On hydrolysis of VIII a high-boiling viscous oil, $C_{22}H_{38}O_3$, besides IX was also obtained in a 12.4% yield. This compound reduced Tollens' reagent and its infrared spectrum showed the presence of a carbonyl group but no hydroxyl group, while almost all characteristic absorption bands in the finger print region, especially those at 1460 to 900 cm^{-1}, showed close resemblance to those of IX. With the Brady reagent this compound afforded the same 2, 4-dinitrophenylhydrazone as that from IX. It was obvious, therefore, that the ether linkage of this compound is readily cleaved by the action of acid to yield IX. Consequently, for this compound (3,4,5-trimethyl-2-formylcyclohexylmethyl-4′, 5′, 6′-trimethyloctahydroisobenzofuryl-3′)-ether (X) was assigned. It can be

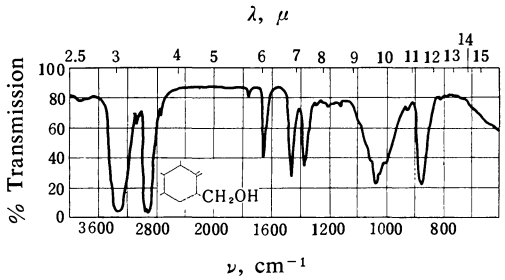
considered that on hydrolysis this compound, through the fission of the tetrahydrofuran ring, was converted into IX via a temporary intermediate XI.

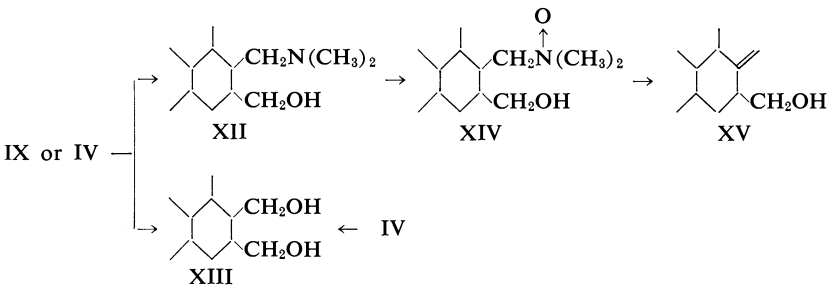
XI

On reductive alkylation of dimethylamine with IX in the presence of a Raney nickel catalyst in ethanol, *N, N*-dimethyl-6-hydroxymethyl - 2, 3, 4 - trimethylcyclohexylmethylamine (XII) was obtained in a yield of 66% accompanying by an appreciable amount of 1, 2-dihydroxymethyl - 3, 4, 5 - trimethylcyclohexane (XIII) which was proved identical with that prepared by hydrogenating the compound IV. In an attempt to prepare XII in one step, IV and dimethylamine were catalytically hydrogenated at 200°C and then was obtained the expected aminoalcohol XII in a 30% yield and a considerable amount of neutral product consisting mainly of XIII and a small amount of IX was also isolated. From the above results, it is presumed for sure that the initial addition of dimethylamine to a carbonyl group of the compound IV has been markedly hindered by a benzyloxymethyl group.

Oxidation of XII to the corresponding *N*-oxide XIV, followed by thermal decomposition of the latter in the same manner as described for *N,N*-dimethyl-2-hydroxymethyl-4,5-dimethylcyclohexylmethylamine[5] afforded in a 67% yield *N, N*-dimethylhydroxylamine which was characterized as hydrochloride and in a 58% yield 2-methylene-3, 4, 5-trimethylcyclohexylmethanol (XV), b. p. 122~124°C/14 mmHg, n_D^{15} 1.4925, whose infrared spectrum (Fig. 1) showed the presence of both hydroxyl (3333 and 1050 and exocyclic methylene group (3096, 1645 and 889 cm^{-1}). The compound XV was further characterized as allophanate, m. p. 152~153°C.

The amino alcohol XII was oxidized to yield





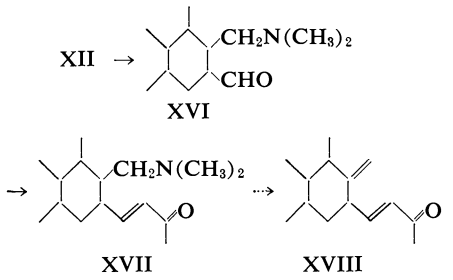


Fig. 1. Infrared spectrum of 2-methylene-3, 4, 5-trimethylcyclohexylmethanol (XV). (liquid film)

N, N-dimethyl-2, 3, 4 - trimethyl - 6 - formylcyclohexylmethylamine (XVI) in a yield of 88% by a modified Oppenauer procedure which involved *p*-benzyloxybenzaldehyde as the hydrogen accepter. For the oxidation of alicyclic primary alcohols to prepare the corresponding aldehydes some modified Oppenauer procedures have been employed successfully, in which cinnamaldehyde[6,7], anisaldehyde[6,8,9] and piperonal[6] as the hydrogen acceptors have hitherto been used. The use of these hydrogen acceptors is particularly advantageous when the desired aldehyde boils at below ca. 100°C/15 mmHg, because an efficient isolation of the resulted aldehyde by continuous distillation can be readily attained. However, in the case of high-boiling material no fruitful result can be expected on account of increasing hazardousness in separation. In this point of view, it was found that only *p*-benzyloxybenzaldehyde is a satisfactory hydrogen acceptor for the oxidation of XII, and that it can be superior in all respects for the case in which the resulted aldehyde boils at below ca. 110°C/1.0 mmHg.

Condensation of the amino aldehyde XVI with acetone in the presence of sodium hydride afforded in a 70% yield the amino ketone XVII, which was fully identified by the infrared absorption spectrum. Several attempts were made in an effort to obtain 4-(2′-methylene-3′, 4′, 5′-trimethylcyclohexyl)-but - 3 - en - 2 - one

(XVIII) through the thermal decomposition of the *N*-oxide of XVII, however, a fruitful result has not yet been obtained.

Experimental[10]

Mixed Dimethyl-1, 3-pentadienes.—The same mixed diene (b. p. 107.5~108°C/753 mmHg, n_D^{20} 1.4664) which is a mixture of 37.5% 3, 4-dimethyl-1, 3-pentadiene (I) and 62.5% 2, 3-dimethyl-1, 3-pentadiene (II) as used in the previous paper[1] was employed.

4-Benzyloxy-2-buten-1-al (III).—4-Benzyloxy-2-buten-1-al (III) was prepared in the manner described previously[5] and had b. p. 122~123°C/2.8 mmHg and $n_D^{18.5}$ 1.5310.

6-Benzyloxymethyl-2, 3, 4-trimethyl-3-cyclohexenylmethanal (IV).—A mixture of III (27.5 g.), the mixed diene (16.5 g.) described above and benzene (35 ml.) was heated with a small amount of hydroquinone at 140~150°C for 14 hr. under nitrogen. The reaction product was fractionated through a short column to yield a pale yellow viscous oil (24.0 g.), b. p. 127~129°C/3×10^{-3} mmHg, n_D^{17} 1.5298. The analytical sample obtained by redistillation exhibited b. p. 129°C/3×10^{-3} mmHg and n_D^{17} 1.5299. ν_{max}^{film} 1720 (C=O), 1098 (C-O-C), 3030, 1502, 742 and 704 cm^{-1} (mono-substituted phenyl group).

Found: C, 78.60; H, 8.87. Calcd. for $C_{18}H_{24}O_2$: C, 79.37; H, 8.88%.

The thiosemicarbazone crystallized from ethanol in needles, m. p. 127~127.5°C. λ_{max}^{EtOH} 271 mμ (ε, 37400).

Found: N, 12.13. Calcd. for $C_{19}H_{27}ON_3S$: N, 12.17%.

The phenylsemicarbazone crystallized from ethanol in needles, m. p. 145~146°C. λ_{max}^{EtOH} 248.5 mμ (ε, 29700).

Found: C, 74.18; H, 7.75. Calcd. for $C_{25}H_{31}O_2N_3$: C, 74.04; H, 7.71%.

The 2, 4-dinitrophenylhydrazone crystallized from ethanol in orange-yellow needles, m. p. 108~109°C.

Found: C, 63.68; H, 6.21. Calcd. for $C_{24}H_{28}O_5N_4$: C, 63.70; H, 6.24%.

6-Benzyloxymethyl-2, 3, 4-trimethyl-3-cyclohexenylmethanal Ethylene Acetal (V).—A mixture of the aldehyde IV (45 g.), ethylene glycol (22 g., 100% excess), benzene (50 ml.) and *p*-toluenesulfonic acid (70 mg.) was heated under reflux at a bath temperature of 120~130°C for 4.7 hr. with an azeotroper. The cooled reaction mixture was neutralized with a 5% aqueous sodium carbonate solution and the benzene layer was separated. The aqueous ethylene glycol layer was thoroughly extracted with benzene. The combianed benzene layers were washed with saturated aqueous salt solution and with water, dried over sodium sulfate and evaporated. Distillation of the residue gave the acetal V (42 g., 80%) as a pale yellow viscous oil, b. p. 132~135°C/3×10^{-3} mmHg, n_D^{16} 1.5281.

Found: C, 75.82; H, 9.01. Calcd. for $C_{20}H_{28}O_3$: C, 75.91; H, 8.92%.

6-Benzyloxymethyl-2, 3, 4-trimethylcyclohexylmethanal Ethylene Acetal (VI).—The unsaturated acetal V (20.0 g.) in ethanol (30 ml.) was hydrogenated in the presence of a palladium-on-charcoal catalyst (2.5% Pd, 0.8 g.) for 5.5 hr. at 130°C and 60 kg./cm^2 in a 100 ml. stainless steel autoclave. Removal of the catalyst and solvent, followed by distillation of the residue gave the acetal VI (18.3 g., 91%) as a colorless viscous oil, b. p. 167~170°C/1.0 mmHg, n_D^{21} 1.5150.

Found: C, 75.05; H, 9.70. Calcd. for $C_{20}H_{30}O_3$: C, 75.43; H, 9.50%.

Hydrogenation and Hydrogenolysis of 6-Benzyloxymethyl-2, 3, 4-trimethyl-3-cyclohexenylmethanal Ethylene Acetal (V).—The acetal V (40 g.) in ethanol (40 ml.) was hydrogenated in the presence of a palladium-on-charcoal catalyst (5% Pd, 3.0 g.) at 110 kg./cm^2. A vigorous absorption of hydrogen began at 60°C and the decrease of inner pressure was finished when the temperature reached to 122°C during 7 hr. After the catalyst was removed the filtrate was evaporated under reduced pressure through a 20 cm. Vigreux column to obtain two clear layers. The lower layer was extracted repeatedly with ether and the ether extracts were combined with the upper layer. The combined ethereal solution was washed with water, dried over sodium sulfate and evaporated. The remaining oil was fractionated through a 10 cm. Vigreux column to give two distinct fractions, b. p. 66~70°C/2.0 mmHg, n_D^{12} 1.4761 and b. p. 85~100°C/2.0 mmHg, n_D^{15} 1.4719. The former was redistilled through a short column to afford 8, 9-*cis*-4, 5, 6-trimethyloctahydroisobenzofuran (VII) (5.4 g., 25.4%) having a strong menthol-like odor, b. p. 67°C/2.0 mmHg, $n_D^{13.5}$ 1.4750. ν_{max}^{film} 1457 (CH_2), 1383 (CH_3), 1053 (C-O-C), 1104, 905 and 886 cm^{-1} (tetrahydrofuran ring).

Found: C, 78.18; H, 11.43. Calcd. for $C_{11}H_{20}O$: C, 78.51; H, 11.98%.

The latter on redistillation gave 3-ethoxy-4, 5, 6-trimethyloctahydroisobenzofuran (VIII) (18.5 g., 69%), b. p. 90~100°C/2.0 mmHg, $n_D^{15.5}$ 1.4719, which showed the presence of a C-O-C-O-C group (1108, 995, 920 and 890 cm^{-1}), while the presence of neither carbonyl nor hydroxyl group was indicated in its infrared absorption spectrum.

Found: C, 73.55; H, 11.28. Calcd. for $C_{13}H_{24}O_2$: C,73.53; H, 11.39%.

Treatment with the Brady reagent gave in an excellent yield 6-hydroxymethyl-2, 3, 4-trimethylcyclohexylmethanal 2, 4-dinitrophenylhydrazone which had m. p. 177°C after crystallization from methanol.

10) All m. p. are uncorrected. The ultraviolet spectra were determined with a Hitachi model EPU-2A spectrophotometer and the infrared spectra were obtained with a Nippon Bunkō model IR-S and a Kōken model DS-301 recording spectrophotometers using sodium chloride prisms.

Found: C, 56.32; H, 6.50. Calcd. for $C_{17}H_{24}O_5 \cdot N_4$: C, 56.03; H, 6.64%.

From the residue leaving after being extracted the lower layer with ether, ethylene glycol (5.1 g., 86.5%) could be obtained.

Acid Hydrolysis of 3-Ethoxy-4, 5, 6-trimethyloctahydroisobenzofuran (VIII).—A mixture of VIII (18 g.), tetrahydrofuran (80 ml.) and 2 N sulfuric acid (80 ml.) was heated under reflux at 70~80°C for 7 hr. The resultant mixture was cooled and neutralized with a 10% aqueous sodium carbonate solution. After the bulk of the solvent was removed under reduced pressure, the remaining oil was extracted with ether and the ether extract was washed with a saturated aqueous salt solution and dried over sodium sulfate. Removal of the solvent, followed by distillation of the residue yielded a colorless oil (11 g.), b. p. 112~118°C/2.0 mmHg, n_D^{20} 1.4852 and a colorless viscous oil (2.6 g.), b. p. 188~195°C/2.5 mmHg, n_D^{16} 1.4977.

The former on redistillation gave the tautomeric mixture of 3-hydroxy-4, 5, 6-trimethyloctahydroisobenzofuran (IXa) and 6-hydroxymethyl-2, 3, 4-trimethylcyclohexylmethanal (IXb) (10.3 g., 64%), b. p. 113~116°C/2.0 mmHg, n_D^{17} 1.4875, whose infrared spectrum (liquid film) showed characteristic absorption bands at 3414, 1103 (OH), 998, 935, 910 cm^{-1} (C-O-C-O) and a weak band at 1721 cm^{-1} indicative of a carbonyl group. $\lambda_{max}^{70\% \text{ aq. dioxane}}$ 224 mμ (ε,102), 290 (9.6).

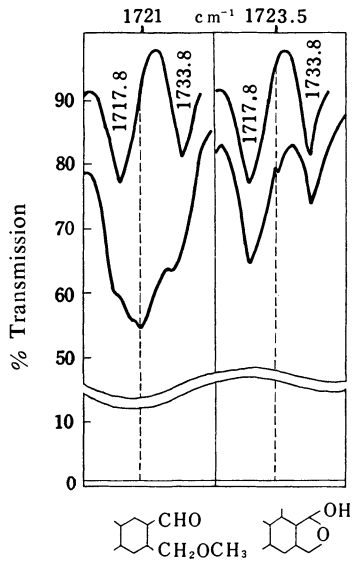

Fig. 2. Determination of the free aldehyde IXb in the tautomeric mixture of IXa and IXb.

(in carbon disulfide solution, 0.125 mm.)		
c (mol./l.)	0.0430	0.176
D	0.2516	0.0853
ε	5.85	0.485

Content of IXb: ca. 8.3%
(Perkin-Elmer model 112 spectrophotometer, NaCl prisms)

Found: C, 71.92; H, 10.98. Calcd. for $C_{11}H_{20} \cdot O_2$: C, 71.69; H, 10.94%.

The proportion of the free aldehyde IXb in the tautomeric mixture was ascertained, as shown in Fig. 2, by comparing the transmittance of the mixture at 1723.5 cm^{-1} with that of 4, 5-dimethyl-2-methoxymethylcyclohexylmethanal[5] at 1721 cm^{-1} in carbon disulfide at 20°C.

The 2, 4-dinitrophenylhydrazone prepared from the tautomeric mixture above was crystallized from ethanol to give yellow leaflets, m. p. 176~177°C, which was undepressed on admixture with that obtained directly from VIII.

After two redistillations the latter, high-boiling fraction afforded (3, 4, 5-trimethyl-2-formylcyclohexylmethyl-4′, 5′, 6′-trimethyloctahydroisobenzofuryl-3′)-ether (X), an intermolecular dehydration product of IX, b. p. 171~172°C, n_D^{19} 1.5017 (1.9 g., 12.4%), which showed a positive Tollens' test. Its infrared spectrum showed a strong carbonyl band at 1721 cm^{-1}, but no hydroxyl band. Moreover, almost all absorption bands indicated in the region of 1460 to 900 cm^{-1} agreed closely with those of IX. $\lambda_{max}^{75\% \text{ aq. dioxane}}$ 224 mμ (ε, 367), 295 (67).

Found: C, 75.48; H, 11.02. Calcd. for $C_{22}H_{38} \cdot O_3$: C, 75.38; H, 10.93%.

Treatment with the Brady reagent X gave in an excelient yield, a yellow 2, 4-dinitrophenylhydrazone which had m. p. 176~177°C after crystallization from ethanol and was identical with that prepared from IX. An attempt to prepare the semicarbazone of this compound in the usual manner has however been unsuccessful.

***N, N*-Dimethyl-6-hydroxymethyl-2, 3, 4-trimethylcyclohexylmethylamine (XII).** — *Reductive Condensation of Dimethylamine and 3-Hydroxy-4, 5, 6-trimethyloctahydroisobenzofuran (IX).*—A solution of IX (10.5 g.) and dimethylamine (4.3 g.) in ethanol (50 ml.) was hydrogenated with a Raney nickel catalyst (1.5 g.) for 2 hr. at 195~200°C and 109 kg./cm^2. After removal of the catalyst and solvent, the remaining colorless oil was dissolved in ether (80 ml.) and then extracted with 2 N hydrochloric acid (20 ml. × 3). The aqueous layer was made, after being washed once with ether, to strongly alkaline with a 10% aqueous sodium hydroxide solution under cooling. The regenerated organic base was taken up in ether and washed with water and dried over potassium carbonate. Removal of the solvent, followed by distillation of the residue yielded *N, N*-dimethyl-6-hydroxymethyl-2, 3, 4-trimethylcyclohexylmethylamine (XII) (8.2 g., 67.5%) as a colorless oil, b. p. 96~97°C/0.6 mmHg, n_D^{12} 1.4880. ν_{max}^{film} 2842, 2790, 2748 (*tert*-amino group), 3380, 1040 (OH), 837 cm^{-1} (unassigned).

Found: C,73.86; H, 12.67; N, 6.54. Calcd. for $C_{13}H_{27}ON$: C, 73.18; H, 12.76; N, 6.57%.

The methiodide crystallized from ethanol-ethyl acetate in leaflets, m. p. 204~206°C.

Found: C, 47.60; H, 8.33; N, 4.15. Calcd. for $C_{14}H_{30}ONI$: C, 47.30; H, 8.50; N, 3.95%.

The ether layer containing the neutral substance was washed with water, dried over sodium sulfate and evaporated. Distillation of the residue gave 1, 2-dihydroxymethyl-3, 4, 5-trimethylcyclohexane (XIII) (1.7 g., 16%) as a viscous oil, b. p. 140~

141.5°C/2.0 mmHg, n_D^{29} 1.4874. ν_{max}^{film} 3320, 1058 cm^{-1} (OH).

Found: C, 71.38; H, 11.90. Calcd. for $C_{11}H_{22}O_2$: C, 70.92; H, 11.90%.

The bis-*p*-nitrobenzoate crystallized from methanol in prisms, m. p. 161~162°C, which gave no melting point depression on admixture with that obtained by the other routes as described below.

Reductive Condensation of Dimethylamine and 6-Benzyloxymethyl-2, 3, 4-trimethyl-3-cyclohexenylmethanal (IV).—A solution of IV (3.5 g.) and anhydrous dimethylamine (1.2 g.) in ethanol (30 ml.) was hydrogenated over Raney nickel (1.0 g.) for 5 hr. at 200°C and 150 kg./cm^2. On similar treatment of the hydrogenated products to the manner in a), the basic fraction (0.85 g.) which had b. p. 97~99°C/0.5 mmHg and showed identical infrared spectrum with XII and the neutral fraction (1.4 g.), b. p. 110~140°C/2.0 mmHg, which was indicated to be mainly the diol XIII contaminated with a small amount of IX by its infrared spectrum, were obtained.

The basic fraction wats treated with methyl iodide to give in a good yield the methiodide of XII as leaflets, m. p. 206~207°C, which gave no melting point depression on admixture with that of the authentic XII and an appreciable amount of what is believed to be the methiodide of *N, N*-dimethyl-6-hydroxy-methyl-2, 3, 4-trimethyl-3-cyclohexenylmethylamine, which exhibited m. p. 258°C (decomp.) after being crystallized from ethanol-ethyl acetate.

Found: C, 47.78; H, 8.20. Calcd. for $C_{14}H_{28}ONI$: C, 47.65; H, 8.01%.

The neutral fraction was fractionated through a short Vigreux column to give the diol XIII (1.1 g., 46%), b. p. 140~142.5°C/2.0 mmHg, n_D^{20} 1.4905, which afforded the bis-*p*-nitrobenzoate, m. p. 162°C, after crystallization from methanol, identified by mixed melting point with an authentic sample.

Preparation of 1, 2-Dihydroxymethyl-3, 4, 5-trimethylcyclohexane (XIII) by Hydrogenation of IV.—The aldehyde IV (3.5 g.) in ethanol (25 ml.) was hydrogenated over Raney nickel (3.5 g.) for 5 hr. at 210~225°C and 190 kg./cm^2. Removal of the catalyst and solvent, followed by distillation of the residue gave a small fore-run and the diol XIII (1.95 g., 81.5%), b. p. 137°C/1.8 mmHg, n_D^{30} 1.4900.

Found: C, 71.11; H, 11.95. Calcd. for $C_{11}H_{22}O_2$: C, 70.92; H, 11.90%.

The bis-*p*-nitrobenzoate crystallized from methanol in leaflets, m. p. 162°C.

Found: C, 61.92; H, 5.96. Calcd. for $C_{25}H_{28}O_8N_2$: C, 61.97; H, 5.83%.

2-Methylene-3, 4, 5-trimethylcyclohexylmethanol (XV).—A mixture of the amino alcohol XII (1.2 g.), methanol (6 ml.) and 30% aqueous hydrogen peroxide (3 ml.) was stirred for 24 hr. at room temperature and allowed to stand for additional 48 hr. with occasional stirring, at which time it gave a negative spot test for the amine with phenolphthalein. Excess hydrogen peroxide was decomposed by stirring the solution with a platinum foil (0.8 g.) for 2 days at room temperature. The solution, after being removed the platinum foil, was concentrated under reduced pressure at a bath temperature of 30~40°C and the residual syrup was diluted with absolute ethanol (7 ml.) and reconcentrated. After the process was repeated five times to remove as much water as possible, *N, N*-dimethyl-6-hydroxymethyl-2, 3, 4-trimethylcyclohexylmethylamine oxide (XIV) was obtained as a colorless syrup.

A 30 ml. Claisen flask fitted with a 10 cm. Vigreux column containing the *N*-oxide XIV prepared as above was connected to a condenser, which led to two receivers in series, first cooled in a freezing mixture and second in a liquid nitrogen respectively. Decomposition of the *N*-oxide and distillation of the product began at 130°C and was complete at 140°C after 1 hr., at which time practically no material remained in the flask. The distillate was dissolved in ether (40 ml.) and washed with cold 5% hydrochloric acid and with water and dried over magnesium sulfate. Removal of the solvent, followed by distillation of the residue under nitrogen afforded 2-methylene-3, 4, 5-tri-methylcyclohexylmethanol (XV) (0.55 g., 58% based on XII) as a colorless oil, b. p. 122~124°C/14 mmHg, n_D^{15} 1.4925. The infrared spectrum of this compound was shown in the theoretical part.

Found: C, 78.12; H, 11.60. Calcd. for $C_{11}H_{20}O$: C, 78.51; H, 11.98%.

The allophanate crystallized from methanol, m. p. 152~153°C.

Found: C, 61.60; H, 8.65. Calcd. for $C_{13}H_{22}O_3N_2$: C, 61.39; H, 8.72%.

The combined washings containing hydrochloric acid were evaporated to dryness. The residue was diluted with absolute ethanol, reconcentrated under reduced pressure and the process was repeated 4 times to remove as much water as possible. The crystalline solid that remained was crystallized from absolute ethanol, after treatment with active charcoal, to afford *N, N*-dimethylhydroxylamine hydrochloride (0.37 g., 67%) as colorless needles, m. p. 105°C, which gave no melting point depression on admixture with an authentic sample.

***p*-Benzyloxybenzaldehyde.**—A solution of *p*-hydroxybenzaldehyde (24.4 g.) in ethanol (40 ml.) was added with cooling to sodium ethylate (prepared from 4.6 g. of sodium) in ethanol (70 ml.). Benzylchloride (25.3 g.) was then added slowly and the mixture was heated in a 300 ml. glass bomb at 130~140°C for 1.5 hr. when sodium chloride was precipitated completely. The reaction mixture was filtered and the precipitate was washed with a small amount of hot benzene. The filtrates were combined and concentrated under reduced pressure. The orange residue was dissolved in a mixture of benzene (200 ml.) and ether (200 ml.), washed with 10% aqueous sodium carbonate and with water, dried over sodium sulfate and evaporated. The residue was distilled under nitrogen or, more conveniently, crystallized from ethanol to give *p*-benzyloxybenzaldehyde (38.0 g., 89.5%), b. p. 187~189°C/5 mmHg, b. p. 155~156°C/1.1 mmHg, m. p. 73.5~74°C (lit.[11] m. p. 72°C).

Found: C, 79.36; H, 5.96. Calcd. for $C_{14}H_{12}O_2$: C, 79.22; H, 5.70%.

11) E. Wörner, *Ber.*, **29**, 142 (1896).

When the reaction was carried out at a temperature of 150~160°C, yield of the product decreased to ca. 60~70%.

p-Benzyloxybenzaldehyde is stable even when it was heated for several hours at 240~250°C under a nitrogen atomosphere.

The semicarbazone crystallized from ethanol in needles, m. p. 201~202°C.

Found: N, 15.75. Calcd. for $C_{15}H_{15}O_2N_3$: N, 15.61%.

The 2, 4-dinitrophenylhydrazone crystallized from ethanol-ethyl acetate in orange needles, m. p. 231~232°C.

Found: N, 14.05. Calcd. for $C_{20}H_{16}O_5N_4$: N, 14.28%.

***N*, *N*-Dimethyl-6-formyl-2, 3, 4-trimethylcyclohexylmethylamine (XVI).**—Aluminum isopropoxide (1.3 g., 120%) was added to the amino alcohol XII (3.4 g.) in a 15 ml. pear-shaped Claisen flask equipped with a 10 cm. Vigreux column. The isopropanol formed was removed over the course of 1.5 hr. at a bath temperature of 70~80°C and 10~12 mmHg pressure. To the XII-aluminate was then added *p*-benzyloxybenzaldehyde (5.6 g., 160%) in one portion, and the mixture was warmed at 80°C for a few minutes to make it homogeneous and distilled slowly by raising the bath temperature from 120 to 180°C. (1.0 mmHg pressure) during 40 min. under nitrogen. Fractionation of the distillate afforded the amino aldehyde XVI (2.95 g., 88%), b. p. 90~92°C/1.2 mmHg, n_D^{18} 1.4833, whose infrared spectrum indicated the presence of a carbonyl (1706) and a *tert*-amino group (2840, 2800 and 2745 cm^{-1}), but no hydroxyl group.

Found: C, 73.86; H, 11.95; N, 6.96. Calcd. for $C_{13}H_{25}ON$: C, 73.88; H, 11.92; N, 6.63%.

An attempt to prepare the 2, 4-dinitrophenylhydrazone of XVI using the Brady reagent gave instead the sulfate of the desiredder ivative. Basifying an aqueous solution of this salt with 10% aqueous sodium hydroxide yielded the free 2, 4-dinitrophenylhydrazone, which was chromatographed from benzene-petroleum ether (1 : 1) on alumina and crystallized from methanol to give orange-yellow needles, m. p. 189~190°C.

Found: N, 17.30. Calcd. for $C_{19}H_{29}O_4N_5$: N, 17.89%.

4-(2'-*N*, *N*-Dimethylaminomethyl-3', 4', 5'-trimethylcyclohexyl)-but-3-en-2-one (XVII). — The amino aldehyde XVI (2.8 g.) in acetone (15 ml.) was added to a solution of sodium hydride (100 mg.) in acetone (25 ml., freshly distilled after being treated with potassium permanganate) and the stirring was continued for 4.5 hr. at room temperature under nitrogen. After removal of the solvent, the residual oil was dissolved in ether and extracted with 10% hydrochloric acid. The aqueous layer was washed once with petroleum ether, basified with 10% aqueous sodium hydroxide and the free base regenerated was taken up in ether. The combined ether extracts were washed with water, dried over sodium sulfate and evaporated. Distillation of the residue gave the amino ketone XVII (2.4 g., 70%) as a pale yellow oil, b. p. 122~123°C/0.6 mmHg, $n_D^{25.5}$ 1.4898. ν_{max}^{film} 1678 (C=O, conju.), 1620 (C=C, conju.), 983 (-CH=CH-, trans), 2836, 2790, 2750 (*tert*-amino group), 1256 (=CH-CO-), 1380 (CH_3), 1361 cm^{-1} (CH_3CO).

Found C, 75.00; H, 11.89. Calcd. for $C_{16}H_{29}ON$: C, 76.44; H, 11.63%.

We wish to thank Dr. Asaji Kondo of the Tokyo Institute of Technology for microanalyses and Dr. Kenji Kuratani of the Aeronautical Institute of the University of Tokyo and Dr. Tadashi Satō of the Waseda University for infrared spectroscopy.

Syntheses of γ-Ionone Analogues. V. 8, 9-cis-4, 5, 6-Trimethyloctahydroisobenzofuran and its Derivatives[1]

By Atsuaki ARAI and Iwao ICHIKIZAKI

(Received July 6, 1961)

In the preceding paper[2] we briefly described an oil, $C_{11}H_{20}O$, which was obtained as one of the hydrogenolysis products of the ethylene acetal of 6-benzyloxymethyl-2, 3, 4-trimethyl-3-cyclohexenylmethanal (V). The infrared spectrum and some properties of this compound resembled those of octahydroisobenzofuran[3] and it showed bands in the infrared region (Fig. 1) at 905 and 886 cm^{-1} characteristic of a tetrahydrofuran ring and at 1053 cm^{-1} indicative of an ether group. M^me^ Mousseron-Canet and her co-laborators[4] have pointed out

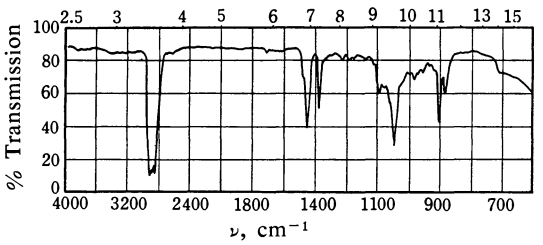
4) M. Mousseron-Canet and M. Granier, *Bull. soc. chim.*, 1959, 473; M^me^ Mousseron, M. Mousseron and M. Granier, ibid., 1960, 1418.

in their study on the infrared spectra of the octahydroisobenzofuran series that the absorption band of a C–O–C group at 1000 to 1100 cm^{-1} offers an available information to determine the conformation of cyclic oxide, and they have shown by pertinent comparison with the two stereoisomers of tricyclic oxide which are derivatives of the gem. dimethyloctaline that the cis isomer indicates a characteristic band at 1056 to 1060 cm^{-1}, whereas the trans shows a band at 1020 cm^{-1}. Thus, the structure of 8, 9-*cis*-4, 5, 6 - trimethyloctahydroisobenzofuran (I) was assigned for the oil and it was supported also by the succeeding experimental evidences as described below.



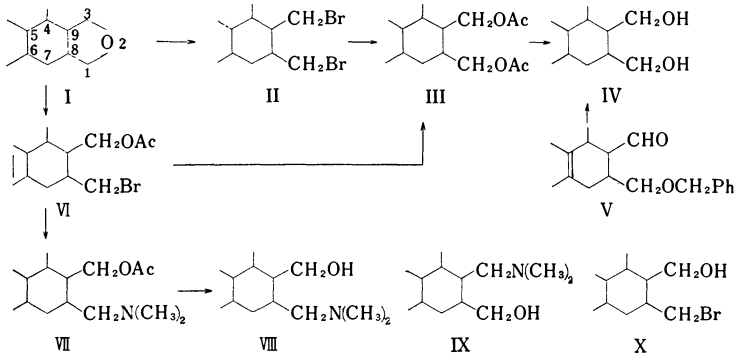


Fig. 1. Infrared spectrum of 8,9-*cis*-4,5,6-trimethyloctahydroisobenzofuran (I).

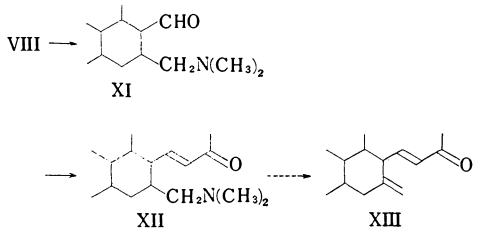
The compound I reacted with hydrogen bromide in glacial acetic acid at 100°C to give a mixture of dibromide II and a small amount of any acetoxy compounds which showed an infrared absorption band with ν_{max} 1737 cm^{-1}. The mixture could be mostly converted into 1, 2-diacetoxymethyl-3, 4, 5-trimethylcyclohexane (III) on being heated under reflux in glacial acetic acid containing potassium acetate and acetic anhyride and simultaneously gave a considerable amount of I. On alkaline hydrolysis III afforded a high yield of 1, 2-dihydroxymethyl-3, 4, 5-trimethylcyclohexane (IV) which was identical with the hydrogenation product[2] of the compound V. On the other hand, with acetyl bromide in the presence of zinc chloride I reacted to give a bromo acetate, $C_{13}H_{23}O_2Br$, in an expellent yield, which upon further acetylation followed by saponification yielded the diol IV. Although it has been well-known that tetrahydro-furans and -pyrans are generally cleaved by hydrogen halides[5-8] or acid halides[8-10] to give the corresponding dihalides or haloesters, no study on the cleavage of the asymmetric oxide ring as in I has been reported. Now it becomes interesting for us whether the cleavage takes place at the C(1)–O or it does at the C(3)–O linkage.

On treatment with an excess of anhydrous dimethylamine in absolute methanol the bromo acetate obtained above afforded 30% yield of an amino acetate, $C_{15}H_{29}O_2N$, and 35% yield of the parent oxide I, while the starting substance was also recovered in part. Alkaline hydrolysis of this amino acetate gave a high yield of the corresponding amino alcohol, $C_{13}H_{27}ON$, whose infrared absorption bands in almost all regions have close resemblance to those of *N*, *N*-dimethyl-6-hydroxymethyl-2, 3, 4-trimethylcyclohexylmethylamine (IX)[2]. Its methiodide, m. p. 202~203°C, resembled that of IX melted at 204~206°C in many respects, but the mixture melting point showed a marked depression. It is, therefore, no doubt that the amino alcohol is to be a structural isomer of IX and that in it the hydroxymethyl and the *N*, *N*-dimethylaminomethyl groups are reversely located as compared with IX. Thus, we assigned *N*, *N*-dimethyl-2-hydroxymethyl-3, 4, 5-trimethylcyclohexylmethylamine (VIII) for this compound. *N*, *N*-Dimethyl-2-acetoxymethyl-3, 4, 5 - trimethylcyclohexylmethylamine (VII) and 2-acetoxymethyl-1-bromomethyl-3, 4, 5-trimethylcyclohexane (VI) were accordingly assigned for the amino acetate and the bromo acetate, respectively. Furthermore, it became clear that the fission of the tetrahydrofuran ring in I with acetyl bromide occurs essentially in the 1, 2-position. And in the course of reaction involving the ring fission and the reverse cyclization it has been proved that the configuration of oxide I is completely retained still in the derivatives as stated for octahydroisobenzofuran[8]. The compound V is believed to have a 1, 6-*cis* conformation according to the Alders' rule authorized by a number of investigators[11,12]. The 8, 9-*cis* conformation previously proposed for the oxide by its infrared spectral analysis, therefore, received further support from the fact that I as well as V gives the same diol IV.



The formation of I in the course of amination of the bromo acetate VI may be conveniently explained by considering the bromo alcohol X as an intermediate, which would be formed readily by the interaction of the acetoxyl group and dimethylamine and converted into oxide I by the base promoted elimination of hydrogen bromide, since such

halo alcohols have been commonly used for the most effective preparation of the oxides in this series[8].

The amino alcohol VIII was oxidized by a modified Oppenauer procedure with *p*-benzyloxybenzaldehyde as a hydrogen acceptor[2] to give a high yield of *N*, *N*-dimethyl-2-formyl-3, 4, 5-trimethylcyclohexylmethylamine (XI), which afforded on condensation with acetone in the presence of sodium hydride 4-(6′-*N*, *N*-dimethylaminomethyl-2′, 3′, 4′-trimethylcyclohexyl)-but-3-en-2-one (XII) in 59% yield. Two compounds XI and XII were fully identified by the infrared spectrum. The latter compound would seem to be an intermediate to 4-(6′-methylene-2′, 3′, 4′-trimethylcyclohexyl)-but-3-en-2-one (XIII), an analogue of γ-irone, but further investigation has not been performed.

Experimental[13]

8, 9-*cis*-4, 5, 6-Trimethyloctahydroisobenzofuran (I).—Compound I was previously obtained[2] as one of the hydrogenolysis products of the ethylene acetal of 6-benzyloxymethyl-2, 3, 4-trimethyl-3-cyclohexenylmethanal (V). A sample having b. p. 66～68°C/1.8 mmHg and n_D^{27} 1.4739 was used for the next experiments. Its infrared spectrum is shown in the theoretical part.

1, 2-Dibromomethyl-3, 4, 5-trimethylcyclohexane (II).—A mixture of oxide I (6.7 g.) and acetic acid (20 ml.) containing anhydrous hydrogen bromide (9.0 g.) was heated for 5 hr. at 100°C in a 50 ml. glass bomb. Hydrogen bromide and acetic acid were distilled off and the remaining oil was dissolved in chloroform (15 ml.). The chloroform solution was washed with 20% aqueous sodium bicarbonate and with water and dried over sodium sulfate. The solvent was removed and the residue was distilled to give a colorless pleasant smelling liquid (7.5 g.), b. p. 106～107.5°C/0.8 mmHg, n_D^{11} 1.5248, whose infrared spectrum showed the presence of an acetate group (1737 cm^{-1}) and no hydroxyl group.

Found: C, 46.46; H, 7.20. Calcd. for $C_{11}H_{20}Br_2$ (II): C, 42.31; H, 6.41%.

From the above infrared spectrum and elemental analysis it was believed that the product consists of 1, 2-dibromomethyl-3, 4, 5-trimethylcyclohexane (II) and a considerable amount of any acetoxy derivative.

1, 2-Diacetoxymethyl-3, 4, 5-trimethylcyclohexane (III).—The crude dibromide (4.3 g.) obtained above was heated under reflux with acetic acid (60 ml.) containing potassium acetate (15 g.) and acetic anhydride (3 ml.) for 37 hr. After the bulk of acetic acid was removed under reduced pressure, the residue was extracted with ether and the ether extract was washed with a 20% aqueous sodium carbonate solution and with water, dried over sodium sulfate and evaporated. Distillation of the residue gave a fore-run (0.9 g.) consisting largely of the oxide I, b. p. 65～67°C/1.65 mmHg, and a high-boiling oil (1.8 g.) had b. p. 105～107°C/0.6 mmHg and n_D^{15} 1.4760, which gave on redistillation through a 10 cm. Vigreux column the diacetate III, b. p. 108°C/0.75 mmHg, n_D^{18} 1.4740. ν_{max} (liquid film) 1737 (ester, C=O), 1237 (ester, C-O-C) and 1035 cm^{-1} (C-O).

Found: C, 66.45; H, 9.76. Calcd. for $C_{15}H_{26}O_4$: C, 66.63; H, 9.69%.

2-Acetoxymethyl-1-bromomethyl-3, 4, 5-trimethylcyclohexane (VI).—A mixture of I (4.4 g.), freshly distilled acetyl bromide (4.0 g., 125%), and zinc chloride (0.2 g.) was heated under reflux for 1.5 hr. in which time boiling had ceased. The dark-brown reaction mixture was dissolved in chloroform and the chloroform solution was washed with aqueous sodium bicarbonate and with water, dried and evaporated. The remaining oil was distilled to afford the bromo acetate VI (5.4 g., 71%) as a pale yellow, pleasant smelling oil, b. p. 102～105°C/

13) All melting points and boiling points are uncorrected. Infrared spectra were measured with a Nippon Bunkō model IR-S double-beam recording spectrophotometer with sodium chloride optics.

0.65 mmHg, n_D^{11} 1.5032. For analysis a sample was redistilled through a 8 cm. Vigreux column; b. p. 104～104.5°C/0.5 mmHg, 121～122°C/1.2 mmHg, n_D^{12} 1.5090. ν_{max} (liquid film) 1738 (ester, C=O), 1234 (ester, C-O-C), 1034 (C-O) and 1384, 1372 cm^{-1} (doublet, CH_3 and O-$COCH_3$ groups).

Found: C, 53.38; H, 7.85. Calcd. for $C_{13}H_{23}O_2 \cdot Br$: C, 53.60; H, 7.92%.

1,2-Dihydroxymethyl-3,4,5-trimethylcyclohexane (IV).—*a) Alkaline Hydrolysis of III.*—A solution of the diacetate III (0.55 g.) and potassium hydroxide (0.3 g.) in methanol (7 ml.) was allowed to stand for 41 hr. at room temperature. The reaction mixture was neutralized with 2 N sulfuric acid under cooling and then extracted, after the removal of the bulk of methanol, with ether. The ether extract was washed with water and dried over sodium sulfate. Removal of the solvent followed by distillation of the residue and yielded diol IV (0.35 g., 92.5%) as a viscous oil, b. p. 128～130°C/0.65 mmHg, n_D^5 1.4925. ν_{max} (liquid film) ～3300 and ～1045 cm^{-1} (OH).

Found: C, 70.99; H, 11.76. Calcd. for $C_{11}H_{22}O_2$: C, 70.92; H, 11.90%.

The bis-*p*-nitrobenzoate crystallized from methanol in needles, m. p. 161～162°C, which gave no melting point depression on admixture with that of the diol obtained previously[2] from 6-benzyloxymethyl-2,3,4-trimethyl-3-cyclohexenylmethanal (V).

Found: C, 61.88; H, 5.96. Calcd. for $C_{25}H_{28} \cdot O_8N_2$: C, 61.97; H, 5.83%.

b) Further Acetylation Followed by Alkaline Hydrolysis of VI.—A mixture of the bromo acetate VI (2.2 g.), acetic acid (25 ml.), potassium acetate (10 g.) and acetic anhydride (1.8 ml.) was heated under reflux for 20 hr. The bulk of acetic acid and acetic anhydride was removed under reduced pressure, and the orange-brown residue was dissolved in solution of potassium hydroxide (3.0 g.) in 90% methanol (15 ml.) and the solution was set aside for 24 hr. at room temperature. The reaction mixture was treated with the same method as described for a) to afford VI (0.8 g., 56.8%), b. p. 140～142°C/2.1 mmHg, n_D^{29} 1.4870, whose infrared spectrum and solid derivative were identical with those of the diol IV prepared in the method of a).

Reaction of the Bromo Acetate VI with Dimethylamine.—A solution of the bromo acetate VI (3.4 g.) and anhydrous dimethylamine (6.5 g., 10 times of the theoretical amounts) in absolute ethanol (17 ml.) was allowed to stand for 10 days at room temperature in a 50 ml. amber glass bomb. After removal of the solvent and dimethylamine under reduced pressure, the residue was dissolved in ether (30 ml.). The ethereal solution was extracted with three 10 ml. portions of 2 N hydrochloric acid and the combined extracts were washed once with light petroleum and then made to basic with 10% aqueous alkali under cooling. The organic base regenerated was taken up in ether and the ether layer was washed with an aqueous saturated salt solution, dried over sodium sulfate and evaporated. Distillation of the residue to give a slightly yellow oil (0.75 g.), b. p. 90～91°C/0.5 mmHg, n_D^{16} 1.4808, whose infrared spectrum showed characteristic absorptions of the acetyl group at 1739 and 1240 cm^{-1} and *tert*-amino group at 2846, 2800 and 2755 cm^{-1}, and weak bands the hydroxyl group at of ～3390 and ～3200 cm^{-1}.

Found: C, 70.88; H, 11.36; N, 5.62. Calcd. for $C_{15}H_{29}O_2N$: C, 70.54; H, 11.45; N, 5.48%.

It is believed, therefore, that above oil consists of *N,N*-dimethyl-2-acetoxymethyl-3,4,5-trimethylcyclohexylmethylamine (VII) contaminated with a small amount of its hydrolyzed product VIII.

The ethereal solution remained was washed with water, dried over sodium sulfate and evaporated. The residue was distilled to give the oxide I (0.7 g., 35%), b. p. 51～52°C/0.5 mmHg, n_D^{12} 1.4803, (Found: C, 78.61; H, 11.82%), and to recover the unchanged VI (0.5 g., 14.7%), b. p. 104～105°C/0.5 mmHg.

***N,N*-Dimethyl-2-hydroxymethyl-3,4,5-trimethylcyclohexylmethylamine (VIII).**—A solution of the amino acetate VII (0.3 g.) and potassium hydroxide (0.3 g.) in methanol (5 ml.) was kept for 40 hr. at room temperature. Ether (50 ml.) was added to the reaction mixture and the resultant solution was washed with a saturated aqueous salt solution, dried over potassium carbonate and evaporated. Distillation gave the amino alcohol VIII (0.24 g.) as a colorless liquid, b. p. 87～89°C/0.5 mmHg, n_D^{10} 1.4852. ν_{max} (liquid film) 3395, 3200, 1041 (OH); 2840, 2790, 2750 (-$N(CH_3)_2$); 848, 833 cm^{-1} (unassigned).

Found: C, 73.17; H, 12.82; N, 6.62. Calcd. for $C_{13}H_{27}ON$: C, 73.18; H, 12.76; N, 6.57%.

In a separate preparation from VI without isolation of the amino acetate VII, 35% over-all yield of VIII was obtained.

The methiodide crystallized from methanol-ethyl acetate in leaflets, m. p. 202～203°C, which showed a marked depression in the mixed melting point determination with that of *N,N*-dimethyl-6-hydroxylmethyl-2,3,4-trimethylcyclohexylmethylamine (IX) melted at 204～206°C.

Found: C, 47.28; H, 8.74; N, 3.83. Calcd. for $C_{14}H_{30}ONI$: C, 47.30; H, 8.50; N, 3.95%.

***N,N*-Dimethyl-2-formyl-3,4,5-trimethylcyclohexylmethylamine (XI).**—To the amino alcohol aluminate prepared from IX (1.5 g.) and aluminum isopropoxide (0.55 g., 115%) *p*-benzyloxybenzaldehyde (2.4 g., 160%) was added and the resultant mixture was distilled under nitrogen with the same method as described for the oxidation of the isomeric amino alcohol IX[2] to give an oil (1.23 g.), redistillation of which through an 8 cm. Vigreux column afforded the aminoaldehyde XI (1.05 g., 81%) as a colorless oil, b. p. 87～89°C/0.85 mmHg, n_D^{20} 1.4744, whose infrared spectrum showed the presence of C=O (1711), -$N(CH_3)_2$ (2844, 2798, 2753), and no hydroxyl group.

Found: C, 73.52; H, 11.98; N, 6.61. Calcd. for $C_{13}H_{25}ON$: C, 73.88; H, 11.92; N, 6.63%.

Treatment of this oil with picric or picrolonic acids gave an orange-red oil which could not be induced to crystallize. An attempt to prepare the analytical sample of the 2,4-dinitrophenylhydrazone of XI was unsuccessful.

4-(6'-*N,N*-Dimethylaminomethyl-2',3',4'-trimethylcyclohexyl)-but-3-en-2-one (XII).—The amino aldehyde XI (1.0 g.) in freshly distilled acetone

(5 ml.) was added to a cold solution of sodium hydride (30 mg.) in acetone (15 ml.) with vigorous stirring under a nitrogen atmosphere. The resultant mixture was stirred for additional 3 hr. at room temperature, and evaporated under reduced pressure to remove the bulk of acetone. The residue was dissolved in ether and the ethereal solution was extracted twice with 10% hydrochloric acid. The combined extracts were basified with 10% aqueous alkali, after being washed once with light petroleum, to regenerate the organic base which was taken up in ether. The ethereal solution was washed with water, dried over potassium carbonate and concentrated. Distillation gave the amino ketone XII (0.7 g., 59%) as a pale yellow oil, b. p. 122~125°C/0.7 mmHg, n_D^{23} 1.4842. For analysis a sample was redistilled; b. p. 122~125°C/0.65 mmHg, n_D^{25} 1.4852.

ν_{max} (liquid film) 1680 (C=O, conju.); 1622 (C=C, conju.); 984 (-CH=CH-, trans); 2839, 2800, 2752 ($-N(CH_3)_2$); 1259 (=C-CO-); 1381 (CH_2); 1361 ($COCH_3$); 840 cm^{-1} (unassigned).

Found: C, 76.22; H, 11.78. Calcd. for $C_{16}H_{29}ON$: C, 76.44; H, 11.63%.

An attempt to prepare the 2,4-dinitrophenylhydrazone of this compound was unsuccessful.

Note on the Solvent Extraction of Some Metals by Tri-n-octyl Phosphine Oxide

By Hideo SAISHO

(Received July 27, 1961)

Tri-*n*-octyl phosphine oxide (TOPO) is one of the alkyl phosphine oxides and has been employed as a solvent extraction reagent for many elements[1,2]. The detailed investigation of the extraction behavior with this reagent has been carried out for a few metals[2]. This paper presents the extraction behavior of zirconium, hafnium, niobium and tantalum in the system of TOPO-cyclohexane and hydrochloric or nitric acid.

TOPO was dissolved in cyclohexane without further purification. The distribution ratio, K_d, was determined radiochemically using the radionuclides Zr-95, Hf-181, Nb-95 and Ta-182. Activities in the aliquots of the two phases were measured with a gamma-ray scintillation counter. The aqueous solution containing a radionuclide such as the metallic ions was shaken vigorously with an organic solution for thirty minutes in a thermostat kept at 25±0.5°C.

Figure 1 shows the variation of the K_d values of zirconium and hafnium in the range of 1×10^{-3} to 1×10^{-2} M TOPO concentration in the organic phase, keeping the acidity of the aqueous phase constant. The plots of $\log K_d$ vs. logarithmic TOPO concentration

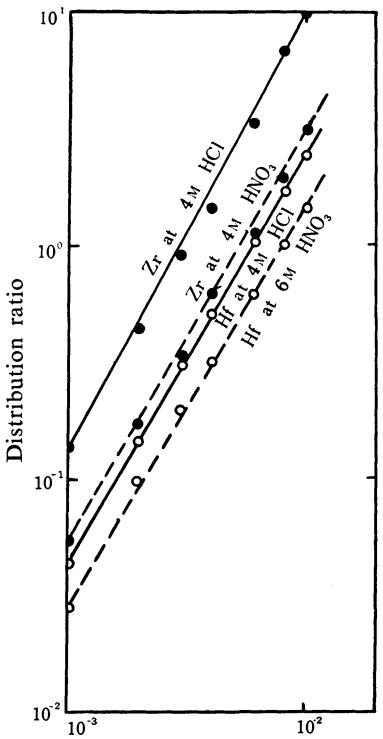

Fig. 1. Power dependence of distribution ratio on TOPO concentration.

1) J. C. White, U. S. AEC Rep., TID-7555, "Analytical Chemistry in Nuclear Reactor Technology", (1957), p. 240.
2) J. C. White, "Symposium on Solvent Extraction in the Analysis of Metals", American Society for Testing Materials, Philadelphia (1958), p. 27.

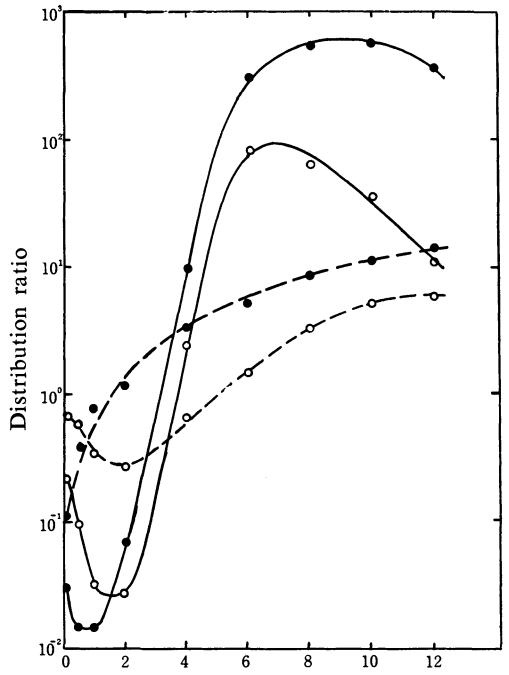

Fig. 2. Distribution ratio of zirconium and hafnium.

——: Hydrochloric acid ----: Nitric acid
● : Zirconium ○ : Hafnium

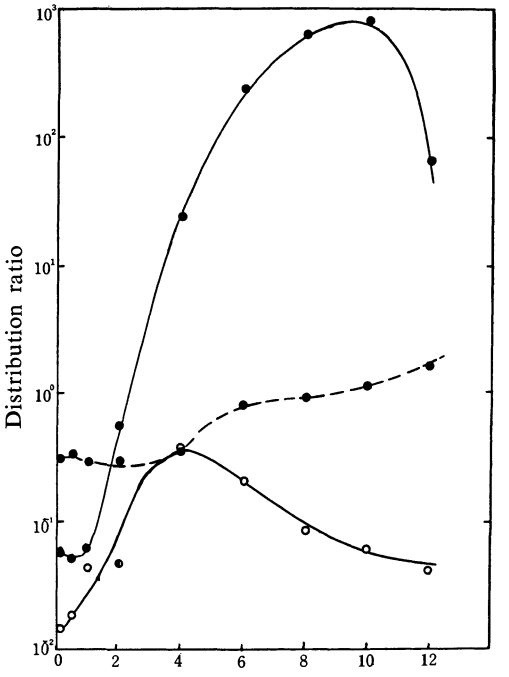

Fig. 3. Distribution ratio of niobium and tantalum.

——: Hydrochloric acid ----: Nitric acid
● : Niobium ○ : Tantalum

show a constant slope of about 2 in all cases. The second power dependence of the K_d values on the TOPO concentration suggests an extracted species that has a value of two for the moles of TOPO per mole of zirconium or hafnium.

Figures 2 and 3 show the K_d values of zirconium, hafnium, niobium and tantalum in the range of hydrochloric or nitric acid concentration from 0.1 to 12 M, keeping the TOPO concentration 1×10^{-2} M except in the case of tantalum in nitric acid. The K_d values for tantalum in nitric acid could not be determined exactly, because the activities extracted into the organic phase were very low. As shown in these figures, the K_d values greatly depend on the kind of acid and on its concentration. Zirconium can be separated from hafnium in the high acidity region, and also from niobium in nitric acid. A mutual separation of niobium and tantalum can be carried out more completely than that of zirconium and hafnium in hydrochloric acid.

Spectrophotometric Determination of Magnesium with Pontachrome Azure Blue B.

By Katsuya UESUGI, Yukiteru KATSUBE and John H. YOE

(Received January 16, 1962)

A new spectrophotometric method for the determination of traces of magnesium has been developed. It is based upon the stable reddish-violet magnesium complex of sodium 2″, 6″-dichloro-4′-hydroxy-3, 3′-dimethylfuchsone-5, 5′-dicarboxylate (Pontachrome Azure Blue B).

Details of this compound have been published in our recent paper[1].

Absorption spectra of the reagent solution (Fig. 1. curve I) and of its magnesium complex (Fig. 1. curve II) indicate the analytical usefulness of this color reaction. At pH 11, the maximum absorbance is at 570 mμ. The complex is formed by adding a small amount of magnesium to the mixture of 5.0 ml. of ammonium chloride-ammonia buffer solution and 2.0 ml. of 0.2% reagent solution in a 25 ml. volumetric flask. The solution is diluted to the mark with distilled water and thoroughly mixed. As seen in Fig. 2, magnesium complex has a maximum absorbance in the pH range 10.8 to 11.4 (λ_{max} 570 mμ). Full color developes within ten minutes and its stability is quite adequate for the determination of magnesium.

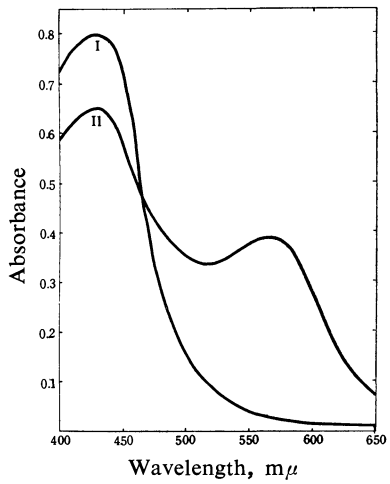

Fig. 1. Absorption spectra of the reagent solution and of its magnesium complex. pH 11.0

Fe^{2+}	Mohr's salt	0.4
Cu^{2+}	Sulfate	0.1
Ca^{2+}	Chloride	0.7
Co^{2+}	Nitrate	0.9

* The limiting concentration was taken to be one that causes a deviation of more than 0.01 unit in the absorbance of a solution containing 2.5 p.p.m. of magnesium.

Beer's law is obeyed up to a magnesium concentration of at least 4 p.p.m. (Fig. 3). The sensitivity of the color reaction is 0.004 μg. Mg/cm^3 for $\log(I_0/I)=0.001$. The limiting concentrations of the common cations are given in Table I. It will be seen that many metal ions must be removed or masked before the determination.

The presence of these interfering metal ions gives the smaller absorbance at 570 mμ. For example, in the presence of 2 p. p. m. of calcium the absorbance is decreased about 50%.

Nuclear Quadrupole Resonance of Chlorine in Hexachloroplatinic(IV) Acid Hexahydrate and Sodium Hexachloroplatinate(IV) Hexahydrate

By Koji Ito, Kazuo Ito, Daiyu Nakamura and Masaji Kubo

(Received January 16, 1962)

The pure quadrupole resonance of ^{35}Cl in hexachloroplatinic(IV) acid hexahydrate $H_2PtCl_6 \cdot 6H_2O$ and sodium hexachloroplatinate(IV) hexahydrate $Na_2PtCl_6 \cdot 6H_2O$ was observed at room temperature using a spectrometer previously described[1]. The observed frequencies are shown in Table I. in which that of potassium hexachloroplatinate(IV)[1] at room temperature is included for comparison.

Table I. Pure quadrupole resonance frequencies of ^{35}Cl in hexachloroplatinic(IV) acid hexahydrate and related compounds

Compound	Temp. °C	Frequency Mc./sec.
$H_2PtCl_6 \cdot 6H_2O$	25.0	26.55 ±0.05
$Na_2PtCl_6 \cdot 6H_2O$	23.5	25.730±0.005 26.470±0.005 27.040±0.005
K_2PtCl_6	23.5	25.813±0.001

At dry ice and liquid nitrogen temperatures, these compounds gave rise to a number of weak signals appearing in the frequency range of 28~35 Mc. and 20~30 Mc., respectively. These signals were attributable to piezoelectricity arising from lattice deformations formed in crystals on cooling[2]. The pure quadrupole resonance lines escaped detection either because they were masked by the piezoelectric signals or because the signal-to-noise ratio was small.

The single resonance line observed for hexachloroplatinic(IV) acid might suggest that all chlorine atoms in the crystals are mutually equivalent. However, it is probable that additional resonance lines escaped observation owing to their small signal-to-noise ratios. In fact, the single line was barely detectable. Sodium hexachloroplatinate(IV) yielded three resonance lines of approximately the same signal-to-noise ratio equal to about 3, indicating the presence of at least three kinds of crystallographically nonequivalent chlorine atoms in the crystals.

No X-ray analysis has ever been performed on the crystals of these two compounds. It is reported[3] that sodium hexachloroplatinate(IV) hexahydrate forms triclinic pinacoidal crystals. In order to obtain some information on the crystal structure of these compounds, powder patterns were taken by means of a Norelco X-ray diffractometer. Since the crystals were deliquescent, high-speed scanning was carried out. The recorded powder patterns of these two compounds were quite different from each other. Unlike potassium hexachloroplatinate(IV), which forms cubic crystals, two compounds under investigation gave powder patterns suggesting lower symmetry than the tetragonal symmetry. Evidently, the crystal structures of these three compounds are of quite different type. It is noteworthy that despite the difference in crystal structures, the observed resonance frequencies of these three compounds are nearly the same, the deviations being within several percent. This indicates that the pure quadrupole resonance frequency of chlorine in $[PtCl_6]^{2-}$ is determined primarily by the electronic distribution in the complex ion without being affected greatly by neighboring cations and complex ions[4].

The present authors have already determined the pure quadrupole resonance of halogens in a number of metal complexes[5,6]. The results have been analyzed through the Townes-Dailey procedure[7] to discuss the covalent character of metal-ligand bonds in complex ions, ignoring the effect of neighboring ions on the pure quadrupole resonance frequencies. The present results confirm the adequacy of the analysis.

The Reactions of Ester with Acyl Chloride in the Presence of Aluminum Chloride. III. Formation of Dibenzoylmethane and Ethyl Dibenzoylacetate

By Hiroo KANEYUKI

(Received June 7, 1961)

Nakata has reported that acetonetricarboxylic acid derivative III and 3-acyl-4-hydroxycoumarin derivative IV were obtained as by-products in the synthesis[1] of 4-hydroxycoumarin (II) by the action of aluminum chloride on the acid chloride of monophenyl malonate (I) as follows[2]:

The formation of III and IV suggests that the active methylene group of I can be acylated with acid chloride in the presence of aluminum chloride. The acylation of the active methylene group is usually accomplished with a basic reagent such as metallic sodium or sodium alcoholate. With reference to the acylation of the active methylene group in the presence of an acidic reagent, only the synthesis of β-diketones by the acetylation of ketones with acetic anhydride in the presence of boron trifluoride has been studied by Meerwein and Vossen[3] and by Hauser and Adams[4]. Recently, Azatyan[5] has reported that some aromatic ketones were prepared by heating aromatic hydrocarbon and acid chloride in the presence of a small amount of metallic aluminum, and that under similar condition diethyl benzoylmalonate was obtained from diethyl malonate and benzoyl chloride.

The present paper describes the study of the reactions of diethyl malonate with one molecular equivalent of benzoyl chloride, *p*-chlorobenzoyl chloride, *p*-nitrobenzoyl chloride and acetylsalicylic acid chloride in the presence of different amounts of aluminum chloride.

Acylation of Diethyl Malonate with Benzoyl Chloride.—The treatment of diethyl malonate with one molecular equivalent of benzoyl chloride and of aluminum chloride afforded diethyl benzoylmalonate (V) and dibenzoylmethane (VII). When three molecular equivalents of aluminum chloride were used, VII and ethyl dibenzoylacetate (VI) were obtained. It was found that carbon dioxide and ethyl chloride are evolved in the course of the reactions. In these reactions, aluminum chloride reacts not only to give benzoyl derivatives, but also to accelerate the decarbethoxylation of the ester.

$$CH_2(COOC_2H_5)_2 + C_6H_5COCl \xrightarrow{AlCl_3} C_6H_5COCH(COOC_2H_5)_2 + (C_6H_5CO)_2CHCOOC_2H_5 + (C_6H_5CO)_2CH_2$$

Acylation of Diethyl Malonate with *p*-Chlorobenzoyl Chloride.—The products of the reactions of diethyl malonate with *p*-chlorobenzoyl chloride were diethyl *p*-chlorobenzoylmalonate (VIII), ethyl di-*p*-chlorobenzoylacetate (IX) and di-*p*-chlorobenzoylmethane (X). The relation between amounts of aluminum chloride and reaction products was similar to that of the acylation with benzoyl chloride.

Acylation of Diethyl Malonate with *p*-Nitrobenzoyl Chloride.—When one molecular equivalent of *p*-nitrobenzoyl chloride was used as an acylating agent, *p*-nitroacetophenone (XI) and ethyl *p*-nitrobenzoylacetate (XII) were obtained. By the use of three molecular equivalents of aluminum chloride at a higher reaction temperature, di-*p*-nitrobenzoylmethane (XIII) was obtained as the main product.

$$CH_2(COOC_2H_5)_2 + NO_2C_6H_4COCl \xrightarrow{AlCl_3} NO_2C_6H_4COCH_3 + NO_2C_6H_4COCH_2COOC_2H_5$$

$$NO_2C_6H_4COCH_2COOC_2H_5 + NO_2C_6H_4COCl \xrightarrow{AlCl_3} (NO_2C_6H_4CO)_2CH_2$$

TABLE I. ACYLATION OF DIETHYL MALONATE WITH BENZOYL CHLORIDE AND *p*-SUBSTITUTED BENZOYL CHLORIDES

Reaction condition: 65°C, * 90°C; 8 hr. Solvent: Nitrobenzene 15 ml.

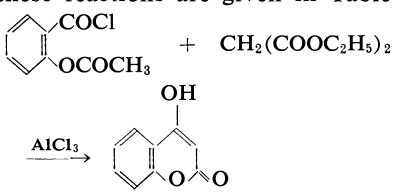
Substituent X	Reactant: X-C_6H_4COCl mol.×10^2	Reactant: $CH_2(COOC_2H_5)_2$ mol.×10^2	Reactant: $AlCl_3$ mol.×10^2	Product and yield: X-BME[a] %	X-DBA[b] %	X-DBM[c] %	X-AP[d] %	X-BAE[e] %	X-C_6H_4COOH %
H	2.1	2.1	2.1	59		8			15
	2.1	2.1	6.3		31	16			23
Cl	1.7	1.7	1.7	59					19
	1.7	1.7	5.1		4	33			43
NO_2	1.6	1.6	1.6				26	10	56
	1.6	1.6	3.2			31	29	8	28
	1.6	1.6	4.8			47	14	8	28
	1.6	1.6	1.6*			58	7	26	7
	1.6	1.6	4.8*			74	7	3	14

Yield: Calculated from X-C_6H_4COCl (X=H, Cl, NO_2).

a) X-BME (V, VIII); X-$C_6H_4COCH(COOC_2H_5)_2$

b) X-DBA (VI, IX); $(X\text{-}C_6H_4CO)_2CHCOOC_2H_5$

c) X-DBM (VII, X, XIII); $(X\text{-}C_6H_4CO)_2CH_2$



d) X-AP (XI); X-$C_6H_4COCH_3$

e) X-BAE (XII); X-$C_6H_4COCH_2COOC_2H_5$

It can be deduced that the formation of XI and XIII in good yields results in the facilitation of decarbethoxylation by the driving force of the nitro group in the *p*-position.

The reaction conditions and the products of these acylation reactions are summarized in Table I.

Acylation of Diethyl Malonate with Acetylsalicylic Acid Chloride.—Reactions carried out with different amount of aluminum chloride all gave only 4-hydroxycoumarin (II), which may have been formed by decarbethoxylation and intramolecular condensation. The results of these reactions are given in Table II.

The aromatic acids, which should be derived from unreacted acid chlorides, were obtained, and their yields generally increased with the amount of aluminum chloride used.

TABLE II. ACYLATION OF DIETHYL MALONATE WITH ACETYLSALICYLIC ACID CHLORIDE

Solvent: Nitrobenzene 25 ml.

Reaction condition: 95~100°C, 8 hr.

Reactant: Acetylsalicylic acid mol.×10^2	Reactant: Diethyl malonate mol.×10^2	Reactant: $AlCl_3$ mol.×10^2	Product and yield: II %	Salicylic acid %
1.7	3.3	1.7	56	13
1.7	1.7	1.7	52	17
1.7	1.7	5.1	7	57

Yield: Calculated from acetylsalicylic acid.

Experimental*

Materials.—Benzoyl chloride[6] (b. p. 192°C), *p*-chlorobenzoyl chloride[7] (b. p. 112°C/23 mmHg) and *p*-nitrobenzoyl chloride[8] (b. p. 160°C/26 mmHg) were prepared from benzoic acid, *p*-chlorobenzoic acid and *p*-nitrobenzoic acid with phosphorus pentachloride respectively in 65, 96 and 92% yields. Acetylsalicylic acid[9] was prepared from salicylic acid and acetic anhydride, m. p. 137~138°C., 82% theoretical yield. Anhydrous aluminum chloride[10] was prepared by passing a stream of dry hydrogen chloride over aluminum (99.99%) heated in a furnace. The diethyl malonate used was a commercial product purified by distillation.

Acylation of Diethyl Malonate with Benzoyl Chloride.—Diethyl malonte was added to benzoyl chloride and aluminum chloride dissolved in nitrobenzene, and the reaction mixture was kept at 65°C for 8 hr. After cooling, the reaction mixture was poured into crushed ice and extracted with ether. The ethereal solution was successively extracted with a saturated sodium bicarbonate solution, with a sodium hydroxide solution (15%) and then with water. After the aqueous layer, which contained aluminum chloride, was heated on a water bath and left for a few days, solid VII was produced. A precipitate was obtained by acidifying the sodium bicarbonate solution with hydrochloric acid and was identified as benzoic acid by the mixed melting point method (m. p. 118~121°C). The sodium hydroxide solution and the water extract were acidified to give solid VI and oil V respectively. The ether solution was evaporated and the residual solution

* The boiling and melting points are uncorrected.

subjected to distillation with water under reduced pressure in order to remove nitrobenzene. Residue VIIa was obtained.

Diethyl Benzoylmalonate (V).—The ethereal solution of the oil V was shaken with a copper acetate solution. The solid obtained on evaporating the ether was crystallized from ethanol as green needles, 3.8 g. (3.3 g. as V), m. p. 180~181°C.

Found: C, 56.90; H, 5.00; Cu, 10.52. Calcd. for $C_{28}H_{30}O_{10}Cu$: C, 56.99; H, 5.12; Cu, 10.76%.

No depression of the melting point was observed on the admixture of this crystalline with copper chelate of diethyl benzoylmalonate (m. p. 180°C) prepared by the method of the literature[11].

Ethyl Dibenzoylacetate (VI).—The solid VI crystallized from ethanol as colorless needles, m. p. 108~111°C, reported m. p. 112°C[12].

Found: C, 72.86; H, 5.52. Calcd. for $C_{18}H_{16}O_4$: C, 72.96; H, 5.44%.

This substance gave copper chelate, which was crystallized from ethanol in the form of light green needles, m. p. 218~220°C, reported m. p. 221°C[12]. The product obtained by boiling the solid VI (0.3 g.) with sulfuric acid (15%) for 15 hr. crystallized from methanol to give light yellow needles, 0.1 g., m. p. 78~79°C. Melting point and mixed melting point with dibenzoylmethane proved the identity of this material.

Dibenzoylmethane (VII).—The solid VII crystallized from methanol as light yellow needles, m. p. 78~79°C. A mixed melting point with dibenzoylmethane prepared by the method of the literature[13] showed no depression.

Found: C, 80.37; H, 5.54. Calcd. for $C_{15}H_{12}O_2$: C, 80.34; H, 5.39%.

This crystalline (0.2 g.) was boiled with semicarbazide hydrochloride (0.2 g.) in methanol (10 ml.) for 4 hr. Water was added to the methanol solution, and the separated crystal was crystallized from ethanol to give colorless plates, 0.19 g., m. p. 199.5 ~200.5°C. The recorded melting point for 3,5-diphenylpyrazol is 200°C[14]. A few drops of concentrated hydrochloric acid was added to the solid VIIa (0.1 g., m. p. above 270°) dissolved in a small amount of tetrahydrofuran, and the solution was kept at room temperature for 1 hr. The precipitated crystal was washed with water and crystallized from methanol, 0.09 g., m. p. 77~78°C. This substance was identified as VII by the mixed melting point method. The yields of products were listed in Table I.

Carbon Dioxide and Ethyl Chloride.—The gas evolved during the reaction was absorbed by a potassium hydroxide solution (30%) and toluene cooled with ice. The alkali solution was analyzed by differential titration with a standard acid solution to determine the amount of carbon dioxide evolved. The obtained value was about 70% of the amount of carbon dioxide which was estimated from the yields of VI and VII. The gas absorbed in toluene was distilled into aniline cooled with ice. The aniline placed in a sealed tube was heated for 7 hr. at 130°C, and then the reaction product was treated with *p*-toluenesulfonyl chloride by the Hinsberg method. The resulting product was crystallized from ethanol to give colorless crystals, m. p. 68~69°C, which agreed with the melting point in the literature[15] for *N*-ethyl-*N*-phenyl-*p*-toluenesulfonamide. The melting point was not depressed on admixture with an authentic sample prepared by the method of the literature.

Acylation of Diethyl Malonate with *p*-Chlorobenzoyl Chloride.—The reaction conditions and treatments of reaction mixture are quite the same as that described for acylation with benzoyl chloride. When the aqueous layer which contained aluminum chloride was heated on a water bath and left to stand for a few days, a solid precipitated. When this solid was collected, washed with water, and extracted with hot ethanol, insoluble solid Xa remained. On cooling the ethanol solution, solid X was obtained. The sodium bicarbonate solution was acidified to give a crystalline substance which gave no depression of melting point on mixture with *p*-chlorobenzoic acid. Nothing was obtained when the sodium hydroxide solution was acidified. The water extract was acidified to give solid IX. The removal of ether and nitrobenzene gave solid Xb. In the experiment used, one molecular equivalent of aluminum chloride, solid VIII, was obtained from the aqueous layer and the water extract.

Diethyl *p*-Chlorobenzoylmalonate (VIII).—The solid VIII crystallized from ethanol in the form of colorless needles, m. p. 52.5~53°C.

Found: C, 56.30; H, 5.05; Cl, 11.73. Calcd. for $C_{14}H_{15}O_5Cl$: C, 56.29; H, 5.06; Cl, 11.87%.

A suspension of the solid VIII in sulfuric acid (30%) was refluxed for 6 hr. The oily substance produced solidified on cooling and crystallized from ethanol as colorless needles, m. p. 20.5~21°C. A mixed melting point with *p*-chloroacetophenone prepared according to the literature[16] showed no depression.

Ethyl Di-*p*-chlorobenzoylacetate (IX).—The solid IX crystallized from ethanol in the form of colorless leaflets, m. p. 127.5~128.5°C.

Found: C, 59.12; H, 3.90; Cl, 19.30. Calcd. for $C_{18}H_{14}O_4Cl_2$: C, 59.20; H, 3.80; Cl, 19.42%.

A suspension of the solid IX (1 g.) in sulfuric acid (30%, 20 ml.) was refluxed for 4 hr., and the resulting product was crystallized from ethanol to give colorless needles, 0.6 g., m. p. 160~160.5°C. This product gave no depression of melting point on mixture with di-*p*-chlorobenzoylmethane.

Di-*p*-chlorobenzoylmethane (X).—The solid X crystallized from ethanol in the form of colorless leaflets, m. p. 160~160.5°C. The literature values for di-*p*-chlorobenzoylmethane are: m. p. 159°C[17], 160~161°C[18].

Found: C, 61.34; H, 3.51; Cl, 24.08. Calcd. for $C_{15}H_{10}O_2Cl$: C, 61.46; H, 3.44; Cl, 24.19%.

A suspension of the solid X (0.5 g.) in a mixture of sulfuric acid (60%, 50 ml.) and ethanol (5 ml.)

was heated under reflux for 15 hr., and the resulting solution was extracted with ether. The ethereal solution was further extracted with a sodium hydroxide solution. With removal of the ether, an oily product (0.2 g.) was obtained. Semicarbazone prepared from this oily product melted at 202～203°C, which was not depressed on admixture with an authentic sample of semicarbazone[19] prepared from *p*-chloroacetophenone. The sodium hydroxide solution was acidified with hydrochloric acid to give a crystalline, 0.2 g., m. p. 236～237°C, which showed no depression on admixture with *p*-chlorobenzoic acid. The solid Xa (0.2 g., m. p. above 270°C) treated by the same merhod as described in the case of solid VIIa gave X, 0.19 g., m. p. 16°C. The solid Xb crystallized from ethanol to afford a crystalline, m. p. 160°C, and was identified as X by the mixed melting point method. The yields of products have been listed in Table I.

Acylation of Diethyl Malonate with *p*-Nitrobenzoyl Chloride.—The reaction conditions and treatments of reaction mixture are quite the same as that described above. The orange-red colored crystalline mass formed when the ethereal solution extracted with a sodium hydroxide solution was collected and washed with ether. The aqueous layer which contained aluminum chloride was heated on a water bath to form a precipitate. The precipitate was collected, washed with water and extracted with hot ethanol and then with cold ethanol-tetrahydrofuran (1 : 2) ; an insoluble solid XIII remained. On cooling the ethanol solution, solid XI precipitated. Upon evaporating the ethanol-tetrahydrofuran solution, solid XIIIa was obtained. The sodium bicarbonate solution was acidified to give a crystalline substance, which was crystallized from ethanol as yellowish white colored crystals and was identified as *p*-nitrobenzoic acid by the mixed melting point method. Nothing was obtained when the sodium hydroxide solution was acidified. When the above-mentioned orange-red colored crystalline was treated with hydrochloric acid and washed with water, it turned into yellow-colored crystalline XIIIb. The water extract was acidified to give solid XII. When the ethereal solution was evaporated and then distilled with water under reduced pressure, solid XIIa was obtained.

***p*-Nitroacetophenone (XI).**—The solid XI crystallized from ethanol in the form of light yellow prisms, m. p. 80～81°C.

Found : C, 58.25 ; H, 4.21 ; N, 8.40. Calcd. for $C_8H_7O_3N$: C, 58.15 ; H, 4.28 ; N, 8.48%.

Phenylhydrazone prepared from the solid XI (0.2 g.) crystallized from ethanol in the form of red needles, 0.2 g., m. p. 133.5～134.5°C.

Found : N, 16.48. Calcd. for $C_{14}H_{13}O_2N_3$: N, 16.46%.

The recorded melting point[20] for *p*-nitroacetophenone and its phenylhydrazone are 80～81°C and 132°C respectively.

Ethyl *p*-Nitrobenzoylacetate (XII).—The solid XII crystallized from ethanol in the form of yellow needles, m. p. 69～72°C. Perkin and Bellenot[21] gave a m. p. of 74～76°C for ethyl *p*-nitrobenzoylacetate.

Found : C, 56.00 ; H, 4.89 ; N, 6.06. Calcd. for $C_{11}H_{11}O_5N$: C, 55.69 ; H, 4.67 ; N, 5.90%.

The solid XII (0.3 g.) was boiled with sulfuric acid (30%) for 8 hr. The separated crystal was crystallized from ethanol as light yellow prisms, 0.1 g., m. p. 80～81°C, and was identified as XI by the mixed melting point method. The solid XIIa which was crystallized from ethanol was determined to be identical with XII by the melting point and mixed melting point, m. p. 69～72°C.

Di-*p*-nitrobenzoylmethane (XIII).—The solid XIII crystallized from ethyl acetate in the form of yellow needles, m. p. 240～243°C, reported m. p. 241～242°C[17].

Found : C, 57.27 ; H, 3.18 ; N, 8.96. Calcd. for $C_{15}H_{10}O_6N_2$: C, 57.33 ; H, 3.21 ; N, 8.91%.

A suspension of the solid XIII (0.4 g.) in a mixture of sulfuric acid (60%, 50 ml.) and glacial acetic acid (4 ml.) was heated at reflux for 17 hr. The reaction mixture diluted with water was extracted with ether. The ethereal solution was extracted with sodium hydroxide solution. Removal of the ether gave a crystalline mass, 0.2 g., m. p. 79～80°C, which showed no depression on admixture with XI. The sodium hydroxide extract was acidified to yield a crystalline substance, 0.2 g., m. p. 234～235°C This substance was identified as *p*-nitrobenzoic acid by the mixed melting point method. XIII was obtained from the solid XIIIa (1 g., m. p. above 270°C) by the same method as has been described in the case of the solid VIIa, 0.97 g., m. p. 240～243°C. The solid XIIIb crystallized from ethyl acetate as yellow needles. The melting point was not depressed on admixture with XIII. The yields of products have been listed in Table I.

Acylation of Diethyl Malonate with Acetylsalicylic Acid Chloride.—Phosphorus pentachloride was added to a solution of acetylsalicylic acid in nitrobenzene, and the solution was warmed at 50～55°C for 3 hr. On cooling, aluminum chloride was added to the solution and dissolved, and then diethyl malonate was added. This solution was kept at 95～100°C for 8 hr. The reaction mixture was poured into crushed ice, and an excess of sodium hydroxide solution (15%) was added until the liquid had a alkaline reaction. The solution was extracted with ether to remove nitrobenzene and stirred into a hydrochloric acid solution (15%). The resulting crystals were crystallized from aqueous ethanol, m. p. 209～210°C. The melting point was not depressed on admixture with an authentic sample of 4-hydroxycoumarin (II)[1]. The filtrate separated from II was extracted with ether. Removal of the solvent from the ether extract gave a crystal. After recrystallization from aqueous ethanol, colorless needles were obtained, m. p. 158～159°C, which showed no depression of melting point on mixture with salicylic acid. The yields of products have been listed in Table II.

The Reactions of Ester with Acyl Chloride in the Presence of Aluminum Chloride. IV. Formation of Tribenzoylmethane

By Hiroo KANEYUKI

(Received June 15, 1961)

The previous paper[1] reported that monoacylated compounds were obtained when diethyl malonate was acylated with equimolecular amounts of benzoyl chloride or *p*-substituted benzoyl chlorides in the presence of equimolecular amounts of aluminum chloride, while a large quantity of catalyst led to decarbethoxylated diacyl compounds.

In this paper, the results of analysis of products obtained by the reactions of diethyl malonate with more than two molecular equivalents of acid chloride in the presence of three molecular amounts of aluminum chloride are reported on.

Acylation of Diethyl Malonate with Benzoyl Chloride.—Ethyl dibenzoylacetate (I), dibenzoylmethane (II), tribenzoylmethane (III) and tribenzoylmethane-*O*-benzoate (IV) were obtained by this reaction. The high-melting substance mentioned in the previous paper was also obtained; it was confirmed by analysis that this substance was aluminum chelate of dibenzoylmethane (IIa). The reaction conditions and the products of these acylation reactions are given in Table I. What differs from the experimental results of the previous paper[1] is the formation of III, IV and II in good yields. From these differences, it can be seen that benzoylation and decarbethoxylation reactions have proceeded further in this case.

$$(C_6H_5CO)_2CHCOOC_2H_5 \text{ or } (C_6H_5CO)_2CH_2 \xrightarrow[C_6H_5COCl]{AlCl_3} (C_6H_5CO)_3CH + (C_6H_5CO)_2C{=}CC_6H_5 \quad (OCOC_6H_5)$$

Acylation of Diethyl Malonate with *p*-Chlorobenzoyl Chloride.—Diethyl *p*-chlorobenzoylmalonate (V), ethyl di-*p*-chlorobenzoylacetate (VI), di-*p*-chlorobenzoylmethane (VII) and tri-*p*-chlorobenzoylmethane (VIII) were obtained by this reaction. Besides these, aluminum chelate of di-*p*-chlorobenzoylmethane (VIIa) of a high melting point was also obtained. These reaction products are given in Table I. From this table, it can be seen that V, VI, VII and VIIa are obtained when two molecular equivalents of *p*-chlorobenzoyl chloride are used, but ester V and VI disappear with the increase in the combined yield of VII and VIIa by the use of three molecular equivalents of *p*-chlorobenzoyl chloride. What differs from the experimental results in the previous paper[1] is the formation of VIII, an increase in the yield of VI accompanied with V, and an increase in the combined yield of VII and VIIa.

Acylation of Diethyl Malonate with *p*-Nitrobenzoyl Chloride.—*p*-Nitroacetophenone (IX), ethyl *p*-nitrobenzoylacetate (X), di-*p*-nitrobenzoylmethane (XI) and its aluminum chelate (XIa) were obtained by this reaction, but tri-*p*-nitrobenzoylmethane was not obtained. These reaction products are given in Table I. From this table, it can be seen that the yield of ester X is decreased, while the combined yield of XI and XIa is increased, when a large quantity of *p*-nitrobenzoyl chloride is used. A good yield of XI and XIa alone is obtained at a high reaction temperature. The species of reaction products are the same as in the case of the previous paper[1], in which equimolecular amounts of *p*-nitrobenzoyl chloride were used. The difference is the increase in the combined yield of XI and XIa.

Experimental*

Materials and reaction method were the same as in the previous paper[1]. The reaction conditions are shown in the above table. The treatment of the reaction mixture was also the same; that is, the product was separated into the aqueous layer containing aluminum chloride, sodium bicarbonate extract, sodium hydroxide extract, water extract and residual solution.

Acylation of Diethyl Malonate with Benzoyl Chloride.—Precipitates were separated after the aqueous layer containing aluminum chloride was heated and left standing. These precipitates were recrystallized from methanol to yield II. Benzoic acid was obtained when the sodium bicarbonate extract was acidified. The sodium hydroxide extract was acidified to give I, which recrystallized from ethanol. By acidifying the water extract, solid A was obtained. By distilling off the ether and the nitrobenzene, together witht he water, under reduced pressure from the residual solution, a residue was obtained. This was separated into an ether soluble substance B and an ether insoluble substance C. Yields of the various products are shown in Table I.

Tribenzoylmethane (III).—The solid A was recrystallized from a large quantity of ethanol to afford colorless needles, m. p. 223~240°C. The melting point was not depressed when melted together with tribenzoylmethane which had been prepared by the method of the literature[2]. The infrared spectrum of this compound was identical with that of an authentic specimen.

Found: C, 80.72; H, 5.19. Calcd. for $C_{22}H_{16}O_3$: C, 80.47; H, 4.91%.

Tribenzoylmethane-*O*-benzoate (IV).—The solid B was recrystallized from ethyl acetate-petroleum ether to give colorless granular crystals, m. p. 125~126°C. When recrystallized from ethanol, however, the same product gave colorless plates, m. p. 112~113.5°C. Tribenzoylmethane-*O*-benzoate prepared according to the method of the literature[3] (m. p. 121~123°C, ethyl acetate-ligroin) gave the same kinds of crystals.

Found: C, 80.26; H, 4.74. Calcd. for $C_{29}H_{20}O_4$: C, 80.54; H, 4.66%.

Tris-(1, 3-diphenyl-1, 3-propanediono) - aluminum (IIa).—A small quantity of concentrated hydrochloric acid was added to a tetrahydrofuran solution of the ether insoluble substance C (0.5 g., m. p. above 270°C). The solution was allowed to stand for an hour, and then water was added until preciptation was complete. The precipitate was filtered and recrystallized from methanol to give needle crystals, 0.44 g., m. p. 76.5~78°C. The melting point and mixed melting point with dibenzoylmethane proved the identity of this material. A colloidal precipitate of aluminum hydroxide was produced on the addition of aqueous ammonia to the acidic filtrate.

* Confirmation of compounds which were confirmed in the previous paper[1] is omitted here. Melting points are uncorrected values.

2) "Beilsteins Handbuch der organischen Chemie", H., 7, 877 (1925).

3) Ibid., H., 9, 158 (1926).

Found: C, 77.52; H, 4.90; Al, 3.90. Calcd. for $C_{45}H_{33}O_6Al$: C, 77.57; H, 4.77; Al, 3.87%.

Acylation of Diethyl Malonate with *p*-Chlorobenzoyl Chloride.—Precipitates obtained from the aqueous layer containing aluminum chloride were separated into ether insoluble D and ether soluble substances. This ether soluble substance was recrystallized from ethanol to yield VII. *p*-Chlorobenzoic acid was obtained by acidifying the sodium bicarbonate extract. A precipitate was not obtained by acidifying the sodium hydroxide extract. Crystals obtained by acidifying the water extract were treated with ether, and ether insoluble substance E was separated. After the removal of the ether, the residue was separated to V and VI by fractional crystallization with ethanol. The residue, which was obtained after removing nitrobenzene from the residual solution of extraction, was recrystallized from ethanol to afford VII. The products and yields are shown in Table I.

Tris-(1, 3-dichloro-diphenyl-1, 3-propanediono)-aluminum (VIIa).—The tetrahydrofuran solution of the solid D (0.18 g., m. p. above 270°C) was treated with hydrochloric acid as has been mentioned above. The resulting precipitate was recrystallized from ethanol as colorless plates, 0.17 g., m. p. 159~160°C. The melting point and mixed melting point with di-*p*-chlorobenzoylmethane proved the identity of this material.

Found: C, 60.20; H, 3.29. Calcd. for $C_{45}H_{27}O_6 \cdot Cl_6Al$: C, 59.83; H, 3.01%.

Tri-*p*-chlorobenzoylmethane (VIII).—The solid E was recrystallized from a large quantity of ethanol to yield colorless long needles, m. p. 225~239°C.

Found: C, 61.59; H, 3.13; Cl, 24.58. Calcd. for $C_{22}H_{13}O_3Cl_3$: C, 61.21; H, 3.03; Cl, 24.64%.

Acylation of Diethyl Malonate with *p*-Nitrobenzoyl Chloride.—Precipitates obtained from the aqueous layer containing aluminum chloride were washed with water, and extracted with hot ethanol and then with a mixed solution of ethanol-tetrahydrofuran (1 : 2). The solid obtained by the evaporation of the ethanol extract was recrystallized from ethanol to give IX. By evaporating the ethanol-tetrahydrofuran solution, solid I was obtained. The residue, insoluble in an ethanol-tetrahydrofuran solution, was recrystallized from ethyl acetate to give XI. *p*-Nitrobenzoic acid was obtained when sodium bicarbonate extract was acidified. The reddish orange precipitate produced during sodium hydroxide extraction was filtered, washed with ether and hydrochloric acid, and then recrystallized from ethyl acetate to give XI. The water extract was acidified, and the resulting precipitate was recrystallized from ethanol to afford X.

Tris-(1, 3-dinitro-diphenyl-1, 3-propanediono)-aluminum (XIa).—The tetrahydrofuran solution of the solid F (0.75 g., m. p. above 270°C) was treated with hydrochloric acid, as has been mentioned above. The resulting precipitate was recrystallized from ethyl acetate to afford yellow needles, 0.70 g., m. p. 238~243°C. The melting point and mixed melting point with di-*p*-nitrobenzoyl methane proved the identity of this material.

The author wishes to express his gratitude to Professor Kiyotada Matsui for his helpful guidance throughout the course of this work, and to Professor Ryozo Goto, Kyoto University, for his unfailing encouragement. He also wishes to thank Mr. Minoru Ota for his help.

Kinetic Studies on Solvolysis. VIII. Phenolysis of Optically Active α-Phenethyl Chloride in Phenol-Benzene Solvent—Three-stage Mechanism in the S_N1-Type Solvolysis*

By Kunio Okamoto, Ken-ichi Takeuchi and Haruo Shingu

(Received June 23, 1961)

The mechanism of phenolysis of α-phenethyl chloride has been extensively investigated by Hart and his co-workers[1]. These authors[1b] carried out the phenolysis in the absence of basic substances and noted that the near identity of rate constants for the racemization of α-phenethyl chloride and for the nuclear alkylation of phenol in various mixtures of phenols and aromatic hydrocarbons. Although they suggested that a common rate-determining step for both reactions would be the ionization step of the halide, they did not refer to the solvolytic

* Presented at the 14th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1961. Part VII. of this series: K. Okamoto, K. Takeuchi and H. Shingu, This Bulletin, **34**, 1137 (1961).

1) a) H. Hart, W. L. Spliethoff and H. S. Eleuterio, *J. Am. Chem. Soc.*, **76**, 4547 (1954); b) H. Hart and W. L. Spliethoff, ibid., **77**, 833 (1955).

nature of the reaction and presented a second-order rate equation with some additional terms for explaining the rate data. In Part V of this series[2] we have illustrated how a reliable criterion of the S_N1 (first-order) two-step mechanism may be established for the phenolysis of *tert*-butyl halides by examination of the rate dependence on initial concentrations of the added base and also on solvent compositions. In addition, we have suggested the applicability of the first-order mechanism to the aralkyl system. Some doubt, therefore, arises about the validity of the second-order mechanism suggested by Hart[1b] for this phenolysis.

One of the purposes of this study was to re-investigate the previous work[1b] in the presence of a base, especially at lower initial concentrations of the chloride, and to substantiate the applicability of S_N1 mechanism on the phenolysis of α-phenethyl system.

Another purpose was to clarify the details of kinetic nature of the intermediates of this phenolysis, and to examine the concept of Winstein's ion-pair intermediates[3].

First-order Nature of the Polarimetric and Titrimetric Rate Constants.—We have previously[2] shown that the titrimetric rate of the phenolysis of α-phenethyl chloride obeys good first-order kinetics in a phenol-nitrobenzene mixture both in the presence of and in the absence of sodium phenolate. In this study anilinium phenolate was used as a base, because in the phenolysis with sodium phenolate crystalline precipitate of sodium chloride makes the polarimetric measurement impossible.

The polarimetric rate constants, k_α, were measured in phenol-benzene (1 : 1 by weight) at 25°C, and satisfactory first-order behavior was observed in the decrease of optical activity, irrespective of presence or absence of the added base, this being illustrated graphically in Fig. 1. The observed rate constants are summarized in Table I.

Titrimetric rate constants, k_t, were also measured for comparison with the corresponding polarimetric values. Decrease of anilinium phenolate or increase of hydrogen chloride associated with the phenolysis obeyed good first-order kinetics, this being illustrated graphically in Fig. 2. The observed titrimetric rate constants are summarized also in Table I.

From these results it is clear, as previously anticipated[2], that the S_N1-type solvolytic mechanism is the only reasonable one for the phenolysis, at least in the range of lower concentrations of the chloride.

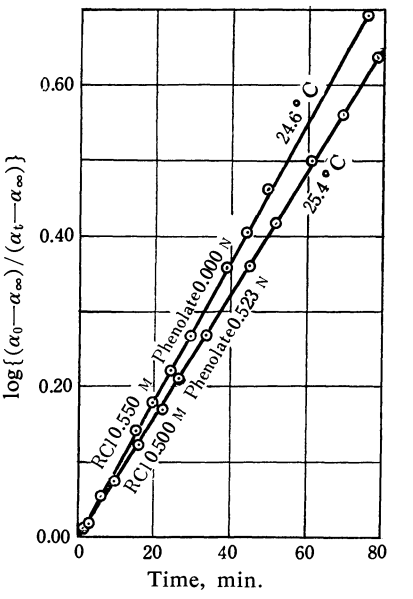

Fig. 1. Polarimetric rate of phenolysis at 25°C of (−)-α-phenethyl chloride in 50 wt.% phenol-benzene.

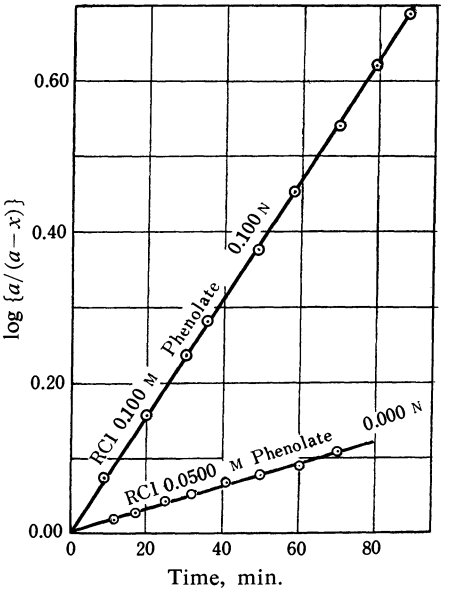

Fig. 2. Titrimetric rate of phenolysis at 25.0±0.1°C of α-phenethyl chloride in 50 wt.% phenol-benzene.

Relationships between the Rate Constants and the Initial Concentrations of the Added Base.—As illustrated graphically in Fig. 3, in the range of the initial anilinium phenolate concentrations from 0 to 0.5 M, the titrimetric rate constant rises very steeply with the phenolate concentration, reaches a maximum value and then decreases gradually. On the other hand,

the polarimetric rate constants exceed the titrimetric values in the whole investigated range of the initial concentrations of the phenolate. The discrepancy between k_α and k_t seems to be definite even in the higher phenolate concentrations. The k_α's may be regarded as fairly constant, because the minor decrease with phenolate concentrations would be explained as originating from the decrease of the net phenol concentration due to the added base.

This result, i. e., the existence of constant gap between k_α and k_t, appears to be similar to the one which Winstein and Robinson[4] found for acetolysis of *threo*-3-*p*-anisyl-2-butyl system. These authors[4] claimed their results as the experimental bases of their "ion-pair" multi-step mechanism. However, the following results of product analysis and of analysis of the steric course for this phenolysis enforced us to consider about the other type of intermediates and mechanism.

Product Analysis and Steric Course of the Phenolysis.—When the reactions were carried out in the presence of anilinium phenolate, it was found that the isolated products were α-phenethyl phenyl ether and a minor amount of α-phenethylphenols. On the other hand, as previously found by Hart and his coworkers[1a], in the absence of the phenolate the only reaction product at a comparable reaction time was a minor amount of α-phenethylphenols. Furthermore, the hydrogen chloride cleavage of α-phenethyl phenyl ether into α-phenethyl chloride and phenol was quite rapid (half-life time, 1~2 min.) in comparison with the phenolysis. In view of these analytical results and the rate-relation, it is clear that the consumption of hydrogen chloride by the anilinium phenolate eliminates the reverse

4) S. Winstein and G. C. Robinson, *J. Am. Chem. Soc.*, **80**, 169 (1958).

formation of α-phenethyl chloride, whereas in the absence of the phenolate the rapid reverse reaction interrupts formation of the phenyl ether.

The establishment of the steric course for this phenolysis made the mechanistic situation clearer. When optically active α-phenethyl chloride was phenolyzed in the absence of anilinium phenolate, the polarimetric measurement showed that almost completely racemic α-phenethylphenols were produced, this being shown in Table I. However, in the presence of anilinium phenolate partially optically active α-phenethyl phenyl ether with retained configuration was obtained along with a minor amount of almost (more than 99%) racemic α-phenethylphenols. It is evident that these optically active products should be derived from an optically active intermediate. This rules out the Winstein's "ion-pair" mechanism[3] which postulates racemic intermediates.

Absence of the Common-ion Effect. — As mentioned above the titrimetric rate constants showed good first-order behavior. This indicates that there is no rate suppression by anilinium hydrochloride produced during the reaction. Furthermore, for the reaction carried out in the presence of tetramethylammonium chloride (0.05~0.100 N) the titrimetric rate constants showed also good first-order kinetics and their values were a little higher than those in the absence of the chloride, probably owing to some ionic strength effects (cf. Table I). These results indicate that there is no common-ion depression for the phenolysis rate of α-phenethyl chloride.

In the case of phenolysis for *tert*-butyl chloride[2], it was found that tetramethylammonium chloride showed extraordinarily marked common-ion depression, and it was concluded that the ion-pair intermediate reacted with the chloride ion, giving the starting chloride through exchange of chloride ion of the intermediate. On the basis of this mechanism the absence of common-ion effect in α-phenethyl system may be explained by the relatively large stability of the ion-pair intermediate. This stability is reflected in the solvolysis rate in α-phenethyl system and may be the cause of the existence of two kinds of intermediates for this system.

Thus it may be concluded that the ion-pair intermediate in this case has no exchangeability for the chloride ion because of the more dipole-like nature of the ion-pair associate or the tightness of the solvation shell around the ion-pair.

Mechanism of the Phenolysis of α-Phenethyl Chloride. — In general the existence of the discrepancy between k_α and k_t merely indicates that the racemization (or ionization) process should preceed the product-formation stage. However, if the discrepancy vanishes at higher concentrations of the base or, in other words, if the rate of product-formation becomes equal to that of racemization (or ionization), it indicates that both of the processes should be connected with the same intermediate and the reaction should obey the two-stage mechanism. This can easily be illustrated by total rate expression for the common S_Ni-type two-stage mechanism. A pertinent example for this is found in the comparison of the ionization rate constants and product-formation rate constants for the acetolysis in 2-*p*-anisylpropyl system[5], although the authors[5] postulated a three-stage mechanism with two species of the intermediate, i. e., "intimate" and "solvent separated" ion-pair.

On the other hand, if the increase of the base concentration dose not lessen the gap between k_α and k_t even at the higher concentrations and the preponderance of k_α over k_t is definitely observed, any rate expression derived from the two-stage mechanism would fail to explain this gap. Therefore, it is suggested that there should be certain, i. e., kinetically distinct, process intervening between the racemization and the product-formation process; in other words, two species of intermediates would be required between these processes, at least. These inferences, of course, are drawn irrespective of the structures of the intermediates and also irrespective of the details of the mechanism for each stage.

From these considerations we are led to postulate the following three-stage (two-intermediate) mechanism for the phenolysis of α-phenethyl chloride. Since the intermediates involved in this reaction should have optical activities, it is required to divide the three-stage mechanism into two parallel series of three-stage reactions of the optically antipodal chlorides, (+)-RCl and (−)-RCl. Thus, each of the series of the reactions involves two species of antipodal intermediates, I_1 and I_2, and the racemization must take place by way of an equilibration between the first antipodal intermediates, i. e., (+)-I_1 and (−)-I_1. If the racemization is caused by an equilibration between the second antipodal intermediates, the coincidence of k_α and k_t at higher phenolate concentrations would result; the process could then be represented by a two-stage mechanism and the kinetical discrimination of I_1 and I_2 would be impossible. The postulated mechanism is illustrated in the following kinetic scheme.

5) S. Winstein and A. H. Fainberg, ibid., **80**, 459 (1958).

$$(+)\text{-RCl} \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} (+)\text{-I}_1 \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} (+)\text{-I}_2 \xrightarrow{k_3} (+)\text{-RY}$$
$$\qquad\qquad k_4 \downarrow\uparrow k_4$$
$$(-)\text{-RCl} \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} (-)\text{-I}_1 \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} (-)\text{-I}_2 \xrightarrow{k_3} (-)\text{-RY}$$

In this scheme k_3 represents the ove-all rate constant for the product formation stage and actually means the sum of two terms, namely, the rate constant, k_3', for the solvent phenol molecule (YH) and the rate constant, $k_3'' \times [Y]$, for the phenolate (Y).

Using steady-state conditions for the concentrations of these intermediates, we obtain the rate expressions for k_α and k_t in Eqs. 1 and 2, respectively.

$$k_\alpha = \frac{k_1}{1+\dfrac{k_{-1}}{2k_4+\{k_2k_3/(k_3+k_{-2})\}}} \qquad (1)$$

$$k_t = \frac{k_1}{1+\dfrac{k_{-1}}{k_2k_3/(k_3+k_{-2})}} \qquad (2)$$

Since the first intermediate, I_1, is considered as an ion-pair (see the next section), k_1 represents an ionization rate constant. Thus it is clear from Eq. 1 that the observed racemization rate constant, k_α, is not always equal to the ionization rate constant, k_1, except at a limiting condition, $k_4 \gg k_{-1}$. This condition is, of course, unapplicable to this reaction.

From Eq. 1, the independency of k_α on the initial concentration of the phenolate is explained by the limiting condition, $k_4 \gg k_2$, this being shown in Eq. 3.

$$k_\alpha = k_1/\{1+(k_{-1}/2k_4)\} \qquad (3)$$

The constancy of k_t as the first-order rate constant is also explained by the limiting condition, $k_3 \gg k_{-2}$, this being shown in Eq. 4.

$$k_t = k_1/\{1+(k_{-1}/k_2)\} \qquad (4)$$

Thus the constant gap between k_α and k_t observed for higher phenolate concentrations can be explained by comparing the above two equations, 3 and 4.

With diminution of the phenolate concentrations, however, the value of k_3 decreases, and reaches finally, in the absence of the phenolate, the value of k_3', i. e., the rate constant for the solvent phenol. This explains a sudden decrease of k_t in the vicinity of zero-concentration of the phenolate (cf. Fig. 3).

Discussion on the Structures of the Intermediates.— In consideration of the existence of the equilibration between the antipodes (−)-I_1 and (+) -I_1 and of the lack of common-ion depression, the intermediate I_1 may be assumed to be an ion-pair surrounded by a solvation shell, and in the shell the carbonium cation may rotate or invert over a difintie but small potential barrier with a relatively large rate constant k_4, giving another antipodal intermediate, I_1. From the predominant retention of configuration in the product, the second intermediate I_2 may be assumed to be a kind of quadrupolar associate consisting of an α-phenethyl chloride ion-pair and a molecule of phenol or of anilinium phenolate originated from one of the members of the solvation shell. At the third stage, i. e., product-formation step, these quadrupoles may collapse to the products with mostly retained configuration. This stage may proceed similarly to the intramolecular reaction of S_Ni-type[6].

As to structure of the intermediates, a short comment about Winstein's "intimate" and "solvent separated" ion-pair mechanism[3] seems to deserve mention here. It has already been stated that Winstein's three-stage mechanism was not necessary for explaining the acetolysis in 2-*p*-anisyl-1-propyl system[5] but that the common two-stage mechanism was applicable to this system. In contrast to 2-*p*-anisyl-1-propyl system, however, for the *threo*-3-*p*-anisyl-2-butyl system[4] Winstein and Robinson found that the gap between the k_α line and the k_t line in acetolysis actually widened as the concentration of the added lithium perchlorate increased. It is evident from our conclusion in the previous section that the definite discrepancy between k_α and k_t for this system requires two discrete intermediates in the formulation of mechanism. In regard to the structures of the intermediates, however, Winstein's two kinds of ion-pairs, namely "intimate" and "solvent separated", do not seem to be kinetically distinguishable as discrete intermediates, because such ion-pairs should be quite rapidly interchanged among them and their stabilities would be closely the same. Therefore, Winstein's discrimination between the ion-pair structures does not seem chemically well founded, and is inapplicable not only to this system but also to any other system which requires two kinds of intermediates.

For the first intermediate in this *threo*-3-*p*-anisyl-2-butyl system an internally compensated phenonium ion-pair structure, just as postulated by Winstein and Robinson[4], may be regarded as kinetically stable and discrete. The second intermediate which should also be a stable species, would be formulated as chemically different from the first one. In analogy with the second intermediate in the phenolysis of α-phenethyl chloride, it seems reasonable to postulate some stable species, such as a new

6) W. A. Cowdrey, E. D. Hughes, C. K. Ingold, S. Masterman and A. D. Scott, *J. Chem. Soc.*, **1937**, 1252.

phenonium ion-pair involving an acetate ion instead of the arylsulfonate ion involved in the first intermediate, or a quadrupolar associate between the first phenonium ion-pair and a molecule of acetic acid.

Unlike in the phenolysis of active α-phenthyl chloride, the racemization rate in the acetolysis for this system is equalized to the ionization rate owing to the formation of internally compensated phenonium ion-pair. This is interpreted by the kinetic Eq. 1 presented for the polarimetric rate constant of the phenolysis, because, in such a specific case where the interconversion rate between the first antipodal intermediates, k_4, is quite rapid, the equation becomes

$$k_\alpha = k_1 \qquad (5)$$

In addition, the discrepancy between k_α and k_t for this system may also be accounted for by application of Eq. 4. Thus, it is clear that the kinetic characteristics of this *threo*-3-*p*-anisyl-2-butyl system are interpreted by the same mechanism as presented for the phenolysis of α-phenetyl chloride.

Experimental[7]

Materials.—The preparation of racemic and of optically active α-phenethyl chloride followed previous practice[8]; b. p. 68.0°C/16 mmHg. for racemic chloride; b. p. 55.0°C/11 mmHg., $[\alpha]_D^{24.4}+17.76\pm 0.03°$, *l* 1 dm., homogeneous, and b. p. 59.0°C/12 mmHg, $[\alpha]_D^{31}$ −36.5°, *l* 1 dm., homogeneous. Aniline, phenol and benzene (reagent grade for each) were dried and purified by fractional distillation; b. p. 42.0~43.0°C/1 mmHg, 179.0~181.0°C and 80.0~81.0°C, respectively. Reagent grade tetramethylammonium chloride was dried to constant weight in a tarred flask at 120~130°C in vacuo.

Kinetic Measurements. — The phenolyses were carried out by the usual method[8], the diminution of anilinium phenolate (or the development of hydrogen chloride) being followed by titration of aliquots (1.000 cc.) with standard perchloric acid (or sodium acetate) in acetic acid. Each run was followed to 60~70% completion.

For the polarimetric rate measurements with Zeiss-Winckel "Kreispolarimeter 0.01°", the reaction mixtures, prepared at the reaction temperature, were immediately placed into a jacketed 2 dm. polarimeter tube maintained at the reaction temperature by circulation of water from a constant temperature bath.

Phenolyses of Racemic and Optically Active α-Phenethyl Chloride in 50 wt.% Phenol-Benzene in the Presence of Anilinium Phenolate.—A solution of (±)-α-phenethyl chloride (5.02 g.) in 0.52 N anilinium phenolate (70 cc.), prepared from desired weights of aniline and 50 wt.% phenol-benzene at 25.0°C, was kept at 25.0°C for 4 hr. (ca. six half-lives). The phenolysis mixture was then washed twice with 30 cc. portions of water and extracted with four 50 cc. portions of 10% aqueous sodium hydroxide and three 30 cc. portions of 20% aqueous sodium hydroxide. After acidification of the alkaline extract, the liberated phenols were extracted with benzene. The benzene solution was dried, and after distillation of the benzene vacuum distillation of the residual material gave phenol (16.8 g., b. p. 69.0°C/7 mmHg) and mixture of *o*- and *p*-α-phenethylphenols (0.50 g., b. p. 140~155°C/3 mmHg; lit.[1a] 165~180°C/5~6 mmHg). After the alkaline extraction of the phenolysis mixture the remaining benzene layer was washed with water and dried with anhydrous sodium sulfate. Distillation of the benzene afforded an oily material which was distilled in vacuo to give α-phenethyl phenyl ether (4.5 g., b. p. 123~128°C/4 mmHg, m. p. 35.0~36.0°C; lit.[9] 143~145°C/10 mmHg, m. p. 38~39°C) and a mixture of *o*- and *p*-α-phenethylphenols (0.50 g., b. p. 140~145°C/5 mmHg). No attempt was made to determine the ortho-para ratio of the phenol mixture. There was not found any styrene fraction before the α-phenethyl phenyl ether fraction, and the recovered benzene did not give any styrene peak in gas-liquid partition chromatographical analysis.

The phenolysis of (−)-α-phenethyl chloride (α_D, see materials section) was carried out polarimetrically and then the product analysis of the reaction mixture was made. A solution of (−)-α-phenethyl chloride (5.220 g.) in 0.550 N anilinium phenolate (70.0 cc.) was kept at 25.0°C for 22 hr. (ca. 44 half-lives). Part of the solution was used for the polarimetric run at 25°C. The combined reaction mixtures, similarly treated to the run with the racemic chloride, gave (+)-α-phenethyl phenyl ether (4.16 g., b. p, 111.0~113.0°C/2 mmHg, yield 56.5%, $[\alpha]_D^{34}+2.29°$, *l* 1 dm., homogeneous; Found: C, 84.68; H, 7.14. Calcd. for $C_{14}H_{14}O$: C, 84.81; H, 7.12%) and (−)-α-phenethylphenols (a mixture of *o*- and *p*-derivatives, b. p. 150~165°C/7 mmHg, yield 13.6%, $[\alpha]_D^{34}-0.42°$, *l* 1 dm., *c* 23.8, benzene).

The second run carried out under the same conditions with (+)-α-phenethyl chloride (3.525 g., α_D see materials section) solution (50.0 cc.) of 0.552 N anilinium phenolate afforded 3.0 g. of (−)-α-phenethyl phenyl ether (b. p. 133~135°C/5 mmHg, n_D^{25} 1.5665, yield 60.0%, $\alpha_D^{24.7}+1.21°$, *l* 1 dm., homogeneous; Found: C, 84.93; H, 7.20%).

Phenolysis of (±)-α-Phenethyl Chloride in 50 wt.% Phenol-Benzene in the Absence of Anilinium Phenolate.—A solution of (±)-α-phenethyl chloride (4.92 g.) in 50 wt.% phenol-benzene (62.8 g.) was kept at 20~25°C for 22 hr., and then at 50.0°C for 7 hr. After similar treatment to the run in the presence of anilinium phenolate, the benzene layer after alkaline extraction gave 0.10 g. of α-phenethylphenols (b. p. 132~133°C/2 mmHg) and from the alkaline extract 3.5 g. of α-phenethylphenols (140~156°C/4 mmHg) was isolated.

Hydrogen Chloride Cleavage of α-Phenethyl Phenyl Ether in 50 wt.% Phenol-Benzene.—The cleavage was followed titrimetrically. In a 20 cc.

volumetric flask, α-phenethyl phenyl ether (137 mg.) solution of 0.045 N hydrogen chloride was made at 25°C. The reaction percentage was estimated to be 74.0% at two minutes after mixing. The diminution of hydrogen chloride reached a minimum value (84.7% of conversion for ether), then the gradual increase of hydrogen chloride concentration, due to the slow phenolysis of α-phenethyl chloride produced, was observed.

Summary

1. Titrimetric and polarimetric rate constants (k_t and k_α) for phenolysis of α-phenethyl chloride in 50 wt.% phenol-benzene at 25°C were measured, and satisfactory first-order behavior was observed irrespective of presence or absence of anilinium phenolate. From this the S_N1-characteristics of this phenolysis was concluded.

2. The values of k_α's were fairly constant at any phenolate concentrations (0.0~0.6 N). The k_t's were also fairly constant at higher phenolate concentrations. However, the k_t's gave smaller values than the k_α's, and showed a sudden decrease in the vicinity of zero phenolate concentration. The gap between the k_α line and k_t line was not diminished and remained fairly constant as the phenolate concentration increased.

3. In the presence of anilinium phenolate the main product was α-phenethyl phenyl ether with predominantly retained configuration, whereas in the absence of the phenolate only a minor amount of α-phenethylphenol was obtained.

4. From the constant gap observed between k_α and k_t it was generally concluded that the phenolysis should proceed by way of a two-intermediate (I_1 and I_2) three-stage mechanism. In view of the predominant retention of configuration in the product, it was postulated that the intermediates should be optically active. Hence the mechanism was divided into parallel series of the three-stage processes for the optically antipodal chlorides and intermediates, namely,

$$(+)RCl \rightleftarrows (+)I_1 \rightleftarrows (+)I_2 \rightarrow (+)RY$$

and

$$(-)RCl \rightleftarrows (-)I_1 \rightleftarrows (-)I_2 \rightarrow (-)RY$$

These parallel series of the processes were connected with each other by fairly rapid equilibration between the first antipodal intermediates ($-I_1$ and $+I_1$). For the first intermediate was suggested an ion-pair surrounded by a solvation shell and for the second a kind of quadrupolar associates which consist of the ion-pair and the reactant dipole (phenol or anilinium phenolate).

5. It was pointed out that a necessary condition for the existence of three-stage mechanism is a kinetically-definite stabilization of the two kinds of intermediates. This stabilization was verified by the absence of common-ion depression for this phenolysis rate. It was also pointed out that unstable ion-pair intermediates, like "solvent separated" and "intimate" ion-pair, could not be kinetically distinguished among themselves, and that in this case any three-stage formulation actually converged to two-stage treatment. This was shown in the case of acetolysis in 2-*p*-anisylpropyl system to which Winstein and Fainberg[5] assumed their three-stage mechanism to be applicable.

6. It was shown that Winstein's three-stage mechanism with the "intimate" and "solvent separated" ion-pairs is generally unapplicable to any cases where a three-stage is required, e.g., not only to this phenolysis but also to the acetolysis in *threo*-2-*p*-anisyl-3-butyl system[4]. For the latter a three-stage mechanism similar to the one suggested for this phenolysis in α-phenethyl system was presented. Fairly stable, two discrete intermediates, namely, a phenonium ion-pair for the first intermediate and a quadrupolar associate between the first intermediate and acetic acid molecule for the second were suggested.

Preparation and Properties of Alkyl Trifluorovinyl Ethers and Related Compounds[1]

By Kunio OKUHARA, Hajime BABA and Rimpei KOJIMA

(Received June 1, 1961)

Since 1946[2], many fluoroethers have been synthesized by the addition of alcohols to fluoroölefins under alkali catalysis, and a mechanism has also been presented[3]. These fluoroethers are usually saturated addition products, and some fluoroethers easily split off hydrogen fluoride to give vinyl ethers[4-6]. According to previous reports[5,6], it can be inferred that the larger the number of fluorine attached to the olefin carbons, the higher the stability of the resulting fluoroether. It was for this reason that the dehydrofluorination of methyl 1, 1, 2-trifluoro-2-chloroethyl ether was found to require a prolonged refluxing over solid potassium hydroxide[7].

Another procedure for preparing fluorovinyl ether has been presented by Meier and Böhler[8]. They synthesized ethyl 1, 2-difluoro-2-chlorovinyl ether directly by the reaction of trifluorochloroethylene with alcohol-free sodium ethylate.

By using the same method, trifluorovinyl, methyl, ethyl, isopropyl and *tert*-butyl ethers were prepared, the first of which has already been described by Dixon[9]. In our experiment the accompanying formation of the corresponding saturated tetrafluoroethyl ethers could not be avoided because highly alcohol-free sodium alcoholates were not available.

$$CF_2=CF_2+NaOR\rightarrow CF_2=CFOR+NaF$$

$$CF_2=CF_2+HOR\rightarrow CF_2HCF_2OR$$

R ; CH_3, C_2H_5, $CH(CH_3)_2$, $C(CH_3)_3$

The apparent reactivity of the alcoholates toward tetrafluoroethylene increased in the following order: methyl, ethyl < isopropyl, *tert*-butyl.

In the alkyl trifluorovinyl ethers, the absorption peak of C=C occurs within the range 5.46～5.50 μ (1832～1818 cm^{-1}). This position seems exceptionally short for C=C, but it is reasonably correlated with those of reference compounds, as is shown in Table II.

Trifluorovinyl and 1, 2-difluoro-2-chlorovinyl ethyl ethers give chlorine and bromine addition products. They are easily hydrolyzed to the corresponding esters according to the method that was used for the hydrolysis of α, α-difluoroethers by Tarrant and Young[10]. The adducts and esters are given in Table III. The adducts are so reactive that crude adducts from the

reaction mixtures were always accompanied by the corresponding esters. Furthermore, in the absence of potassium carbonate, some decomposition to acyl fluoride and alkyl halide could not be avoided during the fractional distillation the crude reaction product.

Methyl trifluorovinyl ether polymerized, even when stored in a refrigerator, to give a white solid deposit. Ethyl trifluorovinyl ether became viscous upon standing in a sealed tube at room temperature, and was polymerized with common free-radical initiators to give a balsam-like mass. Propyl trifluorovinyl ether could not be polymerized. These facts are interesting when compared with the facts[12] that the high polymers of vinyl methyl, ethyl and other alkyl ethers can be obtained only by cationic polymerization, and that isopropyl vinyl ether is also capable of forming a polymer.

tert-Butyl trifluorovinyl ether was very unstable and decomposed, upon standing, to the acyl fluoride and isobutene. This is analogous to the decomposition of 1, 1, 2, 2-tetrafluoro- and 1, 1, 2-trifluoro-2-chloroethyl *tert*-butyl ethers[5,11]. It is noteworthy that the vinyl ether decomposed as easily as the saturated ether.

Postulated Carbonium Ion of the Type $-O-\overset{F}{\overset{|}{\underset{+}{C}}}-$.—The high reactivity of the fluoroethers prepared, and of other α-haloethers, seems to be explained by assuming the formation of a carbonium ion* of the type $-O-\overset{|}{\underset{+}{C}}-$. Tiers postulated carbonium-oxonium ion in the transformation of α-fluoroethers with aluminum trichloride to the corresponding α-chloroethers[13].

With this group of compounds, not only the halogen exchange and the hydrolysis to esters, but also the decomposition to alkyl and acyl halides, are subject to acid catalysis. The operation of acid catalysis is supported by the facts that *tert*-butyl 1, 1, 2-trifluoro-2-chloroethyl ether from which hydrogen fluoride had been removed by adsorption was fairly stable[4], and that potassium carbonate is effective as the stabilizer of the ethers prepared in this experiment. The three reactions, decomposition, halogen exchange and hydrolysis, are thought to proceed through the same intermediate, carbonium-oxonium ion.

As this type of compound is relatively stable when acids are removed, an intramolecular reaction through a cyclic transition state[7] is not sufficient to explain the decomposition. It rather seems to be an intermolecular reaction and to proceed by a chain mechanism. With the compound of the type $-O-\overset{F}{\overset{|}{\underset{X}{C}}}-$ (where

Chart I. Formation of carbonium-oxonium ion and its secondary transformations.

[A]=H^+ or other acid such as $AlCl_3$
X =F or other halogen

X is Cl or Br), X^- is preferentially removed and fluorocarbonium-oxonium ion is formed, judging from the decomposition products of 1, 2-difluoro-2-chloro-1, 2-dibromoethyl- and 1, 2-difluoro-1, 2, 2-trichloroethyl ethyl ethers.

$$C_2H_5OCFCFClBr \xrightarrow{H^+} C_2H_5OCFCFClBr \xrightarrow{-HBr}$$

$$C_2H_5OCFCFClBr \longrightarrow C_2H_5^+ + O{=}CCFClBr$$

$$C_2H_5OCFCFClBr \xrightarrow{C_2H_5^+} C_2H_5OCFCFClBr + C_2H_5Br$$

$$C_2H_5^+ \longrightarrow CH_2{=}CH_2 + H^+$$

Compounds which are capable of forming carbonium-oxonium ion and thus undergoing a similar decomposition (rearrangement, in the case of cyclic ethers) are not only α-halo and vinyl ethers, but also α-carboxy ethers[14], haloformates[15], etc.

In the hydrolysis of α, α-difluoroethers to the esters, it is inconsistent with experimental findings to assume that the reaction proceeds through the oxonium ion in which a proton is attached to the oxygen of the ether[10]. A route through carbonium-oxonium ion could explain the hydrolysis of both α, α-difluoroethers and α-fluorovinyl ethers[8].

Reactions that could be interpreted as electrophilic aromatic substitution involving carbonium-oxonium ion have also been reported[16].

Experimental

Ethyl Trifluorovinyl Ether.—A mixture of 164 g. of sodium ethylate and 450 ml. of dioxane was placed in a 2 l. autoclave. After moderate evacuation, the autoclave was charged with about 200 g. of tetrafluoroethylene at one time and shaken until the pressure was constant. The pressure readings during the shaking were 30 kg./cm² (initial), 23 kg./cm² (1 hr.), 13 kg./cm² (22 hr.), and 5 kg./cm² (120 hr.; final). The liquid products were separated by centrifiguration or suction filtration from the solid products and the liquid remaining on the solid was evaporated under reduced pressure and collected in cold traps. The rectification of the combined dioxane solution over potassium carbonate under nitrogen atmosphere gave ethyl trifluorovinyl ether (161 g., 53% yield), boiling at 38.5°C, and 1, 1, 2, 2-tetrafluoroethyl ether (15 g., 4% yield), boiling at 57°C.

Methyl trifluorovinyl ether was prepared in a similar fashion, but in one experiment a violent explosion of the charged tetrafluoroethylene occurred.

In the preparation of isopropyl trifluorovinyl ether, the first portion (69 g., 15 kg./cm²) of tetrafluoroethylene was taken up completely by 250 g. of sodium isopropylate within 15 min. at 10°C and considerable heat was generated.

***tert*-Butyl Trifluorovinyl Ether.**—Both trifluorovinyl and 1, 1, 2, 2-tetrafluoroethyl *tert*-butyl ethers were unstable and decomposed to form two layers on storage in a sealed tube at room temperature. The decomposition products were not thoroughly examined, but their infrared spectra showed that the upper layers from both compounds are polyisobutene, the lower layer from the vinyl ether is an acyl fluoride, while the one from the tetrafluoroether is a mixture of a carboxylic acid and a small amount of the acyl fluoride. Based upon similar dicomposition[4,5,11], the acyl fluoride is assumed to be difluoroacetyl fluoride and the acid to be difluoroacetic acid.

$$(CH_3)_3COCF{=}CF_2 \longrightarrow (CH_3)_2C{=}CH_2 + O{=}CCF_2H$$

$$(CH_3)_3COCF_2CF_2H \longrightarrow (CH_3)_2C{=}CH_2 + HF + O{=}CCF_2H$$

In the latter case, the hydrogen fluoride and the acyl fluoride may have reacted with the glass wall to yield the carboxylic acid.

$$\begin{cases} SiO_2 + 4HF \longrightarrow SiF_4 + 2H_2O \\ Na_2SiO_3 + 6HF \longrightarrow Na_2SiF_6 + 3H_2O \end{cases}$$

$$O{=}CCF_2H + H_2O \longrightarrow O{=}CCF_2H + HF$$

Bromine Derivatives of 1, 2-Difluoro-2-chlorovinyl Ethyl Ether.—Difluorochlorovinyl ethyl ether[8] (26.0 g.) in chloroform (11 g.) was added dropwise to a solution of bromine (29.7 g.) in chloroform (60 g.) with stirring and cooling. The resultant solution was washed with aqueous potassium carbonate-sodium thiosulfate, dried over sodium sulfate, and fractionated. After the chloroform was distilled, the temperature at the head of the column suddenly dropped and fluctuated between 41 and 48°C, showing the occurrence of a decomposition. The liquid decomposition product (37.1 g.) was shown to be a mixture of an acyl fluoride (5.35 μ) and ethyl bromide (reported b. p. 38.4°C) by its infrared spectra. The fluoride is most likely to be fluorochlorobromoacetyl fluoride. (Ref. a of Table III reports b. p. 51°C.) Ethylene was also noted in the gaseous decomposition product by its characteristic multiplet around 10.5 μ.

In order to prevent decomposition, potassium carbonate was added to the still-pot, and the distillation was successfully carried out. A duplicate run, but with distillation over potassium carbonate, gave 1, 2-difluoro-2-chloro-1, 2-dibromoethyl ethyl ether (33.7 g., 61% yield), boiling at 170°C. Sodium carbonate was not so effective as potassium carbonate in preventing such decompositions.

The bromoether (17.8 g.) was treated with 98% sulfuric acid (70 g.) for 50 min. without cooling, poured into ice-water, extracted with chloroform, washed with aqueous potassium carbonate and dried over sodium sulfate. Distillation of the resultant solution gave ethyl fluorochlorobromoacetate (6.7 g. 53% yield), boiling at 145°C.

Chlorine Derivatives of 1, 2-Difluoro-2-chlorovinyl Ethyl Ether.—Chlorine was bubbled through a solution of difluorochlorovinyl ethyl ether (22.0 g.) in chloroform (83 g.) until the solution turned yellow from an excess of chlorine under ice-salt cooling. The resultant solution was washed with aqueous potassium carbonate, dried over sodium sulfate and distilled. A saturated ether (15.4 g., 39% yield) boiling at 157°C was obtained. The elementary analysis showed that three chlorines were introduced during the chlorination. The ether was tentatively identified as 1-chloroethyl 1, 2-difluoro-1, 2, 2-trichloroethyl ether by its infrared spectrum (6.75 μ, 6.90 μ and 7.27 μ), compared with that of 1, 2-difluoro-1, 2, 2-trichloroethyl ethyl ether (6.91 μ, 7.20 μ).

Dioxane was found to be a suitable solvent to stop the reaction at the stage of chlorine addition. Thus, chlorine was bubbled through a solution of difluorochlorovinyl ethyl ether (15 g.) in dioxane (30 g.) until the solution turned yellow from an excess of chlorine. The resultant dioxane solution was poured into aqueous potassium carbonate, and the lower layer was separated, dried over sodium sulfate and distilled over potassium carbonate. 1, 2-Difluoro-1, 2, 2-trichloroethyl ethyl ether (10.4 g., 46% yield), boiling at 134°C, was obtained. A duplicate distillation without potassium carbonate gave no difluorotrichloroethyl ethyl ether. However, ethyl chloride and ethylene, but no ethyl fluoride, were noted in the gaseous decomposition product.

The ethers and ester from ethyl trifluorovinyl ether were obtained like those from 1, 2-difluoro-2-chlorovinyl ethyl ether; their boiling points and analytical data are given in Table III. However, ethyl 1, 2, 2-trifluoro-1, 2-dichloroethyl ether could not be obtained in a pure state, being contaminated with the corresponding ester, ethyl difluorochloroacetate (reported[17] b. p. 97°C).

summary

Trifluorovinyl methyl, ethyl, isopropyl and *tert*-butyl ethers have been prepared. These trifluorovinyl ethers show C=C absorption at such a short wavelength as 5.46~5.50 μ. The methyl and ethyl ethers can be polymerized by free-radical initiators. Halogen addition products of trifluorovinyl- and 1, 2-difluoro-2-chlorovinyl ethers have also been prepared. With α-halo or vinyl ethers, the reactions that are catalyzed by acids, including decomposition, are best interpreted as proceeding through the carbonium ion stabilized by carbonium-oxonium resonance.

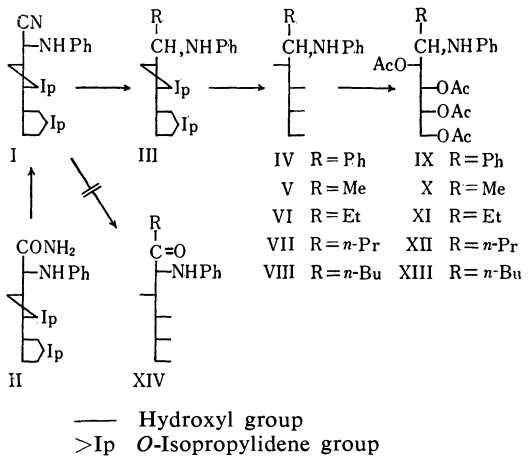
Studies on D-Glucosamine Derivatives. VIII[1]. *1-C-Substituted-1-anilino-1-deoxy-D-arabitols**



By Juji YOSHIMURA

(Received August 3, 1961)

In a previous paper[2], syntheses of 3, 4; 5, 6-di-*O*-isopropylidene-*N*-phenyl-D-glucosaminonitrile (I) and of 3, 4; 5, 6-di-*O*-isopropylidene-*N*-phenyl-D-glucosaminic acidamide (II) have been described. In the present study, the additon of Grignard reagents or alkyl lithiums to the unsaturated function of these compounds is examined, in expectation of obtaining the corresponding 1-*C*-substituted-1-keto-D-glucosamine derivatives (XIV).

Compound I reacted exothermally with Grignard reagents in ether to yield sirupy materials, which on hydrolysis with mineral acid and extraction of the neutrallized hydrolyzate with ethyl acetate gave crystalline materials. These crude crystals were separated into the two diastereoisomers by fractional crystallization from ethyl acetate, of which the one was a dextro-rotating minor product and the other a levo-rotating major product in every case. (In this report, the former is temporarily represented as A-compound and the latter as B-compound.)

The analytical data of these crystals were, however, not consistent with that of XIV. The infrared spectra shown in Fig. 1 indicated the presence of NH and anilino bands at 3300 and 1600 cm^{-1}, but the absence of CN and -CO- bands. It is worthy to note that a few differences between A- and B-compounds in their absorption bands were generally found in the region from 850 to 1050 cm^{-1}. Moreover, the substitution of alkyls to the C-2 of I was deduced from the fact that the diastereoisomers (IV-A and IV-B) obtained from I and phenylmagnesium bromide gave benzoic acid in 70% yield by alkalline permanganate oxidation. The structures of these crystals were, therefore, assigned to the 1-*C*-substituted-1-anilino-1-deoxy-D-arabitols (IV-VIII).

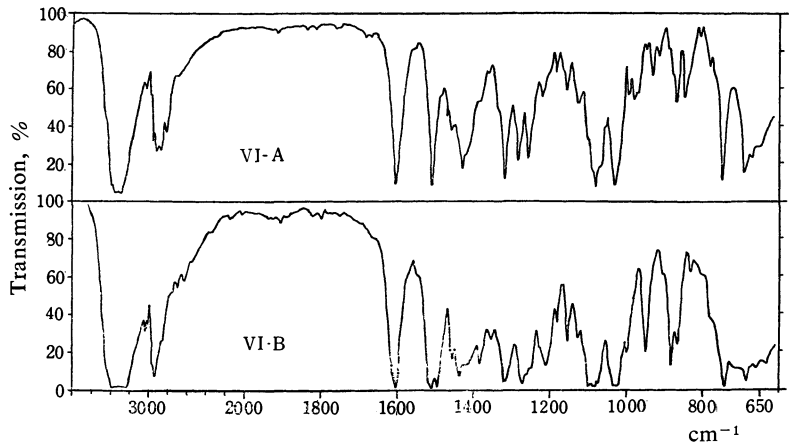


Fig. 1.

* A part of this was presented at the 13th Annual Meeting of the Chemical Society of Japan, Tokyo, 1960.

1) Part VII of this series, This Bulletin, 35, 467 (1962).
2) J. Yoshimura, ibid., 33, 1404 (1960).

These arabitols were converted to the corresponding tetraacetates (IX–XIII) by treating with acetic anhydride in dry pyridine. The melting points, rotation values and analytical data of these diastereoisomeric arabitols and the acetates are listed in Tables I and II.

The reaction products between I and alkyl lithiums were also syrupy, except for 1-*C*-phenyl-1-anilino-1-deoxy-3, 4; 5, 6-di-*O*-isopropylidene-D-arabitol (III; R=phenyl) obtained from I and phenyl lithium, and each crude syrup was hydrolyzed to the two corresponding diastereoisomers, in a manner similar to that in the case of the Grignard reactions. However, the minor products were the B-compounds and the major, the A in this case. A comparison of the yields of both the A- and B-compounds is made in Table III.

To pursue the whereabouts of the nitrile group in I, the cyano ions in the reaction mixture of I and alkyl lithiums, after having been decomposed with water and extracted with ether, were examined qualitatively and quantitatively. It was found that the water layer showed the positive blue coloration of cyano ions with cupric acetate and benzidine, and that the amount were determined, by volumetric titration using silver nitrate, to correspond to the yields of the arabitols (about 60%) in every case.

The above results indicate that the reaction of I with the Grignard reagents or alkyl lithiums gives rise to the replacement of the nitrile group by the alkyls of these reagents instead of the addition to its unsaturated bond. Although this type of reactions has not been

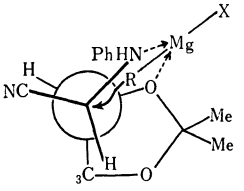
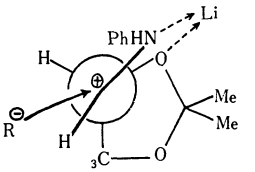
exhaustively investigated, it appears to be fairly general for α, α-disubstituted cyanohydrins[3] and α-aminonitriles[4], among which is I. Kharasch[5] assumed that in all these cases the bond between the nitrile group and the others has a rather high degree of ionic character, with the negative end of the dipole at the cyano group, but the radicals attached to the cyano group are rather weakly electronegative.

On the other hand, the reaction of I with the Grignard reagents led mainly to B-compounds, while alkyl lithiums lead to the A. Although a few examples[6] have been known in which organomagnesium and organolithium compounds showed sterically different behavior, no reports relating to such a characteristic in asymmetric induction has appeared up to the present.



The absolute configuration at C-1 of the diastereoisomers must be determined by another method. However, it seems likely that A-compounds have a glucosamino-structure and the B-compounds a mannosamino-structure, as the former has the same dextro-rotatory character as I. Bonner[7] has already proved that the more dextro-rotatory one of the two diastereoisomers of 1-*C*-phenyl-D-pentitol obtained from 3, 4; 5, 6-diisopropylidene-D-glucosamine and phenylmagnesium bromide, possesses a glucostructure, and the other a manno-structure.

The most stable configuration (XV) of the reaction center of I shown by Newman's representation[8] suggests that it is very reasonable to assume the rigid complex model (XVI) in the transition state, as proposed by Cram et al.[9] as a result of extensive studies on asymmetric induction. Thus, it is concluded that rather polar Grignard reagents reacted smoothly, accompanying Walden inversion[10], to afford a mannosamino-structure.

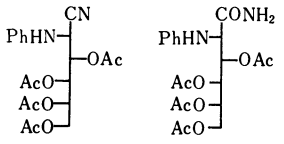


If the nitrile group is eliminated initially through either ionic or free radical mechanism, the alkyl group will predominantly attack from the direction of the previously existing nitrile group on the transition state (XVII), to afford

XV

XVI

XVII



a glucosamino-structure. This mechanism is very suitable to explain the fact that the reaction of I and alkyl lithiums afforded the glucosamino-structure, but the reason for the distinctly different behavior between organomagnesium and organolithium compounds in the reaction described in this paper remains ambiguous. The rather covalent character of the simple organolithium compound, however, has been provided by the non-conductance of solutions of ethyl lithium in benzene[11] and low dipole moment of butyl lithium[12]. This character seems likely to prevent the Walden inversion through the formation of XVI.

The reaction of II with Grignard reagents or alkyl lithiums in ether afforded unchanged II over 80%. Even though the reaction was performed in benzene at 100°C for four hours, 50~56% of II was recovered, and the mother liquor produced a small amount of the D-arabitols when treated in the usual manner. It is interesting that the B-compounds were obtained in the former case and the A-compounds in the latter. From this fact, it can be deduced that the amide II was initially dehydrated to the nitrile[13].

As expected XIV was not obtained in the above-mentioned methods, Hoesch's method[14]

for the synthesis of ketones by condensation of a nitrile with phenols was examined with regard to 3, 4, 5, 6-tetra-*O*-acetyl-*N*-phenyl-L-glucosaminonitrile (XVIII)[2]. The mixed solution of XV, fused zinc chloride in chloroform and phenol or catechol in ether was saturated with hydrogen chloride at 0°C and left to stand 2 weeeks in a refrigerator. However, the product obtained was the corresponding acidamide (XIX). This result indicates that the aminonitrile XVIII has a very weak function as a nitrile.

XVIII XIX

Experimental

General Procedure for the Reaction of 3, 4; 5, 6-Di-*O*-isopropylidene-*N*-phenyl-D-glucosaminonitrile (I) with Organometallic Compounds.—To an ice-cold ether solution of the desired Grignard reagents or alkyl lithiums prepared from 0.045 mol. of the corresponding halides and 0.045 mol. of magnesium ribbon or 0.09 mol. of metal lithium was added 5 g. (0.015 mol.) of I in three portions with stirring. After refluxing on a water bath for 3 hr., the cold reaction mixture was cautiously ponred into ice-water, and precipitates were dissolved by the addition of 2 N hydrochloric acid in the case of Grignard reactions.

The aqueous layer was separated from the ether layer and extracted three times with 30 ml. of ether. The combined ether solution was washed with water, dried over anhydrous sodium sulfate, and concentrated in vacuo. The resultant sirup was hydrolyzed in 50% ethanol containing 2 N hydrochloric acid at 60°C for 40 min. and then concentrated in vacuo. The hydrolysis of the isopropylidene group was also accomplished with a small amount of concentrated hydrochloric acid at room temperature for 20 min.

The sirup obtained from acid hydrolyzate was dissolved in water; the small amount of brown oily substance remained was then filtered off through active carbon on filter paper, and the pH of the filtrate was adjusted to 10 with ammonia. The alkaline solution was extracted three times with 50 ml. of ethyl acetate, and the extracts were washed with water and dried with anhydrous sodium sulfate. After evaporation of the solvent under reduced pressure, the crude 1-*C*-substituted-1-anilino-1-deoxy-D-arabitols obtained (IV—VIII) were fractionally crystallized from ethanol or ethyl acetate.

In general, the crude crystals obtained by the Grignard reactions afford the pure B-compound as plates after one recrystallization in ethyl acetate. After repeated separation of the B-compound, a small amount of the A-compound was obtained as needles. In the case of alkyl lithiums, the crude material were dissolved in a suitable amount of hot ethanol, and a small amount of the B-compound was slowly deposited by leaving it to stand at room temperature.

The amounts of A- and B-compounds in the small amount of remaining crystals were determined from its rotational values and were added to each weight of the separated pure substances.

The physical constants of the arabitols are listed in Table I, and a comparison of the yields of the both diastereoisomers is made in Table III.

1-*C*-Phenyl-1-anilino-1-deoxy-2, 3; 4, 5-Di-*O*-isopropylidene-D-arabitol (III, R=Phenyl).—To an ice-cold ether solution of phenyl lithium prepared from 3.9 ml. of bromobenzene was added 4.2 g. of I with stirring. After refluxing 3 hr. on a water bath, the cooled reaction mixture was poured into ice water. The aqueous layer was then separated from the ether layer and extracted with ether. The volumetric titration of cyano ions in the water layer with 5% silver nitrate was shown to be 62.5% of the theoretical value.

The combined ether solution was washed twice with water, dried over anhydrous sodium sulfate and concentrated in vacuo to dryness. The residual sirup (4.7 g.) afforded colorless needless from ethanol-petroleum ether. Yield, 2.0 g., m. p. 88~89°C.

Found: C, 71.60; H, 7.52; N, 3.73. Calcd. for $C_{23}H_{29}O_4N$ (383.5): C, 72.03; H, 7.62; N, 3.65%.

One gram of the above crystal was dissolved in 2 ml. of concentrated hydrochloric acid and diluted with 30 ml. of water after having been left to stand for 20 min. at room temperature. The resultant clear solution was neutralized with an excess amount of ammonia, and the crystalline materials separated were collected and recrystallized from methanol to afford 0.72 g. of pure 1-*C*-phenyl-1-anilino-1-deoxy-D-arabitol (IV-A), m. p. 191~192°C.

The sirup obtained from the mother liquor of III (R=phenyl) was treated in exactly the same manner as described in the general procedure, and afforded 1.1 g. of IV-A (total yield, 63.0%).

Acetylation of 1-*C*-Substituted-1-anilino-1-deoxy-D-arabitols.—A mixture of 2 g. of each arabitol, 10 ml. of acetic anhydride and 10 ml. of dry pyridine was left to stand overnight at room temperature and then poured into ice-water. The solution was extracted with chloroform in the usual manner. The sirup obtained by evaporation of the solvent was crystallized from ethanol-petroleum ether.

The yield was generally 85~90% of the theoretical value. The physical constants of these tetraacetates are presented in Table II.

Reaction of 3, 4; 5, 6-Di-*O*-isopropylidene-*N*-phenyl-D-glucosaminoamide (II) and Organometallic Compounds.—i) To an ice-cold ether solution of ethylmagnesium bromide prepared from 3.5 ml. of ethyl bromide was added 5 g. of II with stirring. After removing the solvent, 50 ml. of dry benzene was added, and the mixture was refluxed for 3 hr. in an oil-bath at 100°C. The cooled reation mixture was poured into ice-water and treated in the usual manner. The sirup obtained was dissolved into a small amount of ethanol,

and light petroleum ether was added just before clouding took place. After keeping it in a refrigerator overnight, the unchanged II (3.0 g.) was filtered off. The mother liquor was concentrated in vacuo, and the residual sirup afforded crystals of VI-B, m. p. 160°C, 150 mg., after treatment in the manner described in the general procedure. These showed no depression on admixture with authentic samples.

ii) A mixture of II (5.0 g.) and phenyl lithium prepared from 5 ml. of bromobenzene in ether was refluxed for 4 hr. on a water-bath and treated in the same manner as has been described above. Four grams of unchanged II and 60 mg. of IV-A, m. p. 190~191°C, were obtained, and the latter showed no depression on admixture with an authentic sample.

iii) A mixture of 2.5 g. of 3,4; 5,6-di-*O*-isopropylidene-*N*-phenyl-L-glucosaminoamide[2] (L-form of II) and phenylmagnesium bromide prepared from 2.4 ml. of bromobenzene in benzene was refluxed on an oil-bath for 3 hr. and then treated in the usual manner. 1.3 g. of unchanged starting material was filtered off, and the residual sirup obtained from the liquor was re-dissolved in dry benzene, and hydrogen chloride passed into it. The resulted precipitates, when treated in the usual manner, afforded crystalline 1-*C*-phenyl-1-anilino-1-deoxy-L-arabitol, (L-form of IV-B), m. p. 163~165°C, 38 mg., $[\alpha]_D^{25}+3.5°$ (*c* 0.55, methanol) and several milligrams of its diastereoisomer, m. p. 189~191°C.

Found of the former: C, 67.02; H, 7.11; N, 4.66. Found of the latter: C, 66.62; H, 7.29; N, 4.69. Calcd. for $C_{17}H_{21}O_4N$: C, 67.31; H, 6.98; N, 4.62%.

An Attempt at Using the Hoesch Synthesis on 3, 4, 5, 6-Tetra-*O*-acetyl-*N*-phenyl-L-glucosaminonitrile (XVIII) and Catechol. — A clear mixed solution of 2.4 g. of XVIII, 0.65 g. of catechol in 10 ml. of chloroform and 0.7 g. of anhydrous zinc chloride in 20 ml. of ether was saturated with hydrogen chloride at 0°C and stored in a refrigerator. The white sirupy materials separated were gradually crystallized. After being left to stand for two weeks, the supernatant liquid was decanted, and the crystals were rinsed twice with ether, then dissolved in chloroform. The chloroform solution was washed with a small amount of diluted ammonia and water and then concentrated to dryness in vacuo. The remaining material was crystallized from ethanol. Yield 1.5 g., m. p. 160~162°C, $[\alpha]_D^{27}$ −18.5° (*c* 0.67, chloroform).

Found: C, 54.42; H, 6.07; N, 6.43. Calcd. for XIX, $C_{20}H_{26}O_9N_2$ (438.4): C, 54.79; H, 5.98; N, 6.39%.

Summary

In the reaction of 3, 4; 5, 6-di-*O*-isopropylidene-*N*-phenyl-D-glucosaminonitrile and Grignard reagents or alkyl lithiums, the nitrile group was substituted for alkyls to yield each pair of diastereoisomers of the 1-*C*-substituted-1-ailino-1-deoxy-D-arabitols. The levo-rotating diastereoisomer was, moreover, exclusively predominant in the former case, and the dextro-rotating one in the latter.

The reaction mechanism for the above asymmetric induction was discussed.

The author is indebted to Professor Tetsuo Sato for his encouragement throughout this work and to Mr. Hirokichi Ono for his conscientious help during the experiments.

Infrared Spectra and Normal Vibrations of N-Methylformamides $HCONHCH_3$, $HCONDCH_3$, $DCONHCH_3$ and $DCONDCH_3$

By Isao SUZUKI

(Received July 19, 1961)

A number of investigations have been made of the molecular structure and the vibrational spectra of the *N*-methylformaide, $HCONHCH_3$[1-5], which is the simplest molecule containing an NH–CO group. It has been shown that the Raman and infrared spectra of *N*-methylformamide and *N*-deuterated *N*-methylformamide in the liquid state can be interpreted solely in terms of the trans planar model for the molecule[1-4]. The vibrational assignments for the observed frequencies proposed by various

authors differ somewhat, particularly for the bands found in the region below 1100 cm^{-1}.

In order to eliminate ambiguities in the vibrational assignment and to make a detailed analysis of the nature of the normal vibrations of this molecule, the present author has prepared three other deuterated *N*-methylformamides, i. e., $HCONDCH_3$, $DCONHCH_3$ and $DCONDCH_3$, as well as $HCONHCH_3$, and has measured the infrared spectra of these compounds in the region from 3600 to 260 cm^{-1}. Furthermore, the in-plane and out-of-plane normal vibrations of this molecule have been calculated for all of the isotopic species as a nine-body problem, assuming the trans planar configuration (C_s). The Urey-Bradley force field has been employed in the calculation of the in-plane vibrations[6]. To compute the out-of-plane vibrations, this field has been modified by introducing six other force constants associated with the CH and NH out-of-plane and the torsional coordinates. Twenty-seven force constants have been determined, so that all the observed frequencies (sixty-four in number, excepting the hydrogen stretching vibrations) are explained. With these force constants, the vibrational mode and the potential energy distribution among the symmetry coordinates have been calculated for each normal vibration.

From his analysis of the band contours of

N-methylformamide in the vapor phase, Jones reached the conclusion that this molecule takes the cis form in the vapor phase[4]*1. It is, therefore, interesting to calculate the normal vibrations of the cis form and to see how each normal mode changes in these two isomeric forms. Such a calculation has been made for the in-plane vibrations of the cis form; the values of the force constants are taken to be the same as those of the trans form.

The present paper contains the results of these measurements and calculations and a detailed discussion of the nature of the normal vibrations of the molecule. The transferability of the values of the force constants between related molecules is also discussed.

*1 The structure is still a subject of controversy. Miyazawa has pointed out that the spectra in the vapor phase may be explained by assuming the molecule to be predominantly in the trans form[7].

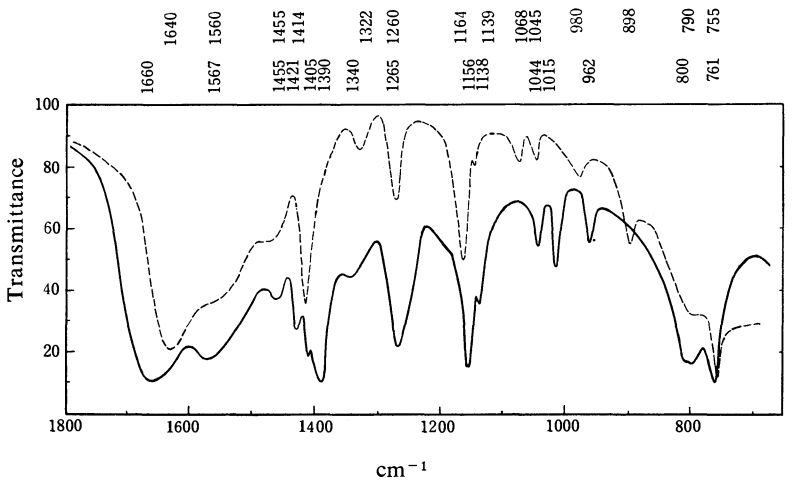

Fig. 3. Infrared spectra of $HCONHCH_3$ and $DCONHCH_3$ in the solid state; —— $HCONHCH_3$, ---- $DCONHCH_3$.

The exchange reaction with deuterium oxide was used to replace the amide hydrogen atom by deuterium.

Infrared Spectra. — The infrared spectra in the liquid state were measured in the region from 3600 to 525 cm^{-1} with a Perkin-Elmer grating spectrophotometer model 112G equipped with a potassium bromide foreprism[9], and in the region from 800 to 260 cm^{-1} with a Nippon Bunko grating spectrophotometer equipped with a cesium bromide foreprism. The spectra of $HCONHCH_3$ and $DCONHCH_3$ in the solid state were obtained with a low temperature cell[10] at the temperature of liquid nitrogen and were recorded in the region from 1800 to 650 cm^{-1} by a Hitachi EPI infrared spectrophotometer with sodium chloride optics.

Infrared Spectra

The infrared spectra of $HCONHCH_3$ and $DCONHCH_3$ in the liquid state are shown in Figs. 1(a)-(c), and those of $HCONDCH_3$ and $DCONDCH_3$, in Figs. 2(a)-(c). The infrared spectra of $HCONHCH_3$ and $DCONHCH_3$ in the solid state are shown in Fig. 3. The values of the observed frequencies for $HCONHCH_3$ and $HCONDCH_3$ agree within a few wave numbers with those give previously by the other authors. In this section, the effects of the *C*-deuteration on the spectra are mainly described. As seen from Figs. 1 and 2, the bands at 2884 and 1386 cm^{-1} of $HCONHCH_3$, which are assigned to the CH stretching and in-plane deformation vibrations ν(CH) and δ(CH) respectively, disappear on *C*-deuteration, and a new band corresponding to the CD stretching vibration is found at 2169 cm^{-1}. It is not easy to identify the band chiefly associated with the CD in-plane deformation vibration. The bands found in the region 1100~900 cm^{-1} are more or less affected by the *C*-deuteration; this fact suggests that the CD deformation motion takes part in each normal mode appearing in this region. In $DCONDCH_3$, the amide III′ band also falls in this region. The nature of these bands will be described more quantitatively in the following section on the basis of the results of the calculation of the normal vibrations.

It is of interest to determine which band is associated chiefly with the CH out-of-plane motion. The 771 cm^{-1} band of $HCONHCH_3$ was assigned to the CH out-of-plane vibration by DeGraaf and Sutherland[3] and by Jones[4], while Miyazawa[1,2] assigned this band to the amide IV (NCO bending) vibration. The fact that the 771 cm^{-1} band of $HCONHCH_3$ is insensitive to the *C*-deuteration excludes the possibility of assigning this band to the CH out-of-plane mode. Considering that the CH out-of-plane vibrations occurs at 1056 cm^{-1} in $HCONH_2$[11], at 1083 cm^{-1} in HCOOH[12], and at 1069 cm^{-1} in $HCOO^-$ [13], it seems reasonable to assign the 1011 cm^{-1} band of $HCONHCH_3$ to this mode. (In $HCONDCH_3$ it is found at 1021 cm^{-1}.) At 864 cm^{-1}, a band with a comparatively weak intensity is found both in $DCONHCH_3$ and $DCONDCH_3$. Since no vibrational mode other than the CD out-of-plane mode, is expected to occur in this region, the 864 cm^{-1} band is assigned to the CD out-of-plane vibration. This assignment is consistent

with the above assignment of the CH out-of-plane vibration.

A band with a strong intensity is found at 353 cm^{-1} in $DCONHCH_3$; this band is hardly affected by the *N*-deuteration. On the *C*-deuteration, on the other hand, the band is shifted by 41 cm^{-1} to a lower frequency. The rather large shift due to the *C*-deuteration shows that this band does not arise from one of the skeletal deformation vibrations, but from the torsional vibration about the C–N bond. This assignment is in agreement with that given by DeGraaf and Sutherland[3].

Calculation of Normal Vibrations

The calculation of the normal vibration was made according to Wilson's method[14]. It was assumed that the molecule is planar (point group C_s) except for two hydrogen atoms attached to the methyl carbon atom (see Fig. 4). Thus, the normal vibrations can be classified into 14 in-plane (A′) and 7 out-of-plane (A″) vibrations. The structural parameters used in this calculation are shown in Table I*[2].

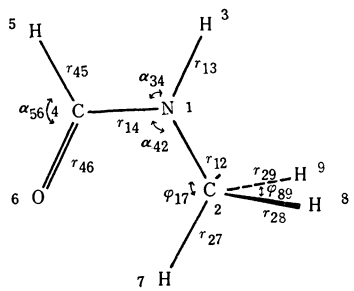

Fig. 4. Molecular structure and internal coordinates of *N*-methylformamide; the H_8 and H_9 atoms lie respectively, above and below the plane determined by the peptide group.

TABLE I. STRUCTURE PARAMETERS*

$r_{C-H}=r_{C'-H}=1.07$ Å	$r_{C'-N}=1.47$ Å
$r_{N-H}=1.04$ Å	$r_{C=O}=1.21$ Å
$r_{C-N}=1.32$ Å	

$\alpha_{ij}^0=120°$ (Bond angles around the C and N atoms)

$\varphi_{ij}^0=109°28'$ (Bond angles around the C′ atom)

* Since no structural analysis has yet been reported for $HCONHCH_3$, the values of the bond lengths are taken from those of $HCONH_2$ [15,16] and $CH_3CONHCH_3$[7].

In-plane Vibrations.—The potential function employed in the calculation is of the Urey-Bradley type[6]:

$$2V=\sum K_i(\Delta r_i)^2+\sum H_{ij}r_i^0r_j^0(\Delta\alpha_{ij})^2+\sum F_{ij}(\Delta q_{ij})^2+\text{linear terms}$$

where r_i and r_j are bond lengths with equilibrium values of r_i^0 and r_j^0, α_{ij}'s are bond angles, and q_{ij}'s, distances between nonbonded atoms. K, H and F are stretching, bending and repulsive force constants respectively. In addition, the intramolecular tension, κ, appears in the elements of the $\boldsymbol{F}$ matrix when the linear terms are eliminated by a redundancy condition[6].

To simplify the computation, the lower frequencies are separated from the four higher frequencies in the region from 3000 to 2000 cm^{-1} [14]. The symmetry coordinates used in the calculation are shown in Table II (a).

The values of the force constants were transferred from formamide[11] and methylamine molecules[18] and were slightly modified so as to obtain a better frequency agreement. The final set of the values of the force constants are given in Table III (a).

Out-of-plane Vibrations. — The type of the internal coordinates associated with the $N-CH_3$ part of the molecule, as well as the form of the potential function, is the same as that used for the calculation of the in-plane vibrations. Besides these six internal coordinates, Ω_1, Ω_4, τ_{25}, τ_{26}, τ_{35} and τ_{36} are introduced for the complete description of the out-of-plane modes, where Ω_i is $(\rho_{ij}\sin\alpha_{kil}+\rho_{ik}\sin\alpha_{lij}+\rho_{il}\sin\alpha_{jik})$ times the distance between the central atom i and the plane of atoms j, k and l, which surround the atom i, $(\rho_{ij}=1/r_{ij})$, and τ_{ij} is $\sin\alpha_{i14}\sin\alpha_{14j}$ times the dihedral angle (θ_{ij}) between the planes determined by atoms $i, 1, 4$ and $1, 4, j$ respectively[12]. Six symmetry coordinates, three of which are redundant, are obtained by the linear combinations of these internal coordinates; these are given in Table II(b). The potential function of the out-of-plane vibrations as a whole is in the following form:

$$2V=\text{Urey-Bradley type for } S_1', S_2' \text{ and } S_3'+f_{44}S_4'^2+f_{55}S_5'^2+f_{66}S_6'^2+2f_{56}S_5'S_6'+2f_{46}S_4'S_6'+2f_{45}S_4'S_5'$$

The values of the Urey-Bradley type force constants are taken to be the same as those used in the in-plane vibrations. Since few data are available for the out-of-plane and torsional force constants, f_{44}, f_{45}, etc., they are determined from the observed frequencies by

the method of least squares[19,20]. The final values of these force constants are given in Table III(b). The methyl torsional vibration lies beyond the limit of the present measurements and is omitted from the calculation.

Results of Calculations. — With the aforementioned force constants given in Tables III (a) and (b), the normal vibrations have been calculated. In Tables IV (a)–(d), the observed and calculated frequencies, percent deviations, the potential energy distributions among the symmetry coordinates for each normal mode, and the signs of the corresponding ***L***-matrix elements are given for the in-plane normal vibrations. In Tables V (a)–(d), those for the out-of-plane vibrations are given.

To visualize the feature of a given normal mode, it is preferable to compute the atomic displacement vectors, which can be obtained

from the L^x matrix defined, in matrix expression, as

$$X = L^x Q$$

where X is the column vector of the Cartesian coordinates of the atoms involved. The L^x matrix was computed for the out-of-plane normal modes, for which vibrational features are somewhat difficult to deduce from the P. E. D. matrices. The results are shown schematically in Figs. 5 (a) and (b).

As mentioned above, the in-plane vibrations of the cis configuration have also been calculated with the values of the force constants given in Table III (a); the results are summarized in Tables VI (a)–(d).

The notations used throughout this paper are the same as those used for the previous paper[11]. All the numerical computations were carried out with a parametron computer PC-1, the routines and the method of calculation are given in detail in the Ref. 21 and so are not discussed here.

Discussion

The Nature of the Observed Bands. — Based on the calculated values of vibrational amplitudes and potential energy distributions shown in Tables IV and V, the nature of the observed bands will be discussed*3.

21) T. Shimanouchi and I. Suzuki, *J. Mol. Spectroscopy*, **6**, 277 (1961).

*3 In this and the following sections, one of the abbreviations given in the final columns of Tables II (a) and (b) is used to refer to a given vibrational mode. For instance, $\delta_a(CH_3)_I$ is used instead of " in-plane CH_3 asymmetric deformation vibration ".

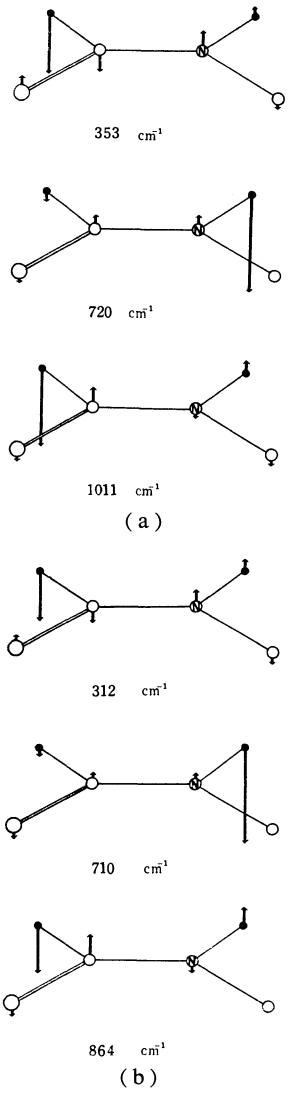

Fig. 5. Schematic representation of vibration features of the out-of-plane normal modes (a) $HCONHCH_3$, (b) $DCONHCH_3$; the movements of hydrogen atoms attached to the C' atom are neglected; ●, ○, Ⓝ and =○ denote hydrogen, carbon, nitrogen and oxygen atoms respectively.

In the Region from 3500 to 2000 cm^{-1}. — The bands chiefly associated with the NH stretching vibration are found in the region from 3500 to 3000 cm^{-1} and those associated with the ND motion, in the region from 2500 to 2400 cm^{-1}. The cause of the doublings of these bands has been discussed in detail by earlier workers[22,23] and so is not discussed here. The bands associated with the various CH stretching vibrations are found around 2900 cm^{-1}. The

* Only the important terms are given in this table.

CD stretching vibrations occur at about 2150 cm^{-1}.

In the Region from 1700 to 1200 cm^{-1}.—Three characteristic bands of monosubstituted amides are found in this region. They are termed the amide I, II and III bands and are found at 1675, 1546 and 1248 cm^{-1} respectively in *N*-methylformamide. The nature of these bands has been discussed in detail for *N*-methylacetamide[24], and the present calculation gives similar results for these bands; i. e., the amide I band is chiefly associated with the ν(C=O) motion, and the amide II and III bands are chiefly due to the mixed vibrations of the ν(CN) and δ(NH). In addition, there are considerable contributions from the ν(CN) and δ(CH) vibrations to the amide I band, which may be the cause of the lowering of this band by 20 cm^{-1} by the *C*-deuteration.

Three CH_3 and CH deformation vibrations occur also in this region. In the undeuterated species, the bands at 1455, 1414 and 1384 cm^{-1} correspond to almost pure $\delta_a(CH_3)$, $\delta_s(CH_3)$ and δ(CH) vibrations respectively. In *N*-deuterated species, a band is found at about 1430 cm^{-1} and is termed the amide II′ band; the present calculations show that this band is rather complicated in its nature. Both $\nu_a(CH_3)_I$ and ν(CN) vibrations are associated with this normal mode, and in addition, the contributions of the δ(ND) and the skeletal deformation [δ(NCO) and δ(CNC′)] vibrations are not negligible. In other words, this normal vibration is not localized in the peptide linkage. On *N*-deuteration, the bands assigned to the $\delta_s(CH_3)$ and δ(CH) modes are hardly affected; they are found at 1405 and 1383 cm^{-1} respectively.

In the Region from 1200 to 850 cm^{-1}. — In $HCONHCH_3$, the ν(C′N), $r(CH_3)$ and π(CH) vibrations are expected to occur in this region. In fact, the bands at 1150 and 960 cm^{-1} can be assigned to the $r(CH_3)_I$ and ν(C′N) modes respectively, although there are also certain contributions from other vibrational modes. In deuterated species, the δ(CD) and/or δ(ND) vibrations couple with the aforementioned vibrations, and the nature of the bands thus becomes much more complex. As seen in Table IV (b) the 1048 cm^{-1} band of $DCONHCH_3$ is a mixed vibration of δ(CD), $r(CH_3)$ and ν(C′N), and the 900 cm^{-1} band is a mixed vibration of ν(C′N), δ(CD), $r(CH_3)_I$ and ν(CN).

A band named the amide III′ band appears at 981 cm^{-1} in $HCONDCH_3$; the δ(ND) and ν(CN) as well as ν(C′N) vibrations play an important role in this normal mode. In $DCONDCH_3$, the $r(CH_3)_I$, δ(CD), δ(ND) and ν(C′N) vibrational modes interact with each other, and this gives rise to four observed bands at 1158, 1095, 951 and 891 cm^{-1}. The present calculation yields the result that the δ(CD) vibration occurs in each of these normal modes in approximately the same amount, although it predominates in none of these modes.

Two types of the methyl rocking modes must be considered; one belongs to the A′ species; $r(CH_3)_I$, and the other to the A″ species, $r(CH_3)_O$, and they are expected to give different frequencies, because the way of coupling with vibrational modes is different in each symmetry species. A weak band found at 1040 cm^{-1} in $NCONHCH_3$ and at 1064 cm^{-1} in $DCONHCH_3$ may tentatively be assigned to the $r(CH_3)_O$ mode, but this is not certain because the present calculation shows that the average splitting of the $r(CH_3)_I$ and $r(CH_3)_O$ frequencies is about 40 cm^{-1} *4.

As has been mentioned earlier in this paper, the π(CH) and π(CD) vibrations also occur in this region. The features of these modes are illustrated in Fig. 5.

In the Region from 850 to 260 cm^{-1}. — The bands associated with two skeletal deformation vibrations, δ(NCO) and δ(CNC′), are expected to appear in this region. Present calculation shows that an interaction occurs between the δ(NCO) and δ(CNC′) vibrations and that this gives rise to two observed bands at 771 and 297 cm^{-1} of $HCONHCH_3$. For the 771 cm^{-1} band, the energy associated with the δ(NCO) vibration is 60% of the total and that associated with the δ(CNC′) is 20%, while for the 297 cm^{-1} band the energy associated with the δ(NCO) mode is 30% and that associated with the δ(CNC′) is 70%*5. The way of coupling of the δ(NCO) and δ(CNC′) motions seems to be unaffected by deuteration.

In Fig. 5, the features of the normal modes of the bands found at 720 and 353 cm^{-1} are shown. It is clear that the 720 cm^{-1} band corresponds to almost pure π(NH) vibration, while the vibrational coupling occuring between the π(CH) and τ(CN) modes makes the 353 cm^{-1} band complex in its nature.

Force Constants.—*Urey-Bradley Type.* — The Urey-Bradley type of force constants have been classified into three groups after their values

24) T. Miyazawa, T. Shimanouchi and S. Mizushima, *J. Chem. Phys.*, **29**, 611 (1958).

*4 If we adopt this assignment, the observed splitting is about three times larger than the calculated. Such a deviation is rather large even though the splitting of the frequencies depends on the type of force field employed in the calculation.

*5 This may also be the cause of the rather high frequency of the amide IV band, as compared with other amides; the value of the force constants chiefly concerned with this vibrational mode, namely H_{NCO} and $F_{N\cdots O}$, are practically unchanged from those used for the evaluation of the $HCONH_2$[11] molecule, which gives the δ (NCO) vibration at about 600 cm^1.

had first been chosen by the following procedure:

(I) The force constants associated with the HCONH- part of the molecule, i. e. K_{CO}, K_{CN}, H_{NCH}, H_{HCO}, H_{NCO}, H_{HNC}, $F_{N\cdots H}$, $F_{H\cdots C}$, $F_{N\cdots O}$ and $F_{H\cdots C}$.—The values of the force constants belonging to group I were first transferred from the formamide molecule, for which the values of the constants had been definitely determined by an analysis of its normal vibrations[11].

(II) The force constants associated with the N–CH_3 part of the molecules, i. e. $K_{C'N}$, $H_{NC'H}$, $H_{HC'H}$, $F_{N(C')H}$, $F_{H\cdots H}$ and κ.—Their values were primarily transferred from the methylamine molecule[18]; in addition, the results of the recent investigation on methyl halides were also taken into account when the initial values of these constants were selected.

(III) The other force constants, i. e. $H_{CNC'}$, $H_{HNC'}$, $F_{C\cdots C}$ and $F_{H\cdots C'}$. — Their values were primarily transferred from *N*-methylacetamide[24], but slightly modified values were used as initial guesses because in that calculation the methyl group was approximated as a dynamic unit.

In order to obtain a better frequency agreement, the values of the force constants were refined as indicated by the elements of the Jacobian matrix $(\Delta\lambda_i/\Delta K_j)$[19,20]. Thus the final set of force constants given in Table III(a) was obtained. The force constants in group I remain almost unchanged, and an analogous result was obtained for the constants belonging to group II, the maximum change from the initial values being only 0.05 (in md./A). The constants involving hydrogen and carbon atoms only, i. e. $H_{HC'H}$, $F_{H\cdots H}$ and κ, are similar to values found for methyl halides[21]. As for the constants in group III, the deviations from the original are found to be comparatively large for some of the force constants.

The above results indicate that the Urey-Bradley type force constants, if determined carefully for a given molecule, can be used for the calculation of the normal vibrations for related molecules, even when they are relatively complicated and large in size.

General Quadratic Type for the A'' Vibrations.—As an initial set of force constants, the following values were taken: $f_{44}=0.051$, $f_{55}=0.136$, $f_{66}=0.271$, and zero for all the cross terms. The method of least squares was applied to refine these constants, and five repetitions of interaction processes give the values shown in Table III(b). The cross terms, f_{45} and f_{56}, are found to be small, while f_{46}, the cross term between the τ(CN) and π(CH) coordinates, is comparatively large. This implies that an interaction takes place between the τ(CN) and π(CH) vibrations to some degree and is quite consistent with the result of the infrared measurements; i. e., the 351 cm^{-1} band of $HCONHCH_3$ is sensitive to the *C*-deuteration while it is not to the *N*-deuteration.

The force constant, f_{44}, can be related to the barrier to internal rotation about the C–N bond[12]. This constant can be written as:

$$f_{44}=4(2V_2+\Delta E/2)/9 \quad (1)$$

if we assume the sinusiodal potential curve of the following form:

$$V(\theta)=\Delta E(1-\cos\theta)/2+V_2(1-\cos 2\theta)/2 \quad (2)$$

where θ is the angle of internal rotation ($\theta=0$ for the trans form) and ΔE is the energy difference between the cis and trans isomers. If we make use of the relations[12,25] $\Delta\theta=\Delta(\theta_{25}+\theta_{26}+\theta_{35}+\theta_{36})/4=2S_4/3$, and $2V(\theta)=(2V_2+\Delta E/2)(\Delta\theta)^2$ for small $\Delta\theta$, the Eq. 1 can be obtained. From the values of f_{44}, the barrier height, $V_0\fallingdotseq V_2+\Delta E/2$, is estimated as 28.5~28.0 kcal./mol. (ΔE is assumed to be 3~1 kcal./mol.). Since the height of the barrier depends on the type of the potential function used for the calculation, the value itself is not important. However, present calculation shows that the barrier height is considerable and that the internal rotation of the molecule about the C–N bond is severely restricted.

The Vibrational Modes of the cis Isomers.—The calculated frequencies and potential energy distributions, shown in Tables VI(a)–(d), were evaluated with the force constants given in Table III(a). They give the features of the normal vibrations for the cis amide; the results are summarized as follows:

(1) The amide I band is not much affected by the change in structure.

(2) In the cis amide, the δ(NH) vibration interacts with the $\delta_a(CH_3)$ rather than with the ν(CN) vibration. This interaction gives rise to two frequencies around 1450 cm^{-1} and may be a cause of the difficulty in finding the corresponding bands in some lactams[26], in which the NH–CO groups take the cis configuration.

(3) The bands associated with the δ(CH) and $\delta_s(CH_3)$ motions are not sensitive to the change in structure.

(4) The vibration chiefly associated with the ν(CN) vibration occurs around 1330 cm^{-1} in $HCONHCH_3$ and $DCONHCH_3$, and around 1400 cm^{-1} in the *N*-deuterated species. There are small contributions from the δ(CH) or δ(NH) vibration to this normal mode.

(5) In the region from 1200 to 900 cm^{-1},

25) T. Miyazawa, This Bulletin, **34**, 691 (1961).
26) L. J. Bellamy, "The Infrared Spectra of Complex Molecules", Methuen & Co., Ltd., London (1958), p. 216.

two bands which are associated with $r(CH_3)$ and $\nu(C'N)$ modes are expected to occur, and in addition, the $\delta(CD)$ and $\delta(ND)$ modes are also found in the deuterated species. The way of coupling between these vibrational modes is different from that in the trans form. This gives a frequency somewhat different from that in the trans form for each normal vibration.

(6) It is well known that skeletal deformation vibrations are quite sensitive to the structure of a given molecule. Such is also the case for *N*-methylfomamide, and the present calculation gives a value of 595 cm^{-1} to a band chiefly associated with the $\delta(NCO)$ motion (amide IV band) and a value of 360 cm^{-1} to that associated with the $\delta(CNC')$ motion. To the former vibration, there is practically no contribution from the $\delta(CNC')$ mode as there is in the trans configuration; this may be a reason for the comparatively low frequency of the vibration. To the latter band, the contribution from the $\delta(NCO)$ motion is less compared to that in the trans form. The amide IV band can be used to check the molecular configuration in the vapor phase. Miyazawa et al. showed that the amide IV band hardly moves with the change of state[2]. Thus, if the molecule of *N*-methylformamide takes the trans configuration in the vapor phase, the position of the amide IV band scarcely moves, while it is expected to shift towards a lower frequency if the molecule takes the cis form, as concluded by Jones[4]. In the spectrum of *N*-methylformamide in the vapor phase, the amide IV band is found at 785 cm^{-1}; this seems to indicate that the molecule is predominantly in the trans form, although there are some bands found in the spectrum due to the cis isomer[7] coexisting as a less stable one.

(7) Although all the fundamental frequencies are correlated with the observed band, there remained a few unassigned bands for each isotopically substituted species, i. e., 1325, (1040), and 624 cm^{-1} for $HCONHCH_3$, 1304, (1064), 981 and 617 cm^{-1} for $DCONHCH_3$, 1125 and 607 cm^{-1} for $NCONDCH_3$, and (1125) and 606 cm^{-1} for $DCONDCH_3$. They may be interpreted as overtones and combination tones of the fundamentals, but there are some difficulties in assigning these bands to certain overtones and combination tones systematically throughout the four isotopic species of the molecule. In addition, it should be noted that their frequencies are in good agreement with the calculated values of the cis characteristic bands; i. e., the band around 1320 cm^{-1} for the NH species corresponds to the $\nu(CN)$ vibration*6, the band around 1120 cm^{-1} for the ND species, to the mixed vibration of the $\delta(ND)$ and $\nu(C'N)$ modes, the band at 980 cm^{-1} of $DCONHCH_3$, to the mixed one of the $\delta(CD)$ and $r(CH_3)$ and the band around 600 cm^{-1}, to the $\delta(NCO)$ motion (see Table VI). However, objections may arise in assigning these bands as those of the cis isomer, since they persist in the solid phase. This fact does not exclude the possibility of the coexistence of the cis isomer as mixed crystals because of the very high barrier hindering internal rotation, as has been described in the preceding section. Therefore, while it is not possible to give an unequivocal answer to this question at present, it is probable that these bands are arising from the cis isomer of the molecule.

The present author expresses his sincere thanks to Professor Takehiko Shimanouchi for his guidance throughout this work, and to Dr. Tatsuo Miyazawa for his valuable discussions. His thanks are also due to Professor Hidetoshi Takahashi for the use of a PC-1 computer.

*6 The shift of the band about 20 cm^{-1} with solidification is also consistent with the above assignments.

A Study of the Adsorption of Detergents at a Solution-Air Interface by the Radiotracer Method. V. The Effect of Inorganic Salts on the Surface Behavior of the Dodecyl Sulfate Ion

By Ryohei MATUURA, Hideo KIMIZUKA, Akira MATSUBARA, Kenji MATSUNOBU and Tadashi MATSUDA

(Received July 20, 1961)

It has been known that certain inorganic salts promote the detergent action of soaps. These substances are known as builders. In studying the detergent action it is of importance to see the nature of the effect of these builders on the adsorption of the detergent. In the preceding paper[1], the effect of the cationic valencies of excess salts and the concentration of sodium chloride on the adsorption of dodecyl sulfate ion (DS^-) at the solution-air interface was measured; it was found that the presence of excess salt increases the rate and the amount of the adsorption of DS^- and that the adsorption takes place in accordance with the Gibbs adsorption isotherm. However, the effect of the anion on the adsorption has not yet been studied systematically. Therefore, we have attempted the measurement of the adsorption of DS^- in the presence of excess sodium salt with an anion of a different valency. The discussions of the surface behavior of DS^- are given for the results obtained in the present study as well as for those in the preceding paper[1].

Experimental

Dodecyl alcohol was distilled through a rectifying column of 65 plates using a reflux ratio of 15, the fraction distilling at 139°C/10 mmHg being collected. The melting point of dodecyl alcohol was 25.0°C. ^{35}S-labeled sodium dodecyl sulfate (SDS) was synthesized as described earlier[2]. To remove the unsulfated alcohol, the crystals of SDS were washed with ether for 50 hr. by using a Soxhlet apparatus.

Of the inorganic salts used, those of a guaranteed grade were used without purification, while those of an extra pure grade were purified by recrystallization.

The procedures used for the experiments were the same as described in the preceding paper[1,2], and the experiments were carried out at temperature 30±1°C.

Results and Discussion

The adsorption of DS^- and the surface tension were measured in the presence of excess (0.1 N) sodium salt of an anion of varying valency. In Fig. 1, the surface tension data are plotted against the logarithmic concentration of SDS. As seen in this figure, the surface tension vs. logarithmic concentration

2) R. Matuura, H. Kimizuka, S. Miyamoto and R. Shimozawa, ibid., 31, 532 (1958).

curves of the detergent solutions containing 0.1 N sodium salts are almost independent of the valencies of the anions of salts. This is true also for the relation between the amount of adsorption of DS^- and the concentration of the detergent solution, as is shown in Fig. 2, although the measured values scatter randomly to some extent in this case.

In Fig. 3, the surface tension of SDS solutions containing excess salt of chlorine with a cation of varying valency, together with the case of sodium chloride of varying concentrations, is plotted against the logarithmic concentration of SDS. It is clear from this figure that the surface tension of the SDS solution decreases with an increase in the valency of the cation of the same normal concentration and decreases in the presence of the same salt (sodium chloride) with an increase in the concentration of the salt.

From the results of Figs. 1 and 3, it may be said that the surface tension lowering of the SDS solution due to the excess salt is governed

not by the ionic strength, but by the normality when the sodium salts are used; it is also very much affected by the valency of cation when the various metal salts are used even with the same normality.

The change in the value of critical micelle concentration (CMC), C_m, with the concentration of sodium chloride is shown in Fig. 4 and that with the valency of cation, in Fig. 5. As shown in Fig. 4, log C_m is linear against the logarithmic concentration of sodium chloride; this is a relation similar to that obtained by Corrin and Harkins[3]. In Fig. 5, log C_m is linear against the valency of the cation. This does not agree with the theory of Shinoda, who expected linearity between log C_m and the reciprocal of valency[4]. Though the effect of a high valent cation on the CMC of SDS solution was studied by Lange[5], he did not find this relation. It must, however, be noted here that the pH of the solution depends on the kind of electrolyte, so that the dependence of CMC upon the valency will require more detailed investigation. In Fig. 6, the surface pressure, π_m, at CMC is plotted against the concentration of salt as well as the valency of cation. This figure shows an increase in π_m with the concentration of sodium chloride, but at the normal concentration the valency of the anion has little effect on the value of π_m and the effect of the valency of the cation is not so appreciable.

Now we can put the reduced quantities as:

$$\phi=\pi/\pi_m, \quad X=C/C_m \tag{1}$$

where π denotes a surface pressure of the

solution of concentration, C. The ϕ vs. X curves are plotted as shown in Fig. 7. This figure indicates that the surface tension vs. concentration curves can be reduced approximately to the same one, regardless both of the concentration of the excess salt and of the type of salt when we use reduced quantities.

The full line in Fig. 7 shows the calculated relation by using the equation

$$\phi = (1/b)\cdot\ln\{1+(e^b-1)X\} \qquad (2)$$

where b is a constant. The value of b is 3.7 in the present case. Belton and Evans[6] considered the ideal mixture in which the surface tensions of the solution, solvent and solute are γ, γ_A and γ_B respectively; they derived a relation between the surface tension and the mole fraction of solute x:

$$\exp(-\gamma\omega/\boldsymbol{kT}) = (1-x)\exp(-\gamma_A\omega/\boldsymbol{kT}) + x\exp(-\gamma_B\omega/\boldsymbol{kT}) \qquad (3)$$

where ω denotes the occupied area per molecule and $\boldsymbol{k}$ and T are Boltzmann constant and absolute temperature respectively. Equation 3 can be reduced to Eq. 2 by putting $x=X$ and

$$b = (\gamma_A-\gamma_B)\omega/\boldsymbol{kT}$$
$$\phi = (\gamma_A-\gamma)/(\gamma_A-\gamma_B) \qquad (4)$$

It may, therefore, be pointed out that the solution of SDS containing excess salt behaves approximately as if it were the ideal mixture consisting of the salt solution, regarded as a solvent, and the detergent solution at CMC containing a given concentration of salt, regarded as a solute. Thus it may be supposed that the reduced quantities are the suitable expressions in studying the detergent solution.

The Gibbs equation is expressed by:

$$\Gamma = (1/\boldsymbol{nRT})\cdot(\partial\pi/\partial\ln C) \qquad (5)$$

where Γ is the surface excess, $\boldsymbol{R}$, gas constant, and $\boldsymbol{n}$ is put unity in the case of excess salts. Differentiating Eq. 2 and combining it with Eq. 5, we obtain a reduced adsorption isotherm

$$\boldsymbol{RT}\Gamma/\pi_m = (e^b-1)X/b\{1+(e^b-1)X\} \qquad (6)$$

The full lines in Figs. 1 and 2 show calculated relations by using Eqs. 2 and 6 respectively. Agreements between observed and calculated values are satisfactory.

Summary

The adsorption of ^{35}S-labeled dodecyl sulfate ion in the presence of excess sodium salts with anions of various valencies was measured directly by the radiotracer method. The anions of the excess salts were chloride, nitrate, carbonate, ferricyanide and ferrocyanide ions, and the concentrations of the excess salts were all 0.1 N. It was found that the adsorption of dodecyl sulfate ion increased remarkably due to the presence of the excess salt and that the surface tension curves and the adsorption isotherms were almost independent of the type of anions.

The behavior of dodecyl sulfate ion was discussed by using the result of the present study together with the previous one, in which the effect of cationic valency and the salt concentration was studied. The logarithmic value of CMC was found to be linear against the logarithmic concentration of excess sodium

6) J. W. Belton and H. G. Evans, *Trans. Faraday Soc.*, **41**, 1 (1945).

chloride and against the valency of cation when the concentrations were all 0.1 N.

The reduced surface pressure and the reduced concentration referred to CMC were proposed, and it was found that the surface tension data of the solutions of sodium dodecyl sulfate containing various kinds of salts and varying concentration of sodium salts were correlated approximately to one curve regardless both of the types and the concentrations of the excess salts. The curve was well expressed by the reduced equation for the surface pressure as a function of the reduced concentration. By combining the reduced equation with the Gibbs equation of $n=1$, the reduced adsorption isotherm was derived.

It was shown that these reduced equations enable us to reproduce the surface tension and adsorption data of the solutions of sodium dodecyl sulfate in the presence of sodium salts with varying valencies of anions.

Effect of Non-hydrogen Bonding Solvents on the Electronic Spectra of Aromatic N-Oxides

By Tanekazu KUBOTA and Masumi YAMAKAWA

(Received July 21, 1961)

In previous papers, the effect of solvents, including active hydrogen atoms, which can form a hydrogen bond, on the electronic absorption spectra of many aromatic *N*-oxides has been reported by us[1-4]. As a result it has been concluded that the absorption spectra of the above compounds show a remarkable blue shift with the increasing polarity of the solvents and that the hydrogen bonding, such as $\gg$N—O···H (solvents), plays an important role in the blue shift phenomena. The effects of non-hydrogen bonding solvents on the absorption spectra of *N*-oxides, however, have hardly been investigated at all. For the present paper, particular interest has been taken in the case of solute-non-hydrogen bonding solvents interactions, and the results have quantitatively been analyzed on the basis of McRae's theory of the solute-solvent interaction[5]. The results thus obtained are compared with the previous results of the solvent effects due to hydrogen bonding polar solvents and the molecular orbital calculations which were carried out by one (T. K.) of the authors to elucidate the electronic structures of heterocyclic *N*-oxides.

Experimental

Ultraviolet absorption spectra were recorded by means of a Hitachi model EPS automatic recording spectrophotometer at room temperature(~25°C), at a scale expansion of 2 (which is just twice as expansible as the normal procedure), at a slow scanning speed (about ten minutes), and using a quartz cell of 1 cm. light path. Measurements of fluorescence spectra were made with a Beckman model DU spectrophotometer which was modified to record fluorescence spectra with good sensitivity[1]. Solvents were purified by the methods recommended by Weissberger and Proskauer[6], and special care was taken to remove contaminating water. Samples used here are pyridine *N*-oxide, 4-nitropyridine *N*-oxide, acridine *N*-oxide and *N*-methylbenzaldoxime. Pyridine *N*-oxide and acridine *N*-oxide were prepared and purified by the usual method[7,18]. 4-Nitro-pyridine *N*-oxide and *N*-methylbenzaldoxime were prepared by Tokuyama of our research laboratory and by Mori of Osaka University respectively. The physical properties and the purification method of the above samples are shown in Table I. The refractive index at the sodium D line (n_D) and the static dielectric constant of solvents used are shown in Table II. These data have been quoted from Ref. 6.

Results and Discussion

Theoretical Equation for the Solvent Effect of Absorption Spectra. — Theoretical investigation of solvent-solute interaction on electronic spectra have recently been made by Ooshika[8], by McRae[5] and by Longuet-Higgins and Pople[9] on the basis of applying the perturbation theory. As to the physical meaning, these authors obtained almost the same general expressions for the frequency shift. In this paper we shall use McRae's formula (Eq. 14 in the original paper) in order to analyze the experimental results, since this formula is well arranged for individual solute-solvent interaction terms such as the dispersion force, the solute dipole-solvent dipole thereby induced, the solute dipole-solvent dipole and the quadratic Stark effect. Nevertheless, the original formula is considerably complex and can not be applied to analyze the experimental data. The following simplifications, which are similar to those used by McRae to interpret the solvent effect of phenol blue[5], have been made with the aid of several assumptions. Firstly, the refractive index of the solvent at all frequencies involving the zero frequency has been replaced by the value at the Na-D line*1. Secondly, the quadratic Stark term representing the contribution from the interactions between the permanent dipoles of solvent molecules and the solute dipoles thereby induced has been neglected, since this term is small compared with the other contributions[5], especially for the relatively low polarity of most solvents used here. Lastly, the weighted mean wavelength (L_o) of the solvent introduced by McRae has been conveniently taken to be constant for all the solvents used, because L_o values of most solvents may exist approximately in the far ultraviolet region (about 100~125 mμ) and show considerable separation from the π-π^* absorption bands of *N*-oxide compounds*2. Thus we obtained

$$\tilde{\nu}_{abs} = \tilde{\nu}^g{}_{abs} + (A+B)\frac{n_D^2-1}{2n_D^2+1} + C\left[\frac{D-1}{D+2} - \frac{n_D^2-1}{n_D^2+2}\right] \quad (1)$$

where $\tilde{\nu}^g{}_{abs}$ is the band position at vapor state, and A, B and C are constants which are independent of the characters of the solvents, as is understood from Eqs. 2, 3 and 4 derived by McRae.

$$A = 1.07\times10^{-14}\cdot\frac{1}{a^3}\left[L_o\left\{-2f^u_{io} + \sum_{j\neq o,i}\left(f^u_{ji}-f^u_{jo}\right)\right\} + \sum_{j\neq o,i}\left(\frac{f^u_{jo}}{\tilde{\nu}^u_{jo}} - \frac{f^u_{ji}}{\tilde{\nu}^u_{ji}}\right)\right] \quad (2)$$

$$B = \frac{1}{hc}\left[\frac{(M^u_{oo})^2-(M^u_{ii})^2}{a^3}\right] \quad (3)$$

$$C = \frac{2}{hc}\left[\frac{\vec{M}^u_{oo}(\vec{M}^u_{oo}-\vec{M}^u_{ii})}{a^3}\right] \quad (4)$$

In these equations, the notations and their meaning are the same as those in McRae's

*1 n_D ordinarily differs little from n for infinite wavelengths except for special solvents (water, etc.).
*2 In practice, it is difficult to estimate L_o for all the solvents used because of a lack of their spectral data.

paper[5]. It was possible to explain, within the range of experimental error, the experimental results by using Eq. 1*[3].

Effect of Solvents on Absorption Spectra.— The absorption spectra of pyridine *N*-oxide, 4-nitropyridine *N*-oxide, acridine *N*-oxide and *N*-methylbenzaldoxime in *n*-heptane are shown in Fig. 1, and the π-π^* absorption bands under consideration are shown by arrows. The maxima of the π-π^* bands of the above compounds in various solvents are given in Table III. $\tilde{\nu}^{I}_{abs}$ and $\tilde{\nu}^{II}_{abs}$ of acridine *N*-oxide denote the band maxima (vibrational components of the π-π^* $-{}^1L_A$-band) at 427.5 mμ and at 454.8 mμ in *n*-heptane solution respectively. Thus $\tilde{\nu}^{g}_{abs}$, $A+B$ and C of Eq. 1 have been determined by applying the least square method to the data of Tables II and III*[4]. The numerical values of Eq. 1 thus obtained are given in Table IV. The relations of the calculated (these values were calculated from Eq. 1 using the values in Table IV) vs. the observed frequency shifts in the π-π^* bands of the above compounds are shown in Figs. 2—6. From the values in Table IV, it should be

	22900	−4660	250
N-Methylbenzaldoxime	35130	−8000	90

*[3] What differs from the solvent effect of the weak $n\rightarrow\pi^*$ transitions, which were investigated recently by Ito et al.[10], is that the dispersion term can hardly be considered independent of the solvents in the case of the strong π-π^* band of *N*-oxide compounds.

10) M. Ito, K. Inuzuka and S. Imanishi, *J. Am. Chem. Soc.*, **82**, 1317 (1960).

*[4] As is seen in Figs. 2—6, solvents showing a distinct discrepancy from a linear relation between the calculated and the observed values have been removed from the calculations by means of the least square method.

pointed out for all the *N*-oxide compounds that dispersion and dipole-dipole interaction terms cause a red shift and a blue shift respectively. Now let us consider how appropriate are the values of Table IV and Figs. 2—6. All the points, with the exception of anomalous solvents, fit a full straight line with a root mean square deviation of 90 cm^{-1} and 50 cm^{-1} for pyridine *N*-oxide and the other *N*-oxide compounds respectively, which is of the same order of magnitude as the experimental error in the determination of band frequency in solution spectra. Therefore it may be considered that Eq. 1 satisfactorily explains the experimental results. Moreover, it is also worth pointing out the following facts: Firstly, the *C*-value of 4-nitropyridine *N*-oxide is considerably small, 13 cm^{-1}; this result is reasonable because the dipole moment of this

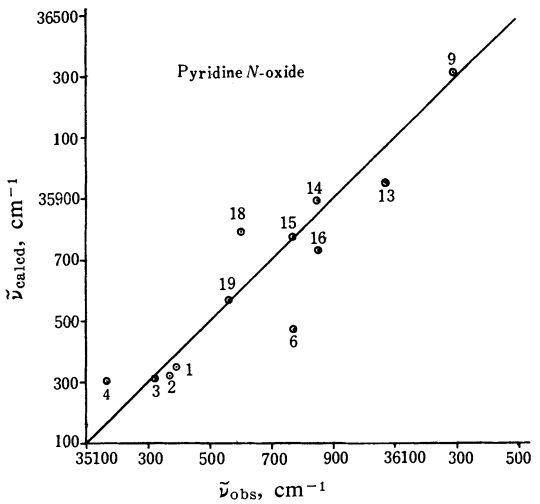

Fig. 2. Relation between $\tilde{\nu}_{obs}$ and $\tilde{\nu}_{calcd}$ for pyridine *N*-oxide.

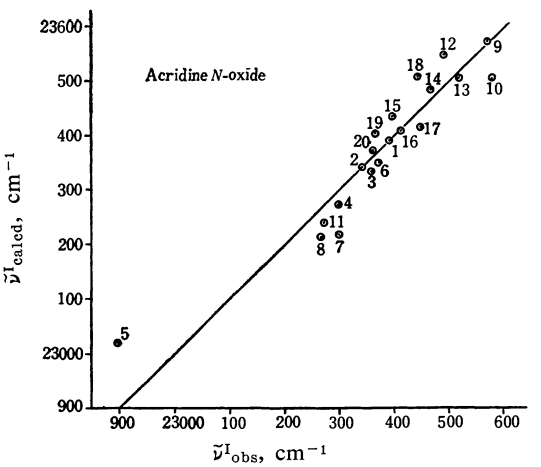

Fig. 6. Relation between $\tilde{\nu}^{I}_{obs}$ and $\tilde{\nu}^{I}_{calcd}$ for acridine *N*-oxide.

compound in the ground state is nearly zero[16]. Secondly, $\tilde{\nu}^{g}_{abs}$ of pyridine *N*-oxide obtained from Eq. 1 is 35980 cm^{-1}; this value agrees well with the experimental value of 36080 cm^{-1} which was measured both by us and by Ito and Hata[11],*5. On the other hand, calculated and observed frequencies frequently do not agree when dioxane and carbon tetrachloride have been used as a solvent; the former is especially irregular for substances having a large *C* value, and the latter, for those having a large $A+B$ value. The abnormal behavior of solvent dioxane is well known[5,10,12]. It is also common that carbon tetrachloride sometimes shows an anomalous behavior owing to short range intermolecular interactions such as molecular complex formation[13]. This fact may be regarded as one of the reasons why carbon tetrachloride shows an anomalous behavior, and some correlation may exist between such anomalous properties and $A+B$ values.

Dipole Moment in the Excited State of Pyridine *N*-Oxide and Acridine *N*-Oxide.—Now it may be possible in principle to evaluate the dipole moment in an excited state from Eq. 4, but practically it is difficult (especially for the absolute $\vec{M}^{u}_{ii}$ value) because the appropriate "a" values ("a" is Onsager's reaction radius of the solute molecule) can not be easily determined and because the molecular symmetries in the ground and the excited states are, in general, not the same. In addition, various assumptions have been made to derive Eq. 4. Taking tentatively "a"=3.5~4 Å with reference to the reports of other authors[5,10,12,14] and assuming that $\vec{M}^{u}_{oo}$ and $\vec{M}^{u}_{ii}$ are parallel, the excited state dipole moments of pyridine *N*-oxide and acridine *N*-oxide are calculated to be 1.9~1.3 D and 0.22~1.5 D, ($\tilde{\nu}^{I}_{abs}$) and 0.3~0.4 D ($\tilde{\nu}^{II}_{abs}$) respectively smaller than those of the ground state. It may be regarded in the first order approximation that such a decrease in excited state dipole moment is based on the change of the π-electron moment (π-moment) arising from an electronic excitation. It has been determined by Linton[15], by Katritzky, Bax et al.[16,17] and by Acheson et al.[18] that the dipole moments of pyridine *N*-oxide and acridine *N*-oxide in the ground state are 4.24 D and 3.90 D respectively and that the total moment ($\sigma+\pi$) is directed very closely from the ring to the oxygen atom along a C_2-axis, while the π-moment vector is in the opposite direction. Therefore, the above experimental fact clearly indicates that the π-electron transfer from the oxygen atom to the ring is much greater in the excited state than in the ground state. Assuming that "a" is taken to be 3.5 Å and 4 Å for pyridine *N*-oxide and acridine *N*-oxide respectively, and making a comparison of the degree of dipole moment decrease in the excited π-π^* state, the degree of pyridine *N*-oxide is 3.2~5.9 times as great as that of acridine *N*-oxide. In the previous papers, one (T. K.) of the authors reported on the electronic structure of various heterocyclic *N*-oxides on the basis of various molecular orbital calculations[19,20]. It was then most reasonable to conclude that the π-π^* bands, that are the subject of discussion, belong to the group species $^1A_1$ and consist of a very large contribution of the single configuration which corresponds to one electronic excitation from the highest occupied orbital to the lowest empty orbital*6. The square values of the above two MO's coefficients are shown schematically in Figs. 7 and 8 for pyridine *N*-oxide and acridine *N*-oxide respectively. As is well understood from Figs. 7 and 8, the degree of the electron transfer from the oxygen atom to the ring of acridine *N*-oxide by an electron excitation is much smaller than that of pyridine *N*-oxide. Therefore, this fact shows a good correspondence with the above estimated values of the π-moment change by an electronic excitation for pyridine *N*-oxide and acridine *N*-oxide.

*5 In this case, however, the reason why $\tilde{\nu}^{g}_{abs}$ and $\tilde{\nu}^{max}_{abs}$ (in vapor state) experimentally determined must rigorously agree can not be found, owing to the several assumptions described above. Moreover, $\tilde{\nu}^{max}_{abs}$ in a vapor state of the other compounds could not be recorded because of the low vapor pressure.

*6 In these calculations the values of SMO parameters are chosen so as to reproduce, by using Jaffé's relation[21], the electronic densities obtained from the experimentally determined Hammett's σ values of the *N*-oxide group in non-polar solvents[22]. The parameters obtained are equal to $k_N=1.6\beta$, $k_O=0.595\beta$ and inductive effect $=(1/3)^n k_N$ respectively. $k_O=0.595\beta$, however, is relatively small to interpret various physico-chemical properties, and $k_O=0.8$ is the best value to reproduce the observed dipole moment, etc. The relative change of π-moments from pyridine *N*-oxide to acridine *N*-oxide will be almost independent of the selection of the k_O-values, either 0.595 or 0.8. In this paper we have used $k_O=0.595$ for discussion, since all the MO calculations for parameter 0.8 are not complete at present.

Pyridine *N*-oxide	5.58	1.88	3.70	2.31
Acridine *N*-oxide	4.24	3.01	1.23	0.77

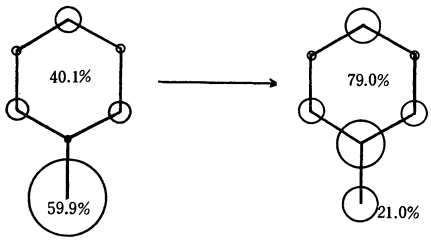

Fig. 7. Distribution of an electron in the highest occupied orbital and the lowest empty orbital of pyridine *N*-oxide.

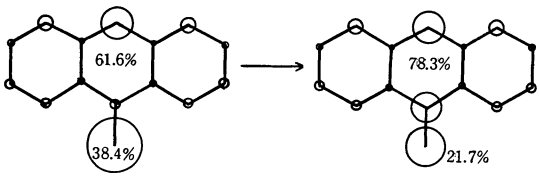

Fig. 8. Distribution of an electron in the highest occupied orbital and the lowest empty orbital of acridine *N*-oxide.

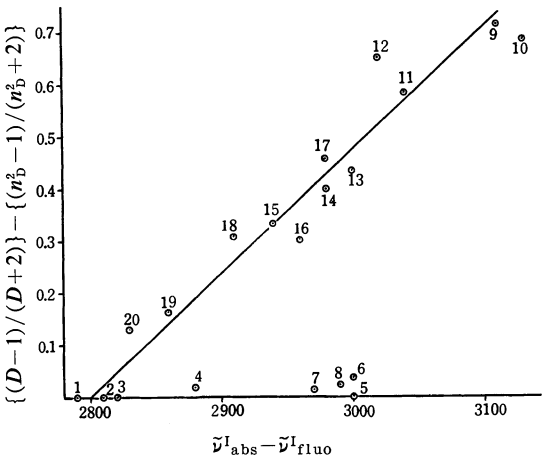

Fig. 9. Relation between $(\tilde{\nu}^{I}_{abs}-\tilde{\nu}^{I}_{fluo})$ and $\{(D-1)/(D+2)\}-\{(n_D^2-1)/(n_D^2+2)\}$ for acridine *N*-oxide.

Making the calculation of the π-moment change between the ground state and the excited π-π^* state shown in Figs. 7 and 8 by applying the molecular orbitals reported in previous papers[19,20], the results in Table V

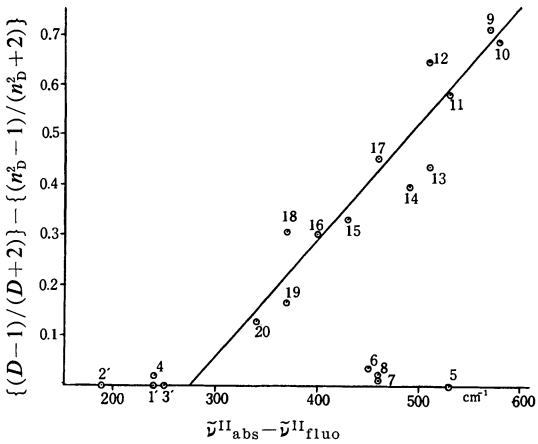

Fig. 10. Relation between $(\tilde{\nu}^{II}_{obs}-\tilde{\nu}^{II}_{fluo})$ and $\{(D-1)/(D+2)\}-\{(n_D^2-1)/(n_D^2+2)\}$ for acridine *N*-oxide.

are obtained*7. As is seen from Table V, the absolute values $({}^{\pi}\vec{M}^{u}_{ii}-{}^{\pi}\vec{M}^{u}_{oo})$ do not show a good agreement with those estimated from the *C* value, this discrepancy being based on the reason described in the beginning of this section. However, comparing the value $({}^{\pi}\vec{M}^{u}_{ii}-{}^{\pi}\vec{M}^{u}_{oo})$ of pyridine *N*-oxide with that of acridine *N*-oxide, the former is 2.93~3.50 times as great as that of the latter; this result agrees well with the experimental value*7,*8.

Effects of Hydrogen Bonding. — As stated above, the electronic spectra of aromatic *N*-oxide compounds show a remarkable blue

*7 In this calculation it has been assumed that the shape of these molecules is a condensed regular hexagon, the bond distance of which is 1.395 Å, and the N—O distance is taken to be equal to 1.28 Å. However, the ratio of the value $({}^{\pi}\vec{M}^{u}_{ii}-{}^{\pi}\vec{M}^{u}_{oo})$ of pridine *N*-oxide to that of acridine *N*-oxide is almost insensitive in the selection of the N→O bond distance (1.28~1.40 Å). According to recent investigations of the crystal structure of phenazine mono-*N*-oxide and 4-nitropyridine *N*-oxide, the N—O distance is 1.24 Å and 1.26 Å for the former and the latter respectively[23,24].

24) E. L. Eichhorn, idid., **9**, 787 (1956).

*8 The nature in the excited and the ground states of *N*-methylbenzaldoxime can not be discussed, since the molecular structure (cis or trans) and the electronic state of this compound have not been investigated as yet. At present we are investigating the electronic structures and the spectroscopic behaviors of nitron type compounds.

TABLE VI. VALUES OF ABNORMAL BLUE SHIFT (cm^{-1}) DUE TO THE HYDROGEN BONDING EFFECT APPROXIMATELY ESTIMATED BY USING EQ. 1 AND OBSERVED VALUES IN WATER AND ETHANOL

Compound	Solvent		
	Water (Obs. value)	Ethanol (Obs. value)	Water/Ethanol
Pyridine *N*-oxide	4860 (39440)	1410 (37660)	3.4
4-Nitropyridine *N*-oxide	5430 (31690)	1200 (30010)	4.5
N-Methylbenzaldoxime	3620 (34990)	940 (34290)	3.9
Acridine *N*-oxide ν^{I}	2270 (24200)	700 (23980)	3.2
Acridine *N*-oxide ν^{II}	2260 (22980)	750 (22730)	3.0

shift in hydrogen bonding solvents, such as alcohol and water. This abnormal blue shift can not be explained by Eq. 1 and is mainly based on the hydrogen bonding complexes such as N→O·····H. The contribution of the normal solvent effect to the frequency shift can be evaluated approximately from Eq. 1 by using n_D and D of the above solvents. The values thus obtained are small, and the remaining portion ($\tilde{\nu}_{hyd}$) of the total frequency shift may mainly be owing to the hydrogen bonding effect, the calculated values being shown in Table VI. The value $\tilde{\nu}_{hyd}$ of water is 3∼4 times as great as that of ethanol in all the compounds used here. It may be considered from the above fact that the hydrogen bonding power of water is about 3∼4 times as great as that of ethanol.

Relation between the Solvent-induced Frequency Shift of the Absorption and the Fluorescence Spectra of Acridine *N*-Oxide.—The difference in solvent effect on the maxima of the absorption and fluorescence spectra was given by Lippert[12], by Mataga et al.[14] and by McRae[5] as in Eq. 5. Here K is approximately constant.

$$\tilde{\nu}_{abs}-\tilde{\nu}_{fluo}=\frac{2}{hc}\cdot\frac{[\vec{M}^{u}_{oo}-\vec{M}^{u}_{ii}]^2}{a^3}\times\left[\frac{D-1}{D+2}-\frac{n_D^2-1}{n_D^2+2}\right]+K \quad (5)$$

As was reported in the previous paper, the fluorescence spectra of acridine *N*-oxide show a good mirror image relative to the absorption band (^1L_a)[1].

The values ($\tilde{\nu}_{abs}-\tilde{\nu}_{fluo}$) in various solvents are given in Table VII. Here $\tilde{\nu}^{I}_{fluo}$ and $\tilde{\nu}^{II}_{fluo}$ correspond to $\tilde{\nu}^{I}_{abs}$ and $\tilde{\nu}^{II}_{abs}$ respectively. Thus the coefficients of Eq. 5 have been determined by means of the least square method by using the above data, and Eqs. 6 and 7 have thereby been obtained*9.

$$\tilde{\nu}^{I}_{abs}-\tilde{\nu}^{I}_{fluo}=2800+420\left[\frac{D-1}{D+2}-\frac{n_D^2-1}{n_D^2+2}\right] \quad (6)$$

$$\tilde{\nu}^{II}_{abs}-\tilde{\nu}^{II}_{fluo}=270+430\left[\frac{D-1}{D+2}-\frac{n_D^2-1}{n_D^2+2}\right] \quad (7)$$

In Figs. 9 and 10, the values $\left(\frac{D-1}{D+2}-\frac{n_D^2-1}{n_D^2+2}\right)$ are plotted against the values ($\tilde{\nu}_{abs}-\tilde{\nu}_{fluo}$) of the $\tilde{\nu}^{I}$ and $\tilde{\nu}^{II}$ bands, and it is found that a good linear relation comes into existence between the above two values, but solvents such as dioxane, toluene and benzene cause a large deviation from the linear relation. The abnormal behavior of dioxane is owing to the same reason as that described in the previous section. The exceptional behavior of benzene and toluene (which in main arises

TABLE VII. EXPERIMENTAL VALUES OF $\tilde{\nu}_{abs}-\tilde{\nu}_{fluo}$ OF ACRIDINE *N*-OXIDE IN VARIOUS SOLVENTS

Isoamyl ether	2830	340

*9 In solvents 1, 2 and 3, $\tilde{\nu}^{II}_{fluo}$ has a tendency to be divided into doublets, but not so in the other solvents. To correct this difference, we used the weighted mean wave number given by the following equation for the determination of $\tilde{\nu}^{II}_{fluo}$ in solvents 1, 2 and 3. The values thus obtained were used to obtain Eq. 7 and are indicated by 1′, 2′ and 3′ in Fig. 10.

$$\tilde{\nu}_{max}=\left[\int\varepsilon\cdot\tilde{\nu}\cdot d\tilde{\nu}\Big/\int\varepsilon\cdot d\tilde{\nu}\right]\fallingdotseq\left[\sum_i\varepsilon_i\cdot\tilde{\nu}_i\Big/\sum_i\varepsilon_i\right]$$

from the abnormal frequency shift in the fluorescence spectra) is caused by mutual short-range interaction between the solute molecules and the π-electrons of the aromatic solvents and coincides with the analogous result that was found previously in the experiment concerning the fluorescence quenching of acridine *N*-oxide[1]. Making the same assumption as that described in the previous section and using the coefficients of Eqs. 6 and 7, the value $(^{\pi}\vec{M}^{u}_{ii} - {}^{\pi}\vec{M}^{u}_{oo})$ can be evaluated to be 1.6~1.8 D. This value, however, does not agree well with the data obtained from the analysis of the absorption spectra. It may reasonably be inferred that this is because the solute-solvent interaction of various types in the excited state differs in some measure from that of the ground state. Therefore, considering the Franck-Condon principle, the frequency shifts of absorption and fluorescence bands do not agree well[12]. In our case, $(\vec{M}^{u}_{oo} > \vec{M}^{u}_{ii})$, the shift of the latter is smaller than that of the former[12]. Indeed, $\tilde{\nu}^{I}_{fluo}$ and $\tilde{\nu}^{II}_{fluo}$ show almost the same wave number in the polar solvents used here, although $\tilde{\nu}^{I}_{abs}$ and $\tilde{\nu}^{II}_{abs}$ do not*10. As a result, some simplifications concerning the treatment of the second term of Eq. 1 have been made, but such simplifications are unnecessary in Eq. 5. Moreover, the character in the excited π-π^* state generally may be considered to be locally more polar than in the ground state, as is understood from the general character of molecular orbitals. The special solute-solvent interactions, which are negligible in the ground state, may be expected in some measure in the excited state, since fluorescence is emitted from the equilibrium state in the excited π-π^* state.

*10 In a hydrogen bonding effect previously investigated[1], such phenomena were frequently found; they have also been discussed by Pimentell[25].

Summary

The strong π-π^* absorption bands of pyridine *N*-oxide, 4-nitropyridine *N*-oxide, acridine *N*-oxide and *N*-methylbenzaldoxime were measured in various solvents, and the frequency shifts induced by solvents were quantitatively analyzed by applying the McRae's theory of the solvent effect. On the other hand, the fluorescence spectra of acridine *N*-oxide have also been recorded in various solvents, and the solvent effect has been discussed in connection with that of the absorption spectra. The results show that the π-electron transfer from the oxygen atom to the ring is much greater in the excited state than in the ground state.

The authors wish to thank Professor Saburo Nagakura of the Institute for Solid State Physics, the University of Tokyo, for valuable discussions and for reading the manuscript; Dr. Noboru Mataga of Osaka Municipal University for valuable discussions; Dr. Kanzi Tokuyama of our research laboratory for supplying a sample of 4-nitropyridine *N*-oxide; and Dr. Yasushi Mori of Osaka University for supplying a sample of *N*-methylbenzaldoxime.

Studies on Lactone Formation in Vapor Phase. II. Synthesis of ε-Caprolactone

By Shinzaburo OKA

(Received July 25, 1961)

The results obtained in a previous study[1] of the dehydrogenation of 1, 4-butanediol to γ-butyrolactone prompted this further investigation on ε-caprolactone.

Dehydrogenation of 1, 4-diols or 1, 5-diols with copper chromite catalyst had been studied by several investigators[2-7] to give γ-lactones or δ-lactones, respectively, in good yields.

7) W. Reppe et al., *Ann.*, **596**, 180 (1955).

Studies on dehydrogenation of 1, 6-diols to ε-lactones are surprisingly few. Carothers[8] showed that ε-caprolactone was isolated as a by-product from hydrogenation products of ethyl adipate with copper chromite catalyst. Reppe[7] claimed that ε-caprolactone and its polymer were obtained by liquid phase dehydrogenation of 1, 6-hexanediol with a copper catalyst. No details on preparation of the catalyst were described. Suitable catalysts for the dehydrogenation of 1, 6-diols to ε-lactones are not found in the literature.

Attempts to dehydrogenate 1, 6-hexanediol to ε-caprolactone with copper-zinc oxide or copper-magnesium oxide catalyst which gave γ-butyrolactone and δ-valerolactone in good yields, were unsuccessful. Apparently the formation of a seven-membered ring is more difficult as compared with that of the five- or six-membered ring. Examinations of numerous mixed catalysts have resulted in finding a new catalyst, copper chromite-zinc oxide, which gives ε-caprolactone in good yields. The dehydrogenation with this catalyst in vapor phase has an advantage over the liquid phase method which produces the undesirable polymer.

Preparation of 1, 6-hexanediol, the starting material for ε-caprolactone, was performed as follows:

(1) $CH{\equiv}CH + HCHO \rightarrow CH{\equiv}CCH_2OH$

(2) $2CH{\equiv}CCH_2OH + 1/2\ O_2 \rightarrow HOCH_2C{\equiv}CC{\equiv}CCH_2OH + H_2O$

(3) $HOCH_2C{\equiv}CC{\equiv}CCH_2OH + 4H_2 \rightarrow HO(CH_2)_6OH$

Since the ethinylation reaction was found by Reppe[9], several investigations[10-12] including the reaction of acetylene with aqueous formaldehyde have been reported. Propargyl alcohol, the initial reaction product, reacts with a second molecule of formaldehyde to give butynediol, which is usually the main product. Murahashi[11] reported the favorable conditions for the propargyl alcohol formation in an aqueous solution. But so far as aqueous formaldehyde is used, isolation of propargyl alcohol from the dilute aqueous reaction mixture is complicated and time-consuming owing to the formation of an azeotropic mixture. It may be, therefore, favorable to carry out the reaction under non-aqueous conditions. For the purpose of raising the yield of propargyl alcohol, it may be preferable to maintain the high concentration of acetylene by using a suitable solvent. Thus, the author studied the reaction of acetylene with anhydrous paraformaldehyde in various solvents.

Experimental

Propargyl Alcohol and Butynediol.—According to Murahashi's procedure[10], a copper acetylide catalyst was prepared from 30 g. of cupric oxide which was obtained by heating basic copper carbonate at 300~350°C. One third of the catalyst was used in each experiment. The reaction was carried out batchwise in a shaking stainless steel autoclave of 300 ml. capacity. The autoclave was charged with paraformaldehyde, solvent and the catalyst. Acetylene was compressed at room temperature. The amount of acetylene compressed was estimated by the pressure drop of the compressor's oil separator which supplied acetylene. After the reaction, the reaction mixture was filtered and about 1 g. of the filtrate was supplied to analytical determination of propargyl alcohol according to Reppe's directions[13]. After removal of the solvent and the propargyl alcohol, the filtrate gave butynediol, b. p. 115~117°C/3 mmHg, m. p. 56~57°C (lit.[10] 57°C).

Hexadiynediol—A shaking stainless steel autoclave of 300 ml. capacity was charged with 56 g. of propargyl alcohol, 6 g. of cuprous chloride, 19 g. of ammonium chloride, and 60 g. of water. Oxygen was filled to 20 kg./cm². The autoclave was heated 55~60°C for one hour. When the pressure fell to 5 kg./cm², oxygen was again changed to 20 kg./cm². The reaction mixture was filtered, and the solid was washed with a minimum amount of water and recrystallized from methanol to yield 51 g. of hexadiynediol, m. p. 112°C (lit.[14] 112°C).

1, 6-Hexanediol.—Hexadiynediol (20 g.) in 180 ml. of methanol was hydrogenated under the initial hydrogen pressure of 50 kg./cm² with 2 g. of Raney nickel W-6 at 50~60°C for two hours. The catalyst was filtered off, and the filtrate, after removal of the solvent, was distilled to yield 20 g. of 1, 6-hexanediol, b. p. 125°C/3 mmHg, m. p. 40~41°C (lit.[15] 41.5°C).

ε-Caprolactone.—A typical catalyst for the dehydrogenation of 1, 6-hexanediol to ε-caprolactone was prepared as follows.

Two solutions, one solution (350 ml.) containing 56 g. of zinc nitrate hexahydrate and 92 g. of cupric nitrate trihydrate, and one solution (350 ml.) containing 24 g. of ammonium dichromate and 56 g. of 28% solution of ammonium hydroxide, were added dropwise into 300 ml. of water with stirring. The orange yellow precipitate formed was filtered and sucked as dry as possible, and dried at 70~80°C for twelve hours. The product was decomposed in a silica tube heated at 260~280°C for

13) W. Reppe et al., *Ann.*, **596**, 34 (1955).
14) J. W. Copenhaver and M. H. Bigelow, "Acetylene and Carbon Monoxide Chemistry", Reinhold Publishing Corp. (1949), p. 123.
15) W. Reppe et al., *Ann.*, **596**, 71 (1955).

three hours. The resulting product was washed with fifteen 2 l. portions of water, and dried at 70~80°C for twelve hours. The composition of the catalyst so obtained was about: 50% cupric oxide, 25% chromium oxide and 25% zinc oxide by weight (mol. ratio=2 : 0.5 : 1).

The apparatus and the procedure for the dehydrogenation were essentially the same as those previously described[1]. The dehydrogenation tube (60 cm.×15 mm.) was packed with 50 ml. of tablets of the above catalyst. After activation of the catalyst with hydrogen at 280~300°C, the pressure in the reaction system was reduced to 5~10 mmHg and 1,6-hexanediol (15 g.) was passed in by vacuum distillation in a period of four hours. The reaction temperature was maintained at 210~220°C. The product was fractionated to yield 0.5 g. of forerun, b. p. 50~65°C/2 mmHg, 7.6 g. of ε-caprolactone, b. p. 78~85°C/2 mmHg and 3.4 g. of unreacted hexanediol, b. p. 110~120°C/2 mmHg. Refractionation gave a sample of b. p. 80°C/2 mmHg, n_D^{25} 1.4615, d_4^{25} 1.071, MR_D: Found, 29.3; Calcd., 29.3.

Found: C, 63.22; H, 8.86. Calcd. for $C_6H_{10}O_2$: C, 63.13; H, 8.83%.

ε-Caprolactone gave a hydrazide melting at 115°C (lit.[8] 115°C).

Found: C, 49.16; H, 9.68. Calcd. for $C_6H_{14}O_2 \cdot N_2$: C, 49.30; H, 9.65%.

From the forerun, a 2,4-dinitrophenylhydrazone of 1-cyclopentene-1-carboxaldehyde was obtained, m. p. 209~210°C (lit.[16] 210~211°C), which showed no depression when mixed with an authentic sample.

Found: C, 52.40; H, 4.44. Calcd. for $C_{12}H_{12} \cdot O_4N_4$: C, 52.17; H, 4.38%.

Cyclopentyl Carbinol.—Copper-magnesium oxide tablets (50 ml.) containing 20% copper were used. After activation of the catalyst with hydrogen at 280~300°C, 1,6-hexanediol (17 g.) was passed in with 20 l./hr. of hydrogen at 270°C in a period of three hours. The products consisted of two layers; the upper water-insoluble layer weighed 11 g. and the lower aqueous layer weighed 2 g. By fractionation of the upper layer, 3.5 g. of forerun, b. p. 50~60°C/22 mmHg and 4 g. of cyclopentyl carbinol, b. p. 73~78°C/22 mmHg were obtained. Refractionation gave a sample of b. p. 74°C/20 mmHg, n_D^{20} 1.4540, d_D^{22} 0.926 (lit.[17] b. p. 161~163°C, n_D^{20} 1.4552, d_4^{20} 0.926), MR_D Found, 29.2, Calcd., 29.2.

Found: C, 71,77; H, 12.14. Calcd. for $C_6H_{12}O$: C, 71.95; H, 12.08%.

Cyclopentyl carbinol gave a phenylurethane melting at 108°C (lit.[18] 110°C).

Found: C, 71.30; H, 7.82. Calcd. for $C_{13}H_{17} \cdot O_2N$: C, 71.20; H, 7.82%.

From the forerun, a 2,4-dinitrophenylhydrazone of cyclopentanecarboxaldehyde was obtained, m. p. 149~152°C. (lit.[19] 158°C).

Found: C, 51.63; H, 5.01. Calcd. for $C_{12}H_{14} \cdot O_4N_4$: C, 51.79; H, 5.01%.

Results and Discussion

Reaction of Paraformaldehyde with Acetylene under Pressure.—The results obtained in various solvents are shown in Table I. Acetylene was compressed to about 15 kg./cm² at room temperature and the amount of acetylene compressed was about 26 g., except in the case of water (35 kg./cm², 14 g.). Obviously chemical structure of the solvent has effects on the relative yields of propargyl alcohol and butynediol to some extents. Methanol, tetrahydrofuran and acetone were suitable solvents for propargyl alcohol formation and benzene for butynediol.

Effects of the reaction temperature are shown in Table II. The relative yields were hardly

Table I. Effects of solvents

Solvent	Reaction pressure kg./cm²	Yield of PA* %	Yield of BD** %
Water	50~33	30	51
Methanol	48~42	52	30
Tetrahydrofuran	47~40	41	38
Acetone	45~40	47	42
Methyl acetate	40~33	36	47
Benzene	45~40	31	60

* Propargyl alcohol ** Butynediol
Reaction temperature: 110°C
Reaction time: 8 hr.
Paraformaldehyde (15 g.) and 100 g. of solvent were used.

Table II. Effects of the reaction temperature

Reaction temp. °C	Reaction pressure kg./cm²	Yield of PA* %	Yield of BD** %
90~100	42~23	28	31
100~110	40~25	32	45
110~120	40~22	36	49

* Propargyl alcohol ** Butynediol
Reaction time: 8 hr.
Paraformaldehyde (20 g.) and 100 g. of methanol were used.

Table III. Effects of reaction pressure

Amount of acetylene charged g.	Reaction pressure kg./cm²	Yield of PA* %	Yield of BD** %
28	40~25	41	37
14	26~15	32	43
8	15~ 2	10	62

* Propargyl alcohol ** Butynediol
Reaction temperature: 110~120°C
Reaction time: 6 hr.
Paraformaldehyde (20 g.) and 100 g. of methanol were used.

affected by the reaction temperature. Under 100°C, the conversion was low.

Results under various pressure are shown in Table III. Similar to the case of aqueous formaldehyde, the distribution of the products depended upon the reaction pressure—the higher the reaction pressure, the higher the yield of propargyl alcohol.

Table IV. Effects of paraformaldehyde concentration

Concn.	Reaction pressure	Yield of PA*	Yield of BD**
%	kg./cm²	%	%
10	50～44	56	26
20	45～35	41	37
30	43～22	32	45
50	50～30	24	52

* Propargyl alcohol ** Butynediol
Reaction temperature: 110～120°C
Reaction time: 8 hr.
A mixture (100 g.) of paraformaldehyde and methanol was used.

Table V. Oxydative coupling of propargyl alcohol

Reaction temp.	Reaction time	PA* : CuCl	Yield of hexadiynediol
°C	hr.	mol. ratio	%
20～25	8	2～4 : 1**	75
25～25	8	16 : 1	58
50～60	1	16 : 1	93
60～70	1	16 : 1	80
75～80	1	32 : 1	71

* Propargyl alcohol
CuCl (6 g.), NH_4Cl (19 g.), H_2O (60 ml.) and propargyl alcohol (56 g.) were used.
** The molar ratio of propargyl alcohol to cuprous chloride was maintained at ratio of 2～4 : 1 by adding propargyl alcohol at intervals.

The effects of paraformaldehyde concentration are shown in Table IV. With increase of the concentration of paraformaldehyde, the relative yield of propargyl alcohol decreased, but the effect was not so noticeable as in the case of aqueous formaldehyde. Therefore, for the purpose of preparing propargyl alcohol batchwise in the laboratory, it is advisable to increase the concentration of paraformaldehyde.

Oxydative Coupling of Propargyl Alcohol.—Hexadiynediol was prepared by the method using air and cuprous chloride catalyst. Reppe[20] described that the molar ratio of propargyl alcohol to cuprous chloride should be maintained at the most favorable ratio of 2 : 1 to 4 : 1 by adding propargyl alcohol at intervals.

The results in Table V show that even at the ratio of 16 : 1, hexadiynediol was easily obtained in a high yield by elevating the reaction temperature to 50～60°C.

Hydrogenation of Hexadiynediol.—Hydrogenation of hexadiynediol in the presence of Raney nickel W-6 proceeded smoothly in methanol solution to give 93% yield of 1, 6-hexanediol. If an unpurified sample containing copper ions is used, a small amount of zinc dust should be added to prevent deactivation of the catalyst.

Dehydrogenation of 1, 6-Hexanediol.—Some of the results obtained in dehydrogenation of 1, 6-hexanediol with numerous mixed catalysts are shown in Table VI. Similar to the previous study[1], a sample was passed in with a steady current of hydrogen. The yields of ε-caprolactone were based upon the amounts of hexanediol consumed. With all the catalysts, the reaction was very slow as compared with that of 1, 4-diols or 1, 5-diols. With the elevation of the reaction temperature, the amount of the forerun increased and the product decreased. With copper-magnesium oxide, it was ascertained

Table VI. Dehydrogenation of 1, 6-hexanediol with mixed catalysts

TABLE VII. EFFECTS OF CATALYST COMPOSITION

Catalyst composition (mol. ratio)			Yield of lactone	Sample recovered	Conversion
CuO	Cr_2O_3	ZnO	g.	g.	%
1	0.5	0.5	7.4	2.8	83
1	0.5	1	6.8	4.5	70
1	0.5	2	6.3	4.5	70
1	0.5	3	6.2	3.5	78
2	0.5	1	7.6	3.4	77
3	0.5	1	3.8	4.5	70
1	1	1	Inactive		
1	0.25	1	7.0	4.2	72
1	0.25	2	4.5	5.0	67

The sample (15 g.) was used in each experiment.

that the forerun contained cyclopentyl carbinol (III) and a small amount of cyclopentane carboxyaldehyde (II). This fact suggested the occurrence of the following side reactions.

Copper-chromite catalyst, which had been used for preparing γ-lactones or δ-lactones in the literatures, gave ε-caprolactone in 30% yield in the present work. It was observed that zinc oxide improved the selectivity of copper chromite for the ε-lactone formation.

The relationship between catalytic activity or selectivity and the composition of copper chromite-zinc oxide catalyst was shown in Table VII. In these experiments, the pressure in the reaction system was kept at 5~10 mmHg and the sample was passed in by vacuum distillation. The reaction temperature was maintained at 210~220°C and the reaction time was four hours. The catalysts were prepared by a modification of the procedure for preparing Adkins' copper chromite. The composition of the catalyst has considerable effects on the yield and conversion. The most favorable catalyst giving ε-caprolactone in a 68% yield and in a 78% conversion, had the composition of $CuO : Cr_2O_3 : ZnO = 2 : 0.5 : 1$. The catalysts which contained one of the components excessively lowered both the activity and selectivity. It was also ascertained that the forerun in these experiments contained 1-cyclopentene-1-carboxaldehyde (I).

The author wishes to express his sincere thanks to Professor Sango Kunichika of Kyoto University, for his invaluable advices and discussions. He also thanks Mrs. Chieko Tsuda for the elementary analyses.

Rotatory Dispersion of Metallic Co-ordination Compounds. III. Absorption Spectra and Rotatory Dispersion of Cobalt(III) Complexes of the $[CoN_2O_4]^-$ Type

By Jinsai HIDAKA, Yoichi SHIMURA and Ryutaro TSUCHIDA

(Received July 29, 1961)

In a former paper of this series[1], the relation between the absorption band and the optical rotatory dispersion of D-[Co edta]$^-$ was discussed. In consequence of this study, the splitting of the first absorption band was considered to be of importance for analyses of the so-called "anomalous" rotatory dispersion curve. In order to study the above problem in more detail, the present paper deals with the absorption spectra and optical rotatory dispersion of the cobalt(III) complex ion which belongs to the general type $[Co\ N_2O_4]^-$, where N and O represent respectively a nitrogen and an oxygen atom of ligands attached directly to the central cobalt(III) ion.

There have been a few reports[2] concerning the preparations and the absorption spectra of the complexes of this type, besides some reports concerning Co(III)-EDTA complexes. The trend of splitting of the first absorption band of those complexes, however, has not completely been clarified up to the present. In the present paper, therefore, the absorption spectra of *cis*(N)-K[Co(ada)$_2$]·2.5 H_2O, *trans*-(N)-K[Co(ada)$_2$]·2H_2O and *cis*(N)-K[Co(ata)·gly]·2 H_2O, which were newly synthesized, will be discussed, mainly in relation to the geometrical struture of the complex ions*.

Furthermore, the absorption spectra and the optical rotatory dispersion of Na[Co en ox$_2$]·H_2O and K[Co en malo$_2$]·H_2O, which were recently resolved by Dwyer et al.[3], will be studies in the same way as was done in a former paper[1].

The absorption spectra of the complexes employed will also be considered for spin-forbidden transition bands, i. e., the so-called "A band" and "B band", in the near-infrared region.

Experimental

Preparation. — *cis(N)-K[Co(ada)$_2$]·2.5 H_2O.* — In a solution of 7 g. adaH_2 in 40 ml. of water containing 5.5 g. of potassium hydroxide, 5 g. of cobalt chloride hexahydrate was dissolved. The mixture was cooled in an ice bath, and 15 ml. of 15% hydrogen peroxide was added drop by drop to the mixture. To complete the reaction the mixture was stirred and the desired complex gradually separated out. After being kept for several hours in a refrigerator, the reddish violet crystals deposited were separated by suction and recrystallized from a little water by the usual procedure. The crude product was contaminated by yellowish brown crystals, the solubility of which is comparatively smaller than that of the reddish violet crystals. Therefore, recrystallization was repeated to obtain the pure product.

After washing with a little ice water, ethanol and finally ether, the product was dried in the air.

Found: C, 26.40; H, 2.94; N, 7.74; H_2O, 11.15. Calcd. for K[Co($C_4H_5O_4N$)$_2$]·2.5 H_2O: C, 26.67: H, 2.79; N, 7.77; H_2O, 11.11%.

trans(N)-K[Co(ada)$_2$]·2 H_2O. — In a solution of 3.5 g.of adaH_2 and 3 g. of potassium hydroxide in 40 ml. of water, 2 g. of cobalt chloride hexahydrate was completely dissolved. The mixture was warmed at about 80°C on a water bath and oxidized with 1 ml. of 30% hydrogen peroxide. A yellowish brown crystalline solid was then gradually deposited. The reaction mixture was cooled to room temperature and filtered by suction. An additional crude product was also obtained by boiling the filtrate on a water bath for half an hour. The yield, in total, was almost quantitative. The crude product was recrystallized from hot water and washed with ethanol and ether.

Found: C, 25.93; H, 2.83; N, 7.65; H_2O, 8.75. calcd. for K[Co($C_4H_5O_4N$)$_2$]·2 H_2O: C, 26.67; H, 2.79; N, 7.77; H_2O, 9.09%.

cis(N)-K[Co(ata)gly]·2 H_2O. — Three grams of potassium acetate and 3 g. of glycine were dissolved in 30 ml. of warm water. To this solution 15 g. of β-K[Co(ata) (OH) (OH_2)]·3 H_2O[4] was added. The solution was warmed for about 20 min. on a water bath. After removal of the insoluble substance by filtration, the reddish violet solution was allowed to cool. A large amount of ethanol was added to

4) M. Mori, M. Shibata, E. Kyuno and Y. Okubo, This Bulletin, 31, 940 (1958).

it, and the solution was kept overnight in a refrigerator.

The reddish violet crystals deposited were collected and recrystallized from the cooled solution by the addition of ethanol. The final product was washed with ethanol and ether.

Found: C, 26.66; H, 2.84; N, 7.77; H_2O, 9.09. Calcd. for $K[Co(C_6H_6O_6N)(C_2H_4O_2N)]\cdot 2H_2O$: C, 26.67; H, 2.79; N, 7.77; H_2O, 9.12%.

Sodium dioxalato-ethylenediamine-cobaltate(III) monohydrate, Na[Co en ox_2]·H_2O, and potassium dimalonato-ethylenediamine-cobaltate(III) monohydrate, K[Co en $malo_2$]·H_2O, were prepared in violet crystals and resolved by the method of Dwyer and his co-workers[3]. The optical active complex of the former was precipitated as a more sparingly soluble salt with D-$[Co\ en_2(NO_2)_2]^+$, and the latter, with L-$[Co\ en_2(NO_2)_2]^+$.

The optically active dinitro bis-ethylenediamine-cobalt(III) ion, which gives a positive value of optical rotation for green lines of mercury, has been denoted as a D-isomer. Potassium dicarbonato-diammine-cobaltate(III) monohydrate, $K[Co(NH_3)_2\cdot(CO_3)_2]\cdot H_2O$ was prepared by the method of Mori and his co-workers[2].

Measurements.—The visible and ultraviolet absorption measurements were made by a Beckman DU spectrophotometer in aqueous solutions. The infrared spectra were obtained with a Parkin-Elmer model 21 (double beams) and a Hilger H-800 infrared spectrophotometer with sodium chloride prisms. The potassium bromide disk method was employed. The rotatory dispersion measurements were carried out in aqueous solutions with a Rudolph photoelectric spectropolarimeter, model 200 S-80. The concentration of the solution was 5.0×10^{-2} g. complex ion per liter.

All the measurements were made at room temperature.

Results and Discussion

Absorption Spectra.—The visible and ultraviolet absorption curves of the violet form and the brown form of bis-ammoniadiacetato-cobaltate(III) are shown in Fig. 1, in which the curve of Na[Co edta][5] is also plotted for comparison. The frequencies of the absorption maxima are summarized in Table I with other numerical data. As is seen in Fig. 1, the absorption curves of the violet form and of Na[Co edta] are similar on the whole. On the contrary, the absorption curve of the brown form differs distinctly; namely, the first absorption band I remarkably splits into two components Ia and Ib, and the second band II is shifted towards a shorter wavelength than those of the other two complexes. As will be seen in the figure, the main difference between the curves of the two isomers occurs in the region of the first band. In the absorption curve of the violet form, a component

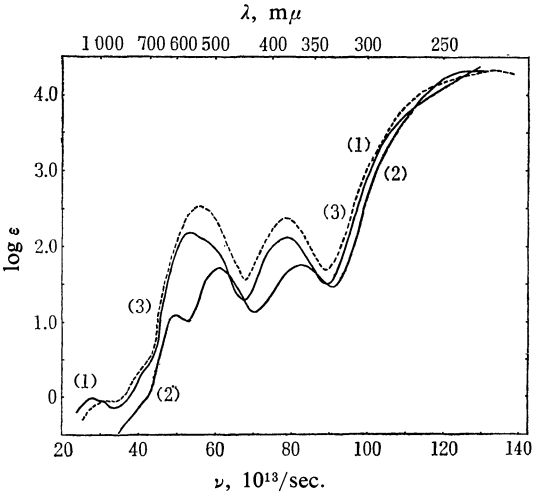

Fig. 1. Absorption spectra of:
1, *cis*(N)-K[Co(ada)$_2$]·2H_2O (violet form)
2, *trans*(N)-K[Co(ada)$_2$]·2H_2O (brown form)
3, Na[Co edta]·4H_2O (dotted curve)

band which is smaller in intensity is recognized in the shorter wavelength side of the first band maximum, at about 58×10^{13}/sec.

Judging from the symmetry of the complex ion, it can reasonably be considered that its first absorption band also splits into two components, Ia and Ib. This fact coincides with the conclusion of the analysis of the optical rotatory dispersion curve of D-K[Co edta][1] in the first absorption band. In the absorption curve of the brown form, the absorption component of the longer wavelength side is smaller in intensity than the component of the shorter wavelength side, and the difference is remarkable. From these trends in the splittings in the first absorption band, therefore, it is concluded that the violet form has one configuration in which the two nitrogen atoms occupy the cis-positions of a coordination octahedron, while the brown form has another configuration in which the two nitrogen atoms occupy trans-positions.

Some similar cases were reported by Linhard and Weigel[6]. Such assignments are also supported by Yamatera from semi-empirical molecular orbital calculations[7].

Three geometrical isomers are possible for the complex ion, $[Co(ada)_2]^-$, as shown in Fig. 2. Two isomers of the trans(N)-form, II and III, are possible. Judging from the bond angles of a nitrogen atom of the ligand, the type suitable for the brown form may be assigned to the structure II.

TABLE II. ABSORPTION MAXIMUM AND INVERSIVE ROTATORY DISPERSION

Complex	ν_{abs} 10^{13}/sec. (log ε_{max})	ν_{rot} 10^{13}/sec.	Sign of Cotton effect	Degree of rotation*
Na[Co en ox$_2$]	55.6(1.93)	52	(−)	4500°
		60	(−)	1500°
K[Co en malo$_2$]	55.6(1.96)	50	(−)	4500°
		56	(+)	6000°

ν_{abs} : Absorption maximum
ν_{rot} : Center of inversive rotatory dispersion
* The difference between the maximum and the minimum value of the partial inversive rotatory dispersion was halved.

The absorption curves of ptassium glycinato-ammoniatriacetato-cobaltate(III) and potassium dicarbonato-diammine-cobaltate(III) are shown in Fig. 3.

As is seen in Figs. 1 and 3 and in Table I, the absorption spectra are quite similar in appearance to the absorption spectrum of the violet form of the bis-ammoniadiacetate-cobaltate(III) ion mentioned above and have a shoulder in the shorter wavelength side of the first band maximum. It is concluded, therefore, that probably these complexes also have a cis-structure involving the two nitrogen atoms of the ligands.

In Figs. 4 and 5, the absorption curves of sodium dioxalato-ethylenediamine-cobaltate(III) and potassium dimalonato-ethylenediamine-cobaltate(III) are shown with the optical rotatory dispersion curves of these complexes. The absorption curves of both the complexes are quite similar to that of Na[Co edta]. The oxalato complex involves two 5-membered chelate rings involving oxygen atoms of the ligands, while the malonato complex contains two 6-membered rings. This difference in structure was not reflected in the appearance of the absorption spectra. However, since the malonato complex is less stable than the oxalato complex in aqueous solution, no absorption spectra of the former were measured in the far ultraviolet region. As will be seen in Figs.

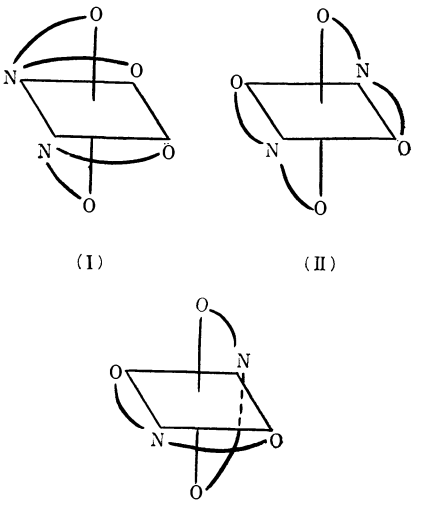

Fig. 2. The possible three geometrical isomers of $[Co(ada)_2]^-$.

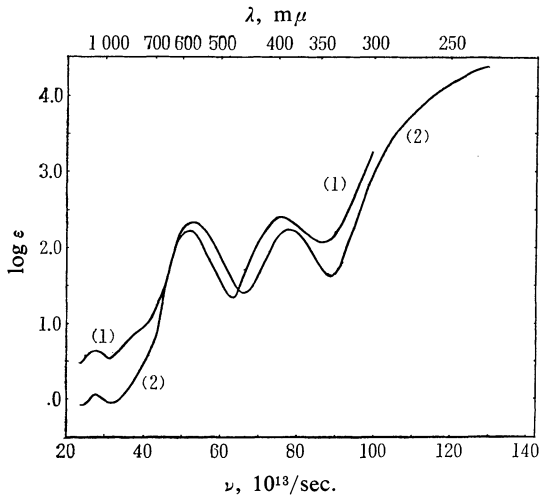

Fig. 3. Absorption spectra of:
1, *cis*(N)-K[Co$(NH_3)_2(CO_3)_2$]·3 H_2O
2, *cis*(N)-K[Co(ata)gly]·2 H_2O

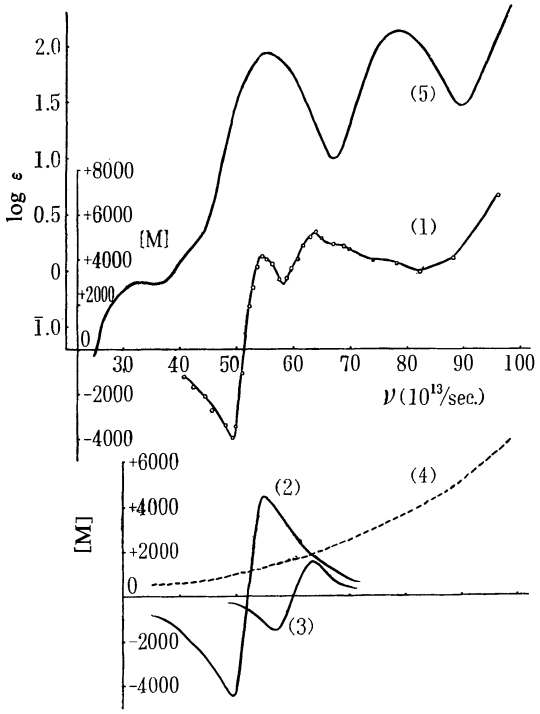

Fig. 4. Rotatory dispersion and absorption of Na[Co en ox_2]:
1, Rotatory dispersion curve; 2—4, Curve analyses of the rotatory dispersion curve; 5, Absorption curve.

1, 3, 4 and 5 and in Table I in the present work, spin-forbidden transition bands are observed in the near-infrared region. After Linhard's notation[8], they can be described as

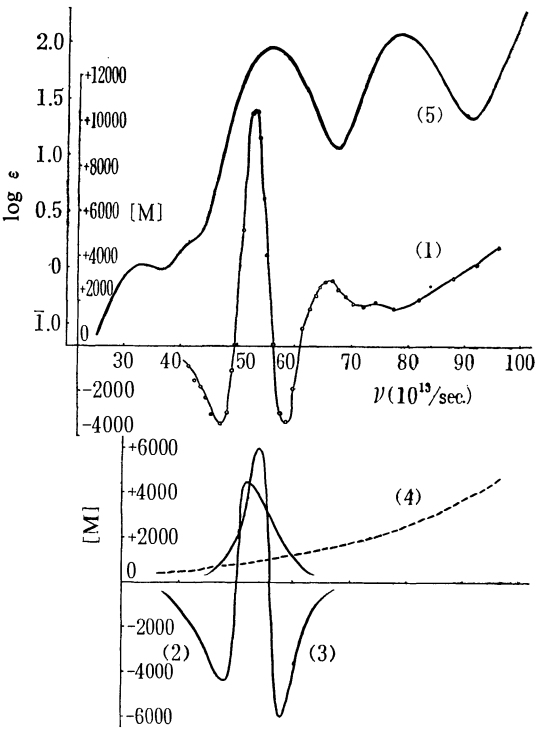

Fig. 5. Rotatory dispersion and absorption of K[Co en $malo_2$]:
1, Rotatory dispersion curve; 2—4, Curve analyses of the rotatory dispersion curve; 5, Absorption curve.

follows: the band in the longer wavelength is the "A bond", and the one in the shorter wavelength, the "B band".

The intensity of the A or B band is found to be about hundredth as weak as that of the first band. The appearance and behavior of the A band are closely related to those of the first band[5]. Frequency differences between the first and the A bands show almost a constant value.

The shape of the A band may suggest that the band splits into some component bands, as does the first band.

The optical resolution of the potassium *cis*(N)-bis-ammoniadiacetato-cobaltate(III) complex was not studied in this work. Further studies will be carried out in the future.

Infrared Absorption Spectra. — Infrared absorption spectra of the three new complexes were measured to confirm that the carboxylate groups were coordinated. It is well known that the carboxylate group in general exhibits strong split bands in the region between 1550 and 1750 cm^{-1} for the free acids. All the spectra of the complexes studied show bands at 1625 and 1660 cm^{-1}.

It is obvious that these bands are due to

8) M. Linhard and M. Weigel, *Z. physik. Chem., N F.*, **11**, 308 (1957).

coordinated carboxylate groups. Similar assignments have been established for some EDTA-complexes by Bush and Bailar[9].

Rotatory Dispersion.—The rotatory dispersion curves and the absorption curves of D-Na[Co en ox_2] and D-K[Co en $malo_2$] are shown in Figs. 4 and 5 and in Table II. The observed curves were analyzed on the basis of the following consideration: It is assumed that the observed curve is the superposition of several partial inversive dispersions[10] and a tail of normal dispersion which has its characteristic frequency in the ultraviolet region.

As is seen in the figures, both the observed curves are apparently displaced to the positive sign. Therefore, the positive tail of the normal dispersion has been presumed to be present. The rotatory dispersion behavior of D-[Co en ox_2]$^-$ in its first absorption band suggests that an overlapping of two inversive dispersions occurs. As a result of curve analyses, it has been shown that the observed curve I is reproduced by the overlap of curves 2, 3 and 4.

Thus, it is concluded that the first absorption band of this complex shows two inversive dispersions and that these two inversive dispersions have the negative signs of the Cotton effect equally. As was described in the preceding section, it is expected that the first absorption band of this complex splits into two components, Ia and Ib.

The two inversive dispersions above obtained, therefore, probably correspond to the two components. There is a small hump at about 75~84(10^{13}/sec.) in the rotatory dispersion.

This is similar to the hump in the second absorption band of an active trioxalato cobalt(III) complex ion which was reported by Kuhn and Bein[11]. It may be considered, therefore, that an inversive dispersion which belongs to the second absorption band also contributes to the observed rotatory dispersion.

The complex ion, D-[Co en $malo_2$]$^-$, also shows two inversive dispersions in the region of the first absorption band, as is seen in Fig. 5. In this case, however, two inversive dispersions which correspond to the two absorption components have different signs of the Cotton effect. The one in the longer wavelength has a negative sign, and the other in the shorter wavelength, a positive one, although the magnitude of these two partial dispersions has been found to be of the same order. The degree of rotation is greater in the malonato complex than in the oxalato complex.

The reason for this difference is unknown, but it may be due to the difference between the 5-membered chelate ring of a dioxalato complex ion and the 6-membered ring of a dimalonato complex ion, although no evidence for this is observed in the absorption curves. The behavior of the dispersion curve in the region of the second absorption band is similar to that of the dioxalato complex ion, and a small hump probably belongs to the second absorption band.

Summary

Three new complexes, *cis*(N)-K[Co(ada)$_2$]·2.5 H_2O, *trans*(N)-K[Co(ada)$_2$]·2 H_2O and *cis*(N)-K[Co(ata)gly]·H_2O, have been synthesized. The visible and the ultraviolet absorption spectra of these complexes have been measured and discussed in relation to the geometrical structures of the complex ions compared with other complexes of the [Co N_2O_4]$^-$ type. Rotatory dispersion measurements have also been made for D-Na[Co en ox_2] and D-K[Co en $malo_2$].

It has been shown that the so-called anomalous rotatory dispersions of these complexes are explicable by assuming the overlap of the two inversive dispersions in their first absorption bands. The slight inversive dispersions are also observed in their second absorption band.

Isolation of 3, 4-Dimethylpenta-1, 3-diene

By Toshiaki NISHIDA, Atsuaki ARAI and Iwao ICHIKIZAKI

(Received July 29, 1961)

In an attempt[1] to prepare 3, 4-dimethylpenta-1, 3-diene (I) by dehydrating 3, 4-dimethylpent-1-en-3-ol with potassium hydrogen sulfate, it was noticed that the major products were three isomeric dienes, i. e., 2-isopropylbutadiene (II) (53%), 2, 3-dimethylpenta-1, 3-diene (III) (21%) and I (18%). Although the latter two compounds had not yet been isolated in pure forms, each structure was assigned by chemical transformation of the enriched sample.

II III I

Since the separation of I and III was not sufficiently achieved by fractional distillation, gas chromatography (Carbowax 6000 on firebrick) was successfully employed for the complete fractionation of these two isomers, whose structures were confirmed on the basis of spectral evidences.

The compound (n_D^{20} 1.4625), with a shorter retention time, was a colorless liquid, and its ultraviolet absorption maximum at 232 mμ (ε=22900 in hexane) was in agreement with the calculated value of a trisubstituted butadiene[2]. Infrared absorption bands at 1640 and 1610 cm^{-1} exhibited the presence of cojugated diene, and strong bands at 880 and 830 cm^{-1} were indicative of unsym-disubstituted and trisubstituted double bonds respectively. Therefore, this compound must be 2, 3-dimethylpenta-1, 3-diene (III). Independent confirmation of this was provided by the NMR spectrum[3] (Fig. 1), which displayed a quartet centered at δ=5.62 p. p. m. (J=6.10 c. p. s.) attributable to an olefinic proton having been split by an adjacent methyl group[4]. Two peaks of almost equal intensity at 4.77 and 4.65 p. p. m. were assigned to the two non-equivalent protons of a terminal methylene group. Two peaks at 1.72 and 1.62 p. p. m. can be associated with two methyl groups on double bond, while a doublet (one of which was overlapping on the peak at 1.62 p. p. m.) centered at 1.57 p. p. m. was due to the methyl group having been split by the adjacent olefinic proton.

Another one (n_D^{20} 1.4729), with a longer retention time, was a colorless liquid and had a

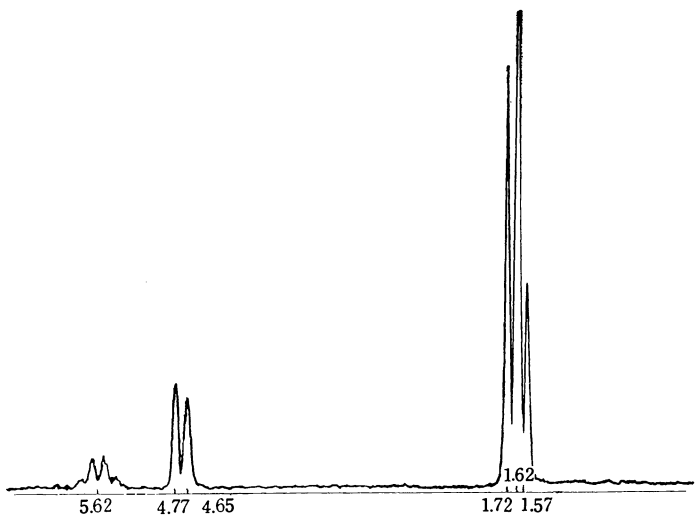

Fig. 1. NMR Spectrum of III.

2) R. B. Woodward, *J. Am. Chem. Soc.*, 64, 72 (1942).
3) NMR Spectra were determined at 60 Mc. using CCl_4 as solvent and siloxane (δ=0.10 p. p. m.) as an internal standard. The chemical shifts were recorded in δ-values (C. Djerassi, T. Nakano, A. N. James, L. H. Zalkow, E. J. Eisenbraun and J. N. Shoolery, *J. Org. Chem.*, 26, 1192 (1961)).
4) L. M. Jackman, "Application of Nuclear Magnetic Resonance Spectroscopy in Organic Chemistry", Pergamon, London (1959), p. 85.

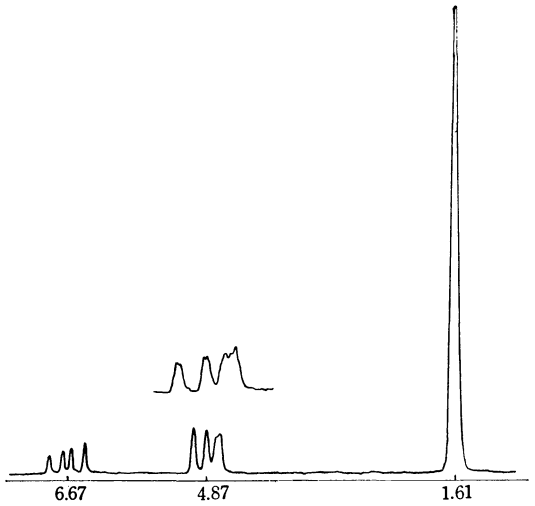

Fig. 2. NMR Spectrum of I.

tendency to polymerize rapidly on standing. Although the ultraviolet absorption spectrum exhibited a bathochromic shift of about 7 mμ[5] (λ_{max} 239 mμ; ε=27700 in hexane) from the calculated value[2], the infrared spectrum showed conjugated diene absorption bands at 1635 and 1605 cm^{-1} and characteristic bands of the vinyl group at 982 and 888 cm^{-1}. Therefore, these pieces of evidence strongly supported the theory that this compound was 3, 4-dimethylpenta-1, 3-diene (I). Finally, the NMR spectrum provided an elegant confirmation of the structure. The spectrum (Fig. 2) showed a typical ABC pattern[6] attributable to the grouping $-CH=CH_2$ with a quartet centered at 6.67 and eight uncompletely resolved lines centered at 4.87 p. p. m. The protons of the methyl groups showed a single peak at 1.61 p. p. m.

As to the mixture of I and III, there was observed a linear relationship between the refractive index and the relative concentration, and the value (1.4729) of our purest sample I was in good agreement with that for I obtained by graphical extrapolation. Although Nazarov and Mavrov[7] have reported the value (1.4691) for the refractive index of I, graphical estimation of their value shows that their hydrocarbon undoubtedly contains a large amount of III and/or other substances. Furthermore, it is noteworthy that, contrary to some claims[7,8], pure diene I did not afford a Diels-Alder adduct with crotonaldehyde even under conditions so drastic as to cause polymerization or isomerization of the diene. The details of this work will be reported elsewhere.

The authors wish to thank Drs. Yoichiro Mashiko, Kenkichi Nukada and Akio Suzuki of Government Chemical Industrial Research Institute of Tokyo for their measurement of the NMR spectra.

Reactions of Active Methylene Compounds. VII. Synthesis of Benzofuro[3′, 2′ : 3, 4]coumarins and 2-Phenylbenzo[b]-furans

By Yoshiyuki KAWASE

(Received August 1, 1961)

In previous papers[1] was reported the action of hydrohalogenic acids, of aluminum chloride and of pyridine hydrochloride on 2-methoxybenzoyl-phenylacetonitriles and related esters. The present paper describes the action of the same reagents on 2-methoxybenzoyl-2-methoxyphenylacetonitriles (Ia, b) and related esters (IIa, b) to give 2-hydroxyphenyl 2-methoxybenzyl ketones (IIIa, b), benzofuro[3′, 2′ 3, 4]-coumarins (IVa, b, b′) and 2-phenylbenzo[*b*]-furans (Va, b′, IX).

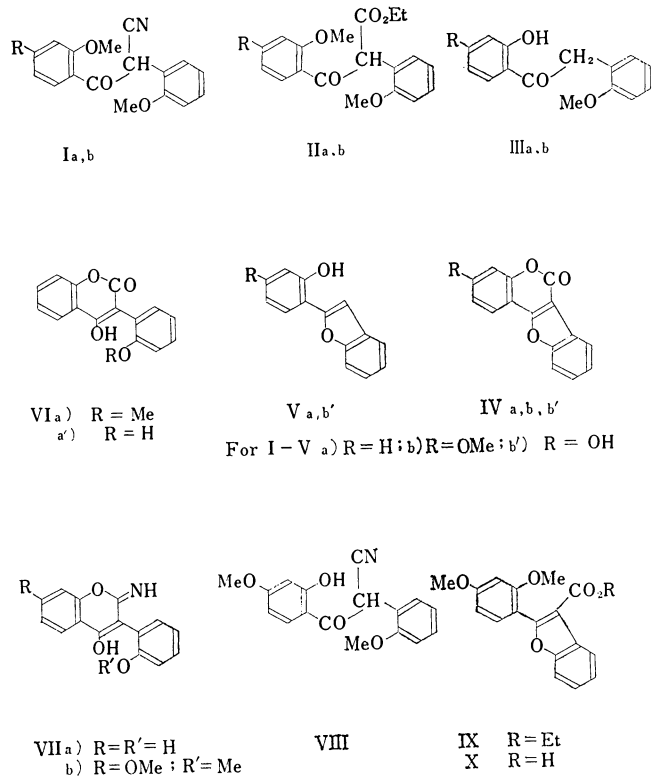

Chart 1

Recently, four derivatives of benzofurocoumarin (wedelolactone[2], coumestrol[3], erosnin[4] and psoralidin[5]) have been isolated from natural sources, and the synthesis of benzofurocoumarins has already been carried out by the action of hydrohalogenic acid, of pyridine hydrochloride, or of aniline hydrochloride on 3-(2-methoxyphenyl)-4-hydroxycoumarins[6] and on 2-methoxybenzoyl-2-methoxyphenylacetonitriles[7]. Also, the formation of 2-phenylbenzofurans has been achieved by the ring closure of 2'-methoxydeoxybenzoins[8] or ω-phenoxyacetophenones[9] and by the interaction of 2-hydroxybenzaldehyde with ethyl α-bromophenylacetates[10].

In the present experiments, benzofurocoumarins (IVa, b, b') were obtained from nitriles Ia, b by the action of hydrobromic or hydroiodic acid in acetic acid or of pyridine hydrochloride, and from esters IIa, b by the action of hydroiodic acid as the main product. It seems that in these cases the reagents cause first a cleavage of the methoxy group ortho to the carbonyl before that cleavage of the nitrile or ester group which forms the coumarin-ring. On the other hand, the action of hydrochloric acid on nitriles Ia, b or esters IIa, b gave deoxybenzoin derivatives, (IIIa, b), while that of hydrobromic acid or pyridine hydrochloride on esters IIa, b gave 2-phenylbenzofurans (Va, b'). In these cases the reagents cause first a cleavage of the nitrile or ester group, followed by that of the methoxy group, furnishing IIIa, b and Va, b' respectively. The action of aluminum chloride on nitrile Ia or ester IIa gave benzofurocoumarin (IVa) through each intermediate, 4-hydroxycoumarin-2-imide derivative (VIIa) or 4-hydroxycoumarin derivative (VIa), but that on nitrile Ib or ester IIb gave only partialy demethylated products,

TABLE I THE REACTION PRODUCTS

Reagent	Starting			
	Ia	Ib	IIa	IIb
HCl-AcOH	IIIa	IIIb	IIIa	IIIb
HBr-AcOH	IVa+IIIa	IVb+Vb'	Va	Vb'
HI-AcOH	IVa+VIa'	IVb'	IVa	IVb'
Pyridine-HCl	IVa+VIa'	IVb'	Va	Vb'
$AlCl_3$-$PhNO_2$	VIIa	VIII+VIIb	IVa+VIa	IX

2-hydroxy analog (VIII) of Ib and its ring-closed isomer 4-hydroxycoumarin-2-imide derivative (VIIb) or benzofuran-carboxylic ester derivative (IX) respectively, as is shown in Table I. The structures of VIa, a' and VIIa, b seem to be chromone derivatives, namely 2-hydroxy- and 2-amino-isoflavones respectively; the wave number of the carbonyl band is smaller than that of 4-hydroxycoumarins[1], e. g., IVa.

Experimental*

Preparation of the Starting Materials.—*2-Methoxybenzoyl-2-methoxyphenylacetonitrile (Ia).*—To a solution of methyl 2-methoxybenzoate (4 g.) and 2-methoxyphenylacetonitrile (3.5 g.) in anhydrous benzene (50 ml.) was added sodium hydride (1 g. or 1.7 mol.), and the mixture was refluxed for 4 hr. on an oil-bath (95~100°C), most of the benzene having been distilled off in the meantime. The well-cooled mixture was treated with a little ethanol and then with water, and was extracted with ether. The aqueous layer was acidified, and the solid product formed was collected, washed with aqueous sodium bicarbonate and recrystallized from ethanol as colorless prisms, m. p. 107~108°C; yield 2.8 g. or 42%, IR 2247 (CN), 1681 cm^{-1} (CO). Reported m. p. is 112°C[7].

Found: C, 72.92; H, 5.71; N, 5.11. Calcd. for $C_{17}H_{15}O_3N$: C, 72.58; H, 5.37; N, 4.98%.

Ethyl 2-Methoxybenzoyl-2-methoxyphenylacetate (IIa).—A solution of Ia (3.3 g.) in ethanol (50 ml.) containing one mole of water was saturated with dry hydrogen chloride, and was left at room temperature for 3 days. Water was added to the solution, and ethanol was removed in vacuo. The gummy product separated was dissolved in ethyl acetate, washed with aqueous sodium hydroxide, and then crystallized from dilute ethanol; m. p. 76~77°C, yield 2.2 g. or 57%, IR 1739 (ester), 1695 cm^{-1} (CO).

Found: C, 69.59; H, 6.42. Calcd. for $C_{19}H_{20}O_5$: C, 69.50; H, 6.14%.

The prerparation of nitrile Ib and ester IIb has been described in a previous paper[1].

Reaction with Hydrochloric Acid.—*Nitrile Ia to Give 2-Hydroxyphenyl 2-Methoxybenzyl Ketone (IIIa).*—A solution of Ia (0.5 g.) in acetic acid (10 ml.) containing concentrated hydrochloric acid (5 ml.) was heated on a steam-bath for 15 hr. The cooled solution was made alkaline with aqueous sodium hydroxide and was then extracted with ether. The residual product from the ether solution was distilled to give IIIa as colorless oil, b. p. 140~150°C/0.004 mmHg; yield 0.2 g. 2, 4-Dinitrophenylhydrazone, m. p. 188~189°C (from ethanol).

Found (for 2,4-dinitrophenylhydrazone): C, 59.82; H, 4.26; N, 13.18. Calcd. for $C_{21}H_{18}O_6N_4$: C, 59.71; H, 4.30; N, 13.27%.

Ester IIa to Give IIIa.—A similar treatment of IIa (0.5 g.) in acetic acid (10 ml.) with hydrochloric acid (5 ml.) gave 0.2 g. of IIIa; 2, 4-dinitrophenylhydrazone, m. p. 187~188°C.

Reaction with Hydrobromic Acid.—*Nitrile Ia to Give Benzofuro[3',2' : 3,4]coumarin (IVa) and IIIa.*—A solution of Ia (0.5 g.) in acetic acid (5 ml.) containing 48% hydrobromic acid (5 ml.) was refluxed on an oil-bath (140°C) for 3 hr. The cooled solution was diluted with water, made alkaline with aqueous sodium hydroxide, and then extracted with ether. The residual product from the ether solution was crystallized from methanol to give IVa as colorless needles, m. p. 180~180.5°C; yield 0.05 g., IR 1730 cm^{-1} (α-pyrone). Reported m. p. is 180~181°C[7] or 181~182°C[6].

Found: C, 76.29; H, 3.32. Calcd. for $C_{15}H_8O_3$: C, 76.27; H, 3.41%.

From the mother solution in the above-mentioned crystallization, 2, 4-dinitrophenylhydrazone of IIIa was obtained by the action of dinitrophenylhydrazine sulfate; m. p. 190~191°C.

Nitrile Ib to Give 3-Methoxybenzofuro[3',2' : 3,4]-coumarin (IVb) and 2-(2,4-Dihydroxyphenyl)-benzo[b]furan (Vb').—A similar treatment of Ib (0.5 g.) in acetic acid (5 ml.) with hydrobromic acid (5 ml.) gave IVb as slightly brown-colored needles, m. p. 192~193°C, 0.05g., from an alkali insoluble part through crystallization from ethanol.

Found: C, 72.32; H, 4.23. Calcd. for $C_{16}H_{10}O_4$: C, 72.18; H, 3.79%.

From a sodium hydroxide soluble part a small amount of Vb', m. p. 133~135°C (from benzene), was obtained through distillation; b. p. 180~200°C/0.004 mmHg, identical with the other sample.

Ester IIa to Give 2-(2-Hydroxyphenyl)-benzo[b]furan (Va).—A similar treatment of IIa (0.4 g.) in acetic acid (5 ml.) with hydrobromic acid (5 ml.) furnished Va, m. p. 93~94°C (form benzene), from an alkali insoluble part; yield 0.1 g. Reported m. p. is 95°C[7], 95~98°C[8] or 96~99°C[8].

Found: C, 79.96; H, 4.87. Calcd. for $C_{14}H_{10}O_2$: C, 79.98; H, 4.79%.

Ester IIb to Give Vb'.—A similar treatment of IIb (0.4 g.) in acetic acid (5 ml.) with hydrobromic acid (5 ml.) furnished Vb' as colorless needles,

* Melting and boiling points are uncorrected, and infrared spectra are measured in Nujol.

m. p. 136~138°C (from benzene), from a sodium hydroxyde soluble part through distillation in vacuo, b. p. 180~210°C/0.004 mmHg, identical with the other sample; yield 0.1 g.

Reaction with Hydroiodic Acid.—*Nitrile Ia to Give IVa and 3-(2-Hydroxyphenyl)-4-hydroxycoumarin (VIa').*—A mixture of Ia (0.5 g.), acetic acid (5 ml.), hydroiodic acid (d=1.7, 10 ml.) and acetic anhydride (5 ml.) was refluxed for 30 min. on an oil-bath (160°C) in a carbon dioxide atmosphere. The cooled solution was diluted with aqueous sodium bisulfite, made alkaline with aqueous sodium hydroxide, and then extracted with ether. From the ether extract, IVa (0.05 g.) was obtained; m. p. 176~177°C (from ethanol).

By acidifying the aqueous alkaline solution of the above-mentioned extraction, a small amount of VIa' was obtained; m. p. 250°C (from dilute ethanol), identical with the other sample.

Nitrile Ib to Give 3-Hydroxybenzofuro[3', 2', : 3, 4]-coumarin (IVb').—A similar treatment of Ib (1 g.) with hydroiodic acid (15 ml.) in acetic acid (7.5 ml.) and acetic anhydride (7.5 ml.) furnished IVb' as slightly brown-colored microcrystals (from ethanol) from a sodium hydroxide soluble part; m. p. 273~274°C, identical with the other sample. Acetate, colorless needles (from ethyl acetate), m. p. 210~211°C, identical with the other sample.

Ester IIa to Give IVa.—A similar treatment of IIa (0.5 g.) with hydroiodic acid (10 ml.) in acetic acid (5 ml.) and acetic anhydride (5 ml.) furnished IVa, m. p. 177~178°C (from ethanol), from an alkali insoluble part; yield 0.1 g.

Ester IIb to Give IVb'.—A similar treatment of IIb (0.5 g.) furnished IVb' as slightly brown-colored microcrystals, m. p. 274~275°C (from ethanol), identical with the other sample; yield 0.1 g.

Reaction with Pyridine Hydrochloride.—*Nitrile Ia to give IVa and VIa'.*—A mixture of Ia (0.5 g.) and anhydrous pyridine hydrochloride (2.5 g.) was refluxed for 40 min. on an oil-bath (220~230°C). Dilute hydrochloric acid was added to the cooled mixture, and the solution was warmed for several minutes on a steam-bath. The crystalline product formed on cooling was collected, washed with aqueous sodium hydroxide, and recrystallized from ethanol to give IVa, m. p. 176~177°C; yield 0.2 g.

By acidifying the alkaline solution in the above-mentioned washing, 0.1 g. of VIa' was obtained as colorless microcrystals, m. p. 261~262°C (decomp.) (from ethanol), IR 3390, 3205 (OH), 1664 cm^{-1} (γ-pyrone). The reported m. p. is 253°C[6]

Found: C, 70.63; H, 4.17. Calcd. for $C_{15}H_{10}O_4$: C, 70.86; H, 3.96%.

This VIa' was converted into IVa, m. p. 179~180°C, by heating at 280°C for 2 hr. following the method of Govindachari's report[6].

Nitrile Ib to Give IVb'.—A similar treatment of Ib (0.5 g.) furnished IVb' as slightly brown-colored microcrystals, m. p. 276~277°C (from ethanol); yield 0.2 g.

Found: C, 71.22; H, 3.34. Calcd. for $C_{15}H_8O_4$: C, 71.43; H, 3.20%.

Acetate was prepared by the pyridine-acetic anhydride method; colorless needles, m. p. 211~212°C (from ethyl acetate).

Found: C, 69.04; H, 3.17. Calcd. for $C_{17}H_{10}O_5$: C, 69.39; H, 3.43%.

Ester IIa to Give Va.—A similar treatment of IIa (0.4 g.) with pyridine hydrochloride (2 g.) furnished Va, m. p. 94~95°C (from benzene), from an alkali soluble part; yield 0.1 g.

Ester IIb to Give Vb'.—A similar treatment of IIb (0.4 g.) furnished Vb' as colorless needles, m. p. 137~139°C (from benzene); yield 0.1 g.

Found: C, 73.95; H, 4.51. Calcd. for $C_{14}H_{10}O_3$: C, 74.33; H, 4.46%.

Reaction with Aluminum Chloride.—*Nitrile Ia to Give 3-(2-Hydroyxphenyl)-4-hydroxycoumarin-2-imide (VIIa).*—A mixture of Ia (0.5 g.) and anhydrous aluminum chloride (0.5 g. or 2.1 mol.) in anhydrous nitrobenzene (5 ml.) was heated for 1 hr. on a steam-bath. The cooled solution was treated with water, and the nitrobenzene was removed by steam-distillation. The residual semi-solid product was taken up in ethyl acetate and washed with aqueous sodium carbonate and with aqueous sodium hydroxide. The product obtained from the ethyl acetate solution was crystallized from ethanol to give VIIa as colorless microcrystals, m. p. 230°C (decomp.), soluble in dilute hydrochloric acid; yield 0.1 g., IR 3571, 3333, 3077 (NH_2, OH), 1613 cm^{-1} (γ-pyrone).

Found: C, 70.92; H, 4.67; N, 5.43. Calcd. for $C_{15}H_{11}O_3N$: C, 71.15; H, 4.34; N, 5.53%.

This VIIa was converted into IVa, m. p. 178~179°C, by hydrolysis with dilute hydrochloric acid.

Nitrile Ib to Give 2-Hydroxy-4-methoxybenzoyl-2-methoxyphenylacetonitrile (VIII) and 3-(2-Methoxyphenyl)-7-methoxy-4-hydroxycoumarin-2-imide (VIIb).—A similar treatment of Ib (0.4 g.) with aluminum chloride (0.7 g. or 4 mol.) furnished VIII, m. p. 168~169°C (from ethanol), from a sodium hydroxide soluble part; yield 0.05 g., with a red ferric chloride reaction, IR 2247 (CN), 1608 cm^{-1} (CO).

Found: C, 68.50; H, 5.17. Calcd. for $C_{17}H_{15}O_4N$: C, 68.67; H, 5.08%.

From an alkali insoluble part was obtained VIIb, m. p. 180~182°C (from dilute ethanol), soluble in dilute hydrochloric acid, with a negative ferric chloride reaction; IR 3450, 3250, 3120 (NH_2), 1655 cm^{-1} (γ-pyrone).

Found: C, 68.53; H, 4.82; N, 4.51. Calcd. for $C_{17}H_{15}O_4N$: C, 68.67; H, 5.08; N, 4.71%.

This VIIb was also obtained from VIII by warming it with dilute aqueous sodium hydroxide for a while.

Ester IIa to Give IVa and 3-(2-Methoxyphenyl)-4-hydroxycoumarin (VIa).—A similar treatment of IIa (0.4 g.) with aluminum chloride (0.7 g. or 4 mol.) in nitrobenzene (5 ml.) furnished 0.1 g. of IVa, m. p. 175~176°C, from an alkali insoluble part, and 0.05 g. of VIa, m. p. 171~172°C (from ethanol), from a sodium carbonate soluble part. The reported melting point of VIa is 176°C[6].

Found (for VIa): C, 71.77; H, 4.91. Calcd. for $C_{16}H_{12}O_4$: C, 71.63; H, 4.51%.

Ester IIb to Give Ethyl 2-(2, 4-Dimethoxyphenyl)-benzo[b]furan-3-carboxylate (IX).—A similar treatment of IIb (0.4 g.) with aluminum chloride (0.6 g. or 4 mol.) in nitrobenzene (5 ml.) furnished 0.1 g. of IX, m. p. 80~81°C (from ethanol), from an alkali insoluble part; IR 1718 cm^{-1} (ester).

Found: C, 70.01; H, 5.89. Calcd. for $C_{19}H_{18}O_5$: C, 69.93; H, 5.56%.

This IX was converted into 2-(2, 4-dimethoxyphenyl)-benzofuran-3-carboxylic acid (X) by hydrolysis with aqueous sodium hydroxide; m. p. 214~216°C (decomp.) (from dilute ethanol), IR 1669 cm^{-1} (CO_2H).

Found: C, 68.05; H, 5.05. Calcd. for $C_{17}H_{14}O_5$: C, 68.45; H, 4.73%.

This acid X was identical with the sample, m. p. 213~214°C (decomp.), prepared from IVb' by methylation with dimethylsulfate and sodium hydroxide, followed by hydrolysis.

The author is grateful to the members of the Institute of Agricultural Chemistry of Kyoto University for microanalysis and to the members of the Faculty of Science of Osaka City University for infrared spectroscopy.

Activations by Anions in the Oxy-acid Phosphors. I. General Consideration and Preliminary Experiments

By Yoshihide KOTERA, Michiko YONEMURA and Tadao SEKINE

(Received August 10, 1961)

Activations by Anions in the Phosphors.—In the case of sulfide phosphors, it has been said that an anion of, for examaple, halogen, oxygen, phosphorus or arsenic ion, may act as an activator. Kroeger and Hellingman[1] showed for first time that the ions Cl^-, Br^- and I^- play an essential part in the blue centers of ZnS phosphors. They introduced the orbital energy diagram for zinc sulfide with blue centers and attributed the blue emission to the electron transition between the conduction band and the activator level which is introduced by the blue centers. They assumed the following three possibilities for the configurations giving rise to the localized activator level, viz., A^+X^-, A^+ or X^-, together with their respective surroundings, where A^+ stands for metallic ion and X^- for halogen. Also they[2] determined chemically the chlorine present in phosphors and claimed that this finding would support their assumption of a blue centers. Further, Kroeger and Dikhoff[3] investigated the activation by the oxygen ion in zinc sulfide matrix. They established that the incorporation of zinc oxide in zinc sulfide causes the appearance both of a new absorption band and, in the presence of activators, of new fluorescence bands displaced about 150 Å toward long wavelengths with respect to the original bands. They explained these effects by the assumption of local oxygen levels and of new centers consisting of associated pairs of oxygen and activator ions. In addition, Bube, Riehl and several other researchers[4] have also studied the action of halogen and oxygen ions. Subsequently McKeag and Ranby[5] reported the activation of zinc sulfide by phosphorus and Prener[6], its activation by arsenic; both phosphors were proposed for use as a single white screen for television and also for the preparation of transparent luminescent screens. Besides zinc sulfide, the activation by polysulfide ions in the matrix of sulfides and sulfates of alkali and alkali earth was found by Gobrecht and Hahn[7]. They assumed that in all cases the polysulfide compound was formed and that the red emission in these phosphors is to be attributed to the polysulfide formation, concluding that these emissions are the same as those occurring in pure tungstate or uranyl compounds. Meanwhile, Thomson[8] assumed that the emission of pure zinc oxide required the presence of sulfide ion; Kroeger and Dikhoff[3], however, denied this assumption on the basis of their investigations.

Activations by Anions in the Oxy-acid Phosphors.—It has not yet been reported that activation by anions occurs in the oxy-acid phosphors. We can, however, find in the literature some experimental results which might be explained by assuming this activation, although the authors have not expressed this idea. One of them was described above; that is, Gobrecht and Hahn[7] found the activation by polysulfide ion in alkali earth sulfates. We suppose that the effect of the existence of sulfur upon the emission of aluminosilicate, which was reported by Kirk[9], might be the same activation as that reported by Gobrecht and Hahn. Tungstate, molybdate, vanadate and uranyl ions act as activators in the oxy-acid phosphors, and we could find some corroborative findings, one of which is that presented by Gobrecht and Weiss[10] regarding alkali earth tungstate and molybdate activated by the uranium compound, and another of which is reported for calcium borate[11] or halophosphate[12] activated by the tungstate compound. Further, we would like to propose that titanium or manganese ion in higher valency acts as an activator[13] which should be thought of as an anion. This idea might be partially supported by the fact that titanium in higher valency acts as an activator only when the matrix makes an eutectic compound with the titanate compound (Kroeger[13]). Also, we might explain the effect of the phosphorus[14] or arsenic[15] ion upon the emission of zinc silicate activated by manganese as the occurrence of anionic activation by the phosphorus or arsenic ion.

It is, however, very difficult to conclude the anionic activation from these results because of the lack of reliable experimental facts for the occurrence of this activation. We thought that anions might be able to give localized levels between the filled and conduction bands in those matrices, and so act as activators, when they have a smaller electron affinity than that of the oxy-anions which compose the host crystal. We have prepared various oxy-acid phosphors activated by anions and have obtained some remarkable results[16].

Experimental

Selection of Matrices and Activators.—First, it was necessary to determine what kind of matrices and activators should be selected. Two types of matrices were used, the sulfates of alkali earth metals and magnesium, and the silicates of alkali earth metals, magnesium and zinc. It was thought that these anions might have a greater electron affinity; also, they were not expected to decompose during firing at relatively high temperatures. For the electron affinity of oxy-anions there are few data, but we presumed that, if two salts were prepared from two anions with a common metal ion and if the fundamental absorption of one salt has an edge at a shorter wavelength than the second, then the former would have a greater electron affinity than the latter. From this idea we supposed that a sulfate or silicate ion would have the greater electron affinity among the oxy-acid anions. As to decomposition during the firing, the facts that calcium[17] or magnesium[18] sulfate decompose partially above 1000°C and that strontium or barium sulfate behaves similarly, would be overcome by lowering their firing temperatures.

As activators, silicate, phosphate, borate, carbonate and sulfide were used, because they surely exist in the matrix as anions. Also tungstate, molybdate, vanadate and germanate ions were tried, as they probably exist in the matrix as anions; further, arsenate, antimonate[19] and aluminate[20] ions were tried, because they are anionic components of the phosphor matrix.

Preparation of Phosphors.—Sulfates of alkali earth metals were precipitated by mixing a purified ammonium sulfate solution with a purified solution of alkali earth salts. In the purification, precaution was taken, by the addition of distilled hydrogen chloride, that the residue of sulfide used for the purification was thoroughly decomposed. In the precipitation, the sulfate solution was poured into the metallic solution and the precipitation was stopped, when the latter solution was slightly in excess, in order to obtain a precipitate with an excess of cations. The silicate matrices were prepared by a well-known process. Magnesium sulfate was prepared by solid-state reaction between purified magnesium oxide and ammonium sulfate. The purity of raw materials was ascertained spectroscopically.

As activators, the following salts were used: $SiO_2 \cdot nH_2O$, $(NH_4)_2HPO_4$, H_3BO_3, metallic carbonate, metallic sulfide, $WO_3 \cdot nH_2O$ or metallic tungstate, MoO_3, NH_4VO_3, GeO_2, As_2O_3, Sb_2O_3 and $Al(OH)_3$. They were purified by a well-known process or by the process previously reported[19,20]. Metallic sulfides were prepared by the reaction between the metallic sulfate and a reducing agent, the details being described in the following report.

In general the amount of activators was optimum at 0.01 to 0.1 mol. per 1 mol. of sulfate and

0.001 to 0.05 mol. for silicate. Some results were obtained in which emission colors were different among samples activated by different amounts of activator.

We could not obtain conclusive results for the form of activator. In the following tables we have used the form which is commonly found for an anion.

Flux was seldom used, and it was found in the following experiments that it has little effect.

Firing was done in air, except for special cases, for 2 to 4 hr. at 1100°C. For the activation of calcium sulfate by vanadate or carbonate ion, firing was done at 500°C, and for barium sulfate activated by carbonate ion, at 900°C, while the firing for the preparation of magnesium sulfate phosphors was carried out at 1000°C.

Results

The reselts are shown in Tables I and II for two kinds of matrices. Most of these emissions are excited both by 2537 and 3650 Å; some of them have the emissions only under 2537 Å excitation, whereas magnesium silicate activated by antimonate ion has emission only for the excitation by 3650 Å. In general, the emission under 2537 Å is stronger than that under 3650 Å.

Discussion

It was confirmed that in oxy-acid phosphors anionic centers are present, though their luminescence is weak in most cases. From the results obtained we suggest that anionic activators are to be divided into two group as follows:

1. The first group might be called "intra-ionic activation". They have emissions almost identical with those found in the matrices whose anion is identical with the activating one. The luminescence originates in this group from the electronic transition in the anions. The activations by tungstate and molybdate ions are typical examples of this group, and that by vanadate may belong to it too.

2. The other group might be called "inter-ionic activation". Their emissions have various colors, depending upon the matrices, even for the same activator. This activation occurs when the electron affinity of the activating anions is smaller than that of the host crystal anions. Some ions of this group show a tendency for the emission color to shift to a longer wavelength in the order of calcium, strontium and barium. Phosphate, germanate,

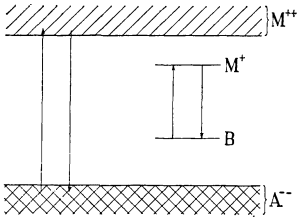

Fig. 1 Energy band model for intraionic activation.

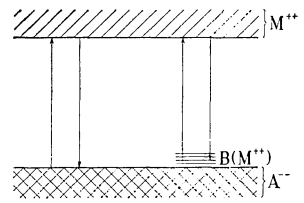

Fig. 2. Energy band model for interionic activation.

aluminate, sulfide and sulfite ions tend to show this tendency.

Phosphors with intraionic activation have a rather strong emission and it might be found that such activation occurs in phosphors which have been studied by other researchers who have assumed them to be activated by other sources[11,12] We assume an energy band model for this group like the one in Fig. 1. This activation may correspond to the activation by divalent manganese or rare earth ions in the case of cationic activation.

In interionic activation, it is difficult to find the relation between the emission and the composition of phosphors because of the weak emission intensity. However, in some cases the regularity is found according to the ionization potential of the cations which compose the matrices. In many cases the emission of this group shows a wide distribution. Such an activation has rarely been found before, the sulfide activation being the only case in this group, but it is not clear whether the sulfide activation belongs to this group or not. We assume an energy band model for the interionic activation as in Fig. 2. Because of the complex structure of the activating anions, their energy levels may be complicated, in turn causing the broadening of the spectral distribution of emission.

Compared to cationic activation, it was found that the amount of activators is considerably large in anionic activation; this may be due to the more complex structure of the anions.

The authors wish to express their thanks to Professor S. Makishima for his general discussions on the subject and on some of their experimental work.

Activations by Anions in the Oxy-acid Phosphors. II. Activations by the Tungstate Ion

By Yoshihide KOTERA, Michiko YONEMURA and Tadao SEKINE

(Received August 10, 1961)

In the previous paper[1] it was found that anionic centers are present in oxy-acid phosphors and that the activation by tungstate ion is a typical example of "intraionic activation", the luminescence originating from the electron transitions in tungstate ion and being rather strong. The activation by the tungstate ion has been reported by several researchers[2], for example, for calcium borate[3] or halophosphate[4], though the activation is assumed to be caused by the tungsten ion. In these cases it has been found that the brightness of phosphors increases with the increase in the added amount of tungsten, but the highest brightness is only equal to or lower than that of calcium tungstate. It is desirable to obtain phosphors which have a higher brightness and,

if possible, a cost cheaper than calcium tungstate, if calcium salts are to be activated by tungstate ion. In the various kinds of matrices discussed, it was expected that sulfate salts would satisfy this desire because of the similarity in crystal structure[5] between sulfate and tungstate salts. Among calcium salts the crystal structure of calcium sulfate is most like that of tungstate, the former being orthorombic with $a_0=6.21$, $b_0=6.95$ and $c_0=6.96$, whereas the latter is tetragonal with $a_0=5.24$ and $c_0=11.38$. Likewise, magnesium sulfate has an orthorhombic structure with $a_0=4.82$ $b_0=6.72$ and $c_0=8.35$, while magnesium tungstate is monoclinic, with $a_0=4.67$, $b_0=5.66$, $c_0=4.92$ and $\theta=89°35'$. An American patent[6] makes an interesting relevant suggestion. It is proposed by this patent that the brightness of calcium tungstate increases when sulfuric acid, in amounts corresponding to the excess calcium oxide in the tungstate, is added on firing for the purpose of preventing the formation of calcium oxide. Accordingly we have prepared various sulfate phosphors activated by tungstate ion and have so achieved some remarkable results.

The Experiments and their Results

The starting materials are $CaSO_4$, $CaCO_3$, $WO_3 \cdot nH_2O$, $CaWO_4$, MgO, $(NH_4)_2SO_4$, ZnO, $CdCO_3$, $PbSO_4$, $BaSO_4$ and MoO_3, which had been purified by the process previously reported[7]. They were mixed in a dry state and fired in air for 4 hr., at 1100°C for calcium sulfate and at 1000°C for magnesium sulfate. The spectral distribution was measured by means of a spectroradiometer[8], and the brightness, by a photocell.

Relation between the Brightness of $CaSO_4$: WO_4 and the Mixing Ratio.—The relation is

shown in Fig. 1 between the brightness of the fired products under 2537Å excitation and the mixing ratio of $CaSO_4$, $CaCO_3$ and $WO_3 \cdot nH_2O$. The brightness and the decay characteristies of these products under X-ray excitation are shown in Figs. 2, 3 and 4.

In Fig. 1 the value of 100 corresponds to the brightness of the commercial product of calcium tungstate phosphor, while the brightness and decay characteristics under X-ray excitation were determined by the blackening of the photographic plate. The commercial product shows a brightness value of 1.40 for those prepared by the precipitation and the firing of calcium tungstate or 1.80 for those prepared by the solid-state reaction between calcium compound and tungsten trioxide, and 1.20 for the decay value.

In Fig. 2 the samples are selected for the mixing ratio from points on the straight line DG in Fig. 1, while in Fig. 3 the mixing ratios of samples are located on DE (A) and on the straight line parallel to DE (B), and in Fig. 4, on JK.

In these preparations it is probable that the reaction

$$CaSO_4 + H_2WO_4 \rightarrow CaWO_4 + H_2SO_4$$

proceeds; that this is the case is confirmed by the formation of white fume, which is presumed to be sulfur trioxide, and by the decrease in the weight of the samples. Then it has to be assumed that, for mixtures of compositions below the line DE (Fig. 1), the composition changes during the firing, along the straight line EF or parallel to EF, the reaction ending when the composition reaches line DE. The spectral distributions are shown in Fig. 5.

The Effect of the Addition of other Components than Calcium and Tungstate Compound to Calcium Sulfate Activated by a Tungstate Ion.—By the addition of lead salt to calcium sulfate activated by a tungstate ion, it might be supposed that the product would be about the same as that of calcium tungstate activated by lead. Actually, this is the case. The change in the spectral distribution by the addition of lead occurs in $CaSO_4$: WO_4 as in the case of calcium tungstate; in this case it was also found that the brightness of the

products is considerably higher than that of calcium tungstate activated by lead. In Figs. 6 and 7 the brightness of the samples under 2537 Å excitation is shown; the value of 100 means the brightness of commercial calcium tungstate activated by lead. The spectral distribution is shown in Fig. 5.

By the addition of barium sulfate, it might be presumed that the absorption of the X-ray increase and barium tungstate, which has no emission at room temperature, would be produced. The brightness and the decay characteristics of the products under X-ray excitation are shown in Table I. Under 2537 Å excitation the spectral distribution is almost the same as that of calcium tungstate, and the brightness decreases proportionally with the amount of the addition.

By the addition of magnesium oxide the products show an emission almost the same as that of magnesium tungstate, when the firing

temperature is below 1000°C. (See Fig. 5. Above 1100°C the emission is the same as for calcium tungstate, and the firing temperature between 1000 and 1100°C gives their mixture.) Also in this case the brightness is higher than that of an ordinary preparation, the results being tabulated in Table II.

By the addition of zinc or cadmium oxide, the spectral distribution shifts to a longer wavelength, which is shown in Figs. 8 and 9. Molybdenum oxide causes the same shift, which is shown in Fig. 10. This result is like that of Kroeger[2], but the details are not in accordance. The brightness of these samples under 2537Å is considerably high when compared with other commercial phosphors.

The Effect of the Precipitating Condition or Firing Condition.—Preliminary tests were carried out for the production of calcium sulfate activated by tungstate ion. Twelve kinds of samples were prepared as follows:

1. Pure calcium chloride ($CaCl_2 \cdot 2H_2O$ 80 g./l.) was mixed with a pure ammonium sulfate solution ($(NH_4)_2SO_4$ 80 g./l.), and precipitated calcium sulfate was mixed with tungstic acid.

The batch obtained was fired at different temperatures, viz., 1000, 1050 and 1100°C.

2. The same process as 1, except that the concentration of the ammonium sulfate solution was 40 g./l.

3. The same process as 1, except that tungstic acid was re-purified from the one use d in process 1.

4. After the preparation by the process 1, the products were re-fired at 1100°C for 4 hr.

The relation between the relative brightness of these samples and the preparative condition

Table III. Relation between the brightness of calcium sulfate activated by tungstate ion and the precipitating or firing condition

Firing temp. °C	Processes (1)	(2)	(3)	(4)
1000	85	87	90	84
1050	87	90	95	89
1100	88	90	93	87

is shown in Table III.

From these results we tried to investigate the effect of the precipitating condition of calcium sulfate and of the prefiring condition on the brightness of the products. The precipitation of calcium sulfate was carried out under the following conditions:

i. A calcium chloride solution (80 g./l.) was poured into an ammonium sulfate solution (80 g./l.).

ii. A calcium chloride solution (40 g./l.) was poured into an ammonium sulfate solution (160 g./l.).

iii. An ammonium sulfate solution (40 g./l.) was poured into a calcium chloride solution (160 g./l.).

iv. An ammonium sulfate solution (80 g./l.) was poured into a calcium chloride solution (80 g./l.).

Half a portion of precipitated calcium sulfate was prefired at 800°C for 2 hr., while the other half was not prefired. The batches were prepared with these eight calcium sulfate samples, the ratio of calcium and tungsten being the same. The relative brightness of these phosphors is shown in Table IV.

Table IV. Effect of precipitating condition and prefiring upon the brightness of calcium sulfate activated by tungstate ion

Prefiring	Precipitating conditions (i)	(ii)	(iii)	(iv)
Unfired	95	95	97	97
Prefired	98	100	100	101

It can be concluded from these experiments that the brightness becomes greater by the purification of tungstic acid or the prefiring of calcium sulfate, but that other factors are not so important as the former.

Relation between the Brightness of $MgSO_4$: WO_4 and the Mixing Ratio.—The relation is shown in Fig. 11 between the brightness of fired products under 2537 Å excitation and the mixing ratio of MgO, $(NH_4)_2SO_4$ and $WO_3 \cdot nH_2O$. The same is shown in Fig. 12, the brightness change being expressed as the function of tungstic acid proportion.

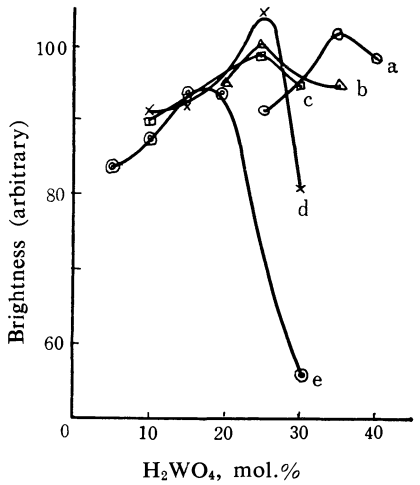

Fig. 12. Brightness of magnesium sulfate activated by tungstate ion as the function of ammount of WO_3 added to magnesium sulfate (under 2537 Å excitation).

Discussion

In his brief studies on the luminescence of tungstates and molybdates, Kroeger[2] presumed from the absorption data of the molybdates that the absorption would be of the characteristic type caused by electronic transitions in the molybdate groups and that the same would be applied to the tungstates. He also assumed from his experiments the absorption and excitation bands on the one hand and the emission band on the other hand must be closely connected, both probably originating in one and the same atomic configuration, which might be tungsten and molybdenum with adjacent oxygen ions. In this case it was not determined whether any tungstate or molybdate group could give rise to an emission or not.

On the other hand, a few reports have been published on the emission of phosphors activated by tungsten or molybdenum. Calcium borate[3] or calcium halophosphate[4] activated by tungsten have been studied, but their details are uncertain, except that it has been explained that the emissions might be the same as those of calcium tungstate and that the brightness increases with the increasing amount of tungsten, its maximum value being the one which is obtained for calcium tungstate. Aluminum oxide activated by tungsten emits an orange light, while activation by molybdenum causes a blue emission[9]; zinc silicate emits a green color when activated by tungsten[10]. These reports are also uncertain but for the last case, where it is obvious that

9) S. Izawa, *Sci. Pap. Inst. Phys. Chem. Res.*, **20**, 163 (1933).
10) Y. Uehara and U. Umekawa, *J. Chem. Soc. Japan* (Nippon Kwagaku Kwaishi), **61**, 107 (1940).

the emission corresponds to that of zinc tungstate. Meanwhile, Robert[6] has found that the brightness of calcium tungstate would increase when sulfuric acid, in amounts corresponding to the excess calcium oxide in the tungstate, is added on firing. This addition of sulfuric acid might cause the formation of calcium sulfate, reducing the amount of calcium oxide, which seems to cause the afterglow in calcium tungstate[11].

It is found that calcium sulfate is activated by the tungstate ion and that the brightness of this phosphor under 2537Å excitation is higher than that of pure calcium tungstate. The spectral distribution of this emission is almost the same as that of calcium tungstate, although a small shift was found in some cases. However, as already stated, the reaction between calcium sulfate and tungstic acid might occur during the firing of their mixture. Further, it was found by us that the addition of ammonium persulfate to calcium tungstate causes its brightness to increase[12]. Thus the results might be explained by the findings of Robert and our above-written finding, that the addition of sulfate ion is favorable for the preparation of calcium tungstate phosphor.

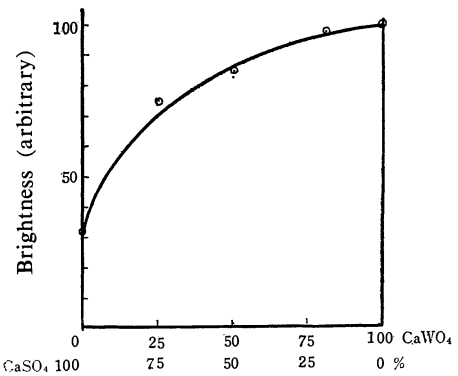

Fig. 13. Relation between the brightness and the mixing ratio of mechanical mixture of calcium sulfate and calcium tungstate.

For these problems it is proposed that, at low contents of tungstic acid, calcium sulfate is being activated by the tungstate ion, because the brightness is much higher than that obtained from a mixture of calcium sulfate and calcium tungstate, whose brightness is increased by the addition of sulfate. However, when the content of tungstic acid is high, a reaction with calcium sulfate occurs to produce calcium tungstae, while the activation by tungstate occurs simultaneously to increase the brightness of the product. In Fig. 13 the brightness of mechanical mixtures of calcium sulfate and calcium tungstate under 2537Å excitation is shown; this clarifies the activation by the tungstate ion compared with Fig. 1. Some qualitative results which might clarify this assumption were obtained from crystallographic analysis by means of a recording X-ray diffractometer. In the phosphor, which was prepared by the firing of a mixture of 1 mol. calcium sulfate and 0.2 mol. tungstic acid, the patterns of both calcium sulfate and tungstate were found, while the pattern of the phosphor from the mixture of 1 mol. calcium sulfate and 0.05 mol. tungstate was almost the same as that of calcium sulfate. Because of this crystallographic similarity, it is quite difficult to determine the content of the constituent. On the other hand, absorption measurements were carried out to compare the spectra of pure calcium sulfate and that activated by tungstate ion, but the special peak was not found until 2800Å, and the measurements at shorter wavelengths were disturbed by the emission which is excited by the light in this region. The final decision as to the occurrence of tungstate activation in the case of calcium sulfate phosphors must be based on measurements of excitation spectra.

Thus, these results may be applied to the preparation of calcium tungstate phosphors. This phosphor is new prepared by two processes, one featuring the solid-state reaction between calcium carbonate or nitrate and tungstic acid, and the other consisting of the precipitation of calcium tungstate in an aqueous solution and its calcination. The former is now applied to the preparation of those phosphors which are used for fluorescent lamps, because they have good characteristics for 2537Å excitation. In this case it might be claimed that better results might be obtained if calcium sulfate were used as a starting material for calcium salt. The advantages of this proposal may be summarized as follows:

1) Compared with the process in which calcium carbonate or nitrate is used as starting material, not so much calcium oxide remains after the firing, though the ratio ($CaO : WO_3$) is large enough, because calcium sulfate decomposes very slowly at 1000°C. (The vapor pressure of sulfur trioxide on calcium sulfate is a few millimeters at 1000°C[13].)

2) The calcium sulfate which might remain after the firing increases the brightness of the prepared phosphor as it is activated by tungstate.

11) T. Nishikawa et al., *J. Chem. Soc. Japan, Ind. Chem. Sec.* (*Kogyo Kagaku Zasshi*), **57**, 890 (1954); **58**, 256 (1955); **61**, 266 (1958).

12) Y. Kotera and T. Sekine, ibid., **54**, 625 (1951).

13) J. Zawadzki, *Z. anorg. u. allgem. Chem.*, **205**, 180 (1932).

3) The phosphor prepared by this procedure is in the form of very fine powder, the size being hardly measurable by an ordinary microscope.

These are advantages for 2537 Å excitation, but for X-ray excitation different considerations are necessary. Under X-ray excitation it is necessary for the phosphor to absorb the X-ray, and it is clear that calcium sulfate has a smaller absorption coefficient than tungstate. From Figs. 2, 3 and 4 it is seen that calcium sulfate activated by tungstate has a weak emission when the amount of tungstate is small. However, advantage 1) mentioned above may, also be important in the case of X-ray excitation, because Nishikawa et al.[11] showed that the decay characteristic depends upon the residual amount of calcium oxide, while advantage 3) may be effective for the preparation of fine phosphor, which is used for X-ray intensifying paper with high resolution.

The effect of the addition of lead or magnesium may be considered for the preparation of calcium tungstate activated by lead or magnesium tungstate. In either case the results show that better phosphors could be prepared than by the ordinary process. It is remarkable that, when magnesium oxide is added to the mixture of calcium sulfate and tungstic acid, the firing temperature determines the characteristic of the product. It might be considered that a solid-state reaction between magnesium tungstate and calcium sulfate occurs. Similar results are obtained in the cases of zinc oxide and cadmium oxide, but in these cases the characteristic are determined by the mixing ratio, and these results could be explained by the formation of a solid solution between the products. The addition of molybdenum oxide causes a somewhat similar effect; the explanation for this case might be given by a combination of that one proposed by Kroeger[2] for the case of mixed crystals $CaWO_4 \cdot CaMoO_4$ and that other which may be concluded from the velocity difference between the solid-state reaction of calcium sulfate and tungstic acid and that of calcium sulfate and molybdenum oxide. It was unsuccessful to attempt to increase the sensitivity for X-ray excitation by the addition of barium sulfate.

The precipitating condition of calcium sulfate or the firing conditions has little influence upon the brightness, and it is shown that the repeated purification of tungstic acid or prefiring makes the brightness higher.

Magnesium sulfate, when activated by tungstate, shows the same characteristic as calcium sulfate. In this case it is necessary to lower the firing temperature, because magnesium sulfate decomposes thermally at a relatively lower temperature (the vapor pressure of sulfur trioxide on magnesium sulfate is reported to be 760 mmHg at 1213°C[14]), and so the firing must be done below 1100°C. It was possible to obtain a phosphor which has a higher brightness than that prepared by the ordinary process.

The authors wish to express their thanks to Dai-Nippon-Toryo Co. for the measurement of phosphor brightness under X-ray excitation.

Spectral Response of Photoconductivity in Polycyclic Aromatic Compounds

By Mizuka Sano and Hideo Akamatu

(Received August 14, 1961)

The photoconductive behaviors of polycyclic aromatic hydrocarbons have been investigated in the previous paper[1]. Concerning the nature of conducting electrons in these organic solids, it is interesting to investigate the spectral response of photoconductivity. In the previous reports[2,3] from our laboratory, it was noted

1) M. Sano, This Bulletin, **34**, 1668 (1961).

2) H. Akamatu and H. Inokuchi, *J. Chem. Phys.*, **20**, 1481 (1952).

3) H. Inokuchi, This Bulletin, **27**, 22 (1954).

that the optical threshold energies for photoconduction were nearly in accord with the long-wavelength edges of the optical absorption spectra of crystals, and also in agreement with the values of the energy gaps which were estimated from the temperature dependence for electrical resistivity. From these observations, it was concluded that the semiconductive properties of polycyclic aromatic compounds are intrinsic.

Meanwhile, a number of investigations have been reported on photoconduction in organic solids. Most of them have been concerned with simple compounds, especially with anthracene crystal. Carswell and Lyons[4] found, by employing a surface-type photocell, that the spectral response curve of photoconduction reproduced quite well the absorption spectrum of anthracene crystal. A similar result was observed by Rosenberg[5], who employed a sandwich-type photocell with conducting glass electrodes. Kommandeur and Schneider[6] have found a more complex behavior by employing a sandwich cell with silver electrodes; e. g., the peaks on the response curve of the photocurrent correspond to the minima of the absorption spectrum.

On the other hand, Kallmann and Pope[7] and Moore and Silver[8] have indicated the extrinsic nature of photoconduction in anthracene; i. e., the injection of holes or electrons from metal electrodes, rather than the generation of charge carriers in the bulk of the crystal, is predominant. This might be due to the high-insulating nature of the materials. At any rate, both effects concerning the carrier generation make the photoconductive behaviors complicated.

Thus, it might be anticipated that polycyclic aromatic compounds, poor insulators or semiconductive materials, would show much simpler behaviors in photoconduction. In this paper, the spectral response of the photoconductivity of polycyclic aromatic compounds is investigated in relation to the optical absorption spectra and the thermal energy gaps.

Experimental

Procedures in the photoconductivity measurements are similar to those described in the previous report[1]. For the investigation of the spectral response of the photocurrent, a single monochromator with the normal Wadsworth arrangement was used, associated with a 1000-watt tungsten lamp as the light source. The calibration for the monochromator was made by referring to emission lines from mercury (435.8 mμ, 546.1 mμ, 579.1 mμ), sodium (589 mμ), lithium (670.8 mμ) and potassium (770 mμ) vapors, and to absorption lines of liquid chloroform (1411 mμ, 1694 mμ, 1861 mμ) and of liquid 1, 2, 4-trichlorobenzene (1660 mμ). All of these spectra were detected by a thermopile or a PbS photocell, which was placed in front of the output slit. The spectrum from the monochromator extends from about 370 mμ to 2500 mμ, with the maximum intensity of 2×10^{16} photons/sec. cm^2 at 1415 mμ.

The surface-type photocell was employed; hence the image of the output slit of the monochromator was directed onto the cell perpendicularly to the direction of the electric field. Aromatic films were about 0.5 μ in thickness.

Absorption spectra, in ultraviolet and visible regions, of aromatics, both in thin films and dissolved in benzene, were recorded at room temperature using a Cary Model 14 spectrophotometer. The films, of a suitable thickness, about one micron or less, were prepared on pyrex plates by the sublimation method. The concentration of the solution was adjusted into the order of 10^{-5} mol./l. Measurements of the absorption spectra of solid phases were not easy because their surfaces were not completely flat. It was necessary, consequently, to take account of the light loss due to scattering at the surface and in the bulk, as well as the reflection loss at the surface. Confusion was avoided by inserting a "diffuser" (a pair of opal glass plates) in front of the photoreceiver of the spectrometer.

Fluorescence spectra excited by 365 mμ ultraviolet irradiation from a mercury discharge lamp were determined with the aid of the spectrophotometer. The irradiation was applied to the surface of film which faced the input slit of the spectrophotometer.

Measurement of the electrical resistivity as a function of temperature was made similarly to that method described by Inokuchi[9].

Results

Absorption Spectra.—The optical absorption spectrum of polycrystalline film was noted to resemble closely that of the solution of the same compound, excepting some broadening and shift of peaks. In consequence, assignments of the bands were made easily, according to Clar's notation[10], to the p-, α- and β-bands. The values of the shift for each transition induced by the phase change from solution to polycrystalline film are given in Table I. The red-shifts of the p-bands are in the order of from 1050 cm^{-1} (0.13 eV.) to 2260 cm^{-1} (0.28 eV.) throughout the series of compounds; the larger molecules show greater shifts. On the

Ovalene	2.68		2.44		0.24	

other hand, the shift of the α-band remains nearly constant at a magnitude of about 400 cm^{-1} (0.05 eV.). However, there is the possibility that the weak α-band underlies the intense p-band; therefore, it is difficult to detect the α-band from the spectrum, especially when it is a broad one. The vibrational structure was seen in the p-band, which possessed a spacing of about 1450 cm^{-1} (0.18 eV.). This value was noted to be nearly constant for the series of compounds studied in polycrystalline film as well as in solution. This mode of vibration which couples with the electronic excitation might be the stretching of the aromatic skeleton.

No variation was found in the spectra by pumping out the ambient air of the film specimen. In general, the absorption curve of film possesses a considerably long tail extending to long-wavelength range. For instance, the absorption spectrum of pyranthrene film extends its tail as long as to 2.6 μ, the long-wavelength limit of the spectrophotometer. This leads to difficulty in specifying a unique absorption edge. In relation to the spectral response of photoconductivity which will be discussed in the later section, careful observation was made on the absorption in the long-wavelength region outside the main absorption region.

In some cases, a band, weak but comparable in sharpness with p-band, was observed on the tail of the film spectrum. Pyranthrene exhibited the maximum at 1.53 μ, and violanthrene at 1.40 μ. These bands possess no vibrational structure. When a thicker film was employed, the band was quite well developed without any change in the position of the maximum. This is shown in Fig. 1 for violanthrene film. Concerning the origin of these weak absorption bands, it is unlikely that the absorption is caused by an inclusion of impure molecules, for an incorporated impurity usually exhibits a much sharper absorption band. It is also unlikely that the absorption is due to a transition between vibrational levels. Polycyclic aromatic hydrocarbons exhibit specific infrared absorption bands in the wavelength region longer than 3.33 μ[11]. All these absorption bands appear out of the wavelength region concerned. However, there remains the possibility that overtone or combination bands of these fundamental vibrations would appear in the region which is

concerned. It was attempted to record the absorption spectra in thick single crystals of pyrene and perylene. Seventeen narrow bands were separated in the region from 2.05 to 2.60 μ (0.13 eV. in interval), of which the most intense band showed a band-width of the order of 0.005 eV. In addition, pyrene exhibited another narrow absorption band at 1.68 μ, 0.01 eV. in width, which was accompanied by a less pronounced peak with the maximum at 1.64 μ. (Fig. 2). In comparison with the bands concerned, these vibrational bands are much sharper in band-width. Other possibilities such as the molecular exciton band or the intermolecular charge transfer band must be kept in mind; however, these have not been clarified at present.

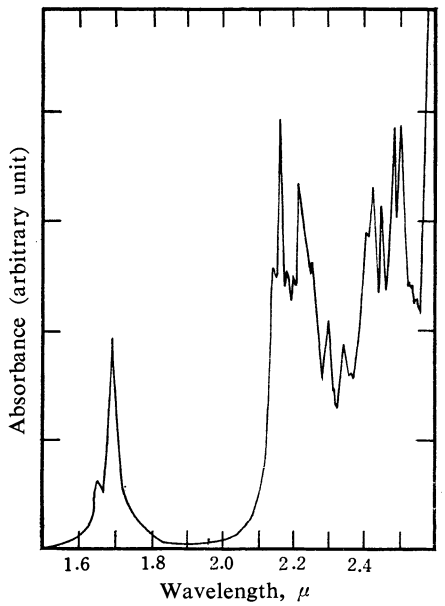

Fig. 2. The optical absorption spectrum of pyrene single crystal in the near infrared region.

Spectral Response of Photoconductivity.— Photocurrent arises whenever light falls in an electronic absorption region of a compound. The magnitudes of the photocurrents were usually in the range of $10^{-9}\sim10^{-14}$ amp. in vacuo (10^{-3} mmHg). A preliminary experiment showed, however, that exposure to air enhanced the photocurrent for most of the specimens. To preclude the oxygen effect, the spectral response of photoconductivity was observed in vacuo, with surface-type cells. The measurements of photocurrent with varying intensity of the incident light indicated that the current observed was almost proportional to the light intensity in the region lower than 10^{16} photons/sec. cm^2. This was true with the different wavelengths[1]. Therefore, in order to normalize the photocurrent to the same input intensity of illumination, the observed photocurrent was divided by the incident light intensity for each wavelength.

The photoconduction spectra of pyranthrene, violanthrene, perylene, violanthrone, anthanthrone and indanthrazine are illustrated in Figs. 3—8. The optical absorption spectra of these films are also shown in the same figures. The photoconduction spectrum resembles the

absorption spectrum of the same film, and a good correspondency was found between peaks on the response curve and peaks on the absorption curve, concerning both position and intensity. (Table II). Consequently, assignments could be made for peaks on the response curve by referring to the p- or β-band on the absorption spectrum.

It is concluded that the photoconduction spectrum reproduces the absorption spectrum essentially and, in consequence, that the photocurrent is produced by the light energy which is absorbed into the bulk of the organic solid.

Out of the region of the principal absorption band, the sensitivity of photoconduction

TABLE III. THE THRESHOLD OF THE PHOTOCONDUCTION

	Practical threshold value	$\lambda_{1/2}$ point of the longest wavelength p-band on the photoconduction spectrum	Thermal energy gap ε

decreased more or less exponentially with the increasing wavelength and continued to extend over the infrared region. This makes it difficult to specify the threshold value. The attempt was made, nevertheless, to find a threshold beyond which the photocurrent could not be detected practically. The practical threshold values are compared with the thermal energy gaps for semiconduction for a series of compounds in Table III. It is to be noted that these values are not coincident with each other and that in some cases a rather large discrepancy was found. In the same table, the photon energies at the $\lambda_{1/2}$ point, where the photoconductive sensitivity falls to half its maximum value (the peak of the p-band), are also shown.

In the cases of pyranthrene, violanthrene and perylene, weak maxima were observed on the response curve in the wavelength region longer than the main peaks. These maxima, which are named here as the X-band and the Y-band respectively, were found at 10300 cm^{-1} and 13900 cm^{-1} for pyranthrene (Fig. 3), at 8800 cm^{-1} and 13400 cm^{-1} for violanthrene, and at 16500 cm^{-1} for perylene. These weak bands (X and Y) were detected by a sandwich-type cell as well as by a surface-type cell. Variation in applied electric field and in temperature (from room temperature to $-100°C$), or opening the film to the air, did not change the shape of these extra bands, in spite of the variation in their magnitudes.

An attempt was made to measure photoconduction under an ambient illumination. The pyranthrene surface-type cell was placed under the illumination (ambient) of a monochromatized light, and the same surface was irradiated with a second monochromatized light. The spectral response curve (of the second irradiation) was found to be unchanged from the response curve which was observed in the absence of the ambient light, independently of its wavelength. This was the case for the extra weak bands also; such a behavior as the infrared quenching of the photocurrent could not be observed. The result implied that the X- and Y- bands could not be distinguished in their natures from the main bands and were not produced by trapped electrons.

Discussion

From comparing our results with those of others[4-6], it can be concluded that the photoconduction spectra of aromatic crystals reproduce the optical absorption spectra. With the surface-type cell, when the irradiation is made normally on the film surface, the greatest variation in electrical conductivity (i. e., photocurrent) will be produced in the uppermost layer of the film, because the photons are absorbed most prominently according to Lambert's law; furthermore, the flux of the electric field is concentrated along the uppermost layer to which the electrodes are attached. If it is assumed that the photoconductivity is of the intrinsic nature of the compound and

that the charge carriers are produced in the bulk of the compound, then the number of carriers will be proportional to the number of photons absorbed into the bulk, with a definite coefficient of quantum yield.

The number of photons (L) absorbed by the film with the thickness d is given by the formula

$$L=L_0(1-10^{-Kd})$$

where L_0 is the incident light intensity and K is the extinction coefficient. As K is the order of $10^4\,cm^{-1}$ for the principal bands, a film 0.5 μ in thickness absorbs nearly 70 per cent of the incident light. When Kd is small enough for its higher powers, L will be proportional to Kd. Thus the photocurrent can be anticipated to be proportional to K when the film thickness is slight. Furthermore, when it is assumed that the quantum yield of photoconduction is constant independently of the wavelength of the illumination, the response curve will reproduce the absorption curve. This is the case we have observed. The principal bands of the absorption spectra consist of the singlet-singlet transitions; thus, all of these excited states are equally responsible for the electronic conduction, but with a probability depending on each transition moment.

Outside the principal bands, a long tail is generally observed on the response curve. No reliable interpretation has been offered for the photosensitivity in the long wavelength region. This makes it difficult to specify the threshold of photoconductivity. The practical threshold value is dependent on the sensitivity of the equipment; thus, the concept becomes rather a vague one. For the intrinsic photoconductors, Moss[12] has proposed a convenient characteristic wavelength at which the photosensitivity falls to half its maximum value (the $\lambda_{1/2}$ point). In the cases of perylene and anthracene, the coincidence of the energy values between the thermal energy gap and the $\lambda_{1/2}$ point is not so bad, but in other cases large discrepancies are noted. (Table III). Similar discrepancies were pointed out by Vartanyan and Karpovich[13] for violanthrone and pyranthrone.

In connection with this, the extra peaks which were found on the tail of the main bands of photoconduction spectra are of interest. Similar extra peaks were found for anthracene by Rosenberg[5], and for pyrene by Kommandeur, Korinek and Schneider[14]. In the latter case, it was reported that the extra bands were observable in crystal possessing a rather considerable thickness. In the present case, however, the film was as thin as 0.5 μ in thickness, and the bands are of the same nature as the main bands, as was mentioned in the previous section. The most characteristic fact for the extra bands is that one of them (the X-band) is located at the energy which corresponds to the thermal energy gap. Thus, the $\lambda_{1/2}$ point of the X-band is in fairly good agreement with the value of the thermal energy gap. This is shown in Table IV.

A number of possible explanations for the extra bands are conceivable; some of them were pointed out by Kommandeur et al.[14], while Rosenberg[5] assumed the electron transfer through the triplet state for anthracene.

The location of the X-band is far below the singlet-singlet transition. Concerning the lowest excited singlet state, the fluorescence spectrum is suggestive. For instance, the p-band of the pyranthrene film ranged from around 400 mμ to 650 mμ, with the maximum at 516 mμ, while the fluorescence band ranged from 496 mμ to 734 mμ, with the maximum at 648 mμ (1.92 eV.) (Fig. 9). The peak-peak separation between the absorption and the fluorescence bands is generally found to be in the order of a few thousands cm^{-1} for polycyclic aromatic compounds in a crystalline state. This might be due to the molecular interaction in the excited state. However, it is clear that the lowest excited singlet level

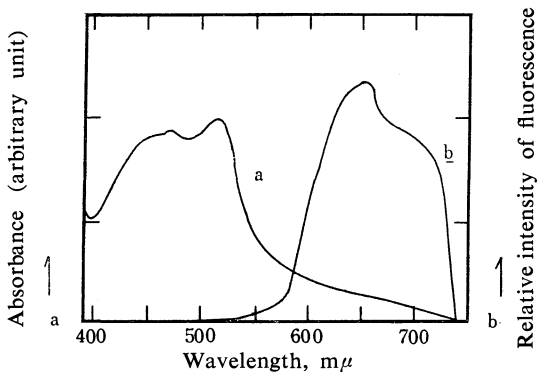

Fig. 9. (a) Absorption and (b) fluorescence spectra of pyranthrene film.

lies above 1.92 eV. for pyranthrene film, while the X-band is located at 1.28 eV. It is known[15] that the lowest triplet state (^3L) is 2.32 eV. below the p-band (^1L_a) in benzene and 1.71 eV. below in naphthalene, while the $^1L_a-{}^3L$ separation is around 1.4 eV. in the larger aromatic

molecules. If it is true for pyranthrene and violanthrene and if the triplet level in the crystalline state is not far from the molecular level, it follows that the bands concerned may be assigned to the lowest triplet state (Table IV).

The weak absorption band which was found at 1.40 μ (0.89 eV.) for violanthrene is not far from its X-band, but 1.53 μ (0.81 eV.) for pyranthrene is not in coincidence with the X-band.

From the above discussion, it may be concluded that the photoconduction takes place by associating with the lowest excited state of molecules in the aromatic crystals. The semiconduction also occurs in the same excited state, or even with smaller energy. It has been frequently presumed[16] that the photoconduction band should be located near the ionization level of the molecule, but that the lowest excited state could not be responsible for the electrical conduction, even though the dipole-dipole interaction between excited states results in developing the molecular exciton band. But this is not coincident with observed results. Recently, Lyons and Morris[17] have attempted ultraviolet irradiation in the vacuum region onto anthracene crystal; however, no photoconductivity distinguishable from the usual one could be found.

Concerning the mechanism for photoconduction in the lowest excited state, there are three possible schemes at least. (1) There might be a sufficient intermolecular orbital overlap which results in developing the true conduction band even in the lowest excited state. (2) If it is not the case, the electrons or the positive holes might be exchangeable between neighboring molecules through the vibrational levels in the lowest excited state during the life time of the excited state ($\sim 10^{-8}$ sec.), which is long enough compared with the vibrational period ($\sim 10^{14}$ sec.). This would result in the hopping conduction. (3) The electron transfer may take place via the triplet state much more easily than via the excited singlet state, because of its long life time; the singlet-triplet transition through the intersystem crossing is well known.

Lyons and Morris[18] have found that the photo-emission of electrons from aromatic crystals can occur at a potential which is lower by 1~2 eV. than the ionization potential of the molecules. However, the ionization continuum in the crystal is still much higher than the energy level of the lowest excited state.

With regard to the second and the third scheme, the temperature dependence for photoconductivity is of interest. As reported in the previous paper[1], the activation energy of photoconduction is 0.18 eV. for pyranthrene; nearly the same value was found for anthracene (0.17 eV.) by Rosenberg[5], and for pyranthrone (0.2 eV.) and for violanthrone (0.2 eV.) by Vartanyan[13]. Thus, this value is apparently quite general for polycyclic aromatics and is coincident with the vibrational energy of the skeletal stretching of aromatics. Some reason might be expected for the fact that such a mode of vibration is the most favorable for the coupling with the electronic excitation as well as for the intersystem crossing.

The photosensitivity which was found in the region of the triplet state supports the possibility of the third scheme. Moreover, it has been confirmed[19] that the electron spin resonance absorption in aromatic crystals under irradiation is due to the triplet state. Thus, the scheme for electron transfer via the triplet state is an attractive one.

Summary

The spectral responses of the photoconductivity of perylene, pyranthrene, violanthrene, anthanthrone, violanthrone and indanthrazine, as well as the optical absorption spectra of these aromatic solids, have been investigated. Associated with the surface-type cells, when the aromatic films are thin enough, the response curves reproduce the absorption spectra. It has been concluded from this that the photoconductivity is the intrinsic property of the compound and that the lowest excited states are responsible for the electrical conduction.

The thresholds for photoconductivity are rather vague. In some cases, however, extra bands are found in the photoconduction spectra outside the main bands. These extra bands locate in the energy regions which correspond to the triplet states of the molecules and are coincident with the thermal energy gaps for the semiconduction.

The cost of this study was defrayed by a grant of the Ministry of Education, to which the authors' thanks are due.

Studies on Solvent Extraction using Radioactive Isotope. X[1]. Solvent Extraction of Zirconium-95 and Niobium-95 with Acetylacetone

By Nobuo SUZUKI and Takashi OMORI

(Received August 15, 1961)

The solvent extraction method has been successfully applied to the separation of zirconium-hafnium[2,3] and niobium-tantalum[4,5]. There have been a few reports on the separation of ^{95}Zr (^{95}Nb) from other fission products[6-8]. The present authors have previously reported that ^{144}Ce is nearly perfectly extracted with acetylacetone and that the extraction of ^{95}Zr (^{95}Nb) with the same reagent is possible. According to the literature, the percentage extraction of zirconium from aqueous phases of pH values ranging from 0.9 to 2.3 are 10~70, but the details are inaccessible[9]. Moreover, no study on niobium exists in the literature. In the present wark the extraction behaviors of zirconium and niobium are investigated, and the results of the extraction separation of ^{95}Zr and ^{95}Nb from each other are presented.

Experimental

Reagents.—*Stock Solutions of ^{95}Zr and ^{95}Nb.*—^{95}Zr and ^{95}Nb were separated, by means of the ordinary anion exchange separation procedure[10], from ^{95}Zr-^{95}Nb equilibrium mixture imported from the Oak Ridge National Lab., U. S. A., by an ion-exchange resin Dowex 2-X8 using a 0.1 M hydrochloric acid-0.01 M oxalic acid mixture as an eluant. The respective effluents were evaporated to fumes with sulfuric and nitric acids to give stock solutions. The acidity of the stock solutions was 9 N for ^{95}Zr and concentrated sulfuric acid for ^{95}Nb. As for ^{95}Zr, a solution less than 2 days old was used to eliminate the error due to the contamination of the ^{95}Nb daughter growth. The stock solutions prepared by potassium hydrogen sulfate fusion gave nearly the same results, but the results of ^{95}Nb were slightly less reproducible. For this paper, therefore, the stock solution prepared by the acid treatment was used.

Acetylacetone.—A commercial reagent was further purified by washing with ammonia water (1 : 10) and was distilled twice. The distillation fraction of 138°C was used.

Organic Solvents.—E. P. grade greagents were distilled twice.

Other Chemicals.—Guaranteed grade chemicals were used without further purification.

General procedure.—An acetate buffer solution containing ^{95}Zr and ^{95}Nb was shaken with an acetylacetone-chlorofrom mixture in a vessel for a suitable period. ^{95}Zr or ^{95}Nb was added just before shaking. The pH of the aqueous phase was adjusted with dilute nitric acid or sodium hydroxide, the ionic strength being kept at 0.6 with component salts. After separation of the layers, the radioactivity was measured* with a well-type scintillation counter made by the Kobe Kogyo Co., and the pH value was measured with a M-3 type glass-electrode pH meter made by the Horiba Instrument Co.

Concentration Effect of Acetylacetone.—To examine the effect of the concentration of acetylacetone, the extractions were carried out with acetylacetone-chloroform mixtures of various concentrations, the volume percentages of acetylacetone being 5, 10, 20, 30, 40, 50 and 100. To obtain the data for ^{95}Zr, the aqueous phase of pH 4.9 was shaken for two minutes. As is shown in Fig. 1, the extraction ratio is nearly constant above ca. 10% of acetylacetone in chloroform, but it drops in the case of pure acetylacetone. The lowering of the extractability in the case of pure acetylacetone

* A correction for the difference in the counting efficiency between the two phases was made by multiplying the counting rate of counting rate of the organic phase by the factor 1.027.

is presumed to be due to the decrease in the partition of the chelated compounds between the two phases. Based on these results, a 20% acetylacetone solution was chosen for further experiments.

Effect of Shaking Time.—The effect of the shaking time on the extraction of ^{95}Zr and ^{95}Nb using a 20 per cent acetylacetone solution was studied. The results are shown in Fig. 2,

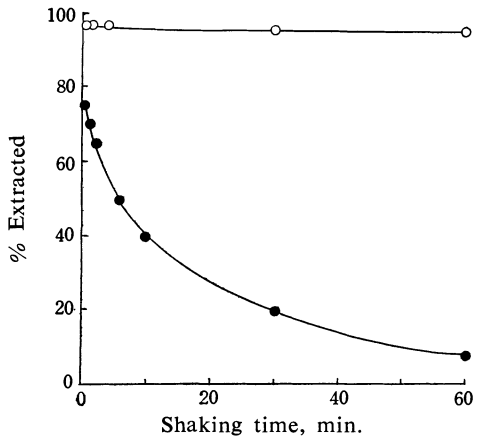

Fig. 2. Extraction of ^{95}Zr and ^{95}Nb with 20% acetylacetone in chloroform as function of shaking time.
-○- ^{95}Zr at pH 5.6
-●- ^{95}Nb at pH 5.7

where no perceptible change in the extraction ratio of ^{95}Zr is seen by the extension of the shaking time up to an hour. On contrary, the the extraction ratio of ^{95}Nb from the aqueous phase having the same pH value of 5.7 decreases remarkably with the length of the shaking time. The lowering of the extractability of ^{95}Nb can be accounted for by hydrolysis, as will be seen in the results of an extraction curve given later. The lowering of the pH value will prevent the hydrolysis, and, in fact, the effect of the shaking time was not appreciable when the pH value was reduced to 3. Based on these results, the shaking time was chosen to be two minutes for ^{95}Zr and one minute for ^{95}Nb for further studies.

Extraction Curve.—To examine the relation between the pH value of the agueous phase and the extractability of ^{95}Zr and ^{95}Nb, extraction with 20% acetylacetone in chloroform was carried out. The extraction curves are shown in Fig. 3, where it is .seen that 98% of the ^{95}Zr was extracted at a pH range of from 3 to 8, and 92% of ^{95}Nb was extracted at a pH range of from 2 to 5 by a single extraction. Thus, the optimum pH range for ^{95}Nb is slightly narrower than that for ^{95}Zr because of hydrolysis. It is doubtful, however,

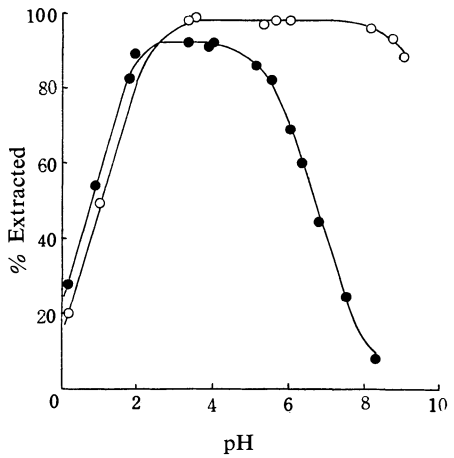

Fig. 3. Extraction of ^{95}Zr and ^{95}Nb with 20% acetylacetone in chloroform as function of pH.
-○- ^{95}Zr -●- ^{95}Nb

that these extraction curves represent the true equilibrium state over the entire pH range examined; the pH range is at least partially in such an unstable condition that hydrolysis is probably occuring.

Extraction by Various Solvents. — Acetylacetone can be used both as a solvent and as an extractant, and in a number of cases various organic solvents are used as a diluent. For example, carbon tetrachloride[1], chloroform[9], and benzene[11-13] were used as a diluent. In the preceding chapter it was reported that an acetylacetone-chloroform mixture showed a higher extractability than pure acetylacetone. The results of the extractions using 20 vol.% solutions of acetylacetone in various solvents are shown in Table I, were the pH values

after the extraction covered the range from 5.7 to 5.8 for ^{95}Zr and from 4.2 to 4.3 for ^{95}Nb. Chloroform showed the highest extractability for both ^{95}Zr and ^{95}Nb, and methylene chloride came next.

Effect of Coexisting Salts.—The coexisting salts show a considerable influence upon the extraction of ^{95}Zr and ^{95}Nb. The results in the presence of a substance such as sodium chloride, sodium nitrate, ammonium sulfate, sodium hydrogenphosphate, potassium thiocyanate, sodium acetate, hydrogen peroxide, hydroxylamine, oxalic acid, citric acid and disodium ethylenediaminetetraacetate (EDTA) are shown in Table II, where the concentrations in the

table denote those of the substances present in the aqueous phase. No effect was observed when the concentration of sodium acetate used as a buffer component was raised to 0.75 M. The extractions of both ^{95}Zr and ^{95}Nb were remarkably interfered with sodium hydrogenphosphate, oxalic and citric acids. In general, ^{95}Nb is more sensitive to the interference from coexisting salts. The use of hydrogen peroxide or hydroxylamine as a masking agent has been found in the literature[6,8]. As is seen in the present results, the extraction ratio of ^{95}Zr was reduced only slightly in the presence of

Table III. Effect of hydrogen peroxide

hydrogen peroxide, whereas ^{95}Nb was perfectly masked by it. In Table III, the extraction ratios obtained in the presence of hydrogen peroxide in various concentrations at pH 5 are given. ^{95}Nb is not extracted under coexistence with hydrogen peroxide, while the extraction ratio of ^{95}Zr increases with the decreasing concentration of hydrogen peroxide. ^{95}Zr could be extracted as high as 98% by successive extraction from the aqueous phase containing a considerable amount of hydrogen peroxide, but it is not practical to extract ^{95}Nb from the residual aqueous layer because 2% of the ^{95}Zr is still left in the aqueous layer.

Back Extraction.—The following experiments were carried out to find the optimum condition for the back extraction of ^{95}Zr and ^{95}Nb from the solvent phase. A 20% acetylacetone-chloroform solution containing ^{95}Zr or ^{95}Nb-acetylacetonate complex was prepared by the standard method, and an aliquot of this solution was shaken with various concentrations of nitric, hydrochloric, and sulfuric acids and hydrogen peroxide solution. The results are shown in Table IV. Sulfuric acid was most effective for the back extraction, both ^{95}Zr and ^{95}Nb being nearly perfectly stripped into the aqueous phase. Nitric and hydrochloric acids were not so effective. ^{95}Nb was more easily

* pH 4.9 acetate buffer

stripped than ^{95}Zr in the pesence of hydrogn peroxide. However, the back extraction ratio of ^{95}Nb was still as high as 66.5% after being shaken for ten minutes. This fact shows that the acetylacetonate complex formed is rather stable.

Mutual Separation of ^{95}Zr and ^{95}Nb.—The experimental results mentioned above suggest two methods for the separation of ^{95}Zr and ^{95}Nb from each other, one being based on the different behavior of ^{95}Zr and ^{95}Nb at a suitable pH value, and the other on the masking of ^{95}Nb with hydrogen peroxide. In the former method, the intention is to make use of the facts that at a high pH value ^{95}Nb is not extracted and that an extension of the shaking time diminishes its extraction ratio. It was not practical, however, to separate ^{95}Zr perfectly by this method, because a small percentage of ^{95}Nb is always accompanied with ^{95}Zr.

Practically, pure ^{95}Zr, free from ^{95}Nb, can be prepared by the latter method. An oxalic acid solution of ^{95}Zr-^{95}Nb was treated with sulfuric and nitric acids, or by potassium hydrogensulfate fusion. The pH value was adjusted to about 5, and hydrogen peroxide was added until the concentration come to 0.2%. Then the solution was repeatedly shaken with a 20% acetylacetone-chloroform mixture. After washing the organic phase with a dilute hydrogen peroxide solution, the aqueous phase was discarded and the organic phase was shaken with 9 N sulfuric acid for ten minutes to strip ^{95}Zr. The acid solution was then washed with chloroform to remove the acetylacetone. The yield was about 96%. The ^{95}Zr obtained was proved to be radiochemically pure by taking a β-ray absorption curve, which showed normal chemical behavior.

Summary

The extraction of ^{95}Zr and ^{95}Nb with an acetylaceton-echloroform mixture was investigated. The percentage extraction of ^{95}Zr with a 20% acetylacetone solution was 98% at pH valves ranging from 3 to 8, and that of ^{95}Nb was 90% at pH values from 2 to 5. The extraction ratio of ^{95}Nb was lowered by the extension of the shaking time. As an diluent, chloroform and methylene chloride were recommended. Phosphate, oxalic acid, citric acid and EDTA interfered remarkably. Sulfuric acid was most efficient for the back extraction. A high purity of ^{95}Zr was obtained by using hydrogen peroxide as a masking agent. The yield was satisfactorily high.

*The Effect of Dissolved Paramagnetic Ion on the ESR Spectra of Diphenyl Nitric Oxide**

By Yasuo DEGUCHI**

(Received August 16, 1961)

In the preceding two papers[1,2], the author has reported on the study of the ESR spectra of diphenyl nitric oxide (DPNO) in crystalline states and in liquid solutions respectively.

During the course of the study, we noticed that dissolved oxygen[3] in solvents played a remarkable negative role in diminishing the proton hyperfine lines.

As will be shown in the succeeding section, the effect on the proton hyperfine lines of the presence of dissolved oxygen or other paramagnetic ions in solutions is to be explained not by chemical reaction but by magnetic dipole-dipole interaction.

3) Y. Deguchi, *J. Chem. Phys.*, **32**, 1584 (1960).

The same effect has already been recognized in the NMR experiments[4,5].

Experimental

All samples have been prepared by the same process as described in the preceding paper[3]. In order to investigate the dissolved oxygen effect, a valve with a tapered ground connector has been attached at one end of a sample tube connected to the vacuum line so that one can introduce air into the sample tube and remove air from it.

For the experiment of the foreign paramagnetic ion effect, a graduated cylinder containing a known volume of it with a certain concentration has been connected to the sample tube so that one can add each known amount of foreign paramagnetic ion to the sample successively. Here we used copper tetraphenyl porphyrin (CuTPP) as the foreign paramagnetic ion.

Results

With Dissolved Oxygen.—Figure 1 shows the effect of dissolved oxygen in solution on the ESR spectra of DPNO. Figure 1a is the spectrum of the degassed sample treated as in reference[3]. We can see the well-resolved proton hyperfine spectra in it. Figure 1b is the spectrum taken after opening the vacuum valve to introduce air into the sample tube. The proton hyperfine lines are all broadened, and only the nitrogen hyperfine lines remain. Again outgassing the sample, one can obtain the same well-resolved proton hyperfine lines in Fig. 1c as in Fig. 1a,

With Copper Tetraphenyl Porphyrin (CuTPP).—In the case of oxygen, it is difficult to control the concentration of oxygen in solution. Therefore, we here employed CuTPP as a foreign paramagnetic ion dissolved in solution.

Figure 2a is the spectrum of the degassed DPNO solution where no foreign paramagnetic ion coexists.

By the addition of 2/11 mg. of CuTPP to the solution, almost all the weak proton hyperfine lines disappear, as in Fig. 2b. Then by dissolving each known amount of CuTPP into the solution successively, as shown in Figs. 2c, 2d and 2e, the proton hyperfine lines become broader and broader until only the broad nitrogen splitting lines can be observed and all the proton hyperfine lines disappear.

Discussion

From the aforementioned experiments, we can conclude that this effect is caused by the magnetic dipole-dipole interaction of DPNO with dissolved oxygen or paramagnetic ions in the solutions.

By this interaction, the spin-lattice relaxation time (T_1) of DPNO will become shorter than when no dissolved paramagnetic ion is present in the solution. Thus, we can follow the theory of Bloembergen, Purcell and Pound[5] (BPP). In their case, the spin orientation of protons is relaxed by the dissolved paramagnetic ions, but in the present case the spin orientation of the unpaired electrons of the free radical will be relaxed by the dissolved paramagnetic ions.

Thus, instead of Eq. 54 in BPP's paper, we will obtain:

$$1/T_1 = 12\pi^2\gamma_e^2\eta N_{\text{ion}}\mu_{\text{eff}}^2/5kT$$

where

γ_e: the gyromagnetic ratio of an electron,
η: the viscosity of the solvent at the temperature T°K,
N_{ion}: the number of dissolved paramagnetic ions per cm^3,
μ_{eff}: the magnetic moment of the dissolved paramagnetic ion in the Bohr magneton number,
k: the Boltzmann constant,
T: the absolute temperature of the experiment.

In the case of dissolved oxygen, knowing that the solubility of oxygen, into ethyl alcohol is

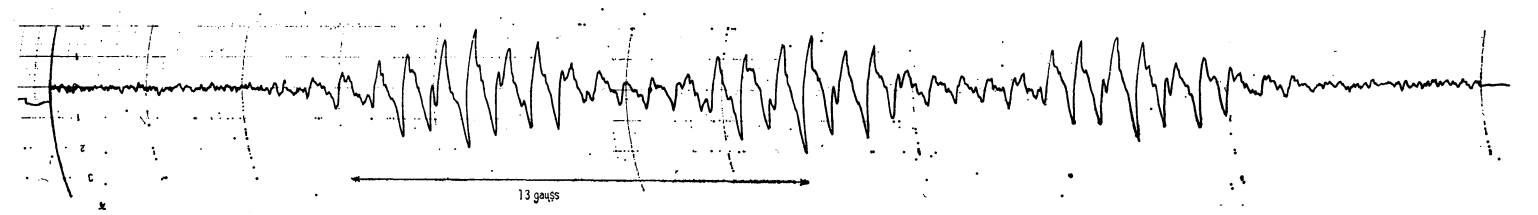
$$143\times10^{-3}\text{ cc. per 1 cc. of ethyl alcohol,}$$

we know that the N_{ion} for this case will be

$$3.844\times10^{18}\text{ cm}^{-3}$$

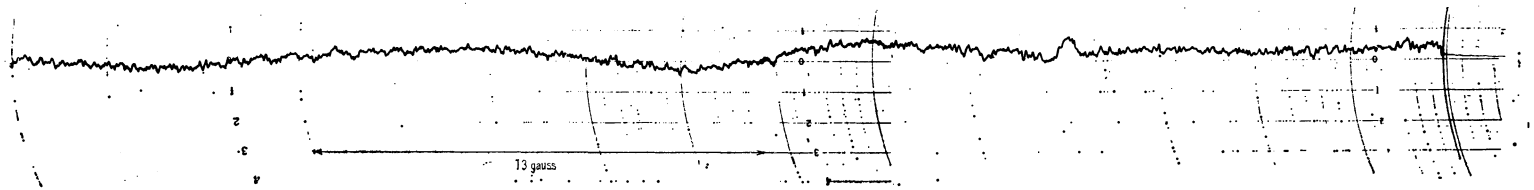
Also the η for ethyl alcohol at 20°C is 1.20×10^{-2} poise, and the μ_{eff} for oxygen in the Bohr magneton number is 2.83.

Then we shall have



$$1/T_1 = 0.327\text{ gauss}$$

Thus, it turns out that each proton hyperfine line of DPNO in degassed solutions will be broadened further by the amount of 0.327 gauss because of the presence of the dissolved oxygen. As stated, in the preceding papers[2,3], the separation between two successive proton hyperfine lines is about 0.98 gauss, and the half-widths of the sharpest lines in each group of the spectrum are of the order of 0.1 gauss. Thus, not every hyperfine lines will be reserved, and only the broad nitrogen hyperfine lines will be observed.



In the same way, foreign paramagnetic ion effect on the proton hyperfine lines can be explained. These results are tabulated in Table I.

There are other spin-lattice relaxation mechanisms such as the exchange interaction[6], the

6/11	0.632×10^{18}	0.165	0.265	Main hf. lines remain but are more broader.
10/11	1.054×10^{18}	0.274	0.374	Only 2 or 3 broad hf. lines remain but broad nitrogen hf. lines can be clearly observed.
52/22	1.097×10^{18}	0.286	0.386	All proton hf. lines disappear and only nitrogen hf. lines are left.

spin-orbit interaction[7], etc. but in the case of organic free radicals one can neglect these interactions.

From the above discussion, then, one can conclude that dissolved oxygen or other paramagnetic ions in the solutions play an important role in the broadening of the proton hyperfine lines in the ESR spectra of organic free radicals through the spin-lattice relaxation.

Summary

The broadening effect of dissolved oxygen and foreign paramagnetic ions on the ESR spectra of the DPNO solution has been discussed. Using the BPP theory, it is explained that this effect is mainly caused by the magnetic dipole-dipole interaction of an electron with with a proton nuclear spin.

The author wishes to express his appreciation and indebtedness to Professor S. I. Weissman for his helpful discussion and suggestion and to Professor J. Townsend for offering him the chance to use the ESR apparatus which he had constructed. He also wishes to thank Professor K. Tomita and Dr. T. Hashi for their helpful discussions.

Inductive Effects in Some Chlorinated Carbonyl Compounds and their Nuclear Quadrupole Resonance Frequencies

By Shinhachiro SAITO*

(Received March 28, 1961)

It is well known that the chlorine nuclear quadrupole resonance (NQR) frequency increases with the increasing number of chlorine atoms attached to the same carbon atom, and that the frequency increase depends upon the electronic state of the molecule containing the chlorine atom. In the study of the NQR spectra of molecular crystals, Allen[1] suggested that the electron withdrawal abilities of carbonyl groups from the $-CH_2Cl$ and $-CCl_3$

* Present address: The Research Institute for Iron, Steel and Other Metals, Tohoku Uuiversity, Sendai.

1) H. C. Allen, Jr., *J. Am. Chem. Soc.*, **74**, 6074 (1952); *J. Phys. Chem.*, **57**, 501 (1953).

groups are different depending on the type of carbonyl group, and that it is useful to compare the quadrupole coupling constants with the shifts in the carbonyl frequencies in the infrared spectra of these compounds. This discussion has hitherto, however, been only qualitative because C=O stretching frequencies had been measured only for mono-chlorinated carbonyl compounds.

In this paper, the relationships between the nuclear quadrupole coupling constant and the C=O stretching frequency in the infrared spectra are investigated for chlorinated acetylchlorides, chlorinated acetic acids, and chlorinated acetamides.

Experimental

A Perkin-Elmer 112 spectrometer with a calcium fluride prism mounted was used to study the C=O stretching bands. Mono-, di- and tri-chloroacetylchloride and mono-, di- and tri-chloroacetic acids were purchased from Tokyo Kasei Kogyo Co., Ltd. and purified by fractionating prior to measurement. The measurement of the 0.1 mol./l. carbon tetrachloride solutions was done at room temperature.

Results and Discussion

The experimental results are listed in Table I, together with the NQR frequencies observed by Allen[1], Bray[2], and McCall and Gutowsky[3]. They show that the C=O stretching frequencies increase with the increase in NQR frequencies, which is accompanied by the progressive introduction of chlorine atoms into the methyl group, though the process is not so obvious for the acetylchlorides. Therefore, let us consider this fact from the viewpoint of the molecular orbital theory.

For a molecule in which the hydrogen atoms of a methyl group adjacent to a π-electron conjugated system are successively replaced by chlorine atoms (Fig. 1), we shall represent a one-electron molecular π orbital Ψ_i as a linear combination of atomic π orbitals in this conjugated system as follows:

$$\Psi_i = \sum_r C_{ri}\phi_r$$

where r is taken over all the atoms with $2p\pi$ or $3p\pi$ electrons in this system. In order to calculate the secular equation, the values for the Coulomb integrals, $\alpha_r = \int \phi_r H \phi_r d\tau$, the resonance integrals, $\beta_{st} = \int \phi_s H \phi_t d\tau$, and the overlap integrals, $S_{st} = \int \phi_s \phi_t d\tau$, are required. From the calculation of the secular equation, we obtain the bond-atom polarizability (denoted by $\pi_{st,r}$). It has been shown by Coulson and Longuet-Higgins[4] that when the Coulomb integral α_r of the r atom in the conjugated system is slightly changed, the π bond-order (P_{st}) in the s−t bond is also changed, and that the change of the π bond-order is represented by the bond-atom polarizability $\pi_{st,r} = (\partial P_{st}/\partial \alpha_r)$ as follows:

$$\delta P_{st} = (\partial P_{st}/\partial \alpha_r)\delta \alpha_r \qquad (1)$$

When the hydrogen atoms in the methyl group are progressively replaced by chlorine atoms, the ionic characters of the C–Cl bonds decrease in the sequence $-CH_2Cl > -CHCl_2 > -CCl_3$. Livingston[5] has shown this to be true in the case of chloromethanes and chloroethanes. The same may be true for a chlorinated methyl group adjacent to a conjugated system. The NQR frequencies of some compounds with such

*** See Refs. 1, 2 and 3.

chlorinated methyl groups are plotted in Fig. 3, together with those (the dotted line in Fig. 3) of chloromethanes for comparison. In this figure, it can be seen that the frequency changes of these conjugated compounds are similar to those of chloromethanes[5]. In the conjugated compounds shown in Table I and Fig. 3, the ionic character of the C–Cl bond in dichloroderivatives is smaller than that of a C–Cl bond in monochloroderivatives. According to Townes and Dailey's rule[6], however, the amount of the ionic character of the C–Cl bond in dichloroderivatives is larger than one-half of that in monochloroderivatives. Similarly, the amount of the ionic character of the C–Cl bond in trichloroderivatives is larger than two-thirds of that in dichloroderivatives. From these considerations, it is supposed that the positive formal charge of the carbon atom in the chlorinated methyl group becomes larger in the order, $-CH_2Cl < -CHCl_2 < -CCl_3$. The increase in the positive formal charge of this carbon atom may be responsible for the inductive effect in the C–C′ bond connecting the methyl group and the conjugated system (see Fig. 2). This effect may increase also in the order of mono-, di- and tri-chloroderivatives. This effect will result in a slight increase in the electronegativity of the C′ atom adjacent to the methyl group, and in the electron withdrawal by the C′ atom from the other atom in the conjugated system. Therefore, the absolute value of the Coulomb integral of the C′ atom may be expected to increase slightly in the order of $-CH_2Cl$, $-CHCl_2$ and $-CCl_3$. On the other hand, it is well known that the C=O stretching vibration is one of the characteristic vibrations which are scarcely perturbed by the coupling with other parts of the molecule. Therefore, the frequency change originates mainly from the change in the force constant, which may be associated with the change in the bond order δP_{st} in the present case. In the C=O bond, however, both π and σ bonds contribute to the force constant. If the influence of the inductive effect due to the introduction of chlorine atoms into the methyl group is much smaller in the σ bond than in the π bond, the $\delta P_{c=o}$ given by Eq. 1 would be connected to the displacements of the C=O stretching frequencies*. Consequently, the NQR frequencies and the C=O stretching frequencies can be correlated through the Coulomb integral of the C′ atom.

For the practical investigation of this correlation by using Eq. 1, it is necessary to evaluate

6) C. H. Townes and B. P. Dailey, *J. Chem. Phys.*, **17**, 782 (1949); ibid., **23**, 118 (1955).

* For Eq. 1, a more discreet expression would require the total differential form:

$$\delta P_{c=o}=\frac{\partial P_{c=o}}{\partial \alpha_c}\delta\alpha_c+\frac{\partial P_{c=o}}{\partial \alpha_o}\delta\alpha_o+\frac{\partial P_{c=o}}{\partial \alpha_R}\delta\alpha_R \quad (1')$$

where R is Cl, (OH) and (NH_2). What we are estimating, however, are the relative differences among the $\delta P_{c=o}$'s of the three groups of chloroderivatives. Therefore, we consider that the first term in the right-hand side of Eq. 1′, which is directly affected by the introduction of chlorine atoms into the methyl group, is most important and that the last two terms are less important.

the bond-atom polarizabilities. Such evaluations are, however, beset by the difficulty of estimating suitable parameters for the hetero atoms. Nevertheless, in order to make a rough guess as to what might be observed, a computation was made for the three derivatives which are shown in Fig. 2. For the Coulomb integrals of the hetero atoms, Coulson's prescription[7]

$$\alpha_r - \alpha_c = (X_r - X_c)\beta_{cc}$$

was used, where X_r, X_c are the electronegativities of the r atom and the C atom respectively. For the resonance integrals between the s atom and the t atom, Wheland's expression[8]

$$\beta_{st} = (S_{st}/S_{cc})\beta_{cc}$$

was adopted. In the above expression, α_c, β_{cc} and S_{cc} were taken to be equal to the corresponding values for benzene. Electronegativity values were used for various atoms where $X_c = 2.5$, $X_o = 3.5$ and $X_{Cl} = 3.0$. The conception of group electronegativity[9] was introduced for the (OH) and (NH_2) groups, and the values 3.72 and 3.36 were used for the two groups. In order to evalute the magnitude of β_{st}, the overlap integrals were calculated by interpolation from the published table[10], using the electron diffraction values of 1.77 Å for the C–Cl bond[11], 1.22 Å for the C=O bond of acetylchlorides[11] or acetamides[12], 1.24 Å for the C=O bond of acetic acids, 1.43 Å for the C–O bond[13], and 1.36 Å for the C–N bond[12]. The order of the obtained bond-atom polarizabilities for the three derivatives is:

$$\left(\frac{\partial P_{c=o}}{\partial \alpha_c}\right)_{O=C-Cl} < \left(\frac{\partial P_{c=o}}{\partial \alpha_c}\right)_{O=C-NH_2} < \left(\frac{\partial P_{c=o}}{\partial \alpha_c}\right)_{O=C-OH} \quad (2)$$

Now for hypothetical equal changes of α_c in the three chloroderivatives, the incured displacements of the C=O frequencies for chlorinated acetic acids or chlorinated acetamides should be larger than that for chlorinated acetylchlorids. Moreover, it is seen in Table I that the rise in the NQR frequencies due to the progressive introduction of chlorine atoms into the methyl group is larger in chlorinated acetic acids or chlorinated acetamides than in chlorinated acetylchlorides. As has been explained above, these changes in the NQR frequencies indicate that the changes of the inductive effect for the former are larger than that for the latter. Therefore, the $\delta\alpha_c$ for chlorinated acetylchlorides, which rise in the sequence mono- to tri-chloroderivatives, is smaller than that for chlorinated acetic acids or chlorinated acetamides. Consequently, the shifts of the C=O frequencies can be expected to be larger for chlorinated acetic acids or chlorinated acetamides than for chlorinated acetylchlorides, as witnessed by the observed C=O frequencies listed in Table I. Although the comparison of these C=O frequencies is beset by splittings of these absorption bands resulting from rotational isomerism or other interplay of several factors[14], close investigation of the relation between wave numbers and the intensities of these bands undoubtedly shows that the increase in wave numbers from mono- to tri-chloroacetic acid (or from mono- to tri-chloroacetamide) is larger than that from mono- to tri-chloroacetylchloride.

For the series of chloroacetamides and chloroacetic acids, the bond-atom polarizability of the former is smaller than that of the latter, as is shown in Eq. 2. On the other hand, on can see in Table I and Fig. 3 that the changes in the NQR frequencies for the former are larger than that for the latter; namely, $\delta\alpha_{c(O=C-NH_2)} > \delta\alpha_{c(O=C-OH)}$ is supposed. The obstruction comes in the estimation of the relative difference of the $\delta P_{c=o}$'s by the product of $\delta\alpha_c$ and $(\partial P_{c=o}/\partial\alpha_c)$, viz. Eq. 1. In the experimental data shown in Table I, the changes in C=O frequencies for the former are slightly larger than that for the latter. It seems that the second term in Eq. 1′ (see footnote p. 604) can fairly easily be altered to $\delta P_{c=o}$, because of the large resonance integral for C–N bond. (β_{C-N} is 0.82 β_{cc}, while β_{C-Cl} and β_{C-OH} are equal to 0.56~0.57 β_{cc}).

The author wishes to express his thanks to Professor Kunio Kozima of Tokyo Institute of Tecknology for his kind guidance. He is also grateful to Dr. Tunéo Yosino of Toyo Rayon Co., Ltd. and Professor Siro Maéda of the Defense Academy for their helpful discussions.

Colloid Chemical Studies on Starching Materials. IV. Viscoelasticity and Structure Change of Starch Solutions

By Masayuki NAKAGAKI

(Received August 21, 1961)

Structural viscosity, that is, the apparent viscosity decreasing with an increasing velocity gradient, is due to the dispersion of highly associated colloidal particles or polymer molecules into smaller aggregates by the effect of the velocity gradient[1]. A structure change like this should obviously affect the dynamic viscosity and the dynamic rigidity of high polymer solutions. The viscoelastic properties of high polymer solutions have been discussed by Rouse[2]. Rouse's theory is satisfactory to the extent that the theory gives the value (−1/2) to the gradient of the relaxation spectra of high polymer solutions[3], but the actual behavior of high polymer solutions is much more complicated than the theory expects. Moreover, Rouse's theory cannot predict the existence of structural viscosity because the theory does not take into account any structure change in the solution.

In the preceding paper of this series[4], experimental data of dynamic viscosity and dynamic rigidity, obtained by using a top-drive coaxial rheometer, have been reported for 3 and 5% potato starch, 5% sweet potato starch and 5% rice starch solutions. Examination of the data, too, has been made on the basis of the modified Rouse equations:

$$\eta=\eta_0 f_1(\tau\omega) \tag{1}$$

$$G=G_0+(6/\pi^2)(\eta_0/\tau)f_2(\tau\omega) \tag{2}$$

where

$$\left.\begin{aligned} f_1&=(6/\pi^2)\sum_{p=1}^{N}[p^2/(p^4+\tau^2\omega^2)] \\ f_2&=\sum_{p=1}^{N}[\tau^2\omega^2/(p^4+\tau^2\omega^2)] \end{aligned}\right\} \tag{3}$$

Here, η is the dynamic viscosity, G is the dynamic rigidity, ω is the angular frequency, p is an integer, and η_0, G_0 and τ are constants. It has been suggested, in the same paper, that the experimental data can be explained satisfactorily if one assumes that there are in the starch solutions large aggregates of polymer molecules with large values of η_0 and G_0 when the frequency is small and that the aggregates change to smaller ones of smaller η_0 and G_0 with the increase of the frequency. In the present paper, the idea described in the preceding paper has been formulated and applied to the experimental data.

Theoretical

According to Rouse's theory, the parameters η_0 and τ in Eqs. 1 and 2 depend on the number N of segments (submolecules) contained in a high polymer molecule as follows:

$$\left.\begin{aligned} \eta_0&=(\pi^2/6)n\boldsymbol{k}T\tau \\ \tau&=\sigma^2N^2/6\pi^2\boldsymbol{B}\boldsymbol{k}T \end{aligned}\right\} \tag{4}$$

where n is the number of molecules in a unit volume of the solution, τ is the longest relaxation time of the polymer molecule (τ_1 in Rouse's original paper), σ is the length of the segment, and B is the mobility of the end of a segment. Therefore, by introducing three parameters α, β and F, defined by:

$$\left.\begin{aligned} \alpha(\tau\omega)&=(2\sqrt{2}/\pi)\sqrt{\tau\omega}\times\sum_{p=1}^{\infty}[p^2/(p^4+\tau^2\omega^2)] \\ \beta(\tau\omega)&=[(2\sqrt{2}/\pi)/\sqrt{\tau\omega}]\times\sum_{p=1}^{\infty}[\tau^2\omega^2/(p^4+\tau^2\omega^2)] \end{aligned}\right\} \tag{5}$$

and

$$F=nN\sigma\sqrt{\boldsymbol{k}T}/4\sqrt{3}\sqrt{B} \tag{6}$$

the modified Rouse equations 1 and 2 can be rewritten into the following equations:

$$\left.\begin{aligned} \eta&=(F/\sqrt{\omega})\alpha(\tau\omega) \\ G&=G_0+F\sqrt{\omega}\beta(\tau\omega) \end{aligned}\right\} \tag{7}$$

The points to be emphasized here are as follows: First, the parameter F is proportional to nN, that is, the total number of segments in a unit volume of the solution, or to the weight concentration, irrespective of the degree of molecular association. Second, the parameters α and β are functions of $(\tau\omega)$ only and have the values cited in Table I. Both α and β approach zero when $(\tau\omega)$ is small and

Table I. Theoretical values of α and β

$\tau\omega$	α	β	$\tau\omega$	α	β
0.0001	0.01480	0	0.5	0.9165	0.2807
0.0002	0.02093	0	1	1.0000	0.5211
0.0005	0.03310	0.00001	2	1.0000	0.6855
0.001	0.04682	0.00003	5	1.0000	0.7986
0.002	0.06620	0.00009	10	1.0000	0.8577
0.005	0.1047	0.00034	20	1.0000	0.8993
0.01	0.1480	0.00097	50	1.0000	0.9362
0.02	0.2093	0.00275	100	1.0000	0.9550
0.05	0.3310	0.01085	200	1.0000	0.9681
0.1	0.4649	0.03055	500	1.0000	0.9799
0.2	0.6459	0.08386	1000	1.0000	0.9858

approach unity when $(\tau\omega)$ is large. However, the manners of approach of α and β to these limiting values are widely different. Under a 1% allowance, α is equal to zero when $(\tau\omega)$ is smaller than 0.0001, but β is already zero when $(\tau\omega)$ is smaller than 0.05; α is already equal to unity when $(\tau\omega)$ is larger than 1, but β is equal to unity when $(\tau\omega)$ is as large as 1000.

In order to consider a mixture of highly associated molecules of N_1 segments and less associated (or not associated) molecules of N_2 segments ($N_2<N_1$), the dynamic viscosity η and dynamic rigidity G of the mixture may be assumed to be:

$$\left.\begin{aligned}\eta&=(x_1\alpha_1+x_2\alpha_2)F/\sqrt{\omega}\\ G&=x_1G_0+(x_1\beta_1+x_2\beta_2)F\sqrt{\omega}\end{aligned}\right\} \quad (9)$$

where x_1 and x_2 are the weight fractions of respective components ($x_2=1-x_1$). α_1 and β_1 are the values of α and β for $(\tau_1\omega)$, and α_2 and β_2 are the values for $(\tau_2\omega)$, where the value of τ_1 is much larger than the value of τ_2 because the suffix 1 designates highly associated, and the suffix 2 less associated, molecules. The G_0 values of the less associated molecules are assumed to be zero.

In order to apply Eq. 9 to experimental values of η and G and to obtain an experimental $x_1-\omega$ relationship, the values of the four parameters F, G_0, τ_1 and τ_2 should be estimated. The choice of the four parameter values is not as arbitrary as it looks, because of the character of the ω dependency of the functions α and β, especially because α_1 should be equal to unity except when ω is very small, and β_2 should be equal to zero except when ω is very large. As a result, the relative value of x_1 (calculated by assuming that the value of x_1 is equal to unity for the smallest ω value used in the experiment) can be obtained without any arbitrariness. The results obtained for starch solutions will be shown later.

By way of application of Eq. 9, it has been recognized that the choice of the values of τ_1 and τ_2 does not affect the final $\log\eta-\log\omega$ relationship and $\log G-\log\omega$ relationship too much. Therefore, an approximate method is also used by assuming $\tau_1\gg1$ and $\tau_2\ll1$, or

$$\alpha_1=1,\quad \beta_1=1,\quad \alpha_2=0,\quad \beta_2=0 \quad (10)$$

In this case, Eq. 9 can be simplified to:

$$\left.\begin{aligned}\eta&=x_1F/\sqrt{\omega}\\ G&=x_1(G_0+F\sqrt{\omega})\end{aligned}\right\} \quad (11)$$

This equation was also applied to starch solutions.

Discussion of Experimental Data

By using either Eq. 9 or 11, the variation of x_1 with the circular frequency ω was calculated for starch solutions, the dynamic viscosity and the dynamic rigidity experimental values of which have been reported in the preceding paper[4]. Results for the 3% potato starch solution are shown in Fig. 1, the 5% potato starch solution in Fig. 2, the 5% sweet potato solution in Fig. 3, and the 5% rice starch solution in Fig. 4. In these figures, the experimental values of $\log\eta$ (○), $\log G$ (●) and x_1 (both values obtained by Eq. 9 (□) and by Eq. 11 (△) are shown) are plotted. The values of the parameters adopted to calculate the values of x_1 are cited in Table II. The values of x_1 thus obtained are linear to $\log\omega$ for potato starch and sweet potato starch solutions, as is

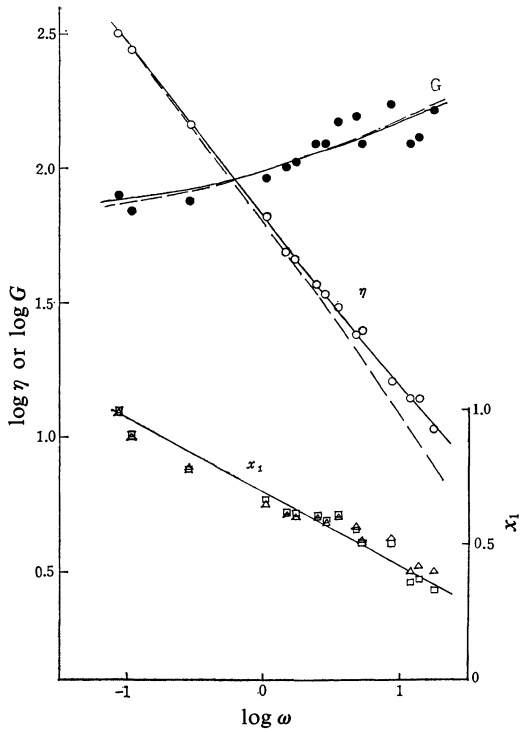

Fig. 1. $\log\eta$ (○), $\log G$ (●), and x_1 by Eq. 9 (□) and Eq. 11 (△) of 3% potato starch solution.

shown by the straight lines in Figs. 1—3. By using x_1 values corresponding to these straight lines, and also by using the parameter values cited in Table II, values of η and G were calculated and shown in these figures by solid lines

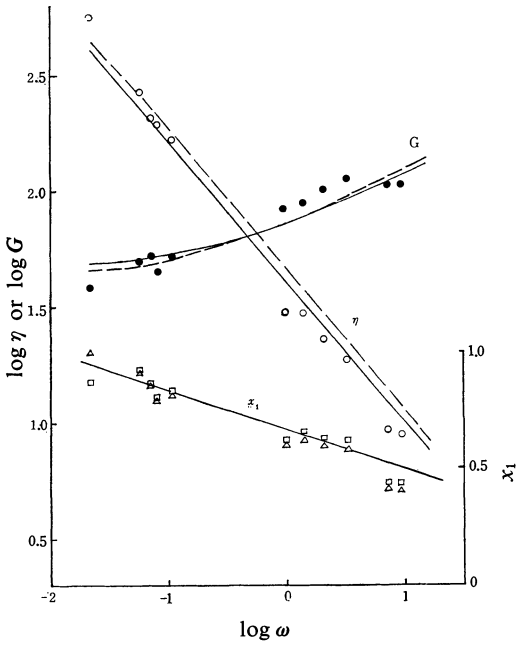

Fig. 2. $\log\eta$ (○), $\log G$ (●), and x_1 by Eq. 9 (□) and Eq. 11 (△) of 5% potato starch solution.

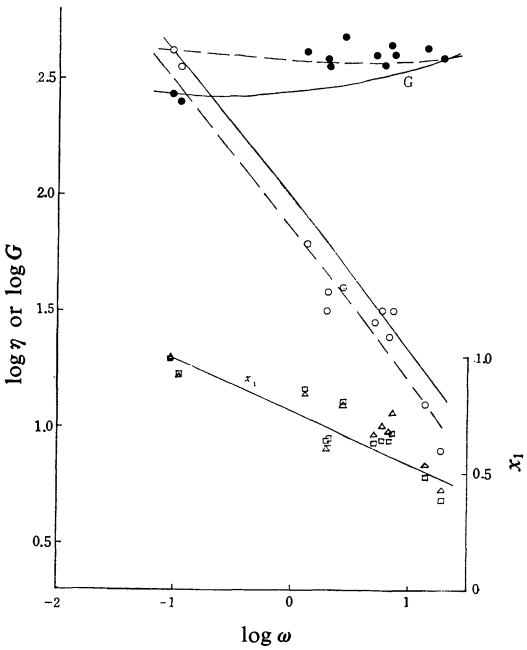

Fig. 3. $\log\eta$ (○), $\log G$ (●), and x_1 by Eq. 9 (□) and Eq. 11 (△) of 5% sweet potato starch solution.

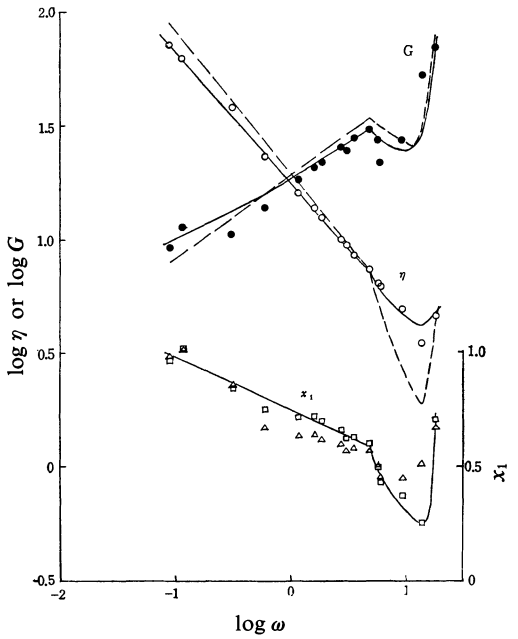

Fig. 4. $\log\eta$ (○), $\log G$ (●), and x_1 by Eq. 9 (□) and Eq. 11 (△) of 5% rice starch solution.

TABLE II. PARAMETERS OF EQS. 9 AND 11 (in c. g. s. units)

Starch	Concn. %	Eq.	F	G_0	τ_1	τ_2
Potato	3	9	93.1	50.9	$\gg 1$	0.0016
		11	99.5	44.1	$\gg 1$	$\ll 1$
Potato	5	9	63.5	47.8	37.2	$\ll 1$
		11	69.7	37.7	$\gg 1$	$\ll 1$
Sweet potato	5	9	127.3	231	$\gg 1$	$\ll 1$
		11	93.4	394	$\gg 1$	$\ll 1$
Rice	5	9	21.3	4.15	190	0.0135
		11	26.6	0	$\gg 1$	$\ll 1$

for Eq. 9 and by broken lines for Eq. 11. Agreements between the experimental plots and the calculated curves are satisfactory for the potato starch solutions (Figs. 1 and 2). In the case of the sweet potato starch solution (Fig. 3), the analysis based on Eq. 9 gave the result that $\tau_1 \gg 1$ and $\tau_2 \ll 1$, so that Eq. 9 turned out to be the same as Eq. 11. The values of the parameter F (and G_0) for Eq. 9 and for Eq. 11 differ because in the case of Eq. 9 the experimental data at about $\log\omega = -1$ were respected highly, while in the case of Eq. 11 they were neglected. It is obvious that a better agreement can be obtained if one adopts for F and G_0 some values between those for Eqs. 9 and 11, if one discards the expectation to the linearity of x_1 to $\log\omega$ and if one adopts more suitable values for x_1 for each $\log\omega$ value. In the case of the rice starch solution (Fig. 4), the value of x_1 decreases linearly as far as

$\log \omega = 0.7$. However, if one attaches importance to the minimum of $\log \eta$ and $\log G$ at about $\log \omega = 1.1$, one should assume a minimum for x_1, too. The rapid increase of x_1 (and consequently of η and G) at high ω values might correspond to the entanglement of rice starch molecules due to mechanical work, a phenomenon familiar to Japanese people in the process of rice-cake making.

Summary

Modified Rouse's equations were applied to solutions consisting of a mixture of highly aggregated and less aggregated polymer molecules. The fraction of higher aggregates, x_1, was calculated for 3 and 5% potato starch solutions, a 5% sweet potato starch solution, and a 5% rice starch solution. The value of x_1 decreased linearly with the increase of $\log \omega$, except for the rice starch. The x_1 value of the latter increased rapidly when the $\log \omega$ became very large.

Solvent Extractive Fractionation of Ziegler Polystyrene

By Akira YAMADA, Yoshio YAMAMURO and Masaya YANAGITA

(Received December 24, 1960)

In the preceding paper[1], one of the authors pointed out the possibility of the extractive fractionation of Alfin Polystyrene with solvents other than acetone[2], ethyl methyl ketone[2,3] and benzene[4]. In the present paper, the authors wish to report that the polystyrene samples polymerized by the Ziegler catalyst were separated into two parts, i. e., crystalline and amorphous, by extractive fractionation with several solvents.

The solvents have been selected on the basis of the results of the solubility-test and the solvent extractive fractionation in the previous work[1]. The densities and the ratios of the intensities of the infrared spectra (D_{984}/D_{1028}) of the extractive residues were measured in order to check the extractive fractional ability; the molecular weights and melting points of the residues were also measured.

One of the authors has reported previously that the infrared intensity (D_{984}) was proportional to the X-ray crystalline content[5]. However, as shown in Fig. 1, the X-ray crystallinity percentage with a vibration of densities between 1.05 to 1.08 did not vary in proportion to the infrared ratio. Accordingly, X-ray diagrams have not been used in the present studies.

The physical properties measured are summarized in Table I.

It is seen that of the densities of the extractive residues resulting from the hot solvent treatment, the lowest is for ethyl methyl ketone. The decreasing order in the case of hot extraction is; tetrahydrofuran, ethyl acetate, dioxane, cyclohexanone and ethyl methyl ketone. In the cold extraction, however, the highest value was obtained by using ethyl methyl ketone, and this was followed by benzene, toluene, ethyl acetate and tetrahydrofuran.

The ratio of the infrared intensities (D_{984}/D_{1028}) is linearly proportional with the density between 1.05 to 1.08, as is shown in Fig. 1. It is considered that these infrared ratios show the difference in crystallinity (or tacticity) of each residue. The decreasing order of the ratio in the hot extraction was as follows: dioxane, tetrahydrofuran, ethyl acetate and cyclohexanone. In the cold extraction, the order was benzene, ethyl methyl ketone, ethyl acetate, toluene, tetrahydrofuran and ether.

The relation of the molecular weight to the fractional weight percentage of residue is shown in Fig. 2.

The dotted line and the curved line (from right to left in Fig. 2) show the over-all process of the extraction. In the initial step, it is observed that the average molecular weight

a) The IR ratio for atactic polystyrene had been presented as 16.

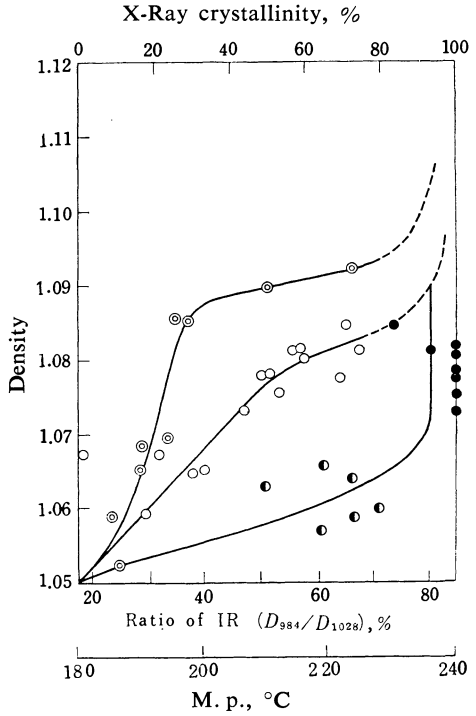

Fig. 1. Relationship between density and X-ray crystallinity, IR ratio and/or melting point.
◎ X-Ray crystallinity previously reported[5].
○ IR ratio in this paper.
● Melting point in this paper.
◐ Melting point of Alfin polystyrene (A. Yamada, *J. Chem. Soc. Japan, Ind. Chem. Sec. (Kogyo Kagaku Zasshi)*, **64**, 2208 (1961).

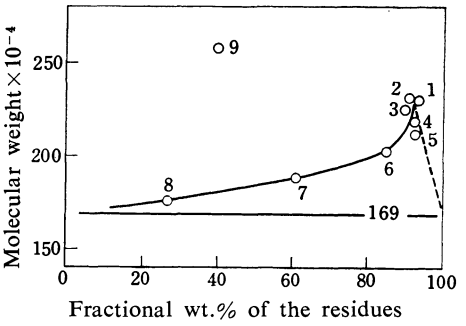

Fig. 2. Relationship between molecular weights and extractive fractional wt. % of residues. Molecular weight of the original sample is 169×10^4. The number in the figure shows hot(h) or cold(c) solvent extraction respectively;

1 c-ether	2 h-ethyl acetate
3 c-toluene	4 c-ethyl methyl ketone
5 c-ethyl acetate	6 h-ethyl methyl ketone
7 h-dioxan	8 h-cyclohexanone
9 c-benzene	

of the residue increases because the lower molecular weight portion was extracted, but thereafter the molecular weight gradually decreases on account of the atactic, higher molecular weight portion that is subsequently extracted. The several extractive types 1 to 6 in Fig. 2 seem to resemble closely those of the hot or cold ethyl methyl ketone extraction. Cold benzene extraction especially, as is seen in Fig. 2, differs from the other in respect to the dependency of the molecular weight on the solvent extractive fractionation.

The residues have a higher melting point, and no information is offered to account for the differences in residues (see Table I).

From the above-described results, it may be considered that the solvent extractive ability in hot extraction decreases in the order: tetrahydrofuran dioxan, ethyl methyl ketone and ethyl acetate. In the cold extraction the

order is: benzene, ethyl methyl ketone, ethyl acetate and toluene. Cold benzene extraction, however, was an exception case.

Experimental

Ziegler Polystyrene. — A four-necked flask with a mechanical stirrer was filled with dried nitrogen. Then 200 ml. of dried isooctane, 13 ml. of titanium tetrachloride and 25 ml. of triethyl aluminum (Al/Ti=3.1) were poured through medical syringes. While the temperature was maintained at 80°C, 500 ml. of freshly distilled styrene monomer diluted with 500 ml. of dried benzene was added dropwise over a six-hour period. After heating the mixture for 18 hr. at 80°C while stirring it, ethanolic hydrogen chloride was poured into the flask at 0°C. The dried crude polymer was obtained in a yield of 88%. The lower molecular weight portion was discarded by hot acetone extraction. After filtration of the small amount of residue, the filtrate was reprecipitated with methanol. The fine polymer was obtained in a yield of 11%.

Treatment with *n*-Heptane[6].—Before extraction, the sample was treated with boiling *n*-heptane for five hours and then cooled gradually to room temperature.

Extraction.—In the hot extraction, a Soxhlet apparatus was used at a temperature several degrees below the boiling point of the solvent. In the cold extraction, a Soxhlet-type apparatus equipped with a drying tower was used at room temperature (15~20°C).

Density. — A floatation method with a sodium chloride aqueous solution was used for the measurement of the density at 25°C. The measurement error is ±0.0005. The sample used was the same as that used for infrared measurement.

Measurement of Infrared Spectra.—Film specimen 0.05 mm. in thickness were prepared by casting on a mercury surface a chloroform solution that had been prepared by heating it in a sealed tube at 100°C. Before the measurement, the films were annealed at 200°C. The infrared spectra were measured in the region of 3500~700 cm^{-1} using a Nippon Bunko DS-201 spectrophotometer.

Molecular Weight. — The molecular weight was determined from viscosity measurements in benzene solution (concentration (C) ; 0.4 g./100 ml.) at 25°C. The molecular weight (M) ; was computed using the two following equations, 1[7] and 2[8]:

$$[\eta]=3(\eta_r^{1/3}-1)/C \quad (1)$$

$$[\eta]=1.06\times10^{-4}M^{0.735} \quad (2)$$

where η_r is the relative viscosity and $[\eta]$ is the intrinsic viscosity.

Melting Point.—Determined as the point of clearance or initial flow using a Shimadzu melting point apparatus.

Materials.—The solvents were purified by the usual methods. The boiling points are shown in parentheses: ethyl methyl ketone (79.6~79.8), cyclohexanone (154.5~156.2), tetrahydrofurane (66), dioxane (100.5~101.2), ethyl acetate (76.9~77.1), ether (34.5), benzene (79.5~79.8) and toluene (110.2~110.5).

Summary

The solvent extractive fractional ability has been described, using Ziegler polystyrene as sample. The order in hot extraction is tetrahydrofuran > dioxane > ethyl methyl ketone ≧ ethyl acetate, while that in cold extraction is benzene ≫ ethyl methyl ketone ≧ ethyl acetate = toluene.

The authors wish to express their sincere thanks to Mr. Toshihide Ishikawa for his help in this experiment and also to Mitsui Chemical Ind. Co. for the supply for triethyl aluminum.

*Vibrational Spectra of Methyl Ether. I. Assignment of the Spectra**

By Yôko KANAZAWA and Kenkichi NUKADA

(Received August 19, 1961)

In a series of aliphatic ethers, methyl ether has significance for the study of molecular spectra in this homologues because of its simplest structure.

A number of investigations on the vibrational spectra of the molecule have been reported. Herzberg[1] gave an assignment of the vibrational bands using the data published previously[2]. By Ryskina[3] and Siebert[4] the calculation of the normal vibration and assignments were given. Although assignments based on the more detailed measurements of infrared and Raman spectra have been given by Hadni[5] and by Taylor and Vidale[6], there still remains some arbitrariness in their results because they studied the spectra of only one isotopic compound. Therefore, it is desirable to measure the spectra of deuterated compounds in order to obtain more reliable results.

The results of the measurement of the infrared and Raman spectra of methyl ether ($(CH_3)_2O$) and of methyl ether-d_6 ($(CD_3)_2O$) and an assignment of the spectra, referring to that of dimethoxy methane and its deuterated compounds[8], are reported here.

Experimental

Samples. — Methyl ether was prepared from methanol and sulfuric acid. Crude gaseous ether was passed through a concentrated aqueous solution of sodium hydroxide and trapped first with ice-salt and finally with acetone-dry ice. Then it was purified by distillation over metallic sodium. Purification was repeated until no change in the infrared spectrum was observed. A sufficiently pure sample for infrared measurement was obtained, but a shoulder near 1050 cm^{-1} still remained in the Raman spectrum after the final purification. It was considered, therefore, that a very small amount of methanol remained in the sample.

Deuterated ether was prepared from deuterated methanol (CD_3OH or CD_3OD) and deuterated sulfuric acid in the same way as non-deuterated ether. The concentration of deuterium in the sample was analyzed by means of proton magnetic resonance and found to be about 99%.

Measurement of Spectra.—Raman spectra were obtained in the liquid state by a Cary 81 spectrophotometer (3500～250 cm^{-1}, 35～38°C). The degree of depolarization was measured with polarizers around the Raman tube. In the case of non-deuterated methyl ether, a Raman tube for a 5 ml. sample was used, and for the deuterated compound, 0.2 and 0.4 ml. Raman tubes were employed, so the measurement of weak bands was difficult in the latter case.

Infrared spectra (3500～280 cm^{-1}) were obtained by using the following spectrophotometers: Perkin-Elmer 12C (LiF prism), 112G (3500～2000 cm^{-1}), 21 and 321 (NaCl and CsBr prisms), and Nippon-Bunko DS 301 (NaCl prism, 1000～1200 cm^{-1}). Measurement was carried out in the gaseous state over the whole range of the spectrum and also, in the carbon tetrachloride solution, in the sodium chloride and lithiam fluoride prism regions. The obtained spectra are shown in Fig. 1.

Assignment and Discussion

The structure of methyl ether was determined from electron diffraction[10] and microwave spectroscopy[11] to be approximately C_{2v} symmetry. If the molecule belongs to point group C_{2v}, vibrational bands can be classified into four species: $\Gamma = 7A_1 + 4A_2 + 6B_1 + 4B_2$. The vibrations belonging to A_2 are infrared inactive. The envelope of infrared absorption bands of a gaseous substance is of the B type for species A_1, A type for B_1, and C type for B_2. Raman lines which belong to species A_1 are polarized. These characteristics are referred to in the assignment of the bands.

Since the number of observed bands is less than the number of normal vibrations, some overlapping of bands is expected. Therefore, it is not always possible to determine definitely the species of bands by observation of the envelope of infrared absorption bands or by the measurement of the degree of depolarization in the Raman spectra.

Before making the assignment of vibrational spectra of the molecule, the authors would like to examine the results of other authors as shown in Table I. In the assignment given by Herzberg[1], a point in question is that he assigned a band at 1180 cm^{-1} to the methyl rocking vibrations belonging to four species. Coincidence of the wave numbers of the four bands would be impossible because two of them (A_1, B_1) are the in-plane methyl rocking, and others (A_2, B_2) are the out-of-plane methyl rocking, vibrations. Moreover, since the band at 1179 cm^{-1} measured in the present experiment has a clear envelope of the A or C type, it is difficult to consider it as the overlapping of four bands.

Ryskina[3] assigned a band at 1122 cm^{-1} to the methyl rocking vibration of species B_1, but we consider it to be a branch of the band at 1102 cm^{-1}. In her assignment, the band at 1102 cm^{-1} was assigned to the overlapping of three bands, the species of which was A_2, B_1 and B_2, but this assignment is also questionable for a reason similar to that mentioned above.

Siebert[4] studied the molecular vibration of methyl sulfide ($(CH_3)_2S$) and of methyl selenide ($(CH_3)_2Se$) as well as of methyl ether, but the bands which he assigned were so few that the present authors will not refer to his results.

Hadni[5] considered that there were three fundamental bands at 940, 932 and 918 cm^{-1}. In the present experiment, however, the asymmetric feature of the R branch of the infrared band is not so marked enough to be the basis of such a conclusion, and, in addition, the infrared spectrum in solution shows a single band at 920 cm^{-1}. Therefore, the bands observed at 940 and 916 cm^{-1} should be considered as branches of a B-type band.

The Raman spectra of the molecule in both gaseous and liquid states were measured by Taylor and Vidale[6]. New bands were observed at 1291 (gas) 1242 (gas and liquid), 1167 (liquid) and 1053 cm^{-1} (gas and liquid). Among these, 1291 cm^{-1} had not been observed by other authors. As suggested by the following fact, this band is due to contaminated carbon dioxide. In the synthesis of the sample, carbon dioxide from dry ice used for the trap or from the reacting mixture could be absorbed in ether to some extent. In fact, the same band was observed in the prepared sample in the present experiment if no care was taken to remove it.

The band at 1053 cm^{-1}, which was also observed in the present Raman measurement as a very weak shoulder, might originate from the strongest band of methanol being included as a trace.

C-H and C-D Stretching Vibrations.—Of the observed bands two bands at 2996 and 2817 cm^{-1}

are characteristic bands of aliphatic methoxyl groups[8,9]. These two bands are assigned respectively to overlapping asymmetric and symmetric stretchings of species A_1 and B_1. The fact that both of them show A or C-type band envelopes instead of the B-type for A_1 species may suggest these overlappings. The band at 2952 cm^{-1} observed only in the Raman measurement is assigned to the asymmetric stretching vibration of the infrared inactive species A_2. Of two bands at 2925 and 2887 cm^{-1} which have strong infrared intensities, the one at 2925 cm^{-1} is assumed to be a B_2 band because to the B_2 species belongs an asymmetric C–H stretching vibration whose frequency should not lie far from the A_1 and B_1 asymmetric stretching vibrations. Detailed discussions of the C–H stretching vibrations of methyl ether have not been given in previous papers, but the assignment given here does not contradict that of homologue which have methoxy groups[8,9]. The strong Raman band at 2869 cm^{-1} and the infrared band at 2887 cm^{-1} are to be assigned to an overtone or combination tone of methyl deformation virations.

Deuterated methyl ether shows clearer envelopes of absorption bands in the C–D stretching region than non-deuterated ether does in the C–H stretching region. This can be explained because the ratio of rotational constants B/A increases as the molecule changes from methyl ether to methyl ether-d_6. The bands at 2248 and 2054 cm^{-1} are of the A type, and the band at 2184 cm^{-1} is of the C type. As in the case of C–H stretching vibrations, the band with the highest frequency (2248 cm^{-1}) is assigned to the overlapping asymmetric stretchings and that with the lowest (2054 cm^{-1}), to the overlapping symmetric stretching vibrations of species A_1 and B_1. Then the C-type band at 2184 cm^{-1} (strong in infrared and weak in Raman) is assigned to the vibration of species B_2. The Raman band at 2202 cm^{-1} is assigned to the asymmetric stretching vibration of species A_2. Though the Raman bands at 2285, 2137 and 2100 cm^{-1} also have no corresponding infrared bands, by referring to the assignment of non-deuterated methyl ether it is reasonable to assume that a band nearer to that of species B_2 is to be assigned to species A_2. The strongly polarized band at 2137 cm^{-1} which has a medium intensity is possibly an overtone or combination band of CD_3 deformation vibrations.

Methyl Deformation Vibrations. — In the region of methyl deformation vibrations, infrared and Raman bands are observed only around 1460 cm^{-1}. The infrared spectrum of gaseous ether shows two sharp absorptions at 1464 and 1456 cm^{-1} which can not be considered as branches of a band both bacause the separation of 8 cm^{-1} between them is too small and because the appearance of the doublet does not seem to be that of any type of band envelopes. Furthermore, the infrared spectrum in solution still shows three bands at 1470, 1464 and 1454 cm^{-1}. Therefore, it is suitable to regard them as the superposition of some bands.

Taylor and Vidale[6] assigned the band at 1242 cm^{-1} to a methyl symmetric deformation. This might seem possible because the band is always observed in this region in molecules having a methoxyl group or groups[8,9]. This assignment, however, is denied by the following facts. The first objection stems from the relationship between the vibrational frequencies of methyl symmetric deformation and methyl rocking given by Wilmshurst[12]. Applying it to the observed frequencies, if the frequency of methyl symmetric deformation is assumed to be 1244 cm^{-1}, that of the rocking vibration should be obtained about 900 cm^{-1} or lower where no bands are observed actually; however, both methyl deformation and rocking vibrations prove to appear in the higher frequency region. The second objection stems from the fact that, as Sheppard[13] mentioned, in CH_3X type molecules with various kinds of atoms or group X, the methyl symmetric deformation of methoxyl groups appeared at about 1460 cm^{-1}.

Nukada observed methyl deformation vibrations of dimethoxy methane and dimethoxy methane-d_2 ($CH_3OCD_2OCH_3$) only near 1460 cm^{-1} and not below. From the relative intensity of the infrared and Raman spectra and the degree of polarization, he assigned the bands at 1460 and 1455 cm^{-1} to the symmetric and asymmetric deformations respectively[8]. Considering these, it seems reasonable to assume that all the methyl deformations of methyl ether lie in the range of 1470~1450 cm^{-1}, though at present it is impossible to assign the observed bands to six normal vibrations individually.

CD_3 deformation vibrations are expected to appear around the region of $\nu_{\delta CH_3}/\sqrt{2}$ cm^{-1} or higher. Corresponding to those of non-deuterated ether, infrared bands of a similar complicated shape and a strong Raman band are observed at 1062 and 1056 cm^{-1} and at 1062 cm^{-1} respectively. The assignment is made, as in the case of methyl ether, by treating the six bands together.

Skeletal Vibrations.—There are three skeletal vibrations: a C–O symmetric stretching

(species A_1), a C–O antisymmetric stretching (B_1), and a COC deformation (A_1).

As can be seen in Table I, the bands at 920 and 420 cm^{-1} have been assigned to the skeletal vibrations of species A_1 by all authors. In the present experiment, strong B-type infrared bands and polarized Raman bands are observed at 928 at 418 cm^{-1} and and are assigned to A_1 bands.

The band of methyl ether-d_6 at 827 cm^{-1} has characteristics corresponding to those of a band at 928 cm^{-1} of methyl ether, so it is assigned to the C–O symmetric stretching vibration. Similarly, the Raman band observed at 365 cm^{-1} is assigned to the COC deformation vibration the measurement of the degree of depolarization, although the corresponding infrared band at 362 cm^{-1} does not show the shape of the B type but a broad singlet structure.

To the assignment of the C–O antisymmetric stretching vibration some consideration should be given. For this vibration an A type infrared band and a depolarized Raman band ether band are to be expected. Methyl ether-d_6 has the very strong A-type infrared band at 1162 cm^{-1} (in the liquid phase the frequency shifts to 1146 cm^{-1}) and no further similar bands in the region, and it also has a Raman band of medium intensity at 1142 cm^{-1}, so the band can be assigned to the C–O antisymmetric stretching vibration.

In the case of methyl ether, one of the two strong infrared bands at 1179 and 1102 cm^{-1} (A or C type) has to be assigned to the C–O antisymmetric stretching vibration of species B_1. Formerly Mashiko[7] observed two pairs of

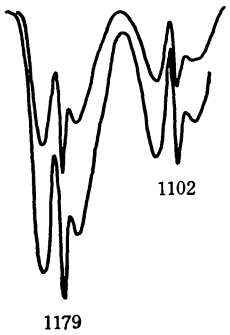

Fig. 2. Infrared spectrum of CH_3OCH_3 (gas) spectral slit width; 1 cm^{-1}.

bands, at 1169 and 1142 cm^{-1} and at 1105 and 1098 cm^{-1}, which had the appearance of B type, but in the present measurement, they proved to be triplet bands having P, Q and R branches. As the matter of fact, only two remarkable bands are observed in this region in the infrared spectrum in solution. The two infrared bands in a geseous state show a similar shape, so it is difficult to decide which one is the antisymmetric skeletal stretching vibration. The infrared spectrum in a gaseous state, measured under various pressures with a constant spectral slit width (1 cm^{-1}, Nippon Bunko DS-301), is shown in Fig. 2. Since the intensity ratios of the Q branch to the P and R branches at 1179 cm^{-1} are larger than those at 1102 cm^{-1}, the two bands could be of different species. If one band is assigned to a C–O antisymmetric stretching vibration, the other should be a methyl rocking vibration of species B_2 because of its strong intensity and shape in the infrared spectrum. As will be shown in a following paper[14], from the calculation of normal vibrations it has been concluded that the band at 1102 cm^{-1} is the C–O stretching vibration and that the one at 1179 cm^{-1} is the methyl rocking vibration.

Methyl Out-of-plane Rocking Vibrations. — Of the two methyl out-of-plane rocking vibrations, one belongs to species A_2 and the other to B_2. As stated above, the infrared band at 1179 cm^{-1} is assigned to the rocking vibration of methyl ether belonging to species B_2 (the corresponding Raman band may be a weak shoulder near 1170 cm^{-1}). In the case of methyl ether-d_6, the band at 931 cm^{-1} surely corresponds to this vibration, which shows a C-type band shape. The corresponding Raman band could not be observed distinctly.

It should be possible to determine the assignment of the methyl rocking vibration of species A_2 from only the Raman spectrum if the molecule belongs to symmetry C_{2v}. Thus, the Raman band at 1150 cm^{-1} is assigned to this vibration, and the fact that the frequency 1150 cm^{-1} is not so far from 1179 cm^{-1} of the B_2 rocking vibration supports the assignment. In deuterated ether, no suitable band could be detected, perhaps because the band is masked by other strong bands or because it has too weak an intensity to be observed in the specta.

Methyl In-plane Rocking Vibrations. — To species A_1 and B_1 belongs one rocking vibration each. In methyl ether, the B-type band is observed at 1244 cm^{-1}, and, from the preceding interpretation, this could not be a methyl deformation vibration. Moreover, the fact that in a molecule including methoxy groups a band was always observed near 1230 cm^{-1} [8,9] suggests that the band is, though weak, a fundamental. This band is therefore assigned to the A_1 methyl rocking vibration.

The depolarized Raman band is observed at 1227 cm^{-1}. In the paper of Tailor and Vidale, the Raman band observed by them at 1242 cm^{-1} was strongly polarized, but the present authors determined the band at 1227 cm^{-1} to be certainly depolarized. Therefore, it is unreasonable to regard the Raman band as corresponding to the infrared band at 1244 cm^{-1}. Therefore, it is assigned to the B_1 methyl rocking vibration.

In methyl ether-d_6, no infrared band with the band shape typical of methyl ether is observed. A shoulder at 1033 cm^{-1} is assigned to the A_1 methyl rocking vibration, and the weak band at 872 cm^{-1} in the Raman and infrared spectrum is assigned to the B_1 band. Applying the product rule to these frequencies, we get the following results which support the assignments.

	A_1	B_1
Theor.	0.1880	0.2150
Calcd.	0.1810	0.2117

The authors wish to express their sincere thanks to Dr. Yo-ichiro Mashiko and Dr. Shinnosuke Saëki of this Institute for their valuable discussions. Also, they wish to thank Dr. Junko Nakamura of The University of Tokyo, who kindly recorded a few of the spectra with a P. E. 112G spectrometer, and Professor Kôji Nakanishi of Tokyo University of Education, who allowed them to use that institution's Nippon Bunko DS-301 spectrometer.

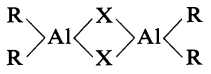
Raman Spectra of Diethyl Aluminum Monohalogenides



By Osamu YAMAMOTO

(Received August 21, 1961)

It has been established that some lower members of trialkyl aluminum have the molecular structure of the dimeric bridged form represented by

in which the plane containing two terminal alkyl groups and an aluminum atom is perpendicular to the bridge plane[1,2]. These compounds have been defined as "electron deficient compounds", and according to Rundle[3] the bondings between the aluminum and bridging alkyl groups are formed by two "half bonds". Monohalogen derivatives of trialkyl aluminum also exist as dimers, and the following structural formulae can be considered for them.

(A)

(B_1) (B_2)

Formula A with symmetry D_{2h} has a halogen bridge which would be formed by the coordination of lone pair electrons in halogen atoms to aluminum. Formula B_1 with symmetry C_{2h} corresponds to the "trans" form, in which two halogen atoms are present on opposite sides of the bridge plane, while formula B_2 with symmetry C_{2v} corresponds to the "cis" form where the halogen atoms are on the same side of the bridge plane. In the latter two, the alkyl bridge would be formed by the half bonds, as in the case of trimethyl aluminum.

There have been several papers reporting on the structure of dimethyl aluminum monohalogenides. Van der Kelen and Herman[4] suggested after a study of the Raman spectra, that these compounds would have the structure B_2, while Growenewege proposed structure A for dimethyl aluminum chloride as a result of Raman[5] and proton nuclear magnetic resonance spectroscopy[6]. Electron diffraction study[7] by Brockway and Davidson also indicated that the compound would have the structure A. Recently Hoffmann[8] reported Raman and infrared spectral data on some members of trialkyl aluminum and dimethyl and diethyl aluminum chlorides, but his work was mainly concerned with CH deformations and little consideration was given to the structure of the diethyl aluminum monohalogenides.

In this paper, the Raman spectra of diethyl aluminum monohalogenides (except fluoride) as well as of triethyl aluminum have been reached from these spectra as to the structure studied, and some conclusions have been of diethyl aluminum monohalogenides.

Experimental

Materials.—All the materials except diethyl aluminum chloride were prepared by Gross and Mavity's methods[9]; diethyl aluminum bromide and iodide were prepared by the reduction of corresponding aluminum sesquihalides with sodium. Diethyl aluminum chloride was provided by the Meguro Laboratory of Mitsui Chemical Industry Co., Ltd. All the samples were distilled into Raman tubes, which were sealed off under reduced pressure to prevent contamination with air and moisture.

Raman Spectra.—The Raman spectra were obtained with a Cary 81 spectrophotometer. Qualitative polarization factor measurements were also made for the purpose of the tentative assignments.

Results and Discussion

The results are shown in Table I. It can be found from this table that the Raman lines are divided into three groups: 0～700 cm^{-1}, 900～1500 cm^{-1}, and 2700～3000 cm^{-1}, which represent skeletal vibrations, CH deformation vibrations and CH stretching vibrations respectively.

Of these three kinds of vibrations, the CH deformations and stretching vibrations are not so important as far as the molecular structure

is concerned. Furthermore, the CH deformations were discussed in some detail by Hoffmann[8], and it appears that there is nothing to be added to his paper. Therefore, the author was interested mainly in the skeletal vibrations and left the CH stretching vibrations to be assigned in the near future.

Tentative assignments for the skeletal vibrations were obtained by comparison with the known spectra of aluminum trihalogenides[10,11], trimethyl aluminum[1], and dimethyl aluminum chloride[5], for which the bridged structure has been firmly established by many authors. The skeletal vibration lines

obtained of the compounds in question are schematically drawn in Fig. 1, in which the notation for the frequencies of Bell and Longuet-Higgins[10] is used. The modes of vibrations of A_2B_6 type molecules are reproduced in Fig. 2 only for Raman active vibrations, symmetry species and polarization characters of which are shown in Table II.

Table II. Symmetry species and polarization characters of the Raman active normal vibrations in Fig. 2

D_{2h}	A_{1g} (p)	ν_1, ν_2, ν_3, ν_4
	B_{1g} (dp)	ν_6, ν_7
	B_{2g} (dp)	ν_{11}, ν_{12}
	B_{3g} (dp)	ν_{15}

Seven to eight Raman lines are observed in the region of the skeletal vibrations of the monohalogenides. In the case of the C_{2h} symmetry model, structure B_2, all of the 18 possible skeletal vibrations are Raman active, while only nine of the vibrations are Raman active for the D_{2h} or C_{2h} symmetry model. It is probable, therefore, that diethyl aluminum monohalogenide has a D_{2h} or C_{2h} symmetry, although this does not appear to be conclusive. Futhermore, in the 400~700 cm^{-1} region of diethly aluminum chloride four infrared absorption bands were observed[8], at 673, 628, 544 and 438 cm^{-1}, which, except for 673 cm^{-1}, do not accord with the Raman lines in Table I. If 673 cm^{-1} in the infrared and 670 cm^{-1} in the Raman spectra can be assigned to each different vibration, and if it is noted that no other infrared band agrees with any of the Raman lines in frequency, it can be considered that the rule of mutual exclusion holds; this fact assures the presence of the center of symmetry in the molecule. Unfortunately, there is no infrared data on diethyl aluminum monobromide and iodide, but the possibility of C_{2v} symmetry can be eliminated with considerable certainty.

In the Raman spectra of trietyl aluminum and diethyl aluminum monohalogenides the following two series of strong lines are observed:

X of $[Al(C_2H_5)_2X]_2$	Series I cm^{-1}	Series II cm^{-1}
Et	560	430
Cl	556	339
Br	547	197
I	544	170

Since both series of lines are polarized, these must be either ν_1, ν_2, ν_3, or ν_4 for D_{2h} symmetry. Furthermore, it is reasonable to assume that series I and II are assigned to either ν_1 or ν_2 by comparison with the assignment of the spectrum of trimethyl aluminum.

Now if the halogen bridge model A with symmetry D_{2h} is acceptable, series II must be assigned to ν_2, the bridge stretching vibration, because it varies in frequency with the increase in the atomic weight of substituents while series I does not. The frequencies of the bridge stretching vibration, ν_2, of aluminum trihalogenides are 340, 204 and 146 cm^{-1} for chloride, bromide and iodide respectively, as is shown in Table III, in which the Raman lines in the skeletal regions of trimethyl aluminum, dimethyl aluminum chloride and aluminum trihalogenides are listed with the normal vibrations to which they are assigned. Thus, it can be found that there is a close relationship in ν_2 between the trihalogenides and diethyl aluminum monohalogenides. When series II is assigned to ν_2, series I is naturally assigned to ν_1, the outer stretching vibration.

If the halogen bridge model A is assumed, the remaining outer vibrations ν_3, ν_7, ν_{11} and ν_{12} must not vary in frequency with the increase in the atomic weight of the substituents. Thus, the series III, 640(Et), 670(Cl), 664(Br) and 664(I) cm^{-1} is assigned to the outer stretching vibration ν_{11} by comparison with methyl compounds and by a consideration of polarization factors. Series IV, 269(Et), 263(Cl), 266(Br) and 268(I) cm^{-} may be assigned to the outer bending vibration ν_3. The depolarized series V, 119(Et), 114(Cl),

ν_6	563 (00)	247 (3)	438 ($^1/_2$ dp ?)	438	(291 ?)	(195 ?)
ν_7	164 (3)	152 (5)	284 (2 dp)	164	176 (2)	—
ν_{15}	—	217 (4)	—	(160)	—	—

95(Br), and 81(I) cm^{-1} might be ν_4 by intensity consideration, although ν_4 has to be a polarized vibration.

So far the assignments have been performed with the halogen bridge model. If the alkyl bridge model, B_1 with symmetry C_{2h} (trans form), is adopted, series which does not vary in frequency is the bridge vibration, so that polarized series I should be a bridge vibration. But even in this case triethyl aluminum must belong to the same symmetry class D_{2h} as trimethyl aluminum, so that, for example, 560 cm^{-1} of triethyl aluminum in series I should be assigned to ν_1, the outer vibration, by comparison with ν_1 and ν_2 of trimethyl aluminum. With the model B, all of the monohalogenides have the alkyl bridge. Then strong lines at approximately 430 cm^{-1} should also be observed as the bridge stretching vibration in the spectra of the monohalogenides as in the case of triethyl aluminum. Actually it is not the case, however. Furthermore, it is impossible to interpret the marked correlation of frequencies between the triethyl aluminum and the diethyl aluminum monohalogenides obtained in Table I.

Accordingly, the results of this study indicate that the Raman spectra of diethyl aluminum chloride, bromide and iodide are consistent with a dimeric bridge structure over the halogen atoms with symmetry D_{2h}.

The author wishes to express his gratitute to Drs. Yoichiro Mashiko and Kenkichi Nukada of the Government Chemical Industrial Research Institute, Tokyo, for their kind encouragement and valuable suggestions given throughout this study. He is also indebted to Misses Michiko Matsushima and Yuriko Matsubayashi of the same Institute for their help in the measurement of the Raman spectra, and to Mr. Ichiro Endo for his experimental assistance.

Elementary analysis			
C, %	86.96	87.22	87.15
H, %	5.71	6.00	6.02

The properties of purified specimens are shown in Table I.

Paal[2] synthesized the β-isomer by a reaction of β-naphthol and potassium nitroso-*p*-tolylsulfamate in benzene and he reported that the compound was red and melted at 135°C. However, the β-isomer which the present author prepared is a white needle and melted at 41~42.3°C. The melting point of the Paal's compound seems to be too high for the β-isomer in comparison with those of phenoxynaphthalenes and also the red color seems unlikely for a naphthyl tolyl ether structure and it probably be due to some impurities. The

physical properties and absorption spectra afford evidence in favor of the compound prepared by the author as the correct β-isomer. In the present experiment, the ethers were synthesized by the Ullmann reaction, that is, the α-isomer from α-bromonaphthalene and *p*-cresol, and the β-isomer from β-naphthol and *p*-bromotoluene.

Experimental

Materials. — *p-Cresol*[3]. — B. p. 200°C (uncorr.), m. p. 32°C.

α-Bromonaphthalene[4].—It was synthesized from naphthalene and bromine in the same manner as described in the literature.

Copper Powder.—It was precipitated from an aqueous solution of cupric sulfate by addition of zinc granules and washed with water, dilute hydrochloric acid and finally with ethanol.

β-Naphthol.—Commercial reagent, m. p. 120～121°C (uncorr.).

p-Bromotoluene.—Commercial reagent was redistilled, m. p. 25.2°C.

Synthesis of α-Naphthyl *p*-Tolyl Ether.—*p*-Cresol was dissolved in an aqueous solution of potassium hydroxide and water was evaporated from the resulting solution in vacuo and to the dried residue were added α-bromonaphthalene and copper powder and the mixture was heated in an oil bath. The cooled mixture was first treated with 20% aqueous solution of potassium hydroxide to dissolve unreacted *p*-cresol and then extracted with benzene. The extract was concentrated and distilled in vacuo. The main fraction was at first pale yellow and viscous which gradually solidified to a white mass by cooling and seeding. This solid was recrystallized once from ethanol to give needles which melted at 36～39°C. The experimental results are shown in Table II.

The crude ether was recrystallized twice from ethanol to give colorless plates which melted at 38～39°C.

Found: C, 86.96; H, 5.71; mol. wt. 234. Calcd. for $C_{17}H_{14}O$: C, 87.15; H, 6.02%; mol. wt. 234.

Solubility.—It is readily soluble in toluene, benzene, chloroform, moderately soluble in cold ethanol and insoluble in water.

Trinitrobenzene Complex.—It was prepared from ether (189 mg.) and trinitrobenzene (182 mg.) in ethanol. Three recrystallizations from ethanol yielded 192 mg. of pale yellow crystals, m. p. 72～73°C.

Found: N, 9.20. Calcd. for $C_{23}H_{17}O_7N_3$: N, 9.40%.

The picrate could not be prepared by the usual method.

Infrared Spectrum. — The spectrum in carbon disulfide is shown in Fig. 1. To make the analysis of the spectrum easier, a comparison with that of the α-phenyl ether is shown in Fig. 2. A band appearing at 13 μ(769 cm^{-1}) and 3 strong bands in the range of 9～10 μ correspond to a 1,2,3-substitution in the benzene ring. This means a substitution in 1-position of naphthalene which may be regarded as a substituted benzene. A band at

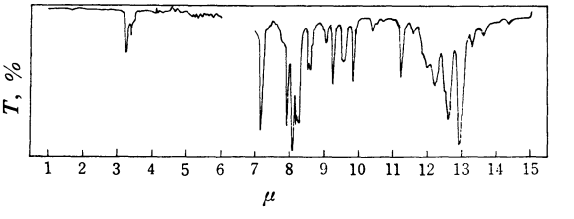

Fig. 1. α-Naphthyl *p*-tolyl ether.

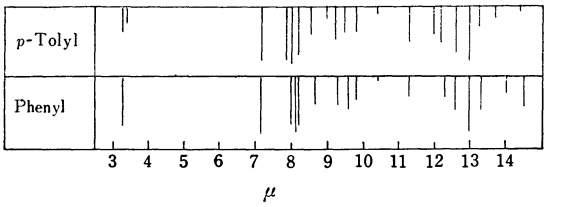

Fig. 2. Aryl α-naphthyl ether.

3) I. Heilbron, "Dictionary of Organic Compounds", Vol. I, Oxford University Press, New York (1953), p. 613.
4) "Organic Syntheses", Collective Vol. I, Second Edition, John Wiley & Sons, Inc., New York (1956), p. 121.

8.1 μ(1235 cm^{-1}) corresponds to an ether linkage and a band at 3.45 μ(2899 cm^{-1}) to aliphatic C-H. As a band at 12.2 μ(820 cm^{-1}) indicates the presence of a para-substitution in the benzene ring, the methyl group is at para position of the phenoxyl bonding. An absorption band at 12.6 μ(794 cm^{-1}) shows 3 adjacent hydrogen atoms in the benzene ring.

Synthesis of β-Naphthyl *p*-Tolyl Ether.—β-Naphthyl ether was synthesized in the same ways as those for α-napththyl ether. The experimental results are shown in Table III.

The crude ether (9.25 g.) was recrystallized from ethanol to give 3.17 g. of short needles, m. p. 41~42°C. This purified specimen distilled at 187~188°C (3 mmHg).

Found: C, 87.22; H, 6.00; mol. wt. 233. Calcd. for $C_{17}H_{14}O$: C, 87.15; H, 6.02%; mol. wt. 234.

Solubility.—It is readily soluble in benzene, toluene and chloroform, moderately soluble in cold ethanol and insoluble in water.

Trinitrobenzene Complex.—It was prepared from the ether and trinitrobenzene in ethanol.—Recrystallized twice from ethanol, pale yellow leaflets were obtained; m. p. 93~94°C. This seems to be unstable.

Infrared Spectrum. — The spectrum in carbon disulfide is shown in Fig. 3 and the comparison with that of the β-phenyl ether is shown in Fig. 4. In this spectrum a band is absent at 14.5 μ. A strong band at 12.2 μ(820 cm^{-1}) shows a para-substitution in the benzene ring, thus indicating the presence of the methyl group at para position. A band at 13.4 μ(746 cm^{-1}) corresponds to the presence of 4 adjacent hydrogen atoms in the benzene ring.

Ultraviolet Spectra. — The spectra of α- and β-isomers of *p*-tolyl ethers and phenyl ethers in cyclohexane are shown in Figs. 5 and 6. Compared with the adsorption maxima of the corresponding phenyl ethers, those of *p*-tolyl ethers are at nearly the same wavelengths.

The Reaction of Hydrogen and Oxygen through a Silent Electric Discharge. II. The Effect of Packings on a Peroxide Formation

By Kihei MORINAGA

(Received August 21, 1961)

The formation of ozone in a discharge tube containing various fillings has been previously reported[1]. To complement this report, similar investigations were carried out on the hydrogen-oxygen reaction. The hydrogen-oxygen reaction is generally known to be influenced by the chemical composition and the nature of the material constituting the surface of the reaction vessel[2-5]. Further, it is conceivable that the reaction through silent discharge may be considerably affected by the composition of the fillings employed in the discharge gap. The results were satisfactory from the viewpoint of confirming this hypothesis.

Experimental

The apparatus used and the procedures followed, were similar to the previously reported work[6]; however, the packing fill of the discharge tube was varied. The reactant gas, consisting of 4.5% oxygen by volume, was sent from a reservoir through the discharge tube after passing through the drying column. After passing through the discharge tube, the reactant gas was immediately cooled in a condensation trap, where the hydrogen peroxide and water produced were caught by freezing. The packing materials consisted of several kinds of ceramics containing titanium(IV) oxide, soda glass, boric oxide and orthoboric acid. Except for boric acid, the granular size of the packing materials was 0.7~1.0 mm. sieve mesh, while for boric acid it was between 0.5~0.85 mm. Thus, the void of the packed discharge tube was 45% in the former case and 38% in the latter case. The discharge tube made of hard glass (Hario glass) had a gap length and electrode area of 2 mm. and 200 cm^2 respectively. The electric source frequency for the silent discharge was 1000 c./sec. and the pulse current was measured in a way similar to that of the previous work[1].

Results

In every discharge tube the experiment was carried out under a constant flow rate so that the resident time was between 3.9 to 4.1 sec. Table I shows the peroxide concentration and the overall conversion rate of the reactant oxygen gas to peroxide and water at a certain fixed pulse current of 100 μ amp.

TABLE I.

No.	Composition of the packings	Dielectric constant	Peroxide concn. %	Overall conversion rate, %
1	Blank	1	46.0	2.4
2	Soda glass	6	4.5	3.7
3	$2\,MgO/TiO_2$	20	1.2	3.3
4	TiO_2	100	1.7	3.6
5	$BaTiO_3$	1200	2.5	3.5
6	$95\,BaTiO_3/5\,SnO_2$	5500~6000	0.7	3.2
7	B_2O_3		45.5	3.1
8	H_3BO_3		42.1	2.5

Discharge tube: Hario glass, $A=200\,cm^2$, $d=2$ mm.
Pulse current: 100 μ amp.
Residence time: 3.9~4.1 sec.

When the packing consisted of soda glass, and especially when the packing consisted of ceramics, the peroxide concentration was appreciably lowered. However, when the packing consisted of boric oxide or boric acid, the peroxide concentration was nearly the same as that resulting from a void discharge tube. The overall conversion rate to peroxide and water is larger when the discharge tube has a packing fill than when the tube is empty. This partly agrees with the finding of the investigation of ozone formation in a packed discharge tube[1].

Concerning the boric oxide packing, a kind of aging phenomena was observed. That is, the fresh boric oxide packing initially gave a high concentration of peroxide and a low conversion rate. After repeated use, the above values approached saturation values. In Fig. 1, the results of the aging phenomena are shown. Each point represents the concentration of the conversion rate of the product in one hour of continuous dicharge. Both the concentration and the conversion rate seem to settle to steady values after a few hours of discharge.

Discussion

In an ordinary discharge tube without packing fill, the overall conversion rate to peroxide and

◎ Peroxide concentration
⊙ Overall conversion rate

water was larger when a smaller gap length was used[6]. This agrees with the results obtained in the investigation of the ozone formation[7]. In a silent discharge with a packing-filled discharge tube, the ozone formation rate and ozone concentration were improved appreciably[1]. This was ascribed to the fact that the shortening of the gap length, which was due to the packing fill, will improve the ozone yield.

In this experiment, however, though the overall conversion rate to peroxide and water was larger in the packing-filled discharge tube, the final product of the reaction was greatly affected by the packing materials employed in the discharge gap. This was not the case in the previously studied formation of ozone. The difference in the peroxide concentration can be seen in Table I. These differences can be ascribed to the effect of the surface of the filling material on the reaction, similar to the case pointed out in the previous paper[6].

Hinshelwood et al.[2] suggested that, in the second explosion limit of hydrogen and oxygen gas, the surface destruction of the HO_2 radical was dominant in halide-coated or in silica vessels. On the other hand, the boric acid-coated vessel does not provide enough reaction for the surface destruction of both HO_2 and H_2O_2; thus, the HO_2 radicals form H_2O_2 either by the surface or the gas phase process. Baldwin et al.[5] showed that the gas phase binary reaction of HO_2 to form H_2O_2 and O_2 was more predominant than the surface process of HO_2 to form $1/2\,H_2O_2$ and $1/2\,O_2$. In the reports[5] it was also concluded that the formation of peroxide from HO_2 and H_2 was preponderant over the formation of water from the same species.

7) K. Morinaga and M. Suzuki, ibid., **34**, 157 (1961).

The peroxide formation resulting from a silent discharge is first assumed to be a gas phase reaction accompanied by the other elementary process of water formation. In the course of the catalytic decomposition of H_2O_2 on the surface of the discharge tube or the packing granules, the quantity of water increased, consequently lowering the peroxide concentration in the product. This tendency will be more preponderant when there is a shorter gap length or when a discharge tube with other than boric oxide and boric acid fillings is used.

Walsh[8] has evidence which has lead him to believe that the anti-knock effect of lead tetra-ethyl is due to the destruction of HO_2 and H_2O_2 on the lead(II) oxide surfaces. In the present case, the ceramics which contained titanium(IV) oxide and other metallic oxides will behave similarly to those described above. Soda glass may be similar to the halide-coated or silica surfaces. On the surface of boric oxide and boric acid, the destruction of HO_2 and H_2O_2 will be suppressed and the concentration of peroxide will be increased.

The overall conversion rate in the packing-filled discharge tube will be increased with the improvement of the discharge efficiency which arises from the packing fill[1,7].

In the case of boric oxide fillings, the water molecules will reside on the fresh surfaces of the granules. After the saturation-like adsorption of water molecules, the surface activity seems to be lowered.

Summary

By applying several packings in the discharge gap space, the peroxide formation through a silent discharge was studied. The peroxide concentration was higher in a void discharge tube or in a boric acid (boric oxide) packing-filled discharge tube and lower in the case of the soda glass and the ceramic packing containing titanium(IV) oxide. This was explained by the insufficient destruction of HO_2 and H_2O_2 on the boric acid surface, and by the great destruction on the surface of the packing consisting of soda glass and ceramics. A kind of aging phenomena observed in the boric oxide packing was tentatively explained.

The author would like to express his great appreciation to Professor Momotaro Suzuki of the Defense Academy for his encouragement and helpful advice throughout this investigation.

The Reaction of Hydrogen and Oxygen through a Silent Electric Discharge. III. The Ignition of the Hydrogen-Oxygen Gas by Silent Electric Discharge

By Kihei MORINAGA

(Received, September 11, 1961)

The ignition of a detonative gas mixture can be actuated by an electric spark with sufficient strength[1,2]. Usually there is a threshold value of the strength above which the initiation of the detonation is realizable. Very few investigations have, however, been reported on the silent electric discharge which is involved in the initiation of the detonation.

In the present paper, the problem of the initiation of the detonation of a hydrogen-oxygen mixture is dealt with mainly from the view-point of the electrical energy necessary to cause any detonation. The electrical energy is expressed as pulse current estimated from an oscillogram pattern.

Experimental

The oxygen and hydrogen gases taken from each cylinder were dried over calcium chloride and silica gel and then stored in the desired composition for several hours before use.

The electrical circuit system of the silent discharge and a brief diagram of the detonation bomb are shown in Fig. 1. The cylindrical bomb, made of mild steel, has an inside diameter of 6 cm. and a depth of 9 cm. A kind of safety diaphragm to prevent a dangerous pressure rise is attached to the bomb. A silent discharge electrode, composed of ordinary glass plates 5×6 cm. and 1 mm. thick, was mounted in the center of the bomb. The area of the electrode and the gap length are 7.5 cm^2 and 2 mm. respectively. The whole system is air-tight, and the measuring gas can be introduced through a tap just before each measurement. Direct current is supplied from a system of storage batteries of 120 V. and 250 amp. hr. As can be seen in Fig. 1, the voltage of direct current from the storage batteries was potentiometrically regulated and was supplied to the transformer via the throwing switch S. In the secondary coil of the transformer, an inductive high tension is induced according as the switch S is "on" or "off". In the present experiment, the shock current which is induced by the "on" position was used exclusively.

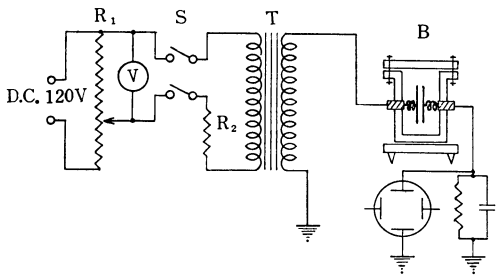

Fig. 1. The electrical circuit system of silent discharge.
R_1, R_2: Resistor
V: Voltmeter
S: Throwing switch
T: Transformer
B: Test bomb

The pulses of the silent electric discharge were observed by an oscilloscope synchronized with the switch S. The time constant of the C-R circuit for observing the pulse current was 5.2×10^{-6} sec.

Whether or not the gas is ignited can easily be detected by a distinct cracking noise of the safety bursting diaphragm, or by the sudden fall of the pressure gauge.

Several shots of the oscillographic pattern of the explosion just above the explosion limit of the primary voltage and of the non-explosion just under the limit were taken. In the experiments the scope of the primary voltage of the explosion and non-explosion patterns could be set within 2.5 V. or, in the worst case, within 5 V.

The composition of the gas mixture covers a range of 8.5~75% oxygen. The ignition is actually observed in gas mixtures of more than 9.9% oxygen.

Results

An oscillographic pattern of the induced high tension which appeared in the secondary coil simultaneously with the primary circuit being closed by switch S is shown in Fig. 2.

With applying the above high tension to the discharge electrode, a kind of one-shot silent discharge was obtained. Figure 3 shows the current diagram of a discharge in a hydrogen and oxygen gas mixture which did not provoke any ignition. The fringe-like figure indicates the pulse current during the silent electric

discharge[3-6], and the thick line shows the basic current in the secondary circuit.

In Fig. 4, some types of the oscillogram pattern accompanying the gas ignition are shown. In type A the discharge current flows for some time t_1, and then an ignition which is indicated by rather high and irregular pulse current comes in at the heel of the discharge current. In type B, there is some time delay t_2-t_1 from the quenching of the discharge current to the beginning of the ignition. Types C and D make their appearance when the condition is most contiguous to the threshold of the ignition and are very difficult to observe. The features are virtually the same as those of A and B.

In these patterns in Fig. 4, the base current or the low frequency discharge current in the gap space was appreciably elevated over the pattern of non-ignition in Fig. 3. These elevations on the current diagram could be ascribed to the ionization of the gases, which is accompanied with the inflamation or explosion of the gas[7].

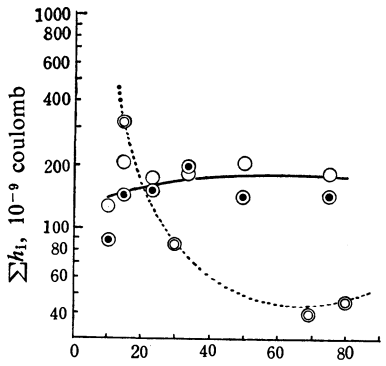

Fig. 6. Threshold value of $\sum hi$ against oxygen content. $P=300$ mmHg.
- ○ $\sum h_1$ value obtained from ignition pattern just above the threshold condition.
- ◉ $\sum h_1$ value obtained from non-ignition pattern just under the threshold condition.
- ◎ modified result of Lewis and von Elbe in the condenser spark ignition.

In Figs. 5 and 6, the total pulse current carried through the electrode for a period of the time t_1 or $\sum h_1$, where the h_1 is the height of a single pulse cuurrent appearing in an oscillogram pattern, was plotted versus the oxygen content of the detonating gas mixture. In these figures, the open circle represents the value of $\sum h_1$, obtained from the oscillographic pattern of discharge, which takes place just above the threshold primary voltage, and the dotted circle represents that of $\sum h_1$ from the pattern just under the threshold primary voltage. The real threshold condition will be in between the two plots, and a little increasing trend is observable. The double circle in Fig. 5 represents the modified result of Lewis and von Elbe in the condenser spark ignition of hydrogen and oxygen gas at 0.33 atm. The numerical value of coulomb is obtained from the C and V values cited in their data[1].

The quantities of electricity are independent of the composition of the detonating mixture, or, in other words, a fixed amount of electricity through a silent discharge is always required to initiate the ignition, no matter what the composition of the detonating gas is.

If the $\sum h_1$ is plotted against the pressure of the detonating gas mixture of a certain definite composition, then a series of straight lines is obtained (Fig. 7). The slope of the straight lines increases as the oxygen content is richer. The quantity of electricity, therefore, which is necessary to initiate a detonation in a gas mixture of a fixed pressure will be more as the oxygen content is richer.

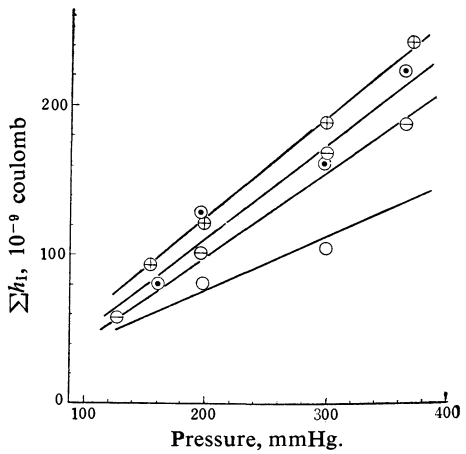

Fig. 7. The relation between $\sum h_1$ and the reactant gas pressure.

Discussion

The fact that the quantity of electricity needed for the initiation of the ignition of a hydrogen and oxygen mixture under fixed pressure is independent of the composition of the gas mixture, implies that a certain amount of chemical entity is essential to initate the ignition. Furthermore, the amount of this chemical entity is constant for the gas composition range used in this measurement.

The chemical entity is tentatively presumed to be a OH radical, which may be concluded according to the chain branching mechanism learned from explosion limit studies[8,9];

$$H+O_2 \rightarrow OH+O \qquad (1)$$

Even then, in some cases in our experiment a ignition delay was observed. The accumulation of the necessary concentration of this radical may then be achieved through any possible secondary decade which will proceed during the delay time.

The fixed amount of electricity provides, shall we say, at first a H radical of enough concentration by which reaction 1 will be initiated. The rate of secondary decades providing a OH radical sufficient for an ignition will be very rapid without an ignition delay, or otherwise, it may not be so rapid some delay time is required to attain the sufficient concentration. The alternatives will be decided by the strength of discharge current and/or by the composition of the gas mixture.

The quantity of electricity incresses linearly

8) R. R. Baldwin and A. D. Walsh, *Discussions Faraday Soc.*, **17**, 96 (1954).

with the pressure of the gas mixture, which indicates that the primary radical, or the H radical in this case, which is necessary to initiate the reaction 1 and then the ignition, increases in the gas mixture while keeping a linear relationship with the pressure of the gas mixture. The reaction pattern is very much like that of the ozone formation in silent electric discharge[10], where the O radical is produced by a collision process between an electron and an oxygen molecule. The same reasoning discussed there can be applied here, and the mechanism of this reaction pattern and the above relationship will then be understood without any further explanation. The study of the electric ignition of the detonative gas mixture greatly contributes to the exploration of the chain ignition mechanism, though further extensive study will be required to elucidate the actual features in more detail.

Summary

The ignition of a hydrogen and oxygen gas mixture by a silent electric discharge was investigated.

The quantity of electricity which must be carried in the course of the discharge before a detonation will take place is almost independent of the composition of the gas mixture. Furthermore, for a gas mixture of fixed composition,the quantity of electricity increases along with the increasing pressure of detonative gas. A tentative view of the possible mechanism of the initiation of the detonation was briefly discussed.

The author would like to express his grateful appreciation to Professor Momotaro Suzuki of the Defense Academy for his encouragement and helpful guidance throughout this investigation.

Dimensions of Vinylidene Chloride-Alkyl Acrylate Copolymers in Flory Theta Solvents

By Mitsuo ASAHINA, Masaki SATO and Takashi KOBAYASHI

(Received August 17, 1961)

The effects of the length of the pendant side chain on the dimensions of polymer molecules in solution have as yet not been fully elucidated. Recent studies by Chinai[1] et al. on poly(alkyl methacrylates) and by Manson[2] et al. on poly(vinyl alkyl ethers) have shown reversals of the polymer chain extension with an increase in side chain length, but no explanation of these reversals has been given. In the present study we determined the unperturbed dimensions of four copolymers of vinylidene chloride and alkyl acrylates in the hope of obtaining experimental material which might aid in clarifying how the dimensions of a polymer molecule in solution are affected by the length of its pendant side chain.

Experimental

Preparation of Copolymers.—For the purpose of the present study, we prepared four vinylidene chloride-alkyl acrylate copolymers. The alkyl acrylates chosen were ethyl acrylate, *n*-butyl acrylate, *n*-hexyl acrylate and *n*-octyl acrylate. Commercial materials of these alkyl acrylates were distilled and, after small amounts of hydroquinone had been added, stored in a nitrogen atmosphere. Immediately before use, they were washed with a dilute aqueous solution of sodium hydroxide and sodium carbonate to remove the hydroquinone added.

For the preparation of each copolymer the following recipe was used: 100 parts of monomers with the molar ratio of vinylidene chloride to alkyl acrylate being 85/15; 200 parts of 0.1 wt.% aqueous solution of methyl cellulose (Metocell. 100 c. p. s.); and lauryl peroxide 0.1 wt.% to monomers. The polymerization was carried out for 15 hr. at 50°C, with the yield ranging from 30 to 40% of charged monomers. The polymers produced were separated by filtration, dissolved immediately in ethyl methyl ketone, and then precipitated by an addition of excess methanol. The precipitate was isolated by filtration and dried in vacuo to a constant weight. The dry material was again dissolved in ethyl methyl ketone and fractionally precipitated at 30 to 40°C, using methanol as a nonsolvent. Both to check the distribution of two monomer units and to evaluate the average fundamental molecular weight, M_0, of the copolymer, the chlorine contents

Table I. Refractive index increments for copolymers in methyl ethyl ketone

Polymer	$\partial n/\partial c$ (λ=4358 Å, at room temperature)
Poly(vinylidene chloride co ethyl acrylate)	0.135
Poly(vinylidene chloride co *n*-butyl acrylate)	0.142
Poly(vinylidene chloride co *n*-hexyl acrylate)	0.130
Poly(vinylidene chloride co *n*-octyl acrylate)	0.130

of the resulting fractions were determined by using the Carius method.

Phase Equilibria.—After a number of preliminary experiments, we found that ethyl acetoacetate is a relevant theta solvent for poly(vinylidene chloride co ethyl acrylate) and that benzyl alcohol is relevant for the remaining copolymers. Given amounts of either of these solvents and a given copolymer were placed in a test tube, 0.8 cm. in diameter, 20 cm. long, and fitted with a ground glass stopper. After the polymer had been dissolved by heating 70 to 80°C for 2 hr., the test tube was immersed in a thermostated water bath. Phase separation occurred when the temperature of the bath was gradually lowered; the rate of cooling used was 0.1°C per min. The temperature at which the separation commenced, T_p, was determined visually with the reproducibility of ± 0.1°C. For each given fraction this temperature was determined as a function of the polymer concentration, and then the critical solution temperature, T_c, of the fraction was found from the maximum of the T_p vs. concentration curve so obtained. By repeating a similar procedure for other fractions with different molecular weights, data for T_c as a function of molecular weight were derived. The desired theta temperature, i. e., the value of T_p for infinite molecular weight, can be deiermined by treating these data in the manner described by Flory[3].

Light Scattering and Viscosity Measurements.—In this work, besides studying the four copolymers in their respective theta conditions, we also measured their dilute solution properties in ethyl methyl ketone for the sake of comparison.

The light-scattering behavior of given solutions was studied by means of a photometer of the Brice type manufactured by Shimadzu Seisakusho, Kyoto. Scattered intensities were measured at 45, 90 and 135°C to the incident beam, and the data obtained were analyzed in terms of the usual procedure[4], assuming a polydisperse random coil for the solute polymer molecule. Dust was removed from the test solutions by centrifugation at 20000 g. for 1.5 hr. Light-scattering measurements were carried out at room temperature. The refractive index increments of the ethyl methyl ketone solution of these copolymers were measured by a Debye-type differential refractometer manufactured by Shimadzu Seisakusho, Kyoto; the values obtained are listed in Table I. The viscosity measurements were performed at 30°C for ethyl methyl ketone solutions and at respective theta temperatures for ethyl acetoacetate or benzyl alcohol solutions.

The viscosities of ethyl methyl ketone solutions of the four copolymers were measured in an Ostwald viscometer; the flow time for ethyl methyl ketone at 30°C was 99.6 sec. Kinetic energy corrections were applied to the measured flow times. Use was made of Ubbelohde dilution viscometers for the study under theta conditions. These viscometers were designed so that their flow times for the theta solvents at the theta temperatures were relatively large; thus no kinetic energy correction was necessary.

Results and Discussion

Composition of Copolymers and Average Fundamental Molecular Weight M_0.—The chlorine contents of fractions of the four copolymers studied are listed in Tables II, III,

Table VI. Composition and fundamental molecular weight, M_0, of copolymers

Polymer	Composition (mol. % of acrylate)	M_0
Poly(vinylidene chloride co ethyl acrylate)	14.9	97.5
Poly(vinylidene chloride co *n*-butyl acrylate)	16.7	102.2
Poly(vinylidene chloride co *n*-hexyl acrylate)	14.5	105.6
Poly(vinylidene chloride co *n*-octyl acrylate)	15.6	110.6

IV and V. Table VI gives the data for the composition and the fundamental average molecular weight, M_0, in each copolymer computed from these chlorine content values. The molar compositions of the four copolymers are not exactly the same, but the differences among them are small. Hence, if we take into consideration the experimental errors in determining the chlorine content, one may assume that these copolymers are uniform in molar composition.

Relation between Limiting Viscosity Number and Molecular Weight for Ethyl Methyl Ketone Solutions. — Tables II, III, IV and V list the limiting viscosity numbers of fractions of respective copolymers in ethyl methyl ketone at 30°C. and the weight-average molecular weights, M_w, of those fractions. Log-log plots for the limiting viscosity number against M_w prepared from these data are shown in Fig. 1 and yield the following relations:

Poly(vinyldene chloride co ethyl acrylate)

$$[\eta]_{MEK} = 2.88 \times 10^{-4} M_w^{0.60}$$

Poly(vinylidene chloride co *n*-butyl acrylate)

$$[\eta]_{MEK} = 3.43 \times 10^{-4} M_w^{0.60}$$

Poly(vinylidene chloride co *n*-hexyl acrylate)

$$[\eta]_{MEK} = 2.07 \times 10^{-4} M_w^{0.62}$$

Poly(vinylidene chloride co *n*-octyl acrylate)

$$[\eta]_{MEK} = 3.55 \times 10^{-4} M_w^{0.58}$$

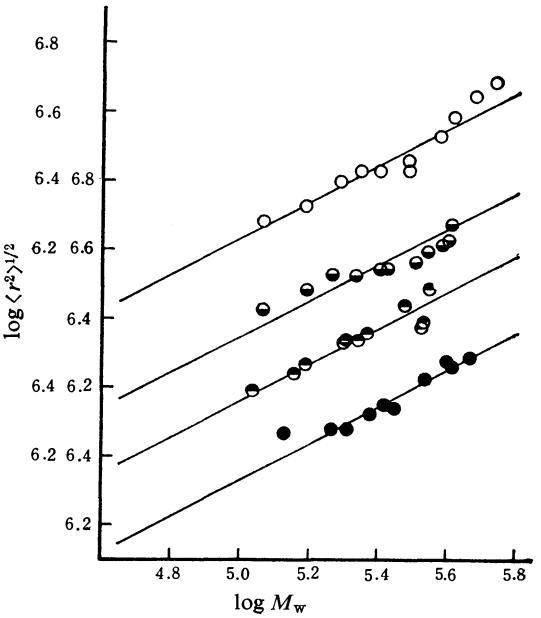

Fig. 2. Logarithmic plot for root mean square end-to-end distance of fractions of copolymers against molecular weight.
○ Poly(vinylidene chloride co *n*-octyl acrylate)
◒ Poly(vinylidene chloride co *n*-hexyl acrylate)
◓ Poly(vinylidene chloride co *n*-butyl acrylate)
● Poly(vinylidene chloride co ethyl acrylate)

It is interesting that the exponent to the weight-average molecular weight is almost identical for the four copolymers, suggesting that the chain flexibilities of these polymers are similar.

Relation between Molecular Dimension in Ethyl Methyl Ketone and Molecular Weight.— Tables II to V also contain values for the weight-average mean square end-to-end distance of the solute molecule, $\langle r^2\rangle_w^{1/2}$, evaluated from dissymmetry data. The log-log plots for $\langle r^2\rangle_w^{1/2}$ against M_w shown in Fig. 2 give the following relations:

Poly(vinylidene chloride co ethyl acrylate)

$$\langle r^2\rangle_w^{1/2}=4.90\times10^{-9}M_w^{0.53}$$

Poly(vinylidene chloride co *n*-butyl acrylate)

$$\langle r^2\rangle_w^{1/2}=5.29\times10^{-9}M_w^{0.53}$$

Poly(vinylidene chloride co *n*-hexyl acrylate)

$$\langle r^2\rangle_w^{1/2}=5.01\times10^{-9}M_w^{0.53}$$

Poly(vinylidene chloride co *n*-octyl acrylate)

$$\langle r^2\rangle_w^{1/2}=3.89\times10^{-9}M_w^{0.53}$$

In order to see the effect of length of the pendant side chain, it is convenient to write these relations in the form in which M_w is replaced by P_w, the weight-average degree of polymerization. The result is

Poly(vinylidene chloride co ethyl acrylate)

$$\langle r^2\rangle_w^{1/2}=5.55\times10^{-8}P_w^{0.53}$$

Poly(vinylidene chloride co *n*-butyl acrylate)

$$\langle r^2\rangle_w^{1/2}=6.14\times10^{-8}P_w^{0.53}$$

Poly(vinylidene chloride co *n*-hexyl acrylate)

$$\langle r^2\rangle_w^{1/2}=5.92\times10^{-8}P_w^{0.53}$$

Poly(vinylidene chloride co *n*-octyl acrylate)

$$\langle r^2\rangle_w^{1/2}=4.71\times10^{-8}P_w^{0.53}$$

The expressions indicate that the difference in the length of the pendant alkyl group has a relatively minor influence on the dimension of the vinylidene chloride-alkyl acrylate copolymer molecule in ethyl methyl ketone (a relatively good solvent for polymer) if the molar ratio of alkyl acrylate is as small as of the order of 0.15.

Theta Temperatures. — Figure 3 illustrates plots for T_p against the polymer concentration of poly(vinylidene chloride co *n*-octyl acrylate) in benzyl alcohol; the data for the other copolymers studied are similar in nature. From the maximum of each cure curve, the value of T_c for each fraction can be determined without ambiguity. According to the theory developed by Flory[3], T_c is related to the molecular weight M by the equation:

$$1/T_c=1/\theta(1+b/M^{1/2}) \qquad (1)$$

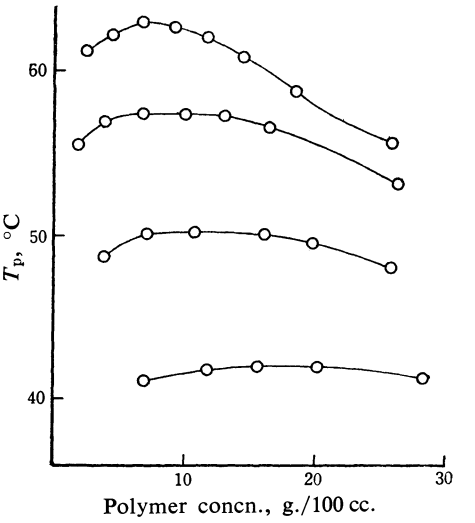

Fig. 3. Phase separation temperature, T_p, of four fractions of poly(vinylidene chloride co *n*-octyl acrylate) as a function of polymer concentration.

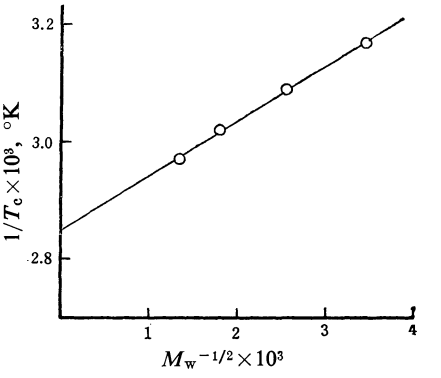

Fig. 4. Reciprocal critical solution temperature, T_c, against reciprocal square root of molecular weight of four fractions of poly(vinylidene chloride co *n*-octyl acrylate).

where b is a constant characteristic of a given polymer-solvent system. The so-called theta temperature θ, i.e., the critical solution temperature for a polymer of infinite chain length, can be determined by plotting $1/T_c$ against $1/M^{1/2}$ and then extrapolating the resulting plot to infiite molecular weight. Figure 4 shows this plot for poly(vinylidene chloride co *n*-octyl acrylate); similar linear plots were obtained for the remaining copolymers. The values of θ found in this way for poly (vinylidene chloride co *n*-butyl acrylate), poly (vinylidene chloride co *n*-hexyl acrylate), and poly(vinylidene chloride co *n*-octyl acrylate), all in benzyl alcohol, were 44.0, 56.8 and 77.9°C respectively, while that for poly(vinylidene

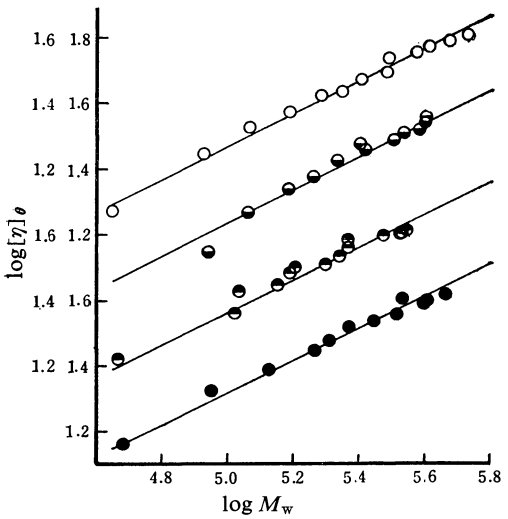

Fig. 5. Logarithmic plot for limiting viscosity number at θ temperature against molecular weight of fractions of copolymers.

- ● Poly(vinylidene chloride co ethyl acrylate)

chloride co ethyl acrylate) in ethyl acetoacetate was 49.6°C.

Relation between Limiting Viscosity Number at Theta Temperature and Molecular Weight.—In Tables II to V are given the limiting viscosity numbers of fractions of the four copolymers in respective theta solvents. These values, $[\eta]_\theta$, are logarithmically plotted against M_w (determined above from light scattering data on ethyl methyl ketone solutions) in Fig. 5. The plots in the figure yield the following relations:

Poly(vinylidene chloride co ethyl acrylate)

$$[\eta]_\theta = 6.64\times10^{-4} M_w^{1/2}$$

(in ethyl acetoacetate)

Poly(vinylidene chloride co *n*-butyl acrylate)

$$[\eta]_\theta = 7.30\times10^{-4} M_w^{1/2}$$

(in benzyl alcohol)

Poly(vinylidene chlorride co *n*-hexyl acrylate)

$$[\eta]_\theta = 5.50\times10^{-4} M_w^{1/2}$$

(in benzyl alcohol)

Poly(vinylidene chloride co *n*-octyl acrylate)

$$[\eta]_\theta = 5.87\times10^{-4} M_w^{1/2}$$

(in benzyl alcohol)

In all case the values of $[\eta]_\theta$ increase in proportion to one half the power of M_w, in conformity with the current theories of dilute polymer solutions.

Dimensions of the Copolymers in Theta Solvents.—The values of the parameter Φ characterizing Flory's theory of dilute polymer solution have been calculated by substituting the data for $[\eta]$, $\langle r^2\rangle_w^{1/2}$ and M_w obtained with ethyl methyl ketone solutions into the equations:

$$[\eta] = k(M_w)^{\alpha} \quad (2)$$

$$K = \Phi\langle r^2\rangle_w^3/(M_w)^{3/2} \quad (3)$$

The results are shown in Tables II to V. It is seen that the Φ values so obtained for poly(vinylidene chloride co ethyl acrylate), poly(vinylidene chloride co *n*-buthyl acrylate), and poly(vinylidene chloride co *n*-hexyl acrylate) agree fairly well with each another and are not very different from the generally accepted value, 2.1×10^{-21}. However, the values for poly(vinylidene chloride co *n*-octyl acrylate) are unusually high. The reason for this is not clear to us but is probably due to the experimental errors involved in $\langle r^2\rangle_w$.

Equations 2 and 3 may be used to calculate the weight-average root mean square end-to-end distance, $\langle r_0^2\rangle_w^{1/2}$, of the polymer molecule in the theta solvent from the measured values of $[\eta]_\theta$ and M_w if the value of the parameter Φ is given, since α is equal to 1/2 under theta conditions. We have made this calculation, assuming $\Phi = 2.1\times10^{-21}$, for all the copolymers studied here. The results are:

Poly(vinylidene chloride co ethyl acrylate)

$$\langle r_0^2\rangle_w^{1/2} = 6.81\times10^{-9} M_w^{1/2} \quad (49.6°C)$$

Poly(vinylidene chloride co *n*-butyl acrylate)

$$\langle r_0^2\rangle_w^{1/2} = 7.03\times10^{-9} M_w^{1/2} \quad (44.0°C)$$

Poly(vinylidene chloride co *n*-hexyl acrylate)

$$\langle r_0^2\rangle_w^{1/2} = 6.04\times10^{-9} M_w^{1/2} \quad (56.8°C)$$

Poly(vinylidene chloride co *n*-octyl acrylate)

$$\langle r_0^2\rangle_w^{1/2} = 6.53\times10^{-9} M_w^{1/2} \quad (77.9°C)$$

In terms of P_w these relations may be written:

Poly(vinylidene chloride co ethyl acrylate)

$$\langle r_0^2\rangle_w^{1/2} = 6.72\times10^{-8} P_w^{1/2} \quad (49.6°C)$$

Poly(vinylidene chloride co *n*-butyl acrylate)

$$\langle r_0^2\rangle_w^{1/2} = 7.11\times10^{-8} P_w^{1/2} \quad (44.0°C)$$

Poly(vinylidene chloride co *n*-hexyl acrylate)

$$\langle r_0^2\rangle_w^{1/2} = 6.58\times10^{-8} P_w^{1/2} \quad (56.8°C)$$

Poly(vinylidene chloride co *n*-octyl acrylate)

$$\langle r_0^2\rangle_w^{1/2} = 6.87\times10^{-8} P_w^{1/2} \quad (77.9°C)$$

The quantity $(\langle r_0^2\rangle_w/P_w)^{1/2}$ provides a measure of the extension of a polymer chain, and it is seen that the values of this quantity for all four copolymers are almost the same. If we take into account the fact that the unperturbed dimension of a polymer molecule may decrease with increasing temperature (due to the enhanced rotation of each chain element), it is likely that, when a comparison is made at a fixed temperature, the values of this quantity for the four copolymers will become closer. We can therefore conclude that if the molar ratio of alkyl acrylate component is relatively small, the unperturbed dimension of vinylidene chloride-acrylate copolymer is hardly affected by the length of the pendant alkyl group.

Table VII summarizes the values of some basic parameters characterizing chain dimensions, such as $(\langle r_0^2\rangle/P)^{1/2}$, $(\langle r_0^2\rangle/\langle r_{0f}^2\rangle)^{1/2}$, and $M_0\ [\eta]_\theta/P^{1/2}$, for the four copolymers studied here, together with those for several other polymers[1,5-9]. Here $\langle r_{0f}^2\rangle^{1/2}$ denotes the root mean square end-to-end distance in the unperturbed state of a polymer molecule in which no hindrance to the rotation of each element is present. Its value has been calculated assuming a value of 1.54Å for the distance between neighboring carbon atoms and a value of 109.5° for the valency angle between successive bonds. The parameter $M_0\ [\eta]_\theta/P^{1/2}$ has been proposed by Chinai and associates.

The authors wish to expresses their grateful appreciation to Professor Shunsuke Murahashi and Professor Hiroshi Fujita of Osaka University and to Professor Akira Kotera of Tokyo University of Education for their encouragement and thoughtful suggestions throughout the course of this study, to Dr. K. Mayumi and to Kureha Kasei Co., Ltd. for their permission to publish this paper.

Dilute Solution Properties of Low-temperature Polymerized Polyvinyl Chloride. I. Effects of Dissolution Temperature and Time

By Takashi KOBAYASHI

(Received August 17, 1961)

Asahina and his coworkers have reported[1-3] that the physical properties of the solid state of polyvinyl chloride depend upon the temperature at which the sample is polymerized. The purpose of the study presented in this paper is to examine if there is any difference in the dilute solution properties of polyvinyl chloride polymerized at different temperatures. Our preliminary experiment had indicated that the samples polymerized at low-temperatures were more difficult to dissolve in tetrahydrofuran than commercially available materials usually polymerized at 50~60°C. In this study we measured the viscosity, osmotic pressure and light scattering of tetrahydrofuran solutions of polyvinyl chlorides polymerized at three different temperatures and the changes with time of these properties when left standing; we aimed at establishing the conditions required for the preparation of a solution of this polymer stable enough to use for the evaluation of its physical behavior.

Experimental

Materials.—Three samples of polyvinyl chloride were studied. They were obtained in the following manner:

S-796—A whole polymer suspension polymerized at 58°C. The 43 wt. % lower molecular weight portion was removed, and the remaining portion was designated as S-796-M.

S0968—This was a whole polymer suspension polymerized at 48°C.

F-5-M—The 3 wt. % higher molecular weight portion and the 29 wt. % lower molecular weight portion of a polymer bulk polymerized at −15°C were removed by fractional precipitation, and the remaining portion was designated as F-5-M.

The solvent used was tetrahydrofuran. After the material purchased in a 20 l. can had been dried for about one week over sodium hydroxide pellets, it was distilled, and the fractions between 65.8~66.2°C were collected.

Preparation of Solutions.—An accurately weighed sample was mixed in an ampoule with the required amount of solvent; after the air in it had been replaced by nitrogen, the ampoule was sealed and heated and occasionaly shaken in an oil bath for two hours at the desired temperature. Then it was transferred into a thermostat regulated at 30°C and kept for fifteen minutes. The ampoul was then cut off, and the solution was ready to use.

The concentration of the solution so obtained was calculated from the amounts of polymer and solvent weighed before mixing for the purpose of plotting viscosity and osmotic pressure data. For the light-scattering study it was determined gravimetrically by drying up an aliquot of the solution.

Viscosity Measurements.—Capillary viscometers of the Ostwald type were used throughout the present study. For example, one of them had the following characteristics: bore diameter=0.037 cm., capillary length=10.4 cm., volume of the upper bulb=1.99 cc., and efflux time for tetrahydrofuran of 30°C=167.7 sec. The kinetic energy correction was applied to all flow times measured. Flow times were determined at four concentrations between 3×10^{-3} and 8×10^{-3} g./ml., and the limiting viscosity number was estimated by graphical extrapolation of the plots for viscosity number against concentration (in g./ml.).

Osmotic Pressure Measurements.—A modified Zimm-Meyerson osmometer fitted with gelcellophane was used. The measurements were made at 30°C using the dynamic method. Data were taken at four concentrations between 3×10^{-3} and 8×10^{-3} g./ml.

Light Scattering Measurements.—Use was made of a photometer of the Brice type manufactured by Shimadzu Seisakusho, Kyoto. The calibration was made by referring to the literatures value[4] for the Rayleigh ration, R_{90}, of pure benzene. Measurements were made in a cylindrical cell over the range of scattered angle from 40 to 140° and at three polymer concentrations, using both unpolarized blue light, $\lambda=4360$ Å, and green light, $\lambda=5460$ Å, emitted from a mercury lamp. The depolarization correction was not applied. Dust was removed from the given solution by centrifuging it at 2×10^4 times gravity for one and a half hours immediately before use. All measurements were performed at room temperature, without any specific temperature-controlling device fixed to the instrument. No marked temperature variation occurred during any series of measurements.

The refractive index increment of this system of polymer and solvent was measured by means of a differential refractometer of the Debye type manufactured by Shimadzu Seisakusho, Kyoto. The values obtained were 0.115 and 0.110 for the lights

of $\lambda=4360$ Å and $\lambda=5460$ Å respectively, in good agreement with the literature's, value[5].

The procedure developed by Zimm[6] was followed to evaluate results from these light-scattering experiments.

Results and Discussion

Effect of Dissolution Temperature. — It is generally accepted that polyvinyl chloride samples polymerized at low-temperatures are less soluble than those prepared at higher temperatures. In order to examine this point in a qualitative manner, we measured viscosities, osmotic pressures, and turbidities of solutions of S-796 and of F-5-M prepared at different temperatures. Table I gives viscosity data for S-796 dissolved in tetrahydrofuran at 60, 100 and 140°C. It can be seen that the viscosity values of sample S-796 in tetrahydrofuran are practically independent of the dissolution temperature in the range above 60°C; this is in accordance with Kuroiwa's results[7]. Similar conclusions were derived also from osmotic pressure and turbidity measurements on this sample.

Figure 1 shows η_{sp}/c (viscosity number) for sample F-5-M in tetrahydrofuran as a function of the temperature at which the solution was made. As has been mentioned above, the polymer was dissolved in the solvent by heating at a given temperature for two hours. It was found that a more prolonged heating did not give rise to any detectable change in the viscosity values. Thus, the results shown in Fig. 1 should be free from the effects of the time used to dissolve the sample polymer. The data for osmotic pressure and for light scattering corresponding to Fig. 1 are given in Figs. 2 and 3 respectively. These figures indicate that, contrary to the case of sample S-796, the viscosity, osmotic pressure and light-scattering

properties of F-5-M all become practically independent of the dissolution temperature only in the region above 100°C or more. In the light-scattering plots shown in Fig. 3, there still exists a distinct, though quite small, difference between the data for 100°C and those for 140°C. One may consider this difference to be negligible or else within the limits of accuracy of the light-scattering measurements. However, since we have checked similar differences by repeated measurements, it is believed that even such a small difference is significant.

The interpretation of these differences in solution properties between S-796 and F-5-M cannot be certain, but the most obvious conclusion is that the intermolecular interaction in polyvinyl chloride becomes stronger as the polymerization temperature is lowered. In order to obtain relevant data on tetrahydrofuran solutions of a polyvinyl chloride polymerized at a temperature much lower than that used for commercially available material, the solute must be dissolved in the solvent at a temperature at least higher than 100°C and the mixture must be kept at least for two hours at that temperature. However, use should not be made of too high a dissolution temperature, since that is likely to induce thermal decomposition of the polymer.

Effect of Standing Time. — It has been reported that dilute solutions of ordinary polyvinyl chloride remain stable for several days[8]. In Table II are given viscosity data for S-796-M solutions in tetrahydrofuran as a function of the time for which the solution was allowed to stand after it had been prepared. Figure 4 shows the Zimm plots for S0968 solutions in tetrahydrofuran allowed to stand for different intervals of time. Apparently these solutions remained stable over the time intervals examined. The data for viscosity, osmotic pressure

* Time in hour after the solution was prepared.

and light-scattering in tetrahydrofuran solutions of F-5-M as functions of the standing time are given in Tables III, and IV, and Fig. 5 respectively. It can be seen that the dilute solution properties of this sample, especially those at higher concentrations, chaneg to a considerable extent with time. This appears to be due to the gradual association of solute molecules taking place during the course of standing.

A straightforward support to this idea is the marked decrease in $Kc/R_{\theta\to 0}$ on prolonged

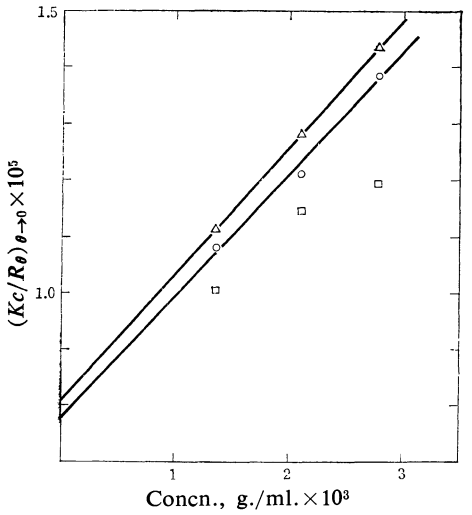

Fig. 5. The time effect on light scattering of solutions of F-5-M. △ 3.5 hr. after the completion of heating; ○ 24.5 hr.; □ 76 hr.

standing, as indicated in Fig. 5, which indicates the formation of increasingly large solute particles by association. It is worth pointing out that the association, if any, had only a minor influence on the viscosity of the solution.

Doty et al.[9] have demonstrated the occurrence of the association of polyvinyl chloride molecules in relatively poor solvents. Since the time effects observed here for tetrahydrofuran solutions of F-5-M are similar to those reported by Doty et al., it appears that tetrahydrofuran, though being though of as a good solvent for ordinary polyvinyl chloride, is a relatively poor solvent for this polymer polymerized at as low a temperature as that employed for the preparation of sample F-5-M.

The author wishes to express his appreciation to Professor Shunsuke Murahashi, Professor Hiroshi Fujita of Osaka University and Professor Akira Kotera of Tokyo University of Education for their encouragement and thoughtful suggestion throughout the course of the study reported in this paper, to Dr. K. Mayumi and Kureha Kasei Co., Ltd., for permission to publish thir paper, and to Mr. M. Sato, Mr. Y. Koshiishi and Mr. S. Aoyagi for their very helpful cooperation in carrying out the experimental work.

Formation Constants of Some Metal Formate Complexes, and the Use of Formate Buffer Solution as an Elutriant for Cation-exchange Chromatography

By Hiroyuki TSUBOTA

(Received August 19, 1961)

Many studies of the elutriants for the ion-exchange separation of mixed fission products have been made over the part several years. Ammonium citrate[1], ammonium butyrate[2] and ammonium α-hydroxy isobutyrate[3] are used as elutriants for the separation of fission products and for the purification of rare earth elements. They have good separability, but some difficulties are encountered in the preparation and preservation of the elutriants and in further treatment of the eluates for analysis.

Honda has shown that ammonium acetate[4,5] or ethylenediaminetetraacetic acid[6] could be effectively used for separating alkaline earth elements and other elements. He has pointed out that ammonium acetate is easily sublimed. Tsubota and Kitano have shown that a new

* A part of this work was done at Kobe University, Kobe. The new elutriant, the formate buffer solution, was first reported on by the present author at the 10th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1957.

elutriant, a mixture of ammonium formate and formic acid, is a good elutriant for analyzing fission products[7] and alkali or alkaline earth elements[8].

A good elutriant will have the following characteristics: 1) To separate various metal ions with cation-exchange resin, it is desirable that the formation constants between the anion of the elutriant and the metal ions to be separated should differ considerably from each other.

2) It is necessary that the reagent used as the elutriant does not interfere with the later procedures of the analysis. For this purpose, it is desirable that the formation constants should not be too large, or that the reagent should be easily removable from the eluates, e. g., by heating.

3) As the separation is done by changing the concentration of the complexing ion in the elutriant, it is desirable that the concentration of the complexing ion be capable of being varied by varying the pH and by keeping the total concentration of the elutriant constant. Therefore, the reagent used as the elutriant should have a buffer action. The reagent used as the elutriant of high quality must be obtainable at low cost, and one must be able to make solutions of various concentrations and pH's without difficulty. As ammonium formate can be vaporized most easily and completely, a formate solution would be the best elutriant if the formation constants of the metal ions to be separated are suitable.

Therefore, determination of the formation constants of these systems was undertaken as follows.

The Formation Constants of Some Metal Formate Complexes

Except for the system of alkaline earth elements[9], the formation constants of the formate complex systems have not yet been measured. In this work, the formation constants of formate are measured for iron, aluminium, rare earth (Ce) and manganese. These elements are essential portions of an analysis of natural waters, rocks and mixed fission products*.

The determination was done by the ion-exchange method[10,11].

Chemicals used.—

Resin: Dowex 50-X8, 60~80 mesh, Na^+-form, air-dried.

Fe^{3+}-solution: perchlorate prepared from $FeCl_3 \cdot 6H_2O$, reagent grade of Merck.

Al^{3+}-solution: perchlorate prepared from pure aluminum plate (99.99%).

Ce^{3+}-solution: perchlorate prepared from $Ce(SO_4)_2 \cdot 4H_2O$, reagent grade of Merck.

Mn^{2+}-solution: perchlorate prepared from $MnCl_2 \cdot 4H_2O$, reagent grade of Wako-Junyaku.

All other chemicals used were of reagent grade.

Analysical Methods.—Ferric ion was titrated with EDTA, using variamine blue B as an indicator. The Al^{3+} was determined by colorimetry of aluminum oxinate in chloroform at a wavelength of 390 mμ. The determination of Ce^{3+} was made both by colorimetry of Ce^{4+} after oxidizing it with ammonium persulfate and by employing the β-counting method with ^{144}Ce; a good coincidence was obtained. Mn^{2+} was colorimetrically analyzed as potassium permanganate after oxidizing it with potassium periodate.

Measurements.—The complex solutions were prepared by mixing the following two solutions in various proportions:

Solution-1

a mol. $M^{n+}(ClO_4)_n$

$(1-na)$ mol. $NaClO_4$

where M^{n+} is a metal ion, and a is kept constant, $1 \sim 5 \times 10^{-3}$ mol., in each series of experiments.

Solution-2

$(1-b)$ mol. HCOOH

b mol. HCOONa

where b is kept constant, 0.2~0.5 mol., in the series of experiments on each metal ion.

Twenty-five milliliters of the mixed solutions were shaken for 24 hr. with 1.000 g. of the dried ion-exchange resin in a thermostat at 25°C. After an exchange equilibrium had been reached, the solution was rapidly separated from resin with glass filter and the metal concentration of the solution phase was measured.

The relative volume decrease of the solution caused by the swelling of the ion exchanger was estimated by the quotient between the initial and equilibrium ion concentrations of the solution. A cation exchanger column in the hydrogen form was used to convert all cations in the solution to H^+. The H^+ was titrated with a 0.1 N sodium hydroxide standard solution, using phenolphthalein as an indicator, to give the initial and equilibrium ion concentrations. The values of these quotients, constant within each series of experiments, were between 0.99 and 0.97.

11) S. Fronæus, *Acta Chem. Scand.*, **5**, 859 (1951).

Calculations.—The following notations are used.

$(M)_T$, $(A)_T$= initial total concentrations of metal ion and anion in the outer solution respectively [mol./l.].

(M), (A)=total concentrations in the outer solution at ion-exchange equilibrium [mol./l.].

$(M)_r$=equilibrium total concentrations of the metal ion in the resin phase [mol./g.].

k_d=distribution coefficient of the total metal ion between the outer solution and the resin phase [l./g.].

$k_d^0=k_d$ at $(A)_T=0$.

K=formation constant.

δ=relative volume decrease of solutions caused by the swelling of the ion exchanger, or $=v/v_1=C_i/C$

When the eqilibrium

$$M+nA \rightleftarrows MA_n \quad (1)$$

exists in the solution, the formation constant can be expressed as

$$K=(MA_n)/(M)(A)^n \quad (2)$$

To obtain the value of the formation constant from the distribution constant k_d and anion concentration (A), the equation derived by Schubert can be used. From the equation

$$\log(k_d^0/k_d-1)=n\log(A)+\log K \quad (3)$$

the formation constant K can be obtained.

The k_d-values are calculated from the relation

$$k_d=(M)_r/(M) \quad (4)$$

The total metal concentration in the resin phase at equilibrium, $(M)_r$, can be calculated from the relation

$$(M)_r=\{(M)_T-(M)/\delta\}\times 25/1000 \quad (5)$$

As the $(M)_T$ was always kept very low, the formate ion concentration of the outer solution was influenced only by the swelling of the resin, not appreciably by the sorption of the complexes. Therefore, (A) was obtained from the relation

$$(A)\cdot\delta=(A)_T \quad (6)$$

Since the values of k_d vary with the $(M)_r$, 3 different values of k_d for 3 different values of $(M)_r$ were estimated for each metal ion, and the corresponding k_d-values were obtained as a function of (A) by interpolation or extrapolation.

Results and Discussions.—The measured data are rearranged and shown in Fig. 1 in order to calculate the formation constants from Eq. 3. As is seen in the figure, the straight lines, the solpes of which are nearly equal to 1, are obtained for Al^{3+}-, Ce^{3+}- and Mn^{2+}-formate ion systems. For Fe^{3+}-formate ion systems, not a straight line, but rather a curve is observed. The straight lines indicate that Al^{3+}, Ce^{3+} and Mn^{2+} mostly form a first order complex with formate ion; even if there were the higher orders, they would exist only slightly. But from the curve for the Fe^{3+}-formate system, it can be concluded that the complex ions between Fe^{3+} and formate ion include the complex ions of higher orders.

TABLE I. FORMATION CONSTANT OF THE SYSTEM OF FERRIC ION AND FORMATE ION

Formation constant			
$K_1(=\beta_1)$	70 ± 5	M^{-1}	
$K_1(=\beta_2)$	4100 ± 500	M^{-2}	K_2 60
$K_1(=\beta_3)$	9000 ± 3000	M^{-3}	K_3 2.5
$K_4(=\beta_4)$	250000 ± 120000	M^{-4}	K_4 28

where

$\beta_n=[Fe(HCOO)_n^{3-n}]/[Fe^{3+}][HCOO^-]^n$

$K_n=\beta/\beta_{n-1}$

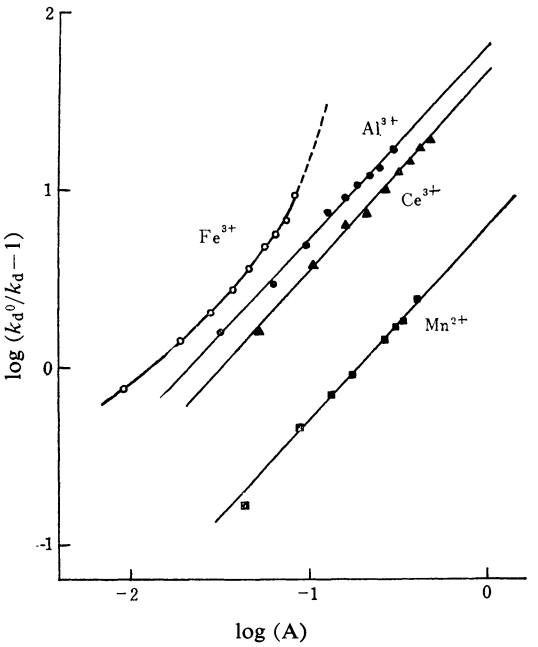

Fig. 1. Relations between log(A) and $\log(k_d^0/k_d-1)$ for Fe^{3+}, Al^{3+}, Ce^{3+}, and Mn^{2+}.

The formation constants for the system between Fe^{3+} and formate ion, therefore, were calculated by the Fronæus method[12],*. The results of the calculations gave four possible complex ions, as shown in Table I. Experiments using an anion exchange column were performed to confirm whether the complex anion, the 4th complex ion, exists or not. Thirty milliliters of the mixed solution of 1 M

* The Fronæus-method was also used to calculate the formation constants for Al, Ce and Mn, but the results were not conclusive because of too small values for the 2nd formation constants compared with the experimental errors.

TABLE II. FORMATION CONSTANT BETWEEN METAL IONS AND FORMATE ION

Metal ion	Codition of measurement (μ=ionic strength)	Method of measurement	Formation constant	Literature
Fe^{3+}	25°C, $\mu=1$	Ion-exchange method	$K_1=70\pm5$	This work
Al^{3+}	25°C, $\mu=1$	Ion-exchange method	61 ± 5	This work
Ce^{3+}	25°C, $\mu=1$	Ion-exchange method	45 ± 5	This work
Mn^{2+}	25°C, $\mu=1$	Ion-exchange method	6.3 ± 0.7	This work
Mg^{2+}	25°C, $\mu=0$	Potentiometry	27.0	10)
Ca^{2+}	25°C, $\mu=0$	Potentiometry	27.0	10)

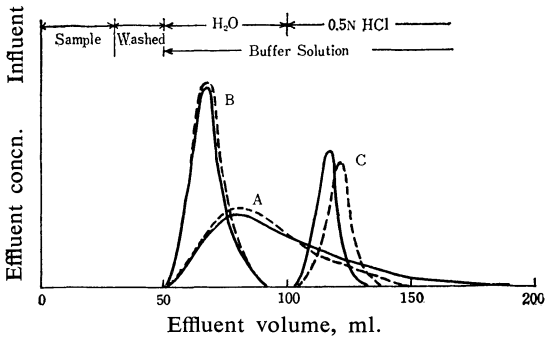

Fig. 2. Adsorption and elution of Fe^{3+} using anion-exchange column.
Curve——pH 3.2} 30 ml. of sample solution and 20 ml. of buffer solution washed
Curve----pH 3.6}
Peak A: eluted with buffer solution
B: washed with water (50 ml.)
C: eluted with 0.5 N HCl after washing with water (Peak B)

formic acid and 1 M ammonium formate containing 3 meq. of Fe^{3+} was passed through a 1.1×10 cm. column of Dowex 1-X4 (50~100 mesh) of formate form and then washed twice with 10 ml. of the mixed solution. Then, the complex ion was eluted with the same mixed solution or water, followed by 0.5 N hydrochloric acid. The results, which are shown in Fig. 2, seem to verify the presence of the anionic, the 4th complex ion.

The values of the formation constants between metal ions and formate ion measured by the author are shown in Table II, together, with the values reported by the other researcher[9]. The elution order from the cation exchanger expected from the table is

$$\text{Fe, Al, R. E. (Ce), Mn,} \quad (7)$$

and

$$\text{R. E., \{Mg, Ca\}, Sr, Ba} \quad (8)$$

To verify the conclusion mentioned above, a sample solution containing 6 meq. of iron(III) and 6 meq. of cerium(III) ions was passed through a 1.1×10 cm. column of Dowex 50-X8 (100~150 mesh) of a hydrogen form. After adsorption and washing, the ferric ion was eluted with 100 ml. of a mixed solution of pH 3.2 prepared from 7 parts of 1 M formic acid and 3 parts of 1 M ammonium formate. The cerous ion was eluted with 100 ml. of another mixed solution of pH 4.0 prepared from 3 parts of 1 M formic acid and 7 parts of 1 M ammonium formate. By this procedure, cerium free from iron was easily obtained, as had been expected.

As an example of separation with anion-exchange resin, the removal of iron(III) from rare earth and alkaline earth elements was carried out. Thirty milliliters of a mixed solution of 1 part of 1 M formic acid and 1 part of 1 M ammonium formate (pH about 3.6) containing 3 meq. of strontium and yttrium (labelled with ^{90}Sr-^{90}Y) was passed through a 1.1×10 cm. column of Dowex 1-X4*(50~100 mesh) of $HCOO^-$ from resin. After the sample solution had passed through, the column was washed twice, with 10 ml. of the buffer solution of the same pH and washed with 20 ml. of water; finally the column was regenerated with 0.5 N hydrochloric acid. The radioactivity of each portion was counted with a GM counter. The results are shown in Table III. It can be seen that only iron was adsorbed on the column, while cerium, yttrium and strontium were not. Thus, it was confirmed that iron could be easily removed from these samples.

As has been previously reported, mixed fission products were completely separated

TABLE III. REMOVAL OF IRON WITH ANION-EXCHANGE RESIN

Influent	Metals in effluent		
	Ce	Sr+Y	Fe
Sample	87.6%	85.7%	0
Washing solution 1	12.3	14.3	0
Washing solution 2	0.03	0.04	0
Washing solution and regenerating hydrochloric acid	0.01	0.01	100

* It is difficult to elute iron from ion-exchange resin of a high D.V.B. content.

using mixed solutions of formic acid and ammonium formate as elutriants[7], and alkaline earth elaments were completely separated by a similar solution[8] of a different pH.

The order of elution of several cations can be predicted by the values of the formation constants between the metal ions to be separated and the anion of the elutriant (cf. (7) and (8)).

However, the other experiments[12] gave slightly different results from those expected:

Fe, Al, Mn, R. E. (Ce), Mg, Ca, Sr, Ba

The elution of Mn and Mg earlier than expected from the formation constant may be attributed to the very small affinity of Mn^{2+} and Mg^{2+} to the resin[13].

From the results mentioned above, it was confirmed that the elution order can be predicted mainly on the basis of the values of the formation constants between the metal ions to be separated and the anion of the elutriant. The separation is easily effected when the difference in formation constants is large, but the separation is due both to formation constants and to affinities between the metal ions and the resin when the difference in formation constants is not large.

The author wishes to express his sincere appreciation to Professor Yasuo Miyake of Tokyo University of Education, Professor Hidetake Kakihana of Tokyo Institute of Technology, Dr. Yasushi Kitano of Nagoya University, and Mr. Masami Izawa of the National Institute of Radiological Sciences for their helpful advice and encouragement throughout his work.

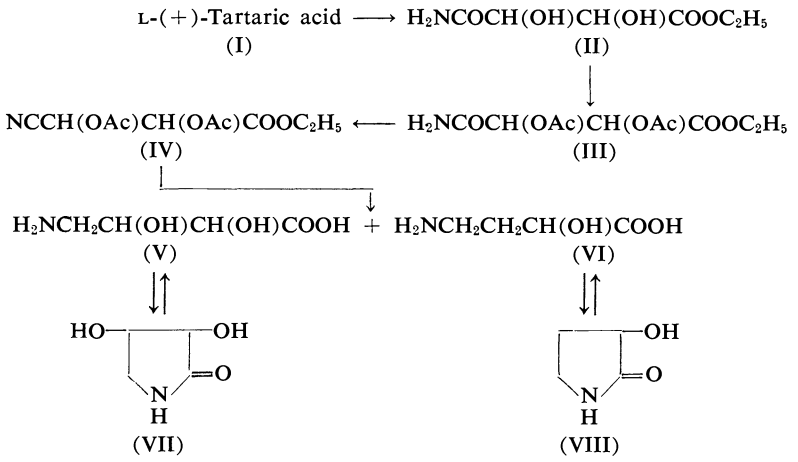
Syntheses of Some Amino Acids and Amino Aldehydes. IV. (+)-4-Amino-2, 3-dihydroxybutyric Acid

By Akira Yokoo and Susumu Akutagawa



(Received August 28, 1961)

The present authors have synthesized (+)-4-amino-2, 3-dihydroxybutyric acid from L-(+)-tartaric acid (I), which failed in crystallization, as reported in the first paper[1] of this series. Ethyl 3-aminocarbonyl-2, 3-dihydroxypropionate (II), obtained from commercial L-(+)-tartaric acid (I) by Weermann's method[2], was acetylated to give ethyl 3-aminocarbonyl-2, 3-diacetyloxypropionate (III). Dehydration of III yielded ethyl 3-cyano-2, 3-diacetyloxypropionate (IV), which was subjected to catalytic reduction over a platinum oxide catalyst in an acetic acid solution containing sulfuric acid to afford (+)-4-amino-2, 3-dihydroxybutyric acid (4-amino-4-desoxy-L-threonic acid) (V), m. p. 221~222°C (decomp.) (picrolonate, m. p. 198~200°C (decomp.)) and a compound of m. p. 195~196°C (decomp.) (picrolonate, m. p. 182~182.5°C (decomp.); phenylhydrazine salt, m. p. 128~129°C), was assumed to be 4-amino-2-hydroxybutyric acid acid (VI)[3]. On being heating above the melting point, V changed into 3,4-dihydroxy-2-oxopyrrolidine (VII), m. p. 139~142°C, which reformed into V by hydrolysis. In the same way, VI gave 3-hydroxy-2-oxopyrrolidine (VIII), b. p. 159~160°C/1 mmHg, and this reformed into VI.

Experimental

Ethyl 3-Aminocarbonyl-2, 3-dihydroxypropionate (II).—A solution of 200 g. of diethyl L-(+)-tartarate in 400 g. of absolute ethanol was saturated with dry ammonia at 0~3°C for less than 2 hr. After having been left standing for 2 hr. at 10°C, the solvent was removed at as low a temperature as possible under reduced pressure. The crystals formed were collected, washed with ethanol and then with ether. The crystals were heated with a smaller amount of absolute ethanol, and the insoluble diamide was filtered off. The ethanolic solution, on standing, gave 95 g. of crystals, m. p. 134~137°C.

1) A. Yokoo, *Bull. Tokyo Inst. Technol.*, **13**, 13 (1948), (*Chem. Abstr.*, **45**, 553).
2) R. A. Weermann, *Rec. trav. chim.*, **37**, 46 (1918).
3) E. Fischer, *Ber.*, **42**, 4880 (1909), **43**, 3272 (1910); A. Mori, *J. Biochem. (Japan)*, **46**, 59 (1959).

Ethyl 3-Aminocarbonyl-2,3-diacetyloxypropionate (III).—To a solution of 43 g. of II in 60 cc. of pyridine was added 70 g. of acetic anhydride. After having been left standing overnight, the pyridine was removed under reduced pressure and ether was added. The crystals formed were collected and washed with ether. The crystals were heated with 80 cc. of absolute ethanol, and some insoluble materials were removed by filtration. To the ethanolic solution was added twice the volume of ether, and any insoluble material was filtered off. The solution was concentrated to a smaller volume under reduced pressure. The crystals formed on standing were filtered and washed with a small amount of ethanol to yield 33 g. of III, m. p. 95~96°C.

Found: N, 4.47. Calcd. for $C_{10}H_{15}O_7N \cdot C_2H_5OH$: N, 4.56%.

After being heated for 2 hr. at 150°C, the nitrogen content was 5.17% (calcd. for $C_{10}H_{15}O_7N$: N, 5.36%).

Ethyl 3-Cyano-2, 3-diacetyloxypropionate (IV).—To 20 g. of cooling III was gradually added 80 g. of phosphorous oxychloride. After the resulting mixture had been heated for 30 min. on a water bath, the remaining oxychloride was removed almost completely under reduced pressure. Ice was added to cool the residue, which was then extracted with ether. The ethereal solution was washed with a sodium carbonate solution and dried over anhydrous sodium sulfate. The ether was removed, and vacuum distillation gave 11 g. of a colorless viscous oil, b. p. 172~174°C/21 mmHg.

Found: N, 5.48. Calcd. for $C_{10}H_{13}O_6N$: N, 5.76%.

(+)-4-Amino-2, 3-dihydroxybutyric Acid (V) and 4-Amino-2-hydroxybutyric Acid (VI).—A solution of 10 g. of IV in 60 cc. of gacial acetic acid containing 2 g. of concentrated sulfuric acid was reduced for 2 hr. at 60°C in an autoclave in the presence of 1 g. of platinum oxide at an initial pressure of hydrogen 62 atm. The catalyst was filtered off and the acetic acid was removed under reduced pressure. After dilution of the residue with 130 cc. of water, 15 g. of lead acetate was added and the mixture was heated and filtered. The filtrate was treated with hydrogen sulfide, filtered and concentrated to a syrup under reduced pressure. The syrup was refluxed with 100 cc. of 6 N hydrochloric acid for 6 hr. and evaporated to dryness under reduced pressure. Water was added to the residue, which was then treated hot with silver oxide and filtered. The filtrate was again treated with hydrogen sulfide and evaporated to dryness as before. The residue was dissolved in a small amount of water and left to stand in order to deposit crystalline V. This was collected and recrystallized from water to yield 0.8 g. of colorless crystals, m. p. 221~222°C (decomp.), $[\alpha]_D^{27} = +42°$ (water).

Found: C, 35.35; H, 6.77; N, 10.13. Calcd. for $C_4H_9O_4N$: C, 35.55; H, 6.71; N, 10.37%.

Picrolonate of V.—A solution of V and picrolonic acid in water was heated and left to stand. The crystals formed were recrystallized from dilute ethanol to give orange yellow crystals, m. p. 198~200°C (decomp.).

Found: N, 16.50. Calcd. for $C_4H_9O_4N \cdot C_{10}H_8O_5N_4 \cdot H_2O$: N, 16.78%.

The mother liquor of V was evaporated to dryness under reduced pressure, and the residue was dissolved in a small amount of water. Ethanol was added until turbidity took place. The crystals deposited on standing were collected and dissolved in a small amount of water. Methanol was added while hot until the solution became turbid, and the solution was then left to stand. The solution, together with the formed crystals, was warmed for a while, the insoluble crystals of V were filtered off, and again the solution was left to stand. The crystals finally formed were recrystallized from dilute methanol to give 1.05 g. of VI, m. p. 195~196°C (decomp.).

Found: C, 40.20; H, 7.67; N, 12.02. Calcd. for $C_4H_9O_3N$: C, 40.33; H, 7.62; N, 11.76%.

Picrolonate of VI. was obtained, as in the case of V, and recrystallized from water in the form of orange yellow crystals, m. p. 182~182.5°C (decomp.).

Found: N, 18.53. Calcd. for $C_4H_9O_3N \cdot C_{10}H_8O_5N_4$: N, 18.27%.

The picrolonates have shown a melting point depression on admixture with 4-amino-3-hydroxybutyric acid prepared by Tomita's method[4].

4) M. Tomita, *Z. physiol. Chem.*, **124**, 253 (1923).

3,4-Dihydroxy-2-oxopyrrolidine (VII).—After heating 0.7 g. of V in an oil bath at 230°C for 30 min. under diminished pressure (water pump), water was added, treated with decolorizing carbon and evaporated to dryness under reduced pressure. The residue was taken up in ethanol, and a little ether was added. The crystals formed were recrystallized from ethanol to give 0.25 g. of VII, m. p. 139~142°C.

Found: C, 40.99; H, 6.27; N, 12.19. Calcd. for $C_4H_7O_3N$: C, 41.02; H, 6.03; N, 11.96%.

2,4-Dinitrophenylhydrazone of VII.—The crude 2,4-dinitrophenylhydrazone of VII was recrystallized from ethanol to give orange plates, m. p. 163~165°C.

Found: N, 23.95. Calcd. for $C_{10}H_{11}O_6N_5$: N, 23.56%.

Hydrolysis of VII.—A mixture of 0.2 g. of VII and 5 cc. of 6 N hydrochloric acid was refluxed for 2 hr. and evaporated to dryness under reduced pressure. The residue was dissolved in water, treated with silver oxide and then with hydrogen sulfide. The filtrate was evaporated to dryness and dissolved in a small amount of water. A little methanol was added, and the solution was left to stand to deposit crystals, which were recrystallized as before. The crystals, m. p. 219~220°C (decomp.), did not depress the melting point on mixed fusion with V.

3-Hydroxy-2-oxopyrrolidine (VIII).—After 0.5 g. of VI had been heated in a tiny Claisen flask at 215~220°C for 20 min., vacuum distillation gave 0.25 g. of VIII, b. p. 159~160°C/1 mmHg, which on standing solidified as strongly hygroscopic crystals.

Found: N, 13.89. Calcd. for $C_4H_7O_2N$: N, 13.86%.

VIII did not give 2,4-dinitrophenylhydrazone.

Phenylhydrazine Salt of VI.—A mixture of 0.1 g. of VIII, 0.3 g. of phenylhydrazine and 0.3 g. of commercial glacial acetic acid was heated at 130~135°C for 30 min. The crystals deposited on standing were recrystallized from ethanol to form colorless crystals, m. p. 128~129°C.

Found: N, 18.56. Calcd. for $C_4H_9O_3N \cdot C_6H_8N_2$: N, 18.49%.

This salt did not depress the melting point on admixture with that derived from VI.

The authors take this opportunity to express their sincere gratitude to the Ministry of Education for its grant-in-aid for Scientific Research and also to Dr. A. Kondo (the Department of Organic Chemistry of Tokyo Institute of Technology) for carrying out the carbon and hydrogen microanalyses.

Effects of Nonelectrolytes on the Temperature of the Maximum Density of Water. I. Alcohols

By Goro WADA and Saburo UMEDA*

(Received April 17, 1961)

The well-known fact that water exhibits its maximum density at 3.98°C under an atmospheric pressure has been discussed by one of the present authors in the previous paper[1] from the viewpoint of the two-state model stating that water holds a chemical equilibrium between the icy and the closely packed states. It may be an interesting problem how the temperature of the maximum density of water varies when a minute quantity of a foreign substance is dissolved in it. The effects of some simple electrolytes on the temperature of the maximum density have already been measured[2], and, so far as is known, electrolytes lower the temperature of the maximum density of water at a rate nearly proportional to the concentrations of electrolytes in dilute solutions, obeying the so-called Despretz's rule[3]. However, nothing is yet known about the effects of nonelectrolytes upon the temperature of the maximum density of water. The authors, therefore, intend in the present paper to find the correlation between the change in the temperature of the maximum density of water and the chemical constitution of some added organic substances, especially of various uni- and polyvalent alcohols.

Experimental

Apparatus and Procedure.—The dilatometer used for the measurement of the volume change of

aqueous solutions with temperature is shown in Fig. 1. Its shape as a whole was of a twisted-W type with a capacity of about 300 cc., to which was attached at either end a vertical capillary 0.6 mm. in inside diameter. This enabled us to detect a volume change in a solution as small as 3×10^{-5}% by observing the movement of the liquid surface in the capillary tubes as the temperature was varied. In order to fill the dilatometer with a sample solution, one of the ends of the capillaries was connected with the reservoir of a solution and the other with an aspirator. On working the aspirator, it had been verified preliminarily that no appreciable change in concentration owing to the fractional evaporation of the individual volatile components of the solution occurred during the transfer of the solution from the reservoir to the dilatometer. The height of the surface of the solution which had been introduced was adjusted to be nearly at the center of each capillary by the advance use of a thin injector.

The temperature of the thermostat was regulated within ±0.005°C. The dilatometer attained thermal equilibrium with the thermostat in half an hour. The change in volume was observed in the temperature range covering ±2°C of the temperature of the maximum density of the solution at intervals of about 0.5°C. The apparent volume of a solution does not show a minimum at its true temperature of the maximum density owing to the thermal expansion of the dilatometer itself. The changes in the casese of pure water and aqueous solutions, in the height of the liquid surface with a change in temperature near the respective temperatures of the maximum density, however, were found to be quite similar in type to each other, irrespective of the nature of the solution as long as the solution was very dilute. The temperature of the maximum density of the sample could, therefore be determined, graphically by comparing the apparent volume change of pure water with that of the sample. This method was very accurate, with a maximum error of ±0.02°C*.

Materials.—Sixteen alcohols, including uni- and polyvalent ones, were used for the experiments; these alcohols were purified by usual methods and were ascertained to be pure enough for the present purpose as judged from boiling points, melting points, densities and refractive indices. Pure water was prepared by passing distilled water obtained from an alkaline permanganate solution, through columns of ion-exchange resin.

* The maximum errors ever reported in cases of electrolyte solutions were as large as ±0.2°C.

Results

The elevation of the temperature of the maximum density ΔT is defined as

$$\Delta T = T_m - T_{m_0} \qquad (1)$$

where T_{m_0} represents the temperature of the maximum density of pure water and T_m that of a sample solution of mole fraction x of alcohol respectively. The observed values of ΔT at various concentrations of various alcohols are shown in Table I.

As examples of ternary systems, a mixture of ethyl alcohol, *tert*-butyl alcohol and water and one of *tert*-butyl alcohol, potassium chloride and water were adopted, the concentration of *tert*-butyl alcohol being kept constant at 0.10×10^{-2} mol./H_2O-mol. in the former and that of potassium chloride at 0.11×10^{-2} and 0.20×10^{-2} mol./H_2O-mol. in the latter. The results are pictured in Figs. 2 and 3.

* In case of polyvinyl alcohol, x represents the fraction of OH groups. The experimental errors are somewhat larger than in the case of other alcohols, caused by the special properties of its solution. The authors thank Dr. T. Mochizuki of Kurashiki Rayon Co. Ltd. for the supply of polyvinyl alcohol.

Discussion

Preliminary Considerations. — It should be pointed out with reference to Table I that although no substance which elevates the temperature of the maximum density of water has hitherto been known, methyl alcohol, ethyl alcohol, *n*-propyl alcohol, isopropyl alcohol, *sec*-butyl alcohol and *tert*-butyl alcohol are now found for the first time to be surely such substances, at least in dilute concentrations. It is especially worth attention that the ΔT of a *tert*-butyl alcohol solution reaches as high as 0.41°C at the concentration $x=0.0043$. Except for the cases mentioned above, ΔT's are usually negative, similar to those of all electrolyte solutions. Instead of obeying Despretz's rule, which states that the ΔT is proportional to the concentration, they fall off more rapidly than the change in concentration.

If a small quantity of liquid substance dissolves in water with neither an increase nor a decrease in the total volume, the resulting volume V of the aqueous solution at θ°C is expressed by

$$V=xV_s+(1-x)V_w \tag{2}$$

where V_s and V_w are the molar volumes of the solute and water respectively at θ°C. Since it is reasonably accepted that V_s increases linearly with temperature over a small temperature range of 0~5°C, while V_w is satisfactorily expressed by a parabolic function of the temperature in the vicinity of its minimum, namely the maximum density of water, the following relations can be given:

$$V_s=V_{s_o}(1+\alpha\theta) \tag{3}$$

$$V_w=V_{w_m}\{1+\beta(\theta-3.98)^2\} \tag{4}$$

in which V_{s_o} and V_{w_m} represent V_s at 0°C and V_w at 3.98°C respectively, and α and β are coefficients relating to the thermal expansion of the respective substances. From the condition $dV/d\theta=0$ at the temperature of the maximum density of the solution, we obtain

$$T_m'=-\frac{x}{1-x}\cdot\frac{\alpha}{2\beta}\cdot\frac{V_{s_o}}{V_{w_m}}+3.98 \tag{5}$$

where T_m' signifies the imaginary temperature of the maximum density of a solution if the solution were an ideal mixture without any appreciable interaction between the solute and water. The imaginary elevation of the temperature of the maximum density ΔT_n is, therefore, as follows:

$$\Delta T_n=T_m'-T_{m_o}=-\frac{x}{1-x}\cdot\frac{\alpha}{2\beta}\cdot\frac{V_{s_o}}{V_{w_m}} \tag{6}$$

According to Eq. 6, ΔT_n should always be negative in ideal systems and should be approximately proportional to the solute concentration as long as the concentration is very low. Therefore, the elevation of the temperature of the maximum density of real solutions owing to mutual interaction between the solute and water, $\Delta T'$, can be defined as follows:

$$\Delta T'=\Delta T-\Delta T_n \tag{7}$$

The necessary values to estimate ΔT_n are the following: $\beta=7.80\times10^{-6}$ deg^{-2}, $V_{w_m}=18.016$ cc./mol., and α's and V_{s_o}'s for various alcohols as listed in Table II. The values of $\Delta T'$ thus obtained are shown in Table I, together with those of ΔT, the former also being approximately represented by an empirical equation of the second order with respect to the concentration

$$\Delta T'=ax+bx^2 \tag{8}$$

because $\Delta T'/x$ versus x is represented by a straight line, as are some examples shown in

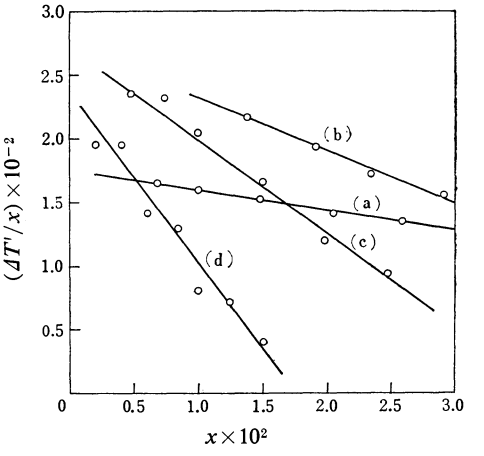

Fig. 4. Linearity of $\Delta T'/x$ against x. (a) Methyl alcohol, (b) ethyl alcohol, (c) *n*-propyl alcohol, (d) *n*-butyl alcohol.

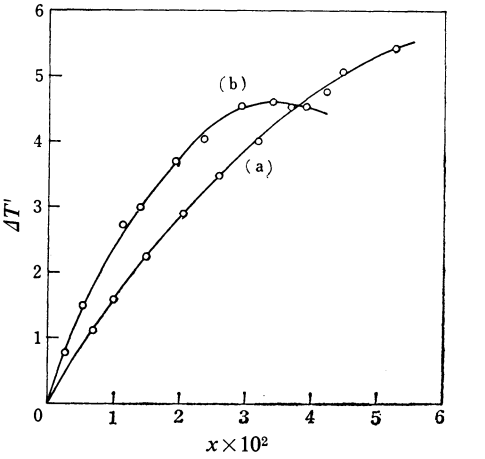

Fig. 5. Variation of $\Delta T'$ with the concentration of (a) methyl alcohol and (b) ethyl alcohol.

Fig. 4*. Parameters a and b obtained graphically for respective alcohols are also shown in Table II.

The General Tendency of $\Delta T'$, a and b.—In order to discuss the mutual interactions between alcohols and water, it is rather convenient to pay attention to the relationships of $\Delta T'$, instead of ΔT, with the concentration; these relationships are reproduced in Figs. 5—8. Generally speaking, the values of $\Delta T'$ for univalent alkyl alcohols are always positive, while those for polyvalent alcohols show a trend toward being negative. In the cases of propyl alcohols and butyl alcohols, the branching of the alkyl radicals is found to have a clear enhancing effect on $\Delta T'$. Moreover, it should be pointed out in Table II that a's are positive only for all univalent alcohols, while b's are negative for all alcohols adopted here, and that the absolute values of both a and b

* In Fig. 4, the plots of $\Delta T'/x$ at very low concentrations of alcohols are omitted because they are subject to larger errors.

increase as the volumes of alkyl radical become larger.

Nature of a. — On mixing the solute and water, if there were no interaction between the two species, $\Delta T'$ should be zero. In reality, however, interaction occurs to some extent, so that α and V_{s_0} vary as much as $\Delta\alpha$ and ΔV_{s_0} respectively; therefore, $\Delta T'$ can be expressed as follows:

$$\Delta T' = -\frac{x}{1-x} \cdot k(\alpha \Delta V_{s_0} + V_{s_0} \Delta\alpha) \qquad (9)$$

Moreover, from Eqs. 8 and 9 one obtains the next relation:

$$a \equiv \lim_{x \to 0} \left(-\frac{\mathrm{d}\Delta T'}{\mathrm{d}x} \right) = -k(\alpha \Delta V_{s_0} + V_{s_0} \Delta\alpha) \qquad (10)$$

where $k = 1/2\beta V_{w_m}$. In these expressions, ΔV_{s_0} and $\Delta\alpha$ are assumed to include the total changes in volume and in the coefficients of the thermal expansion not only of the solute itself but also of the hydration sheaths formed round the solute molecules where the interaction wholly takes place, β and V_{w_m} being regarded as constant.

Univalent alcohol is taken to exist in the form of hydrogen-bonded chains in a pure liquid state[4] but when it is dissolved in water, there occurs the breaking of the hydrogen bondings between alcohol molecules and, succeedingly, the hydration of the water molecules surrounding them. Since the energies of the hydration are higher than those of hydrogen-bond formation in case of univalent alcohols, the contraction of the volume owing to the compression by hydration exceeds the expansion owing to the breaking of hydrogen bondings and, consequently perhaps, $\Delta V_{s_0} < 0$. Moreover, since water undergoes a transition from the free state (an equilibrating mixture of the icy state and the packed state[1]) to another state similar to the packed state when water hydrates to the solute molecules, $\Delta\alpha$ must be positive, because the coefficients of the thermal expansion of water of the icy state and the packed state are 1.52×10^{-4} and 1.013×10^{-3} deg^{-1} respectively[1]. Accordingly, the first term in the parenthesis in the right-hand side of Eq. 10 should be negative, while the second term is positive. In Table II, since the a's for all univalent alcohols except phenol are positive, the absolute value of the first term must be larger than that of the second term in every alcohol*. Especially, the fact that the magnitude of a for *tert*-butyl alcohol is extraordinarily large may be attributed to the greatness of α itself.

Owing to the intramolecular hydrogen bondings of ethylene chlorohydrin, ethylene glycol, propylene glycol and glycerin, and owing to the intermolecular association of phenol, they are greatly contracted by a strong cohesive force and show a relatively small V_{s_0} compared with those of non-substituted corresponding univalent alcohols in a pure state**. Consequently, ΔV_{s_0} may be nearly equal to zero or rather positive when they are dissolved in water. In such cases, the a's may be smaller than those of univalent alcohols and at last negative in certain instances, as can be seen in Table II.

Tendency of b. — Since b is, on the other hand, the parameter of the second-order term with respect to the concentration in Eq. 8, it may be related to the mutual interaction between the solute molecules themselves. However, the tendencies for b to be negative for all substances so far as have been observed and for the absolute value of b to become larger as the molecular volume of the substance is larger can not be interpreted at the present stage of investigation.

Ternary Systems. — Figure 2 illustrates the variation of ΔT with x of ethyl alcohol in curve a as a binary system and in curve b as a ternary one, *tert*-butyl alcohol being kept at a constant concentration of 0.10×10^{-2} mol./H_2O-mol. as a third substance. ΔT in the ternary system is found to be always smaller than the sum of the ΔT's which ethyl alcohol and *tert*-butyl alcohol will exhibit independently in binary systems. This fact shows that there exists a mutual interaction between the molecules of the different alcohols to disturb their individual behavior.

The situation is, on the contrary, quite different in Fig. 3. Curve a is true for *tert*-butyl alcohol only, while curves b and c correspond to the cases when potassium chloride is added to it as a third substance at 0.11×10^{-2} and 0.20×10^{-2} mol./H_2O-mol. respectively. When curve a is moved down parallel to the axis as far as -0.74 and -1.34°C, it just falls on curves b and c respectively. These distances

* The fact that a tends to become larger when the alkyl chain of univalent alcohol is longer, as is seen in Table II, can be understood from the observed thermochemical data that the energy of the dissolution of $-CH_2-$ from paraffin into water is about 0.8 kcal./mol.[5] and that the longer the alkyl radical of univalent alcohol, the larger its hydration energy[6].

5) K. Kinoshita, H. Ishikawa and K. Shinoda, This Bulletin, **31**, 1081 (1958).

6) S. Seki and K. Suzuki, ibid., **26**, 63 (1953).

** For instance, ethylene chlorohydrin and ethylene glycol should be compared with ethyl alcohol, the former being derivatives of the latter by substituting H by Cl and OH respectively.

between the curves agree well with the ΔT's which potassium chloride exhibits when it exists alone in water at those respective concentrations. This fact indicates that *tert*-butyl alcohol and potassium chloride do not greatly influence one another in such dilute solutions.

As to the phenomena of the solvation of ions, it is known that only the hydration is overwhelmingly predominant when the concentration of alcohol is less than 10 mol. %, since water molecules are attracted to ions far more preferentially than alcohol molecules at the solvation equilibrium in ternary systems of lithium chloride-ethyl alcohol-water[7], of lithium fluoride-methyl alcohol-water[8] and of lithium fluoride-ethyl alcohol-water[8]. Considering all these facts, nonelectrolytic molecules and electrolytic ions may exhibit independent behavior in dilute aqueous solutions.

Summary

The effects of various kinds of alcohol on the temperature of the maximum density of water were observed. The results revealed are as follows:

1) The change in the temperature of the maximum density due to alcohols, ΔT, is not proportional to the solute concentration, disobeying Despretz's rule and in contrast with ordinary electrolytes.

2) The ΔT for univalent aliphatic alcohols at low concentrations is generally positive; that for *tert*-butyl alcohol is the largest. The ΔT is likely to become high as the number of carbon atoms and the degree of branching in alkyl radicals increase.

3) The elevation of the temperature of the maximum density due to the interaction of alcohol and water, $\Delta T'$, depends upon the weakness of the cohesion of alcohol and the strength of the hydration of the hydrophilic molecules.

4) As the concentration of alcohol increases, there occurs a lowering of ΔT as a result of interaction between the solute molecules themselves. Similar interactions are seen between different alcohol molecules in ternary systems, but can not be seen between alcohol and electrolytic ions, where the solutes behave independently of each other. In the last case, the additivity of ΔT is realized fairly well.

Studies of the Cage Effect of Solvent. I. Photolysis of Azomethane in n-Hexane

By Sukeya KODAMA

(Received August 31, 1961)

The concept of the cage effect of solvent molecules given in 1936 by Frank, Rabinowitch and Wood[1] has since then frequently been used to explain such experimental findings as the low quantum yield in a photochemical reaction in solution. The presence of the cage effect has been reported in a number of thermal, photochemical or radiation-induced decomposition reactions of the following substances: iodine[2], acetyl peroxide[3], butyryl peroxide[4], α, α'-azobisisobutyronitrile[5], halides[6], etc. To date, however, reliable quantitative studies of the cage effect have been meagre.

It has been found by the present author that the photolysis of azomethane in solution

exhibits a large cage effect; photolysis has therefore been investigated in various solvents. This paper reports on the study in *n*-hexane solution. The results obtained in other solvents will be reported in a later paper.

Experimental

Materials. — Azomethane was prepared by the thermal decomposition[7] of azomethane-cuprous chloride[8] produced from dimethyl hydrazine dihydrochloride[9], purified by removing water and carbon dioxide with calcium chloride and soda lime respectively and by several-times-repeated distillation from a dry ice-acetone trap to a liquid nitrogen trap in vacuo, and stored in a reservoir protected from light. *n*-Hexane was purified as follows: the commercial hexane of a chemically pure grade was repeatedly washed with chlorosulfonic acid for about a month, stirred with alkaline and acid potasium permanganate solutions, washed with sodium carbonate and water, dried over phosphorus pentoxide, and distilled; the fraction 68 to 69°C was then collected. The hexane thus purified showed no absorption in the wavelength range above 250 mμ. Styrene was used as a scavenger of methyl radicals because of its large methyl affinity[10]. It was also purified by vacuum distillation.

Apparatus.—The photolysis was carried out with 366 and 313 mμ obtained from an ultra-high pressure mercury lamp of 100 Watt (Mazda, SHL-100UV). The filter used for 366 mμ was UV-D1 (Mazda). The transmission ratios of 334 and 390 mμ to 366 mμ were about 6 and 1% respectively. For 313 mμ a 1.8 M solution of nickel sulfate 1 cm. in thickness was used, with a glass plate to cut off the light of shorter wavelengths than 290 mμ. The transmission ratios of 334 and 300 mμ to 313 mμ were roughly 29 and 22% respectively.

The reaction cell used for the photolysis below room temperature was a glass cylinder 3.6 cm. in diameter and 1.0 cm. in length, with a capacity of 10 ml. It was connected to the other parts of the apparatus by a mercury cut-off. For the experiments above room temperature, a cell of the same size but with two side tubes was used. One of these side tubes was made of capillary tubing, and was sealed off after the introduction of the reactants, and the other had a breakable seal for analysis of the products. All the side tubes were made of brown-colored glass to prevent the decomposition of azomethane vapor in those parts. A non-plated Dewar vessel was used as a bath in the experiments with 366 mμ, but for those with 313 mμ a copper-made bath equipped with a quartz window was used.

The Procedure.—Before use hexane was subjected to thrice-repeated bulb-to-bulb distillation using dry ice-acetone and was introduced into the reaction cell. When styrene was used as a scavenger, it was introduced into the cell in a similar way. Azomethane was also purified each time before use by condensation and evacuation at −160°C; it was then introduced into the reaction cell cooled with liquid nitrogen. After closing the mercury cut-off or sealing off the capillary tubing, the cell was warmed to room temperature to get a complete mixing of azomethane with hexane. The cell was then immersed in the bath at the experimental temperature and the photolysis started. The mercury cut-off was used also as a manometer, to measure both pressures of hexane and azomethane and the increase in pressure due to the photolysis.

The reaction cell was cooled with dry ice-acetone after the irradiation was over, and it was connected to the analytical system by the mercury cut-off or by the breakable seal. The cell contained hexane, undecomposed azomethane, nitrogen, methane, ethane, various by-products, and styrene if used. The gaseous components were separated by twice-repeated bulb-to-bulb distillation at the dry ice-acetone temperature and cooled to −160°C to condense azomethane, hexane vapor and by-products. Ethane was then condensed at the liquid nitrogen temperature. Nitrogen and methane that were not condensed were collected in a Toepler gauge, and the sum of their amounts were determined. The mixture was then sent into a platinum combustion tube, where the methane was burnt to carbon dioxide and water. By removing the water by condensation, the amount of carbon dioxide was determined; this gave in turn the amount of methane and, accordingly, that of nitrogen. Ethane condensed in the liquid nitrogen trap was evaporated, collected in the Toepler gauge, and its quantity determined.

Results

Table I shows the results obtained at 0°C. V is the volume of the solution at the reaction temperature. CH_4/N_2 and C_2H_6/N_2 represent respectively the yields of methane and ethane referred to nitrogen. The material balance for nitrogen, methane and ethane is represented by $((1/2)CH_4+C_2H_6)/N_2$, since two

methyl radicals and a nitrogen molecule are obtained from an azomethane molecule. The extent of conversion was less than 6% in all the runs except in Runs 3 and 4, where it was nearly 10%.

Runs 1 and 2 show the results of the photolysis of azomethane vapor carried out in comparison with those in solution. Figure 1 shows the variation in yields of methane and ethane with the concentration of styrene in the series of Runs 13−16.

Table II shows the effect of temperature on the photolysis with 366 mμ. The concentration of azomethane in each run was about 3×10^{-2} mol./l. The conversion in each run was again less than 6%. Figure 2 summarizes the results given in Tables I and II, $(CH_4/N_2)_s$ and $(C_2H_6/N_2)_s$ denoting respectively the yields of methane and ethane in the presence of styrene of 3.16 to 3.48 mol. %.

Figure 3 shows the effect of temperature on the quantum yield of photolysis determined as follows: Runs 1—4 show that the ratio of the quantum yield in solution against that in

the vapor phase is 0.65; since in the vapor phase the quantum yield is reported to be unity[11], those in solution at various temperatures are obtained by comparing rates of the formation of nitrogen. However, in view of various uncertainties involved, the quantum yields thus determined have to be taken only as apparent values.

Discussion

The photolysis of azomethane has been studied in the gas phase by a number of workers[11,12] The mechanism that accounts for the main products, i. e., methane, ethane and nitrogen, is relatively simple and can be represented as

$$(CH_3)_2N_2+h\nu \rightarrow 2CH_3+N_2$$
$$CH_3+(CH_3)_2N_2 \rightarrow CH_4+CH_3N_2CH_2$$
$$CH_3+CH_3 \rightarrow C_2H_6$$

The following addition reactions of methyl radicals have also been proposed to explain the fate of methyl radicals that are not accounted for by methane and ethane:

$$CH_3+(CH_3)_2N_2 \rightarrow (CH_3)_3N_2$$
$$CH_3+(CH_3)_3N_2 \rightarrow (CH_3)_4N_2$$
$$CH_3+CH_2N_2CH_3 \rightarrow C_2H_5N_2CH_3$$

The possibility of the direct formation of ethane by the primary process has been excluded by the experiments carried out with a scavenger such as nitric oxide[12a] and butadiene[12b]. The decomposition into three fragments in the primary act may actually take place in two stages, i. e.,

$$(CH_3)_2N_2+h\nu \rightarrow CH_3N_2+CH_3$$
$$\text{and } CH_3N_2 \rightarrow CH_3+N_2$$

However, since the radical CH_3N_2 is very short-lived[13], such a two-stage decomposition cannot be discriminated from that given above so far as subsequent reactions are concerned.

On the basis of the mechanism thus established in the gas phase, the possible reactions in *n*-hexane solution may be supposed as follows:

$$(CH_3)_2N_2+h\nu \rightarrow [2CH_3+N_2] \quad (1)$$
$$[2CH_3+N_2] \rightarrow C_2H_6+N_2 \quad (2)$$
$$\rightarrow CH_3+N_2+CH_3 \quad (3)$$
$$[2CH_3+N_2]C_6H_{14} \rightarrow CH_4+C_6H_{13}+N_2+CH_3 \quad (4)$$
$$[2CH_3+N_2]C_6H_5C_2H_3 \rightarrow C_6H_5C_3H_6+N_2+CH_3 \quad (5)$$
$$CH_3+C_6H_{14} \rightarrow CH_4+C_6H_{13} \quad (6)$$
$$CH_3+CH_3 \rightarrow C_2H_6 \quad (7)$$
$$CH_3+(CH_3)_2N_2 \rightarrow CH_4+CH_2N_2CH_3 \quad (8)$$
$$\rightarrow (CH_3)_3N_2 \quad (9)$$
$$CH_3+C_6H_{13} \rightarrow C_6H_{13}CH_3 \quad (10)$$
$$CH_3+C_6H_5C_2H_3 \rightarrow C_6H_5C_3H_6 \quad (11)$$
$$C_6H_{13}+C_6H_{13} \rightarrow C_{12}H_{26} \quad (12)$$
$$\rightarrow C_6H_{14}+C_6H_{12} \quad (13)$$

The parenthesis in the primary process denotes that two methyl radicals and a nitrogen molecule are formed together in a solvent cage. Reactions 2 and 3 represent respectively the ethane formation in the solvent cage and the separation of the two methyl radicals from each other by diffusion. Reaction 4 is the hydrogen atom abstraction by one of the

13) The decomposition of the CH_3N_2 radical is exothermic by some 29 kcal./mol. (Ref. 14). Sleppy and Calvert (Ref. 12) failed to detect the radical spectroscopically in a flash photolysis of azomethane.
14) C. Steel and A. F. Trotman-Dickenson, *J. Chem. Soc.*, **1959**, 975.

methyl radicals from a solvent molecule constituting the cage, and reaction 5 is an analogue in the case where a styrene molecule participates in constituting the cage. Reactions 6—10 represent various possibilities for methyl radicals distributed at random in the solution. Reaction 11 shows the scavenger action of styrene. Reactions 12 and 13 give possible fates other than reaction 10 for hexyl radicals formed by reaction 6.

The sequence of reactions given above is only a crude picture, but the results obtained in the present work may be discussed by referring to these reactions. The reactions that explain the formation of ethane are those numbered from 2 and 7. As shown in Tables I and II and in Fig. 1, the addition of styrene in an increasing amount reduces the yield of methane nearly to zero, whereas that of ethane remains unaffected, indicating that ethane is formed exclusively by reaction 2 or by the combination of methyl radicals in the solvent cage. Even in the absence of styrene, the results obtained lead to the same conclusion: If ethane is formed by reaction 7, its rate should be proportional to the second power of the steady concentration of methyl radicals, while the rate for methane would be simply proportional to its first power, Runs 3—9, given in Table I, show, however, that the yields of methane and ethane are not affected by increasing the concentration of azomethane, i. e., by increasing the amount of azomethane decomposed per unit time.

As to the formation of methane, the most important process may be supposed to be reaction 6. The effect of styrene shown in Tables I and II and in Fig. 1 is consistent with what is expected for this reaction. Reaction 8 cannot be important, since the mole ratio of azomethane (to *n*-hexane) is (of the order) of 10^{-3} in the present work and the rate constants for reactions 6 and 8 may be of the same order of magnitude[15]. The contribution of reaction 4 is also negligible. If this reaction were important, reaction 5 should also be important; otherwise, the nearly complete suppression of methane formation by styrene could not be explained. However, if reaction 5 were important, the yield of ethane should be reduced in the presence of styrene, which contradicts what was actually found to be true.

The quantum yield of photolysis is, as has been already described, less than unity in *n*-hexane solution, and Fig. 3 shows that it decreases markedly with the lowering of the temperature. In general, a low quantum yield less than unity may be accounted for either by the deactivation of excited substrate molecules or by the recombination of the primary products in the solvent cage, provided that no substrate molecules are regenerated by secondary reactions. Studies of the yield of fluorescence in solution show, however, that quenching by deactivation usually increases with the rise in temperature[16]. The observed falling off of the quantum yield with the lowering of the temperature seems, therefore, to have resulted from the recombination of the initially formed radicals CH_3N_2 and CH_3 in the solvent cage, though the former radical is short-lived, as has been described above, and may not take part in subsequent reactions.

The decomposition of the azomethane molecule into two metyl radicals and a nitrogen molecule requires an energy of 22 kcal./mol[14]. Hence, the photolysis with 366 mμ produces an excess energy of 56 kcal./mol. Though how this excess energy is distributed among the three fragments formed is not clear, there is a possibility that hot methyl radicals are thus formed. In fact, Sleppy and Calvert[12c] concluded, in a flash photolysis of azomethane vapor, the formation of hot methyl radicals from the effect of wavelengths on the yield ratio CH_4/C_2H_6 and from the effect of the addition of C_2F_6. In ordinary photolysis of azomethane, however, no indication of their existence has been reported. Also, in this work, as is shown in Table I, the irradiation with 313 mμ gave almost the same result as that for 366 mμ, although the energy difference between the two mercury lines is not very large (13 kcal./mol.).

As is shown in Fig. 4, the dependence of the yield of ethane on the temperature is approximately represented by

$$1-C_2H_6/N_2=A\exp(-E/RT)$$

with $A=2.08$ and $E=1.17$ kcal./mol. Though the energy value found here probably has some correlation with the diffusion energy of methyl radicals in *n*-hexane, the latter quantity cannot be computed directly from such an energy value since the formula given above is merely an empirical one[17].

15) The rate constants in the gas phase are $k_6=10^{11.1}\exp(-8100/RT)$ and $k_8=10^{11.1}\exp(-7600/RT)$ mol^{-1} cc. sec^{-1}. (A. F. Trotman-Dickenson, "Gas Kinetics", Butterworths, London (1955), p. 200.)

16) For example, E. J. Bowen and J. Sahn, "Photochemistry in the Liquid and Solid States", Ed. by F. Daniels, John Wiley and Sons, Inc., New York and London (1960), p. 55.

17) A simple treatment of reactions 6 and 7 leads to an expression

$$C_2H_6/N_2=k_6/(k_6+k_7)$$

or

$$[1-(C_2H_6/N_2)]/(C_2H_6/N_2)=k_7/k_6$$

where k_6 and k_7 are respective rate constants. If, therefore, k_6 is assumed to be independent of temperature, the Arrhenius plot of the quantity on the left-hand side of the latter equation can be expected to yield the diffusion energy of methyl radicals. The results given in Table II, however, do not give a linear plot, indicating that such a treatment is too crude.

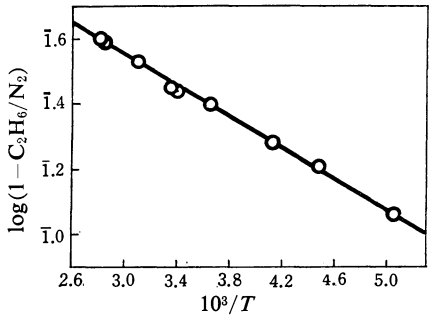

Fig. 4. Arrhenius plot of $1-C_2H_6/N_2$.

As seen in Table II and Fig. 2, the material balance referring to methane and ethane, $((1/2)CH_4+C_2H_6)/N_2$, is nearly 100% below room temperature but slightly falls off at higher temperatures. As has been proposed in the gas phase, the loss in the material balance may be ascribed to addition reactions of methyl radicals such as reactions 9 and 11.

There have been found a number of compounds similar to azomethane in that three fragments are formed by the decomposition of a substrate molecule. Some examples are acetone[18], ethyl methyl ketone[19], diethyl ketone[19], acetyl peroxide[3], butyryl peroxide[4] and dimethyl mercury[20]. None of them, however, have been reported to show such a large cage effect as has been found in the present work. The reason why azomethane behaves exceptionally probably comes from the way in which it decomposes. As has been already described, in the case of azomethane two methyl radicals and a nitrogen molecule are formed almost simultaneously, while in other cases, the decomposition of a substrate molecule probably occurs more clearly in two stages:

$$XYZ \rightarrow XY+Z$$
$$XY \rightarrow X+Y$$

If, therefore, the lifetime of the XY radical is sufficiently large[21], it will become separated from the radical Z before decomposition, and the cage combination $X+Z \rightarrow XZ$ will not be observed. It may still be expected in this case that the recombination $XY+Z \rightarrow XYZ$ takes place in the solvent cage and that this will result in a lowering of the quantum yield, as has been found in the present work. However, such a cage recombination cannot be estimated from quantum yields unless the deactivation of excited substrate molecules is proven to be absent.

20) D. H. Derbyshire and E. W. R. Steacie, ibid., 32, 457 (1954).
21) It takes a time of the order of 10^{-11} sec. at ordinary temperatures for the two solute molecules enclosed together in a solvent cage to become separated from each other, provided that they do not react with each other (R. M. Noyes, *J. Am. Chem. Soc.*, 77, 2042 (1955)).

Summary

Azomethane in *n*-hexane solution has been decomposed by irradiation of 366 mμ over the temperature range -75 to 80°C, in order to study the effect of the solvent cage on the photolysis. The main products have been found to be nitrogen, methane and ethane. The yield of methane increases, but that of ethane, which amounts to 88% of nitrogen at -75°C, decreases with the rise in temperature. The addition of styrene as a scavenger for methyl radicals in an increasing amount suppresses the formation of methane almost completely, while that of ethane is not affected, indicating that ethane is exclusively formed by the cage combination of an azomethane molecule. The formation of methane is explained by the abstraction of the hydrogen atom from a solvent molecule by methyl radicals that have escaped the original cage. The material balance represented as $((1/2)CH_4+C_2H_6)/N_2$ is nearly 100% below room temperature, but it falls off slightly at higher temperatures; this may be ascribed to addition reactions of methyl radicals. The quantum yield of photolysis is apparently smaller than unity and falls off with a lowering of the temperature; this probably arises from the cage recombination of the initially formed pair of radicals CH_3N_2 and CH_3, though the former radical is very short-lived.

The present author is particularly indebted to Professor Osamu Toyama of the College of Engineering for his discussions and encouragement during this investigation. The author wishes also to thank Mr. Yoshiaki Nishimoto for his assistance.

Studies of the Cage Effect of Solvent. II. Photolysis of Azomethane in Various Solvents

By Sukeya KODAMA

(Received August 31, 1961)

It has been reported in a previous paper[1] that ethane, a major product in the photolysis of azomethane in *n*-hexane, is formed exclusively by the combination of a pair of methyl radicals resulting from the substrate molecule in the solvent cage. The photolysis of azomethane in solution thus provides a good example of the cage effect that can be studied quantitatively.

This paper reports the results of a series of experiments carried out to investigate the dependence of the above cage combination of methyl radicals on the nature of the solvent. The solvents selected were *n*-octane, ethanol, ethyl acetate and toluene. They are widely different from each other in molecular structure and in property, and all of them are transparent to the 366 mμ used for the photolysis.

Experimental

The preparation, purification and storage of azomethane have previously been described[1]. *n*-Octane was prepared from *n*-butyl bromide by the Wurts reaction and purified in a way similar to that described for *n*-hexane. Ethanol, ethyl acetate and styrene, used as a scavenger of methyl radicals, were all taken from commercial samples of a special high grade and were used without further purification. Toluene, also obtained from a commercial sample, was boiled with anhydrous aluminium chloride, washed with water, repeatedly shaken with concentrated sulfuric acid until the latter was not colored, washed with a solution of sodium carbonate and with water, dried over calcium chloride and phosphorus pentoxide, and distilled. All the solvents thus obtained were subjected to thrice repeated vacuum distillation each time before use.

The apparatus and procedure were similar to those previously described[1]. A mercury line of 366 mμ was used for the photolysis throughout the whole series of experiments. The extent of conversion in each run was usually less than 4%. In the experiments with toluene it was less than 7%. The concentration of azomethane in each run was fixed at about 3×10^{-2} mol./l., because the previous study showed little dependence of yields of products on the substrate concentration. The volume of the solution in each experiment was adjusted so that it just filled the reaction cell of ca. 10 ml. capacity at the experimental temperature.

1) S. Kodama, This Bulletin, 35, 652 (1962).

Results

Tables I—IV and Figs. 1 and 2 show the results obtained. CH_4/N_2 and C_2H_6/N_2 represent the yields of methane and ethane respectively, since the number of moles of nitrogen formed is equal to that of the azomethane decomposed. $((1/2)CH_4+C_2H_6)/N_2$ gives the material balance referring to methane and ethane.

Figure 3 shows the apparent quantum yields obtained by comparing the rate of formation of nitrogen in a given solution with that in *n*-hexane solution, for which the apparent quantum yield is already known[1].

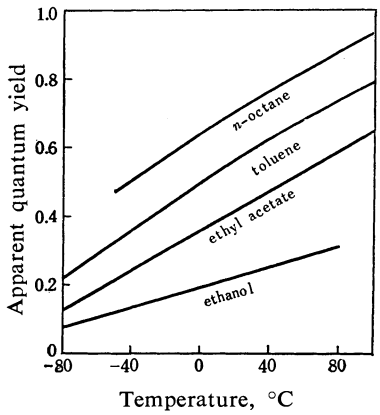

Fig. 3. Dependence of apparent quantum yield on temperature in various solvents.

Discussion

A comparison of the results given in Tables I—IV and Figs. 1 and 2 with those obtained with *n*-hexane[1] shows that the main feature of the photolysis is not affected by the nature of the solvent. Hence, on similar grounds to those previously given, the formation of the main products, i. e., nitrogen, methane and ethane, may be represented as:

$$(CH_3)_2N_2+h\nu \rightarrow [2\,CH_3+N_2] \quad (1)$$

$$[2\,CH_3+N_2] \rightarrow C_2H_6+N_2 \quad (2)$$

$$\rightarrow CH_3+N_2+CH_3 \quad (3)$$

$$CH_3+HR \rightarrow CH_4+R \quad (4)$$

where the parenthesis denotes the solvent cage and HR, the solvent. The hydrogen atom abstraction from azomethane molecules by methyl radicals may be far less important compared to reaction 4. Again, the loss in the material balance, $1-((1/2)CH_4+C_2H_6)/N_2$, may be ascribed to addition reactions such as

$$CH_3+(CH_3)_2N_2 \rightarrow (CH_3)_3N_2 \quad (5)$$

$$CH_3+R \rightarrow CH_3R \quad (6)$$

and the suppression of the formation of methane by styrene to

$$CH_3+S \rightarrow CH_3S \quad (7)$$

where S represents styrene.

As seen in Fig. 3, the quantum yield falls off with a lowering of the temperature in all the solvents investigated; this phenomenon may be ascribed to the recombination of a pair of initially formed radicals, CH_3N_2 and CH_3, in the solvent cage, as previously inferred for the *n*-hexane solution. What the different apparent values of the quantum yield shown in the figure have resulted from cannot be answered for the present. It may be that the absorption curve of azomethane in solution is different from solvent to solvent, but measurements of this have not yet been reported. It may, however, be noted that these apparent quantum yields have some correlation with the dipole moments of the solvents. The latter values are 0(*n*-octane), 0.4(toluene), 1.70 (ethanol) and 1.74 *D*(ethyl acetate); in Fig. 3 the apparent quantum yield increases in reverse order, except for ethanol. The apparent quantum yields in *n*-hexane[1], *n*-octane and cyclohexane[2], whose dipole moments are all zero, have been found to be almost identical at all the temperatures investigated. Ethanol, which apparently gives an exceptionally low quantum yield, is well-known by its tendency to form the hydrogen bond. A comparison of the results given in Tables I—IV with those previously obtained with *n*-hexane shows that the yield of ethane and its dependence on the temperature are rather insensitive to the nature of the solvent. As shown in Fig. 4, the results obtained with various solvents can all be represented by an empirical formula

$$1-C_2H_6/N_2=A\exp(-E/RT)$$

which has been previously found to be applicable to the results obtained with *n*-hexane. The values of the constants *A* and *E* determined from these plots are given in Table V, together with those for *n*-hexane[3]. It is seen that the

2) S. Kodama, ibid., to be published.

3) Although the quantity $1-C_2H_6/N_2$ represents the fraction of methyl radicals that escaped the solvent cage, the constant *E* cannot be taken as the diffusion energy of methyl radicals in solution, as was pointed out in the previous paper.

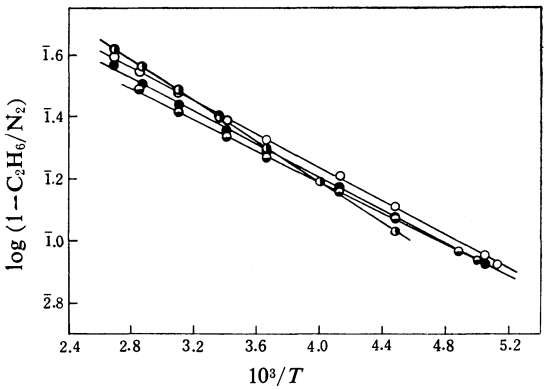

Fig. 4. Arrhenius plots of $1-C_2H_6/N_2$. ○, ethyl acetate; ◒, ethanol; ●, toluene; ◑, *n*-octane.

TABLE V. VALUES OF ARRHENIUS CONSTANTS OBTAINED FROM FIG. 4

Solvent	A	E kcal./mol.
Ethyl acetate	2.22	1.29
Ethanol	1.48	1.12
Toluene	1.90	1.24
n-Octane	2.40	1.51
n-Hexane	2.08	1.17

dependence of the constants A and E on the nature of the solvent is rather small, as has been stated above.

The yield of methane shows a somewhat greater dependence on the nature of the solvent. As has already been described, the values of the material balance $((1/2)CH_4+C_2H_6)/N_2$ show that a small fraction of the methyl radicals is probably lost by addition reactions. Consequently, the greater the number of methyl radicals lost in this way, the lower is the yield of methane. Table III and Fig. 2 show that the relatively low yield of methane above room temperature in the case of toluene arises from a relatively large loss of methyl radicals, which loss may be ascribed to the contribution of the addition of methyl radicals to toluene molecules taking place in this case in addition to those already given. On the other hand, the relatively low yields of methane found with ethanol result from relatively high yields of ethane and not from enhanced addition reactions.

In the presence of styrene as a scavenger, it competes with the solvent for methyl radicals. Accordingly, it follows in the steady state that

$$k_7/k_4=R_{CH_3S}/R_{CH_4}\cdot[HR]/[S]$$

where R's denote respective rates and k's, rate constants. The ratio R_{CH_3S}/R_{CH_4} is obtained by

$$R_{CH_3S}/R_{CH_4}=[(CH_4/N_2)_0-(CH_4/N_2)_S]/(CH_4/N_2)_S$$

where $(CH_4/N_2)_S$ represents the yield of methane in the presence of styrene and $(CH_4/N_2)_0$, that in its absence. Consequently,

$$k_7/k_4=[(CH_4/N_2)_0-(CH_4/N_2)_S]/(CH_4/N_2)_S\cdot[HR]/[S]$$

If, therefore, the rate constant k_4 is known, k_7 is obtained from the observed values of $(CH_4/N_2)_0$ and $(CH_4/N_2)_S$. This is the same principle as that applied by Szwarc[4] to determine the methyl affinities of various compounds in the thermal decomposition of acetyl peroxide.

For the solvents here investigated, exact Arrhenius expressions of k_4 are unknown, but they are expected to have similar activation energies. Figure 5 shows the Arrhenius plots of k_7/k_4 for the results obtained with ethyl acetate and with *n*-hexane[1]. The two plots are parallel to each other and, accordingly, give the same value of 3.2 kcal./mol. for E_4-E_7. The value of E_4 for *n*-hexane is reported as 8.1 kcal./mol.[5] E_7 is therefore obtained as 4.9 kcal./mol.

Figure 5 shows that the frequency factor of the hydrogen atom abstraction from *n*-hexane molecules by methyl radicals is about four times as great as that for ethyl acetate. This can be explained if secondary hydrogen atoms are preferentially abstracted, since the ratio of the number of secondary hydrogen atoms in the two kinds of molecule is just four[6].

The value of 3.2 kcal./mol. found above for

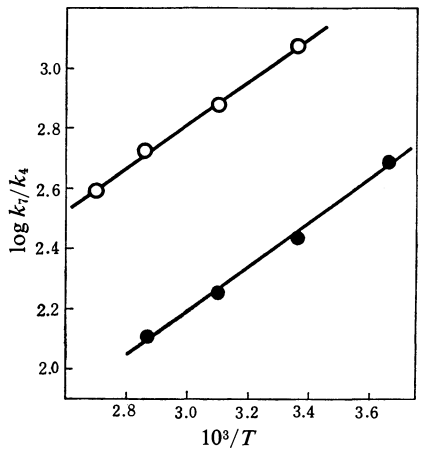

Fig. 5. Arrhenius plots of k_7/k_4 for the results obtained with ethyl acetate and *n*-hexane. ○, ethyl acetate; ●, *n*-hexane.

4) M. Levy and M. Szwarc, *J. Chem. Phys.*, **22**, 1621 (1954); *J. Am. Chem. Soc.*, **77**, 1949 (1955).

5) A. F. Trotman-Dickenson, J. R. Birchard and E. W. R. Steacie, *J. Chem. Phys.*, **19**, 163 (1951).

6) It has been found that the rate of hydrogen atom abstraction by methyl radicals depends on the nature of the hydrogen atom abstracted, and, in general, the order of the reactivity of hydrogen atoms is tertiary>secondary >primary (R. K. Brinton, *Can. J. Chem.*, **38**, 1339 (1960)).

E_4—E_7 is in good agreement with the result obtained by Szwarc[7] with isooctane. However, the reported values of the ratio of rate constants k_7/k_4 in the latter case are higher than those for ethyl acetate shown in Fig. 5. This is contrary to what would be expected, since the isooctane molecule has a tertiary hydrogen atom in addition to as many secondary hydrogen atoms as the ethyl acetate molecule. The reason for this discrepancy is not clear.

Summary

The photolysis of azomethane in *n*-octane, toluene, ethyl acetate and ethanol has been investigated over the temperature range from about −80 to 100°C. The results obtained are very similar to those previously obtained with *n*-hexane and show that, also in these solvents, the ethane, one of the main products, exclusively results from the combination in the solvent cage of a pair of methyl radicals formed from an azomethane molecule. For all the solvents investigated, the temperature dependence of the yield of ethane referred to nitrogen formed, C_2H_6/N_2, can be represented by an empirical expression, $1-C_2H_6/N_2 = A\exp(-E/RT)$, with constants A and E, whose values are rather insensitive to the nature of the solvent. From the reduction of the yield of methane in the presence of styrene, the activation energy of the addition of methyl radicals to styrene molecules is estimated as 4.9 kcal./mol. Apparent quantum yields obtained by comparing the rates of formation of nitrogen fall off with a lowering of the temperature in all the solvents investigated.

The present author is particularly indebted to Professor Osamu Toyama of the College of Engineering for his discussions and encouragement during this investigation. The author wishes also to thank Mr. Katsuji Makino for his assistance.

On the Mechanism of Pulp Bleaching. V. Further Investigations on the Residual Lignosulfonic Acid in Unbleached Sulfite Pulp*

By Koichiro SATO, Akio KOBAYASHI and Hiroshi MIKAWA

(Received February 20, 1961)

The residual lignosulfonic acid in unbleached spruce (*Picea jezoensis*) sulfite pulp has previously been partly dissolved out by intensive beating of the fiber in water[1]. Nearly 20% of the total amount of the residual lignosulfonic acid was thus isolated as barium salt in a pure state and analyzed. The material was isolated from the beating water obtained after beating the fiber until no lignin dissolved. In the present communication the beating of the fiber is described step by step. The paper also tells how the residual lignosulfonic acids dissolved during each step were isolated separately and analyzed to see if any differences exist between these fractions.

As has been reported previously[1], the residual lignosulfonic acid remaining undissolved in the beaten pulp was extracted further by dimethyl sulfoxide together with carbohydrate. It was confirmed that no chemical linkages exist between the two components. This residual lignosulfonic acid was prepared in a pure state and analyzed. Nitrobenzene oxidation of the residual lignosulfonic acids obtained by beating and by dimethyl sulfoxide extraction is described in the present communication, and the yields of vanillin obtained both from these residual lignosulfonic acids and from ordinary α-lignosulfonic acid separated from waste liquor are compared.

The authors also attempt to compare the amount of lignin extracted by beating and by dimethylsulfoxide with the amount of lignin remaining in the pulp undissolved by these processes.

* Presented in part at the Third Lignin Symposium of Japan, November, 1958.

Step by Step Dissolution of Residual Lignin from Soft Wood Unbleached Sulfite Pulp

Emerton reported[2] that the fibrillation of the fiber begins at the so-called P and S_1 layers when the pulp is beaten by an ordinary beater, and proceeds gradually to the inner layer of the fiber. The fiber is fibrillated first to fibrils and then to microfibrils. It is therefore expected that the residual lignosulfonic acid dissolved in the early stage of the beating comes more or less from the outer layer of the fiber cell wall, perhaps from the P and S_1 layers, and from the rather coarse fibrils; on the other hand, that dissolved in the later stage of the beating is from the S_2 and S_3 layers or from fine fibrils.

Unbleached sulfite pulp prepared from *Picea jezoensis* and *Abies mariana* (3 : 1, 1500 g.) was beaten, just as has been reported previously, changing the beating water at appropriate intervals, and six fractions of the residual lignosulfonic acid were prepared (Table I). The first four fractions thus obtained were analyzed for sulfur, sulfonic acid sulfur, and methoxyl. The total amount of the phenolic hydroxyl group was estimated by the so-called $\Delta\varepsilon$-method[3]. Types I and II phenolic hydroxyl groups and carboxyl group were estimated as usual by a combination of conductometric titration and the ultraviolet absorption spectra[4]; the results of the analyses are shown in Table II. Here, the values of the functional groups are shown on a methoxyl basis, as it is already clear from the previous communication[1] that the number of methoxyl groups per C_9-unit is approximately one. Not much variation was observed throughout these fractions. The average of the analytical values shown in the lower part of the table is calculated from the analytical values and the yield of the fractions.

Nitrobenzene Oxidation of the Residual Lignosulfonic Acid Isolated from Unbleached Sulfite Pulp

Among the many reactions of lignin which are used to discover differences in the structure of lignins, ethanolysis and nitrobenzene oxidation are very well studied and are very often used. As has been already reported[1], the amount of the type I phenolic hydroxyl group of the residual lignosulfonic acid is lower than that of ordinary α-lignosulfonic acid separated from the waste liquor, suggesting the existence of some difference in nuclear structure between these two lignosulfonic acid preparations.

2) H. W. Emerton, *TAPPI*, **40**, 542 (1957).
3) G. A. Erdtman, *Svensk Papperstidn.*, **55**, 745 (1952).
4) H. Mikawa, K. Sato, T. Takasaki and K. Ebisawa, This Bulletin, **28**, 653 (1955).

The authors have therefore attempted to see if any difference can be observed in vanillin yields when nitrobenzene oxidation is applied to ordinary α-lignosulfonic acid (from sulfite waste liquor), to residual lignosulfonic acid separated from the unbleached sulfite pulp (by beating), and to that separated by dimethyl sulfoxide extraction of the beaten sulfite unbleached pulp. The nitrobenzene oxidation of the lignin was performed according to Stone's micro method[5]; the results are shown in Table III.

TABLE III. YIELDS OF VANILLIN OBTAINED BY NITROBENZENE OXIDATION OF ORDINARY α-LIGNOSULFONIC ACID, OF RESIDUAL LIGNOSULFONIC ACIDS EXTRACTED BY BEATING AND OF THAT EXTRACTED WITH DIMETHYL SULFOXIDE

	CH_3O% (Ba-salt)	Yield of vanillin % (methoxyl basis)	Aver.
α-Lignosulfonic acid	11.4	26.4 25.8	26.1
Residual lignosulfonic acid (beating)	10.8	28.6 24.0	26.3
Residual lignosulfonic acid (dimethyl sulfoxide)	11.8	26.2 24.8	25.5

As can be seen from Table III, there is not much difference in the yields of vanillin from these lignin preparations. It is well known that ether linkages in lignin at position 4 are cleaved by nitrobenzene oxidation. Leopold[6] reports that acetoguaiacyl-dihydrodehydro-di-isoeugenol and octahydro-tri-(acetoguaiacyl)-acetoguaiacon methyl ether give vanillin by nitrobenzene oxidation in a yield of 60~80% of the theoretical. Purves[7] and Pew[8] recognized the formation of a considerable amount of vanillin from a veratryl type structure.

Probably not such a large difference exists between the etherified structural units of the lignosulfonic acids separated from the waste liquor and from unbleached sulfite pulp to give different vanillin yields, although the amount of the type I phenolic hydroxyl group in the former acid is a little higher than that in the latter acid, as has been stated previously.

On the Lignin Balance in the Beating and Extraction with Dimethyl Sulfoxide of Unbleached Sulfite Pulp

The lignin balance in the beating of unbleached sulfite pulp in water and its extraction with dimethyl sulfoxide was determined by measuring the amount of the residual lignosulfonic acid remaining unextracted in the pulp. Twenty-seven grams of unbleached sulfite pulp (*Picea jezoensis*+*Abies mariana* 3:1) were beaten in a Lampen mill for about 40 hr. with 800 ml. of water. A small amount of beaten pulp was, with a little water, taken out from the mill six times during the beating. The pulp was filtered, and the water was diluted twelvefold and measured for ultraviolet absorption at 280 mμ, from which the amount of the dissolved lignosulfonic acid was calculated (Fig. 1). The pulp was suspended in alcohol and filtered with a fine glass filter to make an extremely thin paper. Ten milligrams of the thin paper thus prepared were shaken with 25 ml. of 85% phosphoric acid (free from ultraviolet absorption near 280 mμ) for 12 hr. in a 50 ml. glass tube[9], and the ultraviolet absorption of the solution thus obtained was measured at 280 mμ (Fig. 2). As can be seen in Figs. 1 and 2, the absorption curves are typical for lignosulfonic acid, having a maximum and minimum at 280 and 260 mμ respectively. The values of the maximum optical density at 280 mμ of Figs. 1 and 2 are plotted in Fig. 3 against the duration

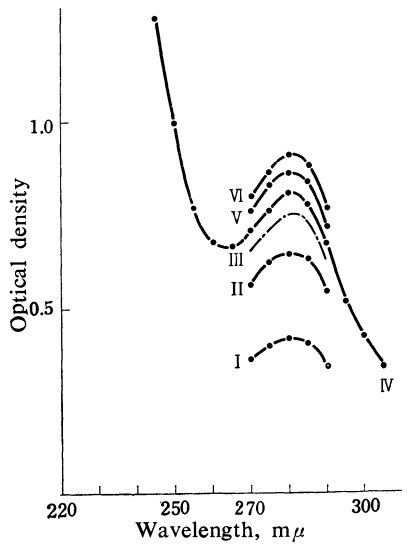

Fig. 1. Ultraviolet absorption curves of beating water obtained at various stages of beating. Curve I, absorption after beating 6 5/6 hr.; II, 20 1/3 hr; III, 25 2/3 hr.; IV, 30 2/3 hr.; V, 35 55/60 hr.; VI, 40 55/60 hr.

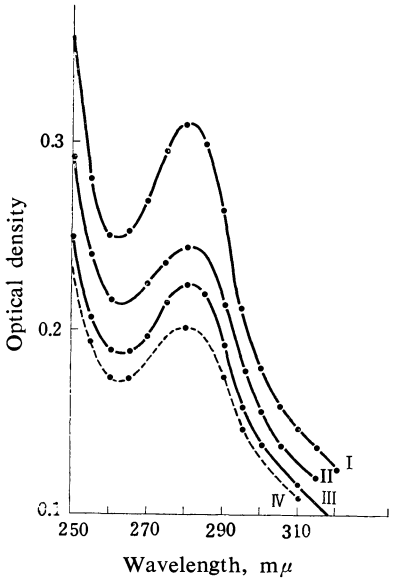

Fig. 2. Ultraviolet absorption curves of phosphoric acid solutions of beaten pulps. Curve I, original pulp; II, pulp beaten for 20 1/3 hr.; III, pulp beaten for 30 55/60 hr.; IV, pulp beaten for 30 55/60 hr. and extracted with dimethyl sulfoxide.

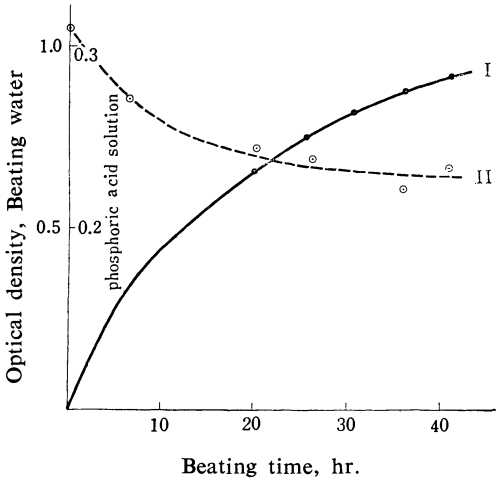

Fig. 3. Optical density at 280 mμ of beating water and phosphoric acid solution of beaten pulp at various stages of beating. Curve I; Beating water, measured after twelvefold dilution. Curve II; Phosphoric acid solution of beaten pulp. (10 mg. of the pulp in 25 ml. of 85% H_3PO_4)

of the beating. Curve I, the optical density of the beating water, continues to increase even after 40 hr., showing that the lignosulfonic acid continues to dissolve even after this time, although the rate of dissolution is small at this time. Curve II, showing the decrease of the ultraviolet absorption of the phosphoric

TABLE IV. LIGNIN BALANCE IN THE EXTRACTION OF UNBLEACHED SULFITE PULP BY BEATING AND BY DIMETHYL SULFOXIDE

	mmol. of CH_3O estimated by UV-absorption		%
	Remaining in pulp*1	Dissolved in solution*2	
Unbleached sulfite pulp used	6.52	—	100
Beating water*3	—	2.73	42
Beaten pulp	4.17	—	64
Dimethyl sulfoxide*4 solution	—	1.13	17
Extracted pulp*5	3.13	—	48

*1 Estimated from the ultraviolet absorption of the phosphoric acid solution of the pulp at 280 mμ.

*2 Estimated from the ultraviolet absorption of the solutions at 280 mμ.

*3 The yield of the residual lignosulfonic acid in this solution is 416 mg. when 27 g. of unbleached pulp are used.

*4 The yield of the dimethyl sulfoxide extract (residual lignosulfonic acid+carbohydrate) in this solution is 353 mg. when 27 g. of unbleached pulp are used.

*5 The mechanical loss of the pulp is about 8%.

acid solution, demonstrates that the rate of decrease of the residual lignosulfonic acid in the beaten pulp is very small after about 40 hr. Assuming the molar absorption coefficient of lignosulfonic acid per methoxyl group as 3200, the amounts of the residual lignosulfonic acid both dissolved and remaining undissolved in the pulp are calculated and listed in Table IV.

The pulp residue remaining after having been beaten for 40 hr. was separated by a centrifuge, washed successively with alcohol, ether and petroleum ether, and dried. The bone dry pulp thus obtained was defibrated by a Bauer

disk refiner and extracted with dimethyl sulfoxide (700 ml.) for 48 hr. with occasional shaking, centrifuged and extracted with the same amount of fresh dimethyl sulfoxide three times more. The ultraviolet absorption spectrum of the dimethyl sulfoxide solution thus obtained is characteristic of lignosulfonic acid, having a maximum and minimum at 280 and 265 mμ respectively; the values of maximum absorption at 280 mμ decrease as shown in Fig. 4 from the first extract to the fourth extract. The amount of the residual lignosulfonic acid in the combined dimethyl sulfoxide extract was estimated from the ultraviolet absorption, assuming the molar absorption coefficient of the lignin at 280 mμ as 3200 per methoxyl, and the residual lignosulfonic acid remaining in the pulp after dimethyl sulfoxide extraction was estimated from the ultraviolet absorption of the phosphoric acid solution of the pulp in just the same manner as has been described above. The results are summarized in Table IV, where the amounts of lignosulfonic acid are expressed in methoxyl group units.

As can be seen from the table, the amount of the residual lignosulfonic acid dissolved by beating is 42%, and the residual lignosulfonic acid remaining in the beaten pulp is 64% of the total amount of residual lignosulfonic acid which existed in the pulp. The amount dissolved by beating, calculated from the lignin remaining in pulp, 100−64=36%, is in good agreement with 42%. The total amount of residual lignosulfonic acid dissolved by beating and by dimethyl sulfoxide extraction is 42+17=59% of the total lignin which existed in the pulp, which is in good agreement with the dissolved amount calculated from the amount remaining undissolved in the extracted pulp, 100−48=52%.

Summary

1) By beating unbleached sulfite pulp step by step and changing the beating water, four fractions of residual lignosulfonic acids were obtained. Analytically not very distinct differences were observed between these fractions.

2) The residual lignosulfonic acids isolated by beating and by dimethyl sulfoxide were oxidized with nitrobenzene, and the yields of vanillin obtained from these lignin preparations were comparad with that from ordinary lignosulfonic acid separated from waste liquor. Almost no difference was observed.

3) The amounts of residual lignosulfonic acid dissolved by beating and by dimethyl sulfoxide extraction were in good agreement with those calculated from the amount of the residual lignosulfonic acid remaining in the pulp, thus proving the accuracy of the estimation. Approximately 40 and 20% of the total lignin in unbleached sulfite pulp were dissolved by beating and by dimethyl sulfoxide extraction respectively.

The authors wish to express their thanks to Professor Yoshikazu Hachihama for his encouragement, and also to the Kokusaku Pulp Ind. Co., Ltd., for permission to publish this paper.

*Thermodynamic Studies on Cobalt Complexes. X. Chemical Equilibrium between Aquopentamminecobalt(III) Complex and Oxalate Ion**

By Ryokichi TSUCHIYA

(Received August 7, 1961)

It was found in the preceding paper[1] of this series that, when the oxalate ion in the mixed solution of oxalic acid and potassium oxalate reacted with the diaquotetramminecobalt(III) ion, the oxalate ion coordinated as a bidentate ligand, producing an oxalatotetrammine cobalt-(III) ion. On the other hand, when ammonium oxalate reacted with the diaquotetramminecobalt(III) ion, an oxalatopentamminecobalt-(III) ion containing an oxalate inon as a unidentate ligand was produced. As is thus shown, the oxalate ion coordinates as a bidentate ligand in some cases and as a unidentate ligand in others.

* Read at the Symposium on Coordination Compounds of the Chemical Society of Japan, Sendai, September, 1960.

1) M. Mori, R. Tsuchiya and E. Matsuda, This Bulletin, **34**, 1761 (1961).

An oxalatopentamminecobalt(III) ion was also produced when the oxalate ion in the mixed solution of oxalic acid and potassium oxalate reacted with the aquopentamminecobalt-(III) ion.

In the present study, the chemical equilibrium between aquopentamminecobalt(III) and oxalate ions is examined spectrophotometrically, just as in the preceding paper[1], to find the thermodynamic properties of the oxalatopentamminecobalt(III) complex. By combining this result of the equilibrium with that between the diaquotetramminecobalt(III) and oxalate ions, the difference in the thermodynamic properties between the oxalatotetramminecobalt(III) and oxalatopentamminecobalt(III) ions, the former containing an oxalate ion as bidentate ligand and the latter as a unidentate ligand, is discussed.

Experimental

Aquopentamminecobalt(III) perchlorate was prepared by the method of Jörgensen[2]. When the buffer solution, consisting of oxalic acid and potassium oxalate, was added to the aqueous solution of aquopentamminecobalt(III) perchlorate at room temperature, the reaction did not take place, but it proceeded when the solution was heated to 65°C. It was found, as is shown below, by spectral and electric conductivity measurements that the reaction product was an oxalatopentamminecobalt(III) complex, in which the hydrogenoxalate ion was contained as a unidentate ligand.

The electric conductivity of the oxalatopentamminecobalt(III) complex in an aqueous solution was measured by a Yanagimoto Conductivity Outfit Model MY-7. The measurement of the equilibrium was made spectrophotometrically by using a Hitachi EPU 2-type spectrophotometer in the same way as in the case of the reaction between a diaquo-complex and an oxalate. The maximum of the first absorption band of aquopentamminecobalt(III) ion is at $\nu=61.6$ ($\log\varepsilon=1.62$)[3], while that of the oxalatopentamminecobalt(III) ion produced is at $\nu=59.2$ ($\log\varepsilon=1.87$)[4]. Since the equilibrium was shifted toward the aquo-complex, the measurement of the absorbancy was made at 490 mμ. A brown flask was used as the reaction vessel to prevent photodecomposition. The measurement of the pH of the solution at equilibrium was carried out with a Horiba HRL Model M pH meter.

Results

Figure 1 shows the absorption spectra of the solution at the equilibria of the reaction of aquopentamminecobalt(III) perchlorate at different concentrations with the buffer solution consisting of oxalic acid and potassium oxalate at different concentrations. The absorption spectra of aquopentamminecobalt(III) and oxalatopentamminecobalt(III) ions are also shown in this figure. It is presumed from this figure that the reaction product between aquopentamminecobalt(III) and oxalate ions is an oxalatopentamminecobalt(III) ion.

TABLE I. MOLECULAR CONDUCTANCES OF OXALATOPENTAMMINECOBALT(III) OXALATE AT DIFFERENT CONCENTRATIONS IN AN AQUEOUS SOLUTION AT 25°C

Values calcd. as $[Co(NH_3)_5HC_2O_4]C_2O_4$	Values calcd. as $[Co(NH_3)_5C_2O_4]_2C_2O_4$
$\Lambda_{200}=236.12$	$\Lambda'_{200}=472.24$
$\Lambda_{250}=247.84$	$\Lambda'_{250}=495.68$
$\Lambda_{500}=261.77$	$\Lambda'_{500}=523.54$
$\Lambda_{1000}=259.21$	$\Lambda'_{1000}=518.42$
$\Lambda_{2000}=274.28$	$\Lambda'_{2000}=548.56$

The number of the suffix in Λ and Λ' is the dilution, i.e., the volume of solution containing one gram molecule of solute.

In order to obtain information about the oxalatopentamminecobalt(III) complex, the electric conductivity of the complex oxalate solution was measured. The molecular conductances obtained are listed in Table I.

In this table, the values Λ and Λ' were

2) S. M. Jörgensen, *Z. anorg. Chem.*, **17**, 461 (1898).
3) Y. Shimura and R. Tsuchida, This Bulletin, **29**, 312 (1956).
4) R. Tsuchida, ibid., **13**, 388, 436 (1938).

calculated on the assumption that the oxalatopentamminecobalt(III) oxalate was formulated by $[Co(NH_3)_5HC_2O_4]C_2O_4$ and $[Co(NH_3)_5 \cdot C_2O_4]_2C_2O_4$ respectively. The former formula is reasonable for oxalatopentamminecobalt(III) oxalate, but the latter should be excluded, since A' is too large to be applied to the formula $[Co(NH_3)_5C_2O_4]_2C_2O_4$. Therefore, the reaction between the aquopentamminecobalt-(III) complex and the oxalate buffer is expressed by

$$[Co(NH_3)_5OH_2]^{3+}(aq.) + HC_2O_4^- = [CO(NH_3)_5HC_2O_4]^{2+}(aq.) + H_2O\ (l) \quad (1)$$

There also exist the following ionization equilibria in the solution:

$$H_2C_2O_2 \rightleftarrows H^+ + HC_2O_4^- \quad (2)$$

$$HC_2O_4^- \rightleftarrows H^+ + C_2O_4^{2-} \quad (3)$$

$$K_2C_2O_4 \rightleftarrows 2K^+ + C_2O_4^{2-} \quad (4)$$

The first and second dissociation constants of oxalic acid, K_1 and K_2, are given a follows:

$$K_1 = \frac{C_{H^+} \cdot C_{HC_2O_4^-}}{C_{H_2C_2O_4}} \quad (5)$$

$$K_2 = \frac{C_{H^+} \cdot C_{C_2O_4^{2-}}}{C_{HC_2O_4^-}} \quad (6)$$

where $C_{H_2C_2O_4}$, $C_{HC_2O_4^-}$, $C_{C_2O_4^{2-}}$ and C_{H^+} are respectively the concentrations of oxalic acid, the hydrogenoxalate ion, the oxalate ion and the hydrogen ion at equilibrium.

When the initial concentrations of oxalic acid and potassium oxalate are expressed by $C^\circ_{H_2C_2O_4}$ anc $C^\circ_{K_2C_2O_4}$, they are given by the sum of the concentration of the oxalatopentamminecobalt(III) ion, C_2, which is equal to the concentration of the hydrogenoxalate ion consumed by the aquo-complex and the concentrations of unionized oxalic acid, the hydrogenoxalate ion and the oxalate ion at equilibrium of reactions 1, 2, 3 and 4:

$$C^\circ_{H_2C_2O_4} + C^\circ_{K_2C_2O_4} = C_2 + C_{H_2C_2O_4} + C_{HC_2O_4^-} + C_{C_2O_4^{2-}} \quad (7)$$

By removing $C_{H_2C_2O_4}$ and $C_{C_2O_4^-}$ from Eqs. 5 and 6 respectively as below,

$$C_{H_2C_2O_4} = \frac{C_{H^+} \cdot C_{HC_2O_4^-}}{K_1}$$

and

$$C_{C_2O_4^{2-}} = \frac{K_2 \cdot C_{HC_2O_4^-}}{C_{H^+}}$$

by inserting them into Eq. 7, and by rearranging it, the following equation is obtained for the concentration of the hydrogenoxalate ion at equilibrium:

$$C_{HC_2O_4^-} = \frac{K_1 C_{H^+}(C^\circ_{H_2C_2O_4} + C^\circ_{K_2C_2O_4} - C_2)}{K_1 C_{H^+} + K_1K_2 + C^2_{H^+}} \quad (8)$$

If the concentrations of aquopentamminecobalt-(III) and water at equilibrium are expressed by C_1 and C_{H_2O} respectively, the equilibrium constant of reaction 1 is given as:

$$K_C = \frac{C_2 \cdot C_{H_2O}}{C_1 \cdot C_{HC_2O_4}} \quad (9)$$

The concentrations of the aquo-complex and the oxalato-complex, C_1 and C_2, at equilibrium are obtained by the observed absorbancy of the solution and the known molar extinction coefficients of the above two complexes[3,4] in the same way as in the preceding paper[1]. The dissociation constants are reported as $K_1 = 5.9 \times 10^{-2}$ [5] and $K_2 = 6.4 \times 10^{-5}$ [5]. By using these values in Eqs. 8 and 9, the apparent equilibrium constant, K_C, is calculated. The concentrations and the ionic strengths of each ion at equilibrium are given as follows:

	Concentration	Ionic strength
$[Co(NH_3)_5OH_2]^{3+}$	C_1	$9C_1/2$
$[Co(NH_3)_5HC_2O_4]^{2+}$	C_2	$4C_2/2$
$3\,ClO_4^-$	$3(C_1+C_2)$	$3(C_1+C_2)/2$
$HC_2O_4^-$	$C_{HC_2O_4^-}$	$C_{HC_2O_4^-}/2$
$C_2O_4^{2-}$	$K_2C_{HC_2O_4^-}/C_{H^+}$	$K_2 \cdot C_{HC_2O_4^-}/2\,C_{H^+}$
K^+	$2C^\circ_{K_2C_2O_4}$	$C^\circ_{K_2C_2O_4}$
H^+	C_{H^+}	$C_{H^+}/2$

The total ionic strength, μ, in the solution is calculated by

$$\mu = 6\,C_1 + 7\,C_2/2 + C_{HC_2O_4^-}/2 + K_2 \cdot C_{HC_2O_4^-}/2\,C_{H^+} + C^\circ_{K_2C_2O_4} + C_{H^+}/2 \quad (10)$$

The value obtained by pH measurement is not that of the hydrogen ion concentration, C_{H^+}, but that of the activity of hydrogen ion. Therefore, the calculations of Eqs. 8 and 10 were at first made by using this activity in place of the hydrogen ion concentration. The hydrogen ion concentration can be obtained by finding the activity coefficient[6] of the hydrogen ion in each ionic strength in the solution calculated by Eq. 10. The recalculations of Eqs. 8 and 10 were carried out by using the hydrogen ion concentration obtained above, and the apparent equilibrium constant, K_C, was calculated.

The results of the measurements and calculations are summarized in Table II.

The logarithm of the apparent equilibrium constant, K_C, is plotted against the aquare root of the ionic strength, μ, in Fig. 2. If it is assumed that this plotting gives a quadratic curve, the equation is calculated as:

$$\log K_C = 3.790\,\mu - 3.954\sqrt{\mu} + 3.428$$

The value of $\log K_C$ obtained by extrapolating this curve up to $\sqrt{\mu} = 0$ is given as:

$$\log K = 3.4$$

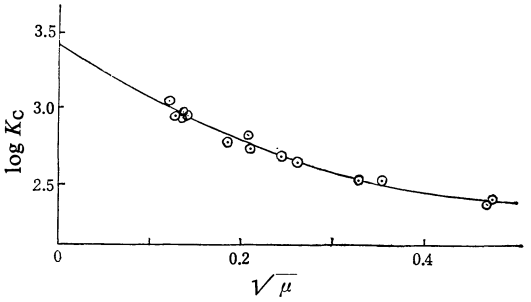

Fig. 2. The relationship between the logarithm of the equilibrium constant of the reaction of aquopentamminecobalt(III) complex with hydrogenoxalate ion, log K_C and the square root of the ionic strength of the solution, $\sqrt{\mu}$.

This is the thermodynamic equilibrium constant of the reaction between the aquopentamminecobalt(III) and hydrogenoxalate ions. The free energy change of the reaction is obtained as:

$$\Delta G^\circ_{298}=-4640 \text{ cal.}$$

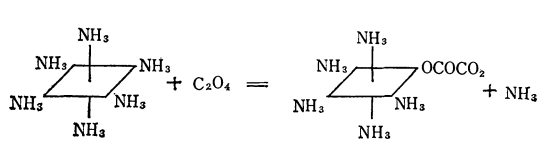
Since the free energies of the formation of the aquopentamminecobalt(III) ion, the hydrogenoxalate ion and water in unit activity are known as −104.5 kcal.[7], −167.1 kcal.[8], and −56.69 kcal.[9] respectively, the free energy of the formation of the hydrogenoxalatopentamminecobalt(III) ion in unit activity is calculated as $\Delta G^\circ_{f298}=-219.6$ kcal.

7) A. B. Lamb and A. T. Larson, ibid., 42, 2038 (1920).
8) F. D. Rossini et al., "Selected Values of Chemical Thermodynamic Properties", United States Government Printing Office, Washington (1952), p. 120.
9) F. D. Rossini et al., ibid., p. 9.

Discussion

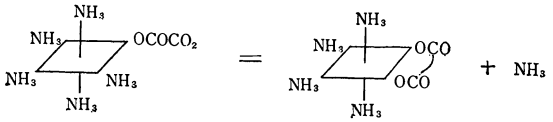
By using the free energies of the formation of the hydrogenoxalatopentamminecobalt(III) ion obtained above, and the oxalatotetramminecobalt(III) ion[1] and hexamminecobalt(III) ion[5] obtained in previous papers, the free energies of the following two reactions are calculated as:

$$[Co(NH_3)_6]^{3+}+HC_2O_4^- = [Co(NH_3)_5HC_2O_4]^{2+}+NH_3(aq.)$$
$$\Delta G^\circ_{298}=-4.37 \text{ kcal.}$$
$$[Co(NH_3)_5HC_2O_4]^{2+} = [Co(NH_3)_4C_2O_4]^{+}+NH_3(aq.)+H^+$$
$$\Delta G^\circ_{298}=-0.77 \text{ kcal.}$$



If it is assumed that the free energy required to drive off the hydrogen ion from the hydrogenoxalatopentamminecobalt(III) ion,

$$[Co(NH_3)_5HC_2O_4]^{2+}=[Co(NH_3)_5C_2O_4]^{+}+H^+$$



is approximately equal to the free energy change of the second dissociation constant of oxalic acid,

$$HC_2O_4^-=H^++C_2O_4^{2-} \qquad \Delta G^\circ_{298}=5.8 \text{ kcal.}$$

then the free energy and entropy changes of the following two reactions are obtained as below:

$\Delta G^\circ_{298}=-4.37$ kcal. $\Delta S^\circ=37.5$ e. u.

$\Delta G^{\circ}_{298} = -6.57$ kcal. $\Delta S^{\circ} = 44.9$ e. u.

The difference in the free energy changes between the two reactions, $\Delta = -2.2$ kcal., corresponds to the difference in those between the change when an oxalate ion coordinates as a unidentate ligand and that when the unidentate oxalate ion undergoes change to a bidentate. It gives a depression of the free energy owing to the formation of a chelate ring. In the same way, the difference in the entropy changes between the two reactions, $\Delta = 7.5$ e. u., gives the entropy effect in the formation of a chelate ring. It is concluded that the chelate effect, having hitherto been interpreted by the entropy effect, can also be applied to the formation of the chelate ring by an oxalate ion.

Summary

It was confirmed by absorption spectral and electric conductivity measurements that the product of the reaction of the aquopentamminecobalt(III) complex with an oxalate ion was a hydrogenoxalatopentamminecobalt(III) complex in which the oxalate ion was coordinated as a unidentate ligand. The equilibrium of the reaction,

$$[Co(NH_3)_5OH_2]^{3+} + HC_2O_4^- = [Co(NH_3)_5HC_2O_4]^{2+} + H_2O$$

was measured spectrophotometrically, by which method the free energy of formation of the hydrogenoxalatopentamminecobalt(III) ion was calculated.

On the basis of this value and the free energy of the formation of the oxalatotetramminecobalt(III) ion obtained in the preceding paper, the differences in free energy and entropy changes between the bidentate and unidentate oxalate ions were calculated. It was verified that the chelate effect of the oxalate ion was due to the entropy effect.

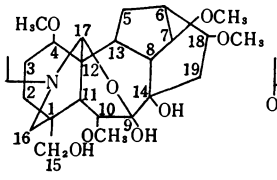
Oxidation Products of Hydroxylycoctonam

By Shozo YAMADA

(Received September 2, 1961)

In a previous paper[1], the author and others reported at length on some oxidation reactions of lycoctonine, but only brief descriptions were reported on the oxidation of hydroxylycoctonam (I), $C_{25}H_{39}O_9N$, with chromic acid. The present communication presents a further consideration of the structures of these oxidation products.



Recently Valenta[2] and, independently, Edwards et al.[3] have proposed the same α-ketol hemiketal structure (II) for hydroxylycoctonine on the basis of several items of experimental evidence.

When I was treated with alkali, there was produced a neutral product, hydroxyisolycoctonam (III), m. p. 185~188°C, $[\alpha]_D^{27}$ −18°, ν_{max}^{Nujol} 3425 (hydroxyl), 1717 (ketone), 1674 cm^{-1} (lactam) (Found: C, 60.62; H, 7.90. Calcd. for $C_{25}H_{39}O_9N$: C, 60.35; H, 7.90%.), and an acid (IV), m. p. 220~222°C, $[\alpha]_D^{34}$ −34°, ν_{max}^{Nujol} 3378, 2551 (hydroxyl), 1715, 1653 (carboxyl), 1587, 1567 cm^{-1} (lactam) (Found: C, 58.12; H, 8.12; OCH_3, 22.93. Calcd. for $C_{25}H_{41}O_{10}N$: C, 58.24; H, 8.01; 4 OCH_3, 24.08%). III was converted into IV by further treatment with alkali. As I has a tertiary α-ketol hemiketal system, the rearragement (I→III) could be expected to proceed in a manner analogous to that of the alkali isomerization of the cevine or germine series[4]. I, however, did not react with sodium bismuthate in acetic acid at room temperature, and when heated at 100°C it gave only a corresponding acetyl derivative. This inertness may be due to its tertiary α-ketol character under steric restriction. IV was proved to be a monocarboxylic acid, but it

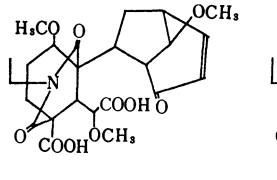
was not proved to have a ketone group or to lack any methoxyl group. It must be considered, therefore, that a cleavage would have proceeded at a bond either between C_9 and C_{14} or between C_9 and C_{10} without the formation of a ketone group. The author preferred to take the former for IV in view of the absence of ready lactonization, the retention of hyxroxyl bands (3448 and 3390 cm^{-1}) in the infrared spectrum of its acetyl derivative (amorphous), and the consumption of a mole of lead tetraacetate (both at 1.5 and at 15 hr.).



Oxidation of I with chromic acid in the same way as described in the previous paper[1] afforded two acids. One of these was Y-acid (V), m. p. 203~205°C decomp.*, $[\alpha]_D^{27}$ −7.5°, λ_{max}^{EtOH} 225 (ε 7180), 315 (ε 50), λ_{min} 280 mμ (ε 35), ν_{max}^{Nujol} 3333, 2740~2597 (hydroxyl), 1709 (broad, carboxyl), 1669 (α,β-unsaturated ketone), 1580 cm^{-1} (lactam) (Found: C, 57.24; H, 7.09; OCH_3, 17.17. Calcd. for $C_{24}H_{35}O_{10}N\cdot{}^1/_2H_2O$: C, 57.36; H, 7.22; 3 OCH_3,

VII

18.53%.). The other was C_1-acid (VI), m. p. 222~223°C decomp.*, $[\alpha]_D^{28}$ −6°, λ_{max}^{EtOH} 220 (ε 14600), 310 (ε 54), λ_{min} 290 mμ (ε 50), λ_{max}^{Nujol} 1754, 1739 (carboxyls), 1661 (α,β-unsaturated ketone), 1709 (shoulder), 1623 (imide), 675 cm^{-1} (cis-substituted double bond) (Found: C, 58.85; H, 6.45; OCH_3, 17.17. Calcd. for $C_{24}H_{31}O_{10}N$: C, 58.41; H, 6.35; 3 OCH_3, 18.86%.). Also produced was a neutral compound Z (VII), m. p. 236~240°C decomp.*, $[\alpha]_D^{29}$ −102°, λ_{max}^{EtOH} 218 (ε 10300), "shoulder" 300 mμ (ε 45), ν_{max}^{Nujol} 1751 (lactone), 1718 (imide), 1678 cm^{-1} (α,β-unsaturated ketone and imide) (Found: C, 61.83; H, 6.76; OCH_3, 16.35. Calcd. for $C_{24}H_{31}O_8N$: C, 62.46; H, 6.77; 3 OCH_3, 20.17%.). In the present case another neutral compound, Y, was not obtained. Each of these three compounds showed both in their infrared and ultraviolet spectra the absorption band attributed to an α,β-unsaturated ketone group. This accorded with the results of the determinations of their methoxyl groups. Thus it was found that the oxidation of I with chromic acid proceeded in the same way as that of I with lead tetraacetate[5]; namely, the α-ketol bond in I was cleaved, followed by the elimination of a molecule of methanol. However, no compound was secured identical with the oxidation products obtained by Edwards et al.[5] from I on oxidation with lead tetraacetate.

On the basis of the empirical formula and the infrared spectral data above, although an attempts to cleave the imide bond in VII and in VI with alkali or sulfuric acid failed, the structure VII can be assigned to Z.

VI was confirmed as a dicarboxylic acid. When VI was heated over its melting point, under effervescence it gave an acid. m. p. 275~280°C, $[\alpha]_D^{27}$ −49°, ν_{max}^{Nujol} 1739 (carboxyl), 1672 (α,β-unsaturated ketone), 1701, 1631 cm^{-1} (imide) (Found: C, 61.60; H, 6.97; OCH_3, 19.77. Calcd. for $C_{23}H_{31}O_8N$: C, 61.45; H, 6.95; 3 OCH_3, 20.71%.). This decarboxylation can be readily interpreted in the same way as that observed in lycoctonamic acid[6]. In view of the above experimental evidence, the structure of C_1-acid can be represented as VI.

V was proved to be a monocarboxylic acid, and its infrared spectrum showed strong hydrogen bonded bands near the 3 and 6μ regions. V was recovered unchanged after treatment with ethereal diazomethane solution. This perhaps indicates the presence of a lactone group in V. In addition, V was acetylated with acetic anhydride and pyridine to give a reversible acetyl derivative (amorphous), $[\alpha]_D^{10}$ −32°, (Found: C, 59.35; H, 6.78. Calcd. for $C_{28}H_{37}O_{11}N$: C, 59.67; H, 6.62%.), the infrared spectrum of which showed no hydroxyl band. Since V showed acid properties, the lactone group in question, if it was present, should be easily hydrolyzable. From a consideration of the above results, one of the most likely structures for Y-acid was shown to be V.

The author wishes now to formally propose names for the above compounds as follows: desmethanol secolycoctimide ketodicarboxylic acid for C_1-acid, desmethanol des-(oxymethylene) secolycoctimide keto monocarboxylic acid for the decarboxylated C_1-acid, and desmethanol secolycoctimde ketolactone for Z.

* Previously melting points at 193~195, 220~222 and 226~227°C were reported for V, VI and VII respectively[1].

Reaction of 7-Substituted 2-Halotropones with Ethyl Sodiocyanoacetate

By Shingo MATSUMURA

(Received July 27, 1961)

In a previous paper, the formation of α-benzopyran, as well as of azulene derivatives, by the condensation of 2-chlorotropone and ethyl sodiocyanoacetate was reported[1]. In the present paper, the reaction of 2-halotropone derivatives and ethyl sodiocyanoacetate is examined and the results obtained are reported on.

The reaction of 2, 7-dibromotropone (I) and ethyl sodiocyanoacetate (II) in a mixed solvent of dioxane and ethanol affords colorless crystals of m. p. 117°C (III), $C_{17}H_{17}O_5N_2Br$, and of m. p. 150°C (IV), $C_{12}H_9O_4Br$. Under the same conditions, 2, 7-dichlorotropone (V) affords colorless crystals of m. p. 123°C (VI), $C_{17}H_{17}O_5N_2Cl$, and of m. p. 146°C (VII), $C_{12}H_9O_4Cl$, and orange-red crystals of m. p. 152°C (VIII), $C_{22}H_{22}O_8N_2$. The same reaction of 2-chloro-7-bromotropone (IX) gives colorless crystals of m. p. 223°C (X), $C_{10}H_5O_4Br$, besides VI and VII.

The reaction of 2-methoxy-7-bromotropone (XI) in ethanol affords colorless crystals of m. p. 125°C (XII), $C_{18}H_{20}O_6N_2$, and a compound corresponding to VIII, while that of 2-methoxy-3, 7-dibromotropone (XIII) gives colorless crystals of m. p. 115°C (XIV), $C_{13}H_{11}O_5Br$. The same reaction of 2-methoxy-3, 5, 7-tribromotropone (XV) gives colorless crystals of m. p. 146°C (XVI), $C_{18}H_{18}O_6N_2Br_2$, and of m. p. 217°C (XVII), $C_{11}H_5O_3NBr_2$.

The ultraviolet absorption spectra*1 of III, VI, XII and XVI (Fig. 1) are similar to that of 2-amino-2-(cyano-ethoxycarbonylmethyl)-3-ethoxycarbonyl-α-benzopyran (XVIII) reported on in a previous paper[1]. The infrared absorption spectra[2] of these compounds showed the presence of amino, cyano and ester carbonyl groups and of an ester carbonyl group conjugated with an unsaturated bond. On the basis of these spectral data, it is assumed that III is the 8-bromo derivative, that VI is the 8-chloro derivative, that XII is the 8-methoxy derivative, and that XVI is the 5, 7-dibromo-8-methoxy derivative of XVIII.

Condensation of 3-bromosalicylaldehyde (XIX) and ethyl cyanoacetate in the presence of piperidine had given III, and the same reaction with 3-chlorosalicylaldehyde (XX) gave VI. These facts clearly indicate that III, VI, XII and XVI are all α-benzopyran derivatives.

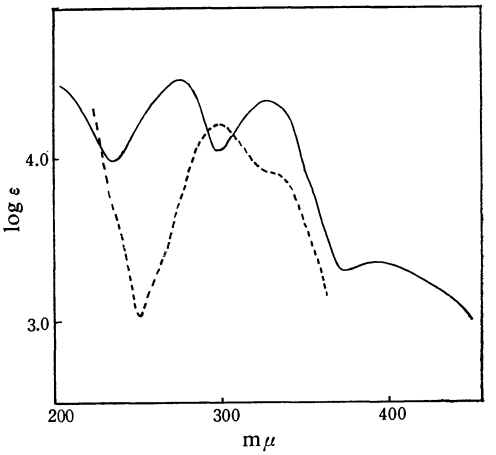

Fig. 3. Ultraviolet absorption spectra of VIII and XXIII in methanol.
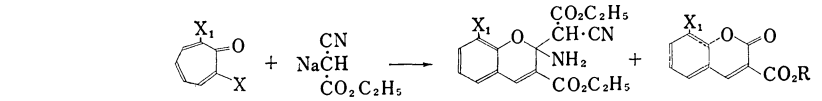
—— VIII, ---- XXIII

The ultraviolet absorption spectra of IV, VII, X, XIV and XVII (Fig. 2) are similar to those coumarin derivatives. These compounds all have absorption bands in the region of 1760~1735 cm^{-1} due to the unsaturated δ-lactonic carbonyl group in the coumarin ring. There is an absorption band due to the ester carbonyl group conjugated with an unsaturated bond in the region of 1710~1690 cm^{-1} in IV, VII and XIV, while an absorption band of a carboxyl group is present at 2750 cm^{-1} in X, and that of a cyano group conjugated with an unsaturated bond at 2215 cm^{-1}, in XVII. These spectral evidences show that IV, VII and XIV are 8-bromo, 8-chloro, and 7-bromo-3-methoxy derivatives of 3-ethoxycarbonylcoumarin respectively, while X is 3-carboxy-8-bromocoumarin and XVII is 3-cyano-5, 7-dibromo-8-methoxycoumarin.



The heating of III with dilute hydrochloric acid for a short time converts it to IV, and a similar reaction of VI gives VII. The treatment of XII with hydrochloric acid gives 3-carboxy-8-methoxycoumarin (XXI), m. p. 172°C, while the treatment of XVI with hydrochloric acid affords 3-ethoxycarbonyl-5, 7-dibromo-8-methoxycoumarin (XXII), m. p. 187°C. XXII is also obtained by the treatment of XVII with absolute ethanol containing hydrochloric acid. On the basis of the ultraviolet spectrum of VIII (Fig. 3), this compound is assumed to be a coumarin derivative. The infrared spectrum of VIII indicates the presence of absorptions due to cyano- and carbonyl groups conjugated with an unsaturated bond and to a carbonyl group not conjugated with an unsaturated bond.

The hydrolysis of VIII with 6N hydrochloric acid gives a compound XXIII, m. p. 215°C, corresponding to the molecular formula of $C_{12}H_8O_6$. The ultraviolet spectrum of XXIII, as shown in Fig. 3, shows an absorption curve similar to that of 3-carboxycoumarin. The infrared spectrum of XXIII indicates the presence of a carboxyl and of a methylene group (1465 cm^{-1}). This spectral evidence shows that XXIII is 3-carboxy-8-carboxymethylcoumarin.

On the basis of the formation of 3-carboxy-8-carboxymethylcoumarin from VIII and the infrared absorption spectrum of VIII, VIII is assumed to be ethyl α-cyano-β-amino-γ-(3-ethoxycarbonylcoumarin-8-yl)-glutaconate.

Recently, the condensation reaction between 2, 4, 7-tribromotropone (XXIV) and II has been examined[3], and seven kinds of structurally unidentified compounds have been obtained; colorless crystals (XXV) of m. p. 177°C, yellow crystals (XXVI) of m. p. 214°C, brown crystals (XXVII) of m. p. 178°C, colorless crystals (XXVIII) of m. p. 155°C, yellow crystals (XXIX) of m. p. 141°C, pale yellow crystals (XXX) of m. p. 181°C, and orange crystals (XXXI) of m. p. above 340°C. From their analytical values, the molecular formula of $C_{17}H_{15}O_5N_2Br$ was given for XXVI, $C_{12}H_9O_3NBr_2$ for XXVII and XXX, and $C_{12}H_8O_3NBr_2Na$ for XXXI. Re-examination of these analytical values showed that the molecular formula of $C_{22}H_{21}O_8N_2Br$ would be more appropriate for XXVI than $C_{17}H_{15}O_5N_2Br$. No molecular formulae were given for XXV and XXVIII, but, from their analytical values, the formula of $C_{12}H_8O_4Br_2$ is now suggested for XXV and $C_{17}H_{16}O_5N_2Br_2$ for XXVIII. The ultraviolet absorption spectra[2] of XXVIII and XXIX are similar

Scheme 2.

to those of III and VI. The infrared spectra[3] of XXVIII and XXIX indicate the presence of cyano and ester carbonyl groups not conjugated with unsaturated bonds and of an ester carbonyl group conjugated with an unsaturated bond. This spectral evidence suggests that XXVIII and XXIX are α-benzopyran derivatives.

The condensation of 3, 5-dibromosalicylaldehyde (XXXII), obtained by the bromination of XIX, with ethyl cyanoacetate in the presence of piperidine affords XXVIII; this indicates that XXVIII is 6, 8-dibromo-2-amino-2-(cyano-ethoxycarbonylmethyl)-3-ethoxycarbonyl-α-benzopyran. The ultraviolet spectrum of XXV is similar to those of IV and VII. XXV is obtained by treatment of XXVIII with hydrochloric acid in ethanol. These facts show that XXV is 6,8-dibromo-3-ethoxycarbonylcoumarin.

The ultraviolet spectrum of XXVI is very similar to that of VIII, and the infrared spectrum of XXVI indicates the presence of amino and cyano, lactonic carbonyl, groups and of ester carbonyl groups conjugated with an unsaturated bond. Therefore, XXVI should be a 5- or 6-bromo derivative of VIII.

On the basis of a consideration of the ultraviolet and infrared absorption spectra, it is assumed that XXX and XXXI are heptafulvene derivatives. These reaction sequences are illustrated in Scheme 2.

Condensation of 2-halotropones substituted in the 7-position and II failed to indicate the

formation of an azulene derivative; only rearrangement products were obtained.

Experimental*2

Reaction of 2,7-Dibromotropone (I) and Ethyl Sodiocyanoacetate (II).—A solution of 500 mg. of I dissolved in 20 ml. of dioxane was stirred into II, prepared from 90 mg. of metallic sodium, 3 ml. of absolute ethanol, and 500 mg. of ethyl cyanoacetate, under ice-cooling, the solution thereby became orange-red, and the colorless sodio compound changed into an orange-red precipitate. After the mixture was allowed to stand overnight at room temperature, the precipitate was collected by filtration and washed with ethanol, and the 400 mg. of colorless crystals that remained was recrystallized from ethanol. The easily soluble portion afforded 120 mg. of III as colorless prisms, m. p. 115~117°C.

Found: C, 50.13; H, 4.06; N, 6.65. Calcd. for $C_{17}H_{17}O_5N_2Br$: C, 49.87; H, 4.15; N, 6.84%.

UV λ_{max}^{MeOH} mμ (log ε): 307 (3.84), 360 (3.56).

The sparingly soluble portion afforded 80 mg. of IV as colorless scales, m. p. 149~150°C.

Found: C, 48.56; H, 3.21. Calcd. for $C_{12}H_9O_4Br$: C, 48.48; H, 3.03%.

UV λ_{max}^{MeOH} mμ (log ε): 300 (4.14), 340 (3.68).

Formation of IV from III.—A solution of 50 mg. of III dissolved in 0.5 ml. of ethanol and with 0.2 ml. of 6 N hydrochloric acid added was heated on a water bath for 5 min., the solid thereby dissolved at once, and sparingly soluble needle crystals then separated out. Recrystallization of these crystals from ethanol gave 20 mg. of IV as colorless needles of m. p. 149~150°C.

Reaction of 2,7-Dichlorotropone (V) and II.—A solution of 500 mg. of V dissolved in 20 ml. of dehydrated dioxane was stirred, while being cooled by ice, into II, prepared from 140 mg. of sodium, 3 ml. of absolute ethanol, and 700 mg. of ethyl cyanoacetate, and the mixture was allowed to stand overnight at room temperature. The dioxane-ethanol mixture was evaporated at a reduced pressure, ethanol was added to the residue, and the precipitated orange-red crystals were repeatedly recrystallized from ethanol. The easily soluble portion afforded 160 mg. of VI as colorless scales, m. p. 122~123°C.

Found: C, 56.18; H, 4.56; N, 7.83. Calcd. for $C_{17}H_{17}O_5N_2Cl$: C, 56.03; H, 4.67; 7.69%.

UV λ_{max}^{MeOH} mμ (log ε): 305 (3.53), 355 (3.31).

The sparingly soluble portion afforded 80 mg. of VII as colorless needles, m. p. 145~146°C.

Found: C, 57.36; H, 3.28. Calcd. for $C_{12}H_9O_4Cl$: C, 57.14; H, 3.57%.

UV λ_{max}^{MeOH} mμ (log ε): 296 (4.13), 340 (3.65).

The sparingly soluble portion also afforded 30 mg. of VIII as orange prisms, m. p. 151~152°C.

Found: C, 59.83; H, 5.29; N, 7.01. Calcd. for $C_{22}H_{22}O_8N_2$: C, 59.72; H, 5.01; N, 6.33%.

UV λ_{max}^{MeOH} mμ (log ε): 275 (4.48), 327 (4.35), 395 (3.35).

*2 All the melting points are uncorrected.

Formation of VII from VI.—A solution of 50 mg. of VI dissolved in 0.5 ml. of ethanol and with 0.2 ml. of 6 N hydrochloric acid added was warmed on a water bath for 5 min., and the colorless needle crystals that separated out were recrystallized from ethanol to give VII, m. p. 145~146°C.

Reaction of 2-Chloro-7-bromotropone (IX) and II.—A solution of 500 mg. of IX dissolved in 20 ml. of dioxane was stirred, while being cooled by ice, into II, prepared from 110 mg. of sodium, 3 ml. of absolute ethanol, and 550 mg. of ethyl cyanoacetate, and the mixture was treated as in the case of the reaction of V and II, affording 40 mg. of VI and 60 mg. of VII. The filtrate obtained after isolation of VI and VII was concentrated, the residue was dissolved in water, and the solution was neutralized with dilute nitric acid, from which 50 mg. of brown precipitate was obtained. Recrystallization of this precipitate from ethanol afforded 20 mg. of X as colorless crystals, m. p. 222~223°C (decomp.).

Found: C, 44.83; H, 1.89. Calcd. for $C_{10}H_5O_4Br$: C, 44.60; H, 1.89%.

UV λ_{max}^{MeOH} mμ (log ε): 300 (4.13).

Reaction of 2-Methoxy-7-bromotropone (XI) and II.—A solution of 500 mg. of XI dissolved in 10 ml. of absolute ethanol was stirred, while being cooled by ice, into II, prepared from 100 mg. of sodium, 4 ml. of absolute ethanol, and 600 mg. of ethyl cyanoacetate; as a result the reaction started at once and the solution became reddish and clear. After the mixture had been left to stand overnight, the mixture was filtered and the filtrate was concentrated under reduced pressure. The tarry substance hereby formed was dissolved in benzene, the solvent was evaporated, and ethanol was added to the oily residue. The crystallized solid was recrystallized from ethanol, and 40 mg. of VIII, m. p. 151~152°C, was obtained. The recrystallization of the mother liquor afforded 340 mg. of XII as colorless prisms, m. p. 124~125°C.

Found (for XII): C, 60.57; H, 5.42; N, 7.83. Calcd. for $C_{18}H_{20}O_6N_2$: C, 59.99; H, 5.59; N, 7.77%.

UV λ_{max}^{MeOH} mμ (log ε): 316 (4.11), 360 (3.65).

Reaction of 2-Methoxy-3,7-Dibromotropone (XIII) and II.—A solution of 600 mg. of XIII dissolved in 15 ml. of dehydrated benzene was stirred, while being cooled by ice, into II, prepared from 100 mg. of sodium, 3 ml. of absolute ethanol, and 600 mg. of ethyl cyanoacetate, and the mixture was allowed to stand overnight at room temperature. The precipitate formed was collected and dissolved in 80 ml. of water, and the solution was neutralized with dilute nitric acid, producing 360 mg. of a greyish white precipitate. This precipitate was recrystallized first from benzene and then from ethanol to produce 260 mg. of XIV as colorless scales, m. p. 115~116°C.

Found: C, 47.34; H, 3.56. Calcd. for $C_{13}H_{11}O_5Br$: C, 47.70; H, 3.33%.

UV λ_{max}^{MeOH} mμ (log ε): 311 (4.29).

Reaction of 2-Methoxy-3,5,7-tribromotropone (XV) and II.—A solution of 500 mg. of XV dissolved in 10 ml. of absolute ethanol was stirred, while being cooled by ice, into II, prepared from 80 mg. of sodium, 3 ml. of absolute ethanol, and 400 mg. of ethyl cyanoacetate, and the mixture

was allowed to stand overnight at room temperature. The orange-red precipitate thereby formed was collected by filtration and recrystallized from ethanol to give 100 mg. of XVI as colorless scales, m. p. 146~147°C.

Found: C, 42.03; H, 3.61; N, 5.86. Calcd. for $C_{15}H_{18}O_6N_2Br_2$: C, 41.69; H, 3.47; N, 5.43%.

UV λ_{max}^{MeOH} mμ (log ε): 266 (4.16), 333 (4.04).

Concentration of the filtrate precipitated colorless crystals which recrystallized from ethanol to produce 60 mg. of XVII as colorless prisms, m. p. 216~217°C.

Found: C, 37.04; H, 1.36; N, 4.25. Calcd. for $C_{11}H_5O_3NBr_2$: C, 36.76; H, 1.39; N, 3.90%.

UV λ_{max}^{MeOH} mμ (log ε): 330 (4.07).

Synthesis of III.—One drop of piperidine was added to the solution of 100 mg. of 3-bromosalicylaldehyde (XIX) and 100 mg. of ethyl cyanoacetate dissolved in 0.2 ml. absolute ethanol; the solution here upon immediately became orange-yellow and prismatic crystals began to separate out. The crystals were collected and recrystallized from ethanol to give 120 mg. of III, m. p. 115~117°C.

Synthesis of VI.—One drop of piperidine was added to a solution of 100 mg. of 3-chlorosalicylaldehyde (XX) and 100 mg. of ethyl cyanoacetate dissolved in 0.2 ml. of absolute ethanol; 150 mg. of VI, m. p. 122~123°C, was obtained.

Reaction of XII with an Acid.—A solution of 100 mg. of XII dissolved in 1 ml. of ethanol and with 0.2 ml. of 6 N hydrochloric acid added was heated for 50 min., and the colorless crystals that separated out were recrystallized from ethanol to give 50 mg. of XXI, m. p. 171~172°C.

Found: C, 60.31; H, 4.24. Calcd. for $C_{11}H_8O_5$: C, 60.00; H, 3.66%.

UV λ_{max}^{MeOH} mμ (log ε): 252 (3.89), 305 (4.15).

3-Ethoxycarbonyl-5,7-dibromo-8-methoxycoumarin (XXII).—a) A solution of 100 mg. of XVI dissolved in 2 ml. of ethanol and with 0.3 ml. of 6 N hydrochloric acid added was heated on a water bath for 20 min.; the colorless crystals that separated out were recrystallized from ethanol to give 40 mg. of XXII, m. p. 186~187°C.

Found: C, 38.20; H, 3.09. Calcd. for $C_{13}H_{10}O_5Br_2$: C, 38.42; H, 2.46%.

b) Hydrogen chloride gas was passed through the solution of 100 mg. of XVII dissolved in 3 ml. of absolute ethanol, and the solution was heated on a water bath for 5 hr. Ethanol was evaporated from the solution and the residual crystals were recrystallized from ethanol to give 80 mg. of XXII.

Reaction of VIII and an Acid.—A solution of 100 mg. of VIII dissolved in 6 ml. of ethanol and with 3 ml. of 3 N hydrochloric acid added was heated at 100~120°C for 5 hr. Ethanol was evaporated from this solution, and the residual crystals were recrystallized from ethanol to give 40 mg. of XXIII as colorless crystals, m. p. 214~215°C (decomp.).

Found: C, 57.27; H, 3.85. Calcd. for $C_{12}H_8O_6$: C, 58.07; H, 3.25%.

UV λ_{max}^{MeOH} mμ (log ε): 297 (4.12).

Reaction of 3,5-Dibromosalicylaldehyde (XXXII) and Ethyl Cyanoacetate.—One drop of piperidine was added to a solution of 50 mg. of XXXII and 50 mg. of ethyl cyanoacetate dissolved in 0.2 ml. of absolute ethanol. The solution thereby immediately colored orange-red. After the solution had been allowed to stand overnight, the colorless crystals that precipitated out were collected and recrystallized from ethanol to give 60 mg. of XXVIII as colorless prisms, m. p. 155~156°C.

Found: C, 42.03; H, 3.56; N, 5.68. Calcd. for $C_{17}H_{16}O_5N_2Br_2$: C, 41.80; H, 3.28; N, 5.71%.

3-Ethoxycarbonyl-6,8-dibromocoumarin (XXV).—A solution of 100 mg. of XXVIII dissolved in 5 ml. of ethanol and with 0.3 ml. of 6 N hydrochloric acid added was heated on a water bath for 20 min., and the colorless crystals that separated out were recrystallized from ethanol to give 40 mg. of XXV, m. p. 176~177°C.

Found: C, 38.49; H, 2.51. Calcd. for $C_{12}H_8O_4 \cdot Br_2$: C, 38.30; H, 2.13%.

The author wishes to express his deep gratitude to Professor Tetsuo Nozoe and Professor Shuichi Seto for their unfailing guidance. Also, the author wishes to thank Mr. S. Ohyama and Miss Y. Endo for their microanalyses and Mr. S. Aono for his infrared spectral measurements.

Condensation Reaction of Troponoids with Ethyl α-Cyano-β-aminoglutaconate. II. Reaction of Alkyl Derivatives of 2-Chlorotropone with Ethyl α-Cyano-β-aminoglutaconate

By Shingo MATSUMURA

(Received July 27, 1961)

It has already been found[1] that the condensation of 2-chlorotropone (I) with ethyl α-cyano-β-aminoglutaconate (II) results in the formation of 2-(cyano-ethoxycarbonylmethylene)-3-ethoxycarbonyl-1-azaazulane (III) and α-amino-α-(1-oxaazulan-2-on-3-yl)-β-cyano-β-ethoxycarbonylethylene (IV).

It has also often been found that the substitution occurs in the 7-position and not in the position previously occupied by the halogen in the amination of 2-halotropones with ammonia[2], and the same sort of abnormal substitution was also observed in the formation of 1-oxaazulan-2-one derivatives by reaction with acetoacetic ester or malonic ester[3], and in the formation of azulene or 1-azaazulan-2-one derivatives by reaction with cyanoacetic ester[4] or cyanoacetamide[5].

In order to determine whether or not such an abnormal reaction took place in the condensation reaction of 2-halotropones with II, the present series of experiments was carried out.

The reaction of 2-chloro-4-isopropyltropone (V) with II in benzene, in the presence of triethylamine, affords red crystals (VI) of m. p. 147°C and orange crystals (VII) of m. p. 184°C. A similar condensation of 2-chloro-6-isopropyltropone (VIII) gives a reddish oily product (IX), while the reaction with 2-chloro-4-methyltropone (X) gives red crystals (XI) of m. p. 190°C and orange crystals (XII) of m. p. 250°C. The same reaction of 2-chloro-6-methyltropone (XIII) affords an orange oily product (XIV).

The ultraviolet absorption spectra*1 of VI and XI (Fig. 1) are similar to that of the 2-methylene-1-azaazulane derivative[1]. The analytical values of VI correspond to those of the isopropyl derivative of III, and those of

------ XII: $Y=\log\varepsilon+0.1$

XI, to those of the methyl derivative of III.

The ultraviolet absorption spectra of VII and XII (Fig. 2) are similar to that of the 1-oxa-azulan-2-one derivative. The analytical values of VII correspond to those of the isopropyl derivative of IV, and those of XII, to those of the methyl derivative of IV. The ultraviolet spectra of IX and XIV (Fig. 3) are similar to that of the starting 2-chlorotropone derivative except for the absorption at around

*1 The ultraviolet absorption spectra were measured with a Hitachi EPS-2 Type recording spectrophotometer.

280 mμ. These facts suggest that IX and XIV are tropone derivatives, but their structure still remains undetermined.

In order to determine the position of the isopropyl group in VI, the following experiment was carried out. The application of phosphoryl chloride to 3-ethoxycarbonyl-7-isopropyl-1-azaazulan-2-one (XV) gives 2-chloro-3-ethoxycarbonyl-7-isopropyl-1-azaazulene (XVI), m. p. 79°C, and the condensation of XVI with ethyl sodiocyanoacetate affords 2-(cyano-ethoxycarbonylmethylene)-3-ethoxycarbonyl-7-isopropyl-1-azaazulane (XVII), m. p. 134°C. The ultraviolet absorption spectrum of XVII is shown in Fig. 1.

The application of phosphoryl chloride to 3-ethoxycarbonyl-5-isopropyl-1-azaazulan-2-one (XVIII) affords 2-chloro-3-ethoxycarbonyl-5-isopropyl-1-azaazulene (XIX), m. p. 101°C, whose condensation with ethyl sodiocyanoacetate gives 2-(cyano-ethoxycarbonylmethylene)-3-ethoxycarbonyl-5-isopropyl-1-azaazulane (XX), m. p. 84°C. The ultraviolet absorption spectrum of XX is given in Fig. 1.

The treatment of 3-ethoxycarbonyl-6-isopropyl-1-azaazulan-2-one (XXI) with phosphoryl chloride gives an orange-yellow oily product (XXII) whose condensation with ethyl sodiocyanoacetate affords 2-(cyano-ethoxycarbonylmethylene)-3-ethoxycarbonyl-6-isopropyl-1-azaazulane (XXIII), m. p. 147°C. The mixed fusion of XXIII and VI failed to show any depression of the melting point, and the ultraviolet absorption spectra of these two substances were identical.

As will be clear from the infrared spectra*2 of VI and XI (Fig. 4), the absorptions in the region of the C–H out-of-plane deformation vibrations are very similar in these two compounds, so the position of methyl substitution in XI should be the 6-position.

The absorption band due to the C–H out-of-plane deformation vibration appears at 850 cm^{-1} in VII, while this absorption is present

*2 The infrared spectra were measured with a Perkin-Elmer Model 21 double beam spectrophotometer by Mr. S. Aono of this Institute; the author is deeply indebted to Mr. S. Aono.

at 834 cm^{-1} in XII. These wave numbers agree with that of the 6-substituted derivatives of 1-oxaazulan-2-one[6]. This evidence shows that VII is a 6-isopropyl derivative of IV and that XII is its 6-methyl derivative.

It has become clear from these experiments that an abnormal reaction occurred also in the condensation reaction of 2-halotropones with II. In this reaction, the carbanion formed from II attacks the 7-position in the tropone ring, and this is followed by a dehydrative cyclization reaction between the amino group and the carbonyl in the 1-position to form a 2-methylene-1-azaazulane derivative.

This is the same mode of reaction as that reported already by Seto and others[5] for the formation of 1-azaazulan-2-one derivatives by the condensation of 2-halotropones with cyanoacetamide.

Experimental*3

Reaction of 2-Chloro-4-isopropyltropone (V) and Ethyl α-Cyano-β-aminoglutaconate (II). — To a solution of 260 mg. of V and 350 mg. of II dissolved in 2 ml. of dehydrated benzene, 200 mg. of triethylamine was added dropwise at room temperature; the solution thereby turned red and a precipitate was gradually deposited. After the mixture had been allowed to stand for 5 hr., the precipitate was collected by filtration, washed thoroughly with water, and recrystallized from acetone to give 250 mg. of VII as orange needles, m. p. 183~184°C.

Found: C, 66.51; H, 5.38; N, 8.67. Calcd. for $C_{18}H_{18}O_4N_2$: C, 66.24; H, 5.56; N, 8.53%.

UV λ_{max}^{MeOH} mμ (log ε): 230 (4.29), 254 (4.44), 410 (4.32).

The reaction solution, separated from the precipitate, was washed thoroughly with water, the benzene was evaporated, and the residue was purified by passage through an alumina column. The reddish crystals thereby obtained were recrystallized from ethanol to afford 120 mg. of VI as red needles, m. p. 145~147°C.

Found: C, 67.84; H, 6.15; N, 7.62. Calcd. for $C_{20}H_{22}O_4N_2$: C, 67.78; H, 6.26; N, 7.91%.

UV λ_{max}^{MeOH} mμ (log ε): 263 (4.46), 290 (4.39), 338 (3.98), 489 (4.48).

Reaction of 2-Chloro-6-isopropyltropone (VIII) and II. — A solution of 730 mg. of VIII and 890 mg. of II dissolved in 4 ml. of dehydrated benzene, with 400 mg. of triethylamine added, was allowed to stand for 2 days at room temperature; colorless needle crystals, easily soluble in water, thereby separated out. The benzene solution was washed with water, dried, and concentrated. The residue was purified by passage through an alumina column, and the column was eluted with benzene. The evaporation of the solvent from the effluent afforded 960 mg. of IX as a reddish oil.

Reaction of 2-Chloro-4-methyltropone (X) and II.—A solution of 320 mg. of X and 470 mg. of II dissolved in 2 ml. of dehydrated benzene, with 240 mg. of triethylamine added, was allowed to stand at room temperature for 5 hr. The precipitate thereby formed was collected by filtration and recrystallized from acetone to give 240 mg. of XII as orange-needles, m. p. 250°C (decomp.).

Found: C, 64.51; H, 4.85; N, 9.56. Calcd. for $C_{16}H_{14}O_4N_2$: C, 64.42; H, 4.73; N, 9.39%.

UV λ_{max}^{MeOH} mμ (log ε): 230 (4.35), 254 (4.46), 410 (4.36).

The solvent was evaporated from the filtrate, and the residue was purified by passage through an alumina column. The crystals thereby obtained were recrystallized from ethanol to afford 60 mg. of XI as red needles, m. p. 189~190°C.

Found: C, 66.52; H, 5.53; N, 8.46. Calcd. for $C_{18}H_{18}O_4N_2$: C, 66.28; H, 5.56; N, 8.58%.

UV λ_{max}^{MeOH} mμ (log ε): 264 (4.48), 289 (4.37), 340 (4.12), 490 (4.53).

*3 All melting points are uncorrected.

Reaction of 2-Chloro-6-methyltropone (XIII) and II.—A solution of 160 mg. of XIII and 240 mg. of II dissolved in 1 ml. of dehydrated benzene and with 120 mg. of triethylamine added was allowed to stand at room temperature for 2 days, and the reaction mixture was treated as in the reaction of VIII and II; 200 mg. of XIV was thereby obtained as an orange oil.

2-Chloro-3-ethoxycarbonyl-7-isopropyl-1-azaazulene (XVI). — A solution of 200 mg. of 3-ethoxycarbonyl-7-isopropyl-1-azaazulan-2-one (XV) dissolved in 1.5 ml. of phosphoryl chloride was sealed in a glass tube and heated at 150~160°C for 5 hr. The phosphoryl chloride was removed from the reaction mixture, water was added to decompose the residual phosphoryl chloride, and the mixture was neutralized with sodium hydrogencarbonate. This was extracted with benzene, and the extract was dried and passed through a column of alumina. The product thereby obtained was recrystallized from petroleum ether to give 110 mg. of XVI as orange-yellow prisms, m. p. 77~79°C.

Found: C, 64.81; H, 5.75; N, 5.32. Calcd. for $C_{15}H_{16}O_2NCl$: C, 64.98; H, 5.77; N, 5.05%.

2-Chloro-3-ethoxycarbonyl-5-isopropyl-1-azaazulene (XIX). — A mixture of 500 mg. of 3-ethoxycarbonyl-5-isopropyl-1-azaazulan-2-one (XVIII) and 5 ml. of phosphoryl chloride was treated as in the preceding case; 350 mg. of XIX was obtained thereby as orange prisms, m. p. 99~101°C.

Found: C, 64.76; H, 5.38; N, 5.13. Calcd. for $C_{15}H_{16}O_2NCl$: C, 64.98; H, 5.77; N, 5.05%.

2-Chloro-3-ethoxycarbonyl-6-isopropyl-1-azaazulene (XXII). — A mixture of 200 mg. of 3-ethoxycarbonyl-6-isopropyl-1-azaazulan-2-one (XXI) and 1 ml. of phosphoryl chloride was treated as in the preceding cases, obtaining XXII as an orange oil.

2-(Cyano-ethoxycarbonylmethylene)-3-ethoxycarbonyl-7-isopropyl-1-azaazulane (XVII). — To the sodio compound prepared from 30 mg. of sodium granulated in dehydrated dioxane and heated with 260 mg. of ethyl cyanoacetate, 150 mg. of XVI was added and the mixture was heated at 90°C for 1 hr.; an orange-red precipitate thereby gradually formed. The dioxane was evaporated from the mixture, and the residue was dissolved in water, neutralized with dilute acetic acid, and extracted with benzene. The extract solution was dried and passed through a column of alumina. The reddish oily product so obtained solidified when allowed to stand after petroleum ether (b. p. 50~60°C) had been added; the product was then recrystallized from the benzene-petroleum ether mixture to give 80 mg. of XVII as red needles, m. p. 132~134°C.

Found: C, 67.65; H, 6.59; N, 7.84. Calcd. for $C_{20}H_{22}O_4N_2$: C, 67.78; H, 6.26; N, 7.91%.

UV λ_{max}^{MeOH} mμ (log ε): 260 (4.41), 290 (4.45), 340 (4.02), 489 (4.43).

2-(Cyano-ethoxycarbonylmethylene)-3-ethoxycarbonyl-5-isopropyl-1-azaazulane (XX). — Treatment of 30 mg. of sodium, 200 mg. of XIX, as in the preceding case, afforded 120 mg. of XX as red needles, m. p. 82~84°C.

Found: C, 67.53; H, 6.12; N, 8.05. Calcd. for $C_{20}H_{22}O_4N_2$: C, 67.78; H, 6.26; N, 7.91%.

UV λ_{max}^{MeOH} mμ (log ε): 262 (4.41), 290 (4.48), 334 (4.05), 489 (4.44).

2-(Cyano-ethoxycarbonylmethylene)-3-ethoxycarbonyl-6-isopropyl-1-azaazulane (XXIII=VI). — A mixture of 30 mg. of sodium, 200 mg. of ethyl cyanoacetate, and 200 mg. of XXII was treated as in the preparation of XVII; 100 mg. of XXIII was thereby obtained as red needles, m. p. 145~147°C. Mixed fusion of XXIII with VI failed to show any depression of the melting point.

The author wishes to express his deep gratituted to Professor Tetsuo Nozoe and Professor Shuichi Seto for their kind and unfailing guidance throughout the course of the present work. The author is also indebted to Mr. Humio Sato for his cooperation in carrying out the experiments, and to Miss Yoko Endo and Mr. Shinichi Ohyama for their elemental analyses.

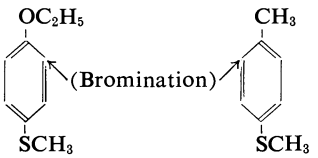
Acid-catalyzed Hydrogen-Deuterium Exchange Reactions of Deuterated Anisole, Thioanisole and Benzene

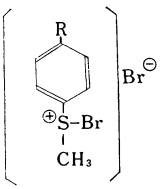
By Shigeru OAE, Atuyoshi OHNO and Waichiro TAGAKI



(Received August 30, 1961)

There have been many reports of the electron-pair releasing conjugative ability of divalent sulfides vs. that of the oxygen analogs. The dissociation constants of substituted benzoic acids[1], phenols[2] and anilines[2,3], the dipole moments of substituted benzenes[4], and the dimerization rates of *p*-substituted isopropenyl[5] benzene and a few other examples[6] have all pointed out that the electron-pair releasing conjugative effect of the sulfide function is smaller than that of the oxygen-analog. In both S_N1[7] and S_N2[8] reactions, chloromethyl alkyl ether has been shown to react substantially faster than the sulfur analog. The theoretical considerations, based on molecular orbital treatments, indicate that 3p-π-bonds are less stable than 2p-π-bonds[9].

Baddeley[10] has also shown that the orders of the ratio of the packing radius vs. the single-bond radius are $F > Cl > Br > I$ and $O > S > Se > Te$.



In seeking better evidence of electrophilic aromatic substitution with which one can compare the relative activating and orienting effects of sulfide groups vs. those of oxygen analogs, we have come across only two examples in the literature; namely, the bromination has been shown to take place meta to the methylthio group in both *p*-ethoxyphenyl sulfide[11] and *p*-tolyl methyl sulfide[12].

Although, these data show that the methylthio group has much less activating ability than the methoxyl or even the methyl group, these

examples are not very adequate, because the initial reaction of bromination should be the attack of bromine on the sulfur atom of the methylthio group, instead of on the benzene nucleus, leading to the formation of an intermediate complex I, which then further reacts to give the final product.

Neither the nitration[13] nor sulfonation[14] reaction is desirable, because the initial attack takes place on the sulfur atom, eventually oxidizing the sulfide group.

(I)

Mercuration is also not desirable for the same reason. The other possible electrophilic substitution reactions are the chloromethylation and hydrogen exchange reactions; we have chosen the latter. The acid-catalyzed hydrogen deuterium exchange reaction has been extensively studied by previous workers[15] and has thus been known to give a rate sequence of aromatic substituents identical with that of such well-studied reactions as nitration. Thus, we have studied the acid-catalyzed hydrogen-deuterium exchange reactions of *p*-deuterated anisole, thioanisole and mono-deuterated benzene as a reference compound, in acetic acid containing sulfuric acid as catalyst.

Deuteration was accomplished by the Grignard reaction of the corresponding bromo-compounds, while *p*-bromothioanisole was made[16] by resting sodium methylmercaptide with diazotized *p*-bromoaniline.

The kinetic results, obtained through analyzing the compounds with a mass-spectrometer, are shown in Table I.

TABLE I. FIRST ORDER RATE CONSTANTS, k_1, AND ENTHALPIES AND ENTROPIES OF ACTIVATION OF THE HYDROGEN-DEUTERIUM EXCHANGE REACTIONS

Compound	Temp. °C	k_1, sec^{-1}	$H^{\neq}$, kcal./mol.	$S^{\neq}$ e. u.
Benzene-d_1	100.0	1.63×10^{-8}		
p-Deutero-anisole	60.8	3.61×10^{-6}		
	79.9	3.55×10^{-5}	26.30	−4.44
	96.6	1.89×10^{-4}		
p-Deuterothio-anisole	80.0	7.68×10^{-7}		
	99.3	6.35×10^{-6}	27.60	−8.37
	119.9	4.36×10^{-5}		

It has previously been established that the relative affinity for a proton is stronger for anisole than for thioanisole. This means that anisole is in a less favorable condition than thioanisole in using its lone electron pair for conjugation, while the electron-withdrawing inductive effect is also stronger for the methoxyl group than for the methylthio group. Yet one finds that the methoxyl group activates the benzene nucleus substantially more than the sulfur counterpart; i. e., anisole reacts thirty to forty times faster than the thioanisole, while both the enthalpy and entropy of the activation of the sulfur compound are larger than those of the oxygen analog by 1.5 kcal./mol. and 4 e. u. respectively.

This result is another support for the well-accepted concept that the electron-releasing conjugative effects decrease with the increasing atomic number of any periodic group.

It is interesting to note that thioanisole reacts fifty times faster than benzene. This means that the methylthio group, in spite of its small value ($\sigma=-0.047$)[17], actually activates the benzene ring in an electrophilic aromatic substitution. In fact, several previous workers have pointed out the strong electron-releasing conjugative effect of the methylthio group in electron-demanding reaction[1a,7,9,18].

Experimental

***p*-Deuteration.** — *p*-Deuteration was carried out by quenching with D_2O the Grignard reagents of *p*-bromoanisole, *p*-bromothioanisole and bromobenzene prepared in anhydrous ether. The boiling points of the deuterated compounds are as follows: anisole, 155.5°C/760 mmHg; thioanisole, 81~81.5°C/18 mmHg; benzene, 81°C/760 mmHg.

Successful deuteration was confirmed by their infrared spectra, near 2200 cm^{-1} and 835 cm^{-1} for deuterated anisole and thioanisole and near 2200 cm^{-1} for benzene-d_1.

Kinetics. — In 10 ml. of acetic acid containing sulfuric acid (molar ratio, $CH_3COOH : H_2SO_4 = 50 : 1$) was dissolved 0.008 mol. of a deuterated compound, and aliquots (1 ml.) of this solution were reacted in ampoules at the desired temperature. At suitable time intervals the contents of the ampoule were poured into 10 ml. of an aqueous 4 N sodium hydroxide solution under cooling with an ice-salt mixture and were extracted with 5 ml. of ether except for benzene-d_1.

After being washed with 2 ml. of water, the ether layer was placed in a mass spectrometer-sample tube and the ether was removed by suction. Without further treatment, the residue was analyzed directly with a mass spectrometer (Atlas CH-3 type).

For benzene-d_1, quenched alkaline solutions were used directly for the analysis. The amount of *p*-deuteroanisole remaining in the reaction mixture (*p*-deuteroanisole plus anisole) was calculated by comparing the peak height of 109 plus 1/8 of that of 107 against that of 108 plus 7/8 of that of 107, assuming that both hydrogen and deuterium split off indiscriminately, giving the peak of 107. This assumption does not seem to be a terribly absurd one in view of the rather small difference in preference for the loss of hydrogen[19]. *p*-Deuterothioanisole gave its main mass peaks at 125,

*Electronic Spectra of Substituted Aromatic Hydrocarbons. III. Anthrols**

By Hiroaki BABA and Satoshi SUZUKI

(Received August 30, 1961)

Analysis of the electronic spectra of the polyacene series has been successfully made from both experimental[1-3] and theoretical[4-6] viewpoints. The correlation diagram of Klevens and Platt[1] for the energy levels of the polyacenes predicted that in anthracene a weak $^1A_g \rightarrow {}^1B_{3u}^-$ ($^1A \rightarrow {}^1L_b$ in Platt's notation[4]) transition is hidden under the stronger $^1A_g \rightarrow {}^1B_{2u}$ ($^1A \rightarrow {}^1L_a$) transition. (Here the group theoretical notation is the same as that used in the preceding paper[7] of this series.) The above prediction was supported by Pariser's calculations[6]. On the other hand, experimental attempts[3,8] to obtain direct evidence for the existence of the hidden transition have failed. It seems impossible at the present time to detect the hidden transition in the spectrum of anthracene itself.

The situation may be different in the case of substitution products of anthracene. When a substituent group is introduced into anthracene, the two transitions in question, $^1A \rightarrow {}^1L_b$ and $^1A \rightarrow {}^1L_a$, undergo changes different both in location and in intensity, on account of differences in their symmetry types. As a result, it is possible that the $^1A \rightarrow {}^1L_b$ transition may emerge from the $^1A \rightarrow {}^1L_a$ transition. With this in mind, the electronic spectra of α- and β-anthrol have been investigated in the present study. It has been proved that the $^1A \rightarrow {}^1L_b$ transition does appear in the spectrum of β-anthrol.

Experimental

Materials.—α-Anthrol was prepared by fusing potassium anthracene-α-sulfonate with potassium hydroxide[9]; it was recrystallized several times from aqueous ethyl alcohol; m. p. 151°C (literature, 152 ~152.5°C[10]). β-Anthrol was prepared by fusion of sodium anthracene-β-sulfonate with potassium hydroxide[11], and it was repeatedly recrystallized from benzene; m. p. 264~266°C under reduced pressure in a sealed tube (literature, 254~256°C[10]). Isooctane (2,2,4-trimethylpentane; Enjay Co., Inc., U. S. A.) was purified by distillation over phosphorus pentoxide.

Apparatus and Procedure.—Absorption spectra were obtained at 20°C in the same manner as in the preceding paper[7], with a Hitachi photo-electric spectrophotometer of the EPU-2A type.

Fluorescence spectra were measured at room temperature by attaching a Hitachi fluorescence accessory of the L-3 type to the spectrophotometer. The 365 mμ line of a mercury lamp was used as an exciting light; the slit width was fixed at 0.2 mm. It was found that while a solution of α- or β-anthrol was being illuminated by the exciting light, the intensity of the fluorescence was considerably reduced. This difficulty was overcome by using a light of an extremely low intensity and by measuring the fluorescence quickly.

For the calibration of the spectral energy of the fluorescence, a standard tungsten filament lamp was used. The brightness temperature of the filament was measured with an optical pyrometer, and the true temperature was determined to be 2350°K in the usual way. From the spectral energy distribution (based on Planck's law) of a black body at this temperature and the spectral emissivity of tungsten, the spectral energy distribution of the

standard lamp was obtained. The transmittance of the envelope of the lamp was assumed to be constant over the range from 380 to 600 mμ. The observed fluorescence spectra were thus corrected to quantum fluorescence spectra by following the procedure of Melhuish[12]. Allowance was made for the reabsorption of fluorescence in the region where fluorescence and absorption overlap.

Results and Discussion

The absorption spectra of α- and β-anthrol in an isooctane solution are shown in Fig. 1, where the spectrum of the parent hydrocarbon, anthracene, is also given for the sake of comparison. Each of the spectra can be divided into two distinguishable parts, with the boundary at about 35000 cm^{-1}. In this paper, particular attention will be devoted to the electronic transitions situated in the low frequency region (<35000 cm^{-1}).

As is seen in the figure, anthracene shows in the low frequency region a single electronic absorption band with a sharp vibrational structure. This band has been conclusively assigned to the $^1A \rightarrow {}^1L_a$ transition[3]. (For brevity this will hereafter be called the ^1L_a transition.)

The transition of α-anthrol in the low frequency region is undoubtedly analogous to the ^1L_a transition of anthracene, though it is shifted as a whole to the red and its vibrational structure is less sharp. It appears at first sight that the spectrum of β-anthrol involves, in the same region, only one electronic band corresponding to the above-mentioned transition of α-anthrol. However, as will be described below, detailed examination of the β-anthrol spectrum reveals that there exist two different transitions in the frequency region under consideration.

Vibrational Analysis.—The ^1L_a transition of anthracene has a prominent progression whose members are the vibrational components P, Q, etc. shown in Fig. 1, where P is the 0–0 transition. The spacings of these components are almost constant (about 1400 cm^{-1}) and are related to a totally symmetric carbon stretching vibration[3,13].

The frequencies of the principal vibrational components for the absorption bands of α- and β-anthrol are given in Table I, together with their differences. The vibrational components P, Q, etc. in α-anthrol are almost equally spaced; they are considered to correspond, respectively, to the components P, Q, etc. in the parent molecule. Thus, the α-anthrol transition, to which the components P, Q, etc. belong, must be of the ^1L_a type.

There are five main vibrational components, A, B, P, Q and R, in the β-anthrol spectrum. Of the intervals of these components, the one between B and P is exceptionally large, so that it is not possible to regard all five components as members of a single progression. One may thus reasonably assume that there are two different overlapping transitions and that the

components A and B belong to one transition and P, Q and R to the other. These two transitions will be referred to as I and II respectively.

Relation between Fluorescence and Absorption. —The fluorescence spectra of α- and β-anthrol in isooctane solution are shown in Figs. 2 and 3, where $F_Q(\nu)$ denotes the relative fluorescence quantum yield per unit frequency interval at frequency ν. In the figures, the absorption spectra are also given for ready comparison.

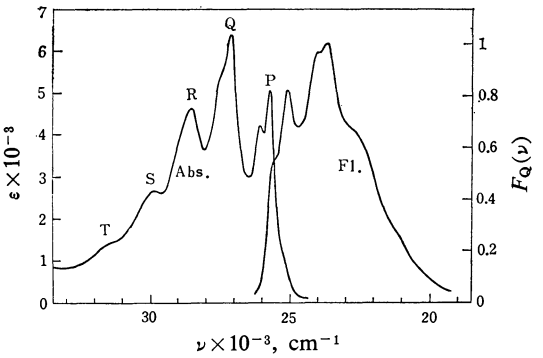

Fig. 2. Fluorescence and absorption spectra of α-anthrol in isooctane. The solute concentration for fluorescence: 5.22×10^{-5} mol./l.

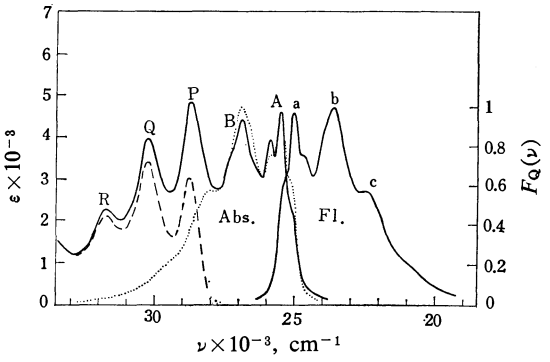

Fig. 3. Fluorescence and absorption spectra of β-anthrol in isooctane. The solute concentration for fluorescence: 4.16×10^{-5} mol./l. See the text for the dotted and broken line curves.

The fluorescence of anthracene is known to be due to the $^1B_{2u} \rightarrow {}^1A_g$ transition[3], which corresponds to the absorption transition of the ^1L_a type. A mirror symmetry has been found between the fluorescence and absorption spectra for anthracene[14]. As is seen in Fig. 2, the fluorescence of α-anthrol has an approximate mirror image relation with the absorption that has been assigned to the ^1L_a transition.

Apparently no such relation exists between the fluorescence and absorption spectra of β-anthrol. In attempting to explain this anomalous fact, let it be assumed, as before, that the low frequency absorption of β-anthrol is due to two overlapping electronic transitions, I and II. It is generally postulated that fluorescence originates in a single electronic transition, which corresponds in most cases to the lowest energy transition. Accordingly, the fluorescence of β-anthrol should be related to that part of the absorption which corresponds to the lower energy transition, I, of the two overlapping transitions.

The above situation can be understood on inspection of the dotted line curve in Fig. 3 which represents the mirror image of the fluorescence spectrum. It is seen that the vibrational peaks a and b of the fluorescence correspond to the absorption peaks A and B respectively. There is another peak, c, in the fluorescence; the corresponding peak cannot be found in the absorption spectrum, probably because it is masked by the absorption due to the higher energy transition, II.

If one is allowed to approximate the absorption due to transition I by the mirror image of the fluorescence, the absorption due to transition II alone may be determined. The latter absorption is depicted in Fig. 3 as a

14) G. Kortüm and B. Finckh, *Z. physik. Chem.*, **B52**, 263 (1942).

broken line curve, wihch is obtained by subtracting the absorption of transition I (dotted curve) from the total absorption (solid curve).

Spectral Changes Accompanying Dissociation of Proton.—The foregoing arguments suggest that two absorption bands due to different electronic transitions appear in the low frequency region when a hydroxyl group is introduced into anthracene at the β-position. This phenomenon is presumably caused by the electron-donating character of that group. It is then to be expected that such a phenomenon will be more distinctly observed in the negative ion of β-anthrol, since the $-O^-$ group is of a more electron-releasing nature than the $-OH$ group. Measurements have therefore been made of the absorption and fluorescence spectra of β-anthrol in a 0.4% aqueous solution of sodium hydroxide[15]. The results are shown in Fig. 4; the frequencies of the absorption maxima are recorded in Table I.

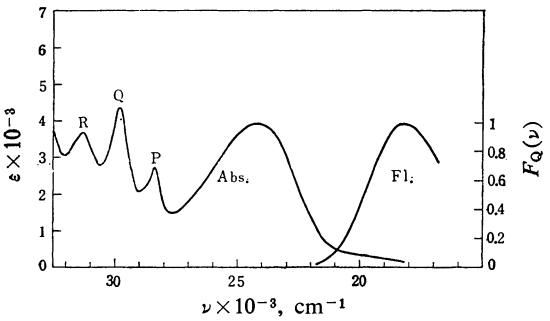

Fig. 4. Fluorescence and absorption spectra of β-anthrol in 0.4% sodium hydroxide solution. The solute concentration for fluorescence: 9.78×10^{-5} mol./l.

As was expected, the negative ion gives two electronic absorption bands at about 24000 cm^{-1} and 30000 cm^{-1}, with a clear minimum between them. Comparison of the absorption spectra for the neutral molecule and the negative ion of β-anthrol shows that, upon dissociation of the proton, transition I is markedly displaced to the red and its vibrational structure is smoothed out, while transition II is shifted only slightly to the red. As a result, the two transitions are separated from each other in the negative ion. The fluorescence of the ion is seen to correspond to the absorption at 24000 cm^{-1}.

Assignment.—It has already been stated that the low frequency absorption of α-anthrol is to be assigned to the ^1L_a transition.

As to the absorption spectrum of β-anthrol in the low frequency region, the results of the present experiments indicate that, in all probability, it consists of two different electronic transitions. It is then natural to consider that the ^1L_b transition, which is believed to be hidden under the ^1L_a transition in the parent molecule, emerges owing to the perturbation of the hydroxyl group at the β-position. If this is the case, the next problem is to decide which of the two transitions, I or II, is of the ^1L_b type.

In order to get a clue to this problem, reference will be made to the absorption spectra of α- and β-naphthol. According to the experimental results reported in the preceding paper[7], substitution of a hydroxyl group into naphthalene at the α-position gives rise to a red shift in both the ^1L_a and ^1L_b transitions. On the other hand, when the substitution is made at the β-position, the ^1L_b transition is noticeably shifted to the red and intensified, whereas the ^1L_a transition is slightly displaced to the blue with a reduction in intensity.

Now, let it be assumed that similar spectral changes take place in the ^1L_a and ^1L_b transitions in going from anthracene to the anthrols. Then the ^1L_b transition is to be expected to appear in β-anthrol on the lower frequency side of the ^1L_a transition, while it remains under the ^1L_a transition in the case of the α-isomer. Transitions I and II of β-anthrol may thus be assigned to the ^1L_b and ^1L_a transitions respectively. The same assignment applies to the transitions of the negative ion of β-anthrol.

It is seen from the observed spectral data that the above assignment in turn leads to the following conclusion: The ^1L_b transition is situated at lower frequencies and is of a higher intensity in β-anthrol (or its negative ion) than in anthracene, while the reverse is true of the ^1L_a transition. The assignment and the interpretation of the individual vibrational peaks are given in Table I for α-anthrol and for the neutral molecule and the ion of β-anthrol.

The effect of substitution on electronic transitions was discussed for anthracene by Jones[16] in terms of the resonance theory. It was suggested that the shift of a transition due to substitution should depend both upon the direction of the electric moment associated with the transition and upon the position of the substitution. Since the ^1L_b and ^1L_a transitions are polarized along the long and short molecular axes respectively, it may be said that the present assignment of the transitions for α- and β-anthrol is compatible with the view of Jones.

15) The absorption spectrum of α-anthrol in the same solution was found to be subject to change during the measurement, so that it is not reported on here.

16) R. N. Jones, *Chem. Revs.*, **41**, 353 (1947).

Mention should also be made of the high frequency transitions. The strong absorption of anthracene at 40000 cm^{-1} has been assigned to a $^1A_g \rightarrow {}^1B_{3u}{}^+$ ($^1A \rightarrow {}^1B_b$) transition[4,6]. It is seen in Fig. 1 that this absorption does not undergo a substantial change when passing from the parent molecule to the anthrols, although a red shift and a change of intensity are seen to occur. Apparently the anthrols have one or two other transitions in the higher frequency region. Discussion of these transitions will be undertaken in a later paper[17].

Summary and Conclusion

The present study of the absorption and fluorescence spectra of α- and β-anthrol has made it possible to explain in a satisfactory manner the origins of their lower electronic transitions. The absorption of α-anthrol in the low frequency region is due to a single electronic transition, which can be assigned to the ^1L_a transition. It is concluded on the basis of vibrational analysis, relation between fluorescence and absorption, and spectral changes accompanying dissociation of the proton that the corresponding absorption in β-anthrol consists of two overlapping electronic bands; this conclusion is further supported by an investigation of spectral changes accompanying the formation of a hydrogen bond between β-anthrol and dioxane[17]. Of the two overlapping bands, the one at the lower frequencies is reasonably assigned to the ^1L_b transition, which has not been found in the spectrum of anthracene, and the other to the ^1L_a transition.

It is of interest to apply to other anthracene derivatives the idea that substitution at the β-position causes the hidden ^1L_b transition of anthracene to appear at lower frequencies. In this connection it is worthy of note that the absorption spectra of β-aminoanthracene and β-acetylanthracene exhibit abnormal features in the lowest frequency region[16]. This fact may perhaps be best explained in the light of the present interpretation of the spectrum of β-anthrol.

The authors wish to express their great gratitude to Dr. Yuichi Kanaoka and Mr. Tetsuya Takeda for preparation of the materials.

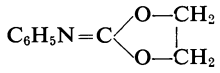
Reactions of Iminocarbonates with Acids

By Teruaki MUKAIYAMA, Tamotsu FUJISAWA and Teruo HYUGAJI



(Received September 2, 1961)

Intramolecular dehydrations of primary nitroparaffins[1,2], aldoximes[3,4,5] and hydroxamic acids[6] into nitrile oxides, nitriles and isocyanates respectively, by means of unsaturated organic reagents, such as isocyanates, carbodiimides, acetylenic ethers, ketene acetals and vinyl ethers, have been described in preceding papers. Further study has now been carried out on the reactions of iminocarbonates, which are considered to be the acetals of isocyanates, with a view to extending the scope of the organic dehydrating reagents.

In the first place, diethyl *N*-phenyl iminocarbonate (I) was chosen. This compound has been reported to be stable towards alkalies and water, but to be split by dilute hydrochloric acid, even while cold, into aniline and diethyl carbonate[7]. Contrary to the cases of isocyanates, however, the reaction of I with benzaldoxime could hardly be observed even at 100°C or in the presence of basic or acidic catalysts, such as triethyl amine or boron trifluoride, and most of the starting materials could be recovered. In the presence of hydrogen chloride, a protonic acid, as a catalyst, the reaction gave the expected ethyl *N*-phenyl carbamate, but the dehydration of benzaldoxime did not take place and the aldoxime was recovered.

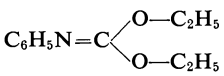
2) T. Mukaiyama and T. Hata, This Bulletin, **33**, 1382 (1960).
3) T. Mukaiyama and T. Hata, ibid., **33**, 1712 (1960).
4) T. Mukaiyama and T. Hata, ibid., **34**, 99 (1961).
5) T. Mukaiyama, K. Tonooka and K. Inoue, *J. Org. Chem.*, **26**, 2202 (1961).
6) T. Mukaiyama and H. Nohira, ibid., **26**, 782 (1961).
7) W. R. Smith, *Am. Chem. J.*, **16**, 372 (1894).

When hydrogen chloride was passed into a solution of I in dry benzene, a violent reaction occurred, forming ethyl *N*-phenyl carbamate in a quantitative yield. This reaction is of the same type as that of diethyl iminocarbonate with hydrogen chloride by which Sandmeyer[8] obtained ethyl chloride and ethyl carbamate. Ethylene *N*-phenyl iminocarbonate (II), which was prepared from phenyl imidophosgene and sodium salt of ethylene glycol, also reacted with hydrogen chloride, giving β-chloroethyl *N*-phenyl carbamate in a 63% yield.

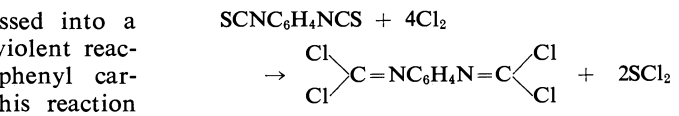


(II)

$$\rightarrow C_6H_5NHCOOCH_2CH_2Cl$$

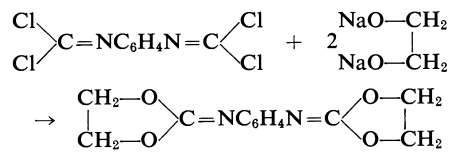
Since it was found that dehydration did not take place in the reaction with the iminocarbonates and that they were readily decomposed by hydrogen chloride, their reactions with carboxylic and with phosphoric acids studied further.

The reaction of I with acetic acid did not take place at room temperature, but it did proceed well after they had been heated on a water bath at 100°C for 1 hr., giving ethyl *N*-phenyl carbamate and ethyl acetate in high yields. Similarly, I reacted with benzoic acid, giving ethyl *N*-phenyl carbamate and ethyl benzoate, when they had been refluxed in dry benzene for 1 hr.



(I)

$$\rightarrow C_6H_5NHCOOC_2H_5 + RCOOC_2H_5$$



Treatments of II with acetic and benzoic acids also afforded the corresponding β-acyloxyethyl *N*-phenyl carbamate in high yields when refluxed in dry benzene for 2 hr.

$$II + RCOOH \rightarrow C_6H_5NHCOOCH_2CH_2OCOR$$

Next, in order to apply these reactions to the field of polymer chemistry, a compound containing two iminocarbonate groups was treated with acids. As the bifunctional iminocarbonate has not been reported on so far, the preparation of *N*, *N'*-*p*-phenylene bis(ethylene iminocarbonate) (III) was tried by a procedure similar to that for II. *p*-Phenylene diimidophosgene was produced by passing dry chlorine through a solution of *p*-phenylene diisothiocyanate in chloroform instead of the carbon tetrachloride which had been used as a solvent in the case of phenyl imidophosgene.

The use of chloroform is better than that of carbon tetrachloride because the latter leads to the decomposition of the reaction products, giving a dark-stained thick oil. *p*-Phenylene diimidophosgene is unstable towards moisture and is subject to decomposition into *p*-phenylene diamine hydrochloride; it is also desirable to keep it in a vacuum desiccator. One mole of *p*-phenylene diimidophosgene and 2 mol. of sodium salt of ethylene glycol gave III in a 25% yield when refluxed in dry benzene for 5 hr.

(III)

$$+ 4NaCl$$

When a solution of 1 mol. of III and 2 mol. of benzoic acid in dry benzene was refluxed for 2 hr., *p*-phenylene bis(benzoyloxyethyl carbamate) was obtained in a good yield.

$$III + 2C_6H_5COOH \rightarrow C_6H_5COOCH_2\cdot CH_2OCONHC_6H_4NHCOOCH_2CH_2OCOC_6H_5$$

Further, the reactions of III with dicarboxylic acids, such as adipic and terephthalic acids, in dry dimethyl formamide were tried, producing substances with alternating ester and urethan linkages.

$$III + HOCORCOOH \rightarrow [—OCORCOOCH_2\cdot CH_2OCONHC_6H_4NHCOOCH_2CH_2—]_n$$

Finally, when the reaction of I with diethyl phosphate was tried, ethyl *N*-phenyl carbamate and triethyl phosphate were obtained in about 85% yields.

$$I + (C_2H_5O)_2POOH \rightarrow C_6H_5NHCOOC_2H_5 + PO(OC_2H_5)_3$$

This type of reaction of iminocarbonates with acids resembles the so-called Pinner decomposition[9], which involves the reactions of imidoesters with acids to form the amides and esters of the corresponding acids; the reactions seem to proceed through an initial formation of intermediate IV, which in turn decomposes to give urethans and esters of the corresponding acids.

8) T. Sandmeyer, *Ber.*, **19**, 862 (1886).

9) F. Cramer, K. Pawelzik and F. W. Lichtenthaler, *Chem. Ber.*, **91**, 1555 (1958).

$$R'N=C\begin{matrix}OR\\OR\end{matrix} + HX \rightarrow \left[R'\overset{+}{N}H=C\begin{matrix}OR\\OR\end{matrix}\right]X^- \quad (IV)$$

$$\rightarrow R'NHCOOR + RX$$

The initial formation of salt by the interaction of acids because of the strongly basic character attributed to their two alkoxyl groups leads to the formation of ester and urethan, in contrast with the reaction of isocyanates with acids, which yields addition compounds.

Experimental

Diethyl *N*-Phenyl Iminocarbonate (I).—This compound was prepared from phenyl imidophosgene and sodium ethylate following the procedure of Smith[7].

Phenyl Imidophosgene.—This was prepared from phenyl isothiocyanate and chlorine according to the procedure of Bly, Perkins and Lewis[10].

Reaction of I with Hydrogen Chloride.—Into a solution of 3.9 g. (0.02 mol.) of I in 10 ml. of dry benzene was passed dry hydrogen chloride. An evolution of heat was noticeable, and when it was over, the mixture was heated on a water bath at 100°C for half an hour in order to complete the reaction. Then the benzene was removed, and ethyl *N*-phenyl carbamate was obtained and was recrystallized from petroleum ether. Yield 3.3 g. (100%); m. p. 49~51°C, while the mixed melting point with the authentic sample was the same.

Ethylene *N*-Phenyl Iminocarbonate (II).—Into 5.3 g. (0.05 mol.) of sodium salt of ethylene glycol suspended in 30 ml. of dry benzene was added, vigorously stirred, over a period of 10 min., 20 ml. of dry benzene, dissolving 8.0 g. (0.05 mol.) of phenyl imidophosgene. Then the reaction mixture was refluxed on a water bath for 2 hr. while the stirring was continued. It was then poured into water and extracted with benzene, and the benzene solution was washed twice with water. The solution was dried with calcium chloride, and the benzene was removed completely in vacuo. II was solidified and was recrystallized from ether to give needles; yield 6.0 g. (80%); m. p. 73~75°C.

Found: C, 66.03; H, 5.72; N, 8.74. Calcd. for $C_9H_9O_2N$ (II): C, 66.24; H, 5.56; N, 8.58%.

Reaction of II with Hydrogen Chloride.—Dry hydrogen chloride was saturated into a solution of 1.3 g. (0.008 mol.) of II in 40 ml. of dry benzene by warming on a water bath for 1 hr. On evaporation of the benzene, crude β-chloroethyl *N*-phenyl carbamate was obtained and was recrystallized from ether-cyclohexane, yield 1 g. (63%); m. p. 49~51°C.

Reaction of I with Acetic Acid.—A mixture of 7.7 g. (0.04 mol.) of I and 2.4 g. (0.04 mol.) of acetic acid was heated on a water bath at 100°C for 1 hr. Then 2.8 g. (80% yield) of ethyl acetate was obtained by distillation at 78~80°C at ordinary pressure. After the residue had been cooled, ethyl *N*-phenyl carbamate was obtained and was recrystallized from petroleum ether; yield 5.8 g. (88%); m. p. and mixed m. p. 49~51°C.

Reaction of I with Benzoic Acid.—A mixture of 7.7 g. (0.04 mol.) of I and 4.9 g. (0.04 mol.) of benzoic acid in 20 ml. of dry benzene was refluxed on a water bath for 1 hr., and then the benzene was removed. Distillation gave 5.7 g. (95% yield) of ethyl benzoate at 88~90°C/12 mmHg. When the residue was cooled, ethyl *N*-phenyl carbamate was solidified and was recrystallized from petroleum ether; yield 5.8 g. (88%); m. p. and mixed m. p. 49~51°C.

Reaction of II with Acetic Acid.—A solution of 4.0 g. (0.025 mol.) of II and 1.5 g. (0.025 mol.) of acetic acid in 20 ml. of dry benzene was refluxed on a water bath for 2 hr. When the benzene had been removed and the brown oily residue kept standing for three weeks, then there were obtained colorless chunky prisms of β-acetoxyethyl *N*-phenyl carbamate which could not be recrystallized from any solvent; yield 2.3 g. (42%); m. p. 43~45°C.

Found: C, 59.06; H, 6.29; N, 6.33. Calcd. for $C_{11}H_{13}O_4N$: C, 59.18; H, 5.87; N, 6.28%.

Reaction of II with Benzoic Acid.—A mixture of 1.6 g. (0.01 mol.) of II and 1.2 g. (0.01 mol.) of benzoic acid in 20 ml. of dry benzene was refluxed on a water bath for 1 hr. After the removal of the benzene, β-benzoxyethyl *N*-phenyl carbamate was obtained and was recrystallized from benzene to give needles; yield 2.3 g. (81%); m. p. 115~116°C.

Found: C, 67.27; H, 5.46; N, 5.03. Calcd. for $C_{16}H_{15}O_4N$: C, 67.36; H, 5.30; N, 4.91.

***p*-Phenylene Diimidophosgene.**—A solution in 100 ml. of chloroform of 19.2 g. (0.1 mol.) of *p*-phenylene diisothiocyanate, which had been prepared according to the procedure of van der Kerk, Pluygers and de Vries[11] and which had been recrystallized from petroleum ether[12], was saturated with dry chloride. As an evolution of heat was noticeable during the reaction, the solution was cooled in ice-water. The color of the reaction mixture gradually became red. After the chloroform and sulfur chloride had been partially removed by distillation, the resulting crude *p*-phenylene diimidophosgene was kept standing in vacuo in order to remove them completely. Recrystallization from ether afforded pale yellow needles; yield 23.0 g. (85%); m. p. 94~96°C.

Found: C, 35.87; H, 1.58; N, 10.45. Calcd. for $C_8H_4N_2Cl_4$: C, 35.55; H, 1.48; N, 10.37%.

***N,N'*-*p*-Phenylene Bis(ethylene iminocarbonate) (III).**—To 8.7 g. (0.04 mol.) of sodium salt of ethylene glycol suspended in 200 ml. of dry benzene was added dropwise, by vigorous stirring and refluxing on a water bath, a solution of 5.4 g. (0.02 mol.) of *p*-phenylene diimidophosgene in 200 ml. of dry benzene at such a rate that the addition was completed in about 1 hr., while the stirring and the refluxing were continued for an additional 4 hr. Then the reaction mixture was filtered while still hot, and from the filtrate about two-thirds of the benzene was distilled off. When it was cooled, III

12) This compound, which was recrystallized from glacial acetic acid, did not give a good result.

was obtained as a white precipitate. By extracting the filtered mass with hot benzene, a considerable increase in the yield was observed. Several recrystallizations from acetone afforded a white solid; yield 1.3 g. (25%); m. p. 188~190°C.

Found: C, 58.13; H, 5.13; N, 11.45. Calcd. for $C_{12}H_{12}O_4N_2$ (III): C, 58.06; H, 4.87; N, 11.29%.

Reaction of III with Benzoic Acid.—A mixture of 0.62 g. (0.0025 mol.) of III and 0.61 g. (0.005 mol.) of benzoic acid in 50 ml. of dry benzene was refluxed on a water bath while being stirred for 2 hr. After the removal of the benzene, *p*-phenylene bis(benzoyloxyethyl carbamate) was obtained and recrystallized from methanol many times to give a white solid; yield 1.0 g. (81%); m. p. 180~182°C.

Found: C, 62.62; H, 5.19; N, 5.69. Calcd. for $C_{26}H_{24}O_8N_2$: C, 63.41; H, 4.91; N, 5.68%.

Reaction of III with Adipic Acid.—A mixture of 0.62 g. (0.0025 mol.) of III and 0.37 g. (0.0025 mol.) of adipic acid in 10 ml. of dry dimethyl formamide was heated and stirred on a water bath at 85°C for 2 hr. and was then vigorously stirred into water to precipitate a polymer, alternating poly(adipate/*p*-phenylene bis(ethylene carbamate)), which separated as a brown solid. The polymer was filtered off and washed several times by stirring with water and dried in vacuo overnight; yield 0.81 g. (81%); m. p. 140°C.

Found: N, 7.59. Calcd. for $(C_{18}H_{22}O_8N_2)_n$: N, 7.10%.

Reaction of III with Terephthalic Acid.—A mixture of 0.62 g. (0.0025 mol.) of III and 0.42 g. (0.0025 mol) of terephthalic acid in 15 ml. of dry dimethyl formamide was heated and stirred on a water bath at 85°C for 2 hr. and then filtered. The clear solution was vigorously stirred into water to precipitate a polymer, alternating poly(terephthalate/*p*-phenylene bis(ethylene carbamate)), which separated as a white solid. The polymer was filtered off and washed several times by stirring with water and dried in vacuo overnight; yield 1.01 g. (97%); m. p. 236°C.

Found: N, 7.44. Calcd. for $(C_{20}H_{18}O_8N_2)_n$: N, 6.76%.

Reaction of I with Diethyl Phosphate.—A solution of 3.1 g. (0.02 mol.) of diethyl phosphate and 3.9 g. (0.02 mol.) of I in 10 ml. of dry benzene was refluxed on a water bath for 3 hr. After the benzene had been removed, distillation gave 3.1 g. (86% yield) of triethyl phosphate at 96~98°C/13 mmHg (Found: P, 16.98%).

When the residue was cooled, ethyl *N*-phenyl carbamate was obtained and was recrystallized from petroleum ether; yield 2.6 g. (87%); m. p. and mixed m. p. 49~51°C.

Summary

Iminocarbonates, whose chemical properties have been little investigated, were prepared from sodium alkoxides and corresponding imidophosgene.

Diethyl *N*-phenyl iminocarbonate gave urethan and esters by reaction with acids, such as hydrogen chloride, carboxylic acids and diethyl phosphate. β-Acyloxyethyl *N*-phenyl cabamates were prepared from the reactions of ethylene *N*-phenyl iminocarbonate with carboxylic acids.

These reactions were applied to the syntheses of polymers, and the alternating poly(urethan/ester)s were obtained.

The authors wish to express their hearty thanks to Mr. Keiji Naruse for his microanalyses.

Molecular Polarisability. The Molar Kerr Constant and Conformation of Diphenyl Ether as a Solute in Benzene

By R. J. W. Le Fèvre, A. Sundaram and K. M. S. Sundaram

(Received August 14, 1961)

Attention has recently[1] been drawn to the problem of assigning a space-formula to diphenyl ether. Both in conversations at Princeton and in Ref. 1, p. 30, Professor K. Higasi has indicated that the Sydney group might provide helpful evidence on the matter. Accordingly we have measured the molar Kerr constant of diphenyl ether at infinite dilution in benzene and now desire to record and discuss our results.

Experimental and Computational Methods.— For brevity we omit details of apparatus and

1) K. Higasi, "Dielectric Relaxation and Molecular Structure", *Monograph Series of the Research Institute of Applied Electricity*, No. 9, Hokkaido University, Sapporo, Japan, 1961.

technique since they are described in detail elsewhere[2,3]. Dielectric constants, ε, densities, d, refractive indexes, n, and Kerr constants, B, of solutions containing weight fractions, w, of diphenyl ether in benzene at 25° are listed in Table I; the n's and B's were measured with Na-light. Suffixes 1, 2, and 12 indicate respectively a property of the solvent, solute, or solution; the prefix Δ denotes a difference between solution and solvent, e. g. $\Delta\varepsilon=\varepsilon_{12}-\varepsilon_1$, $\Delta d=d_{12}-d_1$, $\Delta n=n_{12}-n_1$, and $\Delta B=B_{12}-B_1$. The symbols α, β, γ, and δ are from the equations, $\varepsilon_{12}=\varepsilon_1(1+\alpha w_2)$, $d_{12}=d_1((1+\beta w_2)$, $n_{12}=n_1(1+\gamma w_2)$, and $B_{12}=B_1(1+\delta w_2)$, which are assumed to apply at low w_2's and to be usable whenever Δ(property) appears rectilinear with w_2; γ' refers to the square of the refractive index, $n^2_{12}=n^2_1(1+\gamma' w_2)$. Molar Kerr constants, total polarisations, etc., extrapolated to infinite dilution are written ${}_\infty({}_mK_2)$, ${}_\infty P_2$, etc.; calculations of these are via specific quantities, e. g. ${}_sK_2$, p_2, and r_2, which when $w_2=0$ are given by relations 1, 2, and 3:

$$ {}_\infty({}_sK_2)={}_sK_1(1-\beta+\gamma+\delta-H\gamma-J\alpha\varepsilon_1) \quad (1) $$

where ${}_sK_1=6\lambda n_1B_1/(n^2_1+2)^2(\varepsilon_1+2)^2d_1$

$H=4n^2_1/(n^2_1+2)$

and $J=2/(\varepsilon_1+2)$;

$$ {}_\infty p_2=p_1(1-\beta)+3\alpha\varepsilon_1/d_1(\varepsilon_1+2)^2 \quad (2) $$

where $p_1=(\varepsilon_1-1)/d_1(\varepsilon_1+2)$;

$$ {}_\infty r_2=r_1(1-\beta)+3\gamma' n^2_1/d_1(n^2_1+2)^2 \quad (3) $$

where $r_1=(n^2_1-1)/d_1(n^2_1+2)$

Derivations of Eqs. 1, 2, and 3 may be found in Refs. 2 and 3. Benzene used as solvent was purified as described in Ref. 3, p. 45.

Observations and Quantities Deduced Therefrom.—These are set out in Table I. When $w_2=0$ (i. e. for the pure solvent) the following apply at 25°: $n_1=1.4973$, $n^2_1=2.24191$, $\varepsilon_1=2.2725$, $d_1=0.87378$, and $B=0.410\times10^{-7}$.

TABLE I. DIPHENYL ETHER IN BENZENE AT 25°

10^5w_2	1035	2249	3432	6853	10985	14557	18137
$10^4\Delta n$	7	15	22	46	74	102	131
$10^4\Delta n^2$	20	44	64	135	218	301	387
$10^4\Delta\varepsilon$	114	240	372	737	1165	1551	1805
$10^5\Delta d$	173	373	575	1168	1892	2515	3157
$10^{11}\Delta B$	61	132	210	410	681	870	1120

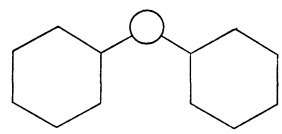
whence $\sum\Delta n/\sum w_2=0.069$

$\sum\Delta n^2/\sum w_2=0.204$

$\sum\Delta\varepsilon/\sum w_2=1.04_6$

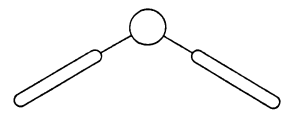
$\Delta d=0.1672w_2+0.0340w^2_2$

$\sum\Delta B/\sum w_2=0.606\times10^{-7}$



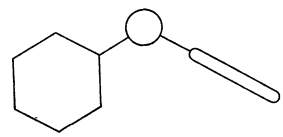
From these data we have: ${}_\infty P_2=80.29$ cc., $R_D=52.68$ cc., ${}_DP=1.05R_D=55.31$ cc., $\mu=1.10_5$D., and ${}_\infty({}_mK_2)=22.4\times10^{-12}$.

Wesson[4] lists two earlier determinations of the dipole moment of diphenyl ether in benzene (viz. 1.02 and 1.13 D.) with neither of which is the new value of 1.10_5 D. in serious disharmony. The Kerr effect of diphenyl ether has never been examined before, either as a pure liquid or as a solute.



Discussion.—The molar Kerr constant of a substance depends upon the principal axes, b_1, b_2, and b_3, of the appropriate polarisability ellipsoid, together with the direction of action of the resultant dipole moment and its magnitude. For a given molecular model, these axes can be calculated from the longitudinal, transverse, and "vertical" polarisabilities of the constituent bonds and groups. (Examples of such operations are given in Refs. 2 or 5.) In the present case only the C–O link[6] and the phenyl-group[7] are concerned:

		C–O	C_6H_5
Longitudinal polarisability	$b_L\times10^{23}$	0.081	1.056
Transverse 〃	$b_T\times10^{23}$	0.039	1.056
"Vertical" 〃	$b_V\times10^{23}$	0.039	0.671



Four models will now be considered, A, B, C and D; only the first three are illustrated here:

A

B

C

Table II. Principal polarisabilities and molar Kerr constants calculated for models A to D

Model*	$10^{23}b_1$	$10^{23}b_3$	$10^{23}b_3$	$10^{12}{}_{\mathrm{m}}K_2$ calcd.
A	2.212	2.253	1.420	+84.1
B	1.635	2.060	2.190	−54.1
C	1.836_5	2.243_5	1.805	−16.6
D	2.003	2.246	1.636	+22.6

* The direction in which b_1 is measured bisects the C_1–O–$C_{1'}$ angle, that for b_2 is parallel to the C_1·····$C_{1'}$ line, and that for b_3 is perpendicular to the C_1–O–$C_{1'}$ triangle.

The molecule is planar in A; in B both phenyl-rings are at 90° to the plane of A; C is Morino's conformation[1] with one ring as in A and one as in B; D is generated from A by twisting each phenyl group by 37° about its O–C_1–C_4 line. In all cases $\mu_{\text{resultant}}$ is taken as acting along the bisector of the C–O–C angle, which—following Higasi[1]—is adopted as 120°. Calculations are summarised in Table II.

Since the molar Kerr constant obtained by experiment is 22.4×10^{-12}, it appears that neither A nor B nor C *alone* represents the diphenyl ether molecule in benzene. It is of course possible to devise mixtures of A and B, or of A with B and C, for which the expected ${}_{\mathrm{m}}K$ would equal that observed, yet there seems to be no recorded evidence against the view that the ether exists as a *single* form, in which case one of type D is indicated.

The angle of twist of 37° was selected by trial and error and is advanced as an "order of magnitude" estimate only (because the data for C–O and phenyl are drawn from paraldehyde[6] and benzene[7] respectively and may not be quite appropriate for diphenyl ether, in which some conjugation effects must also be present). Nevertheless it is interesting that Higasi (Ref. 1, p. 26) calculates that the twist angles for the configuration of minimum energy are 32.5°, and later in the same work (pp. 112—113) explicitly mentions the possibility of a form such as D, which *inter alia* would satisfy Katayama's X-ray study of *o*, *o'*-diiododiphenyl ether (in which the I·····I distance was found to be 5.28±0.07 Å) if the twist angles in this substituted molecule had the values 17.5°.

Finally it is relevant to mention that, via the Kerr effect, Aroney and Le Fèvre[7] concluded that the phenyls in triphenylamine were twisted 65∼70° from the positions in which the three-fold axis of symmetry is parallel to the planes of the Ar-rings, while via electron diffraction, Sasaki, Kimura, and Kubo[8] found angles of 47±5°. By similar arguments to those used with NPh_3, Aroney and Le Fèvre[7] have deduced angles of ca. 45° for triphenylmethane, and unpublished measurements and calculations for benzophenone suggest that twists of about 45° are satisfactory for this molecule also.

Grateful acknowledgement is made to the University of Sydney of the award of an H. B. and F. M. Gritton Research Scholarship to K. M. S. and of the F. A. Q. Stephens Research Fellewship to A. S.

Molecular Configuration of Diphenyl Ether as Revealed by Dielectric Relaxation Times and Molar Kerr Constants

By Keniti HIGASI

(Received September 28, 1961)

Mesomeric Moments in Morino's Structure

Professor Morino[1,2] of the University of Tokyo proposed a space model of a diphenyl ether molecule in 1938. It is easy to see that steric conditions prevent two rings in diphenyl ether from being fully coplanar. Indeed, the nearest non-bonding hydrogen atoms are the small distance of 0.5 Å apart in a coplanar structure. After calculating the repulsive energies between these atoms for a variety of configurations, Morino reached the conclusion that the rings in diphenyl ether tend to be on planes perpendicular to each other. Later, this view

1) Y. Morino, first cited in Ref. 3 and later fully treated in Ref. 2.
2) K. Higasi, "Dielectric Relaxation and Molecular Structure", Research. Inst. Appl. Elec., Hokkaido Univ., (1961).

was found to be in good agreement with experimental results obtained by measurements of the dipole moments of diphenyl ether derivatives[3] and by electron diffraction studies of *p, p'*-dihalogenodiphenyl ethers[4].

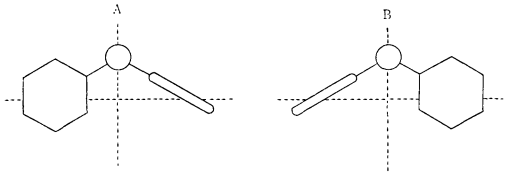

Fig. 1. Two important structures, A and B.

In these earlier studies, however, little attention was paid to the existence of mesomeric moments; Morino's structure in the literature[3] must, therefore, be improved in view of this effect. In order to make this point clearer, two structures, A and B, will be considered, both structures fulfilling Morino's condition: *the two rings are in planes at right angles to each other.* In structure A the ring on the left side of the oxygen atom is taken in the plane of the C–O–C triangle, while the other ring on the right side is perpendicular to the plane of this triangle. In structure B the right ring is in the triangle plane, while the left ring is perpendicular to it.

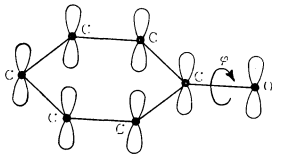

Fig. 2. Overlap of p-orbitals.

Among the atomic orbitals of the oxygen atom, attention will be directed to a pure p orbital which is occupied by two electrons and has its maximum electron density in the direction perpendicular to the C–O–C plane. When the C–O–C triangle is in the plane of a benzene ring, that is, when $\varphi=0$ in Fig. 2, all the p orbitals in the picture are parallel to each other (see Fig. 2). Consequently, in structure A the p orbital of oxygen has a great interaction with the p orbitals of the benzene ring on the left side. On the other hand however, the same orbital has no overlap with the p orbitals belonging to the right ring. It may be said that the oxygen atom is conjugated with the left ring but not with the right ring. According to the molecular orbital theory, π-electrons move freely in the domain of the conjugated part and a fraction of the electrons migrate from the oxygen to the side of the left ring, while no such electron-migration is possible towards the right ring. The so-called "mesomeric moment" is produced only in one direction, that is, towards the left ring in structure A and towards the right ring in structure B.

If the above mesomeric moment had a small magnitude, it seemed that one could usually ignore its effects. However, this seems to have been erroneous. A search in the literature[5] will reveal that the OCH_3 group substituted in benzene is reported to have a mesomeric moment of considerable value, 0.8~0.96 D. If the OCH_3 group lies in the plane of the benzene ring, the mesomeric moment will have a maximum value. Very likely the OCH_3 group has some freedom of rotation. Rotation from the coplanar position will always lower the value of the mesomeric moment; for a twist angle φ mesomeric moment, μ_m, will be expressed by[6]

$$\mu_m = \mu_{max} \cos^2\varphi \qquad (1)$$

The observed values of mesomeric moments show an average value of μ_m for all possible states of rotation, while the mesomeric moment in structure A or structure B corresponds to μ_{max}. Consequently, the latter magnitude must be larger than the former. One may consider that *the moment 0.8~0.96 D will represent the lowest limit of this kind of mesomeric moment in diphenyl ether.*

By a change from structure A to structure B, the region of conjugation is changed and the direction of the mesomeric moment is altered by 120°. Further, such a structural change can be brought about by internal rotation; Morino[1] noticed that the barrier to this sort of internal rotation has an insignificant height. This point was later verified more fully[2].

Dielectric Relaxation Times

According to Debye[7] the dielectric relaxation time of a polar liquid is largely determined both by the size of the polar molecule and by the viscosity of the surrounding medium. Diphenyl ether and benzophenone, both having almost the same molecular size, are expected to have a relaxation time of nearly the same magnitude under the same set of conditions.

6) E. G. McRae and L. Goodman, *J. Chem. Phys.*, **29**, 334 (1958).

7) P. Debye, "Polar Molecules", The Chemical Catalogue Co., New York (1929).

However, this is not what is actually observed. The relaxation time of diphenyl ether in benzene at 25°C, 4.1×10^{-12} sec., is only 22% of that of benzophenone, 18.7×10^{-12} sec.[8] Since the magnitude of the latter substance has been regarded as normal in the light of the Debye theory, the relaxation time of diphenyl ether must be considered anomalous.

Let it be assumed, for the sake of simplicity, that diphenyl ether consists of a mixture of molecules which have structure A or structure B. By application of the electric field, the proportions of the mixture will be changed according to Maxwell's distribution law; hence dielectric polarization will be produced[9]. If an alternating field is applied, dielectric dispersion will occur in the range of a certain critical frequency; the latter is largely determined by the activation energy necessary for the change from structure A to structure B, or vice versa. This predicts a new mechanism of dielectric absorption. It must be entirely different from that proposed by Debye, in whose conception rigid spherical dipoles rotate in the viscous medium. Further, by reason of the low barrier to internal rotation which makes structural change from A to B or from B to A feasible, one will expect that the relaxation time of this mechanism will be small—perhaps smaller than usual. The unusually short relaxation time of diphenyl ether, 4.1×10^{-12} sec., has been explained thus[2,10].

Recently Dr. Vaughan and Prof. Smyth[11] of Princeton University discovered that diphenyl ether has two absorption peaks of unequal height, the smaller one being located at a frequency very near to that of benzophenone. This observation is extremely interesting, because one can estimate the magnitudes of the two dipole moments associated with the two absorption peaks. If μ_1 and μ_2 represent the effective moments of the two peaks which one may consider as arising from overall rotation and internal rotation respectively, then $\mu_1=0.60$ D and $\mu_2=0.97$ D. The smaller peak was detected only on data at 40°C, while data at 60°C closely fit a Cole-Cole arc. Consequently, some might be skeptical as to the existence of the small absorption. If no such absorption exists at all, the magnitude of μ_2 should become identical with that of the molecular dipole moment itself[12]. For this reason one may estimate

$$0.97\text{ D}\simeq\mu_2\leqslant1.14\text{ D} \tag{2}$$

Further we may assume

$$\mu_2=\mu_{\max}\sin\theta/2 \tag{3}$$

in which θ is the oxygen valence angle[2]. If $\theta=120°$, $\mu_{\max}$ will have a magnitude

$$1.12\text{ D}\simeq\mu_{\max}\leqslant1.32\text{ D} \tag{4}$$

The above estimate is considered to be of the right order of magnitude in spite of the fact that it is based on a tentative assumption.

Molar Kerr Constant

Prof. R. S. W. Le Fèvre and his co-workers[13] at the University of Sydney were the first to determine the molar Kerr constant of diphenyl ether in benzene solution. They reached the conclusion that the space formula of Morino does not represent the molecular configuration of diphenyl ether, because K_m calculated for this structure has a negative value of -16.6×10^{-12} while the observed value is a positive $K_m=+22.4\times10^{-12}$. However, there is a point here which is worthy of discussion: they assumed the molecular dipole moment to be acting along the bisector of the C–O–C angle.

We shall define three components of the molecular dipole as follows: the direction of μ_1 bisects the angle C_1–O–C_1, that for μ_2 is parallel to the $C_1\cdots\cdots C_1$ line, and that for μ_3 is perpendicular to the C_1–O–C_1 triangle. The assumption employed by Le Fèvre et al.[13] is:

$$\mu_1=1.105\text{ D}\qquad\mu_2=\mu_3=0.0\text{ D} \tag{5}$$

Indeed, this is essentially the same assumption as that used in 1939 by Higasi and Uyeo[3]. However, this assumption will be valid only for certain configurations if a mesomeric moment of an appreciable magnitude exists on account of the conjugation of the oxygen and some ring or rings.

From the analysis of relaxation times two effective moments μ_1 and μ_2 have been obtained in the previous section. One can use these values here with a certain amount of justification[2,10].

$$\mu_1=0.60\text{ D},\quad\mu_2=0.97\text{ D}\quad\text{and}\quad\mu_3=0.0\text{ D} \tag{6}$$

The molar Kerr constant can be calculated with the use of the above values, resulting in $K_m=45\times10^{-12}$. It is to be noted that the calculated value is no longer a negative quantity. In this calculation three principal polarizabilities, b_1, b_2 and b_3, are taken from Le Fèvre's above-mentioned article[13] as 1.8365, 2.2435 and 1.805×10^{-23} respectively*.

9) H. Fröhlich, "Theory of Dielectrics", Oxford University Press (1949), pp. 15—21.
10) K. Higasi and C. P. Smyth, *J. Am. Chem. Soc.*, **82**, 4759 (1960).
11) W. E. Vaughan and C. P. Smyth, *J. Phys. Chem.*, **65**, 98 (1961).
12) L. G. Wesson, "Tables of Electrical Dipole Moments", Massachusetts Institute of Technology Press (1948).
13) R. J. W. Le Fèvre, (Mrs.) A. Sundaram and K. M. S. Sundaram, This Bulletin, **35**, 690 (1962).

* This is a crude assumption because, as Prof. Le Fèvre remarked, the "longitudinal" polarizability of a partially quinoid phenyl would be greater than the value for ordinary phenyl.

Alternatively we may employ the values of μ_1 and μ_2 given by Higasi and Smyth[10] from an analysis of mesomeric moments,

$$\mu_1=0.54\,\mathrm{D},\quad \mu_2=0.87\,\mathrm{D}\quad \text{and}\quad \mu_3=0.0\,\mathrm{D} \qquad (7)$$

As a result of the use of these values, the molar Kerr constant will become slightly smaller for the above—$K_m=38\times10^{-12}$.

As can be seen from the two examples, one can approach the observed value $K_m=22.4\times10^{-12}$ indefinitely by choosing a larger value for μ_1 and a smaller value for μ_2. However, the writer believes that one might better consider this problem in the following way:

So far the argument has been stated as if a diphenyl ether molecule had a rigid structure shown by structure A or B. On the contrary, the molecule must be non-rigid, with a restricted freedom of rotation around the C–O bonds.

For the purpose of making a little better approximation, a particular type of rotation will be considered, such as satisfying the condition that the two rings are always in planes at right angles to each other. This condition implies that when the left ring in structure A rotates by an angle φ, the right ring must rotate in the same direction by the same amount of angle.

It can be shown by a little calculation[2] that the two components of the molecular dipole, μ_1 and μ_2, will be changed by the above-mentioned rotation in the followlng way:

$$\mu_1=m_0-\frac{1}{2}\mu_{max}$$

$$\mu_2=0.866\,\mu_{max}(\cos^2\varphi-\sin^2\varphi) \qquad (8)$$

in which the valence angle of oxygen is taken as 120°. An estimate of μ_{max} has been given above in Eq. 4. It will be seen that μ_2 is zero only when $\varphi=\pm45°$, $\pm135°$, etc. Consequently, as far as the Morino structure is concerned, one might better consider that the molecular dipole moment is *not* acting along the bisector of the C–O–C angle.

Suppose μ_{max} has quite a large value, 1.4 D, and a magnitude, 0.92 D, for m_0, which represents a dipole arising from two C–O links; we shall obtain for $\varphi=0$

$$\mu_1=0.22\,\mathrm{D}\qquad \mu_2=1.21\,\mathrm{D} \qquad (9)$$

Since μ_2 has a large value while μ_1 is extremely small, K_m for Eq. 9 must have a large magnitude —in fact $K_m=76\times10^{-12}$. This would be the highest possible value for K_m. By use of Eq. 8 one can estimate the variation of K_m with a change in the twist angle φ (see the upper curve* in Fig. 3). It will be seen that if the contribution of rotation to K_m is taken into consideration, the average value of K_m will decrease. The observed value $K_m+22.4\times10^{-12}$ may possibly be accounted for in this manner. The variation of K_m with the twist angle φ when using Eqs. 7 and 8 is shown in the lower curve* of Fig. 3.

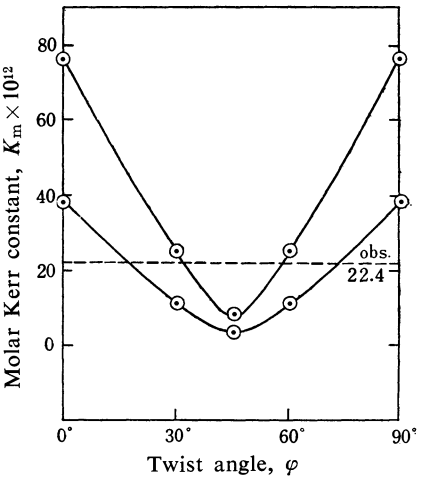

Fig. 3. Variation of the molar Kerr constant of diphenyl ether (Morino) with the twist angle.

It was once suggested by the present writer[2] that the study of the Kerr constant of diphenyl ether might eventually play a decisive role in determining the structure of this molecule. Grateful acknowledgement must be made to Professor Le Fèvre and his group for satisfying this request by carrying out valuable measurements. The analysis of their results has contributed greatly to making many points clearer. However, the magnitude of the molar Kerr constant alone does not appear to be unequivocal evidence *for* or *against* the Morino structure.

Lastly, a few words must be added regarding the dipole moment of diphenyl ether. The dipole moment μ at a twist angle φ is determined by

$$\mu^2=\mu_1^2+\mu_2^2 \qquad (10)$$

in which μ_1 and μ_2 are given by Eqs. 8. Again we shall assume that $\mu_{max}=1.4$ D; then $\mu=1.23$ D, for $\varphi=0$. If free rotation occurs, $\mu=0.88$ D. The observed value, 1.14 D[12], is between the two calculated values.

The above example will suggest that the observed dipole moment and the molar Kerr constant of a non-rigid molecule, diphenyl ether being included, represent average values of various magnitudes corresponding to a great number of possible configurations. The dielectric relaxation time provides two effective dipole moments which are other sorts of

* The estimated values are of only qualitative significance because the three principal polarizabilities are tentatively assumed to be independent of rotation.

average quantities. Possibly the latter is closely associated with the former. However, there is an essential difference: a dipole moment determined from dielectric constant measurements represents a static property of the molecule, while effective moments from dielectric relaxation time analysis are associated with the dynamic nature of the molecule.

The writer wishes to thank Professor R. J. W. Le Fèvre for providing much valuable information. Thanks are also due to Professor C. P. Smyth and Professor Yonezo Morino for their interest in this work.

Identification of Polyphenyls Formed in the Radiolysis of Biphenyl by Reverse Isotope Dilution Analysis

By Hiroaki KŌYAMA*, Gen-ichi TSUCHIHASHI and Akibumi DANNO

(Received January 22, 1962)

The radiolysis of polyphenyls has been studied by many workers[1-4] in order to elucidate the decomposition mechanism of organic coolant-moderator, however no datailed study on the identification of radiolytic products of high molecular weight has hitherto been carried out. The present work aimed to obtain a precise information concerning the radiolytic mechanism for biphenyl, the simplest polyphenyl. Here, reverse isotope dilution analysis by using ^{14}C-labeled compound was applied to determine the yields of terphenyls and quaterphenyls produced by the radiolysis of biphenyl.

Biphenyl-(phenyl-^{14}C) (33.2 mc/mol.)[5,6] was irradiated at 100±5°C in vacuum by gamma-rays (2.60×10^5 r/hr., 150 hr.)[7]. After the compound was irradiated, each carrier component was added to the irradiated sample and was homogeneously mixed using anisole as a homogenizer. Unchanged biphenyl-(phenyl-^{14}C) was removed by sublimation. Each compound was isolated by liquid elution chromatography on activated alumina with petroleum ether and then recrystallized from a suitable solvent several times to give a constant specific activity. Radioactivity of the purified product was determined using a Tri-Carb liquid scintillation spectrometer or an ionization chamber-vibrating reed electrometer.

radiolysis of biphenyl is assumed to occur according to the following equations:

Each molecule of terphenyl or quaterphenyl is presumed to be formed by the attach of a phenyl radical (ion) or a biphenyl radical (ion), respectively on biphenyl while radicals (ions) are undoubtedly produced directly in the primary process of the irradiation. Although we did not determine *G*-values for the formation of the three remaining unsymmetrical quaterphenyls, they would probably be of the same magnitude as those for the symmetrical ones. Then, the sum of *G*-values for quaterphenyl formation becomes several times as large as that for terphenyl. Therefore, the number of C–H bond ruptures becomes about ten times as large as that of C–C (phenyl-phenyl) bond ruptures. The ratio of these numbers agrees with that of the numbers of C–H and of C–C (phenyl-phenyl) bonds in biphenyl. Consequently, the rate of the rupture C–H bond in biphenyl by gamma-rays is of the same magnitude as that of C–C (phenyl-phenyl) bond.

2) If it is assumed that (1) the radical formation by gamma-rays and the following substitution reaction with these radicals take place at all the positions of biphenyl with equal ease and (2) *o*, *o'*-quaterphenyl can exist only as trans form due to steric hindrance, one would expect that the ratios of *G*-values of *o*-, *m*-, *p*-terphenyl and *o*, *o'*-, *m*, *m'*-, *p*, *p'*-quaterphenyl should be 2 : 2 : 1 and 2 : 4 : 1. However this was not the case. Accordingly, it seems that there is an orientation effect in the substitution reaction of biphenyl with these radicals which were produced initially by the irradiation and then thermalized. We are currently investigating the significance of this large *G*-value for *p*, *p'*-quaterphenyl formation.

Details of this study will be published later.

Absolute Configuration of Deoxynupharidine[1]

By Ichiro KAWASAKI and Takeo KANEKO

(Received February 19, 1962)

Recentry, the determination of the conformation of methylquinolizidine by means of the NMR spectrum was reported briefly[2]. Independently, we have prepared 1-, 3- and 4-methylquinolizidine having a definite conformation and their NMR spectra were compared in order to determine the configuration of deoxynupharidine[3,4] with those of 1, 7-dimethyl (III) and 1, 4, 7-trimethylquinolizidine (VI) which were derived from deoxynupharidine by the degragation according to the following schema:

The doublet of 350~354 c. p. s. and the other doublet of 327~333 c. p. s. in the spectrum of III were attributed to a 1-equatorial and a 3-axial methyl group, respectively. The doublet

of 337~344 c. p. s. in the spectrum of VI was assigned to a 4-equatorial methyl group, since the intensity of the peak at 337 c. p. s. was found to be twice that of the peak at 354 c. p. s.

The absolute configuration of deoxynuphridine can thus be shown as either Ia and Ib. Since the configuration of (−)-α-methyladipic acid (VII) obtained from Hofmann degradation of deoxynupharidine was found to have the S(−) configuration[5], we reached to the conclusion that the absolute configuration of deoxynupharidine should be represented by the

Molecular Weight Measurement of Polystyrene by Archibald Method

By Akira KOTERA, Naomichi ISO, Katsumi UMEZAWA and Yuji MIYAZAWA

(Received February 3, 1962)

Archibald[1] and others[2-9] have reported a method of determining molecular weight by ultracentrifuge during approach to sedimentation equilibrium. Application of this method to synthetic high polymer has been studied in this experiment.

Polystyrene which was used as the common sample by the research group of light scattering measurement in Japan was centrifuged with two kinds of ultracentrifuge, the magnetically suspended free running type ultracentrifuge with a Rayleigh interference optical system and a Spinco Model E ultracentrifuge with a schlieren optical system. All this experiments were done in butanone solution.

Weight average molecular weight, M_w, in this method is determined by obtaining the quantity δ_w at the point a and b, the boundary surface of solution and the bottom of cell, according to the following equation.

$$\delta_w = (1/xC)(dC/dx) = (1-\bar{v}\rho)\omega^2 M_w/RT \quad (1)$$

where x is the distance from the center of rotation, C the concentration of solution, $\bar{v}$ the partial specific volume of solute, ρ the density of solution, R the gas constant, T the absolute temperature, and ω the angular velocity of rotation.

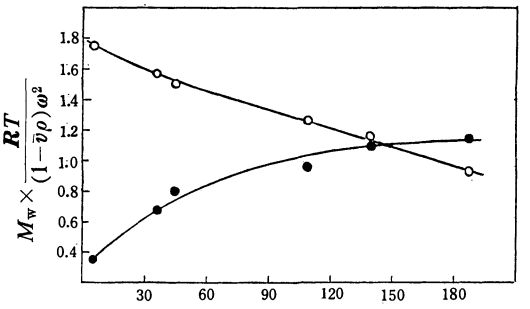

Fig. 1. Time dependencies of the apparent average molecular weights, M_{wb} and M_{wa}, calculated by Archibald's equation.
$C_0=0.243$ RPM$=7.6\times10^3$
● δ_{wa} ○ δ_{wb}

The values of δ_{wa} and δ_{wb} calculated by Eq. 1 vary with time as shown in Fig. 1. In Archbald's expectation, the curve of δ_{wb} will be higher than that of δ_{wa} and both curves should meet when extrapolated to zero time. To the contrary of expectation, however, δ_{wa}'s are larger than δ_{wb}'s at the initial stage of sedimentation. Thereafter δ_{wa}'s decrease and δ_{wb}'s increase gradually with time and both curves become crossing together after some minutes.

Comparing the results of the free running type ultracentrifuge experiments and those of Spinco ultracentrifuge, this crossing point, t_c, seems to be dependent on the time consumed during driving the rotor to experimental speed. On the other hand, in the results obtained by the later experiment it shows that the other experimental conditions, concentratin of solution and the rotor speed, have the effects on t_c. Trautman plot[8] was also examined.

But the both plots corresponding to the boundary surface of solution and the bottom of cell have curvatures indicating the molecular weight heterogeneity and thermodynamical non-ideality of the solution, and they do not meet at zero time.

TABLE I. RESULTS WITH FREE RUNNING TYPE U. C. at 30°C

C_0 g./100 ml.	RPM $\times 10^{-3}$	t_c min.	M_w^{app} $\times 10^{-4}$	M_w^{app}* $\times 10^{-4}$
0.120	5.4	135	29.6	23.0
0.222	5.8	285	23.1	19.5
0.411	5.7	225	20.9	17.8
0.694	5.8	195	19.3	15.8
$C_0 \rightarrow 0$	—	—	31.2	26.4

* The results obtained by sedimentation equilibrium.

TABLE II. RESULTS WITH SPINCO MODEL E U. C. at 20°C

C_0 g./100 ml.	RPM $\times 10^{-3}$	t_c min.	M_w^{app} $\times 10^{-4}$
0.137	10.5	7	20.5
0.209	10.5	12	17.7
0.384	10.5	13	15.4
0.242	8.7	15	17.9
0.242	7.2	18	17.6
0.242	5.1	32	17.0
$C_0 \rightarrow 0$	—	—	23.0

This abnormality is resulted in all our experiments. Then we assumed the values at t_c as δ_w's of the whole solute, and calculated the hypothetical apparent weight average molecular weight, M_w^{app}. The reciprocals of these M_w^{app}'s were plotted against concentration and extrapolated to infinite dilution. The results obtained are shown in Tables I and II with the values obtained by sedimentation equilibrium.

It may be concluded from the results that the Archibald method is a rapid and useful technique in molecular weight measurement but it has some ambiguities in the determination of the average molecular weight of the whole solute which has a molecular weight distribution.

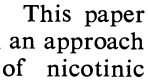
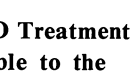
On the Relationship between Electronic State of Molecules and their Biological Actions. I. The Nicotinic Action of Choline Phenyl Ether and the Enzymatic Decomposition of Phenyl Acetate

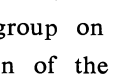




By Akira INOUYE and Yoshiya SHINAGAWA

(Received September 15, 1960)

Several attempts have been made in the quantum-chemical approach for explaining the carcinogenic activity of hydrocarbon molecules since Schmidt's earlier work[1], and some indices correlating the electronic configuration of these molecules with their carcinogenic activity were proposed by these investigators[2-4]. Because of complexities in biological processes involved, however, there remain certain ambiguities concerning their legitimacy from the biochemical point of view, even though their apparent usefulness was established. Indeed, there have been some disputes as to which quantum-chemical index is most effective in predicting the carcinogenic activity of hydrocarbon molecules[5]. It seems rather appropriate at present, therefore, that such a quantum-chemical approach is made in the biological research field on the pharmacological actions or on enzymatic reactions, for their mechanism is simpler and can be analyzed further in detail. But such an attempt has not yet appeared. This paper is principally concerned with such an approach of explaining the effectiveness of nicotinic action of choline phenyl ether derivatives and the substrate specificity of choline esterases by applying the frontier electron method of Fukui et al.[6] A preliminary account of some of their results has already been reported[7].



A Perturbation Theory in the LCAO Treatment of Conjugated Molecules Applicable to the Active Center of Enzyme or Receptor

The perturbation theory in the simple LCAO-MO method has been extensively developed by several investigators (Wheland[8], Coulson and Longuet-Higgins[9], Dewar[10], Mulliken and his co-workers[11], and Fukui et al.[6]) and has been applied successfully to the problem of chemical reactivity of molecules containing π-electrons. Long since, some physiologists and pharmacologists assumed tacitly that the drugs combined with so-called "receptors" of living organism as substrates did with active sites of an enzyme. Provided that the substrate or drug molecules contain π-electrons, it seems highly probable that such a complex formation is due to hyperconjugation of the π-part of the active site of enzyme or receptor to that of substrate or drug molecules.

On the other hand, recent developments in MO theoretical treatment of chemical reactivity in conjugated molecules have made a great contribution to the study of the mechanism of aromatic substitutions. One of these analyses was a theoretical treatment of hyperconjugation by Mulliken et al.[11] which occurred with the CH_2 group on $C_6H_7^+$ ion  . In this ion, the H_2 group was considered to be an atom (pseudo-atom) that has a (ls-ls) π-type orbital (quasi-π orbital). Such a treatment was also applied to a transition state of aromatic substitution by Fukui et al.[6] These workers pointed out an importance of hyperconjugation which occurs with the CBX group on  and derived an effective reactivity index, "superdelocalizability", from the stabilization energy due to this hyperconjugation. These treatments appear to be applicable to analysis of the transition state of enzyme-substrate or drug-receptor complex, to some extent at least. Adopting the method of perturbation theory proposed by Fukui et al.[6], therefore, the present authors attempted in this section a general formulation of the effect of conjugated molecules on the perturbation energy of their separating the properly assumed mesomeric group, its applicability to some biological

reactions being demonstrated in the following section.

Consider a certain atom X in an active center of enzyme or receptor approaching to the rth atom in the π-part of a substrate molecule. Provided that a hyperconjugation such as the CHX group on  occurs, the secular equation of the π-part of the total system containing the quasi-π orbital is, in a simple LCAO-MO treatment, written as

$$D_1(\lambda)=(h-\lambda)\Delta_1(\lambda)-\gamma_1^2\Delta_{1rr}(\lambda)=0 \qquad (1)$$

where

$$\Delta_1(\lambda)=\begin{vmatrix} a_{11}-\lambda & a_{12} \cdots\cdots a_{1n} \\ a_{21} & a_{22}-\lambda \ \ldots a_{2n} \\ a_{n1} \cdots\cdots\cdots\cdots & a_{nn}-\lambda \end{vmatrix}$$

and $\Delta_{1rr}(\lambda)$ is the minor of $\Delta_1(\lambda)$ corresponding to the element $a_{rr}-\lambda$, a_{ii} and $a_{ij}(i\neq j)$ are the well-known Coulomb and resonance integrals respectively, h and γ_1 are the Coulomb integrals of a properly assumed pseudo-atom and the resonance integral between this pseudo-atom and the rth atom of the substrate molecule respectively. All the quantities which represent energy are expressed in units of $(-\beta)$, all the overlap integrals being neglected. As stated above, however, the hyperconjugation of the π-part in the receptor or enzyme should be further taken into consideration. Assuming that the π-part of enzyme or receptor, whose secular determinant is $\Delta_2(\lambda)=0$, conjugates with the X-atom at its sth atom in such a manner as  , we can write the perturbation determinant as follows:

$$D(\lambda)=(h-\lambda)\Delta_1(\lambda)\Delta_2(\lambda)-\gamma_1^2\Delta_{1rr}(\lambda)\Delta_2(\lambda) -\gamma_2^2\Delta_1(\lambda)\Delta_{2ss}(\lambda)=0 \qquad (2)$$

where γ_2 is the resonance integral between the X-atom and the sth carbon atom in the active center. Considering the resonance integrals, γ_1 and γ_2 to be small perturbation terms, we can obtain the perturbation energy, ΔE.

When h is equal to λ_l, the highest occupied orbital of substrate, the perturbation energy is obtained as follows:

$$\Delta E=2\sqrt{-\frac{\Delta_{1rr}(\lambda_l)}{\Delta_1'(\lambda_l)}}\cdot\gamma_1+O(\gamma_1^2,\gamma_2^2)$$

and

$$-2\frac{\Delta_{1rr}(\lambda_l)}{\Delta'(\lambda_l)}=f_r^{(E)}$$

thence $\Delta E\simeq\sqrt{2}\,(f_r^{(E)})^{1/2}\cdot\gamma_1$

As shown in the following section, pharmacological potency or susceptibility to an enzymatic hydrolysis of homologous compounds has a fairly good parallelism to their f_r at a definite position, which is supposed, from the physiological point of view, to be involved in their reaction processes. The above relation might be said, therefore, to provide a quantum-chemical ground for such a supposition, suggesting a possibility that f_r is a fairly good index for estimating the magnitude of ΔE under a certain condition. On the other hand, superdelocalizability, which was considered by Fukui et al.[6] as one of the most useful index for the reactivity of π-electrons in a molecule was defiined as

$$S_r=\sum_{occ}\frac{2(C_r^{(i)})^2}{\lambda_i}$$

In the limit of $h\to 0$ and $\gamma_2\to 0$, therefore, it is apparent that ΔE is proportional to S_r. Thus the perturbation energy of complex formation is expected under a certain condition to vary nearly parallel to the superdelocalizablility of frontier electron in the substrate molecules.

It is obvious from the above discussions that, the larger the frontier electron density or superdelocalizability of the substrate or drug molecules, the larger the perturbation energy ΔE. Thence it would be expected that the susceptibility of homologous compounds to a certain enzyme or their pharmacological activity runs parallel with their frontier electron density or superdelocalizabillity. It will be shown in the following section, that the indices f_r or S_r have a correlation with the magnitude of drug actions or the rate of enzymatic hydrolysis.

Applications of the Frontier Electron Method

Electronic Structure of Choline Phenyl Ether and their Nicotinic Action.—Taking into account the above-mentioned results, the nicotinic action of choline ether derivatives was analyzed from the view-point of their electronic structure. From the pharmacological point of view, the group of $(CH_3)_3N\cdot CH_2\cdot CH_2-$ of these compounds is considered to react with anionic sites of chemoreceptor protein, while the difference in their potency would chiefly originate from the conjugated groups X-  -O- which is assumed to react with esteratic sites of the receptor[14,15]. Some workers suggested that the potency of these drugs in the depressant action was principally determined by electrostatic

bonding between the negative charge on the atom of 1-position adjacent to the ether *O*-atom and the positive charge on the esteratic site[16]. As the present treatment of first approximation, therefore, the conjugated group X-  -O- alone was considered.

The value of integrals concerning the hetero-atom is given in Table I, in which the parameters k, ρ and δ are defined as follows:

$$\alpha_O=\alpha+k_O\beta,\ \alpha_{Cl}=\alpha+k_{Cl}\beta,\ \alpha_\delta=\alpha+\delta\beta$$

$$\beta_O=\rho_O\beta \quad \text{and} \quad \beta_{Cl}=\rho_{Cl}\beta$$

These values used for calculation do not differ much from those of other authors, which have lead to reasonable results in some other problems[12,13]. The Coulomb integral of an oxygen atom in an ether bond is taken as $\alpha+3\beta$, that of carbon atom attached to it being $\alpha+0.3\beta$. Solving the secular equations, the electron densities of the first and second highest occupied levels, $f_r^{(1)}$ and $f_r^{(2)}$, and the approximate superdelocalizability, $S'_r=f_r^{(1)}/\lambda_1+f_r^{(2)}/\lambda_2$, are calculated. These two levels are very close to each other.

The calculated electron densities of two highest occupied levels of the positions 1 and 4, ($f_1^{(1)}+f_1^{(2)}$, $f_4^{(1)}+f_4^{(2)}$) are given in Table II, which demonstrates evidently that $f_1^{(1)}+f_1^{(2)}$ shows a distinct parallelism with the magnitude of activtiy of choline ethers observed on blood pressure of cats (Hey[16]). But the parallelism between $f_4^{(1)}+f_4^{(2)}$ and their activity is somewhat slighter, while neither $f_{(r)}^{(1)}+f_{(r)}^{(2)}$ at other positions nor their S'_r have such a correlation with their potency of nicotinic action. On the other hand, Imamura[17] has

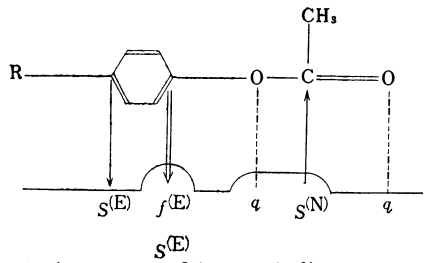
* Percent maximum rate of hydrolysis of Ach.

recently made calculation of S_r on these compounds and found a fairly good parallelism between S_4 and their activity, a fact which suggests that the approximation of S'_r is not so satisfactory.

The results appear, however, to suggest that ethers of choline form weak bondings with the active sites of the receptor at 1- and 4-position, this process being rate-determinant. In this case, the energy level of substrate's frontier electron would be considered to be close to that of the active center in the receptor. The correlation of f_1 with their potency is not a so unexpected one, for this position corresponds to that of acetylcholine which is bound to the esteratic site of Nachmansohn's acetylcholinesterase model. On the other hand, the correlation of f_4 or S_4, though somewhat less than that of f_1, may be considered to provide support to Hey's view[16].



The quantity f_r, as well as S_r, are considered as an index for discussing the reactivity in electrophilic reaction. But, as stated above, the condition for f_r to correlate with ΔE differs from that for S_r. Taking Imamura's results into account, it might be said, therefore, that the two positions of drug molecules would be attached to two positions of the receptor different from each other in their nature. Such a speculation does not conflict with the suggested concept of the esteratic site of the receptor.

Electronic Structure of Phenyl Esters and Substrate Specificity of Cholinesterase.—The electronic structure of choline phenyl ethers has a similarity to that of phenyl acetate, a substrate of cholinesterase, and so we calculated them by the method of LCAO. As indices of reactivity, electron density q_r, frontier electron density f_r and superdelocalizability S_r are calculated by solving the secular equations crresponding to Eq. 1. The values of indices and the rate of hydrolysis by butyrocholinesterase partially purified from human plasma (Whittaker[18]) are given in Table III. A distinct parallelism between frontier electron density f_5 and the magnitude of rate of hydrolysis is clearly seen, only an exception is the case on nitrophenol ester. S_5 shows a slighter correlation with their rate of hydrolysis, while neither f_r nor $S'_r=f_r^{(1)}/\lambda_1$ at any other position in the molecules have such a correlation with their substrate specificity of butyrocholinesterase. In this caes, approximate superdelocalizability S_r' was also found to vary not always parallel to S_r so that their appoximation can said to be not so satisfactory as already suggested in the section above. In view of their similarity to the choline ether derivatives in the molecular structure and pharmacological nature, the position 5 of these compounds corresponds to the position 1 of the latter and so the correlation found on f_5 is not a so unexpected one. The possible sites of an ester molecule making bond with the active center of butyrocholinesterase would be probably such as illustrated in Fig. 1, which can be referred to Nachmansohn's model of true cholinesterase. In this case, the position which should be considered at first as rate-determinant would be position 5.

On the other hand, parallelism was not so striking between the magnitude of rate of hydrolysis of phenyl acetates by acetylcholinesterase and the indices of their electronic structure as in the case of butyrocholinesterase. It is found, however, that the rate of hydrolysis have a slight correlation with indices on the position 8 (except the NO_2-derivative), whose distance to ether oxygen atom is close to that of quarternary nitrogen atom in Ach. This fact seems concordant with Nachmansohn's model of acetylcholinesterase, in which the distance between nitrogen atom and ether oxygen atom can affect the rate of enzymatic hydrolysis. Nevertheless the bonding between the active center and the position 8 in phenyl acetate may

Active center

be not so simple as that of Nachmansohn's model. Based on Wilson's results, Nachmansohn maintained that Coulomb force between quarternary nitrogen and active center is one of the essential factors on the bonding of enzyme-substrate complex, but in our results electron density q_8 has no clearer parallelism to the rate of reaction.

Wilson[19] employed the Michaelis-Menten constant as the basis of estimating contribution of electrostatic energy to enzyme-substrate (or -inhibitor) complex formation. As pointed out elsewhere[20], however, use of this constant involves a certain risk of erring in calculation of free energy change of such a complex catalytic reaction by a factor of ν (ν is the stoichiometric number in the rate-determinant process). It is a well-known classical theorem that $\vec{k}/\overleftarrow{k}=K$, where $\vec{k}$ and $\overleftarrow{k}$ are the forward and backward rate constants and K is the equilibrium constant. This theorem has been applied hitherto to the Michaelis-Menten relation of enzyme reaction,

$$E+S \underset{\overleftarrow{k}}{\overset{\vec{k}}{\rightleftarrows}} ES \xrightarrow{k} E+P$$

(E enzyme, S substrate, ES enzyme-substrate complex)

The Michaelis-Menten constant given by $K_m=\vec{k}/\overleftarrow{k}$ was used to calculate the free energy change of this reaction by Wilson as $-\Delta F=\boldsymbol{RT}\ln K_m$. It was already clearly demonstrated by Horiuti[21], that a theorem $(\vec{k}/\overleftarrow{k})^{\nu}=K$ was valid for any reaction having the stoichiometric number ν. Enzymatic reactions should have such complex rate processes that use of the Michaelis-Menten constant is allowable only for a special case of $\nu=1$. Hence, Wilson's results could not be regarded as a sufficient evidence for electrostatic bonding, other bonds such as hydrogen bonding being also allowable. Furthermore, γ-dimethylbutylacetate, which has no positive charge on the corresponding position, is hydrolyzed by acetylcholinesterase at almost the same rate as acetylcholine[15], a fact which seems also unfavorable to Nachmansohn's view. The difference of substrate specificity found between butyro- and acetylcholinesterase suggests that the quantum-chemical process involved in their reactions are different ones. The bonding mechanism of the latter complex seems to be more complex than the former one. The mechanism of enzymatic reaction proposed in the previous section may not be a rate-determinant in this case. It seems worthy to note here, however, that $S_8^{(N)}$ has better correlation with a rate of hydrolysis than other indices (Table IV), and so the negative charge on the position 8 should be considered at least to affect bonding of the complex.

Comment

Fukui and his co-workers introduced the frontier electron method and have obtained hitherto many fruitful results in their studies on reaction mechanism of aromatic hydrocarbons. As shown above, a fairly good correlation could be also proved between the π-electron density or its superdelocalizability of a certain position calculated by this method and nicotinic action of phenyl ether derivatives of choline or rate of enzymatic hydrolysis of phenyl acetate derivatives. The position, which was found to have such a correlation, is also expected from a pharmacological and chemical point of view. A possibility of such a correlation is demonstrated theoretically under an assumption that the active site of the receptor (or enzyme) has also π-electron system and a complex is formed between active sites and durgs by hyperconjugation through the π-electron system, their highest occupied level being very close to each other. This assumption is rather bold, but seems not so unreasonable: enzyme substrate complex or receptor-drug combination has been widely assumed in enzymological or pharmacological studies, and in the complex assumed, it is only required that π-electron can be transfered and hence its bonding is not needed to be a covalent one, hydrogen bonding being also allowable. In view of these facts the present invetigative approach might be said to demonstrate a possibility of explaining the drug actions at the molecular level. At least, the results suggest that the electronic configuration of molecules is important in quantitative interpretation of drug actions or substrate specificity of enzyme action and qualitative electronic explanation in these fields would be replaced by its systematic computation by an adequate quantum-chemical treatment in future.

Summary

1. Applying the frontier electron method of Fukui et al., it was attempted to explain the effectiveness of nicotinic action of some choline phenyl ether derivatives and the substrate specificity of some phenyl acetates in the enzymatic hydrolysis.

2. A fairly good correlation could be proved between the frontier electron density (f_r) or its superdelocalizability (S_r) of a certain position of these compounds and their potency or susceptibility to hydrolysis.

3. Assuming that the active site of receptor (or enzyme) has also π-electron systems and a drug-receptor (or -enzyme) complex is formed by hyperconjugation through π-electron systems, a general formulation of the effect of such a hyperconjugation on the perturbation energy of their system was attempted. It was demonstrated, qualitatively at least, by our calculations, that the larger the f_r of drug molecules or their S_r the larger the perturbation energy and so a possibility of above-mentioned correlation was predicted to some extent from the quantum-chemical basis.

The Energy of the Intermolecular Interaction between the Proton of the OH Group and the π Electron of Some Compounds

By Shozo WADA

(Received March 18, 1961)

The OH infrared absorption bands of both inter- and intra-molecular interactions between the π electron and the proton of the OH group have been observed by many workers[1]. The energies of the intramolecular interaction between the π electron and the proton have also been measured for some typical compounds by Ōki and Iwamura[2]. However, so far little is known of the energy of the intermolecular interaction between the π electron and the proton.

It does not seem correct to calculate the intermolecular interaction energy simply from the frequency shift of the OH band by the use of Badger's postulation[3], in the same manner as Goldman and Crisler[4] tried in the case of intramolecular interaction. Since certain differences may exist between the inter- and intra-molecular interactions in the factors which contribute to the interaction energy of the proton and the π electron, that is, steric factors between the two interacting groups, the direction character of the π electrons, etc., it seems unreasonable to estimate the energy of the intermolecular interaction simply from the frequency shift relationship which is obtained in the case of intramolecular interaction.

In a series of previous papers[5] it has been shown that lignin is a very good reinforcer for some types of synthetic rubbers, and the mechanism of the interaction between these polymers has also been reported. The main object of the present study is to estimate the interaction energy between the π electron in synthetic rubbers (styrene-butadiene copolymer, SBR, and acrylonitrile-butadiene copolymer, NBR) and the proton of the OH groups in lignin. Since it is difficult to measure the interaction energy between these large molecules, simple molecules with similar chemical structures were chosen as model compounds. As the proton donor, phenol, catechol, vanillin and 3-phenylpropanol were used, and as the proton acceptor, isopropylbenzene, cyclohexene and isobutyronitrile were used.

The intermolecular interaction energies between the OH groups and the π-electrons of these model compounds were estimated from the variation with the temperature of the intensities of the OH absorption bands. Infrared absorption spectra were measured for the ternary system of the proton donor, the proton acceptor and the solvent (carbon tetrachloride).

Experimental

Measurement.—A Perkin-Elmer model 13 infrared spectrophotometer was used, with a lithium fluoride prism. The concentration of the proton donor in carbon tetrachloride was 0.015 mol./l. An absorption cell with potassium bromide windows was placed in an asbestos block equipped with a heating coil, and the temperature of the contents was kept at an appropriate temperature (within ± 1°C) by controlling the electric current in the coil. The temperature was read by a thermometer inserted in a hole in the potassium bromide cell wall. Measurements of the infrared absorption of OH group were made at 25, 40 and 60°C.

Materials. — Phenol and 3-phenylpropanol were distilled in a vacuum. Vanillin was purified by sublimation, and catechol was purified by recrystallization.

Cyclohexane, isopropylbenzene and isobutyronitrile were dried and distilled through a short helix-packed column. Carbon tetrachloride, free of hydroxylic or other basic impurities, was dried and distilled before use.

Calculation.—In the calculation of the energy, it has been assumed that one proton donor molecule forms the hydrogen bond with one proton acceptor molecule and that the following equilibrium is maintained:

$$\text{Donor} + \text{Acceptor} \rightleftarrows \text{Complex}$$

$$K = [\text{C}]/([\text{D}] \cdot [\text{A}])$$

where, [D], [A] and [C] are the concentrations of donor, acceptor and complex, respectively, and K is the equillibrium constant. In order to simplify the calculation, the following assumptions were made:

a) $[\text{A}] \gg [\text{C}]$. Hence, [A] is almost constant and equal to $[\text{A}_0]$, the initial concentration of the acceptor.

b) [D] and [C] are proportional to the area intensities (S_D and S_C) of the free and bonded OH

2) M. Ōki and H. Iwamura, This Bulletin, **33**, 717 (1960).
3) R. M. Badger, *J. Chem. Phys.*, **8**, 288 (1940).
4) I. M. Goldman and R. O. Crisler, *J. Org. Chem.*, **23**, 751 (1958).
5) S. Wada, *Chem. High Polymer* (*Kobunshi Kagaku*), **18**, 541 (1961); S. Wada, ibid., in press.

absorption bands respectively, and the proportional constants are defined as K_D and K_C. As an alternate assumption, [D] and [C] are proportional to the peak values of the molecular absorption coefficients (κ_D and κ_C) of the free and bonded OH absorption bands respectively, the proportional constants being K_D' and K_C'.

c) The changes of entropy and enthalpy in the formation of the bond remain constant throughout the temperature range of the measurement.

From these assumptions, it follows that

$$K=K_C\cdot S_C/K_D\cdot S_D\cdot[A] \quad (2)$$

As
$$-\boldsymbol{R}T\ln K=\Delta H-T\Delta S \quad (3)$$

$$\ln K_{T_1}-\ln K_{T_2}=\ln(S_C/S_D)_{T_1}-\ln(S_C/S_D)_{T_2}$$
$$=-\Delta H/\boldsymbol{R}(1/T_1-1/T_2) \quad (4)$$

Or,
$$K=K_C'\cdot\kappa_C/K_D'\cdot\kappa_D\cdot[A] \quad (2')$$

$$\ln K_{T_1}-\ln K_{T_2}=\ln(\kappa_C/\kappa_D)_{T_1}-\ln(\kappa_C/\kappa_D)_{T_2}$$
$$=-\Delta H/\boldsymbol{R}(1/T_1-1/T_2) \quad (4')$$

Therfore, the enthalpy change ΔH is calculated from the slope of the line obtained by plotting $\ln(S_C/S_D)$ or $\ln(\kappa_C/\kappa_D)$ versus $1/T$. The entropy change ΔS is calculated by Eq. 3, using the values of ΔH and K. In the previous studies[5], the value of the equilibrium constant, K, was obtained from the variation of the molecular absorption coefficient of the free OH band with the concentration of the acceptor.

When the bonded and the free OH absorption bands overlap, as is shown in Fig. 1, the areas of the two bands were estimated as follows: As shown in Fig. 1, the slope of the free OH absorption curve is assumed to be symmetric, and the area of the curve ABCDE is taken for that of the free OH band. The area of the curve EDCF is taken for that of the bonded OH band.

In the case of catechol, another OH absorption band, due to the intramolecular hydrogen bond, appears. However, its intensity remains almost unchanged throughout the temperature range of the measurement and remains almost unaffected even when mixed with the proton acceptor.

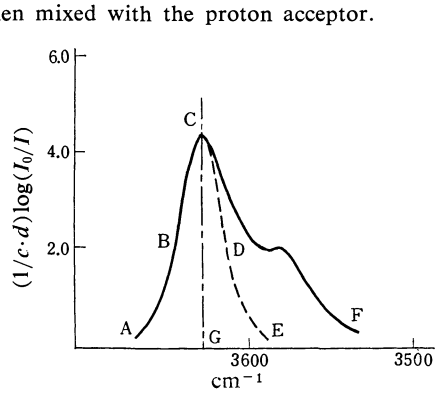

Fig. 1. The infrared absorption spectrum of OH group of 3-phenylpropanol (0.030 mol./l.) in the coexistence of cyclohexene (2.27 mol./l.) in CCl_4. The free OH band and intermolecularly bonded OH band are separated from each other by an extrapolated curve CDE.

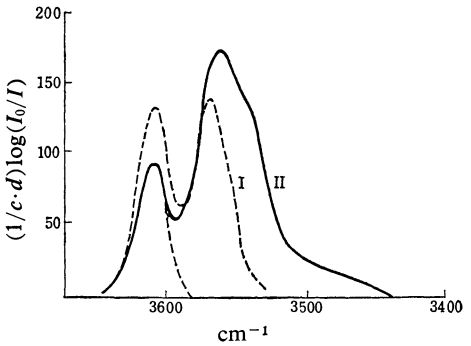

Fig. 2. The infrared absorption spectrum of OH group of catechol. I, 0.015 mol./l. in CCl_4; II, 0.015 mol./l. in CCl_4 in the coexistence of isopropylbenzene (1.80 mol./l.). The area of the intermolecularly bonded OH absorption band is estimated by subtracting the intramolecularly bonded OH absorption I from the absorption curve II.

The intensity ratio of the intramolecularly bonded and the free OH absorption bands is independent of the temperature, being 1.17 at 25°C and 1.12 at 60°C. Moreover, the intensity of the intramolecularly bonded OH absorption band remained almost unaffected even when the amount of free OH decreased very much under the coexistence of isobutyronitrile, the strongest proton acceptor in the present investigation. So, when the inter- and intra-molecularly bonded bands are overlapped, they were separated from each other in a manner similar to that described above by drawing the same intramolecularly bonded absorption curve as in the absence of the acceptor (Fig. 2).

Results and Discussion

The enthalpy change, ΔH, obtained from the slope of the line of the plot of $\ln(S_C/S_D)$ or $\ln(\kappa_C/\kappa_D)$ versus $1/T$, and the entropy change, ΔS, calculated by substituting the values of K and ΔH in Eq. 3, are tabulated in Table I. Generally, when isopropylbenzene is used as an acceptor, the frequency shifts, $-\Delta H$ and $-\Delta S$, are all lower than when cyclohexene is used. This is considered to result from the fact that in isopropylbenzene the degree of localization of the π electrons is lower due to the conjugation in benzene ring and the fact that the proton accepting field is larger, so that the degree of freedom of the complex is greater. When cyclohexene and isobutyronitrile are used as acceptors, $-\Delta S$ are approximately equal to the normal value, 13 e. u., for the ordinary intermolecular hydrogen bond[6,7], while when isopropylbenzene is used, the $-\Delta S$ are generally smaller, as has been stated above, and they amount to as small values as

6~7 e. u. Such small values are also observed in some weak hydrogen bonds, such as those existing in the combinations of *o*-chlorophenol-methyl acetate[7] or chloroform-acetone[9].

Considering from the values of ΔH and ΔS for vanillin, the guaiacyl OH group seems to be able to form a stronger hydrogen bond with the π electron when a carbonyl group is present at the para position. Such a characteristic difference between a simple guaiacyl OH group and that having a carbonyl group in its para position for the hydrogen bond formation, has been observed by Lindberg[9] in a similar case of the interaction of various guaiacyl compounds and dioxane. The ability of the free OH group of catechol to form a hydrogen bond with the π electron is much larger than that of simple phenol, which is quite parallel to the case of the formation of an ordinary hydrogen bond.

The values of $-\Delta H$ for the intermolecular hydrogen bond between the OH groups and the π electron obtained in our present investigation are larger than those obtained by Ōki and Iwamura[2] for intramolecular hydrogen bonds. This may be explained by considering that the steric stress may influence the formation of the intramolecular hydrogen bond. For example, in *o*-allylphenol, the direction of the π electron orbital of an allyl group seems to be difficult to orient towards the favorable direction for the interaction with the phenolic OH group in its ortho position, probably because in being compelled to be oriented parallel to the direction of the π electron of the benzene ring, they repulse each other. Consequently, it is to be expected that the steric condition for the formation of the bond

10) J. J. Lindberg, *Societas Scientiarum Fennica, Commentationes Physico-Mathematicae XX*, 1 (1957).

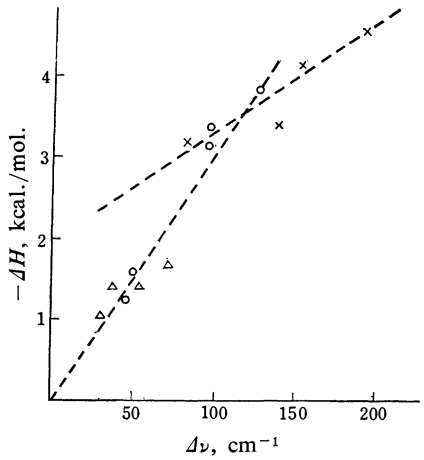

Fig. 4. The relation between $\Delta\nu$ and $-\Delta H$, being used $-\Delta H$ values obtained from the slope of the line $\ln(S_C/S_D)$ versus $1/T$.
×: In the case of isobutyronitrile as accepter.
○: In the case of cyclohexene as acceptor.
△: In the case of isopropylbenzene as acceptor.

is more favorable in the intermolecular interaction than in the intramolecular interaction.

When two acceptors, isobutyronitrile and cyclohexene, are compared, there is no great difference in $-\Delta H$. This is approximately 1 kcal./mol. Therefore, the proton-accepting character of the nitrile group is not always attributable only to the electronegativity of the nitrogen atom, but also rather reasonably to that of the π electron of the triple bond in the nitrile group.

In Figs. 3 and 4 are shown the relations between $-\Delta H$ and the frequency shift $\Delta\nu$. The $-\Delta H$ values in Figs. 3 and 4 are calculated from κ_C/κ_D and S_C/S_D respectively. As seen from these figures, the relations between these two quantities are not linear, which is contrary to Badger's postulation. It seems to be more reasonable to divide the curves into two linear portions:

for $\Delta\nu<100\,\mathrm{cm}^{-1}$;

$$-\Delta H \fallingdotseq \Delta\nu/30 \text{ kcal./mol.}$$

and for $\Delta\nu>100\,\mathrm{cm}^{-1}$;

$$-\Delta H \fallingdotseq 2.0+\Delta\nu/70 \text{ kcal./mol.}$$

The slope in the region of $\Delta\nu<100\,\mathrm{cm}^{-1}$ is considerably greater than that obtained by Badger[2] for ordinary hydrogen bonds.

The Interaction between the Proton of the Carboxyl Group and the π Electron of Some Compounds

By Shozo WADA

(Received June 14, 1961)

The hydrogen bond between the proton and the π electron has been studied mainly by investigating the variation of the infrared absorption of the OH or NH group due to the interaction between the proton of these groups and the π electron. The frequency shift of the OH absorption band increases in proportion to the proton-donating power of these groups, as was observed by West[1]. The author[2] has established that the larger the frequency shift, the stronger the hydrogen bond in the intermolecular interaction between the proton and the π electron is; this was established by using compounds having an OH group such as phenol, vanillin, catechol, 3-phenylpropanol as proton donors and some compounds having π electrons such as cyclohexene, isopropylbenzene, isobutyronitrile as proton acceptors. Therefore, the formation of the stronger hydrogen bond may be expected between the π electron and the proton of the carboxyl group, because the proton-donating power of this group is much larger than that of the other ordinary proton donor groups such as OH or NH. So far, however, no investigation on the interaction between the π electron and the proton of a carboxyl group has been made.

2) S. Wada, This Bulletin, **35**, 707 (1962).

In the present report, therefore, the interaction between the proton of the carboxyl group of benzoic acid or cinnamic acid, and the π electron of squalene, toluene, or acetonitrile, has been investigated by measurement of the infrared spectra. The main purpose of this investigation is, in connection with the previous one[2], to learn the nature of the secondary bond of the π electron of some synthetic rubbers (such as styrene-butadiene copolymer, SBR, and acrylonitrile-butadiene copolymer, NBR) and the proton of the carboxyl group of thiolignin, which is a good reinforcer for these rubbers.

Experimental

The infrared absorption spectra were measured with a Perkin-Elmer model 13 spectrophotometer with a lithium fluoride prism. The slit width was 70 μ. The absorptions of the solutions of binary systems (a) of acid and carbon tetrachloride and of ternary systems (b) of acid, carbon tetrachloride and a proton-accepting compound (squalene, toluene or acetonitrile) were measured, together with those of the corresponding solvents. The sample solution was placed in a quartz cell 10 mm. in length. The absorbance, $\log I_0/I$, of acid was obtained by subtracting the absorbance of the solvent from that of the solution containing acid. The concentrations of acids are 0.003 and 0.007 mol./l. The two absorption curves, a and b, thus obtained were compared, and the frequency shift of the OH band by hydrogen bonding was estimated from the position of the OH band in the carboxyl group of the acid monomer molecule.

The chemicals used were purified according to the usual methods; their phyical constants were as follows: Benzoic acid, m.p. 121~122°C; cinnamic acid, m.p. 135~136°C; squalene, b.p. 238~240°C/2 mmHg; toluene, b.p. 110.5°C; acetonitrile, b.p. 81.6°C.

Results

The absorption spectra of benzoic acid in the mixture of carbon tetrachloride and a proton-accepting compound in the region of the OH absorption of the carboxyl group of monomeric acid molecule are shown in Figs. 1—3, together with those in pure carbon tetrachloride. Similar absorption spectra were obtained in the case of cinnamic acid. The absorption was measured also towards the region of the OH frequency of the dimeric acid molecule as far as 2400 cm^{-1}, but the difference between binary (a) and ternary (b) systems could not but be ambiguous because of the presence of the intense C–H band in the region of the OH absorption of the dimeric acid. However, in the case of acetonitrile, which is more powerful in proton-accepting power compared with the other two, squalene

—— a, ····· b

and toluene, this difference was observed, as is shown in Fig. 4.

The frequency shifts of the OH band of carboxyl groups due to the formation of the hydrogen bond with the π etectron are shown in Table I, with reference to those of some phenolic hydroxyl groups as proton donors, reported on in the previous paper[2]. The frequency shifts are much larger in the case of acid than in the case of phenol and even catechol, although the same proton acceptor was not used in both cases.

The maximum of the OH absoption curve when squalene is used as a proton acceptor is not so clear as in the case of the other two

proton acceptors, toluene (Fig. 2) and acetonitrile (Fig. 3). This may mean that the proton-accepting character of the π electron in each double bond of the squalene molecule, which has five double bonds, is not always the same. Such a tendency may be much greater when the proton acceptor molecule is so large as a rubber molecule.

Even when the concentration of the acid in carbon tetrachloride is so dilute as 0.003 mol./l. or 0.007 mol./l., most parts of the acid exist in the state of dimer, and when a proton-accepting compound is added to this carbon tetrachloride solution of acid, the concentrations of both monomer and dimer change, because they are affected by the formation of the hydrogen bond between the proton of the carboxyl group and the π electron of the proton acceptor and by the increase of the dielectric constant of the medium around the acid molecule. Therefore, both the equilibrium constant of the formation of the hydrogen bond and the energy of the hydrogen bond are difficult to determine. However, the energy may be expected to be considerably large, in view of the fact that the frequency shift of the OH absorption of the carboxyl group is larger than that of catechol and that, consequently, its free OH group forms a stronger hydrogen bond with the π electron, as is shown in Table I.

In row ΔE of this table there are presented the energies of the hydrogen bond between the proton of the carboxyl group and the π electron calculated from the frequency shift

on the assumption that the following linear relationship between the frequency shift ($\Delta\nu$) of the OH group and the hydrogen bond energy (ΔE), that relationship reported in the previous paper[2], is also applicable in the present case:

$$\Delta E = 2.0 + \Delta\nu/70 \quad \text{kcal./mol.}$$

From the above result, it is concluded that there is a possibility of interaction between the π electron in a rubber molecule and the proton of a carboxyl group existing in a free state at the surface of a lignin particle in a lignin-rubber (SBR or NBR) compound. Therefore this interaction seems to contribute greatly to the secondary bond between lignin and rubber. The fact that the air-oxidated thiolignin, having a larger number of carboxyl groups, has a much higher reinforcing power on synthetic rubbers than ordinary untreated thiolignin may also be explained by the enhancement of the interaction between the π electron in synthetic rubbers and the carboxyl groups in oxidized thiolignin.

The Reactions of Ester with Acyl Chloride in the Presence of Aluminum Chloride. V. Reaction Mechanism of the Benzoylation of Diethyl Malonate

By Hiroo KANEYUKI

(Received June 28, 1961)

In a previous paper[1] it was reported that triacylated methanes were obtained in addition to diacylated compounds when diethyl malonate was treated with two or three molecular equivalents of benzoyl chloride or *p*-substituted benzoyl chlorides in the presence of three molecular equivalents of aluminum chloride. This paper describes attempts to achieve a more fundamental understanding of the reaction mechanism of the benzoylation of diethyl malonate.

Reaction of Ethyl Dibenzoylacetate with Aluminum Chloride.—These reactions resulted in the formation of acetophenone, dibenzoylmethane, aluminum chelate of dibenzoylmethane, tribenzoylmethane and benzoic acid (Table I). In every reaction, an appreciable amount of dibenzoylmethane was obtained with tribenzoylmethane. This fact shows that ethyl dibenzoylacetate gives dibenzoylmethane by decarbethoxylation and simultaneously decomposes to benzoyl chloride and ethyl benzoylacetate, which converts into acetophenone. On the other hand, tribenzoylmethane is formed by the benzoylation of the dibenzoylmethane which is formed.

$$(C_6H_5CO)_2CHCOOC_2H_5 \rightarrow C_6H_5COCH_2COOC_2H_5 + C_6H_5COCl + (C_6H_5CO)_2CH_2$$

$$(C_6H_5CO)_2CH_2 + C_6H_5COCl \rightarrow (C_6H_5CO)_3CH$$

$$C_6H_5COCH_2COOC_2H_5 \rightarrow C_6H_5COCH_3 + C_2H_5Cl + CO_2$$

Reactions of Dibenzoylmethane-*O*-benzoate with Aluminum Chloride.—The products of these reactions (Table I) were dibenzoylmethane, tribenzoylmethane and benzoic acid. From this table, it can be noted that dibenzoylmethane-*O*-benzoate is fairly stable in the presence of a small amount of aluminum chloride, but is decomposed to dibenzoylmethane in the presence of a large amount of aluminum chloride.

Reactions of Tribenzoylmethane with Aluminum Chloride.—In every case (Table I) tribenzoylmethane is decomposed to dibenzoylmethane, but it is difficult to decompose it to dibenzoylmethane with only a small amount of aluminum chloride.

g) DBM-*O*-B; Dibenzoylmethane-*O*-benzoate
h) BA; Benzoic acid

Reaction of Tribenzoylmethane-*O*-benzoate with Aluminum Chloride.—It is to be noted that tribenzoylmethane-*O*-benzoate is easily converted into tribenzoylmethane and then further decomposed to dibenzoylmethane (Table I).

Reaction of Dibenzoylmethane with Aluminum Chloride.—Dibenzoylmethane seemed to be stable in the presence of aluminum chloride, for it is recovered in substantial quantities with its aluminum chelate (Table I).

Benzoylation of Ethyl Dibenzoylacetate.—In these reactions (Table II), the yield of dibenzoylmethane is good at a higher temperature, but the yield of tribenzoylmethane is good when a larger amount of aluminum chloride is used. It is fairly difficult to benzoylate ethyl dibenzoylacetate; a considerable amount of this material is recovered unchanged.

Benzoylation of Dibenzoylmethane and its Aluminum Chelate.—In these reactions (Table II), the yield of tribenzoylmethane is small when one molecular equivalent of aluminum chloride is used and is lower at a higher reaction temperature. Using 0.1 molecular equivalent of aluminum chloride, the yield of tribenzoylmethane is much increased. In the absence of aluminum chloride, the yield of tribenzoylmethane is very good, however, aluminum chelate of dibenzoylmethane gives it in a 12% yield. Therefore, it can be seen that the formation of tribenzoylmethane by the benzoylation of dibenzoylmethane is hindered to some extent by the presence of aluminum chloride.

Benzoylation of Tribenzoylmethane.—In every case (Table II), the yield of tribenzoylmethane-*O*-benzoate is low and the decomposition of tribenzoylmethane is greatest at a high temperature.

Benzoylation of Diethyl Malonate in the Presence of a Small Amount of Aluminum Chloride.—After diethyl malonate was warmed at 70°C with 1/3 molecular equivalent of aluminum chloride for 2 hr., one molecular equivalent of benzoyl chloride was added to the reaction mass, and then the mixture was kept at 70°C. When the reaction time is 8 hr., diethyl benzoylmalonate is the only product, but after a reaction of 24 hr., its yield is decreased, and instead small amounts of ethyl benzoylacetate, ethyl dibenzoylacetate and traces of acetophenone, dibenzoylmethane are obtained (Table III). In considering these results, diethyl benzoylmalonate seems to be converted slowly by decarbethoxylation into ethyl benzoylacetate, which is partly changed to acetophenone and ethyl dibenzoylacetate. Therefore, the following reaction sequences may be considered:

$$C_6H_5COCH(COOC_2H_5)_2 \rightarrow C_6H_5COCH_2COOC_2H_5$$

$$C_6H_5COCH_2COOC_2H_5 \rightarrow (C_6H_5CO)_2CHCOOC_2H_5$$

$$\downarrow \qquad\qquad\qquad \downarrow$$

$$C_6H_5COCH_3 \qquad\qquad (C_6H_5CO)_2CH_2$$

It can be concluded that the isolation of ethyl

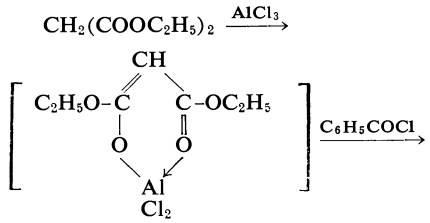
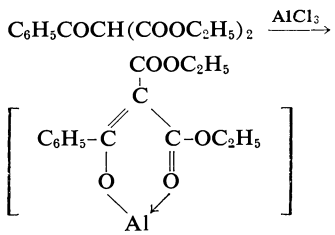
Yield: Calculated from benzoyl chloride.
a) BME; Ethyl benzoylmalonate
b) BAF; Ethyl benzoylacetate
c) AP; Acetophenone
d) DBA; Ethyl dibenzoylacetate
e) DBM; Dibenzoylmethane
f) BA; Benzoic acid

benzoylacetate is due to the difficulty of the benzoylation of itself because of the small amount of aluminum chloride. Like these reaction products, ethyl *p*-nitrobenzoylacetate and *p*-nitroacetophenone were also obtained when diethyl malonate was treated with *p*-nitrobenzoyl chloride[1].



Discussion

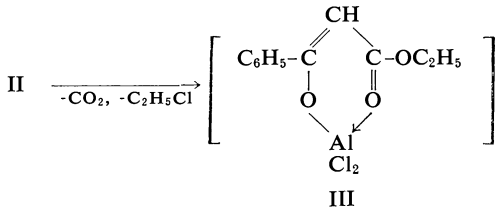
The acylation of an active methylene group with acid chloride has been generally accomplished by means of a basic reagent. On the other hand, using an acidic reagent boron trifluoride, Meerwein[2] and Hauser[3] prepared β-diketone by the acylation of ketone with acid anhydride. Hauser has suggested that the acylation of ketone probably involves the conversion, by boron trifluoride, of both the anhydride and the ketone to reactive intermediates which condense. Therefore, the anhydride is presumably converted into carbonium ion, and the ketone is apparently converted into an enol form.



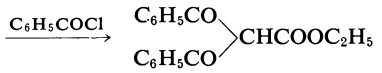
As shown in the experimental part of this paper, by treating diethyl malonate with benzoyl chloride in the absence of a catalyst, only a 4% yield of diethyl benzoylmalonate was obtained. Consequently, it may be considered that in the presence of a proper amount of aluminum chloride, diethyl malonate and β-keto-ester are activated much more effectively than acid chloride. From this standpoint, the

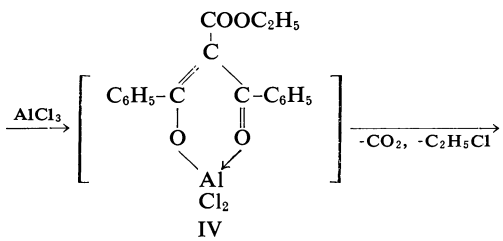
2) H. Meerwein and D. Vossen, *J. prakt. Chem.*, **141**, 149 (1934).
3) R. Hauser and T. Adams, *J. Am. Chem. Soc.*, **66**, 345 (1944).

following mechanism is postulated for the benzoylation of diethyl malonate in the presence of aluminum chloride: Diethyl malonate reacts with aluminum chloride to give the aluminum chloride complex (I). The reaction of I with benzoyl chloride leads to diethyl benzoylmalonate which soon becomes an aluminum chloride complex of diethyl benzoylmalonate (II).



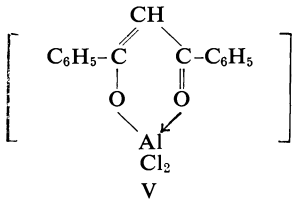
I



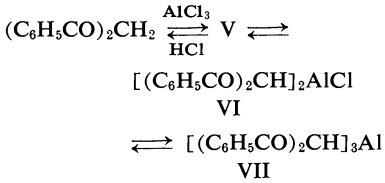


II

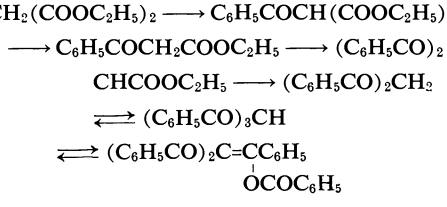
II is converted into an aluminum chloride complex of ethyl benzoylacetate (III) by decarbethoxylation. III will react immediately with benzoyl chloride to give ethyl dibenzoylacetate, which soon becomes an aluminum complex of ethyl dibenzoylacetate (IV). By slow decarbethoxylation, IV would be converted into an aluminum chloride complex of dibenzoylmethane (V).



III



IV



V

The fact that water-insoluble dibenzoylmethane is precipitated from the clear aqueous layer containing aluminum chloride by heating, as has been described in the experimental part of this paper, may show that dibenzoylmethane exists as V or VI in the presence of aluminum chloride. Because dibenzoylmethane and VII were always obtained in any of these experiments, it may be considered that dibenzoylmethane, V, VI and VII are in equilibrium.

When tribenzoylmethane was treated with aluminum chloride only, 22% of tribenzoylmethane was recovered, while dibenzoylmethane-*O*-benzoate gave a small amount of tribenzoylmethane under similar conditions (Table I). Therefore, the formation of tribenzoylmethane is not due to the isomerization of dibenzoylmethane-*O*-benzoate, but to the benzoylation of dibenzoylmethane or such complexes as V, VI and VII. As a similar example with the above reactions, it has been known that a copper complex of β-diketone reacts with *p*-nitrobenzoyl chloride to give copper chelate of triketone[4]. Moreover, in the presence of a large amount of aluminum chloride (Table II), the direct conversion of ethyl dibenzoylacetate into tribenzoylmethane may occur. Besides benzoylation, the reactions of aluminum chloride are complicated by such side reactions as decarbethoxylation, debenzoylation and the cleavage of ester linkage, as shown in Table I.

Owing to the above considerations, the following sequence has to be postulated:

4) W. J. Barry, *J. Chem. Soc.*, **1960**, 670.

Experimental

Reaction methods were the same as in the previous paper[1]. The treatment of the reaction mixture was also the same; that is, it was separated into the aqueous layer containing aluminum chloride, sodium bicarbonate extract, sodium hydroxide extract, water extract and residual solution. Descriptions overlapping with those of the previous paper are omitted here. Reaction conditions are shown in the above tables.

Reaction of Ethyl Dibenzoylacetate with Aluminum Chloride.—Precipitates were deposited with a small amount of an oily substance when the aqueous layer containing aluminum chloride was warmed and allowed to stand. The precipitates were collected, washed with petroleum ether and recrystallized from methanol to afford dibenzoylmethane. 2, 4-Dinitrophenylhydrazone derived from the petroleum ether soluble substance was recrystallized from ethanol to yield crystals, m. p. 245~248°C, which showed no depression of melting point on admixture with 2, 4-dinitrophenylhydrazone of acetophenone.

Reaction of Dibenzoylmethane-*O*-benzoate with Aluminum Chloride.—Dibenzoylmethane-*O*-benzoate was prepared according to the procedure of the literature[5]. By removing the solvent from the residual solution separated from the reaction mixture, dibenzoylmethane-*O*-benzoate was recovered.

Benzoylation of Diethyl Malonate with Benzoyl Chloride in the Presence of a Small Amount of Aluminum Chloride.—An oily substance was precipitated with some solid from the aqueous layer containing aluminum chloride, as has been described above. The solid was collected by filtering, washed with water and recrystallized from methanol to afford dibenzoylmethane. The filtrate was extracted with ether, and the ethereal extract was shaken with a copper acetate solution. A small amount of the yellowish green precipitate formed was filtered. By treating this precipitate with hydrochloric acid, dibenzoylmethane was obtained. After removal of ether from the ethereal solution, a green semi-solid I was obtained. The semi-solid was filtered and washed with ethanol. The ethanol wash was concentrated to yield crystals of copper chelate of diethyl benzoylmalonate. The mother liquor was subjected to steam distillation, and from the distillate 2, 4-dinitrophenylhydrazone was prepared and identified as that of acetophenone by the mixed melting point method. The sodium hydroxide extract was acidified and extracted with ether. After concentrating the ether extract, crystallized ethyl dibenzoylacetate was filtered off. From the ethereal filtrate, copper chelate of diethyl benzoylmalonate was prepared, as has been mentioned above.

Copper Chelate of Ethyl Benzoylacetate.—The solid I was recrystallized from benzene as light green needles, 0.35 g., m. p. 178~184°C, reported m. p. 180°C, 182~183°C[6].

Found: C, 59.53; H, 4.87. Calcd. for $C_{22}H_{22}O_6Cu$: C, 59.25; H, 4.97%.

Reaction of Diethyl Malonate with Benzoyl Chloride.—Diethyl malonate (3.4 g., 0.021 mol.) and benzoyl chloride (3.0 g., 0.021 mol.) were dissolved in nitrobenzene (15 ml.) and kept at 65°C for 8 hr. The treatment of the reaction mixture was the same as has been mentioned above. Benzoic acid (2.3 g.) was obtained on acidifying the sodium bicarbonate extract. The oily substance obtained by acidification of the sodium hydroxide extract and water extract was converted into copper chelate, 0.25 g., m. p. 178~179°C; this was identified as copper chelate of diethyl benzoylmalonate by the mixed melting point method.

The author wishes to express his hearty thanks to Professor Kiyotada Matsui for his kind guidance and encouragement, and to Professor Ryozo Goto, Kyoto University, for his many valuable suggestions.

Activations by Anions in the Oxy-acid Phosphors. III. Activations by the Vanadate Ion

By Yoshihide KOTERA and Michiko YONEMURA

(Received August 10, 1961)

In previous papers[1] it was found that anionic centers are present in the oxy-acid phosphors and that the activation by vanadate might be one of "intraionic activation", then the luminescence would originate from the electron transitions in the vanadate ion. The activation by vanadate ions has been reported by a few researchers[2,3], but in most cases the activation has been assumed to be caused by vanadium ions[2]. We have prepared some magnesium compounds activated by vanadate ions and have obtained some remarkable results.

The Experiments and their Results

Preparation of Phosphors and the Measurements of their Characteristics.—The starting materials were MgO, $(NH_4)_2SO_4$, $SiO_2 \cdot nH_2O$, $(NH_4)_2HPO_4$, NH_4VO_3, As_2O_3, Sb_2O_3, H_3BO_3 and H_2WO_4, which had been purified by the process previously reported[3]. They were mixed in a dry state and fired in air. The spectral distribution was measured by means of a spectroradiometer[4], the brightness was measured by a photocell, and the crystal structure was determined by an X-ray diffractometer.

Activation of Magnesium Compounds by Vanadate Ions.—Magnesium sulfate, silicate or pyrophosphate, was prepared by the reaction between magnesium oxide and oxy-acidic compound. Other phosphates (orthophosphate or halophosphate) or silicates were proved to be worse than those described above. Their spectral distributions are almost the same as that of magnesium vanadate, and their brightnesses are shown in Table I, while their X-ray patterns are shown in Fig. 1.

Effect of the Addition of other Components to Magnesium Silicate Activated by Vanadate Ions.—Magnesium silicate was activated by two ions among the vanadate, phosphate, arsenate, antimonate, germanate and borate ions. Magnesium oxide and amorphous silica were mixed in the molar ratio of 1 : 1.1, and two

ions were added to it, each amount being 0.005 mol. per 1 mol. magnesium oxide. They were fired at 1100°C for 4 hr.; the spectral distributions measured are shown in Fig. 2, and the brightness of some of them, in Table II. The color of emission is tabulated in Table II.

The Spectral Distributions of Mixed Crystal $MgWO_4$-$Mg_2V_2O_7$.—The system of $MgWO_4$-$Mg_2V_2O_7$ was examined to clarify the activation effect of the vanadate ion. Mixtures of magnesium oxide, tungstic acid and ammonium vanadate were fired at 1050°C for 2 hr. The spectral distributions of these phosphors are shown in Fig. 3, in which the numbers attached to the curves represent the relative height at their peaks. The X-ray patterns of some products are shown in Fig. 4.

Discussion

The activation by the vanadate ion in alkali or alkali earth vanadate has been studied by us and by others[2,3], but for other compounds few patents[5] have been found. We prepared various magnesium compounds activated by the vanadate ion, and, when a large amount of vanadate compound was added to them, some of these compounds had a higher brightness than that of pure magnesium metavanadate. In the latter case, it might be concluded from a consideration of the case of the calcium sulfate-calcium tungstate system[6], in which the content of tungstic acid is high, that a

6) Y. Kotera, T. Sekine and M. Yonemura, This Bulletin, 35, 580 (1962).

part of the product is activated by the vanadate ion. The formation of magnesium metavanadate was proved crystallographically in Fig. 1, in contrast to the calcium sulfate-calcium tungstate system, while it was difficult in the latter case to prove the formation of tungstate by means of X-ray analysis because of the structural similarity of the components.

The effect of the addition of other anions to magnesium silicate is relatively small, but it may be concluded that other anions cause the variation in brightness and a small shift in the spectral distribution of the emission.

The system of $MgWO_4$-$Mg_2V_2O_7$ shows almost the same characteristics as the results obtained when zinc or cadmium oxide is added to calcium sulfate activated by a tungstate ion[6]. Those results might be explained by the formation of a solid solution between the constituents, but it was difficult to know its formation from the X-ray pattern shown in Fig. 4.

Activations by Anions in the Oxy-acid Phosphors. IV. Activations by Sulfide and Sulfo-oxide Ions

By Yoshihide KOTERA and Tadao SEKINE

(Received August 10, 1961)

It was found in previous papers[1] that activation by sulfide occurs in alkali earth sulfate phosphors. Meanwhile, Gobrecht et al.[2] reported activation by polysulfide in alkali earth sulfides and alkali sulfides, and Kirk[3] reported the effect of sulfur in natural sodalite. We have prepared alkali earth sulfate activated by a sulfide ion or a sulfo-oxide ion and have obtained some remarkable results.

The Experiments and their Results

Preparation of Phosphors.—The alkali earth sulfides were prepared by the reaction between purified alkali earth sulfate and a reducing agent, for example, cane sugar, while the alkali earth sulfites were precipitated by the addition of a purified sulfite solution to a purified alkali earth salt solution. The optimum conditions for preparing the phosphors are shown in Table I; it was necessary to maintain the firing atmosphere in a neutral condition because oxidizing or reducing atmosphere causes a variation in the characteristics of the products.

Spectral Distribution of the Emissions of the Phosphors.—The spectral distributions are shown in Fig. 1. It was difficult to obtain accurate distributions for calcium and barium sulfate activated by sulfite ion because of their weak emission, while that of strontium sulfate activated by sulfite is somewhat inaccurate. However, it was ascertained that activation by a sulfite ion gave a different product than that by a sulfide ion.

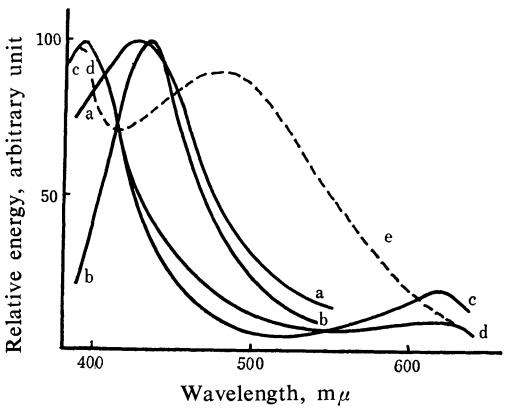

Fig. 1. Spectral distributions of alkali earth sulfate activated by sulfide and sulfite.
a: 0.01 g. $CaS/CaSO_4$ 1 g.
b: 0.1 g. $CaS/CaSO_4$ 1 g.
c: 0.035 g. $BaS/BaSO_4$ 1 g.
d: c+NaCl flux
e: 0.01 g. $SrSO_3/SrSO_4$ 1 g.

It is remarkable that the weak afterglow was detectable in the case of calcium sulfate activated by a sulfide ion.

Discussion

The spectral distribution of the emission of calcium, strontium or barium sulfate activated by a sulfide ion may differ from that of polysulfide, which was reported by Gobrecht et al.[2], but it is impossible to compare our results with theirs because they concluded that preparation by the reduction of sulfate salts is unsuitable for the preparation of their phosphors. Barium sulfate activated by a sulfide ion has an emission like that of barium polysulfide, but it is probable that barium sulfate is produced during the firing of barium polysulfide. Such comparisons are related to the fact the control of the atmosphere is important during the firing of sulfate salt phosphors. In our experiments it was possible to separate the activations by the sulfide ion and by the sulfite ion by precise control of the atmosphere.

Interesting facts were found in the phosphors activated by the sulfide ion; the flux has some effect on the intensity of the prepared phosphor, and the decay of some samples is relatively long. These facts show that the oxy-acid phosphors activated by the sulfide ion may be the intermediates between sulfide and oxy-acid phosphors. The fact that barium sulfate or calcium sulfate activated by sulfide ion emits, under the excitation of 3650Å, a light of almost the same characteristics as when under 2537Å, supports this idea. The excitation spectrum may be considerably longer than those of the oxy-acid phosphors, but it has not yet been measured precisely. It would be interesting to study the other matrices activated by the sulfide ion in relation to the studies by Gobrecht et al.[2], by Kirk[3] and by Thomson[4].

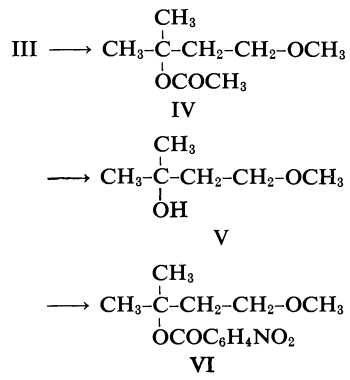
The Reaction of Isobutene with Chloromethyl Methyl Ether in Liquid Sulfur Dioxide

By Niichiro TOKURA, Isoo SHIRAI and Katsuo SHIINA



(Received August 7, 1961)

Isobutene (I) reacts with chloromethyl methylether (II) in liquid sulfur dioxide to give 2-chloro-4-methyl-2-methylbutane (III). Straus and Thiel[1] have reported that the formation of III from I and II requires a catalyst such as mercuric chloride, while the present reaction in liquid sulfur dioxide is very rapid and is practically accomplished in a few minutes without any catalyst and at room temperature.

Structure III was confirmed by preparing some derivatives as follows:

1) F. Straus and W. Thiel, *Ann.*, **525**, 151 (1936).

III was treated with sodium acetate to afford 2-acetoxy-4-methoxy-2-methylbutane (IV). IV was hydrolyzed with alkali to 4-methoxy-2-methyl-2-butanol (V), which gave a *p*-nitrobenzoate (VI), m. p. 74.0°C.

Such cross-linking or jointing by the methylene group as has been seen elsewhere[2] was not observed in the present experiment. The yield of III was depressed by the use of a catalyst such as stannic chloride owing to the predominating self-polymerization of isobutene.

Experimental

Reaction of Isobutene (I) with Chloromethyl Methyl Ether (II) in Liquid Sulfur Dioxide.—To 110 ml. of liquid sulfur dioxide was added 21.5 g. (0.38 mol.) of I, and 38.6 g. (0.48 mol.) of II was then dropped into the mixture. The mixture was allowed to stand at room temperature for ten minutes and then mixed with ice water, and the liquid sulfur dioxide was evaporated. The residue was washed with sodium sulfate and distilled in vacuo. The transparent oil, b. p. 60~66°C 100 mmHg, was redistilled under ordinary pressure to yield 7.8 g. of pure 2-chloro-4-methoxy-2-methylbutane (III), b. p. 141~145°C (lit.[1], b. p. 136°C/751 mmHg. Found: C, 52.74; H, 9.51, Calcd. for $C_6H_{13}OCl$: C, 52.71; H, 9.57%, mol. wt., Found: 143 (benzene), Calcd.: 136.5. IR ν_{max}^{liq} 1295 cm^{-1} (methoxy), no absorption at 1600 cm^{-1} (C=C).

2-Acetoxy-4-methoxy-2-methylbutane (IV).—III was treated with anhydrous sodium acetate by a general procedure to give IV, b. p. 34.8~40.0°C/14 mmHg.

4-Methoxy-2-methyl-2-butanol (V).—IV was hydrolyzed with a 1 N potassium hydroxide solution to 4-methoxy-2-methyl-2-butanol (V), b. p. 54~55.5°C 20 mmHg. V gave a *p*-nitrobenzoate (VI), m. p. 74.0°C. Found: C, 58.38; H: 6.24: N, 5.36. Calcd. for $C_{13}H_{17}O_4N$: C, 58.18; H, 6.63: N, 5.21%.

The present investigation was supported by a grant from the Ministry of Education. The liquid sulfur dioxide was supplied by the Befu Chemical Industries, Ltd. The authors are grateful to all of them.

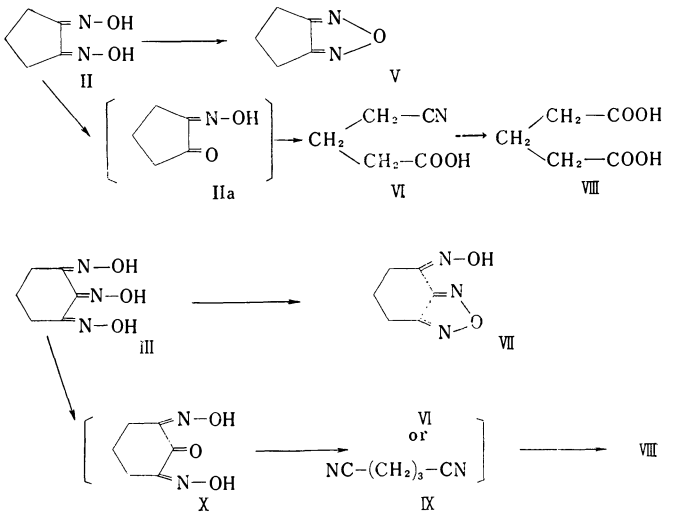
The Reactions of 1, 2-Cyclopentanedione Dioxime and of 1, 2, 3-and 1,3,5-Cyclohexanetrione Trioximes in Liquid Sulfur Dioxide[1]

By Niichiro TOKURA, Isoo SHIRAI and Tokuji SUGAHARA



(Received October 12, 1961)

As has been reported in the preceding papers of this series[2,3], 1, 2-cyclohexanedione dioxime, when subjected to Beckmann rearrangement in liquid sulfur dioxide, gives different products according to the reagents applied. Thus, thionyl chloride yielded an oxadiazole (furazan) derivative by condensation of the two neighboring hydroximino groups; bromine yielded a rearranged product, and sulfur trioxide afforded δ-cyanovaleric acid, a product of ring cleavage. The causes of such various reactions have also been discussed.

The result has prompted the present authors to investigate similar reactions with 1, 2-cyclopentanedione dioxime and 1, 2, 3- and 1, 3, 5-cyclohexanetrione trioximes.

1, 2-Cyclopentanedione dioxime (II) was prepared by the method of Belcher et al.[2,4]

1) The Beckmann Rearrangement in Liquid Sulfur Dioxide, Part IX.
2) N. Tokura, R. Tada and K. Yokoyama, This Bulletin, **34**, 270 (1961).
3) N. Tokura, R. Tada and K. Yokoyama, ibid., **34**, 1812 (1961).
4) R. Belcher, W. Hoyl and T. S. West, *J. Chem. Soc.*, **1958**, 2743.

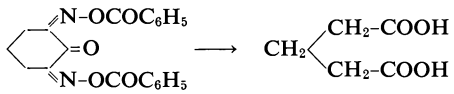
Namely, 2-bromocyclopentanone (I) was converted into 1, 2-cyclopentanedione dioxime by hydroxylamine, but in a low yield, as in the case of 1, 2-cyclohexanedione dioxime[2]. 1, 2, 3-Cyclohexanetrione trioxime (III) was prepared via 1, 2, 3-cyclohexanetrione 1, 3-dioxime by the method of Donald, Batesky and Moon[5]. 1, 3, 5-Cyclohexanetrione trioxime (IV) was prepared from phloroglucinol by the method of Baeyer[6].

In general, the oximes were not completely soluble in liquid sulfur dioxide at first, but they were immediately dissolved to transparent and homogeneous solutions on the addition of the rearranging reagents; the reactions were carried out at room temperature (10~18°C). Because of the unusual instability of the trione trioximes, the addition of the reagents often led to explosive reactions. Therefore, the reactions were sometimes performed at temperature below 0°C. Furthermore, the reactions were accompanied by the formation of large amounts of resinous matters, which has made the quantitative treatment and the discussion of the results difficult.

The reaction of II with thionyl chloride in liquid sulfur dioxide afforded a low melting substance, m. p. 41°C, which was identified as 5, 6-dihydro-4-cyclopenta [*c*] furazan[7] (V) both by analogy with the results disclosed in a preceding paper[2] and from the results of elementary and infrared spectrometric analyses.

The reaction of bromine with II in liquid sulfur dioxide produced only a large amount of a tarry matter, failed to give a product which could be characterized.

The reaction of sulfur trioxide with II in liquid sulfur dioxide afforded the expected γ-cyanobutyric acid (VI) as a product of ring cleavage. However, the yield was very low because of the violent carbonizing and resinifying action of sulfur trioxide. Hydrolysis of VI with aqueous hydrochloric acid gave glutaric acid (VIII). It seems likely that VI was derived through the incipient intermediate (IIa), as has been demonstrated in a preceding paper[2].



When III reacted with thionyl chloride in liquid sulfur dioxide, a product, m. p. 167~167.5°C, was obtained in a good yield. This was proved to be a cyclodehydrated product like V, and the structure of 7-hydroximino-4, 5, 6, 7-tetrahydrobenzo[*c*]furazan (VII) was assigned to it on the basis of elementary and infrared analyses. The presence of one free hydroximino group and of a furazan ring was deduced from the absorption at 1659 cm^{-1} and from the absorptions at 1622 and 1583 cm^{-1} respectively. The reaction of bromine with III yielded only a small amount of VII with a majority of a resinous matter.

The reaction of sulfur trioxide with III was expected to be of interest, but it turned out to be complicated as well. A small amount of VII was found in the reaction mixture. The residual solution, refluxed with 2 N hydrochloric acid, produced glutaric acid (VIII), but no glutaric acid dinitrile (IX), VI or any other intermediate that would produce VIII by acid hydrolysis, was isolated by extraction of the residual solution with ether.

The only product in the residual solution was apparently a mono-deoximated product,

probably cyclohexanetrione 1, 3-dioxime and not 1, 2-dioxime, for it produced no pink coloration with nickel nitrate solution. One plausible explanation is, therefore, that trioxime III was deoximated to trione 1, 3-dioxime X and the latter was then cleaved to dinitrile IX or to mononitrile VI to be hydrolyzed to VIII. The cleavage of the dibenzoyl derivative (XI) of the 1, 3-dioxime (X) with alkali to glutaric acid has already been reported by Treibs and Kuhn[8].

XI

The reactions of IV with thionyl chloride, with bromine and with sulfur trioxide, all ended in the formation of black nitrogen containing tarry materials, which were not extractable with any organic solvent. Since the following tautomerism in IV may be considered, the formation of a large amount of resinous product from IV may be accounted for by the presence of the reactive tautomer (IVa).

IV IVa

Experimental

Materials.—Commercial sulfur dioxide was dried with concentrated sulfuric acid and distilled. Thionyl chloride and sulfur trioxide were each distilled once. Bromine was dehydrated with sulfuric acid and distilled.

Apparatus and General Procedure.—The procedure and manipulation for the reactions were the same as have been described previously[1,2].

2-Bromocyclopentanone (I)[9].—Bromine (19 ml.) was added to a mixture of cyclopentanone (25 g.), glacial acetic acid (15 ml.) and water (60 ml.) at 55~60°C, and the whole was stirred at this temperature for a while. The reaction mixture was then neutralized with sodium carbonate. The orange oil separated was washed with water. The crude 2-bromocyclopentanone (I) (yield, 34 g.) was oximated without further purification.

1, 2-Cyclopentanedione Dioxime (II).—I (34 g.) was stirred into in small portions to a solution of hydroxylamine hydrochloride (42 g.) and sodium acetate (83 g.) in water (160 ml.), and the mixture was then refluxed for half an hour. After the mixture had been refluxed for twenty minutes more, it was treated with active carbon and filtered while hot. The filtrate was cooled to yield crude crystals of 1, 2-cyclopentanedione dioxime (II), which were then washed with water, thoroughly dried and extracted with 99% ethanol. The crystals obtained on evaporation of ethanol were recrystallized from 50% ethanol, m. p. 205~210°C (lit.: 202~212°C[4]), yield 9.0 g. Found: C, 46.68; H, 5.84; N, 21.66. Calcd. for $C_5H_8O_2N_2$: C, 46.87; H, 6.29; N, 21.87%.

1, 2, 3-Cyclohexanetrione Trioxime (III).—Essentially the method of Donald et al.[5] was employed. 1, 2, 3-Cyclohexantrione 1, 3-dioxime, m. p. 196~197°C, was prepared from cyclohexanone (184 g.), concentrated hydrochloric acid (7.5 ml.) and isoamyl nitrite (250 g.) at −5°C (yield 95 g.). The trione dioxime (31.3 g.) in 50% ethanol was oximated with hydroxylamine hydrochloride (17.4 g.) and sodium carbonate (12.9 g.) to give the 1, 2, 3-trione trioxime (III) (20 g.), m. p. 169.5~170°C (recrystallized from dioxane). Found: C, 42.40; H, 4.50; N, 24.02, Calcd. for $C_6H_9O_3N_3$: C, 42.10; H, 5.30; N, 24.55%.

1, 3, 5-Cyclohexanetrione Trioxime (IV).[6]—Potassium carbonate (3.2 g.) was added to a stirred solution of phloroglucinol dihydrate (25 g.) and hydroxylamine hydrochloride (32.2 g.) in water (1130 ml.). The mixture was allowed to stand overnight. The greyish white crystals were collected, washed with water and then with acetone, and dried under reduced pressure, m.p. 150°C (decomp.). Found: C, 42.53; H, 5.20; N, 23.51. Calcd. for $C_6H_9O_3N_3$: C, 42.10; H, 5.30; N, 23.15%.

Reaction of 1, 2-Cyclopentanonedione Dioxime (II) with Thionyl Chloride in Liquid Sulfur Dioxide.—Thionyl chloride (4.0 g.) in liquid sulfur dioxide (20 ml.) was added to a suspension of II (3.0 g.) in liquid sulfur dioxide (80 ml.). The oxime dissolved instantly. The mixture was allowed to stand at room temperature for two hours. The reaction mixture was then poured into ice water, sulfur dioxide was allowed to evaporate, and the residue was extracted with ether. The ethereal solution was washed with dilute sodium hydroxide solution and then with water and dried. Evaporation of this solution gave an oily substance, which turned to crystals on cooling, m. p. 40.5~41°C (recrystallized from ether) (yield 2.5 g.). By analogy with the previous experiment[2], and by infrared and elementary analyses, the substance was identified as 5, 6-dihydro-4*H*-cyclopenta[*c*]-furazan (V). Found: C, 54.26; H, 4.91; N, 25.29. Calcd. for $C_5H_6ON_2$: C, 54.54; H, 5.49; N, 25.44%. IR, 1585 (s) cm^{-1} (KBr).

Neutralization of the alkaline extract from the ethereal solution gave no acid product.

Reaction of II with Bromine in Liquid Sulfur Dioxide.—Bromine (12.0 g.) in liquid sulfur dioxide (20 ml.) was added to dioxime II (3.0 g.) in liquid sulfur dioxide (80 ml.). The dioxime dissolved gradually in the solution. The mixture was allowed to stand at room temperature for two hours. No product except a tarry matter was extracted with ether from the reaction mixture.

Reaction of II with Sulfur Trioxide in Liquid Sulfur Dioxide.—Sulfur trioxide (1.5 g.) in liquid sulfur dioxide (20 ml.) was added to dioxime II (3.0 g.) in liquid sulfur dioxide (80 ml.). The oxime dissolved immediately. The mixture was allowed to stand at room temperature for two

8) A. Treibs and A. Kuhn, *Ber.*, **90**, 1691 (1957).
9) R. M. Acheson, *J. Chem. Soc.*, **1956**, 4232.

hours. The reaction mixture was treated as above and extracted with ether. The ethereal solution was washed with water and dried. Evaporation of the ethereal solution afforded an orange oil, which turned to crystals, m. p. 37.5~38°C, on cooling (yield 0.5 g.). The substance thus obtained was proved to be γ-cyanobutyric acid (VI) by elementary analysis and hydrolysis to glutaric acid (VIII). Found: C, 52.88; H, 5.88; N, 12.60. Calcd. for $C_5H_7O_2N$: C, 53.09; H, 6.24; N, 12.38%.

Hydrolysis of γ-Cyanobutyric Acid (VI).—VI (0.3 g.) was refluxed with 5 N hydrochloric acid for one hour. Then the mixture was extracted with ether. On condensing the ethereal solution, colorless crystals, m. p. 96.5°C, were obtained (yield 0.15 g.). The specimen recrystallized from ethanol showed m. p. 96.5~97.5°C alone and in admixture with authentic glutaric acid (VIII). Found: C, 46.28; H, 5.68. Calcd. for $C_5H_8O_4$: C, 45.45; H, 6.10%.

Reaction of 1, 2, 3-Cyclohexanetrione Trioxime (III) with Thionyl Chloride in Liquid Sulfur Dioxide.—Thionyl chloride (3.4 g.) in liquid sulfur dioxide (40 ml.) was added to trioxime III (5.0 g.) in liquid sulfur dioxide (100 ml.). The dioxime appeared to dissolve into the solution at room temperature in two hours. The reaction mixture was then treated with ice water, and the sulfur dioxide was allowed to evaporate. The residual solution was treated as above. On condensing the ethereal solution, a light yellow substance was obtained. The product, recrystallized from ethanol showed an m. p. of 167~167.5°C (yield 2.4 g.). The melting point was depressed to 156~158°C on admixture with the starting trioxime (III) (m. p. 170°C).

By analogy with the previous experiment[2], and by infrared and elementary analyses, the product was identified as 7-hydroximino-4, 5, 6, 7-tetrahydrobenzo[*c*]furazan (VII).

Found: C, 45.57; H, 4.20; N, 27.20, Calcd. for $C_6H_7O_2N_3$: C, 47.05; H, 4.61; N, 27.44%. Mol. wt., Found: 156 (benzene), Calcd.: 153. IR ν_{max}^{KBr}, 1622(w) and 1583(s) (furazan), 1659 (=NOH) cm^{-1}.

The alkaline solution was neutralized with an acid, but extraction with ether gave nothing.

Reaction of III with Bromine in Liquid Sulfur Dioxide.—Bromine (14.0 g.) in liquid sulfur dioxide (40 ml.) was added to trioxime III (5.0 g.) in liquid sulfur dioxide (100 ml.), and the mixture was allowed to stand at room temperature for two hours. The mixture, containing a large amount of a tarry matter, was treated as above. From the ethereal extract of the residual reaction mixture, a small quantity (1.3 g.) of crystals was obtained, m. p. 166~167°C (recrystallized from ether). The product showed no melting point depression on admixture with the VII described previously. Found: C, 47.20; H, 4.35; N, 26.72. Calcd. for $C_6H_7O_2N_3$: C, 47.05; H, 4.61; N, 27.44%.

Reaction of III with Sulfur Trioxide in Liquid Sulfur Dioxide.—Sulfur trioxide (1.4 g.) in liquid sulfur dioxide (20 ml.) was added to trioxime III (3.0 g.) in liquid sulfur dioxide (80 ml.), and the mixture was kept at −5~−7°C for one hour. The mixture was then treated and extracted as described above. VII (0.3 g.) was obtained from the ethereal solution, m. p. and mixed m. p. 165~166°C. Found: C, 47.78; H, 4.40; N, 27.04. Calcd. for $C_6H_7O_2N_3$: 47.05; H, 4.61: N, 27.44%. The residual solution was again triturated with three times the ether used at first, and the ethereal solution was washed with water, dried and evaporated. The orange substance thus obtained was analyzed, but the specimen was too small to reward further examination. Found: C, 45.48; H, 5.34. Calcd. for $C_6H_5O_3N_2$ (a trione dioxime): C, 46.15; H, 5.16%. There was positive color reaction with nickel nitrate solution.

The residual solution was then refluxed with 2 N hydrochloric acid for five hours. The solution was extracted with ether. Colorless crystals were obtained and recrystallized from ethanol, m. p. 95~96°C (yield 0.4 g.). No melting point depression was observed when the substance was mixed with authentic acid (VIII). Found: C, 46.68; H, 6.03, Calcd. for $C_5H_8O_4$; C, 45.45; H, 6.10%. IR ν_{max}^{KBr}, 2940 (s), (-OH), 1705 (-COOH) cm^{-1}.

Reaction of 1, 3, 5-Cyclohexanetrione Trioxime (IV) in Liquid Sulfur Dioxide.—Thionyl chloride (4.2 g.), bromine (5.7 g.) and sulfur trioxide (1.7 g.) in liquid sulfur dioxide (20 ml.) were added in turn to trioxime IV (3.0 g.) in liquid sulfur dioxide (80 ml.), but only dark and insoluble resinous matters were produced in all cases.

Summary

1, 2-Cyclopentanedione dioxime (II), 1, 2, 3-cyclohexanetrione trioxime (III) and 1, 3, 5-cyclohexanetrione trioxime (IV) were treated with reagents and exhibited different and characteristic behaviors in liquid sulfur dioxide. The formation of 5, 6-dihydro-4*H*-cyclopenta-[*c*]furazan (V) from II with thionyl chloride by a condensation reaction and of γ-cyanobutyric acid (VI) from II with sulfur trioxide by a cleavage reaction were observed. 7-Hydroximino-4, 5, 6, 7-tetrahydrobenzo[*c*]furazan (VII) was found in the the reaction mixtures from III and thionyl chloride and from III and bromine, accompanied by large amounts of resinous matter.

Mono-deoximation by sulfur trioxide was suggested. 1, 3, 5-Cyclohexanetrione trioxime (IV) gave only black tarry matter, which may be attributable to the instability of IV.

The authors are indebted to the Befu Chemical Industries, Ltd., for the donation of liquid sulfur dioxide.

Dilute Solution Properties of Low-temperature Polymerized Polyvinyl Chloride. II. Fractionation and Properties of Fractions

By Takashi KOBAYASHI

(Received August 17, 1961)

In a previous paper of this series (hereafter referred to as Part I) we have shown that the solution behavior of a sample of polyvinyl chloride prepared at −15°C differed significantly from that of samples polymerized at higher temperatures. In order to seek the causes of this difference, we have dermined the molecular weight distributions in some samples of this polymer polymerized at different temperatures and have measured representative solution properties of the fractions of these samples. The present paper is intended to describe the results of this study and to discuss their molecular implications.

Experimental

Materials.—Five samples of polyvinyl chloride were studied. They were as follows:

SO968—A whole polymer suspension-polymerized at 48°C.

XF-13—A whole polymer emulsion-polymerized at 5°C.

F-2 — A whole polymer bulk-polymerized at −15°C.

F-5* — A whole polymer bulk-polymerized at −15°C under conditions similar to those used for F-2.

F-5-M—A middle cut of F-5; the 3 wt.% higher molecular weight portion and the 29 wt.% lower molecular weight portion of F-5 were removed by fractional precipitation.

Of the five samples, SO968 and F-5-M were materials treated also in Part I of this series.

As before, tetrahydrofuran was chosen as the solvent; its preparation has been described in Part I.

Density Measurement. — The film of a given polymer sample cast from its 3% tetrahydrofuran solution was soaked in carbon disulfide and then dried in vacuo. Its density was measured at 30°C in a density gradient tube using carbon tetrachloride and *n*-heptane as the density-forming liquids.

Fractionation. — The polymer was dissolved in tetrahydrofuran by refluxing for three hours at the boiling point of the solvent. At 30°C the precipitant, water in the present case, was vigorously stirred into the polymer solution of 0.625~0.75% until it became turbid. By raising the temperature of the solution to the boiling point of the solvent, again while being vigorously stirred, the once-developed precipitate disappeard. Then the solution was gradually cooled to 30°C and maintained at this temperature until the supernatant became transparent. The precipitate formed was separated and dissolved in tetrahydrofuran. The polymer was recovered from this solution by the addition of excess methanol, and then dried in vacuo to constant weight. This gave the first fraction. The second fraction was obtained by applying the same procedure to the supernatant solution. By repeating this process the desired successive fractions were obtained.

Viscosity, Osmotic Pressure and Light-scattering Measurements. — Details for these measurements were described previously.

Results and Discussion

Fractionation.—For a successful fractionation of a polymeric material, the choice of a solvent and non-solvent is of primary importance. A survey of the literature[1,2] and also our own experience showed that the combination of tetrahydrofuran and water was one of the best for polyvinyl chloride. Preliminary experiments with monohydric alcohols (such as methanol, *n*-propanol and *n*-butanol) as precipitants gave precipitates which were too fine to be separated easily. Therefore, we adopted the system of tetrahydrofuran and water for the present purpose.

Fractionation was made on samples SO968, XF-13, F-2 and F-5; Table I records some related data. For SO968, F-2 and F-5, the fraction number stands for the order in which the precipitates were separated. However, in the case of XF-13, the amount of fraction 4 was so large that it was refractionated into three fractions 4-1, 4-2 and 4-3; moreover,

TABLE I. RELATED DATA OF FRACTIONATION

Sample	Initial concn.	Temp.* °C	Number of fractions	Yield of recovery %
SO968	15 g./2 l.	30	8	93.5
XF-13	25 g./4 l.	30	10	92.5
F-2	30 g./4 l.	20	12	99.7
F-5	50 g./7 l.	20	13	97.1

* Temperature at which precipitate was separated.

* This was prepared later because the sample F-2 had been exhausted in the early stages of this investigation.

fraction 4-1 was separated further into 4-1-1 and 4-1-2. The relative weight and limiting viscosity number, $[\eta]$, in tetrahydrofuran at 30°C of each fraction of these four samples of polyvinyl chloride are listed in Tables II, III, IV and V.

For XF-13, F-2 and F-5, the fractions appearing in the initial stage of fractionation (fractions 1 and 2 for XF-13; up to fraction 4 for F-2; up to fraction 5 for F-5) were obtained in the form of fine powder, in contrast to the case of commercial polyvinyl chloride, where gel-like precipitates are usually obtained. Since such powder-like fractions were difficult to separate in the usual manner, these were specifically precipitated at 20°C (not at 30°C)

and separated by centrifugation at room temperature (which did not differ significantly from 20°C). It was found that the formation of powder-like precipitates in the initial stage of fractionation was characteristic of low-temperature polymerized polyvinyl chloride. Tables IV and V show that, contrary to what is generally observed, the $[\eta]$ of fractions of these low-temperature polymerized polyvinyl chloride increases with the increase of the fraction number in the initial stage of fractionation, comes to a maximum value, and then decreases in the usual manner. From the results reported in Part I, it was apparent that it would have been desirable to dissolve polymer at as high a temperature as 100°C, but because of the lack of a suitable vessel the original solutions for these fractionations had been prepared at the boiling point of tetrahydrofuran; under these conditions associated particles, or undissociated particles, were present in the solutions of XF-13, F-2 and F-5. Anomalous fractionation data on polyvinyl chloride similar to this have been reported by Mencik[2], who attributed the phenomenon to the association of molecules before the phase separation took place. However, the reason why powder precipitates developed is not clear.

Molecular Weight Distribution.—Figures 1—3 give the integral distributions of (weight average) molecular weight, M_w, for samples SO968, XF-13 and F-2 respectively; the values of M_w for fractions whose M_w were not determined experimentally have been estimated by using the viscosity vs. molecular weight relation described below. The two-stage feature appearing in the data for XF-13 and F-2 seems to be characteristic of polyvinyl chloride polymerized at low temperature. Although any definite conclusion must be left for future work, this feature is likely to be due to the presence of undissociated molecules in the original solution and also to the occurrence of molecular association during the fractionation procedure.

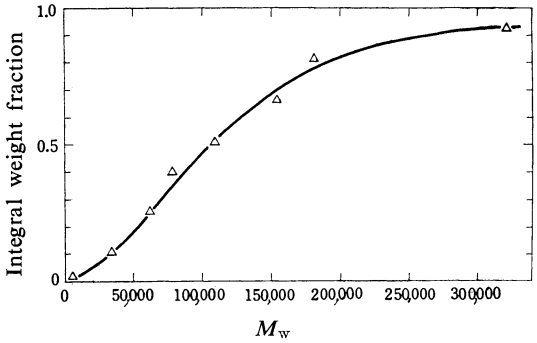

Fig. 1. Molecular weight distribution of SO968.

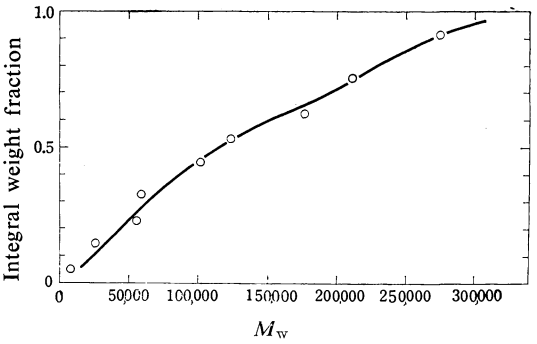

Fig. 2. Molecular weight distribution of XF-13.

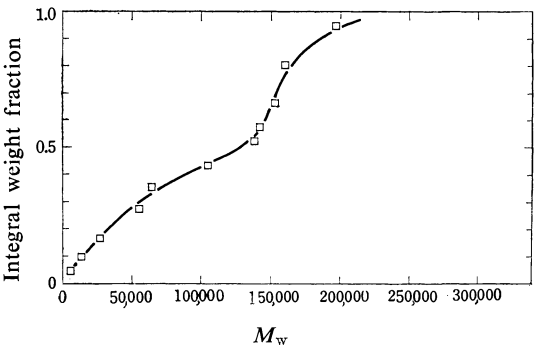

Fig. 3. Molecular weigt distribution of F-2.

Some Physical Properties of Fractions of F-5.—Table V, which gives the densities of successive fractions of F-5, indicates a systematic decrease of the density with the increase of the fraction number. This suggests that the crystallinity or chain regularity is higher for earlier fractions than for later fractions. When the density of each fraction is plotted against its limiting viscosity number in tetrahydrofuran at 30°C, the data for fractions whose fraction numbers are higher than 6 are seen to form a certain order, while those for the remaining

fractions are out of this order. Infrared studies[3-5] on polyvinyl chloride indicate that the ratio of the optical density for absorption at 635 cm^{-1}, which is assigned to the crystalline part, to that for absorption at 690 cm^{-1}, which is assigned to the amorphous part, can be taken as a measure of the crystallinity of a given sample. We measured infrared spectra of several fractions of samples SO968 and F-5 by using a Perkin-Elmer model 13 infrared spectrophotometer; the results obtained are listed in Table VI. One can see that the degree of crystallinity of samples F-5, which was polymerized at −15°C, is higher than that of sample SO968 polymerized at 48°C. Table VI also reveals that, although the values of $[\eta]$ for fractions 1 and 8 of sample F-5 are quite similar, the former fraction is more crystalline than the latter; incidentally, this is in conformity with the preceding suggestion from the density data that the later fractions of F-5 are less crystalline than the earlier fractions. From these results one may consider that white powderlike precipitates of polyvinyl chloride will develop in the tetrahydrofuran-water system when the degree of crystallinity or chain regularity of the polymer is higher than a certain limiting value. If this is the case, it is quite likely that the fractionation of samples XF-13, F-2 and F-5 proceeded in accordance not only with the molecular weight but also with the chain regularity. Previous X-ray[6] and also infrared[3-5] studies showed that the chain regularity of polyvinyl chloride increased as the polymerization temperature was lowered, and this was attributed to the increase in the syndiotactic portion[7] of the polymer.

TABLE VI. CRYSTALLINITY OF FRACTIONS OF SO968 AND F-5

SO968

F-8	123	2.10

Relations between Limiting Viscosity Number and Average Molecular Weights. — The values of the limiting viscosity number $[\eta]$ (in tetrahydrofuran at 30°C), number-average molecular weight M_n, obtained from osmotic pressure measurements, and the weight-average molecular weight M_w, determined from light-scattering measurements, for fractions of SO968, XF-13 and F-2 are summarized in Tables II, III and IV. Figure 4 illustrates Zimm plots for fraction 4 of F-2. When these data for $[\eta]$ and M_n are combined on a log-log plot, the points, though quite scattered, fall within the range of the literature's data[8-11]. The corresponding plots for $[\eta]$ vs. M_w are given in Fig. 5, which shows that even if the polymerization temperature is different, the relation between $[\eta]$ and M_w for polyvinyl chloride in tetrahydrofuran remains practically the same.

The relation between the limiting viscosity number and the molecular weight, M, of a polymer generally obeys an empirical equation of the form:

$$[\eta] = KM^{\alpha} \qquad (1)$$

where K and α are constants characteristic of

the given polymer solvent system. This equation holds not only for a polymer of uniform molecular weight but also for a polymer with a molecular weight distribution, although with the latter polymer M must be replaced by some average molecular weight. For both the monodisperse and polydisperse samples of the same polymer species in the same solvent, the parameter α remains the same although the values of K are different. If α is given and the form of molecular weight distribution is specified, it is possible to examine by calculation the variation of K with the ratio of M_w/M_n. The results of this calculation[12] with logarithmic[13] and exponential[14] distribution functions show that when M_n is substituted for M in Eq. 1, K varies appreciably with the ratio M_w/M_n, but when $[\eta]$ is plotted against M_w, K is almost independent of M_w/M_n. This affords the advantage of using M_w over M_n when we wish to establish a relation between the limiting viscosity number and the molecular weight for a given polymeric substance.

The straight line in Fig. 5, determined by the least square procedure, yields

$$[\eta] = 2.19 \times 10^{-1} M_w^{0.54}$$

or

$$[\eta] = 2.05 \times P_w^{0.54}$$

where P_w denotes the weight-average degree of polymerization. The value 0.54 obtained for the exponent to M_w suggests that the molecules of polyvinyl chloride in tetrahydrofuran assume a random coil form. Ciampa[15], who obtained the value of unity for this exponent, suggested a worm-like form for the molecule of this polymer in cyclohexanone. The lack of non-Newtonian behavior of the solution of F-5-M illustrated in Fig. 6 appears to lend some support to the pertinence of our value for the exponent in the viscosity vs. molecular weight relation.

Weight-average Root Mean Square End-to-end Distance, $\langle r^2\rangle_w^{1/2}$ and Light-scattering Second Virial Coefficient, A_2.—The values of $\langle r^2\rangle_w^{1/2}$ and A_2 for fractions of samples SO968, XF-13 and F-2 determined from light-scattering data are listed in Tables II, III and IV. In converting the directly-obtained $\langle r^2\rangle_z^{1/2}$, the z-average root mean square end-to-end distance, to $\langle r^2\rangle_w^{1/2}$ following relations were assumed between the average molecular weights and the average dimensions of the solute molecule:

$$M_n/l+1 = M_w/l+2 = M_z/l+3 \quad (2)$$

$$M_n/\langle r^2\rangle_n^{1/2} = M_w/\langle r^2\rangle_w^{1/2} = M_z/\langle r^2\rangle_z^{1/2} \quad (3)$$

which are valid for the exponential molecular weight distribution[13]. Figure 7 plots A_2 against

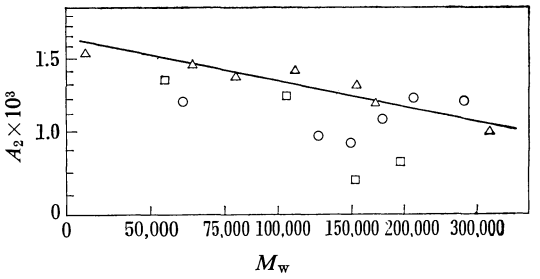

Fig. 7. Relation between A_2 and M_w.

△ Fractions of SO968; ○ XF-13; □ F-2

M_w on a log-log graph paper. The straight line, which was drawn to fit the data for sample SO968, has a slope of -0.21, comparable to the reported values on polyvinyl acetate[16-18] in butanone and polystyrene[19] in toluene at 30°C. The A_2 values for XF-13 and F-2 are generally smaller than those for SO968 when a comparison is made with the same values of M_w. This fact suggests that the thermodynamic interaction between solute and solvent molecules becomes weaker as the polymerization temperature is lowered. In other words, tetrahyhrofuran acts as a poorer solvent for a polyvinyl chloride sample which has been polymerized at a lower temperature. It is interesting that this difference is in line with the differences in solution properties observed in the study described in Part I of this series.

Figure 8 shows a log-log plot for $\langle r^2\rangle_w^{1/2}$ against P_w, together with that for polystyrene in butanone at 25 and 20°C reported by Outer,

Full line is for SO968.

Carr and Zimm[20]. From the straight line drawn, which fits best for SO968, one finds that the weight-average root mean square end-to-end distance of SO968 increases in proportion to the 0.73 power of the weight-average degree of polymerization. One also finds that the average dimension of polyvinyl chloride in tetrahydrofuran increases as the polymerization temperature is lowered. Finally, it is of interest to note that polyvinyl chloride in this solvent has a dimension similar to that of polystyrene in butanone when the degree of polymerization of both polymers are comparable.

Doty et al.[21] pointed out that the polyvinyl chloride molecule has a tendency to become partially syndiotactic, that its chain flexibility is relatively low, and, moreover, that the syndiotactic portions interact with each other through their dipoles, thus limiting its possible configurations in solution. This affords a reasonable explanation for the finding that the molecular dimension of this polymer in solution increases as the polymerization temperature is lowered, since a sample prepared at a lower temperature should be richer in syndiotactic portion. The fact that the relation between the limiting viscosity number and the molecular weight is practically independent of polymerization temperature may be accounted for by the fact that the effect caused by the increase in molecular dimension is cancelled out by the accompanying increase in the permeability of the solute to solvent molecules.

The author wishes to express his appreciation to Professor Shunsuke Murahashi, Professor Hiroshi Fujita of Osaka University and to Professor Akira Kotera of Tokyo University of Education for their encouragement and thoughtful suggestions throughout the course of the study reported in this paper, to Dr. K. Mayumi and Kureha Kasei Co., Ltd., for permission to publish this paper, and to Mr. M. Sato, Mr. Y. Koshiishi and Mr. S. Aoyagi for their cooperation in carrying out the exerimental work.

The Syntheses of 5'-Deoxy-5'-methylthioadenine and its Analogues

By Yôko ISHIKURA, Teiichi KANAZAWA and Tetsuo SATO

(Received August 25, 1961)

9β-(5'-Deoxy-5'-methylthio-D-ribofuranosyl)-adenine (I), known as "adenyl thiomethyl pentoside" or "vitamin L_2", was first isolated from yeast by Mandel and Dunhan[1] in 1912. Recently this nucleoside was directly converted into *S*-(5'-deoxyadenosine-5')-methionine[2], "active methionine", which participates in the transmethylation reaction in living cells. Baddiley et al.[3], Makino et al.[4] and Weygand et al.[5] have succeeded independently, in the synthesis of this nucleoside, using adenosine as the starting material. Their synthetic route analogously involved the introduction of a toluene-*p*-sulfonyl group into the 5'-position of 2', 3'-*O*-isopropylidene-adenosine, followed by its replacement by a methylthio group.

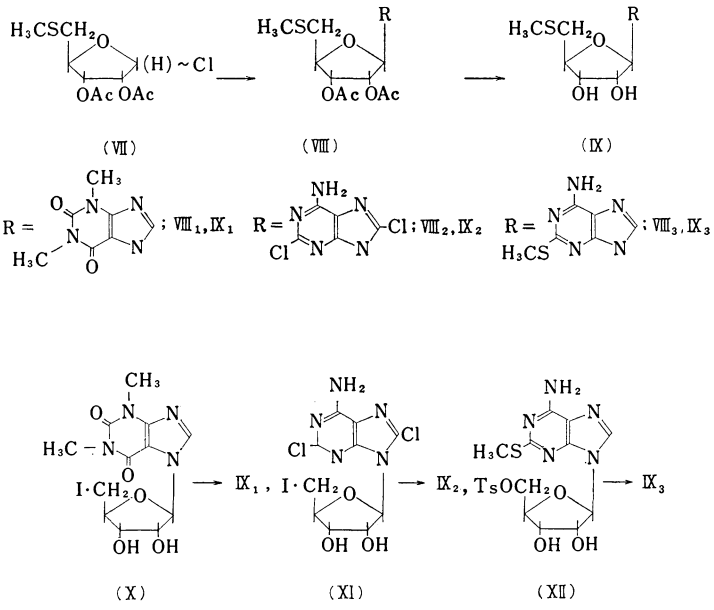
I

In a previous short communication[6] from this laboratory, a new synthetic method for obtaining compound I was described. In the present paper this new method and the synthesis of its analogues are described in detail.

In the authentic method, considerable difficulty was experienced in the formation of an intramolecular 3-5′-cyclic compound. So, to avoid the formation of this cyclic compound, D-ribose was converted into 5′-deoxy-5′-methylthio derivative and its halide was condensed with a purine base. It was reported by Overend and Parker[7] and by Yoshimura and Sato[8] that methyl 2, 3-*O*-isopropylidene-β-D-ribofuranoside (II) was converted into 5-*O*-toluene-*p*-sulfonyl derivative (III), which reacted with sodium methyl sulfide in acetone to give methyl 2, 3-*O*-isopropylidene-5-deoxy-5-methylthio-D-ribofuranoside (IV). The isolation of this compounds in its pure state was not, however, attempted by these authors.

This reaction was repeated by using anhydrous acetonitrile as a solvent in place of acetone. The yield of the product was increased to 85% by this modification. The solation of the pure product from the reaction mixture was achieved by the use of distillation followed by column chromatography on alumina.

The methyl and isopropylidene residues of IV were removed by heating it in 0.01N sulfuric acid. The resultant syrup (V) could not be crystallized, but gave one spot on paper chromatography (with butanol-acetic acid-water 5 : 1 : 4 v/v). The acetylation of this product with pyridine-acetic anhydride in the usual manner afforded crystals, m. p. 66°C (yield 21%) (VIb), and an oily material (yield 48%) (VIa). Elemental analysis found no difference between these products. It was deduced from the values of the optical rotation of these compounds that VIa and VIb are α- and β-isomer respectively.



VIb was chlorinated with hydrogen chloride in absolute ether. Freshly prepared 1-chloro derivative (VII) was condensed with the silver salt of theophylline, which is known to react easily with sugar halide in general. The condensation product was deacetylated by methanolic ammonia to give white needles, m. p. 74～76°C (IX_1). The position of the sugar residue at the purine base and the configuration of the glucosidic linkage of this compound were confirmed as follows. The authentic sample of 7β-(5′-deoxy-5′-iodo-D-ribofuranosyl)-theophylline (X) was treated with sodium methyl sulfide to introduce a methylthio group. The product was identical to IX_1. Thus, the structure was confirmed to be 7β-(5′-deoxy-5′-methylthio-D-ribofuranosyl)-theophylline.

Chloromercuri-2, 8-dichloroadenine and chloromercuri-2-methylthioadenine were also condensed with VII, in the manner described above, to give the corresponding derivatives with a methylthio group at position 5′ ($VIII_2$ and $VIII_3$ respectively). $VIII_2$ and $VIII_3$ were deacetylated with methanolic ammonia, and structures of the resultant compounds (IX_2 and IX_3) were confirmed by derivations from XI and XII to be 9β-(5′-deoxy-5′-methylthio-D-ribofuranosyl)-2, 8-dichloroadenine and 9β-(5′-deoxy-5′-methylthio-D-ribofuranosyl)-2-methylthioadenine respectively. Furthermore, the results of elemental analysis, ultraviolet absorption measurement and Fehling's test supported this structure.

Compound I was not obtained from IX_2 or IX_3 by partial reduction in either cases.

It has been reported[9-11] that the yield of

adenine with a sugar halide of the condensation reaction of metallic salt is less than 2～3%; 6-acetaminopurine and 6-chloropurine, however, were easily condensed with sugar halides, and the substituents at position 6 were converted into amino groups by treatment with methanolic ammonia. These facts suggest that chloromercuri-6-acetaminopurine and chloromercuri-6-chloropurine might be condensed in a good yield with methylthio sugar derivatives and converted into compound I. The test of the condensation showed that 9β-(2',3'-di-*O*-acetyl-5'-deoxy-5'-methylthio-D-ribofuranosyl)-6-acetaminopurine and 9β-(2',3'-di-*O*-acetyl-5'-deoxy-5'-methylthio-D-ribofuranosy)-6-chloropurine are obtainable in 41% and 63% yields repectively. In either case, the products were treated with methanolic ammonia to afford I, m. p. 205～206°C. (The yields from VIb were 17.5 and 35% respectively.)

The synthetic substance and natural "adenyl thiomethyl pentoside" were proved to be identical by measurement of their melting points and paper chromatography.

Experimental

Methyl 2,3-*O*-Isopropylidene-5-deoxy-5-methylthio-β-D-ribofuranoside (IV).—A mixture of III (30 g., 0.084 mol.) and potassium methyl sulfide (15 g., 0.175 mol.) in dry acetonitrile (150 ml.) was heated in a sealed tube for 7 hr. at 100°C. After the solution had been chilled, the insoluble materials were filtered off and the filtrate was evaporated to dryness. The residue was dissolved in a mixture of ice cold water and chloroform. The chloroform layer was washed with water. After being dried with anhydrous sodium sulfate, it was evaporated under reduced pressure. A colorless syrup (24 g.) was obtained by distillation under 0.03 mmHg (b. $p._{0.03}$ 82°C, b. $p._{0.005}$ 62°C). Yield, 94%. This product (15 g.) was chromatographed on a column of active alumina (150 g.). A colorless syrup (13.7 g., 91%) was obtained when it was eluted with 600 ml. of benzene-petroleum ether (1 : 2).

Found: C, 51.31; H, 7.75; S, 13.99. Calcd. for $C_{10}H_{18}O_4S$ (234.3): C, 51.28; H, 7.69; S, 13.70%. $R_f(a)=0.57$*.

5-Deoxy-5-methylthio-D-ribofuranose (V).—A mixture of IV (13.7 g.), dioxane (80 ml.) and 0.1 N sulfuric acid (200 ml.) was heated at 100°C for 2 hr. The acid was then neutralized with barium carbonate. The insoluble materials were filtered off, and the filtrate was evaporated to dryness. An oily product was obtained. Yield, 9.7 g., 92%.

1,2,3-Tri-*O*-acetyl-5-deoxy-5-methylthio-β-D-ribofuranose (VIb) and its α-Anomer (VIa).—Compound V (6 g.) was acetylated with acetic anhydride in pyridine (50 ml.). By fractional distillation of the acetyl derivatives, the following three fractions were obtained. No. 1: b. p. 114～118°C/0.01 mmHg (2.95 g.); No. 2; b. p. 118～125°C/0.01 mmHg (3.5 g.); No. 3: b. p. 130～134°C/0.01 mmHg (3.2 g.). Ether (2 ml.) was added to fraction No. 3, and the solution was left to stand for 1 day. 1.6 g. of crystals were obtained, m. p. 64～66°C. Yield, 50%. The same crystals (0.1 g.) were obtained from No. 2 (3%). These crystals were collected and recrystallized from ether, m. p. 66°C.

Found: C, 46.95; H, 5.87; S, 10.47. Calcd. for $C_{12}H_{18}O_7S$ (306.32): C, 47.06; H, 5.92; S, 10.45%. $[\alpha]_D$ −26.7° (*c* 0.99, ethanol).

No. 1 and mother liquors of No. 2 and No. 3 (6.3 g.) were dissolved in a mixture of benzene

* Solvent systems of paper chromatography: R_f(a) *n*-Butanol-water (saturated) (upper layer): R_f(b) *n*-Butanol-acetic acid-water, 5 : 2 : 3 (upper layer).

and petroleum ether, and the solution was fractionated on a magnesol-celite column (80 g. of 5 : 1 mixture). The solvents used for elution were mixtures of benzene and petroleum ether with successively increasing concentrations of benzene. The effluents were examined as to the weight of the eluates and their rotation. As is shown in Fig. 1, 0.8 g. of crystals (the β-anomer) and 4.4 g. of the α-anomer were obtained. The α-anomer had $[\alpha]_D$ +26.1° (*c* 1.015, ethanol).

Found: C, 47.15; H, 6.29. Calcd. for $C_{12}H_{18}O_7S$ (306.3): C, 47.05; H, 5.99%.

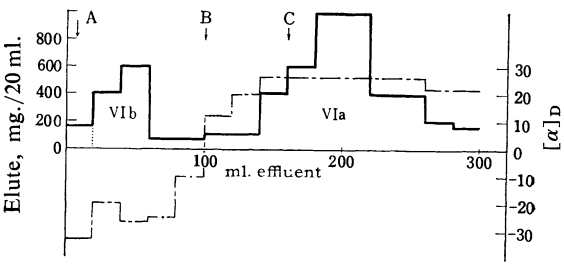

Fig. 1. Chromatographic separation of VI on a magnesol-celite column.
A, B and C are used for elution in which the ratio of benzene to petroleum ether are 0.3, 0.6 and 1 respectively. ——, weight of elute; ———, rotation of elute; VIb, the β anomer; VIa, the α anomer.

2,3-Di-*O*-acetyl-5-deoxy-5-methylthio-D-ribofuranosyl Chloride (VII).—VIb (4 g.) was dissolved in absolute ether (160 ml.), and the solution was saturated with dry hydrogen chloride at −7°C and left to stand for 4 days at 0°C.

7β-(5'-Deoxy-5'-methylthio-D-ribofuranosyl)-theophylline (IX_1).—*From Theophylline Silver.*—A solution of VII, freshly prepared as above from 2.4 g. of VIb in 30 ml. of toluene, was added to an azeotropically-dried suspension of 2.5 g. of theophylline silver in 30 ml. of toluene. The mixture was allowed to reflux for 2 hr. (kept from moisture), and the insoluble materials were filtered off. The filtrate was then evaporated, and the residual syrup was treated with methanolic ammonia. The product (1.4 g.) was recrystallized twice from water, m. p. 66~68°C. Yield, 1.2 g.

Found: C, 45.22; H, 5.30; N, 16.61. Calcd. for $C_{13}H_{18}O_5N_4S$ (342.3): C, 45.61; H, 5.35; N, 16.37%. $R_f(a)=0.66$, $R_f(b)=0.08$. λ_{max}: 275 mμ, $\varepsilon=9300$ (water).

From X.—A mixture of 1 g. of X and 2 g. of dry potassium methyl sulfide was added to 5 ml. of anhydrous dimethylformamide, and the mixture was heated at 100°C for 2 hr. After the solvent had been evaporated in vacuo, the residue was added to water. 0.5 g. of crystals were obtained. This was recrystallized twice from water, m. p. 73~75°C, undepressed on admixture with IX_1.

9β-(2', 3'-Di-*O*-acetyl-5'-deoxy-5'-methylthio-D-ribofuranosyl)-2, 8-dichloroadenine ($VIII_2$).—A solution of sugar halide, prepared as above from 2 g. of VIb in 30 ml. of xylene, was added to chloromercuri-2,8-dichloroadenine on celite (from 2 g. of 2,8-dichloroadenine) in 200 ml. of xylene, and the mixture was allowed to reflux for 2.5 hr. There was obtained 0.9 g. of crystals, m. p. 187~188°C (34% yield).

Found: C, 39.92; H, 3.84; N, 15.37. Calcd. for $C_{15}H_{17}O_5N_5Cl_2S$: C, 40.01; H, 3.78; N, 15.55%. $R_f(a)=0.88$, $R_f(b)=0.92$.

9β-(5'-Deoxy-5'-methylthio-D-ribofuranosyl)-2, 8-dichloroadenine (IX_2).—*From $VIII_2$.*—To a solution of 0.9 g. of $VIII_2$ in 30 ml. of absolute methanol was added 35 ml. of absolute methanol saturated with ammonia at 0°C, and the mixture was left to stand overnight at room temperature. The solution was evaporated in vacuo, and the residual syrup was dissolved in 50 ml. of hot water. After being treated with activated charcoal, the solution was concentrated to 10 ml. and was chilled. White needles were obtained, m. p. 89~92°C. Yield, 0.7 g. 90%. Recrystallization from water, m. p. 94~96°C.

Found: C, 34.61; H, 4.03; N, 18.16. Calcd. for $C_{11}H_{13}O_3N_5S\cdot H_2O$ (313.3): C, 34.39; H, 3.91; N, 18.23%. $R_f(a)=0.79$, $R_f(b)=0.67$. $\lambda_{max}=267$ mμ, $\varepsilon=19500$ (water).

From XI.—A solution of 0.5 g. of XI in 15 ml. of acetonitrile was added to 1 g. of sodium methyl sulfide in a sealed tube at 0°C, and the shaking mixture was kept at 100°C for 7 hr. After the solution had been chilled, the insoluble materials were filtered off and the filtrate was evaporated in vacuo. The residue was dissolved in chloroform and washed with water. The solution was concentrated and dissolved in 30 ml. of hot water and passed through a column of Amberlite IR-120 resin (H form). After washing of the column with 20% alcohol, the product was eluted with a large volume of ammonia (equal parts of water and ammonia of $d=0.880$). The effluent was evaporated to a small volume in vacuo, and the crystalline nucleoside (0.2 g.) was filtered off. Recrystallized from water, m. p. 94~96°C, undepressed on admixture with IX_2.

9β-(2', 3'-Di-*O*-acetyl-5'-deoxy-5'-methylthio-D-ribofuranosyl)-2-methylthioadenine ($VIII_3$).—A mixture of VII (prepared from 1.4 g. of VIb) and chloromercuri-2-methylthioadenine (from 1.8 g. of 2-methylthioadenine) was heated under the reflux condition described above. 0.3 g. of crystals was obtained, m. p. 172~174°C.

Found: C, 44.50; H, 5.10; N, 16.18. Calcd. for $C_{16}H_{21}O_5N_5S_2$ (427.5): C, 44.90; H, 4.95; N, 16.38%. $R_f(a)=0.72$, $R_f(b)=0.78$.

9β-(5'-Deoxy-5'-methylthio-D-ribofuranosyl)-2-methylthioadenine (IX_3)—*From $VIII_3$.*—$VIII_3$ (2 g.) was treated with methanolic ammonia as described in section for IX_2 1.4 g. of crystals, were obtained m. p. 165~166°C.

Found: C, 41.50; H, 5.10; N, 19.86. Calcd. for $C_{12}H_{17}O_3N_5S_2$ (343.4): C, 41.96; H, 4.98; N, 20.39%. $R_f(a)=0.65$, $R_f(b)=0.78$. $\lambda_{max}=235.5$ mμ, $\varepsilon=22900$ and 275 mμ, $\varepsilon=15000$, $\lambda_{min}=250$ mμ, $\varepsilon=8000$ (methanol).

From XII.—A mixture of 0.3 g. of XII and 0.5 g. of potassium methyl sulfide in 12 ml. of dimethylformamide was heated at 100°C for 1.5 hr. and evaporated in vacuo. The residue was dissolved

in chloroform. After the insoluble materials had been filtered off, the solution was washed with water, dried evaporated in vacuo. The obtained syrup was dissolved in 10 ml. of dioxane. 1 N Sulfuric acid (20 ml.) was added, and the solution kept at room temperature for 24 hr. The acid was neutralized with a calculated amount of barium hydroxide solution. Barium sulfate was removed by centrifugation and washed with water, and the combined supernatant liquid and washings were evaporated to dryness in vacuo. The residue was dissolved in 20% ethanol and treated with Amberlite IR-120 as described above. A crystal was obtained m. p. 165~166°C, undepressed on admixture with IX_3.

9β-(5'-Deoxy-5'-methylthio-D-ribofuranosyl)-adenine (I).—*From 6-Acetaminopurine.*—A mixture of chloromercuri-6-acetaminopurine (prepared from 2.1 g. of 6-acetaminopurine) and VII (prepared from 2 g. of VIb) was treated as described above. 9β-(2', 3'-Di-*O*-acetyl-5'-deoxy-5'-methylthio-D-ribofuranosyl)-6-acetaminopurine (1 g.) was obtained. This product was dissolved in 30 ml. of absolute methanol and was added to 35 ml. of methanolic ammonia at 2~4°C. After 24 hr., the solution was evaporated and the residue was dissolved in hot water. After 3 days a crystalline solid was obtained, m. p. 199~201°C. This was recrystallized from water, m. p. 205~206°C, undepressed on admixture with naturally occurring "adenyl thiomethyl pentoside". The mother liquors of the crystallization and recrystallization were purified with Amberlite IR-120; 0.15 g. of the crystals was obtained.

From 6-Chloropurine. — Chloromercuri-6-chloropurine (prepared from 1.5 g. of 6-chloropurine) was condensed with VII (prepared from 1.7 g. of VIb). 1.4 g. of a glass-like material were obtained. Yield from VIb, 63%. This substance was added to 40 ml. of methanol saturated with ammonia at 0°C in a sealed tube, and the mixture was kept at 100°C for 5 hr. The solution was treated as described above. 0.67 g. of the crystals was obtained, m. p. 204~206°C, undepressed on admixture with the natural substance.

Found: C, 44.09; H, 5.29; N, 23.25. Calcd. for $C_{11}H_{15}O_3N_5S$ (297.3): C, 44.43; H, 5.04; N, 23.25%.

Synthetic nucleoside: R_f(a)=0.45, R_f(b)=0.59
Natural nucleoside: R_f(b)=0.42, R_f(b)=0.59.

We are grateful to Dr. Katushi Makino for the gift of a sample of natural "adenyl thiomethyl pentoside".

Studies on Fluorene Derivatives. XV. The Clemmensen Reduction of Fluorenone*

By Kazuo SUZUKI

(Received August 28, 1961)

There have been several investigations of the Clemmensen reduction of fluorenone (I). Harris et al.[1] obtained fluorenol (II), fluorene (III), 10, 10-diphenylene-9-phenanthrone (V), dibiphenylene-ethylene (IX) and -ethane (X) by reduction of I under various conditions in the presence of dilute ethanol.

Bradlow et al.[2] produced III and V in toluene or ethanol, while Ritchie[3] obtained III and X in an ethanolic solution. III was obtained in a fairly good yield in each of these experiments and also in another preparation[4].

However, I has been best reduced to III by the Wolff-Kischner method with or without an alkaline catalyst, as has been observed by Weisburger and Grantham[5].

This is interesting because a great part of I does not normally proceed by way of II in the Clemmensen reduction and also because many related products were obtained by an abnormal reaction. Moreover, some of them do not appear to have been previously reported as direct products from I in this reduction.

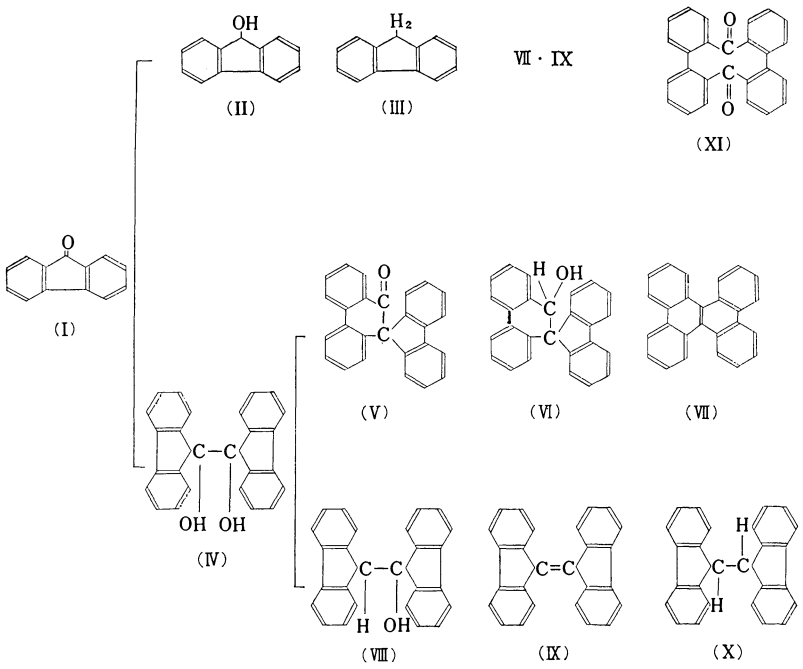

Chart 1

The present author carried out the reduction by the procedure of "Organic Reactions"[6]: I was dissolved in solvents such as toluene, benzene and xylene, which were mixed with the aqueous hydrochloric acid. The mixture was heated under reflux for a period of twenty-four hours, concentrated hydrochloric acid being added at intervals of about six hours. These results are summarized in Table I.

In this work, II, III and dimeric reaction products, namely, 9, 9′-dihydroxy-9, 9′-bifluorenyl (fluorenopinacol) (IV), V, 10, 10-diphenylene-9, 10-dihydro-9-phenanthrol (VI), 9, 10-diphenylene-phenanthrene or tetrabenzonaphthalene (VIII), 9-hydroxy-9, 9′-bifluorenyl (VIII), X and mixed crystals (VII・IX), were isolated by means of a combination of recrystallization and column chromatography. These reaction routes can be outliued as in Chart 1.

Fluorenol (II) and Fluorene (III). — III was obtained in a poor yield by means of steam distillation from the reaction mixture. II was isolated as an intermediate to III in the case of a short reduction period.

In general, it has often been stated heretofore that the carbonyl compound is not reduced to hydrocarbon by way of the corresponding alcohol. However, III was obtained as a normal product from II in a process independent of fluorenopinacol (IV) formation by the Clemmensen reduction.

In another analogous case in this series, 1- and 2-bromo-fluorenone[7] were attacked slowly under the same conditions, whereby substituted fluorenols were also produced, even after twenty-four hours.

III was obtained in an excellent yield and high purity by the reduction of II in a toluene system. In addition, a small amount of 2-(9′-fluorenyl)-fluorene was isolated as an abnormal product. This compound has already been reported by Suzuki et al.[8]

9, 9′-Dihydroxy-9, 9′-bifluorenyl (IV).—IV has been obtained previously by several procedures[9], but not from I by the Clemmensen reduction.

IV exhibits an interesting behavior in the course of the reaction since it reacts further (see Charts 2 and 3). Thus, IV is the main product in the case of a short reduction time such as two hours. Furthermore, the direct reduction of IV was attempted by using the same conditions and leading to other compounds, as are illustrated in Table I.

10, 10-Diphenylene-9-phenanthrone (V).—There have been several reports about V[10,11]. A

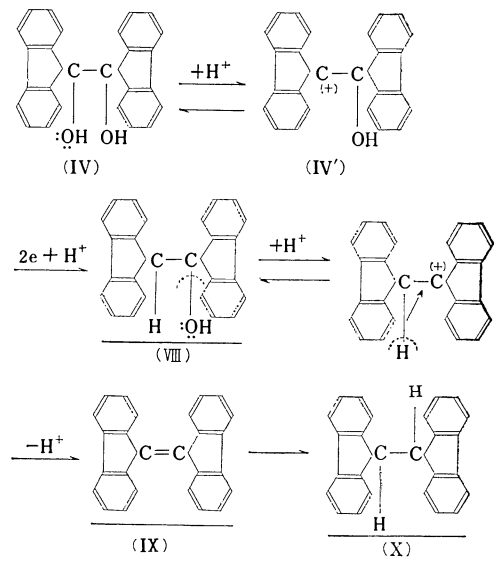
minor part of IV was converted into the β-isomeride of V through the carbonium ion IV′ by a pinacol rearrangement which on further reduction gave VII (10%) as the end-product, as is illustrated in Chart 2 and Table I. V was identical with an authentic specimen prepared by Meerwein's method[10].

9, 10 - Diphenylene - phenanthrene (VII). — VII[11-13] has been reported previously, but it has not been obtained heretofore by the Clemmensen reduction of I. VII would be formed through the intermediate VI. VI[11] was prepared from V by the use of zinc and ammonium hydroxide in an alcoholic solution, and was then converted to VII[cf.14] by treating it under the same conditions as in the Clemmensen reduction but without zinc amalgam.

Furthermore, VII (80%) and intermediate VI (10%) could be isolated by the Clemmensen reduction of V for fifteen hours in the xylene system.

In order to polarize the central double bond, VII was oxidized to tetrabenzocyclodecane-1,6-dione (XI)[11], which was then converted to VII and V by reduction.

The mechanism of the formation of VII via VI from V by the retropinacolone rearrangement involves the intramolecular transfer of the electron pair by formation of a carbonium ion. Thus, the reaction sequences can be written as in Chart 2.



(Underscored compounds were isolated)
Chart 2

Dibiphenylene-ethylene (IX) and -ethane (X). —IX and X were reported by Harpe and Dorp[15] previously. In this reaction, a major part of IV through the IV′ carbonium ion was converted into VIII and then to IX, which on further reduction afforded the end-product X (56%) (see Chart 3 and Table I). VIII was isolated as an intermediate product by short reduction of I (2 hr.) or IV (3 hr). in the toluene solution, as is shown in Table I.

VIII was readily converted to IX[16] by hydrochloric acid in acetic acid. Therefore, IX could be obtained in a better yield by treating VIII under the same conditions as in the Clemmensen reduction but without the amalgamated zinc.

In general, an ethylenic link is reduced easily when it is conjugated with a carbonyl group. In contrast, the reduction of the ethylenic link in IX was extremely slow upon treatment with hydrochloric acid and amalgamated zinc in the toluene solution, and a red color remained even after twenty-four hours.

IX was isolated from the reaction mixture as mixed crystals (red prisms) with VII. However, VII was not obtained by Harris et al.[1] from an alcoholic solution; hence, their product was simply IX.

IV	2.0	Benzene	6.0	24				0.1		0.06		0.1	IV 1.0

The reaction sequences of IX and X can be visualized as in Chart 3.

Mixed Crystals (VII·IX). — The mixed crystals gave 9,9′-dibromo-9,9′-bifluorenyl[17] and VII (no reaction) by bromination; with the Clemmensen reduction of zinc and ammonium hydroxide, they gave X and VII, and with oxidation, I and XI. Therefore, the mixed crystals can be supposed to consist of VII and IX. Moreover, the ultraviolet spectrum showed maxima in the regions of 220~350 and 450 mμ, as is illustrated in Fig. 1. These maxima were almost identical with those of VII and IX respectively[18,19].

The infrared spectrum also indicated a mixture, and the analytical results were identical with $C_{26}H_{16}$.

The same mixed crystals were produced in nearly a quantitative yield from the solution of VII : IX (0.2 : 1) in acetic ester.

VII is slightly yellow, even when recrystallized several times from different solvents. It is best to purify it by reduction and then by recrystallization.

Effects of the Solvents.—The yields in Table I were slightly different depending on the solvents. In the case of benzene, the reaction went slowly and a large amount of I was recovered, perhaps because of the lower boiling point of benzene as compared with these of toluene and xylene.

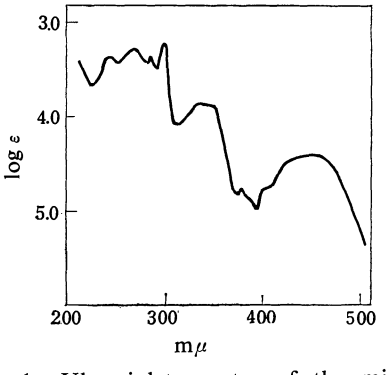

Fig. 1. Ultraviolet spectra of the mixed crystals.

In this study fluorenone was converted to fluorene and the other intermediates, II, IV, V VI, VIII and IX, after a short reduction time (2 hr.) in toluene, as has been described above.

Furthermore, V, VIII and X were increased, but IV was decreased and IV remained almost constant when the reaction was continued for twenty-four hours (red colored toluene). Three kinds of end-products, VII (10%), X (55.6%) and (III, 8.7%) were obtained, as is shown in Chart I and Table I, by extending the refluxing periods for seventy-two hours (almost colorless). VII and X were then obtained in approximately a ratio of 1 : 5.6.

It may, therefore, be assumed that V and VIII were also formed from IV through the positively charged ion IV′ by the action of the acidic medium in the Clemmensen reduction.

In view of these observations, the behavior of each intermediate in the course of the Clemmensen-Martin reduction of fluorenone can be explained. There have also been some other discussions reported recently of the mechanism of the Clemmensen reduction[20].

Experimental*

General Procedure for the Clemmensen Reduction of Fluorenone Materials.—Amalgamated zinc filings were prepared according to Martin's method[6].

A mixture of amalgamated zinc (20 g.), water (15 ml.), xylene (20 ml.), concentrated hydrochloric acid (35 ml.) and fluorenone (10 g.) was refluxed briskly for twenty-four hours in a 500 ml. round-bottomed flask. A 10 ml. portion of concentrated hydrochloric acid was added every six hours during the heating period. The xylene layer turned a bright red color after ten minutes.

The red reaction mixture was cooled to room temperature after 24 hr., and the deposited crystals

* All the melting points are uncorrected.

in the xylene layer were collected and washed free of acid with a small amount of water and then recrystallized from benzene. Colorless crystalline needless of X (1.6 g.) were obtained. (Part of X coats the surface of the zinc; m. p. and mixed m. p. 224°C). The mother liquor was evaporated to half volume. The deposited crystals were filtered and recrystallized from acetic ester to yield V (0.75 g.) as colorless prisms, m. p. 258°C (Found: C, 90.91; H, 4.86%). This was identical with those of a specimen which was prepared from IV with sulfuric acid in acetic acid following the procedure of Gomberg and Bachmann[9]. Further evaporation of the mother liquor to half volume yielded VII (slightly yellow), which recrystallized several times from benzene as nearly colorless material, (1.3 g.), m. p. 214~215°C.

Found: C, 95.28; H, 5.20. Calcd. for $C_{26}H_{16}$; C, 95.09%; H, 49.1%; Picrate, Found: C, 69.21; H, 3.64 N, 7.60. Calcd. for $C_{32}H_{19}O_7N_3$: C, 68.94; H, 3.44; N, 7.54%.

VII, λ_{max}^{MeOH} mμ (log ε): 265 (4.73), 286 (4.69), 299 (4.84), 335 (4.22), 350 (4.20).

The xylene was separated from the water layer and submitted to steam distillation for one hour to remove both the solvent and the fluorene which was recrystallized from alcohol (1.3 g.), m. p. 113~114°C. This was confirmed by mixed melting point.

The red residue was filtered, dried, and recrystallized from benzene to yield additional X (0.8 g.) (total 2.4 g.), m. p. 243~244°C.

The last benzene mother liquor was evaporated to a small volume, and the deposited red crystals were recrystallized from acetic ester in a red prism to give mixed crystals (0.5 g.), m. p. 185°C.

Found: C, 95.10; H, 5.19. Calcd. for $C_{26}H_{16}$: C, 95.09; 4.91%.

λ_{max}^{MeOH} mμ (log ε): 244 (4.62), 268 (4.71), 286 (4.63), 299 (4.76), 335 (4.15), 348 (4.13) 382 (3.23), 450 (3.60).

Then, IV was isolated from the mother liquor as colorless needles (1.0 g.), m. p. 192°C (Found: C, 86.24; H, 5.14%). The identity of this compound was confirmed by mixed melting point with an authentic sample.

The separation of the reaction products was much simpler when the reduction time was longer (72 hr.). In this reduction, the amalgamated zinc and hydrochloric acid were changed every 24 hr.

In the case of a short reduction period (2 hr.) the first deposited crystals were almost pure IV (m. p. 192°C). II (0.1 g., m. p. 158°C) was extracted by 20% boiling alcohol from the red residue of the steam distillation; furthermore, other compounds were separated by the method described above. The last residual benzene solution was chromatographed on alumina, and two products, VIII (0.65 g., m. p. 192~193°C) and I (0.3 g., m. p. 80°C), were isolated; their identity was confirmed by mixed melting point with authentic samples.

In the case of a short reduction period (3 hr.). of IV, each product was separated by a procedure almost identical to that employed for the reduction products of I.

Oxidation of 9, 10-Diphenylene-phenanthrene (VII).—VII (1 g.) was dissolved in a mixture of acetic acid (25 ml.) and sodium bichromate (5 g.) and refluxed for 2 hr., and the reaction mixture was then poured into cold water. The white amorphous products were filtered, dried, and recrystallized from benzene to yield XI (0.42 g.) as colorless prisms, m. p. 269~271°C[12,13].

Found: C, 86.73; H, 4.38. Calcd. for $C_{26}H_{16}O_2$: C, 86.65; H, 4.48%.

I (0.15 g.), m. p. 80°C, was isolated from the mother solution, as shown by mixed melting point with an authentic sample.

Reduction of Tetrabenzocyclodecane-1,6-dione (XI).—A mixture of XI (0.2 g.), red phosphorus (0.1 g.), hydrogen iodide (3 ml.) and acetic acid (5 ml.) was refluxed for 9 hr. After it had been cooled, the reaction mixture was filtered, and the filtrate was poured into water.

The white deposited product was filtered and recrystallized from benzene, m. p. 256~257°C (0.1 g.). This compound was identical with V, as shown by mixed melting point.

To the benzene mother liquor was added 0.1 g. of picric acid. Dark-red crystalline needles (m. p. 198~200°C) were deposited; this picrate was filtered and decomposed by ammonium hydroxide. The product recrystallized from acetone yielded VII (0.045 g.) as colorless needles, m. p. 214~215°C.

Reactions of the Mixed Crystals.—*Reduction.*—A mixture of amalgamated zinc (4 g.), water (3 ml.), concentrated hydrochloric acid (7 ml.), toluene (8 ml.) and mixed crystals (2 g.) was refluxed for 10 hr. The crude product (1.6 g., m. p. 224~237°C) was isolated from the toluene; from this X (1.1 g., m. p. 242~243°C) and VII (0.2 g., m. p. 212~214°C) were separated by recrystallization. Both X (0.45 g.) and VII (0.08 g.) were also obtained from mixed crystals (0.6 g.) by the use of zinc and ammonium hydroxide in an alcoholic solution; X and VII were confirmed by identity with authentic samples.

Bromination.—To the mixed crystals (0.82 g.) dissolved in carbon tetrachloride (30 ml.) there was added 0.4 g. of bromine in 5 ml. of carbon tetrachloride at room temperature. After the mixture had been let standing for 3 hr., the deposited crystals were filtered and recrystallized from benzene (0.6 g.). This was identical with 9,9'-dibromodibiphenyleneethane (m. p. 235°C) prepared by Graebe and Mantz's method[17]. VII (0.1 g., m. p. 213~214°C) was isolated from the mother solution and did not react with bromine.

Oxidation (1).—Mixed crystals (1.0 g.), acetic acid (25 ml.) and potassium bichromate (5 g.) were refluxed for 2 hr. After being poured into cold water, the light yellow precipitate obtained was recrystallized from benzene to yield XI (0.2 g. m. p. 269.5~271°C); this was confirmed by comparison with an authentic sample. I (0.5 g., m. p. 81°C) was isolated from the mother liquor.

Oxidation (2).—To the mixed crystals (0.5 g.) dissolved in 50 ml. of acetone there were added 2 g. of potassium permanganate during 2 hr. at room temperature. Then, most of the acetone was evaporated by reduced pressure and poured into water.

The deposited material was filtered off and refluxed with 3 ml. of alcohol. I (0.4 g., m. p. 81°C) was obtained from the soluble part, while VII (0.1 g., m. p. 213~214°C) was obtained from the alcohol-insoluble part and was recrystallized from benzene.

Formation of Mixed Crystals.—IX (1.0 g.) and VII (0.2 g.) were dissolved in acetic ester by heating. Upon the cooling of the mixture, bright mixed crystals (red prisms) were deposited and were recrystallized from acetic ester, m. p. 185°C (1.0 g.).

Found: C, 95.10; H, 5.19. Calcd. for $C_{26}H_{16}$: C, 95.11; H, 4.89%.

Reduction of 10, 10-Diphenylene-9-phenanthrone (V) to 9, 10-Diphenylene-phenanthrene (VII).—V (2.0 g.), amalgamated zinc (8 g.), concentrated hydrochloric acid (14 ml.) xylene (40 ml.) and water (6 ml.) were refluxed for 15 hr., a 4 ml. portion of hydrochloric acid being added every 6 hr. After the reaction period, the xylene layer was separated and washed with water, and the xylene was steam-distilled. The white residue was filtered, dried, and then chromatographed in benzene on alumina.

Fractional crystallization yielded VII (1.52 g. m. p. 214~215°C) and VI (0.2 g. m. p. 178~179°C), which were confirmed by mixed melting polnt.

The author wishes to express his gratitude to Drs. John and Elizabeth Weisburger of National Institutes of Health, U. S. A. for their valuable suggestions, and also to Dr. Toshio Mukai for the ultraviolet spectra and to Dr. Yûsaku Ikegami for the infrared spectra, both recorded at Tohoku University.

The Aconite Alkaloids. XXXVI[1]*. Oxidation of Lucaconine and its Derivatives*[2b]

By Takashi AMIYA and Takeo SHIMA[3]

(Received August 8, 1961)

Lucaconine (I) ($C_{24}H_{39}O_7N$) and monoacetyllucaconine (II) ($C_{26}H_{41}O_8N$) have been isolated from *Aconitum luciduscul*um, *Nakai*, and have been subjected to continuous research in this laboratory[4-7].

The present authors have further studied the degradation reactions of compound I and its derivatives; the oxidation reactions of these compounds, mainly with the chromium trioxide-pyridine complex, are reported on this paper (cf. Table I).

The oxidation of compound I with the chromium trioxide-pyridine complex yielded neutral products, oxolucaconine (III) ($C_{24}H_{37}\cdot O_8N\cdot 13/4H_2O$), oxolucaconinone-II(IV) ($C_{24}H_{35}\cdot O_8N$), m. p. 218°C, and oxolucaconinedione (V) ($C_{24}H_{33}O_8N$). Compound IV was a monoketo-lactam and showed absorption bands at 5.83 and 6.15 μ characteristic of a six-membered ring ketone and of a lactam carbonyl group in the infrared spectrum respectively. Its ultraviolet absorption spectrum showed a maximum (λ_{max} 298 mμ, log ε 1.90), indicating the presence of a ketone carbonyl group. Compounds III and V are a lactam and a diketo-lactam respectively; they had been previously obtained by Furusawa through other procedures[7]. Compound III manifested absorption bands in the infrared spectrum at 2.94 and 6.20 μ characteristic of hydroxyl and lactam carboxyl groups respectively. It was also obtained by chromium trioxide-pyridine complex oxidation of diacetyllucaconine (VI) ($C_{28}H_{43}O_9N$)[6], followed by hydrolysis. Compounds III and IV were further oxidized to compound V by the same reagent. The infrared spectrum of compound V manifested absorption bands at 5.72, 5.83 and 6.08 μ characteristic of a five-membered ring ketone, a six-membered ring ketone and a lactam carbonyl group respectively. The reduction of compound III with lithium aluminum hydride gave compound I again.

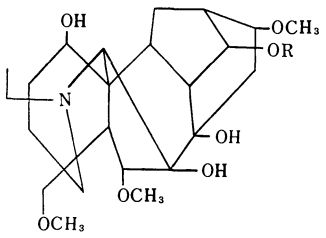
7) S. Furusawa, ibid., **32**, 399 (1959).

TABLE I

Lucaconinone-I (VII) ($C_{24}H_{37}O_7N$), a monoketo-base, was prepared from compound I by Furusawa[7]. It showed a band at 5.72 μ in the infrared spectrum due to the presence of a five-membered ring ketone carbonyl group. The ultraviolet absorption spectrum exhibited a maximum (λ_{max} 292 mμ, log ε 1.53). Compound VII was reduced to deoxylucaconinone-I (VIII) ($C_{24}H_{39}O_6N$), m. p. 165°C, by the Wolff-Kishner method. Its infrared spectrum showed no absorption characteristic of a ketone carbonyl group. The ultraviolet spectra of compounds III, VI and VIII showed only end absorptions.

Next, compound II, a naturally occurring base, was oxidized by the chromium trioxide-pyridine complex and subsequently hydrolyzed, giving compound IV. This result shows that an acetylated hydroxyl group in compound II is a secondary one attached to a carbon atom in a five-membered ring.

In view both of the experimental results previously obtained[7] and of those described in this investigation, the partial formula of compounds I and II may be extended as follows:



$C_{14}H_{17}$ { $(OCH_3)_3$; $(\rightarrow COH)_2$; $>CHOR$ (five-membered ring); $>CHOH$ (six-membered ring); $-N-C_2H_5$; $-CH_2$ }

I, R=H II, R=Ac

On the other hand, it has been suggested by Stern[8] that lucaconine seems to be identical with delcosine[9]. Since then, several reports concerning delcosine have been published by Marion and his co-workers[10-13]. In those reports a structure of delcosine has been proposed after a revision and the further possibility of identifying delcosine with lucaconine has been considered. Comparison of the physical properties of lucaconine and its derivatives and those of delcosine and its derivatives also leads to the supposition that lucaconine is identical with delcosine. Recently, lucaconine has been found to be identical in melting point and infrared spectrum with Takao base-I[14,15], showing no depression in mixed melting point; therefore, lucaconine must be identical with delcosine, which has already been shown to be identical with Takao base-I[14]. Accordingly, the name "lucaconine", must be revised to "delcosine", and derivatives of compound I should be named as those of delcosine.

According to the structure of delcosine (compound I) proposed by Skaric and Marion[13], compound II, a naturally occurring base, ought to have the structure shown in Scheme A. While oxidation and subsequent hydrolysis of monoacetyldelcosine have given dehydrooxodelcosine[13], compound II has yielded compound IV[4] on the same treatment. As compound IV seems to be identical with dehydrooxodelcosine, compound II is probably identical with monoacetyldelcosine, as has been pointed out by Canadian workers[13].

Scheme A

The Wolff-Kishner reduction of compound V, a diketo-lactam, gave a lactam (IX) ($C_{24}H_{37}O_6N \cdot 2H_2O$), m. p. 80~85°C. It showed no absorption band characteristic of ketone carbonyl in the infrared spectrum. The ultraviolet spectrum of compound IX showed only end absorption. From a consideration of the molecular formula as well as of the spectra of compound IX, it has reasonably been assumed that in this reduction two carbonyl groups of compound V were converted into methylene groups. Oxidation of compound IX, a di-tertiary glycol containing no more than two hydroxyl groups, with periodic acid gave an amorphous material X, the infrared spectrum of which showed bands at 5.70 and 5.92 μ. These bands at 5.70 and 5.92 μ suggest the probable presence of a five-membered and of an α,β-unsaturated six-membered ring ketone carbonyl group respectively, derived from the cleavage of a 1, 2-glycol constituent. This experimental consequence confirms the findings of the Canadian group[11-13], in which compound I has been shown to be a di-tertiary 1, 2-glycol; it also coincides with the result of the oxidation of anhydrohydroxydelcosine with periodic acid[12]. Accordingly, it may be concluded that compound I is not a di-tertiary 1,3-glycol[1].

Thus, the experiments mentioned above, together with the NMR spectrum of compound I[16], strongly support the structure of compound I (Scheme A) suggested by Skaric and Marion[13].

Experimental

Oxidation of Lucaconine (I) with the Chromium Trioxide-Pyridine Complex. — *A) Oxolucaconine (III) and Oxolucaconinone-II (IV).* — A mixture of lucaconine (1 g.) and chromium trioxide (1 g.) in pyridine (20 ml.) that had been allowed to stand at room temperature overnight was evaporated to dryness in vacuo. After the addition of water (100 ml.), the residue was reduced with sulfur dioxide. The excess reagent having been reduced, the acid solution thus obtained was extracted with chloroform three times. After removal of the solvent, the chloroform extract gave a residue which was redissolved in chloroform (13 ml.) and chromatographed on alumina (5 g.). The chromatogram was eluted with chloroform alone (100 ml.), and then with chloroform containing 1% of methanol (100 ml.). From the chloroform portion the residue was obtained. It was crystallized from acetone. On recrystallization from ethanol, it melted at 132°C; yield, 0.05 g. Mixture with oxolucaconine prepared according to the directions of Furusawa[7] did not affect the melting point. The ultraviolet absorption spectrum of this compound in methanol showed end absorption and no maximum. The infrared absorption spectrum in Nujol, identical with that of isooxolucaconine[7], showed the presence of hydroxyl groups (2.94 μ) and of a lactam carbonyl group (6.20 μ).

From the portion of the chloroform containing 1% of methanol of elute, oxolucaconinone-II (0.1 g.) was obtained on evaporation. It crystallized from acetone. On two recrystallizations from ethanol, it melted at 218°C; yield, 0.1 g. The ultraviolet absorption spectrum of this compound in methanol showed λ_{max} 298 mμ, log ε 1.90. The infrared absorption spectrum in Nujol showed the presence of hydroxyl groups (2.87 and 2.98 μ), a ketone carbonyl group (5.83 μ) and a lactam carbonyl group (6.15 μ).

Found: C, 62.31; H, 7.64; OCH_3, 18.22. Calcd. for $C_{24}H_{35}O_8N$: C, 61.92; H, 7.58; $3OCH_3$, 19.99%.

The aqueous liquor described above was made alkaline with sodium carbonate and extracted with chloroform. After removal of the chloroform, a basic substance (0.3 g.) was left. It was crystallized from acetone and further recrystallized from ethanol twice. It melted at 199~200°C either alone or mixed with naturally occurring lucaconine.

B) Oxolucaconinedione (V) and Oxolucaconinone-II (IV). — A mixture of lucaconine (1 g.) and chromium trioxide (2 g.) in pyridine (40 ml.) was allowed to stand at room temperature for two days. It was treated by the same procedure as the above A), and the obtained acid solution was extracted with chloroform three times. The chloroform extract was evaporated. The residue was chromatographed on alumina (5 g.) as in the case of the above A). Evaporation of the chloroform portion (100 ml.) of elute and the subsequent addition of acetone gave a crystalline material, m. p. 203°C. Two recrystallizations from ethanol yielded crystals melting at 209°C, reported[13] m. p. 211~212°C. Mixture with oxolucaconinedione, prepared according to the direction of Furusawa[7], did not alter the melting point. The infrared absorption spectrum of this compound in Nujol showed the presence of hydroxyl groups (2.90 μ), ketone carbonyl groups (5.72 and 5.83 μ), and a lactam carbonyl group (6.08 μ)[7]. It was reported[13] as $\lambda_{max}^{chloroform}$ 3446, 1757, 1720 and 1653 cm^{-1}.

Oxime.—It melted at 248°C and did not depress the melting point of the sample of the oxime prepared by Furusawa[7].

The portion of the chloroform containing 1% of

16) A. Suzuki, T. Amiya and T. Matsumoto, This Bulletin, 34, 455 (1961).

methanol (100 ml.) of elute gave a residue crystallized from acetone. On recrystallization from ethanol it melted at 218°C and did not depress the melting point of the oxolucaconinone-II described above.

In this oxidation reaction from the aqueous liquor, the basic substance was not obtained.

Diacetyllucaconine (VI).—The ultraviolet absorption spectrum of this compound in methanol showed end absorption and no maximum.

Oxolucaconine (III) from Diacetyllucaconine (VI)[13].—A mixture of diacetyllucaconine (0.3 g.), chromium trioxide (0.3 g.) and pyridine (6 ml.) was allowed to stand at room temperature overnight. The chloroform extract, obtained from the acid solution prepared by the same treatment as described above, was evaporated to give a residue (0.3 g.). It was then hydrolyzed with boiling ethanolic potassium hydroxide for 1 hr. After cooling, the solution was evaporated, and the residue neutralized with 1 N hydrochloric acid and extracted with chloroform. After removal of the chloroform, the residue (0.2 g.) was crystallized from acetone. Two recrystallizations from ethanol gave crystals, m. p. 132°C, which did not depress the melting point of the authentic sample (oxolucaconine) described above.

Oxolucaconinedione (V) from Oxolucaconine (III).—A mixture of oxolucaconine (0.3 g.), chromium trioxide (0.3 g.) and pyridine (6 ml.) was allowed to stand at room temperature overnight. The reaction mixture was treated in the above-described manner, and the chloroform extract from the acid solution was evaporated to give a residue, which crystallized from acetone. Two recrystallizations from ethanol yielded 0.2 g. of crystals, m. p. 209°C. It did not alter the melting point of the authentic sample (oxolucaconinedione).

Oxolucaconinedione (V) from Oxolucaconinone-II (IV).—A mixture of oxolucaconinone-II (0.5 g.), chromium trioxide (0.5 g.) and pyridine (10 ml.) was treated in just the above-mentioned manner to give 0.4 g. of oxolucaconinedione, m. p. 209°C. Mixture with the authentic sample did not alter the melting point.

Reduction of Oxolucaconine (III) with Lithium Aluminium Hydride. — Oxolucaconine (0.2 g.) was dissolved in dioxane (5 ml.). An ether solution (3 ml.) of lithium aluminium hydride (0.1 g.) was added and the temperature gradually raised until the ether evaporated. Then the solution was further refluxed for an hour. The excess reagent was destroyed by the use of water, and, after removal of the formed aluminium hydroxide, the solution was evaporated in vacuo. After the addition of water (1 ml.), the residue was extracted with chloroform. Removal of the chloroform left a residue, which was crystallized from acetone. Two recrystallizations from ethanol yielded crystals, m. p. 200°C, which did not depress the melting point of lucaconine.

Lucaconinone-I (VII). — The ultraviolet absorption spectrum of this compound in methanol showed λ_{max} 292 mμ, log ε 1.53. The infrared absorption spectrum in Nujol showed the presence of hydroxyl groups (2.99 μ) and a ketone carbonyl group (5.72 μ)[7]. It was reported as λ_{max}^{Nujol} 1751 cm^{-1} [14] and λ_{max}^{Nujol} 1755 cm^{-1} [11].

Deoxylucaconinone-I (VIII) from Lucaconinone-I (VII).—A solution of lucaconinone-I (40 mg.) in triethylene glycol (1 ml.) and 85% hydrazine hydrate (0.5 ml.) was refluxed for 1 hr. at 130°C. Then potassium hydroxide (80 mg.) was added and the temperature gradually raised to 200°C during an hour, while water and excess hydrazine hydrate were distilled off. After it had been refluxed for an additional 5 hr. at 195~200°C, the solution was cooled, diluted with water, and extracted with chloroform three times. After removal of the chloroform, a residue was obtained. Recrystallization from ethanol gave crystals (30 mg.), m. p. 165°C, $[\alpha]_D$ +64.65° ($CHCl_3$) reported[14] m. p. 170~171°C, $[\alpha]_D$ +51° ($CHCl_3$). The ultraviolet absorption spectrum of this compound showed end absorption and no maximum. The infrared absorption spectrum showed the presence of hydroxyl groups (2.99 μ).

Found: C, 66.16; H, 8.96; OCH_3, 19.25. Calcd. for $C_{24}H_{39}O_6N$: C, 65.87; H, 8.98; $3OCH_3$ 21.27%.

The analysis of this compound has also been reported[14].

Oxolucaconinone-II (VI) from Monoacetyllucaconine (II). — A mixture of monoacetyllucaconine (2 g.), chromium trioxide (2 g.) and pyridine (40 ml.) was allowed to stand at room temperature overnight. The reaction mixture was treated in the same way as in the above-described oxidation. The chloroform extract from the acid solution gave an amorphous residue (2 g.) on evaporation which was hydrolyzed with boiling ethanolic potassium hydroxide for an hour. After cooling, the solution was evaporated. The residue was neutralized with 1 N hydrochloric acid and extracted with chloroform. After removal of the chloroform, the residue was crystallized from acetone. Two recrystallizations from ethanol gave 1.6 g. of crystals, m. p. 218°C, which did not depress the melting point of the authentic sample described above.

Deoxyoxolucaconinedione (IX). — A solution of oxolucaconinedione (730 mg.) in triethylene glycol (10 ml.) and anhydrous hydrazine (3.5 ml.) was refluxed for 3 hr. at 140°C, potassium hydroxide (1 g.) was added, and the temperature was gradually raised to 200°C over the course of an hour without the condenser. After it had been refluxed for an additional 5 hr. at about 200°C, the solution was cooled, diluted with water, and extracted with chloroform five times. The chloroform extract was washed with 1 N hydrochloric acid and evaporated. The residue was redissolved in 5 ml. of chloroform and then chromatographed on alumina (5 g.). The chromatogram was eluted with chloroform (100 ml.). The elute was evaporated. The residue was crystallized from petroleum ether and diethyl ether. Two recrystallizations from aqueous ethanol gave 350 mg. of needle, m. p. 80~85°C. The ultraviolet absorption spectrum of this compound in methanol showed end absorption and no maximum. The infrared absorption spectrum in Nujol showed the presence of hydroxyl groups (2.96 and 2.99 μ) and a lactam carbonyl group (6.19 μ).

Found: C, 60.76; H, 8.71; N, 2.86; OCH_3,

20.15; H_2O, 7.55. Calcd. for $C_{24}H_{37}O_6N \cdot 2H_2O$: C, 61.12; H, 8.76; N, 2.97; $3OCH_3$, 19.74; H_2O, 7.64%.

Cleavage of the Lactam (IX) with Periodic Acid. — To the lactam (IX) (230 mg.) in ethanol (20 ml.), 0.1 N periodic acid (30 ml.) was added, and the mixture was allowed to stand at room temperature for 5 days. After the addition of water (100 ml.), the solution was extracted with chloroform. Evaporation of the chloroform gave a residue. The residue was redissolved in a small quantity of chloroform and chromatographed on alumina (3 g.). The chromatogram was eluted with chloroform (50 ml.). The elute was evaporated to leave 0.15 g. of an amorphous residue. The infrared absorption spectrum in Nujol showed the presence of hydroxyl groups (2.96 μ), a five-membered cyclic ketone (5.70 μ), an α,β-unsaturated six-membered cyclic ketone (5.92 μ) and a lactam carbonyl group (6.11 μ).

The authors are grateful to Professor Harusada Suginome, President of Hokkaido University, for his unfailing kindness in encouraging this work, and to Drs. M. Yamaguchi, Wakayama Prefectural Medical College, and A. Fujino, Faculty of Science, Osaka City University, for their kindness in the determination of the infrared spectra.

*Hot-atom Reaction in cis- and trans-Dinitrotetrammine Cobalt(III) Nitrate**

By Nobufusa SAITO, Hirotoshi SANO, Takeshi TOMINAGA, Fumitoshi AMBE and Takeo FUJINO

(Received September 9, 1961)

Several models have been proposed to account for the mechanism of the hot-atom reaction in solids[1-4]. It should be possible to check the validity of these models by investigating the hot-atom reaction in compounds exhibiting optical and geometrical specificity. Zuber[5] irradiated dextro-tris(ethylenediamine)cobalt-(III) nitrate and found the yield of ^{60}Co to be 4.5 per cent in the dextro form and 0.5 per cent in the laevo form. Recently, Rausher, Sutin and Miller[6] have studied the Szilard-Chalmers reaction in *cis-* and *trans*-dichloro-bis(ethylenediamine)cobalt(III) nitrate and have found that the yield of ^{60}Co is 3~7 per cent in the parent isomer and 0.1~0.2 per cent in the other isomer, while the corresponding yields of ^{38}Cl in that order are 12~16 per cent and 0.4~0.7 per cent respectively.

We have investigated the chemical effects of the $^{59}Co(n,\gamma)^{60}Co$ reaction in the cis and trans isomers of crystalline dinitrotetrammine cobalt-(III) nitrate, which show a greater stability to aquation than do the dichloro complex salts. Furthermore, the retentions of nitroammine cobalt(III) complex salts are higher than those of the complex salts cited above.

Experimental

Materials.—The complex salts were prepared by the method of Jorgensen[7]. The salts were purified by recrystallization. The purity of the complex salts was checked by taking the absorption spectra of their solutions in distilled water and comparing the molar extinction coefficients and the maximum wavelengths with those reported by Basolo[8].

Neutron Irradiation.—Samples of *cis*-$[Co(NH_3)_4(NO_2)_2]NO_3$ and *trans*-$[Co(NH_3)_4(NO_2)_2]NO_3 \cdot H_2O$ were irradiated at reactor temperature for one to five hours in the thermal column of the JRR-1 reactor. All bombardments were made in the presence of air. The neutron flux at the bombardment site was $(3\sim5)\times10^{11}$ n/cm^2 sec., and the gamma ray flux, approximately 5×10^5 r/hr.

Separation Procedure.—*Ion Exchange Separation.* —Two to five milligrams of the irradiated sample were dissolved in 10 ml. of water. (In preliminary tests, cobalt(II) nitrate, *cis-* or *trans*-dinitrotetrammine nitrate and nitropentammine nitrate were added prior to the dissolution of the sample, but

no effect on the distribution of ^{60}Co was found.) The solution was passed through a resin column (0.8×17 cm. of Dowex 50W X-8, H-form 100~200 mesh beads). The column was then washed with about 100 ml. of water. The effluent contained anionic and neutral species. Subsequently, 300 to 400 ml. of 1 M sodium chloride solution was passed through the column. Firstly, *trans*-$[Co(NH_3)_4(NO_2)_2]^+$ ions were eluted, and then a mixture of *cis*-$[Co(NH_3)_4(NO_2)_2]^+$ ions and Co(II) species in the next fraction[9]. To the latter fraction were added 10 mg. of cobalt(II) nitrate as a carrier and 10 mg. of *cis*-$[Co(NH_3)_4(NO_2)_2]NO_3$ as a hold-back carrier. The cobalt(II) species were precipitated as hydroxide with a diluted sodium hydroxide solution. After reprecipitation, the precipitates were dissolved in diluted hydrochloric acid.

In another series of experiments, ammonium malonate was used as an eluent instead of sodium chloride. After the sample solution had been passed through a cation exchanger column (under the same condition as mentioned above but kept in ammonium form), the column was washed with about 100 ml. of water. The adsorbed cations were eluted with 300 to 400 ml. of 1/2 M ammonium malonate solution. Anionic and neutral species were collected in the first fraction. The cobalt(II) species was eluted in the second fraction as cobalt(II) malonate*. The *trans*- and *cis*-dinitrotetrammine, and nitropentammine species were eluted in the third, fourth, and fifth fractions respectively.

The non-cationic fraction was poured into an anion exchanger column (Dowex 1 X-8, NO_3-form, 100~200 mesh beads, 0.8×10 cm.). The column was then washed with about 100 ml. of 0.1 M sodium chloride solution. Neutral species were collected in the effluent. The adsorbed anions were eluted with 1 M sodium chloride solution.

All samples were counted as liquids, in a well-type scintillation counter.

Paper Electrophoresis. — Samples of the irradiated compounds were dissolved in a 0.1 M ammonium oxalate solution at a concentration of 1~2 mg./ml. Portions of 20~50 λ were pipetted and placed at a zero-line on electrophoresis paper (Toyo Roshi No. 50). Potentials of the order of 400~600 V. were applied, the useful length of the strips being about 30 cm. The strips were cooled during electrophoresis by immersion in monochlorobenzene. After one to two hours, the voltage was interrupted, the paper dried and cut transversely in 1 cm. strips. These were scintillation-counted in a standard way. It has been known that cis species move faster than trans species toward the cathode[10]. The preliminary tests showed that cobalt(II) species moved toward the anode.

Determination of Cobalt.—Each fraction obtained in the ion exchange separation was dried on a steam bath. After concentrated sulfuric acid and concentrated nitric acid were added, the solution was evaporated almost to dryness. This procedure was repeated until the complexes or malonates were completely decomposed. Then, the amount of cobalt in each fraction was determined spectrophotometrically, using the nitroso-R salt method[11].

Results

It was found that the ion exchange separation using ammonium malonate as an eluting agent was most suitable for our purpose, because those cationic species adsorbed on the resin were eluted chromatographically and, therefore, the precise distribution pattern of ^{60}Co could be obtained. The elution curve of ^{60}Co activity from the cation exchange column is shown in Figs. 1 and 2. Paper electrophoresis was not very effective in the separation of the irradiated cis salts, because the peaks of the trans salt were not sufficiently well-resolved to permit determination.

The percentage distributions of the ^{60}Co activity are summarized in Tables I and II. The most significant result is that there is a considerable amount of ^{60}Co which appears in

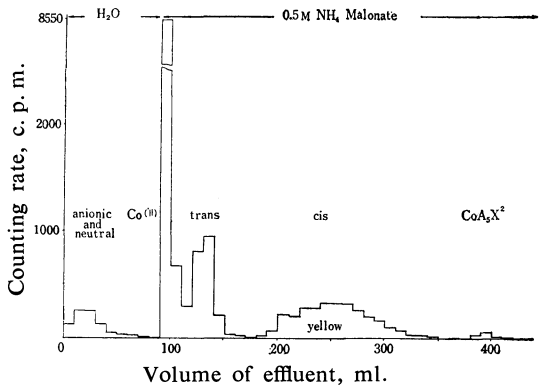

Fig. 1. Elution of ^{60}Co in the 1 hr.-irradiated cis salt.

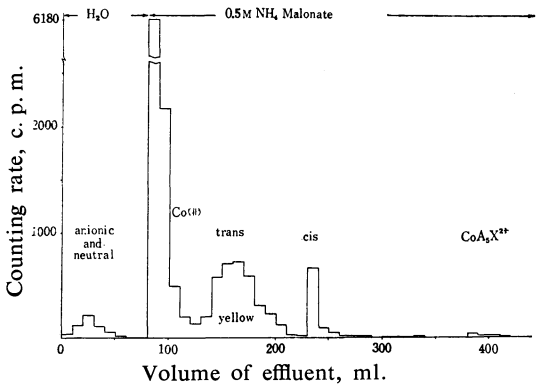

Fig. 2. Elution of ^{60}Co in the 1 hr.-irradiated trans salt.

9) E. L. King and R. R. Walters, ibid., **74**, 1674 (1952).

* From the experiments employing the technique of paper electrophoresis it was found that the species had no charge.

the other isomeric form for either cis or trans targets. Cis isomer was found with an enrichment factor of 23 in the irradiated trans salt, while trans isomer with an enrichment factor of 80 was found in the irradiated cis salt. These results are also shown in Tables I and II.

Discussion

The distribution of ^{60}Co in *cis*-$[Co(NH_3)_4(NO_2)_2]NO_3$ irradiated for one hour is 20.5 per cent in the cis form and 11.9 per cent in the trans form. On storage at room temperature (15~25°C), the retention in the cis form reaches a value of 29.1 per cent, while the distribution of ^{60}Co in the trans form decreases to 4.5 per cent. The distribution of ^{60}Co in *trans*-$[Co(NH_3)_4(NO_2)_2]NO_3 \cdot H_2O$ irradiated for one hour is 23.3 per cent in the trans form and 6.7 per cent in the cis form. On storage at room temperature, the retention in the trans form increases to 43.2 per cent, while the distribution of activity in the cis form decreases to 1.4 per cent. The ratio of isomer formation to retention as parent species is 1/2 to 1/3 in terms of the radioactivity without storage, whereas the ratio decreases to 1/7 to 1/30 after two months storage. It seems important to determine the ratio of isomer formation to retention in a condition where the irradiation is conducted for an extremely short time at solid carbon dioxide temperature, because one-hour irradiation at reactor temperature, as conducted in our experiment, would produce additional annealing, both thermal and radiation.

These facts may indicate that one should prefer a model such as the hot-zone mode[14] to a billiard-ball mode[15], to account for the mechanism of the recoil processes.

It is also worth mentioning that geometric isomerization during recoil processes occurs

more remarkably in cis salts than in trans salts. Although it is too difficult for us at the present stage to give a clear explanation of this, it may be supposed that the cis species yielded in the irradiated trans salts are not so stable to additional annealing processes as the trans species yielded in the irradiated cis salts*.

Summary

The Szilard-Chalmers reaction of cobalt in *cis*- and *trans*-dinitrotetrammine cobalt(III) nitrate have been investigated. After a given isomer was irradiated, ^{60}Co was found in an appreciable amount in the other isomeric form. The distribution of ^{60}Co in *cis*-$[Co(NH_3)_4 \cdot (NO_2)_2]NO_3$ irradiated for one hour is 20.5 per cent in the cis form and 11.9 per cent in the trans form. The distribution in *trans*-$[Co(NH_3)_4(NO_2)_2]NO_3 \cdot H_2O$ is 23.3 per cent in the trans form and 6.7 per cent in the cis form. This observation is consistent with a hot-zone model, where one would except that the original configuration would not be essentially preserved.

* It has been well-known that radiolysis occurs more easily in cis-isomers than in trans-isomers. For example, Dimotakis and Maddock have reported that *trans*-$[Co(en)_2 \cdot Cl_2]NO_3$ and *trans*-$[Co(en)_2Br_2]NO_3$ show a greater stability to radiolysis than do the corresponding cis salts. (International Symposium on Chemical Effects of Nuclear Transformation, Prague, 1960. CENT/18).

Etude sur le Révélateur Photographique 1-Phényl-3-pyrazolidone. I. Titrage Argentopotentiométrique et Observation à l'Aide de l'Absorption Infrarouge

Par Shinichi KIKUCHI et Hiromi YOSHIDA

(Reçu le 11 Septembre 1961)

Le révélateur, 1-phényl-3-pyrazolidone, qui fut introduit en Angleterre[1] sous le nom commercial de "Phénidone" en 1951 est maintenant un produit populaire et se synthétise même au Japon. Il y a déjà beaucoup de rapports sur les recherches théoriques et les applications de ce produit. Les présents auteurs ont fait un premier rapport concernant l'étude potentiométrique de ce produit en 1957[2] et ont continué leurs recherches pour en éclaircir le mécanisme du développement photographique. Ils ont trouvé que le titrage argentopotentiométrique de la solution aqueuse de la 1-phényl-3-pyrazolidone entre les pH 5 et 11 présente des caractères communs avec le résultat du développement essayé dans ces intervalle de pH[3]. Dans ce présent travail, ils ont voulu savoir quelle était la structure de la forme oxydée par l'ion argent au cours du titrage et extraire la partie organique des produits titrés à chaque pH, pour l'essai au spectre infrarouge. Dans la suite des expériences, la 1-phényl-3-pyrazolidone est oxydée dans diverses conditions et à chaque pH, les produits obtenus dans les phases solide et liquide sont soumis à l'essai des spectres d'absorption infrarouge, visible et ultraviolet.

Expérimental et Résultats

Echantillons. — Comme échantillons, 4 marques commerciales de 1-phényl-3-pyrazolidone (notées dans ce rapport comme 1P, 2P, 3P et 4P) ont été employées. Ils ont été desséchés pendant 2 heures à 100°C et soumis aux mesures suivantes :

1. Absorption infrarouge.
2. Analyse élémentaire.
3. Diffraction aux rayons X.
4. Essai de développement photographique.

Analyses Élémentaires.—Les analyses élémentaires de 4 échantillons sont données dans les tableaux I et II.

D'après les analyses élémentaires, 2P est considéré comme le meilleur.

TABLEAU I. POURCENTAGES DE CARBONE ET D'HYDROGÈNE DES 4 MARQUES

	C calculé %	C observé %	H calculé %	H observé %
1P	66.67	66.87	6.17	6.25
2P	66.67	66.62	6.17	6.14
3P	66.67	66.82	6.17	6.24
4P	66.67	66.74	6.17	6.14

TABLEAU II. POURCENTAGES D'AZOTE ET POINTS DE FUSION

	N calculé %	N observé %	Point de fusion °C
1P	17.28	17.33	119.5
2P	17.28	17.27	120.5
3P	17.28	17.34	117~118
4P	17.28	17.36	119

Absorption Infrarouge[4].—Les 4 marques ont été examinées par analyse infrarouge an moyen du Nujol. Il n'y a pas de grandes différences entre elles, mais en les examinant en détail, il y a tout de même quelques petites différences. 3P possède à 1565 cm^{-1} une absorption qui semble montrer la présence d'impuretés. Comme le produit a une structure en -CH-CH-, l'absorption est compliquée à cause de cette structure du côté des petits nombres d'onde. La vibration d'allongement et de contraction de la liaison C=O s'est fortement déplacée (1690 cm^{-1}) du côté des petits nombres d'onde à cause d'une combinaison d'hydrogène. En jugeant l'ensemble de l'absorption infrarouge,

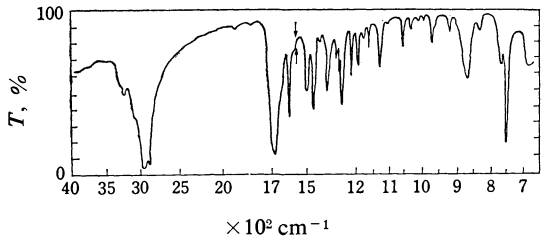

Fig. 1. Spectre d'absorption infrarouge de 1-phényl-3-pyrazolidone (Nujol).

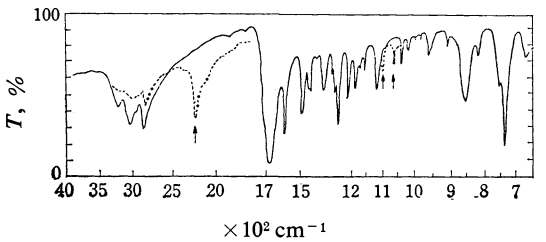

Fig. 2. Spectre d'absorption infrarouge de 1-phényl-3-pyrazolidone (tablette de KBr). Trait interrompu, celle deuterisée.

4) S. Kikuchi et H. Yoshida, Conférence de la Soc. Phot. Sci. Japon, 1959.

la 1-phényl-3-pyrazolidone a une structure de dimère comme la pyridone.

Dans le cas de 2P, les résultats obtenus au moyen du Nujol et au moyen du KBr ne présentent presque pas de différence. La Fig. 1 montre l'absorption de la 1-phényl-3-pyrazolidone obtenue au moyen du Nujol. 3P possède une absorption caractéristique à 1565 cm^{-1}, à l'endroit marqué par la flèche. La Fig. 2 montre celle au moyen du KBr. Dans la même figure la partie de la ligne pointillée montre la différence due à la deutérisation.

Diffraction aux Rayons X.—Les couleurs des cristaux des 4 marques sont: 1P blanc, 2P parfaitement blanc, 3P blanc légèrement rougeâtre, 4P blanc avec un peu de jaune brun clair.

L'ordre de grandeur des grains qui a été observé par diffraction des rayons X (Photo I) est la suivant: 4P < 2P < 1P < 3P

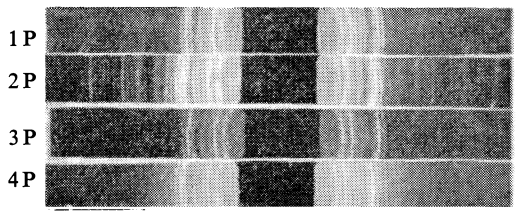

Photo 1. Diffraction aux rayons X des échantillons.

Essai au Développement Photographique.—Le développement du film positif a été fait à 20±0.5°C, soit tout de suite après la préparation, soit 3 jours après la préparation avec le révélateur suivant:

1-Phényl-3-pyrazolide	0.25 g.
Na_2SO_3	25 g.
Hydroquinone	2.5 g.
Na_2CO_3	10 g.
KBr	1 g.
q. s. p. f.	1000 ml.

Les solutions de 1-phényl-3-pyrazolidone et de KBr sont préparées séparément et s'ajoutent au moment de la préparation du révélateur. Les pH des révélateurs préparés avec 4 marques sont mesurés comme l'indique le tableau III dans les 2 cas mentionnés ci-dessus.

Les voiles et les densités maximum des films dans ces conditions de développement sont présentés dans le tableau IV et les courbes

TABLEAU III. pH DES RÉVÉLATEURS

Espèces d'échantillons	1P	2P	3P	4P
Tout de suite après la préparation	10.39	10.39	10.27	10.20
3 Jours après la préparation	10.15	10.20	10.15	10.05

TABLEAU IV. RÉSULTATS DU DÉVELOPPEMENT AVEC LES 4 MARQUES DE PHÉNIDONE

Espèces d'échantillons		Tout de suite après la préparation				3 Jours après la préparation		
		Sans KBr		Avec KBr		Avec KBr		
		5′	12′	5′	12′	5′	10′	15′
Voile	1P	0.09	0.11	0.06	0.10	0.04	0.04	0.04
	2P	0.16	0.29	0.04	0.12	0.04	0.04	0.04
	3P	0.09	0.34	0.08	0.10	0.06	0.04	0.06
	4P	0.08	0.28	0.02	0.10	0.06	0.05	0.08
Densité max.	1P	3.50	3.60	3.36	3.65	3.35	3.45	3.50
	2P	3.35	3.60	3.40	3.60	3.36	3.50	3.54
	3P	3.52	3.70	3.27	3.60	3.25	3.34	3.52
	4P	3.41	3.70	3.35	3.50	3.20	3.40	3.65

caractéristiques du développement avec les 4 marques sont données dans la Fig 3. Même avec le révélateur sans KBr, 1P ne donne pas le voile très fort. Dans ces expériences, on voit que la marque 2P donne le meilleur résultat, et elle est désormais employée pour les expériences principales.

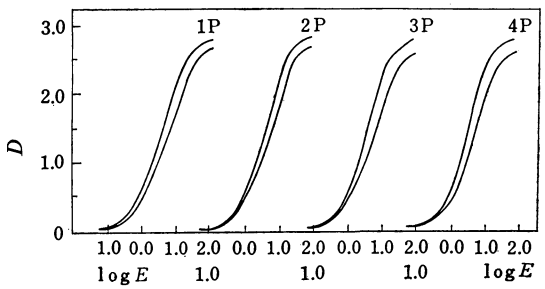

Fig. 3. Essai de développement effectué trois jours après la préparation de solution, 20±0.5°C.
Traits supérieurs, 15 min.
Traits inférieurs, 5 min.

Titrage Argentopotentiométrique.—Au moyen du titrage argentopotentiométrique[5] qui a été souvent utilisé dans le laboratoire des auteurs, une variation de potentiel est automatiquement enregistrée quand l'ion argent est ajouté à la solution de 1-phényl-3-pyrazolidone aux divers pH (Figs. 4 et 5). La vitesse de titrage a été réglée de telle sorte que le temps de versement de l'ion argent correspondant à une mole est de 5 min. A partir du pH 8, la première partie de la courbe de titrage prend un potentiel négatif, de même que le développement donne une grande densité. Le précipité qui se forme dans le mélange de 1-phényl-3-pyrazolidone et d'ion argent, dans le rapport d'un à trois, est filtré; puis le précipité et le filtrat sont extraits du solvant, en éliminant l'argent, et soumis à l'analyse infrarouge. Avec

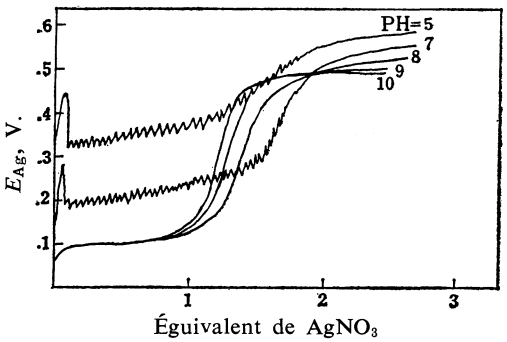

Fig. 4. Courbes de titrage potentiométrique de 1-phényl-3-pyrazolidone pour la solution de $AgNO_3$-potentiels d'électrode d'argent se réfèrent à une électrode normale d'hydrogène.

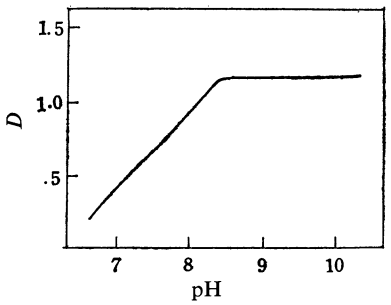

Fig. 5. Densité maximum en fonction du pH de la solution de révélateur.

les courbes de titrage on peut supposer que les produits qui se trouvent dans le mélange de 1-phényl-3-pyrazolidone et d'ion argent, dans le rapport de un à trois, sont exclusivement du type oxydé. (On verra plus tard que celui-ci est la forme oxydée de 1-phényl-3-pyrazolidone.) Quant au mélange de 1-phényl-3-pyrazolidone et d'ion argent dans le rapport 1:1, le précipité et le produit surnageant dans le liquide consistent en oxyde, et l'extrait du filtrat est un mélange de la forme oxydée et du produit original. Ce dernier est la même

5) S. Kikuchi et H. Sakaguchi, *J. Soc. Phot. Sci., Japon*, 12, No 4, 3 (1950).

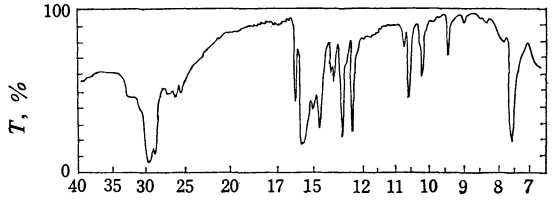

Fig. 6. Spectre d'absorption infrarouge d'un type oxydé de 1-phényl-3-pyrazolidone.

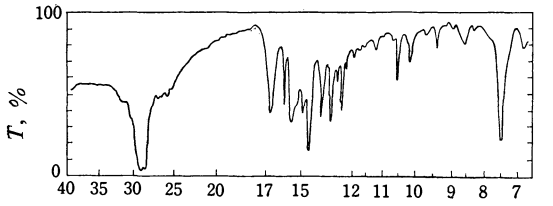

Fig. 7. Spectre d'absorption infrarouge d'un type mélangé.

substance que la 1-phényl-3-pyrazolidone faiblement oxydée par du nitrite de soude. Les produits du mélange dans le rapport 1 : 2 sont aussi examinés en fonction du pH. A partir du pH 7, le mélange est exclusivement la forme oxydée et aux pH 8 et 10, il est identique au produit extrait du filtrat du mélange dans le rapport 1 : 1, c'est-à-dire au mélange de la forme oxydée et du produit original. La Fig. 6 montre l'absorption infrarouge de l'échantillon dans le rapport 1 : 3, la Fig. 7, celle du mélange de l'échantillon avec la forme oxydée et la Fig. 1, celle du produit original.

Forme Oxydée de la 1-Phényl-3-pyrazolidone. —La 1-phényl-3-pyrazolidone et le produit fortement oxydé par l'oxyde de mercure sont soumis à l'analyse infrarouge avec KBr (Fig. 8). Le spectre infrarouge de la forme oxydée est de structure plus simple que celui de la 1-phényl-3-pyrazolidone. La disparition de la vibration de variation d'angle due à chaque CH_2 de structure $-CH_2-CH_2-$ (1230～1150 cm^{-1}), la disparition de la vibration d'allongement et de contraction de la liaison C–N à 1450 et 1365 cm^{-1}, celle de la vibration de variation d'angle de liaison N–H à 862 cm^{-1}, en sont les raisons. Dans la forme oxydée, on peut remarquer une absorption à 2850 cm^{-1} au lieu de 2970 cm^{-1} pour la 1-phényl-3-pyrazolidone et on peut penser que ce changement est dû à la transition de CH_2 de $-C-C-$ à CH de $-C=C-$. D'autre part, de nouvelles absorptions sont dues, vers 2750～2590 cm^{-1} à la vibration d'allongement et de contraction

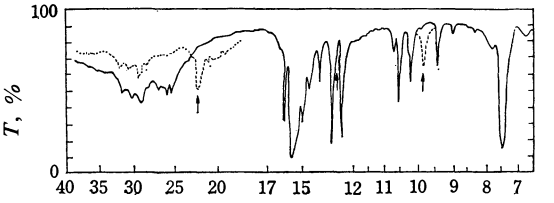

Fig. 8. Spectre d'absorption infrarouge de 1-phényl-3-hydroxypyrazole (tablette de KBr). Trait interrompu, celle deuterisée.

de OH avec forte combinaison d'hydrogène et vers 1570 cm^{-1}, à la vibration d'allongement et de contraction de C=N. La vibration d'allongement et de contraction de C–O à 1325 cm^{-1} et la vibration de variation d'angle à 1266 cm^{-1} apparaissent sensiblement. Les absorptions à 1064, 1025 et 950 cm^{-1} sont aussi les vibrations de variation d'angle qui se trouvent dans le plan ou hors du plan. On peut remarquer cependant que les absorptions à 1602, 1510, 1462 et 755 cm^{-1} dues au radical phényl se trouvent dans la 1-phényl-3-pyrazolidone et dans sa forme oxydée.

Par la suite, la 1-phényl-3-pyrazolidone et sa forme oxydée ont été deutérisées. La première a été obtenue par recristallisation avec la manière habituelle de deutériser. La forme oxydée, peu soluble dans l'eau lourde, ne peut être obtenue de la même façon. Elle a été maintenue dans un mélange de benzène et d'eau lourde à 100°C pendant une heure et desséchée sous vide pour obtenir la forme deutérisée. (L'eau lourde provenait de la Cie. Stuart Oxygen.) L'absorption infrarouge des deux formes deutérisées, a donné les résultats suivants : on a remarqué la vibration d'allongement et de contraction de liaison N–D à 2250 cm^{-1} les vibrations de variation d'angle de liaison N–D à 1137, 1073 cm^{-1} dans la 1-phényl-3-pyrazolidone tandis que dans la forme oxydée, les absorptions dues à la liaison N–D ne sont pas remarquées, mais les vibrations d'allongement et de variation d'angle

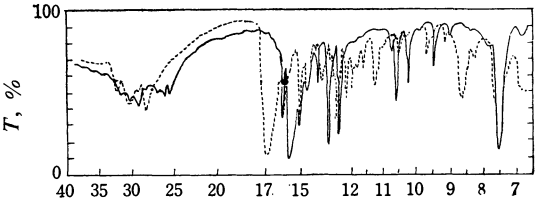

Fig. 9. Spectre d'absorption infrarouge des 1-phényl-3-hydroxypyrazols et 1-phényl-3-pyrazolidone (trait interrompu) (tablette de KBr).

OD[12] à 2260, 1290, 998 cm^{-1} sont observées. D'après les résultats ci-dessus la forme oxydée de la 1-phényl-3-pyrazolidone perd les liaisons C=O, CH_2, C–C, NH et acquiert à nouveau les liaisons C=N, C=C et OH (Fig. 9).

Ce produit oxydé a un point de fusion T_f= 154°C et une composition élémentaire de C= 62.27%, H=5.13%, N=17.14%, qui n'est pas très différente de celle de la 1-phényl-3-pyrazolidone. L'oxydation à l'air de la solution de 1-phényl-3-pyrazolidone au pH 9 et l'extraction par un solvant organique fournissent un produit qui donne la même absorption infrarouge. Le mélange obtenu par le titrage argentopotentiométrique est le simple mélange de 1-phényl-3-pyrazolidone et de sa forme oxydée et il donne la même absorption infrarouge que le produit extrait par le solvant organique de la solution de l'échantillon légèrement oxydé par du nitrite de soude.

Mesure par le Spectre Ultraviolet. — Les spectres ultraviolets de la 1-phényl-3-pyrazolidone et sa forme oxydée ont été mesurés aux pH 5, 7, 9 et 10.8. Les solutions de 1-phényl-3-pyrazolidone et des produits aux pH 5, 7 et 9 avaient un maximum d'absorption à 240 mμ. On a trouvé le point isosbestique aux pH 5~9, mais au pH 10.8, la forme de l'absorption est très différente (Fig. 10). On peut conclure que la forme oxydée a deux formes, une qui se trouve dans la solution aqueuse et à pH 5 a un maximum à 267 mμ et une autre qui se trouve dans la solution de pH supérieur à 7, a un maximum à 292 mμ (Fig. 11). Quand la solution de 1-phényl-3-pyrazolidone à pH 8 est oxydée lentement à l'air, l'absorption à 292 mμ n'aparait pas tout de suite, mais se déplace à 288 mμ. Si l'on ajoute à cette solution un excès d'eau oxygénée, une absorption apparait dès le commencement à 292 mμ (Fig. 12).

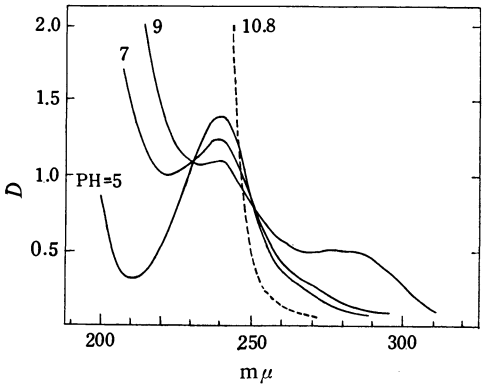

Fig. 10. Spectre d'absorption ultraviolette de 1-phényl-3-pyrazolidone en fonction de pH.

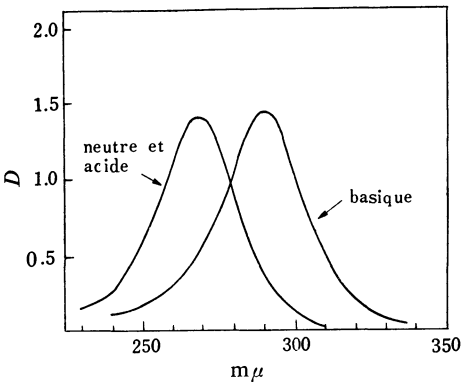

Fig. 11. Spectre d'absorption ultraviolette de 1-phényl-3-hydroxypyrazole en fonction de pH.

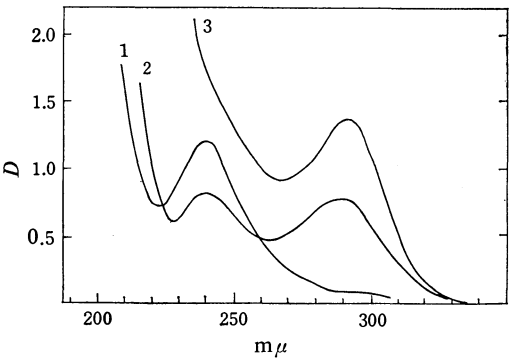

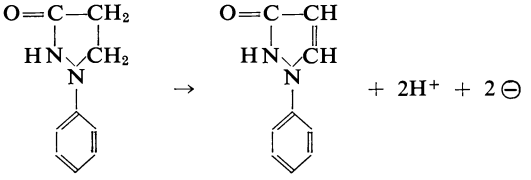

Fig. 12. Influence de l'oxydation à l'air de 1-phényl-3-pyrazolidone.

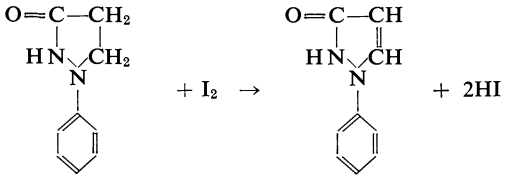
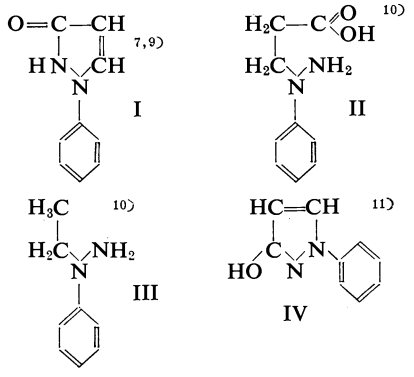


Conclusions

Le fait que γC=O de la 1-phényl-3-pyrazolidone se trouve du côté des nombres d'onde plus petits que le γC=D des substances ordinaires possédant la liaison C=O, fait supposer que ce produit forme une molécule d'association dimère[4]. Kurosaki[6] a montré par l'analyse infrarouge de la phase liquide en faisant varier la concentration et la température, que le produit était un dimère. Axford[7] et ses collaborateurs ont supposé que la forme oxydée de 1-phényl-3-pyrazolidone devait être la suivante :



D'autre part, Levenson[8] a dit, d'après l'analyse iodométrique du révélateur usé que la forme oxydée serait la suivante :

6) K. Kurosaki, *J. Chim. Soc. Japon, Pure Chem. Rec. (Nippon Kagaku Zassi)*, **79**, 1339 (1958).
7) A. J. Axford, J. D. Kendall, *J. Phot. Sci.*, **2**, 1 (1954).
8) G. I. T. Levenson, *J. Phot. Sci.*, **7**, 38 (1959).

L'un et l'autre cas supposent que deux électrons sortent de la 1-phényl-3-pyrazolidone. Les présents auteurs pensent, d'après les résultats argentopotentiometriques que cette réaction ne peut se faire qu'en milieu acide ou neutre, mais pas en milieu alcalin. Aux pH 9, 10 et 11, la solution du mélange 1 : 2 ayant le potentiel noble ne peut se développer même s'il reste de la 1-phényl-3-pyrazolidone. Cela montre que du côté alcalin la combinaison entre la 1-phényl-3-pyrazolidone et sa forme oxydée ou entre deux molécules de 1-phényl-3-pyrazolidone peut se former et que ce fait retarde le développement lui-même. Jusqu'ici 4 formes ont été proposées pour la structure de la forme oxydée de la 1-phényl-3-pyrazolidone.

D'parès nos expériences où l'onde d'allongement C=O dans le spectre infrarouge disparait et où les valeurs des pourcentages de C et H sont assez différentes de celles trouvées dans l'analyse élémentaire, on peut dire que les formes I, II et III sont peu probables. Donc la forme IV est la plus probable. L'absorption à 2250 cm^{-1} de la forme deutérisée de la 1-phényl-3-pyrazolidone et à 2260, 1980~2160 cm^{-1} du produit deutérisé de la forme oxydée de la 1-phényl-3-pyrazolidone sont voisines, mais le nombre et la forme des ondes du produit deutérisé de la forme oxydée ressemblent plus à l'onde OD des phénols. La forme deutérisée de la 1-phényl-3-pyrazolidone a des ondes 1137 cm^{-1} et 1073 cm^{-1} de ND, mais ces ondes n'existent pas dans la forme deutérisée de la forme oxydée.

Les auteurs veulent conclure que la forme oxydée de la 1-phényl-3-pyrazolidone est la 1-phényl-3-hydroxypyrazole qui est peu soluble dans l'eau. On peut supposer d'après les résultats de l'absorption infrarouge basée sur la combinason de OH que cette forme oxydée a une forte liaison hydrogène[13,14].

Les auteurs sont spécialement reconnaissants à Messieurs Suzuki de Konishiroku, Iijima de Kawaguchi Chemical Co., et Shindo de Sankyo Pharmaceutical Co., pour leur amabilité d'avoir donné les réactifs qui ont été utilisés dans cette étude.

Thermal Decomposition of Acetaldehyde in the Presence of Hydrogen Sulfide. I. Kinetics of the Reaction

By Naomi IMAI, Yasuo YOSHIDA and Osamu TOYAMA

(Received September 14, 1961)

Hydrogen sulfide was found by Fromherz[1] to exert a catalytic effect on the thermal decomposition of acetaldehyde. Roth and Rollefson[2] studied this catalyzed decomposition and presented an approximate rate equation, but the mechanism of the catalysis was left unexplained. Recently the present authors have investigated the hydrogen-atom abstraction reaction of hydrogen sulfide molecules with methyl radicals[3] and the photolysis of acetaldehyde in the presence of hydrogen sulfide[4].

These studies have clarified the nature of various elementary reactions taking place in the systems of acetaldehyde and hydrogen sulfide. In this work, we have therefore undertaken to reinvestigate the pyrolysis of acetaldehyde in the presence of hydrogen sulfide in order to elucidate the catalytic effect of the latter. This paper reports on the kinetics of the reaction, and the following paper, Part II, on the effects of various chain-inhibitors on the reaction.

Experimental

Materials.—Acetaldehyde was prepared by distillation of paraldehyde, containing a small quantity of sulfuric acid, and was purified by bulb-to-bulb distillation. Hydrogen sulfide was prepared by dropping water on aluminum sulfide in an evacuated vessel, dried by passing it through a trap at −78°C, and purified by bulb-to-bulb distillation.

Apparatus.—The apparatus used in the present work was similar to that described previously[5]. Three cylindrical vessels were used: A, a quartz vessel of 118 cc., with a ratio of its surface area to its volume of $S/V=1.05\,cm^{-1}$; B, a glass vessel of 137 cc., $S/V=1.20\,cm^{-1}$; C, a glass vessel of 127 cc. packed with glass tubes, $S/V=15.9\,cm^{-1}$.

Procedure.—Required quantities of reactant gases were mixed at room temperature for about 30 min. prior to pyrolysis. They were then introduced into the reaction vessel, which had already been brought to the experimental temperature. In most runs, the change in total pressure with time was followed on a manometer. The products of the decomposition in some runs were analyzed quantitatively in the same way as has been described previously[3]. A Hitachi RMC remodeled mass spectrometer was used to analyze the products in several runs.

Results and Discussion

It has been established by many workers that the products of the thermal decomposition of acetaldehyde are almost exclusively equal quantities of methane and carbon monoxide[6]. Roth and Rollefson[2], analyzing the reaction products in the decomposition of acetaldehyde with added hydrogen sulfide, found that the only appreciable products were about equal amounts of methane and carbon monoxide and that hydrogen sulfide remained unconsumed throughout the course of the reaction. Table I shows the results of the analysis of the reaction products obtained in the present study, together with the pressure changes observed.

Table I. Products of decomposition

a Obtained by mass spectrometric analysis.

5) N. Imai and O. Toyama, ibid., **33**, 1408 (1960).
6) C. N. Hinshelwood and W. K. Hutchson, *Proc. Roy. Soc.*, **A111**, 380 (1926); C. J. M. Fletcher and C. N. Hinshelwood, ibid., **A141**, 41 (1933); C. A. Winkler and C. N. Hinshelwood, ibid., **A149**, 355 (1935); R. V. Seddon and M. W. Travers, ibid:, **A156**, 234 (1936); E. Leifer and H. C. Urey, *J. Am. Chem. Soc.*, **64**, 994 (1942); Ref. 5.

It is seen that the total pressure increase is equal to the pressure of the methane formed as well as to that of carbon monoxide; this is in agreement with the analytical results obtained above by Roth and Rollefson. Mass spectrometric analysis has shown that hydrogen and ethane are also formed in the decomposition, but their amounts are too small to disturb the above relation significantly. These facts indicate that the total pressure increase corresponds to the decrease in acetaldehyde pressure due to decomposition. Accordingly, the initial rate of decomposition is obtained from the initial slope of a total pressure-time curve.

It is generally agreed that the main features of the thermal decomposition of acetaldehyde can be explained by the following mechanism[7]:

$$CH_3CHO = CH_3 + CHO \quad (1)$$

$$CHO = CO + H \quad (2)$$

$$H + CH_3CHO = H_2 + CH_3CO \quad (3)$$

$$CH_3CO = CH_3 + CO \quad (4)$$

$$CH_3 + CH_3CHO = CH_4 + CH_3CO \quad (5)$$

$$CH_3 + CH_3 = C_2H_6 \quad (6)$$

The steady state equations derived from this scheme yield the rate equation

$$-\mathrm{d}[CH_3CHO]/\mathrm{d}t = k_1^{1/2}k_5k_6^{-1/2}[CH_3CHO]^{3/2} \quad (I)$$

420	0.030
440	0.067
460	0.18

which is in general agreement with experimental results obtained by various workers. Also in this work, the rate of decomposition was found to be proportional to the 3/2 power of the pressure of acetaldehyde, as is seen in Fig. 1. From the slope of the straight line in the figure, the value of $k_1^{1/2}k_5k_6^{-1/2}$ at each temperature was obtained and listed in Table II.

In the presence of hydrogen sulfide, it was found that the rate of decomposition increases linearly with the pressure of hydrogen sulfide, as is seen in Fig. 2. Although the intercepts of the straight lines on the ordinate are located very close to the point of origin, they are in agreement with the corresponding values in Fig. 1, indicating the great catalytic effect of

hydrogen sulfide. Several series of runs, where the pressure of acetaldehyde was varied while the pressure of hydrogen sulfide was kept constant, are shown in Fig. 3. As shown below, the results represented by Figs. 2 and 3 conform to the rate equation[8]

$$-\mathrm{d}[CH_3CHO]/\mathrm{d}t = k_0[CH_3CHO]^{3/2} + k[H_2S][CH_3CHO] + k'[H_2S][CH_3CHO]^{1/2} \quad (II)$$

The first term on the right-hand side of the equation, representing the non-catalyzed decomposition, is in most cases much smaller than the other terms and may be neglected. Thus, the rate may be written as

$$-\mathrm{d}[CH_3CHO]/\mathrm{d}t = k[H_2S][CH_3CHO] + k'[H_2S][CH_3CHO]^{1/2} \quad (III)$$

Dividing both sides of Eq. III by $[CH_3CHO]^{1/2}$,

$$(-\mathrm{d}[CH_3CHO]/\mathrm{d}t)/[CH_3CHO]^{1/2} = k[H_2S][CH_3CHO]^{1/2} + k'[H_2S] \quad (IV)$$

Figure 4 shows that Eq. IV and, accordingly, Eq. III fit the results given in Fig. 3. The slope and intercept of the straight line in the figure give the constants k and k'.

In Table III are listed the values of the constants thus determined by various series of experiments in this work. It is seen that the fluctuation in these values is fairly large, apart from the effect of the reaction vessel. The values of the constants were found to be approximately reproducible when the measurements were carried out successively with the same samples of the gases and with the same vessel, whereas a worse reproducibility was obtained with different samples of the gases even in the same vessel. The results obtained by Roth and Rollefson show an even greater fluctuation in the rate. Presumably, minute quantities of an impurity yet unidentified caused these phenomena[9]. The effect of various reaction vessels, with different ratios of surface area to volume is not clearly seen in Table III,

8) Roth and Rollefson proposed the following rate equation
$$-\mathrm{d}[CH_3CHO]/\mathrm{d}t = k_a[H_2S][CH_3CHO] + k_b[H_2S][CH_3CHO]/(1+k_c[CH_3CHO])$$
Their experimental data, however, show too great a fluctuation to justify the rate equation.

9) According to Morris[10], the use of hydroquinone for the purification of acetaldehyde reduces the rate of decomposition of the latter. In this work, however, hydroquinone was not used.

being masked by the fluctuation mentioned above. The effect is, however, not greater than the fluctuation, indicating that the reaction is essentially homogeneous, as has been described by Roth and Rollefson.

In Table III are included the values of the constant k' determined in a somewhat different way: when the pressure of hydrogen sulfide is low, the first term of Eq. III may be negligibly small compared to the second, so that

$$(-d[CH_3CHO]/dt)^2/[H_2S]^2 = k'^2[CH_3CHO] \quad (V)$$

Figure 5 shows that Eq. V is applicable to the results of experiments with a low pressure of hydrogen sulfide. As seen in Table III, the values of the constant k' obtained from the slope of the straight line in Fig. 5[11] are in general agreement with those obtained by the use of Eq. IV.

11) In these experiments the rate of decomposition was obtained from an analysis of the products, carbon monoxide and methane, since the pressure could not be followed accurately on a mercury manometer.

As described in Part II, the addition of a sufficient quantity of propylene or isobutylene, both of which are known as chain-inhibitors, completely eliminates the second term of Eq. III, leaving the first term unaffected. This indicates that the decomposition represented by the second term of Eq. III involves a radical-chain mechanism, while the first term probably represents a molecular decomposition catalyzed by hydrogen sulfide.

The radical-chain decomposition represented by the second term of Eq. III is explained on the basis of the previously studied photolysis of acetaldehyde in the presence of hydrogen sulfide[4]. The kinetics of the photolysis showed that, in the presence of not too much hydrogen sulfide, the decomposition takes place through a chain mechanism which involves, in addition to reactions 1—6, the following reactions[12]:

$$CH_3 + H_2S = CH_4 + HS \quad (7)$$

$$HS + CH_3CHO = H_2S + CH_3CO \quad (8)$$

The reaction sequence 1—8, when applied to the thermal decomposition in the presence of hydrogen sulfide, leads to the rate equation

$$(-d[CH_3CHO]/dt)_{chain} = k_1^{1/2}k_5k_6^{-1/2}[CH_3CHO]^{3/2} + k_1^{1/2}k_7k_6^{-1/2}[H_2S][CH_3CHO]^{1/2} \quad (VI)$$

The first term of the right-hand side of the equation corresponds to the first term of Eq. II, which was neglected in Eq. III, and the second term of Eq. VI explains the second term of Eq. III. It follows, therefore, that

$$k' = k_1^{1/2}k_7k_6^{-1/2}$$

The Arrhenius plots of $k_1^{1/2}k_5k_6^{-1/2}$ and $k_1^{1/2}k_7k_6^{-1/2}$ obtained from the results given in Tables II and III are shown in Fig. 6. These yield

$$k_1^{1/2}k_5k_6^{-1/2} = 10^{12.1\pm0.2}\exp(-43300\pm1100/RT) \ mol^{-1/2}\,ml^{1/2}\,sec^{-1} \quad (VII)$$

$$k_1^{1/2}k_7k_6^{-1/2} = 10^{12.8\pm0.2}\exp(-41100\pm1200/RT) \ mol^{-1/2}\,ml^{1/2}\,sec^{-1} \quad (VIII)$$

If E_1(the activation energy of reaction 1) $=75.0$[13], $E_5=6.8$[14] and $E_6=0$ kcal. mol^{-1}, $E_{VII} = 1/2(E_1-E_6)+E_5 = 44.3$ kcal. mol^{-1}. The value of E_{VII} compares satisfactorily with the 43.3 kcal. mol^{-1} found above. Similarly, when E_7 is taken as 2.6 kcal. mol^{-1} [15], $E_{VIII} = 1/2(E_1 - E_6) + E_7 = 40.1$ kcal. mol^{-1}, which is again in agreement with the above experimental value of 41.1 kcal. mol^{-1}.

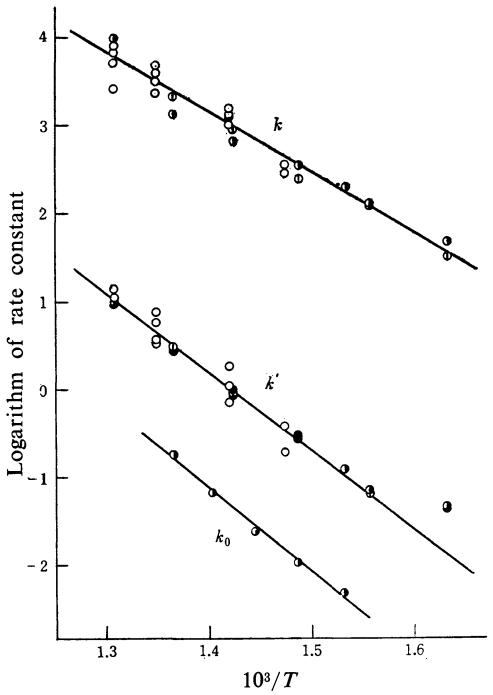

Fig. 6. Arrhenius plots of k_0, k' and k.
○ Vessel A; ◑ Vessel B; ⓘ Vessel C;
● Obtained from Fig. 5.

As has already been described, small quantities of hydrogen and ethane are found among the products of decomposition. Their formation in early stages of the decomposition may be explained by reactions 3 and 6. Their small quantities indicate that the chain length is fairly large.

As has also already been described, the first term of Eq. III probably represents the rate of homogeneous molecular decomposition catalyzed by hydrogen sulfide. Stoichiometrically, the reaction is written as

$$CH_3CHO + H_2S = CH_4 + CO + H_2S \quad (9)$$

since the products obtained in the decomposition are almost exclusively equal amounts of methane and carbon monoxide. The Arrhenius plot of constant k, given in Fig. 6, yields

$$k = 10^{12.7\pm1.0}\exp(-31400\pm3100/RT) \quad (IX)$$

Although this appears to be a reasonable expression for a simple bimolecular process in the gas phase, a detailed mechanism for the catalysis cannot be determined at present from the kinetics alone. It has been known that

12) In the photolysis, the primary step is $CH_3CHO + h\nu = CH_3 + CHO$

the decomposition of acetaldehyde to methane and carbon monoxide is catalyzed by hydrogen chloride and hydrogen bromide in the gas phase[16]. The mechanism of the decomposition is, however, not yet clear in these cases. Recently, Stimson et al.[17] have shown that the hydrogen halides-catalyzed decomposition of alcohols into water and olefins in the gas phase is largely homogeneous and molecular in character in the temperature range 300 to 500°C. Although they present various possible mechanisms for the catalysis, no definite conclusion has yet been obtained. Information from other sources seems necessary to elucidate the mechanism of these reactions.

Summary

The hydrogen sulfide-catalyzed thermal decomposition of acetaldehyde has been investigated over the temperature range 340 to 494°C. The initial rates of decomposition approximately fit the rate equation

$$-\mathrm{d}[CH_3CHO]/\mathrm{d}t = k[H_2S][CH_3CHO] + k'[H_2S][CH_3CHO]^{1/2}$$

where

$$k = 10^{12.7\pm1.0}\exp(-31400\pm3100/RT) \quad \mathrm{mol^{-1}\,ml.\,sec^{-1}}$$

and

$$k' = 10^{12.8\pm0.27}\exp(-41100\pm1200/RT) \quad \mathrm{mol^{-1/2}\,ml^{1/2}\,sec^{-1}}$$

A comparison of the above results with those of the decomposition inhibited by propylene and isobutylene, which will be reported on in the following paper, suggests that the first term of the rate equation probably represents a molecular decomposition catalyzed by hydrogen sulfide, while the second represents a radical-chain decomposition. Combining the chain mechanism generally accepted for the pyrolysis of acetaldehyde alone with the reactions $CH_3+H_2S=CH_4+HS$ and $HS+CH_3CHO=H_2S+CH_3CO$, both of which have been shown to be important in the photolysis of acetaldehyde with added hydrogen sulfide, a rate equation is derived by which the second term of the experimental rate equation and the temperature depedennce of its rate constant k' can be explained.

Thermal Decomposition of Acetaldehyde in the Presence of Hydrogen Sulfide. II. Effects of Chain-inhibitors

By Naomi IMAI, Yasuo YOSHIDA and Osamu TOYAMA

(Received September 14, 1961)

In the foregoing paper[1], the present authors reported on the kinetics of the thermal decomposition of acetaldehyde in the presence of hydrogen sulfide and suggested that a part of the reaction involves a radical-chain mechanism, while the remaining part is probably molecular in character. Such an interpretation is based upon experiments in which the effects of various chain-inhibitors on the rate of decomposition were investigated. This paper reports on the results of these experiments. Propylene, isobutylene and nitric oxide were used as inhibitors.

Experimental

The preparation and purification of acetaldehyde and hydrogen sulfide were described in the foregoing paper[1]. Propylene was prepared by dehydration of isopropyl alcohol by pyrophosphoric acid supported on granular pumice at 250°C. Isobutylene was prepared from *tert*-butyl alcohol by a similar method. Nitric oxide was produced by the reaction of a concentrated sodium nitrite solution with a hydrochloric acid solution of ferrous chloride, decarbonated by a potassium hydroxide solution and dried by concentrated sulfuric acid and phosphorus

1) N. Imai, Y. Yoshida and O. Toyama, This Bulletin, 35, 752 (1962).

pentoxide. All of these gases were prepared in evacuated vessels and were purified by repeated bulb-to-bulb distillations. The apparatus and procedure were the same as those described in the foregoing paper[1].

Results and Discussion

As has been described in the foregoing paper, when acetaldehyde is decomposed thermally in the presence of hydrogen sulfide, the amount of acetaldehyde consumed is directly indicated by the increase in the total pressure. According to Smith and Hinshelwood[2], the pressure of acetaldehyde thermally decomposed in the presence of propylene also corresponds to the total pressure increase. It was confirmed in this work that such a correspondence between the amount of acetaldehyde decomposed and the total pressure change is retained even in the presence of both hydrogen sulfide and an inhibitor. Accordingly, the rate of decomposition was mostly calculated from the increase in the total pressure, as was the case in the absence of inhibitors.

Figure 1 shows the dependence of the rate of decomposition on the pressure of inhibitors, propylene and isobutylene, at constant pressures of acetaldehyde and hydrogen sulfide. It is seen that the rate decreases with the increasing pressure of the inhibitor until it attains a constant value, and that the rate of the fully inhibited reaction is almost the same for both inhibitors under otherwise constant conditions. Figure 1 shows, moreover, that the rate of fully inhibited reaction may be represented as

$$-\mathrm{d}[CH_3CHO]/\mathrm{d}t = k_1[H_2S][CH_3CHO] \quad (I)$$

since the rate is proportional to the pressure of both hydrogen sulfide and acetaldehyde. Further evidence for Eq. I is given by Figs. 2 and 3, in which the rates of decomposition fully inhibited by propylene and by isobutylene are plotted.

It has been shown in the previous paper[1] that the rate of decomposition of acetaldehyde in the presence of hydrogen sulfide, but in the absence of any inhibitor, can be approximately represented by

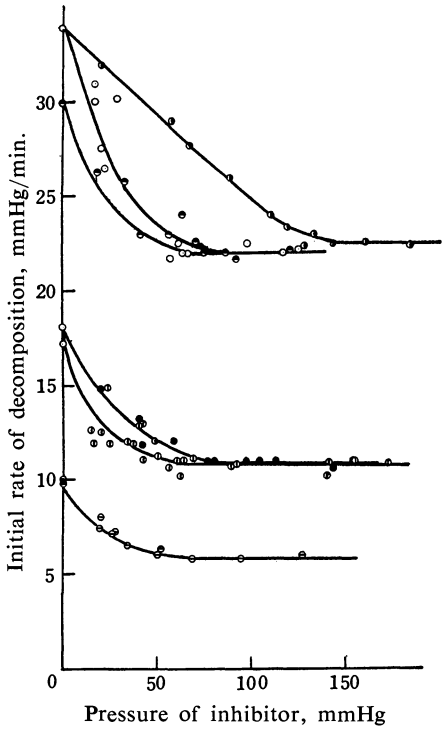

Fig. 1. Inhibition of acetaldehyde decomposition in the presence of hydrogen sulfide by propylene and isobutylene at 469°C.

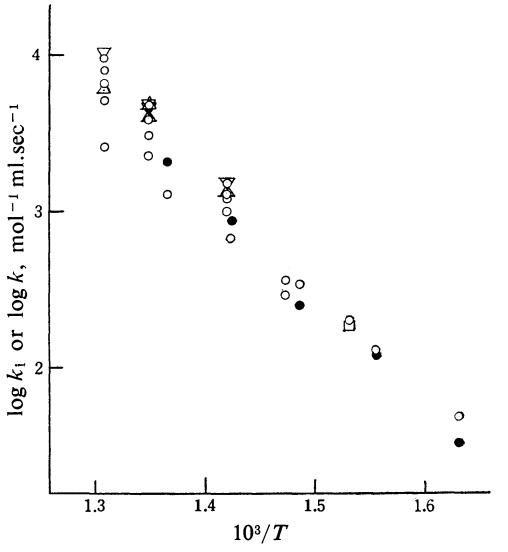

Fig. 4. Arrhenius plot of k_1 and k.
▽ Propylene; △ Isobutylene; □ Nitric oxide; ○ k for the unpacked vessel; ● k for the packed vessel.

$$-d[CH_3CHO]/dt = k[H_2S][CH_3CHO] + k'[H_2S][CH_3CHO]^{1/2} \quad (II)$$

A comparison between Eqs. I and II shows that the former equation is of the same form as the first term of the latter. It is revealed on further examination that they are in fact identical. In Table I are listed the values of constant k_1 in Eq. I obtained from the results given in Figs. 1—3; as seen in Fig. 4, these values are in agreement, within the limit of fluctuation, with those for k given in the preceding paper[1]. It may therefore be concluded that the addition of propylene or of isobutylene, in a sufficient quantity to bring about the maximum inhibition, eliminates the second term of Eq. II, leaving the first unaltered. Although there is much controversy[3] concerning the interpretation that the residual rate of pyrolysis of paraffins maximally inhibited by an inhibitor such as nitric oxide or propylene represents that of a non-chain, molecular decomposition, the results here obtained suggest that the second term of Eq. II represents a radical-chain decomposition, whereas the first term probably represents a hydrogen sulfide-catalyzed molecular decomposition which is not affected by chain-inhibitors.

TABLE I. VALUES OF k_1

Temp. °C	Inhibitor	Method	k_1 mol^{-1} ml.sec^{-1}
380	Nitric oxide	Fig. 5	186
431	Propylene	Fig. 3	1530
	Isobutylene	Fig. 2	1320
469	Propylene	Fig. 1	4760
	Isobutylene	Fig. 1	4800

	Isobutylene	Fig. 2	4010
494	Propylene	Fig. 3	10700
	Isobutylene	Fig. 2	6000

Additional support for such an interpretation is provided by Fig. 5. The thermal decomposition of dimethyl ether in the presence of hydrogen sulfide, as was found in its absence, is explained entirely by a radical-chain mechanism[4]. When inhibited by nitric oxide, the rate of decomposition falls off to an almost negligible value, as is seen in the figure. The situation with acetaldehyde, on the other hand, is quite different. Here the residual rate of decomposition maximally inhibited by nitric oxide is still about half as large as that when uninhibited, and it yields a value of constant

k_1 which is, again, in agreement with that of k as shown in Fig. 4[5].

As is seen in Fig. 5, the rate of decomposition of acetaldehyde as well as of dimethyl ether increases, after passing through a minimum, in proportion to the pressure of nitric oxide added. In view of the complete inhibition of the chain decomposition, as inferred above, these results suggest that nitric oxide catalyzes the molecular decomposition of these compounds[6]. For acetaldehyde in the absence of hydrogen sulfide, a similar behavior of nitric oxide has already been reported by Smith and Hinshelwood[2]. For paraffins, inhibitors such as propylene and isobutylene behave similarly[7]. In the latter case, however, there is serious doubt that the residual decomposition after being maximally inhibited is molecular in character[3].

Jack et al.[7] reported the relative efficiencies of propylene, isobutylene and nitric oxide as inhibitors to be 1 : 1.6 : 11 in the thermal decomposition of *n*-pentane at 560°C. Hinshelwood et al. have shown that nitric oxide is 5 to 100 times as effective as propylene for the inhibition of the decomposition of various organic compounds[2,8]. Figures 1 and 5 show that the results obtained in this work are similar. Rate constants are reported to be $10^{10.8}\exp(-7700/\boldsymbol{RT})$[9], $10^{10.9}\exp(-7300/\boldsymbol{RT})$[9] and $10^{11.1}\,\mathrm{mol}^{-1}\,\mathrm{ml.\,sec}^{-1}$[10] for the reactions between methyl radical and propylene, isobutylene and nitric oxide respectively. Other values of 6.4 and 4.1 kcal. mol^{-1} are reported for the activation energies of the former two reactions respectively[11]. These values are at least qualitatively in agreement with the efficiencies of the three inhibitors.

Summary

The effect of propylene, isobutylene and nitric oxide as inhibitors on the thermal decomposition of acetaldehyde in the presence of hydrogen sulfide has been investigated over the temperature range of 380 to 494°C. Of the three inhibitors, which are all effective in reducing the rate of decomposition, isobutylene is slightly more efficient than propylene, and nitric oxide is far more efficient than the other two. With propylene and isobutylene, the rate of decomposition is reduced with the increasing amount of the inhibitor until a constant rate is reached, while with nitric oxide the rate passes through a minimum value and then increases again in proportion to the pressure of the inhibitor. The residual rate of the maximally inhibited decomposition is almost the same for the three inhibitors and is represented by $-\mathrm{d}[CH_3CHO]/\mathrm{d}t = k_1[H_2S]\,[CH_3\cdot CHO]$. A comparison of the above results with those of the decomposition in the absence of an inhibitor suggests that the residual decomposition remaining after being fully inhibited is a molecular process catalyzed by hydrogen sulfide.

Oxidation of Ferrous Ions in Aqueous Solutions by Cobalt-60 Gamma Rays. III. The Effect of Cupric Ion in Air-free Acidic Solutions

By Hiroshi HOTTA, Shin-ichi OHNO and Nobutake SUZUKI

(Received September 15, 1961)

The effect of cupric ion on the radiolysis of an air-free ferrous acidic solution is usually assumed to be due to the reaction[1]

$$Cu^{2+} + H = Cu^{+} + H^{+} \qquad (10)$$

competing with the reaction

$$Fe^{2+} + H^{+} + H = Fe^{3+} + H_2 \qquad (3)$$

Therefore, the oxidized ferric ion is re-reduced by the reaction

$$Fe^{3+} + Cu^{+} = F^{2+} + Cu^{2+} \qquad (11)$$

On the other hand, it was established in Part II[2] that the reaction

$$Fe^{3+} + H = Fe^{2+} + H^{+} \qquad (4)$$

can not be ignored in some cases. The oxidation rate of the ferrous ion in a mixture of ferrous and ferric ions was evaluated by the equation

$$G(Fe^{III}) = 2G(H_2) + \frac{2G(H)}{1 + \dfrac{k_4(Fe^{III})}{k_3(Fe^{III})}} \qquad (iii)$$

where k is the rate constant of the respective reactions[2,3]. In the present paper, the contribution of reaction 10 in the ferrous-cupric system will be discussed for the analogous equation.

Experimental

Nitrogen-saturated ferrous ammonium sulfate solutions in sulfuric acid, containing some amounts of cupric sulfate, were irradiated by a 10 kc. cobalt-60 gamma ray source, and the amount of ferric ion was measured by optical density at 304 mμ by the usual methods, presented in Part II[2]. All the solutions for Figs. 1 and 3 contained 0.04 M ferrous salt in 0.8 N sulfuric acid. All the solutions for Fig. 4 contained 0.04 M ferrous salt in various concentrations of sulfuric acid. The concentration of cupric sulfate in all the solutions for Fig. 2 was as large as five times that of ferrous salt in 0.8 N sulfuric acid.

Results and Discussion

The Effect of the Cupric Concentration.— The $G(Fe^{III})$ of the 0.04 M ferrous ammonium

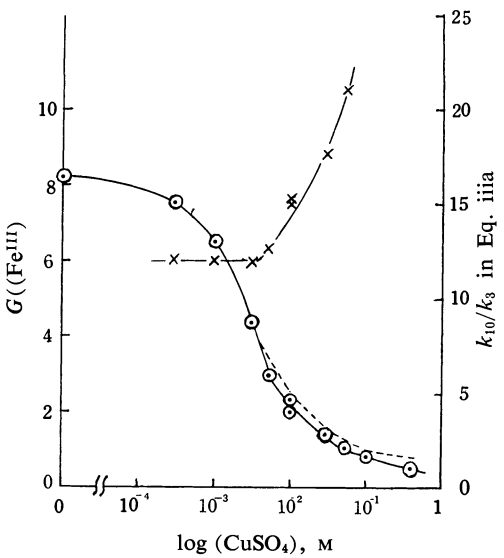

Fig. 1. Effect of cupric sulfate concentration on $G(Fe^{III})$ (⊙) and k_{10}/k_3 in Eq. iiia (×) in air-free 0.04 M ferrous ammonium sulfate solution of 0.8 N sulfuric acid.

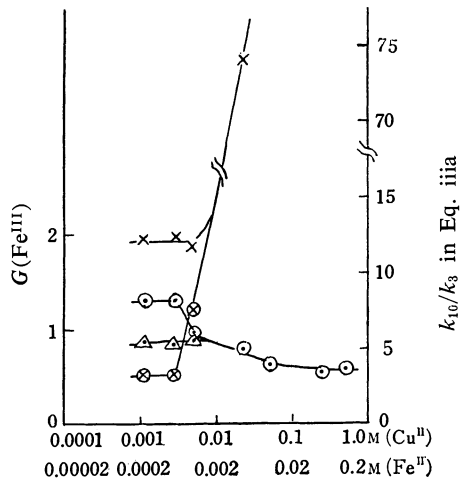

Fig. 2. Effect of concentration of ferrous and cupric sulfate ((Cu^{II})/(Fe^{II})=5) on $G(Fe^{III})$ at initial dose (⊙) and 2×10^5 r (△) and the corresponding k_{10}/k_3 in Eq. iiia (⊗) and (×) respectively, in air-free 0.8 N sulfuric acidic solutions.

1) E. J. Hart, *Radiation Research*, **2**, 33 (1955).
2) H. Hotta and S. Ohno, This Bulletin, **34**, 1640 (1961).
3) W. G. Rothschild and A. O. Allen, *Radiation Research*, **8**, 101 (1958).

sulfate solutions in 0.8 N sulfuric acid is shown by the circles in Fig. 1 as a function of the cupric concentration. Furthermore, in order to confirm the effect of the cupric concentration, the $G(Fe^{III})$ of the 0.8 N sulfuric acidic solutions, containing amounts of cupric sulfate as large as five times that of ferrous ammonium sulfate, was studied, as is shown in Fig. 2. Since the $G(Fe^{III})$ for the dilute solutions in this case decreased above 1×10^5 r, the values at the initial dose and 2×10^5 r were plotted as the circles and triangles respectively in Fig. 2.

When the effect of the cupric ions is assumed as has been mentioned in the introduction, the oxidation rate of the ferrous ions in a mixture of ferrous and cupric ions can be expressed by the equation

$$G(Fe^{III}) = 2G(H_2) + \frac{2G(H)}{1+\dfrac{k_{10}(Cu^{II})}{k_3(Fe^{II})}} \qquad \text{(iiia)}$$

which is like Eq. iii. Therefore, the apparent ratio of the reaction rates, k_{10}/k_3, can be estimated from the observed $G(Fe^{III})$ as is plotted as crosses in Figs. 1 and 2. These ratios increase sharply in the cupric solutions more concentrated than 0.004 M in Fig. 2 as well as in Fig. 1. If this ratio is consistently 12 over the whole range, the $G(Fe^{III})$ can be shown as the dotted line in Fig. 1. This fact shows that the apparent ratio of the reaction rates, k_{10}/k_3, is 12 in the present reaction scheme, and that some reactions must be considered in a concentrated cupric solution in addition to the above scheme. The smaller value of the ratio than 12, corresponding to the initial $G(Fe^{III})$ in Fig. 2, may be due to the effect of the slight residual oxygen.

The smallest $G(Fe^{III})$ for the present reaction scheme should be 0.78 from Eq. iiia. The smaller observed value than 0.78 can be interpreted at first glance by the so-called "track effect", that is, the reaction of the cupric ion with the hydrogen atom, which has the fate of combining with another hydrogen atom or a OH radical outside of the track. Although this may be partially correct in the very concentrated cupric solution, the above cupric concentration, 0.004 M, at which something begins to happen, is too dilute for such a track effect. This suggests that the capture reaction of the cupric ion with the thermerized electron,

$$Cu^{2+} + e = Cu^{+} \qquad (12)$$

must be considered, in addition to reaction 10, in the cupric solution more concentrated than 0.004 M.

All the solutions plotted in Fig. 1 gave the constant $G(Fe^{III})$ up to 1.2×10^6 r, but they were not always constant at higher doses as

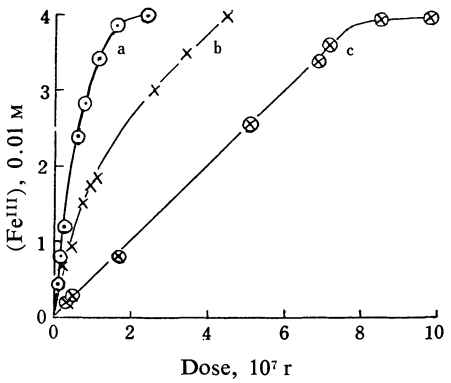

Fig. 3. Oxidation of ferrous ion in air-free 0.04M ferrous ammonium sulfate solutions of 0.8 N sulfuric acid containing a) 0.004 M (⊙), b) 0.04 M (×) and c) 0.4 M (⊗) cupric sulfate.

is shown in Fig. 3, in which the oxidation rate of ferrous ions in 0.04 M ferrous ammonium sulfate solutions of 0.8 N sulfuric acid containing a) 0.004 M, b) 0.04 M and c) 0.4 M cupric sulfate, is shown to be up to 10^8 r. The decrease of the $G(Fe^{III})$ at high doses is expected from Eq. iiia as a result of the decrease in the amount of ferrous ion. Furthermore, at high doses, the reaction between the ferric ions and the thermerized electrons like reaction 12, as has been pointed out by Dobson and Hughes[4], and the effect of the accumulated hydrogen molecules in the system may also be effective. The constancy of $G(Fe^{III})$ (=0.48) for solution c up to 7×10^7 r is due to the complete predominance of reactions 10 and 12 in the highly concentrated cupric solution.

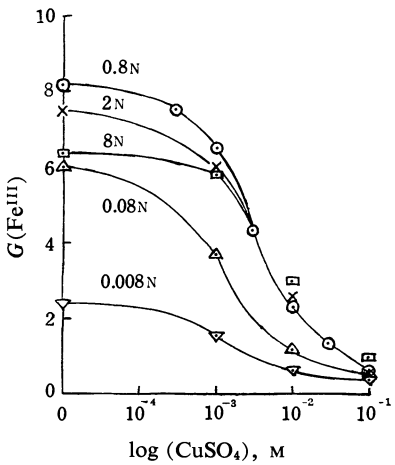

Fig. 4. Effect of concentration of cupric sulfate on $G(Fe^{III})$ for air-free 0.04 M ferrous ammonium sulfate solutions in 0.008 N (▽), 0.08 N (△), 0.8 N (⊙), 2 N (×) and 8 N (⊡) sulfuric acid, respectively.

The Effect of the Sulfuric Acid Concentration. —The $G(Fe^{III})$ of the 0.04 M ferrous ammonium sulfate solutions in 0.008, 0.08, 0.8, 2 and 8 N sulfuric acid respectively is shown in Fig. 4 as a function of the cupric sulfate concentration.

When the $G(H)$ and $G(H_2)$ for various sulfuric acidic solutions are assumed as listed in Table I[3,5], the apparent ratios of reaction rates, k_{10}/k_3, for these solutions containing 0.001 M cupric sulfate as evaluated from Eq. iiia depend on the concentrations of sulfuric acid as listed in the same table. On the other hand, the apparent ratio of reaction rates, k_4/k_3, for the 0.001 M ferrous sulfate solution in 0.01 and 0.8 N sulfuric acid (containing no cupric ion), observed by Rothschild and Allen[3], has the same tendency as the present ratio, k_{10}/k_3, and apparently is somewhat at variance with our previous value[2], as listed in Table II. A detailed discussion of these problems will appear in the next section.

In Fig. 4, the $G(Fe^{III})$ in 2 and 8 N sulfuric acid is also smaller for no and 0.001 M cupric solutions than for those of 0.8 N. However, when it is assumed that energy absorbed by sulfuric acid is dissipated without chemical change, the $G(Fe^{III})$ for energy absorbed only by water in 2 N sulfuric acid is quite equal to that in 0.8 N acid, and the same $G(Fe^{III})$ in 8 N acid is larger than in 0.8 N acid, as is shown in Table III. This indicates that the present assumption is not correct in 8 N sulfuric acid. In fact, there was some smell in the irradiated solution in 8 N sulfuric acid.

The Intrinsic Ratio of the Reaction Rates for k_4/k_3 and k_{10}/k_3. — As was mentioned in Part II[2], ions are not always free, but also form many complexes with solutes and solvents in a solution, and the reactivity with hydrogen atom depends on their state. Therefore, in Part II, as a result of the estimation of the concentration for the ith ferric complex, c_i, the relative reduction rate of the respective species by hydrogen atom, k_4^i, to that of reaction 3 was evaluated by the equations

$$\frac{k_4(Fe^{III})}{k_3(Fe^{II})} = \frac{1}{k_3(Fe^{2+})}\sum(c_i)k_4^i \qquad \text{(iv)}$$

and

$$(Fe^{III}) = \sum(c_i) \qquad \text{(vi)}$$

where (Fe^{II}) and (Fe^{III}) represent the total concentration of ferrous and ferric species, and (Fe^{2+}) and (Fe^{3+}), the concentration of their respective free ions, in the present paper. In Eq. iv, the ratio of reaction rates for the respective complexes, k_4^i/k_3, is now defined as the intrinsic ratio.

When the concentration of respective ferric complexes in a solution is estimated on the same assumption as in Part II[2], the intrinsic ratio of the reduction rate of free ferric ion,

5) D. M. Donald and N. Miller, *Radiation Research*, **9**, 487 (1958).

namely, precisely reaction 4 to the oxidation rate of ferrous ion, is evaluated as in Table II for various solutions. In the present evaluation, the perfect dissociation, that is, $(Fe^{II}) = (Fe^{2+})$, is assumed for the ferrous ion. This assumption was not very significant in Part II, for the relative value was discussed in relation to results in solutions containing almost equal amounts of solute (almost the same ionic strength). In the present cases, the dissociation degree of ferrous sulfate should be somewhat different. When the true concentration of the free ferrous ions is put in Eq. iv[6] on the assumption that the undissociated molecules are not reactive with hydrogen atoms, the intrinsic ratio of the reduction rate of the free ferric ions to the oxidation rate of the free ferrous ions by the hydrogen atoms is reduced to 7 from the values in Table II for all the present cases. Therefore, it is concluded that the correction factor for the free ferrous ions in Eq. iv is one-third for the result for the 0.04 ferrous ammonium sulfate solution of 0.8 N sulfuric acid; that is, all the intrinsic ratios for the reduction rates of ferric complexes, as listed in Table IV in Part II[2], should be corrected as in Table IV.

Table IV. Relative rate constants for R+H at room temperature

R	Relative rate constant
Fe^{2+}	1*
Fe^{3+}	7
$(FeCl)^{2+}$	1100
$(FeBr)^{2+}$	1000
$(FeSO_4)^{+}$	<1
$(FeF)^{2+}$	≈ 0
Cu^{2+}	270

* For $Fe^{2+} + H + H^{+} = Fe^{3+} + H_2$

Since the dissociation constant of cupric sulfate is 0.0045 M[7] and the dissociation degree of 0.04 M ferrous sulfate is one-third, as deduced above, the intrinsic ratio of the reduction rate of the free cupric ions to the oxidation rate of the free ferrous ions by the hydrogen atom, k_{10}^{1}/k_3, is evaluated as in Table I, as for ferric ion, from the equation

$$\frac{k_{10}(Cu^{II})}{k_3(Fe^{II})} = \frac{k_{10}^{1}(Cu^{2+})}{k_3(Fe^{2+})} + \frac{k_{10}^{2}(CuSO_4)}{k_3(Fe^{2+})} \qquad \text{(vii)}$$

For the evaluation, k_{10}^{2}/k_3 is almost zero; this means that the undissociated cupric sulfate molecules are not reduced by the hydrogen atoms. The first value in Table I (270) is the most reliable. Therefore, the ratio of the reduction rates of the free cupric ion to the free ferric ion is about 40. The same ratio is obtained as 22 by other investigators[8,9].

As shown in Tables I and II, the apparent ratio can be consolidated by the intrinsic ratio defined by Eqs. iv and vii.

Another possibility for the dependence of the apparent ratio, k_{10}/k_3, on the concentration of cupric sulfate as shown in Figs. 1 and 2 is that it is due to the dependence of its dissociation degree. However, it is easily seen that its dissociation degree is not so sensitive in 0.8 N sulfuric acid.

Although the contribution of reaction 4 in the ferrous-cupric system is ignored in the above discussion, it could be expressed as

$$G(Fe^{III}) = 2G(H_2) + \frac{2G(H)}{1 + \dfrac{k_4(Fe^{III})}{k_3(Fe^{II})} + \dfrac{k_{10}(Cu^{II})}{k_3(Fe^{II})}} \qquad \text{(viii)}$$

However, when the apparent value for k_4/k_3 and k_{10}/k_3 in Tables I and II and the concentration of ferric ions at the initial stage are inserted into this equation, such a disregard is permissible.

Summary

The yield of ferric ions in the air-free ferrous acidic solutions by cobalt-60 gamma rays is reduced in the presence of cupric ion due to their reduction by the hydrogen atoms. The decrement depends on the composition of the solutions. That is, the apparent ratio of this reduction rate to the oxidation rate of the ferrous ions, estimated directly from the observed ferric yield by Eq. iiia increases with the decrease in acidity. On the other hand, the similar ratio for the reduction rate of ferric ions apparently varies according to the composition of the solutions. However, when these apparent ratios are analyzed by a fine composition of the solutions or reduced to the reaction rate for the fine species in solutions, the intrinsic ratios of the reduction rate of the free ferric and cupric ions to the oxidation rate of the free ferrous ions, by the hydrogen atoms, are 7 and 270 respectively and are independent of the composition of the solutions. On the other hand, the direct capture reaction of the cupric ions with the thermerized electrons is effective, in addition to the above reduction reaction with the hydrogen atoms, in the cupric solutions more concentrated than 0.004 M.

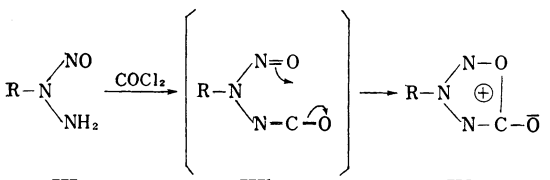
Studies of Meso-ionic Compounds. XV[1]. *The Preparation of ψ-3, 5-Dihydro-3-methyl-5-keto-1-oxa-2, 3, 4-triazole*

By Mutsuko HASHIMOTO* and Masaki OHTA

(Received September 22, 1961)

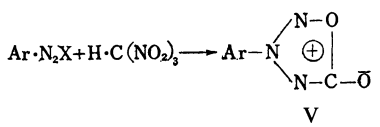


In a previous paper[2], we reported that ψ-oxadiazole (II) was prepared by the action of acyl chloride upon *N*-substituted N-benzoylhydrazine (Ia). The formation of the ψ-oxadiazole ring presumably involves the bond formation between two unsaturated groups of

Ia Ib II

Fig. 1

the intermediate acyl isocyanate (Ib). Thus, it could be expected that replacement of the acyl group of I with a nitroso group gives a new type of meso-ionic compound (IV) having an iso-electronic structure with II.

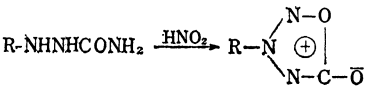


IIIa IIIb IV

R=CH_3

Fig. 2

In the present paper, we report the preparation of compound IV by the action of carbonyl chloride upon *N*-nitroso-*N*-methylhydrazine (IIIa), which is readily accessible.



On the other hand, a few analogues of

V

Fig. 3

compound IV have already been obtained by routes different from that described above; Ponzio[3] prepared 3-aryl derivatives (V) by treating nitroform with diazonium salts, and recently Boyer and Canter[4] reported that 1-(2-methylcyclohexyl)- or 1-menthyl-semicarbazides and nitrous acid give the corresponding 3-alkyl derivatives (VI). The latter reaction

VI

R=2-Methylcyclohexyl, menthyl

Fig. 4

apparently proceeds through the intermediate nitroso isocyanate (IIIb; R=2-methylcyclohexyl or menthyl), and therefore the formation mechanisms of IV and VI are perhaps essentially the same.

In the present experiment, *N*-nitroso-*N*-methylhydrazine (IIIa) was subjected to the action of carbonyl chloride in chloroform in the presence of potassium carbonate to give colorless needles, m. p. 11°C, giving a negative test with the Liebermann nitroso reaction. The product can be distilled at 101~101.5°C (3 mmHg) and is unreactive towards hot absolute ethanol, as has been reported by Ponzio and Boyer and Canter. Elemental analysis indicated the product to be the expected meso-ionic compound, ψ-3,5-dihydro-3-methyl-5-keto-1-oxa-2,3,4-triazole** (IV), whose structure was also supported by the infrared spectrum described below. The disappearance of the N-H stretching bands at 3315 and 3220 cm^{-1} observed for the precursor (IIIa) and the lack of a characteristic band for isocyanate in the infrared spectrum of ψ-oxatriazole IV suggest the formation of the meso-ionic ring. The strong absorption band at 1780 cm^{-1} in the spectrum of IV is indicative of the carbonyl group and

is in close agreement with Boyer and Canter's observation (1790 cm^{-1})[4] and the carbonyl band of ψ-oxadiazole II (1755 cm^{-1})[2] having an iso-electronic structure with IV.

Experimental

***N*-Nitroso-*N*-methylhydrazine (IIIa).**—The compound was prepared by Thiele's method[5].

ψ-3, 5-Dihydro-3-methyl-5-keto-1-oxa-2, 3, 4-triazole (IV).—To a solution of IIIa (2 g.) in chloroform (200 ml.) was added finely powdered, anhydrous potassium carbonate (20 g.), and then a violent stream of carbonyl chloride was vigorously stirred in at $-7\sim-8$°C for 10 min. After the mixture had been kept standing at room temperature for 2 days, the precipitates were filtered off, the filtrate was concentrated and the residue was rectified to give 1.8 g. of IV, b. p. 104~106°C/4 mmHg. Redistillation of IV yielded a fraction boiling at 101~101.5°C/3 mmHg, m. p. 11°C, in the form of colorless needles, giving a negative test with the Liebermann nitroso reaction.

Found: C, 24.00; H, 3.00; N, 40.01. Calcd. for $C_2H_3O_2N_4$: C, 23.77; H, 2.99; N, 41.58%.

A solution of IV in absolute ethanol was refluxed for 3 hr. and evaporated under reduced pressure to give colorless needles, m. p. 11°C, giving a negative test with the Liebermann nitroso reaction.

We are indebted to Dr. Asaji Kondo for his microanalyses and to Dr. Tadashi Sato for his infrared spectroscopic work.

*Reaction of Ferrocene with Acyl Chloride**

By Noboru SUGIYAMA, Hideo SUZUKI, Yoshiaki SHIOURA and Tsutomu TEITEI

(Received September 15, 1961)

The Friedel-Crafts acylation of ferrocene with acetyl chloride was first reported by Woodward and his collaborators[1]. Subsequently the acylation of ferrocene has been reported on by many others. We should like to report briefly on the reactions of ferrocene with succinyl chloride and phenacetyl chloride.

Succinyl chloride is capable of Friedel-Crafts reaction with one or two molecules of aromatic hydrocarbon to give β-aroylpropionic acid or α,β-diaroylethane. The chloride can also react with aromatic hydrocarbons to form γ,γ-diarylbutyrolactone[2]. We found that the chloride reacts with ferrocene to yield β-ferrocenoylpropionic acid (I), γ,γ-diferrocenylbutyrolactone (II) and 1, 2-diferrocenoylethane (III).

$FcCOCH_2CH_2COOH$ (I)

$(Fc)_2CCH_2CH_2$ (II)

$FcCOCH_2CH_2COFc \rightarrow FcCHCH_2CH_2CHFc$ (III) (IV)

IV $\rightarrow$ H_2C——CH_2 / Fc—CH HC—Fc / O (V)

I $\rightarrow$ Fc—$CHCH_2CH_2$ / O——CO (VI)

$FcCOCH_2C_6H_5$ (VII) $FcCHCH_2C_6H_5$ (VIII) $FcCH{=}CHC_6H_5$ (IX)

Fc = Ferrocenyl ; FcCO = Ferrocenoyl**

Diketone III was reduced with lithium aluminum hydride to yield 1, 4-dihydroxy-1, 4-diferrocenylbutane (IV). IV easily gave 2, 5-diferrocenyltetrahydrofuran (V) with acid catalysts. β-Ferrocenoylpropionic acid (I) was readily lactonized by reduction with sodium borohydride in an ethanol solution, giving γ-ferrocenylbutyrolactone (VI). Similarly, phenylacetyl chloride reacts with ferrocene to give benzyl ferrocenyl ketone (VII) in a good yield. VII was reduced with lithium aluminum hydride to yield 1-ferrocenyl-2-phenylethanol (VIII) quantitatively. By treating VIII with

** According to Chemical Abstracts' Nomenclature.

phosphorus pentachloride, 1-ferrocenyl-2-phenylethylene (IX) was obtained instead of the corresponding chloride.

The infrared spectra of II and VI exhibit strong absorption bands at 1770 and 1780 cm^{-1} (KBr) due to a γ-lactone group, and III and VII, at 1660 and 1665 cm^{-1} (KBr) due to a carbonyl conjugated with a ferrocene nucleus. These bands in III and VII are absent from IV and VIII, and new bands at 3400 and 3480 cm^{-1} (chloroform) due to a hydroxyl group appear in IV and VIII respectively. V shows no bands in the region for either hydroxyl or carbonyl. IX shows bands at 1640 and 960 cm^{-1} (KBr) due to a trans-disubstituted ethylene group (-CH=CH-). All these compounds have absorption bands at 1000 and 1110 cm^{-1} [3].

The visible spectra of II, IV, V, VI and VIII show absorption maxima similar to that of ferrocene itself at 445 (141), 443 (205), 443 (192), 442 (66.7) and 440 mμ (ε 104), and, on the other hand, the conjugate-expanded III and VII have absorption maxima at 458 (958) and at 462 mμ (ε 421) respectively in 95% ethanol which maxima correspond to that of acetylferrocene[4]. Strangely, IX showed also an absorption maximum at 460 mμ (ε 1000) in 95% ethanol.

Experimental

Reaction of Ferrocene with Succinyl Chloride.—To a vigorously stirred solution of ferrocene (10.0 g., 0.054 mol.) and aluminum chloride (7.2 g., 0.054 mol.) in methylene chloride (100 ml.) was slowly added a solution of succinyl chloride (4.2 g., 0.027 mol.) in the same solvent (50 ml.) under an atmosphere of nitrogen. After refluxing for 2 hr., the reaction mixture was cooled and poured onto crushed ice and water (100 ml.). On removal of the aqueous layer, the methylene chloride solution was separated into a neutral and an acidic fraction by extraction with 10% sodium carbonate (100 ml.). The acid fraction, on neutralization with 6 N hydrochloric acid, gave β-ferrocenoylpropionic acid (I, 1.0 g.) in leaflets, m. p. 164~166°C (lit.[5] 166.5~167.5°C). After removal of the solvent, the neutral fraction was dissolved in benzene, chromatographed on alumina and eluted as follows: (1) benzene (first portion) gave unchanged ferrocene (3.3 g.), and (2) benzene (second portion) gave γ-lactone (II) in the form of light orange needles, m. p. 165~165.5°C (from ethyl acetate).

Found: C, 63.47; H, 4.87; Fe, 23.60, 23.86. Calcd. for $C_{24}H_{22}O_2Fe_2$: C, 63.44; H, 4.85; Fe, 24.60%.

(3) Ethyl acetate gave 1,2-diferrocenoylethane (III, 2.1 g.) in the form of orange needles, m. p. 185~186°C (from ethyl acetate).

Found: C, 63.34; H, 4.86. Calcd. for $C_{24}H_{22}O_2Fe_2$: C, 63.44; H, 4.85%.

The oxime of III, prepared with hydroxylamine hydrochloride and sodium acetate in methanol (2 hr. refluxing), m. p. 165~166°C (decomp.) crystallized as needles (from methanol).

Found: N, 5.39. Calcd. for $C_{24}H_{24}O_2N_2Fe_2$: N, 5.74%.

1,4-Dihydroxy-1,4-diferrocenylbutane (IV).—A solution of III (1.0 g.) in anhydrous tetrahydrofuran (50 ml.) was gradually added to a stirred slurry of lithium aluminum hydride (0.5 g.) in the same solvent (50 ml.). The mixture was stirred for 2 hr. at room temperature. The excess of the hydride was destroyed with ethyl acetate. The organic layer was washed with distilled water several times and dried over anhydrous sodium sulfate. After removal of the solvent, the solid was crystallized from ethanol, affording IV (0.9 g.) in the form of yellow needles (from ethanol), m. p. 134~135°C.

Found: C, 62.89; H, 5.93. Calcd. for $C_{24}H_{26}O_2Fe_2$: C, 62.88; H, 5.68%.

2,5-Diferrocenyltetrahydrofuran (V).—After reduction of III with lithium aluminum hydride as above, the tetrahydrofuran solution was shaken first with 10% sulfuric acid and then with water, and dried over anhydrous sodium sulfate. After removal of the solvent, the residue was dissolved in benzene and chromatographed on alumina, and 2,5-diferrocenyltetrahydrofuran (V) was crystallized quantitatively from ethanol, as yellow needles, m. p. 124.5~125°C. The same material was also prepared by refluxing IV in acetic anhydride for 1 hr.

Found: C, 65.23; H, 5.56. Calcd. for $C_{24}H_{24}OFe_2$: C, 65.45; H, 5.45%.

γ-Ferrocenylbutyrolactone (VI).—A solution of β-ferrocenoylpropionic acid (I, 1.0 g.) and sodium borohydride (0.3 g.) in ethanol (50 ml.) was refluxed for 2 hr. After removal of the solvent, the residue was treated with water (30 ml.), acidified with concentrated hydrochloric acid (5 ml.), and warmed for 1 hr. on a water bath. The resulting solid was extracted with ethyl acetate. The extract was crystallized from *n*-pentane to yield γ-ferrocenylbutyrolactone (VI, 0.7 g.) in the form of yellow needles, m. p. 130~131°C.

Found: C, 62.02; H, 5.08. Calcd. for $C_{14}H_{14}O_2Fe$: C, 62.24; H, 5.18%.

Benzyl Ferrocenyl Ketone (VII).—Phenacetyl chloride (8.3 g., 0.054 mol.) solution in methylene chloride (50 ml.) was added during 1 hr. to a stirred solution of ferrocene (10.0 g., 0.054 mol.) and aluminum chloride (7.2 g., 0.054 mol.) in methylene chloride (150 ml.) under an atmosphere of nitrogen. After refluxing for 5 hr., the reaction mixture was cooled and poured onto crushed ice and water (100 ml.). On removal of the aqueous layer, the methylene chloride solution was washed with 3 portions of water (50 ml.) and dried over anhydrous sodium sulfate. After removal of the solvent, the residue was dissolved in benzene and chromatographed on alumina. Elution with benzene and ethyl acetate gave material which crystallized from *n*-hexane. Benzyl ferrocenyl ketone (VII, 12.0 g., 73%) separated as orange-red needles, m. p. 128~129°C.

The Tubular Structure of Collagen Fibril

By Masao HAISA

(Received September 12, 1961)

According to Arndt and Riley[1], X-ray powder patterns obtained from all sorts of proteins have two characteristic scattering maxima, the principal and the packing peaks. However, the patterns obtained from collagen have, in addition, another peculiar meridional peak which has the 2.86 Å spacing and which seems to be constant whatever the origin of the collagen fibrils. In this case, the equatorial packing peak varies its spacing from 11 to 17 Å with an increase in the water content of the material and it is accompanied with the gradual appearance of streaking[2]. Although it is generally agreed that the collagen molecule consists of a three-stranded helix, it is not always certain whether the fibril is made up of "Collagen II" or of the "Collagen I" proposed by Crick and Rich[3].

On the other hand, small-angle diffraction studies of dry collagen[4,5] have shown that the meridional spacing is about 640 Å and that the layer lines on the meridian exhibit fanning. It was postulated that a particular kind of disordering of the structure produced such a fanning effect. Tomlin and Ericson[6] have shown that the fanning is due to the regular shearing of the fibrils. On inspection of electron micrographs, Schmitt and Gross[7] have found that the axial repeat of 640 Å contains five primary staining levels.

Although it is now permissible to define collagen as any fibrous protein of the collagen group which gives the above features of X-ray wide-angle as well as small-angle patterns[8], there has yet been reached no general agreement about the interpretation of these patterns. An attempt is made in the present paper to elucidate the general features of the X-ray patterns of collagen-class proteins in terms of the helically grooved tubular structure. Some electron-microscopic findings are also given which support this structure.

Wide-angle X-Ray Diffraction

All experiments described in this paper were made on moist and dried fowl-neck tendon collagen, untreated or treated with formaldehyde or acetic acid. Figures 1 and 2 show the equatorial and meridional spectra respectively, obtained by means of a Geiger-counter X-ray diffractometer, "Geigerflex", using Cu radiation filtered by nickel. It will be seen that the meridional peaks are unaffected in either the intensity or the position of the maxima by treatment with formaldehyde or acetic acid, whereas the equatorial peaks are remarkably affected. It should be noted that the principal peak at 4.4Å spacing on the equator is stronger and broader than that at 4.0Å spacing on the meridian and that the water halo is remarkable for moist materials. The streak for moist collagen treated with formaldehyde or acetic acid is weaker than that for untreated collagen. On the assumption of the validity of von Laue's method[9], the linear dimension of the crystalline region along the fiber axis is estimated to be 76Å for the peak at $2\theta=31.3°$.

A closer examination of Figs. 1 and 2 would lead us to suppose that the tanning with formaldehyde provides interchain cross-linking and therefore prevents the intrusion of water molecules and that the swelling by means of acetic acid is caused by breaking the lateral aggregation of polypeptide chains.

Some Fourier Transforms Related to the Small-angle Pattern of Collagen Fibril

The Fourier transform of a uniform helix of infinite length, radius r and pitch P, takes the form

$$J_n(2\pi Rr)\exp[in(\Psi+\pi/2)] \qquad (1)$$

where r, φ and z are the cylindrical coordinates in real space, R, Ψ and Z, those in reciprocal space, and J_n denotes the nth order Bessel function.

In the case of a discontinuous helix with u units per t turns, the orders of the Bessel functions occurring in the lth layer line are given by those values of n satisfying the relation

$$l=tn+um \qquad (2)$$

where the m's are integers[10]. In a fiber diagram, only the cylindrically averaged intensity is relevant; hence, the cross-terms arising from (1) disappear upon this operation. With $t=1$ and $u=5$, for example, we have

$$\left.\begin{array}{lll} \text{when} & l=0,5,\ldots, & J_0^2+2J_5^2+2J_{10}^2+\ldots \\ \text{when} & l=1,4,\ldots, & J_1^2+J_4^2+J_6^2+J_9^2+\ldots \\ \text{when} & l=2,3,\ldots, & J_2^2+J_3^2+J_7^2+J_8^2+\ldots \end{array}\right\} \qquad (3)$$

The transform of a thin disc of radius a is given by[11]

$$\pi a^2\frac{2J_1(2\pi Ra)}{2\pi Ra} \qquad (4)$$

The Fourier transform of a helically grooved rod can be obtained by the convolution of those of disc and helix, and it is integrated by the separation of the coordinates. The integration along the fiber axis z is obtained by considering the disc of thickness fP spaced uniformly in a period of P, f thus being a fraction. This is given by, on the lth layer line,

$$2\pi f\frac{\sin lf\pi}{lf\pi} \qquad (5)$$

The transform of the central core of the rod takes the form 4. For the part of the residual helical ridge with an inner radius a and an outer one $a+b$, b thus being the depth of ridge, the integration with respect to r is given by the form:

$$\int_a^{a+b}J_n(2\pi Rr)r\mathrm{d}r \qquad (6)$$

This can be calculated by using the recurrence formula:

$$\int xJ_n(x)\mathrm{d}x=xJ_{n+1}(x)+n\int J_{n+1}(x)\mathrm{d}x$$

$$xJ_{n+1}(x)+xJ_{n-1}(x)=2nJ_n(x)$$

and the identity:

$$\int J_n(x)\mathrm{d}x=2\sum_{j=0}^{\infty}J_{n+2j+1}(x)$$

where x is the argument of the Bessel function. That is,

$$\int xJ_n(x)\mathrm{d}x=4(n+1)J_{n+2}(x)$$

$$-4\sum_{j=1}^{\infty}[2jJ_{n+4j}(x)-(n+2j+1)J_{n+4j+2}(x)] \qquad (7)$$

The first maxima of the integral 7 lies at (see Appendix)

$$x=n+2+0.81\times\sqrt[3]{n+2}$$

Small-angle X-Ray Diffraction

One of the most striking differences between the small-angle X-ray patterns of moist and dry collagens lies in the fanning effect of the layer lines. Two distinct types of reflection confirmed by the author are depicted schematically in Fig. 3. The first type, which appears

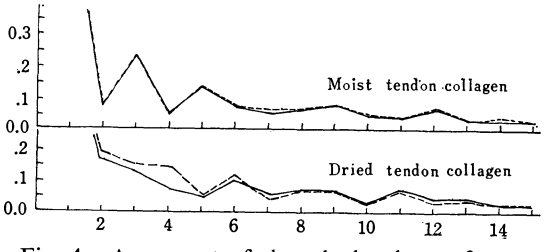

Fig. 4. Agreement of the calculated transform (broken line) and the square root of the observed intensity (full line) for moist and dried fowl-neck tendon collagens.

only on the meridian and is characteristic of moist materials, corresponds to a structure of smooth cylinder scatterers, while the second one, the fanning effect obtained from dry materials, might be attributed to a structure with a helical ridge. As may be readily seen from the theory developed in the foregoing section, the Fourier transform of the former is obtained by the product of (4) times (5). The alteration of intensity with the order of the layer lines may be expressed in excellent agreement with the observation by (5), in which $f=0.47$ (or 0.53) for moist collagen and $f=0.41$ (or 0.59) for dry collagen, as is shown in Fig. 4, (a) and (b) respectively. From a consideration of the transform 6, it is clear that the helical ridge structure is entirely adequate to account for the appearance of fanning and for the phenomenon of complex intensity distribution along the respective layer lines. The point of particular interest is that the intensity distribution of the layer lines is in accord with the transform 3, in which their first maxima occur at the arguments $x=0$, 1.8 and 3.4 respectively.

Electron Micrographs

The possibility of collagen fibrils being of a tubular[12] or a helical[13] structure has been suggested, but there is little conclusive evidence to support such structures. In the present investigation, collagen fibrils obtained from fowl-neck tendon were examined thoroughly. Specimens were picked up on an electron-microscopic grid without use of any supporting film and were shadowed with chromium. Typical electron-micrographs showing the membraneous structure of collagen fibril are reproduced in Figs. 5 to 8. They are cross-striated,

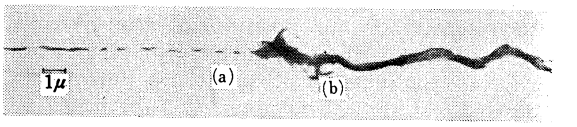

Fig. 5

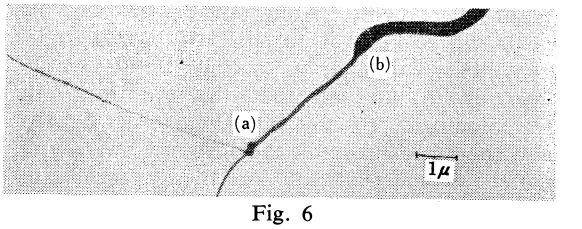

Fig. 6

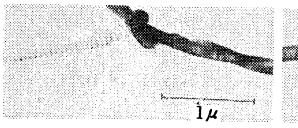

Fig. 6 (a)

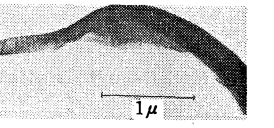

Fig. 6 (b)

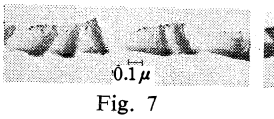

Fig. 7

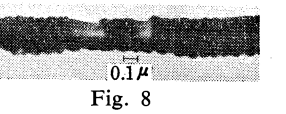

Fig. 8

the period of the striations being of the order of 650Å, i.e., typical of collagen. A feature of interest in relation to this structure is the frequent occurrence of a stepwise transition from an assembly of filaments to a single one. Figs. 5 and 6 show such a transition and higher magnifications of some parts of the specimens. Further evidence for this view is provided by their pronounced tendency to aggregate side to side, with a slight displacement relative to one another, as is shown in Figs. 7 and 8. On the basis of the morphological evidence presented above, the electron-microscopic structure of collagen fibril is considered to be a kind of tubular structure with a circular or flat and coiled cross section.

Structure of Collagen

In view of the experimental and theoretical results obtained above, it may be concluded that the collagen fibril consists of two phases alike in quantity, the crystalline phase characteristic of collagen-class and the amorphous phase, which has more hydration sites and, upon drying, loses water molecules to leave the helical groove. These considerations lead us to suppose that the collagen filament may be composed of coiled coils of a large number of polypeptide chains as follows:

$$([-P-P'-M-A-A'-]_4)_n$$

where P and P′ stand for the crystalline part and are rich in sequences of gly-pro-hypro, gly-pro-ala and other similar ones respectively. A and A′ form the amorphous part and are rich in sequences including gly and two other amino-acid residues. M is the transition part, about which the hydration sites are considered to be crowded. The striations are supposed to arise from the periodical occurrence of the P, P′, M, A and A′ parts, of which the distance between successive repeats causes the meridional identity period of 640Å. The fact that the tanning and the swelling do not alter the intrinsic spacing of the wide-angle reflections suggests that they occur outside the P and P′ parts.

Further evidence adduced to support this structure is as follows:

(a) The analytical data[14] provide some evidence that the sequence gly-pro-hypro may be of frequent occurrence in gelatin and collagen. According to Huggins[15], glutamic and aspartic acids can be in the form of condensed rings similar to the pyrrole ring; hence, they can take the place of pro or hypro in the P part. Thus, half of the total amino-acid residues in collagen can form a sequence of the gly-pro-hypro type.

(b) There are some evidence showing that, in collagen fibril, the amino-acid residues occur in groups. For example, Kuhn et al.[16] have stated from electron-microscopic studies that most of the basic residues are crowded in the α- and β-striations. Very likely they correspond to the A and A′ parts.

(c) The effective length of the side chain of pro and hypro is that of the pyrrole rings; hence, they can constitute the crystalline phase. On the other hand, the fully stretched side-chains of the basic residues are fairly long (ca. 8.8Å), whereas that of non-polar residues found in collagen is very short (ca. 3.4Å).

(d) The results obtained by Boedtker and Doty[17] and by Schmitt et al.[18] are in agreement with the view that the collagen molecule can be considered to have a length of the order of 2800Å.

(e) It is likely that the collagen filaments aggregate to each other by means of electrostatic forces, including hydrogen bonding, laterally. The lateral aggregation of the smooth cylinders having like diameters effects the streaking in the X-ray pattern as shown in Fig. 1. This view is supported by the findings that the crystal energy of the collagen fibrils does not always depend on the hydroxyproline content[19] and that the sorbed water is linked by hydrogen bonds to the CO group projecting outwards from and perpendicular to the fiber axis[20].

(f) A plaid pattern observed by Gross[21] perhaps results from a sheet with a helical structure.

Structure of Elastoidin

Elastoidin, a member of the collagen-class proteins obtained from shark fins, gives a small-angle diffraction pattern in which the expansion of the layer lines with an increase in l is outstandingly prevalent, whereas the central region fades out, as shown in Fig. 3(d). This fact may well be interpreted by assuming that a in transform 6 is very small compared with b. This supports the view that the collagen-class proteins have the tubular structure with a helical groove. It has been pointed out that the hydroxyproline content of elastoidin is but two-thirds that of collagen. The X-ray pattern from collagen has the packing peak, whereas elastoidin exhibits no additional bulbous terminal spot of the streak. This is in agreement with the view that elastoidin fibril is short of the regular lateral arrangement of chains because of a relative lack of the crystalline P and P′ parts and that it hence forms a deep groove on drying.

Summary

1. The X-ray scattering has been measured for moist and dry collagens of fowl-neck tendon, untreated or treated with formaldehyde

or acetic acid. Some modifications of the collagen fibril were also examined by electron microscope.

2. The wide-angle scattering data are compatible with a structure consisting of crystalline and amorphous parts. The intensity distribution of the small-angle diffraction is interpreted by a helical groove structure. The Fourier transform calculated for this model is shown.

3. The electron micrographs show that collagen fibril has a kind of tubular structure with a circular or flat and coiled cross section.

4. The data are discussed with respect to the assumption that collagen fibril is composed of a woven sheet of polypeptide chains in which the crystalline and amorphous parts occur alternatively.

5. A reasonable assignment of hydration to the helical groove is possible; this gives the fibril an approximately uniform electron density in the moist state.

The author wishes to express his appreciation to Dr. Isamu Nitta, Dr. Masao Kakudo and Dr. Sigeo Hasegawa for their encouragement and for the facilities of their laboratories during the work. The Rate of Formation of Cobalt Hydrocarbonyl under Various Conditions of Oxo Reaction

By Ryoji IWANAGA

(Received July 18, 1961)

It has been previously[1,2] reported that the rate of oxo reaction is inversely proportional to the partial pressure of carbon monoxide. In accordance with this kinetic requirement, several mechanisms have been proposed for this reaction which involve, as a rate-determining step, the displacement of a mole of carbon monoxide by the olefin from the dicobalt octacarbonyl[1,2] added as a catalyst, or from the cobalt hydrocarbonyl[3] presumed to be present in the system. Recently Kirch and Orchin[4] have proposed a mechanism for the

oxo reaction which involves the formation and subsequent decomposition of a complex formed from cobalt hydrocarbonyl-olefin-carbon monoxide as follows:

$$2HCo(CO)_4 + RCH{=}CH_2 + CO \rightarrow Complex \quad (1)$$

$$Complex \rightarrow Co_2(CO)_8 + RCH_2CH_2CHO \quad (2)$$

This scheme is based upon the fact that cobalt hydrocarbonyl in hexane reacts with olefin and carbon monoxide to give aldehyde and dicobalt octacarbonyl. They considered that such a complex was formed at the first and rate-determining stage.

We have previously[5] found that the equilibrium concentration of cobalt hydrocarbonyl converted from dicobalt octacarbonyl in benzene is proportional to the rate of the oxo reaction of cyclohexene[1] under various partial pressures of carbon monoxide and hydrogen. From this result it has been considered that the formation of cobalt hydrocarbonyl from dicobalt octacarbonyl may determine the rate of the oxo reaction. However, in order to study the kinetics and mechanism of the oxo reaction it was necessary to determine the rate of formation of cobalt hydrocarbonyl in the system in the course of the oxo reaction.

In the present paper, the rate of formation of cobalt hydrocarbonyl from dicobalt octacarbonyl under various partial pressures of carbon monoxide and hydrogen is presented. In addition, some experimental results concerning the content of cobalt hydrocarbonyl in the system during the oxo reaction of methylacrylate and cyclohexene are presented and discussed.

Experimental

Determination of the Initial Rate of Formation of Cobalt Hydrocarbonyl from Dicobalt Octacarbonyl under Various Partial Pressures of Carbon Monoxide and Hydrogen. — A solution of 0.87 g. (2.55 mmol.) of $Co_2(CO)_8$ in 100 ml. of pure and oxygen-free toluene was placed in a 300 ml. stainless steel rocking autoclave. The autoclave was then sealed, placed in an electrically heated jacket, flushed and pressured with carbon monoxide so as to hold a pressure a little less than the partial pressure of the carbon monoxide to be tested. After the autoclave had been heated to 100°C and the pressure in the autoclave had been adjusted to the partial pressure of the carbon monoxide to be tested, hydrogen was added rapidly from high pressure hydrogen storage up to the mixed gas pressure to be tested, and the autoclave was then maintained at 100°C with rocking. After various periods of time after the addition of hydrogen, about 2 ml. aliquots of the solution were withdrawn directly into a nitrogen atmosphere from the autoclave through a valve and a coil of stainless steel tube of 1 m. in length and 1 mm. inner diameter which was immersed in a bath cooled at −20°C. The cobalt hydrocarbonyl in the aliquot was analyzed by the method described in the preceding paper[6].

Measurement of Cobalt Hydrocarbonyl in the Solution During the Oxo Reaction of Methylacrylate and Cyclohexene. — The apparatus and procedure were the same as has been described above. A solution of 100 ml. toluene containing 0.17 g. of $Co_2(CO)_8$ and 17.2 g. of methylacrylate (98.5% in purity) or 0.22 g. of $Co_2(CO)_8$ and 17.4 g. of cyclohexene (98% in purity) was introduced into a 300 ml. stainless steel rocking autoclave, and the autoclave was then filled with about 75 kg./cm^2 of carbon monoxide. After the autoclave had been heated to 120°C and the pressure had been adjusted to 102 kg./cm^2, hydrogen was added rapidly until the total pressure became 202 kg./cm^2, and the autoclave was then maintained at 120°C with rocking. During the reaction the pressure was maintained at the initial pressure of 202 kg./cm^2 by a continuous addition of the compressed gas mixture of carbon monoxide and hydrogen in a 1 : 1 ratio. The aldehyde in the sample was analyzed by the hydroxylamine hydrochloride method[7].

Results and Discussion

Figures 1 and 2 show plots of the initial rate of the formation of cobalt hydrocarbonyl against the partial pressure of carbon monoxide and hydrogen. From these results, it will be seen that under the constant pressure of carbon monoxide the initial rate increases with the increasing partial pressure of hydrogen, while under the constant pressure of hydrogen, the initial rate inversely decreases with the increasing pressure of carbon monoxide. These effects of partial pressures on the initial rate of formation of cobalt hydrocarbonyl are parallel with the effects of partial pressures on the rate of the oxo reaction reported by Natta[1].

The dotted line in Fig. 1 shows that the rate of formation of hydrocarbonyl is almost constant regardless of the total pressure when the gas mixture consists of equal moles of carbon monoxide and hydrogen. This fact is interesting in connection with Natta's statement[8] that the velocity of the oxo reaction is independent of the pressure of the gas phase of 1 : 1 ratio carbon monoxide and hydrogen.

Although the rate of the oxo reaction determined by Natta et al.[1] decreased with the decreasing pressure of carbon monoxide under

pressure below about 10 atm., the rate of formation of hydrocarbonyl was observed to increase with the decreasing pressure of carbon monoxide in such a low pressure range. This phenomenon is very interesting for us in spite of the difficulty of explaining the rate of oxo reaction on the basis of the rate of formation of hydrocarbonyl. Under pressures less than 10 atm. of carbon monoxide, the rate of oxo reaction may presumably be influenced by certain other rate-determining stages, a study of which is in progress.

From Fig. 1 it was also induced that the rate is inversely proportional to the logarithm of the partial pressure of carbon monoxide under the constant pressure of hydrogen, but that the rate constant of the rate curve at 25 kg./cm² of carbon monoxide is different from that at 50 and 100 kg./cm². Therefore, no rate equation to fit the results throughout the whole range of the pressure of carbon monoxide and hydrogen could be obtained.

Since the formation of cobalt hydrocarbonyl from dicobalt octacarbonyl seems to take place according to the equation,

$$Co_2(CO)_8 + H_2 \rightarrow 2HCo(CO)_4 \qquad (3)$$

it may be a matter of course that the rate increases with the increasing pressure of hydrogen. However, the inverse effect of carbon monoxide pressure on the rate can not be explained from the above equation. Metlin et al.[9] reported that 1 mol. of carbon monoxide is absorbed per mole of dicobalt octacarbonyl at about 400 atm. and 185°C, and that this is due to the formation of a dicobalt nonacarbonyl complex, $Co_2(CO)_9$.

$$Co_2(CO)_8 + CO \rightarrow Co_2(CO)_9 \qquad (4)$$

If any of the dicobalt octacarbonyl would convert to nonacarbonyl under our experimental conditions, the inverse effect of carbon monoxide pressure might be attributed to the decrease of dicobalt octacarbonyl according to

Eq. 4. To examine the occurrence of this reaction, we have measured the amount of cobalt hydrocarbonyl in the equilibrium state by varying the partial pressures of carbon monoxide at a few fixed pressures of hydrogen. As illustrated in Table IV, the amount of cobalt hydrocarbonyl at the equilibrium state was independent of the partial pressure of carbon monoxide under the constant pressure of hydrogen. Thus, the carbon monoxide pressure affects only the rate of formation of cobalt hydrocarbonyl, not the equilibrium state of reaction 3. Therefore, it is clear that neither reaction 4 nor any other reaction to produce any compound other than cobalt hydrocarbonyl takes place under the experimental conditions employed. Furthermore, it can be noted that the inverse effect of carbon monoxide pressure on the rate is not due to a simple physical interference such as the effect of an inert dissolved gas, because it was observed that an added nitrogen pressure could affect neither the rate nor the equilibrium state of the formation of cobalt hydrocarbonyl under some carbon monoxide and hydrogen pressures. From the above observations it is not easy to explain why the carbon monoxide pressure causes a decrease only in the rate of formation of hydrocarbonyl. However, this phenomenon is an interesting fact for the study of the mechanism of the oxo reaction.

Tables II and III indicate the contents of cobalt hydrocarbonyl and aldehyde in the solutions during the oxo reaction of methylacrylate and cyclohexene in toluene at 120°C. In the former solution, in which the oxo reaction proceeds faster, only a trace of cobalt hydrocarbonyl appears when acrylate is present, while a large amount of it appears after the acrylate is consumed. This phenomenon agrees with the observations by Orchin et al.[10] However, in the latter solution, in which the oxo reaction proceeds more slowly, a large amount of hydrocarbonyl is present even at the beginning of the reaction.

From this result it seems likely that cobalt hydrocarbonyl will react rapidly with acrylate and slowly with cyclohexene. Although it could not be confirmed that cobalt hydrocarbonyl is consumed, whether in a main reaction to produce aldehyde or in some side reaction such as a hydrogenation reaction of double bond of olefin during the oxo reaction, it is significant for the study of the mechanism of the oxo reaction that cobalt hydrocarbonyl reacts rapidly with olefin whose oxo reaction is fast and slowly with that whose oxo reaction is slow.

Summary

By treating a solution of dicobalt octacarbonyl in toluene at 100°C under various partial pressures of carbon monoxide and hydrogen,

10) M. Orchin, L. Kirch and I. Goldfarb, *J. Am. Chem. Soc.*, **78**, 5450 (1956).

and by determining the initial rate of formation of cobalt hydrocarbonyl, we have found that the initial rate increases with the increasing pressure of hydrogen and decreases with the increasing pressure of carbon monoxide. These effects of partial pressures on the initial rate of formation of cobalt hydrocarbonyl are parallel with the effects of partial pressures on the rate of the oxo reaction reported by Natta.

In addition, the amount of cobalt hydrocarbonyl in the system during the oxo reaction of methylacrylate and cyclohexene in toluene at 120°C was determined; it was found that only a trace of cobalt hydrocarbonyl appears when acrylate is present, while a large amount of it is present even when cyclohexene is present in the system.

The author wishes to express his deep thanks to Professor S. Murahashi, Dr. T. Yoshida and Mr. J. Kato for their kind guidance and encouragement throughout this work. The author is also indebted to Mr. T. Fujii for his assistance in this experiment.

The Effect of the Partial Pressure of Carbon Monoxide and Hydrogen on the Rate of Oxo Reaction

By Ryoji IWANAGA

(Received July 24, 1961)

It was found by Natta[1] and Martin[2] that the rate of oxo reaction increases with the increasing pressure of hydrogen, but decreases with the increasing pressure of carbon monoxide. These kinetic results led them to propose a mechanism for the oxo reaction which involves the displacement of a mole of carbon monoxide by the olefin from the dicobalt octacarbonyl[1,2] or from the cobalt hydrocarbonyl[3]. Recently Breslow et al.[4] have proposed a mechanism modifying the mechanism postulated by Kirch and Orchin[5]. In Breslow's mechanism the acylcobalt tricarbonyl, $RCH_2CH_2COCo(CO)_3$, produced from cobalt hydrocarbonyl and olefin reacts with hydrogen to give the oxo product and hydrotricarbonyl, $HCo(CO)_3$, or with carbon monoxide to give the unreactive acylcobalt tetracarbonyl, $RCH_2CH_2COCo(CO)_4$, and cobalt hydrotetracarbonyl is regenerated from hydrotricarbonyl.

$$RCH=CH_2+HCo(CO)_4 \rightarrow RCH_2CH_2Co(CO)_4$$

$$RCH_2CH_2Co(CO)_4 \rightarrow RCH_2CH_2COCo(CO)_3$$

$$RCH_2CH_2COCo(CO)_3+CO \rightarrow RCH_2CH_2COCo(CO)_4$$

$$RCH_2CH_2COCo(CO)_3+H_2 \rightarrow HCo(CO)_3+RCH_2CH_2CHO$$

$$HCo(CO)_3+CO \rightarrow HCo(CO)_4$$

The above mechanisms were all based upon the consideration that the cardon monoxide might affect the formation of an intermediate complex of the oxo reaction.

The author established in a preceding paper[6] that the rate of formation of cobalt hydrocarbonyl is increased with the increasing partial pressure of hydrogen but decreased with the increasing partial pressure of carbon monoxide.

To clarify the relationship between this effect of the partial pressure on the rate of formation of cobalt hydrocarbonyl and the effect of the partial pressure on the rate of oxo reaction, the author has studied the initial rate of the oxo reaction of methylacrylate under various partial pressures of carbon monoxide and hydrogen. In this study the reaction was made under the same conditions as have been described in the preceding paper[6], in order that the initial rate of the oxo reaction might be compared directly with that of the formation of cobalt hydrocarbonyl.

Methylacrylate was chosen for this study because it yielded only one kind of aldehyde, methyl-β-formylbutyrate[7], and reacted rapidly even at about 100°C. If the oxo reaction is carried out at a temperature higher than 100°C, cobalt carbonyl often decomposes under the partial pressure of carbon monoxide less than 10 kg./cm².

Experimental

The methylacrylate and toluene to be used were obtained from commercial sources; they were distilled in a nitrogen atmosphere and were kept in nitrogen before use in order to prevent the decomposition of the dicobalt octacarbonyl added as catalyst. The dicobalt octacarbonyl was also freshly recrystallized from ethyl ether before use. The method described in the preceding paper[6] was followed in general.

Determination of the Initial Rate of the Oxo Reaction of Methylacrylate.—One hundred milliliters of the solution containing 20.3 g. (232 mmol.) of methylacrylate and 0.86 g. (25 mmol.) of dicobalt octacarbonyl in toluene were put into a 300 ml. stainless steel rocking autoclave. After the autoclave had been heated to 100°C and the pressure of carbon monoxide had been adjusted to the pressure to be tested, hydrogen was added for a few seconds to bring it up to the pressure to be tested, and immediately the rocking was started. The temperature was controlled within ±1°C. The initial pressure and the initial ratio of carbon monoxide to hydrogen were maintained by a continuous addition of 1 : 1 synthesis gas throughout the time of the reaction, because about equal amounts of carbon monoxide and hydrogen were absorbed in the oxo reaction of methylacrylate. The initial rate of the oxo reaction was obtained as follows:

Several aliquots of about 2 ml. of the reaction mixture were withdrawn from the autoclave at intervals of 2.5 or 5 min. during the reaction through a high-pressure coil of a stainless tube cooled at −20°C; the amount of aldehyde in an aliquot was determined according to the procedure of Adkins[7]. The aldehyde yield per minute at the initial period of reaction time indicates the initial rate of the oxo reaction.

Results and Discussion

The initial rate of the oxo reaction of methylacrylate in toluene at 100°C under various partial pressures of carbon monoxide and hydrogen are listed in Table I. It shows that under the constant pressure of carbon monoxide, the initial rate increases with the increasing pressure of hydrogen, and under

7) H. Adkins and G. Krsek reported that ethyl-β-formylbutyrate was obtained by the oxo reaction of ethylacrylate in 74% of the theoretical yield. (*J. Am. Chem. Soc.*, **71**, 3051 (1949).) We have also obtained an aldehyde in an 83% yield from methylacrylate, and the aldehyde was confirmed to be all methyl-β-formylbutyrate through its 2,4-dinitrophenylhydrazone and by infrared analysis in this laboratory.

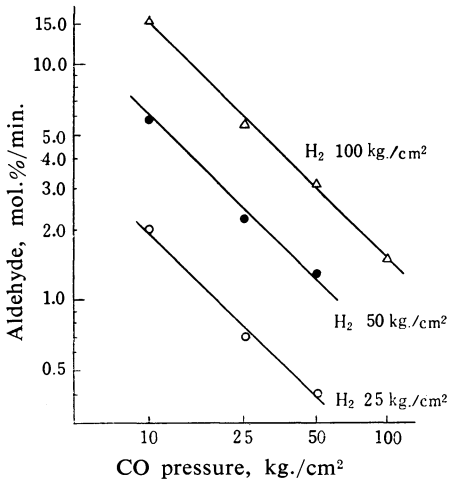

Fig. 2. Initial rate of the oxo reaction of methylacrylate in toluene at 100°C as a function of CO pressure.

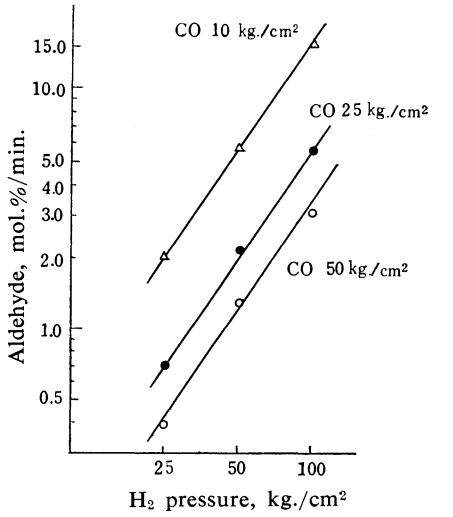

Fig. 3. Initial rate of the oxo reaction of methylacrylate in toluene at 100°C as a function of H_2 pressure.

the constant pressure of hydrogen the initial rate increases with the increasing pressure of carbon monoxide up to about 10 kg./cm^2, but decreases with the increasing pressure in the range of the high pressures of carbon monoxide (refer to Fig. 1). These results are in good agreement with the results obtained by Natta for the oxo reaction of cyclohexene in toluene[1,8]. In the range of the carbon monoxide pressures above 10 kg./cm^2, the plot of the rate against the pressure of carbon monoxide (Fig. 2) and the plot against the pressure of hydrogen (Fig. 3), both in logarithmic graphs, yielded straight lines. Therefore, the initial rate of the oxo reaction of methylacrylate can be represented by the equation:

$$\text{Initial rate} = 0.16\,(P_{H_2})^{1.5}/(P_{CO}) \qquad (1)$$

where P_{H_2} and P_{CO} are partial pressures in kg./cm^2 of hydrogen and carbon monoxide respectively. The data in the fourth column in Table I were calculated by the above equation, and they fit our observations quite well. Martin[2] proposed a rate equation for the case of the oxo reaction of diisobutene,

$$\text{Initial rate} = aP_{H_2}/(bP_{H_2} + cP_{CO}) \cdot [Co_2(CO)_8]\,[C_8H_{16}] \qquad (2)$$

where a, b and c are constants. However, this equation did not fit our observations.

In Fig. 1 the initial rate of the reaction of methylacrylate, together with the initial rate of the formation of cobalt hydrocarbonyl obtained in the preceding paper[6] under identical conditions, are shown. The figure shows that under the pressure of carbon monoxide above 25 kg./cm^2, the former rate is parallel with the latter rate. However, comparing the magnitude of the initial rate of the formation of cobalt hydrocarbonyl from dicobalt octacarbonyl and that of aldehyde from acrylate, it will be seen that the former rate is much lower than the latter rate under identical conditions of partial pressure. For example, it is calculated from the curve in Fig. 1 that when the pressure of carbon monoxide is 25 kg./cm^2 and that of hydrogen is 50 kg./cm^2, the former rate is 0.046 mmol. per minute and the latter rate is 5.1 mmol. per minute. Therefore, assuming that, as Kirch and Orchin described[5], cobalt hydrocarbonyl is the true catalyst of the oxo reaction to combine with olefin, it is impossible to consider that the hydrocarbonyl is formed only from dicobalt octacarbonyl in the oxo reaction. If it is assumed that cobalt hydrocarbonyl is formed from a cobalt carbonyl different from dicobalt octacarbonyl in the oxo reaction and that its rate is very rapid and is affected by the partial pressure, as in the case from dicobalt octacarbonyl, the effect of the partial pressure of carbon monoxide and hydrogen on the rate of the oxo reaction may be attributed to the effect of the partial pressure on the rate of the formation of cobalt hydrocarbonyl from a cobalt carbonyl presumed to be formed in the oxo reaction.

The effect of carbon monoxide pressure on the rate of the oxo reaction under a partial pressure less than 10 kg./cm^2 was observed to be just the opposite to the effect on the rate of the formation of hydrocarbonyl. From this phenomenon, it seems that there may be a certain interaction between carbon monoxide

8) G. Natta, *Brenstoff-Chemie*, **36**, 176 (1955).

and an intermediate complex and that this interaction may determine the rate of the oxo reaction. The author further observed that the color of the solution at an intermediate stage of the oxo reaction under 10 kg./cm^2 of carbon monoxide is light brown, and that at the end of the reaction it turns dark brown, while the color is dark brown throughout the reaction period under the carbon monoxide pressure above 10 kg./cm^2. In addition, analytical work has shown that the ratio of carbon monoxide liberated from the cobalt compound by the addition of iodine to cobalt in the solution is nearly 1.5 : 1 at an intermediate stage of the reaction under less than 10 kg./cm^2 of the carbon monoxide, but that at the end of the reaction the ratio is nearly 4 : 1. On the other hand , at under 10 kg./cm^2 of carbon monoxide, about 4 mol. of carbon monoxide are attached to a mole of cobalt even at the beginning of the reaction (Table II). Although the structure of the above cobalt compound with 1.5 mol. of carbon monoxide to a mole of cobalt could not be confirmed, it is clear that the carbon monoxide pressure significantly affects the structure of the cobalt compound under such a low pressure of carbon monoxide.

Table II. The behavior of cobalt compound during the oxo reaction of methylacrylate in toluene at 100°C

Methylacrylate, 232 mmol./dl.
$Co_2(CO)_8$, 2.16 mmol./dl.

CO pressure	(kg./cm^2)	6	25
H_2 pressure	(kg./cm^2)	50	50
After 10 min. of reaction			
aldehyde formed	(mol.%)	35.0	17.8
acrylate unreacted	(mol.%)	47.7	65.7
Molar ratio of CO : Co		1.55	3.33
After complete reaction			
aldehyde formed	(mol.%)	63.9	
acrylate unreacted	(mol.%)	2.1	
Molar ratio of CO : Co		3.9	

Furthermore, we have observed that at the beginning of the oxo reaction of methylacrylate, cobalt hydrocarbonyl is scarcely found in the reaction solution when the partial pressure of carbon monoxide is higher than 10 kg./cm^2, but that a certain amount of it appears when the partial pressure is lower than 10 kg./cm^2 (Table III). This phenomenon may be accounted for by assuming that in the range of carbon monoxide pressures above 10 kg./cm^2 the velocity of the formation of an intermediate complex from cobalt hydrocarbonyl-olefin-carbon monoxide, the formation of which was proposed by Kirch and Orchin[5], is so rapid that the hydrocarbonyl formed may immediately be consumed, while in the range of carbon monoxide pressures below 10 kg./cm^2 the velocity of the formation of cobalt hydrocarbonyl is so rapid, while the velocity of the formation of the complex is so slow, that some parts of the hydrocarbonyl may appear uncombined.

We have recently observed that in a toluene solution, cobalt hydrocarbonyl, which has been analyzed by the methylene blue method[9], disappears rapidly on the addition of methylacrylate at −20°C in an atmospheric pressure of nitrogen, but disappears slowly on the addition of cyclohexene, and that the molar ratio of the cobalt hydrocarbonyl consumed to the methylacrylate consumed is about 2 : 1. The product of this reaction is now under study. This phenomenon suggests that the effect of olefin structure on the rate of the oxo reaction[10] may be based upon the difference in rate of the combination of olefins with cobalt hydrocarbonyl and that, when the rate of combination is very rapid, as in the case of acrylate, the formation of cobalt hydrocarbonyl may be a rate-determining step in the oxo

reaction. If the intermediate complexes of the oxo reaction could be isolated and the structures could be shown, the mechanism of the oxo reaction could undoubtedly be clarified.

Summary

The initial rates of the oxo reaction of methylacrylate in toluene at 100°C were measured under various partial pressures of carbon monoxide and hydrogen; they were then compared with the initial rate of the formation of cobalt hydrocarbonyl from dicobalt octacarbonyl measured under the same conditions in the preceding paper. The initial rate of the oxo reaction under the carbon monoxide pressure above 10 kg./cm^2 can be represented as follows:

$$\text{Initial rate (mol.\% of aldehyde/acrylate/min.)} = 0.16\ (P_{H_2})^{1.5}/(P_{CO})$$

However, the initial rate decreases with the decreasing partial pressure of carbon monoxide in the range below 10 kg./cm^2 of carbon monoxide. In addition, under the partial pressure of carbon monoxide below 10 kg./cm^2 some behaviors of cobalt carbonyl different from that under the pressure above 10 kg./cm^2 were observed. On the basis of these observations, a possible mechanism of the oxo reaction was discussed.

The author wishes to express his deep thanks to Professor S. Murahashi, Dr. T. Yoshida and Mr. J. Kato for their kind guidance and encouragement throughout this work. The author is also indebted to Mr. T. Fujii for his assistance in this experiment.

Sur les Préparations des Complexes Métalliques. I. Les Préparations de Triacetatotriamminechrome(III)

Par Masayoshi NAKAHARA

(Reçu le 22 Août, 1961)

Jusq'ici les complexes non-électrolytes du chrome(III) étaient assez connus, et on savait bien que le trisglycinatochrome(III) et de trispicolinatochrome(III) pouvaient être facilement préparés, mais les complexes non-chelates qui en sont des homotypes n'étaient pas encore obtenus; aussi avons-nous examiné la formation du triacetatotriamminechrome(III) et du triacetatotripyridinechrome(III), et trouvant possibles leur préparations, nous les avons préparés en les comparant avec leur complexes non-chelates qui leur sont très analogues.

Expériences

Préparations.—*1) Diperoxotriamminechrome(III)*, $[Cr(O_2)_2(NH_3)_3]$. —Hofmann et al.[1], Riesenfeld[2], Werner[3] ou Bhatnager et al.[4] les ont déjà préparés; nous avons vu que la manière suivante est la plus simple et la plus profitable. 20 g. d'oxyde de chrome(VI), dissous dans 40 ml. d'eau, ont été ajoutés à 200 ml. de solution faite en diluant 70 ml. de solution concentré d'ammoniaque (28%). Cette solution jaune a été bien refroidie par le mélange réfrigérant et laissée telle quelle jusqu'à ce que la glace cristallise sur la paroi du bécher. Ensuite on y a fait tomber goutte à goutte 40 ml. d'eau oxygénée. Il faut continuer à la refroidir par le mélange réfrigérant pour maintenir la température de la solution au-dessous de −5°C. On a laissé telle quelle toute une heure la solution brun-sombre ainsi obtenue en la refroidissant par le mélange réfrigérant. Alors des quantités considérables de dichromate d'ammonium se sont cristallisés, mais, sans en tenir compte, la solution brun-sombre a été chauffée jusqu'à 50°C; nous avons vu s'échapper grande quantité d'oxygène; 10 min. après ce dégagement la solution a été chauffée, puis filtrée; le filtrat a été refroidi par le mélange réfrigérant jusqu'à 0°C, et laissé tel quel, toute la nuit, dans le réfrigérateur. Les cristaux menus, bruns ont été bien lavés à l'éthanol (95%), puis lavés à l'éthanol absolu et l'éther et aspirés, et conservés dans un dessicateur contenant de la potasse.

Rendement: 3,5～4,0 g.

2) Trichlorotriamminechrome(III), $[CrCl_3(NH_3)_3]$. —Nous avons fait la préparation selon la méthode de Werner[5].

1) K. A. Hofmann et H. Hiendlmaier, *Ber.*, **38**, 3059 (1905).
2) E. H. Riesenfeld, ibid., **38**, 4068 (1905).
3) A. Werner, ibid., **43**, 2286 (1910).
4) S. S. Bhatnager et al., *J. Chem. Soc.*, **1938**, 1432.
5) A. Werner, *Ber.*, **43**, 2290 (1910).

3) Trichlorotripyridinechrome(III), $[CrCl_3(NC_5H_5)_3]$. — Il a été préparé par Pfeiffer[6,7]; si nous pouvons nous procurer le chlorure de chrome(III) anhydre, il sera plus facile de nous en servir. Nous avons su qu'il était très difficile de produire ce composé en grande quantité si nous nous servions du chlorure de dichlorotetraquochrome(III) dihydraté.

4) Triacetatotriamminechrome(III), $[Cr(OCOCH_3)_3(NH_3)_3]$.—2,5 g. de trichlorotriamminechrome-(III) ont été suspendus dans 50 ml. d'éthanol soigneusement desséché; ensuite il a été ajouté 1 g. d'acétate d'argent purifié et soigneusement séché. Ce mélange été doucement chauffé au bain-marie, dans un flacon muni d'un réfrigérant à reflux; dans ce cas, s'il y entre de l'eau, quelque peu que ce soit, l'hydrolyse peut avoir lieu, et la récolte peu être extrémement réduite. La solution, chauffée pendant quelques temps, a été filtrée avant qu'elle ne devienne froide; le filtrat a été refroidi. Les cristaux rouge-violacés ainsi précipités ont été recristallisés par l'éthanol, lavés avec un peu d'éthanol et d'éther, puis séchés à l'air.

Rendement: 2 g.

Calculé: Cr, 18,56; NH_3, 18,23. Trouvé: Cr, 18,92; NH_3, 18,10%.

Cristaux rouge-violacés en forme d'écailles minces. Quand on les cristallise lentement on obtient des cristaux presque violet noirâtre. Solubles dans l'eau, l'éthanol, l'acide acétique recristallisables. En la solution aqueuse, facilement hydrolysables.

5) Triacetatotripyridinechrome(III), $[Cr(OCOCH_3)_3(NC_5H_5)_3]$. — 1 g. de trichlorotripyridine-chrome(III) a été dissous dans 20 ml. de pyridine bien sèche; 2 g. d'acétate d'argent y ont été ajoutés, et le tout a été chauffé sur bain d'huile et dans un flacon muni d'un réfrigérant à reflux. Suffisamment chauffé, on a filtré avant refroidissement, puis refroidi. La solution rouge-violacée ainsi obtenue a été mise dans le dessicateur sous vide avec de l'acide sulfurique concentré. Des cristaux violets noirâtres ont été obtenus. Ils ont été recristallisés par une petite quantité d'éthanol.

Rendement: 0,5 g.

Calculé: Cr, 11,11. Trouvé: Cr, 10,74%.

Cristaux violets noirâtres en forme d'écailles minces. Insolubles dans l'eau. Solubles dans l'éthanol, la pyridine.

6) Trisglycinatochrome(III), $[Cr(NH_2CH_2COO)_3]\cdot 3H_2O$.—Nous l'avons préparé selon la méthode de Ley et al.[8] On peut se servir de sel de chloro-pentamminechrome(III) au lieu du chlorure de dichlorotetraquochrome(III) dihydraté, comme le disaient Ley et al., mais nous avons constaté qu'on pouvait le préparer aussi bien en se servant du sel d'aquopentamminechrome(III), du sel de rhodochrome ou du sel d'erythrochrome.

7) Trispicolinatochrome(III), $[Cr(NC_5H_4COO)_3]\cdot H_2O$.—Nous avons fait la préparation suivante selon méthode de Ley et al.[9].

Les Spectres d'Absorption. — Les spectres d'absorption du triacetatotriamminechrome(III) et du triacetatotripyridinechrome(III), préparés à nouveau, ont été mesurés; ceux du trisglycinatochrome(III) et du trispicolinatochrome(III), qui avaient déjà été préparés, mais dont les spectres d'absorption n'avaient pas encore été mesurés, ont été aussi mesurés. Les spectres d'absorption de l'acétato-complexe obtenus à nouveau, ont été mesurés dans l'éthanol ou la pyridine, parce qu'il était impossible de les mesurer dans la solution aqueuse à cause de l'aquotisation trop rapide. Ensuite les spectres d'absorption des deux chelates susdits ont été mesurés avec la solution d'acide perchlorique à 60%; nous les avons mesurés en nous servant d'une cellule de quartz de 1,0 cm. et de Marque Hitachi EPU Spectrophotomètre photoélectrique. L'éthanol a été purifié selon la méthode de Danner et al.[10]; on l'a fait bouillir avec de l'azotate d'argent on l'a distillé et fait bouillir avec de l'acide sulfurique concentré, puis distillé, enfin l'a déssèché suffisamment par l'oxyde de calcium et distillé. La pyridine a été transformée on oxalate,

puis décomposée par l'alcali, distillée, sèchée suffisamment par l'oxyde de baryum et distillée[11]. L'acide perchlorique était de qualité spéciale du commerce.

Les résultats sont donnés dans la Fig. 1 et le Tableau I.

Résultats et Discussion

Si l'on regarde les quatre courbes d'absorption montrées dans la Fig. 1, on s'apercevra que leurs formes se ressemblent beaucoup nous avons trouvé, quant au triacetatotriamminechrome(III) et au triacetatotripyridinechrome-(III), que les places de la première et de la deuxième bande d'absorption coïncident presque, ainsi que la valeur du coefficient d'extinction molaire. Seulement, quant au triacetatotripyridinechrome(III), l'augmentation du coefficient d'extinction est remarquable vers 28000 cm^{-1}, dans la région des faibles longueurs d'onde; peut-être est-ce à cause du pied de la bande d'absorption spéciale de la pyridine. Quant au trisglycinatochrome(III) et au trispicolinatochrome(III), nous avons trouvé, de même, que la première et la deuxième bande d'absorption coïncident presque, et que leur coefficient d'extinction sont à peu près égaux; quant au trispicolinatochrome(III), l'augmentation du coefficient d'extinction est plus important autour de 28000 cm^{-1} que pour le trisglycinatochrome(III); ce serait à cause de la bande d'absorption spéciale du noyau de la pyridine de même que pour les acetato-complexes. Ce qui est le plus intéressant—on peut le trouver dans chaque courbe—c'est une petite bande d'absorption autour de 14500 cm^{-1}; nous l'avons classée comme étant celle qui est appelée communément absorption linéaire du chrome[12].

Or l'absorption donnée par deux espèces d'acetato-complexes et celle produite par les complexes chélatés coïncidaient relativement bien entre eux, mais les acetato-complexes et les complexes chélatés nous montrent une absorption assez différente excepté l'absorption linéaire; la première et la deuxième bande d'absorption changent vers les faibles nombres d'onde 700~1000 cm^{-1}. Il semble que l'on ait un grand effet pareil en montrant la différence de structure qui existe entre ces deux matières, mais on n'a pas besoin de tenir compte de ce phénomène qui est l'effet du solvant. Cet effet du solvant sur l'absorption des complexes est présenté dans un mémoire donné par Nakamoto et al.[13] et par nos résultats expérimentaux[14]. On doit penser au changement de la bande d'absorption, suscité par un solvant polaire. On sait bien que la transposition de la première et la deuxième bande d'absorption des complexes chélates apparaît toujours comme étant celle qui se fait vers les courtes longueurs d'onde, à cause de l'effet stabilisateur venant de la chelatisation.

L'absorption linéaire du chrome se trouvant autour de 14500 cm^{-1} ne bouge pas et elle ne subit presque pas l'effet du solvant. Les faits déjà expliqués prouvent avec les effets d'absorption indiqués que l'on peut considérer ces bandes comme étant celles qui sont dues aux complexes homotypes.

Shimura[15] a fait la mesure et la distinction entre les spectres d'absorption de deux isomères (cis-cis- et cis-trans-complexe) du trisglycinatocobalt(III), et Yamatera[16] a déjà donné une thèse sur la séparation de la première bande des complexes de type $[CoX_3Y_3]$. On a constaté que la séparation de cette première bande d'absorption des complexes non-électrolytes se produit à cause de la structure cis-trans. La différence entre la première bande d'absorption des complexes cis-cis et cis-trans est très claire. On peut en conclure facilement que le trisglycinatochrome(III) a la structure cis-cis par analogie avec les complexes du cobalt(III). Il me semble très intéressant, qu'on puisse préparer à la fois les complexes du cobalt(III) cis-cis et cis-trans, alors qu'on ne peut obtenir que les complexes cis-cis du chrome(III), avec les complexes binucléaire di-μ-hydroxo-bis {bisglycinatochrome(III)}. De même, on peut raisonnablement attribuer la forme cis-cis au trispicolinatochrome(III) parce qu'il donne des spectres d'absorption coïncidants presque avec ceux du glycinato-complexe. On peut donc penser que les deux acetato-complexes ayant les spectres d'absorption semblables prennent les structure cis-cis.

Résumé

L'auteur a preparé les deux nouveaux complexes: triacetatotriamminechrome(III) et triacetatotripyridinechrome(III). Il a mesuré les spectres d'absorption de ces deux complexes et il en a conclu que ces complexes obtenus ont tous les deux la structure cis-cis, présentant une coïncidence de spectres d'absorption avec ceux des complexes de genre analogue.

L'auteur exprime ses remerciements sincères à Monsieur le Professeur Taku Uemura pour

Sur les Préparations des Complexes Métalliques. II[1]. *Les Préparations du Trinitratotriamminechrome(III) et du Trinitritotriamminechrome(III)*

Par Masayoshi NAKAHARA

(Reçu le 12 Septembre, 1961)

Dans les complexes du cobalt(III) le trinitrato- et le trinitrito-triammine complexes étaient bien connus et assez communs, mais les complexes homotypes n'étaient pas encore connus jusqu'ici dans les complexes du chrome(III). En général on ne connaissait que les halogéno- ou les pseudohalogeno-complexes comme complexes triammine-types non-électrolytes et, comme autres, les complexes combinés halogéno et oxalato. Il est très étrange qu'on n'ait pas encore obtenu les complexes de chrome(III) correspondants aux complexes du cobalt(III), de forme si simples. Aussi, avons-nous essayé de préparer les complexes de ce type et de les examiner en les comparant avec les complexes du cobalt(III).

Expérience

Préparations—*1) Trichlorotriamminechrome(III)*, $[CrCl_3(NH_3)_3]$.—Obtenu selon la méthode que nous avons montrée dans la partie I[1].

2) Azotate d'argent, $AgNO_3$.— Purifié selon la méthode de Kolthoff et Lingane[2].

3) Azotite d'argent, $AgNO_2$.—Une solution aqueuse d'azotite de sodium a été ajoutée à une solution aqueuse d'azotate d'argent[3]. Les cristaux jaunes clairs ainsi obtenus ont été dissous dans l'eau chaude et recristallisés. On connaît bien leurs deux formes: la forme α et la forme β. Nous les avons employées, toutes les deux, pour l'essai; les résultats étaient les mêmes.

4) Trinitratotriamminechrome(III), $[Cr(NO_3)_3(NH_3)_3]$.—5,3 g. d'azotate d'argent ont été mis en poudre, bien mélangés avec 2,5 g. de trichlorotriamminechrome(III), mis dans un mortier, et broyés. La couleur bleu du trichlorotriamminechrome(III) est passée immédiatement au rouge, mais nous avons continué à broyer pour que la réaction soit complète. Quand ils étaient bien humidifiés par l'eau ou l'éthanol, la réaction se faisait vite, mais quand ils étaient en trop grande quantité, le rendement n'était pas suffisant. La réaction terminée, une solution froide consistant en 3 g. d'azotate de sodium dissous dans 10 ml. d'eau a été ajoutée au produit de la réaction; puis l'extraction et la filtration ont été faites. Nous avons rapidement rassemblé le filtrat et l'avons longtemps laissé tel quel dans le mélange réfrigérant. Les poudres cristallines rouge-violacées ainsi obtenues ont été aspirées, lavées d'abord avec une petite quantité de solution froide, mélange d'éthanol et d'acide d'azotique dilué, puis à l'éthanol et l'éther, enfin séchées à l'air. Rendement: 0,5 g.

Calculé: Cr, 17,99; NH_3, 17,67. Trouvé: Cr, 16,88; NH_3, 16,14%.

Prisme rouge-violacé. Facilement soluble dans l'eau. Pas déliquescent dans l'air, mais sujet à se mouiller quand on le laisse tel quel; on doit le conserver dans le dessicateur. Stable à la température normale, mais, quand on le chauffe, se décompose en explosant au-dessous de 100°C, et laisse l'oxyde de chrome(III). La solution aqueuse est sujette à l'aquotisation.

5) Trinitritotriamminechrome(III), $[Cr(ONO)_3(NH_3)_3]$.— 5 g. d'azotite d'argent ont été mis en poudre, mêlés avec 2,5 g. de trichlorotriamminechrome(III), mis dans le mortier, et broyés soigneusement. La réaction était un peu plus lente que celle du nitrato-complexe; la couleur des poudres est passée lentement du vert bleuâtre au rouge. Puis, au produit complètement broyé a été ajouté une solution froide consistant en 3 g. d'azotite de sodium dissous dans 10 ml. d'eau. Cela a été filtré et le filtrat violet rougeâtre a été laissé tel quel dans le mélange réfrigérant. Suffisamment refroidie, cette solution a donné des cristaux rouge-violacés. Ces cristaux ont été lavés à l'éthanol et séchés à l'air. Rendement: 0,2 g.

Calculé: Cr, 21,75; NH_3, 21,19. Trouvé: Cr, 20,20; NH_3 20,02%.

Poudre cristalline rouge-violacée. Hydrophile dans l'air. Facilement soluble dans l'eau. Stable à la température normale, mais, quand on la chauffe,

se decompose en explosant au-dessous de 100°C.

6) Trinitratotriamminecobalt(III), $[Co(NO_3)_3(NH_3)_3]$.— Nous l'avons préparé selon la méthode de Jörgensen[4]. Ce composé a été préparé aussi par Mori et al.[5]

7) cis-trans-Trinitrotriamminecobalt(III)[6], *cis-trans*-$[Co(NO_2)_3(NH_3)_3]$.—Nous l'avons préparé selon la méthode de Jörgensen[7].

8) cis-cis-Trinitrotriamminecobalt(III), *cis-cis*-$[Co(NO_2)_3(NH_3)_3]$.—Nous l'avons préparé selon la méthode de Suéda[8] et Mori et al.[5]

Spectres d'Absorption.—Les spectres d'absorption dans l'eau des complexes nouvellement préparés ont été mesurés, mais il a été impossible d'obtenir les spectres d'absorption des composés recherchés, selon la méthode ordinaire, car le changement des spectres d'absorption était remarquable avec le temps. Par exemple, même quand on les mesurait sitôt après la dissolution du spécimen, l'aquotisation se faisait immédiatement, et la bande d'absorption spéciale du nitro et du nitrato qui existait à 26000 ~30000 cm^{-1} diminuait tout d'un coup son coéfficient d'éxtinction. Il a été plus facile, certes, de les mesurer dans le mélange eau-éthanol, l'aquotisation étant un peu plus lente, mais, quand même, nous n'avons pu obtenir des données bien exactes. De toute façon, leurs spectres d'absorption, quelques minutes après, finissaient toujours par coïncider avec ceux du triaquotriamminechrome(III). Nous nous sommes servi de la solution d'acide perchlorique concentré ou de la solution d'acide acétique, mais,

(5) *cis-cis*-$[Cr(ONO)_3(NH_3)_3]$
(6) *cis-cis*-$[Co(ONO_2)_3(NH_3)_3]$
(en solution; par Shimura[10])

TABLEAU I. LES MAXIMA DES BANDES D'ABSORPTION ($\tilde{\nu}$: 10^3 cm^{-1})

Complexe	La première $\tilde{\nu}$	La deuxième $\tilde{\nu}$
cis-cis-$[Co(ONO_2)_3(NH_3)_3]$	19,0	27,5
cis-trans-$[Co(NO_2)_3(NH_3)_3]$	23,0	
cis-cis-$[Co(NO_2)_3(NH_3)_3]$	20,8	
cis-cis-$[Cr(ONO_2)_3(NH_3)_3]$	19,3	~27,5
cis-cis-$[Cr(ONO)_3(NH_3)_3]$	19,8	~27,5

dans ces deux cas, les résultats n'étaient pas suffisants. Aussi avons-nous renoncé à mesurer les spectres d'absorption en solution, et nous avons décidé de mesurer les spectres d'absorption des solides. Les mesures ont été faites en employant le spectrophotomètre photoélectrique de Marque Hitachi EPU et ses accessoires. L'échantillon a été bien broyé dans un mortier d'agate, et le pouvoir réflecteur R_d a été mesuré. Nous avons obtenu la valeur f en remplacant R_d par sa valeur dans la formule de Kubelka-Munk[9]:

$$f(R_d) \equiv \frac{(1-R_d)^2}{2R_d} = C \cdot \varepsilon$$

On ne peut obtenir la valeur absolue du coefficient d'extinction molaire ε, mais on peut comparer, par la valeur de log f, le coefficient d'extinction molaire avec les chiffres obtenus en solution aqueuse, car la valeur f est théoriquement proportionnelle à ce coefficient d'extinction molaire. La courbe 1 de la Fig. 1, par exemple, qui montre les spectres d'absorption du trinitratotriamminecobalt(III) mesurés selon cette méthode, coïncide bien avec les données de Shimura[10] pour la place de la bande d'absorption, l'intensité relative, la forme etc. Aussi avons-nous mesuré selon cette méthode les autres spectres d'absorption; nous avons montré dans la Fig. 1. les résultats des mesures de 15000 cm^{-1} à 32000 cm^{-1}. Toutefois, on ne peut que comparer l'allure des courbes, car elles sont décalées verticalement.

Résultats et Discussion

Voyant ces résultats, nous avons jugé, que $[Cr(NO_3)_3(NH_3)_3]$ et $[Cr(NO_2)_3(NH_3)_3]$ avaient, tous les deux, des bandes d'absorption très semblables, leurs premières bandes d'absorption autour de 19500 cm^{-1}, et leurs grandes bandes d'absorption au delà de 26000 cm^{-1}. Ordinairement, quand les spectres de réflexion sont mesurés par les poudres, on peut obtenir les spectres d'absorption exacts, si ces poudres sont assez fine grâce de la réflexion diffuse mais si les grains sont gros, le maximum de la bande d'absorption se brisera, sur la bande d'absorption dont le coefficient d'extinction est grand, à cause de la réflexion régulière sur la surface cristalline[11]. En ce cas, les bandes

d'absorption de nitrato et nitro sont très larges et doivent apparaître autour de 33000 cm^{-1} et 28000 cm^{-1}; elle prennent alors une forme écrasée comme nous l'avons montré dans la Fig. 1. On ne peut pas considérer comme exacte la valeur autour de 30000 cm^{-1}, du point de vue de la sensibilité de l'appareil de mesure, mais on peut voir du moins qu'il y a une bande d'absorption spéciale[12] au delà de 29000 cm^{-1}, et, au pied de celle-ci, la deuxième bande d'absorption. Or, lorsqu'on observe les spectres d'absorption du trinitratotriamminechrome(III) et du trinitratotriamminecobalt(III), on peut voir que les formes de ces deux premières bandes d'absorption sont très ressemblantes, et, de plus, qu'elles se superposent presque entièrement (19300 cm^{-1} et 19000 cm^{-1}). Les deuxièmes bandes d'absorption se situent autour de 27000 ~27500 cm^{-1}, et il y a, de plus, ce qui serait la bande d'absorption spéciale du nitrato. Nous croyons par là, que le trinitratotriammine-chrome(III) a la même structure cis-cis que celle des complexes du cobalt(III) homotypes. Par la bande d'absorption de $[Cr(NO_2)_3(NH_3)_3]$, on voit un état bien différent de celui des complexes du cobalt(III); la première bande d'absorption de $[Cr(NO_2)_3(NH_3)_3]$ se situe à 19800 cm^{-1}, un peu plus près du côté des faibles longueurs d'onde que celle du trinitratotri-amminechrome(III), qui se situe à 19300 cm^{-1}, quoi qu'il en soit elles sont proches l'une de l'autre. Elle est bien séparée des bandes d'absorption des complexes cis-cis (20800 cm^{-1}) et cis-trans (23000 cm^{-1}) du trinitrotriammine-cobalt(III). On est donc amené à concevoir, pour $[Cr(NO_2)_3(NH_3)_3]$, une structure bien différente de celle du trinitrotriamminecobalt-(III). Il est plus raisonnable de penser à un composé de coordination en nitrito ONO, qui est proche de nitrato ONO_2 dans les séries spectrochimique[10], que de penser à un composé de coordination en nitro NO_2. Voyant que, selon les séries spectrochimiques, dans les séries $[CoX(NH_3)_5]$, NO_2 est à 21800 cm^{-1}, ONO à 20400 cm^{-1}, et ONO_2 à 20000 cm^{-1}, sur la première bande d'absorption, it n'est pas si déraisonnable de formuler une telle conclusion. Nous avons donc jugé que le complexe NO_2-chrome ainsi obtenu est le trinitritotriammine-chrome(III). Or les deux complexes nouvelle-ment obtenus ont leurs spectres d'absorption très ressemblants. Nous avons déduit tout à l'heure la structure cis-cis du trinitratotri-amminechrome(III) par sa ressemblance avec les bandes du trinitratotriamminecobalt(III); nous pouvons déduire, de la même manière, la structure cis-cis du trinitritotriamminechrome-(III). Le trinitritotriamminecobalt(III) n'est pas encorec onnu, mais, comme on le verra dans la Fig. 1, la première bande d'absorption du *cis-cis*-trinitrotriamminecobalt(III) se situe à 20800 cm^{-1}, celle du *cis-trans*-trinitrotriammine-cobalt(III), à 23000 cm^{-1}. Quand on pense à ce fait que la différence entre le maximum du *cis-cis*-trinitratotriamminecobalt(III) et du *cis-cis*-trinitrotriamminecobalt(III) est de 1800 cm^{-1}, et la différence correspondante des $[Co(NO_2)(NH_3)_5]$ et $[Co(NO_3)(NH_3)_5]$ est de 1800 cm^{-1} [10], on doit trouver très remarquable la différence (3200 cm^{-1}) entre le *cis-trans*-trinitrotriamminecobalt(III) et le trinitritotri-amminechrome(III). Le fait que la différence de situation entre la première bande d'absorption du *cis-cis*-trinitratotriamminechrome(III) et celle du trinitritotriamminechrome(III) est telle, prouvera que celui-ci aussi est de structure *cis-cis*; on peut donc considérer les composés nouveaux ainsi obtenus comme le *cis-cis*-trinitratotriamminechrome(III) et le *cis-cis*-trinitritotriamminechrome(III).

Résumé

Les *cis-cis*-trinitratotriamminechrome(III) et *cis-cis*-trinitritotriamminechrome(III), composés nouveaux, ont été préparés. Ils sont tous les deux sujets à être aquotisés dans l'eau, et leurs spectres d'absorption en la solution n'ont pu être mesurés. Nous avons donc obtenu les spectres d'absorption par la méthode de la réflexion sur la poudre. Nous en avons examiné les résultats, et avons conclu, à l'aide des séries spectrochimiques, que les deux complexes étaient les nitrato- et nitrito-complexes combinés par l'oxygène avec le métal central, et qu'ils avaient la structure cis-cis.

L'auteur exprime ses remerciements sincères à Monsieur le Professeur Taku Uemura pour l'intérêt qu'il a porté à ce travail en lui donnant des conseils utiles, et il est particulièrement reconnaissant envers Monsieur le Professeur Yukio Kondo qui a participé à la discussion sur l'interprétation des résultats.

Studies on the Phosphorescence Spectra. I. Phosphorescence Spectra of 1-Naphthol and 2-Naphthol

By Tohru AZUMI

(Received August 15, 1961)

The phosphorescence spectra of aromatic compounds have been studied rather extensively. Lewis and Kasha[1] showed that the phosphorescent state of a molecule is equivalent to the lowest triplet state. McClure[2] measured the lifetime of the phosphorescence of various aromatic compounds and interpreted his results from the standpoint of spin-orbit interaction[3]. The symmetry consideration of the spin-orbit interaction operator has been made by McClure[4], Weissman[5], and Mizushima and Koide[6]. A quantitative calculation of the spin-orbit interaction has been given by Pople and Sidman[7,8] and by Hameka and Oosterhoff[9]. Research into the triplet states in relation to the molecular compounds has been done by Reid[10,11], Platt et al.[12], Czekalla et al.[13] and McGlynn et al.[14-16]. Moreover, the triplet states of aromatic compounds have been considered to play an important role in various phenomena, for example, in the energy transfer between molecules[14-17] and in photoelectric coductivity[18].

The analyses of the triplet states of simple molecules themselves, however, are as yet incomplete. Before dealing with the application of the triplet states a more thorough examination of the phosphorescence spectra is necessary.

In this paper, as a first step toward this goal, the phosphorescence spectra of 1- and 2-naphthols are presented.

Only a little research into the phosphorescence spectra of naphthols has been undertaken so far. In 1944 Lewis and Kasha[1] observed the phosphorescence spectra of 1- and 2-naphthols and reported the 0, 0-band positions in EPA solvent (5 parts diethyl ether, 5 isopentane, and 2 ethanol) at 20500 cm^{-1} and 21100 cm^{-1} respectively. McClure[2] measured the lifetimes of the phosphorescence and gave 1.9 ± 1 sec. for 1-naphthol and 1.3 ± 1 sec. for 2-naphthol.

Experimental

Apparatus. — The apparatus used is similar in principle to that devised by Heckman[19], and is shown schematically in Fig. 1. A xenon short arc lamp (1 kW) (A) provides an exciting light, which is, after passing through slits (B) and a lens (C), reflected from a front surface aluminum mirror (D) and enters a cell through a quartz window. The cell is cooled by liquid nitrogen and has been evacuated to prevent adverse effects from oxygen molecules and from condensation of air. Phosphorescent light emitted from the surface of the rigid sample is reflected by another mirror and is collimated to a Shimadzu quartz spectrograph (G) with a dispersion of 100 cm^{-1}/mm. around, 25000 cm^{-1}. The exciting light and the phosphorescent light are separated by a Bequellel type phosphoroscope (E)[20]. The exposure times ranged from a few minutes to several hours on Neopan SSS film. Spectrograms were calibrated

with an iron spectrum and were measured with a Riken B-type microphotometer. The maximum precision is believed to be $\pm 5\,cm^{-1}$ for the sharp bands.

Materials. — The solvents used were ethanol, diethyl ether, *n*-hexane, petroleum ether, and carbon tetrachloride. These were purified in the following ways. Ethanol was distilled with sulfuric acid, heated under reflux with potassium hydroxide and silver nitrate, and then distilled. The distillate was dried with activated aluminum amalgam, filtered and distilled. The distillate was further passed through a silica gel-column and was finally distilled. Diethyl ether was shaken with a solution of sodium carbonate, washed with a saturated sodium chloride solution, dried over calcium chloride, distilled over sodium, passed through a silica gel column, and distilled again. *n*-Hexane and petroleum ether were both treated with concentrated sulfuric acid and fuming sulfuric acid, washed with water containing potassium hydroxide, and distilled. Carbon tetrachloride was heated under reflux with potassium hydroxide and distilled. The distillate was again heated with mercury and distilled. The solvents thus purified had no or practically no phosphorescence.

Both 1- and 2-naphthols were recrystallized from ligroin three times. Further purification was made by sublimation under reduced pressure just before measurement.

Results and Discussion

Naphthol exhibits phosphorescence in ethanol and in diethyl ether. The phosphorescence of naphthol in ethanol is more intense than that in ether. In the other solvents used, namely, in *n*-hexane, petroleum ether, and carbon tetrachloride, there is no detectable phosphorescence. When a very small quantity of ethanol, 1% of the total, is added to any of the above solvents, intense phosphorescence can be observed in each case.

The solvent effect upon the intensity of the phosphorescence seems quite complex. The above result resembles that reported by Fernandes and Becker[21], but the same explanation is not possible. Lewis, Lipkin and Magel[22] and Yamamoto[23] have considered that the solvent for the measurement of phosphorescence must have a hydrogen bonding capacity. The above result, however, is not accounted for by their theories. Discussion will be postponed until further experiments have been carried out.

Figures 2 and 3 show the phosphorescence spectra of 1- and 2-naphthols in ethanol, where

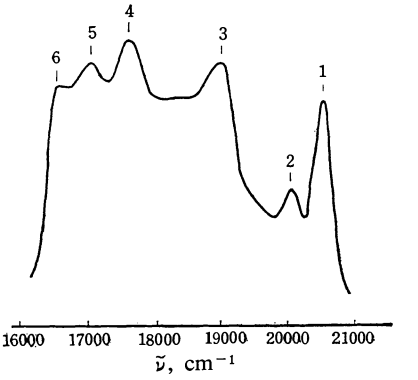

Fig. 2. Phosphorescence spectrum of 1-naphthol.

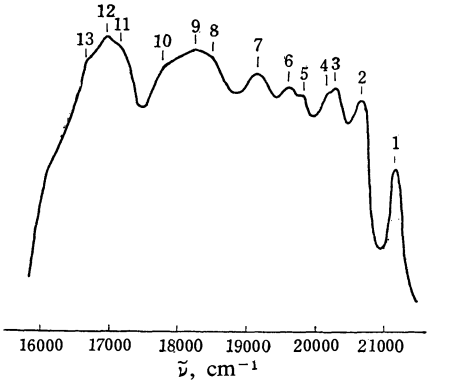

Fig. 3. Phosphorescence spectrum of 2-naphthol.

the ordinates are the plate blackness in arbitrary units. The spectra in ether are almost the same as those in ethanol, except that the latter are less intense.

Vibrational analyses are given in Tables I and II. The infrared and the Raman spectra data determined by the present author are used as a basis of analysis.

A comparison of the spectra of naphthols with the spectrum of naphthalene is of interest. The phosphorescence spectrum of naphthalene was reported by Czekalla et al.[13] As can be seen in Fig. 3, the phosphorescence spectrum of 2-naphthol resembles that of naphthalene in its spectral shape. The spectrum of naphthalene has more vibrational bands than that of 2-naphthol, and every band in the latter, except band 3, has its corresponding band in the former. Both spectra have almost the same progressions. Band 3 at $20325\,cm^{-1}$ in the spectrum of 2-naphthol is quite puzzling. This band is separated by $830\,cm^{-1}$ from the 0, 0-band. Although there is a rather strong band at $842\,cm^{-1}$ in the infrared spectrum, no reasonably matched band is found in the Raman spectrum. Further, there is no corresponding

band in the phosphorescence spectrum of naphthalene. Therefore, in this paper, this band remains unexplained.

The phosphorescence spectrum of 1-naphthol has even fewer vibrational bands than that of 2-naphthol. Bands 4, 5 and 6 are very wide, and their centers could only with difficulty be determined exactly. Every band except band 3 has its counterpart in the spectrum of 2-naphthol and also in that of naphthalene. Band 3 is separated by 1475 cm^{-1} from the 0, 0-band. There is a strong infrared band at 1460 cm^{-1} and a Raman band at 1458 cm^{-1}. Therefore, band 3 may be ascribed to this vibration. However, through comparison of the spectrum of 2-naphthol with the spectra of 1-naphthol and naphthalene, this band is tentatively ascribed to a superposition of 1390 and 1584 cm^{-1}.

As has been stated above, the spectra of 1- and 2-naphthols resemble the spectrum of naphthalene. Accordingly, the lowest triplet state of naphthol may be considered to be like a perturbed triplet state of naphthalene, not a new type of state, such as a charge-transfer state.

Next, the direction of a transition moment will be discussed. Naphthol has no symmetry, apart from its symmetry with respect to the molecular plane. However, on the basis of what has been mentioned above, consideration of a transition moment may be made by analogy with the case of naphthalene.

The 0, 0-band of naphthalene is shifted toward blue by the introduction of a hydroxyl group, as is seen in an ordinary π-π transition. The amount of blue shift is 750 cm^{-1} for 1-naphthol and 145 cm^{-1} for 2-naphthol. That 1-substitution gives rise to a large shift and 2-substitution, to only a small shift shows that the phosphorescence of naphthol, as well as that of naphthalene, has a moment of a short-axis direction. Williams[24] reached the same conclusion by observing the polarization of the phosphorescence of naphthalene.

The author wishs to express my thanks to Professor Hiroshi Azumi for his advice and encouragement.

Studies on Foams. IX[1]. *Foaminess and Foam Stability of Polyvinyl Alcohol Solutions*

By Masayuki NAKAGAKI* and Kazu GOTO

(Received September 18, 1961)

Recently polyvinyl alcohol has been used widely as a synthetic protective colloid soluble in water, e. g., as an emulsifier, a dispersing agent and so forth. In this paper, the protective action for gas particles, that is, the foaminess and foam stability of polyvinyl alcohol solutions, will be studied.

Among the various methods for producing foams[2], such as the pneumatic method, agitation and boiling, the shaking method has thus far been used exclusively in the present series, but this method is not suitable for stable foams like that of polyvinyl alcohol solutions, because sometimes a vessel is filled with the foam after shaking. Therefore, instead of the shaking method, the pour method, which has also been used extensively to test the foaming properties of detergents, will be used in this paper.

Experimental

Materials. — As samples of polyvinyl alcohol, six specimens, Gohsenol GH-20, GM-14, GL-05, NH-20, NM-14 and NL-05, were used. These are the same as those used in previous experiments[3]. The symbol G means partially saponified, (the saponification degree is 87.0~87.6%), and N means almost perfectly saponified (98.8~99.3%) specimens, while 20, 14 and 05 indicate polymerization degrees of about 2000, 1400 and 500 respectively.

A specimen of known weight was put into 800 ml. of distilled water in a flask and left alone at room temperature overnight. Then, after placing the flask in a water bath at room temperature, the bath was warmed up to boiling within 15 min. and kept boiling for 30 min. The flask was then taken out of the bath and cooled by dipping it in cold water, and the solution was transferred to a volumetric flask and made up to 1000 ml. From this original solution, solutions of the desired concentration were prepared by dilution.

Pour Test. — The apparatus used for the pour test is that prescribed by JIS (Japanese Industrial Standards)[4] and similar to that used by Ross and Miles[5]. The apparatus consists of a pipet and a long, cylindrical, jacketted glass receiver. Both the pipet and the receiver are held vertically, and the receiver is kept at 30°C by circulating water from a thermostat. The orifice at the lower end of the pipet is made of a glass capillary tube 2.9 mm. in inner diameter, 7 mm. in outer diameter and 10 mm. in length. The content of the pipet is 200 ml. The upper end of the pipet is connected through a valve with a capillary tube to regulate the flow rate so that the 200 ml. solution in the pipet will fall through the orifice within 30 ± 1 sec. To make the pour test, 50 ml. of the solution is placed in the receiver and 200 ml. is run in from the pipet, the orifice of the latter being held exactly 90 cm. above the surface of the solution in the receiver. The height of the foam thus formed is read, as is its change with time, the time being recorded from just the moment when the pouring of the solution finishes.

Results and Discussion

Change of Foam Height with Time. — The height of the foam zone, A (mm.), was measured at various times, t (min.), for various concentrations of six polyvinyl alcohol solutions. For example, the relation between the foam height and concentration at various times is shown in Fig. 1 for GH-20. At first the curve has a very flat maximum at about 0.4 g./100 ml., but, during the destruction of the foam, another maximum appeared at about 0.1 g./100 ml. and the maximum point was shifted to 0.05 g./100 ml. in time. The similar pattern of GM-14 showed that a slight maximum, which had not been observed at first, appeared at about 0.05 g./100 ml. at $t\simeq4$ min. and disappeared at $t\simeq12$ min. Although no maximum was observed in this case at about 0.4 g./100 ml., the foam height at 0.6~1.0 g./100 ml. remained high until $t\simeq9$ min. The behavior of GL-05 was similar to that of GM-14, except that a maximum of foam height appeared at about 0.01 g./100 ml. during the destruction of the foam. The foam formation of NL-05 was poor, but a maximum of foam height appeared at 0.1 g./100 ml. during the destruction of the foam. On the other hand, the foams of NM-14 and NH-20 were very stable, and the foam height scarcely changed within 35 min.

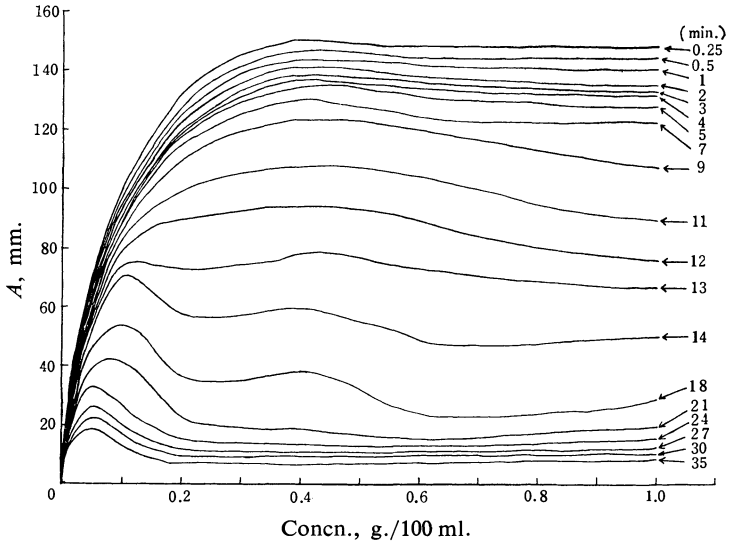

Fig. 1. The relations between foam height and concentration for GH-20 at various times.

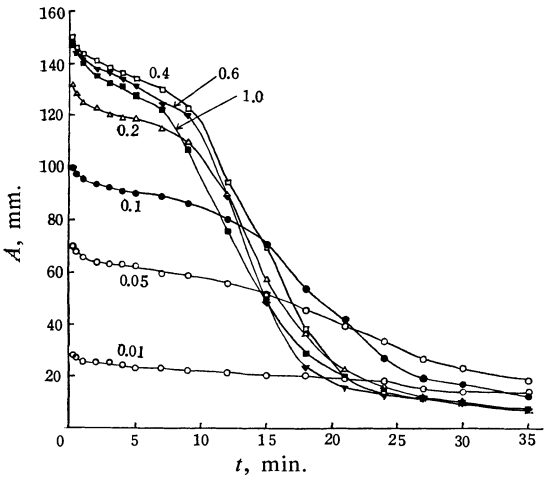

Fig. 2. Time dependence of foam height at various concentrations of GH-20.

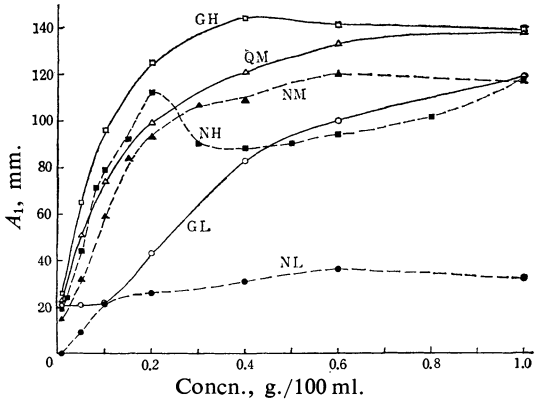

Fig. 3. Relation between foaminess and concentration.

The relationship between the foam height and the time at various concentrations is shown in Fig. 2 for GH-20 as an example. It can be seen that the foam height tends to show a stationary state after about 1 min., and then again rapidly decreases after a certain time. The first rapid decrease of foam height within 1 min. is due to the establishment of a better packing of bubbles in the foam zone, while the second rapid decrease corresponds to the collapse of the foam.

On the basis of these data, the foaminess, lingering fraction and half life of the foam of various polyvinyl alcohol solutions will be discussed.

Foaminess.—In order to show how well the solution foams, the concentration dependence of foaminess is compared in Fig. 3 for six polyvinyl alcohol specimens. As has already been shown above, the foam zone tends to show a steady state at about $t=1$ min., the collapse of foam being not yet serious at that moment. Therefore, the foam height at 1 min., A_1 (mm.), will be of an appropriate quantity to represent the foaminess. The relation between the foaminess, A_1, and the concentration is shown in Fig. 3.

Comparing the partially saponified (G series) and the perfectly saponified (N series) polyvinyl alcohols of the same polymerization degree, the foamer forms better than the latter; that is, GH > NH, GM > NM and GL > NL. Comparing, then, polyvinyl alcohols of the same degree of saponification, the foaminess is the greater, the greater the degree of polymerization; that is, GH > GM > GL and NH > NM > NL, except that NM foams better than NH at the concentration range between 0.26 to

1.0 g./100 ml. It is especially to be noted that the foaminess of NH has a maximum point at about 0.2 g./100 ml.

Lingering Fraction. — In order to compare the stability of foams, the quantity defined by the following equation and called, here, the "lingering fraction" after 35 min., L_{35} (%), is used.

$$L_{35}=(A_{35}/A_1)\times 100 \quad (\%) \qquad (1)$$

where A_{35} is the height of the foam zone remaining after 35 min. The concentration dependencies of the lingering fractions of six polyvinyl alcohol specimens are shown in Fig. 4. At concentrations greater than 0.2 g./100 ml., the foams of partially saponified polyvinyl alcohol solutions are very unstable and mostly collapse within 35 min., while the foams of the perfectly saponified polyvinyl alcohols NM and NH are very stable and practically do not collapse at all within 35 min. The foam of HL is not so stable, but it is still more stable than the partially saponified G specimens. Therefore, the lingering fractions are in the sequence of NH, NM > NL > GH, GM, GL. At concentrations smaller than 0.2%, the lingering fraction of the partially saponified G-series increases with the decrease in the concentration, while the lingering fraction of the perfectly saponified NH and NM decreases with the decrease in the concentration. Therefore, the foams of GH, GM and GL are the less stable, the higher the concentration, while the foams of NH and NM are the more stable, the higher the concentration. On the other hand, the foam of NL has its maximum stability at 0.1 g./100 ml.

Half Life.—Since the decrease in the foam height with time is generally in the manner as shown in Fig. 2, the half life $t_{1/2}$ (min.), defined as the time when the foam height becomes just one half of A_1, is another measure of foam stability. The half lives are shown in Fig. 5, except for NH and NM, the half lives of which can not be determined because the values are greater than 35 min. The curves of unstable GL, GM and GH foams, overlapped

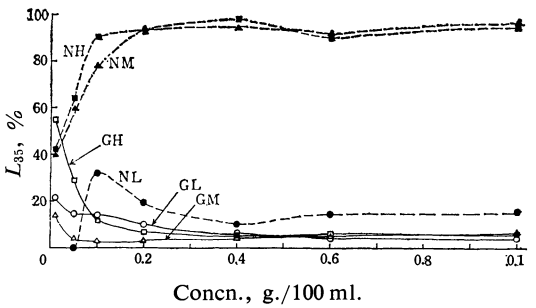

Fig. 4. Relation between lingering fraction and concentration.

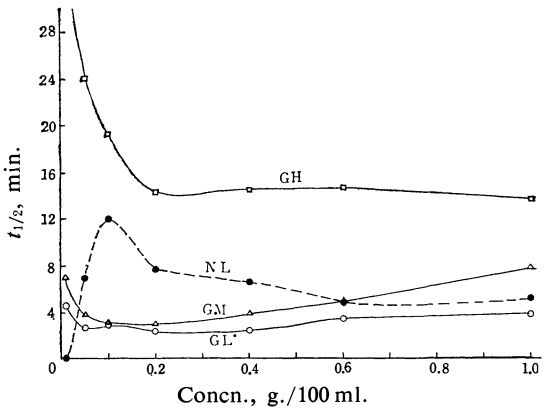

Fig. 5. Relation between half life and concentration. The half lives of NH and NM are not shown here.

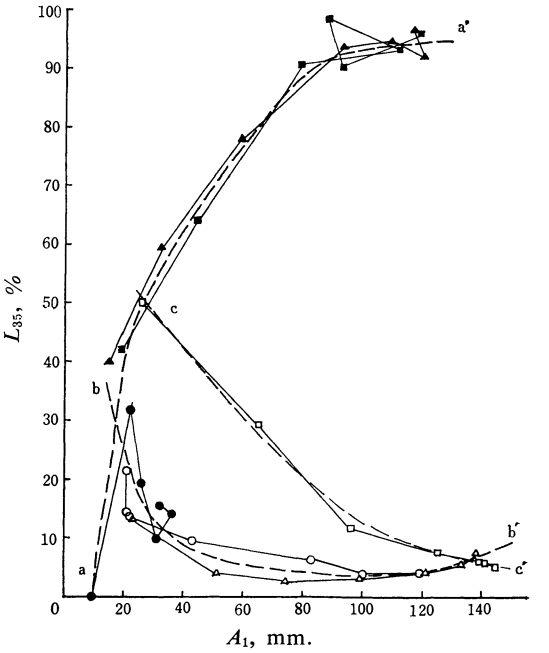

Fig. 6. The relation between A_1 and L_{35} for NH (■), NM (▲), NL (●), GH (□), GM (△) and GL (○).

with each other in Fig. 4, have been separated clearly in Fig. 5. The features observed in both Fig. 4 and Fig. 5 are that the foam stability of GH, GM and GL increases with the decreasing concentration, and that the stability of NL reaches its maximum at about 0.1 g./100 ml. In Fig. 5, however, the points different from Fig. 4 are that half life of GH is greater than that of NL, GM and GL, and that the half life of GM is greater than GL. Consequently, the sequence of half lives is NH, NM > GH > (NL) > GM > GL, although the half life of NL varies greatly with the concentration.

Relation between Foaminess and Foam Stability.—In preceding papers of the present series[6], it has been observed that the foaminess and foam stability are parallel for at least unstable foams formed by shaking. In the case of stable foams of polyvinyl alcohol solutions formed by the pour method, however, the foaminess and foam stability are not always parallel. The relation between the foaminess A_1 and the lingering fraction L_{35} is illustrated in Fig. 6. In this figure, experimental plots are connected with straight lines in the order of concentration. Experimental plots for NH, NM and low concentration solutions of NL are located along a dotted curve, aa′, which indicates that the foam stability is the greater, the greater the foaminess. However, experimental plots for GH, GM, GL and high concentration solutions of NL are located along two dotted curves, bb′ and cc′, which indicates that the foam stability is the greater, the smaller the foaminess, although curve bb′ has a flat minimum and goes up again at high concentrations, at this range the foam stability being the greater, the greater the foaminess. The increase in foam stability at high concentrations of GM and GL has already been shown in Fig. 5.

Summary

The foaminess and foam stability of six polyvinyl alcohol solutions, GH-20, GM-14, GL-05, NH-20, NM-14 and NL-05, were measured by the pour test; the foaminess was represented by the height of the foam zone after 1 min., and the foam stability was represented either by the lingering fraction after 35 min. or by the half life of the foam.

The foaminess of the partially saponified polyvinyl alcohols was greater than that of the perfectly saponified ones of the corresponding molecular weights. Comparing specimens of the same degree of saponification, the foaminess was the greater, the greater the molecular weight. The foaminess was also the greater, the greater the concentration, except for NH, the fomianess of the latter showing a maximum at about 0.2 g./100 ml.

The foam stability of NH and NM was very large, but that of NL was small and showed a maximum at 0.1 g./100 ml. The foam stabilities of GH, GM and GL were small. Comparing the foaminess and the foam stability, these two quantities varied in a parallel manner in the cases of NH, NM, low concentrations of NL, and high concentrations of GM and GL, but in other cases they varied conversely.

The authors wish to thank Nippon Gosei Kagaku Kogyo Co., Ltd., which provided Gohsenols.

Studies on Antibiotics and Related Substances. XIII. Syntheses of 10-Methylene-11-oxododecanoic Acid and 9-Methylene-10-oxo-undecanoic Acid, Antitumor Substances[1]

By Mitsuhiro KINOSHITA, Saburō NAKADA and Sumio UMEZAWA

(Received May 29, 1961)

In previous papers[2], syntheses and antitumor activities of a series of carboxylic acids containing a terminal methylene-keto group were reported. In the course of synthesizing the above mentioned series of carboxylic acids through the corresponding Mannich bases, we found the formation of two kinds of Mannich base isomers in respect to the active methylene groups at either side of the ketone group, and reported[2] the syntheses of β-methylenelevulinic acid and 4-keto-3-methylenepentane-1-carboxylic acid. The present paper is concerned with an extention of this work and presents the syntheses and antitumor activities of 10-methylene-11-oxododecanoic acid (IVa) and 9-methylene-10-oxoundecanoic acid (IVb). The

10-Methylene-11-oxododecanoic Acid (IVa). —10-(Dimethylaminomethyl)-11-oxododecanoic acid hydrochloride (Ia) has been isolated from the mother liquor recovered from the crystallization of the main product[3]. The new Mannich base hydrochloride was esterified, changed into its free base and then converted into a methiodide IIa. Thermal degradation of the methiodide to the desired methylene ester IIIa took place smoothly in a yield of 61%. Hydrolysis of the ester with an aqueous acetone solution of sulfuric acid afforded 10-methylene-11-oxododecanoic acid (IVa).

The ultraviolet absorption spectra of IIIa and IVa in methanol solution showed peaks at 220.5, 319 mμ and 221, 319 mμ, respectively, indicating the presence of α,β-unsaturated ketone group (Fig. 1). The infrared absorption characteristics of IIIa and IVa were just as expected, showing the presence of double

bond, conjugated carbonyl and carboxyl groups (Figs. 2 and 3).

9-Methylene-10-oxoundecanoic Acid (IVb). — 9-(Dimethylaminomethyl)-10-oxoundecanoic acid hydrochloride (Ib) has been isolated from the mother liquor recovered from the crystallization of 12-(dimethylamino)-10-oxododecanoic acid[3]. An analogous sequence of reactions as described above in the synthesis of IVa has been applied to afford the title compound.

Both 10-methylene-11-oxododecanoic acid (IVa) and 9-methylene-10-oxoundecanoic acid (IVb) has been found to possess strong antitumor activity in vitro. However, in contrast to 11-oxo-11-dodecenoic acid[2] having the methylene-keto group at the end of straight carbon chain, the activities of both VIa and VIb were unexpectedly weak in vivo tests.

Experimental

10-(Dimethylaminomethyl)-11-oxododecanoic Acid Hydrochloride (Ia).—The mother liquors remaining after filtration of 13-(dimethylamino)-11-oxotridecanoic acid hydrochloride (10.8 g.) previously described[3] were combined and concentrated in vacuo. The oily residue was dissolved in water (25 ml.) and the solution was extracted with four 15 ml. portions of ether to recover the unchanged keto acid (crude 2.5 g.). The aqueous layer was washed with chloroform several times and evaporated to give a yellow oil (15 g.) which, on standing, slowly turned to a crystalline solid intermixed with oil. Trituration with absolute acetone gave 8.5 g. (24.7%) of colorless crystals, m. p. 96～99°C. Three recrystallizations from absolute methanol-ether afforded an analytical sample of 10-(dimethylaminomethyl)-11-oxododecanoic acid hydrochloride (Ia), colorless needles, m. p. 102～103°C. The product gave a positive iodoform reaction.

Found: C, 58.90; H, 9.36; N, 4.55. Calcd. for $C_{15}H_{30}O_3NCl$: C, 58.54; H, 9.83; N, 4.56%.

Methyl 10-(Dimethylaminomethyl)-11-oxododecanoate Methiodide (IIa).—A mixture of Ia (3.5 g.) and absolute methanol (35 ml.) was saturated with dry hydrogen chloride and allowed to stand overnight. The solvent was removed by distillation in vacuo. The resulting viscous orange-yellow oil (4 g.) was dissolved in water (5.2 ml.) and to this solution was added 50% aqueous potassium carbonate solution (8.7 ml.). The separated oil was extracted with three 12 ml. portions of ether. After being dried over fused potassium acetate, the etherial extract was evaporated to give free amine ester as a slightly yellow liquid (2.5 g., 70.7%). To the etherial solution of the product was added methyl iodide (12 g.) to give a crystalline methiodide (IIa), which was collected and washed with ether, yield 3.5 g. (93.3% from free amine ester). Two recrystallizations from methanol-ether gave an analytical sample m. p. 80.5～81.5°C.

Found: C, 47.60; H, 7.70; N, 3.76; I, 29.60. Calcd. for $C_{17}H_{34}O_3NI$: C, 47.79; H, 7.96; N, 3.28; I, 29.69%.

Methyl 10-Methylene-11-oxododecanoate (IIIa). —The above methiodide (IIa) (3.5 g.) was placed in a small distillation flask and heated at 185～200°C in an oil bath under highly reduced pressure (0.05 mmHg). The resulting oil was redistillated to afford a colorless liquid of methyl 10-methylene-11-oxododecanoate (IIIa), yield 1.2 g. (61%), b. p. (bath temp.) 87～93°C/0.002 mmHg, m. p. 20～22°C; λ_{max}^{MeOH} 220.5 (ε 8170) and 319 mμ (ε 35.9); IR, 1748 (ester C=O), 1688 (conjugated C=O), and 1638 cm^{-1} (C=C) (liquid).

Found: C, 70.10; H, 9.82. Calcd. for $C_{14}H_{24}O_3$: C, 69.96; H, 10.0%.

10-Methylene-11-oxododecanoic Acid (IVa).—A solution of the above ester IIIa (1.15 g.) in a mixture (35 ml.) of acetone, water and concentrated sulfuric acid (18 : 15 : 1 by volume) was allowed to stand for 3 days at 20～22°C. The reaction mixture was neutralized with a saturated solution of sodium bicarbonate and evaporated to remove acetone at about 40°C. The residual solution was shaken with ether to remove any unchanged ester. The aqueous layer was adjusted to pH 2.5 with 3 N hydrochloric acid and again extracted with ether. Evaporation of the dried etherial extract afforded crude crystals of 10-methylene-11-oxododecanoic acid (IVa), yield 0.95 g. (87%), m. p. 28～33°C. Recrystallization from ether gave fine needles, m. p. 33～35°C. λ_{max}^{MeOH} 221 (ε 8280) and 319 mμ (ε 33.6); IR, 2700～2500 (carboxyl OH), 1702 (carboxyl C=O), 1675 (conjugated C=O) and 1630 cm^{-1} (C=C) (Nujol).

Found: C, 68.96; H, 9.62. Calcd. for $C_{13}H_{22}O_3$: C, 68.99; H, 9.80%.

Methyl 9-Methylene-10-oxoundecanoate (IIIb).— The mother liquor remaining after filtration of 12-(dimethylamino)-10-oxododecanoic acid (7.7 g.) previously described[3] was processed by the same procedure as employed for the preparation of Ia to afford a hygroscopic crude product of 9-(dimethylaminomethyl)-10-oxoundecanoic acid hydrochloride (Ib), yield 9.9 g., m. p. 74～79°C. The crude hydrochloride (5 g.) was esterified with methanol-hydrogen chloride and the resulting methyl ester hydrochloride was changed to the free amine ester in the same manner as described in preceding paragraph, yield 3.2 g. (crude). To a solution of the free amine (3.2 g.) in benzene (14 ml.) and acetone (9 ml.) was added methyl iodide (16 g.) and the mixture was allowed to stand for 3 days at room temperature. The resulting crystalline solid was the methiodide of methyl 12-(dimethylamino)-10-oxododecanoate and was removed by centrifuging. The supernatant layer was evaporated to afford the desired methiodide IIb as an orange viscous syrup which did not crystallize, yield 4.7 g. To a solution of the crude methiodide in water (11 ml.) was added 10% aqueous potassium bicarbonate solution (23 ml.) and the mixture was allowed to stand for 2 days at 20°C and then extracted with ether. The ether layer was washed with 0.1 N sulfuric acid and with water. After being dried over fused potassium acetate, the etherial extract was evaporated to afford 1.6 g. of crude methyl 9-methylene-10-oxoundecanoate (IIIb) as a slightly yellow liquid. Redistillation of the

crude material gave a pure sample, colorless liquid, yield 1.54 g. (40% based on the crude Mannich base hydrochloride (Ib)), b. p. (bath temp.) 85~87°C/0.005 mmHg., m. p. 8.0~9.1°C, λ_{max}^{MeOH} 220.5 (ε 8720) and 318 mμ (ε 37.1); IR, 1745 (ester C=O), 1686 (conjugated C=O) and 1627 cm^{-1} (C=C) (liquid).

Found: C, 69.11; H, 9.51. Calcd. for $C_{13}H_{22}O_3$: C, 68.99; H, 9.80%.

9-Methylene-10-oxoundecanoic Acid (IVb).—Hydrolysis of IIIb (1.1 g.) by the same procedure as employed for the preparation of IVa gave crude crystals of the title compound, yield 0.9 g. (87.5%), m. p. 37.0~38.2°C. Recrystallization from ether afforded a pure sample, fine prisms, m. p. 38.2~38.7°C; λ_{max}^{MeOH} 220.5 (ε 8350) and 318 mμ (ε 31.8), IR, 2700~2500 (carboxyl OH), 1714 (carboxyl C=O), 1682 (conjugated C=O) and 1632 cm^{-1} (C=C) (Nujol).

Found: C, 67.88; H, 9.22. Calcd. for $C_{12}H_{20}O_3$: C, 67.89; H, 9.50%.

Bioassays[4].—The minimum necessary concentrations of both 10-methylene-11-oxododecanoic acid (IVa) and 9-methylene-10-oxoundecanoic acid (IVb) for the anti-HeLa cell effect were 125 mcg/ml. Against cells of Ehrlich carcinoma, both IVa and IVb had a potency of 1.9 units/mg. (in terms of sarkomycin potency) by cylinder plate method. From these values it seemed that antitumor potencies of IVa and IVb are about the same with those of 11-oxo-12-tridecenoic acid and 10-oxo-11-dodecenoic acid[3] which have the methylene-keto group at the end of straight carbon chain. However, the daily intraperitoneal injections of 300 mcg/mouse were almost ineffective for mice bearing the ascites type of Ehrlich carcinoma by intraperitoneal route. Intravenous acute toxicity test of IVa and IVb in mice indicated the same LD_{50} dose of 670 mcg/mouse.

Summary

1) 10-(Dimethylaminomethyl)-11-oxododecanoic acid hydrochloride (Ia) and 9-(dimethylaminomethyl)-10-oxoundecanoic acid (Ib) have been obtained from the mother liquors remaining after filtration of 13-(dimethylamino)-11-oxotridecanoic acid hydrochloride and 12-(dimethylamino)-10-oxododecanoic acid hydrochloride, respectively.

2) 10-Methylene-11-oxododecanoic acid (IVa) and 9-methylene-10-oxoundecanoic acid (IVb) have been synthesized from the Mannich bases Ia and Ib, respectively.

3) Antitumor activities of IVa and IVb have been described.

The authors are indebted to Professor Hamao Umezawa, National Institute of Health, Tokyo, for antitumor assays. This work has been supported in part by the Cancer Research Grant of the Ministry of Education and by grant from the Research Society of Microbiological Chemistry, to which the authors' thanks are due.

Dipole Moments of Polyethylene Glycol Diethyl Ethers

By Akira KOTERA, Keizo SUZUKI, Kimiyoshi MATSUMURA, Takao NAKANO, Toshiko OYAMA and Utako KAMBAYASHI

(Received September 5, 1961)

The configurations of high polymer molecules can be studied in various ways; the measurement of their dipole moments is considered to be one of the important of these methods.

Studies have been made, therefore, of some high polymer compounds and, particularly, of the high polymer molecules with elementary dipoles along the polymer chain, for the molecules of the lower degree of polymerization are synthesized easily and the relation of their dipole moments with the degree of polymerization thus made manifest. The series of polyoxymethylene dimethyl ethers, polyethylene glycols and polyethylene glycol diethyl ethers have been studied for this purpose.

This report presents a study in detail of the dipole moments of the lower-membered polyethylene glycol diethyl ethers and to decide the configuration of their skeleton.

Experimental

Polyethylene glycol diethyl ethers are generally represented by the formula; C_2H_5-O-$(C_2H_4$-O$)_p$-C_2H_5.

We studied six compounds of which p were 1, 2,

3, 4, 5 and 6 respectively. They were prepared by the condensation reactions as follows: ethylene glycol diethyl ether ($p=1$), b. p. 121°C, from ethyl bromide and sodium salt of ethylene glycol monoethyl ether (cellosolve); diethylene glycol diethyl ether ($p=2$), b. p. 186°C, from ethyl bromide and sodium salt of diethylene glycol monoethyl ether (carbitol); triethylene glycol diethyl ether ($p=3$), b. p. 118°C/10 mmHg, from ethyl bromide and sodium salt of triethylene glycol monoethyl ether; tetraethylene glycol diethyl ether ($p=4$), b. p. 159°C/10 mmHg, from $\beta\beta'$-dichlorodiethyl ether and sodium salt of cellosolve; pentaethylene glycol diethyl ether ($p=5$), b. p. 175°C/3 mmHg, from ethylene glycol $\beta\beta'$-dichlorodiethyl ether and sodium salt of cellosolve; hexaethylene glycol diethyl ether ($p=6$), b. p. 157°C/0.15 mmHg, from $\beta\beta'$-dichlorodiethyl ether and sodium salt of carbitol.

The dielectric constants and the specific volumes of benzene solutions of these compounds were measured at 25°C and at 50°C.

For the calculation of the molecular polarization at infinite dilution, $P_{2\infty}$, the following equations presented by Halverstadt and Kumler[1] were used;

$$P_{2\infty}=M\left\{(v_0+\beta)\frac{\varepsilon_0-1}{\varepsilon_0+2}+\frac{3\alpha v_0}{(\varepsilon_0+2)^2}\right\}$$

$$\alpha=\frac{\varepsilon-\varepsilon_0}{w},\ \beta=\frac{v-v_0}{w}$$

where M is the molecular weight, ε_0 and v_0 are the dielectric constant and the specific volume of solvent, ε and v are those of solution, and w is the weight fraction of the solute.

For the calculation of the dipole moments, we assume that the value of P_A+P_E is $1.1\,MR_D$, since it is so in diethyl ether[2], while P_A and P_E are the atomic polarization and the electronic polarization, and MR_D is the molecular refraction for the D line.

The observed values and the resultant dipole moments are shown in Table I.

Marchal and Benoit[3] measured the dipole moments of diethylene glycol diethyl ether and hexaethylene glycol diethyl ether at 20°C; they obtained 1.99 and 2.93 D respectively. But they used the equation:

$$\mu^2=4.92\times10^{-4}Tv_0M(\alpha-\gamma)/(\varepsilon_0+2)^2$$

where $\gamma=\lim_{w=0}\partial n^2/\partial w$, and n is the refractive index of solution. That is, they assumed that P_A+P_E equals to MR_D. If they had adopted our assumption ($1.1\,MR_D$), they would have obtained 1.93 D and 2.86 D, respectively. These values are in good agreement with our results.

Discussion

Theoretical Treatment.—we define the following notations to examine the observed data, and to calculate the dipole moments for these compounds[4];

$\vec{a}_i$: the unit vector representing the direction of the ith bond of the molecule ($i=0, 1, 2, \cdots 4+3p$). $\vec{a}_{3h}$, $\vec{a}_{3h+1}$ and $\vec{a}_{3h+2}$ represent C–C, C–O and O–C bonds respectively.

μ_i: the dipole moment of the hth bond.

$\vec{\mu}_{3h}=0$, $\vec{\mu}_{3h+1}=-\mu_{CO}\vec{a}_{3h+1}$, $\vec{\mu}_{3h+2}=+\mu_{CO}\vec{a}_{3h+2}$

μ: the total dipole moment of a molecule.

ρ_{ij}: the angle between $\vec{a}_i$ and $\vec{a}_j$. $\rho_{i-1,i}$ is the supplement of the bond angle of the ith atom, and was assumed to be 70.5° in this paper, that is, $\langle\cos\rho_{i-1,i}\rangle=1/3\equiv c$.

φ_i: the rotation angle around the ith bond; $=0$ when $\vec{a}_{i+1}$ is parallel to $\vec{a}_{i-1}$.

b_i: the average value of $\cos\varphi_i$, i. e. $\langle\cos\varphi_i\rangle$;

$b_0=b_3=b_6=\cdots\equiv b_C$ around the C–C bond.

$b_1=b_2=b_4=\cdots\equiv b_O$ around the C–O bond.

TABLE I. THE OBSERVED VALUES OF THE COMPOUNDS

p	Temp. °C	ε_0	v_0 cc./g	α	β	$P_{2\infty}$ cc.	MR_D cc.	μ^* D

	50	2.223	1.181	2.233	−0.124	187.2	66.6	2.46
5	25	2.273	1.144	2.491	−0.135	226.9	77.7	2.63
	50	2.223	1.180	2.268	−0.151	220.5	77.7	2.67
6	25	2.273	1.144	2.505	−0.141	260.5	88.7	2.82
	50	2.223	1.180	2.313	−0.156	255.8	88.7	2.89

* For the calculations of the dipole moments we assumed that P_A+P_E equals to $1.1\,MR_D$.

1) I. F. Halverstadt and W. D. Kumler, *J. Am. Chem. Soc.*, **64**, 2988 (1942).
2) R. J. W. Le Fèvre, "Dipole Moments", Methuen & Co., London (1953).
3) J. Marchal and H. Benoit, *J. Chim. Phys.*, **52**, 818 (1955); *J. Polymer Sci.*, **23**, 223 (1957).
4) The theory is previously proposed by one of the authors, K. Suzuki, This Bulletin, **20**, 19 (1947).

μ_{CO} was assumed to be 1.04 D, because of the value 1.22 D of diethyl ether in benzene and because of the valency angle of the oxygen atom, 108°.

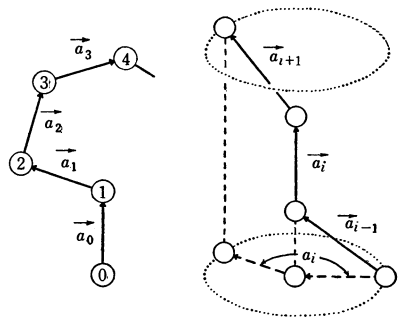

Fig. 1. The feature of the bond vectors.

The total dipole moment of a molecule is expressed by the elementary dipole moments as follows:

$$\langle\mu^2\rangle=\sum_i\mu_i^2+2\sum_{i<j}\sum\mu_i\mu_j\langle\cos\rho_{i,j}\rangle \qquad (1)$$

Assuming that the bond angle of an oxygen atom is equal to that of a carbon atom, i. e.,

$$\langle\cos\rho_{i-1,i}\rangle=c \qquad (2)$$

we have the equations,

$$\langle\cos\rho_{i-2,i}\rangle=c^2(1+b_{i-1})-b_{i-1} \qquad (3)$$

$$\langle\cos\rho_{h,i}\rangle=c(1+b_{i-1})\langle\cos\rho_{h,i-1}\rangle - b_{i-1}\langle\cos\rho_{h,i-2}\rangle \quad \text{for } i\rangle h+2 \qquad (4)$$

Because $\langle\cos\rho_{3i+m,\,3i+m+k}\rangle$ are independent of i (m=0, 1, 2), Eq. 1 leads to

$$\langle\mu^2\rangle=2\mu_{CO}^2\{(p+1)(1-c)+\sum_{i=1}^{p}(p+1-i)(\langle\cos\rho_{1,3i+1}\rangle-\langle\cos\rho_{2,3i+1}\rangle-\langle\cos\rho_{1,3i+2}\rangle+\langle\cos\rho_{2,3i+2}\rangle)\} \qquad (5)$$

in which $\langle\cos\rho_{1,3i+1}\rangle$ etc. can be given by Eq. 4 step by step.

Discussion of Results.—It is well known that the potential minima around each bond in the molecules are close to the trans position (φ=180°, b=−1) or the gauche positions (φ=60° or −60°, b=0.5). Hence, we can assume that the various models having the various trans and gauche forms for each bond in the molecule. The values of the dipole moments of these models, as calculated by Eq. 5, are plotted in Fig. 2.

As shown in Fig. 2, the calculated dipole moments of these compounds do not coincide with the observed ones.

In Fig. 2, when b_C is equal to b_O, it means that the potential values around the C–C bond and the C–O bond are the same; i. e., when $b_C=b_O=-1$, the model of the bonds is a series of trans forms, and similarly, when $b_C=b_O=0.5$ and $b_C=b_O=0$, the models are series of gauche forms and free rotation forms respectively. And in the case $b_C\neq b_O$, the models of the bonds consist of a mixture of the trans, gauche and free rotation forms.

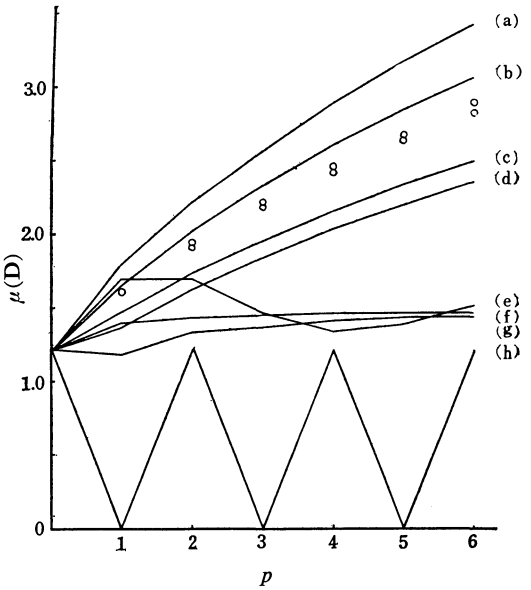

Fig. 2. The calculated moments of the compounds.

(a)	b_C=0.5	b_O=0	(f)	b_C=0	b_O=−1
(b)	0	0		−1	0
(c)	0.5	0.5	(g)	−1	0.5
(d)	0	0.5	(h)	−1	−1
(e)	0.5	−1	○	Observed values	

Furthermore, as shown in Fig. 2, when b_C or b_O is equal to −1, the calculated values of the dipole moments of the models are plotted in a zigzag manner with the increase of p, the degree of polymerization. This fact is in disagreement with the tendency that the observed moments increase in a simple way with the increase of p.

The following hypothesis about the configuration of these polyethylene glycol diethyl ethers may therefore be possible:

1) These compounds consist of a mixture of the various rotational isomers, as shown in Fig. 2. By this hypothesis, the temperature dependence of the observed moments can be explained by the assumption that the mixture ratio of the rotational isomers changes.

In the case of polyoxymethylene dimethyl ethers, it was concluded that their configurations consist of a mixture of various rotational isomers, the predominant ones of which are herical or almost herical structures arising from the gauche minima[5].

5) T. Uchida, Y. Kurita and M. Kubo, *J. Polymer Sci.* 22, 365 (1956).

2) The value of the angle φ in the stable position slightly differs from 180° (trans position), 60° and −60° (gauche positions).

About the configurations of polyethylene glycols, Uchida et al.[6] concluded that these compounds are in a free rotational state in dioxane solutions; on the other hand, about the configurations of polyethylene glycols and polyethylene glycol diethyl ethers in benzene solutions, Marchal and Benoit[3] concluded that the value of b, which is identical with b_C and b_O in this report, is ±0.3. Although Marchal and Benoit do not make any distinction between the value of b_C and that of b_O, these values are generally different. Let us therefore study the relation between the value of b_C and that of b_O to explain the observed dipole moment sufficiently.

When the value of μ in Eq. 5 is taken as the observed value, Fig. 3 can be obtained by plotting the values of b_C and b_O as calculated from Eq. 5.

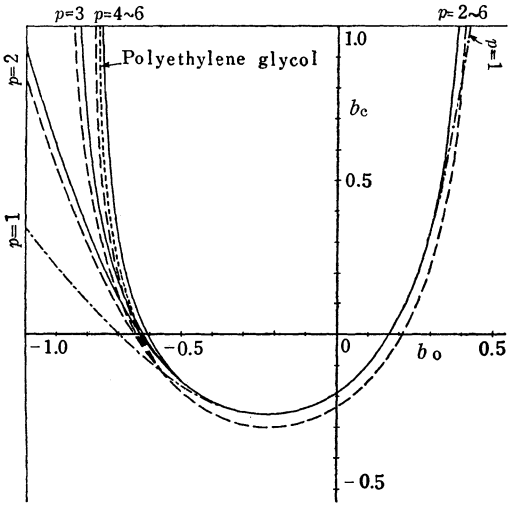

Fig. 3. The relations between the value of b_C and that of b_O.
———; at 25°C (p=2~6)
———; at 50°C (p=2~6)
—·—·; at 25°C and at 50°C (p=1)
------; at 20°C (polyethylene glycol, p=79 and 227)

As shown in Fig. 3, the curve which explains the relation between the value of b_C and that of b_O at 50°C passes the points nearer to the place of origin, where $b_C=b_O=0$, than the curve at 25°C. This fact is considered to show that with the increase in temperature the internal rotations about each bond get more like the free rotation. Moreover, the b_C~b_O curves for the case of p=1 at 25°C are identical with that at 50°C, and this curve for p=1 coincides with the curve for p=2~6 at 50°C.

When p is very large, it is expected that the value of the dipole moment per oxygen atom of polyethylene glycol diethyl ether will be the same as that of polyethylene glycol. Marchal and Benoit[3] measured the value of $\mu^2/p+1$ in a series of polyethylene glycols at 20°C in benzene solutions and got 1.16 when p is 79 and 1.15 when p is 227. They assumed that P_A+P_E is equal to MR_D, but if we assume that P_A+P_E is equal to $1.1MR_D$, the above-mentioned values are 1.11 and 1.10 respectively. The b_C~b_O curve from these values is almost in full agreement with the curve for polyethylene glycol diethyl ethers at 25°C, as is shown in Fig. 3.

In Fig. 3, if we compare the b_C~b_O curves for the compounds, the curves for p=1, 2 and 3 are fairly different from the curves for p=4~6 under the condition $b_O<-0.5$. Therefore, the value of b_O for the compounds should be larger than −0.5, if it is assumed that the degree of the internal rotation around the each bond is independent of the degree of polymerization of the compounds. In fact, under the condition of $b_O<-0.5$, the calculated dipole moments of the compounds are plotted in a zigzag manner when p becomes large. This tendency of the relation between the calculated moments and p disagrees with that of the observed moments and p. Furthermore, as shown in Fig. 3, the value of b_O lies within the range of −0.5~0.4, and in this range we can select a pair of b_C and b_O satisfying the relation between the observed moments and p.

It is considered that the interaction between two C–O dipoles connected with both sides of the C–C bond is fairly large, while the interaction between the C–O dipole and the C–C bond, without the moment, each at one end of the C–O bond, is fairly small. The interactions between the elementary dipoles of each above-mentioned bond make it necessary that the value of b_O be nearer to zero than that of b_C. Taking the above condition, the range of the value of b_O is obtained from Fig. 3; $b_O=-0.3$~0.13 and $b_O>0.28$. However, since the range $b_O=-0.3$~0.13 corresponds to the range $b_C=-0.3$~-0.1 and since these ranges show that each bond takes the positions of the potential maxima, it is considered that these ranges are unreasonable as a basis for explaining the configurations of these compounds, considering the intramolecular potential.

On the other hand, if each bond in the molecule is at the fixed position near the potential minima, the value of b_C should be

6) T. Uchida, Y. Kurita, N. Koizumi and M. Kubo, ibid., 22, 313 (1956).

closer to -1 (trans) or to 0.5 (gauche) than the value of b_O, since interaction between the elementary dipoles exists. The case of $b_C = -1$ cannot then exist, as is shown in Fig. 3; consequently the value of b_C is close to 0.5. Therefore, (1) when the value of b_C is equal to 0.5, the values of b_O are 0.36 (25°C) and 0.33 (50°C), and (2) when the value of b_C is relatively closer to 0.5 than the value of b_O, the range of the value of b_C is 0.3∼0.65.

From what we have seen, it can be concluded that two C–O bonds around the C–C bond approximately take the gauche positions with regard to each other.

Summary

The dipole moments of six lower members of the polyethylene glycol diethyl ethers have been measured, and their configurations have been studied.

As the configurations of these compounds the two models have been considered; one is a mixture of the various rotational isomers, and the other a model in which the positions of the internal rotations of two C–O bonds around the C–C bond approximately take the gauche positions with regard to each other, and the positions of the C–O bond and the C–C bond around the C–O bond take positions similar to those mentioned above with regard to each other.

Dipole Moments of Organosilicon Compounds

By Kimiyoshi MATSUMURA

(Received September 20, 1961)

Although organosilicon chemistry, which has made remarkable progress recently, has produced a large number of new compounds, their molecular configurations remain unknown. The present author has, therefore, been studying them by the determination of their dipole moments, and several of his results will be reported on here.

Experimental

The compounds which have been measured for the present work are:

(I) Methoxytrimethylsilane b.p. 56.1~57.3°C
(II) Dimethoxydimethylsilane b.p. 80.5°C
(III) Trimethoxymethylsilane b.p. 103.5°C
(IV) Tetramethoxysilane b.p. 121.5°C
(V) Tetra-trimethylsiloxy-silane
(VI) Methoxytrichlorosilane
(VII) Dimethoxydichlorosilane
(VIII) Trimethoxychlorosilane.

Of these compounds, tetra-trimethylsiloxy-silane (V) and three methoxychlorosilanes (VI, VII and VIII) were furnished to us by Mr. M. Yokoi of Shinshu University and Mr. H. Murata of Hiroshima University respectively. The others were prepared by the reactions of methyl alcohol upon the corresponding methylhalosilanes[1].

The dielectric constants and the specific volumes of the benzene solutions were measured at 25 and 50°C.

For the calculation of the molecular polarization of the solute at infinite dilution, $P_{2\infty}$, the following equations proposed by Halverstadt and Kumler[2] were used:

$$P_{2\infty}=M\left\{(v_0+\beta)\frac{\varepsilon_0-1}{\varepsilon_0+2}+\frac{3\alpha v_0}{(\varepsilon_0+2)^2}\right\}$$

$$\alpha=\frac{\varepsilon-\varepsilon_0}{w},\quad \beta=\frac{v-v_0}{w}$$

where M is the molecular weight, ε_0 and v_0 are the dielectric constant and the specific volume of the solvent respectively, ε and v are those of the solution, and w is the weight fraction of the solute in the solution.

For the calculation of the dipole moment, (P_A+P_E) is assumed to be 1.1 MR_D, as in the case of hexamethyldisiloxane[3], where P_A and P_E are the atomic polarization and the electronic polarization respectively, and MR_D is the molar refraction for the D line. The results are shown in Table I.

Results and Discussion

Assumed Bond Angles and Bond Moments.—To determine the configurations of the compounds, the bond angles and bond moments

used for the calculations of the dipole moments were assumed as follows.

The bond angle of the silicon atom is tetrahedral, and angle SiOC is assumed to be 113° from the results of the electron diffraction study of tetramethoxysilane[4] and methoxytrichlorosilane[5]. Angle SiOSi for tetra-trimethylsiloxy-silane is assumed to be 140° from the results of the electron diffraction study[4].

The CH_3O group moment, 1.15D, is calculated from the dipole moment of methyl ether, 1.29 D[6], and its angle COC, 111.5°[7]. For the group moment of $(CH_3)_3SiO$, Kurita and Kondo obtained 0.95 D[3] from the dipole moment of hexamethyldisiloxane, 0.80D, assuming that angle SiOSi is 130°[4]. However, the $(CH_3)_3SiO$ group moment is assumed to be 1.05D, assuming that angle SiOSi is 135°*. Therefore, 1.65D is obtained for the SiO bond moment and 0.60D for the CH_3Si group moment.

The SiCl bond moment 2.94D is calculated from the dipole moment study of methoxytrichlorosilane in this report, as will be shown below.

Assumed Configurations.—Using the above bond angles and bond moments, the present author calculated the dipole moments of the compounds, assuming the following models:

1) Fundamental Models (trans and gauche Models).—The CH_3 groups of the CH_3O groups and the $(CH_3)_3Si$ groups of the $(CH_3)_3SiO$ groups are at trans or gauche positions with regard to the nonbonding oxygen atoms. The cis models were rejected because of their instability.

The trans and gauche positions are shown in Figs. 1—3; $a_1, b_1, c_1 \cdots\cdots$ are the positions of the CH_3 groups in Figs. 1 and 2, and of the CH_3 groups or $(CH_3)_3Si$ groups in Fig. 3.

2) The Free Rotation Model.—The CH_3 groups and the $(CH_3)_3Si$ groups are rotating around the SiO bonds freely.

The calculated dipole moments for these models, 1) and 2), are shown in Tables II, IV, VI, VIII, X and XII. Moreover, as it has been known that the bond angle of an oxygen atom in organosilicon compounds shows various values, the angles SiOC and SiOSi are calculated from the observed dipole moments which are shown in the third columns of these tables.

3) The Vibration Models and the Staggered Models.—The CH_3–O bonds and the Si–O bonds

of $(CH_3)_3SiO$ groups are vibrating about given "equilibrium" positions, trans or gauche positions respectively, or staggering from these positions. The amplitude or the staggered angles are denoted by θ. In the case of the staggered model, if CH_3 or $(CH_3)_3Si$ groups are staggered and situated at θ counterclockwise from the given "equilibrium" positions when viewed from the centered Si atom, these staggered angles may be defined $+\theta$.

The calculated angle θ, giving the observed dipole moments, are shown in Tables III, V, VII, IX, XI and XIII; in every case the "equilibrium" model means that one of the trans and gauche models with the smallest dipole moment.

(I) Methoxytrimethylsilane.—The moment is measured only at 25°C, because of its low boiling point.

The observed value, 1.18D, is in coincidence with the dipole moment of ethoxytrimethylsilane, 1.18D[8]. The observed value is consistent with the calculated value, 1.22D. Hence, the assumed bond angle SiOC, 113°, and the $(CH_3)_3SiO$ group moment, 1.05D, seem reasonable.

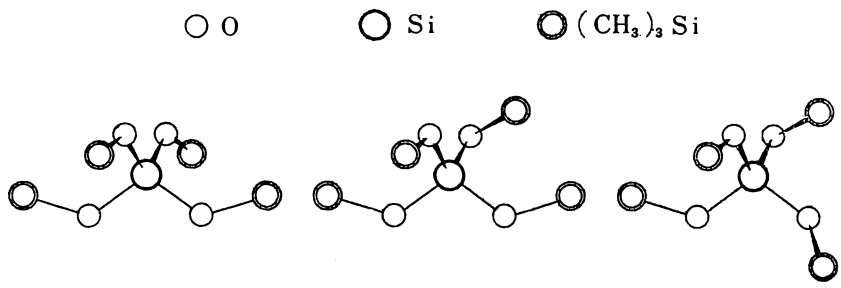
As to the molecule of this type, it should be noticed that it is impossible to determine the precise position of the CH_3 group by only the dipole moment data.

(II) Dimethoxydimethylsilane.—The observed value, 1.33D, is also in good agreement with that of diethoxydimethylsilane, 1.36D[8].

The facts that the calculated dipole moments for various models in Table II are not consistent with the observed value, and that the observed dipole moment is independent of the temperature, suggest that the molecule is in the free rotational state.

When it is assumed that the two CH_3 groups rotate with each other freely, the observed moment is well consistent with the calculated moment, provided that angle SiOC is taken

Table II. The calculated moments of dimethoxydimethylsilane (see Fig. 1)



Model	μ (D)	< SiOC

Fig. 4. The configurations of tetra-trimethylsiloxy-silane.

as 128.5°. In this case the $CH_3\cdots\cdots CH_3$ distance is 2.9Å ; it is a little larger than the sum of the covalent radii of a carbon atom and a hydrogen atom, which makes the free rotation possible.

The value of angle SiOC, 128.5°, is larger than the observed value, 113°, which is obtained by the electron diffraction study of tetramethoxysilane, but it is comparable to the values of angle SiOSi, 130±10° and 137±7° in hexamethyldisiloxane, and 140±5° in tetra-trimethylsiloxy-silane, which values are obtained by electron diffraction studies ; therefore, the value obtained here may not be unreasonable.

Next, in explanation of the observed value, a vibration or fixed staggered model for this molecule, with the b_1-b_2 model as the equilibrium model, was assumed. The calculated results are shown in Table III. In the staggered models two cases are considered ; a) two CH_3 groups are staggering from the given equilibrium positions, b_1 and b_2, in the same direction by angle $+\theta$ or $-\theta$ (++ and −− in Table III), and b) they are staggering in different directions, one by angle $+\theta$ and the other by $-\theta$ (+− and −+ in the same table).

The large amplitude and the staggered angle θ's shown in Table III are difficult to interpret in terms of the intramolecular potential of the molecule. For example, the model with the staggered angle 51° from the b_1-b_2 (gauche) model makes a form almost identical to the cis form. Therefore, it is unsuitable to use these models to explain the experimental results. When the c_1-c_2 model is taken as the equilibrium model, similar relations are obtained.

On the other hand, when the trans (a_1-a_2) model is taken as the equilibrium model, the staggered model, in which one CH_3 group staggers by +150° and the other by −150°, is obtained. This is identical with the case in which the b_1-c_2 model or the c_1-b_2 model is taken as the equilibrium model. That is, for example, if the b_1-c_2 model is chosen as the equilibrium model, the CH_3 group placed at the b_1 position staggers by +30° and the CH_3 group placed at the c_2 position staggers by −30°. This model is considered the most reasonable one, if one ignores the fact that the most stable model, with the smallest dipole moment, is taken as the fundamental equilibrium model.

The third possibility to explain the observed data lies in the consideration of the molecule consisting of a mixture of the various configurations. As there are many configurations which can be mixed with the b_1-b_2 model and the c_1-c_2 model to make the calculated moment fit the observed moment, it is desirable to use the other physical method to determine its details.

(III) Trimethoxymethylsilane.—As is shown in Table IV, these observations can be made about the trans and gauche models and the free rotation model as well as about dimethoxydimethylsilane.

When the $a_1-a_2-a_3$ model or the $a_1-b_2-b_3$ model is chosen as the equilibrium model for

Model type*	μ (D)	<SiOC
$a_1-a_2-a_3$	1.22	<90°
$a_1-b_2-b_3$	1.22	<90°
$a_1-b_2-a_3$	1.39	
$a_1-c_2-b_3$	2.10	128°
$a_1-b_2-c_3$	2.20	136°
$c_1-b_2-a_3$	2.39	148.5°
$a_1-a_2-b_3$	2.79	143°
Free rotation	1.93	128°
(observed 25°C	1.60)	
(observed 50°C	1.62)	

* All of the other trans and gauche models are classified into one of the above models.

Table V. The vibration model (v) and the staggered model (s) similar to Table III but for trimethoxymethylsilane

	Equilibrium model	θ
	$(a_1-a_2-a_3)$	
(v)		80°
(s)	+++	—
	−−−	—
	++−	—
	−−+	—
	+−+	32°
	+−−	32°
	−+−	29°
	−++	29°
	$(a_1-b_2-b_3)$	
(v)		80.5°
(s)	+++	32° 168°
	−−−	29° 110°
	++−	75° 165°
	−−+	15° 104°
	+−+	17° 148°

the vibration model and the staggered models, the calculated angles, θ's, are shown in Table V. The large amplitude, 80°, shows that the vibration model must be rejected upon considering the intramolecular potential. Of all the staggered forms, the models staggering by 15, 17, 29 and 32° from the given equilibrium positions seem reasonable models.

(IV) Tetramethoxysilane.—As is shown in Table VI, of all the trans and gauche models the $a_1-a_2-a_3-b_4$ type models and the $a_1-b_2-a_3-c_4$ type models have the most suitable calculated values to fit the observed dipole moment. Therefore, it is possible to consider that the molecule consists of a mixture of, or one of, these models.

On the other hand, by electron diffraction study[4], the configuration of this molecule is found to be the staggered model in which four CH_3 groups stagger against nonbonding oxygen atoms.

Table VI. The calculated moments of tetramethoxysilane (see Fig. 3)

Model type*	μ (D)	<SiOC
$a_1-a_2-a_3-a_4$	0	
$a_1-b_2-b_3-a_4$	0	
$a_1-a_2-a_3-b_4$	1.83	115°
$a_1-b_2-a_3-c_4$	1.83	115°
$a_1-a_2-b_3-b_4$	2.59	140°
$a_1-a_2-b_3-c_4$	3.18	148.5°
Free rotation	2.12	128.5°
(observed 25°C	1.78)	
(observed 50°C	1.80)	

* All of the other trans and gauche models are classified into one of the above models.

Table VII. The vibration model (v) and the staggered model (s) similar to Table III but for tetramethoxysilane

	Equilibrium model	θ
	$(a_1-a_2-a_3-a_4)$	
(v)		105°
(s)	++++	—
	−−−−	—
	+++−	58°
	+−−−	58°
	+−+−	37°
	++−−	—
	$(a_1-b_2-b_3-a_4)$	
(v)		105°
(s)	++++	37°
	−−−−	37°
	+++−	58°
	++−+	58°
	+++−	58°
	+−+−	58°
	+−−+	—

As is shown in Table VII, of all the staggered models assuming the $a_1-a_2-a_3-a_4$ model or the $a_1-b_2-b_3-a_4$ model as the equilibrium model, the staggered models with the staggered angle of 37° are considered to be most suitable to explain the configuration of the molecule.

Moreover, Asbuzov and Shavsha[9] measured the dipole moment for this molecule and obtained 1.61D, their calculated moment with the free rotation model being 1.7D. From this, they concluded that the free rotation model is reasonable. However, as their report is not available and the details are not known exactly, their results cannot be discussed in the present report.

Configuration of Methoxymethylsilanes and Tetramethoxysilane.—As has been mentioned above, throughout four compounds, three methoxymethylsilanes and tetramethoxysilane, it can be considered first that the configurations for these molecules are in the free rotational state, as the observed dipole moments are independent of temperature, and it has been known in general that organosilicon compounds have a low intramolecular potential barrier as compared with carbon compounds. In methoxytrimethylsilane the observed moment is consistent with the calculated moment, assuming 113° for angle SiOC, while in dimethoxydimethyl-, trimethoxymethyl- and tetramethoxysilane, the angle SiOC must open wider by 15° to make the calculated moments fit the observed moments. These features of the angle may be possible, but it seems difficult

9) B. A. Asbuzov and T. G. Shavsha, *Doklady Akad. Nauk. S. S. S. R.*, **68**, 859 (1949); *Chem. Abstr.*, **44**, 886 (1950).

to accept the free rotation for the configuration of compounds, so long as the bond angles of an oxygen atom are assumed to be the same in these molecules belonging to a series.

As was seen in the conclusion of the electron diffraction study for tetramethoxysilane, some of the staggered models in which the CH_3 groups stagger about each given equilibrium positions seem to be suitable.

The third possibility to explain the configurations of these compounds lies in the assumption that these compounds consist of a mixture of various trans and gauche models. The temperature dependence is expected to appear as more or less in this case.

(V) Tetra-trimethylsiloxy-silane. — The observed moment is independent of temperature. The free rotation model seems preferable. The calculated moment is consistent with the observed moment if angle SiOSi is taken to be 148.5°. This value of the angle is in agreement comparatively with 140±5° according to the results of the electron diffraction study for this compound. But if angle SiOSi is assumed to be 148.5°, the distance between one CH_3 group belonging to one of four $(CH_3)_3Si$ groups and one CH_3 group belonging to another amounts to 1.16Å. The distance between the two above-mentioned CH_3 groups is too small to make the $(CH_3)_3Si$ groups rotate freely, so that the free rotation model is impossible.

TABLE VIII. THE CALCULATED MOMENTS OF TETRA-TRIMETHYLSILOXY-SILANE (see Fig. 3)

Model type*	μ (D)	<SiOSi
$a_1-a_2-a_3-a_4$	0	
$a_1-b_2-b_3-a_4$	0	
$a_1-a_2-a_3-b_4$	1.17	143°
$a_1-b_2-a_3-c_4$	1.17	143°
$a_1-a_2-b_3-b_4$	1.65	154.5°
$a_1-a_2-b_3-c_4$	2.02	159.5°
Free rotation	1.35	148.5°
(observed 25°C	1.10)	
(observed 50°C	1.10)	

* All of the other trans and gauche models are classified into one of the above models.

TABLE IX. THE VIBRATION MODEL (v) AND THE STAGGERED MODEL (s) SIMILAR TO TABLE III BUT FOR TETRA-TRIMETHYLSILOXY-SILANE

	Equilibrium model	θ
	$(a_1-a_2-a_3-a_4)$	
(v)		98°
(s)	++++	—
	----	—
	+++-	54.5°
	+---	54.5°
	+-+-	35°
	++--	—
	$(a_1-b_2-b_3-a_4)$	
(v)		98°
(s)	++++	35°
	----	35°
	+++-	54.5°
	++-+	54.5°
	++--	54.5°
	+-+-	54.5°
	+--+	—

On the other hand, of all the trans and gauche models in Table VIII, the calculated dipole moments of the $a_1-a_2-a_3-b_4$ type models and the $a_1-b_2-a_3-c_4$ type models are most consistent with the observed one. The features of these two models are shown in Figs. 4 (b) and (c). Therefore, it is considered that the configuration of this molecule is identical with one of, or a mixture of, these two types of models.

Considering the resembrance of the structural formula between this molecule and tetramethoxysilane, it is possible that the configuration of the molecule fits any staggered model. For example, when the $a_1-a_2-a_3-a_4$ model or the $a_1-b_2-b_3-a_4$ model is taken as the equilibrium model, the calculated angle of amplitude and the staggered angles are as shown in Table IX. The vibration model is impossible because of its large amplitude, while it seems that, of all the staggered models shown in Table IX, the models having the staggered angle 35° are most suitable as the configuration for the molecule.

According to the conclusion of the electron diffraction study[4], this molecule has a configuration in which two $(CH_3)_3Si$ groups belonging to the different W-shaped chains shown in Fig. 4 (a) are twisted by 60° from each other. The calculated dipole moment of this model is identical with those of the $a_1-a_2-a_3-b_4$ type models and the $a_1-b_2-a_3-c_4$ type models; that is, it is consistent with the observed moment. Little consideration has been given to this model, however, as it is identical with the case in which the two twisted $(CH_3)_3Si$ groups take cis positions against the respective nonbonding oxygen atoms.

(VI) Methoxytrichlorosilane.—The observed dipole moment is independent of temperature.

In order to calculate the dipole moment for this molecule, it is necessary to have the value of the SiCl bond moment. The value, 2.67D, is obtained for the SiCl bond moment from the dipole moment of triethylchlorosilane, 2.07D[10], assuming the SiC_2H_5 group

10) C. Curran, D. M. Witucki and P. A. McCusker, *J. Am. Chem. Soc.*, **72**, 4471 (1950).

moment, 0.60D. Using this bond moment, the calculated moment for this molecule is 1.81D. This value is too small as compared with the observed value.

Using the observed dipole moment, the Cl_3SiO group moment is calculated as 1.29D. From this value, the SiCl bond moment 2.94D is obtained, provided that the SiO bond moment is 1.65D. This SiCl bond moment, 2.94D, is larger than that obtained from the dipole moment study of triethylchlorosilane, 2.67D.

Of this tendency of the SiCl bond moment, the following argument seems to be the most suitable among the various considerations.

It has generally been known that the SiCl bonds in chlorosilane and ethylchlorosilane have the $Cl^+=Si^-$ double bond structure in spite of the fact that the electronegativities of a silicon atom and a chlorine atom are quite different[10,11], and that in many other silane derivatives, such as those containing a phenyl group, there is a so-called "reverse halogen effect" $+\langle\bigcirc\rangle=Si^-$ [12]. In the ClSiO bond of the molecule, it must be considered that the contribution of the structure $Cl^+=Si^--O$ decreases and the contribution of the $Cl^-Si=O^+$ type structure rather increases, leading one to the conclusion that the $Si^-=O^+$ double bond structure contributes appreciably to the normal state of the SiO bond.

Therefore, it is better to assume the SiCl bond moment to be about 2.94D for methoxytrichlorosilane.

The configuration of this molecule cannot be decided only from the dipole moment data, whereas in the results of the electron diffraction study, the CH_3O group is placed at the trans position against one of three chlorine atoms[5].

(VII) Dimethoxydichlorosilane.—Among the fixed trans and gauche models in Table X, the calculated dipole moment of the a_1-b_2 type models is almost consistent with the observed moment. However, the dependence on temperature of the observed moment makes it difficult to select the particular configuration of the molecule.

The next possibility of explaining the observed data lies in the assumption that the molecule consists of a mixture of the various fixed models. That is, the a_1-a_2 model in Table X, where the two CH_3O groups are in the trans position with regard to each other as the most stable configuration, and many other models in Table X which are stable configurations at higher temperatures, are mixed. In this case, it is also expected that the temperature dependence will appear more or less.

According to the electron diffraction study[5], the trans model seems to be the most reasonable one for the molecule, but this conclusion cannot explain the present experimental data.

(VIII) Trimethoxychlorosilane. — The configuration of this molecule is considered to be a mixture of the various trans and gauche models shown in Table XII, similar to the case of dimethoxydichlorosilane.

Configuration of Methoxychlorosilanes. — As has been mentioned above, from the results of the measurement for methoxytrichlorosilane, it is concluded that the SiCl bond moment

	−+−	64°	61°
	−−+	64°	61°

should be 2.94D, which corresponds to the contribution of the $Cl^-Si{=}O^+$ structure to the ClSiO bond.

Of the configurations of dimethoxydichloro- and trimethoxychloro-silane, it seems most suitable to suggest that these compounds consist of a mixture of various trans and gauche models, and not of one particular model, including the free rotation model and the vibration model, on condition that the observed moments depend on temperature.

It is my pleasure to express my gratitude to Mr. Masatoki Yokoi and Mr. Hiroshi Murata for the samples, to Professor Akira Kotera and Professor Keizo Suzuki for their encouragement throughout the experiment, and to Mr. Takao Nakano,Mrs. Toshiko Ooyama and Mrs. Utako Kambayashi for their assistance.

The Mannich Base of Troponoid and its Application. VIII. Reaction of 3-Bromo-5-formyl-7-isopropyltropolone

By Kyozo OGURA

(Received September 28, 1961)

In the preceding paper of this series[1], the synthesis of 3-bromo-5-formyl-7-isopropyltropolone (I) from the Mannich base, 3-bromo-5-piperidinomethyl-7-isopropyltropolone, was described; the present paper concerns the reaction of this aldehyde.

Aldehyde I is highly reactive and is similar to 3, 7-dibromo-5-formyltropolone[2]. It forms an acetal II on merely being warmed in methanol and undergoes a reaction with various amines to form the Schiff base. The reaction of I with aniline, *p*-toluidine, *p*-anisidine and 5-aminotropolone respectively afforded *N*-(3-bromo-7-isopropyltropolon-5-ylmethylene)aniline (III), *N*-(3-bromo-7-isopropyltropolon-5-ylmethylene)-*p*-toluidine (IV), *N*-(3-bromo-7-isopropyltropolon-5-ylmethylene)-*p*-anisidine (V), and *N*-(3′-bromo-7′-isopropyltropolon-5′-ylmethylene)-5-tropolonylamine (VI). The reaction of I and *o*-phenylenediamine afforded 2-(3′-bromo-7′-isopropyltropolon-5′-yl)benzimidazole (VIII) through *N*-(3-bromo-7-isopropyltropolon-5-ylmethylene)-*o*-aminoaniline (VII). The compound VIII was also obtained by the reaction of (3-bromo-7-isopropyltropolon-5-yl)-*N*-(*p*-dimethylaminophenyl)nitrone with *o*-phenylenediamine[1]. The structures of VII and VIII were supported by their ultraviolet spectra. The reaction of I with malononitrile, cyanoacetamide, and ethyl cyanoacetate respectively afforded 3-bromo-5-(β, β-dicyanovinyl)-(IX), 3-bromo-(β-cyano-β-carbamoylvinyl)-(X), and 3-bromo-5-(β-cyano-β-ethoxycarbonylvinyl)-7-isopropyltropolone (XI). The hydrolysis of XI with alkali gave 3-bromo-5-(β-cyano-β-carboxyvinyl)-7-isopropyltropolone (XII). The reaction of I and hippuric acid

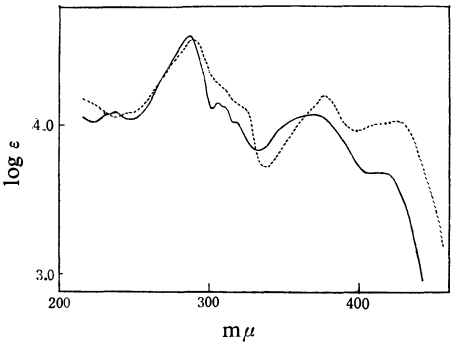
gave the corresponding azlactone compound (XIII), which was hydrolyzed to 3-bromo-5-(β-benzamido-β-carboxyvinyl)-7-isopropyltropolone (XIV).

The aldehyde I underwent condensation with rhodanine to form 3-bromo-7-isopropyltropolon-5-ylmethylenerhodanine (XV), but its treatment with alkali failed to produce the corresponding thioketocarboxylic acid but afforded colorless crystals (XVI) of m. p. 249°C(decomp.), corresponding to the molecular formula of $C_{13}H_{12}O_4S$, and a small amount of I. The bromination



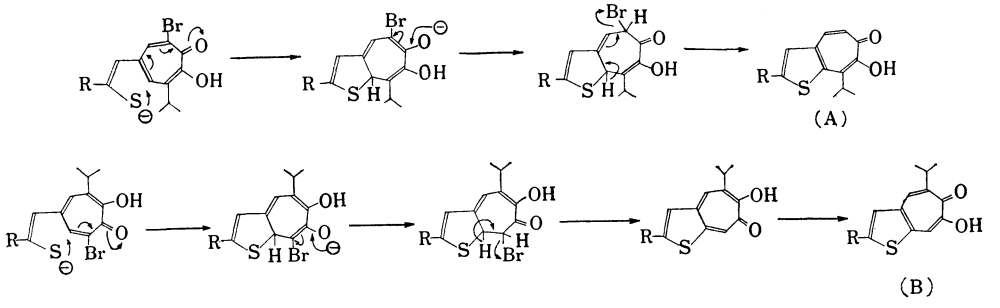


Fig. 2. Ultraviolet spectra of XVI (——) and XVII (·····) in methanol.

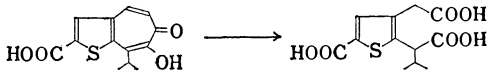
of XVI afforded a monobromo compound (XVII) of m. p. 273°C(decomp.). The ultraviolet spectrum of XVI, as indicated in Fig. 2, is not that of a monocyclic tropolone type. The infrared spectrum of XVI showed absorptions for carboxyl group at 2550 and 1672 cm^{-1}. These facts suggest that XVI is a thieno[2, 3-d]tropolone derivative (A or B) formed by the abnormal intramolecular attack of the sulfide anion at the 6- or 4-position of the tropolone ring, with the liberation of the bromide ion from the 3-position.

It may be presumed that the 6-position is sterically hindered by the isopropyl group in 7-position and is liable to be less attacked than the 4-position, so that the product is more likely to be B. Finally, the structure of this product (XVI) was established as 2-carboxy-5-isopropylthieno[2, 3-d]tropolone (B) by the experiments to be described below.

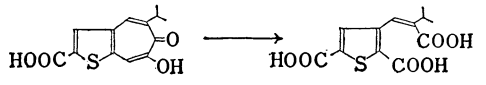
The oxidation of XVI with alkaline potassium permanganate afforded 2, 3, 5-thiophenetricarboxylic acid (XVIII), m. p. 216°C, which formed trimethyl ester XIX, m. p. 83°C with diazomethane. The ester XIX was identified by mixed fusion and through comparison of its ultraviolet and infrared spectra with those of the specimen synthesized by Jones[3]. The

(A)



(B)

R = COOH



Scheme 2

3) R. G. Jones, *J. Am. Chem. Soc.*, **77**, 4164 (1955).

oxidation of XVI with alkaline hydrogen peroxide afforded a colorless acid substance (XX), m. p. 259°C(decomp.). Elemental analyses of XX gave values corresponding to $C_{12}H_{12}O_6S$, while XX formed a trimethyl ester, (XXI), $C_{15}H_{18}O_6S$, m. p. 86°C, with diazomethane and formed XVIII by oxidation with potassium permanganate. By analogy with the facts known on the oxidation of tropolones with hydrogen peroxide[4-7], it is expected that 8-isopropyl derivative A should afford 2-(α-carboxyisobutyl)-3-carboxymethyl-5-carboxythiophene (A′) and that 5-isopropyl derivative B should give 2, 5-dicarboxy-3-(β-isopropyl-β-carboxyvinyl) thiophene (B′). The ultraviolet spectrum of XX

(A) (A′)

(B) (B′)

Scheme 3

exhibited absorption maxima at 250 mμ(log ε, 4.19) and 280 mμ(log ε, 4.09), while the infrared spectrum of XXI showed absorptions for the carbonyl group of unsaturated ester and for the carbon-carbon double bond at 1715 and 1643 cm^{-1}. The nuclear magnetic resonance spectrum of XXI had absorption corresponding to one ethylenic proton at 222 c. p. s. (with cyclohexane standard). These facts indicate that this oxidation product XX is 2, 5-dicarboxy-3-(β-isopropyl-β-carboxyvinyl)thiophene (B′) and that

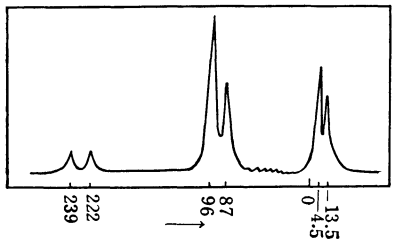

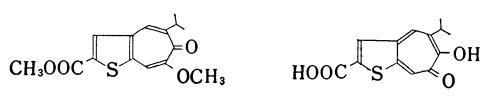

Fig. 6. NMR spectrum of XXI in carbon tetrachloride.

consequently, the position of the isopropyl group in XVI must be 5.

The oxidation of the monobromo compound XVII with potassium permanganate gave 2, 3, 5-thiophenetricarboxylic acid (XVIII), judging from which XVII must be 2-carboxy-5-isopropyl-8-bromothieno [2, 3-d] tropolone. The heating of XVI with acetic anhydride, in the presence of sodium acetate, afforded colorless crystals of m. p. 190°C, $C_{15}H_{14}O_5S$, which showed infrared absorptions of the hydroxyl group at 3160 cm^{-1}, and of the carbonyl group at 1765 and 1730 cm^{-1}. This product was therefore considered to be the anhydride XXII. It reverted to XVI on alkaline hydrolysis. The treatment of XVI with concentrated nitric acid in acetic acid gave yellow needles, of m. p. 185°C, whose elemental analyses and infrared spectrum indicated that this product was 2, 8-dinitro-5-isopropylthieno [2, 3-d] tropolone (XXIII). The ultraviolet spectra of XXII and XXIII are shown in Fig. 4.

The treatment of XVI with diazomethane afforded only one kind of methyl ether XXIV; this is thought to be due to the condensed thiophene ring, as in the case of benzotropolones[6], and there is almost no contribution from the type of XVI′.

XXIV XVI′

Scheme 5

Experimental*

3-Bromo-5-dimethoxymethyl-7-isopropyltropolone (II).—A solution of 20 mg. of I in methanol (1 ml.) was refluxed for 30 min. The evaporation of the methanol left colorless needles. The crystals were collected, with the addition of petroleum ether, and recrystallized from petroleum ether to form colorless rods, m. p. 86~87°C. Yield, 20 mg.

Found: 49.49; H, 5.35. Calcd. for $C_{13}H_{16}O_4Br$: C, 49.38; H, 5.36%.

***N*-(3-Bromo-7-isopropyltropolon-5-ylmethylene)-aniline (III).**—A mixture of I (30 mg.), aniline (15 mg.) and acetic acid (0.1 ml.) was warmed in a water bath, by which the whole first dissolved to form a red solution, but then yellow crystals began to separate out. This mixture was warmed for 30 min., and the crystals were collected and recrystallized from petroleum ether to form yellow scales, m. p. 145~147°C. Yield, 20 mg.

Found: C, 59.71; H, 4.54; N, 3.92. Calcd. for $C_{17}H_{16}O_2NBr$: C, 58.96; H, 4.62; N; 4.05%.

λ_{max}^{MeOH} mμ(log ε): 260(4.50), 340(3.88), 385(4.00).

***N*-(3-Bromo-7-isopropyltropolon-5-ylmethylene)-*p*-toluidine (IV).**—A mixture of I (40 mg.) and *p*-toluidine (20 mg.) in acetic acid (0.1 ml.) was warmed in a water bath for 20 min. and then cooled to room temperature. The crystals that formed were collected and recrystallized from petroleum ether to form yellow needles, m. p. 113~116°C. Yield, 30 mg.

Found: C, 57.71; H, 4.57; N, 3.70; Calcd. for $C_{18}H_{18}O_2NBr.H_2O$: C, 57.15; H, 5.29; N, 3.70%.

λ_{max}^{MeOH} mμ(log ε): 259(4.34), 342(3.78), 390(3.99).

***N*-(3-Bromo-7-isopropyltropolon-5-ylmethylene)-*p*-anisidine (V).**—A mixture of I (20 mg.) and *p*-anisidine (10 mg.) in acetic acid (0.1 ml.) was heated in a water bath for 5 min. and then cooled to room temperature. The crystals that formed were collected and recrystallized from methanol to form yellow needles, m. p. 95~101°C. Yield, 10 mg.

Found: C, 57.39; H, 4.70:, N; 3.91. Calcd. for $C_{18}H_{18}O_3NBr$: C, 57.46; H, 4.79; N, 3.73%.

λ_{max}^{MeOH} mμ(log ε): 259(4.45), 390(4.20).

***N*-(3′-Bromo-7′-isopropyltropolon-5′-ylmethylene)-5-tropolonylamine (VI).**—A mixture of I (20 mg.) and 5-aminotropolone (15 mg.) in acetic acid (0.1 ml.) was heated in a water bath; yellow powder precipitated in 5~6 min. This precipitate was

* All melting points are uncorrected. The microanalyses were carried out by Miss Yoko Endo and Miss Yukiko Endo of this Institute, to whom the author is indebted.

collected and washed with hot methanol and acetic acid, m. p. 203~204°C(decomp.).

Found: C, 55.35; H, 4.06; N, 3.73. Calcd. for $C_{18}H_{16}O_4NBr$: C, 55.40; H, 4.10; N, 3.59%.

λ_{max}^{MeOH} mμ(log ε): 230(4.41), 255(4.52), 420(4.41).

***N*-(3-Bromo-7-isopropyltropolon-5-ylmethylene)-*o*-aminoaniline (VII).**—A mixture of I (40 mg.) and *o*-phenylenediamine (20 mg.) in ethanol (0.1 ml.) was heated in a water bath for a few minutes. The red crystals that precipitated were collected and recrystallized from ethanol to form red prisms, m. p. 104~107°C. Yield, 30 mg.

Found: C, 56.40; H, 4.48; N, 7.55. Calcd. for $C_{17}H_{17}O_2N_2Br$: C, 56.52; H, 4.71; N, 7.75%.

λ_{max}^{MeOH} mμ(log ε): 263(4.37), 406(4.39).

2-(3'-Bromo-7'-isopropyltropolon-5'-yl)benzimidazole (VIII).—A mixture of I (40 mg.) and *o*-phenylenediamine (20 mg.) in 0.1 ml. of acetic acid was heated in a water bath for 5~6 min.; the crystals that formed were collected and recrystallized from methanol to form yellow needles, m. p. 242~243°C(decomp.). Yield, 20 mg.

VIII was also obtained by the use of (3-bromo-7-isopropyltropolon-5-yl)-*N*-(*p*-dimethylaminophenyl) nitrone in place of I and reacted under the same conditions. The compound VII also afforded VIII on being heated in acetic acid.

Found: C, 56.75; H, 3.94; N, 7.68. Calcd. for $C_{17}H_{15}O_2N_2Br$: C, 56.84; H, 4.18; N, 7.81%.

λ_{max}^{MeOH} mμ(log ε): 254(4.39), 383(4.43).

3-Bromo-5-(β, β-dicyanovinyl)-7-isopropyltropolone (IX).—A solution of I (50 mg.), malononitrile (20 mg.), and piperidine (1 drop) dissolved in ethanol (1 ml.) was allowed to stand at room temperature, by which the solution gradually acquired a reddish tint and yellow crystals precipitated out after about 5 hr. After the mixture had been allowed to stand overnight, the crystals were collected, treated with 6 N hydrochloric acid (0.2 ml.), collected on a filter, washed with water, and recrystallized from methanol to form yellow granules, m. p. 145~146°C. Yield, 30 mg.

Found: C, 52.44; H, 3.51; N, 8.30. Calcd. for $C_{14}H_{11}O_2N_2Br$: C, 52.80; H, 3.45; N, 8.78%.

λ_{max}^{MeOH} mμ(log ε): 222(4.20), 280(4.10), 404(4.15), 490(4.70).

3-Bromo-5-(β-cyano-β-carbamoylvinyl)-7-isopropyltropolone (X).—A solution of I (50 mg.), cyanoacetamide (20 mg.), and piperidine (1 drop) dissolved in ethanol (1 ml.) was refluxed for 3 hr., the solvent was distilled off, and the residue was acidified by the addition of 6 N hydrochloric acid. The yellow, powdery precipitate thereby formed was collected and washed thoroughly with water and methanol, m. p. 233°C(decomp.). Yield, 20 mg.

Found: C, 49.14; H, 3.69; N, 7.61. Calcd. for $C_{14}H_{13}O_3N_2Br$: C, 49.87; H, 3.86; N, 8.31%.

λ_{max}^{MeOH} mμ(log ε): 245(4.06), 275(4.14), 466(4.47).

3-Bromo-5-(β-cyano-β-ethoxycarbonylvinyl)-7-isopropyltropolone (XI).—A mixture of I (50 mg.) and ethyl cyanoacetate (30 mg.) dissolved in ethanol (1 ml.) and with one drop of piperidine added was allowed to stand at room temperature for 2 days, and then the ethanol was evaporated. 6N Hydrochloric acid was added to its reddish syrupy residue; the syrup thereby solidified and formed a yellowish powder. This powder was collected and recrystallized from methanol to form yellow needles, m. p. 106~108°C. Yield, 50 mg.

Found: C, 52.71; H, 4.48; N, 3.43. Calcd. for $C_{16}H_{16}O_4NBr$: C, 52.46; H, 4.37; N, 3.83%.

λ_{max}^{MeOH} mμ(log ε): 245(4.04), 276(4.13), 408(4.25), 476(4.57).

3-Bromo-5-(β-cyano-β-carboxyvinyl)-7-isopropyltropolone (XII).—A mixture of XI (60 mg.) and a 20% aqueous solution of sodium hydroxide (0.5 ml.) was heated in a water bath for a few minutes. The mixture formed a red solution and then precipitated out yellow crystals. The mixture was acidified with 6 N hydrochloric acid, and the yellow precipitate thereby formed was collected by filtration. Recrystallization from methanol afforded yellow prisms, m. p. 210~220°C. Yield, 30 mg.

Found: C, 49.67; H, 3.78; N, 3.70. Calcd. for $C_{14}H_{12}O_4NBr$: C, 49.72; H, 3.58; N, 4.14%.

λ_{max}^{MeOH} mμ(log ε): 265(4.28), 290(4.19).

2-Phenyl-4-(3'-bromo-7'-isopropyltropolon-5'-ylmethylene)-5-oxazolone (XIII).—A mixture of I (100 mg.), hippuric acid (80 mg.), freshly fused sodium acetate (40 mg.), and acetic anhydride (0.5 ml). was heated at 80~90°C for 10 min.; the mixture thereby formed a red solution and an orange precipitate separated. The mixture was cooled and diluted with water (0.2 ml.), and the precipitate was collected by filtration. The precipitate was washed thoroughly with water and methanol, m.p. 190~194°C. Yield, 100 mg.

Found: C, 58.29; H, 3.88; N, 2.92. Calcd. for $C_{20}H_{16}O_4NBr$: C, 57.99; H, 3.87; N, 3.38%.

λ_{max}^{MeOH} mμ(log ε): 258(4.28), 320(4.15), 426(4.21); 510(4.43).

3-Bromo-5-(β-benzamido-β-carboxyvinyl)-7-isopropyltropolone (XIV).—A mixture of 100 mg. of azlactone (XIII) and a 10% sodium hydroxide solution (0.5 ml.) in methanol (0.3 ml.) was heated in a water bath for a a few minutes, the methanol was evaporated, and the residual solution was acidified with 6 N hydrochloric acid. The pale yellow precipitate that formed was collected by filtration and recrystallized from methanol to form a yellow powder, m. p. 220°C(decomp.). Yield, 40 mg.

Found: C, 55.98; H, 4.34; N, 3.08. Calcd. for $C_{20}H_{18}O_5NBr$: C, 55.57; H, 4.17; N, 3.24%.

λ_{max}^{MeOH} mμ(log ε): 262(4.42), 375(4.27).

3-Bromo-7-isopropyltropolon-5-ylmethylenerhodanine (XV).—A mixture of I (500 mg.), rhodanine (250 mg.), freshly fused sodium acetate (500 mg.), and acetic acid (3.4 ml.) was heated in a boiling water bath; orange prismatic crystals thereby precipitated out. After the mixture had been heated for 1 hr., water (1 ml.) was added to the mixture, and the crystals were collected and washed with water and methanol. Orange prisms, m. p. 235~240°C. Leaving the filtrate to stand at room temperature further afforded a precipitate of XV. Yield, 700 mg.

Found: C, 44.15; H, 3.10; N, 3.40. Calcd. for $C_{14}H_{12}O_3NS_2Br$; C, 43.55; H, 3.13; N, 3.63%.

λ_{max}^{MeOH} mμ(log ε): 253(4.16), 335(3.96), 430(4.26), 500(4.31).

2-Carboxy-5-isopropylthieno[2, 3-d]tropolone (XVI).—A solution of XV (450 mg.) in a 15% aqueous solution of sodium hydroxide (4 ml.) was heated on a water bath for 1 hr.; the yellow crystals that precipitated out were collected and acidified with 6 N hydrochloric acid, thereby obtaining ca. 20 mg. of I.

The acidification of this filtrate with 6 N hydrochloric acid afforded a colorless precipitate, which was collected after the addition of a small amount of methanol (0.5 ml.). The precipitate was washed with water and methanol and then recrystallized from methanol to form colorless crystals of XVI, m. p. 249°C. Yield, 200 mg.

Found: C, 59.16; H, 4.36. Calcd. for $C_{13}H_{12}O_4S$: C, 59.09; H, 4.58%.

λ_{max}^{MeOH} mμ(log ε); 237(4.09), 287(4.61), 305(4.15), 370(4.08).

2-Carboxy-5-isopropyl-8-bromothieno[2, 3-d]tropolone (XVII).—A solution of bromine (30 mg.) in methanol (0.5 ml.) was added drop by drop into a suspension of XVI (50 mg.) in methanol (2 ml.), while being stirred under ice-cooling, and the whole was stirred at room temperature for 10 min. after the completion of the addition. The crystals that formed were collected and recrystallized from methanol to form pale yellow needles (XVII), m. p. 270~273°C(decomp.). Yield, 20 mg.

Found: C, 45.34; H, 3.30. Calcd. for $C_{13}H_{11}O_4BrS$: C, 45.49; H, 3.21%.

λ_{max}^{MeOH} mμ(log ε): 288(4.58), 377(4.20), 425(4.03).

2, 3, 5-Thiophenetricarboxylic Acid (XVIII).—Into a solution of XVI (100 mg.) dissolved in a 10% sodium hydroxide solution (6.5 ml.), a 5% aqueous solution of potassium permanganate (8 ml.) was stirred drop by drop. After the completion of the addition, the mixture was stirred for 2 hr. and warmed on a water bath for a few min., and the manganese dioxide that had formed was filtered off. The filtrate was concentrated under a reduced pressure to about one-half the original volume, acidified to pH 3~4 by the addition of hydrochloric acid, and extracted three times with ether. The evaporation of ether from the extract left colorless crystals which were collected by filtration, washed with water, and recrystallized from ether to form colorless granular crystals, m. p. 215~216°C. Yield, 30 mg.

Found: C, 38.32; H, 2.40. Calcd. for $C_7H_4O_6S$; C, 38.90; H, 1.87%.

λ_{max}^{MeOH} mμ(log ε): 275(3.97).

Trimethyl 2, 3, 5-thiophenetricarboxylate (XIX).—An excess of diazomethane was added to a solution of XVIII (10 mg.) in ether (1 ml.), and the mixture was allowed to stand in a cold room for 1 hr. The evaporation of the ether left colorless needles which sublimed at 100°C under a reduced pressure. The sublimate afforded colorless needles, m. p. 82~83°C. Yield, 10 mg. This substance showed no depression of melting point on admixture with an authentic sample.

λ_{max}^{MeOH} mμ(log ε): 218(4.11), 274(4.10).

2, 5-Dicarboxy-3-(β-isopropyl-β-carboxyvinyl)-thiophene (XX).—To a solution of XVI (100 mg.) dissolved in 1 N sodium hydroxide (2 ml.), a 35% hydrogen peroxide solution (2 ml.) was added, and the mixture was allowed to stand at room temperature for 2 days. This solution was then acidified (pH 3) with hydrochloric acid and extracted three times with ether, and the extract was concentrated. The colorless crystals that precipitated out were collected and recrystallized form water containing a small amount of ethanol to from colorless prisms, m. p. 256~259°C. Yield 70 mg.

Found: C, 50.39; H, 4.12. Calcd. for $C_{12}H_{12}O_6S$: C, 50.71; H, 4.26%.

λ_{max}^{MeOH} mμ(log ε): 250(4.19), 280(4.09).

2,5-Dimethoxycarbonyl-3-(β-isopropyl-β-methoxycarbonylvinyl)-thiophene (XXI).—An excess of diazomethane was added to a solution of XX (100 mg.) dissolved in ether (5 ml.), and the mixture was allowed to stand at room temperature. The evaporation of the ether left an oily residue which crystallized after being allowed to stand in a cold room with methanol (0.3 ml.). The crystals, m. p. 76~79°C, were collected and sublimed at 100°C under a reduced pressure to form colorless prisms, m. p. 84~86°C. Yield, 60 mg.

Found: C, 54.92; H, 5.58. Calcd. for $C_{15}H_{18}O_6S$: C, 55.21; H, 5.56.

λ_{max}^{MeOH} mμ(log ε): 248(4.21), 282(4.16).

Permanganate Oxidation of XX.—Into a solution of XX (25 mg.) dissolved in a 1 N sodium hydroxide solution (0.5 ml.), a 5% potassium permanganate solution was stirred drop by drop at room temperature, until the color of the permanganate persisted. The manganese dioxide that formed was filtered off, the filtrate was acidified (pH 3) with hydrochloric acid, and the mixture was extracted with ether, by which ca. 5 mg. of XVIII was obtained.

Permanganate Oxidation of XVII.—To a solution of XVII (80 mg.) dissolved in a 5% sodium hydroxide solution (5 ml.), a solution of potassium permanganate (150 mg.) in water (3 ml.) was added drop by drop, and the mixture was stirred until the permanganate color faded. The reaction mixture was treated as in the oxidation of XVI, and XVIII was obtained.

2-Acetoxycarbonyl-5-isopropylthieno[2, 3-d]tropolone (XXII).—A mixture or XVI (20 mg.), freshly fused sodium acetate (10 mg.), and acetic anhydride (0.2 ml.) was heated at 120°C for 30 min. The acetic anhydride was evaporated, water (0.5 ml.) and a drop of 15% sodium hydroxide were added to the residue, and the yellow solution so formed was acidified with hydrochloric acid. The oil that separated crystallized gradually. The crystals were collected by filtration and recrystallized from methanol to form colorless granular crystals, m. p. 186~190°C. Yield, 10 mg.

Found: C, 58.71; H, 4.60. Calcd. for $C_{15}H_{14}O_5S$: C, 58.82; H, 4.61%.

λ_{max}^{MeOH} mμ(log ε): 257(4.25), 289(4.55), 335(4.09), 350(4.10), 367(3.98).

2, 8-Dinitro-5-isopropylthieno[2, 3-d]tropolone (XXIII).—Concentrated nitric acid (0.8 ml.) was added to a solution of XVI (100 mg.) dissolved in acetic acid (16 ml.). After being allowed to stand

at room temperature for 30 min., the mixture was poured into cracked ice. The precipitate that formed was collected, washed with water, and recrystallized from methanol to form yellow needles, m. p. 184~185°C. Yield, 15 mg.

Found: C, 46.19; H, 3.65; N, 9.55. Calcd. for $C_{12}H_{10}O_6N_2S$: C, 46.46; H, 3.25; N, 9.03%.

λ_{max}^{MeOH} mμ(log ε): 328(4.06), 424(4.33).

2-Methoxycarbonyl-5-isopropyl-7-methoxythieno-[2, 3-d]tropone (XXIV).—An excess of an ether solution of diazomethane was added to a solution of XVI dissolved in dioxane (1 ml.) and allowed to stand in a cold room overnight. The colorless crystals that formed were collected and recrystallized from benzene to form colorless needles, m. p. 168~169°C. Yield, 70 mg.

Found: C, 61.94; H, 5.35. Calcd for $C_{15}H_{16}O_4S$: C, 61.64; H, 5.52%.

λ_{max}^{MeOH} mμ(log ε): 230(4.04), 280(4.59), 347(4.21), 375(4.09).

The author wishes to express his deep gratitude to Professor Shuichi Seto for his unfailing guidance throughout this work, and to Dr. Shingo Matsumura and Dr. Yusaku Ikegami for their helpful advice. Also, the author wishes to thank Mr. Kensuke Takahashi for his measurements and advice on NMR spectra, to Mr. Shuji Aono for his infrared spectral measurements, and Mr. Fumio Sato for his ultraviolet spectral measurements. He is also grateful to Dr. R. G. Jones for the gift of the specimen of 2, 3, 5-thiophenetricarboxylic acid and to Sankyo Co., Ltd., which defrayed a part of the expenses for the present research.

Diels-Alder Reaction of 2-Isopropyl-1, 3-butadiene with 4-Benzyloxy-2-butyn-1-al and Crotonaldehyde[1]

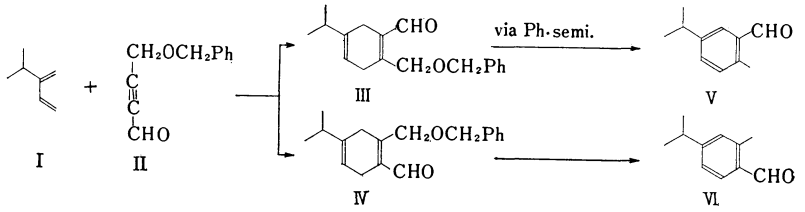
By Atsuaki ARAI and Iwao ICHIKIZAKI

(Received July 18, 1961)

The formation of two isomeric Diels-Alder adducts may be expected when an asymmetric diene and an asymmetric dienophile interact; however, in most cases the isolation of only one isomer has been reported. Moreover, about certain asymmetric addends of the reaction it has been stated[2] that the substituents in the diene generally produce a high degree of specificity in the direction of addition.

In a research program in this laboratory on the Diels-Alder reactions between asymmetric dienes and asymmetric dienophiles, the direction of the addition of 2-isopropyl-1, 3-butadiene (I) to 4-benzyloxy-2-butyn-1-al (II) as well as to crotonaldehyde (X) has been investigated.

A Diels-Alder reaction carried out by heating I and II at 145~150°C in benzene gave an oily product formulated as $C_{18}H_{22}O_2$, b. p. 132~134°C/3×10^{-3}mmHg, λ_{max}^{EtOH} 236 mμ, ε, 6800, in a 79% yield. This product afforded two red 2, 4-dinitrophenylhydrazones, III′ (m. p. 197~198°C) and IV′ (m. p. 160~161°C), in a ratio of approximately 2 : 3 and proved also to consist of two isomeric adducts. Similarly, it gave, in nearly a quantitative yield, heterogeneous phenylsemicarbazone, recrystallization of which afforded pure fine needles (IV″) with an m. p. of 183~183.5°C and two low-melting fractions, both of which were apparently heterogeneous yet. On treatment with the Brady reagent followed by fractional crystallization, phenylsemicarbazone IV″ gave homogeneous 2, 4-dinitrophenylhydrazone IV′, and one melted at 156.5~158°C of the heterogeneous phenylsemicarbazones gave the 2,4-dinitrophenylhydrazones, III′ and IV′, in a ratio of approximately 2.5 : 1.



When subjected to a superheated steam distillation over phthalic and sulfuric acids[3,4], the phenylsemicarbazone IV″ was converted into 4-isopropyl-2-methylbenzaldehyde (VI) in a 51% yield, accompanied by the removal of the benzyl alcohol. On similar treatment, the heterogeneous phenylsemicarbazone described above afforded a yellow oily product consisting of 5-isopropyl-2-methylbenzaldehyde (V) and

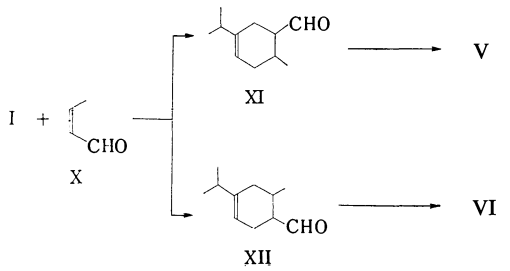
4) A. Arai and I. Ichikizaki, ibid., **35**, 45 (1962).



an appreciable amount of VI, both of which were characterized as solid derivatives.

This experimental evidence thus far obtained has made it possible to conclude that the Diels-Alder adduct of I with II consists of 2-benzyloxymethyl - 5 - isopropylcyclohexa - 1, 4-dienylmethanal (III) and 2-benzyloxymethyl-4-isopropylcyclohexa-1, 4-dienylmethanal (IV) in a ratio of approximately 2 : 3.

The original heterogeneous adduct, after being treated with a diluted methanolic sulfuric acid solution at 60°C for 10 min., showed a decrease in the ε_{max} to about 74% of the original value of the light-absorption maximum at 236 mμ; it simultaneously indicated the appearance of a maximum at 308 mμ characteristic of an α, β-γ, δ-unsaturated aldehyde system[5]. On prolonged treatment with acid, the isomerized aldehydes, e. g., VII, were finally aromaticized to the corresponding benzaldehydes, e. g., VI, which were indicated by a new maximum shown at 256 mμ. Such acid-catalyzed aromaticization, remarkable for the 2-benzyloxymethylcyclohexa-1, 4-dienealdehyde series[6], is presumably accelerated by the initial isomerization to the α, β-γ, δ-unsaturated aldehydes, as represented by VII, which readily lose their benzyl alcohol and convert, via labile intermediates, e. g., IX, into the corresponding benzaldehydes.

According to Nazarov and Mavrov[7], the condensation of I with X carried out at 200°C produces a heterogeneous adduct which is concluded to consist of 3-isopropyl-6-methyl-3-cyclohexenylmethanal (XI) and 4-isopropyl-6-methyl-3-cyclohexenylmethanal (XII) from the fact that terephthalic acid and isophthalic acid can be derived therefrom in a ratio of approximately 1 : 3 by successive oxidative treatments. Some modified methods for the identification and determination of the product in the same Diels-Alder reaction were employed by the present authors. The inseparable reaction product obtained under conditions similar to those cited above was treated with sulfur to give the dehydrogenation product which was determined, by being characterized as the 2, 4-dinitrophenylhydrazones, to consist of 3-isopropyl-6-methylbenzaldehyde (V) and 4-isopropyl-6-methylbenzaldehyde (VI), which apparently came from XI and XII respectively. The proportion of XI to XII could be decided directly by gas-liquid chromatography using a Carbowax-4000 on Celite DM-13A as the column packing material; the value of 1/2.5 was thereby obtained. In connection with the direction of the addition of the diene to the dienophile, it should be noted that the proportion of XII to XI markedly increases, as shown in Tables I and II cited in the experimental section, when the condensation was carried out at a lower temperature.

As described above, the Diels-Alder reaction of I with II as well as with X gave both of the two possible adducts in extremely near proportions, although the predominant direction of the addition conforms to the common rule[2]. In the condensation with unsymmetrical addends, it has been generally reported that a β-substituted diene, $CH_2=C(X)-CH=CH_2$, reacts with such a dienophile, R-CH=CH-Y, containing only a negative group Y as crotonaldehyde to give an adduct with X para to Y. As far as we know, such Diels-Alder dienes as

2-isopropyl-1, 3-butadiene (I), effecting a remarkable decrease in specificity[8] in the direction of addition, have rarely been found in the literature.

Experimental[11]

2-Isopropyl-1, 3-butadiene (I).—2-Isopropyl-1, 3-butadiene (I) was obtained by repeated fractionation with a 100 cm. modified Todd fractionating column of the dehydration product of 3,4-dimethyl-1-penten-3-ol[4] and had b. p. 85.5~86.5°C/760 mmHg and n_D^{20} 1.4312 (lit. b. p. 85~85.5°C, n_D^{20} 1.4316[12]; b. p. 86~87°C, n_D^{20} 1.4324[7]).

4-Benzyloxy-2-butyn-1-al (II).—4-Benzyloxy-2-butyn-1-al (II) was prepared by the method described in a previous paper[3,4] and had b. p. 115~118°C/2 mmHg and n_D^{20} 1.5408.

Condensation of I with II.—A mixture of I (13.5 g.), II (22.0 g.) and benzene (4 ml.) was heated with a small amount of hydroquinone for 13 hr. at 145~150°C in a 100 ml. sealed glass tube. Distillation of the reaction product gave an oil (29.0 g.) having b. p. 120~138°C/3×10^{-3} mmHg and n_D^{21} 1.5438~1.5454; on redistillation this oil afforded an inseparable mixture of the adducts III and IV as a pale yellow oil, b. p. 132~134°C/3×10^{-3} mmHg, n_D^{20} 1.5450. λ_{max}^{EtOH} 236 mμ (ε, 6800).

Found: C, 79.96; H, 8.30. Calcd. for $C_{18}H_{22}O_2$: C, 79.96; H, 8.20%.

In order to determine the proportion of III to IV in the original adduct, the aldehyde (0.55 g.) was converted on treatment with the Brady reagent into 2,4-dinitrophenylhydrazone, which was fractionally crystallized from methanol to give red-orange needles, m. p. 197~198°C (III′) (0.27 g.) and red needles, m. p. 160~161°C (IV′) (0.44 g.).

Found: III′: N, 12.36. IV′: N, 12.42. Calcd. for $C_{24}H_{26}O_5N_4$: N, 12.44%.

The aldehyde (20.0 g.) in ethanol (40 ml.) was treated with phenylsemicarbazide (11.0 g.) in the usual manner to afford crude phenylsemicarbazone (28.8 g., 96.6%), which on fractional crystallization from methanol gave colorless fine needles, m. p. 183~183.5°C (IV″) (8.2 g., 28.4% based on the crude crystalline solid), λ_{max}^{EtOH} 235 mμ (ε, 17200), 284 (34200), and two low-melting fractions which melted at 163~169°C (3.8 g., 13.2%) and 156.5~158°C (15 g., 52.0%), λ_{max}^{EtOH} 235 mμ (ε, 11600), 284 (22900), both of which were apparently heterogeneous.

Found: IV″: N, 10.62. The last fraction: N, 10.48. Calcd. for $C_{25}H_{29}O_2N_3$: N, 10.41%.

On treatment with the Brady reagent, the phenylsemicarbazone IV″ gave the homogeneous 2,4-dinitrophenylhydrazone IV′ in an excellent yield, and the heterogeneous one which melted at 156.5~158°C (2.2 g.), afforded the 2,4-dinitrophenylhydrazones III′ (1.5 g.) and IV′ (0.6 g.).

Treatment of the Original Adduct Obtained Above with Methanolic Sulfuric Acid.—The original adduct (2.0 g.), dissolved in 70% aqueous methanol (13.5 ml.) containing concentrated sulfuric acid (1.4 g.), was warmed for 10 min. at 60°C. To the resultant solution a saturated methanolic solution of potassium acetate was added drop by drop while the mixture was being cooled, until the precipitation of potassium sulfate was complete. The cooled reaction mixture was then filtered, and the filtrate was extracted with benzene. Distillation of the dried benzene solution gave a pale yellow oil (1.15 g.), b. p. 145~146°C/1.5×10^{-2} mmHg, n_D^{28} 1.5481, λ_{max}^{EtOH} 236 mμ (ε, 5000), 308 (1100).

Found: C, 79.24; H, 8.20. Calcd. for $C_{18}H_{22}O_2$: C, 79.96; H, 8.20%.

The oil obtained above (1.0 g.) was again treated with a solution of concentrated sulfuric acid (1.0 g.) in 80% aqueous methanol (7 ml.) for 1 hr. at 60°C and successively for 24 hr. at room temperature. The reaction mixture was neutralized with aqueous potassium carbonate, organic material was taken up in ether and the ether layer was washed with water. After removal of the solvent from the dried solution, the residue was distilled to afford a yellow oil (0.6 g.), b. p. 105~135°C/2×10^{-2} mmHg, which showed light-absorption maxima at 236, 256 and 308 mμ in ethanol.

Condensation of I with Crotonaldehyde (X).—A mixture of I (2.5 g.), X (1.09 g.) and an appropriate solvent (10 ml.) was heated with a small amount of hydroquinone under the conditions listed in Table I in a 50 ml. glass bomb tube. Removal of the solvent, followed by distillation of the residue through a 7 cm. Vigreux column under nitrogen, afforded an inseparable mixture of the expected adducts, 3-isopropyl-6-methyl-3-cyclohexenylmethanal (XI) and 4-isopropyl-6-methyl-3-cyclohexenylmethanal (XII); the properties of these adducts, their elemental analyses and their proportions, determined by gas-liquid chromatography using a 0.6×200 cm., 30% Carbowax-4000 on Celite DM-13A as the column-packing material, are summarized in Table II.

4-Isopropyl-2-methylbenzaldehyde (VI).—*a) Steam Distillation of the Phenylsemicarbazone IV″ with Acid.*—A mixture of IV″ (4.4 g.), propylene glycol (60 g.), *o*-phthalic acid (4.4 g.), concentrated sulfuric acid (22.0 g.) and water (80 ml.) was distilled under superheated steam until no more organic material passed over. The distillate (1400 ml.) was then extracted with ether, and the ether extract was washed with 10% aqueous sodium carbonate and with water and dried over sodium sulfate. Removal of the solvent, followed by fractionation of the residue, gave a fore-run consisting mainly of benzyl alcohol and 4-isopropyl-2-methylbenzaldeheyde (VI) (0.9 g., 51%) in the form of a pale yellow oil. A redistilled sample had b. p. 123~124°C/17 mmHg and n_D^{21} 1.5275. λ_{max}^{EtOH} 259 mμ.

The semicarbazone crystallized from methanol in

8) An asymmetric dienophile, such as β-acetyl acrylic acid[9] and 4-methoxy-β-nitrostyrene[10], possessing two negative groups adjacent to the carbon-carbon double bond will, of course, have the same effect on the direction of the addition of a certain asymmetric diene.

* The gas-liquid chromatogram of the adduct indicated two peaks, at a retention time of 9.7 and 10.3 min., attributable to the compounds XII and XI respectively and the proportion of XII to XI was calculated from their peak areas column temperature, 200°C; the carrier gas, hydrogen, had a flow rate of 30 ml./min.

needles, m. p. 199~200°C, which yellow rapidly on exposure to the light (lit.[13] m. p. 198~199°C).

Found: N, 19.39. Calcd. for $C_{12}H_{17}ON_3$: N, 19.16%.

The 2,4-dinitrophenylhydrazone crystallized from ethanol-ethyl acetate as red-orange needles, m. p. 184~185°C.

Found: N, 16.42. Calcd. for $C_{17}H_{18}O_4N_4$: N, 16.37%.

b) Sulfur Dehydrogenation of the Adduct Obtained in Exp. 1 Listed in Table I.—The adduct (0.9 g.) was heated under reflux with sulfur (1.3 g.) under a nitrogen atmosphere at 230°C for 45 min. at which time the evolution of hydrogen sulfide ceased. The black reaction mixture was distilled under nitrogen and chromatographed on alumina to give a yellow oil (0.4 g.), which provided only the 2,4-dinitrophenylhydrazone of VI, m. p. 184°C, after two recrystallizations from ethanol-ethyl acetate. No depression was observed in melting point on admixture with the 2,4-dinitrophenylhydrazone prepared in a).

5-Isopropyl-2-methylbenzaldehyde (V).—*a) Steam Distillation of the Heterogeneous Phenylsemicarbazone Melted at 156.5~158°C with Acid.*—A mixture of the phenylsemicarbazone (7.0 g.), propylene glycol (70 ml.), *o*-phthalic acid (7.0 g.), concentrated sulfuric acid (30.0 g.) and water (80 ml.) was distilled in the manner described above. Concentration of the dried ether extract, followed by distillation of the residue under nitrogen, gave a small fore-run, b. p. 90~99°C/16 mmHg, consisting largely of benzyl alcohol and a pale yellow oil (1.8 g.), b. p. 115~118°C/16 mmHg, n_D^{21} 1.5288, which on redistillation through a 10 cm. Vigreux column afforded an oil with b. p. 117~118°C/16 mmHg and n_D^{20} 1.5294.

Found: C, 81.32; H, 8.69. Calcd. for $C_{11}H_{14}O$: C, 81.44; H, 8.70%.

The oil obtained above was treated with semicarbazide acetate in methanol to give, after being crystallized from ethanol, the semicarbazone of V, m. p. 169~170°C (lit.[14] m. p. 170~171°C), and an appreciable amount of that of VI, m.p. 198~199°C; the latter exhibited no melting point depression on admixture with that of authentic VI.

Found (for semicarbazone of V): N, 19.29. Calcd. for $C_{12}H_{17}ON_3$: N, 19.16%.

Treatment of this oil with the Brady reagent afforded, after fractional crystallization from ethanol-ethyl acetate, the 2,4-dinitrophenylhydrazone of V, m. p. 193~194°C (lit.[14] m. p. 190~191°C) as brightly red plates.

Found: N, 16.64. Calcd. for $C_{17}H_{18}O_4N_4$: N, 16.37%.

From the soluble fraction, a small amount of the 2,4-dinitrophenylhydrazone of VI, m. p. 183~184°C, was obtained. It exhibited no melting point depression on admixture with the 2,4-dinitrophenylhydrazone prepared from authentic VI.

b) Sulfur Dehydrogenation of the Adduct Obtained in Exp. 3 Listed in Table I.—The adduct (2.0 g.) was heated under reflux with sulfur (1.5 g.) under the same conditions as have been described for the preparation of 4-isopropyl-2-methylbenzaldehyde (VI). The distillate obtained by simple distillation of the reaction mixture was converted into the crude 2,4-dinitrophenylhydrazone (1.32 g.); this, on fractional crystallization from ethanol-ethyl acetate, afforded the 2,4-dinitrophenylhydrazone of VI (0.45 g.), m. p. 184~185°C, and of V (0.35 g.), m. p. 192~193°C, both of which exhibited no melting point depression on admixture with those prepared from authentic VI and V respectively.

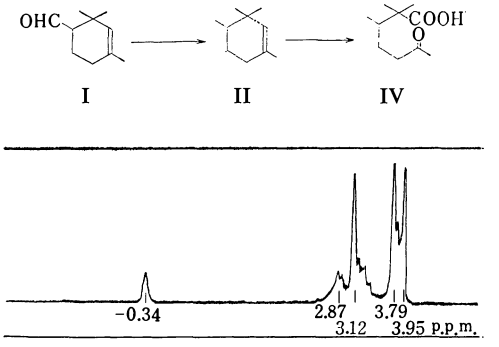
Prins Products from 6-Methyl-β-cyclogeraniolene and Synthesis of 6-Methyl-β-cyclolavandulylideneacetone

By Atsuaki ARAI and Iwao ICHIKIZAKI

(Received September 12, 1961)

The condensation of 6-methyl-β-cyclogeraniolene (1, 3, 3, 4-tetramethyl-1-cyclohexene) (II) with formaldehyde has recently been determined[1,2] to afford 6-methyl-α-cyclogeraniol acetate and 6-methyl-γ-cyclogeraniol acetate, both of which are known[3,4] to be important intermediates for the synthesis of irones. The method employed in the reaction has seemed somewhat unusual, however, for the Prins reaction as generally acknowledged.

The present work was undertaken with the object of determining the structures of some cyclic compounds which might be produced when hydrocarbon II was subjected to the usual conditions for the Prins reaction. The starting hydrocarbon in this work was obtained by Wolff-Kishner reduction of 2, 2, 4-trimethyl-3-cyclohexenylmethanal (I)[1,2,5,6], and the structure assigned to II was attained from infrared data in which the bands due to the trisubstituted double bond (1679 and 798 cm^{-1}) were shown, from the results of oxidation with ozone and/or potassium permanganate, which gave β-methylgeronic acid (IV)[7], and moreover, from the nuclear magnetic resonance spectrum[8] (Fig. 1), in which a singlet peak (−0.34 p. p. m.)



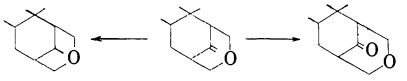


Fig. 1. NMR spectrum of 6-methyl-β-cyclogeraniolene (II).

showed the olefinic proton peculiar to only II of the structures under consideration.

The Prins reaction of II was carried out in a usual manner at −5∼−10°C, and the crude product was divided by fractional distillations into five fractions, as shown in Table I below. The fraction I was demonstrated by gas chromatography and some other means to consist principally of II. From elementary, gas chromatographic and infrared analyses, the principal components of fractions II and IV were revealed to be an unsaturated cyclic oxide and an acetate of unsaturated primary alcohol respectively, while fraction III was also indicated to be a mixture of approximately equal quantities of these two compounds. In order to separate the constituents from each other, the combined fractions of III and IV were treated with alkali and then with boric acid. The oxide was then readily distilled off in vacuo, while the boric ester of the alcoholic component remained in the viscous residue. Redistillation of fraction II combined with the recovered oxide afforded a homogeneous substance, $C_{12}H_{20}O$, whose infrared spectrum showed the presence of a cyclic ether (1111) and an

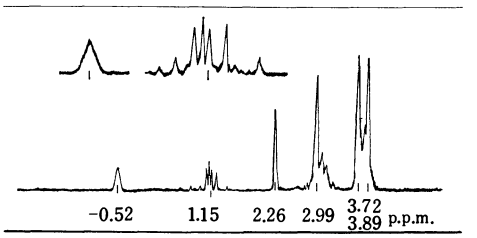
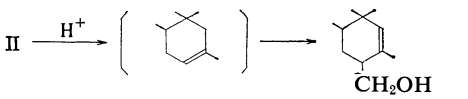
8) The NMR spectra herein recorded were measured with a Varian High Resolution spectrometer, medel V-4300C. All spectra were taken at 56.4 Mc. of a 10% solution of the samples in carbon tetrachloride with an external reference standard of water. All chemical shifts were determined by the side band method. The authors wish to thank Drs. Ichiro Yamaguchi and Naohiro Hayakawa of the Japan Atomic Energy Research Institute for their courtesy in obtaining the spectra.

exocyclic methylene group (3062, 1665, 1414 and 887 cm^{-1}). On catalytic hydrogenation this oxide gave a saturated oxide, $C_{12}H_{22}O$, and on ozonolysis it afforded formaldehyde and a keto-ether, $C_{11}H_{18}O_2$, which was characterized by the presence of bands in the infrared region at 1722 and 1095 cm^{-1}. Thus, the structures of 6, 6, 7-trimethyl-9-methylene-3-oxabicyclo [3, 3, 1] nonane (VII), 6, 6, 7, 9-tetramethyl-3-oxabicyclo [3, 3, 1] nonane (VIII) and 6,6,7-trimethyl-9-oxo-3-oxabicyclo [3, 3, 1] nonane (IX) were assigned respectively for the unsaturated cyclic oxide, the saturated oxide and the keto-ether.

VIII VII IX

The alcohol regenerated from the borate above was found to be an unsaturated primary alcohol, $C_{11}H_{20}O$, and its allophanate, m. p. 167.5°C, was proved to be identical with that of the compound which had been assigned by Fujita[2,9] to 6-methyl-α-cyclogeraniol. Moreover, the alcohol resembled in many respects 6-methyl-α-cyclogeraniol, synthesized by Favre and Schinz[3], to which it had once erroneously been assigned by the present authors[10]. Indeed, the infrared spectrum of the alcohol showed the presence of hydroxyl (3325 and 1041 cm^{-1}) and trisubstituted double bond (1660 and 822 cm^{-1}); however, the nuclear magnetic resonance spectrum failed to conform to the postulated structure. Since the spectrum[8] (Fig. 2) showed for the olefinic proton the singlet peak (−0.52 p. p. m.), which indicates the absence of hydrogen on the carbon atoms adjacent to the olefinic carbon bearing hydrogen, the structure of 6-methyl-α-cyclolavandulol (V) was now furnished to the alcohol. Consequently, it seemed reasonable to consider that the attack of the Prins reagent is extremely difficult on the double bond of II and also that under the reaction conditions II is readily isomerized into 6-methyl-α-cyclogeraniolene (III), which is immediately affected by the reagent to yield V. Examination with the molecular model really showed that the axial approach of the reagent to the double bond in II suffers a large steric hindrance from the gem. dimethyl group and also suggested that III presumably takes the conformation represented as IIIa when it participates in the reaction.





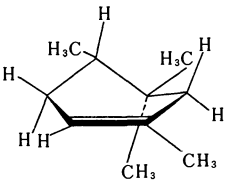


Fig. 2 NMR spectrum of 6-methyl-α-cyclo lavandulol (V).

III V

Va, the acetate

IIIa

Fraction V (Table I) was presumed from the infrared data to contain some acetic esters. An attempted pyrolysis at 350~370°C afforded a small amount of low-boiling liquid which on hydrolysis gave the oxide VII and the alcohol V, whereas most of the high-boiling acetate was recovered unchanged. The latter compound was hydrolyzed to give rise to a glycol which gave a bis-*p*-nitrobenzoate and which was assigned to 3, 3, 4-trimethyl-1-(β-hydroxyethyl)-6-hydroxymethyl-1-cyclohexene (X) by infrared data, in which bands due to a primary hydroxyl (3330 and 1034 cm^{-1}) and to a trisubstituted double bond (1679 and 807 cm^{-1}) were indicated. Thus it was concluded that the fraction V consisted of X-diacetate (Xa) and appreciable amounts of 6,6,7,9-tetramethyl-9-acetoxy-3-oxabicyclo [3,3,1] nonane (XI) and 1, 3, 3, 4-tetramethyl-6-hydroxymethyl-1-cyclohexanol diacetate (XIIa). Although the formation of prim-tert. glycol has been described in many papers[11-16], this is probably the first example in which primary glycol has been isolated.

The mechanism of the Prins reaction has been frequently discussed, and it is generally

9) The authors are indebted to Dr. Yutaka Fujita of the Tokyo Institute of Technology for furnishing a sample of the allophanate, m. p. 166~167°C.

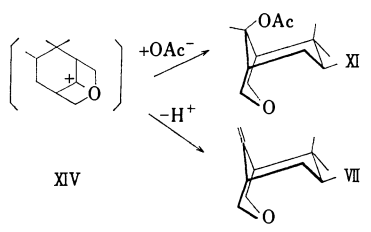
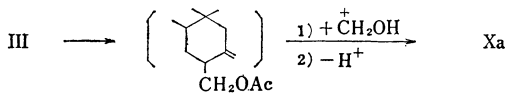
X XI XII



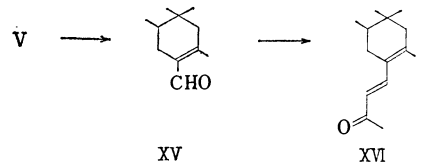
Xa, the diacetate XIIa, the diacetate

accepted[12,13,16] that the first step involves the protonation of a neutral formaldehyde molecule and that the resultant hydroxymethylcarbonium ion carries out an axial attack on a cyclo-olefinic carbon.

The formation of VII and XI offers valuable evidence for the initial axial attachment of the protonated formaldehyde molecule to the double bond in III. These two compounds were plausibly assumed to be produced from an intermediate XIV, which might be provided via the dehydrative cyclization of the hypothetical compound XIII, formed presumably from the interaction between V and another formaldehyde molecule. According to stereochemical considerations, both VII and XI can apparently take up only the 1, 5-diaxial conformation and likely have strainless double-chair forms. If the substituent, $-CH_2OCH_2OH$, in XIII takes the equatrial orientation, the effective approach of C-(4) to C-(5) for cyclization would be obviously impossible; therefore, the hydroxymethylene group in V must have the axial orientation. This was rationally explained independently on the basis of the nuclear magnetic resonance spectrum (Fig. 2), in which the multiplet centering at 1.15 p. p. m. is clearly ascribed to two non-equivalent protons of hydroxymethylene, which is further split by the adjacent ring hydrogen. The non-equivalence of the hydroxymethylene protons is probably due to the restriction of free rotation. Therefore, all the results mentioned above were compatible with the conclusion which involves the initial axial attachment of the hydroxymethylcarbonium ion[12,13,16] to the double bond of cyclic olefins.



XIII



XIV

Additionally, the formation of the primary glycol diacetate Xa might be explained by the attack of another hydroxymethylcarbonium ion on the double bond in the temporarily-formed 6-methylcyclolavandulol acetate (VIa) and the successive elimination of hydrogen.

VIa

Finally, the synthesis of 6-methyl-β-cyclolavandulylideneacetone (XVI) from alcohol V was carried out. Modified Oppenauer oxidation of V with *p*-benzyloxybenzaldehyde as a hydrogen acceptor[17] afforded a high yield of 6-methyl-β-cyclolavandulal (XV), characterized as the semicarbazone whose ultraviolet spectrum revealed the presence of an α, β-unsaturated carbonyl group, while the expected α-isomer was not yielded. Condensation of XV with acetone in the presence of sodium hydride afforded 6-methyl-β-cyclolavandulylideneacetone (XVI)[18], with a strong violet odor, which was authorized by the infrared spectrum and by the light-absorption properties of its solid derivatives.

XV XVI

Experimental[19]

6-Methyl-β-cyclogeraniolene (II). — The Wolff-Kishner reduction of 2,2,4-trimethyl-3-cyclohexenylmethanal (I) was carried out essentially by the method of Fujita[1,2]. Distillation of the reduction product over sodium gave a colorless liquid, b. p. 56~57°C/18 mmHg, whose gas chromatogram, obtained at 196°C with a hydrogen flow of 17.2 ml./min., showed a small peak (about 2% of the total) at a retention time of 3.3 min. and a larger peak (98%) at 3.8 min. The small peak ascribed to an unknown substance disappeared after the sample had been purified by two redistillations with a 40 cm. Vigreux column. The hydrocarbon II had b. p. 60.5~61°C/24 mmHg and $n_D^{18.5}$ 1.4557 (lit.[1] b. p. 59.5~60.5°C/23 mmHg, n_D^{26} 1.4530). IR (film):

18) R. Vonderwahl and H. Schinz, *Helv. Chim. Acta*, 35, 2005 (1952).

19) All melting points were taken on a Kofler-block, and the temperatures are uncorrected. The infrared spectra were determined with a Nippon Bunkō model IR-S spectrophotometer with sodium chloride optics and the ultraviolet spectra, with a Hitachi model EPU-2A spectrophotometer. The gas chromatograms were obtained using a copper column (250 cm.×0.6 cm. ϕ) packed with a Celite DM-13A which was coated with a Carbowax-6000.

1679, 834, 798 (>C=CH-), 1389, 1379, 1362 (CH_3), 854 cm^{-1} (1,3,3,4-tetrasubstituted cyclohexene ring). The NMR spectrum is shown in Fig. 1.

Found: C, 86.76; H, 13.32. Calcd. for $C_{10}H_{18}$: C, 86.88; H, 13.12%.

Oxidation of II.—*a) With Ozone.*—Ozonized oxygen (concentration: 17 g./m^3) was passed through a solution of II (1.2 g.) in carbon tetrachloride (15 ml.) with a flow of 0.5 l./min. over a period of 2.5 hr. The temperature was maintained at −5～−10°C by cooling. Acetic acid (5 ml.) and 30% hydrogen peroxide (1.5 ml.) were added, and the resultant solution was left for 12 hr. at room temperature. After the bulk of the solvent had been removed in vacuo, the residue was made alkaline with 10% aqueous alkali and washed with petroleum ether to remove the neutral substances. The aqueous layer was then made acid with 5% hydrochloric acid and extracted with ether. The ether extract was washed with water, dried over sodium sulfate and evaporated to leave a viscous oil (0.5 g.), which was distilled to give β-methylgeronic acid (IV) (0.35 g.), b. p. 130～135°C/0.8 mmHg, n_D^{21} 1.4564. IR (film): 3060 (broad), ～2680, 1715, 1700, 1472, 1415, 1383, 1369, 1286, 1248, 1167, 1142, 939 cm^{-1} (broad).

The semicarbazone crystallized from methanol in prisms, m. p. 142～143°C (lit.[7] m. p. 141～142°C).

Found: C, 54.38; H, 8.90. Calcd. for $C_{11}H_{21}O_3 \cdot N_3$: C, 54.30; H, 8.70%.

The 2, 4-dinitrophenylhydrazone crystallized from ether-petroleum ether in the form of yellow crystals, m. p. 130～130.5°C (lit.[7] m. p. 130.5～131.5°C).

Found: C, 53.04; H, 6.34. Calcd. for $C_{16}H_{22}O_6 \cdot N_4$: C, 52.45; H, 6.05%.

In this experiment, no formaldehyde was detected in the reaction mixture.

b) With Potassium Permanganate.—A solution of II (1.38 g.) in petroleum ether (b. p. 38～45°C, 30 ml.) was added to an aqueous solution (150 ml.) of potassium permanganate (3.16 g., 3 "O"), and the mixture was stirred vigorously at 5～10°C for 4 hr. Methanol was added, and the resultant mixture was warmed at 60°C for 10 min. to decompose the excess of permanganate and then filtered. The precipitate was repeatedly washed with hot water. The filtrate and washings were combined and concentrated to ca. 30 ml. in vacuo, acidified with 10% hydrochloric acid and extracted with ether. The ether extract was washed with water, dried over sodium sulfate, evaporated and distilled to give an oil (0.3 g.). Its semicarbazone gave no mixed melting point depression with that of IV obtained by the method of a).

Prins Reaction with II.—A solution of II (35 g.) in acetic acid (23 ml.) diluted with ether (8.5 ml.) was added drop by drop over a period of 1 hr. into a mixture of paraformaldehyde (10.3 g.), acetic acid (46 ml.), ether (12.5 ml.) and concentrated sulfuric acid (8.5 ml.), and vigorous stirring was then continued for 7 hr. The temperature was maintained at −5～−10°C by cooling. The reaction mixture was allowed to stand overnight at 0°C, then poured into an ice-cooled 15% aqueous sodium carbonate solution (280 ml.) and extracted with ether. The ether extract was washed with water, dried over magnesium sulfate and evaporated to leave a red-brown oily residue (33.5 g.) which, on repeated fractionations through a 25 cm. Vigreux column, yielded the five representative fractions cited in Table I.

Distillation of fraction I over sodium gave a homogeneous substance (4.3 g.) with a b. p. 51.5°C/14.5 mmHg and $n_D^{18.5}$ 1.4557, which was identified as being the starting hydrocarbon II. Gas chromatogram, infrared and NMR spectra comparisons and ozonolysis showed that II is not subject to isomerization during the reaction.

6-Methyl-α-cyclolavandulol (V).—Combined fractions of III (4.4 g.) and IV (2.9 g.) (Table I) were hydrolyzed by treating them with potassium hydroxide (5.5 g.) in methanol (40 ml.) and water (20 ml.) at room temperature for 44 hr. After removal of the solvent in vacuo, the resulting mixture was neutrallized with 10% hydrochloric acid and extracted with petroleum ether. The petroleum ether extract was washed with water, dried over sodium sulfate and evaporated. The residual oil was heated with boric acid (0.5 g.) at a bath temperature of 160°C and at 500 mmHg for 30 min.; meanwhile, the water formed was distilled off. This work-up was repeated with another boric acid (1.0 g.) to make the esterification of the alcohol complete. The reaction mixture was then distilled gradually until the bath temperature reached 170°C at 0.75 mmHg to give a colorless liquid (2.0 g.), n_D^{25} 1.4833, which was shown by infrared and gas chromatographic analyses to consist mainly of the unsaturated cyclic oxide, and to leave the boric ester as an orange syrup, which was taken up in hot benzene (40 ml.) and hydrolyzed by shaking it with a hot 0.5% aqueous sodium carbonate solution. The

Table I. Fractionation of the reaction mixture

Fraction No.	B. p. °C/mmHg	n_D^T	Fraction wt., g.	Composition C, H %	Infrared maxima cm^{-1}

benzene layer was dried over sodium sulfate, evaporated and distilled to afford 6-methyl-α-cyclolavandulol (V) (3.5 g.) as a colorless oil, b. p. 117～118°C/15 mmHg, n_D^{23} 1.4825. IR (film): 3325, 1041, (OH), 1660, 822 (>C=CH-), 1390, 1379, 1364 (CH_3), 857 cm^{-1} (1, 3, 3, 4, 6-pentasubstituted cyclohexene ring). The NMR spectrum is shown in Fig. 2.

Found: C, 78.50; H, 11.93. Calcd. for $C_{11}H_{20}O$: C, 78.51; H, 11.98%.

The allophanate crystallized from methanol in colorless crystals, m. p. 167.5°C, which gave no mixed melting point depression with that (m. p. 166～167°C) of the so-called 6-methyl-α-cyclogeraniol furnished by Fujita[2,9].

Found: C, 61.44; H, 8.83. Calcd. for $C_{13}H_{22}O_3N_2$: C, 61.39; H, 8.72%.

6, 6, 7-Trimethyl-9-methylene-3-oxabicyclo[3, 3, 1]-nonane (VII).—Fraction II (11.2 g.) (Table I), combined with the above-recovered fraction (2.0 g.) containing oxide, was fractionated over sodium through a 25 cm. Vigreux column to give a fore-run (2.0 g.) with a menthol-like odor, b. p. 96～99.5°C/16.5 mmHg and $n_D^{25.5}$ 1.4828～1.4832, and a colorless oil (8.9 g.), b, p. 100～100.5°C/16.5 mmHg, $n_D^{25.5}$ 1.4852, both of which easily consumed bromine in a carbon tetrachloride solution. Redistillation of the latter afforded 6, 6, 7-trimethyl-9-methylene-3-oxabicyclo[3,3,1]nonane (VII) (8.5 g.) with a strong menthol-like odor, b. p. 72～72.5°C/3.7 mmHg, $n_D^{25.5}$ 1.4853, whose gas chromatogram obtained at 211°C with a hydrogen flow of 28.8 ml./min. showed a single peak at a retention time of 9.3 min.

IR (film): 3062, 1665, 1414, 887 (>C=CH_2), 1775 (over-tone of δ CH (887)), 1111 (ether, C-O-C), 1393, 1380, 1374 (CH_3), 1235, 1198 ($H_3C-\overset{|}{C}-CH_3$), 1009, 760 cm^{-1} (unassigned).

Found: C, 79.60; H, 11.33. Calcd. for $C_{12}H_{20}O$: C, 79.94; H, 11.18%.

From gas chromatography, the fore-run (Found: C, 80.29; H, 11.36%) was shown to consist largely of VII contaminated with ca. 7% of another unknown substance, which appeared as a broad peak at a retention time of 7.6 min. under the same conditions as above; this substance could not be isolated.

6, 6, 7, 9-Tetramethyl-3-oxabicyclo[3, 3, 1]nonane (VIII).—The unsaturated cyclic oxide VII (2.25 g.) in ethyl acetate (20 ml.) was hydrogenated at one atmosphere in the presence of a palladium-calcium carbonate catalyst (5% Pd, 1.0 g.) until one molar equivalent (315 ml. at 21.6°C) of hydrogen had been absorbed. Removal of the catalyst and solvent, followed by distillation of the residue, afforded 6, 6, 7, 9-tetramethyl-3-oxabicyclo[3, 3, 1]nonane (VIII) (1.9 g., 83%) as a colorless liquid with a menthol-like odor, b. p. 110°C/16 mmHg and n_D^{21} 1.4835, which did not decolorize a solution of bromine in carbon tetrachloride. IR (film): 1398, 1386, 1376, 1366 (-CH_3), 1236, 1194 ($H_3C-\overset{|}{C}-CH_3$), 1176, 1134 ($HC-CH_3$), 1088 cm^{-1} (ether, C-O-C).

Found: C, 79.06; H, 12.16. Calcd. for $C_{12}H_{22}O$: C, 79.06; H, 12.16%.

6, 6, 7-Trimethyl-9-oxo-3-oxabicyclo[3, 3, 1]nonane (IX).—The unsaturated cyclic oxide VII (0.5024 g.) in carbon tetrachloride (15 ml.) was ozonized at −10°C for 3 hr., after which time the resultant solution did not consume bromine in a carbon tetrachloride solution. At the end of the apparatus a trap containing water (20 ml.) was equipped to absorb the formaldehyde carried away by the gas stream during the reaction. The reaction mixture was heated under reflux with water (30 ml.) for 2 hr. in a flask fitted with a reflux condenser, the top of which had previously been connected with the water trap. The water in the trap was warmed with a solution of dimedone (0.9 g.) in ethanol (40 ml.) at 60°C for 10 min. to yield the formaldehyde-dimedone condensation product (0.1733 g., 21.2%). The carbon tetrachloride solution was dried over calcium chloride, evaporated in vacuo and distilled to give 6, 6, 7-trimethyl-9-oxo-3-oxabicyclo[3, 3, 1]nonane (IX) (0.25 g., 50%) as a colorless liquid, b. p. 84～84.5°C/1.5 mmHg, n_D^{25} 1.4850. IR (film): 1722 (C=O), 1094 (ether, C-O-C), 1398, 1370 (CH_3), 1220, 1185 ($H_3C-\overset{|}{C}-CH_3$), 861 cm^{-1} (unassigned).

Found: C, 72.06; H, 10.08. Calcd. for $C_{11}H_{18}O_2$: C, 72.49; H, 9.96%.

The semicarbazone crystallized from methanol-ethyl acetate in the form of prisms, m. p. 224～225°C.

Found: C, 60.00; H, 8.99. Calcd. for $C_{12}H_{21}O_2N_3$: C, 60.22; H, 8.85%.

The 2,4-dinitrophenylhydrazone crystallized from methanol-ethyl acetate in the form of yellow needles, m. p. 248～249.5°C.

Found: C, 56.51; H, 6.34. Calcd. for $C_{17}H_{22}O_5N_4$: C, 56.34; H, 6.12%.

Pyrolysis Followed by Alkaline Hydrolysis of the Mixed Acetates (Fraction V in Table I).—Fraction V (6.0 g.) was heated at 350～370°C and 500 mmHg under nitrogen for 4 hr. The pale yellow pyrolyzate (4.9 g.) was taken up in ether and washed with 2% aqueous sodium hydrogencarbonate and with water to remove the acetic acid formed and then dried over sodium sulfate. Removal of the solvent followed by fractionation of the residue gave two fractions, b. p. 74～75°C/2.8 mmHg, $n_D^{21.5}$ 1.4911 (0.5 g.) (Found: C, 80.39; H, 11.32%) and b. p. 100～105°C/0.7 mmHg, $n_D^{21.5}$ 1.4964 (3.9 g.). The low-boiling fraction was hydrolyzed by treating it with potassium hydroxide (0.5 g.) in ethanol (10 ml.) at room temperature for 40 hr. The reaction mixture was neutralized with 10% hydrochloric acid and extracted 5 times with ether. The combined ether extracts were washed with water, dried and evaporated. Distillation of the residue gave a colorless liquid (0.3 g.), b. p. 65～72°C/1.5 mmHg, $n_D^{22.5}$ 1.4858 (Found: C, 79.16; H, 11.57%), which was not yet homogeneous and which showed in the infrared region bands at 3080, 1660, 1413, 891 and 1110 cm^{-1}, attributable to oxide VII, and medium bands at 3350 (broad) and 1041 cm^{-1}, attributable to alcohol V. A small amount of the allophanate of V was obtained, in fact. The high-boiling fraction was hydrolyzed in a similar manner before being used with potassium hydroxide

(1.8 g.) in methanol (20 ml.) to afford 3,3,4-trimethyl-1-(β-hydroxyethyl)-6-hydroxymethyl-1-cyclohexene (X) (1.6 g.) as a viscous liquid, b. p. 123～125°C/0.7 mmHg, n_D^{29} 1.4979. IR (film): 3330, 1034 (OH), 1679, 842, 807 (>C=CH-), 1392, 1378, 1368 (CH_3), 866 cm^{-1} (1,3,3,4,6-pentasubstituted cyclohexene ring).

Found: C, 73.21; H, 11.20. Calcd. for $C_{12}H_{22}O_2$: C, 72.68; H, 11.18%.

The bis-*p*-nitrobenzoate crystallized from ethanol-ethyl acetate in the form of needles, m. p. 131～132°C.

Found: C, 62.41; H, 5.52; N, 5.54. Calcd. for $C_{26}H_{28}O_8N_2$: C, 62.89; H, 5.68; N, 5.64%.

6-Methyl-β-cyclolavandulal (XV).—A mixture of alcohol V (2.0 g.) and aluminum isopropoxide (1.0 g.) was heated at a bath temperature of 70～80°C and at 13 mmHg for 1.5 hr. to form V-aluminate, and then *p*-benzyloxybenzaldehyde (3.78 g., 150%) was added in one portion. The resultant mixture was preheated at a bath temperature of 80°C under ordinary pressure for 2 min. to give the melt, which was subsequently distilled by raising the temperature from 110 to 180°C under nitrogen to afford a product, b. p. 60～101°C/4 mmHg. Redistillation of the product through a 7 cm. Vigreux column afforded 6-methyl-β-cyclolavandulal (XV) (1.35 g., 68.5%), b. p. 93～96°C/13 mmHg, $n_D^{27.5}$ 1.4790.

Found: C, 79.51; H, 10.88. Calcd. for $C_{11}H_{18}O$: C, 79.46; H, 10.92%.

The semicarbazone crystallized from methanol-ethyl acetate in the form of prisms, m. p. 224～225°C (partly decomp.). λ_{max}^{EtOH} 272 mμ (ε, 30300).

Found: C, 64.62; H, 9.69; N, 18.88. Calcd. for $C_{12}H_{21}ON_3$: C, 64.54; H, 9.48; N, 18.82%.

The 2,4-dinitrophenylhydrazone chromatographed on alumina in benzene and crystallized from ethanol-ethyl acetate in the form of red needles, m. p. 207～208°C.

Found: C, 59.04: H, 6.38; N, 16.01. Calcd. for $C_{17}H_{22}O_4N_4$: C, 58.94; H, 6.40; N, 16.18%.

6-Methyl-β-cyclolavandulylideneacetone (XVI).—A solution of XV (1.1 g.) in acetone (10 ml.) was added drop by drop to an acetone solution containing sodium hydride (40 mg.) at room temperature, and the resultant solution was stirred for 6 hr. and then allowed to stand overnight under nitrogen at this temperature. After the solvent had been removed, the residue was taken up in ether, washed with 2 N hydrochloric acid and with water, dried over sodium sulfate and evaporated. Distillation under nitrogen gave a fore-run (0.4 g.), 62～90°C/0.85 mmHg, which consisted largely of unchanged XV and of an oil (0.75 g.), 90～110°C/0.7 mmHg, $n_D^{25.5}$ 1.4940～1.5118. Redistillation of the latter gave the ketone XVI (0.55 g.) as a pale yellow oil with a strong violet odor, b. p. 105～110°C/0.7 mmHg, $n_D^{25.5}$ 1.5118. IR (film): 1675 (C=O, conju.), 1624, 1594 (C=C, conju.), 1382, 1369 (gem. dimethyl), 1268 ($COCH_3$), 970 cm^{-1} (-CH=CH-, *trans*).

Found: C, 81.42; H, 10.94. Calcd. for $C_{14}H_{22}O$: C, 81.50; H, 10.75%.

The 4-phenylsemicarbazone crystallized from methanol-ethyl acetate in the form of fine needles, m. p. 198～199°C, which rapidly turned yellow on exposure to light or air. λ_{max}^{EtOH} 234 mμ (log ε, 4.04), 301 (4.58). (lit.[18] m. p. 196～197°C, λ_{max}^{EtOH} 234 mμ (log ε, 4.70). 307 (4.12)).

Found: C, 74.31; H, 8.66. Calcd. for $C_{21}H_{29}ON_3$: C, 74.30; H, 8.61%.

The 2,4-dinitrophenylhydrazone crystallized from methanol-ethyl acetate in the form of dark-red, silk-like needles, m. p. 209°C. $\lambda_{max}^{CHCl_3}$ 391 mμ (log ε, 4.55). (lit.[18] m. p. 197.5°C, $\lambda_{max}^{CHCl_3}$ 397 mμ (log ε, 4.50)).

Found: C, 62.24; H, 6.76; N, 14.22. Calcd. for $C_{20}H_{26}O_4N_4$: C, 62.16; H, 6.78; N, 14.50%.

The authors wish to express their thanks to Dr. Toshiaki Nishida of this Laboratory for his helpful discussions of the NMR spectra and to Dr. Asaji Kondō of the Tokyo Institute of Technology for his microanalyses. They are also indebted to Mr. Kōsei Tanabe for his technical assistance.

Studies of the Cage Effect of Solvent. III. Photolysis of Azomethane in Frozen Solutions

By Sukeya KODAMA

(Received September 4, 1961)

Previous studies of the photolysis of azomethane in *n*-hexane,[1] *n*-octane, toluene, ethyl acetate and ethanol[2] have suggested that a pair of methyl radicals formed by the decomposition of a substrate molecule combine to form an ethane molecule with a high yield in the solvent cage. The yield of ethane has been found to increase with the lowering of the temperature, and it may be expected that still higher yields would be obtained in frozen solutions if the ethane were formed in the way given above.

This paper reports on experiments carried out to investigate the effect of such freezing as well as to obtain additional results in various other solvents than those already studied. The solvents used are cyclohexane, benzene, styrene, *o*-xylene and *tert*-amyl alcohol.

Experimental

The preparation, purification and storage of azomethane have been described previously[1]. Cyclohexane obtained from a commercial sample of a special high grade was boiled with stannous chloride and hydrochloric acid and then distilled. Benzene, styrene, *o*-xylene and *tert*-amyl alcohol were taken from commercial samples of a special high grade without further purification. All these solvents, as well as azomethane, were subjected to vacuum distillation each time befor use.

The apparatus and procedure have been described in a previous paper[1]. The concentration of azomethane was about 3×10^{-2} mol./l. in all the experiments, and the volume of solution was adjusted so that it just filled the reaction cell of ca. 10 ml. capacity at the temperature of photolysis. A mercury line of 366 mμ was used for the photolysis. The extent of conversion in each run was within several percentage points. Nitrogen, methane and ethane, produced by the photolysis, were analyzed in the way that has been described previously[1].

Results and Discussion

The results obtained are shown in Figs. 1—6. As has been described in previous papers[1,2], CH_4/N_2, C_2H_6/N_2 and $[(1/2)CH_4+C_2H_6]/N_2$ represent respectively the yields of methane and ethane and the material balance referring to them. The main feature of the photolysis in the liquid phase is, as seen in the figures, similar to that found previously for a number of other solvents[1,2]. Hence, the mechanism of the photolysis in the liquid solutions here studied may be envisaged as the same as in the previous work. The formation of ethane may thus be ascribed to the cage combination of a pair of methyl radicals resulting from the decomposition of the substrate molecule, and that of methane, mostly to the hydrogen atom abstraction from the solvent molecules by methyl radicals that have escaped the original solvent cage.

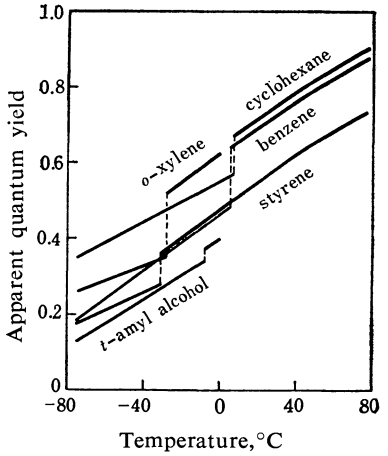

Fig. 6. Apparent quantum yields.

Figures 1—5 show that, on freezing the solution, the yield of ethane is more or less enhanced, while that of methane is mostly reduced. Such a result is in agreement with what is to be expected if the ethane is formed in the way described above, for in the frozen solutions the two methyl radicals formed by the photolysis from an azomethane molecule would not diffuse away from each other with such ease as in liquid solutions.

As the temperature is further lowered, however, the methyl radicals would become more and more immobile, and the yield of ethane would then be determined by the geometrical arrangement of the three fragments produced by the photolysis and by the structure of the environment, rather than by the rate of escaping diffusion of methyl radicals. The small dependence of the yields of ethane and methane in frozen solutions upon temperature as seen in Figs. 1—5 appears to reflect the small variation in the structure of the solid with variations in temperature, as supposed from far smaller expansion coefficients of solids than those of liquids. It seems, however, probable that, in the experiments at very low temperatures, both ethane and methane are partly formed from methyl radicals mobilized on warming up the reaction cell after irradiation.

Frozen solutions are, on the other hand, probably heterogeneous, solute molecules aggregating in boundaries between grains of the frozen solvent. Although it is not feasible to observe the effect of such a heterogeneous structure separately, the variation in the velocity of freezing would lead to different structures and hence, possibly, to different results. Table I shows the results of such experiments carried out with cyclohexane as a solvent. In Runs 1 and 2, the solution was frozen by immersing the cell in liquid nitrogen

TABLE I. PHOTOLYSIS OF AZOMETHANE IN CYCLOHEXANE AT 0°C

Run No.	Time of irradiation min.	Rate of formation $\times 10^{10}$ mol. sec^{-1}			$\frac{CH_4}{N_2}$	$\frac{C_2H_6}{N_2}$	$\frac{\frac{1}{2}CH_4+C_2H_6}{N_2}$
		R_{N_2}	R_{CH_4}	$R_{C_2H_6}$	%	%	%
1	42	22.6	5.33	19.7	23.6	87.2	99.0
2	90	21.3	4.35	18.6	20.4	87.2	97.4
3	66	20.8	4.33	18.1	20.8	87.0	97.4

and in dry ice-acetone respectively, and then warmed to 0°C without melting. In Run 3 the solution was simply cooled from room temperature to 0°C and frozen at the latter temperature. As seen in the table, the yields of ethane in these three runs are identical, though the yield of methane is slightly higher in the solution frozen with liquid nitrogen. The cage combination of methyl radicals thus appears to be rather insensitive to the heterogeneity considered above.

As is seen in Fig. 1, the results obtained with cyclohexane show some anomalies below its melting point; the yields of ethane and methane reflect less sharply the transition from liquid to solid, compared to the other solutions. On inspecting the reaction cell, it was found that the front surface of the frozen solution was melted under irradiation, presumably because of the low heat of the fusion of cyclohexane[3]. It is, therefore, most probable that such partial melting gave rise to the above anomalous behavior in the experiments with cyclohexane.

The results obtained with styrene are of interest in view of its large methyl affinity[4]. In the previous work performed with various solvents, it was used as a scavenger of methyl radicals escaping from the solvent cage. Figures 1—5 show that the yield of ethane in styrene is, in the liquid phase as well as in the solid, of a magnitude comparable to those in the other solvents. This is not an unexpected result, because the scavenging reaction of styrene requires the activation energy of some 5 kcal./mol.[2], while that of the combination of methyl radicals is nearly zero. Figure 3 shows further that the formation of methane is suppressed almost completely in styrene in both the liquid and the solid phases, which may be accounted for by the greater activation energy of the abstraction reaction than that of the addition[5]. The difference $1-C_2H_6/N_2$ in this case may therefore be taken approximately as the fraction of methyl radicals used in the addition to styrene. Such addition may in turn be expected to induce the polymerization of styrene. In the experiments carried out at high temperatures, it has been observed that such polymerization really takes place.

Benzene has also a fairly large methyl affinity[6] owing to its unsaturated structure, and may be expected to show the effect of the addition reaction. The results given in Fig. 2 show that the addition competes with the abstraction, but the effects of temperature on the two reactions suggest that their Arrhenius parameters are appreciably different. By applying the same method as has been described previously[2], the difference in activation energies can be computed as

$$E_{addition} - E_{abstraction} = 1.5 \text{ kcal./mol.}$$

Figure 4 shows that, though *o*-xylene also has double bonds, the contribution of the addition reaction is negligible. On the other hand, Fig. 5 shows a rather large loss in the material balance, though *tert*-amyl alcohol has no double bond. Presumably, impurities in the alcohol have given rise to the loss of methyl radicals in this case.

It has been found in the previous work[1,2] that the variation in the yields of ethane in various solvents can be represented by an empirical equation

$$1-C_2H_6/N_2 = A\exp(-E/RT)$$

wherer A and E are constants. Figure 7 shows that this equation also conforms to the results in the liquid solutions in this work. Table II gives the values of the constants A and E obtained from the figure.

Figure 6 shows the apparent quantum yields obtained by comparing the rates of formation

TABLE II. ARRHENIUS CONSTANTS

	A	E kcal./mol.

of nitrogen. They all decrease with the lowering of the temperature, as has been found previously[1,2], and are, on freezing the solutions, lowered discontinuously, which may be ascribed to reduced absorption of light by the frozen solution as well as to the increased recombination of a pair of initially formed radicals, CH_3N_2 and CH_3[1]. It has been found in the previous work[2] that the apparent quantum yield is low in polar solvents. Figure 6 shows a similar tendency in this work.

Summary

The photolysis of azomethane has been studied in cyclohexane, benzene, styrene, *o*-xylene and *tert*-amyl alcohol in the temperature range both above and below the freezing point of a given solution. The results obtained in the liquid solutions are essentially similar to those previously obtained with other solvents, except for styrene. The photolysis in the latter differs in that it gives little methane because of the strong scavenging action of styrene. Nevertheless, ethane with a yield comparable to those in the other solvents is formed even in styrene. It has been found with all the solutions investigated that the yield of ethane is more or less enhanced by freezing. All these findings provide additional evidence that the ethane is formed by the cage combination of a pair of methyl radicals resulting from the decomposition of a substrate molecule. For all the solvents investigated, the temperature dependence of the yield of ethane in the liquid phase conforms to the empirical equation previously presented. The apparent quantum yields obtained by comparing the rates of formation of nitrogen decrease with the lowering of the temperature, as was found previously.

Studies of the Cage Effect of Solvent. IV. Dependence of the Cage Combination of Methyl Radicals on Solvent and on Temperature

By Sukeya KODAMA

(Received September 15, 1961)

It has been shown in a previous paper[1] that the photolysis of azomethane in *n*-hexane provides a good example of the cage combination of methyl radicals that can be studied quantitatively. This photolysis has further been studied with various other solvents, and the results obtained have subsequently been reported[2,3]. This paper presents a discussion of these results with reference to the dependence of the cage combination of methyl radicals on solvent and on temperature.

Experimental Results

The solvents in which the photolysis of azomethane has been studied are *n*-hexane[1], *n*-octane[2], benzene[3], toluene[2], styrene[3], *o*-xylene[3], cyclohexane[3], ethyl acetate[2], ethanol[2] and *tert*-amyl alcohol[3]. The photolysis was conducted by the irradiation of a mercury line of 366 mμ throughout all the experiments. Some experiments were also carried out with

1) S. Kodama, This Bulletin, 35, 652 (1962).
2) S. Kodama, ibid., 35, 658 (1962).
3) S. Kodama, ibid., 35, 824 (1962).

313 mμ in *n*-hexane[1], but they gave no appreciably different results. The range of the extent of conversion in the runs was usually within several percentage points.

The main products of the photolysis have always been found to be nitrogen, methane and ethane. It has been shown by a scavenger technique using styrene that all the ethane formed by the photolysis can be attributed to the cage combination of a pair of methyl radicals resulting from the decomposition of a substrate molecule[1,2]:

$$(CH_3)_2N_2 + h\nu \rightarrow [2CH_3 + N_2] \quad (1)$$

$$[2CH_3 + N_2] \rightarrow C_2H_6 + N_2 \quad (2)$$

(Here the parentheses denote the solvent cage.) The results obtained with a scavenger show, on the other hand, that the formation of methane is explained by the hydrogen atom abstraction from a solvent molecule by a methyl radical that has escaped the cage:

$$[2CH_3 + N_2] \rightarrow CH_3 + N_2 + CH_3 \quad (3)$$

$$CH_3 + HR \rightarrow CH_4 + R \quad (4)$$

where HR represents a solvent molecule. The material balance referring to nitrogen, methane and ethane, however, indicates that a small fraction of the methyl radicals, increasing in quantity with the temperature, yields other products than methane, presumably by various addition reactions.

Since the rate of photolysis is given by that of the formation of nitrogen, the ratio of the amount of ethane formed to that of nitrogen, C_2H_6/N_2, represents the yield of ethane. According to the mechanism given above, this yield of ethane represents the probability of the cage combination of a pair of methyl radicals produced in the solvent cage. It has been confirmed by experiment that the yield of ethane in a given solvent is affected neither by the rate of photolysis nor by the concentration of substrate, but is dependent only on the temperature. Figure 1 shows the effect of the temperature on the yield of ethane for the various solvents investigated[4]. The figure shows only results obtained in liquid solutions. For some of these solvents, the photolysis in frozen solutions has been studied[3]; the yield of ethane is more or less enhanced on freezing the solution, and the yield in the frozen solution is far less dependent on the temperature than in the liquid. These results are not illustrated here, however, because they have no direct relation to the present discussion.

In this paper viscosity is shown to be an important property of the solvent influencing

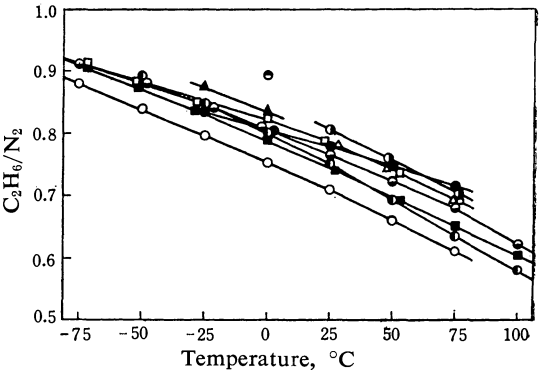

Fig. 1. Yields of ethane obtained with various solvents. ○, *n*-Hexane; ◐, *n*-Octane; ◑, Cyclohexane; ◒, Toluene; ◓, *tert*-Amyl alcohol; ●, Styrene; △, Benzene; ▲, *o*-Xylene; □, Ethanol; ■, Ethyl acetate

the yield of ethane. Table I gives the parameters for the expression $\eta = \eta_0 \exp(E_\eta/RT)$, where η is the viscosity of the solvent. These values were all obtained from Arrhenius plots of the viscosities measured in this work in the temperature range 0 to 60°C, because the solvents used in this work might not always have been pure. For *tert*-amyl alcohol viscosity was measured only at 0°C, with the result that $\eta = 0.1168$ poise. The viscosity values obtained for *n*-octane, ethanol, cyclohexane, benzene, toluene and styrene were in good agreement with those previously reported, while for *o*-xylene, ethyl acetate and *tert*-amyl alcohol somewhat higher values were obtained. *n*-Hexane showed considerably higher values than those in the literature, presumably because the sample used had been prepared from petroleum and so contained higher hydrocarbons, even after purification. All the viscosity values used in the following discussion have been calculated from Table I.

TABLE I. ARRHENIUS PARAMETERS FOR VISCOSITIES OF SOLVENTS

Styrene	0.988 (−25°C)	0.980	0.947 (75°C)

appears to depend on the viscosity of the solvent rather than on any other property. However, the differences in the yields are not large, and both the yield and viscosity are dependent on the temperature. No reliable conclusion can, therefore, be drawn from the table.

It has previously been found[1-3] that the variation in the yield of ethane with the temperature, as shown in Fig. 1, conforms to the following equation for all the solvents investigated:

$$C_2H_6/N_2 = 1 - A_I \exp(-E_I/RT) \qquad (I)$$

where A_I and E_I are constants dependent on the nature of the solvent. In Table III are listed the values of these constants determined for various solvents. The constants A_I and E_I thus reflect the specific behavior of each solvent towards the cage combination of methyl radicals and appear at first sight to deserve further discussion. Nevertheless, unfortunately, the equation is merely an empirical one, and hence neither A_I nor E_I is a well defined quantity.

The mechanism of the photolysis represented by reactions 1−4 gives only a crude picture of what would really take place; reactions 2 and 3 would actually involve sequences of complicated diffusive displacements in a system where methyl radicals are surrounded by solvent molecules of complex structure and with variable configurations and orientations. The

situation thus appears to be intractable to any simple theoretical treatment.

The simplest way to interpret the data obtained in this work may be to treat reactions 2 and 3 as though they were elementary processes[1]. This is probably an over-simplification in view of the argument given above, but it may be of some interest to see what is obtained by the application of such a treatment. Reactions 2 and 3 give in the steady state

$$(1-C_2H_6/N_2)/(C_2H_6/N_2)=k_3/k_2 \qquad (II)$$

where k_2 and k_3 are the respective rate constants. It is generally accepted that two methyl radicals in contact with each other require no activation energy to combine. If, therefore, the chance for such a contact in the cage can be assumed to be approximately independent of the temperature, k_3 would be a constant. Then the Arrhenius plot of the quantity on the left-hand side of the above equation would give the activation energy of reaction 3, which may approximately be taken as the diffusion energy of methyl radicals in solution. Figure 2 shows, however, that actually most such plots have bends at about 25°C. It may be expected that the simplified treatment applied here deviates more from reality with a rise in temperature. In Table III are, therefore, listed the Arrhenius parameters A_{II} and E_{II} determined from linear plots in the low temperature range. As seen in the table, these values differ not greatly from those obtained by Eq. I. E_{II} values are lower than the corresponding diffusion energies of solvents given together in the table. The present work gives no evidence to justify the simple treatment applied here, but these low E_{II} values would not necessarily contradict the interpretation that E_{II} represents approximately the diffusion energy of methyl radicals in solution, since the diffusion energies given in the table are those for self-diffusion[5].

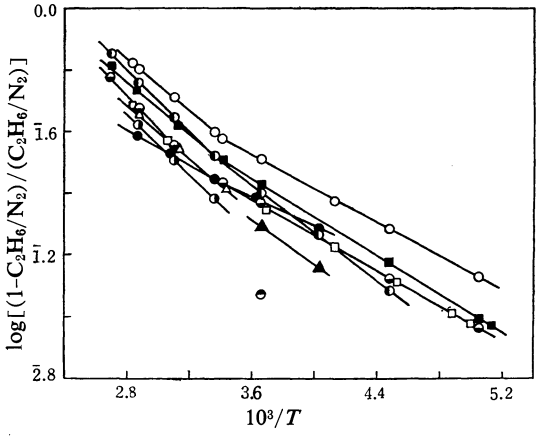

Fig. 2. Arrhenius plots for $(1-C_2H_6/N_2)/(C_2H_6/N_2)$. ○, *n*-Hexane; ◐, *n*-Octane; ◑, Cyclohexane; ◒, Toluene; ◓, *tert*-Amyl alcohol; ●, Styrene; △, Benzene; ▲, *o*-Xylene; □, Ethanol; ■, Ethyl acetate

Another approach to the problem being considered has been given by Noyes[6]. He has derived a theoretical expression for the quantum yield of the photolysis of iodine in solution, assuming that the solvent can be treated as a viscous continuum in which iodine atoms displace by diffusion. The comparison between the theory and experiment has shown that the theory gives rather satisfactory results. The following is an attempt to apply Noyes's theory to the present photolysis, though such a treatment here meets various difficulties.

According to Noyes, if β_0' is the probability that two iodine atoms whose centers were initially separated by a distance s_t will ultimately combine with each other,

$$\beta_0'=2a\beta'/s_t \qquad (III)$$

where a is the radius of the iodine atom and β', the probability that two atoms which were initially in contact with each other will recombine if they separate with an average thermal kinetic energy. The distance of the initial separation s_t is given by

$$s_t=2a+(m\varepsilon)^{1/2}/(3\pi\eta a) \qquad (IV)$$

where m is the mass of an iodine atom, η the viscosity of solvent, and ε the kinetic energy with which two iodine atoms separate in opposite directions. Equations III and IV can be combined to give

$$\beta_0'=\beta'/[1+(m\varepsilon)^{1/2}/(6\pi\eta a^2)] \qquad (V)$$

The expression for β' is obtained in a similar way:

$$\beta'=1/[1+(mkT)^{1/2}/(2\sqrt{6}\,\pi\eta a^2)] \qquad (VI)$$

If ϕ is the quantum yield, β_0' is equal to $1-\phi$. Hence, the quantum yield can be calculated when ε and η are given.

In the photolysis of azomethane, $2a$ in Eq. IV should be replaced by $2s_0$, the distance between the two carbon atoms in an azomethane molecule. Consequently, Eq. V should be written as

$$\beta_0'=a\beta'/s_0[1+(m\varepsilon)^{1/2}/(6\pi\eta a s_0)] \qquad (VII)$$

One of the uncertainties in this case is the magnitude of a, the effective radius of a free methyl radical. Another uncertainty, which

5) Reported values of diffusion energy for free radicals in solution are meagre: Polystyrene radicals (in benzene), 1.9 kcal./mol. (G. M. Burnett, *Trans. Faraday Soc.*, **46**, 772 (1950)); polymethylmethacrylate radicals (in methylmethacrylate), 2.8 kcal./mol. (M. S. Matheson et al., *J. Am. Chem. Soc.*, **71**, 497 (1949); ibid., **73**, 1700 (1951)).

6) a) R. M. Noyes, *J. Chem. Phys.*, **22**, 1349 (1954); b) *J. Am. Chem. Soc.*, **77**, 2042 (1955); c) ibid., **78**, 5486 (1956); d) *Z. Elektrochem.*, **64**, 153 (1960).

gives more difficulty in the evaluation of β_0' is the value of ε. Although an energy of 56 kcal./mol.[1] is liberated in the photolysis with 366 mμ, the share for the methyl radicals is unknown. Moreover, two methyl radicals will not always separate in opposite directions.

On account of these uncertainties, it seems impossible to compute β_0' by Eq. VII in this case. However, approximate values of β' may be estimated, since it has no relation to ε, and, as a first approximation, a may be regarded as equal to s_0, which is known to be 1.80 Å from its molecular structure[7,8]. As seen in Table IV, β' thus calculated is almost unity at low temperatures. It decreases with a rise in temperature, but is still greater than 0.9 at the highest temperature for all the solvents. If, therefore, β' in Eq. VII is put equal to unity,

$$1/\beta_0' = (s_0/a) + (m\varepsilon)^{1/2}/(6\pi a^2)\cdot 1/\eta \quad \text{(VIII)}$$

Since β_0' is equal to the yield of ethane found by experiment, there should be a linear relationship between the ratio N_2/C_2H_6 and the reciprocal viscosity, if Eq. VIII is applicable.

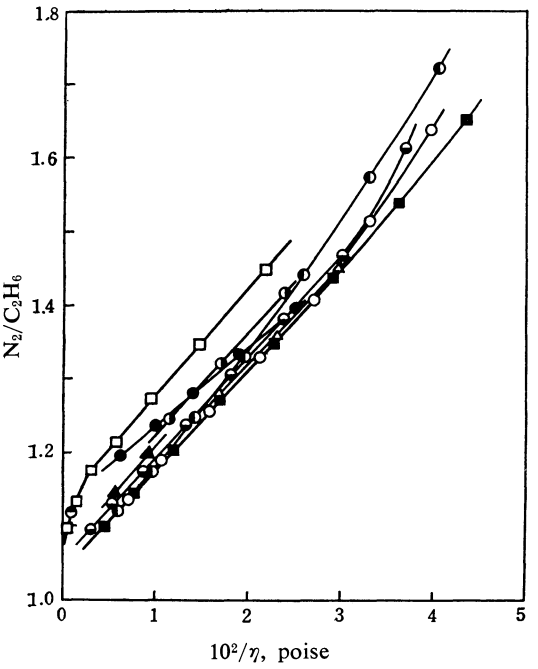

Fig. 3. Plots of N_2/C_2H_6 against reciprocal viscosity. ○, *n*-Hexane; ◐, *n*-Octane; ◑, Cyclohexane; ◒, Toluene; ◓, *tert*-Amyl alcohol; ●, Styrene; △, Benzene; ▲, *o*-Xylene; □, Ethanol; ■, Ethyl acetate

Figure 3 shows that Eq. VIII represents experimental results rather satisfactorily. At high viscosities or at low temperatures, where the equation is expected to be applicable, most plots are linear, run parallel and nearly coincide with each other. The plots for *n*-hexane, *n*-octane and ethyl acetate give identical intercepts on the ordinate, from which a is obtained as 1.73 Å, in approximate agreement with the 1.80 Å assumed above to estimate β'. These plots have almost the same slope at high viscosities, from which ε is obtained as 33.8 kcal./mol. This appears to be not an unreasonable value for the virtual energy separating two methyl radicals in opposite directions to a distance, s_t, in view of the total energy of 56 kcal./mol. liberated in the photolysis. By inserting this ε value into Eq. IV, the distance of initial separation, s_t, is calculated. The values obtained for *n*-hexane, for example, are shown in Table V. These s_t values also appear to be not unreasonable.

Table V. s_t Values for *n*-hexane

Temperature °C	s_t Å	$s_t - 2s_0$ Å

Figure 3 shows however a general tendency, at low viscosities or at high temperatures, for deviation from the linear plot to appear in the direction of yielding less ethane than would be expected from Eq. VIII. A part of the deviation may be ascribed to the factor β' in Eq. VII, since β' becomes smaller with a rise in temperature, as is shown in Table IV. This effect is, however, by far too small to explain the observed deviations. The deviations seem, therefore, to indicate that the effect of the molecular structure of the medium, which was neglected in the theory, has to be taken into account. A simlar indication has been obtained by Noyes and his coworkers in the photolysis of iodine[6d,9]. As was cited by them in their papers, "Rabinowitch's cage"[10] originated from the idea that if two atoms are separated by only a small distance, the surrounding solvent molecules tend to force the atoms toward each other, while, if the atoms are separated sufficiently enough so that solvent molecules can squeeze between them, solvent molecules will force the atoms farther apart. If, in the present work, the distance of initial separation for a pair of methyl radicals is largely controlled

7) According to H. Boersch (*Sitzungsber. Akad. Wiss. Wien.*, **144**, 1 (1935)), azomethane is of the trans form, with C-N=1.47, N-N=1.24 Å and ∠CNN=110°. s_0 is therefore obtained as 1.80 Å.

8) L. Pauling estimates the van der Waals radius of a methyl radical in a molecule as 2.0 Å. ("The Nature of the Chemical Bond", Third Ed., p. 261. Cornell Univ. Press, Ithaca, N. Y. (1960)).

9) D. Booth and R. M. Noyes, *J. Am. Chem. Soc.*, **82**, 1868 (1960); L. F. Meadows and R. M. Noyes, ibid., **82**, 1872 (1960).

10) E. Rabinowitch and W. C. Wood, *Trans. Faraday Soc.* **32**, 547 (1936).

by the viscosity of the medium, it may be expected from the above behavior of solvent molecules that the experimental yield of ethane will be higher at high viscosities but lower at low viscosities than that predicted by Eq. VII, and that it will approximately conform to the equation in an intermediate range of viscosity. Figure 3 appears to be in general agreement with such an expectation, though the deviation from the linear plot to give a higher yield of ethane is not seen in the range of viscosity studied here except for ethanol.

The plots for the various solvents in Fig. 3 do not completely coincide with each other, which indicates that viscosity is not the only controlling factor. It is probably necessary, for a better description of the matter, to take account of the structure and specific nature of the individual molecules of the solvent. The smaller slope of the plot for styrene seems, however, to have resulted from its polymerization, which has been found to be induced by the photolysis[3]. Since the polymerization increases with the temperature, the viscosity of the medium probably becomes higher than in pure styrene at high temperatures.

Summary

Experimental results for the cage combination of methyl radicals, obtained by the photolysis of azomethane in various solvents, have been discussed with reference to the effects of solvent and temperature. An attempt to interpret the results by treating both the cage combination and the escape of methyl radical from the cage as though they were elementary processes has been found to be not very successful, probably owing to the over-simplification involved in such a treatment. Another attempt to apply Noyes's theory, that assumes diffusion in the viscous continuum, has been found to be rather satisfactory. However, a comparison of the theory with the experimental results indicates that the molecular structure of the medium, as well as the structure and property of individual molecules of the solvent, need to be taken into account for a better description of the matter.

The present author is gratefully indebted to Professor Osamu Toyama of the College of Engineering for his helpful advice and kind discussion during this investigation. The author wishes also to thank Mr. Shin'ichi Fujita for his assistance.

The Crystal Structure of D-Tris-ethylenediamine-cobalt(III) Bromide Monohydrate, D-[Co en$_3$]Br$_3$·H$_2$O, and the Absolute Configuration of the D-Tris-ethylenediamine-cobalt(III) Ion, D-[Co en$_3$]$^{3+}$

By Kazumi NAKATSU

(Received October 4, 1961)

The crystal structure of several complex compounds containing $[Co\,en_3]^{3+}$ ions (en: ethylenediamine, NH_2–CH_2–CH_2–NH_2) have been studied to determine the shape and size of the cobalt-ethylenediamine ring[1-3]. The absolute configuration of the complex ion has also been determined[4]. The present work was undertaken to obtain further information on the ion and, at the same time, to confirm the absolute configuration determined for the crystals of D- and L-2 $[Co\,en_3]Cl_3 \cdot NaCl \cdot 6H_2O$.

Since the $[Co\,en_3]^{3+}$ ion is the most familiar and fundamental one in the coordination chemistry and since it exhibits a typical optical isomerism due to the octahedral configuration, the absolute configuration of the complex ion merits further confirmational study. The stability and ease with which this ion can be obtained further favor its use as an internal reference asymmetric center for the determination of the absolute configuration of other

optically active compounds[5].

The details of the structure analysis will be given in Part I, while the determination of the absolute structure of the crystal, as well as the absolute configuration of the complex ion, will be described in Part II.

I. The Crystal Structure

Experimental

D-[Co en$_3$]Br$_3$·H$_2$O (which is generally formulated as dihydrate) was prepared by the method described by Werner[6], who concluded that this substance might be dihydrate from the determination of the cobalt as $CoSO_4$. This method of analysis, however, does not seem to be sensitive enough to fix the number of the water of crystallization. The determination of the water of crystallization was made here by direct dehydration. The results are shown in Table I, together with the densities of the crystals. The table supports the monohydrate formula and shows that the results of the chemical analysis are rather dubious; later structure determination verified the monohydrate formula.

TABLE I. DETERMINATION OF THE WATER OF CRYSTALLIZATION

	Calcd. for $C_6H_{24}N_6Co\cdot 2H_2O$	Calcd. for $C_6H_{24}N_6Co\cdot H_2O$	Found
Co	11.42%	11.87%	11.52% for D-crystal[6]
			11.62% for L-crystal[6]
H_2O	6.99%	3.62%	3.12%*
Density (g. cm^{-3})	2.06	1.995	1.971(25°C)[7]
			2.00(30°C)**

* Dehydrated at 3 mmHg, 110°C, until the sameles reached constant weights. The author is very grateful to Mr. J. Gôda of this Faculty for the use of micro-balance.

** Measured by the flotation method.

The crystals are deep orange in color and appear in ditetragonal bipyramidal form, which agrees with Jaeger's description[7]. The crystallographic and physical data obtained were as follows:

D-Tris-ethylenediamine-cobalt(III) bromide monohydrate, D-[Co en$_3$]Br$_3$·H$_2$O, F. W.=497.1

Crystal system: Tetragonal

Unit cell dimensions: $a=9.95\pm0.03$* and $c=16.73\pm0.05$ Å

Axial ratio $a_0 : c_0 = 1 : 0.8399$ obtained by morphology[7], $a : c/2 = 1 : 0.840_7$ obtained by X-rays

Systematic extinction: $(h\,0\,0)$ present only when $h=2n$, and $(0\,0\,l)$ when $l=4n$

Space group: No. 92, $P4_12_12$-D_4^4 or No. 96, $P4_32_12-D_{8}^{4}$, these two are enantiomorphous with each other

Number of the formula units per unit cell: $Z=4$

Volume of the unit cell: 1656 Å^3

Density: Observed 2.00 g. cm^{-3}, 1.971 g. cm^{-3}[7], calculated 1.99$_5$ g. cm^{-3}

Total number of electrons per unit cell: $F(0\,0\,0)=928$

Linear absorption coefficient for Ni K_α rays ($\lambda=1.651$ Å): $\mu=124.1$ cm^{-1}

Using Ni K_α radiation, a complete set of relative intensities for $(h\,k\,0)$ and $(0\,k\,l)$ reflections were obtained by the integrated Weissenberg procedure. For the recording of the weak reflections, a non-integrating procedure was used. The specimens used were obtained by cutting the crystals in a cylindrical form, until μr, where r is the radius of the specimen, became smaller than unity. The radii of the specimens were 0.01 cm. for the a-axis rotation and 0.009 cm. for the c-axis rotation; thus the μr were estimated to be 0.8 and 0.7 respectively.

Intensity measurements were carried out by visual comparison with a calibrated scale prepared by using the same specimen. The multiple film technique was used to correlate strong and weak reflections, ranging in relative intensity from about 5×10^4 to unity. The maximum $\sin\theta$ observed was 0.975. Within this limit, 53 reflections were measured out of 58 possible $(h\,k\,0)$ reflections, and 167 out of 186 possible $(0\,k\,l)$ reflections.

The corrections for polarization and Lorentz factors were made by use of Cochran's chart[8], and that for absorption was made by regarding the specimens as cylinders[9].

Determination of the Structure

Since the number of formula units in a unit cell is four, and since there are four fold special positions, 4(a), and eight fold general positions, 8(b), in the space group[10], it was assumed that 4Co, 4Br (labeled as Br$_1$) out of 12Br and 4O would lie on 4(a), and that the others would lie on 8(b) (labeled as Br$_2$, N$_1$, N$_2$, N$_3$, C$_1$, C$_2$ and C$_3$).

(0 0 1) Projection. — At the outset the Patterson projection $P(UV)$ was evaluated. Although the interpretation of the map was fairly difficult, owing to overlapping of the interatomic vectors, approximate positions of the heavy atoms Co, Br$_1$ and Br$_2$ were derived. An electron density projection $\rho(XY)$ was then calculated, assuming the structure factor to have the same phases as the contributions of the heavy atoms. However, none of the atoms, except Br$_2$, could be resolved owing to the heavy overlapping.

The main problem in interpreting the electron density map thus obtained was to decide where the light atoms should be placed in a composite peak. This was accomplished to

some extent by the use of partial difference syntheses[11], giving the electron density distribution after subtracting the calculated contributions of those atoms whose parameters were fairly accurately known. The coefficients used in these syntheses were $\Delta F=(F_o-F_c')$, where F_c' included only the contributions of the atoms which were to be subtracted, while the same phase as F_c' was given to F_o. These projections gave more information about the positions of the lighter atoms, and at the same time the necessary changes in the coordinates of heavy atoms were found.

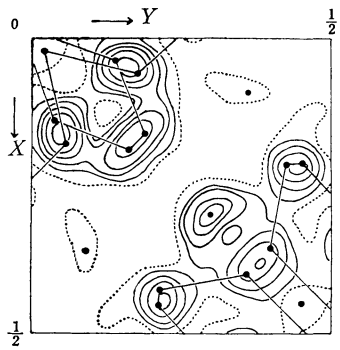

Fig. 1. Electron-density distribution $(\rho_o-\rho_c')$ projected upon (0 0 1) after subtracting the contributions of the cobalt and bromine atoms. Contours are at every 4 e.Å^{-2}, starting at two electron level, whose contours are broken.

Further refinements were made using the ρ_o and ordinary difference syntheses. In some cases difference syntheses using only those reflections with $\sin\theta/\lambda$ larger than 0.35 Å^{-1} were calculated to avoid systematic errors such as the one arising from extinction[12]. A correction for secondary extinction was applied by the method of Pincock et al.[13] Figure 1 shows the result of the partial difference synthesis $(\rho_o-\rho_c')$, where the contributions of heavy atoms were subtracted.

(1 0 0) Projection.—Inspecting $(0\,k\,l)$ reflections, it was found that all the reflections which belong to type $2k+l=4n+2$ were extremely weak intensity compared with the others. The structure factor for this type of reflection can be represented by[10];

$$A=0$$

and

$$B=\sum_j 4f_j \sin 2\pi lz_j(\cos 2\pi ky_j-\cos 2\pi kx_j)$$

where j refers to the jth atom. The values of B will be small only when $\sin 2\pi lz_j$ assumes a small value, because the factor given in parenthesis is not necessarily small, depending on the values of y_j and x_j. This would generally be true for heavier atoms. In order for $\sin 2\pi lz_j$ to become smaller, the z parameters of heavy atoms have to assume 0, 1/4, 1/2 and/or 3/4. Since Co and Br_1 lie on 4(a) and their z parameters take those values, this condition should be imposed for Br_2. If the Br_2 atoms take the z parameters given above, then all the heavy atoms lie on plane (0 0 4), giving rise to a layer structure. The extremely strong intensities of (0 0 l), especially of (0 0 4), also favored this deduction. A Patterson projection $P(VW)$ showed, however, marked peaks which at first seemed to be inconsistent with these parameters. Later it was found that these peaks were due to the multiple overlapping of the interatomic vectors between heavy and light atoms and those between light atoms. Also for the (1 0 0) projection, the refinement procedures were repeated in a similar way. $(\rho_o-\rho_c')$ is given in Fig. 2.

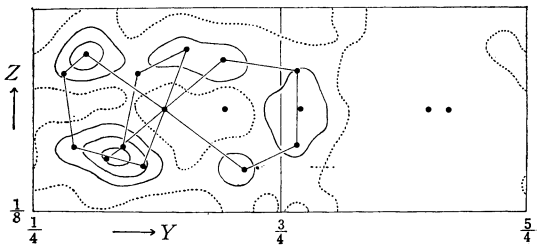

Fig. 2. Electron-density distribution $(\rho_o-\rho_c')$ projected upon (1 0 0). Contours are drawn as same manner as Fig. 1.

TABLE II. ATOMIC COORDINATES

* Extremely large effect of extinction is expected.

Berguis et al.[15] for carbon, nitrogen and oxygen. The correction to be applied to the real part of the atomic structure factor due to the dispersion[16] caused by K-electrons, $\Delta f_K'$, was taken into account for cobalt and bromine. This amounts to -3.5 for cobalt and -1.5 for bromine for Ni K_α rays. No correction was made for the dispersion caused by L-electrons. The isotropic and overall temperature correction was applied in the usual manner. The temperature factor, B, was found to be 3.4Å^2 for $(h\,k\,0)$ and 3.2Å^2 for $(0\,k\,l)$ reflections.

The final reliability indices, $R=\Sigma||F_o|-|F_c||/\Sigma|F_o|$, are 0.128 for $(h\,k\,0)$ and 0.148 for $(0\,k\,l)$ reflections, without the contribution of hydrogen atoms, non-observed reflections being excluded. In the calculation of R, $(0\,0\,l)$ reflections were omitted, because these reflections would be influenced critically by such an effect as extinction.

Description and Discussion of the Structure

The arrangement of the atoms in the unit cell is shown in Figs. 3, 4 and 5, with some interatomic distances. The most striking feature is that the heavy cobalt and bromine atoms and water molecules are in layers, the layers being $c/4$ apart.

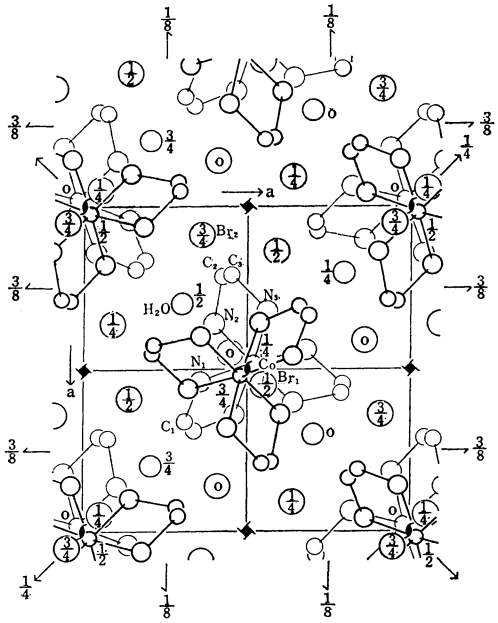

Fig. 3. Projection of the structure upon (0 0 1). The figures in or near the atoms show the z-coordinates of the atoms respectively.

Adopting the absolute configuration of the dextrorotatory complex ion determined previously[4], we can deduce that the present crystal belongs to the space group $P4_32_12$-D_4^8. This choice of space group from the enantiomorphous pair was verified by the anomalous dispersion experiment for the present crystal, as will be shown later.

Since the cobalt atoms lie on the special positions 4(a), having point symmetry 2, the complex ion is required to have a digonal symmetry. This would be compared with the

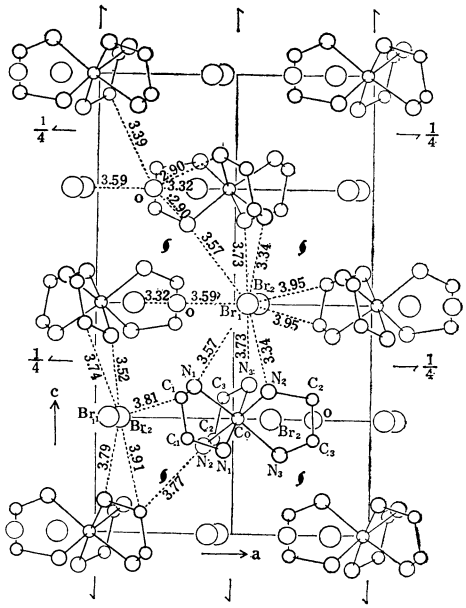

Fig. 4. Projection of the structure upon (1 0 0).

cases of DL-[Co en]$Cl_3 \cdot 3H_2O$[1] and D- and L-2[Co en$_3$]$Cl_3 \cdot NaCl \cdot 6H_2O$[2], where the cobalt atoms lie on the three-fold symmetry axis because of the requirement of the space group. The ethylenediamine molecules take a nearly "gauche" form, and the six nitrogen atoms form a slightly distorted octahedron around the central cobalt atom. There are four possibilities of the configuration of the three cobalt-ethylenediamine rings. To employ the symbols used by Corey and Bailar[17], they are k k k, k′ k k, k k′ k′ and k′ k′ k′*. The relevant combination in the present case is k k k, designated the "lel" form, which is the most stable one according to Corey and Bailar, and which is the same as that existing in the crystals DL-[Co en$_3$]$Cl_3 \cdot 3H_2O$, D- and L-2[Co en$_3$]$Cl_3 \cdot NaCl \cdot 6H_2O$ and [Ni en$_3$]$(NO_3)_2$[18].

The complex ion, therefore, possesses the symmetry D_3-32 within the precision of the experiment. Bond lengths and bond angles within the complex ion are nearly in agreement with those previously found, as is shown in Table IV. The azimuthal angles between the planes determined by the C–C and C–N bonds are found to be 43 and 52° for the two independent ethylenediamine ligands.

TABLE IV. BOND LENGTHS AND BOND ANGLES WITHIN THE COMPLEX ION

Co–N_1	2.03 Å	$\angle N_1CoN_1$	87.3°
Co–N_2	1.98 Å	$\angle N_1CoN_2$	86.3°, 90.5°
Co–N_3	2.00 Å	$\angle N_1CoN_3$	90.4°
C_1–N_1	1.44 Å	$\angle N_2CoN_3$	87.5°, 93.4°
C_2–N_2	1.50 Å	$\angle N_3CoN_3$	93.8°
C_3–N_3	1.49 Å	$\angle N_1C_1C_1$	110.7°
C_1–C_1	1.54 Å	$\angle N_2C_2C_3$	102.0°
C_2–C_3	1.54 Å	$\angle N_3C_3C_2$	114.3°

The complex ions are located at about 0 0 0, 0 0 1/2, 1/2 1/2 1/4 and 1/2 1/2 3/4, and their three-fold axis is nearly in the *c*-direction. This aspect of the complex ions had also been suggested by the study of the dichroism of the crystals[19].

A complex ion is surrounded by 2Br_1, 2Br_2 and H_2O in close approach to the N atoms. Among them, the 2Br_1 lie above and below the complex ion in the *c*-direction and 3.34, 3.57 and 3.73 Å apart from the N_2, N_1 and N_3 atoms respectively. 2Br_2 and O are in the level of Co and form an isosceles triangle. The $Br_2 \cdots N$ distances are 3.20 and 3.38 Å, and the $N \cdots O$ distances are 2.90 Å, probably forming N–H···O type hydrogen bonds. The water molecule is located between the complex ion and the Br_1 lying on the same level. This scheme of the atomic arrangements within a layer can be most easily seen in Fig. 5, where the arrangement of the atoms in one layer around $Z=(1/4)c$ is illustrated. The role of the water molecules is probably to link the positive and negative ions to form a layer.

The layers are related to each other by the operation of the 4_3 axis, and also of the 2_1 axes at $Z=1/8$ or 3/8. No remarkably close contact between two layers, except that one between Br_1 and N_2 has been found.

II. Absolute Structure

"Absolute Structure" vs. "Absolute Configuration"

"Absolute configuration" is usually used to refer to the spatial arrangement of atoms or atomic groups around an asymmetric carbon atom without any ambiguity which otherwise exists between the two antipodes. The crystal which contains only one of the antipodes always lacks a center of symmetry, and if we could determine its crystal structure, including its handedness, we could consequently fix the "absolute configuration" of the antipode involved. On the other hand, there are many crystals which do not contain any optically active group, and yet the handednesses of which present some problems to be solved.

Thus, "absolute structure" means the unambiguous description of the atomic arrangement in a non-centrosymmetric crystal, while "absolute configuration" is to be used when the atomic arrangement within an optically active molecule, ion or atomic group is described in an absolute way. "Absolute structure" rather than "absolute configuration" would be the adequate term for α-quartz[20], sodium chlorate[21], etc. Takéuchi first used the term "absolute structure" in the study of ullmannite[22].

The Problem of Absolute Structure in the Present Case

Since the absolute configuration of D-tartaric acid was determined in 1951 by Bijvoet et al.[23] using the anomalous dispersion effect of X-rays, many attempts have been made to determine the absolute configuration of various com-

pounds in the similar way[24]. The absolute configuration of optically active complex ion D- or L-$[Co\,en_3]^{3+}$, was determined by Saito, Nakatsu, Shiro and Kuroya[4] from the observation of the Bijvoet inequality, and was examined more quantitatively, using the $P_s(u)$ function, by Saito, Okaya and Pepinsky[25] on the crystals D- and L-2$[Co\,en_3]Cl_3 \cdot NaCl_3 \cdot 6H_2O$.

The problem with the present crystal about the absolute structure or absolute configuration is that the crystal has an enantiomorphous pair of space groups which can not be distinguished by the conventional method; this can be done only by the anomalous dispersion technique. If we could substantiate the true space group and therefore, the absolute structure, we could consequently fix the absolute configuration of D- or L-$[Co\,en_3]^{3+}$.

The phase relation among the reflection pairs which are enantiomorphous with each other and whose intensities are to be compared when the anomalous dispersion takes place, is a rather complicated one, depending on the types of $(h\,k\,l)$ in the present space group. In short, it is possible to classify the types of reflections into two groups:

Group I $h\,k\,l$, $k\,h\,\bar{l}$, $\bar{k}\,h\,l$, $\bar{h}\,k\,\bar{l}$, $\bar{h}\,\bar{k}\,l$, $\bar{k}\,\bar{h}\,\bar{l}$, $k\,\bar{h}\,l$ and $h\,\bar{k}\,\bar{l}$

Group II $h\,k\,\bar{l}$, $k\,h\,l$, $\bar{k}\,h\,\bar{l}$, $\bar{h}\,k\,l$, $\bar{h}\,\bar{k}\,\bar{l}$, $\bar{k}\,\bar{h}\,l$, $k\,\bar{h}\,\bar{l}$ and $h\,\bar{k}\,l$

The structure factor for a reflection of a given index which belongs to Group I can find its complex conjugate or its permuted equivalents in the reflections listed in Group II. For example, if $\alpha(h\,k\,l)$ is the phase angle for $(h\,k\,l)$, then $\alpha(h\,k\,\bar{l}) = \alpha(k\,h\,l) = \pi - \alpha(h\,k\,l)$*, and $\alpha(k\,h\,\bar{l}) = \alpha(h\,k\,l)$. The intensities of all the reflections in groups I and II are mutually equal in the ordinary diffraction experiment. However, when comparing the intensities of pairs of reflections whose indices belong to groups I and II respectively, e.g., $(h\,k\,l)$ and $(h\,k\,\bar{l})$ the failure of Friedel's law due to the anomalous dispersion can be observed and, hence, the absolute structure deduceed. If the reflections considered belong to the same group, then the effect of the anomalous dispersion can not be observed.

Experimental Procedure and Result

Peterson[26] and others[21,27] were successful in measuring the effect of anomalous dispersion, even when the X-rays used are far from the absorption edge of any atom in the crystal. However, it is les difficult to observe the Bijvoet inequality if the radiation whose wavelength is close to the absorption edge is available; the photographic method can be used successfully in this case. Therefore, Cu K_α rays ($\lambda = 1.541$ Å) where used, because they can excite just the K-electrons of cobalt atoms ($\lambda_K = 1.608$ Å), and, in addition, a smaller effect

due to the *L*-electrons of the bromine atoms ($\lambda_L = 8$Å) could be expected.

The intensities of $(h\,k\,l)$ and $(h\,k\,\bar{l})$ reflections were compared visually on oscillation photographs taken around the *c*-axis in order to observe the inequalities more conveniently. The specimen used was a small needle about 0.1 mm. in diameter elongated along the *c*-direction. Slight but discernible differences in intensities were found for many pairs of reflections. Large differences were found in some weak reflections. In Table V the observed inequalities are compared with the calculated values. In the calculation of the intensities, the following corrections for atomic scattering amplitude due to anomalous dispersion were used[28] in the form $f = f^0 + \Delta f' + i\Delta f''$, where f^0 is the atomic scattering amplitude for the X-rays far from the absorption edge and $\Delta f'$ and $\Delta f''$ are the corrections for the real and the imaginary parts of the scattering factor respectively:

Atom	$\Delta f'$	$\Delta f''$
Co	−2.2	3.9
Br	−0.9	1.5

The calculated values of the intensities are based on the set of coordinates given in Table II, the space group $P4_32_12$ being assumed. The right-handed coordinate system was used throughout the work.

As a more reliable observation of the effect of dispersion, photometric measurements of intensities for some particular reflections were made. Those reflections were selected which are of moderately low intensity in order to reduce the errors in measurements while reflections of low indices in order to reduce the errors of atomic positions. The results are shown in Table VI, where the observed intensities were measured with a micro-photometer.

The agreement between the observed and calculated inequalities seems to be satisfactory for the present study, and it can be stated with certainty that the atomic positions shown in Table II and Figs. 3 and 4 correspond to the absolute structure of D-[Co en$_3$]Br$_3$·H$_2$O. The absolute configuration of D-[Co en$_3$]$^{3+}$ deduced from the present study thus substantiates the configuration determined previously[4].

Summary

The absolute crystal structure of D-[Co en$_3$]·Br$_3$·H$_2$O was determined by means of X-rays. The space group is $P4_32_12$-D_4^8, with four formula units in a cell of the dimensions a= 9.95 and c=16.73Å. The complex ion takes the "lel" form designated by Corey and Bailar and is in the same configuration as had been determined previously. The structure can be most easily described as consisting of layers of complex ions, two types of bromine ions and water molecules perpendicular to the *c*-axis. The water molecules link the positive and negative ions to form a layer.

A definition of "absolute structure" and "absolute configuration" was proposed. The absolute structure was determined by means of the X-ray absorption edge technique of Bijvoet. CuK_α rays were used to observe visually the effect of the anomalous dispersion between the reflections $(h\,k\,l)$ and $(h\,k\,\bar{l})$, and quantitative measurements of the effect were attempted for some reflections. The absolute configuration of the complex ion deduced from the absolute structure of the crystal is in agreement with the one previously determined for the crystals D- and L-2[Co en$_3$]Cl$_3$·NaCl·6H$_2$O.

The author wishes to express his sincere thanks to Professor Emeritus Isamu Nitta of Osaka University, Professor Tokunosuké Watanabé of Osaka University, Professor Hisao Kuroya of Osaka City University, Professor Yoshihiko Saito of The University of Tokyo and Professor Akira Shimada of Osaka City University for their encouragement and invaluable advice through out the work. Thanks are also due to Dr. Koji Toyoda of Kyoto University for the use of KDC-1 (electronic computer of Kyoto University) for the calculation of the interatomic distances. This research was partly aided by funds from the Scientific Research Fund of the Ministry of Education and the Nishina Memorial Foundation, to both of which the author's thanks are due.

Reduction of Organic Compounds with Urushibara Catalysts under High Pressure. X[1]. *Hydrogenation of 2-Butyne-1,4-diol to cis-2-Butene-1,4-diol with Various Urushibara Catalysts*

By Shin-ichi TAIRA

(Received September 25, 1961)

In the previous paper[1] of this series, the catalytic reduction of some carbonyl compounds with various Urushibara catalysts was reported. Since the discovery of the Urushibara nickel catalyst[2], the preparation of the catalyst has been successively modified and some varieties of the nickel catalysts, U-Ni-B[1-5], U-Ni-BA[6,7], U-Ni-NH_3[8], U-Ni-CB[5], U-Ni-A[1,4,5,9,10], U-Ni-AA[11], U-Ni-CA[5] and U-Ni-A(HCl)[1], have been furnished. Besides these nickel catalysts, some Urushibara cobalt and copper catalysts, namely, U-Co-B[5,8,12,13], U-Co-CB[5], U-Co-A[5,13], U-Co-CA[5], U-Cu[5] and U-Cu-C[1,5], have been reported on. As each of them has its own characteristics and proper activity, one can choose a catalyst in accordance with the compound to be reduced.

In the present paper, the hydrogenation of 2-butyne-1,4-diol with some Urushibara catalysts is studied.

Experimental

Apparatus.—Hydrogenation was carried out in an electro-magnetically stirring-type autoclave with a capacity of 100 ml. (Sakashita SE-10).

2-Butyne-1,4-diol.—A commercially available crude sample was recrystallized from benzene, m.p. 58.5°C.

General Procedure for Hydrogenation.—The catalyst was carefully transferred with ethanol into the autoclave. The air in the autoclave was replaced by hydrogen gas four times. Most operations were carried out under the following conditions: (1) sample; 4.3 g. (0.05 mol.) (2) solvent; ethanol (99%) 50 ml. (3) agitation; 40~45 strokes per minute. Agitation was started when the temperature in the autoclave reached the reaction temperature. (4) pressure; Initial pressure was chosen to be above 50 kg./cm^2. Depression of the pressure was observed at intervals of five minutes.

Hydrogenation Products.—*cis-2-Butene-1,4-diol.*—After the hydrogenation was finished, the catalyst was filtered off and washed with ethanol. The major part of the solvent was distilled off from the combined solution, and the residual liquid was distilled under reduced pressure. *cis*-2-Butene-1,4-diol was obtained as a colorless oil, b.p. 125~126°C/12 mmHg. Yield, 70~75% of the theoretical. The dibenzoate crystallized into colorless prisms from ethanol, m.p. 67~68°C.

1,4-Butanediol.—After removal of the catalyst, the product was distilled to give 1,4-butanediol as a colorless oil, b.p. 131~132°C/25 mmHg. Yield, 73% of the theoretical. The dibenzoate crystallized into colorless prisms from ethanol, m.p. 82.5~83.5°C.

Preparation of Catalysts.—The U-Ni-A(s)*(HCl) was prepared by the method described in the reference cited[1]. Some new Urushibara catalysts were prepared by the methods described below. The U-Fe-BA was also prepared from ferric chloride and aluminum grains in the same way as the U-Ni-BA, but it was found to be inactive.

a) Urushibara Iron Prepared from Ferric Chloride, Abbreviated as U-Fe(III).—To a well mixed zinc dust (25 g.) and water (8 ml.) placed in a 50 ml. beaker, 9.68 g. (containing 2 g. of iron) of the crystal of commercially available ferric chloride ($FeCl_3 \cdot 6H_2O$) was added. The mixture was then well stirred with a glass rod. Soon a vigorous exothermic reaction started, but it subsided within about ten seconds. To complete the reaction the mixture was stirred until the color of the ferric ion disappeared. The reaction mixture (precipitated iron) was washed with 400 ml. of cold water, and then the washing was removed by filtration or decantation. The precipitated iron was digested in 330 g. of 15% acetic acid with occasional stirring at 60~70°C for about 20~25 min. At the end of the digestion, the generation of hydrogen gas subsided, and a solid, adsorbing hydrogen gas came up to the surface of the almost colorless solution. The solid was quickly collected on a glass filter and washed with 300 ml. of cold water and then

* In the present paper the notation (s) temporarily implies the catalysts obtained from the precipitated metals prepared by the simplified method[1].

with 100 ml. of ethanol. In this way a grayish black catalyst, contaminated with a small quantity of zinc, was obtained.

b) Urushibara Iron Prepared from Ferrous Chloride, Abbreviated as U-Fe(II).—To a mixture of zinc dust (20 g.) and water (6 ml.) placed in a 50 ml. beaker, the crystal of commercially available ferrous chloride ($FeCl_2 \cdot nH_2O$) containing 2 g. of iron* was added, and then the mixture was warmed on a boiling water bath and stirred with a glass rod for about 2 min. The reaction mixture (precipitated iron) was washed with 300 ml. of cold water, and then the washing was removed by filtration or decantation. The precipitated iron was treated with occasionl stirring in 300 g. of 15% acetic acid at 60~70°C for about 15~20 min. until the generation of hydrogen gas subsided and a solid came up to the surface of the almost colorless solution. The following operation was similar to that described in a). In this way a bulky brownish black catalyst, containing about 2 g. of iron and a considerable quantity of zinc, was obtained.

c) U-Fe(II)-Ni or U-Fe(III)-Ni.—To the mixture of zinc dust (20 or 25 g.) and water (6 or 8 ml.), 0.2 ml. of an aqueous nickel chloride solution (10 ml. of the solution contains 1 g. of nickel) was added, and then the crystal of ferrous or ferric chloride (containing 2 g. of iron) was added. The following procedure was the same as that described in a) or b).

d) U-Fe(II)-Co or U-Fe(III)-Co.—The procedures for the preparation were the same as those for the U-Fe-Ni, but 0.5 ml. of a cobalt chloride solution (10 ml. of the solution contains 1 g. of cobalt) was used.

e) Urushibara Cobalt A Obtained from the Precipitated Cobalt Prepared by a Simplified Method by Treatment with Hydrochloric Acid, Abbreviated as U-Co-A(s)(HCl).—To a mixture of zinc dust (5 g.) and water (1 ml.), 2.02 g. (containing 0.5 g. of cobalt) of the crystal of commercially available cobalt chloride was added, and then the mixture was well stirred with a glass rod. Soon a weak exothermic reaction occurred and the mixture became slushy after about 5 min. The reaction mixture (precipitated cobalt) was washed with 100 ml. of cold water, and then it was treated with 200 ml. of 0.75 N hydrochloric acid at an ordinary temperature. A vigorous reaction took place, and a black solid came up to the surface of the pink solution within one minute. The solid was quickly collected on a glass filter and washed with 200 ml. of cold water and then with 100 ml. of ethanol.

f) U-Co-B(s).—The precipitated cobalt prepared by the simplified method as described in e) was treated with 80 g. of a 10% aqueous sodium hydroxide solution as in the usual way[5,8,13].

In all procedures, purified water was used for washing except for the preparations of precipitated metals. The U-Ni-A(s)(HCl), U-Co-A(s)(HCl) and U-Co-B(s) were prepared thoroughly with city water. The solid should be protected from contact with air as far as possible after the treatment of the precipitated metals with acid or alkali.

* As the content of iron in commercially available ferrous chloride is usually indefinite, it should previously be determined by analysis.

Results and Discussion

The Urushibara Iron Catalysts.—The problem of the partial hydrogenation of acetylenic compounds to the corresponding ethylenic compounds has attracted many workers. For the partial catalytic hydrogenation of acetylenic compounds in the liquid phase, it it necessary to stop the hydrogenation when one mole of hydrogen has reacted. Palladium has been accepted as a catalyst whose selective action can be utilized for this partial hydrogenation. Campbell and O'Connor[14] reported that Raney nickel exhibits a similar selective property and used it as a catalyst in the preparation of numerous olefins from the corresponding acetylenes. However, both the palladium and the Raney nickel catalyst are unsatisfactory for the partial hydrogenation because they are excellent catalysts also for the hydrogenation of ethylenic bonds, and the hydrogenation must therefore be watched constantly and stopped at a proper moment so as to prevent the saturation of the ethylenic bonds. Therefore, the publication by paul and Hilly on Raney iron catalyst[15], which has been prepared much like Raney nickel but is unable to effect the hydrogenation of ethylenic linkage, is of considerable importance. It is, however, very troublesome to prepare the iron-aluminum alloy in a laboratory. The procedure of preparing such an iron catalyst would be very simple if the iron particles obtained by the Urushibara method had a similar catalytic activity.

As the difference between the standard electrode potentials of iron and zinc is smaller than the difference between those of nickel, cobalt or copper and zinc, a ferric or ferrous chloride solution can only with difficulty be reduced by zinc dust by the ordinary procedure for preparing precipitated metals. Ferric chloride, however, can react vigorously with zinc dust under conditions similar to that described in the preceding paper[1] as a simplified method for the preparation of precipitated nickel, The precipitated iron thus obtained gives a fine, grayish black solid after treatment with acetic acid. As ferrous chloride reacts gently with zinc dust under the same conditions, external heating is advisable to complete the reaction. The precipitated iron obtained from ferrous chloride gives a fine, brownish

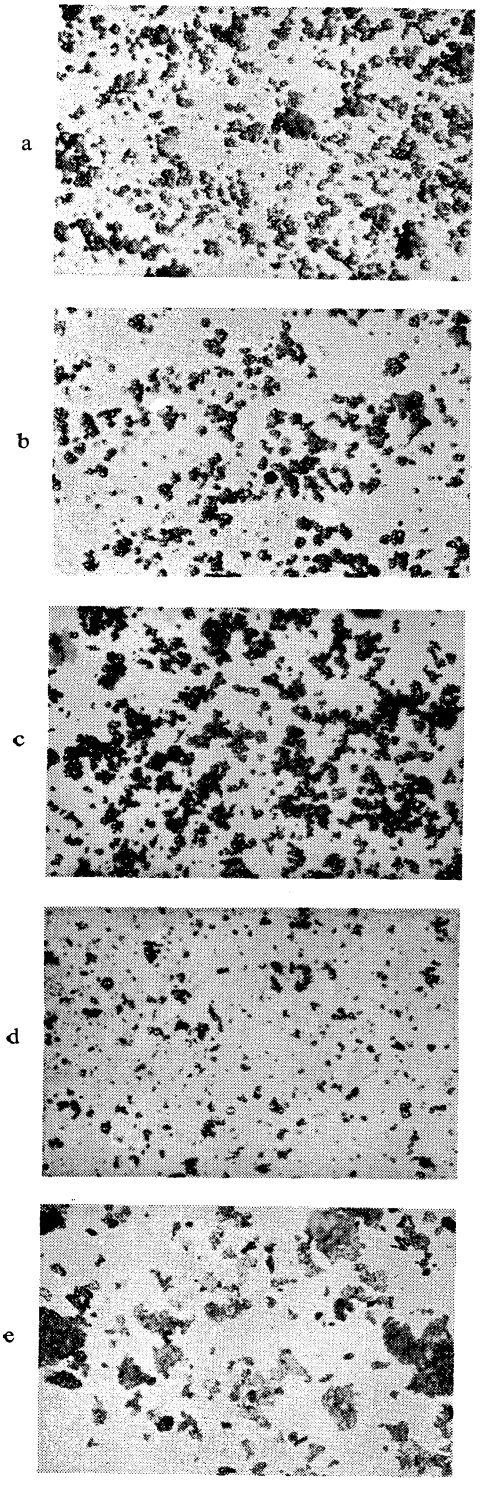
black solid after treatment with acetic acid. Both solids have proved to be active as catalysts. These new catalysts can be named Urushibara iron catalysts, or U-Fe(II) and U-Fe(III) when abbreviated. The figures in parentheses show the original valencies of iron in the chloride. Both U-Fe(II) and U-Fe(III) consist of iron and a quantity of zinc, but the former is somewhat bulkier and contains more zinc than the latter.

In place of zinc dust, aluminum grains are used as a reducing agent for nickel ion in the preparation of the U-Ni-BA[6] or the U-Ni-AA[11]. The diluted ferric chloride solution also reacted vigorously with aluminum grains to give a precipitated iron. However, Urushibara iron BA, similarly obtained by treatment of the precipitated iron with a sodium hydroxide solution, was found to have no catalytic activity.

Partial Hydrogenation of 2-Butyne-1,4-diol. —The partial hydrogenation of 2-butyne-1,4-diol to cis-2-butene-1,4-diol has already been studied by many workers with Raney nickel[16], palladium-calcium carbonate[17], iron[18] or partially poisoned copper, nickel, cobalt and platinum[19] catalysts.

The present author attempted the hydrogenation of 2-butyne-1,4-diol with some Urushibara catalysts and studied the activity of each catalyst. The results are listed in the table. The first experiment was carried out to determine the temperature at which hydrogen uptake begins with the Urushibara iron catalyst. The hydrogen uptake starts at about 80°C, and the rate increased at about 100°C (Exp. No. 1). Accordingly, the following experiments were carried out at about 100°C when the iron catalyst was applied. The result obtained with the U-Fe(II) was similar to that obtained with the U-Fe(III) (Exp. No. 2). No appreciable hydrogen uptake was observed with the U-Fe(III)-BA under similar conditions (Exp. No. 3).



It has been recognized that the increase of the concentration of the substance to be reduced in a solution or the elevation of the reaction temperature exerts a favorable effect on the reduction rate of benzophenone[5].

Micro-photographs of Precipitated Irons and Urushibara Iron Catalysts (×75)
(a) Precipitated iron prepared from ferrous chloride. (b) Precipitated iron prepared from ferric chloride (c) U-Fe(II) (d) U-Fe(III) (e) U-Fe(III)-BA

Accordingly, the hydrogenation of 2-butyne-1,4-diol was attempted in a concentrated solution at a higher temperature, but the results were unsatisactory (Exp. No. 4), probably because of an insufficiency of catalyst.

As seen from the table, the gross weight of the U-Fe(II) is much more than that of the U-Fe(III), though they are prepared so as to contain the same quantity of iron and are nearly equal in apparent bulk. The U-Fe(II) probably contains more zinc than the U-Fe(III). The micro-photographs of both iron catalysts show that the grains of zinc dust contaminated in them are covered with iron and that many spherical iron-zinc couples coagulate to form a block. The above-mentioned difference between the state of the U-Fe(II) and U-Fe(III) may be supposed to be due to the difference between the nature of the two precipitated irons, because they are treated with acetic acid under nearly identical conditions to give each U-Fe catalyst. Probably the state of iron may differ in the two precipitated irons. The precipitated iron from ferric chloride is found to be more easily eroded by acetic acid during the digestion. Therefore, quick collection of the U-Fe(III) is necessary after the completion of digestion to prepare the catalyst containing a sufficient quantity of iron.

The author found that a U-Ni-A obtained from zinc dust and the precipitated nickel prepared from a nickel chloride solution, contaminated with a little ferric chloride, is more active than the usual U-Ni-A in the reduction of acetophenone. The iron is considered to act as a promoter. It is similarly expected that the addition of a little nickel to the iron may have a favorable effect on the activity of the iron catalyst in the hydrogenation. Actually, such catalysts, U-Fe(II)-Ni and U-Fe(III)-Ni (Fe 1 : Ni 0.01), were proved to have higher activities than the U-Fe(II) or U-Fe(III) (Exp. Nos. 5 and 6). The activity of the iron catalyst may also be increased by the addition of cobalt. As a cobalt catalyst is generally less active than a nickel catalyst in the catalytic reduction, especially in the hydrogenation of carbon-carbon double bonds, the ratio of cobalt to iron in the catalyst may safely be increased in the hydrogenation of carbon-carbon triple bonds. A good result was obtained with the U-Fe(III)-Co (Fe 1 : Co 0.025) (Exp. No. 7). In contrast with the U-Fe(III)-Co, the U-Fe(II)-Co was strikingly low in activity (Exp. No. 8). The cause of this low activity is obscure except for the wrong dispersability of the U-Fe(II) into a solution by the up and down agitation employed in those experiments.

It has been reported in the preceding paper[1] that the U-Ni-A(s) is somewhat lower in activity than the U-Ni-A prepared by the usual method, and that hydrochloric acid can be used for the digestion of the precipitated nickel to give a less active catalyst, U-Ni-A(HCl). Accordingly it is expected that U-Ni-A(s)(HCl) may be much less active than the usual U-Ni-A, and that the partial hydrogenation of the acetylenic bond to the ethylenic bond may safely be attained with the catalyst. However, the catalyst was unexpectedly still so active that butynediol was rapidly hydrogenated to butanediol (Exp. No. 9). It is not yet hopeless with a cobalt catalyst, and the U-Co-A(s)(HCl) and U-Co-B(s) served the purpose, though the hydrogenation should have been checked at the point where the hydrogen uptake became very slow after the absorption of almost stoichiometric hydrogen gas (Exp. Nos. 10 and 11). In these experiments, hydrogen uptake was not obsered for five to fifteen minutes after stirring was started at room temperature. The reaction started when the temperature in the autoclave exceeded about 31°C, and the temperature then went on rising owing to the heat of the reaction. As the room temperature was near 31°C, it was not clear whether the first time lag was due to an induction period or to an inadequate temperature for starting the reaction.

Summary

The Urushibara iron catalysts were newly developed. Partial hydrogenation of 2-butyne-1,4-diol to cis-2-butene-1,4-diol was successfully attained with the iron catalysts, and some modified Urushibara cobalt catalysts were also found to be applicable.

The author wishes to express his thanks to Professor Kazuo Hata for his continuous encouragement throughout this work.

Studies of the Urushibara Catalysts. I. Some Structural Features Revealed by X-Ray Diffraction

By Shin-ichi TAIRA

(Received September 25, 1961)

Since the discovery of the Urushibara nickel catalyst[1], some modifications in the preparation of the catalyst have been successively performed; thereby several varieties of the catalyst, such as U-Ni-B[2-5], U-Ni-BA[6,7], U-Ni-NH_3[8], U-Ni-CB[4], U-Ni-A[3-5,9,10], U-Ni-AA[11] U-Ni-CA[4] and U-Ni-A(HCl)[5], have been developed. The Urushibara cobalt, copper and iron catalysts, namely, U-Co-B[4,8,12-14], U-Co-CB[4], U-Co-A[4,13], U-Co-A(HCl)[14], U-Cu[4], U-Cu-C[4,5], U-Fe(II)[14] and U-Fe(III)[14], have also been reported on. With these catalysts, various kinds of organic compounds have successfully been reduced, as with the corresponding Raney catalysts.

In the present paper, a brief study of the crystal structures of the Urushibara nickel and iron catalysts by means of X-ray diffraction is presented.

Experimental

Samples.—Newly prepared catalysts or those recovered after use and then stored were used.

X-Ray Diffraction.—The crystal structures of the catalysts were examined by the X-ray powder diffrac-

tion method. Cu-K_α radiation was used for the Urushibara nickel catalysts, and Fe-$K_{\alpha,\beta}$ radiation, for the Urushibara iron catalysts. The diffraction diagrams were obtained by means of a recording X-ray diffractometer.

Results and Discussion

The preparation of the Urushibara catalyst can be divided into two steps, the preparation of precipitated metal and the digestion of it with acid or alkali. Supposing that the relation of the precipitated metal to the Urushibara catalyst is similar to that of the Raney alloy to the Raney catalyst, the method of preparation of the Urushibara catalyst has some resemblance to that of the Raney catalyst. However, the precipitated metal is essentially different from the Raney alloy. For example, the precipitated nickel is obtained by the reduction of the nickel ion with zinc dust, and it is a mixture of zinc grains covered with precipitated nickel metal and some zinc compounds. The treatment of the precipitated nickel with acid removes the zinc compounds and the major part of the zinc grains to give the Urushibara nickel A. The Urushibara method is one way to prepare fine particles of a metal, and the obtained metal particles may be different from the Raney catalyst in nature. It is possible that the particles could be merely fine particles of the metal and have no catalytic activity. In fact, however, these particles of metals obtained by the Urushibara method have been proved to be as active as the Raney catalysts. Accordingly, the particles must have special crystal structures.

In the catalytic hydrogenation of 2-butyne-1,4-diol to 2-butene-1,4-diol with an Urushibara iron catalyst[14], the author has observed that the U-Fe(II) or U-Fe(III) which is prepared from ferrous or ferric chloride and zinc dust has catalytic activity, while the U-Fe(III)-BA, prepared from ferric chloride and aluminum grains in nearly the same manner as that used to prepare the U-Ni-BA, has not.

The reason why the U-Fe(II) and U-Fe(III) have catalytic activities and the U-Fe(III)-BA has not, may be supposed to be due to the difference in their crystal structures. Their X-ray diffraction diagrams are shown in Fig. 1-a, b and c. The diffraction diagram of the U-Fe(III)-BA (Fig. 1-a) shows a good agreement with that of a sample considered to be pure α-iron and the position of the peak shifts only slightly (0.3°) in diffraction angle (2θ: 51.1° and 56.8°, the former is Fe-K_β reflection) from that corresponding to the reflection from the (110) plane in the regular configuration of α-iron (cf. Table I; All peaks in Fig. 1-b and c also show the same shift). In contrast with the diagram of the U-Fe(III)-BA, the U-Fe(II), which is recovered after the hydrogenation of 2-butyne-1,4-diol[14] and which contains much zinc, gives the sharp peaks of zinc in the diffraction diagram (2θ: 45.8°, 49.4° and 54.9°) in addition to the diffused peaks of iron (2θ: about 50° and 55.3°) (Fig. 1-b, cf. Table I). The U-Fe(III), which is also recovered after use, gives the same diffused peaks of iron, but the peaks of zinc can not be observed, probably indicating that the sample contains, if any, but a trace of zinc (Fig. 1-c). Why does the

inactive U-Fe(III)-BA give a regular diffraction diagram of α-iron while the active U-Fe(II) and U-Fe(III) do not ? Further investigation of this problem will give a clue to clarify the substantial feature of the activity of the Urushibara catalysts.

Urushibara et al.[15] have studied the Urushibara nickel catalysts in detail. As the X-ray diffraction of the Urushibara nickels gave only a diffused peak reflected from the plane regarded as (111) of nickel, which has a face-centered cubic structure, they concluded that the development of the crystal lattices in the Urushibara nickels is insufficient and thus that the nickel exists not in a state of crystals, but in a state of crystallites (Table II). The fact was also revealed by electron diffraction[16].

* The figures are the values of 2θ derived from the interplanar spacing of each plane by using the value of Cu-K_α or Fe-K_α.

The size of the crystallites can be calculated by means of a modified Scherrer's formula:

$$D_{hkl}=\frac{0.9\,\lambda}{\beta_{1/2}\cos\theta}$$

where D_{hkl} is the mean thickness of the crystallites in the perpendicular direction to the $(h\,k\,l)$ plane (Å) (This value is usually called the size of the crystallites.), λ, the wave length of the applied X-ray (Å), and $\beta_{1/2}$, the half value breadth (rad.). The calculation of the size of the crystallites in the Urushibara nickels prepared under various conditions led the cited authors to the following conclusions[15]: (1) The more vigorously the reaction of nickel chloride solution with zinc dust takes place, the smaller the size of the crystallites becomes. That is, crystallites increase in size in the following order; conc. $NiCl_{2\,aq.sol.}$+Zn dust, 100°C< conc. $NiCl_{2\,aq.sol.}$+Zn dust, room temp.<dil. $NiCl_{2\,aq.sol.}$+Zn dust, 100°C<dil. $NiCl_{2\,aq.sol.}$+Zn dust, room temp. (2) The activity of the nickel catalyst declines as the size of the crystallites increases. Supposing that the crystallites are cubic and that the activity of

a) 1 g. of the nickel ion is supplied by 4.04 g. of nickel chloride ($NiCl_2 \cdot 6H_2O$).
b) The figures were calculated by the modified Scherrer's formula.

the nickel catalyst is proportional to the total surface area of the crystallites, the following relation may be deduced, as the total surface area of the nickel catalyst of a definite weight may be roughly said to be in inverse proportion to the size of the crystallites:

Activity of catalyst × Size of crystallites = const. This relation was certified by their experiments. (3) The size of the crystallites was not affected by the temperature of digestion and by the kind of digesting reagent.

The results of X-ray diffraction of the various Urushibara nickels obtained by the present author are tabulated in Tables III, IV and V. The size of the crystallites of the U-Ni-A(s)* shown in Table. IV, Nos. 41—46, are generally smaller than that of the U-Ni-A shown in Table III. If the activity of a nickel catalyst is mainly decided by the size of the crystallites, as has been pointed out by the cited authors, the U-Ni-A(s) should be more active than the U-Ni-A. In fact, the U-Ni-A(s) was proved to be somewhat inferior in activity to the U-Ni-A[5]. In the case of catalytic reduction under high pressure, the apparent activity of a catalyst may be considerably affected by the following factors: (1) The presence and amount of the texture necessary for metal particles to be active as a catalyst; (2) Weight of a catalyst; (3) Apparent size of the catalyst grains; (4) Dispersability of a catalyst into a solution (This factor may be decided by the size of the grains of a catalyst and the presence of contaminating substances. It must be noted that the Urushibara nickels B are contaminated by a large quantity of zinc and zinc compounds); (5) Reaction temperature; (6) Pressure of hydrogen gas; (7) Kind and volume of solvent; (8) Method and degree of agitation; and (9) Nature and purity of the sample to be reduced. A proper selection of experimental conditions may control factors 5 to 9. With the Urushibara catalysts, factors 1 to 4 vary with the method of preparation. The weight of the U-Ni-A(s), prepared to contain a definite quantity of nickel, is usually somewhat smaller than that of the U-Ni-A. Supposing that factors 3 and 4 are similar in them, the inferiority of the U-Ni-A(s) to the U-Ni-A in activity may mainly be ascribed to factor 1. Certainly factor 1 plays an important rôle in the actual activity of the catalyst.

The U-Ni-BA, prepared from a nickel chloride solution and aluminum grains, gives two sharp peaks in the X-ray diffraction diagram corresponding to the reflection from the (111) and (200) planes of nickel, and the position of the peaks lies at the regular angle position for nickel (Fig. 1-d, cf. Table. I). On the other hand, the Urushibara nickel A, prepared from either nickel chlorid or nickel acetate soultion and zinc dust, gives only a diffused peak, and the position accepted as a peak shifts from the regular position to a lower angle (Fig. 1-f, g and h) (In Fig. 1-h some peaks of zinc and zinc oxide are also observed). Occasionally, another diffused peak is observed (Fig. 1-f).

In Scherrer's formula, the calculated values of D_{hkl} are greatly affected by small differences in the value of $\beta_{1/2}$, but not so seriously by those in the values of θ. Samples Nos. 34-a, b and c (Table. III) are the Urushibara nickel catalysts prepared from the same precipitated nickel by separate treatment with the same or different acids. Samples Nos. 35-a, b, c and Nos. 37-a, b form respective groups of the same kind. In each group small differences in the value of $\beta_{1/2}$ cause a difference of several Å in the value for D_{hkl}. However, the values of 2θ are nearly equal in each group. The author has paid attention to the 2θ values.

Many workers have pointed out that in an

* The notation(s) implies temporarily the catalyst obtained from the precipitated metal prepared by the simplified method[5].

actual crystal small blocks (crystallites) of 10~0.1μ in sizes are disorderly accumulated into a so-called "mozaic structure". The smallness of the crystallites and the disorder of accumulation cause an enlargement in the breadth of the X-ray diffraction peaks. In the crystallites having a regular lattice arrangement, however, an enlargement in the breadth of the diffraction peaks takes place at the positions of definite angles determined by the interplanar spacing of the substance, and a large shift of the diffraction angle does not take place. Thus, it is conceivable that the (111) and (200) planes of nickel are indeed present in the U-Ni-BA, but there is much less probability of them in the Urushibara nickel A and B. Why is such a curious phenomenon observed only in the Urushibara nickel A and B? To clarify this problem, the process of preparing the precipitated nickel must be taken into account. The situation is considered to be similar to that of the formation of an evaporated film. From studies of evaporated films by means of electron diffraction, the phenomenon of oriented overgrowth or epitaxy has been brought to light[17]. A definite relation exists between the orientation of the crystallites of the deposit and that of the substrate crystals. The crystal structure of the crystallites in a evaporated film is generally in accordance with the structure of the crystal in the macro state. However, some exceptions have been found. Schulz[18] observed that the oriented overgrowth of crystallites occured in the evaporated films of those substances, which usually crystallize in the cesium chloride structure when, they were evaporated on lithium fluoride, sodium chloride, potassium bromide or mica, and that in such evaporated films there were many substances not with the original structure of the cesium chloride type but with the structure of the sodium chloride type. In the case of the formation of the precipitated nickel from a nickel salt solution and zinc dust, such a epitaxy may be possible to happen. Nickel, having a face-centered cubic structure (abbreviated as f. c. c. structure) in the normal state, is known to be possible to have a hexagonal closest packed structure (abbreviated as h. c. p. structure), as the difference in the energies of the two packings may not be so large. Thus, nickel can crystallize into a h.c.p. structure on the surface of zinc which normally has a h. c. p. structure. On this basis, it is presumed that such a epitaxy happens in the preparation of the precipitated nickel, and that the nickel precipitated on the surface of zinc may crystallize in a h. c. p. structure because it may grow larger on the embryo crystallites to some extent. The state in which nickel has a complete h. c. p. structure is temporarily named the ideal h. c. p. state. In this ideal h.c.p. state, the X-ray diffraction diagrams of Urushibara nickel A and B should be composed of sharp peaks and the position of peaks should be located in the diffraction angle very close to those of zinc (cf. Table I). Besides, in this state the crystals of nickel should come to contain many lattice defects, such as vacancies and dislocations, because the lattice constant of nickel is forced to be unusual. This hypothesis is quite successfully applied to interpreting the diffraction diagrams of the Urushibara nickel A and B.

In the actual Urushibara nickel A and B, the diffraction peaks are diffuse, and the position of the peak, which is divided into many small peaks, shifts to an angle higher than the ideal position. This may be caused by the small size of the crystallites and by the deformation of the structure of the crystallites from the ideal h. c. p. structure. If the extent of the shift of a peak from the position for the ideal h. c. p. structure is proportional to the degree of the deformation from the ideal h. c. p. structure to the proper f. c. c. structure, the amount of lattice defects will be in inverse proportion to the extent of the shift in the diffraction angle. The lattice defects may offer proper seats and spaces in which a foreign atom or molecule (for example, H or H_2) may be so loosely locked that it can move freely to some extent. As such places may be active centers of a catalyst, the more the lattice defects and present in the crystallites, the more active the crystal will become as a catalyst.

The author draws the following conclusions from the above considerations:

(1) In the Urushibara nickel A and B, nickel may have a h. c. p. structure which has been somewhat deformed to the f. c. c. structure. On the contrary, in the Urushibara nickel BA, nickel has a normal f. c. c. structure as a whole, for it is prepared from nickel chloride solution and aluminum, which has the f. c. c. structure. Thus, the Urushibara nickel BA is regarded as a catalyst of quite a different type from the Urushibara nickel A and B. Accordingly, it is naturally accepted that the shape of the diffraction diagram and the activity of the Urushibara nickel BA are quite different from those of the Urushibara nickel A and B.

(2) If a nickel catalyst, prepared by any method, gives a diffraction diagram similar to those of the Urushibara nickels, it will possess a similar catalytic activity when other factors are disregarded.

17) D. W. Pashley, *Advances in Physics*, 5, 173 (1956).
18) L. G. Schulz, *Acta Cryst.*, 4, 487 (1951).

(3) In the Urushibara nickel A and B, the higher the catalyst in activity, the smaller the extent of the shift of a peak in the diffraction angle from the ideal position of the peak for the h. c. p. structure of nickel. Thus, the reason why the U-Ni-A(s) is somewhat inferior in activity to the usual U-Ni-A may naturally be understood by comparing the 2θ values of the former with those of the latter. The same relation can be observed between the U-Ni-A (s) and the U-Ni-CA or the U-Ni-A prepared from nickel acetate solution and zinc dust.

(4) If each catalyst has the same crystal structure, the activity of a catalyst will be affected by the size of the crystallites.

The above considerations may also be successfully applied to solving the problems which lie in the Urushibara iron catalysts. Iron exists in the following two allotropic crystal modifications: at the lower temperature, iron crystallizes as α-Fe in a body-centered cubic structure (abbreviated as b. c. c. structure).

$$\underset{\text{(b.c.c.)}}{\alpha\text{-Fe}} \overset{910^\circ\text{C}}{\rightleftarrows} \underset{\text{(f.c.c.)}}{\gamma\text{-Fe}} \overset{1400^\circ\text{C}}{\rightleftarrows} \underset{\text{(b.c.c.)}}{\delta(\alpha)\text{-Fe}}$$

As aluminum has a f. c. c. structure and as there is an intimate relation between the lattice planes in the b. c. c. and the f. c. c. structure*, iron in the U-Fe(III)-BA must crystallize into a b. c. c. structure. This is the reason why the diffraction diagram of the U-Fe(III)-BA coincides with that of the α-Fe.

Iron in the ideal h.c.p. state must be greatly strained as the stable b. c. c. structure at low temperature is forced into the h. c. p. structure. Then it will get catalytic activity. In the actual U-Fe(II) and U-Fe(III), the crystal lattices of iron may be in the relation of coherency to those of zinc, and then there may be many lattice defects in them. Therefore, the reason why the U-Fe(II) and U-Fe(III) have catalytic activity and the U-Fe(III)-BA has not may be ascribed to the difference in their crystal structures.

Naturally the crystal structure of the metal in a Urushibara catalyst is affected to some extent by the temperature and the concentration of the solution to be applied in the preparation of a precipitated metal. The author esteems the effect of concentration as more important than that of temperature. That is, the decreased concentration of a metal ion in a solution may exert the favorable effect upon the crystal structure necessary for the metal to have catalytic activity, in consideration of the values in the Tables II, III and IV. However, further study is required in this area. As it has been widely recognized that special sections in the crystal of a metal are preferentially attacked by an acid, a digesting reagent for the precipitated metals may exert some secondary action on the Urushibara catalyst. The solution of the subject also belongs to the studies of the future.

* $\{110\}_{\text{b.c.c.}} \longleftrightarrow \{100\}_{\text{f.c.c.}}$. A similar relation has been observed in the epitaxial growth of the CsCl type (b. c. c.) into the NaCl type(f. c. c.)[18].

Summary

Some structural features in the Urushibara catalysts were revealed by means of X-ray diffraction, and a hypothesis regarding the activity of the Urushibara catalysts was proposed.

The author wishes to express his thanks to Professor Kazuo Hata for his continuous encouragement throughout this work.

SHORT COMMUNICATION

Mechanism of the Ninhydrin Reaction on a Filter Paper

By Naotomo TOMINAGA*

(Received March 12, 1962)

It is known that color shades of reaction products of amino acids with ninhydrin on a paperchromatogram are different from one amino acid to another and also from one solvent to another used for development in a paperchromatography[1,2]. However, Ruhemann's purple (I, diketohydrindylidene diketohydrindamine) is known as the final product on the

* Present address: Faculty of Literature and Science, Kagoshima University, Kamoike-cho, Kagoshima.

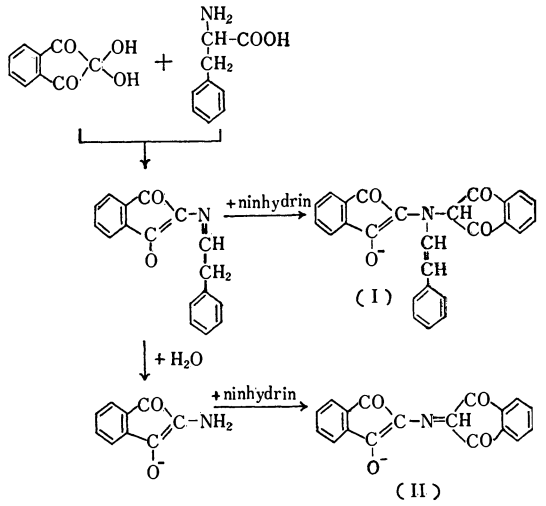
2) C. E. Dent, ibid., **43**, 169 (1948).

ninhydrin reaction of usual α-amino acid in aqueous solution[3]. These facts indicates that side reactions must occur on a paper besides a main reaction which gives I.

In a previous publication[4], it was reported that various by-products on the reaction of 11 α-amino acids with ninhydrin on a paper were separated from I by a paperchromatography using methanol-water (1 : 1, v/v). Therefore, different color shades of products on the reaction of various amino acids with ninhydrin on paper seem to be resulted from differences of quality and quantity of the by-products.

In the present communication, a blue pigment derived from phenylalanine by the side reaction is described. The pigment was easily separated by paperchromatography and extracted from the paper with methanol. The extract showed the maximum absorption at 608~610 mμ and decomposed and faded by heating with an excess of ninhydrin. By the addition of acetic acid or diluted hydrochloric acid into methanolic solution of the pigment, it turned to violet color showing its absorption spectrum not identical with that of I, but regained its original blue color by further addition of pyridine or ammonia.



In an aqueous solution, no blue pigment was produced from phenylalanine by the ninhydrin reaction in spite of the presence of a piece of filter paper or air-bubbling into the solution.

When phenylalanine was heated with ninhydrin in absolute ethanol, black-green crystals, methanolic solution of which showed the same absorption spectrum and R_f value as those of the above blue pigment, were obtained. Namely a suspension of 1 g. of L-phenylalanine and 4 g. of ninhydrin in 50 ml. of absolute ethanol was heated at 60~70°C until carbon dioxide was no longer evolved. After the solution was cooled, the black-green crystals were filtered off (480 mg.) and washed with 50% methanol. They were recrystallized form benzene. M. p. (decomp.) 227~232°C. Found: C, 76.91; H, 3.81; N, 2.75. Calcd. for $C_{26}H_{17}O_4N$ (II) : C, 76.65; H, 4.17; N, 3.43%.

When uniformly labeled ^{14}C-phenylalanine was used, 71% of the expected radioactivity was found in the blue pigment II. Consequently II must contain major parts of the skeleton of phenylalanine.

Comparing the infrared spectrum of I with that of II, both substances showed the absorption at 1670 cm^{-1}(carbonyl), 1640 and 1592cm^{-1}(benzene nucleus), and 1443 cm^{-1} (〉C=C〈$_{O-}$) but 1477 cm^{-1}(-N=C〈) was observed only in I. Characteristic absorption for II were at 1522, 1397 and 986 cm^{-1}(-CH=CH-), and 1351 and 1296 cm^{-1}(〉N-CH〈).

Therefore the reaction of ninhydrin with phenylalanine on a paper seems to proceed through the following two routes.

The present reaction mechanism of phenylalanine on a paper may be extended to those of other amino acids.

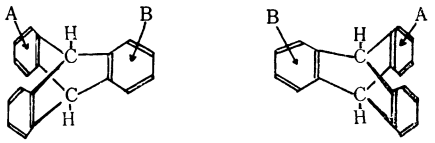
*Synthesis of Trisubstituted Triptycenes and the Optical Resolution of 7-Carboxy-2, 5-diacetoxytriptycene**

By Akio SONODA, Fumio OGURA and Masazumi NAKAGAWA

(Received October 23, 1961)

Triptycene is a novel type of cage compound which was synthesized by Bartlett and his coworkers[1] by the elaboration of the Diels-Alder type addition product of *p*-benzoquinone with anthracene. The three benzene rings in the molecule are tightly connected at their *o*-positions by the two sp^3-hybridized carbon atoms holding the aromatic rings in the fixed spatial positions. The rigid structure of the molecule has been demonstrated by the inert reactivity for various displacement reactions of the substituent group or atom attached to the central tetrahedral carbon atom[2].

Triptycene derivatives bearing different substituent groups in two of the three benzene rings should be capable of existing in the optically isomeric forms shown in Fig. 1.



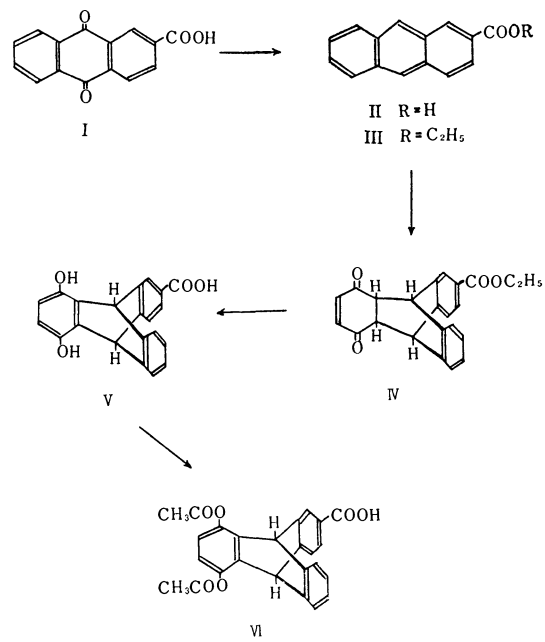


Fig. 1. Optical isomers of substituted triptycene.

Optical active triptycene derivatives may offer best means for studying the dependence of optical activity or rotatory dispersion on the nature of the substituent groups, since the rigid and fixed geometry of the molecule should exclude the influence of the complicated effects arising from the flexibility of the molecule. For the purpose of studying the above-mentioned relationships, the present authors have investigated the synthesis and optical resolution of trisubstituted triptycenes.

2-Methylanthraquinone was prepared according to the well-known procedure starting from toluene and phthalic anhydride[3]. The quinone was oxidized to 2-carboxyanthraquinone (I) by chromium trioxide in acetic acid[4]. This

substance was submitted to the reduction by means of zinc dust in aqueous ammonia[5] to give 2-carboxyanthracene (II). The attempts to condense II with *p*-benzoquinone in various solvents such as ethanol, acetic acid and dioxane gave unsatisfactory results. II was converted into the corresponding ethyl ester III. The ester III was treated with an excess of *p*-benzoquinone in benzene to yield the adduct IV. The structure of IV was inferred from the comparison of the infrared spectrum of IV with that of the adduct of anthracene and *p*-benzoquinone[6]. The adduct was found to be sensitive to a strong alkali and the hydrolysis of IV with aqueous sodium hydroxide to the corresponding free acid resulted in the formation of a resinous material.

Treatment of IV in acetic acid with a small amount of hydrobromic acid yielded 8-carboxy-2, 5-dihydroxytriptycene (V). V was found to be difficult to purify owing to its unstable nature to oxygen. Therefore, the crude V was

converted into the diacetyl derivative VI by treatment with acetic anhydride in the presence of anhydrous sodium acetate. The structure of VI was confirmed by the analytical data and the infrared spectroscopy.

Several unsuccessful attempts were made to resolve the *dl*-VI in its antipodes by using different kind of optical active amines such as quinine, brucine, ephedrine and cinchonine. It was found that the racemic acid VI gives no crystalline salts with these alkaloids. The failure in the optical resolution of VI urged the authors to the synthesis of the isomeric substituted triptycene. 1-Carboxyanthracene (VIII) was derived from 1, 9-benz-10-anthrone by chromic acid oxidation in dilute sulfuric acid[7] followed by the reduction of resulted 1-carboxyanthraquinone (VII) with zinc dust in aqueous ammonia[8]. The reaction of 1-carboxyanthracene (VIII) with *p*-benzoquinone under

various conditions in different solvents resulted in the formation of a polymeric substance with high melting point or in the recovery of the starting materials. Treatment of VIII with absolute methanol in the presence of concentrated sulfuric acid yielded methyl ester IX in good yield. It is to be noted that the esterification of VIII with absolute ethanol under the same condition resulted in the recovery of the acid VIII. Two isomeric adducts X_a (m. p. 190.5°C) and X_b (m. p. 206°C) were obtained from the products of the condensation of *p*-benzoquinone with IX. The infrared spectra of these isomers were found to be almost identical over the entire region of wavelength, but a remarkable depression of the mixed melting point (175°C) was observed. It seems to be reasonable to attribute the formation of the two isomers to the *endo*- and the *exo*- addition of *p*-benzoquinone with regard to the benzene ring bearing methoxycarbonyl group yielding X_a and X_b as illustrated in Fig. 2.

X_a or X_b X_b or X_a

Fig. 2. Possible structures of the isomeric adducts, X_a and X_b.

Both of the isomers gave 7-carboxy-2, 5-dihydroxytriptycene (XI) on treatment with a small amount of hydrobromic acid in acetic acid. XI was converted without further purification into the corresponding diacetyl derivative XII by the reaction with acetic anhydride and anhydrous sodium acetate.

7-Carboxy-2, 5-diacetoxytriptycene (XII) was dissolved in hot absolute ethanol and mixed with half the equivalent of brucine tetrahydrate. Well defined colorless needles were obtained on standing the mixture overnight at room temperature. The crystals were recrystallized five times from absolute ethanol to give an optically pure *d*-salt. The salt was decomposed with acetic acid to give pure *d*-acid, m. p. 269~271°C, $[\alpha]_{5461}^{13} = +96.3°$ (*c* 0.7042, dioxane).

The filtrate was concentrated and treated with acetic acid to remove brucine. The crude *l*-acid thus obtained was converted into the quinine salt. Recrystallization of the salt from 95% ethanol gave the pure quinine salt. The optically pure *l*-acid, $[\alpha]_{5461}^{24} = -93.1°$ (*c* 1.0272, dioxane) was obtained by the decomposition of the pure quinine salt. The infrared spectra of the *d*- and *l*-acid are found to be identical over the entire region of wavelength as recorded in Fig. 3.

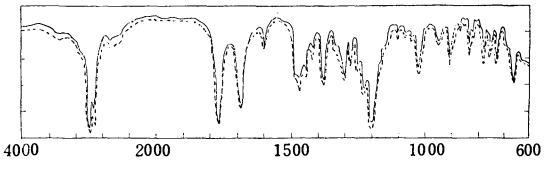

Fig. 3. The infrared spectra of *d*-XII (—) and *l*-XII (- - -) (Nujol mull).

The ultraviolet spectrum and the rotatory dispersion of XII will be discussed together with its homologous series in the following paper.

Experimental**

2-Carboxyanthraquinone (I).—Chromium trioxide (60 g.) was added gradually in small portions with constant mechanical stirring to the solution of 2-methylanthraquinone (20 g.) in acetic acid (500 ml.) at 70°C. After all chromium trioxide had been added, the mixture was stirred at 70~80°C for further 5 hr. The reaction mixture changed to dark brown and then the separation of a crystalline precipitate was observed. The reaction mixture was cooled to room temperature and poured into water (3 l.) yielding the crude I. The product was digested repeatedly with a hot diluted aqueous ammonia. Pure 2-carboxyanthraquinone (I), 19.9 g. (88%), m. p. 283~284°C (value in literature, m. p. 284~285°C[4]) was obtained by neutralizing the ammoniacal solution with concentrated hydrochloric acid.

2-Carboxyanthracene (II).—The solution of II (19 g.) in a dilute aqueous ammonia (1 l.) was heated on a boiling water bath, zinc dust (50 g.) was added in small portions to the hot solution under vigorous mechanical stirring. A small amount of 28% aqueous ammonia was added occasionally to the reaction mixture. Development of a blood red color was observed on the addition of zinc dust and faded in accord with the progress of reduction. After 3 to 5 hr., the hot reaction mixture was filtered and the filtrate was acidified with concentrated hydrochloric acid to precipitate the crude II, m. p. 273°C. This was recrystallized from ethanol to yield pure II, 10 g. (60%), m. p. 277~278°C, (value in literature, 275~276°C[5]).

2-Ethoxycarbonylanthracene (III).—The mixture of II (6 g.), 99% ethanol (500 ml.) and concentrated sulfuric acid (6 ml.) was refluxed for 5 hr. Light yellow crystals, 5.4 g., m. p. 139.5~140°C were obtained on standing the reaction mixture at room temperature. The concentration of the filtrate gave the second crop of III, 1.1 g., m. p. 138~139°C. Total yield, 6.5 g. (95%) (value in literature, m. p. 134°C[9]).

Formation of the Adduct (IV).—The results of several experiments on the addition of *p*-benzoquinone to III are summarized in Table I. All the reactions were carried out at the temperature of the boiling point of the particular solvent. The formation of quinhydrone was generally observed throughout these experimental conditions. The experimental condition shown in Run 7 gave the best yield of the adduct. The reaction mixture was cooled to room temperature precipitating yellow crystal mixed with black crystals of quinhydrone. The crystals were filtered, washed with benzene, ethanol and hot water, successively. The crude crystals were digested with light petroleum under reflux to remove the unchaneged III. The yellow powder obtained (2.6 g. (36.5%), m. p. 187.5~188°C) was recrystallized from ethanol to give pure IV, m. p. 188~189°C.

Found: C, 76.71; H, 5.20. Calcd. for $C_{23}H_{18}O_4$: C, 77.08; H, 5.06%.

IR, 1619, 1661 (C=O); 1710 (C=O of ester); 1278 (-C-O-) and 1175 cm^{-1} (-C-O-).

Isomerization and Hydrolysis of IV to V.—IV (3.3 g.) was dissolved in acetic acid (30 ml.) under reflux. Hydrobromic acid (47%, 15 ml.) was added dropwise to the solution and the mixture was refluxed for 5 hr. The reaction mixture was poured into ice-water (350 g.) to precipitate crude V. The precipitate was filtered and washed with water yielding crude V, 2.1 g. (68%), m. p. 210~214°C (decomp.).

Acetylation of V.—The crude V (2.1 g.) was heated on a boiling water bath for 4 hr. with acetic anhydride (40 ml.) in the presence of a small amount of anhydrous sodium acetate. Water (10 ml.) was

** All melting points were not corrected.

9) C. Liebermann and A. Bischof, ibid., 13, 47 (1880).

added to the reaction mixture. After heating for several minutes the mixture was poured into water (400 ml.). The precipitate formed was recrystallized twice from acetic acid yielding pure 8-carboxy-2,5-diacetoxytriptycene (VI), 1.9 g. (49.5% from IV), m. p. 235~237°C.

Found: C, 72.06; H, 4.43. Calcd. for $C_{25}H_{18}O_6$: C, 72.46; H, 4.38%.

IR, 3200~2500 (-COOH); 1690 (C=O of aromatic acid); 1766 (C=O of phenolic acetate) and 1187 cm^{-1} (-C-O- of phenolic acetate).

1-Carboxyanthraquinone (VII).—1, 9-Benz-10-anthrone was oxidized according to the Bernett's procedure with slight modification. M. p. 286~289°C, yield, 68%.

1-Carboxyanthracene (VIII).—Reduction of VII (22 g.) with zinc dust (40 g.) and diluted aqueous ammonia (50 ml. of 28% aqueous ammonia + 600 ml. of water) with occasional addition of 28% aqueous ammonia (60 ml.) in small portions yielded VIII, 11.8 g. (60%), m. p. 235~243°C. Recrystallization of the crude VIII from ethanol gave pure VIII, yellow rods, m. p. 242~244°C (value in literature, m. p. 245°C[8]).

1-Methoxycarbonylanthracene (IX).—The mixture of the crude VIII (5.2 g., m. p. 235~243°C), absolute methanol (150 ml.) and concentrated sulfuric acid (5 ml.) was refluxed for 3 hr. The mixture was kept for several hours at room temperature precipitating IX as yellow plates. The precipitate was filtered and the filtrate was concentrated under reduced pressure yielding second crop of IX. The total yield of the crude IX (m. p. 101~103°C) was found to be 4.2 g. (77%). This was recrystallized from methanol to give pure IX, m. p. 103.5~104°C.

Found: C, 81.40; H, 5.40. Calcd. for $C_{16}H_{12}O_2$: C, 81.34; H, 5.12%.

Formation of the Adduct (X).—IX (17.7 g., 0.075 mol.) and *p*-benzoquinone (8.9 g., 0.083 mol.) was added to anhydrous benzene (100 ml.). Immediate development of red color was observed. The mixture was refluxed for 3 hr. and cooled to room temperature. Yellow crystals deposited were separated, washed with a small amount of benzene and hot water successively, yielding the crude low melting isomer (X_a), 7.8 g. (32.1%), m. p. 181~183°C. This was recrystallized from benzene to yield the pure material, m. p. 190.5°C.

Found: C, 76.38; H, 4.70. Calcd. for $C_{22}H_{16}O_4$: C, 76.73; H, 4.68%.

Rapid stream of steam was passed into the mother liquor to remove the unchanged quinone and the solvent. The dried residue was ground down into fine powder and then refluxed with methanol (80 ml.) to remove the unchanged IX. The yellow powder thus obtained (8.8 g. (36.2%), m. p. 182~186°C, sintering at 175°C) was successively recrystallized from ethyl acetate, acetone and benzene giving the pure high melting isomer (X_b), m. p. 206~206.5°C.

Found: C, 76.48; H, 4.41. Calcd. for $C_{22}H_{16}O_4$: C, 76.73; H, 4.68%.

X_b showed a depression of the melting point on admixture with X_a (mixed melting point, 174~180°C).

IR, X_a: 1667 (C=O of dihydroquinone), 1717 (C=O of ester) and 1283, 1144 cm^{-1} (-C-O- of ester). X_b: 1667 (C=O of dihydroquinone), 1717 (C=O of ester) and 1285, 1137 cm^{-1} (-C-O- of ester).

7-Carboxy-2,5-diacetoxytriptycene (XII.)—Hydrobromic acid (6 ml., 20% aqueous solution) was added to the hot solution of X_a (6.9 g.) in acetic acid (140 ml.). The mixture was heated on a boiling water bath for 5 hr. The solvent was removed under reduced pressure. The residue was washed with water and dried to give the crude XI, 5.9 g., m. p. 305~310°C (decomp.) as a light brown crystalline mass. The mixture of the crude XI (5.9 g.), acetic anhydride (30 ml.) and a small amount of anhydrous sodium acetate was heated on a boiling water bath for 1 hr. Water (40 ml.) was added to the cooled reaction mixture. The crude XII, 7 g. (84.2%), m. p. 220~231°C was obtained on standing the dilute mixture at room temperature for several hours. This substance was recrystallized 4 times from acetic acid to yield the pure XII, 5 g., m. p. 261~263°C. X_b (14.2 g.) was heated with 20% hydrobromic acid (40 ml.) in acetic acid (280 ml.) to yield the crude XI, 14.7 g. (85.9%), m. p. 245~250°C. This substance was acetylated and recrystallized twice from acetic acid to give pure XII, 11.1 g. (65%), m. p. 261~264°C. This substance showed no depression of the melting point on admixture with XII which was derived from X_a. The analytical sample of XII was obtained by sublimation under reduced pressure (220~230°C/1 mmHg).

Found: C, 72.92; H, 4.16. Calcd. for $C_{25}H_{18}O_6$: C, 72.46; H, 4.38%.

IR, 3200~2500 (-COOH), 1758 (C=O of acetate), 1685 (C=O of -COOH) and 1188 cm^{-1} (-C-O- of acetate).

Optical Resolution of *dl*-7-Carboxy-2, 5-diacetoxytriptycene (XII).—*d-XII.*—The racemic XII (5.950 g., 0.0144 mol.) was dissolved in absolute ethanol (160 ml.). Brucine tetrahydrate (3.344 g., 0.00722 mol.) was added at once to the hot solution and the mixture was refluxed for 30 min. The mixture was allowed to stand overnight at room temperature to precipitate well-defined colorless needles. The mother liquor was separated by decantation and the crystals thus obtained was washed several times with a small amount of ethanol. The crystals obtained were dried under reduced pressure yielding the brucine salt, 5.7 g., $[\alpha]_D^{10} = -7.28°$ (*c* 0.906, acetone). The brucine salt was recrystallized 3 times from absolute ethanol yielding a salt with $[\alpha]_D^{10} = +6.2°$ (*c* 1.46, acetone). This salt was recrystallized from ethanol 2 times affording an optically pure salt with a constant specific rotation $[\alpha]_D^{10} = +7.5°$, (*c* 0.69, acetone).

Found: C, 71.83; H, 5.40; N, 3.39. Calcd. for $C_{48}H_{44}O_{10}N_2$: C, 71.28; H, 5.48; N, 3.46%.

Water (24 ml.) was added to the hot solution of the optically pure salt (2.354 g.) in acetic acid (24 ml.) and the white precipitate formed was filtered, washed with water and dried to yield *d*-XII, 1.088 g., m. p. 263~266°C. This was recrystallized from acetic acid to give pure *d*-XII, m. p. 269~271°C, $[\alpha]_{5461}^{13} = +96.3°$, $[\alpha]_{4358}^{13} = +174.8°$ (*c* 0.7042, dioxane).

Found: C, 72.99; H, 4.40. Calcd. for $C_{25}H_{18}O_6$: C, 72.46: H, 4.38%.

l-XII.—The above-mentioned mother liquor which was obtained by decantation of the brucine salt was concentrated under reduced pressure. Treatment of the residue with 25% acetic acid gave the optically impure *l*-XII, m. p. 261~263°C, $[\alpha]_{5461}^{10} = -49.25°$ (*c* 0.873, acetone). Quinine (6.5 g., 0.023 mol.) was added to the hot solution of the crude *l*-XII (9.6 g., 0.023 mol.) in 95% ethanol (120 ml.) and the mixture was refluxed for 30 min. The solution was allowed to stand overnight in a refrigerator. The colorless crystals deposited were filtered, washed with 95% ethanol to yield the crude quinine salt (9.8 g.). This was recrystallized 4 times from 95% ethanol to give optically pure *l*-salt (3.2 g.). This salt showed no definite melting point. Development of yellow color was observed near 140°C and it decomposed gradually at 155~160°C with frothing. The specific rotation of the pure salt was found to be $[\alpha]_{5791}^{19.5} = -109°$, $[\alpha]_{5461}^{19.5} = -139°$ (*c* 1.028, acetone).

Found: C, 71.59; H, 6.33; N, 3.66. Calcd. for $C_{45}H_{42}N_2O_8 \cdot H_2O$: C, 71.40; H, 5.86; N, 3.70%.

The pure quinine salt obtained (3.1 g.) was heated on a water bath with 25% acetic acid (50 ml.) for 30 min. The mixture was kept at room temperature overnight, and the precipitate formed was filtered, washed with 25% acetic acid and water successively, to result in *l*-acid, (1.5 g.), m. p. 252~263°C. The *l*-acid was recrystallized twice from acetic acid yielding the pure *l*-XII, m. p. 269~271°C, $[\alpha]_{5461}^{24} = -93.1°$, $[\alpha]_{4358}^{24} = -168.2°$ (*c* 1.0272, dioxane).

Found: C, 71.76; H, 4.46. Calcd. for $C_{25}H_{18}O_6$: C, 72.46; H, 4.38%.

The infrared spectra of the *d*- and *l*-acid were found to be completely identical over the entire region of wavelength.

The authors are grateful to Mr. Masakazu Okumiya and Miss Kiku Koike for performing the elementary analyses. Part of the cost of this research was defrayed from the grant-in-aid of the Ministry of Education, to which the authors thanks are also due.

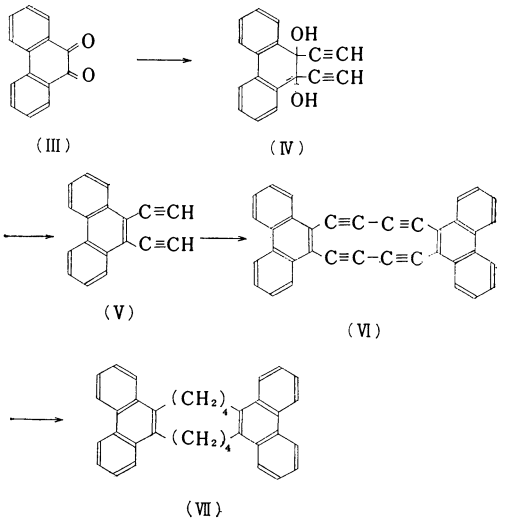
Another Example of the Formation of Highly Strained Cyclic Dimer of o-Diethynyl Compound[1]

By Mamoru MORIMOTO, Shuzo AKIYAMA, Sōichi MISUMI and Masazumi NAKAGAWA



(Received October 23, 1961)

Recently, Raphael, Eglinton and their coworkers have studied the oxidative coupling of *o*-diethynylbenzene (I) by means of cupric acetate in pyridine, and the product was proved unexpectedly to be the highly strained cyclic dimer of I on the basis of chemical and physical evidence[2]. This result is rather surprising, because the starting material I has a rigid geometry favorable for the formation of strainless cyclic trimer[3].

(I) (II)

The present authors have carried out the oxidative coupling of 9, 10-diethynylphenanthrene (V) to confirm whether the forced

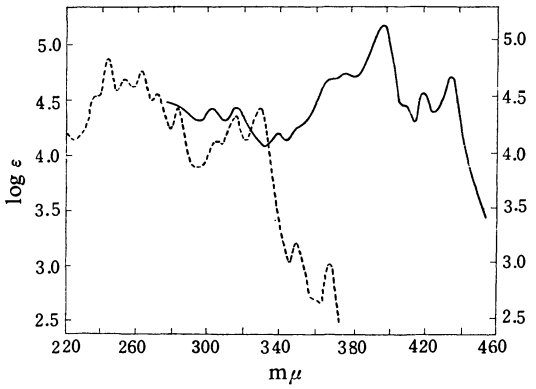

Fig. 1. The ultraviolet spectra of 9,10-diethynylphenanthrene, V (----) and the cyclic dimer, VI (——).

cyclic dimerization of *o*-diethynyl compounds is general or not in the Eglinton's reaction. 9, 10-Diethynylphenanthrene (V), which has a rigid geometry similar to I, was synthesized according to the method of Ried[4] with a slight modification as indicated in the foregoing chart. 9, 10-Diethynyl-9, 10-dihydroxy-9, 10-dihydrophenanthrene (IV) was obtained by the reaction of phenanthrenequinone (III) with sodium acetylide in liquid ammonia. The reductive aromatization of glycol IV afforded 9, 10-diethynylphenanthrene (V) in a reasonable yield. The oxidative coupling of V according to the procedure of Eglinton[2,5] furnished a fairly stable product which is found to be sparingly soluble in common organic solvents. The substance was recrystallized from a large amount of benzene or chlorobenzene yielding orange yellow fine needles. The color of the crystals changed to black on heating to ca. 290°C, but no fusion was observed even at 360°C. The analysis of the crystals suggests that the substance contains 1 mol. of solvent of crystallization. The absence of free ethynyl absorption in the infrared spectrum indicates the cyclic nature of this substance. A remarkable red-shift was observed in the ultraviolet spectrum of this substance as compared with that of V (Fig. 1). After removal of the solvent of crystallization by heating the substance to 110°C in vacuo, the analysis proved the molecular formula of the substance to be $(C_{18}H_8)_n$. The molecular weight of this hydrocarbon could not be determined by Rast's method owing to its poor solubility in camphor or other analogous solvents. Hydrogenation of the orange yellow crystals, $(C_{18}H_8)_n$ in benzene over palladium-on-charcoal furnished a colorless crystalline hydrocarbon, $(C_{18}H_{16})_n$. The determination of the molecular weight of the reduction product revealed the molecular formula of the hydrogenated product to be $(C_{18}H_{16})_2$. The ultraviolet spectra of the reduction product and 9, 10-dimethylphenanthrene[6] resembled closely in their absorption maxima, but the intensities of the former were found to be approximately double the relevant intensities of the latter (Fig. 2). From these observations the structure of VII, diphenanthro [9′, 10′-*a*; 9″, 10″-*g*] cyclododeca-1, 7-diene was given to the reduction product. Therefore, the structure of the parent hydrocarbon, $(C_{18}H_8)_2$, was confirmed to be the highly strained cyclic dimer VI, diphenanthro [9′, 10′-*a*; 9″, 10″-*g*] cyclododeca-1, 7-dien-3, 5, 9, 11-tetrayne.

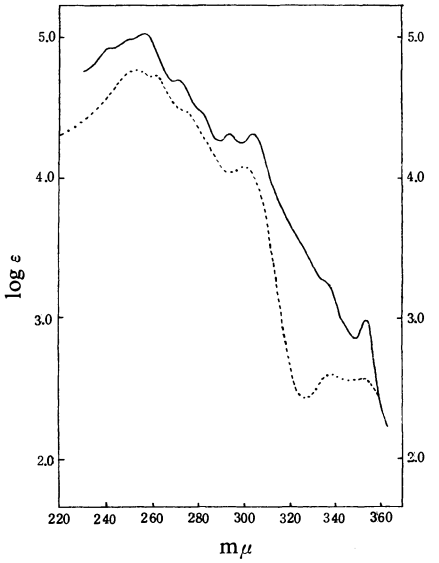

Fig. 2. The ultraviolet spectra of VII (——) and 9,10-dimethylphenanthrene (----).

The above-mentioned result is consistent with that of the oxidative coupling of *o*-diethynylbenzene, and can be regarded as the second example of an unusual cyclic dimerization. On the other hand, it has been reported that the oxidative coupling of aliphatic α, ω-diethynyl compounds under a similar condition results in the formation of the mixture of cyclic di, tri, tetra, penta and hexamer[7]. These facts strongly indicate that some specific cyclization mechanism operates in the Eglinton's coupling reaction of *o*-diethynyl compounds. The mechanism of the forced dimerization or the retardation of the cyclic

trimerization in the coupling reaction is not clear, but it seems to be probable to assume the formation of an intermediate copper complex containing *o*-diethynyl compound as ligand, in which the circumstance should be so favorable for the cyclic dimerization of the *o*-diethynyl ligands that the increase of strain energy can be overcome.

Experimental*

9, 10-Diethynylphenanthrene (V).—A hot solution of 9, 10-diethynyl-9, 10-dihydroxy-9, 10-dihydrophenanthrene (IV, 13 g., 0.05 mol.) in methanol (100 ml.) was added under stirring to a solution of stannous chloride dihydrate (22.5 g., 0.1 mol.) in concentrated hydrochloric acid (45 ml.) and water (30 ml.). The mixture was stirred for 1.5 hr. at 60~65°C. After cooling the mixture, the flocculent brown precipitate was filtered, washed with water and dried in vacuo. The brown mass was dissolved in carbon tetrachloride (140 ml.) and the red solution was filtered through a short column of alumina (35 g.). The same solvent (500 ml.) was passed through the column. The colorless filtrate and the washing were combined, and the solvent was removed under reduced pressure at 45°C in an atmosphere of nitrogen to give yellow crystals (3.6 g., 32%). The analytical sample was prepared by recrystallizing the crude crystals from petroleum benzine (b. p. 60~70°C). Pale yellow prisms, m. p. 130°C (decomp.).

Found: C, 95.52; H, 4.46. Calcd. for $C_{18}H_{10}$: C, 95.54; H, 4.46%.

IR, 3260 cm^{-1} (-C≡CH). UV, $\lambda_{max}^{C_2H_5OH}$ 235 mμ (log ε=4.53), 242.5 (4.85), 252.5 (4.64), 261 (4.74), 271 (4.53), 282.5 (4.41), 303 (4.08), 315 (4.33), 328.5 (4.40), 348 (3.18), 366 (3.02).

Diphenanthro[9′, 10′ - *a*; 9″, 10″ - *g*]cyclododeca-1, 7-dien-3, 5, 9, 11-tetrayne (VI). — 9, 10-Diethynylphenanthrene (V, 4.0 g.) was added under stirring to a mixture of cupric acetate monohydrate (60.0 g.) in pyridine (400 ml.). The mixture was stirred at room temperature for 3 hr., and then at 60°C for 4 hr. The green reaction mixture was cooled to room temperature and the stirring was continued for further 10 hr. The precipitate deposited was filtered, washed thoroughly with water to remove cupric acetate and pyridine, and the residue was washed with small amounts of ethanol and benzene, successively. The coupling product thus obtained was recrystallized twice from chlorobenzene or benzene yielding pure VI, tiny orange needles, 1.38 g., (33%). The determination of solvent of crystallization gave the following results. Benzene: 10.1~11.4%; Chlorobenzene: 16.3~18.2%. It was found that the solvent of crystallization can be removed by heating the crystals to 110°C in vacuo.

Found: C, 96.19; H, 3.61. Calcd. for $C_{36}H_{16}$: C, 96.40; H, 3.60%.

UV, $\lambda_{max}^{benzene}$ 300 mμ (log ε=4.42), 315 (4.42), 338 (4.21), 375 (4.72), 396 (5.51), 420 (4.56), 435 (4.70).

The solubility of VI in benzene was estimated to be 6.3 mg./l. at 10°C by a spectroscopic method.

Diphenanthro[9′, 10′ - *a*; 9″, 10″ - *g*]cyclododeca-1,7-diene (VII).—VI (200 mg.) in benzene (600 ml.) was hydrogenated over 5% palladium-on-charcoal (160 mg.) until no change of the ultraviolet spectrum of the solution was observed. During the course of the hydrogenation the yellow color of the solution disappeared. The catalyst was filtered off, and digested with hot benzene (500 ml.). The solvent was removed under reduced pressure from the combined benzene solution to yield yellow solid (120 mg.). The solid was dissolved in benzene (25 ml.) and the solution was filtered through a short column of alumina (15 g.). The alumina layer was washed with benzene (75 ml.). Removal of the solvent from the combined filtrate and washing gave a yellowish solid contaminated with yellow liquid. A colorless solid (55 mg., m. p. 328~333°C (decomp.)) was obtained on addition of a small amount of benzene-petroleum benzine (1 : 1) to the reduction products. This was recrystallized twice from benzene yielding pure crystals, m. p. 339~340.5°C (decomp.).

Found: C, 92.77; H, 6.63. Calcd. for $C_{36}H_{32}$: C, 93.06; H, 6.94%.

Molecular weight determination (Rast's method in camphor): 445, 468, 487. $C_{36}H_{32}$=465.

IR, 2930, 2860 cm^{-1} (-CH_2-) (KBr-disk). UV, $\lambda_{max}^{tetrahydrofuran}$ 241 mμ (log ε=4.92), 256 (5.02), 272 (4.69), 292.5 (4.31), 304 (4.31), 353 (3.01).

The absorption intensity (256 mμ, ε=105800) was found to be approximately double of the relevant intensity of 9, 10-dimethylphenanthrene (253 mμ, ε=58900).

The financial support for this research was granted by the Ministry of Education, to which the authors thanks are due.

Thermal Decomposition of Dimethyl Ether in the Presence of Hydrogen Sulfide and Nitric Oxide

By Naomi IMAI and Osamu TOYAMA

(Received September 28, 1961)

We have recently studied the catalytic effect of hydrogen sulfide on the thermal decomposition of acetaldehyde[1,2] and of dimethyl ether[3]. It has been suggested from the effects of chain inhibitors such as propylene and isobutylene that the hydrogen sulfide-catalyzed decomposition of acetaldehyde involves two mechanisms, i. e., a free radical chain mechanism and a non-chain molecular mechanism, while the hydrogen sulfide-catalyzed decomposition of dimethyl ether has been explained solely by a radical chain mechanism. There is, however, an indication[2] that nitric oxide catalyzes the molecular decompositon of dimethyl ether even though it suppresses the chain decomposition of the ether almost completely. It seems, therefore, possible that the molecular decomposition of dimethyl ether is also catalyzed by hydrogen sulfide. Although the contribution of such a catalysis, if present, must be considered from the results given above to be usually so small that its existence can hardly be recognized, it may be expected that the suppression of the chain decomposition by a suitable inhibitor will enable the hydrogen sulfide-catalyzed molecular decomposition to be measured.

This paper reports such an attempt, carried out with nitric oxide as an inhibitor, which has been found to be the most efficient of the inhibitors investigated.

Experimental

Materials.—Dimethyl ether was prepared by the dehydration of methyl alcohol by concentrated sulfuric acid at 80°C, decarbonated and dried over potassium hydroxide and calcium chloride. Hydrogen sulfide was prepared by dropping water on aluminum sulfide and dried by passing through a trap at −78°C. Nitric oxide was produced by the reaction of a concentrated sodium nitrite solution with a hydrochloric acid solution of ferrous chloride, decarbonated by a potassium hydroxide solution and dried by concentrated sulfuric acid and phosphorus pentoxide. All of these gases were prepared in evacuated vessels and purified by repeated bulb-to-bulb distillation.

Apparatus and Procedure. —The apparatus used was one for ordinary statical experiments similar to that described previously[4]. The rate of decomposition in most cases was followed by measuring the total pressure change, but, in some runs, the major decomposition products uncondensable at −196°C, i. e., methane, carbon monoxide and hydrogen, were analyzed by a Yanagimoto GCG-2 type gas chromatograph.

Results and Discussion

Figure 1 shows the results of a series of experiments in which the time of pyrolysis was varied under otherwise constant conditions. It had previously been found that the rate of formation of carbon monoxide in the uninhibited reaction[3] is approximately equal to that of hydrogen but smaller than that of methane, and that the total pressure-time curve is of a sigmoidal form. These findings have been explained by decomposition in two stages, i. e., by the reaction $CH_3OCH_3 \rightarrow CH_4 + HCHO$, followed by $HCHO \rightarrow H_2 + CO$, though neither of them is a simple reaction; both are radical chain reactions catalyzed by hydrogen sulfide. Figure 1 shows that the rate of the formation of carbon monoxide in the inhibited pyrolysis is lower than that of methane, but it is about ten times as great as that of hydrogen, indicating that formaldehyde does not decom-

pose according to the stoichiometric equation $HCHO \rightarrow H_2 + CO$ in the presence of nitric oxide. Figure 1 also shows that the total pressure increase is almost identical with that of methane in the initial stage of decomposition. In the experiments described below, the initial rate of total pressure increase was determined as a measure of the initial rate of decomposition. These initial rates of pressure increase may be taken as those for the formation of methane, as is shown above.

Table I shows the initial rates of pressure increase obtained with various gaseous compositions in the temperature range 440~520°C. Figure 2 shows the dependence of the rate on the pressure of nitric oxide in the presence and absence of hydrogen sulfide. Table I and Fig. 2 show that for the ether of 100 mmHg pressure, irrespective of the presence of hydrogen sulfide, the maximum inhibition is attained by about 3 mmHg of nitric oxide, and that the rate of maximally inhibited decomposition is only a fraction of that uninhibited in both the presence and the absence of hydrogen sulfide. As has been shown in the decomposition of acetaldehyde in the presence of hydrogen sulfide[2], the residual decomposition remaining after the maximum inhibition is probably of a molecular character. This, however, does not contradict the previous finding that the uninhibited decomposition of dimethyl ether in the presence or absence of hydrogen sulfide is to be explained solely by a radical chain mechanism[3], since the rate of decomposition maximally inhibited by nitric oxide is only a fraction of that uninhibited, as is shown above.

Figure 2 further shows that, in both the presence and the absence of hydrogen sulfide, the rate of inhibited decomposition increases linearly with the pressure of nitric oxide. This probably indicates that the molecular decomposition of dimethyl ether is catalyzed by nitric oxide, as has already been described in a previous paper[3]. The linear parts of the two plots for the rates in the presence and absence of hydrogen sulfide are parallel, suggesting that the inhibited decomposition of dimethyl ether is catalyzed independently by

hydrogen sulfide and by nitric oxide. Figures 3 and 4 show that the rate of inhibited decomposition increases linearly with the pressure of hydrogen sulfide and with that of the ether. The results shown in Figs. 2, 3 and 4 may, therefore, be combined to give a general expression for the inhibited rate:

$$-\mathrm{d}[CH_3OCH_3]/\mathrm{d}t = k[H_2S][CH_3OCH_3] + k'[NO][CH_3OCH_3]$$

The constant k can be determined from the intercept given by extrapolating the linear part of the plot obtained with hydrogen sulfide in Fig. 2 or from the slope of the straight line in Fig. 3, and k' from the slope of linear

TABLE II. VALUES OF RATE CONSTANTS

520	486	449	202	186

(a) From intercept of upper line in Fig. 2
(b) From slope of line in Fig. 3
(c) From slope of upper line in Fig. 2
(d) From slope of lower line in Fig. 2

parts of the plots given in Fig. 2. The results are listed in Table II, where the values of these constants obtained by different methods are in satisfactory agreement with each other. The slope of the straight line in Fig. 4 is 0.0100 min^{-1}, in good agreement with the value of 0.0105 calculated from these values of k and k'. The least square treatments of the values given in Table II yield the following Arrhenius expressions:

$$k = 10^{(14.7\pm0.35)} \exp\{-(43600\pm1200)/\boldsymbol{RT}\} \quad mol^{-1}\,cc.\,sec^{-1}$$

$$k' = 10^{(13.4\pm0.10)} \exp\{-(40500\pm600)/\boldsymbol{RT}\} \quad mol^{-1}\,cc.\,sec^{-1}$$

As has already been described, these reactions are probably molecular decomposition of the ether catalyzed by hydrogen sulfide and by nitric oxide respectively. Both expressions appear to be reasonable for a simple bimolecular process. However, as has been described previously for acetaldehyde[2], information from other sources than kinetics seems necessary to clarify further the detailed mechanisms of these reactions.

The effect of nitric oxide on the thermal decomposition of dimethyl ether has also been studied by Smith and Hinshelwood[5]. Their

5) J. R. E. Smith and C. N. Hinshelwood, *Proc. Roy. Soc.*, **A180**, 237 (1942).

results, however, differ considerably from those obtained in the present work. According to them, the rate of decomposition was reduced by the addition of an increasing amount of nitric oxide, but after a limiting rate was reached the rate remained constant and did not show any increase with the pressure of nitric oxide. The reason for this discrepancy is not yet clear. On the other hand, Freeman[6] studied the effect of nitric oxide on the thermal decomposition of diethyl ether and found a linear increase of the rate with the pressure of nitric oxide similar to the results shown in Fig. 2.

Summary

Dimethyl ether has been decomposed in the presence of hydrogen sulfide and nitric oxide over the temperature range 440~520°C. On increasing the amount of nitric oxide, the rate of decomposition decreases rapidly but after passing through a minimum value it increases linearly with the pressure of nitric oxide. The minimum value of the rate, which is reached in the presence of a small percentage of nitric oxide, is only a fraction of the uninhibited rate, irrespective of the presence of hydrogen sulfide. The rate of decomposition after being maximally inhibited, which is probably molecular in character, is represented by the equation $-\mathrm{d}[CH_3OCH_3]/\mathrm{d}t=k[H_2S][CH_3OCH_3]+k'[NO]\cdot[CH_3OCH_3]$, indicating that the inhibited decomposition is catalyzed by hydrogen sulfide and by nitric oxide independently. Arrhenius expressions $k=10^{14.7}\exp(-43600/\boldsymbol{RT})$ and $k'=10^{13.4}\exp(-40500/\boldsymbol{RT})\,\mathrm{mol}^{-1}\,\mathrm{cc.}\,\mathrm{sec}^{-1}$ have been obtained.

Determination of Deuterium in Organic Compounds

By Nobuo TAMIYA

(Received July 21, 1961)

The method of Graff and Rittenberg[1] is the basis of the commonly applied deuterium analysis. The water obtained by the combustion of an organic sample is reduced with the aid of heated zinc. The resulting gaseous hydrogen is subjected to mass spectrometric analysis.

Several attempts have been reported to improve this method by reducing the memory effect of the apparatus used for the combustion and the reduction[2-6]. The present paper describes a modification by which both combustion and reduction are carried out in small, sealed glass tubes. The new method is simple, and one can analyze more than twenty samples a day without interference by the memory effect.

Experimental

Apparatus and Procedure.—Figure 1a shows a combustion tube made of Pyrex glass. The tube is dried in an electric furnace at 300°C for 60 min. under vacuum. After dried air is introduced into it, the tube is connected to a magnesium perchlorate tube. An organic sample, which will give about 2.5 mg. (±20%) of water on combustion, is taken into the tube (Fig. 1b). The capillary end of the tube is cut off, and dried oxygen is passed through to replace the air. The tube is then sealed at both ends as shown in Fig. 1c (9 ml. in volume) and placed in an electric furnace of 620°C for 30 min. This is the highest temperature which the glass will stand. When the combustion is completed, the furnace is allowed to cool. The water produced is collected in the capillary end by this procedure (Fig. 1d). One may centrifuge the tube with a vacuum rubber tube as a cap at 1,500 r.p.m. for 5 min. if the water contains bubbles. The water vapor remaining in the main part of the tube must contain less deuterium than the water. The amount of the vapor is, however, too small to affect the results.

Figure 2a shows a reduction tube with a breakable seal on one end. This is essentially similar

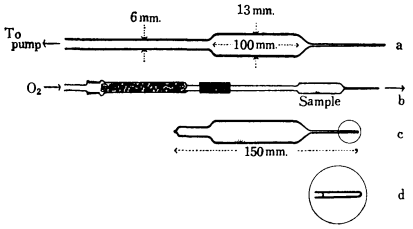

Fig. 1. Combustion tube for organic samples.

c: An evacuated and sealed reduction tube.

to that described by Chinard et al.[3] The tube is dried at 300°C for 60 min. with 0.25 g. of 20~30 mesh zinc granules in it. The capillary end of the combusition tube, which contains the water, is cut off and thrown into the reduction tube. The reduction tube is attached to a magnesium perchlorate tube and made thinner, with a flame at a part of its neck, as shown in Fig. 2b. The tube is then chilled with solid carbon dioxide to freeze the water, evacuated and cut by a flame under vacuum (9 ml. in volume, Fig. 2c). The reduction of the water is carried out at 620°C for 60 min. in an electric furnace. The hydrogen produced is taken out from the breakable seal and subjected to mass spectrometry. A Process and Instruments Model M-60 mass spectrometer was used. The reduction procedure is essentially similar to that described previously[8], except that a larger tube is used and that a higher temperature is applied. The addition of platinum catalyst to zinc, described in the previous paper, is no longer necessary, because the higher temperature is applied.

Results

The results are summarized in Table I. The standard water was prepared by diluting commercially available 99.65 mol.% deuterium oxide.

Table I. Examples of deuterium analysis

Sample		Deuterium found: Atom %	Deuterium found: Atoms per mole
10% (v/v) D_2O	2.5 μl.	9.95 10.01 9.89	
DL-Alanine-2d	3.5 mg.	14.15 14.3 13.5	0.990 1.00 0.945
L-Alanine-2d, $3d_3$	3.5 mg.	54.0	3.78
Glycine-$2d_2$	7.0 mg.	34.8 36.3	1.75 1.82
L-Aspartic acid-2d		14.8	1.04
L-Aspartic acid-3d		13.6	0.95
L-Aspartic acid-2d, 3d		28.9	2.02
DL-Aspartic acid-2d, $3d_2$		39.7	2.78

DL-Alanine-2d was prepared by an electrolytic reduction of pyruvic acid oxime in deuterium oxide in the presence of deuterated sulfuric acid[7]. A rough estimation of the deuterium content at the α- and β-positions of the preparation was made by comparing the infrared absorption peaks at 1308 cm^{-1} (α-CH deformation) and 1451 cm^{-1} ($-CH_3$ degenerating deformation) with that at 1410 cm^{-1} ($-COO^-$ symmetric stretching), which was taken as the standard. According to this estimation, the deuterium content of the α- and β-positions is 90 and 7 atom %, respectively[8,9]. L-Alanine-2d, $3d_3$ was prepared by treating L-alanine with transaminase in deuterium oxide; the infrared absorption spectrum of the preparation showed an almost complete disappearance of the $-CH_3$ and α–CH groups[8,9]. Glycine-$2d_2$ was prepared by treating glycine with salicyl aldehyde and cupric ion in deuterium oxide[10]. The results of the mass spectrometric analysis are in good agreement with the infrared absorption data.

Deuterium derivatives of L-aspartic acid were synthesized enzymically, and their infrared absorption spectra showed that there was almost no contamination of each other[10] and of hydrogen compound.

Summary

A device to simplify the deuterium analysis of organic compounds was described. The

combustion of organic samples and the reduction of deuterium containing the water produced were both carried out in sealed glass tubes. By this procedure one could completely avoid the "memory effect" and get satisfactory results, as shown by the examples of amino acid analysis.

Effects of Organic Bases on the Rate of the Oxo Reaction of Methylacrylate[1)]

By Ryoji IWANAGA

(Received July 25, 1961)

When cobaltic oxide suspended in benzene is treated with synthesis gas under high pressure at about 100°C in the presence of a small amount of dicobalt octacarbonyl as an initiator, carbon monoxide and hydrogen are readily absorbed and cobalt carbonyl is formed. This reaction is considered to be catalyzed by cobalt hydrocarbonyl, which is produced from dicobalt octacarbonyl and which increases in amount as the reaction proceeds.

We have previously[2)] found that the rate of this reaction is remarkably accelerated by the presence of a small amount of pyridine. Studying the mechanism of this reaction, it has occurred to the author that this effect of pyridine on the rate of the formation of cobalt carbonyl may be applied to the oxo reaction for the purpose of increasing the rate.

We have, therefore, examined the rate of the oxo reaction of methylacrylate in benzene in the presence of an amount of pyridine equimolar to cobalt of dicobalt octacarbonyl added as catalyst. It was consequently found that the rate of this oxo reaction is thereby about doubled.

To obtain information on the mechanism of this pyridine effect, we have studied the rate of the oxo reaction by adding various amounts of pyridine. In addition, the effects of various other aliphatic and aromatic amines on the rate were investigated.

Wender et al. previously[3)] reported that the treatment of a solution of dicobalt octacarbonyl in pyridine with synthesis gas at 120°C and 230 atm. results in the conversion of all of the cobalt to the pyridinium salt of cobalt hydrocarbonyl, $[C_5H_5NH]^+ [Co(CO)_4]^-$, and that the oxo reaction of a mixture of 2, 3-dimethylbutene-1 and -2 at 135°C and 230 atm. of synthesis gas was completely inhibited in the presence of triethylamine. The author has also observed that the oxo reaction of methylacrylate is suppressed in the presence of a large amount of pyridine or other amines.

Thus, the effect of pyridine in increasing the rate of oxo reaction appears only in the presence of a small amount of pyridine. Therefore, in the case of the examination of the effects of other amines, an amount of them equi-molar to the cobalt of dicobalt octacarbonyl added as catalyst was used.

Furthermore, to elucidate the mechanisms of the effects of pyridine and other amines on the rate of oxo reaction, the initial rate of the formation of the cobalt carbonyl anion was measured in this paper.

Experimental

Rate of the Formation of Cobalt Carbonyl from Cobaltic Oxide.—Fine powders of 16.6 g. (100 mmol.) of cobaltic oxide and a 180 ml. benzene solution containing 0.47 g. (6 mmol.) or 0.16 g. (2 mmol.) of pyridine were put into a 600 ml. stainless steel rocking autoclave, and then 20 ml. of a benzene solution containing 1.71 g. (5 mmol.) of dicobalt octacarbonyl were slowly pipetted into the solution. The autoclave was immediately sealed, placed in an electrically heated jacket, flushed and pressured with 1 : 1 synthesis gas to 200 kg./cm^2 at room temperature, and heated. After the temperature had risen to 110°C, the rocking was started, and the temperature was controlled at 110 ± 1°C. The

1) R. Iwanaga, T. Fujii and T. Yoshida, presented in part at the 9th Meeting of the Chemical Society of Japan, Kyoto, April, 1956.
2) T. Yoshida, R. Iwanaga and H. Mori, U. S. Pat. 2848304 (1958).
3) I. Wender, H. W. Sternberg and M. Orchin, *J. Am. Chem. Soc.*, 75, 3041 (1953).

rate of the reaction was estimated by the pressure decrease in the autoclave.

Rates of the Oxo Reaction of Methylacrylate in Benzene in the Presence of Pyridine or Other Amines.—Pyridine and other amines were obtained in the best commercial grades available. These were treated with anhydrous sodium sulfate for 24 hr. and then distilled. The middle fractions consistent with the boiling points described in the literature were then collected in dry flasks, protected from any atmospheric moisture, and were used immediately. Methylacrylate and benzene were treated in the same way.

A solution of 148 ml. benzene containing 30.0 g. (348 mmol.) of methylacrylate and 0.60 g. (1.74 mmol.) of dicobalt octacarbonyl was put into a 300 ml. stainless steel rocking autoclave, and 2 ml. of a benzene solution containing pyridine or other amines to be tested were pipetted slowly into the solution in the autoclave. The autoclave was immediately filled with 1 : 1 synthesis gas to 200kg./cm^2 and heated as described above. After the temperature of the solution had reached a temperature a little lower than the temperature to be tested, the rocking was started and the reaction temperature was controlled at 100 ± 1°C or 120 ± 1°C. The rocking was continued until the pressure decrease stopped.

Rates of the Formation of the Cobalt Carbonyl Anion from Dicobalt Octacarbonyl in the Presence of Amines in the Oxo Condition.—The methods described in the preceding paper[4] were in general followed, except that a crystal of dicobalt octacarbonyl was added to a toluene solution of pyridine or of triethylamine after the pressure and temperature had been raised to the reaction condition. Namely, 100 ml. of a toluene solution containing 198 mg. (2.5 mmol.) of pyridine or 254 mg. (2.5 mmol.) of triethylamine were put into a 300 ml. stainless steel rocking autoclave, and, on the other hand, 0.87 g. of dicobalt octacarbonyl crystal was put into a 10 ml. beaker, which was set rigidly with a stainless steel wire on the inside of the cover of the autoclave in order to keep dicobalt octacarbonyl separate from the pyridine or triethylamine until the pressure and temperature had been raised to the reaction condition. The autoclave was then sealed, flushed and pressured to about 70 kg./cm^2 with 1 : 1 synthesis gas. After the temperature of the system had been raised to 100°C and the pressure had been adjusted to 100 kg./cm^2, the autoclave was turned upside down and the rocking was started immediately so that the dicobalt octacarbonyl crystal could be dissolved into the solution. About 2 ml. aliquots of the reaction solution were withdrawn directly into a nitrogen atmosphere from the autoclave through a high pressure coil of tube in the course of the reaction, and the cobalt hydrocarbonyl in the aliquot was analyzed by the methylene blue method.

Results and Discussion

Figure 1, which illustrates the pressure decrease in the autoclave during the production of cobalt carbonyl from cobaltic oxide in benzene, shows that the rate of gas absorption is much higher in the presence of pyridine than when pyridine is absent. After about 62% of the cobaltic oxide was digested, the gas absorption stopped. The stopping was due to the coagulation of powders of cobaltic oxide in the water which was produced during the reaction in a separated phase from the benzene solution. When about 5 g. of dry kieselguhr were added as a absorbent of the water, this reaction could proceed until the cobaltic oxide had been digested completely.

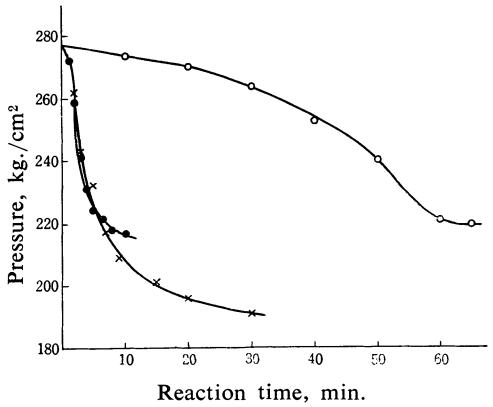

Fig. 1. Effect of pyridine on the rate of formation of cobalt carbonyl from cobaltic oxide.
—○— In absence of pyridine
—●— In presence of pyridine
—×— In presence of pyridine and kieselguhr

In view of the fact that the production of cobalt carbonyl from cobaltic oxide in the absence of cobalt carbonyl under high pressure synthesis gas did not take place until the temperature had been raised to 150°C, whereas in the presence of cobalt carbonyl it took place immediately even at temperatures below 100°C, and the fact the the rate of gas absorption increased with time, as is shown in Fig. 1, it is likely that cobalt carbonyl itself is the catalyst for the production of cobalt carbonyl. Therefore, the author visualizes the reaction as occurring in the following steps:

$$Co_2O_3 + 6HCo(CO)_4 \rightarrow 2Co + 3Co_2(CO)_8 + 3H_2O \quad (1)$$

$$2Co + 8CO \rightarrow Co_2(CO)_8 \quad (2)$$

$$Co_2(CO)_8 + H_2 \rightarrow 2HCo(CO)_4 \quad (3)$$

On the other hand, as illustrated in Table III, the initial rate of the formation of the cobalt carbonyl anion from dicobalt octacarbonyl under a high pressure synthesis gas and at an elevated temperature is greatly increased in the presence of pyridine or triethylamine.

4) R. Iwanaga, This Bulletin, 35, 778 (1962).

In a number of papers it has been shown that Lewis bases react with dicobalt octacarbonyl under mild conditions according to the equation,

$$2xB + 3Co_2(CO)_8 \rightarrow 2[Co(B)_x][Co(CO)_4]_2 + 8CO \quad (4)$$

When B is pyridine or triethylamine, this homomolecular disproportionation occurs similarly. However, under a high pressure of synthesis gas, no carbon monoxide is liberated and all the cobalt in the system is present in the forms of cobalt hydrocarbonyl, cobalt carbonyl anion and dicobalt octacarbonyl, even in the presence of amines. Therefore, it is considered that the effect of pyridine on increasing the rate of the production of cobalt carbonyl may be due to an acceleration of the rate of the reaction (Eq. 3) by a formation of an intermediate complex and a subsequent rapid formation of cobalt hydrocarbonyl from the complex and hydrogen as follows:

$$Co_2(CO)_8 + 2B \rightarrow (CO)_4Co\cdots Co(CO)_4 \quad (5)$$
$$\begin{matrix} \vdots & \vdots \\ B & B \end{matrix}$$
Complex

$$\text{Complex} + H_2 \rightarrow 2HCo(CO)_4 + 2B \quad (6)$$

$$HCo(CO)_4 + B \rightleftarrows [BH]^+[Co(CO)_4]^- \quad (7)$$

However, the amount of free cobalt hydrocarbonyl decreases while the hydrocarbonyl combined with amine, as shown in Eq. 7, increases in amount as the basicity of amine becomes stronger. Therefore, in the oxo reaction the effects of amines must appear in different manners from that in the formation of the anion as shown in Table III.

Plots of $\log\{(P_0-P_f)/(P_t-P_f)\}$ against time in the oxo reaction of methylacrylate in benzene under a 1:1 synthesis gas yielded approximate straight lines (P_0=initial pressure at reaction temperature, P_f=pressure at the end of reaction, P_t=pressure at time t), indicating that the rate of decrease of the pressure was linear with the total pressure drop. Several such plots are given in Fig. 2. The relative rate listed in Tables I and II gives the ratio between the slope of a straight line for the reaction with the amine and that for the reaction without the amine.

As illustrated in Table I, the rate of the oxo reaction of methylacrylate in benzene about doubles in the presence of an amount of pyridine equi-molar to the cobalt of the dicobalt octacarbonyl added as a catalyst, and the rate increases with the increasing amount of pyridine, although the effect becomes smaller, the larger the amount of pyridine is. Although the author did not measure such an amount of pyridine by which the maximum effect could be obtained, the oxo reaction may be rather suppressed or inhibited completely when a large amount of it is present.

The effects of other amines on the rate of the oxo reaction are listed in Table II. The amines listed in Table II are conveniently divided into three structural classifications for the purpose of comparison.

Aromatic Tertiary Amines.—This type of amine shows a completely positive effect on increasing the rate. Like pyridine, pyridine homologues, except 2, 6-lutidine, show the effect to a remarkable extent, but there are small differences in effects. The effect decreases

None	1.7
Pyridine	10.0
Triethylamine	21.2

in the order of the decreasing strength of base, as γ-picoline> β-picoline> pyidine. 2,4-Lutidine and α-picoline are stronger than γ- and β-picoline in basicity, but show smaller effects. This may be due to weak steric factors. The far smaller effect of 2,6-lutidine and *N*,*N*-diethylaniline may be explainable in terms of great steric hindrance, probably in complex formation. Quinoline shows a small effect, and this may be due to its weak basicity.

5) It was reported by Sternberg et al.[6] that dimethylformamide is produced from dimethylamine and dicobalt octacarbonyl at 0°C and atmospheric pressure, and that at 220°C and at carbon monoxide pressure of 200 atm. dimethylamine and piperidine are readily carbonylated to the corresponding formamide in the presence of catalytic amounts of dicobalt octacarbonyl.

6) H. W. Sternberg, I. Wender, R. A. Friedel and M. Orchin, *J. Am. Chem. Soc.*, 75, 3148 (1953).

Primary and Secondary Amines.—This type of amine shows little or no effect on increasing or decreasing the rate. The reason may be that these compounds with an NH-group are readily carbonylated with carbon monoxide to the corresponding formamide in the presence of dicobalt octacarbonyl[5], and consequently are weak in basicity.

Aliphatic Tertiary Amines.—Since all aliphatic tertiary amines have a very strong base and can not be carbonylated, they may form stable salts with cobalt hydrocarbonyl. Therefore, the major part of the cobalt added into the system converts to unreactive cobalt carbonyl anions, and the rate of the oxo reaction may be rather decreased as compared with the rate in their absence. The results obtained for them indeed show great negative effects.

Finally, the effect of pyridine and its homologues on increasing the rate of the oxo reaction may be accounted for by comparing the above results for the three types of amines. Namely, pyridine and its homologues have no NH-group to be carbonylated with carbon monoxide and consequently can be kept active for the formation of an intermediate complex with a cobalt carbonyl formed in the course of the oxo reaction and the rapid formation of that cobalt hydrocarbonyl presumed to be the catalyst of the oxo reaction from the complex. This concept may be supported by the small effect of 2,6-lutidine, which is likely hindered from forming the complex by a steric factor. On the other hand, pyridine and its homologues are far weaker in basicity than aliphatic tertiary amines such as triethylamine, and it may be considered that when the amount of pyridine is small in the solution, the free hydrocarbonyl formed reacts as the catalyst of the oxo reaction without forming a salt with pyridine.

Summary

It has been found that the rate of the formation of cobalt carbonyl from cobaltic oxide in benzene with the high pressure of 1:1 synthesis gas at 110°C is remarkably accelerated by the presence of a small amount of pyridine.

When the oxo reaction of methylacrylate in benzene is carried out in the presence of an amount of pyridine equi-molar to the cobalt of dicobalt octacarbonyl added as a catalyst, the rate is about doubled. By examining the oxo reaction in the presence of other organic bases, the following results were obtained: the rates are decreased by aliphatic tertiarx amines such as triethylamine and tributylamine, and are scarcely affected by primary and secondary amines such as aniline and dibutylamine. Pyridine homologues except 2,6-lutidine, are as

effective as pyridine. On the basis of these results, the mechanism of the effects of organic bases on the rate of oxo reaction has been discussed.

The author wishes to express his thanks to Professor Shunosuke Murahashi, Dr. Tôichi Yoshida and Mr. Jiro Kato for their kind guidance and encouragement throughout this work. The author is also indebted to Mr. Takashi Fujii and Mr. Hachiro Wakamatsu for their assistance in this experiment.

Effects of Solvents on the Rate of Oxo Reaction of Methylacrylate

By Ryoji IWANAGA

(Received August 2, 1961)

While extensive studies on the effect of the structure of olefin and the partial pressure of carbon monoxide and hydrogen upon the rate of oxo reaction have been carried out, very little work on solvents in this regard has yet been done. Wender et al.[1], however, did study the effects of solvents on the oxo reaction rate of cyclohexene and established that the rate is increased only about 1.5 times in going from a saturated hydrocarbon to methanol; they therefore considered that highly polar intermediates may not be involved in the oxo reaction.

However, we have found that the effect of solvent on the rate of oxo reaction varies widely according to the olefin used[2]. For example, the oxo reaction rate of acrylonitrile in methanol at 120°C is about 6 times that in benzene. In this paper the author has investigated the effects of a variety of organic solvents and mixed solvents on the oxo reaction rate of methylacrylate. In addition, to obtain information on the mechanism of the effects of solvents, the rate of "base reaction" of Lewis base solvents such as methanol and acetone with dicobalt octacarbonyl, and the rate of formation of cobalt hydrocarbonyl from dicobalt octacarbonyl in toluene, methanol and acetone at 100°C and at 100 kg./cm^2 of 1 : 1 carbon monoxide and hydrogen, were measured.

Methylacrylate was chosen as the raw material for this study, because it gives a considerably wide variation in the effects of solvents and yields only one aldehyde, methyl-β-formylbutyrate. In addition, the oxo reaction of methylacrylate proceeds with scarcely any side reactions, because it gives a good yield of the aldehyde in every solvent.

Experimental

All of the solvents used were obtained in the best commercial grades available. These were treated with anhydrous sodium sulfate for 24 hr. and then distilled. The middle fraction consistent with the boiling point described in the literature was then collected in a dry flask, protected from atmospheric moisture. Methylacrylate was treated in the same way; its purity as determined by the morphorine method[3] was 98.5%.

Rates of the Oxo Reactions of Methylacrylate in Various Solvents.—The oxo reactions were carried out in a batch system by the same procedure as described in a preceding paper[4].

Thus, 150 ml. of the solvent containing 30.5 g. (350 mmol.) of methylacrylate and 0.60 g. (1.74 mmol.) of dicobalt octacarbonyl were put into a 300 ml. stainless steel rocking autoclave, and the autoclave was immediately filled with 1 : 1 synthesis gas to 200 kg./cm^2 and heated. After the temperature had risen to 120°C, the rocking was started, and the temperature was controlled at 120±1°C. The rocking was continued until the pressure decrease stopped. The rate constant of the oxo reaction, k_a, was obtained from the following equation:

$$k_a = 2.303 \log \{(P_0 - P_f)/(P_t - P_f)\}/t$$

where P_0 is the initial pressure at the reaction temperature, P_f is the pressure at the end of the reaction, and P_t is the pressure at time t.

4) R. Iwanaga, This Bulletin, **35**, 865 (1962).

Rates of "Base Reaction" of Solvents with $Co_2(CO)_8$.—Reactions were carried out at 20°C, and the rates were measured by the same procedure as described in a preceding paper[5]. The rate constants of the base reaction, k_b, were obtained from the following equation;

$$k_b = 2.303 \log \{[A^-]_f/([A^-]_f - [A^-]_t\}/t$$

where $[A^-]_f$ is the final amount of cobalt carbonyl anion, which corresponds to 2/3 mol. of the total cobalt in the $Co_2(CO)_8$ added, and $[A^-]_t$ is the amount of the anion at time t.

Initial Rates of Formation of Cobalt Hydrocarbonyl from $Co_2(CO)_8$ in Methanol and Acetone.—These were measured by the same technique as used in the measurement of the rate of formation of cobalt carbonyl anions from dicobalt octacarbonyl in the presence of amines[4]. Namely, a crystal of 0.87 g. of dicobalt octacarbonyl was added to 100 ml. of methanol or of acetone after the temperature of the system had been raised to 100°C and the pressure of 1 : 1 carbon monoxide and hydrogen had been adjusted at 100 kg./cm², and the amount of cobalt hydrocarbonyl in an aliquot of the reaction solution was analyzed by the methylene blue method.

Results and Discussion

The rates of oxo reaction of methylacrylate in 17 organic solvents at 120°C and at the initial pressure of 260 kg./cm² of 1 : 1 carbon monoxide and hydrogen are listed in Table I, together with their dielectric constants and their rates of "base reaction" with dicobalt octacarbonyl at 20°C. An about eight-fold variation was observed between the fastest and slowest rates. As is illustrated by the data in Table I, no relationship between the rates of oxo reaction and the dielectric constants or the rate of base reaction could be found.

Benzene, toluene, ethylacetate and ethyl ether are considered to be inert in the oxo reaction. Therefore, the value of about 40×10^{-3} min^{-1} may be considered a standard rate constant for the oxo reaction of methylacrylate; a value above it indicates a positive effect of the solvent, and a value below it indicates a negative effect of the solvent.

The rates in alcohols are very great except for the rate in *tert*-butanol. The large effects of alcohols may be explained by the same mechanism as proposed in the effect of pyridine[4], which involves the formation of an intermediate complex with cobalt carbonyl and the consequent rapid formation of cobalt hydrocarbonyl. This consideration agrees well with the observation that the formation of cobalt hydrocarbonyl in methanol is very rapid (cf. Table II).

The small positive effect of *tert*-butanol may be due to a steric hindrance, which may

a) Calculated from the formula; $[Co(C_2H_6O_2)_3][Co(CO)_4]_2$

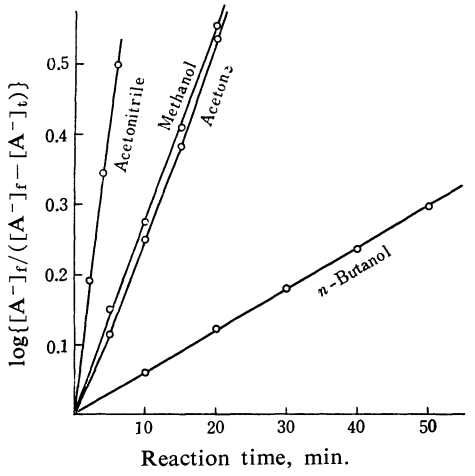

Fig. 1. Rates of the base reaction of dicobalt octacarbonyl with various Lewis bases.

occur in the complex formation with cobalt carbonyl, as described in the effect of 2,6-lutidine on the rate[4].

Acetone shows a moderate effect on the rate. Ethyl methyl ketone has an approximate standard value and is considered to be inert in the oxo reaction on the basis of its presumed steric factors.

In the case of the oxo reaction in acetonitrile, the original dark-brown solution changes to light yellow after the reaction is complete. This is probably due to the formation of amine by some hydrogenation of the nitrile.

In ethylene glycol, the oxo reaction did not take place. As is illustrated by Table III, it was found that dicobalt octacarbonyl reacts with ethylene glycol to form cobalt(II) ions and cobalt carbonyl anions even under the oxo condition, presumably according to Eq. 1.

$$3Co_2(CO)_8 + 6C_2H_6O_2 \rightarrow 2[Co(C_2H_6O_2)_3][Co(CO)_4]_2 + 8CO \quad (1)$$

Because the oxo reaction proceeds with no interference in benzene containing a small amount of ethylene glycol, as is shown in Fig. 2, it will be rather practical to explain the fact that the oxo reaction does not take place in ethylene glycol as follows: the complex salt consisting of a cobalt-ethylene glycol cation and a cobalt carbonyl anion has been produced by the base reaction before the pressure and temperature are raised to the oxo reaction condition, and the salt, once produced, is too stable in a higher polar solvent such as ethylene glycol to be converted to dicobalt octacarbonyl or cobalt hydrocarbonyl. It may be due to the same reason why the oxo reaction does not take place in formamide.

As is illustrated in Fig. 3, the rate is decreased by increasing the amount of water in the methanol. When 15 vol.% or more of water was added to the methanol, the reaction

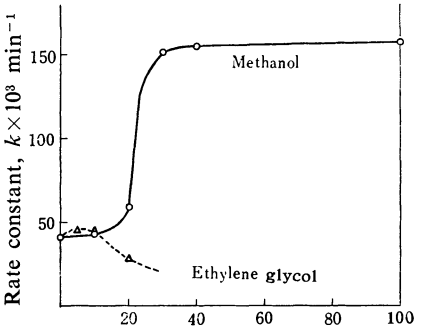

Fig. 2. Rates of the oxo reaction of methylacrylate in mixed solvent of benzene and methanol or ethylene glycol.

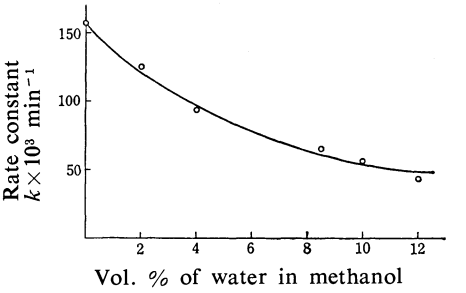

Fig. 3. Effects of water content in methanol as solvent of the oxo reaction of methylacrylate.

did not take place. This negative effect of water may be explained in terms of the dissociation of the cobalt hydrocarbonyl presumed to be a catalyst of the oxo reaction, because it is known that cobalt hydrocarbonyl dissociates completely in water at 26°C[6].

Summary

The rates of methylacrylate oxo reactions in a variety of organic solvents were measured by a batch system at 120°C. In general, the rate varies widely in the following order: alcohols > acetone > toluene; this order did not correspond with the order of their dielectric constants nor with the rates of their "base reactions" with dicobalt octacarbonyl, but it does agree with the order of their rates of formation of cobalt hydrocarbonyl under oxo conditions. *tert*-Butanol shows a positive but small effect on the rate as compared with toluene. When ethylene glycol and formamide having higher dielectric constants were used as solvents, the oxo reaction did not take place. On the bases of these results the mechanisms of the effects of the solvents have been discussed.

The author wishes to express his deep gratitude to Professor Shunsuke Murahashi, Dr. Tôichi Yoshida and Mr. Jiro Kato for their kind guidance and encouragement throughout this work. The author is also indebted to Mr. Takashi Fujii and Mr. Hachiro Wakamatsu for their assistance in this experiment.

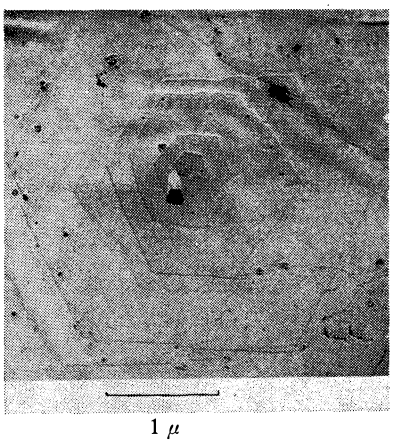
Dendritic Growth of Polyoxymethylene Crystal



By Nobukazu ISHIHARA, Yasumasa TANI and Hiroshi SAKAI

(Received September 28, 1961)

It has been reported by Geil and others[1-3] that polyoxymethylene (POM) crystallized from a dilute phenol solution or from dimethyl phthalate forms the regular hexagonal plate single crystal*. Figure 1 shows that a fresh single crystal of POM grown from aniline has the same hexagonal form.

However, the dendritic growth of the needle-like crystal of POM was observed in some specimens which had been aged for a month after their preparation. A typical electron-micrograph of the POM dendrite is shown in Fig. 2. The crystal aspect of the dendrite is similar to that of the whisker or the snow crystal. To prevent thermal damage to the crystal by electron beam irradiation, the specimen was cooled in an electron microscope by liquid nitrogen below $-50°C$ during the observation.

Though the hexagonal plate and the dendrite were apparently different in form, however, the same crystal structure was obtained from their electron diffraction patterns in the process of our experiment.

Rapid Microdetermination of Dysprosium in Terbium Oxide by Neutron Activation and γ-Ray Spectrometry

By Minoru OKADA

(Received October 4, 1961)

A neutron activation analysis method has been devised to evaluate the dysprosium content of high-purity terbium-oxide powder. Since the activation cross section for terbium is large (more than 22 barns[1] for thermal neutrons), terbium may interfere with the determination of dysprosium unless the matrix is removed. From the calculation based on the data[2] for thermal neutron activation and γ-ray spectrometry, it is seen that the most abundant γ-ray from 0.1 g. of activated terbium is in the same order as that from 1 μg. or more of activated dysprosium when both elements are irradiated at the same flux density of thermal neutrons. This implies that the non-destructive determination of dysprosium in terbium oxide may be interfered with terbium if the dysprosium content is less than 10 p. p. m. The possible interferences from terbium are γ- and X-rays of ^{160}Tb. The energies in MeV. are: 0.96(35%), 0.88(33%), 0.30(30%), 0.05 (~30%), etc.

Experimental

Varying amounts (7~25 mg.) of the sample to be analyzed were sealed in separate polyethylene capsules (1 cm. in diameter and 2 cm. in length) and placed by turns in the Japan-Research-Reactor-1 for 60 sec. to be irradiated with neutrons at a flux of 3×10^{11} neutrons per cm^2/sec. Then, after a 15-sec. interval, the decay of the activities produced was determined by use of a 2 in. thick, well-type, thallium-activated sodium-iodide crystal attached to a 256-channel pulse-height analyzer. In each successive γ-spectra obtained, the height of the photopeak of 0.108 MeV. γ-ray from ^{165m}Dy was measured, and a decay curve was made by plotting the log peak height vs. the time. Identification was made from the γ-ray energy and the half-life. Dysprosium standards were made so as to contain known amounts of dysprosium ranging from 0.05 to 5 μg.

Results and Discussion

Typical γ-ray spectra obtained are shown in Figs. 1 and 2. It can be seen from these figures that the γ-ray spectra for the irradiated terbium-oxide sample consist mainly of those of ^{165m}Dy; that is, the Compton continuum for the γ-rays of ^{160}Tb is negligible. The half-life of the photopeak which appeared at about 0.108 MeV. in the spectra for the sample was equal to that of the photopeak at the same position in the spectra for the dysprosium standard solution.

Table I shows the results of analyses where nine aliquots have been taken from one unknown sample. Since the observed dysprosium contents are nearly constant in the range of the sample amounts below 24 mg., it can be concluded that the self-shielding effect is negligible in this range. Hence, the average

2) M. Okada, Paper presented at the 4th Japan Conference on Radioisotopes, Kyoto, October, 1961.

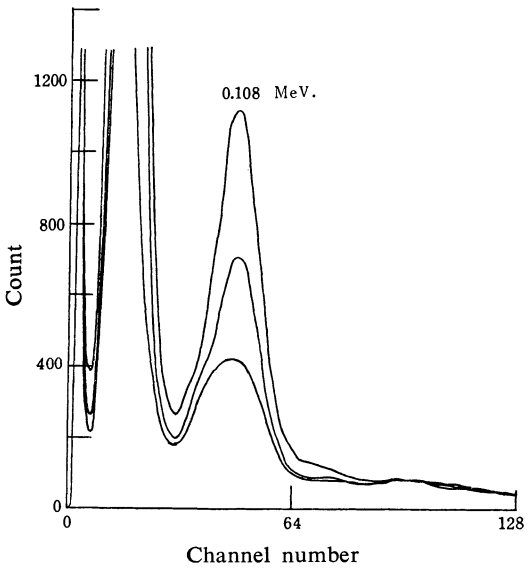

Fig. 1. Spectra for γ-rays of an activated terbium oxide sample (No. 2 in Table I).
Time interval between the 1st (the highest) and the 2nd spectra is 65 sec., and that between the 2nd and the 3rd spectra is 70 sec.

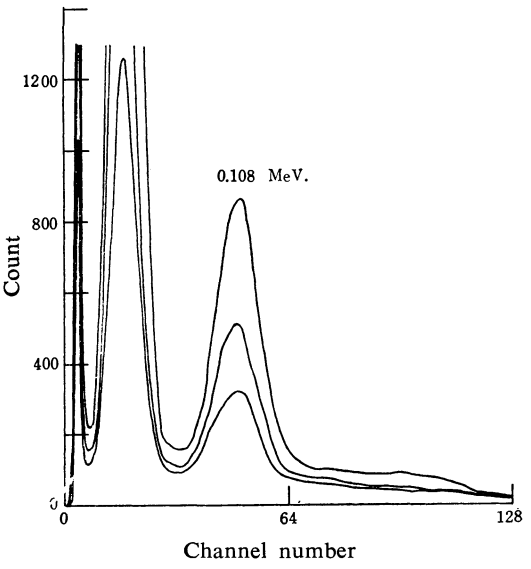

Fig. 2. Spectra for γ-rays of an activated dysprosium standard solution containing 0.22 μg. of dysprosium.
Time intervals are the same as those in Fig. 1.

(48 p. p. m.) can be taken for the dysprosium content. From the five values for "dysprosium found" shown in the lower part of Table I, the coefficient of the variation of single analyses can be estimated at 5.2% for 24.4$_4$ mg. sample.

TABLE I. RESULTS OF ANALYSES OF A TERBIUM OXIDE POWDER SAMPLE

No.	Sample wt. used mg.	Dysprosium found p. p. m.
1	6.96	49
2	11.1	50
3	11.1	45
4	19.4	50
5	24.5	46
6	24.4	52
7	24.5	49
8	24.4	48
9	24.4	45

The production of ^{165m}Dy through ^{165}Ho (n, p) and ^{168}Er(n, α) reactions was neglected in this experiment because their cross sections were expected to be very small and because the amounts of holmium and erbium in the sample were expected to be less than that of the dysprosium.

The radioactive nuclides which were produced by neutron irradiation of the samples and which decay with a γ-ray energy about 0.108 MeV. are ^{183m}W, ^{m}Yb(6 sec.), ^{165m}Dy, ^{161}Gd, ^{79m}Se, ^{151}Nd, ^{188m}Re, ^{155}Sm, ^{149}Nd, ^{165}Dy and ^{153}Sm. The radionuclides which can only slightly be formed upon 60 sec. irradiation with thermal neutrons are omitted. In these eleven nuclides, the ratio of the half-life of ^{165m}Dy to the nearest half-life is 1 : 3.1. Therefore, only a few successive spectra per sample are enough to identify dysprosium so long as the interfering activity of the nearest half-life is negligible. This was true in the sample tested in this work.

It is a good point of this method that the procedures required are simple and can be carried out on a very low-level radioactivity. From Fig. 1, which represents a sample of 48 p. p. m. dysprosium content, it can be deduced that one-tenth of this concentration of dysprosium would produce an adequate size of photopeak. Contamination can hardly become a problem in this method because no chemical procedure is employed for the sample to be analyzed.

Summary

Dysprosium in terbium oxide powder was determined by a simple method involving 1 min. irradiation with pile neutrons of 3×10^{11} neutrons per cm^2/sec. and repeated γ-ray spectrometry using a 2 in. thick sodium-iodide crystal attached to a 256-channel pulse-height analyzer. Both interferences and the self-shielding effect were negligible. The coefficient of variation of single analyses was 5.2% for a 24 mg. sample of 48 p. p. m. dysprosium content.

The author wishes to express his thanks to Professor Shoji Makishima for his keen interest in the work, and to Dr. Toshio Nakai for his permission to use the laboratory facilities.

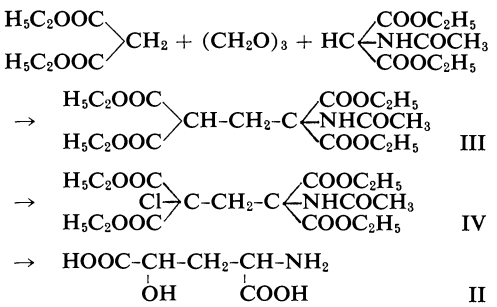
*Syntheses of γ-Hydroxyglutamic Acid**

By Takeo KANEKO, Yong Kyun LEE and Teruko HANAFUSA*1



(Received September 14, 1961)

In 1955 Virtanen and Hietala[1] isolated γ-hydroxyglutamic acid from *Phlox decussata*, and Benoiton and Bouthillier[2] synthesized this hydroxyamino acid from ethyl *o*-acetylchlorolactate and ethyl acetamidocyanoacetate. Later, this synthetic method was improved by Benoiton et al.[3], who deduced the configuration of its optical isomers. Since the absolute configuration of the four optical isomers of β-hydroxyglutamic acid was determined in our laboratory[4], it has seemed to us of interest to study some of the properties of the stereo isomers of γ-hydroxyglutamic acid. First, attempts were made for a new synthesis of γ-hydroxyglutamic acid.

The hydroxyamino acid (II) was synthesized by hydrolysis of condensation product I of ethyl dibromopropionate with diethyl acetamidomalonate.

Two racemic diastereomers of II have been separated with procedures similar to those described by Benoiton et al.[3] When a crude hydrolyzate of the synthetic hydroxyamino acid was saturated with hydrogen chloride, one of the diastereomers, DL-γ-hydroxyglutamic acid (A) was precipitated asits lactone hydrochloride, m. p. 230~232°C (decomp.). From the mother liquor, another isomer, DL-γ-hydroxyglutamic acid (B), m. p. 166°C (decomp.), was obtained after treatment with pyridine and ethanol. After treatment of the amino acid A lactone hydrochloride with pyridine or silver carbonate, DL-γ-hydroxyglutamic acid (A) lactone, m. p. 245°C (decomp.), or DL-γ-hydroxyglutamic acid (A), m. p. 172~173°C (decomp.) was obtained*2.

Since the above synthesis, however, did not give a good yield, the next method was attempted. Tetraethyl α-acetamidomethylene-bismalonate (III), obtained by condensation of diethyl acetamido-malonate and diethyl malonate with paraformaldehyde according to the method of Hellmann and Lingens[5], was chlorinated with sulfuryl chloride in acetic acid to give, in a high yield, chlorinated compound IV, which was then hydrolyzed to γ-hydroxyglutamic acid with hydrochloric acid. The two diastereoisomeric DL-γ-hydroxyglutamic acids were isolated from the crude hydrolyzate in the same manner as has been described

above. The over-all yield from ethyl acetamidomalonate by this procedure was about 60% of the theoretical yield*3.

The solubility behaviors of the two racemates in hydrochloric acid and the melting points of *N*-benzyloxycarbonyl derivatives of the isomer A lactone and of B and its lactone were in good agreement with those reported by Benoiton et al.[3] It is clear from these facts that the two racemic modifications, A and B, correspond to the epimeric compounds (A and B)*4 obtained by the synthetic method. It failed to yield the hydrochloride of the isomer A because of its liability to form a lactone formation with hydrochloric acid.

Benzyloxycarbonyl-DL-γ-hydroxyglutamic acid (A) lactone was formed either by benzyloxycarbonylation of the lactone[3] or by treatment of benzyloxycarbonyl-DL-γ-hydroxyglutamic acid (A) with hydrochloric acid. The benzyloxycarbonyl-DL-γ-hydroxyglutamic acid (B) lactone was also obtained from the corresponding derivative of hydroxyamino acid B by treatment with hydrochloric acid.

Only benzoyl-amino acid A lactone was obtained after benzoylation of amino acid A, whereas both benzoylamino acid B and its lactone were obtained from amino acid B.

Experimental

Method 1.

α-Acetamido-α, γ-diethoxycarbonyl-γ-butyrolactone (I).—To a solution of 4.6 g. (0.2 mol.) of sodium in absolute ethanol, 43.4 g. (0.2 mol.) of ethyl acetamido-malonate were added. After evaporation of the mixture to dryness in vacuo, the residual sodium salt was suspended in anhydrous benzene, into which 54.6 g. (0.2 mol.) of ethyl dibromopropionate were stirred drop by drop at below 35°C. The reaction mixture was stirred until the solution became neutral, and then the reaction mixture was washed with water and dried. Benzene and unreacted ethyl dibromopropionate were removed by distillation, and diethyl acetamido-malonate was removed by vacuum distillation. By further distillation under 10^{-3} mmHg, an oily substance was distilled as 166~180°C with slight decomposition. Yield 35%.

Found: C, 50.38; H, 5.72; N, 4.85. Calcd. for $C_{12}H_{17}O_7N$: C, 50.17; H, 5.97; N, 4.88%.

Almost the same results were obtained from the reaction using dimethyl formamide in place of benzene.

DL-γ-Hydroxyglutamic Acid (II).—The lactone ester I was hydrolyzed and decarboxylated by boiling it with 6 N hydrochloric acid for several hours. After evaporation to dryness in vacuo, the hydrolyzate was dissolved in a minimal amount of water and the solution was saturated with hydrogen chloride to precipitate DL-γ-hydroxyglutamic acid (A) lactone hydrochloride m. p. 230°C (decomp.).

Found: C, 33.02; H, 4.73; N, 7.58; Cl, 19.74. Calcd. for $C_5H_8O_4NCl$: C, 33.07; H, 4.44; N, 7.75; Cl, 19.53%.

From the mother liquor, DL-γ-hydroxyglutamic acid (B) was obtained after treatment with pyridine and ethanol, m. p. 162~163°C (decomp.). Recrystallization from water gave m. p. 166°C. (decomp.).

Found: C, 36.62; H, 5.37; N, 8.56. Calcd. for $C_5H_9O_5N$: C, 36.81; H, 5.56; N, 8.59%.

The over-all yield from diethyl acetamido-malonate was about 20%.

Method 2.

Tetraethyl-1-acetamidopropane-1, 1, 3, 3-tetracarboxylate (III).—To 150 ml. of dried xylene, 67.2 g. (0.3 mol.) of diethyl acetamidomalonate, 67.2 g. (0.42 mol.) of diethyl malonate, 12.6 g. (0.42 mol.) of paraformaldehyde and 1.5 g. of powdered sodium hydroxide were added, and the mixture was refluxed for 7 hr. After cooling, the supernatant solution was separated from the sedimented residue by decantation, and the residue was washed twice with 20 ml. of ethyl acetate. The supernatant solution, combined with the washings, was evaporated in vacuo, and the residue was dissolved in 30 ml. of ethyl acetate. The ethyl acetate solution was washed with water, 5% sulfuric acid, water, 5% sodium bicarbonate and water in turn, dried with anhydrous sodium sulfate and concentrated in vacuo. The residue was crystallized from 30% ethanol; yield 92 g. (80%), m. p. 50~52°C. A pure sample recrystallized from 70% ethanol for elementary analysis melted at 58~59°C.

Found: C, 51.96; H, 7.14; N, 3.38. Calcd. for $C_{17}H_{27}O_9N$: C, 52.43; H, 6.99; N, 3.60%.

Tetraethyl-1-acetamido-3-chloropropane-1, 1, 3, 3-tetracarboxylate (IV).—Into a solution of 15.6 g. (0.04 mol.) of the tetracarboxylic acid ethyl ester III in 60 ml. of acetic acid, 7 g. (0.052 mol.) of sulfuryl chloride were stirred drop by drop at room temperature. Then the bath temperature was raised gradually, and the reaction mixture was heated for 1 hr. at 75°C. After the mixture had been evaporated to dryness in vacuo, the residue was dissolved in 100 ml. of ethyl acetate, washed several times with 5% aqueous sodium bicarbonate, dried, and concentrated in vacuo.

The residue was crystallized from water and triturated with 4 ml. of 40% ethanol. After standing overnight, the mixture was filtered. Yield 16 g., m. p. 83~85°C. A pure sample was obtained after recrystallization from 10 ml. of 70% ethanol. Yield 15.2 g. (90%), m. p. 91~92°C.

Found: C, 48.17; H, 6.18; N, 3.30; Cl, 8.37. Calcd. for $C_{17}H_{26}O_9NCl$: C, 48.41; H, 6.13; N, 3.03; Cl, 8.40%.

DL-γ-Hydroxyglutamic Acid (II).—The chloro compound (IV, 10 g.) was hydrolyzed and decarboxylated by refluxing with 70 ml. of concentrated hydrochloric acid for 7 hr. The hydrolyzate was evaporated to dryness in vacuo after treatment with charcoal, and the residue was redissolved in 15 ml.

*3 Reported at the 12th Annual Meeting of the Chemical Society of Japan, Kyoto, April, 1959.

*4 α-Amino and γ-hydroxyl groups of the A form have a threo type configuration in the Fischer formulation, while those of the B form have an erythro type configuration[3].

of dilute hydrochloric acid and saturated with hydrogen chloride in the cold. After standing overnight, the precipitate was filtered and washed once with concentrated hydrochloric acid and twice with acetone. Yield 1.8 g., m. p. 228~229°C (decomp.). From the mother liquor, 0.2 g. of the same product was recovered. The total yield was 2.0 g. (46.5%). Pure γ-hydroxyglutamic acid (A) lactone hydrochloride, recrystallized by saturation of the aqueous solution with hydrogen chloride, melted at 230~232°C (decomp.).

Found: C, 33.24; H, 4.67; N. 7.88; Cl, 19.50. Calcd. for $C_5H_8O_4NCl$: C, 33.07; H, 4.44; N, 7.75; Cl, 19.53%.

The amino acid A lactone hydrobromide was obtained in a yield similar to that of the hydrochloride by hydrolysis of the chlorinated compound IV with hydrobromic acid, m. p. 230~232°C (decomp.).

Found: C, 26.49; H, 3.81; N, 6.50; Br, 34.82. Calcd. for $C_5H_8O_4NBr$: C, 26.55; H, 3.54; N, 6.20; Br, 35.36%.

γ-Hydroxyglutamic acid (A) lactone was obtained from the amino acid lactone hydrochloride by treatment with pyridine. It was recrystallized from water, m. p. 245°C (decomp.).

Found: C, 41.23; H, 4.89; N, 9.43. Calcd. for $C_5H_7O_4N$: C, 41.38; H, 4.86; N, 9.65%.

After treatment with silver carbonate, the lactone hydrochloride was converted almost quantitatively to γ-hydroxyglutamic acid (A), which was recrystallized from water and ethanol to give a monohydrate, m. p. 172~173°C (decomp.).

Found: H_2O, 10.5. Calcd. for $C_5H_9O_5N \cdot H_2O$, 9.9%. Found with the anhydrous form: C, 36.78; H, 5.40; N, 8.73. Calcd. for $C_5H_9O_5N$: C, 36.81; H, 5.56; N, 8.59%.

The R_f values were 0.13 (80% phenol) and 0.10 (80% phenol containing a small amount of ammonia). Racemic amino acid A had a weak taste of L-glutamic acid.

The mother liquor, from which γ-hydroxyglutamic acid (A) lactone hydrochloride had been isolated, was evaporated to dryness in vacuo. The addition of water and evaporation to dryness was repeated several times to remove hydrochloric acid. When pyridine and ethanol were gradually added to the residue dissolved in water, a precipitate formed. Yield 1.5 g. (40%), m. p. 158°C (decomp.). A pure sample of γ-hydroxyglutamic acid (B) was obtained by recrystallization from water and ethanol. M. p. 166°C (decomp.).

Found: C, 36.74; H, 5.40; N, 8.57. Calcd. for $C_5H_9O_5N$: C, 36.81; H, 5.56; N, 8.59%.

The R_f values were identical with those of the isomeric amino acid (A). Racemic amino acid B had only an acid taste.

The over-all yield from ethyl acetamidomalonate was about 55~60%.

***N*-Benzyloxycarbonyl-DL-γ-hydroxyglutamic Acid (A) and its Lactone.**—To 36 g. (0.2 mol.) of the amino acid A dissolved in 200 ml. of 2 N sodium hydroxide, 52 g. (0.3 mol.) of benzyloxycarbonyl chloride and 110 ml. of 4 N sodium hydroxide were added simultaneously at 10°C, and the mixture was stirred for 1 hr. Then the reaction mixture was washed three times with ether. The aqueous solution was acidified with 6 N hydrochloric acid, with Congo red paper as an indicator, and extracted ten times with ethyl acetate. When the ethyl acetate extract was dried and concentrated, colorless crystals were obtained. After recrystallization from ethyl acetate, 41.6 g. of benzyloxycarbonyl-DL-γ-hydroxyglutamic acid (A) were obtained. Yield 70%, m. p. 109~110°C.

Found: C, 52.34; H, 5.24; N, 4.57. Calcd. for $C_{13}H_{15}O_7N$: C, 52.52; H, 5.09; N, 4.71%.

When the benzyloxycarbonyl-amino acid (A) was treated with 1 N hydrochloric acid, its lactone was obtained in crystalline form. This melted at 165~166°C after two recrystallizations from 1 N hydrochloric acid. No depression of the melting point was observed when it was mixed with another sample of benzyloxycarbonyl-DL-γ-hydroxyglutamic acid (A) lactone (m. p. 165~166°C; lit.[3] m. p. 168~169°C), which was obtained in a yield of 75% from DL-γ-hydroxyglutamic acid (A) lactone hydrochloride in the same manner as described above, and recrystallized from water and ethanol.

Found: C, 55.95; H, 4.85; N, 4.99. Calcd. for $C_{13}H_{13}O_6N$: C, 55.91; H, 4.70; N, 5.02%.

***N*-Benzyloxycarbonyl-DL-γ-hydroxyglutamic Acid (B) and its Lactone.**—*N*-Benzyloxycarbonyl-DL-γ-hydroxyglutamic acid (B) was obtained in a manner similar to that reported by Benoiton et al.[3] M. p. 132~133°C (decomp.) (lit.[3] 132~133°C).

Found: C, 52.53; H, 5.12; N, 4.58. Calcd. for $C_{13}H_{15}O_7N$: C, 52.52; H, 5.09; N, 4.71%

The above *N*-benzyloxycarbonyl-DL-amino acid (B) was converted to its lactone by recrystallization using 1 N hydrochloric acid, m. p. 152~153.5°C (decomp.) (lit.[3] m. p. 152~153°C).

Found: C, 55.55; H, 4.84; N, 4.89. Calcd. for $C_{13}H_{13}O_6N$: C, 55.91; H, 4.70; N, 5.02%.

Benzoyl-DL-γ-hydroxyglutamic Acid (A) Lactone.—To a solution of 3.6 g. (0.02 mol.) of DL-γ-hydroxyglutamic acid (A) lactone hydrochloride and 10 g. of sodium bicarbonate in 100 ml. of water, 4.2 g. (0.03 mol.) of benzoyl chloride were added drop by drop at 10°C; the reaction mixture was then stirred vigorously for one and a half hours at 10~15°C. Then the solution was acidified slightly with 6 N hydrochloric acid, using Congo red paper, and the benzoic acid which precipitated was filtered off. The filtrate was washed twice with ether, and the aqueous layer was evaporated to dryness in vacuo. To the residue dissolved in 10 ml. of water, 4~5 drops of concentrated hydrochloric acid were added, and the precipitate formed was filtered and washed with water. A crude sample of benzoyl-DL-γ-hydroxyglutamic acid (A) lactone was obtained by recrystallization of the precipitate from ethanol; yield 3.1 g. (62%). For elementary analysis, it was further recrystallized from ethanol. m. p. 230~232°C.

Found: C, 58.03; H, 4.61; N, 5.71. Calcd. for $C_{12}H_{11}O_5N$: C, 57.83; H, 4.45; N, 5.62%.

Benzoyl-DL-γ-hydroxyglutamic Acid (B) and its Lactone.—Benzoylation of DL-γ-hydroxyglutamic acid (B) was carried out in the same manner as described above from 9.8 g. (0.06 mol.) of DL-γ-hydroxyglutamic acid (B), 17 g. (0.12 mol.) of

benzoyl chloride, 35 g. of sodium bicarbonate and 200 ml. of water. A crude sample of the benzoyl-amino acid (B) was recrystallized from water. Yield, 11 g. (68%), m. p. 145°C (decomp.).

Found: C, 53.80; H, 5.02; N, 5.44. Calcd. for $C_{12}H_{13}O_6N$: C, 53.93; H, 4.87; N, 5.24%.

When concentrated hydrochloric acid was added to an aqueous solution of benzoyl-amino acid (B) and heated for a short time, its lactone was deposited. A pure sample of benzoyl-DL-γ-hydroxyglutamic acid (B) lactone was obtained after recrystallization from hot water; m. p. 202~203°C (decomp.).

Found: C, 57.42; H, 4.40; N, 5.49. Calcd. for $C_{12}H_{11}O_5N$: C, 57.83; H, 4.45; N, 5.62%.

The authors wish to express their thanks to Mr. Masakazu Okumiya and Miss Kiku Koike for their microanalyses.

Using Iron Ores of Kalabagh. I. Production of Limonite-Alkali Method

By M. I. ALI*

(Received July 24, 1961)

The ammonium sulfate plant at Daudkhel based on pressure gasification of local coal containing sulfur of about 5.0% faced the problem of hydrogen sulfide removal from the process gas. After much deliberation a method of preferential water-washing under pressure (about 15.0 kg./cm^2) has been adopted to effect the removal of hydrogen sulfide along with some carbon dioxide. The efficiency of water-washing-out process ranges between 92.0 and 96.0% and this quantity of hydrogen sulfide is being utilized for the manufacture of sulfuric acid, 60° Bé (20.0 tons/day on 100.0% basis). The remaining 4.0~8.0% hydrogen sulfide constitute 0.1~0.2% of the process gas which is being removed by limonite in the boxes before and after CO-conversion. During normal run of the factory about 7600 Nm^3 gas per hour is being purified which requires about 600 kg. limonite per day. This calculation is based on 0.1% hydrogen sulfide in the gas and absorption efficiency nearly to maximum. Due consideration was also given to the fact that the spent limonite can be regenerated by air oxidation and used over again until sulfur content reaches over 40.0% in the limonite mass. In practice, the consumption will be slightly more than the mentioned quantity. At present imported limonite from European countries especially Holland and Denmark are in use in the factory at an approximate cost of about U. S. $ 45.00 per 1000 kg. In view of this recurring expenditure, it was felt necessary to exploit our own resources by suitable processing, if possible.

The first attempt was made in this regard to assess the availability of naturally occurring limonite in the country. One report[1] shows that the Yellow Ochre of Khewra has 71.6% hydrogen sulfide absorption capacity at maximum pH with respect to ferric hydroxide but other samples are limited within 40.0%. Further informations are lacking. The observations made in some explanatory experiments with oxide ores of Kalabagh, led to look for a method of processing the material to suit the purpose. From a study of available methods of limonite production, alkali method was chosen to be tried. A short review is presented below:

The general alkali methods[2] described as the fusion of iron ores (FeS, FeS_2, Fe_2S_3 and oxides, etc.) with sodium carbonate or hydroxide[3] to produce ferrite first then its hydrolysis to yield hydrated ferric oxide.

The thermal activation of iron oxide by fuller's earth in conjunction with sodium carbonate has also been recognized[4].

Some other methods recommended the use of ammonia or alcohol[5], steam[6], lime, sodium carbonate[1], etc. on ferric chloride or some other iron salts.

One patent[7] claims the use of 25~30% soda lye at 200°C for preparing desulfurizing material using "Boue Rouge" (Bayer process) in aluminum industry.

Another method[8] describes the use of ferric oxide residue from bauxite. Sodium carbonate was reacted upon to form sodium ferrate (Na_2FeO_4) which on subsequent hydrolysis produced hydrated oxide of iron.

Another patent[9] of Metallgesellschaft used the residual mud known as "Lux" or "Lauta" of aluminum industry and also the hydrates of iron in conjunction with 5.0% alkali for desulfurization of gas.

In view of the above facts it was thought to produce the small quantity of limonite to meet the demand in this factory from local iron ore of Kalabagh by alkali method. Sodium hydroxide was considered to be suitable reagent for its possible use on recovery either in carbon dioxide removal plant of this factory or in the proposed soda-ash factory.

Experimental

There are several iron mines of different types of ores in this locality. The iron content of these ores varies within a wide range of 30.0~65.0%. The availability of high grade ore cannot be guaranteed. However, a better quality ore was selected for this purpose to avoid pretreatment and interference of gangue materials during processing. This sample was found to contain 56.5% Fe. A tentative analysis of the sample is given below:

Fe	56.5% (0.6% Fe^{2+})
SiO_2	5.0%
Al_2O_3	1.5%
CaO	2.2%
MgO	0.58%
S	0.32%

The underlying principle of this method was to heat an appropriate mixture of iron oxide ore and sodium hydroxide to produce sodium ferrite and hydrolyze in the subsequent step to obtain hydrated iron oxide along with the recovery of sodium hydroxide used. Alkali used for this purpose was of a commercial grade containing about 96.8% sodium hydroxide and over 2.0% sodium carbonate.

Preparation of Sodium Ferrite.—A known quantity (10 g.) of powdered and sieved (through a sieve of No. 100 French series) sample of iron ore was taken in a stainless steel tank (10×10×2 cm.) with 40.0% solution of sodium hydroxide, having 10.0% excess of the calculated quantity. The whole mass was mixed thoroughly, evaporated to dryness and heated at 200~225°C at least for 3 hr. to complete the reaction:

$$Fe_2O_3+2NaOH \longrightarrow Fe_2O_3,\ Na_2O+H_2O \qquad (1)$$

The reaction proceeded well to completion and resulted a hard mass adhering to the reacting vessel.

Preparation of Limonite.—The mass of sodium ferrite as prepared above was taken out of the vessel, grinded and sieved. The powdered mass (sometimes without crushing) was taken into a beaker, treated with water heated for one hour to effect hydrolysis according to the reaction:

$$Fe_2O_3\cdot Na_2O+H_2O \longrightarrow 2Fe(OH)_3+2NaOH \qquad (2)$$

On settling, the mixture was filtered on a Büchner funnel. The filtrate was the mixture of sodium hydroxide and sodium carbonate (in some cases sodium bicarbonate depending upon the mode of operation). The residue was ferric hydroxide with certain quantity of residual alkali. The mass obtained thus was blended with saw dust (wood shavings or pulp) for proper consistency, humidity (about 30.0%) and bulk density (approx. 0.8). This was then tested for its hydrogen sulfide absorption power* which was found comparable to the imported mass.

Results and Discussion

The progress of the above reactions was found satisfactory for the production of limonite but certain practical difficulties stood on the way e.g.:

1. The mass of sodium ferrite was found to stick to the reacting vessel and was difficult to remove it.
2. The hard mass of sodium ferrite was evassive to hydrolysis if not grinded and was much time consuming.
3. Filtration of hydrolysis product was difficult for its higher alkali concentration and slow rate of sedimentation of the hydrated oxide.
4. Recovery of alkali was incomplete.

However, to find out the optimum condition for the whole process, some experiments were carried out under different conditions of mass-alkali ratio, temperature and time of reaction. Active iron in the hydrolyzed product was the measure of yield. In all cases, grinded mass was hydrolyzed in boiling water for one hour. The results of the above experiments are presented in Table I.

From the results it may be concluded that:

1) The most suitable temperature for reaction 1 was from 200 to 225°C (curve 1 in Fig. 1). Next experiments were carried out at this temperature.

2) Heating for longer time over 3 hr. was found to be useless. Curve 2 in Fig. 1 indicates that the progress of reaction upto 3 hr. was steady but beyond this it was very slow.

3) Further, the effect of mass-alkali ratio

—△—△— C_2 Time-yield
—⊕—⊕— C_3 Fe/NaOH ratio-yield

was distinct arround stoichiometric ratio. The reaction at stoichiometric ratio was 79.5% while with 10.0% excess of alkali it was 95.2%. But with more excess the effect was insignificant (curve 3, Fig. 1).

4) Finally, the optimum condition for this reaction was found to be:

a) Alkali: 10.0% excess of stoichiometric ratio.
b) Temperature: 200~225°C.
c) Reaction time: 3~4 hr.

The first difficulty of adherence of mass to the reacting vessel could somehow be eliminated by stirring thoroughly during evaporation to dryness but the process became laborious. The carbonate (sometimes bicarbonate) content in recovered alkali solution was much high in this case.

Since the reaction[1] was considerably satisfactory, more attention was paid to alkali recovery. To effect maximum alkali recovery without causing deterioration of limonite quality, special stress was given to the hydrolysis under different conditions of temperature and water/mass ratio. Attempt was also made to recover more alkali by passing carbon dioxide in the solution but as it will be seen later, it did not claim any superiority over the others. In all the cases, the recovery reached towards a limiting value upto which it might be economical. However, these results are presented in Tables IIa and IIb.

In view of the difficulties experienced during this work, the macaronies (solid) of 6~10 mm. diameter were prepared from the paste of powdered ore and sodium hydroxide for smooth handling, dried and treated in the same way as those of previous experiments. Some of the results of those experiments are presented in Table III. Some changes in experimental conditions were also tried.

It was interesting to note here that the recovery of alkali as hydroxide was prominent and considerably higher than the recovery with other method tried earlier (cf. Table IIa). This treatment was definitely an improvement over the other in respect of easier handling and slightly better overall recovery (with higher percentage of sodium hydroxide). Limonite quality was more or less the same as prepared otherwise.

Figure 2 presents the curves showing the extent of alkali recovery on hydrolysis of sodium ferrite under different conditions. Curves B, C and D^1 show the influence of

TABLE IIa. RECOVERY OF ALKALI BY HYDROLYSIS OF SODIUM FERRITE

temperature on the progress of hydrolysis. Though at the beginning, higher temperature enhances the hydrolysis but at the later stage with water-mass ratio about 24, all the results tend to reach a limiting value. Beyond this, hydrolysis was very slow. For a recovery of alkali lower than 70.0%, heating has a favorable effect but for higher recovery heating effect is insignificant. From the curve D^2 it was clear that the interaction of carbon dioxide did not offer any improvement.

The curves A and D^1 have shown marked influence of grinding on the progress of hydrolysis at the initial stage. An increase of 13.0% alkali recovery was observed due to grinding at water/mass ratio 16, and thus, the grinding was always preferred before hydrolysis.

Curve E, indicates the better recovery of alkali where procedure D without carbon dioxide was followed. However, the recovery over 80.0% was considered to be uneconomical.

Summary

An industrial process of limonite production has been developed in this laboratory using local iron oxide ore of Kalabagh by alkali method. Sodium hydroxide was allowed to react with pulverized ore at 200~225°C to produce sodium ferrite. This product was then hydrolyzed to obtain hydrated ferric oxide (limonite) and alkali in aqueous solution. The method was further modified in the light of some operational difficulties.

Hydrolysis was carried out under varied conditions for maximum recovery of alkali and the recovery upto 80% found to be economical. A graphical representation of this recovery was also given.

The author wishes to express his thanks to Pakistan Industrial Development Corporation for kind permission to publish this paper. He also thanks Mr. G. Courtois for some suggestions during this work.

Appendix

Activity of Limonite.—The activity of limonite was determined by its hydrogen sulfide absorption capacity and subsequent liberation of elementary sulfur on regeneration according to overall reaction:

$$Fe_2O_3(H_2O)_x + 3H_2S \rightarrow Fe_2S_3(H_2O)_x + 3H_2O$$

$$Fe_2S_3(H_2O)_x + 3/2O_2 \rightarrow Fe_2O_3(H_2O)_x + 3S$$

In other words, free sulfur liberate on air oxidation was the measure of activity of limonite. The experimental arrangement was as shown in Fig. 3.

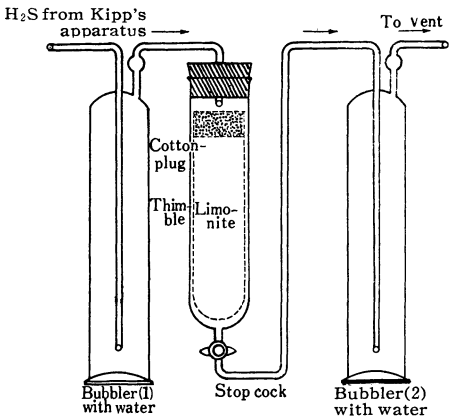

Fig. 3. H_2S absorption system for activity test of limonite.

Procedure.—Ten grams limonite was taken in a thimble and it was moistened thoroughly. A cotton plug was placed at the mouth of the thimble. The thimble was then placed into a cylindrical separating funnel having an internal diameter 16 mm. This was connected to the bubblers containing water according to the diagram. Hydrogen sulfide was generated in a Kipp's apparatus. Moist gas was passed through the limonite bed for a considerable period of time. When the rate of gas flow shown by two bubblers almost the same, the stop-cock was then closed for 3 min. If there was no bubble in bubbler (1) during this period, the hydrogen sulfide absorption by limonite was considered to be complete. The impregnated limonite was then oxidized by passing air through the same system for 12 hr. at the rate of 60 l./hr. using suction pump. The oxidation was complete during this period.

The thimble was taken out and dried at 80°C. The dry mass was then extracted with carbon disulfide (CS_2) in a Soxhlet apparatus. The extracted sulfur was weighed directly.

All the tests were carried out under identical conditions. The activity of natural "Bog ore" (imported from Holland and Denmark) and the limonite produced by the above method was comparative. Ninety-seven per cent iron content of limonite (produced) was found to be active.

Using Iron Ores of Kalabagh. II. Production of Limonite-Acid Method

By M. I. Ali*

(Received July 24, 1961)

Earlier work[1] done in this laboratory on limonite production from local iron oxide ore by alkali method was technically disadvantageous. In view of those results, some other suitable process was looked for. Next attempt was made to utilize acid method. Several acid methods covered under patents acclaimed satisfactory results. A brief review is given below:

A mixture of ferrous and ferric sulfate and chloride on heating produced iron oxide[2] and liberated chlorine which was recycled for production of further chloride.

The oxidation of ferrous sulfate was carried out by passing oxygen or air through the hot solution in presence of zinc or magnesium oxide[3]. Sometimes iron shaving were added and oxidation was carried out under pressure (5 atm.) at 120°C[4].

Another cyclic process[5] utilized iodine as attacking agent to produce iodide which on oxidation liberated free iodine for reuse.

Thermal decomposition of nitrate, oxalate and carbonyls of iron, etc. constituted another method of limonite production[6].

One patent[7] has been claimed the production of limonite and free chlorine by decomposing iron chloride at 1000°C. Chloride was produced by using hydrogen chloride and chorine.

Recently, U. C. B.[7] tried to produce limonite from oxide ores of iron. The ore was first reduced to ferrous oxide (FeO) by using process gas ($CO+H_2=56.0\%$) at 700°C. Ferrous oxide was treated with chlorine or hydrochloric acid to obtain ferric oxide and chloride. This on treating with ammonia yielded hydrated ferric oxide (and ferric hydroxide) i. e. limonite.

Another method[9] described the production of iron sulfate by heating soluble iron salt with ammonium sulfate. This iron sulfate was treated with ammonia in oxidizing medium to obtain hydrated ferric oxide. Ammonium sulfate was being recovered as alum by treating it with bauxite.

None of the above methods was found to suit the purpose. Finally, the use of locally produced dilute sulfuric acid was tried to produce iron sulfate from limonite ore. This proved satisfactory (presenteted in A). Iron sulfate was then treated with ammonia to obtain ferric hydroxide (and hydrated oxide) and ammonium sulfate (in solution). Ferric hydroxide was dried and blended to proper consistency while ammonium sulfate solution was suggested to be sent to sulfatation plant.

Disposal of spent limonite was another problem. Sulfuric acid manufacturing facilities in the country either use elementary sulfur or hydrogen sufide gas. So, the spent material cannot be disposed there. On the other hand, the standard methods of washing out sulfur from spent limonite leaving revivified material ready for further use, could not be practised due to non-availability of cheap solvent. The production of limonite by sulfuric acid method opened up the idea of recovering both limonite and sulfur simultaneously from spent material by following the same procedure. This is presented in B.

A) Production of Limonite from Iron Oxide Ore

(Using Sulfuric Acid)

Considering the scopes and limitations of the above-mentioned methods, none of them was found suitable for the purpose. The use of corrosive chemicals like chlorine, nitric acid and hydrochloric acid, etc. were not desired. The non-availability of the required chemicals in the country was another vital consideration. Finally, it was thought that locally produced sulfuric acid (60° Bé) could be tried for the production of ferric sulfate. This could easily be converted into ferric hydroxide by the action of ammonia. Recovery of by-product ammonium sulfate was also thought to be

feasible. The reactions involved were likely to be as follows:

$$Fe_2O_3 + 3H_2SO_4 \rightarrow Fe_2(SO_4)_3 + 3H_2O \quad (1)$$

$$Fe_2(SO_4)_3 + 6NH_4OH \rightarrow 2Fe(OH)_3 + 3(NH_4)_2SO_4 \quad (2)$$

$$2Fe(OH)_3 \rightarrow Fe_2O_3(H_2O)_x \quad \text{(Partly)} \quad (3)$$

Experimental

A suitable variety of limonite ore was procured from Kalabagh iron mines. The sample was crushed and grinded to 100 mesh (French series) and analyzed[1]. Some exploratory experiments were carried out to ascertain the possibility of the reaction 1 under varied conditions of acid concentration, temperature and reaction time.

The general procedure of the experiments were as follows: 10.0 g. sample was taken in a beaker with requisite quantity of sulfuric acid and it was heated slowly to boiling. This condition was maintained for a desired length of time which was termed "reaction time". On completion of the reaction the whole mass was treated with water, allowed to settle and filtered. After filtration, the filtrate was analyzed for iron content. The results were expressed in percentage (reaction %) on the basis of total iron contents of the sample ore.

The first set of experiments was carried out with varried concentrations of acid. In this case, 40 ml. of sulfuric acid at different concentrations was used. The results are tabulated below in Table I (Fig. 1, curve I)

TABLE I. EFFECT OF SULFURIC ACID CONCENTRATIONS ON THE SAMPLE ORE

TABLE II. EFFECT OF TEMPERATURE, REACTION TIME AND ACID/MASS RATIO ON THE PROGRESS OF REACTION 1

Sample taken, 10.0 g. Sulfuric acid concn., 70.0%

Quantity. of acid, ml.	Acid/mass ratio, w/w	Acid ratio (Quantity used / Stoichiometric quantity)	Reaction (%) at room temp. (25°C) for 30 min.	Reaction % at 98°C		Reaction (%) at boiling temp. 160~170°C	
				30 min.	60 min.	10 min.	30 min
13.3	2.12	1.44	4.6	26.0	—	—	—
25.0	4.00	2.70	4.8	38.0	—	65.5	—
50.0	8.07	5.45	5.0	41.0	—	70.0	—
100.0	16.14	10.95	5.0	44.0	66.0	73.5	71.5

Remarks: The reactions at boiling temperature produced a dry pasty mass. So, lengthy reaction time was not possible.

From the above observation 70.0% acid was chosen for further experiments. This time the temperature and reaction time were changed. The results are presented in Table II.

The above results are shown in Fig. 2 (curves I, II and III). It was clear that sulfuric acid needed was much higher than the stoichiometric quantity. The recovery of sulfuric acid as ammonium sulfate was imperative. Some of the experiments were carried out with 1.0 kg. charges each and those were carefully observed to ascertain the prospect of utilizing the method on semi-pilot plant scale. The following observations made thereof are discussed hereunder briefly:

a) Formation of Ferric Oxide Hydrate.—On dilution after sulfuric acid digestion, a fluffy brown precipitate found to remain suspended in the liquid while the undigested material settled at the bottom. This was found to be as active as ferric hydroxide towards hydrogen sulfide and was assumed to be ferric oxide hydrate. It was about 5.0% (as Fe) of the total iron. This was, of course, an addition to the overall yield of limonite.

b) Decantation and Transfer of Ferric Oxide Hydrate.—It was possible to separate undigested mass from the rest (Fe in solution and suspended hydrate) by decantation. Ferric oxide hydrate settled only on long standing. Residue was rejected generally.

c) Ammonia (20~25%) Treatment and Filtration.—Ammonia directly from the purge tank of the ammonia section was used for the purpose. Gelatinous iron hydroxide precipitate was formed, the filtration of which was rather difficult. It was improved to some extent by boiling the whole mass with pulp (or saw dust). Though saw-dust was useful, it could not be recommended due to its resin content, which was apprehended to cause trouble in the evaporator. This warrants further investigation.

d) Drying and Final Removal of Ammonium Sulfate from Residue.—Hot air at about 100°C was passed over the residue after filtration c) till it was half dried. At this stage, the limonite lost its gelatinous character. It was then washed with water to remove ammonium sulfate. The resultant material was dried under shade at a temperature below 50°C by occasional turning.

e) Analytical Results.—Alkaline ammonium sulfate filtrate was analyzed. This was compared with the analysis of ammonium sulfate solution in the neutralization tank of "ammonium sulfate" plant. The results obtained are as follows (Table III):

Table III. Analysis of ammonium sulfate solutions: (1) after ferric hydroxide filtration and (2) solution from neutralization tank

Ingredient	Ammonium sulfate solution	
	After Fe-hydroxide filtration	From neutralization tank
Acidity (H_2SO_4)	—	0.05 g./l.
NH_3 (free)	1.8 g./l.	—
$(NH_4)_2SO_4$	448.0 g./l.	485.0 g./l.
Fe	0.08 mg./l.	0.3 mg./l.
Ca	20.0 mg./l.	540.0 mg./l.
Cl	nil	17.7 mg./l.

f) Recovery of Different Materials.—1) Loss of iron ores ····· about 40% (silicous material over 50.0%). 2) Recovery of sulfuric acid ····· 90~95.0% as free acid and Fe-sulfate. 3) Recovery of ammonia as ammonium sulfate and free ammonia, a) 1st stage filtration ····· 80~83.0%; b) 2nd stage washing out ····· 10~12%.

As a matter of fact, these obesrvations stimulated further investigation to find out some more easily digestible material. In this case, high temperature produced better results but it is feared that the corrosion problem will arise in operating at an elevated temperature. Further one sample of "siderite" (available plenty) was found to be more easily digestible. The nature of reaction was more or less similar to that of oxide ore, the yield was high and could be operated at low temperature.

B) Recovery of Spent Limonite and Sulfur (Using Sulfuric Acid)

The spent limonite containing about 50.0% sulfur could not be utilized for the manufacture of sulfuric acid in the country because of the existing plants are based on either elementary sulfur or hydrogen sulfide. The use of carbon disulfide for sulfur extraction in situ was not practicable due to non-availability of cheap solvent. Its economic disposal was a problem. About 100 tons of sulfur could be recovered every year from the spent limonite. The observations made on limonite production by acid method led to the interesting idea of recovering both limonite and sulfur simultaneously. The reactions involve in limonite purifying process may be represented through a cyclic scheme comprising oxide-sulfide-oxide reactions as follow:

$$Fe_2O_3(H_2O)_x + 3H_2S \rightarrow Fe_2S_3(H_2O)_x + 3H_2O \quad \cdots\cdots \text{(Absorption)} \quad (4)$$

$$2Fe_2S_3(H_2O)_x + 3O_2 \rightarrow 2Fe_2O_3(H_2O)_x + 6S \quad \cdots\cdots \text{(Regeneration)} \quad (5)$$

Non-regenerative FeS_2 and Fe_8S_9 was also reported to form at elevated temperature.

However, sulfuric acid was considered to be useful for the recovery of sulfur. The experimental procedure adopted was more or less the same as with the iron ores. The first step reaction with regenerated material was:

$$[Fe_2O_3(H_2O)_x + S] + H_2SO_4 \rightarrow Fe_2(SO_4)_3 + H_2O + S \quad (6)$$

Experimental

The technical analysis of the raw material (spent limonite) was as follows (Table IV):

TABLE IV. ANALYSIS OF SPENT LIMONITE

Constituent	%
Acidity	Neutral
Humidity	26.9
Ash content	37.4
Iron (Fe)	23.8
Sulfur	
a) As sulfate	2.2
b) Elem. sulfur	45.8
Specific weight	
a) Loose packing	680 g./l.
b) Close packing	900 g./l.

The spent limonite was found to be more reactive with sulfuric acid than the oxide ores. One series of experiments was carried out using different concentrations of acid. The results are presented in Table V and in Fig. 1 (curve II). One sample of unregenerated sample was also tried for the purpose.

From the above results, 70.0% acid was found to be most suitable for the reaction. Another set of experiments was carried out with this acid to ascertain the optimum quantity. Those results are shown in Table VI and also by Fig. 2 (curve IV).

From the above Tables V and VI, 40 ml. sulfuric acid (70%) was found to be the requisite quantity for 10.0 g. spent limonite. Some experiments were also carried out with 5.0 kg. sample. The results were found satisfactory. The similar difficulties of iron hydroxide filtration as with the oxide ores were also encountered here. The advantages in this case were that the reaction temperature was lower while the progress was better. The over-all recovery of limonite was 80.0% by this method (considering the loss during processing).

Recovery of Sulfur.—The residue obtained after digestion of spent limonite with sulfuric acid contained mainly sulfur, iron oxide and little organic matters. The approximate compositions was found to be:

Sulfur	75.0%
Iron oxide	20.0%
Others	5.0%

TABLE V. EFFECT OF SULFURIC ACID CONCENTRATION ON THE PROGRESS OF REACTION WITH THE SPENT LIMONITE

Sample taken, 10.0 g. Quantity of acid used, 40 ml.

† 100 ml. water was used for dilution in two portions of 50 ml. each.

TABLE VI. EFFECT OF QUANTITY OF ACID ON THE PROGRESS OF REACTION

Sample taken, 10.0 g. Concn. of acid used, 70.0%
Reaction time, 10 min. Water used for dilution, 100 ml.
Temperature, to boiling

Quantity of acid used ml.	Acid ratio (Quantity used / Stoichiometric quantity)	Reaction, %	Remarks on reaction product	
			before dilution	after dilution
14.0	2.52	71.0	Paste	Easily decantable (sp. gr. 1.05)
25.0	4.5	79.5	Paste	Easily decantable
40.0	7.2	87.2	Thin paste	Easily decantable
50.0	9.0	89.0	Pasty liquor	Decantable
100.0	18.0	90.0	Muddy	Decantable with time (sp. gr. 1.19)

The impure sulfur thus recovered was purified to about 90.0% by melting out process. For further purification any standard method could be adopted.

In view of the above observations, it appears fairly agreeable to operate such plant. It is, of course, not free from difficulties. The main difficulty with this method that it is a lengthy process. It is always difficult to realise movement of such type of materials through the process equipments. However, it may be concluded that 80.0% of the spent limonite can be recovered by this method. The rest 20.0% make up limonite may be supplemented by producing it from local iron ores preferably "siderite".

Summary

A method of limonite production has been developed in this laboratory and it was produced from both "Kalabagh iron ores" and "spent limonite" by using local sulfuric acid (60° Bé). Ammonium sulfate, by-product, was also recovered. The process comprised of (i) digestion of the raw materials with 70.0% sulfuric acid, (ii) ammonia treatment of the resultant ferric sulfate solution to produce ferric hydroxide and (iii) careful drying and blending of ferric hydroxide (and oxide) to the desired consistency. The over-all recovery of spent limonite was found to be 80.0%. A material balance sheet is also presented. For the production of 20.0% make-up limonite "siderite" iron ore is suggested to be of use.

The author wishes to express his thanks to Pakistan Industrial Development Corporation for providing facilities to carry out this work.

Regeneration of Spent Limonite using Gasoline. I

By M. I. ALI*

(Received July 24, 1961)

It was observed that the crude gasoline, a by-product in coal gasification process, could dissolve certain quantity of sulfur when hot, from the spent limonite and the dissolved sulfur could easily be crystallized out by cooling. This observation suggested that it could be utilized profitably as a solvent for sulfur. Some important characteristics of this gasoline were studied including the solubility of sulfur in it. On satisfactory preliminary tests, a batch process of regeneration of limonite was tried. It was possible to recover 90.9% sulfur from spent limonite at a regeneration temperature of 85°C using a weight ratio 11.7 : 1 of gasoline and spent limonite respectively.

Next, a continuous flow of hot gasoline through a fixed bed of spent limonite was tried. This had shown some improvement over the batch process mentioned above, 96.0% sulfur was recovered at 86°C with gasoline limonite ratio 12 : 1 (w/w). The main difficulty encountered in this process was the sticking of sulfur crystals on the cooling surface and thereby heat transfer was retarded. This was overcome by direct quenching in cold water. Another problem was to remove the retained gasoline from the regenerated limonite. The removal was effected by passing nitrogen through the limonite bed in suit at regeneration temperature. The exit gas was then washed with oil to recover gasoline. The over-all activity of this regenerated limonite was found to be over 80.0%.

It has already been discussed in part I[1] and part II[2] that the recurring import of fresh limonite and the disposal of spent limonite are problems to this factory. A practical method[2] (cf. part II) for the production of limonite from iron ore has since been developed. Relatively easier method of solvent extraction was also considered but due to non-availability of indigenous solvent it was not tried earlier. In the meantime, the problem of by-product gasoline purification was at hand. The crude gasoline could not be marketed for its high sulfur content in the form of H_2S, mercaptans and other organic sulfur compounds. It has a nauseating odor. Attempt was made to use limonite for gasoline purification. Almost complete removal of sulfide-sulfur was effected by limonite but last trace could not be removed by this. Thus purified gasoline could not stand Doctor's test. The treated gasoline was of rather dark color while the fresh one is of straw color. It may be mentioned here that fresh gasoline on long exposure to atmosphere became dark. Presently, the gasoline is being utilized as fuel in the power station. This is equivalent to twice its weight of coal.

During this experimentation with gasoline and limonite two important observations were made:

1) Hot gasoline dissolved considerable amount of sulfur from spent limonite and the crystalline sulfur could be obtained from rich gasoline on cooling.

2) The gasoline did not wet limonite and the treated limonite could be dried easily. These stimulated to undertake the present work, the extraction of sulfur from spent limonite with gasoline and thereby to regenerate the spent limonite.

Study of Gasoline

First, the study of gasoline was necessary to find out its suitability for the purpose. The characteristics of gasoline are presented in Table I.

TABLE I. CHARACTERISTICS OF CRUDE GASOLINE

1.	Physical appearance	Straw colored liquid
2.	Color on standing	Dark
3.	pH	>7 (slightly alkaline)
4.	Specific gravity	0.79 at 20°C
5.	Viscosity	1.13°E at 20°C
6.	Flash point	<20°C
7.	Calorific value (gross)	11000 cal./g.
8.	Specific heat	0.450 cal./g./°C at 37°C
9.	Sulfide sulfur (H_2S)	0.714g./1.
10.	Sulfate	Trace
11.	Total sulfur	0.770g./1.
12.	Phenol content	3.5 g./1.

Fractionation of Gasoline.—The composition of gasoline was not known. But it was reported[3]

* Present address: Natural Gas Fertilizer Factory, Fenchuganj, Sylhet, East Pakistan.

1) M. I. Ali, This Bulletin, 35, 878 (1962).

2) M. I. Ali, ibid., 35, 883 (1962).

to contain 12.0% benzene. It is understood that higher aromatic hydrocarbons e. g. toluene or xylene are found to be good solvent for sulfur at an elevated temperature. So it was necessary to assess the availability of suitable fraction. The fractionation of gasoline was carried out by using a Vigreux model 800 mm. long fractionating column. The results are presented in Table II. Further, the fractionation of gasoline saturated with sulfur was also carried out, under similar conditions, for comparison.

Table II. Fractionation of crude gasoline and sulfur impregnated gasoline

130	55.4	54.0	
140	68.8	63.0	
150	72.0	74.0	
155	79.0	80.0	

From the close study of above results, gasoline fractions may be divided into 4 parts.

1) Fraction below 70°C……10.0% light fraction.
2) Fraction between 70~85°C……18.0% rich in benzene.
3) Fraction between 85~110°C……12.0% rich in toluene.
4) Fraction above 110°C……40.0% heavy fraction containing xylene and others.

The remaining 20.0% polymerized and decomposed at the distilling temperature. The light fraction and benzene fraction are obviously unsuitable for the purpose.

But it was observed that the residue was readily soluble in the light fraction. The solution was, of course, dark. However, for the practical purposes the gasoline fractions may be divided into two parts a) fraction below 85°C lighter fraction (LF) and b) the fraction above 85°C heavy fraction (HF). Heavy fraction was considered to be useful for the purpose. The above study revealed that there was not much influence of dissolved sulfur on fractionation except at the initial stage. The residue obtained was a plastic one, probably due to allotropic modification of sulfur. In view of the above observations, the solubility of sulfur in gasoline was studied only with the heavy fraction (above 85°C).

Solubility of Sulfur in Gasoline.—A sample of sulfur was recovered from the spent limonite by using gasoline. This was purified with LF gasoline and carbon disulfide. It was needle shaped crystalline sulfur of m. p. 114 (±0.5)°C. Optimum contact period for saturation of sulfur in gasoline and its solubility at different temperature were established. Eight minutes contact period at 70°C was found to be sufficient to reach saturation point. Therefore, 10 min. contact period was chosen for further solubility experiments at different temperature from 20 to 112°C. The results are presented in Table III (Fig 1). A depression of melting point of sulfur by 2°C was observed during these experiments. At 112°C excess sulfur formed a molten layer at the bottom.

The melting point of sulfur used in above experiments was 114°C. But in gasoline it melted at 112°C. The depression may be due to the presence of gasoline. Similar effect was also observed previously (melting point of crude

Table III. Solubility of sulfur in gasoline with temperature

recovered sulfur 111~112°C). However, the solubility of both the sulfur samples, purified in gasoline (LF) and carbon disulfide, were more or less the same. Solubility was expressed with respect to volume of gasoline at 16°C.

Study of Limonites

A sample of spent limonite was collected from the heap and stored in well stoppered cans. The sample was analyzed and found to contain:

Moisture	13.5%
Sulfur (elem.)	45.8%
Limonite etc.	Rest

There are several varieties of limonite $Fe_2O_3 \cdot H_2O$ of which only α and γ varieties are known[4] to be most active towards hydrogen sulfide. The structure and properties of these materials are susceptible to the climatic conditions. Temperature has much influence to that effect. Limonite looses its activity at high temperature. So, to retain the desired activity, the temperature is required to control within 40°C during normal use.

The main object of this work was to regenerate spent limonite and to recover sulfur as secondary product. A series of experiments were performed at different temperatures to find out the optimum regeneration temperature. The activity of each regenerated sample was studied (cf. Appendix I, part I). The results are presented in Table IV; Fig. 2.

It may be concluded from the above results that the activity of limonite decreases with increase of regeneration temperature and remarkably above 80°C. However, considering the solubility of sulfur in gasoline and activity loss of limonite with temperature, 85°C was chosen for further experiments. The loss of activity of limonite, at this regeneration temperature was about 10.0%. In view of above informations, a systematic study of limonite regeneration by gasoline was made with a batch process.

TABLE IV. ACTIVITY OF LIMONITE REGENERATED AT DIFFERENT TEMPERATURES

Regeneration temp. °C	Activity %	Remark
50	98.0	The activity was calculated only on the basis of active iron (Fe) content in regenerated limonite according to the equation: $A\ (\text{activity}) = \frac{X}{Y} \times 100$ where X=active iron (Fe) and Y=total iron present in the limonite.

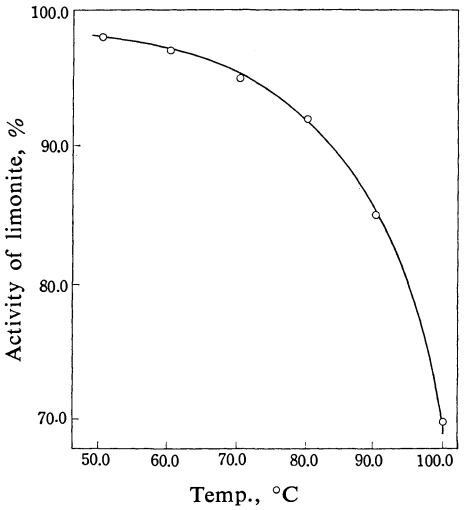

Fig. 2 Activity loss of limonite with temperature.

Regeneration of Spent Limonite

Batch Process.—One hundred grams spent limonite was taken in a separating funnel containing 200 ml. gasoline (HF). The funnel with its content was immersed in a water bath at 85°C and agitated slowly. This was continued for 10 min. The solid-liquid mixture attained the same temperature of bath (85°C) within 3~4 min. Then, gasoline rich in sulfur was drained out and filtered at 85°C. Let this liquid be called "overflow". This was cooled down to 16°C and sulfur crystallized out was measured. Certain quantity of gasoline was retained by limonite mass and this liquid was termed "underflow".

Next, the mass in the separating funnel (including "underflow") was treated with another 200 ml. fresh gasoline in the same way as before. The batch leaching was continued until sulfur concentration in "overflow" became negligibly low.

The results of one set of experiments with 7th batch leaching are presented in Table V.

The progress of extraction falls too low with the increasing number of washings i. e. with the decrease of sulfur concentration in limonite. After sixth washing further treatment was almost useless. This fall of efficiency probably due to the fact that gasoline could not reach into the core of limonite particle to dissolve out sulfur therein entrapped. It is more clear from the extraction of sulfur (Table V), particularly extraction efficiencies there. It means

that a longer contact period is required. To produce the desired effect, it was thought that a modified procedure of continuous liquid flow at 85°C through the fixed bed of limonite would be suitable.

Continuous Liquid Flow Processes.—In view of the above observations, it was thought that a continuous liquid (gasoline) flow through the fixed bed of limonite may be useful. Due consideration was given to temperature condition, gasoline-limonite contact period, the quality of recovered sulfur and the by-products. Provision for direct feeding of crude gasoline was also kept in view.

It was thought that the distillation process would be suitable to effect both extraction of sulfur by reflux and separation of lighter fraction as distillate in the same process and equipments. To achieve this end, a modified equipment had been drawn up. It was also thought that the cyclic regenerative process would be a complementary measure against short supply of gasoline.

First attempt was made to separate lighter fraction of gasoline by distillation and utilize reflux gasoline for leaching the spent

TABLE VI. SOME PHYSICAL CONSTANTS OF GASOLINE AND LIMONITE AND THEIR USEFUL RELATIONS

1 Specific gravity of gasoline (HF): 0.84 at 16°C
2 Expansion of gasoline volume with temperature: 10.0% at 85°C on the vol. at 16°C
3 Specific heat of gasoline (HF): 0.545 cal./g./°C at 37°C
4 Latent heat of vaporization: 207 cal./g.
5 Packing density of spent limonite
  a) Loose packing: 725 g./l.
  b) Close packing: 820 g./l.
6 a) Free space in spent limonite packing (loose): 62.0%
  b) Free space in regenerated limonite packing (loose): 68.0%
7 Retention of gasoline
  a) HF by spent limonite: 37.0% (by vol.)
  b) HF by regenerated limonite: 38.0% (by vol.)
  c) LF by regenerated limonite: 36.0% (by vol.)
8 Reduction in volume of limonite on regeneration: 25.0%
9 Specific gravity of regenerated limonite: 0.52 (approx.)

limonite at the same time. But recovered sulfur was dirty while the heat loss was much. Moreover, the process was time-consuming.

In view of these observations it was further modified were hot gasoline at 85°C was passed through the fixed bed of limonite. By this "hot gasoline flow process" recovered sulfur was of 99.0% purity. The process is shown in Fig. 3. Arrangement was also made to dry up regenerated limonite by passing nitrogen gas through it and to recover lighter fraction of gasoline as distillate with steam. For smooth operation of the process, some physical constants of gasoline and limonite and their useful relations have been established. Those are presented in Table VI.

Having the above informations ready at hand to calculate the results under changing conditions, a systematic study of "hot gasoline flow process" was started. This was done

TABLE VII. RECOVERY OF SULFUR AND GASOLINE UNDER DIFFERENT CONDITIONS

Experimental condition	Ratio (w/w) Gasoline / S. limonite	Gasoline recovered* Rich %	Gasoline recovered* Distillate %	Sulfur recovered %	Water removed from limonite %	Remark

* In the continuous liquid flow process "underflow" is assumed to be constant which is neglected in gasoline recovery calculations. This should be accounted only at the end of the experiment.

under varied operating conditions. The variables were (a) liquid velocity, (b) contact period of gasoline and (c) gasoline-limonite ratio, etc. The results of one set of experiments are presented in Table VII.

A close study of Table VII revealed that the best result was obtained under the conditions of experiment IV (temp. 86°C). The result of experiment V (temp. 84°C) was also almost equally good. These results are compared with that of batch process. The "hot gasoline flow process" was found to have some superiority over other two processes—"batch process" and "distillation process", with respect to both sulfur recovery and its quality. Moreover, this was much advantageous from operational point of view.

It was interesting to note that the liquid flow and contact period have marked influence at the initial stage up to gasoline/spent limonite ratio 8. Beyond this ratio in all cases, the efficiency of extraction slowed down rapidly. From Table VII, it appears that sulfur extraction never reaches completion within reasonable gasoline/limonite ratio.

During these experiments, the percentage of gasoline escaped as distillate and the quantity of water eliminated from the system (i.e. from limonite) were also accounted.

However, a certain quantity of sulfur and water always remain in regenerated limonite. An average analysis of the same is presented in Table VIII for comparison with that of fresh limonite.

Table VIII. A comparative study of fresh and regenerated limonite

	Particular	Regenerated limonite*	Fresh limonite
1.	Humidity, %	5~10	30~35
2.	Sulfur content, %	6~8	Nil
3.	Iron content, % (dry basis)	34.0	38.0
4.	H_2S absorption (Sulfur % on limonite)	23.0 (against 26.% theor.)	20.5
5.	Efficiency**, %	90.0	Standard

* This analysis was done before conditioning the regenerated limonite.

** This efficiency is on the basis of active iron content only. The presence of 6~8% sulfur reduces the iron content in the bulk and thereby lowers the efficiency. Finally, the overall efficiency of thus regenerated limonite stands at about 85%.

Discussion

Recovery of Sulfur.—Impregnated gasoline on cooling yields crystalline sulfur of different shape and sizes depending upon mode of operation. Under ordinary condition, the crystals used to stick to the cooling surface and thereby retarded the heat transfer in the system. This would cause operation difficult. To make it much easier, direct quenching was tried and found to be satisfactory. The arrangement for the quenching process is shown by Fig. 4.

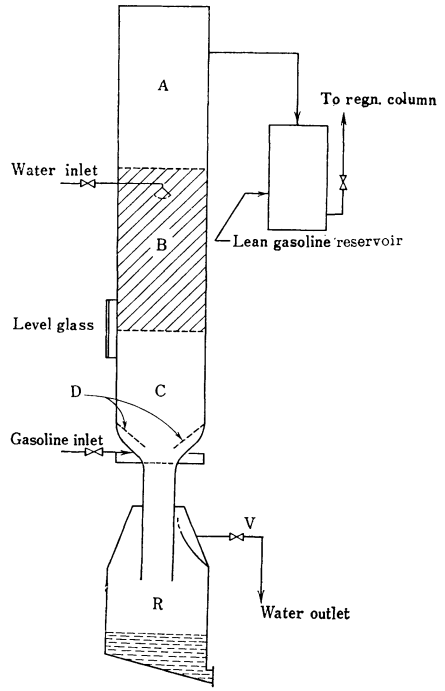

Fig. 4. Quenching column.
A Top zone
B Middle zone
C Bottom zone
D Distributor
R Receiver (sulfur settling)
V Control valve

The quenching apparatus consisted of a quenching column and a receiver for sulfur. Quenching column was a straight one, vertically placed on the receiver R. There were three distinct liquid phases in the column:

A Top zone: lean gasoline
B Middle zone: emulsion of gasoline-water.
C Bottom zone: clear water with bubbling gasoline and falling sulfur crystals.

The column was provided with a gasoline inlet at the bottom (at two points) under the distributor D, and exit at the top (zone A). Water was introduced at the top of middle zone. It was then allowed to flow down through the central clearance of the distributor, carrying sulfur to the receiver. Cryslals of sulfur settled down at the bottom of the receiver while water overflowed through the level controlling valve, V. A level glass would be necessary for this apparatus at the junction of zones B and C.

It is very important to maintain water level in the column and counter current flow ratio of gasoline and water rate. Gasoline flow at low pressure would stop if water flow is much higher. On the other hand increased gasoline flow would cause inefficient separation of sulfur. In short, the efficiency of the process is the function of (1) gasoline-water flow ratio, (2) gasoline-water contact period and (3) temperature of the liquids.

It was necessary to adjust all the variables for optimum condition. It has been observed that a streamline flow is required for effective cooling and separation of sufur. However, the working condition of a small column (30×2.5 cm. ϕ) particularly at maximum flow rates is presented here:

a) Rich gasoline feed 500 ml./min. (445.0 g.)
b) Gasoline pressure 0.1 kg./cm^2
C) Gasoline-water contact period (in bottom zone) 3 sec.
d) Quenching water 579.0 ml
e) Temperatures of inlet and outlet water, −20°C and 50°C respectively
f) Temperatures of inlet and outlet gasoline, −83°C and 23°C respectively

Under this limiting condition the cooling efficiency was found to be 71.6%. A better efficiency could be achieved if the contact period is increased reasonably by increasing the column length and operating under higher gasoline pressure head. A modified column would help bettering stream-line flow of gosoline.

Crystalline sulfur accumulated in the receiver was of sizes arround 60 mesh. Some crystals used to agglomerate to form loose and soft lumps bound by emulsion film of gasoline while others moved freely in quenching water. On long standing bound gasoline in the lumps and emulsion film bubbled up to the surface. Thus settled sulfur became almost pure. It is interesting to note here that there was no appreciable oxidation of sulfur during quenching. Purification of recovered sulfur could be effected by steam treatment.

Drying of Regenerated Limonite.—It has been observed that a considerable quantity of gasoline was retained (underflow) in regenerated

TABLE IX. REMOVAL OF RETAINED GASOLINE BY NITROGEN

Regenerated limonite: 256.0 ml.
Gasoline to be removed: 97.0 ml.
Temperature: 60~80°C

Expt.	N_2/gasoline ratio (v/v) $\times 10^2$	Gasoline recovery wt. %	Remark
I. Gas flow 42 l./hr.; space velocity, 433 cc./cc./hr.; time, 83 min.	2.18	50.0	During drying process, the temperature was lowered as a precaution against activity loss of limonite. Too much lowering of temperature would cause drying inefficient. To maintain the temperature inlet nitrogen might be necessary to heat up occasionally.
	2.93	74.5	
	3.8	86.0	
	4.7	93.0	
	5.65	96.5	
II. Gas flow 12 l./hr.; space velocity, 124 cc./cc./hr.; time, 110 min.	2.25	48.5	
	2.92	75.0	
	3.66	90.0	
	4.46	97·0	
III. Gas flow 87.5 l./hr.; space velocity, 903 cc./cc./hr.; time, 43 min.	2.21	49.5	
	3.0	70.5	
	4.05	81.0	
	5.0	87.5	
	6.0	91.0	
IV. Gas flow 30 l./hr.; space velocity, 310 cc./cc./hr.; time, 114 min.	2.23	49.0	
	2.92	75.0	
	3.71	88.0	
	4.54	96.5	
	5.52	99.0	

Note: (1) Nitrogen/gasoline ratio was calculated on the quantity of gas passed and total quantity of gasoline to be removed. (gas vol./liquid vol.)
(2) Average gas flow is indicated here.

limonite. Removal of this gasoline was important. Open air drying must not be permitted for its hazardous effect. It is inflamamble liquid and forms explosive mixture in air. It is also injurious for health. Its permissible limit[5] in U. S. A. is 1000～1500 p. p. m. and U. S. S. R. is 55～115 p. p. m. After careful consideration locally available nitrogen gas was the choice to be used for the purpose. A study of space velocity of carrier gas on gasoline removal system is presented in Table IX.

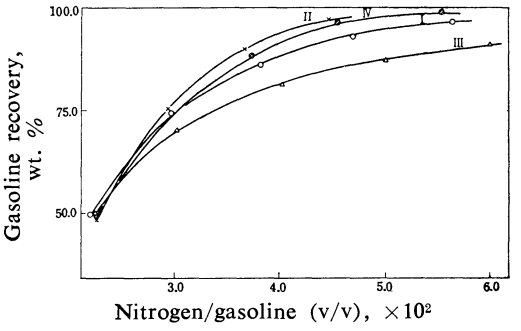

Fig. 5. Removal of retained gasoline by nitrogen.

I	Space velocity	433 cc./cc./hr.
II	Space velocity	124 cc./cc./hr.
III	Space velocity	903 cc./cc./hr.
IV	Space velocity	310 cc./cc./hr.

From above data and curves in Fig. 5 it is clear that gas flow and space velocity have bearing on the removal of gasoline from regenerated limonite. At higher space velocity, the removal of gasoline was relatively low (curve III), while at lower space velocity it was slow. An intermediate space velocity arround 310 cc./cc./hr. was found to be satisfactory.

Arrangements were also made to recover gasoline from the exit gas by oil washing and subsequent rich oil on distillation yields gasoline.

In conclusion, it may be said that the plant should be modified in the light of above observations by replacing the "overflow receiver" (F in Fig. 3) with a quenching column and adding one gasoline recovery unit.

The author extends his thanks to Pakistan Industrial Development Corporation for providing facilities to carry out this work.

Regeneration of Spent Limonite using Gasoline. II. Continuous Countercurrent Process

By M. I. ALI*

(Received July 24, 1961)

Earlier, a process of regeneration of limonite using hot gasoline on fixed bed was worked out. This study indicated the possibility of developing a countercurrent process where both gasoline and limonite could move physically in opposite directions. For this purpose, free movement of different limonite particles under gravity in still and flowing gasoline was studied. After careful consideration, regeneration column was designed for further experiments and operated under varied conditions. Optimum liquid velocity and solid-liquid contact period at different limonite velocity were ascertain and discussed. Finally, a modified process flow sheet has been drawn up and presented.

Regeneration of Spent Limonite Continuous Countercurrent Process

In view of earlier observations[1] and data obtained thereof, attempt was made to realize a continuous countercurrent process in which both gasoline and limonite could move physically. The Dorr multideck classifier was the only suitable equipment for this type of closed circuit leaching. But the fact that limonite did not get wet in gasoline and its movement was considerably free, led to think otherwise. It was thought that gravity flow of limonite through gasoline might be feasible. To achieve this end, it was first necessary to study counter-

Remarks: i) 1, 2, 3 and 4 in this table correspond to the experiments with still gasoline and flowing gasoline of rates 4.9, 9.8 and19.7 ml./cm² min. respectively.
ii) For this short distance movement acceleration of the particles is neglected.
iii) Higher per cent of 5 mm. particles of fresh limonite was due to agglomerated lumps.

current flow of limonite particles through gasoline. The experiments were carried out with different size particles of fresh, spent and regenerated limonite.

Procedure. A long glass tube (2.7 m.× 160 mm.ϕ) was erected vertically. Lower end was closed and gasoline poured into it. In still gasoline the particles of limonite were allowed to fall under gravity. Time taken by individual particle to travel a distance of 2.5 m. was noted. The velocity of the falling particle was then calculated. Next, gasoline was forced to flow upward in the column at a certain velocity and the above experiments were repeated with only regenerated and spent limonite. These results are presented in Table I and Fig. 1.

From the above table and Fig. 1, it appears that the average particles of both spent and regenerated limonite are not affected much by upstream flow of gasoline even at flow rate 19.7 ml./cm² min. Only the fine particles 0.5~1.0% of the mass were affected and some showing negative velocity i. e. the particles were moving upwards with flowing gasoline. If above mentioned gasoline velocity is considered as limiting velocity, then the contemplated regeneration column may be examined by the following way (Fig. 2).

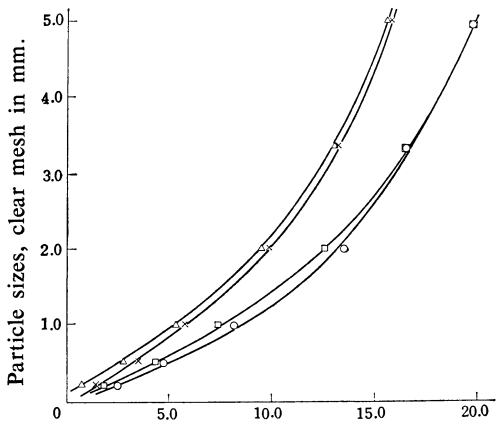

Fig. 1 Change of falling velocity of Limonite in gasoline with particle sizes.
Regenerated limonite particles:
in still gasoline (×); in flowing gasoline, 19 ml./cm² min. (△).
Spent limonite particles:
in still gasoline (○); in flowing gasoline, 19 ml./cm² min. (□).

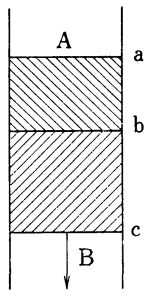

Fig. 2. Upper section of regeneration column.

Let AB is a section of contemplated regeneration column. Rich gasoline leave the column at 'a', limonite particles enter into the column at 'b' while limonite bed starts from 'c' to downwards. Then, ac is liquid zone. If only particle sizes below 0.21 mm. are considered it will be seen that 10.2% in spent limonite and 23.8% in regenerated limonite constitute this fraction. Their spatial distribution in the column may be as follows:

The spent limonite particles would normally be in zone 'bc' and below. These particles from 'b' will, of course, have slow fall and ultimately come down to c-line. At this position there should be some eddy zone e, in Fig. 3, where there is no upward movement of

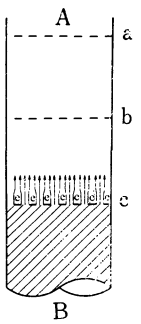

Fig. 3. Upper section of regeneration column. Arrow heads indicate gasoline flow while 'e' indicates 'eddy zones'. Other notations are same as in Fig. 2.

gasoline (rather downward) and even the stationary particles will settle on the limonite bed there. Once it is settled, it will be soon covered by the larger particles which are continuously falling on the bed. Thus covered small particles will have restricted movement and it will move down with other particles. Further, downward movement of fine particles in zone 'bc' will be enhanced by the impact of falling particles.

As regards regenerated limonite, particles below 0.21 mm. is much higher than that of spent limonite. It is due to breakage of particles during processing, and sulfur elimination. These particles are mostly at the bottom of limonite bed where its movement is much restricted. There is a little chance of its being carried by gasoline. However, a filter must be used at 'a' to take care of carried particles, if any.

In view of the above observations, it was deemed fit to realize a continuous counter current process in which both limonite and gasoline would move physically in opposite direction. Finally, a small apparatus was used to regenerate about 10.0 kg. spent limonite per

V Cone valve

day. The operation was manual. In this case, other set up remained unchanged as in "hot gasoline flow process" except the regeneration column which was modified. Feeding system was changed. The regeneration column is shown in Fig. 4.

Description of the Equipments and Operation. Spent limonite was introduced into regeneration column B at A, and hot gasoline at C, under the distributor D. Rich gasoline was led to the quenching column through filter F. On opening the cone-valve V. limonite was allowed to fall down slowly to the receiver R, after regeneration. The movement of limonite was regulated by the cone-valve. Valve V was closed when the receiver was almost full. Gasoline was drained out from the receiver and nitrogen was passed for drying the mass.

After drying, the regenerated material was removed from the bottom. During drying of limonite, leaching was stopped. But it could be made continuous by installing one more receiver. The distillate gasoline was passed to the condenser E.

Equipment Specifications.—

Material movement:

a) Limonite particles; 25.0 g./min.

b) Gasoline; 360.0 ml./min.
(gasoline/limonite = 12.0)

A regeneration column (120 cm. × 10 cm. ϕ) was selected. This could operate under conditions of 0.44 cm. limonite velocity with 273 min. contact period and 7.4 cm. gasoline velocity with 16.2 min. contact period. The velocity and contact period of both limonite and gasoline is changeable. The experiments were carried out under varied conditions.

A review of contact periods of limonite in different experiments done earlier could not give any clear indication for its requirement. Therefore, special attention was paid to "contact period of limonite" in subsequent experiments. These results are presented in Table II and Fig. 5.

The above results indicate that contact period of limonite has some bearing on the recovery of sulfur at the final stage. To ascertain the behavior at earlier stages a few experiments were carried out with lower gasoline/limonite ratio. These results are presented in Table III.

From the results in Table III it appears that at the initial stage contact period of limonite has practically no influence on sulfur recovery. As gasoline/limonite ratio increases, the effect of contact period of limonite becomes significant. This may be explained from the fact

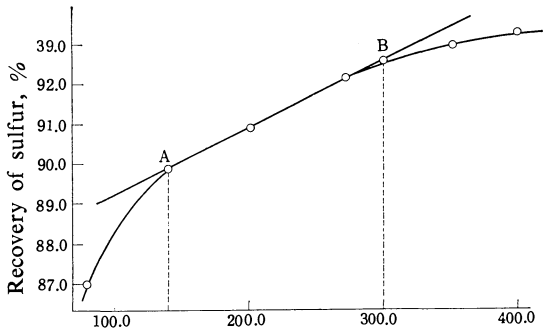

Fig. 5 Progress of sulfur recovery with contact period of limonite.

TABLE II. PROGRESS OF SULFUR RECOVERY WITH CONTACT PERIOD OF LIMONITE

Gasoline/limonite: 12.0; temperature: 85.0°C

Limonite		Gasoline		Sulfur recovery %	Remark
Velocity cm./min.	Contact period min.	Velocity cm./min.	Contact period min.		
* 1.5	80	24.8	4.85	87.0	"Overflow" and "distillate" gasoline are about 95.0% and 5.0% respectively.
0.86	140	14.2	8.45	89.9	
0.60	200	10.0	12.0	90.9	
0.44	273	7.4	16.2	92.2

that sulfur remains entrapped in the particles and does not come in contact with gasoline readily. It takes time. It can be explained easily from the peculiar phenomenon "the migration of iron oxide" during reverse oxidation process[2]. The liberated sulfur does not form film on the surface of the particles. On the contrary, ferric oxide migrates so that sulfur forms the core of each particle. Moreover, caking also occurs frequently due to careless operation at elevated temperature.

The effect of contact period of limonite was found to be uniform and linear between the range of 140~300 min. (AB in Fig 5). Beyond 300 min., the effect of contact period becomes insignificant. But in case of lower contact period yield was found to be low which may be due to insufficient contact period of gasoline (minimum contact period desired 6 min. for saturation (1)).

It is evident that longer contact period is desired for better efficiency. It is possible to regulate the contact period to some extent by controlling the production. It would have been much appreciating if arrangement could be made to pass gasoline through regenerated limonite using a by-pass line for final washing out of sulfur. However, a modified flow sheet for this process is presented in Fig. 6.

Diphenylcarbazone as an Internal Indicator in Volumetric Analysis. VII. Determination of Mercury

By G. S. DESHMUKH and A. L. J. RAO

(Received December 26, 1960)

While many gravimetric procedures are available for the determination of mercury only a few indirect titrimetric procedures have been reported in the literature. Mercury is determined by the titrimetric precipitation analysis as the thiocyanate using ferric ion as the indicator[1]. An indirect alkalimetric procedure[2] involving the addition of sodium hydroxide and potassium iodide and titrating the liberated alkali with standard acid is also known. Mercury is precipitated as iodate[3] and also as periodate[4] and in both the cases the precipitate is treated with potassium iodide and hydrochloric acid and titrated iodimetrically with standard thiosulfate. It is also precipitated as 2-(*o*-hydroxyphenyl)-benzimidazole[5] and the amount of mercury in the precipitate is determined by the bromate method.

Diphenylcarbazone as an indicator in volumetric analysis was first used by Roberts[6] and mercurimetric determination of thiocyanate using this indicator is already well known. Recent studies[7] in these laboratories have reported the applicability of this indicator to various types of titrimetric procedures. The present work deals with the direct determination of mercury by titrating with potassium iodide in presence of the above indicator.

Experimental

Reagents.—Mercuric nitrate solution was prepared by dissolving Merck's reagent grade sample in appropriate volume of water adding two drops of concentrated nitric acid and was standardized with thiocyanate. Potassium iodide solution contained an accurately weighed pure AR reagent in water and was standardized against potassium iodate. A saturated solution of diphenylcarbazone in alcohol was used as the indicator.

Procedure.—To 10 ml. of iodide solution 4~5 drops of the indicator and 2 ml. of alcohol were added. This was slowly titrated with mercuric nitrate from a burette. The original faint red brown color of the solution (due to the presence of the indicator) faded and the precipitate formed due to the addition of mercuric nitrate redissolved during the initial stage of titration. Towards the end a bright red precipitate of mercuric iodide was obtained. Mercuric nitrate was now added dropwise until the bright red precipitate turned dark. At the end point the precipitate turned reddish violet imparting a bright pink tinge to the supernatant solution. The end point is very easy to detect and there is no risk of over titration. It is, however, possible to rectify the error due to over titration by adding a measured amount of iodide and continuing the titraction in the usual way. Alternatively the reverse titration may also be carried out successfully. The molecular ratio of mercury to iodide calculated from the amount of mercury reacting with iodide at the equivalence

TABLE I

point is 1 : 2 and the composition of the precipitate, therefore, corresponds to mercuric iodide.

The results of a set of typical titrations are given in Table I.

The chief advantage of this procedure is its simplicity, accuracy and the sharpness of the end point. Moreover this is a direct method for the determination which may be readily adopted in the routine analysis of mercury.

Summary

A simple and direct method of estimating mercury by standard potassium iodide with diphenylcarbazone as an indicator has been described. The results are accurate and comparable favorably with the classical procedures.

The authors wish to express their sincere thanks to Professor G. B. Singh for providing the facilities during the above work.

Sur les Préparations des Complexes Métalliques. III[1]. *Les Préparations des Sels du Diacidobiséthylènediaminecobalt(III) et du Diacidobiséthylènediaminechrome(III)*

Par Masayoshi NAKAHARA

(Reçu le 12 Septembre, 1961)

Dernièrement Linhard et Stirn[2] ont préparé les composés du $[Co\,en_2\,ac_2]ClO_4$ (ac est l'acide monocarboxylique acylique). Ils ont utilisé comme ac, de l'acide formique (nombre de carbones de radical alcoyle: 0) à l'acide caprylique (nombre de carbones de radical alcoyle: 0), et ils ont obtenu, dans tous les cas, les trans-sels et les cis-sels. En les préparant, ils ont toujours obtenu les perchlorates de *trans*-diacidobiséthylènediaminecobalt(III) en se servant comme matières premières du perchlorate de *trans*-dichlorobiséthylènediaminecobalt(III) ou du perchlorate de carbonatobiséthylènediaminecobalt(III), et les perchlorates du *cis*-diacidobiséthylènediaminecobalt(III), en se servant du perchlorate de *cis*-diaquobiséthylènediaminecobalt(III). Mais nous y trouvons une seule exception: ils ont obtenu le perchlorate de *cis*-distearinatobiséthylènediaminecobalt(III) en se servant du perchlorate de *trans*-dichlorobiséthylènediaminecobalt(III). Nous avons essayé, nous intéressant à cette isomerisation trans-cis, d'examiner son mécanisme de réaction, du point de vue du procédé de préparation. Et alors, nous avons fixé notre attention sur la situation où les composés, dont la chaîne carbonée est longue, comme le radical stéarique, se coordinaient au métal, et l'avons comparée avec celle de la coordination des composés dont la chaîne carbonée est courte. Pour cela nous avons fait réagir, dans des conditions constantes, les perchlorate de *trans*- et de *cis*-dichlorobiséthylènediaminecobalt(III) et de *trans*- et de *cis*-dichlorobiséthylènediaminechrome(III) avec le carboxylate de sodium dans l'éthanol, et obtenu de nouveaux sels complexes.

Expériences

Préparations.—*1) Perchlorate de trans-Dichlorobiséthylènediaminecobalt(III), trans-*$[Co\,en_2\,Cl_2]ClO_4$ *(le sel de trans-Co).*—Selon le procédé de Linhard et al.[2]

2) Perchlorate de cis-Dichlorobiséthylènediaminecobalt(III), cis-$[Co\,en_2\,Cl_2]ClO_4\cdot$*(le sel de cis-Co).*—Perchlorate de carbonatobiséthylènediaminecobalt-(III)[2] a été mis dans l'éthanol saturé de chlorure d'hydrogène, et chauffé. On y a vu apparaître du dioxyde de carbone, mais on l'a laissé au bain-marie jusqu'à la fin de cet dégagement. Les poudres violet-bleuâtres ainsi obtenues ont été filtrées, lavées plusieurs fois à l'éthanol, et séchées. Le rendement était très grand, proche de la quantité calculée.

Trouvé: Co, 16.75, N, 8.00. Calculé: Co, 16.87; N, 8.01%.

3) Perchlorate de trans-Dichlorobiséthylènediaminechrome(III), trans-$[Cr\,en_2\,Cl_2]ClO_4$ *(le sel de trans-Cr).*—Selon le procédé de Pfeiffer[3].

1) Partie II, M. Nakahara, *Ce Bulletin*, 35, 785 (1962).
2) M. Linhard et G. Stirn, *Z. anorg. Chem.*, 268, 105 (1952).
3) P. Pfeiffer, P. Koch, G. Lando et A. Trieschmann, *Ber.*, 37, 4255 (1904).

4) Perchlorate de cis-Dichlorobiséthylènediaminechrome(III), cis-[Cr en$_2$ Cl$_2$]ClO$_4$ (le sel de cis-Cr). —Le perchlorate de triséthylènediaminechrome(III) a été mis dans l'acide chlorhydrique concentré, chauffé pendant 6 hr. à 75°C[4]. Les cristaux rouge-violacés ainsi obtenus ont été recristallisés dans une solution de perchlorate de sodium.

5) Purifications des Acides Carboxyliques. — Les acides carboxyliques du commerce été estérifiés selon le procédé habituel, et sont devenus les esters de méthyle. Chaque ester de méthyle a été fractionné au point d'ébullition désigné dans la littérature et purifié[5]. L'ester purifié a été hydrolysé et est devenu le sel de sodium.

6) Perchlorate de trans-Dicaprinatobiséthylènediaminecobalt(III), trans-[Co en$_2$ ($C_9H_{19}COO$)$_2$]ClO$_4$.— 3.5 g. du sel de *trans-* Co ont été suspendus dans 100 ml. d'éthanol; on y a ajouté une solution d'éthanol de 3.5 g. du caprinate de sodium. Cela a été mis dans un flacon muni d'un réfrigérant à reflux et chauffé une heure au bain-marie. La solution rouge a été filtrée avant qu'elle ne devienne froide; le filtrate a été refroidi et les cristaux ont été séparés; ces cristaux ont été recristallisés à l'éthanol, lavés plusieurs fois à l'eau, puis séchés.

Rendement: 5,0 g. (80%).

Trouvé: Co, 9.40; N, 4.50. Calculé: Co, 9.49; N, 4.51%.

Cristaux rouge-violacés luisants en forme d'écailles. Insolubles dans l'eau. Solubles dans l'éthanol et l'acétone.

7) Perchlorate de trans-Dicaprinatobiséthylènediaminechrome(III), trans- [Cr en$_2$($C_9H_{19}COO$)$_2$]ClO$_4$.— Nous nous sommes servis de 3.4 g. du sel de trans-Cr et 3.9 g. de caprinate de sodium, et nous avons opéré de la même façon qu'au 6).

Rendement: 4.3 g. (70%).

Trouvé: Cr, 8.41; N, 4.54. Calculé: Cr, 8.47; N, 4.56%.

Cristaux rouge-violacés sales. Insolubles dans l'eau, solubles dans l'éthanol.

8) Perchlorate de trans-Dilaurinatobiséthylènediaminecobalt(III), trans-[Co en$_2$($C_{11}H_{23}COO$)$_2$]ClO$_4$.— Nous nous sommes servis de 3.5 g. du sel de *trans-* Co et 4 g. de laurinate de sodium, et nous avons opéré comme au 6).

Rendement: 4.5 g. (70%).

Trouvé: Co, 8.65; N, 4.10. Calculé: Co, 8.70; N, 4.14%.

Cristaux rouge-violacés sales en forme d'écailles. Insolubles dans l'eau, solubles dans l'éthanol. Par desséchement donne une poudre rose.

9) Perchlorate de trans-Dilaurinatobiséthylènediaminechrome(III), trans-[Cr en$_2$($C_{11}H_{23}COO$)$_2$]ClO$_4$. —Nous nous sommes servis de 3.4 g. du sel de trans-Cr et 4 g. de laurinate de sodium, et nous avons opéré comme au 6).

Rendement: 4.3 g. (70%).

Trouvé: Cr, 7.68; N, 4.14. Calculé: Cr, 7.76; N, 4.18%.

Cristaux brun-violacés. Insolubles dans l'eau, solubles dans l'éthanol.

10) Perchlorate de cis-Dilaurinatobiséthylènediaminecobalt(III), cis-[Co en$_2$($C_{11}H_{23}COO$)$_2$]ClO$_4$.— Nous nous sommes servis de 3.5 g. du sel de *cis-*Co et 4 g. de laurinate de sodium, et nous avons opéré comme au 6).

Rendement: 3.0 g. (47%).

Trouvé: Co, 8.59; N, 4.01. Calculé: Co, 8.70; N, 4.14%.

Cristaux rouge-violacés luisants. Solubles dans l'éthanol.

11) Perchlorate de cis-Dilaurinatobiséthylènediaminechrome(III), cis-[Cr en$_2$($C_{11}H_{23}COO$)$_2$]ClO$_4$.— Nous nous sommes servis de 3.4 g. du sel de *cis-*Cr et 4.0 g. de laurinate de sodium, et nous avons opéré comme au 6).

Rendement: 2.5 g. (40%).

Trouvé: Cr, 7.70; N, 4.02. Calculé: Cr, 7.76; N, 4.18%.

12) Perchlorate de cis-Dimyristinatobiséthylènediaminecobalt(III), cis-[Co en$_2$($C_{13}H_{27}COO$)$_2$]ClO$_4$. — Nous nous sommes servis de 3.5 g. du sel de *trans-*Co ou *cis-*Co et 5.2 g. de myristate de sodium, et nous opéré comme au 6).

Rendement: 4.5 g. (60%).

Trouvé: Co, 8.14; N, 3.73. Calculé: Co, 8.04; N, 3.82%.

Poudre rose. Insoluble dans l'eau, et soluble dans l'éthanol.

13) Perchlorate de cis-Dimyristinatobiséthylènediaminechrome(III), cis-[Cr en$_2$($C_{13}H_{27}COO$)$_2$]ClO$_4$.— Nous nous sommes servis de 3.4 g. du sel de *trans-*Cr ou *cis-*Cr et 5.2 g. de myristate de sodium, et nous avons opéré comme au 6).

Rendement: 4.5 g. (70%).

Trouvé: Cr, 7.03; N, 3.66. Calculé: Cr, 7.16; N, 3.86%.

Poudre rouge-violacée. Insoluble dans l'eau, soluble dans l'éthanol.

14) Perchlorate de cis-Dipalmitinatobiséthylènediaminecobalt(III), cis-[Co en$_2$($C_{15}H_{31}COO$)$_2$]ClO$_4$.— Nous nous sommes servis de 3.5 g. du sel de *trans-*Co et 5.9 g. de palmitate de sodium, et nous avons opéré comme au 6).

Rendement: 6.8 g. (83%).

Trouvé: Co, 7.49; N, 3.50. Calculé: Co, 7.47; N, 3.55%.

Poudre rose. Insoluble dans l'eau, soluble dans l'éthanol, le propanol et le benzène.

15) Perchlorate de cis-Dipalmitinatobiséthylènediaminechrome(III), cis- [Cr en$_2$($C_{15}H_{31}COO$)$_2$]ClO$_4$.— Nous nous sommes servis de 3.4 g. du sel de *trans-*Cr et 5.9 g. de palmitate de sodium, et nous avons opéré comme au 6).

Rendement: 5.8 g. (71%).

Trouvé: Cr. 6.51; N, 3.60. Calculé: Cr, 6.65; N, 3.58%.

Poudre rouge-violacée. Insoluble dans l'eau, soluble dans l'éthanol et le benzène.

16) Perchlorate de cis-Distéarinatobiséthylènediaminechrome(III), cis-[Cr en$_2$($C_{17}H_{37}COO$)$_2$]ClO$_4$.— Nous nous sommes servis de 3.4 g. du sel de *trans-*Cr ou *cis-*Cr et 5.1 g. de stéarate de sodium, et nous avons opéré comme au 6).

Rendement: 5.5 g. (66%).

Trouvé: Cr, 6.06; N, 3.42. Calculé: Cr, 6.20; N, 3.34%.

4) M. Linhard et M. Weigel, *Z. anorg. Chem.*, **271**, 115 (1952).

5) Haller et Youssoufian, *Compt. rend.*, **143**, 805 (1857).

Poudre rouge-violacée. Insoluble dans l'eau, soluble dans l'éthanol à chaud, et facilement soluble dans benzène à chaud.

Spectres d'Absorption.—Les spectres d'absorption du perchlorate de diacidobiséthylènediaminecobalt-(III) et du perchlorate de diacidobiséthylènediaminechrome(III), nouvellement préparés, ont été mesurés. La mesure a été faite dans une solution d'éthanol. Les résultats obtenus sont montrés dans la Fig. 1. Toutes les courbes d'absorption ont été classées en quatre espèces; toutes coïncidaient presque entièrement.

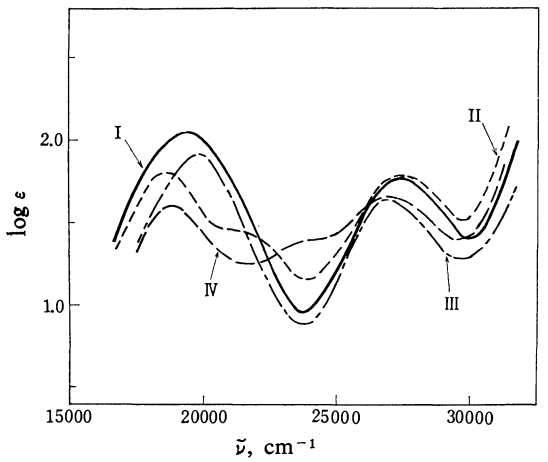

Fig. 1. Spectres d'absorption de:
(I) *cis*-[Co en$_2$ ac$_2$]ClO$_4$
(II) *trans*-[Co en$_2$ ac$_2$]ClO$_4$
(III) *cis*-[Cr en$_2$ ac$_2$]ClO$_4$
(IV) *trans*-[Cr en$_2$ ac$_2$]ClO$_4$

Résultats et Discussion

Quand nous observons chaque courbe d'absorption montrée dans la Fig. 1, nous pouvons facilement voir leur différence de structure. On sait bien, par de nombreux exemples, que la séparation de la première bande d'absorption est suscitée par la structure trans du [Co en$_2$ ac$_2$]$^+$ [6,7]. Et les courbes ainsi obtenues sont tout à fait correspondantes aux courbes d'absorption de l'acetato-complexe, [Co en$_2$(CH$_3$COO)$_2$]$^+$. Par conséquent, la différence de structure du perchlorate de diacidobiséthylènediaminecobalt(III) visible sur les courbes d'absorption de I et II provient du fait que I correspond à la structure trans et II à la structure cis. De même, quant au perchlorate de diacidobiséthylènediaminechrome(III), de la différence qui existe entre les structures trans et cis vient la séparation distincte de la première bande d'absorption; III correspond à la structure trans, IV à celle de cis. Or le Tableau I montre les résultats

Tableau I

de la réaction de l'isomérisation trans-cis sur les complexes que nous avons ainsi préparés. Lors de la réaction de tous les complexes de départ, avec le stéarate, le palmitate et le myristate, nous avons toujours obtenu les complexes cis comme produits de réaction. Il est donc certain que nous avons vu l'isomérisation à travers la réaction des trans-complexes avec le carboxylate. Il en est de même des complexes du cobalt et du chrome. Mais on obtiendra toujours les trans-complexes par la réaction des trans-complexes du cobalt et du chrome avec le laurate, le caprinate etc., et de même, les cis-complexes par la réaction des cis-complexes avec le carboxylate. De plus, on peut ajouter à cela les résultats de Linhard et al.[2]: par la réaction du perchlorate de carbonatobiséthylènediaminecobalt(III) avec l'acide caprylique, l'acide caproique, l'acide valérique, seront toujour obtenus les trans-complexes, mais, selon le même procédé, on ne pourrait obtenir les cis-complexes (en évaporant et concentrant à la température ordinaire le perchlorate de *cis*-diaquobiséthylènediaminecobalt-(III) et les carboxylate de potassium, on peut obtenir les cis-complexes). De là, lorsque nous examinons ces réactions d'isomérisation trans-cis, il serait le plus naturel que nous cherchions leur cause à la longueur du radical alcoyle. On obtiendra toujours, quels que soient les complexes de départ, les cis-complexes, au delà de l'acide myristique dont le nombre de carbones du radical alcoyle est 13, le radical carboxyle exclus; avec l'acide laurique ou l'acide caprique dont le nombre de carbones est 11 ou 9, les résultats dépendent de la structure des complexes de départ, et, avec des radicaux dont le nombre de carbones

6) M. Linhard et M. Weigel, *Z. anorg. Chem.*, **267**, 121 (1951).
7) Y. Shimura, Ce Bulletin, **25**, 49 (1952).

est inferieur à 7, dans les conditions expérimentales susdites, on pourra toujours obtenir les trans-complexes.

Or, en tenant compte de ces faits, considérons, par exemple, la réaction du *trans*-$[M\,en_2\,Cl_2]\cdot ClO_4$ (M=Co, Cr) avec le radical carboxyle. Au cours de cette réaction, le *trans*-$[M\,en_2\cdot Cl(ac)]\,ClO_4$ sera d'abord obtenu. Ensuite, quand on sera passé au $[M\,en_2\,ac_2]\,ClO_4$, les radicaux alcoyles qui doivent être combinés dans la position trans s'arrangent comme l'indique à la Fig. 2 par attraction entre eux, lorsque la chaîne du carbone est longue, et pour cela ils feront une distorsion vers la

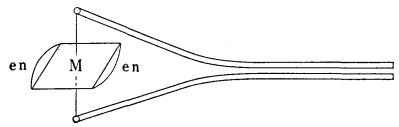

Fig. 2

position coordinée de l'autre coordinat (l'éthylènediamine à cette place-ci), et par conséquent il en resultera l'isomérisation. On obtient la même réaction, que le radical carboxyle qui coordiné en second s'arrange avant la coordination ou après la coordination. On peut considérer ce pouvoir d'attraction comme ressemblant à celui qui est dû aux forces de van der Waals. Et alors à cause du prolongement de la chaîne carbonée, l'attraction par les longs radicaux alcoyles l'effet de la charge du radical carboxyle exclus, devient plus grande que la répulsion par les charges négatives des radicaux carboxyles. Et au contraire, on peut considérer la réaction d'isomérisation cis-trans, où la chaîne carbonée est courte, comme suscitée par le phénomène inverse, et quand l'isomérisation n'a pas lieu, on peut croire que ces pouvoires sont proportionnels. Des faits qui ressemblent beaucoup aux résultats susdits, sont connus par expérimentation sur les agents actifs de surface. Et alors quand on ajoute des agents actifs de surface divers dont les nombres de carbones sont différents, au sol d'hydroxyde de fer(III) la cohésion a toujours lieu. Mais, ensuite, quand on ajoute avec excès un agent actif de surface ayant, par exemple, un nombre de carbones superieur à 12 comme le dodecylsulfate de sodium, cette précipitation se disperse à nouveau ; mais, elle ne se disperse pas entièrement si le nombre de carbones est inferieur à 10[8]. De même, l'action de l'alcoylsulfate sur la cohésion et la dispersion du colorant et de la protéine etc.[9], sera influencée par la longueur de la chaîne. Ces phénomènes sont expliqués par le mécanisme suivante : la charge du sol, du colorant et de la protéine etc., est d'abord neutralisée par l'ion alcoylsulfate et les suspensoïdes précipitent. Si c'est un radical alcoyl long, les chaînes alcoyle de l'ion alcoylesulfate dissous s'arrangent dans la direction contraire à celles des précipitations, et par ces attractions, les précipitations sont dispersées de nouveau.

Il est très intéressant, selon les résultats que nous avons obtenus, que cette distinction ait lieu, de même, autour du nombre du carbone 12, grâce à cela on peut concevoir un mécanisme analogue.

Résumé

Les *trans*- et *cis*-$[M\,en_2\,ac_2]\,ClO_4$ (M=Co, Cr) de plusieurs sortes, composés nouveaux, ont été préparés. Nous avons considéré l'isomérisation lors de la préparation des complexes. Nous avons conclu que l'isomérisation se fait, dans tout les cas, par les attraction des radicaux alcoyles.

L'auteur exprime ses remerciements sincères à Monsieur le professeur Taku Uemura pour l'intérêt qu'il a porté à ce travail et il est particulièrement reconnaissant envers Monsieur le professeur Yukio Kondo qui a participé à la discussion sur l'interprétation des résultats. Il est aussi reconnaissant envers Monsieur Takeo Miyake qui a assisté à la purification des acides carboxyliques.

A Semi-empirical Theory of the π-Electronic Spectra of Aromatic Derivatives

By Kichisuke NISHIMOTO and Ryoichi FUJISHIRO

(Received October 11, 1961)

In a previous paper[1], we have reported a convenient method (VO method) for calculation of the molecular diagrams of aromatic derivatives. In this paper, a semi-empirical theory of the π-electronic spectra of aromatic derivatives based on the antisymmetrized molecular orbital method (ASMO method) is formularized by the use of the results of the VO method and is applied to calculation of the π-electronic spectra of hydroquinone and phloroglucinol.

Theory

The framework of the present theory is similar to that of Pariser[2] and of our previous paper[3]. The procedure of calculation is as follows:

i) MO's are determined by a simple LCAO MO method based on π-electron approximation, using appropriately chosen parameters.

ii) We give each π-electron a molecular spin orbital (MSO) which is given by the product of a MO and spin function α or β.

iii) Configurational wave functions are built up as antisymmetrized products, or Slater determinants, of these MSO's.

iv) Configurational energies are calculated by a semi-empirical procedure based on zero differential approximation.

v) Electronic state functions and their energies are calculated by the method of the linear combinations of these configurational wave functions.

A) Calculation of MO's.—When the molecule contains n 2pπ atomic orbitals (2pπ AO), the MO, ψ_i, is represented by the linear combination of these AO's as follows:

$$\psi_i=\sum_{\mu}C_{i\mu}\phi_\mu \qquad (1)$$

where ϕ_μ is the μ-th 2pπ AO and $C_{i\mu}$ is the coefficient to be determined by the variational method. First of all, from the variational theory we obtain the following equations for the coefficients which form the simultaneous equations of n dimensions:

$$\left.\begin{aligned}&\sum_{\mu=1}^{n}C_{i\mu}\left(\int\phi_1 H\phi_\mu d\nu-E\delta_{1\mu}\right)=0\\&\qquad\vdots\\&\sum_{\mu=1}^{n}C_{i\mu}\left(\int\phi_n H\phi_\mu d\nu-E\delta_{n\mu}\right)=0\end{aligned}\right\} \qquad (2)$$

where H is an effective one-electron Hamiltonian and $\delta_{\mu\nu}=1$ if $\mu=\nu$, $=0$ otherwise. E is orbital energy defined by H and MO. Now, we assume the matrix elements, $H_{\mu\nu}=\int\phi_\mu H\phi_\nu\, d\nu$, as follows:

$$\left.\begin{aligned}&H_{\mu\mu}=\alpha && (\phi_\mu \text{ is carbon 2p}\pi \text{ AO})\\&H_{\mu\mu}=\alpha+\delta_\mu\beta && (\phi_\mu \text{ is heteroatom 2p}\pi \text{ AO})\end{aligned}\right\} \qquad (3)$$

$$\left.\begin{aligned}&H_{\mu\nu}=\beta && (\mu \text{ and } \nu \text{ are nearest neighbor carbon atoms})\\&H_{\mu\nu}=k_{\mu\nu}\beta && (\mu \text{ and } \nu \text{ are nearest neighbors, but one or both of them are heteroatom})\\&H_{\mu\nu}=0 && (\mu \text{ and } \nu \text{ are non-neighbors})\end{aligned}\right\} \qquad (4)$$

where the numerical values of δ_μ and $k_{\mu\nu}$ are determined by a semi-empirical procedure; e. g., for the case of phenol we have determined these values from the experimental ionization potentials of benzene, methanol and phenol[3]. Energies E_i are obtained as the roots of the following secular determinant:

$$\begin{vmatrix}(H_{11}-E) & H_{12} & \cdots\cdots & H_{1n}\\ H_{21} & (H_{22}-E) & \cdots\cdots & H_{2n}\\ \vdots & & & \\ H_{n1} & H_{n2} & \cdots\cdots & (H_{nn}-E)\end{vmatrix}=0$$

which is defined by Eq. 2. From the secular determinant we obtain the n E_i's. If we substitute the lowest energy E_1 into Eq. 2 and use the normalization condition

$$\int\phi_1^2 d\nu=\sum_{\mu=1}^{n}C_{1\mu}^2$$

we obtain the coefficients $C_{1\mu}$'s for the lowest MO, ψ_1. In the same way we obtain the MO's, ψ_2, ψ_3, ……, ψ_n associated with the energies E_2, E_3, ……, E_n respectively. When E is expressed by

1) K. Nishimoto and R. Fujishiro, This Bulletin, **32**, 699 (1959).
2) R. Pariser, *J. Chem. Phys.*, **24**, 250 (1956).
3) K. Nishimoto and R. Fujishiro, This Bulletin, **31**, 1036 (1958).

$$E_i=\alpha-x_i\beta \tag{5}$$

the MO's corresponding to $x_i<0$ are called bonding orbitals, whereas the MO's corresponding to $x_i>0$ are called antibonding orbitals. In the case of a molecule having m π-electrons, the ground state of the molecule is given by the state in which the lower MO's, ψ_1, ψ_2, ……, $\psi_{m/2}$ are used twice. We call the MO's, ψ_1, ψ_2, ……, $\psi_{m/2}$, occupied orbitals, and the other MO's vacant orbitals. Consequently, the π-electron density of the μth atom, q_μ, and π-bond order (or quantity analogous to it) for the $\mu\nu$ atom pair, $p_{\mu\nu}$, in the ground state of the molecule are expressed as follows:

$$\left.\begin{aligned} q_\mu&=2\sum_{i}^{\text{occ.}}C_{i\mu}^2=2-2\sum_{i'}^{\text{vac.}}C_{i'\mu}^2=2-q_\mu^v \\ p_{\mu\nu}&=2\sum_{i}^{\text{occ.}}C_{i\mu}C_{i\nu}=-2\sum_{i'}^{\text{vac.}}C_{i'\mu}C_{i'\nu}=-p_{\mu\nu}^v \end{aligned}\right\} \tag{6}$$

where $\sum_{i}^{\text{occ.}}$ and $\sum_{i'}^{\text{vac.}}$ indicate the sums over occupied orbitals and vacant orbitals respectively. The relations of Eqs. (6) are found in our previous paper[1]. The calculation of q_μ's and $p_{\mu\nu}$'s using vacant orbitals is simple compared with that using occupied orbitals.

B) Reduced Formula for the Calculation of π-Electronic State Energies.—The configurational wave function of the ground state of the molecule, χ_0, is now represented by a Slater determinant having the form of:

$$\chi_0=\frac{1}{\sqrt{m!}}\cdot\begin{vmatrix} (\psi_1\alpha)^1(\psi_1\beta)^1\cdots\cdots(\psi_{m/2}\alpha)^1(\psi_{m/2}\beta)^1 \\ (\psi_1\alpha)^2(\psi_1\beta)^2\cdots\cdots(\psi_{m/2}\alpha)^2(\psi_{m/2}\beta)^2 \\ \vdots \qquad\qquad\qquad\qquad \vdots \\ (\psi_1\alpha)^m(\psi_1\beta)^m\cdots(\psi_{m/2}\alpha)^m(\psi_{m/2}\beta)^m \end{vmatrix}$$

$$\equiv(1\,\bar{1}\,2\,\bar{2}\cdots\cdots\frac{1}{2}m\frac{1}{2}\bar{m})$$

The configurational wave function of the excited state corresponding to the one-electron transition from ψ_i to $\psi_{k'}$, $\chi_{i\to k'}$, is given by:

$$\chi_{i\to k'}^1=2^{-1/2}[(1\,\bar{1}\cdots\cdots i\bar{k}'\cdots\cdots\frac{1}{2}m\frac{1}{2}\bar{m})-(1\,\bar{1}\cdots\cdots k'\bar{i}\cdots\cdots\frac{1}{2}m\frac{1}{2}\bar{m})]$$

$$\chi_{i\to k'}^3=2^{-1/2}[(1\,\bar{1}\cdots\cdots ik'\cdots\cdots\frac{1}{2}m\frac{1}{2}\bar{m})+(1\,\bar{1}\cdots\cdots\bar{i}\bar{k}'\cdots\cdots\frac{1}{2}m\frac{1}{2}\bar{m})]$$

where superscripts 1 and 3 indicate singlet and triplet states, respectively. When we use complete many electron Hamiltonian $\mathscr{H}$ instead of an effective one-electron Hamiltonian, the configurational energies are given by:

$$\mathscr{H}_{i\to k}=\int\chi_{i\to k'}\mathscr{H}\chi_{i\to k'}\,dv$$

$$\mathscr{H}_{00}=\int\chi_0\mathscr{H}\chi_0 dv$$

where

$$\mathscr{H}=\sum_i H_{\text{core}}(i)+\frac{1}{2}\sum_{ij}\frac{e^2}{r_{ij}}$$

where $H_{\text{core}}(i)$ is core Hamiltonian, which consists of the kinetic energy term of the ith π-electron and potential energy terms representing the attraction among the σ-cores and this electron. A rigid core which consists of a nucleus, inner shell electrons and valence electrons except π-electrons, is called a σ-core. Therefore the σ-core of μth atom with q_μ^0 π-electrons in its free state has a q_μ^0 $|e|$ positive charge. According to Pariser[2], the energy $\Delta E_{ik'}$ associated with a one-electron transition from ψ_i to $\psi_{k'}$ is given by

$$\begin{aligned}\Delta E_{ik'}&=\mathscr{H}_{ik'}-\mathscr{H}_{00}\\&=I_{k'k'}-I_{ii}+[ii|k'k']\pm[ik'|ik']\\&\quad-[ii|ii]-\sum_{f\neq i}\{2[ff|ii]-2[ff|k'k']\\&\quad-[fi|fi]+[fk'|fk']\}\end{aligned} \tag{7}$$

where the upper and lower signs are associated with the singlet and triplet configurations respectively. Summation over the index f means that over the occupied MO's in χ_0. The integrals $[ij|kl]$ and I_{ij} are

$$[ij|kl]=\int\psi_i(1)\psi_j(1)\frac{e^2}{r_{12}}\psi_k(2)\psi_l(2)dv$$

$$I_{ij}=\int\psi_i(1)H_{\text{core}}(1)\psi_j(1)dv$$

When we define the following quantities:

$$\mathscr{H}_{\mu\mu}=-I_\mu+\frac{1}{2}q_\mu\gamma_{\mu\mu}+\sum_{\nu\neq\mu}(q_\nu-q_\nu^0)\gamma_{\nu\mu}$$

$$\mathscr{H}_{\mu\nu}=\beta_{\mu\nu}-\frac{1}{2}p_{\mu\nu}\gamma_{\mu\nu}$$

$$\bar{\varepsilon}_i=\sum_{\mu\nu}C_{i\mu}C_{i\nu}\mathscr{H}_{\mu\nu} \tag{8}$$

where

$$\int\phi_\mu^2(1)\frac{e^2}{r_{12}}\phi_\nu^2(2)dv=\gamma_{\mu\nu}$$

$$\int\phi_\mu(1)H_{\text{core}}(1)\phi_\mu(1)dv=I_\mu$$

$$\int\phi_\mu(1)H_{\text{core}}(1)\phi_\nu(1)d\nu=\beta_{\mu\nu}$$

Equation 7 can be rewritten by these quantities as

$$\Delta E_{i\,k'}^{1,3}=\bar{\varepsilon}_{k'}-\bar{\varepsilon}_i+[ik'|ik']-[ii|k'k']\pm[ik'|ik']$$

In many cases we have a number of configurational wave functions χ_i, belonging to the same symmetry. Therefore, the allowed electronic state function Ψ_a must be given by the linear combination of these χ_i's; that is,

$$\Psi_a=\sum d_{ai}\chi_i$$

where d_{ai} is a coefficient to be determined by variational procedure. Energies E associated with allowed electronic states are determined by following secular determinant:

$$\begin{vmatrix} (\mathscr{H}_{00}-E) & \mathscr{H}_{01} & \mathscr{H}_{02}\cdots\cdots \\ \mathscr{H}_{10} & (\mathscr{H}_{11}-E) & \mathscr{H}_{12}\cdots\cdots \\ \vdots & & \end{vmatrix}=0$$

Excitation energy $\Delta E_{0\to a}$ associated with a transition from Ψ_0 to Ψ_a is given by:

$$\Delta E_{0\to a}=E_0-E_a$$

General formulas for interconfigurational matrix elements $\mathscr{H}_{ij}$ were given by Pariser[2]. These can be rewritten as follows:

$$[\chi_0|\chi_i^{1\to k'}]=\int\chi_0\mathscr{H}\chi_i^{1\to k'}dv=\sqrt{2}\sum_{\mu\nu}C_{i\mu}C_{k'\nu}\mathscr{H}_{\mu\nu}$$

$$[\chi_i^{1\to k'}|\chi_j^{1\to l'}]=\int\chi_i^{1\to k'}\mathscr{H}\chi_j^{1\to l'}dv=2[ik'|jl']-[ij|k'l']$$

$$[\chi_i^{1\to k'}|\chi_i^{1\to l'}]=\sum_{\mu\nu}C_{k'\mu}C_{l'\nu}\mathscr{H}_{\mu\nu}+2[ik'|il']-[ii|k'l']$$

$$[\chi_i^{1\to k'}|\chi_j^{1\to k'}]=-\sum_{\mu\nu}C_{i\mu}C_{j\nu}\mathscr{H}_{\mu\nu}+2[ik'|jk']-[ij|k'k']$$

$$[\chi_0|\chi_i^{3\to k'}]=0$$

$$[\chi_i^{3\to k'}|\chi_j^{3\to l'}]=-[ij|k'l']$$

$$[\chi_i^{3\to k'}|\chi_i^{3\to l'}]=[\chi_i^{1\to k'}|\chi_i^{1\to l'}]-2[ik'|il']$$

$$[\chi_i^{3\to k'}|\chi_j^{3\to k'}]=[\chi_i^{1\to k'}|\chi_j^{1\to k'}]-2[ik'|jk']$$

C) Semi-empirical Estimation of Basic Integrals and Semi-empirical Formulation of $\mathscr{H}_{\mu\nu}$ and $\bar{\varepsilon}_i$. — All molecular integrals can be expanded into integrals over AO's which are I_μ, $\beta_{\mu\nu}$ and $\gamma_{\mu\nu}$. These basic integrals are estimated by a semi-empirical procedure. The two-center electron repulsion integral, $\gamma_{\mu\nu}$, is calculated from the expression which we found in the previous paper[4]; that is,

$$\gamma_{\mu\nu}=\frac{e^2}{a_{\mu\nu}+r_{\mu\nu}}$$

where $r_{\mu\nu}$ is the interatomic distance between the μ and ν atoms.

$a_{\mu\nu}$ is a characteristic constant which is given by

$$\frac{e^2}{a_{\mu\nu}}=\frac{I_\mu+I_\nu-A_\mu-A_\nu}{2}$$

where I_μ and A_μ are the valence state ionization potential and the electron affinity of the μ atom respectively. The core integrals, I_μ and $\beta_{\mu\nu}$, are estimated in the following manner:

i) In case both ϕ_μ and ϕ_ν are carbon 2pπ AO's, we assume that:

a) I_μ is the valence state ionization potential of the carbon atom

b) $\beta_{\mu\nu}=\beta_{CC}$ for the $\mu\nu$ bond

c) $\beta_{\mu\nu}=0$, if μ and ν are nonneighbors

In this case, $\mathscr{H}_{\mu\mu}$ and $\mathscr{H}_{\mu\nu}$ can be rewritten as follows:

$$\mathscr{H}_{\mu\mu}=-y_c+\frac{1}{2}(1-q_\mu^\nu)\gamma_{\mu\mu}+\sum_{\nu\neq\mu}(2-q_\nu^0-q_\nu^\nu)\gamma_{\nu\mu}=-y_c+G_{\mu\mu}$$

$$\mathscr{H}_{\mu\nu}=\beta_{cc}+\frac{1}{2}p_{\mu\nu}^\nu\gamma_{\mu\nu}=\beta_{cc}+G_{\mu\nu} \qquad (9)$$

where y_c and q_ν^0 are the valence state electronegativity of the carbon atom and the core charge of the ν atom respectively. By definition,

$$G_{\mu\mu}=\frac{1}{2}(2-q_\mu^0-q_\mu^\nu)\gamma_{\mu\mu}+\sum_{\mu\neq\nu}(2-q_\nu^0-q_\nu^\nu)\gamma_{\nu\mu}$$

$$G_{\mu\nu}=\frac{1}{2}p_{\mu\nu}^\nu\gamma_{\mu\nu}$$

ii) In case either ϕ_μ or ϕ_ν is a heteroatom 2pπ AO, we assume that:

$$\mathscr{H}_{\mu\mu}=-y_c+\delta_\mu\beta_{cc}+\frac{1}{2}(2-q_\mu^0-q_\mu^\nu)\gamma_{\mu\mu}+\sum_{\nu\neq\mu}(2-q_\nu^0-q_\nu^\nu)\gamma_{\nu\mu}=-y_c+\delta_\mu\beta_{cc}+G_{\mu\mu}$$

$$\mathscr{H}_{\mu\nu}=k_{\mu\nu}\beta_{cc}+G_{\mu\nu} \qquad (10)$$

where we assign the same values as in Eqs. 3 and 4 for δ_μ and $k_{\mu\nu}$. $(2-q_\mu^0-q_\mu^\nu)$ gives the net charge of the μ atom. Substituting Eqs. 9 and 10 into Eq. 8, we obtain the following expression:

$$\bar{\varepsilon}_i=-y_c-x_i\beta_{cc}+\sum_{\mu\nu}C_{i\mu}C_{i\nu}G_{\mu\nu}$$

where x_i has the same value as in Eq. 5. The numerical estimation of β_{cc} is carried out by a semi-empirical procedure to fit the observed spectra.

D) Oscillator Strength. — The oscillator strength, f, associated with a one-electron

4) K. Nishimoto and N. Mataga, *Z. physik. Chem.* [*N. F.*), **12**, 335 (1957); N. Mataga and K. Nishimoto, ibid., **13**, 140 (1957).

transition from Ψ_a to Ψ_b is given by Mulliken and Rieke[5] as follows:

$$f=1.085\times10^{11}\tilde{\nu}_{ab}D_{ab}^2$$

where $\tilde{\nu}_{ab}$ is the frequency of the transition in cm^{-1}. D_{ab} is the so-called transition moment which is defined by

$$D_{ab}=\int\Psi_a\sum_i e_i r_i\Psi_b\,dv$$

where e_i and r_i are the charge and the position vector of the ith charged particle respectively. From the calculation of D_{ab}, we can know the direction of the polarization of the transition. The knowledge of the direction of the transition moment is not only useful for the classification of the electronic state, but also plays an important role in the study of intermolecular interaction[6].

Application to the Spectra of Hydroquinone and Phloroglucinol

We have also applied the method to the π-electronic spectra of hydroquinone, phloroglucinol and parent hydrocarbon, benzene. The parameters used are collected in Table I. Many of them are the same as those of phenol[3]. The core structures of the molecules are shown in Fig. 1. The calculated MO's are given in Table II. In the calculation of configuration interaction, the four lowest singly excited singlet configurations, $\chi^1{}_{1\to1'}$, $\chi^1{}_{1\to2'}$, $\chi^1{}_{2\to1'}$ and $\chi^1{}_{2\to2'}$, and the ground state, χ_0, are taken into account. The calculated molecular integrals are collected in Table III. Other kinds of integrals not involved in the table be come to zero. The $\bar{\varepsilon}_i$'s correspond formally to the orbital energies in the sence of the self-consistent field method. Therefore, $\bar{\varepsilon}_1$'s are regarded as the calculated apparent first ionization potentials. With same reason $\bar{\varepsilon}_{1'}$'s are regarded as calculated electron affinities. From the table we expect that the magnitudes of first ionization potentials are in the order; benzene > hydroquinone > phloroglucinol. Similarly, the order of electron affinity should be benzene > hydroquinone > phloroglucinol. Unfortunately, experimental data to be compared with our calculated ones are not available. The calculated electronic state energies E_a and the corresponding electronic state functions Ψ_a are given in Table IV. The results in this table show that the calculated excitation

energies agree satisfactorily with the observed ones. It is natural results that β_{cc}'s have different values for various molecules, because the π-electron distribution varies from molecule to molecule. From the calculation of transition moment, $D_{0\to a}$, we can show that all Ψ_1's given in the table have the polarization in the direction of x axis, whereas all Ψ_2's have the polarization in the direction of y axis. This fact means that the Ψ_1's of hydroquinone and of phloroglucinol may be regarded as modified Ψ_1 of benzene, on the other hand, the Ψ_2's of them may be regarded as modified Ψ_2 of benzene. This situation is shown in Fig. 2.

Summary

A semi-empirical theory of the π-electronic spectra of aromatic derivatives based on anti-symmetrized molecular orbital method is given and is applied to the calculations of the singlet π-electronic states of hydroquinone and of phloroglucinol. In the theory the core integrals over AO's of heteroatoms are expressed as the functions of the core integrals over carbon atom $2p\pi$ AO's. The calculated excitation energies for these molecules agree satisfactorily with the observed ones. In addition, our calculations give some informations with respect to the nature of their electronic state and their first ionization potentials.

The authors express their gratitude to Dr. Noboru Mataga for his helpful discussion.

Electronic Structures and Spectra of Non-benzenoid Hydrocarbons: Fulvene, Heptafulvene, Fulvalene, Heptafulvalene and Sesquifulvalene

By Takeshi NAKAJIMA* and Shigeyoshi KATAGIRI

(Received October 11, 1961)

Fulvene, the most fundamental non-benzenoid hydrocarbon, has received considerable attention from both theoretical and experimental points of view. Among previous theoretical treatments[1-4], François and Julg's recent calculations of the dipole moment and spectrum have been in quite satisfactory quantitative agreement with the experimental information. Compared with fulvene, however, its seven-membered analogue, heptafulvene, has been relatively little studied either theoretically or experimentally. Only recently has the attempted synthesis of heptafulvene succeeded[5]. Earlier theoretical treatments of heptafulvene[1,2] have achieved notable success in pointing out the basic causes for its dipole moment and color, but quantitative agreement with the experimental values has not been very satisfactory.

On the other hand, Doering[6] has recently reported the synthesis of the interesting non-benzenoid hydrocarbons, fulvalene and heptafulvalene, together with their ultraviolet-visible spectra. Furthermore, their even more interesting relative, sesquifulvalene, which consists, so to speak, of joined five- and seven-membered rings, has been long exposed to repeated attempts to synthesize it. Earlier theoretical predictions of the spectra of fulvalene[7-9] and heptafulvalene[9] have proved to be far from satisfactory when compared with the now available experimental data.

The aim of this paper is to add, in view of these circumstances, to the understanding of the structures and spectra of heptafulvene and fulvalenes through an attempt to calculate these by a theoretical method within the framework

of the LCAO MO approximation. The method starts from the Fock self-consistent orbital equations. These are simplified by approximation of the Fock matrix elements; at the same time, special attention will be paid to the marked bond alternation inherent in these molecules. To test the validity of this method, it will be applied first to fulvene.

Method and Procedure

It will be noted at the outset that the fulvenes and fulvalenes that concern us belong to the class of molecules called "classical",[10] a typical example of which is a linear polyene such as butadiene, and therefore that all these molecules are expected to exhibit a bond alternation to almost the same considerable degree as butadiene does. The carbon skeleton structure of fulvene, heptafulvene, fulvalene, heptafulvalene and sesquifulvalene are taken as in Fig. 1, with the lengths of the single and double bonds set equal to 1.48 and 1.34 Å respectively, as in butadiene[11], the rings being assumed to be regular in all cases.

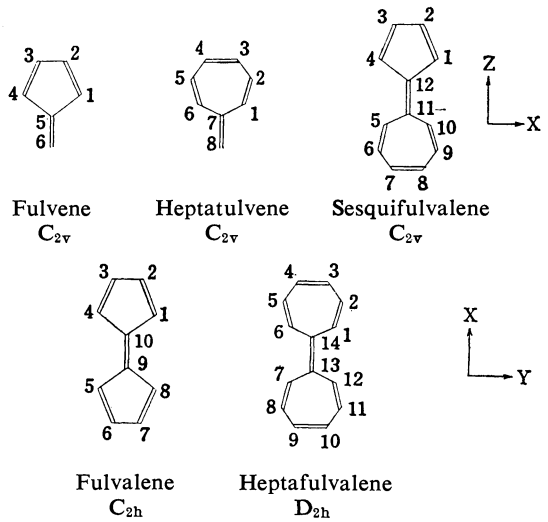

Fig. 1. Carbon skeleton, choice of axes, and numbering of non-benzenoid hydrocarbons.

According to the self-consistent orbital theory[12], the orbital energies of a conjugated hydrocarbon are obtained by solving the Fock secular equation,

$$| F_{pq} - S_{pq}\varepsilon | = 0 \qquad (1)$$

where F_{pq} is the Fock matrix element and S_{pq} the overlap integral between atoms p and q. The simplifying approximations that we make in order to build and solve the Fock equations for conjugated hydrocarbons are as follows: (a) The overlap integral, S_{pq} is neglected unless $p=q$, in which case it is unity. (b) The diagonal Fock elements, F_{pp}, are taken as empirical parameters, α_p^F and the off-diagonal ones, F_{pq}, as parameters, β_{pq}^F for nearest neighbors, and zero otherwise[13]. The Fock secular equations thus reduce to expressions involving empirical parameters analogous to those in the Hückel theory. (c) All the carbon atoms are presumed to have the same α^F. The energy zero is therefore assumed to be such that $\alpha^F=0$, and energies are computed in units of one of the β_{pq}^F in the same manner as in the Hückel theory.

In setting up the Fock equations for the non-benzenoid hydrocarbons that concern us, we introduce, in addition to the above simplifying parameters, the bond alternation parameter defined by

$$\gamma = \beta_{\text{single}}^F / \beta_{\text{double}}^F, \qquad (2)$$

where the subscripts single and double mean the single and double bonds in the Kekulé structures respectively. The value for γ used throughout this paper is so chosen as to reproduce, with the above simplifications of the secular equation, the self-consistent orbitals of butadiene (trans) calculated by using the standard self-consistent field technique. This makes practically unnecessary successive solutions of the Fock equations to find the self-consistent orbitals and so they are not allowed for in this paper. Of the self-consistent orbitals of butadiene so far reported[14-16], we take Lefebvre and Moser's as the reference orbitals to determine the value of γ. The reason for this choice is that in Lefebvre and Moser's procedure, the overlap is neglected, as in the present procedure, and the Coulomb repulsion integrals necessary for the spectral calculations were estimated using the same approximation (Pariser and Parr's) as will be used in this paper (vide infra). The value for γ with which Lefebvre and Moser's orbitals can be reproduced was found to be equal to 0.55[17].

10) A classical molecule is defined as one for which only a single (unexcited) resonance structure can be written.

17) In butadiene, the ratio of the Fock element for the single bond (−3.3 eV.) to that for the double bond (−6.5 eV.) actually proves to be about 0.5, while the ratio of the core resonance integral for the single bond (−2.40 eV.) to that for the double bond (−2.95 eV.) is about 0.8; for the numerical values, see A. Julg, *J. chim. phys.*, **57**, 19 (1960).

The electron transition energies are calculated by the following formula, no configuration interaction being allowed for:

$$\left.\begin{matrix}{}^1E_{ij}\\ {}^3E_{ij}\end{matrix}\right\} - E_N = (\varepsilon_j - \varepsilon_i) - (J_{ij} - K_{ij}) \pm K_{ij} \qquad (3)$$

where E_N, ${}^1E_{ij}$, and ${}^3E_{ij}$ designate the energy of the ground, excited singlet, and excited triplet states respectively, the electronic excitation being from i to j. J_{ij} and K_{ij} are the Coulomb repulsion and exchange repulsion integrals in terms of molecular orbitals. Neglecting differential overlap, these may be rewritten in terms of Coulomb repulsion integrals over atomic orbitals. The integrals of the latter type are evaluated using Pariser and Parr's procedure[18]. Orbital energies are computed in units of β^F_{double}. The value for β^F_{double} was determined so as to reproduce, by application of Eq. 3, the observed energy of the lowest singlet transition ($B_{1u} \leftarrow A_{1g}$), i. e., 5.9 eV. of *trans*-butadiene, and was found equal to -7.0 eV. The oscillator strengths are calculated on the basis of the well-known formula:

$$f = 1.085 \times 10^{11} \nu Q^2 \qquad (4)$$

where Q designates the transition moment.

Results and Discussion

The calculated transition energies and oscillator strengths are summarized and compared with experimental data in Tables I. Tables II, III, IV, V and VI present the molecular orbitals and energies of fulvene, heptafulvene, fulvalene, heptafulvalene and sesquifulvalene respectively. The bond orders and charge densities are also included in these Tables.

Fulvene. — Comparison of the calculated orbitals with those so far obtained by using the SCF technique, among others, Francois and Julg's orbitals, which have been calculated with the same skeleton structure as assumed in this paper, shows that these two sets of orbitals agree well with each other. Further, application of Coulson's formula for bond order vs. bond distance[19] predicts 1.35 Å for the double bonds and 1.47 to 1.48 Å for the single bonds, while the assumed lengths are 1.34 and 1.48 Å respectively, the situation being satisfactorily self-consistent. The calculated dipole moment proves to be 1.14 D, which is in remarkable agreement with the experimental value, 1.1 D.[20] The direction of

The C_{pi} corresponding to $(\chi_5\pm\chi_8)$ and $(\chi_6\pm\chi_7)$ are the same as those corresponding to $(\chi_1\pm\chi_4)$ and $(\chi_2\pm\chi_3)$, respectively, for MO's of symmetry b_{1u} and a_{1u} and different in sign from these for MO's of symmetry b_{2g} and b_{3g}.

c) + and − refer to MO's of symmetry b_{1u} and b_{2g}, respectively.

the moment is such that the ring is negative with respect to the methylenic group.

The lowest singlet transition corresponds to a $^1B_1\leftarrow{}^1A_1$ electronic transition, with its moment directed along the short axis, whereas the next singlet corresponds to an $^1A_1\leftarrow{}^1A_1$ transition with its moment directed along the long axis. The predicted energies of these singlet transitions are in remarkably good agreement with the experimental values[20]. The calculated f value for the lowest singlet transition is lower than that for the next one, which is in agreement with the order of magnitude of the experimental f values. However, as is often the case[21], the absolute values of the calculated f values are too high. A correction factor of 0.30 is introduced, which is the ratio of f_{obs} to f_{calcd} for the lowest allowed singlet transition in benzene. It will be seen that the corrected values accord well with the observed ones.

The validity of the present theoretical approach is thus demonstrated by the results for the spectrum as well as for the dipole moment of fulvene.

Heptafulvene.—The bond lengths predicted from the bond orders, 1.48 Å for the single bonds and 1.34 to 1.35 Å for the double bonds, are in satisfactory agreement with the assumed lengths. The dipole moment was calculated to be 0.63 D, reduced considerably from the value, 4.6 D, predicted by the conventional Hückel

a) See footnotes to Table II.

theory[1]. No experimental dipole moment data for heptafulvene are available. However, a comparison may be made with an experimentally estimated moment, e. g., the value of about 0.7 D estimated from the observed moment of tropone[22]. The direction of the moment is such that the ring is positive, contrary to the case of fulvene, with respect to the exocyclic carbon atom. This contradicts the prediction based on the non-empirical SCF theory[1] but accords with the conclusions put forward on the basis of the conventional Hückel[1] and semi-empirical SCF theories[2].

No unambiguous spectral assignment in heptafulvene has been made so far. According to the results of the present calculations, the first long wavelength absorption band, with its maximum at 427 mμ, is assigned to a $^1B_1\leftarrow{}^1A_1$ transition (transverse polarization), and the next band, at 280 mμ, to an $^1A_1\leftarrow{}^1A_1$ transition (symmetry-axis polarization). The expected energies for these two transitions are in good agreement with the experimental values. In addition, the relative order of magnitude of the calculated oscillator strengths for the two transitions is consistent with these assignments. If, further, a correction factor of 0.30 is introduced, the calculated and experimental f values are brought into good agreement in their numerical values.

Fulvalene.—The calculated bond lengths are 1.35 to 1.36 Å for the double bonds and 1.47 to 1.48 Å for the single bonds. These are in fairly good agreement with the assumed lengths.

Brown[7] and Pullman and Berthier[8] have discussed the orbitals and spectrum of fulvalene on the basis of the conventional Hückel theory.

22) Y. Kurita et al., This Bulletin, 26, 272 (1953). See also M. Yamakawa et al., *J. Am. Chem. Soc.*, 82, 5665 (1960). The latter authors have estimated a value of 3.07 D from the observed moment of heptafulvene dinitrile. This unreasonably high value for the moment of heptafulvene is not compatible with the results of the present calculation. On the other hand, one of the present authors and his associates have independently measured the moment in heptafulvene dinitrile and estimated from it the moment of heptafulvene to be from 0.7 D to 1.0 D; S. Katagiri et al., (to be published).

The predicted orbitals and spectrum possess the following curious features: (a) The lowest vacant orbital is bonding in the sense that its energy value is positive in β units. (b) If electron interactions are taken into account using Eq. 3, the first and second excited states of symmetries B_{1g} and B_{2u} respectively prove to be lower in energy than the ground state (A_{1g}), which implies that the lowest energy state is not totally symmetric. (c) If the value $\gamma=23$ k.cm^{-1}*, which was found to be moderately successful in accounting for the spectra of the ring conjugated hydrocarbons[23], the lowest allowed singlet transition, with excitation energy $0.296\,\gamma$ is predicted to appear in the infrared. These are somewhat unexpected, since in no known hydrocarbons have such circumstances been known to occur. The orbitals of fulvalene calculated by using the present procedure show no such unusual features. The lowest vacant orbital is very sensitive to bond alternation and becomes anti-bonding in the sense that its energy value is now negative.

The fulvalene absorption spectrum shows an intense band characterized by a series of comparatively sharp maxima, which is no doubt due to the vibrational fine structures and culminates in a maximum at 314 mμ, and a weak maximum at 416 mμ, followed by long tailing into the visible[6,24]. The calculated transition energies and oscillator strengths are compared with the experimental values in Table I. The longer wavelength weak maximum is assigned to the electronic transition ($^1B_{2u}\leftarrow{}^1A_{1g}$), with its moment directed along the short axis, whereas the shorter wavelength strong maximum is assigned to the transition ($^1B_{3u}\leftarrow{}^1A_{1g}$), with its moment directed along the long axis.

Heptafulvalene.—The predicted bond lengths, 1.35 to 1.36 Å for the double bonds and 1.47 to 1.48 Å for the single bonds, are in fairly good agreement with the assumed lengths.

Heptafulvalene molecular orbitals calculated on the basis of the conventional Hückel theory[9] are similar in their unusual features to the fulvalene Hückel orbitals; that is, the top occupied orbital is anti-bonding in the sense that its energy value is negative in β units, and if electron interactions are taken into account, the lowest energy state loses its total symmetry. Further, the lowest allowed transition is predicted to appear in the infrared, which is not supported by the experimental facts now available.

The top occupied orbital of heptafulvalene is calculated to be bonding in the present procedure. Bond alternation stabilizes it considerably. The absorption spectrum of heptafulvalene shows an intense maximum at 362 mμ ($\log\varepsilon=4.32$), followed by an almost linearly decreasing absorption throughout the visible region[6,24]. According to the results of the present calculations of transition energies and oscillator strengths, it appears that the intense maximum at 362 mμ is to be assigned to an electronic transition ($^1B_{3u}\leftarrow{}^1A_{1g}$), with its moment directed along the long axis, and that the long tail is composed of one singlet-allowed transition ($^1B_{2u}\leftarrow{}^1A_{1g}$), with its moment directed along the short axis, one singlet-forbidden transition ($^1B_{1g}\leftarrow{}^1A_{1g}$), and three triplet transitions.

Sesquifulvalene.—The calculated distribution of bond orders reproduces fairly well the assumed bond lengths. In this connection, it is interesting to note the order of the central bond calculated on the basis of the conventional Hückel theory. The Hückel bond order of this bond is 0.446[9], which is particularly small as an order of double bonds[25]. This is not consistent with the high double bond character of the central bond expected from the fact that only a single Kekulé structure can be written for sesquifulvalene.

The predicted dipole moment is 3.0 D, reduced considerably from the value of about 12 D predicted using the conventional Hückel theory. The direction of the moment is such that the negative pole is directed toward the pentagonal ring. This accords with the expectation based upon the aromatic sextet rule.

Sesquifulvalene Hückel orbitals show no peculiar characteristics such as those seen in fulvalene and heptafulvalene Hückel orbitals. The top occupied orbital is positive, and the lowest vacant orbital is negative in β units. Neither of the orbitals is so sensitive to bond alternation as in fulvalene and heptafulvalene.

As for the predicted spectrum of sesquifulvalene, it should be noted that the lowest singlet transition is expected to correspond to an $^1A_1\leftarrow{}^1A_1$ electronic transition polarized along the long axis*. The electronic transitions ($^1B_1\leftarrow{}^1A_1$) polarized along the short axis are expected to be considerably higher in energy than the corresponding transitions in fulvalene and heptafulvalene.

* For the spectral calculations in the conventional Hückel approximation, orbital energies are corrected for the overlap and written in units of γ instead of β.

23) J. R. Platt, *J. Chem. Phys.*, **18**, 1168 (1950).

24) W. von Doering, private communication.

25) It is noted that the Hückel bond order of the central single bond of butadiene is 0.447.

* *Note added in proof*: Very recently Prinzbach and his associates have reported the synthesis of sesquifulvalene; see Prinzbach et al., *Angew. Chem.*, **73**, 169, 543 (1961). The absorption spectrum of sesquifulvalene shows an intense maximum at 404 mμ ($\log\varepsilon=4.4$) which may be assigned to the lowest singlet transition ($^1A_1\leftarrow{}^1A_1$).

Summary and Conclusion

It appears now well established that in fulvene, heptafulvene, and the fulvalenes that we have dealt with in this paper, there is a remarkable difference in length between the single bonds and the double bonds, the bond alternation being substantially in a degree comparable to that in open chain polyenes. The foregoing calculations show that the assignment of a value of 0.55 to the bond alternation parameter is essential for the theoretical elucidation of the electronic structures and spectra of these molecules. In conclusion, it may be said that although all the above molecules can be shown to be endowed a priori with an aromatic character on the basis of Craig's criterion[26], none of them can, from the viewpoint of bond alternation, be regarded, as a matter of fact, as belonging to the "aromatic" category in a traditional sense. They have, rather, characteristics of the cyclic polyolefins. Indeed, neither fulvene, heptafulvene, fulvalene, nor heptafulvalene has been shown to exhibit the chemical integrity characteristic of the so-called aromatic hydrocarbons[5,6].

The authors would like to thank Professor William von Doering for sending us copies of the ultraviolet spectra of fulvalene and heptafulvalene prior to publication. They are also grateful to Professors Hiroshi Azumi and Yoshio Kitahara for their continued interest during this work.

Studies on Micro-paraffin. VI. Properties of the Micro-paraffin

By Kazuo NEGORO

(Received March 22, 1961)

Although micro-paraffin has been reported[1] to consist of side-chain hydrocarbons, the author has considered the problem from different standpoints and has confirmed that micro-paraffin contains a considerable amount of straight-chain compounds and that the carbon number is slightly larger than that of crystalline paraffins[2,3]. When crystalline wax or *n*-dotriacontane was crystallized in the presence of those organic compounds with a hydroxyl group attached to the benzene ring and of a similar molecular structure, it was observed that micro-crystallization occurred[4]. The alcohol-extracted fraction obtained by chromatography from those asphalt components which had been isolated from micro-paraffin was also found to give micro-crystallization effects, and its ultraviolet and infrared spectra revealed that it also had the same hydroxyl groups and benzene ring as other pure organic compounds.

The present paper deals with the properties of the micro-paraffin from the above viewpoints.

Results and Discussion

The Micro-crystallizing Properties of the Micro-paraffin are Caused by Secondary Factors. —Although micro-paraffin has previously been reported to consist mainly of isoparaffin[5,6], about 60% of the micro-paraffins have been found by the present study to be urea-adductible when treated by the urea method. None of these urea-adductible paraffins are *n*-paraffins, because paraffins having few side-chains and long carbon chains are urea-adductible[7]. However, the fraction, which was obtained by treating the urea-adductible paraffins by chromatography with silica gel and then extracting it by pentane, was found to be straight-chain crystalline paraffin. Namely, the micro-paraffin forms micro-crystals, as is shown in Fig. 1, and its

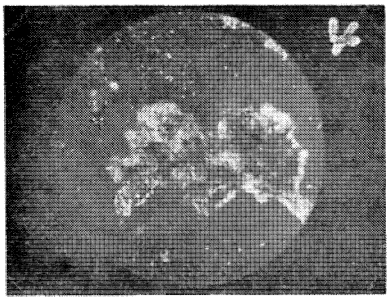

Fig. 1. Micro-crystals of the micro-paraffin.

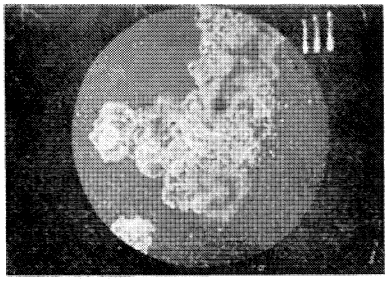

Fig. 2. Crystals of the pentane fraction which had been obtained from the urea-adductible paraffin by chromatography.

X-ray diffraction curve shows that the crystals are imperfect. However, the author recognized that the pentane fraction of the chromatography, with urea-adductible paraffin, formed tabular crystals similar to those of crystalline paraffin and *n*-paraffin[2,8], as is shown in Fig. 2, and that the X-ray diffraction pattern was similar to those of crystalline paraffin and *n*-paraffin[3].

As described above, a considerable amount of *n*-paraffin was clearly contained in micro-paraffin, and so it is not true that the micro-paraffin is essentially micro-crystallized paraffin with side-chains. The ordinary paraffin waxes consist mainly of *n*-paraffin and contain a small quantity of low melting point hydrocarbons and probably side-chain paraffins[9-12].

According to the reports of the compositions of crystalline paraffins obtained by the mass spectrum analysis method[13,14], they consist of 80~95% *n*-paraffin, 5~15% isoparaffin, 1~10% cycloparaffin, and 0~0.9% alkylbenzene, though there are small differences corresponding to the sorts of crude oils. On the contrary, studies of the compositions of micro-paraffins have very seldom been reported; Ridenour et al.[15], however, recently explained that the quantities of urea-adducting material contained in the three sorts of micro-paraffins were 47, 60 and 20% respectively.

** Measured by the methods described in a previous report[2].

quantity of urea-adductible paraffins which were almost *n*-paraffins was about 60%; furthermore, micro-paraffin showed crystalline properties when isolated by the above treatment.

Clark[16] has described how hydrocarbons (carbon number 26) having alkyl groups, or a naphthene or benzene ring, etc. at any position of the structure, formed crystals as well as *n*-paraffins. From the above facts, it can be deduced that the peculiar micro-crystallization of the micro-paraffin is caused by secondary, not essential, factors.

Micro-crystallizing Substances.—As has been previously described[2], the paraffin formed crystals when asphalt components were removed perfectly from the micro-paraffin by applying the propane de-asphalting method. Therefore, the author considered that original substances for forming fine crystal grains would be present in the asphalt component. Asphalt components form amorphous crystals and are mixtures of various compounds. By chromatography through

16) E. W. Clark, *Ind. Eng. Chem.*, 43, 2526 (1951).

a column packed with alumina gel, the asphalt components were separated into three fractions by being extracted by pentane, benzene and ethyl alcohol. The properties of each fraction were measured, and the results are shown in Table II and in Figs. 3 and 4.

The last absorption band changed to a deep color when the side-chain numbers increased in benzene derivatives. The last absorption band of the asphalt components was 277 mμ, which represented a shift of about 9 mμ from that of the benzene of no side-chains[17], and substances having some side-chains of benzene ring were considered to be present in the asphalt components. Therefore, small amounts of various series of aromatic hydrocarbons besides such benzene derivatives, were also contained in each fraction.

The crystal band was observed at 723~717 cm^{-1} in the infrared spectrum of the pentane fraction of asphalt components (as has also been found in *n*-dotriacontane or crystalline paraffin). This fraction of asphalt components was almost the same as the ordinary paraffin waxes, and if the fraction was added to crystalline paraffin (m. p. 53.5°C, mean carbon number 28) or *n*-dotriacontane (m. p. 69.5°C, carbon number 32), micro-crystallization effects could not be observed, as is shown in Figs. 5 and 6*.

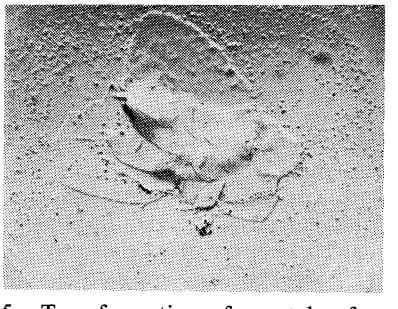

Fig. 5. Transformation of crystals of crystalline paraffin caused by the addition of the pentane fraction of asphalt components (almost no transformation).

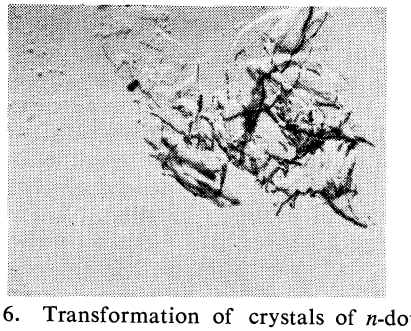

Fig. 6. Transformation of crystals of *n*-dotriacontane caused by the addition of the pentane fraction of asphalt components (almost no transformation).

17) "Hydrocarbon Chemistry (Tankasuiso Kagaku)", Vol. 2, Kyoritsu Shuppan, Tokyo (1956), p. 69.

The crystal band was not seen in the infrared spectrum of the benzene-extracted fraction, and it was shown to be amorphous. Therefore, this fraction caused almost no transformation when added to *n*-paraffin.

In the case of an alcohol-extracted fraction, the author discovered that the addition of a small amount of crystalline paraffin formed fine crystal grains, as is shown in Fig. 7; it was also clearly observed, as is shown in Fig.

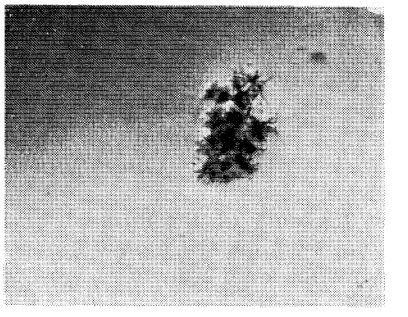

Fig. 7. Transformation of crystals of crystalline paraffin caused by the addition of the alcohol fraction of asphalt components (micro-crystallized).

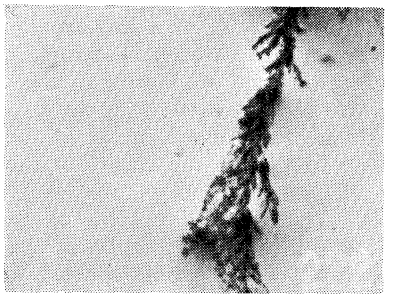

Fig. 8. Transformation of crystals of *n*-dotriacontane caused by the addition of the alcohol fraction of asphalt components (micro-crystallized).

8, that the fraction caused a remarkable transformation of crystals on *n*-dotriacontane[4], on which the asphalt components themselves had almost no noticeable effects. Therefore, the residues of the asphalt components were recognized as showing small micro-crystallization effects.

From the data of the infrared spectrum of the alcohol fraction, the atomic groups present in the fraction were deduced as shown in Table III.

The absorption band which originated in hydroxyl groups at 3410 cm^{-1} was remarkably attractive. As has previously been described[4], the infrared spectra of Santopour, picric acid, and *p*-hydroxydiphenyl formed fine crystal grains of crystalline paraffin or *n*-dotriacontane, as is shown in Fig. 9. In each spectrum, however, the absorption band originating in the carboxyl groups was seen at 3190~3520 cm^{-1}.

The shape of the above curves of the spectra was very similar to the curves of the spectra of the alcohol fraction of the asphalt components. The infrared spectra of Santopour and those of the alcohol fraction of the asphalt components (in the whole sphere) were very similar, and it was concluded that their structures were similar, too.

Santopour has been reported to be 2, 3, 5, 6-tetraalkylbenzene[18],  and its mean molecular weight was measured to be 265. The alkyl chains at the 4 radicals of the benzene ring were therefore considered to consist of C_4.

If the alcohol-extracted fraction, isolated from the asphalt components, had a structure like Santopour, the length of the methylene chain was presumed to be C_{34}, because its molecular weight was 571. Therefore, the alcohol fraction was considered to have parts of alkyl chains much longer than Santopour.

It is noticeable that the formation of fine crystal grains of paraffin is caused in the presence of the compounds of similar structures having hydroxyl groups and benzene rings.

Crystal Structure of the Micro-paraffin. — Many studies have been made on the crystals of *n*-paraffin[19-23]; its unit cell has been reported to form hexagonal, orthorhombic, monoclinic, or triclinic system, according to the sort of individual hydrocarbons and the temperature. As has been mentioned above[3], the crystal systems of paraffin waxes and micro-paraffins were orthorhombic.

The values of d_{110} and d_{200}, the length of the a and b axis, the cross-sectional area occupied by one molecule, and the molecular volume were calculated; the results are shown in Table IV.

The above values on crystal lattice are mean values, because micro-paraffin is a mixture of various hydrocarbons. The tips of carbon chains are not arranged in order. It seems to be reasonable to consider that its lattice spacings are somewhat larger than those of *n*-paraffin and that its side-chains are seen at some places of the paraffin chains. In particular, the values of both d_{110} and d_{200} of the urea non-adducting paraffins, isolated from the micro-paraffin by the urea method, were so large that it was proved to have many side-chains.

According to Edwards[24], the development of crystal lattice was affected by the molecular weights of hydrocarbons and by the presence of non-*n*-hydrocarbons. The mean carbon chain of micro-paraffins was somewhat longer than that of ordinary crystalline paraffins, and the molecular volume was nearly 20~30% larger than that of ordinary paraffins.

Several peaks of the X-ray diffraction curve of 001, 002, etc. were seen in the case of the crystalline paraffin of *n*-dotriacontane, but the

Urea-adducting micro-paraffin, pentane fraction	4.16	3.75	7.50	5.01	18.8	867
Urea non-adducting micro-paraffin, pentane fraction	4.20	3.79	7.56	5.04	19.0	909
n-Dotriacontane	4.15	3.77	7.54	5.03	19.0	804

peak was only one in the case of the micro-paraffin[3]. Moreover, the peaks of less than 002 in the urea-adducting materials of micro-paraffin and its pentane-extracted fraction revealed that their crystal structures resembled those of *n*-paraffin. This presumption was verified by observation of the crystal structure of paraffins traced on a carbon film with an electron microscope by applying the replica method[25,26].

Micro-crystallization Phenomenon. — A few reports have been made on the spiral growth of the crystal of *n*-paraffin[27-29]; it was studied by the present author[8] and also by Jaccordine[30] with a phase-contrasts microscope on paraffin crystals. Asphalts resins or dark color substances, etc. in petroleum inhibited the crystallization of paraffins[31] in the case of ordinary paraffin waxes, and very slight dust particles prevented the grow-step of the crystal growth[29] in the studies of the spiral growth.

The author has already reported several phenomena revealing that the formation of fine crystal grains of micro-paraffin is caused by secondary factors[2-4,32] and has discussed the cause of the micro-crystallization phenomena.

The relation between the concentration of Santopour, picric acid, *p*-hydroxybiphenyl, and the alcohol fraction of asphalt components and log ε at each wavelength are shown in the graphs. Therefore, 10 mg. of each organic compound was added to 100 mg. of the crystalline paraffin or *n*-paraffin to crystallize, and the mother liquor was taken out to measure the log ε, which was plotted in the above graphs for investigation. However, the amount of each organic compound in the liquor was discovered to be not very different from that previously added, even taking into consideration the effects of the presence of paraffin on the log ε. Accordingly, it may be surmised that very few compounds are contained in the crystal lattice of paraffin.

Moreover, the amount of crystallized paraffin was weighed, and the crystal growth of 100 mg. of the crystalline paraffin (m. p. 53.5°C) was inhibited by the presence of such organic compounds; the non-crystallized amounts have been calculated and are shown in Table V.

TABLE V. CHANGE IN AMOUNTS OF THE PARAFFIN CRYSTAL CAUSED BY SOME SORTS OF ORGANIC COMPOUNDS

Name of Compounds	Crystallized amount, mg.	Non-crystallized amount, mg.
—	94.1	5.9
Picric acid	69.9	30.1
Santopour	67.2	32.8
p-Hydroxydiphenyl	66.2	33.8
Alcohol fraction of asphalt components	64.5	35.5

It was made clear by those results that the crystallization of the paraffin was fairly much inhibited by the presence of such organic compounds. As has been described previously, micro-paraffin contained more side-chain components than the crystalline paraffin; therefore, its crystal growth was more prevented, and its tendency to inhibit crystallization was larger than that of crystalline paraffin. Accordingly, it seems reasonable to consider that the formation of fine crystal grains of micro-paraffin is made possible by the presence of the alcohol fraction, which has been separated from micro-paraffin materials and which is supposed to have a structure consisting of an alkyl chain and a benzene ring with hydroxyl groups.

The compounds with a similar structure wrap up the paraffin molecules in the crystallization of paraffin and inhibit the formation of the crystal lattices by a continuous arrangement of paraffin molecules to form larger crystals. As a result, the crystallization is partially prevented, and the formation of fine crystal grains occurs. Very small tabular crystals are also rolled up to form needle crystals, by which the direction perpendicular to the 110° side agrees with the length for the smaller surface area and the more stable form before the crystals grow up in the direction of a and b axes.

Experimental

Chromatography. — Fifty grams of an asphalt component isolated from the tank residues of Arabian crude oil (Aramco oil of Saudi-Arabia)[32] was extracted by a Soxhlet extractor at 50~60°C with 1 l. of purified benzine (b. p. 50~60°C) for about 10 hr. The benzine-extracted components were isolated from the insoluble components by filtration. The yields were 39 and 12 g. respectively. The system for chromatography consisted of 5 columns 100 cm. long and 2 cm. in diameter and of 5 columns 75 cm. long and 1.5 cm. in diameter; all the columns were packed with 1.6 kg. of 200 mesh alumina gel (a product for chromatography, manufactured by the Kanto Kagaku Co.). Then, the benzine-extracted-components solution was poured into the top of the first column. The refractive index of the elute solution showed a larger value than that of benzine. Then the solution was poured into the second column. The index was examined successively at each column, and the last index agreed with that of benzine. Then it was extracted by 52 l. of pentane (b. p. 40~50°C), 67 l. of purified benzene (b. p. 80°C), and 42 l. of purified ethyl alcohol (b. p. 78°C), successively and classified into its extracted fractions. In this case, the index of each solvent had been measured previously; as well, each index of each elute solution was examined. It was extracted by the same solvents (pentane, benzene and ethyl alcohol) until the latter value agreed with the former. Then, each extracted fraction was obtained by using the above amounts of the solvents.

X-Ray Diffraction and Absorption Spectra.—A X-ray diffractometer (Geiger flex, manufactured by the Rigaku Denki Co.) was used for the measurement of the X-ray diffraction[33]. The samples were fixed on glass, and the measurements were made in the range of 0°~90° of 2θ (scanning speed, 1 deg./min.) and 25~31° (scanning speed, 1/4 deg./min.) with FeK_α, and in the range of 0~5° (scanning speed, 1 deg./min.) with CuK_α.

As has already been reported[2], the sample solution of purified *n*-hexadecane was prepared by the weighing method, and a photo-electric spectrophotometer of type EPU-2 (manufactured by the Hitachi Mfg. Co.) was used for the measurement of the ultraviolet spectrum. An infrared spectrophotometer (Perkin Elmer Model-21) with a sodium chloride prism was used for the measurement of the infrared spectrum. As has previously been reported[2], each sample of the various paraffins or the asphalt components was applied to the spectrophotometer for measuring. However, organic compounds were measured by the Nujol method with purified liquid paraffin.

Action of Various Organic Compounds (Table V). — 10, 5 and 1 mg. each of Santopour, picric acid, *p*-hydroxydiphenyl, and the alcohol fraction of the asphalt components were weighed out and dissolved in 25 ml. of purified ethyl alcohol, which had been confirmed as suitable for use as a diluent by the measurement of the ultraviolet spectrum in the range of 200~400 mμ.

Each amount was diluted with ethyl alcohol to the constant ratio (*p*-hydroxybiphenyl 0.001 wt. %, and the others 0.01 wt. %), and the absorptions at each wavelength (Santopour, 264 mμ; picric acid, 270 mμ; *p*-hydroxydiphenyl, 256 mμ; the alcohol fraction of asphalt components, 277 mμ), which had been selected according to the results of the ultraviolet spectrum of each organic compound measured previously, were measured to determine ε. The relation between the concentration and ε is shown in the graph. One hundred milligrams of the crystalline paraffin (m. p. 53.5°C; mean carbon number, 28) was weighed in an Erlenmeyer flask with a stopper, and 10 mg. of each of the various organic compounds described above was added to the flask to be treated[4]. The crystallized paraffins were isolated by filtration and dried at below 30°C until reaching a constant weight, which was measured to compute the amount of non-crystallized paraffins. Then, the absorption at respective constant wavelengths was measured to compute for each filtrate, and each content of organic compounds was determined.

Summary

1) The micro-paraffin has longer mean carbon chains than those of ordinary crystalline paraffins, and the content of side-chain hydrocarbons is less than that in ordinary paraffins; its crystals belong to an orthorhombic system, and the formation of fine crystal grains is a result of secondary causes.

2) If the paraffin is recrystallized in ethyl alcohol in the presence of organic compounds of a similar structure which have benzene rings with hydroxyl groups such as Santopour, picric acid, *p*-hydroxybiphenyl, etc., the crystal growth is inhibited and the crystallized amount of the paraffin crystals is reduced, which is the cause of the formation of fine crystal grains.

3) The alcohol-extracted fraction, isolated from the micro-paraffin materials, has a fairly long alkyl chain and benzene rings with the hydroxyl groups. The crystalline or *n*-paraffin is micro-crystallized, the same as the above organic compounds, when a very small amount of the fraction is added to it.

4) The content of *n*-paraffin in the micro-paraffin is less than that in ordinary crystalline paraffin, but the former contains more side-chain components. The paraffin forms fine crystal grains in the presence of compounds such as the alcohol-extracted fraction.

5) As a result of the purification by the urea method and chromatography, X-ray diffraction, etc., a considerable amount of the crystalline *n*-paraffins has clearly been found to be contained in micro-paraffin. Therefore, the micro-paraffin does not consist of side-chain paraffin and is not originally micro-crystallized, as has hitherto been believed.

6) The effects of such additive organic compounds on *n*-dotriacontane, on crystalline paraffins or on a mixture of various hydrocarbons are not the same. In the case of the latter, the tips of the carbon chain in the crystal lattice are arranged in disorder, with a few side-chains; therefore, the crystal growth of the paraffin is believed to be inhibited and then the formation of fine crystal grains occurs.

7) The additive organic compounds wrap up paraffin molecules in the crystallization of paraffin, and the process from the formation of the crystal lattices to the growth of large crystals is so inhibited that the crystal growth is prevented. Crystallization seems to be partially prevented, and micro-crystallization or needle crystallization of small tabular crystals occurs.

The author wishes to express his deep appreciation to Professor Ryozo Goto and Professor Saburo Yagi, Kyoto University, for their cordial guidance and discussion throughout this research; he also is grateful to Dr. Kenziro Asai and Dr. Tsuneo Seto, Kyoto University, for their cordial guidance in the analyses of X-ray diffraction, and to Mr. Kazuo Naito and Mr. Osamu Nanbu, Osaka Ind. Tech. Lab., who co-operated in the infrared spectrum experiments. He also wishes to thank Mr. Takashi Matsuoka and the personnel of the Central Research Lab. of Nippon Mining Co., for their co-operation in the measurement of the X-ray diffraction and to all the other personnel of Nippon Mining Co. for their great kindness throughout this research.

Quantitative Analysis of Mixtures of L-Glutamic Acid Polymorphs by X-Ray Diffraction

By Hiroshi TAKAHASHI, Tadao TAKENISHI and Nobuya NAGASHIMA

(Received November 1, 1961)

Two polymorphic forms of L-glutamic acid have been reported by a few authors. One form, α, reported by Bernal[1], has an orthorhombic structure, with $a=7.06$, $b=10.3$, $c=8.75$ kX. The other form, β, which has been studied by Hirokawa[2], also has an orthorhombic structure, with $a=5.17$, $b=17.34$, $c=6.95$ Å. The X-ray diffraction patterns of these two polymorphic forms of L-glutamic acid are given in Fig. 1. L-Glutamic acid crystallizes in a mixture consisting of various proportions of the α- and the β-forms, from an aqueous solution under certain conditions. In industrial processes, it is necessary to control the formation of the L-glutamic acid polymorphs. To analyze the two forms quantitatively, usual chemical methods are useless. The X-ray diffraction method does, however, give satisfactory results for this purpose. The application of

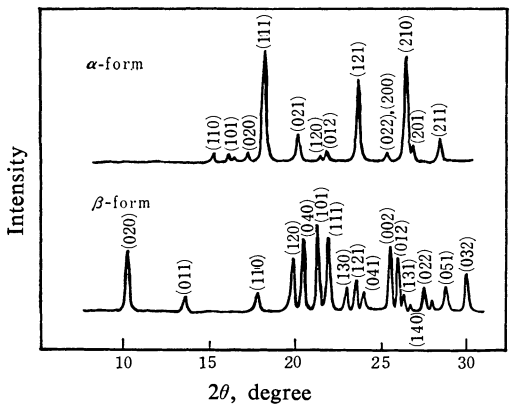

Fig. 1. X-Ray diffraction patterns of L-glutamic acid polymorphs. (CuK_α radiation)

such a diffraction method to the quantitative analysis of crystalline organic systems has been investigated by Christ et al.[3] This paper describes an analytical method for polymorphs of organic crystals using the X-ray diffractometer. Sufficiently accurate results can be obtained within 40 min.

A general theory of quantitative X-ray analysis by the diffractometer has been reported by Klug and Alexander[4] and by Copeland and Bragg[5]. They have shown that the integrated intensity of the $(h\,k\,l)$ line of the jth component in the diffraction pattern is given by

$$I_{(h\,k\,l)j}=K_{(h\,k\,l)j}\ (x_j/\rho_j\mu) \qquad (1)$$

where $K_{(h\,k\,l)j}$ depends upon the nature of the component j and the geometry of the apparatus, x_j is the weight fraction, ρ_j, the density of the jth component, and μ, the total mass absorption coefficient of the sample. In the case of such mixtures of polymorphic forms, μ does not change with the composition. Equation 1 indicates that the intensity is directly proportional to the concentration of the component.

For a binary mixture (α- and β-forms), Eq. 1 can be written:

$$I_{(h\,k\,l)\alpha}=k_{(h\,k\,l)\alpha}x_\alpha,\quad I_{(H\,K\,L)\beta}=k_{(H\,K\,L)\beta}x_\beta \qquad (2)$$

where $k_{(h\,k\,l)\alpha}$ and $k_{(H\,K\,L)\beta}$ are constant. The following selected lines were used:

$I_{(1\,1\,1)\alpha}$: Intensity of the 4.87Å line of the α-form, (1 1 1) reflection.

$I_{(1\,0\,1)\beta}$: Intensity of the 4.17Å line of the β-form, (1 0 1) reflection.

Each $(1\,1\,1)\alpha$, $(1\,0\,1)\beta$ line is the strongest in its respective pattern. Fig. 1 shows that the $(1\,0\,1)\beta$ line is superposed with the (1 2 0) line of the α-form. In practice, Eq. 2 must be modified to:

$$I_{(1\,1\,1)\alpha}=k_{(1\,1\,1)}x_\alpha$$
$$I_{(1\,0\,1)\beta}=k_{(1\,0\,1)\beta}x_\beta+k_{(1\,2\,0)\alpha}x_\alpha \qquad (3)$$

Division of $I_{(1\,0\,1)\beta}$ by $I_{(1\,1\,1)\alpha}$ gives:

$$I_{(1\,0\,1)\beta}/I_{(1\,1\,1)\alpha}=K_1(x_\beta/x_\alpha)+K_2 \qquad (4)$$

where K_1 and K_2 are constant. The plotted values of $I_{(1\,0\,1)\beta}/I_{(1\,1\,1)\alpha}$ vs. x_β/x_α give a straight line having the slope K_1 and the interception K_2. K_1 and K_2 can be obtained experimentally from the synthetic mixtures.

Equation 4 combined with $x_\alpha=1-x_\beta$, on solving for x_β, yields:

$$x_\beta=[K_1\{(I_{(1\,0\,1)\beta}/I_{(1\,1\,1)\alpha})-K_2\}^{-1}+1]^{-1} \qquad (5)$$

Equation 5 gives the relation between the intensity ratio $I_{(1\,0\,1)\beta}/I_{(1\,1\,1)\alpha}$ and the concentration x_β. By this calibration curve, direct analysis is possible.

To analyse the quantities of the α- and the β-forms of L-glutamic acid when these forms are mixed with other substances, the internal standard method should be used.

A known amount of the internal standard is added to the sample. Let the weight fraction of the internal standard be x_s, and let the weight fraction of the component j after adding the internal standard be x_j'. Then the intensity of the jth component $I_{(h\,k\,l)j}$ and that of the internal standard $I_{(H\,K\,L)s}$, are given from Eq. (1):

$$I_{(h\,k\,l)j}=K_{(h\,k\,l)j}(x_j'/\rho_j\mu),$$
$$I_{(H\,K\,L)s}=K_{(H\,K\,L)s}(x_s/\rho_s\mu)$$

Dividing $I_{(h\,k\,l)j}$ by $I_{(H\,K\,L)s}$ gives:

$$I_{(h\,k\,l)j}/I_{(H\,K\,L)s}=K(x_j'/x_s)$$

where K is constant. As an internal standard, sodium chloride was suitable, because of the following properties:

i) Satisfactory purity.
ii) Sharp diffraction lines.
iii) It has a suitable line free from interference and superposition (see Fig. 2).

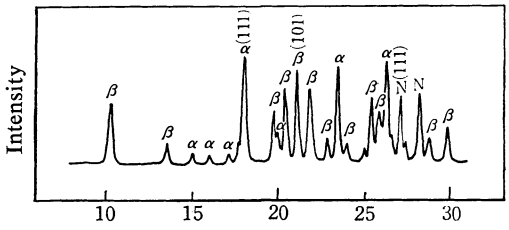

Fig. 2. Diffraction pattern of a sample for the internal standard method.
α: α-form L-glutamic acid, β: β-form L-glutamic acid, N: sodium chloride

3) C. L. Christ, R. B. Barnes and E. F. Williames, *Anal. Chem.*, **20**, 789 (1948).
4) L. Alexander and H. P. Klug, ibid., **20**, 886 (1948).
5) L. E. Copeland and R. H. Bragg, ibid., **30**, 196 (1958).

Calibration curves were prepared by measuring the following intensities:

$I_{(1\,1\,1)\alpha}$: Intensity of the 4.87Å line of the α-form, (1 1 1) reflection.

$I_{(1\,0\,1)\beta}$: Intensity of the 4.17Å line of the β-form, (1 0 1) reflection.

$I_{(1\,1\,1)s}$: Intensity of the 3.26Å line of NaCl, (1 1 1) reflection.

To determine the concentration of the α- or the β-form, Eq. 6 is modified as (the (1 0 1) line of the β-form is superposed with the (1 2 0) line of the α-form),

$$I_{(1\,1\,1)\alpha}/I_{(1\,1\,1)s}=K_\alpha'(x_\alpha'/x_s)$$

$$I_{(1\,0\,1)\beta}/I_{(1\,1\,1)s}=K_{\beta 1}'(x_\beta'/x_s)+K_{\beta 2}'(x_\alpha'/x_s)$$

When x_s is held constant, the weight fractions of the components α and β-forms, in the original sample, x_α and x_β, are given by:

$$x_\alpha=x_\alpha'/(1-x_s)=K_\alpha(I_{(1\,1\,1)\alpha}/I_{(1\,1\,1)s})$$

$$x_\beta=x_\beta'/(1-x_s)=K_{\beta 1}(I_{(1\,0\,1)\beta}/I_{(1\,1\,1)s})-K_{\beta 2}(I_{(1\,1\,1)\alpha}/I_{(1\,1\,1)s}) \quad (7)$$

where K_α, $K_{\beta 1}$, $K_{\beta 2}$ are constant. Thus, when the internal standard is added in a constant proportion, the concentration of the component α or β is a linear function of the intensity ratio $I_{(1\,1\,1)\alpha}/I_{(1\,1\,1)s}$ and $I_{(1\,0\,1)\beta}/I_{(1\,1\,1)s}$.

Experimental

Instrumentation. — The diffractometer used was a "Geigerflex" D-3F type (Rigakudenki Co.) using CuK_α radiation (filtered through Ni). The operating conditions were as follows: CuK_α, 30 kV. 15 mA.; Divergence slit, 1°; Scatter slit, 1°; Receiving slit, 0.2 mm.; Time constant, 2 sec.; Counter speed, 1/2° per minute; Chart speed, 1 cm. per minute.

The intensity ratio was obtained by measuring relative peak heights above their backgrounds. It is essential in accurate work to measure peak areas rather than peak heights, although the latter may be sufficient for simple analysis.

Preparation of Calibration Curves. — The compositions of the mixtures prepared for the calibration curves for the analysis in the binary system and in the multicomponents system are given in Tables I and II respectively. Each sample was ground in an agate mortar to about a 5 μ particle size. The β-form crystal has a tendency to crystallize in various habits. When crystallites were ground, they were frequently oriented in a preferred

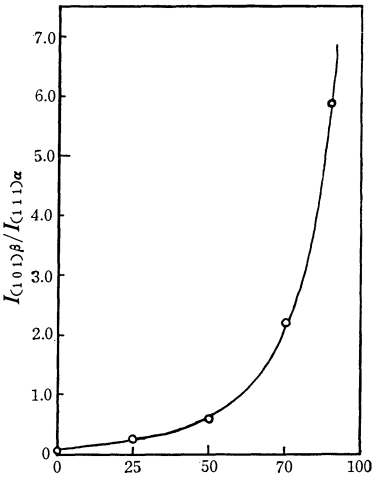

Fig. 3. Calibration curve for the analysis of the β-form concentration by the direct method.

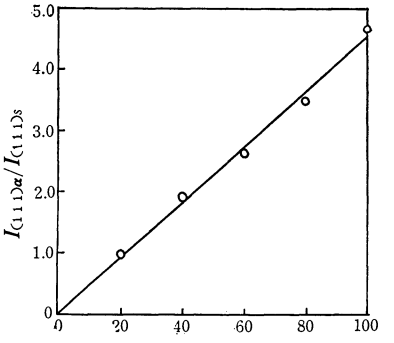

Fig. 4. Calibration curve for the analysis of the α-form concentration by the internal standard method.

Table I. Composition of synthetic mixtures for binary system

Sample	B-1	B-2	B-3	B-4	B-5
α-Form (g.)	1.00	0.753	0.502	0.248	0.101
β-Form (g.)	0	0.249	0.499	0.745	0.902
β-Form (wt.%)	0	25	50	75	90

Table II. Composition of synthetic mixtures for multi-component system

Sample	M-1	M-2	M-3	M-4	M-5	M-6
α-Form (g.)	0	0.201	0.400	0.601	0.801	1.001
β-Form (g.)	0.999	0.800	0.600	0.400	0.201	0
NaCl (g.)	0.500	0.499	0.501	0.500	0.500	0.500
β-Form (wt.%)	100	80	60	40	20	0

direction, and the preferred orientation caused an abnormal increase in the intensity of the $(0\,k\,0)$ lines in the diffraction pattern. However, sufficient grinding reduced this effect, and the intensity of the line (1 0 1) for the analysis in question was scarcely effected by the preferred orientation. The data for the calibration curves are given in Table III. Each value is an average of 7—8 specimens of each sample. From these data, using the method of least squares, the values of K_1 and K_2, and of K_α, $K_{\beta 1}$ and $K_{\beta 2}$ are obtained as follows:

$$K_1=0.673, \quad K_2=0.037$$

$$K_\alpha=21.7, \quad K_{\beta 1}=32.1, \quad K_{\beta 2}=2.08$$

From Eqs. 5 and 7, each combined with these experimental values, the calibration curves can be obtained (Figs. 3 and 4).

Results and Discussion

Three samples of different concentrations were analyzed by the internal standard method and the direct method. These results are given in Table IV. From these data the standard deviations in analytical work were estimated at about 1 wt.% by the direct method. The reproducibility of the analytical results by the internal standard method was generally poorer than by the direct method. This may be due to the lower peak heights caused by the X-ray absorption of sodium chloride and the imperfection of mixing of the standard with the samples. In practice, glutamic acid crystallites have good purity, so polymorphic analysis can be carried out by the method of the binary system. Many experiments suggest that the lower limit of detection of each component in practical samples is about 2%. To obtain more accurate results, it seems necessary to repeat the experiment. Quantitative analysis based on the intensities of two or more selected lines of one component seems to be more accurate, but in organic substances, it is difficult, because of their complex diffraction patterns, to choose lines free from the superposition of other materials. High stabilization of the tube current and voltage is important in obtaining reproducible data.

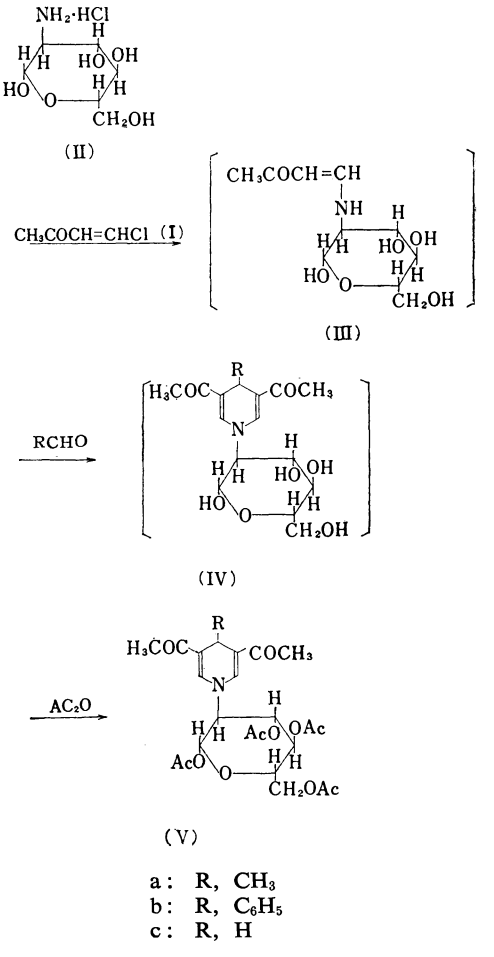
Synthesis of 1,4-Dihydro-N-[1′ : 3′ : 4′ : 6′-tetraacetylglucosyl-(2′)]-3,5-diacetylpyridine Derivatives



By Noboru SUGIYAMA, Goro INOUYE** and Kimie ITO

(Received October 13, 1961)

Fischer et al.[1] had reported the synthesis of *N*-[tetraacetylglucosyl-(1′)]-pyridinium salts by the condensation of pyridine and tetraacetylglucosyl bromide. As a model compound of DPN*1, Karrer[2] and Todd[3] synthesized various sugar derivatives of nicotinamide by this method. We could not find any other *N*-sugar derivatives of pyridine or pyridine derivatives in the literature.

In his previous papers[4], Inouye has reported that 1,4-dihydro-3,5-diacetylpyridine derivatives are obtained in a good yield by the condensation of aldehydes with methyl β-(*N*-monosubstituted amino)-vinylketone. According to this method, 1,4-dihydro-*N*-[glucosyl-(2′)]-3,5-diacetylpyridine derivatives (IV) will be obtained by the condensation of aldehydes with methyl β-[*N*-glucosyl-(2′)-amino]-vinylketone (III), which, in trun, is prepared from methyl β-chlorovinylketone (I) and glucosamine (II). In fact, we could obtain the expected compound, V. Although the yield of V was not good, similar derivatives with other sugar or substituents can be synthesized by this method. We will report on the results of this experiment.

In the presence of potassium carbonate, aldehyde was added to the condensation products of methyl β-chlorovinylketone (I) with glucosamine hydrochloride (II) in water or ethanol. From the reaction mixture, the expected compounds IV could not be obtained in a crystalline state. However, by acetylation, pure 1,4-dihydro-*N*-[1′ : 3′ : 4′ : 6′-tetraacetylglucosyl-(2′)]-3,5-diacetylpyridine derivatives Va, Vb were obtained. Formaldehyde did not give the corresponding compound, Vc.

a: R, CH_3
b: R, C_6H_5
c: R, H

The structure of Va and Vb were confirmed by a comparison of their spectral data with those of the corresponding 1,4-dihydropyridine derivatives, VI, VII, VIII and IX (Table I). The infrared spectra of 3,5-diacetyldihydropyridine derivatives show a band at 1640 and 1642 cm^{-1} respectively. The absorption maxima of the ultraviolet spectra of Va and Vb (377, 375 mμ) are nearly the same. The same relationships exist between the spectra of VI and VIII or VIII and IX. The shift of λ_{max} on the nitrogen atom by changing substituents seems to be due to the difference in the

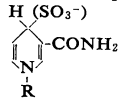
effects of the methyl, phenyl and tetraacetylglucosyl groups on the nitrogen atom*2.

Experimental

1,4-Dihydro-*N*-[1' : 3' : 4' : 6'-tetraacetylglucosyl-(2')]-4-phenyl-3, 5-diacetylpyridine (Va). — I (10 g.) was stirred drop by drop into an ice-cooled solution of glucosamine hydrochloride (21 g.) and potassium carbonate (30 g.) in water (70 ml.), and the stirring was then continued for 6 hr. Acetaldehyde (5.5 g., 80% aqueous solution) was added to the reaction mixture, and the mixture was left overnight at room temperature. After filtering off the precipitates, concentrated hydrochloric acid (20 ml.) was added to the filtrate. The solution was evaporated to dryness under reduced pressure in an atmosphere of nitrogen. The residue was acetylated by refluxing in acetic anhydride (50 ml.) for an hour. The acetic anhydride was removed under reduced pressure in an atmosphere of nitrogen. After dissolving in ethyl acetate and chromatographing on an alumina column, the residue gave 1,4-dihydro-*N*-[1' : 3' : 4' : 6'-tetraacetylglucosyl-(2')-4-methyl-3, 5-diacetylpyridine (Va) in the form of pale yellow needles (from benzene), m. p. 180°C (decomp.).



Found: N, 2.43. Calcd. for $C_{24}H_{31}O_{11}N$: N, 2.74%.

1, 4-Dihydro-*N*-[1' : 3' : 4' : 6'-tetraacetylglucosyl-(2')]-4-phenyl-3, 5-diacetylpyridine (Vb).—I (10 g.) was stirred drop by drop into an ice cooled mixture of glucosamine hydrochloride (21 g.), ethanol (50 ml.) and a saturated aqueous solution (50 g.) of potassium carbonate, and the stirring was continued for 6 hr. Benzaldehyde (10 g.) was added to the reaction mixture, and the mixture was left overnight at room temperature. After acidification with concentrated hydrochloric acid, the excess benzaldehyde was removed by steam distillation. The solution was evaporated to dryness under reduced pressure in an atmosphere of nitrogen. The residue was acetylated by refluxing in acetic anhydride (50 ml.) for an hour. After cooling, saturated aqueous solution (50 ml.) of sodium acetate was added to the mixture. 1,4-Dihydro-*N*-[1' : 3' : 4' : 6'-tetraacetylglucosyl(2')]-4-phenyl-3,5-diacetylpyridine (Vb) was separated and crystallized from acetic acid-water in the form of pale yellow needles, m. p. 265°C (decomp.).

Found: C, 60.41; H, 5.74; N, 2.28. Calcd. for $C_{29}H_{33}O_{11}N$: C, 60.94; H, 5.77; N, 2.45%.

Effects of Tyrosyl Residue on the Polypeptide Monolayers

By Takuya YAMASHITA and Toshizo ISEMURA

(Received November 21, 1961)

Protein has a definite conformation which is responsible for its biological activity. This conformation is believed to be chiefly maintained by the intramolecular hydrogen bonding. Tyrosyl residue is very specific among other amino acid residues in protein because of the potency of its hydrogen bonding. In our previous investigations[1,2], we have studied the monolayers of poly-L-tyrosine, poly-DL-tyrosine, poly-*o*-benzyl-DL-tyrosine and poly-DL-phenylalanine in terms of the hydrogen bonding of the phenolic hydroxyl group of tyrosyl residue at the air/water and oil/water interfaces.

Poly-*o*-benzyl-DL-tyrosine was found, like most polypeptide films, to be spread in a β-configuration. Poly-L-tyrosine and poly-DL-tyrosine, however, showed solvent effects at the air/water interface owing to their phenolic hydroxyl group. If they were spread from the solution in a mixture of pyridine and isopropyl alcohol, they occupied much less area per residue than polypeptide films such as poly-DL-phenylalanine in a β-configuration. This fact suggests that poly-L-tyrosine might not be spread in an extended monolayer in a strict sense, but in a coiled state probably owing to the hydrogen bonding between the phenolic hydroxyl group and the carbonyl or imino group in a main chain. On the other hand, if poly-L-tyrosine is spread from the solution in a mixture of dichloroacetic acid and benzene, it probably assumes a β-form.

In the present study, we have investigated the effects of the phenolic hydroxyl group of tyrosyl residue on the polypeptide monolyers. For this purpose, the monolayers of poly-L-tyrosine, copoly-1 : 1-(L-tyrosine, L-phenylalanine), copoly-1 : 1 : 2-(L-tyrosine, *o*-benzyl-L-tyrosine, L-phenylalanine) and copoly-1 : 1-(L-tyrosine, glycine) have been investigated. For comparison, the monolayer of poly-DL-phenylalanine was also studied.

Experimental

Materials.—The same samples of poly-L-tyrosine and poly-DL-phenylalanine were used as in the preceding study. Copolypeptides containing tyrosyl residue were kindly supplied by Professor J. Noguchi of Hokkaido University.

As spreading solvents, mixtures of dichloroacetic acid and benzene were used. The ratio of dichloroacetic acid (DCA) to benzene is various for different polypeptides, as can be seen in Table I.

TABLE I. THE RATIOS OF DCA TO BENZENE IN SPREADING SOLUTIONS

Sample	DCA : Benzene (v/v)
Poly-DL-phenylalanine	3 : 7
Poly-L-tyrosine	7 : 3
Copoly-1 : 1-(L-tyrosine, L-phenylalanine)	3 : 7
Copoly-1 : 1 : 2-(L-tyrosine, *o*-benzyl-L-tyrosine, L-phenylalanine)	3 : 7
Copoly-1 : 1-(L-tyrosine, glycine)	1 : 1

Method.—The films were spread at the air/water and oil/water interfaces. The surface pressure and surface potential were measured simultaneously by the Wilhelmy hanging plate method and by the vibrating electrode method respectively. Interfacial pressure was measured by the ring method. At the oil/water interface, the interfacial concentration was changed by the successive injection method, using a micrometer syringe, and was corrected by the Thomas theoretical correction formula[3]. Measurements were carried out five minutes after every injection. The pH value of the subphase was adjusted to any desired value by adding hydrochloric acid or potassium carbonate and was measured with a Horiba M-3 glass electrode pH meter. Petroleum ether with a boiling point of 85~115°C was used as an oil phase. All the experiments were carried out at room temperature without any temperature regulation. However, the change never exceeded more than one degree in the course of the experiment.

The limiting area per residue of the film was obtained from the minimum of its compressibility, $\delta = -dA/Ad\Pi$, and the surface moment, μ, was calculated from the surface potential, ΔV, using the Helmholtz formula, $\mu = \Delta VA/4\pi$.

The average residual weight of copolypeptide was calculated on the basis of its polymerization ratio.

Results

The surface pressure-area (Π-A) and surface moment-area (μ-A) curves of poly-DL-phenylalanine at the air/water interface are shown

in Fig. 1. The *Π-A* curves were nearly independent of the pH value of the subphases, although the *μ-A* curves were affected. The limiting area per residue was 15.6 Å² irrespective of the pH value of the subphases. On the alkaline subphase, the surface moment is lower by 50~60 mD than on the acid subphase.

The *Π-A* and *μ-A* curves of poly-L-tyrosine spread from a solution in a dichloroacetic acid-benzene mixture at the air/water interface are given in Fig. 2. In a low pressure region the film expands slightly more on 0.02 N potassium carbonate than on distilled water. Among the three subphases the film expands most on 0.1 N potassium carbonate. On the alkaline subphase, the surface moment is lower by 90~100 mD than on distilled water.

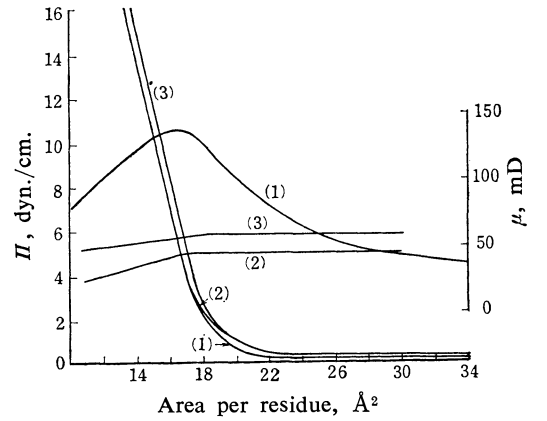

Fig. 4. Surface pressure-area and surface moment-area curves of copoly-1 : 1 : 2-(L-tyrosine, *o*-benzyl-L-tyrosine, L-phenylalanine) (10°C): (1), on distilled water; (2), on 0.02 N K_2CO_3; (3), on 0.1 N K_2CO_3.

(L-tyrosine, *o*-benzyl-L-tyrosine, L-phenylalanine) at the air/water interface are given in Figs. 3 and 4 respectively. The effects of the change in the pH values of the subphases on the *Π-A* relations of these copolypeptides are smaller than in the case of poly-L-tyrosine. The difference between surface moments of copoly-1 : 1-(L-tyrosine, L-phenylalanine) on acid and alkaline subphases is comparable to that between those of poly-DL-phenylalanine. The surface moment of copoly-1 : 1 : 2-(L-tyrosine, *o*-benzyl-L-tyrosine, L-phenylalanine) increased steeply on distilled water, as the film was compressed, as has been found with the film of poly-*o*-benzyl-DL-tyrosine[2]; it reached 137 mD at its maximum.

The Π-A and μ-A curves of copoly-1 : 1-(L-tyrosine, glycine) at the air/water interface are shown in Fig. 5. This copolypeptide occupies much less limiting area per residue in the surface film than those of any other

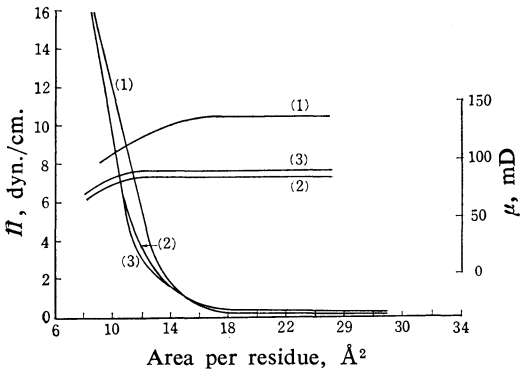

Fig. 5. Surface pressure-area and surface moment-area curves of copoly-1 : 1-(L-tyrosine, glycine) (10°C): (1), on distilled water; (2), on 0.01 N K_2CO_3; (3), on 0.1 N K_2CO_3.

polypeptide mentioned above.

The film characteristics obtained from the *Π-A* and *μ-A* relations are listed in Table II.

The *Π-A* curves of poly-DL-phenylalanine, copoly-1 : 1-(L-tyrosine, L-phenylalanine) and copoly-1 : 1-(L-tyrosine, glycine) at the oil/water interface are shown in Fig. 6. The *Π-A* curve of poly-DL-phenylalanine measured by the ring method was slightly shifted to the left (namely, to the smaller area) in comparison with the curve obtained by the hanging plate method employed in the previous study[2]. This discrepancy is probably caused by the neglect in the previous work of the change in the contact angle of the glass handging plate. At the oil/water interface, the films expanded more than at the air/water interface. The film of copoly-1 : 1-(L-tyrosine, glycine) occupied much less area per residue than any other polypeptides at the oil/water interface as well as at the air/water interface.

Discussion

Effect of Subphase pH on the Surface Potential or Moment.—*Poly-DL-phenylalanine.*—The surface potential or moment of poly-DL-phenylalanine changes considerably in spite of its lack of ionizable side chains. The difference between constant values of the surface moments on the acid and alkaline subphases, $\Delta\mu$, is 50~60 mD. Because the change cannot be attributed to the ionization of the side chain, it must be caused by a change in the main chain. A similar change in surface potential or moment has been found for several synthetic polypeptides with a non-polar side chain, e. g., poly-DL-alanine[4], poly-DL-leucine[5], and poly-α-aminolauric acid[6].

Glazer and Dogan[4] found that the maximum value of the surface potential of poly-DL-alanine decreased with the increase in subphase pH. They attributed the decrease in surface potential with pH to the varying degree of ionization of the carboxyl and amino end groups. However, in the polypeptide of a high degree of polymerization, the ionization effect of end groups on the surface potential or moment might not be so effective.

Davies[5] found that values of the surface moment of poly-DL-leucine at 20 Å^2 per residue were 188 mD on 0.01 N hydrochloric acid, 137 mD on 0.02 N phosphate (pH 6.8), and 113 mD on 0.1 N sodium hydroxide. From this finding, he suggested that on the neutral and alkaline subphases the hydrogen bond between keto-imide groups in neighboring chains was formed and that on the acid subphase the hydrogen bond would be broken. However, his view that the hydrogen bond is maintained on such a strong alkaline subphase as 0.1 N sodium hydroxide is very doubtful, because the protein is unfolded in an alkaine solution, owing to the breaking of the hydrogen bonding as commonly accepted, while the breaking of the hydrogen bonding on the acid subphase is probable, although the effect of the acid seems to appear at a very high acidity.

The probable explanation of the change in surface potential or moment of non-polar synthetic polypeptide with pH seems to be the keto-enol transformation of the peptide bond. According to Pankhurst[7], the keto-imide group of polypeptide chain in gelatin is capable of resonance between the keto and the enol forms as amides, while the addition of a hydrogen ion would prevent the resonance. Schauenstein and Perko observed this effect for 3, 6-dioxo-1, 2, 4-triazine[8] with $HO\cdot C_6H_4\cdot CH_2-$, $C_6H_5\cdot CH_2-$ or CH_3- in the 5 position, and poly-L-tyrosine[9] from the differences in ultraviolet absorption spectra between their acid and alkaline solutions; they called this effect "peptenol effect". Owing to the peptenol effect, the surface moment or potential of the polypeptide monolayer can decrease more on alkaline than on the acid subphase, because most of the keto-imide groups in the main chain are in an enolate form, and the film would be more condensed on the subphase of a high pH, as has been found for the poly-DL-leucine monolayer[10], since the increase in the double bond nature of the peptide bond enhances the rigidity of the film.

Accordingly, the change in the surface moment or the potential of non-polar synthetic polypeptides with the pH might be caused primarily by the keto-enol transformation of peptide bond, i. e., the peptenol effect, although the ionization of the end groups and the breaking of the hydrogen bond on a strong acid solution may be effective to some extent on the change in the surface potential or the moment with pH. The *Π-A* relation of poly-DL-phenylalanine seems not to be affected by the change in the pH value of the subphase because of the effect of its large side chains.

Polypeptides other than Poly-DL-phenylalanine.—The difference between the constant or maximum values of the surface moments on

acid and alkaline subphases, $\Delta\mu$, is about 100 mD for poly-L-tyrosine and higher by 40~50 mD than that for poly-DL-phenylalanine. The abnormally large difference in the surface moment is probably due both to the peptenol effect of the main chain and to the ionization of the phenolic hydroxyl groups of the side chains.

The $\Delta\mu$ value of copoly-1 : 1-(L-tyrosine, L-phenylalanine) is about 60 mD and is comparable to that of poly-DL-phenylalanine. From the fact that the film expands slightly more on the alkaline than on the acid subphase, the decrease in surface moment seems to be due not only to the peptenol effect of the main chain, but also to the partial ionization of the side chains.

The surface moment of copoly-1 : 1 : 2-(L-tyrosine, *o*-benzyl-L-tyrosine, L-phenylalanine) on distilled water steeply increases with the compression of the film, as was found with the film of poly-*o*-benzyl-L-tyrosine[2]. This change is probably caused by reorientation of the large polar side chain of the *o*-benzyl-L-tyrosyl residue. On the other hand, the surface moment is nearly constant on the alkaline subphase. This fact suggets that the remarkable reorientation of the side chain is not accompanied by a compression of the film on the alkaline subphase. The $\Delta\mu$ values of this copolypeptide are 91 mD on 0.02 N potassium carbonate and 75 mD on 0.1 N potassium carbonate. These values are greater than those for copoly-1 : 1-(L-tyrosine, L-phenylalanine) film, although this copolypeptide has much less ionizable groups.

The $\Delta\mu$ value of copoly-1 : 1-(L-tyrosine, glycine) is about 50 mD and is comparable to that of poly-DL-phenylalanine. This finding suggests that the effect of the ionization of the phenolic hydroxyl group is slight in this case.

Effect of Subphase pH on the *II-A* Relation. —*Air/Water Interface.*— The film of poly-L-tyrosine spread from a solution in pyridine-isopropyl alcohol mixture is affected remarkably by the pH of the subphase, as has been previously reported[1,2]. On the other hand, the effect of subphase pH on the *II-A* relation is not so remarkable if it is spread from a solution containing dichloroacetic acid as a component of the solvent, and the limiting area per residue is close to 15 Å^2. Therefore, in this case, there is no hydrogen bonding between the phenolic hydroxyl group and the carbonyl or imino group in the main chain, and poly-Ltyrosine is probably spread in the β-form.

Schauenstein and Perko[9] found the pK value of the phenolic hydroxyl group of poly-L-tyrosine to be 11.0, and Katchalski and Sela[11] found that the spectrophotometric titration curve fitted the theoretical curve computed by assuming the pK_0 to be 9.5. Therefore, on 0.02 N potassium carbonate (pH 10.3), about a half of the side chains may be dissociated. However, the *II-A* relation here is little affected compared with that on distilled water, although the monolayers of poly-L-glutamic acid[12] and copoly-1 : 2 : 1-(L-lysine, L-leucine, L-glutamic acid)[13] are affected remarkably by the pH of the subphase. This is probably due to the peptenol effect of the main chain and to the van der Waals attraction between the large side chains, both of which prevent the expansion of the film. On 0.1 N potassium carbonate (pH 10.7), however, the film rather expands since the side chains dissociate more, and the repulsive force between the ionized side chains can overcome the van der Waals force and the peptenol effect.

The effect of the subphase pH on copoly-1 : 1-(L-tyrosine, L-phenylalanine) is between that on poly-DL-phenylalanine and that on poly-L-tyrosine. Since this copolypeptide consists of equal numbers of ionizable and unionizable side chains, the effect of the pH appears between poly-DL-phenylalanine and poly-L-tyrosine.

The *II-A* relation of copoly-1 : 1 : 2-(L-tyrosine, *o*-benzyl-L-tyrosine, L-phenylalanine) is little affected by the change in the subphase pH because it consists of fewer ionizable side chains (25%) than the tyrosine-polypeptides mentioned above.

The film of copoly-1 : 1-(L-tyrosine, glycine) condenses more on the alkaline subphase than on distilled water, probably because of the peptenol effect. This copolypeptide can condense by peptenol effect because only half of all its residues have side chains and the contraction of the main chain is rather easy owing to the steric effect.

All the polypeptide monolayers mentioned above except copoly-1 : 1-(tyrosine, glycine) seem to be in the β-form because their limiting areas per residue are very close to 15 Å^2.

Oil/Water Interface.—At the oil/water interface, the films of poly-DL-phenylalanine, copoly-1 : 1-(L-tyrosine, L-phenylalanine) and copoly-1 : 1-(L-tyrosine, glycine) expand more than at the air/water interface and change from a condensed type at the air/water interface into an expanded type. These changes are caused by the release of van der Waals force between the side chains due to oil.

11) E. Katchalski and M. Sela, *J. Am. Chem. Soc.*, **75**, 5284 (1953).
12) T. Isemura and K. Hamaguchi, This Bulletin, **27**, 339 (1954).
13) T. Isemura, K. Hamaguchi and S. Ikeda, *J. Polymer Sci.*, **23**, 651 (1957).

The change in the subphase pH appears to be more effective than at the air/water interface. The films of copoly-1 : 1-(L-tyrosine, L-phenylalanine) and copoly-1 : 1-(L-tyrosine, glycine) are more expanded on the alkaline than on the acid subphase, while at the air/water interface, the films of these copolypeptides are slightly affected by the change in pH. At the oil/water interface, the release of the van der Waals force between the side chains causes the expansion of the film by the repulsion among ionized groups.

Effect of Glycyl Residue on Polypeptide Monolayers.—At both the air/water and oil/water interfaces, the film of copoly-1 : 1-(L-tyrosine, glycine) occupies much less area per residue than in any other polypeptide mentioned above.

This copolypeptide contains the same number of tyrosyl and glycyl residues, so both the residues should affects its film properties. However, the tyrosyl residue would not be responsible for a small area per residue of copoly-1 : 1-(L-tyrosine, glycine) because poly-L-tyrosine and tyrosine-copolypeptides without glycyl residue, such as copoly-1 : 1-(L-tyrosine, L-phenylalanine) and copoly-1 : 1 : 2-(L-tyrosine, *o*-benzyl-L-tyrosine, L-phenylalanine), were spread in the β-form. The presence of glycyl residue in polypeptide chain might result in a small limiting area per residue.

Polyglycine (in trifluoroacetic acid) and copoly-1 : 2-(L-tyrosine, glycine) (in a DCA-benzene mixture) could not be spread as a monolayer at the air/water interface[14]. Davies[5] also found polyglycine not to be spread as a monomolecular film. Isemura and Hamaguchi[15] found that at the air/water interface the film of copoly-1 : 1-(glycine, DL-alanine) occupied a very small area per residue. They attributed this fact to the folding of the polypeptide chain due to the presence of the glycyl residue.

From these facts, the reason why copoly-1 : 1-(L-tyrosine, glycine) occupies much less area at both the air/water and oil/water interfaces than any other polypeptides studied here may be attributed to the folded structure caused by strong intrachain hydrogen bonding due to the presence of a glycyl residue which lacks a side chain.

Summary

The monolayers of poly-DL-phenylalanine (I), poly-L-tyrosine (II), copoly-1 : 1-(L-tyrosine, L-phenylalanine) (III), copoly-1 : 1 : 2-(L-tyrosine, *o*-benzyl-L-tyrosine, L-phenylalanine) (IV), and copoly-1 : 1-(L-tyrosine, glycine) (V) have been investigated at the air/water and oil/water interfaces.

The surface moment of I decreased by 50~60 mD more on alkaline than on the acid subphase, probably owing to the keto-enol transformation of the peptide bond. The decrease in the surface moment of II is about 100 mD; this decrease seems to be caused by the ionization of the side chains and by the enolation of the peptide bond.

At the air/water interface, the effects of the dissociation of the tyrosyl residue on the *II-A* relations of II, III, IV and V were not very remarkable, probably because of the peptenol effect and the van der Waals force between side chains. It was found that the monolayers of I, II, III and IV assume a β-configuration. On the other hand, the film of V occupies much less area per residue than those in the β-form, which might be attributed to the folded structure caused by the strong intrachain hydrogen bond due to the glycyl residue.

At the oil/water interface, the films of I, III and V expand more and the change in subphase pH seems to be more effective than at the air/water interface. These facts might be caused by the release of van der Waals force between the side chains.

The authors wish to express their hearty thanks to Professor Junzo Noguchi of Hokkaido University, to Professor Hisaya Tani and Dr. Heimei Yuki of the Faculty of Science, Osaka University, and to Professor Ephraim Katchalski and Dr. Michael Sela of the Weizmann Institute of Science for supplying valuable samples. Absorption Spectra of Dyes. VII[1]. *Some Steric Effects and Auxochrome-Effects on Complex Formation*[*1]

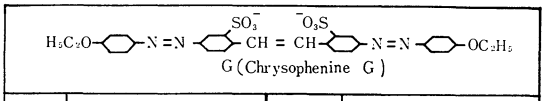
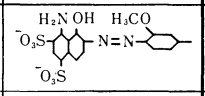
By Teruaki KOBAYASHI[*2], Kenzo SAITO[*2], Yoshié TANIZAKI and Noboru ANDO

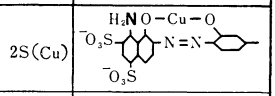
(Received October 21, 1961)

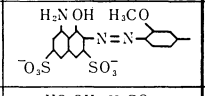


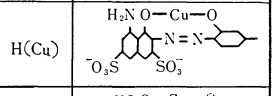
The interaction between molecules of different kinds of dyes in aqueous solutions has been studied extensively[2-4]. This problem is especially interesting because the forces involved in the complex formation are considered to be closely related to those responsible for the combination of dye molecules or ions with cellulose[2,3]. According to the conventional theory of the substantivity of dyes, it is important for substantivity that the molecule be planar so as to maintain a conjugated system between the terminal auxochromes, and that the hydrogen bonding be capable of being formed between such auxochromes and functional groups of cellulose. As for the latter, no direct experimental evidence has yet been obtained, though the possibility of hydrogen bonding between dyes and cellulose seems to be great. Nevertheless, there is no doubt that the auxochromes, by their functional property, play an essntial role in the formation of the complex or in the adsorption on cellulose.

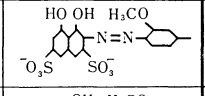
In the present investigation, in order to obtain some preliminary information on how the above two factors, i. e., the steric effect by which the planarity of the dye molecule is hindered and the effect of the auxochromes, are reflected in the 1 : 1 complex formation, we examined the spectral changes of the binary mixtures of dyes described in the preceding paper[1], with Chrysophenine G as the common ingredient.

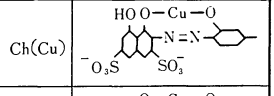


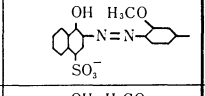


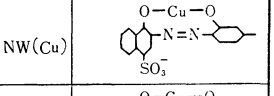


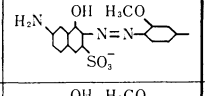


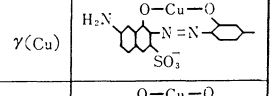


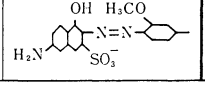


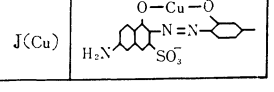












Experimental

Sample.—The dyes used are shown by notations in Table I, with the drawings of their half structures,

TABLE I. THE CHEMICAL STRUCTURE OF CHRYSOPHENINE G AND HALF CHEMICAL STRUCTURES OF DYES USED AND THEIR NOTATIONS

G (Chrysophenine G)

Notation	Half chem. structure	Notation	Half chem. structure
2S		2S(Cu)	
H		H(Cu)	
Ch		Ch(Cu)	
NW		NW(Cu)	
γ		γ(Cu)	
J		J(Cu)	

except for Chrysophenine G, a full-structure drawing is given. Since all the dyes but Chrysophenine G differ only in their coupling components, for convenience let us call them by abbreviations such as 2S or NW taken from the name of the coupling components. Corresponding copper derivatives will also be called 2S(Cu), NW(Cu), etc. The J dye was prepared by coupling diazotized J acid with dianisidine, and J(Cu) was obtained from the J dye and copper sulfate by the usual method[5]. The other dyes were the same as those used before[1].

Absorption Spectra.—Most absorption spectra were measured with a Shimadzu QR-50 spectrophotometer at room temperature (21±3°C); the spectra of only the mixture of J and G (Chrysophenine G) were recorded with a Hitachi EPS-2 recording spectrophotometer. The other experimental procedures followed have already been reported[1,4],*3.

Results

In the dyes containing no copper a similar change against the G concentration was seen in the difference between the sum of the individual absorption curves and those observed with the mixed system, as seen in 2S (Sky Blue) and G[4]. Examples are illustrated in Figs. 1 and 2 for the mixtures of the Ch dye or of the NW dye and G respectively. Two well-defined isosbestic points appear, indicating the formation of two sorts of complexes, a 1 : 1 and a 1 : 2 complex. As seen from the first isosbestic point shown in Figs. 1 and 2, the molar ratio in the complex formed is 1 : 1 when the amount of G is not over the concentration of the partner dye. An equilibrium constant K for the formation of a 1 : 1 complex can be determined by the method mentioned elsewhere with the condition that the formation of a 1 : 2 complex is extremely small[4]. The K values thus determined for the 1 : 1 complex formation are listed in Table II*[4].

Figure 3 illustrates the absorption spectra (solid lines) in an aqueous solution of nearly equimolar mixtures (ca. 1×10^{-5} mol./l.) of G and second components not containing copper. The broken lines in the figure indicate the results of the individual curves of the components,

See the footnotes of Table II.

each observed with the same concentration as in the mixture. The order of magnitude of the difference between the sum (broken line) and the mixture (solid line) curves in Fig. 3 appears to be comparable with that of the equilibrium constants. Indeed, in the present case, comparing the differences of the two curves in the following values, i.e., the difference in wave number, $\Delta\nu$ cm^{-1}, of the two peaks (around 400 mμ) corresponding to the first band of G, and the decreasing ratio in optical density, $\Delta D/D$ %, at the maximum point (around 600 mμ) of the partner dye of G, it is seen that both of the orders of the values thus obtained are approximately parallel to that of K as shown in Table II. These values, therefore, may be taken as a measure for comparing the relative order of the amounts of complex formed.

Figure 4 shows the absorption spectra of mixtures of copper derivatives and the G dye observed in the same way as above. It is noticed in Fig. 4 that the copper dyes are divided into two classes; one is the class in which the dyes reveal apparent spectral differences, the other, the class in which the differences are extremely small. The values of $\Delta\nu$ and $\Delta D/D$ for these dyes are given in Table III, divided into two groups.

Discussion

When the dyes not containing copper are combined with the G dye, judging from the examples shown in Figs. 1 and 2, two sorts of complex 1 : 1 and 1 : 2 are formed. Moreover, the correlation between the first isosbestic point and the mixing ratio of the components indicates that in the region where the G concentration does not exceed that of the partner dye, only a 1 : 1 complex is formed. Accordingly, at the present stage, when only the 1 : 1 complex formation is to be considered, discussion will be possible under the conditions of relative concentration just mentioned. (A detailed investigation, including the 1 : 2 complex formation, will be undertaken in the next paper.) According to Table II, the order of the magnitudes of the equilibrium constant K for the formation of a 1 : 1 complex is approximately parallel to the order of $\Delta\nu$ and $\Delta D/D$ observed with the equimolar mixture. Therefore, at least insofar as the 1 : 1 complex formation is concerned, $\Delta\nu$ and/or $\Delta D/D$ may rather safely be employed instead of K as a relative measure of the extent of the formation of a 1 : 1 complex. Such a comparison by $\Delta\nu$ and $\Delta D/D$ will be made below.

The skeletal structure of dyes used here is sterically restricted by the introduction of copper[1]. Thus, first, the case of the copper derivatives (Table III) in which the steric condition is simplified will be discussed; next, the case of those not containing copper (Table II) will be considered.

According to Table III, the magnitude of $\Delta D/D$ is about 15% for 2S(Cu), H(Cu) and Ch(Cu), but it is zero or almost zero for the rest, NW(Cu), γ(Cu) and J(Cu). These dyes can thus be clearly divided into two groups. A similar separation is even more distinctly revealed concerning the magnitude of the $\Delta\nu$ value; the value for the former group is about 1000 cm^{-1} and for the latter, zero. So the dyes 2S(Cu), H(Cu) and Ch(Cu), which are considered to form a 1 : 1 complex to some extent, will be termed the first group, and the rest, considered to form no complex, the second group.

Since the G dye is the common ingredient of all the combinations used here, it must be considered that the results mentioned above were brought about by certain differences in the nature of the partner dyes. Now, as these dyes are copper derivatives, they are regarded as of sterically similar skeletal structure, as has already been established[1]. Consequently, as dominant factors responsible for the interaction with the G molecule, only two factors may be considered at the present stage, the number and the position of sulfonic groups, and the presence and the position of effective auxochromes (amino, hydroxyl). Discussion of these factors will be undertaken below.

First, let us consider the effect of the sulfonic groups. The nearer the sulfonic groups are to the center of the partner molecule, and the more the number of the groups, the smaller in amount should be the complex produced, because the repulsion of the ionic charges of the sulfonic groups from those in the G molecule probably acts to prevent the complex from being formed*5. According to Table III, however, the difference in position of the sulfonic groups of 2S(Cu) and H(Cu) of the first group is not appreciably revealed in the results. From a comparison of the results of the first and the second categories, it is also clear that those in the first category with more sulfonic groups produce more complexes, while those in the second category produce almost none. For the above reason, it may be said in this case that the ionic charge of the sulfonic group has no great influence in outline on the complex formation.

The other possible factor is the influence of the auxochromes. As has been pointed out before[4], the effect of the auxochromes upon the complex formation with the G dye is such that the complex is stabilized by the occurrence of an intermolecular charge-transfer through the auxochromes, and at the same time the $\Delta\nu$ value grows large. This is reflected in the fact that all the dyes in the first group with large $\Delta\nu$ values have amino or hydroxyl groups which are terminal groups of a conjugated system. On the other hand, in the second group, with zero values of $\Delta\nu$, NW(Cu) especially has no auxochromes of such kinds, and γ(Cu), though it has two amino groups, can also be considerd to have no effective auxochromes because they are not conjugated terminal groups in a usual sense. Thus, the expected effect of the auxochromes and the experimental results show a good correspondence. However, the case of the J(Cu) dye, which has amino groups as its conjugated terminal groups, deviates from the above reasoning; the experimental results indicate that almost no complex is produced. However, whether or not amino groups of J(Cu) exerts a positive effect on the complex formation is obviously connected with its configuration relative to the G dye under the complex formation. Therefore, it is supposed here that the amino groups of J(Cu) could not reveal such a characteristic of auxochromes as seen in the

*5 The model of the complex formed assumes that the molecules overlap each other so as to be parallel longitudinally. See Ref. 4.

first group, owing to some reason, a correlation of geometric configuration, for instance.

Therefore, it may safely be said for the copper derivatives that the presence of the auxochromes as the terminal groups of a conjugated system is the necessary condition, even though not sufficient, to cause a spectral change with the formation of a complex.

Next, let us consider the case of Table II, where no copper is included. In this case, the hydroxyl group becomes free from copper to act as an effective auxochrome, and at the same time some dyes take a more planar structure as a result of being disengaged from the sterical restriction by copper. Namely, the 2S dye and the NW dye become more suitable structures for the complex formation than 2S(Cu) and NW(Cu) respectively, while the rest are left in nearly the same steric structure as the copper derivatives[1]. As mentioned above, the adding of effective auxochromes promotes the forming of a complex. Comparing Table II with Table III, the $\Delta\nu$ and $\Delta D/D$ of H, Ch, γ and J are evidently larger than those of the respective copper derivatives. This indicates the effect of hydroxyl. Moreover, according to the above considerations, 2S and NW ought to exhibit planar effects on their skeletal structures in addition to the effect of hydroxyl. Indeed, these dyes, as compared with 2S(Cu) and NW(Cu), respectively, show a more remarkable increase in $\Delta\nu$ and $\Delta D/D$ than expected from the hydroxyl effect. This indicates that the planar effect promotes the formation of a complex and, moreover, that it is quite large.

According to the qualitative results discussed above from Tables II and III, the disazo dyes must have effective amino or hydroxyl groups as auxochromes and be planar to some extent, in order to produce a complex by combination with G and to show the spectral change with the complex formation. Further, the sulfonic groups attached to the coupling components are important not because of the number of their ionic charges, but rather because of such steric effects as that the sulfonic groups prevent the dye from taking a more planar structure, or in some influence of their configuration relative to those of the G dye.

Thus, at the present time, nothing has been obtained more than a qualitative decision on the respective effects. However, some quantitative estimation of the effects will become possible after the detailed investigation being carried out on the equilibrium constants and their temperature dependence, etc., including the 1 : 2 complex formation.

Summary

1. The absorption spectra of the dyes prepared by coupling disazotized 2S-, H-, chromotropic, NW-, γ- and J- acid with dianisidine, and of their copper derivatives were observed in aqueous solutions of the binary mixture with Chrysophenine G, and were compared with the sum curves of the component absorption spectra.

2. The order of the equilibrium constants for a 1 : 1 complex formed between the dyes not containing copper and Chrysophenine G was parallel to the respective values of the difference in wave number ($\Delta\nu$ cm^{-1}) between maximum positions in the region of 390~420 mμ of the curve simply added and that observed with the equimolar binary mixture of about 1×10^{-5}mol./l.; it was also parallel to those of the decreasing ratio in optical density ($\Delta D/D$) of the mixed system at the first maximum position of the sum curve.

3. Under the same conditions as above, $\Delta\nu$ and $\Delta D/D$ were also determined for the mixture of the copper derivatives and Chrysophenine G. In this case, the copper derivatives of 2S-, H-, and chromotropic acid, in the presence of effective auxochromes, still revealed large values of $\Delta\nu$ (ca. 1000 cm^{-1}) and $\Delta D/D$ (ca. 15%), while the values for the rest of the derivatives were almost zero.

4. Discussing the above results, it was shown that in order to display a spectral change due to the formation of a 1 : 1 complex in a binary mixture with Chrysophenine G, it is necessary that the partner dye has effective auxochromes (amino, hydroxyl) as terminal groups of a conjugated system. It was also shown that the sulfonic groups which are attached to the terminal naphthalene nuclei act on the structure of the dye itself as a steric factor rather than as an electric effect (repulsion) between the ionic charges in the groups and those of Chrysophenine G, and that the more planar structure, resulting in a smaller steric effect, produces more complex.

The authors wish to express their thanks to Mr. Toshihiko Hoshi for his help in the measurement of absorption spectra.

Organoboron Compounds. IV. The Dyeing Property of Polyvinyl n-Butylboronate with Congo Red*

By Seiji KATO, Yoshiko KURANO and Yojiro TSUZUKI

(Received June 22, 1961)

Recently Fujino and Fujimoto reported on the dyeing properties of two kinds of polyvinyl alcohol films[1], one of which had previously been heat-treated and the other, formalized. They showed that the dye sorbed by films decreases in quantity with the extent of formalization. In a previous paper[2], the present authors reported on the reaction of polyvinyl alcohol with *n*-butylboronic acid and on some properties of the products, showing that it is possible to prepare some films with various esterification grades. Generally it is considered that the force binding dye molecules to polyvinyl alcohol is chiefly due to the hydrogen bond and some mechanical retention. If the binding force comes into play by co-ordination, even in the absence of mordants, it will strengthen the bond between the dye molecule and the substrate. The aim of this investigation consists in the point mentioned above. Since it is well known that the boron atom can co-ordinate easily with such negative atoms as oxygen, nitrogen and halogens, the dyeing capacity of polyvinyl boronate is expected to become large. In a previous communication[3] the authors showed that the quantity of the dye sorbed by films increases with the increasing esterification grade and that the apparent diffusion coefficient also corresponds to the esterification grade. The authors have observed some facts regarding the property of polyvinyl *n*-butylboronate films dyed with Congo red, the former containing boron atoms and the latter, nitrogen atoms.

Experimental

Substrates.—Boronate films were prepared, as described in a previous paper[2], by pouring a carbon tetrachloride solution of polyvinyl *n*-butylboronate with different esterification grades on a surface of mercury and then drying it for several days at room temperature. The films were all cut in pieces 1 cm.×2 cm. The thickness was about 0.1 mm. Congo red was purified according to Robinson and Mills' method[4].

Dyeing Procedure.—The films with different esterification grades were immersed into a Congo red solution at various temperatures. Then the sample were taken out one by one at definite intervals, well washed with cold water, and desorbed with a pyridin-water mixture. The amounts of dye sorbed by the samples were measured with a photo-electric colorimeter.

Measurement of the Heat of Sorption by Micro-desorption Method.—The samples having various esterification grades were previously dyed with Congo red and immersed into water kept at 20, 40 and 60°C according to the method which was proposed by Gilbert and Rideal[5]; after reaching equilibria, the desorbed dye was measured by a photo-electric colorimeter.

Results and Discussion

In dyeing experiments, it is generally necessary to record the time needed to reach the equilibrium of sorption. The sorption rate here was always faster than that of the polyvinyl alcohol film prveiously studied by Fujino and Fujimoto[1]. Figure 1 shows the relation between the rate and the temperature obtained with samples of the same esterification grade. Above 60°C the samples swelled for the first 10 hr. and later partially dissolved owing to

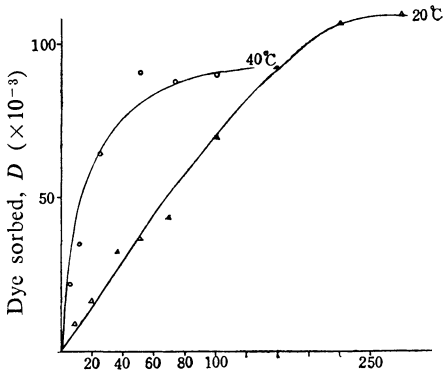

Fig. 1. Dye sorbed and absorption rate.

the hydrolysis of the samples; therefore, the rate curves above 60°C were all neglected.

With samples of different esterification grades (E_g), differences in sorption were also observed. At the same time the quantity of the dye sorbed corresponds to the value of E_g, the data of which are given in Table I.

TABLE I. RELATION BETWEEN THE QUANTITY OF THE DYE SORBED AND ESTERIFICATION GRADE (E_g)

No. of sample	E_g, %	Dye sorbed (g./g. dry film) $\times 10^2$ 20°C	40°C	Activation energy kcal./mol.
B-1	75.4	5.6	4.7	17.4
B-2	80.6	7.9	6.0	16.1
B-3	85.6	10.9	9.2	13.0

Esterification grade (E_g) can be estimated from the boron content of the products by the following equation:

$$E_g = (133.74 \times B\%)/(16.41 - B\%)$$

Heat of Sorption.—In order to learn whether co-ordination takes place or not in this dyeing mechanism, the measurement of the heat of sorption was desirable. In the case of cellulose fiber and Vinylon, the heat of sorption was estimated to be about 10 to 20 kcal./mol.[6] According to Laubengayer and Condike[7], the heat of formation of the complex between trimethylboron and ammonia is 41.3 kcal./mol. This value seems to represent the energy of the B–N bond. The heat of sorption can be measured by means of the microdesorption method, which is quite convenient and can be used smoothly*. The results were shown in Fig. 2.

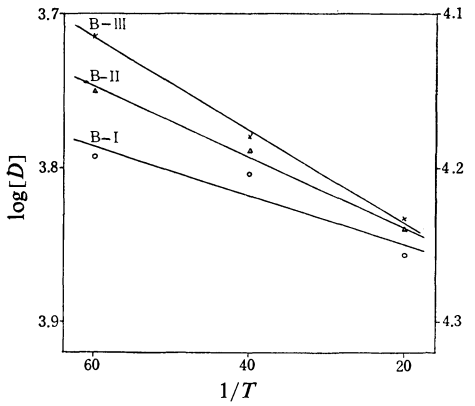

Fig. 2. Temperature dependance of the desorption of dye in equilibrium.

The slopes of the three lines in Fig. 2 represent the heat of sorption. These values apparently correspond to E_g. The values obtained are, however, not so high as those observed with cellulose and Vinylon fibers, as can be seen in Table II.

TABLE II. THE HEAT OF SORPTION AND ESTERIFICATION GRADE

No.	% E_g	Heat of Sorption (HS) kcal./mol.	HS/E_g
B-1	75.4	15.9	0.21
B-2	80.6	22.5	0.23
B-3	85.6	30.1	0.35

In order to study this problem, deeper infrared spectra were taken with dyed as well as undyed films, the data of which are shown in Fig. 3.

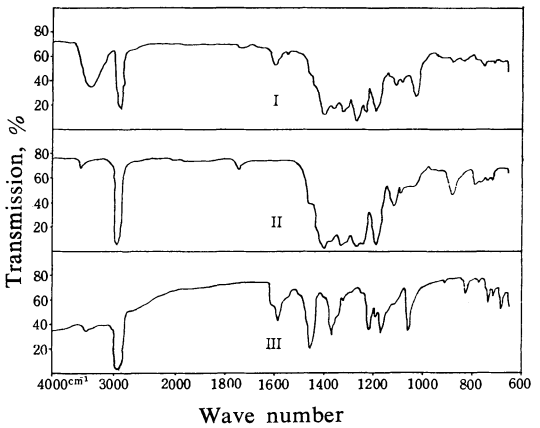

Fig. 3. Infrared spectra.

II Film not dyed
III Congo red in Nujol

The absorption band at 1580 cm^{-1} can be assigned to the azo bond, that at 3420 cm^{-1} to the bonds of amino group, and many bands below 1300 cm^{-1} in III to those of the aromatics[8]. Among the bonds of the boron atom linked with such negative atoms as oxygen, nitrogen and halogens, the B–N bond is the strongest, so bonding can be expected to occur with the azo and amino groups. The weak band at 3510 cm^{-1} may be regarded as due to a free type of hydroxyl group in II, and this absorption peak and that of the amino group at 3420 cm^{-1} shift to a lower frequency after the dyeing with Congo red, while the absorption band of the azo group shifts to a slightly higher frequency. From these results, it is considered that the bonding between the boron

8) L. J. Bellamy, "The Infra-red Spectra of Complex Molecules", Methuen & Co., London (1958), p. 272.

atom and the nitrogen atoms may take place, for the most part, at the amino group in the dye molecules. Of course, the hydrogen atom of the amino group in the dye molecule can make a hydrogen bond with the oxygen atom[9] in polyvinyl *n*-butylboronate; hence, the presence of the broad band at 3400 cm^{-1} in the spectrum of I can be ascribed to two factors, one of which is the formation of the hydrogen bond between the amino group of the dye and the oxygen atom of polyvinyl *n*-butylboronate, and the other is the co-ordination of the boron atom to the nitrorgen atom of the amino group. The energy of dyeing should become ca. 40 kcal./mol. if all dye molecules are fixed to polyvinyl *n*-butylboronate by co-ordination, but, in fact, the values of the heat of sorption per E_g are not always equal. This means that the dyeing proceeds not only through co-ordination but also through a hydrogen bond.

Another factor which should be considered regarding the results of the relation between E_g and the dyeing property is the destruction of the dense polyvinyl alcohol structure by the treatment with boronic acid. Sakurada and Okada[10] have studied the reaction of boric acid with polyvinyl alcohol by means of X-ray diffraction; on the basis of the diminished fine structure in the diffraction pattern, they concluded that the crystalline part of polyvinyl alcohol is thereby decreased. In the case of the reaction of *n*-butylboronic acid with polyvinyl alcohol the molecular weight and the size of this acid are larger than those of boric acid, so that the crystalline part of polyvinyl alcohol, will diminish with the increasing esterification grade. The results of the estimation of activation energy suggest this consideration. Thus, experimenial results show that the two factors mentioned above overlap. In order to demonstrate the co-ordination, further experiments with various dyes should be carried out. The effects of various reactants on the spectra of the polyvinyl *n*-butylboronate in solution will be discussed later.

Studies on Sulfabenzothiazoles

By Prithwi Nath BHARGAVA and Suresh Chandra SHARMA

(Received September 15, 1961)

With a view to examining the medicinal and industrial importance of "benzothiazole derivatives", sulfabenzothiazole, sulfa-6-methyl-, -6-chloro-, -6-methoxy-, -6-nitro-benzothiazoles and sulfa-β-naphthothiazole, have been synthesized. As an extension of the previous work on 2-aminobenzothiazole derivatives[1], acetylamino-, benzoylamino-, 2-(2-hydroxy-1-naphthylazo)- and 2,2'-azobisbenzothiazole derivatives from the substituted 2-aminobenzothiazoles have also been prepared.

The starting compound, 2-aminobenzothiazole[2] was obtained by the action of liquid bromine on asymmetrical phenylthiourea in an inert medium like chloroform. Similarly other substituted, 2-amino-4-methyl-[3], -5-methyl-[1], -6-methyl-[4], -5-chloro-, -6-chloro-[4], -4-methoxy-, -6-methoxy-[1], -4-ethoxy-[4], -6-nitro-[1]benzothiazoles and 2-amino-α-naphtho-[1], -β-naphtho-[1]thiazoles have been prepared from the corresponding substituted asymmetrical arylthioureas and the latter were subsequently prepared[5,6] by the interaction of ammonium thiocyanate with the corresponding amine hydrochlorides.

The compound, sulfathiazole[7] was obtained by the condensation of acetylsulfanilyl chloride[8] (ASC) and 2-aminothiazole in pyridine and

by subsequent alkaline hydrolysis of the condensed product. Following the same procedure all the sulfabenzothiazoles and sulfanaphthothiazoles have been synthesized and tested for bactericidal activity[9]. Further an absorption spectra study of these sulfabenzothiazoles has been made as a physical evidence in confirmation of structure of these compounds.

Experimental

2-(*p*-Aminobenzenesulfonamido)-benzothiazole.—Into a flask 3 g. of 2-aminobenzothiazole, 4.4 g. of acetylsulfanilyl chloride and 18 ml. of pyridine were taken and heated under reflux on a water bath for about two and a half hours. The contents were poured on cooling into water and the solid was filtered and crystallized from dilute ethanol. This intermediate product was heated under reflux on a low flame with 20 ml. of alcoholic 10% sodium hydroxide solution for two hours. The solution of the flask was poured into cold water and the solid substance filtered, dried and finally crystallized from ethanol into a white crystalline form, m. p. 213°C.

Similarly other substituted sulfabenzothiazoles were prepared. Their proprties and analytical data are recorded in Table I. However, with this procedure, the synthesis of sulfabenzothiazoles was not successful with 2-amino-4-methyl-, -5-methyl-, -5-chloro-, -4-methoxy-, -4-ethoxy-benzothiazoles and 2-amino-α-naphthothiazole.

2-Acetylamino-6-methylbenzothiazole.—One gram of 2-amino-6-methylbenzothiazole and 4 ml. of acetic anhydride were heated under reflux for 15 min. and then on cooling poured into cold water. The solid substance was filtered, dried and crystallized from ethanol into a white crystalline form, m. p. 202°C.

Similarly acetylamino derivatives of 2-amino-5-chloro-, -6-chloro-, -4-methoxy-benzothiazoles were prepared and on analysis the number of acetyl group in these derivatives was found to be one. Their properties and analytical data are given in Table II.

2-Benzoylamino-6-methylbenzothiazole. — Into a flask 1 g. of 2-amino-6-methylbenzothiazole was dissolved in 10 ml. of 20% sodium hydroxide solution and then it was treated with 1.5 ml. of benzoyl chloride, small quantity at a time with vigorous shaking and cooling. After the addition of the latter, the flask was warmed on a water bath under reflux to hydrolyze the excess of benzoyl chloride. The solid was cooled, filtered, washed with water, dried and crystallized from ethanol into a colorless crystalline from, m. p. 178°C.

Similarly, 2-benzoylamino derivatives of 5-chloro-, -6-chloro-, -4-methoxy-, -6-methoxy-benzothiazoles were prepared and on analysis the number of benzoyl groups in these derivatives was found to be one. Their properties and analytical data are mentioned in Table III.

6-Methyl-2-(2-hydroxy-1-naphthylazo)-benzothiazole.—Into a flask 20 ml. of dilute hydrochloric acid 1 g. of 2-amino-6-methylbenzothiazole was dissolved and diazotized as usual. The diazotized product was coupled with 0.9 g. of β-naphthol dissolved in 10 ml. of 4% sodium hydroxide solution. The orange brown azo compound on extraction with ether and crystallization in vacuum gave chocolate crystals, m. p. 124°C. It developed rosy red color in glacial acetic acid and gave the original

2-amino-6-methylbenzothiazole on reduction with tin and concentrated hydrochloric acid.

Similarly six more azo-compounds were prepared from different substituted 2-aminobenzothiazoles. Their properties and analytical data are recorded in Table IV.

2,2'-Azobis(6-methylbenzothiazole). — One gram of 2-amino-6-methylbenzothiazole was suspended in 30 ml. of water taken in a beaker and was gradually treated with 50 ml. of 0.3 N solution of sodium hypochlorite and kept for half an hour. The brown solid, after being washed with ether, was extracted with a mixture of chloroform and light petroleum ether (1 : 1). After evaporation of the solvents the products was left as dark brown crystals, m. p. above 300°C. It developed brownish red color in glacial acetic acid and gave the original benzothiazole on reduction with tin and concentrated hydrochloric acid.

Similarly other azobisbenzothiazole derivatives were prepared from 2-amino-5-chloro-, -6-chloro-, -4-methoxy-, -4-ethoxy-benzothiazoles and their properties and analytical data are given in Table V.

Absorption Spectra Measurements of Sulfabenzothiazoles.—The study of ultraviolet spectra of sulfabenzothiazoles was carried out in spectroscopically pure absolute ethanol on Beckman D. U. spectrophotometer. The values of λ_{max} for different peaks observed from the curves are given in Table VI.

The λ_{max} at 226 mμ in 2-(*p*-aminobenzenesulfonamido)-benzothiazole is due to the presence of benzenesulfonamido nucleus and the second peak at 269.5 mμ is due to the presence of 2-aminobenzothiazole (a shift of λ_{max} from 262 to 269.5 mμ due to the presence of benzenesulfonamido nucleus). Substituents like chlorine atom, methyl and methoxy groups in 2-aminobenzothiazoles at position 6 have little effect on the shift. But in sulfa-6-nitrobenzothiazole a tendency of absorption peak to appear at higher wavelength is observed because of the presence of chromophoric group like nitro group which has pronounced effect to increase absorption from ultraviolet to visible region and thus cause for the appearance of color (yellow). So in this case the second absorption peak appeared at 352 mμ. In the case of sulfa-β-naphthothiazole absorption peaks are found at 229.75, 257.5 and 299.5 mμ, as the latter two are due to the presence of β-naphthothiazole.

Assay of Sulfabenzothiazoles for Bactericidal Activity.—The compounds were tested in Central Drug Research Institute, Lucknow, India, for bactericidal activity according to the method[9] and it was found that sulfa-6-methyl-, -6-chloro-, -6-methoxy-, -6-nitro-benzothiazoles were inactive upto a dilution of 1 : 1000 against Klebsilla pneumonial; Salmonella paratyphi; Salmonella typhi; Escherichia coli; Shigella dysenteriae (Shiga); Micrococcus pyrogenes Var aureus; Acrobactor aerogenes and B. subtillis.

Thanks of the authors are due to Professor Gurbakhsh Singh, head of the Department of Chemistry and other authorities of the Banaras Hindu University for providing necessary facilities and also to Dr. Dashrath Lal Srivastava, Deputy Director C. D. R. I., Lucknow for the assaying of sulfabenzothiazoles.

Electronic Spectra and Electronic Structures of Some Basic Heterocyclic N-Oxides

By Tanekazu KUBOTA

(Received January 24, 1961)

In a series of previous papers[1,2], we reported on the electronic spectra and electronic structures of various basic heterocyclic *N*-oxides such as pyridine, quinoline, acridine *N*-oxides, etc. and also on their derivatives. The assignment of ultraviolet absorption bands and the interpretation of other physicochemical properties (such as dipole moments, infrared spectra, molecular diagrams, reactivities, dissociation constants, etc.) of basic heterocyclic *N*-oxides were made from the experimental and theoretical points of view. It was concluded that the strongest band near 280 mμ observed with pyridine *N*-oxide and its simple derivatives can not be assigned to the ^1L_b band whose transition moment is parallel to the x-axis as shown in Fig. 4 and that, on the other hand, it may reasonably be interpreted as a new band (charge transfer band) whose transition is associated with the charge displacement from the oxygen atom to the pyridine nucleus*1.

As to the absorption bands of polyheterocyclic *N*-oxides, however, band assignments by means of Platt's treatment were possible. In the present work, the spectra and the electronic structures of some basic *N*-oxides are reported in a development of our previous work*2. The electronic absorption spectra of pyrazine mono- and di-*N*-oxides and 4-methylpyrimidine *N*-oxide and the electronic structures of pyrazine di-*N*-oxide and some other compounds have been studied and compared with the results in the previous studies.

Experimental

Materials. — Pyrazine mono- (m. p. 108°C) and di- (d. p. 260°C) *N*-oxides were prepared by the oxidation of pyrazine with an equivalent and an excess of hydrogen peroxide respectively, and were purified by sublimation in vacuum. A pure sample of 4-methylpyrimidine *N*-oxide (m. p. 76~79°C) was supplied by Dr. Yamanaka of Tohoku University[7]. Organic solvents such as *n*-heptane, dioxane, alcohol, etc. for spectrophotometric measurements were purified according to the standard method[8].

Measurement. — A Hitachi recording spectrophotometer model EPS-2 and a Beckman spectrophotometer model D. U. were used for the ultraviolet absorption measurements of solutions. Measurements were usually carried out at room temperature (20~25°C), using the quartz cell with a stopper of a 1 cm. light path. For measurements of weak absorption bands, quartz cells of 2, 5 and 10 cm. light path were also used. If necessary, however, the temperature of the absorption cell was kept constant by circulating water of a desired constant temperature through the cell jacket.

Experimental Results

Absorption Spectra of Pyrazine Di-*N*-oxide. — As is shown in Fig. 1, the spectrum in an absolute dioxane solution*3 apparently consists of the three main bands (i. e., 324, ~260 and 223 mμ*4) and of some bands of a lower intensity superposed on the main absorption band near 350~370 mμ. Figure 1 also shows our band analysis based on the method which was used by Stephenson for the interpretation of the $n\rightarrow\pi^*$ and $\pi\rightarrow\pi^*$ bands of pyridine and its simple derivatives[9]. Oscillator strengths of each band obtained by the above analysis were calculated in terms of Eq. 1,

$$f=4.32\times10^{-9}\int\varepsilon d\tilde{\nu} \qquad (1)$$

where the value of the integral, $\int\varepsilon d\tilde{\nu}$, was estimated by the approximate formula, $\int\varepsilon d\tilde{\nu}\fallingdotseq$ [(half wide value in cm^{-1})$\times\varepsilon_{max}$] and the

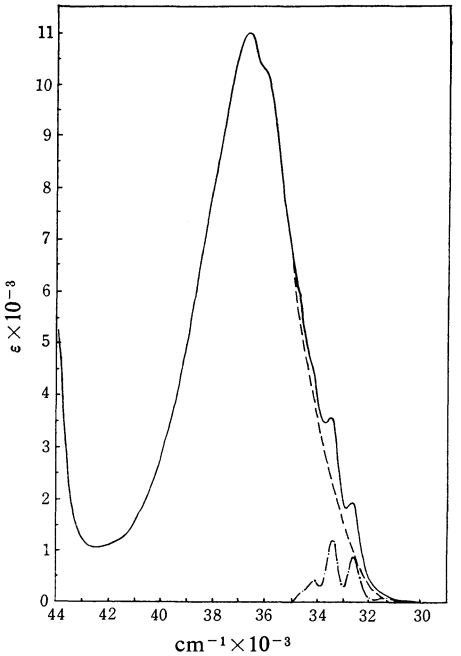

Fig. 2. Absorption spectrum in *n*-heptane solution and band analysis of pyrazine mono-*N*-oxide.

graphic integration for the main band and the weak bands respectively. The results are shown in Table I. In solvents such as alcohol and water, the absorption bands show a blue shift with the increase in solvent polarity. Especially, the weak band which appeared obviously in the longest wavelength region in non-polar solvents could not be observed even by careful measurement using the cell of a 10 cm. light path[6]. It may be possible that the blue shift of the above weak bands due to the change from non-polar to polar solvents is much greater than that of the main $\pi \rightarrow \pi^*$ band*[5], and that therefore we could not find the weak bands in polar solvents, which are hidden below the main $\pi \rightarrow \pi^*$ band.

Absorption Spectra of Pyrazine Mono-*N*-oxide. —As is shown in Fig. 2, the spectrum of this compound in an *n*-heptane solution shows distinct maxima at 275 and 222 mμ*[6] which exhibits three fine structures. The spectrum also shows some fine structures superposed on the long wavelength side of the $\pi \rightarrow \pi^*$ band. Our band analysis of the above spectrum is also shown in Fig. 2. It may be inferred that the above weak band has a fine structure consisting of three peaks. The behavior of the spectra in polar solvents is similar to that of pyrazine di*N*-oxide[6], while the weak band could not be observed in polar solvents. The results of our band analysis are shown in Table I.

Absorption Spectra of 4-Methylpyrimidine *N*-oxide. — The spectra of this compound in *n*-heptane and water solutions are shown in Fig. 3 and in Table I. A distinct difference compared with the above two compounds is that the low intensity band which appears obviously in non-polar solvents at the longest wavelengh region can also be found partly in water. Our band analysis was carried out by the following method. First, the tail of the strong longest wavelength $\pi \rightarrow \pi^*$ band in water was extended as smooth as possible; the $\pi \rightarrow \pi^*$ band thus obtained was symmetrical with respect to the band's center line. This band was then subtracted from the total absorption band. Thus we obtained band I. Second, the same procedure was applied to the spectrum in *n*-heptane, and band II was obtained. Finally, it was assumed that band I had almost the same intensity in *n*-heptane as in water, and band I′ (the absorption band in *n*-heptane corresponding to the band I in water) was subtracted from band II as shown in Fig. 3. This

*5 According to the general rule for the UV spectra of heterocyclic *N*-oxides, these $\pi \rightarrow \pi^*$ bands show a remarkable blue shift with the above-described variation in solvent[1,6]. On the other hand, the hydrogen bonding such as $\rangle N \rightarrow O \cdots\cdots H$ (solvent) is an essential mechanism in such general spectral behavior[10,11].

*1 See Ref. 22.
*2 See Ref. 1.
*3 If we should assume that all weak bands in the longest wavelength region are due to $n\rightarrow\pi^*$ transition, the value of $[f_{n\rightarrow\pi^*}/f_{CT}]$ is 0.174. This value, however, is abnormally large.

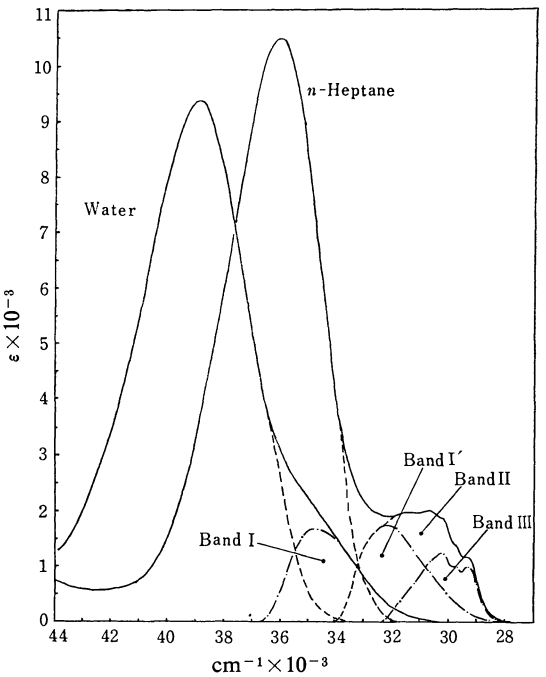

Fig. 3. Absorption spectra in *n*-heptane and water solutions and band analysis of 4-methylpyrimidine *N*-oxide.

way of subtraction would be fairly reasonable. The weak band in *n*-heptane was thus divided into bands I′ and III. The results obtained by the above band analysis are shown in Table I.

Theoretical

Electronic State and Electronic Spectrum of Pyrazine Di-*N*-oxide. — Theoretical calculation based on π-electron approximation, in which electron repulsion terms are taken into account, was carried out on pyrazine di-*N*-oxide. The method is almost the same as that of the previous calculation on pyridine *N*-oxide. Following the procedure of Longuet-Higgins and Murrell, pyrazine di-*N*-oxide is divided into two parts, pyrazine nucleus and two oxygen atoms, and self-consistent field (SCF) calculations for the above two parts are carried out. Then the interaction between the above two parts is calculated. Now, let us explain the procedure in some detail.

SCF Calculation of the Pyrazine Residue.— The electronic structure of pyrazine residue may differ considerably from that of the normal pyrazine molecule, because the N–O bond may be considered to be like a semi-polar bond. In view of the above point[2], a virtual proton model, which was used to calculate the electronic structure of pyridine *N*-oxide, is also adopted in the present calculation. This model is shown in Fig. 4. Hamiltonian calculations for the total π-electrons may be written as:

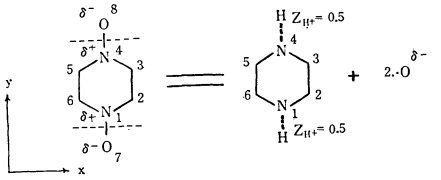

Fig. 4. The model of pyrazine di-*N*-oxide for MO calculation by composite system method. The proton potential, where Z_{H^+} was taken equal to 0.5, should be regarded as representing the core potential due to the formally charged nitrogen atom "$N^{\delta+}$".

$$H=\sum_i\left[H_i^{\text{core}}-\sum_p\frac{Z_{H^+}\cdot e^2}{r_{pi}}\right]+\sum_{i<j}\frac{e^2}{r_{ij}} \quad (2)$$

Here, r_{pi} represents the distance (1.032 Å)[2] between a virtual proton and an ith electron, while $Z_{H^+}\cdot e$ represents the effective charge of the virtual proton, the value being 0.5. We have used here the semiempirical SCF MO method, including zero-differential overlap approximation, as developed by Pople[12]. According to this method, the matrix elements of Fock's Hamiltonian calculation in terms of AO's can be written as follows:

$$F_{\mu\mu}=\alpha_\mu^{\text{core}}+V_\mu^p+\frac{1}{2}p_{\mu\mu}\cdot\gamma_{\mu\mu}+\sum_{k(\neq\mu)}(p_{kk}-1)\gamma_{\mu k} \quad (3)$$

$$F_{\mu\nu}=\beta_{\mu\nu}^{\text{core}}-\frac{1}{2}p_{\mu\nu}\cdot\gamma_{\mu\nu} \quad (4)$$

V_μ^p in Eq. 3 can be written as

$$V_\mu^p=-Z_{H^+}\cdot e^2\int\sum_p(\phi_\mu^2(i)/r_{pi})\mathrm{d}\tau_i \quad (5)$$

where ϕ_μ represents a 2pπ-AO of atom μ. V_μ^p was calculated by Roothaan's formula[13] using Slater type AO for ϕ_μ. As for the molecular dimensions of the pyrazine residue, it was assumed for the sake of simplicity that the pyrazine residue was a regular hexagon of V_h symmetry. The virtual proton potential as shown in Eq. 5 does not necessarily mean the simple electrostatic potential; it can be regarded as representing the modifications of core potentials due to the formally charged nitrogen atom "$N^{\delta+}$" in the pyrazine residue. Z_{H^+} is taken to be 0.5 in view of the fact that, in the previous calculation of pyridine *N*-oxide by the method of the composite system, SCF MO's of the pyridine residue obtained by the virtual proton model*7, where Z_{H^+} was taken to be equal to 0.5, were in nice agreement with the SMO's (simple molecular orbitals) of the pyridine residue obtained by the following procedures*8. The values of parameter k_N and k_O in Eqs. 7 and 8 are chosen so as to reproduce the electron densities obtained from the experimentally-determined Hammett's σ-value of the aromatic *N*-oxide group in non-polar solvents, using Jaffe's relation[2]. In this case

$$\alpha_N=\alpha+k_N\cdot\beta \quad (7)$$

$$\alpha_O=\alpha+k_O\cdot\beta \quad (8)$$

all resonance integrals including β_{NO} are assumed equal to β, and the inductive effect is put at $(1/3)^n\cdot k_N$. The SMO's of the pyridine residue were calculated by using the parameters k_N and $(1/3)^n\cdot k_N$ thus obtained.

The values of the two center electronic repulsion integrals $\gamma_{\mu\nu}$ have been evaluated by Mataga's method[15], where the point-charge model[12] was modified by means of Pariser-Parr's treatment[16]. The values of the integrals α_N^{core}, α_C^{core}, γ_{NN}, γ_{CC}, β_{CC}^{core} and β_{CN}^{core} are taken to be the same as those used in the previous paper[2]. The values of V_N^p and V_C^p are -8.107 and -5.455 eV. respectively.

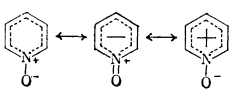
As for the starting MO in the SCF procedure, the SMO obtained by the use of parameters $k_N=k_1=\alpha+1.6\beta$ and $\alpha_2=\alpha+0.711\beta$ (0.711 is a sum of inductive effects—$(1/3)^n\cdot k_N$—contributed from each nitrogen atom) from the above point of view was used; this SMO is near to the SCF MO's obtained by the iterative calculation of Eq. 9.

$$\sum_\nu F_{\mu\nu}\cdot C_{i\nu}=\varepsilon_i\cdot C_{i\mu} \quad (9)$$

The SCF MO's, eigen-values and symmetries of orbitals obtained in this way are shown in Table II and in Fig. 5. Here, symmetries of the orbitals are the same as those described in the previous paper[2].

Energy Levels of Oxygen Atoms.—The MO's of two oxygen atoms can be written as follows:

$$(b_{2u})\phi_7=1/\sqrt{2}(\phi_7+\phi_8) \quad (10)$$



$$(b_{3g})\phi_8=1/\sqrt{2}(\phi_7-\phi_8) \quad (11)$$

Here, ϕ_7 and ϕ_8 represent the 2pπ AO of oxygen atoms 7 and 8 respectively. ϕ_7 and ϕ_8 are nearly degenerate, and the eigen-value for these MO's was evaluated using Eq. 12, were $\overline{F}^c{}_{\mu\mu}$ and $\overline{F}^c{}_{\mu\nu}$ represent the mean value of $F_{\mu\mu}$'s for carbon atoms and that of $F_{\mu\nu}$'s for the nearest neighbor carbon atoms respectively, because the matrix elements ($F_{\mu\mu}$ and $F_{\mu\nu}$) in the SCF MO method correspond reasonably to the matrix elements in the SMO method (for example, Eq. 7 and 8):

$$F_{OO}=\overline{F}^c{}_{\mu\mu}+k_O\cdot\overline{F}^c{}_{\mu\nu} \quad (12)$$

k_O was taken to be 1, since the F_{OO} value obtained from the previous ASMO CI calculation on pyridine *N*-oxide corresponds to the case $k_O=1$[1], and thus $F_{OO}=-15.34$ eV. was obtained.

Obtained energy levels are shown in Fig. 5. Now, it may be possible that electronic transitions, as shown by arrows in Fig. 5, make a great contribution to the near-ultraviolet absorption of pyrazine di-*N*-oxide. Therefore, these transitions were taken into account. The calculation of the excitation energies was made as follows. First, the energy values of the locally excited states were calculated on the basis of the results shown in Table II, using the method of configuration interaction. These results are shown in Table III. In this table, for example, ${}^1\chi_{3\to4}$ denotes the configuration produced by one electron transition from ϕ_3 to ϕ_4, and the necessary formulas for transition energies and interaction energies between these configurations are shown in the footnote*9.

The energy values of the charge transfer configurations due to electron transfers from ϕ_7 and ϕ_8 to the orbitals of pyrazine nucleus are also shown in Table III. In this case, it is assumed that r_{NO}, $r_{77}=r_{88}$ and $\beta_{71}^{\text{core}}=\beta_{84}^{\text{core}}$ are equal to 1.27 Å, 14.127 eV. and −2.00 eV. respectively, owing to the same reason as described in a previous paper[2]. The values

*9 $[{}^1\chi_{i\to j}\,|\,H\,|\,{}^1\chi_{i\to j}]=\varepsilon_j-\varepsilon_i+2(ij\,|\,G\,|\,ji)-(ij\,|\,G\,|\,ij)$

$[{}^1\chi_{i\to j}\,|\,H\,|\,{}^1\chi_{k\to l}]=2(kj\,|\,G\,|\,li)-(kj\,|\,G\,|\,il)$

$[{}^1\chi_{i\to j}\,|\,H\,|\,\Psi_0]=\sqrt{2}\,\varepsilon_{ij}$

$[{}^1\chi_{i\to j}\,|\,H\,|\,{}^1\chi_{k\to j}]=-\varepsilon_{ik}+2(kj\,|\,G\,|\,ji)-(kj\,|\,G\,|\,ij)$

$[{}^1\chi_{i\to j}\,|\,H\,|\,{}^1\chi_{i\to l}]\varepsilon_{jl}+2(ij\,|\,G\,|\,li)-(ij\,|\,G\,|\,il)$

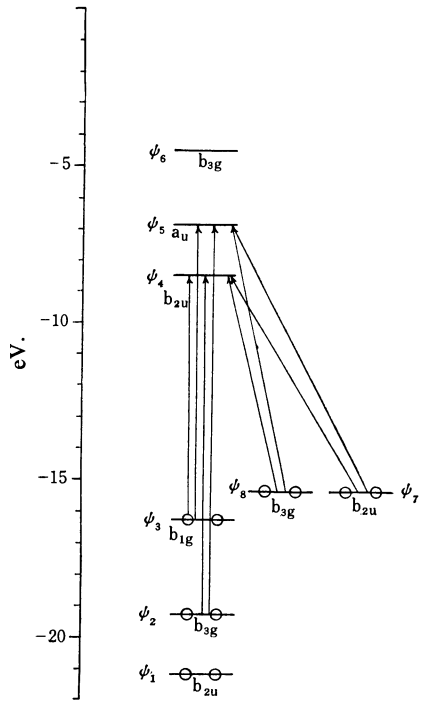

Fig. 5

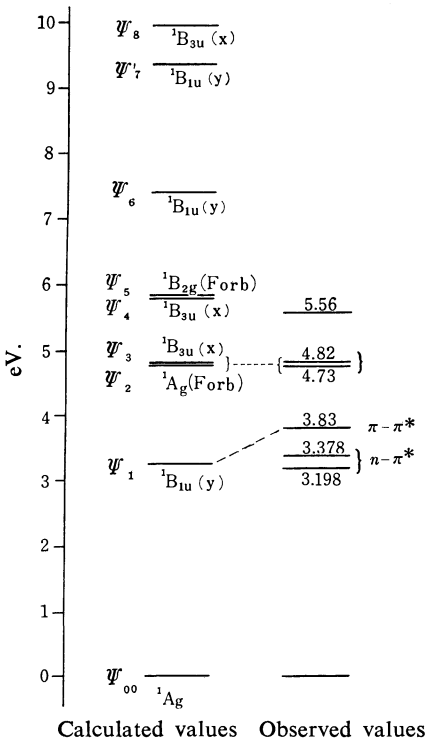

Fig. 6. The calculated energy levels and observed values in dioxane solution of pyrazine di-*N*-oxide.

of $\gamma_{7\mu}$ etc. were evaluated in the same way as that for the pyrazine nucleus. Next, the matrix elements of the interactions between each state of ^1L_b, ^1B_b, ^1L_a and ^1B_a and each state of the above charge transfer configurations were calculated. Therefore, we could obtain the energy levels of pyrazine di-*N*-oxide as solutions of secular equations belonging to the same symmetry, such as Eq. 13 etc. (Eq. 13 is for $^1B_{3u}$ (x)).

$$\begin{vmatrix} {}^1\chi_{8-5} & {}^1L_b & {}^1B_b \\ 4.8299-E & 0.5091 & -1.7131 \\ 0.5091 & 4.4817-E & 0 \\ -1.7131 & 0 & 8.2246-E \end{vmatrix} = 0 \quad (13)$$

The results obtained by the above treatment were shown in Table IV and Fig. 6, together with the experimental results.

The Electronic States of Isoquinoline *N*-Oxide and Acridine *N*-Oxide. — The following values of parameters for SMO can be shown to be suitable for interpreting various physicochemical properties of heterocyclic *N*-oxides[2]. Namely,

TABLE V. DIPOLE MOMENTS AND REACTIVITIES ESTIMATED FROM SMO CALCULATIONS

Substance	π-Moment (Debye unit)		Total moment (Debye unit)*		
	π/1.6	The angle between x-axis and π-moment	Calculated values	The angle between x-axis and total moment	Observed value
	0.76		4.33		—
	1.88		3.14		3.90[20]

Substance	Electrophilic reaction**	Nucleophilic reaction	Radical reaction
	10≫6≈8>2	10≈3>5≈8	10≫3>8
	8>6>4	8>6>4≈3	8>6>4

* Following Katritzky's analysis[30], total moments were calculated with vector addition between π-moment and observed value (5.02 D) of trimethylamine *N*-oxide.

** Recently, bromination and nitration of acridine *N*-oxide which were investigated by R. M. Acheson et al. gave 8-Br- and 8-NO_2- acridine *N*-oxides[20]. This fact agrees with present theoretical prediction.

k_N, k_O and inductive effects in Eqs. 7 and 8 were set equal to 1.6, 0.595 and $(1/3)^n \cdot k_N$ respectively. We also carried out the SMO calculations on isoquinoline *N*-oxide and acridine *N*-oxide, because the calculations using the above parameters were not carried out on these compounds in the previous paper[2]. Molecular diagrams and MO's obtained in this way are shown in Figs. 7 and 8 and in an appendix respectively, while the calculated dipole moments ($\vec{\mu}$) and active points for electrophylic, nucleophylic and radical reactions are shown in Table V. The π-moments ($\vec{\mu}_\pi$) obtained from the present calculations are considerably larger than those estimated from the observed value. Therefore, by Orgel et al.'s procedure[17], $\vec{\mu}_\pi$ was divided by 1.6.

The geometrical structure of the molecules used to calculated the dipole moments was the same as that described in the previous paper[2]. Namely, it was assumed that the shape of these molecules was a condensed regular hexagon the bond distance of which was 1.395 Å, and r_{NO} was taken to be equal to 1.27~1.28 Å. The prediction of reaction centers was based upon the frontier orbital method as used in previous papers[2,18].

The reaction centers of acridine *N*-oxide obtained from the above calculations are in approximate agreement with those of the

18) K. Fukui, T. Yonezawa and H. Shingu, *J. Chem. Phys.*, **20**, 722 (1952); K. Fukui, T. Yonezawa, C. Nagata and H. Shingu, ibid., **22**, 1433 (1954).

previous calculation in which parameters for *N*-oxide molecules in polar solvents were employed instead of the present ones.

As for isoquinoline *N*-oxide, it is interesting that even if the reaction types are different from one another, the tenth position in Fig. 7 is always the most active position*10).

Moreover, some molecular constants (charge densities and bond orders) obtained by the present calculation on isoquinoline *N*-oxide, and also those of isoquinoline obtained by the use of parameters close to the present ones, are shown in Fig. 9 for the purpose of comparison[21].

As can be well understood from Fig. 9, electron migration from the oxygen atom to ring, which does not include the *N*-oxide group, is quite small. Therefore, it may be reasonable to consider the reactivity for such a ring as almost the same as that of isoquinoline.

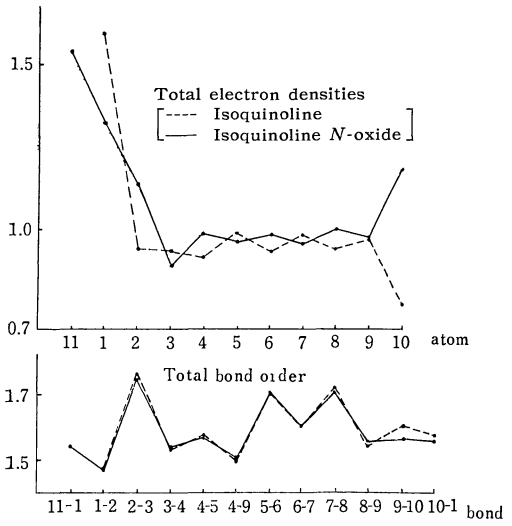

Fig. 9. The comparison of total electron densities and bond orders between isoquinoline *N*-oxide and isoquinoline ($k_N = 2$; $k_{C'} = 0.25$ on isoquinoline)[21].

Discussion

On the Absorption Bands of Pyrazine Mono-*N*-Oxide and 4-Methylpyrimidine *N*-Oxide. — According to our previous investigations[1,2] and those of the other authors[22,23], it is evident that the near ultraviolet absorption of pyridine *N*-oxide and related compounds exhibit three main absorption bands from both experimental and theoretical points of view. These bands are the $n\rightarrow\pi^*$ band (this is due to electron transitions from lone pair orbitals of oxygen to π^*-orbitals), the charge transfer (CT) band and the ^1L_b band (this corresponds to the $^1B_{2u}$ band of benzene). We can make an approximate interpretation of the electronic spectra of pyrazine mono*N*-oxide and 4-methylpyrimidine *N*-oxide based on the previous results of ASMO CI calculation for pyridine *N*-oxide[2] because the effects of the replacement of –CH= by –N= and the substitution for ring hydrogen of methyl on the electronic spectra are rather small and because the intrinsic natures of the absorption bands of the parent compound seem to be scarcely affected by such replacement and substitution*11.

As can be seen in Table I, Fig. 2 and Fig. 3, it would be moderately possible for the weak bands which pyrazine mono-*N*-oxide and 4-methylpyrimidine *N*-oxide show at 300 mμ and at 331 mμ respectively to be assigned to the $n\rightarrow\pi^*$ bands, because these weak bands having fine structures in non-polar solvents shift obviously toward a shorter wavelength with an increase of solvent polarity and can not be found in water or alcohol solutions.

According to Ito's rule[22], obtained from the comparison in oscillator strength (f) between the $n\rightarrow\pi^*$ and $\pi\rightarrow\pi^*$ bands of conjugated compounds, the value of $f(n\rightarrow\pi^*)/f(\pi\rightarrow\pi^*)$ should be about 0.05 and may not exceed $\sim$0.1*12.

*10 Whenever a nitration is tried for isoquinoline *N*-oxide in the usual manner, the nitro group is introduced into a benzene ring[19]. This fact does not agree with the above theoretical prediction. As has been reported in a previous paper as well as in the present paper[2], however, theoretical predictions on pyridine *N*-oxide, quinoline *N*-oxide and acridine *N*-oxide[20] agree with the experimental results. The discrepancy in the case of isoquinoline *N*-oxde may perhaps be due to the so-called ortho effect. Namely, the main reason of this discrepancy between experimental results and theoretical predictions may be attributed to steric effects and to various mutual interactions between *N*-oxide and the nitro groups, which are very polar bulky substituents and occupy the ortho position relative to each other.

*12 We have examined whether or not Ito's rule is valid for many other compounds. For example, the above ratios on pyridine, 2-pycoline, 3-pycoline, 4-pycoline, 3-fluoro-, 3-chloro- and 3-bromopyridine are 0.073, 0.040, 0.049, 0.072, 0.045, 0.032 and 0.023 respectively[26]. It seems that the rule is approximately applicable to the other compounds.

26) The experimental values of these compounds are cited from Stephenson's paper[9].

Testing the above rule for each band obtained from the band analysis, we can find that the rule is approximately valid for the compounds used here, as is shown in Table I.

The band I′ near 310 mμ in 4-methylpyrimidine *N*-oxide (Fig. 3) can also be found in a water solution and may perhaps be the ^1L_b band which could not be found experimentally in the cases of pyridine *N*-oxide and pyrazine mono-*N*-oxide. It may be considered that the band can be observed in this case because the band has shifted slightly from that of pyridine *N*-oxide owing to the lower symmetry of this compound. A band which may be assigned to the ^1L_b band has also been found on many other compounds, such as 4-aminopyridine *N*-oxide[6,27,28].

The high intensity bands which 4-methylpyrimidine *N*-oxide and pyrazine mono-*N*-oxide show near 278 mμ with $\varepsilon=10480$ and near 274 mμ with $\varepsilon=10980$ respectively can reasonably be assigned to the CT band as it was reported in a previous paper in the case of pyridine *N*-oxide[2].

Absorption Spectra of Pyrazine Di-*N*-oxide.—As shown in Table I, this compound has weak bands in the longest wavelength region. The behavior of these bands is similar to that of the corresponding bands of pyrazine mono-*N*-oxide and 4-methylpyrimidine *N*-oxide, and the bands can conceivably be ascribed to the $n\rightarrow\pi^*$ transition. As can be seen from Fig. 2, they are apparently two $n\rightarrow\pi^*$ bands. We can explain the above two weak bands from two different points of view, but it is difficult to determine which point of view is valid. The one is to ascribe the apparent two weak bands to vibrational structures. The other is as follows. In the case of pyrazine di-*N*-oxide, two group orbitals, whose wave functions are similar to Eqs. 10 and 11, can be obtained from the lone pair orbitals belonging to the O_7 and O_8 atoms as shown in Fig. 4. Consequently, two bands may be expected, owing to the electron transitions from the above two lone pair orbitals to the π^* orbital of the pyrazine nucleus, just as in the case of two $n\rightarrow\pi^*$ bands found on pyrazine[23].

The high intensity $\pi\rightarrow\pi^*$ band near 323.6 mμ of pyrazine di-*N*-oxide can reasonably be assigned to the CT band, the excited state wave function of which has a great contribution from $^1\chi_{8\rightarrow4}$ configuration in view of the results of the calculation described in the Theoretical section, and the direction of the transition moment of this band is expected to be parallel to the y-axis. In the case of these *N*-oxide compounds, however, it may be considered that the character of absorption bands was emphasized by using the method of the composite system adopted here, and that the degree of charge transfer from the oxygen atoms to the ring is smaller than that expected from the present calculation[29]. The calculated energy levels of pyrazine di-*N*-oxide do not give such a nice agreement with the experimental results as in the case of pyridine *N*-oxide. The main reason for this discrepancy may be ascribed to the fact that the various energy integrals are assumed to be the same as those of pyridine *N*-oxide.

The weak band near 260 mμ in Fig. 1 may probably be due to the transition from the ground state to the $^1A_{1g}$ (Ψ_2: forbidden) state or the $^1B_{3u}$ (Ψ_3: x) state in view of the calculated results, as indicated in Table IV. However, it can not be concluded which assignment is more plausible. It is probable that the ^1A_g (Ψ_2) band appears near 260 mμ with a low intensity due to the vibrational interactions.

Moreover, the stabilization energy (0.973 eV.) for the ground state of pyrazine di-*N*-oxide is about twice as large as that (0.437 eV.) of pyridine *N*-oxide[2]. From this fact, it is probable that the electronic structure for the ground state of pyrazine di-*N*-oxide may be represented by a resonance hybrid in which each of two oxygen atoms makes resonance with the pyrazine residue almost independently.

On the Parameter of Oxygen Atoms of Heterocyclic *N*-Oxides.—It has been pointed in a previous paper[2] and in a previous section of this paper that the π-electron densities obtained from the SMO calculation using $\alpha_0=\alpha+0.595\beta$ were an over-estimation of the electron migration from the oxygen atom to the heterocyclic nucleus. For example, about the same values as observed dipole moments were obtained by dividing the π-moments obtained from the above calculation by 1.6. These results are ascribed to the use of a small k_O value in Eq. 8. On the other hand $k_O\approx1$ was derived from the ASMO CI calculation for the ultraviolet spectra of pyridine *N*-oxide. However, the dipole moment calculated by the SMO method using $k_O\approx1$ is somewhat smaller compared to the observed one. To estimate a reasonable k_O value, pyridine *N*-oxide has been selected as a model compound, and SMO calculations have been undertaken under various sets of k_O values. The values of dipole moments obtained by the same treatment as that described in the previous paper[2] are shown by curve 1 in Fig.

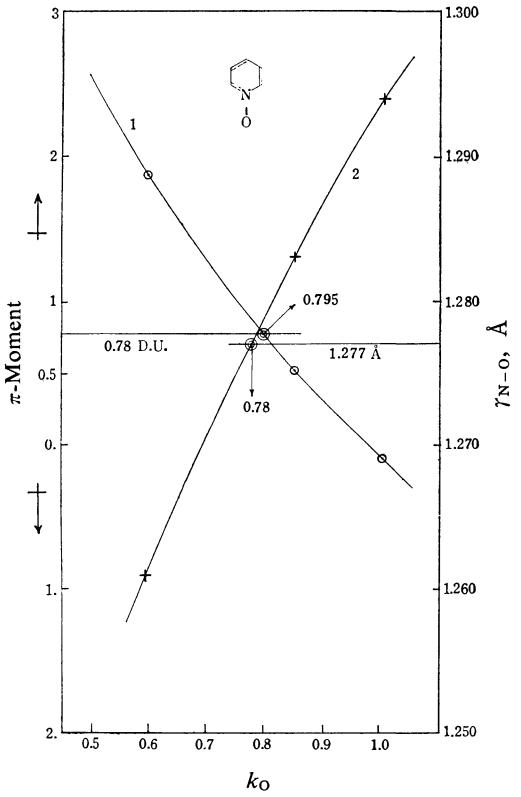

Fig. 10

10*[13]. The value (0.78 Debye unit) of the π-moment estimated from the analysis of the observed total moment was taken from Katritzky's paper[30]. As shown in Fig. 10, $k_O \approx 0.8$ is the best value, and a nice agreement with the observed dipole moment was obtained with this value of k_O. Moreover, as shown by curve 2 in Fig. 10, the N–O distance (this is calculated by the same method as in footnote 13) obtained from the SMO calculation using $k_O \approx 0.8$ is nearly equal to the value (1.277 Å) obtained from an empirical relation between the N–O stretching frequency and the N–O bond length; this fact means that $k_O \approx 0.8$ is reasonable.

13* The bond order of N-O changes somewhat according to the selection of the k_O value. Therefore, the N-O distance may also change to some extent. However, whether or not the change in bond distance estimated from the order-length relation for the N-O bond described in the previous paper[2] is taken into account, the calculated results of dipole moment are almost the same.

Summary

The ultraviolet absorption spectra of pyrazine mono-*N*-oxide, 4-methylpyrimidine *N*-oxide and pyrazine di-*N*-oxide have been measured under various conditions, and band analyses of those spectra have been carried out. In order to interpret the spectra and other physicochemical properties of pyrazine di-*N*-oxide, semi-empirical LCAO MO calculations including the treaments of configuration interactions, have been undertaken in a manner similar to previous calculations on pyridine *N*-oxide. On the other hand, the spectra of pyrazine mono-*N*-oxide and 4-methylpyrimidine *N*-oxide have been interpreted on the basis of the calculated results on pyridine *N*-oxide described in a previous paper. The high intensity bands (278, 274 and 323.6 mμ for 4-methylpyrimidine *N*-oxide, pyrazine mono- and di-*N*-oxides respectively) can reasonably be assigned to charge transfer bands such as the 282 mμ band of pyridine *N*-oxide.

The above substances also exhibit weak bands in the longest wavelength region in non-polar solvents. These weak bands may possibly be due to the $n \rightarrow \pi^*$ transitions. SMO calculations on isoquinoline *N*-oxide and acridine *N*-oxide have also been carried out with the same parameters as those in the case of pyridine *N*-oxide in non-polar solvents, and various physicochemical properties have been discussed on the basis of these calculations. As has been pointed out in a previous paper, the parameter for the oxygen atom used here is too small. To estimate the most reasonable value, SMO calculations were carried out many times on pyridine *N*-oxide, which was used as a model compound. As a result, it was found that k_O (in Eq. 8) ≈ 0.8 is the best value.

The author wishes to express his deep gratitude to Professor Saburo Nagakura of the Institute for Solid State Physics, The University of Tokyo, for valuable discussions and for reading the manuscript; to Dr. Kenichi Takeda, Director of this Research Laboratory, Dr. Noboru Mataga of Osaka Municipal University and Dr. Mituo Itō of Kyushu University for valuable discussions; to Mr. Masumi Yamakawa of this Research Laboratory for his cooperation in the SMO calculation of isoquinoline *N*-oxide, and to Dr. Hiroshi Yamanaka of Tohoku University for supplying a sample of 4-methylpyrimidine *N*-oxide.

Neutron Irradiation of Acetoxime and Acetaldoxime

By Enzo TACHIKAWA and Gen-ichi TSUCHIHASHI

(Received September 12, 1961)

Previously, the present authors irradiated propionamide[1] with thermal neutrons and found that the yields of methylation products from propionamide, ^{14}C-isobutyramide and ^{14}C-butyramide were proportional to the number of hydrogen atoms which are available for substitution. These results served to indicate that "synthesis"[2] products were mainly formed by the methylation reaction.

In order to understand the mechanism more completely, however, further studies were required. The present authors carried out the neutron irradiation of acetoxime and acetaldoxime and so separated a few "synthesis" products and "re-entry"[2] products.

Particular attention was paid to the relationship between the yields of these products. The Beckmann rearrangement product of acetoxime was also examined. Carbon-14 distributions in the product molecules from acetoxime were determined by a stepwise degradation method.

On the basis of these results, the relationship between "re-entry" and "synthesis" reactions is discussed.

Experimental

Materials. — Acetoxime was synthesized from hydroxylamine hydrochloride and acetone[3]. Acetaldoxime, ethylmethylketoxime and propionaldoxime were synthesized by a method analogous to that for acetoxime. *N*-Methylacetamide was obtained from acetic anhydride and methylamine hydrochloride. These compounds were purfied in a Podbielniak high-temperature distillation apparatus (with a 60-plates heli-grid packing column).

Neutron Irradiation. — About 15 g. of acetoxime was sealed in a polyethylene tube, which was then packed in a polyethylene capsule. Also, 15 g. of pure acetaldoxime was sealed in a quartz tube under a pressure of 10^{-4} mmHg, and then the ampoule was packed in an aluminum capsule. These assemblies were irradiated for 120 hr. in the No. 13 experimental hole of the J. R. R.-1, with an approximate flux of 10^{11} n./cm^2·sec. Samples were cooled for about two weeks after irradiation in order to eliminate short-living activities stemming from impurities in the polyethylene capsule or the aluminum capsule.

Processing of Irradiated Acetoxime.—In order to determine the reaction products, the isotope-dilution method was used. After the irradiated sample was divided into four portions, each portion was distilled in order to remove polymeric substances produced. Before beginning the distillation, known amounts of corresponding carriers were first added to the distillation vessel separately. Gas liquid partition chromatography was employed for the final purification of the desired compounds.

For chromatography, a 6 ft. column, 1/2 inch i. d., packed with 30~80 mesh fire brick coated with polyethylene glycol-600, was used. The column was operated at 100°C, and the flow rate of helium carrier gas was kept about 150 ml./min.

Degradation of ^{14}C-Acetoxime.—After 3 g. of the irradiated sample had been distilled in the usual way, the portion of acetoxime was purified by gas chromatography. ^{14}C-acetoxime purified was divided into two portions. By the usual iodoform reaction[4], one portion of ^{14}C-acetoxime was converted to iodoform, which was then recrystallized until it showed a constant specific activity. The remaining ^{14}C-acetoxime was converted into *N*-methylacetamide by the Beckmann rearrangement and was then hydrolyzed to acetic acid. The acetic acid was treated with benzoyl chloride and ammonia, and the resulting acetamide was recrystallized from methanol-ether.

Degradation of ^{14}C-Ethyl Methyl Ketoxime.—After 4 g. of ethyl methyl ketoxime had been added to 3.99 g. of the irradiated sample as a carrier, the mixture was distilled and the ^{14}C-ethyl methyl ketoxime collected was purified further by gas chromatography. Purified ^{14}C-ethyl methyl ketoxime was also divided into two portions. The first portion was hydrolyzed to ethyl methyl ketone, which was then converted to iodoform by the iodoform reaction. The rest of the ^{14}C-ethyl methyl ketoxime was converted to propionic acid by the bromoform reaction[5]. The propionic acid thus obtained was decarboxylated to ethylamine by Schmidt's method in order to locate the distribution of carbon-14 according to the suggestions of Phares[6]. The ethylamine produced was converted to acetic acid by the method of Phares and was further degraded to methylamine. The methylamine produced was oxidized to carbon dioxide by the same method.

Degradation of ^{14}C-*N*-Methylacetamide. — *N*-Methylacetamide (3.02 g.) was added to the

irradiated sample (3.00 g.) as a carrier. The ^{14}C-*N*-methylacetamide separated from the mixture by the same procedure was hydrolyzed by refluxing it for two hours with potassium hydroxide. The acetic acid obtained was fractionated by gas-liquid chromatography, using 50% D. C. 710 silicone plus 10% stearic acid as the liquid phase. The methylamine was oxidized to carbon dioxide.

Processing of Irradiated Acetaldoxime. — The irradiated sample was distilled in order to remove polymeric substances after the sample had been divided into several portions. The acetoxime and propionaldoxime formed by the neutron irradiation of acetaldoxime were identified separately by gas chromatography after suitable amounts of acetoxime or propionaldoxime had been added as a carrier. The separated oximes were further purified by gas chromatography until they showed constant specific activity.

Measurement of Activity. — The purified compounds were converted to carbon dioxide by the Van Slyke-Folch method[7]. The resulting carbon dioxide was converted to barium carbonate by the same method as in the previous paper[1]. About 150 mg. of the barium carbonate suspended in ethyl alcohol was poured into a particular type of counting dishes (0.8 cm.ϕ). Using an infrared lamp, ethyl alcohol was evaporated and barium carbonate was dried up. This barium carbonate was mounted in the dishes in infinite thickness. The specific activity of barium carbonate was measured with an Aloka low-back ground counter (model: BD-1). Barium carbonate of 22.4 d.p.s./mg. was used as a standard sample. These measurements are reproducible to about 3% for samples of the same material and to about 3~4% samples of different compound containing the same labelled group. The absolute accuracy of the assays is probably good to about 7%.

Results and Discussion

The Distribution of Carbon-14 in Neutron Irradiation Products. — As is well known, an ^{14}N(n, p)^{14}C reaction occurs on the nitrogen atom of oxime during neutron irradiation. Because ^{14}C recoil atoms have high energy, they are supposed to undergo various reactions. Among them, "re-entry" and "synthesis" products have been considered in the present study, together with the Beckmann rearrangement product. In the neutron irradiation of acetoxime, the ^{14}C-acetoxime, ^{14}C-ethyl methyl ketoxime and ^{14}C-*N*-methylacetamide produced are here called "re-entry", "synthesis" and rearrangement products respectively. Table I shows the distribution of carbon-14 in each compound.

Analogously, neutron irradiation of acetaldoxime will bring about reactions similar to those for acetoxime. In this reaction, ^{14}C-acetaldoxime is a "re-entry" product. Both ^{14}C-acetoxime and ^{14}C-propionaldoxime are referred to as "synthesis" products.

The comparative yields of these compounds are shown in Table II. Table II shows that the ratio of the yields of ^{14}C-acetoxime and ^{14}C-propionaldoxime is about 1 : 3, which agrees with the ratio of the number of hydrogen atoms available for the substitution in acetaldoxime to give acetoxime or propionaldoxime. This result is in accord with that for the neutron irradiation of propionamide[1].

Carbon-14 Distribution on Molecules. — Recently, many researchers have carried out stepwise degradations of "synthesis" and "re-entry" products[8]. These results have shown that the differences betwen theoretical and experimental values for the distribution of carbon-14 are not so large in "re-entry" products, while the differences become remarkable in "synthesis" product. Especially in the latter case, one finds a considerable number of carbon-14 atoms at positions where carbon-14 could not be found theoretically. In the present study, degradations of ^{14}C-acetoxime,

^{14}C-ethyl methyl ketoxime and ^{14}C-*N*-methylacetamide were carried out in order to discover the distributions of carbon-14 atoms in these molecules. Degradation of ^{14}C-acetoxime showed that 72% of the carbon-14 activity was present in methyl groups. Similar studies on the ^{14}C-ethyl methyl ketoxime showed that 70% of the activity was in the 4-position. Tables III and IV illustrate the observed values together with the theoretical values.

The results in Table III seem to indicate that ^{14}C-acetoxime has resulted from a "knock on" reaction between carbon-14 and carbon-12 in acetoxime. The methyl group is tagged with about 8 per cent more carbon-14 than the central carbon atom. This is perhaps caused by the steric effects of neighboring CH_3 groups that hinder the attack of carbon-14 on the central carbon atom.

As Table IV shows, the 1-, 2- and 3-positions in ethyl methyl ketoxime are all labelled with carbon-14. This result coincides well with those of others[8]. In this compound, the amount of compound, the amount of carbon-14 in the 1-position exceeds that in the 2- or 3-position. This is also caused by the steric effects similar to that in the case of acetoxime.

When an organic molecule reacts with a carbon-14 hot atom, the kinetic energy given to the organic molecule is so high that isomerizations or some other reactions could easily take place. The distribution of carbon-14 in *N*-methylacetamide, the Beckmann rearrangement product of acetoxime, is shown in Table V.

Table V. Carbon-14 distribution in ^{14}C-*N*-methylacetamide produced from the neutron irradiation of acetoxime

	Product		
	CH_3	CONH	CH_3
Theoretical	33	33	33
Found	50		50

From Table V, one finds a higher C-14 distribution in the migrating methyl group than in the other positions. Possibly the mechanism for the formation of ^{14}C-*N*-methylacetamide differs from that of the acid-catalyzed Beckmann rearrangement. In this case, the rearrangement probably takes place for the following reason. When a methyl group in acetoxime is labelled with carbon-14, a high kinetic energy is given to it. An excited acetoxime isomerizes rather easily into *N*-methylacetamide by the migration of the labelled methyl group before the kinetic energy in this methyl group completely diffuses over the molecule.

The Relation between the Yields of "Re-entry" and "Synthesis" Products.—Acetoxime contains three carbon atoms, each of which could be tagged with carbon-14, forming ^{14}C-acetoxime. Also, it contains six hydrogen atoms which are available for methylation, resulting in ^{14}C-ethyl methyl ketoxime. Also, acetaldoxime contains two carbon atoms, three hydrogen atoms attached to carbon atom 2, and one hydrogen atom attached to carbon atom 1, all of which are available for giving ^{14}C-acetaldoxime, ^{14}C-propionaldoxime and ^{14}C-acetoxime respectively. Similarly, propionamide has three carbon atoms, two hydrogen atoms attached to carbon atom 2, and three hydrogen atoms attached to carbon atom 3.

These carbon or hydrogen atoms are capable of being used for the formation of "re-entry" or "synthesis" product. The preceeding paper[1] gave the results of the neutron irradiation of propionamide, results shown in Table VI.

The above results seem to show that some relationship exists between the yields of "re-entry" or "synthesis" products and the number of carbon or hydrogen atoms in the mother compounds. Table VII shows the number of atoms which are available for the formation of "re-entry" or "synthesis" products, together with the ratio of the yields of "synthesis" products to that of "re-entry" products.

Previously, Wolf et al.[9] examined the neutron irradiation of benzene, toluene, aniline, pentane, methanol, acetamide and alanine. Except for pentane and methanol, similar results were observed. In pentane and methanol, hydrogen replacement was found to be favored twofold over carbon replacement.

In Fig. 1, the relative values of activity found in "synthesis" product, divided by that in "re-entry" products, are plotted as a function of the ratio of the number of hydrogen atoms which are available to form "synthesis"

products to the number of carbon atoms available for the formation of "re-entry" products. This figure is based on the present authors' results, together with results obtained by Wolf et al.

This figure shows that a linearity exists over nearly the range from zero to two of the horizontal values; beyond this range the yields of "synthesis" products increase rapidly.

Fig. 2.

In the range where the ratios of the number of hydrogen atoms to that of carbon atoms are less than two, it seems that the amount of "synthesis" and of "re-entry" products are proportional to the number of hydrogen and carbon atoms available for the product formation.

Since in the present results, nearly 70% of the activity in the "synthesis" product exists in the methyl group attached to the mother skeleton, the major reaction undoubtedly being the methylation.

The distribution of the activity in ^{14}C-acetoxime is nearly uniform, and the yields of "re-entry" products are proportional to the carbon atoms. These results seem to suggest that the "knock on" and methylation reactions are the main paths for the formation of "re-entry" and "synthesis" products respectively when the two reactions occur simultaneously in a constant ratio as shown in Fig. 1. However, as the ratio of hydrogen to carbon atoms increases, the methylation reaction gradually predominates, as in pentane and methanol.

Summary

The neutron irradiation of acetoxime and acetaldoxime was studied. Degradation of the products obtained from the neutron irradiation of acetoxime shows that the distribution of carbon-14 activity deviates a little from the statistical behavior on account of steric and other effects.

However, the yields of "synthesis" product are found to be proportional to the number of hydrogen atoms available for their formation. Also there seems to be a linear relationship between the yields of "re-entry" or "synthesis" products and the number of atoms available for formation. The present results suggest that the main process forming the "synthesis" products is simple methylation by ^{14}C-methyl or ^{14}C-methylene radicals, while that giving the "re-entry" products is a "knock on" reaction of carbon-12 by carbon-14.

The authors wish to express their thanks to Professor K. Kimura, Dr. A. Danno and Dr. T. Ishimori for their kind encouragement and helpful discussions throughout the present work.

Determination of Small Amounts of Copper and Iron with X-Ray Fluorescent Spectroscopy. Combination with Organometallic Precipitation

By Kichinosuke HIROKAWA and Hidehiro GOTÔ

(Received September 28, 1961)

The determination by X-ray fluorescent spectroscopy[1] of small amounts of copper and iron in metals without separation is difficult. Therefore, the application of organometallic precipitation to X-ray fluorescent spectroscopy has been investigated. In previous determinations of small amounts of metals by X-ray fluorescent spectroscopy, the element to be analyzed has been concentrated on filter paper or on Mylar film or metal foils[2]. The organic precipitate of metals without carriers[3], however, has not been used as a sample for X-ray spectroscopy.

On the other hand, it has been recognized that alizarin blue reacts with copper and iron[4] in acidic solutions. Investigation was therefore carried out, first, to find the optimum conditions for the reaction of alizarin blue with copper and iron and then X-ray fluorescent spectroscopy, combined with this organic precipitation separation, was applied to the determination of small amounts of copper and iron.

Experimental and Results

Reagents.—*Alizarin Blue Solution.*—Alizarin blue-saturated solution in tetrahydrofran was used.

Standard Solution of Copper.—Copper (0.4~0.5 g.) was dissolved with nitric acid, and a solution containing 5~100 μg. of copper was prepared by dilution with water when needed. A standard solution of iron was also prepared, as well as a copper standard solution. The nitric acid, hydrochloric acid and sulfuric acid used were all analytical grade reagents. A 0.2 M EDTA solution, a 0.1 M glycine solution and a 20% potassium thiocyanate solution were also used in the experiment.

Instruments. — G. E. XRD-5 X-ray spectrometer with AEG50-S tungsten tube, lithium fluoride analyzer, 0.025 cm. solar slit, and 2 SPG detector, was used. The X-ray irradiation area was controlled by the aluminum plate with a round window 1.5 cm. in diameter. A Hitachi spectrophotometer, model EPU-2, with 1 cm. cells was also used.

Condition of Precipitation. — The formation of alizarin blue precipitate with copper or iron in an acid solution has been already reported[4]. In order to determine the optimum conditions for the precipitation, the following experiments were carried out.

From the copper standard solution, 40.4 μg. of copper was placed in a beaker. The acidity of this solution was controlled with hydrochloric acid and ahydr ochloric acid-glycine buffer solution, and the total volume was made up to about 50 ml. After 10 ml. of the alizarin blue solution* had been added, the rest was left to stand for a few minutes; the precipitates formed were then filtered and washed with water a few times. The precipitate and filter paper were together transferred back into the original beaker, and the precipitate was completely decomposed by heating with 5 ml. of sulfuric acid and 10 ml. of nitric acid. After the fuming of the sulfuric acid, the deposited salt was dissolved with 20 ml. of nitric acid (1+2) and cooled. This solution was diluted with water to 100 ml., one-fifth of this solution was taken into a separatory funnel; then the amount of copper in it was determined by the diethyl dithiocarbamate method. From these results, the relation between the pH of the solution and the content of copper in the precipitate was determined, as shown in Fig. 1; it was discovered

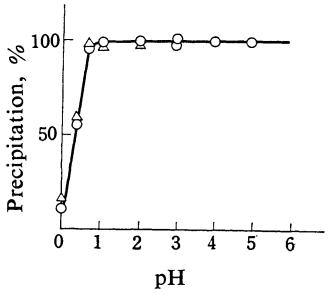

Fig. 1. The precipitation of Cu at various pH.
—○— KSCN not present
—△— KSCN present

that the copper was completely precipitated above a pH of 0.7. Next, the same attempt was carried out for the precipitation at a more acidic range in the presence of 2 ml. of 0.2% potassium thiocyanate, but the presence of potassium thiocyanate did not affect the precipitation. Similarly, 282 μg. of iron was treated with the same procedure as has been previously described. The precipitation of iron with alizarin blue was decomposed, and the amount of

* Five milliliters of the alizarin blue solution was enough to from the precipitate with about 400 μg. of copper; 10 ml. of the alizarin blue solution was used throughout the experiments.

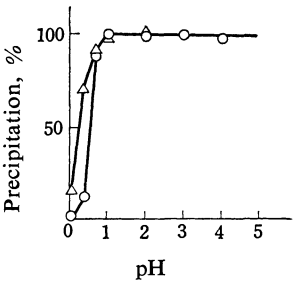

Fig. 2. The precipitation of Fe at various pH.
—○— KSCN not present
—△— KSCN present

iron was determined by the spectrophotometric method using potassium thiocyanate. The relation between precipitation and pH is shown in Fig. 2. In this case, the presence of potassium thiocyatate had no effect on the precipitation of iron. From these results, it was recognized that copper and iron was completely precipitated with alizarin blue at pH values above 1.0.

Precipitation of Calibration Curves of Copper and Iron, and their Interaction.—As has been reported in the previous paragraph, copper and iron were completely precipitated with alizarin blue at pH values above 1; calibration curves for the X-ray spectroscopy of copper and iron can, therefore, be prepared with the following procedure.

Copper (20~100 μg.) were taken into a beaker and made up to 50 ml. of a 0.02~0.1 N hydrochloric acid solution. Ten milliliters of alizarin blue solution was added to it, forming the precipitate. After being left standing for a few minutes, the preci pitate was filtered with the apparatus as shown in Fig. 3. The precipitate on the filter paper was washed a few times with water and stuck with cellophane tape to the filter paper. Iron (20~100 μg.) was treated the same way as the copper. These samples were put in the sample holder and baked with aluminum plate. The fluorescent X-ray intensity of each element in these samples was measured under the conditions shown in Table I. The results are shown in Fig. 4 for copper and in

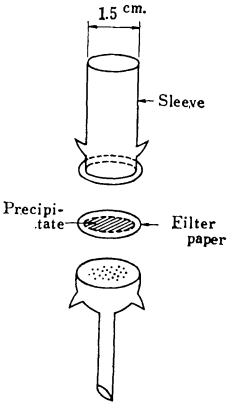

Fig. 3. Schematic diagram of filter.

Fig. 5 for iron. Below 100 μg. of iron or copper, the X-ray intensity is proportional to the amounts of the element in the samples. Using these calibration curves, the effect of iron on copper and of copper on iron could be investigated. The results obtained appear in Tables II and III. The possibility of a simultaneous determination of copper and iron under the same conditions was also recognized. Therefore, this method was applied to the determination of copper and iron in some metals.

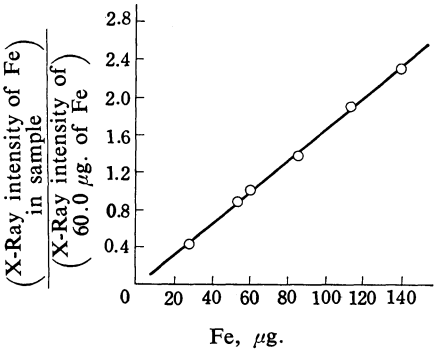

Fig. 5. Calibration curve for Fe.

Simultaneous Determination of Copper and Iron in Nonferrous Metals.—Using the system of measurement described above the determination of coppr and iron in nonferrous metals was undertaken. The nonferrous metals used were aluminum, zinc, manganese and nickel, which do not react with alizarin blue at pH values below 5; the analytical procedure used was as follows.

Procedure. — A definite sample (0.5~1.0 g.) was taken and dissolved with 5~10 ml. of hydrochloric acid or nitric acid, and the sample solution was prepared as a 0.02~0.1 N acid solution of 100 ml. From this solution a one-tenth or one-twentieth solution (containing below about 100 μg. of copper and iron) was taken out, and an alizarin blue solution was added. In accordance with the procedure for the preparation of the calibration curve previously described, copper and iron were analyzed. These results are shown in Table IV. On the basis of these results, small amounts of copper and iron in these metals can be rapidly analyzed with a simple procedure.

Discussion

The simultaneous determination of copper and iron in aluminum, zinc, manganese or nickel has been investigated. Copper in zinc, iron in manganese, or copper in nickel is difficult to analyze with a non-destructive method due to the high background of the matrix. Therefore, it is necessary to diminish this matrix effect as much as possible. Examples of spectrograms of iron in manganese, of copper in nickel and of zinc after separation are indicated in Fig. 6; these excitation conditions are similar to those in Table I. In the case of manganese and zinc, the separation was complete, but in the case of nickel, a small amount of it remained. However, as indicated in Table IV, the remaining nickel had little effects on the copper and iron. On the basis of these facts, it was considered that the presence of organic materials decreases the effect of diverse metals, and hence, that the effect of nickel is negligibly small for the X-ray spectroscopic determination of copper. Iron, nickel and copper also exhibited similar behavior regarding X-ray intensity, so the presence of a small amount of nickel has no effect if the total amount of copper and nickel is below three times that of iron.

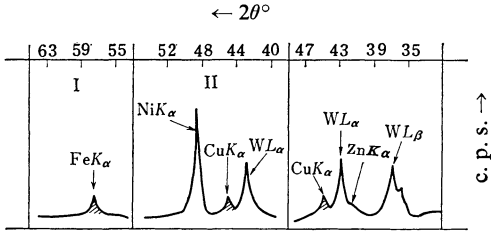

Fig. 6. Examples of spectrograms of Fe in Mn (I), and Cu in Ni (II) and Zn (III) after separation.
I 0.104 g. of Mn was taken, and full scale of the chart was 100 c. p. s.
II 0.082 g. of Ni was taken, and full scale of the chart was 500 c. p. s.
III 0.114 g. of Zn was taken, and full scale of the chart was 500 c. p. s.

Adding these findings to the results of the previous experiments, oxine and other organic reagents may be used for concentration of a small amounts of an element for purposes of fluorescent X-ray spectroscopy. Alizarin blue has the advantages that the precipitation reaction takes place at low pH regions and that it can be treated with a simple procedure. The amounts of silver and molybdenum, which react with alizarin blue under the same conditions[4], can be determined as well as those of copper and iron.

Summary

The simultaneous determination of small amounts of copper and iron with X-ray fluorescent spectroscopy combined with organic precipitation was investigated. Using an alizarin blue solution, which reacts with copper and iron at a low pH value, as the precipitant, satisfactory results were obtained. The amounts of copper and iron in aluminum, zinc, manganese and nickel were rapidly determined with X-ray fluorescent spectroscopy after this separation.

Determination of Uranium in Thorium by X-Ray Fluorescent Spectroscopy. The Organometallic Precipitation Method

By Kichinosuke HIROKAWA and Hidehiro GOTÔ

(Received September 28, 1961)

For the determination of a small amount of uranium in thorium, Cheng[1] has suggested the PAN *o*-dichlorobenzene extraction method. This method[2], however, requires complicated procedures. Therefore, X-ray spectroscopy after organic precipitation separation was applied in this analysis. When the amount of uranium in thorium is determined by X-ray fluorescent spectroscopy, the effect of matrix element, thorium, is so great that it is necessary to isolate uranium from thorium. In order to separate them, the solvent extraction

2) R. F. Clayton, *Analyst*, **83**, 13 (1948); A. R. Eberle, *Anal. Chem.*, **29**, 1134 (1957); H. Matsuyama, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zassi*), **79**, 958 (1958).

method[1,2], accompanied by the precipitation method[3], is investigated here. In this study alizarin blue[4] is used as the precipitant for uranium, and an X-ray fluorescent spectroscopic determination for uranium is proposed.

Experimental and Results

Reagents.—An alizarin solution was prepared by the methed described in a previous report[4]. For the uranium standard solution, 1 g. of uranium nitrate, analytical grade, was dissolved in a 1 N sulfuric acid solution. The uranium content of this solution was determined as 8.5 mg. 1 ml. by the zinc amalgam reduction potassium permanganate titration method. The solution was then diluted to the proper concentration before being used.

For the thorium standard solution, 1.5 g. of thorium nitrate, analytical grade, was dissolved in water; the concentration of thorium in it was determined by weighing the oxide after precipitation with oxalic acid (0.0107 g. 1 ml.). The acetic acid-sodium acetate buffer solution was prepared by mixing 0.2N acetic acid and 0.2N sodium acetate. The glycine buffer solution was prepared by mixing 0.1M glycine solution and 0.1M hydrochloric acid. The hydrochloric, nitric and other acids used were of an analytical grade. A 0.2M EDTA solution, a 0.1% PAN methanol solution, a 1% potassium cyanate solution, and an *o*-dichlorobenzene and buffer solution of pH 10 were also used.

Apparatus. — A G. E. XRD-5 X-ray spectrometer with AEG-50S tungsten tube was used, as described in the previous paper[4].

Conditions for the Formation of Metal Alizarin Blue Precipitate.—Uranium reacts with alizarin blue and forms a red-violet precipitate at once in neutral solutions, while thorium first develops a blue color with alizarin blue and then gradually forms a blue precipitate. In this case, the presence of EDTA prevents the formation of thorium precipitate. On the basis of these facts, the following conditions for precipitation were set up.

One hundred and seventy micrograms of uranium were taken from the uranium standard solution, the pH value of which was controlled with hydrochloric acid, a glycine-hydrochloric acid buffer solution or an acetic acid-sodium acetate solution; then the total volume of the solution was made up to about 50 ml. with water. Ten milliliters of alizarin blue solution was added. After the solution had stood for a few miuntes, the precipitate formed was filtered and repeatedly washed with water. The precipitate was put into the original beaker together with the filter paper. The precipitate and the filter paper were decomposed with 5 ml. of sulfuric acid and 10 ml. or more if necessary, of nitric acid by heating. Then it was diluted to 50 ml. with water, and one-tenth of it was taken for the extraction. The uranium content in this solution was determined by the PAN-*o*-dichlorobenzene extraction method. These results are shown in Fig. 1. From these results, the uranium was precipitated completely with alizarin blue in the pH range of 2~10. The effects of the presence of EDTA at pH values from 2 to 6 were not visible, as is shown in Fig. 1.

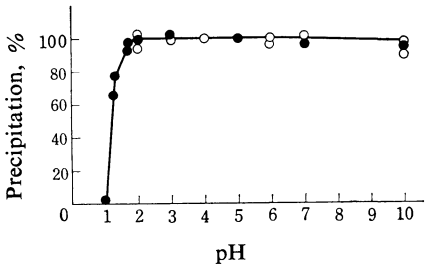

Fig. 1. Precipitation of U at various pH.
-○- 4 ml. of 0.2M EDTA soln. present.
-●- EDTA soln. not present.

Preparation of the Calibration Curve and Separation of Thorium.—In previous investigations, it was established that uranium forms a precipitate with alizarin blue in the presence of EDTA at pH values above 2. Therefore, the calibration curve for uranium was prepared as follows:

Various amounts of uranium, from 15 to 350 μg., were taken, and 4 ml. of a 0.2M EDTA solution and 20 ml. of an acetic acid-sodium acetate buffer solution (4; 6) were added; the pH value of this solution was controlled between 4 and 5, and its total volume was diluted with water to about 50 ml. After the addition of 10 ml. of the alizarin blue solution, the precipitate formed was filtered with the apparatus described in the previous report[4] and washed a few times with water. The precipitate on filter paper was fixed with cellophane tape directly and put in the sample holder with a round irradiation area 1.5 cm. in diameter and with aluminum plate backing. The fluorescent X-ray intensity from it was measured under the conditions of Table I. In Fig. 2, the calibration curves for uranium up to 100 μg. (a) and up to 350 μg. (b) are given. A spectrograph of the sample is shown in Fig. 3. The X-ray intensity of thorium caused by the absence of EDTA or by the unsatisfactory separation of thorium gives its peak at the notch part. According to the previous procedure, thorium below 0.05 g. was completely masked by EDTA and so was not affected. However, when the pH value of the solution was above 10 before the addition of EDTA, the peak of thorium appeared. As this thorium peak seemed to be due to thorium hydroxide, the addition of EDTA should be carried out before the control of the pH value.

Determination of Uranium in Thorium. — As in previous studies, a small amount of uranium in thorium was analyzed as follows:

Procedure. — From 0.1 to 0.5 g. of the sample was dissolved with a small amount of nitric acid as well as possible. This solution was diluted to 100 ml. with water, and one-tenth or one-fifth of this solution was put into a beaker. Four milliliters of EDTA solution and 20 ml. of an acetic acid-sodium acetate buffer solution were added to this solution. The pH of this solution was controlled at 4~5, and the total volume of this solution was increased to about 50 ml. The milliliters of an alizarin blue solution was added and the specimen for X-ray was prepared by the method described in the section dealing with the preparation of the calibration curve. The prepared specimen was irradiated with X-ray under the same conditions as listed in Table I, and the uranium content was determined from the intensity ratio of the uranium in the sample against that of the standard sample (85.0 μg. of U in this experiment). The amount of uranium in thorium was determined with this method; the results obtained are shown in Table II. These results agreed well with those obtained by the PAN *o*-dichlorobenzene extraction method.

TABLE II. DETERMINATION OF U IN Th

Sample	Chem. anal., %	X-Ray anal., %

B	0.44	0.48
C	0.45	0.43
D	0.22	0.23
E	0.17	0.18

Discussion

Various other precipitants for uranium can be considered besides alizarin blue. This alizarin blue solution, however, has the advantage of forming the precipitate over a wide pH range. When this alizarin blue solution is used, copper, iron and silver form precipitates under the same conditions, although these precipitations were masked by the addition of EDTA[4]. When the thorium metal was dendritic and porous, the non-destructive method could not be applied. Therefore, analysis using oxide powder was tried. An X-ray spectrographs of a thorium sample containing 2 and 4% of uranium oxide form were obtained, as is shown in Fig. 4. From this spectrograms, it was considered that uranium content below 1% was difficult to determine without separation because of the high background of X-ray due to thorium near the uranium peak.

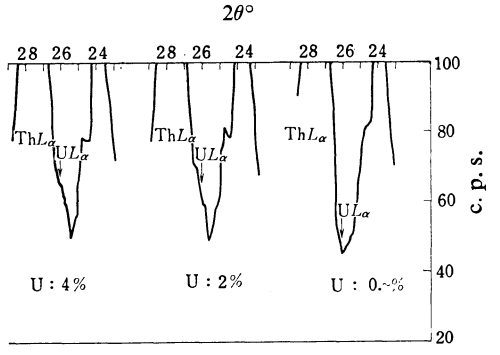

Fig. 4. X-Ray spectrograms of U in Th as oxide without separation.

Summary

A method for the determination of a small amount of uranium in thorium using the separation method with precipitation, combined with X-ray fluorescent spectroscopy, was investigated. About 100 μg. of uranium in thorium could be determined simply and rapidly by using alizarin blue as the precipitant for uranium and EDTA as the masking reagent for thorium.

*Infrared Spectra of Troponoid Compounds. IV. Infrared and Raman Spectra of Tropone**

By Yusaku IKEGAMI

(Received August 23, 1961)

Infrared absorption spectrum of tropone (I) has been reported by a number of workers[1-4] but no detailed reports have been made on the assignment of the absorption bands. No work seems to have been done on the measurement of its Raman spectrum. As a part of the studies on the infrared spectra of troponoids, tropone was taken up as a compound having the most fundamental structure of this series. Measurements were made on the infrared spectra in the region of 4000~400 cm^{-1} and on Raman spectrum, and considerations were made on the vibrational assignments for these spectra.

Experimental

Measurement of Infrared Spectra.—Infrared spectra were measured with a Perkin-Elmer model 21 infrared spectrophotometer, using sodium chloride prism for the region of 4000~700 cm^{-1} and potassium bromide prism for the region of 700~400 cm^{-1}. The absorption bands in the region of 4000~1700 cm^{-1} were measured also by using a calcium fluoride prism which has a higher resolution.

Measurement of Raman Spectrum. — Raman spectrum was measured with a Shimadzu automatic grating Raman spectrometer, type GRS-750, using the Hg-e line (4358 Å) from the Toronto type mercury lamp for the exciting line. In this case, a solution containing 0.2 g. of Ethyl Violet and 39 g. of *p*-nitrotoluene in 1.8 l. of denatured alcohol was used as the filter for the light source. This filter solution had a 1 cm. light pass, and the cell was cooled by circulating water to avoid the rise in temperature of the sample cell. Tropone is easily colored on exposure to light, and, in order to avoid this coloration, the sample was preserved in a dark, cool place after purification and caution was taken to shorten the time required for measurement.

Sample. — Tropone used for the measurement was prepared by the known method[5], recrystallized as picrate, and passed through an alumina column to liberate picric acid. The purified tropone was distilled in vacuum more than five times. $n_D^{18}=1.6190$.

Infrared and Raman Spectra of Tropone

Infrared absorption spectrum of liquid tropone is shown in Fig. 1a. This spectrum hardly shows the absorption band at around 3530 cm^{-1} due to the adsorbed moisture always present in the spectra reported to date[2-4]. The spectra of tropone in carbon tetrachloride and carbon disulfide are shown in Fig. 1b. The wave number of absorption bands in these spectra and those in the spectrum measured in a vapor state earlier[4] are listed in Table II.

The Raman spectrum of liquid tropone is shown in Fig. 2, and the wave numbers, their approximate, relative intensities, and depolarization factors are listed in Table II. The relative intensities are given taking the peak intensity of the most intense line at 1520 cm^{-1} as the standard.

Molecular Structure and Vibrational Modes of Tropone

Tropone, C_7H_6O, has the structure of cycloheptatrienone (Ia). Therefore, a structure with all the 14 atoms in the plane and having a symmetric plane including a C=O line perpendicular to that plane can naturally be presumed to be tropone. Under such a presumption, a vibrational spectrum of tropone can be treated as a planar ring structure of C_{2v} symmetry, and, therefore, normal vibrations corresponding to 36 degrees of vibrational freedom can be classified as shown in Table I. In this table, the expected frequency ranges were assigned with reference to the vibrational frequencies of benzene, tropylium cation[6],

tropilidene[7], and azulene[8] whose vibrational spectra had already been analyzed.

As can be seen from this table, all the vibrational modes are Raman active, and 31 of them except those of A_2 species are also infrared active. However, the observed spectra show that the number of Raman lines are much smaller than the anticipated number and this is probably due to the non-observation of weak Raman lines by the afore-mentioned defect in the measurement and also to the superposition of adjacent lines.

Vibrational Assignment

From the distribution of vibrational modes and the spectral data, the following considerations were made on the vibrational assignments for tropone. Results are summarized in Table II.

Around 3000 cm^{-1}.—Six vibrations due to the CH stretching mode, active both in the infrared and Raman spectra, can be anticipated in this region, which should not be higher than 3100 cm^{-1} but higher than 3000 cm^{-1}. The observed spectra show the bands assignable to CH stretching vibrations as an absorption of strong intensity with 3~4 shoulders in the infrared spectrum and as two lines at 3055 and 3031 cm^{-1} in the Raman spectrum. These bands are probably the six vibrations overlapped due to the low resolution of the spectrometer. The infrared spectrum using a calcium fluoride prism does not give an excellent separation. It should further be noted that, in this region, the foot of CH stretching absorption bands in the infrared spectra is extended outside the region of 3100~3000 cm^{-1}, with several shoulders, and that a distinct band has been recorded at 2972 cm^{-1} in the Raman spectrum. Such bands, extending outside the expected range, should naturally be explained in most cases, as the combination bands or over-tones of the vibrations in the lower frequency region, especially in the region of 1660~1450 cm^{-1}, where the bands of strong intensity appear in both the infrared and Raman spectra. This Raman line at 2972 cm^{-1} is not improbable as a CH stretching vibration, refering to the assignment of naphthalene spectrum[9], but there is no evidence to support this assignment. A Raman line at 3055 cm^{-1} belongs to A_1 species by its depolarization factor.

Region of 1660~1450 cm^{-1}. — It is noticed that the bands in this region are very strong in both infrared and Raman spectra, as compared with those of tropilidene (II)[7] which has the same C_{2v} symmetry as tropone. Of the stretching vibrations anticipated from the tropone skeleton, the four vibrational modes due to C=O and C=C bonding are expected to appear in a higher side in this region. A most intense, polarized Raman line at 1520 cm^{-1} is assigned to the C=C in-phase stretching vibration belonging to A_1 species, and is analogous to the most intense Raman lines of tropilidene and tropolone (1535[7] and 1473 cm^{-1} [10] respectively). In the higher side than this line, there are three distinct lines in the Raman spectrum, as anticipated, and two absorption bands of strong intensity with several shoulders are observed in the infrared spectrum. The nature and assignment of these bands will be discussed in a later paper[11] with consideration of the infrared spectra measured in various solvents. A Raman line at 1598 cm^{-1} belongs to B_1 species and other two bands in the region of 1651~1580 cm^{-1} are explained as the vibrations whose main components are the C=O and C=C stretching modes.

The shoulder at 1512 cm^{-1} is thought to correspond to the combination band, 932+577 cm^{-1}. Another distinct band at 1473 cm^{-1}, in both infrared and Raman spectra, may be assigned to the C–C stretching vibration belonging to B_1 species, although it locates rather higher, compared to that in tropilidene[7].

Region of 1450~700 cm^{-1}.—Absorptions of CH out-of-plane bending vibrations belonging to B_2 species and present in the region below 1000 cm^{-1} are generally expected to have strong intensity in the infrared spectrum but weak or indistinct in the Raman spectrum. The three bands at 893, 830 and 779 cm^{-1} are assigned to this vibration. The strong lines at 934 and 716 cm^{-1} in Raman spectrum are assigned to the C–C stretching modes belonging to A_1 species because of their depolarization factors. The latter is analogous to the strong Raman line at 744 cm^{-1} in tropolone[10,12].

The CH out-of-plane bending vibration belonging to A_2 species should be weak in the Raman spectrum and only observed as forbidden bands in the infrared spectrum. In accordance with this presumption the band at 867 cm^{-1} is assigned to this bending vibration. The characteristic weak bands in the region of 2000~1600 cm^{-1} in benzenoids, depending on the position of substituents, are explained

10) Y. Ikegami, unpublished data. The Raman spectra of tropolone and 3- and 4-isopropyltropolones were measured in carbon tetrachloride solution and the spectra showed the most intense Raman lines respectively at 1473, 1489 and 1475 cm^{-1}.

11) Y. Ikegami, Part V, This Bulletin, 35, 972 (1962).

12) S. Imanishi and M. Ito, ibid., 28, 75 (1955); 29, 632 (1956); *J. Chem. Phys.*, 24, 1272 (1956).

as the combination bands or over-tones of CH out-of-plane bending vibrations[13]. If such an interpretation were to apply in the case of planar tropone skeleton, the infrared absorption band at 2013 cm^{-1} would probably by the anticipated over-tone of CH out-of-plane bending vibration at around 1000 cm^{-1}, because, if this band is the combination of two fundamental frequencies, one of these must be higher than the expected frequency range to the CH out-of-plane bendings. This vibration belongs to A_2 species and corresponds to the shoulder of a band at 1017 cm^{-1}. Under such consideration, the probable combination, 934+867 cm^{-1}, is assumed to be a weak band at 1808 cm^{-1}. Accordingly, another CH out-of-plane bending vibration belonging to A_2 species probably exists at around 934 cm^{-1} together with the C–C stretching vibration.

It is noticed that, in this region, the CH out-of-plane bendings of tropone appear at 120~150 cm^{-1} higher than those of tropilidene (II)[7]*.

Ia Ib II

In the region higher than 1000 cm^{-1}, there should be one C–C stretching (B_1 species) and six CH in-plane bending vibrations. Of the observed frequencies, the band at 1253 cm^{-1} can be assigned to the vibration belonging to A_1 species from its depolarization factor. The four bands at 1412, 1309, 1217 and 1017 cm^{-1} are considered to belong to B_1 species, and one of them would be assigned to the C–C stretching vibration. Although there are no definite grounds, the line at 1017 cm^{-1} may probably be assigned to the C–C stretching vibration, since many troponoids show the characteristic absorption band, independent of substituents, in this region[14]. Of the remaining bands, those weak in both infrared and Raman spectra may be assigned as combination bands or over-tones, as indicated in Table II, and distinct bands at 1204 and 1151 cm^{-1} are assumed to belong to A_1 species though indistinct in Raman spectrum.

Region Lower than 700 cm^{-1}.—The bands in this region are assigned to the deformation vibrations of the tropone skeleton. A Raman line at 396 cm^{-1} is assigned to the vibration of A_1 species, similar to that of tropilidene at 420 cm^{-1} and that of tropylium cation at 433 cm^{-1}, although this is doubtful in its depolarization factor. The bands at 576 and 492 cm^{-1} which are strong in the infrared spectrum and weak in the Raman spectrum are assigned to that of B_2 species, and the bands at 644 and 664 cm^{-1}, indistinct in infrared and weak in Raman, are probably assigned to those belonging to the A_2 species. The remaining bands at 653, 386 and 329 cm^{-1} distinct in Raman spectrum were assumed to be assigned to the B_1 species.

Others.—Due to the lack of reliable data, two deformation modes of oxygen atom have been excluded. Of the remaining observed absorption, combination bands or over-tones in the region higher than 1650 cm^{-1} are included in Table II.

The author expresses his deep gratitude to Professor Susumu Kinumaki, Professor Shuichi Seto, and Assistant Professor Koyo Aida for the unfailing guidance throughout the course of the present work. He is also indebted to Mr. Shuji Aono and Miss Hisako Minegishi for their technical cooperation in the spectral measurement.

Infrared Spectra of Troponoid Compounds. V. Absorption Bands in the Region of 1700~1530 cm^{-1} of Tropone, 2-Chlorotropone and Tropolone[*1]

By Yusaku IKEGAMI

(Received August 23, 1961)

Infrared absorption bands due to the vibration of tropone skeleton are generally not present in the higher wave number side than 1651 cm^{-1}, and appear as two or more bands in the region of 1651~1530 cm^{-1} [1]. In most reports made to date, the absorption bands with the highest wave number have been treated as that of C=O stretching and the next higher absorption as the C=C stretching mode. Such an assignment, however, has little experimental or evidental basis. Accordingly, it should naturally be considered that $\nu_{C=O}$ might show a lower wave number than $\nu_{C=C}$, as was considered earlier by Kloster-Jensen and others[2] with $\nu_{C=O}$ of 2, 7-polymethylene-4, 5-benzotropones.

As shown in the previous reports[3,4], the infrared spectrum of tropone (I) in this region shows considerable variation of absorption wave numbers according to the condition of measurement, and the relative intensity of Band I[*2] and Band II[*2] is just reverse, according to whether it is observed in a vapor or liquid state. Such a difference in spectrum may be attributed to the association of molecules. Then, as one of the means for obtaining some informations on the assignment of these bands, the variation of the intensity and the shift of the absorption bands accompanying changes in the state and solvent were examined. Discussions are also given on the results obtained by the measurement of infrared spectra in the region of 1700~1500 cm^{-1}, in various solvents. Besides tropone, 2-chlorotropone (II) and tropolone (III) were also examined.

Measurement

The infrared absorption spectra were measured with a Perkin-Elmer model 21 infrared spectrophotometer equipped with a sodium chloride prism. The measurement on solids were made with the potassium bromide disk method and the sample cell with potassium chloride windows was used for the measurement in solution and liquid. Standard absorption lines of water vapor and polystyrene film were used for wave number calibration. The probable error of the wave number in Tables I, II and III is about ± 2 cm^{-1}. Tropone, 2-chlorotropone[5], and tropolone were prepared by known methods and purified. The kind of solvents to be used and the concentration of the solution were selected considering the infrared absorption of solvents themselves and the solubility of samples.

Results and Discussion

Tropone.—The spectra measured on tropone are shown in Fig. 1. The spectrum obtained earlier[4] in the vapor state is also shown in Fig. 1a. The wave number (ν) of absorption bands found, relative wave number shift ($\Delta\nu/\nu_0$), apparent molecular extinction coefficient (ε^a) at each wave number, and apparent half band width ($(\Delta\nu)_{1/2^a}$) are summarized in Table I. The value of $\Delta\nu$ shows the wave number shift ($\nu_0-\nu$) and is given taking the wave number (ν_0) in the vapor state as the standard. The values of ε^a and $(\Delta\nu)_{1/2^a}$ are rough values, because the Bands I and II are often accompanied with shoulders. However, these values will be sufficient in knowing the tendency of spectral variation. As a measure to compare the intensities of Bands I and II, the values of r are taken as shown in Table I. These values show $[\varepsilon^a\times(\Delta\nu)_{1/2^a}]_I/[\varepsilon^a\times(\Delta\nu)_{1/2^a}]_{II}$ and roughly mean the ratio of the area of Band I to that of Band II.

Following features in the spectra are found in Fig. 1 and Table I:

a) The direction of the shift of absorption bands according to changes in the measuring condition is the same in Bands I and II but the magnitude of this shift is greater in Band II (maximum of $\Delta\nu$: 39 cm^{-1}) than in I (maximum of $\Delta\nu$: 18 cm^{-1}). Bellamy and Williams[6] discussed the relation between the

[a]; Relative wave number shifts were estimated in all cases by reference to the wave number presumed to vapor state.

relative wave number shift for C=O stretching absorption band in various ketones and that of acetophenone in various solvents. According to their method, the values of $\Delta\nu/\nu_0$ of tropone in various solvents are plotted against their values of benzophenone, in Fig. 2*[3]. As is clearly noticed from this figure, an effect, which is similar to that of solvent on the carbonyl group of benzophenone, appears in both Bands I and II of tropone. The effect appeared is smaller in Band I and larger in Band II, than that for the carbonyl group of benzophenone. This effect on Band II is typical as the effect on the usual C=O stretching absorption[6].

b) The Band I is stronger than Band II in a vapor state but Band II is stronger and has wider width in other states.

c) As the Bands I and II shift towards the lower wave number side, the value of ε^a of Band I decreases slightly and that of Band II tends to increase. Consequently, value of r decreases.

d) The spectrum of liquid tropone in this

*[3] Benzophenone was chosen as the standard because two π-electron systems are conjugated with the carbonyl group in a molecule as in tropone. The values of $\Delta\nu/\nu_0$ of tropone in *n*-heptane and in diisopropyl ether corresponded respectively to those of benzophenone in *n*-hexane and in *n*-butyl ether.

region is similar to that of tropone in ethanol or acetonitrile, generally known as a polar solvent.

On the basis of these features, following discussions are built. There is no doubt that the absorption bands in this region are due to the stretching vibrations of C=O and C=C linkages[7]. According to the consideration on the vibrational assignments of tropone spectrum, one C=O stretching (A_1 species) and two C=C stretching (A_1 and B_1 species) vibrations are expected in the region of 1700~1530 cm^{-1}, as discussed in the preceding paper[3]. That of B_1 species was observed

7) That the $\nu_{C=O}$ in tropone is less than 1651 cm^{-1} is generally explained as follows. The $\nu_{C=O}$ of saturated cycloheptanones is between 1708 and 1698 cm^{-1}, according to many references. When the molecule has a double bond conjugated with a C=O group, the frequency is less than this value by ca. 40 cm^{-1} (for example, eucarbone: 1660 cm^{-1}). Therefore, the $\nu_{C=O}$ of tropone is expected at the lower than 1650 cm^{-1} because tropone has a longer conjugated system and the polar character of Ib type. Moreover, from the the length of C=O bond, which was determined as 1.26 Å by electron diffraction analysis, we can expect the $\nu_{C=O}$ of tropone at around 1610 cm^{-1} because of the relation between the bond length and the frequencies reported by Leyton et al. (Cf. K. Kimura, S. Suzuki, M. Kimura and M. Kubo, This Bulletin, 31, 1051 (1953); E. M. Leyton, R. D. Kross and V. A. Fassel, *J. Chem. Phys.*, 25, 135 (1956).)

distinctly at 1598 cm^{-1} in the Raman spectrum but it is not so clear in the infrared spectra and is probably superposed in Band II. Consequently, Bands I and II both must belong to the A_1 species, as they are also supported from their depolarization factors[3].

It is well known in general that the C=O stretching vibration appears strongly in infrared spectra and the wave number of absorption band and the intensity are easily affected by the internal or external effects[8]. Such properties are found in both of Bands I and II in tropone, although often more in Band II than I, as shown in the foregoing a)—c). On the other hand, it is hardly expected that the out-of-phase C=C stretching vibration of tropone appears strongly, because of the fact that the absorption of tropilidene[9], which has the same C_{2v} symmetry as tropone, is very weak in this region. The wave number 1580 cm^{-1} in the liquid tropone, for example, is too low for pure out-of-phase C=C stretching vibration belonging to A_1 species, compared with that of tropilidene (1609 cm^{-1})[9] and of tropylium cation (1594 cm^{-1})[10].

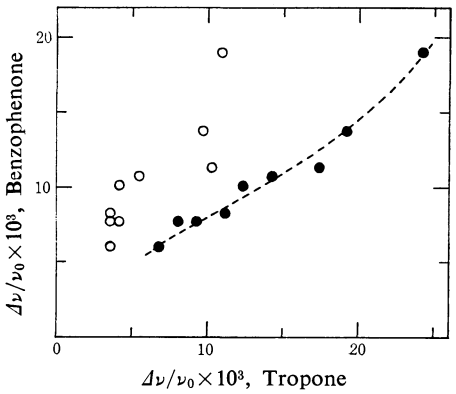

Fig. 2. Relation between the values of $\Delta\nu/\nu_0$ of Bands I and II in tropone and of $\nu_{C=O}$ in benzophenone in various solvents. ○ ; Band I, ● ; Band II

Considering the facts described above, it is natural to assume that both Bands I and II have contributions from the C=O and C=C stretching vibrations, which belong to A_1 species and both are expected at around 1600 cm^{-1}. If such is the case, there would be relative variation in the frequency, intensity, and width of absorptions in both Bands I and II as the C=O bond is polarized by external effects, and the foregoing characteristics a)—c) in spectra should mean that the character of C=O stretching vibration in Band II is greater than that in Band I, except in a vapor state. If the Ib character of a tropone skeleton becomes stronger and the double bond character of C=O bond becomes smaller, it is likely that the $\nu_{C=O}$ appears in a further lower wave number region. For example, Buchanan

and others[11] assumed that the strong absorption at 1540~1470 cm^{-1} in associated 4-hydroxy-2, 3-benzotropone is that of the C=O bond, and the same treatment was also made regarding to the band at 1465 cm^{-1} in associated 4-hydroxytropone[1].

Solvation effect on C=O bond in tropone, as far as it appears in $\nu_{C=O}$, is similar to that on the carbonyl group in benzophenone, as clearly noticed in Fig. 2. The fact d) that the spectrum of liquid tropone is similar to that in a polar solvent, which generally has a strong effect on the C=O bond, means that tropone itself is strongly associated with the Ib type polar character. The polar character of tropone is distinctly seen in its large dipole moment (4.17 D)[12].

2-Chlorotropone.—Figure 3 shows the spectra obtained with 2-chlorotropone (II). In the same way as with tropone, the values of ν, $\Delta\nu/\nu_0$, ε^a, $(\Delta\nu)_{1/2}{}^a$, and r are summarized in Table II. The value of ν_0 was presumed from the frequencies in solutions, as it is not known in the vapor state. Plotting of the values of $\Delta\nu/\nu_0$ against those of $\nu_{C=O}$ in benzophenone, Fig. 4 is obtained. The tendency of spectral variation, as observed from these figures and table, is essentially the same as that of tropone, and the assignment of Bands I and II can be discussed by the coupling of $\nu_{C=O}$ and $\nu_{C=C}$ in the same way as in tropone. Further, the followings are clear from the comparison with tropone.

e) The difference in wave number (27～39 cm^{-1}) in Bands I and II is much less than that in tropone (38～59 cm^{-1}).

f) Band I is stronger than II in non-polar solvents and Band I is weaker than II in polar solvents. The variation of relative intensity is noticeble.

The fact e) suggests that the carbonyl group in 2-chlorotropone is less affected by the external effects than that of tropone. Also, comparing the fact f) with Fig. 4, it is found, that the $\Delta\nu/\nu_0$ values of the two bands are close to each other when the intensities of Bands I and II are nearly equal, but the variation of $\Delta\nu/\nu_0$ is generally larger with a stronger band than with a weaker band. This may be indicated that the one with larger character of C=O stretching vibration shows more variation in wave number.

Tropolone.—In tropolone (III), the carbonyl group is fixed by a intramolecular hydrogen bond. So it is of interest to examine how the effects of solvents appear in the spectra. Figure 5 shows the spectra measured in various states and solvents, as well as in vapor state obtained earlier[4]. The various values obtained from Fig. 5 are shown in Table III, and the relative wave number shifts are given in Fig. 6.

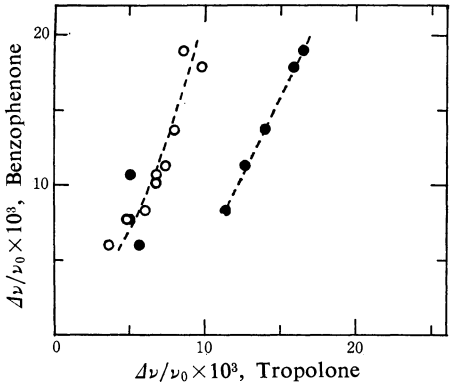

Fig. 6. Relation between the values of $\Delta\nu/\nu_0$ of Bands I and II in tropolone and of $\nu_{C=O}$ in benzophenone in various solvents.
○; Band I, ●; Band II.

From these results the following features are found.

g) In accordance with the results on tropone, the direction of shift is the same for both of Bands I and II and the degree of shift of Band II is larger than that of Band I. However, the peak intensity of Band I is larger than that of II and Band II is broader.

h) The wave numbers of Bands I and II are smaller than those of tropone by 23～21 and 38～27 cm^{-1}, respectively.

i) The values of $\Delta\nu/\nu_0$ of Bands I and II in polar solvents are smaller than those of tropone, 2-chlorotropone, and $\nu_{C=O}$ of benzophenone.

j) ε^a of Band II does not show the tendency to decrease with the shift to the lower wave number side. As is noticed from the values of r, the variation of the intensity of Band II is less than that of tropone, though the values of intensity are not sufficiently reliable because of the absorption of the solvent itself and the broad absorption at around 1490 cm^{-1} due to a C–O–H group[13].

The variation of spectrum is thus the same in tendency as in the cases of tropone and 2-chlorotropone but is very small in its degree. This means that the C=O stretching absorption shifts to the lower side than that of tropone by 23～40 cm^{-1} by the effect of intramolecular hydrogen bond and that, by this hydrogen bond, the carbonyl group is affected little by the external actions at any state of measurement. This effect is comparatively large in polar solvents.

Summary

Infrared absorption spectra of tropone, 2-chlorotropone, and tropolone in the region of 1700～1500 cm^{-1} were measured in various states and in various solvents, and the variation of two strong Bands I and II in the region of 1700～1530 cm^{-1} was investigated. The data are shown in tables and figures. These two bands are explained as the participation of both of the C=O and C=C stretching vibrations in a tropone skeleton. The variation of the spectrum of tropolone with the measuring condition is much smaller than that of tropone. This is because the carbonyl group in tropolone is fixed by the intramolecular hydrogen bond.

Grateful acknowledgement is made to Professor Susumu Kinumaki, Professor Shuichi Seto, and Assistant Professor Koyo Aida who gave valuable guidance to this study and to Mr. Shuji Aono who performed part of the measurement.

Spectrophotometric Studies on the Kinetics of Decomposition of Tetramethylmurexide in Acid Medium

By R. K. CHATURVEDI

(Received August 12, 1961)

Murexide or ammonium purpurate (I) has

(I)

found extensive application in analytical procedures for qualitative detection and quantitative estimation[1-8] of various metal ions. For these purposes murexide is used both in acidic[9] as well as alkaline media[10], but in highly acidic or alkaline solutions this metal ion indicator is quite unstable. A research programme was therefore, undertaken on the kinetics of decomposition of murexide in acidic[11] and alkaline[12] media in order to elucidate the reaction mechanism (s) and to formulate proper conditions for the analytical use of murexide[13]. These kinetic studies are now being extended to various compounds related to murexide. The present communication refers to the study on the kinetics of decomposition of tetramethylmurexide (ammonium tetramethylpurpurate) in acid solutions.

Experimental

Tetramethylmurexide was prepared by the method of Gysling and Schwarzenbach[15] by the action of ammonium carbonate on tetramethylalloxantin. This last named compound was obtained by careful degradation of caffeine following the procedure outlined by Biltz[16]. Repeated recrystallization of ammonium tetramethylpurpurate by salting it out from its aqueous solution[17] by the addition of ammonium chloride gave a sample of satisfactory purity. Hydrochloric acid used was an Analar sample; diluted solutions of this acid were standardized against a standard sodium carbonate solution. Throughout these studies redistilled water was used for preparing the solutions etc. All the spectrophotometric measurements were made with a Beckman DU spectrophotometer using corex cells of 1 cm. width. The temperature of the reaction system was maintained at desired value with an accuracy of ± 0.05°C (or better) by employing a Beckman dual thermospacer set in combination with an externally connected thermostat; this last was operated by a micro relay.

Results and Discussion

Absorption Spectra of Tetramethylmurexide. —Figure 1 gives a typical set of results on the absorption of tetramethylmurexide solution in the visible region; the curve in this figure refers to a concentration of 0.05 mM. It may be noted from Fig. 1 that tetramethylmurexide exhibits an absorption maximum at $\lambda = 530$ mμ.

Further, this wavelength of maximum absorption was unaffected by the change in the concentration or/and pH of the system. Studies on the variation of optical density with concentration of tetramethylmurexide were carried out in the concentration range 0.01～0.08 mM. It is evident from Fig. 2 that the absorption of tetramethylmurexide at $\lambda=530$ mμ is governed by Beer's law; the value of the Beer's constant from the slope corresponds to 1.464×10^4.

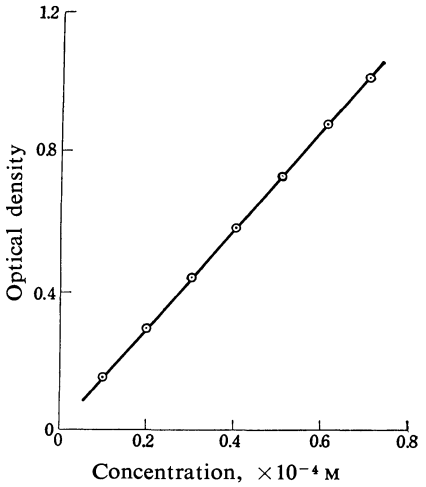

Fig. 2. Application of Beer's law to the absorption of tetramethylmurexide at $\lambda=530$ mμ.

The observations recorded above thus provide a method for following the reaction kinetics by observing the variation with time of the optical density of acidic solution of tetramethyl murexide at $\lambda=530$ mμ. In the experiments reported here the concentration of hydrochloric acid and tetramethyl murexide were 5 and 0.05 mM respectively. Thus the temperature was the only variable parameter in these experiments; the range of temperature investigated in these experiments was from 25～45°C.

Determination of the Rate Constants.—For a first order reaction, we have

$$\ln C=\ln C_0-kt \qquad \text{(i)}$$

Where C_0 is the initial concentration of the substance and C is the concentration after a time interval t. Equation 1 suggests that $\log C$ vs. t plots should be linear with slope being equivalent to $-k/2.303$. Instead of concentration one may also employ a physical property linearly dependent upon C such as optical density (vide supra). Figure 4 gives the plots of log(OD) vs. t for the reaction under investigation; from the slope of these plots, we get the value of the apparent rate constant (in time^{-1})

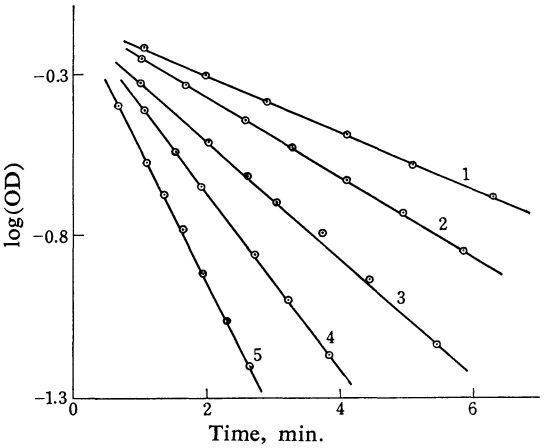

Fig. 3. log(OD) vs. time plots: concentration of HCl, 5 mM; concentration of tetramethylmurexide, 0.05 mM. Temperature: curve 1, 25°C; curve 2, 30°C; curve 3, 35°C; curve 4, 40°C; curve 5, 45°C.

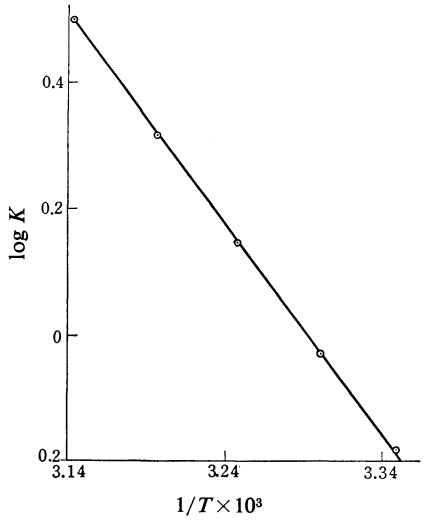

Fig. 4. Arrhenius plot.

for the reaction. As pointed out previously[18], these k values are linearly variant with hydrogen ion concentration $[H^+]$ and refer here to the experimental conditions under which the initial concentration of H^+ is taken in much excess over that of the tetramethylmurexide. The reaction is in fact bimolecular and the rate constant characteristic of the reaction is given by the relationship.

$$k=\frac{2.303\,\Delta\log(\mathrm{OD})}{[H^+]\times\Delta t}$$

which differs from the values obtained from the slope in Fig. 4 by the factor $[H^+]$ which appears in the denominator. These values of k (expressed in sec^{-1} l. mol^{-1}) corresponding to

18) Cf. Ref. 14.

TABLE I. RATE CONSTANTS OF DECOMPOSITION OF TETRAMETHYLMUREXIDE IN ACID SOLUTIONS

Temp., °K	298	303	308	313	318
Rate constant $l.mol^{-1}sec^{-1}$	0.67	0.93	1.39	2.07	3.17

TABLE II. FREQUENCY FACTOR, ENERGY AND THERMODYNAMIC QUANTITIES OF ACTIVATION (25°C)

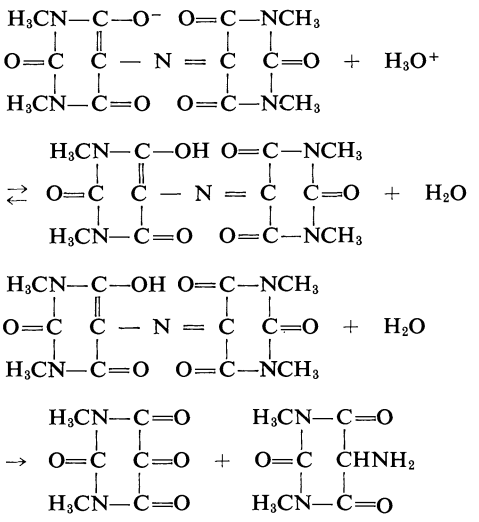
E	15.49 kcal.
$\log A$	11.18
$\Delta F^{\ddagger}$	17.69 kcal. $deg^{-1}\,mol^{-1}$
$\Delta S^{\ddagger}$	−4.75 e. u.
$\Delta H^{\ddagger}$	16.27 kcal. mol^{-1}

different temperatures are returned in Table I. Thus for example the values of k were 0.937 and 3.17 at 30°C and 45°C respectively.

Determination of Quantities of Activation.—For computation of the energy of activation of the reaction, the well-known Arrhenius equation was applied. Figure 4 gives the linear plot of $\log k$ vs. $1/T$; from the slope of this plot, we get a value of 15.49 kcal. for the energy of activation. This value of E along with the values of k in Table I, gives a value of 11.18 for the Arrhenius frequency factory ($\log A$)[19]. Also presented in this table are the data on the free energy and entropy of activation calculated from the relationship[20]

$$\Delta F^{\ddagger}=2.303\,\boldsymbol{R}T\left(\log\frac{\boldsymbol{R}T}{Nh}-\log k\right) \qquad (1)$$

$$\Delta S^{\ddagger}=2.303\,\boldsymbol{R}\left(\log A-\log e\frac{\boldsymbol{R}T}{Nh}\right) \qquad (2)$$



and the value of $\Delta H^{\ddagger}$ obtained from the values of $\Delta F^{\ddagger}$ and $\Delta S^{\ddagger}$.

Comparison with Collision Theory.—From consideration based on the collision theory one can shown that for a biomolecular reaction the kinetic collision frequency is given by[21]

$$Z=\frac{N}{1000}\,\sigma^2\left[8\Pi\boldsymbol{R}T\left\{\frac{1}{M_a}+\frac{1}{M_b}\right\}\right]^{1/2} \qquad (3)$$

where σ is the distance of approach between the reactions for effective collision, M_a and M_b are molecular weights of the reactants and the terms N, Π, $\boldsymbol{R}$ and T have their usual significance. From Eq. 3 we get a value of 11.62 for $\log Z$ in good agreement with a value of 11.18 obtained experimentally for the Arrhenius frequency factor. Similar agreements have been obtained for various reactions in solutions[22] which are free from complications arising out of ionic interactions etc.

Possible Reaction Mechanism.—In view of the above observations and with the knowledge of the reaction products, a possible mechanism of the reaction can be formulated. The problem of the products formed as a result of the decomposition of murexide and substituted murexides in acid solutions has been widely discussed[23]. The presence of alloxan and uramil along with some alloxantin has been detected[24]. In fact it was a controversial point as to whether the alloxan and uramil are primary products or the alloxantin. It was, however, convincingly shown by Davidson[25] that the decomposition of murexide in acid medium gives alloxan and uramil; these compounds then undergo secondary reactions to give alloxantin. For tetramethylmurexide the products of the primary reaction would thus be dimethyl substituted alloxan and uramil. It is suggested that this process takes place according to the following mechanism:

It is of interest to point out here that it has not been so far possible to isolate the free purpuric acid or substituted purpuric acids because of their extreme instability. On the other hand in case of certain compounds related to murexide for which the corresponding acids are stable, the addition of acids to say ammonium salts results in the liberation of free acid[26]. Further the direct interaction of the tetramethylpurpurate ion and the hydronium

ion cannot be the rate determing one, as for such a process the kinetic data should be such as to suggest an ionic interaction. Moreover the tetramethylpurpurate is considered to be in equilibrium with tetramethylpurpuric acid as a result of the ionic combination of the former with the hydronium ion. This process will be governed by an equilibrium constant the reciprocal of which will be, according to the modern concepts[27], the ionization constant of tetramethylpurpuric acid; the ionic combination of tetramethylpurpurate and the hydronium ion cannot be considered to be the rate determing one, as such processes are known to be extremely fast[28]. Thus it appears very likely that the instability of tetramethylpurpuric acid, the formation of which is favored in presence of excess of acid, is responsible for the decomposition of tetramethylmurexide in acid medium and for the observed kinetics of the reaction.

Summary

Kinetics of the decomposition of tetramethylmurexide in acid solutions have been investigated spectrophotometrically by following the absorption at $\lambda=530$ mμ. The optical density of tetramethylmurexide at this wavelength has been shown to obey Beer's law with a value of 1.464×10^4 for the Beer's constant. The change in the optical density with time of tetramethylmurexide solutions in presence of hydrochloric acid has been shown to obey a first order law and from these data the rate constants of the reaction have been computed at different temperatures in the range 25~45°C. These data have been employed to obtain quantities such as energy and entropy of activation etc. and the Arrhenius frequency factor; the comparison of this last has been made with the collision theory. The possible mechanism of the reaction has been discussed.

Author's grateful thanks are due to Dr. H. Trivedi, Principal, for facilities and encouragement and to Dr. J. B. Lal, head of the Chemical Engineering Department, for his kind interest in the work.

Electrical Conduction in the Violanthrene-Iodine System

By Tokiko UCHIDA and Hideo AKAMATU

(Received November 30, 1961)

With relation to the nature of conductive electrons or the mechanism of electrical conduction in organic solids, the intermolecular charge transfer complexes are interesting, because the complex formation results in a remarkably low electrical resistivity compared with that of the constituents[1-5]. However, there is a variety in their electrical properties, which depend on the combination of the electron donor compounds and the acceptor compounds. The complexes which possess a relatively high conductivity are those which belong to the "strong" charge transfer complexes, whereas the "weak" charge transfer complexes possess a relatively high resistivity. The former can be characterized by its strong electron spin resonance absorption at room temperature; a correlation between the charge carriers and the unpaired electrons has even been suggested. The typical examples with which we are concerned here are the complexes between polycyclic aromatic hydrocarbons and halogens. Most of these complexes consist of definite stoichiometic compositions in the solid state, for instance, pyrene-iodine (1 : 1 and 1 : 2), perylene-iodine (2 : 3 and 1 : 3), pyranthrene-iodine (1 : 2), etc. Under X-ray diffraction,

these complexes show particular crystal patterns. In contrast to these complexes, violanthrene forms a complex with iodine, which has a non-stoichiometric composition; furthermore, X-ray diffraction indicates that it is completely amorphous. The structure of the violanthrene-iodine complex has been discussed in a previous paper[6], where we concluded that this complex is to be regarded as the solid solution between iodine and violanthrene. From the view point of semiconducting material, a system like this is specially interesting, because iodine molecules (acceptor) can be distributed homogeneously among violanthrene molecules (host matrix) at any concentration. This will result in a semiconducting system which is analogous to an impurity semiconductor or a valence-controlled semiconductor, lithium-nickel oxide, for instance.

Experimental and Results

Preparation.—Violanthrene was prepared from violanthrone by reduction with zinc-dust. After the usual purification, it was carefully purified by repeated sublimation in vacuo. In order to vary the iodine content in the complex widely, the following two procedures were applied according to the iodine concentration.

For High Iodine Content Complex.—Crystalline powder of violanthrene was suspended in a benzene solution of iodine and boiled for about 30 min. using a reflux condenser. After cooling, the black-colored precipitate was filtered off with a glass filter. (When this precipitate was heated, iodine was liberated and the original hydrocarbon could be recovered. This indicates that the black precipitate was not a substitutional product but a molecular additional compound.) The quantity of added iodine was determined from the difference in weight between the original hydrocarbon and the precipitate. The amount of violanthrene dissolved into the benzene solution was disregarded as being too small compared with the total amount of the sample.

For Low Iodine Content Complex.—Finely powdered violanthrene was suspended in a carbon tetrachloride solution of iodine and, being kept at room temperature for more than three days, was shaken from time to time. Then the precipitate was filtered off with a glass filter. The amount of added iodine was determined from the difference between the initial and the final concentration of dissolved iodine, which difference was measured by iodometry with sodium thiosulfate.

In both procedures, the iodine content in the precipitates could be varied by controlling the amounts of dissolved iodine in the initial solutions. The high iodine content complex was black colored, while, as the iodine content decreased, the color approched that of the original hydrocarbon (dark red).

Electrical Resistivity.—The measurement of electrical resistivity was made with a sample packed into an ebonite pipe (3 mm. in diameter), both ends of which were attached to electrodes of platinum or silver-coated copper. At least 116 kg./cm^2 pressure was applied to the sample in order to reduce the contact resistance at the grain boundary. The resistance was read with an ohmmeter for the samples with low resistivity, while it was measured also with a galvanometer for the samples possessing higher values of resistivity. The applied voltage was less than 20 V./cm., at which the electrolysis did not take place.

The resistivities at room temperature are shown in the third column in Table I. The second column denotes the composition of the sample in the mole ratio of iodine to violanthrene.

All the specimens showed a negative temperature coefficient of resistivity and changed in value in accordance with the formula $\rho = \rho_0 \exp(E/kT)$. The observed values for activation energy, E, for the electrical conduction are shown in the fourth column in Table I. The temperature ranges for these observations are indicated in the last column.

The results show that the conductivity is enhanced by the addition of a small quantity of iodine and increases monotonously with the increase in iodine content (Fig. 1), while the activation energy has a nearly constant value in the range of low iodine content. If the iodine molecules are assumed to be distributed homogeneously in the host matrix, they might be separated from each other by 13 molecules of violanthrene (about 100 Å) in the sample with the least iodine content.

Qualitative observation for thermoelectric power was attempted to know the sign of the predominant charge carriers. Both electrodes of the specimen cell, the mole ratio of which was 1.90, were connected to a galvanometer. By heating one side of the electrodes, a minute current flow was observed. The direction of the flow through the galvanometer was from the cold side electrode to the hot side electrode. Namely, the contribution of the positive holes was more predominant than that of the electrons to the conduction in this complex, while the opposite was observed in pure violanthrene.

Hall Effect.—The Hall effect has not been observed in semiconductive simple organic compounds because of their high resistivities. The only report presented has been on a rather special compound, poly-copper-phthalocyanine[7].

8	1.0×10^{18}	—	—	1.5×10^{14}	3.0×10^{-5}

It was hoped to observe the Hall effect successfully in the halogen-complexes, because they possess low resistivities. The attempt was made with a sample with the mole ratio of 1.90. The specimen powder was pressed into a frame of Bakelite plate with a load of 1000 kg. The dimensions of the specimen were $5\times20\times1.73$ (t) mm. Platinum electrodes and leads were mounted in the frame. The electrical resistance of the specimen was 140 ohm between current leads and 700 ohm between potential leads. This frame was placed between poles of a magnet. The applied electrical current (I) was 8.5 mamp. The magnetic field (H) was 8000 oersted. For the electromotive force measurement, a Leed & Northrup potentiometer was employed in association with a galvanometer (Kaken) possessing the sensitivity of 4.6×10^{-8} V. All the apparatus was carefully insulated from the ground to avoid a slight irregular current.

When the magnetic field was applied, a slight potential difference was recognized between the potential leads. Although the magnitude was very small (about 0.5 mm. movement on the scale of the galvanometer), a quite definite change in direction of the electromotive force was noted following alternation of the direction of the magnetic field or electric current in the specimen. This direction indicated the hole conduction, which was consistent with the results of the thermoelectric power. From this, it might be concluded that a very weak Hall effect was perceived in the violanthrene-iodine complex. However, the Hall voltage was small, restricted by the limits for the sensitivity of the galvanometer, $\Delta V<4.6\times10^{-8}$ V. Thus, the Hall coefficient was $R=10^{8}\cdot\Delta Vt/HI<1.2\times10^{-2}$ cm³/coulomb. If the conduction is assumed to be carried by positive holes, the number of carriers and the mobility might be estimated as:

$$n_h=\frac{3\pi}{8}\frac{1}{Re}>7\times10^{20}\ \mathrm{cm}^{-3}$$

$$\mu_h=\frac{8}{3\pi}R\sigma<1.6\times10^{-3}\ \mathrm{cm}^2/\mathrm{V.\ sec.}$$

This indicates that the mobility possesses a very small value, and this is the reason for the difficulty of Hall effect measurement for these organic compounds. These values quoted the lower limit and the upper limit respectively due to the sensitivity of the galvanometer. However, they are perhaps not far from the real values, which will be discussed in a later section.

ESR Absorption.—The electron spin resonance absorption was observed at room temperature with a Hitachi MPS-1 ESR X-band spectrometer. All the samples showed absorption and, consequently, the existence of unpaired electrons. No fine structure was found in the absorption line.

The g-value was determined by referring to a standard sample of ultramarine ($g=2.028$). The g-value of the violanthrene-iodine system was 2.0035, regardless of the composition, which is very close to the value of the free electron or of organic free radicals. The spin concentration of the samples was determined from the integral areas of absorption lines by comparison with that of a standard sample of diphenylpicrylhydrazyl. The observed values are summarized in Table II. For the samples of lower iodine content, the estimationof spin numbers could not be made quantitatively because of their weak absorptions. Violanthrene usually shows a weak absorption (for a reason unknown at present), and the values quoted in Table II are those for which correction has been made for the absorption of violanthrene (2×10^{18}/g.). Such being the case, a spin concentration of less than 10^{18} per cc. (for sample 5) is not reliable.

Discussion

It has been found that a small amount of iodine added to violanthrene enhances the electrical conduction remarkably, and that the resistivity decreases monotonously with an increase in the iodine concentration until the mole ratio 1:2, where the intermolecular pseudo-compound is formed[6]. This effect of iodine is almost comparable to that of lithium oxide added to nickel(II) oxide. The resistivity of pure oxide nickel is 10^{13} ohm-cm. at room temperature, which is comparable to that of violanthrene, 10^{14} ohm-cm. It is well known[8,9] that the alloying of lithium oxide with nickel(II) oxide in a homogeneous solid solution leads to a semiconducting material (the so-called valence control semiconductor) with a remarkable range of resistivity depending on the lithium concentration. In Fig. 1, the variation of resistivity with the concentration of the impurity is illustrated for the systems of both violanthrene-iodine and nickel(II) oxide-lithium oxide. One can see that the two curves are quite similar to each other. Moreover, a few common characteristics can be noted between these two systems. In the nickel oxide system, the activation energy for electrical conduction is as small as around 0.1 eV. and depends on the lithium content; the conduction is carried by positive holes, and its mobility is so small that the Hall effect could hardly be observed. However, from the Seebeck effect it has been estimated

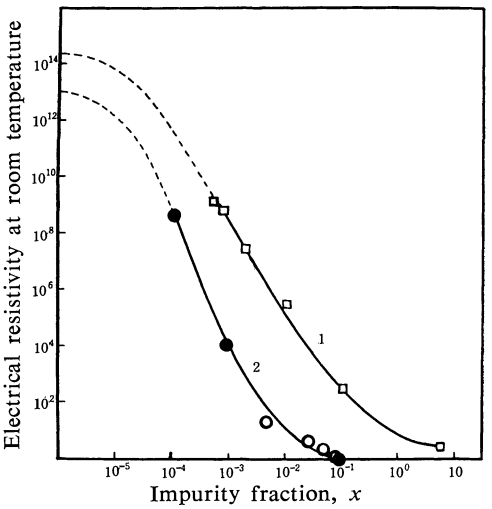

Fig. 1. Electrical resistivity for various impurity content.
Curve 1: Violanthrene-iodine. Curve 2: $Li_xNi_{(1-x)}O$. (After Morin. Ref. 9, p. 622). Impurity content is represented by the fractional number x for both curves.

as 10^{-3} cm^2/V. sec. at room temperature, depending on the lithium content.

The mechanism of electrical conduction in the nickel oxide system has long been discussed as a typical example to which the energy band model could not be applied. Recently, the "hopping" type electrical conduction theory has been proposed and has been quite successful[10]. Thus, it might be interesting to speculate on the conduction mechanism in the violanthrene-iodine system on the analogy of the nickel(II) oxide-lithium oxide system.

In nickel oxide, neighboring Ni^{2+} ions are so far separated from each other that the overlap of 3d wave functions is very small and the 3d charge carriers can be considered to occupy energy levels localized on the cations. In consequence, pure nickel oxide possesses a high resistivity. However, nickel oxide can be made conducting by introducing Ni^{3+} ions into the lattice by the substitution of Li^+ ions for some of the Ni^{2+} ions. The Ni^{3+} ions (holes) are not bound to definite positions in the lattice, but can wander through the crystal by jumping from ion to ion if there is some overlap between hole wave functions localized on neighboring ions. However, the hole tends to be "self-trapped" in the crystal as a result of the polarization of the surrounding lattice, and when the hole can jump, the polarization associated with the hole must jump with it. The jumping process is then

10) J. Yamashita and T. Kurosawa, *J. Chem. Phys. Solids*, 5, 34 (1958).

expected to involve an activation energy associated with the self-trapping of the holes.

In the violanthrene-iodine system, the electron transfer takes place from violanthrene (D) to neighboring iodine (A) through an overlap of molecular orbitals by the quantum mechanical resonance; the dative structure (D^+A^-) will result, in which the violanthrene molecule can be regarded as a positive ion. The dative structure may not be bound to a definite donor molecule, but may wander by the resonance among the neighboring molecules; thus resulting in a positive hole. However, the hole may be localized (trapping) around the acceptor molecule (I_2^-), and an activation energy is then expected to make it the "free" hole, which gives rise to electrical conduction by the jumping process. In transport of this type one may expect low mobility and a low value of activation energy because of the polarization effect, as in the case of nickel oxide.

In such a scheme, as many dative structures will be produced as the number of iodine molecules in the violanthrene matrix, but the number of free holes must be smaller than this. This is characteristic of the charge transfer complexes which possess a relatively high conductivity; i. e., a strong ESR absorption is generally observed. Singer and Kommandeur[11] have found, for the complex of pyrene-iodine and perylene-iodine, that the spin concentration increases with the temperature and that the activation energy for the spin generation is in accordance with that for the electrical conduction. Calvin et at.[12] assumed that the number of charge carriers is the same as the number of unpaired spins in the phthalocyanine-chloranil complex. The origin of the observed spins in the charge transfer complex has not yet been clarified; however, a close relation between these unpaired spins and the charge carriers can be presumed. The observable number of unpaired spins is much less than the number of iodine molecules added to violanthrene, and just a small percentage of it at room temperature. If one can assume that the trapped holes are thermally excited and give rise to the free holes, then the number of free holes N^* might be given by $N_{I_2} \exp(-E/kT)$, where N_{I_2} is the number of iodine molecules and E is the activation energy for electrical conduction. In Table II, the calculated values of N^* are shown. These values are almost comparable with the observed numbers of spins in samples 1, 2, 3 and 4, whose spin concentration could be measured quantitatively.

Further speculation can be made on the mobility of charge carriers, which can be given by $\mu = \sigma/N^*e$. The calculated values for the mobility are shown in the last column of Table II. These values are likely reasonable and consistent with the results of the measurement of the Hall effect. In this speculation, it has been assumed that the unpaired spins are observable only when associated with the free holes, but no spin is observable when the hole is trapped by the acceptor ion. Furthermore, the observed activation energy is assumed to be associated predominantly with the delocalization of the hole, rather than with the polarization effect in the transportation process.

Summary

Electrical conduction and ESR absorption in the violanthrene-iodine system have been investigated, varying the iodine content. Observation of the Hall effect has been attempted, but the Hall voltage was so small that the effect could not be determined. It was pointed out that, concerning conductive behaviors, the violanthrene-iodine system is analogous with the nickel(II) oxide-lithium oxide solid solution, and that the hopping model of electrical conduction can be applied. From such a view point, the correlation between the observed unpaired spins and charge carriers has been estimated.

Studies on Lactone Formation in Vapor Phase. III. Mechanism of Lactone Formation from Diols

By Shinzaburo OKA

(Received September 19, 1961)

In previous papers[1,2], it was clarified that the catalytic dehydrogenation of 1,6-hexanediol to ε-caprolactone was very difficult as compared with those of 1,4-butanediol and 1,5-pentanediol, and that it yielded 1-cyclopentene-1-carboxaldehyde, cyclopentanecarboxaldehyde and cyclopentylcarbinol as by-products. These facts aroused the author's interest in the mechanism of this reaction. Reppe[3] considered that first dialdehyde or oxyaldehyde was formed and that then an intramolecular reaction of the Cannizzaro type or an intramolecular acetalization, followed by a dehydrogenation to lactone, took place. For example, in the case of 1,4-butanediol:

Copenhaver[4] wrote that the latter route seemed more likely in view of the nature of the catalyst. Wagner[5] also supported the latter route on the basis of the fact that δ-valerolactone is readily prepared by air oxydation of the corresponding oxyaldehyde[6].

The reactions of dialdehydes or oxyaldehydes leading to the corresponding lactones have, however, been studied by only a few investigators. Meerwein[7] and Longley[8], for instance, prepared δ-valerolactone derivatives by the action of sodium ethoxide or sodium hydroxyde upon dialdehydes in the liquid phase. Bremmer[6] studied the air oxydation of δ-oxyvaleraldehyde to δ-valerolactone in the presence of a cobalt salt in the liquid phase. But the reaction conditions and the catalysts in their investigations are different from those of the dehydrogenation of diols to lactones with the copper catalysts. A study of the behavior of dialdehydes or oxyaldehydes over the copper catalysts used in the previous studies[1,2] has therefore been made.

Experimental

γ-Oxybutyraldehyde (2-oxytetrahydrofuran).—The oxyaldehyde was obtained by thermal decomposition of butane-1,4-dinitrite in the vapor phase, as has been described by Kuhn[9]. From 50 g. of butanedinitrite (b. p. 62~63°C/23 mmHg, n_D^{25} 1.4049), there was obtained 13 g. of γ-oxybutyraldehyde, b. p. 72°C/18 mmHg, n_D^{25} 1.4400, d_4^{25} 1.0808 (Found: C, 54.47; H, 9.20%). Its infrared spectrum (Fig. 1) showed a strong band due to a hydroxyl group at 2.95 μ and a weak band due to a carbonyl group at 5.80 μ, and it formed a 2,4-dinitrophenylhydrazone, m. p. 116°C (lit.[9] 120°C).

δ-Oxyvaleraldehyde (2-oxytetrahydropyran).—The oxyaldehyde was prepared by hydrolysis of 3,4-dihydro-α-pyran[10], as has been described in "Organic Syntheses"[11]. From 60 g. of dihydropyran (b. p. 85~86°C, n_D^{25} 1.4350, d_4^{25} 0.9072), there was obtained 25 g. (33%) of δ-oxyvaleraldehyde, b. p. 54~55°C/3 mmHg, n_D^{25} 1.4515, d_4^{25} 1.0527 (Found: C, 58.63; H, 9.95%). Its infrared spectrum (Fig. 2) showed a strong band due to a hydroxyl group and a weak band due to a carbonyl group, and it formed a 2,4-dinitrophenylhydrazone, m. p. 106~107°C (lit.[12] 109°C).

1,1,4,4-Tetraethoxybutane.—1,1,4,4-Tetraethoxy-2-butyne[13] (42 g., b. p. 104°C/3 mmHg, n_D^{25} 1.4319) in 100 ml. of ethanol was hydrogenated under 80 kg./cm² of initial hydrogen pressure with 6 g. of Raney nickel W-6 at 50~60°C for 2 hr. The catalyst was filtered off, and the filtrate was distilled to yield 40.5 g. (92%) of tetraethoxybutane, b.p. 92~93°C/4 mmHg, n_D^{25} 1.4150 d_4^{25} 0.9136 (Found: C, 61.45; H, 11.32%).

Succinaldehyde Dioxime.—A mixture of 47 g. of tetraethoxy butane and 100 ml. of 0.2 N sulfuric acid was stirred at 30°C. After the mixture had been stirred for 2 hr. the water-insoluble layer disappeared. After another 2 hr., 34 g. of hydroxylamine chloride was added. Then, 50 g. of anhydrous sodium carbonate was added in small portions. After the mixture had been kept in the refrigerator overnight, the crystals were filtered, washed with

water, and dried. The yield of dioxime was 18 g. (74%). Recrystallisation from aqueous ethanol gave a sample melting at 168~169°C (lit.[14] 171~172°C).

Succinaldehyde.—The dialdehyde was obtained by treating its dioxime with sodium nitrite in dilute sulfuric acid, as has been described by Keagle[14]. From 18 g. of the dioxime, there was obtained 6.5 g. (49%) of succinaldehyde, b. p. 78°C/25 mmHg, n_D^{25} 1.4240, d_4^{25} 1.0492 (Found: C, 55.77; H, 7.29%). Its infrared spectrum (Fig. 3) showed a medium band due to C-H group in aldehyde at 3.65 μ and a strong band due to carbonyl group at 5.80 μ.

Glutaraldehyde.—The dialdehyde was prepared by hydrolysis of 2-methoxy-3,4-dihydro-α-pyran, as has been described by Longley[8]. From 30 g. of methoxydihydropyran (b. p. 126~127°C, n_D^{25} 1.4400, d_4^{25} 0.9961), there was obtained 16 g. (61%) of glutaraldehyde, b. p. 53~55°C/3 mmHg, n_D^{25} 1.4280, d_4^{25} 1.0077 (Found: C, 59.14; H, 8.19%). It formed a dioxime, m. p. 164~166°C (Found: C, 46.42; H, 7.83%).

1, 1, 6, 6-Tetraethoxyhexane.— Tetraethoxyhexane was prepared by essentially the same method as that of Kranzfelder[13]. From 150 g. of ethyl orthoformate, 24 g. of magnesium, and 108 g. of tetramethylene bromide, there was obtained 62 g. (47%) of tetraethoxyhexane, b. p. 115~117°C/4 mmHg, n_D^{25} 1.4220, d_4^{25} 0.9085. (Found: C, 64.21; H, 11.40%).

Adipaldehyde.—A mixture of tetraethoxyhexane (52 g.) and 0.4 N sulfuric acid (100 ml.) was stirred at 30°C. After the mixture had been stirred for 3 hr., the water-insoluble layer disappeared. The solution was kept at room temperature for another 4 hr. Then the solution was neutralized with sodium bicarbonate, saturated with sodium chloride and extracted with ether. The dried ether extract gave 14 g. (62%) of adipaldehyde, b. p. 110~112°C/20 mmHg, n_D^{25} 1.4335, d_4^{25} 0.9754 (Found: C, 63.13; H, 9.17%). It formed a dioxime, m. p. 170~171°C (Found: C, 49.96; H, 8.58%).

Vapor Phase Reactions. — The apparatus, procedures, and methods for the preparation of the catalysts were essentially the same as those previously described[1,2]. Tablets of the catalyst (50 ml.) were used. The pressure in the reaction system was reduced to 20~30 mmHg. A sample was passed in by vacuum distillation in a period of one hour. The reaction temperature was maintained at 220~230°C. Some experiments are shown below.

γ-Butyrolactone.—The copper-zinc oxide catalyst was used. γ-Oxybutyraldehyde (15 g.) gave a product (13 g.), b. p. 98~100°C/25 mmHg, n_D^{25} 1.4350, which was identified as γ-butyrolactone. It formed a hydrazide, m. p. 92°C, which gave no depression when mixed with an authentic sample.

14) L. C. Keagle et al., ibid., 68, 1609 (1946).

δ-Valerolactone.—The copper chromite-zinc oxide catalyst was used. δ-Oxyvaleraldehyde (10 g.) gave a product (6.2 g.), b. p. 73~74°C/4 mmHg, n_D^{25} 1.4550, which was identified as δ-valerolactone. It formed a hydrazide, m. p. 105~106°C, which gave no depression when mixed with an authentic sample.

The infrared spectra of the lactones obtained in the present work (Figs. 4—6) showed strong bands due to lactone group at 5.75 and 8.60 μ.

1-Cyclopentene-1-carboxaldehyde. — The copper chromite-zinc oxide catalyst was used. Adipaldehyde (10 g.) gave a product (4.5 g.), b. p. 55~57°C/25 mmHg, n_D^{24} 1.4765, d_4^{25} 0.9522, which was identified as 1-cyclopentene-1-carboxaldehyde (lit.[15] b. p. 57~59°C/27 mmHg, n_D^{20} 1.4866). MR_D Found: 27.1. Calcd.: 27.3.

Found: C, 74.62; H, 8.79. Calcd. for C_6H_8O; C, 74.97; H, 8.39%.

Cyclopentenecarboxaldehyde gave a 2,4-dinitrophenylhydrazone melting at 209~210°C (lit.[16] 210~211°C).

Found: C, 52.16; H, 4.48. Calcd. for $C_{12}H_{12}O_4N_4$: C, 52.17; H, 4.38%.

Cyclopentylcarbinol. — The copper - magnesium oxide catalyst was used. Unlike as in the above experiment, adipaldehyde (10 g.) was passed in with a steady current of hydrogen (20 l./hr.) in a period of one hour. The reaction temperature was maintained at 230~240°C. The product (5.2 g.), b. p. 75~78°C/25 mmHg, n_D^{25} 1.4550, d_4^{25} 0.9309, was identified as cyclopentylcarbinol. It formed a phenylurethan, m. p. 108°C, which gave no depression when mixed with an authentic sample.

Results and Discussion

The results are summarized in Table I. With all the catalysts used, it was ascertained that the oxyaldehydes gave the corresponding lactones as easily as the diols did. On the contrary, the dialdehydes examined gave no lactones, and they were recovered up to 70%

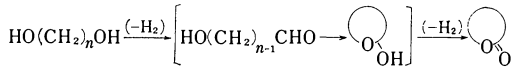

TABLE I. LACTONE FORMATION FROM DIOLS, OXYALDEHYDES AND DIALDEHYDES

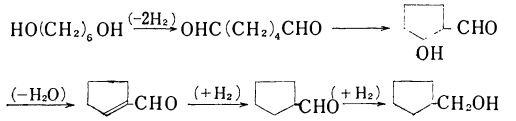
Catalyst	Copper-zinc oxide	Copper chromite	Copper chromite-zinc oxide
Sample	Yield of lactone %	Yield of lactone %	Yield of lactone %
1,4-Butanediol	95	53	78
γ-Oxybutyraldehyde	93	53	80
Succinaldehyde	0	0	0
1,5-Pentanediol	84	54	76
δ-Oxyvaleraldehyde	76	55	65
Glutaraldehyde	0	0	0
1,6-Hexanediol	trace	28	68
Adipaldehyde	0	0	0



Reaction temperature: 220~230°C. Reaction time: 1 hr.

except in the case of adipaldehyde. Adipaldehyde gave 1-cyclopentene-1-carboxaldehyde even in the presence of the copper chromite-zinc oxide catalyst which was the most favorable catalyst for ε-caprolactone formation. Adipaldehyde gave cyclopentylcarbinol as well as 1,6-hexanediol, under a hydrogen stream over the copper-magnesium catalyst. From these experimental results, it is concluded that the dehydrogenation of the diols to the lactones proceeds according to the latter route mentioned above, although the formation of ε-caprolactone from ε-oxycaproaldehyde could not be examined.

The products obtained from adipaldehyde support the occurrence of the side reaction proposed in the previous paper[2].

From a study of the ultraviolet spectra, Hurd et al.[17] concluded that, in aqueous dioxane, γ-oxybutyraldehyde and δ-oxyvaleraldehyde exist predominantly as cyclic lactoles, and that ε-oxycaproaldehyde exists as 85% free aldehyde. The infrared spectra of γ-oxybutyraldehyde and δ-oxyvaleraldehyde in the present work were in accord with the above results.

The difficulty of lactone formation from 1,6-hexanediol can be understood by considering that of seven-membered lactole ring formation from ε-oxycaproaldehyde. The slow lactole formation would cause undesirable dehydrogenation to adipaldehyde, from which 1-cyclopentene-1-carboxaldehyde is formed by intramolecular aldol condensation followed by dehydration. The occurrence of this side reaction was observed especially in the case of the copper-magnesium oxide catalyst. The high selectivity of the copper chromite-zinc oxide catalyst may be attributed to its accelerating effect on the lactole formation.

Ester formation[18,19] in the dehydrogenation of alcohol to aldehyde with coeppr chromite has been believed to be a result of the Tischtschenko reaction:

$$2RCHO \longrightarrow RCOOCH_2R$$

However, the mechanism of lactone formation

17) C. D. Hurd et al., *J. Am. Chem. Soc.*, **74**, 5324 (1952).
18) H. Adkins et al., ibid., **55**, 2714 (1933).
19) R. E. Dunbar, *J. Org. Chem.*, **3**, 242 (1938).

in the present work explains the ester formation more reasonably in the following manner:

$$RCH_2OH \xrightarrow{(-H_2)} RCHO \xrightarrow{(+RCH_2OH)}$$

$$RCH(OH)(OCH_2R) \xrightarrow{(-H_2)} RCOOCH_2R$$

The author wishes to express his thanks to Professor Ryozo Goto and Professor Sango Kunichika of Kyoto University for their invaluable advice and criticisms. He also wishes to thank Mr. Tohru Takenaka for his infrared spectra analyses and Mrs. Toshiko Ikegami for her elementary analyses.

Study on Nickel Oxide-Silica-Alumina Catalyst for Ethylene Polymerization. I. Catalyst Activity for Ethylene Polymerization and Selectivity in the Formation of Butene-Isomers

By Hiroshi UCHIDA and Hisao IMAI

(Received October 12, 1961)

A number of papers[1-7] have dealt with the catalytic polymerization of olefins over nickel oxide-silica-alumina catalysts, but the catalyst selectivity from the view point of isomer formation has not been described at all. In this paper both the catalyst activity for ethylene polymerization and the selectivity in butene-isomer formation are presented on a series of catalysts with a progressively increasing aluminum content and with a fixed amount of nickel oxide.

Experimental

Catalyst. — Coprecipitated catalysts comprising silica, alumina, and nickel oxide were used in this study. The catalysts contained a fixed amount of nickel oxide, 0.03[8] in terms of the atom ratio Ni/(Ni+Al+Si), while the aluminum content, given by the atom ratio Al/(Al+Si), varied from 0 to 0.5. The precipitation was made by vigorously mixing a sodium silicate solution containing 5 wt. % of silica with another solution of nitrates of aluminum and nickel. Caution was exercised to keep the pH of the resulting hydrogel solution within the small range of 8±0.5. This was achieved either by adding, prior to the mixing, an amount of caustic soda to the sodium silicate solution or an amount of nitric acid to the solution of nitrates, according to whether a greater amount of silica or of alumina was to be contained in the finished catalyst. Moreover, the product concentration[9] was maintained at 0.03 g./cc. The solution was then subjected to a treatment similar to that of Holm et al.[7]: after filtration on a Buchner funnel, the hydrogel was broken up, placed in evaporating dishes under heat lamps, and allowed to dry in this manner for a day, after which it was dried for several hours in an oven at 110°C. The dried catalyst was treated with successive portions of a 5% hot ammonium nitrate solution and then with hot water in order to remove the sodium. After drying, it was heated at 350°C for 4 hr. The compositions of the catalysts prepared in this way (hereafter designated as catalysts A) are shown in Table I.

Besides the catalysts A, two other catalysts, designated as calalyst AI-4 and AII-4, of the same composition as catalyst A-4 but prepared by different methods, were used. In the preparation of

catalyst AI-4, the hydrogel was washed before the drying, while catalyst AII-4 was a sample of aerogel prepared by means of the method of Kistler[11] from the washed hydrogel of catalyst A-4.

The catalyst samples were crushed into granules 1~2 mm. in size and heated at 500°C for 15 hr. in a stream of air, atter which they ware evacuated at the same temperature for 3 hr. under a reduced pressure of 1×10^{-4} mmHg and were used for the polymerization.

Ethylene.—Ethylene was produced by the dehydration of ethanol over an alumina catalyst. It was purified by successive passages through 30% caustic soda solution, 87% sulfuric acid, and finally a trap placed in a bath of dry ice and methanol. After the purification, it was frozen in a trap cooled with a liquid nitrogen bath. The solid ethylene was distilled in vacuo into another trap by replacting the liquid nitrogen bath with a dry ice bath. The distillation was repeated four times to get rid of the last traces of inert gas, and then the gaseous ethylene was introduced into a gas reservoir.

Catalyst Activity.—The apparatus was a circulatory flow system with a total volume of 2.1 l. and a catalyst cell containing 5 cc. of the catalyst. The flow rate throughout was 70 l./hr. at N. T. P., and the initial ethylene pressure was 350 mmHg. Immediately after the catalyst cell there was placed a U-trap which had been cooled in a bath of dry ice and methanol. Since butene at −78°C retains a vapor pressure of 10 mmHg, all the butene produced was circulated throughout the system until the butene formation had proceeded so far as to attain the pressure of 10 mmHg (an earlier stage of the polymerization); as soon as butene attained this pressure, a part of the circulating butene began to condense in the trap in an amount corresponding to the amount produced (a subsequent stage). The pressure decrease in the system within time of polymerization was measured by means of a mercury manometer attached to the system; the decrease at the subsequent stage gave a measure of the catalyst activity.

After the polymerization had proceeded to such an extent that the total pressure of the system was as low as 0.57 times the initial pressure, the catalyst cell was removed by sealing off the glass tube on both sides of the cell. Part of the condensation product in the trap was then evaporated into the system by replacing the dry ice bath with an ice bath. After the evaporation the gaseous product comprised ethylene and butene, while the liquid product comprised hydrocarbons higher than hexene. The liquid product remaining in the trap was weighed. The experiments made in this manner will be denoted as in series A.

On the other hand, another series of experiments (series B) was made with a few modifications in the experimental procedure, using the same apparatus with a smaller catalyst bed of 1 cc. The modifications were that the trap was cooled with ice and that small portions of the exit gas from the cell were withdrawn at frequent intervals. The change in the composition of butene isomers with time was followed by a gas chromatographic analysis of the portions at 32°C by the use of a 5 m. column of benzyl cyanide plus silver nitrate on cellite 408[12]. In this procedure all the butene produced was circulated throughout the system, together with reactant ethylene, while a major part of the product hydrocarbons higher than hexene were condensed in the trap.

Specific Surface Area Pore Volume, Pore Size Distribution and Density.—The specific surface area was obtained by the aid of the BET method applied to the nitrogen adsorption isotherm determined at −196°C. The amount of nitrogen adsorbed at the relative pressure of 0.967 gave the the pore volume, including pores smaller than 300 Å in radius. Furthermore, the desorption isotherm was determined on three kinds of catalysts, A-, AI- and AII-4. On the basis of the isotherm, the pore size distribution was calculated by the aid of Barrett's method[13]. The catalyst density was measured by the helium displacement method[14] at 20°C.

Experimental Results

Catalyst Activity for Ethylene Polymerization.—The data on the pressure decrease in the experiments of series A are found to follow the following rate equation proposed for the ethylene polymerization by Koizumi et al.[3], provided that the reaction does not proceed too far:

$$-dp/dt=kP/(1+b(P_0-P)) \quad (1)$$

or upon integration,

$$(P_0-P)/t=(P_0+1/b)\ln P_0/P-k/b \quad (2)$$

In the equations, P_0 is the initial pressure of ethylene, P is the observed ethylene pressure at time t, k is the rate constant, and b is a

constant. In this paper, k_g, which gives the rate constant per gram of the catalyst, is used as a comparative measure of the catalyst activity. It decreases with the increasing temperature (refer to Fig. 1), but the Arrhenius plot of the k_g is not linear.

In Fig. 1, the k_g is plotted against the Al/(Al+Si) ratio, and a maximum is produced in the narrow range from 0.03 to 0.05. On the other hand, the values of k_g for catalysts A-, AI- and AII-4 are listed in Table II, which includes also the data on the specific surface area and the other matters. The k_gs have been found to be almost the same among the three catalysts.

In the ethylene polymerization, a major part of the broduct is usually butene, while a part of the product consists of the trimer and the higher polymers. The fraction of the amount of ethylene converted to butene in the total polymerization product (the fraction is designated as F_b hereafter) is given approximately by $2(P_b+10)/(P_0-P+10)$, where P_b is the pressure rise caused by the evaporation of that butene which has been condensed in the trap during the polymerization, and 10 (mmHg) stands for the vapor pressure of the butene in the circulatory system. The values of F_b at the different reaction temperatures of 40, 60 and 100°C are plotted in Fig. 2 as a function of the Al/(Al+Si) ratio. Comparison of the

figure with Fig. 1 discloses that F_b is lowest for the catalyst of the highest k_g.

Catalyst Performance in the Selectivity of Isomer Formation.—Additional data from the experiments of series B give information on the distribution of butene isomers but not any on the rates of polymerization. The data are exemplified in Fig. 3, showing the reaction at 40°C on catalyst A-1 with no aluminum and on A-3 with some aluminum[15]. As regards catalyst A-3, both the ratios of *cis*- and *trans*-2-butene to 1-butene tend to increase with the duration of reaction time. This is the case with all the catalysts with aluminum,

15) There has been found hardly any evidence of the presence of isobutene.

more or less pronounced according to the aluminum contents, but it is not the case with the catalysts with no aluminum. Emphasis should be laid on the fact that throughout all the catalysts the ratio between two 2-butene isomers is maintained at values approximate to 1 regardless of the amount of butene formed[16]. Anyhow, the isomer composition at the beginning of the reaction is far removed from the thermodynamical equilibrium composition[19].

Specific Surface Area, Volume and Size of Pore and Density.—Figure 4 shows the specific surface area (S) and the pore volume (V) as respective functions of the Al/(Al+Si) ratio. The S shows a maximum at the ratio of 0.05; as the ratio increases further, it gradually decreases to about a half of the S of catalyst A-1 with no aluminum. The V is largest at catalyst A-1 and decreases, at first rapidly and then more slowly, with the increasing ratio. The average pore radius calculated from the values of S and V is plotted against the ratio and shows a minimum at the ratio corresponding to the maximum of S.

The pore size distribution curves are given in Fig. 5 for catalysts A-, AI- and AII-4.

—◑— Catalyst AI-4
—●— Catalyst AII-4

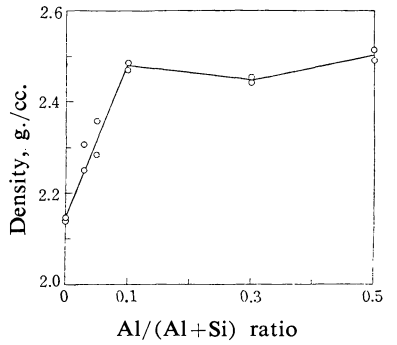

Fig. 6. Density as function of Al/(Al+Si) ratio.

The distribution curves differ markedly from each other, even though the catalysts have the same composition. The pore radii corresponding to the maximum in the curves ($\Delta V/\Delta r_{max}$) are 22.5, 12.5 and 47.5 Å for catalysts A-, AI- and AII-4 respectively.

Figure 6 shows the plot of the density vs. the Al/(Al+Si) ratio. The density at first rises rapidly with the increasing ratio, and it remains nearly constant in the range above 0.1.

Discussion

Specific Activity per Unit Surface Area.—As regards catalysts A-, AI- and AII-4, comparison of the pore size distribution curves (Fig. 5) or of the pore radii at $\Delta V/\Delta r_{max}$ with the k_g (Table II) reveals no direct relationship existing between them. Moreover, catalyst A-3 with the smallest pore radius, gives the highest k_g (compare Fig. 1 with Fig. 4). These facts may lead to the reasonable assumption that the polymerization takes place uniformly along the pore well. Under this assumption, the specific catalyst activity per unit surface area (hereafter denoted by k_s) can be obtained

16) In this connection, Foster et al.[17] stated that, in the isomerization of 1-butene to 2-butene isomers on a clay catalyst, the ratio of trans- to cis-isomer was kept at values approximate to 1 independent of conversion, whereas Lucchesi et al.[18] pointed out that in the isomerization on a silica-alumina catalyst the ratio increased.

18) P. J. Lucchesi, D. L. Baeder and J. P. Longwell, ibid., **81**, 3235 (1959).

19) The thermodynamical equilibrium composition of butene isomers at 40°C has been calculated on the basis of the physical constants given by Kilpatrick et al.[20], as follows: 1-butene, 4.2%: *cis*-2-butene, 13.3%: *trans*-2-butene, 82.5%.

by dividing k_g by S, and it is shown in Fig. 7 as a function of the Al/(Al+Si) ratio. The figure shows a maximum of the k_s at the Al/(Al+Si) ratio where the maxima of k_g and S appeared. The high k_g is therefore to be attributed to the high k_s as well as to the large S.

The structures of the catalyst responsible for the high k_s will be described in the next paper[21].

Selectivity in the Formation of Butene-isomers. —The tendency in the ratio of *cis*- or *trans*-2-butene to 1-butene to increase with the reaction time may be due to the increasing amount of 2-butene isomers converted from the 1-butene which has been once present in the gas phase as the desorbed product. Nevertheless, it by no means follows that all the 2-butene isomers are produced by way of the desorbed 1-butene. In this connection, Fig. 3 reveals that the ratio of cis- or trans-isomer to 1-butene is not reduced to zero even at a very short period of the reaction.

Applying the method proposed by Schneider et al.[22] to their study of the catalytic isomerization of *n*-butenes, Foster et al. plotted the ratio of the product isomers (for instance, the ratio of cis- to trans-isomer) against the corresponding per cent conversion of the reactant isomer (for instance, 1-butene), and obtained the ratio between the product isomers at zero conversion by extrapolation of the plot. This procedure is now followed; the extrapolation to $t=0$ of the plots in Fig. 3 results in the initial ratio at zero extent of the polymerization. The initial ratios thus obtained are shown in Fig. 8 as a function of the Al/(Al+Si) ratio. Both the initial ratios of cis- and trans-isomers to 1-butene increase with the increasing aluminum content up to the highest value at the Al/(Al+Si) ratio of 0.1, beyond which they remain almost constant. In contrast, the initial ratio between the two 2-butene isomers remains at about 1 throughout the aluminum content of the present study, except for a slight maximum at the content corresponding to the maximum of the k_g.

The initial isomers ratio thus obtained gives the relative rates for the formation of the two isomers. There are, then, the following relations:

$$r_{01}/r_{02} = [\text{cis-}]/[\text{1-butene}] \quad \text{at } t=0$$
$$r_{03}/r_{01} = [\text{trans-}]/[\text{1-butene}] \quad \text{at } t=0$$
$$\text{and } r_{03}/r_{02} = [\text{trans-}]/[\text{cis-}] \quad \text{at } t=0 \qquad (3)$$

where r_0 is the initial rate of formation, and the subscripts 1, 2 and 3 stand for 1-butene, *cis*- and *trans*-2-butene respectively. On the other hand, the initial rate of ethylene polymerization (r_0) is given by

$$r_0 = r_{01} + r_{02} + r_{03} \qquad (4)^{23}$$

Eq. 3 being combined with Eq. 4, r_{01}, r_{02} and r_{03} can be evaluated, if r_0 is known. In this connection, the initial polymerization rate based on the unit surface area can be calculated with the aid of Eq. 1, in which k_s, in place of k_g, is taken into account[24]. Figure 9 shows the calculated r_{01}, r_{02} and r_{03} based on the unit surface area at a fixed pressure (345 mmHg) and at a fixed temperature (40°C) as a function of the Al/(Al+Si) ratio. The figure reveals that, as the aluminum content is varied, the

21) At present it can at the most be pointed out that the density of the catalyst granule is not directly correlated to the specific activity, as can be seen by a comparison of Fig. 6 with Fig. 7.
22) V. Schneider and P. K. Frolich, *Ind. End. Chem.*, **23**, 1405 (1931).
23) At the beginning of polymerization, all the ethylene polymerized may be assumed to produce butene[6].
24) Since k_g was evaluated from the data at the subsequent stage of the reaction, the calculation is rather uncertain, but the initial rates obtained may be adequate for the comparative discussion in this study.

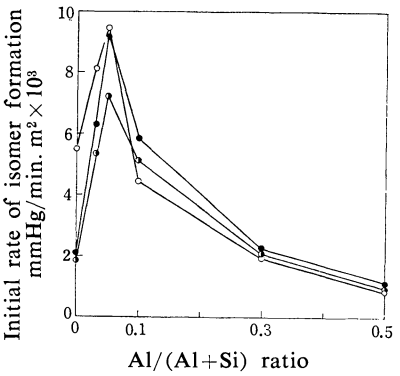

Fig. 9. Dependency of initial rates of isomer formation on Al/(Al+Si) ratio.
—○— Initial rate of 1-butene formation
—◑— Initial rate of *cis*-2-butene formation
—●— Initial rate of *trans*-2-butene formation

initial rates r_{01}, r_{02} and r_{03} change in approximately the same manner as r_0, rising with the increasing aluminum content until a maximum is attained at the Al/(Al+Si) ratio of 0.05 and decreasing with the further-increasing content. However, a closer examination of Figs. 8 and 9 reveals that not all the rates change in exactly the same manner; on the catalyst with the highest r_0, the cis- and trans-isomers are formed about four times as fast as on the catalyst with no aluminum, whereas 1-butene is formed only 1.7 times as fast as the rate on the catalyst with no aluminum.

Effects of Aluminum Addition on Catalytic Activity for Polymerization and Selectivity in Isomer-formation.—All the mechanisms which have been proposed for the hydrocarbon reactions on the acid catalysts, such as the carbonium ion mechanism, the hydrogen transfer mechanism, and the others[25], as well as the mechanism proposed by Horiuchi[26], predict the formation of a chemisorbed species of 1-butene on the catalysts when the mechanisms are applied to the dimerization of ethylene. For instance, the carbonium ion mechanism modified by Lucchesi et al.[18] indicates the following scheme[27];

$$H_2C{=}CH_2 + H^+X^- \rightarrow H_2C\overset{\overset{H}{\cdots+\cdots}}{-}CH_2\ X^-$$

I

$$I + H_2C{=}CH_2 \rightarrow H_3C{-}CH_2{-}C\overset{\overset{H}{\cdots+\cdots}}{-}CH_2\ X^- \qquad (5)$$

II

where H^+X^- represents the acid site. If with no rearrangement, the chemisorbed species II leads to 1-butene as the desorbed product,

$$II \rightarrow 1\text{-Butene} + H^+X^- \qquad (6)$$

while, with rearrangement, it leads to either one of the 2-butene isomers by way of III or IV respectively.

$$II \rightarrow H_3C{-}\overset{H}{C}\overset{\overset{H}{\cdots+\cdots}}{-}\overset{H}{C}{-}CH_3 \rightarrow \textit{cis}\text{-2-Butene} + H^+X^-\ X^-$$

III (7)

$$II \rightarrow \begin{matrix}H_3C\\|\\HC\end{matrix}\overset{\overset{H}{\cdots+\cdots}}{-}\overset{H}{C}{-}CH_3 \rightarrow \textit{trans}\text{-2-Butene} + H^+X^-\ X^-$$

IV (8)

The scheme represented by 5—6 can explain the simultaneous formation of the three isomers as the initial dimerization products and can explain also the constant ratio of about 1 between the two 2-butene isomers regardless of the duration of the reaction time, provided that rearrangement 7 can proceed at a rate equal to that of rearrangement 8 and provided also that the direct rearrangement between III and IV can be excluded at the low temperature.

However, the above scheme can not explain the present experimental facts on the catalyst selectivity related to the aluminum content, as is shown below. According to the above scheme, both the polymerization and the isomerization are to take place on the same site, H^+X^-. The increase in polymerization activity, which comes from the increase in the surface concentration of polymerization sites, can not, therefore, be expected to change the selectivity in initial butene isomer formation, whereas the experimental facts demonstrate that both the polymerization activity and the selectivity are changed by the addition of aluminum, and, moreover, that the changes take place in different manners (cf. Figs. 1 and 8).

The fact thus seems to be too complicated to be explained in terms of the above scheme, in which only one kind of acid site was considered. In this respect, we should like to suggest that, in addition to H^+X^-, another kind of acid site, H^+Y^-, which could serve as the site for the rearrangements II → III and II → IV, might be present on the catalyst and

26) J. Horiuchi, *Catalyst (Shokubai)*, **1**, 67 (1948).

27) For convenience, the mechanism is discussed from this point of view.

that H^+X^- and H^+Y^- could be separately increased in number by the addition of aluminum. The experimental facts capable of demonstrating the presence of the two kinds of acid sites will be described in the next paper.

Summary

The activity for the ethylene polymerization per unit mass of the catalyst has been found highest for the catalyst with the Al/(Al+Si) ratio of 0.05. The high activity is ascribed to the high specific activity per unit surface area as well as to the large specific surface area of the catalyst. The pore sizes scarcely produce any effect on the catalyst activity.

Even at a very short reaction time, the three isomers of *n*-butene are produced simultaneously. The ratios both of *cis*- and of *trans*-2-butene to 1-butene increase with the reaction time more or less according to the aluminum content, whereas for all the catalysts the ratio between the two 2-butene isomers is kept at values approximate to 1. At the zero extent of reaction, the former ratios, given as a function of the aluminum content, show an increase with the progressively increasing content up to the highest value at the Al/(Al+Si) ratio of 0.1, while the latter remains nearly constant throughout all the catalysts.

For the sake of a convenient explanation of the change in the selectivity as well as in the activity related to the aluminum content of the present catalysts, two kinds of acid sites are suggested as possibly present.

Study on Nickel Oxide-Silica-Alumina Catalyst for Ethylene Polymerization. II. Catalyst Structures Related to Catalyst Activity

By Hiroshi UCHIDA and Hisao IMAI

(Received November 2, 1961)

Our preceding paper[1] presented the results concerning the catalyst activity for ethylene polymerization and the selectivity in butene-isomer formation which were obtained for a series of nickel oxide-silica-alumina catalysts. The catalysts contained progressively increasing amounts of alumina with a fixed nickel oxide content. The results showed that both the activity and the selectivity change in a particular manner that is greatly dependent on the alumina content. In the present study, the catalysts were successively treated with hydrogen and carbon monoxide to remove nickel oxide, and the catalyst acidities before and after the treatment have been measured, along with the determinations of the changes in the activity and specific surface area. The valence state of nickel has also been determined. The results may serve for the elucidation of catalyst structure which, in turn, determines the activity.

Experimental
