell of the crystal. The corresponding two O–H···O distances were roughly estimated to be 3.01 and 2.58 Å respectively by the use of Glemser's relationship between the stretching frequency and the hydrogen bond distance.

On the Basicities of the Nitro-derivatives of Benzoanthrones

By Takashi HANDA

(Received February 25, 1961)

Benzene is considered to be a weak base or electron-donor in relation to bromine and iodine owing to the existence of its π-electrons. Its trinitro-derivative, however, behaves as an acid or electron-acceptor in relation to naphthalene, anthracene and other highly condensed aromatic hydrocarbons. This is a result of the strong electron-accepting power of the nitro-group, which is due to the group's inductive and resonance effect. In the nitro-derivatives of aniline, it is observed that the influence of the substituted nitro-group on the lone-pair electrons of the nitrogen atom of the amino-group reduces its proton-affinity or basicity.

The present author has observed that the influence of electron-donating methyl-groups on the basicities of matrix-benzenes in the methyl-derivatives of aromatic compounds can be explained in terms of the amount of decrease in empirical resonance energies among such complexes as solvated ions and original compounds. The influence can be expressed as $\log(N^*/N)$ with the application of Carter's equation by estimating the number of resonance structures of polarized polymethylbenzene, including polarization on methyl-groups, on the assumption that the resonance structures polarized on methyl-groups possess the same weight or maintain a constant ratio (α) of weights to those polarized in a matrix compound. The details of these studies will be submitted elsewhere[1].

In this paper, the influence of the nitro-group on the decrease in basicity of the carbonyl-oxygen atom of the nitro-derivatives of benzoanthrone is explained with reference to the resonance effect.

Experimental Procedures

The measurement of optical absorption was carried out with a Beckman DU-type spectrophotometer according to the method of Hammett and Dingwall[2]. The observed values satisfied Beer's law considerably well in the range of concentration from 10^{-5} to 10^{-6} mol. per liter.

The applied specimens were synthesized in the manner proposed by M. Shioda of the University of Tokyo.[3] These were recrystallized from *o*-dichlorobenzene and further purified by means of sublimation in vacuo of the order of 10^{-3} mmHg. The solutions were prepared by a dilution method from the standard solution with a definite concentration. The chemical structures of the specimens used in this experiment are shown in Table I.

Results and Discussion

The absorption spectra of mono-nitrobenzoanthrone, di-nitrobenzoanthrone and tri-nitrobenzoanthrone in concentrated sulfuric acid of various acidities are shown in Figs. 2–4. From these spectral curves, the pK-value of each compound is obtained as listed in Table I according to the method of Hammett[2]. The substitution of one nitro-group decreases the basicities of benzoanthrone by the amount of two in a pK unit as shown in Table I.

Similar results were obtained in the nitro-substitution of aniline and also of anthraquinone, as illustrated in the table. In order to explain this decrease in basicity by nitro-substitution from the point of view of the change of empirical resonance energy, in such

a manner as we have used to explain the basicities of hydrocarbons and their related quinones, it is necessary to estimate the number of Keküle resonance structures in the ground-state of the original compound and those in the ground-state of a complex such as solvated ion protonated at its carbonyl-oxygen atoms.

In the preceding papers[1,4], in the explanation of the basicities of polymethylbenzenes as measured by McCanlay, et al.[6], we estimated structure I due to the resonance in the matrix and structure II due to the resonance of the polarized methyl-group, as shown in Fig. 5 in the previous report[4], equally or with a definite ratio of weights, for the purpose of making a rough estimation of the number of resonance structures, explaining the contribution of methyl-groups to basicity as a change in empirical resonance energy with the use of Carter's empirical equation.

In the case of nitro-derivatives of benzoanthrone, structures I and II are the principal structures, where it is estimated that II possesses a weight equal to that of I, or where the weight of I is in a definite ratio to that of II

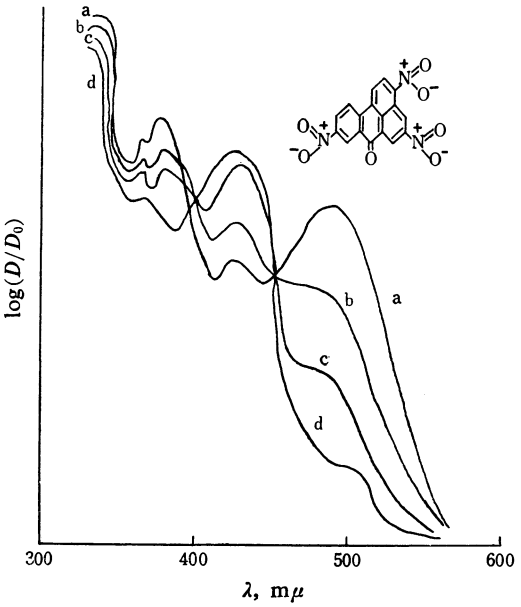

Fig. 4. The spectral response curves of trinitrobenzoanthrone in 100% (a), 95% (b), 90% (c), and 85% (d) sulfuric acid.

in nitrobenzoanthrone, though that ratio may in fact be considerably small.

As for the structures of the protonated nitrobenzoanthrone, structures III and IV belong to the localized non-bonding part, as in the case of the quinones[1,4]*, and structures V and VI belong to the dative part of that complex. The contribution of the VI structures with a double charge in the same molecule may be very small.

In the same manner, for protonated dinitro- and trinitrobenzoanthrone, we assume the contribution of various structures to the resonance energy. Structures X, XI and XII, with weights equal or in a definite ratio (α) to those the former group, are the principal structures belonging to the non-bonding part of the complex, and XV, XVI and XVII are the structures of trinitrobenzoanthrone. Structures XIII and XIV, with weights equal or in a definite ratio (α) to that of XIII, are also principal factors in the dative part of the complexes in the ground-state, while XIX and XX are such factors for trinitrobenzoanthrones.

Therefore, as was explained in the previous reports[1,4], Eq. 1 is derived approximately for the nitro-derivatves of benzoanthrone:

$$\Delta H_G \fallingdotseq \Delta R_G + C' \fallingdotseq R_2 - R_1 + C' = C_0 + C_2^2(R_H^+ - R)\ ^{4)} \quad (1)$$

or $$\Delta R_G \fallingdotseq C + 69\beta^2 \log N_D/N\ ^{1)} \text{ kcal./mol.}$$

where R_H^+ and R represent the resonance energies of the protonated ion and the original compound, and C_2 is the coefficient of the wave function expressing the dative part in the ground-state of the complex-ion. ΔR_G is the change in empirical resonance energy in the ground-state as a result of complex-formation, and β^2 and N_D are the coefficients of the wave function expressing the dipole-oriented state and the number of the resonance structures in this state respectively. The meaning of R_H^+ is taken to be the same in this case as in that of R_D.

In estimating the resonace energy of the nitro-derivatives of benzoanthrone, when we assume that the contribution from the nitro-group (an) can be included in the estimation independently from that of the matrix polarized by the resonance of the charge of the nitro-group, it is expressed in terms of Eq. 2, as was described by Carter for hydrocarbons:

$$R = a_0 + an + bD + c \log N \quad (2)$$

where a_0, a, b and c are constants, n is the number of nitro-groups, D is the number of double bonds, and N is the number of Keküle resonance structures, which are explained above.

When we take α as 1.0**, pK may be plotted versus log (N^*/N) lineary in Fig. 1, as well as in the case of nitroanthraquinones. By the application of Eq. 2, we can roughly estimate the weights of the dipole-oriented structure in the ground-state of the complex from the gradient observed in Fig. 1.

Thus, we are able to explain the decrease in the basicities of benzoanthrone by the nitro-substitution from the resonance effect of the nitro-groups.

When we plot the pK values of the chloro-derivatives of benzoanthrone versus log(N^*/N),

* Basicity which corresponds to the change in the total energy in the ground-state, ΔH_G, between the complex and its matrix is estimated as follows; assuming the term $T\Delta S$ to be constant for a series of compounds:

$$\Delta H_G = C + 69b^2\{\log(N_{Ip}/N) - \beta^2 \log(N_D/N)\} + 69\beta^2 \log(N_D/N) \quad (3)$$

where N_{Ip} is the number of cannonical resonance structures in the ionized-state, N_D is that of those in the dipolar excited state, and b and β are the coefficients of the wave-function expressing the dative part of the ground-state of the complex and the dipole oriented-states respectively. The energy of the dipole-oriented state W_{00} is assumed to be as follows:

$$W_{00} = \alpha^2 W_0 + \beta^2 W_{01} \quad (4)$$

where W_0 is the energy of the original hydrocarbons in the ground-state and W_{01} is that of the perturbed dipole-oriented state. This relation is discussed in detail in another report[1]. In the case of proton-complexes which existed as solvated ions (σ-from), the term $b^2\{\log(N_{Ip}/N) - \beta^2 \log(N_D/N)\}$ becomes very small owing to the greatly increased values of β^2 in strongly acidic media, as compared to the second term in Eq. 3, $69\beta^2 \log(N_D/N)$.

** The real value of α can be estimated by comparing the empirical resonance energies of this series of nitro-compounds with the gradient of 69 kcal./mol. in Carter's equation.

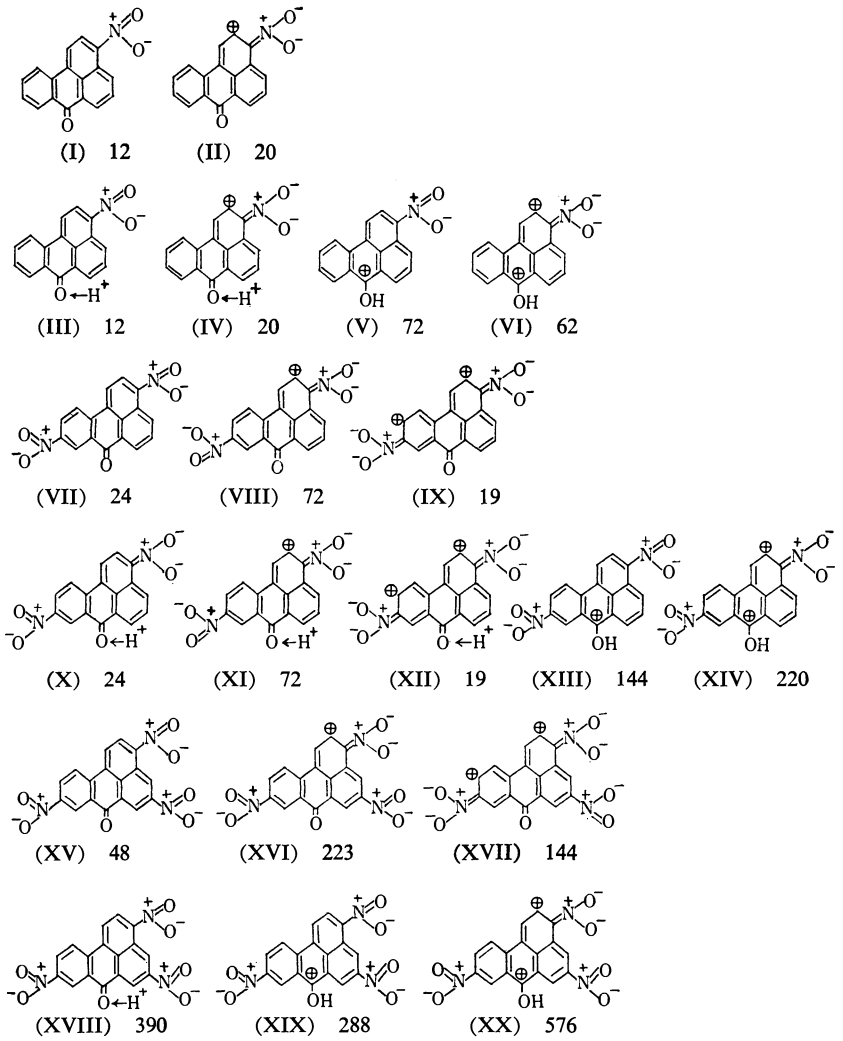

Fig. 5. The resonance srtuctures of nitrobenzoanthrone derivatives.

values which are estimated formally as in the case of nitrobenzoanthrones, they correspond with $\log(N^*/N)$ approximately linearly. In this case, the gradient of the line is smaller than that in the case of the nitro-derivatives. This means that the contribution of the polarized structure in the ground-state is larger in the case of nitro-derivatives than in the case of chloro-derivatives.

Summary

The basicities of the nitro-substituted benzoanthrones were measured. One nitro-substitution decreases the basicity of beazoanthrone by about two pK units, as in the case of nitro-substituted aniline and anthraquinone. This is explained qualitatively not by the inductive effect but by the resonance effect of the nitro groups on the carbonyl group of benzoanthrone in such way as to estimate approximately the change of resonance energies in the cases of both hydrocarbons and their related quinones. The gradient of the straight line of pK plotted versus $\log(N^*/N)$ in the case of nitro-substitution is greater than in the case of chloro-substitution. This means that the contribution of the polarized structure in the ground state to resonance effect is greater in the case of the nitro-derivatives of benzoanthrone than in the case of the chloro-derivatives.

The anthor wishes to extend his hearty thanks to Professor Hideo Akamatu for his kind guidance throughout this study, and to Dr. Hiroo Inokuchi, Dr. Yoshio Matsunaga, and Mr. Hidetsuru Matsushita for their kind advice.

Chain Transfer to Telomer[1]. *II. In the Case of Catalyzed β-Polymerization*

By Seizo OKAMURA and Keizo KATAGIRI

(Received March 15, 1961)

In the previous report[1] the transfer constants of telomer prepared by the thermal polymerization of styrene in a carbon tetrachloride solution were determined in the thermal β-polymerization[2] of styrene as $C_M=2\times10^{-4}$ and $KC_E=4\times10^{-2}$ (at 100°C) by the method previously suggested by Schulz et al.[3], where C_M and KC_E are the chain transfer constants belonging respectively to the middle part and to the end along the telomer chain. However, at a high rate of conversion of monomer, C_M and KC_E values were lower than the above values. In other words, a somewhat greater degree of polymerization was obtained than that at the lower conversion rate. The present investigation is concerned with this problem.

Moveover, the present report treats the effect of the presence of a catalyst on the apparent degree of polymerization. The contribution of a catalyst in β-polymerization has not been discussed by any other investigators but Hayes[4], who observed the graft efficiency in the emulsion polymerization. Such an observation appears to be a more logical consequence of the chain transfer reaction of a catalyst radical with the α-polymer competing with the usual initiation reaction. Although his findings can not be applied directly to the present homogeneous polymerization, in order to examine the effect of such a catalyst chain transfer reaction experimentally, the following experiments were carried out by polymerizing styrene in the presence of azobisisobutyronitrile (AIBN) as a catalyst and telomer as a α-polymer. The experimental conditions differed from those of the previous report only in the addition of 1 ml. of the catalyst solution to the mixture of styrene (5 ml.) and α-polymer in β-polymerization.

Experimental

Materials.—Styrene was purified by washing it with alkali and water to remove the inhibitor, drying it with calcium chloride, and distilling it twice under reduced pressure. G. R. grade benzene and carbon tetrachloride were distilled before use.

α-Polymer was prepared by uncatalyzed styrene-carbon tetrachloride polymerization at 100°C. Ampoules were thoroughly cleaned with chromic acid, washed with water and then with steam, and dried. α-Polymer was precipitated with methyl alcohol and dried.

The degree of polymerization of β-polymer, P_β, was determined from the relation of $P_n=K[\eta]^a$, (where P_n indicates the degree of polymerization, $[\eta]$, the intrinsic viscosity, and K and a are constants)[5]. The viscosity measurements were done in a benzene solution at 30°C. The fractionation of α-polymer (telomer) was not carried out for the reason stated previously[1].

Procedures.—The catalyst solution consists of AIBN 0.1623 g. in benzene 100 ml. Mixtures of 5 ml. of styrene, various amounts of telomer, and 1 ml. of the catalyst solution were taken in the ampoules, frozen in dry ice, evacuated and sealed. The polymerizing temperature is 100°C, and its time, 1 hr. and 20 min. As the concentrations of the catalyst were in the range of from 1.56 to 1.67×10^{-3} mol./l. in all the experiments, the largest difference in the overall rates between minimum and maximum concentrations of the catalyst is still with in the range of experimental error. Total polymers were precipitated with methyl alcohol and dried.

The total polymer obtained by the above procedures was weighed. (This gives $W+W_\alpha$ according to a definition proposed below.)

The intrinsic viscosities for the total polymer were measured in a benzene solution at 30°C by the use of an Ostwald viscometer.

Results

The experimental results are summarized in Table I, in which the intrinsic viscosity of β-polymer, $[\eta]_\beta$, freshly produced in the presence of α-polymer, was calculated from the relation between the intrinsic viscosities of α-polymer, $[\eta]_\alpha$, and that of the total polymer, $[\bar{\eta}]$, which is expressed by the equation

$$[\bar{\eta}]=W_\alpha[\eta]_\alpha+W_\beta[\eta]_\beta \qquad (1)$$

where, W_α and W_β are the weight fractions of α- and β-polymers respectively. At this

time the weight fraction of monomer converted, W, is conveniently assumed to be equal to W_β. The values of $[\eta]_\beta$ calculated above will be discussed later on the basis of a consideration of a less abbreviated equation than Eq. 1,

A plot of $1/P_\beta$ against the ratio of the concentration of α-polymer to that of monomer [Poly]/[M] is presented in Fig. 1 with the aid of the data shown in Table I. In the present report, P_β was not corrected for the small change in the rate of polymerization, because of that changes small effect on P_β.

In the previous report the acceleration of the rate at the high concentration and at the high degree of α-polymer was explained by the gelation effect, but this is not true in the present case because of the addition of benzene to the polymerizing system.

Discussion

By comparing our present findings with the previous results, the conversion of monomer in the present experiment is found to be present to the extent given in the previous report. In both cases, W is comparable with W_α. Although in the present reports P_β is lowered by the addition of catalyst, the limiting condition of $[\eta]_\alpha \ll [\eta]_\beta$ holds. As the gelation effect is not observed at present, the very confused features revealed in Fig. 1 seem to come from the presence of a catalyst. Therefore, it seems that the catalyst plays an important role through the reaction discussed below.

An inactive compound X and a telomer radical T·, which afterward becomes a block polymer, are produced as a consequence of the polymer transfer reaction of the radical R· produced from AIBN or a polymer radical M_n· with a telomer T shown below, with the reaction containing β-polymer:

$$R\cdot \text{ (and } M_n\cdot) + T \rightarrow X + T\cdot$$

$$R\cdot \text{ (and } M_n\cdot) + \beta\text{-Polymer} \rightarrow X + \beta\text{-Polymer radical (Catalyzed } \beta\text{-polymer)}$$

The amount of block polymer increases more in the catalyzed β-polymerization than in the thermal polymerization, where the polymer transfer reaction occurs only by:

$$M_n\cdot + T \rightarrow M_n + T\cdot$$

$$M_n\cdot + \beta\text{-Polymer} \rightarrow X + \beta\text{-Polymer radical (Thermal } \beta\text{-polymer)}$$

where M_n is the dead polymer containing n monomer units. The above discussion is also supported by the finding of Henrici-Olivé and Olivé[6] that the ratio of rate constants (k_{tri}/k_{st}) of the following reactions is about 10^{-1}:

$$R\cdot + M \rightarrow k_{st}$$

$$R\cdot + \text{Polystyrene} \rightarrow k_{tri}$$

The above reactions containing catalyst radicals are considered to make W_B and $W_{\beta\beta}$ larger than in the absence of a catalyst, where W_B and $W_{\beta\beta}$ are the weight fractions of the block polymer and the branched β-polymer which is produced from the reaction of β-polymer with the growing or catalyst radicals respectively. Thus, with the same extent of conversion, W_B and $W_{\beta\beta}$ are comparatively larger than those obtained in the previous report.

Accordingly, Eq. 1 used in the calcution of P_β in Table I becomes inadequate when applied to the present case, in which a large amount of block and branched polymer are produced. One must return to the unabbreviated form[1], i. e., to Eq. 2.

If Z is defined by $2[\eta]_\alpha[\eta]_\beta/([\eta]_\alpha + [\eta]_\beta)$ and $[\eta]_{\beta\beta}$ is the intrinsic viscosity of the branched β-polymer, one obtains:

$$[\bar{\eta}] = W_\alpha[\eta]_\alpha + (W - W_{\beta\beta})[\eta]_\beta + W_B Z + W_{\beta\beta}[\eta]_{\beta\beta} \quad (2)$$

And if $[\eta]_{\beta\beta}$ is assumed to be approximately equal to $2[\eta]_\beta$, Eq. 3 can be derived:

$$[\bar{\eta}] = W_\alpha[\eta]_\alpha + W[\eta]_\beta + W_B Z + W_{\beta\beta}[\eta]_\beta \quad (3)$$

It can be seen that the $[\eta]_\beta$ value in Eq. 3 increases if $W_\beta Z + W_{\beta\beta}[\eta]_\beta$ is neglected. By the use of C_M and KC_E values obtained in the previous report, the actual $[\eta]_\beta$ value, which is, for the sake of convenience, defined as $[\eta]_\beta'$ in Table II, is calculated when it is

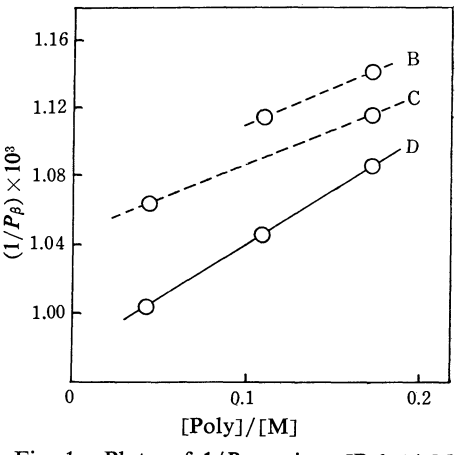

Fig. 1. Plots of $1/P_\beta$ against [Poly]/[M] indexes are to be referred to Table I.

D3		0.602	0.037

P_α, the degree of α-polymer is calculated by the following equation[7],

$$P_\alpha=(2-x)[M]_0/2C_s[S]_0$$

where $[M]_0$: the initial concentration of monomer
$[S]_0$: the initial concentration of solvent
C_s: the chain transfer constant of solvent
x: the conversion ratio of monomer to polymer

assumed that the intercept of each line at [Poly]/[M] $=0$ in Fig. 1 remains constant. The $W_BZ+W_{\beta\beta}[\eta]_\beta$ value may also be calculated as shown in Table II, which shows that the value increases with the increase in [Poly]/[M] and as it moves from the B to the D group; the somewhat greater degree of polymerization at a high rate of conversion in the previous paper can be explained from the same discussion even for uncatalyzed β-polymerization.

Although $W_{\beta\beta}$ and W_B are not obtainable separately by the present treatment, the kinetical attempt of using the considerable elementary reactions was suggested in the styrene-carbon tetrachloride polymerization[7].

It may be concluded that $W_{\beta\beta}$ and W_B are increased by the reactions between a catalyst radical and a telomer or a β-polymer under the same experimental conditions as those of the previous report except for the presence of a catalyst. Therefore, the apparent degrees of polymerization of β-polymer larger than they actually are.

Summary

Catalyzed styrene polymerization in the presence of azobisisobutyronitrile and telomer has been carried out to investigate the effects of the conversion of monomer and of the addition of catalyst on the degree of polymerization of polymer under the same conditions as in the previous report.

The apparent degree of polymerization of polymer was obtained as a rather larger value than expected. This situation is qualitatively explained by the reactions of a catalyst fragment radical with telomer and with polymer freshly produced.

The authors wish to thank Professor Ichiro Sakurada and Professor Kenichi Fukui for their kind advice, and Professor G. V. Schulz for his valuable discussion.

This report is a part of K. Katagiri's doctorate thesis for Kyoto University.

Thermodynamical Studies on Binary Systems Consisting of Polar and Non-polar Liquids. VI. Refined Calculation of the Electrostatic Part of van Laar Coefficients and Comparison with the Experimental Results

By Kazuo AMAYA

(Received June 13, 1961)

In a previous paper, the electrostatic parts of the heat mixing polar and non-polar liquids were calculated on the assumptions that the polar molecule was a sphere with isotropic polarizability and that the dipole was located at the center of the sphere. The comparison of these results with those of the experiment for the group of systems containing non-aromatic non-polar liquid showed qualitative agreements. However quantitative agreements were poor, especially for systems containing polar liquid with a large dipole moment.

To ascertain the reason for these poor quantitative agreements, the electrostatic parts of the van Laar coefficients were calculated for two cases, one where the polar molecule was spherical with anisotropic polarizability and the other where it was an ellipsoid with anisotropic polarizability. The dipole was not located at the center of the ellipsoid. These results were compared with the experimental results.

The Effect of the Anisotropy of the Polar Molecule

First, the effect due only to the anisotropy of the polar molecule will be examined by assuming a spherical molecule. In the previous paper[1], the polarizability of the molecule was assumed to be isotropic, and in the subsequent calculations approximate values of the mean polarizability derived from the refractive index of liquids for the sodium D line were used. However, the reaction field of the surrounding medium is always in a direction parallel to the axis of the dipole; therefore, strictly speaking, the polarizability α in the previous paper[1] should be replaced by α_1 polarizability, parallel to the axis of the dipole, if the anisotropy of the polar molecule is to be taken into consideration.

Actual polar molecules are more or less anisotropic; this effect may be significant for the derivatives of benzene or for those molecules having many anisotropic polar groups, such as C≡N. Mean polarizability $\bar{\alpha}$ is defined as

$$\bar{\alpha}=\frac{1}{3}(\alpha_1+\alpha_2+\alpha_3) \qquad (1)$$

where α_1, α_2 and α_3 are the polarizabilities along each of three principal axes.

Table I. Polarizability of polar molecules in unit of 10^{-25} cc./mol.

Substance	α_1	α_2	α_3
Chlorobenzene	155.1	138.2	74.2
Bromobenzene	168.4	121.3	95.6
Benzonitrile	163.8	121.1	84.9
Nitrobenzene	171.6	141.9	74.1
Diethylketone	100.1	126.4	71.5

The values of α_1, α_2 and α_3 for some of the above polar molecules are taken from the literature and are reproduced in Table I, where α_1 is the polarizability along the direction of the dipole and α_2 and α_3 are those perpendicular to the direction of the dipole.

In the same table, the $n_{21}^2/\bar{n}_2^2$ ratio is shown where n_{21} is the refractive index of the polar molecule along the direction of the dipole and $\bar{n}_2$ is the mean value for three axes, expressed as:

$$\frac{n_{21}^2-1}{n_{21}^2+2}=\frac{4}{3}\pi N\alpha_1, \quad \frac{\bar{n}_2^2-1}{\bar{n}_2^2+2}=\frac{4}{3}\pi N\bar{\alpha} \qquad (2)$$

It can be seen from Table I that the polarizability parallel to the dipole for benzene derivatives is about 30% larger than the mean polarizability.

It is likely that other molecules, not shown in Table I, have a similar tendency. This suggests that the values of n_2^2 in expression (11) of the previous paper[1] must be replaced with values about 30% larger. This would change the values of integrands g and h the expressions (5) and (6) of the previous paper[1] and, accordingly, that of $\alpha_{\text{calcd.}}^{\text{el}}$.

Wilson[2] derived the following expression for the dielectric constant of pure polar liquid and of a solution based on Onsager's model, taking the anisotropy of the polar molecule

1) K. Amaya, This Bulletin, **34**, 1584 (1961).

2) J. N. Wilson, *Chem. Revs.*, **25**, 377 (1939).

into consideration. For a pure liquid he obtained:

$$\frac{\varepsilon_2-1}{\varepsilon_2}-\frac{3(n_2^2-1)}{2\varepsilon_2+n_2^2}=\frac{4\pi N}{9kT}\mu^2\frac{(2\varepsilon_2+1)(n_{21}^2+2)^2}{2\varepsilon_2+n_{21}^2} \tag{3}$$

where n_{21} is the refractive index of the polar molecule along the dipole axis and n_2 is the mean refractive index.

For a binary solution consisting of polar and non-polar molecules,

$$\frac{\varepsilon_{12}-1}{\varepsilon_{12}}=\frac{4\pi N_2}{9kT}\mu^2\frac{(n_{21}^2+2)^2(2\varepsilon_{12}+1)}{(2\varepsilon_{12}+n_{21})^2}+\frac{3v_2(n_2^2-1)}{2\varepsilon_{12}+n_2^2}+\frac{3v_2(n_1^2-1)}{2\varepsilon_{12}+n_1^2} \tag{4}$$

in which the following notations were used;

N_2: the number of the polar molecule in unit volume,

v_2: volume fraction of the polar component,

v_1: volume fraction of the non-polar component,

n_2: mean refractive index of the polar molecule,

n_1: mean refractive index of the non-polar molecule,

n_{21}: refractive index along the dipole axis of the polar molecule,

ε_{12}: dielectric constant of the solution.

Following a procedure similar to that used before, we can express ε_{12} by using values for pure components; the following expression is obtained:

$$\frac{\varepsilon_{12}-1}{\varepsilon_{12}}=v_2\cdot\frac{(2\varepsilon_2+n_{21}^2)^2}{2\varepsilon_2+1}\times\left(\frac{\varepsilon_2-1}{\varepsilon_2}-\frac{3n_2^2-1}{2\varepsilon_2+n_2^2}\right)\cdot\frac{2\varepsilon_{12}+1}{(2\varepsilon_{12}+n_{21}^2)^2}+\frac{3v_2(n_2^2-1)}{2\varepsilon_{12}+n_2^2}+\frac{3(1-v_2)(n_1^2-1)}{2\varepsilon_{12}+n_1^2} \tag{5}$$

where ε_1 and ε_2 are the dielectric constants of non-polar and polar liquids respectively.

By the use of the above expression, the volume fraction of the polar component v_2' for any value of ε_{12} can be determined from the data of the pure liquids. To see how the anisotropy of the polar molecule affects the calculated values of the volume fraction, the values of v_2' * for chlorobenzene-cyclohexane and nitrobenzene-cyclohexane systems were compared with v_2, for which the anisotropy of the polar molecule is not taken into consideration. It was found that the differences were of the order of 0.01.

By using these values of the volume fraction v_2' and by replacing the values of n_2 with those along the dipole axis, n_{21}, van Laar coefficients $\alpha_{\text{calcd}}^{\text{el}'}$ were calculated for the above two systems and are shown in Table II. The $\alpha_{\text{calcd}}^{\text{el}'}/\alpha_{\text{calcd}}^{\text{el}}$ and $\alpha_{\text{calcd}}^{\text{el}'}/\alpha_{\text{obs}}^{\text{el}}$ ratios for $v_2=1$, 0.75, 0.5, 0.25 and 0 are also shown in Table III.

It can be seen from the above results that the introduction of the anisotropy of polarizability makes the calculated values of α^{el} in these two systems larger by 10 to 50%. For other systems, similar changes may be expected. The agreement between the calculated and observed values is not very much improved by consideration of the anisotropy.

* v_2' designates the value of v_2 obtained by taking into consideration the anisotropy of the polar molecules.

The Effect of the Position of the Dipole on the Molecule and on Molecular Shape

The calculations were based on the assumptions that the molecule was spherical and that the dipole was located at the center of the

molecule. The deviations in the position of the dipole from the center of the molecule and the deviation in molecular shape from a sphere will be discussed here to see how they affect the results.

First, the deviation in the position of the dipole from the center of the molecule will be considered. Assuming that the radius of the sphere is a, and that the dipole point is located at a distance s from the center of the sphere, Böttcher[3] derived the following expression for the electrostatic free energy, W, of a non-polarizable dipole whose dipole moment is μ, in the dielectric medium as a function of ε, the dielectric constant of the medium, and the ratio s/a:

$$W=-\frac{\varepsilon-1}{2\varepsilon}\frac{\mu^2}{a^3}\times\left[\sum_{l=0}^{\infty}\frac{l^2(l+1)(2\varepsilon+1)}{2(\varepsilon l+\varepsilon+l)}\left(\frac{s}{a}\right)^{2l-2}\right] \quad (6)$$

When the dipole is at the center of the sphere, the value in the bracket become unity; hence, the correction factor for the deviation in the position of the dipole is obtained by evaluating the value in the bracket.

For actual molecules, however, their dipoles are polarizable and their molecular shapes are not spherical. It may be assumed that for the polarizable dipole the correction factor for the deviation in the position of the dipole from the center of the sphere does not differ from that for the non-polarizable dipole; it may also be assumed that for an ellipsoidal molecule the correction factor for the ellipsoid does not differ from that for the sphere. Instead of s/a in the above formula, we may take the ratio s_i/l_i, where s_i is the distance between the center of the ellipsoid and the projection of the center of the dipole on each principal axis i, and l_i is half the length, along the corresponding principal axis i. By using the values for van der Waals' radii and the bonding radii of atoms found in the literature, the length along each principal axes, $2a$, $2b$ and $2c$, of the molecule can be obtained. By assuming that the molecule is an ellipsoid with principal axes $2a$, $2b$ and $2c$ and that the dipole is located at the center of that bond, the results shown in Table IV are obtained.

In some molecules the centers of the dipoles are not on one of their three principal axes and the direction of the dipole does not coincide with that of one of three principal axes. In these cases, the circumstances may be changed, but this problem will not be considered here in detail.

By using the values in Table IV, the correction factors r_p were calculated at eleven or twelve points of the dielectric constants for each system. Only the extreme values ($v_2=1$ and 0) are shown in Table V.

Table IV. Values of a, b, c, s_a/a, s_b/b and s_c/c for the polar molecules ($a>b>c$)

Kind of polar molecule	$2a$ Å	$2b$ Å	$2c$ Å	s_a/a	s_b/b	s_c/c
Chlorobenzene	8.6	6.7	3.7	0.37	0	0
Bromobenzene	8.9	6.7	3.9	0.35	0	0
Benzonitrile	9.3	6.7	3.7	0.54	0	0
Nitrobenzene	8.6	6.7	3.1	0.51	0	0
n-Butyl chloride	9.0	4.5	4.1	0.44	0.02	0
n-Butyl cyanide	9.2	4.8	4.1	0.57	0.25	0
Diethyl ketone	9.1	5.4	4.1	0	0.26	0
Cyclohexanone	7.5	7.1	5.1	0.50	0.24	0
Chlorocyclohexane	8.6	7.1	5.1	0.39	0.03	0
Bromocyclohexane	8.8	7.1	5.1	0.36	0.02	0

It can be seen from these results that the effect of the deviation in the position of the dipole from the center of the molecule is considerable and that the correction factors are always greater than unity and amount to as much as about 4 for *n*-butyl cyanide.

Next, the effect of the deviation in the molecular shape from a sphere will be considered. For an ellipsoid with principal axes $2a$, $2b$ and $2c$, the reaction field factor along the direction of the principal axis a, f_a, in a medium with a dielectric constant ε is expressed as:

$$f_a=\frac{3}{abc}A_a(1-A_a)(\varepsilon-1)/\{\varepsilon+(1-\varepsilon)A_a\}$$

$$A_a=\frac{abc}{2}\int_0^{\infty}\frac{\mathrm{d}x}{(x+a^2)\sqrt{(x+a^2)(x+b^2)(x+c^2)}} \quad (7)$$

For other axes similar expressions were obtained.

For an ellipsoid $a\geqq b\geqq c$, A_a A_b and A_c are expressed as:

$$A_a=\frac{(b/a)\cdot(c/a)}{\{1-(c/a)^2\}^{3/2}}\cdot\frac{1}{k^2}\{F(k,\rho)-E(k,\rho)\} \quad (8)$$

$$A_b=\frac{(b/a)\cdot(c/a)}{\{1-(c/a)^2\}^{3/2}}\cdot\frac{1}{k'^2}\left\{\frac{E(k,\rho)-k'^2F(k,\rho)}{k^2}-\frac{(c/a)\cdot\sqrt{1-(c/a)^2}}{b/a}\right\} \quad (9)$$

$$A_c=\frac{(b/a)\cdot(c/a)}{\{1-(c/a)^2\}^{3/2}}\cdot\frac{1}{k'^2}\left\{\frac{b}{a}\cdot\tan\rho-E(k,\rho)\right\} \quad (10)$$

where

$$k_2=\{1-(b/a)^2\}/\{1-(c/a)^2\}$$

$$k'^2=1-k^2$$

$$\sin^2\rho=1-(c/a)^2$$

$$F(k,\rho)=\int_0^{\rho}\frac{d\theta}{\sqrt{1-k^2\sin^2\theta}}$$

$$E(k,\rho)=\int_0^{\rho}\sqrt{1-k^2\sin^2\theta}\;d\theta$$

For a spherical molecule A becomes 1/3, for elongated molecules, the values of A are smaller than 1/3, and for oblate molecules, they are greater than 1/3. Therefore, the reaction field factor is smaller than that for a shpere when A is smaller than 1/3, and is larger than that of a sphere when A is larger than 1/3.

When the direction of the dipole does not coincide with one of the principal axes, the values of A for the direction of the dipole moment, A_μ, may be approximated as

$$A_\mu=\sum A_i\cos^2\theta_{\mu i} \qquad (11)$$

where $\theta_{\mu i}$ is the angle between the direction of the dipole moment μ and that of the principal axis i. Using the molecular dimensions shown in Table IV, the values of A for each polar molecule have been calculated and are shown in Table VI. If an ellipsoidal model is assumed and if also an anisotropy of the polarizability of the polar molecule is taken into consideration, integrand g in expression (2) in the previous paper[1] must be replaced by g'

$$g'=f_{\mu e}/(1-f_{\mu e}\alpha_\mu) \qquad (12)$$

where $f_{\mu e}$ is the reaction field factor along the direction of the dipole of a non-polarizable ellipsoid and α_μ is the polarizability along the direction of the dipole. α_μ is expressed as

$$\alpha_\mu=\sum_i\alpha_i\cos^2\theta_{\mu i} \qquad (13)$$

where α_i is the polalizability along the principal axis i and $\theta_{\mu i}$ is the same as has been mentioned above.

α_i's are calculated from the bond polarizability and molecular structure when the experimental values are not available; thus the ratio $\alpha_\mu/\bar{\alpha}$ was obtained, where $\bar{\alpha}$ is the mean polarizability, $\bar{\alpha}=(1/3)\cdot\sum_i\alpha_i$.

The ratios of $\alpha_\mu/\bar{\alpha}$ are shown in Table VI.

The correction factor r_s due to the deviation of the shape of the molecule from sphere r_s for integrand g of the expression (2) in the previous paper[1] may be expressed as

$$r=\frac{g'}{g}=\frac{f_\mu/(1-f_{\mu e}\alpha_\mu)}{f_s/(1-f_s\cdot\bar{\alpha})} \qquad (14)$$

where $f_s=\{(2\varepsilon-2)/(2\varepsilon+1)\}\cdot 1/a^2$, and f_s relates to g as $g=f_s/(1-f_s\alpha)$.

By using the above values of $\alpha_\mu/\bar{\alpha}$ and $\bar{\alpha}=(n_D^2-1)/(n_D^2+2)$, and assuming that a^3 in f_s, the reaction field factor for a sphere, is equal to abc in f_e, the values of r_s were calculated at eleven or twelve points of dielectric constant for each system, only extreme values are shown in Table V.

The effect of deviation in molecular shape from a sphere and that of the deviation in the position of the dipole from the center of the molecule is simultaneously represented as a product of both. The products of both correction factor are also represented in Table V.

It may be assumed that the resultant correction factors for h are the same as that for g. In calculating the van Laar coefficient the integrand h for a definite value of ε is multiplied by the resultant correction factor for the corresponding values of ε, and the corrected h is integrated with the volume fraction which is obtained by solving the equation relating volume fraction and ε derived according to the ellipsoidal model. However, as the resultant correction factor obtained above for g varies very little with the concentration, the approximate values of the refined van Laar coefficient

Bromocyclohexane-Methylcyclohexane	16.83	21.82	6.61

may be obtained by multiplying the values formerly calcurated for the spherical model by a constant, that is, the mean values of the resultant correction factors in Table V averaged over the whole concentration, if the difference between v_2 calculated by a spherical model and that calculated by an ellipsoidal model is disregarded as small. By assuming that these approximations are permissible, the refined van Laar coefficients $\alpha^{el}_{calcd\,r}$ are obtained. The ratio $\alpha^{el}_{calcd\,r}/\alpha^{el}_{obs}$ is plotted in Fig. 1.

It will be seen from the results that in general, the agreement between the refined calculation and the experimental results is similar to those of the former calculation for systems of polar liquids of a small dielectric constant, but for systems of polar liquids of a large dielectric constant the agreement is even poorer than before. Since the values of α^{el}_{obs} are correlated to the assumed values of α^{n-el} by the relation $\alpha_{obs}=\alpha^{n-el}+\alpha^{el}_{obs}$, the impropriety of the assumed values of α^{n-el} affect α^{el}_{obs}, and hence $\alpha^{el}_{calcd}/\alpha^{el}_{obs}$. However, the values of $d\alpha^{el}/dv$ are not affected by the assumed values of α^{n-el} whatever they may be, provided that α^{n-el} is independent of the concentration. The calculated values of $d\alpha^{el}/dv_2$ at $v_2=0$ obtained by the former calculation and by the refined calculation are shown in Table VII, together with the experimental values. It can be seen from the table that the agreement is not improved.

It may be concluded that the main sources of the poor agreement of the former theory with the experimental results, especially for solutions of polar liquids with a large dielectric constant, is not the assumption of a spherical molecule with its dipole at the center.

To make clear what is responsible for the poor quantitative agreement between theory and experiment in the heats of mixing a polar liquid (especially one with a large dielectric constant) and a non-polar liquid, the following points have to be considered from a theoretical as well as from an experimental point of view:

(1) To consider the orientational effect of polar molecules in pure liquids and in their concentrated solutions, due to dipole and anisotropy similar to that which is observed for toluene molecules in its solutions with polar molecules and to examine the assumption that the van Laar coefficient due to the non-electrostatic part of the energy is constant over the whole concentration.

(2) To examine the assumption that the microscopic dielectric constant near the polar molecule is the same as the microscopic one.

(3) To employ an extended dipole instead of a point dipole one in deriving the theory.

(4) To eliminate the error caused by using calculated values of the dielectric constant of solutions, by making use of the observed values of dielectric constants and of the temperature dependence of solutions

Summary

The electrostatic parts of van Laar coefficients for binary systems of polar and non-polar liquids were calculated, assuming that (1) the polar molecule is anisotropic in polarizability, (2) that the polar molecule is an ellipsoid, and (3) that the dipole is a point dipole and its position is not at the center of the molecule.

The results were compared with the experimental results.

The agreement between the experimental values and the calculated values based on the refined model cannot be said to have been improved compared with the previous results, in which the calculations were made based on the much simpler model in which the polar molecule was spherical and isotropic, and the dipole was at the center of the sphere.

*Dye-sensitized Photopolymerization of Vinyl Monomers. I. Preliminary Report on the Polymerization of Acrylonitrile by Various Dyes**

By Fukuo TAKEMURA

(Received July 27, 1961)

In the past decade it has been found that vinyl monomers can be polymerized by visible light in the presence of certain dyes[1-10]. The following types of the mechanism of dye-sensitized photopolymerization have been proposed; (1) direct energy transfer from the excited dye to monomer[3], (2) direct interaction between an excited molecule of the dye and the vinyl monomer[5,6,10], and (3) the production of free radicals by the self-decomposition of the excited dye or by the reaction of the excited dye with a third substance involved in the system[4,8].

Ueberreiter and Sorge[3], in their study of the sensitized polymerization of styrene by neutral red, attributed the chain initiation to the transference of energy from the excited dye to the monomer. However, Miyama[7] reported later that the polymerization by neutral red was really accompanied by a decomposition of the dye. Koizumi and Watanabe[6,10] investigated the photopolymerization of styrene induced by excited cyanine dyes. They established that direct interaction between the excited dye and the monomer was responsible for the initiation of polymerization. It was shown by Oster et al.[4,8] that vinyl compounds such as acrylonitrile or acrylamide could be polymerized by using the proper combination of a certain dye and an appropriate reducing agent in the presence of oxygen.

From the photochemical point of view, the first two types, in particular the first type, are interesting and important, but there are few reports on the sensitized polymerization belonging to these types. The present investigation was undertaken to select the dyes capable of sensitizing the polymerization of vinyl monomers even in the absence of a third substance and oxygen; it aimed, namely, at selecting such dyes whose excited state might directly take part in the initiation of polymerization, so as to elucidate the mechanism of polymerization sensitized by an excited dye.

Acrylonitrile was used as a vinyl monomer. One of the reasons for this selection is that aqueous solutions of dyes can be conveniently used, as acrylonitrile is able to some extent to dissolve water in itself. Another reason is that the progress of polymerization can be followed by observing the precipitation of its polymer insoluble to the system. Then acridine yellow, when chosen for a more detailed study, was found to be the most effective as a sensitizing agent.

Experimental

Materials.—Commercial acrylonitrile was purified by successive washings with dilute sulfuric acid, an aqueous solution of sodium carbonate, and water. After drying with calcium chloride, it was twice distilled at atmospheric pressure and stored in a dark room.

The dyes used in these experiments were arbitrarily chosen; most of them were made by E. Merck Co. or by G. Grübler Co. The aqueous solutions of dyes were prepared without further purification, the concentrations being about 10^{-2} mol./l.

Experimental Procedure.—In the preliminary experiments, 3 ml. of acrylonitrile and 2 drops of

an aqueous solution of a dye were put into a glass tube (8 mm. in diameter; 15 cm. in length). The tube was attached to the vacuum system (10^{-4} mmHg), degassed three times by successive evacuations and thawings, and then sealed off. All of these procedures were carried out in a dark room. The concentrations of dyes in the reaction systems thus prepared were of the order of 10^{-4} mol./l. These tubes were placed in a thermostat (40°C) and illuminated for 24 hr. with a 500 W. tungsten lamp 1 m. distant from them. The polymers thus obtained were separated by the use of glass filters, washed with water, and dried to a constant weight. When the concentrations of dyes in the reaction system were allowed to change, more diluted aqueous solutions of dyes were used for the above-mentioned procedure instead of the original stock-solutions.

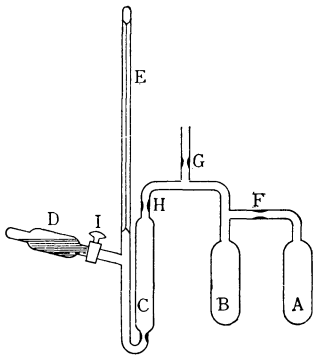

Fig. 1. Dilatometrical apparatus.

A, B : Reservoir for monomer and dye-solution respectively
C : Reaction vessel
D : Reservoir for Hg
E : Capillary tube (30 cm. long)
I : Stopcock

The kinetic experiments were studied dilatometrically, the reaction vessel being suspended in a thermostat (30 or 50°C). Figure 1 shows a schematic representation of the type of dilatometer used in these experiments. This dilatometer was designed to fill its capillary tube with mercury purposely to avoid the precipitation of polymers in it. Definite amounts of the monomer and of the dye solution in *n*-butanol were weighted in storage reservoirs A and B respectively. After a through evacuation as described above, the monomer in A was distilled into B in vacuo and mixed there with the dye solution. Then, the dilatometer was sealed off from reservoir A at F and also from the vacuum system at G. Finally, all of the reactant in reservoir B was allowed to pour into the reaction vessel C by inclining the reservoir. The dilatometer was enclosed at the top of reaction vessel H, turned upside down with caution while keeping the reactant in the reaction vessel, and filled up with mercury through the stopcock I. The meniscus of mercury in the capillary tube being adjusted, the dilatometer was immersed in a thermostat. After thermal equilibrium had been attained, the change in the meniscus was followed by a catheto-meter. The light source was a 500 W. tungsten lamp 50 cm. distant from the thermostat.

The rate of polymerization was calculated from the rate of contraction, assuming that a 23.5% contraction at 30°C and a 25.7% contraction at 50°C correspond to a 100% conversion of the monomer[11].

The viscosities of the solutions of acrylonitrile polymers in dimethylformamide were measured at 30°C in an Ostwald viscosimeter. The molecular weights were calculated by using the following equation quoted by Bamford and Jenkins[11]:

$$[\eta] = 1.75 \times 10^{-3} M^{0.66}$$

where the concentration unit was g./100 ml.

Experimental Results and Discussion

The Sensitizing Effects of Various Dyes on the Polymerization of Acrylonitrile. — Table I shows a series of comparative experiments. Of

* In this column, (−) points out no polymerization induced and (+), (++) and (+++) indicate that the polymerization have been well accelerated in that order: namely, (+) shows the conversion less than 1% in 24 hr., (++) less than 10%, and (+++) more than 10%.

11) C. H. Bamford and A. D. Jenkins, *Proc. Roy. Soc.* **A216**, 515 (1953).

course, no polymerization was induced by any dye in the dark at 40°C. From Table I, it will be seen that the overall efficiency varies over a very wide range. Of all the dyes tested, acridine dyes are the most effective, followed by xanthene dyes. It was shown by Oster[4] that acrylonitrile in an aqueous solution could be polymerized by eosin and erythrosin (jodeosin) only in the simultaneous presence of a mild reducing agent and of oxygen. However, in the present preliminary experiments, both eosin and erythrosin were shown to be able to induce to some degree the polymerization, even in the absence of a reducing agent and of oxygen.

The concentrations of dyes used in these preliminary experiments were not necessarily the same for all dyes, though they were of the order of 10^{-4} mol./l. Thereupon, the dependence of the rate of polymerization on the concentration of these effective dyes was roughly examined; the results are shown in Fig. 2. For acridine yellow and acryflavine, there appears to be an optimum concentration, probably indicating that they play the role of retarder for polymerization as well as that of sensitizer.

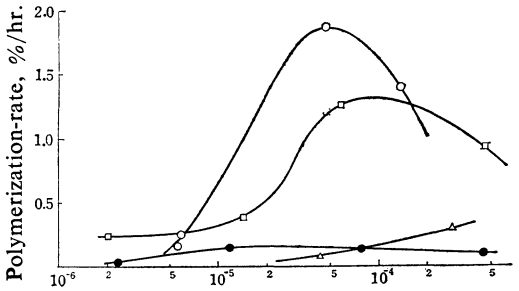

Fig. 2. Dependence of the rate of photopolymerization of acrylonitrile on dye-concentration.
○ Acridine yellow ● Iodeosin
□ Acryflavine △ Pyronine

In view of the fact that acridine yellow is the most effective, this dye was chosen for a more detailed study in these preliminary investigations.

Acridine Yellow-Sensitized Polymerization of Acrylonitrile.—The course of a typical run is shown in Fig. 3, where it will be seen that there is a gradual increase in the rate of contraction and, thus, in the rate of polymerization also, until a steady state is reached. This would appear to mean that the initial stage of polymerization is complicated by the necessity of generating some intermediate product before real sensitization can occur, or by an induction period resulting from the presence of a trace of an inhibitor such as oxygen.

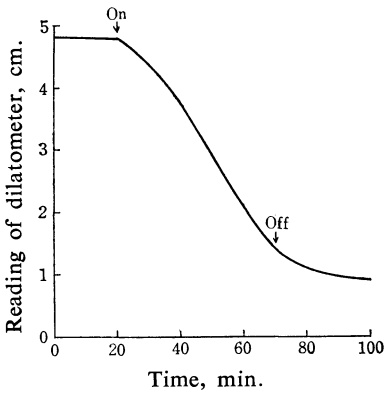

Fig. 3. Course of acridine yellow-sensitized polymerization of acrylonitrile.

When the light was switched off, the reaction did not cease immediately but exhibited a long decay period. This may be caused by the after-effect owing to the presence of trapped radicals in the precipitated polymers. Bamford and Jenkins[11] made a kinetic study of the polymerization of acrylonitrile and found that the reaction showed kinetic features which were different from those of homogeneous vinyl polymerization, e. g., (a) an initial increase in rate with time in the thermal catalyzed- and photo-polymerization, and (b) a photochemical after-effect. The observations in the present study are similar to those made by Bamford and Jenkins.

When the steady rates of polymerization are plotted against the concentration of acridine yellow (Fig. 4), the rate is shown to be proportional to the concentration in the range studied at both temperatures (30 and 50°C). This seems to be different from the usual

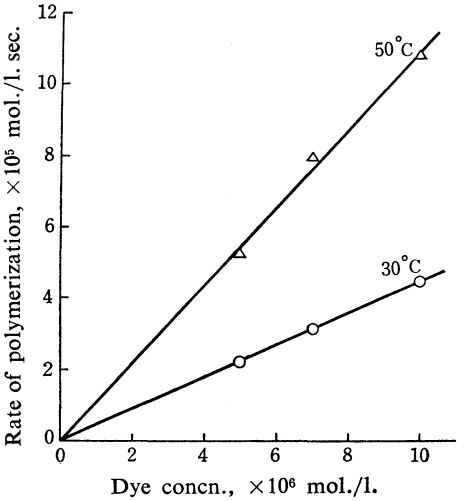

Fig. 4. Dependence of polymerization-rate on dye concentration.

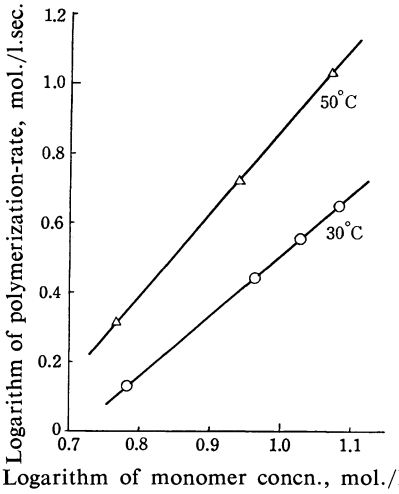

Fig. 5. Dependence of polymerization-rate on acrylonitrile concentration.

cases, in which the rate depends upon the square root of the concentration of the sensitizer, and seems to be characteristic for the polymerization of acrylonitrile in a heterogeneous system, in which Thomas and Pellon[12] have shown a 0.82 power dependence of the rate on the concentration of an initiator (azobisisobutylonitrile).

In Fig. 5 the logarithm of the rate is plotted against the logarithm of the monomer concentration, which was changed by the use of *n*-butanol as a solvent. The experimental points determine a line whose slope is about 1.7 and 2.4 at 30 and 50°C respectively. It is difficult at present to interpret these results satisfactorily, but Nakatsuka[13] has also found a discrepancy in the dependence of the rate on the monomer concentration between at 30°C and at 60°C, i. e., one power and two power dependence at the two temperatures respectively. This discrepancy may be attributed to the heterogeneous condition of the polymerization of acrylonitrile. In view of such a higher power dependence of the rate on the monomer concentration, it seems probable that the monomer plays a part in the initiation process, together with an excited molecule of the dye, and that the interaction between them give rise to the bleaching of the dye.

The dependence of the molecular weight of the polymer thus obtained on the dye and the monomer concentration were also investigated. They are shown in Tables II and III, together with kinetic data. It is worth noticing that the molecular weight of polymer is nearly independent of the dye concentration at 30°C,

	5.8	6.4	2.1	1.60

although the rate is dependent on it. From Table III it is found that the molecular weight decreases with the decrease in the monomer concentration. This may be caused by chain transfer to the solvent and will be discussed below in detail.

The overall activation energy can be roughly estimated from the rates at two temperatures. It is about 8.6 kcal./mol., the value being conceivable for the photochemical reaction.

In short, these results are not concordant with a simple familiar theory on homogeneous free radical polymerizations with respect to the following points: (1) one power dependence of the rate on the sensitizer concentration, (2) a higher power dependence of the rate on the monomer concentration, and (3) the molecular weight of the polymer independent of the sensitizer concentration.

Development of a Kinetic Scheme. — In developing a kinetic scheme to account for these observations, it is assumed that: the polymers obtained in this system, being highly insoluble in the monomer, precipitate as soon as they are formed, so that the propagating free radical chains become occluded in polymer aggregates during polymerization, resulting in a unimolecular termination. As mentioned above, the initiation process seems likely to be an interaction between the excited dye and the

monomer, which leads also to bleaching of the dye. Therefore, the reaction scheme will be as follows:

Absorption	$D \xrightarrow{h\nu} D^*$	I
Deactivation	$D^* \rightarrow D +$ heat or light	
Initiation	$D^* + M \rightarrow R\cdot$	k_i
Propagation	$R\cdot + M \rightarrow R\cdot$	k_p
Transfer to monomer	$R\cdot + M \rightarrow P + R\cdot$	k_{trM}
Transfer to solvent	$R\cdot + S \rightarrow P + S\cdot$	k_{trS}
Reinitiation	$S\cdot + M \rightarrow R\cdot$	k'_{tr}
Termination	$R\cdot \rightarrow P$	k_t

where D, D*, M, S, R·, S· and P indicate dye, excited dye, monomer, solvent, propagating free radical, solvent radical and stable polymer involving an occluded radical respectively. Furthermore, I is the light intensity absorbed, and k_i, k_p, k_{trM}, k_{trS}, k'_{tr} and k_t are the rate constants of initiation, propagation, transfer to monomer, transfer to solvent, reinitiation of solvent radical and termination respectively.

Assuming that most of the excited molecules of the dye are deactivated with the release of energy and also that these concentrations are proportional to the light intensity absorbed or approximately to the dye concentration at the constant light intensity, the following reaction rate, R_p, may be given by the steady-state treatment:

$$R_p = \frac{-d[M]}{dt} = \frac{kk_ik_p}{k_t} I[D][M]^2 \qquad (1)$$

where k is a constant, corresponding to the quantum efficiency for the initiation. The average degree of polymerization of polymer, $\overline{P}$, may be expressed by

$$\overline{P} = \frac{k_p[M]}{k_t + k_{trS}[S]} \qquad (2)$$

if the chain transfer to the monomer is disregarded. In regard to the variation in dye concentration, the experiments support Eq. 1, although the dependence of the rate on the monomer concentration is not necessarily coincident with the experimental results. This may be due to the complications of the heterogeneous system. The experimental finding that the molecular weight of the polymer is independent of the dye concentration at the constant monomer concentration appears to satisfy Eq. 2.

As shown above, the molecular weight of the polymer varied with the concentration of the monomer. Supposing that the proposed kinetic scheme is true, the degree of polymerization must be given by Eq. 2, rewriting it, the following equation is obtained:

$$\frac{[M]}{\overline{P}} = \frac{k_t}{k_p} + \frac{k_{trS}}{k_p}[S] \qquad (3)$$

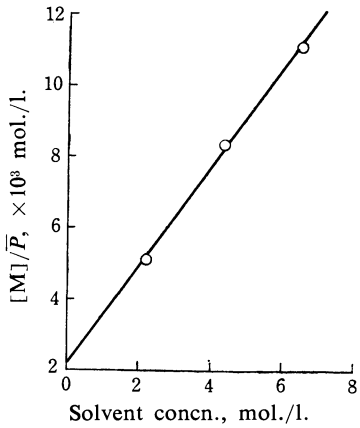

Fig. 6. Plots of $[M]/\overline{P}$ against butanol concentration according to Eq. 3.

Eq. 3 shows that $[M]/\overline{P}$ will vary in a linear relation with the solvent concentration. The data at 30°C fell reasonably close to a straight line, as shown in Fig. 6, though those at 50°C did not do so well. The slope of the line gives a value of k_{trS}/k_p of 13.7×10^{-4}, while the intercept gives a value of k_t/k_p of 22×10^{-4} mol./l.

As described above, the conclusion that the initiation process is the interaction between excited dye and monomer has been obtained only from the kinetic study of the polymerization. However, it will be desirable to confirm it from a absorption-spectrometric investigation of the dye in the reaction system. Such a kind of investigation was abandoned in the present system, due to the disturbance of the insoluble polymers, but it will be taken up in future studies, so as to elucidate the mechanisms of sensitization in detail.

Summary

Among various dyes, the dyes suitable for the sensitization of the polymerization of acrylonitrile have been determined. Acridine and xanthene dyes have been found to be the most effective.

Using acridine yellow, one of the most effective, the dye-sensitized photopolymerization has been investigated in detail; it has been shown that the reaction has several features characteristic of heterogeneous polymerization, e. g., its order is higher than one-and-a-half on monomer concentration.

Assuming the initiation process to be a direct interaction between excited dye and

monomer, and assuming the unimolecular termination by occlusion of the propagating radicals, the kinetic data has been interpreted.

The author wishes to express his hearty thanks to Professor Masao Koizumi, Tohoku University, and to Professor Kozo Hirota, Osaka University, for their encouragement and advice, and also to Mrs. I. Tanaka and Miss K. Yamashita for their assistance in part of this work.

*Dye-sensitized Photopolymerization of Vinyl Monomers. II. Photobleaching of Acridine Yellow in Some Vinyl Monomers**

By Fukuo TAKEMURA

(Received July 27, 1961)

In the first paper of this series[1], it was reported that, among the various dyes tested, acridine yellow was the most effective in sensitizing the polymerization of acrylonitrile and that, from the kinetic study of that polymerization using this dye, the initiation of polymerization seemed to be attributable to the direct interaction of the excited molecule of the dye with the monomer. However, no knowledge of the behavior of the dye in the course of polymerization could be obtained, since it was impossible to measure the absorption spectra of the dye in the reaction system because of the precipitation of polymers thereby produced.

Now, in order to account in more detail for the mechanism of such a sensitization by acridine yellow, we have undertaken to examine the bleaching of the dye in some vinyl monomers (vinyl acetate, styrene, α-methylstyrene and methyl methacrylate) besides acrylonitrile, and to discuss the mechanism of sensitization.

Experimental

Materials.—Acrylonitrile was purified by the same method as that employed in the first paper[1]. Vinyl acetate was obtained from the Katayama Kagaku Co. and was distilled three times at atmospheric pressure. It was shown by dilatometrical measurement that, whenever vinyl acetate and a solution of the dye were put together into a reservoir and were degassed in vacuo, the monomer was appreciably polymerized even in the dark, perhaps owing to impurities such as aldehyde. This was overcome by further distillation of the monomer in vacuo. Therefore, not only vinyl acetate but also all of the other monomers were enclosed in reaction vessels by the procedure of distillation in vacuo as described below. Styrene was prepared from β-phenylethyl alcohol by dehydration, heating it with caustic potash. The crude styrene thus obtained was washed with aqueous solutions of caustic soda and sodium bisulfite, dried with calcium chloride, and distilled twice under reduced pressure. α-Methylstyrene was obtained from the Tokyo Kasei Co. and was purified in the same way as styrene. Methyl methacrylate was made by the Fujikura Kagaku Co. It was shaken with an aqueous caustic soda solution to remove the inhibitor, washed with water, dried with potassium carbonate anhydride, and then twice distilled under reduced pressure.

Acridine yellow was added to the reaction systems as a *n*-butanol solution with the exception of the case of acrylonitrile. Azobisisobutylonitrile was twice recrystallized from ethanol. Hydroquinone was used without further purification.

Apparatus.—The thermostat was doubly constructed; the inner bath was regulated within $\pm 0.002°$ at 30°C, and the outer bath, within $\pm 0.02°$ at a slightly lower temperature than 30°C. The cell holder supporting a reaction vessel in the inner bath was the same as that usually used in a spectrophotometer. The light source (a 75V,750W. tungsten projection lamp) in the outer bath was convered with a metallic housing with a window and was supplied by a. c. source controlled at 60 V. by means of a voltage regulator or by means of a slide rheostat and a resistance box. In order to prevent overheating caused by the light source, cold water was forced to flow into the metallic housing during the experiment by a gear pump controlled by a relay connected with a toluene-Hg regulator.

In all of the experiments, a Mazuda color glass filter V-B3$_B$ was inserted between the reaction vessel and the light source. It had its maximum transmission near the maximum (about

460 mμ) of the absorption band of acridine yellow. The intensity of light was, if necessary, changed with a blackened metallic net, whose shielding efficiency was 30.5%.

The reaction vessel was the same glass cell, 1 cm. in thickness, used as a absorption cell for a spectrophotometer except that it was provided with an arm, as is shown in Fig. 1.

Experimental Procedure.—In the glass apparatus shown in Fig. 1, definite amounts of monomer and dye-solution were weighted in storage reservoirs A and B respectively. After complete degassing by successive evacuation and thawing, the monomer in A was distilled into B in vacuo and mixed with the dye-solution. Then, having been sealed off from reservoir A at D and from the vacuum system at E, the reaction vessel was filled with the reaction mixture by inclining it and was sealed off at F. The quantity of the reaction mixture was sufficient to fill it up above the edge of the window of a cell holder, and if necessary, it was obtained from the initial quantities of monomer and dye-solution substracted the residual quantity in reservoir B.

Generally the reaction systems in photobleaching experiments were prepared from 1 ml. of an acridine yellow solution in *n*-butanol and 3 ml. of vinyl monomers. The initial concentrations of the dye in the reaction systems were about 2×10^{-5} mol./l. In changing the monomer concentration,the monomer was replaced with appropriate amounts of a suitable solvent, e. g., ethyl acetate instead of vinyl acetate, or benzene or ethylbenzene instead of styrene, α-methylstyrene and methyl methacrylate.

By way of exception, acrylonitrile was diluted with dimethylformamide, which was a good solvent for the polymer of acrylonitrile. Otherwise polyacrylonitrile would be precipitated in the course of the reaction. The dye was, of course, added as a solution in dimethylformamide in this case.

In a run of irradiation, the vessel was taken out of the thermostat at some minutes' intervals, and the absorption spectra were measured with a Hitachi spectrophotometer (model EPU-2).

Results and Discussion

Preliminary Tests of the Photobleaching in Various Solvents.—The bleaching of the dye was preliminarily investigated in such solvents as dimethylformamide, methanol, *n*-butanol, benzene and ethylbenzene. In these experiments one of these solvents (except dimethylformamide) was taken up instead of the monomer in the recipe of the reaction mixture described above. (As the bleaching of the dye in the solution of acrylonitrile in dimethylformamide needed to be compared with that in dimethylformamide alone, the dye was added as a solution in dimethylformamide in this case.)

In all solvents examined, the bleaching of the dye was very slight even in the light, not to mention in the dark, and may be considered negligible as compared with the photobleaching in the presence of monomers. Therefore, the appreciable photobleaching in the presence of monomers described below is undoubtedly due to the interaction of some excited molecules of the dye with the monomers.

No bleaching was observed when a solution of the dye in benzene was heated in the presence of azobisisobutylonitrile at 60°C for 80 min. From this finding, it appears that the dye is not attacked by radicals from azobisisobutylonitrile nor, presumably, by polymer radicals.

Photobleaching in the System of Acrylonitrile.—No shift of the absorption maximum of the dye in this reaction system was observed during irradiation, and the main absorption band in the visible region declined monotonously with irradiation. The relation of the optical density at the absorption maximum (465 mμ) to the irradiation time is simple, with no induction period (Fig. 2).

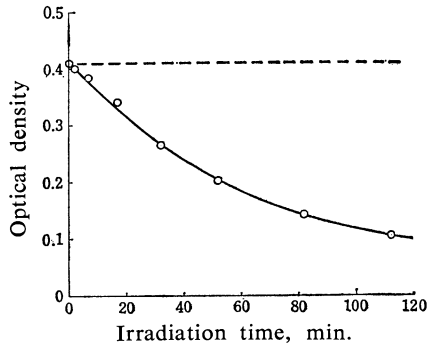

Fig. 2. The variations of optical densities at 460 mμ of the dye in acrylonitrile with irradiation time.
Dotted line; in the presence of KI or in the dark

After the irradiation, the reaction mixture was poured into a large amount of methanol, and the polymer was precipitated. Therefore, the bleaching seems to be accompanied by the polymerization of acrylonitrile.

In the presence of potassium iodide, which was added as a quencher of fluorescence, it

was shown that neither photobleaching nor polymerization occurs. This fact suggests that the singlet-excited dye molecule would otherwise lead to the photobleaching and the polymerization.

Rate Formula of the Bleaching.—According to Imamura[2], such a simple photobleaching curve can be expressed by Eq. 1 under the assumption that the rate of photobleaching depends on and is proportional to only the light absorbed:

$$-\frac{dc}{dt}=k'I_0(1-e^{-\alpha cd}) \quad (1)$$

where c is the concentration of the dye; d, the thickness of the solution, α, the average molar absorption coefficient; I_0, the total light intensity, and k', the overall rate constant.

By integration, Eq. 1 may be transformed into

$$\ln(1-e^{-\alpha c_0 d})-\ln(1-e^{-\alpha cd}) + \alpha d(c_0-c)=\alpha dk'I_0t \quad (2)$$

where c_0 is the initial concentration of the dye.

For the sake of convenience in dealing with the data, Eq. 2 was rewritten in terms of optical density as follows:

$$\log(1-10^{-D_0})-\log(1-10^{-D}) + D_0-D=\varepsilon dk'I_0t \quad (3)$$

where D and D_0 are the optical densities at time $t=t$ and $t=0$, and ε is the average molar extinction coefficient.

Since ε, d, k' and I_0 are constant in each run, the product, $\varepsilon dk'I_0$, is expressed in k and the left side of Eq. 3 is expressed in terms of S for convenience. Therefore, Eq. 3 shows that S would be proportional to t. As is shown in Fig. 3, it seems that these results are consistent with Eq. 3. From the slope of the straight line, the apparent overall rate constant k was found to be 0.0074 min^{-1} in this experimental condition.

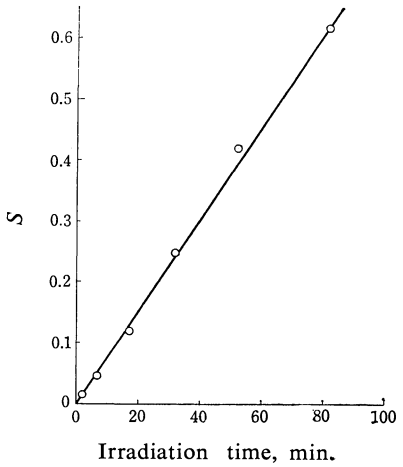

Fig. 3. S vs. irradiation time in acrylonitrile. S is the left side of Eq. 3

In view of the fact that the photobleaching of the dye did not occur in the absence of the monomer but did in its presence, the monomer must play a part in the photobleaching of the dye. However, the relation of the rate of bleaching to the monomer concentration could not be examined, since the monomer concentration was not allowed to increase owing to the precipitation of polymers. Therefore in order to understand more clearly the relationship between photobleaching and polymerization, other vinyl monomers than acrylonitrile were chosen for the following experiments.

Photobleaching in the System of Vinyl Acetate.—The absorption maximum of this system did not shift at various irradiation times, similarly as in the case of acrylonitrile. The optical densities at the maximum wavelength (456 mμ) are plotted against the irradiation time in a series of monomer concentrations in Fig. 4. It has been examined whether or not these photobleachings obey the simple rate formula, Eq. 3. As is seen from Fig. 5, linear relationships between S and t can not be always obtained. However, it may be considered that at the initial stage of irradiation the slopes of these lines correspond to the apparent overall rate constants in various monomer concentrations. Then, these rate constants seem to be roughly proportional to the monomer concentrations. Therefore, it may be concluded that the apparent overall rate constant is also a function of the monomer concentration, and that the photobleaching is not due to the self-decomposition of the dye but to the

interaction of the excited dye molecule with the monomer.

Under aerobic conditions, neither photobleaching nor polymerization could be brought about. This might be because oxygen deactivated the excited state of the dye.

Photobleaching in the System of Styrene.— The experiment was further extended to the system involving styrene. In various concentrations of styrene, the change in optical density at the initial absorption maximum (460 mμ) was plotted against time, as is shown in Fig. 6. From the results, it can be seen that the bleaching of the dye was very rapid and that its rate was nearly independent of the styrene concentration if it was higher than about 2 mol./l. When the light intensity was reduced to 30.5% by inserting a blackened

metallic net, the rate of bleaching decreased as compared with that carried out under full intensity, as is shown in Fig. 7.

When the absorption spectra in the range of 400~500 mμ were followed in the order of the irradiation time (Fig. 8), it was unexpectedly found that the optical density decreased rapidly in spite of the reduced intensity of light and that, at the same time, an absorption maximum appeared at the shorter wavelength. This new absorption did not change in the dark, but disappeared only on irradiation. This phenomenon was soon observed whenever both photobleaching and polymerization occurred in these experiments, but it was observed only after a time in the presence of air or hydroquinone, where the polymerization was hardly able to occur. Since it is well

known that hydroquinone can not inhibit polymerization without the coexistence of air and that it is a good quencher for a phosphorescent state, it is clear that the effect of hydroquinone in this case does not result from the inhibition of polymerization but from the quenching of a triplet state of the dye.

The addition of polystyrene to the reaction system in the dark did not lead to the shift in absorption maximum. This result may indicate that the shift does not result from the mere adsorption or binding of the dye on the polymer.

From these reasons, the photobleaching and the shift in the absorption maximum do not always accompany the polymerization of styrene but may be realized prior to it.

Analysis of the Absorption Spectra in the System of Styrene.—Although a gradual shift in the absorption maximum was observed during irradiation in the above system, its limiting position in every case was in the neighborhood of 443 mμ. Since the above results strongly suggest the formation of a coloring product from acridine yellow, identification of the product was attempted from an analysis of absorption spectra. The method is entirely the same as that reported by Imamura[3].

An example of absorption curves obtained for a coloring product by such an analysis is given in Fig. 9, from which it can be seen that the optical density of the product increases with irradiation time, moderately at the initial stage and more slowly at the intermediate stage, and then begins to decrease, though slowly. The absorption band of the coloring product is quite broad and has a maximum at 443 mμ which is not displaced with time.

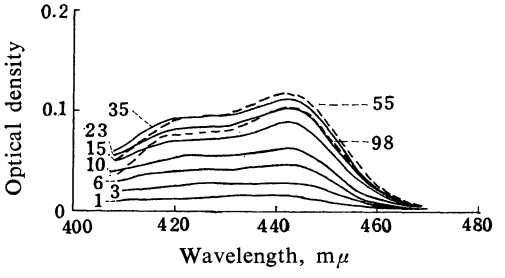

Fig. 9. The change of spectra estimates for a intermediate product in styrene from Fig. 12 with irradiation time

Estimation of the Coloring Product in the System of Styrene.—An attempt was undertaken to decide if the coloring product was a substance produced photochemically by a direct interaction of the excited dye with the styrene monomer. After the reaction system was irradiated for a suitable period, it was poured into a proper amount of methanol. The polystyrene thus precipitated was separated by filtration. The filtrate showed the same spectra, with an absorption maximum at 443 mμ, as that obtained by the above-mentioned analysis. The polystyrene thus obtained had spectra with a broad absorption maximum at ca. 450 mμ in the benzene solution, in spite of the repeated treatment of successive precipitation and dissolution, as is shown in Fig. 10.

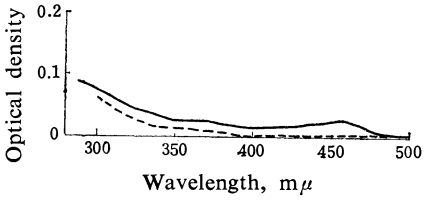

Fig. 10. The absorption spectra of the benzene solutions of the polystyrene obtained photochemically and thermally in the presence of the dye.
Full line; Photochemically
Dotted line; Thermally

On the other hand, when the same reaction system was polymerized thermally in the dark, the filtrate obtained by the same procedure as before showed essentially the same absorption spectra as those of the original reaction system. The polystyrene obtained in this case did not show an absorption maximum near 450 mμ (Fig. 10).

Therfore, it may be concluded that the coloring product was photochemically produced only by a direct interaction of the excited dye with the styrene monomer, and that it was bound to the polymer in the course of the polymerization.

Rate of Photobleaching in the System of Styrene.—It is therefore clear that the optical density at the initial absorption maximum (460 mμ) does not obey Eq. 3, but that on the other hand, at the initial stage of irradiation the decrease in the optical density at 460 mμ may be taken to represent the bleaching of the initial dye. The values of k_{Init} thus obtained correspond to the apparent overall rate constants of the bleaching. By plotting them against the monomer concentration, as in Fig. 11, it is found that k_{Init} increases rapidly with the monomer concentration but is nearly independent of it in the region higher than about 2 mol./l., even though the conditions of irradiation is different. In addition, it is shown that k_{Init} is approximately proportional to the light intensity. These results suggest that the bleaching of the dye is so rapid that the rate of bleaching is

mainly determined in the case of concentrated monomer concentrations by the intensity absorbed, while it depends both upon the light intensity and upon the monomer concentration in the case of more dilute solutions. Therefore, it may be concluded that the decrease in optical density at the initial absorption maximum (460 mμ) of the dye is attributed to the interaction of the dye molecule, excited to the triplet state, with the monomer to produce a new coloring product which will be destroyed by further irradiation.

Photobleaching in the System of α-Methylstyrene. — The photobleaching in α-methylstyrene (α-MS) was found to closely resemble that in styrene. The absorption curves of a reaction system, as is shown in Fig. 12, shifted towards a shorter wavelength with irradiation time. For the sake of convenience, the optical densities at 460 mμ at various monomer concentrations are plotted against irradiation time in Fig. 13. It can be seen that the rate of bleaching is smaller than that in styrene. On the same assumption as in the case of styrene, the apparent overall rate constants k_{init} were calculated from Eq. 3. The dependence of k_{init} on the monomer concentration appears to be proportional to the square root of the concentration in this region, as is shown in Fig. 14. The efficiencies in polymerizing this monomer were very low. This may be attributable to the low polymerizability of α-MS. It is interesting the features of the photobleaching of acridine yellow are alike in styrene and α-MS. This may be due to the production of coloring products similar in their structure.

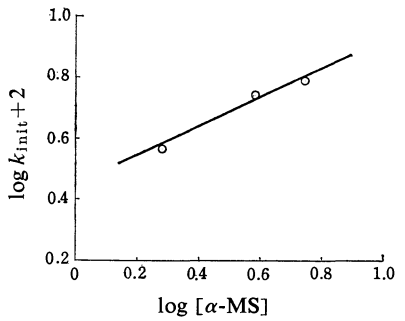

Fig. 14. Logarithm of k_{init} vs. logarithm of the concentration of α-MS.

Photobleaching in the System of Methyl Methacrylate.—In view of the fact that the apparent behaviors of the bleaching of acridine yellow may be differentiated in two groups (acrylonitrile and vinyl acetate; styrene and α-MS), it is attractive to extend the experiments to the system involving methyl methacrylate (MMA), which is one of the most well-known vinyl monomers. Contrary to the author's expectation, it was found that the bleaching ceased after an initial slight photobleaching, the rate of which depended upon the monomer concentration and the extent of which was nearly always in the same ratio to the initial dye concentration even though the concentra-

tions of the dye and the monomer differed (Fig. 15.), while the monomer continued to polymerize as long as the system was irradiated[4]. In this case, no shift in the absorption maximum of the dye was observed. In the presence of air or hydroquinone, the photobleaching was very slight, without polymerization even in the light; moreover, the optical density of the reaction system could be restored to its initial value after a long period in the dark. This may be evidence for the transient production of a comparatively stable intermediate. Furthermore, the bleaching could not occur in the dark at 30 and 60°C, irrespective of the presence of azobisisobutylonitrile. This leads to the conclusion that acridine yellow can not be attacked by radicals produced thermally from the radical source and, so, perhaps not by polymer radicals.

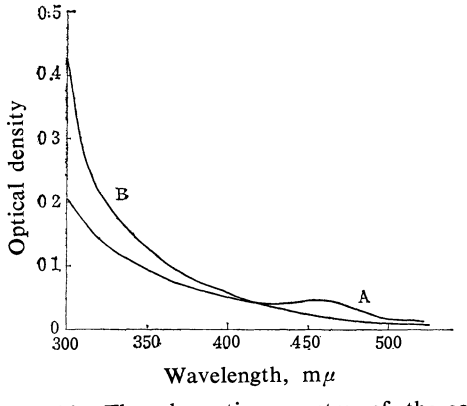

Fig. 16. The absorption spectra of the solution of poly-MMA obtained photochemically (A) and thermally (B) in the presence of the dye.

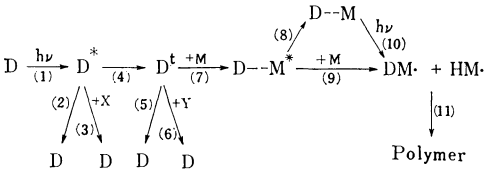
The absorption spectra of the solution of polymers, which were obtained photochemically in the light and thermally in the dark, are shown in Fig. 16. In spite of the treatment of these polymers by a procedure similar to that described before, the polymers obtained photochemically showed a broad absorption maximum near 460 mμ, while those obtained thermally did not. It is sure that the broad absorption near 460 mμ may be attributed to the dye bound to the polymer and not to the dye merely adsorbed on it, and that the bonding of the dye to the polymer is caused by the action of light in the course of the sensitization of the polymerization.

General Discussion

Acridine dyes are characterized by their resistance to reduction in the dark. Millich and Oster[5] reported that those acridines which had amino groups in both the 3- and 6-positions underwent photoreduction rapidly in the presence of a suitable reducing agent such as allylthiourea. It has now been found that acridine yellow, which was also included in their research, underwent photobleaching in the presence of various vinyl monomers in vacuo without any reducing agent and at the same time, sensitized their polymerizations.

It has been shown that the photobleaching of acridine yellow was apparently different in feature depending on the type of monomer: a) the absorption curves of the dye declined monotonously without any shift in absorption maximum in such monomers as acrylonitrile and vinyl acetate; b) the photobleaching was brought about rapidly with a shift towards shorter wavelengths in both styrene and α-MS, and c) the decreases in its optical density at the absorption maximum with irradiation ceased after a decrease of about 20% from the initial values in the reaction system containing MMA, and even thereafter the polymerization continued as long as irradiation was carried out.

In view of the fact that the intermediate coloring products, which are produced by an interaction of the excited dye with the monomer, seem to be bound to the polymers only in the cases of the photopolymerization of styrene and MMA but not in the dark thermal polymerization, it seems likely that the intermediate products are produced only under the influence of light and play a role in initiating



4) The Kinetic experiments involving this sensitize polymerization will be reported on in a forthcoming paper.

5) F. Millich and G. Oster, *J. Am. Chem. Soc.*, **81**, 1357 (1959).

polymerization either for themselves or in the course of their production. The apparent features of the photobleaching of the dye in various monomers may be attributed to such properties of the intermediates as optical properties and their photochemical stabilities. Thus, although the photobleaching in vinyl acetate seemed to be simple, it obeyed Eq. 3 only incompletely. After a long period of irradiation, the absorption curves of the system involving vinyl acetate seem to shift slightly towards shorter wavelengths. In this case, an intermediate coloring product would be gradually produced by irradiation and be rather rapidly lost by further irradiation. Therefore, the polymers thereby obtained did not have an absorption band in visible regions. On the contrary, the poly-MMA obtained photochemically in the presence of the dye had a relatively clear absorption band near the same wavelength as the absorption maximum of the original dye. This shows the intermediate products to have absorption spectra similar to those of the dye itself and probably to be rather stable.

Considering the effects of such quenchers as potassium iodide and hydroquinone, it may be concluded that the first singlet and triplet-excited states of the dye are involed in the course of interaction between the dye and monomers. In the acridine yellow-sensitized polymerization of an aqueous solution of methacrylic acid[6], it has been found that potassium thiocyanate, which is well-known as a quencher for fluorescence, can retard the photosensitized polymerization and that the efficiency of the retardation is of the same magnitude as that of the quenching of fluorescense,

Accordingly, the over-all reaction scheme of the photobleaching of acridine yellow in various monomers and the sensitization of polymerization may be expressed by the following:

(1) absorption of light with excitation to the first excited singlet state; (2) reversion to the ground state by a radiationless transition or by emission of fluorescence; (3) fluorescence quenching by potassium iodide or probably by oxygen; (4) transition to the triplet state; (5) transition from the triplet state to the ground state; (6) quenching of the triplet state by hydroquinone or probably by oxyen; (7) production of an activated intermediate product by the interaction of the triplet state with the monomer; (8) transformation to a stable coloring product; (9) initiation of polymerization; (10) re-absorption of light by the stable coloring product, which may lead to polymerization and to photobleaching of the coloring product; and (11) growth of polymer chains, which may be retarded or inhibited by oxygen. For styrene process (7) seems to be very rapid and process (1), a rate-determining step in the concentration range of more than 2 mol./l. For vinyl acetate, process (7) is the rate-determining step. For MMA the coloring product is so stable that it may induce the polymerization, probably by the energy transfer mechanism, without further bleaching.

Watanabe[7] has discussed, in the sensitized polymerization of styrene, the state activated by the use of cyanine dyes and has estimated that an electon transfer from X^- to D^+ was involved in the process of activation, where D^+ and X^- were a dye cation and a halogen anion respectively. In the present cases, it is difficult to decide whether or not such a electron transfer is involved, but it may be reasonable to assume that the intermediate product, which is produced by the direct interaction of the triplet state of the dye with the monomers, is responsible for the photobleaching and leads to the polymerization.

Summary

The photobleaching of acridine yellow has been studied in various vinyl monomers, such as acrylonitrile, vinyl acetate, styrene, α-methylstyrene and methyl methacrylate.

It has been found that (a) the photobleaching is apparently different in featue depending on the type of monomer; (b) the absorption maximum of the dye in the reaction systems shifted rapidly to a shorter wavelength in the cases of both styrene and α-methylstyrene by the irradiation of light, while it did not in the cases of acrylonitrile, vinyl acetate and methyl methacrylate; (c) a new absorption maximum at a shorter wavelength may result from the production of a relatively stable intermediate from the dye and styrene.

Considering also the effects of such quenchers as potassium iodide and hydroqinone on the photobleaching and the polymerization, it has been concluded that the interaction of the triplet state of the dye molecule with the monomers is responsible for both the bleaching and the polymerization.

6) This will be reported on in a forthcoming paper.

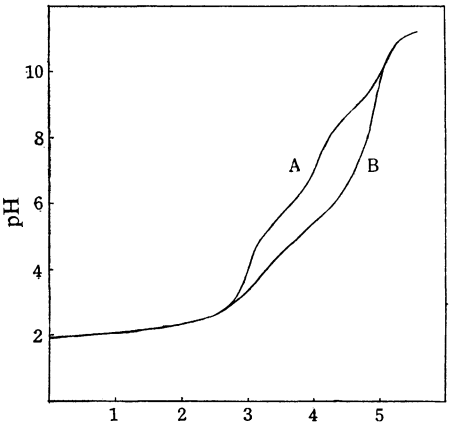
Stability of Condensed Phosphate Complexes. I. Alkaline-earth Metal Complexes

By Akira ROPPONGI and Takio KATO

(Received August 23, 1961)

It has been reported that a mixture of soap and a condensed phosphate such as hexametaphosphate is more effective than soap alone for removing radioactive contaminations on surfaces of concrete, glass, various metals and films[1]. It has been further found that EDTA and condensed phosphate are more useful as complexing agents than surface active agents for cleaning cotton goods contaminated with radioactive nuclides[2].

Condensed phosphate has been used as a boiler cleaner. In this case, the addition is very minute compared with the amount necessary to keep metallic ions as soluble complexes in hard water. Thus, the condensed phosphate is thought to have two different functions: complex formation and surface activity.



Many investigators have measured the ability of condensed phosphates to make complex formations by using various methods, but the metal elements used were limited to alkali and alkaline-earth metals. Furthermore, the stability constants measured by different methods do not agree with each other[3].

In order to obtain fundamental information about the washing ability of condensed phosphates, as well as about their usefulness as decontaminating agents, the stability constants of the complexes formed between condensed phosphates and metals were measured in this experiment.

Theoretical

The stabilty constants were measured either by acid-base titration using a glass electrode or by the replacement reaction. Schwarzenbach et al.[4] and Watters et al.[5-6] have evaluated the stability constants of magnesium and calcium complexes with triphosphoric acid by method A.

Method A. — If triphosphoric acid in the presence of a relatively large excess of metal ions can be titrated without precipitation, the decrease in pH should be attributed to the complex formation, as is expressed by the reaction:

a: alkali mol./triphosphoric acid mol.

Fig. 1. The effects of metal ion on titration curve of triphosphoric acid with alkali solution.
Curve A: 10^{-3} M triphosphoric acid titrated with 0.1 M KOH solution, Curve B: 10^{-3} M triphosphoric acid containing 10^{-3} M alkaline-earth metal ion titrated with 0.1 M KOH solution.

3) J. R. Van Wazer et al., *Chem Revs.*, **58**, 1011 (1958).
4) G. Schwarzenbach et al., *Helv. Chim. Acta*, **38**, 653 (1955).
5) J. I. Watters et al., *J. Am. Chem. Soc.*, **79**, 5606 (1957).
6) J. I. Watters et al., ibid., **81**, 3201 (1959).

$$mM^{+p}+l(H_{n+1}P_3O_{10})^{-(5-n-1)} \rightleftarrows M_m(H_nP_3O_{10})_l^{-((5-n)l-pm)} + lH^+ \quad (1)$$

As the metal ions are present in a large excess and as no pH change is observed in the region $a<3$ in Fig. 1, it is probable that only a 1 to 1 complex exists in the corresponding region, $a>3$. In such a case, the stability constants of the normal complex, K_{ML}, and the acidic complex, K_{MHL}, can be evaluated by Eqs. 2 and 3:

$$K_4'=K_4+K_{MHL}K_4[M] \quad (2)$$

$$K_5'=\frac{K_5+K_{ML}K_6[M]}{1+K_{MHL}[M]} \quad (3)$$

where [M] is the free metal ion concentration, K_n is the dissociation constant of triphosphoric acid, and K_n' is the apparent dissociation constant defined by Eq. 4 or 5.

$$K_4'=\frac{(H)\{[MHP_3O_{10}]+[HP_3O_{10}]\}}{[H_2P_3O_{10}]} \quad (4)$$

$$K_5'=\frac{H\{[MP_3O_{10}]+[P_3O_{10}]\}}{\{[MHP_3O_{10}]+[HP_3O_{10}]\}} \quad (5)$$

As the metal ion is present in a large excess, the free metal ion concentration can be considered to be equal to the total metal concentration. The apparent dissociation constants can be evaluated by Eq. 6 in a way similar to that used for acid-base titration. When the acid is not too dilute, pK_{5-n}' has the same value as the pH at the point where a is $5-(n+0.5)$.

$$K_{5-n}'=\frac{(H)\left[(5-n-a)\cdot C_L-\frac{K_W}{(H)\cdot f}+\frac{(H)}{f}\right]}{\left[(a-4+n)\cdot C_L+\frac{K_W}{(H)\cdot f}-\frac{(H)}{f}\right]} \quad (6)$$

Method B.—In Schwarzenbach's method, the constants are evaluated only in a system in which no precipitate is formed and in which metal ions can exist in a large excess compared with triphosphate ions. In the system of triphosphate and alkaline-earth metal, a precipitate is formed unless the system is kept under such conditions that triphosphate ions are present in an excess over the metal ions. Thus, the number of ligands bound with metal ions will increase to $1, 2, \cdots\cdots, n$, and the complexes of $M(HP_3O_{10})_n$ and $M(P_3O_{10})_m$ may coexist. In the investigation of polyamino complexes, Schwarzenbach[7] proposed general formulae to evaluate stability constants for the case where the ligand is the only one in the presence of an excess of amines.

The present authors tried to evaluate the stability constants of triphosphate complexes formed in a system in which triphosphate is present in an excess as compared with metal ions.

In the $a>3$ region, the total triphosphate concentration is expressed as

$$C_L=[H_2L]+[HL]+[L]+\sum n[M(HL)_n]+\sum m[ML\,m] \quad (7)$$

where L represents the P_3O_{10} ion. The concentration of replaceable hydrogen is given by

$$C_H=2[H_2L]+[HL]+[H]+\sum n[M(HL)_n] \quad (8)$$

Subtracting Eq. 7 from 8 gives

$$C_H-C_L=[H_2L]+[H]-[L]-\sum m[ML\,m] \quad (9)$$

If C_L is greater than C_M and $[H_2L]-[L]$ is much greater than $\sum m[ML\,m]$, we obtain the following approximate expression:

$$C_H-C_L=[H_2L]+[H]-[L] \quad (10)$$

The mean ligand number per metal ion, $\bar{n}$, is expressed by Eq. 11, obtained by combining Eq. 10 with α defined by Eq. 12:

$$\bar{n}=\frac{[MHL]+2[M(HL)_2]+\cdots\cdots+[ML]+2[ML_2]+\cdots}{[M]+[MHL]+[M(HL)_2]+\cdots\cdots+[ML]+[ML_2]+\cdots}=\frac{C_L-\frac{C_H-C_L-[H]}{\alpha}}{C_M} \quad (11)$$

$$\alpha=\frac{[H_2L]-[L]}{[H_2L]+[HL]+[L]} \quad (12)$$

$\bar{n}$ is also expressed in the following way by using successive stability constants:

$$\bar{n}=\frac{k_1\cdot[HL]+2\cdot k_1\cdot k_2\cdot[HL]^2+\cdots+k_1'\cdot[L]+2\cdot k_1'\cdot k_2'\cdot[L]^2+\cdots}{1+k_1\cdot[HL]+k_1\cdot k_2\cdot[HL]^2+\cdots+k_1'\cdot[L]+k_1'\cdot k_2'\cdot[L]+\cdots} \quad (13)$$

where k_n' and k_n are the n-th successive stability constants of the normal and the acidic complexes respectively. The spreading factors of k_n and k_n' being different, Bjerrum's successive approximation method can not be applied. Thus the authors employed the following method. In the $\bar{n}<1$ region, $\bar{n}$ is expressed by

$$\bar{n}=\frac{k_1\cdot[HL]+k_1'\cdot[L]}{1+k_1\cdot[HL]+k_1'\cdot[L]} \quad (14)$$

As both [HL] and [L] are known, k_1 and k_1' are calculated at the same time. In the $1<\bar{n}<2$ region, $\bar{n}$ is expressed by

$$\bar{n}=\frac{k_1\cdot[HL]+2\cdot k_1\cdot k_2\cdot[HL]^2+k_1'\cdot[L]+2\cdot k_1'\cdot k_2'\cdot[L]}{1+k_1\cdot[HL]+k_1\cdot k_2\cdot[HL]^2+k_1'\cdot[L]+k_1'\cdot k_2'\cdot[L]} \quad (15)$$

7) G. Schwarzenbach et al., *Helv. Chim. Acta*, 33, 985 (1950).

Using the values of k_1 and k_1' calculated from Eq. 14, k_2 and k_2' can also be evaluated. Repeating the above calculation allows the determination of k_n and k_n'.

Method C.—In method B, the existence of ML is neglected in the calculation of $\bar{n}$. Therefore, the error become naturally greater with the increasing ML concentration. In the present calculation, $\bar{n}$ was found in the following manner.

In the $a>3$ region, if the complexes are formed according to reaction 16, the difference in the amounts of alkali required for the titrations of the triphosphate solution and of the solution containing metal ions and triphosphate ions is equal to the amount of triphosphate combined with the metal.

$$\begin{aligned} &M+nH_2L \rightleftarrows M(HL)n+nH \\ &M+mHL \rightleftarrows MLm+mH \end{aligned} \qquad (16)$$

$\bar{n}$ is then expressed as

$$\bar{n}=\frac{C_L\cdot \Delta a}{C_M} \qquad (17)$$

where Δa is the difference in the amounts ot alkali explained above. Furthermore, k_n and k_n' are calculated in a way similar to method B.

The dissociation of the acidic complexes may be considered as

$$M(HL)_n \rightleftarrows M(HL)_pL_q+qH \qquad (18)$$

where p, $q>0$ and $p+q=n$.

In such a case, $\bar{n}$ will become greater than the true value, and mixed complexes are formed. If the formation of such mixed complexes is considered, it is not so easy to evaluate the stability constants of the acidic, normal and mixed complexes.

Method D.—*Replacement Reaction Method.*—The equilibrium constant between two kinds of ligands and a metal is given by Eq. 19:

$$K=\frac{[ML_2]\cdot[L_1]}{[L_2]\cdot[ML_1]} \qquad (19)$$

The constant is further expressed as the ratio of the stability constant of each complex.

$$K=\frac{K_2}{K_1} \qquad (20)$$

In the case where one ligand is a dye such as a metal indicator and the other is condensed phosphate, the concentration of ligands and complexes can be measured spectrophotometrically; therefore, K can be calculated. From K and the stability constant of the dye complex, the stability constant of the condensed phosphate complex is evaluated.

Experimental

Recrystallization of commercial anhydrous sodium triphosphate, Nippori, with ethanol was carried out three times according to the procedure described by Quimby[8]. The purified triphosphate, when tested by the X-ray diffraction method, showed only patterns of sodium triphosphate hexahydrate.

Trimetaphosphate was prepared from monosodium di-hydrogen orthophosphate by heating it for 5 hr. at 530°C[9] and recrystallizing it three times with ethanol. The dehydrated salt showed the X-ray patterns of anhydrous trimetaphosphate.

Tetrametaphosphate was prepared as follows[10]. Diphosphorous pentoxide, 100 g., was dissolved in 600 ml. of water at 15°C, and the solution was neutralized with sodium hydroxide. After ethanol was added to 50 v/o, the precipitated salt was filtered and redissolved in water. Repeating these procedures three times yielded crystalline tetrametaphosphate tetrahydrate, whose X-ray diffraction patterns showed no evidence of the existence of any other substances except tetrametaphosphate tetrahydrate.

EBT and Phthalein Complexon, obtained from the Dozin Yakukagaku Research Institute, were used as metal indicators for the replacement reaction.

A solution of triphosphoric acid was prepared by passing a solution of sodium triphosphate through an ion exchange column filled with an Amberlite IR-120 H-form. To avoid the effect of the complex formation of alkali metal with triphosphate, Watters used tetramethyl ammonium hydroxide and chloride. The stability constants obtained by Schwarzenbach in the titration of the triphosphate complex with potassium hydroxide in the presence of potassium chloride were not greatly different from Watters' values. Therefore, 20 ml. of the eluate from the column was mixed with 10 ml. of the metal standard solution and 3.3 ml. of 1 M potassium chloride solution, and the solution was finally titrated with a standard potassium hydroxide solution. The pH measurements were made by using a Hitachi EHP-1 pH meter with a glass electrode. The concentration of triphosphoric acid was determined by tiration prior to the experiment. Solutions of magnesium and calcium were prepared by dissolving magnesium bicarbonate and calcium carbonate in hydrochloric acid and by removing the free acid respectively. Solutions of strontium and barium were further prepared by dissolving their chloride salts in distilled water.

Replacement reactions were performed as follows. The dissociation constant of EBT was evaluated from the change in the absorbance of the EBT solution with a pH value at the maximum absorption in the visible range of the spectrum; the molar extinction coefficient was also evaluated from the change in concentration. The stability constants of phosphate complexes were found from the equilibrium constants and the stability constants

of the dye complexes. On calcium, strontium and barium, the measurements of the constants were performed in replacement reactions of phosphate with Phthalein Complexon in a way similar to that used for the EBT-magnesium system, since the stability of EBT complexes with the metals is too low and the complexes are not formed in a concentration suitable for the replacement reaction. The measurements were performed at an ionic strength of 0.1 with a buffer solution consisting of ammonium hydroxide and chloride.

Results

Though the results obtained by Watters show that the M_2L-type complex is present in the system of triphosphate and magnesium, the following experimental results make it seem probable that the main species of soluble complexes is a 1 to 1 complex. That is, the relations of the pH value and the volume of the 0.01 M sodium triphosphate solution which was added to 10 ml. of 0.01 M alkaline-earth metal solution are as shown in Fig. 2. As

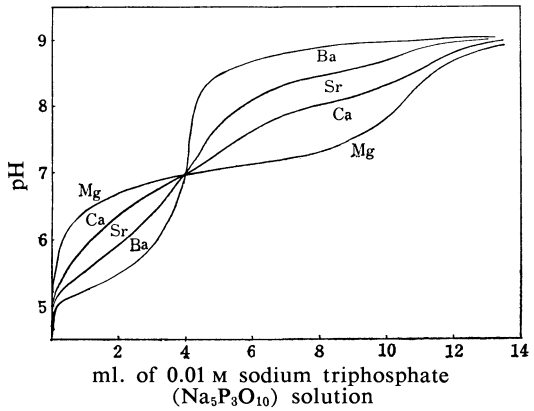

Fig. 2. The titration curves of 10 ml. of 0.01 M alkaline-earth metal solutions with 0.01 M sodium triphosphate solution.

can be seen in Fig. 2, the precipitated salt is normal salt ($P_3O_{10}/M=2/5$), and it redissolves in the form of a 1 to 1 complex in a higher region of the ratio of L/M than 2/5.

The stability constants calculated by method A, as given in Table I, are found at various

metal concentrations at which no precipitation occurs. The results on magnesium obtained by method B are plotted in Fig. 3, in which the relation between $\bar{n}$, pHL and pL is illustratrated. In the range where $\bar{n}$ is less than unity, both k_1 and k_1' are found graphically from the intersection of the lines corresponding to Eq. 21, as is seen in Fig. 4.

$$\left.\begin{aligned}
0.191 &= 0.809\times 1.28\times 10^{-4}\times k_1 \\
&\quad + 0.809\times 2.81\times 10^{-8}\times k_1' \\
0.319 &= 0.681\times 2.48\times 10^{-4}\times k_1 \\
&\quad + 0.681\times 7.86\times 10^{-8}\times k_1' \\
0.517 &= 0.483\times 4.59\times 10^{-4}\times k_1 \\
&\quad + 0.483\times 2.96\times 10^{-7}\times k_1' \\
0.601 &= 0.399\times 7.28\times 10^{-4}\times k_1 \\
&\quad + 0.399\times 8.37\times 10^{-7}\times k_1' \\
0.731 &= 0.269\times 9.91\times 10^{-4}\times k_1 \\
&\quad + 0.269\times 1.76\times 10^{-6}\times k_1'
\end{aligned}\right\} \quad (21)$$

The mean values of k_1 and k_1' are 3.24 and 5.69 respectively.

The results obtained by method C with magnesium, calcium, strontium and barium are plotted in Fig. 5. In the region where $\bar{n}$ is below unity, the k_1 and k_1' of magnesium are evaluated as mentioned above; their logarithms were found to be 3.63 and 5.41 respectively. In the case of calcium, strontium and barium, k_1' in Eq. 14 becomes zero, indicating that the concentration of ML is negligible compared with that of MHL.

Table II. Stability constants of acidic complexes calculated by method C

	Mg	Ca	Sr	Ba

Therefore, in the region where $\bar{n}$ is below unity, Eq. 22 gives the relation between $\bar{n}$, k_1 and HL. The values of k_1 are listed in Table II.

$$\bar{n} = \frac{k_1\cdot[\mathrm{HL}]}{1+k_1\cdot[\mathrm{HL}]} \quad (22)$$

As ring phosphoric acids are comparatively strong acids, the stability constants of the complexes between alkaline-earth metals and ring phosphoric acids cannot be evaluated by the usual titration method. In place of the titration method, the replacement reaction was utilized in the present experiments. The stability constants of magnesium complexes of ring phosphate and triphosphate are given in Table III.

The dissociation constants of phthalein complexon (H_6F) and the stability constants of the dye complexes with calcium and barium were reported by Schwarzenbach[11]. According to his data, the ratio of the concentration of CaF and CaHF is 0.01 at pH 9. At this pH,

Discussion

Because of the formation of precipitate at high pH values, the stability constants of triphosphate complexes cannot be evaluated by method A. The logarithmic values of the stability constants reported by Schwarzenbach and his coworkers are 3.7 and 3.1 respectively for magnesium and calcium acidic complexes MHL, and 5.80 and 4.85 for magnesium and calcium complexes ML. The values obtained by Watters are 3.34 and 3.01 respectively for magnesium and calcium acidic complexes, and 5.83 and 5.44 for magnesium and calcium complexes at an ionic strength of 0.1. With calcium, however, titration cannot be continued up to the alkaline region without causing precipitation. Therefore, the values for calcium complexes reported by them do not seem reasonable. However, if the stability of the complex is low, the amount of metal present in the form of the complex is negligible compared with the total concentration of metal ion, even if the latter is smaller than the concentration of acid.

In method B, the error becomes greater with the increasing concentration of ML, as can be seen from Eq. 9. In method C, the value of $\bar{n}$ becomes greater with the increasing dissociation of MHL as acid, as is evident from Eq. 18.

Our values found by methods B and C indicate that the dissociation of MHL is not very great; therefore, the assumption involved in the above methods is considered to be quite reasonable. The values obtained by the replacement reactions are consistent with the results found by using methods B and C. Further, the values evaluated at the largest metal concentration in the measurements by method A are nearly equal to those evaluated by the other methods, and the values summarized in Table V seem to be near to the true values.

Figure 6 shows the relation of the stability constants of the complexes to the ratio of the square of the charge of metal ions to the

ionic radius. The stability of principally ionic complexes of alkali and alkaline-earth metals is affected by both the charge and the ionic radius of the metal ions. Figure 7 shows the relation between $\log K$ and e^2/r for the series of alkaline-earth metal complexes. The two different trends are also observed with other ligands[12]. One group of ligands exhibits a maximum stability with calcium, while the stability of complexes with the other group of ligands increases monotonously from barium to magnesium. Ligands belonging to the former group possess a greater number of functional groups and form a greater number of chelate rings (e. g., EDTA) than do those belonging to the latter group.

As the stability of the condensed phosphate complexes increases monotonously from barium to magnesium, they do not seem to form complicated rings.

In Fig. 6, the values measured by electroconductivity and solubility methods by Monk et al.[13] are also included. The curves show a maximum at calcium, but there are no significant differences between the metals. Our data are different from theirs, and the values of Monk have already been criticized as too great by Gross[14].

It is already known that the complexes with ring phosphate are less stable than the chain phosphate complexes. This difference is attributed to the steric hindrance, which acts against the formation of chlelate rings, and to the stronger acidity of ring phosphate than chain phosphate. The results obtained by us also show that ring phosphate complexes are less stable than chain phosphates.

Stability of Condensed Phosphate Complexes. II. Rare-earth Metal Complexes

By Akira ROPPONGI and Takio KATO

(Received January 22, 1962)

Condensed chain phosphate has become an important commercial product since it has been known that its chemical properties, based on complex formation and surface activity, are useful in many fields of chemical industry.

Its ability of complex formation has been investigated by various methods, but the metal elements studied have been limited to alkali and alkaline-earth metals because of the precipitate formation of heavy metals with condensed chain phosphates over a wide range of pH values.

In order to investigate fundamentally the washing ability of chain phosphate, the present authors evaluated the stability constants of soluble complexes with various metals. As has been reported previously[1], triphosphate forms a precipitate in the presence of an excess of alkaline-earth metal ions except when magnesium is over the phosphate. On rare-earth metals, too, precipitate formation is observed in the presence of excess metal ions[2,3].

Therefore, the authors evaluated the stability constants of triphosphate complexes with the rare-earth metals by a new method to be described in the later part of this paper.

The ratio of triphosphate to metal in the complex was estimated by the following experiment: the change in the pH value of 10 ml. of a 0.01 M metal solution due to the addition of a triphosphate solution was measured by a glass electrode pH meter; the relation of the pH value to the ratio of the phosphate concentration to the metal concentration for several rare-earth metals is shown in Fig. 1. The abrupt change in pH value at the point where C_L/C_M is 3/5 means that the precipitate is normal salt and begins to dissolve as the concentration ratio of the phosphate to the metal becomes greater. The pH value of the solution increases again at the point where

1) A. Roppongi and T. Kato, This Bulletin, 35, 1086 (1962).

2) E. Giesbecht et al., *J. Inorg. Nuclear Chem.*, 6, 308 (1958).

3) E. Giesbecht, ibid., 15, 265 (1960).

C_L/C_M is 2/1; this means that the greatest number of the phosphates bound with the metal is equal to 2. Between 3/5 and 2/1 of C_L/C_M, 1 to 1 and 2 to 1 complexes may form successively; therefore, the precipitate dissolves in the presence of an excess of triphosphate.

Theoretical

A solution containing triphosphoric acid and rare-earth metal corresponding to one-fourth of the triphosphate concentration can be titrated with an alkaline hydroxide solution without precipitation up to an alkaline region; the pH value of the solution is lower than that of the solution which contains triphosphate only at a certain value in the region between 5 and 3 of *a*, which is the molar ratio of the added alkali per triphosphate. The decrease in pH value may be attributed to the complex formation of triphosphate with metal.

It is assumed that the species of complexes are only acidic, MHL and $M(HL)_2$, in the low pH region.

The equilibrium constants which are expressed by Eqs. 1 and 2:

$$k_1=\frac{[MHL]\cdot[H]}{[M]\cdot[H_2L]} \tag{1}$$

$$k_2=\frac{[M(HL)_2]\cdot[H]^2}{[M]\cdot[H_2L]^2} \tag{2}$$

are related to known values, that is, the total concentrations of the phosphate, and the metal, the dissociation constants of triphosphoric acid and the hydrogen ion concentration as follows:

The total concentration of triphosphate, C_L, and the replaceable hydrogen ion concentration, C_H, are:

$$C_L=[H_3L]+[H_2L]+[HL]+[MHL]+2[M(HL)_2] \tag{3}$$

$$C_H=3[H_3L]+2[H_2L]+[HL]+[H]+[MHL]+2[M(HL)_2] \tag{4}$$

and C_L is four times as large as the total metal ion concentration, C_M. The free phosphate ion concentration is expressed by

$$[H_3L]+[H_2L]+[HL]=\frac{C_H-C_L-[H]}{\frac{2[H]}{K_3}+1}\times\left(\frac{[H]}{K_3}+1+\frac{K_4}{[H]}\right) \tag{5}$$

where K_3 and K_4 are the third and the fourth dissociation constants of triphosphoric acid. The concentration of triphosphate combined with metal is

$$[MHL]+2[M(HL)_2]=[MHL]\times\left(1+\frac{2k_2}{k_1}\cdot\frac{\frac{C_H-C_L-[H]}{\frac{2[H]}{K_3}+1}}{[H]}\right) \tag{6}$$

Therefore, the concentration of MHL is

$$[MHL]=\frac{C_L-\frac{C_H-C_L-[H]}{\frac{2[H]}{K_3}+1}\cdot\left(\frac{[H]}{K_3}+1+\frac{K_4}{[H]}\right)}{1+\frac{2k_2}{k_1}\cdot\frac{\frac{C_H-C_L-[H]}{\frac{2[H]}{K_3}+1}}{[H]}} \tag{7}$$

By combining the condition that C_L is equal to $4\times C_M$ with Eqs. 5—7, the free metal concentration may be expressed by Eq. 8:

$$[M]=\frac{1}{4}\left[\left\{\frac{2(C_H-C_L-[H])}{\frac{2[H]}{K_3}+1}\times\left(\frac{[H]}{K_3}+1+\frac{K_4}{[H]}\right)-C_L\right\}-2\left\{\frac{C_L-\frac{C_H-C_L-[H]}{\frac{2[H]}{K_3}+1}\cdot\left(\frac{[H]}{K_3}+1+\frac{K_4}{[H]}\right)}{\frac{2k_2}{k_1}\cdot\frac{(C_H-C_L-[H])}{\frac{2[H]}{K_3}+1}\cdot[H]}\right\}\right] \tag{8}$$

By substituting Eqs. 5—8 into Eq. 1, Eq. 9 is obtained; it is then transformed into Eq. 10, in which k_1 is the tangent of the straight line and k_2 is the intercept in the y-axis.

$$k_1=\frac{C_L-\frac{C_H-C_L-[H]}{\frac{2[H]}{K_3}+1}\cdot\left(\frac{[H]}{K_3}+1+\frac{K_4}{[H]}\right)}{1+\frac{2k_2}{k_1}\cdot\frac{(C_H-C_L-[H])}{\frac{2[H]}{K_3}+1}\cdot[H]}\cdot[H]\Bigg/\frac{1}{4}\left[\left\{\frac{2(C_H-C_L-[H])}{\frac{2[H]}{K_3}+1}\cdot\left(\frac{[H]}{K_3}+1+\frac{K_4}{[H]}\right)-C_L\right\}-2\left\{\frac{C_L-\frac{C_H-C_L-[H]}{\frac{2[H]}{K_3}+1}\cdot\left(\frac{[H]}{K_3}+1+\frac{K_4}{[H]}\right)}{1+\frac{2k_2}{k_1}\cdot\frac{(C_H-C_L-[H])}{\frac{2[H]}{K_3}+1}\cdot[H]}\right\}\right]\times\frac{C_H-C_L-[H]}{\frac{2[H]}{K_3}+1} \tag{9}$$

$$k_1\cdot\frac{A}{B}\cdot D+k_2=\frac{C}{B}\cdot D^2 \tag{10}$$

where

$$A=1-\frac{3}{4}\cdot\frac{C_L}{\frac{C_H-C_L-[H]}{\frac{2[H]}{K_3}+1}\cdot\left(\frac{[H]}{K_3}+1+\frac{K_4}{[H]}\right)}$$

$$B=1-\frac{1}{2}\cdot\frac{C_L}{\frac{C_H-C_L-[H]}{\frac{2[H]}{K_3}+1}\cdot\left(\frac{[H]}{K_3}+1+\frac{K_4}{[H]}\right)}$$

$$C=\frac{C_L}{\frac{C_H-C_L-[H]}{\frac{2[H]}{K_3}+1}\cdot\left(\frac{[H]}{K_3}+1+\frac{K_4}{[H]}\right)}-1$$

$$D=\frac{[H]}{\frac{C_H-C_L-[H]}{\frac{2[H]}{K_3}+1}}$$

Both k_1 and k_2 can be evaluated graphically from the plot of $(A/B)\cdot D$ against $(C/B)\cdot D^2$. The stability constants are calculated from the equilibrium constants and the dissociation constants of triphosphoric acid. With an increase in the pH value of the solution, normal complexes such as ML and ML_2 may coexist, and the plot for Eq. 10 will deviate from a linear relation. In such a region, the stability constants of ML and ML_2 are obtained as follows by using the stability constants of the acidic complexes calculated above.

The constants are calculated on the assumption that the concentration of MHL is much greater than that of ML, since the main species of normal complexes is ML_2, as is seen in Fig. 1.

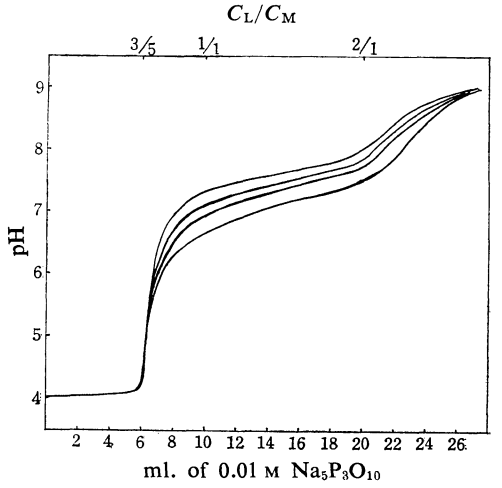

Fig. 1. The titration curves of 10 ml. of 0.01 M rare-earth metal solutions with 0.01 M sodium triphosphate ($Na_5P_3O_{10}$) solution.

Based on this assumption, the free metal ion concentration is derived from Eq. 11, where K_1^* is the stability constant of MHL.

$$4[M]+4[MHL]+4[ML]+4[M(HL)_2]+4[ML_2]=[H_2L]+[HL]+[L]+[MHL]+[ML]+2[M(HL)_2]+2[ML_2] \quad (11)$$

$$[M]=\frac{[H_2L]+[HL]+[L]-\frac{C_L}{2}}{K_1^*\cdot[HL]+2} \quad (12)$$

The total phosphate concentration, C_L, and the replaceable hydrogen concentration, C_H, are expressed as:

$$C_L=[H_2L]+[HL]+[L]+[MHL]+[ML]+2[M(HL)_2]+2[ML_2] \quad (13)$$

$$C_H=2[H_2L]+[HL]+[H]+[MHL]+2[M(HL)_2] \quad (14)$$

Combining Eqs. 12 and 14, Eq. 15, containing the stability constants of the acidic complexes, K_1^* and K_2^*, is induced.

$$C_H-[H]=\left(\frac{2[H]^2}{K_4\cdot K_5}+\frac{[H]}{K_5}\right)\cdot[L]+\frac{\left(\frac{[H]^2}{K_4\cdot K_5}+\frac{[H]}{K_5}+1\right)[L]-\frac{C_L}{2}}{K_1^*\cdot\frac{[H]}{K_5}\cdot[L]+2}\times\left(K_1^*\cdot\frac{[H]}{K_5}\cdot[L]+2K_2^*\cdot\left(\frac{[H]}{K_5}\right)^2\cdot[L]^2\right) \quad (15)$$

Equation 15 is then transformed to Eq. 16, which is the third order equation of [L] and can be solved graphically at a certain pH value.

$$2K_2^*\cdot\left(\frac{[H]}{K_5}\right)^2\cdot\left(\frac{[H]^2}{K_4\cdot K_5}+\frac{[H]}{K_5}+1\right)\cdot[L]^3+\left\{K_1^*\cdot\frac{[H]}{K_5}\cdot\left(\frac{3[H]^2}{K_4\cdot K_5}+\frac{2[H]}{K_5}+1\right)-K_2^*\cdot C_L\times\left(\frac{[H]}{K_5}\right)^2\right\}\cdot[L]^2+\left\{2\left(\frac{2[H]^2}{K_4\cdot K_5}+\frac{[H]}{K_5}\right)-K_1^*\cdot\frac{[H]}{K_5}\cdot\left(\frac{C_L}{2}+C_H-[H]\right)\right\}\cdot[L]-2(C_H-[H])=0 \quad (16)$$

Without neglecting the existence of ML, the concentration of ML_2 is expressed as:

$$[ML_2]=\frac{C_L-C_H+2[H]+[H_2L]-[L]}{\frac{K_1'}{K_2'}\cdot\frac{1}{[L]}+2} \quad (17)$$

and the concentration of M is:

$$[M]=\frac{[H_2L]+[HL]+[L]-\frac{C_L}{2}}{2+K_1^*\cdot[HL]+K_1'\cdot[L]} \quad (18)$$

where

$$K_1' = \frac{[ML]}{[M]\cdot[L]} \tag{19}$$

$$K_2' = \frac{[ML_2]}{[M]\cdot[L]^2} \tag{20}$$

Substituting Eqs. 17 and 18 into Eq. 20, K_2' is expressed as:

$$K_2' = \frac{\dfrac{C_L - C_H + 2[H] + [H_2L] - [L]}{\dfrac{K_1'}{K_2'}\cdot\dfrac{1}{[L]} + 2}}{\left(\dfrac{[H_2L] + [HL] + [L] - \dfrac{C_L}{2}}{2 + K_1^*\cdot[HL] + K_1'\cdot[L]}\right)\cdot[L]^2} \tag{21}$$

Equation 21 is transformed into the first order equation for K_1' and K_2', and the constants are evaluated by the plot of variables possible to be calculated from the concentration of L obtained graphically and the pH value measured.

$$\frac{2K_5 + K_1^*\cdot[L]\cdot[H]}{K_5\cdot[L]} \times \frac{C_L - C_H + [H] + \left(\dfrac{[H]^2}{K_4\cdot K_5} - 1\right)\cdot[L]}{C_H - \dfrac{3}{2}C_L - [H] + \left(\dfrac{[H]}{K_5} + 2\right)\cdot[L]} = K_1' + 2K_2'\cdot[L]\cdot\frac{\left(\dfrac{[H]^2}{K_4\cdot K_5} + \dfrac{[H]}{K_5} + 1\right)\cdot[L] - \dfrac{C_L}{2}}{C_H - \dfrac{3}{2}C_L - [H] + \left(\dfrac{[H]}{K_5} + 2\right)\cdot[L]} \tag{22}$$

If this assumption is reasonable, the plots should be on a linear line. In a high pH value region, complexes containing a hydroxyl group may be formed, and the difference in pH value for different rare-earth metals decreases. Therefore, it is reasonable that the estimation of the stability constants in the lower pH value region is better.

Experimental

In the case where the triphosphate concentration was twice as much as that of metal, a precipitate was slightly formed in the range of low pH values, approximately in the vicinity of 4. Thus the experiment were performed when the triphosphate concentration was four times the metal concentration.

Rare-earth metal solutions were prepared by dissolving 99.9% oxide in hydrochloric acid and removing the free acid completely by evaporation; the concentration was thus finally kept to 0.005 M.

A solution of 0.02 M sodium triphosphate was prepared by dissolving the recrystallized salt in distilled water; it contained 0.2 M of sodium perchlorate.

After mixing 10 ml. of a metal solution with a sodium triphosphate solution, the resulting solution was titrated with a 0.05 M perchloric acid solution containing 0.1 M sodium perchlorate.

The pH value was measured by a Hitachi pH meter EHP-1 type with a 0.02 unit.

Results and Discussion

The values of the variables in Eq. 10 were calculated by using the dissociation constants of triphosphoric acid, and the hydrogen ion concentration was obtained by dividing the pH values by Kieland's activity coefficient at the ionic strength, $\mu = 0.1$.

The dissociation constants are $10^{-2.15}$, $10^{-6.00}$ and $10^{-8.73}$ for K_3, K_4 and K_5 respectively.

The values of the variables in Eq. 10 for lanthanum are shown in Table I, while the values calculated for various rare-earth metals are plotted in Fig. 2. The stability constants for MHL and $M(HL)_2$ obtained from the lines in Fig. 2 are tabulated in Table II. In order to evaluate the stability constants of normal complexes, the values of [L] at various pH values were obtained from Eq. 16 by using the stability constants of acidic complexes obtained above. By substituting the values of [L] into Eq. 22, the variables were calculated. The values for lanthanum are tabulated in Table III. Further, the values of the left term and the right term in Eq. 22 for various rare-earth metals are plotted in Fig. 3. From the inclination and the intercept of the straight lines giving the relation between K_1' and K_2' for the rare-earth metals, the stability constants of ML and ML_2 were obtained; these results are shown in Table IV.

In Fig. 2, the deviation from linearity in variables of a smaller value may be attributed to the formation of the normal complexes. As the calculated values have a linear relation MHL and $M(HL)_2$ coexist, and neither ML nor

$$\frac{2[L]\cdot\left(\frac{[H]^2}{K_4\cdot K_5}+\frac{[H]}{K_5}+1\right)\cdot[L]-\frac{C_L}{2}}{C_H-\frac{3}{2}C_L-[H]+\left(\frac{[H]}{K_5}+2\right)\cdot[L]}$$

Fig. 3. The relations of K_1' and K_2' in Eq. 22 for rare-earth metals.

ML_2 exist appreciably in the pH range in which calculations were made.

ML and ML_2 may form successively as the value of pH becomes greater. However, as is seen in Fig. 3, the intercepts in the y-axis of the lines are nearly zero for all the metals measured. This shows that the main species of normal complexes is ML_2 under the conditions for which the measurements were made.

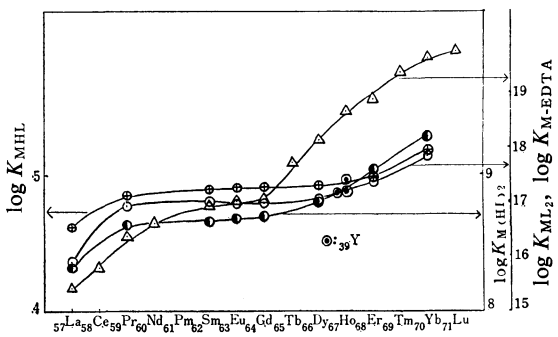

Fig. 4. The relations of the stability constant with the atomic number of rare-earth metals.
⊕ : $\log K_{MHL}$, ◐ : $\log K_{M(CHL)_2}$,
⊙ : $\log K_{ML_2}$, △ : $\log K$ for EDTA complex

Thus, the assumption made for the calculation seems to be reasonable.

The relation between the stability constants and the atomic number of the rare-earth metals is shown in Fig. 4; the tendency is the same as that of the EDTA complex[4].

Triphosphate can keep the rare-earth metal in solution over a wide range of pH values if it exists in a large excess over the metal.

Ultraviolet Spectrophotometric Determination of Boron Using Tiron as a New Reagent

By Kazuo HIIRO*

(Received September 6, 1961)

Previous publications have described how many kinds of colorimetric reagents, such as oxyanthraquinones, flavone compounds, curcumin, etc., have been examined photometrically for boron. In the case of oxyanthraquinones, the colored complexes are formed in a concentrated sulfuric acid medium, while in the case of flavones or curcumin, sample solution should be evaporated with the reagent solution under conditions carefully controlled for color development. Since these procedures are very tedious and time-consuming, it would seem advantageous if the color development could be achieved simply and rapidly in an aqueous medium.

Tiron, disodium 1, 2-dihydroxybenzene-3, 5-disulfonate, was initially proposed as a photometric reagent for iron by Yoe and Jones[1]; thereafter this reagent has been utilized for the determination of titanium[2-7], iron[3,6], cerium[8-10], molybdenum[11,12], uranium[13] and niobium[14] in many kinds of samples.

This compound is expected to be a useful reagent of boron, because it has vicinal hydroxy groups which may be functional groups for boron. As a result of preliminary experiments based upon the above expectation, it was found that tiron could be applicable to the photometric determination of boron. The new photometric method is very convenient and advantageous, because the procedure is carried out rapidly in an aqueous medium and the boron-tiron complex formed is very stable under controlled conditions.

In this paper, the application of the reagent to the new spectrophotometric method for boron is described. The absorption spectra of dilute tiron solutions with various pH values were taken, and the existence of four isosbestic points, at 230, 243, 279 and 293 mμ, was confirmed. Then the absorption curves of mixed solutions of boron and tiron with various pH values against tiron solution as a reference were taken, and the optimum pH value and wavelengths for measurements were found. The effects of the concentrations of a tiron and buffer solution, of diverse salts and of the temperature were examined. It was found that the boron-tiron complex had a mole ratio of 1 : 1 under the proposed conditions, and that Beer's law was obeyed in the range from 0.40 to 3.20 p. p. m. of boron at the wavelengths of both 252 and 306 mμ.

Experimental

Apparatus. — Spectrophotometric measurements were made with a Shimadzu quartz spectrophotometer, model QB-50, using 1.000 cm. quartz transmission cells. A Horiba glass electrode pH meter, model H-3, was used for all pH measurements.

Materials.—*Standard Boron Solutions.*—Dissolve 0.5716 g. of reagent grade boric acid in 1000.0 ml. of water. This solution corresponds to 100.0 p.p.m. of boron. Dilute an aliquot of the solution with water, and prepare 10.0 p. p. m. of a standard boron solution.

Tiron Solution.—Dissolve 3.1422 g. of tiron (Dotite-Tiron) in 1000.0 ml. of water and prepare a 10^{-2}M solution.

Buffer Solution.—Prepare a buffer solution of the Michaelis type by mixing 4 parts of a 0.5 M disodium hydrogen phosphate solution and 1 part of a 0.5 M potassium dihydrogen phosphate solution, and adjust the pH to 7.40~7.50. Various other salt solutions were prepared from the reagents of an analytical grade.

Procedure.—Pipet an aliquot of the boron solution into a 25.0 ml. measuring flask, and add to it 2.0 ml. of a 10^{-2} M tiron solution and 1.0 ml.

of a buffer solution of pH 7.40~7.50, and dilute it to the mark with water. Mix thoroughly and measure the absorption of the solution at 252 or 306 mμ against a reagent blank.

In order to study the effect of diverse salts, color developments were made using 30.0 μg. of boron in the presence of varying amounts of 2.0% salt solutions.

To ascertain the stability of the color, absorbances of the solution were measured at proper time intervals after color development.

Measurements of the absorption spectra of the dilute tiron solution at various pH values are made as follows: Into a 50.0 ml. measuring flask, pipet 2.0 ml. of a 10^{-3} M tiron solution, and add 5.0 ml. of a buffer solution of 0.5 M disodium hydrogen phosphate-potassium dihydrogen phosphate, 1 M sodium acetate-acetic acid, and or 1 M aqueous ammonia-ammonium chloride to the flask and dilute it to the mark with water. The absorption spectra of these solutions were measured at 5 mμ intervals of wavelength against water as a reference.

Results

Absorption Spectra of Tiron Solution.—As shown in Fig. 1, when the pH of the solution increases, two absorption maxima (260 and 305 mμ) appear, while when the pH decreases, absorbance at the absorption maximum (290 mμ) increases. There are four isosbestic points, at 230, 243, 279 and 293 mμ.

Effect of pH.—In Fig. 3, the absorbances at the absorption maxima are plotted against the pH values. It was found that the maximum absorptions were obtained over the pH range of 7.40~7.50. For the photometric measurements, it is advantageous to select the wavelengths of maximum absorption, at 252 and 306 mμ, as is shown in Fig. 4, in which graphs are plotted of the maximum wavelengths against the pH values.

Reagent Concentration.—In order to find a proper concentration of tiron, the measurement of the absorbances of a series of solutions containing 2.00 or 4.00 p. p. m. of boron with varying amounts of the reagent was undertaken, using the reagent blanks of the same concentration as references. As is shown in Fig. 5, 2.0 ml. of a 10^{-2} M tiron solution in 25.0 ml. is the optimum amount.

Effect of the Buffer Solution.—The effect of the buffer solution was tested with varying amounts of a 0.5 M disodium hydrogen phosphate-potassium dihydrogen phosphate buffer solution. 1.0~2.0 ml. of the buffer solution is favorable, as is shown in Fig. 6. The addition of 1.0 ml. of the buffer solution is thus adopted in the following experiments.

	100	0.517	0.479

Stability of Absorbance.— The absorbances of the solution of a boron-tiron complex show no appreciable change during about 20 hr., although they decrease slightly after 3 days.

Effect of Temperature.—It is observed that the absorbances are affected by the temperature of the solution; that is, the values of absorbance increase as the temperature falls. The temperature coefficients are 0.00159~0.00176/°C at 252 mμ and 0.00161~0.00176/°C at 306 mμ for 1.00 p. p. m. of boron.

Effect of Diverse Salts.— As is shown in Table I, it is found that sodium sulfate and sodium acetate do not interfere when they are present 20 mg. per 25.0 ml. However, sodium sulfite interferes seriously at a concentration of 10 mg. per 25.0 ml.

Mole Ratio of Boron to Tiron in Solution.— In order to confirm the mole ratio of the boron-tiron complex, two methods were employed, the continuous variation and the slope ratio methods. In the first method, the measurement of the absorbances of a series of solution containing a varying mole per cent of 10^{-2} M boron and 10^{-2} M tiron was undertaken, using as references the reagent blanks of the same concentrations. As is shown in Fig. 7, the maximum absorbance of the complex was obtained when the mole ratio of boron to tiron is 1 to 1.

In the second method, two series of solutions were prepared: one with a varying concentration of boron in the presence of a large, constant amount of tiron, and the other with a varying concentration of tiron in the presence of a large, constant amount of boron. The absorbances of each series of solutions were also measured. Two linear absobance-concentration curves with the same tangential value of the slope were obtained, as is shown in Fig. 8. From the results of these experiments, it is confirmed that the mole ratio of boron to tiron in the complex formed is 1 to 1.

—●— Boron; A ml. Tiron; 2.0 ml.
—○— Boron; 2.0 ml. Tiron; A ml.

Calibration Curves.—To establish calibration curves, measurements of absorbance readings were made with a number of the boron-tiron solutions containing different amounts of boron; they were plotted against boron content. The results show that Beer's law is obeyed over the range from 0.40 to 3.20 p. p. m. of boron at the wavelengths of both 252 and 306 mμ,

—○— Obtained at 252 mμ
—●— Obtained at 306 mμ

as in Fig. 9. The sensitivities of this method are 0.17/cm^2 and 0.20/cm^2, and the molar extinction coefficients are 1620 and 1370 at 252 and 306 mμ respectively.

Discussion

The proposed new photometric method for the determination of boron with tiron as a color reagent is more simple and rapid than other methods. As is shown in Figs. 7 and 8, the constitution of the boron-tiron complex has the mole ratio of 1 : 1. Because the measurements of absorbance are made in the ultraviolet region, some obvious interferences with diverse metal ions are to be expected. Therefore, for the determination of boron in many kinds of practical samples, a proper separation of boron is desired. In this procedure, absorbance is affected by the temperature, so the absorption measurements must be done under as constant temperature as possible. Fortunately, the effect of temperature difference can be eliminated, provided that the calibration curves are made simultaneously with the sample analysis. Determination of the boron content of many samples is now proceeding in this laboratory. In this procedure, however, absorbance is very stable for about 20 hr.; this is advantageous for the spectrophotometric measurements.

The author is indebted to Dr. Yuroku Yamamoto, Hiroshima University, for his guidance, and to Dr. Isao Muraki, Chief o the 5th Department of our Institute, for his useful suggestions.

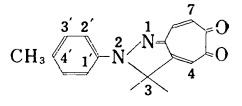
*The Bromination Product of 2-(p-Tolyl)-hinopurpurin**

By Seiji EBINE

(Received September 14, 1961)



As has been previously reported by Nozoe et al., hinokitiol, i.e., 4-isopropyltropolone, couples with diazotized amines to yield azo-hinokitiols, which, on heating in an acetic acid solution or in an ethanolic solution in the presence of *p*-benzoquinone, bring about its transformation into so-called hinopurpurins[1]. It has recently been found that 2-phenyl-hinopurpurin is brominated to yield 2-phenyl-4, 7-dibromohinopurpurin[2]. This paper reports on similar experiment undertaken in order to determine the position of bromine atoms of dibromo-2-(*p*-tolyl)-hinopurpurin (A).

The dibromo compound A was obtained by bromination of 2-(*p*-tolyl)-hinopurpurin (I)[3] and also by bromination of 2-(*p*-tolyl)-7-bromohinopurpurin (II). The ultraviolet spectrum of A was closely analogous to that of I. These facts indicate that A is not a bromine-addition product but a bromine-substitution product of I, and that one of its two bromine atoms is situated at the 7-position in the tropoquinone ring. An ortho directing effect exerted by methyl and nitrogen substituents and an electromeric effect (shown by Ia) suggest that the substitution reaction of I with bromine may take place at the 2′- or 3′-position in the benzene ring, or at the 4- or 7-position in the tropoquinone ring. Accordingly, it can be presumed that A is either a 7, 2′-, 7, 3′- or 4, 7-dibromo derivative of I. An attempt, therefore, was made to synthesize these dibromo derivatives of I as well as some other bromo derivatives of 5-(*p*-tolylazo)-hinokitiol.

Hinokitiol was coupled with diazotized 2- and 3-bromo-4-methylanilines to yield 5-(2′-bromo-4′-methylphenylazo)- and 5-(3′-bromo-4′-methylphenylazo)-hinokitiols (III and IV), which, on heating with *p*-benzoquinone in an ethanolic solution, were then transformed into the corresponding 2-(2′-bromo-4′-methylphenyl)- and 2-(3′-bromo-4′-methylphenyl)-hinopurpurins (V and VI) respectively. The bromination of V and VI gave 2-(2′-bromo-4′-methylphenyl)- and 2-(3′-bromo-4′-methylphenyl)-*x*,*x*-dibromohinopurpurins. The coupling of 7-bromohinokitiol with diazotized 2-bromo-4-methylaniline afforded 5-(2′-bromo-4′-methylphenylazo)-7-bromohinokitiol (VII), which was subsequently transformed into 2-(2′-bromo-4′-methylphenyl)-7-bromohinopurpurin (VIII). Although 5-(*p*-tolylazo)-hinokitiol is brominated to its 7-bromo derivative[3], bromination of III did not give VII but, rather, yielded a tribromo hinopurpurin identical with a bromination product of V. The coupling of 7-bromohinokitiol with diazotized 3-bromo-4-methylaniline afforded 5-(3′-bromo-4′-methylphenylazo)-7-bromohinokitiol (IX), which was also prepared by bromination of IV. The transformation of IX into 2-(3′-bromo-4′-methylphenyl)-7-bromohinopurpurin (X) was effected in the usual manner. Neither of the dibromohinopurpurins, VIII or X, was identical with A. The coupling of 3, 7-dibromohinokitiol with diazotized *p*-toluidine failed to occur in an alkaline solution, but it did take place in a pyridine solution to yield 5-(*p*-tolylazo)-3, 7-dibromohinokitiol (XI). XI was somewhat stable towards hinopurpurin-transformation and recovered unchanged when its acetic acid solution was heated on a water bath for 3 hr. However, when heated with *p*-benzoquinone in an ethanolic solution under reflux for 5 hr., XI underwent transformation, accompanied by the elimination of one of its bromine atoms, to yield II. Thus it was impossible to prepare 2-(*p*-tolyl)-4, 7-dibromohinopurpurin (XII) from XI, which had its bromine atoms at known positions. Nevertheless, it has now become evident that XII is the only possible structure for A because neither VIII nor X proved to be identical with A, as has been described above. Therefore, it is furthermore presumed that the above-mentioned bromination products of V and VI are 2-(2′-bromo-4′-methylphenyl)- and 2-(3′-bromo-4′-methylphenyl)-4, 7-dibromohinopurpurins (XIII and XIV) respectively.

It is of interest to note that 2′-brominated 2-(*p*-tolyl)-hinopurpurins, such as V, VIII and XIII, are light red-colored compounds, while all other hinopurpurins are dark purple or deep blue. The light color of 2′-brominated 2-(*p*-tolyl)-hinopurpurins may be ascribed to the steric hindrance of the 2′-bromine atoms which rotate the benzene rings, out of the plane of the hinopurpurin molecules.

Experimental

Monobromo-5-(*p*-tolylazo)-hinokitiols.—*5-(2′-Bromo-4′-methylphenylazo)-hinokitiol (III).*—2-Bromo-4-methylaniline hydrochloride (1.5 g.), dissolved in 8 ml. of 1.2 N hydrochloric acid, was diazotized with a solution of 0.42 g. of sodium nitrite in 4 ml. of water. The diazotized solution was added drop by drop to a solution of 1 g. of hinokitiol and 1.2 g. of potassium hydroxide in 30 ml. of water. The product which separated out on acidification with dilute hydrochloric acid was collected, washed with water, dried and crystallized from benzene to yield 1.65 g. (75%) of III, in the form of orange needles, m. p. 147.5°C.

Found: C, 56.47; H, 4.94; N, 7.85. Calcd. for $C_{17}H_{17}O_2N_2Br$: C, 56.52; H, 4.74; N, 7.75%.

5-(3′-Bromo-4′-methylphenylazo)-hinokitiol (IV).—This was prepared by the coupling of hionkitiol with diazotized 3-bromo-4-methylaniline in the same way as described above. Yield, 77% in the form of reddish orange needles (from benzene), m. p. 147°C.

Found: C, 56.28; H, 4.96; N, 7.88. Calcd. for $C_{17}H_{17}O_2N_2Br$: C, 56.52; H, 4.74; N, 7.75%.

Dibromo-5-(*p*-tolylazo)-hinokitiols.—*5-(2′-Bromo-4′-methylphenylazo)-7-bromohinokitiol (VII).*—A solution of 0.5 g. of 7-bromohinokitiol[4] and 0.4 g. of potassium hydroxide in 50 ml. of water was coupled with a diazotized solution prepared from 0.5 g. of 2-bromo-4-methylaniline hydrochloride, 0.14 g. of sodium nitrite and 2.7 ml. of 1.2 N hydrochloric acid. The crude product obtained was crystallized from acetone to yield 0.6 g. (66%) of VII, as reddish orange needles, m. p. 132.5°C.

Found: C, 46.53; H, 3.55; N, 6.65. Calcd. for $C_{17}H_{16}O_2N_2Br_2$: C, 46.39; H, 3.66; N, 6.35%.

5-(3′-Bromo-4′-methylphenylazo)-7-bromohinokitiol (IX).—a) It was prepared by the coupling of 7-bromohinokitiol with diazotized 3-bromo-4-methylaniline in the same way as cited above. b) To a solution of 0.5 g. of IV in 70 ml. of acetic acid was added, drop by drop, 0.35 g. of bromine dissolved in 3.5 ml. of acetic acid. After the mixture had been left standing for 30 min., the precipitate was collected by filtration. The product obtained was an addition compound which, on crystallization from acetone, regenerated IV with the liberation of bromine. The addition compound was dissolved in pyridine, and the solution was warmed at 80°C for 10 min., and diluted with water. The precipitate formed was recrystallized from acetone to yield 0.32 g. (52%) of IX, in the form of orange needles, m. p. 168~169°C.

Found: C, 46.58; H, 3.75; N, 6.55. Calcd. for $C_{17}H_{16}O_2N_2Br_2$: C, 46.39; H, 3.66; N, 6.35%.

5-(p-Tolylazo)-3,7-dibromohinokitiol (XI).—3, 7-Dibromohinokitiol[4] (500 mg.) dissolved in 50 ml. of pyridine was coupled with a diazotized solution prepared from 185 mg. of *p*-toluidine, 107 mg. of

4) T. Nozoe, E. Sebe, S. Mayama and S. Iwamoto, *Sci. Repts. Tohoku Univ.*, I, 36, 184 (1952).

sodium nitrite and 3.4 ml. of 1.2 N hydrochloric acid. After the mixture had been left standing overnight in an ice-chest, the pyridine was removed in vacuo below 30°C and the residue was treated with boiling ligroin. The ligroin solution gave a crystalline precipitate on cooling, which precipitate was collected and recrystallized from methanol or acetone to yield 110 mg. (16%) of XI, as orange needles, m. p. 167°C.

Found: C, 46.26; H, 3.56; N, 6.14. Calcd. for $C_{17}H_{16}O_2N_2Br_2$: C, 46.39; H, 3.66; N, 6.35%.

Monobromo-2-(*p*-tolyl)-hinopurpurins.—An ethanolic solution consisting of monobromo-5-(*p*-tolylazo)-hinokitiols and of a 1 mol. equiv. of *p*-benzoquinone was refluxed for 5 hr. The ethanol was then evaporated, and the residue was recrystallized from ethanol or acetic acid to yield the corresponding hinopurpurins.

2-(2'-Bromo-4'-methylphenyl)-hinopurpurin (V).—A solution of 200 mg. of III and 60 mg. of *p*-benzoquinone in 10 ml. of ethanol was refluxed for 5 hr. to yield 150 mg. (75%) of V, in the form of orange, prismatic needles, m. p. 222~223°C.

Found: C, 56.79; H, 4.31; N, 7.91. Calcd. for $C_{17}H_{15}O_2N_2Br$: C, 56.84; H, 4.21; N, 7.80%.

2-(3'-Bromo-4'-methylphenyl)-hinopurpurin (VI).—IV (200 mg.) and 60 mg. of *p*-benzoquinone dissolved in 10 ml. of ethanol gave 140 mg. (70%) of VI, as dark blue crystals with a greenish luster, m. p. 241°C.

Found: C, 57.12; H, 4.38; N, 7.55. Calcd. for $C_{17}H_{15}O_2N_2Br$: C, 56.84; H, 4.21; N, 7.80%.

2-(p-Tolyl)-7-bromohinopurpurin (II).—A solution of 200 mg. of XI and 60 mg. of *p*-benzoquinone in 80 ml. of ethanol was refluxed for 5 hr. to give 100 mg. (61%) of II, in the form of steel-blue prisms, m. p. 222°C (Found: C, 57.18; H, 4.01; N, 7.86. Calcd. for $C_{17}H_{15}O_2N_2Br$: C, 56.84; H, 4.21; N, 7.80%), the melting point of which was not depressed on admixture with an authentic sample[5] prepared by the transformation of 5-(*p*-tolylazo)-7-bromohinokitiol.

The same tranformation was effected when an acetic acid solution of XI was refluxed for 5 hr. Dilution of the reaction mixture with water gave II in a 55% yield, and an addition of silver nitrate to the filtrate caused the precipitation of a quantitative amount of silver bromide.

Dibromo-2-(*p*-tolyl)-hinopurpurins.—*2-(p-Tolyl)-4,7-dibromohinopurpurin (XII).*—a) To a solution of 200 mg. of I in 160 ml. of acetic acid was added 250 mg. (2.2 mol. equiv.) of bromine dissolved in 3 ml. of acetic acid. A crystalline product began to separate immediately. After the solution had been left standing for 30 min., the product was collected and recrystallized from acetic acid to yield 220 mg. (70%) of XII, m. p. 227°C. XII dissolves in boiling acetic acid, forming a deep purple solution, from which on cooling it separates in the form of golden yellow scales with a metallic luster. XII showed a marked melting point depression on admixture with VIII and X, as is described below.

Found: C, 46.32; H, 3.56; N, 6.58. Calcd. for $C_{17}H_{14}O_2N_2Br_2$: C, 46.60; H, 3.22; N, 6.39%. Treatment of I with a 1 mol. equiv. of bromine again gave XII, the corresponding monobromo derivative not being formed. b) Bromination of 100 mg. of II with 75 mg. of bromine in 110 ml. of acetic acid gave 90 mg. (74%) of XII.

2-(2'-Bromo-4'-methylphenyl)-7-bromohinopurpurin (VIII).—A solution of 70 mg. of VII and 35 mg. of *p*-benzoquinone in 30 ml. of ethanol was refluxed for 3 hr.; the ethanol was then evaporated, and the residue was recrystallized from ethanol to give 45 mg. (64%) of VIII, in the form of reddish orange crystals, m. p. 207.5~208°C.

Found: C, 46.39; H, 3.20; N, 6.20. Calcd. for $C_{17}H_{14}O_2N_2Br_2$: C, 46.60; H, 3.22; N, 6.39%.

2-(3'-Bromo-4'-methylphenyl)-7-bromohinopurpurin (X).—A solution of 100 mg. of IX in 5 ml. of acetic acid was heated at 100°C for 3 hr. The product which separated on cooling was crystallized from acetic acid to afford 55 mg. (55%) of X, as dark violet prisms, m. p. 248~249°C.

Found: C, 46.58; H, 3.33; N, 6.15. Calcd. for $C_{17}H_{14}O_2N_2Br_2$: C, 46.60; H, 3.22; N, 6.39%.

Tribromo-2-(*p*-tolyl)-hinopurpurins.—*2-(2'-Bromo-4'-methylphenyl)-4,7-dibromohinopurpurin (XIII).*—To a solution of 100 mg. of III in 15 ml. of acetic acid at 60°C was added 100 mg. of bromine. The solution was allowed to stand for 30 min. at the same temperature. Dilution with 5 ml. of water gave a precipitate, which was collected and crystallized from ethanol. Yield, 85 mg. (59%), in the form of reddish orange prisms, m. p. 179°C.

Found: C, 39.65; H, 2.72; N, 5.25. Calcd. for $C_{17}H_{13}O_2N_2Br_3$: C, 39.49; H, 2.54; N, 5.42%.

XIII was reduced with alkaline hydrosulfite to a leuco compound which regained its original red color on exposure to air and which gave a quinoxaline derivative of red plates melting at 189°C.

Found: C, 47.19; H, 2.86; N, 9.18. Calcd. for $C_{23}H_{17}N_4Br_3$: C, 46.89; H, 2.91; N, 9.51%.

2-(3'-Bromo-4'-methylphenyl)-4,7-dibromohinopurpurin (XIV).—Bromine (200 mg.) dissolved in 2 ml. of acetic acid was added to a solution of 100 mg. of VI in 300 ml. of acetic acid; the resulting solution was allowed to stand for 30 min. Dilution with water gave the product, which was collected and recrystallized from acetic acid. Yield, 90 mg. (62%) in the form of scales with a golden metallic luster, m. p. 246°C.

Found: C, 39.22; H, 2.67; N, 5.70. Calcd. for $C_{17}H_{13}O_2N_2Br_3$: C, 39.49; H, 2.54; N, 5.42%.

The author takes this opportunity to express his gratitude to Professor Tetsuo Nozoe of Tohoku University for his encouragement. The author is also indebted to Mrs. Kuniko Kodaira of Tohoku University for her microanalyses.

Dehydration Reactions of Benzaldoxime by Means of Compounds Having a Nitrogen-Carbon Double Bond

By Teruaki MUKAIYAMA, Tamotsu FUJISAWA and Ohyo MITSUNOBU

(Received October 14, 1961)

Preceding papers of this series have shown that acetylenic ethers, vinyl ethers, vinyl acetate, ketene acetals, isocyanates and carbodiimides dehydrate aldoximes, primary nitroparaffins and hydroxamic acids, giving nitriles, nitrile oxides and isocyanates respectively[1-6]. These results lead to the conclusion that compounds having either a cumulate double bond or a multiple bond, with alkoxyl or acyloxyl groups, are effective as dehydrating reagents. This paper reports a further study of the dehydration reactions of benzaldoxime by means of phenylimidophosgene, ethyl *N*-phenyliminochloroformate and ethyl *N*-phenylformimidate. These substances are nitrogen-carbon double bond compounds which have halogen(s) and/or an alkoxyl group as substituents attached to the carbon atom.

First, when 1 mol. of phenylimidophosgene was treated with 1 mol. of benzaldoxime in dry benzene under stirring, an evolution of heat was noticeable, and phenyl isocyanate and benzonitrile were obtained in good yields, along with hydrogen chloride and a small amount of aniline hydrochloride (Eq. 1).

$$\begin{aligned} &C_6H_5N{=}C\begin{matrix}Cl\\Cl\end{matrix} + HON{=}CHC_6H_5 \\ &\longrightarrow \underset{\text{(I)}}{\left[C_6H_5N{=}\overset{Cl}{C}ON{=}CHC_6H_5\right]} + HCl \\ &[C_6H_5NHCOCl] + C_6H_5C{\equiv}N \longleftarrow \text{(I)} \\ &[C_6H_5NHCOCl] \longrightarrow C_6H_5N{=}C{=}O + HCl \end{aligned} \quad (1)$$

It is reasonable to postulate that the reaction proceeds through the intermediate I, which in turn decomposes to give benzonitrile and *N*-phenylcarbamyl chloride. The latter subsequently decomposes to produce phenyl isocyanate and hydrogen chloride. The formation of aniline hydrochloride may be attributed to the decomposition of adduct II of phenyl isocyanate and benzaldoxime by hydrogen chloride, as is shown in the following equation:

$$\begin{aligned} &C_6H_5N{=}C{=}O + HON{=}CHC_6H_5 \\ &\longrightarrow \underset{\text{(II)}}{C_6H_5NHCOON{=}CHC_6H_5} \\ &\longrightarrow C_6H_5NH_2 + C_6H_5C{\equiv}N + CO_2 \\ &\quad \xrightarrow[HCl]{} C_6H_5NH_2HCl \end{aligned} \quad (2)$$

In order to confirm the above assumption, the reaction of 2 mol. of benzaldoxime with 1 mol. of phenylimidophosgene was tested. When they were allowed to react in dry benzene at room temperature under vigorous stirring for a while, a violent reaction suddenly took place and aniline hydrochloride and benzonitrile were obtained in good yields, along with the evolution of hydrogen chloride and carbon dioxide. The results show that the violent reaction is initiated by the hydrogen chloride initially formed.

Secondly, the treatment of ethyl *N*-phenyliminochloroformate with benzaldoxime was attempted. When they reacted in dry benzene, the evolution of hydrogen chloride and carbon dioxide was observed, and ethyl *N*-phenylcarbamate and benzonitrile were produced in good yields, along with a small amount of aniline hydrochloride and *sym*-diphenylurea (Eq. 3).

$$\begin{aligned} &C_6H_5N{=}\overset{Cl}{C}OC_2H_5 + HON{=}CHC_6H_5 \\ &\longrightarrow \underset{\text{(III)}}{\left[C_6H_5N{=}\overset{OC_2H_5}{C}ON{=}CHC_6H_5\right]} + HCl \\ &C_6H_5NHCOOC_2H_5 + C_6H_5C{\equiv}N \longleftarrow \text{(III)} \end{aligned} \quad (3)$$

Analogous to the case of phenyl imidophosgene, the reaction can be explained by assuming the existence of the intermediate III, which is the condensation product of ethyl *N*-phenyliminochloroformate and benzaldoxime. This readily decomposes to give ethyl *N*-phenylcarbamate and benzonitrile. Further, since ethyl *N*-phenyliminochloroformate is decomposed with hydrogen chloride or at temperatures over 100°C, yielding phenyl isocyanate and ethyl chloride (Eq. 4), the formation of

2) T. Mukaiyama and T. Hata, This Bulletin, **33**, 1382 (1960).
3) T. Mukaiyama and T. Hata, ibid., **33**, 1712 (1960).
4) T. Mukaiyama and T. Hata, ibid., **34**, 99 (1961).
5) T. Mukaiyama and H. Nohira, *J. Org. Chem.*, **26**, 782 (1961).
6) T. Mukaiyama, K. Tonooka and K. Inoue, ibid., **26**, 2202 (1961).

aniline hydrochloride and *sym*-diphenylurea is attributed to the reactions of the isocyanate with benzaldoxime (Eq. 2) and with aniline (Eq. 5) respectively.

$$C_6H_5N{=}\underset{\underset{Cl}{|}}{C}OC_2H_5 \rightarrow C_6H_5N{=}C{=}O + C_2H_5Cl \qquad (4)$$

$$C_6H_5N{=}C{=}O + C_6H_5NH_2 \rightarrow (C_6H_5NH)_2CO \qquad (5)$$

On the other hand, it is noteworthy that diethyl *N*-phenyliminocarbonate, which has two alkoxyl groups to the carbon atom of the nitrogen-carbon double bond, hardly reacted with benzaldoxime, even in the presence of basic or acidic catalyst, such as triethylamine or boron trifluoride, and most of the starting materials were recovered[7].

Finally, the reaction of ethyl *N*-phenylformidate with benzaldoxime gave benzonitrile and formanilide, in 83 and 66% yields respectively, when refluxed in dry benzene with boron trifluoride and yellow mercuric oxide as catalysts (Eq. 6).

$$C_6H_5N{=}CHOC_2H_5 + HON{=}CHC_6H_5 \xrightarrow[BF_3\cdot HgO]{} \underset{(V)}{\left[\begin{array}{c} C_6H_5NHCHOC_2H_5 \\ | \\ O \\ | \\ N{=}CHC_6H_5 \end{array}\right]} \longrightarrow C_6H_5C{\equiv}N + C_6H_5NHCHO + C_2H_5OH \qquad (6)$$

This reaction can be represented by the above scheme, which involves the initial formation of the intermediate V, the adduct of ethyl *N*-phenylformimidate and benzaldoxime, analogous to the explanation proposed for the dehydrations of aldoxime with vinyl ethers[3]. The V subsequently decomposes to give benzonitrile, formanilide and alcohol.

Experimental

Phenylimidophosgene.—This compound was prepared from phenyl isothiocyanate and chlorine according to the procedure of Bly, Perkins and Lewis; b. p., 102~104°C/28 mmHg[8].

Reaction of Phenylimidophosgene with Benzaldoxime (1 : 1).—When a solution of phenylimidophosgene (3.5 g. 0.02 mol.) and benzaldoxime (2.4 g. 0.02 mol.) in dry benzene (20 ml.) was stirred vigorously, an evolution of heat was noticeable and aniline hydrochloride precipitated. Then the reaction mixture was refluxed for an hour. The hydrochloride was filtered and was recrystallized from ethanol; yield, 0.3 g. (11%); m. p. and mixed m. p., 195~197°C. Benzene was removed from the filtrate, and the residual materials were fractionated. Two grams (84% yield) of phenyl isocyanate (b. p., 48~50°C/10 mmHg) and 1.5 g. (72% yield) of benzonitrile (b. p., 70~72°C/10 mmHg) were obtained.

Reaction of Phenylimidophosgene with Benzaldoxime (1 : 2).—A solution of phenylimidophosgene (3.5g., 0.02 mol.) and benzaldoxime (4.8g., 0.04 mol.) in dry benzene (20 ml.) was stirred. After a while, a violent reaction suddenly took place and aniline hydrochloride precipitated. By the same procedure as described above, the hydrochloride (yield, 2.3 g., 92%; m. p. and mixed m. p., 195~197°C) and benzonitrile (yield, 3.1 g., 75%; b. p., 66~68°C/10 mmHg) were obtained.

Ethyl *N*-Phenyliminochloroformate.—This compound was prepared from phenylimidophosgene and sodium ethylate according to the procedure of Smith; b. p., 114~116°C/12 mmHg[9].

Reaction of Ethyl *N*-Phenyliminochloroformate with Benzaldoxime.—Into an ice cold solution of ethyl *N*-phenyliminochloroformate (3.7 g. 0.02 mol.) in dry benzene (20 ml.) was vigorously stirred, drop by drop, a solution of benzaldoxime (2.4 g., 0.02 mol.) in dry benzene (20 ml.). The reaction mixture was refluxed for an hour, and the precipitated aniline hydrochloride was filtered; yield, 0.2 g. (8%); m. p. and mixed m. p., 197~199°C. After the removal of the benzene from the filtrate, 1.6 g. (78% yield) of benzonitrile (b. p., 85~87°C/25 mmHg) and 2.5 g. (76% yield) of ethyl *N*-phenylcarbamate (b. p., 106~115°C/2 mmHg) were obtained by distillation. The latter solidified on cooling and was recrystallized from petroleum ether; m. p. and mixed m. p., 48~50°C. *sym*-Diphenylurea remained in a distillation flask and was recrystallized from acetic acid; yield, 0.6 g. (14%); m. p. and mixed m. p., 234~236°C.

Decomposition of Ethyl *N*-Phenyliminochloroformate with Hydrogen Chloride.—Into a solution of ethyl *N*-phenyliminochloroformate (1.8 g., 0.01 mol.) in dry benzene (20 ml.) was passed dry hydrogen chloride, with refluxing for an hour. After the removal of the benzene, phenyl isocyanate was distilled; yield, 0.8 g. (66%); b. p., 58~60°C/15 mmHg.

Ethyl *N*-Phenylformimidate.—This compound was prepared from aniline and ethyl orthoformate according to the procedure of Roberts and Vogt; b. p., 117~118°C/40 mmHg.[10]

Reaction of Ethyl *N*-Phenylformimidate with Benzaldoxime.—A solution of ethyl *N*-phenylformimidate (3.0 g., 0.02 mol.), benzaldoxime (2.4 g., 0.02 mol.), boron trifluoride etherate (5 drops) and a catalytic amount of mercuric oxide in dry benzene (5 ml.) was refluxed for 5 hr. and was then filtered. The benzene was removed from the clear filtrate, and 1.7 g. (85% yield) of benzonitrile (b. p., 76~78°C/18 mmHg) and 1.6 g. (67% yield) of formanilide (b. p., 108~112°C/0.35 mmHg) were obtained by distillation. The latter solidified on cooling; m. p., 40~44°C.

Summary

The dehydration reactions of benzaldoxime with such nitrogen-carbon double bond compounds having halogen and alkoxyl groups as

phenylimidophosgen, ethyl *N*-phenyliminochloroformate and ethyl *N*-phenylformidate were studied.

One mole of phenyl imidophosgene, when reacted with 1 mol. of benzaldoxime, gave phenyl isocyanate and benzonitrile as main products. On the other hand, with 2 mol. of the aldoxime, aniline hydrochloride and benzonitrile were obtained in good yields. The aldoxime was also dehydrated effectively by ethyl *N*-phenyliminochloroformate to give, among other byproducts, the nitrile and ethyl *N*-phenylcarbamate. The nitrile and formanilide were obtained by the reaction of the aldoxime with ethyl *N*-phenylformimidate.

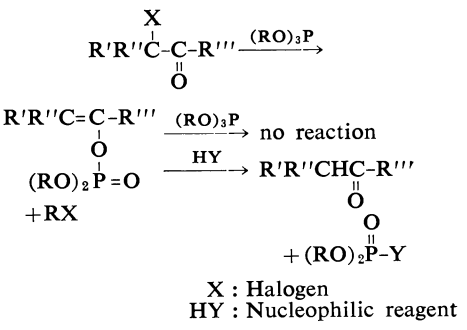
A Selective Phosphorylation by Means of α-Bromocyanoacetamides and Trialkyl Phosphites

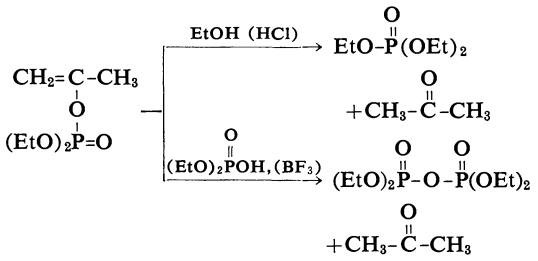


By Tsujiaki HATA and Teruaki MUKAIYAMA

(Received October 17, 1961)

Phosphorylation by means of ketene dimer, ethyl vinyl ether, tetraethyl pyrophosphite and diethylphosphorochloridite has been described in a preceding paper[1].

The well-known methods of phosphorylation by means of dehydrating reagents mostly consist of the initial formation of enol-phosphate by the addition of a monohydrogen or a dihydrogen phosphate to the organic dehydrating reagents with a triple or a cummulated double bond, such as carbodiimides[2], acetylenic ethers[3] and trichloroacetonitrile[4], followed by alcoholysis or phosphorolysis. However, except in the case of trichloroacetonitrile, the isolation of an intermediate adduct, enol-phosphate, was not possible, with the result that the coupling of two different phosphates invariably produced a mixture of the two symmetrical pyrophosphates, together with the unsymmetrical product. The formation of undesirable symmetrical pyrophosphates is attributed to the fact that phosphates used in the phosphorylation react more rapidly with the enol-phosphates than with the dehydrating reagent, thereby causing the formation of symmetrical pyrophosphates. Therefore, the enol-phosphate must be isolated in advance if a selective phosphorylation is to take place.



The preparation of the intermediates, the enol-phosphates, by the Perkow reaction from trialkyl phosphites and α-haloketones or α-haloaldehydes involves the oxydation of phosphite to phosphate. Since the enol-phosphate thus formed does not further react with the trialkyl phosphite but reacts exclusively with nucleophilic reagents, such as alcohols, monohydrogen phophates and amines, a selective phosphorylation can be effected successfully without isolating the enol-phosphate.

Most of the enol-phosphates obtained by the Perkow reaction[5], however, are not suitable for the purpose of phosphorylation because they are prepared under severe conditions or are sluggish toward nucleophilic reagents, except in the case of a ketene acylal reported by Cramer[6]. The low reactivity of enol-phosphates

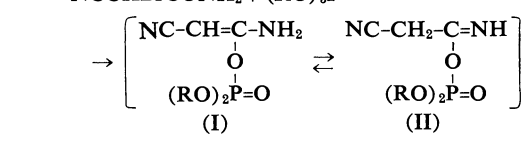
toward alcohols and monohydrogen phosphates has been demonstrated. The reaction of diethyl isopropenyl phosphate, an example of enol-phosphates, with ethanol could not be observed even when they were heated for 2 hr. at 150°C. However, when they were treated in the presence of a catalytic amount of hydrogen chloride for 12 hr. at 100°C, they gave a 55% yield of triethyl phosphate. Similarly, a 55% yield of tetraethyl pyrophosphate was obtained by heating the above enol-phosphate with diethyl hydrogen phosphate in the presence of a catalytic amount of boron trifluoride for an hour at 100°C.

However, one of the enol-phosphates which are reactive toward nucleophilic reagents can be prepared from monobromocyanoacetamide and trialkyl phosphites, as will be described below.

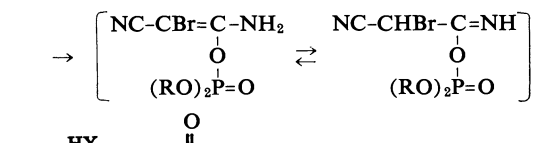


When a solution of 1 mol. of monobromocyanoacetamide and 1 mol. of either an alcohol, a monohydrogen phosphate or aniline in ether was treated with a solution of 1 mol. of trialkyl phophite at −50°C, the reaction started instantly, cyanoacetamide soon separated from the solution, and the corresponding phosphate, pyrophosphate or phosphoramidate was obtained in a high yield, along with an alkyl bromide, as is shown in the following:

$NCCHBrCONH_2 + (RO)_3P$

The reactions seem to proceed through the initial formation of the enol-phosphate as a result of the interaction of monobromocyanoacetamide with trialkyl phosphite, followed by the attack of nucleophilic reagents to form phosphates, pyrophosphates and phosphoramidate.

$NCCHBrCONH_2 + (RO)_3P$



$\xrightarrow{HY}$ $Y\text{-}P(O)(OR)_2 + NCCH_2CONH_2 + RBr$

HY : Alcohol, monohydrogen phosphate or aniline

It is reasonable to postulate that the enol-phosphate (I), which possesses an amino group attached to its carbon-carbon double bond, is capable of existing in both the amine I and imine II forms. The phosphorylation probably proceeds as a result of the contribution of the imine form II rather than the amine form I which existed in equilibrium. It has been shown that when *N, N*-diethyl monobromocyanoacetamide, which does not exist as the imine form, was treated with triethyl phosphite and ethanol, not triethyl phosphate but a tar product was produced. As phosphorylation proceeds, the imine II is continually removed from the equilibrium by an irreversible phosphorylation, and eventually the amine I is transformed through the imine intermediate II into cyanoacetamide.

Similarly, when a solution of 0.5 mol. of dibromocyanoacetamide was used in place of the 1 mol. of monobromocyanoacetamide, the corresponding phosphates, pyrophosphate and phosphoramidate were obtained in good yields.

$NCCBr_2CONH_2 + (RO)_3P$

$\xrightarrow{HY}$ $Y\text{-}P(O)(OR)_2 + NCCHBrCONH_2{}^{*} + RBr$

HY : Alcohol, monohydrogen phosphate or aniline

* Monobromocyanoacetamide further reacts with trialkyl phosphite through the former equation.

In addition, a new method for the preparation of monobromocyanoacetamide was found. When a solution of dibromocyanoacetamide and cyanoacetamide was treated in the presence of a catalytic amount of boron trifluoride, monobromocyanoacetamide was obtained in a yield 74% of the theoretical one. This is a simpler treatment and produces a higher yield than those hitherto reported in the literature[7].

$NCCBr_2CONH_2 + NCCH_2CONH_2 \xrightarrow{BF_3} 2\,NCCHBrCONH_2$

Experimental

Reaction of Diethyl Isopropenyl Phosphate with Ethanol.—A mixture of diethyl isopropenyl phosphate (1.94 g.), ethanol (0.55 g.) and 2 drops of concentrated hydrochloric acid was heated for 12 hr. at 100°C. The mixture was then distilled under reduced pressure to give triethyl phosphate (1.0 g., 55%), b. p., 67~69°C/1.2 mmHg., along with acetone and ethyl bromide.

Reaction of Diethyl Isopropenyl Phosphate with Diethyl Hydrogen Phosphate.—A mixture of diethyl isopropenyl phosphate (1.94 g.), diethyl hydrogen phosphate (1.54 g.) and 2 drops of boron trifluoride etherate was heated at 100°C for an hour. Diethyl isopropenyl phosphate (1.0 g.) was recovered, and tetraethyl pyrophosphate (1.6 g., 55%), b. p., 132~~135°C/0.8 mmHg., was obtained.

Monobromocyanoacetamide.—A solution of dibromocyanoacetamide (24.2 g.) and cyanoacetamide (8.4 g.) in 150 ml. of ethanol, in the presence of 10 drops of boron trifluoride etherate was refluxed for 5 hr. After removal of the ethanol, a large amount of white precipitate was separated, washed with benzene, and recrystallized from benzene; monobromocyanoacetamide (24 g., 74%), m. p., 116 117°C, was obtained.

Reactions of Alcohols, Phenol or Diethyl Hydrogen Phosphate with Monobromocyanoacetamide and Trialkyl Phosphites.—*Ethanol.*—To a solution of ethanol (0.28 g.) and monobromocyanoacetamide (1.0 g.) in dry ether (90 ml.) was added, drop by drop a solution of triethyl phosphite (1.0 g.) in dry ether (10 ml.) at −50°C. A white precipitate, cyanoacetamide, soon separated; the solution was kept for an additional hour at room temperature and was then filtered. After removal of the ether and ethyl bromide, triethyl phosphate (1.0 g., 91%), b. p., 65~67°C/1 mmHg., was obtained.

In a similar fashion, other alcohols, phenol and diethyl hydrogen phosphate gave the corresponding phosphates or pyrophosphates. The results of the phosphorylation of alcohols, phenol and diethyl hydrogen phosphate by means of monobromocyanoacetamide and trialkyl phosphites are summarized in Tables I and II.

Reactions of Ethanol, Phenol or Diethyl Hydrogen Phoshate with Dibromocyanoacetamide and Triethyl Phosphite.—*Ethanol.*—To a solution of ethanol (0.9 g.) and dibromocyanoacetamide (2.4 g.) in dry ether (30 ml.) was added, drop by drop a solution of triethyl phosphite (3.3 g.) in dry ether (10 ml.) at −50°C. A white precipitate, cyanoacetamide, soon separated; the solution was kept for

TABLE I. PHOSPHORYLATION OF ALCOHOLS AND PHENOL BY MEANS OF MONOBROMOCYANOACETAMIDE AND TRIETHYL PHOSPHITE

Alcohol	Charge g.	Product: Phosphate	Yield %	B. p. °C/mmHg	Cyanoacetamide Yield %
Methanol	2.20	Methyl diethyl-	77	102~104/25	93
Ethanol	0.28	Triethyl-	91	65~67/1	88
n-Propanol	0.37	*n*-Propyl diethyl-	85	73~74/0.8	82
Phenol	0.58	Phenyl diethyl-	72	103~120/1	94

an additional 2 hr. and was then worked up in the usual manner, producing cyanoacetamide (0.5 g., 96%), m. p., 120°C, and triethyl phosphate (2.6 g., 72%), b. p., 94~95°C/11~12 mmHg.

In a similar fashion, phenol and diethyl hydrogen phosphate gave phenyl diethyl phosphate and tetraethyl pyrophosphate respectively. The results of the phosphorylation of these compounds are summarized in Table III.

Reactions of Mono- or Dibromocyanocetamide with Aniline and Triethyl Phosphite.—*Monobromocyanoacetamide.*—To a solution of monobromocyanoacetamide (1.0 g.) in dry ether (90 ml.) was added, drop by drop, a solution of aniline (0.57 g.) and triethyl phosphite (1.0 g.) in dry ether (10 ml.) at −50°C. A white precipitate, cyanoacetamide, (0.51 g., 98%) was filtered off. After removal of the ether and ethyl bromide, diethyl *N*-phenylphosphoramidate (1.3 g., 93%) was obtained and recrystallized from benzene, m. p. and mixed m. p., 94~96°C.

Dibromocyanoacetamide.—When dibromocyanoacetamide (1.5 g.) was used in place of monobromocyanoacetamide (1.0 g.), diethyl *N*-phenylphosphoramidate (1.3 g., 93%) was obtained.

Summary

A method of selective phosphorylation by means of α-bromocyanoacetamides and trialkyl phosphites was devised. In this method, various phosphates, pyrophosphates and phosphoramidate were obtained in excellent yields under mild conditions without isolating the intermediate, enol-phosphate.

The use of dibromocyanoacetamide in place of monobromocyanoacetamide produced the same results, the yields being, however, less.

A new method for the preparation of monobromocyanoacetamide was also described.

The authors wish to express their hearty thanks to Mr. Ohyo Mitsunobu for his kind advice, and to Mr. Isao Kuwajima and Mr Kowa Tasaka for their assistance during the course of this experiment.

Rotational Isomers of Vinyl Ethers. Studies of the Vibrational Spectra and Dipole Moments of cis- and trans-β-Chlorovinyl Methyl Ethers

By Yukio MIKAWA, Shiro MORITA and Sukenari TSUNAKAWA

(Received November 1, 1961)

In the course of organic studies for the synthesis of β-chlorovinyl methyl ether in our laboratory, two kinds of compounds with the same chemical composition, C_3H_5OCl, were obtained. The first was distilled out at 85～86°C, and the second, at 105～106°C. These two compounds were considered to be the *trans-* and *cis-β*-chlorovinyl methyl ethers. Though the one having the lower boiling point has been supposed to be the trans compound and the other the cis compound, no real evidence has been given for deciding which is the cis or the trans compound. This study was initiated with the aim of identifying the cis and trans compounds in the light of the structural chemistry. First the infrared spectra of these compounds were recorded. The results, however, were not simple enough to enable us to decide confidently which was the cis or the trans compound. Especially, the spectrum of the compound having the lower boiling point proved complex. It seemed to be difficult to explain the complexity of the spectrum in the usual ways, and to be necessary for us to take internal rotation into account. In order to make clear the cis-trans isomerism, the dipole moments were also measured. As the result of these experiments, not only has the compound having the lower boiling point been identified with the trans compound and the other with the cis compound, but also some interesting imformation in connection with the rotational isomerism have been obtained.

The vinyl ether, CH_2=CH–O–R, has a freedom of internal rotation about the axis of the C–O bond adjacent to the double bond.

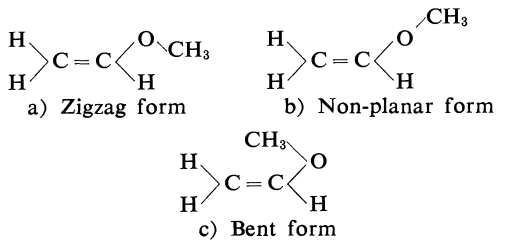

Fig. 1. Rotational isomers of vinyl ether.

Therefore, three types of spacial configuration are possible with regard to the position of alkyl group R: i.e., the zigzag, non-planar and bent forms, which are indicated in Fig. 1.

In a previous study[1] the infrared spectra of several vinyl ethers were investigated, and the observed spectra were assigned in conformity with the assumption that the molecule had the zigzag (planar) configuration. Davison and Bates[2] investigated the infrared spectra of several vinyl ethers and discussed some of the characteristic absorption bands. Kirrman and Chancel[3] also published an elaborate study of the Raman and infrared spectra of vinyl ethers, paying particular attention to the doublets which appeared around 1630 cm^{-1} in most of the spectra investigated, and suggested that the doublets were due to rotational isomers. Since the doublets can also be explained in terms of Fermi resonance[1], uncertainty about the existence of rotational isomers will remain until further experimental evidence is offered.

In the present paper, from the investigation of the Raman and infrared spectra and measurements of the dipole moments of the two compounds, in addition to identifying the cis and trans compounds, we will show that the cis compound* having the higher boiling point consists of a single molecular species which has a non-planar configuration and that the trans compound* having the lower boiling point consists of two rotational isomers, both of which have planar configurations.

Experimental

Preparation of the Samples.—Both *cis*- and *trans*-β-chlorovinyl methyl ethers were prepared by workers in this laboratory. The samples were purified by fractional distillation. The boiling points of the cis and trans compounds were 105~106°C and 85~86°C respectively. Although a small amount of the cis compound had not been perfectly removed from the trans compound, it did not disturb the interpretation of the spectra to a large extent.

Infrared Absorption Spectra.—Infrared spectra were obtained by a Perkin-Elmer model 21 spectrometer equipped with sodium chloride, calcium fluoride and potassium bromide prisms. Vapor spectra were recorded at 130~150°C using a heated 5 cm. cell[4]. For the trans compound, the spectra in the solid state were also measured, using a low temperature cell[4] constructed in our laboratory. The spectra are reproduced in Figs. 2 and 3, and the data are tabulated in Tables I and II. Since the solvent effect was not found in any appreciable amount, the spectra in solutions are not reproduced here.

Raman Spectra.—Raman spectra were obtained using 4358 Å excitation with a three-prism spectrograph (17 Å/mm. at 4358 Å) constructed in this laboratory. A low-pressure mercury arc lamp was used. A double layer composed of a sodium nitrate solution (40 g./100 g. solution) and a Rhodamine 6G dilute solution was used as a liquid filter. Exposure was for from one to six hours. The data are tabulated in the first columns of Tables I and II. Approximate line intensities on the photographic plates are indicated by the numbers in parentheses.

Dipole Moments.—The dielectric constants of the benzene solution of the compounds were observed in several dilutions at 20~60°C. Densities were also measured by a pycnometer. From those values, the dipole moments were calculated by the conventional way; 2.53 D was obtained for the cis compound, and 1.6 D for the trans compound, at 25°C. It was also found that, as to the trans compound, its dipole moment did not depend on the temperature in the range 20~60°C.

Discussion

Rotational Isomers.—As can be seen in Figs. 2b and 3b, the spectrum of the trans compound in the liquid state is very complicated compared with that of the cis compound. Thirteen absorption bands are theoretically expected in the 600~1700 cm^{-1} region for this compound. Nevertheless, nineteen bands are observed for the trans compound in liquid. Since most of the bands have fairly strong intensities and their intensities did not change through repeated purifications of the samples, those bands are believed to be inherent to the molecule and not to come from impurities. Furthermore, the fact that some bands disappeared on the solidification of the sample (see Fig. 3c), is strong evidence for the presence of rotational isomers in the liquid. The number of bands in the solid spectra is in accordance with the theoretical expectations. That means the trans compound in the liquid state is a mixture of two or more rotational isomers, and that, in the course of solidification, every molecule takes on an unique configuration suitable for the low temperature by rotating the methoxy group around the C–O bond axis. On the other hand, the liquid spectrum of the cis compound is very simple, and the numbers of bands is so few that it seems possible that only one molecular species seems to exist.

Dipole Moments.—The dipole moments are estimated for both the trans and cis compounds on the basis of the vector model shown in

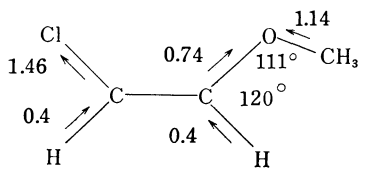

Fig. 4. Bond moments of chlorovinyl methyl ether.

Fig. 4*. It should be noted that the estimated values for the trans compound did not depend upon the angle of internal rotation. The estimated value, 1.55 D, is in good agreement with the observed value, 1.6 D. The fact that the observed values remained constant within the temperature range of 20~60°C does not contradict the presumption of rotational isomers, because even if the ratio of the number of the two rotational isomers varies with the temperature of the system, the dipole moment of the whole system should not change.

As for the cis compound, the estimated dipole moments are 3.08, 2.55 and 1.75 D as the angle of rotation, τ, increases from 0° to 90° and 180° (corresponding to the zigzag, the non-planar and the bent form respectively). Since the observed value was 2.53, the results of the calculation indicate that, as far as the bond moments approximation is valid, the molecule in the solution at 25°C takes on a non-planar configuration with an angle of internal rotation of about 90°.

At any rate, there is no doubt that the "trans compound" having a lower boiling point has a trans configuration and that the "cis compound" has a cis configuration.

* In Fig. 4. the figure for the cis molecule is given. The same bond moments are used for the trans molecule.

Vibrational Spectra.—*cis-Chlorovinyl Methyl Ether.*—It can be seen from Table I that most of the Raman bands are also observed in the infrared spectra and that, except for the rotational structure of the vapor spectra, no essential difference between the infrared absorption frequencies measured in the liquid and vapor states is found. Furthermore, the number of the absorption bands is in accordance with the expectations. These facts exclude the possibility of the existence of the rotational isomers in the liquid or the vapor state. This exhibits a contrast to the trans compound, which will be mentioned later.

The observed frequencies can be interpreted as a superposition of the characteristic frequencies of vinyl and ether compounds. For instance, the bands at 1655, 1337, 1265 and 879 cm^{-1} correspond to those at 1601, 1360, 1271 and 908 cm^{-1} [5] of vinyl chloride. The fact that C=C stretching and =CH out-of-plane frequencies appear at 1655 and 707 cm^{-1} respectively gives strong spectroscopic evidence for the cis configuration, because the compound having the group

has, in general, two distinct characteristic bands in the regions 1635~1675 and 665~730 cm^{-1} [6]. The bands, at 466, 988 and 1118 cm^{-1} are due to the ether linkage, corresponding to those of dimethyl ether at 418, 929 and 1115 cm^{-1}, which were assigned[7] to the COC bending, symmetric and anti-symmetric stretching vibration respectively.

As was discussed in the previous study[1], methyl vinyl ether and other alkyl vinyl ethers have characteristic frequencies which distinctly differ from compounds having a vinyl group alone or an ether group alone, and the spectra of vinyl ethers can be interpreted on the assumption of a planar configuration. The reason why the cis compound concerned does not have the characteristic frequencies of vinyl ether can be explained only by rejecting the assumption of a planar configuration, i. e., by assming instead that the molecule of the cis compound takes on a non-planar configuration. In this case no resonance effect is taken into consideration, and consequently, the force constant of -C=C- or -C-O- keeps its original value. Therefore, some of the bands characteristic of vinyl compounds and ethers can be expected in the cis compound.

Though the angle of internal rotation cannot be predicted from the spectroscopic data, the conclusion is in conformity with that deduced from dipole moment measurement.

trans-Chlorovinyl Methyl Ether.—Several bands of the liquid spectra disappeared in the solid spectra. The bands which remain in the solid spectra are considered to be the spectra arising from the stable form of the rotational isomers. From this point of view, the liquid spectra as well as the vapor spectra were interpreted as superposed spectra of two or more configurational isomers, and the bands belonging to the stable form were tentatively assigned on the basis of an assumed model.

In the vapor spectrum (see Fig 3a), the band at 1322 cm^{-1} shows a very distinctive band shape. As will be seen later, this band is assigned to the =CH in-plane bending mode. The C=C stretching mode is expected around 1650 cm^{-1}, and it is known that the frequency of the trans compound usually appears at a higher frequency range than of the corresponding cis compound. However, in the present case, a strong band to be assigned to C=C stretching mode appears at 1623 cm^{-1}, or on the lower frequency side of the corresponding band of the cis compound. Furthermore, the general features of the spectra of this compound have a strong resemblance to those of methyl vinyl ether. The correlation between the two compounds is given in Table III. Based on these considerations, the molecular configuration of the stable form of the trans compound is supposed to be planar in form, probably the zigzag form, which had been shown to be plausible in the case of methyl vinyl ether. Thus, the assignment for most of bands was performed by reference to methyl vinyl ether. Though conclusive assignments are not possible at this stage, tentative assignment are shown in Table II.

TABLE III. CORRELATION BETWEEN THE BANDS OF *trans*-CHLOROVINYL METHYL ETHER AND THOSE OF VINYL METHYL ETHER

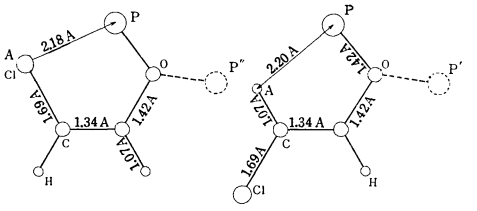
unstable form cannot be decided on, it may be supposed to be a planar-bent form which is stabilized by the contribution of the resonance structure



for the C=C frequency at 1635 cm^{-1} is still lower than that of the cis compound.

The Band Shape.—The moments of inertia and the direction cosines of the three principal axes of the trans molecule (in the zigzag form) are listed in Table IV. The bond lengths and the bond angles adopted in the calculation are shown in Fig. 5b. The calculation was carried out for every 30° from 0 to 180° of τ, and it was found that the symmetric top model could be approximately applied in every case. The degree of separation between the P and R branches of the parallel bands was estimated by the Gerhard-Dennison method[8], being found within the values 11.25 and 12.17 cm^{-1} at 400°K for any value of τ. The observed separation, 12 cm^{-1}, at the 1322 cm^{-1} band is in good agreement with the predicted value.

The exact modes of the normal vibrations can be pictured only by the normal coordinate treatment of the molecule. However, if the C–H in-plane bending vibration is localized in C–H bonds and there is on mixing with the other mode, the direction of the change of dipole moment can be decided upon. Therefore, it is easy to calculate the angle between one of the principal axes of the moment of inertia and the direction of the change of the bond moment of the C–H in-plane vibration. The calculated values for the zigzag and the bent forms of the trans compounds were 3°30′ and 7° respectively; i. e. the bands, in both cases, should exhibit an almost pure parallel type. Thus, for the C–H in-plane vibration, it is predicted that the band shape and the frequency do not change appreciably no matter what value the angle of internal rotation takes. This is why the band at 1322 cm^{-1} is assigned to the C–H in plane mode.

Many bands beside 1322 cm^{-1} show very complex band shapes. The band features of these bands are interpreted as the overlapping of two bands. For instance, the band at 1130～1170 cm^{-1} is composed of two doublets; the one is of 1135 cm^{-1} and 1146 cm^{-1}, and the other is of 1162 cm^{-1} and 1170 cm^{-1}. Similarly, the band at 850～890 cm^{-1} is composed of the doublets of 855 cm^{-1} and 865 cm^{-1}, and of 881 cm^{-1} and 891 cm^{-1}. These doublets are separated by 8～11 cm^{-1}, a separation compatible with the calculated value within the margins of experimental error.

(a) *cis*-Chlorovinyl methyl ether (b) *trans*-Chlorovinyl methyl ether

Fig. 5. The molecular configurations of chlorovinyl methyl ethers.

Internal Potential.—In the preceding sections, it was concluded that the cis compound takes just one non-planar configuration, while the trans compound in the liquid or vapor states two types of configuration, both of which are considered to be planar. It is of interest to discuss the internal forces which determine the stable configuration of the rotational isomers.

Three main factors are taken into consideration:

8) S. L. Gerhard and D. M. Dennison, *Phys. Rev.*, **43**, 197 (1933).

TABLE V. DIPOLE INTERACTION ENERGY (kcal./mol.)

Angle of internal rotation	Cis-compound			Trans-compound
	$\rho=0.4$	$\rho=0.5$	$\rho=0.7$	$\rho=0.5$
0° (zigzag)	0.55	0.96	1.30	1.17
90° (non-planar)	0.14	0.37	0.28	0.92
180° (bent)	−1.49	−1.28	−1.13	1.17

i) The steric repulsion
ii) The contribution of the resonance structure, $C^--C=O^+$
iii) The electrostatic force

First, the steric repulsion of the non-bonded atom in the molecule must be considered. Interatomic distances are shown in Fig. 5. If the methyl group is situated at P (Fig. 5), the interaction between the group at P and the atom at A becomes prominent. Especially for the cis compound, the distance between A and P is 2.18Å, much less than the sum of the van der Waals radii of the chlorine atom and the methyl group. Consequently, the methyl group cannot be situated at P on the plane of the vinyl group. Thus, the bent form is excluded from consideration for the cis compounds. Secondly, the resonance effect has to be considered. From the infrared study[1], it was concluded that in vinyl ether there was an appreciable single bond-double bond resonance. Therefore, the resonance effect would be of considerable importance for the chlorovinyl ethers concerned. If there is no other predominant factor than the resonance effect, the planar configurations, both the bent and the zigzag forms, become the stable forms. Such is the case with the trans compound. As has deen described before, the infrared spectra and the observed dipole moment are compatible with this model. However, as to the cis compound, the other effect seems to dominate over the resonance effect. The electrostatic interaction plays a significant role in this case, as will be shown below.

The interaction energy between two dipoles, μ_1 and μ_2, can be evaluated by the equation:

$$\mu_1\mu_2(\cos\theta-3\cos\alpha\cdot\cos\beta)/R \qquad (4)$$

where R is the distance between the dipoles, θ denotes the angle betwee μ_1 and μ_2, and α or β denotes the angle between one of the dipoles and the line connecting the two. On the base of the bond moments as shown in Fig. 4, the interaction energy of the dipoles was calculated with several values of τ, varying from 0 to 180°. Some of the results are listed in Table V, where the ρ value, which is a parameter which decides the apparent position of a dipole on the line connecting the atoms cencerned, is assumed to be 0.4, 0.5, or 0.7 for the cis compound. From Table V it can be seen that the difference between the values at $\tau=0°$ and $\tau=180°$ does not seriously depend upon the choice of the ρ value. In the cis compound, the bent form is more stable by 2.2±0.2 kcal, than the zigzag form. As to the trans compound, the dipole-dipole interaction seems to be minor; the zigzag, the non-planar and the bent forms have almost the same energy in so far as the electrostatic forces are concerned.

Form the consideration of these three factors, it is concluded that the trans compound takes the zigzag form as the most stable configuration, and that if the resonance energy overcomes the steric repulsion, the bent form also becomes stable. The non-planar configuration is unfavorable in all respects. On the other hand, as to the cis compound, the zigzag form is not always the most stable because it can have a higher energy than the non-planar form; i. e., if the amount of resonance energy is quite small in comparison with the dipole-dipole interaction, the zigzag form is less stable than the non-planar form. Although many other factors beside the three mentioned above could be considered in connection with the internal rotation, and although the estimation of the dipole-dipole interaction was made only roughly, it is sure that the dipole-dipole interaction plays a significant role in the cis compound which takes the non-planar configuration.

Summary

Raman and infrared spectra of *cis*- and *trans*-β-chlorovinyl methyl ethers ($ClCHCHOCH_3$) were measured in the vapor and liquid states, and the infrared spectra in the solid state were also measured for the trans compound. The dipole moments were measured for both of the compounds in a benzene solution. From the observed value of the dipole moments, it was decided that the compound having the lower boiling point had a trans configuration and the other, a cis configuration.

On the basis of these configuration, interpretation of the vibrational spectra of both compounds was undertaken. As for the trans compound, the existence of the rotational isomers arising from the internal rotation around the C–O axis was verified by the fact that some of the infrared bands disappeared on solidification of the samples. The spectra

in the liquid and vapor states were interpreted as a mixture of those of two rotational isomers, and tentative assignments were given for one of the isomers by reference to the spectra of methyl vinyl ether. The most probable form of the molecule was supposed as the planar zigzag form.

On the contrary, it was established that there existed no rotational isomer in the cis compound in any state. The spectra of the cis compound did not resemble those of the trans compound or the methyl vinyl ether and were interpreted as a superposition of group frequencies of the ether linkage and of the -CH=CH- group. Consequently, a non-planar model was proposed, and the angle of internal rotation was determined to be about 90° from the observed value of the dipole moment. In order to explain the difference in the spacial configuration between the cis and the trans compounds, the electrostatic effect, in addition to the resonance effect and the steric repulsion, was considered. From the results of the calculation of the dipole-dipole interaction, it was shown that this electrostatic force played a very significant role in the internal rotation.

The authors wish to express their thanks to Professor Takehiko Shimanouchi of the University of Tokyo for his valuable advice and to Mr. Saburo Hattori, who prepared the samples for this work.

Stereospecificity and Dipole Moment of Polymers. I. Dielectric Property of Polyvinyl Chloride Solution

By Akira KOTERA, Mikiko SHIMA, Noriko FUJISAKI and Takeshi KOBAYASHI*

(Received November 8, 1961)

The properties of polyvinyl chloride (PVC) vary according to the temperature at which it is polymerized. Studies of the infrared absorption spectrum reveal that low-temperature polymerized PVC, compared with commercial PVC[1], is rich in syndiotactic portion. Owing to their high crystallinity, however, most of the studies of stereospecific polymers have been limited to a consideration of their solid state properties, such as X-ray diffraction, infrared absorption spectrum and melting point. It is expected that molecules of isotactic, syndiotactic and atactic polymers, which are stereoisomers of each other, may take different shapes in solution and, therefore, give their solutions different porperties. However, not many reports on studies of the solutions of stereospecific polymers have yet been published. Danusso and his coworkers[2,3] pointed out that the second virial coefficients of a toluene solution of isotactic polystyrene obtained from osmotic pressure measurements are different from that of atactic polystyrene. Differences in Flory temperature and in entropy parameter between isotactic and atactic polystyrene were reported by Wessling et al.[4] New approaches in this field seem to be found in the study of tacticity through the measurement of the nuclear magnetic resonance absorption spectra of isotactic and syndiotactic polymethyl methacrylates in a chloroform solution[5] and in the estimation of the tacticity of polyalkyl methacrylate from the reaction velocity of hydrolysis[6].

The dipole moment of polar vinyl polymer is related to the orientation of monomer units carrying polar groups, and the observed moment is the statistical average over the molecular conformations. Its theoretical treatment was originally developed by Eyring[7] and by Suzuki[8] et al., and has been recently extended by Volkenstein[9], Nagai[10] and Suzuki[11].

Recently Pohl[12] et al. measured the dipole moments of isotactic, syndiotactic and atactic polymethyl methacrylates and found that their values differ.

With low-temperature polymerized PVC, one of the authors measured the viscosity, osmotic pressure and light scattering of a tetrahydrofuran solution and found that both the solvent-solute interaction parameter and the extension of the molecule are somewhat larger than those of commercial PVC[13].

For this report, the dielectric properties of both low-temperature polymerized and commercial PVC solutions were measured in order to discuss the relation between the dipole moment values and the tacticity of polymers.

Experimental

Samples.—Sample I is PVC obtained by radical polymerization carried out at −15°C, and sample II is commercial PVC obtained by radical polymerization at 58°C. Both samples were purified by being dissolved in tetrahydrofuran, precipitated by the addition of a large amount of methanol, and dried in vacuo to a constant weight.

Measurement of Dielectric Polarization and Method of Calculation. — The dielectric constants and densities of tetrahydrofuran solutions of samples I and II were measured and the average dipole moment per monomer unit was determined according to the generally accepted procedure[14].

$$p_2 = p_1\{3\alpha/(\varepsilon_1-1)(\varepsilon_1+2) - \beta/d_1 + 1\} \quad (1)$$

$$\mu = 0.0128\sqrt{(P_2 - [MR]_D)T}\ \text{D} \quad (2)$$

where $[MR]_D$ is the molcular refraction of the molecular unit.

The specific polarization p_2, determined by formula 1, proposed by Halverstadt-Kumler[15], multiplied by the molecular weight M of the monomer unit gives the molecular polarization, $P_2(=M\times p_2)$. Orientation polarization was obtained by subtracting $[MR]_D$ from P_2, and the dipole moment, μ, per monomer unit of polymer was determined by formula 2.

α and β in formula 1 are increments of the dielectric constant and the density of the solution respectively. When ε_1, ε_{12} and d_1, d_{12} denote the dielectric constants and the densities of the solvent and solution respectively, and w denotes the weight fraction of the solute, α and β will be given by:

$$\alpha = \{(\varepsilon_{12}-\varepsilon_1)/w\}_{Av}$$

$$\beta = \{d_{12}-d_1)/w\}_{Av}$$

P_1 in formula 1 is the specific polarization of the solvent given by

$$P_1 = (\varepsilon_1-1)/(\varepsilon_1+2)d_1$$

The dielectric moment measurements were made at 500 kc/sec. by the heterodyne beat method. Details of the apparatus were given in a previous report[16].

The cell is composed of three concentric cylindrical platinum electrodes, the first and the third of which are earthed. The three-electrode system makes the shielding better and the capacity larger;

it is approroximately 75 $\mu\mu$F. Density was determined by means of a density bottle of a flask shape, the volume of which was approximately 10ml.

Meaurements were carried out at four concentrations between 2~7% for each sample at 20 and 40°C. Each solution was prepared by heating polymer and tetrahydrofran in a sealed glass ampoule for two hours at 100°C immediately before the measurement. The results are listed in Tables I, II and III. The errors in μ-values are estimated to be $\pm$0.02D.

Results and Discussion

Dipole Moment of Stereospecific Polymer.— The results in Table III show that the dipole moment per monomer unit of sample I is 1.39 D, and that of sample II is 1.31 D, both independent of the measurement temperature. This 6% decrease may be attributed to the decrease in the syndiotactic portion, although the values are apparent ones, affected by the interaction between the polymer and the polar solvent, tetrahydrofuran.

TABLE III. DIPOLE MOMENT OF POLYVINYL CHLORIDE IN TETRAHYDROFURAN

$[MR]_D=14.11$ cc.

The dipole moments of stereospecific polymers were reported by Pohl et al. for isotactic and syndiotactic polymethyl methacrylates[12], by Krigbaum et al. for isotactic polystyrene in toluene[17], and recently by Imamura et al. for isotactic polyvinyl isobutyl ether[18].

The values reported in these papers are listed in Table IV. Isotactic polymers have larger moments than atactic polymers in all cases. With polymethyl methacrylates the values are of the order of iso. > atac. > syn. In this experiment the inverse tendency, syn. > atac., was observed with PVC.

Some of the theories shown above derived the formulae to express the values of the dipole moment per monomer unit of polar vinyl polymers, and concluded that generally the values for isotactic and syndiotactic chains are not the same. However, it can not be concluded either that isotactic polymers always have larger dipole moment values than syndiotactic polymers or the inverse. The formula should contain many factors in order to give an exact numerical value of the dipole moment.

Under the present circumstances, it is impossible to explain the inverse tendency obtained here.

However, it may be said that the stereospecificity of the chain can be related to the dipole moment value, and that it will be possible to determine the magnitude of the stereospecificity of the polar vinyl polymer through the measurement of the dipole moment.

TABLE IV. DIPOLE MOMENTS OF STEREOSPECIFIC POLYMERS

Polymer		Dipole moment D	Solvent	Temp. °C
Polystyrene[17]	isotactic	0.435	Toluene	38.4

Effect of the Solvent on the Conformation of Polymer Molecules.—The dipole moment measurements so far mentioned were carried out with a polar solvent, tetrahydrofuran, because low-temperature polymerized PVC is insoluble in any nonpolar solvent. The effect of polar solvent should be discussed.

The total dipole moment of N-mer, μ_T, is expressed by

$$\langle \mu_T^2 \rangle / N = \mu^2 = \mu_0^2 \phi$$

where μ_0 is the moment of the individual dipole and ϕ is the interaction parameter.

Marchal and Benoit[19] explained that ϕ is independent of N when $N \to \infty$ under the conditions; (1) the dipole of each monomer unit is on a bisector of the valence angle of skeleton chain, and (2) the mean square end-to-end distance of the chain is proportional to N^α, where $\alpha < 2$.

The first condition can be easily modified: it is on the bisecting plane. Then both conditions seem to be satisfied by polyvinyl chloride. In such a case ϕ becomes the function only of the short-range conformations, such as valence angles, internal rotations etc., and long-range ones can be neglected.

Taking μ_0 to be the dipole moment of the reference substance close in the structure to the monomer unit, we can determine ϕ from the measurement of μ_0 and μ. In this way the solvent effect upon short-range conformation can be estimated.

Of course, the values of μ_0 and μ are affected by the choice of solvent, owing to the change in electrostatic interaction, but when the values of ϕ determined from μ_0 and μ in polar and nonpolar solvents coincide, one may assume that the short-range conformation of the molecules is not affected appreciably by the interaction between the solvent and polymer molecules.

Marchal et al. showed that the value of ϕ is almost independent of the polarity of solvents with polymethyl methacrylate[19,20]. In order to see if the same situation holds with PVC, *sec*-butyl chloride was selected as the reference substance; its dipole moment and that of commercial PVC were measured in dioxane and in tetrahydrofuran by the use of the same apparatus at the same temperatures as above. ϕ values were determined from the observed dipole moments and are listed in Table V.

TABLE V. INTERACTION BETWEEN POLYVINYL CHLORIDE AND SOLVENT

Temp. °C	Solvent	μ_0, D	μ, D	ϕ
20	Dioxane	2.12	1.61	0.59
20	Tetrahydrofuran	1.64	1.31_5	0.64
40	Dioxane	2.12	1.62	0.59
40	Tetrahydrofuran	1.66	1.31	0.62

μ : Dipole moment per monomer unit of PVC
μ_0: Dipole moment of *sec*-butyl chloride

TABLE VI. INTERACTION BETWEEN POLYMETHYL METHACRYLATE AND SOLVENT[19,20]

Temp. °C	Solvent	μ_0^2	μ^2	ϕ	ϕ_{MB}
25	Benzene	2.99	1.87	0.62	—
25	Dioxane	2.96	1.82	0.61	0.65
25	Chloroform	1.98	1.22	0.61	0.62
25	Butyl acetate	0.34	0.20	0.60	0.58

μ : Dipole moment per monomer unit of polymethyl methacrylate
μ_0: Dipole moment of methyl propionate

They proved to be 0.63 (tetrahydrofuran) and 0.59 (dioxane) and do not differ appreciably. The results reported by Marchal et al. with polymethyl methacrylate are listed in Table VI for purposes of reference, where ϕ_{MB} is the value of ϕ reported in the older report.

As in the case with polymethyl methacrylate, it can be said that the interaction between the molecules of the polymer and the solvent seems to have no significant effect on the short-range conformation of the PVC molecules in tetrahydrofuran and that the determination of the apparent dipole moment in polar solvent will serve for purposes of relative comparison.

The authors wish to express their thanks to Professor Keizo Suzuki for his discussions concerning the interpretation of the theories.

The Reaction of Carbon Monoxide with Organometallic Compounds. VI. Synthesis of Symmetrical Ketones by the Reaction of Carbon Monoxide with Organolithium Compounds*

By Membo RYANG and Shigeru TSUTSUMI

(Received November 22, 1961)

In the last previous paper[1] of this series, the present authors reported that carbon monoxide reacted with an organolithium compound in an ether solution at −10°C, producing various products. The formation of these products could be interpreted in terms of an ionic reaction mechanism from the results of the reaction of carbon monoxide with organomagnesium halides[2].

The reaction of an organolithium compound with carbon monoxide occurs violently, so it seems desirable to control the reaction on applying this reaction to a synthetic method.

In this regard, we have undertaken a study of the reaction of carbon monoxide with phenyllithium in an ether solution at −70°C.

Phenyllithium[3] was prepared from bromobenzene and metallic lithium in anhydrous ether, and then dry, pure carbon monoxide was bubbled into the solution at −70°C.

The above reaction gave benzophenone in a 55% yield, instead of the benzoin which was expected on the basis of the previous results[2,3].

The symmetrical ketones were prepared by various methods. For example, Marvel[4] prepared benzophenone from benzene and carbon tetrachloride in the presence of aluminum chloride, but this method was not used for preparing other ketones. Sommelet[5] obtained 4, 4′-ditolyl ketone from *p*-toluic acid chloride and toluene in a poor yield.

Furthermore, the preparations of di-*n*-butyl ketone[6], di-*n*-amyl ketone[7] and diisopropyl ketone[8] by earlier methods are not satisfactory in yield and involve complicated starting materials.

We have found that the new method is simple and can be extended to similar reactions in good yields.

The symmetrical ketones prepared by this new method are as follows: benzophenone (55%), 4, 4′-ditolyl ketone (50%), di-*n*-amyl ketone (28%), di-*n*-butyl ketone (40%) and diisopropyl ketone (30%).

Results and Discussion

The results of the synthesis of various ketones according to our new method are summarized in Table I.

Although the mechanism of this reaction is still open to question, two probable reaction paths may be considered.

In the first, the carbon monoxide adducts (A), mentioned in previous papers, react with organic halides (Wurz-Fitting type reaction) to produce ketones (Eq. 1).

$$R\text{-}\overset{\overset{O}{\|}}{C}\text{-}Li + R\text{-}X \longrightarrow R\text{-}\overset{\overset{O}{\|}}{C}\text{-}R + LiX \qquad (1)$$

In the second, carbon monoxide attacks organolithium compounds and abstracts lithium as lithium carbonyl, producing ketone (Eq. 2). The stoichiometric equation is shown as follows:

$$2R\text{-}Li + 3CO \longrightarrow R\text{-}\overset{\overset{O}{\|}}{C}\text{-}R + 2LiCO \qquad (2)$$

The reaction path of Eq. 1 may be considered to be improbable for the following reasons: 1) The carbonation of organolithium compounds by solid carbon dioxide gave acids in good yields, and the number of organic halides was found to be very small[9]. 2) The yields of ketones in this reaction are parallel with those of organolithium compounds (C_6H_5–Li 97.5%[10], *p*-$CH_3C_6H_4$–Li 95.6%[10], *n*-Bu–Li 85%[11], *n*-Am–Li 85%[11], *iso*-Pr–Li 75%[11]) and, in the case of phenyllithium, the further addition of equimol bromobenzene did not increase the yield of benzophenone. 3) The Wurz-Fittig type reaction would not be expected at such a low temperature.

TABLE I

Starting material	Solvent	Temp., °C	Ketone	Yield*, %
Bromobenzene	Ether	−70	Benzophenone	55
p-Tolyl bromide	Ether	−70	4,4'-Ditolyl ketone	50
n-Amyl chloride	Ether and petroleum ether	−70	Di-*n*-amyl ketone	28
n-Butyl chloride	Ether	−70	Di-*n*-butyl ketone	40
Isopropyl chloride	Petroleum ether	−70	Diisopropyl ketone	30

* The calculations of yields are based on the number of the organic halides used.

The above consideration indicates that the unreacted organic halides do not react with (A) in Eq. 1.

If the reaction path of Eq. 1 is improbable for the above reasons, the ketones must be formed by the reaction path of Eq. 2.

Although there is no experimental evidence for the formation of lithium carbonyl in these reaction systems, several workers have reported that ionized alkali metals react easily with carbon monoxide, producing alkali metal carbonyls.

For example, Liebig[12] obtained potassium carbonyl by passing carbon monoxide over heated potassium, and Joannis[13] more easily prepared alkali metal compound corresponding to the formulas, KCO and NaCO, by the action of carbon monoxide on alkali metals in a liquid ammonia solution.

Pearson[14] also prepared the carbonyls of lithium, rubidium and calcium by passing carbon monoxide into the solution of the metals in liquid ammonia at −60°C.

Although there are various opinions about the behavior of alkali metals in a liquid ammonia solution, it is generally believed that the metals exist in a positively charged state[15].

The above facts seem to suggest that carbon monoxide can react more easily with an ionized alkali metal than with an alkali metal itself.

As the carbon-lithium bond in an organolithium compound has a 43% ionic character, it seems probable that the nucleophilic attack of carbon monoxide on positively charged lithium gives lithium carbonyl and ketone.

Furthermore, the authors carried out the reaction of iron pentacarbonyl with phenyllithium in an ether solution at −70°C. It is improbable to suppose the formation of lithium carbonyl by the reaction of iron pentacarbonyl with the organolithium compound, because the carbon monoxide in iron pentacarbonyl is coordinated to the iron atom and has not the ability to abstract lithium as lithium carbonyl.

For the above reasons, benzophenone was not obtained in this reaction; benzoin (25%) was the main product, the formation of which was explained by an ionic reaction mechanism, as has already been discussed.

Experimental

Materials.—*Bromobenzene.*—Commercial bromobenzene was purified by fractional distillation; b. p. 150°C, n_D^{15} 1.5625. *p*-Bromotoluene was prepared by the Sandmeyer reaction of *p*-toluidine[16]; b. p. 185°C, m. p. 25~26°C.

n-Amyl chloride was prepared from *n*-amyl alcohol by reaction with thionyl chloride[17]; b. p. 106°C, n_D^{20} 1.4122.

n-Butyl Chloride. — Commercial *n*-butyl chloride was purified by fractional distillation; b. p. 78°C, n_D^{20} 1.4022.

Isopropyl Chloride.—Commercial isopropyl chloride was purified by fractional distillation; b. p. 36°C.

Carbon monoxide was prepared by the reaction of formic acid with concentrated sulfuric acid, was washed with a 10% sodium hydroxide solution, and dried with calcium chloride and phosphorus pentoxide.

Synthesis of Symmetrical Ketones. — *Benzophenone.*—Into a 500 ml. four-necked flask equipped with a mechanical stirrer, a low temperature thermometer, a reflux condenser protected from moisture, a gas bubbler and a dropping funnel, were placed 50 ml. of anhydrous ether (dried over sodium) and, after sweeping the apparatus with dry oxygen-free nitrogen, 4.9 g. (0.7 g. atom) of lithium in the form of small pieces of thin coil. A solution of 47.1 g. (0.3 mol.) of bromobenzene in 200 ml. of anhydrous ether stirred in from the dropping funnel over a period of 2 hr., while the internal temperature was maintained at 35°C. After the addition was completed, the stirring was continued for a further 2 hr., after which the reaction mixture was cooled to −70°C with a dry ice-methanol bath kept at −78°C.

Dry pure carbon monoxide was next introduced from the gas bubbler at a rate of 0.5 l/min. for 2 hr.

The reaction mixture was then decomposed with 50 ml. of 95% ethanol and further with 100 ml. of 4 N hydrochloric acid. The separated organic layer was treated with three succesive 100 ml. portions of saturated aqueous potassium carbonate and then with three succesive 100 ml. portions of 5% aqueous sodium hydroxide and divided into (1) the organic layer, (2) potassium carbonate solution and (3)

sodium hydroxide solution. The organic layer containing neutral compounds was washed with water and dried over anhydrous sodium sulfate. The brownish residual oil obtained after removal of the solvent was distilled under reduced pressure to give the following fractions: (1) b. p. 70~120°C/4 mmHg 3.5 g., (2) b. p. 120~125°C/4 mmHg 15 g., (3) b. p. 130~140°C/2 mmHg 2.4 g., (4) b. p. 190~210°C/2 mmHg 3.3 g. and a dark orange residue.

Fraction 1 was assumed to be mainly diphenyl and was identified by mixed melting point measurement.

Fraction 2 was identified as benzophenone by mixed melting point measurement of its 2,4-dinitrophenylhydrazone (m. p. 236°C, recrystallized from ethyl acetate) or its semicarbazone (m. p. 165°C, recrystallized from ligroin and benzene) (theoretical yield: 55%).

Fraction 3 was recrystallized from benzene and ligroin to give colorless crystals, m. p. 87~88°C, while fraction 4 gave white crystals by recrystallization from benzene, m. p. 201~202°C. The structures of the above two compounds have not yet been determined.

The acidic and phenolic compounds which were involved in the potassium carbonate solution and the sodium hydroxide solution respectively were confirmed to be the same as those of a previous report[1].

4,4'-Ditolyl Ketone.—The procedure employed here was identical to that described above. The ether solution of *p*-tolyllithium was prepared by using 34.2 g. (0.2 mol.) of *p*-bromotoluene, 3.5 g. (0.5 g. atom) of lithium and 250 ml. of anhydrous ether, and the introduction of carbon monoxide into the solution was carried out at −70°C. The organic layer, separated after the decomposition of the reaction mixture, was divided into a neutral part, an acidic part and a phenolic part by means of the above-mentioned method. The neutral part was distilled under reduced pressure to give the following fractions: (1) b. p. 115~140°C/9 mmHg 1.8 g., (2) b. p. 175~185°C/9 mmHg 10.4 g., (3) b. p. 180~215°C/1 mmHg 4.6 g. and a dark, brownish residue. Fraction 1 was identified as 4,4'-ditolyl by its mixed melting point measurement (m. p. 121°C, recrystallized from ethanol).

Found: C, 92.36; H, 7.67. Calcd. for $C_{14}H_{14}$: C, 92.26; H, 7.74%.

Fraction 2 was recrystallized from ethanol to give 4,4'-ditolyl ketone as colorless prisms, m. p. 95~95.5°C (theoretical yield: 50%).

Found: C, 86.03; H. 6.71. Calcd. for $C_{15}H_{14}O$: C, 85.68; H, 6.71%.

Fraction 3 solidified on standing and was recrystallized from ligroin to give yellow crystals, m. p. 109~110°C, the structure of which has not yet been determined.

Found: C, 84.02; H, 6.30%.

The acidic and phenolic parts were not examined.

Di-n-butyl Ketone.—Dry pure carbon monoxide was introduced into an ether solution, cooled to −70°C, of *n*-butyllithium prepared from 27.75 g. (0.3 mol.) of *n*-butyl chloride, 4.9 g. (0.7 g. atom) of lithium and 300 ml. of anhydrous ether at the rate of 0.51/min. for 2 hr. The reaction mixture was decomposed immediately and divided into a neutral part and an acidic part. The neutral part was distilled under reduced pressure to give the following fractions: (1) b. p. 105~115°C/50 mmHg 9.3 g. and (2) b. p. 147~150°C/35 mmHg 2.2 g.

The infrared absorption spectra measurement showed the presence of a carbonyl group in fraction 1 and that the semicarbazone of fraction 1 had an identical melting point with that of di-*n*-butyl ketone (m. p. 90°C, recrystallized from ligroin).

Found: C, 60.38; H, 10.59. Calcd. for $C_{10}H_{21}ON_3$: C, 60.26, H, 10.62%.

The results of gas chromatographic analysis showed that fraction 1 was mainly di-*n*-butyl ketone and that about 10% of impurities was included. (Column-SiDC 550 2 m.; column temperature, 167°C; carrier gas, H_2; gas pressure, 0.3 kg./cm²; retension time of di-*n*-butyl ketone, 14~15 min.) (theoretical yield: 40%). Pure di-*n*-butyl ketone was obtained by purification of fraction 1 using preparative gas chromatography (column-SiDC 550; column temperature, 170°C; carrier gas, N_2; gas pressure, 1 kg./cm²). B. p. 111~112°C/70 mmHg, n_D^{15} 1.4210.

Found: C, 75.60; H, 12.86. Calcd. for $C_9H_{18}O$: C, 75.99; H, 12.76%.

Fraction 2 and the acidic part were not examined.

Di-n-amyl Ketone.—Carbon monoxide was introduced at −70°C, into an ether solution of *n*-amyllithium prepared by using 32 g. (0.3 mol.) of *n*-amyl chloride, 4.9 g. (0.7 g. atom) of lithium, 150 ml. of ether and 150 ml. of petroleum ether (b. p. 40~50°C). The distillation of the neutral part, obtained from the reaction mixture, under reduced pressure gave the following fractions: (1) b. p. 100~120°C/37 mmHg 2 g., (2) b. p. 123~133°C/37 mmHg 7.5 g., and high boiling fractions. Fraction 2 was purified by preparative gas chromatography. (Column-SiDC; column temperature, 160°C; carrier gas, N_2; gas pressure, 1 kg./cm²). The colorless liquid, thus obtained 6.9 g., was confirmed to be di-*n*-amyl ketone. B. p. 110~111°C/19 mmHg, n_D^{15} 1.4301.

Found: C, 77.50; H, 12.97, Calcd. for $C_{11}H_{22}O$; C, 77.58; H, 13.02%.

Diisopropyl Ketone.—Carbon monoxide was introduced at −70°C into a solution of isopropyllithium prepared from 23.7 g. (0.3 mol.) of isopropyl chloride, 4.9 g. (0.7 g. atom) of lithium and 200 ml. of petroleum ether. The distillation of the neutral part, obtained from the reaction mixture, gave 5 g. of an oily product, boiling at 120~127°C/760 mmHg. This was identified as diisopropyl ketone from the results of infrared absorption spectra measurement and a mixed melting point test of its semicarbazone (m. p. 144~145°C, recrystallized from ligroin and benzene) (theoretical yield: 30%).

Found: C, 56.37; H, 9.93. Calcd. for $C_8H_{17}ON_3$: C, 56.11; H, 10.01%.

The other high boiling products were not identified.

The Reaction of Iron Pentacarbonyl with Phenyllithium.—To an ether solution of phenyllithium, prepared from 31.4 g. (0.2 mol.) of bromobenzene, 3.5 g. (0.5 g. atom) of lithium and 250 ml.

of anhydrous ether, was added 9.4 g. (0.048 mol.) of iron pentacarbonyl in 100 ml. of anhydrous ether at −70°C over a period of 30 min. The reaction mixture was decomposed with ethanol and dilute hydrochloric acid, and the organic layer was divided into neutral, acidic and phenolic parts. The distillation of the neutral part under reduced pressure gave the following fractions: (1) b. p. 80~100°C/2 mmHg 2.9 g., (2) b. p. 144~147°C/3mmHg 5.2 g., (3) b. p. 150~170°C/3 mmHg 0.9 g. and a dark brownish residue.

Fraction 1 was identified as diphenyl. Fraction 2 solidified on standing and was recrystallized from ethanol to give white crystals, m. p. 132~133°C, which were identified as benzoin by a mixed melting point test (yield: 25%).

Found: C, 79.14; H, 5.61. Calcd. for $C_{14}H_{12}O_2$: C, 79.22; H, 5.70%.

Fraction 3 was recrystallized from ethanol to give triphenylmethane, m. p. 93°C (yield: 5.6%).

Found: C, 93.34; H, 6.66. Calcd. for $C_{19}H_{16}$: C, 93.40; H, 6.60%.

Summary

The reaction of carbon monoxide with an organolithium compound at −70°C yielded symmetrical ketones.

Benzophenone (55%), 4, 4′-ditolyl ketone (50%), di-*n*-butyl ketone (40%), di-*n*-amyl ketone (28%) and diisopropyl ketone (30%) were prepared by this new method.

A reaction path for the formation of ketones was discussed.

Organoboron Compounds. On the Reaction of Phenylboronic Acid with Diols and Diamines

By Seiji KATO, Moriyasu WADA and Yojiro TSUZUKI

(Received November 28, 1961)

In previous papers[1] the present authors showed that when polyvinylalcohol (PVA) is treated with phenylboronic acid, it is readily converted into polyvinylboronic ester, which is characterized by being soluble in some organic solvents, insoluble in water, and capable of being transformed into colorless strong films or fibers with a water resistance superior to that of PVA itself. The dyeing property of PVA can be improved by this esterification in some respects[2].

From these facts, it can be expected that by introducing boron into polymeric substances, remarkable specialities will appear in its properties. However, relatively little is known of polymeric substances which contain boron, especially in the main chain of polymers. It is the main object of this experiment to devise a method of preparing such polymeric substances, containing boron atoms bonded directly to a nitrogen or carbon atom in the main chain of polymers. In order to prepare these substances, phenylboronic acid was heated at 120~200°C with organic reagents containing a reactive hydrogen atom until any water or hydrogen chloride formed as a by-product was eliminated. In general, it is preferable to use bifunctional organic reagents such as glycol and diamines with at least one hydrogen atom on each terminal carbon or nitrogen atom, since the acid reacts with them to give linear polymers. Beside these reactants, organosilane compounds such as diphenylsilanediol and dichlorodiphenylsilane were used.

Experimental

Preparation of Phenylboronic Acid[3].—From bromobenzene and methylborate, phenylboronate was prepared, and after hydrolysis phenylboronic acid was obtained. Yield, 82%; m. p., 214°C.

Preparation of Phenylboronic Anhydride.—Phenylboronic acid can easily be converted to the anhydride by azeotropic distillation of water with toluene.

Preparation of Phenylboronic Dichloride.—A mixture of phenylboronic anhydride (32 g., 0.31 mol.) and phosphorus pentachloride (74 g., 0.36 mol.) was melted at 160°C and heated under reflux at 120~130°C for 24 hr. Subsequent distillation gave phosphorus oxychloride as a forerun. The main fraction, after redistillation, consisted of

3) "Organic Syntheses", Vol. 39 (1959), p. 3.

phenylboronic dichloride. Yield, 4.9 g. (11%); b. p., 48~50°C/5 mmHg.

Preparation of Diphenylsilanediol. — Into a heterogeneous mixture of 26 ml. of toluene, 54 ml. of *tert*-amyl alcohol and 220 ml. of water was stirred drop by drop 67 g. of diphenyldichlorosilane dissolved in 26 ml. of toluene. The solution was maintained at 25°C with a cooling bath. About one-half hour was required for the addition of the chloride, after which the solution was stirred for ten minutes. The solution was then filtered by suction. The crystals obtained were washed with water until they became free of acid, and were then dried in air and recrystallized from warm ethyl methyl ketone. Yield, 49 g.; (90%) m. p., 143°C.

Reaction of Phenylboronic Acid with Diamines. —All the following reactions were carried out in an atmosphere of dry oxygen-free nitrogen.

a-1) With Ethylenediamine. — Ethylenediamine (1.34 ml., 1.2 g., 0.02 mol.), together with a 5% excess of phenylboronic acid, was placed in a 50 ml. three-necked Claisen flask with a receiver, a thermometer, and an inlet for dry oxygen-free nitrogen. Reaction took place spontaneously with the evolution of heat. The flask was heated in a silicone oil-bath. At about 140°C (bath temperature), reaction set in. Water distilled off freely during the first hour and very slowly during the succeeding two hours at 120°C (inner temperature). The flask was provided with a very fine capillary, and heating was continued in vacuum (5 mmHg) for about half an hour, the temperature of the bath being raised to 160~170°C. During this period a little distillate was collected. The residue, which was a glassy, granular, slightly brown substance, was readily soluble in hot water, absolute methyl and ethyl alcohol, but insoluble in carbon tetrachloride, chloroform, dimethylformamide, ethyl ether, benzene, xylene, aceton and dioxane. This polymer-like substance melts at 80°C and can be drawn out into thread at that temperature, but it seems to be readily hydrolyzed by atmospheric moisture. Analysis indicates that this crude substance contains 23.52% nitrogen, 38.20% carbon and 7.20% hydrogen.

a-2) About 2.8 g. (ca. 002 mol.) of phenylboronic acid and 1.34 ml. (0.02 mol.) of ethylenediamine were simultaneously added to 40 ml. of toluene. Reaction took place spontaneously with evolution of heat. The mixture was then refluxed for an hour. The water formed in this reaction was distilled by means of water-toluene azeotropic distillation. After removal of the residual toluene at 5 mm., no further distillation took place up to the bath temperature of 180°C. The residue showed the same properties as were found in a-1).

b) With Trimethylenediamine. — In a two-necked flask equipped with a condenser and a nitrogen inlet were placed about 2.8 g. (ca. 0.02 mol.) of phenylboronic acid and 1.48 g. (1.67 ml., 0.02 mol.) of trimethylenediamine (b. p. 135~136°C/738 mmHg). The flask was thoroughly swept with dry nitrogen and was heated first at 130~150°C for 13 hr., and then at 150~190°C for the succeeding two hours under 5 mmHg. During the heating at 140~160°C, water was distilled, and the viscosity of the reaction mixture increased greatly. When this viscous liquid was heated under 5 mmHg, there remained a bright brittle material in the bottom of the flask. The appearance and solubility were the same as with a). Analysis showed that this crude substance contained 12.27% nitrogen, 30.67% carbon and 6.21% hydrogen.

c) With Hexamethylenediamine.—A mixture of 2.8 g. (ca. 0.02 mol.) of phenylboronic acid and 2.4 g. (0.02 mol.) of hexamethylenediamine was heated to 190~195°C under atmospheric pressure for six hours and then for two and one-half hours at 210°C under 5 mmHg. About 3.2 g. of microcrystalline powder were obtained.

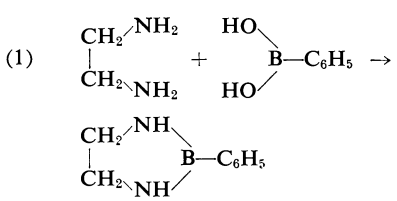
d) With p-Phenylenediamine.—In a mortar 3.8 g. (0.03 mol.) of phenylboronic acid and 3.3 g. (0.03 mol.) of *p*-phenylenediamine (m. p. 145~147°C) were triturated. This mixture was placed in a flask filled with dry nitrogen and heated to 210°C for twenty minutes. At about 150°C reaction set in; water distilled off during this period. Heating was continued for an additional ten minutes under reduced pressure. The final residue, which was a light brown, resinous mass, was soluble in hot water and alcohols, but insoluble in warm benzene, carbon tetrachloride and chloroform. This substance became dark brown on standing in the air.

Esterification of Phenylboronic Acid with Glycols. — *a) With Ethylene Glycol.*—An attempt to condense phenylboronic acid with ethylene glycol was unsuccessful.

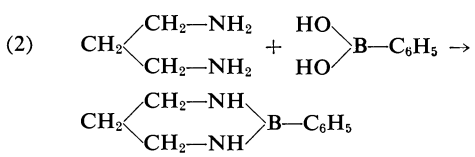
b) With Tetramethylene Glycol. — Phenylboronic acid (2.5 g., ca. 0.02 mol.) and tetramethylene glycol (1.8 ml., ca. 0.02 mol.) were heated together in a nitrogen atmosphere from 120°C to 130°C for ten hours. Additional heating was continued below 140°C under reduced pressure for an hour. The final residue was a brittle, transparent solid which could be drawn out into thread from a molten condition. This thread seemed to be easily hydrolyzed by moisture in the air. Analysis indicated that this substance contained 64.7% carbon and 8.13% hydrogen.

c) With Pentamethylene Glycol.—About 2.5 g. of phenylboronic acid and 2.08 ml. (0.02 mol.) of pentamethylene glycol was added to 50 ml. of toluene. This mixture was refluxed for an hour, followed by removal of the water as a ternary azeotrope. The product showed the same properties as were found in b) above.

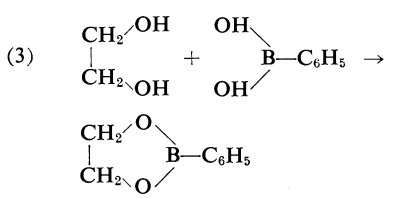
d) With Diphenylsilanediol.—A mixture of 4.32 g. (0.02 mol.) of diphenylsilanediol and 2.6 g. of phenylboronic acid was heated in a reaction flask equipped with a condenser, a thermometer and an inlet for dry oxygen-free nitrogen. The mixture was heated for 24 hr. at 190~200°C and for a further hour at 200°C under a pressure of 6 mmHg. The resulting resinous substance was a light yellow, glassy solid melting at about 90°C. This substance is soluble in benzene, ethyl methyl ketone, alcohol, etc., slightly soluble in carbon tetrachloride, and insoluble in water. When molten, this material can be drawn out into elastic threads. A flame



test showed that this substance contains boron.

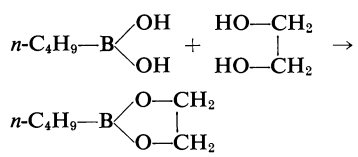


e) With Dichlorodiphenylsilane.—To a reaction vessel equipped with a thermometer, a nitrogen inlet tube extending to the bottom of the flask, and a glass tube leading to an 1 N sodium hydroxide solution, were added 3.8 g. (0.03 mol.) of phenylboronic acid and 6.7 g. (0.03 mol.) of dichlorodiphenylsilane. The reaction mass was heated in an atmosphere of nitrogen for 20 hr. at 190~200°C and then for an hour at 210°C under a pressure of 5 mmHg. The hydrogen chloride evolved during the reaction hours was absorbed in 100 ml. of an 1 N sodium hydroxide solution. Titration of the sodium hydroxide solution with a 1.011 N hydrochloric acid solution indicated that this reaction proceeded to the extent of 70% of the theoretical. About eight grams of the resinous mass were obtained. This residue showed the same properties as observed in experiment d).

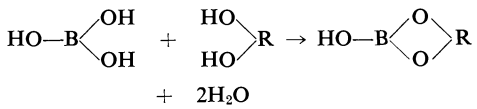


f) An attempt to get phenylboron dichloride to react with bifunctional substances by way of interfacial polycondensation was unsuccessful.

Discussion

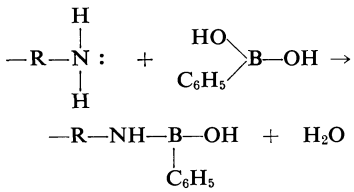


It is a well-known fact that if a 5- or 6-ring can be formed by esterification, the intramolecular reaction usually prevails over the inter-molecular reaction; in the case of 6- and 7-membered rings, both a monomolecular ring and linear polymers of a medium molecular weight are produced. It follows from this well-established fact that three of the reagents used, i. e., ethylenediamine, trimethylenediamine and ethylene glycol, might react with phenylboronic acid to give reaction products of the intra-molecular type:



However, two of these three cyclic structures, 1 and 2, do not appear to have the indicated structures, since they could be drawn out into threads. Lestinger and Skoog[4] obtained the ethylene glycol ester of *n*-butylboronic acid by the addition of ethylene glycol and toluene to a concentrated aqueous solution of *n*-butylboronic acid, followed by removal of the water as a ternary azeotrope.

On the other hand, the ethylene glycol ester of phenylboronic acid could not be obtained by the same method. The reason for this is partly that phenylboronic acid is more easily deboronated by heating with water[5]:



$$C_6H_5B(OH)_2 + H_2O \rightarrow C_6H_6 + B(OH)_3$$

Therefore, the following side reaction seems to accompany the main reaction:

Thus, the reaction product between phenylboronic acid and glycols must be a mixture of products of the linear and cyclic types.

The reaction of phenylboronic acid with diamines can be formulated as follows:

In this reaction the nitrogen atom of the diamine donates a pair of electrons to the boron atom. This results in a partial polarization of each atom, and the positive charge on the nitrogen atom will facilitate the removal of hydrogen atom as a proton. On the other hand, the negative charge on the boron atom promotes the removal of the hydroxyl group as a hydroxyl ion. Thus, the reaction proceeds with the formation of water, and the nitrogen-boron bond may be produced as a covalent bond.

Becher and his co-workers[6] investigated the Raman and ultraviolet spectra of methylamino- and diethylaminoboron and showed that the boron-nitrogen bond has a considerable double bond character. The infrared absorption

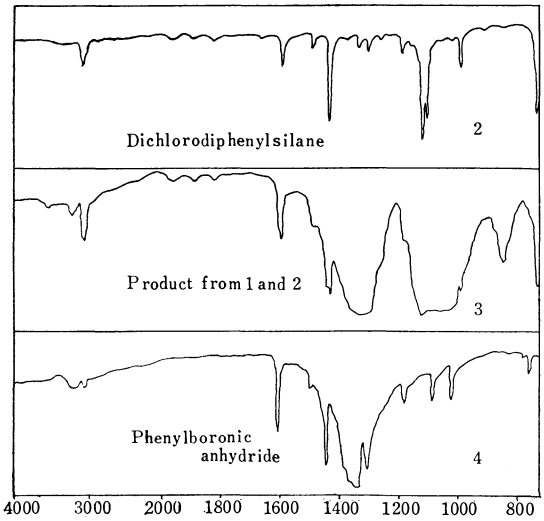

Fig. 2

spectra of the derivatives of phenylboronic acid condensed with a diamine as well as with an organo-silicone are shown in Figs. 1—4. As regards the compounds formed from phenylboronic acid and ethylenediamine (Fig. 1), perhaps the most striking feature in the generally, weak absorption spectrum is a broad band in the region of 1300～1400 cm^{-1}. The same absorption band occurred with *N, N, N*-trimethylborazol[7]. It seems certain that the band is associated with the B–N group (1330～1380 cm^{-1}) and the B–O group (1330～1390 cm^{-1}). Figure 2 shows the absorption spectrum of dichlorodiphenylsilane, while Fig. 4 is that of phenylboronic anhydride. Figure 3 is also the spectrum of the compound formed from these two. The three bands at 850, 1000～1100 and 1300～1350 cm^{-1} seen in Fig. 3 are characteristic of this condensed compound. The band at 850 cm^{-1}, which can not be found in either of the parent spectra, suggests the formation of some new bond during the reaction. Moreover, the broad and strong band in the 1000～1100 cm^{-1} region is probably connected with the stretching vibration of the Si–O–B bond, the band of which casually comes near the 1100 cm^{-1} absorption due to the ether linkage C–O–C. In conclusion, the most notable feature observed in this spectrum is that the polymer formed from phenylboronic acid and dichlorodiphenylsilane shows a very strong band in the 1000～1100 cm^{-1} range; this band is probably due to Si–O–B absorption, and therefore the product must be polyborosiloxane.

Hot-Atom Chemistry of Arsenates.—Effect of Cation, Water of Crystallization and Irradiation Temperature on the Retention of Radioarsenic in Neutron-irradiated Solid Arsenates

By Nobufusa SAITO and Isao TOMITA

(Received December 1, 1961)

On the retention of radioarsenic as arsenate after neutron irradiation of arsenic acid or sodium arsenates in a solid state or in an aqueous solution, several investigators have obtained various results[1-5]. Typical results given by these workers are shown in Table I.

In the present investigation, the effect of cation, water of crystallization in molecules, irradiation temperature and storage time have been studied. The nuclide under investigation is 26.8 h ^{76}As, a hard-beta-emitter (E_{max}= 2.965 MeV.) with accompanying gamma rays.

Experimental

Arsenates of lithium, ammonium, sodium, potassium, cobalt(II) and barium were used as target materials for neutron irradiation. Irradiation of

these salts was carried out for 2.5 to 3 hr. with neutrons produced by Be-D reaction. Deuterons were accelerated by the cyclotron of the Institute of Physical and Chemical Research, Tokyo. The flux was approximately $10^7 n/cm^2 \cdot sec$. Neutrons were thermalized through a paraffin block or through water. In some cases, they were slowed down through ethanol. The temperatures of the bombardment site were −196°C (liquid nitrogen), −72°C (mixture of dry ice and ethanol), and room temperature.

After irradiation, each of the irradiated samples was dissolved in water containing an arsenic(III) carrier (arsenite solution). To this solution were added magnesia mixture and ammonia water to precipitate ammonium magnesium arsenate, $NH_4 \cdot MgAsO_4 \cdot 6H_2O$. The precipitate was dissolved in hydrochloric acid, hold-back carrier of arsenic(III) was added, and then precipitation was repeated by adding ammonia and an excess of a magnesia mixture. Hydrogen peroxide was added to the combined filtrate to oxidize arsenic(III). The precipitate formed contained radioarsenic, which was originally in the valence state of III as a result of the recoil process or a subsequent reaction. The precipitate was again dissolved in hydrochloric acid and diluted to 25 ml. The β-activity of each fraction was measured with a dipping counter. Finally, the retention value of radioarsenic as arsenate was calculated on each salt as follows:

$$R = \frac{I(\mathrm{AsV})}{I(\mathrm{AsIII}) + I(\mathrm{AsV})} \times 100 \ (\%)$$

were I is the intensity of radioactivity.

Results

First, the effect of irradiation temperature and storage time on retention was investigated. The irradiated sample was principally sodium

20—24 Irradiated for 1.0 hr.

arsenate, $Na_2HAsO_4 \cdot 7H_2O$, of an especially pure grade obtained from the Merck Co. The crystal size was not uniform but was roughly within the range of 1~3 mm. in diameter. The results are given in Table II. In the case of irradiation at 150~100°C, the state of the target crystals differed from that at room temperature. Having a large amount of water of crystallization, the crystal melted at these high temperatures, and then the water was evaporated. The target had probably been partly changed into $Na_4As_2O_7$.

The results of the irradiation of Li_3AsO_4 and $H_4As_2O_7$ at low or room temperatures are shown in Table III. Further, the dependence of retention upon storage time was investigated for several kinds of arsenates, the results being given in Table IV.

Table III. Effect of irradiation temperature, storage temperature and storage time on retention of irradiated Li_3AsO_4 and $H_4As_2O_7$

Compound	Irrad. temp. °C	Storage temp. °C	Storage time hr.	Retention %
Li_3AsO_4	−196	−196	1	36.2
Li_3AsO_4	−196	−196	4	36.2
Li_3AsO_4	Room	Room	1	40.6

$H_4As_2O_7$	Room	Room	1	55.2

Table IV. Dependence of retention upon storage time

Compound	Storage time hr.	Retention %
Li_3AsO_4	1.0	40.6
Li_3AsO_4	4.0	44.0
Li_3AsO_4	21.0	44.0
Li_3AsO_4	24.5	46.4
$Na_3AsO_4 \cdot 12H_2O$	1.0	39.5
$Na_3AsO_4 \cdot 12H_2O$	42.5	40.9
$Na_2HAsO_4 \cdot 7H_2O$	0.5	64.6
$Na_2HAsO_4 \cdot 7H_2O$	1.0	65.1
$Na_2HAsO_4 \cdot 7H_2O$	18.0	67.8
$Na_2HAsO_4 \cdot 7H_2O$	119	72.6
$NaH_2AsO_4 \cdot 2H_2O$	1.0	46.9
$NaH_2AsO_4 \cdot 2H_2O$	42.5	54.0
$KH_2AsO_4 \cdot H_2O$	1	54.9
$KH_2AsO_4 \cdot H_2O$	23.0	59.5
$BaHAsO_4$	1.0	49.4
$BaHAsO_4$	24.5	51.5
$Co_3(AsO_4)_2 \cdot 8H_2O$	1.0	21.1
$Co_3(AsO_4)_2 \cdot 8H_2O$	24.5	50.5

Irradiated salts were stored at room temperature.

In general, the results show a gradual increase in retention values, i. e., an increase in the arsenic(V) fraction, when the irradiated salts are stored at room temperature.

Table V. Retentions in irradiated crystalline arsenates

Arsenate	Retention %
Li_3AsO_4	40.6±1.1
$(NH_4)_3AsO_4 \cdot 3H_2O$	41.0±0.5
$Na_3AsO_4 \cdot 12H_2O$	39.5±0.1
$(NH_4)_2HAsO_4$	46.8±0.4
$Na_2HAsO_4 \cdot 7H_2O$	65.1±0.5
$Co_3(AsO_4)_2 \cdot 8H_2O$	21.1±0.6
NaH_2AsO_4	52.7±1.0
$NaH_2AsO_4 \cdot 2H_2O$	46.9±0.3
$KH_2AsO_4 \cdot H_2O$	54.9±0.1
$BaHAsO_4$	51.8±2.4
$BaHAsO_4 \cdot H_2O$	49.6±0.2

Fluctuation of obtained retention value was shown after mean value in the form such as 41.0±0.5.

In Table V, the results of the irradiation of various kinds of crystalline arsenates are shown; here the effects of cation atom and of water of crystallization can be observed. The given values have been obtained for the irradiation at room temperature and for the storage for one hour. It was found that each salt had its characteristic retention value and that the value for $Na_2HAsO_4 \cdot 7H_2O$, 65%, agreed with the results of Müller and Broda, and also agreed roughly with those by Malý and Šimáňová, who had obtained the value of 67%.

Discussion

It is clear from the data of the retention values of irradiated $Na_2HAsO_4 \cdot 7H_2O$ after one hour's storage that the values at the two lower temperatures are nearly the same, about 50%, and that they show a fairly large difference from the value, 65%, obtained for the irradiation at room temperature. When the irradiated crystals were stored for 17~18 hr. at liquid nitrogen or dry ice-ethanol temperature, the retention values increased very little, while the storage of radioactive crystals at room temperature resulted in a gradual increase in the radioactivity of the 'arsenate' fraction, and the retention values increased. It is considered that, in these cases, the recoil process and subsequent reactions in solids play an important role in the observed retention. The lower values obtained at lower irradiation- and storage temperatures suggest that, after the recoil process, very slow or no subsequent reaction occurred to produce radioarsenic atoms in an oxidation state higher than III.

In the preliminary experiment, solutions containing arsenate or arsenic acid at various pH's were irradiated and the retention values,

15~21%, were obtained, independent of the pH of the solution*.

Considering the above results, it is quite probable that the chances for recombination or other reactions of the recoil species with collision fragments or with parent molecules may be larger in the solid phase than in the liquid phase because of the large cage energy and the longer lifetime of the 'hot zone'[6]. For example, the following speculation may be true: a recoil fragment containing ^{76}As, which otherwise can oxidize the water upon solution of the irradiated target, may be able to react with oxygen ions or parent species in the neighborhood in the crystal to form a new fragment which is liable to hydrate to arsenate ion when dissolved. This reaction would result in the high initial retention and the gradual increase in its value during storage of irradiated arsenate crystals**.

Low temperatures at the bombardment site would affect the reaction period or the lifetime of the 'hot zone', thus resulting in lower retention than in the case of bombardments at room or higher temperatures. A few experimental data in Table I support the above statement; that is, when target salts which had been irradiated at -196 or $-72°C$ were stored at room temperature, the retention increased rather rapidly with lengthening storage time. It can be thought that the thermal- or radiation annealing effect and storage effect are so remarkable even at room temperature that the slight difference in experimental conditions affects the reproducibility of the experimental results. In fact, when the crystals were irradiated at room temperature for 1 hr. instead of 3 hr., the resulting retention was 60.9% after the storage of the irradiated salts for 0.5 hr. This value is lower than that for 3 hr's irradiation, 64.6%.

The dependence of retention upon irradiation temperature is also observed for arsenates other then sodium arsenate (Table III). It seems that these phenomena are caused by the reaction mechanism described above, although the absolute values of retention are very specific for each salt.

Similar results were obtained from the experiment to investigate the dependence of retention upon storage time of radioactive crystals (Table IV). An increase in retention with storage at room temperature is considered a general tendency for all irradiated arsenated salts, since the activation energy barrier opposing the recombination reaction of recoil arsenic ions with oxygen is assumed to be rather small.

In Table V are shown the retentions in various crystalline arsenates. No regularity can be found in the obtained values with regard to the mass of cation which has collided with a recoil atom, and a model which is based upon elastic-collision between them cannot account for the experimental data, which are common to the studies of the Szilard-Chalmers process in oxyanion salts. Harbottle and Sutin[8] suggested that ammonium ion and water of crystallization would act as reducing agents in the 'hot zone' and would result in low retentions in case of the irradiation of the salts containing them. Our results, although not so remarkable, do not contradict their suggestion. For example, low retentions for $Na_3AsO_4 \cdot 12H_2O$ and $Co_3(AsO_4)_2 \cdot 8H_2O$ are assumed to be due to their high content of water of crystallization; ammonium salts such as $(NH_4)_3AsO_4 \cdot 3H_2O$ and $(NH_4)_2HAsO_4$ also have rather low retentions as compared with those of salts of alkali metals except lithium salts. Further, the retentions of hydrate and anhydrous form of one compound such as $NaH_2AsO_4 \cdot 2H_2O$ and NaH_2AsO_4 can be compared in some cases, and lower values are obtained for hydrate crystals.

The presence of elementary radioarsenic, which has been suggested by Harbottle and Kawahara, could not be confirmed because only the precipitation method was adopted in the present experiment. Perhaps, parallel experiments using several kinds of separation methods would be valuable in studying the behavior of radioarsenic in the state of oxidation number of zero, or in intermediate valency states in the solid phase.

*The Crystal Structure of trans-Dichloro-bis-l-propylenediamine Cobalt(III) Chloride Hydrochloride Dihydrate and the Absolute Configuration of the Complex Ion, [Co l-pn_2Cl_2]$^+$**

By Yoshihiko SAITO and Hitoshi IWASAKI

(Received December 5, 1961)

During the past several years the crystal structures of various cobalt-ethylenediamine complexes have been determined by one of the present authors (Y. S.), Kuroya et al.[1-4] and Becker et al.[5] The puckered form of the cobalt-ethylenediamine ring has thus been established. In connection with this, the present investigation was initiated in order to determine the configuration of the cobalt-propylenediamine ring;

with special interest in the orientation of the substituted methyl group. Corey and Bailar[6] have recently discussed the geometry of various metal-chelate rings. Their conclusion for the metal-propylenediamine ring agrees quite well with the results obtained here. The absolute configuration of the complex ion [Co l-pn_2Cl_2]$^+$ has also been determined by the usual absorption edge technique.

Experimental

Crystals of [Co l-pn_2Cl_2]Cl.HCl.$2H_2O$ were prepared by the method of Werner and Fröhlich[7]**. They are well-developed dark green tablets, showing predominant (100) faces. In polarized light, they exhibit a marked dichroism similar to that observed for [Co en_2Cl_2]Cl.HCl.$2H_2O$. This fact suggest that the structure is closely related to those of the ethylenediamine-analogues.

As the crystals of [Co l-pn_2Cl_2]Cl.HCl.$2H_2O$ decompose gradually when exposed to air, special precautions had to be taken to preserve the crystals. It was found that adequate protection was afforded by a thin layer of grease. Specimens treated with grease were preserved intact for several weeks.

From measurements made by using an X-ray diffractometer with Cu$K\alpha$ radiation ($\lambda=1.5418$ Å), the unit cell is found to be monoclinic, with

$$a=22.092\pm0.004\text{ Å}$$
$$b=8.406\pm0.002\text{ Å}$$
$$c=9.373\pm0.004\text{ Å}$$

and $$\beta=99°39'\pm7'$$

The cell contains four formula units of [Co l-pn_2Cl_2]Cl.HCl.$2H_2O$ (density, calculated 1.494 g./cc.; found 1.495 g./cc. at 26°C). The space group was found to be $C2/m$, Cm or $C2$ from Weissenberg photographs taken with Fe$K\alpha$ radiation. The former two space group estimates can be excluded since it is certain that the compound is optically active and cannot have a center or a plane of symmetry in the arrangement in the crystals.

The structure determination was based on analysis of the ($h0l$) and ($hk0$) reflections, which could be carried out in quite a straightforward fashion.

Intensity data for the ($h0l$) and ($hk0$) reflections were recorded on zero level Weissenberg films about the b- and c-axes by the multiple-film technique. Fe$K\alpha$ radiation was used ($\lambda=1.937$ Å). The intensities of the reflections were measured by visual comparison with an intensity scale. They were corrected for absorption, Lorentz and polarization factors. Observed structure amplitudes were brought to an absolute scale afterwards by scaling them against the calculated values, the maximum $\sin\theta/\lambda$ observed being 0.514.

Patterson functions could be solved without difficulty by comparison with those of the ethylenediamine-analogues, yielding approximate positions not only for the heavy atoms but also for lighter atoms. Thus, Fourier syntheses of the electron density projections along [001] and [010] could be computed.

Fourier refinements were repeated as usual. Final projections of the electron density along [010] and [001] are shown in Figs. 1 and 2 respectively. They can be interpreted in terms of Figs. 3 and 4 respectively. The final set of parameter values is

listed in Table I. This gives the reliability index $R=\sum \big|\,|F_o|-|F_c|\,\big|/\sum |F_o|$ of 0.14 and 0.15 for ($h0l$) and ($hk0$) respectively, non-observed reflections being excluded. The contributions of hydrogen atoms were neglected. The agreement between the observed and calculated structure factors is shown in Table II.

Calculation of the structure factors as well as of the electron density projections was carried out with a PC-1 parametron computer in the Faculty of Science of this University. In the calculation of the structure factors, the atomic scattering factors were taken from the paper of Vand, Eiland and Pepinsky[8]. Different isotropic temperature factors were applied for each atoms; these are listed in the last column of Table I.

Determination of the Absolute Configuration

The absolute configuration of *l*-propylenediamine has been chemically related to D-alanine by modification of COOH in the latter to CH_2NH_2 of the former[9]. Since the absolute configuration of D-alanine is already known, *l*-propylenediamine must possess the absolute configuration shown by I:

(I)

On the basis of the principles of stereochemical analysis developed by Corey and Bailar, it is possible to correlate the absolute configurations of various complex ions, for instance, those of L-$[Co\ en_3]^{3+}$, L-$[Co\ l\text{-}pn_3]^{3+}$ and *l*-pn. The result of the assignment of the absolute configuration of L-$[Co\ en_3]^{3+}$ based on that of *l*-propylenediamine agrees with the absolute configuration found for L-$[Co\ en_3]^{3+}$ by X-ray analysis[10]. Nevertheless, it was thought worthwhile to check the absolute configuration of the *l*-propylenediamine molecule, since so much stereo-specificity depends upon this chemical assignment of *l*-propylenediamine, and also, this will add support to our previous findings on the absolute configuration of L-$[Co\ en_3]^{3+}$.

The absorption edge of the K electrons of cobalt is 1.608 Å. Since Cu$K\alpha$ radiation (λ= 1.542 Å) has a wavelength a little shorter than the absorption edge of cobalt, it can excite the K electrons, and it was found that $\Delta f' = -2.2$ and $\Delta f'' = 3.9$[11]. Corrections for chlorine atoms due to the anomalous dispersion caused by K-electrons were also taken into account. They were: $\Delta f' = +0.2$ and $\Delta f'' = +0.7$ (calculated from the Table in James' book[12]).

Intensities were calculated for the structure model which corresponds to the *l*-configuration shown by I. In Table III experimental and calculated relations between I_{hkl} and $I_{h\bar{k}l}$ are compared, the latter being equal to $I_{\bar{h}k\bar{l}}$ by symmetry. Visual estimations of the last column have been made, on a series of oscillation photographs taken around the b-axis, by several people independently. It is seen that the configuration is in agreement with the chemical convention.

Description of the Structure and Discussion

The determined structure seems most easily understood with the aid of the projection upon (010) shwon in Fig. 3. The interatomic distances and bond angles are given in Table IV.

The estimated errors of interatomic distances are; ± 0.01 Å for Co–Cl, ±0.04 Å for O–Cl, N–Cl, and Co–N, and ±0.06 Å for other interatomic distances between lighter atoms.

The structure is essentially ionic and consists of the complexes, [Co *l*-pn_2Cl_2]$^+$ and [H_2O. H. H_2O]$^+$ and the Cl^- ion. Figure 5 shows a perspective drawing of the [Co *l*-pn_2Cl_2]$^+$ ion. Two chlorine atoms are coordinated, at

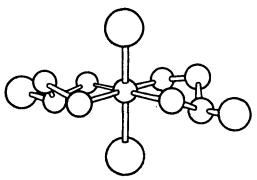

Fig. 5. A perspective drawing of the complex ion [Co *l*-pn_2Cl_2]$^+$.

a distance of 2.29 Å, to a cobalt atom in trans positions. A line joining them is approximately perpendicular to the plane in which the four nitrogen atoms of the two propylenediamine molecules were found to lie. Within the range of experimental error, these ligand atoms (4N and 2Cl) form a distorted octahedron around a cobalt atom. The bond length found for Co–Cl agrees with those found in [Co en_2Cl_2]·Cl.HCl.$2H_2O$[1] and [$Co(NH_3)_3H_2OCl_2$]Cl[13]. However, it is significantly longer than the value of 2.22 Å found in the crystals of anhydrous [Co en_2Cl_2]Cl[5]*. The chelating molecule assumes a gauche configuration with an azimuthal angle of 55° between the planes determined by the C–C and C–N bonds. The azimuthal angles between the planes determined by the C–C and C–N bonds and that determined by the Co–N and C–N bonds are, on the average, 38°. Consequently, the configuration of the five membered cobalt propylenediamine ring can be assigned as gauche-gauche-gauche with respect to the N–C, C–C and C–N bonds.

The shape and size of this five-membered ring agree well with those of the cobalt-ethylenediamine rings found in [Co en_2Cl_2]$^+$, and [Co

* This big difference might have some relation to the difference in stability between [Co en_2Cl_2]Cl.HCl.$2H_2O$ and [Co en_2Cl_2]Cl.

$en_3]^{3+}$. The same type of puckered rings is also found in other metal-ethylenediamine complexes, such as [Cr $en_2Cl_2]^{+}$ [14], [Ni $en_3]^{2+}$ [15] and [Cu $en_2]^{2+}$ [16].

The presence of a substituted methyl group on the carbon of the ethylenediamine molecule does not disturb the essential features of the five-membered ring.

The complex ion possesses approximate two-fold symmetry around the Cl–Co–Cl bond. Therefore, this complex ion assumes the *kk* form; that is, the two cobalt propylenediamine rings take the same configuration. The complex ions [Co $en_2Cl_2]^{+}$ and [Co *dl*-$pn_2Cl_2]^{+}$ [17], however, are found to take the *kk'* configuration; namely, two kinds of ligand molecules, the one being the mirror image of the other, are coordinated to the central atom in such a way that one is related by the operation of a center of symmetry to the other. According to Corey and Bailar, the *kk* form is intrinsically more stable than the *kk'* form. The reason why the *kk'* form often occurs in crystals of various complex compounds may be that the *kk'* form is favored by specific intermolecular forces in the solid state.

Since the five-membered ring is puckered, there are two possibilities of the orientation of the C–CH_3 group, namely, axial and equatorial types with respect to the Cl–Co–Cl bond. It was found that the bond is equatorial in the complex ion [Co *l*-$pn_2Cl_2]^{+}$, in agreement with the conclusion of Corey and Bailar that the equatorial orientation is of a lower energy than the axial one.

Since the structure is closely related to that of the en-analogue, a similar consideration of the arrangement of chlorine ions around the two water molecules leads us to locate a proton midway between the water molecules. The O–O distances were found to be 2.57 Å. A molecule of H_2O possesses two Cl^- ions as the nearest neighbor anions, the $Cl^-\cdots O$ distance being shown in Table II. Thus, every [H_2O.$H.H_2O]^{+}$ group is surrounded by four Cl^- ions. The complexes [$H_2O.H.H_2O]^{+}$ form a chain of the composition:

this chain runs parallel to the c-axis.

Such complexes have been found in crystals of Co-en analogues[1,2] and in a Cr-en analogue[14]

with an average O–O distance of 2.60 Å. The existence of the complex $[H_2O.H.H_2O]^+$ was suggested by Huggins[18] and was indeed verified by our investigations of these coordination compounds.

As in the case of the en-analogues, the complex ions form a layer parallel to the plane (100). The Cl–Co–Cl bond is inclined to the plane (010) at an angle of 5°, and the projection of this direction upon (010) makes an angle of 9.5°C with the c-axis.

In the case of the en-analogues, these angles are 14.5° and 10°. The closest distance of approach between the complex ions in the layer was found to be about 3.19 Å, between the coordinated Cl atom of one complex ion and the N atom of the adjacent. Thus, the complex ions are held together in layers by these Cl···N bonds. One complex $[Co\ l\text{-}pn_2Cl_2]^+$ ion has four nearest Cl^- ions. The closest approach of a complex ion and Cl^- ion is between N′(2) and Cl(2), the Cl···N distance being 3.10 Å. Other Cl^-···N distances are 3.37, 3.40 and 3.54 Å. These values may be compared with those found in crystals of the en-analogues.

Between the layers of the complex $[Co\ l\text{-}pn_2Cl_2]^+$ ions are arranged the complexes $[H_2O\cdot H\cdot H_2O]^+$ and Cl^- ions. These general features of the structure are quite similar to those of the ethylenediamine analogues. This fact can be more easily seen if an alternative a-axis is taken along one of the face diagonals. Then the propylenediamine ligands lie approximately on the new (001) plane. This new unit cell is very similar to that of the en-analogues in projection. However, the packing of the chlorine ions and water molecules is different from those in the en-analogues because of the methyl groups attached to the cobalt ethylenediamine ring. Thus, there is a twofold axis of rotation midway between the water molecules instead of a center of symmetry. This situation leads to a doubling of the a-spacing in the case of the present propylenediamine analogue.

Thin tabular crystals extended on (010) appear blue when the electric vector is parallel to the c-axis, while they appear yellowish green when the light is polarized along the b-axis. Such a striking dichroism may be reasonable, since there is a large component of the Cl–Co–Cl bond along the c-axis. This dichroism is quite similar to that of the en-analogues. The dichroism of the latter crystals have been extensively measured by Yamada et al.[19]

The absolute configuration of the *l*-propylenediamine molecule is found to be given by I and to agree with the chemical convention. The absolute configuration of $[Co\ l\text{-}pn_2Cl_2]^+$ corresponds to the drawing given in Fig. 5. Accordingly, on the basis of the principles of Corey and Bailar, the absolute configuration of the complex ion $[Co\ en_3]^{3+}$ can be shown to agree with our previous results, directly obtained by X-ray techniques.

In conclusion, the stereochemical principles and the method for correlation of absolute configuration developed by Bailar et al. have been proved to be reliable and useful.

Part of the cost of this investigation was defrayed by the Scientific Research Expenditure of the Ministry of Education and by The Nishina Memorial Foundation, to which the authors' thanks are due. They are also indebted to Professor R. Sadanaga and his colleagues for their aid in calculations on the PC-1 Parametron Computor.

The Electron Spin Resonance Absorption of the Complex of Thianthrene with Antimony Pentachloride

By Minoru KINOSHITA

(Received January 22, 1962)

In a previous note[1] we presented some preliminary results of the ESR absorption study of the complexes of some aromatic sulfur compounds with strong Lewis acids, in both the solid and dissolved states. In the course of the study it was found that thianthrene, when treated with antimony pentachloride, formed a very stable complex which showed a very strong ESR absorption. Its absorption consists of three broad lines in the powdered state, while in the dissolved state the complex shows the hyperfine structure which has been known to be characteristic of the sulfuric acid solution of thianthrene[2,3]. In the case of aromatic hydrocarbons such as anthracene, tetracene and perylene, it has been observed that a complex with antimony pentachloride[4] or aluminum chloride[5] shows the hyperfine structure in the dissolved state similar to that of the sulfuric acid solution of the corresponding hydrocarbon; meanwhile, in the solid state the absorption is only a single sharp line[6]. In this report, the system of thianthrene and antimony pentachloride is investigated; the results will be discussed with reference to the case of aromatic hydrocarbons.

Experimental

Preparation and Composition of the Complex.—Similarly to the case of aromatic hydrocarbon[6,7], the complex of thianthrene with antimony pentachloride was prepared by mixing the dilute solutions of both the components in dried chloroform. When the solutions were mixed, a brownish purple precipitate was formed immediately. This precipitate was filtered, washed with dried chloroform, and then dried in a vacuum for about 30 min. The dried complex is very stable and has a definite melting point of 152~153°C. For the determination of the composition, it was decomposed in boiling water, and the concentration of the free chlorine ion was determined by titration with silver nitrate solution. It was estimated that the complex consists of one mole of thianthrene and 0.93 mol. of antimony pentachloride. The complexes of thianthrene with aluminum chloride and titanium tetrachloride were prepared in a similar way. These complexes were not so stable as the complex with antimony pentachloride. Stannic chloride did not seem to form any solid complex with thianthrene in a dried condition.

Measurements.—The ESR absorption spectra of the complexes were examined at 9.4 kMc./sec. by the use of a Hitachi MPS-1 spectrometer. The unpaired spin concentration and the *g*-value of the complex were estimated by comparison with a standard piece of diphenylpicrylhydrazyl, for which the *g*-value of 2.0036 had been decided upon.

The magnetic susceptibilities of thianthrene and its complex were measured by the Gouy method, and the electronic absorption spectra were obtained in association with a Cary model-11 spectrophotometer. All the mesurements in this work were carried out at room temperature.

Results

The complex formed by the reaction of thianthrene with antimony pentachloride was a brownish purple powder. When examined by an X-ray diffractometer, it gave a sharp crystalline pattern which was quite different from that of thianthrene itself. The complex remained unchanged after being exposed to the air for about one year, but when boiled with water, it decomposed completely, leaving thianthrene.

The ESR Absorption Spectra. — The ESR absorption spectrum of the complex in its powdered state was found to consist of three broad lines which were distributed asymmetrically (Fig. 1). The separations between the three lines increased in proportion to the resonance frequency (Fig. 1b). The *g*-value for the main center line was found to be 2.0080 ± 0.0001, and the spin population was estimated as 1.3×10^{21} per gram, with an error of about 10%. Similar ESR absorption patterns were obtained for the complexes with aluminum chloride and titanium tetrachloride, but, as they were very weak, they were not investigated further.

In the nitrobenzene solution, the complex showed, in contrast to the spectrum of the

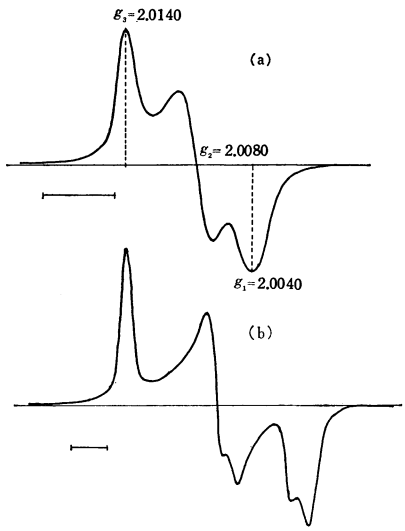

Fig. 1. The derivative curves of the ESR absorption for the powdered complex of thianthrene-$SbCl_5$, at the frequencies of 9.4 kMc./sec. (a), and of 23 kMc./sec. (b). The scale (10 gauss) is indicated in the spectra. The magnetic field increases from left to right.

solid, a hyperfine structure consisting of five equally spaced lines with an intensity ratio of about 1 : 4 : 6 : 4 : 1 (Fig. 2a). This hyperfine structure is identical with that of thianthrene or thianthrene disulfoxide in a concentrated sulfuric acid solution (Fig. 2b and c), which has been investigated by previous workers[3]. The g-value for the center of the structure was found to be $g=2.0080\pm0.0001$, while the spacing of the five lines was about 1.2 gauss.

The Electronic Absorption Spectra. — The solutions of the complex in nitrobenzene and in *o*-dichlorobenzene displayed identical spectra, characterized by an absorption band with a maximum at 547 mμ, which was in coincidence with the band at 546 mμ observed in the sulfuric acid solution of thianthrene[3]. In these solutions the complex decomposed slowly. The spectrum of the complex in the solid state was obtained by the KBr-disk method. This spectrum was similar to that of the solution, but the absorption band was shifted by about 30 mμ to the longer wavelength side. In the KBr-disk, the complex was also unstable.

The Magnetic Susceptibilities.—The observed susceptibilities are as follows:

Thianthrene: $\chi_g=-0.601\times10^{-6}$ per gram, or $\chi_M=-129.8\times10^{-6}$ per mole.

This molar susceptibility is in good agreement with the value of -129.3×10^{-6} reported by Banerjee[8].

The complex of thianthrene with antimony pentachloride: $\chi_g=1.74\times10^{-6}$ per gram, or $\chi_M=897\times10^{-6}$ per mole.

The molar susceptibility of the complex was calculated assuming the composition to be one to one in mole ratio.

Discussion

The facts that identical ESR patterns can be observed in the powdered complexes of thianthrene with antimony pentachloride, with aluminum chloride and with titanium tetrachloride, and that in solution the complex with antimony pentachloride shows the hyperfine structure which has been found in the sulfuric acid solution of thianthrene suggest that the paramagnetism of these complexes originates from thianthrene, presumably its monopositive ion, and not from the chlorides. From this investigation only, the form of these chlorides in complexes can not be deduced. However, it has been suggested, in the case of the complexes of diphenylamine derivatives

with antimony pentachloride, that the diamagnetic form of $(SbCl_6^- + SbCl_4^-)/2$ might result[9].

The three absorption lines may be attributed to the g-factor anisotropy because of the proportionality of their spacing change to the microwave frequency. Such an anisotropy has been found in some organic free-radicals, e. g., the irradiated proteins[10] and amino acids[11] containing sulfur. In the case of the organic free-radicals containing sulfur atoms, the anisotropy is often observed very clearly, but it can only with difficulty be obtained so clearly in many other free-radicals in powdered or glassy states. This fact has been interpreted qualitatively by the localization of an unpaired electron on the sulfur atom, which can be expected because of the large g-values and broad absorptions in free radicals containing sulfur. Recently this explanation has been confirmed to be valid in the quantitative treatment of the γ-irradiated single crystal of thiodiglycolic acid[12]. The principal g-values, g_1, g_2 and g_3, of the complex with antimony pentachloride, shown in Fig. 1a, are obtained by the method described by Kneubühl[13], who has made a theoretical treatment of line shapes for the powdered samples. This method has given results agreeing well with the single crystal work when applied to copper chloride powder which shows very broad anisotropic lines.

Another explanation for the three absorption lines is that they might be due to the coexistence of three kinds of paramagnetic species. In the case of the mixture of tetracene and antimony pentachloride, it has been shown that there are two kinds of paramagnetic compounds which give the two ESR absorption lines in its powdered state, the intensity ratio of which is dependent on the amount of antimony pentachloride[6]. Also, the presence of two kinds of paramagnetic species has been suggested in the systems of thio-β-naphthol and 2, 2'-dinaphthyl disulfide with the same reagent[1]. In the present complex, it was found that the absorption line shape was not changed by repeated evacuations, but the addition of a small amount of the chloride to the dried complex generated new lines at the near position of the peak with $g=2.0040$.

Although the possibility of the presence of some kinds of compounds could not be excluded completely, the suggestion of the g-factor anisotropy for the dried complex may be supported by the facts that the isotropic hyperfine structure, which is characteristic of the sulfuric acid solution of thianthrene, can be observed in a nitrobenzene solution of the complex, and that the optical absorption spectra for both solid and solution are identical (that is, the same species is responsible for the paramagnetism in both the solid and dissolved states). In the case of some polycyclic aromatic hydrocarbons, it has been shown that the same species is formed in the complex with antimony pentachloride and in the sulfuric acid solution, and identical ESR hyperfine structures[4] and optical absorption spectra[14,15] can be observed. This seems to hold in the present case also.

The concentration of 1.3×10^{21} spins/g. obtained from the ESR absorption intensity indicates that there are 6.7×10^{23} unpaired electrons in one mole of the complex, assuming that the complex is formed by each mole of thianthrene and antimony pentachloride. Since the measurements of the ESR absorption intensities have errors of about 10%, it may be considered likely that each thianthrene molecule has one unpaired electron in the complex. If so, the paramagnetic part of the molar susceptibility of this system can be calculated as about 1250×10^{-6} at room temperature. On the other hand, the observed magnetic susceptibility of the complex is 897×10^{-6}. This leads to 1150×10^{-6} as the paramagnetic part of the susceptibility after the diamagnetic correction is made, assuming that the susceptibility of thianthrene is not altered in the course of the complex formation and that antimony pentachloride takes the diamagnetic form mentioned above, for which the susceptibility is estimated as -124×10^{-6} [9]. The paramagnetic part derived from the susceptibility measurement shows a somewhat large depression below that of the ESR method. This may be ascribed to the unsuitable diamagnetic correction, the experimental error, or other elements such as the Weiss constant, if any. Among these factors, the diamagnetic correction of thianthrene is of especial interest.

In the thianthrene molecule there may be no π-electron conjugation between the two benzenoid rings through the lone pair electrons on sulfur atoms, because of the non-planarity of the molecule. This can be demonstrated from the magnetic susceptibility of thianthrene. From the values of the molar susceptibilities of thianthrene and benzene, $\chi_M = -129.8\times10^{-6}$

and $\chi(\text{Benz.}) = -55.6 \times 10^{-6}$ respectively, and the atomic susceptibility of hydrogen, $\chi(\text{H}) = -2.93 \times 10^{-6}$, the atomic susceptibility of sulfur, $\chi(\text{S})$, can be calculated as:

$$\chi_{\text{M}} = 2\chi(\text{Benz.}) - 4\chi(\text{H}) + 2\chi(\text{S})$$
$$\chi(\text{S}) = -15.2 \times 10^{-6}$$

This value agrees with Pascal's constant, $\chi(\text{S}) = -15.0 \times 10^{-6}$, within the range of experimental error. If the conjugation can cover the whole molecule of thianthrene, the atomic susceptibility of sulfur must become more diamagnetic by the above treatment. In the complex, however, it may be suggested that the thianthrene molecule, which is presumably presented as a monopositive ion, may be capable of taking a more diamagnetic planar (or nearly planar) form and that the diamagnetism may be increased by π-electron conjugation over the whole molecule. This suggestion is supported by the stability of the complex and by the ESR hyperfine structure which can be assigned to the four equivalent protons.

The author would like to express his appreciation to Professor Hideo Akamatu, Dr. Hiroo Inokuchi and Dr. Yoshio Matsunaga for their valuable advice and discussion, and to Professor Eitaro Abe, of the Institute of the Solid State Physics, for his work of ESR measurement at 23 kMc./sec.

Polyterpenes. IV[1]. *The Oxidation Products of Thujopsene*[*1, *2]

By Shizuo NAGAHAMA, Hiroshi KOBAYASHI and Saburo AKIYOSHI

(Received December 22, 1961)

As a result of a recent investigation by Erdtman and Norin[2], the sesquiterpene hydrocarbon thujopsene has been shown to possess structure I. In a previous communication[3] we described the isolation of the keto acid, together with four other degradation products of thujopsene formed by permanganate oxidation. Now using sodium bichromate these same products were again isolated. On the basis of structure I for thujopsene, we now wish to propose structures for these degradation products (II, III, IV and V)[4].

Acid II, $C_{15}H_{22}O_4$, on further permanganate oxidation, afforded IV, $C_{14}H_{22}O_3$[5], which was oxidized by sodium hypobromite to the known C_{13}-dicarboxylic acid VI[1]. The structure of the latter was established by Erdtman and Norin[2].

Acid II did not show the ultraviolet absorption expected of an α-keto acid; furthermore, its infrared spectrum exhibited a hydroxyl band at 3300 cm^{-1}. However, on esterification a methyl ester was obtained which showed ultraviolet and infrared absorptions consistent with the structure VII (R=Me). It therefore appears that, in the solid state, diketo acid II exists in a lactone form. This confirmed by the presence of a band at 1761 cm^{-1} in its infrared spectrum. The compound is therefore formulated as VIII; the alternative structure of IX may be ruled out on the basis of the ultraviolet evidence.

Keto acid IV, on the basis of spectral evidence, exists as a pseudo acid and may therefore be formulated as X. This was confirmed by its dehydration to the enol lactone XI, which on subsequent hydrolysis regenerated the original compound X. The methyl ester of this pseudo acid showed spectral bands in agreement with the structure XII (R=Me).

The treatment of II with alkali gave a further acid III, also isolated by the direct oxidation of thujopsene; the assignment of structure III is based on the following reactions. Chromic acid oxidation of III gave the β-diketone XIII, which on further oxidation

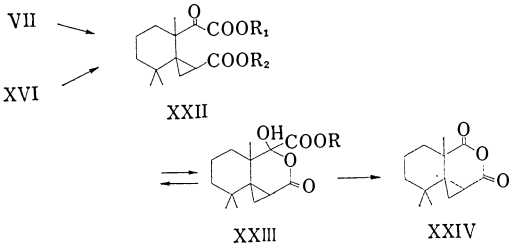
4) These correspond to II, III, IV and V respectively in Part I[3]. The same results for II, III and V have been reported by T. Nozoe et al., *Chem. Pharm. Bulletin*, **8**, 936 (1960).

5) Previously described as an oxyacid $C_{12}H_{14}O_3$ in Ref. 3.

Scheme 1



Scheme 2

afforded the yellow α-diketone XIV previously obtained from cycloketone XV[1]. The β-diketone XIII was also obtained by treatment of the enol lactone XI or methyl ester XII (R=Me), with methanolic potassium hydroxide. The dehydration of III gave unsaturated keto acid XVI, $C_{15}H_{20}O_3$[3], which on Huang-Minlon reduction gave the unsaturated acid XVII. XVII could be reoxidized back to XVI. The decarboxylation of XVI, using copper and quinoline, afforded the unsaturated ketone V[6], which was also obtained by direct oxidation of thujopsene. The Huang-Minlon reduction of V gave a mixture of the two hydrocarbons XVIII and XIX. Compound XVIII was also obtained by the decarboxylation of XVII, whereas hydrocarbon XIX was formed by the decarboxylation of hinokiic acid XX. The oxidation of XVIII with potassium permanganate gave C_{13}-dicarboxylic acid VI, and that of XIX, the known C_{14}-dicarboxylic acid XXII.

Acid II and methyl ester VII (R=Me), on oxidation with sodium hypobromite, gave a dicarboxylic acid formulated as XXII (R_1=R_2=H). Different samples of the latter compound, however, exhibited different infrared spectra; this may perhaps be attributed to varying proportions of a lactonoid form such as XXIII (R=H). On methylation, these samples all gave the same dimethyl ester XXII, (R_1=R_2=Me).

The acid XXII, (R=H) was also obtained by the ozonolysis of XV and, on chromic acid oxidation, it gave anhydride XXIV corresponding to C_{13}-acid VI.

Scheme 3

The bichromate oxidation of ester VII (R=Me) gave an acid product $C_{15}H_{22}O_5$, m. p. 190°C. Its infrared spectrum showed bands at 3322, 1762 and 1712 cm^{-1}. Therefore, it might be represented by XXIII (R=Me), rather than by XXII (R_1=Me, R_2=H). Attempted chromic

6) This derivation was first reported by T. Ozeki, S. Seto and T. Nozoe, at the First Symposium on Perfumary, Terpene and Essential Oil Chemistry, Osaka, November, 1957.

acid oxidation of the dimethyl ester XXII ($R_1=R_2=Me$) gave the same product.

Experimental

Permanganate Oxidation of Thujopsene. — An ice-cooled mixture of thujopsene (100 g.) and acetone (400 cc.) was oxidized with finely powdered permanganate (250 g.).

Separation of Acid Products.—The acid part was obtained as an oil or semisolid. When benzene was added to it, acid III, if produced during separation, was precipitated. The benzene extract was concentrated and ketonic acid was crystallized on cooling. The mother liquor was diluted with petroleum ether and cooled in a refrigerator for several weeks or more, giving acids II and IV. After the second or third crop was obtained, the remaining acid II was converted to acid III, which was easily separable, by treating it with alkali for two or three days.

Separation of Neutral Products. — About 750 g. of the neutral part was obtained by several runs; it was separated in 5 fractions by distillation. (The yields in this paragraph are shown as percentage of the whole neutral part.) Fraction 1 (b. p.~119°C/11 mmHg, n_D^{23} 1.5030~1.5050 28.4%) was mainly unreacted thujopsene containing a small number of isomerized hydrocarbons. Fraction 2 (b. p. 119~130°C/11 mmHg, n_D^{23} 1.5057~1.5090, 5.9%) was redistilled, and the fraction of maximum refractive index (b. p. 95~100°C/6 mmHg, n_D^{23} 1.5097, 1.6%) was chromatographed on an alumina column. Petroleum ether eluate was hydrocarbon (0.9%), n_D^{30} 1.5111, d_4^{30} 0.9245, $[\alpha]_D^{30}$ +40.4°, IR, 1515, 812 cm^{-1}. From a benzene eluate, cycloketone XV was obtained. Fraction 3 (b. p. 130~143°C/11 mmHg, n_D^{23} 1.5018~1.5030, 5.8%) was redistilled, and the fraction of minimum refractive index (b. p. 125°C/6 mmHg, n_D^{23} 1.4987, 1.5%) was chromatographed. The petroleum ether eluate was a mixture of ketones; one of them was separated as semicarbazone, m. p. 205~206°C (decomp.).

Found: C, 69.21; H, 9.80; N, 15.40. Calcd. for $C_{16}H_{27}ON_3$: C, 69.27; H, 9.81; N, 15.15%.

Another impure semicarbazone, m. p. 201.5~202.5°C (decomp.), was obtained from the mother liquor. Cycloketone XV was obtained successively, and benzene eluate gave a crystalline alcohol, $C_{15}H_{26}O$ m. p. 85.5~86°C, which was identified as cedrol by infrared spectrum and mixed melting point tests with an authentic specimen[7]. When petroleum ether was added to the ethyl acetate eluate and the mixture was cooled, it was partly crystallized. This was filtered quickly and recrystallized from petroleum ether, giving crystals of m. p. 116~117.5°C IR, 3330 and 1740 cm^{-1}.

Found: C, 76.27; H, 10.28. Calcd. for $C_{15}H_{24}O_2$: C, 76.22; H, 10.24%.

A similar treatment of fraction 4 (b. p. 143~165°C/10 mmHg, n_D^{20} 1.5060~1.5100, 18.2%) gave 0.4% of V from petroleum ether and benzene eluate. Ethyl acetate eluate gave an oxyketone, m. p. 68~70.5°C, (0.5%) IR, 3384, 3195 and 1702 cm^{-1} (Nujol).

Found: C, 76.15; H, 10.46. Calcd. for $C_{15}H_{24}O_2$: C, 76.22; H, 10.24%.

Semicarbazone of the oxyketone, m. p. 214°C (decomp.).

Found: C, 65.31, 65.37; H, 9.29, 9.24; N, 14.23, 14.31. Calcd. for $C_{16}H_{27}O_2N_3$: C, 65.49; H, 9.28; N, 14.32%.

Methanol eluate gave a lactone, m. p. 81.5~82.5°C (1.4%) IR, 1795 cm^{-1}.

Found: C, 72.13; H, 8.87. Calcd. for $C_{15}H_{22}O_3$: C, 71.97; H, 8.86%.

Fraction 5 (b. p. 165~180°C/10 mmHg n_D^{18} 1.5178, 3.3%) gave only ketone V (0.7%) as a crystalline substance.

Bichromate Oxidation of Thujopsene. — Into a mixture of thujopsene (100 g.) and acetic acid (200 g.), a solution of sodium bichromate (250 g.) in acetic acid (750 g.) was stirred drop by drop over a period of nine hours, and the temperature was kept at 50~70°C. After the solution had been left standing overnight, about 250 g. of acetic acid was distilled. The remainder was poured into water (3 l.) and extracted with benzene. The acid part was separated and treated as above. Benzene was removed, and the residue was distilled in vacuo. The fraction of b. p. 140~146°C/11 mmHg (28 g.) deposited crystals which were identified as ketone V (4.1 g.). The mother liquor was chromatographed on an alumina column, giving ketone V (4.0 g.) and oxyketone (0.2 g.). The results are summarized in Table I.

Oxidation of Acid II. — An acetone solution of II (280 mg. in 15 cc.) was treated with potassium permanganate (420 mg.) in acetone (40 cc.) below 50°C. The reaction mixture was treated in the usual manner, and the product was recrystallized from benzene-petroleum ether or ethanol-water; melting point and mixed melting point with IV, 154.5~156°C.

Bichromate Oxidation of Acid IV.—IV (270 mg.) was dissolved in acetic acid (5 cc.), and a solution of sodium bichromate (500 mg.) in acetic acid (5 cc.) was added. The mixture, after being left overnight, showed no color change. Diluted sulfuric acid (5 cc.) was added, and the mixture was left for 2 days. The excess bichromate was decomposed with ethanol, the mixture was diluted with water, and the product was taken into an ether phase. The residue remaining after evaporation of the ether was triturated with benzene, affording a benzene insoluble product (45 mg.) which was identified as C_{13}-dicarboxylic acid VI m. p. 183~185°C (decomp.).

Found: C, 64.94; H, 8.40. Calcd. for $C_{13}H_{18}O_4$: C, 64.98; H, 8.39%.

From the benzene solution, the unchanged IV was recovered.

Hypobromite Oxidation of Acid IV. — IV (500 mg.) was treated with a hypobromite solution, and carbon tetrabromide (400 mg.) was isolated. Working up of the acid products afforded C_{13}-diacid VI (100 mg.).

Methyl Ester of Acid II (VII, R=Me) and its Saponification. — The methyl ester of II was prepared with diazomethane, m. p. 85~87° (from petroleum ether). $[\alpha]_D^{17}$ −187° (*c* 0.593, ethanol).

7) The authors are indebted to Ogawa Perfumary Co., Osaka, for an authentic sample of cedrol.

TABLE I

Substance	Formula	M. p. °C	$[\alpha]_D$	Yield (g. from 100 g. of thujopsene) $KMnO_4$ oxid.	Yield (g. from 100 g. of thujopsene) $Na_2Cr_2O_7$ oxid.
Acid part					
Keto acid	$C_{15}H_{24}O_3$	165	−120°	10	0.2
II	$C_{15}H_{22}O_4$	124	− 28.0°	3.5	2.0
III	$C_{15}H_{22}O_4$	193(d)	+ 21.6°	4.9	0.4
IV	$C_{14}H_{22}O_3$	156	− 85.5°	0.3	4.0
Neutral part					
V	$C_{14}H_{20}O$	77	+193.5°	0.6	8.1
Oxyketone	$C_{15}H_{24}O_2$	70.5		0.2	0.2
Lactone	$C_{15}H_{22}O_3$	82.5		0.7	
XV	$C_{13}H_{20}O$	121		Trace	
Ketone	$C_{15}H_{24}O_2$	117.5		Trace	

Found: C, 68.41; H, 8.85. Calcd. for $C_{16}H_{24}O_4$: C, 68.54; H, 8.63%.

When the ester was treated with methanolic potassium hydroxide, acid III was obtained.

Isomerization of Acid II to Acid III. — A solution of II in a 5% sodium hydroxide solution was left at room temperature overnight. Acidification and working up in the usual manner gave III. From ethanol or ether solution of II containing hydrogen chloride, only the starting material was recovered.

Huang-Minlon Reduction of Acid XVI.—A mixture made from XVI (2.55 g.), hydrazine hydrate (2 cc.), potassium hydroxide (2.5 g.), and diethylene glycol (25 cc.) was refluxed for 4 hr. The reaction mixture was diluted with water and acidified, giving precipitates (XVII, 1.54 g.) which were recrystallized three times from ethanol, m. p. 171～172°, $[\alpha]_D^{30}$ −21.2° (*c* 1.19 chloroform).

Found: C, 76.82; H, 9.53. Calcd. for $C_{15}H_{22}O_2$: C, 76.88; H, 9.46%.

This shows a marked melting point depression when mixed with hinokiic acid (XX).

Permanganate Oxidation of Acid XVII. — To a solution of XVII (186 mg.) in a 3% potassium hydroxide solution (4 cc.), a 2% potassium permanganate solution (10 cc.) was added. The mixture was stirred for 1.5 hr. and was then treated with sodium bisulfite after acidification. The precipitate was recrystallized from ethanol-water, giving acid XVI, melting point and mixed m. p. 206°C and superimposable infrared spectra.

Found: C, 72.59; H, 8.14. Calcd. for $C_{15}H_{20}O_3$: C, 72.55; H, 8.12%.

Permanganate Oxidation of Hinokiic Acid (XX). —Hinokiic acid (2.4 g.) was dissolved in acetone (20 cc.) and treated with permanganate (5.0 g.) in acetone for 1.5 hr. The acetone was removed, and the remainder was dissolved in ether and extracted with a sodium bicarbonate solution. The neutral part crystallized (120 mg.) was identified as C_{13}-anhydride XXIV. From the acid part, C_{14}-diacid XXI (200 mg.), m. p. 206～211°C, was separated. The mother liquor was treated with diazomethane, giving a product (1.03 g.) which was absorbed onto an alumina column. Elution with petroleum ether-benzene (1 : 1) afforded C_{13}-diacid dimethyl ester (165 mg.).

Decarboxylation of Hinokiic Acid (XX), Acid XVII and Acid XVI.—A mixture of hinokiic acid (1.05 g.), copper powder (1.05 g.) and quinoline (10 cc.) was heated in a distillation flask at 230～250°C for 2 hr. The copper was removed and the filtrate, combined with the distillate, was diluted with ether and extracted with hydrochloric acid. The ether layer was washed with a sodium bicarbonate solution and water, and, after it was dried over potassium carbonate the ether was removed. The solid residue (320 mg.) was distilled in vacuo, and the distillate was recrystallized from methanol three times, m. p. 47°C, $[\alpha]_D^{33}$ −135° (*c* 0.933 ethanol) (XIX).

One gram of acid XVII was treated similarly and afforded an oily product (XVIII), n_D^{17} 1.5042, $[\alpha]_D^{30}$ −114° (*c* 0.957 ethanol), which solidified on cooling, m. p. 12～14°C.

Treatment of acid XVI in a similar manner gave ketone V.

Huang-Minlon Reduction of Ketone V.—Ketone V (5 g.) was reduced with a mixture of hydrazine hydrate (3.3 cc.), potassium hydroxide (4.8 g.), and diethylene glycol (50 cc.). The waxy product was recrystallized several times from methanol, using a methanol-dry ice mixture as a cooling agent, m. p. 33～35°C, (2.85 g.). This was shown to be a mixture of XVIII and XIX by the infrared spectrum.

Permanganate Oxidation of Hydrocarbon XVIII and XIX. — To a solution of XIX (550 mg.) in acetone (10 cc.), a solution of permanganate (2 g.) in acetone (50 cc.) was added; the mixture was then stirred for 1.5 hr. below 40°C. After being left overnight, it was worked up as usual. The product was recrystallized from ethanol-water, m. p. 210～211.5°C, (60 mg.). Admixture with authentic C_{14}-diacid (XXI, m. p, 209.5～210.5°C) showed m. p. 210～211°C.

A similar treatment of XVIII (710 mg.) gave C_{13}-diacid VI, (170 mg.).

Permanganate Oxidation of Acid XVI. — XVI (290 mg.) was oxidized in an alkaline permanganate solution in the usual manner. From the neutral part, C_{13}-anhydride XXIV (76 mg.) was obtained and recrystallized three times from petroleum ether, m. p. 211～212°C.

Found: C, 70.42; H, 8.59. Calcd. for $C_{13}H_{18}O_3$: C, 70.24; H, 8.16%.

Permanganate Oxidation of Ketone V. — To ketone V a solution of permanganate (4.27 g.) in water (100 cc.) was added. The oxidation was allowed to proceed for 2.5 hr. below 70°C, and the product was then treated as usual. The acid part contained C_{13}-diacid VI (90 mg.), and the neutral part, the corresponding anhydride (XXIV) m. p. 206~207°C (165 mg.).

Bichromate Oxidation of Acid III. — To a mixture of III (30 g.) and acetic acid (450 cc.) (not a complete solution) a solution composed of sodium bichromate (12 g.) and acetic acid (50 cc.) was added; the mixture was left at room temperature for one week. The insoluble material (7.84 g.) was identified to be the starting material, m. p. 205.5~207°C (decomp.). The filtrate was concentrated to about 1/3 of the original volume and was poured into water (1 l.). The precipitate filtered and triturated with hot benzene gave an insoluble product which was recrystallized from ethanol to give XIII, m. p. 218~221°C (4.0 g.), $[\alpha]_D^{14}$ +272° (*c* 0.93, ethanol).

Found: C, 75.91; H, 9.12. Calcd. for $C_{14}H_{20}O_2$: C, 76.32; H, 9.15%.

The benzene extract contains a mixture of yellow diketone XVI and C_{13}-diacid anhydride XXIV. From the acid part, C_{13}-diacid VI (440 mg.) was obtained. The amount of sodium bichromate (20 g.) relative to III (15 g.) was increased and the yield of XIII was diminished, but a larger amount (8 g.) of a mixture of XIV and XXIV was obtained.

Bichromate Oxidation of Diketone XIII.—XIII (1.34 g.) was dissolved in acetic acid (40 cc.), and a solution of sodium bichromate (1.75 g.) in acetic acid (10 cc.) was added. The mixture was kept below 50°C for 5 hr., and then concentrated to 1/2 volume. The yellow precipitates obtained upon dilution with water were dissolved in benzene and freed from acids. Recrystallization from methanol-water gave yellow crystals of diketone XIV, m. p. 175~180°C (960 mg.). Chromatography on an alumina column gave a sample, m. p. 179.5~180°C and mixed melting point with XIV prepared from cycloketone XV[1], 181~182.5°C.

Methyl Ester XII (R=Me) and its Saponification. — Treatment of acid IV with diazomethane gave crystals, m. p. 69~71°C. $[\alpha]_D$ −211° (*c* 0.78, ethanol).

Found: C, 71.40; H, 9.80. Calcd. for $C_{15}H_{24}O_3$: C, 71.39; H, 9.59%.

The product (140 mg.) was refluxed with 5% methanolic sodium hydroxide for 2 hr. and then poured into water and acidified. The precipitates, on trituration with petroleum ether, were crystallized. Recrystallization from ethanol-water gave β-diketone XIII (5 mg.) as the first crop, m. p. 219~220°C (decomp.). From the second crop, acid IV was obtained.

Enol Lactone XI and its Saponification.—Treatment of acid IV with acetic anhydride in pyridine gave the anhydroderivative XI, m. p. 80.5~83°C (from ethanol).

Found: C, 76.29; H, 9.39. Calcd. for $C_{14}H_{20}O_2$: C, 76.32; H, 9.15%.

Saponification. a) XI (46 mg.) in a 5% sodium hydroxide solution (5 cc.) was refluxed for an hour; 12 mg. of acid IV was isolated. b) XI (85 mg.) in a methanolic potassium hydroxide solution was refluxed for two hours, and about a half of the methanol was removed. The remainder was poured into water, and the precipitates were purified, giving the ester XII (R=Me). The filtrate was acidified and a small amount of β-diketone XIII was obtained. Both were identified by their infrared spectra.

Hypobromite Oxidation of Ester XII (R=Me). —A solution of XII (R=Me) (450 mg.) in dioxane (22 cc.) was treated with a hypobromite solution (20 cc.) for 30 min. Water (30 cc.) was added and extracted with ether. The acid product was recrystallized from aqueous methanol, giving C_{13}-diacid monomethyl ester (168 mg.) m. p. 139~141°C. The infrared spectrum was identical with an authentic sample[1].

Hypobromite Oxidation of II.—Fine crystals of II (680 mg.) were added to a hypobromite solution (20 cc.) and left for 2.5 hr. When sodium bisulfite and hydrochloric acid were added, the whole solution became a gel. A crude material obtained from air-dried gel showed infrared bands at 3390 and 1690 cm^{-1} (broad). The gel was shaken with ether. Evaporation of ether left fine needles, which were recrystallized from a mixture of ether-petroleum ether, m. p. 178~180°C (decomp.). IR, 3378, 1745 and 1667 cm^{-1}.

Found: C, 62.49; H, 7.66. Calcd. for $C_{14}H_{20}O_5$: C, 62.67; H, 7.51%.

Alternatively the gel-product was treated with an alkaline hydrogen peroxide solution overnight and then acidified. The precipitates were dissolved in methanol-water. An oil separated and solidified on standing, then needles were crystallized from the solution. The needles, m. p. 178~180°C, show infrared bands at 3408, 3155 and 1721 cm^{-1}. The solidified oil shows infrared bands at 3333, 1727 and 1675 cm^{-1} (Nujol). With diazomethane both of them gave the same dimethyl ester (XXII, R=Me) m. p. 80.5~82.5°C, which was identical with the dimethyl ester obtained from the gel without hydrogen peroxide treatment.

Found: C, 64.91; H, 8.39. Calcd. for $C_{16}H_{24}O_5$: C, 64.84; H, 8.16%.

Ozonolysis of Acid XVI.—To a solution of XVI (1.1 g.) in a carbon tetrachloride-chloroform mixture (1 : 1, 80 cc.), ozone was passed for three hours while the solution was cooled in an ice-bath. The solvent was removed, and the residue was taken up in ether, from which the acid product was extracted. The product (air-dried gel) was identified as acid XXIII by infrared spectral comparison.

Chromic Acid Oxidation of Acid XXIII.—XXIII (90 mg.) was dissolved in acetic acid (3 cc.), and a solution composed of chromic acid (200 mg.) and concentrated sulfuric acid (3 drops) was added. The mixture was kept for 24 hr. and diluted with water. C_{13}-anhydride XXIV (20 mg.) m. p. 208°C was obtained.

Bichromate Oxidation of Ester VII ($R=M_e$).— To an acetic acid solution (2 cc.) of VII (500 mg.), a solution of sodium bichromate (2.0 g.) in acetic acid (3 cc.) was added. Four drops of concentrated sulfuric acid was added, and the mixture was left

for a few minutes. The precipitates occurring were recrystallized from a benzene-petroleum ether mixture and sublimed under reduced pressure, giving XXIII (R=Me), m. p. 188~190°C.

Found: C, 64.03; H, 8.03. Calcd. for $C_{15}H_{22}O_5$: C, 63.81; H, 7.85%.

Attempted Oxidation of Ester XXII ($R_1=R_2=$ Me).—The ester was treated with chromic acid in a mixture of acetic and sulfuric acid for 1.5 hr. Water was added, and the resulting precipitates were filtered. They contain mostly the starting material, besides a small amount of a petroleum ether-insoluble material, which was recrystallized from benzene, m. p. 187~190°C, and was shown to be identical with the XXIII (R=Me) obtained from VII (R=Me).

The authors wish to express their gratitude to Dr Peter J. L. Daniels and Dr. Yuan-Lang Chow of the Royal Institute of Technology, Stockholm, Sweden, for revising the language of the manuscript. They are also indebted to Mr. Michio Shido for his elementary analyses.

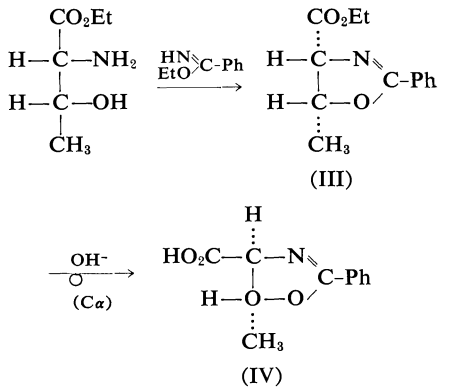
*Oxazolidone Derivatives of Hydroxyamino Acids. III. Inversion of the erythro- to the threo-Form of Threonine via Oxazolidone Ester**

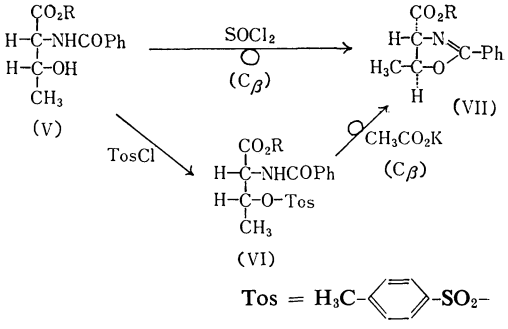
By Takeo KANEKO and Toshishige INUI

(Received December 5, 1961)



In a previous paper of this series[1], it was shown that α-amino-β-hydroxylic acids (I) in an alkaline solution cyclised to oxazolidone derivatives (II) under the action of phosgene. During this reaction the configuration at both

(I) (II)



the asymmetric centers remains unchanged, and DL-*trans*- and DL-*cis*-5-methyl-2-oxo-oxazolidine-4-carboxylic acids (II; R=H, R′=CH_3) are easily obtained from DL-threonine and DL-allothreonine respectively.

Oxazoline derivatives, as is well known, are important intermediates for the configurational transformation of allothreonine into threonine, and this conversion has been achieved by epimerization at either the α- or the β-carbon position. According to the first method, the less stable *cis*-oxazoline-ester (III) derived from allothreonine ester is transformed into the more stable trans-configuration IV with epimerization at the α-carbon atom and with

(III) (IV)

the simultaneous hydrolysis of the ester group[2,3] under the action of aqueous alkali. According to the second method, on the other hand, *N*-benzoyl-allothreonine ester (V) or its *O*-tosyl derivative (VI) is converted into the *trans*-oxazoline ester (VII), with the inversion

(V) (VII) (VI)

* This work was partly presented at the 11th and 13th Annual Meetings of the Chemical Society of Japan, Tokyo, April, 1958, and April, 1960.

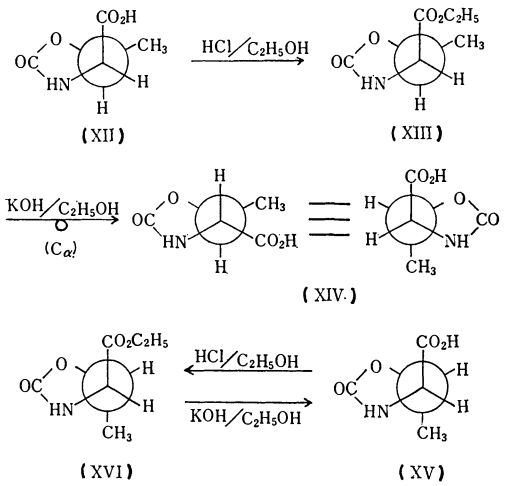
of the configuration at the β-carbon atom, by the action of thionyl chloride[4,5] or potassium acetate[5] respectively. In both cases, the resulting *trans*-oxazoline derivatives (IV and VII) give threonine on acid hydrolysis.

These facts suggest that the *cis*-oxazolidone derivative derived from allothreonine by the present authors may be similarly converted into the stable trans-configuration, because of the expected instability of the cis-configuration of oxazolidone ester. In the present paper, it is reported that *cis*-oxazolidone-carboxylic ester converts into *trans*-carboxylic acid on alkaline hydrolysis.

Upon treatment with hydrogen chloride in absolute alcohol, DL-*cis*-5-methyl-2-oxo-oxazolidine-4-carboxylic acid (VIII)[1] derived from DL-allothreonine yielded DL-*cis*-4-ethoxycarbonyl-5-methyl-2-oxo-oxazolidine (IX), b. p. 126~128 °C/10^{-3} mmHg. without any detectable change in the configuration. The configuration assigned was confirmed by isolating pure DL-allothreonine from the acid-hydrolyzate of this oxazolidone-carboxylic ester (IX). The same ester IX was also obtained by the reaction of DL-allothreonine ethyl ester hydrochloride with phosgene in aqueous potassium carbonate. In a similar way, DL-threonine ethyl ester hydrochloride gave DL-*trans*-4-ethoxycarbonyl-5-methyl-2-oxo-oxazolidine (X), b. p. 115~118°C/10^{-3} mmHg. The configuration of this ester X was also assigned by hydrolyzing it with hydrochloric acid and by isolating the resulting pure DL-threonine.

When DL-*cis*-ester IX was heated with one equivalent of alcoholic aqueous sodium hydroxide according to the method employed by Elliott[3], only the hydrolysis of the ester group took place, without any inversion; on the other hand, if the same ester IX was treated with a slightly excessive amount of 0.4 N alcoholic potassium hydroxide, both the conversion and the hydrolysis of ester took place. The resulting product possessed an infrared spectrum similar to that of DL-*trans*-5-methyl-2-oxo-oxazolidine-4-carboxylic acid (XI) derived from DL-threonine, but its melting point (120~122°C) was somewhat lower than that of XI (127~128°C). On the other hand, DL-*trans*-ester X gave DL-*trans*-carboxylic acid XI with the retention of configurations under the same conditions, and the infrared spectrum of the product was identical with that of an authentic sample. Therefore, it may be supposed that the less stable DL-*cis*-ester IX converted to the more stable DL-*trans*-form XI but not from



trans to cis, under the conditions used. The compound obtained from DL-*cis*-ester IX seemed to be impure DL-*trans*-carboxylic acid XI contaminated with DL-*cis*-carboxylic acid VIII, as the hydrolysis of this compound with hydrochloric acid gave DL-threonine, together with a small quantity of DL-allothreonine, both of which were identified by paper chromatographic analysis[6]. Recently, chromatographic separation and determination of a synthetic mixture of *N*-2,4-dinitrophenylated threonine and allothreonine were carried out by Seki using a column of carboxylic type resin, Amberlite IRC-50[7]. By the use of this method, the ratio of DL-threonine to DL-allothreonine in the acid-hydrolyzate was estimated to be 6.1. From these results, it was presumed that the conversion was due to epimerization at the asymmetric center corresponding to the α-carbon atom of the original amino acid molecules.

In order to prove this presumption exactly, this conversion should be applied to optically active material. Thus, the conversion at the α-carbon atom should result in the conversion of L-*cis*-ester to D-*trans*-carboxylic acid. To obtain L(−)-*cis*-ester XIII, the DL-*cis*-carboxylic acid VIII was resolved by means of brucine[8], and the resulting L(−)-*cis*-carboxylic acid (XII)

was treated with hydrogen chloride in absolute alcohol. Hydrolysis of this ester XIII with hydrochloric acid yielded pure L(+)-allothreonine, confirming the configuration assigned. Upon the treatment of this L(−)-*cis*-ester XIII with alcoholic potassium hydroxide, an optically active acid XIV, m. p. 131~133.5°C, $[\alpha]_D$ −37.7°, was obtained. Hydrolysis with hydrochloric acid yielded a mixture of D(+)-threonine and L(+)-allothreonine. Chromatographic analysis of this mixture as the dinitrophenyl derivative[7] showed that the ratio of D(+)-threonine to L(+)-allothreonine was identical with that of the optically inactive case mentioned already. As a comparison, L(+)-*trans*-carboxylic acid XV was obtained by the reaction of L(−)-threonine with phosgene in the presence of potassium hydroxide[8]. The infrared spectrum of the compound XIV was similar to that of L(+)-*trans*-carboxylic acid XV. As a result, it was proved that this levorotatry acid XIV was D(−)-*trans*-carboxylic acid contaminated with L(−)-*cis*-carboxylic acid XII. The L(+)-*trans*-ester XVI derived from L(+)-*trans*-carboxylic acid XV gave pure L(−)-threonine upon hydrolysis with hydrochloric acid. Moreover, the treatment with alcoholic potassium hydroxide resulted only in the hydrolysis of ester group, yielding L(+)-*trans*-carboxylic acid XV without any configurational change.

From the results of this investigation, it was concluded that this conversion of the cis- to trans-form was the result of epimerization at the asymmetric center corresponding to the α-carbon atom in the original amino acid molecules.

Experimental**

DL-*cis*-Ethoxycarbonyl-5-methyl-2-oxo-oxazolidine (IX). *Method A. By Esterification of DL-cis-5-Methyl-2-oxo-oxazolidine-4-carboxylic Acid (VIII).*—a) A suspension of DL-*cis*-carboxylic acid[1] VIII (8.0 g., 0.055 mol.) in 100 ml. of absolute alcohol was saturated with hydrogen chloride by passing the dry gas as a vigorous stream at 0°C. The solution, after being left standing overnight at room temperature, was evaporated to dryness under reduced pressure. The residue was dissolved in water and extracted with four 60 ml. portions of ethyl acetate. The combined extract was dried over sodium sulfate, and the solvent was removed by distillation. The residue, on distillation under reduced pressure, yielded 8.0 g. (84%) of DL-*cis*-ester IX, b.p., 126~128°C/10^{-3} mmHg, n_D^{20} 1.46376.

IR, 3300 (amide), 1760 (cyclic amide and ester) cm^{-1} (liquid film).

Found: C, 48.41; H, 6.39; N, 7.87. Calcd. for $C_7H_{11}O_4N$: C, 48.55; H, 6.40; N, 8.09%.

b) A suspension of the above DL-*cis*-carboxylic acid[1] VIII (3.6 g., 0.025 mol.) in 80 ml. of ether was treated with an excess of diazoethane dissolved in ether. After the evaporation of the solvent and the reagent, the residue was distilled under reduced pressure. Yield, 2.7 g. (63%); b. p., 138~140°C/10^{-2} mmHg. The infrared spectrum was identical with that of the ester obtained by a).

Method B. By Cyclization of DL-Allothreonine Ethyl Ester Hydrochloride.—Crude DL-allothreonine ethyl ester hydrochloride[2] obtained from DL-allothreonine (7.2 g., 0.06 mol.) was dissolved in 200 ml. of water, and the solution was covered with 105 ml. of toluene. To the mixture, after it was cooled to 3°C, 1 N potassium hydroxide (70 ml., 0.07 mol.) and 26.0 g. (0.18 mol.) of anhydrous potassium carbonate were added, and then a solution of 14.6 g. (0.147 mol.) of phosgene in toluene (45 ml.) was stirred in drop by drop over a 40 min. period. After being stirred for an additional hour, the aqueous layer separated from the toluene layer was acidified with concentrated hydrochloric acid and extracted with four 60 ml. portions of ethyl acetate. The combined extract was dried over sodium sulfate, the solvent was removed by distillation, and the residue was distilled under reduced pressure. Yield, 4.1 g. (39% for DL-allothreonine); b. p., 122~124°C/10^{-3} mmHg., n_D^{20} 1.46420. All properties of this sample were identical with those of the product obtained by the above method A.

The aqueous layer remaining after the extraction with ethyl acetate was evaporated under reduced pressure, and the residue was extracted with four 50 ml. portions of ethyl acetate while hot. The extract was concentrated under reduced pressure. On scratching of the side of the vessel, DL-*cis*-carboxylic acid VIII crystallized out. Yield, 2.0 g. (23% for DL-allothreonine); m. p., 193~195°C (decomp.). All properties of this sample were identical with those of an authentic sample[1].

DL-Allothreonine.—A solution of 0.99 g. (0.0057 mol.) of DL-*cis*-ester IX in 20 ml. of 1 : 1 hydrochloric acid was refluxed for 8 hr. After being cooled at room temperature, the reaction mixture was extracted with ethyl acetate, and the aqueous

** All melting points and boiling points are uncorrected. Infrared spectra were recorded with a Hitachi EPI-2 type infrared spectrophotometer, and refractive indices were determined with a Bausch and Lomb precision refractometer.

solution was evaporated to dryness under reduced pressure. The residue was dissolved in 17 ml. of 94% alcohol, and pyridine (3 ml.) was added. DL-Allothreonine crystallized out. Yield, 0.5 g. (86%); m. p., 241~242°C (decomp.). On recrystallization from water and alcohol, its melting point rose to 246~247°C (decomp.). All properties of this sample were identical with those of an authentic sample.

DL-*cis*-5-Methyl-2-oxo-oxazolidne-4-carboxylic Acid (VIII).—*By Hydrolysis of DL-cis-Ester IX with Aqueous Alcoholic Sodium Hydroxide.*—To a solution of 0.74 g. (0.00428 mol.) of DL-*cis*-ester IX in 40 ml. of 94% alcohol, 3.9 ml. (0.00426 mol.) of 1.09 N sodium hydroxide was added. The mixture was heated under reflux for 20 min. After being cooled, the solvent was evaporated in vacuo, and the residue was dissolved in water. The aqueous solution was extracted with ethyl acetate, acidified with concentrated hydrochloric acid, and then evaporated in vacuo to dryness. The residue was extracted with three 40 ml. portions of ethyl acetate. When the combined extract was evaporated in vacuo, DL-*cis*-carboxylic acid VIII crystallized out. Yield, 0.42 g. (68%); m. p., 193~195°C (decomp.). The melting point could be raised to 196~197°C (decomp.) by recrystallization. All properties of this sample were identical with those of an authentic sample[1].

DL-*trans*-4-Ethoxycarbonyl-5-methyl-2-oxo-oxazolidine (X).—According to the same method as used in the synthesis of DL-*cis*-ester IX by method B, DL-threonine ethyl ester hydrochloride[2] obtained from DL-threonine (4.8 g., 0.04 mol.) was cyclized to DL-*trans*-ester X with phosgene (11.8 g., 0.119 mol.) in the presence of potassium carbonate. Yield, 3.4 g. (49%); b. p., 115~118°C/10^{-3} mmHg., n_D^{20} 1.46105.

IR, 3300 (amide), 1765 (cyclic amide and ester) cm^{-1} (liquid film).

Found: C, 48.17; H, 6.32; N, 7.81. Calcd. for $C_7H_{11}O_4N$: C, 48.55; H, 6.40; N, 8.09%.

DL-*trans*-Carboxylic acid XI could not be obtained from the remaining aqueous solution.

Treatment of DL-*trans*-carboxylic acid XI with hydrogen chloride in absolute alcohol also yielded the same ester X.

DL-*trans*-5-Methyl-2-oxo-oxazolidine-4-carboxylic Acid (XI).—*A) By Hydrolysis of DL-cis-Ester IX with Alcoholic-Potassium Hydroxide.*—To a solution of 1.16 g. (0.00670 mol.) of DL-*cis*-ester IX in 7.5 ml. of absolute alcohol, 7.5 ml. (0.00677 mol.) of 0.89 N alcoholic potassium hydroxide was added, and the mixture was refluxed for 15 min. After the mixture had been cooled, 15 ml. of water was added, and the solution was acidified with concentrated hydrochloric acid. The aqueous solution was evaporated to dryness under reduced pressure. The residue was extracted with 3 times with 30 ml. of ethyl acetate. The combined extract was evaporated in vacuo to a syrup, which was crystallized on scratching of the side of the vessel. Yield, 0.57 g. (77%); m. p., 119~121.8°C. The melting point could be raised to 121~123°C by recrystallization. Its infrared spectrum was similar to that of DL-*trans*-carboxylic acid XI[1], m. p. 127~128°C.

B) By Hydrolysis of DL-trans-Ester X.—In a similar way, DL-*trans*-ester X (1.72 g, 0.010 mol.) was hydrolyzed with 0.40 N alcoholic potassium hydroxide (25 ml., 0.010 mol.). Yield, 1.07 g. (74%); m. p., 125~126.5°C. The melting point could be raised to 126.5~127.5°C by recrystallization, and it was undepressed on admixture with a pure authentic sample[1]. All properties of both compounds were identical.

DL-Threonine.—*A) By Hydrolysis of DL-trans-Carboxylic Acid XI Derived from DL-cis-Ester IX.*—The substance XI (6.06 g., 0.035 mol.) was refluxed with 120 ml. of 1 : 1 hydrochloric acid. From the hydrolyzate, DL-threonine containing a small quantity of DL-allothreonine was obtained by the usual method. Yield, 3.71 g. (73%); m. p., 230.5~231.5°C (decomp.). Its infrared spectrum was similar to that of pure DL-threonine. The proportion of DL-threonine (R_f 0.16) to DL-allothreonine (R_f 0.12) present was determined by paper chromatography using the upper layer from a mixture of *n*-butanol-acetone-concentrated aqueous ammonia-water (8 : 1 : 1 : 6 by volume)[6] as the developer. The ratio of DL-threonine to DL-allothreonine was about 5. Chromatographic analysis of the dinitrophenylated sample[7] showed that the ratio was 6.1. On recrystallization from water and alcohol, its melting point rose to 231~232°C (decomp.). Chromatographic analysis of this sample showed that the ratio was 10.1.

B) By Hydrolysis of DL-trans-Ester X.—One gram (0.0058 mol.) of DL-*trans*-ester X was hydrolyzed with hydrochloric acid (1 : 1; 16 ml.) in the usual way. Yield, 0.46 g. (67%); m. p., 232.5.~233.5°C (decomp.). The melting point could be raised to 236~237°C (decomp.) by recrystallization. All properties of this sample were identical with those of an authentic sample.

L(−)-*cis*-Ethoxycarbonyl-5-methyl-2-oxo-oxazolidine (XIII).—Four grams (0.0376 mol.) of L(−)-*cis*-carboxylic acid XII[8], m. p., 169.5~170.5°C, $[\alpha]_D$ −19.2±0.5°C (H_2O), were esterified with hydrogen chloride in absolute alcohol. Yield, 4.1g. (86%); m. p., 71~73°C. After recrystallization from ethyl acetate and petroleum ether, it melted at 72~73°C. $[\alpha]_D^{27}$ −3.6°C (*c* 3.29, 99% EtOH).

IR, 3290 (amide), 1760, 1750, 1730 (cyclic amide and ester) cm^{-1} (Nujol).

Found: C, 48.75; H, 6.39; N, 8.16. Calcd. for $C_7H_{11}O_4N$: C, 48.55; H, 6.40; N, 8.09%.

L(+)-Allothreonine.—L(−)-*cis*-Ester XIII (0.79 g., 0.00456 mol.) was hydrolyzed with hydrochloric acid (1 : 1; 20 ml.) in the usual way. Yield, 0.47g. (89%); m. p., 273.5~275°C (decomp.), $[\alpha]_D^{29}$ +9.1° (*c* 2.97, H_2O). All properties of this sample were identical with those of an authentic sample[2].

L(+)-*trans*-4-Ethoxycarbonyl-5-methyl-2-oxo-oxazolidine (XVI).—Four and a half grams (0.031 mol.) of L(+)-*trans*-carboxylic acid XV[8], m. p., 139.5~140.5°C, $[\alpha]_D$ +41.2±0.5° (H_2O), were esterified with hydrogen chloride in absolute alcohol. Yield, 4.0 g. (75%); b. p., 123~125°C/10^{-3} mmHg; m. p., 63~65°C. On recrystallization from small amounts of ethyl acetate and petroleum ether, its melting point rose to 64~66°C. $[\alpha]_D^{28}$ +37.4° (*c* 3.50, 99% EtOH).

IR, 3260 (amide), 1750, 1715 (cyclic amide and ester) cm^{-1} (Nujol).

Found: C, 48.53; H, 6.12; N, 7.98. Calcd. for $C_7H_{11}O_4N$: C, 48.55; H, 6.40; H, 8.09%.

L(−)-Threonine.—In the usual way, 0.84 g. (0.00485 mol.) of L(+)-*trans*-ester XVI was hydrolyzed with 20 ml. of hydrochloric acid (1 : 1). Yield, 0.51 g. (89%); m. p., 261~262°C (decomp.), $[\alpha]_D^{28}$ −28.4° (*c* 2.81, H_2O). All properties of this sample were identical with those of an authentic sample[8].

L(+)-*trans*-5-Methyl-2-oxo-oxazolidine-4-carboxylic Acid (XV).—To a solution of 1.14 g. (0.00658 mol.) of L(+)-*trans*-ester XVI in 8.0 ml. of absolute alcohol, 7.6 ml. (0.00661 mol.) of 0.87 N alcoholic potassium hydroxide was added. After the mixture bad been lett standing for 1.5 hr. at room temperature, 20 ml. of water was added. The solution was acidified with concentrated hydrochloric acid and evaporated in vacuo to dryness. The residue was extracted 3 times with 40 ml. of hot ethyl acetate. When the extract was evaporated under reduced pressure, L(+)-*trans*-carboxylic acid XV crystallized out. Yield, 0.8 g. (85%); m. p., 139.8~140.2°C, $[\alpha]_D^{29.8}$ +41.8°(*c* 2.70, H_2O). All properties of this sample were identical with those of an authentic sample[8].

D(−)-*trans*-5-Methyl-2-oxo-oxazolidine-4-carboxylic Acid (XIV).—*Conversion of L(−)-cis-Ester XIII.*—In a similar way, 1.57 g. (0.00907 mol.) of L(−)-*cis*-ester XIII were hydrolyzed with 21.2 ml. (0.00915 mol.) of 0.43 N alcoholic potassium hydroxide. Yield, 1.10 g. (84%); m. p., 131~133.5 °C, $[\alpha]_D^{27}$ −37.7° (*c* 2.71, H_2O). Its infrared spectrum was similar to that of L(+)-*trans*-carboxylic acid XV.

D(+)-Threonine.—In the usual way, 0.54 g. (0.00454 mol.) of D(−)-*trans*-carboxylic acid XIV obtained from L(−)-*cis*-ester XIII was hydrolyzed with 20 ml. of hydrochloric acid (1 : 1). Yield, 0.37 g. (83%); m. p., 251~253.5°C (decomp.), $[\alpha]_D^{29}$ +24.8° (*c* 2.82, H_2O). Chromatographic analysis of the dinitrophenylated sample[7] showed that the ratio of D(+)-threonine to L(+)-allothreonine was 5.7.

The authors wish to express their thanks to Dr. Tokuichiro Seki for his assistance in carrying the chromatographic analysis and to the Ajinomoto Co., Inc., for its gift of amino acids. Thanks are also due to Mr. M. Okumiya and Miss. K. Koike for micro analyses.

*The Absolute Configuration of α-Methyladipic Acid**

By Takeo KANEKO, Ken-ichi WAKABAYASHI** and Hakuji KATSURA

(Recieved December 11, 1961)

Recently, determinations of the stereostructures of terpenoids, alkaloids and antibiotics have become important. In order to obtain clear sterostructures of key-substances, absolute configurations of a few compounds containing branched alkyl groups have been determined[1]. The absolute configuration of α-methyladipic acid, obtained as an oxidation product of an alkaloid nupharidine[2], has however, never been determined. The present paper deals with the chemical determination of the absolute configuration of α-methyladipic acid by the establishment of the configurational correlation between this acid and methylsuccinic acid, the absolute configuration of which is already known[3].

(I) (II) (III)

α-Formyl-γ-butyrolactone (II) was synthesized from γ-butyrolactone (I) by the modified methods described by Korte[4] and McGraw[5]. DL-α-Hydroxymethyl-γ-butyrolactone (III) was obtained from formyl derivative II in a high

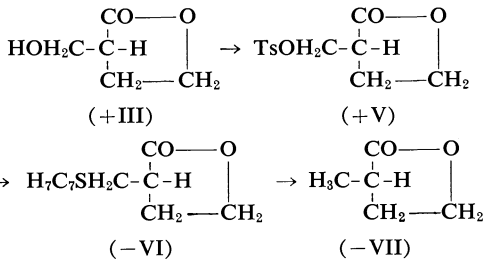
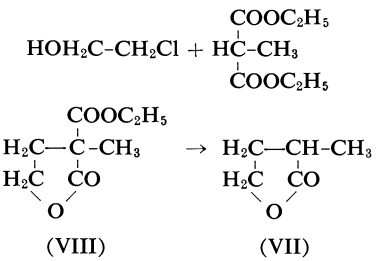
yield by catalytic reduction according to the method of McGraw[5]. An optical resolution of hydroxymethylbutyrolactone (III) was attempted, but no optically pure substances were obtained. Then, optically active (+)-α-hydroxymethyl-γ-butyrolactone (+III) ([α]D+10.4°) was prepared from (+)-alloisocitric lactone



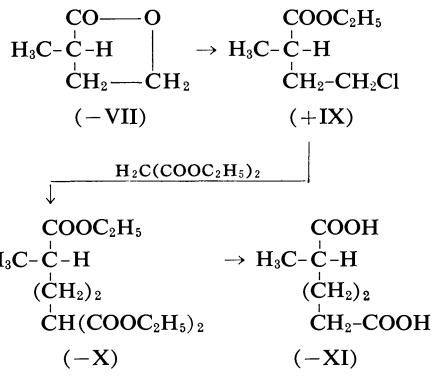
(+IV)



(+III)

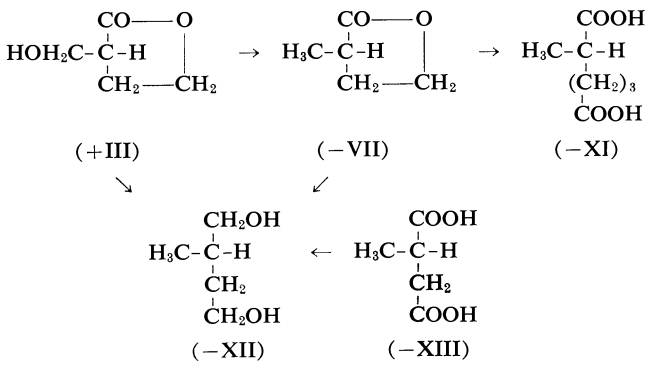
(+IV) by the methods described earlier[6]. (−)-Benzyl thioether (−VI), which was derived from the (+)-tosylate (+V) of +III by the action of benzylmercaptan, was converted into (−)-α-methyl-γ-butyrolactone([α]D −0.2°(*c* 23,

Ts=*p*-CH_3-C_6H_4-SO_2-
C_7H_7=C_6H_5-CH_2-



l=2 dm., absolute ethanol))(−VII) by treatment with a Raney-nickel catalyst. In another

(VIII) (VII)



way, DL-α-methyl-γ-butyrolactone (VII) was synthesized from lactone-ester VIII, the condensation product of diethyl methylmalonate with ethylene chlorohydrin, by hydrolysis followed by decarboxylation. Its enatiomers were obtained in an almost optically pure state([α]D −21.5°, +11.9°) by methods of optical resolution.

Optically active α-methyladipic acid([α]D −1.4°)(−XV) was obtained by means of saponification and decarboxylation of triester −X, which was formed by condensation of diethyl malonate with ethyl (+)-γ-chloro-α-methylbutyrate (+IX), derived from (−)-α-methyl-γ-butyrolactone ([α]D−21.5°)(−VII).

(−VII) (+IX) (−X) (−XI)

As the correlations of (+)-α-hydroxymethyl-γ-butyrolactone (+III) and (−)-2-methyl-1,4-butanediol (−XII) with La-(−)-methylsuccinic acid (−XIII) have previously been shown by

(+III) (−VII) (−XI) (−XII) (−XIII)

6) T. Kaneko, H. Katsura, H. Asano and K. Wakabayashi, *Chem. & Ind.*, **1960**, 1187; H. Katsura, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **82**, 91 (1961).

us[6], it is clear that the configuration of (−)-α-methyl-γ-butyrolactone (−VII) is the same as that of L$_a$-(−)-methylsuccinic acid (−XIII) and is to be represented by L$_a$ or s.

Because the absolute value of the optical rotation of the (−)-α-methyl-γ-butyrolactone-(−VII) obtained from (+)-α-hydroxymethyl-γ-butyrolactone (+III) was small, (−)-2-methyl-1, 4-butanediol (−XII) was derived from (−)-α-methyl-γ-butyrolactone (−VII) obtained by resolution, using lithium aluminum hydride reduction to confirm the latter configuration. From the above results, it was concluded that (−)-α-methyl-γ-butyrolactone has the s-configuration, or belongs to the L$_a$-series, while (+)-α-methyl-γ-butyrolactone has the R-configuration, or belongs to the D$_a$-series, as (−)-2-methyl-1, 4-butanediol (−XII) is related to L$_a$-(−)-methylsuccinic acid (−XIII). (−)-α-Methyladipic acid had the s-configuration (L$_a$-series), as it is related to L$_a$-(−)-α-methyl-γ-butyrolactone, while (+)-α-methyladipic acid has the R-configuration (D$_a$-series).

Experimental

DL-α-Hydroxymethyl-γ-butyrolactone (III).—To prepare α-formyl-γ-butyrolactone (II), γ-butyrolactone (I) was condensed with ethyl formate, as described by Korte[4], except that the extraction of the reaction mixture with ethyl acetate instead of with ether was employed.

Yield, 55%; b. p., 93∼100°C/3 mmHg (lit., b. p. 68°C/0.03 mmHg[4], 83∼85°C/1 mmHg[5]).

This formyl derivative was reduced with a Raney-nickel catalyst to give III, following the procedures of McGraw[5]:

Yield, 76%; b. p. 105∼112°C/1 mmHg. Found: C, 52.02; H, 6.98. Calcd. for $C_5H_8O_3$: C, 51.72; H, 6.94%.

Resolution of α-Hydroxymethyl-γ-butyrolactone (III).—To a solution of 18.0 g. of barium hydroxide octahydrate in 100 ml. of water, 11.6 g. of DL-α-hydroxymethyl-γ-butyrolactone (III) was added, and the solution was heated to 90°C over a 2-hr. period. After the solution had cooled, 10% sulfuric acid was added, and the precipitated barium sulfate was removed by filtration. To the filtrate, 36.0 g. of quinine was added, and the mixture was heated at 90°C to make a clear solution. After standing over night, the solution was concentrated under reduced pressure, and the residue was recrystallized from acetone-methanol six to ten times. From a purified, less soluble quinine salt, optically impure α-hydroxymethyl-γ-butyrolactone (yield 0.5 g., b. p. 105∼107°C/1 mmHg, $[\alpha]_D^{14}$ −4.1°(*c* 12.2, ethanol)) was obtained, while the maximum value of its specific rotation was +10.4°.

(+)-α-Hydroxymethyl-γ-butyrolactone (+III).—It was obtained from (+)-alloisocitric lactone (+IV), as has been previously described[6].

Yield, 19%; b. p., 103∼107°C/0.5∼1 mmHg, $[\alpha]_D$ +10.4°(*c* 5.6, ethanol). Found: C, 51.83; H, 6.94. Calcd. for $C_5H_8C_3$: C, 51.72; H, 6.94%.

Tosylate (V) of α-Hydroxymethyl-γ-butyrolactone (III).—To an ice-cold solution of 11.9 g. of DL-α-hydroxymethyl-γ-butyrolactone (III) in 5 ml. of anhydrous pyridine, a solution of 21.5 g. *p*-toluenesulfonyl chloride in 45 ml. of anhydrous pyridine was added drop by drop during the course of 30 min., and the solution was then stirred continuously in an ice bath for another 3 hr. The reaction mixture was stirred into 3 N hydrochloric acid containing ice, and the separated crystalline substances were recrystallized from 94% ethanol.

Yield, 16 g. (60%); m. p., 86°C. Found: C, 53.26; H, 5.27; S, 11.53. Calcd. for $C_{12}H_{14}O_5S$: C, 53.32; H, 5.22; S, 11.86%.

From 7.0 g. of (+)-α-hydroxymethyl-γ-butyrolactone ($[\alpha]_D$+10.4°), (+)-tosylate (+V) was obtained in the manner described above.

Yield, 8.9 g. (54.6%); m. p., 97°C, $[\alpha]_D^{10}$ +3.0° (*c* 3.6, acetone). Found: C, 53.52; H, 5.16; S, 11.81%.

α-Benzylthiomethyl-γ-butyrolactone (VI).—To a boiling sodium ethoxide solution (4.2 g. of metallic sodium in 100 ml. of absolute ethanol), 22.0 g. of benzylmercaptan was added drop by drop over a half-hour period, and to this mixture, a solution of DL-tosylate (V) in 250 ml. of hot absolute ethanol was added at once. Crystals of sodium *p*-toluenesulfonate began to separate immediately. After the reaction mixture had been heated and stirred for 3 hr., the crystals were removed by filtration and the filtrate was evaporated under reduced pressure. The residue obtained was dissolved in water, and after acidifying with concentrated hydrochloric acid, the solution was extracted with benzene. After the benzene layer had been dried and the solvent removed by distillation, the residue was distilled to give DL-benzylthiomethyl-γ-butyrolactone.

Yield, 12.9 g. (58%); b. p., 145∼152°C/1 mmHg. Found: C, 64.95; H, 6.29. Calcd. for $C_{12}H_{14}O_2S$: C, 64.85; H, 6.35%.

From 8.9 g. of (+)-tosylate (+V), (−)-benzyl thioether (Yield, 4.4 g. (59.4%); b. p., 163°C/0.05 mmHg, $[\alpha]_D$−0.46°(*c* 8.0, benzene)) (−VI) was obtained in the manner described above.

Found: C, 65.28; H, 6.46; S, 14.21. Calcd. for $C_{12}H_{14}O_2S$: C, 64.85; H, 6.35; S, 14.42%.

α-Methyl-γ-butyrolactone (VII) from Benzyl Thioether (VI).—To a solution of 12.9 g. of benzyl thioether (VI) in 400 ml. of absolute ethanol, Raney-nickel (developed from 100 g. of alloy) was added and refluxed for 12 hr. The insoluble materials were removed by centrifugation, and the alcohol was removed carefully by rectification using a 50 cm. column. DL-α-Methyl-γ-butyrolactone (yield, 2.5 g. (55%); b. p., 92.5°C/20 mmHg) (VII) was obtained on distillation of the residual oil.

Found: C, 60.21; H, 7.96. Calcd. for $C_5H_8O_2$: C, 59.98; H, 8.05%.

From 4.4 g. of (−)-benzyl thioether (−VI), (−)-α-methyl-γ-butyrolactone (b. p., 94∼95°C/20 mmHg, $[\alpha]_D^{10}$ −0.2°(*c* 23, l=2 dm., absolute ethanol)) (−VII) was obtained in the manner described above.

Found: C, 60.45; H, 8.28%.

DL-α-Methyl-γ-butyrolactone (VII) from Diethyl Methylmalonate.—To a warm sodium ethoxide

solution (50°C) (9.5 g. of sodium in 120 ml. of absolute ethanol), 140 g. of diethyl methylmalonate was added drop by drop; the solution was then heated under reflux for 30 min. To this solution, 32 g. of ethylene chlorohydrin was added drop by drop and after the solution had been refluxed for 3 hr., the ethanol was removed by distillation. The residue was dissolved in water and extracted with ether. After the solvent was removed by distillation from the extract, α-carbethoxy-α-methyl-β-butyrolactone (yield, 43.5 g. (63.3%); b. p., 130~131°C/10 mmHg) (VIII) was obtained by fractional distillation of the residue.

Found: C, 55.74; H, 7.07. Calcd. for $C_8H_{12}O_4$: C, 55.80; H, 7.03%.

A mixture of 33 g. of this ester VIII and 350 ml. of 3 N hydrochoric acid was refluxed for about 20 hr. until hydrolysis and decarboxylation were complete. The reaction mixture was evaporated under reduced pressure, and the residue was dissolved in ether. After the ether extract had been dried over anhydrous sodium sulfate and the solvent removed, DL-α-methyl-γ-butyrolactone (yield, 13.1 g. (70%); b. p., 95~98°C/21mm Hg) (VII) was obtained by distillation of the residue.

Found: C, 59.77; H, 8.29. Calcd. for $C_5H_8O_2$: C, 59.98; H, 8.05%.

Optical Resolution of DL-α-Methyl-γ-butyrolactone (VII).—To a solution of 15 g. of barium hydroxide octahydrate in 100 ml. of water, 8.4 g. of DL-α-methyl-γ-butyrolactone was added. After the solution had been heated at 90°C for 2 hr., it was neutralized by the addition of 10% sulfuric acid; the barium sulfate precipitated was removed by filtration. To this filtrate, 35 g. of quinine was added; it was then heated at 90°C until dissolution was complete. After standing overnight, the reaction mixture was evaporated under reduced pressure, and the residue was dissolved in 85 ml. of acetone. After the solution had stood overnight in a refrigerator, the less soluble quinine salt precipitated was collected and recrystallized 3 times from acetone-methanol (9 : 1). (−)-α-Methyl-γ-butyrolactone (yield, 1.5 g.; b. p., 92.5°C/20 mmHg, $[\alpha]_D^{15}$ −21.5°C (*c* 5.5, absolute ethanol)) was obtained from this purified, less soluble quinine salt by the usual manner.

Found: C, 59.69; H, 7.98. Calcd. for $C_5H_8O_2$: C, 59.98; H, 8.05%.

From the mother liquor, after removing less soluble salt, (+)-α-methyl-γ-butyrolactone (yield, 1.2 g.; b. p., 93~95°C/22 mmHg, $[\alpha]_D^{15}$ +11.9° (*c* 6.9, absolute ethanol)) was obtained.

Ethyl γ-Chloro-α-methylbutyrate (IX).—A solution of 20 g. of DL-α-methyl-γ-butyrolactone (VII) in 150 ml. of absolute ethanol was saturated with dry hydrogen chloride under cooling with ice-water. After standing for 48 hr., the reaction mixture was poured into ice-water to give an oily layer, which was separated. The aqueous layer was extracted with chloroform. The oily layer and the chloroform extract were then combined, washed with water and aqueous sodium hydrogen carbonate solution, and dried over anhydrous sodium sulfate. After the solvent was removed, ethyl DL-γ-chloro-α-methylbutyrate (yield, 29.5 g. (90%); b. p., 92~95°C/25 mmHg) was obtained by means of fractional distillation of the residual oil under reduced pressure.

Found: C, 50.93; H, 7.82. Calcd. for $C_7H_{13}O_2Cl$: C, 51.06; H, 7.96%.

From 1.5 g. of (−)-α-methyl-γbutyrolactone ($[\alpha]_D$ −21.5°), ethyl (+)-γ-chloro-α-methylbutyrate (yield, 1.9 g. (77%); b. p., 90.7°C/23 mmHg, $[\alpha]_D^{15}$ +26.7° (*c* 14.9, absolute ethanol)) was obtained in the manner described above.

Found: C, 50.98; H, 7.80%.

Diethyl α-Methyl-α'-carbethoxyadipate (X).—Seventy three milliliters of absolute ethanol, 1.8 g. of sodium and 3.1 g. of sodium iodide were dissolved. Into this solution, 21.0 g. ethyl malonate was stirred at 80°C, and the mixture was refluxed for 30 min. To the reaction mixture 11.0 g. of ethyl DL-γ-chloro-α-methylbutyrate was added over a 1 hr. period, and the solution was refluxed for 20 hr. After reaction had ceased, the solvent was removed by distillation in vacuo, and the residue was acidified by the addition of 5 ml. of glacial acetic acid. After water was added to the mixture, the solution was extracted with benzene; the extract was washed with water and aqueous sodium hydrogen carbonate solution, and then dried with anhydrous magnesium sulfate. After the solvent was removed, diethyl DL-α-methyl-α'-carbethoxyadipate (yield, 11.3 g. (60%); b. p. 111~114°C/1 mmHg) (X) was obtained on distillation of the oily residue.

Found: C, 58.32; H, 8.44. Calcd. for $C_{14}H_{24}O_6$: C, 58.31; H, 8.39%.

From 1.9 g. of ethyl (+)-γ-chloro-α-methylbutyrate ($[\alpha]_D$+26.7°C), diethyl (−)-α-methyl-α'-carbethoxyadipate (yield, 2.0 g. (60.6%); b. p., 115~116°C/1 mmHg, $[\alpha]_D^{15}$ −0.64° (*c* 11, ethanol)) was obtained in the manner described above.

Found: C, 58.37; H, 8.25%.

α-Methyladipic Acid (XI).—A mixture of 38.7 g. of ethyl DL-α-methyl-α'-carbethoxyadipate (X) and 400 ml. of 3 N hydrochloric acid was refluxed for 18 hr. After hydrolysis and decarboxylation were ended, the reaction mixture was treated with active charcoal and condensed under reduced pressure. On distillation of the residue in vacuo, a fraction, b. p., 150~155°C/1 mmHg, was obtained, which formed waxy crystals immediately. It was recrystallized from benzene, m. p., 59~60°C. This sample showed no depression of melting point on admixture with an authentic sample and its infrared spectra were identical with that of the authentic sample.

From 1.9 g. of diethyl (−)-α-methyl-α'-carbethoxyadipate ($[\alpha]_D$ −0.64°), (−)-α-methyladipic acid (m. p. 53~54°C, $[\alpha]_D$ −1.4° (*c* 4, ethanol)) was obtained in the manner described above.

Found: C, 52.07; H, 7.51. Calcd. for $C_7H_{12}O_4$: C, 52.49; H, 7.55%.

2-Methyl-1, 4-butanediol (XII) from α-Methyl-γ-butyrolactone (VII) via its Acetate.—DL-2-Methyl-1, 4-diacetoxybutane (b. p. 115~117°C/16 mmHg) was obtained from 5 g. of DL-α-methyl-γ-butyrolactone (VII) by lithium aluminum hydride reduction, followed by acetylation with acetic anhydride.

Yield, 3.0 g. (32%). Found: C, 57.22; H, 8.53. Calcd. for $C_9H_{16}O_4$: C, 57.43; H, 8.57%.

The diacetate (2.2 g.) was hydrolyzed with barium hydroxide to give 2-methyl-1, 4-butanediol (b. p., 112°C/6 mmHg). Yield, 0.8 g. (77%).

From 2.2 g. of (+)-α-methyl-γ-butyrolactone ($[\alpha]_D$ +11.9°), (+)-2-methyl-1, 4-diacetoxybutane (yield, 1.0 g.; b. p., 118°C/15 mmHg, $[\alpha]_D^{15}$ +0.41°(*c* 21, acetone)) was obtained.

Found: C, 57.21; H, 8.69. Calcd. for $C_9H_{16}O_4$: C, 57.43; H, 8.57%.

The above (+)-diacetate gave (+)-2-methyl-1, 4-butanediol ($[\alpha]_D^{17}$ +2.3°(*c* 4.2, acetone)) in the manner described above.

(−)-2-Methyl-1, 4-butanediol (−XII) from (−)-α-Methyl-γ-butyrolactone (−VII) by Means of Ether Extraction.—To a suspended mixture of 0.5 g. of lithium aluminum hydride in 25 ml. of absolute ether, a solution of 1.2 g. of (−)-α-methyl-γ-butyrolactone ($[\alpha]_D$−7.5°) in 15 ml. of absolute ether was added and refluxed for 3 hr. The reaction mixture was decomposed by the addition of water, acidified with 10% sulfuric acid, and extracted repeatedly with ether. The extract was washed with an aqueous sodium hydrogen carbonate solution and dried over anhydrous magnesium sulfate. After the solvent had been removed, the residual oil was distilled under reduced pressure.

Yield, 0.5 g.; b. p,, 110~112°C/6 mmHg, $[\alpha]_D^{14}$ −2.1°(*c* 10, acetone). Diphenylurethane, m. p., 123°C. Found: C, 66.55; H, 6.47; N, 8.20. Calcd. for $C_{19}H_{22}O_4N_2$: C, 66.65; H, 6.48; N, 8.18%.

The authors wish to express their thanks to Kyowa Fermentation Ind. Co., Ltd., for its gift of (+)-alloisocitric lactone.

On the Absolute Configuration of l-Carnitine (Vitamin B_T)[*1]

By Takeo KANEKO and Ryonosuke YOSHIDA[*2]

(Received January 9, 1962)

The chemical structure of (−)-carnitine[1] or vitamin B_T[2,3] has been conclusively established by Tomita et al.[4] as (−)-γ-trimethyl-β-hydroxybutyrobetaine by synthesizing natural (−)-carnitine through the methylation of (−)-β-hydroxy-γ-aminobutyric acid, which was obtained by resolution of its racemic modification. The configuration of the β-asymmetric carbon atoms of (−)-β-hydroxy-γ-aminobutyric acid and (−)-carnitine, however, has not yet been established. In this paper the determination of these configurations by a chemical method is reported.

It has been known that the racemic modification of β-hydroxyglutamic acid could be decarboxylated by the action of decarboxylase and that the rate of the decarboxylation of the threo isomer is higher than that of the erythro isomer[5-7]. Recently, we resolved two racemic modifications of β-hydroxyglutamic acid to four optical isomers and determined their configurations[7]. One of the optical isomers, *threo*-β-hydroxy-L(+)-glutamic acid hydrochloride ($[\alpha]_D$ +9.5° in water), which was represented by the configurational formula I, was treated with glutamic acid decarboxylase of *E. Coli.*, and (−)-γ-amino-β-hydroxybutyric acid was isolated as the decarboxylated product of I by means of ion exchange chromatography, using Dowex 50. The melting points, specific rotations, R_f values and infrared spectra of the isolated γ-amino-β-hydroxybutyric acid and its benzoyl derivative were identical with those of the authentic specimens[*3], as is shown in Table I, and no depressions of melting point were observed.

Ls(−)-γ-Amino-β-hydroxybutyric acid
or 2,4-Didesoxy-4-amino-Lg-threonic acid
or R(−)-γ-amino-β-hydroxybutyric acid

Vitamin B_T
or Ls(−)-Carnitine
or R(−)-Carnitine

Scheme 1

Consequently, the configuration of the asymmetric carbon atom of (−)-γ-amino-β-hydroxybutyric acid must be the same as that of the β-asymmetric carbon atom of *threo*-β-hydroxy-L(+)-glutamic acid. Although the β-asymmetric carbon atom of the latter has a Ds configuration[7], a Ls or Lg configuration II to be assigned to that of (−)-γ-amino-β-hydroxybutyric acid, since the carboxyl group of (−)-γ-amino-β-hydroxybutyric acid corresponded to the γ-carboxyl group of *threo*-β-hydroxy-L(+)-glutamic acid. Strictly speaking, it should be designated as the R configuration according to the nomenclature of absolute configuration presented by Cahn, Ingold and Prelog[8].

(−)-γ-Amino-β-hydroxybutyric acid was methylated to its betaine with some modifications by Carter's method[9], which was applied to racemic amino acid. The properties of the betaine and its obtained salts were consistent

8) R. S. Cahn and C. K. Ingold, *J. Chem. Soc.*, **1951**, 612; R. S. Cahn, C. K. Ingold and V. Prelog, *Experientia*, **12**, 81 (1956).
9) H. E. Carter and P. K. Bhattacharyya, *J. Am. Chem. Soc.*, **75**, 2503 (1953).

with that of natural (−)-carnitine, as is shown in Table II.

As it is clear from these results that (−)-carnitine and (−)-γ-amino-β-hydroxybutyric acid have the same configuration, the natural (−)-carnitine may be designated as R(−)-carnitine.

Experimental*4

Decarboxylation of *threo*-β-Hydroxy-L(+)-glutamic Acid.—To 630 mg. of *threo*-β-hydroxy-L(+)-glutamic acid hydrochloride ($[\alpha]_D$ +9.5° (water)), 0.1 N sodium hydroxide was added until a pH of 5.0 was reached. To this solution, 4.5 g. of dry, powdered E. Coli. and 50 ml. of phosphate buffer (pH 5) were added, and the suspension was shaken mechanically at 37°C for 3 hr. until the theoretical amount of carbon dioxide was evolved. The reaction mixture was centrifuged, and the sediment was mixed with water and centrifuged again. The combined supernatant liquid was treated with charcoal under warming and filtered.

In another experiment, 731 mg. of *threo*-β-hydroxy-L(+)-glutamic acid hydrochloride was treated as mentioned above. The combined filtrate was passed through a column (4×50 cm.) of Dowex 2-X8 (50~100 mesh, H form), which was then washed thoroughly with water. The elution of the amino acid from the column was carried out first with 1800 ml. of 0.05 N acetic acid and then with 2000 ml. of 0.1 N acetic acid, using a 15 ml. fraction collector. An aliquot of each fraction was subjected to paper chromatography to test it for the presence of the amino acid. The combined solution of tubes number 237 to 258, which contained γ-amino-β-hydroxybutyric acid, was concentrated in vacuo, and the residue was crystallized by adding ethyl alcohol; m. p., 208~209°C (decomp.); yield, 600 mg. The product was recrystallized from water and ethyl alcohol repeatedly to give 236 mg. of pure crystals; m. p. 216~217°C (decomp.), $[\alpha]_D^{20}$ −20.7° (*c* 1.83, water). The melting point was not depressed on admixture with the authentic specimen. The R_f values of the sample were 0.43 and 0.21, using 80% phenol and *n*-butanol: acetic acid: water (4 : 1 : 1) as the solvents. Its infrared spectrum and other properties were identical with those of the authentic specimen.

Found: C, 40.17; H, 7.66; N, 11.67. Calcd. for $C_4H_9O_3N$: C, 40.33; H, 7.62; N, 11.76%.

***N*-Benzoyl-(−)-γ-amino-β-hydroxybutyric Acid.** Two hundred and eighty eight milligrams of (−)-γ-amino-β-hydroxybutyric acid and 0.5 g. of sodium carbonate were dissolved in 8 ml. of water, and the solution was cooled in an ice bath. To this solution 0.4 g. of benzoyl chloride was added, and the mixture was vigorously stirred for 2 hr. The solution was extracted with ether to remove the benzoic acid; then the aqueous layer was concentrated. (−)-*N*-Benzoyl-γ-amino-β-hydroxybutyric acid separated out as a solid which was removed by filtration; after recrystallization from water, 0.2 g. of monohydrate was obtained; m. p., 70~85°C. The anhydrous crystals were obtained by recrystallization from ethyl acetate; m. p. 112~113°C, $[\alpha]_D^{23}$ −11.2° (*c* 1.43, water), p*K*a' 4.45. The melting point was not depressed on admixture with the authentic specimen. The infrared spectrum was also identical with that of the authentic specimen.

Found: C, 59.17; H, 5.96; N, 6.39. Calcd. for $C_{11}H_{13}O_4N$: C, 59.18; H, 5.87; N, 6.28%.

The optically pure (−)-γ-amino-β-hydroxybutyric acid could be recovered by refluxing the *N*-benzoyl-derivative with 48% hydrogen bromide for 4 hr.

(−)-Carnitine.—A solution of 5.8 g. of methyl iodide in 60 ml. of methanol was added to a solution of 1.2 g. of (−)-γ-amino-β-hydroxybutyric acid ($[\alpha]_D$ −20.3° (water)) and 2.2 g. of potassium hydroxide in 10 ml. of water. After standing overnight at room temperature, the mixture was concentrated in vacuo and the residue was dissolved in 50 ml. of water. The solution was extracted four times with 50 ml. of 80% phenol[9]. After the combined phenol extract had been washed with 20 ml. of water, 600 ml. of ether was added. The aqueous layer was separated, and the ether-phenol layer was extracted four times with 50 ml. of water. The combined aqueous layer was washed with 150 ml. of ether and passed through an anion exchanger column (IR4B, 3×25 cm.), which was then washed with 500 ml. of distilled water. The alkaline fraction of the effluent was concentrated in vacuo to a syrupy residue, which crystallized on standing in a desiccator. It was filtered using ethyl alcohol-acetone (2 : 3); yield, 1.0 g. After recrystallization two times from the same mixed solvent, 0.5 g. of hygroscopic crystals were obtained. M. p., 197~198°C (decomp.) $[\alpha]_D^{30}$ −23.9° (*c* 0.86, water).

Found: C, 52.17; H, 9.59; N, 9.08. Calcd. for $C_7H_{15}O_3N$: C, 52.15; H, 9.38; N, 8.69%.

(−)-Carnitine chloroaurate was obtained by the usual method[4]. M. p. 153~155°C (decomp.)

Found: C. 17.02; H, 3.28; N, 2.62. Calcd. for $C_7H_{16}O_3N \cdot AuCl_4$: C, 16.77; H, 3.22; N, 2.79%.

(−)-Carnitine chloroplatinate was also obtained[4]. M. p., 228°C (decomp.)

All properties of the synthetic product were practically identical with those of natural (−)-carnitine as cited in the literature.

The authors wish to express their deep thanks to Dr. Yoshio Hirose and Mr. Kiichi Nishimura of the Research Institute for Food Chemistry, Foundational Juridical Persons, for their kind gift of authentic samples of (−)-γ-amino-β-hydroxybutyric acid and its benzoyl derivative; Dr. Setsuji Sakurai, Central Institute of Ajinomoto Co., Inc., for his kind gift of the enzyme, and Dr. Kazuo Okunuki for his advice and for affording facilities for carrying out the decarboxylation experiments. Thanks are also due to Messrs. Masakazu Okumiya and Kenzi Yoshimura for their microanalysis.

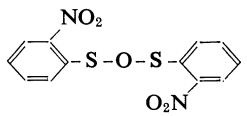
*4 All melting points are uncorrected.

The Structures of Zincke's So-called o- and p-Nitrobenzenesulfenic Anhydrides



By Shigeru OAE and Shunichi KAWAMURA

(Received December 22, 1961)

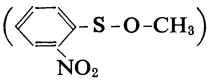
Zincke[1,2], in the neutral hydrolysis of *o*- and *p*-nitrobenzenesulfenyl chlorides, obtained compounds corresponding to $C_{12}H_8N_2S_2O_5$ and he then assumed these compounds to be the sulfenic anhydrides, I and II, respectively.

I

II

Much later Kharasch[3] has cited five more examples of similar anhydrides and presumed that they arise in the following fashion:

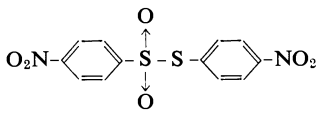
$$ArSCl \xrightarrow{HOH} [ArSOH] \xrightarrow{ArSCl} ArSOSAr$$



All these compounds are known to darken or sinter before melting or decomposing.

We have interested in Zincke's so-called *o*- and *p*-nitrobenzenesulfenic anhydrides, since we thought these would be the ideal compounds for the determination of the bond length of sulfur-oxygen single bond which has hitherto been unknown. However, somewhat unexpected patterns of the ultraviolet and infrared spectra of both compounds have led us to suspect the authenticities of the structures of these compounds hitherto accepted.

The compound, obtained from the hydrolysis of *p*-nitrobenzenesulfenyl chloride, when recrystallized from benzene[1], has a distinct band in infrared region, i. e., 1145 cm^{-1} which corresponds either to sulfoxide or sulfone. Meanwhile, the compound corresponding to I, would display a strong band below 1000 cm^{-1} in view of other examples shown in Table I which indicates that the characteristic bands of Si–O–Si and of P–O–P are both similar or shifted slightly toward longer wavelengths as those of Si–O–C and of P–O–C.



Since the oxygen exchange is known to take place in sulfuric acid with the sulfoxide but not with the sulfone[5] and also we found that nitrobenzene does not exchange oxygen in the same medium, we carried out the oxygen exchange experiment with the ^{18}O-enriched Zincke's compound in sulfuric acid. However, the compound recovered by diluting in water did not lose any excess of ^{18}O.

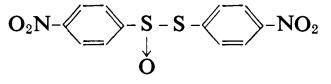
TABLE I*. CHARACTERISTIC BANDS OF ETHER LINKAGES OF SECONDS-ROW ELEMENTS

		cm^{-1}
Si–O–C		1090～1020 (s)
Si–O–Si	(ring)	1090～1020 (s)
Si–O–Si	(chain)	1090～1010 (s)
P–O–C	(aliphatic)	1050～1030 (s)
P–O–C	(aromatic)	1240～1190 (s) 1160 (w)
P–O–P		970～910 (s)
S–O–C		990 (s)

* About the spectra of six compounds except for the last methyl ether, for instance see the Ref. 4.

Infrared spectra of *p*-nitrophenyl *p*-nitrobenzenethiolsulfonate (III) and *p,p'*-dinitrodiphenyl disulfide (IV) were then taken.

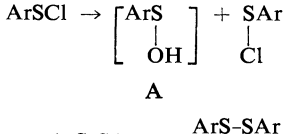
III



IV

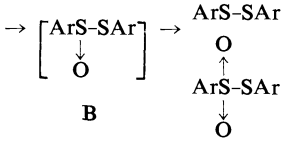
When these spectra were compared with that of recrystallized Zincke's compound, we could find virtually all the bands of III and IV in Zincke's compound. When an equimolar mixture of III and IV was recrystallized from benzene, the resulting mixture, which could not be separated by ordinary recrystallization,

1) T. Zincke and S. Lenhardt, *Ann.*, **400**, 1 (1913).
2) T. Zincke and F. Farr, ibid., **391**, 55 (1912).
3) N. Kharasch, S. J. Potempa and H. L. Wehrmeister, *Chem. Revs.*, **1947**, 327.
4) L. J. Bellamy, "The Infra-red Spectra of Complex Molecules", 2nd Ed., Methuen, London (1958).
5) S. Oae, T. Kitao and Y. Kitaoka, *Chem. & Ind.*, **1961**, 291.



gave completely identical infrared and ultraviolet spectra with those of Zincke's compound. These results point to the fact that Zincke's so-called *p*-nitrobenzenesulfenic anhydride is actually an equimolar mixture of *p*-nitrophenyl *p*-nitrobenzenethiolsulfonate (III) and *p*, *p*'-dinitrodiphenyl disulfide (IV).

In searching a possible intermediate in the hydrolysis of *p*-nitrobenzenesulfenyl chloride, we carried out the oxidation of *p*, *p*'-dinitrodiphenyl disulfide by perbenzoic acid, following the method of Backer[6] and Small[7], hoping to obtain *p*-nitrophenyl *p*-nitrobenzenethiolsulfinate (V). However, what we obtained was also an equimolar mixture of *p*-nitrophenyl *p*-nitrobenzenethiolsulfonate (III) and *p*, *p*'-dinitrodiphenyl disulfide (IV).



V

In the meantime, fresh hydrolysis product of *p*-nitrobenzenesulfenyl chloride, when only washed with ether and quickly dried, gave a very strong band at 1118 cm^{-1} and darkened at about 123°C. When this fresh product was subjected to heating in vacuo, storing for a long time or recrystallization, it gradually ceased darkening before melting and lost the band at 1118 cm^{-1} while changing its ultraviolet spectrum. This band at 1118 cm^{-1} is close to that of *p*-tolyl *p*-toluenethiolsulfinate, 1094 cm^{-1} [8] and is likely to be that of thiolsulfinate but is shifted toward shorter wavelength on account of strong electron-attracting nitro groups. This means that the fresh hydrolysis product is likely to be *p*-nitrophenyl *p*-nitrobenzenethiolsulfinate (V), which subsequently disproportion to *p*-nitrophenyl *p*-nitrobenzenethiolsulfonate (III) and *p*, *p*'-dinitrodiphenyl disulfide (IV) when the fresh product is recrystallized or kept standing for a while.

A

B

The consideration of *p*-nitrophenyl *p*-nitrobenzenethiolsulfinate (V) as an intermediate* is quite likely in view of the facts that many known thiolsulfinates are very unstable and disproportion easily to corresponding thiolsulfonates and disulfides[6] and also that the sulfur atom of A, being more nucleophilic than oxygen atom, would attack sulfenyl chloride in the second step of the hydrolysis giving B rather than the anhydride, I.

o-Nitrobenzenesulfenyl chloride, when hydrolyzed following Zincke's procedure[2] gave the product which was claimed to be the sulfenic anhydride. The fresh product had a strong band at 1108 cm^{-1}, corresponding to the thiolsulfinate band of *p*-isomer and also a medium band at 1145 cm^{-1} corresponing to that of thiolsulfonate. These bands subsisted even after repeated recrystallizations from benzene or heating in vacuo for a few hours, while the darkening point fluctuated up and down around 70°C on each batch. We tried similar oxidation of *o*, *o*'-dinitrodiphenyl disulfide with perbenzoic acid[6,7], hoping to obtain the thiolsulfinate. The reaction was very sluggish even under irradiating with ultraviolet light[9], and the only compound we could isolate was a small amount of the thiolsulfonate, recovering most of the starting material. We tried a few other attempts to synthesize the authentic *o*-nitrophenyl *o*-nitrobenzenethiolsulfinate in vain. When an equimolar mixture of *o*-nitrophenyl *o*-nitrobenzenethiolsulfonate and *o*, *o*'-dinitrodiphenyl disulfide was recrystallized from benzene and this mixture was compared with Zincke's compound, we found some small discrepancies in both ultraviolet and infrared spectra, while the melting point also did not show identity. However, we found that Zincke's compound has all the infrared bands of the equimolar mixture of *o*-nitrophenyl *o*-nitrobenzenethiolsulfonate and *o*, *o*'-dinitrodiphenyl disulfide in addition to the characteristic band at 1108 cm^{-1}. This seems to indicate that Zincke's so-called *o*-nitrobenzenesulfenic anhydride is the mixture of *o*, *o*'-dinitrodiphenyl disulfide, *o*-nitrophenyl *o*-nitrobenzenethiolsulfinate and *o*-nitrophenyl *o*-nitrobenzenethiolsulfonate. Since we could not obtain the thiolsulfinate, there is no way to estimate in what ratio these three compounds are mixed to make up Zincke's ortho compound.

A question still remains why the *o*-nitrothiolsulfinate does not disproportion so readily as compared to the *p*-isomer. We cannot offer

6) H. J. Backer and H. Kloosterziel, *Rec. trav. chim.*, **73**, 129 (1954).

any satisfactory answer with our present knowledge. Probably the steric arrangement of ortho groups has some role in stabilizing the thiolsulfinate. In this connection, it is interesting to note that *o*-nitrobenzenesulfenyl methyl ether was easily obtained when *o*-nitrobenzenesulfenyl chloride was reacted with sodium methoxide[2] and is quite stable while the *p*-isomer could not be obtained in pure form. We could not reproduce the same result when we followed Zincke's procedure[1], or slightly modified ways. Everytime, we found that the product was mixed with *p*-nitrophenyl *p*-nitrobenzenethiolsulfonate and *p*, *p'*-dinitrodiphenyl disulfide.

Experimental

So-called Zincke's *p*-nitrobenzenesulfenic anhydride was prepared by hydrolyzing the corresponding sulfenyl chloride[1]. Zincke reported this compound darkened at 126°C and melted with decomposition at 160°C. After repeated recrystallization from benzene, it lost the darkening point and melted with decomposition at 151~153°C. Fractional crystallization was tried using benzene as solvent, always obtaining the same compound.

Found: C, 44.69; H, 2.63. Calcd. for $C_{12}H_8N_2O_5S_2$: C, 44.44; H, 2.49%.

UV λ_{max} mμ (log ε): 270 (4.15), 303 (4.17).

IR characteristic band: 1145 cm^{-1} (s).

***o*-Nitrobenzenesulfenic anhydride** was also prepared in the same way[2]. The darkening point of this compound fluctuated around 70°C, melted at 181~196°C (darkened at 92~93°C., fused and did not melt until heated abov 180°C)[2].

Found: C, 44.31; H, 2.60%. Calcd. the same to *p*-isomes.

UV λ_{max} mμ (log ε): 234 (4.37), 326 (3.88).

IR characteristic band: 1108 (s), 1145 cm^{-1} (m).

***p*-Nitrophenyl *p*-nitrobenzenethiolsulfonate and ortho analog** were both prepared from the reaction of the silver salts of sulfinic acids and sulfenyl chlorides[1,2], m. p. 182~183°C and 145~145.5°C respectively.

UV spectrum for *p*-nitrophenyl *p*-nitrobenzenethiolsulfonate: λ_{max} mμ (log ε): 262 (4.29), 290 (4.00) and IR characteristic band: 1145 cm^{-1} (s).

UV spectrum for ortho analog: λ_{max} mμ (log ε): 231 (4.30) and IR characteristic bands: 1360 (s), 1145 cm^{-1} (s).

***o*-Nitrobenzenesulfenyl methyl ether** was prepared from the reaction of *o*-nitrobenzenesulfenyl chloride and sodium methoxide[2], m. p. 51~52°C.

***p*-Nitrobenzenesulfenyl methyl ether** was obtained following the procedure by Zincke[1]. The compound darkened at 125~135°C and melted with decomposition around 151~156°C. The reaction was also carried out in hexane as solvent, cooling with ice or shortening the reaction time always attaining the same result.

Found: C, 44.96; H, 2.64. Calcd. for $C_7H_7NO_3S$: C, 45.40; H, 3.70%.

UV λ_{max} mμ (log ε): 270, 312 (3.99).

IR characteristic band: 1145 cm^{-1} (s).

Oxidation of *p*, *p'*-Dinitrodiphenyl Disulfide.—To 10 g. of *p*, *p'*-dinitrodiphenyl disulfide dissolved in 450 cc. of chloroform was added for 40 min. an equivalent amount of perbenzoic acid in chloroform with vigorous stirring and cooling in an ice-bath[6,7]. Stirring was continued to next day at room temperature. When the disulfide was completely dissolved, the solution was neutralized with sodium bicarbonate solution, washed with water and dried over sodium sulfate. Chloroform was evaporated at room temperature and the precipitate was collected fractionwise after separated off the starting material. The second crop was recrystallized from benzene. This crystals gradually got dark and melted at 148~151°C with decomposition, giving 2 g. of pale yellow crystals.

Found (for the second crop): C, 44.94; H, 2.55. Calcd. for $C_{12}H_8N_2O_5S_2$: C, 44.44; H, 2.49%.

UV spectrum for the second crop; λ_{max} mμ (log ε): 271 (4.14), 305 (4.18).

IR characteristic band of the second crop: 1145 cm^{-1} (s).

IR characteristic bands of the third crop: 1145 cm^{-1} (s), 1118 cm^{-1} (s).

Oxidation of *o*, *o'*-Dinitrodiphenyl Disulfide.—*o*, *o'*-Dinitrodiphenyl disulfide was oxidized similarly with perbenzoic acid under irradiating with ultraviolet light[9], obtaining a small amount of product which darkened at about 100°C and decomposed at 128~130°C. When recrystallized from petroleum ether-benzene mixture, white and yellow crystals formed. Both crystals were mechanically separated. The white crystals were recognized by infrared spectra to be corresponding to the thiolsulfonate and the yellow to the disulfide, respectively.

Identification of the Equimolar Mixture.—When an equimolar mixture of authentic *p*-nitrophenyl *p*-nitrobenzenethiolsulfonate and *p*, *p'*-dinitrodiphenyl disulfide was recrystallized from benzene, the resulting crystals melted at 152.5~153.5°C. Ultraviolet and infrared spectra of the crystals coincided well with those of the corresponding alleged sulfenic anhydride I.

UV λ_{max} mμ (log ε): 270 (4.15), 302 (4.16).

IR characteristic band: 1145 cm^{-1} (s).

The crystals, recrystallized from an equimolar mixture of *o*-nitrophenyl *o*-nitrobenzenethiolsulfonate and *o*, *o'*-dinitrodiphenyl disulfide melted gradually from 136°C to 157°C with decomposition and had bands at 1360 and 1145 cm^{-1}, but had no band at 1108 cm^{-1}.

^{18}O Exchange Reactions.—Nitrobenzene, 0.7 g., was dissolved in 10 cc. of ^{18}O-enriched 98% sulfuric acid (0.5 atom % ^{18}O) at 0°C for 10 min., then was diluted with ice-water. The nitrobenzene recovered was distilled once, obtaining 0.5 g., and was subjected to ^{18}O analysis[10].

^{18}O for $C_6H_5NO_2$	0.209%
^{18}O for tank CO_2	0.210%

^{18}O Enriched Zincke's So-called *p*-nitrobenzenesulfenic anhydride was prepared from the hydrolysis of *p*-nitrobenzenesulfenyl chloride with equimolar amount of $H_2{}^{18}O$ (1.5 atom % ^{18}O) in glacial acetic acid.

TABLE II

Treatment	Darkening point	Melting point, °C	The ratio of intensity ($-\log T$) at 270 mμ and 303 mμ
Only washed with ether, quickly dried	~123°C	145~155	1 : 0.885
Heated at 72~73°C for 3 hr. in vacuo	Obscure	148~150	1 : 0.948
Heated at 72~73°C for 6 hr. in vacuo	Almost indistinct	149~151	1 : 1.032
Repeated recrystallization, well dried in vacuo	Did not occur	151~153	1 : 1.017

^{18}O for p,p'-$O_2NC_6H_4S^{18}OSC_6H_4NO_2$ 0.46%
^{18}O for tank CO_2 0.210%

One gram of this compound was dissolved into 98% H_2SO_4 at 0°C, and was kept standing for 15 min., then filtered and the filtrate was poured into ice-water. The precipitate formed was collected, washed with a sufficient amount of water, repeatedly, dried, and recrystallized from benzene, m. p. 156~168°C, 0.25 g.

^{18}O for p,p'-$O_2NC_6H_4S^{18}OSC_6H_4NO_2$ 0.44%
^{18}O for tank CO_2 0.210%

In the case of ortho compound, the starting material could not be recovered.

The Variation of Melting Point and Ultraviolet Spectrum of *p*-Nitrobenzene-sulfenic Anhydride only Washed with Ether. — Fresh *p*-nitrobenzene-sulfenic anhydride only washed with ether and quickly dried was treated under various conditions, and melting points and the ultraviolet spectra taken with the corresponding changes are as shown in Table II.

Ultraviolet Spectra.—All spectra were taken on Shimadzu model RS-27 auto-recording spectrophotometer using the solutions of the compounds dissolved in purified dioxane.

Infrared Spectra. — In all spectrophotometries potassium bromide disks were used.

The Radiation-Induced Oxidation of Stannous Chloride in Aqueous Hydrochloric Acid

By Ken'ichi SUGIMOTO and Shigeru OAE

(Received January 5, 1962)

Numerous investigators[1-6] in recent years have suggested a radical diffusion model for various radiation-induced chemical reactions in aqueous media. According to this model radiation-induced chemical reactions in aqueous solutions are initiated by radicals generated from water as a result of energy degradation processes. In fact, a few supporting evidences[7-9] have been presented in the study of the effect of gamma irradiation from cobalt-60 on ferrous sulfate in 0.8 N sulfuric acid.

For this model investigations of the radiation-induced oxidations or reductions of other inorganic compounds in aqueous media have been studied by many workers[10-14]. Solutions of oxidizing agents are reduced by gamma irradiation usually in a yield of about 2.3 atom-equivalents per 100 eV. While, these of common reducing agents are oxidized in the same yield as that of hydrogen gas formed, the radiation-induced oxidation of stannous to stannic ion was also investigated as one of these reactions and could be used for chemical dosimetry.

from cobalt-60, yields stannic ion and hydrogen gas as the products. This system is of particular interest because of the transfer of two electrons is involved in the oxidation of stannous to stannic ion. Since stannous ion is powerful reducing agent in aqueous solutions, it could be used as a scavenger for radicals produced in the irradiation of aqueous solution, and also as a chemical dosimeter.

Boyle, Weiner and Hochanadel[15] have studied the irradiation of stannous ion in aqueous sulfuric acid and mixtures of stannous ion with ferrous and ferric ion. All their experiments were carried out in 0.8 N sulfuric acid. Amell[16] studied the irradiation of stannous chloride in aqueous hydrochloric acid, but his study has to be extend further in detail in order to use this reaction for chemical dosimetry. Therefore, we have undertaken this investigation.

Experimental

Irradiations.—Cylindrical and basket style sources of cobalt-60 gamma rays, which have 1000 and 3800 curies respectively, were used. Energy absorption in solutions was determined with the Fricke ferrous sulfate dosimeter taking G as 15.6[9]. Initial dose rate values for the two sources are shown in Table I. The dose rates were corrected for decay. All the irradiations were carried out at ambient temperature between 27 and 32°C.

For continuous measurements, a dropping mercury apparatus with mercury pool electrolysis cell was placed in the irradiation room, while lead wires were led outside from the room, and were connected with a polarographic recorder. The measurements of polarogram were taken periodically during the irradiations.

TABLE I. DOSE RATES ON THE VARIOUS POSITIONS AT THE IRRADIATION FACILITIES

Co-60 source curies	Distance from source to sample cm.	Dose rate $\times 10^{19}$ eV./l. min.
3800	15	10.3
3800	20	6.8
1000	12	3.7
1000	20.5	2.0

Preparation of Solutions.—Water used was prepared by at first distillation over acid permanganate, then over alkaline permanganate, and finally by ordinary distillation. This water was used throughout this experiment. Solutions used for irradiation were made oxygen free. Because of rapid air oxidation of stannous ion it was necessary to avoid oxygen during preparation, irradiation and analysis of the solution. Stock solution of stannous chloride was prepared by dissolving reagent grade stannous chloride in concentrated hydrochloric acid and diluting with water to the final desired concentrations for both stannous ion and the acid. These solutions were stored in nitrogen atmosphere to minimize the oxidation of the stannous ion by oxygen.

Standard solutions of stannic ion were prepared by dissolving reagent grade stannic chloride. The concentration of stannic ion was determined gravimetrically as stannic oxide.

Deaerated solutions of the stannous chloride (0.5~3 mM) in 6 N hydrochloric acid were used in most cases. The solutions were then irradiated and analyzed in the following method.

Analytical Methods.—The stannous and stannic ion were determined polarographically, using a Yanagimoto PA-101 polarography with the temperature controlled at 30±1°C. The reduction of stannic to stannous ion produces wave suitable for this analytical purpose when the supporting electrolyte was 6 N hydrochloric acid. This wave is diffusion controlled and occurring at a half-wave potential of −0.25 V. vs. S. C. E. The measurements were taken in mercury pool electrolysis cell. The diffusion constant for stannic ion used in this study were taken by $I=i_d/m^{2/3}t^{1/6}c=4.77$ μA/mM.

Dissolved oxygen was removed satisfactorily by bubbling nitrogen through the solution for 10 min. before each polarographic determination. The nitrogen stream was purified by bubbling through alkaline pyrogallol solution and distilled water.

The polarographic measurements were made both by the ordinary method and continuous measurement method. The former determined diffusion current difference between non-irradiated sample and irradiated sample. This difference corresponds to conversion value from stannous to stannic ion. Analyses generally were made within half an hour after taking out the sample from the irradiation room. Continuous measurements were taken during the irradiations, where variation of measurements appeared to have no effect on diffusion current.

Results and Discussion

The effects of irradiation time, initial stannous ion concentration, stannic ion concentration and dissolved oxygen on the yield were investigated.

Irradiation Time.—Figure 1 shows a fews plots of stannic ion formed against irradiation time. The amount of stannic ion formed from stannous ion in hydrochloric acid is proportional to that of energy absorbed up to at least 5×10^{22} eV./l. and is essentially independent of dose rate. The G-values obtained from stannic ion formation are shown in Table II. The continuous measurement method gave a variety of formation curves of stannic ion. A few typical curves for stannic ion formation are shown in Fig. 2. However, in most cases we obtained curve similar to B, which indicate that the rate of oxidation is a linear function of irradiation time over the range we studied.

TABLE II. THE *G*-VALUES FOR STANNIC ION FORMATION

Deaerated solutions of the stannous chloride in 6 N hydrochloric acid were irradiated.

Dose rate $\times10^{19}$ eV./l. min.	Oxidation rate mM/hr.	*G*-value
10.3	0.146	1.4_1
6.8	0.091	1.3_5
3.7	0.052	1.4_1
2.0	0.031	1.5_7
2.0	0.021	1.0_1[a]

a) In 0.8 N hydrochloric acid

Fricke and Hart[17,18] irradiated with X-rays air-free solutions of a number of common reducing agents. The pH for the most of these solutions was varied over a wide range from 2 to 11. In most cases the amounts of reducing agents oxidized are equivalent to $G_{H_2}=0.5=G_{H_2O_2}-(G_H-G_{OH})/2$. While in air-free ferrous sulfate solutions ferrous ion is oxidized in a yield of $G(Fe(III))=8.2=G_H+G_{OH}+2G_{H_2O_2}$[7-9]. Boyle et al.[15] reported that the yield of $G(Sn(IV))=0.49$ is equivalent to G_{H_2} in 0.8 N sulfuric acid solutions by the gamma irradiation, indicating that oxidation is done by H_2O_2 and OH and reduction by H.

In aqueous hydrochloric acid the yield $G(Sn(IV))=1.50$ was shown by Amell[16]. It is interesting to note the marked difference of *G*-values between 0.8 N sulfuric acid and hydrochloric acid. This difference was explained by Amell that stannous ion forms many different complex ions with chloride ion as the concentration is changed, thus be changing the reacting species which have both different oxidation potentials and different rates of reaction.

Using the values for the individual radical and molecular yield generated from water, the following sequence should give rise to the *G*-value.

$$H_2O \text{ -W-> } H + OH + H_2O_2 + H_2 \quad (1)$$

$$Sn(II) + OH \rightarrow Sn(III) + OH^- \quad (2)$$

$$Sn(III) + OH \rightarrow Sn(IV) + OH^- \quad (3)$$

$$2\,Sn(III) \rightarrow Sn(II) + Sn(IV) \quad (4)$$

The results can be interpreted to mean that the tin is being oxidized by OH only while H does not react with anything, but merely combine with itself to forms H_2. In view of the abundant evidences for the general high reactivity of H and OH, it seems quite unlikely that these radicals can wait around to

17) H. Fricke and E. J. Hart, *J. Chem. Phys.*, 3, 365 (1935).
18) H. Fricke and E. J. Hart, ibid., 3, 596 (1935).

combine with one another in the presence of such chemically reactive species as stannous chloride. More likely, the H atoms can reduce Sn(II) to Sn(I), and can also oxidize Sn(II) to Sn(III) as follows.

$$Sn(II) + H \rightarrow Sn(I) + H^+ \quad (5)$$

$$Sn(II) + H + H^+ \rightarrow Sn(III) + H_2 \quad (6)$$

$$Sn(I) + Sn(III) \rightarrow 2\,Sn(II) \quad (7)$$

The oxidation-reduction potential calls for all of these stannous ions to be oxidized by hydrogen peroxide. Nevertheless, the reaction between stannous ion and hydrogen peroxide is apparently slow, and $G(Sn(IV))$ to be equal to $G_{OH}/2+G_{H_2O_2}$ if this reaction is occurring.

Hydrochloric acid in contrast to sulfuric acid, is relatively less stable to irradiation. Chloride ion does not react effectively with OH in neutral solutions, probably because of the reaction

$$Cl^- + OH \rightarrow OH^- + Cl \quad (8)$$

is endothermic. However, the reaction

$$Cl^- + OH + H^+ \rightarrow H_2O + Cl \quad (9)$$

is exothermic and chloride ion does react with OH in acid solution. The rate of reaction of Cl^- with OH would therefore be expected to increase with acid concentration and in fact, it is found that chloride ion changes as chlorine radical and the radical reacts with stannous ion the higher acid concentration.

On the other hand, the increase of G-value at higher acid concentrations is probably due to the direct deposition of energy by irradiation into the chloride ion. This becomes important at higher concentrations of hydrochloric acid, and leads to oxidation in a higher yield over that of the formation of radicals from water alone.

$$Cl^- \text{-}\!\!\sim\!\!\rightarrow Cl \quad (10)$$

$$Sn(II) + Cl \rightarrow Sn(III) + Cl^- \quad (11)$$

$$Sn(III) + Cl \rightarrow Sn(IV) + Cl^- \quad (12)$$

Effect of Initial Stannic Ion Concentration.—To determine the effect of the initial concentration of stannous ion on the oxidation, various solutions were prepared for irradiation. These solutions differed only in stannous ion concentration. The results of these concentration are shown in Fig. 1. Within these concentrations (0.5~3 mM) there is no effect of stannous ion concentration on the oxidation.

Effect of Stannic Ion Concentration.—The concentration of stannic ion was varied to determine this effect. After the stannous ion is half depleted, stannous ion is oxidized at the rate which depends on stannic ion as shown by Fig. 2-C curve. The G-value as a function of stannic ion is given in Fig. 3.

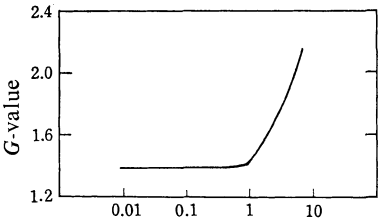

Fig. 3. Effect of stannic ion concentration.
Sn(II)+Sn(IV); 1.57×10^{-3} M in 6 N HCl
Dose rate; 3.7×10^{19} eV./l. min.

The G-value from the radiation-induced oxidation of stannous and stannic ion mixtures is significantly higher than that obtained by stannous ion alone. Although we can offer no statisfactory explanation for this difference, it is probably due to the catalytic effect of stannic ion in the reaction of stannous ion with hydrogen peroxide.

Dissolved Oxygen.—Various experiments showed that the oxidation of stannous ion by irradiation is greatly increased when oxygen or air is present. This is seen in Fig. 2-A. After oxygen is depleted, formation curve shows linearity. Thoroughly bubbled solution by purified nitrogen gas does not show any increase of oxidation.

Application for Dosimetry

The good reproducible data obtained on the determinations of stannic ion suggest that this system can be used as a dosimeter for higher doses of irradiation. The analysis of stannous or stannic ion can be performed conveniently. However, it should be pointed out that even though the oxidation of stannous ion is pre-

TABLE III. REPRODUCIBLE RESULTS OF CHEMICAL DOSIMETRY

Irradiation dose	Conversion value	Reproducibility	
		Range	Standard deviation
$\times10^5$ r.	mM	mM	mM
4.20	0.66 0.59 0.58 0.57	0.09	0.04
2.79	0.42 0.36 0.34 0.37	0.08	0.03
1.51	0.18 0.21 0.22 0.22	0.04	0.02
0.82	0.14 0.11 0.13 0.13	0.03	0.01

sented to be the reaction only with OH radical, the quantities of products involved are still quite small. Consequently, for doses less than 10^4 r., microtechniques would have to be employed. By irradiating 1 cc. of 6 N hydrochloric acid solution of stannous ion one would expect only 1.4×10^{-5} mmol. of stannic ion to be produced by 10^4 r.

Summary

The radiation-induced oxidation of stannous to stannic ion in aqueous hydrochloric acid has been studied and that this system is proposed as a chemical dosimeter for higher doses.

The amount of oxidation is proportional to the energy absorbed and the yield of stannic ion is independent of dose rate and initial stannous chloride concentration over a wide range studied, but increases when stannic conconcentration is high or oxygen is present. Mechanism for this oxidation based on *G*-values is discussed in terms of the primary decomposition products of water radiolysis. The results can be interpreted to mean that the stannic ion is oxidized only by OH radical. This system could be used for a chemical dosimeter having 8% reproducibility.

Studies of the Drawing of Polyamide Fibers. I. Dependence of Some Physical Properties on the Draw Ratio

By Hiroshi HATTORI, Yasuo TAKAGI and Tatsuro KAWAGUCHI

(Received January 5, 1962)

It is well-known that an oriented fiber is obtained from synthetic linear high polymer by drawing it to several hundred per cents of its original length, and that various properties of the fiber are changed by this drawing.

The relation between the draw ratio and some physical properties of nylon 6 monofilament—especially the tensile strength and the shrinkage in boiling water—has been studied in order to elucidate the process of the change in polymer structure during the course of the drawing.

A curious relation was discovered between the draw ratio and the tensile strength; that is, the tensile strength becomes the smallest at a draw ratio near two.

Experimental

Samples.—*Group I.*—An undrawn monofilament of nylon 6 (1300 denier), which had been meltspun and quenched in water, was drawn immediately after spinning in hot water at 90°C to various draw ratios, from 1 to 5.2, at intervals of 0.3. The feeding speed of the undrawn sample at the drawing was 26 m./min.

Group II.—The same undrawn monofilament as that in group I was drawn 53 days after it had been meltspun. The feeding speed of the undrawn sample at the drawing was 5 m./min., and the temperature of the water bath was 95°C.

Measurement.—Tensile tests of these samples were carried out with an Instron tensile tester at 20°C and at 65% RH. From the load-elongation curves thus obtained, the tensile strength and Young's modulus were measured. The shrinkage was measured by treating the samples in boiling water for 30 min. without tension. Birefringence was measured as follows: The sample was cut obliquely, and its wedge-shaped end was laid between crossed Nichol's prisms of a polarization microscope. From the number of the interference fringes which were observed on the wedge portion of the sample when the monochromatic light of a sodium lamp was used as the light source, the birefringence was determined according to the following equation:

$$\Delta n = N\lambda/d \qquad (1)$$

where Δn is the birefringence, N, the number of interference fringes, λ, the wevelength of the light, and d, the diameter of the sample.

Results

Change of Tensile Strength by Drawing.—In many kinds of fibers made from synthetic linear high polymers, the tensile strength of a filament changes with the draw ratio[1-4]. Generally, the strength of a filament from such

1) T. Yoshida, *J. Soc. Textile and Cellulose Ind. Japan*, **11**, 230 (1955).
2) J. Furukawa, K. Muramatsu and S. Ohya, *J. Japan Soc. Testing Materials*, **8**, 320 (1959).
3) R. Suda, *J. Soc. Textile and Cellulose Ind. Japan*, **8**, 272 (1952).
4) A. R. Urquart, *J. Appl. Chem.*, **4**, 195 (1954).

a polymer, whose crystallinity increases with orientation, tends to increase with the draw ratio. Polyamide filaments also become stronger as the degree of orientation increases, when the draw ratio is high enough.

The present authors investigated the change in tensile strength of nylon 6 monofilaments over a wide range of draw ratios. Figure 1 is the plot of the tensile strength against the draw ratio. This figure shows that the strength decreases, reaches a minimum and then increases again as the draw ratio increases, though the draw ratio and the decrease in strength at the minimum point differ between group I and group II. In group I, a 90%-drawn sample is 60% weaker than the undrawn sample, but in group II a 150%-drawn sample (the weakest one) is 35% weaker than the undrawn sample.

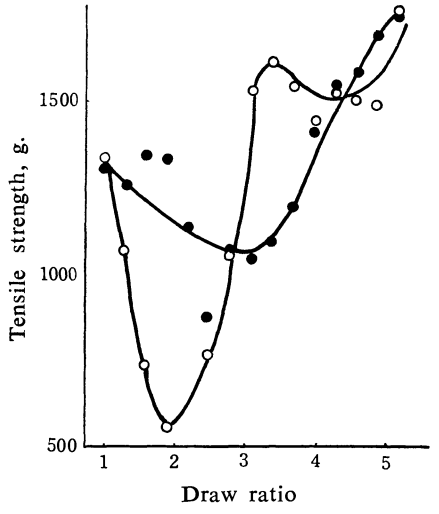

Fig. 1. Dependence of tensile strength on the draw ratio. ○, Group I ●, Group II

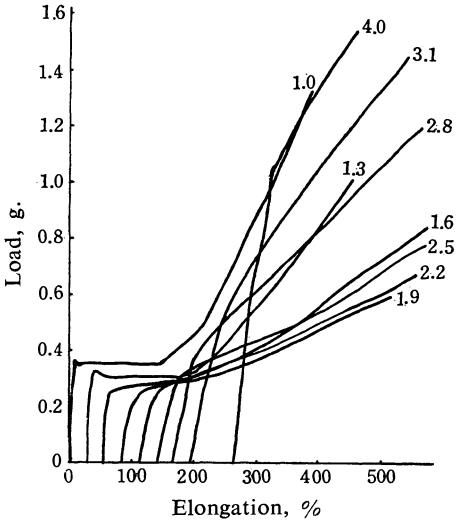

Fig. 2. Load-elongation curves for group I.

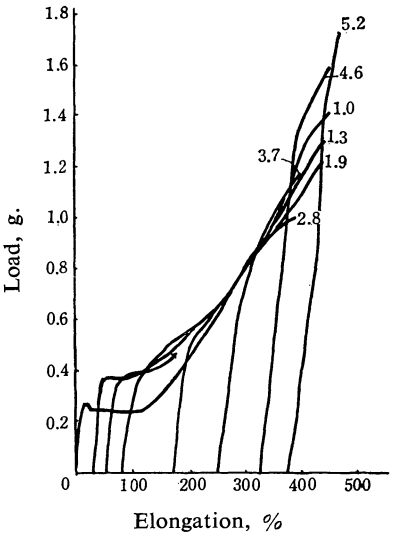

Fig. 3. Load-elongation curves for Group II.

These differences may result from some change in the structure of the undrawn filament during the lapse after spinning.

The load-elongation curves of these samples were shown in Figs. 2 and 3.

There is a contrast between the groups of curves of these two groups. In the case of group I, the yield value and the slope at the higher elongation of the load-elongation curve become smaller and reach a minimum at a draw ratio near 2; then the yield value increases, and the slope becomes steeper as the draw ratio increases.

The curves of group II do not show such tendencies, but they nearly overlap one another in the range of high elongation percentages.

Young's modulus obtained from the initial slope of the load-elongation curve was plotted against the draw ratio of the sample in Fig. 4. Young's modulus is nearly constant in the range of draw ratio from 1 to ca. 2, and then it increases with the draw ratio. This behavior suggests that the mechanism of drawing in the

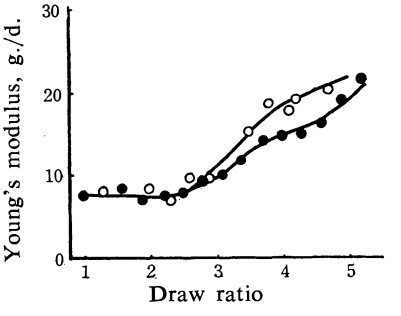

Fig. 4. Plot of Young's modulus against draw ratio. ○, Group I ●, Group II

range of lower draw ratio differs from that in the higher draw ratio.

Other polyamides (nylon 66, 69 and 610) exhibited behavior similar to that of nylon 6.

Shrinkage in Boiling Water.—The shrinkage of group I in boiling water, as shown in Fig. 5, is kept nearly constant in the range of draw ratio lower than ca. 2, increases rapidly in the range of draw ratio from ca. 2 to ca. 3.5, and gradually approaches to a saturation point as the draw ratio increases.

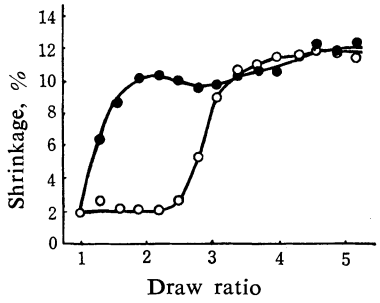

Fig. 5. Relation between draw ratio and shrinkage in boiling water.
○, Group I ●, Group II

Such behavior seems to be related to the existence of a minimum strength point near draw ratio 2, but, as is shown in Fig. 5, the dependence of the shrinkage of group II on the draw ratio differs from that of group I. In this case, the shrinkage increases quite rapidly in the first stage of drawing and then nearly saturates near the draw ratio of 2.

This difference between I and II seems to be a proof that the difference in the inner structure of the undrawn samples influences the mechanism of drawing.

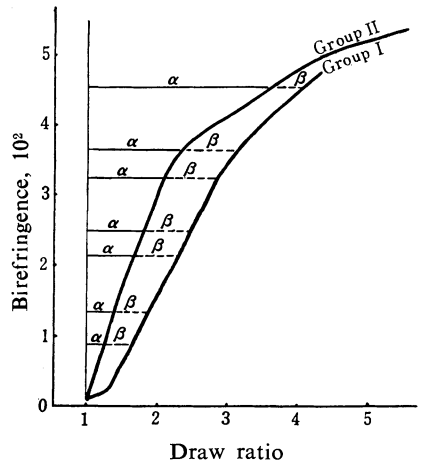

Fig. 6. Change of birefringence with draw ratio.

Birefringence.—Figure 6, a plot of the birefringence against the draw ratio, also shows a difference between groups I and II.

The rate of increace in birefringence at a low draw ratio is less in group I than in group II. This means that the degree of orientation does not always correspond to the draw ratio, but depends on the history of the undrawn sample.

Discussion

These curious relations between the draw ratio and some physical properties of polyamide filament seem to be due to one cause, that is, the process of the change of polymer structure during the drawing changes near the draw ratio of 2.

At first, the flow phenomenon during drawing was considered to be the cause. This phenomenon is known to occur when an amorphous undrawn polymer, such as polyethylene terephthalate, is drawn under a controlling condition; it is called "super drawing" [5]. In an extreme case of flow, orientation does not occur at all and the fiber becomes weaker. In the case of polyamide monofilament, it is probable that the flow phenomenon occurs because the polyamide melt was quenched in water, with the result that the crystallinity of the undrawn filament is low (the crystallinity of the undrawn sample of group I is less than 10%, and that of group II is 14%).

The fact that the decrease in strength at the minimum is more striking in the case of group I (lower crystallinity) than in the case of group II (higher crystallinity) also suggests the possibility of the flow.

In order to give a more quantitative explanation of this, the authors assume, as the first approximation, (a) that during the process of the drawing of group II, no flow phenomenon occurs at all, and (b) that unless flow occurs when group I is drawn, its birefringence is quite the same as that of group II at a same draw ratio.

According to these assumptions, α in Fig. 6 corresponds to an effective drawing accompanying real orientation, and β is a deformation due to the flow. Figure 7 is the drawing of a model in which α and β are shematically distinguished from each other. Now we suppose that an undrawn filament of a unit length is "effectively" drawn $(1+\alpha)$ times and then elongated further $(1+\gamma)$ times by flow deformation, where $\gamma=\beta/(1+\alpha)$, the final length being $(1+\alpha+\beta)$. So, $(1+\gamma)$ or $((1+\alpha+\beta)/(1+\alpha))$ is the draw ratio due to the flow only.

5) A. B. Thompson, *J. Polymer Sci.*, 34, 741 (1959).

Fig. 7. Model of deformation.
(A) undrawn sample; (B) drawn sample

The values of α, β and $(1+\gamma)$ are listed in Table I.

If the monofilament did not become thinner because of the flow, the strength would be equal to the measured strength multiplied by the factor $(1+\gamma)$. The right column of Table II is the result of this multiplication. Although the magnitude of strength-decrease becomes smaller by this correction, the value is still the smallest at the draw ratio of 1.82 and becomes extraordinarily large near the draw ratio 3.

TABLE I. CALCULATION OF THE RATIO OF FLOW DEFORMATION

Draw ratio[a]	α	β	$1+\alpha$	$\frac{1+\alpha+\beta}{1+\alpha}$
1.00	0.00	0.00	1.00	1.00
1.28	0.03	0.25	1.03	1.24
1.54	0.21	0.33	1.21	1.27
1.82	0.35	0.47	1.35	1.35
2.09	0.58	0.51	1.58	1.32
2.38	0.71	0.67	1.71	1.39
2.66	0.99	0.67	1.99	1.34
2.94	1.20	0.74	2.20	1.34
3.78	2.36	0.42	3.36	1.12

[a]Actual draw ratio: (denier on undrawn filament) ÷ (denier of drawn filament)

TABLE II. CORRECTED TENSILE STRENGTH

Draw ratio	Measured strength s, g.	Corrected strength $s\times\frac{1+\alpha+\beta}{1+\alpha}$, g.
1.00	1340	1340
1.28	1063	1320
1.54	735	933
1.82	558	754
2.09	765	1010
2.38	1050	1390
2.66	1538	2060
2.94	1620	2170
3.78	1450	1620

Therefore, we cannot give a satisfactory explanation of the phenomenon of minimum strength by considering only the flow as the cause, though this seems to contribute partly to the phenomenon, because the assumptions mentioned above are not always correct.

Another possible cause of the phenomenon is a change in the mechanism of drawing in the intermediate stage of drawing. It is known that the crystal form of nylon 6 changes from α form to β form when it is drawn about 150%[6]. Therefore, it may be reasonable to consider that the phenomenon of minimum strength is related to the transition of crystal form. However, as the crystallinity of the undrawn samples is rather low and as the strength of a sample seems to depend chiefly on the state of the amorphous part and not on the crystal form, the transition of the crystal form itself has no direct influence on the change in strength. Therefore, it is more natural to consider that on the intermediate stage of drawing, where the transition of crystal form can occur, the structure of the polymer becomes most unstable, as the result of which the strength reaches a minimum, though the authors are not sure how or why the structure becomes most unstable.

As to the difference in the changes of some properties between groups I and II, the authors have considered the influence of the history of the sample from spinning to drawing. The decrease in tensile strength of group II is less than that of group I, and the shrinkage of group II increases more rapidly in the first stage of drawing than that of group I.

Therefore, we suppose (1) that sufficient time is necessary for a network structure in the polymer to be completed, and (2) that, if a structure is once completed, it does not completly disappear but partly remains after the sample has been deformed.

Thus, when a sample is drawn immediately after spinning (before the structure of the undrawn filament is formed), it becomes either stronger or weaker, depending on the draw ratio, becoming the weakest near the draw ratio of 2. On the contrary, when the sample is drawn after the structure of undrawn filament is completed (group II), the structure of the undrawn sample remains in the drawn one, and, as a result, the strength decrease at the minimum becomes less than that of group I.

The difference in birefringence-shrinkage relationship, shown in Fig. 8, between groups I and II can be explained to some extent by these assumptions. The sample drawn before the structure of the undrawn filament is formed retains less residual internal stress than the sample in which the structure of undrawn filament has not disappeared; therefore, the shrinkage of group II increases rapidly with the draw ratio from the first stage of drawing, while that of group I does not.

As the phenomenon of minimum strength near the draw ratio of 2 is observed not only in the case of monofilaments drawn in hot

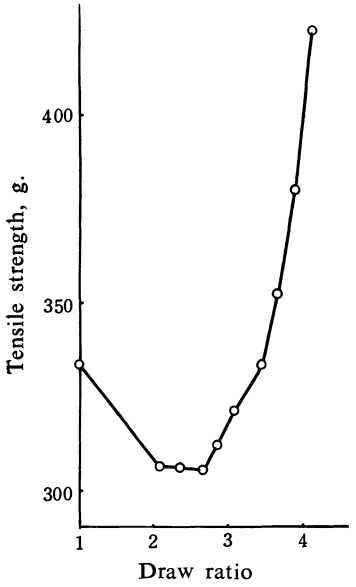

Fig. 9. Change of tensile strength of nylon filament yarn with draw ratio.

water, but also in the case of multifilament yarns cold-drawn with an ordinary draw-twister (Fig. 9), this phenomenon seems to be peculiar to polyamide fibers, irrespective of the way of drawing.

Further efforts will be made in order to explain the change in physical properties by drawing more systematically and quantitatively in the experiments to be described in later papers of this series.

Conclusion

From some peculiar behaviors of nylon 6 monofilament concerning the change in physical properties with the change in draw ratio, the authors have discussed the change in the molecular structure of the polymer during drawing.

Although no definite conclusions were obtained, the following assumptions seem to fit the observed phenomena:

(a) The flow of the polymer occurs during drawing to some extent.

(b) The structure of polyamide filament becomes most unstable near the draw ratio of 2.

(c) Sufficient time is necessary for a network structure in the polymer to be completed.

(d) If a structure is once completed, it does not completely disappear but partly remains even after the polymer has been deformed.

Summary

The relation between the draw ratio and some physical properties of nylon 6 fibers was investigated, using monofilament drawn in hot water to various draw ratios. The tensile strength decreases, passes through a minimum at a draw ratio near 2, and then increases as the draw ratio becomes higher. The decrease in strength at the minimum in the sample drawn immediately after spinning amounts to 60% of the strength of the undrawn sample. The shrinkage in boiling water of the sample drawn immediately after spinning is nearly zero in the range of a low draw ratio, increases in the range of the ratio from ca. 2 to ca. 3.5, and gradually approaches a saturating value, but that of the samples drawn many days after spinning increases most rapidly in the range of the ratio from 1 to ca. 2 and then gradually approaches to a saturating value with the draw ratio. On the first stage of drawing, the rate of increase in birefringence with the draw ratio of the sample drawn immediately after spinning is smaller than that of the sample drawn many days after spinning. On the basis of these results, the authors discussed the mechanism of the drawing of polyamide filaments.

Electrolytic Process for the Preparation of Dianisidine Using Rotating Cathode Cell for the Reduction of o-Nitroanisole to Hydrazoanisole

By K. S. UDUPA, G. S. SUBRAMANIAN and H. V. K. UDUPA

(Received June 28, 1961)

Dianisidine is largely employed as a dye intermediate in the production of direct cotton colors and the same to the extent of 573 Cwts. was imported into this country in 1959. An electrochemical method for the process would therefore be of interest to meet the immediate requirements of the country. Hydrazoanisole (II) is generally prepared[1] by the reduction of

(I) (II)

(III)

o-nitroanisole (I) with zinc and sodium hydroxide in alcoholic or benzene solution. The hydrazoanisole thus obtained is rearranged to dianisidine (III) by reaction with acids.

Chemical Methods of Reduction.—Pellegrini[2] studied the reduction of *o*-nitroanisole by means of sodium amalgam and found that hydrazoanisole is formed when solvents like alcohol and pyridine are used without which the nitro group is reduced to the amine. In this reduction he concluded that the initial concentration of sodium hydroxide is of great importance, the formation of primary amines as a by-product being greater, the smaller the amount of alkali present initially. Gandry and Keirstead[3] have used dextrose and sodium arsenite as a reducing agent for the reduction. Reduced nickel prepared from nickel nitrate mixed with a compound containing sulfur or chlorine as a reducing agent for the reduction has been suggested by Rikagaku[4]. Recently Iida and Konishi[5] have studied the reduction by using a ferrosilicon alloy and found that the best condition for the reduction are obtained by using 10 g. of *o*-nitroanisole with 6～9 g. of ferrosilicon (Si content 15%) in 15～30 g. of 13～18% sodium hydroxide solution containing 7.9 g. of calcium hydroxide at 100°C for 2～6 hr.

Electrolytic Methods of Reduction.—The first electrolytic reduction of *o*-nitroanisole has been reported by Haussermann[6] by reducing *o*-nitroanisole in alcoholic solution. Elbs[7] and Brand[8] have also reported the electrolytic reduction of *o*-nitroanisole. McKee and Gerapostolou[9] have extensively studied the reduction of *o*-nitroanisole in concentrated solution mixtures of sodium and potassium xylene sulfonates at different pH and reported that hydrazo compounds are formed only under alkaline pH. Dey and co-workers[10] have also studied the electrolytic reduction of an alkaline emulsion of *o*-nitroanisole, employing stationary cathode and low current densities of the order of 2 amp./dm^2 to obtain an yield of 67.7% of hydrazoanisole.

The use of rotating cathode technique in the reduction of nitro compounds in acid medium was reported from this laboratory earlier[13,14]. The reduction of nitrobenzene and *o*-chloronitrobenzene in alkaline emulsion using the same technique was reported in subsequent studies by the authors[11,12] and the application of this technique in the reduction of other substituted nitro compounds has led us to the present investigation.

Experimental

Electrolytic Cell.—The cell (Fig. 1) consisted of a 600 cc. Pyrex beaker (A) without spout, and

was fitted with a cement asbestos sheet cover having the necessary openings for the introduction of cathode (B), diaphragm (D), condenser (F) and thermometer (T). The cathode (B) was of a mild steel disk type each disk being 2.5 cm. diameter and with a spacing of 1.25 cm. There are 5 such disks and the cathode is rotated at about 1800 r. p. m. by means of a fractional H. P. motor. The catholyte was 200 cc. of 10% soduim hydroxide (Commercial grade) containing 2 g. of commercial grade litharge (yellow) PbO. The anolyte was 25% sodium hydroxide. *o*-Nitroanisole (L. R. grade B. D. H.) was used in the ratio of 1 : 4 (1 g. of nitro compound per 4 cc. of the catholyte). The diaphragm was of asbestos cloth wound on a nickel plated mild steel cage — 2.5 cm. diameter ×12.5 cm. height — and the anode was a strip of stainless steel plate (C) — 1.25 cm. breadth ×15 cm. height ×0.16 mm. thick. A cathode current density of 30 amp./dm² was employed.

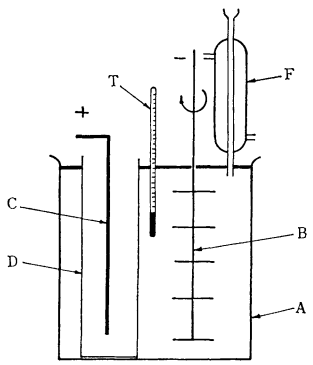

Fig. 1. Cell diagram using a rotating disk-type cathode.
A, Cell container; B, Rotating cathode; C, Anode; D, Diaphragm; T, Thermometer; F, Condenser

Procedure.—After the lead had been deposited on the rotating cathode by pre-electrolysis, with a current of 8 amp., 50 g. of *o*-nitroanisole was added to the hot electrolyte (85°C) and theoretical current for reduction to hydrazoanisole passed from a selenium rectifier. After 90% of the current was passed, xylene (50 ml.) was added into catholyte to keep the solid hydrazoanisole in solution and to favor further reduction of azoanisole and any nitroanisole trapped in the solid.

Conversion to Dianisidine and Isolation of the Product.—The xylene layer from the electrolyte was separated and poured into a mixture of ice and 19 cc. of sulfuric acid (specific gravity 1.84) and stirred for 5 hr. in the cold condition after which the temperature was raised to 90°C. The dianisidine free base was liberated by basifying the crude sulfate and the ansidine is separated by steam distillation and dianisidine was then filtered after cooling and estimated as free base. The xylene layer was steam-distilled and the *o*-azoanisole remaining in the still was cooled, filtered, dried and weighed.

Results

The results of the investigation are given in Table I. It may be seen that *o*-azoanisole is a fairly poor depolarizer, because by passing nearly 10% excess current, the dianisidine yield could be increased only by about 2%.

Cathode Potential Studies.—The measurement of cathode potentials was carried out with a view to study the nature of the reduction process. For this purpose, a cylindrical iron cathode was used and the potential measured

Energy consumption: 9.0 kwh./kg.

against Hg/HgO/N NaOH reference electrode and a calibrated Heathkit vacuum tube voltmeter.

The influence of current density on the cathode potential was studied for the cathode that was plated rotating as well as that plated stationary. Graphs 1 and 2 in Fig. 2 show the polarization under stationary and rotating conditions of the respective cathodes plated under stationary and rotating conditions. It is necessary to indicate here that the lead deposit is spongy and not adherent when deposited on a stationary cathode and hence cannot be rotated after deposition without dropping out the deposit. Hence only the cathode on which lead was deposited while rotating can alone be used in the reduction of nitroanisole with rotation. These results clearly indicate the advantages of rotation of the cathode while depositing lead. The deposit though somewhat spongy, is quite adherent, and does not peel off during the reduction of nitroanisole so that the cathode can be used several times without having to redeposit lead. The rotating cathode is polarized to a greater extent because the deposit is less spongy. The cathode potential was also measured at different current densities after adding *o*-nitroanisole. Graphs 3 and 4 in Fig. 2 show considerable lowering of the cathode polarization on addition of *o*-nitroanisole.

A study of the cathode polarization curves shows that *o*-nitroanisole is a good depolarizer. A maximum displacement of 0.39 V. in the case of stationary cathode and of 0.64 V. in the case of rotating cathode in the positive direction was observed. This displacement is observed at a particular depolarizer ratio of 1 : 4

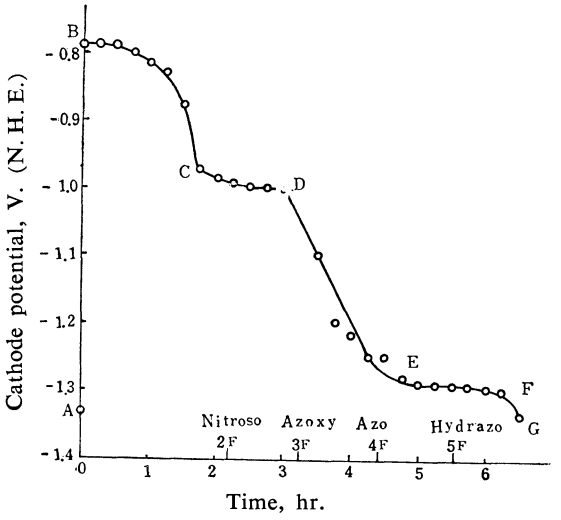

Fig. 3. Plot of cathode potential vs. duration on electrolysis using rotating cathode.

and at a temperature of 80~85°C. The maximum displacement in the cathode polarization occured at a current density of 7.8 amp./dm^2 in the case of stationary and at 23.4 amp./dm^2 for the rotating cathodes respectively. Figure 3 shows the change of cathodic polarization during the actual course of reduction of *o*-nitroanisole in alkaline emulsion at a rotating cathode with a deposit of lead at a current density of 25 amp./dm^2. The curve indicates the combined effects of the depolarizing action of different compounds which are likely to be formed at various periods during the course of reduction of the nitro compound. The first steep fall (A to B) is probably due to the depolarization of *o*-nitroanisole and the portion (B to C) represents the reduction to the nitroso stage and the fairly steady state (C to D) is probably due to the combined action of reduction of the nitro and nitroso to the azoxy stage. The steep fall (D to E) points to the reduction to the azo and/or hydrazo stage and thereafter the steady portion E to F probably represents the reduction of azo to hydrazo only and the potential slowly approaches the hydrogen evolution potential.

Summary

The technique of using rotating cathodes for electrolytic reduction of nitro compounds developed in this Institute earlier has now been extended to the study of the reduction of *o*-nitroanisole in an alkaline emulsion to obtain hydrazoanisole, which is subsequently converted to dianisidine by reaction with acid. The various chemical methods of obtaining hydrazoanisole as well as the previous attempts for obtaining the same by electrolytic reduction of *o*-nitroanisole are briefly reviewed.

The experimental technique adopted, the isolation of the product and the subsequent conversion of the hydrazoanisole to dianisidine are described.

Cathode potential has been measured at different current densities using lead deposited iron cathode under stationary and rotating condition of the cathode without the addition of nitro compound. The effect of the nitro compound addition on the cathode potential at different current densities has also been studied. The potential of a rotating cathode measured during the course of an experiment is graphically presented and the results discussed.

The authors sincerely thank Professor K. S. G. Doss, Director of the Institute, for his keen interest in this investigation.

Viscosities of O/W Emulsions Stabilized by Nonionic Surfactants. I. Characteristics of Nonionic Surfactants in Emulsion Viscosities

By Noriaki OHBA

(Received June 30, 1961)

Numerous reports are available on the viscosities of emulsions stabilized by the ionic emulsifiers. Viscosity has been discussed in detail in relation to the several factors affecting viscosity, such as the phase-volume ratio, the particle size distribution, the role of the interfacial films or of the stabilizers, the electroviscous effect, etc.[1]

On the other hand, there are relatively few data on and discussions of the viscosity of emulsions stabilized by the nonionic surfactants. Therefore, we have studied the behavior of nonionic surfactants towards the viscosity of emulsions. We first made the experiments on the emulsifications of mineral oil, using several types of nonionic surfactants; then we measured the viscosities of the emulsions thus obtained with a "MacMichael type" rotating-cup viscometer[2]. From these experiments, we have obtained a conclusion with relation to the HLB concept proposed by Griffin[3] on the nature of nonionic surfactants.

Experimental

Mineral Oil.—"Carnation White Mineral Oil" produced by Sonneborn Co., USA, was used as the oil phase in the emulsification, its average viscosity being 70 cp.

Nonionic Surfactants.—To examine the relative effects of nonionic surfactants on the emulsion viscosity, several samples differing in molecular constitution were selected for use; part of these were the same as those listed in the preceding report[4], and the other samples are listed in Table I.

TABLE I. GLYCERYL MONOSTEARATES

Abbr.	Type[a]	MG, %[b]	
MGS-I	N	45	Free glycerol <10%
MGS-II	N	55	Free glycerol <2%
MGS-III	S	—	MGS-I + K-soap
MGS-IV	S	—	MGS-II + K-soap
MGS-V	S	—	MGS-II + Nonionic surfactant

a : N, Noneself-emulsifying type
S, Self-emulsifying type
b : Monoglyceride content (%) determined with periodate.

Viscosity Measurements.—The viscometer employed in the present experiments was a "MacMichael type" rotating-cup viscometer equipped with a heating device to control the temperature of the emulsions measured. The angular velocity (Ω) of this viscometer can be varied from 25 to 100 r. p. m., and the values of the deflection angle (θ) at 50 r. p. m. were used for comparisons of the relative viscosity.

Results and Discussion

Emulsions of mineral oil were prepared by means of emulsification by inversion[5]. A composition of these emulsions is shown in Table II.

TABLE II. COMPOSITION OF EMULSION

Mineral oil	40.0%
Emulsifier	8.0%
Distilled water	52.0%

The process of emulsification is as follows; Into a mixture of mineral oil and emulsifier, which has been kept at about 90°C, water, which has also been kept at about the same temperature, is gradually added with an adequate stirring. This stirring is continued until the temperature of the emulsion decreases to about 40°C. After the emulsion has been left standing for about 20 hr., the viscosities of these emulsions are measured, at 25°C.

The HLB Method and the Viscosity of the Emulsion.—In the case of emulsifications using nonionic surfactants as stabilizers, there is the well-known HLB method to obtain the most stable emulsion[3]. To study the relations between the stabilities and viscosities of emulsions, sorbitan monostearate (SMS; HLB=4.7) and polyoxyethylene sorbitan monostearate (E-SMS -20; HLB=14.9) were adopted as standards for the emulsifiers[4]. To simplify comparison, one of these two standards was kept as a fixed component in any pair of surfactants in the emulsion studies. In this way, it was possible to study the relative effect of the nonionic surfactant upon the viscosity.

5) N. Ohba, K. Meguro and T. Kondo, Presented at the 12th Symposium of Colloid Chemistry, Hiroshima University, October, 1959.

In Table III, an example of the HLB values for mixtures composed of two emulsifiers, SMS and E-SMS-20, is shown.

To measure the relative viscosity, the resultant angle of deflection (θ) was plotted against the angular velocity (Ω), as is shown in Fig. 1.

TABLE III. HLB VALUES FOR MIXED EMULSIFIERS, θ AT 50 r. p. m., AND STABILITIES OF EMULSIONS

No.	Emulsifier composition (g.)		HLB (Eq.1)	θ at 50 r. p. m.	Stability
	SMS	E-SMS-20			
1	3.4	4.6	10.55	214	+
2	3.5	4.5	10.43	320	++
3	3.6	4.4	10.30	366	++
4	3.7	4.3	10.18	335	++
5	3.8	4.2	10.05	445	++
6	3.9	4.1	9.80	298	++

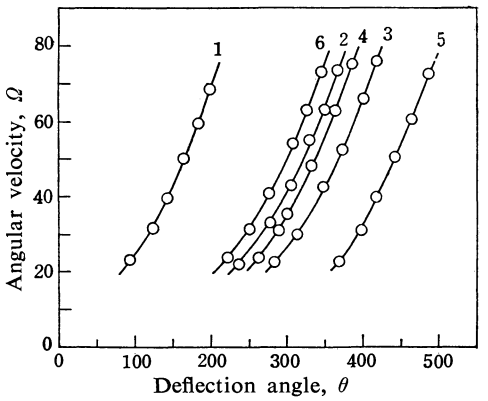

Fig. 1. The relations between deflection angle and angular velocity of viscometer.

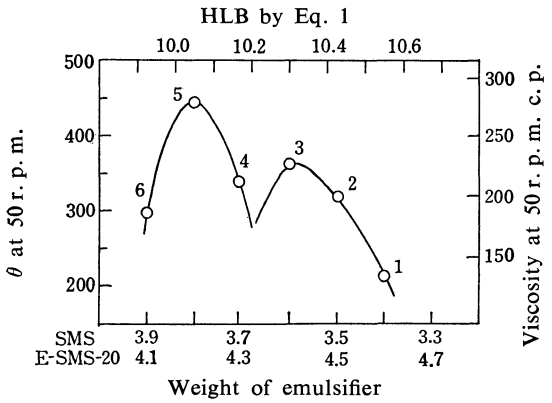

Fig. 2. The relations between the viscosity, the composition of emulsifier, and HLB.

On the basis of this figure, to show the effect of emulsifier composition on the relative viscosities of these emulsions, the values of θ at 50 r. p. m., which is an intermediate value of angular velocity, were listed in the 5th column of Table III and were plotted against the composition of the mxied emulsifiers, as is shown in Fig. 2.

At the top of this figure, a scale of the HLB values for the mixture is shown, calculated from the assumption of the weighed mean of HLB values of their components, using Eq. 1[6].

$$[\mathrm{HLB}] = [\mathrm{HLB}]_a x/100 + [\mathrm{HLB}]_b(100-x)/100 \quad (1)$$

where [HLB], $[\mathrm{HLB}]_a$ and $[\mathrm{HLB}]_b$ are the HLB values of the mixed emulsifier, surfactant "a" and "b" respectively, and x is the percentage content of surfactant "a" in the mixture.

In the case of SMS and E-SMS-20, $[\mathrm{HLB}]_a$ is 4.7, $[\mathrm{HLB}]_b$, 14.9, and

$$x = (\text{weight of SMS}) \times 100/8$$

This scale enables us to follow the $\theta \sim x$ relation with respect to the HLB of the mixed emulsifier.

Following the concept of HLB, it is assumed that the most stable state of emulsions results when the suitable HLB value is attained.

In the case of the series of emulsions shown in Table III, the following relations were found to exist among the HLB values, the particle size by a visual observation, the stability against creaming, and the relative viscosity of these emulsions:

1) The particle size of these emulsions first becomes smaller with the decrease in the HLB value for the emulsions numbered from 1 to 3, and then it becomes larger again with the further decrease in the HLB value for those of 5 and 6:

$$1 > 2 > 3 \geqslant 4 \leqslant 5 < 6$$

2) The stability of these emulsions varied with the decrease in the HLB value as shown in the last column of Table III; that is:

$$1 < 2 < 3 \approx 4 \approx 5 > 6$$

3) The relative viscosity of these emulsions has two maxima with respect to the HLB of the mixed emulsifier, as is shown in Fig. 2. As a whole, the relative viscosity of these emulsions shows two maxima as the HLB decreases with the change in composition of the mixed emulsifiers. Between these two maxima of viscosity, we can observe a deep or flat minima according to the nature of mixed surfactants, as is shown in Fig. 3.

In the case of ionic emulsifiers, it was reported by Richardson[7] that the apparent viscosity of emulsions having the same concen-

tration and a similar type of particle size distribution is inversely proportional to their mean grobule diameter. Applying his opinion to our case of the series of emulsions in Table III, the relation between the particle size, the stability and the relative viscosity of these emulsions can reasonably be understood, excepting for the region between the two maxima. To discuss the phenomena occuring in this region, further detailed studies must be made.

Sorbitan Fatty Acid Esters.—In Fig. 3, the cases of sorbitan fatty acid esters, curves 1—6, which were used with E-SMS-20 as the mixed emulsifiers, are shown.

All of the curves have two maxima in relative viscosities, like those shown in Fig. 2. In this figure, the relative viscosities, as a whole, are shown to decrease in the following order:

SMS > SMP > SML > SMO > SSO > STS

We can see, as a whole, that this order is in agreement with the increasing order of carbon numbers in the fatty acid radicals for saturated fatty acid monoesters and with the melting points of these acids, involving unsaturated acid monoesters. In the case of STS, the emulsions obtained were coarse and gave low relative viscosities.

Polyoxyethylene Sorbitan Fatty Acid Esters. —Derivatives having about 20 and 6 mol. of ethoxy-units in a molecule are used as component emulsifiers, and the results, curves 7—12, are shown in Fig. 3. These curves also gave two maxima, except for the case of E-SMS-6, the magnitude of relative viscosities (and of melting point) being in the following order:

E-SMS-20 > E-SMP-20 > E-SMO-20 > E-SML-20

We can also see that this order is in agreement with the order of the carbon numbers of the saturated fatty acid esters. Thus we can confirm that the melting points of these varying components run parallel with the above series. However, if we consider the melting point of the fixed emulsifier component, the situation is not so simple. For instance, in the case of mixed emulsifiers consisting of SMS and polyoxyethylene fatty acid esters containing 20 mol. of ethoxy-unit in a molecule, SMS has a higher melting point than the rest of these polyoxyethylene derivatives, while the amounts in the emulsifier mixture required for optimum emulsification increase with the decrease in the relative viscosities. These relations are contrary to what can be expected from simple reasoning based upon the fact that the higher melting component increases the viscosity of the emulsion at its optimum composition.

Glyceryl Monostearates. — In Fig. 3, the results obtained, curves 13—17 are shown; all of these curves show two maxima, like the preceding examples. GMS-I and II gave levels of relative viscosities similar to those of the sorbitan esters. However, in the case of the so-called "self-emulsifying types", GMS-IV and III gave the considerably high levels compared with the rest of the cases examined, although those for GMS-V were in an order of magnitude comparable with that of the other nonionic surfactants.

The relative viscosities of this group decreased

TABLE IV. HLB VALUES BY EMULSIFICATION TEST, (A), VISCOSITY TESTS, (B) AND ASSIGNED, (C)

POENP-10	15.5	16.1	13.4	POEOP-10	—	17.8	13.6

in the following order:

$$\text{GMS-IV} > \text{GMS-III} \gg \text{GMS-V} > \text{GMS-II} > \text{GMS-I}$$

The anomalous large values of relative viscosity observed for GMS-III and IV are probably due to the presence of K-soap in these self-emulsifying types, that is, to the effects of the ionic surfactants. On the other hand, the relative viscosity observed for GMS-V, which involves nonionic surfactants alone as a component to make the self-emulsifying type, differs from those for those others involving K-soap.

Other Nonionic Surfactants.—For most of this group, two maxima in the curves of relative viscosities were also observed, as is shown in Fig. 3. (curves 18—26). The magnitudes of the relative viscosities did not show a considerable difference or a systematic variation among them, except for the case of POEL-5, which has a lower viscosity level.

HLB and Viscosities of O/W Emulsions.—In Fig. 3, the top scale $[HLB]_a$ of these figures is of the virtual values of HLB for varying components of the surfactant mixture calculated from the following equations, based upon reasoning similar to that leading to Eq. 1:

$$[HLB]_a = \{[HLB]_m - [HLB]_b x/100\}100/(100-x) \quad (2)$$

where $[HLB]_m$ indicates the HLB value of standard mineral oil, 10.2[4], $[HLB]_b$ is the HLB value for the fixed component, 4.7 for SMS and 14.9 for E-SMS-20, and x is the percentage of the fixed component in the emulsifier mixture. Therefore, when SMS is combined with any other surfactants, Eq. 2 becomes

$$[HLB]_a = (10.2-4.7x/100)100/(100-x) \quad (3)$$

while in the case of E-SMS-20, we have

$$[HLB]_a = (10.2-14.9x/100)100/(100-x) \quad (4)$$

Now, from these virtual values of $[HLB]_a$, we can determine the most probable value of the HLB of the component emulsifier in question from the value of x, which gives the most stable emulsions corresponding to the minima between the two maxima of the $[HLB]_a$ vs. θ curve. The HLB values thus obtained from the relative viscosities of emulsions can be directly compared with the HLB values of nonionic surfactants determined by emulsification tests by visual observation. In our recent paper[3], the HLB values of several nonionic surfactants by emulsification tests were reported. Although the water-oil-emulsifier ratio in the tests differed from that of the present systems, and this makes comparison somewhat difficult, the HLB values reported and the values corresponding to the viscosity minimum between two maxima as listed in Table IV show a good agreement for all nonionic surfactants. However, these experimental values do not always agree with the values calculated from the structural or analytical data of nonionic surfactants, C in Table IV.

Shapes of the Two Maxima and the Distances between Them.—The shapes of the two maxima and the distance between them may be an important measure to specify the characters of a given nonionic surfactant in emulsifications. Throughout these emulsification tests, it can generally be confirmed that the more distant are the two maxima separated in the viscosity curve, the more insensitive becomes the stability of the emulsion towards its surfactant composition. For this reason, we may introduce the term, "Viscosity Spectra of the Nonionic Surfactant".

Summary

O/W emulsions of mineral oil were prepared, using several types of nonionic surfactants, and their relative viscosities were measured with

a rotating-cup viscometer, together with microscopic and visual observation of the emulsions.

It was found that there are two maxima in the curve of the relative viscosity vs. the ratio of the two surfactants in the mixed emulsifier employed. From these figures, the relative effects of the nonionic surfactants on the emulsion viscosities were discussed.

It was confirmed that the emulsion viscosity at the optimum composition decreases in the following order:

for sorbitan fatty acid esters,

$$SMS > SMP > SML > SMO > SSO > STS$$

for polyoxyethylene sorbitan fatty acid esters,

$$E\text{–}SMS\text{–}20 > E\text{–}SMP\text{–}20 > E\text{–}SMO\text{–}20 > E\text{–}SML\text{–}20$$

for glyceryl monostearates,

$$GMS\text{–}IV > GMS\text{–}III \gg GMS\text{–}V > GMS\text{–}II > GMS\text{–}I$$

For the other types the order of the series was not distinct. In the former two series, the orders of the arrangements are parallel with those of the decreasing carbon atom numbers in the molecule in the case of saturated fatty acid derivatives.

The soap effect is considered to appear in the case of glyceryl monostearates, the so-called self-emulsifying types of the emulsifier.

Using the scale of viscosity vs. virtual HLB value, we can determine by means of emulsification the most probable HLB value of the nonionic surfactants.

Good agreements are seen between the HLB values determined by viscosity minimum and those determined by the emulsification test reported on in the preceding paper.

The author wishes to thank Professor Tsunetaka Sasaki, of Tokyo Metropolitan University, for his encouragement and advice in this work.

Viscosities of O/W Emulsions Stabilized by Nonionic Surfactants. II. Effects of Oil Mixtures on the Emulsion Viscosities

By Noriaki OHBA

(Received August, 28, 1961)

In a preceding paper[1], the effects of nonionic surfactants on the emulsion viscosities were measured, and the relations between the structures of nonionic surfactants and the viscosities of emulsions stabilized by them were studied. In another paper[2], the effects of the substances added to the oil on the HLB values of the mixtures thus obtained were determined, according to the concept of HLB suggested by Griffin[3], as being equal to the HLB value of that mixed surfactant which gives the most stable emulsion. Thus we studied the relations between the HLB values and the nature of the materials added to the mineral oil.

Several factors which influence the viscosities of the emulsion have been discussed by several workers[4] in connection with the properties of the oil phase of O/W emulsions. In the practice of emulsion techniques, a certain "thickener" is added to increase the viscosity of a given emulsion. Certain waxes and higher fatty alcohols, such as beeswax, cetyl alcohol and stearyl alcohol, are such examples.

Concerning thses problems, several oil mixtures were selected and were emulsified with nonionic surfactant mixtures of a fixed constituency. The viscosities of the emulsions thus obtained were measured and discussed in relation to the properties of the components of the oil mixture.

Experimental

Nonionic Surfactants.—To make comparison simple, sorbitan monostearate (SMS) and polyoxyethylene sorbitan monostearate (E-SMS-20) were adopted as standards of the nonionic emulsifiers, as has been described in the preceding paper[2]. The HLB values adopted for these materials are 4.7 for SMS and 14.9 for E-SMS-20. When the required HLB of an oil mixture is over 14.9, polyoxyethylene

cetyl ether (POEC-20), having the HLB value of 18.4, was adopted in place of E-SMS-20.

Oil and Waxes.—"Carnation White Mineral Oil" produced by the Sonneborn Co., USA, was used as the fixed component of the oil mixture to be emulsified, its HLB value being 10.2 and its average viscosity, 70 cp.

Several materials were used as the varying component of the oil mixture. They were selected from those described in the foregoing paper[2]; in this paper we distinguish acetylated glyceryl mono-oleate into two, i. e.,

AGMO-I Acetylated mono-oleate (OH. V.=4)
AGMO-II Acetylated mono-oleate and mono-stearate (OH. V.=4).

These materials were used in a varying ratio to the fixed component of mineral oil.

Viscosity Measurements.—The emulsions used in the present experiment were prepared by the same method as has been described in a preceding paper[5], i. e., that method involving phase inversion. The HLB values of these emulsions were also determined by the same method as presented in another paper[2].

TABLE I. COMPOSITION OF O/W EMULSIONS

Oil mixture	40.0%
Emulsifiers	
SMS+E-SMS-20	4.0%
Distilled water	56.0%

The compositions of these emulsions are shown in Table I. After these emulsions had been left standing for about 20 hr., their viscosities were measured, by a "MacMichael type" rotating-cup viscometer which indicates the values of strain θ as the deflection angle of inner cylinder, for varying angular velocities, Ω, of the cup. For convenience, the values of strain θ at 50 r.p.m. were adopted as the relative viscosities of the emulsions.

Results and Discussion

Viscosity and Composition Diagrams.—The results obtained are illustrated in Figs. 1—4.

In Fig. 1 we can see that the viscosities of S-Ac/mineral oil mixtures increase steeply when the S-Ac content exceeds 10% of the oil mixture. On the other hand, in the case of L-Ac, such an increase was observed in the concentration ranges beyond 15%.

In the case of fatty alcohols, as shown in Fig. 2, the effects of C-Alc were remarkably greater than those of La-Alc and L-Alc. A sudden increase in this viscosity vs. the composition diagram for C-Alc was observed at a 5% content of C-Alc in the oil mixture, while for the cases of the other two alcohols a similar increase was observed at a 20% content.

We can see from these results that, among these fatty acids and alcohols, C-Alc is the most effective additive to the oil phase to increase the emulsion viscosity, both with respect to the amount required and to the degree of viscosity increase. Such an effect of C-Alc can be succcssfully applied in certain fields of emulsion technique.

In Fig. 3, viscosity vs. composition diagrams for acetylated esters are shown. In this figure, it can be seen that AGMS-I, -III and -IV have a greater effect on the viscosities of emulsions than AGMO-I and II. Among these three stearates, AGMS-IV shows a remarkably large effect on the emulsion viscosity, its magnitude being comparable to that of C-Alc. It is also used for the similar purpose of increasing viscosity. AGMS-III and I are effective to the same extent.

The viscosities of emulsions containing AGMO-I and II are considerably different

from that of AGMS-I in the range of concentration studied. As to AGMO-I and -II, the former being oleic acid ester and the latter being a mixture of oleic and stearic acid ester, as can be confirmed from the analytical data, AGMO-II shows a slight effect in increasing the emulsion viscosity, while AGMO-I does not, in the region beyond a 20% content in the oil.

Figure 4 shows the results of viscosity measurements for waxes. B-W had a fairly large effect in increasing the emulsion viscosity, while La and C-W showed little influence over the whole range of concentration examined.

The sudden increase in the emulsion viscosity by B-W occurs at a certain content of B-W within the region from 10 to 20% of the oil mixture, as in the case of C-Alc, AGMS-IV, etc., but the increase is smaller for B-W.

As a whole, we can see in Figs. 1—4 that the magnitudes of the effects of these additives on the increasing emulsion viscosity are in the following order, with respect both to the amount required for the sudden increase in viscosity and to the rate of its increase:

C-Alc, AGMS-IV > S-Ac, AGMS-III > La-Alc > AGMS-I, L-Ac, L-Alc > B-W > AGMO-II, AGMO-I, C-W, La

Factors Affecting the Emulsion Viscosities.— It was reported in a preceding paper[2] that the effects of additives on the required HLB values of the oil mixtutres vary both with the nature and the amount of the additives in the oil mixture.

Concerning the emulsion viscosities, Toms[6] and Sherman[7] reported that the emulsion viscosity is affected greatly by the chemical nature of the internal phase, while the viscosity of the internal phase is of no consequence.

To make sure of the factors affecting the emulsion viscosities, several data were measured and are listed in Table II; the substances are arranged in the decreasing order of influence on the emulsion viscosities shown above. In this table, the following abbreviations are used:

A: Amount of additive required to increase the emulsion viscosity ten times as much as that of the mineral oil emulsion without any additives; these amounts are determined from the results shown in Figs. 1—4.

Δ: The increase in the required HLB value of the mixture from that of mineral oil[2] at the additive contents corresponding to A.

Figure 5 shows graphically the correlations between "A" and other factors. From these figures we cannot deduce any simple correlation between these factors which may be used to find an effective additive for increasing emulsion viscosity. However, we can safely say that in order to be effective as an additive in increasing emulsion viscosity, a substance's iodine value should be small, while an ineffective additive always shows a low Δ as well as a low hydroxyl value. The melting point of an additive has, on the whole, no correlation with the power of increasing emulsion viscosity. The acid value also shows no correlation with the viscosity of the emulsion formed.

These general tendencies may sometimes become useful guides for the selection of additives to increase emulsion viscosity.

Critical Phenomena. — Throughout all the experiments shown in Figs. 1—4, we can see a fairly distinct critical phenomenon. That is, the viscosities of these O/W emulsions increase steeply beyond a certain critical content of the

additives, and these critical contents form characteristics of each material. The critical contents determined for the substances are listed, though roughly, in Table III. In this table, the substances are arranged in the decreasing order of their critical contents, which order agrees as a whole with that shown in Table II. That is, a substance having a lower

TABLE III. CRITICAL CONTENTS OF SUBSTANCES

	Critical content, %		Critical content, %
C-Alc	5	L-Ac	10∼20

La-Alc	10∼20	La	>30
AGMS-I	10∼20		

critical content shows a stronger tendency to increase the emulsion viscosity than a substance having a higher critical content.

We may also notice that the additive shows no effect in increasing emulsion viscosity when it does not contain any polar group other than ester linkage.

Besides the critical point, the inclination of viscosity vs. additive content diagrams beyond the critical point also offers some measure of the efficiency of additives in increasing emulsion viscosity, with some exceptions, as in the case of B-W, where the small critical content does not always correspond to the steep inclination of the viscosity vs. content diagram beyond the critical point. Precisely speaking, therefore, we should take account of both the critical point and the inclination of the steeper part of the diagram in estimating the efficiency of an additive in increasing emulsion viscosity.

Although many studies on the emulsion viscosities have been carried out by several workers[4,6,7], none of them is entirely satisfactory in explaining the phenomena. At least, the chemical structure of the additives, and the change in the viscosity of the external phase produced by the solubilization of the oil component into micelles of the emulsifier which is considered to exist in the external

phase, are considered to be important in elucidating the phenomena. For the further elucidation of these critical phenomena, however, more details must be studied.

Summary

To study the effects on the viscosities of O/W emulsions of the addition of several materials to the oil phase, oil mixtures were emulsified and the viscosities of the emulsions so obtained were measured with a rotating-cup viscometer,

The effects of these additives in increasing emulsion viscosity are in the following order, with respect both to the amounts required to give a specified increase in viscosity and to the minimum amount required for a sudden increase in viscosity:

C-Alc, AGMS-IV > S-Ac, AGMS-III > La-Alc > AGMS-I, L-Ac, L-Alc > B-W > AGMO-II, AGMO-I, C-W, La

It was confirmed that in order to be effective as an additive in increasing emulsion viscosity, the iodine value should be small, while an ineffective additive always shows a low Δ as well as a low hydroxyl value. The melting point of an additive has, on the whole, no correlation with the power of increasing the emulsion viscosity. The acid value also shows no correlation with the viscosity of the emulsion formed.

A sudden increase in emulsion viscosity was observed beyond a certain amount characteristic of each additive.

The author wishes to express his deep gratitude to the members of his laboratory for their close cooperation in this work.

The Synthesis of Azulene Derivatives from Troponoids[*1]

By Tetsuo NOZOE, Shuichi SETO[*2], Shingo MATSUMURA[*2] and Yasuhiro MURASE[*3]

(Received January 9, 1962)

Various methods for the synthesis of azulene derivatives have in the past been reported by numerous organic chemists. Almost all of these methods required a dehydrogenation reaction in the final stage, and, although many improvements have been effected, these have resulted generally in a poor yield[1].

The present authors have recently found that the condensation of troponoids, such as 2-halo- and 2-methoxytropone derivatives, with ethyl cyanoacetate or malononitrile, in the presence of a base, afforded 2-amino- and 2-hydroxyazulene derivatives in one step and in a fairly good yield. Although short summaries of this work have already been published[2], a detailed description of the new synthetic method has not yet been given.

In this paper, the authors wish to describe this synthetic procedure in full detail. The reaction of 2-chlorotropone (Ia) with two molar equivalents of ethyl cyanoacetate in absolute ethanol, in the presence of two molar equivalents of sodium ethoxide, was allowed to stand at room temperature; a sparingly soluble sodium salt, from which an acid substance (II) (m. p. 188~189°C), was liberated by treatment with mineral acid, and orange crystals (III), $C_{16}H_{17}O_4N$ (m. p. 93~94°C) precipitated out. The mother liquor from these precipitates afforded a small amount of colorless crystals (IV), m. p. 135~137°C. The main product III was obtained in about a 70% yield. Under the same conditions, the condensation of 2-bromotropone (Ib) with ethyl cynoacetate

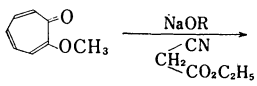
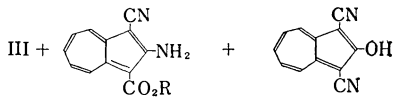
gave III in about a 60% yield. The reaction of Ia with two molar equivalents of ethyl sodiocyanoacetate in dehydrated benzene yielded II and III, but not IV.



Ia: X=Cl
Ib: X=Br



II III IV

The use of tertiary amine in place of alkoxide as the condensation agent resulted in the formation of III in a 35% yield and of a small amount of orange crystals (V) (m. p. above 300°C), sparingly soluble in organic solvents. The reaction of 2-methoxytropone (Ic) with two molar equivalents of ethyl cyanoacetate, in the presence of two molar equivalents of sodium ethoxide, afforded III in a 5% yield and a 7% yield of orange crystals (VI), $C_{14}H_{12}O_2N_2$, of m. p. 167~168°C. The remainder

Ic

VI: R=C_2H_5 VII
XX: R=CH_3

(about 75%) was an acid substance (VII), m. p. above 300°C, sparingly soluble in organic solvents. The application of one molar equivalent of alkoxide to Ic afforded III in over a 70% yield, while the yields of VI and VII were very poor.

It was interesting that the ratio of these products differed markedly according to the amount of alkoxide[3].

The ultraviolet absorption spectra[4] (Fig. 1) of II, III and VII are very similar to each other, and these compounds are assumed to have a common skeletal structure.

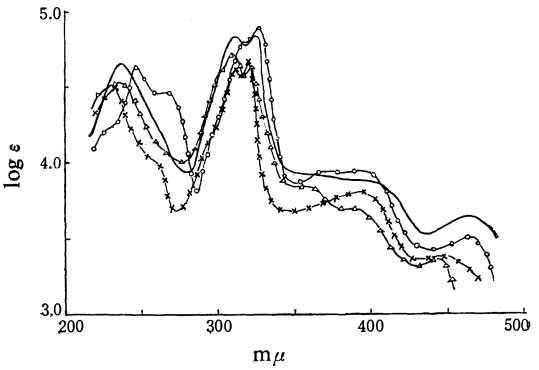


Fig. 1. UV absorption spectra of II, III, VII and XXI in methanol.
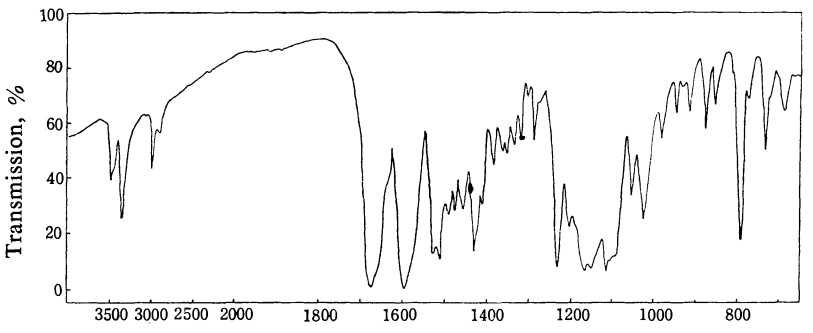
——— II, —○— III, —△— VII, —×— XXI

The main product III easily formed picrate melting at 125°C and styphnate melting at 150°C. The passage of dry hydrogen chloride gas through a dehydrated benzene solution of III formed reddish orange crystals assumed to be the hydrochloride of III, but the free compound III was easily liberated when the salt was left in the air.

The infrared absorption spectrum[5] of III,



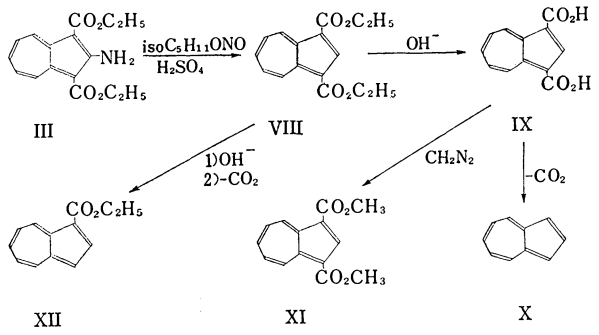


Fig. 2. IR absorption spectrum of III in KBr disk.

3) A similar phenomenon has also been observed in the cases of the reaction of tropolone methyl ether (2-methoxytropone) derivatives, such as hinokitiol methyl ether and 4-methyltropolone methyl ether etc., with ethyl cyanoacetate (T. Nozoe et al., to be published).

4) Ultraviolet spectra were measured with a Beckman Model DU spectrophotometer.

5) Infrared spectra were measured with a Perkin-Elmer Model 21 double-beam spectrophotometer.

as indicated in Fig. 2, exhibits absorption bands at 3500 and 3310 cm^{-1} for the primary amino group, and at 1660 and 1225 cm^{-1} for the ester group conjugated with the unsaturated bond. The attempted acetylation of III with acetic anhydride containing one drop of pyridine failed to give its acetate. The attempted deamination of the compound III with isoamyl nitrite in its ethanolic solution, in the presence of concentrated sulfuric acid, resulted in changing the color from orange to brownish red, and gave reddish violet crystals (VIII), $C_{16}H_{16}O_4$, of m. p. 120~121°C. The hydrolysis of VIII with an ethanol-aqueous solution of potassium hydroxide afforded a crystalline dicarboxylic acid IX, m. p. 270°C (decomp.), very sparingly soluble in organic solvents.

The thermal decomposition of IX produced blue crystals X, m. p. 98~99°C, with an odor of naphthalene. The ultraviolet (Fig. 3), visible[6], and infrared absorption spectra of compound X and its melting point are identical with those of azulene; by mixed fusion it was confirmed that X was azulene.

The position of the principal maximum (513 mμ) in the visible spectrum of compound VIII (Fig. 3) was found to be in excellent agreement with that of dimethyl azulene-1, 3-dicarboxylate (511 mμ), first synthesized by Anderson et al.[7] The action of diazomethane on IX afforded red crystals XI, m. p. 170~171°C. The melting point of XI was in good agreement with that of dimethyl azulene-1, 3-dicarboxylate reported in the literature.

Consequently, compound VIII was diethyl azulene-1, 3-dicarboxylate, and IX was its free dicarboxylic acid, azulene-1, 3-dicarboxylic acid. The maximum absorption of compound III (465 mμ) in the visible region causes a shift toward a shorter wavelength (48 mμ) than that of VIII. The additivity of the spectral shifts in the visible region caused by alkyl groups on the different positions of azulene ring was first found by Plattner et al.[1a] Not only alkyl groups, but also other *o, p*-directing groups are found to cause a hypsochromic shift of the absorption bands when substituted at the even-numbered positions in the azulene nucleus[8,9]. These considerations supported the view that compound III was diethyl 2-aminoazulene-1, 3-dicarboxylate. The hydrolysis of VIII with one molar equivalent of potassium hydroxide gave a red crystalline carboxylic acid sparingly soluble in organic solvents, and its decarboxylation by heating at 240~250°C under a partially reduced pressure afforded, in addition to azulene, ethyl azulene-1-carboxylate (XII) as a reddish violet oil which formed a picrate of m. p. 124°C.

The infrared absorption spectrum of compound VI exhibits the absorption bands due to the primary amino group and to the cyano and ester carbonyl groups conjugated with an unsaturated bond. From these spectral data and from the molecular formula, it was assumed compound (VI) was ethyl 2-amino-3-cyano-azulene-1-carboxylate[10]. The hydrolysis of III with an ethanol-aqueous solution of potassium hydroxide afforded 2-aminoazulene-1, 3-dicarboxylic acid (XIII), m. p. 158~160°C (decomp.), sparingly soluble in organic solvents. Its decarboxylation by heating at 125~130°C in pyridine or heating at 170~175°C under a reduced pressure gave, in a good yield, 2-aminoazulene (XIV) as red crystals, m. p. 93~94°C, the acetylation of which with acetic anhydride afforded 2-acetamidoazulene (XV) as violet crystals, m. p. 168~169°C. Compound XIV easily formed an unstable picrate of m. p. 145°C (decomp.). 2-Aminoazulene appears more stable than the 1-aminoazulene prepared

6) Visible absorption spectra were measured with a Beckman DK spectrophotometer.

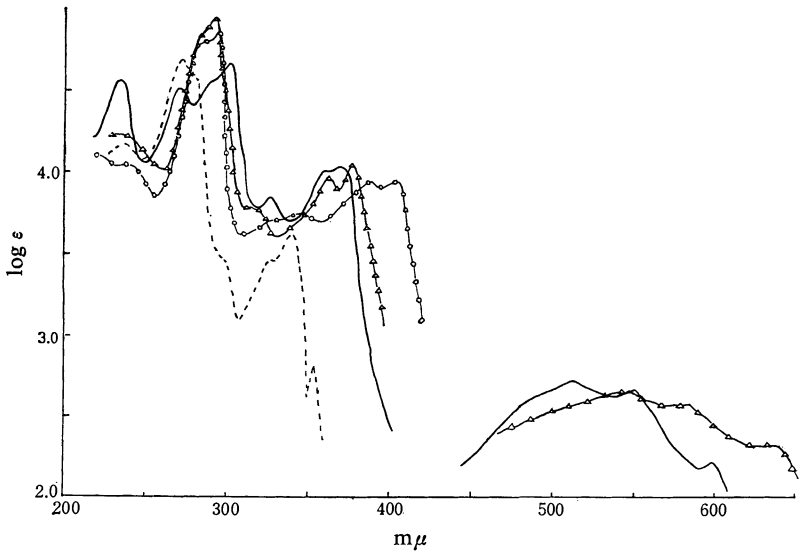
10) The present authors have previously given an erroneous structure of ethyl 2-amino-3-cyano-azulene-1-carboxylate for compound A of m. p. 135~137°C[1b]. Re-examination of the structure of the compound A has shown that A is not an ethyl ester but a methyl ester converted from compound VI by ester exchange reaction.



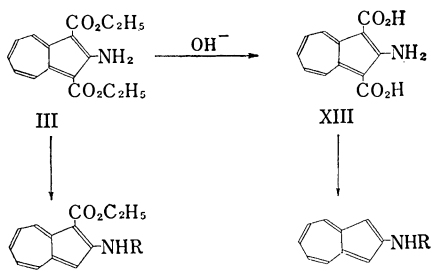


Fig. 3. UV absorption spectra of VIII, X, XIV and XV in methanol.
——— VIII, ------ X, —○— XIV, —△— XV

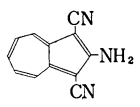
by Schulze and Heilbronner[11]. However, 2-aminoazulene also becomes a brownish black substance on exposure to air and light for a few days. The hydrolysis of III with one molar equivalent of potassium hydroxide yielded a crystalline carboxylic acid, and its decarboxylation by heating in pyridine afforded ethyl 2-aminoazulene-1-carboxylate (XVI) as red crystals, m. p. 68~70°C. The acetylation of XVI with acetic anhydride gave ethyl 2-acetamidoazulene-1-carboxylate (XVII) as red crystals, m. p. 140~141.5°C.

XVI : R=H
XVII : R=Ac

XIV : R=H
XV : R=Ac

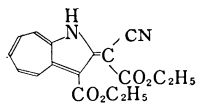
The ultraviolet and visible absorption spectra of XIV and XV are shown in Fig. 3. The application of nitrous acid to XIV resulted in a change of color from green to dark brown, and no pure product could be isolated.

Although compounds II and VII are acid substances, these compounds do not dissolve in an aqueous solution of sodium hydrogencarbonate, but exhibit a dark brown coloration with ferric chloride in ethanol. There are absorption bands for the unsaturated ester carbonyl group at 1655 cm^{-1}, for the unsaturated cyano group at 2200 cm^{-1}, and for the hydroxyl group at 3100 cm^{-1} in compound II, while absorption bands due to unsaturated cyano and hydroxyl groups are present at 2200 and 3100 cm^{-1} respectively in compound VII. The heating of II with an excess of acetic anhydride containing pyridine gave its acetate XVIII as red crystals, m. p. 142°C. Under the same conditions, VII afforded its acetate XIX as red crystals, m. p. 192°C. The infrared absorption band due to the carbonyl group at 1655 cm^{-1} in compound II is displaced to the higher frequency region of 1702 cm^{-1} in compound XVIII. It would be rational to attribute this shift to an intramolecular hydrogen bonding between the carbonyl and hydroxyl groups in compound II. From these facts, it was assumed that compound II was ethyl 3-cyano-2-hydroxyazulene-1-carboxylate and that compound VII was 1, 3-dicyano-2-hydroxyazulene (1, 3-dicyanoazulen-2-ol).



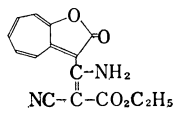
The reaction of Ic with ethyl cyanoacetate, in the presence of two molar equivalents of sodium methoxide in place of sodium ethoxide, afforded methyl 2-amino-3-cyanoazulene-1-carboxylate[10] (XX) as orange crystals, m. p. 135~137°C, in a poor yield, besides III, VI and VII. The condensation of 2-chlorotropone (Ia) with malononitrile, in the presence of sodium ethoxide or tributylamine, afforded, in a quantitative yield, very sparingly soluble orange

11) J. Schulze and H. Heilbronner, *Helv. Chim. Acta*, **41**, 1492 (1958).



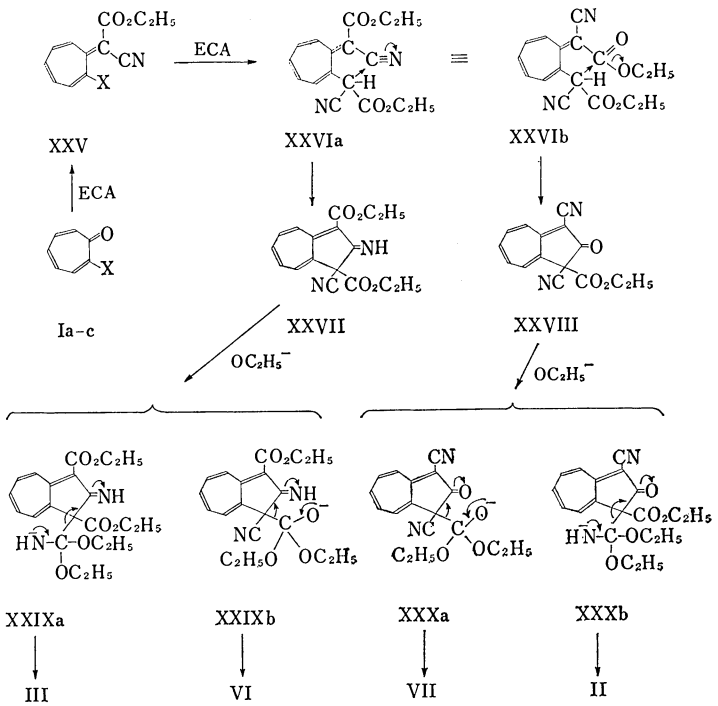
crystals (XXI), m. p. above 300°C. The ultraviolet absorption spectrum of compound XXI, as indicated in Fig. 1, is very similar to that of III; moreover, there are absorption bands for amino and unsaturated cyano groups in the infrared spectrum of compound XXI. Consequently, these observations support the view that compound (XXI) is 2-amino-1, 3-dicyanoazulene(1,3-dicyano-2-azulenamine). The hydrolysis of the cyano group of II, VII and XXI by acid or alkali was unsuccessful.

The formation of 2-amino-1, 3-dicyanoazulene (XXI) is explained by the reaction of two moles of malononitrile with one mole of 2-chlorotropone; even when one mole of malononitrile was reacted with one mole of 2-chlorotropone the same azulene derivative XXI was formed. The same result was found in the reaction of 2-chloro- or 2-methoxytropone with ethyl cyanoacetate. The use of one mole of the dimer of ethyl cyanoacetate, i. e. ethyl α-cyano-β-aminoglutaconate (XXII), instead of two moles of ethyl cyanoacetate, however, failed to give any azulene; the products were the heterocyclic azulenoid compounds XXIII and XXIV[12].



From the foregoing experimental facts, it is considered that the first intermediate XXV

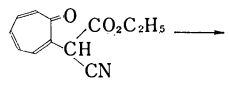
XXI



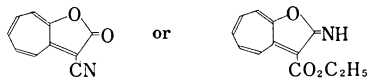
XXIII

XXIV

formed by the reaction of both ethyl cyanoacetate and 2-halo- or 2-methoxytropone is much more reactive than the original troponoids Ia–c and immediately reacts with the second mole of the reagent to form second intermediates such as XXVIa and XXVIb, whose Ziegler-type condensation, forming a five-membered ring, would give a bicyclic intermediate XXVII and XXVIII. By the polarizing effect of the carbonyl or imino group in the 2-position, and the attack on the ethoxycarbonyl or cyano group by the base (alkoxide anion), the intermediate suffers a cleavage of the C–C bond[13] through the third intermediates, XXIXa–b and



ECA=Ethyl cyanoacetate



Scheme 1

13) A. C. Cope, "Organic Reactions", Ed. by R. Adams, Band IX, John Wiley & Sons, Inc., New York (1957), p. 107.

XXXa–b, and forms the final azulenoid products II, III, VI and VII, as is shown in Scheme 1. More recently, it has been found that an application of malononitrile to tropone itself[14], or ethyl cyanoacetate or malononitrile to 8, 8-disubstituted heptafulvenes[15] (e.g. XXV: X=H), also gives the afore-mentioned azulene. The structure of the first intermediate might also be tropone derivative XXXI or its cyclization product XXXIIa or b, rather than the afore-mentioned heptafulvene derivative XXV.

XXXI

XXXIIa XXXIIb

In this connection, it is interesting to note that the compound of the XXXIIa type also gave azulene derivatives in its reaction with ethyl cyanoacetate in the presence of an excess of sodium alkoxide[16]. All this evidence seem to confirm the general correctness of our proposed mechanism of this novel azulene synthesis starting with the troponoids.

After the completion of this study[2a], Ziegler and Hafner very interestingly reported a practical synthetic method of azulenes; they also found that the alkylation and arylation of the 4- and 8-positions could be effected by the application of organometallic compound to azulenes[17]. However, this method would have some disadvantages for the synthesis of special azulene derivatives possessing versatile groups, such as hydroxyl, amino, hydrazino and mercapto groups, on the five or seven-membered ring. In our method, the azulenes first formed always have a versatile functional group, i.e., amino or hydroxyl in the 2-position, which may be easily substituted afterwards by various groups; moreover, such groups may be easily introduced in the seven-membered ring while in the troponoid stage used for this synthesis. Accordingly, our process would complement the Ziegler-Hafner method for azulene synthesis.

As a simpler and more useful process has recently been found in several laboratories for the synthesis of tropone and tropolone[18], the novel process for the synthesis of azulene derivatives elaborated by us would have a very great significance. Thus, a large number of new azulene derivatives produced by the application of this process are now continuously being synthesized in the authors' laboratory[15b].

The yield of compound V is so very poor that further examination of this product was not made. Compound IV is identical with the product obtained by the condensation of salicylaldehyde with ethyl cyanoacetate, and the structure of compound IV was established to be 2-amino-2-(cyano-ethoxycarbonylmethyl)-3-ethoxycarbonyl-α-benzopyran[19].

Experimental[20]

Reaction of 2-Chlorotropone (Ia) and Ethyl Cyanoacetate.—a) To a suspension of ethyl sodiocyanoacetate prepared from 5 g. of metallic sodium, 27 g. of ethyl cyanoacetate and 100 ml. of absolute ethanol, a solution of 15 g. of Ia dissolved in 100 ml. of absolute ethanol was added drop dy drop under ice-cooling, and the mixture was stirred thoroughly. Immediately the color of the solution changed from yellow to orange. The mixture was allowed to stand at room temperature for 4 hr., and the orange crystals that separated out were then collected by filtration. The collected crystals were dissolved in benzene to be separated into benzene-insoluble and soluble portions. The addition of water to the benzene-insoluble portion precipitated 900 mg. of orange-yellow crystals insoluble in water. This substance was extremely sparingly soluble in various organic solvents. Its recrystallization from a large quantity of ethanol afforded the orange-yellow sodium salt of II, m.p. above 300°C.

Found: N, 4.98. Calcd. for $C_{14}H_{10}O_3NNa$: N, 5.34%.

A mixture of sodium salt of II and 5 ml. of 6 N hydrochloric acid was warmed on a water bath for 1 hr. The orange crystals that separated out were recrystallized from benzene, and 370 mg. of orange needles II, m.p. 188~189°C, was obtained.

Found: C, 69.78; H, 4.63; N, 5.92. Calcd. for $C_{14}H_{11}O_3N$: C, 69.70; H, 4.59; N, 5.80%.

UV λ_{max}^{MeOH} mμ (log ε): 235 (4.53), 311 (4.72), 325 (4.49), 355 (3.77), 470 (3.34).

The evaporation of the solvent of the benzene-soluble portion left orange crystals, m.p. 80~83°C. Repeated recrystallization from ethanol afforded 19 g. of orange prisms III, m.p. 93~94°C.

Found: C, 66.93; H, 6.26; N, 4.82. Calcd. for $C_{16}H_{17}O_4N$: C, 66.88; H, 5.96; N, 4.88%.

20) All melting points are uncorrected. The microanalyses were carried out by Mr. S. Ohyama, Mr. S. Azumi and Miss. A. Iwanaga, to whom the authors are deeply indebted.

UV λ_{max}^{MeOH} mμ (log ε): 245 (4.42), 265 (4.36), 315 (4.77), 326 (4.69), 380 (3.84), 465 (3.41).

The mother liquor, after the separation of the above products, was evaporated under a reduced pressure, the residue was dissolved in benzene, and the solution was washed with water. After being dried over anhydrous sodium sulfate, the solvent was evaporated. The orange crystalline residue thereby obtained was recrystallized from ethanol and 5 g. of colorless prisms IV, m. p. 135~137°C, was obtained.

Found: C, 61.37; H, 5.25; N, 8.42. Calcd. for $C_{17}H_{18}O_5N_2$: C, 61.81; H, 5.49; N, 8.49%.

UV λ_{max}^{MeOH} mμ (log ε): 296 (3.72), 305 (3.69), 357 (3.60).

The recrystallization of the mother liquor afforded 2.5 g. of III.

b) To a sodium ethoxide solution prepared from 1 g. of metallic sodium and 20 ml. of absolute ethanol, 5.4 g. of ethyl cyanoacetate was added to form its sodio compound, and the ethanol was evaporated completely. The sodio compound was suspended in 30 ml. of dehydrated benzene, and the solution of 3 g. of Ia dissolved in 50 ml. of dehydrated benzene was stirred into it, by which process the solution became a dark reddish orange and an orange precipitate began to separate out. The orange precipitates were collected by filtration, and the addition of water afforded 200 mg. of sodium salt of II. The reaction mixture left after the removal of the above substance was washed with water. After being dried over anhydrous sodium sulfate, the solution was passed through a column of alumina. The column was eluted with benzene, and the solvent of the effluent was evaporated. The crystalline residue was recrystallized from ethanol to afford 1.2 g. of III.

c) To a solution of 500 mg. of Ia and 2.7 g. of ethyl cyanoacetate dissolved in 10 ml. of absolute ethanol, 1.7 g. of tributylamine was added; the color of the solution gradually changed from yellow to orange. The reaction mixture was allowed to stand overnight at room temperature, and the solvent was evaporated. The orange residue was dissolved in benzene, and the solution was washed with dilute nitric acid and water. After being dried over anhydrous sodium sulfate, the solution was passed through a column of alumina. The column was eluted with benzene, and 350 mg. of III was obtained. Further elution of the column with ethyl acetate afforded ca. 10 mg. of orange crystals. Recrystallization from acetone gave orange scales V, m. p. above 300°C.

Picrate of III.—Found: C, 51.25; H, 3.63; N, 10.64. Calcd. for $C_{22}H_{20}O_{11}N_4$: C, 51.16; H, 3.90; N, 10.85%. Reddish orange needles, m. p. 125~126°C, as recrystallized from ethanol. The solution of picrate-dissolved ethanol was passed through a column of alumina. The column was eluted with benzene, and III was easily regenerated.

Styphnate of III.—Found: N, 10.15. Calcd. for $C_{22}H_{20}O_{12}N_4$: N, 10.52%. Orange scales, m. p. 147~150°C, as recrystallized from ethanol.

Hydrochloride of III.—Dry hydrogen chloride gas was passed through a solution of III dissolved in dehydrated benzene, and the reddish orange prisms that separated out were collected by filtration. The product underwent a change to the starting material by atmospheric moisture.

Action of Acetic Anhydride on III.—A solution of 100 mg. of III dissolved in 1 ml. of acetic anhydride, in the presence of one drop of pyridine, was heated at 120~130°C for 3 hr. The excess acetic anhydride was evaporated under a reduced pressure, and the residues were recrystallized from ethanol, by which 80 mg. of III was recovered.

Reaction of 2-Bromotropone (Ib) with Ethyl Cyanoacetate.—To a suspension of ethyl sodiocyanoacetate prepared from 780 mg. of metallic sodium, 4 g. of ethyl cyanoacetate and 10 ml. of absolute ethanol, a solution of 3 g. of Ib dissolved in 7 ml. of absolute ethanol was added and the mixture was stirred thoroughly. Immediately the color of the solution changed from yellow to a dark reddish orange. After the solution had stood overnight at room temperature, the orange crystals that separated out were collected by filtration. The collected crystals were dissolved in benzene, and the solution was passed through a column of alumina. The column was eluted with benzene, and the solvent was evaporated. The crystallized residue was recrystallized from ethanol, and 2.6 g. of III was obtained. The mother liquor, after the separation of the above crystals, was concentrated, and the residue thereby obtained was dissolved in benzene. The solution was passed through a column of alumina, and the column was eluted with benzene. Evaporation of the solvent from the effluent afforded 400 mg. of III.

Reaction of 2-Methoxytropone (Tropolone Methyl Ether) (Ic) with Ethyl Cyanoacetate.—a) Into a suspension of ethyl sodiocyanoacetate prepared from 600 mg. ($2.6/10^2$ mol.) of metallic sodium, 3.0 g. ($2.67/10^2$ mol.) of ethyl cyanoacetate and 10 ml. of absolute ethanol, a solution of 1.8 g. ($1.3/10^2$ mol.) of Ic dissolved in 10 ml. of absolute ethanol was stirred under ice-cooling. After allowing the solution to stand overnight at room temperature, a large amount of precipitate separated out and was collected by filtration. The collected precipitate was dissolved in benzene to be separated into benzene-soluble (A) and benzene-insoluble (B) portions. Evaporation of the solvent of A portion left orange crystals, m. p. 160~164°C. Four recrystallizations from ethanol afforded 210 mg. of orange scales VI, m. p. 167~168°C.

Found: C, 69.41; H, 4.88; N, 11.82. Calcd. for $C_{14}H_{12}O_2N_2$: C, 69.99; H, 5.03; N, 11.66%.

UV λ_{max}^{MeOH} mμ (log ε): 238 (4.06), 310 (4.75), 322 (4.78), 368 (3.81), 445 (3.04).

The benzene-insoluble portion was dissolved in water, and the solution was neutralized with dilute sulfuric, acid, from which 2.1 g. of a brown precipitate was obtained. This substance was sparingly soluble in organic solvents. Its recrystallization from a large quantity of acetone afforded 1.92 g. of orange-yellow scales VII, m. p. above 300°C.

Found: C, 73.98; H, 3.42; N, 14.06. Calcd. for $C_{12}H_6ON_2$: C, 74.22; H, 3.11; N, 14.43%.

UV λ_{max}^{MeOH} mμ (log ε): 233 (4.35), 311 (4.72), 322 (4.62), 362 (3.86), 448 (3.50).

The mother liquor, after the separation of the

above products, was evaporated under reduced pressure. The orange residue thereby obtained was dissolved in benzene; the evaporation of the benzene left an oily substance. The residue was repeatedly digested with hot petroleum ether (b. p. 60~70°C) to be separated into petroleum ether-soluble and insoluble portions. The solvent of the petroleum ether-soluble portion was evaporated. The orange crystalline residue hereby produced was recrystallized from ethanol to give 190 mg. of III. Recrystallization of the petroleum ether-insoluble portion from the ethanol-benzene mixture afforded ca. 10 mg. of VI.

b) To a suspension of ethyl sodiocyanoacetate prepared from 600 mg. ($2.59/10^2$ mol.) of metallic sodium, 6.04 g. ($5.34/10^2$ mol.) of ethyl cyanoacetate and 10 ml. of absolute ethanol, 3.64 g. ($2.74/10^2$ mol.) of Ic was added, drop by drop under ice-cooling, and the mixture was stirred thoroughly. When the reaction mixture was treated as in the foregoing case, 5.5 g. of III, 100 mg. of VI and 500 mg. of VII were obtained.

c) To a suspension of ethyl sodiocyanoacetate prepared from 1.42 g. of sodium methoxide, 3.02 g. of ethyl cyanoacetate and 5 ml. of absolute ethanol, a solution of 1.8 g. of Ic dissolved in 10 ml. of absolute ethanol was added, and the mixture was treated as in the foregoing cases. The orange crystals were separated out from the benzene-soluble portion, besides 200 mg. of III, and 120 mg. of VI. The orange crystals were recrystallized from ethanol to afford 40 mg. of orange scales XX, m. p. 135~137°C.

Found: C, 68.98; H, 4.36; N, 12.56. Calcd. for $C_{13}H_{10}O_2N_2$: C, 69.01; H, 4.46; N, 12.38%.

UV λ_{max}^{MeOH} mμ (log ε): 238 (4.05), 310 (4.73), 322 (4.77), 368 (3.79), 445 (3.03).

The benzene-insoluble portion was acidified with dilute sulfuric acid, from which 2 g. of VII was obtained.

Diethyl Azulene-1, 3-dicarboxylate (VIII). — To a solution of 1 g. of III dissolved in 100 ml. of ethanol containing 500 mg. of concentrated sulfuric acid, 500 mg. of isoamyl nitrite was added. The reaction mixture was allowed to stand overnight at room temperature. The color of the solution gradually changed from an orange, reddish green, to a brownish red. The ethanol was then evaporated under reduced pressure. The dark red residue was suspended in water, and the suspension was neutralized with an aqueous solution of sodium carbonate. The residue thereby formed was extracted with benzene and the extract was dried over anhydrous sodium sulfate. The solution was passed through a column of alumina, and the column was eluted with benzene, by which 450 mg. of red crystals was obtained. Recrystallization from ethanol afforded 400 mg. of reddish violet prisms VIII, m. p. 120~121°C.

Found: C, 70.88; H, 5.71. Calcd. for $C_{16}H_{16}O_4$: C, 70.57; H, 5.92%.

UV λ_{max}^{MeOH} mμ (log ε): 234 (4.56), 271 (4.50), 302 (4.67), 326 (3.83), 365 (3.99), 371 (4.03), [513 (2.71), 550 (2.65), 604 (2.21) in cyclohexane].

Azulene-1, 3-dicarboxylic Acid (IX).—A solution of 1 g. of VIII dissolved in 10 ml. of a 10% ethanol-water (4:1) solution of potassium hydroxide was warmed on a water bath for 30 min. The color of the solution changed from red to violet. After being cooled, the solution was acidified with 6 N hydrochloric acid. The precipitate thereby formed was collected by filtration and repeatedly washed with water, by which 800 mg. of a sparingly soluble red substance IX, m. p. 270°C (decomp.), was obtained.

Azulene (X).—The low-pressure (200 mmHg) sublimation of 500 mg. of IX by heating at 270~280°C produced blue crystals. The crystals were dissolved in petroleum ether (b. p. 50~60°C), and the solution was passed through a column of alumina. The column was eluted with petroleum ether, and the solvent was cautiously removed. The crystalline residue was recrystallized from a methanol-water (4:1) mixture to afford 250 mg. of X as blue leaflets, m. p. 98~99°C, which showed no depression on admixture with an authentic specimen of azulene.

UV λ_{max}^{MeOH} mμ (log ε): 238 (4.17), 273 (4.68), 279 (4.64), 295 (3.55), 326 (3.45), 341 (3.60), 352 (2.70), 580 (2.50), 633 (2.41), 700 (1.98).

Dimethyl Azulene-1, 3-carboxylate (XI). — An ether solution of diazomethane was added to 100 mg. of IX suspended in 10 ml. of methanol, and the mixture was allowed to stand overnight. The solvent was evaporated, and the residue was dissolved in benzene. The solution was passed through a column of alumina. The column was eluted with benzene, and the solvent was distilled off. The crystallized residue was recrystallized from methanol to give 80 mg. of reddish violet scales XI, m. p. 171~172°C.

Found: C, 68.64; H, 4.86. Calcd. for $C_{14}H_{12}O_4$: C, 68.84; H, 4.95%.

Ethyl Azulene-1-carboxylate (XII).—To a solution of 100 mg. of potassium hydroxide dissolved in 5 ml. of an ethanol-water (4:1) mixture, 500 mg. of VIII was added; the mixture was then warmed on a water bath for 15 min. After being cooled, the solution was acidified with 6 N hydrochloric acid. The precipitate thereby formed was collected by filtration and repeatedly washed with water, by which 60 mg. of crystalline carboxylic acid was obtained. The low-pressure (100 mmHg) sublimation of the carboxylic acid by heating at 240~250°C produced a violet oil. The oil was dissolved in petroleum ether (b. p. 60~70°C) and chromatographically purified through an alumina column. The product separated into blue and reddish violet bands. The elution of the blue band with petroleum ether afforded ca. 10 mg. of X. The further elution of the reddish violet oil produced XII.

UV $\lambda_{max}^{Cyclohexane}$ mμ (log ε): 234 (4.30), 291 (4.61), 296 (4.65), 351 (3.76), 365 (3.95), 545 (2.65), 588 (3.60), 645 (2.23).

Picrate of XII.—Found: C, 53.41; H, 5.48; N, 9.81. Calcd. for $C_{19}H_{15}O_9N_3$: C, 53.15; H, 3.52; N, 9.79%. Red needles, m. p. 123~124°C, as recrystallized from ethanol.

2-Aminoazulene-1, 3-dicarboxylic Acid (XIII).—To a solution of 200 mg. of potassium hydroxide in 5 ml. of an ethanol-water (4:1) mixture, 500 mg. of III was added; the mixture was then refluxed in a water bath for 3 hr., by which the solution clearly colored orange-yellow. The solution was

acidified with 6 N hydrochloric acid. The precipitate hereby formed was collected by filtration and repeatedly washed with water; 350 mg. of crude 2-aminoazulene-1,3-dicarboxylic acid (XIII), m. p. 158~160°C (decomp.), sparingly soluble in organic solvents, was obtained.

2-Aminoazulene (XIV).—a) A suspension of 400 mg. of XIII in 2 ml. of pyridine was heated at 125~130°C for 15 min. to effect decarboxylation. The residue obtained by evaporation of the excess pyridine was dissolved in benzene, and the solution was passed through a column of alumina. The column was eluted with benzene. Evaporation of the solvent from the effluent afforded red crystals. Recrystallization from benzene-cyclohexane mixture gave 200 mg. of red needles (XIV), m. p. 93~94°C.

Found: C, 83.31; H, 6.44; N, 9.40. Calcd. for $C_{10}H_9N$: C, 83.88; H, 6.34; N, 9.78%.

UV λ_{max}^{MeOH} mμ (log ε): 218 (4.10), 240 (4.08), 284 (4.80), 294 (4.89), 345 (3.74), 387 (3.92), 403 (3.83).

b) The low-pressure (2 mmHg) sublimation of 60 mg. of XIII by heating at 170~175°C afforded red crystals. Their recrystallization from the benzene-cyclohexane mixture gave 20 mg. of XIV.

2-Acetamidoazulene (XV).—When 2-aminoazulene (200 mg.) was added to 0.2 ml. of acetic anhydride, the mixture colored violet immediately. After allowing the mixture to stand at room temperature for 2 hr., the violet crystals that separated out were collected by filtration; recrystallization from benzene afforded 200 mg. of violet needles XV, m. p. 168~169°C.

Found: C, 77.49; H, 5.80; N, 7.49. Calcd. for $C_{12}H_{11}ON$: C, 77.81; H, 5.99; N, 7.56%.

UV λ_{max}^{MeOH} mμ (log ε): 240 (4.23), 285 (4.84), 294 (4.97), 345 (3.73), 363 (3.94), 379 (4.06), 548 (2.64), 584 (2.57), 640 (2.31).

Ethyl 2-Aminoazulene-1-carboxylate (XVI).—To a solution of 250 mg. of potassium hydroxide dissolved in 4 ml. of an ethanol-water (4 : 1) mixture, 1.3 g. of III was added, and the mixture was refluxed in a water bath for 3 hr. The solution was acidified with 6 N hydrochloric acid. The precipitate thereby obtained was collected by filtration and washed with water. After being dried, the precipitate was suspended in 2 ml. of pyridine, and the suspension was heated at 120~130°C to effect decarboxylation. The residue produced by evaporation of the excess pyridine was dissolved in benzene, and the solution was passed through a column of alumina, by which the products were separated into red, reddish-orange and orange bands. Elution of the red band with benzene gave a small amount of XIV. Elution of the reddish orange band with benzene afforded a reddish orange oil which was crystallized from cyclohexane to crystals of m. p. 60~65°C. Recrystallization from cyclohexane afforded 400 mg. of reddish orange needles (XVI), m. p. 68~70°C.

Found: C, 72.48; H, 5.97; N, 6.67. Calcd. for $C_{13}H_{13}O_2N$: C, 72.54; H, 6.09; N, 6.51%.

UV λ_{max}^{MeOH} mμ (log ε): 304 (4.76), 314 (4.93), 358 (3.96), 378 (3.86).

Ethyl 2-Acetamidoazulene-1-carboxylate (XVII).—A mixture of 200 mg. of XVI and 2 ml. of acetic anhydride was treated as in the preparation of XV, and 200 mg. of XVII as red leaflets, m. p. 140~141.5°C, was obtained.

Found: C, 69.96; H, 5.85; N, 5.15. Calcd. for $C_{15}H_{15}O_3N$: C, 70.02; H, 5.88; N, 5.44%.

UV λ_{max}^{MeOH} mμ (log ε): 246 (4.32), 304 (4.82), 314 (4.97), 356 (3.96), 371 (3.96), 503 (2.55).

Ethyl 2-Acetoxy-3-cyanoazulene-1-carboxylate (XVIII).—A mixture of 50 mg. of II and 0.2 ml. of acetic anhydride containing one drop of pyridine was heated at 120~130°C for 3 hr., by which the II dissolved completely. The mixture was evaporated under reduced pressure, and the crystalline residue was recrystallized from ethanol to give 40 mg. of XVIII as reddish orange needles, m. p. 141~142°C.

Found: C, 67.74; H, 4.61; N, 4.81. Calcd. for $C_{16}H_{13}O_4N$: C, 67.84; H, 4.63; N, 4.95%.

2-Acetoxy-1,3-dicyanoazulene (XIX).—A mixture of 50 mg. of VII and 1 ml. of acetic anhydride was treated as in the foregoing case, and 30 mg. of reddish orange scales XIX, m. p. 191~192°C, was obtained.

Found: C, 70.97; H, 3.67; N, 11.63. Calcd. for $C_{14}H_8O_2N_2$: C, 71.18; H, 3.41; N, 11.86%.

Reaction of 2-Chlorotropone (Ia) with Malononitrile.—a) Into a suspension of sodiomalononitrile prepared from 320 mg. ($1.4/10^2$ mol.) of metallic sodium, 920 mg. ($1.4/10^2$ mol.) of malononitrile and 10 ml. of absolute ethanol, a solution of 1 g. ($7/10^3$ mol.) of Ia dissolved in 8 ml. of absolute ethanol was stirred, drop by drop, ice-cooling. The mixture was allowed to stand at room temperature for 1 hr., by which the solution became clearly a green color and orange crystals began to separate out. The crystals were collected by filtration and washed with water. Their recrystallization from a large quantity of acetone afforded 1.2 g. of orange needles XXI, m. p. above 300°C.

Found: C, 74.83; H, 3.41; N, 21.62. Calcd. for $C_{12}H_7N_3$: C, 74.60; H, 3.65; N, 21.75%.

UV λ_{max}^{MeOH} mμ (log ε): 231 (4.50), 309 (4.58), 322 (4.64), 393 (3.75), 445 (2.90).

b) To a solution of 500 mg. ($3.5/10^3$ mol.) of Ia and 460 mg. ($7/10^3$ mol.) of malononitrile dissolved in 10 ml. of absolute ethanol or dehydrated benzene was added 1.3 g. ($7/10^3$ mol.) of tributylamine, by which the solution immediately turned reddish-orange and a precipitate gradually deposited. The precipitate was collected by filtration and recrystallized from acetone to give 700 mg. of XXI.

c) When a solution of 500 mg. ($3.5/10^3$ mol.) of Ia, 230 mg. $3.5/10^3$ mol.) of malononitrile and 650 mg. ($3.5/10^3$ mol.) of tributylamine dissolved in 5 ml. of absolute ethanol was treated as in the foregoing cases, 300 mg. of XXI was obtained.

The authors wish to take this opportunity to express their gratitude for the donation of a grant-in-aid for Scientific Research from the Ministry of Education and for financial assistance from the Sankyo Pharmaceutical Co., Ltd. The authors gratefully acknowledge

their debt to Dr. Y. Ikegami for his infrared spectral measurements and to Mr. A. Sato for his co-operation in carrying out the experiments.

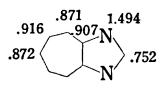
*Synthesis and Reactions of 2, 6-Disubstituted 1, 3-Diazaazulene**

By Tetsuo NOZOE, Toshio MUKAI and Toyonobu ASAO

(Received January 16, 1962)

Since 1, 3-diazaazulene derivatives have been synthesized by the reaction of 2-methoxytropones with guanidine or thiourea[1-3], and also by the reaction of 2, 5-diaminotroponimine with formic or acetic acid[4], widespread theoretical interest in this series of compounds has been aroused among physical chemists, and calculations by the molecular orbital method have been carried out by Kon[5].

According to him, the electron densities of the 1- and 3-positions are much higher than those of the 2-, 4(8)-, 5(7)- and 6-positions of 1, 3-diazaazulene. In fact, as has been reported[6], 1, 3-diazaazulene has a large dipole moment, such as 4.03D in a benzene solution at 25°C. Furthermore, it has been reported that the substituents in the 2-position[2,3,7] can be easily replaced by nucleophilic reagents, as can those in the 4-[8], 5-[5] and 6-positions[10].



Since the findings concerning the electron density of 1, 3-diazaazulene as calculated by the MO method varied according to the manner of correction**, it is difficult to anticipate which substituent of the 2- or 6-position of 2, 6-disubstituted 1, 3-diazaazulene is most easily replaced by nucleophilic reagents.

The present series of experiments was undertaken to clarify this respect experimentally. First, several kinds of 2, 6-disubstituted 1, 3-diazaazulene were synthesized. By the condensation reaction with guanidine, tropolone methyl ethers with a nitro group[11], a bromine[12] or a chlorine[13] atom at the 5-position afforded 6-nitro (I), 6-bromo (II) and 6-chloro derivatives (III) of 2-amino-1, 3-diazaazulene respectively. I is soluble in an alkaline solution and shows a bathochromic shift in its ultraviolet spectrum in an alkaline medium compared with that in methanol (Fig. 1). This is due to the formation of an aci-form (Ia). The heating of 2-amino-6-nitro-1, 3-diazaazulene (I) with concentrated hydrochloric acid in a sealed tube at 130°C gives 2-amino-6-hydroxy-1, 3-diazaazulene (IV), while the more severe condition, heating at 200°C, affords 2, 6-dihydroxy-1, 3-diazaazulene (V). IV and V are soluble in acid

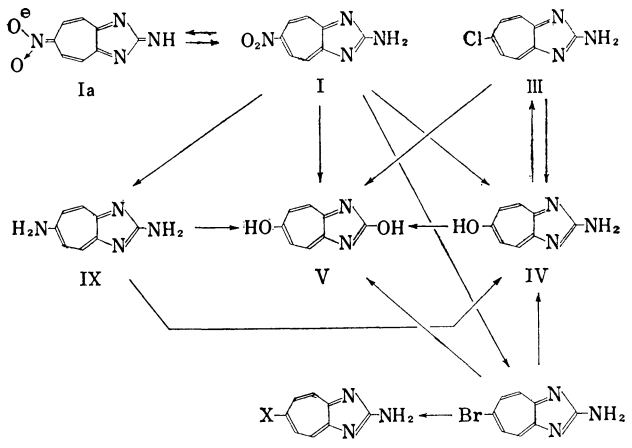
** The calculated results by three different corrections for the hetero-atomic Coulomb integral and the induction effect are as follows[5]:

Correction I



Correction II

Correction III

Correction I; $\delta\alpha$ Naza $=\beta$, no correction for induction.
Correction II; $\delta\alpha$ Naza $=\beta$, correction for induction effect on the two carbon atoms adjacent to an aza-nitrogen atom $=0.3\beta$.
Correction III; $\delta\alpha$ Naza $=0.5\beta$, correction for induction effect $\fallingdotseq 1/3\cdot\delta\alpha$ Naza.

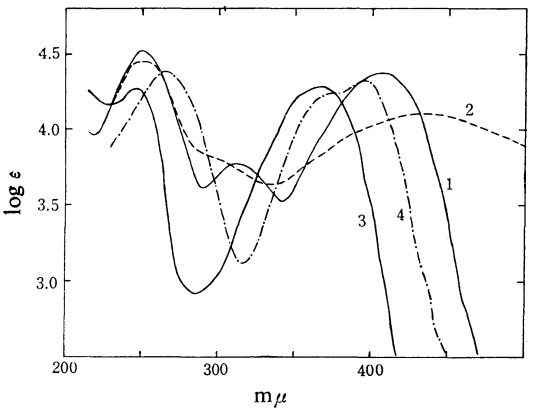

Fig. 1. Ultraviolet absorption spectra.
1, 2-Amino-6-nitro-1,3-diazaazulene (I) in methanol
2, I in 1 N NaOH
3, 2,6-Dihydroxy-1,3-diazaazulene (V) in methanol
4, V in 1 N NaOH

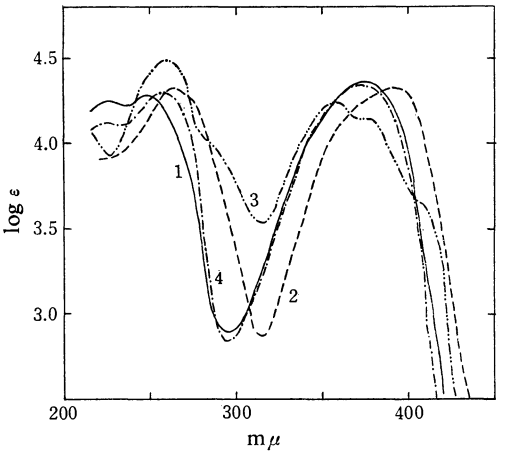

Fig. 2. Ultraviolet absorption spectra.
1, 2-Amino-6-hydroxy-1,3-diazaazulene (IV) in methanol
2, IV in 1 N NaOH
3, 2-Amino-6-methoxy-1,3-diazaazulene (VI) in methanol
4, 2-Amino-1-methylimidazolo[4, 5-d]-tropone (XV) in methanol.

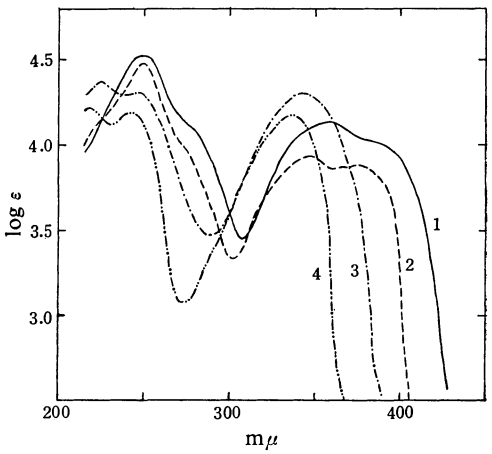
and alkali, and their ultraviolet spectra shift to a longer wavelength region in an alkaline medium compared with those in methanol (Figs. 1 and 2). V does not form a picrate, but IV and the methylated compound of V do form picrates. I also gives 2-amino-6-bromo-1, 3-diazaazulene (II), although the yield is rather low, on heating with acetic acid saturated with hydrogen bromide in a sealed tube. The reaction of IV and phosphoryl chloride in the presence of pyridine affords 2-amino-6-chloro-1, 3-diazaazulene (III). Structural proof of both the halogenated products is given by their identification with the condensed products of 5-bromo- and 5-chloro-tropolone methyl ether and guanidine respectively. On refluxing in 6 N hydrochloric acid, II and III give a 2-amino-6-hydroxy compound IV, and heating both in concentrated hydrochloric acid in a sealed tube gives 2, 6-dihydroxy-1, 3-diaza-azulene (V). The bromine atom of II was replaced with methoxide, methylamine and dimethylamine, giving 6-methoxy (VI), 6-methylamino (VII) and 6-dimethylamino derivatives (VIII) of 2-amino-1, 3-diazaazulene respectively. VI is identical with one of the products obtained from the reaction of IV with diazomethane, as will be described later.

From these results, it is clear that the substituents in the 2- and 6-positions of 1, 3-diazaazulene suffer from the attach of nucleophilic reagents.

To establish the order of the reactivity to nucleophilic reagents of the substituents of the 2- or 6-position, however, it is neccessary to experiment by using 2, 6-disubstituted 1, 3-diazaazulene having the same substituents in the 2- and 6-positions. While any attempted synthesis of 2, 6-diamino-1, 3-diazaazulene by the reaction of II or III with ethanolic ammonia or liquid ammonia results only in the recovery of the starting material, the catalytic reduction of the 2-amino-6-nitro compound I in acetic acid using Pd-C as a catalyst is successful in giving 2, 6-diamino-1, 3-diazaazulene (IX). The heating of IX with concentrated hydrochloric acid in a sealed tube affords V, whereas the refluxing of IX in 6 N hydrochloric acid gives IV, in which the 6-amino group is only hydrolyzed.

2, 6-Dichloro-1, 3-diazaazulene (X) is obtained from 2, 6-dihydroxy-1, 3-diazaazulene (V) by treatment with phosphoryl chloride in the presence of pyridine, accompanying monochloro monohydroxy 1, 3-diazaazulene (XI). The same treatment of XI gives X. X and XI can also be converted to V by heating with concentrated hydrochloric acid, but the heating of X with 2 N acetic acid affords monochloro monohydroxy 1, 3-diazaazulene (XII), which is different from XI. Similarly, the reaction of X and methanolic ammonia gives, in a good yield, monoamino monochloro 1, 3-diazaazulene (XIII), which is different from 2-amino-6-chloro-1, 3-diazaazulene (III).

The structures of XI and XII are examined by comparing their ultraviolet spectra with those of 2-[3] and 6-hydroxy-1, 3-diazaazulene[10] respectively. There are some differences between the absorption curves of 2- and 6-hydroxy-1, 3-diazaazulene, as is shown in Fig. 3. The similarity of XI in the ultraviolet spectrum to that of the 2-hydroxy compound and the similarity of XII to the 6-hydroxy compound indicates that XI would be 6-chloro-2-hydroxy-1, 3-diazaazulene and XII, 2-chloro-6-hydroxy-1, 3-diazaazulene. In the same manner, XIII is ascertained to be 6-amino-2-chloro-1, 3-diazaazulene. In Fig. 4, the ultraviolet spectra of III, XIII and 2-[1] and 6-amino-1, 3-diazaazulene[4] are shown; the spectrum of XIII is more similar to that of the 6-amino compound than to that of the 2-amino compound. Incidentally, isomeric 2-amino-6-chloro-1, 3-diazaazulene (III) has an absorption curve similar to that of the 2-amino compound.



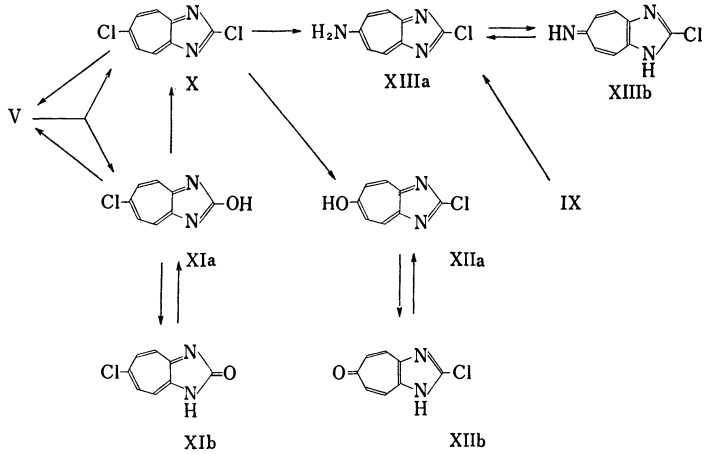


Fig. 3. Ultraviolet absorption spectra in methanol.
1, 6-Chloro-2-hydroxy-1, 3-diazaazulene (XI)
2, 2-Hydroxy-1, 3-diazaazulene
3, 2-Chloro-6-hydroxy-1, 3-diazaazulene (XII)
4, 6-Hydroxy-1, 3-diazaazulene

From this series of experiments, it is clear

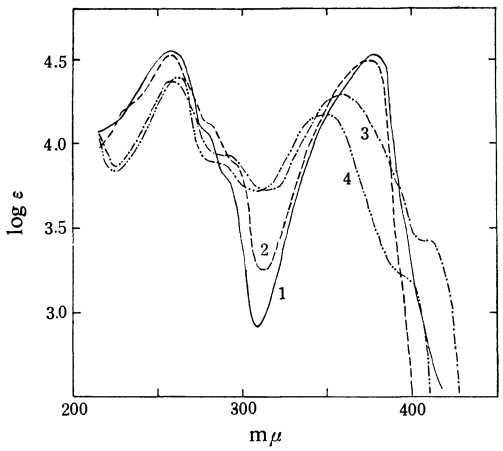

Fig. 4. Ultraviolet absorption spectra in methanol.
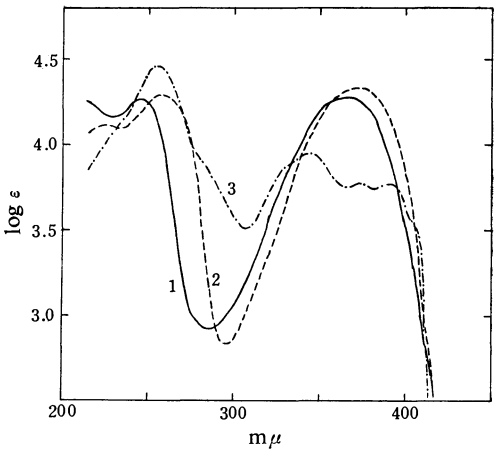
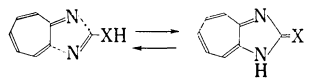
1, 6-Amino-2-chloro-1,3-diazaazulene (XIII)
2, 9-Amino-1, 3-diazaazulene
3, 2-Amino-6-chloro-1,3-diazaazulene (III)
4, 2-Amino-1,3-diazaazulene





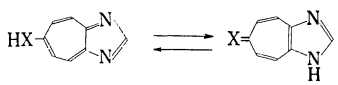


Fig. 5. Ultraviolet absorption spectra in methanol.
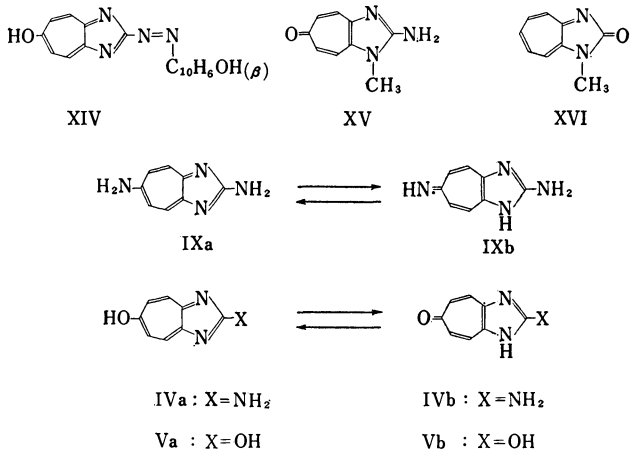
1, 2,6-Dihyroxy-1,3-diazaazulene (V)
2, 2-Amino-1-methylimidazolo[4,5-d]-tropone (XV)
3, 1-Methylcycloheptimidazol-2-one (XVI)

that nucleophilic substitution occurs preferentially at the 6-position rather than at the 2-position in 2, 6-disubstituted 1, 3-diazaazulene. In other words, the electron density at the 6-position is less than that at the 2-position of 2, 6-disubstituted 1, 3-diazaazulene.

Furthermore, it has been reported[3,5,10,14] that 2- or 6-hydroxy-1, 3-diazaazulene are present in the so-called lactim-lactam or keto-enol tautomerisms (A and B type: X=O) and that its tautomeric equilibrium tends towards the lactam or keto form (B type: X=O). It has also been reported that there are similar tautomerisms (A and B type: X=NH) in 2- and 6-amino-1,3-diazaazulene and that the imino form (B: X=NH) is preferred to the amino form (A: X=NH). Consequently, the ultraviolet spectra of XI, XII and XIII in Figs. 3 and 4 supported that their equilibrium tends to XIb, XIIb and XIIIb rather than to XIa, XIIa and XIIIa.

A type B type



A type B type

It is also interesting to discuss the tautomerism of IV, V and IX. Although 2- or 6-amino-1, 3-diazaazulene is not diazotized[1,4], 2-amino-6-hydroxy-1, 3-diazaazulene (IV) and 2, 6-diamino-1, 3-diazaazulene (IX) are diazotized. The diazonium salt of IV couples with β-naphthol to give an azo-compound XIV. IX consumes only one equivalent of nitrous acid, while the Sandmeyer reaction of its diazonium salt gives 6-amino-2-chloro-1, 3-diazaazulene (XIII). Preferential diazotization of the 2-amino group of IX is also compatible with the fact that the electron density at the 2-position is higher than at the 6-position. This means that the tautomeric equilibrium of IX seems to be tend towards IXb rather than IXa.

Methylation of 2-amino-6-hydroxy-1, 3-diazaazulene (IV) with diazomethane affords two compounds, 6-methoxy-2-amino-1, 3-diazaazulene (VI) and 2-amino-1-methylimidazolo[4, 5-d]tropone (XV), in approximately a 1 : 4 ratio. The ultraviolet spectra of IV, VI and XV are shown in Fig. 2. The spectrum of IV is very similar to that of XV or 6-hydroxy-1, 3-diazaazulene, but it is different from that of VI. The infrared spectrum of XV exhibits a carbonyl band at 1663 cm^{-1}, and that of IV, at 1660 cm^{-1}. In Fig. 5, the ultraviolet spectra of 2, 6-dihydroxy-1, 3-diazaazulene (V), XV and 1-methylcycloheptimidazol-2-one[3] (XVI) are shown. The absorption curve of V is similar to that of XV rather than to that of XVI, and the infrared spectrum of V exhibits a carbonyl band at 1686 cm^{-1}. From these facts, the tautomeric equilibrium of IV and V seems to tend towards IVb and Vb respectively rather than towards IVa and Va.

Experimental*

2-Amino-6-nitro-1, 3-diazaazulene (I). — To a suspension of 1 g. of 5-nitrotropolone methyl ether in 100 ml. of ethanol, a solution of 0.33 g. of potassium hydroxide (or 0.13 g. of sodium) and 0.56 g. of guanidine hydrochloride in 50 ml. of ethanol was added, and the mixture was refluxed for about 3 hr. The yellowish brown prisms which precipitated out were collected by filtration and recrystallized from acetic acid, giving 0.75 g. (75%) of I as yellow needles, m. p. over 300°C.

Found: C, 50.45; H, 2.92; N, 29.56. Calcd. for $C_8H_6O_2N_4$: C, 50.53; H, 3.18; N, 29.42%.

Picrate.—Organge prisms, turned to black from around 240°C.

Found: C, 39.42; H, 2.56; N, 23.82. Calcd. for $C_{14}H_9O_9N_7$: C, 39.82; H, 2.86; N, 23.39%.

2-Amino-6-bromo-1, 3-diazaazulene (II).—a) To a solution of 420 mg. of 5-bromotropolone methyl ether in 10 ml. of ethanol, a solution of 250 mg. of guanidine hydrochloride and 130 mg. of potassium hydroxide dissolved in 10 ml. of ethanol was added, and the mixture was refluxed for 2 hr. The yellow crystals which precipitated out were collected by filtration, washed with water and recrystallized from ethanol, affording 320 mg. of II as yellow prisms, which slowly changed to black from around 240°C.

Found: C, 43.28; H, 2.55; N, 18.45. Calcd. for $C_8H_6N_3Br$: C, 42.90; H, 2.70; N, 18.75%.

Picrate.—Orange yellow prisms, m. p. 262~263°C (decomp.).

Found: N, 18.58. Calcd. for $C_{14}H_9O_7N_6Br$: N, 18.54%.

b) After heating 50 mg. of I with 3 ml. of acetic acid saturated with hydrogen bromide in a sealed tube for 5 hr. at 90°C, the solid which precipitated out was dissolved in water. Neutralization of the solution with sodium hydrogen carbonate gave crystals, which were recrystallized from ethanol, giving II as yellow prisms, which slowly changed to black from around 240°C. The infrared spectrum of these crystals showed the same maxima as that of the sample obtained by method a).

2-Amino-6-chloro-1, 3-diazaazulene (III) — a) 2.5 g. of III was obtained from 2.8 g. of 5-chlorotropolone methyl ether by method a), by which II was obtained. Yellow prisms, gradually changing to black from around 247°C.

Found: C, 53.24; H, 3.68; N, 22.90. Calcd. for $C_8H_6N_3Cl$: C, 53.60; H, 3.36; N, 23.40%.

Picrate.—Yellow powder, slowly changing to black from around 280°C.

Found: N, 20.78. Calcd. for $C_{14}H_9O_7N_6Cl$: N, 20.56%.

b) A mixture of 90 mg. of 2-amino-6-hydroxy-1,3-diazaazulene (IV), 3 ml. of phosphoryl chloride and 0.15 ml. of pyridine was heated at 105°C for 2.5 hr. while being stirred. After the excess of phosphoryl chloride had been distilled off, the residue was poured onto ice. Yellow crystals soon separated out. The crude crystals were dissolved in diluted hydrochloric acid, treated with charcoal and neutralized with sodium hydrogen carbonate, giving 60 mg. of yellow micro needles. Recrystallization of these crystals from ethanol gave II as yellow prisms, which changed to black from around 247°C.

2-Amino-6-hydroxy-1, 3-diazaazulene (IV).—After heating 0.5 g. of I with 2 ml. of concentrated hydrochloric acid in a sealed tube for 12 hr. at 130°C, the mixture was evaporated to dryness on a steam bath. The residue was dissolved in a small amount of water and treated with charcoal. Neutralization of this solution with sodium hydrogen carbonate gave 330 mg. of yellow needles. Recrystallization from water afforded IV as yellow needles, which slowly changed to black from around 240°C.

Found: C, 53.20; H, 4.72; N, 23.27. Calcd. for $C_8H_7ON_3 \cdot H_2O$: C, 53.62; H, 5.06; N, 23.45%.

Picrate. — Yellow powder, slowly changing to black from around 250°C.

Found: C, 42.71; H, 3.40. Calcd. for $C_{14}H_{10} \cdot O_8N_6$: C, 43.08; H, 2.58%.

Reaction of IV with Phenylhydrazine.—A solution of IV and phenylhydrazine in ethanol was refluxed for 5 hr. in the presence of a small amount of acetic acid. After removing the solvent, the

* All melting points are uncorrected. The microanalyses were carried out by Mr. S. Ohyama and Miss A. Iwanaga, to whom the author's sincere gratitude is hereby extended.

residue was recrystallized from ethanol, affording red micro meedles, m. p. over 280°C.

Found: C, 67.03; H, 4.45. Calcd. for $C_{14}H_{13}N_5$: C, 66.91; H, 5.21%. Calcd. for $C_{14}H_{11}N_5$: C, 67.45; H, 4.45%.

Ultraviolet; λ_{max}^{MeOH} mμ (log ε): 250 (4.38), 300~315 (4.17), 416 (4.42).

2,6-Dihydroxy-1,3-diazaazulene (V).—A solution of 0.5 g. of I in 3 ml. of concentrated hydrochloric acid was heated in a sealed tube for 24 hr. at 200°C. The black material which separated out was removed by filtration, and the filtrate was evaporated to dryness. Recrystallization of the residue from water afforded 300 mg. of V as yellow needles, m. p. over 300°C.

Found: C, 52.98; H, 4.84; N, 15.74. Calcd. for $C_8H_6O_2N_2 \cdot H_2O$: C, 53.33; H, 4.48; N, 15.55%.

Diacetate.—Pale yellow needles, m. p. over 300°C.

Found: N, 12.67. Calcd. for $C_{12}H_{10}O_4N_2$: N, 12.61%.

Dimethyl Derivative.—V was methylated with diazomethane in the mixture of methanol and ether, giving a dimethyl derivative as yellow needles, m. p. 254~255°C (decomp.).

Found: N, 14.74. Calcd. for $C_{10}H_{10}O_2N_2$: N, 14.68%.

Picrate of Dimethyl Derivative.—Yellow needles, m. p. 240~241°C (decomp.).

Found: N, 16.70. Calcd. for $C_{16}H_{13}O_9N_5$: N, 16.63%.

2-Amino-6-methoxy-1,3-diazaazulene (VI).—A mixture of 150 mg. of II and 80 mg. of sodium methoxide in 20 ml. of absolute methanol was refluxed for 6 hr. After the mixture had been cooled, 50 mg. of II was recovered by filtration, was and the filtrate passed through an alumina column. Crystals obtained from the effluent were recrystallized from ethanol, giving VI as yellow needles, m. p. 237~238°C (decomp.).

Found: C, 61.68; H, 5.24; N, 23.90. Calcd. for $C_9H_9ON_3$: C, 61.70; H, 5.18; N, 23.99%.

Picrate.—Yellow powder, m. p. 266~267°C. (decomp.).

Found: N, 20.22. Calcd. for $C_{15}H_{12}O_8N_6$: N, 20.79%.

2-Amino-6-methylamino-1,3-diazaazulene (VII). After heating a mixture of 100 mg. of II, 40 mg. of methylamine hydrochloride, 30 mg. of sodium methoxide and 1.5 ml. of absolute methanol in a sealed tube at 160°C for 6 hr., an orange solid was obtained by evaporating the solvent. This solid was dissolved in methanol and passed through a column of ion-exchange resin (Amberite IRA-410). 40 mg. of VII was obtained as orange yellow prisms, m. p. 264~265°C (decomp.) (from ethanol).

Found: C, 56.24; H, 6.24; N, 29.31. Calcd. for $C_9H_{10}N_4 \cdot H_2O$: C, 56.23; H, 6.29; N, 29.15%.

2-Amino-6-dimethylamino-1,3-diazaazulene(VIII).—The reaction of II with dimethylamine gave VIII as orange yellow prisms, which slowly changed to black from around 240°C (from water).

Found: C, 63.28; H, 6.20; N, 29.89. Calcd. for $C_{10}H_{12}N_4$: C, 63.81; H, 6.43; N, 29.77%.

2,6-Diamino-1,3-diazaazulene (IX).—A solution of 500 mg. of I dissolved in 20 ml. of acetic acid was submitted to hydrogenation in the presence of 200 mg. of 5% Pd-C. 180 ml. of hydrogen was absorbed. The solvent was distilled off under reduced pressure, and the resulting reddish crystalline was dissolved in ethanol and passed through a column of ion-exchange resin (Amberlite IR-4B). The ethanol was evaporated off from the elute, and the residue was sublimed under reduced pressure. Recrystallization of the sublimate from water afforded 170 mg. of IX as yellow silky needles, m. p. over 300°C.

Found: C, 59.99; H, 5.05; N, 34.56. Calcd. for $C_8H_8N_4$: C, 59.98; H, 5.03; N, 34.98%.

Bis-picrate.—Yellow powder, m. p. over 300°C.

Found: N, 22.71. Calcd. for $C_{20}H_{14}O_{14}N_{10}$: N, 22.65%.

Dihydrochloride.—Pale yellow prisms, m.p. over 300°C.

Found: N, 24.26. Calcd. for $C_8H_8N_4 \cdot 2HCl$: N, 24.04%.

2,6-Dichloro-1,3-diazaazulene (X) and 6-Chioro-2-hydroxy-1,3-diazaazulene (XI).—A mixture of 270 mg. of V, 7 ml. of phosphoryl chloride and 0.9 ml. of pyridine was stirred for 3 hr. at 110°C. The excess of phosphoryl chloride was distilled off under reduced pressure, and the residue was poured onto ice. The solution was adjusted to a slightly acidic state with sodium hydrogencarbonate and extracted with chloroform. The chloroform was then removed, the residue was redissolved in benzene, and the benzene solution was passed through an alumina column. The benzene was distilled off from the eluate, and the residue was recrystallized from benzene, affording 110 mg. of 2,6-dichloro-1,3-diazaazulene (X) as colorless needles, m. p. 226~227°C (decomp.).

Found: C, 48,97; H, 2.36; N, 14.38. Calcd. for $C_8H_4N_2Cl_2$: C, 48.27; H, 2.03; N, 14.08%.

After the chloroform extraction, the water layer was adjusted to a slightly alkaline state with sodium hydrogen carbonate, affording yellow needles. Recrystallization of the crystals from water gave 80 mg. of 6-chloro-2-hydroxy-1,3-diazaazulene (XI), which gradually changed to black from around 240°C.

Found: C, 53.12; H, 3.21; N, 15.71. Calcd. for $C_8H_5ON_2Cl$: C, 53.21; H, 2.79; N, 15.51%.

2-Chloro-6-hydroxy-1,3-diazaazulene (XII).—A mixture of 50 mg. of X, 4 ml. of 2 N acetic acid and 1 ml. of ethanol was refluxed for 1.5 hr. Thirty milligrams of colorless needles were obtained by cooling the reaction mixture in an ice box. Recrystallization of the crystals from water gave XII as colorless needles, m. p. 237~237.5°C (decomp.).

Found: C, 52.79; H, 3.21; N, 15.52. Calcd. for $C_8H_5ON_2Cl$: C, 53.21; H, 2.79; N, 15.51%.

6-Amino-2-chloro-1,3-diazaazulene (XIII).—a) The heating of 40 mg. of X in 2 ml. of methanol saturated with ammonia in a sealed tube at 100°C for 1 hr. afforded 35 mg. of yellow crystals. The crystals were dissolved in dilute hydrochloric acid and neutralized with a sodium hydrogencarbonate solution, giving XIII as yellow needles, m. p. over 300°C.

Found: C, 53.46; H, 3.34; N, 23.47. Calcd. for $C_8H_6N_3Cl$: C, 53.60; H, 3.36; N, 23.40%.

b) Fifty milligrams of IX dissolved in 0.6 ml. of

acetic acid was diazotized with sodium nitrate, and the reaction mixture was poured into a solution of 50 mg. of cuprous chloride in 0.3 ml. of concentrated hydrochloric acid. The mixture was adjusted to a slightly alkaline state with sodium hydrogencarbonate, affording a brown solid. The solid was extracted with ethanol continuously, and yellow crystals were obtained. Recrystallization of the crystals from ethanol gave yellow needles, m. p. over 290°C. The ultraviolet and infrared spectra of these crystals completely agreed with those of XIII obtained by procedure a).

6-Hydroxy-2-(2-hydroxy-1-naphthyl)-azo-1, 3-diazaazulene (XIV).—One hundred milligrams of IV dissolved in 2 ml. of 6 N hydrochloric acid were diazotized with a solution of 50 mg. of sodium nitrate dissolved in 0.4 ml. of water. The reaction mixture was slowly poured into a solution of 90 mg. of β-naphthol dissolved in 3 ml. of a 3 N sodium hydroxide solution. The color of the mixture immediately turned to violet, and a deep-colored solid was salted out. The solid was then dissolved in water and neutralized with dilute hydrochloric acid, giving 60 mg. of violet crystals. Recrystallization of these crystals from pyridine afforded XIV as brownish violet needles, m. p. over 300°C.

Found: C, 68.13; H, 3.70. Calcd. for $C_{18}H_{12}O_2N_4$: C, 68.35; H, 3.82%.

Ultraviolet: λ_{max}^{MeOH} mμ (log ε): 225 (4.71), 290 (4.20), 355 (418), 510 (4.59).

Reaction of IV with Diazomethane.—To a solution of 300 mg. of IV dissolved in 6 ml. of methanol, 25 ml. of diazomethane ether solution prepared from 2.5 g. of *N*-nitrosomethylurea was added and left to stand overnight. The crystals which precipitated out were filtered and washed with benzene, affording 190 mg. of crystals. Recrystallization of the crude crystals from ethanol afforded XV as yellow prisms, which gradually changed to black from around 290°C.

Found: C, 55.92; H, 5.73; N, 21.37. Calcd. for $C_9H_9ON_3 \cdot H_2O$: C, 55.95; H, 5.74; N, 21.75%.

Picrate.—Yellow needles, gradually changing to black from around 240°C.

Found: C, 44.78; H, 2.74; N, 21.18. Calcd. for $C_{15}H_{12}O_8N_6$: C, 44.56; H, 2.99; N, 20.79%.

The solvent was distilled off from the original reaction filtrate, and the residue was dissolved in benzene and passed through an alumina column. Benzene was removed from the eluate, leaving 50 mg. of crystals. Recrystallization of these crystals from ethanol afforded yellow needles, m. p. 236°C (decomp.), which showed no depression of melting point on admixture with VI.

Condensation of the Triad System with Carbonyl Compounds. I. Condensation of Ethyl Itaconate with Ketones[*1]

By Chiaki KATSUTA[*2] and Noboru SUGIYAMA

(Received September 16, 1961)

Although the chemical behavior of itaconic acid has already been studied in detail, there has yet been no report on the condensation of its active methylene group with carbonyl compounds other than the classical paper by Fittig and Bock[1]; this lack is a result of the isomerisation of the ester in a strongly basic media to a mixture of its isomers[2].

From the close structural resemblance of the acid to succinic acid and alkylidenesuccinic acid (A) the ethyl ester of itaconic acid(I) was

$$(R_1R_2)C{=}C(H_2C{-}COOH){-}COOH \qquad (R_1R_2)C{=}C(H_2C{-}COOH){-}COOH$$

(A) (B)

expected to condense with carbonyl compounds by Stobbe condensation[3] and to afford new fulgenic acids (B). However, Fittig et al. obtained, by condensation of I (a molecule) with benzaldehyde (two molecules) in the presence of

*1 This paper is a part of a doctoral thesis and was partly presented at the Symposium of the Organic Reaction Mechanism, Shirahama, October, 1960.

sodium ethoxide, two isomeric heptenedilactones which can not be explained by Stobbe condensation in a straightforward manner. Their findings supported the possibility of the condensation of I with other carbonyl compounds and suggested that I behaves quite differently from ethyl alkylidenesuccinats (A).

In this paper, the novel reactions of I with ketones are described.

Resuits and Discussion

The condensation of I with acetone was conducted in the presence of alcohol-free sodium ethoxide in an ice bath or an ice-salt bath. In the ice bath, the condensation reaction afforded two acidic products, II (R_1=R_2=CH_3) and III(R_1=R_2=CH_3), while in the ice-salt bath the reaction gave only III(R_1=R_2=CH_3).

I also condensed with cyclohexanone. The reaction afforded an acid, II [R_1, R_2=$-(CH_2)_5-$], in the ice bath, and, in the ice-salt bath, two acidic products, II [R_1, R_2=$-(CH_2)_5-$] and III [R_1, R_2=$-(CH_2)_5-$].

II

III

The yields, properties and analytical data of these products are shown in Tables IV, V and VI.

The II products were monobasic acids and gave methyl esters and anilides by ordinary procedures.

Structures.—The structures of the II products were determined to be as follows:

i) The analytical data (Table VII) showed that they were condensation products of I(C_5)

Table I. Infrared absorption spectra (in KBr)

Compound	γ-Lactone C=O	Carboxyl C=O	C=C
α, γ, γ-Trimethylaconic acid (II, R_1=R_2=CH_3)	1725	1700(sh)	1650
Methyl α, γ, γ-trimethylaconate	1765	1720[a]	1650
Anilide of α, γ, γ-trimethylaconic acid	1755	1693[b] 1540	1664

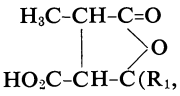
Methyl α-methylaconate (II, R_1=R_2=H)	3.87	4.01	4.04	3.88

* The Sample was given by Professor Shoji Shibata. The authors want to appreciate him.

Table III. Infrared spectra of α-alkylidenemethylaconic acids (III) (cm^{-1})



Compound	γ-Lactone C=C	COOH C=O	C=C
α-Isopropylidenemethyl-γ, γ-dimethylaconic acid (in KBr)	1720	—	1660 1610
α-Isopropylidenemethyl-γ, γ-dimethylaconic acid (chloroform solution)	1753	1690	1650 1610
α-Cyclohexylidenemethyl-γ, γ-pentamethyleneaconic acid (in KBr)	1772	1710	1685 1620

with molecules of acetone and cyclohexanone respectively.

ii) The infrared spectrum of these methyl esters and anilides indicated the presence of C=C and of α,β-unsaturated γ-lactone C=O bands (Table I). In free acids, II showed broad bands with a shoulder near 1725 cm^{-1}, bands which were attributable to α,β-unsaturated γ-lactone C=O[4] and carboxyl C=O.

iii) The close resemblance of ultraviolet spectrum of II and of their methyl esters to those of metaconic acid, aconic acid,and more especially, lichesterinic acid (II, R_1=H, R_2=*n*-$C_{13}H_{27}$)[5] and ethyl ester of α-methylaconic acid (II, R_1=R_2=H)[5] tended to confirm the presence of a substituted O=C-C=C-C=O (trans) conjugated system (Table II).

iv) II [R_1=R_2=CH_3 and R_1, R_2=-$(CH_2)_5$-] afforded a corresponding paraconic acid(IV) by reduction with a sodium amalgam. The infrared spectrum of IV [R_1=R_2=CH_3 and R_1, R_2=-$(CH_2)_5$-] well agreed with those of γ,γ-dimethyl paraconic acid and γ,γ-pentamethyleneparaconic acid.

IV

v) The NMR spectrum of the methyl ester of II(R_1=R_2=CH_3) showed three peaks, corresponding to $COOCH_3$, =C-CH_3 and $C(CH_3)_2$[6] (Fig. 1).

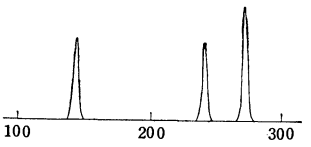


Fig. 1. NMR of methyl α,γ,γ-trimethylaconate.

From the following evidence, the structures of the III products were determined:

i) The analytical data of the III products [R_1=R_2=-CH_3 and R_1, R_2=-$(CH_2)_5$-] showed that I condensed with two molecules of the corresponding ketone.

ii) The infrared spectrum of the III products suggested that they were conjugated dienoic acid, which has an α,β-unsaturated γ-lactone ring (Table III).

iii) The ultraviolet spectrum of the III products showed end absorption and broad bands near 277 mμ (both log ε = 3.67). This suggested

TABLE IV. CONDENSATION REACTIONS

Exp.	Ester, g.	Ketone, g.	Cooling media	Time[a]
a	I, 13.6	Acetone, 8.8	Ice bath	Overnight
b	V, 13.6	Acetone, 8.8	Ice bath	Overnight
c	VI, 13.6	Acetone, 8.8	Ice bath	Overnight
d	I, 18.6	Acetone, 11.6	Ice-salt bath	Overnight

f	I, 18.6	Cyclohexanone, 22.5	Ice-salt bath	Overnight[b]

a) Times for keeping at room temperature.
b) The reaction mixture was allowed to stand overnight in ice-salt bath.

TABLE V. CONDENSATION PRODUCTS

Exp.	Products	Yields, %	M. p., °C	Properties
a	II	65.6	231~232	Colorless acid, sublimable
	III	23.0	131~132	Colorless acid, sublimable
b	II	9.7		
c	II	13.7		
d	III	62.0		
e	II	47.2	276 (decomp.)	Colorless acid, sublimable
f	II	40.1		
	III	11.9	137~138	Colorless acid

4) The C=O bands of saturated or α,β-unsaturated γ-lactone β-carboxylic acids were of exceptionally lower frequencies than those acids in the normal saturated or α,β-unsaturated γ-lactone C=O region. This spectral behavior may be attributed to intermolecular hydrogen bonding between carboxyl OH and lactone C=O (cf. L. J. Haynes and J. R. Plimmer, *Quart. Revs.*, 14, 307 (1960); Y. Hirata, *J. Japan. Chem.* (*Kagaku-no-Ryoiki*), Supplement, 42, 76 (1961).

5) E. E. Van Tamelen, C. E. Osborne and S. R. Bach, *J. Am. Chem. Soc.*, 77, 4625 (1955).

6) N. F. Chemberlain, *Anal. Chem.*, 31, 56 (1959).

7) The normal frequencies of the lactone C=O(1772 cm^{-1}) of III[R_1, R_2=-$(CH_2)_5$-] suggested the absence of intermolecular hydrogen bonding between carboxyl OH and lactone C=O by bulky substituents.

(A) α-Isopropylidenemethyl-γ, γ-dimethylaconic acid (III)
(B) β-Methylcrotonic acid

Reaction Mechanism.—However, I condensed readily with the ketones, its isomerides, ethyl citraconate (V) and ethyl mesaconate (VI), which were expected to be produced from I by a prototropic change of its triad system (CH–C=CH) in the reaction condition; it also dully condensed with acetone and afforded II(R_1=R_2=CH_3) in poor yields. From this fact and the structure of II, it is clear that I condensed with ketones at its active methylene group and that the isomerisation of I to the isomerides is negligible under the reaction conditions.

The formation of II and III can not simply be explained by Stobbe condensation but only by the following mechanism:

8) K. Hirayama, "Jikken Kagaku Koza", Vol. I-1, Ed. by Chem. Soc. of Japan, Maruzen Co., Tokyo, (1957) p. 125.

9) L. M. Jackman, "Application of Nuclear Magnetic Resonance Spectroscopy in Organic Chemistry", Pergamon Press, London (1959), p. 120. From the resemblance of this NMR to that of β-crotonic acid [S. Fujiwara et al., This Bulletin, 33, 428 (1960)], the peaks b(broad), c and d are attributed to protons of =CH-, cis-methyl and trans-methyl of $=C-CH=C(CH_3)_2$ respectively.

In this process, the formation of II is explained by a mechanism similar to that employed by Stacy et al.[10] to account for the condensation of ethyl oxaloacetate with carbonyl compounds. The change of anion VIII to anion IX is a tautomerism of the triad system. Moreover, the formation of III was explained by the extended Stobbe condensation[11] of anion IX with the ketones.

By this reaction mechanism, the formation of Fittig's heptenedilactones may be explained. The dilactone X and Fittig's heptenedilactone will be reported on in the near future.

Experiments

Ethyl Itaconate (I).—I was prepared by the conventional procedure from itaconic acid, using hydroquinone as a polymerisation inhibitor without isomerisation[12]; b. p., 118°C/20 mmHg and n_D^{20}= 1.4383 (b.p. 117.5°C/20 mmHg, and n_D^{20}=1.4377[12]).

Ethyl Citraconate (V).—V was prepared from citraconic anhydride[13] by the ordinary procedure without isomerisation; b. p., 121°C/20 mmHg and n_D^{20}=1.4440 (b. p. 122°C/20 mmHg, and n_D^{20}=1.4442[12]).

Ethyl Mesaconate (VI).—VI was prepared from mesaconic acid[14] by the ordinary procedure without isomerisation; b. p., 118°C/20 mmHg and n_D^{20}=1.4485 (b.p. 118°C/20 mmHg, and n_D^{20}=1.4488[12]).

Condensation of the Esters with Ketone. General Procedure.—Alcohol-free sodium ethoxide was prepared by Fittig's method[15] in a 300 ml. three-necked flask. The flask was fitted with a dropping funnel and a reflux condenser, each protected by calcium chloride tubes, and with a mercury-sealed mechanical stirrer. The molar ratio of the sodium ethoxide, the ester and the ketone was 2 : 1 : 2. The flask was cooled in an ice or ice-salt bath. The mixture of the ester and the ketone was dropped from the funnel into the stirred suspension of sodium ethoxide in ether over a period of one hour. After the addition of the mixture and an additional two hours' cooling, the flask was allowed to stand overnight at room temperature. The reaction mixture was dissolved in water (150 ml.), and the resulting aqueous solution was extracted with ether (50 ml.) several times. The aqueous layer was acidified with excess hydrochloric acid (1 : 1); then the condensation products, which separated as an oil or slurry, were extracted by ether and purified according to the usual procedure. The details of these reactions, products and analytical data are shown in Tables 4, 5 and 6.

Aconic Acid.—Aconic acid was prepared from itaconic acid by the method of Champbell[16].

Methyl α,γ,γ-Trimethylaconate.—α,γ,γ-Trimethylaconic acid (II, R_1=R_2=CH_3) 1.70 g. was esterified by diazomethane[17], and the ester was obtained in the form of colorless prisms (1.45 g.) (from light petroleum); m. p., 30~31°C.

Methyl α-Methyl-γ,γ-pentamethyleneaconate.—The ester was prepared from α-methyl-γ,γ-pentamethyleneaconic acid (II, R_1, R_2=$-(CH_2)_5-$) 0.51 g. and diazomethane, in the form of colorless prisms (from light petroleum), 0.45 g., m. p., 93~94°C.

Anilide of α,γ,γ-Trimethyl Aconic Acid.—The acid (1.05 g.) was converted to the anilide by the ordinary procedure. Colorless prisms (from ethanol), 0.92 g.; m. p., 187~188°C.

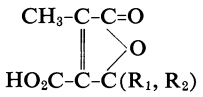
Anilide of α-Methyl-γ,γ-pentamethyleneaconic Acid.—From the acid (1.00 g.), the anilide (0.73 g.) was obtained in the form of colorless prisms (from ethanol); m. p., 182~183°C.

α,γ,γ-Trimethylparaconic Acid (IV, R_1=R_2=CH_3).—α,γ,γ-Trimethylaconic acid (1.54 g.) was suspended in water (20 ml.), dissolved by neutralization with a 10% sodium hydroxide solution, and then stirred with a 1% sodium amalgam (53 g.) for 10 hr. at room temperature. The aqueous layer was separated and was acidified with cold 1 : 1 hydrochloric acid in ice bath, and then extracted with three portions (10 ml.) of ether. The acidic products were thoroughly extracted with a saturated sodium bicarbonate solution. After careful acidification, extraction with ether yielded the acid as a colorless solid (0.77 g.) (m. p., 186~189°C) that crystallized from acetonitrile as colorless scales; m. p., 191~192°C.

α-Methyl-γ,γ-pentamethyleneparaconic Acid.—This acid was obtained by reduction of α-methyl-γ,γ-pentamethyleneaconic acid (II) (0.52 g.) as above; 0.38 g.; in the form of colorless scales (from ethyl acetate); m. p., 196~197°C.

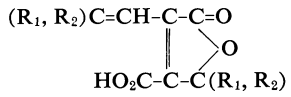
γ,γ-Dimethylparaconic acid.—This acid was prepared by the lactonization[18] of teraconic acid, obtained by Stobbe condensation of ethyl succinate and acetone[19]. Colorless scales (from acetonitrile); m. p., 173~174°C.

γ,γ-Pentamethyleneparaconic acid.—This acid was prepared by the method of Robinson[20] from the Stobbe condensation of ethyl succinate with cyclohexanone. Colorless scales (from acetonitrile); m. p., 184~185°C.



Measurements.—The ultraviolet spectra were determined with a Hitachi ESP-2 spectrophotometer. Infrared measurements were made with a Nihon Bunko IR-S and a 301 spectrophotometer. NMR measurements were made with a Varian V 4300 spectrometer (56.4 Mc) using a 10% chloroform solution with toluene as the internal standard.

Summary



In the presence of sodium ethoxide, ethyl itaconate condensed with ketones (acetone and cyclohexanone) at the terminal carbon atoms of its triad system without any appreciable

Dielectric Behavior of Hydrated Crystals. IV. Cupric Formate Tetrahydrate, $Cu(HCO_2)_2 \cdot 4H_2O$

By Hideko KIRIYAMA (née IBAMOTO)

(Received January 20, 1962)

As part of the studies of the dielectric properties of salt hydrate crystals[1], a single crystal of cupric formate tetrahydrate, $Cu(HCO_2)_2 \cdot 4H_2O$, has now been examined. The crystal has a predominant layer structure[2] in which two non-equivalent water molecules are sandwiched between $\{Cu(HCO_2)_2\}_\infty$ layers. One kind of water molecule coordinates to a copper atom directly, but the other does not. The results of the structure analysis by X-rays suggest that the two kinds of water molecules are linked together by weak hydrogen bonds. It was considered that the crystal might have characteristic dielectric properties with a large anisotropy because of the peculiar arrangement of the water molecules.

This substance undergoes a solid phase transition at $-36°C$ which is accompanied by a sudden change in the permittivity. The large dielectric dispersion and absorption observed above the transition temperature can be ascribed to the dipole orientation of the water molecules within the crystal lattice. A further absorption at much lower frequencies is also found for one particular direction of the single crystal. It may be suggested that this low frequency absorption is associated with lattice imperfections in the hydrogen-bonded systems.

In respect to the motion of the water molecules, definite information can be obtained from the results of proton magnetic resonance studies[3].

Experimental

The material was prepared by dissolving basic cupric carbonate in a dilute formic acid solution which had been made from cupric chloride and potassium carbonate, while the pure polycrystalline salt was obtained by several recrystallizations from cold aqueous water solution. A large single crystal was grown from a seed crystal in a silightly acidic solution. The crystal was cut into sections about 1.5 mm. thick and $1.5 \times 1.5\ cm^2$ in area; the main faces of the two square plates were parallel to (0 1 0) and (0 0 1) respectively, and the other was 11°5′ (i.e. the monoclinic angle β, 101°5′, minus 90°) out of (1 0 0). Considerable care in cutting and grinding the crystal was necessary because of the perfect cleavage parallel to (0 0 1).

The specimen was inserted directly between the platinum-coated electrodes of a parallel-plate condenser. The condenser was mounted in a cylindrical glass container placed in an acetone bath or liquid nitrogen bath of a large Dewar flask. By the careful addition of powdered dry ice into the acetone bath or by controlling the electric current of a heater wound around the cell, the temperature was kept constant within 0.2°C. Since the crystal was efflorescent, the specimens were usually kept in diffusion pump oil, and on measurements the crystal grains were spead on the bottom of the glass container to obtain the equilibrium water vapor pressure.

3) H. Kiriyama, This Bulletin, **35**, 1205 (1962).

The frequency range from 30 c./sec. to 10 Mc./sec. was covered. In the audio and radio frequency regions, a wide-range conductance-capacitance bridge (Ando Elec. Co. Type TR-1B), and at the highest frequency of measurement, a commercial Q-meter (Yokogawa Elec. Co.), were used. The value of the permittivity was determined from the ratio of the capacity of the specimen to that of a rock salt plate with the same thickness; a standard value of 5.62 for rock salt was used throughout the measurements.

Results

Permittivities and Dielectric Losses at Room Temperature.—The permittivities ε' and corresponding loss factors ε'' of this monoclinic crystal at 20°C are shown in Table I. The complex dielectric constant ε, $(\varepsilon=\varepsilon'+i\varepsilon'')$, is denoted as follows: ε_a and ε_b mean those with the electric field along the *a*- and the *b*-axis respectively, while ε_c is that with the external field perpendicular to the *c* plane, the cleavage plane. As indicated in Table I, there was a marked dielectric anisotropy, the values of ε_a and ε_b being much larger than that of ε_c. In addition, remarkable dielectric dispersions and absorptions were observed for both the *a* and *b* directions.

TABLE I. PERMITTIVITIES AND LOSS FACTORS AT 20°C AS A FUNCTION OF FREQUENCY

	3 Mc./sec.		3 kc./sec.		0.3 kc./sec.	
	ε'	ε''	ε'	ε''	ε'	ε''
ε_a	6.5	2.2	18.7	7.5	28.0	8.5
ε_b	7.0	3.5	31.6	2.5	33.5	2.8
ε_c	4.8	0.0	6.3	0.3	7.3	1.0

Temperature Dependence of Dielectric Properties. — Figure 1 shows the temperature dependence of the permittivities and ratios $\varepsilon''/\varepsilon'$ $(=\tan\delta)$ for various directions of the applied electric field in the audio frequency range. At the lowest temperature of measurement, −170°C, the value of permittivity was about 4.5 in every direction, a magnitude usually found in ionic solid dielectrics. There was no evidence of dielectric loss at low temperatures, and the permittivity increased slightly with an increase in temperature. When a temperature of −36°C was reached, a distinct change in dielectric character occurred, and remarkable dielectric relaxation phenomena were observed above this temperature. Such discontinuity suggests that this crystal undergoes a phase transition. The measurement of specific heat[4] has shown that the transition of the first order occurs at −36°C. Above the transition temperature, T_{tr}, there were great differences in

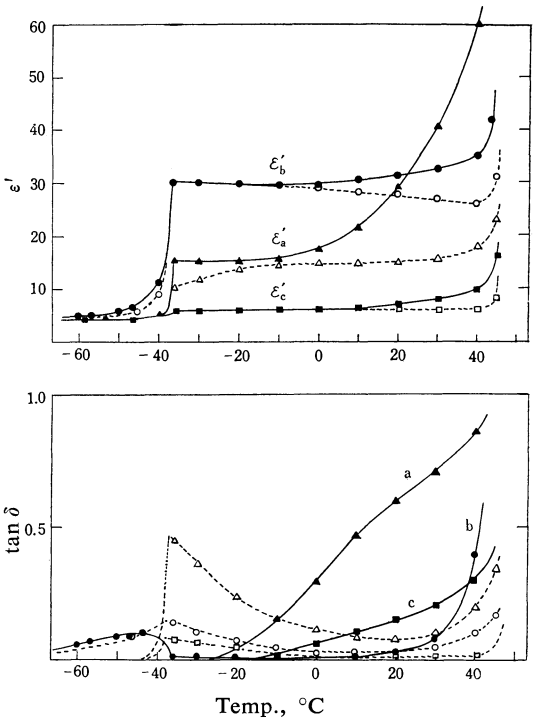

Fig. 1. Temperature dependence of the permittivity and dielectric loss angle at audio frequencies. Hollow symbols represent values obtained at 10 kc. and filled symbols at 0.1 kc.

dielectric properties in the three directions. Thus, just above T_{tr} ε'_b had the largest value among them, ε'_a, about half the value of ε'_b and ε'_c, only 6 at 0.1 kc. Moreover, at higher temperatures another type of dielectric absorption began to appear in different fashions, dependent on the direction of the applied electric field. In the *a* direction, ε'_a and also $\tan\delta_a$ rapidly increased again above about −20°C with a rise in temperature, and an apparent loss maximum was frequently observed at the lowest frequency of measurement, whereas in the *b* direction no such high dielectric losses were observed, while both ε'_b and $\tan\delta_b$ gradually increased up to 30°C. The shapes of the ε'_c-*T* and $\tan\delta_c$-*T* curves were rather similar to those in the *b* direction, but the dielectric absorption and dispersion in the former direction were quite small compared with those in the latter.

At the dehydration temperature of 46°C, a sudden increase in the permittivities and corresponding losses were observed in all three directions. Similar phenomenon was always observed in the dielectric measurements for a hydrated crystal when dehydration took place. This may be, therefore, a result of a d.c. conduction in the adsorbed layers of dehydrated water molecules on the crystal surface.

4) The thermal measurement was kindly carried out by Dr. Hiroshi Suga of the Faculty of Science, Osaka University.

Frequency Dependence of Dielectric Constants. —As is shown in Fig. 1, audio frequencies could not cover the dispersion region sufficiently. To obtain full information about the relaxation process, further measurements were made over a wide range from 30 c./sec. to 10 Mc./sec. at several fixed temperatures above the transition point. Representative results of these measurements with the electric field along the *a*- and *b*-axis are shown in Figs. 2 and 3 respectively, in which figures the permittivity and the loss factor are plotted against frequency. The absorption feature with the external field perpendicular to the cleavage plane was similar to that in the *b*-axis direction. In every direction, the absorption in the radio frequency region behaved as a typical relaxational one, and the absorption maxima gradually shifted to higher frequencies as the temperature was increased. The absorption curve in every set of measurements was a little wider than a Debye curve, indicating a spread in relaxation times. Consequently, the experimental maximum value of the loss factor, ε''_{max}, was lower than the value obtained from the term $(1/2)(\varepsilon'_0-\varepsilon'_\infty)$[5] in the Debye expression, where ε'_0 and ε'_∞ were the permittivities respectively below and above the absorption region. According to the method of Cole and Cole[6], ε'' was plotted against ε' in Fig. 4. The plots in the *a*- and the *b*-axis directions at 0°C were circular arcs, the diameters of which made angles of $0.09(\pi/2)$ and $0.16(\pi/2)$ respectively with the ε' axis. These values were rather small as compared with those obtained for a number of solid dielectrics.

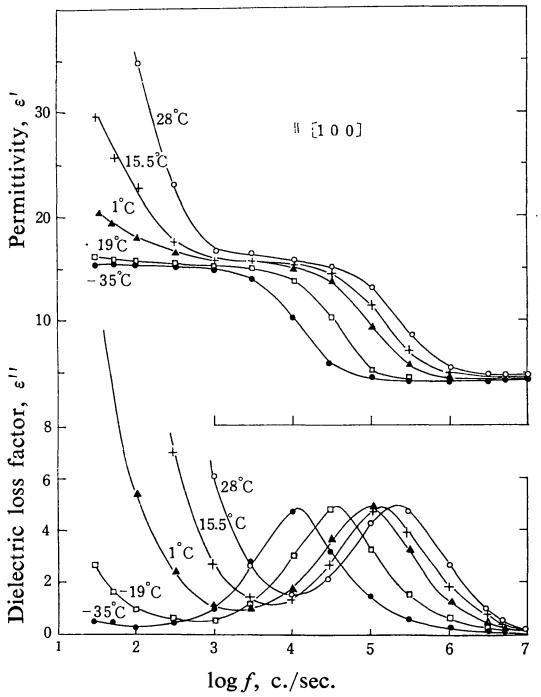

Fig. 2. Dielectric dispersion and absorption with electric field along the *a*-axis at various temperatures above T_{tr}.

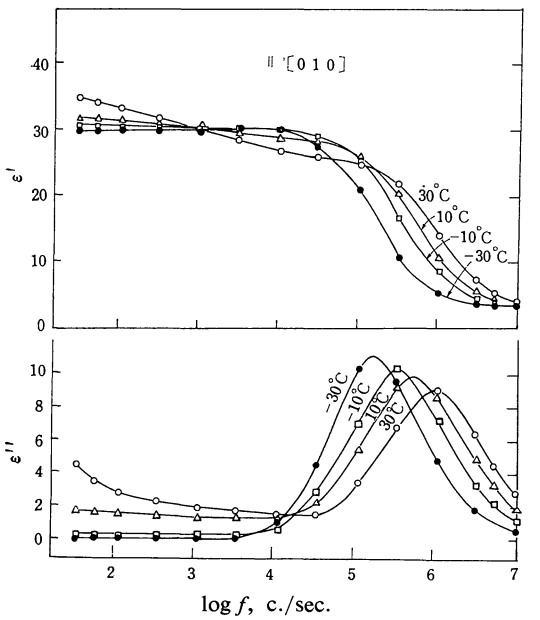

Fig. 3. Dielectric dispersion and absorption with electric field along the *b*-axis above T_{tr}.

The dielectric absorption observed at radio frequencies was ascribed to the dipole orientation resulting from the transition of the dipole from one equilibrium position to another over an energy barrier. The characteristic relaxation time for dipole orientation, τ, was obtained from the frequency of the maximum absorption, f_{max}, according to the relation:

$$\tau=1/(2\pi f_{max})$$

Then the height H of the energy barrier could be determined from the temperature dependence

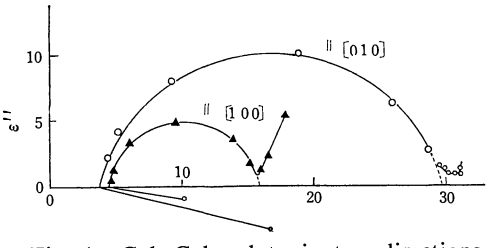

Fig. 4. Cole-Cole plots in two directions of the single crystal at 0°C.

of the relaxation time by means of the usual rate law:

$$\log \tau = -\log A + H/(2.3\,RT)$$

where R was the gas constant, T the absolute temperature, and A the frequency factor. Figure 5 shows the variation of $\log \tau$ with $1/T$ for the three cases, and the values of the energy barrier, H, and the frequency factor, A, are listed in Table II.

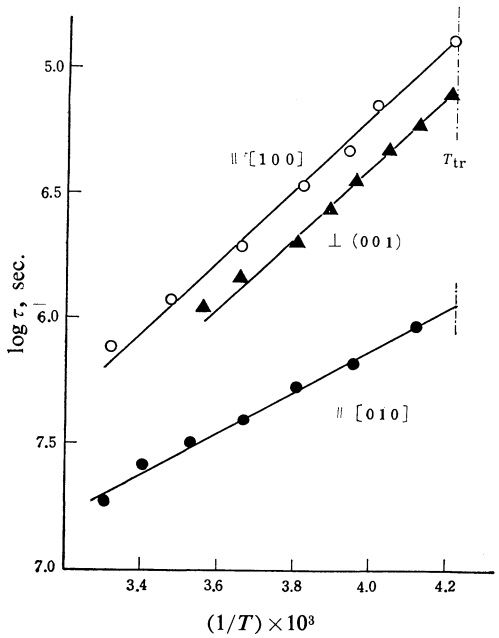

Fig. 5. Plots of $\log \tau$ (sec.) for the high frequency dispersion against reciprocal temperature (°K).

TABLE II. THE VALUES OE THE ENERGY BARRIER AND THE FREQUENCY FACTOR DESCRIBING THE OBSERVED DISPERSIONS

Direction of electric field	A sec^{-1}	H kcal./mol.
∥ [1 0 0]	1×10^{11}	6.7
∥ [0 1 0]	8×10^{9}	4.5
⊥ (0 0 1)	7×10^{10}	6.3

It can be seen in Fig. 2 that a further absorption region, in which the dielectric loss continues to increase with a decrease in frequency, is present at much lower frequencies. This type of absorption was prominent when the electric field was applied along the a-axis as mentioned above. However, the magnitudes of permittivity ε'_a and loss factor ε''_a for the low frequency absorption were somewhat variable from one sample to another, and the values obtained initially for a particular sample could not be reproduced after cooling it to the low-temperature phase and then rewarming it, whereas the results for the radio frequency absorption were quite reproducible in different runs. It would appear that in each run the loss factors of the low frequency absorption do finally attain a region where ε''_a is proportional to $1/f$, this being the evidence of d. c. conductivity.

The Atomic Arrangement in the Crystal Lattice

The crystal structure of the high temperature modification has already been determined by X-rays[2]. The structure projected on the (0 1 0)

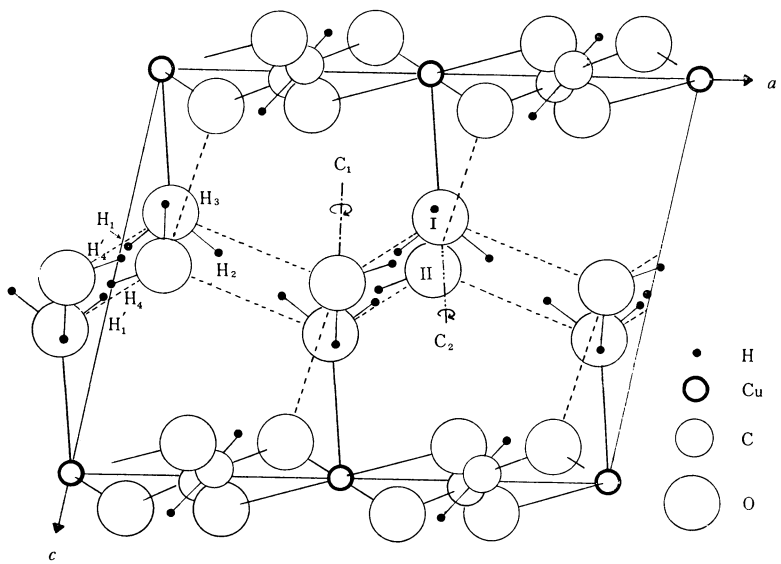

Fig. 6. Projection of the crystal structure on (0 1 0). —— Chemical bonds, ---- Possible hydrogen bonds. C_1 and C_2 represent axes of reorientation of the water molecules.

plane is represented in Fig. 6. A distinct layer structure is formed parallel to the (0 0 1) plane, in which one formate ion is coordinated to two copper atoms and each copper atom is surrounded by four oxygen atoms of four different formate ions in an approximately square configuration. Two non-equivalent water molecules are sandwiched between these layers. One kind of water molecule (H_2O-I) is coordinated to a copper atom with a far longer Cu–O distance, 2.36Å, than the ordinary covalent Cu–O distance of about 2.0Å. Another kind of water molecule (H_2O-II) is not linked to any copper atom, but to one oxygen atom of the formated ion and two oxygens of the first kind of water molecule with hydrogen bond distances of 2.82, 2.78 and 2.74Å respectively.

This crystal has a transition point at −36°C, as has already been mentioned. Though the crystal structure of the low temperature modification has not yet been available, there is no evidence of any significant change in the atomic arrangement above or below the transition point. First, even if the crystal was gradually cooled to the temperature of liquid nitrogen through the transition point, it did not collapse, and the dielectric behavior in the radio frequency region was almost reproducible after such treatment. Moreover, no visible change in optical properties in the neighborhood of T_{tr} was disclosed under a polarizing microscope. Secondly, the heat capacity and volume expansion of the crystal have already been measured by Suga[4], who found that the slight discountinuity at −36°C was due to a transition of the first order. The enthalpy, entropy and volume changes associated with the transition were estimated as follows: $\Delta H=$ 206 cal./mol., $\Delta S=0.87$ e. u., $\Delta V=0.22$ ml./mol. These values are too small to account for a structural change in the transition. Thirdly, a preliminary X-ray study made by superimposing Weissenberg photographs taken at −95°C on the 25°C photographs revealed that the low temperature crystal structure was almost the same as that of room temperature except for a little contraction of about 0.1Å in *c*.

On the basis of this evidence, the hydrogen atoms of water molecules have been located by the proton magnetic resonance experiment[3]; these results are also included in Fig. 6. Two protons (H_1 and H_2) of the water molecule H_2O-I contribute to form bent hydrogen bonds between the oxygen of its own water molecule and the two nearest oxygens of H_2O-II, whereas one proton (H_3) of H_2O-II makes a rather close approach to one oxygen of the formate ion, where a weak hydrogen bond is also predicted from the X-ray method and the remaining proton (H_4) is free from any hydrogen bond. It should be noted that two folding chains of hydrogen bonds run along the *a*-axis direction. Furthermore, with respect to packing in the *b*-axis direction, some of the hydrogen atoms, H_1', H_4, H_4', H_1, neighbor each other with H–H distances of 1.9∼2.3Å, these values being smaller than twice the van der Waals radius of 1.2Å.

Discussion

In the temperature range between −170°C and about −80°C, the permittivities in the three directions are almost independent of the frequencies, and those temperature coefficients which are present are positive and have values found in usual ionic crystals. Above about −80°C, the permittivity with the applied electric field parallel to the *b*-axis increases gradually up to the transition point, and the corresponding dielectric loss appears to be distinctly measurable, while in both directions of the *c*- and the *a*-axis no such dielectric anomalies are observed. It is, therefore, evident that the molecular motion of water within the crystal lattice is almost frozen below the transition point; this is consistent with the result of the proton magnetic resonance experiment. The gradual increase in permittivity in the *b* direction, however, indicates that some sort of reorientational motion of the water molecules has already been excited at several tens of degrees below T_{tr}.

When a temperature of −36°C is reached, the crystal undergoes a phase transition, a process which is associated with a slight volume expansion but without any significant structural change. The transition is also accompanied by a large increase in the permittivities parallel to the cleavage plane and a little increase perpendicular to it. These results indicate that the phase transition does involve freezing and releasing processes of electric dipoles. Thus, the large dielectric absorption and dispersion above T_{tr} must be due to the onset of the rotation of water molecules; this is confirmed by the proton magnetic resonance spectra. Hitherto, we have encountered difficulty in distinguishing the dipole orientation of water molecules from apparent dispersions due to cationic conduction in some hydrated salts, especially in zeolite crystals, for instance, analcite[7] and synthetic zeolites[8]. In the present case, however, there is no possibility of ionic conduction due to the cupric ions

7) R. Kiriyama, H. Ibamoto, M. Koizumi and R. Kitagaki, *Min. J.*, 1, 313 (1955).
8) R. Kiriyama, H. Kawai and W. Murayama, to be published.

present, referring to the crystal structure and the bond nature. It may, therefore, be inferred that the slight expansion along the *c* direction at T_{tr}, with a little change in the crystalline field but any without fundamental alternation in the structure, is able to give sufficient freedom to the water molecules to permit their reorientation in the external field. The second order transition caused by such sorts of the orientational motion of water molecules was also found in hydrated chromic sulfate, $Cr_2(SO_4)_3 \cdot 18H_2O$[9].

Dielectric absorptions due to the reorientation of water molecules have previously been observed in a number of hydrated crystals, such as $MgPt(CN)_4 \cdot 7H_2O$, $Y_2Pt_3(CN)_{12} \cdot 21H_2O$[10], $(NH_4)Cr(SO_4)_2 \cdot 12H_2O$[11], $Na_2HPO_4 \cdot 12H_2O$, $Na_2SO_4 \cdot 10H_2O$, $Na_2CO_3 \cdot 10H_2O$[12] and pinacol hydrate[13]. The dispersion phenomena in some of these crystals have been explained on the assumption that the water molecules are grouped together in the crystal to form a hydrogen-bonded system similar to that of ice, but from a lack of detailed knowledge of the crystal structure, except for that of alum, definite information about the molecular mechanism of the rate process has not yet been given. For the present case, the atomic arrangements, including also the proton positions, are available; therefore, the large dielectric anisotropy can be elucidated qualitatively on the basis of the individual motion of two kinds of water molecules with different neighbors.

The results of proton magnetic resonance[3] reveal that the axial rotations of both kinds of water molecules are excited in the high temperature phase. If the motion of every water molecule is possible only around the molecular dipole axis, this being a unique two-fold axis C_2 for water molecule, the dielectric properties should then be unaffected by this type of motion. Therefore, to explain the observed dielectric relaxation, the possibility of dipole orientation caused by another type of motion must be considered. In respect to H_2O-I, however, such a type of motion is rather unlikely because of the electrostatic interaction between the cupric ion and the water dipole. The dipole moment of H_2O-II may be easily oriented to the external field, in contrast to that of H_2O-I, because of the weak interactions between it and its surroundings. The permittivity values at a frequency of 30 c./sec. just above T_{tr} were 30, 15 and 6 when the electric field was, respectively, parallel to the *b*- and the *a*-axis and perpendicular to the *c* plane. The remarkable dielectric anisotropy means that the axes about which the water dipoles can rotate are closely bunched around an axis nearly perpendicular to the cleavage plane (referred to as the C_1 axis). Under these circumstances, it is suggested that H_2O-II may rotate about the C_1-axis, whereas H_2O-I rotates most probably about the Cu–O bond; consequently, the effective orientational polarization is mainly due to the dipole orientation of H_2O-II.

The activation energies associated with the dielectric relaxation in the radio frequency absorption are found to be 6.7 for the *a*-direction and 4.5 kcal./mol. along the *b*-axis. These values are much smaller than the values for ice[14] and also for crystalline *n*-primary alcohol[15] and pinacole hydrate[13], in which the dielectric absorptions are associated with the hydrogen bondings of hydroxyl groups. The low energy barrier and the high value of critical frequency suggest that the mechanism of the dielectric relaxation for cupric formate tetrahydrate is of a different nature from those proposed for ice and the others. On the basis of the atomic arrangement in the crystal, it seems that the C_1 axis around which the water molecule H_2O-II can rotate corresponds to the O–H···O bond between H_2O-II and the nearest formate oxygen. A characteristic feature of the arrangement of water molecules is the presence of an isolated hydroxyl group, i.e., $O–H_4$ of H_2O-II. Because of this and the consequent absence of hydrogen bonding, the $O–H_4$ group can easily rotate about the C_1-axis, giving the large dielectric absorption and dispersion with the marked anisotropy. The small distribution of relaxation times may support the proposed mechanism involving the rotation of the hydroxyl group.

The data for the absorption at much lower frequencies are somewhat divergent from sample to sample and also depend on their thermal histories. These structurally sensitive characters suggest that the low frequency absorption is associated with lattice imperfections or ionic impurities. For instance, the origin of hydronium impurity may be considered to be as follows: To obtain a good single crystal, it was necessary to add a few drops of formic acid to the salt solution. In view of this, the crystals used in the present experiments might contain a minute amount of hydronium ions (H_3O^+) replacing water molecules in normal sites. If

proton conduction starts from such a impurity center, the ionic state can move under the influence of the external field from one molecule to another by the successive transfer of protons along the hydrogen bond. The fact that the conducting effect is predominant only in the *a*-direction may be the most favorable evidence for the proposed mechanism.

Summary

The dielectric properties of single crystals of cupric formate tetrahydrate have been investigated over the range 30 c./sec. to 10 Mc./sec. from the liquid nitrogen temperature to the dehydration point, 46°C. This crystal undergoes a phase transition at −36°C, indicated by a sudden change in the dielectric properties. Above the transition point, large dielectric dispersion and absorptions are present when the applied electric field is along the crystallographic *a*- and *b*-axes, whereas along the normal to (0 0 1) plane, the variations in permittivity and the loss factor with temperature and frequency are quite small.

The results for the radio frequency absorption can be explained on the basis of a molecular mechanism involving the axial reorientation of two water dipoles in the formula unit of $Cu(HCO_2)_2 \cdot 4H_2O$. The energy barrier H(kcal./mol.) and the frequency factor $A(sec^{-1})$ associated with the dipole orientation have been obtained as follows: along the *a*-axis $A=1\times10^{11}$, $H=6.7$; along the *b*-axis $A=8\times10^{9}$, $H=4.5$; and in the direction normal to (0 0 1) $A=7\times10^{10}$, $H=6.3$.

A further absorption at much lower frequencies is remarkable only in the *a*-axis direction. The observed high dielectric loss suggests the possibility of proton transfer in the hydrogen-bonded chains found in this crystal structure.

The author wishes to express her sincere thanks to Professor Isamu Nitta and Professor Ryôiti Kiriyama for their helpful discussions and encouragement.

Proton Magnetic Resonance in Cupric Formate Tetrahydrate, $Cu(HCO_2)_2 \cdot 4H_2O$

By Hideko KIRIYAMA (née IBAMOTO)

(Received January 20, 1962)

In the preceding paper[1] the results of the dielectric measurement of a single crystal of cupric formate tetrahydrate, $Cu(HCO_2)_2 \cdot 4H_2O$, have been described. This substance undergoes a phase transition of the first order at 237°K. The transition is characterized by a sudden increase in the dielectric constant as it passes through the transition region towards higher temperatures. Above the transition point, the crystal exhibits marked dielectric dispersions and absorptions with a large anisotropy. The atomic arrangement in the crystal lattice at room temperature has been determined by X-rays[2], except for that of the hydrogen atom. On these bases, it has been concluded that certain types of the orientational motion of the water molecule should occur above the transition temperature.

For the purpose of locating the protons of the water molecules in this crystal below the temperature of the phase transition, and also in order to ascertain the motion of water molecules above that, the proton magnetic resonance (PMR) spectra have been studied as a function of the orientation and the temperature in both single crystal and polycrystalline samples. Some results of the proton magnetic resonance experiment will give additional information on the nature of the transition.

It is to be noted that this crystal contains paramagnetic Cu^{2+} ions which in principle cause the resonance spectra to be broad at very low temperatures. Bloembergen has already examined the proton resonance in a single crystal of cupric sulfate pentahydrate, $CuSO_4 \cdot 5H_2O$, both theoretically and experimentally[3]. With this work in mind, we have

1) H. Kiriyama, This Bulletin, **35**, 3146 (1962).
2) R. Kiriyama, H. Ibamoto and K. Matsuo, *Acta Cryst.*, **7**, 482 (1954).
3) N. Bloembergen, *Physica*, **16**, 95 (1950).

made an experiment above the temperature of liquid air and at a quite low field of about 1300 gauss. Under these conditions, the expected paramagnetic effect could be almost ignored and the problem could be treated by Pake's method[4] for the water molecule in gypsum, $CaSO_4 \cdot 2H_2O$.

Experimental

The experimental method and the apparatus were almost the same as have already been reported[5]. A Pound-Watkins r. f. spectrometer was used to observe the first derivative of the resonance line. All the experiments herein reported were made at a fixed frequency of about 5.5 Mc./sec., and the magnetic field was slowly swept by a resistance network. The applied magnetic field was modulated with a small amplitude at 60 c./sec., and the derivative of the resonance line was plotted as a function of the applied field by a recording milliammeter, preceded by a phase-sensitive detector and a narrow-band amplifier. The absorption curve was obtained by graphical integration of the derivative.

The powdered sample was prepared by dissolving basic cupric carbonate in formic acid, and the single crystal was grown from the aqueous solution by slow cooling. The single crystal sample used was a cylinder, 8 mm. in diameter and 25 mm. long, cut from large crystals. The axes of three sorts of cylindrical samples were chosen to be parallel to [010], to the normal of (001) and to that of (100) respectively. The crystal was rotated around a given axis perpendicular to the external magnetic field H_0, and the spectra were observed at regular intervals.

The temperature was varied from 110 up to 310°K. Liquid air or dry ice was used as the cooling material, and a heating coil was wound on the probe to obtain a temperature higher than that achieved with the given refrigerant. Temperatures were measured with a copper-constantan thermocouple set close to the sample. Recording was always taken after a steady condition had been reached for a time far longer than the observed time lag.

Preliminary Remarks

The Crystal Structure.—The crystal structure[2] of $Cu(HCO_2)_2 \cdot 4H_2O$ has been studied at room temperature. The crystal is monoclinic holohedral, and the corresponding space group is $C_{2h}^5 - p2_1/a$. The unit cell contains two formula units, and its dimensions are $a=8.18$, $b=8.15$, $c=6.35$ Å, $\beta=101°5'$. The water molecules are sandwiched between layers in which two copper ions are bridged by one formate ion to form two-dimensional networks parallel to (001). Each copper ion is surrounded by four oxygen atoms of four formate ions ($Cu-O = 2.00$ and 2.01 Å) in a nearly square configuration and by two water molecules (H_2O-I) above and bolow this planar CuO_4 at a greater distance (2.36 Å). Another water molecule (H_2O-II) is linked not to the copper ion, but to an oxygen atom of formate ion and two oxygens of water molecules (H_2O-I) with hydrogen bond distances of 2.82, 2.78 and 2.74 Å respectively. It is an interesting structural problem that there are four available protons as against three O-O lines capable of forming hydrogen bonds.

Though the crystal structure below the transition temperature has not yet been refined by X-ray studies, as has already been mentioned in the preceding paper[1], some experimental evidence indicates that the low temperature crystal structure is almost the same as the room temperature one, except, of course, for the positions of the hydrogen atoms. Only a small contraction of about 0.1 Å in c, and no appreciable changes in either a or b are found by superimposing Weissenberg photographs taken at 180° on the 300°K photograph.

It is easy to locate the proton of the formate ion in the lattice because the direction and the distance of the C–H bond are known approximately, but this is outside our problem. Therefore, our interest will be confined to the protons of the water molecule.

The Effect of Paramagnetic Ion.—The paramagnetic resonance absorption for a single crystal of this substance was investigated by Shimada et al.[6] in a millimeter wave region. Their conclusion was that there is an exchange interaction between the cupric ions; only one absorption line is observed in every direction, whereas two non-equivalent ions are contained in the unit cell. More recently, Martin and Waterman[7] have measured the temperature variation of the magnetic susceptibility between 80 and 300°K on the polycrystalline sample. According to them, this crystal obeys the Curie-Weiss law of the form $\chi \propto (T-\theta)^{-1}$ where θ, the Weiss constant, has the large value of $-175°$. Although the exchange energy is not known accurately, these results indicate that the exchange interaction between the non-equivalent cupric ions in this crystal is fairly strong. Consequently, the broadening action of cupric ions may be considerably reduced by exchange interaction between them.

The time-averaged magnetic moment μ_c of the cupric ion is given in order of magnitude by Curie's law:

$$\bar{\mu}_c = (\mu_c^2/3kT)H_0 \qquad (1)$$

where μ_c is the magnetic moment of the cupric ion. In an applied field of 1300 gauss at 110°K, which is the lowest temperature of our measurements, the value of $\bar{\mu}_c$ given by Eq. 1 is very small, of the order of 1 nuclear magneton, and it is much smaller still at higher temperatures. The average local field due to cupric ions, therefore, will not produce any further splitting in the proton resonance lines under consideration. The only effect of the paramagnetic ions is a slight shift of the center of the absorption line from the resonance field of liquid water, a shift which amounts to about 0.5 gauss or less, according to the formula of Bloembergen[3].

Results and Discussion

Proton Resonance below the Transition Temperature.—The experiment at liquid air temperature was made with the single crystal mounted in such a way that it could be rotated about the *b*-axis, which was perpendicular to the applied magnetic field, H_o. The derivative curve was recorded at 10° intervals as the crystal was rotated thruogh 180°. Typical traces and the corresponding integral curves are shown in Fig. 1. The absorption curves were almost symmetrical about the center of line, and no distortion due to cupric ions was disclosed within the range of experimental error. Furthermore, the resonance pattern in every orientation remained unchanged from 110° up to about 230°K. These experimental results have given a direct confirmation of the expectation discussed in the previous section. It is, therefore, evident that the fine structure observed in the present study is not to be attributed to the copper-proton interaction but to the proton-proton interaction in each water molecule.

If a proton pair exhibits only dipole-dipole interaction, the displacement of component lines, ΔH in gauss, from the field strength corresponding to free protons is related to the orientation of crystal by the formula given by Pake[4]:

$$\Delta H = \pm\alpha\,[3\cos^2(\phi-\phi_o)\cos^2\delta - 1] \qquad (2)$$

Here $\alpha = (3/2)\mu r^{-3}$, in which μ is the proton magnetic moment and r is the pair separation. ϕ is the angle between the external magnetic field, H_o, and a reference axis attached to the crystal that is in the plane of crystal rotation. ϕ_o is the angle between the projection of the p-p line (let p-p indicate proton-proton) onto the plane of rotation and the reference axis in the crystal, and δ is the angle between the p-p line and the plane of rotation. The effect of the paramagnetic cupric ions should be added to expression 2, but it is very small in this case, less than 0.5 gauss.

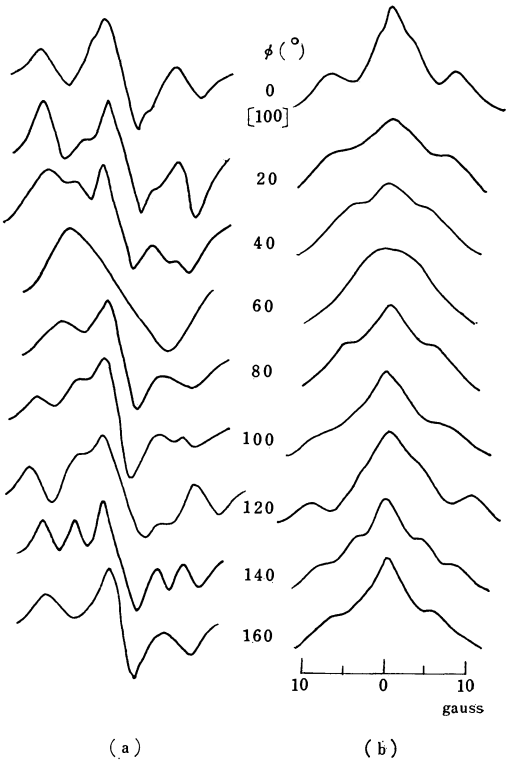

Fig. 1. Resonance patterns with various directions of H_o in the *ac*-plane at 110°K, (a) derivatives, (b) integrals.

When the crystal is turned about the two-fold axis *b*, two resonance doublets and, in addition, a central peak may be expected, because the unit cell would contain only two types of proton pairs of two non-equivalent water molecules and isolated protons of formate ions. At some orientations, the experimental derivative curves obviously displayed up to three peaks on either side of the center. However, owing to the broadening effect of the cupric ions, and also to the interaction between the proton pairs, each component line was quite broad; the overlap of the peaks was serious over part of the range, and the values of the peak displacements had to be derived by a decomposition procedure described later. As may be seen in Fig. 1, near $\phi = 0°$ and 120° the outermost peaks of the absorption curves were fairly well (though not completely) resolved. The measured peak displacements, ΔH (after correction for the effect of the paramagnetic ions), are shown as closed symbols in Fig. 2 against ϕ, which is, herein, the angle of H_o measured from the *a*-axis in the monoclinic angle β chosen above.

If, however, the shape of each component

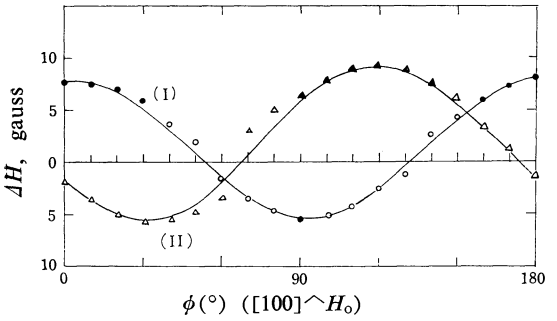

Fig. 2. Angular variation of the peak displacement ΔH in the *ac*-plane at 110°K. Closed symbols represent experimental points and open symbols denote decomposition procedure (see text). Calculated curves: I, $\phi_0=3°$, $\delta=25°$, $\alpha=5.4$ g.; II, $\phi_0=120°$, $\delta=20°$, $\alpha=5.4$ g.

line is assumed to be symmetrical, the area of the outermost peaks on the experimental absorption curves near $\phi=120°$ would amount to roughly half as much as that of the outermost peaks near $\phi=0°$. Thus, near $\phi=0°$ the ratio of the area under these peaks to that under the rest of the curve is close to 2 : 3, whereas near $\phi=120°$ the area ratio is only about 1 : 4 rather than the expected 2 : 3. Such a difference in peak height was an essential feature, because different samples behaved in the same manner because relaxation measurements confirmed that the PMR signals were unsaturated. The near-Gaussian form of the resolved outermost peaks near both $\phi=0°$ and $\phi=120°$, and also the approximate correlation between the areas, suggested the presence of residual proton pairs, but the derivative curves at no setting provided any evidence for it. Instead, it was more plausible that dipole-dipole interaction between the proton and the next nearest protons gave rise to further splitting in the resonance lines; consequently, the shape of the peak might not be symmetrical with respect to its maximum. On this supposition, we tried to resolve the absorption curves. To do this, mean absorption half curves were constructed from at least four experimental half-traces. On each of these, a standard curve, derived from the outer peak at $\phi=0°$, was superimposed at the appropriate peak displacement, and another standard curve, derived from the outer peaks at $\phi=120°$, was shifted along the field axis until the sum of the two standard curves yielded a close approximation to the outer part of the averaged experimental curve; substraction from the total curve left a residue corresponding to the protons of formate ions. The less reliable peak displacements derived from such a decomposition procedure are shown as open symbols in Fig. 2. By fitting the angular variation of the peak displacements to Eq. 2, ϕ_0 was measured to be 3° for one p-p line and 120° for the other, and the δ values were estimated to be about 25° and 20° respectively. Curves I and II in the figure are those calculated from Eq. 2, assuming $2\alpha=10.8$ gauss for all proton pairs.

In order to ascertain the p-p orientations given above, two other axes of rotation were examined. Figure 3 shows representative experimental absorption patterns for the various directions of H_0 in the *ab*-plane at 110°K. The angle ϕ between H_0 and the *a*-axis is stated with each spectrum. The angular dependence of the peak displacement ΔH is given in Fig. 4. As expected from the symmetry of the crystal, the resonance pattern at an angle $-\phi$ was just the same as one for $+\phi$; namely, two orientations of ϕ_0 and $-\phi_0$ for each group of proton pairs were allowed. The Pake curves in the *ab*-plane were calculated from Eq. 2 using the angular dispositions just determined from the peak displacements in the *ac*-plane and are presented in Fig. 4 as curves I (I_1 and I_2) and II (II_1 and II_2) for each of two non-equivalent proton pairs respectively. Since nine component lines were expected usually, a complete analysis of the resonance patterns was more difficult than that in the *ac*-plane.

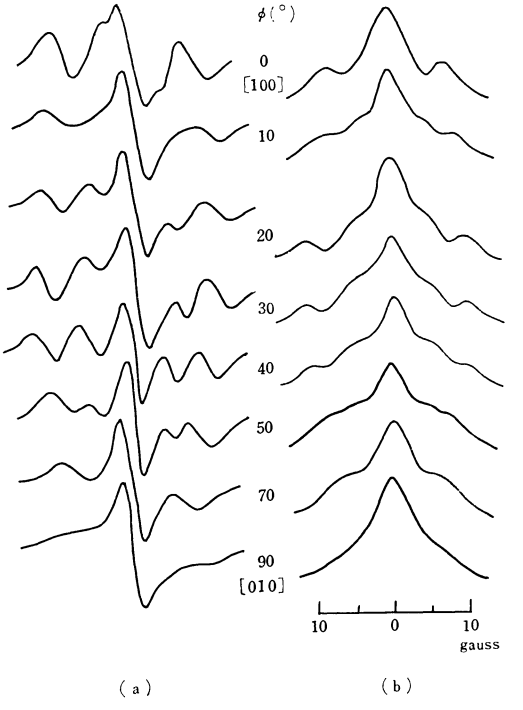

Fig. 3. Resonance patterns for various directions of H_0 in the *ab*-plane at 110°K, (a) derivatives, (b) integrals.

However, some additional evidence concerning the orientation of proton pairs may be drawn from this experiment as follows: (i) the maximum peak-to-peak separation, $2\Delta H$, for proton pair I occurs at $\phi=\pm25°$ from the *a*-axis, and both p-p vectors lie very nearly in the *ab*-plane. The maximum separation is 21.6 gauss, corresponding to a p-p distance, *r*, of 1.58 Å. The ratio of the area under these outer peaks to that under the rest of the curve is close to the expected 1 : 4; (ii) each resonance spectrum seems always to have some component lines with an ΔH of 2~5 gauss, so that the other proton pair II may be about 60° out of the *ab*-plane; (iii) near $\phi=90°$, the absorption curves were unduly broad. This broadening obviously means that some of the protons of adjacent water molecules might be close together in the *b*-axis direction.

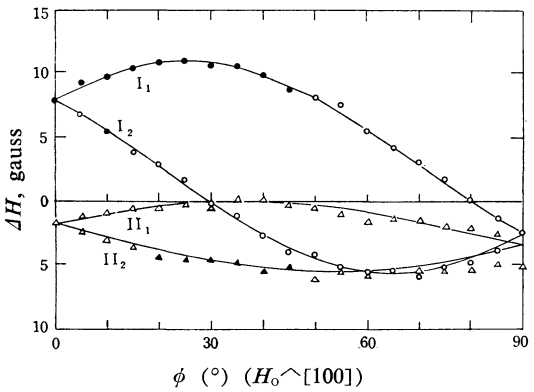

Fig. 4. Angular variation of the peak displacement ΔH in the *ab*-plane at 110°K. Calculated curves: I_1 and I_2, $\phi_0=\pm25.2°$, $\delta=2.5°$, $\alpha=5.4$ g.; II_1 and II_2, $\phi_0=\pm36°$, $\delta=54.5°$, $\alpha=5.4$ g.

The result of the measurement at 110°K with H_0 in the *bc*-plane did not contradict that obtained in the case of the *b*-axis rotation. By taking the values of ϕ_0 and δ and by using spherical trigonometry, one can compute the direction angles of the p-p lines with respect to the crystallographic axes. They were $\alpha_0=25°$, $\beta_0=65°$ and $\gamma_0=97°$ for proton pair I, while they were $\alpha_0=118°$, $\beta_0=70°$ and $\gamma_0=27°$ for proton pair II. These angles are measured away from the positive sides of the crystallographic axes, *a*, *b* and *c* respectively.

The Position of Protons below the Transition Temperature.—Although the positions of hydrogen atoms can not be determined directly from the results of the present study, it is possible to locate the most likely sites for them within the framework of the heavy atoms. As has been described above, the atomic arrangement in the low temperature form is almost the same as that of the room temperature form and the change in interatomic distances in the transition is negligible. Therefore, there is no trouble in locating the p-p vector based on the structure of the room temperature form. As the water molucule H_2O-I is coordinated to the cupric ion directly, it should orient itself by placing two protons opposite the "positive" copper ion. Thus, the direction of the p-p vector in H_2O-I will be nearly parallel to the *ab*-plane. Furthermore, the protons of H_2O-I will not deviate much from the two O-O lines where the hydrogen bonds were predicted by X-rays. It has therefore been concluded that the proton pair I should be assigned to that of H_2O-I and, consequently, the other pair II, to that of H_2O-II.

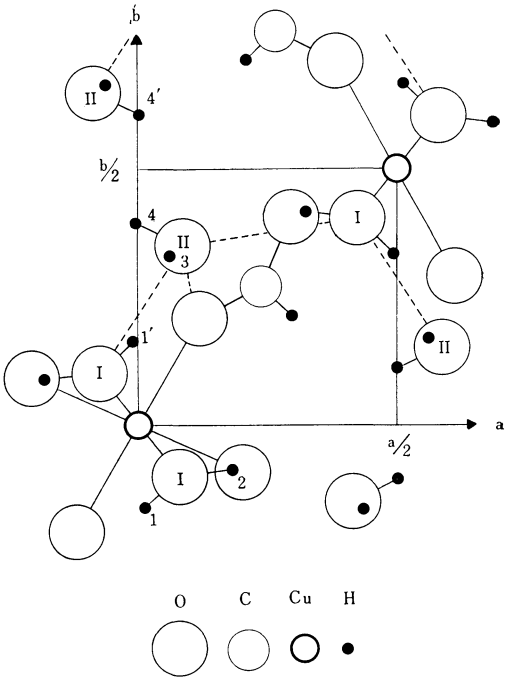

Fig. 5. Projection of the structure of $Cu\cdot(HCO_2)_2\cdot4H_2O$ on the (001) plane. Broken lines represent possible hydrogen bonds.

By using the p-p separations and the orientations of the p-p vectors, and assuming the O–H distance in the water molecule to be 0.96 Å[8], the location of the hydrogen atoms can be obtained. The deduced parameters of water hydrogen atoms are given in Table I. The projections on (001) and (010) are shown in Figs. 5 and 6 respectively. It appears that two protons (H_1 and H_2) of H_2O-I form two non-linear hydrogen bonds with two adjacent

8) G. Herzberg, "Infrared and Raman Spectra of Polyatomic Molecules", Von Nostrand, New York (1945), p. 489.

oxygens of H_2O-II in the same water layer; meanwhile one proton (H_3) of H_2O-II serves to bind the water oxygen to one oxygen of formate ion, and the other proton (H_4) is free from any hydrogen bond. With respect to packing in the *b* direction, hydrogen atoms neighbor each other as expected from the breath of the absorption spectrum. Consequently, some of the hydrogen atoms along the *b*-axis are separated by 1.9~2.3 Å, a little less than twice the van der Waals radius of 1.2 Å for the hydrogen atom.

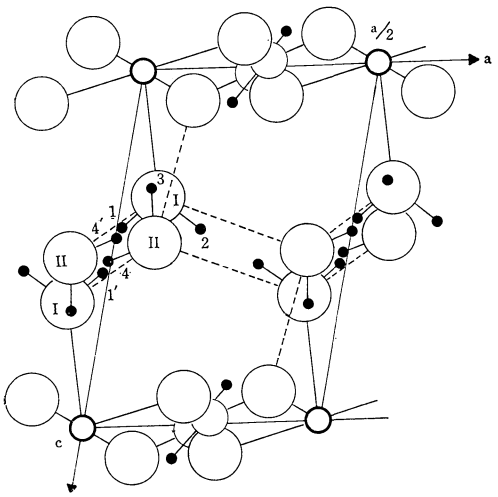

Fig. 6. Projection of the crystal structure on (010).

TABLE I. SET OF POSSIBLE COORDINATES FOR PROTONS IN WATER MOLECULES

		x	*y*	*z*
H_1	(H_2O-I)	0.01_2	-0.16_2	0.43_9
H_2	(H_2O-I)	0.18_0	-0.09_2	0.44_7
H_3	(H_2O-II)	0.06_1	0.33_1	0.33_1
H_4	(H_2O-II)	-0.00_6	0.39_3	-0.46_5

The present study is based upon Pake's method, which is applicable to the model of a "two-proton system", but the structure of this substance is much more complex than such an ideal case in two important respects: first, the water molecules lie close to each other, forming a sheet structure, and then the broadening of the fundamental line shape is so great that details are somewhat obscured; second, one must consider the effect of the cupric ions, which prevents one from using the second moment method for the purpose of structure determination. In spite of these difficulties, the positional determination of the proton pair has been fairly successful, since the resonance line shape fortunately retained the characteristic feature of the two-proton system. However, for further refinement of the proton position, a direct method of determination, such as neutron diffraction analysis at low temperatures, would be desirable.

Proton Resonance above the Phase Transition Temperature and Motion of the Water Molecules

The resonance pattern observed at the lowest temperature measured did not significantly change up to 233°K, a few degrees below the phase transition temperature, T_{tr}, 237°K. It is, therefore, certain that the hydrated water molecules are effectively stationary within the crystal lattice of the low temperature phase. When the temperature reached T_{tr}, absorption lines began to narrow with the increasing temperature at all settings of the single crystal. Two typical series of resonance line integrals for various temperatures are shown in Fig. 7, where ϕ is the angle between the applied field H_0 and the *a*-axis in the *ac*-plane. The outer peaks on the absorption curves at $\phi=0°$ and 120° have been assigned just above to the proton pairs of H_2O-I and H_2O-II respectively. In the direction of $\phi=0°$, the peak-to-peak separation, $2\Delta H$, gradually decreased from 16 to 12.5 gauss over a range of about 40° above T_{tr}, and these peaks retained prominent features well until 287°K. Then the outer

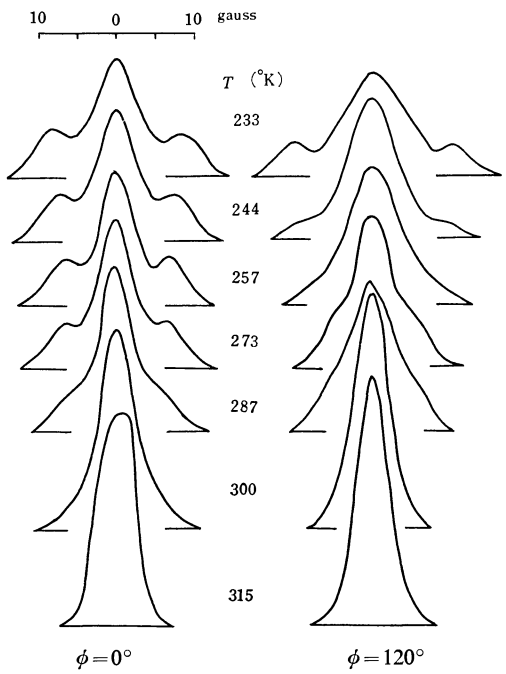

Fig. 7. Resonance absorption lines at various temperatures above T_{tr} for two special ϕ's of the single crystal. ϕ is the angle between the *a*-axis and H_0.

peaks started to collapse towards the center of the spectrum, a process which continued until the temperature was 300°K. At 300°K the absorption curve consisted of a single peaks 3.0 gauss wide, the line width being defined as the distance between the points of maximum slope. As the temperature was raised further, this single line then split up, so that at 315°K the spectrum seemed to consist of three peaks. On the other hand, the separation between the well-resolved peaks on the absorption line at $\phi=120°$ decreased much more rapidly than those at $\phi=0°$ in the temperature range 237~287°K so that prominent features of the outer peaks were barely observable even at 257°K. Then the spectrum showed further narrowing to a single peak 3.3 gauss wide between 300 and 315°K. In this temperature range the proton magnetic resonance curves at particular settings of the crystal are completely resolved into three peaks, as we shall see later.

It is known that the second moment of a resonance spectrum should be theoretically independent of the thermal motion of the nuclei[9]. However, side-spectra on absorption curves developed by thermal motions are usually too weak to be observed. If these side-spectra are neglected, the second moment of the central line would be affected by the motion. The experimental second moments for both single crystal and powdered samples are plotted against temperature in Fig. 8. The contribution of the dipole-interaction between the protons to the total second moment in the rigid state was calculated by Van Vleck's formula[10]. This value amounted to about 28.6 gauss^2 for the powder, while the experimental value was 29.0 gauss^2. The apparent change in the second moment extends over a wide temperature range from 235° to 310°K, and its total reduction for the powdered sample was 24 gauss^2. This large change indicates that the reorientation of the water molecules occurs around one axis or even more than one axis.

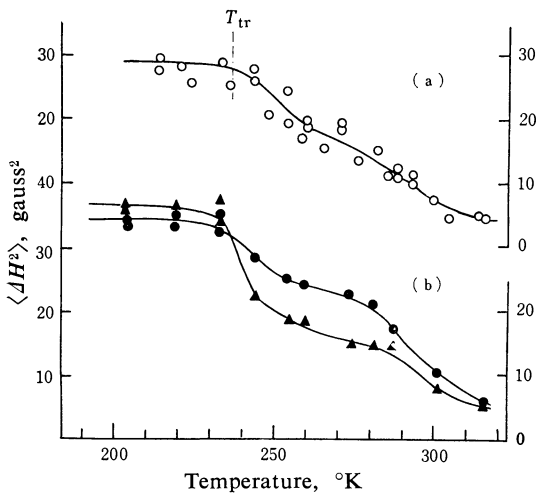

Fig. 8. Second moment as a function of temperature: for the powdered sample, (a); for the single crystal, (b).
○ Powder, ● $\phi=0°$, ▲ $\phi=120°$

In the middle of the line-width transition region, the second moment decreased with the temperature much less rapidly than at the ends of the transition region. The rather discontinuous change in the separation between the peaks or the line width, particularly near $\phi=0°$, was responsible for this stepwise decrease of the second moment. Because of the r^{-6} dependence of the second moment, a 0.2% increase in the c lattice dimension occurring at T_{tr} should produce only a 1% decrease in the second moment; hence it seems unlikely that the change in the second moment near 240°K is only a result of the lattice expansion. A study of the changes in the derivative curves indicates that both kinds of water molecule are set in motion just above the phase transition temperature and that the reorientation becomes sufficiently rapid to collapse the characteristic rigid hydrate spectra at different temperatures for the water molecules at two non-equivalent lattice sites. As is to be expected from the crystal structure, H_2O-I is subjected to a higher energy barrier to rotation than that to which H_2O-II is subjected, this being a main cause of the observed stepwise reduction in the second moment.

If the motion of the water molecule at higher temperatures is rapid rotation or reorientation about an arbitrary axis, as in Fig. 9,

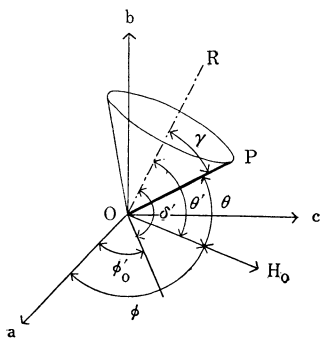

Fig. 9. Diagram showing definition of the angles for the rotating proton pair system.

9) E. R. Andrew and R. A. Newing, *Proc. Physic. Soc.*, **72**, 959 (1958).

10) J. H. Van Vleck, *Phys Rev.*, **74**, 1168 (1948).

then the absorption line should have two component lines, as given by the formula[11].

$$\Delta H = \pm(\alpha/2)(3\cos^2\gamma - 1)(3\cos^2\theta' - 1)$$

Then

$$\Delta H = \pm(\alpha/2)(3\cos^2\gamma - 1) \times [3\cos^2\delta' \cos^2(\phi - \phi_0') - 1] \qquad (3)$$

where γ, θ', δ', ϕ and ϕ_0' are as shown in the figure; OP is the vector r joining the two protons of the water molecule, and OR is the rotation axis making angle θ' with H_0 and angle γ with r.

In the temperature range of 300° to 315°K, the absorption curves with the magnetic field in the *ac*-plane consisted of a central peak and only one double line, whose separation strongly depended on the orientation of the crystal. The central peak was assigned to the proton of the formate ion, and the doublet to the water molecule. Some of the measured derivatives and the angular variation of the line-pair separation, $2\Delta H$, at 310°K are shown in Fig. 10. The extreme separations were 4.5 and 5.3 gauss respectively. Assuming that the peak-to-peak separation of 5.3 gauss corresponds to $\phi - \phi_0 = 90°$ in Eq. 3, and using $r = 1.58$ Å, as given in the previous section, the value of angle γ is computed to be 90° or 35°. Since the water molecule has a symmetry axis perpendicular to the p-p line, the former figure seems to be more acceptable. If, however, γ equals 90° for all p-p vectors, this form of motion of H_2O would not affect the dielectric properties. The large dielectric absorption and the corresponding dispersion found above T_{tr} lead us to postulate that one isolated hydroxyl group, O–H_4, of H_2O-II does reorient about the remaining O–H_3 bond in the same water molecule (see Figs. 5 and 6). On the basis of the nature of the chemical bonds between each water molecule in two different sites and its surroundings as well as of the character of the dielectric anisotropy, it is suggested that the value of γ for H_2O-II should be 35° rather than 90°, whereas the angle γ for H_2O-I has the expected value of 90°.

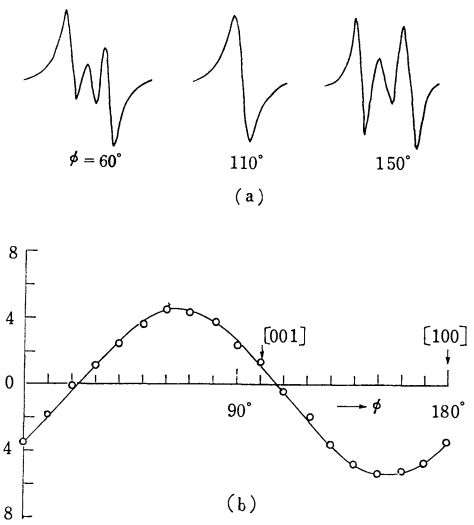

Fig. 10. Resonance patterns as the single crystal is turned about the *b*-axis at 310°K, (a) derivatives in three directions of H_0, (b) angular variation of the peak-to-peak separation.

If the data in Fig. 10 conforms to Eq. 3, the remaining parameters, ϕ_0' and δ', may be estimated from the field splittings at various orientations. The maximum line-pair separation occurs in the region of 60~70°; this yields a value for ϕ_0' of 65°. The ratio of the extreme separations is 4.5/5.3, and, also, ΔH appears to pass through zero at $\phi = 15°$ and 105°. These results lead to an estimate for projection angle δ of 38°. Thus, a set of plausible values for the parameters in Eq. 3 are $\phi_0' = 65°$, $\delta = 38°$, and $(\alpha/2)(3\cos^2\gamma - 1) = 2.7$ gauss; the continuous line in Fig. 10 indicates the corresponding line-pair separations. It is to be noted that there is no difference between the rotational states of two non-equivalent water molecules over the last few degrees before reaching the dehydration point at 319°K.

Now one can estimate the proton contribution to the second moment for the powdered sample in the rotational state. It may be considered that the component line shown in Fig. 10 owes its width to the inter-molecular broadening. The smallest values of the line width are found from the single crystal data, to be 1.2 gauss for the doublet and 0.8 gauss for the central line, the inter-molecular broadening being estimated to be about 0.4 gauss[2]. The rigid lattice second moment of an isolated water molecule is 23 gauss[2] for an H–H distance of 1.58 Å. When the water molecules rotate about an axis making an angle γ of 90° or 35° with the interproton line, the second moment may be reduced to $23/4 = 5.7$ gauss[2]. Since the water molecules include 4/5 of the protons in the chemical formula, the total second moment is expected to be 5.0 gauss[2], which is in good agreement with the observed value at 315°K.

Summary

The proton magnetic resonance spectra of $Cu(HCO_2)_2 \cdot 4H_2O$ have been investigated over the range 110° to 315°K, using both single crystal and powdered samples. The water molecules are effectively rigid below the phase transition temperature, 237°K, and the most

11) H. S. Gutowsky and G. E. Pake, *J. Chem. Phys.*, **18**, 162 (1950).

probable positions of the protons of the two non-equivalent water molecules are postulated on the basis of Pake's method.

The narrowing of the absorption line occurs above 237°K; this implies the gradual onset of a certain motion of both kinds of water molecules. The absorption spectra in the higher temperature range of 300~315°K indicate that the reorientation of the water molecules takes place almost exclusively about one axis.

The author wishes to express her sincere thanks to Professor Isamu Nitta, Professor Junkichi Itoh and Professor Ryôiti Kiriyama for their valuable discussions and continued interest, and to Mr. Teruo Yukitoshi for his collaboration in some of the experiments.

Factors which Determine Solubility

By Kōzō SHINODA

(Received January 24, 1962)

The factors which determine solubility in regular solutions have been analyzed by Hildebrand[1]. After being trained by Hildebrand, I have directed my efforts toward applying the regular solution concept to various non-regular solutions. I have been able to extend it to many non-regular systems[2]. However, there are also many systems where the aspects of dissolution are quite different from those in regular solutions. Particularly, the solutions of a surface active agent, a polymer (including polyelectrolyte) and a poly-soap are markedly different from regular solutions. Yet these solutions are very important for practical purposes and are interesting to tackle. The present paper was undertaken to analyse the dominant factors which determine the solubility of these substances.

Factors which Determine Solubility in Regular Mixtures.—The entropy of mixing, the heat of mixing and the free energy of the solute in equilibrium with the solute molecule in solution are the most important factors controling solubility in regular solutions. The basic solubility equation of the regular solution theory is[1]:

$$\ln a_2 = \ln x_2 + \frac{V_2\phi_1^2(\delta_1-\delta_2)^2}{RT} \qquad (1)$$

where a_2 is the relative activity of the solute in equilibrium with the solute molecule in solution, x_2, the solubility expressed as mole fraction, V_2, the molal volume of solute, ϕ_1, the volume fraction of the solvent, and δ_1 and δ_2, the solubility parameters of the solvent and the solute.

Accordingly, devices to increase the solubility of certain substances at a constant temperature are 1) to decrease the heat of the solution by selecting a suitable solvent, 2) to increase the activity of the solute, for example, to increase the solute pressure in the case of gas solubility, and 3) to use a solvent of a small molecular size so that when the solubility expressed as the mole fraction, x_2, remains the same, the amount which dissolves in the same volume of solvent is large. If the use of solutes of a small molecular volume and of similar chemical properties is permitted, the solubility increases very much, because the heat of solution can be reduced by a factor of V_2'/V_2. (V_2' is the molal volume of a solute of chemical properties similar to those of solute 2.)

If the super-cooled liquid state is easily attainable and relatively stable, the solubility can be increased metastably by cooling (at the temperature at which the crystal is a preferred state for the solute). In this case a solubility increase results from the enhanced free energy. In polymer, poly-soap, and surface active agent solutions this process is a rather important one as a means of increasing the solubility.

If the temperature can be changed, one way to increase the solubility of ordinary substances is to raise the temperature, because 1) the heat of mixing usually decreases with the temperature and the heat term (second term

in Eq. 1), which is divided by the temperature, decreases more rapidly, and because 2) the relative activity of the solid increases so very rapidly that the solubility of the solid also increases very rapidly. The relative activity does not change in a liquid solute, and the solubility does not increase so much as in the case of a solid at a temperature well below critical mixing. In the case of gases, the solubility, which is usually measured under constant pressure, decreases somewhat, usually because the relative activity decreases as compared with the liquid state.

If there is a strong dipole-dipole interaction or a dipole-induced dipole interaction, the molecules orientate so as to decrease the heat of mixing. Any intermolecular force, such as hydrogen bonding or differences in the positive and negative character of the components, causes a deviation from regular behavior and increases solubility. We should now add a charge transfer force[3] as a new type of intermolecular force. These, the ordinary procedures to increase the solubility, are widely applicable in many non-regular systems.

Pseudo-phase Dispersion of Surface Active Agent.—The substances studied in the solution theory are usually nearly symmetrical in their physical nature. However, molecules which have completely different properties at either end show quite non-regular behavior. Yet this type of molecule, the surface active molecule, is becoming more and more important in almost all fields of industry. In the case of surface active substances, the mechanism of dissolution is quite different. If we immerse a dry surface active agent in water, the water molecule penetrates into the hydrophilic layer so that the distance between bimolecular leaflets becomes large. If the temperature is high enough for the interior of bimolecular leaflet, i. e. the hydrocarbon chain, to be in the liquid state, the hydrocarbon chains orient end to end and the hydrophilic groups are directed to the aqueous environment. This particle, consisting of scores of surface active agent molecules (ions), is called a micelle. Since the micelle is slightly more stable than the solid hydrated surface active agent, as has been discussed elsewhere[2], a large amount of surface active agent disperses into the solution. The micelle is a small particle compared with the wave length of light and gives a clear transparent solution. Micelles are in equilibrium with singly-dispersed surface active molecules (ions), and this saturation concentration stays almost constant above the concentration at which micelle formation begins. Hence, the solubility of a surface active agent proceeds at first, up to the critical concentration for the formation of the micelle, just like an ordinary solution, but above the CMC the solubility increases very much, without any appreciable difference in the partial molal heat, entropy or free energy. The solubility of sodium dodecyl sulfate just below the Kraff point (above this temperature, the liquid state becomes preferable) is about 0.2%, but above the Kraff point it is about 10~20%. The longer the chain of surface active salts, the larger the ratio of the solubility. It becomes several hundred times more soluble as a result of micellar dispersion. The temperature rise is the most important process in increasing the solubility. Another device may be to change the structure of the molecule or to add a third component, such as alcohol, thus depressing the Krafft point. We may assume complete random mixing, as in the regular solution for singly dispersed molecules, but micelle formation is treated on the basis of a complete orientation and a complete non-mixing of water and surface active ions in the micelle.

Dissolution by the Addition of a Third Component.—We well know that the addition of a third component, such as acetic acid, to the benzene+water system increases the mutual solubility of water and benzene, finally leading to a single homogeneous phase. This is more or less a result of the orientation of the acetic acid. The methyl group will be directed more strongly toward the benzene molecule, and the carboxylic group may be bonded to the water molecules, on a statistical average.

The extreme case would be micelle formation by the third component and the solubilization of the second component by the micelle. In this case, the acetic acid is replaced by a paraffin chain salt. Alcohols, hydrocarbons, etc. dissolve in the aqueous phase and in the micelle. The process is something like dissolution into a heterogeneous mixture of water+hydrocarbon, the hydrocarbon chain aggregate of the surface active agent comprising the hydrocarbon medium[4]. In addition, it is known that the addition of surface active agent as a third component increases the solubility of some substances, such as dimethyl phthalate[5] and some kinds of dyes, which are rather difficult to dissolve in either water or hydrocarbon. We may classify this process as partition dissolution in aqueous solution containing a pseudo-phase.

Solubility of the Macromolecule.—Flory and Huggins[6] proposed to use the excess entropy of mixing due to an excess configuration based on the lattice model of a liquid. However, as was revealed by a recent study[7], the Flory-Huggins excess entropy is certainly an overestimate for a molecule which is not completely flexible.

If a polymer (macromolecule) in an equilibrium with solution is in the crystalline form, it is rather difficult to dissolve. Even a very small heat of mixing per unit volume results in a large heat of mixing per mole of polymer. However, if the polymer is in the liquid state, the solvent molecule, which is usually much smaller than the polymer, can easily dissolve because of the small heat of mixing. Even the more concentrated phase of the two phases which are in equilibrium contains much more solvent than polymer[8]. Hence, it is very important that a macromolecule be in the liquid state in order for it to dissolve in a solvent.

This can be seen from the basic solubility equation of a liquid-liquid mixture[1]:

$$\ln x'_2+\frac{V_2\phi'^2_1(\delta_1-\delta_2)^2}{RT}=\ln a_2$$

polymer rich phase

$$=\ln x_2+\frac{V_2\phi_1^2(\delta_1-\delta_2)^2}{RT} \qquad (2)$$

solvent rich phase

or

$$\ln \phi'_2+\phi'_1\left(1-\frac{V_2}{V_1}\right)+\frac{V_2\phi'^2_1(\delta_1-\delta_2)^2}{RT}=\ln a_2$$

$$=\ln \phi_2+\phi_1\left(1-\frac{V_2}{V_1}\right)+\frac{V_2\phi_1^2(\delta_1-\delta_2)^2}{RT} \qquad (2')$$

Flory-Huggins entropy of mixing is used in Eq. 2'.

In the ordinary liquid-liquid solubility of sparingly soluble compounds, $\phi_1'^2$, the volume fraction of the solvent in the solute phase, is very small, so that $\ln x'_2 \cong \ln a_2 \cong 1$.

Hence,

$$-\ln x_2 \cong \frac{V_2\phi_1^2(\delta_1-\delta_2)^2}{RT} \cong \frac{V_2(\delta_1-\delta_2)^2}{RT}$$

If the heat of mixing is large, this is compensated for by a very small value of x_2. However, in the case of polymer solutions, the volume fraction of solvent in the polymer phase is large. This is because the heat of solution of the solvent molecule in the polymer is much smaller than in the inverse process. This means that the heat term on the left-hand side of Eqs. 2 or 2' largely cancels the heat term on the right-hand side of the equation or, in other words, that the heat of the transfer of the polymer molecule from the concentrated phase to the dilute phase is small because the volume fraction of the solvent in both phases is large. Hence, we can conclude that the dissolution of a polymer (macromolecule) essentially means the dissolution of solvent in the polymer. Polymers which do not swell in a solvent do not dissolve well.

Effect of Dissociation.—If a compound contains an ionic bond and it the solvent has a large dielectric constant, the compound dissociates in solution. Dissociation proceeds as a result of the increase of entropy, and the electrical energy for dissociation acts so as to supress dissociation. If either anion or cation is readily soluble in the solution and the opposite ion is not, the soluble ion dissolves first and the solid phase in equilibrium with the solution becomes charged and becoms more soluble because of the electrical repulsion. If the anion and cation have the same tendency to dissolve, the separate solute phase may not be charged. However, the solubility is very large because the heat of solution per ion is much smaller, approximately one half, as compared with that of an ionic pair. The solubility expressed in the unit of mole fraction increases to roughly the square root as compared with a hypothetical non-dissociated species. In fact, the saturation concentrations of a single dispersion of ionic agents are roughly the square root of those of non-ionic agents which have the same oleophilic group and a similar hydrophilic group except with regard to dissociation[2b].

Solubility of Poly-soap.—In the case of the dissolution of a poly-soap polymer, to the long chain of which soap-like side chains are attached[9], many factors come into play. The poly-soap is a polymer; hence, the molecule has to have a shape and properties which make it difficult to crystallize in order for the solvent to dissolve into poly-soap. Poly-soaps have oleophilic groups as well as hydrophilic groups in the molecule. At least a fairly large part of the molecule must be strongly solvated with solvent in order to decrease the heat of mixing. However, the most important factor in the dissolution of poly-soap seems to be 1) a large amount of dissolution of the solvent into the poly-soap and 2) something similar to an inversion of the phase in the poly-soap rich phase. This means that in the first

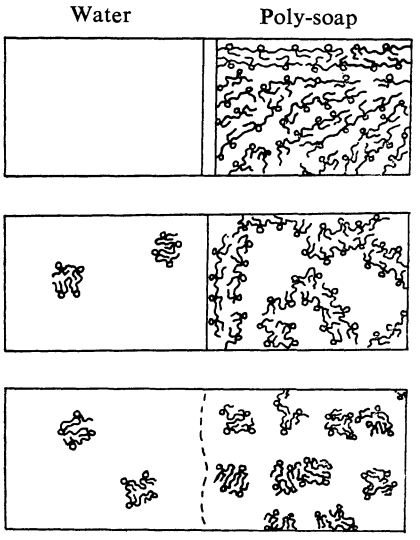

Fig. 1. Schematic diagram to illustrate probable mode of mutual dissolution of water—poly-soap.

instance the poly-soap is the solvent medium and that water (a common solvent for poly-soap) is the dispersed solute in the poly-soap phase, but in the next step the poly-soap molecules orient themselves so as to decrease the heat of mixing, hydrophilic groups being oriented outside and less hydrophilic groups inside, and finally water becomes the solvent medium and the poly-soap molecules the solute particles. Once this pseudo-phase inversion occurs in the poly-soap phase, the dispersion can be easily diluted by the very dilute poly-soap solution, formerly a separate liquid phase in an equilibrium with the poly-soap phase. The micro-Brownian motion, convection current, etc. may be sufficient for mixing. The solution is transparent because both phases are transparent. The solution may show a relatively intense light-scattering owing to the fluctuations of the concentration and the large size of the poly-soap molecule.

The addition of a certain amount of surface active agent as a third component seems to promote the solubility of the surface active polymers[10], including protein[11] in some systems.

Summary

The factors which determine solubility in various systems have been analyzed and discussed. The orientation of the molecule, the pseudo-phase dispersion, the liquid state of the solute, solvation and the pseudo-phase inversion are important factors in increasing solubility in various non-regular solutions.

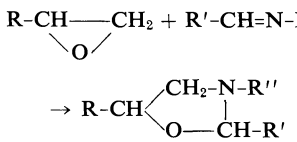
New Addition Reactions. II. Addition of Aliphatic Epoxides to Schiff Bases



By Ryohei ODA, Masaya OKANO, Shohei TOKIURA and Akira MIYASU

(Received January 24, 1962)

Some studies of the formation of five-membered heterocycles by the addition of epoxides to aldehydes, ketones, esters and isocyanates have already been reported. We described in a previous paper[1] the results of a new reaction of epoxides with ketene. By analogy, the addition of epoxides to Schiff bases may be expected to produce oxazolidines. In 1950, Doughty et al.[2] observed the formation of these compounds by a similar addition of ethylenimine to aldehydes or ketones. It has now been found that in the presence of catalytic amounts (5~10 mol.%) of stannic chloride, the expected cyclization of aliphatic epoxides with Schiff bases proceeds smoothly, according to the following equation:

1) R. Oda, S. Munemiya and M. Okano, *J. Org. Chem.*, **26**, 1341 (1961).

2) J. B. Doughty, C. L. Lazzell and A. H. Collett, *J. Am. Chem. Soc.*, **72**, 2866 (1950).

All reactions were carried out in carbon tetrachloride at 10~20°C for three hours. The results of several experiments are shown in Table I. Unfortunately, in a similar reaction with styrene oxide, the attempt to isolate the desired adduct was unsuccessful, probably because of contamination with a hydroxyl compound (see Experimental).

The yields in this addition were generally not very high, and they were not improved by varying the reaction temperature or time. The use of boron trifluoride as a catalyst resulted in a lower yield of the desired product. It is of interest to note that *N-tert*-butylazomethine is capable of reaction with epoxides, even in the absence of a catalyst. This may be due to its high nucleophilicity. In the case of the reaction with benzalaniline, a considerable amount (ca. 70~90%) of the unreacted Schiff base could be recovered, but complete recovery was impossible because of the thermal instability of the product. On the other hand, when *N-tert*-butylazomethine was used as a Schiff base, a great loss (ca. 50%) of this compound was observed in a blank experiment, presumably due to simultaneous evaporation on distillation of the solvent and hydrolysis during the after-treatment. Therefore, no effort was made to recover it from the reaction mixture.

To ascertain the direction of the ring-opening of the substituted ethylene oxides, the adduct from propylene oxide and *N-tert*-butylazomethine was compared with two authentic specimens, i. e., 3-*tert*-butyl-4-methyl- and 3-*tert*-butyl-5-methyloxazolidines, prepared by the usual condensation method[3]. The results of mixed melting point determinations as their picrates showed that the product was the 3, 5-isomer. Moreover, vapor phase chromatographic analysis indicated that the liquid adduct did not contain any 3, 4-isomer. The structure of the solid propyleneoxide-benzalaniline adduct was also confirmed by independent synthesis from 1-anilino-2-propanol and benzaldehyde. In the case of epichlorohydrin, it has been shown that ring-opening always occurs at the primary position[4]; hence, the exclusive formation of the 3, 5-isomer would be expected.

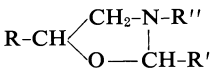
Based on the observed orientation, an S_N2-like mechanism[5], which involves a nucleophilic attack by the Schiff base on the epoxide, may be postulated, but some additional evidence would seem to be desirable before a detailed mechanism can be proposed.

Experimental[6]

Some illustrative examples are given below.

3-*tert*-Butyl-5-methyloxazolidine.—A solution of 6.6 g. (0.025 mol.) of stannic chloride in 60 ml. of carbon tetrachloride was dropped over a period of 1 hr. into a stirred solution of 21.2 g. (0.25 mol.) of *N-tert*-butylazomethine (prepared by the procedure of Hurwitz[7]) and 15.9 g. (0.275 mol.) of propylene oxide in 100 ml. of carbon tetrachloride. The addition was carried out at 10~15°C. After additional stirring for 2 hr. at 20°C, the solution was poured into 100 ml. of water, and filtered to remove stannic hydroxide. The aqueous layer was separated from the organic layer and extracted with 50 ml. of carbon tetrachloride. The combined carbon tetrachloride layers were washed with water, dried, and evaporated. Distillation in vacuo gave 8.6 g. (24%) of the base, b. p. 56~57°C (20 mmHg). The picrate (monohydrate), after recrystallization from 98% ethanol, melted at 180°C. No mixed melting point depression was observed with the picrate of authentic 3-*tert*-butyl-5-methyloxazolidine, but there was a lower mixed melting point with the picrate of authentic 3-*tert*-butyl-4-methyloxazolidine.

Vapor phase chromatographic analysis of the crude distillate was carried out, using a 1-meter column containing polyethylene glycol 1500-Celite 545 (3 : 7 by weight), with nitrogen as a carrier gas, at 70°C. The chromatogram indicated that the product consisted mainly of the 3,5-isomer. No trace of the 3,4-isomer was detected.



In this case, the authentic 3,5-isomer was synthesized by condensation between 1-bromo-2-propanol and *tert*-butylamine, followed by cyclization with formaldehyde. The pure base boiled at 53~54°C (15 mmHg), and its picrate (monohydrate) melted at 180~181°C (Analytical data are included in Table I). The authentic 3,4-isomer was similarly prepared from ethyl α-bromopropionate, via ethyl α-(*N-tert*-butyl)aminopropionate and 2-(*N-tert*-butyl)aminopropanol. The pure base boiled at 52~53°C (19 mmHg), and its picrate melted at 185~186°C.

The free base. Found: C, 67.01; H, 12.18; N, 9.56. Calcd. for $C_8H_{17}NO$: C, 67.09; H, 11.96; N, 9.78%. The picrate. Found: C, 45.20; H, 5.57; N, 15.03. Calcd. for $C_{14}H_{20}N_4O_8$: C, 45.16; H, 5.41; N, 15.05%.

5-Methyl-2, 3-diphenyloxazolidine.—A solution of 3.3 g. (0.0125 mol.) of stannic chloride in 30 ml. of carbon tetrachloride was added, drop by drop, over a period of 1 hr., to a solution of 45.3 g. (0.25 mol.) of benzalaniline and 15.9 g. (0.275 mol.) of propylene oxide in 100 ml. of carbon tetrachloride maintained at 10°C. Stirring was continued at

k M. p.
l Reported m. p. 84～85°C [G. A. R. Kon and J. J. Roberts, *J. Chem. Soc.*, **1950**, 980].
m Reported m. p. 88.5～89.5°C (Ref. 8).
n Found: C, 70.00; H, 6.04; N, 5.22; Cl, 13.23. Calcd. for $C_{16}H_{16}NOCl$: C, 70.19; H, 5.89; N, 5.12; Cl, 12.95%.

20°C for an additional 2 hr. The reaction mixture was then poured into 100 ml. of water, made slightly basic with aqueous potassium hydroxide, and filtered. The organic layer was washed, dried, evaporated and distilled in vacuo to remove unreacted benzalaniline (28 g.). Recrystallization of the residue from ethanol afforded 18.0 g. (30%) of the product, m. p. 88°C. A mixed melting point with the authentic material prepared by condensation between 1-anilino-2-propanol and benzaldehyde[8] showed no depression.

5-Chloromethyl-2,3-diphenyloxazolidine.—The procedure employed was similar to that used for the preparation of 5-methyl-2,3-diphenyloxazolidine, except that 25.4 g. (0.275 mol.) of epichlorohydrin was employed. The product which separated from the carbon tetrachloride solution at the end of reaction was filtered, washed with water, and dried. Some additional product was also obtained from the solvent layer. Recrystallization from an ethanol-dimethylformamide mixture gave 47.8 g. (70%) of pale yellow crystals, m. p. 114～115°C.

An Attempt to Prepare the Adduct from Styrene Oxide and *N-tert*-Butylazomethine.—In a similar way, 33 g. of styrene oxide was treated with 21.2 g. of *N-tert*-butylazomethine in the presence of a stannic chloride catalyst. The isolated basic fraction, b. p. 111～113°C (4 mmHg), weighed 8.5 g. Even after duplicate vacuum distillations, its elemental analysis disagreed with that of the expected adduct. However, the infrared spectrum was similar to those of other 3-*tert*-butyloxazolidines except for the appearance of a strong hydroxyl absorption in the 3400 cm^{-1} region. The picrate obtained from this product melted at 152～154°C and showed analytical data corresponding to the picrate of the desired adduct.

Found: C, 52.69; H, 5.35; N, 12.61. Calcd. for $C_{19}H_{22}N_4O_8$: C, 52.53; H, 5.10; N, 12.90%.

No further study of the structure of the product was undertaken.

The authors are indebted to the Ube Industries, Ltd., for financial support of this work. They also wish to thank Dr. Toshihiko Oiwa for his vapor phase chromatographic analysis.

New Addition Reactions. III. Addition of Aliphatic Epoxides to Nitriles

By Ryohei ODA, Masaya OKANO, Shohei TOKIURA and Fujio MISUMI

(Received January 24, 1962)

In a previous paper[1], the formation of oxazolidines by the cyclic addition of Schiff bases to epoxides in the presence of Lewis acid catalysts was described. In this connection, the early study of a similar addition of sodium cyanamide to ethylene oxide to yield 2-amino-2-oxazoline by Fromm et al.[2] is of interest.

We have now extended this addition to study the reactions of aliphatic or aromatic nitriles with aliphatic epoxides in concentrated sulfuric acid. The formation of the cyclic adduct is illustrated by the following equation. When a Lewis acid catalyst was employed, however, no product, except for a polymeric product of the epoxide, was obtained:

R=CH_3, C_6H_5, etc.

In this concentrated sulfuric acid medium, some competitive reactions — e. g., addition of water and sulfuric acid to the epoxide, and hydrolysis of the nitrile—may be expected. In fact, the reaction of ethylene oxide with phenylacetonitrile afforded a 37% yield of phenylacetamide, in addition to the desired adduct (5%) and the unchanged nitrile (51%). However, isolation of the by-products derived from the epoxide was difficult because of their water-soluble nature, but the observation that, in a blank experiment with epichlorohydrin, the loss amounted to roughly 80% and no water-insoluble product except for the unchanged epoxide was isolated, seems to support the possibility of the occurrence of the above-mentioned side-reactions.

In view of the appreciable loss of epoxide, all reactions were carried out in a molar ratio of 2 epoxide to 1 nitrile. The reaction temperature was maintained at 5~10°C. The results of several experiments are shown in Table I. At somewhat higher temperatures, a decrease in the yield of the desired product was observed. Moreover, an attempted reaction with styrene oxide was unsuccessful owing to its rapid hydration.

In the addition of propylene oxide to acetonitrile, two isomers of the product, i. e., 2, 4- and 2, 5-dimethyl-2-oxazolines, are possible. In fact, although only one basic fraction was obtained by distillation, vapor phase chromatographic analysis indicated that it was composed of 70% of the 2, 4-isomer and 30% of the 2, 5-isomer. A similar orientation was observed on the addition of the same epoxide to benzonitrile. Here, the authentic materials used for the assignments of structure were prepared by a condensation reaction[3]. The predominant ring-opening at secondary carbon suggests an S_N1-like mechanism[4] which involves a nucleophilic attack by nitrile on the carbonium ion resulting from the ring-opening of the protonated epoxide. On the other hand, the reaction of epichlorohydrin with acetonitrile afforded only one isomer which was chromatographically homogeneous; no characterization of it was made because of the failure of an attempted independent synthesis. If the orientation is much influenced by the electron-withdrawing chlorine atom, as is seen in other acidic additions to epichlorohydrin[5], the 2, 5-isomeric structure rather than the 2, 4-isomeric structure for the adduct would be more likely.

Experimental[6]

Illustrative examples are given below.

2-Phenyl-2-oxazoline.—Benzonitrile (51.5 g., 0.50 mol.) was gradually dissolved in 55 ml. of concentrated sulfuric acid at ca. 0°C. Into this solution 44.5 g. (1.00 mol.) of ethylene oxide was dropped over a period of 3 hrs. with stirring. The temperature was maintained at 5~10°C. After completion of this addition, stirring at 10°C was continued for 2 hr. The reaction mixture was then allowed to stand overnight below 10°C and poured slowly into ca. 200 ml. of ice and water. The solution was made slightly acidic below 20°C with aqueous sodium hydroxide, and the precipitated mixture of sodium sulfate and benzamide was filtered off. The filtrate was extracted with benzene to remove the unchanged nitrile and then made strongly basic by the addition of a concentrated sodium hydroxide solution. It was then extracted with three 100 ml. portions of ether. The combined ether extracts were washed with a saturated sodium chloride solution and

dried. The solvent was removed by evaporation, and the resulting oil was distilled to yield 13.9 g. (19%) of 2-phenyl-2-oxazoline, b. p. 121°C/13 mmHg. The recovered benzonitrile from the benzene extact weighed 28.4 g. (54%).

A Mixture of 2, 4- and 2, 5-Dimethyl-2-oxazolines.—Into a solution of 20.5 g. (0.50 mol.) of acetonitrile in 55 ml. of concentrated sulfuric acid, 58 g. (1.00 mol.) of propylene oxide was dropped over a period of 3 hr. at 5～10°C. Stirring was continued at 10°C for an additional 2 hr. After the solution had stood overnight below 10°C, the reaction mixture was gradually poured into 200 ml. of ice and water. The solution was then neutralized with aqueous sodium hydroxide, and the resulting precipitate was filtered off. The filtrate was made strongly basic with concentrated sodium hydroxide and extracted three times with 100 ml. of ether. After the removal of the ether, the residue was distilled and 4.1 g. (8%) of the product, b. p. 116～118°C, was obtained. Recovery of unchanged acetonitrile was difficult due to its water-solubility. A redistilled sample prepared for elemental analysis was chromatographed on a 2-meter column containing polyethylene glycol 4000-Celite 545 (3 : 7 by weight), with hydrogen as a carrier gas, at 70°C. Data showed that it was composed of 70% of 2,4-dimethyl-2-oxazoline (low retention) and 30% of the 2,5-isomer (high retention). Authentic 2,4- and 2,5-dimethyl-2-oxazolines used as references were prepared by the method of Wenker[3] from 2-amino-1-propanol and 1-amino-2-propanol with acetic acid respectively. The 2-amino-1-propanol used here was synthesized by esterification of *dl*-alanine[7], followed by reduction with lithium aluminum hydride[8]. 1-Amino-2-propanol was commercially available. The pure 2,4-isomer boiled at 116～117°C [lit.[9] 30°C/35 mmHg], and its picrate melted at 130～131°C (lit.[9] 130～135°C). The 2,5-isomer boiled at 117～118°C (lit.[10] 117～119°C), and its picrate at 114～115°C (lit.[10] 114～115°C).

***x*-Chloromethyl-2-vinyl-2-oxazoline and its Polymer.**—The procedure employed was similar to that used for the preparation of the above oxazoline except that a small amount of hydroquinone was added as a polymerization inhibitor. The product, b. p. 92～93°C/22 mmHg, easily polymerized on

High-Kinetic Energy Fragment Ions from Aliphatic Hydrocarbons under Electron Impact. I. Measurement and High-Kinetic Energy Methyl Ions from 1,3-Butadiene

By Toshikazu TSUCHIYA

(Received November 20, 1961)

It has long been known that fragment ions from diatomic and polyatomic molecules by electron impact often have appreciable kinetic energies. The distribution of kinetic energies among the fragment ions formed from the diatomic molecules of a given species can now be explained satisfactorily on the basis of potential energy diagrams of the normal state and of the various ionized states using the Franck-Condon principle[1].

Fragment ions from polyatomic molecules have not been so thoroughly studied as those from diatomic molecules. Hustrulid et al.[2], in a study of the mass spectrum of benzene, showed that the satellite peak on the high mass side of each of the peaks of the masses *m/e* 15, 26, 27, 14, 13 and 12, is caused by ions to which the dissociation process has imparted a large kinetic energy lying within a narrow range. It was suggested that the high energy ion came from the dissociation of doubly charged molecules into two singly charged fragments. The appearance potential of the satellite peaks was found to be much higher than the main peaks, a finding consistent with this explanation.

Hipple et al.[3] gave the collector of their mass spectrometer a positive potential, relative to the analyzer, sufficient to stop all ions of a zero initial velocity, and so was able to record the satellite peak alone. This experimental result shows that the satellite peak came from ions with a high initial velocity, too. Mohler et al.[4] measured the kinetic energies and intensities of satellites which accompany the *m/e* 15 spectra of 15 hydrocarbons; they also discussed the reaction mechanism by which the high kinetic energy ions are produced. Their mass spectrometer was provided with a metastable ion suppressor slit between the exit slit of the analyzer and the ion collector. The slit could be set at an adjustable positive potential to stop any ions which have lost kinetic energy while traversing the analyzer tube. The slit had a focusing action for ions and increased the resolving power of the instrument. They observed satellites on *m/e* 15 by applying the appropriatepoten tial to the suppressor slit and by using very low ion-accelerating voltages ranging from 500 to 145 V.

Berry[5], in a study of discrimination effect, has measured the velocity distribution of methyl ions from *n*-butane, and of various other ions, by deflecting the ion beam parallel to the magnetic field by an electric field. He confirmed that there are two groups of ions, one with a thermal distribution and the other with a high kinetic energy.

In this paper a method for measuring high energy ions with a conventional analytical mass spectrometer without any such equipment as an additional deflecting electrode or a metastable ion suppressor slit, and some results are described.

Experimental

A Consolidated Model 21-103C analytical mass spectrometer with a dual collector slit was used in this research. This instrument has a mass-resolving power of about 600 when a 7 mil (ca. 0.2 mm.) slit is used. With the slit, if the magnetic field is reduced and the m/e 15 ion of propane is focused at about 500 V. or less, the satellite peak described by Mohler et al. appears. Figure 1 illustrates the mass spectrum of propane, m/e 15 and 14 under these conditions. The m/e 15 satellite originates from ions having excess kinetic energies* as has been well established[4]. However, if a satellite peak is observed in the mass spectrum of a new substance, the satellite may be a KE peak, or a peak which originates from metastable ions or from ordinary TE ions having an m/e value slightly different from the m/e value of the "mother" peak. We must, therefore, distinguish KE peaks from those peaks mentioned above. In the experiments made by Mohler et al. metastable ions, if desired, could be eliminated by the use of a metastable ion-suppressor slit.

Fig. 1. Doublets at m/e 14 and m/e 15 in the spectra of propane.
Electron current; 19.5 μA, $V_i \fallingdotseq 500$ V., $V_r = 0$ V.

In order to study KE ions by means of a conventional mass spectrometer, we shall consider, for a moment, how to distinguish KE peaks from the other peaks in the spectrum. For this purpose, we shall now study the properties of the following doublets and peaks by varying the ion-accelerating and ion-repeler voltages: (1) m/e 15 doublets in the spectrum of n-butane and propane, (2) the m/e 31.9 peak of n-butane, and (3) the m/e 44 peaks of propane and carbon dioxide. The higher mass side peak of the m/e 15 doublet is the KE peak; the m/e 31.9 peak is a metastable peak, and the m/e 44 peaks are TE peaks.

Distinction between KE and Other Peaks.—*Influence of* V_i.—Figure 2 shows the effect of varying the ion-accelerating voltage, V_i, on various peaks. The spectra were taken by voltage scanning in appropriate magnetic fields. Curve 1 in this figure represents the m/e 15 peak ratio, I_k/I_t, for propane. The ion-repeler voltage, V_r, was about 5 V. Curve 2 is the peak ratio $(m/e\ 31.9)/(m/e\ 30)$ for n-butane. V_r's were set at optimum positions for m/e 31.9 peak focusing. Curve 3 is the m/e 44 peak ratio of propane to the carbon dioxide in a mixture of these compounds. V_r's were about 0.5 V.

Curve 1 in Fig. 2, which gives the m/e 15 intensity ratio, I_k/I_t, for propane, has a large positive

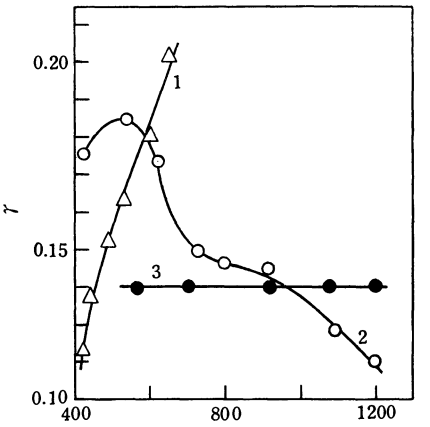

Fig. 2. Peak ratios γ versus ion accelerating voltage, V_i.
Curve 1: m/e 15 peak height ratio of propane, (Higher mass side peak)/(Lower mass side peak).
Curve 2: Peak height ratio of n-butane, $(m/e\ 31.9)/(m/e\ 30)$.
Curve 3: m/e 44 peak height ratio, $(C_3H_8)/10\times(CO_2)$.

gradient, and can easily be distinguished from curves 2 and 3 in the same figure. According to Berry[5], the larger the initial kinetic energies of the ions, the larger the absolute value of the tangent of the ion intensity versus V_i curve. The behavior of curve 1 can be well explained by assuming that the ions on the higher mass side peak have greater kinetic energies.

Metastable peaks result from the spontaneous dissociation of an ion after the ion has been accelerated but before it has passed very far into the analyzing magnetic field. The peaks do not follow the equation

$$m/e \propto H^2/V_i$$

where H is the magnetic field. The point where the dissociation takes place depends on the speed of the mother ion and is a function of V_i. Curve 2 in Fig. 2, which gives the peak intensity ratio $(m/e\ 31.9)/(m/e\ 30)$ of n-butane, shows that the metastable peak intensity, I_m, tends to decrease relative to the normal ion intensity, I_t, as V_i is reduced in the range of V_i larger than about 500 V. This may be explained as follows. The smaller the V_i value is, the nearer to the point of formation of ordinary ions is the point of dissociation of the mother ion, and consequently, the more efficiently focused is the beam of the dissociated product ions. The details of curve 2 may be explained by the potential distribution in the various parts of the ion source. This explanation is a tentative one, and, moreover, the experiment concerns only the m/e 31.9 ion of n-butane. Therefore, to establish that the behavior of the metastable ion is proper to all metastable ions, further investigations on various ions are, of course, necessary. However, if a doublet is observed and if the ratio of the peak intensities

* For convenience, ions having excess kinetic energies will hereafter be called KE ions, and the peaks due to KE ions will be called KE peaks. Similarly, ions having thermal energies corresponding to the temperature of the ion-source will be called TE ions, and the peaks due to TE ions will be called TE peaks. The intensities of the KE and TE peaks will be indicated by I_k and I_t respectively.

for the components behaves in the way shown by curve 2 in Fig. 2, the peaks invariably do not come from KE ions. The distinction between curves 1 and 2 is outstanding, as may be seen from a comparison of curves in Fig. 2.

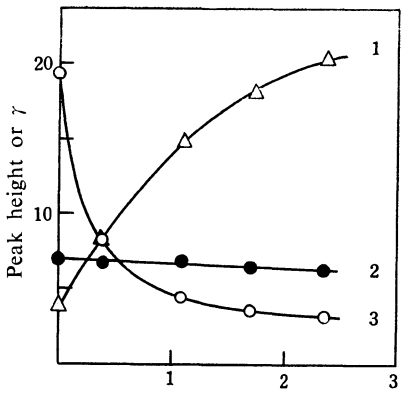

Fig. 3. KE peak height, I_k, TE peak height, I_t, and the ratio I_k/I_t versus ion repeller voltage, V_r.

Curve 2: I_t, $(m/e\ 30)$
Curve 3: γ, $(I_m/I_t)\times 10^3$

Curve 3 in Fig. 2, which gives the *m/e* 44 peak ratio of propane to carbon dioxide, concerns two spepcies of ions which are produced at a normal position in the ionization chamber and which have close *m/e* values. These ions have only a kinetic energy corresponding to the temperature of the ionization chamber. The curve shows that the influences of V_i on these ions are nearly the same.

Influences of V_r.—Figures 3 and 4 show the influences of the ion-repeller voltage, V_r, on various peaks. The data in Fig. 3 were obtained by measurements of the doublet at *m/e* 15 of *n*-butane, with the V_i being fixed at about 500 V. In Fig. 3, curve 1 shows the I_t, i.e., the lower mass side peak height of the doublet, while curve 2 shows the I_k, the higher mass side peak height of the doublet, and curve 3 shows the ratio I_k/I_t. In Fig. 4, the height, I_m, of the *m/e* 31.9 metastable peak (curve 1), the height, I_t, of the *m/e* 30 peak (curve 2), and the ratio, I_m/I_t, (curve 3) are given as functions of V_r.

The *m/e* 44 peak versus the V_r curves for both propane and carbon dioxide showed much the same tendency as curve 1 in Fig. 3, and the ratio of the two peaks was almost constant over the range of V_r used.

The influence of the ion-repeller voltage, V_r, on metastable ion peaks was investigated by Hipple et al.[3] They showed that an increase in V_r increases both normal TE ion peaks and metastable ion peaks, and that the effect is more pronounced in the case of metastable peaks. They also pointed out that KE ions are less affected by V_r than TE ions. Curve 3 in Fig. 4, which represents the ratio of the metastable peak to the TE peak, has a positive tangent, as they demonstrated. Curve 3 in Fig. 3, which represents the ratio of the KE peak to the TE peak, has a negative tangent.

The ions produced in the ionization chamber are pushed out through the ionization chamber slit into the ion accelerating system by the action of the repeller voltage, V_r. When a small voltage V_r is applied to the repeler, I_t is increased by this action, as may be seen from curve 1 in Fig. 3. If ions with an initial kinetic energy are produced in the ionization chamber and have a velocity component perpendicular to the plane of the exit slit of the chamber, the ions are expected to pass through the slit irrespective of V_r values above zero. This expectation is shown to be true by curve 2 in Fig. 3, which, as Hipple et al. pointed out qualitatively, shows that the V_r values have only a slight effect on these ions, which are considered to have appreciable kinetic energies.

The finding that the ratio of the *m/e* 44 peaks of propane to carbon dioxide was practically independent of V_r shows that the influences of V_r on TE peaks are the same.

Measurement. — The KE peak, TE peak, metastable peak, and their ratios have been investigated as functions of V_r and V_i, by taking the peaks of *n*-butane and propane as examples. As is clear from a consideration of the results, the properties shown in Figs. 2, 3 and 4, except for the $I_m \sim V_i$ relation, are not specific to the substances taken as examples, but are specific to each species of ions.

To distinguish between the TE, KE, and metastable peaks, we may vary V_i or V_r and examine the resulting influences on the intensity, I, of the peak under consideration or on the intensity ratio of I to a peak which is known to be a TE peak.

All the KE ions observed so far have accompanied TE ions and have appeared as doublets. When a doublet spectra appeared in the mass spectrum of a compound, the high mass side peak was examined by the procedure mentioned above to determine whether or not it was KE peak. After a peak was identified as a KE peak, the kinetic energy, E, the ion-accelerating voltage difference of the doublet[4], was measured by one or both of the following procedures: (a) The ion accelerating voltages of the doublet are measured by setting the voltage manually on each peak, with the potentiometer supplied with the instrument to calibrate the mass scale. E is obtained as the difference of the voltages. (b) The ion-accelerating voltages of the two peaks just before and after a doublet are measured. From these values and the distances, recorded on the chart, between the two peaks and between the peaks of the doublet, the ion-accelerating voltage difference corresponding to the doublet is calculated by interpolation.

When the resolution and intensity are favorable, the reproducibility of the measurements was within ± 0.2 eV.

The influences of the ion-accelerating voltage, V_i, and the ion-repeller voltage, V_r, on the measured kinetic energy values were checked by varying V_i and V_r values in the ranges 400~600 and 0~10 V. respectively. The results showed that the variation in these voltages has no influence on the measured kinetic energies.

Because of the overlapping of the tails of the major and minor peaks of a doublet, an error in locating the maximum point of the minor peak may result from a marked unbalance of the peak heights of a doublet. To minimize the effect of the overlapping of peak tails on the measured E value, all E values were measured with a repeller voltage of $V_r=0$.

Results and Discussion

Table I summarizes the results of the measurements of the kinetic energy peaks for methyl ion in ethane, propane, *n*-butane, isobutane, propylene, and 1, 3-butadiene. Since the first four substances were investigated by Mohler et al.[4], their results are also listed in the table as a check.

The second column gives the kinetic energy value found in the present work, and the fifth column, the value reported by Mohler et al. Taking the accuracies of measurements into account, the coincidence of data is reasonable.

The third column gives the intensity, found by the present measurements, of the satellite peak relative to the thermal energy peak, and the sixth column, the intensity found by Mohler et al. A comparison of the data shows that the values of the present work are about 10 times larger than those of Mohler et al. As can be seen from curve 1 in Fig. 2 and curve 3 in Fig. 3, these ratios depend markedly on the ion-accelerating voltage, V_i, and the ion-repeler voltage, V_r. The values of V_i and V_r used in this work were, respectively, about 500 and 0 V. On the other hand, the value of V_i used by Mohler et al. was 140 V.; their V_r value was not indicated. The discrepancies in the intensity ratios may be due to the differences in these experimental conditions.

In the present experiment, the m/e 15 KE ion of an appreciable intensity was found in the spectrum of 1, 3-butadiene. KE ions of m/e 14 were detected by Hipple et al.[3] in the spectrum of this compound. The m/e 15 peaks of 1, 3-butadiene are rearrangement peaks, and are unique in that the intensity of the KE peak is about four times higher than that of the TE peak. This phenomenon may be explained as follows: The first and fourth carbon atoms of the compound are more reactive than the second and third atoms. In an excited state, proposed by Eyring et al.[6], of the compound under electron impact, the more reactive first or fourth carbon atom takes the hydrogen atom from the adjacent second or third carbon atom and forms a methyl group. During this transfer, the equilibrium C=C distance is assumed to remain approximately the same. Since the equilibrium distance of CH_3–C is longer than that of CH_2=C, the Franck-Condon region corresponding to the CH_2=C bond of the mother compound crosses the CH_3–C potential energy curve for an upper state at a region higher than the dissociation asymptote of the curve; thus, the methyl ion, formed by rearrangement, dissociates with a high kinetic energy.

Hustrulid et al.[2] suggested that these ions of a high kinetic energy result from the dissociation of doubly-charged ions formed by electron impact. Mohler et al.[4] computed the repulsive energies of various compounds on this assumption. The "Coulomb energy" calculated by them, i. e., the calculated repulsive energy, is cited in the last column of Table I. When a molecular ion dissociates into two fragments, these fragments have equal momenta. By assuming that doubly-charged ions dissociate into two fragments, one of the two being methyl ion, and that the law of conservation of momenta holds, the total kinetic energy of both fragments has been computed from the value in column 2; this is listed in the fourth column of Table I. In the seventh column the total energy calculated by Mohler et al. is

TABLE I. CH_3^+ IONS OF HIGH KINETIC ENERGY IN MASS SPECTRA OF HYDROCARBONS

Compound	Present experiment			Result of Mohler et al.*			
	KE of satellite	Relative intensity	Total KE	KE of satellite	Relative intensity	Total KE	Coulomb energy
Ethane	2.5	0.54	5.0	2.3	0.03	4.6	5.6
Propane	2.4	0.89	3.6	2.2	0.076	3.3	3.7
Propylene	2.6	0.52	4.0	—	—	—	—
n-Butane	2.3	1.41	3.1	2.2	0.137	3.0	2.9
Isobutane	2.5	1.16	3.4	2.6	0.11	3.5	3.7
1,3-Butadiene	2.5	4.15	3.3	—	—	—	—

Energy unit is eV.

* F. L. Mohler, V. H. Dibeler and R. M. Reese, *J. Chem. Phys.*, **22**, 394 (1954).

given for purposes of comparison. In the cases of ethane and propane, the total energies found in this work are nearer to the "Coulomb energy" than those found by Mohler et al. The total energies of other substances are nearly the same in both cases.

If the mechanism proposed by Hustrulid-Mohler* is valid, the total energy is approximately inversely proportional to the distance between the carbon atoms at both ends of the molecular chain[4]. In the cases of two series of substances, ethane, propane, and *n*-butane, and propylene and propane, this expectation is realized qualitatively, as may be seen from the fourth column, Table I; the assumption of H-M appears to be true from this consideration. However, if a doubly-charged ion actually dissociates into two fragment ions, two species of ions with the same momentum must be observed. To clarify the origin of high kinetic energy ions from this point of view, it is desirable to study the kinetic energies of all the fragment ions of a compound.

Taking ethylene as an example, all peaks were examined, and kinetic energy satellites were found at *m/e* 13 and 14. Table II summarizes the results of these measurements. The first column gives the *m/e* values at which kinetic energy satellites were found; the second and third columns give, respectively, the kinetic energy value and the intensity of the satellite peak. The conditions of measurements were much the same as those for the measurements in Table I.

The following reactions were studied for the fragmentation of ethylene, according to the H-M mechanism:

$$C_2H_4 \rightarrow C_2H_4^{2+} \rightarrow \begin{cases} 2CH_2^+ & (1) \\ CH_2^+ + CH^+ + H & (2) \end{cases}$$

From Table II, the measured total energy for reaction 1 is 4.4 eV., if it is assumed that the fragments have only translational kinetic

* Abbreviated as H-M.

TABLE II. IONS OF HIGH KINETIC ENERGY IN MASS SPECTRA OF C_2H_4

m/e	KE of satellite	Intensity (arbitrary unit)
13	2.1 eV.	2.4
14	2.2 eV.	6.6

energies. If the H-M assumption were valid, the total energy for the fragmentation of KE ions of ethane would be smaller than that for reaction 1. However, since the value for ethane is 5.6 eV. according to the computation by Mohler et al.[4], is 5.0 eV. according to the computation made in the present work (Table I), the H-M mechanism of fragmentation does not hold for reaction 1.

If it is assumed that the H-M mechanism holds and that the hydrogen atom produced carries away a large amount of kinetic energy, the reaction represented by Eq. 2 can take place. However, according to the relation between the ion intensities of methylene ion and methylidyne ion in Table II, it is considered that all the methylene ions are not formed by the reaction. It follows that, from the standpoint of the H-M mechanism, a fraction of methylene KE ions is produced, together with neutral fragments.

Summary

With a conventional analytical mass spectrometer and without any additional electrodes, fragment ions produced with excess kinetic energies by electron impact can be detected and studied quantitatively. Mainly methyl KE ions in the spectra of seven hydrocarbons have been measured. A comparison of the results on methyl ions in four hydrocarbons with reported values showed a satisfactory consistency.

An appreciable part of the *m/e* 15 rearrangement ions of 1,3-butadiene had excess kinetic energies. The mechanism of the formation of the ions has been proposed which assumes a transfer of the hydrogen atom from a second

carbon atom of the molecule to the first carbon atom followed by the recoil of the resulting two groups of atoms. The study of the KE ions in the spectra of the ethylene molecule from the standpoint of the H-M assumption shows that the mechanism of the formation of various KE ions is complicated and deserves more detailed study.

Infrared Spectra of Acyclic Imides. V. Infrared Spectra and Structure of Acyclic Imides in Solutions

By Toyozo UNO and Katsunosuke MACHIDA

(Received January 11, 1962)

In earlier papers of this series[1-4], it has been shown that the infrared spectra of saturated acyclic imides in the crystalline state are closely related to the configuration of the -CONHCO- group. Some higher homologs of diacetamide (R-CONHCO-R', R=CH_3, C_2H_5 and *n*-C_3H_7; R'=C_2H_5 and *n*-C_3H_7) have been proved to be crystallized in a stable form taking the trans-trans configuration[2,3]. The characteristic frequencies of the trans-trans -CONHCO- group have been assigned, and their similarity to the characteristic frequencies of the trans -CONH- group has been pointed out[2]. No example of the trans-cis -CONHCO- group, however, has been found to exist in the crystalline state except for the stable form (form A) of diacetamide[1], the first member of the homologous series. In connection with these results, the present paper deals with the infrared spectra (4000 to 900 cm^{-1}) of these acyclic imides dissolved in various non-polar solvents. It will be shown that the higher homologs, as well as diacetamide itself, take the trans-cis configuration when dissolved in a non-polar solvent, such as carbon tetrachloride, tetrachloroethylene or carbon disulfide. The characteristic frequencies of the trans-cis -CONHCO- and -CONDCO- groups in the rock salt region will also be discussed in detail.

Results and Discussion

Diacetamide in Non-polar Solvents.—In the infrared measurements of the solutions of diacetamide, the three non-polar solvents, carbon tetrachloride, tetrachloroethylene and carbon disulfide, lead to nearly identical spectra except for covering the regions where their own absorptions arise. By using these solvents in turn, an almost complete range of the spectra of diacetamide dissolved in a non-polar solvent at a concentration between 0.25 and 0.01 mol./l. can be recorded from 4000 to 900 cm^{-1}. The infrared spectra thus obtained for several solutions of diacetamide and diacetamide-*d* are shown in Fig. 1[5].

Most of the bands observed for the concentrated solution show, in intensities as well as in frequencies, marked correspondences with the bands of the crystal of diacetamide in form A[1] (see Table I). The N–H stretching band appears near 3220 cm^{-1}, indicating the presence of hydrogen bonds. The complicated feature of this band is quite analogous to that of the triplet observed in the same region for the crystal in form A. The 0.34 mol./l. solution shows two C=O stretching (imide I) bands, at 1747 and 1698 cm^{-1}, of which the band with the lower frequency is stronger than the other, as in the case of form A. The analogy in infrared spectra between the concentrated solution and the crystal in form A is preserved

on deuteration. For instance, the bands at 1503, 1301 and 1216 cm^{-1} observed for diacetamide in the solution disappear on deuteration. Instead, diacetamid-*d* shows a strong doublet near 1340 cm^{-1} and a weak band at 1286 cm^{-1}. These features of spectral change have also been observed for form A in a quite similar way[1].

It has been pointed out previously[1] that the difference in the configurations of the N–H and the C=O bonds in the –CONHCO– group results in the marked difference in the characteristic bands of this group. In this connection, the present results strongly suggest that the configuration of the –CONHCC– group of diacetamide in the concentrated solution in the non-polar solvents is similar to that involved in the crystal in form A, that is, it is similar to the trans-cis configuration. The dimeric association of diacetamide dissolved in nitrobenzene has been suggested on the basis of the cryoscopic study[6]. Although the difference in the nature of the solvents must be taken into account, it seems quite probable that the association of diacetamide dissolved in the non-polar solvents is also dimeric, the two molecules involved being in the trans-cis configuration. If this is valid, the characteristic bands of the –CONHCO– group observed for the concentrated solution must be given reasonable assignments on the basis of the trans-cis configuration. Taking into account the spectral change on deuteration, we can pick up several characteristic bands of the –CONHCO– group besides the C=O stretching (imide I) bands, which may be assigned without question. Thus, the imide II, III and II′ frequencies shown in Table I were determined by analogy with the corresponding characteristic frequencies of the trans-trans configuration[2]. In the following sections, the nature of these characteristic bands will be discussed in relation to the configuration of the –CONHCO– group.

The frequency shifts on the change from the crystal in form A to the concentrated solution in the non-polar solvents are rather small for these characteristic bands. This is analogous to the case of *N*-methylacetamide, the characteristic bands of which have been reported to show small frequency shifts on the change from the crystal in the stable form above the transition point to the concentrated solution in carbon tetrachloride[7]. The characteristic bands of diacetamide dissolved in the non-polar solvents undergo marked changes on the change in concentration. The N–H stretching and the imide II bands (3222 and 1503 cm^{-1}) of the associated molecules are replaced gradually by the monomer bands at 3416 and 1465 cm^{-1} respectively on successive dilution. The directions of these frequency shifts are in agreement with those of the corresponding characteristic bands of monosubstiuted amides[7]. On the other hand, the imide I and III bands of the monomers are observed at 1720 and 1263 cm^{-1} respectively for the solutions at a concentration below 0.1 mol./l. Thus, it is seen that a monomer band appears between the two dimer bands for each of these characteristic vibrations (see Tables I and II). In this respect, the situation for diacetamide, involving two C=O, and two C–N bonds, seems to be different from the case of monosubstituted amides.

Besides the characteristic bands described above, all the bands due to the CH_3 deformation vibrations are easily assigned, except for those due to the CH_3 rocking modes. The bands at 1424 and 1383 cm^{-1} are assigned to the CH_3 asymmetric and symmetric deformation vibrations respectively. Appreciable frequency shifts for these bands do not occur on either deuteration or dilution.

Higher Homologs in Non-polar Solvents.— The infrared spectra of the higher homologs of diacetamide dissolved in the three non-polar solvents are shown in Figs 2—5[5]. In some cases, the concentrations of the saturated solutions at room temperature are so small that the observed band intensities are not sufficient for the 0.1 mm. cell. Thus, infrared spectra in which the monomer bands are absent could not be recorded for some of these higher homologs. It is seen, however, that these higher homologs show, at a variety of concentrations, infrared spectra resembling that of diacetamide at the corresponding concentration. This fact is in marked contrast with the case of the crystalline state, in which the stable form (form A) of diacetamide shows a quite different spectrum from those of the higher homologs[2]. The spectral difference between diacetamide and the higher homologs in the crystalline state was explained as resulting from the difference in the configuration of the

–CONHCO– group[1,2]. That is to say, diacetamide in form A takes the trans-cis configuration, while the higher homologs are in the trans-trans configuration. The present results suggest, however, that the higher homologs take the same configuration as diacetamide takes when dissolved in the non-polar solvents. In other words, the higher homologs undergo an inversion of the –CONHCO– group from the trans-trans to the trans-cis configuration in going from the crystals to the solutions in the non-polar solvents. Previously[4] we found that the addition of some alkali halides to diacetamide in form A gives rise to the inversion from the trans-cis to the trans-trans configuration and pointed out that this inversion is due to the electrostatic and steric effects of the cations and of the anions of the alkali halide added. Similarly, the above inversion of the higher homologs suggested as taking place on the change of state can be interpreted in terms of the analogous effects of the functional group and of the alkyl residues of these molecules.

With respect to an isolated molecule, the trans-trans configuration is expected to be less stable than the trans-cis configuration since the strong electrostatic dipole-dipole interaction between the two C=O groups may be involved in the former. On the other hand, if the alkyl chains of the higher homologs are assumed to be in the trans zigzag arrangement, the molecules involving the trans-trans and the trans-cis –CONHCO– group may be considered to take the linear and the bent form respectively. Di-*n*-butyramide in these two forms is illustrated in Fig. 6. With respect to the packing of the molecules in a unit cell, the linear form is expected to have greater advantages than the bent form. Thus, in the case of the higher homologs in the crystalline state, the advantage for the molecular packing overcomes the electrostatic interaction. In the case of diacetamide, however, difference between the linear and the bent form is not so distinct as in the higher homologs. Thus, the electrostatic interaction determines the configuration of diacetamide in the crystalline state; the trans-cis –CONHCO– group is therefore involved in the stable form (form A). On the other hand, diacetamide as well as the higher homologs takes the trans-cis configuration when dissolved in the non-polar solvents; in this case the advantage for the packing is not required, so only the electrostatic interaction may determine the configuration. The trans-cis acyclic imides dissolved in the non-polar solvents may be associated to construct the cyclic dimers involving the two equivalent hydrogen bonds of the N–H···O type. From the above considerations, it may be seen that both the electrostatic and the steric effects play important roles in determining the configuration of the –CONHCO– group.

(a) Linear form (trans-trans)

(b) Bent form (trans-cis)

Fig. 6. The configurations of di-*n*-butyramide with the trans zigzag alkyl groups.

The Characteristic Bands of the trans-cis Imides.—The characteristic bands of the associated trans-cis –CONHCO– group in the rock salt region are listed in Table I. The assignment of these bands will now be discussed in comparison with the results for the trans-trans[2] and the cis-cis[8] –CONHCO– groups.

Imide I Bands.—Since the –CONHCO– group contains two C=O and two C–N bonds, we may expect two bands for each of the C=O and the C–N stretching vibrations. It has been pointed out, however, that the symmetric arrangement of atoms in the trans-trans configuration results in a decrease in intensity or even in the vanishing of the C=O out-of-phase and the C–N–C symmetric stretching bands[2]. On the other hand, the reduced symmetry of the trans-cis configuration may result in agreement between the number of possible stretching modes and the number of observed bands. In fact, as shown in Fig. 1, two C=O stretching bands are observed for the 0.34 mol./l. solution of diacetamide. For convenience, the weaker band at 1747 cm^{-1} and the stronger band at 1698 cm^{-1} will be called the imide Ia and Ib band respectively. The higher homologs show these bands in a quite similar way. As the first approximation, the Ia and Ib bands are attributable to the free and the bonded C=O stretching vibration respectively, although the coupling between the two C=O stretching vibrations is more or less expected[9]. With respect to the features of the C=O stretching bands, the trans-cis –CONHCO– group of these

8) T. Uno and K. Machida, This Bulletin, **35**, 276 (1962).
9) R. A. Abramovitch, *J. Chem. Soc.*, **1957**, 1413; H. K. Hall, Jr. and R. Zwinden, *J. Am. Chem. Soc.*, **80**, 6428 (1958).

acyclic imides is rather similar to the cis-cis –CONHCO– group of succinimide and maleimide[8], except that the ring strain raises the free C=O stretching frequency of these cyclic imides by about 30 cm^{-1} in comparison with acyclic imides. This may be related to the similarity in the hydrogen bonds resulting from these two configurations. By X-ray diffraction study[10], the crystal of succinimide has been proved to consist of ring dimers involving both the bonded and the free C=O bonds.

Imide II Band.—In contrast with the case of the imide I bands, the presence of the imide II band near 1500 cm^{-1} differentiates the infrared spectra of the trans-cis –CONHCO– group from those of the cis-cis group. This band results from the coupling between the N–H in-plane deformation and the C–N stretching vibrations of the –CONHCO– group containing the trans –CONH– group. Thus, the imide II band is characteristic of the trans-cis and the trans-trans –CONHCO– group, although the vibrational modes involved may be different for these two configurations. Table I shows that the difference in the alkyl frameworks hardly affects the imide II frequency, suggesting that the vibration is almost localized in the –CONHCO– group.

Imide III Bands.—As has been seen for the imide I bands previously, the features of the imide III bands are also affected by the difference in symmetry between the trans-trans and the trans-cis –CONHCO– group. The two strong bands at 1301 and 1216 cm^{-1} observed for diacetamide dissolved in the non-polar solvents disappear on deuteration. This fact may be well elucidated since the trans-cis –CONHCO– group, for which all the in-plane vibrations belong to the same symmetry species, A′, involves two C–N stretching modes being allowed to couple with the N–H in-plane deformation vibration. The imide III frequencies of the trans-cis –CONHCO– group, as in the case of the trans-trans group, vary with the change in alkyl framework. This means that the coupling between the vibrations of the functional group and the alkyl frameworks is appreciable with respect to the imide III bands. The higher homologs other than *N*-acetylpropionamide show the two imide III bands, consistent with the above consideration for diacetamide. On the other hand, the three imide III bands of *N*-acetylpropionamide (Fig. 2) seem to indicate the presence of the rotational isomers. The trans-cis –CONHCO– group of *N*-acetylpropionamide differentiates the two configurations in which the C=O bond in the acetyl group takes the trans and the cis position with respect to the N–H bond. In the infrared spectra of fatty acid esters, the acetyl group is distinguished from other acyl groups with respect to the C–O–C antisymmetric stretching frequency[11]. A similar peculiarity of the acetyl group was observed for the imide III frequencies of acyclic imides in the trans-trans configuration[2]. Thus, the imide III frequencies may be different for the two trans-cis configurations of *N*-acetylpropionamide, so that in carbon tetrachloride solutions this compound shows more than two bands related to the C–N stretching vibrations in the region 1350 to 1100 cm^{-1}.

Imide II′ and III′ Bands.—The difference in the alkyl framework affects the imide II′ and III′ frequencies of the *N*-deuterated compounds. Each of the acyclic imides investigated has turned out to show the two imide II′ bands in the region 1360 to 1150 cm^{-1} on deuteration. These bands are due to the two C–N stretching vibrations released from the coupling with the N–H in-plane deformation vibration. The contribution of the framework vibrations seems to remain on deuteration, since in some cases the band with the higher frequency shows a complicated feature with several peaks. This band is always stronger than the other band with the lower frequency. The frequency of the weaker band for each compound is 10 to 20 cm^{-1} lower than the higher imide III frequency of the corresponding undeuterated compound (see Table I). On the basis of these results, it is suggested that the antisymmetric and the symmetric C–N–C stretching vibrations are related to the stronger and the weaker band respectively. For the former band, however, the amplitude of the stretching coordinate of the shorter C–N bond may be greater than that of the longer bond, and vice versa for the latter band. As with the related compounds[7,12], the N–D in-plane deformation vibration seems to couple appreciably with the framework vibrations. The two bands at 1112 and 913 cm^{-1} of diacetamide-d are considered to result from such a coupling, in which an in-plane vibration contributing to the band at 1028 cm^{-1} of diacetamide is expected to be involved on deuteration. In fact, the features of the band at 1028 cm^{-1} are also changed on deuteration. This interpretation is consistent with the product rule applied to diacetamide in the trans-cis configuration. For the in-plane (A′) frequencies below 2000 cm^{-1}, the observed and the theoretical ratios,

$\Pi(\nu_H/\nu_D)$, are 1.41[13] and 1.44 respectively. Here, the theoretical ratio has been calculated from the same molecular constants as those used in the calculation of the A'' ratio[1]. The high-frequency separation has been made in analogy with that applied to succinimide[8]. For the solution of the higher homologs of diacetamide, the bands in the 1100 to 900 cm^{-1} region are much obscured by the destruction of the trans-zigzag arrangement of the alkyl chains. As with the imide III' band, however, each *N*-deuterated compound shows a fairly strong band in this region which is not observed for the corresponding undeuterated compound. Although this band results mainly from the N-D in-plane deformation vibration, the varying of the frequency with the alkyl groups seems to indicate some contribution of the framework vibrations.

N-H and N-D Stretching Bands.—As has been seen for the trans-trans[3] and the cis-cis[8] configurations, the features of the N-H and N-D stretching bands of the trans-cis configuration may well be elucidated in terms of Fermi resonance. All the in-plane vibrations of the trans-cis configuration belong to a single symmetry species, A', of the point group C_s. Thus, the imide Ia and Ib vibrations of this configuration can combine with the imide II vibration to give rise to two combination tones, which take part in the Fermi resonance with the N-H stretching vibration. The three peaks in the 3280 to 3150 cm^{-1} region observed for each undeuterated compound are attributed to this Fermi resonance (see Table I). It is seen from Figs. 1—5 that the vanishing of the resonance on deuteration leads to a single peak near 2390 cm^{-1} for the N-D stretching band of the trans-cis -CONDCO- group. It may be noted here that the intermolecular interaction is improbable as the cause of the splitting of the N-H stretching band in this case, since the symmetry of the associated ring dimer in the solution leads to only one infrared active N-H stretching vibration.

13) Calculated from the following frequencies: diacetamide, 1747, 1698, 1503, 1301, 1216, 1028; diacetamide-d, 1737, 1695, 1338 (the mean value of 1350 and 1326), 1286, 1112, 913.

Conclusion

The infrared spectra of the aliphatic acyclic imides dissolved in the non-polar solvents indicate that the -CONHCO- group of these compounds takes the trans-cis configuration in the associated molecules. This means that the higher homologs of diacetamide (trans-trans in the crystalline state) undergo an inversion of the configuration of the -CONHCO- group upon the change of state. One of the anomalous features observed for the infrared spectra of the higher homologs of diacetamide is the marked decrease (30～40 cm^{-1}) in the frequencies of the strongest C=O stretching band on going from the crystals to the solutions in the non-polar solvents. This may result not only from the change in the vibrational modes due to the change in the configuration, but also from the change in the force constants due to the change in the type of hydrogen bond.

Experimental

The samples used in the present study are the same as those reported previously[1,2]. Commercially available, guaranteed-pure grade carbon tetrachloride, tetrachloroethylene and carbon disulfide were dried with silica gel and redistilled before use. The infrared measurements were made with a Perkin Elmer Model 221 spectrophotometer equipped with a lithium fluoride prism (4000～2600 cm^{-1}) and a Koken DS-301 spectrophotometer equipped with two rock salt prisms (2600～900 cm^{-1}). The water vapor and the polystyrene bands were used for the wave number calibration.

The authors wish to express their thanks to Dr. Tatsuo Miyazawa of Osaka University and to Dr. Kiyoshi Nakamura of the Research Laboratory, Dainippon & Co., Ltd., for their helpful advice throughout this work. Thanks are also due to Dr. Kunio Fukushima of Osaka University for his measurement in the 4000 to 2600 cm^{-1} region.

Kolbe's Reaction of Higher Fatty Acids. III. Anode Potential in the Electrolysis of Lauric Acid with Platinum Anode

By Ryoichi MATSUDA, Takeo HISANO, Toshio TERAZAWA and Norio SHINOHARA

(Received April 26, 1961)

Several investigators who have dealt with the anodic potentials of Kolbe's reaction and of those closely related to it in the electrolysis of acetic acid[1-5] have found that there are two stages of the anodic potential with a smooth platinum anode. They are 1.8~2.0 and 2.2~2.8 V. vs. hydrogen electrode, which are regarded as the potentials of oxygen evolution and the discharge of acetate ion respectively. In the electrolysis of the aqueous solution of acetic acid, Kolbe's reaction normally occurs. In other words, the discharge of acetate ions, which have a higher discharge potential than hydroxyl ions, predominates over that of the latter under ordinary conditions. This fact will be, according to Hickling[1], a formidable problem for any theory of anodic reactions. Adam and others[6] have stated that the formation of a surface film of acetate ions would disturb the discharge of hydroxyl ions and give rise to a higher potential. However, Hickling emphasized that the anode showed the higher potential from the very beginning of the electrolysis; therefore, it was not a question of the replacement of a lower potential process by one of a higher potential after the electrolysis had been run for some time. Aoyagi and Sugino[4] have mentioned that the realization of the higher potential stage was caused by the adsorption by the anode of such ions as were not oxidized or discharged at the potential of oxygen evolution.

The present authors have not come across any work on the characteristic nature of the anodic potential in the Kolbe reaction of higher fatty acids, which might behave somewhat unlike the lower members, and so have undertaken the study of the anodic potential with a smooth platinum anode in the electrolysis of lauric acid.

Experimental

Electrolyte Solution.—Either ethanol or methanol is often employed, together with water, to increase the poor solubility of lauric acid in water. In order to avoid the effect of such an alcohol as that mentioned above on the anodic potential, however, electrolyte solutions were made by adding an aqueous solution of potassium hydroxide of a proper concentration to a solution of lauric acid and potassium carbonate which had been prepared by treating a mixture of these two solutes with warm water. The composition of the electrolyte solutions employed is shown in Table I, in which [La], [K_1] and [K_2] denote the concentrations in mol./l. of lauric acid, potassium hydroxide and potassium carbonate respectively. The lauric acid was obtained by recrystallizing two times a raw lauric acid which was 99.9% pure with a mixture of ethanol and water. The other chemicals were of the special grade for analysis.

Apparatus and Electrodes.—The electrolytic cell employed in the current-potential and time-potential measurements was a glass cylinder, and 100 ml. of the electrolyte solution were used for each run. The anode was a smooth platinum plate with a total surface area of 0.5 cm^2. To keep the current distribution as uniform as possible, the anode was surrounded by a platinum plate cathode which had an area of about 5 cm^2 on each side, almost large enough to avoid the effect of cathodic polarization. Before electrolysis, both electrodes were thoroughly cleaned with ethanol, with concentrated nitric acid and finally with pure water. The reproducibility of the equilibrium potential of the anode in the electrolyte solution was about ± 0.02 V. The Luggin capillary, which was 1 mm. in outside diamete at its tip, was filled with the electrolyte solution and then connected to a saturated calomel electrode through a potassium chloride solution. At the middle of the capillary tube a glass stop cock was fitted; this was kept closed during the experiment to prevent the contamination of the electrolyte solution with potassium chloride. The potential was measured by an electronic valve potentiometer, the imput impedance of which was 10 MΩ.

Since Kolbe's reaction of lauric acid produces docosane[7], which is solid and oily at room

[K_2]/[La]	1.4	1.4	1.4	0.54	0.54	0.54	0.54	0.54

temperature and 40°C respectively, the electrolysis was conducted at 40±0.5°C without any mechanical agitating device.

Determination of the Current Efficiency of Oxygen Evolution.—Both the anode and cathode employed in this case had a larger surface area (7 and 100 cm^2 respectively) than those mentioned above. The electrolytic cell was fitted with a side tube in order to adjust the level of the electrolyte solution, and the cell was completely filled with the solution before electrolysis. During electrolysis the constant anodic potential was maintained by manual adjustment of the current. The evolved gas, which was collected into a syringe of a 20 ml. capacity, was treated with potassium hydroxide and alkaline pyrogallol solutions succesively. Special attention was paid to prevent the entrance of air into the gas samples. The efficiency of the oxygen evolution at the anode was calculated, assuming that the efficiency of hydrogen evolution was 100% at the cathode and that the residual gas after absorption contained hydrogen only. According to these assumptions, the current efficiency of oxygen evolution will be lower than it should be if the electrolytic gas contained any unabsorbable gas other than hydrogen.

Results and Discussion

From Fig. 1, showing the relation between the current and anodic potential in the

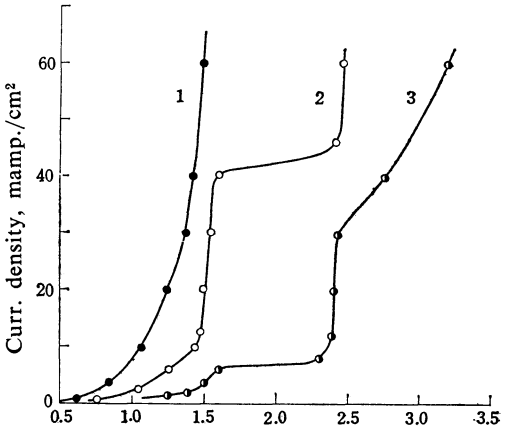

Fig. 1. Relation between anodic current and potential. Curves 1, 2 and 3 are related to solutions 1, 2 and 3 respectively.

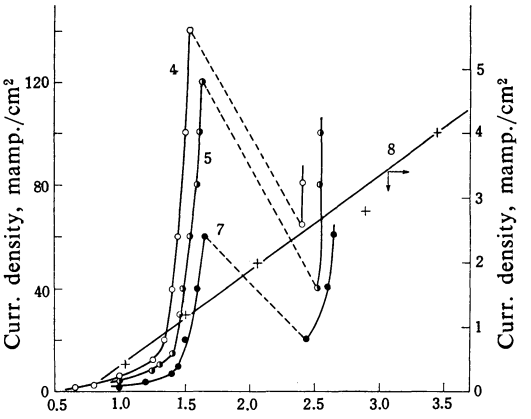

Fig. 2. Relation between anodic current and potential. Curves 4, 5, 7 and 8 are related to solutions 4, 5, 7 and 8 respectively.

electrolysis of solutions 1, 2 and 3, in which the value of [K_2]/[La] was always equal to 1.4, the following two facts may be observed. First, when [K_1] is not very high compared with [La], as in the cases of curves 2 and 3, two stages of anodic potential are clearly marked. The first stage lies at 1.5~1.6 V., and the second at a potential a little higher than about 2.3 V. Secondy, when [K_1] is very large compared with [La], the current increases so much that it reaches beyond the estimation range, and the second stage of potential disappears. In the potential range between 1.5 and 2.4 V., both curves 2 and 3 have a plateau which looks as if it were a saturation or limiting current. However, strictly speaking, this is not the case, since it is impossible to maintain a constant current at a constant potential, particularly in a part of the potential range below 2.4 V. The current decreases if the potential is kept constant. Moreover, as the current approaches a certain high value, the potential increases more rapidly than with the former. For these reasons curves 2 and 3 were obtained by reading the potential immediately after adjusting the current to as constant a level as possible. The values of the height of the plateau in curves 2 and 3 are, consequently, not very precise. Yet it is clear that the height

of the plateau has a close connection with the value of $[K_1]$.

The relation between the current and potential was also observed for solutions 4, 5, 6, 7 and 8. In this case the current was left without adjustment during the rapid potential transition. Some of the results are represented in Fig. 2. According to these curves, there occurs a phenomenon something like the passivity of a soluble anode. The first and second potential stages are situated like that case, at 1.5~1.6 V. and 2.4~2.6 V. vs. S. C. E. respectively. Curve 8 represents the case of a solution which contains lauric acid and potassium carbonate but no potassium hydroxide. This curve is nearly linear and shows that a higher anodicpot ential is attained by a lower current density than with the other curves. It can well be considered that this is due to the resistance overpotential caused by some filmy substance on, in the vicinity of, the anode. As a matter of fact, a transparent viscous substance was observed on the anode during electrolysis, although it disappeared after opening the circuit. This is probably potassium laurate liberated.

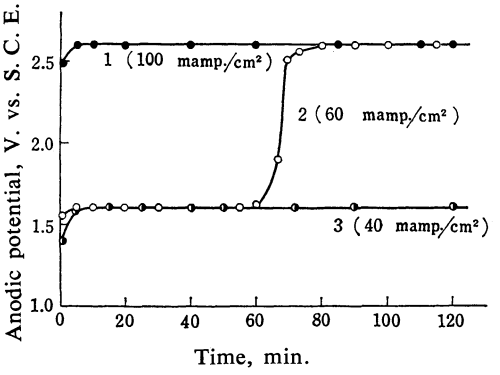

Fig. 3. Variation of anodic potential during electrolysis of solution 7 at constant current.

Figure 3 shows typical curves observed as to the variation in anodic potential during the electrolysis of solution 7 under a constant current. Whereas curves 1 and 3 reach 2.6 and 1.6 V. respectively soon after the commencement of electrolysis, and both remain constant as time goes on, curve 2 proceeds along with curve 3 for the first period and then ascends quickly to 2.6 V. and remains constant thereafter. With an ordinary electronic valve potentiometer, the potential under high current densities is observed to be 2.4~2.6 V. from the beginning of electrolysis, as illustrated by curve 1. A cathode ray oscillograph, however, shows distinctly that, under the same conditions as mentioned above, the rapid displacement of the potential stage from the first to the second still occurs at the moment of closing the circuit. At any rate, it is evident from these observations that the displacement of the potential stage takes place at a certain time after the beginning of the electrolysis of alkali laurate.

The relation between current density and the time of potential displacement will be reported on later.

From the result mentioned above, the transition of the potential and the realization of the higher potential stage in preference to the lower one may by supposed to be caused by the formation of some sort of film on the anode surface. Three possible types of film which can bring about an abnormally high overpotential are as follows;

(1) a highly resistant film of the oxide of the anode material;

(2) a film of a resistant substance formed of discharged anion, and

(3) a film of adsorbed anion[4].

In the present study, (2) or (3) is likely to occur, but (1) is unlikely since it is already known[8] that the steady evolution of oxygen on a platinum anode occurs on its oxide layer, which has an unusual capacity for electron conduction.

Table II. Electrolyses at two constant potentials

Anode area, 7.0 cm²; Solution, 6.

Anode potential, V.	1.5~1.6	2.5~2.6
Mean curr. density, mamp/cm²	11	57
Quantity of electricity, coulombs	ca. 300	120~345
Curr. efficiency of O_2 evolution, %	99.2±0.1	25.0±2.4
Docosane formation	None	Confirmed

Table II represents the current efficiency of oxygen evolution at two constant anode potentials. The value at the lower potential stage amounts to 99% and differs decidedly from that at the higher stage. That is, the anode reaction occuring at the lower potential was almost entirely the evolution of oxygen. In the electrolysis at the higher stage of anode potential, the solution became utterly opaque soon after the commencement of electrolysis, and a floating substance, which was identified by its melting point as docosane, rose to the surface of the solution. During electrolysis at the lower potential, the solution was clear or only slightly opaque. If docosane be formed at the lower potential stage, its appearance on the surface of the solution would be perceptible

8) H. A. Laitinen and C. G. Enke, *J. Electrochem. Soc.*, 107, 773 (1960).

after the electrolysis had been conducted with a sufficiently large quantity of electricity, since it is sparingly soluble in the solution employed. However, no floating substance was found after electrolysing 250 ml. of solution 6 with 8000 coulombs of electricity at the constant potential of 1.5~1.6 V. Although the above-mentioned method is not complete for the detection of docosane, it seems not to be right, by reason of the following observation, to suppose that the displacement of the anode potential is due to the formation of a resistant film of docosane which is produced out of the discharged laurate ions. The displacement of the lower potential by the higher one was observed not immediately but some time after the start of a second run of electrolysis at the lower potential of a certain solution which, for the first time, had been electrolyzed for a long time at the higher potential and, therefore, should have been saturated with docosane and other products.

In conclusion, it seems, to the authors, as far as the present study is concerned, that the most probable mechanism of the displacement of the anode potential stages in the electrolysis of the alkali laurate solution is related to the formation of an adsorbed film of laurate ions, and that at the lower potential stage of 1.5~1.6 V. vs. S. C. E. the main reaction is the evolution of oxygen. As laurate ions are adsorbed on the anode surface, the effective surface area of the latter for the discharge of hydroxyl ions decreases; therefore, the potential rises to 2.4~2.6 V., at which point laurate ions begin to discharge.

As has previously been reported[9] docosane is formed on a graphite anode with a pulsating direct current, whereas with ordinary direct current there occurs a rapid diminution of current; thus it will be interesting to investigate the behavior of graphite and platinized platinum anodes in the light of the anodic potential, since these have atomically irregular surfaces, on which large laurate ions may be expected to be adsorbed in a manner somewhat dissimilar to that which is the case with a smooth platinum surface.

9) R. Matsuda, T. Hisano and D. Kubota, This Bulletin, 34, 649 (1961).

Summary

An aqueous solution of lauric acid, containing potassium hydroxide and potassium carbonate, was electrolysed at 40±0.5°C with smooth platinum electrodes. Not only were two constant anodic potential stages, 1.5~1.6 and 2.4~2.6 V. vs. S. C. E., clearly found, but also an abrupt shift from the lower stage to the higher one was distinctly observed. The main reaction at the lower stage is the evolution of oxygen. In addition, at the higher stage the discharge of laurate ions is accompanied by an oxygen evolution that is markedly retarded compared with that at the lower stage. It may therefore, be inferred that the transition of potential from the lower stage to the higher is caused by the formation of a film of adsorbed laurate ions.

The authors wish to express their thanks to Nippon Oils and Fats Co., Ltd., which kindly provided them with lauric acid.

NOTES

Relation between Vapor Pressure and Internal Pressure in Solutions and Pure Liquids

By C. V. SURYANARAYANA and
K. K. JANARDHANAN PILLAI

(Received October 13, 1961)

Recently Suryanarayana[1] proposed internal pressure as the basis of a unified theory of solutions. If it should be tenable, several fundamental properties of solutions as well as pure liquids should be explicable on the basis of internal pressure. A search has been made by us if vapor pressure over a liquid, be it pure or a solution, has any relation with the internal pressure. For computing internal pressure, recently Suryanarayana and Govindaswamy[2] formulated an equation,

$$\Pi = K \cdot \rho^{4\frac{1}{3}} / M^{1/3} \qquad (1)$$

based on a relationship pointed out by Young[3] and Leplace[4]. In Eq. 1 K is an incomputable constant independent of temperature, whereas Π, ρ and M are internal pressure, density and molecular weight of the medium respectively. Equation 1 is applicable to solutions in the form,

$$\Pi = K \cdot \rho^{4\frac{1}{3}} / (M_1 x_1 + M_2 x_2)^{1/3} \qquad (2)$$

where x_1 and x_2 are the mole fractions of the two components, for example in a binary solution, and M_1 and M_2 are respectively the molecular weights. Suryanarayana and Govindaswamy (loc. cit) showed that Eq. 2 is applicable to solutions of nonelectrolytes and fully dissociated electrolytes. The computable part on the right hand sides of Eqs. 1 and 2 has been called the Π-factor. For purposes of comparison of internal pressures a study of the Π-factor must be sufficient and reliable.

Vapor pressure data for electrolyte solutions of sodium carbonate, lithium bromide, nitric acid, hydrochloric acid, sodium sulfate, sulfuric acid, ammonium chloride, sodium chloride, sodium nitrate, sodium hydroxide, potassium sulfate, sodium iodide, ammonium sulfate and sodium bromide, at least at six temperatures in each case were obtained from the International Critical Tables, Vol. III, 1928. Graphical studies showed that in almost all cases vapor pressure varies linearly with the internal pressure of a solution,

$$P = A - B\Pi' \qquad (3)$$

where P is the vapor pressure, Π' the Π-factor and A and B cnstants. Substituting the Π-factor for pure water in Eq. 3, computed from its density and molecular weight, we can get the vapor pressure P at a given temperature. Values thus obtained from Eq. 3 agreed excellently with those given in standard tables at all the temperatures tested. The following table gives at 40°C a comparison of vapor pressure values between the standard ones and those obtained from 3 of different salts by substituting Π' of water in the respective equations.

TABLE I. DATA AT 40°C*

Electrolyte	Vapor pressure of water from the equation mmHg	% deviation from the accepted value
Sodium carbonate	55.25	−0.1266
Lithium bromide	55.14	−0.3254
Nitric acid	55.03	−0.5242
Hydrochloric acid	57.98	+4.808
Sodium sulfate	55.08	−0.4338
Sulfuric acid	57.56	+4.049
Ammonium chloride	54.55	−1.392
Sodium chloride	55.46	+0.253

* The accepted vapor pressure of water at 40°C is 55.32 mmHg.

Sodium nitrate, bromide, iodide, hydroxide, potassium sulfate and ammonium nitrate solutions give for a plot of vapor pressure versus Π-factor in each case two straight lines intersecting at a point. These can be explained on the basis of 1-1, 1-2 and 2-2 interactions.

The internal pressure of a liquid increases as the temperature decreases. At each temperature probably a quantitative relationship exists between the vapor pressure and internal pressure of a liquid. In expectation of a fundamental relationship between the two, thirty liquids namely, methyl sulfide, diethyl amine, ethyl propyl ether, methyl ethyl ether, cyclohexane, isopropyl isobutyrate, chlorobenzene, methyl acetate, *n*-propyl acetate, benzene, methyl formate, ethyl formate, ethyl acetate, methyl isobutyrate, ethyl sulfide, methyl propionate, ethyl

1) C. V. Suryanarayana. *J. Sci. Ind. Research (India)*, **A20**, 141 (1961).
2) C. V. Suryanarayana and S. Govindaswamy, *Acta Chim. Hung.*, **25**, 341 (1960).
3) T. Young, *Phil. Trans.*, **1**, 65 (1805).
4) P. S. Laplace, "Oeuvres", Vol. IV, 389.

propionate, acetic acid, methyl alcohol, *n*-propyl alcohol, diethyl ether, *n*-pentane, bromobenzene, ethyl alcohol, methyl *n*-butyrate, *n*-propyl formate, acetone, isopropyl alcohol, carbon tetrachloride, and water have been studied. Data of vapor pressure and density for the first six are from International Critical Tables (McGraw-Hill), Vol. III, 1928 and for the rest from Timmermans Physico-chemical Constants of Pure Organic Compounds, Amsterdam, 1950. In almost all cases we found the simple relationship,

$$\log P = A - B\Pi \qquad (4)$$

applicable in almost all cases excepting *n*-propyl formate and water, which requir to be explained.

Thus in solutions we observe from Eq. 3 that the vapor pressure varies linearly with internal pressure, whereas in the case of pure liquids the logarithm of the vapor pressure is found to vary as in Eq. 4 linearly with the internal pressure. In the case of solutions, the causative factor that changes internal pressure is the solute concentration whereas in the the case of pure liquids it is the temperature. Normally speaking, provided the vapor pressure and the internal pressure are quantitatively related, whatever may be the causative factor that changes the internal pressure, the fundamental relation between the two should remain universal and undisturbed. Invalidation of this expectation and the existence of two types of relations as in Eqs. 3 and 4 signifies a difference in the mechanism of change of internal pressure in the two cases. A detailed study of these and other aspects will be published elsewhere in due course.

Microhardness of Coal Immersed in Various Solvents

By Yuzō SANADA and Hidemasa HONDA

(Received November 29, 1961)

The intrinsic mechanical strength of coal, shown by the microhardness number, may be related to inter and/or intramolecular forces[1-3]. When coal is immersed in a solvent, the solvent penetrates into coal, causing swelling. The resultant loosening of inter and/or intramolecular forces leads to changes in the mechanical strength of the coal. Recently, the microhardness of coals immersed in pyridine has been measured[4]. The hardness ratio, $H_k/H_{k,o}$, where H_k is the equilibrium Knoop hardness number of the coal immersed in in pyridine and $H_{k,o}$ is the Knoop hardness number of the original coal, when plotted against the rank of coal, shows a characteristic curve with a minimum at about an 80% carbon content[4].

In the present paper, the microhardness of coals immersed in various solvents has been measured further. The solvents used are benzene, ethanol, *p*-dioxan and dimethyl formamide (DMF). The details of measurement and the degree of error in the determination of the Knoop hardness number have been described elsewhere[1,4].

The Knoop hardness number of coal decreases with the increase in immersion time and reaches an equilibrium value after a few hours for all solvents as well as for pyridine[4]. The relation between the $H_k/H_{k,o}$, when coal is immersed in DMF and benzene respectively, and the rank of coal is shown in Fig. 1. In the case of immersion in DMF, the variation of $H_k/H_{k,o}$ in relation to the rank of coal is similar to that of pyridine, but the action of DMF is smaller than that of pyridine. In the case of benzene, the minimum in the curve of $H_k/H_{k,o}$ plotted against the rank shifts to a higher carbon content. As the constitution of coal is complex, it is difficult to explain these phenomena precisely, but the marked variation

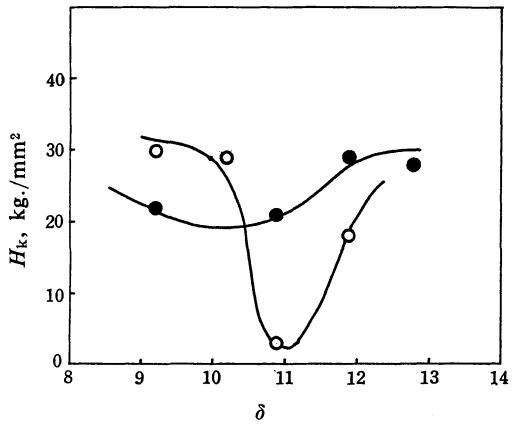

Fig. 2. Relation between equilibrium hardness number and solubility parameter of solvent, for Yūbari and Bibai vitrain immersed in solvent.
○ Bibai vitrain, ● Yūbari vitrain

in the value of $H_k/H_{k,o}$ with the rank would be expected to depend on the physical or chemical properties of the solvent and of the coal.

Figure 2 shows the relation between the H_k of Yūbari (d. a. f. 85%C) or Bibai (d. a. f. 81%C) coal immersed in solvents, and the solubility parameter*, δ, of solvents. It shows that H_k has a minimum at around 10 and 11 in the values of δ for Yūbari and Bibai coal respectively. It is known that the swelling of the polymer by various organic liquids correlates to a large extent with the cohesive energy density (CED) of the solvent and the polymer[5,6]. Such a relationship between the CED of solvents, including very highly polar ones, and the yield of extract of coals has been found[7]. Consequently, it seems that the CED is an important factor determining the solvent action on the mechanical behavior of coal.

Mechanism of the Carbonization of Chromium(III) Oxide

By Hiroaki TAGAWA and Hitoshi NAKAJIMA

(Received on November 8, 1961)

Many kinds of carbides are formed by the solid state reaction of metal oxides with carbon at high temperatures. As most solid-solid reactions occur by counter diffusion of the cations of the reactants through the product layer, the kinetics of compound formation are considered to depend on the nature of the reactant and of the product. In the present study, the carbonization of chromium oxide was thermogravimetrically examined, and the mechanism was compared with that of the previously reported reaction of calcium oxide with carbon[1].

Experimental.—Extra pure chromium(III) oxide was obtained from Wako Chemicals Co. The particles were about 1 μ in diameter. Artificial graphite ($d_{002}=3.389$ Å, pulverized below 250 mesh sieve) for an atomic pile was used as carbon. A mixture of 1.00 g. of carbon and 2.92 g. of chromium oxide was compressed at about 1 ton/cm^2 into a cylindrical pellet, 15 mm. in diameter and 8 mm. in height. It was found by X-ray and chemical analysis that only chromium carbide, Cr_3C_2, was formed on the reaction of chromium oxide with carbon in the temperature range between 1060 and 1200°C and at 2×10^{-2} mmHg. The mixing ratio of carbon to chromium oxide was chosen according to the following equation: $3Cr_2O_3+13C=2Cr_3C_2+9CO$.

The apparatus for the kinetic experiments consisted of a spring balance in a vacuum electric furnace[1]. In the hot zone of the furnace a graphite bucket was suspended with fine molybdenum wire from the spring. The shrinkage of the spring upon a loss in weight was observed with a microscope with an eyepiece scale. The elongation of the spring against weight was 1.036 cm./g. The reaction temperature was measured with a platinum-platinum·13% rhodium thermocouple and was maintained at a desired value within ±3°C with the aid of an automatic temperature controller. The electric furnace was evacuated to 2×10^{-2} mmHg during the course of the experiments.

Results and Discussion.—All the curves of the weight decrease against time were parabolic in the temperature range 1060 to 1200°C. Figure 1 shows the course of the reaction at four temperatures.

Generally, the rate of solid state reaction determined by a diffusion process is expressed by the following equation:

$$(1-\sqrt[3]{1-x})^2=2kt \qquad (1)$$

1) H. Tagawa, H. Sugawara and H. Nakajima, *J. Chem. Soc. Japan, Ind. Chem. Sec.* (*Kogyo Kagaku Zasshi*), **64**, 1751 (1961).

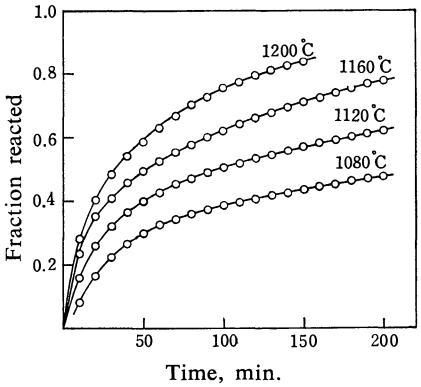

Fig. 1. Relation between fraction reacted and time.

where x is the fraction reacted, t the time, and k the reaction rate constant. To determine whether the reaction followed the parabolic kinetics shown in Eq. 1, the data in Fig. 1 were plotted as the values of $(1-\sqrt[3]{1-x})^2$ vs. time in Fig. 2. The linearity of the curve suggests that the diffusion process is rate-controlling. The constant k in Eq. 1 was found from the slope of each curve. The logarithm of the slope was plotted against the reciprocal of the absolute temperature in Fig. 3. The activation energy was calculated as 89.4±3.4 kcal./mol. from the least-squares slope of this plot.

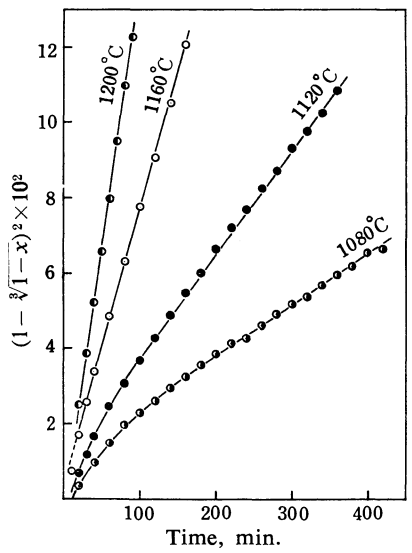

Fig. 2. Relation between $(1-\sqrt[3]{1-x})^2$ and time.

Boericke[2] has concluded that the reduction of chromium oxide with carbon involves four distinct, consecutive and reversible reaction steps:

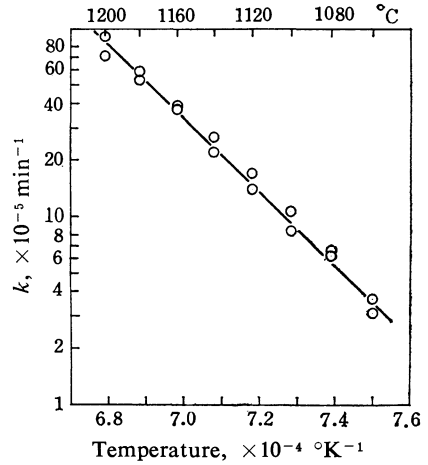

Fig. 3. Relation between the reaction velocity and reciprocal absolute temperature in the reaction of chromium oxide with carbon.

$$3Cr_2O_3 + 13C = 2Cr_3C_2 + 9CO \quad (2)$$

$$5Cr_2O_3 + 27Cr_3C_2 = 13Cr_7C_3 + 15CO \quad (3)$$

$$5Cr_2O_3 + 14Cr_7C_3 = 27Cr_4C + 15CO \quad (4)$$

$$Cr_2O_3 + 3Cr_4C = 14Cr + 3CO \quad (5)$$

It has been shown in this experiment that Cr_3C_2 is formed as an intermediate compound between chromium oxide and metallic chromium. The predominant formation of Cr_3C_2 is to be expected, as the equilibrium carbon monoxide pressure in Eq. 2 is the largest one in the reaction system of chromium oxide with carbon.

It is recognized that calcium vapor and carbon monoxide are formed in the reaction of calcium oxide with carbon below 1400°C in vacuo according to the following equation: $CaO+C=Ca+CO$[3]. As has previously been reported[1], when the plot of the weight decrease vs. time became linear, the reaction rate constant was obtained from the slopes of these curves. The activation energies from the Arrhenius plots were 92±5, 136±10 and 147±6 kcal./mol. for calcium oxides burned at 900, 1100 and 1300°C respectively for 3 hr. The difference in activation energy may be due to the sintering of calcium oxide during the course of the experiments and to the decrease in the reactivity with carbon.

When chromium carbide and calcium carbide are formed by the diffusion of cations through the oxide and the product layer, the reaction rate may depend on the mobility of the cations and on the reactivity of carbon as a reducing agent at the interface. Oxygen ions may not be considered to play an important role in

carbonization, as their mobility is small in comparison with that of the cations.

The solid state reaction of carbon with chromium oxide and calcium oxide is considered from the standpoint of diffusion phenomenon. The self-diffusion coefficient of chromium ions in the oxide was determined by Lindner[4], the activation energy being 100 kcal./mol. The activation energy of the self-diffusion of calcium ions in the oxide was 80 kcal./mol.[5], while that of ^{14}C in graphite was 163 kcal./mol.[6] In the reaction of carbon with chromium oxide and with calcium oxide, the activation energy was 89 and 147 kcal./mol. respectively, the former value being similar to the activation energy for the self-diffusion of chromium ions in the oxide and the latter being similar to that of the self-diffusion of carbon and the lattice energy of graphite (170.9 kcal./.g.atom)[7]. Consequently, it may be considered that the rate determing factor is closely related to the diffusion of chromium ions in the oxide in the chromium carbide formation and to the structure of the carbons for the reduction of the oxide in the reaction with calcium oxide.

Structure of the So-called Tricoordinated Copper Complexes

By Michihiko KISHITA and Masaji KUBO

(Received February 10, 1962)

We have determined the magnetic moments of a number of tricoordinated copper(II) complexes such as acetylacetone-mono-(*o*-hydroxyanil) copper(II)[1]. From the observed subnormal magnetic moments 0.87~1.37 B.M. per copper atom, it was concluded that binuclear complex molecules are formed in crystals, in which pairs of copper atoms exist: the Cu-Cu distance being so small as to permit exchange interaction between two copper atoms in a pair. Attention was called to the fact that all tricoordinated copper(II) complexes showing a subnormal magnetic moment so far investigated have a planar monomeric structure, because the copper atom is involved in two rings, both of which are either a five-membered ring or a six-membered one having conjugated double bonds[2]. These conclusions have been confirmed by the recent X-ray analysis of a single crystal of acetylacetone-mono-(*o*-hydroxyanil) copper(II) carried out by Barclay et al.[3] It was found that two copper atoms are 3.00 Å distant from each other in a dimer molecule having a planar configuration shown in Fig. 1. In this binuclear complex, each copper atom has one nitrogen and three oxygen atoms as coordinating atoms at the corners of a slightly distorted square.

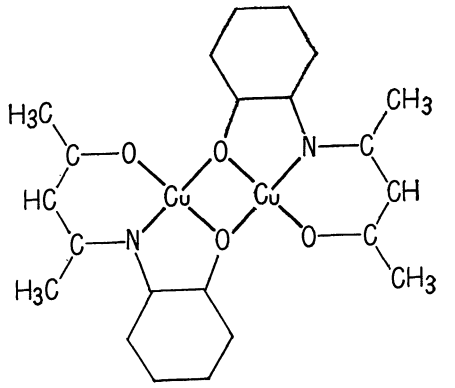

Fig. 1. Binuclear structure of acetylacetone-mono-(*o*-hydroxyanil) copper(II).

We have found[2] that some tricoordinated copper(II) complexes show a normal moment slightly greater than the spin moment for one unpaired electron 1.73 B.M. 5-Nitrosalicylalanthranilic acid copper(II) is an example. It was pointed out that these copper complexes showing a normal magnetic moment have a carbonyl group, the oxygen atom of which is capable of being coordinated on a copper atom and that they contain a six-membered chelate ring possibly having a three-dimensional structure, because only one double bond is involved in the ring[4].

In order to explain the observed moments, we propose a new binuclear structure for the so-called tricoordinated copper(II) complexes having a normal magnetic moment. The structure is shown in Fig. 2 with 5-nitrosalicylalanthranilic acid copper(II) as an example. It is analogous to that shown in Fig. 1 in that the two copper atoms in the binuclear complex have

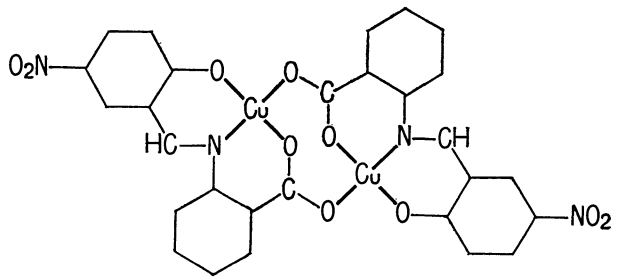

Fig. 2. Binuclear structure of 5-nitrosalicylalanthranilic acid copper(II).

a square coordination of nitrogen and oxygen atoms. It differs from the latter structure in that the copper atoms are involved in an eight-membered ring instead of forming a square with two oxygen atoms and are farther apart from each other than in the structure shown in Fig. 1. Consequently, the direct spin interaction between the two copper atoms is negligible, i.e., the low diamagnetic singlet energy level of the pair of spins practically coincides with the higher paramagnetic triplet level, leading to a situation equivalent to the independent orientation of each spin in the external magnetic field. The eight-membered ring and two six-membered rings adjacent to it are presumably nonplanar for reasons described above. As a result, the distance between two oxygen atoms closest to the center of symmetry of the dimer molecule is of reasonable magnitude as a non-bonded distance between oxygen atoms (ca. 3.0 Å). In fact, the configuration of Cu–O–C–O–Cu links in the eight-membered ring is quite analogous to the anti-syn bridging arrangement determined by X-ray diffraction experiments carried out by Barclay and Kennard[5] for the royal-blue modification of anhydrous copper(II) formate. The stereochemical requirements such as the normal values for bond lengths and valency angles, the coplanar structure of conjugated systems, the absence of appreciable steric hindrance, etc. are well satisfied and one can construct a plausible molecular model for this structure.

The proposed structure implies that the so-called tricoordinated copper(II) complexes are really binuclear complexes having copper atoms of ligancy 4, regardless of whether they show a subnormal or normal magnetic moment and that "tricoordinated" copper(II) complexes in the literal sense of the word do not exist. It must be recalled that the unusual coordination number 3 for a copper atom has been conceived from the method of synthesis and the chemical analysis of the complexes along with the tridentate nature of the single ligand molecules under a tacit assumption that the complex molecules have only one copper atom. It is evident that the normal magnetic moment of a copper(II) complex does not necessarily lead to the conclusion for the existence of separate monomeric molecules in crystals. Mention should be made here of the cryoscopic determination of the molecular weights of *N*-salicylidene-*N'*-*n*-caprinylhydrazino copper(II) and *N*-salicylidene-*N'*-*n*-palmitylhydrazino copper(II) by Ohta[6], who found that these tricoordinated copper(II) complexes form dimer molecules. However, Grün and Freiesleben[7] found monomeric molecular weights for some nickel complexes of formazyls in benzene and are of opinion that the nickel atom has the coordination number 3.

In the monopyridine derivatives of the so-called tricoordinated copper(II) complexes, all of which show a normal magnetic moment, a nitrogen atom of pyridine is presumed to be coordinated on a copper atom to complete the square coordination. As a result, the molecule of these monopyridine derivatives must have a single copper atom.

In short, the coordination number 3 for a copper atom does not afford the only possible interpretation nor the most probable one. On the contrary, with the concept of binuclear complexes, one can dispense with the unusual coordination number 3 in favor of the ligancy 4, irrespective of whether or not the so-called tricoordinated copper(II) complexes show a normal moment.

SHORT COMMUNICATIONS

The Reductive Aminations of α-Keto Acids with Cobalt Complex Ions in Homogeneous Solution

By Masuo MURAKAMI and Jung-Wong KANG

(Received March 24, 1962)

It has been known[1] that the reductive amination of α-keto acid with aqueous ammonia can be carried out with an active metal such as platinum, palladium and Raney-nickel. However, the same reaction using metal complex ion under homogeneous conditions is still unknown. It has been shown recently[2] that various unsaturated compounds using cyano cobalt complex which prepared from cobaltous chloride and five moles of potassium cyanide were hydrogenated in aqueous solution.

In this communication, we wish to report that reductive amination of α-keto acids with aqueous ammonia can be made either with cyano cobalt complex as a catalyst or chloropentamminecobalt(III) chloride as a reagent of the reductive amination in alkaline solution.

Most of the experiments using cyano cobalt complex were carried out at 30~70°C under a hydrogen pressure of 50 kg./cm^2 using 6% aqueous ammonia. The results of the reductive amination of α-keto acids are summarized in Table I.

When the reaction was carried out at room temperature under an atmospheric pressure,

phenylalanine was not detected among the products even by the paper chromatographic analysis of the products.

At run 5, the reductive amination of phenylpyruvic acid was carried out with cobaltous chloride under the similar conditions. Comparison of runs 3 and 5 indicated that the yield of phenylalanine increases appreciably by the addition of potassium cyanide to the reaction mixture.

The above results also indicated that cyano cobalt complex acts as a catalyst for the reductive amination of α-keto acids with aqueous ammonia. The mechnism of this reaction seems to be as follows: the unstable intermediate, α-imino acid, coordinates with cobalt complex ion and then the complex is reduced.

When α-keto acids were treated with chloropentamminecobalt(III) chloride[3] alone or together with potassium cyanide at 70°C under hydrogen pressure of 50 kg./cm^2 for five hours in alkaline solution, α-amino acids were obtained. The results of the reductive aminations with $[Co(NH_3)_5Cl]Cl_2$ are summarized in Table II.

While the reductive amination of phenylpyruvic acid with $[Co(NH_3)_5Cl]Cl_2$ gave phenylalanine in 29.6% yield, the yield was greatly increased by the addition of five moles of potassium cyanide. The yield of the amino acid decreased with the decrease of the molar ratio of $[Co(NH_3)_5Cl]Cl_2$ to α-keto acid.

The mechanism of this reaction seems to be similar to that of the reductive amination of α-keto acid with aqueous ammonia using cyano cobalt complex. A more detailed description of this work will be published shortly

Structure of the C_8-Base, an Acid Degradation Product of Tetrodotoxin

By Toshio Goto, Yoshito Kishi and Yoshimasa Hirata

(Received May 1, 1962)

Alkaline degradation of tetrodotoxin[1] (swellfish poison) afforded a yellow compound (C_9-base), whose structure was reported in the previous communication[2]. Tetrodotoxin also gave another yellow compound (C_8-base) when treated with sulfuric acid. That the C_8-base is 2-amino-6-hydroxyquinazoline (I) is deduced from the following evidences.

(II) R=R′=H
(II) R=CH_3CO, R′=H
(III) R=H, R′=CH_3

Tetrodotoxin was dissolved in concentrated sulfuric acid and the solution allowed to stand at room temperature for three days. Then the reaction mixture was neutralized with aqueous barium hydroxide and filtered. The filtrate was acidified with hydrochloric acid, evaporated to dryness under vacuum, and the residue was sublimed to give the C_8-base hydrochloride, m. p. over 250°C (in a sealed tube). Treatment of the hydrochloride with acetic andydride and pyridine afforded the diacetate (II), m. p. 198°C (in a sealed tube), $C_8H_5ON_3(COCH_3)_2$ (Found: C, 58.64; H, 4.55; N, 17.31. Calcd.: C, 58.77; H, 4.52; N, 17.14%); λ_{max}^{EtOH} mμ (log ε): 248 (4.3), $\lambda_{max}^{NaOH-EtOH}$ 258 (4.1); ν_{KBr} 1745 (phenol ester), 1675 cm^{-1} (amide).

2-Amino-4-methyl-6-hydroxyquinazoline (III) was synthesized for comparison of its ultraviolet spectrum with that of the C_8-base. 2-Nitro-5-hydroxyacetophenone[3], m. p. 146~147°C, was reduced catalytically (H_2/PtO_2) to give 2-amino-5-hydroxyacetophenone, m.p. 183~187°C (decomp.), which was then condensed with cyanamide. The quinazoline III thus obtained was converted to its hydrochloride, m. p. over 250°C (in a sealed tube). The ultraviolet spectrum of the C_8-base hydrochloride [$\lambda_{max}^{H_2O}$ mμ (log ε): 233 (4.3), λ_{max}^{NaOH} 245 (4.4)] was almost superimposable with that of the quinazoline III hydrochloride [$\lambda_{max}^{H_2O}$ mμ (log ε): 233 (4.3), λ_{max}^{NaOH}

245 (4.4)]. For a methyl substituent at C_4-position would not contribute much to the ultraviolet spectrum of the quinazoline III, the C_8-base must have the structure I. The NMR spectrum of C_8-base in deuterium oxide shows only three signals (all singlets) at -2, -23 and -73 c. p. s.[4] (area ratio 1 : 2 : 1), which were assigned to one proton at C_4, two at C_7 and C_8, and one at C_5, respectively.

Isomerization of Flavan-3, 4-diols during the Formation of Isopropylidene Derivatives

By Shin-ichiro FUJISE, Shinzaburo HISHIDA, Toshio ONUMA, Koichiro ADACHI, Yutaka FUJISE and Takashi MUNEKATA

(Received May 10, 1962)

The stereochemistry of flavan-3, 4-diols is being studied in recent years. Corey et al.[1] reported that *cis*- and *trans*-flavan-3, 4-diols could respectively be converted to cyclic carbonates and that one of these carbonates was a trans derivative. Bokadia et al.[2] have shown that *trans*-flavan-3, 4-diol, *trans*-5-methylflavan-3, 4-diol, and *trans*-5-methyl-4′-methoxyflavan-3, 4-diol afforded the isopropylidene derivatives of the corresponding *cis*-diols. These results show that the formation of a cyclic derivative could no longer be regarded as diagnostic for a *cis*-configuration.

TABLE I

Flavan-3, 4-diols			Isopropylidene derivatives

1) E. J. Corey, E. M. Philbin and T. S. Wheeler, *Tetrahedron Letters*, No. 13, 429 (1961).

2) M. M. Bokadia et al., *J. Chem. Soc.*, **1961**, 4663.

Authors report analogous results shown below (Table I). The two stereoisomers of flavan-3, 4-diols (at C-4) were synthesized by the reduction (with $NaBH_4$, $LiAlH_4$, or catalytic hydrogenation) of the corresponding 3-hydroxyflavanones and the third isomers were synthesized by catalytic hydrogenation of the corresponding flavonols in the presence of copper chromium oxide, Raney nickel, or platinium oxide. The isopropylidene derivatives were obtained from flavan-3, 4-diols by the reaction with acetone in the presence of anhydrous cupric sulfate at room temperature.

Some pairs of flavan-3, 4-diols, X and XI, XIII and XIV, XVI and XVII, gave the same isopropylidene derivatives. The stereochemical change in the course of the formation of isopropylidene derivatives may be caused by the ionization of the benzylic 4-carbon atom.

The Color of Liquid Caustic Soda Produced by the Ammonia-Soda Process

By Hiroshi AWAYA

(Received January 7, 1961)

Inasmuch as the chromium in an electrolyte has an influence on chlorine-caustic electrolysis in the electrolytic-soda process, small amounts of chromium in the electrolyte and in the products have been measured, but in the ammonia-soda process, the amount of chromium in the products has not yet been measured.

Caustic liquor produced by the ammonia-soda process has a characteristic yellow color. For the present article, the cause of such coloring was studied by polarographic and spectrophotometric methods, and it was found that the coloring was due to a chromate contained as an impurity in the caustic liquor.

Then the chromate content in many steps of the manufacturing process was determined. As a result of this experiment, it was found that the chromate in the caustic liquor comes from the milk of lime used for causticization.

Preliminary Experiments

Polarographic Method.—Caustic liquor samples from both ammonia and electrolytic processes were used. The sample of the ammonia process had a marked tinge of yellow. This sample was diluted with water and tartaric acid was added to make 0.2 M of an acid tartrate solution (pH 4.5). A small quantity of gelatin was also added. The polarograms of these solutions are shown in Fig. 1.

The polarogram of the sample from the ammonia process shows an abnormal wave. This wave seems to be due to a hydrolysis current[1].

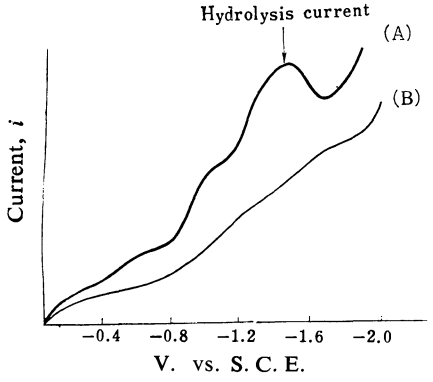

Fig. 1. Polarograms of caustic liquor as 0.2 M acid tartrate (pH=4.5).
(A) Ammonia-soda process
(B) Electrolytic process

Although the polarographic study of chromate ions by Lingane and Kolthoff[2] did not describe this hydrolysis current, and the half-wave potential did not coincide exactly with the values obtained by Lingane for chromate ions[3]; it seems to the author that the existence of chromate in the sample caused this hydrolysis current. This method did not give however, reproducible results. It might be that the coloring was due to the chromate, but this could not be confirmed by the polarographic method.

Absorption Spectra. — If the coloring of the caustic liquor was caused by the chromate contained as an impurity, the absorption spectra of the sample would show an absorption maximum at the wavelength of 370 mμ[4]. Therefore, the absorption spectra of many sorts of caustic soda were determined.

The samples were diluted to a 25% solution, and their absorbancy was determined photometrically over the wavelength range from 340 to 700 mμ. The data obtained are shown in Fig. 2.

2) J. J. Lingane and I. M. Kolthoff, *J. Am. Chem. Soc.*, **62**, 852 (1940).
3) J. J. Lingane and R. L. Pecsock, ibid., **71**, 425 (1949).
4) E. B. Sandel, "Colorimetric Determination of Traces of Metals", Interscience Publishers, Inc., New York (1959), p. 390.

process had an absorption maximum at 370 mμ, agreeing with the characteristic absorption band of chromate. When the caustic liquor was concentrated to an anhydrous solid, even if it was produced by the ammonia process, it showed no absorption maximum at 370 mμ. This was due to the addition of sulfur, used as a refining reagent for solid caustic soda.

Experimental and Results

The Determination of Chromium. — As it was established that the coloring of the caustic liquor produced by the ammonia process was caused by chromate, the chromium content at many steps of the caustic manufacturing process was determined[5].

The chromium content in the electrolytic caustic soda was also determined.

Preparation.—Liquid caustic soda (50%): Dilute 50 ml. of the sample with water to about 200 ml.

Sodium carbonate solution: Dilute 100 ml. of the sample with water to about 200 ml.

Salt: Heat 100 g. of the sample with 100 ml. of 1 : 9 hydrochloric acid, add water until dissolution, and filter the solution in order to remove insoluble substance.

Limestone and burned lime: Take 20 g. of limestone and 5 g. of burned lime respectively. Moisten the sample powder with water, add 6 N hydrochloric acid until the bubbles of the carbon dioxide gas disappear, and dilute the mixture with water. Then heat the solution and, after cooling, filter it for removal of the insoluble substance.

Milk of lime: Dilute 10 ml. of the sample with water, and 6 N hydrochloric acid until the bubbles of the carbon dioxide gas disappear, and dilute the mixture with water. Then heat the solution.

Operation of Analysis.—If the sample solution is neutral of alkaline, add hydrochloric acid to the solution until it is acidic (pH 1~2). If the sample solution is highly acidic, add aqueous ammonia. Heat the solution carefully, add 5 ml. of a ferrous solution (1 mg. Fe^{2+} per mol.) for the reduction of the chromate and, after a while, add 0.5 ml. of concentrated nitric acid in order to oxidize the ferrous ion. Add aqueous ammonia (12 N) excessively to the solution at 30 to 40°C. The precipitates of ferric and chromium hydroxides are filtered and dissolved with 20 ml. of hot mixed acid (10% concentrated sulfuric acid, 10% concentrated phosphoric acid, and 80% water by volume). Dilute to about 40 ml. with water, heat the solution and, keeping it warm, add the potassium permanganate solution (0.5%), drop by drop, until the solution comes to have a tinge of the purple color of the permanganate for 10 min. After cooling, add 10 ml. of a urea solution (10%) and then sodium nitrite solution (10%), drop by drop, until the pink color disappears. Stir the solution vigorously until the bubbles are broken, transfer the solution to a 100 ml. volumetric flask. Add 3 ml. of diphenylcarbazide solution (0.2% alcoholic solution) and then shake it and allow it to settle for a minute. Add 5 ml. of hydrofluoric acid (4%) in order to mask the ferric ion, dilute to 100 ml., determine the absorbancy photometrically at 540 mμ using a blank solution (containing ferric ion and all reagents) as a reference and compare it with the calibration curve.

Solid caustic soda		No. 1	0.000007
		No. 2	0.000062

The results of the determination of chromium content are shown in Table I.

The chromate was also found in the caustic liquor produced by several ammonia process makers in Japan.

As shown in Table I, the salts used as raw material and the sodium carbonate solution used for causticization contained little chromium. A considerable amount of chromium was found in limestone, burned lime and milk of lime. It was thus confirmed that the chromate in the caustic liquid came from the limestone.

Discoloring of the Yellow Colored Caustic Liquor.—Discoloring of the caustic liquor produced by the ammonia process was attempted.

The caustic liquor samples used were 10% solutions.

Treatment 1.—Add the powder of ferrous sulfate or strontium sulfate up to 1% of the solution, then stir and filter the solution. The chromate in the solution was reduced by this method, precipitated as chromium hydroxide and removed from the solution.

Treatment 2. — Let the sample solution pass through a column of anion exchange resin (Amberlite IRA-410, OH-form). The chromate in the solution was adsorbed in the resin, and the solution was purified. After each treatment, the

TABLE II. DISCOLORING OF CAUSTIC LIQUOR

Treatment	Cr, %
Before treatment	0.000034
Addition of excess of $FeSO_4$	0.000012
Addition of excess of $SrSO_4$	0.000014
Treatment with anion exchange resin*	0.000008

* Amberlite IRA-410, OH-form

chromium content of these solutions was determined. These results are shown in Table II.

Yellow colored caustic liquor was discolored by the addition of ferrous sulfate or strontium sulfate.

The application of anion exchange resins was also effective.

Summary

It is found that the coloring of caustic liquor produced by the ammonia-soda process is due to chromate in the milk of lime given to the sodium carbonate solution for causticization. But the solid caustic soda, even produced by the ammonia-soda process, contains a little chromate. The coloring of caustic liquor by chromate is found in products of all ammonia process makers in Japan.

The existence of chromate not only gives the yellow color to the product, but also has an undesirable effect on viscose production in the rayon industry.

Yellow-colored caustic liquor can be discolored by the addition of the reducing reagent. Refining by anion exchange resin is also effective, but there is a risk of the corrosion of the resin by the caustic liquor. As the chromate was identified in the caustic liquor, it was concluded that the abnormal wave of the polarogram caustic liquor was probably due to the hydrolysis current.

By measuring the absorbancy of caustic liquor at the wavelength of 370 mμ, the chromate content can be nearly exactly determined.

As much limestone contains a considerable impurities, it is not desirable to use the milk of lime for the purification of the brine in the electrolytic-soda process also.

Thanks are due to Professor Mutsuaki Shinagawa of Osaka University for his helpful advice.

On Glumamycin, a New Antibiotic. II[*1]. *Isolation and Identification of Amino Acids Constituting Glumamycin*

By Michitaka INOUE[*2]

(Received March 31, 1961)

Glumamycin[1-3], an antibiotic isolated from the culture broth of a soil streptomyces *Streptomyces zaomyceticus* No. 7548, shows a strong activity against Gram positive bacteria, particularly penicillin- and tetracycline-resistant bacteria such as *M. aureus* and *B. subtilis*. It is interesting to note that glumamycin is more active in vivo than in vitro[4]. The author has long been engaged in the investigation of glumamycin, and as described in previous communications[2,3] the antibiotic was found to consist of the following amino acids; L-aspartic acid, α(L), β-methylaspartic acid, L-proline, L-valine, glycine, D-pipecolic acid, and α, β-diaminobutyric acid. This paper deals with the identification of these amino acids.

As already reported[1,2] glumamycin was extracted from a filtered broth with isoamylalcohol or *n*-butanol at pH 2.0, transferred to water at pH 7.0~8.0, and separated from brown pigments by column chromatography on active carbon. Further purification was effected by Craig's countercurrent distribution (300 transfers).

Pure glumamycin, a white crystalline powder, is soluble in water and methanol, and when dissolves in a sodium hydrogen carbonate solution, produces carbon dioxide. But it is insoluble in chloroform, benzene and ethyl acetate. Analysis of glumamycin gives a value consistent with the molecular formula of $C_{59}H_{91}O_{20}N_{13}$. The antibiotic is an optically

active substance and gives biuret reaction but no ninhydrin reaction. Infrared spectrum of glumamycin shows the presence of the linkage characteristic of peptide, but its ultraviolet spectrum exhibits no specifuity. From these results glumamycin was presumed to be an acidic peptide, so its amino acids were investigated by hydrolytic degradation. Hydrolysis of glumamycin with 6 N hydrochloric acid separated an oily substance, which was removed by extraction with ether. In the water layer seven amino acids were detected by paper chromatography and paper electrophoresis, of which two were acidic, one was basic, and the remaining four were neutral. In general, peptide-type antibiotics so far known belonged to D-series or specific amino acids, so the seven amino acids were isolated by a combination of ion-exchange chromatography and partition chromatography, and their properties were investigated.

One of the two acidic amino acids was L-aspartic acid and three of the four neutral amino acids were L-proline, L-valine and glycine, and they were identified by their infrared spectrum, optical activity and behavior in paper chromatography.

One of the remaining three amino acids was obtained as fine needles, $C_5H_9NO_4$, and though acidic, it was not identical with glutamic acid on paper chromatography. The compound was presumed to be methylaspartic acid from detection of one C–CH_3 group by the Kuhn-Roth method, and identified as α(L), β-methylaspartic acid[5] from its optical rotation, melting point and infrared spectrum*3.

Another compound of the three unidentified amino acids was isolated as a neutral amino acid, fine needles, $C_6H_{11}NO_2 \cdot HCl$, and containing no *N*-methyl group and no amino-nitrogen, and giving a specific color with ninhydrin, it was presumed to be a piperidine carboxylic acid. The compound was compared with synthetic DL-pipecolic acid (piperidine-α-carboxylic acid) and its isomers by paper chromatography, and it was assumed to be pipecolic acid. Further, as the optical rotation of the compound was in reverse relation with that of L-pipecolic acid monohydrochloride obtained from a plant[6], it was presumed to be D-pipecolic acid. Therefore, its (+)tartrate[7] was compared with D-pipecolic acid (+)tartrate obtained by optical resolution of synthetic DL-pipecolic acid, and they were observed to be in good agreement in the melting point, optical rotation and infrared spectrum. These findings establish conclusively that the neutral amino acid is D-pipecolic acid.

Table II. Comparison with α, β-diaminobutyric acid and α, γ-diaminobutyric acid

	M. p., °C		R_f Value Solvent systems	
	Monohydrochloride	Monopicrate	A	B
α, β-Diaminobutyric acid (from glumamycin)	202	209	0.15	0.32
α, γ-Diaminobutyric acid (synthetic)	228~230	184~185	0.13	0.20

such antibiotics as Polymixin B[8], it seems different from α, γ-diaminobutyric acid because it gave a values of nearly one mole of C-CH_3 by the Kuhn-Roth method, and the melting points of its hydrochloride and picrate and its R_f-value were all different from those of α, γ-diaminobutyric acid. So this basic amino acid was presumed to be α, β-diamino-*n*-butyric acid or α, β-diaminoisobutyric acid. To clarify its identity the amino acid was deaminated with one mole of sodium nitrate carefully and resulting ninhydrin positive product $C_4H_9O_3N \cdot H_2O$, which gave acetaldehyde on oxidation with periodic acid, was assumed to be α-hydroxy-β-aminobutyric acid, and thus the above-mentioned basic amino acid was established to be α, β-diamino-*n*-butyric acid.

To confirm the result more positively, attempt was made on the synthesis of α, β-diaminobutyric acid. As to the synthesis there is found no other report than that of Neuberg[9], who effected it with α, β-dibromobutyric acid and aqueous ammonia under pressure, but as the product was a syrupy substance, it was isolated as phenylisocyanate or picrate. However, since the α-bromine seems readily to be split off in this method as pointed out by Neuberg[9], the present author employed the method used by Horner[10] for the synthesis of β-alanine. Namely, ethyl α, β-dibromobutyrate (I) was allowed to react with sodium azide, the resulting ethyl α, β-diazidobutyrate (II) was further reacted with triphenylphosphine, and the phosphinimide thus produced was hydrolyzed with hydrobromic acid to give α, β-diaminobutyric acid (IIIa). The diamino acid was also obtained by reducing the diazide compound under high pressure and hydrolyzing the reaction mixture directly, but in this case, besides IIIa, its isomer IIIb crystallizable as hydrochloride was obtained.

Benzoylation of IIIa and IIIb by Schotten-Baumann's method afforded IVa, m. p. 216°C and IVb, m. p. 106~108°C, respectively. Dehydration of IVa with benzoyl chloride in pyridine yielded a substance assumable as the corresponding azlactone, which was converted to ethyl α, β-dibenzoylaminobutyrate (Va) by boiling with ethanol. The infrared spectrum of the product was in accord with that of α, β-dibenzoylaminobutyrate prepared by the same method from the dibenzoyl compound derived from glumamycin.

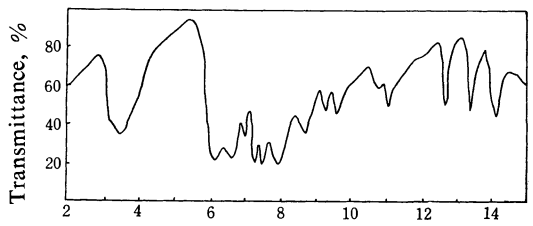

Fig. 3. Infrared spectrum of α, β-diaminobutyric acid monopicrate, KBr.

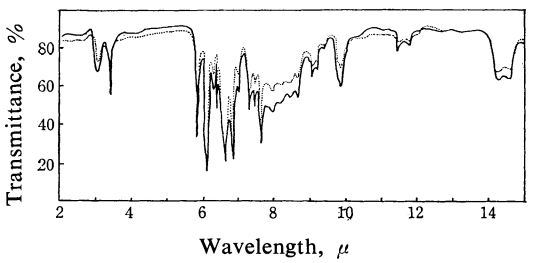

Fig. 5. Infrared absorption spectrum of ethyl dibenzoylaminobutyrate, KBr.
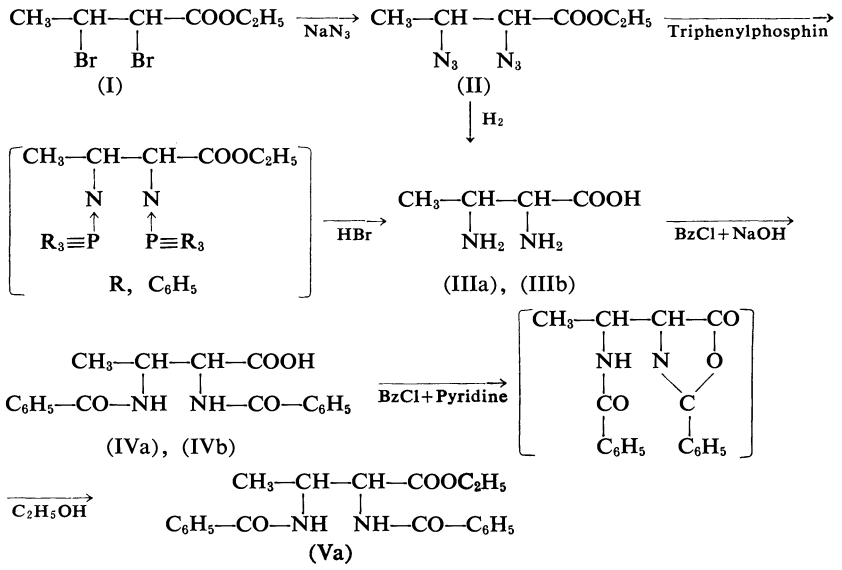
—— From glumamycin
····· Synthetic



From the results mentioned above the plane structure of the basic amino acid of glumamycin was established to be α, β-diamino-*n*-butyric acid.

Of the seven amino acids constituting glumamycin, α(L), β-methylaspartic acid, D-pipecolic acid and α, β-diaminobutyric acid are the first to be isolated as components of peptide-type compounds. It was found that glumamycin

10) L. Horner and A. Gross, *Ann.*, **591**, 117 (1955).

also follows the rule that peptide-type antibiotics contain always D-series amino acids.

Experimental

Paper Chromatography.—Whatman No. 1 paper and Toyo Roshi No. 50 paper were employed with the following solvent systems: A, *n*-butanol-acetic acid water (4 : 1 : 5); B, *n*-butanol-pyridine-water (1 : 1 : 1); C, phenol-water (4 : 1).

Paper Electrophoresis. — Whatman No. 1 paper employed with the following conditions: Buffer; 2 N acetic acid. Voltage; 300 V. Time; 3 hr.

Glumamycin. — The crude antibiotic which was obtained as described in a previous paper[1] was purified by countercurrent distribution (300 transfer: 20 ml.) in the system chloroform-methanol-0.02 hydrochloric acid (2 : 2 : 1). The materials in the tubes (158~168), whose distribution corresponded closely to the theoretical $k=1.17$, were combined and recrystallized to yield the material for all degradative studies. Glumamycin was obtained as a white crystalline powder by recrystallization from a methanol-ethyl acetate mixture, m. p. 230°C (decomp.), $[\alpha]_D^{20}$ +8.5±0.5 (*c* 1, in ethanol).

Found: C, 54.58; H, 7.25; N, 13.60. Calcd. for $C_{59}H_{91}O_{20}N_{13}$: C, 54.25; H, 6.99; N, 13.99%.

Acid Hydrolysis.—Hydrolysis of glumamycin at 110°C for 12 hr. with 6 N hydrochloric acid and, after removing the ether soluble material and working up in the usual way, gave a mixture of amino acids which, when examined by paper chromatography (solvent system A, Toyo Roshi No. 50) and paper electrophoresis, was found to contain seven amino acids. Prolonged heating with hydrochloric acid did not change the composition of this mixture.

Separation and Identification of Hydrolyzate.—The acid hydrolyzate of the antibiotic (5 g.) was treated with ether and concentrated in vacuo in the usual way.

Aspartic Acid.—The above residue was dissolved in 200 ml. of water. The solution was put on a column (3 cm.×20 cm.) of Amberlite IR-4B (OH-form). The column was eluted with 1 N hydrochloric acid, the ninhydrin positive fraction was collected and concentrated under reduced pressure, and the residue was recrystallized from ethanol to give colorless granular crystals, m. p. 160°C $[\alpha]_D^{23}$ +23° (*c* 8, in 6 N hydrochloric acid).

Found: C, 36.10; H, 5.41; N, 10.30%.

α(L), β-Methylaspartic Acid.—The mother liquor from the aspartic acid was evaporated to dryness and the residue was subjected to partition chromatography, using a column (3 cm.×35 cm.) of cellulose powder and developing with *n*-butanol-acetic acid-water (120 : 30 : 50). Amino acids were detected in the eluate fractions (5 ml.) by subjecting them to paper chromatography (solvent system A). The fractions showing a single spot at about R_f 0.35, which colored purplish red with ninhydrin, were combined and evaporated to dryness. The residue was dissolved in water, the solution was passed through a column of Amberlite IR-120 (H-form), and the column, after washing with water and 0.2 N acetic acid, was eluted with 0.2 N aqueous ammonia. The eluate was concentrated under reduced pressure, the residue was dissolved in aqueous butanol, the acetone was added to the solution, giving colorless needles, which were purified by recrystallization from aqueous ethanol, m. p. 254~256°C (decomp.), $[\alpha]_D^{21}$ +13.0° (*c* 1, in 5 N hydrochloric acid).

Found: C, 40.52; H, 6.18; N, 9.27; C-CH_3, 10.33. Calcd. for $C_5H_9NO_4$: C, 40.80; H, 6.12; N, 9.52; C-CH_3, 10.20%.

Separation of Neutral Amino Acids.—The above effluent from Amberlite IR-4B was combined with the washing and evaporated to dryness in vacuo. The residue was dissolved in 20 ml. of ammonium acetate buffer (pH 5.0), the solution was passed through a column (8 cm.×40 cm.) of Dowex 50-X8 (100~200 mesh) treated beforehand with the same buffer, and the column was eluted with the same buffer. The effluent was collected in fractions of 200 ml. each and investigated by paper ionophoresis, finding that all neutral amino acids were eluted out in 200~800 ml. of the effluent.

This portion of the effluent was evaporated to dryness under reduced pressure and the residue was extracted several times with 30 ml. portions of methanol to divide it into methanol soluble and methanol insoluble parts.

D-Pipecolic Acid.—The solution of the methanol soluble part was evaporated to dryness and developed on a column (3 cm.×35 cm.) of cellulose powder with *n*-butanol-acetic acid-water (4 : 1 : 5). Of the effluent the part which flowed out first and gave a single spot coloring bluish purple with ninhydrin was evaporated under reduced pressure, and the residue was recrystallized from a mixture of methanol and ether, m. p. 240°C (decomp.), $[\alpha]_D^{21}$ +10.0° (*c* 1, in water).

Found: C, 43.82; H, 7.47; N, 8.76; Cl, 22.61. Calcd. for $C_6H_{11}NO_2 \cdot HCl$: C, 43.50; H, 7.30; N, 8.76; Cl, 21.40%.

D-Pipecolic Acid (+)Tartrate. — According to the method of Morrison[7], an aqueous solution of 250 mg. of the above pipecolic acid monohydrochloride was passed through a column (0.9 cm.× 6.0 cm.) of Amberlite IR-4B (OH-form) to remove the hydrochloric acid and evaporated to dryness. The residue and 232 mg. of (+)tartaric acid were dissolved in 2.5 ml. of hot methanol and the solution was allowed to cool, precipitating the desired product, which melted at 187°C after recrystallization from ethanol.

Found: C, 43.54; H, 6.06; N, 4.80. Calcd. for $C_{10}H_{17}O_8N$: C, 43.00; H, 6.14; N, 5.02%. $[\alpha]_{25}^{D}$ +20° (*c* 10, in water). D-Pipecolic acid (+)tartrate[7], m. p. 187°C, $[\alpha]_D^{25}$ +18° (*c* 10, in water).

Proline.—In the treatment of the methanol soluble part mentioned before, an effluent giving a yellow ninhydrin reaction flowed out after the eluate of D-pipecolic acid. This portion was evaporated and the residue was recrystallized from *n*-butanol to yield prisms, m. p. 218°C (decomp.) $[\alpha]_D^{21}$ −82° (*c* 1, in water).

Found: C, 52.13; H, 8.04; N, 11.87%.

Valine.—The methanol insoluble part mentioned above was developed on a column of cellulose powder with *n*-butanol-acetic acid-water (4 : 1 : 5). The effluent which flowed out first and gave a single ninhydrin positive spot was evaporated and the residue was recrystallized from water, furnishing colorless prisms, m. p. 312°C, $[\alpha]_D^{23}$ +25° (*c* 3.4, in 6 N hydrochloric acid).

Found: C, 51.10; H, 9.46; N, 11.98%.

Glycine.—The eluate which flowed out after valine and which exhibited a single ninhydrin positive spot corresponding to glycine was evaporated and the residue was recrystallized from aqueous methanol yielding prisms, m. p. 233°C.

Found: C, 32.34; H, 7.20; N, 18.69%.

Synthesis of DL-Pipecolic Acid. — A mixture of 10 g. of α-bromo-ε-benzoylaminocapric acid, 100 ml. of water, 100 g. of acetic acid, 100 g. of concentrated hydrochloric acid was boiled under reflux for 6 hr. The reaction mixture was evaporated under reduced pressure to remove the hydrochloric acid and acetic acid, and an aqueous solution of the residue was passed through a column of Amberlite IR-120 (H-form), the effluent being discarded. The column was washed with water and eluted with 0.5 N aqueous ammonia, and the eluate was evaporated to dryness under reduced pressure. The residue was extracted with ethanol, the extract, after addition of a small amount of hydrochloric acid, was evaporated again to dryness, and the residue was recrystallized from a mixture of ethanol and acetone to yield colorless needles, m. p. 240°C (decomp.), $[\alpha]_D^{21}$ 0 (*c* 1, in water).

Found: C, 43.62; H, 7.42; N, 8.80; Cl, 22.34%.

Optical Resolution of DL-Pipecolic Acid. — D-Pipecolic acid (+)tartrate was prepared from DL-pipecolic acid monohydrochloride by the method of Morrison[7] as in the case of D-pipecolic acid described before. The melting point and optical rotation were 187∼188°C and $[\alpha]_D^{25}$ +20° (*c* 1, in water), respectively.

Found: C, 43.80; H, 6.06; N, 4.08. Calcd. for $C_{10}H_{17}O_8N$: C, 43.00; H, 6.14; N, 5.02%.

α,β-Diaminobutyric Acid Monohydrochloride.— The column Dowex 50-X8, which was eluted with 1000 ml. of ammonium acetate buffer (pH 5.0) as mentioned before, was further eluted with 0.25 N aqueous ammonia, and it was found by paper ionophoresis that 400∼800 ml. of the effluent contained a basic amino acid. This fraction was evaporated under reduced pressure, the residue was dissolved in a small amount of hydrochloric acid, and the solution, after addition of mathanol and ether, was allowed to stand in a cool place, whereupon colorless needles melting at 202°C (decomp.) after recrystallization from aqueous ethanol precipitated.

Found: C, 31.39; H, 7.30; N, 17.64; Cl, 21.99. Calcd. for $C_4H_{10}O_2N_2 \cdot HCl$: C, 31.06; H, 6.48; N, 18.11; Cl, 22.95%. $[\alpha]_D^{22}$ +19° (*c* 1, in 6 N hydrochloric acid), $[\alpha]_D^{22}$ +16° (*c* 1, in water), $pk_a' < 2$, 6.6, 9.6. Treated with picric acid it gave α,β-diaminobutyric acid monopicrate, m. p. 209°C (decomp.).

Found: C, 34.72; H, 3.84; N, 19.95. Calcd. for $C_4H_{10}N_2O_2 \cdot C_6H_3O_7N_3$: C, 34.59; H, 3.74; N, 20.10%.

Benzoylated by the Schotten-Bauman's method it gave α,β-dibenzoylaminobutyric acid, m. p. 210°C.

Found: C, 66.14; H, 5.59; N, 8.42. Calcd. for $C_{18}H_{18}O_4N_2$: C, 66.24; H, 5.56; N, 8.58%.

α-Hydroxy-β-aminobutyric Acid.—To a solution in 30% acetic acid of 1 g. of α,β-diaminobutyric acid from glumamycin was added dropwise a solution of 4.5 g. of sodium nitrite in 10 ml. of water over a period of about 1 hr. with stirring and cooling with ice water. The reaction mixture was left standing for 10 hr. The product, diluted with water, was absorbed on a column of Amberlite IR-120 (H-form) and the column was eluted with 1 N aqueous ammonia. The eluate was evaporated in vacuo, and the residue was recrystallized from water, m. p. 123°C (decomp.).

Found: C, 35.08; H, 7.98; N, 9.81; H_2O, 13.98. Calcd. for $C_4H_9O_3N \cdot H_2O$: C, 35.03; H, 8.03; N, 10.21; H_2O, 13.00%.

Periodic Acid Oxidation of α-Hydroxy-β-aminobutyric Acid. — To a solution of 113 mg. of α-hydroxy-β-aminobutyric acid in 10 ml. water was added dropwise a solution of 230 mg. periodic acid in 5 ml. of water with stirring and cooling with ice water. The reaction mixture was left standing

for 2 hr. at room temperature and the product was distilled with 20 ml. of water. To the distillate was added a solution of 180 mg. of dimedon in aqueous alcohol and the resulting colorless substance was recrystallized from aqueous alcohol, m. p. 140°C. Yield, 220 mg. A mixed melting point with authentic acetaldodimedon (m. p. 140°C) showed no depression and infrared spectrum of the two were quite identical.

Ethyl α, β-Diazidobutyrate (II).—To a solution of 27.4 g. of ethyl α, β-dibromobutyrate (I) in 137 ml. of ethanol was added dropwise a solution of 19.5 g. of sodium azide in 78 ml. of water over a period of about 3 hr. with stirring and heating on a water-bath. After the reaction was completed by heating about one hour more, the ethanol was distilled off under reduced presssure, and the aqueous solution was extracted with benzene. The benzene solution, after washing with water, diluted hydrochloric acid and sodium hydrogen carbonate solution successively and drying over anhydrous sodium sulfate, was evaporated under reduced pressure, leaving 16.8 g. of a residue. The residue was distilled in vacuo and the portion b. p. 70~85°C/2 mmHg. (11.2 g. or 56.6%) was redistilled to give the diazide compound, b. p. 80~83°C/2 mmHg.

DL-α, β-Dibenzoylaminobutyric Acid (IVa), (IVb).—i) To a solution of 5 g. of the diazide compound II in 100 ml. of benzene was added dropwise a benzene solution of 13 g. of triphenylphosphin with stirring, when a reaction set in with evolution of heat and nitrogen gas. The reaction temperature was kept at 30°C. After addition of triphenylphosphin the reaction mixture was heated on the water-bath for 2 hr. and then the benzene was distilled off. The crude phosphinimine compound thus obtained was heated with 50 ml. of 40% hydrobromic acid, the reaction mixture was concentrated under reduced pressure and after dilution with water, the precipitate was filtered off. The filtrate was passed through a column of Amberlite IR-120 (H-form), the column was eluted with 4 N aqueous ammonia, and the eluate was evaporated to dryness under reduced pressure, leaving a residue, which gave crystals by addition of ethanol, m. p. 178°C (decomp.).

This compound IIIa was benzoylated by the method of Schotten-Baumann and the resulting crude product was recrystallized from ethanol after treating it with ligroin, m. p. 216~218°C.

Found: C, 66.14; H, 5.41; N, 8.73. Calcd. for $C_{18}H_{18}O_4N_2$: C, 66.24; H, 5.56; N, 8.58%.

ii) A solution of 20 g. of the azide compound in 80 ml. of ethanol was reduced on Adams platinum oxide at room temperature under 100 atmospheric pressure. The catalyst was filtered and the filtrate was evaporated under reduced pressure to give a light yellow syrupy substance. The substance was boiled with 175 ml. of 20% hydrochloric acid for 3 hr., the hydrolyzate was evaporated in vacuo, and the residue was allowed to stand with ethanol-ether, separating 5.5 g. (37.6%) of white prisms (IIIb), m. p. 199~201°C (decomp.). The mother liquor was concentrated in vacuo, the residue was dissolved in water, and the solution was treated by the same method in IIIa, giving 3 g. of IIIa, m. p. 178°C.

Compound IIIb was benzoylated by the same method and the resulting product was recrystallized from aqueus ethanol, yielding white needles, m. p. 106~108°C.

Found: C, 62.82; H, 5.81; N, 8.20. Calcd. for $C_{18}H_{18}O_4N_2 \cdot H_2O$: C, 62.78; H, 5.85; N, 8.14%.

DL-Ethyl α, β-Dibenzoylaminobutyrate (Va). To a solution of 700 mg. of the dibenzoyl compound (IVa) in 7 ml. of pyridine was added 0.2 ml. of benzoyl chloride under cooling with ice water. After one hour, the reaction mixture was poured onto chipped ice, neutralized with hydrochloric acid, and extracted with ethyl acetate. The extract, after washing with water, sodium hydrogen carbonate solution and water successively and drying over anhydrous sodium sulfate, was evaporated under reduced pressure and the residue was treated with ether, leaving a substance, m. p. 187°C, which was assumed to be an azlactone. The substance, was dissolved in ethanol, the solution, after being boiled for one hour, evaporated and the residue was recrystallized from aqueous ethanol to given colorless needles, m. p. 187°C.

Found: C, 67.00; H, 6.20; N, 7.68. Calcd. for $C_{20}H_{24}O_4N_2$: C, 67.78; H, 6.26; N, 7.91%.

Summary

Isolation of the amino acids constituting glumamycin, a new antibiotic, was effected. As a result, α(L), β-methylaspartic acid, besides L-aspartic acid was obtained as an acidic amino acid. In addition to L-valine, glycine, and L-proline, D-pipecolic acid was yielded as a neutral amino acid. Further, α, β-diaminobutyric acid was obtained as a basic amino acid and its structure was established to be α, β-diamino-*n*-butyric acid. For positive confirmation of the structure the acid was synthesized, and it was found that the *N*, *N*-dibenzoyl ethyl ester of the synthetic product and that of the basic amino acid derived from glumamycin were in complete agreement.

The author wishes to express his sincere thank to Dr. Satoru Kuwada, the Director of Research Laboratories, Dr. Sueo Tatsuoka, Vice Director of Research Laboratories, Dr. Kuniyoshi Tanaka, the Head of the 2nd Division of Research Laboratories, for their guidance and encouragement, and to Drs. Kôichi Nakazawa, Akira Miyake, Jisaburo Ueyanagi and Mr. Masahiko Fujino for their kind advices. The author is indebted to Messrs. Masami Kan, Hironobu Kashiwagi and Miss Fusa Suzuki and Mrs. Yoshiko Tsukamoto for performing microanalysis and to Messrs. Hideo Kamio and Hideo Nakamachi for determination of spectra.

On Glumamycin, a New Antibiotic. III[*1]. *Fatty Acid, a Constituent of the Antibiotic*

By Michitaka INOUE[*2]

(Received March 31, 1961)

Investigations reported in previous papers of this series[1] have found that the constituents of the peptide portion of glumamycin are seven kinds of amino acids, i. e. L-aspartic acid, α(L), β-methylaspartic acid, D-pipecolic acid, L-proline, L-valine, glycine and α, β-diaminobutyric acid. An acid hydrolysis of glumamycin, however, gave an oily substance which was insoluble in water, soluble in ether, and, when dissolved in sodium hydrogen carbonate solution, produced carbon dioxide. In the present work, investigation is made of the oily substance.

This substance boiled at 139°C/1 mmHg and corresponded to an unsaturated fatty acid having an empirical formura of $C_{13}H_{24}O_2$, and its hydrogenation product and *S*-benzylthiuronium salt consisted of $C_{13}H_{26}O_2$ and $C_{13}H_{24}O_2 \cdot C_8H_{10}N_2S$ respectively. Since the substance was optically active and its C-CH_3 value, as measured by the Kuhn-Roth method, was 1.2 mol., it was presumed to be an unsaturated fatty acid possessing more than one side-chain.

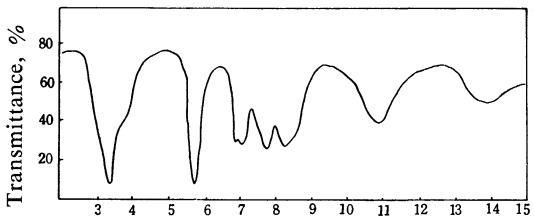

Fig. 1. Infrared absorption spectrum of $C_{13}H_{24}O_2$ from glumamycin.

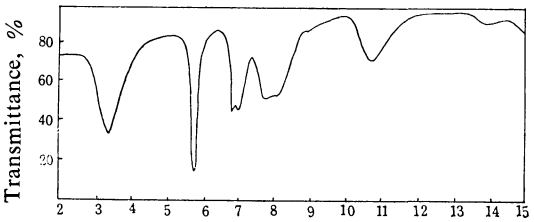

Fig. 2. Infrared absorption spectrum of $C_{13}H_{26}O_2$.

The 2-tridecenoic acid ($C_{13}H_{24}O_2$) obtained by Ogawa et al.[2] from the decomposition product of esperin, an antibiotic produced by *B. mesentercius*, was a straight chain compound and differed from the present substance in its infrared spectum. Therefore, the substance was oxidized with ozone, and then the product was further oxidized with silver oxide, giving a saturated fatty acid corresponding to $C_{10}H_{20}O_2$ and a dibasic acid of $C_3H_4O_4$.

$$C_{13}H_{24}O_2 \xrightarrow{O_3} C_{10}H_{20}O_2 + C_3H_4O_4$$
$$\downarrow H_2$$
$$C_{13}H_{26}O_2$$

The former was like capric acid in constitution but was optically active, and the mixed melting point of its amide with that of capric

acid showed a clear depression; hence, it was assumed to be isocapric acid.

From the above results, the fatty acid ($C_{13}H_{24}O_2$) contained in glumamycin seems to have a double bond at position 3 and side chains at the $C_9H_{19}CH=$ part, and it may be represented by a partial constitution (C_9H_{19}·CH=CHCH$_2$COOH) of 3-isotridecenoic acid.

There has been found no report on the fatty acid parts of amphomycin[3,4] and zaomycin[5] which resemble glumamycin. Crystallomycin[6] contains a straight chain fatty acid with 17 carbon atoms, and aspartocin is also different from glumamycin at the fatty acid portion, according to a private letter from Dr. N. Bohonos of Lederle Laboratory.

Experimental

***S*-Benzylthiuronium Salt of 3-Isotridecenoic Acid.**—A mixture of 10 g. of pure glumamycin and 200 ml. of 6 N hydrochloric acid was heated at 110°C for 24 hr., and the reaction mixture, after being diluted with 200 ml. of water, was extracted with two 100 ml. portions of ether. The ether solution was washed with water, dried and evaporated to give 1.4 g. of a light brown oil. The oil was suspended in 100 ml. of water, and sodium hydrogen carbonate was added portionwise until the pH of the mixture became 7.5, when the oil dissolved completely. A solution of 1.5 g. of *S*-benzylthiuronium chloride in 100 ml. of ethanol was added to the solution, and the resulting *S*-benzylthiuronium salt was recrystallized from 50% ethanol to give 1.4 g. of colorless plates, m. p. 141°C.

Found: C, 66.57; H, 9.11; N, 7.01; S, 8.40. Calcd. for $C_{21}H_{34}N_2SO_2$: C, 66.63; H, 9.05; N, 7.40; S, 8.46%.

3-Isotridecenoic Acid.—A solution of 1.1 g. of the *S*-benzylthiuronium salt in 150 ml. of 50% ethanol was passed through a column of ion exchange resin Amberlite IR-120 (H-form) previously treated with the same solvent, the column was washed well with 50% ethanol, and the combined washings were evaporated, giving a colorless oil. The oil was taken in ether, and the ether solution was dried over anhydrous sodium sulfate and evaporated to afford 400 mg. of a colorless oil, b.p. 139°C/1 mmHg, $[\alpha]_D^{22}$ +4.0° (*c* 1, in ethanol), $[\alpha]_D^{22}$ +4.2° (*c* 10, ethanol).

Found: C, 73.40; H, 11.33. Calcd. for $C_{13}H_{24}O_2$: C, 73.53; H, 11.39%. Mol. wt., Found: 225±25 (Barger's method), 210 (titration method), Calcd: 212.

The brown oil obtained by the hydrolysis of glumamycin was purified directly by distillation in vacuo to give a colorless oil, b. p. 139°C/1 mmHg.

Found: C, 73.45; H, 11.55. Calcd. for $C_{13}H_{24}O_2$: C, 73.53; H, 11.39%. The *S*-benzylthiuronium salt of the oil, m. p. 131°C.

Found: C, 66.53; H, 9.30; N, 7.42%. Calcd. for $C_{21}H_{34}N_2O_2S$: C, 66.63; H, 9.05; N, 7.40%.

Isotridecanoic Acid.—A portion of 50 mg. of 3-isotridecenoic acid was subjected to catalytic reduction on palladium carbon as usual, and the product was distilled in vacuo, giving a colorless oil, b. p. 150°C/2 mmHg.

Found: C, 72.74: H, 12.19. Calcd. for $C_{13}H_{26}O_2$: C, 72.84; H, 12.23%. The *S*-benzylthiuronium salt, m. p. 149°C.

Found: C, 66.36; H, 9.65; N, 7.05. Calcd. for $C_{21}H_{36}O_2N_2S$: C, 66.28; H, 9.54; N, 7.36%.

Ozone Oxidation of 3-Isotridecenoic Acid.—A solution of 10 g. of the unsaturated fatty acid ($C_{13}H_{24}O_2$) in 100 ml. of pure chloroform was oxidized with ozone for one hour's cooling with ice (flux: 1 l./min., voltage: 8000 V., content of O_3: 6%), and the reaction mixture was evaporated under reduced pressure, leaving a colorless syrup. The ozonide thus obtained was decomposed by heating with 100 ml. of water for 30 min. on the waterbath, and the resulting hot solution was stirred, drop by drop, into a suspension of 30 g. of silver oxide in 100 ml. of a 2% sodium hydroxide solution at 60°C.

After about one hour, when a test for aldehyde became negative, the silver oxide was filtered and washed well with water. The combined filtrate and washing were acidified with hydrochloric acid and extracted two times with 100 ml. of ether, and the extract was washed with water.

Isocapric Acid.—The above ether solution was evaporated and the residue was distilled under reduced pressure, giving a colorless oil, b. p. 145°C/2 mmHg.

Found: C, 70.03; H, 11.62. Calcd. for $C_{10}H_{20}O_2$: C, 69.72; H, 11.70%. $[\alpha]_D^{21}$ +3° (*c* 1, in ethanol).

Isocapric Acid Amide.—A mixture of 200 mg. of the above oil and 1 g. of thionylchloride was heated on the water-bath for one hour, the excess thionylchloride was distilled off, and 20 ml. of cool concentrated aqueous ammonia was added to the residue to separate a white precipitate, which was purified by recrystallization from 50% ethanol, m. p. 93°C.

Found: C, 69.81; H, 12.37; N, 8.25; Calcd. for $C_{10}H_{21}ON$: C, 70.12; H, 12.34; N, 8.13%. $[\alpha]_D^{21}$ +8° (*c* 1, in ethanol). Mixed melting point determination of the product with capric acid amide prepared in the same manner from capric acid showed a depression.

Malonic Acid.—The filtrate from the silver oxide was combined with the washing of the above ether extract and concentrated to 100 ml. The concentrate was extracted with ether, the extract was evaporated and the residue was recrystallized from a mixture of ether and petroleum ether to give colorless prisms, m. p. 134°C (decomp.). Mixed melting point with authentic malonic acid showed no depression.

Summary

Investigation was made of the ether soluble part of glumamycin hydrolysate. After this oily substance was purified by distillation, the distillate corresponded to unsaturated fatty

acid, having an epimerical formula $C_{13}H_{24}O_2$.

This unsaturated fatty acid was optically active and by oxidation with ozone gave an optically active saturated fatty acid $C_{10}H_{20}O_2$ and malonic acid $C_3H_4O_4$. Therefore, the fatty acid constituted glumamycin corresponding to 3-isotridecenoic acid.

The Secondary-emission Electron Multiplier Tube Used on a Mass Spectrometer and its Amplification of Ion Currents

By Toshio SUGIURA

(Received June 13, 1961)

The requirement for a detector both reliable and very sensitive for the measurement of ion beam currents in mass spectrometry has greatly increased in the past few years. This requirement can be attributed largely to the following:

1. Studies of the measurement of ionization potentials, especially by means of the ionization produced by vacuum-ultraviolet light.
2. The measurement of very small amounts of inert gases occluded in minerals or meteorites in order to determine their age.
3. The mass spectrometric measurement of ions produced by the alpha-ray in the study of ion-molecular reactions.

Various types of electrometers and electrometer tube amplifiers have been used to measure the ion currents collected by the Faraday cage of the mass spectrometer. By such means, ion currents as low as 10^{-14} amp. have been detected. Probably the best commercially available device for the reliable measurement of very small ion currents is the vibrating-reed electrometer, but this instrument has two important limitations which cause trouble at low input currents. First, the time constant of the input reed circuit increases to about 1 sec. when a 10^{11} ohms resistor is used, and, second, the alpha particle activity of about 1 alpha particle per 2 min., which results from the radioactive elements present in the vibrating-reed head in trace amounts, gives rise to bursts of charge. It is generally accepted that the measurement of very small ion currents of less than 10^{-16} amp. are extremely difficult to measure by ordinary methods.

In order to carry out this type of measurement, the secondary-electron emission multiplier is useful. Several types of electron multipliers have been used in mass spectrometry, namely, the electro-static focused multiplier[1-3], the magnetic focused multiplier[4,5], and the scintillator type multiplier[6,7]. The construction of the electrode system in the magnetic-focused electron multiplier is simple, but the preparation of the emitter of the secondary electrons is difficult. On the scintillator type multiplier, a scintillator fit to use in high vacuum conditions is difficult to obain. The electro-static focused type electron multiplier is considered to be the most convenient for use as an amplifier of very small amounts of ions in mass spectrometric studies. The author has already investigated the characteristics of the secondary electron emission by positive ions from the surface of copper-beryllium for the purpose of making use of the dynode

material for the electro-static focused type secondary electron multiplier[8-10].

There are, in the literature, a large number of papers reporting investigations of the characteristics of the electron multiplier, but many of these papers are contradictory because of the large number of variables involved in this phenomenon[11]. Thus, with respect to the reported results concerning the mass dependency of the amplification factor of the electron multiplier for various ions, Nier et al.[1] have reported that its multiplicity for inert gas ions is inversely proportional to the square root of the ion mass, while, on the other hand, White and Collins[3] have reported that the multiplicity of the electron multiplier is independent of ion mass, and Barnett et al.[12] have produced evidence which purports to show that the mass dependency of the multiplicity of the electron multiplier depends on the conditions for treating the dynodes.

In this study, the author has designed and constructed a 12-stage secondary electron multiplier tube using copper-beryllium dynodes treated with electro-polish and with activation by oxidation, and the electron multiplier so constructed has been installed to with the mass spectrometer. The amplification factor of the secondary electron multiplier for inert gas ions has been measured as a function of the supplied voltage to the conversion dynode of the electron multiplier, and the results have been compared with those obtained with the multiplier using electro-polished and activated dynodes. The best amplification was obtained 2×10^5 by the electron multiplier constructed with activated dynodes for helium ions.

Experimental

The Mass Spectrometer its Reconstruction.—In this study, the instrument used was a modified Hitachi RMC-1 type mass spectrometer, which is of the 90° sector type, its radius of the curvature of the ion path and its maximum resolution in mass units being 135 mm. and 150 respectively.

In order to install the secondary electron multiplier and to determine the amplification factor of the ion current by the secondary electron multiplier, the collector block of the mass spectrometer was reconstructed of stainless steel, as is shown in Fig. 1. As may be seen in Fig. 1, the 96 mm. square collector block was welded to the analyzer tube in order to have the center of the collector block deviate by 10 mm. from the center of the analyzer tube. In Fig. 1, S_E and S_S are the earth slit and the suppresser plate for the Faraday cage F respectively. The width of the earth slit is variable over a range from 0 to 5 mm. by means of the driving screw, shown as D.S. in the diagram. The Faraday cage, F, may be moved a distance of 30 mm. without breaking the vacuum condition, for the purpose of measuring the amplification factor of the electron multiplier in the same ion path. After removing the Faraday cage, the electron multiplier tube can approach the earth slit, S_E, shown in Fig. 1. The maximum range of displacement of the electron multiplier tube is 30 mm. The electron multiplier was assembled on the E. M. flange by the method described below.

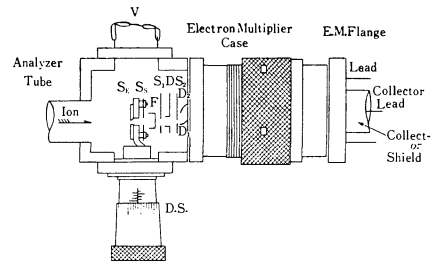

Fig. 1. Schematic diagrams of the collector block of the mass spectrometer and the electron multiplier. D.S. is the driving screw for variation of the width of the earth slit S_E, V is the pumping line, S_S is suppressor plates for secondary electrons from Faraday cage F, S_1, D, S_2, D_1 and D_2 are entrance slit of the ion beam, ion deflecting plate, second entrance slit, conversion dynode and second dynode of the electron multiplier, respectively.

Electron Multiplier Tube Design.—The electron multiplier tube was designed by reference to the electron multiplier used by Nier et al.[1] * The assembly and the details of the actual electrode system of the electron multiplier are shown in Fig. 2. In Fig. 2, B, S_E, S_S and F are the baffle slit, the earth slit, the suppressor plate for secondary electrons from the Faraday cage and the Faraday cage respectively. To the right of S_1 in Fig. 2, the assembly of the electrodes of the electron multiplier is shown. In Fig. 2, S_1 and S_2 are disks, 40 mm. in diameter and 1 mm. in thickness, made from stainless steel; each disk has an entrance slit of 10×3 mm^2 for the ions; D indicates the ion deflector plates, that were constructed from two plates, 4×10 mm^2 in area, installed parallel to each other at a distance of 7 mm. D_1 is the conversion dynode which gives off secondary electrons which are accelerated and focused onto a second dynode, D_2. The electrodes from D_2 to D_{12} are a succession of dynodes which give off multiplied secondary electrons which are accelerated and focused onto the following dynode. These dynodes are pressed from a copper-beryllium plate, 0.2 mm. in thickness,

S_1, D, S_2 are the entrance slit for the ion beam, ion deflecting plates, and second entrance slit of the electron multiplier tube, respectively. D_1 is the conversion dynode, the electrodes indicated from D_2 to D_{12} are succeeding dynodes, C and G are the electron collector and its shielding grid.

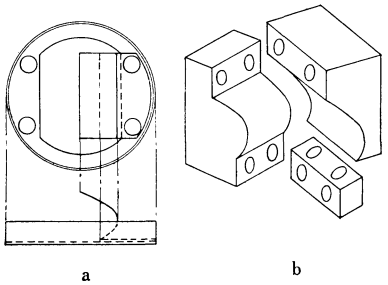

Fig. 3. Schematic diagram of a dynode of the electron multiplier and its shielding plate (a), and schematic view of the mold for shaping the dynodes of the electron multiplier (b).

in the mold shown in Fig. 3b. C and G in Fig. 2 are the electron collector and the shielding grid of the electron collector respectively. Both C and G are in the form of a grid made from tungsten wire 0.07 mm. in diameter, and the rim is made from stainless steel 0.1 mm. in thickness. The electron collector, C, is supported by a molybdenum rod fixed in the center of the E. M. flange by means of a glass-kovar seal. Each dynode was treated after shaping by the method described below, after which each dynode was put into the shielding plate, with a shielding rim 5 mm. in height and 0.3 mm. in thickness, as is shown in Fig. 3a; the shielding plates and the dynodes successively installed pass through four supporting rods, one on top of another, electrically insulated from each other by the quartz spacers. The supporting rods were made from stainless steel 3 mm. in diameter and covered by slender quartz tubes 4.8 mm. in outer diameter and 3.2 mm. in inner diameter. The quartz spacers, 6 mm. in length, were carved from a quartz tube 8 mm. in outer diameter and 5 mm. in inner diameter, and these quartz spacers were burnished up 1/100 mm. precision in length. The electrical connection for each dynode and electrode was provided from the fifteen lead connections

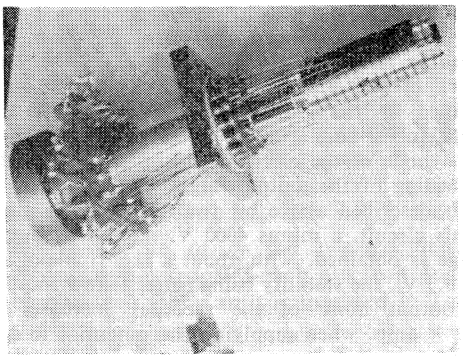

Fig. 4. The electrode structure of a electron multiplier tube used on a mass spectrometer, and the quartz insulators and dynode (lower part of the figure).

sealed by the glass-kovar seal surrounding the collector lead on the E.M. flange. In Fig. 4, a picture of the electron multiplier tube is shown, together with the quartz insulators and the dynodes.

Electronic Circuit for Supplying the High Voltage.—The electronic circuit for supplying a high voltage to each dynode of the secondary electron multiplier, as shown in Fig. 5, was constructed by the author himself. To obtain a high voltage, a commercially offered flyback-transformer was employed, as were a 6CM5 tube as a high frequency input supply for the flyback-transformer, and a 12AU7 tube as a symmetrical multi-vibrator for the rectangular input of the 6CM5 oscillator. The high voltage obtained by the flyback-transformer was rectified by a 1B3-GT tube and a simple RC filter. The oscillator, flyback-transformer, rectifier and RC filter were constructed

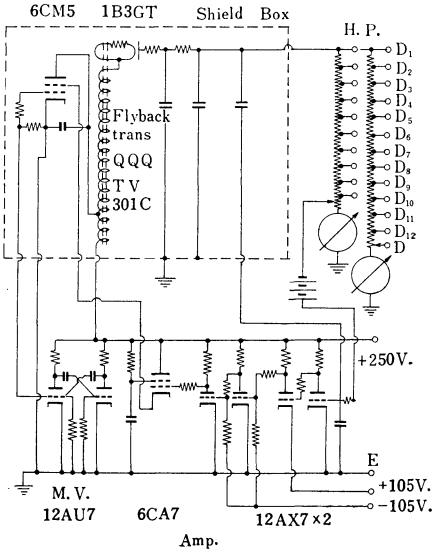

Fig. 5. Electrical circuit of the high potential supply for the electron multiplier tube. H.P. is the output of the high potential, M. V. is the symmetrical multivibrator using 12AU7 tube, Amp. is the d. c. amplifier.

in the shieled box, which was made from copper net. The output voltage was stabilized by means of feeding back to the screen grid of the oscillator a part of the output current after it had been amplified by the amplifier, which employed two 12AX7 tubes and a 6CA7 tube. The voltage to each dynode of the electron multiplier was supplied by dividing of the output high voltage from the circuit described above by twelve 3 MΩ resistors. By this circuit, a minus 4000 V. maximum output voltage is obtained, with about a 8kc. ripple of less than 0.1 V., the stability being better than 2.5×10^{-5}. The output noise of the recorder increases by 2×10^{-14} amp. when supplying the potential to each dynode.

Activation of Dynodes.—The apparatus for the activation of the dynodes of the electron multiplier has been described in previous papers[8,9]. The dynodes of the electron multiplier were activated in the following manner: The shaped and electro-polished dynodes were placed in a quartz tube and evacuated to higher than 5×10^{-6} mmHg at about 800°C for about three hours. Then the temperature of the quartz tube was lowered to 420°C, and oxygen was introduced at an initial pressure of 1 mmHg. After 20 min. the oxygen was pumped out, and the temperature was lowered to room temperature.

Experimental Procedure.—For the measurement of the ion and the amplified electron currents, a conventional type D.C. amplifier was used; this amplifier employed a HT-1005 tube, a modified 6C6 tube as a priamplifier tube, and a 6SN7 tube as a second-stage differential amplifier. For the recorder a four-element oscillo-galvanometer was used. In order to determine the total gain of the secondary electron multiplier, high resistances of 1×10^{10} ohms for direct measurement of the ion current and 1×10^{8} ohms for measurement of the electron current amplified by the electron multiplier were used in the circuit of the D.C. amplifier.

Results

The amplification factors of the 12-stage secondary electron multipliers, which are constructed from electro-polished copper-beryllium dynodes and from activated copper-beryllium dynodes, were obtained for inert gas ions, using different voltage supplies to the conversion dynodes. In Figs. 6 and 7, the amplification factors for the electron multiplier using inert gas ions are plotted as functions of the supplied voltage to the conversion dynode in the range from −1800 to −3000 V. In these

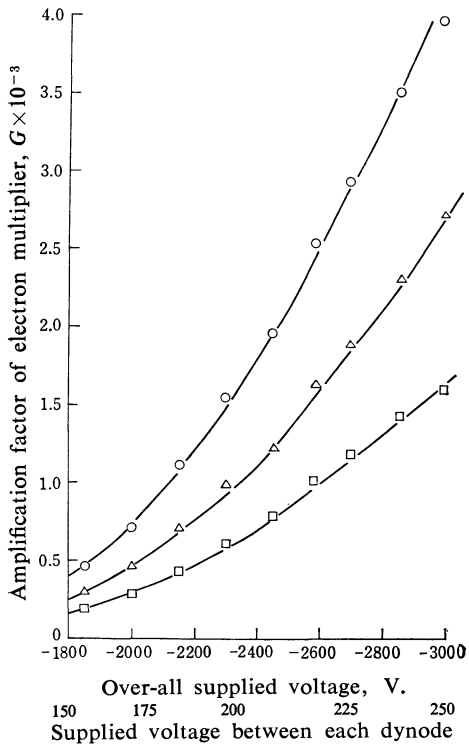

Fig. 6. Amplification factor of the electron multiplier tube using the electro-polished dynodes, as functions of supplied voltage to conversion dynode for inert gas ions. Circular, triangular and square points indicate results for $^{4}He^{+}$, $^{20}Ne^{+}$ and $^{40}A^{+}$ ions, respectively.

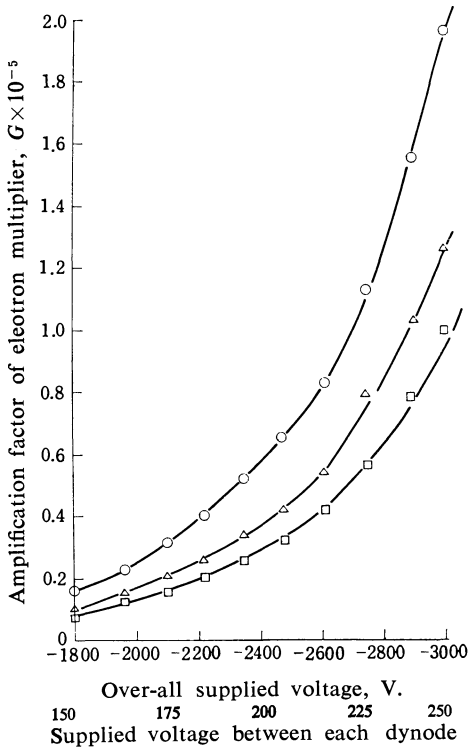

Fig. 7. Amplification factor of the electron multiplier tube constructed by the activated dynodes, as functions of supplied voltage to conversion dynode for inert gas ions. Circular, triangular and square points indicate the results for $^{4}He^{+}$, $^{20}Ne^{+}$ and $^{40}A^{+}$ ions, respectively.

figures, circles, triangles and squares indicate the results for helium 4, neon 20 and argon 40 ions respectively. The ions were accelerated by 1200 V. to earth potential during these measurements.

Discussion

The Influence of Ion Species on the Amplification Factor of the Secondary Electron Multiplier.—As may be seen from Figs. 6 and 7, the amplification factors of the electron multiplier are different for different ion species under the same conditions. In these results, the amplification factors of the ion currents were in the sequence, helium, neon and argon ions. In the results from the electro-polished dynodes, the ratios of the amplification factors are $He^+ : Ne^+ : A^+ = 2.45 : 1.79 : 1.00$ with each voltage. These ratios indicate that the amplification factors are roughly inversely proportional to the square root of the ion mass. This correlation obtained from the electro-polished dynodes agrees with the results obtained by Nier et al.[1] On the other hand, the ratios of the amplification factors obtained from the electron multiplier constructed with the activated dynodes are approximately $He^+ : Ne^+ : A^+ = 2.00 : 1.28 : 1.00$ for each voltage. These ratios indicate that the amplification factors have not the same correlation as the results from the electro-polished dynodes. These results indicate that the amplification factors vary according to the conditions of the treatment of the dynodes, a finding which is in agreement with the results obtained by Barnett et al.[12]

Average Yield of Secondary Electrons by Electron Bombardment. — The amplification factor of the electron multiplier, G, is given by the following relation:

$$G=\gamma_i\times\bar{\delta}^{n-1}$$

when γ_i is the ratio of the number of secondary electrons to positive ions at the conversion dynode, $\bar{\delta}$ is the average ratio of primary to secondary electrons on the succeeding dynodes, and n is the number of stages of the secondary-electron multiplier. γ_i is governed by the following factors: the chemical and physical natures of the dynode, the incident angle of the ions, the kinetic and potential energies of ions and ionic charge, etc., $\bar{\delta}$ is governed by the chemical and physical natures of the dynode, and the kinetic energy of the incident electrons. With regard to the results of this study, the kinetic energy of the ions bombarding the conversion dynode is the difference between the ion acceleration potential and the supplied voltage to the conversion dynode. Assuming that the ion energy dependency of the value γ_i is not varied in the ion energy above 1200 V. the value of γ_i can be obtained by the extrapolation of the data measured in a previous study[8]. The values of γ_i for ion energy obtained in the manner described above are shown in Tables I and II for the electro-polished and activated copper-beryllium dynodes. By using these γ_i values, the value of $\bar{\delta}$, the average yield of the secondary electrons at each electron energy, can be obtained; they are summarized in Tables I and II.

Influence of the Activation of Dynodes on the Amplification Factor of the Secondary Electron Multiplier.—For comparison of the electro-polished dynodes with the activated dynodes, the logarithms of the amplification factors are plotted as functions of the supplied voltage to the conversion dynode; they are shown in Fig. 8. In Fig. 8, the upper three curves are the results obtained from activated dynodes, while the lower three curves are the results obtained from electro-polished dynodes; the circles, triangles and squares indicate the helium, neon and argon ions respectively. As

4000	11.2	240	2.24
4200	11.5	250	2.29

is seen in Fig. 8, the amplification factors of the electron multiplier were radically increased by the activation of the dynodes, and the results show that the amplification factor increased almost exponentialy with the increasingly supplied voltage for all ions, while this was not so in the case of the electro-polished dynodes. When Tables I and II are compared, the values of γ_i and $\bar{\delta}$ show an increase as a result of the dynode activation. The voltage dependency of the amplification factor is mainly governed by the value of $\bar{\delta}$. From the value of $\bar{\delta}$ shown in Tables I and II, the difference in the energy dependency of the value $\bar{\delta}$ due to dynode activation is not clear, but from a comparison of the results in Fig. 8, the energy dependency of $\bar{\delta}$ is considered to be larger for the activated dynodes than for the electro-polished dynodes. In the previons studies[8-10], the increase in the secondary electron yield by activation of the copper-beryllium was explained by the contribution of the beryllium oxide formed near the surface, while for the ions having an energy higher than 1200 V. it was explained by the fact that the stopping power of the beryllium oxide is larger than that of the copper oxide. The increased values of $\bar{\delta}$ by dynode activation for electrons having an energy between 150 and 250 V. can be understood in the same way.

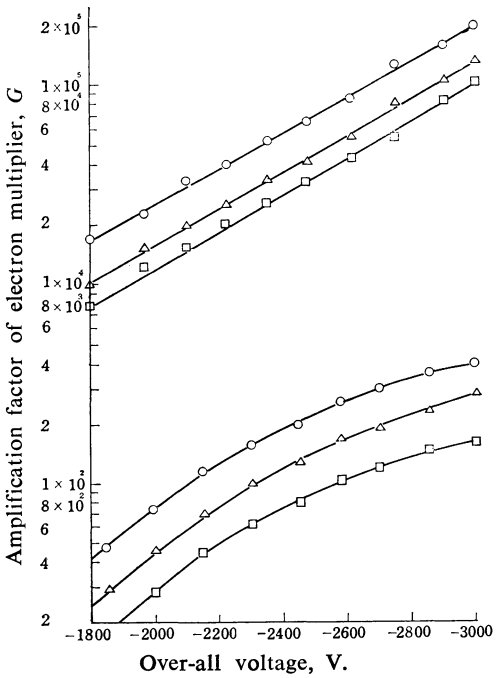

Fig. 8 Semilog plots of the amplification factor of the electron multiplier tube as a function of supplied voltage to conversion dynode for inert gas ions. Upper three curves are the results for activated dynodes, and lower three curves are the results for electro-polished dynodes, the signs of the curves are same as Figs. 6 and 7.

Summary

For the purpose of measuring very small ion currents by the mass spectrometer, a secondary electron multiplier, using the dynodes of copper-beryllium, has been constructed and installed. The amplification by the electron multiplier of various supplied voltages to the conversion dynode was measured for inert gas ions, and the amplification factor and its variation with the supplied voltage to the conversion dynode was compared with both the activated and the electro-polished dynode. For the electron multiplier using the electro-polished dynodes, the amplification was roughly inversely proportional to the square root of the ion mass, while for the activated dynode this was not the case. The average yield of the secondary electrons impacted by electrons on the copper-beryllium dynodes was determined, using the values of γ_i which had been estimated by extrapolation of the data obtained in a previous study. The increase of the amplification factors of the electron multiplier due to the dynode activation was explained on the basis of an increase in γ_i and $\bar{\delta}$ due to dynode activation, an increase to be attributed to the formation of beryllium oxide layers. In this study, an amplification factor of a 10^5 order for inert gas ions has been obtained with the electron multiplier constructed with dynodes made from activated copper-beryllium. By using this electron multiplier, ion currents of 10^{-19} amperes are easily detectable with a mass spectrometer using a conventional D. C. amplifier.

The Behavior of Fission Products Captured in Graphite Powder by Nuclear Recoil. V. Effect of Fission Fragment Damage on the Diffusion of the Fission Product Xenon

By Seishi YAJIMA, Sumio ICHIBA, Kazumi IWAMOTO and Koreyuki SHIBA

(Received November 18, 1961)

The radiation damage to graphite caused by neutron irradiation is of great importance in reactor technology, and many studies have been made in this field[1-4]. However, in the case of the dispersed type of fuel, when the fissionable material is dispersed throughout a matrix of graphite powder, the damage from fission fragments is more severe than the neutron damage[5-8].

The present authors have been studying[9-12] the behavior of fission products captured in several kinds of graphite powder by fission recoil.

For the present work, diffusion experiments on Xe-133 and Xe-135 captured in graphite powder were carried out over an extensive range of fission product concentrations. It has become clear through this work that with natural graphite the diffusion behavior of xenon in graphite is far more strongly affected by fission fragment damage than by neutron damage to the graphite crystal, and that the behavior changed markedly with an increase in the fission product concentration. However, in the case of artificial graphite, the effects of both fission fragment damage and neutron damage were insignificant over the range of fission product concentrations covered in this experiment.

Experimental

Preparation and Irradiation of Samples.—The graphite samples examined in this experiment were of two kinds, natural graphite (NG-1) and artificial graphite (AG), as described in our previous report[12]. Mixed with this graphite was natural uranium in the form of dioxide powder with a particle size of less than 1 μ, which ensured that most of the fission products would recoil out of the uranium dioxide particles into the surrounding graphite. The relation of the fission product capturing factor of the graphite to the uranium dioxide ratio of the mixture were discussed in detail in a previous report[5].

The mixing ratios adopted for the samples in the present experiments were 33 : 1 and 1 : 1 by weight, at which ratios the capturing factors were 0.95 and 0.70 respectively.

The prepared mixtures were sealed in quartz ampules in a vacuum and were irradiated in the JRR-1*1, the JRR-2*2 and the research reactor of the Brookhaven National Laboratory. Data concerning the preparation and irradiation of the samples are given in Table I. In this table the fission product concentration was calculated according to the equation given in the footnote below*3.

Since the radioactivity of samples numbered 13, 14, 15 and 16 was too strong for them to be handled immediately upon initial irradiation, these samples were cooled for four months. After this time, they were reirradiated with thermal neutrons to a ϕt ratio of 8 to produce the fission-recoiled Xe-133 in the samples.

Samples No. 17 and No. 18, after four months' cooling, were treated with nitric acid*4 to remove the uranium dioxide; then the remaining graphite powder was washed with water and acetone, and dried. The powder was then heated for 2 hr. in an argon flow at 1000 and 1440°C respectively. After the heat treatment, the graphite powder was again mixed with uranium dioxide powder to a

*1 Japan Research Reactor-1, water boiler type, operated at 50 kW thermal out-put.
*2 Japan Research Reactor-2, CP-5 type, operated at 1000 kW thermal out-put.
*3 The number of fission product atoms captured in a unit volume of graphite was calculated according to the following equation:

$$\text{Number of f. p. atoms/cm}^3 \text{ of graphite} = 2 \cdot {}^{235}\mathrm{U} \cdot \sigma \cdot \phi \cdot t \cdot \alpha \cdot d$$

where,
^{235}U : Number of U-235 atoms
σ : Fission cross-section of U-235
ϕ : Neutron flux
t : Irradiation time
α : Capturing factor of fission products in graphite
d : Density of graphite

*4 The fission products captured in graphite did not leach out of the graphite to any significant extent by this nitric acid treatment[9].

weight ratio of 33 : 1 and reirradiated with thermal neutrons to a ϕt ratio of 8, to produce the fission-recoiled Xe-133 in the samples.

Samples No. 19 and No. 20 were irradiated at 500°C and, after four months' cooling, were reirradiated with thermal neutrons to a ϕt ratio of 2, to produce the fission-recoiled Xe-133 in the samples.

The difference between the effects on the diffusion of xenon in the graphite of neutron damage and of fission fragment damage was examined with sample No. 21. In this sample natural graphite powder alone was first irradiated with neutron to a ϕt ratio of 58 in JRR-2; then, after this irradiation, the powder was mixed with uranium dioxide powder to a weight ratio 33 : 1, and reirradiated with neutrons to a ϕt ratio of 1 to produce the fission-recoiled Xe-133 in the sample.

Obtaining the Heating Curve.—To obtain the heating curves, Xe-133 was used as the tracer for most experiments, but in some cases of low fission product concentration, Xe-135 was used as the tracer. The optimum cooling times for the experiments, after irradiation or reirradiation, were 1 day for Xe-135 and 7 days for Xe-133. After cooling, the samples were dissolved in nitric acid to remove the uranium dioxide, and the remaining graphite powder was washed with water and acetone and then dried.

The apparatus used for the diffusion experiment was the same as that described in a previous report. A prepared graphite sample was placed in an alundum boat and inserted into an alundum tube, forming the core of an electric furnace with a platinum heater. The temperature was raised at the rate of 5°C/min. The radioactive xenon released from the graphite crystal was carried off with purified argon*5 and trapped in an activated charcoal trap cooled with dry ice. To remove the undesirable radioactive iodine released from the graphite with the radioactive xenon, a trap of glass wool with a silver nitrate deposit was inserted in front of the charcoal trap. The charcoal trap was changed every five minutes until the temperature reached 1500°C. Then the graphite sample was fired with oxygen mixed with argon (volume ratio 1 : 1) at 1200°C, and the residual xenon which had not diffused out of the graphite during heating was caught in the charcoal trap. The excess oxygen and carbon dioxide were removed with a mixture of pyrogallol and potassium hydroxide solutions, and then the water vapor was trapped with a phosphorus pentoxide drying tube.

The Xe-133 and Xe-135 collected in the charcoal traps were placed in a sodium iodide well (2 inches in diameter by 1.75 inches high) attached to a Baird Atomic γ-ray spectrometer to obtain their spectra.

When Xe-133 was used as the tracer, the spectra obtained were radioactively pure, but with Xe-135, traces of the Xe-133 spectrum were discernible along with the Xe-135 spectrum. The portion of

*5 The argon used was 99.99% pure and was further passed through a copper gauze bed heated to 400°C, a phosphorus pentoxide trap, and a sponge titanium bed heated to 800°C to remove the small amounts of oxygen, water vapor and other impurities.

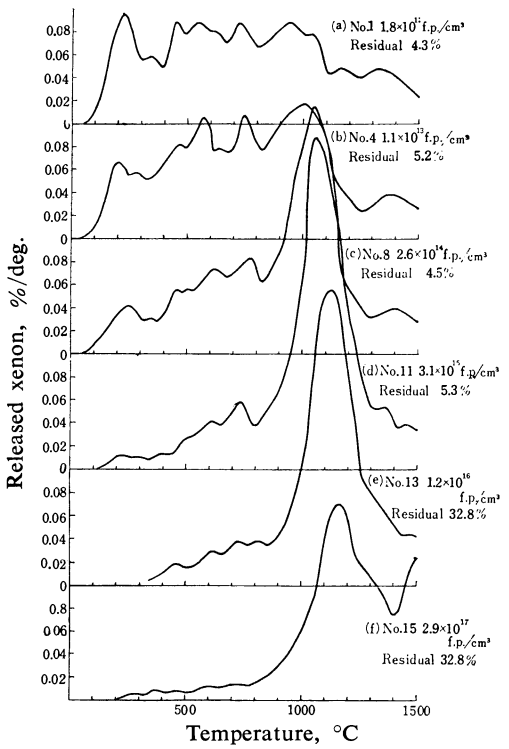

Fig. 1. Heating curves (5°C/min.) of natural graphite (NG-1).

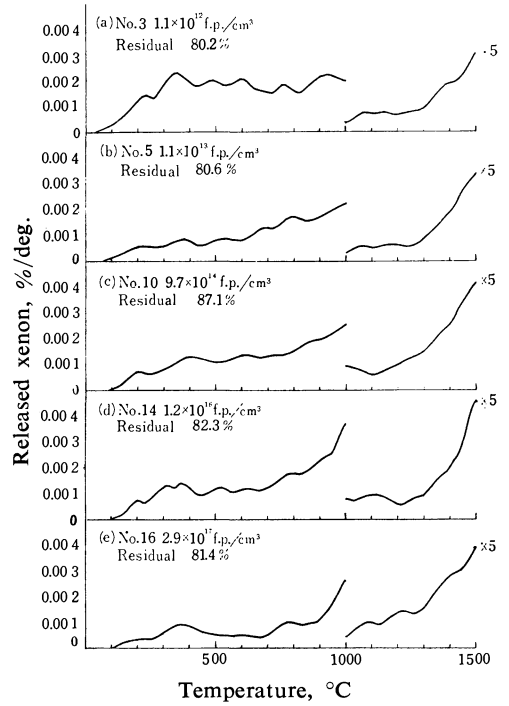

Fig. 2. Heating curves (5°C/min.) of artificial graphite (AG).

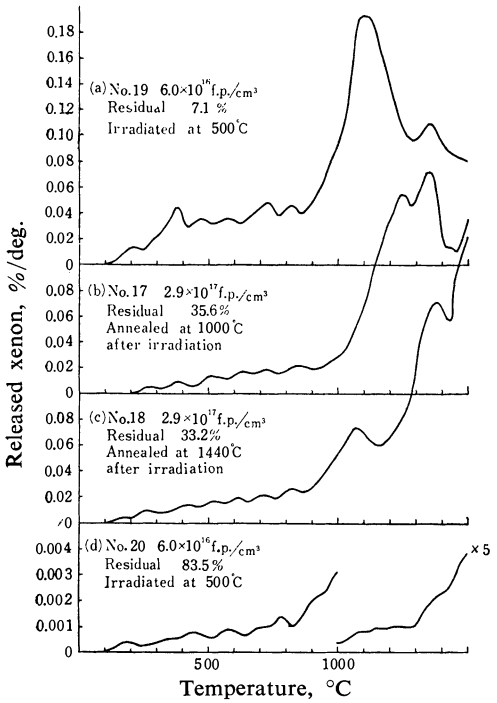

Fig. 3. Heating curves (5°C/min.) of heat-treated graphite sample.

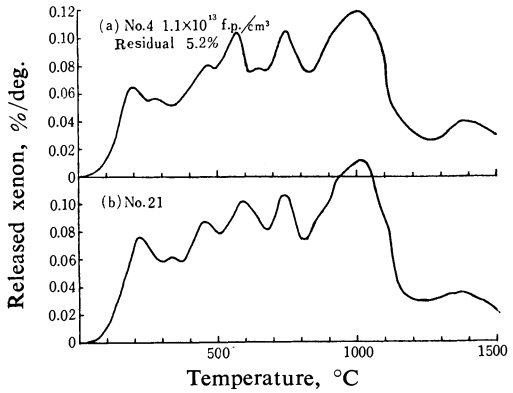

Fig. 4. Heating curve (5°C/min.) of preliminarily neutron-irradiated graphite sample.

Xe-133 was, therefore, subtracted from the obtained total spectrum area. The portion of Xe-135 was, furthermore, calibrated by means of its decay curve, because the Xe-135 nuclide is short-lived.

The fraction of the total activity formed by the activity of each charcoal trap was divided by the temperature rise in the 5 min. interval during which the trap was in use. The plots of this value against the temperature (heating curve) are shown in Figs. 1, 2, 3 and 4.

Determination of Activation Energy.—As is shown in Fig. 1, the heating curves of natural graphite change markedly with the fission product concentration. The activation energy for the

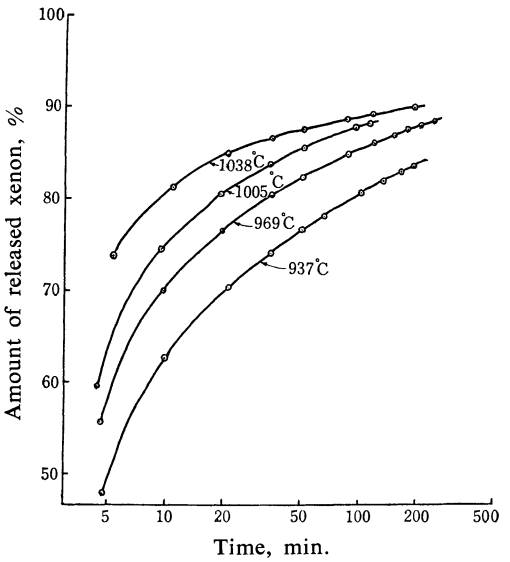

Fig. 5. Isothermal curves in the range 937~1038°C.

diffusion of xenon in natural graphite at a temperature corresponding to the peak seen in Fig. 1 (about 1000°C) was measured by Dienes' method[13]. The furnace was maintained at a fixed temperature, and the graphite sample inserted into the heating tube as rapidly as possible. The released xenon was trapped in a charcoal trap, which was replaced by a new one at the optimum time interval of about 3 hr. The radioactivity of the charcoal traps was plotted against the time (isothermal curve) (Fig. 5). The samples were prepared by the same irradiation treatment as No. 4 in Table I. These samples were preheated to 700°C for 30 min. to eliminate the spectra from xenon released in the range below 700°C and thereby to bring out the isothermal curves of diffusion at about 1000°C. Thus, the ordinate in Fig. 5 does not represent the fraction of released xenon referred to the total activity but the fraction referred to the residual after the preheat treatment. The isothermal curves were obtained for 937, 969, 1005 and 1038°C respectively. The relation between the annealing time (plotted logarithmically) and the temperature (reciprocal of the absolute temperature) is given in Fig. 6. The activation energy can be obtained from the slopes of the $1/T$ plot according to the following equation, derived by Dienes et al.:

$$t \times e^{-E/RT} = C$$

where,

t = diffusion time required to obtain a certain diffusion fraction of the isothermal curve
E = activation energy, cal./mol.
R = gas const., 1.978 cal./deg.
T = temperature, °K
C = constant

Results

The heating curves of natural graphite sample (Nos. 1, 4, 8, 11, 13 and 15) are shown in Fig. 1, and those of artificial graphite samples (Nos. 3, 5, 10, 14 and 16), in Fig. 2. The curves of natural and artificial graphite samples irradiated under heat (Nos. 17 and 18) and

natural and artificial graphite samples annealed after irradiation (Nos. 19 and 20) are shown in Fig. 3. Figure 4 represents the neutron-irradiated natural graphite sample (No. 21).

The following remarks may be made on the basis of the above figures.

1) Sample No. 15 was irradiated with the same doses as No. 13, but the fission product concentration of No. 15 was 24 times larger than that of No. 13, and their heating curves (e) and (f) in Fig. 1 were found to differ considerably from each other.

The graphite portion of sample No. 21 was preliminarily irradiated with a dosage 58 times larger than that of No. 4, but the fission product concentrations in both samples stayed almost identical in shape (Fig. 4). From this, it can be said that the effect of neutron irradiation on the heating curve spectra is very much smaller than the irradiation of fission fragments, at least in the range of the dosage in question.

2) The heating curves of natural graphite represent a continuous spectrum, possessing several peaks.

3) The positions of these peaks do not change appreciably with the fission product concentration.

4) To determine the influence of the fission products concentration on the temperatures at which radiation damage is mainly brought about, three temperature ranges, A (0～850°C), B (850～1350°C) and C (above 1350°C), were arbitrarily established. The fraction of the total xenon released in each temperature range was plotted against the fission product concentration (Fig. 7). In this figure, the fraction. of xenon released in range A is seen to begin

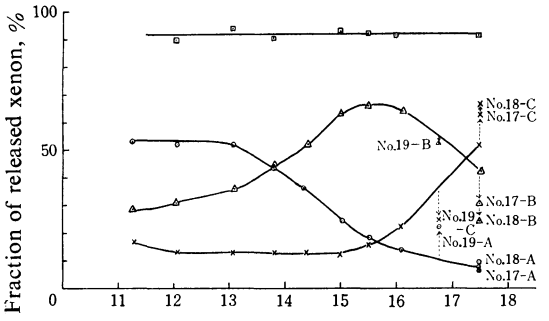

Fig. 7. Change of xenon fraction released from three temperature ranges A, B and C with fission product concentration in unit volume of graphite.

⊙ Natural graphite, range A (0～850°C)
△ Natural graphite, range B (850～1350°C)
× Natural graphite, range C (>1350°C)
⊡ Artificial graphite, range C (>1350°C)

decreasing at about 10^{13} f. p./cm³ graphite, but the fraction of range B goes on increasing with the fission product concentration to reach its maximum at about 10^{15}～10^{16} f. p./cm³ graphite. The fraction of C stays unchanged up to 10^{15} f. p./cm³ graphite; from there on, it increases rapidly. This would appear to indicate that with the increasing fission product concentration, the imperfections of graphite crystal corresponding to range A are taken over by imperfections corresponding to range B and, further, to range C.

5) Returning to Fig. 1, the position of the peak near 1000°C (in range B) shifts toward higher temperatures with the increase in fission product concentration; that is, the position of the peak is 1010°C in curve (b) and shifts with the increasing fission product concentration to reach 1170°C in curve (f). This temperature shift might be explained as a lag of the release rate of xenon against the rising temperature, taking account of the fact that the chance of xenon being captured before diffusing out of the graphite increases with the number of imperfections, which influences the position of the peak, which in turn would depend on the fission product concentration. Another explanation is that the trapping power of the imperfections corresponding to this peak increases gradually with the fission product concentration; that is, the depth of imperfection becomes deeper with the increasing fission product concentration. This temperature shift is not observed in other peaks found in the lower temperature range.

6) As in the case of natural graphite, the heating curves of artificial graphite (Fig. 2) were translated into a curve relating the portion of the released xenon to the fission product concentration (uppermost curve in Fig. 7). This curve represents the fraction of xenon released in range C and indicates that the fraction of C retains a constant value of over 90% and is thus predominant over those of both A and B, which are so small as to be within the range of experimental error. In conclusion, it is obvious that, in the range of fission product concentration examined in this experiment, xenon trapped in natural graphite can more easily diffuse out than that trapped in artificial graphite.

7) The curves of heat-treated samples, Nos. 17, 18 and 19 (Fig. 3), were also analyzed; they are plotted in Fig. 7. It is seen that the fraction of xenon release in temperature range C is greater for samples 17 and 18 than that of the corresponding non-treated sample, No. 15. From this it may be said that heat treatment at 1000 or 1440°C after irradiation will heal radiation damage corresponding to ranges

A and B, but not to that of range C. It may also be seen that the fission fragment damage due to reirradiation is very small compared with the residual from range C caused by initial irradiation.

In the same figure, the plot for sample No. 19 lies above the curve for non heat-treated samples in the case of the fraction for range A. This means that heat treatment of the sample at 500°C during irradiation will impede damage in range C. It may be concluded that heat treatment after irradiation is not effective in removing damage corresponding to higher temperatures, but, on the other hand, that heat treatment during irradiation will considerably reduce this damage. This phenomenon is in accord with the release curve of stored energy in artificial graphite irradiated with fast neutrons of the order of 10^{20} nvt. (see remark 8 below). The heating curve of sample No. 20 in Fig. 3 does not differ from that of the samples unheated during irradiation in Fig. 2.

8) The release of stored energy in artificial graphite irradiated with fast neutrons of the order of 10^{20} nvt. has already been extensively studied[1,4]. The release curve of stored energy (an example was given in Fig. 8) has peaks at points apparently in good correspondence with the xenon release curve of natural graphite. This correspondence might be explained by considering that they both represent the progress of annealing or recovery from strain caused in the graphite crystal by neutrons or by fission fragments, manifesting itself on the one hand in a release of stored energy and, on the other hand, in a release of xenon from the crystal. It should be noted that, while the stored energy release curve represents by the temperature scale, the absolute quantity as well as the depth of damage, the xenon heating curve represents only the depth of damage by the same scale.

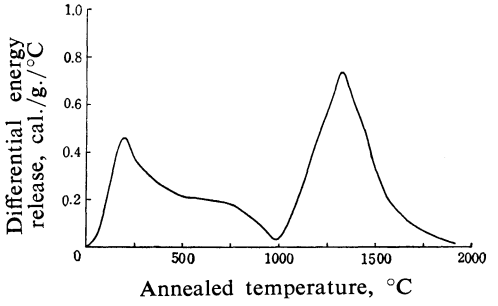

Fig. 8. Differential stored energy release (after Woods et al.[1]).

Xenon atoms trapped in imperfections of graphite crystal are released from the imperfections by heating at a given temperature, when some of them will diffuse out from the graphite particles*6 and others will be trapped again in other imperfections of a higher trapping power. The probability of either happening will be determined by the chemical and physical state of the diffusing atom, the depth of the trapping power of the imperfection, and the number of imperfections per unit volume.

The release curve of stored energy in artificial graphite irradiated with neutrons indicates that the imperfections corresponding to temperature range C are insignificantly few in number (Fig. 8), but the heating curves of artificial graphite (Fig. 2) indicate the fraction of the range C to far surpass those of ranges A and B. This brings out the significance of the studies that should be undertaken on the capturing process of xenon in artificial graphite.

9) The activation energy of xenon diffusion in natural graphite at the peak of about 1000°C in the heating curves is 65.5 kcal./mol. According to Suzuki's study[15], the imperfections existing in ranges A and B may be presumed to be interstitial cluster and mono-vacancy respectively.

The diffusion experiments of highly irradiated samples (Nos. 6—20) were carried out at the Brookhaven National Laboratory. S. Yajima and K. Iwamoto, those of the present authors who went to the Laboratory to undertake the experiment, are particularly indebted to Dr. F. T. Miles, Dr. D. H. Gurinsky Dr. E. Fujita and Mr. H. Munkelwitz for invaluable help and suggestions during their work at Brookhaven.

Japan Atomic Energy Research Institute
Tokai, Ibaraki-ken

*6 Suzuki et al.[14] reported that the xenon atoms which exist between the layers of graphite crystal diffuse very easily and that the calculated activation energy of this diffusion is about 0.03 eV.

Molecular Rotations of Glucides in Relation to their Structures. VIII[1]. *On the Product of the ζ-Coefficients of the Hydroxyl and the Methyl Groups*

By Shukichi YAMANA

(Received December 12, 1961)

Recently, the author introduced an adjustable parameter, the ζ-coefficient, in order to make up Kirkwood's polarizability theory of optical rotatory power; he named this manner of the calculation of optical rotation the "PM-method"[2]. By using the PM-method, it is possible to explain logically the relation between the $[M]_D^{20}$(W) of some optically active substances (i.e. glucocides, polyhydroxycyclohexanes[4] and menthol-like substances[5]) and their molecular structure. Moreover, the product of the ζ-coefficient of the hydroxyl group and that of the methyl group, $\zeta_{OH}\zeta_{CH_3}$, was calculated as about $1.6\{3/((n^2+2)\}$ in molecules which have a cyclohexane-ring (i.e. (−)-trans-2-methylcyclohexanol and menthol-like substances[5]). Nevertheless, in the case of carbohydrates which have an aldopyranose-ring in their molecules, the value of $\zeta_{OH}\zeta_{CH_3}$ had been calculated as either $0.3096\{3/((n^2+2)\}$[6] (when using the $[M]_D^{20}$(W) of β-L-arabinose written in Bates' book[8]) or $0.6671\{3/(n^2+2)\}$[9] (when using the $[M]_D^{20}$(W) of β-L-arabinose observed by Hudson[10]), which values are fairly different from that in the case of molecules which have a cyclohexane-ring, as has been mentioned above. For these reasons, the recalculation of the value of $\zeta_{OH}\zeta_{CH_3}$ in carbohydrates (methyl pentose) becomes necessary.

New Treatment Applied

Into the "Method Proposed" of the previous paper[7], the following two alterations were introduced:

(i) Molecular Model. — In the previous paper[7], the molecular model which had been determined by McDonald and Beevers[11] from the results of the X-ray analysis of crystalline α-D-glucose (hexose) was used. Strictly speaking, however, the shape of its aldopyranose-ring is not perfectly the same as that in methyl pentose. Therefore, as with the molecular model in this article, the one proposed by Geachin and Beevers[12] in the case of crystalline α-rhamnose monohydrate is used. However, this change in the molecular model will not cause much difference[13].

(ii) The $[M]_D^{20}$(W) of α-D-Isorhamnose. — In this series of studies, the data for $[M]_D^{20}$(W) which are listed in Bates' book[8] have been used preferentially. However, after its publication (1942), new data on the $[M]_D^{20}$(W) of carbohydrates have been reported year after year, and those new data should be taken into account. Particularly, in 1951 Hudson reported 163.7 as the $[M]_D^{20}$(W) of α-D-isorhamnose[15], a value which is far different from that listed in Bates' book, 120.3. Therefore, it should be discussed here which of these two values should be chosen. Generally, the $[M]_D^{20}$(W) of an aldopyranose changes widely as time elapses (this phenomenon is called "mutarotation"), and the determination of the initial $[M]_D^{20}$(W) at the time of resolution is difficult. However, the $[M]_D^{20}$(W) of its methyl glycoside is almost constant and can be easily observed. Therefore, it is desirable that an experimental datum of the $[M]_D^{20}$(W) of an aldopyranose should be examined by using the $[M]_D^{20}$(W) of its methyl glycoside.

On the other hand, concerning $[M]_D^{20}$(W)-Diff<methyl glycoside−cor. al. pyranose[16]>[17], Hudson's empirical rule is well known. This

16) "cor." and "al." mean "corresponding" and "aldo-" respectively.
17) In order to represent the difference between A and B simply, the abbreviated symbol, Diff <A−B>, will be used hereafter. For example, $[M]_D^{20}$(W)-Diff<methyl α-D-isorhamnoside−α-D-isorhamnose> means the difference in $[M]_D^{20}$(W) between methyl α-D-isorhamnoside and α-D-isorhamnose, and so on.

TABLE I. $[M]_D^{20}$(W)-DIFF.<METHYL GLYCOSIDE −COR. AL. PYRANOSE[16]>[17]

Name	$[M]_D^{20}$(W) of methyl glycoside	$[M]_D^{20}$(W) of cor. al. pyranose	$[M]_D^{20}$(W)-Diff.
β-L-Arabinose	403.0[8]	303.3[10]	99.7
α-L-Arabinose	28.4[8]	133.6[10]	−105.2
α-D-Xylose	252.6[8]	140.5[8]	112.1
α-D-Fucose	351.2[21]	251.0[8]	100.2
β-D-Fucose	−25.3[21]		
α-D-Isorhamnose	272.1[22]	163.7[15]	108.4
β-D-Isorhamnose	−97.3[22]		
α-D-Rhamnose	111.4[8]	15.7[8]	95.7
β-D-Rhamnose	−170.0[8]	−63.0[8]	−107.0
α-D-Galactose	380.5[8]	271.5[8]	109.0
β-D-Galactose	0.0[8]	95.1[8]	−95.1
α-D-Glucose	308.6[8]	202.1[8]	106.5
β-D-Glucose	−66.4[8]	33.7[8]	−100.1
α-D-Mannose	153.8[8]	52.8[8]	101.0
β-D-Mannose	−135.5[8]	−30.6[8]	−104.9
		Mean of the absolute value	103.5

rule says that the absolute value of this $[M]_D^{20}$(W)-Diff. is not far from 100[18-20].

By using this rule, the approximate value of the $[M]_D^{20}$(W) of α-D-isorhamnose can be obtained by the following equation:

$$272.1^{23,18)} - 100 = 172.1$$

Accordingly, Hudson's datum of the $[M]_D^{20}$(W) of α-D-isorhamnose, 163.7, seems to be more reliable than that in Bates' book, 120.3.

Data Used

Therefore, Table I of the previous paper[7] is rewritten as Table II of this article.

The optical data of the unit groups used in the previous paper[7] are adopted again without any correction[24]. An optical center of the unit group is located at the center of the mass of the bond with which it is combined.

Re-calculation

$\zeta_{OH}\zeta_{CH_3}$.—By using Table II in this article, Eqs. 1, 2 and 3 of the previous paper[7] can be

24) The mean polarizability, α, of OH is 1.04×10^{-24} cc.; the α of CH_3 is 2.27×10^{-24} cc.; the anisotropy ratio, β, of OH is 0.35 and the β of CH_3 is 0.35. The refractive index, *n*, is 1.34.

rewritten as the following Eqs., 1', 2' and 3', respectively.

$$\text{Yo. Diff.}\langle\alpha\text{-D-isorhamnose}-\alpha\text{-D-fucose}\rangle^{17)} = 163.7-251.0^{25)} = -87.3 \equiv (F-E)$$
$$= \{(4\alpha)\,\text{Å}\,(1\alpha) + (4\alpha)\,\text{Å}\,(2\alpha) + (4\alpha)\,\text{Å}\,(3\beta) + (4\alpha)\,\text{Å}\,(\text{CH}_3)^{5\beta} + (4\alpha)\,\text{Å R}\} - \{(4\beta)\,\text{Å}\,(1\alpha) + (4\beta)\,\text{Å}\,(2\alpha) + (4\beta)\,\text{Å}\,(3\beta) + (4\beta)\,\text{Å}\,(\text{CH}_3)^{5\beta} + (4\beta)\,\text{Å R}\} \quad (1')$$

$$\text{Yo. Diff.}\langle\alpha\text{-D-xylose}-\beta\text{-L-arabinose}\rangle = 140.5-303.3^{25)} = -162.8 \equiv \{(4\alpha)-(4\beta)\}\,\text{Å}\{(1\alpha)+(2\alpha)+(3\beta)+\text{R}\} = \{(4\alpha)\,\text{Å}\,(1\alpha) + (4\alpha)\,\text{Å}\,(2\alpha) + (4\alpha)\,\text{Å}\,(3\beta) + (4\alpha)\,\text{Å R}\} - \{(4\beta)\,\text{Å}\,(1\alpha) + (4\beta)\,\text{Å}\,(2\alpha) + (4\beta)\,\text{Å}\,(3\beta) + (4\beta)\,\text{Å R}\} \quad (2')$$

$$\{(4\alpha)\times(\text{CH}_3)^{5\beta} - (4\beta)\times(\text{CH}_3)^{5\beta}\}\zeta_{\text{OH}}\zeta_{\text{CH}_3} \times\{(n^2+2)/3\} = 75.5 \quad (3')$$

On the other hand, all $[\mu]^{20}_{\text{D calcd}}\{3/(n^2+2)\}$, values caused by the dynamical coupling effect between any two members of the unit groups (except the ring) in the molecular model are calculated by using the theoretical formulae of Kirkwood and are shown in Table III.

It is apparent in Table III that $(4\alpha)\times(\text{CH}_3)^{5\beta}$ and $(4\beta)\times(\text{CH}_3)^{5\beta}$ are 24.52 and −24.38 respectively[26]. By using these values in Eq. 3',

$$\{24.52-(-24.38)\}\zeta_{\text{OH}}\zeta_{\text{CH}_3}\{(n^2+2)/3\} = 75.5$$

or
$$\zeta_{\text{OH}}\zeta_{\text{CH}_3} = 1.5440\{3/(n^2+2)\} \quad (4')$$

The value of $\zeta_{\text{OH}}\zeta_{\text{CH}_3}$ in Eq. 4' is nearly equal to $1.6\{3/(n^2+2)\}$ which was obtained as the values of $\zeta_{\text{OH}}\zeta_{\text{CH}_3}$ in the case of those substances which have a cyclohexane-ring.

$[M]^{20}_{\text{D}}$(W) of β-D-Isorhamnose.—In the footnote *29 of a previous paper[7], the author proposed an equation to presume an approximate value of the $[M]^{20}_{\text{D}}$(W) of β-D-isorhamnose, now unknown, without using any ζ-coefficient. That is the {$[M]^{20}_{\text{D}}$(W) of the An. Diff.[27] of D-mannose} minus the {$[M]^{20}_{\text{D}}$(W) of the An. Diff. of D-rhamnose}=the {$[M]^{20}_{\text{D}}$(W) of the An. Diff. of D-glucose} minus the {$[M]^{20}_{\text{D}}$(W) of the An. Diff. of D-isorhamnose} (*29)

On the other hand, some $[M]^{20}_{\text{D}}$(W) values had already been observed, as below[18]:

52.8 (α-D-mannose), −30.6 (β-D-mannose),
15.7 (α-D-rhamnose), −63.0 (β-D-rhamnose),
202.1 (α-D-glucose), 33.7 (β-D-glucose)
and 163.7 (α-D-isorhamnose).

Therefore, if the $[M]^{20}_{\text{D}}$(W) of β-D-isorhamnose is y,

$$\{52.8-(-30.6)\}-\{15.7-(-63.0)\} = \{202.1-33.7\}-\{163.7-y\}$$
$$\therefore\quad y = 0.0$$

As the $[M]^{20}_{\text{D}}$(W) of methyl β-D-isorhamnoside is −97.3[18], $[M]^{20}_{\text{D}}$(W)-Diff.⟨methyl β-D-isorhamnoside−β-D-isorhamnose⟩ = −97.3 −0.0 = −97.3.

As the absolute value of this $[M]^{20}_{\text{D}}$(W)-Diff. is about equal to 100, it can be said that the $[M]^{20}_{\text{D}}$(W) of β-D-isorhamnose, presumed above, 0.0, satisfies Hudson's methyl glycoside rule[20] and may be trusted.

Discussion

In the previous paper[7], the value of $\zeta_{\text{OH}}\zeta_{\text{CH}_3}$ then obtained was first applied in the calculation of the $[\mu]^{20}_{\text{D obs}}$ of the An. Diff.[27] of D-rhamnose, and the calculated $[\mu]^{20}_{\text{D obs}}$ coincided with its corresponding observed value, $[M]^{20}_{\text{D}}$(W). But in that paper, the $[M]^{20}_{\text{D}}$(W) of β-D-isorhamnose was calculated as −46.6[28]. In that case,

$$[M]^{20}_{\text{D}}\text{(W)-Diff.}\langle\text{methyl }\beta\text{-D-isorhamnoside}-\beta\text{-D-isorhamnose}\rangle = -97.3 - (-46.6) = -50.7$$

The absolute value of this $[M]^{20}_{\text{D}}$(W)-Diff., 50.7, deviates greatly from 100. (In other words, −46.6 of the $[M]^{20}_{\text{D}}$(W) of β-D-isorhamnose does not satisfy Hudson's methyl glycoside rule.) Therefore, −46.6 seems to be unreliable as a presumed value of the $[M]^{20}_{\text{D}}$(W) of β-D-isorhamnose. The principal reason for that mis-presumption in the previous paper[7] may be the inadequacy of using 120.3 as the $[M]^{20}_{\text{D}}$(W) of α-D-isorhamnose; accordingly, the value of $\zeta_{\text{OH}}\zeta_{\text{CH}_3}$ then obtained, 0.3096 $\{3/(n^2+2)\}$ (or $0.6671\{3/(n^2+2)\}$), may be untrustworthy. Concerning the accidental coincidence of $[\mu]^{20}_{\text{D obs}}$ with its corresponding $[M]^{20}_{\text{D}}$(W) for the case of the An. Diff. of D-rhamnose in the previous paper[7], further examination will be necessary in the future.

Summary

By using a new molecular model and the new datum concerning the $[M]^{20}_{\text{D}}$(W) of α-D-isorhamnose, the $\zeta_{\text{OH}}\zeta_{\text{CH}_3}$ in the case of methyl pentose and the $[M]^{20}_{\text{D}}$(W) of β-D-isorhamnose, now unknown, were re-calculated. The obtained value of $\zeta_{\text{OH}}\zeta_{\text{CH}_3}$ was nearly equal to that in the case of substances which have a

25) Cf. Table II.

Chlorination by Sulfuryl Chloride. II[1]. *Action of Sulfuryl Chloride on the Methylenedioxy-ring*

By Mannosuke ARAI

(Received December 25, 1961)

In the first part of this series[1], the author reported on the action of sulfuryl chloride on aromatic aldehyde (including anisaldehyde) in the presence of benzoyl peroxide. The reaction resulted in the formation of the corresponding acid chlorides by the attack of chlorine on aldehydic hydrogen. At the same time, the author noticed that the reaction with phenolic aldehyde usually leads to nuclear chlorination, the aldehydic hydrogen being intact. The investigation of this type of reaction has now been extended to an aromatic aldehyde, such as piperonal, with etheric linkage.

The reaction of sulfuryl chloride on piperonal has already been reported on in a patent[2]. On heating at 130°C, the reaction proceeded to give dichloropiperonal, which afforded protocatechualdehyde on being hydrolyzed. Later investigation by Weisse[3] indicated that no reaction took place by heating, but that, after the substance had been allowed to stand for two days at room temperature, only nuclear chlorination occurred, the methylenedioxy bridge being intact.

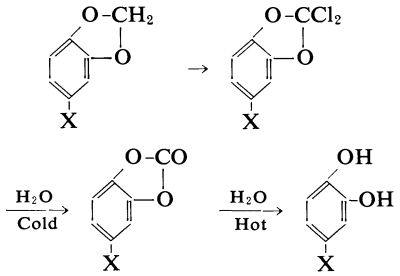
A survey has now also been made using methyl piperonylate and 1, 2-methylenedioxy-4-nitrobenzene in the presence of benzoyl peroxide in order to see which of the reactions, nuclear chlorination or cleavage of the ethereal ring, would occur preferentially.

Results and Discussion

To confirm Weisse's findings, piperonal and sulfuryl chloride were heated without a solvent. After hydrolysis with water, 6-chloropiperonal (89%) and protocatechualdehyde (8%) were obtained, showing that mainly nuclear chlorination had occurred. When carbon tetrachloride was used as a solvent, complete recovery of the starting material resulted.

Following the procedure of the previous paper[1], piperonal was heated in benzene with two moles of sulfuryl chloride in the presence of benzoyl peroxide. On treatment of the reaction products with aniline, protocatechuic anilide, not piperonyl anilide, was obtained. An attempt was made to isolate the chlorinated product by distillation under reduced pressure. However, polymerization occurred as a result of the heat, and the attempt failed to obtain any pure substance.

Moreover, piperonal was submitted to the reaction with one or two moles of sulfuryl chloride, followed by hydrolysis with water. The results, shown in Table I, indicate that protocatechualdehyde and protocatechuic acid are the reaction products and that no 6-chloropiperonal, a nuclear substitution product, is detectable. The quantitative formation of protocatechuic acid with two moles of sulfuryl chloride indicates that one mole of the reagent attacks the methylenedioxy bridge and the other the aldehyde group. It is also clear that the chlorination occurred first at the methylenedioxy bridge and then at the aldehyde group, since no piperonylic acid is formed in a benzene solution.



The chlorination of the methylenedioxy-ring and its cleavage has been studied. The dichloro-compound is considered to be produced by chlorination with phosphorous chloride[4,5], thionyl chloride[5], sulfur chloride[2,3,6] or gaseous chlorine[7], and its hydrolysis is assumed to proceed through the cyclic carbonate, as is shown in the following scheme:

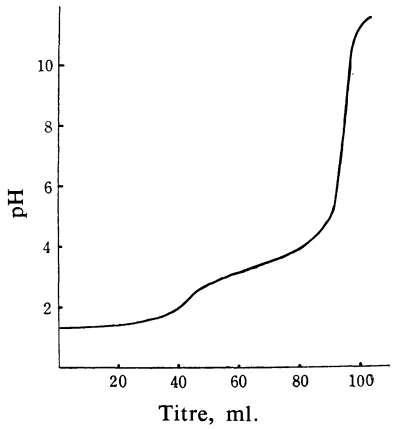
TABLE I. CHLORINATION OF PIPERONAL BY SULFURYL CHLORIDE[a)]

Exp. No.	Reactants: Piperonal mol.	Reactants: SO_2Cl_2 mol.	Reactants: Solvent ml.	React. time. hr.	Products, %[b)]: Protocatechuic acid	Products, %[b)]: Protocatechualdehyde	Products, %[b)]: Piperonylic acid
1	0.01	0.01	C_6H_6, 15	6	30 (60)	36	
2	0.01	0.02	C_6H_6, 15	8	90	8 (4)	
3	0.01	0.01	CCl_4, 15	48	54 (108)	8	4
4	0.01	0.02	CCl_4, 15	48	98		

a) In the presence of benzoyl peroxide at 85°C.
b) Based upon the amount of piperonal used, and the numerical values in parentheses are based upon the amount of SO_2Cl_2.

As had been reported by the author[1)], chlorination by sulfuryl chloride is a radical chain reaction. Therefore, the intermediate is assumed to be a monochloro-compound. In Experiment 3), piperonylic acid was formed, and the yield of protocatechuic acid was greater than that expected from the amount of sulfuryl chloride. This result suggests a further radical reaction of piperonal and carbon tetrachloride during the reaction.

In order to confirm this cleavage reaction, methyl piperonylate was heated in benzene with sulfuryl chloride in the presence of benzoyl peroxide. After distillation of the solvent, the chlorinated product was hydrolyzed with water to give methyl protocatechuate quantitatively. The titration curve (Fig. 1)



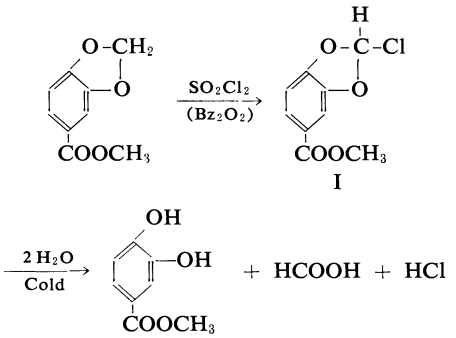


Fig. 1. Titration curve of the mother liquor for the hydrolysis of chlorinated products of methyl piperonylate by 0.1 N NaOH (f=0.985).

of the mother liquor for hydrolysis indicates that the liquor contains two kinds of acids, the one being stronger in acidity than the other. The latter was identified as formic acid by the formation of *p*-bromophenacyl ester (Kubota and Matsuura's method[8)]), and the former must be hydrochloric acid formed by the decomposition of the monochloro compound I. Consequently, the entire course of the reaction should be depicted as follows:

This reaction sequence was also supported by the quantitative isolation of viscous fuming oil, b.p. 101~101.5°C/0.15 mmHg, which yielded methyl protocatechuate on the addition of water, and an equivalent number of chloride ions (Mohr's method). The infrared absorption spectrum of the oil (Fig. 2) lacks the peaks to be expected at 2780, 925, 720 cm^{-1} judging from the methylenedioxy group in the starting substance, while it exhibits a newly developed broad peak at 705 cm^{-1} attributable to the C–Cl bond.

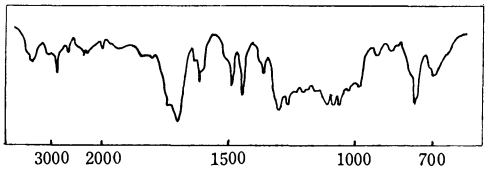

Fig. 2. Infrared absorption spectrum of chlorinated methyl piperonylate (I).

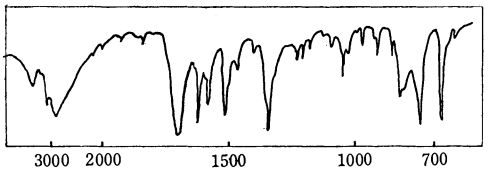
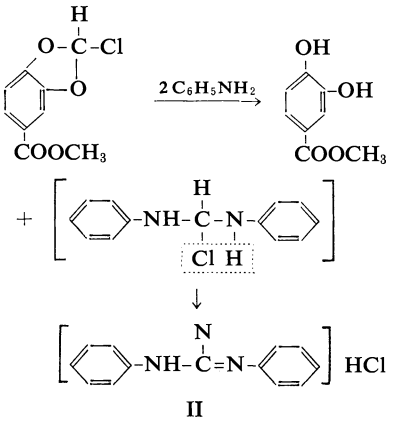
8) T. Kubota and T. Matsuura, *J. Chem. Soc. Japan, Pure Chem. Sec. (Nippon Kagaku Zassi)*, **72**, 482 (1951).





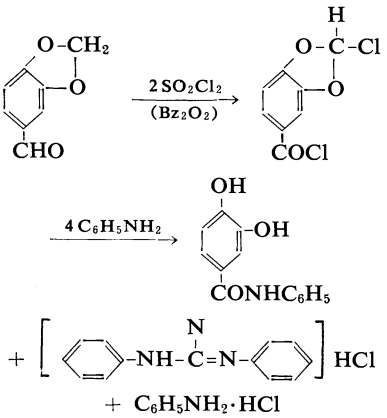


Fig. 3. Infrared absorption spectrum of *N*, *N'*-diphenylformamidine (II) hydrochloride.

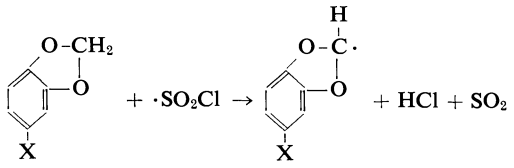
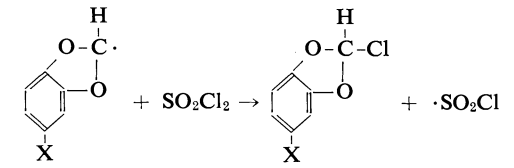
Treatment of the oil with aniline gave a colorless featherly crystalline substance, $C_{13}H_{18}N_2Cl \cdot H_2O$, m. p. 253°C, besides methyl protocatechuate. The infrared absorption spectrum of this substance shows a strong absorption at 1700 cm^{-1} ($\nu_{C=N}$), suggesting the hydrochloride of compound II.

II

The free base II, m. p. 139°C, has an absorption maximum at 274 mμ. The value[9] for *N*, *N'*-diphenylformamidine supports the figure of II. The imide II was also obtained, together with protocatechuic anilide, by the reaction of two moles of sulfuryl chloride on piperonal, followed by treatment with aniline.



9) L. Claisen, *Ann.*, **287**, 366 (1895); Brit. Pat. 353138 (1930); French Pat. 717145 (1932); W. Bradley and I. Wright, *J. Chem. Soc.*, **1956**, 640; R. N. Roberts and R. H. De. Walfe, *J. Am. Chem. Soc.*, **76**, 2411 (1954).



Further chlorination of the oil I was attempted under the same conditions, but the inertness of the tertiary hydrogen of I for chlorination by stlfuryl chloride was recognized upon obtaining *N*, *N'*-diphenylformamidine hydrochloride by treatment with aniline.

In another experiment, a similar chlorination of 4-nitromethylenedioxy-benzene was carried ont. The quantitative formation, 4-nitrocatechol, was recognized after treatment with water, though the reaction rate was rather small.

From the results mentioned above, the mechanism of this chlorination is shown to be as follows;

III

IV

The chlorosulfonyl radical (·SO_2Cl), formed by the reaction of sulfuryl chloride and benzoyl peroxide, attacks the methylenedioxy group and abstracts a hydrogen atom to produce the radical III, hydrogen chloride and sulfur dioxide. The radical III stabilizes by abstracting a chlorine atom from sulfuryl chloride to form the compound IV and the chlorosulfonyl radical, completing a radical chain. The preference for the chlorosulfonyl radical over the chlorine atom for the first step of the chain reaction is based on the fact that the dichloro-compound, which should have resulted from the reaction of the molecular chlorine[7], was not produced in this reaction. It is quite natural to assume that the chlorosulfonyl radical is not capable of attacking compound IV, but is capable of attacking only the methylenedioxy group of the starting substance in preference to decomposing to sulfur dioxide and a chlorine atom.

Experimental

Reaction of Piperonal and Sulfuryl Chloride.—1) In the Absence of Benzoyl Peroxide. — *a) Without a Solvent.*—A mixture of 1.50 g. of piperonal and 2.70 g. of sulfuryl chloride was heated under reflux in an oil bath at 105~110°C for 2 hr., with moisture excluded. After the mixture had been cooled, water (20 ml.) was added to the reaction mixture, which was then made alkaline and extracted with ether. The evaporation of ether gives 1.65 g.

of colorless needles, which were recrystallized from ethanol to 6-chloropiperonal, m. p. 115°C (Found: C, 52.39; H, 2.68%). An alkali-soluble part gives, by separation with toluene, 0.11 g. of plates which give a dark green coloration with ferric chloride. The 2,4-dinitrophenylhydrazone of this compound, m. p. 273°C, (Found: N, 17.54%), coincides with that of protocatechualdehyde.

b) *In Carbon Tetrachloride.*—The same reaction was carried out in carbon tetrachloride (10 ml.). After refluxing for 10 hr., the starting material was completely recovered and identified as 2, 4-dinitrophenylhydrazone.

2) **In the Presence of Benzoyl Peroxide.**—In an atmosphere of dry nitrogen, piperonal and sulfuryl chloride (1 or 2 equiv.) were heated at 85°C in benzene or carbon tetrachloride in the presence of benzoyl peroxide (1% of the amount of sulfuryl chloride) until the evolution of hydrogen chloride ceased. After evaporation of the solvent, the product was decomposed by the addition of a small amount of water, and the resultant mixture was fractionated with benzene. Protocatechuic acid was obtained from the insoluble part and protocatechualdehyde from the benzene-layer, as is shown in Table I.

3) **Treatment with Aniline.**—The same reaction was carried out using more than 2 mol. of sulfuryl chloride. After the solvent was removed, a solution of 4 mol. of aniline in ether was added to the resultant viscous oil. A vigorous reaction took place, and an yellow solid was separated out. The solid was washed with 5% hydrochloric acid and recrystallized from dilute methanol to give colorless prisms, m. p. 166~167°C. The solid was identified with protocatechuanilide by the melting point test, and gave a dark green color with ferric chloride (Found: N, 6.01%).

The yellow solid described above was treated with 5% of an aqueous solution of sodium hydroxide, filtered, and washed with a small amount of ether. The crystals remaining were recrystallized from benzene-peteroleum ether to give colorless needles, m. p. 139°C. The compound obtained was identified as *N,N'*-diphenylformamidine, obtained from methyl piperonylate, by the mixed-melting point test (vid. Fig. 3).

Reaction with Methyl Piperonylate. — In an atmosphere of nitrogen, 0.90 g. (0.005 mol.) of methyl piperonylate, an equivalent of sulfuryl chloride and 10 mg. of benzoyl peroxide were heated in 10 ml. of benzene at 85°C for 6 hr. in an oil bath. After the complete evaporation of the solvent in vacuo at 80°C, the addition of cold water (ca. 1.5 ml.), the filtration of the separated crystal and, washing with cold water, 0.82 g. of colorless crystals were obtained. Recrystallization from water gave methyl protocatechuate, m. p. 134°C, in a 97.6% yield. Dark green on conbination with ferric chloride (Found: C, 57.08; H, 4.76%). The filtrate and washing were combined and titrated with 0.1 N of an aqueous solution of sodium hydroxide (titration curve: Fig. 1). After adjusting the pH value to 7, the titrated solution was evaporated to dryness, and the residue was triturated with absolute ethanol (50 ml.) and absolute methanol (5ml.). The alcoholic solution was treated with *p*-bromophenacyl bromide, giving *p*-bromophenacyl formate as colorless plates, m. p. 100°C.

The same reaction was carried out using 4.50 g. of methyl piperonylate at 85°C for 15 hr. The reaction mixture was distilled in vacuo to give a viscous liquid, b. p. 101~101.5°C/0.15 mmHg, in a quantitative yield (The infrared absorption spectrum is shown in Fig. 2). On standing in the air, the liquid decomposed to give methyl protocatechuate.

Found: Cl, 16.22 (Mohr's method). Calcd. for $C_9H_7O_4Cl$; Cl, 16.53%.

After evaporation of the solvent, a solution of 2 mol. of aniline in ether was added, drop by drop, to the reaction mixture under cooling. The precipitate formed was filtered. Methyl protocatechuate was obtained quantitatively from the ether-layer, and feathery crystals, m. p. 253°C, were obtained after recrystallization of the precipitate from water. The infrared absorption spectrum of the latter indicates that the product is *N, N'*-diphenylformamidine hydrochloride, as is shown in Fig. 3.

Found: C, 62.39; H, 6.13; N, 11.34. Calcd. for $C_{13}H_{13}N_2Cl \cdot H_2O$; C, 62.24; H, 6.25; N, 11.17%.

After treatment of the hydrochloride with 5% of an aqueous solution of sodium hydroxide, the free base was obtained as colorless needles, m. p. 139°C.

Found: N, 14.57. Calcd. for $C_{13}H_{12}N_2$; N, 14.28%.

Reaction with 4-Nitromethylenedioxybenzene.—4-Nitromethylenedioxybenzene (0.64 g.) was submitted to the reaction described above with an equivalent amount of sulfuryl chloride. After the decomposition with water, the reaction mixture gave yellow needles, m. p. 176°C (4-nitrocatechol melts at 175°C[10]). The needles gave a dark green color when treated with ferric chloride solution.

Found: N, 9.17. Calcd. for $C_6H_5O_4N$; N, 9.03%.

The author wishes to express his gratitude to Professor Mamoru Yamaguchi of Tohoku University for his constant guidance in the course of this work. He also wishes to thank the members of Professor Fujise's laboratory of the Faculty of Science for their microanalyses.

The Kinetics of the Formation of Calcium Carbide in a Solid-Solid Reaction

By Hiroaki TAGAWA and Hideo SUGAWARA

(Received January 22, 1962)

Calcium carbide is generally made from calcium oxide and carbon according to the following equation:

$$CaO + 3C = CaC_2 + CO \quad (1)$$

Our fundamental information on the kinetics of this reaction, however, is limited.

The most extensive thermodynamic investigations into calcium carbide formation from calcium oxide and carbon have been made by the Kameyama's group[1]. They have found that the reaction of calcium oxide with carbon involves the following two main steps:

$$CaO + C = Ca + CO \quad (2)$$

$$Ca + 2C \rightleftharpoons CaC_2 \quad (3)$$

They concluded that the carbon monoxide pressures of Eqs. 1 and 2 were equal at 1460°C, and that the reaction of Eq. 1 was predominant in comparison with that of Eq. 2 above 1460°C.

Calcium carbide is commercially produced in the molten phase and in a complex reaction system. In order to clarify the kinetics of the reaction of calcium oxide with carbon, the corbonization of calcium oxide was, in the present study, thermogravimetrically examined in a solid-solid reaction at temperatures between 1600 and 1800°C and at various carbon monoxide pressures.

Experimental

Materials. — Calcium oxide was produced by burning precipitated calcium carbonate in an electric furnace at 1200°C for 2 hr. The carbon specimen used was charcoal which had been preheated at 1000°C for 2 hr. in order to remove volatile matters. Calcium oxide and carbon were pulverized to pass through a 200 mesh sieve and mixed at a ratio of 1 : 3 by mole. Nine grams of the mixture were compressed at about 1 ton/cm^2 into a cylindrical pellet, 20 mm. in diameter and 30 mm. in height.

Apparatus.—The apparatus used for the kinetic experiments consisted of a spring balance in a vacuum electric furnace of which the internal volume was about 150 l.[2] The pumping speed of a connected rotary pump was 1600 l./min. A graphite bucket, 45 mm. in diameter and 35 mm. in height, was suspended from the spring in the hot zone of the furnace by a fine molibdenum wire. The shrinkage of the spring by the weight loss of the sample was observed with a microscope with an eyepiece scale. The sensitivity of the spring was 0.278 g./mm. The reaction temperature was measured with a radiation pyrometer and was maintained at a desired value within ±3°C with the aid of an automatic temperature controller. The error in temperature measurement caused by the calcium vapor and the carbon monoxide atmosphere was corrected with a W/50%W-Mo thermocouple[3], which had been calibrated by an optical pyrometer in vacuo. The electric furnace was kept at the desired carbon monoxide pressure during the course of the experiments. The pressures were 50, 100 and 200 mmHg.

Procedure. — The velocity of the formation of calcium carbide was determined as follows. The reaction was stopped at a defined time, and the residual specimen was chemically analyzed for calcium carbide and for residual calcium oxide and carbon. If the formation expressed in Eq. 1 and the decomposition of the calcium carbide formed occur as main reactions in these experimental conditions, there are the following relationships among the analyzed quantities:

Weight loss = CO (evolved)
+ Ca (from decomposed CaC_2)

Residual CaC_2 = CaC_2 (formed)
− CaC_2 (decomposed)

Residual CaO = CaO (unreacted)

Residual C = C (unreacted)
+ C (from decomposed CaC_2)

Each quantity was obtained from the material balance calculations in the above equations.

The notations used in Figs. 2 to 6 and in the kinetic equation are as follows:

Reaction ratio = Formed CaC_2/Theoretically formed CaC_2

Decomposition ratio = Decomposed CaC_2/Theoretically formed CaC_2

Residual ratio (yield) = Reaction ratio
− Decomposition ratio

Results

All curves of the weight decrease against the time were parabolic in the temperature range 1600 to 1800°C and at 50, 100 and 200 mmHg of carbon monoxide pressure. Figure 1 shows the course of the reaction at five temperatures and at 100 mmHg of carbon monoxide. The weight loss is presumed to be due to the evolution both of carbon monoxide produced in the formation of calcium carbide and of calcium vapor produced by the decomposition of the freshly formed calcium carbide. The curves of the reaction ratio vs. time, the residual ratio vs. time, and the decomposition ratio vs. time at 100 mmHg of carbon monoxide are shown in Figs. 2, 3 and 4 respectively. The reaction ratio curves are parabolic, whereas the decomposition curves are approximately linear with time. The curves of the residual ratio vs. time and of the decomposition ratio vs. time at 1760°C are shown in Figs. 5 and 6 respectively. The decomposition ratio decreases with the increasing carbon monoxide pressure at any temperature.

The reaction ratio curves were parabolic in all experiments. The rate of solid state reaction when the diffusion process is rate-determining is expressed by the following equation[4]:

$$(1-\sqrt[3]{1-x})^2=kt \qquad (4)$$

where x is the reaction ratio, t the time, and k the reaction rate constant. This is derived from the reaction of a sphere of component A completely surrounded by spheres of component B. To determine whether the reaction followed the parabolic kinetics given in Eq. 4, the data in Fig. 2 were plotted as the value of $(1-\sqrt[3]{1-x})^2$ vs. time in Fig. 7. The linearity of the $(1-\sqrt[3]{1-x})^2$ vs. time curve means that the reaction is apparently diffusion-controlled. The apparent rate constant, k, in Eq. 4 was found from the slope of each line.

The logarithm of the slope was plotted against the reciprocal of the absolute temperature at 50, 100 and 200 mmHg of carbon monoxide in Fig. 8. The rate constant decreases as the pressure of carbon monoxide increases.

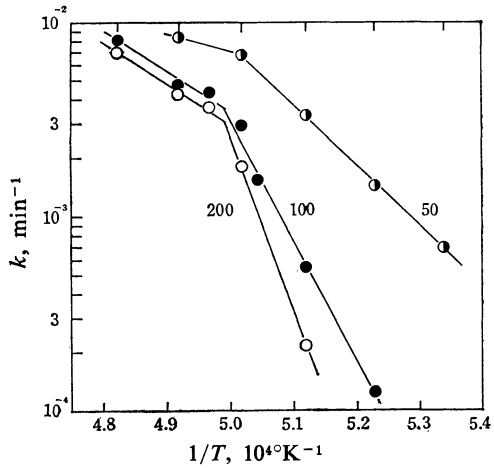

Fig. 8. Relation between logarithm of reaction velocity and the reciprocal absolute temperature at 50, 100 and 200 mmHg of CO.

Discussion

The formation of calcium carbide in a solid state reaction has been studied by Kameyama et al.[1] and by Mukaibo and Yamanaka[5]. Kameyama has found that calcium carbide is formed by the following successive reactions.

$$CaO + C = CaO\cdot C \text{ (Interdiffusion state)} \quad (5)$$

$$CaO\cdot C \text{ (Interdiffusion state)} = Ca + CO \quad (6)$$

$$Ca + 2C = CaC_2 \quad (7)$$

It has been found that the interdiffusion between calcium oxide and carbon occurs at temperatures above 1000°C. Although the reactions of 5 and 6 are determined by diffusion, the kinetics of $CaO+C=Ca+CO$ is described as a zero-order reaction because the products of the reaction of calcium oxide with carbon vaporized from the surface of the reactants[2,5]. The activation energy of the reaction was 147 kcal./mol.[2]

The formation of calcium carbide is apparently expressed by the following equation: $(1-\sqrt[3]{1-x})^2=kt$. In this kinetics, the following steps are considered to be rate-determining:

1) Diffusion of carbon into calcium oxide, and vice versa.
2) Diffusion of carbon monoxide through the product layer.

The apparent activation energy at 50 mmHg of carbon monoxide obtained from Fig. 8 was 143 kcal./mol., while that above 100 mmHg was more than 200 kcal./mol. The effect of the varied carbon monoxide pressure on the

5) T. Mukaibo and Y. Yamanaka, *J. Chem. Soc. Japan, Ind. Chem. Sec.* (*Kōgyō Kagaku Zassi*), **58**, 643 (1955).

activation energy may be involved in the pressure term of the kinetics equation, but the general formula of this kinetics has not yet been determined. From the fact that the velocity, k, depends on the pressure of carbon monoxide and that the activation energy is close to that of the first step of the carbide formation at about 1400°C, the rate-determining step may be the diffusion of gas through the product layer as well as that of solids into the solid and product layer. As the calcium carbide formed simultaneously enters upon consecutive decomposition, the reaction velocity, k, is considered to be not an absolute measure, but a relative one.

The apparent reaction rate vs. the reciprocal absolute temperature curves have a break point at about 1700°C. It is considered that reactions expressed in Eqs. 8 and 9, besides the reaction of $CaO+3C=CaC_2+CO$, occur at higher temperature, above 1700°C:

$$mCaC_2 + nCaO = mCaC_2 \cdot nCaO \quad (8)$$

$$mCaC_2 \cdot nCaO = (m-1)CaC_2 \cdot (n-2)CaO + 3Ca + 2CO \quad (9)$$

Summary

The kinetics of the formation of calcium carbide in the solid state reaction of calcium oxide with carbon has been examined by using a thermobalance in the temperature range 1600 to 1800°C and at 50, 100 and 200 mmHg of carbon monoxide. The reaction ratio vs. time curves were parabolic in all experimental runs, and the reaction followed parabolic kinetics: $(1-\sqrt[3]{1-x})^2=kt$. On the other hand, the decomposition of calcium carbide as a successive reaction occurred from the specimen surface and was described as a zero-order reaction. As the reaction velocity depended strongly on the pressure of carbon monoxide, it is considered that the reaction rate is governed by the diffusion process of gas through the product layer, as well as that of solids into the solid and product layer.

Infrared Spectra and Normal Vibrations of Acetamide and its Deuterated Analogues

By Isao SUZUKI

(Received January 25, 1962)

It has been shown in previous papers[1,2] that normal coordinate analyses of formamide and *N*-methylformamide molecules can be made satisfactorily by employing the Urey-Bradley force field and that the force constants determined for formamide can be used without any significant alternations in value in the normal coordinate treatment of *N*-methylformamide. As a continuation of this research, the acetamide molecule is treated in the present paper.

Only a limited number of spectroscopic investigations of acetamide have been reported[3-5], and the main interests of these authors have been focused rather on the protonated systems of the molecule than on acetamide itself. The vibrational assignments for this molecule are very uncertain. Therefore, infrared measurements have been made not only of CH_3CONH_2, but also of three deuterated species of acetamides, CH_3COND_2, CD_3CONH_2 and $CD_3CO\cdot ND_2$. From the combined results of these measurements and of the calculation of normal vibrations, the nature of the observed frequencies is discussed in detail in the present paper. The Urey-Bradley force constants obtained in the present work are compared with those in formamide and in *N*-methylformamide, and the values of some constants are discussed.

an alcohol solution[6]. The acetamide precipitated was collected, dried in vacuum, and used in the measurements; m. p., 80°C.

C-Deuterated Acetamide CD_3CONH_2.—First, CD_3COOD was prepared by the thermal decomposition of $CD_2(COOD)_2$, which was obtained from the exchange reaction of $CH_2(COOH)_2$ with D_2O[7]. Then, CD_3COOD was reacted with liquid ammonia. The ammonium acetate obtained was heated at about 200°C for four hours in a sealed tube, and the CD_3COND_2 (containing CD_3CONHD) thus formed was distilled out in vacuum. It was purified by the method described above.

The exchange reaction with D_2O was employed to replace the amide hydrogen atoms by deuterium.

Infrared Spectra.—The measurements of the infrared spectra were made in the region from 4000 to 650 cm^{-1} with a Hitachi EPI spectrophotometer equipped with sodium chloride optics, and in the region from 800 to 300 cm^{-1} with a Nippon Bunko grating spectrophotometer equipped with a cesium bromide foreprism. The infrared spectra of CH_3CONH_2 and CH_3COND_2 were measured in the solid and liquid states and in solutions. The solid state

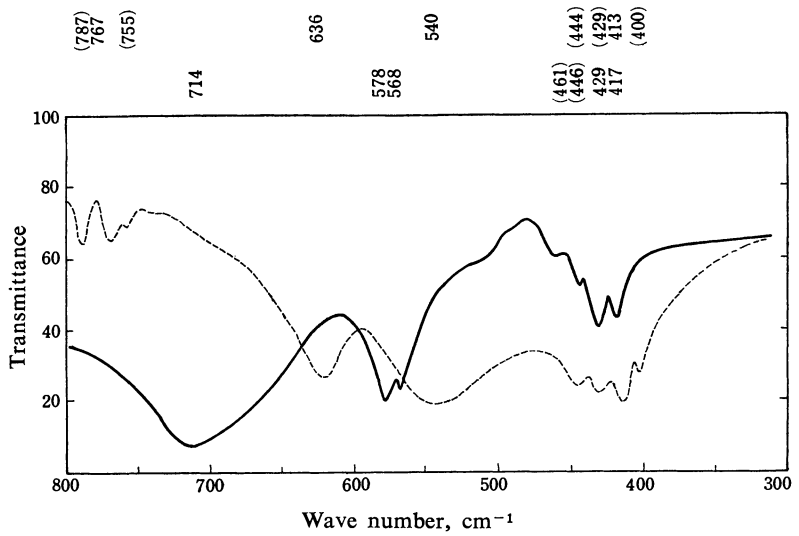

Fig. 4. Infrared spectra of CD_3CONH_2 (solid line) and CD_3COND_2 (broken line) in the solid state in the region from 800 to 300 cm^{-1}.

spectra were taken in Nujol or hexachlorobutadiene mulls and are shown in Figs. 1 and 2. A small heating cell was used to obtain the spectra in the liquid state. The observed frequencies are summarized in Table I. The spectra of CD_3CONH_2 and CD_3COND_2 in the solid state are shown in Figs. 3 and 4. As may be seen from these figures, the spectra of both CD_3CONH_2 and CD_3COND_2 are complicated, particularly in the region below 1000 cm^{-1}. This is due to the presence of bands arising from the CHD_2-species which are contained in the samples. Therefore, the assignments of those vibration bands which are mainly associated with the CD_3 rocking and CC' in-plane deformation vibrations are uncertain. When the values of the force constants were refined, they were not used as frequency data.

Normal Coordinate Treatment

The calculation of normal vibrations was made as a nine-body problem by Wilson's method[8]. The planar model (C_s), except for two hydrogen atoms attached to the methyl carbon atom (C')*[1], was adopted (see Fig. 5).

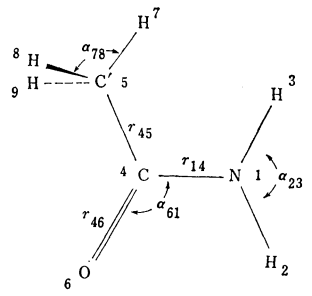

Fig. 5. Molecular structure and internal coordinates of acetamide.

The normal vibrations are classified into 14 in-plane (A′) and 7 out-of-plane (A″) vibrations, of which the in-plane vibrations are treated. The structural parameters used in the present work are as follows: the bond lengths of r(C=O) = 1.28 Å, r(C–N) = 1.38 Å, r(C–C′) = 1.51 Å, r(N–H) = 1.02 Å and r(C′–H) = 1.09 Å[9] and the bond angles of 120° for those around the N and C atoms and of 109°47′ for those around the C′ atom. To simplify the calculation, lower frequencies are separated from four higher frequencies which are mainly associated with the CH and NH(D) stretching vibrations[8]. The symmetry coordinates used are given in Table II (see also Fig. 5 for definitions of the internal coordinates).

Force Constants.—As has already been mentioned, the potential function used in the calculation is of the Urey-Bradley type[10]:

$$2V=\sum_i K_i(\Delta r_i)^2+\sum_{i\neq j} H_{ij}r_i^0r_j^0(\Delta\alpha_{ij})$$
$$+\sum_{i\neq j} F_{ij}(\Delta q_{ij})^2+\text{Linear terms}$$

The same notations as in the preceding papers[1,2] are used. In addition, the intramolecular tension, κ, is introduced in the elements of the F-matrix when the linear terms are eliminated by a redundancy condition[10].

* Initial set of values for the force constants in group A are given in parenthesis.

Therefore, eighteen force constants are necessary to calculate normal vibrations of the acetamide molecule. As may be seen from Table III, these force constants are classified into three groups, A, B and C, and their values were first determined by the following method: The constants in group A were directly transferred from the formamide molecule[1]. The constants in group B are associated with the "joint" of the CH_3 and amide groups, and $K_{CC}=3.00$ md./A, $H_{CCN}=0.23$ md./A, $H_{CCO}=0.31$ md./A, and $F_{C\cdots N}=F_{C\cdots O}=0.50$ md./A were first assumed*2. Those belonging to group C are associated with the methyl group. In our laboratory, a number of compounds containing methyl groups have been studied, and it has been found that one set of constants, $H_{HCH}=0.43$ md./A, $F_{H\cdots H}=0.03$ md./A and $\kappa=-0.05$ md·A, always gives a good frequency fit with the observed data. These values have also been adopted in the present work; they are not varied in the course of refinements. As for other constants, $H_{HCC}=0.25$ md./A and $F_{H\cdots C}=0.45$ md./A were used.

The normal vibrations were calculated from these force constants, and they give fairly good agreement with the observed frequencies. Then the values of the constants were refined as indicated by the Jacobian matrix[12] to obtain a better frequency fit. At the first step of the refinements, only the frequencies of CH_3CONH_2 and CH_3COND_2 were used. Then at the final step those of CD_3CONH_2 and CD_3COND_2 above 1000 cm^{-1} were also taken into account. However, the frequencies of the latter two molecules found below 1000 cm^{-1} *3 were not used for the reason indicated in the preceding section. At first the force constants in group B were subjected to refinements, since their values were less certain than those in groups A and C.

Although only five constnats were refined, the frequency fit between the observed and the calculated was improved remarkably. In fact, the agreements were so good that refinement was practically unnecessary for the constants in groups A and C, except for two stretching constants, K_{CN} and K_{CO}. The final set of force constants is listed in Table III.

Results and Discussion

Assignments of Vibration Bands. — The frequencies calculated from the force constants given in Table III are compared with the observed frequencies in Tables IV(a)—(d) for each isotopic species of acetamide. In Tables IV(a)—(d), the potential energy distribution among the symmetry coordinates is also given for each normal mode. This represents the quantitative assignment.

In CH_3CONH_2, each normal vibration takes place along one or two symmetry coordinates and is easily identified. As expected, the band at 1676 cm^{-1} of acetamide is associated with the ν(CO) mode. However, the ν(CN) and $b(NH_2)$ vibrations also contribute to this band. The bands at 1632 and 1152 cm^{-1} are mainly associated with the $b(NH_2)$ and $r(NH_2)$ vibrations respectively, and the fact that they move to lower frequencies in a $CHCl_3$ solution is consistent with the above assignments. The bands at 1457, 1360 and 1005 cm^{-1} are associated with the methyl deformation vibrations and are assigned, respectively, to the $\delta_a(CH_3)$, $\delta_s(CH_3)$ and $r(CH_3)$ vibrations. The nature of the 1404 cm^{-1} band is a little complicated. This band can be called the ν(CN) band, although there are considerable contributions from the $\nu(CC')$, $r(NH_2)$, δ(NCO) and $\delta_s(CH_3)$ vibrations. The band at 864 cm^{-1} is associated with the $\nu(CC')$ vibrations, while the bands at 581 cm^{-1} and 464 cm^{-1} are associated with δ(NCO) and $\delta(CC')$ vibrations respectively.

Instead of the 1632 cm^{-1} band, a band appears at 1189 cm^{-1} in CH_3COND_2; this is assigned to an almost pure $b(ND_2)$ vibration. The ν(CO) band is lowered, probably by the decoupling of the $b(NH_2)$ vibrations, while the ν(CN) band moves to a higher frequency and appears at 1427 cm^{-1}. The $b(ND_2)$ vibration

*2 Miyazawa et al., obtained a good frequency agreement for the skeletal deformation vibrations of *N*-methylacetamide[11] from the values of $H_{CH_3\text{-}C\text{-}N}=H_{CH_3\text{-}C=O}=0.30$ md./A and $F_{CH_3\cdots N}=F_{CH_3\cdots O}=0.50$ md./A, although they treated the methyl group as a dynamic unit.

*3 Those frequencies are given in parentheses in the first column of Tables IV (c) and (d).

$\Delta\nu=\nu_{obs}-\Delta\nu_{calcd}$, $\Delta=|\Delta\nu|/\nu_{obs}$

also contributes to the latter band. The $r(ND_2)$ vibration takes part in both the 934 and 809 cm^{-1} bands. The $\nu(CN)$, $b(ND_2)$ and $r(CH_3)$ vibrations also contribute to the former band, and the $\nu(CC')$ vibration to the latter.

The nature of the 1676, 1632, 1404 and 1152 cm^{-1} bands of CH_3CONH_2 is not much affected by the *C*-deuteration; they are found at 1672, 1620, 1413 and 1144 cm^{-1} in CD_3CONH_2, The 1414 cm^{-1} band is assigned to a composite mode in which the $\nu(CN)$, $\nu(CC')$ $r(NH_2)$ and $\delta(NCO)$ vibrations take place. In $CD_3 \cdot COND_2$, it is found at 1425 cm^{-1}, and the $b(ND_2)$ vibration contributes to this band instead of $r(NH_2)$ vibration. The $\delta_a(CD_3)$ vibration occurs at 1058 cm^{-1}, which is lower by 28 cm^{-1} than the $\delta_s(CD_3)$ vibration. The reversal of these two methyl deformation vibrations is often observed in the spectra of compounds containing CD_3 groups[13]. For the CD_3-species of acetamide, the vibrational assignments of the observed bands below 1000 cm^{-1} are very difficult, because of the presence of the bands arising from the CHD_2-species contained in the sample. (The 1257 cm^{-1} band is assigned to the CH bending vibration of the CHD_2-species.) Aside from the bands of the CD_3-species, CD_2 wagging, bending, rocking and twisting vibrations are expected to appear in this region. Therefore, the assignments given in Table IV are tentative. The features of the $\delta(CC')$ vibration region are very interesting; four small peaks are observed around 420 cm^{-1} in the spectra of both CD_3CONH_2 and CD_3COND_2. The present calculations indicate that an interaction takes place between the $\delta(CC')$ and $r(CD_3)$ vibrations. It is also probable the vibrational interaction occurs between the $r(CD_2)$ and $\delta(CC')$ modes. However, the degrees of the interaction depend on the mutual positions of the CHD_2 group to the plane determined by the amide group. Several stable but non-equivalent configurations can be considered as for the positions of the CHD_2 group, and this may be the cause of the complexity of the $\delta(CC')$ bands.

Several bands can be assigned to the out-of-plane vibrations. In the NH_2-species, a broad band is found around 700 cm^{-1} and is assigned to the NH_2 wagging vibration. The NH_2 twisting band may overlap with this band. The corresponding bands are found around 500 cm^{-1} in the ND_2-species. A strong band found at about 640 cm^{-1} in the ND_2-species may be associated with the CC' out-of-plane vibration*4. but the ND_2 twisting and wagging vibrations may also contribute to this band.

Force Constants. — The force constants in group A are associated with the $O\!\!\nearrow\!\!C\text{-}N\!\!\swarrow^{H}_{H}$ part of the molecule and are transferred form formamide[1]. As may be seen from the process of determining their values, they can be used without significant alternations in value. This is the second example of showing a fine transferability of the constants determined in the formamide molecule[2]. A stretching force constant, *K*, has often been used as a measure of the bond order or character of the corresponding bond. In the series of amides, the K_{CO} and K_{CN} values are always found, respectively, around 8.50 and 6.00 md./A and are considered to indicate the partial single and double bond characters of the respective C=O and C–N bonds. In urea, however, the K_{CO} value falls to 6.47 md./A[14]. The lowering of the K_{CO} value may partly be accounted for by the presence in urea of two C–N bonds adjacent to the C=O bond*5. In the Urey-Bradley force field, the value of a given stretching constant is closely correlated with those of the repulsive constants around the bond. It is often odserved for a molecule which contains conjugated systems that some repulsion constants become very large[17]. In such a molecule, the resonance term $k_{ab}(\Delta r_a)(\Delta r_b)$*6, which is neglected in the Urey-Bradley field, is of considerable magnitude and affects the corresponding force constant $F_{a\ldots b}$. In the present case, the $F_{N\ldots O}$ value is found to be as large as 1.50 md./A. The lowering of the K_{CO} value in urea as compared with that in acetamide can be explained by the superposed effect of $F_{N\ldots O}$ from two adjacent C–N bonds. It should be noted that the direct comparison of stretching constants sometimes leads to an incorrect conclusion, especially when some repulsive force constants are considerably large.

The force constants in group B are primarily

concerned with the C–C bond of the molecule. The present results, if combined with those of *N*-methylformamide, give the reliable set of force constants necessary to describe the peptide skeletals: $\overset{C}{\underset{O}{\rangle}}C-N\langle^{H}_{C'}$. The force constants in group C are concerned with the CH_3 group, and it is shown that the values of the force constants recommended in our laboratory can also be used in this molecule.

The present author wishes to express his deep gratitude to Professor Takehiko Shimanouchi for his kind guidance and encouragement in the present work. His thanks are also due to Professor Hidetoshi Takahashi for the use of a PC-1 computer.

Infrared Spectra and Normal Vibrations of Thioamides. I. Thioformamide

By Isao SUZUKI

(Received February 2, 1962)

As has been reported in previous papers[1-3], the values of the Urey-Bradley type force constants for the simple primary and secondary amides, $HCONH_2$, CH_3CONH_2 and $HCONH \cdot CH_3$ were determined from their vibrational frequencies, and it was shown that these constants are transferable throughout the series of the molecules and that they give a good account of the nature of the normal vibrations of these molecules. About the vibrational spectra of the thioamides, on the other hand, few systematic investigations have yet been reported, and there are ambiguities in the assignments of many observed bands. As has been shown in the previous papers[1-3], all the values of the force constants necessary to calculate the normal vibrations of simple thioamides are now known except those concerning the sulfur atom. Therefore, the work has been extended to the thioamide group for the purpose of clarifying the nature of the normal vibrations of these molecules as well as to make a further check on the transferability of force constants of the Urey-Bradley type. The nature of the C=S and C–N bonds in thioamides is also discussed in connection with the force constants obtained. In the present paper, the results of infrared measurements and normal vibration calculations of thioformamide $HCSNH_2$, the first member of the series, are reported. The results for CH_3CSNH_2, $HCSNHCH_3$ and $CH_3CSNHCH_3$ will be given in subsequent papers.

Thioformamide and *N*-deuterated thioformamide were prepared, and their infrared spectra were measured in both liquid and solid states. The spectrum of $HCSNH_2$ in the liquid state corresponds well with that given earlier by Davies and Jones[4], except the band found at 439 cm^{-1} with medium intensity which was not reported. The assignments of the observed bands, however, differ considerably from theirs. The normal vibrations for thioformamide were first calculated with the force constants which were directly transferred from formamide[1] and thiourea[5]. Since the computed frequencies show a good agreement with the observed, the assignments of the infrared absorption bands can be made without difficulty. Then the values of the force constants were refined to obtain a better frequency fit. Based on the results of this calculation, the nature of the observed bands is explained in terms of the potential energy distributions and the vibrational amplitudes.

Experimental

Samples. — Thioformamide was prepared from formamide and P_2S_5 suspended in tetrahydrofuran[6] and was purified by the method shown in Ref. 7.

Exchange reaction with D_2O was employed to displace the amide hydrogen atoms by deuterium. Since thioformamide slowly decomposes at room temperature, the sample was mixed with a large

excess of D_2O and shaken vigourously for a minute, and then the excess D_2O was quickly pumped out with a method analogous to freeze drying and measured immediately. Although thioformamide was reported to form monohydrate[7], no deuterium oxide seems to remain with the sample by this procedure; we did not detect the 1200 cm^{-1} band which is characteristic of D_2O.

Infrared Spectra.—The infrared spectra of these compounds were measured with a Hitachi EPI spectrophotometer equipped with sodium chloride optics, in the region from 4000 to 650 cm^{-1}, and with a Nippon Bunko grating spectrophotometer equipped with a cesium bromide foreprism in the region from 800 to 300 cm^{-1}. The solid state spectra were obtained with a low temperature cell[8] cooled with mixture of dry ice and methanol.

Infrared Spectra

The infrared spectra of $HCSNH_2$ in the liquid and solid states are shown in Figs. 1 (a)—(c), and those of $HCSND_2$, in Figs. 2 (a)—(c). As may be seen from Fig. 2, the spectra of the deuterated species are a little complicated by the presence of the bands arising from monodeuterated thioamides (HCSNHD,

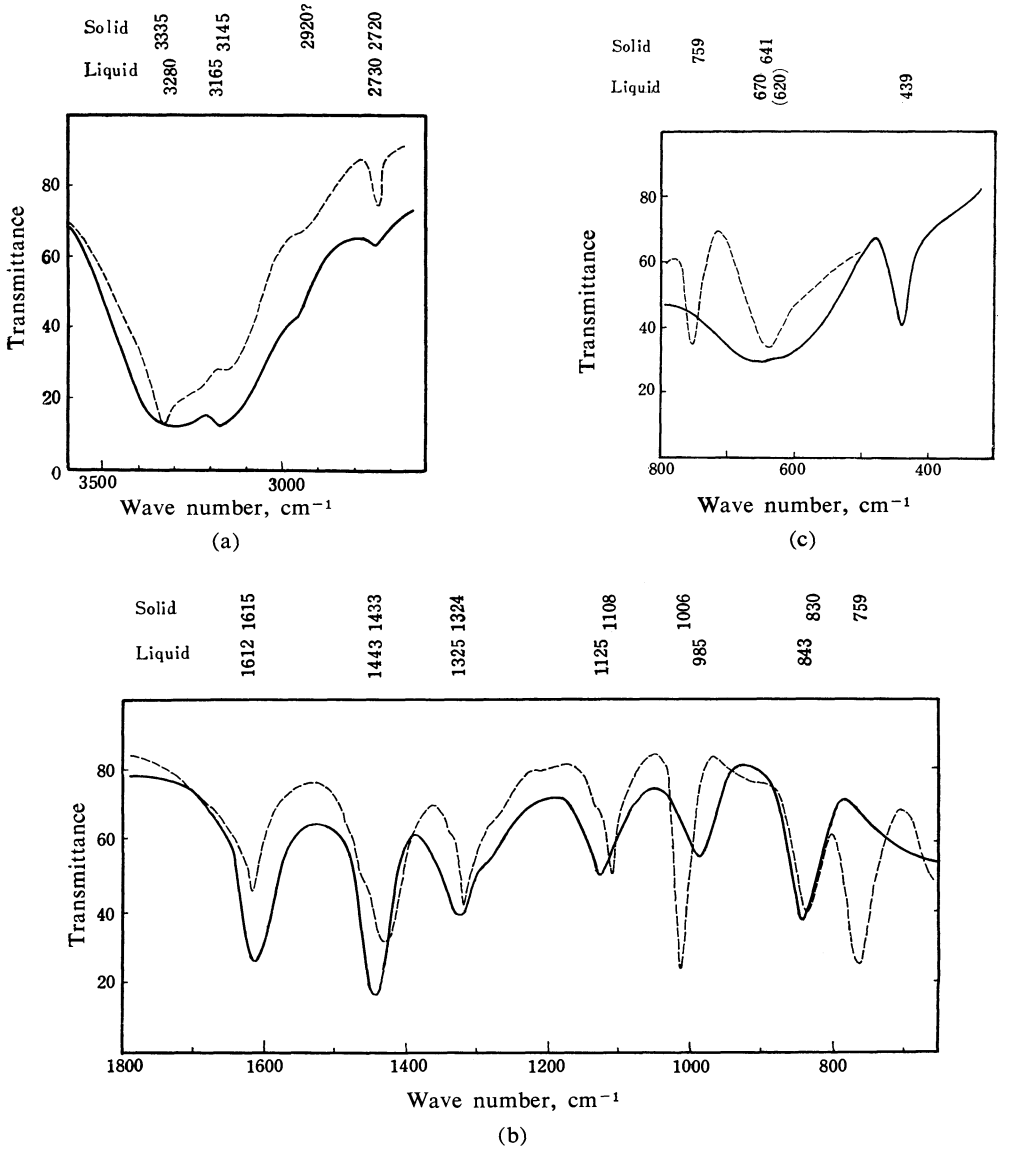

Fig. 1. Infrared spectra of $HCSNH_2$ in the liquid (solid line) and solid states (broken line). (a) 3600~2600 cm^{-1}, (b) 1800~650 cm^{-1}, (c) 800~300 cm^{-1}

8) T. Miyazawa, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zassi*), **76**, 821 (1955).

cis and trans) as well as of those from dideuterated species. When the sample was exposed to the atmosphere for a while, the former bands became strong in intensity as a result of the partial hydrogenation caused by the atmospheric vapor, while the latter became weak. In this way, the bands due to the NHD species could be identified. In Fig. 2, the bands whose wave numbers are given in parentheses are those arising from the NHD species.

Spectral changes due to the state of aggregation are sometimes very helpful in assigning the observed bands. In the case of $HCSNH_2$, changes in the spectra by solidification are not so significant as are those of formamide, and little change is observed in a number of vibration bands, including those chiefly associated with the NH_2 stretching, NH_2 bending, CN stretching and CH bending vibrations. However, the 985, 670 and 620 cm^{-1} bands in the liquid state change their positions considerably, and are found respectively at 1002, 759 and 641 cm^{-1} in the solid state. It will be shown in subsequent sections that these bands can reasonably be assigned to three out-of-plane (A'') vibrations: namely, the CH out-of-plane, NH_2 wagging and NH_2 twisting (CN torsional) vibrations; π(CH), $w(NH_2)$ and $t(NH_2)$.

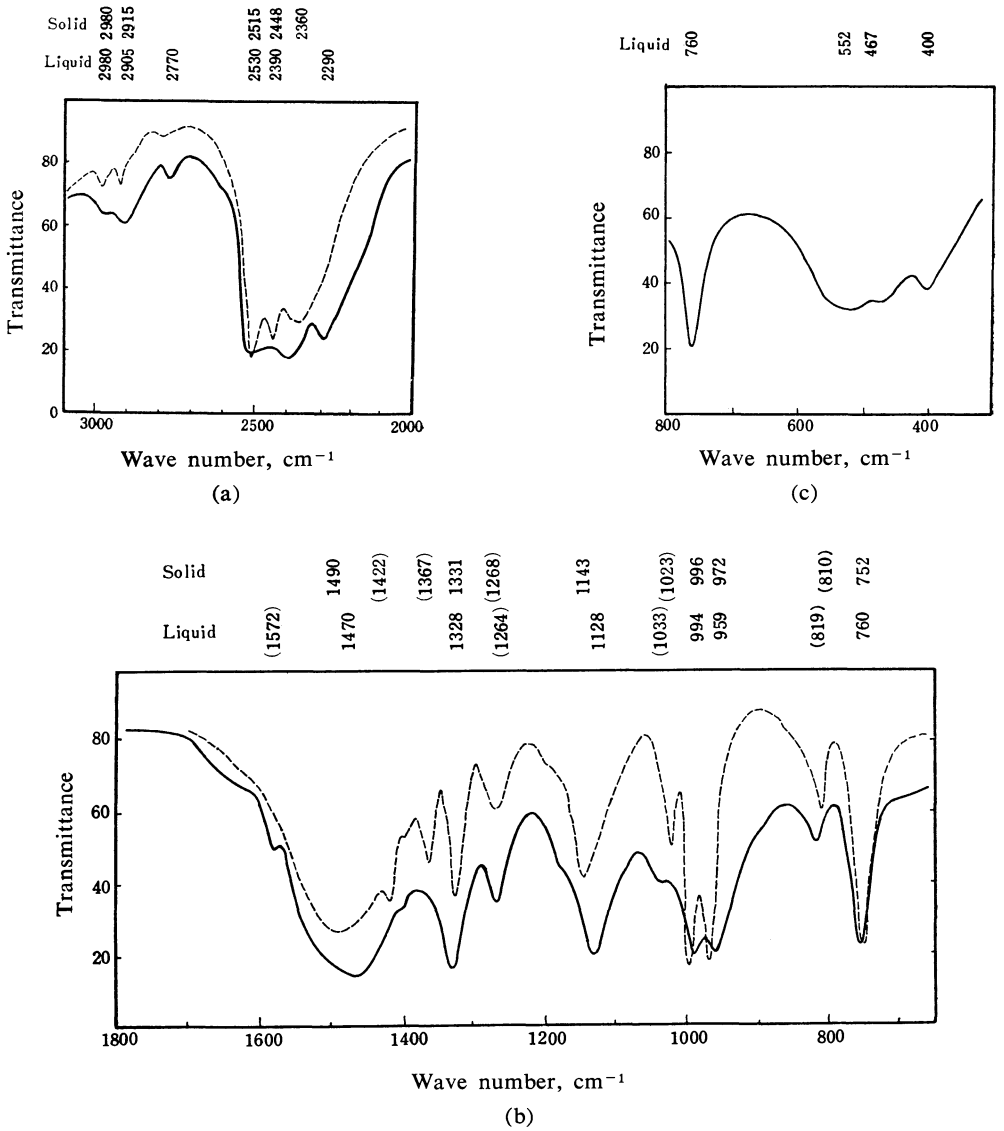

Fig. 2. Infrared spectra of $HCSND_2$ in the liquid (solid line) and solid states (broken line). (a) 3100~2000 cm^{-1}, (b) 1800~650 cm^{-1}, (c) 800~300 cm^{-1}

The difference in the strength of the NH···S hydrogen bonding between the solid and liquid states seems to be small, but the force field perpendicular to the molecular plane may be affected by solidification.

The assignment of the observed bands is chiefly based on the calculation of the normal vibration for $HCSNH_2$ and $HCSND_2$ molecules, so it will be discussed together with the results of that calculation.

Normal Coordinate Treatment

The calculation of the normal vibrations was made according to Wilson's method[9]. It was assumed that the molecule is planar, so the normal vibrations can be classified into 9 inplane (A′) and 3 out-of-plane (A″) vibrations. In the present paper the inplane vibrations are mainly treated*1. The structural parameters used in the present calculations are as follows, the bond lengths of $r(NH)=1.04$Å, $r(CH)=1.07$Å, $r(CN)=1.324$Å and $r(CS)=1.713$Å. All the bond angles are assumed to be 120°*2.

The symmetry coordinates used in the calculation are given in Table I.

Force Constants. — The potential function employed in the calculation is of the Urey-Bradley type[13]:

$$2V=\sum_i K_i(\Delta r_i)^2+\sum_{i\neq j} H_{ij}r_i^0 r_j^0(\Delta\alpha_{ij})^2 + \sum_{i\neq j} F_{ij}(\Delta q_{ij})^2+\text{Linear terms}$$

where r_i and r_j are bond lengths with the equilibrium values r_i^0 and r_j^0; α_{ij}'s are bond angles, and q_{ij}'s, distances between nonbonded atoms. K, H, and F are stretching, bending and repulsive force constants respectively.

As has already been mentioned, the values of these force constants were first transferred from formamide[1] and thiourea[5]*3 they are given in the first column of Table II. The

* The asterisk means that the corresponding L-matrix element is negative.

frequencies calculated from these values are given in the second column of Table III. As the force constants, H_{HCS} and $F_{H\cdots S}$, for which few data were available, the values of 0.18 and 0.70 md./A respectively were assumed. Then the values of the force constants were refined to obtain a better frequency agreement. The final set of their values are given in the second column of Table II.

Results of Calculations.—With the values of the force constants given in the second column of Table II (Set II), the normal vibrations have been calculated. In Tables III (a) and (b), the observed and calculated frequencies, the percent deviations, and the potential energy distributions (P. E. D.) among the symmetry coordinates for each normal mode, as well as the signs of the corresponding L-matrix elements, are given. In Tables III (a) and (b), the calculated frequencies based on Set I of the force constants are also given for comparison.

In order to visualize the features of the normal mode, it is preferable to compute the elements of the L^x matrix, which is defined, in matrix expression, as:

$$X=L^xQ$$

where X is the column vector of the Cartesian coordinates of the atoms involved and Q is the normal coordinate vector. From the calculated values of the corresponding elements

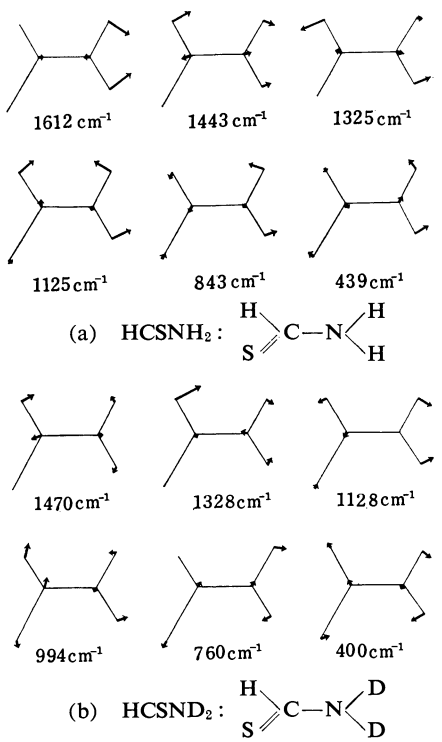

Fig. 3. The in-plane normal modes of thioformamides in Cartesian displacement vectors (A/unit change in normal coordinate).

of the L^x matrices, the vibrational feature of each normal mode is schematically shown in Figs. 3 (a) and (b) for both $HCSNH_2$ and $HCSND_2$. The features corresponding to the three higher frequencies are hydrogen (or deuterium) stretching vibrations and are obvious, so they are omitted from the figures.

The numerical computations were carried out with a PC-1 computer; the routines and the methods employed in the calculations have been described in detail in Refs. 14 and 15 and so are not discussed here.

Discussion

Force Constants.—As has been shown in the previous paper[1], the nature of the normal vibrations of the formamide molecule has been well elucidated from the simple Urey-Bradley force field without the terms $C_{ij}(\Delta q_{ij})^2$, which were used to refer to the repulsion between two nonbonded atoms situated at the cis position[16]. It has also been shown that the force constants obtained for $HCONH_2$ can be used without significant alteration in their values for $HCONHCH_3$ and CH_3CONH_2 molecules[2,3]. These facts suggest that the force field of this type can safely be applied in the study of thioamide groups, and that the force constants concerning the HC-NH_2 part of the molecule, at least as a starting set of values, may be assumed to be the same as those of formamide. A few additional data concerning the force constants involving the sulfur atom are transferred from thiourea.

The values of the force constants, Set I, of Table II, were determined in this way. As can be seen from Table II, the agreements between the observed and calculated frequencies, ν^{I}_{calcd}, are far better than one might expect, the maximum deviation being 5.5% and the average, 2.2%. This shows that the assumption that was made was not far from the truth. The agreements are good enough to make the assignment of each observed band without ambiguities, except in the case of $HCSND_2$, which will be discussed later.

Once the assignment is settled, it is not difficult to refine the values of the force constants due to the indication given by the elements of the Jacobian matrix $(\delta\lambda_i/\delta K_j)$[17,18]. Such refinements were repeated, and the force constants given in the second column of Table II (Set II) were obtained. They give most of the calculated frequencies within 1% of the observed values; the maximum deviation is only 1.5%.

The values of some force constants are worth mentioning. The present calculation gives the value of K_{CN} to be 6.35 md./A, which is only 0.20 larger than that of $HCONH_2$. The value of K_{CN} is correlated closely with some repulsion force constants, such as $F_{H\cdots H}$, $F_{H\cdots C}$ and $F_{N\cdots S}$ ($F_{N\cdots O}$), and it is somewhat indefinite. However, it is sure that there is little difference between formamide and thioformamide in the nature of the C-N bond, and it has a considerable double bond character. Therefore, the value of K_{CS} obtained (3.95 md./A) should be considered to be much lower than that corresponding to the pure C=S bond*4.

It is of interest to compare the values of $F_{H\cdots S}$ and $F_{N\cdots S}$ with those of $F_{H\cdots O}$ and $F_{N\cdots O}$ in $HCONH_2$. Although the sulfur atom has a larger van der Waals radius and is bulkier than the oxygen atom, the former values are about two-thirds of the latter. This is probably due to the much longer N···S or S···H distances. In this case, the distance between two non-bonded atoms becomes a dominant factor in determining the magnitudes of the repulsion constants.

Assignments of the Observed Bands.—For each in-plane normal vibration, the potential energy distributions among symmetry coordinates and Cartesian displacement vectors have been calculated; they are given, respectively, in Table III and Fig. 3. Based on these values, the qualitative assignments of the observed bands will be described.

The Bands above 2000 cm^{-1}.—The bands at 3280 and 3165 cm^{-1} of $HCSNH_2$ undoubtedly correspond to the $\nu_a(NH_2)$ and $\nu_s(NH_2)$ vibrations respectively. The band associated with the ν(CH) motion is found around 2900 cm^{-1}, but it is too weak for its precise position to be determined. The spectrum of $HCSND_2$ is rather complicated. The bands at 2530 and 2290 cm^{-1} might be associated with the $\nu_a(ND_2)$ and $\nu_s(ND_2)$, vibrations respectively, while the 2448 cm^{-1} is associated with the ν(ND) of the HCSNHD molecule. However, if these assignments were correct, the separation of the $\nu_a(ND_2)$ and $\nu_s(ND_2)$ frequencies is much larger than that of the $\nu_a(NH_2)$ and $\nu_s(NH_2)$

*4 Truter suggests, from her recent X-ray investigation of thioacetamide, that the obtained values of 1.32 Å for the C-N bond length and 1.713 Å for the C-S bond length probably represent the lengths of the pure single C-N and double C-S bonds respectively[10]. However, the value of K_{CN} corresponding to the pure C-N bond is around 3.15~3.20 md./A[3,19]. The high values found in various amides and thioamides exclusively indicate the partial double bond character of the C-N bond.
19) A. Yamaguchi, ibid., **80**, 1105 (1959).

frequencies. This is highly improbable. In addition, the central peak is too strong in intensity and behaves somewhat differently from other peaks arising from the NHD species when the sample is exposed to atmospheric air. In the spectrum of $HCSNH_2$, a weak but well-defined band is found at 2454 cm^{-1}; this is probably due to the combination tone of the 1325 and 1125 cm^{-1} frequencies. In the N-dideuterated species, two bands are found at 1328 and 1128 cm^{-1}. Fermi resonance probably occurs between the $\nu_a(ND_2)$ vibration and the combination tone of the above two frequencies. This, as well as the coexistence of the ν(ND) band of HCSNHD, is the cause of the complexity of the spectrum. The unperturbed $\nu_a(ND_2)$ frequency is estimated as about 2450~2460 cm^{-1}.

The Band at 1612 cm^{-1}. — The band at 1612 cm^{-1} of $HCSNH_2$ can be assigned to an almost pure $b(NH_2)$ vibration; this is in agreement with the assignment by Davies and Jones[4]. In addition, there is small contribution of the ν(CN) mode. As seen in Fig. 3 (a), the C–N bond stretches when the HNH angle increases in this mode. In the deuterated species, the band corresponding to an almost pure $b(ND_2)$ vibration occurs at 1128 cm^{-1}. Contributions of the other vibrational modes to this band are found to be very small.

The Bands at 1443 and 1325 cm^{-1}.—Davies and Jones assigned the 1443 cm^{-1} band of $HCSNH_2$ to the ν(CN) vibration, and the 1325 cm^{-1} band to the δ(CH) vibration. The present calculations establish that these two vibrational modes couple with each other almost completely, and that each of the bands can not be assigned to a particular vibrational mode. The δ(CH) and ν(CN) vibrations also couple with each other in $HCONH_2$[1], but they are not so strong as in the case of $HCSNH_2$. The force constants H_{HCS} and $F_{H...S}$ are smaller in value than H_{HCO} and $F_{H...O}$ and lower the intrinsic frequency of the δ(CH) vibration, while that of the ν(CN) vibration increases as a result of the absence of the ν(CO) mode. This may be the cause of such a strong coupling. On deuteration, the band at 1443 cm^{-1} shifts towards higher frequencies by 27 cm^{-1}, while the 1325 cm^{-1} band scarcely moves.

The Bands at 1125 and 843 cm^{-1}.—The band at 1125 cm^{-1} $HCSNH_2$ is chiefly associated with the $r(NH_2)$ vibration, although there is a small contribution from the ν(CS) vibration. It is of general interest in the infrared investigation of thioamides to determine in what region the frequency characteristic of the ν(CS) mode appears. Various authors indicate various ranges for the ν(CS) vibration*5; e. g., 1500~1470 cm^{-1}, around 1300 cm^{-1}, around 1100 cm^{-1}, etc. In thiolactams, Mecke and Mecke assigned the bands around 1100 cm^{-1} to this mode[21]. In the case of $HCSNH_2$, Davies and Jones indicated that the interaction probably occurs between the ν(CS) and ν(CN) modes and gives rise to the two frequencies at 1443 and 1288 cm^{-1}. However, as may be seen from Fig. 1 (b), the 1288 cm^{-1} band is a weak shoulder of the strong 1325 cm^{-1} band, and, it can hardly be assigned to one of the fundamental frequencies. The present calculations show that the 843 cm^{-1} band of $HCSNH_2$ corresponds to an almost pure ν(CS) mode, while there is a small contribution from the $r(NH_2)$ vibration to this band. It is true that there are some difficulties in specifying tne characteristic C=S frequency as suggested by Davies and Jones. As will be shown in the subsequent papers, the ν(CS) vibration interacts with several vibrational modes in CH_3CSNH_2, $HCSNHCH_3$ and $CH_3CSNHCH_3$, and it is rather hard to tell which band is to be called the C=S stretching band. However, in the case of $HCSNH_2$, the band at 843 cm^{-1} corresponds to an almost pure ν(CS) vibration.

In *N*-dideuterated species, the vibrational interaction occurs between the $r(ND_2)$ and the ν(CS) modes; this gives rise to two observed frequencies at 994 and 760 cm^{-1}. Energetically, both the ν(CS) and $r(ND_2)$ vibrations contribute to these modes in approximately the same degree. The above facts suggest that the intrinsic frequency of the ν(CS) vibration lies in the region from 900 to 850 cm^{-1}.

Close to the 994 cm^{-1} band, another strong band is found in $HCSND_2$ at 959 cm^{-1}. This band is assigned to the π(CH) vibration. It may be possible to reverse the assignment for these two bands. However, the present assignment is supported by the following evidence: (1) A band is found at 985 cm^{-1} in $HCSNH_2$ which is assigned to the π(CH) mode without doubt. If we adopt the reverse assignment, the π(CH) band would seem to shift towards a higher frequency on *N*-deuteration. This is quite improbable. (2) The 985 cm^{-1} band of $HCSNH_2$ shifts to a higher frequency by 21 cm^{-1} on solidification. The 959 cm^{-1} band of $HCSND_2$ also moves to a higher frequency by 13 cm^{-1}, while the 994 cm^{-1} band shifts very little*6. (3) The computed frequency always favors the present assignment.

*5 As a summary of the ν(CS) frequency, see Ref. 20, p. 350.

20) L. J. Bellamy, "The Infrared Spectra of Complex Molecules", Methuen & Co., Ltd., London (1958), p. 350.

21) R. Mecke and R. Mecke Jr., *Ber. deut. chem. Ges.*, **89**, 343 (1959).

*6 In $HCONH_2$[8], and in $HCONHCH_3$[3], the bands associated with the π(CH) mode shift towards higher frequencies on solidification.

The Band at 439 cm^{-1}.—Present calculation shows this band arises from the δ(NCS) vibration and corresponds well with the 412 cm^{-1} band of thiourea[5]. On *N*-deuteration, the $r(ND_2)$ vibration interacts with the $\delta(NCS_2)$ mode and lowers the band by 39 cm^{-1}. This is in good agreement with the calculated shift.

The Out-of-plane (A'') Vibrations.—Once the assignments for the in-plane normal vibrations are settled, it is not difficult to pick up the bands associated with the out-of-plane vibrations. In $HCSNH_2$, they are found at 985, ca. 670 and ca. 620 cm^{-1}. The absorption around 650 cm^{-1} in the liquid spectrum is very broad, and it is difficult to judge whether it is due to a single, very broad band or to two broad bands overlapping each other. The inspection of the spectrum taken in the solid phase shows that the latter is the case. It gives two distinct bands at 641 and 759 cm^{-1}. The 985 cm^{-1} band is assigned to the π(CH) vibration without ambiguity, while the bands at 670 (759) and 620 (641) cm^{-1} are assigned to the $w(NH_2)$ and $t(NH_2)$ vibrations respectively. The $t(NH_2)$ vibration is closely associated with the nature of the C–N bond, since it should accompany the torsional movement around the C–N bond. The bands at 1443 and 1325 cm^{-1}, which are associated with the ν(CN) vibration, are insensitive to solidification; therefore, the band less sensitive to solidification is chosen as due to the $t(NH_2)$ vibration. In $HCSND_2$, the band found at 959 cm^{-1} is assigned to the π(CH) vibration, as has been described above. The bands corresponding to the $w(ND_2)$ and $t(ND_2)$ vibrations are found at 552 cm^{-1} and 467 cm^{-1} respectively.

Thus complete assignments for the observed bands of both the $HCSNH_2$ and $HCSND_2$ molecules have been made. The present assignment for the $HCSNH_2$ molecule considerably differs from that made by Davies and Jones. However, this assignment is supported firmly by the calculations of the normal vibrations and by the change in the spectrum due either to *N*-deuteration or to solidification.

The author wishes to express his deep gratitude to Professor Takehiko Shimanouchi for his guidance and encouragement throughout this work, and to Professor Hidetoshi Takahashi for the use of a PC-1 computer. His thanks are also due to Dr. Akiko Hirakawa, who made her unpublished data on thiourea available to him.

Temperature Dependences of the Nuclear Quadrupole Resonance Frequencies in 1,4-Dihalogenocyclohexanes

By Tadashi TOKUHIRO

(Received January 24, 1962)

By our studies of the halogen nuclear quadrupole resonance in *cis*-1, 4-dibromo- and diiodo-cyclohexanes, it has been found that the chemical inequivalence of the two halogen nuclei, which are, respectively, in the 1e and 4a positions[1] of the cyclohexane ring, leads to doublet lines. As for *trans*-1, 4-dibromo- and diiodo-cyclohexanes, it is no surprise that only one line was observed in the iodo-derivative and that two lines, separated by only 0.11 Mc./sec., were observed in the bromo-derivative, since both the halogen atoms in these compounds occupy the e-positions of the ring in the solid. From only a comparison of the frequencies of the doublet lines in the cis-compound with those in the trans-compound, the assignment of the doublet lines could not be made, however, be cause two frequencies of the doublet lines are not close to those in the trans-compound. However, as it has been found that the doublet separation varies considerably with the rising temperature, it seemed probable that this phenomenon is due to the different contribution from molecular torsional motions to the temperature dependence of the resonance frequency of each line and that a consideration of this would shed light on the assignments. In an attempt to clarify this

point, the following studies have been carried out.

Experimental

Preparations of 1,4-Dibromocyclohexanes. — A mixture of quinit and a hydrobromic-sulfuric acid solution was allowed to stand overnight[2] and was then heated for 3 hr. on a steam bath. By standing at room temperature, an oily layer was separated from the solution. The product was washed with water and dried over calcium chloride. A fractional distillation of the product under reduced pressure gave two parts of the distillates, namely, *trans*-1,4-dibromocyclohexane, and a mixture of *trans*- and *cis*-1,4-dibromocyclohexanes. The trans-isomer was recrystallized from ethyl alcohol. By fractional crystallizations, in which ethyl alcohol and petroleum ether were alternately used as solvents, the cis-isomer was isolated from the mixture. The trans-isomer had a m. p. of 112°C, the cis-isomer, a m. p. of 49°C. These values agreed with those reported previously[3]. The purity for both isomers was ascertained by infrared spectra.

Preparations of 1,4-Diiodocyclohexanes. — By using a method similar to that of Kwestroo et al.[4], *trans*- and *cis*-1,4-diiodocyclohexanes were prepared from quinit and a 52% hydroiodic acid solution. The melting point values for the isomers (trans-, 142°C; cis-, 67°C) agreed with those reported by Kwestroo. By infrared evidence it was shown that no impurity was contained in either of the isomers.

Apparatus.—The spectrometer used in this work was a frequency-modulated (50 c./sec.) super-regenerative oscillator with 955 acon tubes[5]. A push-pull oscillator with a transmission line-tuned circuit was quenched by an oscillator of a few kilocycles. By displacing the movable reflecting disk and the 955 acon tubes at points $\lambda/2$ and $\lambda/4$ of the transmission line in the plate circuit respectively, the oscillator has a workable range of from 160 to 360 Mc./sec. In this frequency range, the quenching frequencies were from 100 to 300 Kc./sec. In order to obtain the maximum sensitivity of the detector, the quenching frequency, the quenching voltage, and shorted point of the transmission line in the cathode circuit were suitably chosen. The signal was picked up through the anode resistance, amplified by four stage audio-amplifiers (12AX7×2), and displayed on a cathode-ray oscilloscope screen. For the line-width measurement, the derivative of the signal was recorded by the help of a narrow-band lock-in system, followed by a chart-recorder. The resonance frequencies were measured with a heterodyne frequency-meter calibrated within the order of 10^{-5}.

The sample tube was directly immersed in liquid nitrogen and in petroleum ether cooled with dry ice for the measurements at −196 and −76°C respectively. For measurements at temperatures between −76 and 0°C, temperature regulation was achieved by using a gear pump and a wide-mouthed, 1.5 liter Dewar vessel with a cover of styrofoam as a thermal insulator. The vessel was filled with a high-boiling petroleum ether, in which the sample tube was immersed. The intermediate temperatures of petroleum ether in the vessel were reached by passing ethyl alcohol cooled with dry ice through a helicoid-type tube which was immersed in the petroleum ether of the vessel. The sample coil and the transmission line were connected through condensers to prevent heat conduction. The temperature was measured by means of a copper-constantan thermocouple placed at the surface of the sample tube. In order to avoid the temperature inhomogeneity of the sample, the measurements of the resonance frequencies were carried out after the sample tube had been placed in petroleum ether for one hour. By using the above procedure for temperature regulation, petroleum ether gave a temperature stability of about ±0.1°C.

Results and Discussion

The temperature dependences of the ^{79}Br and ^{127}I nuclear quadrupole resonance frequencies measured in 1,4-dibromo- and diiodo-cyclohexanes are shown in Fig. 1.

At the temperature of liquid nitrogen the resonance lines of the cis-dibromo- and diiodo-derivatives showed a similar pattern of strong doublet lines, except that the latter gave rather a larger doublet separation than the former. The doublets are undoubtedly due to the fact that the two halogen atoms in

these molecules are in two chemically inequivalent positions, namely the 1e and 4a positions, although the crystal structures of these compounds are not known.

According to the results of X-ray analysis[6], both crystals of the trans-isomers of dibromo- and diiodo-derivatives contain two equivalent molecules in a unit cell. Therefore, it would be very natural for the resonance to give a singlet line since the two halogen atoms in the isomer are in chemically equivalent positions (1e and 4e) in the free molecule. In the case of the iodo-derivative, this is actually the case. However, the pattern of the trans-dibromo-derivative gave doublet lines near one another. The doublet separation in frequency, about 110 Kc./sec. at 77°K, may reflect the effect of the intermolecular forces which render the two bromine positions in the unit cell somewhat inequivalent.

In the case of cis-compounds, the bromine and the iodine resonance lines were observable in the solid up to their melting points. However, the bromine and the iodine resonance lines in the solid trans-compounds faded out at temperatures considerably below their melting points. In the trans-dibromo-compound, the line at −77°C was so broad that the signal could hardly be detected, and the iodine resonance of the diiodo-derivative was found to fade out at about −43°C, although it does not melt until 142°C.

As shown in Fig. 1, it is easily seen that the resonance frequencies of the trans- and the cis-isomers of 1, 4-dihalogenocyclohexanes continuously decrease with the rising temperature, but the temperature dependences of the frequencies differ slightly. From this fact, it follows that no phase transitions in these solids occur within the temperature range described above and that the temperature dependence of the frequency may be ascribed to molecular torsional motions in the solids.

The theory and the extensive experimental results of the effect of temperature and pressure on nuclear quadrupole resonance frequencies have been discussed in detail by Kushida, Benedek and Bloembergen[7]. In molecular crystals, they found that the temperature dependence of the resonance frequency was due primarily to the explicit temperature dependence of the amplitudes of lattice vibrations, namely Bayer's effect[8], because of a much smaller contribution of the volume dependence of the resonance frequency. In the present article also we shall confine our attention only to Bayer's effect.

It is assumed that the direction of the maximum principal axis of the field gradient tensor at the halogen nucleus coincides with the direction of the C–X bond (X denotes halogen), and that the gradient has axial symmetry about the C–X bond (asymmetry parameter $\eta=0$). When a molecule containing the C–X bond executes torsional motions about an axis perpendicular to the C–X bond, the inclination, θ, of the C–X bond relative to its equilibrium direction in the solid gives rise to the shift of the resonance frequency $\nu(T)$ given by Eq. 1:

$$\nu(T)=\nu_0(1-3\theta^2/2) \tag{1}$$

where ν_0 is the resonance frequency when $\theta=0$. Since the frequencies of molecular vibrations and of lattice vibrations are much higher than the nuclear quadrupole resonance frequencies, the square of angular displacement, θ^2, must be averaged over all vibrational states. Therefore, we should replace θ^2 of Eq. 1 by the mean square of the angular displacement $\langle\theta^2\rangle$ of the C–X axis relative to its equilibrium direction.

When a torsional vibration can be approximated by a harmonic oscillator, $\langle\theta^2\rangle$ is expressed as follows:

$$\langle\theta^2\rangle=\frac{\boldsymbol{h}}{4\pi^2 I_t\nu_t}\left[\frac{1}{2}+\frac{1}{\exp(\boldsymbol{h}\nu_t/\boldsymbol{k}T)-1}\right] \tag{2}$$

where ν_t is the torsional frequency, I_t the corresponding moment of inertia, T the absolute temperature, $\boldsymbol{h}$ Planck's constant, and $\boldsymbol{k}$ Boltzmann's constant. From Eqs. 1 and 2 the temperature coefficient of the resonance frequency can be expressed as follows:

$$\frac{\Delta\nu}{\Delta T}=-\frac{3\boldsymbol{h}^2\nu_0}{8\pi^2\boldsymbol{k}T^2}\frac{1}{I_t}\frac{\exp(\boldsymbol{h}\nu_t/\boldsymbol{k}T)}{[\exp(\boldsymbol{h}\nu_t/\boldsymbol{k}T)-1]^2} \tag{3}$$

From Eq. 3 it can be seen that the contribution to the temperature coefficient of the resonance frequency from any other normal (intramolecular) vibrations is negligible, as compared with that of the torsional vibrations around the principal molecular axes, because the torsional frequencies, in general, are considerably lower than the frequencies of molecular vibrations.

When the torsional vibration does not take place about an axis perpendicular to the C–X bond, Eq. 3 should be modified. For this purpose a parameter, α, given by the following relation is introduced:

$$\theta=\alpha\phi$$

where θ and ϕ are the angular displacements of the C–X bond from its equilibrium direction caused by the torsional motions about an axis

1) ν_1 and ν_2 are assigned to the equatorial and the axial bromine nucleus respectively.
2) The assignment of ν_1 and ν_2 is the reverse of case I.

perpendicular to the C–X bond and about an axis of the principal molecular axes respectively. By considering the relation between the geometrical configurations of molecules and the three principal molecular axes, the value of α can be evaluated. The method is similar to that used by Tatsuzaki and Yokozawa[9]; the values of the square of α_i for the equatorial and the axial halogen atom in 1,4-dihalogenocyclohexanes are listed in Table I. Since molecules in the solid undergo torsional motions about the three principal molecular axes, $\langle\theta^2\rangle$ can be written by Eq. 4 as:

$$\langle\theta_i^2\rangle=\alpha_i^2\langle\phi_i^2\rangle, \qquad \langle\theta^2\rangle=\sum_i\langle\theta_i^2\rangle \tag{5}$$

where i denotes one of the principal molecular axes. Upon consideration of the first relation of Eq. 5, the following modification of Eq. 2 is obtained:

$$\langle\theta_i^2\rangle=\frac{\alpha_i^2\hbar}{4\pi^2I_i\nu_i}\left[\frac{1}{2}+\frac{1}{\exp(\hbar\nu_i/kT)-1}\right] \tag{6}$$

where I_i is the moment of inertia around the i axis, and ν_i the corresponding torsional frequency. From the second relation of Eq. 5 and Eq. 6, Eq. 3 should be modified as follows:

$$\frac{\Delta\nu}{\Delta T}=-\frac{3\hbar^2\nu_0}{8\pi^2kT^2}\sum_i\frac{\alpha_i^2}{I_i}\left[\frac{\exp(\hbar\nu_i/kT)}{\{\exp(\hbar\nu_i/kT)-1\}^2}\right] \tag{7}$$

where the summation runs over the three principal axes (the a, b and c axes).

As for *cis*-1,4-dihalogenocyclohexanes, there is a considerable difference between the values of α_a^2 and α_b^2 for the equatorial and the axial halogen atom. Therefore, there may be expected to be some difference between the temperature coefficients of the resonance frequencies of the equatorial and the axial halogen atom. This is actually the case (Fig. 1). The theoretical value of the temperature coefficient cannot be obtained by the use of Eq. 7, since the vibrational spectra of isomers in the solid state over low frequency regions have not yet been measured. So far as the cis-isomer is concerned, it may approximately be assumed that the torsional frequencies ν_b and ν_c are nearly the same because the moments of inertia around the b and the c axis of the molecule are almost identical in magnitude. When ν_b or ν_c, and I_b or I_c, of Eq. 7 are replaced by the average value of $\langle\nu_t\rangle$ and $\langle I_t\rangle$ respectively, Eq. 7 becomes:

$$\frac{\Delta\nu_j}{\Delta T}=-\frac{3\hbar^2\nu_0}{8\pi^2kT^2}\left[\frac{\alpha_b^2+\alpha_c^2}{\langle I_t\rangle}\frac{\exp(\hbar\langle\nu_t\rangle/kT)}{\{\exp(\hbar\langle\nu_t\rangle/kT)-1\}^2}+\frac{\alpha_a^2}{I_a}\frac{\exp(\hbar\nu_a/kT)}{\{\exp(\hbar\nu_a/kT)-1\}^2}\right] \tag{8}$$

where ν_j denotes one of the doublet lines. By using Eq. 8, the calculated moments of inertia, $\langle I_t\rangle$ and I_a, and the experimental values of $\Delta\nu_j/\Delta T$ at various temperatures, the torsional frequencies $\langle\nu_t\rangle$ and ν_a are calculated. The results thus obtained for the bromo-derivative are tabulated in Table II. In a similar way, $\langle\nu_t\rangle$ and ν_a for the iodo-derivative are calculated. The results thus obtained are given in Table III. Two cases are shown in Tables II and III, since a complete blank in our knowledge of the X-ray analysis of the crystal structure and of the Zeeman pattern for the nuclear quadrupole resonance of the cis-isomer

1) The frequency difference between the points of maximum slope in the absorption curve.

does not permit us to determine the assignment of the doublet.

As may be seen in Table II, in case I, where the two resonance lines, ν_1 and ν_2, are assigned to the equatorial and the axial bromine nucleus respectively, it is found that the difference between the two torsional frequencies, $\langle\nu_t\rangle$ and ν_a, is small and that ν_a is rather smaller than $\langle\nu_t\rangle$ at any temperature. On the other hand, in case II, where the assignment of ν_1 and ν_2 is the reverse of case I, the value of ν_a is about twice as large as that of $\langle\nu_t\rangle$.

The simple sinusoidal potential was assumed, because the form of the potential barrier for the torsional vibration in the crystal is hard to assess theoretically. Therefore, the frequency ν_i is given by:

$$\nu_i=\frac{n}{2\pi}\sqrt{\frac{V_0}{2I_i}} \quad (i=t \text{ or } a)$$

where V_0 is the height of the potential barrier with an n-fold symmetry, and I_i, the moment of inertia. If the heights of the potential barriers for different torsional axes have the same order of magnitude, the frequency, ν_i, is exclusively determined by the magnitude of the moment. From the study of the temperature dependence of the resonance frequency, of the asymmetry parameter and of the Raman spectra for the *p*-diiodobenzene, Shimauchi[10] have recently pointed out that the heights of the potential barriers for the three torsional vibrations are nearly the same.

10) A. Shimauchi, *Science of Light (Japan)*, **10**, 59 (1961).

As for 1,4-dihalogenocyclohexanes, it seems probable that the molecules execute torsional vibrations under the influence of the same heights of the potential barriers, since the molecular structures of 1,4-dihalogenocyclohexanes are not so different from those of *p*-dihalogenobenzenes. Therefore, ν_a in the cis-dibromo-compound becomes about 1.3~1.4 times as large as $\langle\nu_t\rangle$, because the moment of inertia, I_a, is about a half of $\langle I_t\rangle$ in magnitude. As is shown in Table II, case II, where ν_a is nearly twice as large as $\langle\nu_t\rangle$, seems to be more reasonable than case I. It therefore follows that the line of higher frequency at 77°K may be assigned to the equatorial bromine nucleus.

As for the cis-diiodo-derivative, the results obtained are analogous to those of the bromine-compound, but the assignment of the doublets is even more difficult, because the experimental temperature coefficients for each line do not appreciably differ when compared with those of the cis-dibromo-compound.

In the trans-compound, it may be assumed that the contribution to the temperature coefficient from the torsional motion around the a-axis is negligible, because the square of parameter α_a is very small as compared with the square of the other parameters. However, the fact that the resonance in the trans-diiodo-derivative gives a singlet line makes it impossible to determine the two torsional frequencies around the b- and the c-axes by the use of Eq. 7. Therefore, the values of the average torsional frequency, $\langle\nu_t\rangle$, at 77, 196

and 213.5°K were calculated. The average moment of inertia, $\langle I_t \rangle$, is $(I_b+I_c)/2$, and $\langle \nu_t \rangle$ denotes the corresponding frequency. The results thus obtained are listed in Table IV.

As is seen in Tables II, III and IV, all the torsional frequencies, $\langle \nu_t \rangle$ and ν_a, decrease with the increasing temperature. Such a variation of $\langle \nu_t \rangle$ and ν_a with temperature seems to imply the variations of the intermolecular potentials in the crystal caused by the thermal expansion. On the other hand, it was found, from Raman studies on various molecules, that the frequencies of lattice vibrations or torsional vibrations in molecular crystals vary with the temperature and that the experimental formula can be expressed as

$$\nu_i = \nu_i^0(1-g_i t)$$

where g_i is a constant and has a value of the range $(5\sim1.5)\times10^{-3}$ deg^{-1}, ν_i is the torsional frequency at an arbitrary temperature, ν_i^0 is the torsional frequency at some definite temperature t^0, and t is the temperature measured from t^0. By using the value of $\langle \nu_t \rangle$ or ν_a given in Tables II, III and IV, the constant, g_i, is calculated as shown in the seventh or the ninth column in Tables II and III, and in the fourth column in Table IV. As is seen in Tables II, III and IV, the agreement between the constant, g_i, obtained and those obtained by Ichishima[11] may be regarded as satisfactory.

A final point to be noticed concerns the fade-out of the resonance of the trans-compound. In the solids CCl_3CCl_3[9,12], and $CH_3 \cdot CCl_3$[12,13], it has been established that the fade-out of the resonance at a temperature far below the melting point arises from the re-orientational motion around the C–C axis. This motion leads to an exponential broadening of the line-width with the increasing temperature. In order to investigate whether or not the fade-out of the resonance of the trans-compound can be attributed to the similar motion, the line-width for the *trans*-1, 4-diiodocyclohexane was measured[14]; the results obtained are given in the fifth column of Table IV. From a comparison of the experimental value of the line-width at 77°K with those at 196°K, it is likely that the re-orientational motion responsible for the fade-out does not occur at 196°K.

In order to establish this point, the investigation of the proton magnetic resonance was carried out at room temperature and at the temperature of liquid nitrogen. Whereas it was expected that such motions would produce drastic changes in the line-width and in the line-shape of the proton magnetic resonance in solids[16], and that, for *trans*- and *cis*-1, 4-dihalogenocyclohexanes, the motion would give rise to a narrowing of the line-width of the resonance, no marked changes in the line-width or in the line-shape with the increasing temperature could be observed for either isomer. It follows that the motion cannot be responsible for the fade-out of the nuclear quadrupole resonance of the trans-isomer. To understand what causes may produce the fade-out of the nuclear quadrupole resonance of the trans-isomer, it would be necessary to measure the relaxation times at various temperatures.

Summary

The temperature dependences of the ^{79}Br and ^{127}I nuclear quadrupole resonance frequencies in 1, 4-dihalogenocyclohexanes were investigated. According to Bayer's theory (Eq. 8), the torsional frequencies were calculated by the use of the calculated moments of inertia and the experimental values of the temperature coefficients of the resonance frequencies at various temperatures. From a comparison of the torsional frequencies, the line of higher frequency at 77°K in *cis*-1, 4-dibromocyclohexane may be assigned to the equatorial bromine nucleus. All the calculated torsional frequencies decrease with the increasing temperature. Such variation in the frequencies agrees with the variation obtained by Raman studies of various molecules in crystals. The resonance lines in the trans-compounds fade out at temperatures considerably below their melting points.

The author wishes to express his deep thanks to Professor Kunio Kozima for his kind guidance and encouragement throughout this work. The author wishes also to thank Dr. Akira Shimauchi of the Institute for Optical Research, Tokyo University of Education, for his helpful advice in the development of the instrumentation. Studies on Fluorene Derivatives. XIX[1]*. The Clemmensen Reduction of 2-Bromofluorenone*

By Kazuo SUZUKI, Tsutomu MAEDA, Nagateru NAWA and Yoshitomo SŌDA

(Received January 27, 1962)

Some interesting findings noted during the Clemmensen reduction of fluorenone were reported in a preceding paper[2] of this series. Thus, fluorene was obtained in a poor yield, but a great part of the fluorenone was converted abnormally into the related dimeric products, dibiphenylene-ethylene, -ethane, 10, 10-diphenylene-9-phenanthrone, 9, 10-diphenylenephenanthrene and other intermediates through 9, 9-dihydroxy-9, 9'-bifluorenyl (fluorenopinacol).

The present study deals with the effect on this reduction of an electron-attracting group such as bromine at the 2-position of fluorenone. This is of interest because the substituent influences may be transmitted to the carbonyl at the 9-position, both directly through the substituted ring and indirectly through the unsubstituted ring.

There is only one reference in the literature to the Clemmensen-Martin reduction of 2-bromofluorenone (I), that by Miller and Bachman[3], who reported a nearly quantitative yield of 2-bromofluorene (II).

In this study, I was submitted to the same procedure as was fluorenone[2]. I was refluxed vigorously for twenty-four hours with amalgamated zinc, water, concentrated hydrochloric acid and toluene or xylene, more acid being added at intervals of about six hours. From this reduction, II, 2-bromofluorenol (III) and

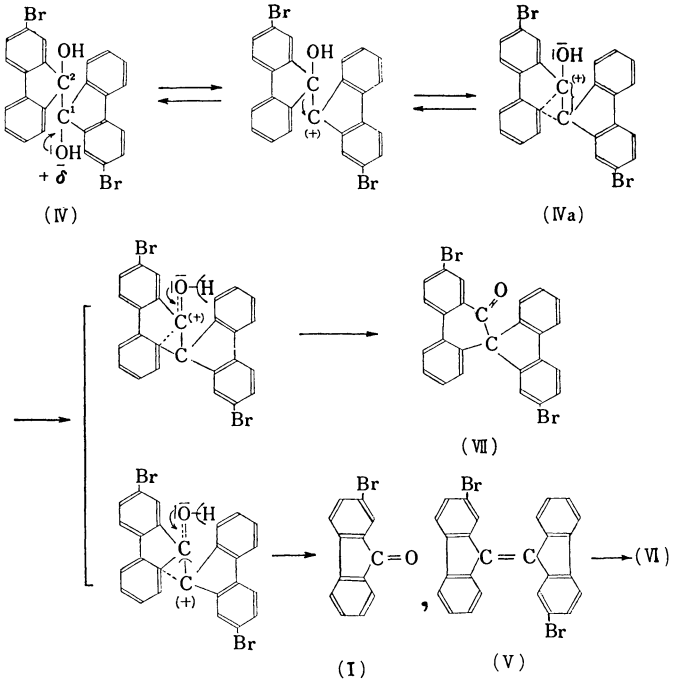

Chart 2.

several dimeric reaction products, namely 2, 2'-dibromo-9, 9-dihydroxy-9, 9'-bifluorenyl (2, 2'-dibromofluorenopinacol) (IV), 2, 2'-dibromodibiphenylene-ethylene (V)[4], -ethane (VI)[4] and a trace of spiro-[2-bromofluorene-9, 9'(10')-2'-bromophenanthrone] (VII), were isolated by means of a combination of recrystallization and column chromatography.

These reaction products are shown in Chart 1.

The reduction of I is very slow; only 11% of it was recovered after 72 hr. On the other hand, III was isolated after just a 24 hr.-period, while fluorenol has the short reduction period of 2 hr. of fluorenone. The yield of IV is increased by the use of a more concentrated hydrochloric acid, as is shown in Table I (No. 4).

IX was, however, not isolated from this series, in contrast to the comparable reduction of fluorenone. The formation of IX is controlled by the formation of VII from IV. Actually, VII was obtained only in trace amounts by this reduction, as is described in the experimental section.

First, the results can mean that the oxygen atom of the hydroxyl group attached to the carbon, C^1, is positively charged by the electron-attracting bromine in IV. For this reason, the hydroxyl group is relatively more hindered for the elimination than it is in fluorenopinacol[2] owing to the electron-repelling effect on the protonation. Under these conditions, carbonium ion formation is unlikely.

A second possible explanation is that, due to being stabilized by the formation of the transition carbonium ion, IVa, by resonance, the hydroxyl group is dehydrated from the carbon, C^1. However, state IVa must cross a high energy barrier to reach stable state VII.

These sequences can be visualized, as in Chart 2.

It seems that the formation of I and V from IVa occurs preferentially to that of VII. This is indicated in view of the following experimental evidence.

Traces of VII, V and VI were also obtained by the Clemmensen reduction of I (Table I, No. 2). I, V and VI were isolated from IV by the same reduction procedure.

Therefore, IV was treated with hydrochloric acid in toluene under the same conditions but without amalgamated zinc; a small amount of I and V was isolated.

Subsequently the quantity of the reduced form of V and VI was gradually increased after 72 hr. (Table I, No. 3).

On the other hand, the fairly large amount of VII accompanying I and V was obtained from IV by pinacol rearrangement.

The following new compounds: VII, spiro-[2-bromofluorene-9, 9'-(10')-2'-bromophenanethrol] (VIII), 2, 2'-dibromophenanthreno-9',10':

4*	20	Toluene 40	24	1.21	1.7	10.0	0.01	1.35	1.4	m. p. >300°C Orange-red needles, trace

* In this case, 15 ml. of water and 85 ml. of concentrated hydrochloric acid were used.

9, 10-phenanthrene (IX) and 2, 11-dibromotetrabenzocyclodecane-9, 18-dione (X), were synthesized separately by the same procedure as that with which the corresponding compounds were obtained in the case of fluorenone[2].

VII was reduced to VIII by zinc and ammonium hydroxide in an alcoholic solution and then converted into IX by retropinacol rearrangement with hydrochloric acid in acetic acid. IX was also obtained directly by the Clemmensen reduction of VII in toluene, or by hydrogen iodide and red phosphorus in acetic acid.

IX was converted into X by sodium bichromate in acetic acid, and X was also reduced to IX by hydrogen iodide in acetic acid.

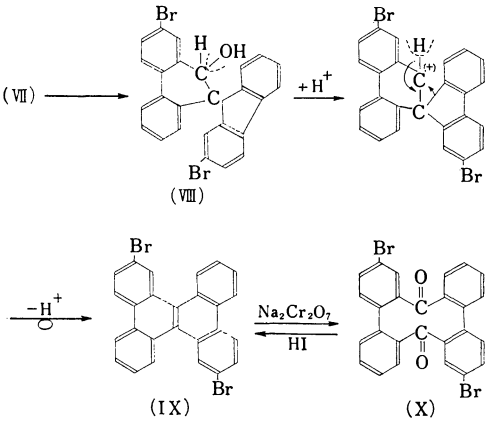

Chart 3.

Experimental*

General Procedure for the Clemmensen Reduction of 2-Bromofluorenone (I). — *Materials.* — Amalgamated zinc filings were prepared according to Martin's method[5].

2-Bromofluorene was obtained by the bromination of fluorene in chloroform; it was then oxidized to I[6] in over 80% yields.

About 0.077 mol. (20 g.) of the ketone I was refluxed vigorously for 24 hr. with 40 g. of amalgamated zinc, 30 ml. of water, 70 ml. of concentrated hydrochloric acid and 40 ml. of xylene in a 1000 ml. flask.

Concentrated hydrochloric acid (20 ml.) was added every six hours, according to Martin's method. The xylene layer turned an orange-red color after 24 hr.

When the mixture had been left standing, the crystals in the xylene layer were recrystallized from benzene, m. p. 195~196°C (4.7 g.), identical with 2,2'-dibromofluorenopinacol (IV).

Found: C, 59.99; H, 3.13. Calcd. for $C_{26}H_{16}O_2Br_2$: C, 60.02; H, 3.10%. IR 3450 (OH) cm^{-1} (KBr-disk).

The products which coated the surface of the zinc were filtered, dried and dissolved in benzene by heating; upon cooling, VI (m. p. 274°C, 0.36 g.) was obtained and I (m. p. 140°C, 0.5 g.) was recovered from the benzene mother solution. The identity of both compounds was confirmed by mixed melting point determination.

The original xylene mother liquor was evaporated, and VI (m. p. 275°C, 0.05 g.), VII (m. p. 253~254°C, 0.005 g.), and recovered I (m. p. 140°C, 0.35 g.) were isolated by fractional recrystallization. VII was identical with the material which had been prepared by the pinacol rearrangement of IV with sulfuric acid in acetic acid.

Found: C, 61.95; H, 2.70. Calcd. for $C_{26}H_{14}OBr_2$: C, 62.18; H, 2.81%.

The xylene mother solution was steam-distilled to remove the solvent, and II (m. p. 112°C, 2.7 g.) was obtained; this was confirmed by mixed melting point determination.

The orange residue was filtered and dried, and VI (m. p. 275°C, 0.38 g.), V (m. p. 264°C, 0.01 g.), I (m. p. 140°C, 1.3 g.) and III (m. p. 130°C, 0.26 g.) were separated by a combination of fractional recrystallization and chromatography in benzene on an alumina column. Mixed melting points established the nature of the products.

Clemmensen Reduction of IV. — A mixture of amalgamated zinc (11 g.), concentrated hydrochloric acid (18.2 ml.), water (6.5 ml.), toluene (13.4 ml.) and IV (4.2 g.) were refluxed for 24 hr. A 5 ml. portion of concentrated hydrochloric acid was added every six hours.

The toluene layer turned yellow after five minutes, and orange-yellow after 12 hr.

After the mixture had been left standing 24 hr., the deposited products were filtered and then recrystallized from benzene, whereupon (m. p. 195°C,

* All the melting points are uncorrected.

5) E. L. Martin, "Organic Reactins", Vol. 1, Chapman and Hall, London (1942), p. 155.

6) J. Schmidt and K. Bauer, *Ber.*, **38**, 3753 (1905).

1.2 g.) was recovered. Then V (m. p. 263°C, 0.2 g.) was isolated by evaporation and recrystallization from the mother liquor.

The last toluene mother liquor was subjected to steam distillation, and the yellow residue was filtered and recrystallized from benzene to yield VI (m. p. 273°C, 0.005 g.), then IV (m. p. 195°C, 0.8 g.) and I (m. p. 140°C, 0.51 g.) from the benzene mother solution. These compounds were confirmed by mixed melting point determinations.

Reaction of IV with Hydrochloric Acid. — IV (0.5 g.), toluene (2 ml.), water (0.8 ml.) and concentrated hydrochloric acid (1.8 ml.) were refluxed for 24 hr. A 0.5 ml. portion of hydrochloric acid was added every six hours.

The toluene layer turned an orange-yellow color after 20 hr. When the mixture had been left standing, the precipitate was filtered and recrystallized from benzene, m. p. 193°C (0.21 g.), identical with the recovered IV. The toluene mother liquor was steam-distilled to remove the solvent, yielding I (m. p. 140°C, 0.05 g.), which was recrystallized from alcohol.

The residual products were filtered; I (m. p. 142°C, 0.06 g.) and V (m. p. 263°C, 0.002 g.), obtained by means of chromatography in benzene on alumina, were confirmed by mixed melting point determinations.

Pinacol Rearrangement of IV to VII.—IV (5 g.) was dissolved in acetic acid (50 ml.), and concentrated sulfuric acid (0.5 ml.) was added; the mixture was then refluxed for 30 min. When the mixture had cooled, the deposited products were filtered and recrystallized from acetic acid to yield VII (m. p. 252°C, 3.0 g.) as colorless crystals. The mother liquor was poured into water, the precipitate was filtered, and additional VII (m. p. 252°C, 0.42 g.), recovered pinacol (IV) (m. p. 194°C, 0.06 g.) and I (m. p. 141°C, 0.11 g.) were separated by a combination of recrystallization and column chromatography in benzene on alumina. Moreover, a small amount of V (m. p. 264°C) was isolated from the mother liquor by recrystallization.

Reduction of VII to VIII.—Finely powdered VII (1 g.) was suspended in 600 ml. of ethyl alcohol, zinc dust (3 g.) and concentrated ammonium hydroxide (30 ml.) were added, and the mixture was refluxed for 10 hr. Concentrated ammonium hydroxide (30 ml.) was added every 3 hr. The reaction mixture was filtered, and the filtrate was evaporated to half volume. The white product deposited was filtered, then recrystallized from benzene to give unreacted VII (m. p. 253°C, 0.31 g.). The first mother liquor was evaporated to a small volume, and the precipitate was recrystallized from benzene to give crystals, m. p. 153~154°C (0.05 g); these were identical with VIII.

Found: C, 62.21; H, 3.32. Calcd. for $C_{26}H_{16}OBr_2$: C, 61.93; H, 3.20%. IR 3484 (OH) cm^{-1} (KBr-disk).

Rearrangement of VIII to IX.—To a solution of VIII (0.2 g.) in acetic acid (10 ml.) there was added 1.5 ml. of concentrated hydrochloric acid, and the mixture was refluxed for 2 hr. When the mixture had cooled, the precipitate was filtered and recrystallized from benzene, m. p. 305°C, (0.05 g.); this was identical with IX.

Found: C, 64.11; H, 3.07. Calcd. for $C_{26}H_{14}Br_2$: C, 64.22; H, 2.90%.

Rearrangement of VII to IX by Reduction.—A mixture of VII (1 g.), acetic acid (190 ml.), hydrogen iodide (10 ml.) and red phosphorus (1 g.) was refluxed for 9.5 hr. Upon cooling, the reaction mixture was filtered, and the filtrate was poured into water. The precipitate was then filtered and washed well with water. It was recrystallized from benzene to give IX (m. p. 305~307°C, 0.2 g.) as small colorless needles; unreacted ketone VII (m. p. 253°C, 0.4 g.) was also recovered.

Clemmensen Reduction of VII to IX.—A mixture of amalgamated zinc (6.0 g.), water (1.5 ml.), toluene (10 ml.), concentrated hydrochloric acid (5 ml.) and VII (1 g.) was refluxed vigorously for 24 hr. in a 100 ml., round-bottomed flask. A 1 ml. portion of concentrated hydrochloric acid was added every 6 hr. After reaction, the deposited material was filtered and recrystallized from benzene to yield IX (m. p. 305°C, 0.5 g.). Then VIII (m. p 150~152°C, 0.005 g.) and unreacted VII (m. p. 253°C, 0.66 g.) were also isolated from the mother liquor by fractional recrystallization.

Oxidation of IX to X.—IX (0.4 g.) in a mixture of acetic acid (700 ml.) and sodium bichromate (6 g.) was refluxed for 13 hr. Upon cooling, the reaction mixture was poured into water. The white amorphous product was recrystallized from benzene, m. p. 224~225°C (0.25 g.); this was identical with X.

Found: C, 60.53; H, 2.91. Calcd. for $C_{26}H_{14}O_2Br_2$: C, 60.26; H, 2.72%. IR 1672 (C=O) cm^{-1} (KBr-disk).

Reduction of X to IX.—A mixture of X (0.1 g.), acetic acid (15 ml.), hydrogen iodide (1 ml.), and red phosphorus 0.1 g. was refluxed for 9 hr. Then the reaction mixture was filtered, and the filtrate was poured into water; the white precipitate was recrystallized from benzene, m. p. 305°C, (0.05 g.). This compound was identical with IX, as was shown by mixed melting point determination.

It is a pleasure to acknowledge our helpful discussions of problems related to this paper with Drs. John and Elizabeth Weisburger of National Institutes of Health and with Dr. Yoshiro Ogata of Nagoya University, and to thank Dr. Shoji Kajigaeshi for his assistance.

We are also indebted to Idemitsu Industries Co., Ltd., for the infrared spectra measurement.

Raman Spectrum of γ-Glycine

By K. BALASUBRAMANIAN, R. S. KRISHNAN and Yoichi IITAKA*

(Received January 30, 1962)

A study of Raman spectra of crystalline glycine and its addition compounds is of great interest because of the existence of strong hydrogen bonding in these substances. A systematic study of Raman effect in single crystals of these substances was therefore undertaken in the Department of Physics of the Indian Institute of Science a few years ago. The Raman spectra of α-glycine[1], triglycine sulfate[2], diglycine nitrate[3], diglycine hydrochloride[3] and diglycine hydrobromide[3] have already been reported. It is well known that besides the α-form, two other polymorphic forms of glycine exist. These are (1) an unstable β-form first described by Fischer[4] and (2) γ-form the existence of which was reported by one of us[5]. The crystal structure of the γ-form has been determined very accurately[6]. This γ-variety can be obtained in single crystal form and is quite stable. It is therefore considered desirable to have its Raman spectrum photographed and compared with that of α-glycine.

Experimental Details

Single crystals of γ-glycine were grown in the following way[5,6]. A saturated aqueous solution of α-glycine was prepared at 60 to 80°C. This was made acidic with 15% acetic acid and was cooled slowly in an ice-box with seeding γ-glycine crystals. They usually grow in massive aggregates; but, with some difficulty single crystals of small size could be obtained. Two specimen of roughly 5 mm. in size were used for taking the Raman spectrum using λ 2536.5 excitation. Exposure for about one day was found to be necessary for recording a satisfactory spectrogram with a Hilger medium quartz spectrograph. The crystals did not get spoiled due to irradiation with ultraviolet light.

Results

An enlarged photograph of the Raman spectrum of γ-glycine obtained with λ 2536.5 excitation is reproduced in Fig. 1 (b) and the corresponding microphotometer record is shown in Fig. 1(c). Fig. 1(a) represents the Raman spectrum of α-glycine taken under identical conditions. The frequency shifs in cm^{-1} of the observed Raman lines are marked in the microphotometer record. They are also tabulated in Table I, column 2. The figures given in brackets are the intensities of the lines for the unspecified orientation that was used. These intensities are estimated spectrophotometrically. The Raman frequency shifts of α-glycine[1] are also entered in column 1 of Table I. On the whole 39 Raman lines are

i, Intense; w, Weak

recorded in γ-glycine of which the first nine lines (43～270 cm^{-1}) belong to low frequency spectrum and the remaining 30 lines belonging to internal oscillations. The Raman spectrum of α-glycine reproduced in Fig. 1 (a) is more intense than that of γ-glycine. This is due to the fact that the specimen of γ-glycine used was less perfect than that of α-glycine.

Discussion

γ-Glycine crystallizes in hexagonal class with space group $P3_1$ or $P3_2$ and shows piezoelectric properties along the c-axis. The cell dimensions are $a=7.037$ Å and $c=5.483$ Å. There are 3 molecules in the unit cell. Here also the glycine units exist in the zwitter ion form as in α-glycine. According to the detailed structure analysis carried out by one of us (Iitaka[6]) the N atom is 0.309 Å (12.8°) out of the best plane through C_I, C_{II}, O_I, O_{II} as against 0.436 Å (18.6°) in α-glycine. The N atoms are surrounded by 5 oxygen atoms at short distances out of which 3 short distances are attributed to be making hydrogen bonds (N–H···O); these hydrogen bond (N–H···O) distances are as follows; 2.801 Å, 2.817 Å and 2.970 Å. In α-glycine two hydrogen atoms are participating in strong hydrogen bonds which hold the molecule in a sheet and the third hydrogen atom forms a weak bifurcated bond with glycines in the next sheet. Whereas, in γ-glycine there is no such bifurcated bond and all these bonds are nearly of equal strength. The directional properties of the hydrogen bonds are more fully satisfied in γ-glycine than that in the other form. The hydrogen bonding between amino N and carboxyl O atoms links the molecules in helical chains about the 3-fold screw axis. These chains are linked together by lateral hydrogen bonds forming the 3-dimensional network of hydrogen bonds.

Internal Oscillations.—The frequencies corresponding to the absorption maxima of γ-glycine in infrared reported by Tsuboi and others[7] are given in column 3 of Table I. The data on the far-infrared absorption spectrum of γ-glycine (85～200 cm^{-1}) was supplied by Tsuboi[8]. There is a very close correspondence between the frequency shifts observed in the Raman spectrum of γ-glycine and its infrared absorption frequencies. This is not surprising because the crystal belongs to the hexagonal class $P3_1$ or $P3_2$ for which the selection rules are such that the Raman effect and infrared absorption are not mutually exclusive. Some additional maxima are observed in the

7) M. Tsuboi, T. Onishi, I. Nakagawa, T. Shimanouchi and S. Mizushima, *Spectrochim. Acta.*, 12, 253 (1958).
8) M. Tsuboi, unpublished work.

infrared. The Raman line corresponding to the absorption 602~607 cm^{-1} in infrared can not be identified in the spectrum taken with λ 2536.5 excitation as it falls very close to the mercury line λ 2576.3Å. In the infrared absorption, above 1700 cm^{-1} no data are available for comparison with the observed Raman frequencies.

As is to be expected there is a close agreement between the Raman frequencies of γ-glycine and α-glycine. From a comparative study of the two spectra the assignments have been given for most of the internal oscillations. Many of the internal oscillations are influenced by the hydrogen bonds and especially those which contain N–H group. A very careful comparison of the spectra of α-glycine and γ-glycine reveals the fact that the influence of hydrogen bonds on some of the internal frequencies is different in the two crystals. This is not surprising if one remembers the fact that in γ-glycine there are 3 equally strong hydrogen bonds, whereas in α-glycine there are only two strong hydrogen bonds and one comparatively weaker bond. As in the case of α-glycine and other glycine addition compounds, a large number of Raman frequency shifts are observed in the spectrum of γ-glycine in the region 2500~2900 cm^{-1}, the intensity increasing with increasing frequency shift. They are all assigned to N–H ··· O oscillations. The presence of the Raman line at 3120 cm^{-1} adjacent to intense mercury line λ 2752.8 clearly indicates the existense of NH_3^+ group. This supports the X-ray evidence that the glycine molecules in γ-glycine exist in the zwitter ion configuration. The planarity of the glycine molecule is different in the α and γ forms. This appears to have some influence on the C–H stretching frequency. The C–H frequencies in γ-glycine, in which the glycine molecule is more planar, are lower than the corresponding frequencies of α-glycine, whereas the difference in the frequency shifts between the symmetric and antisymmetric (C–H) oscillations remains the same. Similar observations have also been made with addition compounds of glycine (Balasubramanian[3]).

Low Frequency Spectrum.—In the Raman spectrum, one observes 9 distinct lines in this region, some of them being very intense. Of these the lines at 186 and 217 which are also observed in the spectrum of α-glycine should be attributed to the vibrations of hydrogen bond i. e., NH···O (Gross[9]). The remaining seven low frequency Raman lines belong to the lattice oscillation of rotatory and translatory types of glycine units. There is practically no similarity between the lattice spectra of α- and γ-glycine. This is not surprising because they belong to two different crystal systems. In infrared absorption, Tsuboi[8] has also observed seven maxima. However, only four of them with frequencies 90.3, 105, 138 and 173, which are the intense ones, agree closely with those observed in Raman effect.

From a group theoretical analysis, taking each glycine molecule as an individual unit, it can be shown that there are, on the whole (for the unit cell of γ-glycine) only 10 external oscillations, which are active both in infrared and Raman effect. These are as follows: 2 translatory and 3 rotatory oscillations coming under the symmetric class, and 2 translatory and 3 rotatory coming under the doubly degenerate class. Taking all the observed frequencies in infrared as well as in Raman effect, one observes that they are actually twelve in number. Therefore, at least two of them should be assigned to combination or overtones. The oscillations with frequencies 101, 116 and 127 appear very weakly in infrared absorption and do not appear in Raman effect. It is possible that with a better and more clear specimen of γ-glycine and a longer exposure these faint lines may also be recorded in Raman effect. The appearance of two lowest frequency lines 43 and 58 in infrared absorption is yet to be confirmed. Tsuboi's observations in infrared extends only up to 85 cm^{-1}. The Raman line at 152 cm^{-1} is extremely intense and sharp while the corresponding frequency is absent in infrared absorption. This might be due to the fact that for this particular oscillation though there might be a great change in polarizability, the change in dipole moment may not be appreciable.

Summary

Using λ 2536.5 excitation the Raman spectrum of single crystal of γ-glycine has been recorded for the first time. Thirty-nine Raman frequencies have been reported. Comparing the spectrum of γ-glycine with its infrared absorption spectrum and also with the Raman spectrum of α-glycine, proper assignments have been given to the internal frequencies. The lattice lines observed in Raman effect and infrared absorption have been satisfactorily accounted for.

The authors wish to express their grateful thanks to Professor San-ichiro Mizushima and Professor Masamichi Tsuboi for their kind interest in the work and also for supplying the far-infrared absorption data of γ-glycine.

Adsorption of Cesium by Japanese Acid Clay

By Noboru Oi and Eijiro Ohashi

(Received February 3, 1962)

We have already reported[1] the separation of uranium from fission products by the adsorption of the latter to Japanese acid clay in an organic solution. We pointed out the strong preference for adsorbing cesium to other fission product nuclides. This phenomenon was found also in aqueous solutions, so we extended the survey to aqueous systems, especially in regard to the effect of the heat treatment of the clay on adsorption.

Experimental

Sample Description.—Japanese acid clay, from Ōmi, Niigata prefecture, was obtained from the Koso Chemicals Co. The clay was used without pretreatment or was used after heating it at different temperatures up to 1200°C for 1.5~2 hr., followed by gradual cooling.

The ion exchange capacities were determined by using the barium-saturation-acid titration technique described by Suto[2].

The Measuring of the K_d Values of Cesium.—About 10 ml. of an aqueous solution, containing 1~2μC. of carrier free cesium-137, was placed in a graduated glass cylinder with a stopper, and 30~50 mg. of the clay were added. After equilibrium was reached with intermittent shaking, the solution was centrifuged. One milliliter of aliquot was counted in a well-type scintillation counter with a NaI (Tl) crystal, after the mixture had been left standing for 20 min. to ensure radioactive equilibrium with ^{137m}Ba. The K_d values were then calculated by the following equation:

$$K_d = \frac{[\text{Cs concn. of the sample soln. before adding the clay (c. p. m./ml.)} - \text{Cs concn. after equilibration (c.p.m./ml.)}] \times [\text{Vol. of the soln. (ml.)}]}{[\text{Weight of the clay (g.)}] \times [\text{Cs concn. after equilibration(c. p. m./ml.)}]}$$

The time of equilibration was almost the same in various solutions, either carrier free, with carrier, or containing a salt such as sodium nitrate: this time was found to be 0.5~1.0 hr.

Compared with the data of montmorillonite[3] and kaolinite[4], where the times of equilibration for the cesium adsorption in aqueous systems were 16~696 hr. and 40 days, the adsorption by Japanese acid clay is rapid. Presumably this is due to the ease of defloculation of this clay; a larger proportion of sites is soon made available for exchange. It was also noticed that the adsorption of cesium was better at a lower temperature; for example the K_d values of cesium from aqueous solution were 6430, 6450, 5570, 5470, 4270 and 3980 at 0, 10, 20, 30, 40 and 50°C respectively.

Results and Discussion

The Meaning of the K_d Values.—Many surveys have been made of the ion-exchange properties of clay minerals. Almost all of them, however, treated the results of the experiments by hold-up volume or by the percentage of adsorption at various concentrations and various pH values. This seems due to a lack of information as to whether the phase equilibrium really exists, even in the case of clay minerals. We confirmed this point by the following two methods and discussed all the data using K_d values.

(1) In some K_d value measurements, the volume of the solution and the amounts of the clay to be added were changed, only to find that the calculated K_d values were changed only a little with varying these two factors.

(2) Cesium was adsorbed to the clay from a 0.2 M nitric acid aqueous solution, and the supernatant solution was rejected. This clay was next brought in contact with 0.2 M nitric acid, the K_d value of the desorption being measured. The same experiments were repeated, and the changes in the K_d values of desorption were observed. The results are shown in Table I. The gradual increase in K_d

Table I. Desorption of cesium-137 which was adsorbed on Japanese acid clay

No.	Total activity (c.p.m.)	Desorbed activity (c.p.m.)	K_d
1	1246000	109140	2080

values seems to show the existence of some irreversible adsorption, but on the whole we can probably assume a phase equilibrium.

The Influence of the Concentration of Acid, Alkali and Salt.—The K_d values of cesium-137 at various concentrations of nitric acid, hydrochloric acid, ammonia, sodium chloride, sodium nitrate, aluminum nitrate and cesium nitrate in an aqueous solution were measured; they are shown in Figs. 1 and 2. Here it must be pointed out that the adsorption of cesium by this clay is much more highly specific than that of these ions: H^+, Na^+, NH_4^+ and Al^{3+}. It was also shown that the cesium adsorption was at its maximum in water (pH=7), the K_d value then being 7000. When the concentration of the solute in the solution increased except in the case of ammonia, which is one of the weak electrolytes, the K_d values decreased rapidly, and to almost the same value; the K_d value was below 1000 above 0.2 M. This indicates, on the contrary, the possibility of cesium desorption by a solution of a higher concentration.

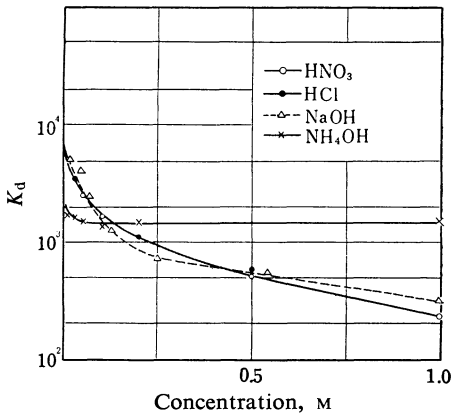

Fig. 1. Influence of acids and alkalis on the K_d values of cesium.

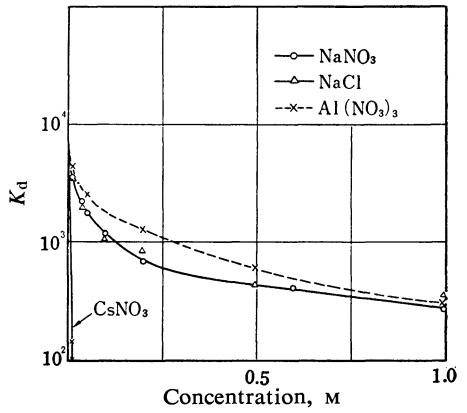

Fig. 2. Influence of salts on the K_d values of cesium.

Above all, it seems to indicate that the adsorption is a cationic exchange in nature and that the decrease in K_d values is due to the competition between cesium and other ionic species at the higher concentrations.

Influences of the Heat Treatment of Japanese Acid Clay.—It is known that the adsorbability for cesium of clay minerals, especially montmorillionite, is enhanced by heat treatment. In this case, the basal diffraction of the X-ray diffraction pattern changes from 15~17 Å to about 10 Å. Tamura et al.[3-5] suggested the importance of this 10 Å c-axis spacing for the adsorption of cesium; they also pointed out the affinity for cesium of illite and synthetic micas, which have a 10 Å c-axis spacing.

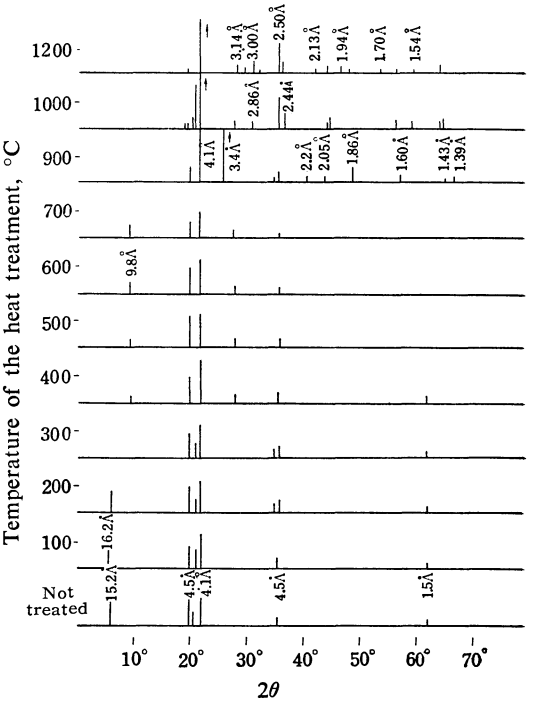

Fig. 3. X-Ray diffraction patterns of the heat treated Japanese acid clay.

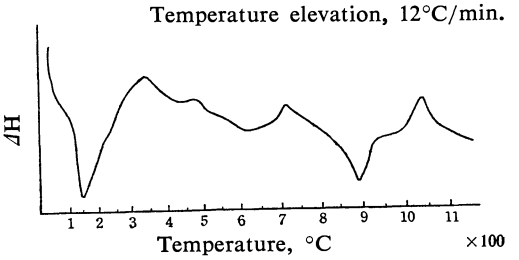

Fig. 4. Curve obtained by the differential thermal analysis of the Japanese acid clay.

5) T. Tamura and D. G. Jacobs, *Health Physics*, 5, 149 (1961).

We carried out the experiment with heat-treated clay and considered our results using X-ray diffraction patterns (Fig. 3) and differential thermal analysis (Fig. 4). The changes in the K_d values of some systems are shown in Fig. 5. It is shown that the selectivity for cesium was most improved by heating it to a temperature in the 400~500°C range. By comparing these results, the following conclusions[6] were reached:

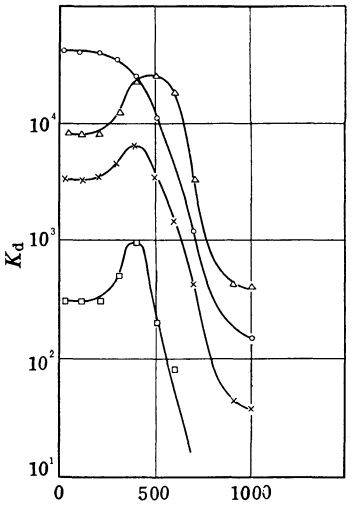

Fig. 5. Changes of the K_d values of cesium by using heat treated Japanese acid clay.
—○— *n*-Butylacetate, uranyl nitrate 0.1 M
—×— 0.1 M uranyl nitrate aqueous solution
—△— Water
—□— 1 M Nitric acid

(1) Japanese acid clay loses about 10%. of its weight at 100~150°C by the removal of its absorbed water. This process, however, does not work positively but rather somewhat negatively in cesium adsorption.

(2) Up to 700°C, the patterns of X-ray diffraction show little change except in their basal reflection. This changes from 15~16 Å at 100~200°C to about 10 Å at 400~700°C, while its intensity also increased. The process of the formation of the 10 Å axis corresponds to the maximum point of the adsorption.

(3) The endothermic peak of 350~650°C is due to the removal of the structural water (or -OH), and in this process the c-axis changes to 10 Å. After the complete dispersion of the structural water, the K_d values drop. The pattern of differential thermal analysis indicates two stage changes within this temperature range, one rather moderate in the range of 350~450°C and the other slightly steep up to 500°C. The clay of the first stage showed the maximum K_d values.

(4) The endothermic-exothermic peak of the 850~1100°C range corresponds to the change in colloidal silica, which is one of the components of this clay, to α-crystobalite via α-quartz. This is clear from the X-ray patterns. Here the K_d values decreased to a minimum.

Thus, the K_d maximum corresponds to the process of 10 Å c-axis formation and also to the removal of the structural water. These results qualitatively agree with Tamura et al's data[3].

Fripiat et al.[7] studied the relation of the dehydration of montmorillonite to its infrared spectroscopy. They pointed out the increase in the stretching vibration frequency of the hydroxyls as the dehydration progressed. We also took infrared spectra of the untreated and heat treated clays, but we could not clearly determine the relation between the increase in OH stretching and the maximum K_d value. This is presumably because the K_d maximum is due to the structural factor and not to the ion exchange character.

In Fig. 5. a curve showing the K_d changes in *n*-butylacetate is also included. This shows no maximum value. This seems to indicate that the mechanism of the adsorption in an organic solution is mainly molecular and is different from that in an aqueous solution, ion exchange adsorption.

On the other hand, when cesium was adsorbed by this clay and was heated for half an hour at about 1000°C, it was fixed to the clay and was not eluted even when boiled with large amounts of water.

The Cesium Concentration and the Change in K_d Values.—The experiment above was carried out using carrier-free (about 10^{-7} mol./l.) cesium-137. However, as much as 10^{-4} mol./l. of cesium is handled in high-level waste. Besides, the behavior of cesium at a higher concentration also seems interesting with regard to the adsorption mechanism: therefore, we carried out experiments up to 0.1 mol./l., using both untreated and heat-treated clays at 400°C. The results are shown in Fig. 6. In the cesium concentration range of below 10^{-6} mol./l. heat-treated clay showed higher K_d values, but at a higher cesium concentration untreated clay showed better adsorption. The adsorption isotherms of both clays at a higher cesium concentration indicated a maximum adsorption, the amounts of adsorption being almost the same as their ion exchange capacities, 0.45 and

7) J. J. Fripiat, J. Chaussidon and R. Touillaux, *J. Phys. Chem.*, **64**, 1234 (1960).

0.14 meq./g. and 59 and 17 mg. of cesium adsorption per gram of the clay for untreated and for treated clays respectively. These results show that ion exchange plays a major role in the adsorption of cesium, but that at a lower cesium concentration a somewhat specific, perhaps structural adsorption takes place and causes an increase in the K_d values.

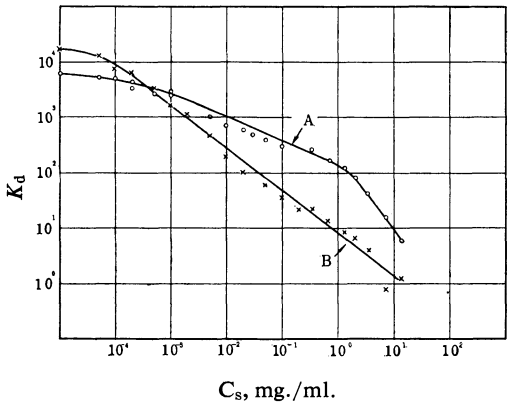

Fig. 6. Changes of the K_d values of cesium by increasing cesium nitrate concentration in water.
A, Untreated clay
B, Heat treated clay at 400°C

Adsorption of Cesium-137 from Fission Products Mixture.—A simple survey of cesium adsorption from the fission products of this clay showed that cerium, zirconium and niobium were adsorbed at about 1% of the K_d value of cesium. Ruthenium was eliminated more efficiently. The behavior of nuclides was altered by the heat treatment of the clay; for example, in the case of 200 day-cooled fission products, the gross K_d values of total γ-activities in water were 460 and 16, by the untreated clay and the clay treated at 500°C respectively.

Summary

Japanese acid clay, a montmorillonite-type one, exhibited a special affinity for cesium-137 from an aqueous solution. The phase epuilibrium of the adsorption was confirmed, and the K_d values were used to analyze the data.

The K_d value of cesium was highest in pure water, but it was decreased by increasing the aqueous acid, alkali and salt concentration.

When clay which had been treated at 400~500°C was used, the K_d value increased two- or three-fold. This phenomenon corresponds to the formation of 10 Å c-axis spacing and the dispersion of the structural water of the clay. This peculiarity, however, appears only at a low cesium concenration, below 10^{-6} mol./l. At a higher cesium concentration, the adsorption of cesium depends simply on the cation exchange capacity of the clay; heat-treated clay showed a poorer adsorption.

The adsorption of cesium from a fission products mixture was also simply examined.

The authors wish to express their deep thanks to Dr. Kakuzo Tada and Dr. Tsutomu Takamura of Toshiba Central Research Laboratory for their encouragement and valuable advice.

Studies of 2-Oxazolidinones. I. A Convenient Synthesis of 3-Substituted 2-Oxazolidinones

By Ryohei ODA, Masahiko MIYANOKI and Masaya OKANO

(Received February 2, 1962)

Although several methods for the formation of 3-substituted 2-oxazolidinones (I) are known, these preparative routes may be classified into three general groups: (i) the condensation of β-hydroxyethylamines with carbonic acid derivatives such as dialkyl carbonates[1], urea[2], or phosgene[3]; (ii) the addition of isocyanates to

epoxides[4,5]; (iii) the dehydrochlorination of β-chloroethyl carbamates[6-9]. Among instances of route iii, β-chloroethyl carbamates have recently been obtained by the condensation of amines with ethylene carbonate, followed by the chlorination of the resulting β-hydroxyethyl carbamates[9,10]. However, the authors have considered that Nemirowsky's well-known method A[6-8,11] may have an abvantage over the above method from the synthetic standpoint.

Method A:

$$COCl_2 + HOCH_2CH_2Cl \rightarrow ClCOOCH_2CH_2Cl$$

$$RNH_2 + ClCOOCH_2CH_2Cl \rightarrow RNHCOOCH_2CH_2Cl$$

Making another combination of the three reactants, the following method B may be considered, although it has not previously been reported.

Method B:

$$RNH_2 + COCl_2 \rightarrow RNCO$$

$$RNCO + HOCH_2CH_2Cl \rightarrow RNHCOOCH_2CH_2Cl$$

Method B is a modification of the method ii mentioned above.

This paper deals with the preparation of β-chloroethyl carbamates by method A or B and with the ring-closure of these compounds to form 3-substituted 2-oxazolidinones. The results of the carbamate syntheses are summarized in Table I. These results seem to prove that our method B is comparable to method A in yields and is applicable as a convenient method of 2-oxazolidinone synthesis.

In the dehydrochlorinative ring-closure of β-chloroethyl carbamates, many workers have used more than one molar equivalent of alkali. However, it is known that the oxazolidinones are less stable in alkaline media and are easily hydrolyzed by aqueous alkali to yield β-hydroxyethylamines[3,7]. In this research, optimum yields were obtained by the use of approximately one molar equivalent of sodium ethoxide in dioxane or ethanol. For example, although Naiki[12] failed in the synthesis of 3-(1-anthraquinonyl)-2-oxazolidinone using aqueous alkali as a ring-closure agent, we have succeeded in this synthesis using an equivalent amount of

alcoholate. In preparing 3-*p*-nitrophenyl-2-oxazolidinone, the use of alcoholate gave a satisfactory result, but the use of aqueous alkali resulted in the formation of *N*-*p*-nitrophenylethanolamine. Data on the dehydrochlorination of β-chloroethyl carbamates are given in Table II.

Experimental

All melting and boiling points are uncorrected.

β-Chloroethyl Chloroformate.—The preparation of the ester was carried out by a modification of the procedure of Nekrassow et al.[13] Phosgene was passed rapidly into 161 g. of ethylene chlorohydrin for 3 hr. at 0°C. The reaction mixture was then allowed to stand at room temperature (approximately 15°C) until the evolution of hydrogen chloride had subsided; it was then weighed. If the weight increase did not approach the theoretical expectation, this procedure was repeated. The resulting liquid was then refluxed for 2 hr. Upon distillation, 263 g. (93%) of the ester, b. p. 149~153°C (lit.[13] b. p. 152~153°C), was obtained.

Isocyanates.—Except for tetramethylenediisocyanate, all isocyanates were prepared from the corresponding amine hydrochlorides according to the well-known phosgene method[14]. The boiling points (or melting points) and yields of the isocyanates obtained were as follows: *n*-butyl-, b. p. 114°C (lit.[14] 115°C), 80%; phenyl-, b. p. 50~51°C/10 mmHg lit.[14] 56°C/16 mmHg, 82%; *p*-tolyl-, b. p. 110°C/72 mmHg lit.[14] 67.7°C/10 mmHg, 75%; *p*-nitrophenyl-, m. p. 57°C (lit.[14] 56~57°C), 88%; *m*-phenylenedi-, m. p. 51°C (lit.[14] 51°C), 79%; *p*-phenylenedi-, m. p. 94°C (lit.[14] 95°C), 85%. Tetramethylenediisocyanate was synthesized by a Curtius rearrangement of adipodiazide prepared from adipic acid[15]. The over-all yield was 50%. The product boiled at 80.5°C/5 mmHg, lit.[15] 93°C/7 mmHg.

***N*-Substituted β-Chloroethyl Carbamates.**—Typical examples are given below.

By Method A.—(*a*) *N-tert-Butyl-β-chloroethyl Carbamate.*—β-Chloroethyl chloroformate (59 g., 0.41 mol.) was stirred, drop by drop, into a mixture of 25 g. (0.34 mol.) of *tert*-butyl amine and 41 g. (0.41 mol.) of triethylamine. The reaction mixture was heated to 70°C for 30 min. and then poured into 200 ml. of water. The mixture was extracted with two 100 ml. portions of ether. The extract was dried over anhydrous sodium sulfate, and the ether was distilled off. When the residue was fractionated under reduced pressure, 38 g. (63%) of the carbamate, b. p. 90°C/7 mmHg, was obtained.

(*c*) *N-o-Nitrophenyl-β-chloroethyl Carbamate.*—A mixture of 43 g. (0.30 mol.) of β-chloroethyl chloroformate and 34.5 g. (0.25 mol.) of *o*-nitroaniline was heated to 120°C. Heating and stirring were continued for ca. 1 hr., until the evolution of hydrogen chloride ceased. Owing to the intermediate formation of the amine hydrochloride, the reaction mixture became heterogeneous, but subsequently it became clear again. This clear mixture was then cooled, and the precipitate of the carbamate was filtered, washed with ethanol, and dried. It weighed 61 g. (98%). Recrystallization from a benzene-ligroin mixture gave the pure product, m. p. 70.5°C.

By Method B. (*a*) *N-n-Butyl-β-chloroethyl Carbamate.*—A mixture of 25 g. (0.25 mol.) of *n*-butyl-isocyanate and 21 g. (0.26 mol.) of ethylene

13) W. Nekrassow and J. F. Komissarow, *J. prakt. Chem.*, [2], **123**, 163 (1929).

14) W. Siefken, *Ann.*, **562**, 75 (1949); R. L. Shriner et al., "Organic Syntheses", Coll. Vol. II., (1943), p. 453.

chlorohydrin in 50 ml. of dry benzene was refluxed for 5 hr. After evaporation of the benzene, distillation of the residue yielded 39 g. (83%) of the carbamate, b. p. 113°C/4.3 mmHg.

(b) N-p-Tolyl-β-chloroethyl Carbamate.—A mixture of 33.3 g. (0.25 mol.) of *p*-tolylisocyanate and 21 g. (0.26 mol.) of ethylene chlorohydrin in 50 ml. of dry toluene was refluxed for 2 hr. Removal of the solvent gave 54 g. of the crude product, and the yield was nearly quantitative. Recrystallization from benzene afforded the pure compound, m. p. 61°C.

3-Substituted 2-Oxazolidinones.—In all experiments, sodium ethoxide was used as a ring-closure agent and the reaction was carried out in dioxane or ethanol. A few examples follow.

(a) 3, 3'-Tetramethylene-bis-(2-oxazolidinone).—A solution of sodium ethoxide, prepared from 7.5 g. (0.33 g. atom) of sodium and 50 ml. of absolute ethanol, was stirred, drop by drop, into a solution of 48.5 g. (0.16 mol.) of *N, N'*-tetramethylene-bis-(β-chloroethyl carbamate) in 50 ml. of dioxane at 70~80°C. After completion of the addition, stirring and heating were continued for another hour. The precipitate of sodium chloride was filtered from the warm mixture. After evaporation of the solvent form the filtrate, 31 g. (95%) of the bis-(2-oxazolidinone) was obtained. The pure compound had a m.p. of 118°C after recrystallization from ethanol.

(b) 3-Phenyl-2-oxazolidinone.—A solution of 5.0 g. (0.22 g. atom) of sodium in 50 ml. of ethanol was gradually stirred into 39.5 g. (0.20 mol.) of *N*-phenyl-β-chloroethyl carbamate in 50 ml. of ethanol at 65~70°C. After the addition was complete, this temperature was maintained for 1 hr.; 100 ml. of water was then stirred into the reaction mixture to dissolve the sodium chloride. The crude 3-phenyl-2-oxazolidinone which separated on cooling was collected by filtration, washed with ethanol, and dried. The yield was 30 g. (94%). The pure product melted at 118°C after recrystallization from benzene.

(c) 3-p-Nitrophenyl-2-oxazolidinone.—A ca. 10% sodium ethoxide solution was stirred, drop by drop, into 46.5 g. (0.19 mol.) of *N-p*-nitrophenyl-β-chloroethyl carbamate in 150 ml. of ethanol at 75°C, until the reaction mixture became slightly brown. The consumption of the sodium ethoxide was nearly the theoretical expectation. Upon the stirring in of 300 ml. of water to the above mixture, 37.5 g. (95%) of 3-*p*-nitrophenyl-2-oxazolidinone crystallized out as yellow needles. Recrystallization from a benzene-ethanol mixture gave the pure compound, m. p. 154°C.

When an alcoholic solution of *N-p*-nitrophenyl-β-chloroethyl carbamate was treated with two molar equivalents of 30% aqueous potassium hydroxide at 60°C, crude *N-p*-nitrophenylethanolamine separated out in a nearly quantitative yield. This was recrystallized from benzene, and the pure product melted at 109°C. Its structure was confirmed by elemental analysis and by infrared measurement.

Found: C, 52.72; H, 5.79; N, 15.77. Calcd. for $C_8H_{10}N_2O_3$: C, 52.74; H, 5.53; N, 15.38%.

Summary

A convenient synthesis of 3-substituted 2-oxazolidinones starting from three components —aliphatic or aromatic amines, phosgene and ethylene chlorohydrin—has been developed.

The author wish to express their gratitude to Hodogaya Kagaku Co., Ltd., for the gift of phosgene and to Mr. A. Miyasu for the preparation of some isocyanates.

The Behavior of Silver in Glass. I. The Diffusion of Silver into Glass from a Melt of Silver Nitrate[*1]

By Taro Ito

(Received February 10, 1962)

Previously the present author, together with his co-worker, studied[1] the diffusion of silver into a glass material in a temperature range somewhat below the softening temperature, namely, from 500 to 600°C. It was ascertained that a colorless glass gradually turned yellow or, further, brown as a result of the immigration of silver therein. According to previous authors, the following three consecutive stages of change are involved: first, the immigration of silver ions due to exchanges between silver

*1 The major part of this report was presented at the 8th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1955.

1) S. Kinumaki and T. Ito, *Sci. Repts. Research Inst., Tohoku Univ.*, **A8**, 60 (1956).

and sodium ions[2], second, the reduction of the ions[3], and, last, the formation of silver colloid in the glass medium[4]. The first quantitative investigations of the immigration were done by Schulze[2], who observed that silver diffuses from a silver nitrate melt into Thuringian glass and stains it intensively and that ions of silver and of sodium are exchanged. However, as to how each of these stages contributes respectively to the coloring, we do not have sufficient knowledge, especially in the former two cases; the problem must be studied in the future. However, in any cases, the degree of coloring may be taken as a measure corresponding to the immigration of silver into the glass material.

Consequently, the amount of silver immigrated in the glass material can be estimated by measuring the absorption of light at a characteristic wavelength, if it exists. The present investigation attempted to study the problem of the penetration of silver into a glass medium in particular connection with the light absorption.

Experimental

Material and Measurement of Absorbance. — The specimens were made from a glass plate, 1.93 $\pm$0.03 mm. thick, the composition of which was the same*2 as that glass used in the previous work. This glass plate was cut into rectangles 12×50 mm^2 as the optimum size of the specimens; in addition, as a point of reference, a piece was cut out of the same glass plate next to every piece, in order to eliminate the discrepancies in the following observations due to fluctuation in the composition or in the thickness of the glass material.

The specimens were immersed for definite periods in melts of silver nitrate, which were kept at the constant temperatures of 250, 280, 310, 340, 370 and 400$\pm$1°C. Then they were taken out of the melts, cooled and washed with distilled water to remove the salt clinging to the surface of the glass.

Absorption spectra were measured on these glass plates with a Shimadzu QB-50 type spectrophotometer.

After the optical measurements, the border parts of the glass plates were cut off in order to avoid the boundary effects in the diffusion processes; then the residual parts were cut into rectanglar pieces 6×12 mm^2 for the sake of simple calculation. These pieces were used as specimens for measuring the changes in density due to the silver immigration. As points of reference, pieces cut out of the original pile, as mentioned above, were used, having been heat-treated to have the same thermal histories as salt-immersed pieces.

Measurement of the Shifting of Glass Densities. —We know that we can coveniently determine the density of a tiny piece of a solid material when we have a liquid the density of which can vary over a range including that of the specimen. Thus, if the density of the liquid be adjusted so that the specimen can stay at any depth in the liquid, neither rising nor sinking, then the density of liquid, determinable with a pycnometer or by other means, can be taken to be that of the solid. For this purpose, in the present work, solutions were prepared as follows: a suitable quantity of red mercuric iodide was suspended in water; then potassium iodide was added thereto, enough for the bulk to become a clean solution, probably due to the formation of some complex ions. By such processes we can obtain solutions of desired densities, in the range from unity to 3.5, corresponding to the concentrations; moreover, we can, in the above-mentioned range, increase or decrease the densities of given solutions by the evaporation or addition of water. Thus, the solution consisting of 113 g. of mercuric iodide, 91 g. of potassium iodide and 46 g. of water, the total weight amounting to 250 g. and the volume to 100 ml., has a density of 2.5, which is nearly equal to those of the glasses. This was, therefore, suitable as the starting solution.

As, in the present work, the change in the density of the glass due to the immigration, rather than its absolute values, was essential, the following procedures were preferred: a piece of salt-treated glass, together with a piece of the original glass, was put into a solution denser than both of them, and thereinto was poured, little by little, pure water from a micro buret, the volume being read frequently. First, the denser one of the two pieces reached the state of suspension; then, after the addition of a definite quantity of water, the other reached suspension. Thus, from the quantity of added water between the two suspensions, the required value can be calculated.

Then, because of the small density differences, the density differences between the specimens were evaluated by interpolation from the rising or sinking velocity measures instead of adjusting the densities of the liquids exactly to the perfect suspension of the specimens.

On the original glass, it was confirmed by the same procedure that the density remains unchanged on the thermal exposure in the temperature range from 250 to 400°C; this fact about glass of a similar kind has already been indicated by previous authors[5].

Thermostat.—All through the measurements of the densities, the temperature was kept at 25$\pm$0.001°C by means of a thermostat regulated by a combination of an infrared radiator and a water cooler. The room temperature was 25$\pm$3°C.

Results and Calculation

Absorbance.—The absorption spectrum of non-treated sodium-glass was obtained with the usual profile, as is shown in Fig. 1; it was ascertained that this spectrum does not suffer any annealing effect. The absorption of silver-glass was obtained with reference to this non-treated glass. Accordingly, the measure of absorbance is the difference between the absorptions of silver- and sodium-glasses and may be regarded as corresponding to the change in composition due to the immigration of silver. Typical curves of the absorbance spectra of silver-glass obtained as mentioned above are shown in Fig. 2. These curves all have one resemblance. The depth of penetration layer was estimated by the diminution of the thickness of the specimen ground until the yellow layer had disappeared. Now it was obtained as about 0.4 mm. under these conditions of treatment. As is seen in Fig. 2, the maxima of the absorbance curves lie at a wavelength of 314±1 mμ. Thus, the wavelengths of maximum absorption can be taken to have a constant value, the small deviation in the above-mentioned results being attributable to the fluctuation in the properties of the particular glass pieces. The heights of peaks are dependent on the time and the temperature of treatment. The relations, at various temperatures, between the heights of the maxima and the times of treatment are shown in Fig. 3.

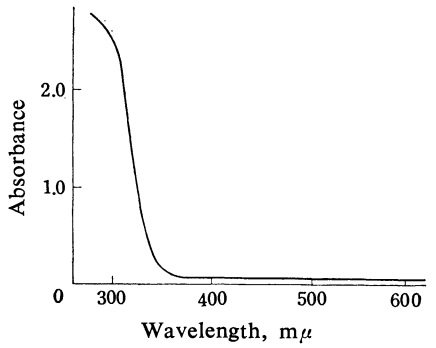

Fig. 1. Absorbance spectrum of sample glass refered to air. Since the conversion into the value per unit thickness is not important in this case, this is a figure obtained from non-converted values.

● 340, ⊖ 370, ⊙ 400C
Errors are indicated by the lengths of the vertical lines.

Calculation of Density.—The pieces used in the measurement of density differences were selected particularly from those specimens which had reasonable values of absorbance as ascertained by the above-mentioned methods. We will denote the volume of water added to the reference solution from the beginning to the first suspension state by a in ml., and the volume, the weight and the density of the solution in this state by V, W and ρ respectively. Further, the volume of water added from the first to the second suspension states is v, the volume, the weight and the density of the solution thus arrived at being V_0, W_0

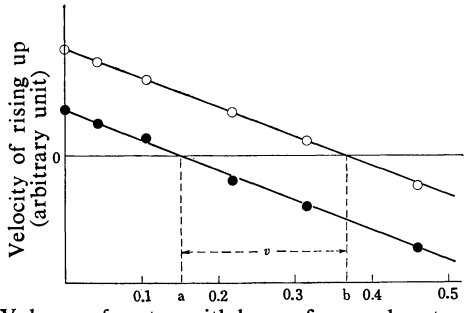

Fig. 4. The relation of the velocity of rising up against the volume of water withdrawn.
-○- Sodium-glass -●- Silver-glass

and ρ_0 respectively. One of the relations of the rising or sinking velocity against the volume of withdrawn water was plotted as shown in Fig. 4. The difference in density between the two glass pieces is given by:

$$\Delta\rho=\rho-\rho_0=\frac{W}{V}-\rho_0$$

Then $$W=W_0-w=V_0\rho_0-vd$$

where v, w and d are the volume, the weight and the density*3 of the water withdrawn from the buret.

So $$\Delta\rho=\frac{V_0\rho_0-vd-V\rho_0}{V}$$

$$=\frac{(V_0-V)\rho_0-vd}{V}$$

In the present work, it was confirmed that the volume contraction due to the dilution of the solution does not exceed the limit of acceptable approximation, namely $V_0-V=v$.

Consequently, $$\Delta\rho=\frac{v(\rho_0-d)}{V}$$

The value thus obtained is the change in the weight of the glass per ml. caused by the immigration of silver. The area of the precise rectangle through which silver ions had penetrated into the glass was measured with a screw micrometer. The penetrated amounts per unit area thus calculated are plotted against absorbance in Fig. 5.

Diffusion Constant.—It has been described how both the absorbance and the change in density resulting from an immersion treatment occur as a result of a diffusion of silver ions and depend on the total amount of exchanged silver. With the inclination of the straight line given in Fig. 5, the absorbance can be converted into the amount of silver. The ratio of the exchanged amount of silver per unit

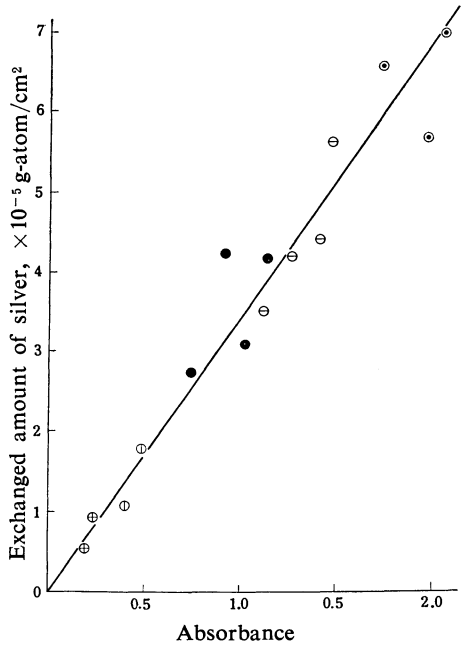

Fig. 5. The relation of the exchanged amount of silver against absorbance (cf. Fig. 3 for notes).

area vs. the absorbance was obtained as follows:

$$r=\frac{\text{amount per area}}{\text{absorbance}}=3.408\times10^{-5}\ \text{g-atom/cm}^2$$

The results of the conversion are placed vertically on the right of Fig. 3. On the other hand, according to Fick's law[6], the amount of silver can be represented with

$$M=2N\sqrt{\frac{Dt}{\pi}} \qquad (1)$$

Accordingly, $$D=\left(\frac{M}{\sqrt{t}}\right)^2\frac{\pi}{4N^2} \qquad (2)$$

where M is the immigrated amount of silver, N the saturation concentration, and t the reaction time. The $M/\sqrt{t}$ was obtained from the inclination of the straight lines in Fig. 3 at the respective temperatures. N can be taken as the concentration of sodium ions in the glass. It was calculated with the following equation:

$$N=\rho_0\times C\times\frac{1}{1/2(Na_2O)}$$

Inserting $\rho_0=2.511$, $C=14.11/100$ (the wt.% of Na_2O) and $Na_2O=61.98$ (molecular weight),

$$N=1.31\times10^{-2}\ \text{g-atom/ml.}$$

Putting these values into Eq. 2, the diffusion constant, D, was obtained. The logarithms of

*3 $d=0.9971\pm0.0007$ (at 25 ± 3°C), according to Landolt-Bernstein, "Physikalisch-Chemische Tabellen".

6) J. Crank, "The Mathematics of Diffusion", Clarendon Press, Oxford (1956), p. 31.

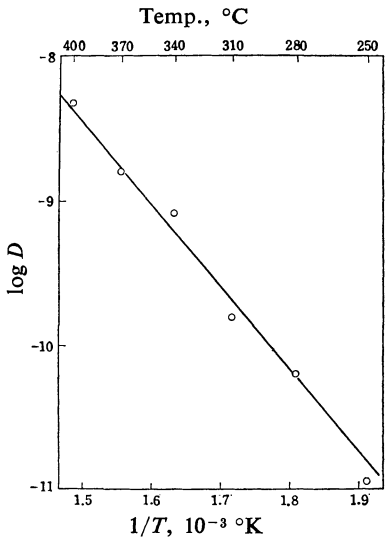

Fig. 6. The relation between $\log D$ and $1/T$.

D thus obtained are plotted against the reciprocal absolute temperature in Fig. 6. The relation of $\log D$ to $1/T$ is linear, as is seen in this figure. From the inclination of the line, the energy of activation, E, can be calculated to be

$$E=26.3 \text{ kcal./mol.}$$

also $$D_0=9.85\times10^{-1} \text{ cm}^2/\text{sec.}$$

Discussion

By measuring the electrical resistance, the diffusion of sodium in glass was studied[7]. In this work the means of absorbance has been successfully applied to the calculation of the diffusion, accompanied with the measurement of density difference.

The value of $E=26.3$ kcal./mol. is of the same order as that obtained in the previous work[1]. The value of $D_0=9.85\times10^{-1}$ cm^2/sec., on the other hand, is slightly larger than that obtained previously. However, they are both reasonable values. In this work, treatment at temperatures above 400°C could not be carried out because of the instability of the nitrate and because of the anomaly of glass-density in its thermal history.

The figures in many reports of the absorption spectra of silver-containing glass have not agreed with each other. According to Wells[8], the coloration of silver salts depends on the length of the Ag—O bonds. Helmholz[9], on the contrary, has suggested that the color is related to the nature of the Ag—O bonds.

Most silver salts are colorless, although some of them are yellow or a similar color. Their absorption spectra have relatively low bands at wave lengths near 300 mμ[10]. Glass is not crystalline but amorphous. Therefore, the coloration, as well as the diffusion, involves more complicated problems than the salts, the space conditions in the glass media being in chaos. The absorption spectrum of silver-containing glass annealed at higher temperatures had a different band[1]. The coloration of glass has been, hitherto, dealt with in terms of the formation of the colloid of some metals in glass. The color of various kinds of silver glass would depend on the chemical state of silver, that is, on whether it is ionic, atomic or colloidal. The color obtained in the present experiment was yellow and not fluorescent, so it should be regarded as due to the state of the ions[11]. A detailed study of this problem will be carried out in the future.

The author wishes to express his deep gratitude to Professor Susumu Kinumaki of the Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, for his helpful counsel and for supplying the author with material help of various kinds in the course of this study.

Proton Magnetic Resonance of Ammonia-Borane Derivatives

By Osamu OHASHI, Yukio KURITA, Tetsushi TOTANI, Haruyuki WATANABE, Toshio NAKAGAWA and Masaji KUBO

(Received February 19, 1962)

The present authors have already studied the proton magnetic resonance of borazole and some of its derivatives[1,2]. There is another group of compounds having a bond between boron and nitrogen known as ammonia-boranes (or borazanes), i.e., the derivatives of ammonia-borane H_3NBH_3[3]. For instance, both boron trichloride (or trichloroborane) BCl_3 and triethylborane $B(C_2H_5)_3$ are known to form addition compounds with amines through a donor-acceptor bond. Whereas borazole is isoelectronic with benzene, ammonia-borane is isoelectronic with ethane. Accordingly, one has in ammonia-boranes a typical example of donor-acceptor bonds as contrasted with the case of borazoles, in which covalent σ bonds are involved in addition to donor-acceptor bonds between boron and nitrogen. This paper presents the results of investigation on the proton magnetic resonance of ammonia-boranes.

Experimental

Triethylborane was prepared by adding the calculated amount of the addition compound between boron trifluoride and *n*-butyl ether, $BF_3 \cdot O(C_4H_9)_2$, drop by drop to the solution of ethylmagnesium bromide in *n*-butyl ether at room temperature. The resulting triethylborane was purified by distillation in the stream of nitrogen at ordinary pressure, b.p. 95~96°C (lit.[4] 94~97°C).

Trimethylamine-triethylborane $(CH_3)_3NB(C_2H_5)_3$ was synthesized by a method due to Brown[4]. Triethylborane was treated with an excess of trimethylamine. After the excess was removed by distillation from the reaction mixture, the liquid was subjected to distillation at low temperature under reduced pressure, m.p. −47 to −46°C (lit.[4] −46 to −45°C).

Triethylamine-triethylborane $(C_2H_5)_3NB(C_2H_5)_3$ was synthesized from triethylborane and excess triethylamine and purified in the same manner as above. This compound decomposes in the gas phase at room temperature, decomposition products being presumed to exist in the liquid state also. No data are available in the literature for comparison.

Trimethylamine-trichloroborane $(CH_3)_3NBCl_3$ was prepared by allowing boron trichloride to react with the equivalent amount of trimethylamine in carbon tetrachloride at −70°C. The addition compound was soluble with difficulty in this solvent. After filtration, the precipitates were recrystallized from ethanol, m.p. 243~244°C (lit.[5] 243~244°C). Anal. Calcd. for $(CH_3)_3NBCl_3$: N, 7.96%. Found: N, 7.89%.

Triethylamine-trichloroborane $(C_2H_5)_3NBCl_3$ was synthesized from boron trichloride and triethylamine in a similar manner to above and was recrystallized from methanol. It decomposed on melting at 81~83°C (lit.[6] 75°C). Anal. Calcd. for $(C_2H_5)_3NBCl_3$: N, 6.42%. Found: N, 6.16%.

The proton magnetic resonance spectra were recorded at room temperature by means of a JNM-3 high-resolution NMR spectrometer of Japan Electron Optics Laboratory Company operating at 40 Mc. Chemical shifts were evaluated using appropriate internal standards so as to avoid the overlap of signals of samples under investigation with that of the standard used. In case when samples were unstable, they were sealed in a cell with an external standard. No correction was made for the bulk magnetic susceptibility of the samples.

Assignments

The NMR spectra of triethylborane were recorded in pure liquid state as well as in carbon tetrachloride solution with cyclohexane as an internal standard. These spectra were essentially identical with each other. The spectra showed a fairly sharp composite signal attributable to ethyl groups bonded to boron as illustrated in Fig. 1a.

Trimethylamine-triethylborane was examined in pure liquid state with water as an external standard. A very sharp intense line appearing at −0.77 p.p.m. as calculated with cyclohexane as the standard* was ascribed to protons in methyl groups bonded to nitrogen. In addition,

Conversion was made with the proton chemical shifts −3.4 and +1.6 p.p.m. of water and tetramethylsilane referred to cyclohexane. J. A. Pople, W. G. Schneider and H. J. Bernstein, "High-resolution Nuclear Magnetic Resonance", McGraw-Hill, New York (1959), pp. 89, 236.

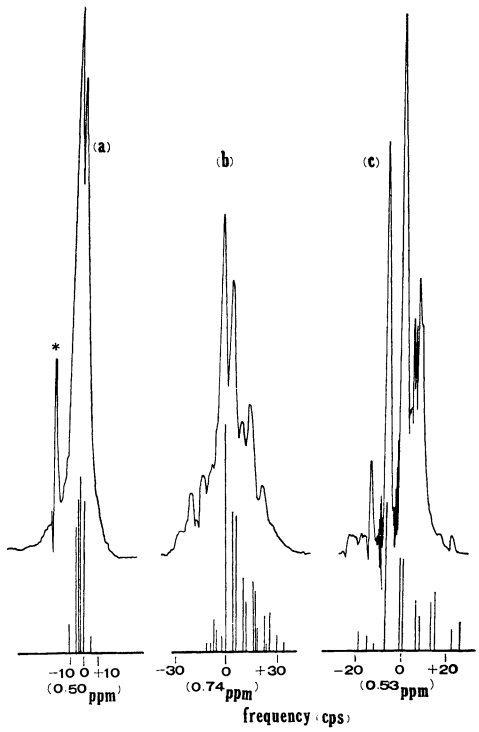

Fig. 1. $B\text{-}C_2H_5$ proton signals of (a) triethylborane, (b) trimethylamine-triethylborane and (c) triethylamine-triethylborane. The theoretical patterns are shown below. For the sake of clarity, some sets of closely spaced theoretical lines are shown by single bars. The peak marked with an asterisk is the reference line of cyclohexane. In order to increase resolution, a different sweep rate was employed for (c).

a group of weak peaks appeared on the lower field side of this peak. Presumably, some decomposition products were responsible for it. Ethyl groups in this compound yielded a complicated group of lines shown in Fig. 1b, suggesting that intermediate coupling exists rather than weak coupling, in which case one would have a simple three-four pattern for the signal of ethyl groups[7].

Triethylamine-triethylborane was studied in pure liquid state with water as an external reference. The spectrum showed a quartet at −2.13 p.p.m. attributable to methylene protons in ethyl groups bonded to nitrogen. The separation between multiplet components yielded the spin coupling constant J_{HH} equal to 6.7 c.p.s. The corresponding signal of methyl protons appeared at about 0.16 p.p.m., although the triplet structure was not very clear because of masking by BC_2H_5 signals described below. As in the spectra of the foregoing two compounds, ethyl groups bonded directly to boron gave rise to a complicated signal shown in Fig. 1c. This compound readily decomposes in the gaseous state. In fact, signals presumed to be due to some decomposition products from intensity considerations appeared between the triplet and the quartet of ethyl groups bonded to nitrogen, rendering unequivocal assignment very difficult.

Trimethylamine-trichloroborane was dissolved in chloroform and the NMR spectrum was recorded with tetramethylsilane as an internal reference. The spectrum showed a group of closely spaced lines centered at −1.57 p.p.m. in addition to a very strong peak attributable to chloroform, which was accompanied by spinning side bands and weak satellites due to $^{13}CHCl_3$. Unlike the signals of NCH_3 protons in *N*-trimethylborazoles, which were found to be rather sharp, that of this compound consisted of four almost equally spaced quartet lines separated by 2.6 c.p.s., a line at the highest field being weaker than three others. The small separation of this magnitude[2] suggests spin coupling between protons and a nitrogen nucleus separated by two chemical bonds, although the reason for the appearance of a quartet rather than a triplet is not clear.

Triethylamine-trichloroborane was dissolved in chloroform and the spectrum was taken with tetramethylsilane as an internal standard. The spectrum was comprised of a typical 1 : 2 : 1 triplet centered at 0.04 p.p.m. attributable to methyl protons in ethyl groups and a quartet centered at −2.37 p.p.m. originating from methylene protons. The spin coupling constant J_{HH} was evaluated at 7.6 c.p.s. In addition, a very strong peak due to $^{12}CHCl_3$, weak satellites arising from $^{13}CHCl_3$ and spinning side bands were recorded.

Discussion

The numerical values of chemical shifts and spin coupling constants are summarized in Table I. Those of trimethylamine[8], triethylamine[8] and borazoles[1,2] also are listed for comparison. The observed chemical shifts and spin coupling constants are of the correct order of magnitude compared with those of borazole[1,2] already studied, indicating the adequacy of the present assignments.

The observed NCH_2 and $NCCH_3$ proton chemical shifts of triethylamine, triethylamine-triethylborane and triethylamine-trichloroborane decreases in this order in agreement with increasing extent of charge transfer from nitrogen to boron due to the formation of an

N→B bond and the effect of electronegative chlorine atoms. The same trend is observed for the NCH_3 proton chemical shifts of trimethylamine, trimethylamine-triethylborane and trimethylamine-trichloroborane.

A striking difference between ammonia-boranes and borazoles is that whereas ethyl groups attached to boron in the latter compounds give rise to a single sharp signal of proton resonance, those in the former yield a group of lines showing a complicated pattern of line spacings and relative intensities. The observed ethyl signals of triethylborane, trimethylamine-triethylborane and triethylamine-triethylborane were compared with theoretical calculations by Corio[7] for an A_3B_2 spin system. In other words, further splitting of ethyl proton signals due to magnetic boron nuclei was disregarded for the following reasons. In the first place, the spin coupling constants between a boron nucleus having a small atomic number and ethyl protons across two or more chemical bonds are presumed to be small[9]. Secondly, because boron nuclei have an electric quadrupole moment, spin decoupling is presumed to take place between boron nuclei and protons. In fact, Onak et al.[10] have observed the ^{11}B nuclear magnetic resonance spectra of a number of boron compounds including triethylborane and evaluated spin coupling constants between directly bonded boron and hydrogen but not those between boron nuclei and protons separated by two or more chemical bonds. Considering possible overlap of closely spaced theoretical lines, the relative internal shifts δ (unmodified by spin interactions) between methyl and methylene proton signals and spin-spin coupling constants were evaluated as shown in Table II. Theoretical spectra calculated with these values yield a fairly good fit with experiments as shown in Fig. 1.

TABLE II. THE INTERNAL CHEMICAL SHIFTS (p.p.m.) AND THE SPIN-SPIN COUPLING CONSTANTS (c.p.s.) OF BC_2H_5 PROTONS IN TRIETHYLBORANE AND RELATED COMPOUNDS.

Compound	$\Delta CH_3-\Delta CH_2$	J	Electro-negativity of boron

$(CH_3)_3NB(C_2H_5)_3$	−0.47	7.1	1.4, 1.8*
$(C_2H_5)_3NB(C_2H_5)_3$	−0.43	7.3	1.4, 1.8*

* The modified Dailey-Shoolery equation was employed in the calculation.

Dailey and Shoolery[8] have shown that the methyl signal and the methylene signal of an ethyl group showing the characteristic three-four pattern ($J \ll \delta$)* draw together as the electronegativity of an atom bonded to the ethyl group decreases: a linear relation holds between the electronegativity and the difference, $\delta=\Delta CH_3-\Delta CH_2$, between the chemical shifts of methyl protons and methylene protons in an ethyl group.

$$\text{E.N.}=0.695(\Delta CH_3-\Delta CH_2)+1.71$$

When the difference between the chemical shifts (in frequency units) of these two groups becomes small and comparable with the spin-spin coupling constant, one has the case of intermediate coupling ($J \approx \delta$) as in triethylborane. In the extreme case in which the spin-spin coupling predominates over the effect of chemical shifts ($J \gg \delta$), a single sharp line results as in *B*-triethylborazoles[11]. When δ

* The sign of J is trivial in interpreting the present spectra. J refers to absolute values and hence is positive.
11) J. A. Pople, W. G. Schneider and H. J. Bernstein, "High-resolution Nuclear Magnetic Resonance", McGraw-Hill, New York (1959), p. 116.

decreases further to assume a negative value with its absolute value comparable with the spin-spin coupling constant, we have again the case of intermediate coupling as in trimethylamine-triethylborane and triethylamine-triethylborane. The negative internal chemical shifts between methyl and methylene protons have already been reported for aluminum triethyl, diethylaluminum chloride[12], some mercury dialkyls[13], mercury diethyl[14] and tin tetraethyl[9].

The aforementioned empirical equation first proposed by Dailey and Shoolery for electronegativity values ranging over 2.6~3.9 was found by Baker[12] to be valid approximately even for electronegativity values less than 1.71, i.e., for negative internal shifts of ethyl groups. The electronegativity of boron calculated for triethylborane and related compounds are shown in Table II along with values calculated by the modified Dailey-Shoolery equation[15], in which the constant in the original equation is changed from 1.71 to 2.10 for atoms of low electronegativity.

The present results lead to the conclusions that the formation of an N→B bond interchanges the positions of the methyl and methylene signals of triethylborane and that boron in ammonia-boranes is less electronegative than that in borazoles. This supports the view that the extent of electron transfer from nitrogen to boron in ammonia-boranes is almost the same as but slightly greater than that in borazoles.

Mention should be made in this connection that Becher[16] has determined the dipole moments of some ammonia-boranes (ammonia-trimethylborane $H_3NB(CH_3)_3$ and trimethylamine-trimethylborane $(CH_3)_3NB(CH_3)_3$) and aminoboranes (aminodimethylborane $H_2NB(CH_3)_2$ and dimethylaminodimethylborane $(CH_3)_2NB(CH_3)_2$) in benzene solutions and evaluated from them the NB bond moment in ammonia-boranes and aminoboranes (or borazenes). The former was found to amount to about 30% of the value calculated for the N→B bond. This implies that ammonia-boranes resonate between the no-bond structure $R_3N.BR_3$ and the donor-acceptor bond structure $R_3N{\rightarrow}BR_3$ (R=alkyl group), the contribution of the latter being about 30%. On the other hand, from the measurement of the diamagnetic susceptibilities of borazole and some of its derivatives, the present authors[17] have estimated the diamagnetic anisotropy of a borazole ring and concluded that the contribution of the donor-acceptor double bond structure to the normal state of borazole is 24%.

From the greater extent of the donor-acceptor bond character in ammonia-boranes than that in borazoles, one might expect that nitrogen in the former compounds is more electronegative and hence the chemical shift difference $\Delta CH_3-\Delta CH_2$ of ethyl groups attached to nitrogen is greater than the corresponding values of the latter compounds. However, as shown in Table III, the chemical shift differences of triethylamine-triethylborane and triethylamine-trichloroborane are smaller than those of hexaethylborazole and *B*-trichoro-*N*-triethylborazole, respectively. The reason for this is presumed to be twofold. In the first place, the diamagnetic ring current induced by the external magnetic field in a borazole ring makes a negative contribution[18] to the chemical shifts of protons in the same molecule. Owing to the greater distance from the ring, the effect is smaller for methyl protons than for methylene protons. As a result, the diamagnetic ring current increases the internal chemical shift of ethyl groups in borazoles, regardless of whether the ethyl groups are attached to nitrogen or boron. Secondly, although charge migration from nitrogen to boron is slightly greater in ammonia-boranes than in borazoles, electron withdrawal by nitrogen from three ethyl groups in ammonia-boranes rather than one as in borazoles, more than compensates the decrease in the electronic population of the nitrogen atom due to the formation of an N→B bond. Accordingly, the nitrogen in ammonia-boranes becomes less electronegative than that in borazole derivatives

TABLE III. THE INTERNAL CHEMICAL SHIFTS (p.p.m.) OF NC_2H_5 PROTONS IN TRIETYLAMINE, TRIETHYLAMINE-BORANES AND *N*-TRIETHYLBORAZOLES.

Compound	$\Delta CH-\Delta CH_2$	Electronegativity of nitrogen
$N(C_2H_5)_3$	1.83*	2.98
$(C_2H_5)_3NB(C_2H_5)_3$	2.29	3.30
$(C_2H_5)_3NBCl_3$	2.41	3.38
$[(C_2H_5)NB(CH_3)]_3$	2.38	3.36
$[(C_2H_5)NB(C_2H_5)]_3$	2.57	3.50
$[(C_2H_5)NBCl]_3$	2.58	3.50

as was actually found by the present investigation. This complication does not arise in discussing the BC_2H_5 proton resonance, because electron transfer between boron and ethyl groups is inappreciable as suggested by the electronegativity of boron in triethylborane, which is close to that of a free boron atom equal to 2.0. For this reason, BC_2H_5 proton signals are more suitable than NC_2H_5 signals in discussing the nature of NB bonds in ammonia-boranes and borazoles.

Coyle and Stone[19] have reported the results of measurements on the proton chemical shifts in some boron-containing addition compounds of Lewis bases and showed that the chemical shift criterion is not uniformly successful in predicting the stabilities of addition compounds. However, direct comparison between their results and the present conclusion is not feasible, because no compounds were examined both by them and by the present authors.

Summary

The proton magnetic resonance spectra of triethylborane, trimethylamine-triethylborane, triethylamine-triethylborane, trimethylamine-trichloroborane and triethylamine-trichloroborane were recorded at room temperature using an NMR spectrometer operating at 40 Mc. The assignments of observed signals were made and the chemical shifts and spin coupling constants were evaluated. The extent of electron transfer from nitrogen to boron in ammonia-boranes is slightly greater than that in borazoles.

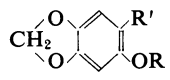
Synthetic Studies of Sesamol Derivatives. I. A New Synthesis of Ayapin

By Kenji FUKUI and Mitsuru NAKAYAMA

(Received February 23, 1962)



Ayapin, a coumarin isolated from the leaves of *Eupatorium ayapana Vent.*[1,2] is an interesting compound because of its biological activity[3]. Its chemical structure has been established by Späth, Bose and Schläger[2] as Ia, and it is the only known natural methylenedioxycoumarin. It was synthesized by the action of methylene iodide on aesculetin (6,7-dihydroxycoumarin)[2].

This paper describes an improved synthesis of Ia by two routes, that is, by the Knoevenagel and by the Perkin reaction from 2-hydroxy-4,5-methylenedioxybenzaldehyde (IIb).

I

a) R=H
b) R=$COOC_2H_5$
c) R=$COCH_3$
d) R=COOH

II

a) R=R'=H
b) R=H, R'=CHO
c) R=CH_3CO, R'=CHO

2-Hydroxy-4,5-methylenedioxybenzaldehyde (IIb), which was used as the starting material, was readily prepared from seamol (IIa)[4,5], either by formylation by the Gattermann reaction[5] or by the dimethylformamide method. The aldehyde IIb was acetylated to the 2-acetoxy-4,5-methylenedioxybenzaldehyde (IIc), m.p. 125~126°C, with acetic anhydride in the presence of pyridine or anhydrous sodium acetate.

The condensation of hydroxyaldehyde (IIb) with ethyl malonate by the Knoevenagel reaction gave ethyl 6,7-methylenedioxycoumarin-3-carboxylate (Ib), m.p. 190~191°C. On the other hand, when IIb was treated with ethyl acetoacetate in absolute ethanol, it gave 3-acetyl-6,7-methylenedioxycoumarin (Ic), m.p.

237～238°C. Compound Ib was easily converted by alkaline hydrolysis to acid (Id), m. p. 263～265°C. This acid Id was also obtained by the reaction of IIb with malonic acid, cyanoacetic acid and ethyl cyanoacetate. It was then decarboxylated in quinoline with copper powder to ayapin (6,7-methylenedioxycoumarin) (Ia), m.p. 227～228°C.

In an alternate route, Ia was prepared by the Perkin reaction. This substance exhibited no melting point depression when mixed with the above sample.

Experimental *

2 - Hydroxy - 4, 5 - methylenedioxybenzaldehyde (IIb).—*a) Dimethylformamide Method.*—To a solution of sesamol (IIa) (2.0 g.) in dimethylformamide (3.0 ml.), phosphorous oxychloride (2.0 ml.) was added drop by drop with ice cooling. The reaction mixture was heated on a steam bath for 1 hr. and frequently shaken. After being cooled in an ice bath, the solution was diluted with a saturated sodium acetate solution (ca. 50 ml.) and was heated for 0.5 hr. on a steam bath. Upon cooling of the mixture, the solid which had deposited was collected and recrystallized from ethanol to give IIb in the form of colorless needles, m. p. 125～126°C (reported m. p. 125～126°C)[6], with a blue violet ferric reaction in ethanol; yield, 1.9 g. (79%).

Found: C, 57.84; H, 3.70. Calcd. for $C_8H_6O_4$: C, 57.83; H, 3.64%.

b) Gattermann Reaction.—This aldehyde IIb was prepared from sesamol (IIa) (2.0 g.) and zinc cyanide (4.0 g.) by the Gattermann reaction[4]; m. p., 124～125°C; yield, 2.0 g. (83%). This substance showed no depression of the melting point on admixture with the specimen derived by the above-mentioned method a).

2 - Acetoxy - 4, 5 - methylenedioxybenzaldehyde (IIc).—a) A mixture of IIb (500 mg.), acetic anhydride (3 ml.) and pyridine (5 ml.) was kept at room temperature for 24 hr. and then poured into dilute hydrochloric acid. The precipitates were collected and recrystallized from ethanol to give IIc in the from of colorless needles, m. p., 125～126°C (reported m. p. 126～7°C)[7], with a negative ferric reaction; yield, 620 mg. (99%).

Found: C, 57.64; H, 3.88. Calcd. for $C_{10}H_8O_5$: C, 57.69; H, 3.87%.

b) A mixture of IIb (1.0 g.) and anhydrous sodium acetate (1.2 g.) in acetic anhydride (10 ml.) was refluxed for 4 hr. The cooled mixture was poured into water, and the precipitates were collected. This was recrystallized from ethanol to give IIc in the form of colorless needles; m. p. 125～126°C; yield, 1.0 g. (78%). This substance showed no depression of the melting point on admixture with the specimen derived by the above-mentioned method a).

Ethyl 6,7-methylenedioxycoumarin-3-carboxylate (Ib).—To a solution of IIb (2.0 g.) in pyridine (20 ml.), ethyl malonate (3.0 g.) and piperidine (5 drops) were added. The mixture was refluxed for 0.5 hr., kept at 100°C for 2 hr., and then poured into dilute hydrochloric acid (150 ml.). The precipitates were collected and recrystallized from ethanol to give Ib in the from of pale yellow needles, m. p. 190～191°C, with a strong fluorescence in concentrated sulfuric acid (green) and in ethanol (blue) and with a negative ferric reaction; yield, 2.6 g. (81%); IR; 1739 (C=O); 1029, 938 cm^{-1} (O—CH_2—O) (Nujol)[8].

Found: C, 59.97; H, 4.14. Calcd. for $C_{13}H_{10}O_6$: C, 59.54; H, 3.84%.

3-Acetyl-6,7-methylenedioxycoumarin (Ic).—To a solution of IIb (1.5 g.) in warm absolute ethanol (20 ml.), ethyl acetoacetate (1.5 g.)and piperidine (3 drops) were added. The mixture was refluxed for 5 min. After the mixture had been cooled, the crystalline products were filtered and recrystallized from ethanol to give Ic in the torm of pale yellow needles, m. p. 237～238°C (decomp.), with a fluorescence in ethanol (pale blue) and a negative frric reaction; yield, 2.0 g. (95%); IR; 1725, 1682 (C=O); 1030, 926 cm^{-1} (O—CH_2—O) (Nujol).

Found: C, 61.84; H, 3.43. Calcd. for $C_{12}H_8O_5$: C, 62.07; H, 3.47%.

6, 7 - Methylenedioxycoumarin-3-carboxylic Acid (Id).—*a) From Ib.*—A suspension of ester Ib (1.0 g.) in a 4% sodium hydroxide solution (50 ml.) was stirred for 10 hr. The resulting mixture was filtered, the filtrate was acidified with dilute hydrochloric acid, and the precipitates were collected and recrystallized from ethanol to give Id in the form of pale yellow needles, m. p. 263～265°C, with a strong fluorescence in concentrated sulfuric acid (green) and in ethanol (blue); yield, 0.7 g. (89 %); IR: 1736, 1674 (C=O); 1026, 918 cm^{-1} (O—CH_2—O) (Nujol).

Found: C, 56.43; H, 2.58. Calcd. for $C_{11}H_6O_6$: C, 56.42; H, 2.58%.

b) From IIb.—To a solution of IIb (1.0 g.) and malonic acid (1.3 g.) in pyridine (10 ml.), aniline (5 drops) was added. The mixture was heated on an oil-bath at 55°C for 4 hr. and then poured into dilute hydrochloric acid (150 ml.). The precipitates were collected and recrystallized from ethanol to give Id, m. p. 263～265°C, with a negative ferric reaction; yield, 1.0 g. (71%). This was found to be identical with the specimen obtained by method a).

c) From IIb.—A mixture of IIb (1.0 g), a 20% sodium hydroxide solution (30 ml.) and cyanoacetic acid (1.0 g.) was stirred at room temperature for 24 hr. The resulting mixture was acidified with dilute hydrochloric acid, and the precipitates were collected and recrystallized from ethanol to give Id, m. p. 260～262°C, with a negative ferric reaction; yield, 1.1 g. (78%). This was found to be identical with the specimen obtained by method a).

d) From IIb.—By a method similar to that described for Ic, the products were obtained from IIb (1.0 g.), ethyl cyanoacetate (1.0 g.), piperidine

* All melting points are uncorrected.

(3 drops) and absolute ethanol (20 ml.). Then, a mixture of the products and a 5% sodium hydroxide solution was heated on a steam bath for 8 hr. and kept at room temperature for 12 hr. The resulting mixture was filtered, and the filtrate was acidified with dilute hydrochloric acid. The precipitates were collected and recrystallized from ethanol to give Id, m. p. 263~264°C, with a negative ferric reaction; yield, 400 mg. (38%). This was found to be identical with the specimen obtained by method a).

Ayapin (6,7-Methylenedioxycoumarin) (Ia)—*a) From Id.* —A mixture of the acid (Id) (500 mg.), copper powder (500 mg.) and quinoline (20ml.) was heated while being stirred in an atmosphere of nitrogen for 20 min. at 200~220°C until the evolution of carbon dioxide ceased. The cooled mixture was diluted with ether (100 ml.), filtered and extracted with 8% hydrochloric acid. After being washed with aqueous sodium bicarbonate and then with water, the ethereal solution was dried and evaporated. The residue was recrystallized from ethanol to give Ia in the form of colorless crystals; m. p. 227~228°C (reported 231~232°C in sealed tube)[2]; yield, 350 mg. (86%); IR: 1712 (C=O); 1036, 938 cm^{-1} (O—CH_2—O)[9] (Nujol).

Found: C, 63.36; H, 3.39. Calcd. for $C_{10}H_6O_4$: C, 63.16; H, 3.18%,

9) IR spectrum of ayapin: H. Bickel and H. Schmid, *Helv. Chem. Acta*, **36**, 670 (1953).

b) From IIb.—A mixture of IIb (1.0 g.), anhydrous sodium acetate (1.5 g.) and acetic anhydride (15 ml.) was vigorously refluxed for 10 hr. The cooled mixture was poured into water, and the precipitates were collected. These recrystallized from ethanol to give Ia in the from of colorless crystals, m. p., 226~227°C, with a negative ferric reaction; yield, 700 mg. (61%). This substance showed no depression of its melting point on admixture with the specimen derived by the above-mentioned method a).

The authors are grateful to Professor M. Nakajima of Kyoto University and Professor T. Matsuura of Hiroshima University for their IR spectroscopy and to Professor T. Mitsui and his associates, Kyoto University, for their annalyses. This work was partially supported by a grant-in-aid for Scientific Research from the Ministry of Education, which is acknowledged with gratitude.

Infrared and Ultraviolet Spectra of α- and γ-Pyrones

By Kiyoyuki YAMADA

(Received February 26, 1962)

There have been known a number of pyrone derivatives; both synthetic ones and naturally occurring ones. The characteristic features of infrared and ultraviolet spectra of the pyrone nucleus itself cannot be obtained from those of benzopyrones, i. e. coumarines and chromones, owing to the presence of the fused benzene ring. It is, therefore, necessary to examine the pyrone derivatives without any fused aromatic rings, in order to obtain the spectral properties of pyrones. In connection with the investigation of aureothin[1], the studies of various pyrones without aromatic rings were carried out, and in the present paper, the spectroscopic aspects of pyrones are reported.

Infrared Spectra. — Since α- and γ-pyrones show some aromatic nature, the bands associated with the double bonds of the ring as well as carbonyl band are characteristic for the identification of pyrone rings. The effects of the substituents on these bands were examined.

α-Pyrone.—Since the position and the shape of the carbonyl band are, in many cases, sensitive to the condition of measurement[2], the band positions were compared in the same

1) Y. Hirata, H. Nakata, K. Yamada, K. Okuhara and T. Naito, *Tetrahedron*, **14**, 252 (1961).

2) As to α-pyrone and 5-methyl-α-pyrone, Jones and his coworkers[3] observed anomalous absorption in the carbonyl stretching region; the single absorption band expected for these compounds is replaced by two bands, the relative intensities of which are dependent on the solvent polarity and temperature. Various interpretations including Fermi resonance were presented but they could not reach any conclusion regarding this phenomenon.

solvent. The carbonyl frequency was reported[4,5] to be in the range of 1720~1750 cm^{-1}, and the variance in the band position is mainly due to the substituents, as illustrated later. As characteristic bands of α-pyrones, there appear two bands arising from the double bonds of the ring; one lies usually within the range 1650~1630 cm^{-1}, and the other within 1570~1520 cm^{-1}. In general, the lower band shows stronger intensity than the higher one, but the reverse is sometimes observed (4, 6-dimethyl-3-bromo-α-pyrone, methyl coumalate). The infrared spectra of substituted α-pyrones are shown in Fig. 1. In comparison with the conjugated systems of ketones and lactones, the effect of the substituent on the position of a carbonyl band is unique in some respects, which may be ascribed to the aromatic character of the pyrone ring. While an electron-donating substituent conjugated with a $>C=O$ group has a small influence on the carbonyl band (i.e., variance of $\nu_{C=O}$ in No. 2→No. 4 and No. 3→No. 5 in Fig. 1), an electron-attracting group shifts the carbonyl band to a higher frequency[6]. (Changes of $\nu_{C=O}$ in No. 1→No. 9 and No. 1→No. 10. $\nu_{C=O}$ of the type I was reported[8] to fall within 1760~1750 cm^{-1}). When the

substituent R_3 in Fig. 1 is an ester group (No. 9, No. 10), there appear two carbonyl bands, one of which at higher frequency is considered to be a band due to a pyrone carbonyl group. It has been known that halogen substitution in the alpha position of a carbonyl group results in a high-frequency shift of the carbonyl absorption as illustrated in α-haloketones[9], α-halo-esters[9] and $\Delta^{\alpha,\beta}$-α-halo-γ-lactone[10]. This general finding is expected for 3-bromo-α-pyrone derivative, but in fact this phenomenon was not an actual case and there was an indication that α-bromination rather resulted in a lowering of a carbonyl frequency[11] (see $\nu_{C=O}$ change in No. 2→No. 3 and No. 4→No. 5 in Fig. 1). This fact would be explicable if a factor leading to a low-frequency shift of $\nu_{C=O}$ (plausible one is +M effect of bromine[12]) is operative in addition to the dipole-dipole interaction which causes a high-frequency shift of carbonyl band. This apparent anomaly is not observed, when the more electronegative substituent is introduced into an α-position of carbonyl group (3-nitro-α-pyrone derivatives), and in this case $\nu_{C=O}$ appears at fairly high frequency region. The effects of substituents on the bands related to the double bonds of pyrone ring seem to be complicated, but the clear points worthy of mention are that two bands appear in every case examined and that the band at a higher frequency is insensitive to the introduction of the substituent whereas the other is deeply influenced. As mentioned before, the carbonyl band differs in shape and position according to the condition of measurement—that is, solution or solid state. A remarkable example is triacetic lactone (II) (No. 6 in Fig. 1), the infrared spectrum of which taken in a solid state is complex in comparison with that in dioxane[13]. Two tautomeric forms IIa, IIb are possible for this compound and it is evident

IIa IIb

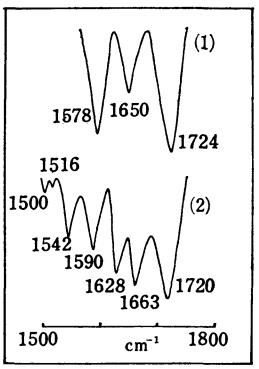

Fig. 2. Infrared spectra of triacetic lactone. (1) Dioxane (2) KBr

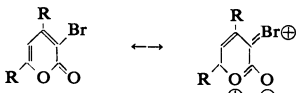

that IIa is an overwhelmingly predominant form in solution on the infrared and ultraviolet evidence (see Fig. 1 and Table I). In the solid state, II exhibits a complicated pattern of bands in 1800～1500 cm^{-1} region as shown in Fig. 2, and the bands due to strong hydrogen bonds are observed. It should be noted that a spectrum of II is similar to that of methyl-ether of IIa (No. 4 in Fig. 1) in 1000～700 cm^{-1} region.

γ-Pyrone.—As in α-pyrone series, the most characteristic frequencies available for detection of a γ-pyrone ring arise from carbonyl and C=C double bond vibrations. Usually a band near 1660 cm^{-1} (first band) is believed to originate from the carbonyl group[4h,14] and the bands (second and third bands) observed in 1650～1560 cm^{-1} would correspond to the double bonds of γ-pyrone (see Fig. 3). However, intense couplings among $\nu_{C=C}$ and $\nu_{C=O}$ might occur in the compound of this series and the definite assignments of the bands are therefore difficult[15]. According to the data available from literatures[4h,14] and in Fig. 3, the introduction of a substituent makes but a small influence on the position of the first band near 1660 cm^{-1} and no significant change on this band was observed under various conditions of measurement. Though the carbonyl absorption of γ-pyrone itself shows the doublet peaks, no such phenomenon was found on the substituted γ-pyrones examined. In general, there appear two bands (the second band, the third band) associated with the double bonds. In comparison with those of α-pyrone series, the two bands are separated to a smaller

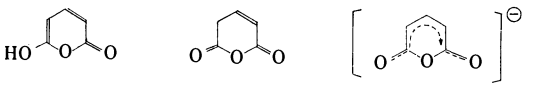
* KBr



extent and their relative intensities to that of the carbonyl band are fairly strong.

Ultraviolet Spectra. — *α-Pyrone.* — Ultraviolet spectra of a few α-pyrones were already reported[4h,7,16], especially 6-methyl-4-hydroxy-α-pyrone[17]. In order to avoid the factors of conjugation and/or strain, α-pyrone derivatives examined in the present study are those without fused rings—aromatic or alicyclic. In Table I are listed the ultraviolet spectra of various α-pyrones. Almost all the compounds recorded in Table I have their maxima near 300 mμ, and in some type of the substituted pyrones, the second absorption maximum with the higher intensity appears in the short wavelength region (250 mμ). In general, the introduction of substituents such as alkyl, carbonyl, bromine, etc. causes a bathochromic shift of the absorption band near 300 mμ.

γ-Pyrone. — The absorption maxima of γ-pyrones appear in the shorter wavelength region (near 250 mμ) in comparison with those of α-pyrones. In Table II are shown absorption maxima of some γ-pyrone derivatives. The properties of the substituents are not so widely varied in the present study as well as in the compounds already reported[16c,18], as to permit to infer the substituent effect on the ultraviolet absorption.

On the Structural Problems of Some Pyrone Derivatives.—With these spectral characteristics at hand, the structural problems of pyrones are easily solved in some cases.

1) Tautomerism of Glutaconic Anhydride. — Glutaconic anhydride (III) and its derivatives have been assigned 6-hydroxy-α-pyrone structure (IIIa) on evidence from their chemical behaviors[19].

IIIa IIIb IIIc

In the infrared spectra of III, bands appeared at 1805, 1740, 1650 cm^{-1} in the solid state (KBr) and at 1800, 1760, 1650(w) cm^{-1} in chloroform solution and no hydroxyl bands were observed. Thus, it becomes evident that glutaconic anhydride exists as normal anhydride form IIIb in the solid state and chloroform solution. This conclusion is supported from the fact that no strong absorptions ascribable to α-pyrone structure IIIa were detected in the ultraviolet region (chloroform solution). In contrast to the transparency of III in chloroform solution, the ultraviolet absorptions with high intensities (λ_{max} 350 mμ, log ε, 4.21 ; 233 mμ, log ε, 3.91) were observed in ethanol, which are expected and accounted for by assuming the presence of the anion IIIc, since III is strongly acidic and hence is likely to dissociate in polar solvent such as

8		CH_3	CH_3	OCH_3	263 (248	3.90 3.84)

* Measurements were made in ethanol. A figure in parenthesis shows a position of the shoulder of the absorption.

ethanol. Upon addition of a drop of hydrochloric acid, the absorption maximum at 350 mμ disappeared and instead the new absorption appeared at 328 mμ (log ε, 3.04). Considering the α-pyrone structure IIIa, the new absoption, though quite reasonable as to its position, is unusually weak in intensity, implying that the equilibrium between two undissociated forms IIIa, IIIb is in favor of keto-form IIIb even in the polar solvent and

a fraction of an enol form IIIa is small[20].

2) Structures of Triacetic Lactone Derivatives.—Both α- and γ-pyrone forms are possible for the 2, 4-pyronone system and it is a matter of importance, which of the two predominates in various substituted 2, 4-pyronones. As shown before, triacetic lactone (No. 6 in Fig. 1) exists as an α-form and the same result was obtained on 4-hydroxycoumarin[21], while the preferential existence of γ-form under the subtle influences of substituents and fused rings was reported[4h,22] in some derivatives of 2, 4-pyronone. There was some confusion as to the structures of triacetic lactone methylether, but two isomers were unambiguously isolated and assignments of the isomers to α- and γ-forms were carried out[23]. As one of the problems regarding the isomeric α- and γ-pyrones, Arndt and Avan reported the methylethers of 3-bromotriacetic lactone and 3-nitrotriacetic lactone[24]. It is evident from the spectral viewpoints (Fig. 1 and Table I) that α-pyrone structures are assigned to 3-bromotriacetic lactone (IV) and 3-nitrotriacetic lactone (V)[25], to which no structural reference was made by Arndt et al. Methylation of IV and V under conditions employed by Arndt et al., gave corresponding methylethers VI, VII.

IV : R=Br VI : R=Br VI′ : R=Br
V : R=NO_2 VII : R=NO_2 VII′ : R=NO_2

Arndt and Avan assigned γ-pyrone structures VI′, VII′ to these methylethers on the basis of their solubilities to concentrated hydrochloric acid. However, this conclusion is unacceptable. The infrared spectrum of bromo-derivative VI in solution is, as shown in Fig. 1, typical of α-pyrone structure and also in solid state the same is true (bands at 1703, 1640 and 1522 cm^{-1}). The ultraviolet spectral result also favors the α-pyrone structure for VI (λ_{max} 305 mμ, log ε, 3.95). Similarly, α-pyrone structure is established for nitro derivative (VII) from the infrared (bands at 1735, 1644, 1543 and 1525 cm^{-1} in chloroform) and ultraviolet (λ_{max} 310 mμ, log ε, 3.68 : 300 mμ, log ε, 3.75) spectral data. Accordingly, the methylethers obtained by Arndt et al., in fact, have α-pyrone structures.

Experimental

Infrared spectra were measured with a Hilger H 800 Model. The ultraviolet spectra were measured with a Beckman DK-2 spectrophotometer.

Synthesis and Characterization of Compounds.—*Dehydroacetic Acid (No. 12 in Fig. 1).*—Commercial sample recrystallized from ethanol, m. p. 107～108°C.

Summary

Effects of substituents on the characteristic bands of pyrones were examined in the infrared spectra. Ultraviolet spectra of various α- and γ-pyrones were recorded and the application of the spectroscopic results obtained, disclosed the problems of tautomerism and isomerism concering some of the pyrone derivatives.

The author is greatly indebted to Professor Yoshimasa Hirata of this University of his guidance and encouragement in this work and is also grateful for the fellowship from Parke Davis & Co., Michigan, U. S. A. This work was supported by a research grant from the Ministry of Education, to which the author's thanks are due.

Reduction of Pyrones with Complex Metal Hydrides[1]

By Kiyoyuki YAMADA

(Received February 26, 1962)

It has been known that α- and γ-pyrones have an aromatic character which is reflected on their physical properties—for example, their infrared spectra. The aromatic nature of γ-pyrone is also reflected on its chemical properties; in comparison with a normal ketone, carbonyl group of γ-pyrone is generally unreactive, which is illustrated by the fact that γ-pyrone does not form 2, 4-dinitrophenylhydrazone[2]. However, condensation of γ-pyrone with an active methylene compound was reported[3] and in this case γ-pyrone reacted as a normal ketone. α-Pyrone behaves as α, β-γ, δ-unsaturated lactone[2] in various reactions including ozonization, hydrolysis, catalytic hydrogenation[4] and Diels-Alder reaction. So far, little is known about the reduction of α- and γ-pyrones with various complex metal hydrides except for limited examples of benzo-α-[5,6], benzo-γ-pyrones[7] and xanthone[8]. In case of benzo-α-pyrones, the formation of diol expected for the usual reduction of a lactone was reported. An α-pyrone derivative was known to be unreactive towards sodium borohydride under mild condition[9]. As to benzo-

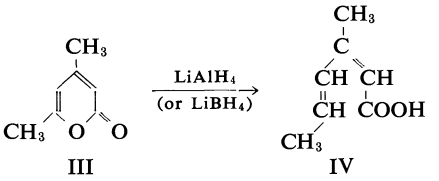
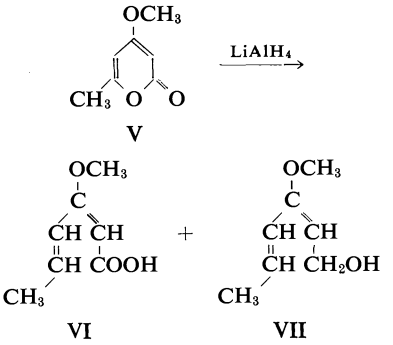
γ-pyrone derivatives[7], it was reported that the expected reduction of a ketone group to γ-pyranol took place.

In isoaureothamine (I) which is one of the derivatives of natural nitro compound aureothin[10], the presence of an α-pyrone ring was inferred from infrared and ultraviolet spectral data. Treatment of I with sodium borohydride or lithium borohydride led to a product aminol H, which was acidic and still showed a carbonyl band in the infrared spectrum[11]. Later, structure II was assigned to aminol H[12]. This would be regarded as unusual reduction product if α-pyrone moiety of I is expected to behave like a lactone. Admitting the correctness of the structure II, there remained a problem whether or not this unexpected reduction occurred under the influence of other part of the molecule.



(I)

(II)



The result obtained in the reduction of isoaureothamine (I) is, thus quite different from those in benzo-α-pyrones, suggesting that the presence of the fused benzene ring in benzo-α-pyrone would account for this difference. From this viewpoint, monocyclic α-pyrones were prepared and their reductions with various complex metal hydrides were examined.

Reduction of α-Pyrones.—Firstly, reduction of 4, 6-dimethyl-α-pyrone (III) was carried out as a simple and standard α-pyrone. On treatment with sodium borohydride under various conditions (temperature, 20, 50, 70°C: solvent, ethanol or tetrahydrofuran) no reaction took place, though the reaction conditions employed in the present study were more drastic than that of Bharucha et al.[9] Lithium borohydride treatment of III in tetrahydrofuran, though a considerable amount of III was recovered, gave a reduction product identified as β-methylsorbic acid (IV) from the melting point and elemental analysis. When the more powerful reducing reagent, lithium aluminum hydride was used, the acid IV was obtained from III in fairly good yield (about 60%) and hence the recovery of III was decreased in amount (ca. 20%) as compared with lithium borohydride treatment.

III IV

Secondly, 6-methyl-4-methoxy-α-pyrone (V) was employed in the reduction reaction. The enhanced reactivity of V towards reducing reagents is evident from the following results. Even on treatment with sodium borohydride in ethanol, β-methoxysorbic acid (VI) was obtained from V, besides a large amount of starting material. Considerable amount of VI was produced from V in the reduction using lithium borohydride together with a small amount of starting material. Lithium aluminum hydride reduction of V afforded the acid VI in rather poor yield and the neutral product VII, which turned out to be a diene-alcohol derived from VI by further reduction of carboxyl group to hydroxymethyl group[13].

V VI VII

A large excess amount of lithium aluminum hydride (molar ratio, V/$LiAlH_4$=1/2) was used in the reduction of V, and the formation of VII becomes predominant with a raise of temperature (Table I).

Since the product ratio VII/VI is sensitive to the reaction conditions, it was necessary to carry out the experiments shown in Table I under the same concentrations and the same mode of addition, i.e., "inverse" addition method[14]. In order to get an information on the product ratio VII/VI from the other point of view, the influence of the relative amount of lithium aluminum hydride to V was examined (Table II). As indicated in Table II, large excess amount of lithium aluminum hydride

25~27	3.00	1.81	0.24	1.11	5.1
48~50	3.00	1.82	0.01	2.15	238

a) Molar ratio
b) Starting material V was partly recovered.

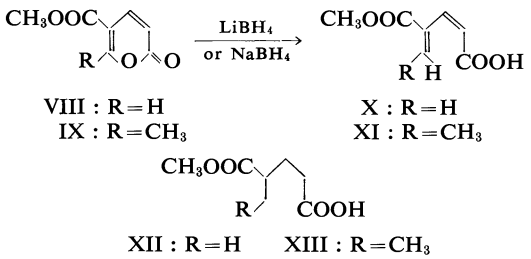

Table II. Reduction of 6-methyl-4-methoxy-α-pyrone. Dependence of product proportions on the amount of lithium aluminum hydride

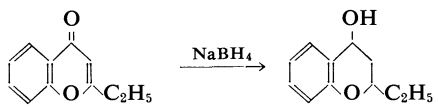
Temp. °C	Reactant V mg.	Reactant $LiAlH_4$[a] mg.	Product VI mg.	Product VII mg.
10~12	280	45	90	—[b]
58~60	280	48	85	—[c]
10~12	280	110	84	(50)[d]
58~60	280	115	50	(60)[d]
10~12	280	220	65	140
58~60	280	220	Trace	205

a) The purity of $LiAlH_4$ was determined before use (Ref. 13, p. 8).
b) The formation of VII was very small in amount. As a neutral fraction, starting material (80 mg.) was recovered.
c) VII was detected by infrared spectrum, but the main part of the neutral fraction (110 mg.) was V.
d) In these cases, the neutral fraction was a mixture of VII and V and, on account of incomplete separation of two compounds, these figures would overestimate the amount of VII.

is markedly effective for the production of the alcohol VII even at rather low temperature. When the different mode of addition, normal addition[14] was applied in the reduction of V with lithium aluminum hydride, the acid VI and a neutral fraction were obtained. From the infrared analysis, this neutral fraction was shown to be a mixture of a ketonic compound[15] and the alcohol VII.

Further, methylesters of coumalic acid and 6-methylcoumalic acid, VIII, IX were treated with lithium borohydride and sodium borohydride. These α-pyrones showed enhanced reactivities and especially methyl coumalate VIII was so reactive as to form immediately a deeply colored complex near 0°C with lithium borohydride. The product was ester-carboxylic acid in each case. From the infrared and ultraviolet spectral evidence, structure X and XI were assigned to the products. These were further supported by the fact that the reduced products X, XI could by catalytic hydrogenation be led to XII and XIII, obtained[16] directly by catalytic hydrogenation of VIII and IX respectively (identification by comparison of infrared spectra).



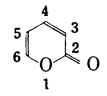
VIII : R=H
IX : R=CH3

X : R=H
XI : R=CH3

XII : R=H XIII : R=CH3

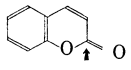
In order to avoid reduction of the ester group of the side chain, an experiment using lithium aluminum hydride was not undertaken.

Reduction of Benzo-γ-pyrone.—From the infrared evidence, a carbonyl group of monocyclic γ-pyrone in aureothin was reported[11] to be reduced with lithlum borohydride, but the structure of product is still uncertain. In connection with the reduction of aureothin, 2, 6-dimethyl-γ-pyrone (XIV) was treated with complex metal hydrides ($LiAlH_4$, $LiBH_4$) to give a liquid mixture from which no definite compounds could be isolated[17]. While the monocyclic γ-pyrone (XIV) was inert to sodium borohydride, benzo-γ-pyrone showed an enhanced reactivity and was reduced with this reagent, as follows. Treatment of 2-ethylchromone (XV) with sodium borohydride under the same condition as employed in XIV, gave 2-ethyl-4-hydroxychroman (XVI).



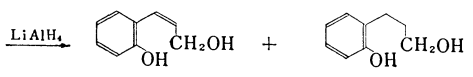
XV XVI

When treated with lithium borohydride, XV afforded, in addition to XVI, an oily product, the formation of which increased further with lithium aluminum hydride reduction.

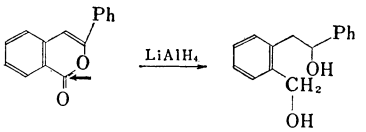


14) N. G. Gaylord, "Reduction with Complex Metal Hydrides", Interscience Publishers Inc., New York (1956), p. 1008.
15) In spite of the repeated experiments under various conditions, this compound was produced in poor yield. Though the structure is still ambiguous on account of difficulties in separation and purification, this would arise from the reduction of 1, 2-linkage of V, which means the normal lactonic behavior of α-pyrone.
16) J. Fried and R. C. Elderfield, *J. Org. Chem.*, 6, 566 (1941).
17) Main fraction of the products showed a strong band at 1710 cm^{-1}.

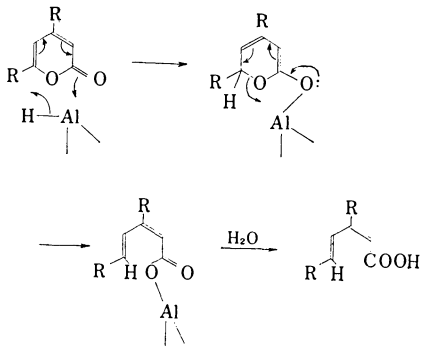
Discussion



Reduction with complex metal hydride is considered as nucleophilic reaction involving hydride ions, though the active entity during the reduction process is still uncertain. Nucleophilic attack of hydride ion at 2-position of α-pyrone led to the same result as encountered in a usual lactone and, in fact, this mode of



reaction is found in lithium aluminum hydride reductions (hydride ion as a nucleophile) and Grignard reactions (carbanion as a nucleophile) of benzo-α-pyrones XVII[5,6], XVIII[18].



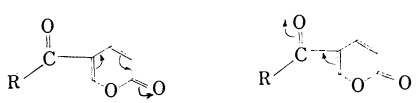
XVII

XVIII

A reaction of monocyclic α-pyrone with Grignard reagent involving an attack at 2-position of an α-pyrone was reported[19] recently, while, as described in this paper, the results of reduction of monocyclic α-pyrones with complex metal hydrides are unique, i.e., a general type of reduction of monocyclic α-pyrone with complex metal hydride reagent is a hydrogenolytic cleavage of 1, 6-linkage to afford an α, β-γ, δ-unsaturated carboxylic acid. This result is, at first sight, unexpected for the lactonic property of α-pyrone but can be explained as follows. According to the concept of vinylogy in reaction, possible points of attack by a nucleophile are 2-, 4- and 6-positions of an α-pyrone. In a complex metal hydride reduction, an attack of hydride to 6-position (1, 6-conjugate addition) occurs selectively and then the redistribution of electrons under the participation of metal ion takes place to afford a carboxylic acid, as shown in the scheme.

The difference of the reaction centers of monocyclic α-pyrone between hydride reduction and Grignard reaction[19] would be accounted for by considering the bulkiness of the reagent and/or a role of metallic ion involved in each reaction. Though a role of metallic ion in the hydride reduction is important, a precise mechanism of its participation during the reaction is not clear and hence aluminum is tentatively shown in the scheme as an electron acceptor. A high reactivity at 6-position of an α-pyrone is expected to be furthermore increased by introducing an electron-attracting substituent at 5-position[20], and this is encountered in the coumalic acid derivatives which were reduced under mild conditions.

In benzo-α-pyrone, carbon-carbon double bond of α-pyrone constitutes a part of benzene skeleton and the electronic displacement illustrated in the scheme would be accomplished with reluctance or prohibited[21], thus leading to a preferential attack of a nucleophile at a lactone-carbonyl carbon.



In the reduction of V, there were obtained an acid VI and an alcohol VII, and the amount of VII increased with a raise of temperature, when a large excess of hydride reagent was used—this is an expected result. The relative amount of the reducing reagent to V was found to have a more remarkable effect on the product proportions VI, VII, than temperature change. In the present case, reduction of COOH→ CH_2OH is sensitive to the amount of the reagent (Table II).

Reduction of 2-ethylchromone (XV) takes place under milder conditions, than in case of

19) R. Gompper and O. Christmann, *Chem. Ber.*, **94**, 1784 (1961).

20) Electropositive property of 6-position is increased by an addional effect of electronic displacement in B besides A.

(A) (B)

21) In other words, an electropositive character at 6 position of monocyclic α-pyrone is weakened in benzo-α-pyrone system by supply of electrons from a benzene ring.

monocyclic γ-pyrone (XIV), indicating that a carbonyl group of XV loses an inert character of γ-pyrone carbonyl and instead has a property of a usual conjugated ketone. In case of XV, the first stage of the reaction is, of course a conjugate addition (1, 4-addition) of hydride ion, followed by further reduction of the ketone group.

Experimental

The infrared spectra were measured with a Hilger H 800 Model and Nihonbunko model IR-S. The ultraviolet spectra were measured with a Beckmann DK-2 spectrophotometer.

4, 6-Dimethyl-α-pyrone. — Prepared from ethyl acetoacetate[22]. M. p. 48~49°C.

Reduction of 4, 6-Dimethyl-α-pyrone.—*a) Sodium Borohydride.*—To an ethanolic solution (10 ml.) of 500 mg. of sample was added 300 mg. of sodium borohydride. The mixture was kept at 70°C for 2.5 hr. After cooling, a small amount of hydrochloric acid was added, and on removal of the solvent at reduced pressure, the residue was extracted with ether. The ethereal solution was dried with anhydrous sodium sulfate and after filtration, ether was removed to afford colorless crystals (460 mg.), m. p. 45~48°C which were identified as starting material. To the residue was added hydrochloric acid until the solution became strongly acidic and the aqueous solution was extracted with ether. From this ethereal solution, the expected carboxylic acid IV could not be obtained. The same procedure was repeated at 50 and 20°C only to recover a starting material. When tetrahydrofuran was employed as solvent, sodium borohydride was suspended in it.

b) Lithium Borohydride.—A suspension of lithium borohydride in tetrahydrofuran (240 mg./10 ml.) was added to a solution of a sample in tetrahydrofuran (720 mg./10 ml.) and the mixture was kept under reflux for 3 hr. The solution became yellow and turbid. After removal of the solvent under reduced pressure, 5 ml. of water was added to decompose the formed complexes and excess reagent. The aqueous solution was extracted with ether (50 ml.). From this ethereal layer, starting material was recovered. On acidification of the aqueous layer with hydrochloric acid, a white precipitate appeared, was collected and recrystallized from benzene, 120 mg. M. p. 97~98°C (reported 98~99°C)[23]: this acid proved to be β-methylsorbic acid.

Found: C, 67.00; H, 8.10. Calcd. for $C_7H_{10}O_2$: C, 66.64; H, 7.99%.

UV: λ_{max}^{EtOH}, 260 mμ (log ε, 4.22).

c) Lithium Aluminum Hydride.—To a solution of 5.0 g. of a sample in tetrahydrofuran (15 ml.) was gradually added a suspension of 1.0 g. of lithium aluminum hydride in tetrahydrofuran (30 ml.). The mixture was stirred at 40°C for 4 hr. After cooling, the solvent was removed under reduced pressure and water was added to decompose complexes and excess reagent. The aqueous solution was extracted with ether and starting material (1 g.) was recovered from this ethereal layer. After filtration, the aqueous layer was acidified with hydrochloric acid to afford white crystals which was identical with an acid obtained with lithium borohydride treatment, yield 3 g.

6-Methyl-4-methoxy-α-pyrone.—Triacetic lactone was prepared from dehydroacetic acid with concentrated sulfuric acid at 130°C. Treatment of triacetic lactone with ethereal diazomethane gave 6-methyl-4-methoxy-α-pyrone contaminated with a small amount of isomeric γ-pyrone.

After separation[24] of γ-isomer, 6-methyl-4-methoxy-α-pyrone melted at 83~85°C.

Reduction of 6-Methyl-4-methoxy-α-pyrone.—*a) Sodium Borohydride.*—To a solution of 500 mg. of sample in ethanol (10 ml.) was added a solution of 300 mg. of sodium borohydride. The mixture was worked up in a manner identical with that used for 4, 6-dimethyl-α-pyrone. From the ethereal layer, starting material was recovered (350 mg.). To the residue was added 5 ml. of water and after filtration, aqueous solution was acidified with hydrochloric acid to give a white solid. Recrystallization from benzene gave colorless prisms (β-methoxysorbic acid), 25 mg., m. p. 146~148°C (reported 152°C (decomp.)[25]).

Found: C, 59.17; H, 7.13. Calcd. for $C_7H_{10}O_3$; C, 59.14; H, 7.09%.

UV: λ_{max}^{EtOH}, 264 mμ (log ε, 4.1).

b) Lithium Borohydride.—To a solution of 500 mg. of sample in tetrahydrofuran (10 ml.) was added 300 mg. of lithium borohydride in tetrahydrofuran (10 ml.) and the mixture was kept under reflux for 1 hr.

After removal of the solvent, 5 ml. of water was added to decompose yellow complexes. The aqueous solution was extracted with ether (40 ml.). From the ethereal layer was obtained an oily product, which gradually solidified and was identified as starting material (80 mg.). The aqueous solution was acidified to give a white precipitate which was collected, dried and recrystallized from benzene, m. p. 147~149°C (β-methoxysorbic acid), 305 mg.

c) Lithium Aluminum Hydride. — To a solution of 4.5 g. of sample in anhydrous tetrahydrofuran (60 ml.) was added with stirring a solution of lithium aluminum hydride (2.6 g.) in tetrahydrofuran (50 ml.) gradually. The mixture was kept at 30°C for 2 hr. Greenish precipitates appeared and the solution became yellow. Water was added carefully and the precipitates were removed by filtration.

The filtrate was concentrated to give an aqueous solution (an alcohol VII separated from the aqueous layer).

The aqueous solution was extracted with 150 ml. of ether. From the aqueous layer, β-methoxysorbic acid was obtained, 820 mg. The ethereal solution was dried with anhydrous sodium sulfate and the

solvent was removed to give a yellow liquid, of 3.1 g. This was fractionally distilled under reduced pressure in a small apparatus. Almost the whole part of the liquid was distilled between 100~104°C 16 mmHg. This was again distilled, yielding a colorless liquid, b. p. 102~104°C/16 mmHg.

IR, 3600, 3470(br.), 1665, 1605 cm^{-1} ($CHCl_3$) : UV, λ_{max}^{EtOH}, 239 mμ (log ε, 3.9).

Found : C, 65.92; H, 9.60. Calcd. for $C_7H_{12}O_2$: C, 65.59; H, 9.44%. Methoxyl analysis (Zeisel) : 0.93 group.

This liquid was obtained also from β-methoxysorbic acid (500 mg.) and lithium aluminum hydride (200 mg.) in tetrahydrofuran (20 ml.) at 40°C for 30 min. This substance is 3-methoxy-2, 4-hexadienol and is rather unstable when exposed to air and light and becomes colored and viscous.

d) Experiment on Table II.—When reduction of V was carried out using various amounts of lithium aluminum hydride, it was sometimes necessary to separate V from VII in a mixture of neutral fraction. Though complete separation was difficult, a small difference of solubility of carbon tetrachloride was used for the separation. The extent of separation was checked by infrared spectrum.

e) Reduction using a Normal Addition. — To a solution of 800 mg. of lithium aluminum hydride in 20 ml. of tetrahydrofuran was added 2.0 g. of a sample of tetrahydrofuran (40 ml.). The mixture was kept at 30°C with stirring for 2 hr. The reaction mixture was worked up in the same manner as described in the inverse addition method and β-methoxysorbic acid (280 mg.) was obtained.

The neutral fraction (1.1 g.) showed a carbonyl band at 1710 cm^{-1} in addition to the bands at 1665 and 1605 cm^{-1} of VII and is positive for iodoform test.

Methyl Coumalate.—Coumalic acid was treated with 1.5 equivalent amount of ethereal diazomethane, m. p. 71~72°C.

Methyl 6-Methylcoumalate.—Coumalic acid was treated with a large excess amount of diazomethane (3~4 mol. equiv.) at room temperature. M. p. 83~85°C.

Reduction of Methyl Coumalate.—To a solution of 460 mg. of sample in 10 ml. tetrahydrofuran was added 100 mg. of lithium borohydride in 10 ml. tetrahydrofuran under cooling. The solution immediately turned yellow and then became brown. After 20 min., the mixture became dark-red and brown complexes appeared. After removal of the solvent, water (20 ml.) was added and the brown solution was extracted with ether. From the colorless ethereal layer nothing could be obtained. Yellow aqueous solution was acidified with 4 N sulfuric acid. The solution was tubid and extracted with ether (40 ml.). From the ethereal solution, a slightly yellow liquid was obtained (420 mg.). Infrared spectrum, 1725(sh), 1705, 1650(w), 1610 (w) cm^{-1} (film). UV, λ_{max}^{EtOH}, 263 mμ.

Neutralization of the liquid with sodium bicarbonate (or triethylamine) gave a solid, which showed bands at 1720, 1590(s) cm^{-1}. Catalytic hydrogenation (PtO_2 as catalyst) of this liquid in methanol, gave, after uptake of about two equivalent moles of hydrogen, a liquid which was chromatographed on silicic acid. The main fraction thus obtained was identical with liquid obtained[16] by direct hydrogenation of methyl coumalate by infrared comparison. The same result was obtained, when the sample (500 mg.) was treated with sodium borohydride (200 mg.) in ethanol (20 ml.) at room temperature.

Reduction of Methyl 6-Methylcoumalate.—To a solution of 670 mg. of sample in 10 ml. of tetrahydrofuran was added 110 mg. of lithium borohydride in 10 ml. of tetrahydrofuran at room temperature (10~15°C). The solution became yellow and then orange red. The same procedure as described in methyl coumalate was employed.

Reduction of 2-Ethylchromone.—To an ethanolic solution (200 ml.) of 1.04 g. of sodium borohhydride was added 2.06 g. of 2-ethylchromone[26] in ethanol (50 ml.) and the mixture was kept under reflux for 3 hr. The solvent was removed under reduced pressure, and the extraction with ether was repeated. Concentration of ethereal solution gave an oil which gradually solidified. The solid was recrystallized from petroleum ether to give white feathery needles, 1.3 g., m.p. 77~78°C (reported for 2-ethyl-4-hydroxychroman, 78~79°C[27]).

Found : C, 74.19; H, 7.83. Calcd. for $C_{11}H_{14}O_2$: C, 74.13; H, 7.92%.

Summary

Reduction using complex metal hydrides was carried out on monocyclic α-pyrones and benzo-γ-pyrone. It was established that generally the hydrogenolysis of the 1, 6-linkage of an α-pyrone ring occurred. In benzo-γ-pyrone, carbon-carbon double bond and ketone were reduced. The effects of the substituents on the reactivity of α-pyrone were discussed.

The author is greatly indebted to Professor Yoshimasa Hirata of this University for his guidance and encouragement throughout this work and also expresses his gratitude to Mr. M. Ishizaka and Mr. Y. Kato for their technical assistance. The author is grateful for the fellowship from Parke Davis and Co., Michigan, U. S. A. This work was supported by a research grant from the Ministry of Education, to which the author's tkanks are due.

The Stereochemistry of Deoxynupharidine: The Absolute Configuration of Deoxynupharidine[1]

By Munio KOTAKE, Ichiro KAWASAKI, Tadashi OKAMOTO, Shigeru MATSUTANI, Shiro KUSUMOTO and Takeo KANEKO

(Received February 27, 1962)

In 1956, Kotake, Kusumoto and Ohara[2] assigned structure I to deoxynupharidine, an alkaloid isolated from the roots of the water lily *Nuphar japonicum*, DC., and a compound that seemed to have the same structure was synthesized[3]. Though the infrared spectrum of synthetic deoxynupharidine could almost be superimposed on that of the natural product, a slight difference was found in the fingerprint region. Since the 2-[5-methyl-pyridyl-(2)]-5-[furyl-(3)]-pentane obtained by the dehydrogenation of the synthetic sample had an infrared spectrum identical with that obtained from natural deoxynupharidine by the same procedure, the synthetic deoxynupharidine was probably a mixture of diastereomers. In this paper the determination of the absolute configuration of deoxynupharidine by means of a conformational analysis using the NMR spectrum is reported on.

1,7-Dimethylquinolizidine (III) (defuryldeoxynupharidine) was obtained by the sodalime distillation of nupharidinic acid hydrochloride, which was obtained by the oxidation of deoxynupharidine. On the other hand, the methyl ester of II was reduced with lithium aluminum hydride to alcohol IV, which was converted with thionyl chloride to chloro compound V, and V was then reduced with palladium on charcoal to 1, 4, 7-trimethylquinolizidine (VI), which has a 4-methyl group in place of the β-furyl group of deoxynupharidine. Nitrile VII, obtained from chloro compound V by treatment with sodium cyanide, was hydrolized and esterified to VIII. Methyl ester VIII was reduced with lithium aluminum hydride to 1, 7-dimethyl-4-hydroxyethylquinolizidine (IX). In this compound IX, an equatorial hydroxyethyl group would make intramolecular hydrogen bonding between the hydroxyl and nitrogen possible. Actually, the absorption band of the hydroxyl group of IX in the infrared region appeared at 3260 cm^{-1} (in carbon tetrachloride), and a dipole moment of 2.63 D was found[4]. These results suggested that compound IX had an equatorial hydroxyethyl group.

Recently, the determination of the conformation of methylquinolizidine by means of the NMR spectrum has been reported on briefly[5]. Independently, we have prepared 1-, 3- and 4-methylquinolizidines with a definite conformation, and their NMR spectra have been compared in order to determine the configuration of deoxynupharidine with those of di- and trimethylquinolizidines, III and IV.

The preparation of the diastereomer of 1-methylquinolizidine was as follows: diethyl 2-[pyridyl-(2)]-allylmalonate[6] (XI) gave diethyl

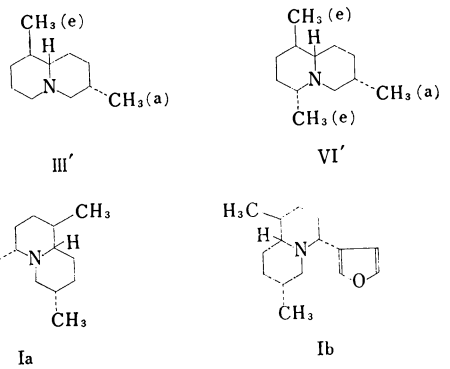
2-[piperidyl-(2)]-propylmalonate (XII) by hydrogenation at an ordinary pressure and temperature over a platinum catalyst. This diester, XII, afforded 1-methyl-4-ketoquinolizidine (XIII) through successive hydrolysis, esterification and cyclization. The hydride reduction of XIII gave an epimeric mixture of 1-methylquinolizidine (XIV), which was separated into two racemates by chromatography on alumina; the picrates were formed, m. p. 185~188 and 162~164°C. On the other hand, synthetic 1-lupinine has been separated, by chromatography on alumina[7], to *dl*- and *epi*-isomers, which were converted into 1-methylquinolizidine by Karrer's method[8]. The isomer from *dl*-lupinine formed a picrate which melted at 180~181°C, while the isomer obtained from the *epi*-isomer melted at 160~161°C. From these results, it is suggested that the higher melting picrate has the axial methyl group, while the other has the equatorial methyl group.



3-Methylquinolizidine (XVIII) was prepared from diethyl 2-[pyridyl-(2)]-ethyl methylmalonate (XV)[9] through XVI and XVII by the same manner as that used in the preparation of 1-methylquinolizidine, which was separated on an alumina chromatogram into two isomers. The corresponding picrates melted at 151~152 and at 183~185°C. Moreover, synthetic 3-lupinine was separated into *dl*- and *epi*-forms by the same manner as that used for 1-lupinine. The reduction of 3-*dl*-lupinine afforded an isomer, its picrate melted at 151~152°C, and 3-*epi*-lupinine gave a higher melting picrate, m. p. 177~178°C. Thus, we have suggested that the isomer of the lower melting picrate has the axial methyl group and the other has the equatorial methyl group.

The diastereomers of 4-methylquinolizidine have been obtained previously[10,11], and Boekelheide[12] has suggested that the methyl group of the higher melting picrate can be assigned to the equatorial group. We obtained 4-methylquinolizidine by the catalytic hydrogenation of 1-[pyridyl-(2)]-4-pentanone with simultaneous cyclization, and the two racemates which were separated by chromatography on alumina formed picrates; m. p. 193~196 and 187~190°C.

The NMR spectra of methylquinolizidines in a benzene solution (Figs. 1—6) showed that in the 1- and 3-methyl compounds the peak for an axial methyl group is at a lower field than that for the corresponding equatorial methyl group, but that for the 4-methylquinolizidine, in which the methyl group seemed to be equatorial, the peak is at a lower field than that of the axial isomer[5].

A doublet of 350~354 c. p. s. and another doublet of 327~333 c. p. s., present in the spectrum of 1, 7-dimethylquinolizidine (III), were assigned to 1-equatorial and 3-axial methyl groups respectively. A doublet of 337~344 c. p. s. in the spectrum of 1, 4, 7-trimethylquinolizidine (VI) was assigned to a 4-equatorial methyl group, since the intensity of the peak at 337 c. p. s. was twice that of the peak at 354.

The relative configurations of these compounds can thus be shown as III′ and VI′,

and the absolute configuration of deoxynupharidine, as either Ia or Ib. Since the configuration of (−)-α-methyladipic acid (X), obtained from the Hofmann degradation of deoxynupharidine, was found to have an s(−)-configuration[13], we came to the conclusion that the formula Ib shows the absolute configuration of deoxynupharidine.

Experimental

The NMR spectra were measured in a benzene solution at 56.4 Mc/sec. using a Varian Associates 4300 C instrument and the c.p.s. value was calculated from benzene.

Dehydrogenation of Synthetic Deoxynupharidine.—A mixture of 500 mg. of synthetic deoxynupharidine and 100 mg. of palladium black was heated at 280~290°C for 1 hr. After filtration of the catalyst, 250 mg. of pale yellow oil, b.p. 87~90°C/0.02 mmHg, was obtained.

The infrared spectrum of this oil was identical with that of 2-[5-methyl-pyridyl-(2)]-5-[furyl-(3)]-pentane derived from natural deoxynupharidine.

Nupharidinic Acid (II).—Hydrochloride: $[\alpha]_D$ −40.3° (*c* 1.18, ethanol), $[\alpha]_D$ −68.05° (*c* 1.44, water), $[\alpha]_D$ −75.16° (*c* 3.02, 6 N hydrochloric acid). (Found: C, 58.31; H, 9.02; N, 5.66. Calcd. for $C_{12}H_{21}O_2N \cdot HCl$: C, 58.16; H, 8.95; N, 5.65%).

Methyl ester; b. p. 87~90°C/1 mmHg, $[\alpha]_D$ −76.15° (*c* 2.78, ethanol).

1, 7-Dimethylquinolizidine (III).—A mixture of 3.7 g. of II-HCl salt and 10 g. of soda lime was distilled. The distillate was dissolved in dilute hydrochloric acid and extracted with ether, and the aqueous layer was made basic with potassium carbonate and extracted with ether. The basic ether extracts were washed with water and dried over sodium sulfate, and the solvent was distilled off. The residue was distilled at 65°C/15 mmHg; yield 1.0 g. (40%) (Found: C, 79.16; H, 12.36. Calcd. for $C_{11}H_{21}N$: C, 78.97; H, 12.65%), $[\alpha]_D$ −34.28° (*c* 2.45, ethanol). The picrate crystallized from ethanol as orange yellow prisms, m. p. 124~125°C (Found: C, 51.66; H, 6.05; N, 14.09. Calcd. for $C_{17}H_{24}O_7N_4$: C, 51.51; H, 6.10; N, 14.14%). The picrolonate from ethanol was in the form of yellow needles, m. p. 200~204°C (Found: C, 58.71; H, 6.92; N, 16.03. Calcd. for $C_{22}H_{29}O_5N_5$: C, 58.95; H, 6.77; N, 16.23%).

Alcohol (IV).—A solution of 12.3 g. of methyl ester of II in 30 ml. of absolute ether was added, drop by drop, to a solution of 2 g. of lithium aluminum hydride in 100 ml. of ether, After being heated under reflux for 3 hr. the reaction mixture was decomposed with the required amount of water and the precipitated hydroxide was extracted with boiling ether, the extracts evaporated and the residue distilled. The product was a colorless oil, b. p. 119~122°C/3.5 mmHg; yield 9.6 g. (90%) (Found: C, 72.76; H, 11.69; N, 6.93. Calcd. for $C_{12}H_{23}ON$: C, 73.04; H, 11.75; N, 7.10%). $[\alpha]_D$ −37.10° (*c* 2.57, ethanol). The infrared absorption band in carbon tetrachloride was at 3460 cm^{-1} (OH). The hydrochloride, prepared in an ethereal solution with dry hydrogen chloride and recrystallized from acetone-ethanol, was colorless and cubic; m. p. 195~196°C (Found: C, 61.41; H, 10.27; N, 5.88. Calcd. for $C_{12}H_{23}ON \cdot HCl$: C, 61.65; H, 10.35; N, 5.99%). The methiodide recrystallized from acetone-ethanol as colorless prisms; m. p. 173~174°C (Found: C, 46.17; H, 7.65; N, 4.39. Calcd. for $C_{12}H_{23}ON \cdot CH_3I$: C, 46.02; H, 7.72; N, 4.13%).

Chloride (V).—To a solution of 7.6 g. of IV in 200 ml. of ether was added 30 ml. of thionyl chloride, and the mixture was refluxed for 2 hr. The reaction mixture was evaporated in vacuo and added to a small amount of ice. The solution was carefully made basic with potassium carbonate and extracted with ether, and the solvent was removed and residue distilled at 93~95°C/1 mmHg; yield 7.1 g. (86%). $[\alpha]_D$ −69.4° (*c* 4.27, ethanol) (Found: C, 67.18; H, 10.40; N, 6.26. Calcd. for $C_{12}H_{22}NCl$: C, 66.80; H, 10.28; N, 6.49%).

1, 4, 7-Trimethylquinolizidine (VI).—A solution of 1.1 g. of V in 20 ml. of ethanol was shaken with hydrogen at atmospheric pressure in the presence of 500 mg. of 5% palladium charcoal. After 7 hr., the catalyst was filtered off and the solvent evaporated. Distillation of the residue in vacuo gave trimethylquinolizidine; b. p. 74~78°C/15 mmHg, yield 0.7 g. (76%). $[\alpha]_D$ −47.8° (*c* 2.56, ethanol) (Found: C, 78.96; H, 12.76. Calcd. for $C_{12}H_{23}N$: C, 79.49; H, 12.79%). It was volatile. The picrolonate recrystallized from ethanol as yellow needles, m. p. 180~184°C (Found: C, 59.17; H, 7.13; N, 15.57. Calcd. for $C_{22}H_{31}O_5N_5$: C, 59.31; H, 7.01; N, 15.72%). The methiodide recrystallized from acetone as colorless needles, m. p. 189~191°C (Found: C, 48.21; H, 8.13; N, 4.17. Calcd. for $C_{12}H_{23}N \cdot CH_3I$: C, 48.30; H, 8.11; N, 4.33%).

Nitrile (VII).—A solution of 3.4 g. of chloride V in 40 ml. of ethanol was added, drop by drop, to a boiling solution of 2.4 g. of sodium cyanide in 36 ml. of ethanol and 12 ml. of water. After being heated under reflux for 8 hr., the reaction mixture was evaporated in vacuo. The residue was

extracted several times with boiling chloroform, and the combined extracts were evaporated to an oil, which was distilled, b. p. 96~99°C/1 mmHg, yield 2.5 g. (76%). The infrared absorption spectrum was at 2280 cm^{-1} (CN). $[\alpha]_D$ −78.1° (*c* 3.52, ethanol) (Found: C, 75.75; H, 10.81. Calcd. for $C_{13}H_{22}N_2$: C, 75.67; H, 10.75%).

Methyl Ester (VIII R=CH_3).—A solution of 10.0 g. of nitrile VII in 100 ml. of concentrated hydrochloric acid was heated for 2 hr. and evaporated to dryness. The residue was dissolved in 100 ml. of methanol and saturated with hydrogen chloride. After standing overnight at room temperature, the solvent was removed in vacuo. Water was added to the residue, and the solution was made basic with potassium carbonate; it was then extracted with ether and the extract dried. On distillation there was obtained 10.3 g. (89%), b. p. 105~108°C/1.5 mmHg, $[\alpha]_D$ −30.2° (*c* 4.97, ethanol) (Found: C, 70.59; H, 10.76; N, 6.21. Calcd. for $C_{14}H_{15}O_2N$: C, 70.25; H, 10.53; N, 5.85%).

1,7-Dimethyl-4-hydroxyethylquinolizidine (IX).—A solution of 4.0 g. of methyl ester VIII in 10 ml. of absolute ether was added to a solution of 1 g. of lithium aluminum hydride in 60 ml. of ether. The reaction mixture was refluxed for 2 hr., decomposed with the required amount of water, and the precipitate extracted several times with boiling ether. The extracts were evaporated, and the residue distilled. The product was obtained as an oil (b.p. 122~124°C/1.5 mmHg, yield 3.1 g. (88.5%)), which solidified and which was recrystallized from acetone as colorless needles, m. p. 84~85°C. The infrared absorption band of the hydroxyl group was at 3140 cm^{-1} (Nujol) and 3260 cm^{-1} (carbon tetrachloride). $[\alpha]_D$ −18.8° (*c* 1.06, ethanol) (Found: C, 73.67; H, 11.83; N, 6.39. Calcd. for $C_{13}H_{25}ON$: C, 73.88; H, 11.92; N, 6.63%).

The dipole moment was determined in a benzene solution. The dielectric constants were measured at 25°C with a measuring condenser of 300 p*F* and a liquid condenser of 30 p*F*. The density was determined at 25°C in a Lipkin's Pyknometer. The refraction of compound IX was calculated from the atomic refraction. The results were evaluated according to the procedure of Halverstadt and Kumler[14] and are summarized below:

ω	ε^{25}	d^{25}
0.0000	2.2724	0.8729
0.0048	2.2938	0.8736
0.0088	2.3035	0.8738

0.0311	2.3852	0.8760

R_D=63.30, P=207.1, μ=2.63

α-Methyladipic Acid (X).—$[\alpha]_D$ −12.0° (*c* 3.00, ethanol).

1-Methyl-4-ketoquinolizidine (XIII).—A solution of diethyl 2-[pyridyl-(2)]-allylmalonate (XI) in a glacial acetic acid was hydrogenated over platinum oxide at room temperature and atmosphere. After filtration of the catalyst, the solvent was removed in vacuo and concentrated hydrochloric acid was added and then refluxed for 6 hr. The solution was evaporated to dryness. Absolute ethanol was then added to the residue, and the solution was saturated with hydrogen chloride and left to stand overnight. The solution was concentrated and neutralized with potassium carbonate. After extraction with ether, the ethereal solution dried over sodium sulfate. The solvent was then distilled off, and the residue, on heating to 180~200°C, began to distill at 102~105°C/1 mmHg with an overall yield of 60%.

1-Methylquinolizidine (XIV) and its Chromatogram.—A solution of XIII (15.2 g.) in 100 ml. of absolute ether was added, drop by drop, to a solution of lithium aluminum hydride (3.5 g.) in ether (200 ml.), and the mixture was refluxed for 3 hr., and then decomposed with the required amount of water. The precipitated hydroxides were extracted several times with boiling ether, and the solvent was then distilled off. The residue, on distillation under reduced pressure, yielded 10 g. (72%) of a colorless oil, b. p. 76~78°C/11 mmHg. This product (5.6 g.) was dissolved in petroleum ether and chromatographed on alumina (75 g.).

Fraction	Eluent	Volume ml.	Weight g.
1	Petroleum ether	200	2.5
2,3	Petroleum ether	400	1.1
4	Petroleum ether : benzene (1 : 1)	200	0.6

The picrate from fraction-1 was in the form of yellow plates, m. p. 185~188°C (Found: C, 50.46; H, 5.73; N, 14.62. Calcd. for $C_{16}H_{22}O_7N_4$: C, 50.26; H, 5.80; N, 14.65%). The picrate from fraction-2, 3 melted at 167~175°C. The picrate from fraction-4 was in the form of yellow needles, m. p. 162~164°C (Found: C, 50.46; H, 5.86; N, 14.56%). The picrate from mother liquids of fraction-1 melted at 163~165°C; that of fraction-2, 3 at 164~166°C, and that of fraction-4 at 175~177°C.

1-Methylquinolizidine from 1-Lupinine.—Synthetic 1-lupinine (18.6 g.) was dissolved in petroleum ether and chromatographed on alumina (100 g.).

Fraction	Eluent	Volume ml.	Weight g.	Residue
1	Petroleum ether	300	6.80	B.p. 100~103°C/2.2 mmHg
2	Petroleum ether	120	3.00	M.p. 73~80°C
3	Ether	200	5.50	M.p. 81°C
4	Ether	250	1.80	M.p. 81°C
5	Ether	280	7.50	M.p. 76~80°C
6	Methanol	190	1.20	

To 1-*dl*-lupinine (fraction-1; 5.5 g.) was added, drop by drop, thionyl chloride (8 g.) under ice cooling. The mixture was kept at 50°C for 10 min. and evaporated in vacuo. Ice was added to the residue, and the mixture was made basic with sodium carbonate and then extracted with ether.

14) I. F. Halverstadt and W. D. Kumler, *J. Am. Chem. Soc.*, **64**, 2988 (1942).

The ether extract was dried, and the solvent was removed. On distillation, there was obtained a colorless oil, b. p. 105~107°C/9 mmHg, yield 4.3 g.

A solution of 4.3 g. of the above chloride in 50 ml. of absolute alcohol at the reflux temperature was treated with 4 g. of sodium, added in small pieces. After completion of the addition, the reaction mixture was heated under gentle reflux for 4 hr. The excess sodium was then decomposed by the addition of ethanol and water. The mixture was acidified with 6 N hydrochloric acid and was concentrated to remove the ethanol in vacuo. The residue was then made basic with sodium carbonate and extracted with ether. The ether extract was dried, and the ether was removed. The residual oil was distilled at 81°C/15 mmHg, yield 2.2 g. The picrate was prepared in and recrystallized from ethanol, m. p. 180~181°C (Found: C, 50.07; H, 5.82; N, 14.40%).

Following the procedure given above for 1-*dl*-lupinine, 1-*epi*-lupinine (fraction-3,4; m. p. 81°C, 3.8 g.) was reduced to 1-*epi*-lupinane (b. p. 72~75°C/12 mmHg, 1.3 g.). The picrate melted at 160~161°C (Found: C, 50.26; H, 6.04; N, 14.26%).

Diethyl 2-[Pyridyl-(2)]-ethyl Methylmalonate (XV).—B. p. 132~135°C/1 mmHg.

3-Methylquinolizidine (XVIII) from XV.—Following the procedure given above for the preparation of 1-methylquinolizidine, the product (9.2 g.) was dissolved in petroleum ether and chromatographed on alumina (100 g.).

Fraction	Eluent	Volume ml.	Weight g.
1-3	Petroleum ether	600	7.5
4-9	Petroleum ether	1200	0.5
10	Ether	200	0.7

The picrate from fraction 1-3 was in the form of yellow plates, m. p. 150~153°C, (Found: C, 50.13; H, 5.90; N, 15.08%). The picrate from fraction 4-9 appeared as yellow needles, m. p. 183~185°C. The picrate from fraction 10 was also in the form of yellow needles, m. p. 183~185°C (Found: C, 50.09; H, 5.80; N, 14.79%).

3-Methylquinolizidine from 3-Lupinine.—Synthetic 3-lupinine (38 g.) was dissolved in petroleum ether and chromatographed on alumina (400 g.).

Fraction	Eluent	Volume ml.	Weight g.	Residue
1—5	Petroleum ether	1300	0.9	M.p. 49~52°C
6	Petroleum ether	300	3.2	M.p. 56~58°C
7	Ether	300	2.1	M.p. 55~57°C
8	Ether	300	1.5	M.p. 51~53°C
9	Ether	400	1.7	M.p. 50~52°C
10	Ether	300	0.8	M.p. 48~51°C
11—16	Ether	2500	3.3	Oil
17	Methanol	500	24.3	Oil

Following the procedure given above for the preparation of 1-lupinane from 1-lupinine, 3-*dl*- and 3-*epi*-lupinine were converted to 3-*dl*- and 3-*epi*-lupinane. 3-Methylquinolizidine (1.6 g., b. p. 71~72°C/15 mmHg) was obtained from 1.5 g. of 3-*dl*-lupinine (m. p. 57~58°C, fraction-6, 7). The picrate was prepared in and recrystallized from ethanol, m. p. 151~152°C, in the form of yellow plates (Found: C, 49.83; H, 5.86; N, 14.74%).

On distillation of the oil (fraction-17), there were obtained 3 fractions: b. p. ~118°C/5 mmHg, 1.0 g; b. p. 118~123°C/5 mmHg, 17.9 g.; b. p. 123~125°C/5 mmHg, 4.9 g.

The product (10 g., b. p. 118~123°C/5 mmHg) was chromatographed on alumina (100 g.).

Fraction	Eluent	Volume ml.	Weight g.	Residue
18	Petroleum ether : Ether	200	1.5	Oil
19	Ether	200	1.4	Oil
20	Ether	160	0.6	Oil
21	Ether	200	1.0	Oil
22	Ether	230	0.9	Oil
23	Ether	200	0.8	Oil
24	Ether	40	0.5	Oil
25	Ethanol	270	3.4	Oil

Two and half grams of fractions 19, 20 and 21 was converted into 3-lupinane b. p. 77~79°C/15 mmHg, 1.1 g.; the picrate melted at 144~151°C and at 163~165°C (trace). The product (4.9 g., b. p. 123~125°C/5 mmHg) was chromatographed on alumina (100 g.).

Fraction	Eluent	Volume ml.	Weight g.	Residue
26	Petroleum ether : Ether	300	0.3	Oil
27	Ether	450	0.3	Oil
28	Ether	380	0.4	Oil
29	Ether	300	0.2	Oil
30	Ethanol	250	3.8	Oil

Nine tenths grams of fractions 27, 28 and 29 was converted into 3-lupinane, b. p. 79~81°C/17 mmHg, 0.6 g. The picrate was in the form of yellow needles, m. p. 177~178°C (Found: C, 50.32; H, 5.74; N, 14.99%).

4-Methylquinolizidine.—The hydrogenation of 1-[pyridyl-(2)]-pentan-4-one was carried out at an ordinary temperature and pressure over a platinium catalyst. 4-Methylquinolizidine was taken up in the usual manner and distilled at 17 mmHg, 81~86°C; yield 74%. The product (9.1 g.) was dissolved in petroleum ether and chromatographed on alumina (100 g.).

Fraction	Eluent	Volume ml.	Weight g.	M. p. of picrate
1—2	Petroleum ether	200	8.2	190~196°C
3	Petroleum ether	100	1.2	193~196°C
4—6	Petroleum ether	300	0.8	193~196°C
7	Ether	100	0.6	189~193°C
8	Ether	100	0.5	187~192°C

The picrate from fraction-3 was recrystallized three times from ethanol; it appeared as yellow prisms,

m. p. 193～196°C (Found: C, 50.07; H, 5.88; N, 14.56%). The picrate from fraction 8 was recrystallized three times from ethanol, appearing as small yellow plates, m. p. 187～190°C (Found: C, 50.51; H, 5.82; N, 14.50%).

The author wishes to thank Professor Yasuhide Yukawa for his helpful discussions, and Mr. Naohiro Hayakawa, of the Japan Atomic Energy Research Institute, and Mr. Shiro Sato, of the Institute of Scientific and Industrial Research, Osaka University, for their measurement of the NMR spectra.

Studies of the Cross-linking and Glass Transition of Fatty Acid-Modified Alkyd Resins

By Jū Kumanotani, L. W. Chen and Tsutomu Kuwata

(Received February 27, 1962)

The air drying of oil paints and varnishes has been considered to proceed by the autoxidative polymerization of the unsaturated part of the acyl groups. Reactions in the process of air-drying have been studied, resulting in some information, but how the unsaturated part of the acyl groups takes part in the cross-linking has scarcely been studied. It is well known that alkyd resin, a thermosetting amorphous polymer, is used as one of the main consituents of synthetic resin varnishes. In this paper, using fatty acid-modified alkyd resins, several factors which might have an influence on the degree of cross-linking and on the glass transition temperature of the films made from the resin have been investigated in order to get further information about the cross-linking reactions of acyl groups and some suggestions for the improvement of synthetic varnishes. The factors studied were:

a) The constitution of alkyd resins, i. e., the ratio of reactants (fatty acid, phthalic anhydride and glycerol).

b) The reaction time (the molecular weight changes with the reaction time).

c) The method of film formation (with or without the addition of a drier, air-drying or baking).

d) The aging of the films.

Experimental

Reagents.—The reagents used, phthalic anhydride, glycerol, lineseed oil fatty acids and soybean oil fatty acids, were chemically pure. The iodine values of the linseed oil fatty acids and soybean oil fatty acids were 183 and 128 respectively (as measured by Wijs' method). Xylene, the thinning solvent, was also chemically pure. Naphthenates of cobalt, lead and manganes were employed as the driers.

Synthesis of Alkyd Resins. — A 300 ml. four-necked flask with a glass stirrer was used, into one neck introducing carbon dioxide gas, into one neck inserting a thermometer, and into another one inserting a 25 ml. Stark & Dean trap for dehydration. The flask was immersed in a silicon oil bath and heated by a gas burner. The reagents were all introduced at once, and the temperature was raised to 230°C within $1^1/_2$ hr. and kept at that temperature for 5 hr.

The Process of Making Films. — The varnishes were prepared in 50% xylene solutions. The varnishes, with or without driers, were brushed on tin plates and dried in air or by baking. The quantity of the drier added to the resin was Mn 0.05%, Co 0.1% and Pb 0.2%. Since film more than 0.1 mm. thick is desirable, the varnishes were brushed 8 times every other day in the case of air drying, and the films were heated 8 times in an electric drier at 105°C for 8 hr. each time in the case of baking.

The Glass Transition Temperature (T_g) and the Degree of Cross-linking.—*The Physical Meaning of T_g and the Degree of Cross-linking.*—The term "glass transition" refers to the characteristic change in polymer properties from those of a relatively hard, brittle, glassy state to those of a softer, more flexible rubbery state as the temperature is raised through the glass transition temperature (T_g). Below the T_g, thermal energy is not available to allow the segments of the chain to move as a whole. The motions of the individual atoms are restricted to small excursions around their equilibrium positions. As the temperature approaches the T_g, the increased thermal energy becomes sufficient to allow larger molecular motions involving the coordinated movement of several atoms. Of course, the rigidity modulus G of a polymer decreases sharply with temperatures near the T_g,

until it reaches a definite value enough above the T_g; on further raising of the temperature, the value keeps constant or rises a little. Since the chain segments can move freely at higher temperatures, the rigidity is sustained by the entropy elasticity of the network chains. As predicted by the kinetic theory of rubber elasticity, the rigidity modulus at high temperatures (G_h) is in proportion to the degree of cross-linking.

The Torsional Pendulum Method. — The torsional pendulum method[1] developed by Inoue was employed for observing the T_g and G of the dried films. The period and the amplitudes of the damping oscillation of the film were measured; then the rigidity modulus G and logarithmic decrement λ were calculated. The temperature dependences of G and λ were measured in the range of $-70\sim90$°C. When these were plotted on a graph, a kind of characteristic spectrum of the polymer similar to a relaxation spectrum was obtained. As λ is defined as the ratio of the energy consumed by internal friction to the supplied energy, λ is considered to reach its maximum at T_g; reversely, T_g is found from λ_{max} on the garph. The rigidity modulus at high temperatures (G_h) is a direct measure of the degree of cross-linking.

Apparatus.—The inner structure of the films was considered to be at mechanical and thermal equilibrium when the films were left at room temperature for a time. The procedure of the measurement was separated into two parts, one part heating up from room temperature and another part cooling drown from room temperature. For the former, as is shown in Fig. 1, an electric drier was devised for hanging down the films and oscillating the pendulum from the outside. The temperature of the cabinet was controlled by a slide regulator and was raised at the rate of 0.5°C/min. For the latter, as is shown in Fig. 2, a core was installed in an ethanol-dry ice bath. The device for oscillating the pendulum, the same as in the electric drier, was set on the upper part of the core. The crushed dry-ice was thrown in the bath for cooling at the rate of 0.5°C/min. The core was equipped with a small fan for keeping the distribution of the temperature homogeneous, and nitrogen gas was suplied to the core continuously to prevent the freezing of moisture on the films.

Results and Discussion

The Influence of Oil Length*. — Linseed oil fatty acid-modified alkyd resins of oil lengths 50%, 60% and 70% were prepared. Their acid values were 10.1, 7.5 and 5.1; their molecular weights were 1000, 740 and 690 respectively (as measured by Rast's method). The results are shown in Figs. 3 and 4, and in Table I**.

G_h increased with the oil length; i.e., 2×10^8 dyn./cm^2 for 50%, 2.7×10^8 dyn./cm^2 for 60% and 1.5×10^9 dyn./cm^2 for 70% in the case of baked film without the addition of a drier

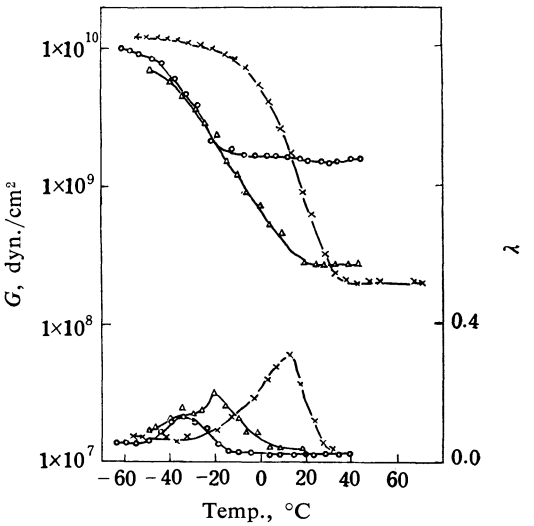

Fig. 3. Influence of oil length. Baking film of linseed oil fatty acid modified alkyd resin without addition of drier, measured at 6 months after preparation.
○ Oil length 70% △ Oil length 60%
× Oil length 50%

* $\text{Oil length} = \dfrac{\text{oil}}{\left(\begin{array}{c}\text{oil+glycerol+phthalic}\\ \text{anhydride−water(calcd.)}\end{array}\right)} \times 100$

** Sample films were exposed to the air for 6 months.

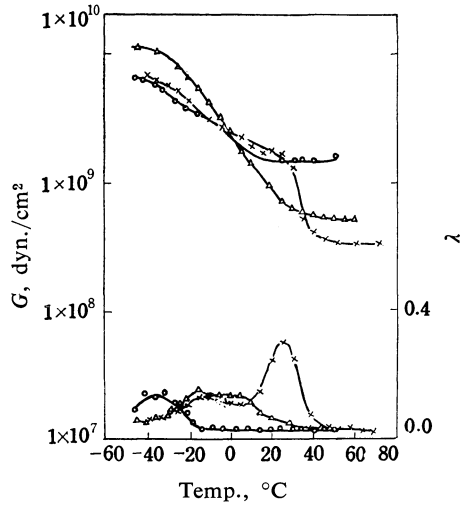

Fig. 4. Influence of oil length. Baking film of linseed oil fatty acid modified alkyd resin with addition of drier, measured at 6 months after preparation.
○ Oil length 70% △ Oil length 60%
× Oil length 50%

and 3.2×10^8 dyn./cm² for 50%, 5.0×10^8 dyn./cm² for 60% and 1.5×10^9 dyn./cm² for 70% in the case of baked film with the addition of a drier. Therefore, the degree of cross-linking increased with the oil length. Since the double bond is considered to be the source of cross-linking and the number of double bonds to increase with the increase in oil length, it is reasonable to assume that the degree of cross-linking increased with the increase in oil length. On the contrary, the T_g decreased with the increase in oil length; i.e., 12°C for 50%, −20°C for 60% and −33°C for 70% in the case of baked film without the addition of a drier, and 25°C for 50%, 0°C for 60%, and −35°C for 70% in the case of baked film with the addition of a drier. The benzene ring plays an important role in preventing molecular movements, resulting in the elevation of the T_g. It is reasonable to assume that the T_g decreased with the increase in oil length, as the concentration of the benzene ring increased with the decrease in oil length. It is also known that the T_g rises as the degree of cross-linking increases. The authors conclude that, in raising the T_g, the steric hindrance of the benzene ring plays a more important role than the degree of cross-linking. The λ_{max} increased with the decrease in oil length as a result of the internal friction of the benzene ring, the cohesive energy of which is relatively large.

The Effect of the Molecular Weight. — Fifty per cent oil length linseed oil fatty acid-modified resin was prepared under the conditions mentioned above. In the course of preparation, the samples of prepolymers of different molecular weights, 430, 570, 1000 and 1400, were taken, and air dried as well as baked film (heated for 16 hr. each time) was prepared from each prepolymer. The results are shown in Figs. 5 and 6 and in Table II. In the case of baked films without

Table I. Influence of oil length*

b Measured at 2 months after preparation of the films

the addition of a drier, the T_g and G_h values were: 28°C, 0.75×10^8 dyn./cm^2 for mol. wt. 1400, 18°C; 0.6×10^8 dyn./cm^2 for mol. wt. 1000, and −1°C for mol. wt. 430*, and in the case of air-dried films with the addition of a drier, those values were: 20°C, 0.4×10^8 dyn./cm^2 for mol. wt. 1400, 20°C, 0.28×10^8 dyn./cm^2 for mol. wt. 1000, and −5°C for mol. wt. 570*. The results show that both the T_g and the G_h increase with the increase in the molecular weight of the prepolymer. The results may be considered as follows:

a) The configuration of the prepolymers of a high molecular weight may favor cross-linking.

b) The prepolymers of a low molecular weight contain more unreactant, which act as plasticizers for the polymer.

In the glass transition state, both the *G-T* and λ-*T* curves were sharp compared with the curves found in the samples of the same oil length used above, because the cross-linking was not fully completed, and the λ_{max} increased with the increase in the molecular weight of the prepolymer. This suggests that the λ-*T* curve's tendency to be flat is not a mere result of the progress of the cross-linking.

The Effect of Excess Glycerol. — In connection with reducing the acid value of resins less than 10, which is important practically, two 50% soybean oil fatty acid-modified resins were prepared: (A) with an equivalent weight of glycerol and (B) with a 20% excess (by weight) of glycerol. The acid values were

32.7 for A and 9.6 for B. The results are shown in Fig. 7 and Table III. The G_h and T_g values were 3.2×10^8 dyn./cm², 21°C for B, 2.0×10^8 dyn./cm², 10°C for A in the case of baked films and 1.5×10^8 dyn./cm², 20°C for B, 0.4×10^8 dyn./cm², −11°C for A in the case of air-dried films. The results show that both the T_g and the G_h of B were larger than those of A. This may be considered to be result of the effects of the molecular weight and of the plasticizing action of the unreactant for the polymer.

The Effect of the Drier and the Method of Drying.—A 40% oil length, linseed oil fatty acid-modified resin was prepared under the same reaction conditions mentioned above, except

that the reaction time was limited to 2 hr. in order to avoid gelation. Because the functionality per mole is larger in this case, it gels at a higher acid value[2]. The acid value of the resin in this case was relatively large, i. e., 26.1. Air-dried (A) and baked film (B) with a drier (A_2, B_2) and without a drier (A_1, B_1) were

1400	2 months	20	0.4×10^8	1.0	

prepared. The results are shown in Figs. 8 and 9 and in Table IV. The degree of cross-linking was in the order of $A_1<A_2<B_1<B_2$; the T_g was in the same order, and the λ_{max} decreased in this order. The G at a sufficiently low temperature was 10^{10} dyn./cm², and the same G values were observed in other films.

Aging of Films.—*Early Period of Drying.*—A 50% oil length linseed oil fatty acid-modified resin was prepared, from which air-dried and baked films were made. Their properties were measured 2 weeks and 2 months after the preparation. The results are shown in Figs. 10, 11, 12 and 13 and in Table V. For baked films, no distinguishable difference in the T_g and the G_h was observed between the films prepared from the prepolymer of a larger molecular weight. For air-dried films, the elevation of the G-T curve and the T_g (about 10°C) were observed, and the cross links were developed to the extent of sustaining the applied load.

Aging at a Later Period.—A 40% oil length linseed oil fatty acid-modified resin was prepared, from which air-dried and baked films were made. The results of the measurement 6 months and 10 months after the preparation are shown in Fig. 14. In the course of 4 months, the elevation of the G-T curve and the raising of the T_g (10~20°C) were observed. The λ_{max} was larger, and the λ-T curve tended to be sharp. It is notable that, in the case of baked film with the addition of a drier, no change in the G_h was observed, although the T_g was raised more than 10°C. This may be explained by the fact that, in the course of time, the film was gradually air-oxidized with the formation of polar groups, with the result that their cohesive energy became larger and led to a rise in the T_g. Owing to the increase in the energy consumed by the internal friction caused by the increase in the concentration of

- ---- Measured at 6 months after preparation

the polar group, the λ_{max} became larger. Generally the driers accelerate the drying of film in the early period, resulting in the G_h values of the films with a drier being higher than those of the films without a drier (measured 6 months after the preparation of the films); this effect of acceleration still held even 10 months after the preparation of the films. Both the T_g and the G_h were larger in the case of baked films. Comparing the baked to the air-dried films, the authors found that the effect of heating held even 10 months after the preparation of the films. Concerning

* Values at sub-glass transition
** Values at main glass transition

the acceleration of the cross-linking, heating was found to be more effective than driers. It may be suggested that the mechanism of cross-linking is not the same in the case of baking and of air-drying.

Sub-glass Transition. — In some experiments, two glass transition points were observed; the authors have named the higher one, the main glass transition point, and the lower one, the sub-glass transition point. The sub-glass transition was observed between −30 to −40°C. In the case of air-dried film prepared from the prepolymer of a low molecular weight, the sub-glass transition was found in the early period of drying (Fig. 15). Comparing the films two weeks and two months after preparation, the λ_{max} of the sub-glass transition tended to be small and the λ-T curve at the sub-glass transition state became flat; on the other hand, the λ_{max} of the main glass transition tended to be larger and the λ-T curve at the main glass transition state became sharp. The same glass transition phenomenon was observed in the case of a 50% oil length soybean oil fatty acid-modified resin using an equivalent weight of glycerol even 10 months after the preparation of the films (Fig. 16 and Table VI). Though the reasons are not fully understood, this finding suggests that such a kind of sub-glass transition is due to the unrestrained chain of the acryl groups.

Summary

a) The degree of cross-linking observed in films of fatty acid modified alkyd resins increases with the content of unsaturated acids. Moreover, cross-linking is not so effective in raising the T_g as the benzene ring, which has a larger cohesive energy.

b) Both the T_g and the degree of cross-linking increase with the increase in the molecular weight of the prepolymer.

c) The excess of glycerol employed in fatty acid-modified alkyd resin is effective in raising the T_g and encouraging the progress of the cross-linking.

d) Generally, the cross-linking is not soon completed; as time elapses, the T_g rises, and the cross-linking progresses. No change in the G_h with the elevation of the T_g (baked film with the addition of a drier) is considered to be caused by the formation of polar groups by air-oxidation.

e) In the early period of drying, a sub-glass transition caused by the unrestrained chain of the acyl groups is observed.

*Studies of the Structure and Properties of Aromatic Polyamide. I. Physical Properties of Poly(m-xylyleneadipamide)**

By Naoya YODA

(Received March 13, 1962)

It has been reported that *m*-xylylenediamine reacts with various aliphatic dibasic acids to form high molecular weight polyamides[1].

The polymer of *m*-xylylenediamine and adipic acid shows the effects caused by a reversal of the position of the carbonyl groups relative to the amide nitrogen, compared to that of the polymer of isophthalic acid and hexamethylenediamine[2,3]. *m*-Xylylenediamine has the characteristic high reactivity of aliphatic diamines mainly due to the side-chain methylene group, which is considerably more reactive than aromatic diamines[4,5]. The present investigation was undertaken to study the physical properties of a melt-spun filament of aromatic polyamide obtained from *m*-xylylenediamine and adipic acid; as described herein, studies of the dynamic mechanical properties as well as of the chemical behavior of the polymer reveal that it possesses properties intermediate between poly-ε-capramide and polyethylene terephthalate.

Experimental

Polymerization of *m*-Xylylenediamine and Adipic Acid.—Commercially available *m*-xylylenediamine was distilled under reduced pressure, and the fraction boiling at 114°C/1 mmHg was used for the polymerization. The purified adipic acid (m. p. 133°C) was obtained by crystallization of commercially available dibasic acid from aqueous ethanol. The *m*-xylylenediamine adipic acid salts were prepared according to the following procedure[6]: 14.6 g. (0.1 mol.) of adipic acid was added into a solution of 13.6 g. (0.1 mol.) of *m*-xylylenediamine in 28.2 ml. of water in order to obtain a concentrated warm solution of the salt. When the solution had been cooled, a white crystalline solid precipitated out slowly. In order to complete the precipitation of the salt, 113 ml. of isopropanol was added. The white solid was filtered, washed with isopropanol, and dried under vacuum at 60°C. The yield of salt was 93%, m. p. 193~194°C. The nylon salt thus obtained was polymerized at an elevated temperature with the following procedure: Excess adipic acid (0.075 mol. %) was added as a stabilizer, and the salt was heated at 180 to 190°C in a Claisen flask under a nitrogen atmosphere. Then the polymerization temperature was gradually raised to 260°C over a 1~1.5 hr. period. The polymer was held at 260°C for 2 hr. at atmospheric pressure before applying a vacuum (1 to 5 mmHg) for 0.5 to 1 hr. to complete the polymerization. The resulting polymer had a melting point of 243°C, $d_4^{25}=1.2059$, and the intrinsic viscosity measured in *m*-cresol at 25°C was 0.96. It showed the typical infrared spectrum of polyamide, indicating a NH band (hydrogen bonding) at 3297 cm^{-1}, an amide I band at 1639 cm^{-1} and an amide II band at 1545 cm^{-1}. Experimental details will be discussed in a forthcoming paper**.

Melt-spinning of Poly(*m*-xylyleneadipamide).—A small scale melt-spinning instrument, composed of a heating cylinder, plunger, spinneret (0.5029 mm. diameter, 0.402 mm. length) and with a

heating and cooling jacket, a cooling bath and a take-up roller, as shown in Fig. 1, was used as the apparatus.

The spinning block of the polymer was prepared by melting the polymer flakes in a sillicone-varnished (DC 20) glass cylinder under dry nitrogen atmosphere under vacuum at an elevated temperature. After pressing the melt with the steel plunger to complete the deairation at 245~250°C, it was cooled gradually to form the polymer block, which was ready to use for spinning.

The following spinning conditions were employed for the melt-spinning of poly(*m*-xylyleneadipamide) shown in Table I.

TABLE I. MELT-SPINNING CONDITIONS OF POLY-(*m*-XYLYLENEADIPAMIDE)

Item	Condition
Spinning temperature	265°C
Diameter of polymer block	27 mm.
Pressing speed	0.260 cm./min. (press, 282 r. p. m.)
Diameter of spinneret	0.5029 mm. (length : 0.402 mm.)
Rate of take up	30 m./min.
Length of air cooling	1.5 m. (at 25°C)
Cooling bath temperature	5°C

Drawing and Heat-setting of the Undrawn Filament. — The undrawn filament thus obtained was heat-stretched in a water bath at 79°C, the draw ratio of 3.4—4.5 was found to be the optimum. (Low speed, 5 m./min., high speed 25 m./min.) The stretched filament was treated either at 180°C for 5 min. or at 187°C for 10 min. in a thermostat drier for the heat setting.

Measurement of Density. — A mixed solvent composed of carbon tetrachloride and toluene was used, and the density was measured by the flotation method[7].

Measurement of the Stress-strain Curves of the Filaments.—Stress (g./D) and strain (%) curves were obtained by the use of an Instron tensile-testing instrument.

Measurement of Light Resistance.—The drawn filaments were exposed to light by means of a Atlas Fade-O-meter for a certain period of time and the tensile strength of the irradiated specimens was then measured.

Results and Discussion

Stress-strain Diagram of Poly(*m*-xylylene-adipamide) Mono-filament.—The stress-strain curves of melt-spun mono-filaments are shown in Fig. 2. The stress-strain characteristics change as expected with an increase in the strain rate. The tenacity of the drawn filament is 5.93 g./D., whereas the heat-set filament shows a tenacity of up to 6.79 g./D.

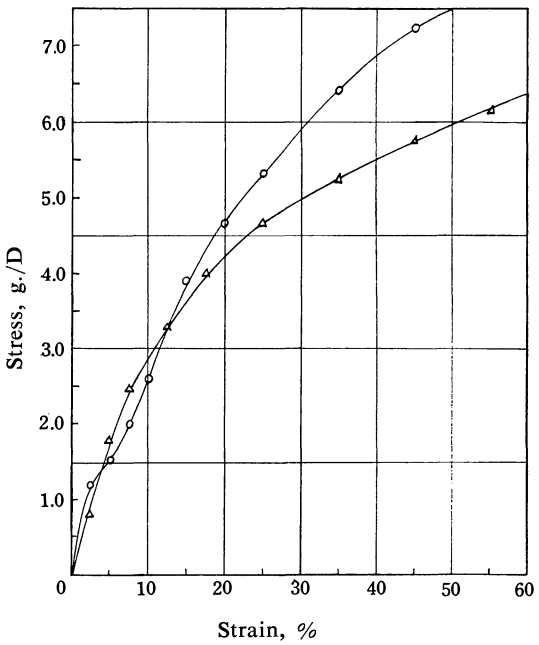

Fig. 2. Stress-strain curve of poly (*m*-xylylene-adipamide) mono-filament.
○ Heat-set filament △ Drawn filament

Wet and Dry Knot, and Loop Tenacity.—The wet and dry knot, and the loop tenacity are compared with those of polycapramide and polyethylene terephthalate in Table II and Fig. 3.

7) C. E. Black and M. Dole, *J. Polymer Sci.*, 3, 358 (1948).

Table II. Dry and wet knot, and loop tenacity

Polymer	Dry, knot, and loop tenacity g./D	Wet, knot, and loop tenacity g./D
MXDA-6	5.36	4.18
Polyester	4.5—7.0	4.5—7.0
Polycapramide	4.5—7.0	4.0—6.5

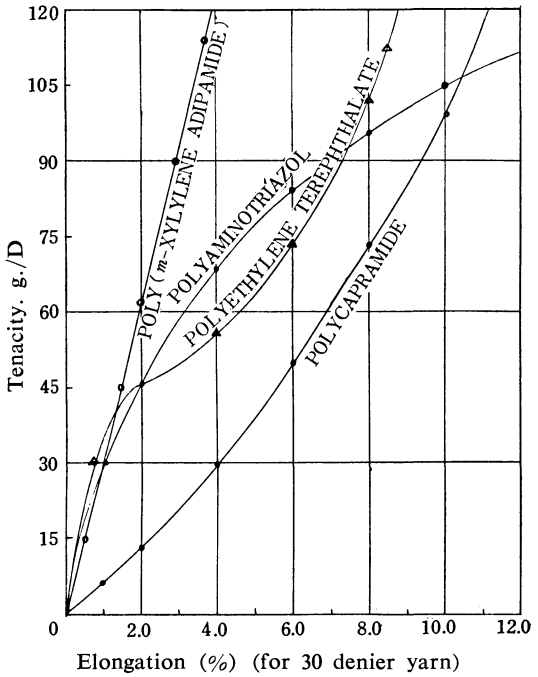

Fig. 3. Relation between elongation and tenacity of poly(*m*-xylyleneadipamide) mono-filament[8].

Measurement of Shrinkage.—The shrinkage of the heat-set filament in boiling water was measured at 4.0%.

Measurement of Light-resistance.—The light-resistance of the heat-set filament was measured by means of an Atlas Weather-o-Meter over the periods of 10, 20, 40 and 80 hr.

The ratio of the tenacity of irradiated to that of unirradiated filament is plotted against the irradiation time in Fig. 4. It can be seen in Fig. 4 that a 25% decrease in the tenacity was observed for 40 hr. irradiation, and 30% for 80 hr. exposure.

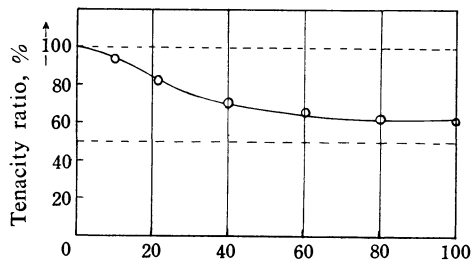

Fig. 4. Relation between irradiation time and tenacity ratio.

Elastic Recovery of the Heat-set Filament.—The elastic recovery was measured by the Instron instrument at a 5% elongation and a 10% elongation, the results are summarized in Tables III and IV respectively.

Table III. Elastic recovery of poly-(*m*-xylyleneadipamide) filament

No.	Immediate recovery	Delayed recovery	Deformation
1	57/81=0.705	24—20/81=0.0495	20/81=0.247
2	67/80=0.815	15—12/80=0.0376	12/80=0.150
3	54/77=0.700	23—20/77=0.0390	20/77=0.261
$\overline{X}$	0.740	0.042	0.219

Table IV. Elastic recovery of poly-(*m*-xylyleneadipamide) filament

No.	Immediate recovery	Delayed recovery	Deformation
1	110/197=0.560	87—54/197=0.167	54/197=0.273
2	110/196=0.561	86—55/196=0.158	55/196=0.280
3	110/196=0.561	86—53/196=0.168	54/196=0.270
$\overline{X}$	0.561	0.164	0.274

It was found that the elastic recovery of the filament is 78.2% or better at the 5% elongation and that at the 10% elongation the elastic contribution (immediate plus delayed) drops

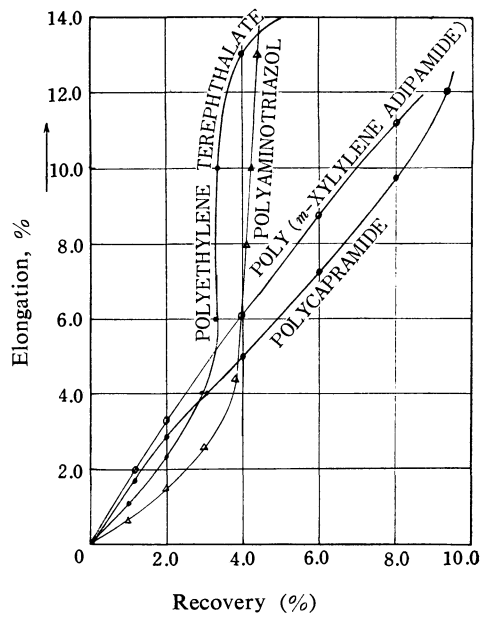

Fig. 5. Elastic recovery and elongation of poly (*m*-xylyleneadipamide) yarn, as compared with other fibers.

to 72.5%. Similar results were obtained from the repeated stress data. The elastic recovery of the poly(*m*-xylyleneadipamide) filament is compared with that of polyester, polycapramide and polyaminotriazole in Fig. 5.

Measurement of the Dynamic Modulus of Elasticity and of the Loss Factor (tan δ).—The dynamic modulus of elasticity, E_2, is expressed in terms of the product of the frequency, ω, and the dynamic coefficient of the viscosity, η, as follows;

$$E_2 = \omega\eta \quad (1)$$

The loss factor, tan δ is expressed in Eq. 2, where E_1 is the modulus of the elasticity.

$$\tan\delta = E_2/E_1 \quad (2)$$

The observed data in Eqs. 1 and 2 are shown in Table V.

TABLE V

Filament	Dynamic modulus of elasticity, $E_2\times10^{10}$ dyn./cm^2,	Loss factor tan δ $\times10^{-2}$
Stretched and nonheat-set filament	5.08	2.2
Stretched and heat-set filament	5.34	1.9

The values thus obtained are compared with those of polycapramide and polyethyleneterephthalate in Table VI.

TABLE VI

Polymer	Dynamic modulus of elasticity, $E_2\times10^{10}$ dyn./cm^2	Loss factor tan δ $\times10^{-2}$
Nylon 6	4.2	10
Nylon 6.10	4.5	4.4
Polyester ($\times5$ drawn)	4.5	1.5
Polyester ($\times7$ drawn)	1.3	1.5

It can be seen from Table VI that the poly(*m*-xylyleneadipamide) filament possesses physical properties intermediate between nylon 6 and polyester.

Measurement of Density.—The density was measured by the floating method, using a toluene/carbon tetrachloride solvent mixture. A modified pycnometer was employed at 25.0°C for the measurement.

The observed values are summarized in Table VII.

TABLE VII. DENSITY OF POLY-(*m*-XYLYLENEADIPAMIDE)

Density	Un-stretched	Stretched	Annealed
d_4^{25}	1.2059	1.2219	1.2248

It was again concluded that the density of poly(*m*-xylyleneadipamide) shows a value intermediate between polycapramide and polyethylene terephthalate, as is shown in Table VIII.

TABLE VIII

Density	Polycapramide	Poly (MXD-6)	Polyethylene terephthalate
d_4^{25}	1.14	1.23	1.38

Viscosity Measurement.—The intrinsic viscosity was measured in *m*-cresol at 25.0°C.

$$[\eta]_{m\text{-cresol}}^{25°C} = 0.96$$

In a diluted concentration range of the *m*-cresol solution, an abnormal increase in specific viscosity was observed, as is shown in Fig. 6.

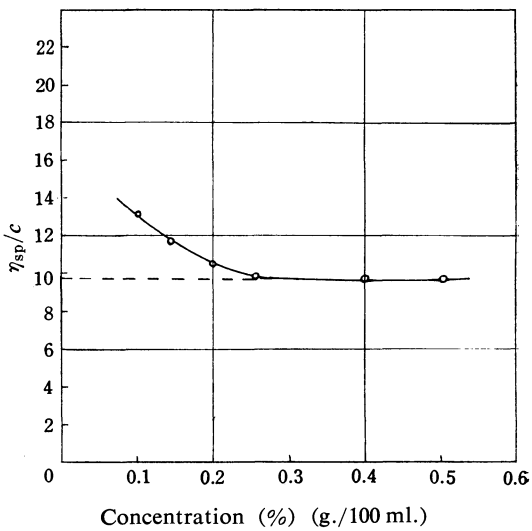

Fig. 6. Relation between reduced viscosity and concentration of poly(*m*-xylyleneadipamide) measured in *m*-cresol at 25°C.

Summary

Poly(*m*-xylyleneadipamide) was synthesized by the polycondensation of *m*-xylylenediamine and adipic acid, and the resulting polymer was melt-spun to afford a mono-filament. The physical properties of the undrawn filament, the stretched filament, and the stretched and annealed filament were investigated. It was found that the dynamic mechanical behavior and the chemical property of the aromatic polyamide are intermediate between poly-ε-capramide and polyethylene terephthalate.

The Kinetics of the Transition of Titanium Dioxide

By Akira SUZUKI and Yoshihide KOTERA

(Received February 24, 1962)

The kinetics of the transition of anatase to rutile have previously been investigated[1,2]. In these studies samples, after being heated, were analyzed by means of the X-ray diffraction method. The rate of the transition of compounds such as titanium dioxide, germanium dioxide and silica is complicated by the variation in the size of the particles, the temperature, the surrounding atmosphere and the presence of small amounts of impurity.

Attention should be paid to the values of the activation energy of the transition. It has been reported that the value of the activation energy of the transition was equal to that of the sublimation energy in some organic compounds[3,4] and in sulfur[5], while the value of a compound such as mercuric iodide was not equal to that of the sublimation energy[6]. It is, therefore, important to determine the value of the activation energy in the transition of titanium dioxide as correctly as possible and to compare it with other thermodynamic values.

Meanwhile, it has been proved that there is a large difference between the dielectric constants of anatase and rutile; from this fact it was possible to analyze both elements in the mixture. We have measured the transition rate of anatase to rutile, analyzing their mixture by the dielectric constant method, and have obtained some interesting results to explain the transition process.

Experimental

In this study the raw materials of titanium dioxide (anatase) was prepared by the following procedure. Titanium tetrachloride was distilled after the impurities in it had been precipitated by letting hydrogen sulfide pass through it. The distillate was added, drop by drop, to a 50% sulfuric acid solution, and the mixture was heated to drive off hydrochloric acid until no Cl^- was detected. The solution thus obtained was diluted with distilled water and then hydrolyzed at 90~100°C. The precipitated gel was washed with distilled water, and then the product obtained was heated for five hours at 700°C in an electric furnace. Two kinds of samples, "a" and "b" were used in this study, both being prepared in the same manner. It was later proved that they have different rates of transition.

Zn, Mg, Pb, Fe, Al, V, Ca, Cu, Ga, Cr and Sn were not detected spectroscopically, while the lines of Si were faintly observed. According to the electron-microscopic observation, the crystal size of the raw materials was 0.09~1 μ, while the crystal size of sample "a" was a little larger than that of sample "b". The pattern of rutile was not detected by the X-ray diffraction.

The dielectric constant of the mixture of anatase and rutile was measured by the method reported by Oehme[7]. The measuring equipment used was a DK Scope, type 59 (Yanagimoto Co., Ltd.). In the measurement of the dielectric constant of powder by the immersion method, it is necessary to eliminate completely the foams of air occluded in the powder. By using the coaxial cylindrical cells shown in Fig. 1, it is possible to measure the difference in capacity between liquid and powder suspension. 0.700 g. of the sample was accurately weighed and put into A in the figure. After pouring aceton into A and B until half the height of a bakelite cylinder was reached, the powder suspension in A cell was agitated carefully by a stainless steel wire until no bubble rose. By switching C on the respective side, the capacities of the A and B cells were compared with one other. From the difference in the readings on the scale, ΔS, it is possible to determine the proportion of rutile or anatase in powder. Figure 2 shows the calibration curve obtained in this work.

The X-ray diffraction patterns of the samples were obtained by the Geiger Counter X-ray Diffractometer, and the results were compared with those of the dielectric constant method.

The sample in the sintered alumina boat was placed in a quartz tube, which was then set in a platinum electric furnace equipped with a voltage transformer and a chromel-alumel thermocouple. The position where the sample was placed in the furnance was selected so as not to be affected by the temperature variation in the furnace. In any given run, the temperature fluctuation did not exceed ±2°C. The temperatures of the experiments were established within 3 min. after the boat had been put in the furnace.

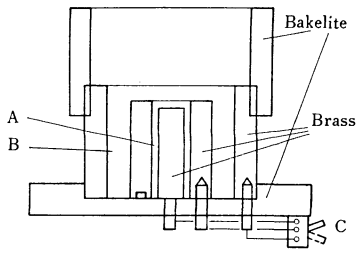

Fig. 1. Coaxial cylindrical cell for the analysis of the anatase-rutile mixture by means of the dielectric constant measurements.

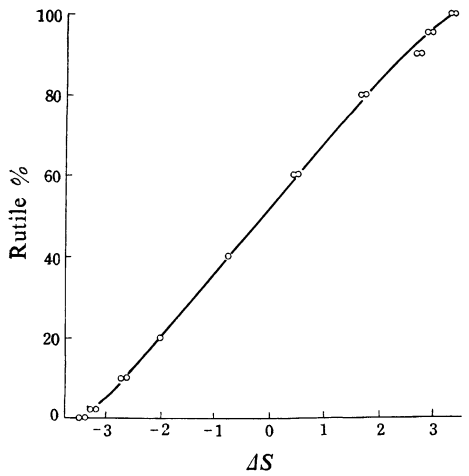

Fig. 2. Calibration curve for the analysis of the anatase-rutile mixture by means of the dielectric constant measurements.

The oxygen atmosphere was obtained from a bomb containing oxygen prepared electrolytically from distillated water. The oxygen was dried by letting it pass through sulfuric acid and calcium chloride. By using a u-type flow meter, the flow velocity of the oxygen was controlled.

Potassium chloride or lithium chloride was added to the samples in the form of solutions, and the mixtures were dried at 150°C before heating.

Experimental Results

The results of experiments on many samples, which were subjected to different heat treatments or surrounding atmospheres and which contained different additives, are sammarized in Figs. 3—6. Within the range of experimental uncertainty, no variation in the lattice parameter was encountered for any sample, and the diffraction patterns of anatase and rutile agreed fairly well, with respect to both the *d* values and the relative intensities, with those previously reported[8] by means of the

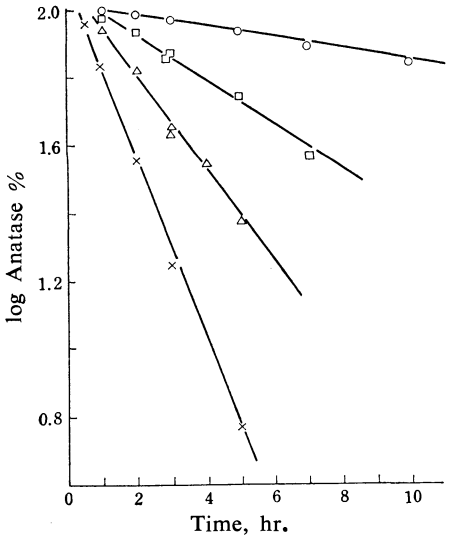

Fig. 3. First-order plots of the data in the sample "a" in air.

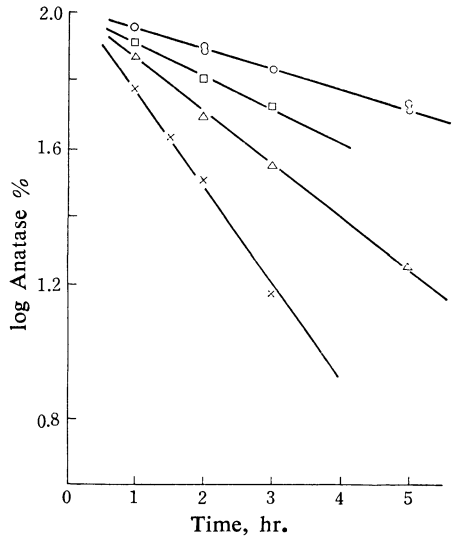

Fig. 4. First-order plots of the data in the sample "b" in air.

8) A. S. T. M. X-ray powder diffraction card.

X-ray diffraction method. No line broadening was encountered throughout the whole stage, nor was there any evidence for the existence of solid solutions, i. e., of disordered structures.

The color of most samples turned from white to yellowish as the transition proceeded, but the color of the sample with potassium chloride turned greyish.

Transition of Pure Titanium Dioxide in Air. —The transition from anatase to rutile modification was found to occur between 750 and 800°C in pure titanium dioxide in air. The rate of transition depends on the heating time and the temperature. Figures 3 and 4 show the transition of pure titanium dioxide in air, log(Anatase %) against time being illustrated. Fig. 3 shows the transition of "a", and Fig. 4, that of "b". These data were treated as previously reported by Czanderna, Rao and Honig[1] and by Rao[2]. In this study the data were plotted for the first-order equation; the data follow the first-order law fairly well for two kinds of samples, "a" and "b". However, there was a large difference between the rates of the transition of "a" and "b" as shown in Table I. In Table I the values of the rate constants, k, are shown for the transitions without and also with flux.

The activation energy was computed from the standard Arrenenius plot of $\log k$ against $1/T$ shown in Fig. 7. The deviation of each plot from the straight line is within the range of experimental error. The values of the activation energy thus obtained were 110 and 116 kcal./mol. for "a" and "b" respectively.

Attention should be paid to the fact that the values of activation energy do not differ significantly between "a", and "b" even

-△- b, air; -○- b, O_2

TABLE I

Sample	Heating condition	Rate constant, $k\times10^2$, hr^{-1}	
		780°C	790°C
a	Air	19.6	34.5
a	Air, LiCl	100.0	—
b	Air	36.5	69.2
b	O_2	51.8	78.1

though the difference in rates is large.

Transition of Pure Titanium Dioxide in an Oxygen Atmosphere. — Czanderna, Rao and Honig[1] reported that the transition was not significantly affected by the atmosphere. In this study, the "b" samples were heated in an oxygen atmosphere; the results obtained are shown in Fig. 5. The rate of transition was greater in an oxygen atmosphere than in air, as is shown in Table I. The deviations from the first-order rate law and the standard Arrhenius plot are very small. The value of activation energy estimated from Fig. 7 was 92 kcal./mol.

Transition of Titanium Dioxide with Flux.— The rate of transition with lithium chloride was determined with sample "a" in the same way as has been described above. Figure 6 illustrates the transition in air with 1% lithium chloride. The rate of transition in the presence of lithium chloride was greater than that without lithium chloride, as is shown in Table I, and the deviations from the first-order rate law and from the standard Arrhenius plot are small. The value of the activation energy estimated from Fig. 7 was 150 kcal./mol.

The transition with potassium chloride was very different from that with lithium chloride. We could not estimate rate constants because of the fluctuation of the data. The percentages of rutile in the samples after heating them till 800°C did not exceed 15%.

Discussion

A large number of polymorphic transitions of chemical compounds have been studied in recent years, and it has been pointed out that in those cases difficulties remain in obtaining reproducible data. These difficulties are perhaps, partly caused by the fluctuation in the behavior of the starting materials. In the present study attention was directed to the following items in order to obtain the starting material of titanium dioxide; (a) it was made as chemically pure as possible, (b) the crystal growth of anatase ended in it, and (c) it contained no rutile-type compound. Thus, it was possible in this study to obtain reproducible data for one sample. Nevertheless, different transition rates were found for two samples prepared by the same procedure, as was seen in the transition of pure titanium dioxide in air. This may be caused by the facts that the preparing conditions were not yet completely controlled and that the physicochemical behavior of the samples, for example, in the particle size and in the number of lattice defects differed; therefore, the frequency factors in the equation of transition rates were different.

The kinetics of the transition of anatase to rutile have been studied by Rao et al.[1,2], by means of the X-ray diffraction method. In the present study the transition rate was measured from the change in the dielectric constant of the samples. It might be suggested that the analysis of a mixture of anatase and rutile by the X-ray diffraction method, in which the heights of the diffraction peaks of the two components are compared, is accompanied by error when the crystal growth of anatase is incomplete. The analysis of the anatase-rutile mixture by the measurement of the dielectric constant, which has recently been described by Oehme[7], was tried in this study; it was proved that the analysis could also be successfully carried out in a sample which contains anatase below 10% or above 90%. The analysis of such a sample is known to be difficult to perform by the X-ray diffraction method.

The activation energy for the anatase-rutile transition in air was measured by Czanderna, Rao and Honig[1] as 110 ± 10 or 90 ± 10 kcal./mol., and later by Rao alone[2] as 80 ± 10 kcal./mol. They empolyed as a starting material anatase obtained by precipitation from an ammoniacal solution of titanium after elimination of the impurities. However, in our study the value of this energy is calculated as 110 kcal./mol. or 116 kcal./mol. It is thought that this discrepancy is caused by the fact that Rao et al. dried their samples at a relatively low temperature (160°C). It is difficult to dehydrate completely the titania gel prepared by hydrolysis in an aqueous solution of titanium salt; furthermore, the crystal growth of anatase is incomplete in this case.

It was assumed by Czanderna et al. that atmosphere had no effect upon the anatase-rutile transition, but it was recognized in our experiment that the value of the activation energy of this transition is somewhat larger in air than in oxygen.

As for the effect of the flux, it is probable that the lithium or potassium atom may enter into the lattice of titanium dioxide, and/or that flux may react with titanium dioxide to form a titanate of lithium or potassium. It was proved by flame photometric analysis that the lithium or potassium ion was not found in the washing liquid obtained by the cold or hot washing of the samples which had been heated with flux. However, it was found that the lithium or potassium ion was present in that solution which had been obtained by dissolving the samples in sulfuric acid. On the other hand, it was impossible to recognize the change in the lattice constant by means of X-ray diffraction analysis. Also, there was

no abnormal change in the dielectric constant of the samples. It might be necessary to carry out accurate measurements in order to clarify the atomic behavior of the flux.

The rate of tranision has been theoretically treated by Avrami[9], and his equation has been applied to explain the phenomena in the transition of several materials. However, in the transition of titanium dioxide, it has been proposed that treatment by Avrami's equation may provide only a formal account of the conversion process. The results obtained in our experiments fit fairly to the first-order rate law, the deviations from the straight line being found not to exceed the range of experimental error. The induction period might exist in the case of the transition of sample "a" in air, but it was impossible to clarify this phenomena because of the fluctuation of the analytical process. The data fluctuate when the conversion takes place only in a small amount of anatase or rutile, especially below 2%.

It might be worth comparing the values of the activation energy in the transition with those of the thermodynamical properties. It has been reported that the activation energy is equal to the energy of sublimation, e. g., in the transition of sulfur[5], *o*-nitroaniline[3] and azoxybenzene, but not in mercuric iodide[6]. Meanwhile, de Boer[10] has proposed that the transition of the tridymite form of silicon dioxide into the cristobalite form would resemble that of wurtzite into zinc-blende. He has assumed that it might be neccessary to break the links between the Si- and O-atoms before SiO_4 tetrahedra can be shifted and that after such shifts the Si-O links might be re-established; consequently, such a transition might not proceed easily.

It might be assumed that the transition would be accompanied by the rupture of the bond in such compounds as AB_2, e. g., in silica, germanium dioxide, or titanium dioxide, and that the bond energy would be nearly equal to the activation energy. In the quartz-tridymite transition of silica, it has been reported that the activation energy is 96 kcal./mol., while the bond energy of Si-O is calculated to be 89.3 kcal./mol. by Pauling[11] and 101 kcal./mol. by Huggins[12]. Furthermore, it will be reported that the activation energy is about 100 kcal./mol. in the hexagonal-tetragonal transition of germanium dioxide[13], while the bond energy of Ge-O was reported to be 104 kcal./mol. as calculated from Huggins' data[12], It was impossible to find the bond energy of Ti-O, but, with the assumption that the bond energy would be obtained by dividing the heat of formation[14] by the number of bonds per stoichiometric molecule of such compounds as titanium dioxide, it is possible to establish the bond energy of Ti-O as 109 kcal./mol., which value is nearly equal to the activation energy of the anatase-rutile transition. Such an assumption might also explain the transition in mercuric iodide. It might be necessary, however, to carry out an investigation into the transition in compounds similar to titanium dioxide in order to prove the above idea.

Summary

The kinetics of the transition of anatase to rutile have been studied in the temperature range 750~800°C by means of dielectric constant measurements. The kinetic data can be fitted reasonably well by the first order equation. The transition rate is significantly affected by the heating atmosphere and the flux, and the values of the activation energy show a significantly large difference in these cases. In an air or oxygen atmosphere the value of the activation energy in the transition of pure titanium dioxide is 110 or 116 kcal./mol. and 90 kcal./mol. respectively. When 1% of lithium chloride is added to the titanium dioxide, the value of the activation energy of the transition is 150 kcal./mol.

The authors wish to thank Dr. R. Ishida for his spectroscopic analysis of samples, Dr. Y. Kamura for his discussion of the measurement of the dielectric constant, and Mr. E. Asada for his discussion of analysis by the X-ray diffraction method.

*Solvent Extraction of Coal—Relation between the Yield of Extract and the Solubility Parameter of the Solvent**

By Yuzō SANADA and Hidemasa HONDA

(Received November 29, 1961)

In spite of the obvious variations in the yield of extract found with different solvents, only a few workers have attempted to study systematically the solvent effect of extraction for coal. The most extensive work on the extraction of coal has been done by Dryden[1-3]. Dryden developed an interesting classification of suitable coal solvents from his results, and observed that the yield of extract obtained from a given coal varies largely with the type of solvent employed and that the better solvents for coals, such as ethylene diamine, have structures containing a nitrogen or oxygen atom possessing an available unshared pair of electrons. Recently Halleux and Tschamler have, from a study of coal extraction with a series of closely related pyridine bases[4], expanded the hypothesis put forward by Dryden. These investigators indicate that the acid-base interaction is important in explaining the relative solvation power of pyridine bases for coal.

The most important studies made of the relation between the physical or chemical nature of solvents and the yield of extract are those by Kiebler[5,6]. A statistical analysis was done from the values of the yield of extract and from the various physical properties of the solvent. The physical properties considered were internal pressure, surface tension, dipole moment, dielectric constant, refractive index, and so on. Of these properties, the internal pressure had the most significant relationship to the yield of extract as shown by correlation coefficients. Kiebler showed that the relation between the yield of extract and the internal pressure of solvent at a given temperature is approximately linear, and that deviations from the resulting regression line could not be related to any physical properties[5,6]. There are, however, several reasons why Kiebler's conclusions are not wholly acceptable[2]: (i) Kiebler rejected a number of solvents on the suspicion of chemical effects; therefore, his experiments were based on a selected range of liquids; (ii) he excluded water and glycol, because their dissolving power against coal is poor in spite of their high internal pressures; (iii) his extraction method was not based on the Soxhlet principle; therefore, it is doubtful whether the completeness of extraction by all solvents is of the same order.

According to the regular solution theory, on the other hand, cohesive energy density (CED)** is an important factor in determining the action of a solvent on a solute[7]. It is also well known that the solvation of a polymer by various organic liquids correlates to a large extent with the CED of the solvent and the polymer[8,9]. Consequently, one may expect some relationship between the CED of the solvent and the yield of extract obtained from coal.

Experimental

The coal specimen was pulverized enough to pass through a 30-, and to stand on a 60-, Tyler mesh sieve. The lighter fraction, with a specific gravity of less than 1.30, was isolated by the float-or-sink method, using a mixture of benzene and carbon

TABLE I. CHARACTERISTICS OF SAMPLES USED

Source	Proximate analysis, %				Ultimate analysis d. a. f., %		
	Moisture	Ash	Volatile matter	Fixed carbon	C	H	O+N+S
Yūbari	1.7	2.4	42.0	53.9	85.2	6.3	8.5
Ashibetsu	3.0	4.1	42.9	50.0	81.1	5.5	13.4

tetrachloride. These fractions have ash contents of less than 3% and are estimated to be almost vitrain. The characteristics of the various vitrains are listed in Table I. All solvents were commercial reagents (grade: guaranteed reagent or extra pure) and were used without further purification.

Instead of the customary method of Sexhlet extraction, a modified Soxhlet method at the boiling temperature of the solvent was used. The apparatus is shown in Fig. 1. The extraction was done exactly at the boiling temperature of the solvent. Vitrain samples (dried in vacuo at 110°C) were extracted under the standard conditions, namely, a coal to solvent ratio of 150 mg. to 30 ml. and under dry air for 48 hr. The extraction residue was dried in vacuo at 110~180°C for 7 hr. The extraction residues by the higher boiling solvents were washed with acetone before drying. The extraction yield was determined by direct weighing of the residue. The absorption effect of the solvent on the residue was not considered, because examination of ethyene diamine, one of the more powerful solvents, showed only a small difference (about 2% or so between the yield obtained by the direct weighing method and that obtained by calibrating the nitrogen in increase in the residue.

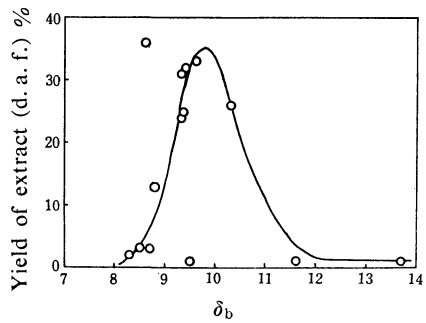

Fig. 2. Relation between yield of extract and solubility parameter of solvent at b. p. (Yūbari vitrain).

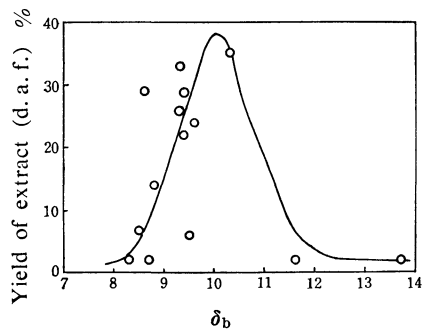

Fig. 3. Relation between yield of extract and solubility parameter of solvent at b. p. (Ashibetsu vitrain).

Experimental Results

The CED of the solvent, e_{ss} (cal./cc.), was calculated from the following relationship:

$$e_{ss}=(L_b-\mu RT)/V_b \quad (1)$$

where L_b is the latent heat of vaporization at the boiling point in cal./mol., V_b is the molecular volume at a normal boiling point in cc./mol., R is the gas constant, T is the boiling temperature in °K, and μ is the correction term in $\mu=PV/RT$. (For substances boiling above 50°C, and, therefore, for all solvents used, the μ correction can be neglected.) The V_b value was calculated by the additive method using LeBas's volume increments[10]. The average error for the compound tested was 4.7%. The value of L_b was available in the references[11-13].

TABLE II. YIELD OF EXTRACT AT BOILING TEMPERATURE TOGETHER WITH CERTAIN PHYSICAL DATA FOR THE SOLVENTS USED

Solvent	t_b, °C	δ_b	Yield of extract d. a. f., %	
			Yūbari	Ashibetsu
Chloroform	61	8.7	2.6	2.3

If L_b was unknown, the estimation was made by the Watson-Negishi method according to the following equation[14]:

$$L_b = 2.48\ (t_b+273)^2/(A+0.11t_b) \qquad (2)$$

where A is the constant within a given homologus series, and t_b is the boiling point in °C. Therefore, the solubility parameter, δ_b, at the boiling point is deduced from the CED as follows:

$$\delta_b = \sqrt{e_{ss}} \qquad (3)$$

The yields of extract for Yūbari coal and for Ashibetsu coal by various solvents are presented in Table II, together with the t_b and δ_b values of various solvents. Figures 2 and 3 show the relation between the yield of extract and the value of δ_b for Yūbari coal and for Ashibetsu coal respectively. The yield of extract increases with the increase of δ_b, reaches a maximum at about 10 of δ_b, and then decreases with the increase of δ_b.

Discussion

Several attempts to find a correlation between the yield of extract and some physical properties of the solvents have been proposed[5,6,15-17]. These methods can, however, be successful in only a limited number of case, for example, in a series of chemically related solvents[4].

In spite of the fact that the solvents we used included various chemically different types, including alcohols (though they were excluded by Kiebler), and have a wide range of boiling temperatures from 61 to 202°C, a good relationship between the yield of extract and the δ_b value of the solvents has been found, as is shown in Figs. 2 and 3, with the exception of acetophenone and butanol.

The poor dissolving power of alcohol and water against coal, in spite of their high CED values, may be explained by the following reasons. Alcohol and water are strongly hydrogen-bonded substances and have high CED values, owing to their hydroxyl associations. These liquids are all substances which form 'solvent-solvent' contacts (hydrogen bonds) with the evolution of a large amount of energy. It seems that they form 'solvent-coal' contacts less readily and that the energy gained in forming these contacts does not balance the energy lost in breaking the 'solvent-solvent' and 'coal-coal' contacts.

From these results, it appears that the CED value is one of the most important factors determining the solvent action of liquids on coal. Moreover, our conclusions, based on the Soxhlet principle and resulting from the employment of solvents having CED values over a wide range, should be borne in mind.

It is possible to propose the following explanations for the deviations from the resulting correlation curves. The solvents include various chemically different types and have a wide range of boiling temperatures. The various polar groups in solvents, therefore, may have some specific influences on coal. Coal is a mixture of complex compounds, and the CED value of coal varies with the temperature. Moreover, the estimation error of the CED value at the boilng temperature may contribute to the deviation.

Further strict experiments on the action of solvents on coal have been made; these results will be reported later[18].

On the Association of Condensed Polycyclic Aromatic Compounds in Concentrated Sulfuric Acid

By Takashi HANDA

(Received February 25, 1961)

Several investigations have been made of the aggregation of dye molecules or ions in aqueous solutions, and it seems clear that some dyes form dimers and polymers under suitable conditions. Qualitative discussions of the factors determining the associations and also of the spectral shifts caused by them have also been made[1-9].

The polycyclic aromatic hydrocarbons and their related quinons in concentrated sulfuric acid possess strong absorptions in the visible region which are ascribed to monomeric proton-complexes. Some of these spectral responses show a blue shift with an increasing concentration of the solute. These phenomena are interpreted as being caused by association of molecules.

These associates are considered, from experimental spectral facts, to be in equilibrium with the monomeric proton-complexes. For instance, dibenzopyrene forms successively, an octamer and the higher polymers in 96 per cent sulfuric acid with an increase in the concentration of the solute. However, it forms a dimer in 86 per cent sulfuric acid and shows no eminent blue spectral shift. Also the case of some of the related quinones such as anthraquinone, which forms a tetramer, *p*-naphthoquinone, and anthanthrone, which forms dimers, no blue shift is observed either. Moreover, tetracene and benzoanthrone form no polymers up to 10^{-2} mol. per liter of the concentration of the solutes.

The object of the present paper is to report these points, with some discussion of the mechanism or of the association of these compounds with reference to the considerations of the above-described investigations[1-9].

Experimental

The measurement of the absorption spectra was carried out with a Beckman DU-type spectrophotometer with quartz-cells, 1.0, 0.1 and 0.05 cm. thick, and with, in the visible region, a thin, transparent glass plate 0.01 cm. thick. The read-off value of the spectral measurement was the mean value of three readings in the concentrated region of solute molecules.

The specimen used in this experiment was prepared and recrystallized from appropriate solvents and was further purified by the repeated sublimation in vacuo of 10^{-3} to 10^{-4} mmHg. The concentrated sulfuric acid used in this experiment was an extra pure grade reagent of the Kanto Chemical Co., Ltd., which was considered to be chemically pure and to be transparent in the visible region of the spectrum. The concentration of the acid was to be ca. 98 per cent.

The solutions of different concentrations used in this experiment were prepared by dilution of the concentrated stock solution, the concentration of which was about 10^{-2} to 10^{-3} mol. per liter and which was freshly prepared before each measurement.

Results and Discussion

Dibenzopyrene (I). — Two strong absorption bands appear in succession in the spectra of the sulfuric acid solution, 10^{-6} mol. per liter,

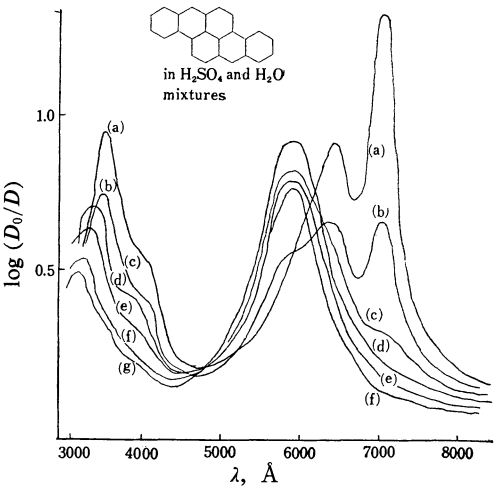

Fig. 1. The absorption spectra of dibenzopyrene in H_2SO_4 of 96% (a), 90% (b), 85% (c), 80% (d), 75% (e) and 70% (f).

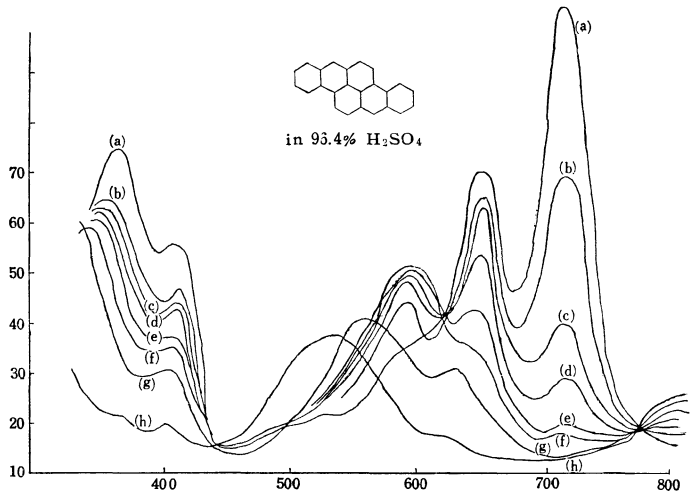

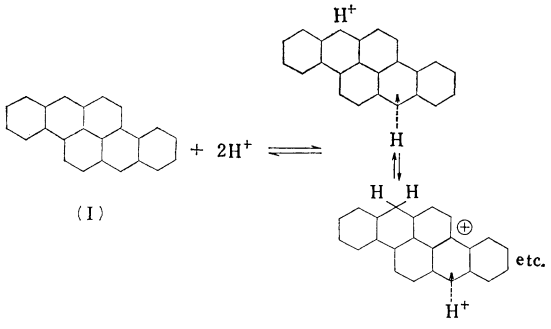

Fig. 2. The absorption spectra of dibenzopyrene with its concentration of $2.7\times10^{-6}\sim 5.4\times10^{-5}$ (a), 6.75×10^{-5} (b), 9×10^{-5} (c), 1.35×10^{-4} (d), 2.7×10^{-4} (e), 9×10^{-4} (f), 2.7×10^{-3} (g) and 1.4×10^{-2} mol./l. (h) in 96.4% sulfuric acid.

with the increase in acidity, as is shown in Fig. 1. When this hydrocarbon is dissolved in 86 per cent sulfuric acid, the peak of the absorption band is found in the region of 580 mμ. When 98 per cent sulfuric acid is used, the band shifts to the longer wavelength region, 725 mμ. Both are considered to be in equilibrium with each other and with the protons in the acid. Therefore, the dibenzopyrene molecule is considered to be doubly protonated*. The protons which form a complex with the molecule are believed to be attached to the position of the largest charge-density as follows:

However, a discrepancy from Beer's law occurs with the increase of the concentration of solute up to 10^{-3} mol. per liter in 98 per cent sulfuric acid. New absorption bands appear near 595, 555 and 535 mμ with solute concentrations of 10^{-5}, 10^{-4} and 10^{-3} mol. per liter respectively. They may be interpreted as corresponding to the blue shift of the absorption band at 712 mμ by the influence of association and as being in equilibrium with each other; they have isobestic points near 770, 620, 570, 500, 465, 440 and 350 mμ, as is illustrated in Fig. 2.

Anthrone and Anthraquinone. — No new absorption peaks are found in the wavelength range from 350 to 1000 mμ, and only a decrease in the extinction coefficient at the absorption peak of monomer is observed with an increase in the concentration of the solute.

In the case of anthraquinone, however, a slight increase in the extinction coefficient is found beyond the region of the isobestic point near 460 mμ, in the skirt of the strong absorption peak of the monomer, with an increase in the concentration. This increase may be interpreted as being due to the slight change in the electronic state of monomer as a result of a weak intermolecular hydrogen bond formation between two molecules. As the configuration of the associate, a proton and a $(H_3SO_4)^+$ ion may be supposed to be resonating among a pair of two oxygen atoms of the molecules, which are assumed to take a parallel plane configuration. The structure is centrally symmetrical and possesses many resonating structures in the ground and excited states, unlike the model of the acridine-orange double ion by Zanker[6], which is anti-symmetric for one axis.

On the other hand, the absorption peak of anthrone in sulfuric acid, where polymerization of the 16th-degree occurs, shows a red-shift,

* As was reported in a preceding paper (T. Handa, This Bulletin, **28**, 483 (1953)), we were able to obtain the two pK_B values of −5.0 and −7.4.

as is illustrated in Fig. 3, and also a slight increase in the extinction coefficient in the skirt of the main absorption band beyond the isobestic point near 415 mμ with an increase in the solute concentration. The configuration of the associate is supposed not to be coplanar and to be anti-symmetric like the acridine-orange double cation.

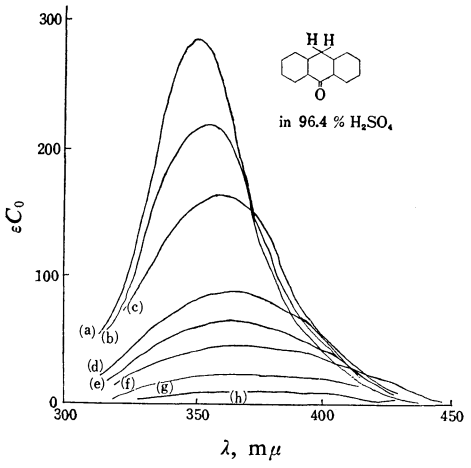

Fig. 3. The spectral response of the absorption spectra of anthrone with its concentration of 5.5×10^{-5} (a), 9.6×10^{-5} (b), 1.45×10^{-4} (c), 2.9×10^{-4} (d), 3.4×10^{-4} (e), 5.6×10^{-4} (f), 1.05×10^{-3} (g), and 5.78×10^{-3} (h) in 96.4% sulfuric acid.

Several quinones, such as *p*-naphthoquinone, anthanthrone and isoviolanthrone in sulfuric acid, whose degrees of polymerization are 2, 4 and 2 respectively, exhibit similar behavior.

Benzanthrone and Benzonaphthenone.—These compounds form no polymers. It is considered that, because of the larger weight of the existence of π-complexes in the ground state which gives the resonating carbonium ion, the potential barrier in the Morse curve in Fig. 5 may be higher than those in other cases because of the electrostatic repulsion of carbonium ions and the fact that they can not ride over this potential barrier to form stable polymers.

From the foregoing experimental facts, the association constant, k, and the degree of polymerization have been estimated.

When the equilibrium between monomer and polymer, an associate of n-th degree, exists, the association constant, k, is expressed as

$$k=\frac{X}{nC_0{}^{n-1}(1-X)^n} \qquad (1)$$

where X is the fraction of polymer and C_0 is the concentration of the solute molecule.

The apparent extinction coefficient, ε, at a definite wavelength is expressed as:

$$\varepsilon=\frac{X}{n}\varepsilon_n+(1-X)\varepsilon_m \qquad (2)$$

where ε_n and ε_m are the extinction coefficients of the polymer and the monomer respectively.

From Eqs. 1 and 2, we can obtain the following relation:

$$\log C_0(1-\varepsilon/\varepsilon_m) =\log(Ck)+n\log C_0\left(\frac{\varepsilon}{\varepsilon_m}-\frac{\varepsilon_n}{n\varepsilon_m}\right) \qquad (3)$$

where

$$C=n^n\left(n-\frac{\varepsilon_n}{\varepsilon_m}\right)^{1-n}$$

As a rough approximation, we can neglect $\varepsilon_n/\varepsilon_m$ as compared with $\varepsilon/\varepsilon_m$; therefore

$$\log C_0\left(1-\frac{\varepsilon}{\varepsilon_m}\right) =\log(Ck)+n\log C_0\left(\frac{\varepsilon}{\varepsilon_m}\right) \qquad (4)$$

When we apply Eq. 4 to determine the n for the dibenzopyrene molecule in 96 per cent concentrated sulfuric acid this degree is 8, as is shown in Fig. 4. Further, the new absorption band at the wavelength of 985 mμ may correspond to that of the octamer of the dibenzopyrene diprotonium cation, while the equilibrium constant, k, at 20°C is estimated to be approximately 3×10^{28}. We may expect the qualitative dimerization of the octamer of the dibenzopyrene diprotonium cation from the new absorption band near 555 mμ. The high degree polymerization proceeds in successive steps with the increase in the concentration of the dibenzopyrene molecule in such a manner as 8, 16, 32, and so on.

With the elevation of the temperature of the solution from 20 to 70°C, the intensity of the

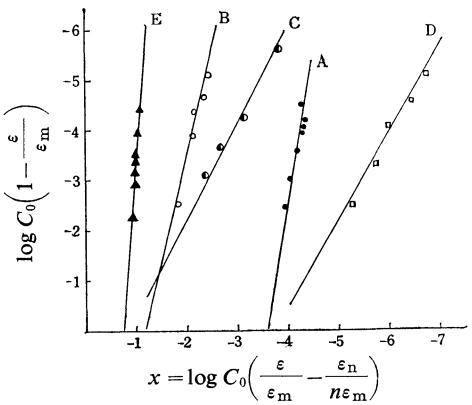

Fig. 4. The equilibrium relation (Eq. 3) between the monomer and the polymer of dibenzopyrene (A), anthraquinone (B), isoviolanthrone (C), anthanthrone (D) and anthrone (E) in sulfuric acid.

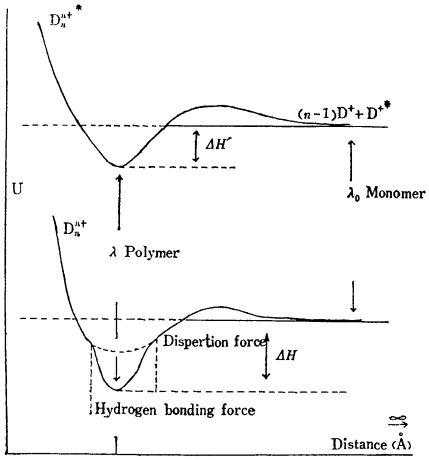

Fig. 5. The assumed Morse-curve of the polymers of the mono-protonium cations of a condensed aromatic compound in concentrated sulfuric acid.

absorption band at 580 mμ, which corresponds to the optical absorption of the octamer, decreases, while that at 710 mμ, corresponding to the monomer, increases. This may be understood as being due to the thermal decomposition of the polymers. The values of $\log k$ at temperature of 20, 45 and 70°C are 28.5, 25.4 and 22.3 respectively. From the above temperature dependency of the equilibrium constant, the heat of the association of the octamer of dibenzopyrene in concentrated sulfuric acid is estimated to be 54 kcal./mol. from the following equation (Eq. 3):

$$\Delta H = \frac{RT_1T_2 \ln k_2/k_1}{T_2 - T_1} \qquad (5)$$

where k_1 and k_2 are association constants at temperatures of T_1 and T_2 respectively. The value of the entropy may be estimated, for the association of the dibenzopyrene octamer, as 47 cal./mol. deg.

From these experimental results, the equilibrium constants of isoviolanthrone at temperatures 20, 45 and 70°C are determined to be 3.4, 3.0 and 2.7 respectively. Therefore, the heat of association for this molecule is roughly estimated as 6.4 kcal./mol.

Discussion

The foregoing results suggest that the formation of the associates of complexes among sulfuric acid and the condensed polycyclic aromatic hydrocarbons and their related quinones are divided into three types. The first type exhibits a blue-shift of the absorption-peaks of the spectra of the associates and forms the higher associates in successive steps with the increase in the concentration of the solute. A typical example is the case of doubly protonated dibenzopyrene in 96 per cent sulfuric acid.

The second type does not exhibit any blue-shift of the absorption-peaks of the spectra of the associates but forms one kind of associate with a definite degree of association and does not form the higher associate with the increase of the concentration of the solute. Examples are singly protonated dibenzopyrene in 86 per cent sulfuric acid and singly protonated anthraquinone in 96 per cent sulfuric acid. The third type forms no associate. An example of this is benzoanthrone in 96 per cent sulfuric acid.

Concerning the cause of association, we may imagine, firstly, the London-type dispersion force and, secondly, a hydrogen bonding-like force among proton and oxygen atoms. It is very uncertain whether or not such forces are exerted on monomers in a strongly polarized solvent. Rabinowitch and Epstein have ascribed the cause of the dimerisation of thionine molecules in water and ethanol to the London-type dispersion force and have estimated the stable intermolecular distance, r_0, by assuming that the minimum potential energy, U_0, in the Morse curve is approximately equal to the heat of association.

When we ascribe the cause of the association in the case of doubly protonated dibenzopyrene with the association degree of 8, to the London-type dispersion force, we can estimate the mean intermolecular distance, r_0, as do Rabinowitch et al.*, on the assumption that the heat of association per pair of the octamer or $\Delta H/7$ is equal to the minimum potential energy, U_0, in this case. The estimated value of r_0 is approximately 3.2 Å when we put the experimental oscillation-strength, f, as equal to 0.53 and λ as equal to 6825 Å, which figures are estimated from the absorption spectrum, and the refractive index of the solvent, n as 1.44.

This is a reasonable value compared with the one estimated in the case of the dimerization of thionic molecules studied by Rabinowitch et al. and compared with the van der Waals radii of the aromatic molecule in the solid state.

When we assume the experimental heat of association to consist of only the dispersion energy in the case of the singly protonated dibenzopyrene (where no blue-shift is observed dimerization), the intermolecular distance, r_0, is estimated to be ca. 2.6 Å, which is considered to be unreasonably small. This is also the

* $$\partial U/\partial r = 0 \qquad (1)$$

$$U_0 = -1.74\times10^{-7} f^2 \lambda_0^3/r^6 \quad -3.287\times10^{-10} f^3 \lambda_0^4/r^8 - 5.825\times10^{-13} f^4 \lambda_0^5/r^{10} + 330/D_T + x/r^{12} \qquad (2)$$

$$f \fallingdotseq 4.32\times10^{-9} \times n \int \varepsilon \, d(1/\lambda) \qquad (3)$$

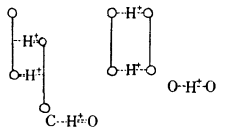

TABLE I

Name of substance	pK	Degree of polymerization	log K*1	f*2	λ_0 Å	H*3 kcals./mol.
p-Naphthoquinone	−7.5	1.7	1.9	0.21	4100	
Anthraquiaone	−7.5	4.1	12.3	0.39	4100	ca. 23

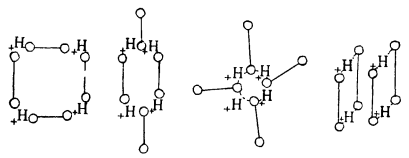
case for isoviolanthrone in 96 per cent sulfuric acid. In this case, the r_0 is estimated to be ca. 2Å, as it is in the cases of anthraquinone, anthanthrone, *p*-naphthoquinone and anthrones.



These intermolecular distances are considered to be unreasonably small. In these compounds, we can not observe the blue-shift of the absorption-peak of the monomers.

○ Oxygen atom ● $H_3^+SO_4$ ion
—— Dibenzopyrene (d)

Therefore, it may be necessary to assume some force like the intermolecular hydrogen-bonding which such combinations as O···H^+···O, C···H^+···O and C···H^+···C exert within a certain range of the intermolecular distance in the Morse curve, in addition to the dispersion force as illustrated in Fig. 5, in the strongly polarized environment with both positive and negative charges. The experimental heat of association may be put approximately as the sum of the potential energy, U', of the dispersion force and the heat of the formation of the weak intermolecular hydrogen-bonding, U''.

In the case of the related quinones, the effect of the intermolecular hydrogen-bonding, O···H^+···O and O^+···H···O, may be considered to play an important role in the association compared with the effect of the dispersion force. The amount of the hydrogen-bonding may be estimated as 2∼4 kcal./mol., assuming the state of the existence of polymer to be as is illustrated in Fig. 6.

In the case of benzoanthrone, the term from the electrostatic repulsive energy among those positive charges in the carbon skelton which are caused by the larger basicity of the molecule might play an important role in the above considerations.

Summary

The effect of the concentration on the absorption spectra of condensed polycyclic aromatic hydrocarbons and their related carbonyl derivatives in concentrated surfuric acid was studied in the concentration range from 10^{-6} to 10^{-3} mol. per liter. The free energies and heats of formation of these associates were also measured.

In the case of the dibenzopyrene molecule in 96 per cent sulfuric acid, it is observed that various kinds of association, such as 8, 16 etc., were obtained in successive steps with the

increase in the concentration of the solute, while in the case of carbonyl derivatives, only one kind of associate was observed, the number of degree of association of which was observed to be 2, 4 and 16.

In the case of dibenzopyrene in 96 per cent sulfuric acid, where it is believed to be doubly protonated, the cause of association might be explained by the dispersion effect, while the blue-shift of the absorption peak of the monomer is clearly observed in successive steps succession with the increase in the concentration of the solute.

However in the case of carbonyl derivatives and dibenzopyrene in 86 per cent sulfuric acid, where they are singly protonated, it is observed that they do not show any blue-shift of their absorption peaks but a lowering of the extinction coefficient.

As is illustrated in Table I, their experimental heat of association may possibly not be explained by the dispersion effect alone. It may be necessary to take into consideration some kind of hydrogen-bonding between the carbonyl oxygen atoms and the proton.

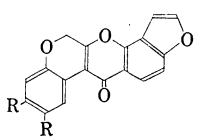
Synthetic Studies on the Benzofuran Derivatives. VIII. Synthesis of Furo[2,3-f]chromeno[3,4-b]chromone[*1]

By Yoshiyuki KAWASE and Chûji NUMATA



(Received October 20, 1961)

Miyano and Matsui[1] have succeeded in the reduction of chromenochromones to give chromanochromanones, and recently the total syntheses of rotenone[2], deguelin[3] and munduserone[4] have been accomplished by this method.

Therefore, it seems desirable for the synthesis of elliptone[5] (I), a kind of rotenoids, to prepare dehydroelliptone (II) because I may be obtained from II by the method mentioned above.

I

II) R=OMe
III) R=H

Now the synthesis of furo[2,3-f]chromeno-[3,4-b]chromone (III), the parent nucleus of II, has been carried out by two routes. Both routes started from 7-hydroxy-2'-methoxy-2-ethoxymethylisoflavone (IV), but differed from each other in the order of furan-ring construction and chromen-ring closure.

For the preparation of chromenochromones, two methods are available; those are by chromenochromone-ring formation of phenoxyacetic acid-2-(2-hydroxy)-acetophenone[6] (the Robertson's method) and by chromen-ring formation of 2-methyl[7] or 2-ethoxymethyl[8] derivatives of 2'-methoxyisoflavone (the Seshadri's method). In the latter method, Mehta and Seshadri reported that 7-hydroxy-2'-methoxy-2-ethoxymethylisoflavone (IV) was converted directly by the action of hydrogen bromide in acetic acid into 2', 7-dihydroxy-8-bromomethylisoflavone (VI) which was converted into 9-hydroxychromeno[3,4-b]chromone (VII), and Seshadri and Varadarajan reported that VII was also obtained by the action of potassium carbonate in acetone on 2', 7-dihydroxy-2-hydroxymethylisoflavone (V) which

was prepared from 7-hydroxy-2'-methoxy-2-methylisoflavone (XVII) through four steps.

But in the author's experiments, the hydroxybromomethyl compound VI was not obtained directly from IV but only the 2'-methyl ether (XIV) of VI was obtained by the procedure reported by Mehta and Seshadri, and also some attempts to obtain the 2-halomethyl analog of VI from IV by the action of other reagents (e. g. hydrochloric, hydrobromic or hydroiodic acid in acetic acid or pyridine hydrochloride) resulted in a failure. Further, the 2-phenoxy analog (XV) of IV was not affected by hydrogen bromide in acetic acid, and was converted into only the 2'-demethylated compound XVI by the action of anhydrous aluminum chloride.

On the other hand, IV was readily converted by the action of anhydrous aluminum chloride into the trihydroxy compound V which had been, with difficulty, prepared from XVII. But it proved to be impossible to convert this compound V directly into the chromenochromone VII by the procedure reported by Seshadri and Varadarajan, and also by other dehydrating reagents (e.g. *p*-toluenesulfonic acid in benzene, concentrated sulfuric acid, polyphosphoric acid, acetic anhydride, and tosyl or thionyl chloride in pyridine). Therefore, the trihydroxy compound V was made to react with hydrogen bromide in acetic acid to give the hydroxybromomethyl compound VI smoothly, which was readily converted into the chromenochromone VII*2 by the action of potassium carbonate in acetone.

Then, constructing the chromenochromone-ring by the above-mentioned modification of the Seshadri's method and building up the furan-ring by a method analogous to that reported previously for isoflavones[9], the authors synthesized the furochromenochromone III from IV as follows:

In one route, the chromenochromone VII was formylated by the hexamine method to give the 8-formyl compound VIII, which was converted into furochromenochromone-2-carboxylic acid (X) by the action of ethyl bromomalonate and potassium carbonate followed by alkaline hydrolysis. Decarboxylation of this acid X furnished the furochromenochromone III, slightly red colored microcrystals, m. p. 239.5~240°C.

In the other route, the furochromenochromone III was obtained more smoothly by the chromen-ring closure of 2'-methoxy-2-ethoxymethylfuro-[2,3-f] isoflavone (XI), its preparation from the isoflavone IV was reported in the previous paper[9]: Furoisoflavone XI was treated with aluminum chloride in nitrobenzene not in benzene to give the dihydroxy compound XII, which was converted into the bromo compound XIII and then finally into III, slightly orange colored microneedles, m. p. 241.5~242.5°C, identical with the other sample. The structure of III and of the other intermediates was confirmed by ultraviolet and infrared spectroscopy and by microanalysis.

Experimental*3

7-Hydroxy-2'-methoxy-2-bromomethylisoflavone (XIV).—A mixture of IV (1 g.), acetic acid (10 ml.) and hydrogen bromide-acetic acid (50%, 10 ml.) was allowed to stand over night, then the mixture

*2 This VII was also prepared by the Robertson's method.

9) T. Matsumoto et al., This Bulletin, 31, 688 (1958); Y. Kawase and K. Fukui, ibid., 31, 693 (1958); Y. Kawase et al., ibid., 33, 1240 (1960).

*3 Melting points are uncorrected and infrared spectra were measured in Nujol unless otherwise noted.

was heated for 45 min. on a steam-bath with the addition of more hydrogen bromide-acetic acid (50%, 10 ml.). Ice water was added to the cooled solution, and the solid products obtained were recrystallized from ethanol to give XIV in colorless microcrystals, m. p. 192~193°C, which gave a positive Beilstein test.

Found: C, 57.22; H, 3.79. Calcd. for $C_{17}H_{13}O_4Br$: C, 56.53; H, 3.63%.

7-Hydroxy-2'-methoxy-2-phenoxymethylisoflavone (XV).—To a solution of 2,4-dihydroxyphenyl 2-methoxybenzyl ketone (2.6 g.) in pyridine (50 ml.) was added phenoxyacetyl chloride (5 g.) drop by drop with ice cooling and stirring. By the usual treatment of the mixture, XV was obtained in colorless microcrystals, m. p. 232~233°C (from ethanol); yield 1.25 g. (33.5%).

Found: C, 73.34; H, 4.86. Calcd. for $C_{23}H_{18}O_5$: C, 73.79; H, 4.85%.

2',7-Dihydroxy-2-phenoxymethylisoflavone (XVI).—Anhydrous aluminum chloride (1.5 g.) was added to a solution of XV (0.5 g.) in benzene (or nitrobenzene), and the mixture was refluxed for 2.5 hr. on a steam-bath. The solvent was removed (by steam-distillation in the case of nitrobenzene), and the cooled residue was treated with ice water and hydrochloric acid. Next day, the precipitates were collected, washed with water, dissolved in aqueous sodium carbonate, and the alkaline solution was filtered and acidified. The crystaline products obtained were recrystallized from ethyl acetate or from dilute ethanol to give XVI in colorless microcrystals, m. p. 218~220°C; yield 0.2 g. (40%). IR: 3600, 3000 (broad) (OH), 1630 cm^{-1} (γ-pyrone).

Found: C, 73.03; H, 4.75. Calcd. for $C_{22}H_{16}O_5$: C, 73.33; H, 4.44%.

2',7-Dihydroxy-2-hydroxymethylisoflavone (V).—Powdered anhydrous aluminum chloride (12 g.) was added to a solution of IV (4 g.) in benzene (200 ml.) or in nitrobenzene (100 ml.), and the mixture was treated similarly as described for XVI. The product obtained from the sodium carbonate soluble part was crystallized from dilute ethanol to give V in colorless microcrystals, m. p. 225~226°C (decomp.)*4, identical with the sample kindly sent from Seshadri; yield 3 g. (86%). IR: 3200 (OH), 1630 cm^{-1} (γ-pyrone) (KBr).

Found: C, 67.56; H, 4.35. Calcd. for $C_{16}H_{12}O_5$: C, 67.60; H, 4.22%.

2',7-Dihydroxy-2-bromomethylisoflavone (VI).—A mixture of V (2.2 g.), acetic acid (22 ml.) and hydrogen bromide-acetic acid (50%, 33 ml.) was heated gradually to 100°C (20 min.) and kept for 45 min. at the temperature. Ice water was added to the cooled solution, and the crystalline product obtained was washed with water and with ethyl acetate, then was recrystallized from ethanol to give VI in colorless microcrystals, m. p. 221~224°C (decomp.)*5, which gave a positive Beilstein test and was identical with the sample from Seshadri; yield 2.1 g. (82%).

9-Hydroxychromeno[3,4-b]chromone (VII).—Anhydrous potassium carbonate (9 g.) was added to a solution of VI (0.9 g.) in anhydrous acetone (300 ml.), and the mixture was refluxed for 4 hr. and then for further 6 hr. with the addition of more potassium carbonate (9 g.). The solvent was distilled off, and the residue was dissolved in water, filtered and acidified. The crystalline product obtained was recrystallized from ethanol to give VII in colorless needles, m. p. 245~250°C (decomp.), identical with the sample prepared by the Robertson's method; yield 0.7 g. (quantitative).

UV λ_{max}^{EtOH} mμ (log ε): 270 (5.02), 297 (4.55).

9-Hydroxy-8-formylchromeno[3,4-b]chromone (VIII).—A mixture of VII (1.5 g.), hexamine (8 g.) and acetic acid (60 ml.) was heated on a steam-bath for 6 hr. and then for further 10 min. with the addition of hot hydrochloric acid (20%, 27 ml.). The crystalline product obtained from the cooled solution was recrystallized from ethyl acetate to give VIII in slightly yellow colored needles, m. p. 261~262°C, which gave a red ferric chloride reaction; yield 0.7 g. (40%). IR: 1730 (CHO), 1630 cm^{-1} (γ-pyrone).

Found: C, 69.18; H, 3.69. Calcd. for $C_{17}H_{10}O_5$: C, 69.39; H, 3.43%.

Furo[2,3-f]chromeno[3,4-b]chromone-2-carboxylic Acid (X).—Anhydrous potassium carbonate (4 g.) was added to a solution of VIII (0.9 g.) and ethyl bromomalonate (1.2 g.) in anhydrous acetone (130 ml.), and the mixture was refluxed for 8.5 hr. Acetone was distilled off, and the residual product was crystallized from ethanol to give ethyl furo[2,3-f]chromeno[3,4-b]chromone-2-carboxylate (IX) in slightly brown colored microcrystals, m. p. 225~226°C; yield 0.4 g. (36%).

A mixture of this ester IX (0.4 g.), acetone (115 ml.) and 5% aqueous sodium hydroxide (30 ml.) was refluxed for 3 hr. The resulting mixture was acidified by hydrochloric acid, acetone was distilled off, and the crystaline product was collected and recrystallized from ethanol to give X in orange colored plates, m. p. 300°C (decomp.); yield 0.25 g. (68%). IR: 3500, 3320, 1700 (CO_2H), 1630 cm^{-1} (γ-pyrone).

Found: C, 66.33; H, 3.68. Calcd. for $C_{19}H_{10}O_6 \cdot 1/2\,H_2O$: C, 66.47; H, 3.23%.

2'-Hydroxy-2-hydroxymethylfuro[2,3-f]isoflavone (XII).—Powdered aluminum chloride (1.2 g.) was added to a solution of 2'-methoxy-2-ethoxymethylfuro[2,3-f]isoflavone[9] (XI)*6 (0.4 g.) in nitrobenzene (30 ml.), and the mixture was heated for one hour on a steam-bath. The resulted solution was treated with a little dilute hydrochloric acid, nitrobenzene was removed by steam-distillation, and the residue was extracted with ethyl acetate. The ethyl acetate solution was washed with dilute hydrochloric acid and then extracted with 5% aqueous sodium hydroxide. The precipitates obtained by acidifying the alkaline solution were recrystallized from ethanol to give XII in colorless microcrystals, m. p. 224~225°C; yield 0.2 g. (50%). IR: 3280 (OH), 1630 cm^{-1} (γ-pyrone).

Found: C, 70.32; H, 4.25. Calcd. for $C_{18}H_{12}O_5$: C, 70.12; H, 3.93%.

*4 Melting point was 212~214°C (decomp.) when the temperature was raised slowly.

*5 Melting point was 212~214°C (decomp.) when the temperature was raised slowly.

*6 M. p. 119~120°C; UV λ_{max}^{EtOH} mμ (log ε): 240 (4.98), 307 (4.14); IR: 1640 cm^{-1} (γ-pyrone) (KBr).

2'-Hydroxy-2-bromomethylfuro[2,3-f]isoflavone (XIII).—A mixture of XII (0.15 g.), acetic acid (2 ml.) and hydrogen bromide-acetic acid (50%, 3 ml.) was treated similarly as described for VI. The product was recrystallized from ethyl acetate to give XIII in colorless microcrystals, m. p. 210°C (decomp.), which gave a positive Beilstein test; yield 0.1 g. (60%). IR: 3380, 3190 (OH), 1630 cm^{-1} (γ-pyrone).

Found: C, 58.46; H, 3.06. Calcd. for $C_{18}H_{11}O_4Br$: C, 58.24; H, 2.98%.

Furo[2,3-f]chromeno[3,4-b]chromone (III).—*a) From the Acid X.*—A mixture of X (0.2 g.), copper powder (0.1 g.) and quinoline (10 ml.) was heated on an oil-bath (190~210°C) for 20 min. under nitrogen gas stream with stirring until the evolution of carbon dioxide ceased. The resulting mixture was filtered from copper, quinoline was removed by steam-distillation, and the crystalline product obtained was dissolved in ethyl acetate. The ethyl acetate solution was washed successively with dilute sulfuric acid, aqueous sodium hydroxide and water. The solvent was removed and the residual product was crystallized from ethanol then from ethyl acetate to give III in slightly red colored microcrystals, m. p. 239.5~240°C, identical with the other sample; yield 0.1 g. (70%).

b) From the Furoisoflavone XIII.—Anhydrous potassium carbonate (1.2 g.) was added to a solution of XIII (0.12 g.) in acetone (40 ml.), and the mixture was refluxed for 4 hr. and then for further 4 hr. with the addition of potassium carbonate (1.2 g.). Acetone was removed from the filtered solution, and the residual product was treated with dilute hydrochloric acid. Recrystallization from ethanol then from ethyl acetate furnished III in slightly orange colored microneedles, m. p. 241~242.5°C. UV λ_{max}^{EtOH} mμ (log ε): 264 (4.93), 304 (4.48); IR: 1630 cm^{-1} (γ-pyrone).

Found: C, 74.26; H, 3.67; Mol. wt. (Rast), 300. Calcd. for $C_{18}H_{10}O_4$: C, 74.48; H, 3.47%; Mol. wt., 290.

The authors are grateful to Dr. Mitsuru Nakayama for assistance, to the members of the Faculty of Pharmacology of this University for microanalysis and to the members of the Institute of Agricultural Chemistry of Kyoto University for microanalysis and infrared spectroscopy.

Chloromethylation of 7-Methoxyisoflavone

By Yoshiyuki KAWASE, Mitsuru NAKAYAMA* and Shigeru MATSUTANI

(Received March 31, 1962)

Chloromethylation of flavones has already been carried out by Nakazawa and Matsuura[1] and by Da Re and Verlicchi[2] to give 6- and 8-chloromethyl derivatives from acacetin 7-methyl ether and 8-chloromethyl derivative from 7-methoxy-3-methylflavone respectively, and of flavanones by Matsuoka[3], but that of isoflavone has not yet been reported. Now the chloromethylation of 7-methoxyisoflavone (II) has been carried out.

For the reaction are available two methods, those are by the action of formaline or paraformaldehyde[2] and hydrochloric acid and by that of chloromethyl methyl ether and acetic acid[1,3].

In this experiment, II was chloromethylated by the paraformaldehyde-hydrochloric acid method to give 7-methoxy-8-chloromethylisoflavone (III), colorless needles, m. p. 143~144°C, in 59% yield. The structure of III was confirmed by converting it into 8-acetoxymethyl derivative IV by the action of sodium acetate and acetic anhydride, and further by an alkaline hydrolysis of IV into 8-hydroxymethyl derivative V, which was identical with the authentic sample prepared from 7-hydroxy-8-formylisoflavone[4] (VI) by another route: Reduction of VI by the Meerwein-Ponndorf method or by sodium borohydride*2 furnished 8-hydroxymethyl derivative VII, which was methylated by diazomethane to give V as shown in the Chart.

The chlorine atom of III is fairly reactive: The methoxy- or ethoxy-methyl derivative (VIII or IX) was obtained by the action of sodium

*2 It was confirmed that this reagent does not affect the isoflavone nucleus.

methoxide or ethoxide and the iodomethyl derivative X by the action of potassium iodide in acetone, and only the acetoxymethyl derivative IV instead of the reduced compound was obtained by the action of zinc and acetic acid. An attempted chloromethylation of 7-hydroxyisoflavone (I) by the similar method was unsuccessful.

Experimental*3

7-Methoxyisoflavone (II).—*a) By Methyl Iodide.* To a stirred mixture of 7-hydroxyisoflavone (I) (30 g.), anhydrous potassium carbonate (30 g.) and anhydrous acetone (350 ml.) was added dropwise a solution of methyl iodide (18 g.) in acetone (50 ml.), and the mixture was refluxed for 6 hr. and then treated as usual to give II, m. p. 156~157°C (from benzene), identical with the other sample; yield 21.5 g. (67%).

b) By Diazomethane.—To a suspension of I (20 g.) in benzene (500 ml.) was added an ethereal solution of diazomethane (prepared from 7.8 g. of nitrosomethylurea), and the mixture was allowed to stand for 2 days. By the usual treatment, 9.8 g. (46.5%) of II was obtained through recrystallization from benzene; m. p. 156~157°C.

Found: C, 76.06; H, 4.66. Calcd. for $C_{16}H_{12}O_3$: C, 76.18; H, 4.80%.

7-Methoxy-8-chloromethylisoflavone (III).—A mixture of II (9.8 g.), paraformaldehyde (4 g.), acetic acid (98 ml.) and concentrated hydrochloric acid (49 ml.) was saturated with hydrogen chloride under stirring and heating at 60~70°C, and then was allowed to stand at room temperature over night. The solid product obtained was washed with water and recrystallized from acetone to give III in colorless needles, m. p. 143~144°C, giving a positive Beilstein test; yield 7.1 g. (59%). IR: 1645 cm^{-1} (γ-pyrone).

Found: C, 67.29; H, 4.43. Calcd. for $C_{17}H_{13}O_3Cl$: C, 67.89; H, 4.36%.

7-Methoxy-8-acetoxymethylisoflavone (IV).—*a) From III by Sodium Acetate and Acetic Anhydride.*—A mixture of III (2 g.), anhydrous sodium acetate (1.4 g.) and acetic anhydride (20 ml.) was heated for 3 hr. on an oil-bath (170~180°C). By the usual treatment, 1.7 g. of IV was obtained in colorless needles, m. p. 197~198°C (from ethanol). IR: 1720 (acetate), 1650 cm^{-1} (γ-pyrone).

Found: C, 70.21; H, 4.92. Calcd. for $C_{19}H_{16}O_5$: C, 70.36; H, 4.98%.

b) From III by Zinc and Acetic Acid.—A mixture of III (0.3 g.), zinc powder (1 g.) and acetic acid (80%, 5 ml.) was heated at 80°C for 2 hr., and the resulting mixture was poured into water. The crystalline product obtained was recrystallized from ethanol to give IV, m. p. 196~198°C.

c) From V.—A mixture of V (0.2 g.), sodium acetate (0.15 g.) and acetic anhydride (2 ml.) was treated similarly as described for a) to give IV, m. p. 196~198°C.

7-Hydroxy-8-hydroxymethylisoflavone (VII).—*a) By the Meerwein-Ponndorf Method.*—To a solution of 7-hydroxy-8-formylisoflavone[4] (VI) (0.5 g.) in absolute isopropyl alcohol (15 ml.) was added aluminum isopropoxide (prepared from 2.75 g. of aluminum ribbon and 30 ml. of isopropyl alcohol), and the mixture was heated on an oil-bath for 4 hr., most of the solvent was distilled off in the meantime. Dilute sulfuric acid was added to the residue, and the crystalline product obtained was recrystallized from ethanol then from ethyl acetate to give VII in colorless microcrystals, m. p. 172°C (decomp.); yield 0.2 g. IR: 3300~2400 (OH), 1620 cm^{-1} (γ-pyrone).

Found: C, 71.56; H, 4.54. Calcd. for $C_{16}H_{12}O_4$: C, 71.63; H, 4.51%.

b) By Sodium Borohydride.—A solution of sodium borohydride (0.2 g.) in water (100 ml.) was added to a solution of VI (1 g.) in 1% aqueous sodium hydroxide (50 ml.), and the solution was heated at 60~70°C for 2 hr. on a steam-bath. The cooled solution was acidified with dilute hydrochloric acid, and the crystalline product obtained was recrystallized from ethanol then from ethyl acetate; m. p. 172°C (decomp.), identical with the other sample.

7-Methoxy-8-hydroxymethylisoflavone (V).—*a) From VII.*—To a suspensin of VII (0.1 g.) in benzene (150 ml.) was added an ethereal solution of diazomethane (prepared from 1.5 g. of nitrosomethylurea), and the mixture was allowed to stand over night. The solvent was removed, and the residual product was washed with 5% aqueous sodium hydroxide then was recrystallized from benzene to give V in colorless microcrystals, m. p. 185~186°C. IR: 3300 (OH), 1625 cm^{-1} (γ-pyrone).

Found: C, 72.23; H, 5.03. Calcd. for $C_{17}H_{14}O_4$: C, 72.33; H, 5.00%.

*3 Melting points are uncorrected and infrared spectra were measured in Nujol.

b) From IV.—A mixture of IV (0.5 g.), ethanol (5 ml.) and 0.5 N ethanolic potassium hydroxide (2 ml.) was refluxed for 1.5 hr. The cooled solution was diluted with water and the crystalline product obtained was recrystallized from benzene to give V in colorless microcystals, m. p. 186~187°C, identical with the other sample; yield 0.2 g.

Found: C, 72.51; H, 5.02. Calcd. for $C_{17}H_{14}O_4$: C, 72.33; H, 5.00%.

7-Methoxy-8-methoxymethylisoflavone (VIII).—To a solution of III (1.5 g.) in benzene (100 ml.) was added methanolic sodium methoxide (prepared from 0.1 g. of sodium and 5 ml. of methanol), and the mixture was refluxed for 4 hr. The resulting mixture was filtered, the solvent was distilled off, and the residual product was crystallized from ethanol to give VIII in colorless needles, m. p. 142~143°C; yield 1 g.

Found: C, 72.58; H, 5.47. Calcd. for $C_{18}H_{16}O_4$: C, 72.96; H, 5.44%.

7-Methoxy-8-ethoxymethylisoflavone (IX).—A similar treatment of III with sodium ethoxide furnished IX in colorless needles, m. p. 115~117°C (from acetone).

Found: C, 72.80; H, 5.68. Calcd. for $C_{19}H_{18}O_4$: C, 73.53; H, 5.85%.

7-Methoxy-8-iodomethylisoflavone (X).—A mixture of III (1 g.), potassium iodide (1 g.) and acetone (20 ml.) was refluxed for 1.5 hr. The acetone was distilled off, and the residual product was washed with water and then was crystallized from acetone to give X in colorless needles, m. p. 166~167°C, giving a positive Beilstein test; yield 1 g.

Found: C, 51.98; H, 3.39. Calcd. for $C_{17}H_{13}O_3I$: C, 52.06; H, 3.34%.

The Molecular Structure of trans-4-Halogenocyclohexanol

By Yoshiko TAKEOKA

(Received December 12, 1961)

It has been well established that the cyclohexane ring has a chair form and that some cyclohexane derivatives have mutually convertible isomers, viz., inverted isomers. Since *trans*-4-halogenocyclohexanol should also have such isomers, it seemed very interesting to study the stability of the isomers in these compounds.

Experimental

Preparation of *trans*-4-Halogenocyclohexanol.—*trans*-4-Chlorocyclohexanol was prepared by adding hydrochloric acid to 1,4-epoxycyclohexane which had been obtained from 1,4-cyclohexanediol by dehydration with activated alumina. The product was recrystallized from ligroin, m. p. 82.0～83.0°C[1,2].

The preparation of *trans*-4-bromo- and of *trans*-4-iodocyclohexanol was similar to that of the chloro-derivative. The melting point of the bromo-derivative is 81.0～81.5°C, while that of the iodo-derivative is 59.2～60.3°C.

The Bromo-derivative. — Found: C, 39.95; H, 6.28. Calcd. for $C_6H_{11}OBr$: C, 40.24; H, 6.19%.

1) E. A. Fehnel, *J. Am. Chem. Soc.*, 73, 4978 (1951).
2) E. L. Bennett and C. Niemann, ibid., 74, 5076 (1952).

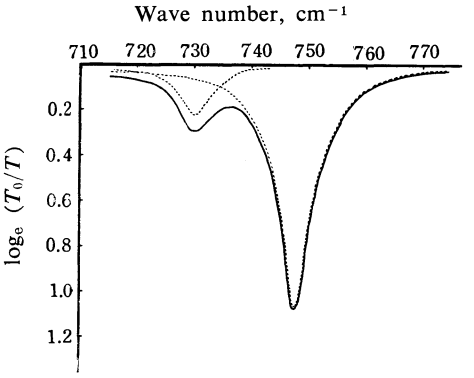

Fig. 1. Bands of C-Cl stretching vibration in the carbon disulfide solution (0.030 mol./l.).

The Iodo-derivative.—Found: C, 32.28; H, 5.41. Calcd. for $C_6H_{11}OI$: C, 31.88; H, 4.91%.

Dipole Moment. — The dipole moment of the chloro-derivative was obtained, by Debye's solution method, in the dilute carbon tetrachloride solution at 20.0°C. The dielectric constants were measured by the usual heterodyne beat method. The results are listed in Table I.

Infrared Spectra. — The measurements of the spectra were made with a Perkin-Elmer spectrometer

	748	(1e, 4e)	1.35	6.7	

the chloro-derivative were observed by the use of a potassium bromide prism. The slit width used was 0.248 mm., and the spectral widths were 3.8 cm^{-1} at 730 cm^{-1} and 4.0 ml^{-1} at 748 cm^{-1}. Measurements were made at 27 and −27°C. The cell thickness was 3 mm. Since these bands partly overlap each other, these were separated by assuming that the band shapes are given by Lorentz's equation, as is shown in Fig. 1. The integrated intensities A of the bands were obtained by Ramsay's method[3] of direct integration corrected for finite slit widths. The intensities are given by the following equation:

$$A = (K/cl) \log_e (T_0/T)_{max} \times \Delta\nu^a_{1/2}$$

where c is the concentration of the solute in moles per liter, l is the cell length in cm., T_0 and T are the apparent intensities of the incident and transmitted radiation when the spectrometer is set at frequency ν_{max}, and $\Delta\nu^a_{1/2}$ is the apparent half-intensity width.

The values of K were obtained from Ramsey's table[3]. The results are listed in Table III.

Discussion

It has been concluded on the basis of chemical evidence that the compound obtained by adding hydrochloric acid to the epoxy-compound is the trans-isomer. In order to confirm this conclusion, the dipole moment of this molecule was determined. The results obtained are shown in Table I. As may be seen in the table, the molecular polarization, P_2, depends upon the concentration of the solution. However, at concentrations lower than 0.00425 in molar fraction, it takes a constant value, 107. It was shown, by infrared absorption measurement, that in Soln. I there is practically no intermolecular hydrogen bond. Therefore, the P_2 value of 107 was taken as that for the extreme dilution ($P_{2\infty}$). From this value of $P_{2\infty}$, the dipole moment was calculated as 1.87 D.

Since it is very probable that the cyclohexane ring of this compound has the chair form, stable forms may be expected for both the trans- and the cis-isomer of this compound. These structures may be schematically represented as in Fig. 2. The positions of the atoms attached to the cyclohexane ring are represented by the usual symbols, e and a[4].

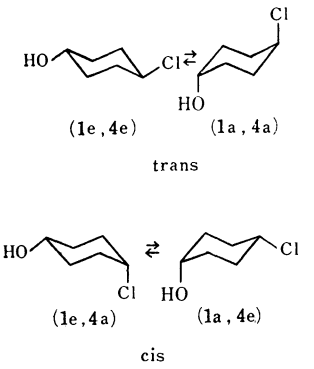

Fig. 2. Inverted isomers of 4-chlorocyclohexanol.

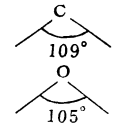

TABLE IV. BOND MOMENTS AND VALENCY ANGLES

$\mu_{C-O} = 0.8$ D

$\mu_{H-O} = 1.5$ D

$\mu_{C-Cl} = 1.6$ D

$\mu_{H-C} = 0.3$ D

Beginning from the law of the vector addition of bond moments, and by assuming that an almost free rotation of the OH group around the C–O axis is possible, it can be easily seen that the values of the dipole moments of both the cis- and the trans-isomer are not changed by converting the cyclohexane ring; viz., the value of the (1e, 4e)-form is equal to that of the (1a, 4a)-form, and the value of the (1e, 4a)-form is equal to that of the (1a, 4e)-form. Upon the basis of simple vector addition and by using the values shown in Table IV, the values of 2.3 and 1.9 D were obtained for the cis- and the trans-isomer respectively. Since the observed value, 1.87 D, agrees well with the calculated value of 1.9 D for the trans-isomer, it is very probable that the compound is the trans-isomer.

The wave numbers of the infrared bands of these compounds in the liquid and in the solid states are listed in Table II. Because similar methods were used for the preparation of these compounds and because the spectra of the bromo- and the iodo-derivative are similar to that of the chloro-derivative, it may be concluded that the bromo- and the iodo-derivative

3) D. A. Ramsay, ibid., **74**, 72 (1952).
4) D. H. R. Barton, O. Hassel, K. S. Pitzer and V. Prelog, *Nature*, **172**, 1096 (1953); *Science*, **119**, 49 (1953).

are the same geometrical isomers as that of the chloro-derivative, viz., the trans-isomer.

As for the trans-isomers of these compounds, the existence of two mutually convertible or "inverted" isomers is probable. As can be seen from Table II, the bands at 730 and 805 cm^{-1} for the chloro-derivative disappear when the state is changed from liquid to solid. From this fact, it follows that the equilibrium of the two isomers, which exists in the liquid, breaks down in the course of crystallization and that only one isomer persists in the solid. Therefore, it seemed interesting to determine the form of the isomer.

It has been known that chlorocyclohexane[5] has two mutually convertible isomers, viz., the (e)- and the (a)-form, in the vapor and in the dilute carbon disulfide solution, and that the energy difference between them is about 0.3 kcal./mol. in these states, the (e)-form being stable. Cyclohexanol[6] also has the (e)- and the (a)-form in solutions and in the liquid, and the energy difference between them seems to be larger than that for chlorocyclohexane.

Considering the energy difference for chlorocyclohexane and that for cyclohexanol, it seems very probable that the stable form of *trans*-4-chlorocyclohexanol is the (1e, 4e)-form and that only this form exists in the solid state. However, since it has been known[5] that the energy difference between the two isomers of *trans*-1, 4-dichlorocyclohexane, viz., the (1e, 4e)- and the (1a, 4a)-form, is not twice that between the two isomers of chlorocyclohexane, further, evidence for this is needed.

The bands at 730 and 745 cm^{-1} in the liquid spectrum may be assigned to the C–Cl stretching vibrations. As for the bands assigned to the C–Cl stretching vibrations of the chloro-derivatives of cyclohexane, it is known[7] that the frequencies of the bands which are due to the chlorine atoms attached to the (e)-position of cyclohexane ring are higher than those of the bands due to the chlorine atoms of the (a)-position. Therefore, the band at 730 cm^{-1}, which disappears in the solid state, can be assigned to the (1a, 4a)-form. Then the same conclusion as described above can be drawn from this information.

According to the other experimental rule[8] that the frequency of the breathing vibration of the molecule of cyclohexane derivatives having substituents in the (a)-position does not markedly shift from that of cyclohexane, viz., 802 cm^{-1}, the band at 805 cm^{-1} may be assigned to the (1a, 4a)-form. The fact that this band disappears in the solid spectrum favors the above conclusion.

In order to determine the energy difference between the two isomers of the chloro-derivative, the ratios of the integrated intensity of the band at 730 cm^{-1} of the (1a, 4a)-form to that at 748 cm^{-1} of the (1e, 4e)-form were measured in a carbon disulfide solution at 27 and $-27°C$. As for the solution of 0.4 mol./l., the very broad band assigned to the out-of-plane deformation vibration of the intermolecular bonded OH group appears in the region from about 400 to 800 cm^{-1}. Therefore, the measurements were made in the more dilute solution, in which no bands assigned to the hydrogen bond could be detected. From the data of Table III, we can calculate as usual the difference, ΔE, between the energy, E_a of the (1a, 4a)-form and the energy, E_e, of the (1e, 4e)-form ($\Delta E = E_a - E_e$) by the equation;

$$c_a A_a / c_e A_e = (\alpha_a f_a / \alpha_e f_e) \exp(-\Delta E / RT)$$

where A_a and A_e are the true integrated absorption intensities of the bands at 730 and 748 cm^{-1}, c_a and c_e the concentrations (mol./l.), α_a and α_e, the molar absorption coefficients, and f_a and f_e, the partition functions of the forms shown by the suffixes. As the measurements were made at two temperatures, the unknown quantity ($\alpha_a f_a / \alpha_e f_e$) can be eliminated. The ratio of the partition functions, f_a/f_e, is taken to be constant, because of the narrow temperature range. The value obtained for ΔE is 0.76 kcal./mol., the (1e, 4e)-form being more stable.

By using this value of the energy difference and by assuming as usual that f_a is nearly equal to f_e, a rough estimate of the abundance ratio, n_a/n_e, can be made by the equation:

$$n_a/n_e = f_a/f_e \, e^{-\Delta E/RT}$$

The value of the ratio obtained is 1/3.6 at room temperature. From this it can be surmised that a small number of the bands disappear when the state is changed from liquid to solid.

It is expected that the bromo- and the iodo-derivative also have the (1a, 4a)- and the (1e, 4e)-forms, since their structures are similar to that of the chloro-derivative. From the fact that the energy difference between the (a)- and the (e)-form of halogenocyclohexanes, where the halogen is chlorine, bromine or iodine, becomes larger with the increasing atomic number of the halogens[5,9], it is very probable that in the case of *trans*-4-halogenocyclohexanol also the energy differences for the bromo- and the iodo-derivative are larger than that of the

chloro-derivative. From this it may be surmised that, for the spectra of the bromo- and the iodo-derivative, only the one weak band disappears when the state is changed from liquid to solid, as is shown in Table II.

The author wishes to express her sincere thanks to Professor Kunio Kozima for his kind guidance. Her thanks are also due to Dr. Asaji Kondo for his elementary analyses.

Studies on Mixture Dyeing. I. The Kinetics of the Mixture of Benzopurpurine 4B and Sky Blue 6B

By Minoru SEKIDO and Zenzo MORITA

(Received December 22, 1961)

In practical dyeing, dye mixtures are usually used to produce a desirable shade. Moreover, some commercial dyes are deliberate mixtures in order to provide certain specific properties and shades. This implies that to study dyeing is practically the same as to study mixture dyeing. However, little has been done in the quantitative study of such mixture dyeing. Neale and Stringfellow[1] and recently Horiki et al.[2,3] have investigated the equiliburium adsorption of binary direct dye mixtures, but the diffusion of dye mixtures has been little studied. Recently, however, many studies of diffusion in multi-component systems have been made from the view point of the thermodynamics of irreversible processes[4]. Uedaira[5] and Tsuda[6] applied this theory to the mixture dyeing process.

For this paper, the kinetics of the single dyeing of Benzopurpurine 4B (C. I. 23500) and of Sky Blue 6B (C. I. 24410) has been investigated in detail in order to study quantitatively their behavior in mixture dyeing. Then the kinetics of mixture dyeing has been studied theoretically on the basis of the information about the single dyeing.

Experimental

Purified dyes were used throughout. They were prepared from commercial dyes (Diacotton Benzopurpurine 4B (MCI) and Diacotton Sky Blue 6B (MCI)) by the method of Robinson and Mills[7]. The high purity of these samples was checked by titanometry and also by the ashing method. The absence of colored impurities was confirmed by paper chromatography.

A cellophane sheet, made by Tokyo Cellophane Co., Ltd., was used as the dyeing substrate. It was cut into pieces 6 cm. wide and 55 cm. long, which pieces were then scoured by distilled water and layered round on a glass tube. This cylindrical cellophane-film roll[8] was dyed under certain conditions. After dyeing, the film roll was rinsed in a dilute sodium chloride solution for a short time. Then the dyed cellophane was unrolled and dried. The dried sample was cut, layer by layer, for colorimetry by a Hitachi EPB-V type spectrophotometer, or the dyes adsorbed by each layer were stripped with 25% aqueous pyridine and the dye content of the solution was measured by the spectrophotometer. The mean thickness of each swollen cellophane sheet was 4.66×10^{-3} cm.

In single dyeing, the concentration of dye in the dye bath was 1.0, 2.5, 5.0, or 10.0×10^{-5} mol./l., while that of sodium chloride was 0.01, 0.02, 0.03, or 0.04 mol./l. In mixture dyeing, the experimental conditions were as shown in Tables IV and V. The dyeing time was 3000 min. (90°C); 4500 min. (85°C); 6000 min. (80°C) or 7500 min. (75°C).

Theoretical

The cylindrical cellophane roll[8] may well be considered a semi-infinite media in the direction of the center of the roll. The surface dye concentration of rolled cellophane is maintained constant throughout the whole period of dyeing by means of the infinite dye bath condition.

Single Dyeing.—Assuming that the diffusion coefficient of dye through the dyeing substrate, D (cm^2/min.), is constant at a given temperature and concentration of dye and electrolyte in the dye bath, the diffusion equation is

$$\frac{\partial C}{\partial t}=D\frac{\partial^2 C}{\partial x^2} \tag{1}$$

where C (mol./cm^3 s. c.*) denotes the concentration of dye in the substrate, t (min.), the time, and x (cm.), the distance measured from the surface to the center. The solution of Eq. 1 for this system is

$$\frac{C}{C_0}=\mathrm{erfc}\frac{x}{2\sqrt{Dt}} \tag{2}$$

where

$$\mathrm{erfc}\,x=\frac{2}{\sqrt{\pi}}\int_x^\infty e^{-\eta^2}d\eta \tag{3}$$

and C_0 is the surface concentration of dye.

The calculation of the diffusion coefficient and of the surface dye concentration can be made by the method of Sekido and Matsui[9].

Mixture Dyeing.—The diffusion of a mixture of dyes has recently been studied by Uedaira[5] and by Tsuda[6]. Assuming for the diffusion coefficient the same conditions as those in the case of single dyeing, the diffusion equations of binary mixture dyeing[5,10] are

$$\frac{\partial C_1}{\partial t}=D_{11}\frac{\partial^2 C_1}{\partial x}+D_{12}\frac{\partial^2 C_2}{\partial x^2} \tag{4}$$

$$\frac{\partial C_2}{\partial t}=D_{21}\frac{\partial^2 C_1}{\partial x^2}+D_{22}\frac{\partial^2 C_2}{\partial x^2} \tag{5}$$

where C_1 and C_2 are the concentrations of dyes 1 and 2 respectively, D_{11} and D_{22} are the main diffusion coefficients, and D_{12} and D_{21} are the cross-term diffusion coefficients.

These equations may be solved by the method of Fujita and Gosting[11], as was done by Uedaira[5]. The initial and boundary conditions are

$$C_1=C_2=0, \qquad x>0, \qquad t=0 \tag{6}$$

$$C_1=C_1^\circ, \qquad C_2=C_2^\circ, \qquad x=0, \qquad t>0 \tag{7}$$

where C_1° and C_2° are the surface concentrations of dyes 1 and 2 respectively.

Therefore, the solutions of these equations are

$$\frac{C_1}{C_1^\circ}=K_1^+\,\mathrm{erfc}\frac{\sqrt{\sigma_+}}{2\sqrt{t}}x+K_1^-\,\mathrm{erfc}\frac{\sqrt{\sigma_-}}{2\sqrt{t}}x \tag{8}$$

$$\frac{C_2}{C_2^\circ}=K_2^+\,\mathrm{erfc}\frac{\sqrt{\sigma_+}}{2\sqrt{t}}x+K_2^-\,\mathrm{erfc}\frac{\sqrt{\sigma_-}}{2\sqrt{t}}x \tag{9}$$

where

$$K_1^+=\frac{(D_{22}-D_{11})+\sqrt{(D_{22}-D_{11})^2+4D_{12}D_{21}}-2D_{12}C_2^\circ/C_1^\circ}{2\sqrt{(D_{22}-D_{11})^2+4D_{12}D_{21}}} \tag{10}$$

$$-K_1^-=\frac{(D_{22}-D_{11})-\sqrt{(D_{22}-D_{11})^2+4D_{12}D_{21}}-2D_{12}C_2^\circ/C_1^\circ}{2\sqrt{(D_{22}-D_{11})^2+4D_{12}D_{21}}} \tag{11}$$

$$K_2^+=\frac{(D_{11}-D_{22})+\sqrt{(D_{22}-D_{11})^2+4D_{12}D_{21}}-2D_{21}C_1^\circ/C_2^\circ}{2\sqrt{(D_{22}-D_{11})^2+4D_{12}D_{21}}} \tag{12}$$

$$-K_2^-=\frac{(D_{11}-D_{22})-\sqrt{(D_{22}-D_{11})^2+4D_{12}D_{21}}-2D_{21}C_1^\circ/C_2^\circ}{2\sqrt{(D_{22}-D_{11})^2+4D_{12}D_{21}}} \tag{13}$$

$$\sigma_+=\frac{(D_{22}+D_{11})+\sqrt{(D_{22}-D_{11})^2+4D_{12}D_{21}}}{2(D_{11}D_{22}-D_{12}D_{21})} \tag{14}$$

$$\sigma_-=\frac{(D_{22}+D_{11})-\sqrt{(D_{22}-D_{11})^2+4D_{12}D_{21}}}{2(D_{11}D_{22}-D_{12}D_{21})} \tag{15}$$

The surface concentrations C_1° and C_2° are determined by extrapolation of the dye distribution curves in the cellophane roll. The four diffusion coefficients should be determined simultaneously. However, the calculation of these coefficients from the dye distribution curve is not possible. It is assumed that the main diffusion coefficients, D_{11} and D_{22}, are the diffusion coefficients of each single dyeing whose surface concentration is equal to that in the mixture dyeing. Therefore, the cross-term diffusion coefficients, D_{12} and D_{21}, are determined by the trial and error from Eqs. 8—15, using the values of C_1°, C_2°, D_{11} and D_{22} obtained above.

Results

Single Dyeing.—The results for single dyeings are shown in Tables I (Benzopurpurine 4B) and II (Sky Blue 6B), which show the surface dye concentrations and the diffusion coefficients of single dyeing. According to the theory of activated diffusion, the observed diffusion coefficient at a given temperature is given by the equation

$$\log D=\log D_0-E/2.303RT \tag{16}$$

where E is the apparent activation energy of the diffusion.

From the experiments at various dye concentrations, the apparent activation energy of

various times in the dyeing process are shown in Figs. 3 (Benzopurpurine 4B) and 4 (Sky Blue 6B).

The salt effects on mixture dyeing were also examined at 90°C, the results are shown in Table IV. The dye distributions in one of these experiments are shown in Fig. 5, where the solid curves are theoretical curves derived from Eqs. 8 and 9.

The temperature effects on mixture dyeing at a certain sodium chloride concentration (3.0×10^{-2} mol./l.) are shown in Table V.

Discussion

Activation Energy of Diffusion.—The apparent activation energy of the diffusion of Sky Blue 6B, as determined by Boulton and Morton[12], is in the range of 15~19 kcal./mol. for viscose rayon. These values are for a constant dye bath concentration. However, as the diffusion coefficient of a dye is a function of the dye content in a substrate, and since under the conditions of a constant dye bath concentration the surface dye concentration decreases with the increasing temperature, the activation energy of the diffusion should be estimated for a constant dye content, i. e., at a constant surface concentration.

The values we found for Sky Blue 6B, as shown in Table IV, are greater than those of Boulton and Morton[12]. These differences may be attributed to the concentration dependence of the diffusion coefficients. If the values of the activation energy of the diffusion for a constant dye bath concentration (5.0×10^{-5} mol./l.) are calculated, they are 22~25 kcal./mol. for Benzopurpurine 4B and 13~19 kcal./mol. for Sky Blue 6B. The values for Sky

12) J. Boulton and T. H. Morton, quoted by T. Vickerstaff, "The Physical Chemistry of Dyeing", 2nd Ed., Oliver & Boyd, London (1954), p. 268.

Blue 6B are similar to those of Boulton and Morton[12].

Mixture Dyeing.—As is shown in Figs. 3 (Benzopurpurine 4B) and 4 (Sky Blue 6B), the dye distributions in the mixture dyeing are considerably different from that in the single dyeing, and the surface concentration of each dye is maintained constant throughout the whole period of mixture dyeing.

Let us consider the case of Fig. 5. The surface concentration of each dye is smaller in the mixture dyeing than that in the single dyeing, irrespective of the constant dye concentrations in the dye bath. Clearly the diffusion of Sky Blue 6B cannot be described by means of Fick's law, as given in Eq. 1. Owing to the concentration dependence, the (main) diffusion coefficient of each dye should decrease with the decrease in surface concentration. If the main diffusion coefficients are obtained from the experiments of single dyeing and if the cross-term diffusion coefficients are estimated properly, as is mentioned in the theoretical section, the theoretical curves derived from Fqs. 8 and 9 agree well with the dye distributions of the mixture dyeing. The diffusion of Sky Blue 6B was greatly accelerated by the presence of Benzopurpurine 4B, as the value of the cross-term diffusion coefficient of blue dye is plus. In the case of Figs. 3 and 4, too, there are good agreements between the experimental results and the theoretical curves.

The effect of salt and temperature on mixture dyeing is very difficult to study, for the main diffusion coefficients and the surface concentrations vary with the salt concentration and temperature. According to the findings on the salt effect on mixture dyeing at 90°C, in which only the concentration of sodium chloride is varied from 0.01 to 0.04 mol./l., the interaction between two dyes will increase with an increase in the concentration of sodium chloride, for the absolute values of the cross-term diffusion coefficients change more than those of the main diffusion coefficients do. It is considered that the effect of a decrease in temperature is similar to that of an increase in salt concentration.

In mixture dyeing there may be two different interactions between two dyes, one in the dye bath and the other in the substrate. The interaction in the dye bath reduces the surface dye concentration below its normal value, as was studied earlier by Neale and Stringfellow[1] and by Horiki et al.[2,3] The cause of the interaction in the substrate may be that Sky Blue 6B is easy to diffuse, as a large amount of Benzopurpurine 4B adsorbed in the substrate reduces the available surface for the blue dye.

Summary

1. The single and mixture dyeing of Benzopurpurine 4B (C. I. 23500) and Sky Blue 6B (C. I. 24410) were examined kinetically.

2. The diffusion coefficient of each dye decreased with a decrease in the surface concentration. The apparent activation energy of diffusion at a constant surface concentration was evaluated.

3. In mixture dyeing, the dye distributions in the substrate were considerably different from that in the single dyeing, but there was good agreement between the dye distributions experimentally determined and those theoretically calculated in terms of the thermodynamics of irreversible processes.

4. The interaction between two dyes in the substrate increased with an increase in the sodium chloride concentration in the dye bath and with a decrease in the temperature.

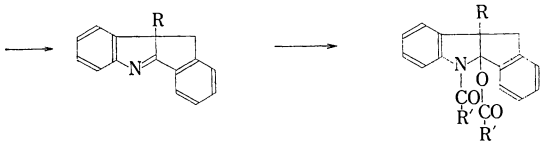
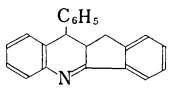
*Medium Ring-size Effect in 2′, 3-Polymethylen-3-alkyl-2-phenylindolenines**



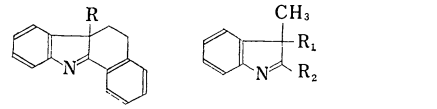
By Masao NAKAZAKI and Minoru MAEDA

(Received September 15, 1961)

The pronounced reactivity of the C=N group of indolenine[1] to add various reagents was first observed when Leuchs and his co-workers[2] heated 2-benzyl-1-indanone (Ia) with excess phenylhydrazine at 130°C to yield a substance, $C_{28}H_{25}N_3$, m. p. 192°C, which, on treatment with hydrochloric acid, lost the phenylhydrazine and formed the hydrochloride (decomp. p. 206~208°C) of the expected indolenine IIIa ($C_{22}H_{17}N$, m. p. 123~124°C). It was soon

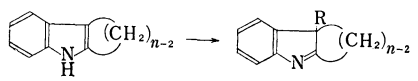


Ia R=$CH_2C_6H_5$ IIa R=$CH_2C_6H_5$
b R=CH_2CH_3 b R=CH_2CH_3

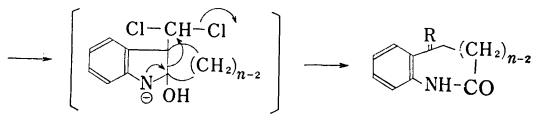


IIIa R=$CH_2C_6H_5$ IV
b R=CH_2CH_3

found that the indolenine IIIa was formed directly without a catalyst and that IIIa then immediately added phenylhydrazine to form the addition compound IIa. The C=N group adds not only amines, ammonia and phenylhydrazine, but also acid anhydrides (acetic, benzoic and phthalic anhydride) to give the indoline derivatives which have the general formula of IV.



V



VIa R=$CH_2C_6H_5$ VIIa R_1=CH_3, R_2=C_6H_5
b R=CH_2CH_3 b R_1=$CH_2C_6H_5$, R_2=CH_3

A possibility that the active methylene of the benzyl group might be involved in the ring closure reaction giving the dihydroquinoline V, and that it is V instead of the indolenine IIIa which is responsible for the facile addition reactions, was ruled out by their subsequent findings. It was found that 2-ethyl-1-indanone (Ib) also gave a compound ($C_{17}H_{15}N$, m. p. 79~80°C) which, because of the lack of the active methylene of the benzyl group, should have the indolenine structure of IIIb, but which behaved like an aldehyde[3], e. g., by the addition of amines, ammonia and acid anhydrides as well as of sodium bisulfite.

Their further observation[4] that VIIa and the six-membered analogues of IIIa, b (VIa, b) were incapable of adding phenylhydrazine and sodium bisulfite led them to the conclusion that ring system III, with a five-membered ring fused to the indolenine nucleus, is essential to

VIIIa n=5 IXa n=5, R=$CHCl_2$

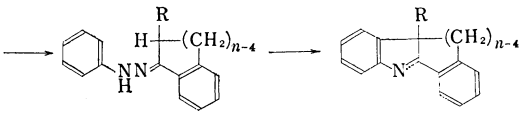
smooth addition reactions. The same sort of ring-size effect on the reactions of indolenines was encountered in our study[5] of "Plancher's base"[6] (Xa) and of the mechanism of its formation from pentindole (VIIIa) with alkali and chloroform.

Whereas tetrahydrocarbazole (VIIIb) affords stable 11-dichloromethyltetrahydrocarbazolenine (IXb), which can be converted into the lactam Xb only by prolonged reflux in the presence of alkali[7], the lactam Xa ("Plancher's base) is a sole product isolated from the reaction mixture of pentindole (VIIIa) with alkali and chloroform, presumably because of the enhanced reactivity of the C=N group in the intermediate IXa, which has a five-membered ring fused to the indolenine nucleus. It is not surprising, therefore, to find that the hydroperoxide, IXd, is stable enough to be isolated as such, but that the hydroperoxide IXc, from pentindole, is directly rearranged to the lactam Xc[8], suggesting a close relationship between the reactivity of indolenine and the size of the ring fused with it.



This paper will report on the preparation of 2′,3-polymethylen-3-alkyl-2-phenylindolenines (XIV) and on the observations of the changes of their properties as the ring members are varied from 5 to 6, 7 and 8, compared with those of 3,3-dimethyl-2-phenylindolenine (VIIa)[9] and 2,3-dimethyl-3-benzylindolenine (VIIb)[10].

The indolenines (XIV)[11,12] were prepared by Fischer-Brunner's method from 4-alkyl-1,2-benzocycl-1-en-3-one (XII); of these the seven-membered ketone (XIIa) (b. p. 153~160°C/28 mmHg; semicarbazone, m. p. 197~198°C) and

XIa $n=7$, $R_1=CH_3$
b $n=8$, $R_1=CH_3$

XIIa $n=7$, $R=CH_3$
b $n=8$, $R=CH_3$
c $n=6$, $R=CH_3$
d $n=5$, $R=CH_2CH_3$

XIII

XIVa $n=5$, $R=C_2H_5$
b $n=6$, $R=CH_3$
c $n=7$, $R=CH_3$
d $n=8$, $R=CH_3$

the eight-membered ketone (XIIb) (b. p. 109~111°C/1 mmHg; 2,4-dinitrophenylhydrazone, m. p. 170~171°C) were prepared from the corresponding acids (XIa, b) by polyphosphoric acid cyclization[13] (61%) and high dilution

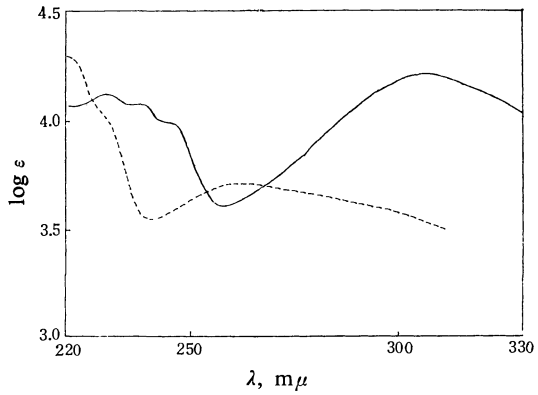

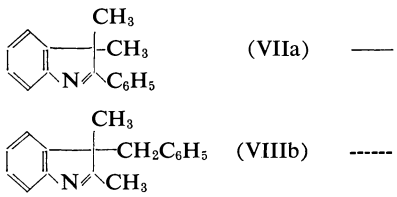

Fig. 2

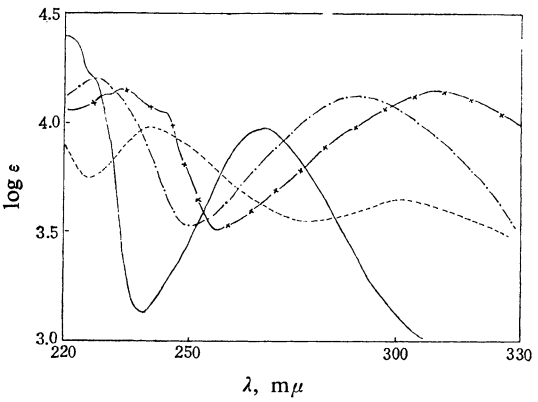

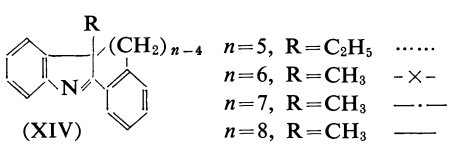

Fig. 3

Friedel-Crafts cyclization (62%) respectively[14].

The ultraviolet absorption spectra of the ketone XIIa, b, c, d[15] and isobutyrophenone are shown in Fig. 1.

In Table I the properties of these indolenines are summarised, together with those of VIIa and VIIb.

Ultraviolet Absorption Spectra[16] (See Table I, Figs. 2 and 3).—The six-membered indolenine XIVb exhibits almost the same ultraviolet spectrum as the indolenine VIIa, which has a phenyl group capable of conjugating with the indolenine system by free rotation. Moreover, the coincidence of the fine structures of their absorption pattern at a shorter wavelength is remarkable. However, a different situation arises in the seven- and eight-membered indolenines (XIVa, b), in which the polymethylene bridge pushs the ortho position of the phenyl group aside so as to force the benzene ring to pivot around out of the plane of the indolenine conjugate system, thus decreasing the effective conjugation between the indolenine system and the benzene ring. An inspection of the molecular model of the eight-membered indolenine (Fig. 4) reveals

Fig. 4

14) R. Huisgen, W. Rapp, I. Ugi and H. Walz, *Ann.*, **586**, 52 (1952). Their yield for the eight-membered ketone (XIIb, without a methyl group) was 70% by the high dilution Friedel-Crafts cyclization technique. For a general discussion of the synthetic methods of large ring compounds, see K. Ziegler's excellent article in Houben-Weyl, "Methoden der organischen Chemie", Ed. by E. Muller, Band IV, Teil 2, George-Thiem Verlag, Stuttgart (1955), p. 930.

15) The ultraviolet spectra of 1,2-benzocycl-1-en-3-one (XII) without methyl substitution have been thoroughly discussed. R. Huisgen, W. Rapp, I. Ugi, H. Walz and E. Mergenthaler, *Ann.*, **586**, 1 (1954).

16) Their infrared absorption spectra (C=N streching band) are summarized in Table I, but no conspicuous regular change in absorption maximum with the ring size can be found.

17) Free from Baeyer strain. The conformational relationships among the four methylene groups, 1—2 is semieclipsed, while 2—3 and 3—4 are skew.

that, to achieve the most favorable conformation[17], the benzene ring must be brought almost perpendicular to the indolenine ring, which explains the fact that eight-membered indolenine XIVd shows marked hypsochromic shifts of the absorption bands associated with its diminished extinction coefficients. Although its ultraviolet absorption maximum and ultraviolet absorption minimum become quite close to those of VIIb, which has no phenyl group at the C_2 position, the higher extinction coefficient of XIVd seems to show that complete steric inhibition of the mesomerism is not attainable, even in the eight-membered indolenine. The parallel observation of the medium ring-size effect on ultraviolet spectra in the indole series XV was reported by Huisgen and Ugi[18].

It is of interest also to note the extraordinarily low extinction coefficient of the absorption (in both the 240 mμ and 300 mμ regions) of the five-membered indolenines XIVa, whose positions of absorption bands are not shifted much from that of the six-membered indolenine XIVb. Although its detailed theoretical interpretation presents considerable difficulties[19,20], there is no doubt that the Baeyer strain imposed upon the five-membered ring (normal bond angle: 108°) with three sp^2 carbon atoms (normal bond angle: 120°) deforms the conjugated system of the indolenine to a great extent, thus causing the pattern of the absorption band to deviate considerably from that of the indolenines, which do not suffer Baeyer strain[21].

Dissociation Constant[22].—As can be seen from Table I, the p*Ka*′ values of the indolenines XIV are also effected by the size of the ring fused to the indolenine nucleus.

Table I summarizes the values of p*Ka*′ of the conjugated acids of the indolenines determined spectrophotometrically[23], while Fig. 5 reproduces typical spectra of the seven-membered indolenine at different pH values which show clearly marked isosbestic points. If the

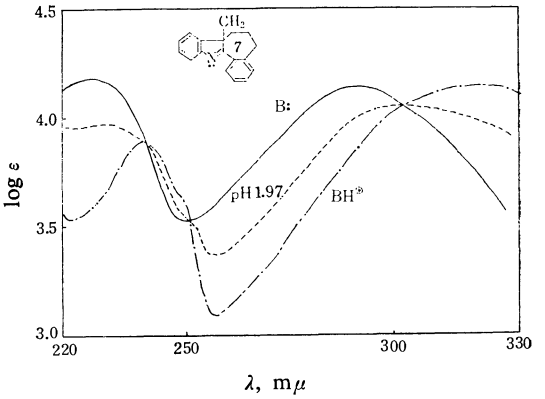

Fig. 5

phenyl group is allowed to be coplanar with the indolenine conjugation system, the +M effect of the phenyl group will be such as to increase the electron density at the nitrogen atom (XVI), i. e., to increase the basic strength of the indolenine. From the evidence previously adduced from the spectroscopic data (vide supra), there can be expected a considerable steric inhibition of the mesomerism and, hence, a decrease in the basic strength of the eight-membered indolenine XIVd; Table I shows this to be the case.

Polarographic Half-wave Potential.—If the polarographic electrode process[24] of indolenine

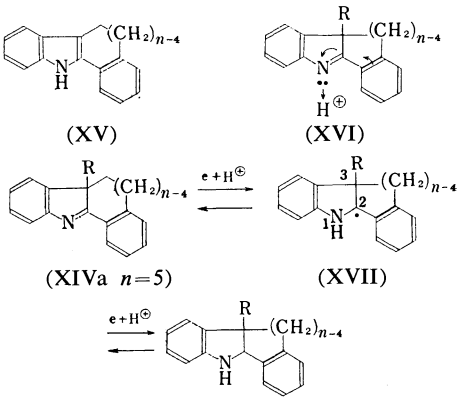

Fig. 6

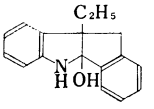
18) R. Huisgen and I. Ugi, *Ann.*, **610**, 57 (1957).



19) For the medium ring-size effect in 1,2-benzocycl-1-en-3-one and related compounds, see Huisgen's excellent review. R. Huisgen, *Angew. Chem.*, **69**, 341 (1957).

20) Ultraviolet absorption in relation to steric conformation about a single bond in a conjugated system is fully discussed in W. Klyne, "Progress in Stereochemistry", Vol. 1, Butterworths Pub. Ltd., London (1954), p. 136 and Vol. 2, (1958), p. 99. Numerous papers presented in G. W. Gray, "Steric Effects in Conjugated Systems", Butterworths Pub. Ltd., London (1958) are also worth consulting.

21) This Baeyer strain is reflected much more clearly in the polarographic study and will be discussed more thoroughly there.

22) H. C. Brown, D. H. McDaniel and O. Häfliger, "Dissociation Constants", in E. A. Braude and F. C. Nachod, "Determination of Organic Structures by Physical Methods", Academic Press, Inc., New York (1955), p. 567, and the literature cited in footnotes 19) and 20).

23) Attempts to measure the dissociation constant of XIVa were fruitless because its ultraviolet absorption spectra at various pH values did not show any clear isosbestic points, probably owing to the irreversible formation of (i) by the addition of water.

(i)

24) J. M. Kolthoff and J. K. Kingane, "Polarography", Vol. 1, Interscience Pub. Inc., New York (1952), p. 685; P. Pasternak, *Helv. Chim. Acta*, **31**, 753 (1948).

can be expressed as in Fig. 6, the stability of the intermediate free radical XVII may be expected to influence the half-wave potential.

When the π-orbital of the sp^2 center of XVII at C_2 can overlap effectively with the π-orbital of the phenyl group at C_2, the intermediate XVII will be stabilized and the half-wave potential will shift to positive. The high value of $-E_{1/2}$ of the eight-membered indolenine is clearly to be ascribed to the non-co-planarity of the iodolenine system and the phenyl group at the C_2 carbon atom.

The remarkable susceptibility of five-membered indolenine XIVa to polarographic reduction[25] is remarkable, conceivably because of the Baeyer strain being relieved in a five-membered ring with three sp^2 carbon atoms fused to a five-membered indolenine ring.

Experimental[26]

Diethyl Benzylethylmalonate.—To a stirred suspension of 4.6 g. of sodium powder (pulverized under boiling xylene and decanted from it) in 30 cc. of benzene was added slowly 23 cc. of absolute ethanol. After the sodium had been completely converted into sodium ethoxide, 35.4 g. of diethyl benzylmalonate was added over a 10 min. period. This mixture was refluxed while being stirred for 10 min.; then 46.5 g. of ethyl iodide was added over a period of 25 min. The temperature of the mixture was kept at 60~70°C for 5.5 hr. and then at 70~80°C for 7.5 hr. The solvent was then removed on a water bath, and water was added to dissolve the precipitated salt. The reaction mixture was extracted with ether. After the ether extract had been washed with water and dried over anhydrous sodium sulfate, the solvent was removed to yield an oil, b. p. 143~147°C/3 mmHg, 33.4 g. (85% yield) (literature[27]; b. p. 184°C/18 mmHg).

1-Benzyl-*n*-butyric Acid (XI) ($n=5$, $R_1=C_2H_5$, $R_2=OH$).—A mixture of 32.6 g. of diethyl benzylethylmalonate and 100 cc. of 45% aqueous potassium hydroxide was refluxed for 2 hr. (the mixture became homogenous after 20 min.) The aqueous solution was made acidic with dilute hydrochloric acid and extracted continuously with ether for 6 hr. Removal of the solvent gave a residue which was decarboxylated by heating at 180°C for 1 hr.; the residual oil was distilled to give 20.0 g. of a viscous oil (96% yield), b. p. 127~140°C/3 mmHg (literature[28]; b. p. 172~174°C/13 mmHg).

1-Benzyl-*n*-butyroyl Chloride (XI) ($n=5$, $R_1=C_2H_5$, $R_2=Cl$).—After a mixture of 19 g. of 1-benzyl-*n*-butyric acid and 17.8 g. of thionyl chloride had been heated on a water bath, the excess thionyl chloride was removed in a vacuum. Distillation of the residue afforded an oil, b. p. 124~131°C/15 mmHg, 20 g. (96% yield) (literature[27]; b. p. 128~131°C/15 mmHg). The anilide prepared from it was recrystallized from diluted ethanol, m. p. 86~87°C (literature[28]; m. p. 88~89°C).

2-Ethyl-1-indanone (XIId).—To a stirred mixture of 18.8 g. of powdered aluminum chloride and 50 cc. of carbon disulfide was added a solution of 1-benzyl-*n*-butyroyl chloride in 50 cc. of carbon disulfide over a period of 15 min. After being refluxed for 50 min., the reaction mixture was decomposed with ice and water. The usual working up gave an liquid with a pleasant smell, b. p. 130~136°C/13 mmHg, 14.8 g. (91% yield) (literature[29]; b. p. 143~144°C/22 mmHg). The semicarbazone was recrystallized from ethanol, m.p. 201.5~202.5°C (literature[29]; m.p. 202°C).

8b-Ethyl-2, 3-benzo-1, 2, 3, 4-tetrahydrocyclopent-(b)*pseudo*indole (XIVa)[30].—After a mixture of 2.0 g. of the indanone XIId, 1.4 g. of phenylhydrazine and 0.5 g. of sodium acetate was heated on a water bath for 2 hr., a solution of 12.5 g. of zinc chloride in 10 cc. of ethanol was added; this reaction mixture was kept at 150~155°C for 4 hr. Then 1 N hydrochloric acid was added to precipitate a complex salt which was collected and washed with 1 N hydrochloric acid and then with ether. Aqueous ammonia was added to the suspension of the complex salt on ether to liberate the indolenine XIVa, which was extracted with ether. After being washed with water and dried over anhydrous sodium sulfate, the solvent was evaporated to give a residual oil which distilled at 156°C/1 mmHg and which weighed 1.9 g. The crude indolenine was directly converted into the picrate and was recrystallized from ethanol to give yellow crystals, m. p. 164~165°C which were suspended on ether and decomposed with 0.5 N sodium hydroxide to regenerate the indolenine XIVa, b. p. 150~155°C/1 mmHg[31].

Found: C, 87.35; H, 6.61; N, 6.01. Calcd. for $C_{17}H_{15}N$: C, 87.51; H, 6.48; N, 6.00%.

The picrate was recrystallized from ethanol, m.p. 166~167°C.

Found: C, 59.49; H, 3.84; N, 12.33. Calcd. for $C_{23}H_{18}O_7N_4$: C, 59.74; H, 3.92; N, 12.12%.

Diethyl 3-Phenylpropylmalonate.—After 6 g. of sodium had been pulverized by vigorous stirring under 60 cc. of boiling toluene, the toluene was removed by decantation and was replaced by 50 cc. of benzene. Then 27 cc. of absolute ethanol was carefully added in order to convert the sodium powder into sodium ethoxide, and 63 cc. of freshly distilled diethyl malonate was added over a 45 min. period. To the refluxing reaction mixture was added a solution of 35 g. of 3-phenylpropyl bromide[32] in

25) On the medium ring-size effect of 1, 2-benzocyclo-1-en-3-one and related compounds on its half-wave potential, see the literature cited in footnote 15) and also H. Adkins, R. M. Elofson, A. G. Rossow and C. C. Robinson, *J. Am. Chem. Soc.*, **71**, 2622 (1949).

26) All ultraviolet spectra were measured in ethanol with an EP-2 Hitachi pen-recording spectrophotometer. The analyses were performed in the Microanalytical Laboratory of the Department of Chemistry, Osaka City University.

27) E. Mohr, *J. prakt. Chem.*, (2), **71**, 330 (1905).

28) B. Anschütz and W. Berns, *Ann.*, **261**, 307 (1891).

29) E. A. Speight, A. Stevenson and J. F. Thorpe, *J. Chem. Soc.*, **125**, 2191 (1924).

30) According to the nomenclature of A. M. Patterson and L. T. Capell, "The Ring Index", Reinhold Pub. Corp., New York (1940).

31) Leuchs and his coworkers (cf. footnote 2 c)) reported this indolenine as a crystal, m.p. 79~80°C, b.p. 202~204°C/14 mmHg, but our attempts to crystallize failed.

32) Prepared from 3-phenylpropanol according to the procedure of O. Kamm and C. S. Marvel, "Organic Syntheses", Coll. Vol. I, 25 (1948). B. p. 128~134°C/30 mmHg (86% yield).

50 cc. of benzene; the refluxing was then continued for 7 hr. on a water bath. After water was added, the reaction mixture was made acidic with dilute hydrochloric acid, and the benzene layer was separated. The aqueous solution was extracted with ether, and the ether extract was combined with benzene extract. After the mixture had been washed with water and dried over anhydrous sodium sulfate, the solvent was removed to give an oil which distilled at 143~149°C/1 mmHg and which weighed 44.7 g. (91.4% yield) (literature[33]; b. p. 189~194°C/13 mmHg).

Diethyl Methyl-3-phenylpropylmalonate.—To a sodium ethoxide solution prepared from 5.3 g. of sodium and 80 cc. of ethanol was added 44.4 g. of diethyl 3-phenylpropylmalonate. Into the stirred, refluxing solution, 39.2 g. of methyl iodide was add and then, after 2 hr. 10 g. of methyl iodide was added to make the solution neutral to wet litmus paper.

After the solvent had been removed, water was added and the mixture was extracted with ether. After the ether extract had been washed with water and dried over anhydrous magnesium sulfate, the ether was removed and the residual oil was distilled. The malonate distilled at 140~145°C/1 mmHg, and weighed 40.6 g. (87% yield) (literature[34]; b. p. 194°C/13 mmHg).

1-(3-Phenylpropyl)propionic Acid (XIa) (R_2=OH).—A mixture of 39.9 g. of diethyl methyl-3-phenylpropylmalonate, 90 g. of potassium hydroxide and 110 cc. of water was refluxed for 2~3 hr. The reaction mixture was then chilled in an ice bath and was made acidic with concentrated hydrochloric acid to precipitate crystals (methyl-3-phenylpropylmalonic acid), which were collected and washed with water. The malonic acid was decomposed by heating at 180°C and was distilled to give the acid XIa, b. p. 141~143°C/1 mmHg, 23.1 g. (88% yield) (literature[35]; b. p. 190°C/12 mmHg).

Found: C, 74.77; H, 8.89. Calcd. for $C_{12}H_{16}O$: C, 74.87; H, 8.39%.

The anilide was recrystallized from aqueous ethanol, m. p. 78.5~79.5°C.

Found: C, 80.85; H, 8.03; N, 5.45. Calcd. for $C_{18}H_{21}ON$: C, 80.86; H, 7.92; N, 5.24%.

4-Methyl-1,2-benzocyclohept-1-en-3-one (XIIa).—To stirred polyphosphoric acid prepared from 60.5 g. of phosphorus pentoxide and 38.7 g. of concentrated phosphoric acid was added 10 g. of the acid XIa; the reaction mixture was then heated at 100°C for 2 hr. The temperature of the mixture was raised to 160°C over a 1-hour period, and the reaction mixture was decomposed with water and extracted with ether. The ether extract was washed with 2 N sodium hydroxide and water, then dried over anhydrous sodium sulfate. Removal of the solvent gave a residual oil which distilled at 153~160°C/28 mmHg and which weighed 5.5 g. (61% yield). From alkaline washing, 1 g. of the acid XIa was recovered.

Found: C, 84.36; H, 8.14. Calcd. for $C_{12}H_{14}O$: C, 82.72; H, 8.10%.

The semicarbazone was recrystallized from aqueous ethanol, m. p. 197~198°C.

Found: C, 69.19; H, 7.51. Calcd. for $C_{13}H_{17}ON_3$: C, 67.50; H, 7.41%.

10a-Methyl-6,7-benzo-5,6,7,8,9,10-hexahydrocyclohept(b)*pseudo*indole (XIVc)[30]. — A mixture of 2 g. of the ketone XIIa and 1.3 g. of phenylhydrazine was heated on a water bath for 1.5 hr., the generated water was then removed by azeotropic distillation with benzene. After removal of the benzene, the residue was dissolved in 20 cc. of absolute ethanol and the solution was saturated with dry hydrogen chloride gas while being chilled in an ice-salt cooling bath. After being allowed to stand at room temperature for 5 hr., the solution was diluted with water and washed with ether to remove any neutral substance. The ether washing was extracted with dilute hydrochloric acid, and the acidic aqueous extracts were combined. The combined aqueous solution was then made basic with 2 N sodium hydroxide to precipitate the indolenine XIVc, which was extracted with ether. Removal of the solvent afforded a viscous oil which was purified via picrate. The picrate (2.1 g.) melted at 182~183°C after being recrystallized from ethanol and was decomposed with 0.5 N sodium hydroxide, then extracted with ether. The pale yellow ether extract was washed three times with 0.5 N sodium hydroxide until the ether layer became colorless; it was then washed with water and dried over anhydrous sodium sulfate. The solvent was removed to give a residue which was recrystallized from aqueous ethanol, m. p. 105~106°C.

Found: C, 87.56; H, 6.92; N, 5.91. Calcd. for $C_{18}H_{17}N$: C, 87.41; H, 6.93; N, 5.66%.

The picrate was recrystallized from ethanol to give yellow needles, m. p. 182~183°C.

Found: C, 60.61; H, 4.29; N, 11.58. Calcd. for $C_{24}H_{20}O_7N_4$: C, 60.50; H, 4.23; N, 11.76%.

4-Phenyl-*n*-butanol.—A mixture of 56 g. of ethyl 3-phenyl butyrate[36] and 7 g. of copper chromite catalyst was hydrogenated in a 500 cc. steel bomb at 98 atm. of hydrogen and at 256°C for 2 hr. After being separated from the catalyst, the alcohol was distilled to give a viscous oil, b. p. 145~151°C/26 mmHg, 33.5 g. (76.6% yield) (literature[37]; b. p. 137°C/14 mmHg).

4-Phenylbutyl Bromide.—This bromide was prepared from 4-phenyl-*n*-butanol following Kamm and Marvel's procedure[32], b. p. 142~148°C/24 mmHg (literature[38]; b. p. 132°C/12 mmHg).

Diethyl 4-Phenylbutylmalonate.—This was prepared from 4-phenylbutyl bromide following the procedure described in the preparation of diethyl 3-phenylpropylmalonate, b. p. 148~155°C/1 mmHg (91% yield) (literature[33]; b. p. 215~218°C/11 mmHg)

Diethyl Methyl-4-phenylbutylmalonate.—This was prepared from diethyl 4-phenylbutylmalonate by alkylation with methyl iodide following the procedure described in the preparation of diethyl

methyl-3-phenylpropylmalonate. The yield was 87.3%, and the malonate distilled at 155~160°C/1 mmHg.

Methyl-4-phenylbutylmalonic Acid.—Diethyl methyl-4-phenylbutylmalonate was hydrolyzed with 45% potassium hydroxide to give the malonic acid, which melted at 109~110°C after recrystallization from aqueous ethanol.

Found: C, 67.69; H, 7.50. Calcd. for $C_{14}H_{18}O_4$: C, 67.18; H, 7.25%.

1-(4-Phenylbutyl)propionic Acid. (XIb) (R_2=OH).—Methyl-4-phenylbutylmalonic acid was decomposed by heating at 180°C, and the propionic acid XIb was distilled, b. p. 138~149°C/1 mmHg (75.6% yield).

Found: C, 75.86; H, 9.15. Calcd. for $C_{13}H_{18}O_2$: C, 75.69; H, 8.80%.

The anilide was recrystallized from aqueous ethanol, m. p. 118~119°C.

Found: C, 80.89; H, 8.73; N, 5.09. Calcd. for $C_{19}H_{23}ON$: C, 81.10; H, 8.24; N, 4.98%.

1-(4-Phenylbutyl)propionyl Chloride (XIb) (R_2=Cl).—A mixture of 21.3 g. of the acid XIb and 17.8 g. of thionyl chloride was heated on a water bath for 1 hr., and the excess thionyl chloride was distilled off. The residual oil distilled at 161~167°C/15 mmHg, and weighed 23.2 g.

4-Methyl-1,2-benzocyclooct-1-en-3-one (XIIb).—The simplified Ziegler's high dilution apparatus[39] consists of a 3-l. three-necked round-bottomed flask equipped with a Vibro-Mischer and an efficient Dimroth condenser. The acid chloride solution is introduced at the middle point of the arm which connects the flask and the condenser, so the solution is immediately diluted and is carried down into the reaction flask by the solvent running down from the condenser. In the flask was placed 900 cc. of carbon disulfide; a small amount of the solvent was distilled off through the condenser in order to dry the apparatus while the cooling water was temporarily cut off. Then 37 g. of powdered aluminum chloride was introduced, and the mixture was refluxed on a water bath while being vigorously stirred. To the mixture was added a solution of 23.2 g. of the acid chloride XIb (R_2=Cl) in 750 cc. of carbon disulfide over a period of 76.5 hr., during which time 11 g. of powdered aluminum chloride was added at the 24th, 34th, 49th, 64th and 74th hr. from the starting point of the reaction. After 1.2 l. of the solvent had been removed, the reaction complex was decomposed with ice, water and concentrated hydrochloric acid. After being saturated with sodium chloride, the mixture was extracted with ether. A dark colored solid which appeared between the aqueous layer and ether layer was collected and treated separately.

After the ether extract had been washed and dried over anhydrous sodium sulfate, the solvent was removed to give a residual oil which distilled at 105~110°C/1 mmHg and which weighed 6.0 g. The collected dark colored solid was continuously extracted with benzene for 6 hr., and the benzene extract was washed with water and dried over anhydrous sodium sulfate. After removal of the solvent, the extract gave 6.1 g. of an oil which distilled at 109~111°C/1 mmHg and which raised the total yield to 62.3%. On one more distillation, 9.8 g. of the crude ketone gave 8.6 g. of purified ketone, which boiled at 104~112°C/1 mmHg.

Found: C, 82.91; H, 8.74. Calcd. for $C_{13}H_{16}O$: C, 82.93; H, 8.57%.

The 2,4-dinitrophenylhydrazone was recrystallized from ethanol, m. p. 170~171°C.

Found: C, 61.68; H, 5.27; N, 14.95. Calcd. for $C_{19}H_{20}O_4N_4$: C, 61.94; H, 5.47; N, 15.21%.

11a-Methyl-6,7-benzo-5,6,7,8,9,10-hexahydrocyclooct(b)*pseudo*indole (XIVd)[30].—A mixture of 2.0 g. of the ketone XIIb and 1.2 g. of phenylhydrazine was heated on a water bath, and the generated water was removed by azeotropic distillation with benzene. After removal of the benzene, the residue was dissolved in 19 cc. of absolute ethanol, and the chilled solution was saturated with dry hydrogen chloride gas. After the solvent had been evaporated in a vacuum, the reaction mixture was diluted with water and washed with ether. The aqueous layer was made basic with a concentrated ammonia solution, and the basic fraction liberated was extracted with ether. Removal of the solvent afforded a solid which crystallized upon cooling and trituration. Recrystallization from aqueous ethanol yielded crystals, m. p. 145.5~146.5°C.

Found: C, 87.15; H, 7.40; N, 5.41. Calcd. for $C_{19}H_{19}N$: C, 87.31; H, 7.33; N, 5.36%.

The picrate was recrystallized from ethanol to give yellow crystals which deteriorated on heating at 100°C and were found to have 1 mol. of ethanol of crystallization.

Found: C, 60.19; H, 5.38; N, 10.46. Calcd. for $C_{25}H_{22}O_7N_4 \cdot C_2H_5OH$: C, 60.44; H, 5.26; N, 10.44%.

After being heated at 65°C and 3 mmHg for 12 hr., the picrate melted at 119~120°C.

Found: N, 11.56. Calcd. for $C_{25}H_{22}O_7N_4$: N, 11.42%.

Polarographic Measurement.—The apparatus used for the measurement of the polarographic half-wave potential was a Yanagimoto pen-recording polarograph model P-B 4, while the pH values were measured on a Beckman pH meter model G.

The supporting electrolyte and buffer solution were that used by Huisgen and his co-workers[15]: 50% isopropanol containing potassium chloride (0.1 M), phosphoric acid (0.05 M) and acetic acid (0.05 M), the pH value was adjusted by the addition of 6 N ammonia in 50% isopropanol. The indolenine solution (ca. 10^{-4} M) was mixed with a gelatin solution, incuvated in a thermostat (26°C), and swept by a stream of nitrogen to replace the oxygen, which process took 30~90 min.

The authors are very grateful to Dr. Ken-ichi Takeda and Dr. Masakazu Inaba, The Shionogi Research Laboratory, Shionogi & Co., Ltd., for making it possible for them to use their polarograph. They are also indebted to Mr. Eiichi Togashi, Shiono Koryo Kaisha,

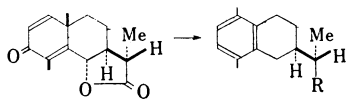
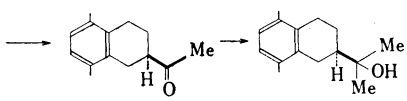
Absolute Configuration of (+)-Occidol



By Masao NAKAZAKI

(Received March 30, 1962)

(+)-Occidol (I), a new sesquiterpene alcohol, m. p. 69~70°C, $[\alpha]_D$ +163.7° (in chlorofom) isolated as a minor constituent from the neutral fraction of the essential oil of *Thuja occidentalis* L. was shown to have the structure I by degradative works[1] and by the comparison of its infrared spectrum with a synthetic racemic compound[2].

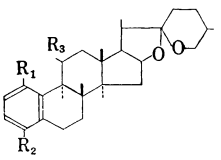


Because this compound has an unusual structure feature, which is apparently derived from eudesmane sesquiterpene precursor by the dienol-benzene rearrangement or similar mechanism[3], determination of the absolute configuration of this alcohol is interesting from a biogenetic point of view.

This paper is concerned with the correlation of C_7 absolute configuration with (−)-santonin (II)[4].

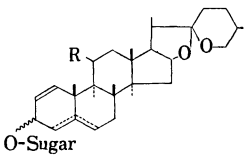
II

III R=CO_2H
IV R=COCl
V R=COMe
VI R=OAc
VII R=OH



VIII I

Hyposantonous acid (III), prepared from (−)-santonin (II) via the oxime and hyposantonin, was converted by thionyl chloride into acid chloride IV, which afforded the ketone V with dimethycadmium. Baeyer-Villiger oxidation of V with perbenzoic acid in chloroform gave the acetate VI, which was separated from the unchanged ketone V using Girard P reagent. The crude acetate VI was hydrolyzed directly with methanolic potassium hydroxide to alcohol VII. Chromatography on Florisil gave a viscous oil, b. p. 140~180°C/0.5 mmHg. The alcohol VII was oxidized with chromic anhydride-pyridine complex to ketone VIII. Grignard reaction of ketone VIII with methylmagnesium iodide afforded a tertiary alcohol which was purified by chromatography on Florisil. Recrystallization from petroleum ether gave crystals, m. p. 69~70°C, $[\alpha]_D$ +76.7° (in chloroform), the identity of which with (+)-occidol[5] was established by the mixed melting point determination and comparison of infrared spectra in chloroform.



These findings show that (+)-occidol has the *R* configuration at C_7, typical of the natural eudesmane type sesquiterpenes and this fact suggests the close relationship of (+)-occidol with eudesmane type compounds[4]. In the steroid field, compounds which have an aromatic A ring are common, especially among female hormones, where the biological passway involving the splitting of the angular methyl group at C_{10}, has been worked out thoroughly.

However, there had not been reported a steroid with an aromatic ring containing the methyl group originally attached to C_{10}. Recently the sapogenins, meteogenine and luvigenin, isolated from *Metanarthecium luteo-virid* Maxim. were shown to have the structures IX and X, respectively[6], and as possible

precursors the dienol-glycosides (XI) were suggested.

Although its absolute configuration is still to be elucidated, (+)-occidentalol (XII)[7], isolated as the major constituent of the essential oil of *Thuja occidentalis* L., might be a precursor of (+)-occidol (I). It is suggested that a careful examination of the mother liquor of the extract of the sapogenins IX and X might reveal the existence of the $\Delta^{1,3}$-sapogenins.

Experimental*

Hyposantonin[8].—To a solution of 26 g. of (−)-santonin oxime in 1 l. of 90% ethanol, 50 cc. of concentrated sulfuric acid was added, and was chilled to 20°C. After a solution of 1 g. of copper sulfate in 5 cc. of water was added, 150 g. of zinc powder was added slowly and the reaction temperature was kept below 40°C with vigorous stirring (with Vibro-Mischer) and cooling. After the initial exothermic reaction had subsided (50 g. of zinc powder), the remainder of zinc powder could be added rapidly. The stirring was continued for 10 hr. and during this time the temperature was kept at 31~35°C.

The zinc powder was filtered and washed repeatedly with warm ethanol (40°C), and the filtrate and washings were combined. After evaporation of the solvent at 40°C, the viscous residue was extracted twice with 350 cc. of warm water (40°C). The combined extracts were freed from polymeric viscous mass by filtration through a layer of Hyflo super cell, and was boiled to precipitate hyposantonin, which weighed 14 g., m. p. 142~149°C. Recrystallization from aqueous ethanol gave cystals, m. p. 151~152°C, $[\alpha]_D^{23}$ +36.1° (*c* 1.05, in benzene) (literature[9]; m. p. 152~153°C, $[\alpha]_D$ +32.75° (*c* 2.4), in benzene).

Hyposantonous Acid (III)[8].—Three hundred grams of zinc powder was adedd in two portions to a boiling solution of 24.3 g. of hyposantonin in 1.5 l. of acetic acid with vigorous stirring (Vibro-Mischer). After heating under reflux with stirring for 16 hr., the zinc powder was removed by filtration, and washed with hot acetic acid. The combined acetic acid solutions were concentrated under reduced pressure, and the viscous residue was diluted with water to precipitate crystals, which were recrystallized from aqueous acetic acid to give colorless prisms, 16 g., m. p. 92~94°C. The mother liquor was evaporated and the residue was distilled to afford a viscous oil, b. p. 155°C/0.01 mmHg (bath temp. 200~210°C), which solidified by scratching, 5.6 g., m. p. 91°C, and made total yield 93%. $[\alpha]_D^{12}$ +85.0° (*c* 0.31, in 95% ethanol) (literature[10]; m. p. 95.5°C, $[\alpha]_D^{28}$ +75.95° in ethanol).

Hyposantonous Acid Chloride (IV).—A mixture of 11.6 g. of hyposantonous acid, 13 g. of thionyl chloride and 15 cc. of benzene was refluxed for 1 hr. After the solvent and excess thionyl chloride were removed at reduced pressure, the residue was distilled to afford 11.6 g. (93% yield) of an oil, b. p. 133~137°C/0.5 mmHg, n_D^{18} 1.5480. After standing at room temperature it solidified to give srystals, m. p. 45~46°C. IR spectrum: 1765 cm^{-1} (in chloroform).

Anilide: recrystallized from aqueous ethanol, m. p. 138~141°C.

Found: C, 82.09; H, 8.25; N, 4.77. Calcd. for $C_{21}H_{25}ON$: C, 82.04; H, 8.25; N, 4.56%.

3-(5, 8-Dimethyl-1, 2, 3, 4-tetrahydro-2-naphthyl)-butanone-2 (V).—To a suspension of 1 g. of magnesium in 60 cc. of absolute ether, a stream of methyl bromide was passsed with stirring for 1 hr. until the magnesium disappeared. Then, at room temperature and in an atmosphere of nitrogen, 2.3 g. of cadmium chloride (dried at 130°C) was added during 5 min., and the reaction mixture was refluxed for 45 min. After 28 cc. of ether was removed by distillation, 30 cc. of benzene was added and then 28 cc. of benzene-ether mixture was evaporated under vigorous stirring to disperse the solid mass which formed. After 25 cc. of benzene was added, the viscous material adhering to the wall of the reaction flask was dislodeged by scratching with a spatula. A solution of 6 g. of the acid chloride IV in 10 cc. of benzene was slowly added, and stirring under refluxing was continued for 1.5 hr. The reaction mixture was decomposed by adding a mixture of 20 cc. of water and 20 cc. of 4 N sulfuric acid, and extracted twice with benzene. After washing with water, 5% sodium carbonate solution and saturated aqueous sodium chloride, the benzene solution was dried over anhydrous magnesium sulfate. Evaporation of the solvent gave an oil, which distilled at 154~155°C/0.5 mmHg (bath temp. 180~200°C) and weighed 3.8 g. (yield, 69%), n_D^{18} 1.5342, $[\alpha]_D^{22}$ +69.5° (*c* 2.74, in 95% ethanol). IR spectrum: 1700 cm^{-1} (in chloroform).

Found: C, 82.31; H, 9.61. Calcd. for $C_{12}H_{22}O$: C, 83.43; H, 9.63%.

9) D. Gucci, *Gazz. chim. ital.*, **19**, 367 (1889) (*Chem. Zentr.*, **1889**, II, 595); G. Grassi-Gristaldi, ibid., **19**, 382 (1889) (*Chem. Zentr.*, **1889**, II, 597).

10) G. Grassi-Cristaldi, ibid., **26**, 459 (1896) (*Chem. Zentr.*, **1897**, I, 170).

Semicarbazone: recrystallized from ethanol, decomp. p. 216~225°C.

Found: C, 71.07; H, 9.05; N, 14.80. Calcd. for $C_{17}H_{25}ON_3$: C, 71.04; H, 8.77; N, 14.62%.

1-(5, 8-Dimethyl-1,2,3,4-tetrahydro-2-naphthyl)-ethanol (VII).—A mixture of 3.12 g. of the ketone V and 32 cc. of chloroform which contained 2.53 g. of perbenzoic acid was kept in a dark place at room temperature for one week. After 50 cc. of ether was added, the solution was washed with 1N sodium hydrogen carbonate and saturated sodium chloride solution. After drying with anhydrous magnesium sulfate, the solvent was removed to give a viscous oil, which was dissolved in a solution of 1.7 g. of the Girard P reagent in 40 cc. of 99% ethanol. Then 2.31 g. of acetic acid was added, and the solution was refluxed on a water bath for 1 hr. The pale yellow solution was cooled in an ice bath, and brought to pH 7 by adding a solution of 1.85 g. of sodium carbonate in 200 cc. of water. The turbid aqueous solution was extracted with six portions of 50 cc. of benzene.

The Acetate Fraction.—The benzene extract was washed with saturated sodium chloride solution and dried over anhydrous magnesium sulfate. Removal of the solvent gave a viscous oil, which was directly hydrolyzed by boiling with a mixture of 0.8 g. of potassium hydroxide in 15 cc. of methanol for 2 hr. After the solvent was removed on a water bath, the residue was diluted with 20 cc. of water and extracted with ether. The ether extract was washed with water and saturated sodium chloride solution and dried over anhydrous magnesium sulfate. The solvent was removed and the residue was distilled to give 0.8 g. of an oil, b. p. 140~180°C (bath temp.)/0.1 mmHg. Since the infrared spectrum showed the contamination with a small amount of the unchanged ketone V, the alcohol VII was purified by chromatography on Florisil (10 g.). Elution with petroleum ether (b. p. 60~80°C) gave unchanged ketone, followed by alcohol VII which was eluted with benzene-petroleum ether. IR spectrum: 3340 cm^{-1} (in chloroform). $[\alpha]_D^{20}$ +63.2° (c 2.12, in pyridine).

The Ketone Fraction.—From the aqueous solution separated from the ester, 0.84 g. of ketone V was recovered.

(5, 8-Dimethyl-1,2,3,4-tetrahydro-2-naphthyl)-methylketone (VIII).—Pyridine-chromic anhydride complex was prepared by careful addition of 0.9 g. of chromic anhydride in 16 cc. of pyridine cooled at 15~20°C. A solution of 0.618 g. of alcohol VII in 16 cc. of pyridine was added to the suspension of the complex, and the solution was allowed to stand at room temperature overnight. After being diluted with 400 cc. of water, the reaction mixture was extracted six times with total amount, of 500 cc. of ether. The ether extract was washed with saturated sodium sulfate solution four times, and dried over anhydrous magnesium sulfate.

After evaporation of the solvent, the residue distilled at 120~140°C (bath temp.)/0.1 mmHg and weighed 0.589 g. IR spectrum: 1700 cm^{-1} (in chloroform). $[\alpha]_D^{21}$ +51.6° (c 1.95, in ethanol), 2,4-Dinitrophenylhydrazone: bright yellow needles from ethanol-ethyl acetate, m. p. 206~207°C. Found: C, 62.93; H, 6.08; N, 14.48. Calcd. for $C_{20}H_{22}O_4N_4$: C, 62.81: H, 5.80 N, 14.65%.

(+)-Occidol (I).—To the Grignard solution prepared from 0.3 g. of magnesium and 0.54 g. of methyl iodide in 20 cc. of anhydrous ether, a solution of 0.5 g. of ketone VIII in 10 cc. of ether was added, and the reaction mixture was refluxed for 1 hr. The Grignard complex was decomposed by adding 1.5 cc. of saturated ammonium chloride solution, and the clear ether supernatant was decanted. The residue was washed three times with ether, and the combined extracts and washings were dried over anhydrous magnesium sulfate. Removal of the solvent gave a viscous oil (0.574 g.) which was purified by chromatography on 13 g. of Florisil. The fractions which were eluted with petroleum ether-benzene (17 : 3), after evaporation of the solvent, crystallized upon rubbing and weighed 0.388 g. Recrystallization from petroleum ether (b. p. 50~60°C) gave crystals which melted at 69~70°C.

The mixed melting point determination and the comparison of infrared spectra (in chloroform) with an authentic sample established their identity. $[\alpha]_D^{17}$ +76.7° (c 0.90, in chloroform). Found: C, 82.35; H, 10.22. Calcd. for $C_{15}H_{22}O$: C, 82.51; H, 10.16%.

The author is very grateful to Dr. H. Watanabe, Fujisawa Pharm. Co., for his generous supply of (−)-santonin. This work was partially supported by the grant-in-aid for Fundamental Scientific Research from the Ministry of Education to which the author's thanks are due.

Catalytic Activities of Copper-nickel Alloys for Hydrogenating Reactions

By Toyosaburo TAKEUCHI, Masakazu SAKAGUCHI, Ikkei MIYOSHI and Takeo TAKABATAKE

(Received October 23, 1961)

The catalytic activities of copper-nickel alloys for hydrogenating reactions have been interpreted by Dowden and Reynolds[1] in the light of the modern electronic theory of metals. In their studies, massive copper-nickel alloys (foils) were employed as the catalysts. Since an early study by Schwab and Brennecke[2], many investigations[3-7] of hydrogenating reactions have been carried out employing granular copper-nickel alloys prepared chemically. However, no such obvious relation to the number of holes per atom in the 3d-band of these alloy has been found as Dowden and Reynolds found for the massive alloys. Moreover, the results are not in accordance with one another. The cause of this discrepancy in the results has not yet been explored. It was sometimes proposed that the granular catalyst might be joined with a homogeneous alloy as in the case of the massive alloys. As a result of previous studies[8,9] with an electron diffraction of the reactions between hydrogen chloride and the catalysts, the writers proposed that the concentration of nickel at the surface of the granular copper-nickel alloy differs from that of the interior of the composing particles. The present work is concerned with the catalytic activities of hydrogenations of ethylene and benzene over two copper-nickel series, i. e., granular and massive alloys, in order to make sure whether the discrepancy in catalytic activities between granular alloys and massive alloys can be explained by the nonuniform distribution of nickel in the granular alloys. In addition, the heat of the adsorption of hydrogen and the amounts of hydrogen adsorbed on granular alloys were measured in order to confirm the previous data reported by the writers[10] and to discuss the relation between the heat of adsorption and the catalytic activity of the copper-nickel alloy.

Experimental

The tests of the activity of two series of catalysts (granular and massive alloys) were made by a static method, using ethylene. The test of benzene was made only for granular alloys by a flow method.

Granular alloys were prepared from solutions of copper and nickel nitrates and their mixtures, by evaporating them to dryness and by igniting them to metal oxides in a furnace at 500°C, in a way which was described elsewhere[8,9,11]. Prior to use, the oxides were then reduced at 200°C for about three weeks in an atmosphere of hydrogen, which was replaced about five times. At the end of the reduction period, the catalysts were evacuated for several hours at 200°C to a pressure of 10^{-5} mmHg. Several samples of each catalyst were analyzed for total nickel and total copper to provide data for a study of the composition variable.

Massive alloys were prepared from mixtures of electrolytic copper and nickel by completely melting them in a furnace. The ingots containing less than 40% nickel were rolled in the form of a sheet 0.1 mm. thick, while those of 65% and 80% nickel were cut down in the form of a plate 1 mm. thick. These sheets and plates were polished with emery paper and washed by pure alcohol and distilled water; then they were reduced in an atmosphere of hydrogen.

The ethylene used was prepared by the dehydration of ethyl alcohol with sulfuric acid and was purified by vacuum distillation using a liquid oxygen bath. The benzene used was commercially available material which was purified by stirring it with sulfuric acid, with sodium hydroxide solution and then with water, and which was dried by contact with calcium chloride and then distilled.

The hydrogen used for the adsorption measurement or for the hydrogenation reaction of ethylene was prepared by the electrolysis of water and was purified by diffusion through a palladium thimble, preceded and followed by liquid oxygen traps. The commercial electrolytic hydrogen was used for the test of the activity of benzene. It was purified by

copper wire at 350°C, followed by anhydrous calcium chloride.

The apparatus used for the hydrogenation of benzene was a modification of that of Ipatieff[4]. The diameter of the reaction tube was 20 mm., and the length of tube was 30 cm. In every experiment, 20 g. of oxide was mounted on a glass boat 25 cm. in length. After the end of the reduction of the oxide at 200°C with the stream of hydrogen, the mixture of hydrogen and benzene at atmospheric pressure was passed in a volume ratio of 8 : 1 at a flow rate 100 ml./min. over the catalyst at 190°C; then about 2 l. of hydrogen were used to sweep the catalysate which remained in the catalyst into the receiver. Three grams of benzene was used for each run. The composition of the liquid catalysate, a mixture of benzene and cyclohexane, was determined by means of the refractive index.

The apparatus used for the hydrogenation of ethylene and for the adsorption of hydrogen was the same as that described in a previous paper[11]. In the case of the hydrogenation of ethylene, the apparatus was connected with a U-tube manometer of apiezon oil to facilitate the measurement of the pressure change in the reactions. The volume of the reaction vessel which included the U-tube manometer was 155 cc. For the test of activity, about 0.5 or 2 g. of granular oxide or about 0.2 m^2 (apparent area) of massive alloy were loaded in the vessel. Care was taken by using a liquid oxygen trap or a dry-ice trap, to prevent the contamination of the catalyst. A mixture of ethylene and hydrogen in a volume ratio of 1 : 1 and a total pressure of 20 mmHg was admitted into the reaction vessel; then the decrease in pressure was followed by the manometer, controlling the temperature of the reaction vessel at a constant value. The temperatures of the reaction were 100, 120, 140 and 160°C. In every interval of the test, catalysts were reduced afresh with hydrogen for two or three days at 200°C. The isotherms of the hydrogen adsorption on granular samples, i.e., 2.0 g. of 40% nickel and 0.5 g. of 86% nickel and pure nickel, were obtained at three temperatures, 100, 120 and 140°C, in the same way as has been described elsewhere[11]. The samples used for the adsorption of hydrogen were of 40% nickel, 86% nickel and pure nickel. After the catalyst testing had been completed, each sample was evacuated at 200°C for about three hours until a pressure of better than 10^{-5} mmHg had been attained. The B. E. T. area measurements were then made on each catalyst by ethylene, its cross-sectional area being taken to be 17.2 $Å^2$.

Results

In the hydrogenation of ethylene, both on the granular and the massive alloys, the relation of the logarithms of the rates to the time was represented by linear lines, except for a few minutes of the initial stage of the reaction. Figure 1 shows examples of the massive 80% nickel alloy. As can be recognized in the figure, the inclination of the linear part of the curve is not practically affected by the reaction temperature. In order to know the cause of the discontinuity in these curves, the adsorptions of hydrogen and ethylene were observed under the same initial pressures as in the hydrogenation, and a comparison between the two pressure changes was made. It was concluded after the comparison that the steep decrease in every initial stage of the hydrogenating reaction is probably due to the adsorption of ethylene on the catalyst. Figure 2 shows the relation of the activities in the hydrogenation of ethylene to the nickel percentage in the massive catalysts. The rates in the figure, at 120°C, were obtained from the inclination of each linear part of the curve. The figure shows that the pure copper was practically

inactive for the reaction, and that alloying 60% or less of nickel with copper causes a gradual rise in the activity, while increasing the nickel content to over 70% causes a conspicuous rise in the activity, showing a maximum in pure nickel. Figure 3 shows the results of the hydrogenation of ethylene at 120°C and that of benzene at 190°C over the granular alloys. In the case of ethylene, the activity of pure copper is quite small, while it increases markedly on a slight addition of nickel (1%). The activity does not increase, but declines slightly on a further increasing of the nickel content; it is

kept constant for the wide range of nickel content from about 10% to 60% and then increases again, showing a maximum in pure nickel. In the case of benzene, the activity is taken as the amount (in the unit, g.) of benzene converted to cyclohexane per unit area of the catalysts while 3.0 g. of benzene was being passed at a constant velocity over the catalysts. The figure shows that the activity of the alloyed catalysts is not substantially affected by the nickel content. Figure 4 shows the isotherms of the adsorption of hydrogen on 40, 86 and 100% nickel alloys of a granular form. Figures 5 and 6 show the relation of the heat of the adsorption of hydrogen at sparse coverage and of the amount of hydrogen adsorbed to the component of granular alloys findings which were given by the isotherms. The heats were calculated by adapting the Clausius-Clapeyron equation to the isotherms. The open circles and triangles in the figure show findings previously determined[10]. Linear relations can be found within the range of experimental accuracy over a wide range of alloy composition, except in the high-content range of both copper and nickel, as in the case of the hydrogenations of the same alloys. Table I shows the B. E. T. areas of the alloys used.

Discussion

The results reveal that the activities of the massive copper-nickel alloys in the hydrogenation of ethylene may be interpreted by the Dowden theory. However, the activities of the granular alloys can not be interpreted simply by his theory.

The surface of the granular copper-nickel alloy has been discussed over a long period by many researchers[3,12-15]. Among them, Best and Russell[6] and Hall and Alexander[15] have proposed that the surface is composed of an equilibrium alloy. Their opinion were based on the coincidence of the lattice parameters given by X-ray diffraction with those of the equilibrium alloys. Problems will remain, however, in accepting their opinion inasmuch as the rather strong penetrating power of X-rays is not suitable for the investigation of the surface.

Our previous studies[16] of the granular copper-nickel alloys by an electron diffraction had led to the conclusion that the surface of copper-nickel powder is composed of microcrystals of various compositions. A more detailed conclusion could be derived from studies[8,9] of the reaction of the granular alloys (1 and 12% nickel) with hydrogen chloride gas. These results show that the amount of nickel was greater in the upper layer of the composing particle than in the interior and that the amount per unit area of the catalyst was smaller in the 12% nickel alloy than in the 1% nickel alloy. From these facts, it can be surmised that the great increase in activity caused by a slight addition of nickel (1% nickel) in a granular alloy depends upon the preferential aggregation of nickel on the surface and that the activity is determined mainly by the amount of nickel on the surface. The decline in activity caused by the increase in the concentration of nickel from 1 to 12% would be due to the decrease in the amount of nickel on the surface, and the extensive and essentially linear portion of the catalytic activity would reveal an invariablity in the concentration of nickel on the surface. Interpretations can be made in the same way for the heat of adsorption and for the amount of hydrogen adsorbed on the granular alloys. A discrepancy can be recognized, however, between the heat of adsorption and the amount adsorbed in the 1% nickel alloy. The heat seems to be quite small in the light of the great amount of hydrogen adsorbed. This would be due to the following troublesome fact which has been established by the present writers[11] concerning the adsorption of hydrogen on pure copper and on the 1% nickel alloy: the rates of the adsorption of hydrogen on these catalysts were too slow for it to be possible to find readily a distinct equilibrium pressure, because of the irreversibility of adsorption.

It has been recognized by many researchers[17]

that the reaction is of the first order with respect to hydrogen and of zero order with respect to hydrocarbons. This would indicate that the amount of hydrogen adsorbed on a catalyst is far less than that of hydrocarbon. We can now understand the fact, established in our study, that the adsorbing ability of hydrogen is related to the catalytic activity.

Shallcross and Russell[18] have recently studied the ortho-parahydrogen interconversion over granular copper-nickel alloys prepared by a solution of ammonium bicarbonate. They found a constant activity in the alloy region from about 10 to 95% nickel. The shape of the curve for the activity of the reaction is substantially the same as those for the hydrogenation reactions of the granular alloys used in our study. In their report, they claimed that the catalysts were homogeneous both in bulk and on the surface. Very recently, Shield and Russell[19] have studied the heats of the adsorption of hydrogen on the same catalysts. In their paper, they ignored our results, which we had shown to them. Their scanty results are, however, quite similar to those measured by the writers. The agreement in both heats would indicate that the surfaces of the two granular alloys do not differ from one another.

In our study, the activity of granular pure nickel was the greatest for the hydrogenation of ethylene, but not for that of benzene. These results do not agree with those reported in other papers. Schwab[2] and Hall[7] found the maximum activity for the hydrogenation of cinnamic acid and benzene in a nickel-rich region, but Best and Russell[6] found the greatest for that of ethylene in a copper-rich region. The situation is very complicated. However, it can be noted that the results which gave the maximum activity in an alloy were obtained by the flow method. In the case of the flow method, the hydrogen used for the reduction of the catalyst occasionally remains in the catalyst because of the difficulty in evacuating sufficiently due to the characteristics of the apparatus. Attention should be called to the recent work of Hall[7]. He has found that the hydrogen added in the temperature range 100 to 300°C acts as a promoter for copper-nickel catalysts but as an inhibitor for pure nickel. Although a theoretical interpretation of his results has not yet been established, it seems certain that the decrease in the activity found in the studies of the pure nickel and nickel-rich regions might be related to the hydrogen preadsorbed on (or dissolved in) alloys or pure nickel.

Many other factors might cause the decrease in the catalytic activity in the nickel-rich region and the disagreement in the relation of the activity to the composition of the alloy between studies. It should be emphasized, however, that the activity of the granular copper-nickel alloy may best be discussed by taking account of the non-uniform distribution of nickel on the surface.

Summary

The hydrogenation of ethylene and benzene on two series of copper-nickel alloys, i. e., massive alloys prepared physically and granular alloys prepared chemically, was carried out in order to determine the cause of the disagreement of the catalytic activities which have been found in these alloys. The adsorption of hydrogen on granular alloys was also examined to learn the heat of adsorption and the amount adsorbed; the results were compared with the activities of the alloys.

The activities of massive alloys may be interpreted by the Dowden theory, but those of granular alloys could not. The activities of granular alloys were interpreted in connection with the concentration of nickel at the surface, which can be considered to be different from that in the interior. It was concluded that the amount of hydrogen adsorbed, the heat of adsorption, and the catalytic activity of granular alloy are related to the concentration of nickel at the surface.

*Syntheses of Chelating Agents. I. Stability of the Metal Chelate of Benzylamine-N, N-diacetic Acid and its Nitro Derivatives**

By Takeshi ANDO

(Received November 30, 1961)

Although many papers[1-7] have been published concerning the stabilities of the metal chelates of iminodiacetic acid and its derivatives, no investigation has been undertaken of the stability of its benzyl derivatives.

During the course of our search for new chelating agents of the aminopolycarboxylic acid type, benzylamine-*N*, *N*-diacetic acid and two of its nitro derivatives have been synthesized.

This paper is to report on the syntheses of new ligands as well as on the stabilities of their metal chelates, with an attempt to correlate the structure of the ligand with the stability of the metal chelates.

The synthesis of benzylamine-*N*, *N*-diacetic acid (BADA) has been reported on in the literature[8]. The syntheses of the new ligands, *o*- and *p*-nitrobenzylamine-*N*, *N*-diacetic acid (*o*-NBADA and *p*-NBADA), has been carried out by the standard procedure[9] from the corresponding nitrobenzylamine and monochloroacetic acid.

The chelate stability measurements were carried out by the pH titration method on these ligands only for a 1 : 1 ratio of the ligand to the metal ion, and the first stability constants have been obtained.

For BADA, the chelate stability constants with copper(II), nickel(II), cobalt(II), lead(II), zinc(II), calcium(II) and magnesium(II) were obtained. The results indicate that the behavior of BADA in relation to metal ions is similar to that of iminodiacetic acid. The copper chelate is so stable that it exists even in a strongly acid solution where the undissociated form of the ligand predominates. It forms relatively stable chelates with nickel, zinc, lead and cobalt, and forms very unstable chelates with magnesium and calcium. It was also noted that the pH titration curves indicated the formation of hydrogen complexes with some metal ions in the low pH region.

For *o*- and *p*-nitrobenzylamine-*N*, *N*-diacetic acid, the stability constants of magnesium(II) and calcium(III) have been obtained, the results indicated that the nitro substitution on the benzene ring had an appreciable effect on the dissociation constant of the ligand as well as on the stability constant of the chelates.

Experimental

Syntheses of Ligands.—BADA, which had been prepared according to the method of Chase and Downer[8], was purified by repeated recrystallization from water. The pure product decomposed at 204°C.

Found: N, 6.17. Calcd. for $C_{11}H_{13}NO_4$: N, 6.28%.

Syntheses of *o*-NBADA and *p*-NBADA.—These were synthesized from *o*- and *p*-nitrobenzylchloride respectively, according to the following reaction scheme, in which both compounds were processed in the way otherwise mentioned:

$$C_6H_4(NO_2)CH_2Cl \xrightarrow[\text{in dimethylformamide}]{C_6H_4(CO)_2NK} C_6H_4(NO_2)CH_2N(CO)_2C_6H_4 \xrightarrow[\text{dil.HCl}]{H_2NNH_2}$$

(I)

$$C_6H_4(NO_2)CH_2NH_2\cdot HCl \xrightarrow{ClCH_2CO_2H}$$

(II)

$$C_6H_4(NO_2)CH_2N(CH_2CO_2H)_2$$

(III)

o- and p-Nitrobenzylphthalimide (I). — The corresponding nitrobenzylchloride (18 g.) and potassium phthalimide (18 g.) were suspended in dimethylformamide**, and the mixture was heated while being stirred in an oil bath at 100~110°C. The temperature was kept below 120°C to prevent any side reaction. After two hours, the mixture was cooled; then it was poured into 500 ml. of water and stirred well. After the mixture had been left

** The use of dimethylformamide, which was recently suggested by Sheehan and Bolhofer, has an advantage of a lower reaction temperature with an increased yield, while avoiding tar formation (*J. Am. Chem. Soc.*, **72**, 2786 (1950)).

standing for a while, the separated precipitate was filtered off and washed repeatedly. The crude product was purified by recrystallization from acetic acid. The melting point was 218°C for *o*-nitrobenzylphthalimide and 174°C for *p*-nitrobenzylphthalimide.

Found: *o*-isomer N, 9.91. *p*-isomer N, 9.92. Calcd. for $C_{15}H_{10}N_2O_6$: N, 9.91%.

o- and p-Nitrobenzylamine (II).—The corresponding phthalyl compounds I were decomposed with hydrazine hydrate and dilute hydrochloric acid in an ordinary manner[10]. The hydrochlorides thus obtained were recrystallized several times from 95% ethanol and were then used for the next step. *o*- and *p*-Nitrobenzylamine hydrochloride decomposed at 248 and 249°C respectively.

o- and p-NBADA. — The same general procedure was also followed in this step. To 70 ml. of a 2 M aqueous solution of monochloroacetic acid which had been carefully neutralized with sodium hydroxide, 10 g. of the corresponding nitrobenzylamine hydrochloride was added. The pH value of the mixture was adjusted to 10 by dropping in a 2 N sodium hydroxide solution. After the mixture had been stirred for three hours at 50°C, the temperature was raised to 70~80°C to complete the reaction, while the pH value of the reaction mixture was maintained between 7 and 10 by the intermittent addition of a sodium hydroxide solution. After it had cooled, the reaction mixture was filtered to remove some precipitates. The crude acid was precipitated as barium salt from the filtrate, and free acid was regenerated by treating barium salt with the theoretical amount of sulfuric acid.

The free acid was further purified by repeated recrystallization from 70% ethanol or methanol. Colorless crystls of *o*-NBADA, which decomposed at 189°C, were obtained in a 50% yield. Pale yellow crystals of *p*-NBADA, which decomposed at 201~202°C, were obtained in a 40% yield.

Found for *o*-NBADA: C, 49.31; H, 4.47; N, 10.65. Found for *p*-NBADA: C, 49.46; H, 4.41; N, 10.45. Calcd. for $C_{11}H_{12}N_2O_6$: C, 49.26; H, 4.51; N, 10.45%.

Both compounds were slightly soluble in water (about 1.8×10^{-2} mol./1000 ml. water) and were appreciably soluble in ethanol.

Measurement of Dissociation and Chelate Stability Constants.—The experimental method consisted of the potentiometric titration of the ligand in both the absence and the presence of the metal ion being investigated. The ionic strength was kept constant ($\mu=0.1$) by using potassium nitrate as a supporting electrolyte and by employing relatively low concentrations (about 2×10^{-3} mol.) of the metal ion and the ligand. The titrations were carried out on a solution of only a 1:1 ratio of the ligand to the metal ion concentration. All measurements were carried out at 25±0.1°C.

The titration assembly consisted of a Hitachi-Horiba model P pH meter with glass and calomel electrodes and of a jacketed glass titration cell 130 ml. in capacity. Instead of using the standard buffer, the calibration of the pH meter was carried out under a constant ionic strength ($\mu=0.1$) by referring to the hydrogen ion concentration calculated from the hydrochloric acid-sodium hydroxide titration system for the regions below pH 3 and above pH 7, and from the acetic acid-sodium hydroxide system for the region between pH 3~7.

The titrations were carried out by the usual procedure in an atmosphere of carbon-dioxide free nitrogen. The pH reading were taken until the pH value reached 10.5~11.0 for each titration. The concentrations of the ligand and the metal ion were about 2×10^{-3} mol. for BADA, and about 8×10^{-4} mol. for *o*- and *p*-NBADA because of their low solubilities. The concentrations of the metal ion stock solutions were determined by the EDTA titration.

All reagents used in this investigation were of the analytical grade.

Calculation

Calculation of Acid Dissociation Constants.—The acid dissociation constants were calculated from the titration curves of ligands in the absence of metal ions (Figs. 1, 2 and 3). The equilibria involved and the dissociation constants to be determined are:

$$H_2A \rightleftarrows HA^- + H^+ ; \quad k_1=(H^+)(HA^-)/(H_2A) \tag{1}$$

$$HA^- \rightleftarrows A^{2-} + H^+ ; \quad k_2=(H^+)(A^{2-})/(HA^-) \tag{2}$$

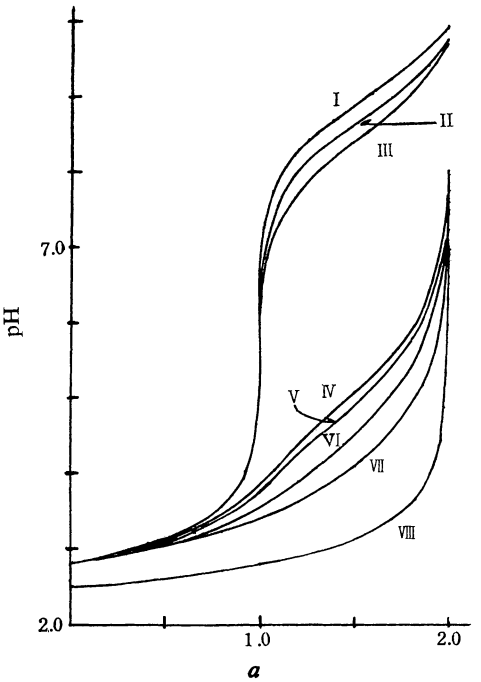

Fig. 1. Titration of BADA in the presence of equimolar concentrations of metal ions.

a, denotes moles of base added per mole of acid.

where H_2A represents the undissociated ligand. As is shown in Figs. 1, 2 and 3, the two buffer regions are so clearly separated that each dissociation stage can be treated independently. If C_A represents the total concentraions of the ligand species and a represents the number of moles of the base added per mole of the ligands present, it follows that in the low pH buffer region

$$C_A=(H_2A)+(HA^-) \tag{3}$$

$$aC_A+(H^+)=(HA^-) \tag{4}$$

Also, the first dissociation constant may be calculated from the following equation:

$$k_1=\frac{(H^+)\,[aC_A+(H^+)]}{C_A-[aC_A+(H^+)]} \tag{5}$$

In the high pH buffer region, the concentration of the acid form (H_2A) of the ligand may be neglected, and Eqs. 3 and 4 can be rewritten as

$$C_A=(HA^-)+(A^{2-}) \tag{6}$$

$$(a-1)C_A-(H^+)/K_W=(A^{2-}) \tag{7}$$

Under these conditions, k_2 may be expressed as

$$k_2=\frac{(H^+)\,[(a-1)C_A-(H^+)/K_W]}{C_A-[(a-1)C_A-(H^+)/K_W]} \tag{8}$$

where $K_W=(H^+)(OH^-)$. Alternatively, the second dissociation constant could be obtained directly from the titration curve, if one preserved a relationship in which the value of pk_2 is equal to the pH value at $a=1.5$ on the titration curve of the ligand. In this investigation, the k_2 value of BADA was determined by both methods, while the k_2 value of *o*-NBADA and *p*-NBADA were obtained only by the graphical method.

Calculation of the Chelate Stability Constants.—It has been reported[1] that, in the case of iminodiacetic acid and iminodipropionic acid, the formation of 1:2 chelate (MA_2) could be neglected in the region around $a=1.5$ in the titration curve of a 1:1 metal ligand mixture. Accordingly, it may be safe to assume for BADA chelates that in the pH range corresponding to *a* values of about 1.0~1.8, the equilibria involved in the chelate formation may be expressed as follows:

$$M^{2+}+A^{2-} \rightleftarrows MA;$$

$$K_{MA}=(MA)/(M^{2+})(A^{2-}) \tag{9}$$

where M represents the divalent metal ion used. Therefore, K_{MA} can be calculated by the following equation, which was derived by Chaberek and Martell[1]:

$$K_{MA}=\frac{C_A-\alpha(A^{2-})}{(A^{2-})\,[C_M+\alpha(A^{2-})-C_A]}=\frac{C_A-\alpha(A^{2-})}{\alpha(A^{2-})^2} \tag{10}$$

The last formula in Eq. 10 may be obtained because $C_A=C_M$ in this case. In this equation, (A^{2-}) and α are expressed as

$$(A^{2-}) = \frac{(2-a)C_A - (H^+) + (OH^-)}{2(H^+)^2/k_1k_2 + (H^+)k_2} \quad (11)$$

$$\alpha = (H^+)^2/k_1k_2 + (H^+)/k_2 + 1 \quad (11')$$

where C_M represents the total concentration of the metal ion species.

In general, Eqs. 10, 11 and 11' can be used for the calculation of the stability constants of divalent metal chelates. However, in the case of calcium and magnesium chelates, they can be simplified, as will be discussed below. It can be seen from the titration curves (Figs. 1, 2 and 3) of these chelates that the chelate formations occur in approximately the region of $a=1.0\sim2.0$, where the first dissociation step of the ligand can be neglected. Therefore, the following stoichiometric relationships can be written for ligand ion species, metal ion species and the titrable hydrogen ion respectively:

$$C_A = (HA^-) + (A^{2-}) + (MA) \quad (12)$$

$$C_M = (M^{2+}) + (MA) \quad (13)$$

$$(2-a)C_A = (H^+) - (OH^-) + (HA^-) \quad (14)$$

Since $C_A = C_M$, as defined in the experimental conditions, Eqs. 2, 12 and 13 may be combined to give

$$K'_{MA} = \frac{C_A - \alpha'(A^{2-})}{(A^{2-})^2} \quad (15)$$

Here K'_{MA} represents the stability constants for magnesium and calcium chelates, while α' and (A^{2-}) can be given in the more simplified form:

$$(A^{2-}) = \frac{(2-a)C_A + (OH^-) - (H^+)}{(H^+)/k_2} \quad (16)$$

$$\alpha' = (H^+)/k_2 + 1 \quad (16')$$

with the aid of Eqs. 15, 16 and 16', the stability constants of magnesium and calcium chelates of BADA, *o*-NBADA and *p*-NBADA were calculated.

Finally, as there is an indication of the formation of a hydrogen complex in the relatively low pH region in certain ions, the stability constants of the hydrogen complex were calculated. If one assume that, in a low pH region, only the formation of the hydrogen complex is predominant, the other reactions being negligible, the equilibria involved in this pH range can be given as follows:

$$H_2A \rightleftarrows H^+ + HA^-;$$

$$k_1 = (H^+)(HA^-)/(H_2A) \quad (17)$$

$$M^{2+} + HA^- \rightleftarrows MHA^+;$$

$$K_{MHA} = (MAH^+)/(M^{2+})(HA^-) \quad (18)$$

Also the total concentration of the ligands, metal ions and titrable hydrogen ions are given respectively by;

$$C_A = (H_2A) + (HA^-) + (MHA^+) \quad (19)$$

$$C_M = (M^{2+}) + (MHA^+) \quad (20)$$

$$(2-a)C_A = (H^+) - (OH^-) + (MHA^+) + (HA^-) + 2(H_2A) \quad (21)$$

On the basis of these equations, K_{MHA} is expressed as

$$K_{MHA} = \frac{aC_A + (H^+) - \beta k_1/(H^+)}{\beta^2 k_1/(H^+)\,[1 + k_1/(H^+)]} \quad (22)$$

where $\beta = (H_2A) = C_A(1-a) - (H^+)$. Calculations were carried out with the aid of the above equations, employing the data taken from the $a=0.5\sim0.8$ region of the titration curves (Fig. 1)

Results and Discussion

The acid dissociation constants of BADA and its chelate stability constants are listed in Table I. If one consider the basicity of the donor nitrogen, the value of the second dissociation constant and the chelate stability constants of BADA may be expected in between those of aniline-*N*, *N*-diacetic acid[7] and of methylamine-*N*, *N*-diacetic acid[7]. The data obtained are in good accordance with our estimates, as is shown in Table I.

The other of the decreasing stability of the metal chelate is Cu(II)>Ni(II)>Pb(II)>Zn(II)>Co(II)>Ca(II)>Mg(II), as is listed in Table I. These values were calculated using Eqs. 15 and 16 for calcium and magnesium, and 10 and 11 for the rest of the metal ions, employing the data obtained from nine points on the titration curve in the $a=1.1\sim1.8$ range for each metal ion. The calculated values on each metal ion are found to be in good agreement within the range of experimental error, thus indicating the reasonableness of the assumption. The order of chelate stability for

TABLE I. THE STABILITY CONSTANTS OF CHELATES OF BADA AND RELATED LIGANDS
$\mu=0.1$ (KNO_3)

Ligand		 [7]	 [7]
	25°C	20°C	20°C
pk_1	2.24	2.12	2.40
pk_2	8.90	9.65	4.96
log K_{MA} for			
Cu(II)	10.51	10.09	6.57
Ni(II)	7.98	8.73	3.53
Pb(II)	7.39	—	3.49
Zn(II)	6.97	7.66	3.22
Co(II)	6.88	7.62	2.90
Ca(II)	3.13	3.75	1.50
Mg(II)	2.63	3.44	1.15

these ions is quite similar to that of methylamine-*N*, *N*-diacetic acid, as is shown in Table I. Moreover, the decreased values for the BADA chelates may be due to the electronegative effect of the phenyl group through $-CH_2-$ linkage.

Although we tried to apply this calculation to the range below $a=1.0$ for copper, nickel, zinc, lead and cobalt, it was only successful in the case of copper and nickel, failing for the rest of metal ions. For copper and nickel, the consistent values were obtained even in this earlier part of the titration curve, and their mean values were identical with those obtained from the later part of the curve.

If one carefully examines the titration curves for zinc, lead and cobalt, a slight inflection will be noticed at a point near $a=1.0$. This inflection may indicates that the chelate formation reaction proceeds in two steps. The first step involves the formation of a hydrogen complex which predominates at the first buffer region of $a=0.8$, while the second step involves the formation of a neutral complex which predominates at the second buffer region of $a=1.3$. In the $a=0.8\sim1.3$ region, both reactions proceed simultaneously. Proceeding from this assumption, the stability constants of the hydrogen complex (K_{MHA}) with three metal ions were calculated in the first buffer region of $a=0.5\sim0.8$, the points used for the calculation being only five. The calculated values were found to be fairly consistent for the hydrogen complexes of cobalt and zinc, but not for lead. The values for cobalt and zinc thus determined are found to be $\log K_{CoHA}=2.7$ and $\log K_{ZnHA}=3.0$.

As the data used for the calculation were obtained from a relatively narrow range, these values may not be accurate enough. However, the formation of a hydrogen complex will be quite probable for zinc and cobalt. Although the calculation of the stability constant of a hydrogen complex for lead did not give satisfactory results, the formation of the hydrogen complex may also occur to some extent in this case.

The acid dissociation constants of *o*- and *p*-NBADA, as well as their chelate stability constants for calcium and magnesium, are listed in Table I. The first and second dissociation constants of both compounds indicate that these are more acidic than BADA. The higher acidity can be attributed to the electron inductive effect of the nitro group, which decreases the basicity of the donor nitrogen through $-CH_2-$ linkage. In the case of the *o*-isomer, the coplanarity of the nitro group is so hindered by the neighboring bis-(carboxymethyl)-iminomethylene group that the resonance of nitro group is decreased, which in turn reduces the inductive effect of the nitro group. Thus, the *o*-isomer is less acidic than the *p*-isomer, whose nitro group does not suffer from steric hindrance.

Table II. Alkaline earth chelating tendencies of BADA and its nitro derivatives

$t=25°C$, $\mu=0.1$ (KNO_3)

Ligand			
pk_1	2.24	1.99	1.80
pk_2	8.90	8.29	7.65
$\log K_{MA}$ for			
Ca(II)	3.13	2.93	2.53
Mg(II)	2.63	2.65	1.6

The stability constants of these two ligands with calcium and magnesium are found to be reasonable in comparison with those of BADA, and their stabilities decrease with the decreasing pk_2 values. The accuracy of the stability constant of magnesium chelate of *p*-NBADA is attained only to one decimal place on account of its low stability.

Summary

1. The acid dissociation constants of benzylamine-*N*, *N*-diacetic acid, and the stability constants of its chelates with Cu(II), Ni(II), Pb(II), Zn(II), Co(II), Ca(II) and Mg(II) at 25°C and 0.1 ionic strength, have been determined by the pH titration method.

2. *o*- and *p*-Nitrobenzylamine-*N*, *N*-diacetic acid have been newly synthesized from the corresponding benzylamine.

3. The acid dissociation constants of the above two ligands, and the stability constants of its chelates with Ca(II) and Mg(II), have been determined at 25°C and 0.1 ionic strength.

The author wishes to express his gratitude to Professor Keihei Ueno for his guidance and to Assistant Professor Yukito Murakami for his kind advice during the course of this investigation. He also wishes to thank Mr. Michio Shido, Miss Sachiko Indo and Miss Takeko Tahara for their microanalysis.

Finally, the expenses have been defrayed in part by a grant given by the Ministry of Education, to which the author's thanks are due.

Concentration and Temperature Profiles in a Tubular Reactor for Methanol Synthesis with an Outer-wall of Uniform Temperature. I. Profiles in a Reactor without a Heat Exchanger in a Catalyst Bed

By Hiroshi UCHIDA, Yoshisada OGINO, Masaaki OBA and Kinya SHIMOMURA

(Received January 6, 1962)

The heat transfer problem concerning methanol synthesis reactor placed in a bath of boiling heat transfer medium has been discussed in a paper by Wirth[1], but his paper deals with neither the concentration profile nor the temperature profile in the catalyst bed. The present paper provides sets of concentration and temperature profiles obtained by the use of a tubular reactor for the methanol synthesis. The reactor was placed in a bath of flowing hot oil, and the determination of the profiles was conducted in essentially the same way as that used with the Fischer-Tropsch synthesis reactors in this laboratory[2,3]. Starting with the experimental concentration profile, calculation of the axial temperature profile by means of the conventional procedure was attempted in order to find out the reasonable values of heat transfer coefficients by comparison of the resultant profile with the experimental profile. In view of the most favorable temperature profile for methanol production, the experimental profile, in conjunction with the heat transfer efficiencies thus obtained, may be helpful in predicting a suitable means for improving the reactor performance.

Experimental

The synthesis gas, consisting of three parts hydrogen and one part carbon monoxide plus a small amount of inert gas (5~7% nitrogen), was furnished in a gas holder (400 m^3) by adding an amount of electrolytic hydrogen to water-gas produced in a water-gas generator. Before this addition, the water-gas was passed through a gas purification train in a method described elsewhere[1], and the sulfur content was reduced to about 1 p.p.m. Figure 1 shows a schematic diagram of the methanol synthesis. The synthesis gas was compressed by a gas compressor (A) to 250 kg./cm^2 and was then introduced into a high pressure gas storage (B), from which the compressed gas was injected as a make-up gas into a synthesis loop through a reducing valve (V_1). The synthesis loop consisted of a gas purifier (D) filled with active charcoal, a preheater (E) for

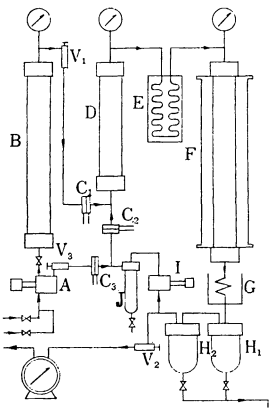

Fig. 1. Schematic diagram of methanol synthesis.

the synthesis gas, a reactor (F), a cooler (G), two methanol separators (H_1 and H_2), a gas circulating pump (I), and an oil separator (J) for removal of oil from the pump. Injection of the make-up gas was made immediately before the purifier in the synthesis loop in order that the gas might be removed from the last traces of sulfur prior to its entering the reactor. Part of the circulating gas was always being purged from the loop through a reducting valve (V_2) to keep the inert gas content below a certain limit, and the flow rate of purged gas was determined by means of a gas meter at atmospheric pressure. Moreover, the compressor was connected in order to allow compression of hydrogen into the synthesis loop through a reducing valve (V_3). The flow rates of the make-up gas and the circulating gas were determined by means of high pressure flow meters, C_1 and C_2 respectively.

A detailed sketch of the reactor is given in Fig. 2. The reactor had a total length of 2 m., an outer diameter of 100 mm., and an inner diameter of 50 mm., and was made of chromium steel (13% Cr). It was placed coaxially in a cylinder 300 mm. in diameter. Into the bottom of the cylinder, a heat tranfer medium (Kanechlol) was fed at a flow rate of 1.2 m^3/hr.; it passed upwards through an annular space between the reactor and the cylinder wall to the top, where the medium was allowed to flow down into a reservoir maintained at a fixed high temperature. The catalyst charge was 1.74 l. with a layer of 1 l. copper granules placed above the catalyst bed. The catalyst bed was 950 mm. high, occupying the intermediate range of the

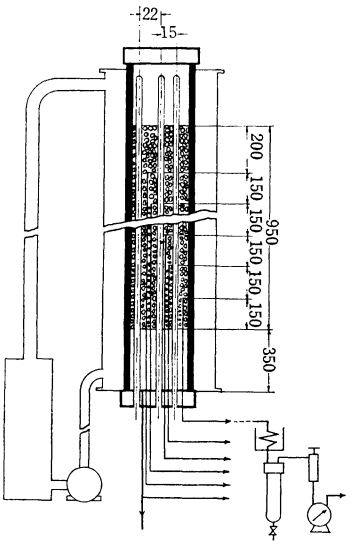

Fig. 2. Methanol synthesis reactor.

reactor between 350 and 1300 mm. from the bottom. Three thermocouple protection tubes of stainless steel went through the whole length of the catalyst bed. One of the tubes was a center thermocouple tube 8 mm. in outer diameter and with a thickness of 2 mm., while the others were off-center thermocouple tubes 5 mm. in outer diameter with a thickness of 1 mm. and were arranged in such a manner that they went through the bed 13 mm. and 22 mm. apart from the center axis respectively. The thermocouples could be moved upwards and downwards to permit scanning of the axial temperature profiles along the protection tubes.

Five small copper tubes, 2 mm. in outer diameter and 0.5 mm. thick, of different lengths were placed parallel in the catalyst bed, and from five successive ports, at 150, 300, 450, 600 and 750 mm. above the bottom of the bed, small portions of the fluid in the catalyst bed were withdrawn at a flow rate of 30 l./hr. out of the reactor; they then passed separately through small coolers and separators (50 cc. in volume) in order to produce the liquid product. Moreover, a small portion was led in the same way from the outlet tube by way of a tee placed immediately after the reactor. The gaseous product was reduced to atmospheric pressure, metered and analyzed, while the liquid product obtained in the small separators was weighed and analyzed. The analyses were made by means of gas chromatography as well as by conventional chemical methods. From the results of the analyses and the amounts of methanol obtained in the separators, the composition of the fluids at the five ports in the catalyst bed, as well as that of the exit gas, could be calculated.

For satisfactory performance of the reactor, caution had to be exercised, particularly at the beginning of the synthesis, to avoid a sudden temperature rise in the catalyst bed, which would cause an ignition of the catalyst granules. The entire system, accordingly, was first charged with hydrogen, which was circulated at about 100 kg./cm^2, while the heat transfer medium was heated up to 295°C. The make-up gas was then gradually introduced until the total pressure reached 200 kg./cm^2. The carbon monoxide content was subsequently increased by discharging continuously part of the circulating gas and by charging, in turn, the make-up gas until the synthesis could allow the collection of reliable performance data.

A three-component catalyst consisting of oxides of zinc, chromium and copper was used in this synthesis. Prepared in the way described previously[4], it contained zinc, chromium and copper in the atom ratios of Cr/Zn=0.49 and Cu/Zn=0.16. Before use in the synthesis, the catalyst was reduced in a separate oven at about 240°C in a current of the synthesis gas at atmospheric pressure. The catalyst granules were 3 mm. in diameter by 4 mm. high, and 1.74 l. of the reduced granules weighed 2.43 kg.

Results

Methanol Yield.—The methanol yields are illustrated in Table I, together with the corresponding operation variables. The yield, expressed by the space-time yield of the reactor, is rather lower than is usual with commercial reactors. It becomes higher as either the flow rate of the inlet gas is increased or as the

[a] Numerals in bracket indicate the inert gas content (vol. %).

ratio of hydrogen to carbon monoxide is decreased. The synthesis product contains only 1~3% water and 0~0.3% methyl formate as its impurities. Very little carbon dioxide or methane was detected in the exit gas from the reactor.

Temperature and Concentration Profiles in Catalyst Bed.—As is shown by the examples in Figs. 3 and 4, the axial profiles differ in minor details, even though the flow rate of the inlet gas and the composition of the synthesis gas vary within a certain range. The bed temperature remains below the oil bath temperature in the top zone of the catalyst bed, it rises rapidly in the intermediate zone, and, after having its maximum value, it decreases slowly in the bottom zone. In contrast to this, the methanol concentration is extremely low in the top zone, begins to rise in the intermediate zone, and continues to rise more slowly until the equilibrium concentration is attained at the bottom of the bed.

As is shown in Fig. 5, the radial temperature profile is concave upwards at the top of the bed, becomes flat in the intermediate zone, and finally turns convex upwards at the lower zone. The temperature rise over a cross section of the catalyst bed reaches as high as about 40°C in the bottom zone. Within the present

range of operation conditions, the magnitude of the temperature rise increases with a decreasing ratio of hydrogen to carbon monoxide.

Axial Distribution of Reaction Heat.—The combination of the concentration data along the bed with the methanol yield of the reactor, as well as with the flow rate of the inlet gas, leads to the methanol flow rate as a function of the bed length (cf. the solid-line curve in Fig. 6). When the whole bed length is divided into six steps according to the heights of the ports at which a small portion of the fluid is withdrawn, the methanol yield within each step can be readily obtained from the flow rate curve (cf. the step-by-step dotted-line plot). Multiplication of the methanol yield by Thomas'[5] thermochemical data on the reaction heat of the methanol synthesis results in a step-by-step plot of the reaction heat (cf. the dotted and dashed-line plot). In the multiplication, the reaction heat is assumed to take a value corresponding to the temperature averaged throughout each step on the basis of the average temperature over a cross section.

Catalyst Activity.—The activities for the methanol synthesis of the catalyst samples before and after the present synthesis have been determined by the use of a small separate reactor (catalyst bed, 10 cc.), as has been reported previously[6]. The operating variables

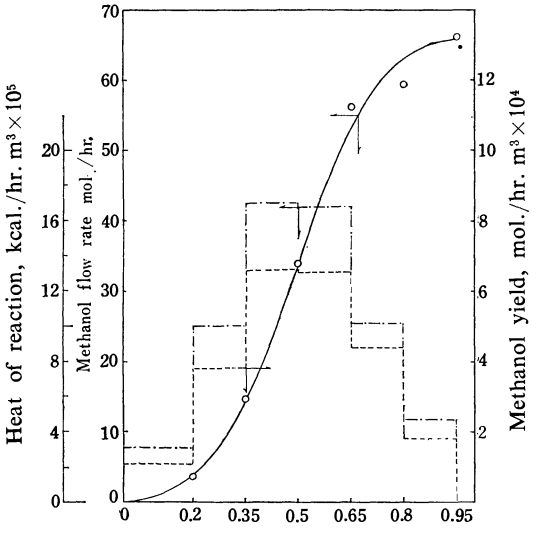

Fig. 6. Methanol flow rate, methanol yield and reaction heat of methanol synthesis as function of bed length. Exp. 1.

—○— Activity after runs 1—10

were as follows: the pressure was 150 kg./cm², the space velocity was 1×10^4 hr^{-1}, and the H_2/CO ratio was 2. The results are shown in Fig. 7. Although the activity is high immediately after the reduction of the raw catalyst at 250°C (plot A), it becomes lower as the catalyst undergoes heating at higher temperatures, as is shown by plots B and C, obtained with the catalyst samples after heating them at 360 and 450°C for two hours respectively. The activity of the catalyst sample after the synthesis runs (plot D) 1—10 lies even lower than plot C. This low activity is probably due to the poisoning effect of sulfur, a minute amount of which is perhaps contained in the inlet gas.

Discussion

Calculation of Temperature Profiles.—The heat balance equation for a tubular reactor packed with catalyst granules is given generally as

$$C_pG\frac{\partial t}{\partial x}=\frac{1}{r}\left\{\frac{\partial}{\partial r}\left(\lambda_r\cdot r\frac{\partial t}{\partial r}\right)+\frac{\partial}{\partial x}\left(\lambda_x\cdot r\frac{\partial t}{\partial x}\right)\right\}+Q \qquad (1)$$

where C_p is the heat capacity of the fluid, G is the mass velocity based on an empty tube,

5) W. J. Thomas, *Ind. Eng. Chem.*, **50**, 967 (1958).
6) H. Uchida and Y. Ogino, This Bulletin, **31**, 45 (1958).

t is the over-temperature in the catalyst bed (which is defined by $t_b - t_w$, where t_b is the bed temperature and t_w is the temperature of heat transfer medium), x is the distance from the catalyst inlet, λ_x and λ_r are the respective thermal conductivities of the bed in the axial and lateral directions, and Q is the heat of the reaction. Strictly speaking, Q in Eq. 1 is to be given as a function of the reaction rate, and hence as a function of the temperature and concentration. For the sake of simplicity, the reaction heat was sometimes approximated to a function of x alone, and Eq. 1 was solved after this substitution. This approach was made by Kodama and Fukui, by Shindo, by Maeda, by Kjaer, and by Kuraishi et al., who have proposed the following formulae: $Q = q_0 e^{-cx}$ with $\lambda_x = \lambda_r$[7], or with $\lambda_x \neq \lambda_r$[8], $Q = Ae^{-cx} + B$[9], and $Q = c_1 e^{-Mx} + c_2 e^{-Nx}$[2], where q_0 is the reaction heat at the catalyst inlet and c, A, B, c_1, c_2, M, and N are constants conveniently chosen to fit the profile of the reaction heat. None of the above formulae, however, could express the present axial distribution data of the reaction heat. The solution of Eq. 1 along this line has, therefore, been given up, and a more simplified method, a step by step calculation of the temperature profile, has been adopted. In this method, the total bed length is divided into steps, and throughout each of the steps the heat of the reaction is assumed to be constant.

Under the further assumptions that the catalyst bed is cylindrical[10] and that λ_x and λ_r are identical and equal to λ_e, the solutions of the heat balance equations for the individual steps with the following boundary conditions,

$$(t_i)_{x=0} = t_{0i} - t_w, \quad (\lambda_e \partial t_i/\partial r + U t_i)_{r=R} = 0$$

are summarized by Eq. 2:

$$t_i = (t_i)_{x_i=0} \sum_{n=1}^{\infty} \frac{2J_0(a_n r/R) e^{-\alpha^2 y}}{a_n (1 + a_n^2/b^2) J_1(a_n)} + (Q_i/\lambda_e) \sum_{n=1}^{\infty} \frac{(R/a_n)^2 2J_0(a_n r/R)(1 - e^{-\alpha^2 n y})}{a_n (1 + a_n^2/b^2) J_1(a_n)} \tag{2}$$

in which the following abbreviations are introduced:

$$b = UR/\lambda_e, \quad A = (\lambda_e/C_p G)^2, \quad \text{and} \quad y = \lambda_e x_i / C_p G$$

In the above equations, t_i is the bed over-temperature, t_{0i} is the bed temperature at the top of the ith step ($x_i = 0$), R is the inner radius of the reactor tube, and U is the overall heat transfer coefficient, which is based upon the temperature difference between the catalyst bed at $r = R$ and the heat transfer medium and which is referred to the inner diameter of the reactor. Further, a_n's and α_n's are the positive roots of the following auxiliary equations, $a_n J_1(a_n) = b J_0(a_n)$ and $A\alpha_n^4 + \alpha_n^2 - a_n^2/R^2 = 0$, respectively. J_0 and J_1 are Bessel functions of the first kind, zero and first order respectively.

In the calculation of t by Eq. 2, the constants, such as C_p, k (the thermal conductivity of fluid) and μ (the viscosity of fluid), are evaluated in the sampe way as has been described elsewhere[1]; from k and μ thus obtained, λ_e is determined by the aid of the formula proposed by Hatta and Maeda[11]. U is usually defined by the equation:

$$1/U = 1/h + (1/h_L)(R/R_O) + (R/\lambda_s) \ln R_O/R \tag{3}$$

where h and h_L are the heat transfer coefficients referred to the inner and outer tube surfaces respectively, λ_s is the thermal conductivity of the reactor tube material, and R_O is the outer radius of the reactor tube. However, the evaluation of U is impossible, because the characteristic constants of the heat transfer medium, and consequently of h_L, are not available. As it is, a trial and error method has been adopted for the determination of U, as is described in the next paragraph.

The step lengths used in the calculation of the temperature profiles are 0.2 m. for the first step and 0.15 m. for the other steps; the Q_i corresponding to each step is found in Fig. 6. Furthermore, it should be noted that the application of Eq. 2 to the step by step calculation is permissible only if the radial temperature profile is uniform at the top of each step (cf. footnote 13). This, however, is not the case with the present experimental profiles. A more conventional procedure is, therefore, adopted to calculated the axial profile based on the average temperature over a cross section. Under the assumption that the catalyst inlet

9) L. Kjaer, "Measurement and Calculation of Temperature and Conversion in Fixed-bed Catalytic Reactors", Jul. Gjellerups Vorlag, Copenhagen (1958), p. 85.

10) The assumption is rather conventional. A similar solution of Eq. 1 for an annular-shaped cylindrical bed, through which passes a thermocouple tube, and a calculation of t by the aid of the solution were also made. The results have proved to be almost identical with those obtained by the use of Eq. 2. The cooling effects due to the other thin tubes placed in the bed are conventionally ignored in the present calculations.

11) $\lambda_e/k = 0.209(R_{ep})^{0.87}$, $R_{ep} = d_p G/\mu$, where R_{ep} is the modified Reynolds number, d_p is the diameter of catalyst granules (cf. footnote 12).

temperature is radially uniform with an arithmetically average temperature of the three experimental temperatures, the calculation of t at the end of the first step by the aid of Eq. 2 leads to a radial profile which is reduced to an average temperature over the cross section[14]. The average temperature is, then, assumed to be equal to that at the top of the second step; the same calculation is repeated as regards the second step, and so forth. In the calculation, a value of U was chosen in order that the calculated average temperature might fit the experimental temperature based on the arithmetically average one of Exp. 1 as closely as possible. The value of U thus obtained is given in Table II, together with the other constants. The procedure was then applied to the data of Exps. 7 and 9 as well as of Exp. 1; the resultant average temperatures are plotted as a function of the bed length in Fig. 8. For the sake of comparison, the figure includes the experimental profiles based on the arithmetically average temperature. The comparison shows that the profiles are almost, though not entirely, consistent with each other.

14) The average temperature t_{av}, is calculated by means of the equation: $t_{av}=\int_0^R 2\pi rtdr/\pi R^2$.

This, however, may be the order of accuracy to be expected in the present performance data.

On the basis of the experimental facts in Exp. 1 that the radial temperature profile happens to be flat at a cross section 0.35 m. from the catalyst inlet and that the Q_i's are nearly equal between the third and the fourth steps (cf. Fig. 6), Eq. 2 may be applied to the calculation of the radial temperature profiles over cross sections within these steps. The calculated profiles are shown in Fig. 5. The discrepancy between the experimental and calculated profiles is small at the cross section very near the top of the third step, but it tends to increase to some extent with the increasing bed length.

Once U has been obtained for the present synthesis, h_L, in turn, is obtained from Eq. 3, since h in the equation can be calculated from the formula of Hatta and Maeda[15]. The values of h_L thus obtained are listed in Table III, together with those of U, h, and λ_s. By the use of these values, radial temperature profiles in the range from the bed at $r=R$ to the heat transfer medium can be drawn in the same way as has been reported previously[2]. Sample profiles are given in Fig. 5 for Exp. 1. The figure, like the table, clearly indicates that the heat transfer resistance is largest at the outer tube surface.

TABLE III. HEAT TRANSFER CONSTANTS

Exp.	h kcal./m²hr.°C	h_L kcal./m²hr.°C	λ_s kcal./m.hr.°C
1	2.797×10^3	2.091×10^2	2.530×10
7	2.859×10^3	2.084×10^2	2.530×10
9	2.722×10^3	2.099×10^2	2.530×10

Optimum Reaction Temperatures.—The determination of the optimum reaction temperature, at which the maximum rate of methanol synthesis is attained, is of interest in estimating the optimum operation conditions for a reactor. The determination can be conducted by the aid of a chart in which lines of constant conversion, with reaction rates as ordinates and temperatures as abscissas, are drawn.

As has been stated previously[4], the rate of

15) $hD/\lambda_e=254(R_{ep}d_p/D)^{-0.87}$, where D is the equivalent diameter of the catalyst bed (cf. footnote 12).

methanol synthesis is represented by the following equation:

$$r=k_d(a_{CO}a^2_{H_2})^{0.7}\ (1-a_{CH_3OH}/Ka_{CO}a^2_{H_2}) \qquad (4)$$

Upon substitution of the following relation for the reaction rate in a fixed-bed reactor, $r=(273\,\boldsymbol{R}c_mA)^{-1}\cdot dF/dx$, and subsequent rearrangement, Eq. 4 is rewritten as:

$$k=273\,\boldsymbol{R}c_mk_d=(dF/Adx)/(a_{CO}a^2_{H_2})^{0.7} \times(1-a_{CH_3OH}/Ka_{CO}a^2_{H_2}) \qquad (5)$$

In the equation, k_d is the rate constant, $\boldsymbol{R}$ is the gas constant, a is the activity, c_m is the mean compressibility coefficient of gas at a normal state, K is the equilibrium constant of methanol synthesis, F (m^3 (N. T. P.)/hr.) is the flow rate of methanol, and A is the cross sectional area of the bed. By the aid of Eq. 5, k at any x is calculated from experimental data, for instance, from the data of Fig. 6. Furthermore, one can draw an Arrhenius' plot of k, because the average temperature over a cross section at the x is determined from the experimental radial temperature profile. The plot is shown in Fig. 9, where an approximate activation energy of the methanol synthesis is found to be 15 kcal./mol. From combining the rate constants with the activation energy thus obtained, the rates at various methanol concentrations and temperatures in Exp. 1 are calculated by Eq. 4, and the resultant data are plotted in Fig. 10 as the lines mentioned above. This chart is restricted to a pressure of 200 kg./cm^2 of the synthesis gas, with a fixed composition and flow rate corresponding to those of Exp. 1. In the figure, the maximum rate curve, which indicates the most favorable temperature profile in the catalyst bed, is given by a thick broken-line curve, whereas the experimental rate curve is given by a thick solid-line curve. Comparison of the two curves discloses that. for attaining the efficient performance of the reactor, the temperature in the zone of low methanol concentration, or in the top zone of the catalyst bed, is too low, whereas the temperature in the zone of high methanol concentration, or in the bottom zone, is too high.

δ=inert gas/CO

If the heat transfer referred to the outer tube surface is improved, the axial temperature profile could be more uniform, becoming higher in the top zone and lower in the bottom zone, and, as a consequence, the experimental rate curve would approach the maximum rate curve. Nevertheless, this improvement alone would not necessarily diminish the large magnitude of the temperature rise in the catalyst bed. With the increasing methanol output, the magnitude is liable to increase more considerably in the bottom zone. An alternate means of providing a suitable control of the bed temperature is the use of a heat exchanger in the catalyst bed, by which the temperature could be controlled by radial heat transfer through the bed. The effect of a heat exchanger on the bed temperature profile, and consequently on the reactor performance, will be described in our next paper.

Summary

On the basis of the experimental concentration and temperature profiles for one of the synthesis runs, the experimental rate curve has been drawn on a chart in which lines of constant conversion with reaction rates are given as ordinates and temperatures as abscissa. In a step by step calculation of the temperature profiles from the experimental profiles by the use of a set of analytical solutions of the heat balance equation, which includes the respective constant reaction heat terms given by the step by step distribution plot, the heat transfer coefficients are conveniently chosen to match the calculated profiles with the experimental ones. Taking the heat transfer efficiencies thus obtained into consideration, a comparison of the experimental rate curve with the maximum rate curve on the afore-mentioned chart discloses that, for attaining an efficient performance of the reactor, not only should the heat transfer referred to the outer tube surface be improved, but also the temperature rise in the catalyst bed should be controlled by a suitable means.

Investigation of Chemisorption by Desorption Rate Measurement; CO_2 on ZnO and NiO; CO on NiO

By Yutaka KUBOKAWA and Osamu TOYAMA

(Received January 31, 1962)

The importance of desorption rate measurements in the investigation of chemisorption has been emphasized in recent work[1] by one of the present authors. It would seem that the most general method would be to determine the heats of adsorption from adsorption isotherms at various temperatures, but in this case the measurements are often limited to a narrow range of coverage because of a slow attainment of equilibrium, particularly at low temperatures. On the other hand, measurements of the desorption rate have no such limitations, permitting an investigation over a wide range of coverage; they also make it possible to obtain information concerning the energy relation for a given chemisorption. In addition, it has been shown that desorption measurements can lead to definite conclusions concerning the relation between the electronic state of an oxide and its chemisorption, the nature of surface heterogeneity, and also the problem of whether or not two types of chemisorption are operative. The present work describes an extension of such desorption experiments to a number of chemisorption systems.

The chemisorption of carbon dioxide on zinc oxide has been investigated by Kwan et al.[2], who have shown that the heat of adsorption as determined from adsorption isotherms ranges from 35 to 48 kcal./mol. On the other hand, the calorimetric measurements carried out by Garner and Veal[3] have shown that the heat of adsorption is only 13 kcal./mol. As for the chemisorption of carbon monoxide on nickel oxide, there seems to have been no studies made of the heat of adsorption apart from the calorimetric measurements of Dell and Stone[4]. Further work is necessary to obtain a complete knowledge of all of the above systems. According to the electron barrier theory suggested by Hauffe and others[5], both systems mentioned above belong to a class characterized by anionic chemisorption on an *n*-type conductor or by cationic chemisorption on a *p*-type conductor, in which a depletion of charge carriers occurs in the boundary layer. If the formation of such a depletive layer played a large part in determining the behavior of the chemisorption, the amount adsorbed and other properties would be seriously affected by oxygen treatment at a high temperature, which would be expected to change the concentration of carriers markedly. Thus, in the present work, the energy relations of, as well as the effects of oxygen treatment

on, both of these systems have been investigated by making use of desorption measurements.

Experimental

Materials. — Nickel oxide was prepared by the thermal decomposition of nickel nitrate at 400°C and then by sintering it at 700°C for 5 hr. Zinc oxide was prepared from zinc oxalate in a method described in a previous paper[1]. The reagents were of an extra pure grade. Carbon dioxide and oxygen were obtained from the thermal decomposition of magnesium carbonate and potassium permanganate respectively. Carbon monoxide was prepared by the reaction of air-free formic acid and concentrated sulfuric acid. All the gases used were purified as usual with liquid nitrogen.

Apparatus and Procedure.—The amount adsorbed was determined by using a conventional constant volume apparatus. The method for measuring the rate of desorption has been described previously and will be repeated here only in outline. The chemisorbed gas was desorbed by means of a mercury diffusion pump, and the desorbed gas was collected in a McLeod gauge and its pressure followed at definite intervals. The activation energy of desorption was determined as follows: The temperature of desorption was lowered abruptly during the desorption experiment, and the rates before the temperature drop were extrapolated to those for the smaller amounts adsorbed when the measurements were carried out after the temperature drop. Thus, the rates at the two temperatures corresponded to the same amount adsorbed, and, hence, the activation energy of desorption could be obtained. It was found that the process of readsorption had no effect on the rates of desorption, or at least on the activation energy of the desorption or on the value of $d \ln v_{des}/dq$ (v_{des}, rate of desorption; q, adsorbed amount).

Prior to the chemisorption experiments, all the adsorbents were evacuated for five hours at 450°C. The weight of the adsorbent and the surface area determined by the B. E. T. method using nitrogen adsorption are shown in Table I.

TABLE I

Adsorbent	Weight g.	Surface area $m^2/g.$
ZnO	16.72	6.1
NiO I	5.49	3.1
NiO II	28.61	3.4

NiO I was used for CO_2 chemisorption and NiO II for CO chemisorption.

Results and Discussion

Activation Energies of Desorption at Various Coverages.—*Carbon Dioxide Chemisorption on Zinc Oxide and Nickel Oxide.* — After carbon dioxide had been allowed to chemisorb at about 300°C for 2 hr., the temperature of the specimen was raised from −30 to 400°C in stages, at each of which the activation energy of the desorption was determined in the manner given above. The results are shown in Fig. 1. It is seen that in the range below room temperature the activation energy of the desorption is about 16 kcal./mol., while above room temperature it increases with the temperature of the desorption, up to 40 kcal./mol. After carbon dioxide had been adsorbed at about 400°C, the adsorption isotherms were determined by successive withdrawals of the gas by a method described in the previous paper[1]. The isotherms thus determined were reproducible on increasing or decreasing the pressure. The results are represented in Fig. 2. The heats of adsorption determined from these isotherms are represented in Fig. 1,

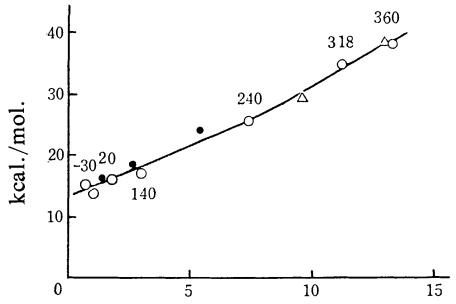

Fig. 1. Activation energies of desorption of carbon dioxide chemisorbed on zinc oxide. The amount adsorbed at room temperature before desorption was 14.33 cc. before oxygen treatment and 13.31 cc. after oxygen treatment. together with the activation energy of the desorption. It follows from this figure that, for the range with an activation energy of desorption of 40 kcal./mol., which is close to the maximum value for this system, the chemisorption involves no activation energy. Consequently, for the range with a lower activation energy of desorption, the same conclusion may also be applicable.

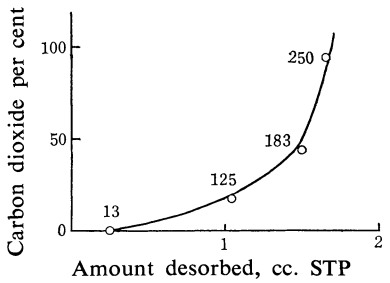
For carbon dioxide chemisorption on nickel oxide, the activation energies of desorption at various coverages were determined in a similar manner. The results are represented in Fig. 3. A comparison with the heats of adsorption determined from the adsorption isotherms shows that the chemisorption is also of a non-activated type. It is evident from Figs. 1 and 3 that the activation energy of desorption, as well as the adsorbed amount per unit area, is much less on nickel oxide than on zinc oxide.

Carbon Monoxide Chemisorption on Nickel Oxide. — After carbon monoxide had been chemisorbed at room temperature, the activation energies of desorption were determined in a similar manner in the range below room temperature. The results are represented in Fig. 4. Figure 5 shows similar results obtained with a specimen on which carbon monoxide chemisorption had been carried out at about 260°C. The carbon dioxide content of the desorbed gas was examined by immersing the trap attached to the McLeod gauge in liquid nitrogen. As is seen in Fig. 6, the content is negligibly small below room temperature, but it increases steadily with the increasing temperature of the desorption. At 250°C, most of the desorbed gas consists of carbon dioxide.



Amount left adsorbed, cc. STP

Fig. 4. Activation energies of desorption of carbon monoxide chemisorbed on nickel oxide. The amount adsorbed at room temperature before desorption was 2.82 cc. before oxygen treatment and 2.64 cc. after oxygen treatment. -○-, before treatment; -●-, after treatment. The symbol -△- refers to the heat of adsorption.

Amount desorbed, cc. STP

Fig. 5. Activation energies of desorption of carbon monoxide chemisorbed on nickel oxide. Carbon monoxide was chemisorbed at about 260°C. Figures indicate the temperature of desorption. The amount adsorbed at room temperature before desorption was 2.69 cc.

Amount desorbed, cc. STP

Fig. 6. Carbon dioxide content of the desorbed gas. Figures indicate the temperature of desorption.

Such behavior indicates the existence of two types of chemisorption, one being reversible, the other, irreversible. As is seen in Fig. 6, most of the carbon monoxide reversibly adsorbed can be desorbed below 200°C, suggesting that the upper limit of the activation energy of the desorption for the reversible type is about 16~20 kcal./mol. (Fig. 5).

The adsorption isotherms were determined to be between 0°C and −22°C in a manner similar to that described above. The heat of adsorption determined from these isotherms is represented in Fig. 4. It follows from this figure that the reversible chemisorption is of a non-activated type. On the other hand, it was found that the adsorption isobar obtained on increasing the temperature of the specimen, which had chemisorbed carbon monoxide at room temperature, showed a maximum at about 250°C, suggesting that some part of the irreversible chemisorption involves an activation energy.

Two Types of Chemisorption and their Behavior in Desorption.—According to previous work by one of the present authors[1], there seems little doubt that, at least in the case of the chemisorption on oxides, the heat of the adsorption or the activation energy of the desorption increases with the adsorbed amount mainly as a result of an a priori heterogeneity of the surface rather than an induced heterogeneity[6] or interaction between the adsorbed species. For such a heterogeneous surface the rate of desorption can be derived by introducing the following method, first given in a previous work[7]. The surface may be divided into a number of sets of identical sites, each of which has a particular activation energy of desorption. At any moment during the desorption experiments, there exists a certain set of sites, S_m, for which the rate of desorption passes through a maximum. Such a maximum rate may be assumed to be approximately proportional to the rate for the whole surface. The rate expression thus derived is given as

$$\mathrm{d} \ln v_{\mathrm{des}}/\mathrm{d}q = -(\mathrm{e}^{\beta}/RTN\theta)$$

where θ and N are the coverage at equilibrium and the distribution function of the sites respectively, both referring to the set of sites, S_m, mentioned above, and β is a constant associated with the distribution of sites. As was described in a previous work, the term of e^{β} is of secondary importance in determining the value of $\mathrm{d} \ln v_{\mathrm{des}}/\mathrm{d}q$. It may therefore be expected that the value of $\mathrm{d}q/\mathrm{d} \ln v_{\mathrm{des}}$ will increase with the increasing value of $N\theta$ and vice versa.

In the desorption rate measurements, if the temperature of the specimen is raised in stages, as has been described above, the set of sites, S_m, will be shifted in the direction of a higher activation energy of desorption, that is, of a higher value of θ, with the increasing temperature of the desorption. The variation of N, accompanied by such a shift of S_m, depends upon the distribution of sites; without any information about this, however, a quantitative discussion of it does not seem feasible. However, at least for the case in which only one type of adsorption is operative, it would not be expected that the value of N, and hence the product $N\theta$, would pass through a minimum with the progress of the desorption, since θ is increased with the increasing temperature of the desorption. Thus, the occurrence of such a minimum in $N\theta$, i.e., $\mathrm{d}q/\mathrm{d} \ln v_{\mathrm{des}}$, suggests that the adsorption sites are divided into two groups, which is to be expected for two types of chemisorption. As an illustration, we can mention the results of the chemisorption of carbon monoxide on nickel oxide, for which the existence of two types of chemisorption has been confirmed. From the plots of $\log v_{\mathrm{des}} - q$ at various temperatures for this system, the values of $\mathrm{d}q/\mathrm{d} \log v_{\mathrm{des}}$ at different amounts adsorbed were determined to be as shown in Fig. 7. It is seen that this value shows a minimum at 150~170°C, below which temperature most of the carbon monoxide reversibly chemisorbed can be desorbed (Fig. 6), thus confirming the above conclusion.

Similar treatments were carried out using

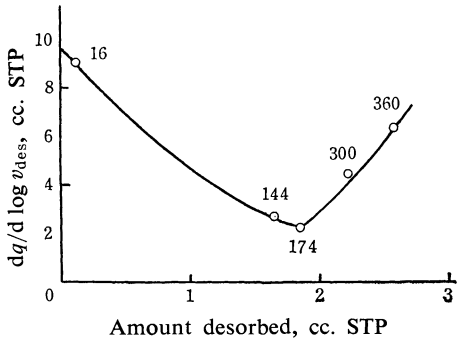


Fig. 7. Values of $\mathrm{d}q/\mathrm{d} \log v_{\mathrm{des}}$ for carbon monoxide chemisorption on nickel oxide. Figures indicate the temperature of desorption.

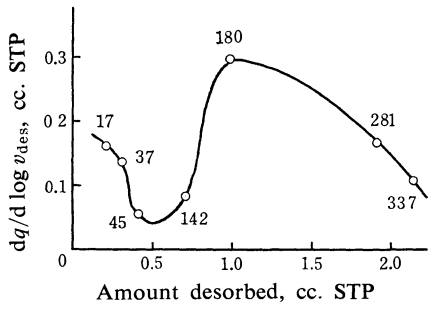

Fig. 8. Values of $\mathrm{d}q/\mathrm{d} \log v_{\mathrm{des}}$ for carbon dioxide chemisorption on zinc oxide. The weight of adsorbent used in these runs was 3.51 g. Figures indicate the temperature of desorption.

6) M. Boudart, *J. Am. Chem. Soc.*, **74**, 3556 (1952).
7) Y. Kubokawa, This Bulletin, **33**, 734, 1226, 1227 (1960).

the results of desorption experiments on other systems. For carbon dioxide chemisorption on zinc oxide, a similar minimum is observed, as may be seen in Fig. 8. This suggests the existence of two types of chemisorption, the existence of which has been recently supported by the work of Matsushita[8] on the infrared spectrum of carbon dioxide chemisorbed on zinc oxide. On the other hand, for the carbon dioxide-nickel oxide system, somewhat different results were obtained, the value of $dq/d \log v_{des}$ decreasing steadily with the increasing temperature of the desorption. Such behavior is inconsistent with that expected for the two types of chemisorption. Further study, therefore, seems necessary before we can understand the difference between the nickel oxide and zinc oxide systems and clarify the true nature of the two types of chemisorption on zinc oxide.

Effect of Oxygen Treatment on the Chemisorption.—This problem was investigated in the following way. All the adsorbents were treated with oxygen at about 450°C, followed by evacuation at 260°C for carbon dioxide and at 100°C for carbon monoxide chemisorption. The activation energies of the desorption at various coverages were then determined in a similar manner. As may be seen in Figs. 1 and 4, for carbon monoxide on nickel oxide and for carbon dioxide on zinc oxide such an oxygen treatment has little or no effect on either the adsorbed amount or on the activation energy of the desorption. This indicates that both chemisorptions are essentially independent of the electronic state of the adsorbents. It may, therefore, be concluded that the formation of an electrical double layer at the interface, which has been emphasized by Hauffe and others, probably plays no significant role in determining the features of the chemisorption already mentioned, although some contribution by ionic binding to the adsorption bond is undeniable. It seems likely that the above-mentioned marked change in the activation energy of the desorption with the change in coverage is mainly to be attributed to a heterogeneity of the surface, as was concluded in a previous work. Such a conclusion is supported by a marked variation in the value of $dq/d \log v_{des}$ with a slight change in the coverage, examples being given in Figs. 7 and 8. As has been described previously, such a phenomenon seems very difficult to explain in terms of the concept of induced heterogeneity.

For carbon dioxide on nickel oxide, somewhat different results were obtained, the amount adsorbed being appreciably reduced after the oxygen treatment. However, if q is replaced by cq (c, constant) in the plots of the activation energy of the desorption against q, then the resulting plots before and after the oxygen treatment lie on the same curve, as may be seen in Fig. 3. This slight effect on the activation energy of the desorption and the results obtained with zinc oxide suggest that the decrease of the adsorbed amount is not closely associated with a change in the electronic state.

Carbon dioxide chemisorption on doped zinc oxide has been investigated by Hart and Sebba[9]. According to their work, the doping with aluminum oxide, which increases the electrical conductivity of zinc oxide, increased the heat of the adsorption, while the doping with lithium oxide had a reverse effect; they have discussed such effects in terms of the change in the Fermi level of zinc oxide. As has been suggested by various workers, however, it should be taken into consideration that such doping will change the surface heterogeneity as well as the electronic state of zinc oxide, both changes affecting the features of the chemisorption. It seems questionable, therefore, to attribute the effect of doping to only the change in the electronic state, as these workers have done. In fact, rather unusual behavior is observed in their work, since they show that the adsorbed amount per unit area is the largest on lithium-doped zinc oxide, which shows the lowest heat of adsorption.

Summary

As an extension of previous work, the study of chemisorption by desorption rate measurement was carried out for carbon dioxide adsorbed on zinc oxide and nickel oxide, and also for carbon monoxide adsorbed on nickel oxide. For the chemisorption of carbon dioxide, the activation energy of the desorption was increased with the decreasing amount adsorbed from 16 to 40 kcal./mol. on zinc oxide and from 7 to 30 kcal./mol. on nickel oxide. In the case of the chemisorption of carbon monoxide, where the two types of chemisorption are seemingly operating, the activation energy of the desorption for the reversible type ranged from 5 to 18 kcal./mol. A method of distinguishing these two types of chemisorption from the behavior on desorption has been proposed, for it has been found that there are two types of chemisorption for the carbon dioxide-zinc oxide system. From the effect of oxygen treatment at high temperatures on the chemisorption, it was concluded that the effect

of the surface barrier, emphasized by Hauffe and others, seems to be only of secondary importance in the above system.

We wish to express our sincere thanks to Mr. Seishi Takeuchi and Mr. Hironori Kushiro for their collaboration in this work.

Polymerization of Isoprene with a Tin Tetraalkyl-Titanium Tetrachloride Catalyst

By Nobuyuki ASHIKARI, Hirotaka HIRATA and Kazuo YANAGISAWA

(Received January 31, 1962)

Many studies[1,2] of the polymerization of isoprene have been undertaken in an attempt to prepare a natural rubber-like polymer using such a typical Ziegler catalyst as aluminum trialkyl-titanium tetrachloride. Moreover, Saltman et al.[3] studied the mechanism of isoprene polymerization with aluminum triisobutyl-titanium tetrachloride.

There is a patent[4] concerning isoprene polymerization using tin tetraalkyl as a component of the catalyst system of SnR_4-$TiCl_4$-$AlCl_3$. However, the catalyst system is so complicated that any analysis of the reaction scheme is comparatively difficult. The authors, therefore, studied the polymerization by a comparatively simple catalyst system consisting of two components, tin tetraalkyl and titanium tetrachloride, in order to obtain fundamental data prior to treating a more complicated system.

Experimental

Materials. — Isoprene was synthesized by the thermal decomposition of limonene according to Staudinger's method[5] and was purified by redistillation. Commercial solvents such as *n*-hexane, benzene and toluene were purified by distillation after drying them with sodium. Titanium tetrachloride was treated with copper dust and distilled. Tin tetraalkyl was synthesized by the usual method[6], i. e., by the reaction between a Grignard reagent and tin tetrachloride in ether, and was employed after a by-product, R_3SnCl, had been removed.

Polymerization. — In every case, the catalyst complex was prepared by mixing the two components at room temperature in a polymerization tube filled with gaseous nitrogen. Then the complex was aged at that temperature for about 30 min., except for the case of finding the effect of the aging time on the polymerization rate. The complex thus produced was usually a large block. After a solvent, benzene or hexane, had been poured into the tube, the block was divided as finely as possible by high speed shaking. Then the tube was cooled in dry ice-methanol and sealed after a desired amount of monomer had been introduced into it. The reaction was started by transferring the tube into a constant temperature bath. The polymer produced was dipped in methanol containing hydrochloric acid to decompose the catalyst residue, filtered, washed thoroughly with methanol, and dried.

Investigation of Microstructure. — The microstructure of the polymer was investigated by infrared-measurement of the absorption bands in the 750～900 cm^{-1} region. The sample was placed between two rock salt plates to protect it from oxidation during the measurement. This protective procedure was found to be necessary, particularly in the case of measurements at elevated temperatures.

Measurement of Viscosity. — The Viscosity of the soluble part of the polymer was measured in toluene as a solvent at 30°C. Thus, the intrinsic viscosity was obtained.

Results

Effect of the Aging Time on the Polymerization Rate.—The relation between the aging time and conversion is shown in Fig. 1. In this case, the polymerization was carried out with a tin tetraethyl-titanium tetrachloride catalyst at 25°C for one hour. The Sn/Ti ratios shown by the A, B and C lines were 1.40, 2.25 and 0.28 respectively. The polymerization rate dropped suddenly in the initial stage and became almost constant after

$TiCl_4$, 5.46×10^{-3} mol.; monomer, 5 cc.; hexane, 5 cc.

a certain aging time although the time required for this constancy to be attained was different according to the variation in the molar ratio of the catalyst components.

Effect of Catalyst Composition on the Properties of the Polymer.—Here, properties of polymer' indicates the solubility, the intrinsic viscosity and the microstructure. The experiments for investigating these properties were performed on the polymers produced by the $Sn(i\text{-}C_3H_7)_4$-$TiCl_4$ catalyst at 40°C. In this case, the amount of monomer used was 10 cc. in each polymerization. The polymer was extracted by boiling toluene after being purified. Solubility and intrinsic viscosity are summarized in Table I.

Table I. Polyisoprene produced by $Sn(i\text{-}C_3H_7)_4$-$TiCl_4$

No.	SnR_4 $\times10^2$ mol.	Sn/Ti	Soluble part %	$[\eta]\times10^2$
1	0.203	0.22	71.0	5.64
2	0.406	0.44	90.8	5.68
3	0.812	0.88	75.4	4.88
4	1.218	1.31	73.3	4.57
5	1.624	1.75	81.3	5.30

$TiCl_4$, 9.26×10^{-3} mol.; monomer, 10 cc.; benzene, 10 cc.; temp., 40°C, time, 4 hr.

From the table it can be concluded that the yield of a soluble part and the intrinsic viscosity have no direct connection with the catalyst composition. Generally, the molecular weight (deduced from the intrinsic viscosity) of polyisoprene produced by the SnR_4-$TiCl_4$ catalyst seems to be low.

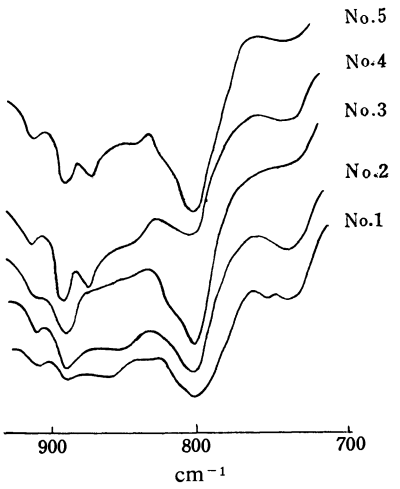

Fig. 2. Infrared spectra of the samples produced by $Sn(i\text{-}C_3H_7)_4$-$TiCl_4$.

Microstructure.—The infrared spectra of the samples shown in Table I are represented in Fig. 2. The spectra indicate that the microstructure of the polymers is similar to that of gattapercha, shown in Fig. 3. Therefore, it is clear that the polymers consist for the most part of *trans*-1, 4 structure.

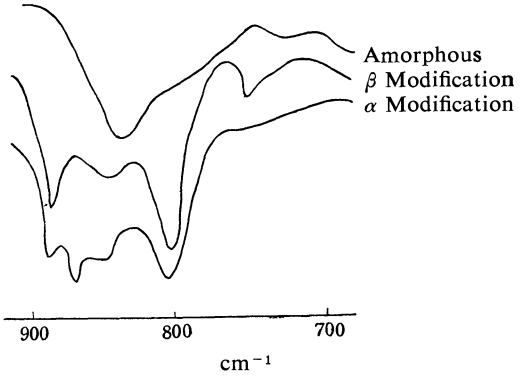

Fig. 3. Infrared spectra of guttapercha, cited from Richardson's paper[7].

Later some of the absorption bands which appeared in 750~900 cm^{-1} region will be discussed. Here, let it only be noticed that the microstructure is greatly affected by the catalyst composition. When the tin tetraalkyl increased to some extent, the microstructure had a close resemblance to that of the α type of guttapercha.

Crystalline Band.—The infrared spectra of the sample of No. 5 were observed in a molten and annealed state (Fig. 4). The specimen was treated carefully to prevent it from oxidation. Figure 4 shows the results obtained

7) W. S. Richardson and A. Sacher, *J. Polymer Sci.*, **14**, 353 (1953).

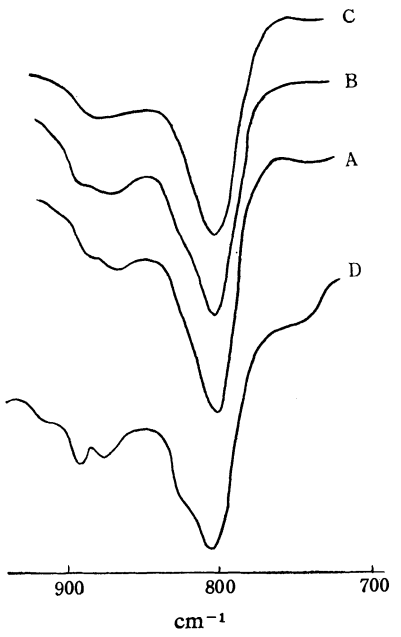

Fig. 4. Infrared spectra of No. 5 at various temperatures.

at 85, 105 and 150°C and in the annealed state. Since the intensity of the bands at 870 and 890 cm^{-1} decreased with an increase in the temperature and since they reappeared in the re-cooled state, it may be said that they resulted from the crystalline structure.

Here, it must be noted that the crystalline band does not reappear, even if the polymer is crystallizable, when the observation is made as soon as the specimen is re-cooled. The facts was confirmed by a preliminary experiment using a crystalline guttapercha.

Simple Kinetics.—The effects of monomer and catalyst concentration on the polymerization rate were investigated using the $SnEt_4$-$TiCl_4$ catalyst, in which the Sn/Ti ratio is constant (1.09). Tables II and III show the results obtained from the polymerization with a constant concentration of monomers and a constant concentration of catalysts respectively. The tables show that the over-all reaction rate is of the first order with respect to the

concentration of the catalysts and monomers, [C] and [M].

$$R_p = k\,[C]\,[M]$$

Here, [C] means the concentration of titanium tetrachloride.

Over-all Energy of Activation. — In all experiments at various temperatures, 0.1 mol. of monomer was polymerized in 5 cc. of an *n*-hexane solution containing 10.12×10^{-3} mol. of tin tetraethyl and 9.26×10^{-3} mol. of titanium tetrachloride. The results are represented in Fig. 5. By plotting the R_p calculated from Fig. 5 against $1/T$, Fig. 6 was obtained. Therefore, the value of the apparent activation energy was obtained as 13.6 kcal./mol.

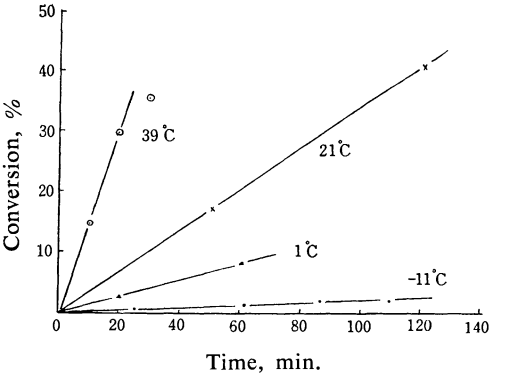

Fig. 5. Polymerization rates at various temperatures.

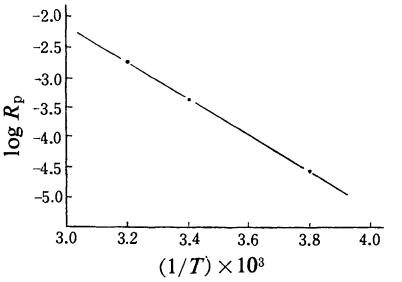

Fig. 6. Relation between log R_p and $1/T$.

Discussion

From the reaction of SnR_4 and $TiCl_4$, such reaction products as R_3SnCl, R_2SnCl_2, etc., and

$RTiCl_3$, R_2TiCl_2, etc., can be expected. However, any one product may have little or no catalytic activity, so that the true catalyst causing the polymerization to start might be a complex the form of which is not clear.

As we[8] discussed previously in connection with the polymerization of propylene with the same catalyst, the catalyst system has a cationic or an anionic character according to the existence of either $TiCl_4$ or SnR_4 in excess.

Since the polymerization rate is of the first order with respect to the concentration of the catalysts, the reaction mechanism can be considered to be a typical ionic type-probably a coordinated anionic type. It was also considered that termination will occur as a result of the abstraction of the hydrogen from the solvent or from other materials.

The comparatively small value of the activation energy is also in good agreement with a concept of an ionic mechanism. The value is slightly smaller than that (14.4 kcal./mol.) obtained by Saltmann, who used an aluminum triisobutyl titanium tetrachloride catalyst.

It must be noted that when SnR_4 is used as a catalyst component, the charactor of the complex depends not only on the catalyst composition but also on the aging time, because the reaction between SnR_4 and $TiCl_4$ is rather slower than the reaction between AlR_3 and $TiCl_4$. As is well known, the reaction of the latter combination is so violent that the complex is produced as soon as the two components are mixed. In the case of the former combination, so long as the reaction of the components is incomplete, free titanium tetrachloride remains in the catalyst system. which gives rise to a comparatively rapid polymerization. Figure 1 clearly shows the relationships. The abrupt drop in the polymerization rate which appeared at the initial stage of reaction (hence, a shorter aging time), means a decrease in the free titanium tetrachloride and an increase in the catalyst complex.

The reason why the catalytic activity of C is the highest will be due to the somewhat cationic character of the catalyst system because of excess titanium tetrachloride. The other lines, A and B, represent anionic polymerization except for the initial stage, because tin tetraalkyl was used in excess. The fact that the B line is higher than the A line may be attributed to the existence of more effective complexes in the former than in the latter.

We will now discuss the results shown in Fig. 2. The following descriptions concerning the assignment of various absorption bands are based on Richardson's paper[7]. Absorption bands are present at 750, 800 and 909 cm^{-1} in every polymer (Nos. 1—5); the bands represent β modification, a crystalline type of *trans*-1,4 structure, or a *cis*-1,4, *trans*-1,4 and 1,2 structure respectively.

Other specific bands in the polymers of Nos. 4 and 5 (the first group) exist at 870 and 890 cm^{-1}; the former band is attributed to α modification and the latter to both α- and β modification. Comparing the two bands, the latter is relatively more intense than the former, and hence the polymer in the first group can be considered to be a mixture of the two modifications. The variation in crystalline type between α and β is affected by the temperature, so that both types may exist as a mixture at a suitable temperature.

A specific band in the other polymers (Nos. 1—3, the second group), at 887 cm^{-1}, is attributed to the 3,4 structure. If the polymer were an example of β modification, a specific band for the type would be present at 890 cm^{-1}. Therefore, the band at 750 cm^{-1} mentioned above may be due to the *cis*-1,4 structure. After all, it is not clear from the infrared study whether or not the crystallinity is present in the polymers of the second group.

Further investigation concerning the spectra is being undertaken from the viewpoint of catalyst composition. The polymers in the first group are produced by the complex where the Sn/Ti ratio is larger than unity, while those in the second group are produced under the reverse conditions. Accordingly, it may be said that a complex having an anionic character produces a crystalline polymer, exemplifying α- and β-modification of *trans*- 1,4-polyisoprene, and that that having a cationic character produces a polymer consisting of various structures.

In addition to the infrared study, we examined the X-ray diffraction pattern of the sample, which had been considered a crystalline polymer as a result of the infrared study, but we could not obtain the crystalline pattern. This may be because the crystallite contained in the polymer is too small to represent the crystalline X-ray pattern, while it is large enough to represent the crystallinity in infrared measurement.

NOTES

Thermodynamics of Ionization of Substituted Benzoic Acids: 3, 4, 5-Trimethoxybenzoic Acid

By R. K. CHATURVEDI and Sarvagya S. KATIYAR

(Received December 18, 1961)

The studies on the dissociation of carboxylic acids at different temperatures were undertaken by us originally in connection with our studies on the interaction of these acids with the metal ions[1]. The knowledge of dissociation constant of these acids which we found essential to have, led to some interesting conclusions regarding the influence of the substituents on the dissociation of the acids. It was, therefore, considered of value to examine this latter aspect by studying a number of substituted benzoic acids. The present paper reports the pH metric determination of dissociation constant of 3, 4, 5-trimethoxybenzoic acid in the temperature range 20~60°C and the thermodynamic functions associated with the dissociation of this acid.

Experimental

3, 4, 5-Trimethoxybenzoic acid was synthesized by the method described in the literature[2]. Recrystallization from water gave a product of satisfactory purity with m. p. 169°C (reported 168°C[3]). Solutions of the acid prepared in double distilled water were titrated pH metrically against standard sodium hydroxide solution prepared from a Merck "Guaranteed" reagent. All the pH metric measurements were made with a Beckmann pH meter model G employing the extension electrode assembly. The arrangement for the temperature control was the same as described earlier[4].

Results and Discussion

Figure 1 gives the typical set of results on the pH metric titration of the acid against standard sodium hydroxide solution. The curves refering to different temperatures (indicated in the body of the Fig. 1) show a marked inflexion characteristic of the carboxylic acids. The values of the classical dissociation constant of the acid at different temperatures were calculated from the data in Fig. 1 by the method discussed by Britton[5]; these values at various temperatures are returned in Table I,

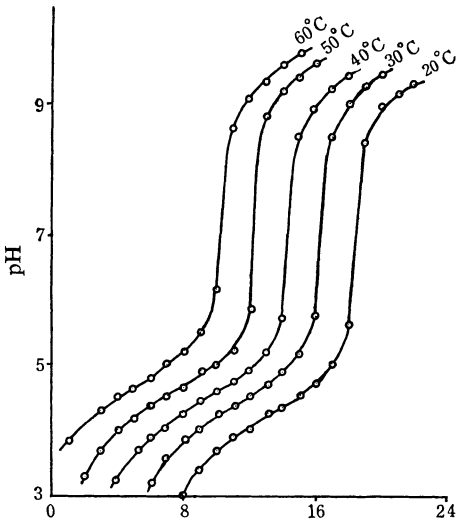

Fig. 1

7) G. G. Manov, R. G. Bates, W. H. Hamer and S. E. Acree, *J. Am. Chem. Soc.*, **65**, 1765 (1943).

Table I. It may be seen from these data that increase in the temperature causes an increase in the pK of the acid; the values, for example, are 4.30±0.07 and 4.65±0.05 at 30 and 60°C respectively.

By applying the method of least squares the following equation,

$$-\ln K = \frac{7430.55}{T} - 44.24 - 9.725 \times 10^{-2} T \quad (1)$$

was derived[8] which governed satisfactorily the variation of pK with T. From the values of the constant of Eq. 1 the thermodynamic functions such as change in free energy, entropy, enthalpy and heat capacity were computed from the well known thermodynamic relationships[8]; the values of these quantities at different temperatures are given in Table II.

Table II. Thermodynamic functions of dissociation of 3, 4, 5-trimethoxybenzoic acid

Temperature °K	ΔF kcal./mol.	ΔH kcal./mol.	ΔS cal./mol. deg.	ΔC_p cal./mol. deg.
293	5.59	−1.83	−25.33	−113.24
303	5.87	−2.98	−29.19	−117.10
313	6.18	−4.17	−33.06	−120.96
323	6.53	−5.39	−36.93	−124.83
333	6.92	−6.66	−40.79	−128.69

For a number of substituted benzoic acids it was shown by Shorter and Stubbs[9] that the total effect of the substituents in different positions on ionization of the parent acid is roughly the sum of the individual contributions of the substituents; this is especially true in case the substituent occupies meta or para positions. These observations indicating the additivity of pK have been theoretically well discussed by a number of workers[10]. It is of interest to examine the applicability of the additivity principle to the data on pK of the 3, 4, 5-trimethoxybenzoic acid. From the data in column 3 of Table III, it may be seen that the substitution of a methoxy group in meta position lowers the pK of benzoic acid by 0.12 unit while that in the para position enhances the same by 0.26 unit. These consideration suggest, by the application of the above principle, a value of 4.23 at 25°C for pK of the acid under investigation is good agreement with our values in this temperature range.

Table III. Observed and calculated values of pK and ΔF

Acid	pK	Contribution to pK	ΔF kcal./mol.	Contribution to ΔF
Benzoic	4.21	—	5.74	—
m-Methoxybenzoic	4.09	−0.12	5.58	−0.16
p-Methoxybenzoic	4.47	+0.26	6.09	+0.35
3, 4, 5-Trimethoxybenzoic	4.23	+0.02	5.77	+0.03

Further, the change in free energy of ionization obeys additivity principle in cases in which steric effects are not significant. Even in certain cases when steric effects are considerable the additivity of ΔF is maintained presumably because of the compensation of the steric effects on ΔH and $T\Delta S$[11]. Besides steric effects, the solvent effects are also known to influence the additivity of ΔF. But the large size of −COO group and the fact that the charge is carried by both the oxygen atoms because of resonance, minimizes the possibility of a significant solvent effect in case of benzoic acids[12,13]. The data in column 4 of Table III gives the ΔF values for benzoic and methoxybenzoic acids. From the contribution to ΔF of methoxy group in *p*- and *m*-positions we get a value of 5.77 kcal./mol. at 25°C in good agreement with our value in the same temperature range. The application of the additivity principle to ΔF values might lead to the view that purely polar effects arising out of inductive influences are operative. But the consideration of the ΔS value clearly shows that this is not the case. It is known that purely polar effects hardly cause any change in ΔS. Thus for example ΔS for *m*-methoxybenzoic acid (−18.5) and *p*-methoxybenzoic acid (−18.5) are hardly different from the value of −18.9 for benzoic acid whereas the value of ΔS for 3, 4, 5-trimethoxybenzoic acid is significantly different from that of benzoic acid.

Author's grateful thanks are due to Dr. Hrishikesh Trivedi, Principal, for facilities and kind encouragement and to Dr. Jagraj Behari Lai for his kind interest in the work.

Preparation of 2-Bromo-2-nitro-pentylamine

By Mitsuo MASAKI and Masaki OHTA

(Received March 8, 1962)

Only a few β-halogeno-β-nitro amines are known to be the products of the addition of ammonia or amines to α-halogeno-α-nitro-olefines. The reaction of β-bromo-β-nitrostyrene with ammonia gives 2-bromo-2-nitro-1-phenylethylamine[1], and the reaction of 1-bromo-1-nitrobutene with ammonia or amines gives unstable adducts[2], but in most cases the products have not been characterized.

We wish to report the preparation of 2-bromo-2-nitro-pentylamine (I, $R=C_3H_7$) required for other work by a new method, which involves the reaction of 1, 2-dibromo-2-nitropentane with potassium phthalimide.

2-Nitropentene-1[3] (b. p. 73~74°C/45 mmHg), which was prepared in a good yield by the direct dehydration of 2-nitropentanol using the technique of Buckley and Scaife[4], was converted, by the addition of bromine in chloroform, into 1, 2-dibromo-2-nitropentane (II), a colorless oil with a b. p. of 99~100.5°C/7.5 mmHg. (Found: N, 4.93; C, 21.87; H, 3.48. Calcd. for $C_5H_9O_2 \cdot NBr_2$: N, 5.09; C, 21.82; H, 3.27%).

The dibromide II was heated under reflux with potassium phthalimide in acetone for 30 hr., cooled to room temperature, and filtered to remove the potassium bromide. After the bulk of acetone had been removed by distillation, the resultant syrup was crystallized by the addition of ethanol and then recrystallized from ethanol, giving colorless prisms of 1-phthalimide-2-bromo-2-nitropentane (III). M. p. 90~92°C (yield 70%). (Found: N, 8.35; C, 45.68; H, 3.99. Calcd. for $C_{13}H_{13}O_4N_2Br$: N, 8.22; C, 45.75; H, 3.81%).

The reaction of III with hydrazine hydrate in ethanol gave I ($R=C_3H_7$), which was isolated as its stable hydrochloride IV; the latter was then recrystallized from ethylacetate or ethanol-ether to give colorless needles with a m. p. of 126~127°C (yield 63%). (Found: N, 11.35; C, 23.84; H, 5.31. Calcd. for $C_5H_{11}O_2N_2Br \cdot HCl$: N, 11.31; C, 24.24; H, 4.85%). The infrared absorption band in IV at 1440 cm^{-1}, which has disappeared in I ($R=C_3H_7$), is ascribed to $-\overset{+}{C}H_2\overset{+}{N}H_3$; therefore, I ($R=C_3H_7$) is not the alternative nitro-amine, 1-bromo-2-amino-2-nitropentane.

This nitro-amine (I, $R=C_3H_7$) was also characterized by its conversion into the picrate (m. p. 156~157°C. Found: N, 15.64. Calcd. for $C_{11}H_{14}O_9N_5Br$: N, 15.86%), its reduction on Raney nickel to the corresponding diamine[5] (picrate m. p., 224~227°C. Found: N, 19.79; C, 36.79; H, 3.80. Calcd. for $C_{17}H_{20}N_8O_{14}$: N, 20.00; C, 36.43; H, 3.57%), its benzoylation to give the *N*-benzoyl compound of I ($R=C_3H_7$) (m. p. 90~91°C. Found: N, 8.63. Calcd. for $C_{12}H_{15}O_3N_2Br$: N, 8.89%), and its reaction with phenyl isocyanate to give the corresponding derivative of urea (m. p. 103~104°C. Found: N, 12.36. Calcd. for $C_{12}H_{16}O_3N_3Br$: N, 12.73%).

The applicability of this method in the preparation of other β-bromo-β-nitro-alkylamines (I) is now under study in this laboratory.

We are indebted to Mr. Keiji Naruse for performing the microanalyses.

On the Nitration of 2-Thenyl Acetate

By Tyo SONE, Kensuke TAKAHASHI and Yasuo MATSUKI

(Received March 14, 1962)

A recent paper[1] has reported that the nitration of 2-thenyl acetate with acetic anhydride-nitric acid at 10°C gives a 65% yield of 5-nitro-2-thenyl acetate (I), b. p. 132°C/0.3 mmHg, m. p. 35°C, but also that in spite of some attempts, the formation of 3-nitro-2-thenyl acetate (II), which can be expected from the presence of the *o*-, *p*-directing acetoxymethyl group in the 2-position of the thiophene ring, is not observed.

During the identification and the structural investigation of thenyl derivatives by means of the NMR technique, we early examined the same reaction and observed, unlike the paper mentioned above, the formation of II as a by-product in a relatively high proportion. To a solution of 2-thenyl acetate (15.6 g.) in acetic anhydride (30 ml.), a mixture of nitric acid (d=1.50, 6 ml.) and acetic anhydride (12 ml.) was added at −10°C, and the reaction mixture was stirred at −5∼0°C for 2.5 hr. Nitro-2-thenyl acetate was obtained as a pale yellow oil (13.6 g., 67.6%), b. p. 120∼125°C/2∼2.5 mmHg (Found: C, 42.02; H, 3.27; N, 6.47%), which, on being left standing, partially solidified to colorless needles, m. p. 38∼39°C[2] (from low boiling petroleum ether). The NMR spectrum (Fig. 1a[3], 40 Mc., cyclohexane as an internal reference) of the oil shows several lines with a medium intensity in the aromatic region, in addition to the four lines (227.8, 231.9, 252.7 and 256.6 c. p. s., J=4.0 c. p. s.) on the basis of which the major part of the oil can be identified as I, 2,5-disubstituted thiophene[4]. Besides these, two lines (155 and 168 c. p. s.) due to the methylene group and a line (31 c. p. s.) due to the methyl group are observed at the high field side. This indicates the presence of an isomer other than I. Upon treating the acetate (b. p. 120∼125°C/2∼2.5 mmHg) with 10% sulfuric acid, the corresponding nitro-2-thenyl alcohol (b. p. 115∼118°C/2 mmHg) was obtained in a 72% yield (Found: C, 38.03; H, 2.87; N, 8.61; Calcd. for $C_5H_5 \cdot NO_3S$: C, 37.73; H, 3.17; N, 8.80%). Benzoate, m. p. 97.5∼99°C (from alcohol) (Found: N, 5.25; Calcd. for $C_{12}H_9NO_4S$: N, 5.32%). In the NMR spectrum (Fig. 1b) of the alcohol, the shifts and the coupling constants (J=4.1 and 5.4 c. p. s.) obviously show the alcohol to be a mixture of 5-nitro- and 3-nitro-2-thenyl alcohol. Thus, it is evident that the original nitro-2-thenyl acetate is also a mixture of I and II. From the relative peak area of the NMR spectra, the ratio of II to I in the nitration products of 2-thenyl acetate under the conditions studied is of the order of 1 to 8 or higher. There has been hitherto little systematic or quantitative investigation of the ratio of isomer formed in the electrophilic substitution of thiophene derivatives with an *o*-, *p*-directing group in the 2-position; it has been assumed that the substitution occurs almost exclusively at the 5-position and at the 3-position, if at all, to a minor extent. However, from the results of the nitration of 2-methoxy thiophene[5] and 2-thenyl chloride[6] and of the present study, it seems that 3-substitution occurs in a relatively higher proportion than had been expected.

Molecular Rotations of Glucides in Relation to their Structures. IX[1]. *The Value of the ζ-Coefficient of the Hydroxyl Group in Hydro-D-xylal*

By Shukichi YAMANA

(Received March 19, 1962)

The value of the ζ-coefficient of the hydroxyl group, ζ_{OH}, in hydro-D-xylal has been calculated. The unit groups in the molecule and its $[M]_D^{20}(W)$ are shown in Table I (Fig. 1).

TABLE I

Name	Unit groups	$[M]_D^{20}(W)$
Hydro-D-xylal	$[(OH)^{3\beta}, (OH)^{4\alpha}, Ring^{0}$ [2]$]$	−53.0[3]

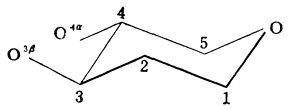

Fig. 1. Perspective drawing of the molecular model of hydro-D-xylal.

In the aldopyranose-ring, R^0 [2], of hydro-D-xylal, the O atom is combined with two methylene radicals, (i. e. $-C^1H_2-$ and $-C^5H_2-$). Therefore, the shape of R^0 is considered to be almost symmetrical. Therefore, in order to simplify the calculations, an ideal model of glucide[4] is used here. By using the PM-method[6],

$$[M]_D^{20}(W) \text{ of hydro-D-xylal,}$$

$$-53.0 \equiv \sum [\mu]_{D\,obs}^{20} \text{ of hydro-D-xylal}$$

$$= (3\beta)\,\Lambda\,(4\alpha) + (3\beta)\,\Lambda R^0 + (4\alpha)\,\Lambda R^0 \qquad (1)$$

As R^0 is symmetrical,

$$(3\beta)\,\Lambda R^0 = 0 \qquad (2)$$

On the other hand, as the orientation of 4α is almost parallel with the average plane of R^0 (equatorial bond), it is expected that the absolute value of $(4\alpha)\,\Lambda R^0$ will be very small[7]. Therefore, for the sake of simplicity of calculation, the next equation is available;

$$(4\alpha)\,\Lambda R^0 \simeq 0 \qquad (3)$$

Combining Eqs. 1, 2 and 3,

$$-53.0 \simeq (3\beta)\,\Lambda\,(4\alpha) \qquad (4)$$

However,

$$(3\beta)\,\Lambda\,(4\alpha) = \{(3\beta) \times (4\alpha)\}\zeta^2_{OH}\{(n^2+2)/3\}^{9)}$$

$$= \{[\mu]_{D\,calcd}^{20} \text{ between } (OH)^{3\beta} \text{ and } (OH)^{4\alpha}\}$$

$$\times \{3/(n^2+2)\}\zeta^2_{OH}\{(n^2+2)/3\}^{11)}$$

$$= -A\zeta^2_{OH}\{(n^2+2)/3\}^{12)}$$

$$= -11.73\zeta^2_{OH}\{(n^2+2)/3\} \qquad (5)$$

From Eqs. 4 and 5,

$$-53.0 \simeq -11.73\zeta^2_{OH}\{(n^2+2)/3\}$$

or

$$\zeta^2_{OH} \simeq 4.5183\{3/(n^2+2)\}$$

This value is almost equal to the value of ζ^2_{OH} in (−)1/2 cyclohexanediol, which has only two hydroxyl groups in its molecule, $4.1091\{3/(n^2+2)\}$[13]. This fact may mean that the value of the ζ-coefficient of a unit group is nearly constant, regardless of the kind of ring in the molecule with which it is concerned.

SHORT COMMUNICATIONS

A Synthetic Resin Catalyzing Racemization of Amino Acids. I

By Koji Toi, Yoshiharu Izumi and Shiro Akabori

(Received March 19, 1962)

It has been demonstrated that salicylaldehyde, a benzene analogue of pyridoxal, catalyzes the racemization of amino acids in the presence of metal ion[1]. In the present work a resin which contain the salicylaldehyde group was prepared from *o*-cresol-formaldehyde resin by converting the methyl substituent of *o*-cresol to aldehyde. Crushed resin was oxidized with chromium trioxide in a mixture of acetic acid and acetic anhydride, and the acetal produced was hydrolyzed with 4 N hydrochloric acid. The formyl content of the resin was found to be 0.16 mmol./g. of dry resin. This synthetic resin was used as a catalyst for the racemization of amino acids in the presence of cupric ion.

The racemization experiment was conducted with L-alanine, L-glutamic acid, and L-aspartic acid. An aqueous solution of each amino acid, which was adjusted to pH 10 with sodium hydroxide and which contained 0.2 mol. of amino acid and 0.9 g. of cupric chloride in a total volume of 100 ml., was prepared. Fifteen milliliters of the above solution, 15 ml. of 0.2 M borate buffer of pH 10, and 5 g. of the resin were stirred at 100°C. The reaction mixture was removed at varing intervals of time and diluted with 12 N hydrochloric acid, and its optical rotation was measured. The amino acid content of the reaction mixture was checked by the ninhydrin colorimetric method during

Abnormal Reaction of Ferrocene with Unsaturated Dibasic Acid Chloride and NMR Spectra of Ferrocene Derivatives

By Noboru SUGIYAMA and Tsutomu TEITEI

(Received April 2, 1962)

Treatment of ferrocene (10.0 g., 0.054 mol.) with fumaryl chloride (4.1 g., 0.027 mol.) in presence of aluminum chloride (7.2 g., 0.054 mol.) in methylene chloride (150 ml.) gave a mixture from which were isolated a saturated compoud, 1, 2-diferrocenoylethane (I, 2.3 g.), orange needles, m. p. 185~186°C, not depressed on admixture with an authentic specimen[1], and β-ferrocenoylpropionic acid (4.5 g.). The expected *trans*-diferrocenoylethylene was not obtained as in the case of benzene[2]. Found: C, 63.58: H, 4.83. Calcd. for $C_{24}H_{22}O_2Fe_2$: C, 63.44; H, 4.85%.

Dihydropyridazine derivative of I; brown needles, m. p. 266°C (decomp.). Found: N, 6.27. Calcd. for $C_{24}H_{22}N_2Fe_2$: N, 6.22%. Infrared, ultraviolet and NMR spectra of I are identical with those of 1, 2-diferrocenoylethane[1]; IR, 1660 cm^{-1} (>CO) (KBr), UV (95% ethanol), 460 mμ (ε, 910). The NMR spectrum of I contains one singlet at $\tau=6.86$ (methylene protons), and another singlet at $\tau=5.76$ (unsubstituted ring protons) and two widely separated triplets at $\tau=5.51$ and 5.18; $J=1.64$ c.p.s. (substituted ring protons).

Under the same conditions as above 1, 2-diferrocenoylpropane (II, 1.8 g.) and 1-methyl-2-ferrocenoylpropionic acid (III, 5.2 g.) were obtained by reaction of ferrocene (10 g.) with citraconyl chloride (4.5 g.).

2, 4-Dinitrophenylhydrazone of II; purple crystals, m. p. 234°C. Found: C, 56.84; H, 4.15; N, 8.53. Calcd. for $C_{31}H_{28}O_5N_4Fe_2$: C, 57.41; H, 4.32; N, 8.64%. IR, 1665 (>CO), 1615 (>C=N-), 1518, 1500, 1320 cm^{-1} ($-NO_2$) (KBr). *p*-Bromophenacyl ester of III (IV); light orange needles, m. p. 149~150°C. Found: C, 55.71; H, 4.24. Calcd. for $C_{23}H_{21}O_4BrFe$: C, 55.53; H, 4.23%. IR; 1740 (ester CO), 1715 (PhCO-), 1665 cm^{-1} (FcCO-) (KBr). UV (95% ethanol), 464 mμ (ε, 435). The NMR spectrum of IV contains three singlets at $\tau=5.76$, 5.51 and 5.20 (ferrocene ring protons), with an expected doublet at $\tau=8.66$; $J=6.22$ c.p.s. (methyl protons) and multiplet at $\tau=6.60\sim7.16$ (methylene protons and a proton at a tertiary carbon). Besides these it contains two quartets at $\tau=4.70$; $J=8.2$ c.p.s. and 2.32; 8.53 (benzene ring and methylene protons respectively) due to the phenacyl group.

It is a very interesting fact that the monosubstituted ferrocene derivatives (I and IV) have three peaks in the NMR specta. Rinehart[3] reported that the spectrum of 1, 1'-(tetramethylethylene)-ferrocene contains the expected methyl proton singlet at $\tau=8.74$, but the ring protons are found in two widely separated triplets at $\tau=6.11$ and 5.37; $J=1.6$ c.p.s.; and the considerable chemical shift is best explained as arising from the ring proton's unequal distance from the iron nucleus in a molecule where the rings are tilted. However, the chemical shift in our case is best explained as arising from the unequal inductive effect of carbonyl group on the ring protons. Thus α protons are assigned to the lower peak and β protons to the higher one in the substituted ring. This interpretation is in accord with the reactivity of acetylferrocene[4].

The authors wish to express their thanks to Professor Koji Nakanishi and his co-workers for their kind advices.

Infrared Absorption Spectrum of Boron Carbide

By Hiroaki TAGAWA and Shin'ichi MATSUDA

(Received May 7, 1962)

Boron is dissolved in boron carbide at high temperature[1] and the ratio of boron and carbon in boron carbide prepared by reaction of boron oxide with carbon always becomes greater than four[2-4]. Although lattice dimension of boron carbide increases with dissolving boron, a detail of the structural change has not yet been explained. In this communication, the infrared absorption spectra of boron carbide having various B/C ratios are presented with the result of X-ray examination of the change of lattice dimension.

Samples of boron carbide employed were fabricated by the reaction of boron oxide with carbon black at about 2800°C by means of 40 kW closed electric furnace. Crystalline boron (purity, more than 99 percent; tetragonal) was provided from Borax Consolidated Ltd. (England). The infrared absorption spectra were observed by using potassium bromide pellet techniques.

The infrared absorption spectra of boron carbide and boron in the range between 1600 and 700 cm^{-1} are shown in Fig. 1 and they agree with the results reported by Brame[5]. The absorption bands at 1158, 1084, 798 and 781 cm^{-1} remain unaffected by the difference of composition, and are the same as that of elemental boron. On the other hand, the band at 1578 cm^{-1} moves gradually toward to small wave number region with the increase of the B/C ratio. It is evident from Fig. 2 that the variation of the wave number with carbon content has some regularity, and the knee point is found at 17.5 percent of carbon. The result of the examination of these carbides by X-rays is shown in Fig. 3, values of 2θ of the (603) reflections are plotted against atom percent of carbon. The carbon content of the reflection point shown in Fig. 3, which agrees with the result found in Fig. 2, may show the limitation of solubility of carbon into boron carbide. The structural unit of boron carbide is linear chain of three carbon atoms and a group of twelve boron atoms arranged at the vertices of a regular icosahedron, and these are distributed approximately in an NaCl type of structure[6]. The shift of the absorption band at 1578 cm^{-1} by dissolving boron may be closely related to the change of the structure; the central carbon of the linear chain of three carbons connecting between boron icosahedron is replaced by a boron atom, which is 14 percent larger than carbon in atomic radius.

Crystallinity of Boron Nitride Fabricated in Various Ways

By Hiroaki TAGAWA and Kikuo ISHII

(Received May 7, 1962)

Crystallinity of boron nitride fabricated in variety of ways has been investigated by means of X-ray diffraction. The structure of boron nitride is very similar to that of graphite[1]. As is shown in graphitizing nature of carbon, the physical and chemical properties of boron nitride may vary considerably according to the nature of starting materials and the conditions of preparation. This communication describes the difference between the crystallinity of boron nitride fabricated by the gas phase reaction and that of the one prepared by the solid state reaction.

The methods of preparation of boron nitride used were as follows; (1) gas phase reaction of boron trichloride with ammonia on a SiC resistor heated at 900 or 1050°C[2], (2) decomposition at 800 or 1000°C of the complex formed by the reaction of boron trichloride with ammonia in gas phase at room temperature[3], (3) solid-gas reaction of boron oxide coated on tri-calcium phosphate with ammonia at 800 or 1000°C for four hours[4], (4) solid-gas reaction of sodium tetraborate with ammonia at 800 or 1000°C for two hours, and (5) solid-solid reaction of boron oxide with sodium amide (mixing ratio by mole, 1 : 3) at 800°C in nitrogen[5,6].

Interlayer spacings of (002), and La- and Lc-dimensions of crystallite of boron nitride fabricated by the methods mentioned above were measured using an automatic recording X-ray spectrometer. As the observed diffraction maximum is not corrected for polarization and absorption, the true value may slightly become less than the measured one. La-dimension, the width of the graphite-like layer, was obtained from (10) band or (100) line, and Lc-dimension, the thickness of the parallel packet of layers, was obtained from (002) line.

The result of X-ray measurement is summarized in Table I. The crystallinity of boron nitride fabricated at 1000°C is more developed than that at 800°C. Interlayer spacing of the

TABLE I. BORON NITRIDE FABRICATED IN A VARIETY OF WAYS

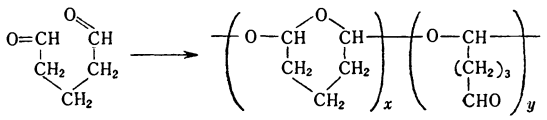
Intramolecular-Intermolecular Polymerization of Glutaraldehyde[1]

By Chuji Aso and Yuzo Aito

(Received May 7, 1962)



Recently, many studies were reported on the intramolecular-intermolecular polymerization of nonconjugated diolefins[2]. This reaction process was extended to the addition polymerization of glutaraldehyde (I). It was reported that certain dialdehydes yielded glassy materials without catalyst, but their structures were not described[3].

I was polymerized to the white, powdery polymer with an organometallic catalyst such as triethylaluminum or partially hydrolyzed one. Boron trifluoride-ether complex and other cationic catalysts were also effective. These polymers cantained a few residual aldehyde groups by infrared analysis. This suggests that the ring formation was occurred during the propagation process.

Some results of the polymerization with triethylaluminum-water catalyst are shown in Table I. The soluble fraction (II) of considerably high viscosity and low residual aldehyde content, melted at about 75~85°C, and was depolymerized quantitatively to I by pyrolysis in vacuo. II has the strong infrared absorption bands at 1150~950 cm^{-1}, which are assigned to ether bond. The sharp absorption bands are also observed at 805 and 855 cm^{-1}. A sample of 2-ethoxycyclooxahexane prepared for comparison shows the corresponding bands at 811 and 872 cm^{-1}.

Therefore, it would seem reasonable to believe that II posessed the six-membered cyclic ether units and the linear nature evidenced by solubility and fusibility.

It was presumed from these results that the polymerization proceeded mainly by intramolecular-intermolecular mechanism and the polymer thus obtained had the ring structure as shown below:

where the ratio of x to y was nearly equal to ten.

The soluble tetramer or pentamer obtained from I after being kept at room temperature without catalyst, contained about one aldehyde group per one molecule, and showed the similar infrared spectrum to that of II. The polymers obtained with the cationic catalysts, on the other hand, were less soluble and showed the different infrared spectrum from II.

The authors are grateful to the Asahi Glass Technical Aide Association for the fund to this investigation.

The Color and the Structure of Tetramineplatinum(II) Tetrahalogenoplatinate(II)

By Shoichiro YAMADA

(Received June 4, 1962)

Magnus's green salts having an empirical formula of $[Pt(NH_3)_4][PtCl_4]$ and a related compound, $[Pt(NH_3)_4][PtBr_4]$ are peculiar in that the salts in the crystalline state are green, whereas the component complex ions are colorless and red in solution. In order to elucidate this peculiarity of the color, the present author formerly determined the dichroism of the compounds in the visible and near-ultraviolet region, and concluded that the unusually deep color of the compounds was due most probably to a weak bond between platinum ions along the needle axis[1]. It was also found that compounds represented by a general formula of $[Pt(amine)_4][PtCl_4]$ are colored either red or green, depending upon the amine[2]. The compounds of the pink series show a dichroism similar to that of $K_2[PtCl_4]$, in which no specific bond is involved between platinum ions, while the green compounds show a dichroism which differs remarkably from that of the potassium salt. The main difference between the two series lies in the following point. The green series shows an absorption band in the longer wavelength region than the red series, and the band is polarized along the c-axis of the crystal, along which the Pt-Pt bond is assumed to occur. The difference in the dichroism as well as in the color between the two series of compounds is so marked that it is possible to tell, by using the dichroism or the color as a criterion, whether a compound with an empirical formula of $[Pt(amine)_4][PtCl_4]$ involves the Pt-Pt bond or not. The results of the examinations are given in Table I, together with the previous data.

A similar examination has been extended to the corresponding bromo-complexes, $[Pt(amine)_4][PtBr_4]$, the results being included in Table I. Thus dichroism of $[Pt(NH_2CH_3)_4][PtBr_4]$, which has been determined by the present author using the microscopic method[3], shows the main features similar to that of Magnus's green salt.

Inspection of Table I shows that a drastic change occurs between methylamine and ethylamine in the case of $[Pt(amine)_4][PtCl_4]$. This may be ascribed to the steric factor[2]. Comparison of $[Pt(amine)_4][PtCl_4]$ with $[Pt(amine)_4][PtBr_4]$ also indicates that the bromo-complexes are more favorable for the formation of the Pt-Pt bond than the corresponding chloro-complexes. Since the bromide ion is larger than the chloride ion, this difference is not to be ascribed to the steric factor, but must be due to the difference in the inductive effect of the halide ions on the electronic state of the platinum ion. Similar results were obtained when a binuclear complex, $[Pt_2Br_6]^{2-}$, was used instead of $[PtBr_4]^{2-}$.

The same thing is again observed for the iodo-complexes. Thus $[PtI_4]^{2-}$ is colored dark-red, in the form of the potassium salt, but its combination with $[Pt(amine)_4]^{2+}$ ions yields complexes with color of greenish yellow, where amine represents ammonia, methylamine, *n*- and isopropylamine, *n*-butylamine, *n*-amylamine, ethylenediamine and propylenediamine.

The consideration, in the light of the criterion used in the cases of the chloro- and the bromo-complexes, indicates that these iodo-complexes all involve the Pt-Pt bond. It is most probable

TABLE I. Pt-Pt BOND IN THE CRYSTALS OF $[Pt(amine)_4][PtX_4]$

1) S. Yamada, *J. Am. Chem. Soc.*, **73**, 1579 (1951); S. Yamada and R. Tsuchida, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zassi*), **70** 142 (1949).

2) S. Yamada and R. Tsuchida, This Bulletin, **31**, 813 (1958).

3) R. Tsuchida and M. Kobayashi, "The Color and the Structure of Metallic Compounds" (Kinzokukagōbutsu no Iro to Kōzō), Zoshindo, Osaka (1944), p. 180.

that in the iodo-complexes the inductive effect, together with the π-bonding, is more important for the Pt-Pt bond formation than the steric factor, since the iodide ion is much larger than the bromide ion as well as the chloride ion.

It is interesting to note the difference between $[Pd(amine)_4][PtCl_4]$ and $[Pd(amine)_4] \cdot [PtBr_4]$, where amine represents those used in the other series of the complexes. It is found that the former show normal color of pink and the latter abnormal color of green. This fact seems to show that the Pd-Pt bond is absent in the former, while the bond exists in the latter. This result is in agreement with the conclusion derived in the foregoing part of the present communication.

The author wishes to thank the late Professor Ryutaro Tsuchida for his encouragement during the course of this work.

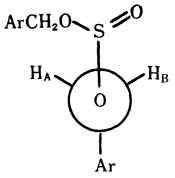
NMR Spectra of Methylene Protons in Benzyl Sulfites and Benzenesulfinate

By Michinori Ōki and Hiizu Iwamura

(Received June 7, 1962)

Abnormal splitting of the methylene proton signal in diethyl sulfite found by Finegold[1] could be due either to i) the non-equivalence of the two methylene groups, because of a) a different bond character of S–O linkages contributed differently with $\pi_{p,d}$- bonding orbital[1], b) geometrical asymmetry, or c) internal C–H ···O–S hydrogen bonding of one side of the ethyl groups with the other left intact, or to ii) the long-range spin-spin coupling effect. Waugh and Cotton[2] rejected all the above possibilities by finding the same phenomenon also in ethyl benzenesulfinate, and attributed it to the magnetic non-equivalence of two protons on a methylene group caused by neighbors of asymmetric center (S atom)[3]. Lately Kaplan and Roberts[4] have shown that the analysis of the spectra of diethyl sulfite as ABC_3 spin system leads to a good agreement with those observed. Thus, it seems to be a timely contribution to offer a conclusive experimental support for the computation results.

The syntheses and the physical properties of the samples will be reported later. Spectral measurement was carried out with a Varian model DP 60 NMR spectrometer at 60 Mc./sec. The samples were dissolved in carbon tetrachloride to give 10% solution, except the nitro-derivative for which the saturated solution in chloroform was employed. Cyclohexane (1%) added to the solvent served as an internal standard, the side band technique[5] being employed throughout the reading of the signals.



The methylene protons in these benzyl esters give a typical quartet signal of AB spin system[6] which can rigorously be solved to afford the $\nu_A-\nu_B$ and J_{AB} values in Table I. The skewness of the spectra of alkyl sulfites may be interpreted similarly.

Since $\nu_A-\nu_B$ is independent of the ring substituents in spite of the dependence of $(\delta_A+\delta_B)/2$ on them, it must be the S=O bond anisotropy that shifts a hydrogen signal to the lower applied magnetic field by the amount observed. Moreover, as $\nu_A-\nu_B$ is about 7 c.p.s. and is comparable with that in rather rigid ethylene sulfite[7], the most populating conformation of benzyl sulfites can be regarded as I and its residence time should be relatively long as suggested by the scarce temperature dependence of the signal. In benzyl benzenesulfinate, $\nu_A-\nu_B$ rises up to 31.38 c.p.s. In this case (II), H_B is suffering from the S=O bond anisotropy, while H_A is situated in the diamagnetic second field produced by the ring current of the benzene ring in the magnetic field[8], resulting in a large $\nu_A-\nu_B$ value.

Far Infrared Spectra and Torsional Vibrations of Polyoxymethylene

By Hiroyuki TADOKORO, Masamichi KOBAYASHI, Shunsuke MURAHASHI, Akiyoshi MITSUISHI and Hiroshi YOSHINAGA

(Received June 13, 1962)

In the previous paper[1], it was reported that the results of the calculation of the normal vibrations of polyoxymethylene (POM) were in fairly good agreement with the observed infrared and Raman frequencies. In that case, the measurements were limited to the region higher than 300 cm^{-1}, and the torsional coordinates were neglected in the calculation. Although the infrared spectra of POM and POM-d_2 have been already measured in the region of 5000~300 cm^{-1} by Novak and Whalley[2], the spectra in the far infrared region have not yet been reported. In this communication, we will report the results of the far infrared measurements of POM and POM-d_2, and of the consideration about the torsional vibrations of the skeletal chain.

The spectra were measured by using a single beam far infrared spectrophotometer constructed in the Faculty of Engineering of this University. The detail of the spectrophotometer was described in the previous report[3]. A film sample of POM (3 cm.×7 cm.×0.03 mm.) was prepared from pellets of Delrin-acetal resin (du Pont Corporation) by rolling between a couple of heated rolls. The polarization spectra of POM were also measured by using a transmission polarizer made of polyethylene sheets[4]. The spectrum of POM-d_2 (paraformaldehyde-d_2 manufactured by Merck & Co., Inc.) was measured as Nujol paste.

The results are shown in Fig. 1. A parallel band (belonging to the A_2 species) was found at 235 cm^{-1} in the spectra of POM[5] and a band was found at a slightly lower frequency (212 cm^{-1}) in the spectrum of POM-d_2.

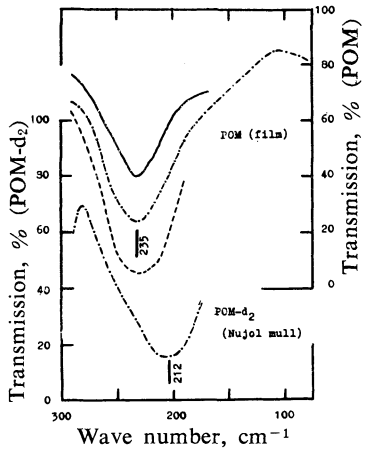

Fig. 1. Far infrared spectra of POM and POM-d_2.

-·-· Unpolarized

---- Electric vector parallel to the orientation direction.

The calculation of the normal vibrations was carried out by using the Urey-Bradley potential field according to the method described in the previous papers[6]. In this calculation the torsional displacement coordinates of the skeleton were taken into account. The numerical computation was made by using a NEAC 2203 electronic digital computer installed in the Computation Center of this University. The results show fairly good agreement between the observed and calculated frequencies. The maximum and average deviations are 6.15 and 2.19% for POM, and 9.90 and 2.51% for POM-d_2, respectively. The detailed results of the vibrational calculations will be reported in elsewhere.

As to the bands at near 200 cm^{-1}, the calculated frequencies [POM: 237 cm^{-1} (A_2), POM-d_2: 212 cm^{-1} (A_2)], are in good agreement with the observed results. The potential energy distributions calculated for the A_2 235

4) A. Mitsuishi et al., ibid., **50**, 433 (1960).
5) This frequency (235 cm^{-1}) agrees with the calculated values, 253 cm^{-1}, for the skeletal model of POM by Miyazawa (*J. Chem. Phys.*, 35, 693 (1961)).
6) H. Tadokoro. *J. Chem. Phys.*, **33**, 1558 (1960); **35**, 1050 (1961).

and 212 cm^{-1} bands are $\tau_a(96\%)+r(CH_2)(3\%)$ and $\tau_a(93\%)+r(CD_2)(5\%)$, respectively[7]. The E_1 fundamental of the lowest frequency (calculated as 22 cm^{-1} for POM and 21 cm^{-1} for POM-d_2) corresponds to the approximately pure torsional vibration of the skeleton with the potential energy distribution $\tau_s(56\%)-\tau_a(40\%)$ for both POM and POM-d_2[7]. These bands could not be observed definitely because of the difficulties in the experimental technique in this region.

The torsional force constant F_τ was defined so that the diagonal elements of the $\boldsymbol{F}$-matrix associated with the torsional coordinates are expressed as $R_0^2 \sin^2\Theta_0 F_\tau$, where R_0=equilibrium C–O distance and Θ_0=equilibrium COC or OCO angles. The value of F_τ was calculated to be 0.061 md/Å, from which the height of the potential barrier for the internal rotation about the C–O bond, V_0, can be estimated by using a sinusoidal potential function

$$V=(V_0/2)(1-\cos 3\phi)$$

where $\phi=\tau-\tau_0$. V_0 was found to be 3.6 kcal./mol.

The authors express their gratitude to Professor Kenzo Joh and Dr. Saburo Makinouchi for the use of the computer and the helpful suggestions for programming.

Cobalt(II) Complexes with Schiff's Bases Derived from Salicylaldehyde and ortho-Substituted Aromatic Amines

By Hiroaki NISHIKAWA and Shoichiro YAMADA

(Received June 18, 1962)

It has been generally believed that quadri-co-ordinate cobalt(II) complexes are not formed with Schiff's bases having substituents on the carbon atom in the 2-position (I)[1]. In fact, bis(salicylidene-2-anisilato)cobalt(II) was reported, but the formation of the compound was ascribed to extra stabilization due to the additional linkage of the oxygen atom of the methoxygroup with the cobalt(II) ion to complete sexa-co-ordination[1]. The present authors have recently succeeded in preparing several cobalt(II) compounds with Schiff's bases having substituents in the 2-position, which are listed in Table I.

The main procedure of the preparations was to add the mixture of $Co(salal)_2 \cdot 2H_2O$*1 (0.015 mol.) and one of the amines (about 0.045 mol.) into a flask which contained ethanol and was filled with its vapor above the liquid phase, keep the reaction mixture closed tightly, allow it to stand overnight and cool it eventually. Red or orange-red crystals are then obtained. In the case of the *o*-chloroaniline, dark-brown crystals are obtained by this procedure. These crystals were recrystallized from pyridine, and the resulting crystals of $Co(2\text{-}Cl \cdot C_6H_4 \cdot N : CH \cdot C_6H_4 \cdot O)_2 \cdot (py)_2$*2 were heated at 70°C in vacuo to yield orange-yellow crystals of $Co(2\text{-}Cl \cdot C_6H_4 \cdot N : CH \cdot C_6H_4 \cdot O)_2$.

Absorption spectra of these compounds in non-co-ordinating organic solvents have been determined in the present study. Since all these compounds display similar absorption spectra, only some of the typical spectra are shown in Fig. 1, together with the absorption spectra of bis(salicylidene-methyliminato)- and bis(salicylidene - isopropyliminato) - cobalt(II). Most bis(salicylidene-alkyliminato)cobalt(II) complexes, absorption spectra of which were recently reported by the present authors[2], are stable in the air at least during the measurements, except for the methyliminato compound of cobalt(II), which is unstable in the air. Since the measurements in the previous

"salcomine" in chloroform, 3. $Co(O\cdot C_6H_4\cdot CH:N\cdot 2\text{-}Cl\cdot C_6H_4)_2$ in benzene, 4. $Co(O\cdot C_6H_4\cdot CH:N\cdot 2\text{-}CH_3\cdot C_6H_4)_2$ in benzene, and 5. $Co(O\cdot C_6H_4\cdot CH:N\cdot 2,6\text{-}(CH_3)_2C_6H_3)_2$ in benzene.

work[2] were done in the presence of air, it seems likely that the oxidation of the methyliminato compound may have taken place during the measurements. The measurements in the present work with bis(salicylaldehyde)ethylenediimine-cobalt(II), ("salcomine"), bis(salicylaldehyde)propylenediimine-cobalt(II) and bis(salicylidene-methyliminato)cobalt(II), which are most readily oxidized in the air, have been carried out in the atmosphere of nitrogen to avoid the undesirable oxidation.

It was formerly found that the absorption spectra, especially the ligand field bands, of the compounds of this sort are diagnostic in determining the configuration of these compounds[2]. Actually the present measurements indicate that "salcomine" and the corresponding propylenediimine complex, which have square-planar configuration, show absorption spectra quite different from the spectra of the methyliminato- and other alkyliminato-derivatives, which were concluded to have a configuration distorted from the square-plane[2,3]. The main difference between the two types lies in that the complexes of the series having a configuration distorted from the square-plane show ligand field bands with characteristic shape in the near-infrared region, while "salcomine" with square-planar configuration does not show a similar pattern, but a rather sharp band in that wavelength region.

Bis(salicylidene-2,6-xylidinato)cobalt(II), which suffers steric hindrance against forming the square-planar co-ordination around a cobalt(II) ion, shows absorption spectrum, similar to those of bis(salicylidene-alkyliminato)-cobalt(II) complexes. Moreover, all the compounds with a substituent on the carbon atom in the 2-position show absorption spectra which are similar to each other, having the main features observed for bis(salicylidene-alkyliminato)-cobalt(II) complexes. The spectra of these compounds, however, are different from the spectrum of "salcomine". It is concluded, therefore, that all these compounds synthesized in the present study, as well as bis(salicylidene-methyliminato)cobalt(II), have a configuration distorted from the square-plane.

It is concluded in a similar way that bis(salicylidene-anilinato)cobalt(II) is also distorted from the square-planar co-ordination, since the compound shows ligand field bands with features similar to those of bis(salicyl-

idene-2, 6-xylidinato)cobalt(II). In the former there is only slight steric hindrance between the hydrogen atom in the 2-position and the oxygen atom of the neighboring ligand. The favorable condition in energy, together with this slight steric hindrance, may be one of the main factors which give rise to the distortion from the square-planar co-ordination in this type of compounds.

The present authors wish to thank the late Professor Ryutaro Tsuchida for his encouragement during the course of this work.

The Determinations of Some Metal Ions by Using Hexamminecobalt(III) Chloride and Sodium Thiosulfate as Precipitants

By Jun YOSHIMURA, Yoshimasa TAKASHIMA, Yoshio MURAKAMI and Toyoaki KUSABA

(Received January 16, 1962)

Many studies for the determinations of various metals using hexamminecobalt(III) chloride as the reagent have been reported. For example, indium has been determined gravimetrically[1,2], colorimetrically[3,4], volumetrically[3], and radiometrically[3] in the form of $[Co(NH_3)_6]InCl_6$ in a hydrochloric acid system. Moreover, thallium has been determined as $[Co(NH_3)_6]TlCl_6$[5-9], aluminum as $[Co(NH_3)_6]AlF_6$[10], gallium as $[Co(NH_3)_6]GaF_6$[11], scandium as $[Co(NH_3)_6]ScF_4$[12,13], iron as $[Co(NH_3)_6]FeF_6$[14], phosphate as $[Co(NH_3)_6]PO_4 \cdot 4H_2O$[15-18], vanadate as $[Co(NH_3)_6](VO_3)_3$[19], and beryllium as $[Co(NH_3)_6][(H_2O)_2Be_2(CO_3)_2(OH)_3] \cdot 3H_2O$[20,21].

Recently Yatsimirskii and Roslyakova have studied the precipitation reactions of copper and lead, using hexamminecobalt(III) chloride and sodium thiosulfate as precipitants[22]; that is, when these reagents were added to the solutions of the metal ions mentioned above, these metals were precipitated, forming insoluble complexes such as $[Co(NH_3)_6]_5[Cu(S_2O_3)_3]_3 \cdot 12H_2O$ and $[Co(NH_3)_6]_2[Pb_2(S_2O_3)_5]$; they have also developed iodometric determination methods. As one of a series of these studies, and in order to develop Yatsimirskii's method, this work was performed.

It was found in this study that silver, cadmium, mercury and bismuth were precipitated forming insoluble complex salts immediately, when hexamminecobalt(III) chloride and sodium thiosulfate solutions were added to the solutions of the metal ions mentioned above; the compositions of these complex salts, except bismuth salt were confirmed to be $[Co(NH_3)_6][Ag(S_2O_3)_2]$, $[Co(NH_3)_6]_4[Cd(S_2O_3)_3]_3 \cdot 6H_2O$ and $[Co(NH_3)_6]_4[Hg(S_2O_3)_3]_3 \cdot 10H_2O$ respectively. The composition of the slightly soluble complex salt which is formed by adding a hexamminecobalt(III) chloride solution to a sodium thiosulfate solution was found to be $[Co(NH_3)_6](S_2O_3)Cl \cdot H_2O$, while Rãy prepared the complex salt $[Co(NH_3)_6]S_2O_3Cl$ by the addition of ammonia to a mixed solution of cobalt(II) chloride, ammonium chloride and sodium thiosulfate in a current of air[23].

We have studied various methods of the determination of metal ions based on the formation of metal complexes; that is, we studied silver by measuring volumetrically the excess of sodium thiosulfate with a standard iodine solution, copper and mercury by weighing gravimetrically their complex salts, and mercury and lead by EDTA titration after their salts had been decomposed.

Experimental

Preparation of Hexamminecobalt(III) Chloride Thiosulfate.—To 10 ml. of a 0.1 M hexamminecobalt(III) chloride solution, an equimolar solution of sodium thiosulfate was added and stirred; after a while a precipitate was obtained. The precipitate was then filtered through a glass filter (1G No. 4), washed 2~3 times successively with 5 ml. of distilled water, and dried on calcium chloride in a dessicator for a month.

Preparation of Silver, Cadmium and Mercury Complexes.—To the mixture of 1.0 ml. of 0.1 M metal chloride and 15 ml. of 1 M ammonium acetate solutions, 10 ml. each of 0.1 M hexamminecobalt(III) chloride and 0.1 M sodium thiosulfate solutions were added. A precipitate of the metal

complex salt was formed immediately. The precipitate was filtered through a glass filter, washed repeatedly with 5 ml. of water and dried on calcium chloride for a month.

Analytical Methods of Complex Salts.—*Determination of the Hexamminecobalt(III) Ion.*—A known quantity of the dried precipitate was dissolved in a 10% sodium hydroxide solution and boiled untill the black brown precipitate of cobalt(III) hydroxide was obtained. The solution containing the precipitate was acidified by adding hydrochloric acid and boiled to dissolve the cobalt(III) hydroxide. After the solution had been allowed to cool the concentration of cobalt(III) ion in the solution was determined by the nitroso-R and EDTA methods. The quantity of hexamminecobalt(III) ion was calculated by making use of their factors.

Determination of the Thiosulfate Ion.—In the case of hexamminecobalt(III) chloride thiosulfate, a known quantity of the sample was dissolved in distilled water and the thiosulfate ion was determined by iodometric titration. As for the metal complexes, after the metal complex formed had been filtered off through a glass filter, the concentration of thiosulfate ion in the filtrate was determined by iodometric titration, and then the content of this ion in the complex was calculated from the difference between the total concentration of this ion and that in the filtrate.

Determination of the Chloride Ion.—After the sample had been treated with a 10% hot sodium hydroxide solution, the cobalt(III) hydroxide formed was filtered off. Then a few milliliters of 3% hydrogen peroxide were added to the filtrate, and this mixture was warmed in boiling water, to oxidize the thiosulfate to the sulfate ion or to sulfur[24]; this treatment was followed by the addition of copper(II) nitrate for the decomposition of the excess of hydrogen peroxide[25]. After the solution had been allowed to cool, the concentration of the chloride ion was determined by Mohr's method.

Determination of the Water of Crystallization.—The sample was dried again up to a constant weight on the phosphorus pentoxide under reduced pressure (below 20 mmHg), and the water content was calculated from the weight difference.

Determination of the Silver Ion.—After the sample had been decomposed by the same treatment as in the determination of the hexamminecobalt(III) ion in the complex salt, the silver hydroxide formed was filtered and dissolved again in dilute aqueous ammonia; then silver chloride was precipitated by acidifying the solution with nitric acid, and the concentration of silver ion was determined gravimetrically.

Determination of the Cadmium and Mercury Ions.—After alkali and acid treatments, these metals were determined by EDTA titration.

Procedures.—*General Procedure for the Determination of Silver by Iodometric Titration.*—To about 10 ml. of a solution containing 5~50 mg. of silver and 15 ml. of a buffer solution, 10 ml. each of 0.1 M hexamminecobalt(III) chloride and equimolar thiosulfate solutions were added and stirred, so a precipitate of silver complex was formed immediately. After the solution had been left standing for 5 min., the precipitate was filtered through a glass filter (1G, No. 4), washed 3 times with 10 ml. of distilled water, and the filtrate and the washings were collected into a 100 ml. dry flask. The filtrate was titrated with a standard iodine solution to determine the excess of sodium thiosulfate, and the number of thiosulfate ions in the precipitate was calculated from the difference between the total thiosulfate concentration added and that in the filtrate. The concentation of silver was determined indirectly by making use of their factors.

Procedure for Determination of Copper, Mercury and Lead by the Gravimetric Method.—To a sample solution containing about 2 ml. of a 0.03~0.1 M metal chloride solution, 15 ml. of a buffer solution and 10 ml. each of the two reagents were added; a precipitate of the metal complex was then formed. After the solution had been left standing for about 15 min., the precipitate was filtered through a weighed glass filter (1G No. 4) and washed with distilled water and then with alcohol and ether. It was dried in an air bath at 50°C for 3 hr. and weighed after cooling.

Procedure for the Determination of Mercury and Lead by EDTA Titration.—A precipitate formed by the same procedure as in the gravimetric method was filtered through filter paper (Toyo-roshi 5C) and washed with distilled water, transferred to the beaker, and decomposed with the alkali and acid treatments previously mentioned; then the concentration of metal ions was determined by EDTA titration.

Results and Discussion

Stability of Sodium Thiosulfate in Solutions of Various pH Values from 1 to 10.5.—In this study, the most important finding was that the hexamminecobalt(III) chloride and sodium thiosulfate used as precipitants were stable under the experimental conditions. It is well known that hexamminecobalt(III) chloride is very stable in solutions over this pH range. Sodium thiosulfate, on the other hand, was unstable in solutions with pH values below 4 and decomposed, separating out sulfur, but it was stable in solutions with pH values above 5; therefore, the experiment could not be done below this pH value.

Effect of the Ammonium Acetate Solution Added.—When a 0.1 M sodium thiosulfate solution was mixed with a 0.1 M hexamminecobalt(III) chloride solution and stirred, an orange, needle-shaped precipitate [hexamminecobalt(III) chloride thiosulfate] was formed; the coprecipitation of this salt with a metal complex salt caused a large error in the determination of the metal ions, but the formation of this complex salt was repressed by adding a certain amount of acetate salt. When 10 ml. of each

24) S. Utsumi, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zassi*), **74**, 608 (1953).
25) S. Utsumi, ibid., **74**, 609 (1953).

precipitant was added to 15 ml. of a 1 M ammonium acetate solution, this complex salt was not formed at least for 20 min. It was evident from this fact that the ammonium acetate solution acted not only as a buffer but as a masking agent. It was then decided to use 10 ml. of each 0.1 M precipitant and 15 ml. of the 1 M ammonium acetate solutions in the following study.

Possibility of the Formation of Various Metal Complexes.—By adding 1 ml. of a 0.1 M solution of various metal ions to the mixed solution of the three reagents mentioned above, the possibility of the formation of various metal complex salts was examined. The elements used in this examination were lithium, sodium, potassium, silver, beryllium, magnesium, calcium, strontium, barium, zinc, cadmium, mercury, boron, aluminum, gallium, indium, thallium, scandium, germanium, tin, arsenic, antimony, bismuth, vanadium, chromium, molybdenum, tungsten, uranium, manganese, iron, cobalt and nickel. It was also found that, in addition to copper and lead, silver, mercury and cadmium were precipitated, forming an insoluble complex salt in solutions with 5.0~10.5 pH values and that bismuth precipitated as its hydroxide in the neutral solution, but formed an insoluble complex in the solution with a pH value of 3.

Determination of the Compositions of Various Complexes.—

1) Hexamminecobalt(III) chloride thiosulfate.

Found: $[Co(NH_3)_6]^{3+}$, 49.4; $S_2O_3^{2-}$, 34.3; Cl^-, 11.6; H_2O, 5.0. Calcd. for $[Co(NH_3)_6](S_2O_3)Cl\cdot H_2O$: $[Co(NH_3)_6]^{3+}$, 49.3; $S_2O_3^{2-}$, 34.3; Cl^-, 10.9; H_2O, 5.5%.

2) Silver complex.

Found: $[Co(NH_3)_6]^{3+}$, 31.3; Ag^+, 21.9; $S_2O_3^{2-}$, 45.1. Calcd. for $[Co(NH_3)_6][Ag(S_2O_3)_2]$: $[Co(NH_3)_6]^{3+}$, 32.6; Ag^+, 21.8; $S_2O_3^{2-}$, 45.4%.

3) Mercury complex.

Found: $[Co(NH_3)_6]^{3+}$, 26.9; Hg^{2+}, 24.0; $S_2O_3^{2-}$, 42.0; H_2O, 7.4. Calcd. for $[Co(NH_3)_6]_4[Hg(S_2O_3)_3]_3\cdot 10H_2O$: $[Co(NH_3)_6]^{3+}$, 26.5; Hg^{2+}, 24.7; $S_2O_3^{2-}$, 41.4; H_2O, 7.4%.

4) Cadmium complex.

Found: $[Co(NH_3)_6]^{3+}$, 31.2; Cd^{2+}, 15.8; $S_2O_3^{2-}$, 48.8; H_2O, 5.2. Calcd. for $[Co(NH_3)_6]_4[Cd(S_2O_3)_3]_3\cdot 6H_2O$: $[Co(NH_3)_6]^{3+}$, 30.7; Cd^{2+}, 16.1; $S_2O_3^{2-}$, 48.1; H_2O, 5.2%.

5) Bismuth complex.

As has been previously mentioned, this complex was formed in the solution with a pH value of 3, but the composition of this complex was not determined, for this complex could not be separated from the sulfur formed as a result of the decomposition of the sodium thiosulfate reagent.

Relation between the Amount of the Precipitate and the pH Value of the Solution.—As the compositions of the silver, cadmium and mercury complexes were determined in addition to those of copper and lead, we studied on the determination methods for these metal ions based on the formation of a complex salt. At first, the relation between the amount of the precipitate and the pH value of the solution was studied under the same conditions as for the preparation of a metal complex. The results are shown in Figs. 1a and 1b. From these results, the cadmium complex was shown not to precipitate quantitatively; when the pH value of the solution became larger than 8, lead did not precipitate as its complex salt, but as its hydroxide, and the gravimetric determination of lead by making use of its complex became useless.

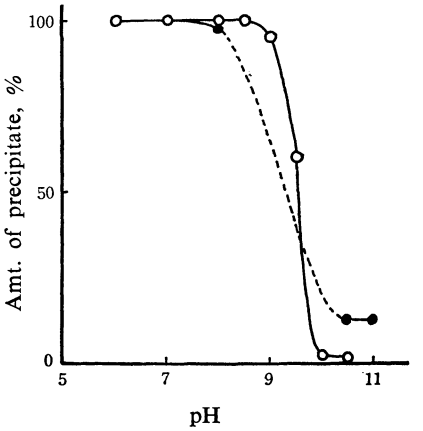

Fig. 1a

The Effect of Ammonium Acetate on the Precipitation of the Metal Complex. — We studied the effect of ammonium acetate on the precipitation of a silver complex by measuring the concentration of excess sodium thiosulfate by iodometry, for we were afraid that the acetate repressed not only the formation of hexamminecobalt(III) chloride thiosulfate but also that of the metal complex. The results are shown in Table I. It is evident from this table that the addition of 2~30 ml. of a 1 M ammonium acetate solution does not repress the formation of the silver complex.

10.8	5	10.7
10.8	10	10.8
10.8	15	10.8
10.8	30	10.7

Relation between the Amount of the Precipitate and the Time Allowed for the Precipitate to Form.—The effect of the time on the amount of the precipitate was studied under general conditions. The results are shown in Fig. 2. From these results, the time which the solution should be allowed to stand after the precipitants had been added to the sample solution was concluded to be 5 min. for the volumetric method for silver and 20 min. for the other metals.

—●— Lead —■— Cadmium
—□— Mercury

Washing and Drying of Metal Complexes.—Metal complexes were almost insoluble in water, acid, alcohol, ether, acetone, etc., while hexamminecobalt(III) chloride thiosulfate was fairly soluble in water. These salts were decomposed by heating above 60°C but were stable below 50°C, so in the gravimetric determination the precipitate was washed with water, alcohol and ether and then dried in an air bath at 50°C.

Volumetric Determination of Silver.—Silver was precipitated, forming the insoluble complex salt in the neutral solution by adding hexamminecobalt(III) chloride and sodium thiosulfate solutions to a silver nitrate solution. We studied the determination method of silver by measuring volumetrically the excess of sodium thiosulfate, and various concentrations of silver were determined by the general procedure; the results are shown in Table II. It was also concluded that the indirect titration of silver was satisfactorily carried out. As has been previously mentioned, copper, cadmium, mercury and lead were precipitated together with

silver, forming insoluble complex salts, and this causes serious interference on the determination of the silver. When the sample solution contained calcium, magnesium, aluminum, chromium, manganese, iron, cobalt and nickel together with silver, the precipitate of the silver complex was not formed quantitatively, for the foreign ions existing in the solution formed thiosulfate complexes and, consequently, the free thiosulfate ion in the solution decreased and was not enough to produce the insoluble silver complex perfectly. In this case, good results in the determination were obtained by adding a large excess of sodium thiosulfate. The results are shown in Table III.

Gravimetric Method.—We studied the gravimetric determination of copper, mercury and lead, for these metals are precipitated quantitatively, producing insoluble complex salts. The results obtained by the general procedure are shown in Table IV. The positive error of the observed value in every run seems to be caused by the water adhering to the precipitate.

Determination by EDTA Titration. — As mercury and lead existing in the solution together with cobalt can be determined by EDTA titration without being separated from cobalt[26,27], these metal ions were determined by this method after their complexes had been decomposed by alkali and acid treatments. The results obtained by the general procedure are shown in Table V.

Studies of the Isolation of these Complex-forming Metals.—In order to mask the formation of bismuth hydroxide in the neutral solution and of lead hydroxide in a solution with a pH value above 8, the masking actions of ammonium oxalate, ammonium citrate, ammonium succinate and ammonium tartrate solutions were examined; among them only the ammonium citrate solution was effective in preventing the hydroxides from forming, but at the same time this reagent repressed the formation of the metal complex to be measured and so was found to be useless. It is evident from the results described above that silver and mercury could be separated from copper and cadmium, but that the ultimate isolation of each element could not be effected.

Summary

1) When hexamminecobalt(III) chloride and sodium thiosulfate solutions were mixed, a precipitate was formed; the composition of this salt was found to be

$$[Co(NH_3)_6](S_2O_3)Cl\cdot H_2O$$

2) In addition to copper and lead, silver, cadmium, mercury and bismuth were precipitated, forming insoluble metal complexes, by adding hexamminecobalt(III) chloride and sodium thiosulfate solutions as precipitants to the solutions of these metal ions. The compositions of these salts, except for bismuth salt, were found to be

$$[Co(NH_3)_6][Ag(S_2O_3)_2],$$
$$[Co(NH_3)_6]_4[Cd(S_2O_3)_3]_3\cdot 6H_2O \text{ and}$$
$$[Co(NH_3)_6]_4[Hg(S_2O_3)_3]_3\cdot 10H_2O$$

3) Various determination methods based on the formation of metal complexes were studied; that is, silver was studied by volumetrically measuring the excess of sodium thiosulfate with an iodine solution, copper and mercury, by gravimetrically weighing their complex salts, and mercury and lead, by EDTA titration after their complex salts had been decomposed.

Synthesis of Methylpyridine and 1, 8-Naphthylidine Derivatives

By Toshihiro TAKATA

(Received January 18, 1962)

Usually, pyridine and 1, 8-naphthylidine derivatives are prepared from carbonyl compounds and from α-aminopyridines respectively[1,2]. The present paper describes a synthesis of those derivatives from aliphatic dinitriles[3] or from trinitriles accomplished through the scheme shown below:

The ring-closure reactions of dinitriles (I and II) and trinitriles (XI, XII and XIII) were carried out according to the techniques of Elvidge[4] for succinonitrile, using sodium amide to give glutaroimidine derivatives (III and IV) or diimino-1, 8-naphthylidine derivatives (XIV, XV and XVI).

Those cyclic imidine-type compounds (III, IV, XIV, XV and XVI) were hydrogenated in an alcoholic solution with sodium to give piperidine derivatives (V and VI) or decahydro-1,8-naphthylidine derivatives (XVII, XVIII and XIX), the imino groups were eliminated almost quantitatively as ammonia, as in the case of α-aminopyridine[5].

Dehydrogenations of the cyclic compounds (III, IV, V, VI and XVII) were carried out by treating them with a palladium catalyst to yield α, α'-diaminopyridines (IX and X), methylpyridines (VII and VIII), or dimethyl-1,8-naphthylidine (XX). Monomethyl-α, α'-diaminopyrine (X) was also obtained from VIII by treating it with sodium amide[6]; between the infrared spectra of the X derived from VIII and that derived from IV, no difference could be detected, as is shown in Fig. 1.

Therefore, the formation of α, α'-diaminopyridines from glutaroimidines suggests the possibility of the mechanism shown below, in which reaction B may be more probable than A.

As another route for the synthesis of 1,8-naphthylidines, we followed the procedure of Reissert[7,8] except for the preparation of the δ-carboxyheptamethylene diamines, which had been prepared from γ-bromopropylphthalimide and diethyl malonate by Reissert, but which we derived from diethyl malonate and acrylonitrile or methacrylonitrile. This scheme is shown below.

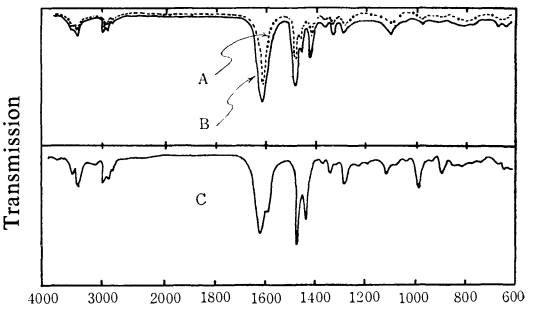

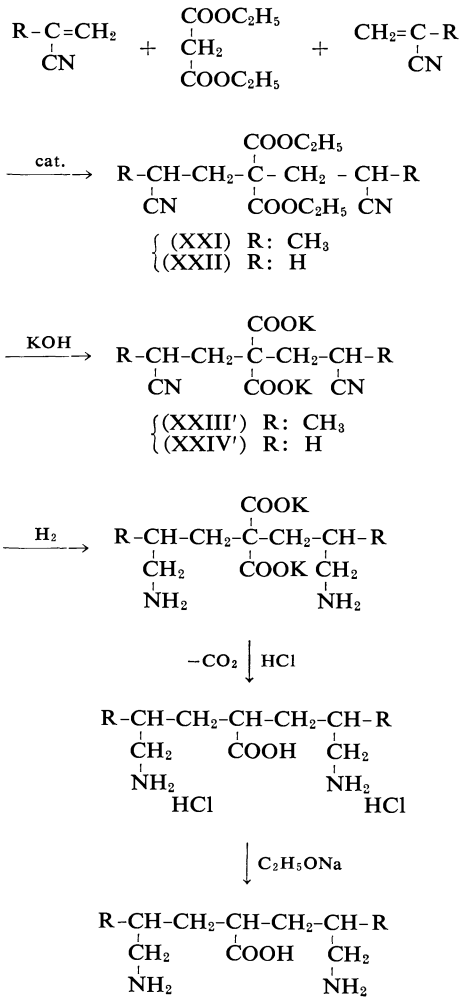

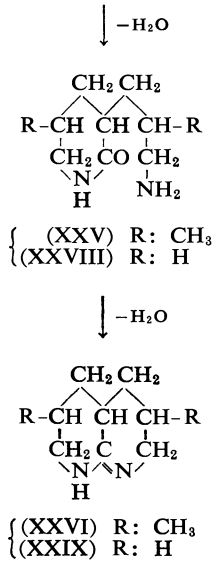

Fig. 1. Infrared spectra of 2,6-diamino-pyridine derivatives in chloroform.
A: 2,6-Diamino-3-methylpyridine (X), derived from 3-methylpyridine (VIII)
B: 2,6-Diamino-3-methylpyridine (X), derived from 2-methylglutaroimidine (IV)
C: 2,6-Diamino-3,5-dimethylpyridine (IX), derived from α, α'-Dimethylglutaroimidine (III)

In this route γ,γ-diethoxycarbonylpimeronitriles (XXI and XXII) were prepared from diethyl malonate and acrylonitrile (by the use of potassium hydroxide[9] as a catalyst, although Koelsh[10] used sodium ethoxide for this purpose) or from methacrylonitrile (by using sodium ethoxide).

The compounds XXI and XXII were then saponified with potassium hydroxide to potassium salts (XXIII' and XXIV'), which were hydrogenated in the presence of a Raney-nickel catalyst to diaminodicarboxylic acid derivatives. When these diaminodicarboxylic acids were treated with concentrated hydrochloric acid, decarboxylation occurred and the hydrochlorides of diaminomonocarboxylic acids were formed; these hydrochlorides were not isolated but were treated with sodium ethoxide in ethanol to liberate diaminomonocarboxylic acids. These diaminomonocarboxylic acids were pyrolyzed to lactam derivatives (XXV and XXVIII), which also were not isolated but which were identified by infrared spectra and by the formation of picrates.

By the pyrolysis of XXV and XXVIII, the octahydro-1, 8-naphthylidines (XXVI and XXIX) reported by Reissert[7,8] were not obtained, but dimethyltetrahydro-1, 8-naphthylidine (XXVII) and hexahydro-1, 8-naphthylidine (XXX) were obtained. This fact suggests that the dehydrogenation[11] with air was accompanied with dehydration in order to give XXVI and XXIX in the thermal treatments of XXV and XXVIII.

In Fig. 2 below, the infrared spectra of dimethyldecahydro-, dimethyltetrahydro- and dimethyl-1, 8-naphthylidine are compared with one other.

A: 3, 6-Dimethyldecahydro-1, 8-naphthylidine (XVII)
B: 3, 6-Dimethyltetrahydro-1, 8-naphthylidine (XXVII)
C: 3, 6-Dimethyl-1, 8-naphthylidine (XX)

Experimental

α,α'-Dimethylglutaroimidine (III). — α,α'-Dimethylglutaronitrile (I)[3] (43 g.) was added to a cooled solution of sodium amide (30 g.) in formamide (258 ml.); after standing for 2 days at room temperature, this solution gave a crystalline product, which was collected by filtration, washed with *n*-propanol, ethyl acetate, and ether, and recrystallized from absolute ethanol, affording III (41.0 g., 83.7%) as colorless prismatic needles, m. p., 209~210°C (decomp.).

Found: C, 59.81; H, 9.39; N, 30.04. Calcd. for $C_7H_{13}N_3$: C, 60.40; 9.41; N, 30.19%.

α-Methylglutaroimidine (IV). — By a method similar to that described above, IV was obtained from α-methylglutaronitrile (II)[3] (37 g.) and sodium amide (26 g., in 222 ml. of formamide) in the form of colorless prismatic needles, m. p., 154~155°C (decomp.) (from absolute ethanol); yield. 30.0 g. (70.1%).

Found: C, 57.71; H, 8.88; N, 30.31. Calcd. for $C_6H_{11}N_3$: C, 57.57; H, 8.86; N, 35.57%.

3, 5-Dimethylpiperidine (V).—Into a solution of III (7 g.) in absolute ethanol (100 ml.) on an oil bath at 130~140°C were alternately stirred sodium (98 g.) and absolute ethanol in small portions. Then the reaction mixture was submitted to steam distillation. The distillate was acidified with hydrochloric acid, concentrated, and treated with excess sodium hydroxide to liberate the free base, from which 4.6 g. (80.7%) of V was obtained by distillation; b. p., 144°C, d_4^{20} 0.8532, n_D^{20} 1.4560.

During this reaction the evolved gas was bubbled

through aqueous sulfuric acid; by titration of this sulfuric acid solution, 1.45 g. of ammonia was detected. (The calculated amount of ammonia from 7 g. of III is 1.71 g.).

The Picrate of V.—M. p., 184°C (from water). Found: C, 45.60; H, 5.35; N, 16.22. Calcd. for $C_{13}H_{18}N_4O_7$: C, 45.61; H, 5.30; N, 16.37%.

3-Methylpiperidine (VI).—By a method similar to that described above, VI was obtained from IV (7 g. in 100 ml. of absolute ethanol), sodium (98 g.) and absolute ethanol (600 ml.). B. p., 125~126°C, d_4^{20} 0.8570, n_D^{20} 1.4506; yield, 3.2 g. (58.2%).

In this reaction 1.68 g. of eliminated ammonia was detected. (The calculated amount of ammonia for 7 g. of IV is 1.90 g.).

The Picrate of VI.—M. p., 105°C (from water). Found: C, 44.08; H, 4.92; N, 17.14. Calcd. for $C_{12}H_{16}N_4O_7$: C, 43.90; H, 4.91; N, 17.07%.

3, 5-Dimethylpyridine (VII).—In an atmosphere of nitrogen, compound V (0.5 g.) was heated at 230°C for 5 hr. in the presence of a palladium catalyst (0.2 g.). Then 0.35 g. (74.5%) of VII was obtained by distillation; b. p., 168~171°C, d_4^{20} 0.9096, n_D^{20} 1.4501.

The Picrate of VII.—M. p., 242~243°C (decomp.) (from water). Found: C, 46.26; H, 3.61; N, 16.44. Calcd. for $C_{13}H_{12}N_4O_7$: C, 46.43; H, 3.60; N, 16.66%.

3-Methylpyridine (VIII).—By a method similar to that described above, 0.35 g. (74.5%) of VIII was obtained from VI (0.5 g.). B. p., 142°C, d_4^{20} 0.9556, n_D^{20} 1.5053.

The Picrate of VIII.—M. p., 149~150°C (from ethyl acetate). Found: C, 44.73; H, 3.23; N, 17.35. Calcd. for $C_{12}H_{10}N_4O_7$: C, 44.73; H, 3.13; N, 17.39%.

2, 6-Diamino-3, 5-dimethylpyridine (IX).—In an atmosphere of nitrogen, compound III (1 g., in 4 ml. of diphenyl ether) was heated at 300°C for 11 hr. in the presence of a palladium catalyst (0.6 g.). The reaction mixture was then dissolved in ether and shaken with dilute hydrochloric acid. The aqueous layer was treated with sodium hydroxide to liberate the basic product, which was extracted with ether. The crystals obtained after evaporation of the ether were recrystallized from benzene to give IX, in the from of colorless needles; m. p., 186~187°C, yield, 0.3 g. (30.6%).

Found: C, 61.62; H, 8.18; N, 31.00. Calcd. for $C_7H_{11}N_3$: C, 61.28; H, 8.08; N, 30.63%.

Tetraacetyl-2,6-diamino-3,5-dimethylpyridine.—Compound IX (21 mg.) was treated with acetic anhydride (1 ml.) at 170°C for 1 hr. in a sealed glass tube. After removal of the acetic acid and unreacted acetic anhydride by distillation, the residue was recrystallized from benzene to give the tetraacetyl derivative of IX as colorless crystals; m. p., 149°C; yield, 20.7 mg. (44.2%).

Found: N, 13.77. Calcd. for $C_{15}H_{19}N_3O_4$: N, 13.76%.

Diacetyl-2, 6-diamino-3, 5-dimethylpyridine. — Compound IX (17 mg.) was treated with acetic anhydride (1 ml.) at 95°C for 1 hr. to give the diacetyl derivative of IX in the form of colorless crystals; m. p., 197°C; yield, 5 mg. (18.2%).

Found: N, 18.43. Calcd. for $C_{11}H_{15}N_3O_2$: N, 18.99%.

2, 6-Diamino-3-methylpyridine (X). — *a) By the Tschitschibabin-Seide Method*[6]. — Compound VIII (12.2 g.) was treated with sodium amide (16 g.) in tetraline (16 g.) at 150~153°C for 4 hr. and thereafter at 198~200°C for 17 hr. The reaction mixture was then poured into water and extracted with benzene. From the benzene extract X was obtained in the form of colorless plates; m. p., 156~157°C (from benzene); yield, 2.5 g. (15.5%).

Found: C, 58.48; H, 7.31; N, 34.54. Calcd. for $C_6H_9N_3$: C, 58.51; H, 7.37; N, 34.12%.

b) By the Dehydrogenation of IV.—By a method similar to that described for IX, X was obtained from IV (0.5 g.) as colorless plates; m. p., 156~157°C (from benzene), undepressed on admixture with the specimen derived from VIII; yield, 0.15 g. (30.6%).

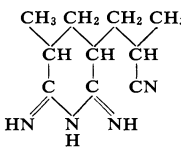
Triacetyl-2, 6-diamino-3-methylpyridine.—By a method similar to that described for tetraacetyl-2, 6-diamino-3, 5-dimethylpyridine, compound X (99.8 mg.) was treated with acetic anhydride (3 ml.) at 170~180°C for 3 hr., giving the triacetyl derivative of X in the from of colorless crystals; m. p., 142~144°C (from benzene); yield, 53.4 mg. (26.4%).

Found: N, 16.72. Calcd. for $C_{12}H_{15}N_3O_3$: N, 16.86%.

Diacetyl-2, 6-diamino-3-methylpyridine. — Compound X (100.3 mg.) was treated with acetic anhydride (2 ml.) at 90~100°C for 1 hr. to give the diacetyl derivative of X as colorless crystals; m. p., 220~221°C (from petroleum ether); yield, 78.1 mg. (46.4%).

Found: N, 20.39. Calcd. for $C_{10}H_{13}N_3O_2$: N, 20.28%.

3, 6-Dimethyl-2, 7-diaminooctahydro-1,8-naphthylidine (XIV).—By a method similar to that described for III, XIV was obtained from 2, 4, 6-tricyano-*n*-heptane (XI)[3] (75 g.) and sodium amide (50 g., in 300 ml. of formamide) in the form of pale greenish-yellow crystals; m. p., 222~224°C (decomp.); yield, 71.6 g. (87%).



Found: C, 62.50; H, 8.46; N, 29.23. Calcd. for $C_{10}H_{16}N_4$*: C, 62.47; H, 8.39; N, 29.14%.

3-Methyl-2, 7-diiminooctahydro-1, 8-naphthylidine (XV).—By a method similar to that described for III, XV was obtained from 1, 3, 5-tricyano-*n*-hexane (XII)[3] (77 g.) and sodium amide (52 g., in 310 ml. of formamide) in the form of pale greenish yellow crystals; m. p., 204~206°C (decomp.); yield, 55.3 g. (65.0%).

Found: C, 60.26; H, 7.74; N, 31.09. Calcd. for $C_9H_{14}N_4$: C, 60.65; H, 7.92; N, 31.44%.

---

* The calculaled value for $C_{10}H_{16}N_4$ also satisfies the structure:

but this possibility can be omitted because of the lack in the infrared spectrum of the absorption band (near 2250 cm^{-1}) due to CN.

2, 7-Diiminooctahydro-1, 8-naphthylidine (XVI).—By a method similar to that described for III, XVI was obtained from 1, 3. 5-tricyano-*n*-pentane (XIII)[9] (33 g.) and sodium amide (22 g., in 123 ml. of formamide) in the form of pale greenish-yellow crystals; m. p., 205~206°C (decomp.); yield, 31.3 g. (82.3%).

Found: C, 58.25; H, 7.27; N, 34.04. Calcd. for $C_8H_{12}N_4$: C, 58.51; H, 7.37; N, 34.12%.

3,6-Dimethyldecahydro-1,8-naphthylidine (XVII). To a solution of XIV (1.5 g.) in amyl alcohol (240 ml.) was added sodium (21 g.) at 130~140°C. The reaction mixture was then submitted to steam distillation. The distillate was acidified with hydrochloric acid, concentrated, and treated with excess sodium hydroxide to liberate the free base, from which by extraction with ether, was obtained XVII in the form of colorless needles; m. p., 162~163°C (from benzene); yield, 1.0 g. (75.3%).

Found: C, 72.14; H, 11.27; N, 16.88. Calcd. for $C_{10}H_{20}N_2$: C, 72.24; H, 10.91; N, 16.85%.

In this reaction, 0.254 g. of eliminated ammonia was detected. (The calculated amount of ammonia for 1.5 g. of XIV is 0.266 g.).

The Dipicrate of XVII.—M. p., 213°C (decomp.) (prepared in ethyl acetate).

Found: C, 42.28; H, 4.23; N, 17.85. Calcd. for $C_{22}H_{26}N_8O_{14}$: C, 42.18; H, 4.18; N, 17.89%.

3-Methyldecahydro-1,8-naphthylidine (XVIII).—By a method similar to that described for XVII, XVIII was obtained from XV (7 g., in 800 ml. of amyl alcohol) and sodium (98 g.) in the form of colorless needles; m. p., 113~114°C (from benzene); yield, 4 g. (66.7%).

Found: C, 69.79; H, 11.79; N, 17.69. Calcd. for $C_9H_{18}N_2$: C, 70.07; H, 11.76; N, 18.17%.

The Dipicrate of XVIII.—M. p., 205°C (decomp.) (prepared in ethyl acetate).

Found: C, 41.47; H, 4.16; N, 17.93. Calcd. for $C_{21}H_{24}N_8O_{14}$: C, 41.18; H, 3.95; N, 18.30%.

Decahydro-1, 8-naphthylidine (XIX).—By a method similar to that described for XVII, XIX was obtained from XVI (1.2 g., in 200 ml. of amyl alcohol) and sodium (17 g.) in the form of colorless needles; m. p., 116~117°C (from benzene); yield, 0.9 g. (90.0%).

Found: C, 68.42; H, 11.50; N, 19.78. Calcd. for $C_8H_{16}N_2$: C, 68.52; H, 11.50; N, 19.98%.

The Dipicrate of XIX.—M. p., 195°C (decomp.) (prepared in ethyl acetate).

Found: C, 40.26; H, 3.93; N, 18.54. Calcd. for $C_{20}H_{22}N_8O_{14}$: C, 40.14; H, 3.71; N, 18.74%.

3, 6-Dimethyl-1, 8-naphthylidine (XX).—In an atmosphere of nitrogen, compound XVII (0.15 g., in 2 ml. of diphenyl ether) was heated at 200~270°C for 20 hr. in the presence of a palladium catalyst (0.2 g.). Thereafter, treatment by a method similar to that described for IX gave XX as light yellowish-orange, prismatic needles; m. p., 191~192°C (from benzene); yield, 0.1 g. (71.0%).

Found: C, 75.66; H, 6.36; N, 17.70. Calcd. for $C_{10}H_{10}N_2$: C, 75.92; H, 6.37; 17.71%.

The Monopicrate of XX.—M. p., 210~211°C (decomp.) (prepared in benzene).

Found: C, 49.57; H, 3.45; N, 17.90. Calcd. for $C_{16}H_{13}N_5O_7$: C, 49.62; H, 3.38; N, 18.08%.

α, α'-Dimethyl-γ, γ-dicarbethoxy-pimeronitrile (XXI).—Into a mixture of diethyl malonate (320 g., 2 mol.) and methacrylonitrile (280 g., 4.2 mol.) sodium ethoxide (11 g., in 80 g. of absolute ethanol) was stirred at 32~50°C for 8 hr. and thereafter at 80~90°C for 2 hr. After neutralization with hydrochloric acid, this mixture was poured into water to separate an oily substance, which was submitted to distillation to give XXI; b. p., 175°C/2 mmHg; m. p., 61~63°C; yield, 338 g. (57.5%).

Found: C, 61.25; H, 7.52; N, 9.47. Calcd. for $C_{15}H_{22}N_2O_4$: C, 61.20; H, 7.54; N, 9.52%.

γ, γ-Dicarbethoxy-pimeronitrile (XXII).—To a cooled and stirred mixture of diethyl malonate (187 g., 1.1 mol.), acrylonitrile (123 g., 2.3 mol.) and dioxane (233 g.) a methanolic 30% potassium hydroxide solution (10.6 ml.) was slowly added below 20°C and thereafter stirred for 2 hr. at room temperature. After neutralization with hydrochloric acid, the mixture was poured into water to separate an oily substance, which crystallized slowly and which was recrystallized from ethanol to give XXII; m. p., 60~62°C; yield, 224 g. (76.4%).

Found: C, 58.75; H, 6.90; N, 10.18. Calcd. for $C_{13}H_{18}N_2O_4$: C, 58.63; H, 6.81; N, 10.52%.

α, α'-Dimethyl-γ, γ-dicarboxy-pimeronitrile (XXIII).—A mixture of XXI (115 g.) and potassium hydroxide (55 g.) in absolute ethanol (500 ml.) was left for a few days at room temperature to precipitate the potassium salt of XXIII, which was then collected by filtration; yield, 106 g. (86.2%).

The potassium salt was dissolved in water, acidified with hydrochloric acid, and extracted with ethyl acetate to give XXIII; m. p., 134~136°C (decomp.) (from water).

Found: C, 55.27; H, 6.30; N, 11.76. Calcd. for $C_{11}H_{14}N_2O_4$: C, 55.45; H, 5.88; N, 11.76%.

γ, γ-Dicarboxypimeronitrile (XXIV).—By a method similar to that described above, from XXII (133 g.) and potassium hydroxide (65 g., in 650 ml. of absolute ethanol) was obtained the potassium salt of XXIV (135 g., 94.4%), from which XXIV was obtained after acidification with hydrochloric acid and extraction with ethyl acetate; m. p., 158°C (decomp.) (from water).

Found: C, 51.87; H, 4.90; N, 12.87. Calcd. for $C_9H_{10}N_2O_4$: C, 51.43; H, 4.80; N, 13.33%.

3-(β-Methyl-ω-amino-*n*-propyl)-5-methylpiperidone-2 (XXV).—In a 220 ml. autoclave, the potassium salt of XXIII (47.1 g., in 50% aqueous ethanol) was hydrogenated under ca. 100 atm. of hydrogen pressure below 60°C in the presence of a Raney-nickel catalyst (from 38 g. of Ni-Al alloy 50 : 50). The reaction mixture was concentrated and acidified with 300 ml. of concentrated hydrochloric acid and heated on a water bath to complete the decarboxylation. After concentration, this mixture was heated at 200°C for another 3 hr. to remove thoroughly the volatile component; the residue was then extracted with absolute ethanol. This ethanolic solution was treated with sodium ethoxide to liberate the free aminolactam (XXV) from the hydrochloride. After elimination of the sodium chloride and evaporation of the ethanol crude XXV (20 g.) was obtained, a hygroscopic sticky substance which was not purified, but in the infrared spectrum of

which there was detected the characteristic absorption band at 1670 cm^{-1} which was assigned to the lactam groups of the six-membered ring[12].

The Picrate of XXV.—M. p., 184~186°C (prepared in ethanol).

Found: N, 17.65. Calcd. for $C_{16}H_{23}N_5O_8$: N, 16.94%.

3,6-Dimethyltetrahydro-1,8-naphthylidine (XXVII).—By pyrolysis of crude XXV (0.71 g.) at 330°C a crystalline substance (carbonate of XXVII ?) was deposited on the neck of the reaction flask. This crystalline product was acidified with hydrochloric acid and treated with excess sodium hydroxide to liberate the free base, which was then extracted with benzene to give XXVII in the form of colorless plates; m. p., 110~111°C (from benzene-petroleum ether); yield, 0.02 g.

Found: C, 74.33; H, 8.65; N, 17.41. Calcd. for $C_{10}H_{14}N_2$: C, 74.03; H, 8.63; N, 17.26%.

The Monopicrate of XXVII.—M. p., 256°C (decomp.) (prepared in benzene). Found: C, 49.42; H, 4.49; N, 17.93. Calcd. for $C_{16}H_{17}N_5O_7$: C, 49.16; H, 4.38; N, 17.90%.

Dehydrogenation of XXVII.—In an atmosphere of nitrogen, compound XXVII (0.11 g., in 2 ml. of diphenyl ether) was heated at 250~280°C for 20 hr. in the presence of a palladium catalyst (0.2 g.). The reaction mixture was treated by a method similar to that described for XX in order to obtain the dehydrogenated product (0.05 g.); m. p., 191~192°C (from benzene), undepressed on admixture with the specimen of XX.

Hydrogenation of XXVII.—By a method similar to that described for XVII, compound XXVII (0.2 g., in 130 ml. of amyl alcohol) was treated with sodium (7 g.). A hydrogenated product (0.2 g.) was obtained; m. p., 162~163°C (from benzene), undepressed on admixture with the specimen of XVII.

3-(ω-Amino-*n*-propyl)-piperidone-2 (XXVIII).—By a method similar to that described for XXV, potassium salt of XXIV (28 g.) was hydrogenated in the presence of a Raney-nickel catalyst (prepared from 25 g. of Ni-Al alloy 50 : 50), giving crude XXVIII (13 g.).

The Picrate of XXVIII.—M. p., 207°C* (prepared in ethanol). Found: N, 18.11. Calcd. for $C_{14}H_{19}N_5O_8$: N, 18.18%.

Hexahydro-1,8-naphthylidine (XXX).—By a method similar to that described for XXVII, crude XXX was obtained from XXVIII in the form of a basic sticky substance which gave the picrate.

The Monopicrate of XXX.—M. p., 228~230°C (decomp.) (prepared in benzene). Found: C, 46.59; H, 4.00; N, 18.94. Calcd. for $C_{14}H_{15}N_5O_7$: C, 46.03; H, 4.14; N, 17.91%.

Determination of Aluminum, Cerium(III) and Lead with Fluoride by an Amperometric Indicator Method

By Asha VARMA

(Received November 25, 1961)

In a recent study in these laboratories, it has been shown that the amperometric indicator method with polarized electrodes can be applied with success for the determination of barium, lanthanum and thorium with fluoride involving precipitation reactions[1]. The field of application of this method is wide and the method is more general than conventional voltammetry. However, formation of complexes and neutralization, in general, had scarcely been made use of as titration reactions.

This paper reports the results of determination of aluminum, cerium and lead with fluoride involving both complex forming and precipitation reactions, using two identical polarized platinum electrodes at constant applied voltage in the presence of small amounts of ferric chloride as an indicator and the appropriate supporting electrolytes.

Various methods for the determination of aluminum[2-4], cerium[2,5] and lead[2,6-9] have been developed. Ringbom and Wilkman[3] titrated aluminum with fluoride amperometrically at the dropping mercury electrode versus saturated calomel electrode using trivalent iron as indicator whose reduction at the cathode produces diffusion current. So long as the ferric iron remains uncomplexed, it can be reduced at the dropping mercury cathode and the current passes through the cell; and excess fluoride complexes the ferric ions and stops the current. This method is much simpler in technique and has several advantages over conventional potentiometric or amperometric method.

Experimental and Results

Standard potassium fluoride solutions were prepared by accurate dilution of a more concentrated solution which has been standardized potentiometrically[10]. Stock solution of aluminum chloride was prepared by dissolving a weighed quantity of pure aluminum wire in dilute hydrochloric acid, which was transferred to 500 ml. standard volumetric flask. The amount of aluminum was determined potentiometrically by the Scott's method[4]. Cerium chloride solution was prepared by dissolving the weighed quantity of Merck's extrapure cerium carbonate in dilute hydrochloric acid in 250 ml. standard flask. Hydrogen peroxide was added to aliquot, a weakly ammoniacal solution of cerous chloride to oxidize it completely to ceric form, and the resulting solution was titrated by potentiometric method[11] and also amperometrically with two polarized electrodes[12] against standard ferrous ammonium sulfate solution. The stock solution of Merck's extrapure lead nitrate was standardized amperometrically with standard potassium dichromate solution[13]. Conductivity water was used for the preparation of all solutions, and test solutions were obtained after appropriate dilution of the stock solution with air-free water. All other chemicals used were of reagent grade.

Experimental arrangements for the amperometric titrations were essentially the same as described earlier[12,14]. Two platinum electrodes were immersed in the titration cell and a constant voltage of 0.04 V. was applied to these electrodes. Current through the cell was measured using a sensitive galvanometer, 0.5 μA with lamp and scale arrangements. The solution was stirred uniformly during the titration using a magnetic stirrer. Twenty milliliters of titration mixture in an appropriate buffer containing the suitable supporting electrolyte and a small amount of indicator was placed into the titration cell. Fig. 1 Titration of 2.788 mg. lead with fluoride in 20 ml. acetate buffer, pH 5.5~6.5, containing 0.1 M KBr in equal volume of 96% ethyl alcohol, at 40 mV. with two polarized electrodes, indicator; $FeCl_3$.

was administered from 2 ml. semimicroburette with 0.01 ml. divisions. Readings were taken at uniform regular intervals, usually one minute, after each addition of the titrant. Equivalence points were found graphically by the usual plot of galvanometer deflections against the volume of titrant added. A typical titration curve is shown in Fig. 1. The end points were quite reproducible. A large number of experiments were carried and each determination was repeated several times for good and satisfactory results. Summarized results for the determination of aluminum, cerium(III) and lead are recorded in Tables I—III respectively. In column three is given the best experimental value observed for these estimations at the particular concentration.

Discussion

It has been observed that fluoride is an excellent titrant in precipitation and complex forming reactions. The fluoride ion is the smallest and the least deformable of the halide ions, and it should form the fewest complexes in accordance with the covalency rule, yet it forms far more complexes by electrostatic forces similar to those which hold "ion pairs" together[15,16]. This view is supported from the paramagnetism of such double salts as K_3FeF_6; the bonding is covalent and the electrons are paired and the molecules diamagnetic. Fluorine, having small size of the fluoride ion, brings

15) N. Bjerrum, *Kgl. Danske. Videnskb. Selskabs.*, **7**, 9 (1926).
16) R. M. Fuoss, *Chem. Revs.*, **17**, 27 (1935).

out the highest coordination number of the atom with which it combines.

Fluoride ions have greater tendency to complex aluminum ions than trivalent iron ions and in neutral solution aluminum reacts with fluoride to form stable, AlF_6^{3-} ion; therefore on addition of potassium fluoride to the titration mixture, reaction shifts towards the formation of potassium cryolite:

$$AlCl_3 + 6\,KF \rightarrow AlF_3,\ 3\,KF \downarrow + 3\,KCl$$

Aluminum first precipitates out as aluminum trifluoride, and this reacts with excess potassium fluoride forming the said stable complex.

Fluoride precipitates cerium trifluoride at pH 6.0 to 6.5, $CeCl_3 + 3\,KF \rightarrow CeF_3 \downarrow + 3\,KCl$; and the precipitate is insoluble in excess potassium fluoride. Lead is partially precipitated as lead chloride in presence of potassium chloride or as lead bromide in presence of potassium bromide in the titration mixture. On addition of potassium fluoride, the reaction proceeds towards completion yielding leadchlorofluoride or leadbromofluoride. These precipitation reactions are stoichiometric and quantitative especially in presence of equal volume of 96% ethyl alcohol, at pH 5.5 to 6.5.

In all these determinations, upto the equivalence point, corresponding to the stoichiometric completion of the reaction, current remains constant. After it, the excess fluoride ions complex the indicator ferric ions whose reduction constitutes the end point, and the current falls (cf., curve Fig. 1). The end point is sharp and quite reproducible.

Data recorded in Tables I–III show that the results are good and satisfactory with excellent accuracy upto 10^{-4} M. At lower concentrations, the maximum error is about $\pm 5.0\%$.

Summary

Determinations of aluminum, cerium(III) and lead by fluoride involving complex formation, $KAlF_6$ and precipitations, CeF_3 and PbClF or PbBrF have been carried out successfully using amperometric indicator method at 0.04V. with two identical polarized platinum electrodes. A small amount of ferric chloride is used as an indicator, the reduction of which beyond end point constitutes the indicating system. Upto the equivalence point, current remains constant, and then it falls due to the reduction of the trivalent iron complex which is formed on addition of excess fluoride. The method is simpler in technique, sensitive and rapid, and the results obtained are good and satisfactory with accuracy of the right order of magnitude even at lower concentrations, as low as 10^{-4} M. At still higher dilutions the maximum error rises to about $\pm 5.0\%$.

My sincere thanks are due to Dr. D. Singh, Department of Chemistry, BHU, for suggesting the problem, his continuous guidance, valuable criticism and advice.

Reaction of Styrene Glycol with Aqueous Acids

By Tsutomu MATSUDA and Masahiko SUGISHITA

(Received January 18, 1962)

Although Zincke[1] reported in 1882 that, when treated with aqueous acid, styrene glycol yielded phenylacetaldehyde (I), together with higher boiling materials, there have been few investigations to examine the utility of the procedure for the synthesis of I, except that Emerson[2] has reported a vapor phase isomerization of styrene glycol to I in a yield of 74%. This reaction is a well-known pinacolic rearrangement and it may be a possible synthetic route for I. As styrene glycol[2] is easily prepared from styrene, we undertook to explore the procedure to clarify the course of reaction and to find the most suitable conditions for the preparation of I.

2) W. S. Emerson, *J. Am. Chem. Soc.*, **67**, 516 (1945).

Results and Discussion

Effect of Reaction Conditions.—As Zincke's paper was concerned chiefly with the structure of the higher boiling material and did not disclose any optimum conditions for obtaining I, we first examined the effect of reaction conditions upon the yield of I, varying the kind of acids, the acid concentrations and the

* Mixtures of styrene glycol (10 g.) and the aqueous acid (15 ml.) were refluxed for the specified periods.

reaction times. The results are summarized in Tables I and II.

These results reveal that the yield of I in the simple treatment was relatively low but that a higher boiling material was formed in an appreciable quantity; however, severe conditions, prolonged reaction periods, or treatment with more concentrated acid solutions lowered the yields of the higher boiling material. It was also noticed that, under the more severe conditions, the refractive indices of the higher boiling materials were higher and that the intensity of their infrared absorptions at 1730 and 1698 cm^{-1} were stronger. Especially, the product c (indicated in Table I) was found at 1130 cm^{-1} to lack the C–O–C absorption which appeared in the others. These observations seemed to indicate that another type of by-product was formed under the more severe conditions, especially on treatment with an aqueous hydrochloric acid. The higher boiling fractions, with a lower refractive index (product a and b in Table I), were combined and redistilled. The results of the elemental analysis of the redistilled product (Found: C, 80.43; H, 6.80%: hereafter named "dimer A") coincided well with the composition of phenylacetaldehyde dimer ($C_{16}H_{16}O_2$), to which Zincke assigned either structure II or III and which he considered as an intermediate to I.

II

III

As Zincke pointed out that dimer A also afforded I on treatment with aqueous acid, dimer A was treated with aqueous sulfuric acid repeatedly in order to confirm the formation of I. The results are shown in Table III.

1	13.6	80.3	1.5772
2*	14.0	70.0	1.5900
3	13.3	76.7	1.5960

* The recovered dimer A in No. 1 (n_D^{25} 1.5772) was used as the reactant in experiment No. 2, and so on.

The results show that, in each run, the ratios of I to the higher boiling fraction were kept nearly constant, but that the refractive indices of the recovered dimer A increased gradually in this case, too. These results seemed strongly to support the hypotheses that dimer A was not a simple intermediate but was in equilibrium with I and that any device to remove I from the reaction mixture would increase the yield. A preliminary experiment was made, in which styrene glycol was treated with acid in methanol and in ethanol instead of in water in order to remove I in the form of the acetals, but the products isolated were neither the expected acetals nor dimer A respectively. In another attempt, the reaction mixture obtained from styrene glycol with aqueous acid was steam-distilled; this procedure seemed to be promising because I was isolated in a 31% yield.

Structure of Dimer A.—If such an equilibrium between dimer A and I existed, we could expect that I would give a similar equilibrium mixture in the treatment of I with an acid solution. After being refluxed for two hours

with aqueous acid, I gave a product which was found to consist of recovered I (18%) and of a higher boiling material. The higher boiling material showed a boiling range similar to that of dimer A but a somewhat higher refractive index. The infrared spectrum of the latter (hereafter named "dimer B") revealed that the product thus obtained was different from dimer A but was identical with the product c in Table I. In the reaction with aqueous acid, dimer A did not give I and was recovered unchanged in a 90% yield. These results lead us to the presumption that another structure of dimer A, one which can account for its molecular formula ($C_{16}H_{16}O_2$) and for its infrared absorption behavior, should be sought. Among others[3], the structure of 2-benzyl-4-phenyl-1, 3-dioxorane (IV) could well interpret the observed results, especially that dimer A was hydrolyzed easily in acidic conditions and that both styrene glycol and I were necessary for the formation of dimer A. The acetal IV was prepared in a yield of 94% by the reaction of I and styrene glycol in benzene in the presence of monochloroacetic acid as a catalyst. The product was proved to be identical with dimer A by its infrared spectrum and yielded 18% of I and 70% of the starting material when treated with aqueous sulfuric acid, but the latter was proved to be contaminated with a small amount of dimer B by the presence of a weak absorption in its carbonyl range and by its higher refractive index. Thus we have concluded that dimer A was 2-benzyl-4-phenyl-1, 3-dioxorane and that the equilibrium mixture of I, styrene glycol and IV is rapidly formed in the reaction of the glycol with an aqueous acid under suitable conditions, while I gradually changed to dimer B. The course of the reaction may be represented by the following scheme;

IV (dimer A)

Preparation of Phenylacetaldehyde. — Based upon the above-mentioned results, the following procedure was used for the preparation of I. A mixture of styrene glycol and of an aqueous acid was refluxed for one hour; steam was then introduced immediately into the reaction mixture to distill out the I, avoiding the dimerization resulting from prolonged contact with the acid. The volume of the reaction mixture was kept almost constant during the course of the steam distillation by applying a controlled external heating. By this technique we realized a significantly higher yield (as much as 70%) of I, as is summarized in Table IV.

TABLE IV. PREPARATION OF PHENYLACETALDEHYDE

No.	Materials	Acid		Yield of phenylacetaldehyde %
		Kind	Concn. mol./l.	
1	Styrene glycol	H_2SO_4	2.24	31.3*
2	Styrene glycol	H_2SO_4	1.01	62.2
3	Styrene glycol	H_2SO_4	1.78	70.2
4	Styrene glycol	H_2SO_4	2.29	63.3
5	Styrene glycol	H_2SO_4	3.49	56.4
6	Dimer A	H_2SO_4	2.23	66.7
7	Styrene glycol	H_3PO_4	5.03	70.2
8	Styrene glycol	H_3PO_4	5.96	57.5

* Steam distillation was performed without external heating.

Experimental

Styrene Glycol. — Styrene glycol was prepared from styrene by the method of Emerson[2] through styrene chlorohydrin; it appeared as white needles; m. p., 67.0~67.5°C.

Reaction of Styrene Glycol with Aqueous Acid. —A mixture of styrene glycol (10 g.) and aqueous acid (150 ml.) was refluxed for two hours. The reaction mixture was then cooled and extracted with ether (50 ml.×3), and the combined extract was washed with a 5% sodium carbonate solution and water and dried over anhydrous sodium sulfate. The ether was distilled off, and the residue was vacuum-distilled to yield: 1. phenylacetaldehyde (b. p. 56.0~58.0°C/5 mmHg); 2. a higher boiling fraction (b. p. 150~157°C/5 mmHg). The yields of these fractions under a variety of conditions are shown in Tables I and II. Redistillation of the combined fraction 1 gave pure phenylacetaldehyde, b. p. 57.0~57.5°C/5 mmHg, n_D^{25} 1.5319, semicarbazone, m. p. 150~151°C. The higher boiling fractions a and b indicated in Table I were combined and redistilled; b. p., 157~158°C/5 mmHg, n_D^{25} 1.5697.

Found: C, 80.42; H, 6.80. Calcd. for $C_{16}H_{16}O_2$: C, 80.00; H, 6.70%.

Reaction of Phenylacetaldehyde with Aqueous Acid.—A mixture of phenylacetaldehyde (5 g.) and 2.42 mol./l. aqueous sulfuric acid (100 ml.) was refluxed for two hours, and the reaction mixture was treated as above to give: 1. phenylacetaldehyde, 0.9 g. (18%) (b. p. 55.5~58.0°C/5 mmHg); 2. a higher boiling fraction, 3.5 g. (70%) (b. p. 158~161°C/5 mmHg, n_D^{25} 1.5970). The latter showed strong absorptions at 1730 and 1698 cm^{-1} but lacked

3) L. A. Bryan, W. M. Smedley and R. K. Summerbell (ibid., 72, 2206 (1950)) have reported that 2, 5-diphenyl-1, 4-dioxane (II) was a solid with a m. p. of 121~122 and of 173°C (cis and trans forms respectively).

them in the 1150~1100 cm^{-1} region, and treatment with an aqueous sulfuric acid gave only the recovered material in a yield of 90%.

2-Benzyl-4-phenyl-1, 3-dioxorane (IV). — A mixture of styrene glycol (5 g.), phenylacetaldehyde dimethylacetal (6 g.), and monochloroacetic acid (4 g.) in 50 ml. of benzene was refluxed for two hours. Thirty milliliters of benzene was distilled off from the reaction mixture, and the residue was neutralized with a 5% sodium carbonate solution, washed with water, and dried over anhydrous sodium sulfate. Distillation under vacuum gave 8.3 g. (94%) of 2-benzyl-4-phenyl-1,3-dioxorane; b. p., 187~188°C/14 mmHg, n_D^{25} 1.5669. Treatment of the compound with 2.42 mol./l. aqueous sulfuric acid gave an 18% yield of phenylacetaldehyde and a 70% yield of dimer A; b. p., 177~182°C/12mmHg, n_D^{25} 1.5675.

Preparation of Phenylacetaldehyde.—A mixture of styrene glycol (10 g.) and 1.78 mol./l. aqueous sulfuric acid (150 ml.) was refluxed for one hour. The reaction mixture was then immediately steam-distilled under external heating of the flask so that the volume of the content was kept constant. The distillate was saturated with sodium chloride and extracted with ether (50 ml.×3). The combined extract was washed with a 10% sodium bicarbonate solution and water and dried over anhydrous sodium sulfate. The ether was distilled off, and the residue was vacuum-distilled to give 6.1 g. (70.2%) of phenylacetaldehyde. The results under other conditions are given in Table IV.

Infrared Spectra and Normal Vibrations of Thioamides. II. Thioacetamide

By Isao SUZUKI

(Received February 2, 1962)

In a preceding paper (hereafter refered to as (I))[1], the results of a normal coordinate analysis of thioformamide, the first member of the thioamide group, as well as its *N*-deuterated analogue, were reported on. It was shown in (I) that the Urey-Bradley force field[2] can be applied to the $HCSNH_2$ molecule successfully, and that it gives a very good account of the nature of the normal vibrations of the molecule. As a continuation of that research, an analysis of the vibrational spectra of thioacetamide and *N*-dideuterated thioacetamide has now been made; the results will be given in the present paper.

The Raman and infrared spectra of thioacetamide have been studied by several investigators[2-7] and the assignments of some vibration bands have been reported. Recently Kutzelnigg and Mecke studied the infrared spectra of thioacetamide and its complexes and presented assignments for the observed frequencies[7]. In order to make a detailed analysis of the nature of normal vibrations and to determine the values of the force constants more precisely, it is vitally important to investigate the spectrum of CH_3CSND_2 as well as that of CH_3CSNH_2. Therefore, *N*-dideuterated thioacetamide was prepared, and the infrared spectra of both CH_3CSNH_2 and CH_3CSND_2 were measured in the solid and liquid states and in solutions. A normal coordinate treatment for the in-plane vibrations of these molecules was undertaken, the Urey-Bradley force field being employed in the calculations.

Experimental

Sample.—Thioacetamide (CH_3CSNH_2) was obtained from a commercial source and was purified by recrystallization from chloroform; m. p., 110.5°C (uncorr.).

Exchange reaction with deuterium oxide was employed to prepare *N*-dideuterated thioacetamide (CH_3CSND_2); thioacetamide was mixed with excess D_2O and was heated until it was completely dissolved in D_2O. Then the solution was cooled and the excess D_2O was pumped out in vacuum; this procedure was repeated until the NH stretching bands around 3200 cm^{-1} became almost undetectable.

Infrared Spectra. — The infrared spectrophotometers used in the present work were the same as described in (I), and the measurements were made in the region from 3500 to 300 cm^{-1}. The spectra in the solid state were measured as Nujol or hexachlorobutadiene mulls; they are given in Figs. 1 (a)—(c). Those in the liquid state were obtained by heating samples between KCl or KRS-5 plates

to slightly above the melting point with a heater embedded between two thin mica plates*1. Acetonitrile, chloroform and carbon disulfide were used as solvents for the measurements in solutions. Owing to the low solubility of the sample in nonpolar solvents, the measurements were made with a variable thickness cell with a thickness up to 5 mm. The results of these measurements are summarized in Tables I (a) and (b).

Normal Coordinate Treatment

The normal vibrations were calculated as a nine-body problem, assuming a planar structure for the molecule similar to that of acetamide. The procedures of the calculation are quite analogous to those for the acetamide molecule[8], so they are not described here. The

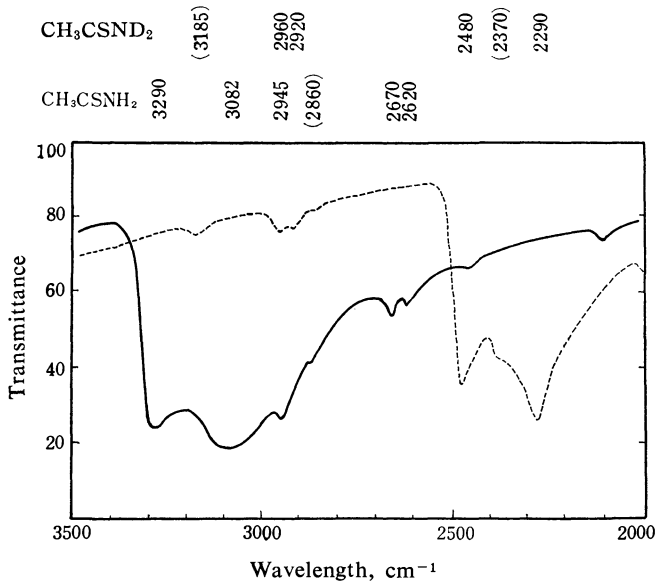

Fig. 1 (a)

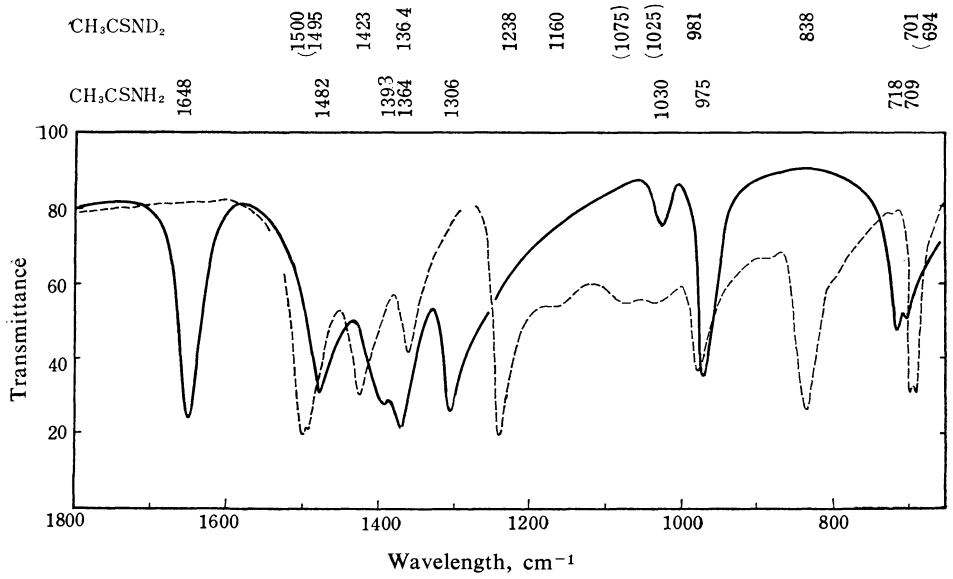

Fig. 1 (b)

*1 Since thioacetamide is less stable under these conditions, the positions of the observed bands were determined by repeating the measurements several times.

structural parameters used are the bond lengths of r(C=S) = 1.713 Å, r(C–N) = 1.324 Å, r(C'C)*2 = 1.494 Å, r(N–H) = 1.02 Å and r(C–H) = 1.09 Å, and the bond angles of 120° for those around the C and N atoms and of 109°47' for those around the C' atom[9],*3. The symmetry coordinates used are listed in Table II.

TABLE II. SYMMETRY COORDINATES*

S_i	Vibrational Modes	Abbr.
S_1	CN stretching	ν(CN)
S_2	CC' stretching	ν(CC)
S_3	CS stretching	ν(CS)
S_4	NH_2 bending	$b(NH_2)$
S_5	NH_2 rocking	$r(NH_2)$
S_6	NCS deformation	δ(NCS)
S_7	CC' deformation	δ(CC')
S_8	CH_3 asym. deformation	$\delta_a(CH_3)$
S_9	CH_3 sym. deformation	$\delta_s(CH_3)$
S_{10}	CH_3 rocking	$r(CH_3)$

* Higher frequencies are separated from lower frequencies[10,11]. Combinations of the internal coordinates in each symmetry coordinate are shown in Ref. 8.

All the numerical computations were carried out with a parametron computer, PC-1. The methods and the routines used in the present study are the same as those described in Refs. 12 and 13.

Results and Discussion

Force Constants.—A considerable amount of data has now been accumulated on the values of the Urey-Bradley force constants for simple amides and thioamides; this is summarized in Table III. It is not difficult to select an appropriate set of force constants for this molecule. The normal vibrations were first calculated from the constants mainly transferred from $HCSNH_2$[1] and CH_3CONH_2[8]; then the values of the constants were refined so as to obtain a better frequency fit. The final set of these values are given in the last column of Table III.

The force constants listed in Table III can be roughly classified into two groups: (A) the constants involving the sulfur or oxygen atoms, and (B) those concerned with other atoms. As was pointed out in (I), the repulsive force constants involving the sulfur atom are found to be always smaller than the corresponding constants involving the oxygen atom. This is also the case for the stretching,

*2 C and C' denote the thiocarbonyl and methyl carbon atoms respectively.

9) M. Truter, *J. Chem. Soc.*, **1960**, 997.

*3 The bond lengths are based on recent X-ray investigation of thioacetamide[9]. The bond angles are assumed, for the sake of simplicity, to be tetrahedral and 120°; these values are not, however, far from the reported values.

* The definitions of K, H and F are the same as in (I), κ is an intramolecular tension defined by Shimanouchi[2].

** X denotes oxygen or sulfur atom. In this table, values of the force constants associated with the sulfur atom are given in bold-faced letters.

and bending force constants*4. The force constants belonging to (B) show excellent transferability throughout the series of thioamides as well as that of amides. The nature of the NH_2, CN and CH_3 groups seems to be scarcely affected by the substitution for the oxygen of the sulfur atom.

The repulsive force constants $F_{N\cdots S}$ are found to be comparatively large, as in the case of $F_{N\cdots O}$. The Urey-Bradley type force field does not contain resonance terms such as $k_{NS}(\Delta r_{CS})\cdot(\Delta r_{CN})$ explicitly, where K_{NS} is a force constant. Therefore, the value of $F_{N\cdots S}$ is partly affected by the resonance force constant k_{NS} and is somewhat effective.

Assignments of the Observed Bands. — The computed frequencies given in Tables IV (a) and (b) are obtained from the force constants listed in the final column of Table III, and correspond to the observed frequencies very closely. Therefore, the potential energy distributions among the symmetry coordinates given in Tables IV (a) and (b) can be considered to represent the quantitative assignments of the observed frequencies. In order to visualize the normal vibration modes corresponding to these vibration bands, the Cartesian displacement vectors have also been calculated*5; they are illustrated in Figs. 2 (a) and (b). Based on the results of calculation, the nature of some vibration bands characteristic of the thioamide group is discussed in this section.

As has been pointed out by Kutzelnigg and Mecke, one of the difficulties in interpreting the spectrum of thioacetamide is the complexity of the spectrum in the region from 1500 to 1300 cm^{-1}. However, the present calculation gives a good account of the nature of these bands. Among the four bands observed in this region, the 1364 cm^{-1} band can reasonably

*4 It is interesting to note that the ratio of K_{CO}/K_{CS} obtained from carbon dioxide and carbon disulfide ($K_{CO}=15.5$, $K_{CS}=7.5$) is close to the value obtained here[14].

14) Ref. 11, p. 311.

*5 In the present calculation, the CH and NH stretching frequencies are separated from the lower frequencies. Therefore, care should be taken in calculating the L^X matrix, which is usually obtained by equation 1.

$$L^X=M^{-1}B'G^{-1}L \qquad (1)$$

Miyazawa and the author have found that the process for higher frequency separation is equivalent to transforming G into $G^*=TGT'$, where G, G^* and T have the following expressions, if we adopt Wilson's notation[14]:

$$G=\begin{Vmatrix} G_{11} & G_{12} \\ G_{21} & G_{22} \end{Vmatrix}, \quad G^*=\begin{Vmatrix} G_{11} & 0 \\ 0 & G_{22}-G_{21}G_{11}^{-1}G_{12} \end{Vmatrix}$$

$$\text{and } T=\begin{Vmatrix} E_{11} & 0 \\ -G_{21}G_{11}^{-1} & E_{22} \end{Vmatrix}.$$

Instead of Eq. 1, one should employ the following equation for obtaining the L^X matrix:

$$L^X=M^{-1}B'T'G^{*-1}L \qquad (2)$$

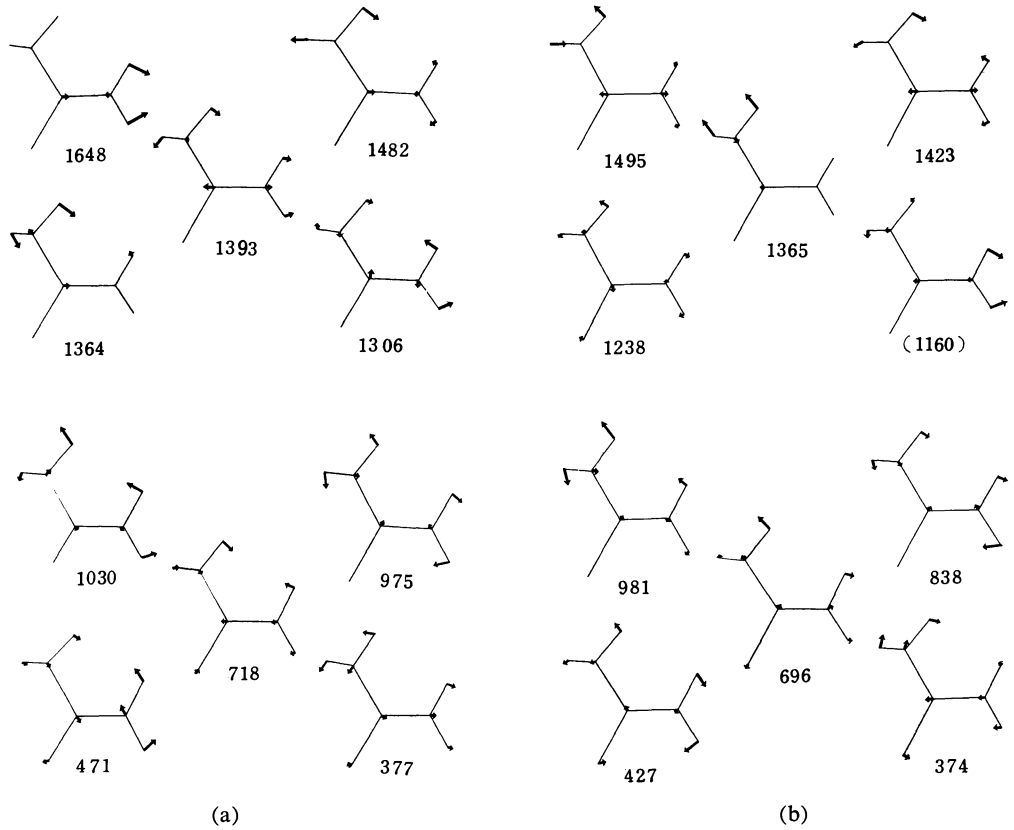
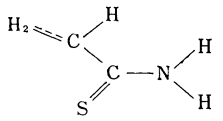
* $\Delta\nu=\nu_{obs}-\nu_{calcd}$, $\Delta=|\Delta\nu|/\nu_{obs}$

be assigned to an almost pure $\delta_s(CH_3)$ vibration. Of the remaining three, the 1482 cm^{-1} band is found to be chiefly associated with the $\delta_a(CH_3)$ vibration, while the band at 1392 cm^{-1}, with the ν(CN) vibration, although a coupling between these two vibrational modes takes place. In the *N*-dideuterated species, the coupling occurs more strongly than in the normal species; this gives rise to two observed bands at 1495 and 1423 cm^{-1}.

The present calculations show that the nature of the 1306 cm^{-1} band of CH_3CSNH_2 is very complicated and that it cannot be attributed to one or two vibration modes. This may be the cause of the difficulty in interpreting the nature of this band. The $r(NH_2)$, ν(CC), ν(CS) and δ(NCS) vibrations contribute to this band. As may be seen from Fig. 2 (a), this normal vibration involves the rocking motion of the NH_2 group as well as the movements of the two carbon atoms perpendicular to the C–N bond and antiparallel to each other. In the *N*-dideuterated species, the band found at 1238 cm^{-1} corresponds to this normal mode, although the contribution of the $r(NH_2)$ motion to this mode decreases considerably, while that of the ν(CC) vibration increases.

The band at 1030 cm^{-1} is assigned to the hybridized vibration containing the $r(NH_2)$ and $r(CH_3)$ vibrations, and these two vibrations also contribute to the 975 cm^{-1} band. It is of interest to seek in which region the band chiefly associated with the ν(CS) vibration appears. In the case of $HCSNH_2$, it was found that the band at 843 cm^{-1} corresponds to an almost pure ν(CS) vibration. In thioacetamide, the situation is rather complicated by the existence of the C–C bond adjacent to the C=S bond. The ν(CC) and ν(CS) vibrations are coupled with each other. In fact, the normal vibrations at 1306, 975 and 718 cm^{-1} of CH_3CSNH_2 involve considerable contributions from the ν(CC) and ν(CS) vibrations. Above all, the contribution of the ν(CS) vibration to the 718 cm^{-1} band is comparatively large; the energy associated with this motion is about 60% of the total. This is consistent with the fact reported by Kutzelnigg and Mecke that this band is shifted by 29 cm^{-1} toward a lower frequency on the





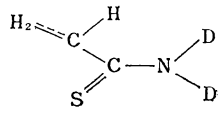


Fig. 2. The normal modes of CH_3CSNH_2 and CH_3CSND_2 in Cartesian displacement vectors projected to the molecular plane. (A/unit change in normal coordinate)

(a) CH_3CSNH_2:

(b) CH_3CSND_2:

formation of a complex with cupper chloride[7].

In the region below 800 cm^{-1}, the bands of CH_3CSNH_2 found at 471 and 377 cm^{-1} are assigned to two skeletal deformation vibrations. The spectrum of CH_3CSND_2 is complicated, since some out-of-plane vibrations also occur in this region, but the bands found at 427 and 374 cm^{-1} can safely be assigned to these deformation vibrations. The approximate assignment of each observed band is given in the last column of Tables I (a) and (b).

Three out-of-plane (A'') vibrations are expected to appear in the region below 800 cm^{-1}. They are the NH_2 wagging, NH_2 twisting and CC out-of-plane bending vibrations, $w(NH_2)$, $t(NH_2)$ and τ(CC); the assignments for these modes are also included in Tables I (a) and (b). The present assignments are based on the fact that the out-of-plane vibrations are sensitive to change in the states in which the substance is measured. In order to check the assignments of the out-of-plane vibrations, the product rule is applied[15]. The ratio of the three observed frequencies is $(700\times700\times517)/(556\times476\times454)=1.83$ for the solid state spectra*6, and $(650\times650\times512)/(553\times476\times454)=1.81$ for the solution spectra. This is in good agreement with the theoretical value of 1.83[2].

A more detailed analysis of the out-of-plane vibrations is now in progress for various

*6 The $w(NH_2)$ and $t(NH_2)$ frequencies appear around 700 cm^{-1}. In $HCSNH_2$, they occur at 670 and 620 cm^{-1} in the liquid state and at 754 and 645 cm^{-1} in the solid state (I). Although we cannot resolve the absorption around 700 cm^{-1}, it seems reasonable to assume that these vibrations happen to be at approximately the same frequency. It should be emphasized that three distinct bands are found at 769, 735 and 690 cm^{-1} in the spectrum of the CH_3CSNH_2-CuCl complex[7].

amides and thioamides; the results will be published elsewhere.

The present author wishes to express his deep gratitude to Professor Takehiko Shimanouchi for his guidance and encouragement throughout this work. His thanks are also due to Professor Hidetoshi Takahashi for the use of a PC-1 computer.

Infrared Spectra and Normal Vibrations of Thioamides. III. N-Methylthioformamide and N-Methylthioacetamide

By Isao SUZUKI

(Received February 2, 1962)

It has been shown in preceding papers[1,2],*1 that a normal coordinate analysis of the $HCSNH_2$ and CH_2CSNH_2 molecules can be made quite successfully by applying the Urey-Bradley force field[3]. The nature of normal vibrations have been clarified, and the values of the force constants have now been settled for these primary thioamides. The work has also been extended to secondary thioamides, RCSNHR', and in this paper the results obtained for *N*-methylthioformamide and *N*-methylthioacetamide will be presented.

N-Methylthioformamide and *N*-methylthioacetamide, as well as their *N*-deuterated analogues, were prepared, and their infrared spectra were measured in the solid and liquid states and in solution. It is now well accepted that the simple secondary amides, RCONHR', predominantly take the planar configurations in which R and R' are in the trans-position with regard to each other[4]. It will be shown in the present investigation that the vibrational spectra of secondary thioamides are also interpreted satisfactorily in terms of the trans planar models. The in-plane normal vibrations of $HCSNHCH_3$ and $HCSNDCH_3$ have been calculated from the force constants directly transferred from $HCSNH_2$ (I) and $HCONHCH_3$[5]; the calculated frequencies for the trans configuration agree well with the observed frequencies.

In the present paper, the results of these measurements and calculations are reported. Based on these results, the nature of the normal vibrations and the problem of a stable configuration for the secondary thioamides are discussed.

Experimental

Materials.—*N-Methylthioacetamide* $CH_3CSNHCH_3$. —This compound was prepared by heating *N*-methylacetamide, with phosphorus pentasulfide suspended in benzene at about 50°C for 3 hr.[6] The sample was purified by recrystallization from ether containing petroleum ether; m. p., 59°C (uncorr.).

N-Methylthioformamide $HCSNHCH_3$. — This was prepared from *N*-methylformamide by a method analogous to that used for *N*-methylthioacetamide. This compound is not as stable as *N*-methylthioacetamide, and it was usually kept in a refrigerator as an ethereal solution. When it was distilled, it showed obvious signs of decomposition, even at a reduced pressure. Therefore, it was purified by recrystallization from ether containing petroleum ether at about −50°C.

The exchange reaction with deuterium oxide was used to replaced the amide hydrogen atom with deuterium.

Infrared Spectra. — The infrared measurements of $HCSNHCH_3$ were made in the liquid and solid states and in solutions; the results are given in Figs. 1 and 3, and the observed frequencies, in Table I(a). Those of $HCSNDCH_3$ are given in Figs. 2 and 3. A low temperature cell[7] cooled with a mixture of dry ice and methanol was used to obtain the spectra in the solid state. The infrared measurements of $CH_3CSNHCH_3$ were also made in the solid and liquid states and in solutions; the results are given in Figs. 4 and 5, and the observed frequencies, in Table I(b). Those of the deuterated species are given in Figs. 4 and 5. The spectra in

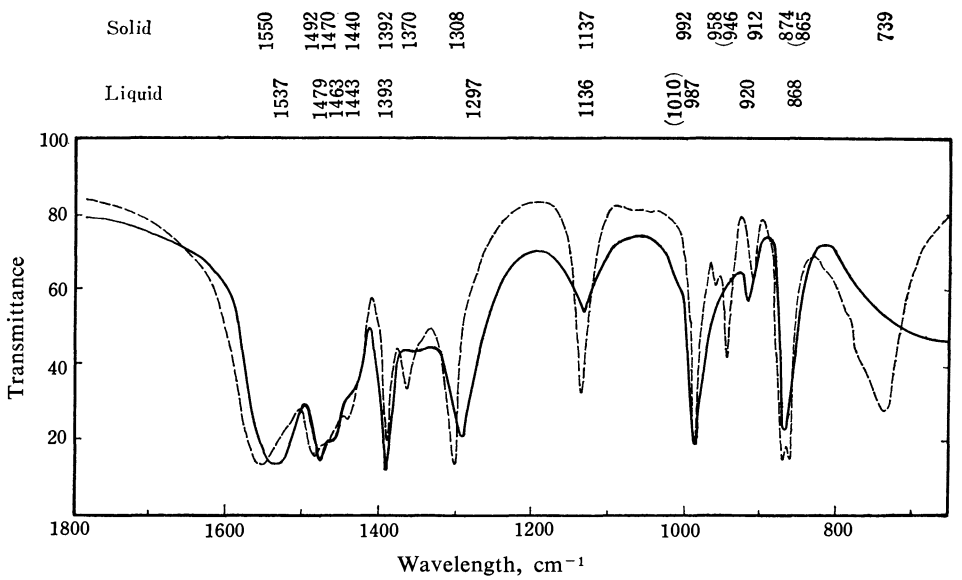

Fig. 1. Infrared spectra of $HCSNHCH_3$ in the liquid state (solid line) and in the solid state (broken line) in the region from 1800 to 650 cm^{-1}.

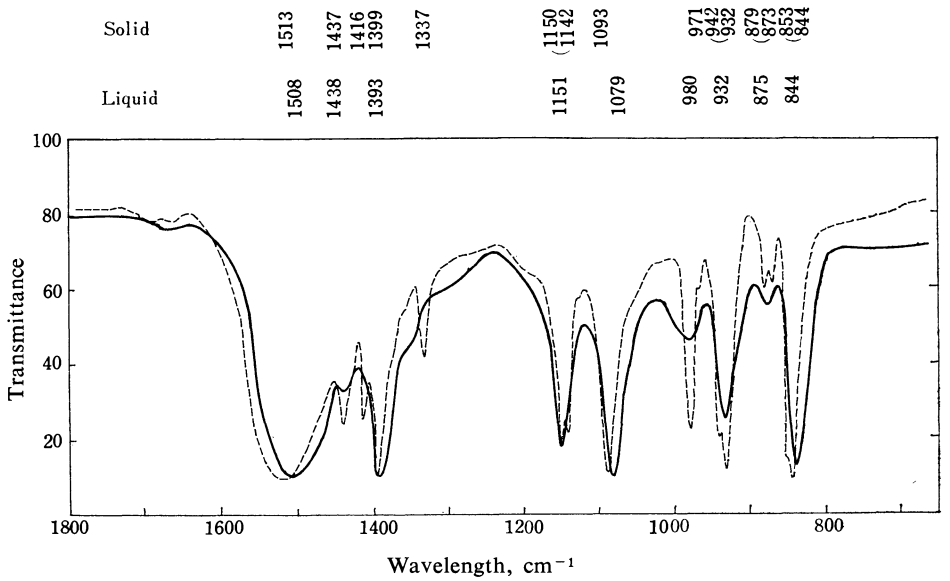

Fig. 2. Infrared spectra of $HCSNDCH_3$ in the liquid state (solid line) and in the solid state (broken line) in the region from 1800 to 650 cm^{-1}.

the solid state were obtained as Nujol or hexachlorobutadiene mulls. A small heating cell was used to measure the spectrum in the liquid state. Carbon tetrachloride, carbon disulfide or chloroform were used as solvents in the region from 3500 to 800 cm^{-1} and acetonitrile in the region from 800 to 400 cm^{-1}.

The spectrophotometers used in the present work are the same as those described in (I). In addition, a high-resolution Perkin-Elmer 112G grating spectrophotometer equipped with a KBr fore-prism was employed for the measurement of the NH stretching bands in carbon tetrachloride in the 3μ region. The results are given in Fig. 6.

Normal Coordinate Treatment

The normal coordinate treatments were undertaken for the in-plane vibrations of $HCSNHCH_3$ and $HCSNDCH_3$ as a nine-body problem, assuming a trans planar structure for the molecule which was analogous to $HCONHCH_3$[5]. The calculation procedures

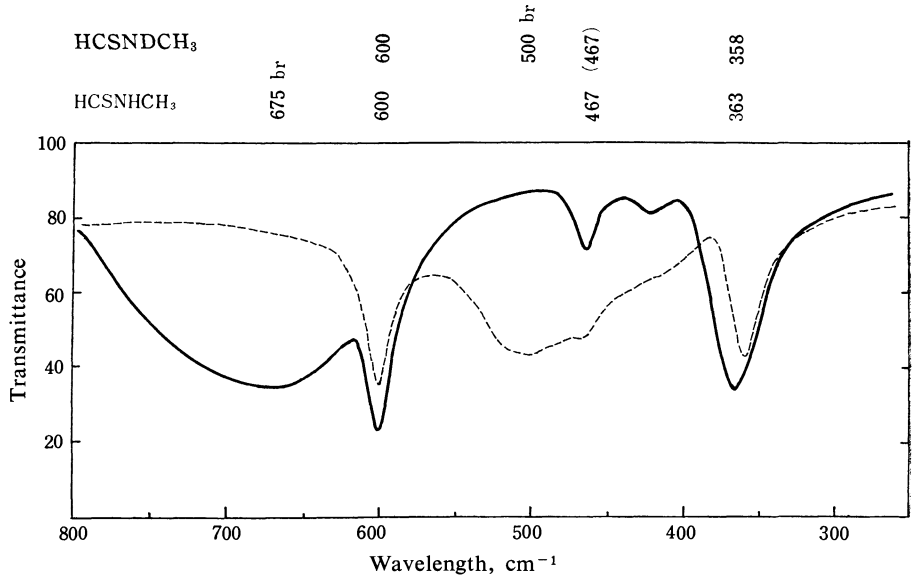

Fig. 3. Infrared spectra of $HCSNHCH_3$ (solid line) and $HCSNDCH_3$ (broken line) in the liquid state in the region from 800 to 260 cm^{-1}.

are similar to those for the $HCONHCH_3$ molecule and do not be described here. The structural parameters used in the calculation are the bond lengths of $r(C{=}S) = 1.713$ Å, $r(C{-}N) = 1.324$ Å, $r(C'{-}N)$*2 $= 1.47$ Å, $r(C'{-}H) = r(C{-}H) = 1.07$ Å, and the bond angles of 120° for those around the C and N atoms and of 109°47′ for those around the C′ atom. The symmetry coordinates used in the calculation are listed in Table II; the combinations of

*2 C and C′ denote the thiocarbonyl and methyl carbon atoms respectively.

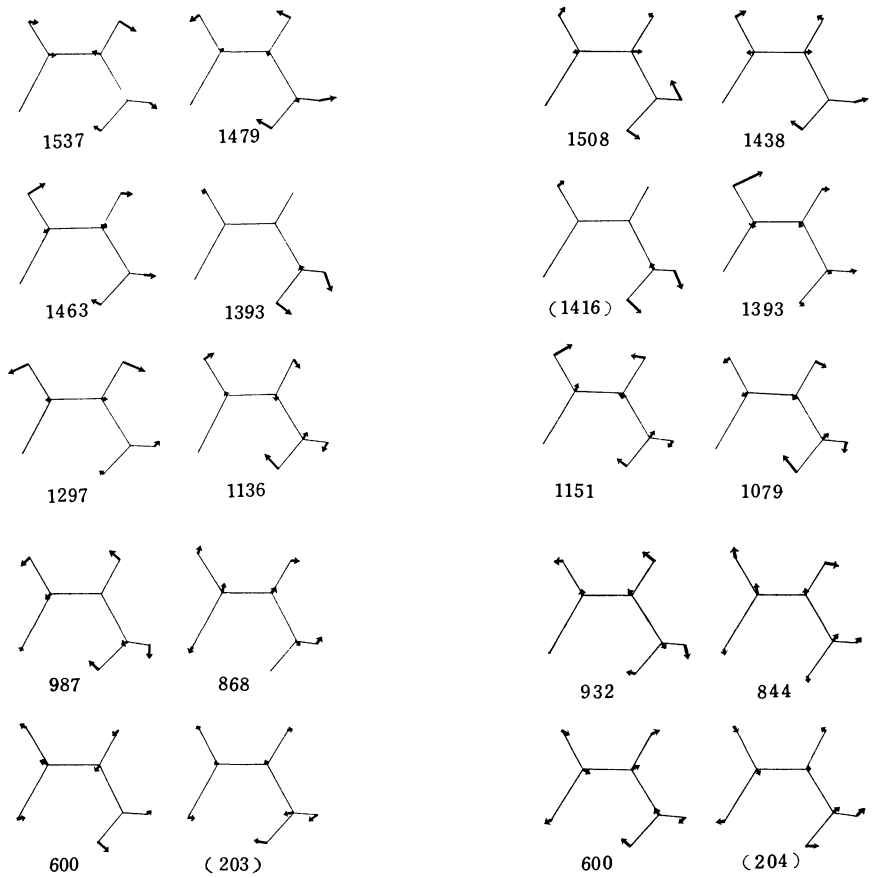
the interal coordinates in each symmetry coordinate are given in Ref. 5 and so are not reproduced here. Four higher frequencies corresponding to the CH and NH(D) steretching vibrations are separated from the lower frequencies[8].

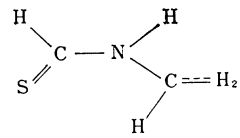
8) E. B. Wilson, *J. Chem. Phys.*, **7**, 1047 (1939); **9**, 96 (1941).

Force Constants. — As in (I) and (II), the Urey-Bradley force field was employed in the calculation. In Table III, the values of the force constants used are listed. They were determined by the following methods: the values of the force constants in group I were directly transferred from the $HCONHCH_3$[5] molecule, while those in group II are from the $HCSNH_2$ molecule (I). The force constants belonging to group III are related to the N–CH_3 part of the molecule. They are also transferred from $HCSNHCH_3$, but slightly modified values were used*3.

Results of Calculation.—The computed frequencies from the force constants given in Table III are shown in Tables IV (a) and (b). They show a surprisingly good agreement with the observed frequencies, with a maximum deviation of 3.6%. The agreement is so good that the refinement of the force constants is unnecessary

*3 The Urey-Bradley force constants have been obtained in our laboratory for a number of compounds containing methyl groups. The set of H_{HCH}=0.43 md./A, $F_{H\cdots H}$=0.03 md./A and κ=−0.05 md.·A has been found to be the best choice for explaining the frequency data.





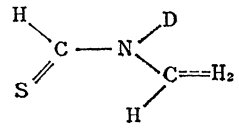


Fig. 7. The in-plane normal modes of *N*-methylthioformamides in Cartesian diplacement vectors projected to the molecular plane (A/unit change in normal coordinate).

(b) $HCSNDCH_3$:

for the present purposes. Tables IV (a) and (b) list the potential energy distributions among the symmetry coordinates, as well as the signs of the corresponding elements of the L matrix. The Cartesian displacement vectors*4 obtained from the L^x matrix have also been calculated; they are given in Figs. 7 (a) and (b).

The numerical computations were carried out with a PC-1 computer; the routines and methods of calculations are described in Refs. 9 and 10 and so are not described here.

*4 Special treatment is necessary to calculate the L^x matrix when higher frequencies are separated from lower ones. The details were given in (II).

Discussion

Possible Rotational Isomers. — As shown in (I) and (II), the C–N bonds of the thioamide molecules possess a considerable double-bond character, and the molecules take approximately planar configurations. Therefore, the secondary thioamides have two possible configurations, cis and trans, in which the amide hydrogen and thiocarbonyl sulfur atoms take, respectively, the cis and trans positions with regard to each other. Russell and Thompson[11] have proposed that the two closely situated NH stretching bands of the secondary amides in dilute carbon tetrachloride solutions arise from these two isomers;

* The asterisk means that the corresponding $\boldsymbol{L}$ matrix element is negative.

the band with a higher frequency corresponds to the NH stretching vibration of the trans form, and the band with a lower frequency, to that of the cis form. This proposal was supported by our dielectric and infrared measurements of some anilides over a wide range of concentrations[12,13], although there is a certain limitation in applying the rule, especially to aromatic amides[14]. It was also shown that the rule is applicable not only to secondary amides but also to thioamides[13].

The infrared absorption curves of $HCSNHCH_3$ and $CH_3CSNHCH_3$ in dilute carbon tetrachloride solutions are shown in Fig. 6. Only a single absorption peak is observed at 3427.6 cm^{-1} for $CH_3CSNHCH_3$. In addition to the main peak at 3434.3 cm^{-1}, $HCSNHCH_3$ shows a satellite peak at a lower frequency. The positions and the relative intensities*5 of these two bands correspond well to those of $HCONHCH_3$. Therefore, it can be concluded that $CH_3CSNHCH_3$ takes the trans configuration, even in a dilute non-polar solvent, and that $HCSNHCH_3$ takes both trans and cis forms, of which the former is predominant. In analogy with the secondary amides, these facts indicate that thioamides are also in the trans form in the condensed phases. The calculations of the normal vibrations of $HCSNHCH_3$ and $HCSNDCH_3$ described below also indicate that the vibrational spectra of these molecules are satisfactorily explained by assuming that the molecules are predominantly in the trans form.

Assignments of the Observed Frequencies.— As has already been stated, the computed frequencies of $HCSNHCH_3$ and $HCSNDCH_3$ given in Tables IV (a) and (b) are in good agreement with the results of observation. Not only does it indicate the excellent transferability of the Urey-Bradley force constants, but it also shows that the assumption of the trans planar model for the molecule is generally correct. Therefore, the potential energy distributions among the symmetry coordinates given in Tables IV (a) and (b), as well as the Cartesian

14) I. Suzuki, M. Tsuboi and T. Shimanouchi, ibid., **16**, 467 (1960).
*5 The relative intensity of the satellite band to the main band is a little stronger than that of $HCONHCH_3$; this is consistent with the results obtained from anilides and thioanilides[12,13].

displacement vectors given schematically in Figs. 7 (a) and (b), can be considered to represent the quantitative assignments of the observed frequencies.

Next, the out-of-plane vibrations should be treated in order to complete the vibrational assignments of *N*-methylthioformamide. Of seven out-of-plane vibrations, four are chiefly associated with the CH_3 group vibrations. The methyl asymmetric stretching, asymmetric deformation and rocking vibrations are expected to occur around the corresponding in-plane vibrations. The methyl torsional vibration is expected to appear at a much lower frequency and to lie beyond the limits of the present investigation. The remaining three are the NH and CH out-of-plane and CN torsional vibrations, π(NH), π(CH) and τ(CN). The 680 and 363 cm^{-1} bands of $HCSNHCH_3$ correspond well with those at 720 and 353 cm^{-1} of $HCONHCH_3$ in their positions, intensities, and spectral changes due to *N*-deuteration and to the alternation of the states of aggregation as well. They are assigned, respectively, to the π(NH) and τ(CN) vibrations*6. The assignment of the π(CH) vibration is slightly ambiguous. In $HCSNH_2$ it was found at 985 cm^{-1}, and a band found at 980 cm^{-1} of $HCSNDCH_3$ is probably to be assigned to this vibration. In $HCSNHCH_3$, there is a strong band at 987 cm^{-1} belonging to one of the in-plane vibrations. Therefore, it is not clear whether a weak shoulder band at 1010 cm^{-1} is to be ascribed to the π(CH) mode or it overlaps the strong band mentioned above. In the last column of Table I (a), the approximate assignments of the observed frequencies are given.

If we combine the results of the normal coordinate analysis of $HCSNHCH_3$ with those of CH_3CSNH_2 and $CH_3CONHCH_3$[4], it is not difficult to assign the observed bands of $CH_3CSNHCH_3$. The results of these vibrational assignments are given in the last column of Table I (b). In the next section vibrational assignments of some bands in $CH_3CSNHCH_3$ and $CH_3CSNDCH_3$ are discussed in connection with the characteristic frequencies of secondary thioamides.

The Characteristic Frequencies of Secondary Thioamides. — The nature of some vibration bands characteristic of the secondary thioamides will now be discussed in detail on the basis of the assignments described in the previous section.

The Band around 1550 cm^{-1}.—As can be seen from Table IV (a) and Fig. 7 (a), the band at 1537 cm^{-1} of $HCSNHCH_3$ is assigned to the mixed vibration of the ν(CN) and δ(NH). The nature and the frequency of the band, as well as its change due to the states of aggregation, correspond to those of the amide II band in secondary amides[4]. In $CH_3CSNHCH_3$ this band is found at 1564 cm^{-1} in the solid state and at 1547 cm^{-1} in the liquid state. On *N*-deuteration, this band moves to a frequency lower by about 30 cm^{-1}. Instead of the δ(NH) vibration, the $\delta_a(CH_3)$ vibration couples with the ν(CN) motion in *N*-deuterated species; this gives rise to two frequencies at 1508 and 1438 cm^{-1} in $HCSNDCH_3$. In the case of $CH_3CSNDCH_3$, the $\delta_a(CH_3)_C$*7 vibration also couples with the ν(CN) vibration, as in the case of CH_3CSND_2 (II), the three frequencies are observed at 1515, 1483 and 1442 cm^{-1}.

The Band around 1300 cm^{-1}. — The band at 1297 cm^{-1} of $HCSNHCH_3$ is also assigned to the mixed δ(NH) and ν(CN) vibrations and corresponds to the amide III band of monosubstituted amides. However, the δ(CH) vibration also contributes to this band considerably. Although the spectra of *N*-methylthioacetamides are complicated, it is quite probable that a strong band at 1261 cm^{-1} of the *N*-deuterated species corresponds to the band at 1238 cm^{-1} of CH_3CSND_2 (II) in its nature, which is assigned to the composite vibration of skeletal stretching and deformation. In $CH_3CSNHCH_3$ a vibrational interaction certainly takes place between this skeletal and the δ(NH) modes, and the features of the vibration would resemble those of the amide III band. The amide III band occurs at 1299 cm^{-1} in $CH_3CONHCH_3$, which is about 50 cm^{-1} higher than that of $HCONHCH_3$. If we take the above facts into account, the position of the amide III-like band of $CH_3CSNHCH_3$ is estimated at around 1350 cm^{-1} and probably overlaps the $\delta_s(CH_3)_C$ band. This explains the lowering of the band in the carbon tetrchloride solution*8.

The Skeletal Stretching Vibrations.—As has been pointed out in (II), the values of the force constants, K_{CS}, K_{CC} and $K_{C'N}$, are close to each other, and interactions occur between the ν(C'N), ν(CS) and ν(CC) vibrations. Therefore, the nature of the observed frequencies in the region from 1100 to 800 cm^{-1} becomes complicated. In addition, the $r(CH_3)_N$ and $r(CH_3)_C$ vibrations are also in this region.

Both (C'N) and ν(CS) vibrations take place in the normal modes of 987 and 868 cm^{-1} of

*6 In $HCSNDCH_3$, the bands at ca. 500 and 358 cm^{-1} are assigned, respectively, to the π(ND) and τ(CN) vibrations.

*7 In $CH_3CSNHCH_3$, $(CH_3)_C$ and $(CH_3)_N$ are used to refer to the methyl groups attached, respectively, to the carbon and nitrogen atoms.

*8 The intensity of the band becomes very strong.

$HCSNHCH_3$. The $r(CH_3)$ vibration also contributes to the former vibration. As for the 868 cm^{-1} band, the energy associated with the ν(CS) vibration is about 55% of the total, and so this band may be called the ν(CS) band. In *N*-deuterated species, the δ(ND) vibration should also be taken into account; the bands at 932 and 844 cm^{-1} are assigned to the mixed vibrations of the ν(C'N) and δ(ND), and of the ν(CS) and δ(ND), respectively.

In $CH_3CSNHCH_3$, three strong bands at 1099, 955 and 684 cm^{-1} are assigned to the skeletal stretching vibration. The $r(CH_3)_N$ vibration may also contribute considerably*9 to the 1099 cm^{-1} band. The band at 684 cm^{-1} corresponds to the 718 cm^{-1} band of CH_3CSNH_2 and is certainly associated with the mixed mode of the ν(CS) and ν(CC) vibrations, of which the former is predominant. In *N*-deuterated species, the 956 cm^{-1} band is split into two bands at 990 and 930 cm^{-1}; the δ(ND) vibration probably takes place in both of these vibrations.

The NH Out-of-plane Vibrations. — The π(NH) band is termed the amide V band in secondary amides, and can easily be identified by its broadness and sensitivity to a change in states. In secondary thioamides it also occurs at about 680 cm^{-1} in the liquid state and on solidification moves to a frequency higher by about 60 cm^{-1}. The π(ND) band is found at about 500 cm^{-1}.

The Skeletal Deformation Vibrations.—The band at 600 cm^{-1} of $HCSNHCH_3$ (and of $HCSNDCH_3$) is assigned to one of the skeletal deformation vibrations. The rather high frequency*10 of the deformation vibration is explained by the vibrational coupling of the δ(NCS) and δ(CNC') modes. In this vibration the N–C=S angle increases while the C–N–C' angle decreases, or vice virsa. In other words, it corresponds to a kind of asymmetrical deformation vibration. Therefore, the band corresponding to the "symmetrical" deformation vibration falls at too low a frequency to be detected.

In $CH_3CSNHCH_3$ the bands at 559, 374 and 287 cm^{-1} are assigned to the skeletal deformation vibrations. The 374 cm^{-1} band corresponds to the band at 378 cm^{-1} of CH_3CSNH_2 and is assigned to the δ(CC') vibration, while the other two are assigned to the "asymmetric" δ(NCS) and δ(CNC') and "symmetric" δ(NCS) and δ(CNC') vibrations respectively.

Thus, the complete assignments of two secondary thioamides, $HCSNHCH_3$*11 and $CH_3CSNHCH_3$, have been made from the calculation of the normal vibrations and from the correspondence of the bands between the related molecules. It has been shown that the assignments of the vibration bands can be made by the trans planar model for the molecules. It has also been shown that the Urey-Bradley force constants so far obtained[1,2,5] have an excellent transferability and can be used without any modification of their values.

The author wishes te express his deep gratitudes to Professor Takehiko Shimanouchi for his guidance and encouragement throughout this work. His thanks are also due to Professor Hidetoshi Takahashi for the use of a PC-1 computer.

Hongo, Tokyo

*9 The band at 1099 cm^{-1} of $CH_3CSNHCH_3$ probably corresponds to those around 1100 cm^{-1} of thiolactams which are assigned to the ν(CS) vibration[15].

*10 The δ(NCS) vibration usually occurs at about 450 cm^{-1} (I), and the δ(CNC'), at 350 cm^{-1} [5].

15) R. Mecke and R. Mecke Jr., *Ber. deut. chem. Ges.*, 89, 343 (1959).

*11 In the spectrum of $HCSNHCH_3$, there remain two bands unassigned, e. g. the bands at 467 and 920 cm^{-1}. As has been pointed out previously, the vibration associated with the δ(NCS) mode usually occurs about 450 cm^{-1}. Like the band around 600 cm^{-1} found in $HCONHCH_3$[5], this band may be assigned to the δ(NCS) vibration of the cis isomer, in which the interaction between the δ(NCS) and δ(CNC') vibrations is considerably weaker than in the trans form.

*An Attempt to Prepare Linear Chelate Polymers**

By Shunsuke MURAHASHI and Hiroaki KUBOTA

(Received February 16, 1962)

Three new tetraoximes, in which two pairs of glyoxime groups are linked together by hexamethylene, decamethylene or a *p*-phenylene group, have been synthesized. The possible formation of coordinated high polymers by the coordination reaction between these tetraoximes and some metal ions has been studied. In the case of aliphatic tetraoximes, instead of the expected coordinated linear polymers, cyclization was found to have occurred, giving multimembered ring compounds of a low molecular weight. The aromatic tetraoxime also gave coordination compounds, but the product was infusible and insoluble in all solvents tested. Although there was a possibility of obtaining high polymers and the possibility may be considered reasonable from the study of molecular models, the high polymeric nature of the product could not be fully established experimentally.

The main chain of synthetic high polymers is usually linked by covalent bonds. Recently there have appeared in the literature descriptions of some polymeric materials having coordinated bonds with metal ions in the main chain. Such polymeric materials would be of interest from the standpoint of practical importance as well as of academic interest, since they lie on a borderline between organic and inorganic polymers and could be expected to introduce an inorganic character into conventional organic polymers.

Owing to their insolubility in general, there had been no reliable proof of the formation of high polymers before the present authors started their work. The reaction between dimethylglyoxime and the nickel ion has been well studied in chelate chemistry, and the structure of the complex of nickel(II) dimethylglyoximate has been established as having stable coordination bonds in it.

Attempts were made, therefore, on the basis of the above considerations, to prepare linear coordination polymers which would have stable coordination bonds in the main chain and would be easily soluble in organic solvents.

Three new tetraoximes with two symmetrically situated glyoxime groups were synthesized. One has two glyoxime groups connected by a *p*-phenylene group, which will give little flexibility to the main chain of the resulting polymer owing to the rigidity of the *p*-phenylene group. The other two have their oxime groups connected with polymethylene groups of a different number, which will dilute the mutual polar effect of the glyoxime groups and give more or less flexibility. The reaction between these oximes and metal ions, especially the nickel ion, was carried out.

Results

Bis-α-dioximes were synthesized in the following scheme:

$$2CH_3COCH_2COOC_2H_5 + Br(CH_2)_nBr \xrightarrow{C_2H_5ONa} CH_3COCH(CH_2)_nCHCOCH_3$$
$$\qquad\qquad\qquad

The intermediate I, II and III hydroxyiminoketones as well as the IV, V and VI tetraoximes are all new compounds; their infrared spectra are presented in Figs. 1 and 2. The I, II and III compounds have absorption bands for the carbonyl and hydroxy groups at 1640~1680 and at 3200~3400 cm^{-1} respectively. In IV, V and VI, the strong absorption band of the carbonyl group disappeared, and instead a strong and broad band for hydroxyl group was seen at around 3250 cm^{-1}. Many geometrical isomers of each one of the tetraoximes may exist; attempts were made to determine whether the product was a mixture of isomers or not, but only one species, presumably the most stable one, was isolated.

Coordination compounds of tetraoximes with metal ions have been prepared by the reaction of tetraoximes with metal salt in dry dimethylformamide or in an aqueous dimethylformamide solution in the presence of or absence of ammonia. The properties of the coordination compounds are shown in Table I. The oximes were allowed to react with Cu^{2+}, Co^{2+} and Fe^{2+} to yield precipitates of black, dark brown, and brown color respectively, but the reaction medium did not show any appreciable increase in viscosity during the reaction. The coordination compounds with nickel ion were all microscopically amorphous, but the VII and IX complexes showed crystalline X-ray patterns (Figs. 3 and 4).

VI	$-C_6H_4-$	IX	Orange-red powder	—	None	Became dark red

* General formula $CH_3-\underset{\underset{NOH}{\|}}{C}-\underset{\underset{NOH}{\|}}{C}-R-\underset{\underset{NOH}{\|}}{C}-\underset{\underset{NOH}{\|}}{C}-CH_3$

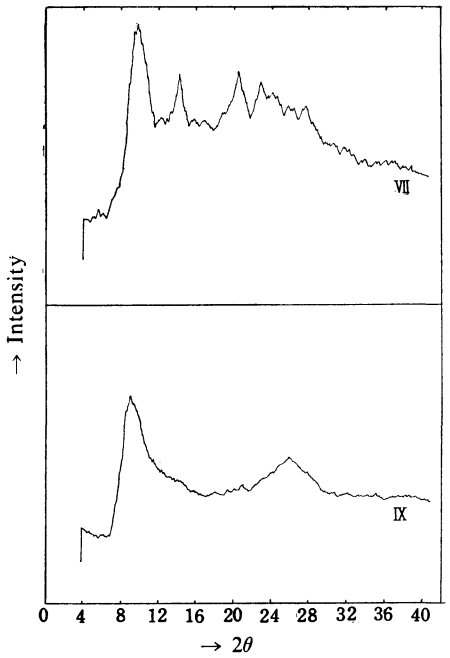

Fig. 3. X-Ray powder spectra (Cu K_α) of [VII] and [IX].

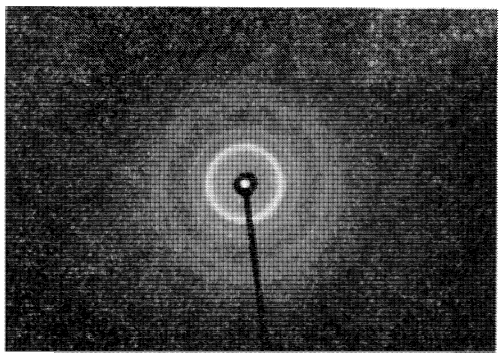

Fig. 4. X-Ray diffraction pattern of (VII). (CuK_α).

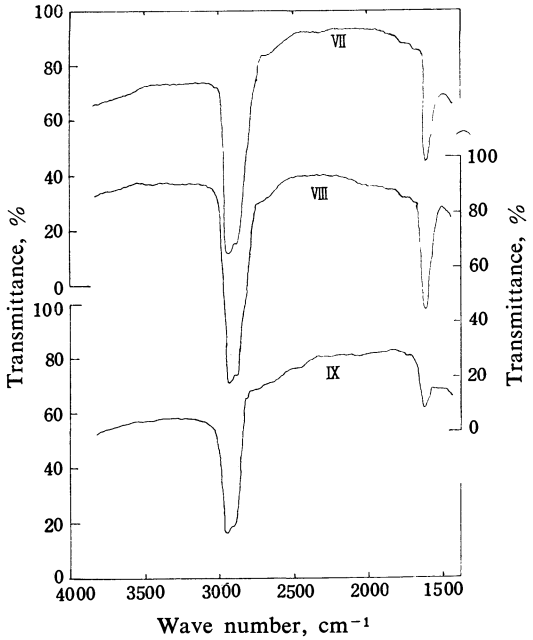
The infrared spectra of these coordination compounds are shown in Fig. 5. The broad absorption band of tetraoximes at 3250 cm^{-1} disappeared completely, and new bands appeared at 1560 cm^{-1} in VII and VIII and at 1545 cm^{-1} in IX. There are no indications of the presence of the oxime end-group, and the spectra showed a great resemblance to that of nickel-(II) dimethylglyoximate. Therefore, it may be concluded that the complete coordination of the glyoxime group to the nickel ion took place. A broad and weak band at about 1775 cm^{-1} in the spectra of VII and VIII, and a very weak one in that of IX, may be considered due to hydrogen bonding in the planar coordination structure around the central nickel ion[1]. It may also be deduced that the



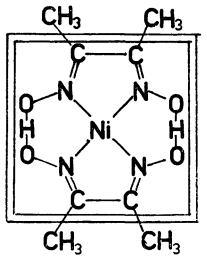


Fig. 5 Infrared spectra of Ni-complexes [VII], [VIII] and [IX].

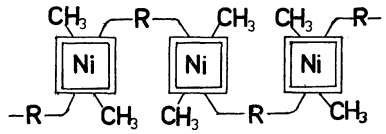
glyoxime groups coordinated to the nickel ion have the same structure as that of nickel(II) dimethylglyoximate.

Molecular weight measurement by the Rast method, using *p*-phenylphenol or *p*-nitrophenol as the solvent, showed that VII has a molecular weight of about 400 to 610 (empirical formula weight 343) and VIII, of about 560 to 620 (empirical formula weight 399). The molecular weight of IX was not measured because of its insolubility in the solvents.

Discussion

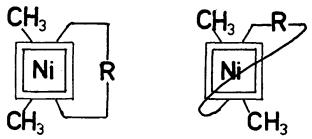
The coordination structure of nickel(II) dimethylglyoximate is known to be planer with the central nickel ion and with the two hydrogen bonds between the two dimethylglyoxime molecules, as is shown below[2].



The planer chelate structure of nickel(II) dimethylglyoximate

1) R. E. Rundle and M. Parasol, *J. Chem. Phys.*, **20**, 1487 (1952).
2) L. E. Godycki and R. E. Rundle, *Acta Cryst.*, **6**, 487 (1953).

The planer units are piled up on one another in the crystal. On the basis of the above-mentioned facts, the coordination complexes of the tetraoximes with the nickel ion are considered to have the same chelated structure as that of nickel(II) dimethylglyoximate. Leaving aside the problem of steric effect and the tendency of ring formation, and the possible structures of complexes can be represented as either one or as a mixture of the A, B, C and D forms.



According to the inspection of the Stuart model, the A structure is possible for all the tetraoxime complexes. The B structure is possible only for V, since VII can not take the B structure because of the rigidity of the *p*-phenylene group, nor can IV owing to the shortness of the polymethylene chain. The C structure is probable for IV and V, but is unprobable for VI because of the rigidity of the *p*-phenylene group.

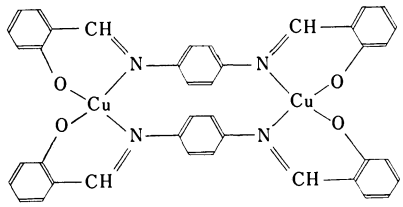
Except for the A structure with end groups, the forms B, C and D have the same composition and can not be distingished from each other by mere chemical analysis. In order to draw a conclusion about the structural assignment, further information must be acquired from a detailed examination of the product or from measurements of molecular weight.

The formation of cyclic low-molecular-weight compounds by condensation polymerization is known to occur in the case of polyamides and polyesters: it depends on the length of the chain unit and is modified by the existence of aromatic rings. Since Carothers and his co-workers explored this problem, a large amount of evidence has been accumulated indicating that, unless the formation of stable 5- or 6-member rings were expected in the reaction, the linear polymerization could occur exclusively. In chelate chemistry, although it is known that the formation of the 5- or 6-membered chelate ring is most feasible, the formation of larger membered rings are, surprisingly, just as feasible. For instance, Pfeiffer and his co-workers were able without difficulty to prepare 7-, 8- and 13-membered compounds X (n=4, 5 and 10 respectively) by the reaction



[X] (Pfeiffer)

cis trans

[XI] (Schlesinger)

[XII] (Pfeiffer)

of the cupric ion with bis-salicylaldehyde-polymethylene diimine[3]. The formation of the XI and XII complexs are other examples described by Schlesinger[4] and Pfeiffer[5] respectively. From these facts, it is apparent that

3) P. Pfeiffer et al., *Ann.*, **503**, 804 (1933).
4) N. Schlesinger, *Ber.*, **58**, 1877 (1925).
5) P. Pfeiffer and H. Pitzer, *J. prakt. Chem.*, **145**, 243 (1936).

the relation between the ring formation and the structural unit in the usual linear condensation polymerisation does not hold in the formation of the co-ordination polymer. Therefore, in assigning the reaction product it seems necessary to study carefully what kinds of unit structure have been or will be favorable to form the linear polymer in each type of coordination compound.

The results of molecular weight measurement indicate that the coordination product VII may be either B or C. The infrared spectrum of VII did not show the absorption band for the oxime end-group, pointing to either a B or C structure, or a mixture thereof. From the study of molecular models, however, the VII compound is considered unable to take the monomeric form B because of the short polymethylene chain. Thus, the VII product may be assigned to the dimer C.

The VIII product also did not show the infrared absorption band for the oxime end-group, and so it may have the structure of either the monomeric B or of the C or D. From the determination of the molecular weight, it may considered to be a mixture of types B and C.

The product IX did not show the oxime end-group in the infrared spectrum and showed a little amorphous character in an X-ray diffraction pattern. From the consideration of molecular models, it may be plausible to consider either the IX product has the A (high molecular weight) or D polymeric structure. However, the polymeric nature of the IX product could not be established definitely owing to its insolubility and infusibility.

Experimental

Dodecane-2, 3, 10, 11-tetraone-3, 10-dioxime (I).—Into a solution of 4.6 g. (0.2 atom) of sodium in 60 ml. absolute alcohol was stirred 30 g. (0.23 mol.) of ethyl acetoacetate. Hexamethylene bromide (27 g., 0.11 mol.) was then added slowly for about one hour at about 100°C (bath temperature). The reaction temperature was maintained at about 100°C until the solution became neutral, about 12 to 15 hr. of continuous stirring being required. Ethanol was distilled off from the reaction mixture by heating it up to 140°C, and there was obtained a viscous brown oil containing a white precipitate. To the oil was added just enough water to dissolve the precipitates and the mixture was extracted with ether. The ether layer was washed with water and dried over anhydrous sodium sulfate. Then the ethereal solution was evaporated and the residue was stripped under 5 mmHg until no distillate was obtained by heating it up to 170°C; about 34 g. of brown viscous syrup was obtained.

To the syrup was added a solution of 12 g. (0.3 mol.) sodium hydroxide in 120 ml. water; hydrolysis was effected at room temperature with constant stirring. The heterogeneous mixture was made into a solution in about twenty hours; a clear orange solution was obtained. To this solution was added 16 g. (0.23 mol.) of sodium nitrite, and it was kept below 5°C. An aqueous solution of 10% sulfuric acid was stirred in order to retain the color of potassium iodide-starch paper at least for fifteen minutes.

Aqueous sodium hydroxide was stirred in until all the solid that had separated by the acidification had dissolved. The alkaline solution was extracted with ether to remove any unreacted materials. The alkaline layer was cooled in an ice-salt bath and acidified by stirring in 2 N sulfuric acid. The solid separated by acidification was extracted with ether, producing an orange-red extract. The ether extract was washed with an aqueous 2 N sodium carbonate solution until the aqueous layer became almost colorless. The ether layer was washed with water and dried over anhydrous sodium sulfate. Evaporation of the solvent gave a solid product, which was recrystallized from a mixture of 10 ml. of ether and 120 ml. of benzene to give 9.6 g. of crude, faintly yellow crystals. The crude product was further recrystallized, using active charcoal, to yield 7.8 g. of colorless crystals; m. p., 129.5~131°C (corr.). The overall yield was 22.6%.

Found: C, 56.24; H, 7.73; N, 10.88. Calcd. for $C_{12}H_{20}O_4N_2$: C, 56.23; H, 7.85, N, 10.93%.

The compound I was easily soluble in ether, alcohol, dimethylformamide and pyridine, was soluble in hot benzene, was sparingly soluble in cold benzene and was inslouble in petroleum benzine and petroleum ether. It was soluble in alkali hydroxide solutions, giving a yellow solution, and also a little soluble in concentrated aqueous ammonia, again yielding a yellow solution.

After being heated in a water bath at about 80°C with a nickel salt in an alcohol solution, compound I showed no reaction, but gave, in the presence of ammonia, red precipitates. It gave carbonyl derivatives of hydroxylamine, *p*-nitrophenylhydrazine and semicarbazide. *p*-Nitrophenylhydrazone was soluble in dimethylformamide, pyridine and hot nitrobenzene and was recrystallized from nitrobenzene to give yellow crystals; m. p., 232~233°C (decomp.) (corr.).

Found: N, 21.08. Calcd. for $C_{24}H_{30}O_6N_8$: N, 21.28%.

Dodecane-2, 3, 10, 11-tetraonetetraoxime (IV).—To a mixture of 2.5 g. of I (0.01 mol.), 2 g. of hydroxylamine hydrochloride (0.03 mol.), 1.5 g. of sodium carbonate (0.015 mol.) and 30 ml. of alcohol water was added bit by bit so as to make the mixture clear. The solution was refluxed for more than ten hours and was kept standing overnight. The white precipitates thus formed were filtered and washed with water till no chloride ion were detected. The precipitates were dissolved in 10 ml. of dimethylformamide, and the solution was filtered. Methanol (40 ml.) was then added to the solution and the mixture was kept at room temperature overnight to yield 2 g. of colorless crystals, which decomposed at 250~253°C (corr.). Yield, 70%.

Found: C, 50.39; H, 7.50; N, 19.21. Calcd. for $C_{12}H_{22}O_4N_4$: C, 50.33; H, 7.74; N, 19.57%.

Compound IV was soluble in almost all organic solvents. It was also soluble in an alkali hydroxide solution.

The reaction of IV with Ni^{2+}, Co^{2+} and Cu^{2+} salts in aqueous dimethylformamide solutions immediately gave orange, dark brown and almost black precipitates respectively in the presence of ammonia or alkali hydroxide. In the absence of an alkali catalyst, the reaction took a long time by standing at room temperature and several hours by heating.

Nickel Complex of Dodecane-2, 3, 10, 11-tetra-one-tetraoxime (VII).—Nickel was purified through its hexammine complex. Hexaamminenickel bromide (0.231 g. 0.5 mmol.) was decomposed by boiling it with water until no more evolution of ammonia was detected. A few drops of concentrated hydrochloric acid were added, and the solution was evaporated on a water bath. This procedure was repeated several times, a yellowish-brown residue being obtained. To this residue was added just enough water to dissolve the residue, 2 ml. of dimethylformamide and a few drops of concentrated aqueous ammonia, resulting in a homogeneous solution. A solution of 143 mg. (0.0005 mol.) of IV in 6 ml. of dimethylformamide was added to the solution, an orange precipitates being formed immediately. The mixture was heated on a steam bath for 20 hr. and kept standing overnight. The precipitates were filtered out, washed with hot dimethylformamide to remove the unreacted tetraoxime, with water until no more Ni^{2+} and Cl^- were detected, and finally with methanol, and then dried in vacuo at 100°C to yield 150 mg. (92.6%) of the VII complex of an orange color.

Found: C, 41.90; H, 5.81; N, 16.66; Ni, 17.23. Calcd. for $C_{12}H_{20}O_4Ni$: C, 42.05; H, 5.88; N, 16.34; Ni, 17.11%.

The compound showed neither a definite melting point nor a decomposition point. Upon being heated over 300°C in a capillary tube, it changed to a black powder. It was slightly soluble in hot pyridine to give an orange-red solution, was sparingly soluble in nitrobenzene and was insoluble in a wide variety of organic solvents. It was insoluble in 4 N sodium hydroxide and was decomposed with 6 N sulfuric acid and formic acid, but it was not attacked by boiling acetic acid.

Hexadecane-2, 3, 14, 15-tetraone-3, 14-dioxime (II).—The preparation was carried out in the same way as that of compound I. From 4.6 g. of sodium (0.2 atom.), 100 ml. absolute alcohol, 30 g. of ethyl acetoacetate and 33 g. of decamethylene bromide (0.11 mol.), 40 g. of the condensation product was obtained. Hydrolysis of the condensation product and the following formation of oxime gave a crude product, II, which was recrystallized from a benzene-ether mixture to give colorless crystals; m. p., 138~139°C (corr.). The overall yield was 5.4 g. (17.2%).

Found: C, 61.63; H, 8.85; N, 8.87. Calcd. for $C_{16}H_{28}O_4N_2$: C, 61.51; H, 9.03; N, 8.97%.

The compound was soluble in alcohol, ether and hot benzene and sparingly soluble in cold benzene, but it was insoluble in petroleum benzine or in petroleum ether. The behavior of this compound was similar to that of I.

Hexadecane-2, 3, 14, 15-tetraone-tetraoxime (V).—Preparation of this compound was carried out in the same way as that of IV. The yield of oximation was 88%; m. p., 240~242°C (corr.).

Found: C, 56.40; H, 8.70; N, 16.07. Calcd. for $C_{16}H_{30}O_4N_4$: C, 56.12; H, 8.83; N, 16.36%.

Compound V was soluble in dimethylformamide, in pyridine, and in hot nitrobenzene, but insoluble in a wide variety of other organic solvents.

Reactions of V with Ni^{2+}, Co^{2+} and Cu^{2+} salt in an aqueous dimethylformamide solution gave orange, dark brown and black precipitates respectively when heated for several hours, or immediately in the presence of ammonia.

Nickel Complex of Hexadecane-2, 3, 13, 14-tetra-one-tetraoxime (VIII).—The preparation was carried out in the same way as that of VII, except that the mixture was kept for a week at room temperature (93.3% yield).

Complex VIII was an orange yellow powder, showing no melting point. When heated, it sintered at about 165°C and changed to a black solid at from 220 to 360°C.

Found: C, 48.60; H, 6.93; N, 14.07; Ni, 14.77. Calcd. for $C_{16}H_{28}O_4N_4Ni$: C, 48.15; H, 7.07; N, 14.04; Ni, 14.71%.

Complex VIII was hydrophobic and soluble in pyridine, yielding an orange-red solution. In hot nitrobenzene it became paste-like at first and, after a long time of heating, dissolved to give an orange-red solution. In chloroform, it became paste-like but was sparingly soluble, forming a faintly yellow solution. It was insoluble in a wide variety of other organic solvents.

It was decomposed with formic acid at room temperature, but it was stable with acetic acid.

Terephthaloyl Chloride.—This compound, obtained by heating the mixture of powdered phosphorus pentachloride and terephthalic acid, recrystallized from ligroin in the form of colorless needles; m. p., 81~82°C (93% yield).

***N, N, N', N'*-Tetraethyl Terephthalic Diamide.**—The compound was synthesized from terephthalyl chloride and diethylamine by Schotten-Baumann reaction in benzene. It was recrystallized from benzene in the form of colorless crystals; m. p., 128~129°C (127°C in the literature[6]) (88.5% yield).

***p*-Dipropionylbenzene.**—The compound was obtained by the method of Maxim from *N, N, N', N'*-tetraethylterephthalodiamide and ethylmagnesium bromide in ether, with the by-product of 4-propionylbenzodiethylamide. The yield was 56.5% in the form of colorless crystals; m. p., 102.5~103.5°C (corr.) (100°C in the literature[7]).

Found: C, 75.83; H, 7.42. Calcd. for $C_{12}H_{14}O_2$: C, 75.76; H, 7.27%.

Dioxime was prepared in the usual manner and was recrystallized from alcohol in the form of colorless crystals; m. p., 226~228°C (corr.).

Found: C, 65.45; H, 7.28; N, 12.10. Calcd. for $C_{12}H_{16}N_2O_2$: C, 65.43: H, 7.32; N, 12.72%.

***p*-Bis(1, 2-dioxopropyl)benzene-2, 2'-dioxime (III).**—*p*-Dipropionylbenzene (5.7 g., 0.03 mol.) was

6) N. Maxim, *Ann. Chim.*, [10] **9**, 66.
7) N. Maxim, *Compt. rend.*, **184**, 690 (1927).

dissolved in 60 ml. of dry benzene, and then dry hydrogen chloride and dry methyl nitrite were introduced to the solution, the temperature being kept below 50°C by constant stirring. The reaction mixture was left standing overnight. The mixture was shaken vigorously after the addition of 60 ml. of water. The precipitates formed were filtered, washed thoroughly with water, dried, and then boiled with 20 ml. of benzene and filtered again. The crude product was recrystallized from aqueous alcohol to give 4.8 g. of colorless needles (64.6% yield).

Found: C, 58.11; H, 4.44; N, 11.06. Calcd. for $C_{12}H_{12}O_4N_2$: C, 58.06; H, 4.87; N, 11.29%.

Compound III was soluble in dimethylformamide, tetrahydrofuran, boiling alcohol and boiling ether. It was also soluble in aqueous alkali hydroxide and slightly soluble in aqueous concentrated ammonia, yielding an yellow solution. It did not show any reaction with Ni^{2+} salt in a hot alcohol solution after 8 hr., but, in the presence of ammonia, it formed dark brown precipitates.

p-Bis(1, 2-dioxopropyl)benzene-tetraoxime (VI).—The tetraoxime was prepared by refluxing a mixture of 2.1 g. (0.03 mol.) of hydroxylamine hydrochloride, 1.5 g. (0.015 mol.) of sodium carbonate, and 1.2 g. (0.015 mol.) of *p*-bis(1,2-dioxopropyl)-benzene-2,2'-dioxime in aqueous alcohol for 30 hr. The crude tetraoxime was dissolved in hot dimethylformamide and precipitated by adding methanol, yielding 0.46 g. of colorless crystals, which did not show any melting point (40% yield).

Found: C, 51.77; H, 4.83; N, 19.61. Calcd. for $C_{12}H_{14}O_4N_4$: C, 51.79; H, 5.07; N, 20.14%.

The compound was soluble in hot dimethylformamide and in hot pyridine.

Nickel Complex Compound of *p*-Bis(1, 2-dioxopropyl)benzene-tetraoxime (IX).—The chelate compound of VI with nickel ion was prepared in the same way as that of VII, an orange-red powder being obtained. The unreacted tetraoxime was removed from the product by extraction with hot dimethylformamide. The yield was 83%. Compound IX did not show any melting point or definite decomposition point up to 360°C; it darkened at about 260°C and changed to a black powder at about 300°C.

Found: C, 42.61; H, 3.85; N, 15.96; Ni, 17.72. Calcd. for $C_{12}H_{12}O_4N_4Ni$: C, 43.03; H, 3.61; N, 16.73; Ni, 17.52%.

The compound was insoluble in a wide variety of organic solvents and even in hot phenol, hot nitrophenol and *p*-phenylphenol. It was decomposed by 6 N sulfuric acid and by formic acid at room temperature, but it was not decomposed by boiling acetic acid. It is a marked difference of this complex from the other two that it was slowly attacked by 4 N sodium hydroxide to give a dark red solution.

The authors wish to thank Dr. M. Huggins for his interest in their work during his stay at their University in 1956.

Relations between the Degree of Orientation and the Conditions of the Deposition of Pyrolytic Graphite

By Tokichi NODA, Michio INAGAKI and Hajime KATO

(Received February 23, 1962)

Pyrolytic graphite is produced by the thermal decomposition of a carbonaceous gas. Recently, this graphite has attracted considerable attention and has been widely studied because it possesses many interesting physico-chemical properties. In a number of investigations concerning pyrolytic graphite, it has been found that its electrical, thermal, and mechanical properties are extremely different from those of ordinary graphitized products. Its tensile strength along a deposition surface is about ten times higher than that of ordinary graphitized products[1], and its strength-to-weight ratio is the highest of all high-temperature materials[2]. This graphite has a high density and a high impermeability to gases. In addition, it is more resistant to oxidation. Its thermal and electrical conductivities are strongly anisotropic, higher in a plane parallel to the deposition surface than in a plane perpendicular to it, because the crystallites in pyrolytic graphite are highly oriented in placing their layer-planes parallel to the deposition surface. It can be said that many interesting physico-chemical properties of pyrolytic graphite are largely dependent upon the orientation of the crystallites. However, the direct

2) Anon., *Industrial Heating*, **27**, 593 (1960).

measurement of the orientation for pyrolytic graphite had not yet been carried out. Therefore, the present work was carried out to discover the relations between the degree of orientation and the conditions of the deposition, such as the rate of flow of hydrocarbon gas and the temperature of the deposition. The degree of orientation was directly measured by means of the X-ray diffraction method. The graphitizability of pyrolytic graphite is also discussed on the basis of X-ray diffraction profiles.

Experimental

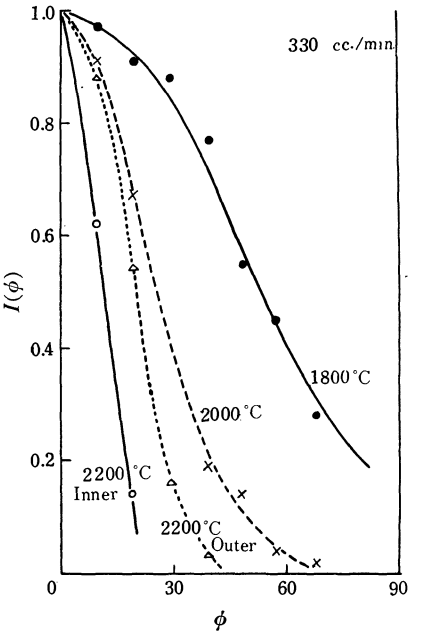
Preparation of Pyrolytic Graphite. — Pyrolytic graphite was prepared by passing gaseous hydrocarbons on the heated surface of an electrographitized carbon rod. The rod was 9 mm. in diameter and had a reduced central part 9 mm. wide, 1 mm. thick and 60 mm. long; it was placed in a bell-jar type metallic chamber. The rod was heated by the passage of electric current directly through it, and the temperature of the surface of the reduced part was measured with the aid of an optical pyrometer. The pressure of gas in the chamber was measured with a mercury manometer, and the rate of gas flow, with a flowmeter. The gas used was a commercial propane gas which was a mixture of light hydrocarbons, such as propane, propyrene, butane, and butene. After the chamber had been evacuated, the propane gas was admitted at a constant rate of gas flow—45, 115, 330, 665 or 1110 cc./min., and then the rod was heated to the desired temperature of deposition—1600, 1800, 2000, 2200 or 2400°C. The heating of the rod was performed in a moment. Deposition was carried out at a constant temperature of the deposition surface and at a constant rate of gas flow until the deposited graphite had thickness enough.

The Anisotropy Factor and the X-Ray Diffraction Profile.—The orientation function, $I(\phi)$, of graphite crystallites in a specimen was obtained from a (002) diffraction ring[3] taken by using unfiltered CuK radiation. In order to make a specimen, the deposited graphite was sliced in the direction perpendicular to the deposition surface.

The orientation anisotropy factor (σ_{oz}/σ_{ox}) proposed by Bacon[3] can be calculated as

$$\sigma_{oz}/\sigma_{ox}=2\cdot\frac{\int_0^{\pi/2}I(\phi)\cdot\cos^2\phi\cdot\sin\phi\cdot d\phi}{\int_0^{\pi/2}I(\phi)\cdot\sin^3\phi\cdot d\phi} \quad (1)$$

The orientation functions of all slices could well be approximated to curves of $\cos^n\phi$, that is to say, $I(\phi)=\cos^n\phi$. Therefore, Eq. 1 can be reduced to



$$\sigma_{oz}/\sigma_{ox}=n+1 \quad (2)$$

The profiles of the (002) or (004) diffraction of the deposited graphites were obtained by using a recording diffractometer.

Results and Discussion

Relations between the Anisotropy Factor and the Conditions of Deposition.—The orientation functions of the deposited graphites, which were produced at a constant rate of gas flow, i. e., 330 cc./min., and at various temperatures of deposition, are shown in Fig. 1a. The

Fig. 2. Anisotropy factors (σ_{oz}/σ_{ox}) of pyrolytic graphites.

anisotropy factor, which was calculated from the orientation function, is shown in Fig. 2a as a function of the temperature of deposition. From the two figures, it can be seen that the degree of crystallite orientation in the pyrolytic graphite increases with the increase in the temperature of deposition and that the anisotropy factor is directly proportional to the deposition temperature between 1800 and 2400°C, when the anisotropy factor is taken as a measure of the crystallite orientation. Brown and Watt[4] reported that the electrical resistivity of pyrolytic graphite decreases in the direction parallel to the deposition surface and increases in the direction perpendicular to it as the temperature of deposition rises. This strong dependence of the electrical resistivity on the temperature of deposition has been explained on the assumption that the graphite crystallites are more highly oriented as the temperature of deposition increases. In the present work, this assumption is experimentally verified by the direct measurement of the orientation.

The orientation functions of deposited graphites which were produced at a constant temperature, i. e., 2000°C, and at various rates of gas flow are shown in Fig. 1b. The variation of the anisotropy factor with the rate of gas flow is shown in Fig. 2b. On the basis of the two figures, it can be said that the degree of crystallite orientation increases and that, accordingly, the anisotropy factor becomes larger as the rate of gas flow decreases.

A cross-section of the deposited graphite, which was produced at a temperature above 2000°C, consisted of two or three layers. These layers were easily distinguishable from one another on the basis of their lusters. An inner layer, which was closer to the graphite substrate, had more metallic luster than an outer one.

The anisotropy factor of an inner layer was found to be larger than that of an outer one. These large anisotropy factor values of the inner layer have never been found in ordinary graphitized products[3,5]. It has been previously reported, however, that graphite crystallites in carbon which had been obtained by vacuum evaporation were highly oriented with their layer-planes parallel to the evaporated surface and that the degree of orientation increased with the increase in the temperature of the heat-treatment[6].

X-Ray Diffraction Profiles.—As is shown in Fig. 3, almost all the (002) or (004) diffraction profiles of the deposited graphites have been found to be asymmetrical and to be apparently composed of two kinds of profiles, whose values of c_0 are 6.72 and 6.86Å. Similar phenomena have been observed with charcoals heat-treated at various temperatures[7,8]. The similarity of the asymmetrical diffraction profile of pyrolytic graphite to that of charcoal is of great interest in regard to their graphitization.

Diefendorf reported that soot particles, produced in a gas phase by the thermal decomposition of methane, were incorporated in pyrolytic graphite when the pressure of the gas was above 5 mmHg[9]. The observed asymmetry of the diffraction profile of the pyrolytic graphite may be caused by the incorporation of these soot particles.

The profile of an inner layer of the deposited graphite was sharply defined, and its c_0 value was 6.71~6.72Å; i. e., the inner layer of the deposited graphite was highly graphitized. Because the crystallites were strongly oriented, the thermal conductivity in a direction perpendicular to the deposition surface was very

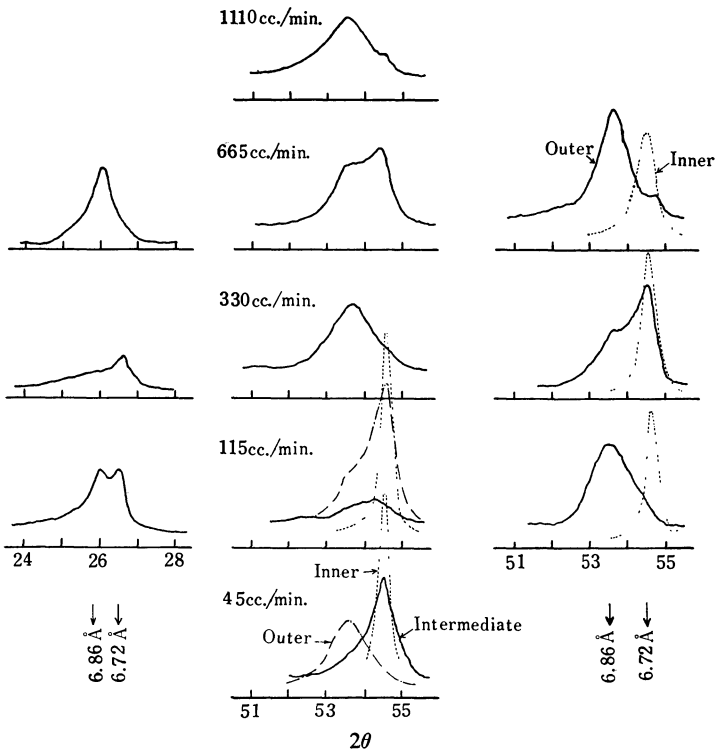

Fig. 3. X-Ray diffraction profiles of pyrolytic graphites.

low[2] and a large temperature gradient seemed to be produced in the deposited graphite. Therefore, it is thought that the temperature of an inner layer is higher than that of the deposition surface.

Petroleum coke is the most easily graphitizable carbon of all raw carbon materials, but the c_0 value of one sample of petroleum coke (Greate Lake Co.) was not less than 6.718Å, even when it was heat-treated at 3400°C[7]. It has also been reported that vacuum-evaporated graphite had a c_0 value of 6.710Å when it was heat-treated at 2800°C under atmospheric pressure[6]. The inner layer of pyrolytic graphite had a c_0 value of 6.71~6.72Å. It can be said that a carbon in which graphite crystallites are strongly oriented, such as pyrolytic graphite and evaporated graphite, is much more graphitizable than ordinary raw carbon materials, for instance, coke and carbon black.

Summary

Pyrolytic graphites were deposited on carbon rods by the thermal decomposition of a commercial propane gas at various temperatures and at various rates of gas flow. The orientation functions of the graphite crystallites in the deposited graphites were measured by means of the X-ray diffraction method. It was shown that the degree of orientation in the deposited graphites increased with the increase in the temperature of deposition and decreased with the increase in the rate of gas flow. The graphites deposited at temperatures above 2000°C were composed of two layers; the inner layers had a larger degree of orientation and a higher graphitizability than the outer layers. Almost all the (0 0 l) diffraction profiles of the deposited graphites were found to be asymmetrical and to the apparently composed of two kinds of profiles, whose c_0 values were 6.72 and 6.86Å.

An NBMO Method for Saturated Compounds

By Kenichi Fukui, Hiroshi Kato and Teijiro Yonezawa

(Received March 12, 1962)

By the use of the extremely simple character of the nonbonding molecular orbital (NBMO) method, explanations have been offered of some physico-chemical properties of conjugated systems, for instance, the chemical reactivity, radical stability, and the basicity[1,2].

In the present paper, we will apply this method to σ electron systems. Consider, for example, a fission of a C–C or a C–H bond in a saturated hydrocarbon molecule (or vice versa, a recombination of the two corresponding radicals). It may be reasonable to assume in the first place that an "unpaired" sp^3 hybridized orbital of carbon* might appear just after the fission (or just before the recombination). Our previous papers[3,4] treated the saturated compounds by the simple LCAO MO method. This can also be applied to those compounds with an unpaired sp^3 hybridized orbital. In these compounds with an odd electron, the highest half-occupied orbital has an energy nearly equal to that of the Coulomb integral of an sp^3 hybridized orbital of a carbon atom (α). We will attempt to discuss the bond strength and the reactivity of the saturated compounds by using the characteristic regularity of the electron distribution in this half-occupied orbital. For the sake of simplicity, the compounds with an unpaired "σ" hybridized orbital are hereafter represented by the notation** R–, while the highest half-occupied molecular orbital is referred to as the "σ NBMO". The R– compounds treated in the present paper are CH_3–, C_2H_6–, n-C_3H_7–, n-C_4H_9–, i-C_3H_7–, t-C_4H_9– and so on. At the same time, the compounds which have an unpaired sp^2 hybridized orbital such as C_2H_3(vinyl)– and C_6H_5(phenyl)–, are also treated, together with those having an sp^3 unpaired orbital, since the procedure of calculation is common to both classes of compounds.

* The unpaired hybridized orbital stands for the AO of the carbon atom, which does not participate into the C-C or C-H bonding.

4) K. Fukui, H. Kato and T. Yonezawa, ibid., **34**, 1111 (1961).

** R– should be discriminated from the species usually represented by R·, in which the reorganization of the odd electron may in general have already taken place.

The Electronic Energy Levels and the Electron Distribution in R– Compounds

The calculations are carried out by the simple LCAO MO method, including all bonding atomic orbitals in the saturated compounds[3,4]. Hence, the calculated molecular orbital energies of the occupied orbitals of R– compounds are obtained in terms of $\lambda_i = \varepsilon_i - \alpha/\beta$, in which α is the Coulomb integral of sp^3 (or sp^2 in, e. g., the C_6H_5–) hybridized orbital of a carbon atom and β is the resonance integral between the sp^3 (or sp^2) orbitals of the adjacent carbon atoms. These values are listed in Fig. 1, together with those of the corresponding parent RH compounds. The calculated energies of σ NBMO (λ_N) and the electron distributions of the σ NBMO in these R– compounds are shown in Fig. 2.

The following conclusions can be derived from these results:

1) The energy value of σ NBMO in R– compounds is nearly equal to α. It may be observed in Fig. 1 that one σ-MO localized at the C–H bond in the parent RH compound disappears and that an NBMO appears in the R– compound. The energy difference between the corresponding occupied orbitals of the R– and RH compounds is very small.

2) The odd electron of the σ NBMO is largely located in the unpaired hybridized orbital, the odd electron density at this orbital being nearly equal to unity, while those of the other hybridized orbitals are alternately equal to zero and the value of the non-zero density rapidly decreases with the distance from the unpaired hybridized orbital. This implies that the R– compounds are very unstable and that the most reactive position is that of the unpaired hybridized orbital.

3) The odd electron density of the unpaired hybridized orbital in various R– compounds decreases in the order CH_3– > C_2H_5– > n-C_3H_7– > n-C_4H_9– > i-C_3H_7– > i-C_4H_9– > t-C_4H_9–. The density values are listed in Table I, along with the energy values of the σ NBMO.

According to the conclusions stated above, one can say that the energy of the σ NBMO is nearly equal to α, as it was in the π NBMO, whereas the mode of the odd electron distribution in the σ NBMO shows a remarkable

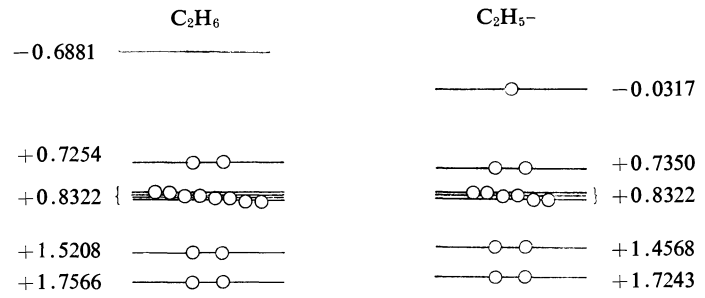

Fig. 1. The relation of energy levels of occupied orbitals between C_2H_6 and C_2H_5-.

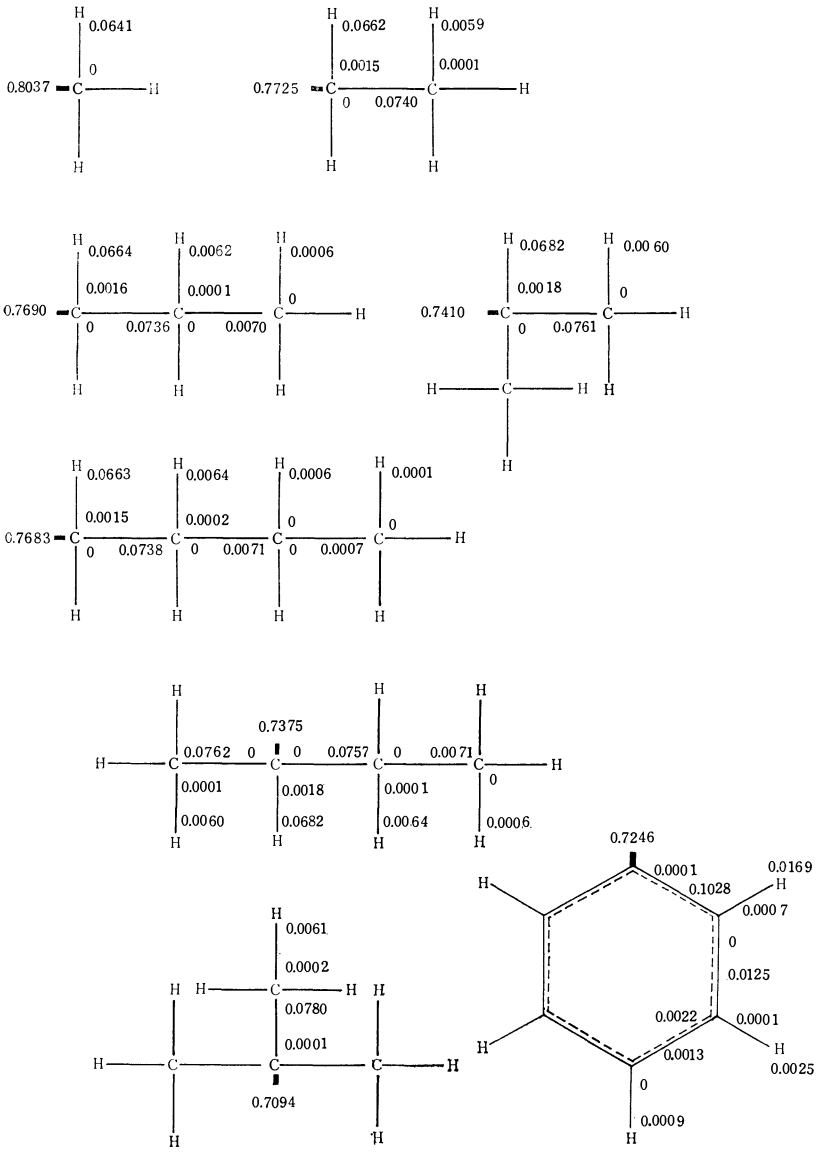

Fig. 2. The odd electron distributions in the σ NBMO of some R- compounds.

difference from that of the π NBMO; i.e., the former localizes and the latter does not (see appendix). In the following sections, it will be shown that the reactivity of alkyl compounds and the bond strength of C–C bonds in saturated compounds can be discussed by means of the extremely simple calculations based upon the properties of the σ NBMO.

The Reactivity Indecis Derived from the σ NBMO Method

In this section, some indecis for the chemical reactivity of saturated compounds are derived by means of the σ NBMO method. It may be worthwhile to recollect here that the activation energy of the reaction in the frontier electron theory has been discussed in terms of the stabilization energy at the transition state. Once the stabilization energy, ΔE, can be obtained, the activation energy, E, is written in the form:

$$E=C-\Delta E \tag{1}$$

in which C is a constant denoting the repulsive term due to the interaction between the reactant and the reagent[2,5]. For a definite type of reaction, it may be assumed that C is a constant and that E is determined only by the difference in the magnitude of ΔE.

In some types of reactions of saturated compounds, the stabilization of the σ-electronic energy, ΔE_σ, may easily be obtained by the σ NBMO method in the following way:

Abstraction Reaction.—The abstraction reaction in saturated compounds is represented by the following formula:

$$RX+Y\cdot \rightarrow [R\text{—}X\cdots Y] \rightarrow R\cdot+XY$$

where RX is a saturated compound and Y· is an odd electron system. In this case, ΔE_σ is given by

$$\Delta E_\sigma=2\left(\sum_j^{occ}\sum_i^{unocc}-\sum_i^{occ\text{-}N}\sum_j^{unocc}\right)\times\frac{(C_r^j)^2(C_s^i)^2}{\lambda_j(RX)-\lambda_i(Y)}+\left(\sum_j^{occ}-\sum_j^{unocc}\right)\times\frac{(C_r^j)^2(C_s^N)^2}{\lambda_j(RX)-\lambda_N(Y)} \tag{2}$$

(in units of $\gamma(-\beta)$)

in which C_r^j and C_s^j are the coefficients of the r-th atomic orbital in the j-th molecular orbital of the RX molecule and of the s-th atomic orbital in the i-th molecular orbital of the reagent Y·; N denotes the half-occupied molecular orbital of Y; $\lambda_j(RX)$ is the energy of the j-th molecular orbital of the RX compound, and $\lambda_i(Y)$ is that of the i-th molecular orbital of Y: compound respectively. The unit is $\gamma(-\beta)$, which represents the absolute value of the resonance integral between the two NBMO's, X and Y. Since it may reasonably be considered that the radical Y· is converted to the Y– form in the transition state, λ_N is nearly equal to zero and the values of $(C_s^N)^2$ are larger than those of $(C_s^i)^2(N\neq i)$. Thus, the first term in Eq. 2 can be ignored, since this should be much smaller than the second term. In this way, we obtain a simplified formula of ΔE_σ as

$$\Delta E_\sigma\cong D_r^{(R)}(C_s^N)^2 \tag{3}$$

in which $D_r^{(R)}$ is nothing but what we called "delocalizability", derived for the radical reaction of saturated compounds in our previous paper[4],*. That is, ΔE_σ is the reactivity index obtained by considering the interaction explicitly between the σ orbitals of the reactant molecule and the attacking radical.

Radical or Ionic Recombination Reaction.—A similar procedure is applicable when discussing the easiness of the reactions which are covered by the following general equation:

$$R+X \rightarrow [R\cdots X] \rightarrow RX$$

In this equation, the type of reaction may be classified as follows according to the number of electrons occupying the σ NBMO of R and X:

1. One electron each exists in both the NBMO's, R and X (R·+X· → RX: radical recombination).
2. Two electrons in the NBMO of R, and none in the NBMO of X, or vice versa ($R^-+X^+\rightarrow RX$ or $R^++X^-\rightarrow RX$: ionic recombination).

It may be considered that both R and X have one σ NBMO each in the transition state. If we can ignore the energy difference between the two σ NBMO's**, ΔE_σ can be obtained by the first order perturbation theory. Hence, ΔE_σ for all the cases stated above may be simply given as follows:

$$\Delta E_\sigma=2|C_r^N C_s^N| \text{ (in unit of } \gamma(-\beta)) \tag{4}$$

In the series of reactions in which X does not change, the coefficient C_s^N is a constant, so ΔE_σ is proportional only to $|C_r^N|$.

Radical or Ionic Dissociation Reaction.—Consider a dissociation reaction proceeding:

5) T. Yonezawa, K. Hayashi, C. Nagata, S. Okamura and K. Fukui, *J. Polymer. Sci.*, **14**, 312 (1954).

* Delocalizability, $D_r^{(R)}$, for the radical reaction was defined by the following formula[4]:

$$D_r^{(R)}=\sum_j^{occ}\frac{(C_r^j)^2}{\lambda_j}+\sum_j^{unocc}\frac{(C_r^j)^2}{-\lambda_j}$$

** In general, the energies of the two -NBMO's of R and X are not exactly the same. Both of these levels, however, lie very close to α, so that it might be possible to ignore the difference.

$$RX \rightarrow [R\cdots X] \rightarrow R+X$$

In this case we also assume that both the R and X compounds have a σ NBMO each in the transition state. The magnitude of ΔE_σ is shown to be a measure of the activation energy. Namely, the activation energy, E, of the reaction is given by

$$E=\varepsilon(R\cdots X)-\varepsilon(RX) \qquad (5)$$

where $\varepsilon(R\cdots X)$ and $\varepsilon(RX)$ denote the total energy of R···X and RX respectively. Equation 5 may be written in another form as:

$$E=\{E(R\cdots X)-E(R+X)\} -\{E(RX)-E(R+X)\} \qquad (6)$$

As was pointed out in the last section, the first term is put equal to $(C-\Delta E_\sigma)$. The term in the second parenthesis may become $(C-\Delta E'_\sigma)$ so long as one considers that the energy $E(RX)$ may be deemed an extreme of $E(R\cdots X)$ and that the stabilization due to the covalent interaction between R and X may be proportional to ΔE_σ, resulting from an incipient bond*. Therefore, the prime of ΔE_σ indicates that the resonance integral $(\gamma\beta)$ between R and X has a very large value. Let it be $\gamma'\beta$.

Based on these considerations, we can conclude that the activation energy of the dissociation reaction may be proportional to the difference between $\Delta E'_\sigma$ and ΔE_σ as

$$E=F_{rs}\simeq\Delta E'_\sigma-\Delta E_\sigma\simeq 2|C_r^N C_s^N| \quad \text{(in units of } |(\gamma'-\gamma)(-\beta)|) \qquad (7)$$

in which F_{rs} is σ new index representing the relative strength of the bond (rs).

In the present simplified treatment, the activation energy of the dissociation reaction does not vary according to whether it takes place in the radical or in the ionic mechanism. From this equation it is found that the larger the stabilization in the formation of the incipient bond between R and X, the less easily does the dissociation of the compound RX into R and X proceed.

Results and Discussion

Hydrogen Abstraction Reaction.—The reaction, $RH+R'\cdot \rightarrow R\cdot+R'H$, has also been discussed in our previous paper in terms of the reactivity indecis $f_r^{(R)}$ and $D_r^{(R)}$[3,4]. On that occasion we discussed the comparison of the reactivity of various RH's against a common R'· radical, so the energetical contribution of the attacking radicals was not taken into account. The new reactivity index, ΔE_σ, in Eq. 2, which has been derived by considering both the reactant molecule and the reagent with a σ NBMO in the transition state, enables us also to compare, e. g., the reactivity of RH against various alkyl-radicals. In Table II, the calculated values of ΔE_σ and $D_r^{(R)}$ for the hydrogen abstraction of saturated hydrocarbons are listed, together with values of the observed activation energy, E (kcal./mol.)[6]. In Fig. 3, the values of ΔE_σ are plotted against those of E. The linearity between the calculated and the observed values is seen; therefore, the value of $|C_r^N|$ in ΔE_σ for radical reactions may be said to reflect the reactivity of the alkyl radical.

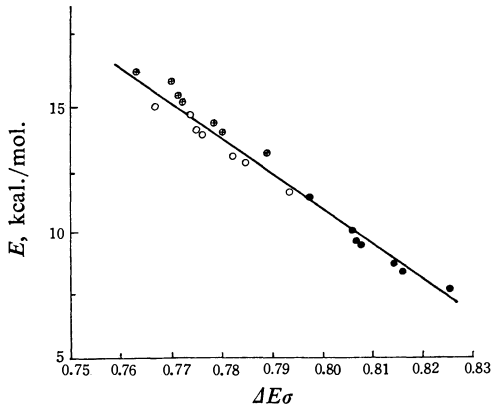

Fig. 3. The activation energy, E, of the reaction $RH+R'\cdot\rightarrow R\cdot+R'H$ vs. $\Delta E_\sigma=D_r^{(R)}(C_s^N)^2$.

Ionic Reaction.—The ionic dissociation reaction of saturated compounds is represented by the general formula $RX\rightarrow R^+ + X^-$, where X is, e. g., a halogen atom or a OH group. The quantity, F_{rs}, in Eq. 7 is adopted as the reactivity index of this type of reaction, assuming that the energy of the half-occupied orbital appearing in the X group in the transition state is nearly equal to α. Referring to the absolute value of the coefficient of the σ NBMO of various R– compounds, $|C_r^N|$, the order of easiness of dissociation of alkyl groups is predicted as follows:

$$CH_3 < C_2H_5 < n\text{-}C_3H_7 < n\text{-}C_4H_8 < i\text{-}C_3H_7 < i\text{-}C_5H_{12} < t\text{-}C_4H_9$$

In Fig. 4, the values of the heat of the gas-phase ionic dissociation of alkyl derivatives[7] are plotted against the $|C_r^N|$ values of the alkyl groups. Here, the upper oblique line corresponds to the dissociation reaction of ROH, the lower one, to that of RCl. In Fig. 5, the values of the heat of the reaction of the $RH\rightarrow R^+ + H^-$ type are plotted against

* It may be allowed to consider that repulsion term in RX does not differ so much from that in R···X.

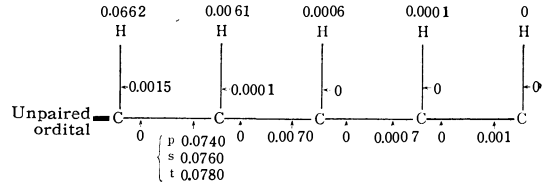
those of the $|C_r^N|$ values of various alkyl groups. The parallelism between the observed and the calculated values is obvious.



C–C Bond Fission.—How to obtain easily the strength of the C–C bond of a hydrocarbon molecule is a problem of interest not only from a theoretical but also from a practical point of view. The fission of a C–C bond is in general represented by

$$R\text{–}S \rightarrow R + S$$

in which R and S are alkyl groups. Using the σ NBMO method, we can easily obtain from Eq. 7 the activation energy of a C–C fission which we can adopt as a measure of the relative strength of the C–C bond. Namely,

$$F_{rs}=2|C_r^N C_s^N|$$

in which F_{rs} is the relative strength of the bond (rs) of the parent molecule. The calculated values of F_{rs} to each C–C bond in the isomeric hexanes are listed in Table III, together

(The notations p, s, and t stand for the cases where the carbon atom having the unpaired hybridized orbital is a primary, a secondary, and a tertiary carbon, respectively.)

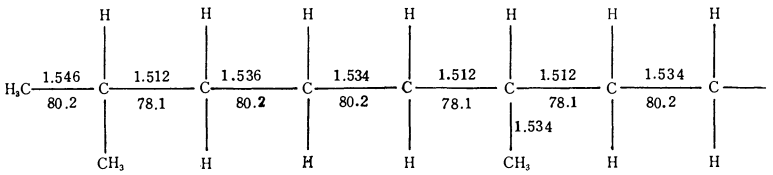
Fig. 6. Diagram of approximate distribution of odd electron density of saturated hydrocarbons.

with the calculated bond energies[8] and the observed G-values obtained by radiolysis[9]. The parallelism between the calculated and the observed results is good. The calculated values of $|C_r^N|$ are obtained by means of the approximate values of odd electron distribution, as shown in Fig. 6, which is estimated by the regularity, as shown in Fig. 1. In Fig. 7, two calculated values[10] for the squalane molecule ($C_{30}H_{62}$) are given. The agreement between the calculated and the observed results[10] is almost entirely on satisfactory. From the two examples stated above, one can see that the F_{rs} index is a good and extremely simple index for the relative strength of a C–C bond.

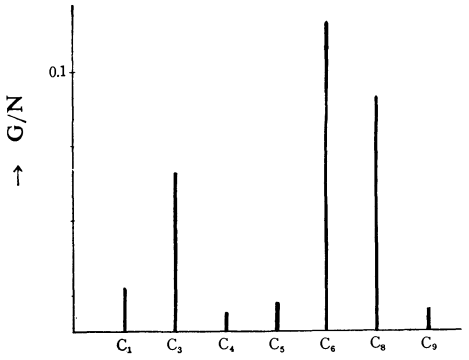
The next problem is the catalytic cracking of hydrocarbons. Consider the decomposition of a carbonium ion represented by

$$R_1^+ \rightarrow R_2^+ + \text{olefin}$$

Several examples of this type of reaction are as follows:



1 $R\text{–}CH_2\text{–}CH_2^+ \rightarrow R^+ + C_2H_4$



2 $R\text{–}CH_2\text{–}CH^+\text{–}CH_3 \rightarrow R^+ + C_3H_6$

3 $R\text{–}CH(CH_3)\text{–}C^+(CH_3)\text{–}CH_3 \rightarrow R^+ + i\text{-}C_4H_9$

In this case, the observed energy of the bond fission, ΔH (kcal./mol.)[11], is expected to be parallel to the value of F_{rs}, provided that one can assume the appearance of two σ NBMO's at the R_r–C_s bond in the transition state. In each series, 1, 2 and 3, of the reactions indicated above, the olefin molecule produced is the same, so the value of F_{rs} is proportional to the $|C_r^N|$ value of R only. In Fig. 8, the calculated $|C_r^N|$ values of R and the observed values of ΔH are given for the sake of comparison.

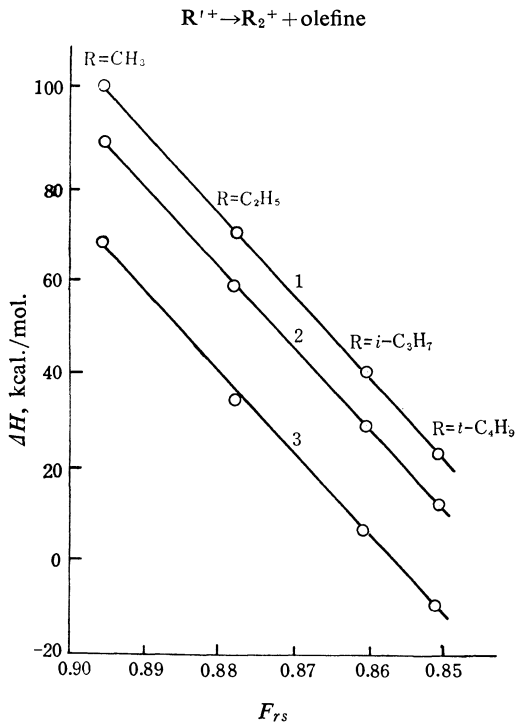

Fig. 8. The heat of reaction, ΔH, of C-C bond fission in alkyl cations vs. $F_{rs}=\text{const}\times|C_r^N|$ at the bond rs in R'^+ to be cloven.
1 $R\text{-}CH_2\text{-}CH_2^+ \rightarrow R^+ + C_2H_4$
2 $R\text{-}CH_2\text{-}CH^+\text{-}CH_3 \rightarrow R^+ + C_3H_6$
3 $R\text{-}CH_2\text{-}C^+(CH_3)\text{-}CH_3 \rightarrow R^+ + C_4H_8$

β-Fission Rule.—The C–C bond, β, to the charged carbon atom in an alkyl cation is often selectively cloven. This phenomenon is well known as the β-fission rule. This rule is satisfactorily explained by the relative bond strength of F_{rs}. That is, in the actual species of an alkyl ion or an alkyl radical, the hybridization of the carbon atom in question may be changed from sp^3 to sp^2. The odd electron distribution of some alkyl, i. e., $\overset{*}{C}H_2$–, $\overset{*}{C}H_2CH_2$– and $\overset{*}{C}H_2CH_2CH_2$–, are calculated by using the parameters of the sp^3 and sp^2 hybridized orbitals for the carbon atom designated by *[12]. The calculated results are shown in Fig. 9. For a long straight chain hydrocarbon, the $|C_s^N|$ coefficient of the unpaired hybridized orbital in the σ NBMO of the radical R′ appearing as the result of the fission of the rs bond $|C_s^N|$ (see the figure below) is almost independent of the position s. Hence, the relative C–C bond strength of these * compounds is measured by the $|C_r^N|$ values with respect to the C–C bond in question.

$$\underbrace{\overset{*}{C}H_2\text{–}CH_2\cdots CH_2}_{R}\overset{r\ \ s}{\text{——}}\underbrace{CH_2\cdots\cdots CH_3}_{R'}$$

These results are summarized in Fig. 10, where it is observed that the value of $|C_r^N|$ is the smallest at the β bond to the carbon atom

designated by *. It is thus found that the β C–C bond becomes the weakest owing to the change in the hybridization of the * carbon atom.

This procedure will also be applied to treating the β fission problem of alkyl aromatics.
